Upon coordination, the macrocyclic ligand generates four six-membered rings containing the Zn metal, which, in all cases, adopt a chair conformation. The aromatic rings are oriented in a parallel manner and the coordinated nitrates are disposed in an *anti* configuration, as expected from a steric viewpoint. Finally the Zn···Zn distance is 8.73 Å. The structure is completed by two non-coordinating nitrate anions which could only be refined isotropically. Two oxygen atoms of each nitrate are within H-bond range (2.95−3.1 Å) of the N atoms of the macrocyclic ligand, on the opposite side of the $N_3Zn(\eta^2$-*O*,*O*)NO_3 unit.

The molecular structures of **5**, **7** and **8** consist of a neutral Zn_2Cl_4L unit. The macrocyclic molecules are again centrosymmetric. In sharp contrast to the previous structure and related complexes described in the literature — $[Pd_2Cl_2(Me2p)](ClO_4)_2{\cdot}H_2O$,[22] $[Cu_2Cl_2(Me2p)](BPh_4)(ClO_4){\cdot}CH_3CN$,[23] $[Cu_2(Me2p)(CO)_2](ClO_4)_2{\cdot}2H_2O$ and $[Cu_2(Me2m)(t\text{BuNC})_2](CF_3SO_3)_2$ [24] — the Zn atoms adopt a distorted tetrahedral geometry coordinated to only four of the six available N atoms of the macrocyclic ligand; each Zn coordinates to two chlorine atoms and two adjacent N atoms of the macrocycle, leaving two benzylic amines of the macrocycle as non-coordinating. Binding of the metal ion to only two N atoms of the macrocycle in **5**, **7** and **8** probably reflects that formation of the second Zn−Cl bond, in combination with the release of the strain imposed by the macrocyclic ligand, can overcome the breakage of a rather weak $Zn-N_{tertiary}$ bond.[25]

The coordination of Zn1 to two adjacent macrocyclic N atoms results in a five- (**5**), or six-membered (**7** and **8**) chelate ring where the six-membered ring always adopts a chair conformation. The Zn bond lengths and angles are within the expected range for Zn polyaza complexes previously reported in the literature.[26] The number of atoms that form the chelate cycle dramatically affects the N1−Zn−N2 and Cl1−Zn−Cl2 angles. The six-membered chelate rings of **7** and **8** result in N1−Zn−N2 angles of 100.72(14)° and 100.95(10)°, slightly smaller than the corresponding Cl1−Zn−Cl2 angles [115.14(6)° and 119.12(4)°, respectively], whereas the more constrained five-membered ring formed in the ethylene-based macrocycle **5** forces a more acute N1−Zn−N2 angle [87.38(7)°], remarkably smaller than the corresponding Cl1−Zn−Cl2 angle [121.19(3)°]. These parameters indicate a significant distortion from a tetrahedral geometry in **5**, which is further evidenced by the dihedral angle of 80.80° formed between the planes described by N2−Zn1−Cl2 and N1−Zn1−Cl1. It is interesting to note here that in all the structures described in the present work the aromatic rings are disposed in a parallel manner. Finally, complex **7** cocrystallises with a third of a molecule of severely disordered CH_2Cl_2.

For dinuclear complexes containing hexaazamacrocyclic ligands, such as the ones described here, the "internal cavity" of the complex can be defined as the smallest macrocycle containing the two metals. For complexes with all N atoms coordinated to the metal centre, as in **3**, the cavity dimension, expressed in terms of the number of member units, is dependent on the aromatic substitution (the *para* case having an internal cavity with two more units than the *meta*) and independent of the number of methylenic units within the amines. On the other hand, with a partial coordination of the macrocyclic ligand, such as that obtained in complexes **5**, **7** and **8**, the internal cavity will now depend on both factors. Thus, complex **7**, containing the Me3p ligand, will have a larger internal cavity than **3**, its H3p analogue, due to the enlargement produced by the partial coor-

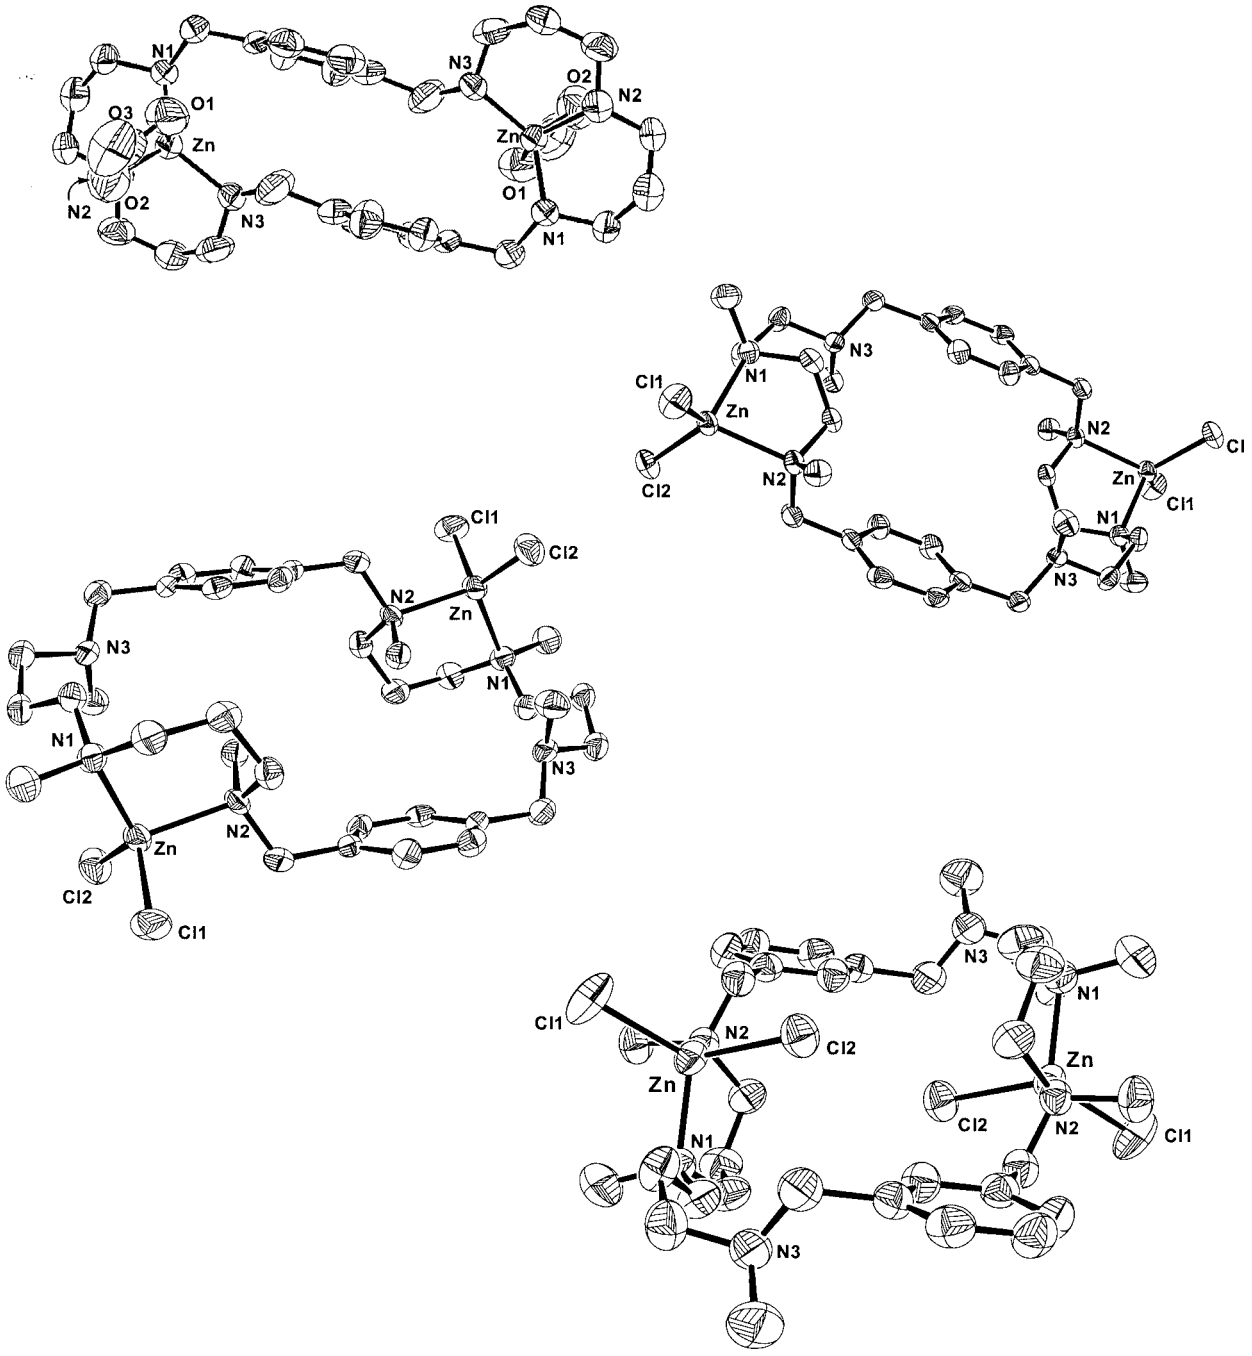

Figure 1. ORTEP diagram (50% probability) of the cationic part of complex **3** (top left), complex **5** (top right), complex **7** (bottom left) and **8** (bottom right)

dination of the former ligand. As a consequence the complex with the tertiary amine has a Zn···Zn distance larger than the corresponding secondary amine. Complex **5**, containing the Me2p ligand, has a smaller internal cavity than complex **7**, containing the analogous ligand but with propylene linkers instead of ethylene. In sharp contrast, **5** has a larger Zn···Zn distance than **7**, due to the relative disposition of the metal complexes produced by the methylene linkers. Finally, complex **8**, containing the Me3m ligand, which produces the largest internal cavity, presents the shortest Zn···Zn distance. This is due to the different arrangement that the *meta* aromatic substitution provokes with regard to the *para*, the former being more compact. As a consequence of this, in complex **8** (*meta* substitution) two of the Cl ligands bonded to the metal centres are directed towards the inside the cavity, whereas in complexes **5** and **7** (*para* substitution) all Cl ligands are clearly oriented outside the cavity and are pointing in opposite directions.

NMR Spectroscopy and Solution Structure

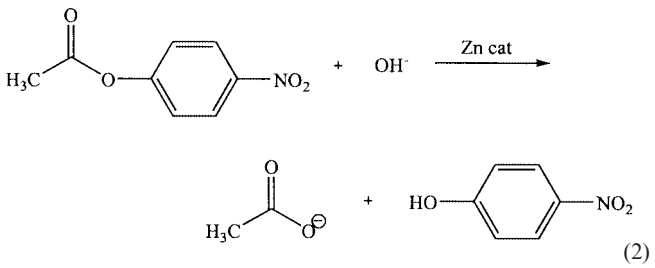
The ^1H and ^{13}C NMR spectra of complexes **1**−**7** at room temperature in different deuterated solvents are presented as Supporting Information and are assigned in the Exp. Sect. No NMR spectra could be obtained for complex **8** due to its low solubility.

In the spectra, the resonances are shifted downfield relative to the free ligand demonstrating that the metal ion remains bound to the macrocycle in solution. However, it is interesting to point out here that the fine structure of the spectra of these complexes is not well resolved either due to poor resolution of multiple superimposed signals or, more likely (vide infra), the presence of fluxional behaviour. The latter may be attributed to fast exchange between different conformers in solution, although these phenomena alone cannot explain the apparent simplicity of the spectra, which is not consistent with the more asymmetric structure of the complexes in the solid state, as determined by X-ray crystallography. If retained in solution, the structure determined in the solid state should give rise to two different signals (assuming fast aromatic ring rotation) for the aromatic protons in the complexes containing *para*-substituted macrocycles (**5** and **7**). In addition, the benzylic protons in **5**, **6** and **7** should also give rise to at least two different signals in a 1:1 ratio. However, the ^1H NMR spectra of **5** in CD_2Cl_2 (D_2O) and **7** in DMSO (D_2O) show only one broad singlet at δ = 7.39 (7.56) and 7.24 (7.47) ppm, respectively, indicating that all the aromatic protons are equivalent on the NMR timescale. The benzylic protons also appear as a broad singlet at δ = 3.78 (3.99) for **5**, 3.77 for **6** and 3.46 (3.91) ppm for **7**, which implies that the four benzylic groups are again equivalent. Thus, these symmetric spectra could either indicate the presence of a symmetric structure in solution, where the six N atoms participate in the simultaneous binding of the Zn atoms, or, alternatively, it may suggest the presence of two or more species in solution, such as the one determined by X-ray crystallography, undergoing fast inter-exchange. This process supposes rapid Zn−N bond formation and breaking involving all the amino nitrogen atoms of the ligand. This type of behaviour is not uncommon for d^{10} metal ions probably due to the lack of ligand field stabilisation.[27] Further support for the fluxional behaviour of the complexes is provided by variable temperature NMR spectroscopy of **5** in CD_2Cl_2 (Figure S10). The initially simple room temperature ^1H NMR spectra become complicated upon lowering the temperature. For example, the aromatic and benzylic protons, which appear as singlets at 295 K, convert into multiple poorly resolved signals. The higher complexity of the low temperature spectra is consistent with the freezing-out of the fluxional processes, although even at 160 K the signals do not became completely resolved, thus precluding a complete assignment of the spectra.

The spectra of **3** and **4**, which show two broad singlet signals, with a 5:3 integration ratio that are assigned to the benzylic protons, are also unusual. The data are consistent with at least two dramatically different isomeric forms of the complex. However, the singlet structure of the signals strongly suggests again the presence of fluxional behaviour and that each of the signals does not belong to a single species but to a number of inter-exchanging isomers. The solvent strongly influences the nature of the fluxional behaviour, as deduced from the sharpening of the resonances when using D_2O instead of CD_2Cl_2 or [D_6]DMSO. Even though the signals do not totally resolve, it is obvious that in aqueous solution the speed of the process is enhanced. Another interesting aspect of the chemistry of these complexes emerges when comparing the ^1H NMR spectra of complex **2** or **4** with **5** or **7**, respectively, in the same solvent — the comparison of the spectra of Zn complexes bearing secondary or tertiary amine macrocyclic ligands, showing a sharp narrowing for the latter. This observation favours the description of the fluxional behaviour as bond formation and breaking rather than a unique structure since it indicates that the breaking of the weaker $Zn-N_{tertiary}$ bonds[25] requires lower activation energies. Thus $Zn-N_{tertiary}$ bonds can form and break faster than the stronger $Zn-N_{secondary}$ analogues, finally resulting in the narrowing of the resonances.

Hydrolytic Activity

The Zn complexes containing *para*-substituted ligands (**1**, **3**, **5** and **7**) described in the present work were tested in the hydrolysis of 4-nitrophenyl acetate (NA) [Equation (2)]. The *meta* derivatives could not be used due to their low solubility in water. Figure 2A shows the linear dependency of the initial rate constant k_{in} (defined as v_{in}/[NA]) with regard to [$ZnCl_4$(Me2p)] (**5**) at different pH values ranging from 7.31 to 8.40; more-detailed kinetic data related to the hydrolysis of NA in the presence of different Zn complexes is included as Supporting Information in Table S1. As expected, the increase in pH results in a monotonical increase of k_{in}. This behaviour can be interpreted in terms of the generation of the nucleophilic LZn−OH species which has been shown to be the active species in previous works with related ligands.[11,28] This behaviour also rules out the possibility of the free metal ion being the active species since, as the pH is increased, its concentration strongly decreases. On the other hand blank experiments with only free ligand or free metal ion under similar conditions display a much smaller hydrolytic capacity. Furthermore, the free ligand is not observed in the NMR spectra of the complexes reported here. It is interesting to point out here that the rate constants observed for [$ZnCl_4$(Me3p)] (**7**) and for its nitrate analogue [$Zn(NO_3)_2$(Me3p)]$(NO_3)_2$ (data not shown) are



(2)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

virtually the same within experimental error. These results manifest the strong dependency of the rate constant with regard to the ligand system and, in contrast, the weak influence of the labile chloride and nitrate ligands.

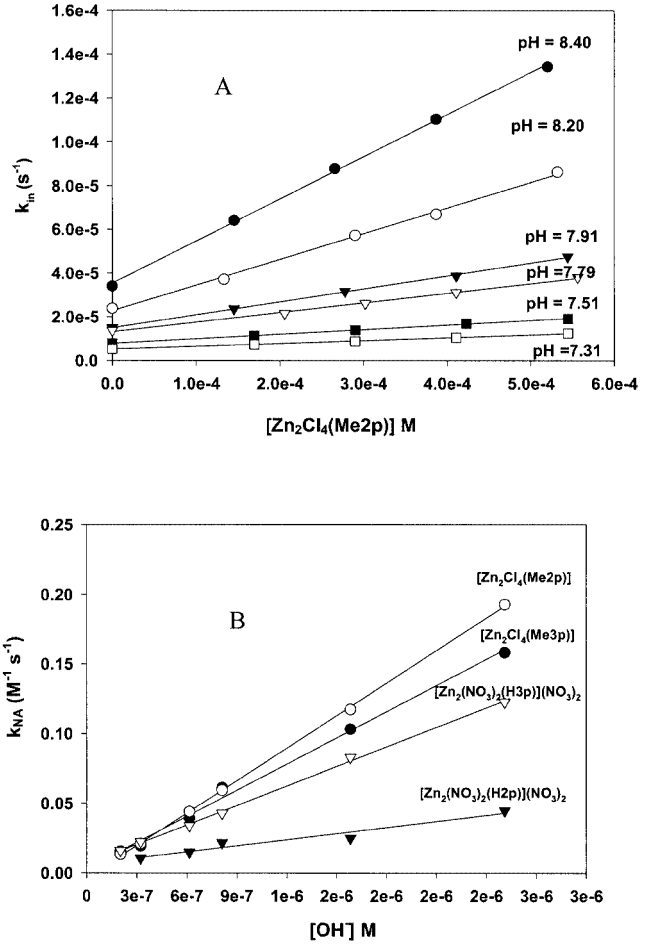


Figure 2. Kinetic data for the hydrolysis of 4-nitrophenyl acetate (NA) by the macrocyclic Zn complexes: A) initial rate constant k_{in} relative to [$ZnCl_4$(Me2p)] at different pH; B) second-order rate constants, k_{NA}, relative to [OH] for different macrocyclic Zn complexes

Unfortunately, in our case, at higher pH values the complexes start to precipitate out of the solution, preventing further kinetic analysis. A similar linear dependency is also found for complexes **1**, **3** and **7** and is presented as Supporting Information.

Second-order rate constants, k_{NA}, were obtained at a given pH from a plot of k_{in} vs. complex concentration. The linear dependency of this second-order rate constant against [OH] is shown in Figure 2B for the four *para* complexes. As can readily be seen, at a given pH complexes **5** (for instance at pH 8.4, k_{NA} = 0.193 $M^{-1}s^{-1}$) and **7** (0.158 $M^{-1}s^{-1}$), bearing tertiary amine ligands, give higher rate values than complexes **1** (0.045 $M^{-1}s^{-1}$) and **3** (0.123 $M^{-1}s^{-1}$) containing secondary amines. These values are about an order of magnitude lower than the best complexes reported in the literature for the same reaction under similar conditions,[28,29] although the low solubility of our complexes at pH's higher than 8.4 precludes a fair comparison.

Our results for the second-order rate constants are in agreement with tertiary amines generating more nucleophilic LZn−OH species than secondary amines due to the hydrophobicity of the former,[30] which precludes charge delocalisation among solvated species. When comparing complexes **5** and **7**, both with tertiary amines, at a given pH it is found that **5** has higher k_{NA} values than **7** even though the latter has four more methylenic groups. This is due to the fact that at the same pH the Me2p ligand generates a much higher concentration of LZn−OH species than Me3p, as has been previously shown in the literature for similar complexes.[31] Finally, for complexes bearing secondary amines the tendency is just the opposite than in the case of the tertiary amines just discussed. In particular, complex **1** presents significantly lower k_{NA} values than the rest of the studied complexes. At this moment it is not obvious to us why **1** has such a low hydrolytic activity, although, presumably, the structure of the ligand does not favour the interaction between the electrophile (Zn−OPO_2R) and nucleophile (Zn−OH) units.

Conclusion

A family of new dinuclear Zn complexes bearing hexaazamacrocyclic and chloride or nitrate ligands have been prepared and characterised from the corresponding metal salt and ligand as the starting materials. In the solid state, the metal coordination geometry as well as the ligand coordination mode are strongly dependent on the Zn starting material. Thus, $ZnCl_2$ generates a Cl_2N_2 tetrahedrally distorted environment for Zn with a coordination number (CN) of four whereas the $Zn(NO_3)_2$ salt generates an N_3O_2 environment with a CN of five. Furthermore the macrocyclic ligand in the former case coordinates through only four of the six possible N atoms, whereas in the latter case it coordinates through all its N atoms. These different coordination modes, together with the flexibility of the macrocyclic ligands, allows a certain control of the relative spatial Zn−Zn disposition.

NMR spectroscopy clearly indicates that the solution structure of these macrocyclic complexes is radically different from their structure in the solid state. In the case of the chloride complexes **2** and **4**−**8**, NMR spectroscopy reveals the presence of a fluxional behaviour that presumably involves exchange between conformational isomers and the formation and breaking of Zn−N bonds including all N atoms of the macrocyclic ligand.

Finally, complexes **1**, **3**, **5** and **7** have been shown to be capable of hydrolyzing *p*-nitrophenyl acetate (NA). Their different hydrolysis rates reveal how small variations in the ligand can significantly influence hydrolytic activity.

Experimental Section

Physical Methods: IR spectra were recorded on a Mattson-Galaxy Satellite FT-IR spectrophotometer as solid KBr pellets. Elemental

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

analyses were conducted on a Carlo−Erba Instrument, Mod. CHNS 1108. UV/Vis spectra were recorded on a Varian Cary-50 spectrophotometer, using quartz cuvettes. NMR spectra were recorded at 298 K on a Bruker DPX200 Model Avance (4.7 T) operating at 200 MHz for proton. Spectra were referenced to the residual protio solvent peaks or TMS (tetramethylsilane).

Electrospray ionisation mass spectra were acquired using a Navigator quadrupole instrument (MassLab Group, Finnigan, Manchester, UK) equipped with an Aqua system for atmospheric pressure chemical ionisation (APCI) and electrospray (ESI). The samples were introduced either with a liquid chromatographic pump (P2000, Thermo Separation Products) at a flow rate of 0.3 mL/min using different proportions of H_2O/methanol as the mobile phase, or by direct infusion by the Aqua system. Positive ion spectra were acquired in full scan 2−1600 *m*/*z* in continuum mode.

Materials and Synthesis: Solvents were purchased from SDS as synthesis grade. Acetonitrile was distilled from over P_2O_5 (Prolabo) and stored over molecular sieves. Diethyl ether and THF were distilled from over Na (Panreac) or benzophenone (Fluka), respectively, just previously to their use. CH_2Cl_2 was distilled from over CaH_2 (Aldrich) and stored over molecular sieves. Methanol was distilled from over Mg (Aldrich) and stored in the dark over molecular sieves. Acetone was dried over $CaCl_2$ (Panreac) and stored over molecular sieves.

The macrocyclic ligands 3,6,9,16,19,22-hexaazatricyclo[22.2.2.2^{11,14}]-triaconta-1(27),11(30),12,14(29),24(28),25-hexaene (**H2p**), 3,7,11,18,22,26-hexaazatricyclo[26.2.2.2^{13,16}]tetratriaconta-1(31),13(34),14,16(33),28(32),29-hexaene (**H3p**), 3,6,9,16,19,22-hexamethyl-3,6,9,16,19,22-hexaazatricyclo[22.2.2.2^{11,14}]triaconta-1(27),11(30),12,14(29),24(28),25-hexaene (**Me2p**) 3,6,9,17,20,23-hexamethyl-3,6,9,17,20,23-hexaazatricyclo[23.3.1.1^{11,15}]triaconta-1(29),11,13,15(30),25,27-hexaene (**Me2m**), 3,7,11,18,22,26-hexamethyl-3,7,11,18,22,26-hexaazatricyclo[26.2.2.2^{13,16}]tetratriaconta-1(31),13(34),14,16(33),28(32),29-hexaene (**Me3p**) and 3,7,11,19,23,27-hexamethyl-3,7,11,19,23,27-hexaazatricyclo[27.3.1.1^{13,17}]tetratriaconta-1(33),13,15,17(34),29,31-hexaene (**Me3m**) were prepared according to the published procedures or slight modifications thereof.[17−20] (for structural drawing see Scheme 1).

[$Zn_2(NO_3)_2$(H2p)]$(NO_3)_2$·11/3H_2O (1·11/3H_2O): A methanol (3 mL) solution of $Zn(NO_3)_2$·6H_2O (179 mg, 0.60 mmol) was added dropwise to a vigorously stirred solution of H2p (123 mg, 0.30 mmol) in methanol (6 mL). A white precipitate rapidly appeared. The mixture was stirred for 30 min and then cooled down in an ice bath. The white solid that precipitated was then filtered, washed with methanol and dichloromethane and dried under vacuum. (168 mg, 0.21 mmol, 71%). FT-IR (KBr): ṽ, 3223, 2933, 2878 and 1383 cm^{-1}. $C_{24}H_{38}N_8O_6Zn_2$·11/3H_2O (855.5): calcd. C 33.70, H 5.34, N 16.37; found C 33.87, H 5.36, N 16.31. ^{1}H NMR (200 MHz, D_2O, 25 °C): δ = 2.50−3.20 (m, 16 H, NCH_2), 3.80−4.20 (m, 8 H, $ArCH_2$), 7.36 (s, 8 H, arom.) ppm. ^{13}C NMR (50 MHz, D_2O, 25 °C): δ = 45.9 (NCH_2), 52.0 ($ArCH_2$), 129.8 (arom. tert.), 136.6 (arom. quat.) ppm. MS: *m*/*z* = 727.56 [$Zn_2(NO_3)_2$(H2p)], 538.08 [$Zn(NO_3)$(H2p)].

[Zn_2Cl_4(H2p)]·4H_2O (2·4H_2O): A methanol (3 mL) solution of $ZnCl_2$ (28 mg, 0.20 mmol) was added dropwise to a vigorously stirred solution of H2p (41 mg, 0.10 mmol) in methanol (2.5 mL). A white precipitate rapidly appeared. The mixture was stirred for 30 min and then cooled down in an ice bath. The white solid that precipitated was then filtered, washed with methanol and dichloromethane and dried under vacuum. (25 mg, 0.04 mmol, 37%). $C_{24}H_{38}Cl_4N_6Zn_2$·4H_2O (755.3): calcd. C 38.17, H 6.14, N 11.13; found C 38.08, H 5.43, N 10.93. FT-IR (KBr): ṽ, 3217, 2930, 2874 and 1445 cm^{-1}. ^{1}H NMR (200 MHz, D_2O, 25 °C): δ = 2.50−3.20 (m, 16 H, NCH_2) 3.85 (m, 8 H, $ArCH_2$) 7.34 (s, 8 H, arom.) ppm. ^{13}C NMR (50 MHz, D_2O, 25 °C): δ = 47.8 (NCH_2), 55.3 ($ArCH_2$), 132.4 (arom. tert.), 139.3 (arom. quat.) ppm.

[Zn_2Cl_4(H3p)]·7/3H_2O (4·7/3H_2O): A methanol (5 mL) solution of $ZnCl_2$ (27 mg, 0.20 mmol) was added dropwise to a vigorously stirred solution of H3p (47 mg, 0.10 mmol) in methanol (3 mL). A white precipitate rapidly appeared. The mixture was stirred for 2 h and then cooled down in an ice bath. The white solid that precipitated was then filtered, washed with methanol and dried under vacuum. (25 mg, 0.34 mmol, 34%). FT-IR (KBr): ṽ, 3212, 2933, 2874 and 1431 cm^{-1}. $C_{28}H_{46}N_6Zn_2Cl_4$·7/3H_2O (781.3): calcd. C 43.04, H 6.54, N 10.76; found C 43.01, H 6.59, N 10.80. ^{1}H NMR (200 MHz, D_2O, 25 °C): δ = 1.74 (m, 8 H, $CH_2CH_2CH_2$), 2.89 (m, 16 H, NCH_2), 3.96 (s, 5 H, $ArCH_2$), 3.80 (s, 3 H, $ArCH_2$), 7.46 (s, 8 H, arom.) ppm. ^{13}C NMR (50 MHz, D_2O, 25 °C): δ = 22.2 ($CH_2CH_2CH_2$), 43.2, 43.9 (NCH_2), 50.5 ($ArCH_2$), 128.0, 128.2 (arom. tert.), 132.4, 133.5, 134.3 (arom. quat.) ppm. MS: *m*/*z* = 704.01 [Zn_2Cl_3(H3p)], 603.09 [$ZnCl_2$(H3p)], 567.64 [ZnCl(H3p)].

[Zn_2Cl_4(Me2p)] (5): Me2p (50 mg, 0.10 mmol) was dissolved in MeOH (2 mL). A solution of $ZnCl_2$ (28 mg, 0.20 mmol) dissolved in acetone (2 mL) was added to this solution. A white solid rapidly precipitated. The mixture was stirred for 30 min and the white solid filtered. The solid was collected and dissolved in CH_2Cl_2 (3 mL), filtered through celite and the solvent removed under vacuum. The residue that remained was washed with acetone and methanol to obtain the product as a white solid (56 mg, 0.07 mmol, 72%). FT-IR (KBr): ṽ = 1467 cm^{-1}. $C_{30}H_{50}Cl_4N_6Zn_2$ (767.3): calcd. C 46.96, H 6.57, N 10.95; found C 46.84, H 6.82, N 10.75. ^{1}H NMR (200 MHz, CD_2Cl_2, 25 °C): δ = 2.41 (s., 12 H, NCH_3), 2.50−3.10 (m, broad, 22 H, NCH_2 and NCH_3), 3.78 (s, 8 H, $ArCH_2$), 7.39 (s, 8 H, arom.) ppm. ^{13}C NMR (50 MHz, CD_2Cl_2, 25 °C): δ = 32.7, 44.9, 43.3 (NCH_3), 56.0 (NCH_2), 63.7 ($ArCH_2$), 131.2 (arom. tert.), 135.7 (arom. quat.) ppm. ^{1}H NMR (200 MHz, D_2O, 25 °C,): δ = 1.98 (s, 6 H, NCH_3), 2.68 (s, 12 H, NCH_3), 2.85 (m, 8 H, NCH_2), 2.99 (m, 8 H, NCH_2), 3.99 (s, 8 H, $ArCH_2$), 7.56 (s, 8 H, arom.) ppm. ^{13}C NMR (50 MHz, D_2O, 25 °C): δ = 42.0, 43.9, (NCH_3), 53.7, 54.4, (NCH_2), 63.0 ($ArCH_2$), 134.1 (arom. tert.), 136.4 (arom. quat.) ppm. MS: *m*/*z* = 631.14 [$ZnCl_2$(Me2p)], 595.69 [ZnCl(Me2p)].

[Zn_2Cl_4(Me2m)]·2H_2O·CH_3OH (6·2H_2O·CH_3OH): Me2m (78 mg, 0.16 mmol) was dissolved in MeOH (2 mL), and $ZnCl_2$ (43 mg, 0.32 mmol) dissolved in MeOH (2 mL) was added. A white precipi-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tate rapidly appeared which redissolved upon stirring. The solvent was removed under vacuum and the residue was then dissolved in warm MeOH (5 mL). Upon standing, the product crystallised as white blocks (81 mg, 0.11 mmol, 67%). FT-IR (KBr): $\tilde{\nu}$, 1467 cm^{-1}. $C_{30}H_{50}N_6Zn_2Cl_4 \cdot 2H_2O \cdot CH_3OH$ (835.4): calcd. C 44.57, H 7.00, N 10.06; found C 44.44, H 6.89, N 10.23. ^1H NMR (200 MHz, [D$_6$]DMSO, 25 °C): δ = 2.32 (s, 12 H, NCH_3), 2.41 (s, 9 H, NCH_3 and DMSO) 2.50−2.571 (m, 16 H, NCH_2), 3.43 (s, CH_3OH), 3.77 (s, 8 H, $ArCH_2$), 4.16 (s, broad, OH), 7.38 (m, 6 H, arom.), 7.77 (s, broad, 2 H, arom.) ppm. ^{13}C NMR (50 MHz, [D$_6$]DMSO, 25 °C): δ = 42.8, 43.4 (NCH_3), 48.7 (CH_3OH), 53.3, 54.7 (NCH_2), 60.3 ($ArCH_2$), 127.8, 129.1 (arom. tert.), 136.4 (arom. quat.).

[Zn_2Cl_4(Me3p)]·1/3CH_2Cl_2 (7·1/3CH_2Cl_2): Me3p (65 mg, 0.12 mmol) was dissolved in MeOH/CH_2Cl_2 (2:1 v:v; 3 mL) and a solution of $ZnCl_2$ (32 mg, 0.24 mmol) in MeOH (3 mL) was added. A white precipitate rapidly appeared which was filtered, collected and dried under vacuum (65 mg, 0.08 mmol, 67%). FT-IR (KBr): $\tilde{\nu}$ = 1467 cm^{-1}. $C_{34}H_{58}Cl_4N_6Zn_2 \cdot 1.5CH_2Cl_2$ (950.8): calcd. C 44.84, H 6.47, N 8.84; found C 44.59, H 6.67, N 8.61. ^1H NMR (200 MHz, [D$_6$]DMSO, 25 °C): δ = 1.67 (m, 8 H, $CH_2CH_2CH_2$), 2.18 (s, 12 H, NCH_3), 2.28 (s, 6 H, NCH_3), 2.70−2.30 (m, 16 H, NCH_2), 3.46 (s, 8 H, $ArCH_2$), 7.24 (s, 8 H, arom.) ppm. ^{13}C NMR (50 MHz, [D$_6$]DMSO, 25 °C): δ = 23.3 ($CH_2CH_2CH_2$), 42.2 (NCH_3), 55.0, 55.2 (NCH_2 and CH_2Cl_2), 61.5, 79.6 ($ArCH_2$), 129.1 (arom. tert.),137.5 (arom. quat.) ppm. ^1H NMR (200 MHz, D_2O, 25 °C): δ = 1.89 (m., 8 H, $CH_2CH_2CH_2$), 2.53 (s, 12 H, NCH_3), 2.53 (s, 6 H, NCH_3), 2.83, (m, 16 H, NCH_2), 3.91 (s, 8 H, $ArCH_2$), 7.47 (s, 8 H, arom.) ppm. ^{13}C NMR (50 MHz, D_2O, 25 °C): δ = 23.4 ($CH_2CH_2CH_2$), 43.4 (NCH_3), 56.2, 56.9 (NCH_2), 62.8 ($ArCH_2$), 133.7 (arom. tert.), 136.8 (arom. quat.) ppm. MS: *m*/*z* = 687.25 [$ZnCl_2$(Me3p)], 651.80 [ZnCl(Me3p)].

[Zn_2Cl_4(Me3m)]·H_2O (8·H_2O): Me3m (142 mg, 0.26 mmol) was dissolved in MeOH (3 mL). $ZnCl_2$ (71 mg, 0.52 mmol) dissolved in MeOH (1 mL) was added to this solution. The solution was vigorously stirred until a fine white powder precipitated. The solid was filtered, collected and dried under vacuum (125 mg, 0.15 mmol, 59%). The product was recrystallised from $CHCl_3$ to obtain a white microcrystalline solid insoluble in most common solvents (42 mg, 0.05 mmol, 19.8%). FT-IR (KBr): $\tilde{\nu}$ = 1467 cm^{-1}. $C_{34}H_{58}Cl_4N_6Zn_2 \cdot H_2O$ (841.5): calcd. C 48.53, H 7.19, N 9.99; found C 48.61, H 6.85, N 9.94.

Kinetics of *p*-Nitrophenyl Acetate (NA) Hydrolysis: The hydrolysis rate of NA in the presence of the Zn complexes was measured in a H_2O/CH_3CN (90:10 v:v) solution by an initial-slope method, following the increase in the 402 nm absorption of the released *p*-nitrophenolate at 298 K (± 0.05 K). The molar absorbance of *p*-nitrophenolate was determined at the pH of each measurement. The qionic strength was adjusted to 0.1 with $NaNO_3$. pH was adjusted with Tris buffer (pH 7−9; 50 mM). In a typical experiment, after mixing NA (5.15×10^{-4} M) and the Zn complex (0.1−0.5 mM) in 10% CH_3CN solution at appropriate pH (the reference experiment uses only the Zn^{II} complex), the UV absorption decay was recorded immediately and was followed generally until 2% decay of NA. This provided v_{in} values from which pseudo-first-order rate constants, k_{in}, calculated according to the expression $k_{in} = v_{in}/[NA]$. Second-order rate constants, k_{NA}, were obtained at a given pH from the plot of k_{in} vs. complex concentration.

X-ray Crystallography: Single crystals of $[Zn_2(NO_3)_2(H3p)](NO_3)_2$ (**3**) suitable for X-ray analysis were obtained from a concentrated methanol solution of the complex upon standing. Suitable crystals of [Zn_2Cl_4(Me2p)] (**5**) were obtained as colourless plates by slow evaporation of a CD_2Cl_2 solution. Suitable crystals of [Zn_2Cl_4(Me3p)]·1/3CH_2Cl_2 (**7·1/3CH_2Cl_2**) were obtained as colourless blocks by slow evaporation of a CH_3OH/CH_2Cl_2 (1:1 v:v) solution. Suitable crystals of [Zn_2Cl_4(Me3m)] (**8**) were obtained as colourless blocks by recrystallisation of the crude reaction mixture from a $CHCl_3$/MeOH/benzene/THF (2:1:1:1 v:v) mixture.

For **3**, data were collected on a Bruker Smart CCD diffractometer, using Mo-K_α (λ = 0.71073 Å) radiation. A summary of the fundamental crystal data and refinement data are given in Table 1. Data were collected over a hemisphere of the reciprocal space by combination of three exposure sets. Cell parameters were determined and refined by a least-squares fit of all reflections collected (θ range = 2.33 to 25°, *hkl* from −16, −17, −19 to 13, 18, 19, respectively). Each frame exposure time was of 20 s, covering 0.3° in ω. The first 50 frames were recollected at the end of the data collection to monitor crystal decay. No appreciable decay in the intensities of standard reflections was observed. The structure was solved by direct methods and refined by full-matrix least-squares on F^2 (SHELXS-97).[32] Anisotropic parameters were used in the last cycles of refinement for all non-hydrogen atoms, with exceptions. For the NO_3^- counteranion, no resolvable positional disorder of these atoms was found, and they were isotropically refined. Hydrogen atoms were included in calculated positions and refined as riding on the respective carbon atoms, with the thermal parameters related to the bonded atoms, except H1, H2 and H3, bonded to nitrogen atoms, which were located in a Fourier synthesis, included and their parameters fixed. The largest residual peaks in the final difference map, maximum 1.052 e·$Å^{-3}$, are close to the non-coordinating NO_3^- anion.

The intensity data were collected at 298 K (**8**) or 223 K (**5** and **7·1/3CH_2Cl_2**) on a Stoe Image Plate Diffraction System[33] using Mo-K_α (λ = 0.71073 Å) graphite-monochromated radiation. Image plate distance: 70 mm; φ oscillation scans: 0−200°; step Δφ: 1.0°; 2θ range: 3.27−52.1°; $d_{max}-d_{min}$ = 12.45−0.81 Å. The structures were solved by direct methods using the program SHELXS-97.[34] The H-atoms were included in calculated positions and treated as riding atoms using the SHELXL default parameters. The refinement and all further calculations were carried out using SHELXL-97.[34] The non-H atoms were refined anisotropically, using weighted full-matrix least-squares on F^2. For **7·1/3CH_2Cl_2** a small amount of residual electron density was located in a final difference Fourier synthesis at the origin of the unit cell about a threefold inversion axis. The SQUEEZE routine in PLATON[35] indicated the presence of a solvent accessible region of ca. 100 electrons for a volume of 1507 $Å^3$. This was equated to be equal to one third (1/3) of a highly disordered CH_2Cl_2 molecule per molecule of complex, and the HKL file was modified accordingly. The molecular structure and crystallographic numbering scheme are illustrated in the ORTEP drawing (Figure 1).

Crystallographic data for the structure included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-212656 ... -212659, for the complexes **3**, **5**, **7·1/3** CH_2Cl_2 and **8**, respectively. These data can be obtained free of charge at http://www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Supporting Information Available: NMR spectral characterisation data for the complexes described in the present work and VT-^1H NMR spectra of **5**. Kinetic data for the hydrolytic reactions.

Synthesis, Characterization and Properties of Transition Metal Pd/Pt [60]Fullerene Complexes Containing Phosphane Ligands − Crystal Structure of $[Pd(\eta^2\text{-}C_{60})\{Ph_2PCH_2(CH_2OCH_2)_2CH_2PPh_2\}]$

Li-Cheng Song,*[a] Guang-Ao Yu,[a] Hu-Ting Wang,[a] Fu-Hai Su,[a] Qing-Mei Hu,[a] Ying-Lin Song,[b] and Ya-Chen Gao[b]

Keywords: Fullerenes / Palladium / Phosphanes / Platinum

A solution of C_{60} in toluene reacts with $Pd(dba)_2$ or $Pd_2(dba)_3$ (dba = dibenzylideneacetone) and monophosphanes in a 1:1:2 molar ratio to give the corresponding Pd monophosphane fullerene derivatives $[Pd(\eta^2\text{-}C_{60})L_2]$ [L = $P(2\text{-Fu})_3$ (Fu = furyl) **1**; L = $P(2\text{-Fu})Ph_2$ **2**; L = PPh_2H **3**; L = $P(Fc)Ph_2$ (Fc = ferrocenyl) **4**; L = $P(Fc)_2Ph$ **5**], whereas reaction with $M(dba)_2$ (M = Pd, Pt) and subsequent treatment with diphosphanes in 1:1:1 molar ratio afforded the corresponding Pd/Pt diphosphane fullerene complexes $[Pd(\eta^2\text{-}C_{60})\{Ph_2PCH_2(CH_2OCH_2)_nCH_2PPh_2\}]$ (n = 1 **6**; n = 2 **7**; n = 3 **8**) and $[Pt(\eta^2\text{-}C_{60})\{Ph_2PCH_2(CH_2OCH_2)_nCH_2PPh_2\}]$ (n = 1 **9**; n = 2 **10**; n =3 **11**). All the new fullerene complexes **1**–**11** were characterized by elemental analysis, IR, ^1H NMR and ^{31}P NMR spectroscopy, as well as by X-ray diffraction analysis (for **7**). The optical limiting properties of **3**–**5** were determined and the possible pathways for the "one pot" reactions leading to **1**–**11** are briefly discussed.

Introduction

The synthesis, structural characterization, and properties of transition metal fullerene complexes have attracted great attention,[1] since the discovery of [60]fullerene[2] and its synthesis in macroscopic quantities.[3] These complexes may be classified into two major categories: exohedral metal complexes in which the fullerene behaves mainly as an electron-deficient alkene ligand directly π-bonded to transition metal center,[1] and endohedral compounds in which the metal atom is encapsulated by the fullerene cage.[4] We are interested in exohedral transition metal fullerene complexes[5] because it can be expected that the exohedral modification of the fullerene core using different metals with ancillary ligands may change the structure and properties of the fullerene itself and allow us to obtain new transition metal fullerene derivatives, possibly with novel structures and unique properties. In this article we will describe the synthesis and spectroscopic characterization of a series of new transition metal Pd/Pt [60]fullerene complexes containing mono- and diphosphane ligands. The nonlinear optical properties of some of the new derivatives and the crystal structure of one representative fullerene complex — $[Pd(\eta^2\text{-}C_{60})\{Ph_2PCH_2(CH_2OCH_2)_2CH_2PPh_2\}]$ — are also reported.

Results and Discussion

Synthesis and Characterization of $[Pd(\eta^2\text{-}C_{60})L_2]$

A toluene solution of C_{60} reacts with the mononuclear Pd complex $Pd(dba)_2$ (dba = dibenzylideneacetone) and the monophosphanes $P(2\text{-Fu})_3$ (Fu = furyl), $P(2\text{-Fu})_2Ph$, PPh_2H or $P(Fc)Ph_2$ in a 1:1:2 molar ratio at room temperature to give the corresponding monophosphane fullerene complexes **1**−**4**, respectively, in 63−93% yields, whereas it reacts with the dinuclear Pd complex $Pd_2(dba)_3$ and the monophosphane $P(Fc)_2Ph$ (Fc = ferrocenyl) under similar conditions to afford complex **5** in 76% yield (Scheme 1). Our attempts to prepare $[Pd(\eta^2\text{-}C_{60})\{P(Fc)_3\}_2]$ by the reac-

tion of a toluene solution of C_{60} with $Pd(dba)_2$ or $Pd_2(dba)_3$ followed by treatment with the monophosphane $P(Fc)_3$ under similar conditions were unsuccessful, probably due to the very low nucleophilicity of $P(Fc)_3$ caused by the three bulky ferrocenyl groups attached to the phosphorus atom.

It is believed that the sequential "one-pot" reactions leading to **1**−**5** include an intermediate fullerene complex $(C_{60}Pd)_n$ generated from C_{60} and $Pd(dba)_2$ or $Pd_2(dba)_3$, which reacts further with the monophosphanes to yield **1**−**5**. This pathway is suggested as C_{60} is known to react with $Pd_2(dba)_3$ to produce a black, insoluble polymer $(C_{60}Pd)_n$ ($n \approx 1$),[6] which can be depolymerized by monophosphanes to give the fullerene derivatives $[PdC_{60}L_2]$ (L = PPh_3, PEt_3).[7] This pathway is consistent with our observation that C_{60} reacts with $Pd(dba)_2$ or $Pd_2(dba)_3$ in toluene to give black suspensions.

Complexes **1**−**5** are air-stable solids that dissolve in polar solvents such as toluene, chlorobenzene, THF and CS_2, but do not dissolve in nonpolar solvents such as petroleum ether and hexane. In solution, **1**−**5** are air sensitive, and can release C_{60} completely within 1−2 days.

The IR spectra of **1**−**5** display four absorption bands in the range $\tilde{\nu}$ = 1435−521 cm^{-1} for their C_{60} cores,[8] while the ^{31}P NMR spectra of **1**−**5** each exhibit one singlet in the region δ = 7−30 ppm for the two identical P atoms. The ^1H NMR spectra of **1**−**5** show the corresponding signals for their respective hydrogen-containing groups. The UV/Vis spectra of **1**−**5** display two intense bands between 200 and 400 nm; the new weak broad band appearing at ca. 440 nm suggests that the C_{60} ligand is coordinated to palladium in an η^2-fashion in each of the compounds.[9]

The nonlinear optical properties of [60]fullerene and its derivatives are of considerable interest, largely because of their potential applications as optical limiting materials.[10−13] We recently studied the optical limiting properties of the fullerene derivatives **3**−**5**. Figure 1 shows the optical limiting curves of **3**−**5**, from which it can be seen that the optical limiting properties of **4** and **5** are virtually the same within the experimental accuracy. They display better optical limiting characteristics than **3**, probably due to both phenyl and ferrocenyl groups having stronger electron-donating ability than that of a hydrogen atom.[14]

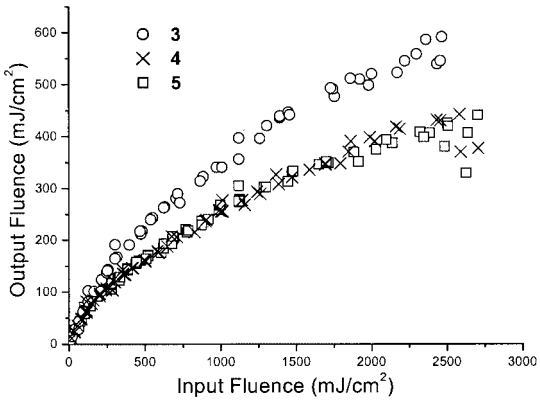

Figure 1. Optical limiting of **3**−**5** determined in toluene solution: **3** (6.26×10^{-5} mol/L); **4** (3.74×10^{-5} mol/L); **5** (5.10×10^{-5} mol/L)

Scheme 2

Synthesis and Characterization of $[Pd(\eta^2\text{-}C_{60})\{Ph_2PCH_2(CH_2OCH_2)_nCH_2PPh_2\}]$ and $[Pt(\eta^2\text{-}C_{60})\{Ph_2PCH_2(CH_2OCH_2)_nCH_2PPh_2\}]$

Similarly, C_{60} reacted with mononuclear complexes $M(dba)_2$ (M = Pd, Pt) in toluene, followed by in situ treatment with diphosphanes $Ph_2PCH_2(CH_2OCH_2)_nCH_2PPh_2$ (n = 1−3) in 1:1:1 molar ratio at room temperature to afford the first examples of the ether-chain-bridged diphosphane fullerene complexes **6**−**11** (M = Pd: n = 1 **6**, n = 2 **7**, n = 3 **8**; M = Pt: n = 1 **9**, n = 2 **10**, n = 3 **11**) in 61−94% yield (Scheme 2).

Presumably, these "one-pot" reactions for production of **6**−**11** also involve an intermediate polymer, either $(C_{60}Pd)_n$ or $(C_{60}Pt)_n$, generated from C_{60} and $M(dba)_2$ (M = Pd, Pt); the in situ reaction of $(C_{60}Pd)_n$ or $(C_{60}Pt)_n$ with the diphosphanes affords **6**−**11**. C_{60} is known to react with $Pt(dba)_2$ to give a black, insoluble polymer $(C_{60}Pt)_n$ ($n \approx 1$), and treatment of $(C_{60}Pt)_n$ with monophosphanes affords $[PtC_{60}L_2]$ (L = PPh_3, PEt_3).[15] Similarly, reaction of C_{60} with $Pd_2(dba)_3$ produces the polymer $(C_{60}Pd)_n$ ($n \approx 1$),[6] which reacts with dppe to yield $[PdC_{60}(dppe)]$.[7] We also observed the formation of black suspensions when C_{60} was reacted with $M(dba)_2$ (M = Pd, Pt) in toluene.

Similar to **1**−**5**, complexes **6**−**11** are air-stable solids, which are soluble in polar solvents, but insoluble in nonpolar solvents. In solution, **6**−**11** are air sensitive, but less so than **1**−**5**; they release C_{60} completely after two or three days. Compounds **6**−**11** were fully characterized by elemental analysis and spectroscopy, and **7** by X-ray crystallography. For instance, the IR spectra of **6**−**11** show four bands in the range $\tilde{\nu}$ = 1434−525 cm^{-1} for their C_{60} spheres,[8] whereas the UV/Vis spectra of **6**−**11** display two intense bands in the 200−400 nm range and one weak broad band at ca. 440 nm, indicating that the C_{60} ligand is coordinated to Pd or Pt in an η^2-mode in each of these complexes.[9] In addition, the ^{31}P NMR spectra of **6**−**8** show a singlet at about δ = 16 ppm for the two identical P atoms in each of **6**−**8**, whereas the spectra of **9**−**11** exhibit a singlet at about δ = 18 ppm, along with two satellite singlets due to ^{195}Pt-

^{31}P coupling, attributed to the two identical P atoms in each of **9**−**11**.

Crystal Structure of 7

The molecular structure of **7** has been unequivocally confirmed by single-crystal X-ray diffraction techniques (Figure 2). Figure 3 displays its cell packing. Selected bond lengths and angles are listed in Table 1. As can be seen from Figure 2, complex **7** indeed consists of a C_{60} ligand bound to the Pd atom in an η^2-fashion by the C(1)−C(2) 6:6 bond, and a diphosphane ligand $Ph_2PCH_2(CH_2OCH_2)_2CH_2PPh_2$ chelated to the Pd atom through the P(1) and P(2) atoms. In addition, from Figure 3 it can be seen that each crystal cell contains two molecules of **7** and two molecules of MeOH. The closest contact between solvent MeOH and **7** [2.467 Å, from the oxygen atom of MeOH to C(10) of the C_{60} ligand] is less than the sum of the van der Waals radii of C and O (3.22 Å),[16] which might be due to disorder of the MeOH molecule. In addition, the disordered MeOH molecule could also give rise to the relatively high *R* value (0.1426) for the structure of **7**.

To the best of our knowledge, **7** is the first crystallographically characterized transition metal fullerene complex containing an ether-chain-bridged diphosphane ligand. The Pd coordination geometry of **7** is similar to that of its monophosphane PPh_3-containing analogue [Pd(η^2-C_{60})(PPh_3)$_2$].[17] Figure 4 shows that the corresponding bond lengths and angles within the coordination spheres of the Pd atoms of these two complexes are very similar.

It is noteworthy that the C(1)−C(2) bond lengths of **7** and [Pd(η^2-C_{60})(PPh_3)$_2$][17] are slightly longer than the 6:6 bond length in free C_{60},[1a] due to the metal-to-C_{60} π-back-

donation.[1b] In addition, the Pd coordination geometries of **7** and $[Pd(\eta^2\text{-}C_{60})(PPh_3)_2]$ are square planar, the five atoms C(1), C(2), P(1), P(2) and Pd being coplanar, with deviations from the least-squares plane of less than 0.02 Å for **7** and 0.06 Å for $[Pd(\eta^2\text{-}C_{60})(PPh_3)_2]$.[17]

Interestingly, complex **7** could be regarded as a hybrid of a metallocrown ether and a fullerene, in which the Pd atom, part of an eleven-membered metallocrown ether ring [Pd(1)P(1)C(73)C(74)O(1)C(75)C(76)O(2)C(77)C(78)P(2)], is bound to the fullerene through the C(1)−C(2) 6:6 bond. In view of the unique structures and novel properties of both crown ether and fullerene, it can be expected that such modified hybrids might find practical applications in catalysis, molecular recognition and materials science.[1,18]

Experimental Section

General: All reactions were carried out under a highly purified nitrogen atmosphere using standard Schlenk or vacuum-line techniques. Toluene and hexane were distilled from Na/benzophenone ketyl. Other solvents were bubbled with nitrogen for at least 20 minutes before use. $Pd(dba)_2$,[19] $Pd_2(dba)_3$,[20] $P(Fc)_3$,[21] $P(Fc)_2Ph$,[22] $P(Fc)Ph_2$,[22] PPh_2H,[23] $P(2\text{-}Fu)_3$,[24] $P(2\text{-}Fu)Ph_2$ [25] and $Pt(dba)_2$ [26] were prepared according to literature methods. C_{60} (99.9%) is available commercially.

^1H NMR and ^{31}P NMR were recorded on a Bruker AC-P200 spectrometer, UV/Vis spectra on a Shimadzu UV-240 spectrometer and IR spectra on a Bio-Rad FTS 135 spectrometer. Elemental analysis was performed on an Elementar Vario EL analyzer. Melting points were determined on a Yanaco MP-500 apparatus.

Preparation of $[Pd(\eta^2\text{-}C_{60})\{P(2\text{-}Fu)_3\}_2]$ (1): A 50-mL three-necked flask equipped with a magnetic stir-bar, a rubber septum and a nitrogen inlet tube was charged with C_{60} (0.036 g, 0.05 mmol) and toluene (16 mL). $Pd(dba)_2$ (0.029 g, 0.05 mmol) was added to the purple toluene solution and then the mixture was stirred at room temperature for 0.5 h to give a black suspension. $P(2\text{-}Fu)_3$ (0.023 g, 0.10 mmol) was added to this suspension and the new mixture was stirred for another 0.5 h to produce a deep green solution. The solution was carefully layered with hexane (40 mL). After standing overnight, the mixture was filtered to give a precipitate, which was washed with (10 × 2 mL) of toluene and dried in vacuo. 0.054 g (84%) of **1** was obtained as a black solid. M.p. > 300 °C. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 6.39 (s, 6 H, 6 H^4 of furan ring), 6.78 (s, 6 H, 6 H^3 of furan ring), 7.64 (s, 6 H, 6 H^5 of furan ring) ppm. ^{31}P NMR (81.0 MHz, $CDCl_3$, H_3PO_4): δ = 30.04 (s, 2 P) ppm. IR (KBr disk): $\tilde{\nu}$ = 2327 (m), 1458 (m), 1427 (m) (C_{60}), 1364 (m), 1213(m), 1183 (m) (C_{60}), 1159 (m), 1122(m), 1009 (s), 906 (m), 745 (s), 592 (m), 577(m) (C_{60}), 524 (s) (C_{60}), 490 (s), 438 (m) cm^{-1}. UV/Vis (PhCl): λ_{max} (log ε) = 285.0 (4.93), 333.3 (5.11), 406.7 (3.85), 435.5 (3.84) nm. $C_{84}H_{18}O_6P_2Pd$ (1291.43): calcd. C 78.12, H 1.40; found C 77.95, H 1.50.

Preparation of $[Pd(\eta^2\text{-}C_{60})\{P(2\text{-}Fu)Ph_2\}_2]$ (2): This complex was prepared similarly, with $P(2\text{-}Fu)Ph_2$ (0.025 g, 0.10 mmol) instead of $P(2\text{-}Fu)_3$; 0.042 g (63%) of **2** was obtained as a black solid. M.p. > 300 °C. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 6.35 (s, 2 H, 2 H^4 of furan ring), 6.78 (s, 2 H, 2 H^3 of furan ring), 7.14−7.75 (m, 22 H, 4 C_6H_5, 2 H^5 of furan ring) ppm. ^{31}P NMR (81.0 MHz, $CDCl_3$, H_3PO_4): δ = 7.04 (s, 2 P) ppm. IR (KBr disk): $\tilde{\nu}$ = 1481 (m), 1434 (m) (C_{60}), 1356 (m), 1212 (m), 1183 (m) (C_{60}), 1120 (m), 1097 (m), 1009 (s), 904 (m), 874 (m), 742 (s), 693 (s), 577(m) (C_{60}), 524 (s) (C_{60}), 489 (m), 432 (m) cm^{-1}. UV/Vis (PhCl): λ_{max} (log ε) = 285.0 (4.91), 333.3 (4.93), 405.8 (4.17), 437.5(3.99) nm. $C_{92}H_{26}O_2P_2Pd$ (1331.58): calcd. C 82.98, H 1.97; found C 82.93, H 2.10.

Preparation of $[Pd(\eta^2\text{-}C_{60})(PPh_2H)_2]$ (3): This complex was prepared similarly, with PPh_2H (0.019 g, 0.10 mmol) in place of $P(2\text{-}Fu)_3$; 0.056 g (93%) of **3** was obtained as a black solid. M.p. 282−283 °C. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 7.48−7.74 (m, 20 H, 4 C_6H_5), 8.08 (d, J = 484 Hz, 2 H, 2 HP) ppm. ^{31}P NMR (81.0 MHz, $CDCl_3$, H_3PO_4): δ = 22.50 (s, 2 P) ppm. IR (KBr disk): $\tilde{\nu}$ = 2923 (m), 1457 (m), 1435 (m) (C_{60}), 1183 (m) (C_{60}), 1107 (m), 1036 (m), 1000 (m), 821 (m), 746 (m), 696 (s), 577(m) (C_{60}), 524 (s) (C_{60}), 489 (m), 430 (m) cm^{-1}. UV/Vis (PhCl): λ_{max} (log ε) = 285.0 (4.50), 331.7 (4.42), 405.8 (3.85), 436.0 (3.92) nm. $C_{84}H_{22}P_2Pd$ (1199.47): calcd. C 84.11, H 1.85; found C 84.15, H 2.00.

Preparation of $[Pd(\eta^2\text{-}C_{60})\{P(Fc)Ph_2\}_2]$ (4): This complex was prepared similarly, with $P(Fc)Ph_2$ (0.037 g, 0.10 mmol) instead of $P(2\text{-}Fu)_3$; 0.053 g (68%) of **4** was obtained as a black solid. M.p. > 300 °C. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 3.84 (s, 4 H, 2 H^3, 2 H^4), 4.01 (s, 10 H, 2 C_5H_5), 4.19 (s, 4 H, 2 H^2, 2 H^5), 7.25−7.75 (m, 20 H, 4 C_6H_5) ppm. ^{31}P NMR (81.0 MHz, $CDCl_3$, H_3PO_4): δ = 17.16 (s, 2 P) ppm. IR (KBr disk): $\tilde{\nu}$ = 3052 (m), 1570 (m), 1480 (m), 1458 (m), 1434 (m) (C_{60}), 1354 (m), 1306 (m), 1185 (m) (C_{60}), 1160(m), 1098 (m), 1028 (m), 1001 (m), 820 (s), 741 (s), 696 (s), 622 (m), 579(m) (C_{60}), 524 (s) (C_{60}), 485 (s), 430 (m) cm^{-1}. UV/Vis (PhCl): λ_{max} (log ε) = 287.0 (4.82), 333.0 (4.73), 405.6 (4.12), 432.5 (4.04) nm. $C_{104}H_{38}Fe_2P_2Pd$ (1567.51): calcd. C 79.69, H 2.44; found C 79.50, H 2.54.

Preparation of $[Pd(\eta^2\text{-}C_{60})\{P(Fc)_2Ph\}_2]$ (5): This complex was prepared similarly, with $Pd_2(dba)_3{\cdot}C_6H_6$ (0.026 g, 0.025 mmol) and $P(Fc)_2Ph$ (0.048 g, 0.10 mmol) instead of $Pd(dba)_2$ and $P(2\text{-}Fu)_3$; 0.068 g (76%) of **5** was obtained as a black solid. M.p. > 300 °C. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 4.18 (s, 8 H, 4 H^3, 4 H^4), 4.38 (s, 20 H, 4 C_5H_5), 4.83, 5.03 (s, s, 8 H, 4 H^2, 4 H^5), 7.30−7.95 (m, 10 H, 2 C_6H_5) ppm. ^{31}P NMR (81.0 MHz, $CDCl_3$, H_3PO_4): δ = 13.84 (s, 2 P) ppm. IR (KBr disk): $\tilde{\nu}$ = 2923 (m), 2851(m), 1456 (m), 1434 (m) (C_{60}), 1185 (m) (C_{60}), 1161 (m), 1056 (m), 1106 (m), 1026 (m), 1002 (m), 821 (s), 740 (m), 697 (s), 578(m) (C_{60}),

UV/Vis (PhCl): λ_{max} (log ε) = 285.0 (4.62), 314.0 (5.10), 318.6 (5.11), 437.5(3.94) nm. $C_{88}H_{28}OP_2Pt$ (1358.22): calcd. C 77.82, H 2.08; found C 77.75, H 2.10.

Preparation of [Pt(η²-C_{60}){$Ph_2PCH_2(CH_2OCH_2)_2CH_2PPh_2$}] (10): This complex was prepared similarly, with Pt(dba)$_2$ (0.033 g, 0.05 mmol) and $Ph_2PCH_2(CH_2OCH_2)_2CH_2PPh_2$ (0.024 g, 0.05 mmol) instead of Pd(dba)$_2$ and P(2-Fu)$_3$; 0.066 g (94%) of **10** was obtained as a black solid, M.p. > 300 °C. ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 2.50−2.75 (m, 4 H, 2 CH_2P), 3.65−3.95 (m, 8 H, 4 CH_2O), 7.10−7.70 (m, 20 H, 4 C_6H_5) ppm. ^{31}P NMR (81.0 MHz, $CDCl_3$, H_3PO_4): δ = 19.34 (s, $J_{P\text{-}Pt}$ = 3949 Hz, 2 P) ppm. IR (KBr disk): ṽ = 2921 (m), 2853 (m), 1479 (m), 1459 (s), 1434 (s) (C_{60}), 1331 (m), 1279 (m), 1184 (m) (C_{60}), 1128 (s), 1099 (s), 994 (s), 743 (s), 696 (s), 673 (m), 577(m) (C_{60}), 527 (s) (C_{60}), 484 (m), 414 (m) cm^{-1}. UV/Vis (PhCl): λ_{max} (log ε) = 285.0 (4.69), 314.2 (5.15), 318.3 (5.16), 440 (3.84) nm. $C_{90}H_{32}O_2P_2Pt$ (1402.27): calcd. C 77.09, H 2.30; found C 76.99, H 2.38.

Preparation of [Pt(η²-C_{60}){$Ph_2PCH_2(CH_2OCH_2)_3CH_2PPh_2$}] (11): This complex was prepared similarly, with Pt(dba)$_2$ (0.033 g, 0.05 mmol) and $Ph_2PCH_2(CH_2OCH_2)_3CH_2PPh_2$ (0.026 g, 0.05 mmol) instead of Pd(dba)$_2$ and P(2-Fu)$_3$; 0.064 g (89%) of **11** was obtained as a black solid, M.p. > 300 °C. ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 2.60−2.85 (m, 4 H, 2 CH_2P), 3.50−3.95 (m, 12 H, 6 CH_2O), 7.11−7.70 (m, 20 H, 4 C_6H_5) ppm. ^{31}P NMR (81.0 MHz, $CDCl_3$, H_3PO_4): δ = 19.35 (s, $J_{P\text{-}Pt}$ = 3946 Hz, 2 P) ppm. IR (KBr disk): ṽ = 2910 (m), 2853 (m), 1481 (m), 1459 (m), 1434 (s) (C_{60}), 1332 (m), 1280 (m), 1183 (m) (C_{60}), 1141 (m), 1101(s), 976 (m), 903 (m), 740 (s), 694 (s), 577(m) (C_{60}), 526 (s) (C_{60}), 489 (m) cm^{-1}. UV/Vis (PhCl): λ_{max} (log ε) = 287.0 (5.09), 333.0 (5.09), 405.0 (4.25), 438.5 (4.17) nm. $C_{92}H_{36}O_3P_2Pt$ (1446.32): calcd. C 76.40, H 2.51; found C 76.42, H 2.54.

Determination of the Optical Limiting Properties: The investigation of the optical limiting properties of the fullerene derivatives was conducted at a wavelength of 532 nm. They were housed in quartz cells with a path 2 mm long with the same linear transmittance of 83%. The laser pulses used in experiments were supplied by a frequency-doubled, Q-switched, mode-locked Continuum ns/ps Nd:YAG laser system, which provides linearly polarized 8 ns (FWHM) optical pulses at 532 nm with a repetition of 1 Hz. The transverse mode of the laser pulses is nearly Gaussian. The input laser pulses adjusted by an attenuator were split into two beams. One was employed as reference to monitor the incident laser energy, and the other was focused onto the sample cell by using a lens with 30 cm focal length. The sample was positioned at the focus. The incidence and transmitting laser pulses were monitored by utilizing two energy detectors (818J-09B, Newport Corp). The optical limiting was studied by measuring the nonlinear fluence transmittance change with input fluence.

Crystal Structure Determination of 7: Single crystals of **7** suitable for X-ray diffraction analysis were obtained by slow diffusion of MeOH into a toluene solution of **7** at room temperature. A crystal of **7** was glued to a glass fiber and mounted on a Bruker SMART 1000 automated diffractometer. Data were collected at room temperature, using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) in the ω-2θ scanning mode. Absorption correction was performed with SADABS.[27] The structure was solved by direct methods using the SHELXS-97 program and refined by full-matrix least-squares techniques (SHELXL-97) on F^2.[28] Hydrogen atoms were located by using the geometric method. The crystal data and structural refinements details are listed in Table 2. CCDC-216076 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structural, Magnetic and Electrochemical Studies of Antiferromagnetically Coupled Symmetric Oxamidate-Bridged Binuclear Copper(II) Complexes

Duraisamy Saravanakumar,[a] Nallathambi Sengottuvelan,[a] Vengidusamy Narayanan,[a] Muthusamy Kandaswamy,*[a] Kandaswamy Chinnakali,[b] Gopal Senthilkumar,[b] and Hoong Kun Fun[c]

Keywords: Magnetic properties / Electrochemistry / Copper / N,O ligands

The new binuclear copper(II) complexes Cu_2L^{1-3} and $[Cu_2L^{4,5}](ClO_4)_2$ were synthesized by reaction of the monomeric *cis*-*N*,*N*′-bis(3-aminopropyl)oxamidatocopper(II) complex [Cu(oxpn)] with acetylacetone, benzoylacetone, salicylaldehyde, 2-pyridinecarboxaldehyde and diacetyl monoxime in the presence of copper(II) acetate or perchlorate owing to the *trans* isomerisation of the *cis*-oxamidato complex. The crystal structure of Cu_2L^1 consists of centrosymmetric binuclear copper(II) ions which are bridged by an oxamidato group in the *trans* conformation with a copper–copper distance of 5.121 Å. Each copper(II) ion occupies an inner site of the N_2O_2 donor with a distorted square-planar environment. Electrochemical studies showed that two quasireversible one-electron reduction waves are obtained in the cathodic region (E^1_{pc} = −0.48 to −1.02 V, E^2_{pc} = −1.08 to −1.34 V). The conproportionation constants K_{con} for the mixed-valence $Cu^{I}Cu^{II}$ complexes have been determined electrochemically. Room-temperature magnetic-moment studies of binuclear copper(II) complexes reveal the presence of a strong antiferromagnetic interaction (μ_{eff} = 1.14–1.24 μ_B) which is also observed from the broad spectra with g = 2.1. A variable-temperature magnetic-susceptibility study of the complexes **1** and **4** gives J values of −510 cm^{-1} and −497 cm^{-1} respectively.

Introduction

Inorganic chemists are interested in synthesizing bi- and polymetallic complexes to design new molecular materials with unusual magnetic and electrical properties[1−5] and these bi- and polymetallic systems are also attractive as synthetic models of metallo biomolecules[6−8] due to the close proximity of the metal centers. To prepare polynuclear complexes, the use of polynucleating ligands[9,10] and the use of metal complexes as ligands are the most commonly followed strategies.[11−14] Self-assembly of a mononuclear oxamidato complex with a metal ion leads to a novel coordination polymer.[15] Oxamide-based ligands such as *N*,*N*′-bis(3-aminopropyl)oxamide (H_2oxpn) have been of great interest due to their ability to form polynuclear complexes.[16] The oxamide bridge is known to be very efficient in transmitting the exchange interaction between magnetic ions.[17−19] Oxamide ligands with two distinct coordination sites are used in the design of ditopic receptors to allow the translocation of a metal ion driven by pH variation which can lead to mechanical work at the molecular level.[20,21] This possibility gives rise to a new class of potential artificial molecular machines.[22,23] It is also possible to use substituted oxamate and oxamide ligands in the stabilization of unusual high oxidation state transition metal ions.[24,25] Furthermore, the monomeric *cis*-oxamidato complex Cu(oxpn) easily yields binuclear[26,27] and polynuclear[28] complexes by changing its conformation from *cis* to *trans*. It has also been shown that the NH_2 group of *N*,*N*′-disubstituted oxamides can be condensed with a carbonyl group of several compounds to yield new binucleating ligands.[29,30]

The work reported here is concerned with the synthesis, structural, spectral, magnetic and electrochemical properties of disubstituted oxamidate-bridged binuclear copper(II) complexes. These complexes can be used to synthesize polynuclear complexes with suitable multidentate ligands. A schematic diagram of the ligand frames is given in Figure 1.

Results and Discussion

Binuclear complexes are synthesized by condensation between the terminal NH_2 group of [Cu(oxpn)] with acetyl-

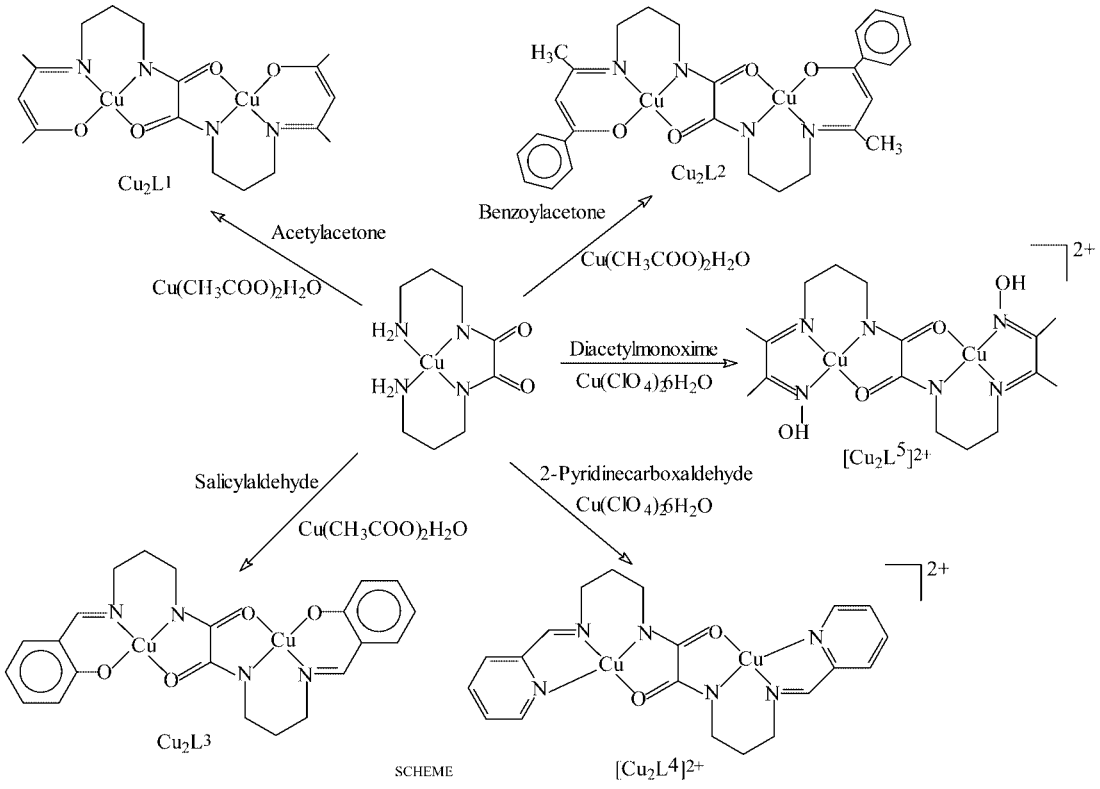
acetone (L^1), benzoylacetone (L^2), salicylaldehyde (L^3), 2-pyridinecarboxaldehyde (L^4) or diacetyl monoxime (L^5) in the presence of copper(II) acetate (L^{1-3}) or copper(II) perchlorate ($L^{4,5}$). Complexes $[Cu_2L^{1-3}]$ contain N_2O_2 coordination sites, whereas complexes $[Cu_2L^{4,5}](ClO_4)_2$ have N_3O coordinating sites. The synthetic pathway of the complexes is shown in Scheme 1.

X-ray Structural Study of the Complex $[Cu_2L^1]$

$[Cu_2L^1]$ crystallizes from a methanol/chloroform solution in the space group *Pbca*. The ORTEP view of the binuclear copper(II) complex, which consists of centrosymmetric binuclear copper(II) ions, along with the atomic labeling scheme, is given in Figure 2. Crystal data and structure refinement details are given in Table 1, with selected bond lengths (Å) and angles (°) in Table 2. Within the binuclear molecule, an oxamidate group in the *trans* conformation bridges crystallographically equivalent copper(II) ions. Each copper(II) ion is four-coordinate, with an N_2O_2 coordination environment in a distorted square-planar geometry. The oxamidato bridge is planar within experimental uncertainties and has a dihedral angle of 5.7° with the N_2O_2 coordination plane, so that the whole centrosymmetric molecule can be considered as planar. The bridging group N2−O1−C7−C7A−N1A−O1A is planar, with the copper atom being displaced by −0.0084(3) Å from this plane. The Cu1−Cu1A separation within the binuclear unit is 5.121 Å. One alkylamino nitrogen, one oxamidato nitrogen, one oxamidato oxygen and one acetonato oxygen atom are coordinated to each Cu ion with distances of Cu1−N2 = 1.954(2) Å, Cu1−N1 = 1.960(2) Å, Cu1−O1 = 2.008(2) Å and Cu1−O2 = 1.8871(19) Å, respectively. The Cu1−O1 distance is 0.1211 Å longer than the Cu1−O2 distance. Both the nitrogen atoms N1 and N2 are present at nearly the same distance from the Cu atom, within experimental error. The copper−amidic nitrogen (Cu−N2) distance is



Scheme 1

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1.954 Å, which is close to those of several reported oxamidato complexes.[17,36] The copper−iminic nitrogen (Cu−N1) distance is 1.960 Å and the copper−oxamide oxygen (Cu−O1) bond length is 2.008 Å, which are comparable to those reported earlier.[17] The bond angles around the Cu atom show significant deviations from 90°, two of them – O1Cu1O2 [84.69°(9)] and N2Cu1O1 [82.98°(11)] – being narrower than the other two N1Cu1N2 [97.2°(11)] and N1Cu1O2 [95.41°(10)]. The sum of the angles around C7, O1and N2 is 360.0° indicating that these atoms are trigonal planar. This implies that Cu1−O−C−*N*−Cu1A is a delocalised unit as a result of conjugation of the electrons from the oxygen atoms and the lone pairs on the nitrogen atoms. This is further supported by the average O−C and C−N bond lengths [1.272(3) and 1.295(4) Å, respectively], which are shorter than expected for single O−C or C−N bonds (ca. 1.481 and 1.462 Å, respectively). From the molecular packing it is observed that there are no intermolecular contacts that are less than the sum of the corresponding van der Waals radii. This suggests that there are no forces other than van der Waals interactions stabilizing the structure.[30]

Spectral Studies

The IR spectra of all the complexes show sharp bands resulting from the C=N stretching vibration (1640 cm^{-1}) and the oximidato C=O stretching vibration (1590 cm^{-1}). The presence of an uncoordinated perchlorate anion in complexes Cu_2L^4 and Cu_2L^5 is inferred from a single broad band at 1100 cm^{-1} (ν_3 antisymmetric stretching), which is not split, and a medium band at 650 cm^{-1} (ν_4 antisymmetric bending). The absence of any band at 930 cm^{-1}(ν_2 symmetric stretching) indicates the lack of coordination of the perchlorate ion.[31−33] The UV/Vis spectrum of the mononuclear complex Cu(oxpn)[13] exhibits a d → d transition around 510 nm consistent with a tetracoordinate Cu atom in a nearly square-planar CuN_4 geometry. The binuclear complexes Cu_2L^{1-5} display a d-d band in the range 572−592 nm. The λ_{max} value of the binuclear complexes is higher than that of the mononuclear species; such a red shift implies that the conformation of the ligand is altered from *cis* to *trans*, which changes the environment of the Cu^{II} ions from N_4 to N_2O_2 and N_3O. This is consistent with a previously reported observation.[18] Besides the d → d transition, a moderately intense band in the range 300−400 nm is due to a ligand-to-metal charge transfer ($\pi \rightarrow d_\sigma$) transition and a band below 300 nm is assigned to an intraligand transition ($\pi \rightarrow \pi^*$). The absorptions around 570 nm are attributed to square-planar CuN_2O_2 and CuN_3O chromophores.[34] Therefore, it appears that there is a distorted square-planar geometry of the Cu centers in the copper(II) complexes. The solution X-band ESR spectrum of Cu_2L^1 is shown in Figure 3. The solution (10^{-3} M in DMF) ESR spectra of the complexes Cu_2L^{1-5} display one broad absorption at g = 2.10 centered at 3200 G at room temperature. The ESR spectra with no hyperfine splitting

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the parallel component indicate that there is a strong antiferromagnetic interaction between the two copper(II) ions in the molecule.[16] Due to the favourable relative orientation of the magnetic orbitals a strong antiferromagnetic interaction is observed in spite of a Cu−Cu separation of about 5.121 Å. The fine structure of a triplet state for a Cu^{II} pair has two origins, namely the dipolar interaction and the combined effect of the local spin-orbit coupling and the exchange interaction, which leads to anisotropic and antisymmetric exchanges.[35] The above observation can be explained by earlier reports.[36,37]

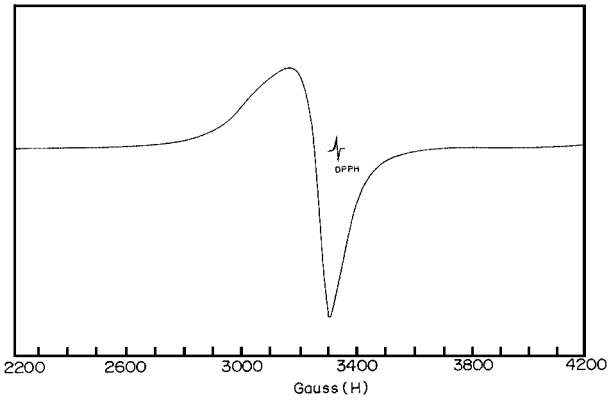

Figure 3. ESR spectrum of $[Cu_2L^1]$

Magnetic Susceptibility

The values of the magnetic moment for the binuclear copper(II) complexes measured at room temperature (298 K) are, at 1.14−1.24 μ_B, lower than the spin-only value and this clearly indicates that a strong antiferromagnetic exchange coupling is operating between the copper(II) ions. This behaviour shows a great similarity to that of binuclear Cu^{II} complexes involving bridging oxamido ligands and displaying a singlet−triplet energy gap of 500−600 cm^{-1}.[16,38−40] In order to determine the extent of magnetic interaction between the metal ions and to evaluate the singlet−triplet energy gap value $-2J$, magnetic susceptibilities at various temperatures (298−75 K) were measured. The temperature variation of $\chi_m T$ for the complexes $[Cu_2L^1]$ and $[Cu_2L^4](ClO_4)_2$ are shown in Figure 4. The experimental magnetic susceptibility values corrected for diamagnetism were fitted with the theoretical values defined by the modified Bleaney−Bowers equation.[41]

$$\chi_m = (Ng^2\beta^2)/(3kT)[3 + \exp(-2J/kT)]^{-1}(1 - P) + (0.45P/T) + N_\alpha$$

where χ_m is the molar magnetic susceptibility of the complex, P is the percentage of monomeric impurities, N is Avogadro's number, β is the Boltzmann constant, g is the average gyromagnetic ratio, $-2J$ is the singlet−triplet separation, and N_α is the temperature-independent paramagnetism (120×10^{-6} $cm^3 \cdot mol^{-1}$). A nonlinear least-square fitting program was employed to calculate $-J$, g and P. From the best fit of the susceptibility data with this equation, a J value of -510 cm^{-1} was obtained with $g = 2.10$ and $P = 0.0012$ for $[Cu_2L^1]$. $[Cu_2L^4]$ gave a J value of -497 cm^{-1} with $g = 2.12$ and $P = 0.0020$. Even though both complexes have the same bridging groups, $[Cu_2L^4]$ has a lower J value than $[Cu_2L^1]$ due to electronic effects. $[Cu_2L^1]$, containing an N_2O_2 coordination environment, has an enriched electron density facilitating the exchange interaction, whereas in the case of $[Cu_2L^4]$, the electron density at the N_3O site is lower than in $[Cu_2L^1]$ and hence the exchange interaction is also less. Electronic effects in symmetrical ligands have little influence on the magnetic exchange between copper(II) ions.[42] Higher J values are observed for $[Cu_2L^1]$ and $[Cu_2L^4]$, in which the oxamide bridge has the *trans* configuration and the two copper atoms have the same environment so that the two copper atoms are equal in energy. The large J values reveal that the strong antiferromagnetic interaction between two bridged Cu^{II} ions in complexes $[Cu_2L^1]$ and $[Cu_2L^4]$ is mainly due to the enhanced in-plane overlap of the oxamidato bridge.[43] The J value reported in this case is consistent with earlier reports[44−47] for *trans*-oxamidate-bridged binuclear copper(II) complexes.

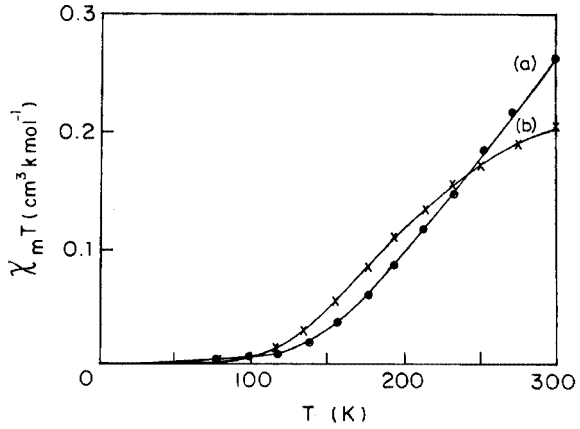

Figure 4. Temperature dependence of the magnetic properties for: (a) $[Cu_2L^1]$, and (b) $[Cu_2L^4](ClO_4)_2$

Electrochemical Studies

The molar conductivity of freshly prepared solutions of the complexes $[Cu_2L^{1-3}]$ in DMF falls in the range 10−15 Λ_m/S cm^2 mol^{-1}, indicating that the complexes are neutral. The molar conductance values of the complexes $[Cu_2L^{4,5}]$ are in the range 107−110 Λ_m/S $cm^2 \cdot mol^{-1}$ indicating that the complexes are 1:2 electrolytes.[48]

Cyclic Voltammetric Studies

The cyclic voltammograms for the copper(II) complexes at negative potential were recorded in the potential range 0 to −1.5 V; the data are summarized in Table 3. The cyclic voltammograms obtained for the complexes $[Cu_2L^1]$ and $[Cu_2L^5](ClO_4)_2$ in the cathodic region are shown in Figure 5. All the binuclear copper(II) complexes show two-step, one-electron, quasi-reversible reduction waves. Controlled potential electrolysis performed at a potential 100 mV more negative than the reduction wave indicates the consumption

[a] Measured by CV at 50 mV/s. *E* vs. Ag/AgCl. Conditions: GC working and Ag/AgCl reference electrode; supporting electrolyte TBAP; [complex] = 1×10^{-3} M, [TBAP] = 0.1 M.

of one electron per molecule for both the first and second reduction wave. Cyclic voltammograms for all the complexes are similar and involve two quasi-reversible redox processes. Even though in all the complexes both the metal ions have the same geometry and same environment, two reduction waves are obtained in the cathodic region corresponding to stepwise one-electron reductions through a Cu^ICu^{II} intermediate to give a binuclear Cu^I species. In spite of the ligands being symmetrical, their dicopper(II) complexes show two quasi-reversible reduction waves.[49] The two redox processes are represented as follows:

$$Cu^{II}Cu^{II} \rightleftarrows Cu^{II}Cu^{I} \rightleftarrows Cu^{I}Cu^{I}$$

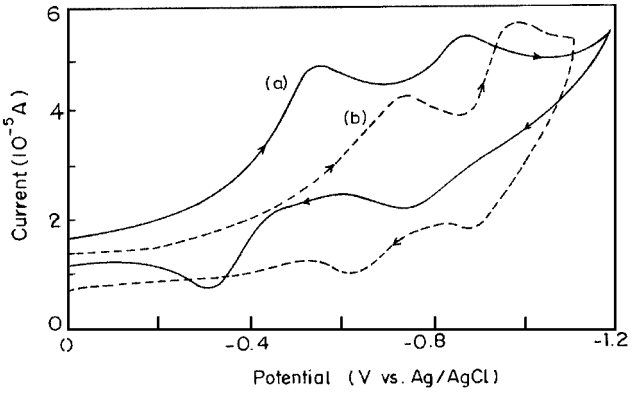

Figure 5. Cyclic voltammograms of: (a) $[Cu_2L^5](ClO_4)_2$, and (b) $[Cu_2L^1]$

The reason for the observation of two reduction waves may be due to electronic exchange between the metal ions: after the first one-electron reduction some of the electron density is transferred from the reduced metal ion to the other metal ion through the oxamidato bridge, and hence the second reduction appears at higher negative potential. The reduction waves are somewhat broad. This may be due to the equilibrium binding of solvent to the Cu^{II} center. The peak broadening diminishes as the scan rate increases.[50] The first reduction wave appears in the potential range −0.48 to −1.02 V. The second reduction wave occurs in the potential range −0.68 to −1.34 V. The potentials at the first reduction waves of the $[Cu_2L^{3-5}]$ are lower than for $[Cu_2L^{1,2}]$. This indicates that $[Cu_2L^{4,5}]$, with an N_3O coordination environment, are reduced more easily. Even though $[Cu_2L^3]$ possesses an N_2O_2 site like $[Cu_2L^{1,2}]$, the first reduction potential of $[Cu_2L^3]$ is lower than that of $[Cu_2L^{1,2}]$, possibly due to the combined effect of the phenoxide ion and unsaturation that reduce the electron density around the metal ion. The difference between the half-wave potentials of the two-redox processes is a measure of the relative stability of mixed-valence species. This approach used for symmetrical complexes with two metal ions in the same coordination environment. The stability of the mixed-valence species Cu^ICu^{II}, can be related to their conproportionation constants, K_{con}. The conproportionation constant for the equilibrium was calculated using the relationship $\log K_{con} = \Delta E/0.0591$. A greater K_{con} value indicates greater stability for the mixed-valence species or that the exchange interaction is greater with respect to the isovalent species.[51] This indicates that the enhanced stability for the Cu^ICu^{II} intermediate species is probably due to the exchange interaction between the metal centers[52] through the oxamido bridge. The larger the separation between the potentials of the couple, the greater the stability of mixed-valence species with respect to conproportionation.[53,54] Among the copper(II) complexes, $[Cu_2L^4]$ has a lower separation between the potentials than the other complexes, and the lower K_{con} value of $[Cu_2L^4]$ suggests easier access to the Cu^ICu^{II} species. This is because the exchange interaction is less due to distortion of the geometry, and the stability of the mixed-valence species is lower than that of the rest of the complexes. $[Cu_2L^3]$ and $[Cu_2L^5]$ have higher K_{con} values due to a larger separation between the potentials, and there may be a greater exchange interaction between the metal ions in $[Cu_2L^3]$ and $[Cu_2L^5]$. The conproportionation constant was calculated by following the equilibrium:

$$Cu^{II}\,Cu^{II} \rightleftharpoons Cu^{II}\,Cu^{I} \rightleftharpoons Cu^{I}\,Cu^{I}$$

$$Cu^{II}\,Cu^{II} + Cu^{I}\,Cu^{I} \overset{K_{con}}{\rightleftharpoons} 2Cu^{II}\,Cu^{I}$$

Conclusion

A series of *N*,*N*′-bis(disubstituted) oxamidato-bridged binuclear copper(II) complexes has been synthesized. The spectral, electrochemical and magnetic properties of the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complexes were studied. From these studies it can be seen that a small variation in the ligand environment imposes an influence on the spectral, magnetic and electrochemical properties of the complexes.

Experimental Section

General: Elemental analysis was carried out on a Carlo Erba Model 1106 elemental analyzer. Electronic spectral studies were carried out on a Hitachi 320 model double beam spectrophotometer in the range 250−800 nm in DMF. IR spectra were recorded on a Hitachi 270−50 spectrophotometer as KBr disks in the range 4000−400 cm^{-1}. Cyclic voltammograms were obtained on a CH instruments electrochemical analyzer. The measurements were carried out at 50 mV/sec under oxygen-free conditions using a three-electrode cell with a glassy carbon electrode as the working electrode, a saturated Ag/AgCl electrode as the reference electrode and platinum wire as the auxiliary electrode. Tetra(*n*-butyl)ammonium perchlorate (TBAP) was used as the supporting electrolyte. The ferrocene/ferrocenium(1+) couple was used as an internal standard ($E_{1/2}$ of the Fc/Fc^+ couple under these experimental conditions is 470 mV in DMF and ΔE_p for Fc/Fc^+ is 70 mV at a 50 mV/sec scan rate). The conductivity measurements were carried out with an Elico digital conductivity bridge model CM-88 using freshly prepared 10^{-3} M solutions of the complexes in DMF. Room temperature magnetic moment and variable-temperature magnetic studies were performed on a PAR model 155 vibrating-sample magnetometer in the temperature range 77−300 K, and the instrument was calibrated using metallic nickel. All data were corrected for diamagnetism of the ligand estimated from Pascal's constants. X-band solution ESR spectra of the complexes (10^{-3} M in DMF) were recorded at 25 °C on a Varian EPR-E 112 spectrometer using diphenylpicrylhydrazine (DPPH) as the reference.

All the chemicals and solvents were of analytical grade and were used as received. The TBAP used as supporting electrolyte in electrochemical measurement was purchased from Fluka and recrystallised from hot methanol. (***Caution!*** *TBAP is potentially explosive, hence care should be taken in handling the compound*). DMF (HPLC) was obtained from Merck.

Preparation of [Cu(oxpn)]: The ligand H_2oxpn {*N*,*N*′-bis(3-aminopropyl) oxamide}[55] and its mononuclear copper(II) complex[18] were prepared following literature procedures.

Synthesis of [Cu_2L^1]: A methanolic solution (40 mL) of acetylacetone (0.40 mL, 3.8 mmol) and $Cu(CH_3COO)_2{\cdot}H_2O$ (0.38 g, 1.9 mmol) were added to a stirred suspension of Cu(oxpn) (0.5 g, 1.9 mmol) in methanol (20 mL). After stirring for an hour, the solution was heated to reflux for 20 min. The resulting solution was filtered and kept at room temperature. Green microcrystals were obtained on slow evaporation of the solution. Yield: 0.9 g (80%). Plate-shaped dark-green crystals suitable for XRD were obtained on recrystallisation from a methanol/chloroform mixture (1:1). $C_{18}H_{26}N_4Cu_2O_4$ (489.51): calcd. C 44.17, H 5.31, Cu 25.96, N 11.45; found C 44.15, H 5.28, Cu 25.43, N 11.42. Selected IR data (KBr): $\tilde{\nu}$ = 1618 (sh, I = 23.7%), 1598 (sh, 28.2%), 1552 (sh, 27.6%) cm^{-1} (sh = sharp, I = intensity). Conductance (Λ_m/S cm^2 mol^{-1}) in DMF 10. λ_{max} (nm) (ε/$M^{-1}{\cdot}cm^{-1}$) in DMF: 572 (200), 329 (18400), 263 (16500). g = 2.10; μ_{eff} = 1.15 μ_B; J = −510 cm^{-1}.

Synthesis of [Cu_2L^2]: This complex was synthesized by following the above procedure using benzoylacetone (0.61 g, 3.8 mmol) instead of acetylacetone. A dark-green crystalline compound was obtained. Yield: 0.75 g (67%). $C_{28}H_{30}Cu_2N_4O_4$ (613.66): calcd. C 54.81, H 4.89, Cu 20.71, N 9.13; found C 54.78, H 4.87, Cu 20.68, N 9.09. Selected IR data (KBr): $\tilde{\nu}$ = 1625 (sh, 7.6%), 1596 (sh, 20.5%), 1525 (sh, 17.6%) cm^{-1}. Conductance (Λ_m/S cm^2 mol^{-1}) in DMF: 14. λ_{max} (nm) (ε/$M^{-1}{\cdot}cm^{-1}$) in DMF: 581 (250), 344 (13600), 266 (11200). g = 2.10; μ_{eff} = 1.18 μ_B

Synthesis of [Cu_2L^3]: This complex was synthesized by following the above procedure using salicylaldehyde (0.39 mL, 3.8 mmol) instead of acetylacetone. A pale-green compound was obtained. Yield: 0.83 g (79%). $C_{22}H_{22}Cu_2N_4O_4$ (533.53): calcd. C 49.53, H 4.12, Cu 23.82, N 10.50; found C 49.52, H 4.10, Cu 23.75, N 10.49. Selected IR data (KBr): $\tilde{\nu}$ = 1615 (sh, 9.1%), 1593 (sh, 41.6%), 1530 (sh, 46.3%) cm^{-1}. Conductance (Λ_m/S cm^2 mol^{-1}) in DMF: 15. λ_{max} (nm) (ε/$M^{-1}{\cdot}cm^{-1}$) in DMF: 599 (240), 366 (47200), 261 (46100). g = 2.10; μ_{eff} = 1.14 μ_B

Synthesis of [Cu_2L^4] $(ClO_4)_2$: A methanolic solution (40 mL) of 2-pyridinecarboxaldehyde (0.36 mL, 3.8 mmol) and $Cu(ClO_4)_2{\cdot}6H_2O$ (0.7 g, 1.9 mmol) was added to a stirred suspension of Cu(oxpn) (0.5 g, 1.9 mmol) in methanol (20 mL). After stirring for an hour, the solution was heated to reflux for 20 min. The resulting solution was filtered and kept at room temperature. A brown crystalline compound was obtained on slow evaporation of the solution. Yield: 0.95 (71%). $C_{20}H_{22}Cl_2Cu_2N_6O_{10}$ (704.42): calcd. C 34.09, H 3.12, Cu 18.05, N 11.93; found C 34.02, H 3.15, Cu 17.92, N 11.89. Selected IR data (KBr): $\tilde{\nu}$ = 1624 (sh, 6.5%), 1590 (sh, 38.7%), 1098 (str, 4.3%), 650 (m, 24.2%) cm^{-1}. Conductance (Λ_m/S cm^2 mol^{-1}) in DMF: 110. λ_{max} (nm) (ε/$M^{-1}{\cdot}cm^{-1}$) in DMF: 592 (105), 345 (42400), 268 (47300). g = 2.10; μ_{eff} = 1.24 μ_B, J = −497 cm^{-1}.

Synthesis of [Cu_2L^5]$(ClO_4)_2$: This complex was synthesized by following the above procedure using diacetyl monoxime (0.61 g, 3.8 mmol) instead of 2-pyridinecarboxaldehyde. A green compound was obtained. Yield: 1 g (86%). $C_{16}H_{26}Cl_2Cu_2N_6O_{12}$ (692.41): calcd. C 27.74, H 3.75, Cu 18.36, N 12.73; found C 27.69, H 3.71, Cu 18.25, N 12.69. Selected IR data (KBr): $\tilde{\nu}$ = 2750 (str, 42.6%), 1622 (sh, 10.2%), 1591 (sh, 43.3%), 1102 (str, 7.6%), 1230 (str, 44.7%), 648 (m, 31.7%) cm^{-1}. Conductance (Λ_m/S cm^2 mol^{-1}) in DMF: 107. λ_{max} (nm) (ε/$M^{-1}{\cdot}cm^{-1}$) in DMF: 572 (140), 334 (48400), 262 (43800). g = 2.10; μ_{eff} = 1.21 μ_B

Crystal Structure Determinations: Accurate unit cell parameters and orientation matrices were obtained by a least-squares fit of high angle reflections with Mo-K_α radiation on a Siemens SMART CCD area detector in the ω-scan mode for [Cu_2L^1]. Cell refinement and data reduction were carried out using SAINT (Siemens, 1996). A total of 11341 reflections were collected, resulting in 2461 independent reflections of which 1805 had $I > 2\sigma(I)$ and these were considered as observed. The intensities were corrected for Lorentz and polarization effects. The structure was solved by direct methods as implemented in SHELXTL-97.[56] The positions of all non-hydrogen atoms were included in the full-matrix least-squares refinement using SHELXTL-97. The positions of all the hydrogen were geometrically fixed at calculated positions and they were allowed to ride on the corresponding non-hydrogen atoms. The final R factor was 0.0562, maximum and minimum values of the electron densities in the final electron density map were 0.800, −1.078 e·Å^{-3}. A dark-green crystal of [Cu_2L^1] of dimension 0.50 × 0.46 × 0.10 mm^3 was used for indexing and intensity data collection on a Siemens Smart CCD diffractometer equipped with a fine focus, 3 kW sealed tube X-ray source and graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 183(2) K. Empirical absorption corrections were applied for compound by using SADABS (Sheldrick, 1996) program for the Siemens area detector.

Tuning the Catalase Activity of Dinuclear Manganese Complexes by Utilizing Different Substituted Tripodal Ligands

Nicole Reddig,[a] Daniel Pursche,[a] Michael Kloskowski,[a] Caroline Slinn,[a] Sascha M. Baldeau,[a] and Annette Rompel*[a]

Keywords: Manganese / Tripodal ligands / Bioinorganic chemistry / Enzyme models

A series of five new dinuclear manganese(II/II) compounds with derivatives of 2-{[bis(pyridin-2-ylmethyl)amino]-methyl}phenol (HL_1) were synthesized and structurally characterized. All complexes crystallize in monoclinic space groups and exhibit Mn···Mn separations in the range of 3.392(8)–3.493(2) Å caused by bis(μ-phenoxo) bridging modes. The derivatives of HL_1 contain either electron-donating or -withdrawing substituents. A correlation between the electronic character of the different ring substituents, the redox potentials of the dinuclear transition metal complexes and the catalase activity has been revealed. In analogy to manganese catalase, all complexes show saturation kinetics at high substrate concentration. The investigated catalase activity places the compounds in the upper range of functional catalase mimics.

Introduction

The manganese catalases are the most intensively studied dinuclear manganese enzymes. By disproportionating hydrogen peroxide into water and dioxygen, manganese catalases protect cells from deleterious effects caused by this harmful by-product of respiration. In addition to heme-type catalases,[1] there is another class of manganese catalases that has been found in three bacterial organisms, *Lactobacillus plantarium*,[2,3] *Thermus thermophilus*,[4,5] and *Thermoleophilum album*.[6] The manganese catalase from *Thermus thermophilus* is the best characterized one. During the catalytic cycle the oxidation states of the dinuclear manganese center change between Mn_2(II/II) and Mn_2(III/III). There are also two inactive forms [Mn_2(II/III) and Mn_2(III/IV)], which are caused by one-electron transitions during the disproportionation of hydrogen peroxide.[7,8]

So far only three functional model systems for the catalase reaction have been described which employ Mn_2(II/II) and Mn_2(III/III) in their catalytic cycles. The first system, $[Mn_2(L^1)(\mu\text{-OAc})]^{2+}$, is based on a heptadentate ligand L^1 [*N*,*N*,*N*′,*N*′-tetrakis(2-methylenebenzimidazolyl)-1,3-diaminopropan-2-ol] and was the first functional catalase mimic.[9–12] The second model system is the [Mn_2(2-OHsalpn)$_2$] [2-OHsalpn = 1,3-bis(salicylideneamino)-2-propanol] system. It has been fully crystallographically and spectroscopically characterized in four different oxidation states and serves as both a structural and functional manganese catalase mimic.[13–15] At the moment the most efficient catalase mimic is based on the ligand bpia [bis(picolyl)-(*N*-methylimidazol-2-yl)amine], which belongs to the class of tripodal ligands. The [Mn_2(bpia)$_2$] system consists of four dinuclear complexes, that mimic structural, spectroscopic and functional features of manganese catalases. $[Mn_2(bpia)_2(\mu\text{-OAc})_2](ClO_4)_2$ and $[Mn_2(bpia)_2(\mu\text{-O})_2](ClO_4)_2$-$(PF_6)\cdot 2CH_3CN$ are the most efficient catalysts using the Mn_2(II/II) and Mn_2(III/IV) redox couple reported to date for the disproportion of hydrogen peroxide.[16]

In this paper we report the synthesis, characterization and catalase activity of five new dinuclear Mn_2(II/II) complexes. They are based on tripodal ligands featuring an N_3O donor set, where the parent ligand is 2-({bis[(pyridin-2-yl)-methyl]amino}methyl)phenol. The phenol moiety of the ligands leads to a bis(μ-phenoxo) bridging motif, leaving one vacant coordination site at each manganese center. These are occupied by two mutually *trans*-positioned chloride ions. The catalytic activity regarding the disproportionation of hydrogen peroxide depends on the ring substituents. It will be shown that electron-withdrawing groups decrease the ability to disproportionate hydrogen peroxide, whereas electron-donating groups increase this ability. The catalase activities of the model compounds described in this paper range between those of [Mn_2(bpia)$_2$] and [Mn_2(2-OHsalpn)$_2$] and place the five dinuclear manganese(II/II) complexes in second position for functional manganese catalase mimics.

Results and Discussion

Reaction of manganese(II) chloride tetrahydrate with the corresponding ligand under basic conditions yields the di-

nuclear manganese complexes $[Mn_2(L_1)_2Cl_2]\cdot 2CH_2Cl_2$ (**1**), $[Mn_2(L_2)_2Cl_2]\cdot C_2H_5OH$ (**2**), $[Mn_2(L_3)_2Cl_2]\cdot 2CH_2Cl_2$ (**3**), $[Mn(L_4)_2Cl_2]\cdot 2CH_2Cl_2$ (**4**) and $[Mn_2(L_5)_2Cl_2]$ (**5**). All compounds crystallize in the monoclinic crystal system. Complexes **1**−**3** crystallize in the space group $P2_1/c$ (no.14), while **4** and **5** crystallize in $I2/a$ (no.15). Each unit cell consists of four complex molecules, except for compound **3**, where only two complex molecules can be found. Either eight (**1**), four (**2**, **3**, and **4**), or no (**5**) solvent molecules complete the unit cells. The manganese ions are in the oxidation state +II. They are bis(μ-phenoxo)-bridged by the ligands' phenol groups resulting in Mn···Mn-distances in the range from 3.392(8) Å (**5**) to 3.493(2) Å (**4**). The distorted octahedral coordination environment of each manganese center is formed by an N_3O_2Cl donor set, where, except for the chloride ions, all donor atoms are provided by the ligands. The crystal structure of the metal complexes are depicted below. Selected bonds and angles for all complexes are listed in Table 1.

Table 1. Selected distances [Å] and angles [°] of **1**−**5**

	1[a]	**2**[a]	**3**	**4**	**5**
Mn(1)···Mn(1a)[b]	3.411(1)	3.440(1)	3.406(2)	3.493(2)	3.392(8)

[a] Bond lengths and angles for Mn(2) are omitted for clarity. [b] Mn(1a) = Mn(2) and O(1a) = O(2) for **1**.

$[Mn_2(L_1)_2(Cl)_2]\cdot 2CH_2Cl_2$ (1; Figure 1): Mononuclear Cu,[17] Fe,[18] Re,[19] and Zn[20] complexes of HL_1 are known. In addition, dinuclear Fe,[21,22] Cu,[23] and Zn[20] complexes have also been published.

The Mn−N bond lengths around Mn(1) range from 2.254(5) for Mn(1)−N(3) to 2.367(5) Å for Mn(1)−N(1). The distances for the Mn(1)−O bonds are 2.119(4) [O(1)] and 2.203(4) Å [O(2)]. The longest bond to be found is Mn(1)−Cl(1) [2.451(2) Å]. Except for small deviations, the manganese−donor atom bonds for Mn(2) are in the same range as for Mn(1). The average N(1)−Mn(1)−N(X) (X = 2, 3) and N(4)−Mn(2)−N(Y) (Y = 5, 6) angles of 72.7 and 72.3° differ significantly from 90° and show the distortion from octahedral geometry due to constraints imposed by the ligand.

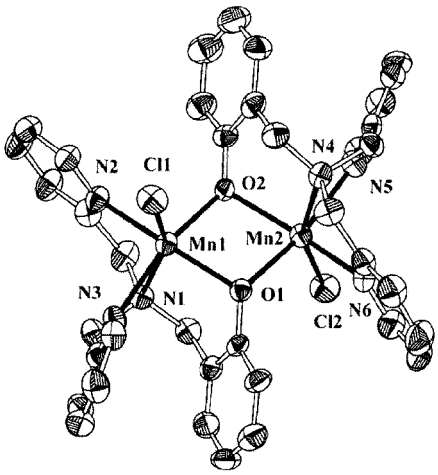

Figure 1. Ellipsoid plot of **1** showing 50% probability thermal ellipsoids; hydrogen atoms are omitted for clarity

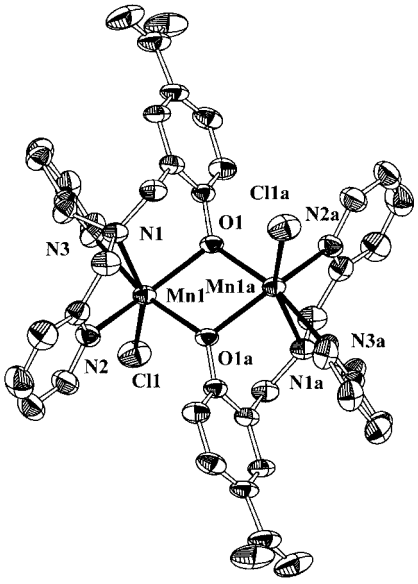

Figure 2. Ellipsoid plot of **2** showing 50% probability thermal ellipsoids; hydrogen atoms are omitted for clarity

$[Mn_2(L_2)_2(Cl)_2]\cdot C_2H_5OH$ (2; Figure 2): In 1987 an analogous structure of complex **2** was published by Nishida with NCS ligands instead of chloride ligands ($P2_1/n$).[24] In addition, mono- and dinuclear copper complexes[23,25−27] and mononuclear iron complexes[18,28] of HL_2 have been described in the literature.

There are two half complex molecules and one ethanol molecule in the asymmetric unit. Both manganese(II) centers of each independent complex molecule are related by a crystallographic inversion center. The coordination environment of Mn(1) is described as it is representative of both Mn(1) and Mn(2). The longest bond to be found is

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Mn(1)−Cl(1) [2.426(1) Å]. The chloride ion is bonded *trans* to the aliphatic nitrogen atom N(1), with a bond length of 2.360(3) Å. This is considerably longer than the manganese−pyridine distances Mn(1)−N(2) [2.263(3) Å] and Mn(1)−N(3) [2.288(3) Å]. The average distance for the Mn−O bonds is 2.168 Å.

The five-membered chelate rings containing Mn(1), N(1), N(2/3) cause a distortion from an ideal octahedral geometry. Hence, for the average N(1)−Mn(1)−N(X) (X = 2, 3) angles a deviation of 17.8° from the ideal 90° angle is observed. The distortion is shown best in the angles including *trans*-bonded donor atoms. The largest difference from linearity occurs in the angles O(1)−Mn(1)−N(2) [146.9(1)°].

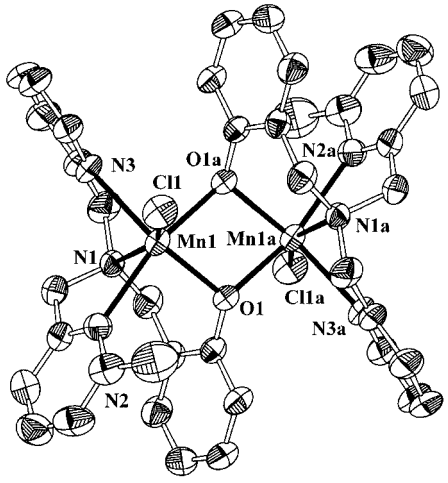

Figure 3. Ellipsoid plot of **3** showing 50% probability thermal ellipsoids; hydrogen atoms and a depiction of the chloride disorder are omitted for clarity

$[Mn_2(L_3)_2(Cl)_2]\cdot 2\ CH_2Cl_2$ (3; Figure 3): There is a crystallographic inversion center found in the middle of the dinuclear complex, rendering the two halves of the molecule crystallographically equivalent. The chloride ion is disordered. The occupation factors for both forms were refined to 0.71 and 0.29. The manganese−chlorine bonds show an average value of 2.407 Å. The aliphatic nitrogen atom N(1) is bonded *trans* to the chloride ion, with a bond length of 2.330(4) Å. This is shorter than the manganese−pyridine distances. The bond Mn(1)−N(2) [2.399(4) Å] is the longest manganese−nitrogen bond in the complex, which can be attributed to the steric effects of the methyl substituent in the *ortho* position of N(2). The Mn−O bond lengths are in the same range. The average N(1)−Mn(1)−N(X) (X = 2, 3) angle of 71.7° differs significantly from 90° and shows the distortion from octahedral geometry due to constraints imposed by the ligand.

$[Mn_2(L_4)_2(Cl)_2]\cdot 2CH_2Cl_2$ (4; Figure 4) and $[Mn_2(L_5)_2(Cl)_2]$ (5; Figure 4): A crystallographic inversion center in the middle of the complexes generates the corresponding symmetric equivalent half. Mn(1) is surrounded by an N_3O_2Cl donor set while the position of the chloride ion is slightly disordered. The occupation factors for both

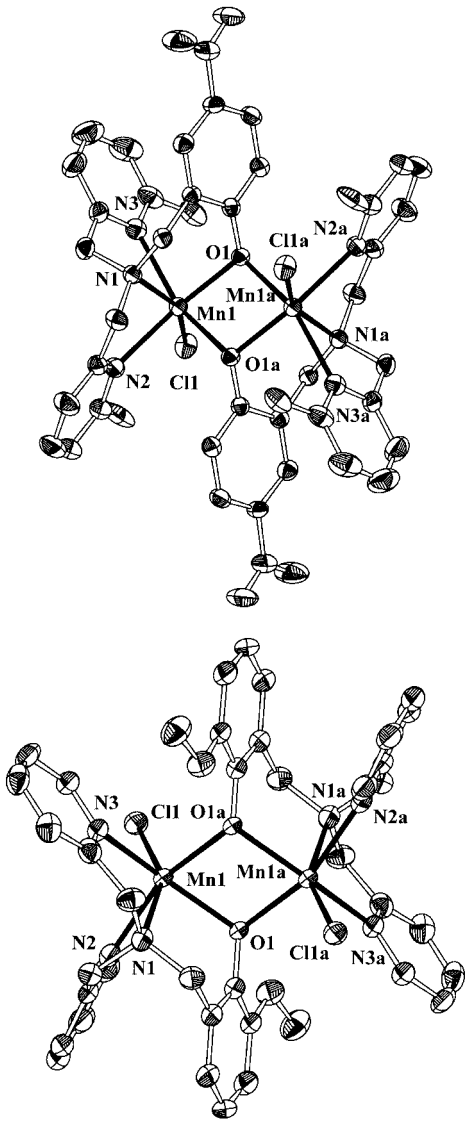

Figure 4. Ellipsoid plots of **4** (top) and **5** (bottom) showing 50% probability thermal ellipsoids; hydrogen atoms and a depiction of the chloride disorder are omitted for clarity

positions have been refined to 0.84 and 0.16 for complex **4** and 0.95 and 0.05 for **5**. In addition, compound **4** shows a disorder of the methyl substituent, where the occupation factors for both positions have been refined to 0.80 and 0.20.

The Mn(1)−Cl(1) bonds are the longest to be found in both compounds and show values of 2.425(9) Å (**4**) and 2.454(1) Å (**5**). The aliphatic nitrogen atom N(1) is bonded *trans* to the chloride ion with distances for **4** of 2.305(2) Å and for **5** of 2.372(2) Å to Mn(1). As expected, in **5** both pyridine nitrogen atoms N(2) and N(3) exhibit shorter bonds to the metal center with values of 2.273(2) Å and 2.312(2) Å, respectively. In complex **4** the Mn(1)−N(2, 3) distances are longer compared to Mn(1)−N(1) (see Table 1). This can be attributed to the steric effects of the disordered methyl substituent in the *ortho* position of N(2) and N(3), respectively. The two oxygen atoms O(1) and O(1a)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are bonded *trans* to the aromatic nitrogen atoms N(2) and N(3). Distances of 2.156(2) Å (**4**) and 2.138(2) Å (**5**) for Mn(1)−O(1) and 2.205(2) Å (**4**) and 2.142(2) Å (**5**) for Mn(1)−O(1a) have been determined. The bis(μ-phenoxo)-bridging mode results in Mn···Mn separations of 3.493(2) Å for compound **4** and 3.392(8) Å for complex **5**. The distortion from ideal octahedral symmetry is best clarified by comparing the values for the two angles N(1)−Mn(1)−N(X) (X = 2, 3) and O(1)−Mn(1)−N(2) with their ideal values. The latter differs significantly from the ideal 180° with angles of 147.4(7)° (**4**) and 150.6(8)° (**5**), while the average angles for N(1)−Mn(1)−N(X) (X = 2, 3) deviate by around 17.2° from the ideal 90°.

There is a correlation between the Mn···Mn distances and the type of ring substituent. In particular, the influence of the electron-withdrawing effect of the NO_2 groups, that are *p*-bonded to the phenol oxygen atom in **2** and **4**, is conspicuous. Because of its −M effect the electron density of the phenolic oxygen atom is reduced through the aromatic π-system. This results in a weaker Mn−O bond, leading to larger Mn···Mn distances than in complexes **1**, **3**, and **5**. On the other hand electron-donating groups like methyl and methoxy moieties stabilize the Mn−O bonds resulting in shorter Mn···Mn separations than in the parent complex **1**.

Electrochemistry

The redox potentials of complexes **1**−**5** are summarized in Table 2. Figure 5 shows the cyclic voltammogram of compound **2** in acetonitrile as the most representative.

Table 2. Redox potentials of complexes **1**−**5**

Complex	$E_{1/2}$ (ΔE) [V] vs. Ag/AgCl $Mn_2^{II/II}/Mn_2^{II/III}$
1	0.44 (0.14)
2	0.76 (0.15)
3	0.45 (0.07)
4	0.64 (0.07)
5	0.45 (0.16)

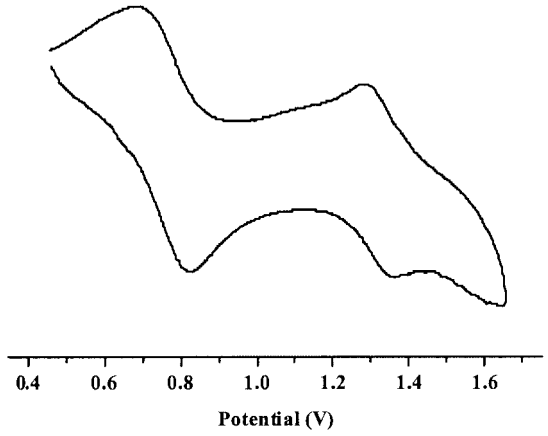

Figure 5. Cyclic voltammogram of **2** in acetonitrile

The observed redox potentials for the oxidation $Mn^{II}Mn^{II}/Mn^{II}Mn^{III}$ are in good agreement with data reported in the literature for similar dinuclear manganese compounds.[29−32]

For a reversible single-electron redox transition an ideal peak separation of 59 mV has to be detected. For compounds **3** and **4** the differences in peak potentials for the first redox transition show little difference from the ideal 59 mV (ΔE = 70 mV). This shift can be attributed to solvent effects.[33] Therefore these waves can clearly be attributed to a single-electron transfer in both complexes from Mn^{II}/Mn^{II} to Mn^{II}/Mn^{III}.

In the case of quasi-reversible electron transitions the determination of *n*, the number of electrons involved in the redox process, is more complicated. The large peak-separation for the first redox transition in the cyclic voltammogram of compounds **1**, **2**, and **5** (ΔE = 140−160 mV) indicates that the electron transfer is slow. For a system undergoing slow electron transfers it has been shown that the number of electrons can be determined using the following equation:[31,34] $\alpha n = 0.048/(|E_p - E_{p/2}|)$.

In the present case a value of 0.5 can be considered for the charge-transfer coefficient α due to the symmetrical shape of the corresponding wave. E_p is the peak potential of the considered wave and $E_{p/2}$ represents the potential value at half the intensity of the peak current. From the obtained data listed in Table 3 one can ascertain that $n = 1$ for the first redox transition.

Table 3. Potential peak values for the $Mn^{II}Mn^{II}/Mn^{II}Mn^{III}$ oxidation in **1**, **2**, and **5**

Compound	E_{pa} [V]	$E_{pa/2}$ [V]	E_{pc}	ΔE [V]
1	0.37	0.46	0.51	0.14
2	0.68	0.78	0.83	0.15
5	0.37	0.48	0.53	0.16

Thus, on the time scale of cyclic voltammetry (250 mV s^{-1}) our investigations lead to the following conclusion. For compounds **1**−**5** the first redox transition can clearly be attributed to a single-electron transfer from $Mn^{II}Mn^{II}$ to $Mn^{II}Mn^{III}$.

It is noteworthy that both oxidation waves in the cyclic voltammogram of **2** differ in intensity by a factor of 1.3. For the remaining complexes this difference is significantly smaller. To further investigate this second oxidation peak, additional electrochemical studies were performed on the pure ligand. In analogy to data reported by Blondin et al., oxidation of the phenolic part of the ligands occurs at higher potentials.[31] Those irreversible, ill-defined cyclic voltammetric traces overlay any supposed oxidation from $Mn^{II}Mn^{III}$ to $Mn^{III}Mn^{III}$.

However, there is a clear correlation between the revealed redox potentials and the type of ring substituent. As shown in Table 2, the increase of the redox potentials for the first transition is directly commensurate with the intensity of the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

electron-withdrawing effect of the ring substituents. This was observed before by Walton et al.[35] Their investigations on transition metal redox behavior were based on a series of mononuclear manganese compounds. Using different phenol-substituted triimine and triamine ligands an analogous influence on the redox potential was observed for CH_3O, CH_3, and NO_2 groups as *para*-substituents of the phenol group.

Catalase Activity

Compounds **1**−**5** are stable under ambient conditions and are not oxidized by atmospheric oxygen. All complexes are able to disproportionate hydrogen peroxide in aqueous solution. Like $[Mn(bpia)(\mu\text{-}OAc)]_2(ClO_4)_2$, they are examples of synthetic catalysts showing saturating kinetics at high substrate concentrations (see Figure 6).[16]

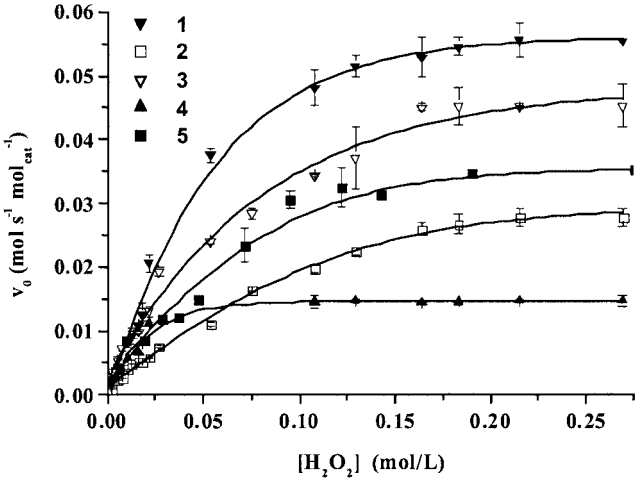

Figure 6. Initial rate of substrate consumption versus substrate concentration at constant concentration of **1**−**5**

Consequently, the data were fitted to the Michaelis−Menten equation, and the *turnover* number k_{cat}, the Michaelis constant K_M and k_{cat}/K_M were determined from the double reciprocal Lineweaver−Burk plot (Figure 7). The values of k_{cat}, K_M and k_{cat}/K_M are listed in Table 4.

Taking K_M as a measure of substrate affinity, the methoxy-substituted compound **5** exhibits the highest affinity for hydrogen peroxide (lowest value of K_M) while the parent complex **1** shows the lowest value for substrate binding (highest value of K_M). This is noteworthy if one considers that the unsubstituted ligand should allow easier access to the metal center, resulting in a higher affinity for hydrogen peroxide. Therefore electronic reasons must be the rate-determining effects for substrate binding. It is conceivable that the methoxy lone pairs interact with the substrate leading to higher substrate binding.

The *turnover number* k_{cat} can be interpreted as the rate of substrate conversion into the corresponding products. Once H_2O_2 is bonded to the metal center the rate of conversion is best for the parent complex **1**, followed by complex **3**

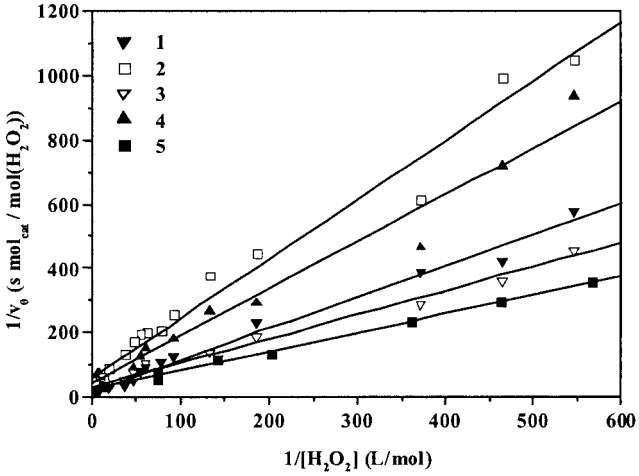

Figure 7. Lineweaver−Burk plots for **1**−**5**

(methyl substituted) and compound **5** (methoxy residue). The slowest complex in terms of *turnovers* is the *p*-nitro-substituted complex **2**, exhibiting a threefold slower catalytic conversion than **1**. The electron-withdrawing effect of the nitro group is presumably the decisive difference. This effect causes a reduction of the electron density of the manganese centers via the aromatic π-system. Since the disproportionation of hydrogen peroxide is a redox process this effect decreases the speed of substrate conversion.

In order to understand the observed kinetic data a comparison of k_{cat}/K_M as a criterion for catalytic efficiency and the determined redox potentials is necessary. By comparing the k_{cat}/K_M criteria of the five complexes a dependence of the rate of the hydrogen peroxide disproportionation on the ring substituents is also observed. Starting with complex **1**, which contains the unsubstituted parent ligand, the activity increases if electron-donating groups like methyl or methoxy substituents are bound to the pyridine or phenol arm (**2** and **5**). Although the methoxy group is bigger than the methyl group, complex **5** is more efficient than **2**. This can be attributed to the increased ability to donate electrons into the aromatic π-system compared to the methyl group. It seems to be that the complexes' catalase activity is more dependent on electronic than on steric effects. Therefore, by using a methoxy substituent k_{cat}/K_M of **5** is larger than for both **1** and **2**. On the other hand k_{cat}/K_M decreases if an NO_2 group is bonded in the *para* position to the bridging phenol oxygen atom. This is caused by its strong electron-withdrawing effect, which reduces the electron density of the manganese centers via the aromatic π-system. The use of both an electron-withdrawing and -donating group, as in **4**, leads to a higher k_{cat}/K_M than for **2**.

As shown by CV experiments (vide supra) the redox potentials correlate with the insertion of electron-withdrawing or -donating substituents. The cyclic voltammograms of compounds **1**, **3** and **5** exhibit lower values for the observed redox transitions, while the corresponding $E_{1/2}$ values for the remaining complexes are shifted to higher potentials. This coherence between the redox potentials and the utilized ring substituents underlines the determined catalase ac-

[a] No saturation kinetics observed/reported. [b] tacn = 1,4,7-trimethyl-1,4,7-triazacyclononane; bpy = 2,2′-bipyridine. [c] L^1 = *N*,*N*,*N*′,*N*′-tetrakis(2-methylenebenzimidazolyl)-1,3-diaminopropan-2-ol.

tivity. This is in good agreement with experiments reported previously concerning the binding efficiency of hydrogen peroxide to the manganese center,[13] where it has been reported that the manganese compounds donating the most electrons have the highest affinity for the substrate.

Since complexes **1**−**5** are hexacoordinate in the solid state it is most likely that at least one chloride ligand is replaced in solution by a solvent molecule that can easily be replaced by the substrate. This has been proved by MALDI experiments (see Exp. Sect.). This soft ionization method ensures that each species in solution is detected without further conversion into fragments. As is shown in the Exp. Sect. either an $[M^+ - Cl]$ or $[M^+ - HCl]$ species was detected in every spectrum. This is convincing evidence that the dinuclear structure is preserved in solution without the coordination of one chloride ion to the dinuclear metal core. Therefore one manganese ion provides a labile coordination site. This is sufficient to disproportionate H_2O_2 as it is postulated for the catalytic cycle of Mn catalase.[7]

The observed catalase activities place the complexes **1**−**5** within approximately three orders of magnitude of the three characterized manganese catalases in terms of both k_2 and k_2/K_M criteria.

Conclusion

The synthesis and structural characterization of five dinuclear manganese(II/II) compounds has been reported. The utilized tripodal ligands share two pyridine and one phenol moiety but differ in the type of substituents coordinated to the aromatic rings. It seems that the electronic character of the different ring substituents tunes the catalase activity, which correlates with the observed redox potentials of the dinuclear transition metal complexes. Groups donating electrons into the aromatic π-system lead to higher catalytic activity involving lower $E_{1/2}$ values while electron-withdrawing substituents cause the opposite effect, namely higher $E_{1/2}$ values and lower catalase activity. All compounds belong to the class of synthetic model complexes showing saturation kinetics at high substrate concentrations. The observed catalase activity places the complexes **1**−**5** within approximately three orders of magnitude of the three characterized manganese catalases in terms of both k_2 and k_2/K_M criteria. Compared to the two most efficient systems $[Mn_2(bpia)_2]$ and $[Mn_2(2\text{-}OHsalpn)_2]$, described by Triller et al.[16] and Gelasco et al.,[13] respectively, compounds **1**−**5** are the second best functional manganese catalase mimics.

Experimental Section

Physical Measurements: IR spectra were recorded with a Perkin−Elmer Spectrum GX FT-IR spectrometer in the range of 4000−400 cm^{-1}. Samples were prepared as KBr pellets. Elemental analyses were carried out with a Perkin−Elmer 2400 Series 2 analyzer. MALDI experiments were performed with a Bruker Daltonics MALDI Reflex IV spectrometer. The compounds were dissolved in the same solvent system as used for the kinetic measurements. Cyclic voltammetric experiments were performed with a BAS CV-27 voltammograph equipped with a BAS C-1B cell stand and a BAS RXY recorder. The concentration of the samples was 1×10^{-3} M in acetonitrile for **2**, 1×10^{-3} M in acetonitrile/DMF (15:1) for **4** and **5**, 3×10^{-3} M in acetonitrile/DMF (15:1) for **1** and **3**. Prior to use, solvents were purified by standard literature methods.[41] Tetrabutylammonium hexafluorophosphate (recrystallized from ethanol) was used as supporting electrolyte at a concentration of 0.1 M. A three-electrode array consisting of a glassy carbon working electrode, a platinum wire counter electrode and an Ag/AgCl reference electrode was used.

Kinetic Measurements: Catalase activities of all complexes were measured at 25 °C on the basis of fluorescence quenching using an oxygen sensor.[42] Hydrogen peroxide solution in water was placed in a vessel equipped with a thermostat (5 mL, prepared in different

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

concentrations from 36.6% hydrogen peroxide solution in water, concentration determined iodometrically and manganometrically). Before each measurement, a calibration of the oxygen sensor was carried out by saturating the solution with dioxygen (100% dioxygen) and then with argon (0% dioxygen). The dioxygen concentration in dioxygen-saturated water has been determined to be 1.388 mM.[43] After a baseline had been established, 0.1 mL of a 0.01 M solution of the complex in degassed methanol was added, and the oxygen evolution was monitored. The average initial rate over three independent measurements, expressed as $mol(H_2O_2)\cdot s^{-1}\cdot[mol(catalyst)]^{-1}$,[12] was determined by linear regression from the slope of concentration versus time plots.

Syntheses: The ligands HL_3 and HL_4 were prepared according to the previously reported syntheses of HL_1 [21] and HL_2,[44] respectively, using *N*-[(6-methylpyridin-2-yl)methyl]-*N*-(pyridin-2-ylmethyl)amine instead of *N*,*N*-bis(pyridin-2-ylmethyl)amine.

2-[{[(6-Methylpyridin-2-yl)methyl](pyridin-2-ylmethyl)amino}-methyl]phenol (HL_3): Yield: 5.43 g (17 mmol, 75%). $C_{20}H_{21}N_3O$ (319.0): calcd. C 75.24, H 6.58, N 13.17; found C 75.13, H 6.34, N 13.15. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.59 (s, 3 H, CH_3), 3.80 (s, 2 H, CH_2), 3.85 (s, 2 H, CH_2), 3.88 (s, 2 H, CH_2), 6.77−7.64 (m, 10 H, Ar-H), 8.57 (d, *J* = 4.8 Hz, 1 H, Ar-H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 24.2, 56.9, 59.2, 59.3, 116.6, 118.9, 120.1, 121.7, 122.2, 122.9, 123.3, 129.0, 130.2, 136.7, 137.0, 149.0, 157.6, 157.7, 158.0, 158.5 ppm. IR (KBr): $\tilde{\nu}$ = 3440 cm^{-1} (m, br), 3049 (s), 2956 (s), 2922 (s), 2855 (s), 2801 (s), 2708 (m), 2608 (m), 2256 (w), 2007 (w), 1979 (w), 1935 (w), 1905 (w), 1876 (w), 1789 (w), 1688 (w), 1612 (m), 1583 (vs), 1512 (w), 1488 (vs), 1465 (s), 1437 (s), 1428 (s), 1375 (s), 1362 (s), 1316 (w), 1289 (m), 1246 (w), 1204 (m), 1181 (w), 1161 (m), 1141 (m), 1122 (m), 1091 (m), 1039 (m), 1003 (m), 990 (w), 973 (m), 955 (w), 937 (w), 899 (w), 892 (w), 870 (w), 789 (s), 760 (vs), 717 (m), 646 (w), 604 (m), 558 (m), 542 (w), 479 (m), 444 (m).

2-[{[(6-Methylpyridin-2-yl)methyl](pyridin-2-ylmethyl)amino}-methyl]-4-nitrophenol (HL_4): Yield: 2.4 g (17 mmol, 57%). $C_{20}H_{20}N_4O_3$ (365.1): calcd. C 65.74, H 5.48, N 15.34; found C 65.60, H 5.39, N 15.26. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.60 (s, 3 H, CH_3), 3.85 (s, 2 H, CH_2), 3.90 (s, 2 H, CH_2), 3.92 (s, 2 H, CH_2), 6.95−8.12 (m, 9 H, Ar-H), 8.58 (d, *J* = 4.8 Hz, 1 H, Ar-H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 24.0, 56.0, 58.8, 59.0, 117.2, 120.0, 122.0, 122.4, 123.2, 123.6, 125.6, 126.6, 137.0, 137.2, 137.9, 148.8, 156.8, 157.9, 161.2, 162.6 ppm. IR (KBr): $\tilde{\nu}$ = 3434 cm^{-1} (m, br), 3074 (m), 3049 (m), 3002 (m), 2930 (m), 2820 (m), 2717 (m), 2491 (w), 1736 (w), 1619 (m), 1600 (m), 1582 (s), 1511 (s), 1488 (s), 1460 (m), 1431 (m), 1377 (m), 1333 (vs), 1292 (s), 1262 (m), 1240 (s), 1178 (m), 1149 (m), 1133 (m), 1110 (m), 1088 (m), 1049 (m), 1009 (m), 976 (m), 931 (w), 904 (w), 878 (m), 839 (m), 823 (m), 750 (s), 733 (m), 641 (w), 610 (w), 566 (w), 511 (w), 494 (w), 450 (m).

The ligand 2-{[bis(pyridin-2-ylmethyl)amino]methyl}-6-methoxyphenol (HL_5) was synthesized as follows.

2-Methoxy-6-{[(pyridin-2-ylmethyl)amino]methyl}phenol: Equivalent amounts of 2-pyridylmethylamine (2.70 g, 25 mmol) and 2-hydroxy-3-methoxybenzaldehyde (3.80 g, 25 mmol) were dissolved in 100 mL of methanol and stirred for 2 h. After reduction with $NaBH_4$ (0.47 g, 12.5 mmol), the solution was stirred for a further 12 h. The mixture was acidified with hydrochloric acid to pH = 1 and, after concentrating under vacuum, extracted with chloroform (5 × 20 mL) to separate side products and impurities. In order to neutralize the hydrochloride, the pH was adjusted to 8 with an aqueous solution of NaOH and the free amine was extracted with chloroform (5 × 20 mL). The combined organic layers were dried ($MgSO_4$) and the solvent was removed under vacuum yielding the oily product. Yield: 5.73 g (23.6 mmol, 94%). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 3.88 (s, 3 H, O-CH_3), 3.92 (s, 2 H, CH_2), 4.02 (s, 2 H, CH_2), 6.59−7.69 (m, 6 H, Ar-H), 8.56 (d, *J* = 4.8 Hz, 1 H, Ar-H).

2-{[Bis(pyridin-2-ylmethyl)amino]methyl}-6-methoxyphenol (HL_5): 2-Methoxy-6-{[(pyridin-2-ylmethyl)amino]methyl}phenol (4.88 g, 20.0 mmol) and 2-chloromethylpyridine hydrochloride (3.28 g, 20.0 mmol) were dissolved in 100 mL of methanol. A pH value of 9 was adjusted by adding solid potassium carbonate. The mixture was stirred at room temperature for 3 d while the pH value was controlled every 24 h. After the remaining K_2CO_3 was filtered off, the mixture was acidified carefully with hydrochloric acid to pH = 1. Further purification was performed with the method described above to yield an orange brown product. Yield: 3.99 g (11.9 mol, 50%). $C_{20}H_{21}N_3O_2$ (335.4): calcd. C 71.62, H 6.31, N 12.53; found C 71.50, H 6.19, N 12.76. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 3.73 (s, 3 H, OCH_3), 3.89 (s, 2 H, CH_2), 3.90 (s, 4 H, CH_2), 6.71 (dd, *J* = 7.6 Hz, *J* = 7.9 Hz, 1 H, Ar-H), 6.74 (d, *J* = 7.9 Hz, 1 H, Ar-H), 6.83 (d, *J* = 7.6 Hz, 1 H, Ar-H), 7.13−7.66 (m, 6 H, Ar-H), 8.57 (d, *J* = 4.8 Hz, 2 H, Ar-H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 55.9, 56.7, 59.0, 111.3, 118.5, 122.3, 122.4, 123.2, 123.3, 134.9, 137.0, 146.9, 148.7, 158.2 ppm. IR (KBr): $\tilde{\nu}$ = 3434 cm^{-1} (m, br), 3054 (m), 3010 (m), 2935 (m), 2917 (m), 2835 (m), 2805 (m), 2750 (w), 2609 (w), 1947 (w), 1888 (w), 1586 (s), 1570 (m), 1486 (s), 1472 (s), 1433 (s), 1389 (m), 1372 (m), 1299 (m), 1250 (s), 1235 (s), 1160 (m), 1134 (m), 1073 (s), 1049 (m), 1006 (m), 994 (m), 976 (m), 954 (m), 933 (m), 886 (w), 837 (m), 777 (s), 761 (m), 737 (m), 631 (m), 617 (w), 561 (w), 539 (w), 510 (w), 483 (w), 467 (w).

Synthesis of the Dinuclear Complexes 1−5: All complexes were prepared according to the same method. Equivalent amounts of manganese(II) chloride tetrahydrate (0.25 mmol, 49.5 mg) and corresponding ligand were dissolved in 10 mL of ethanol and triethylamine (0.3 mmol, 42 μL) was added. After stirring the mixture for 12 h, the resulting precipitate was isolated and redissolved in 10 mL of dichloromethane. Crystals suitable for X-ray diffraction analysis were obtained by layering with hexane.

$[Mn_2(L_1)_2(Cl)_2]\cdot 2CH_2Cl_2$ (1): Yield:113.78 mg (0.12 mmol, 47%). $C_{38}H_{36}Cl_2Mn_2N_6O_2$ (789.52): calcd. C 57.81, H 4.60, N 10.64; found C 56.96, H 4.46, N 10.49. MS (MALDI): *m*/*z* = 754 [M^+ − Cl]. IR (KBr): $\tilde{\nu}$ = 3436 cm^{-1} (m, br), 3050 (m), 3021 (m), 3002 (m), 2982 (w), 2954 (m), 2913 (m), 2878 (m), 2830 (m), 2776 (w), 2604 (w), 2497 (w), 1885 (w), 1602 (vs), 1571 (s), 1476 (vs), 1452 (vs), 1396 (w), 1368 (w), 1349 (s), 1326 (w), 1308 (w), 1269 (vs), 1190 (w), 1150 (m), 1129 (m), 1095 (m), 1052 (m), 1037 (m), 1014 (m), 999 (m), 978 (m), 960 (m), 926 (m), 881 (s), 837 (m), 759 (vs), 737 (s), 660 (w), 638 (m), 576 (m), 517 (w), 493 (w), 477 (m).

$[Mn_2(L_2)_2(Cl)_2]\cdot EtOH$ (2): Yield: 155.41 mg (0.17 mmol, 67%). $C_{38}H_{34}Cl_2Mn_2N_8O_6$ (879.51): calcd. C 51.89, H 3.90, N 12.74; found C 51.46, H 3.86, N 12.24. $[Mn_2(L_5)_2(Cl)_2]$ (5): Yield: 131.51 mg (0.16 mmol, 62%). $C_{40}H_{40}Cl_2MnN_6O_4$ (848): calcd. C 56.55, H 4.75, N 9.89; found C 56.23, H 4.89, N 9.24. MS (MALDI): m/z = 813 [M$^+$ − Cl]. IR (KBr): $\tilde{\nu}$ = 3429 cm^{-1} (s, br), 3055 (w), 2921 (m), 2849 (m), 1603 (s), 1571 (m), 1478 (vs), 1456 (m), 1441 (m), 1388 (w), 1346 (w), 1308 (m), 1273 (m), 1237 (m), 1154 (w), 1126 (w), 1079 (m), 1051 (m), 1014 (m), 1000 (m), 970 (w), 897 (w), 849 (m), 767 (m), 736 (m), 638 (w), 618 (w), 494 (w), 442 (w), 410 (w).

X-ray Crystallographic Study: Single-crystal X-ray studies of complexes **1**−**3** were performed with a Stoe IPDS diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 213 K; studies on compound **4** were done with a Bruker AXS SMART APEX with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 100 K; studies on compound **5** were done with a Bruker AXS SMART 6000 with Cu-K_α radiation (λ = 1.54178 Å) at 100 K. All structures were solved with direct methods and refined by full-matrix least-squares procedures on F_o^2 values (SHELXTL-Plus-97[45,46]). Anisotropic displacement parameters were used to refine the positions of all non-hydrogen atoms. Hydrogen atoms were placed at calculated positions according to a riding model with group isotropic temperature factors. The residual value wR_2 in Table 5 is defined as $[w(F_o^2 - F_c^2)^2/w(F_o^2)^2]^{1/2}$. Selected distances and angles are listed in Tables 1−4. CCDC-205842 (**1**), -205843 (**2**), -205844 (**3**), -205845 (**4**), and -205846 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Iridium Complexes with Chiral and Achiral β-Aminophosphane Ligands: Catalysts for >C=O Hydrogenation and H/D Exchange Involving both Homo- and Heterolytic H_2 Activation[‡]

Lutz Dahlenburg*[a] and Rainer Götz[a]

Dedicated to the memory of Professor Dieter Sellmann, who has shed much light!

Keywords: Chirality / Hydrogenations / Isotopic exchange / Iridium

Chiral and achiral *P,N*-chelated Ir^I complexes of the general type $[(COD)Ir(P\cap NR^1R^2)]BF_4$, where COD = η^4-1,5-C_8H_{12} and $P\cap NR^1R^2$ = (1*R*,2*R*)-, (1*S*,2*S*)-, or (1*R*,2*S*)-$Ph_2PC^1H(Ph)C^2H(Me)NR^1R^2$ (NR^1R^2 = NH_2, NHMe, $NHCH_2Ph$, $NHCHMe_2$, NMe_2), $Ph_2PCH_2CR_2NH_2$ (R = H, Me), or 2-$Ph_2PC_6H_4NHMe$, have been prepared by treating $[Ir(COD)_2]BF_4$ with the required β-aminophosphane in THF. The monolithiated ligands $Ph_2PCH_2CMe_2N(Li)H$ and 2-$Ph_2PC_6H_4N(Li)Me$ interacted with $[\{(COD)Ir(\mu\text{-}Cl)\}_2]$ to give the neutral alkyl- and arylamido compounds [(COD)-$Ir(Ph_2PCH_2CMe_2NH)$] and [(COD)Ir(2-$Ph_2PC_6H_4NMe$)]. All Ir^I complexes $[(COD)Ir(P\cap NR^1R^2)]BF_4$ acted as catalysts for the direct hydrogenation of alkyl aryl ketones to the corresponding 1-phenylalkanols, if combined with an alkaline or amine base in methanol under H_2 (10–50 bar) between 25 and 50 °C. The reaction occurred with modest to moderate enantioselectivity (ca. 20–75% *ee*) if chelate complexes bearing the various optically active β-aminophosphanes were used as catalysts. The base-free amido complexes [(COD)-$Ir(P\cap NR)$] displayed similar catalytic activity to the combined systems $[(COD)Ir(P\cap NHR)]BF_4$–KOH ($P\cap NHR$ = $Ph_2PCH_2CMe_2NH_2$, 2-$Ph_2PC_6H_4NHMe$). The ability of both the cationic β-amino- and the neutral β-amidophosphane Ir^I complexes to undergo oxidative H_2 addition and the observation of H_2/D^+ as well as H_2/D_2 exchange processes during catalysis provided evidence for a mechanism involving reversible "$[Ir^{III}(H)_2\text{–}P\cap NHR]^+ \rightleftarrows [(\eta^2\text{-}H_2)\text{–}Ir^{III}(H)\text{–}P\cap NR]^+$" proton-to-hydride transfer and heterolytic H_2 cleavage on amino–dihydride and amido–dihydrogen–monohydride tautomers. The crystal structures of [(COD)Ir{(1*S*,2*S*)-$Ph_2PCH(Ph)CH(Me)NHCH_2Ph$}]$BF_4$·2THF, [(COD)Ir{1*R*,2*S*-$Ph_2PCH(Ph)CH(Me)NHMe$}]BF_4·THF, and the orthometalated 18e Ir^I complex [(COD)Ir{(1*R*,2*S*)-$Ph_2PCH(C_6H_4\text{-}o)$-$CH(Me)NHCHMe_2$}], which resulted from treatment of [(COD)Ir{(1*R*,2*S*)-$Ph_2PCH(Ph)CH(Me)NHCHMe_2$}]$BF_4$ with excess KOH, have been determined by single crystal X-ray diffraction studies.

Introduction

Metal complexes containing both *P* and *N* donor ligands have been dominating the field of homogeneous catalytic hydrogenation of organic carbonyl compounds for several years. In particular, Noyori's ruthenium complexes $[RuCl_2\{bis(phosphane)\}(1,2\text{-diamine})]$ have been found to be excellent catalysts for the enantioselective reduction, by H_2, of simple ketones if activated by an excess of strong base.[1] Intramolecular heterolytic H_2 splitting across the polar metal−amide bond of initially formed amine-amido hydrido complexes, $[RuH(P\cap P)(HN\cap NH_2)]$, to reversibly give diamine dihydrides, $[RuH_2(P\cap P)(H_2N\cap NH_2)]$, has been shown to be a key step involved in the catalytic cycle. From the latter, $H^{\delta-}/H^{\delta+}$ equivalents are transferred simultaneously to the ketonic substrate once the carbonyl group has come into close contact with the second coordination sphere of the catalyst through an unconventional $Ru-H^{\delta-}\cdots>C^{\delta+}=O^{\delta-}\cdots H^{\delta+}-N$ "metal−ligand bifunctional" interaction.[2,3,4]

A different type of a highly enantioselective >C=O hydrogenation catalyst is exemplified by Zhang's Rh−PennPhos system, made up from in situ generated [(COD)Rh{(*R*,*S*,*R*,*S*)-Me-PennPhos}]Cl and a weakly coordinating base of moderate strength, such as 2,6-lutidine ["(*R*,*S*,*R*,*S*)-Me-PennPhos" denotes *P*,*P*′-1,2-phenylene-bis{(1*R*,2*S*,4*R*,5*S*)-2,5-dimethyl-7-phosphabicyclo[2.2.1]-heptane}].[5] Zhang's catalyst is believed to support the homogeneous hydrogenation of ketones following the classic Schrock−Osborn pathway,[6] i.e., homolytic scission of the H_2 molecule by oxidative addition with subsequent

>C=O/Rh−H insertion to produce an alkoxo hydrido rhodium(III) complex, in which the remaining hydride is *trans* to the alkoxo ligand so that reductive elimination of the product alcohol cannot easily occur. The authors speculated that the key function of the basic additive is to deprotonate the Rh−H bond forming baseH$^+$ as the conjugate acid, which in turn cleaves the Rh−alkoxo function by protonation.[5]

Based on this background, our recent activities have focussed on the catalytic potential in asymmetric >C=O hydrogenation of a class of optically active β-aminophosphane complexes of Ir^I and Rh^I, [(COD)M{Ph_2PCH-(Ph)CH(Me)NHR}]BF_4 (COD = η^4-1,5-C_8H_{12}; R = H, alkyl), having a chelated d^8 metal center (as found in Zhang's catalyst) embedded in a *P*,*N*-dominated coordination environment (which is an important characteristic of the Noyori systems).[7a,7b] An important further aspect of our work with these complexes arose from our interest in establishing whether the dihydrogen molecule is activated during catalysis by homolytic or heterolytic H−H bond breaking.[7b] Since it is well known that M−H derivatives of iridium, especially of Ir^{III}, are generally more stable and, hence, more readily accessible than those of rhodium, it has primarily been the family of iridium complexes that has been studied in detail up to now, notwithstanding a single observation that the Rh-based catalysts could be somewhat more selective than their iridium homologues (see below). Additional justification for the choice of aminophosphane-coordinated iridium complexes as potential >C=O hydrogenation catalysts arises from the observation that in situ systems composed of [{(COD)Ir(μ-Cl)}$_2$] or [Ir(COD)$_2$]BF_4 and 1,2-diphenylethylene-based chiral diamines can indeed catalyze the asymmetric reduction of ketones and α-keto esters with reasonable enantioselectivities.[8]

Results

Synthesis and Characterization of Ligands and Complexes

In earlier work[7a] we have worked out several useful procedures for the preparation of various optically active bidentate β-aminophosphanes, starting from commercially available (nor)ephedrine and pseudoephedrine diastereomers. In the first step of the syntheses, the different β-amino alcohols were stereospecifically converted into *cis* or *trans* aziridines using established synthetic organic methods.[9,10,11,12] Transformation of the aziridines into the desired *P*,*N* ligands was subsequently accomplished by regio- and stereospecific ring-opening with Ph_2PH in the presence of BF_3 as an activating additive. Enantiopure *P*,*N* ligands thus prepared included (+)-(1*S*,2*S*)-$Ph_2PCH(Ph)CH(Me)NH_2$ [(*S*,*S*)-**1**] hereafter, (−)-(1*R*,2*S*)-$Ph_2PCH(Ph)CH(Me)NH_2$ [(*R*,*S*)-**1**], and (−)-(1*R*,2*R*)-$Ph_2PCH(Ph)CH(Me)NHMe$ [(*R*,*R*)-**2**].[7a]

In a similar manner, (+)-(2*S*,3*S*)-*trans*-1,2-dimethyl-3-phenylaziridine[12] was used as a source of (−)-(1*R*,2*S*)-$Ph_2PCH(Ph)CH(Me)NHMe$ [(*R*,*S*)-**2**] for which a less direct four-step sequence had previously been described by Beck and Nagel[13] [Scheme 1, reaction (1)]. (−)-(2*S*,3*R*)-*cis*-1-benzyl-2-methyl-3-phenylaziridine analogously afforded (+)-(1*S*,2*S*)-$Ph_2PCH(Ph)CH(Me)NHCH_2Ph$ [(*S*,*S*)-**3**]. The required *N*-benzylaziridine had earlier been synthesized from (−)-norephedrine by consecutive reactions with PCl_5, benzaldehyde, and sodium borohydride[14] but was also readily accessible by alkylating the corresponding *N*-unsubstituted aziridine with *n*BuLi/benzyl chloride [Scheme 1, reaction (2)]. The (−)-(2*S*,3*R*)-*cis*- and (+)-(2*S*,3*S*)-*trans*-1-isopropyl-2-methyl-3-phenylaziridine isomers were obtained from (−)-*N*-isopropylnorephedrine[15] by the Gabriel method[9] or by reaction with the Horner reagent PPh_3/Br_2[11a] and nucleophilically opened with $Ph_2PH/F_3B{\cdot}OEt_2$ to furnish (+)-(1*S*,2*S*)-$Ph_2PCH(Ph)CH(Me)NHCHMe_2$ [(*S*,*S*)-**4**] and the corresponding (−)-(1*R*,2*S*) diastereomer (*R*,*S*)-**4** [Scheme 1, reaction (3)]. Conversion of (−)-*N*-methylephedrine with methanesulfonyl chloride to the *N*,*N*-dimethylaziridinium salt,[16] followed by treatment of the latter with Ph_2PH/NEt_3, cleanly afforded the *N*,*N*-dialkylated *P*,*N* ligand (−)-(1*R*,2*S*)-$Ph_2PCH(Ph)CH(Me)NMe_2$ [(*R*,*S*)-**5** Scheme 1, reaction (4)]. Additional β-aminophosphanes used in this study included the known achiral compounds $Ph_2PCH_2CH_2NH_2$ (**6**),[17] and 2-$Ph_2PC_6H_4NHMe$ (**7**)[18] and, as a new member of this family of ligands, $Ph_2PCH_2CMe_2NH_2$ (**8**) which resulted in the usual fashion from ring-opening of 2,2-dimethylaziridine, itself made from 2-amino-2-methylpropanol by the Wenker method[10,19] [Scheme 1, reaction (5)].

Similar to the procedures previously employed for the preparation of (−)-[(COD)Ir{(1*S*,2*S*)-$Ph_2PCH(Ph)$-$CH(Me)NH_2$}]BF_4 [**Ir**$^+$-(*S*,*S*)-**1**] and [(COD)M{(1*R*,2*R*)-$Ph_2PCH(Ph)CH(Me)NHMe$}]BF_4 [M = Rh: **Rh**$^+$-(*R*,*R*)-**2**; M = Ir: **Ir**$^+$-(*R*,*R*)-**2**],[7a] the new optically active chelate complexes [(COD)Ir{(1*S*,2*S*)-$Ph_2PCH(Ph)CH(Me)$-NHR}]BF_4 [R = CH_2Ph: **Ir**$^+$-(*S*,*S*)-**3**; R = $CHMe_2$: **Ir**$^+$-(*S*,*S*)-**4**] and [(COD)Ir{(1*R*,2*S*)-$Ph_2PCH(Ph)CH(Me)$-NR^1R^2}]BF_4 [R^1 = H, R^2 = Me: **Ir**$^+$-(*R*,*S*)-**2**; R^1 = H, R^2 = $CHMe_2$: **Ir**$^+$-(*R*,*S*)-**4**; R^1 = R^2 = Me: **Ir**$^+$-(*R*,*S*)-**5**] as well as their achiral analogues [(COD)Ir-($Ph_2PCH_2CR_2NH_2$)]BF_4 (R = H: **Ir**$^+$-**6**, R = Me: **Ir**$^+$-**8**) and [(COD)Ir(2-$Ph_2PC_6H_4NHMe$)]BF_4 (**Ir**$^+$-**7**) were isolated in high yield (>80%) from ligand exchange reactions between [Ir(COD)$_2$]BF_4 and equimolar quantities of the corresponding β-aminophosphane in THF (Scheme 2).

The monolithiated ligands 2-$Ph_2PC_6H_4N(Li)Me$ and $Ph_2PCH_2CMe_2N(Li)H$ interacted with [{(COD)Ir(μ-Cl)}$_2$] in hydrocarbon solution to give the neutral aryl- and alkylamido complexes [(COD)Ir(2-$Ph_2PC_6H_4NMe$)] [**Ir-7a**] and [(COD)Ir($Ph_2PCH_2CMe_2NH$)] [**Ir-8a**] as conjugate bases of their parent **Ir**$^+$-**7** and **Ir**$^+$-**8** cations (Scheme 3).

Crystallization of **Ir**$^+$-(*S*,*S*)-**3** and **Ir**$^+$-(*R*,*S*)-**2** from THF/pentane solvent mixtures afforded the two complexes as single-crystalline addition compounds, [(COD)Ir{(1*S*,2*S*)-$Ph_2PCH(Ph)CH(Me)NHCH_2Ph$}]$BF_4{\cdot}2$THF and [(COD)-Ir{(1*R*,2*S*)-$Ph_2PCH(Ph)CH(Me)NHMe$}]$BF_4{\cdot}$THF, respectively. The X-ray structural analyses of the two adduct complexes showed the presence of discrete ion pairs with the tetrafluoroborate anion hydrogen-bonded to the coordi-

nated amino functions (Figures 1 and 2). The Ir−P bond lengths of 2.279(7) and 2.298(4) Å, measured for the two compounds respectively, differ only slightly, if at all, and the same applies to the Ir−N distances which are 2.14 Å in both complexes. The chelate bite angles P−Ir−N are 83.0(6) and 83.7(3)° and thus compare well with the value of 82.3(2)° previously measured for the related rhodium cation $\mathbf{Rh}^+$-(*R*,*R*)-**2**.[7a] A common structural feature of the three complexes in the solid state is the equatorial alignment of the phenyl ring bonded to C-1 with respect to the five-membered chelate ring, causing the puckered metallacycle to adopt the δ conformation if the configuration at C-1 is *S* and, vice versa, to exist as a λ conformer if C-1 is in the *R* configuration. As a further consequence, the adjacent methyl group attached to C-2 is oriented equatorially if the two carbon atoms have like configuration (Figure 3; see also Figure 4 of ref.[7a]) but points to an axial direction if the configuration at C-2 is opposite to that at C-1 (Figure 4). Taking the surrounding of the coordinated nitrogen atom also into account, crystals of $\mathbf{Ir}^+$-(*S*,*S*)-**3**·2THF are seen to contain the chelate complex as a $\delta(S_{C\text{-}1},S_{C\text{-}2},S_N)$ diastereomer, the $\lambda(R_{C\text{-}1},S_{C\text{-}2},R_N)$ form being present in the solid state of $\mathbf{Ir}^+$-(*R*,*S*)-**2**·THF.

For $\mathbf{Rh}^+$-(*R*,*R*)-**2**, single crystals of which have been shown to be composed of the $\lambda(R_{C\text{-}1},R_{C\text{-}2},S_N)$ stereoisomer,[7a] and for its iridium homologue $\mathbf{Ir}^+$-(*R*,*R*)-**2** as well, ^{31}P NMR spectroscopic data indicated the presence in solution of three diastereomers in a roughly 10:3:1 distribution. Assuming that steric hindrance between the substituents attached to the chelate ring increases in the series $\lambda(R_{C\text{-}1},R_{C\text{-}2},S_N)$ (*C*-Ph, *C*-Me, and *N*-Me groups *all-trans-eq* aligned) < $\delta(R_{C\text{-}1},R_{C\text{-}2},S_N)$ (*all-trans-ax* conformer) ≈ $\lambda(R_{C\text{-}1},R_{C\text{-}2},R_N)$ (*C*-Ph/*C*-Me *trans-eq* oriented, *C*-Me/*N*-Me *cis-eq-ax* positioned) < $\delta(R_{C\text{-}1},R_{C\text{-}2},R_N)$ (*C*-Ph/*C*-Me in *trans-ax*, *C*-Me/*N*-Me in *cis-ax-eq* orientation), the observed isomers were previously assigned as sterically locked conformers $\lambda(R_{C\text{-}1},R_{C\text{-}2},S_N)$ (major), $\delta(R_{C\text{-}1},R_{C\text{-}2},S_N)$ (intermediate), and $\lambda(R_{C\text{-}1},R_{C\text{-}2},R_N)$ (minor).[7a] We have now ob-

served that acetone solutions of the *N*-benzyl complex **Ir**$^+$-(*S*,*S*)-**3** exhibit NMR spectra (^{1}H, ^{13}C, ^{31}P) consistent with the existence of the cation in the dissolved state existing as only two ring conformers in an approximately 2:3 molar ratio (from ^{31}P{^{1}H} NMR; cf. Table 1). Assuming that the crystallographically established δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,S_N) form contributes significantly to the isomeric distribution formed in solution, we can assign the NMR spectra displaying 40% relative intensity to that (*C*-Ph/*C*-Me)-*trans-eq*/(*C*-Me/*N*-Me)-*cis-eq-ax* conformer and ascribe the resonances showing up with 60% relative intensity to the sterically more favorable *all-trans-eq* δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,R_N) isomeric cation. By implication, it becomes necessary to re-assign the conformers previously observed for the two Rh and Ir complexes M$^+$−(*R*,*R*)-**2** at intermediate concentration (vide supra)[7a] as λ($R_{C\text{-}1}$,$R_{C\text{-}2}$,R_N), i.e. enantiomeric to δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,S_N), rather than δ($R_{C\text{-}1}$,$R_{C\text{-}2}$,S_N), which accordingly can be attributed to the conformational isomers formed at minor concentration (Table 1 and Scheme 4). By similar reasoning the conformers of **Ir**$^+$-(*S*,*S*)-**4** in a 1:3 distribution in solution can be formulated as δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,S_N) and δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,R_N), respectively.

Solution ^{31}P NMR spectra of **Ir**$^+$-(*R*,*S*)-**2** and **Ir**$^+$-(*R*,*S*)-**4** indicate the presence of one exclusive [**Ir**$^+$-(*R*,*S*)-**4**] or at least one predominant [**Ir**$^+$-(*R*,*S*)-**2**] conformer. These can be assigned as λ($R_{C\text{-}1}$,$S_{C\text{-}2}$,R_N), i.e. identical with the isomeric form observed for **Ir**$^+$-(*R*,*S*)-**2** in the solid state. The favorable δ($S_{C\text{-}1}$,$S_{C\text{-}2}$) or λ($R_{C\text{-}1}$,$S_{C\text{-}2}$) foldings of the chelate rings with like or unlike configurations of the two bridging carbon atoms can also be ascribed to the single conformers

Catalytic >C=O Hydrogenation

If combined with an alkaline or amine base (1−5 equiv.) in methanol under H_2 (10−50 bar) between 25 and 50 °C, all the complexes shown in Scheme 2 act as catalysts for the hydrogenation of alkyl aryl ketones to the corresponding 1-phenylalkanols (Tables 2−4). The homogeneous >C=O reduction occurs enantioselectively if chelate complexes bearing the various (pseudo)ephedrine-based β-aminophosphanes are used as catalysts (Scheme 5).

The success of the hydrogenation reaction depends on the presence of an extra base in the catalytic system and the use of a protic reaction medium. Thus, virtually no catalytic

[a] 0.02 mmol of [(COD)M(P∩NR^{1}R^2)]$^+$−KOH or [(COD)M(P∩NR^{1}R^2)]$^+$−(−)sparteine (M/KOH = 1:1.1; M/(−)-sparteine = 1:5.0), and 2.0 mmol of acetophenone in 3 mL of methanol. [b] KOH-activated precatalysts: $p(H_2)$ = 10 bar, T = 25 °C. [c] (−)-Sparteine-modified complexes: $p(H_2)$ = 25 bar, T = 50 °C. [d] $p(H_2)$ = 50 bar, T = 50 °C.

tone reduction proceeding by metal-assisted direct transfer of $H^{\delta-}/H^{\delta+}$ equivalents from the H_2 molecule to the carbonyl function was substantiated by ruling out the alternative pathway involving $H^{\delta-}/H^{\delta+}$ transfer from the primary alcohol. No transformation of acetophenone to 1-phenylethanol was observed when the ketone and a catalytic system composed of **Ir**$^+$-(*R*,*R*)-**2** and (−)-sparteine in a 1:5 molar ratio (vide infra) were kept in a catalyst-to-substrate ratio of 1:100 in methanol at 50 °C for 40 h in the absence of hydrogen gas, although quantitative >C=O hydrogenation did occur if the same catalyst was combined with the ketone in a 1:100 stoichiometry under 25 bar of H_2 at 50 °C for 40 h in Me$_3$COH which, as a tertiary alcohol, cannot serve as a proton/hydride source.

The influence on the catalytic activity of the different oxygen and nitrogen bases depicted in Scheme 5 was qualitatively studied for a standard system composed of the acetophenone substrate and the **Ir**$^+$-(*R*,*R*)-**2**−base catalyst in question (Table 2). While pyridine and the two enantiomers of Tröger's base did not support the hydrogenation reaction, tertiary and secondary alkylamines such as NEt$_3$, (−)-sparteine, and iPr$_2$NH performed reasonably if added in fivefold excess relative to the **Ir**$^+$-(*R*,*R*)-**2** concentration. Reaction times required for complete transformation of the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ketone at 50 °C under a pressure of 25 bar of H_2 were ≈ 40 h with triethyl and isopropylamine and only ca. 16 h with (−)-sparteine as auxiliary bases. It can therefore be concluded that the strength of the base which, compared with alkylamines, is low for heteroaromatic and arylamines,[20] exerts the important influence. In full agreement with this reasoning, strong oxygen bases such as LiOH, K_2CO_3, and particularly KOH were found to further decrease the times needed for quantitative hydrogenation, even if employed in a near equimolar **Ir**$^+$-(*R*,*R*)-**2**/base ratio at reduced temperature (25 °C) and H_2 pressure (10 bar). The addition of optically active chelating β-amino alcohols or -phosphanes had no significant influence on the selectivity of the catalysts but exerted a detrimental effect on their activity in that only reduced yields of the alcohol products were obtained after prolonged periods of time. Hence, for the catalytic runs described in the next section, potassium hydroxide or (−)-sparteine were employed as the "optimized" alkaline and amine bases.

The enantiomeric excesses of (*R*)- or (*S*)-PhCH(OH)Me that could be achieved in the hydrogenation of the standard acetophenone substrate in the presence of KOH-activated complexes ranged from 19−21% (*S*) for the iridium (pre)-catalyst **Ir**$^+$-(*R*,*S*)-**4** to 71−77% (*S*) for the rhodium system **Rh**$^+$-(*R*,*R*)-**2** (Table 3). Although the iridium homologue of the latter, **Ir**$^+$-(*R*,*R*)-**2**, was comparable in activity (≈ 7 vs. ≈ 6 h for quantitative >C=O reduction) it afforded a decidedly lower *ee* of only 55−62%. In the series of iridium complexes bearing chiral β-aminophosphanes with like configuration of their chelate backbone carbon atoms, viz. **Ir**$^+$-(*R*,*R*)-**2** and **Ir**$^+$-(*S*,*S*)-**1**,-**3**,-**4**, the *ee*'s were observed to increase in the order of their nitrogen substituents i.e. R = CH_2Ph < H < $CHMe_2$ < Me, suggesting that substitution by a medium sized methyl group is sufficient to afford the maximum enantioselectivity that can be achieved with these systems. Catalyst complexes bearing chiral *P*,*N* ligands with unlike stereochemistry of their backbone carbon atoms, i.e. **Ir**$^+$-(*R*,*S*)-**2**, **Ir**$^+$-(*R*,*S*)-**4**, and **Ir**$^+$-(*R*,*S*)-**5**, required much longer times for complete >C=O hydrogenation and also showed lower selectivities than their diastereomers with like carbon configurations in the C_2 linkages, viz. **Ir**$^+$-(*R*,*R*)-**2** and **Ir**$^+$-(*S*,*S*)-**4**. Furthermore, catalytically sluggish as *N*,*N*-dialkylated **Ir**$^+$-(*R*,*S*)-**5** proved to be, its mere ability to act as a catalyst gives unequivocal evidence that the presence of at least one NH function (which is met in all other complexes) is *not* a prerequisite for the particular compound to exhibit catalytic behavior. Nevertheless there exist major differences between the two classes of complexes with respect to their reactivity towards the dihydrogen molecule as will be shown below. Finally, the preferential formation of the product alcohol in the (*R*) configuration induced by complexes with δ($S_{C\text{-}1}$) stereochemistry of their chelate rings and, correspondingly, the predominance of the (*S*) enantiomer in the isomeric mixtures resulting from reactions promoted by all λ($R_{C\text{-}1}$) conformers shows that the hydrogenation catalysts described herein follow a λ/δ rule which predicts that λ chelates will give the (*S*) enantiomeric alcohol while δ chelates will produce the (*R*) enantiomer. Similar stereoselection has previously been documented for Ru^{II}-catalyzed >C=O hydrogenations.[3c][3d] The somewhat disappointing result that the product alcohols are generally formed, at best, in moderate optical yields either indicates an inherently low enantioselectivity of the systems or points to side reactions overriding the true selectivity of the complexes; e.g. the mixture of diastereomeric ring conformers detected in solution (Table 1) might act as interfering catalysts involved in competitive hydrogenation reactions.

Prochiral alkyl aryl ketones other than acetophenone which could be enantioselectively hydrogenated included propio- and isobutyrophenone, 3-chlorobutyrophenone, as well as 1-indanone (Table 4). Using the **Ir**$^+$-(*R*,*R*)-**2**-(−)-sparteine catalytic system, the product alcohols were formed as (*S*) enantiomers with optical yields between 29 and 68%, in full agreement with the empirical λ/δ rule formulated before. Attempts at the metal-assisted hydrogenation of dialkyl ketones such as 2-butanone, isopropyl methyl ketone, or pinacolone failed. Due to the basic conditions, these substrates underwent aldol reactions rather than reduction to give solids that were also isolated if the ketones were allowed to react in the presence of base but the absence of any added metal complex.

Table 4. Enantioselective hydrogenation of alkyl aryl ketones using the **Ir**$^+$-(*R*,*R*)-**2**−(−)-sparteine catalytic system[a]

Ketone	*t* [h]	yield [%]	*ee* [%] (polar.)
	16	100	53 (*S*)
	16	100	42 (*S*)
	23	100	48 (*S*)
	40	46[b]	68 (*S*)
	20	100	29 (*S*)

[a] 0.02 mmol of **Ir**$^+$-(*R*,*R*)-**2**, 0.1 mmol of (−)-sparteine, and 2.0 mmol of the ketonic substrate in 3 mL of methanol; $p(H_2)$ = 25 bar, *T* = 50 °C. [b] As a result of base-induced HCl elimination, the formation of 2-phenyltetrahydrofuran in low yield (≈4%) was also observed.

The mandatory presence of base in the catalytic systems suggests the intermediacy of in situ generated species that have lost H^+. For all catalysts derived from precursor complexes possessing *P*,*N* ligands with primary or secondary amine functions these could conceivably be amidoiridium(I) or -rhodium(I) complexes. In fact, the amides **Ir-7a** and **Ir-8a** (which were intentionally prepared for this specific pur-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pose) did catalyze the hydrogenation of acetophenone to 1-phenylethanol without the addition of base, quantitatively transforming the ketone to the alcohol under the usual conditions in approximately the same periods of time as the combined catalytic systems **Ir**$^+$**-7**−KOH and **Ir**$^+$**-8**−KOH, respectively. Thus, with 1 mol % of **Ir-7a** and **Ir**$^+$**-7**−KOH as catalysts, the reactions were complete after 2 and 3 h under 10 bar of H_2 at 25 °C, while 60−65 h at 50 °C under 50 bar of H_2 were needed for the quantitative formation of the alcohol in the presence of 1 mol % of **Ir-8a** or **Ir**$^+$**-8**−KOH. The ability of the two base-free β-amidophosphane iridium(I) complexes to catalyze the homogeneous >C=O reduction by molecular hydrogen likewise depends on the use of alcohols (MeOH, *t*BuOH) as reaction media, wherein the iridium−amide bond remains unprotonated. The obviously low amide basicity can be attributed to the involvement of the nitrogen lone-pair in π bonding to the central metal[21] with resultant $sp^3 \rightarrow sp^2$ rehybridization, similar to the situation that has previously been encountered for the closely related anilide [Ir(CO)(PPh_3)(2-$Ph_2PC_6H_4NMe$)], where the nitrogen atom features a trigonal-planar rather than a pyramidal surrounding and can be protonated only by very strong acids such as hydrochloric[22a] or tetrafluoroboric.[22b]

In view of the catalytic efficacy of **Ir-7a** and **Ir-8a**, numerous attempts were made to obtain similar amides also by deprotonation of the *chiral* [(COD)Ir(P∩NHR]$^+$ precatalysts but they remained unsuccessful. Either the amine function stayed unattacked, e.g. by amines or dilute KOH/methanol, or complex reaction mixtures containing ketonic and/or imine-type components [IR (KBr): $\tilde{\nu}$ = 1685 and 1715 cm^{-1}] were produced, if the cationic aminophosphane complexes were treated with very strong bases such as excess alkoxide or *n*BuLi. Obviously, those amine complexes which are different from **Ir**$^+$**-7** and **Ir**$^+$**-8** and possess CH units adjacent to the amino group tend to undergo degradation of their *P*,*N* ligands in the presence of strong base − most probably by >C=NR elimination from initially formed β-H containing amides which decompose easily due to their coordinative unsaturation.

Only in a single and probably serendipitous case we were able to isolate a well-defined product from such reactions. Combination of **Ir**$^+$-(*R*,*S*)-**4** with concentrated methanolic KOH and subsequent crystallization of the crude product from hot acetone gave cyclometalated [(COD)Ir{(1*R*,2*S*)-$Ph_2PCH(C_6H_4$-*o*)CH(Me)NHCHMe$_2$}] [**Ir**-(*R*,*S*)-**4a**] (Figure 5); i.e. deprotonation had occurred at one of the *ortho* C−H bonds of the phenyl ring attached to chelate backbone rather than at the amino function; Scheme 6. Presumably because of the hemilabile nature of the extraordinarily long Ir−N bond, measured as 2.448(6) and 2.514(6) Å for the two crystallographically independent molecules, this coordinatively saturated complex does exhibit some catalytic activity, slowly transforming acetophenone in methanol under 10 bar of H_2 to racemic 1-phenylethanol. The formation of the product alcohol without any notable stereodiscrimination strongly suggests that the orthometalated complex is not an actual intermediate maintaining the catalytic cycle

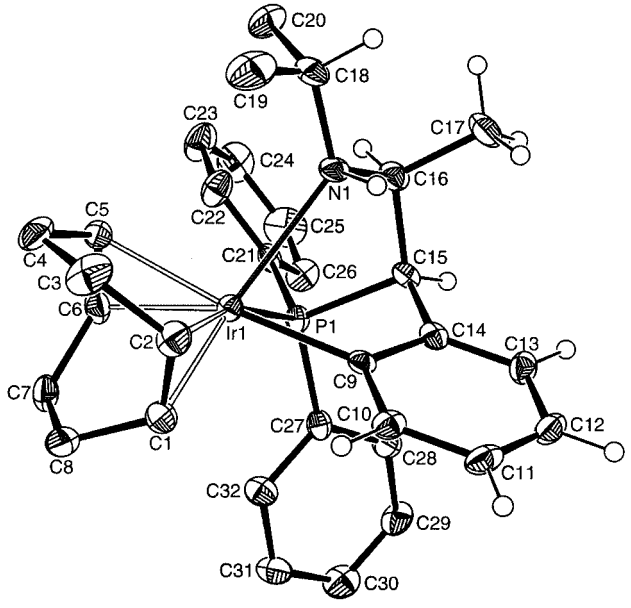

Figure 5. Perspective view of one of the two crystallographically independent molecules of orthometalated [(COD)Ir{(1*R*,2*S*)-$Ph_2PCH(C_6H_4$-*o*)CH(Me)NHCHMe$_2$] ("molecule 1"); selected bond lengths [Å] and angles [°]: Ir1−P1, 2.2917(18); Ir1−N1, 2.514(6); Ir1−C1, 2.099(7); Ir1−C2, 2.137(7); Ir1−C5, 2.183(7); Ir1−C6, 2.216(7); Ir1−C9, 2.104(7). of enantioselective >C=O reduction but should rather be looked upon as a by-product resulting from a base-induced side reaction.

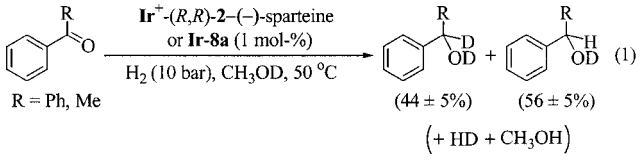
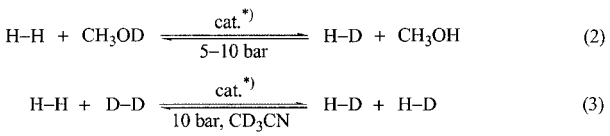
H/D Exchange Processes and H_2 Activation

When aceto- or benzophenone, dissolved in CH_3OD, were hydrogenated with H_2 employing either the base-free amide **Ir-8a** or the combined system **Ir**$^+$-(*R*,*R*)-**2**-(−)-sparteine as catalysts, the product alcohols were invariably characterized by NMR spectroscopy (^{1}H, ^{2}H, ^{13}C{^{1}H}; see Exp. Sect.) as mixtures containing the two isotopomers R^1R^2CHOD and R^1R^2CDOD in an almost 1:1 molar ratio. The evolution of *HD* gas was observed to be concomitant with the incorporation of solvent deuterons as $D^{\delta-}$ equivalents into the product carbinols [Scheme 7, reation (1)], as was the increasing formation of non-deuterated MeOH. No such uptake of D^+ as D^- by the ketonic substrate was noted if the hydrogenation was catalyzed by complex **Ir**$^+$-(*R*,*S*)-**5** possessing a tertiary amino donor group. Iridium-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

catalyzed H_2/D^+ exchange with concomitant formation of HD was similarly observed when MeOD solutions of all base-free aminophosphane complexes containing at least one N−H bond were pressurized in the absence of any ketonic substrate in an NMR tube to 5−10 bar of H_2 [Scheme 7, reation (2)], but again did not take place on attempted catalysis by the *N*,*N*-dialkylated cation **Ir**$^+$-(*R*,*S*)-**5**. Hence, the exchange of isotopes between the protic solvent and the hydrogen atmosphere, which is typical of heterolytic H−H cleavage during reaction,[3,23−30] neither depends on the presence of base nor is contingent on simultaneous >C=O hydrogenation but requires at least one acidic N−H bond in the coordination sphere of the catalyst complex.



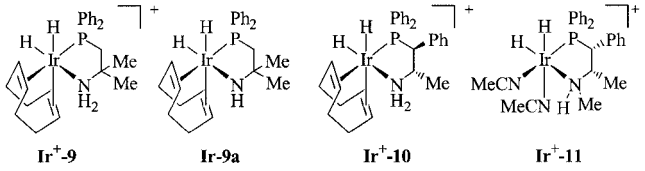


*) catalyzed by any NH-containing Ir^+ complex as well as by **Ir-7a** and **Ir-8a**

Scheme 7. Catalytic H_2/D^+ isotope exchange and H_2/D_2 scrambling in the presence [reation (1)] and absence of ketonic substrates [reations (2) and (3)]

Catalytic scrambling of isotopes with formation of HD was also detected when acetonitrile solutions of all NH-containing $[(COD)Ir(P\cap NHR)]^+$ complexes were exposed to 10 bar of an equimolar H_2/D_2 mixture [Scheme 7, reation (3)] but once more did not occur in the presence of the *N*,*N*-dialkylated derivative **Ir**$^+$-(*R*,*S*)-**5**. Control experiments in CD_3CN making use of a D_2-free hydrogen atmosphere ruled out the possibility that the observed HD did actually result from H_2/D^+ exchange between the H_2 component and the moderately acidic C−D bonds of the solvent molecules. The observed exchange of isotopes between the two gases implies the intermediate coordination of H_2 or D_2 to iridium, although the formation of any sufficiently long-lived Ir−H_2 adduct could not be traced by NMR spectroscopy down to −60 °C. Similar to the H_2/D^+ exchange described above, the observed H_2/D_2 scrambling process should involve heterolytic fission of the H−H and D−D bonds, respectively, since any isotope exchange brought about by homolytic cleavage of the two molecules would require simultaneous coordination of H_2 and D_2 to the same central metal, which is regarded as highly unlikely.[23c,23i,30]

Despite all failures to transform the iridium(I) amine complexes into their conjugate amides (vide supra), both the H_2/D_2 and the H_2/D^+ exchange processes were also catalyzed by the two amido complexes **Ir-7a** and **Ir-8a** [Scheme 7, reations (2) and (3)]. Furthermore, the initial product of the reaction between dihydrogen (5 bar) and **Ir-8a** in CD_3CN solution was unequivocally identified (see Exp. Sect.) as an *amido dihydride*, *cis*-[(CO-D)$IrH_2(Ph_2PCH_2CMe_2NH)$] (**Ir-9a**), originating from homolytic oxidative H_2 addition to the central metal (Scheme 8), rather than an *amino monohydride*, [(CO-D)$IrH(Ph_2PCH_2CMe_2NH_2)$] which would result from heterolytic H_2 addition to the N−H bond. The preference of **Ir-8a** to add the dihydrogen molecule by homolytic bond cleavage clearly contrasts with the heterolytic H−H fission concluded from the foregoing exchange experiments, notwithstanding that it corresponds to the low basicity of its amide function and also parallels the behavior of the related anilide $[Ir(CO)(PPh_3)(2\text{-}Ph_2PC_6H_4NMe)]$ described in previous work.[22a] As a further seemingly paradoxical result, the cationic aminophosphane complexes **Ir**$^+$**-8** and **Ir**$^+$-(*S*,*S*)-**1** were likewise seen to interact with molecular hydrogen by conventional oxidative addition, giving *cis*-[(CO-D)$IrH_2(Ph_2PCH_2CMe_2NH_2)]BF_4$ (**Ir**$^+$**-9**) and *cis*-$[(COD)IrH_2\{(1S,2S)\text{-}Ph_2PCH(Ph)CH(Me)NH_2\}]BF_4$ (**Ir**$^+$-**10**) as the first formed products (Scheme 8). Prolonged exposure of the iridium(I) precursors to H_2 at elevated pressures (> 10 bar) resulted in hydrogenic loss of the cyclooctadiene ligand with formation of solvate-stabilized adducts with *cis*,*cis*-$[(MeCN)_2IrH_2\{(1R,2S)\text{-}Ph_2PCH(Ph)CH(Me)NHMe\}]BF_4$ (**Ir**$^+$-**11**) being a representative example.



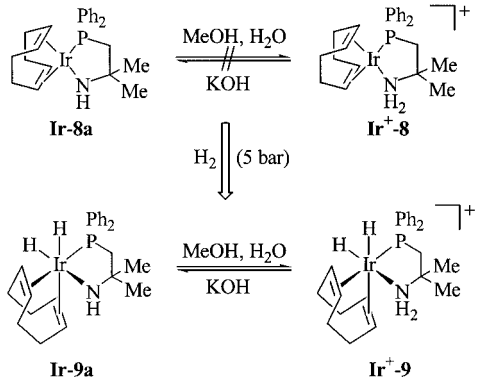
Scheme 8. Products of oxidative H_2 addition to β-amino- and β-amidophosphane iridium(I) precursors (cationic complexes: BF_4^- salts)

It was two important properties of the neutral amido and the cationic amino iridium(III) dihydrides that served to unravel the perplexing inconsistencies emerging, on the one hand, from the experimentally established homolytic H_2 addition by both the $[(COD)Ir(P\cap NHR)]^+$ and [(CO-D)$Ir(P\cap NR)$] complexes and, on the other hand, from the ability of the very same compounds to catalyze H_2/D_2 and H_2/D^+ scrambling processes.

Firstly, while the *amino*phosphane iridium(I) complex **Ir**$^+$**-8** and its (formally) conjugate *amide* **Ir-8a** do not coexist in alcoholic media in an acid−base equilibrium, the products of oxidative H_2 addition to these two d^8 substrates, **Ir**$^+$**-9** and **Ir-9a**, do so (Scheme 9). Pressurizing a solution of **Ir-8a** in methanol to 5 bar of H_2 which, as mentioned above, does not lead to any detectable **Ir**$^+$**-8**, not only gave the amido dihydride **Ir-9a** but also produced the conjugate amino dihydro complex **Ir**$^+$**-9** at spectroscopically

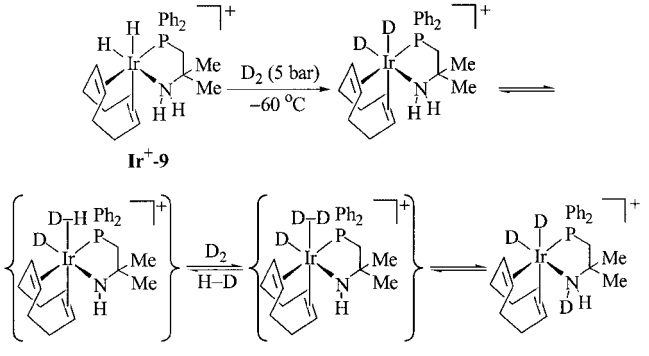
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

detectable concentrations. The same result was obtained if a droplet of water was added to a solution of preformed **Ir-9a** in carefully dried CD_3CN. Vice versa, the latter amido dihydride was detected in addition to the predominantly formed amino dihydride $\mathbf{Ir^+}$**-9**, if a solution of $\mathbf{Ir^+}$**-8** in methanol containing dilute aqueous KOH at low concentration was pressurized with H_2 (Scheme 9). The basic properties of the amido function of the 18*e* complex **Ir-9a** can safely be attributed to its coordinative saturation which prevents the nitrogen lone-pair from engaging in π-bonding to the central metal. The reversible protonation of amido donor groups attached to an Ir^{III} center has some precedent in the literature: the amido-/aminophosphane complexes $[Ir(H)(Cl)(2\text{-}Ph_2PC_6H_4NR)(2\text{-}Ph_2PC_6H_4NHR)]$ (R = Et, CH_2Ph) react with protic acids HX (X = Cl, OH, O_2CMe) to yield cationic bis(aminophosphane) products, $[Ir(H)(Cl)(2\text{-}Ph_2PC_6H_4NHR)_2]^+$, from which the amido-/aminophosphane precursors can be restored by the addition of strong bases such as DABCO.[31]



Scheme 9. Reversible (*de*)protonation of coordinatively saturated amino and amido dihydro Ir^{III} complexes

Secondly, cationic amino dihydrido complexes of the type $[(COD)IrH_2(P\cap NHR)]^+$ will undergo substitution of their hydride ligands by deuteride forming $[(COD)IrD_2(P\cap NHR)]^+$ (and presumably $[(COD)IrD_2(P\cap NDR)]^+$ as well) if treated with D_2. This behavior has been verified for $\mathbf{Ir^+}$**-9**, which was generated in situ by exposing an acetonitrile solution of $\mathbf{Ir^+}$**-8** at −60 °C in a high-pressure NMR tube to 5 bar of H_2. The diagnostic NMR signals of the H_2 adduct [δ(IrH) = −15.78 (d, *cis*-$^2J_{P,H}$ = 10.95 Hz), −12.60 (d, *cis*-$^2J_{P,H}$ = 15.91 Hz); δ(^{31}P) = 31.87] persisted when the excess pressure was released from the tube showing that $\mathbf{Ir^+}$**-9**, which at ambient conditions under an inert atmosphere reductively eliminates dihydrogen, remains stable if kept under 1 bar of hydrogen at low temperature. With constant cooling to −60 °C, the H_2 atmosphere was then replaced by D_2 under normal pressure, which was subsequently raised again to 5 bar. As a result, the original dihydride $[(COD)IrH_2(Ph_2PCH_2CMe_2NH_2)]^+$ was converted into the dideuteride $[(COD)IrD_2(Ph_2PCH_2CMe_2NH_2)]^+$ manifesting itself by (i) the disappearance of the IrH doublets in the ^{1}H NMR spectrum, (ii) the persistence of the ^{31}P singlet (δ = 31.4 for the deuterated compound) and (iii) the appearance of two high-field ^{2}H peaks at δ = −15.7 and −12.7, indicating an IrD_2 substructure with non-equivalent Ir−D bonds. As a particularly illuminating feature, the ^{2}H NMR spectrum furthermore displayed an HD doublet at δ = 4.37 ($^1J_{H,D}$ = 42.6 Hz) in addition to the D_2 singlet at δ = 4.33, demonstrating that catalytic H_2/D_2 scrambling goes together with $IrH_2 \rightarrow IrD_2$ exchange (Scheme 10). A comparatively broad resonance centered at δ = 2.3 and partly overlapping the CDH_2CN triplet at δ = 1.98, could not be assigned with certainty It may originate from deuterated amino functions which would then be consistent with the presence in solution of $[(COD)IrD_2(Ph_2PCH_2CMe_2NHD)]^+$ and $[(COD)IrD_2(Ph_2PCH_2CMe_2ND_2)]^+$ isotopomers as required by the equilibria shown in Scheme 10. However, the assignment to C−D bonds resulting from deuteration and de-coordination of the cyclooctadiene ligand, could not be excluded.



Scheme 10. Intermolecular D_2/Ir−H exchange and intramolecular Ir−D/N−H scrambling involving reversible "$[Ir^{III}(H)_2-P\cap NH_2]^+$" ⇄ "$[(\eta^2\text{-}H_2)\text{-}Ir^{III}(H)-P\cap NH]^+$" tautomerization

In an independent concluding experiment aiming at the unequivocal demonstration of the $[(COD)Ir(P\cap NHR)]^+$-catalyzed exchange of protons between the amino group and the gas, *N*-deuterated $[(COD)Ir\{(1R,2S)\text{-}Ph_2PCH(Ph)CH(Me)ND CHMe_2\}]^+$ [IR (KBr): $\tilde{\nu}$ = 2398 (ND) cm^{-1}] was first prepared from $\mathbf{Ir^+}$**-(*R*,*S*)-4** [IR (KBr): $\tilde{\nu}$ = 3209 (NH) cm^{-1}] and [D_1]methanol and then allowed to interact with H_2 under pressure in dry [D_8]THF. The solid that was recovered after removal of all volatile material displayed the characteristic N−H stretching vibration of the starting $\mathbf{Ir^+}$**-(*R*,*S*)-4**$^+$ complex, showing that an H_2/−NDR → HD/−NHR re-exchange of isotopes had occurred.

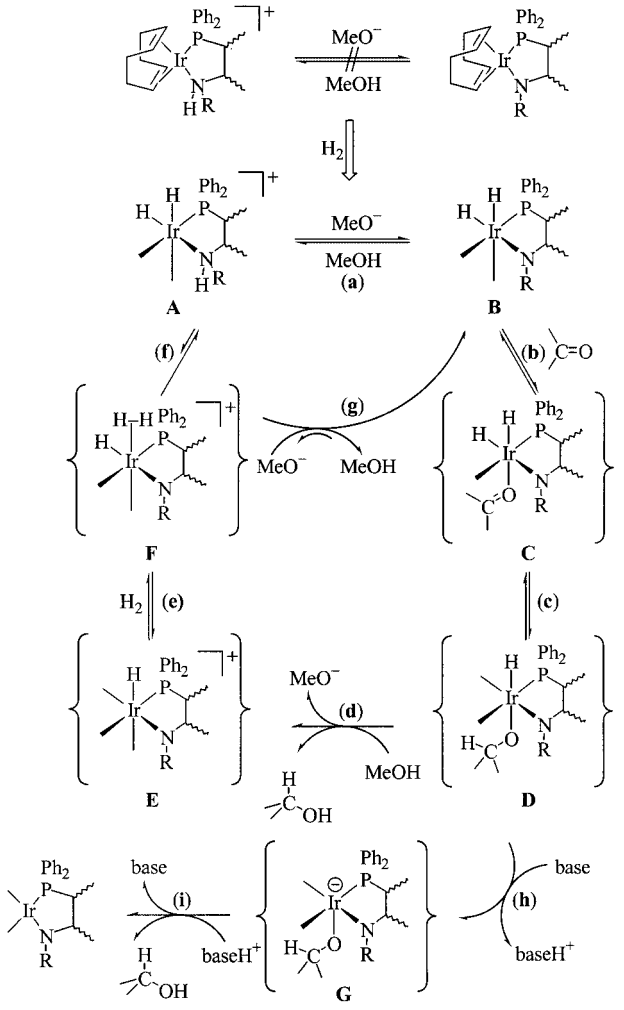
The formation of HD as a product obligatorily accompanying the hydride/deuteride exchange at the Ir^{III} center and the observation that both the catalyzed H_2/D_2 scrambling and the exchange of isotopes between dihydrogen molecules and solvent protons is only supported by complexes containing at least one N−H bond [Scheme 7, reactions (2) and (3)] are strongly suggestive of an equilibrium between two amino−dihydrido and amido−dihydrogen−monohydrido tautomers, "$[Ir^{III}(H)_2-$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

P∩NH$_2$]$^+$" and "[(η^2-H$_2$)-Ir^{III}(H)−P∩NH]$^+$", even if the η^2-H$_2$ isomeric form, which maintains the exchange of isotopes by intramolecular H/D scrambling (cf. Scheme 10),[23c,23e,23i,25] remained undetected by NMR spectroscopy down to −60 °C. Related equilibria that have previously been established, generally in an indirect fashion by the observation of H$_2$/D$^+$ exchange processes and/or isotopic scrambling between metal−hydride and protonated ligand sites, include the pairs of tautomers "H−M^{II}−S(H)R ⇄ (η^2-H$_2$)−M^{II}−SR" (M = Ru,[23h,27c,27d] Os,[28b,28c], Ni[27e,27f]) and "H−M^{III}−LH ⇄ (η^2-H$_2$)−M^{III}−L" (M = Rh: LH = RSH;[27a,27b] M = Ir: LH = NH$_3$,[26] OH$_2$,[25a,25b] RSH[28a]) as well as a family of Ir^{III} complexes containing a pendant basic aniline (acidic anilinium) function in addition to an acidic η^2-bound H$_2$ ligand (basic hydride).[25c,25d] Only in favorable cases where the pK_a of the coordinated dihydrogen molecule and the protonated ancillary ligand were similar[23i] was it possible to directly observe the equilibrium between the two tautomers.[28c] For the most part however, either the η^2-H$_2$ complex[25c,25d,26,27b,28] or the metal hydride containing the protonated N,[25c,25d] O,[25a] or S[27c] ligand remained undetected transients in the isotopic scrambling, depending on whether the coordinated H$_2$ molecule or the ligand bearing the proton was the stronger Brønsted acid or, vice versa, whether the ancillary deprotonated ligand or the metal−hydride bond[32] was the stronger Brønsted base.[25c,25d] With regard to the "[IrH$_2$(Ph$_2$PCH$_2$-CMe$_2$NH$_2$)]$^+$" ⇄ "[(η^2-H$_2$)(H)(Ph$_2$PCH$_2$CMe$_2$NH)]$^+$" tautomerization, we conclude that the amido−dihydrogen−monohydrido complex cannot be seen but resembles the undetected dihydrogen amide forms "[Ir^{III}(η^2-H$_2$)NH$_2$]$^{n+}$" of the long known hydrido ammine complexes [Ir^{III}(H)(NH$_3$)$_2$(PEt$_3$)$_2$L]$^{n+}$ (n = 1; L = Cl; n = 2: L = NH$_3$, PEt$_3$)[26] in being a transient species immediately yielding the other tautomer because the basicity of the coordinated amide by far exceeds that of the metal−hydride bond in the adjacent *cis* position.

Concluding Discussion

Putting all evidence together, we propose that H$_2$ activation as well as H$_2$/D$^+$ and H$_2$/D$_2$ exchange follow the cycle outlined in Scheme 11, which rests on the formation of either COD-coordinated or solvated *amino* and *amido* dihydro iridium(III) complexes, A and B, as the first key intermediates. Because of their coordinative saturation, amides B can act as bases toward the protic solvent to generate the conjugate amino complexes A at equilibrium concentrations (step a) and, equally important, are inert towards elimination of imine fragments from *P*,*N* ligands possessing β-hydrogen atoms. The readily occurring H$_2$/D$_2$ exchange processes, which require the presence of at least one acidic N−H function, points to a tautomeric equilibrium between A and the dihydrogen−hydrido−amido form F. Even if the tautomerization step f yields F only at spectroscopically undetectable transitory concentrations, these are sufficient to



Scheme 11. Proposed catalytic cycle for >C=O hydrogenation and concomitant H$_2$/D$^+$ and H$_2$/D$_2$ exchange reactions (unlabeled coordination sites occupied by weakly bonded solvent molecules)

account for the observed H/D exchange processes since cationic Ir^{III}(μ-H$_2$)(H) complexes combine the possibility of facile *inter*molecular exchange between the bound H$_2$ ligand and free D$_2$ molecules (or molecules containing exchangeable protons) with low barriers to *intra*molecular exchange with the hydride ligand.[23c,23i]

The transient formation of tautomers F also explains the incorporation of solvent deuterons as D$^{\delta-}$ equivalents into the product alcohols that were obtained if the [(COD)Ir(P∩NHR)]$^+$−base-assisted hydrogenation of ketones was conducted in MeOD [Scheme 7, reaction (1)]. We propose that the catalysts described herein follow the classic Schrock−Osborn pathway[6] of >C=O/Ir−H insertion rather than the alternative Noyori−Morris mechanism of "metal−ligand bifunctional" interaction with the substrate,[2,3,4] mainly because the latter[5,6] does *not* depend on the use of protic reaction media but also occurs with comparable results in aprotic solvents such as benzene.[3] In the associated catalytic cycle the first formed amido dihydrides B are converted via ketone adducts C into alkoxo hydrides D, where the *trans* bond weakening H$^-$ ligand is expected

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to be bonded opposite to the alkoxide so that release of the alcohol by reductive elimination is impeded (steps b and c).[5] Protonation of the alkoxide ligand by the solvent with subsequent release of the product from the metal (step d) is a more feasible option which would also explain why the use of protic reaction media is essential for the catalysis. Addition of H_2 to the vacant (or weakly solvated) coordination site of the remaining cationic Ir^{III} species E (step e) leads back to F as the key transient that is able to connect the cycle of catalytic >C=O hydrogenation with the pathway of H_2/D^+ scrambling. *Intra*molecular deprotonation of the acidic H_2 ligand by the amide site (step f) will restore the amino dihydrido species A, which in turn can be converted into the conjugate amides B by the added base. Alternatively, *inter*molecular deprotonation (g) by the methoxide released during product formation (or even by the solvent itself) will directly regenerate the starting amido dihydrides B and, hence, can likewise serve to close the two interlinked cycles. An additional function of the mandatory base may be to deprotonate the alkoxo hydride D at the Ir−H bond forming G as a transient anionic Ir^{III} species which then is re-protonated by the conjugate acid baseH^+ at the alkoxo site[5,6] to release the product and regenerate the starting Ir^I amido complex (steps h and i). In this context, we briefly note that the proposed >C=O/Ir−H pathway can also explain the finding that *N*,*N*-dialkylated $[(COD)Ir\{(1R,2S)\text{-}Ph_2PCH(Ph)CH(Me)NMe_2\}]^+$ [**Ir**$^+$-(*R*,*S*)-**5**] in the presence of base *does* exhibit some catalytic activity for homogeneous ketone hydrogenation *but does not* act as a catalyst for either the H_2/D_2 or H_2/D^+ exchange processes. Oxidative addition of H_2, followed by coordination and insertion of the ketone, will give a *cationic* alkoxo hydrido intermediate in place of the *neutral* species D proposed in Scheme 11. Removal of the alcohol from the coordination sphere on the MeO^-/MeOH-driven pathway h → i therefore leads back to $[L_2Ir\{(1R,2S)\text{-}Ph_2PCH(Ph)CH(Me)NMe_2\}]^+$ as a solvated analogue of the starting compound **Ir**$^+$-(*R*,*S*)-**5**, thus maintaining the cycle of >C=O hydrogenation but barring the way to concomitant isotopic scrambling.

In summary, evidence has been presented for a mechanism of >C=O hydrogenation and H/D exchange catalyzed by iridium β-aminophosphane complexes which involves both homo- and heterolytic H_2 activation at the same metal center.[33]

Experimental Section

General Remarks: All manipulations were performed under nitrogen using standard Schlenk techniques. Solvents were distilled from the appropriate drying agents prior to use. IR: Mattson Polaris. NMR: Bruker DPX 300 (300.1 MHz for ^1H, 75.5 MHz for ^{13}C, 121.5 MHz for ^{31}P, and 46.1 MHz for ^2H) at 20±2 °C (if not stated otherwise) using $SiMe_4$ (or the solvent) or H_3PO_4 as internal or external standards, respectively (downfield positive; "m": deceptively simple multiplets); high-pressure experiments in Wilmad 528-PV-1 tubes (inner diameter: 2.2 mm). Polarimetry: Perkin−Elmer PE 241 (1 dm cells at room temperature). $[\alpha]_\lambda$ in 10 deg·cm^2·g^{-1} (estimated accuracy: ±3%), *c* in g 100 mL^{-1}. HPLC: Thermoquest P 4000 (UV detector).

(2-Aminoethyl)diphenylphosphane as well as the β-amino alcohols (−)-norephedrine, (−)-ephedrine, (−)-*N*-methylephedrine, (+)-pseudoephedrine, (−)-pseudoephedrine, and 2-amino-2-methylpropanol were used as obtained commercially (Fluka, Aldrich). Other starting materials, including (−)-*N*-isopropylnorephedrine,[15] diphenylphosphane,[34] the aziridines 2,2-dimethyl-,[19] (−)-(2*S*,3*R*)-*cis*-2-methyl-3-phenyl-,[7a][9b] (−)-(2*S*,3*S*)-*trans*-2-methyl-3-phenyl-,[7a][12c] (+)-(2*R*,3*S*)-*cis*-1,2-dimethyl-3-phenyl-,[7a] and (+)-(2*S*,3*S*)-*trans*-1,2-dimethyl-3-phenylaziridine,[12b][12c] the *P*,*N* ligands (2-diphenylphosphanyl)-*N*-methylaniline,[18] (+)-(1*S*,2*S*)-(2-amino-1-phenylpropyl)-, (−)-(1*R*,2*S*)-(2-amino-1-phenylpropyl)-, and (−)-(1*R*,2*R*)-(2-methylamino-1-phenylpropyl)diphenylphosphane[7a] as well as the iridium and rhodium complexes *trans*-$[IrCl(CO)PPh_3)_2]$,[35] $[\{(COD)Ir(\mu\text{-}Cl)\}_2]$,[36] $[Ir(COD)_2]BF_4$,[37] (−)-$[(COD)Ir\{(1S,2S)\text{-}Ph_2PCH(Ph)CH(Me)NH_2\}]BF_4$, and $[(COD)M\{(1R,2R)\text{-}Ph_2PCH(Ph)CH(Me)NHMe\}]BF_4$ (M = Rh, Ir)[7a] were prepared as described previously.

(−)-(2*S*,3*R*)-*cis*-1-Benzyl-2-methyl-3-phenylaziridine: A solution of (−)-(2*S*,3*R*)-*cis*-2-methyl-3-phenylaziridine (480 mg, 3.60 mmol) in THF (40 mL) was treated with *n*-butyllithium (2.25 mL of a 1.6 M solution in hexane) at 0 °C. After the addition of benzyl chloride (0.44 mL, 3.80 mmol) and stirring overnight, 2% aqueous citric acid (40 mL) and dichloromethane (50 mL) were added. The aqueous layer was saturated with NaCl and repeatedly extracted with CH_2Cl_2. The combined organic phases were thoroughly washed with $NaHCO_3$ and the solvents evaporated to dryness. The remaining colorless oil was purified by chromatography on a silica gel column with diethyl ether/*n*-pentane (1:8) as the eluent. Evaporation of the solvent from the eluate left the product as a colorless oil; yield 460 mg (57%). ^1H NMR ($CDCl_3$, ppm): δ = 0.87 (d, $^3J_{H,H}$ = 5.49 Hz, 3 H, CH_3), 1.82 ["qui", 1 H, C(2)-H)], 2.57 [d, $^3J_{H,H}$ = 6.57 Hz, 1 H, C(3)-H], 3.49, 3.66 (AB-dd, $^2J_{H,H}$ = 13.91 Hz, 2 H, CH_2), 7.1−7.5 (m, 10 H, C_6H_5). $^{13}C\{^1H\}$ NMR ($CDCl_3$, ppm): δ = 12.79 (CH_3), 41.72 (C-2), 46.18 (C-3), 64.42 (CH_2), 126.4−139.4 (C_6H_5). The NMR spectroscopic data corresponded to those reported in the literature in every respect.[14] $[\alpha]_{589}$ = −112.4 (*c* = 1.3, CH_2Cl_2).

(−)-(2*S*,3*R*)-*cis*-1-Isopropyl-2-methyl-3-phenylaziridine: (−)-(1*R*,2*S*)-*N*-Isopropylnorephedrine (830 mg, 3.97 mmol) was combined in chloroform (30 mL) at 0 °C with PCl_5 (1.10 g, 5.30 mmol). The mixture was heated to reflux for 1 h, then cooled in an ice bath and worked up by the cautions addition of methanol (15 mL). The residue remaining after evaporation to dryness, addition of ethanol (20 mL), and renewed removal of all volatile material was triturated with diethyl ether, separated by filtration and re-dissolved in chilled 5 M sodium hydroxide solution (40 mL). The resultant mixture was heated at 90 °C for 2 h, cooled to room temperature and extracted with diethyl ether. The combined organic layers were dried with Na_2SO_4, evaporated, and then distilled at 70 °C in the vacuum of an oil pump to give the product as a colorless liquid which solidified overnight forming tiny needle-shaped crystals; yield 375 mg (54%). ^1H NMR ($CDCl_3$, ppm): δ = 0.74 (d, $^3J_{H,H}$ = 5.67 Hz, 3 H, CH_3), 1.00, 1.02 [both d, $^3J_{H,H}$ = 5.85 Hz each, both 3 H, $CH(CH_3)_2$], 1.53 [sept, $CH(CH_3)_2$], 1.58 ["qui", 1 H, C(2)-H], 2.33 [d, $^3J_{H,H}$ = 6.75 Hz, 1 H, C(3)-H], 7.0−7.2 (m, 5 H, C_6H_5). $^{13}C\{^1H\}$ NMR ($CDCl_3$, ppm): δ = 13.70 (CH_3), 21.88, 22.08 [both $CH(CH_3)_2$], 40.51 (C-2), 45.87 (C-3), 61.34 [$NCH(CH_3)_2$], 125.4−138.0 (C_6H_5). $[\alpha]_{589}$ = −106.1 (*c* = 6.1, CH_2Cl_2).

(+)-(2*S*,3*S*)-*trans*-1-Isopropyl-2-methyl-3-phenylaziridine: A solution of bromine (255 μL, 4.95 mmol) in acetonitrile (5 mL) was

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

added dropwise at 0 °C to triphenylphosphane (1.30 g, 4.95 mmol) dissolved in MeCN (15 mL). The resultant mixture was stirred for 2 h at room temperature, cooled in an ice bath, and then treated with an acetonitrile solution (5 mL) containing (−)-(1*R*,2*S*)-*N*-isopropylnorephedrine (1.035 g, 4.95 mmol) together with triethylamine (1.38 mL, 9.89 mmol). Stirring overnight caused a precipitate of triethylammonium bromide to separate from the solution, which was filtered off. The filtrate was thoroughly extracted with *n*-pentane and the combined extracts were concentrated to a small residual volume to deposit a white precipitate of triphenylphosphane oxide which was removed by filtration. The filtrate was evaporated in vacuo and then distilled with an oil pump generated vacuum at 70 °C to give 317 mg (43%) of the aziridine as a colorless liquid. ^{1}H NMR ($CDCl_3$, ppm): δ = 1.07, 1.10 [both d, $^3J_{H,H}$ = 6.21 Hz each, both 3 H, CH(C*H*$_3$)$_2$], 1.33 (d, $^3J_{H,H}$ = 5.85 Hz, 3 H, CH_3), 2.06 [d, $^3J_{H,H}$ = 2.91 Hz, 1 H, C(3)-H], 2.11 [m, 1 H, C(2)−H], 2.36 [sept, 1 H, C*H*(CH$_3$)$_2$], 7.0−7.3 (m, 5 H, C_6H_5). ^{13}C{^{1}H} NMR ($CDCl_3$, ppm): δ = 11.14 (CH_3), 22.87, 22.94 [both CH(*C*H$_3$)$_2$], 42.45 (C-2), 46.94 (C-3), 51.70 [N*C*H(CH$_3$)$_2$], 126.1−141.1 (C_6H_5). [α]$_{589}$ = +64.8 (*c* = 4.7, CH_2Cl_2).

(−)-(1*R*,2*S*)-(2-Methylamino-1-phenylpropyl)diphenylphosphane [(*R*,*S*)-2]: Boron trifluoride−diethyl etherate (2.32 mL, 18.50 mmol) was added dropwise to a $CHCl_3$ solution of (+)-(2*S*,3*S*)-*trans*-1,2-dimethyl-3-phenylaziridine (2.717 g, 18.45 mmol) and diphenylphosphane (3.20 mL, 18.50 mmol). The mixture was heated to reflux overnight, then hydrolyzed and adjusted to pH 8 by addition of $NaHCO_3$. The organic phase was separated, washed with 5% aqueous sodium hydrogencarbonate, dried over Na_2SO_4, and the solvents evaporated to leave a yellowish oily residue. The oil was re-dissolved in diethyl ether, filtered, evaporated again, and heated at 100 °C under a dynamic vacuum in order to remove any remaining diphenylphosphane; yield 289 mg (47%) of (*R*,*S*)-**2** as a colorless wax. ^{1}H NMR ($CDCl_3$, ppm): δ = 0.98 (d, $^3J_{H,H}$ = 6.39 Hz, 3 H, CCH_3), 1.83 [s (br), 1 H, NH], 2.30 (s, 3 H, NCH_3), 2.80 [m, 1 H, C(2)-H], 3.62 ["t", Σ|$^2J_{P,H}$ + $^3J_{H,H}$| = 11.70 Hz, 1 H, C(1)-H], 7.0−7.7 (m, 15 H, C_6H_5). ^{13}C{^{1}H} NMR ($CDCl_3$, ppm): δ = 18.60 (d, $^3J_{P,C}$ = 4.36 Hz, C*C*H$_3$), 34.11 (s, NCH_3), 51.89, 56.52 (both d, $J_{P,C}$ = 13.08, 16.72 Hz, C-1/*C*-2), 126.5−138.6 (C_6H_5). ^{31}P{^{1}H} NMR ($CDCl_3$, ppm): δ = −7.00. [α]$_{589}$ = −218 (*c* = 0.9, THF). $C_{22}H_{24}NP$ (333.4): calcd. C 79.25, H 7.26, N 4.20; found C 79.47, H 7.43, N 4.11.

(+)-(1*S*,2*S*)-(2-Benzylamino-1-phenylpropyl)diphenylphosphane [(*S*,*S*)-3]: The preparation was carried out as described for (*R*,*S*)-**2** by reacting BF_3-activated (−)-(2*S*,3*R*)-*cis*-1-benzyl-2-methyl-3-phenylaziridine (367 mg, 1.65 mmol) with diphenylphosphane (0.29 mL, 1.65 mmol); yield 325 mg (48%) of (*S*,*S*)-**3** as a white powder. ^{1}H NMR ($CDCl_3$, ppm): δ = 1.04 (d, $^3J_{H,H}$ = 6.57 Hz, 3 H, CCH_3), 1.41 [s (br), 1 H, NH], 2.81 [m, 1 H, C(2)-H], 3.64, 3.66 (AB-dd, $^2J_{H,H}$ = 13.45 Hz, 2 H, CH_2), 3.83 [dd, $^2J_{P,H}$/$^3J_{H,H}$ = 5.49/5.67 Hz, 1 H, C(1)-H], 6.9−7.5 (m, 20 H, C_6H_5). ^{13}C{^{1}H} NMR ($CDCl_3$, ppm): δ = 17.90 (d, $^3J_{P,C}$ = 9.45 Hz, C*C*H$_3$), 50.63 (s, NCH_2), 48.98, 53.54 (both d, $J_{P,C}$ = 14.53, 17.43 Hz, C-1/C-2), 119.5−140.2 (C_6H_5). ^{31}P{^{1}H} NMR ($CDCl_3$, ppm): δ = −8.05. [α]$_{589}$ = +64.5 (*c* = 6.7, CH_2Cl_2). $C_{28}H_{28}NP$ (409.5): calcd. C 82.12, H 6.89, N 3.42; found C 81.95, H 7.01, N 3.31.

(+)-(1*S*,2*S*)-(2-Isopropylamino-1-phenylpropyl)diphenylphosphane [(*S*,*S*)-4]: This material was obtained as outlined before by treating (−)-(2*S*,3*R*)-*cis*-1-isopropyl-2-methyl-3-phenylaziridine (263 mg, 1.50 mmol) in the presence of $F_3B{\cdot}OEt_2$ with diphenylphosphane (0.26 mL, 1.50 mmol); yield 421 mg (78%) of a colorless waxy solid. ^{1}H NMR ($CDCl_3$, ppm): δ = 0.63 (d, $^3J_{H,H}$ = 6.03 Hz, 3 H, CCH_3), 0.83, 1.00 [both d, $^3J_{H,H}$ = 6.21, 6.60 Hz, both 3 H, CH(C*H*$_3$)$_2$], 2.74 [m, 1 H, C(2)-H], 2.91 [sept, 1 H, C*H*(CH$_3$)$_2$], 3.81 [dd, $^2J_{P,H}$/$^3J_{H,H}$ = 3.84/6.60 Hz, 1 H, C(1)-H], 6.9−7.7 (m, 15 H, C_6H_5); NH not observed. ^{13}C{^{1}H} NMR ($CDCl_3$, ppm): δ = 18.20 (d, $^3J_{P,C}$ = 8.72 Hz, C*C*H$_3$), 22.24, 23.04 [both s, both CH(*C*H$_3$)$_2$], 43.94 [s, N*C*H(CH$_3$)$_2$], 47.70, 50.00 (both d, $J_{P,C}$ = 14.53, 16.71 Hz, C-1/C-2), 126.4−137.7 (C_6H_5). ^{31}P{^{1}H} NMR ($CDCl_3$, ppm): δ = −9.04. [α]$_{589}$ = +37.1 (*c* = 2.4, CH_2Cl_2). $C_{24}H_{28}NP$ (361.5): calcd. C 79.75, H 7.81, N 3.87; found C 79.63, H 7.99, N 3.79.

(−)-(1*R*,2*S*)-(2-Isopropylamino-1-phenylpropyl)diphenylphosphane [(*R*,*S*)-4]: The compound was prepared in a similar way to its (1*S*,2*S*) diastereomer above using BF_3-activated (+)-(2*S*,3*S*)-*trans*-1-isopropyl-2-methyl-3-phenylaziridine (371 mg, 2.12 mmol) together with an equimolar quantity of diphenylphosphane (0.37 mL) in $CHCl_3$; yield 669 mg (87%) of a colorless sticky solid. ^{1}H NMR ($CDCl_3$, ppm): δ = 0.64 (d, $^3J_{H,H}$ = 6.24 Hz, 3 H, CCH_3), 0.86, 0.88 (both d, $^3J_{H,H}$ = 6.39 Hz each, both 3 H, CH(C*H*$_3$)$_2$], 2.70 [sept, 1 H, C*H*(CH$_3$)$_2$], 2.99 [m, 1 H, C(2)-H], 3.52 [dd, $^2J_{P,H}$/$^3J_{H,H}$ = 4.84/6.60 Hz, 1 H, C(1)-H], 6.9−7.6 (m, 15 H, C_6H_5); NH not observed. ^{13}C{^{1}H} NMR ($CDCl_3$, ppm): δ = 20.32 (d, $^3J_{P,C}$ = 5.08 Hz, C*C*H$_3$), 22.01, 24.22 [both s, both CH(*C*H$_3$)$_2$], 45.34 [s, N*C*H(CH$_3$)$_2$], 51.41, 51.90 (both d, $J_{P,C}$ = 15.26, 12.35 Hz, C-1/C-2), 126.4−130.5 (C_6H_5). ^{31}P{^{1}H} NMR ($CDCl_3$, ppm): δ = −7.68. [α]$_{589}$ = −205 (*c* = 1.1, CH_2Cl_2). $C_{24}H_{28}NP$ (361.5): calcd. C 79.75, H 7.81, N 3.87; found C 79.52, H 8.02, N 3.73.

(−)-(1*R*,2*S*)-(2-Dimethylamino-1-phenylpropyl)diphenylphosphane [(*R*,*S*)-5]: Methanesulfonyl chloride (1.27 mL, 16.35 mmol) and triethylamine (3.50 mL, 24.52 mmol) were sequentially added to a chilled THF solution (40 mL) of (−)-*N*-methylephedrine (1.465 g, 8.17 mmol). The aziridinium methanesulfonate which was formed after stirring the mixture for 1 h at room temperature was further reacted by heating to reflux a toluene solution (50 mL) containing diphenylphosphane (1.42 mL, 8.17 mmol) and an additional amount of NEt_3 (2.30 mL, 16.35 mmol). After hydrolysis the product was isolated following the workup procedure described above for (*R*,*S*)-**2**; yield 1.11 g (39%) of the aminophosphane as a colorless wax. ^{1}H NMR ($CDCl_3$, ppm): δ = 0.87 (d, $^3J_{H,H}$ = 6.75 Hz, 3 H, CCH_3), 1.96 [s, 6 H, N(CH$_3$)$_2$], 3.04 [m, 1 H, C(2)-H], 3.55 [dd, $^2J_{P,H}$/$^3J_{H,H}$ = 6.03/7.68 Hz, 1 H, C(1)-H], 6.9−7.7 (m, 15 H, C_6H_5). ^{13}C{^{1}H} NMR ($CDCl_3$, ppm): δ = 18.60 (d, $^3J_{P,C}$ = 4.36 Hz, C*C*H$_3$), 34.11 [s, N(CH$_3$)$_2$], 51.89, 56.52 (both d, $J_{P,C}$ = 13.08, 16.72 Hz, C-1/C-2), 126.5−138.6 (C_6H_5). ^{31}P{^{1}H} NMR ($CDCl_3$, ppm): δ = −4.24. [α]$_{589}$ = −318 (*c* = 3.1, THF). $C_{23}H_{26}NP$ (347.4): calcd. C 79.51, H 7.54, N 4.03; found C 79.84, H 7.88, N 3.92.

(2-Amino-2-methylpropyl)diphenylphosphane (8): A mixture composed of 9.96 mmol in each case of 2,2-dimethylaziridine (708 mg), boron trifluoride diethyl etherate (1.26 mL), and diphenylphosphane (1.73 mL) in $CHCl_3$ (50 mL) was heated to reflux for 3 h. An oily precipitate resulting from polymerization of the aziridine was removed by decanting the supernatant liquid, which was worked up by hydrolysis as outlined before for (*R*,*S*)-**2** to give 870 mg (34%) of the *P*,*N* ligand as a clear colorless oil. ^{1}H NMR ($CDCl_3$, ppm): δ = 1.21 (s, 6 H, CH_3), 1.36 [s (br), 2 H, NH_2], 2.36 (d, $^2J_{P,H}$ = 3.66 Hz, CH_2), 7.2−7.6 (m, 10 H, C_6H_5). ^{13}C{^{1}H} NMR ($CDCl_3$, ppm): δ = 32.01 (d, $^3J_{P,C}$ = 7.99 Hz, CH_3), 45.83, 50.00 (both d, $J_{P,C}$ = 15.25, 15.26 Hz, C-1/C-2), 128.3−139.5 (C_6H_5). ^{31}P{^{1}H} NMR ($CDCl_3$, ppm): δ = −23.09. $C_{16}H_{20}NP$ (257.3): calcd. C 74.69, H 7.83, N 5.44; found C 74.79, H 7.98, N 5.21.

[(COD)Ir(Ph$_2$PCH$_2$CH$_2$NH$_2$)]BF$_4$ [Ir$^+$-6]: To [Ir(COD)$_2$]BF$_4$ (472 mg, 0.95 mmol) suspended in THF (10 mL) was added dropwise a solution of **6** (220 mg, 0.96 mmol) in THF (15 mL). The dark red solution which formed on stirring overnight was reduced in vacuo to a small residual volume. Dilution with diethyl ether and *n*-pentane (20 mL each) caused the product to separate from solution as an orange microcrystalline precipitate which was collected by filtration, thoroughly washed with diethyl ether, and dried under a dynamic vacuum; yield 540 mg (91%). ^{1}H NMR (CDCl$_3$, ppm): δ = 1.7−2.3 (m, 8 H, diene CH$_2$), 2.85, 2.95 (both m, 2 H each, PCH$_2$/NCH$_2$), 3.36 [s (br), 2 H, NH$_2$], 4.7, 5.1 (both m, 2 H each, both diene CH), 7.1−7.7 (m, 10 H, C$_6$H$_5$). ^{13}C{^{1}H} NMR (CDCl$_3$, ppm): δ = 29.30 (s, 2 diene CH$_2$), 31.56 (d, $^1J_{P,C}$ = 32.69 Hz, PCH$_2$), 32.41 (s, 2 diene CH$_2$), 44.69 (d, $^2J_{P,C}$ = 5.09 Hz, NCH$_2$), 61.64 (s, CH=CH *trans* N), 93.33 (d, $^2J_{P,C}$ = 11.62 Hz, CH=CH *trans* P), 128.8−133.2 (C$_6$H$_5$). ^{31}P{^{1}H} NMR (CDCl$_3$, ppm): δ = 38.61. C$_{22}$H$_{28}$BF$_4$IrNP (616.5): calcd. C 42.86, H 4.58, N 2.27; found C 43.02, H 4.67, N 2.09.

The following complexes were prepared by a procedure analogous to that detailed before.

[(COD)Ir(2-Ph$_2$PC$_6$H$_4$NHMe)]BF$_4$ [Ir$^+$-7]: Yield, from [Ir(COD)$_2$]BF$_4$ (574 mg, 1.16 mmol) and the chelate ligand (338 mg, 1.16 mmol), 630 mg (80%) of **Ir$^+$-7** as a reddish brown solid. ^{1}H NMR (CDCl$_3$, ppm): δ = 1.6−2.5 (m, 8 H, diene CH$_2$), 2.85 (d, $^3J_{H,H}$ = 6.03 Hz, 3 H, CH$_3$), 3.1, 4.0, 5.2, 5.75 (all m, 1 H each, all diene CH), 7.2−8.0 (m, 14 H, C$_6$H$_5$ and C$_6$H$_4$); NH not observed. ^{13}C{^{1}H} NMR (CDCl$_3$, ppm): δ = 28.94, 31.13, 31.48, 34.77 (all s, all diene CH$_2$), 48.28 (s, CH$_3$), 61.92, 65.92 (both s, CH=CH *trans* N), 94.81, 98.99 (both d, $^2J_{P,C}$ = 13.08, 10.17 Hz, CH=CH *trans* P), 123.3−135.5 (C$_6$H$_5$ and C$_6$H$_4$), 157.83 (d, $^2J_{P,C}$ = 18.17 Hz, phenylene C-1). ^{31}P{^{1}H} NMR (CDCl$_3$, ppm): δ = 30.39. C$_{27}$H$_{30}$BF$_4$IrNP (678.6): calcd. C 47.79, H 4.46, N 2.06; found C 47.62, H 4.67, N 1.94.

[(COD)Ir(Ph$_2$PCH$_2$CMe$_2$NH$_2$)]BF$_4$ [Ir$^+$-8]: Yield, from [Ir(COD)$_2$]BF$_4$ (131 mg, 0.26 mmol) and the β-aminophosphane (68 mg, 0.26 mmol), 151 mg (88%) of **Ir$^+$-8** as a dark reddish brown solid. ^{1}H NMR (CDCl$_3$, ppm): δ = 1.40 (s, 6 H, CH$_3$), 1.7−2.4 (m, 8 H, diene CH$_2$), 2.51 (d, $^2J_{P,H}$ = 9.51 Hz, 2 H, PCH$_2$), 3.41 [s (br), 2 H, NH$_2$], 4.8, 5.3 (both m, 2 H each, both diene CH), 7.3−7.8 (m, 10 H, C$_6$H$_5$). ^{13}C{^{1}H} NMR (CDCl$_3$, ppm): δ = 28.88, 28.98, 29.28, 31.72 (all s, all diene CH$_2$), 32.31 (d, $^3J_{P,C}$ = 2.91 Hz, CH$_3$), 43.61 (d, $^1J_{P,C}$ = 30.52 Hz, PCH$_2$), 61.77 (d, $^2J_{P,C}$ = 5.09 Hz, NCH$_2$), 61.86 (s, CH=CH *trans* N), 93.73 (d, $^2J_{P,C}$ = 12.35 Hz, CH=CH *trans* P), 129.0−133.4 (C$_6$H$_5$). ^{31}P{^{1}H} NMR (CDCl$_3$, ppm): δ = 29.14. C$_{24}$H$_{32}$BF$_4$IrNP (644.6): calcd. C 44.73, H 5.00, N 2.17; found C 44.42, H 5.09, N 2.09.

[(COD)Ir{(1*S*,2*S*)-Ph$_2$PCH(Ph)CH(Me)NHCH$_2$Ph}]BF$_4$ [Ir$^+$-(*S*,*S*)-3]: Yield, from [Ir(COD)$_2$]BF$_4$ (235 mg, 0.48 mmol) and (*S*,*S*)-**3** (195 mg, 0.48 mmol), 314 mg (82%) of the complex as an orange solid containing the δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,S_N) conformer (≈ 40%) together with the δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,R_N) form (≈ 60%) as sterically locked ring conformers (isomeric distribution estimated from ^{1}H and ^{31}P{^{1}H} NMR). ^{1}H NMR ([D$_6$]acetone, ppm): δ[δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,S_N)] = 1.32 (d, $^3J_{H,H}$ = 6.39 Hz, 3 H, CCH$_3$), 1.4−2.5 (m, 8 H, diene CH$_2$), 2.92 [m, 1 H, MeC(2)-H], 3.20, 3.39 (both m, 1 H each, both diene CH), 4.20, 4.22 (AB-dd, $^2J_{H,H}$ = 6.93 Hz, 2 H, CH$_2$), 4.58 [dd, $^2J_{P,H}$/$^3J_{H,H}$ = 6.39/3.63 Hz, 1 H, PhC(1)-H], 5.63 (m, 2 H, diene CH), 6.3 [s (br), 1 H, NH], 6.8−8.1 (m, 20 H, C$_6$H$_5$); δ[δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,R_N)] = 1.19 (d, $^3J_{H,H}$ = 6.03 Hz, 3 H, CCH$_3$), 1.4−2.5 (m, 8 H, diene CH$_2$), 2.65 [m, 1 H, MeC(2)-H], 3.61, 3.67 (both m, 1 H each, both diene CH), 4.57 [dd, $^2J_{P,H}$/$^3J_{H,H}$ = 6.75/4.41 Hz, 1 H, PhC(1)-H], 4.71, 4.75 (AB-dd, $^2J_{H,H}$ = 6.48 Hz, 2 H, CH$_2$), 5.51 (m, 2 H, diene CH), 5.9 [s (br), 1 H, NH], 6.8−8.1 (m, 20 H, C$_6$H$_5$). ^{13}C{^{1}H} NMR ([D$_6$]acetone, ppm): δ[δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,S_N)] = 17.37 (d, $^3J_{P,C}$ = 13.80 Hz, C*C*H$_3$), 26.1−37.6 (diene CH$_2$; partially obscured by solvent), 47.09 (d, $^1J_{P,C}$ = 24.71 Hz, PCH), 51.23 (s, CH$_2$), 64.40 (d, $^2J_{P,C}$ = 9.45 Hz, NCH), 64.52, 69.12 (both s, CH=CH *trans* N), 82.35, 94.20 (both d, $^2J_{P,C}$ = 16.72, 7.99 Hz, CH=CH *trans* P), 125.0−138.5 (C$_6$H$_5$); δ[δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,R_N)] = 16.50 (d, $^3J_{P,C}$ = 13.80 Hz, C*C*H$_3$), 26.1−37.6 (diene CH$_2$; partially obscured by solvent), 53.45 (s, CH$_2$), 54.18 (d, $^1J_{P,C}$ = 25.43 Hz, PCH), 60.02 (d, $^2J_{P,C}$ = 9.45 Hz, NCH), 60.79, 65.65 (both s, CH=CH *trans* N), 92.89, 98.31 (both d, $^2J_{P,C}$ = 14.54, 8.72 Hz, CH=CH *trans* P), 125.0−138.5 (C$_6$H$_5$). ^{31}P{^{1}H} NMR ([D$_6$]acetone, ppm): δ = 39.97 [δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,S_N) conformer], 46.65 [δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,R_N) conformer]. C$_{36}$H$_{40}$BF$_4$IrNP (796.8): calcd. C 54.27, H 5.06, N 1.76; found C 54.52, H 5.21, N, 1.62.

[(COD)Ir{(1*S*,2*S*)-Ph$_2$PCH(Ph)CH(Me)NHCHMe$_2$}]BF$_4$ [Ir$^+$-(*S*,*S*)-4]: Yield, from [Ir(COD)$_2$]BF$_4$ (347 mg, 0.70 mmol) and (*S*,*S*)-**4** (300 mg, 0.76 mmol), 456 mg (87%) of the product as an orange solid composed of the two ring conformers δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,S_N), ≈ 25%, and δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,R_N), ≈ 75% (isomeric distribution estimated from the relative intensities of the ^{31}P resonances). ^{1}H NMR (CDCl$_3$, ppm): δ[δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,R_N)] = 1.37 ["t", Σ|$^3J_{H,H}$ +$^5J_{H,H}$| = 13.14 Hz, 6 H, CH(C*H*$_3$)$_2$], 1.50 (d, $^3J_{H,H}$ = 6.78 Hz, 3 H, CCH$_3$), 1.5−2.4 (m, 8 H, diene CH$_2$), 3.22 [m, 1 H, MeC(2)-H], 3.34 [s (br), 1 H, NH], 3.63 (sept, $^3J_{H,H}$ = 6.57 Hz, 1 H, C*H*(CH$_3$)$_2$], 4.29 [dd, $^2J_{P,H}$ = 12.17, $^3J_{H,H}$ = 7.04 Hz, 1 H, PhC(1)-H], 4.87, 5.15, 5.37, 5.75 (all m, 1 H each, all diene CH), 6.8−7.6 (m, 15 H, C$_6$H$_5$). ^{13}C{^{1}H} NMR (CDCl$_3$, ppm): δ[δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,R_N)] = 19.83 (d, $^3J_{P,C}$ = 13.08 Hz, C*C*H$_3$), 21.98, 24.23 [both s, CH(*C*H$_3$)$_2$], 26.10, 27.18, 31.81, 36.78 (all s, all diene CH$_2$), 54.71 (d, $^1J_{P,C}$ = 25.43 Hz, PCH), 55.03 [s, *C*H(CH$_3$)$_2$], 56.31, 62.88 (both s, CH=CH *trans* N), 60.75 (d, $^2J_{P,C}$ = 7.99 Hz, NCH), 93.90, 97.87 (both d, $^2J_{P,C}$ = 13.80, 9.44 Hz, CH=CH *trans* P), 124.5−136.9 (C$_6$H$_5$); ^{1}H and ^{13}C{^{1}H} spectra of the minor δ[δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,S_N)] conformer not assigned. ^{31}P{^{1}H} NMR ([D$_6$]acetone, ppm): δ = 40.79 [δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,S_N) conformer], 45.44 [δ($S_{C\text{-}1}$,$S_{C\text{-}2}$,R_N) conformer]. ***cis*,*cis*-[(MeCN)$_2$IrH$_2${(1*R*,2*S*)-Ph$_2$PCH(Ph)CH(Me)NHMe]BF$_4$ (Ir$^+$-11):** A solution of **Ir$^+$-(*R*,*S*)-2** (90 mg, 0.12 mmol) in acetonitrile (2 mL) was stirred under 25 bar of H$_2$ for 2 h in an autoclave. The solid residue remaining after removal of all volatiles in vacuo

was re-dissolved in CD_2Cl_2 and immediately characterized by NMR spectroscopy. ^1H NMR (CD_2Cl_2, ppm): δ = −21.20, −21.14 (*AB*X m, *cis*-$^2J_{P,H}$ = 17.22, 22.11, *cis*-$^2J_{H,H}$ = 7.13 Hz, 1 H each, IrH_2), 1.09 (d, $^3J_{H,H}$ = 6.06 Hz, 3 H, $CHCH_3$), 1.73, 2.37 (both s, 3 H each, both CH_3CN), 2.87 (d, $^3J_{H,H}$ = 6.06 Hz, 3 H, NCH_3), 3.19 [m, 1 H, MeC(2)-H], 3.42 [s (br), 1 H, NH)], 4.01 [dd, $^2J_{P,H}$ = 13.71, $^3J_{H,H}$ = 4.38 Hz, 1 H, PhC(1)-H], 6.9−7.7 (m, 15 H, C_6H_5). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, ppm): δ = 1.70, 2.97 (both s, CH_3CN), 15.27 (d, $^3J_{P,C}$ = 10.90 Hz, $CHCH_3$), 37.04 (s, NCH_3), 51.62, (d, $^1J_{P,C}$ = 34.15 Hz, PCH), 64.40 (d, $^2J_{P,C}$ = 5.81 Hz, NCH), 115.99 [s (br), CH_3CN *trans* H], 119.63 (d, $^3J_{P,C}$ = 18.90 Hz, CH_3CN *trans* P), 123.0−134.4 (C_6H_5). $^{31}P\{^1H\}$ NMR (CD_2Cl_2, ppm): δ = 32.27.

X-ray Structure Determinations: Single crystals of **Ir**$^+$-(*S*,*S*)-**3**·2THF (size 0.33 × 0.10 × 0.08 mm), **Ir**$^+$-(*R*,*S*)-**2**·THF (size 0.38 × 0.33 × 0.28 mm), and **Ir**-(*R*,*S*)-**4a** (size 0.50 × 0.45 × 0.23 mm) were grown from THF/*n*-pentane [**Ir**$^+$-(*S*,*S*)-**3**·2THF and **Ir**$^+$-(*R*,*S*)-**2**·THF] or acetone [**Ir**-(*R*,*S*)-**4a**]. Diffraction measurements were made at −90±2 °C [**Ir**$^+$-(*R*,*S*)-**2**·THF] and at −80±2 °C [**Ir**$^+$-(*S*,*S*)-**3**·2THF and **Ir**-(*R*,*S*)-**4a**] on an Enraf−Nonius CAD-4 MACH 3 diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å); orientation matrices and unit cell parameters from the setting angles of 25 centered medium-angle reflections; collection of the diffraction intensities by ω scans (data corrected for absorption either empirically by ψ scans[38] [**Ir**$^+$-(*S*,*S*)-**3**·2THF: T_{min} = 0.406, T_{max} = 0.777; **Ir**$^+$-(*R*,*S*)-**2**·THF: T_{min} = 0.217, T_{max} = 0.316] or by refined absorption methods[39] [**Ir**-(*R*,*S*)-**4a**: T_{min} = 0.087, T_{max} = 0.318]. The structures were solved by direct methods and subsequently refined by full-matrix least-squares procedures on F^2 allowing for anisotropic thermal motion of all non-hydrogen atoms employing the WinGX package[40a] with the relevant programs (SIR-97,[41] SHELXL-97,[42] ORTEP-3[40b]) implemented therein. **Ir**$^+$-(*S*,*S*)-**3**·2THF: $C_{36}H_{40}IrNP$, BF_4, $2(C_4H_8O)$ (940.9); monoclinic, $P2_1$, a = 14.8593(15), b = 9.215(2), c = 15.108(2) Å, β = 93.506(9)°, V = 2064.8(5) Å^3, Z = 2, $d_{calcd.}$ = 1.513 g·cm^{-3}, μ(Mo-K_α) = 3.327 mm^{-1}; 2.59° ≤ Θ ≤ 22.48°, 6018 reflections collected (−15 ≤ h ≤ +15, −9 ≤ k ≤ +9, −16 ≤ l ≤ +16, including Friedel pairs), 5363 unique; wR = 0.1824 for all data and 488 parameters, R = 0.0835 for 3495 structure factors F_o > 4σ(F_o), absolute structure parameter[43] x = 0.00(3). **Ir**$^+$-(*R*,*S*)-**2**·THF: $C_{30}H_{36}IrNP$, BF_4, C_4H_8O (792.7); orthorhombic, $P2_12_12_1$, a = 9.268(2), b = 12.889(1), c = 27.147(6) Å, V = 3243(1) Å^3, Z = 4, $d_{calcd.}$ = 1.642 g·cm^{-3}, μ(Mo-K_α) = 4.218 mm^{-1}; 2.18° ≤ Θ ≤ 25.17°, 6122 reflections collected (−11 ≤ h ≤ +11, −15 ≤ k ≤ +15, −25 ≤ l ≤ +25, including Friedel pairs), 5418 unique; wR = 0.1328 for all data and 390 parameters, R = 0.0633 for 3963 structure factors F_o > 4σ(F_o), x = 0.02(2). **Ir**-(*R*,*S*)-**4a**: $C_{32}H_{39}IrNP$ (660.8); monoclinic, $P2_1$, a = 9.097(2), b = 19.312(4), c = 15.709(6) Å, β = 98.99(2)°, V = 2726(1) Å^3, Z = 4, $d_{calcd.}$ = 1.610 g·cm^{-3}, μ(Mo-K_α) = 4.978 mm^{-1}; 2.11° ≤ Θ ≤ 26.56°, 12154 reflections collected (−11 ≤ h ≤ +11, −24 ≤ k ≤ +24, −19 ≤ l ≤ +19, including Friedel pairs), 11382 unique; wR = 0.0734 for all data and 637 parameters, R = 0.0321 for 10345 structure factors F_o > 4σ(F_o), x = −0.012(6). CCDC-215609 [**Ir**$^+$-(*S*,*S*)-**3**·2THF], CCDC-215607 [**Ir**$^+$-(*R*,*S*)-**2**·THF], and CCDC-215608 [**Ir**-(*R*,*S*)-**4a**] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

General Procedure for Catalytic >C=O Hydrogenation: A 10 mL capacity Schlenk tube equipped with a small magnetic stirring bar was charged with the catalyst complex dissolved in methanol (typically 0.02 mmol in 3.0 mL). The required equivalent of activating nitrogen or alkaline base (cf. Tables 2−4) and 2.0 mmol of acetophenone were added, the mixture was stirred for 10 min at ambient conditions, and the tube was inserted into an argon-filled stainless steel autoclave. The autoclave was sealed, pressurized and vented several times with H_2 (Messer-Griesheim; 99.999%), and subsequently pressurized (usually to 10−25 bar) and maintained with stirring at 25 or 50 °C. At the end of the reaction, the pressure was released, the solvent removed in vacuo, and the residue diluted with *n*-pentane to precipitate the catalyst as a red oil. The pentane solution was decanted and chromatographed on a silica gel column using diethyl ether/*n*-pentane (1:1) as the eluent. Volatiles were distilled off and the mixture of products was analyzed by ^1H NMR spectroscopy. Conversions and product compositions were determined on the basis of the integrations of the $PhC(O)CH_3$ and $PhCH(OH)CH_3$ signals. Enantiomeric excesses were measured either by HPLC using a Daicel Chiralcel OD column or by polarimetry as detailed elsewhere.[7a] Optical rotations were referenced to the following $[\alpha]_D$ values of the pure enantiomers taken from the literature: (*R*)-1-phenylethanol, +48.6 (*c* = 1, CH_2Cl_2);[44a] (*S*)-1-phenylpropanol, −47.7 (*c* = 6.8, Et_2O);[44b] (*S*)-2-methyl-1-phenylpropanol, +5.3 (*c* = 1.1, EtOH);[44c] (*S*)-1-indanol, +31.7 (*c* = 1, $CHCl_3$);[44d] (*S*)-4-chloro-1-phenylbutanol, −33 (*c* = 1, $CHCl_3$).[44e]

Representative Catalytic >C=O Hydrogenations and H_2/D^+ Exchange Experiments in CH_3OD: (a) A solution of of **Ir**$^+$-(*R*,*R*)-**2** (9.5 mg, 0.013 mmol), (−)-sparteine (14 μL, 0.065 mmol) and benzophenone (150 mg, 1.25 mmol) in CH_3OD (3 mL) was kept, in an autoclave, under 10 bar of H_2 at 50 °C for 10 h. The residue remaining after removal of the solvent was analyzed by NMR spectroscopy. ^1H NMR (CD_2Cl_2, ppm): δ = 5.76 (s with half intensity relative to 10 phenyl H, Ph_2CHOD), 7.2−7.5 (m, 10 H, C_6H_5). ^2H NMR (CH_2Cl_2, ppm): δ = 2.42 (br., OD), 5.78 (s, Ph_2CDOD). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, ppm): δ = 76.52 (1:1:1 t, $^1J_{C,D}$ = 22.16 Hz, Ph_2CDOD), 76.93 (s, Ph_2CHOD). (b) The solution of catalyst complex, auxiliary base, and ketone in [D_1]methanol was prepared as before, transferred into a high-pressure NMR tube, exposed to 10 bar of H_2 at ambient conditions overnight, and then examined by ^1H NMR (ppm): δ = 4.37 (1:1:1 t, $^1J_{H,D}$ = 42.63 Hz, *H*D), 4.42 (s, H_2), 4.46 (s, OH), 5.92 (s, ≈ 0.6 H relative to 10 phenyl H, CH), 7.2−7.5 (m, 10 H, C_6H_5). (c) Experiment (b) was repeated in the absence of the base and the ketone. ^1H NMR: δ = 4.39 (1:1:1 t, $^1J_{H,D}$ = 42.63 Hz, *H*D), 4.42 (s, H_2), 4.46 (s with increasing intensity, OH).

General Procedure for H_2/D_2 Exchange Experiments: A high pressure NMR tube was charged with a solution of ≈0.01 mmol of any [(COD)Ir(P∩NHR]BF_4 complex in CD_3CN or CH_3CN. The solution was exposed to 10 bar of a 1:1 H_2/D_2 mixture and immediately analyzed by NMR spectroscopy. ^1H NMR (CD_3CN, ppm): δ = 4.37 (1:1:1 t, $^1J_{H,D}$ = 42.63 Hz, *H*D), 4.41 (s, H_2). ^2H NMR (CH_3CN, ppm): δ = 4.33 (s, D_2), 4.37 (d, $^1J_{H,D}$ = 42.5 Hz, H*D*).

Acknowledgments

We thankfully remember many fruitful and inspiring discussions with Professor Dieter Sellmann, initiator and first speaker of the Sonderforschungsbereich 583: Redox-Active Metal Complexes − Control of Reactivity via Molecular Architecture. Support of this work by the Deutsche Forschungsgemeinschaft (Bonn, SFB 583) and the Fonds der Chemischen Industrie (Frankfurt/Main) is gratefully acknowledged. We are also indebted to Mrs. S. Kammerer for her skilful assistance.

[33] In the reviewing process, an alternate mechanism based on the intermediacy of [Ir(P∩NR)] and [IrH(P∩NHR)] as spectroscopically undetected but kinetically relevant transients was proposed for isotopic scrambling and >C=O reduction: [Ir(P∩NR)] + H_2 = [IrH(P∩NHR)]; [IrH(P∩NHR] + H_2 = [IrH_3(P∩NHR)]; [IrH_3(P∩NHR)] + MeOD = [IrH_3(P∩NDR)] + MeOH; [IrH_3(P∩NDR)] = [IrH(P∩NDR)] + H_2; [IrH(P∩NDR)] = [Ir(P∩NR)] + HD etc.; [IrH_3(P∩NHR)] + R_2CO = [IrH_2(P∩NR)] + R_2CHOH. This sequence does not, however, fit the experimental evidence in that it involves IrH_3 intermediates which should be quite stable and inert but were never met in the chemistry described in this communication. Furthermore, in order to make the suggested >C=O reduction step catalytic, the resulting amido dihydrides [IrH_2(P∩NR)] must regenerate the postulated [IrH_3(P∩NHR)] amino trihydrides either by hydrogen transfer

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

from the solvent or by H_2 addition across the Ir−N bond. Again, no such chemistry was observed for amido dihydro complex **Ir-9a** reacting with MeOH under H_2 to reversibly produce $[IrH_2(P\cap NHR)]^+$ (**Ir**$^+$**-9**; Scheme 9) rather than H_2CO and/or $[IrH_3(P\cap NHR)]$.

Some Properties and Molecular Orbitals of Planar Heterodinuclear Phthalocyanines

Nagao Kobayashi*[a] and Hiroshi Ogata[a]

Keywords: Circular dichroism / Cyclic voltammetry / Phthalocyanines / UV/Vis spectroscopy

The electronic absorption and magnetic circular dichroism (MCD) spectra, and differential pulse (DP) voltammograms of planar heterodinuclear phthalocyanine (Pc) dimers consisting of Pc and pyrazinoporphyrazine (PyZ), [Mt_2PcPyZ (Mt = H_2 and Zn)] and of Pc and naphthalocyanine (Nc), [Mt_2PcNc (Mt = H_2 and Co)] have been recorded. These dimers commonly show broad absorption bands between ca. 500 and 1000 nm, while the DP voltammograms suggest that the dimers are unstable towards oxidation, and that the two relatively independent chromophore units interact with one another. Molecular orbital (MO) calculations using the ZINDO/S Hamiltonian were performed in order to enhance the interpretation of the experimental results. Dimer orbitals were expressed by coupling the orbitals of the same symmetry, of the constituting mononucleates. It was suggested that for the HOMO of the dimers, the contribution of the more electron-rich moiety is large, while conversely for the LUMO, the contribution of the more electron-deficient moiety is large. The calculations suggested that there are three prominent transitions in the Q band region of the heterodimers. The intensity and position of these bands were suggested to be affected by the constituting mononucleates.

Introduction

For three quarters of a century, mononuclear phthalocyanines (Pcs) have been the subject of an intensive study in both the academic and applied fields.[1] Cofacial sandwich type Pc dimers have been known since1936,[2] while the first planar dimer was reported in 1987.[3] Since then, many papers have been published on both cofacial Pc dimers[4] and planar homodimers of Pc and Pc derivatives.[5] However, reports on heterodinuclear planar dimers are still rare.[6] In particular, the physicochemical and electrochemical properties have not been well elucidated.[7] We report here on some spectroscopic and electrochemical properties, together with the results of molecular orbital (MO) calculations on planar heterodinuclear phthalocyanine-pyrazinoporphyrazine (Pc-PyZ) and phthalocyanine-naphthalocyanine (Pc-Nc) complexes, which were not described in our preliminary communications (Figure 1).[6a,6b,6d]

Results and Discussion

(i) Electronic Absorption and MCD Spectra

In the cases of H_4PcPyZ and H_4PcNc, there is an ambiguity as to the position of the pyrrole protons, thus it is not appropriate to compare their spectra with the results of the MO calculations. Figure 2 therefore shows the absorption and MCD spectra of PcPyZ and PcNc obtained by the addition of $(Bu)_4NOH$, and of Co_2PcNc. All compounds show broad Q bands which stretch from ca. 500 to 1000 nm, and which are not a simple superimposition from those of the constituting mononuclear *tert*-butylated Pc and PyZ or Nc. The Q bands of PcPyZ and PcNc are similar in shape, having at least two peaks, of which those at the shorter wavelength are broader. The Q bands of PcNc and Co_2PcNc appeared at almost the same wavelength, which is longer than that of PcPyZ by ca. 10 nm. The absorption coefficients of the two Q peaks of PcNc are larger than those of PcPyZ, consistent with the results of MO calculations described later.

The Q band MCD spectra of the three complexes have common characteristics. Negative Faraday *B*-terms appeared corresponding to the absorption peaks at a longer wavelength,[5m] and dispersion type, Faraday *A*-term like curves were observed, associated with the Q band peak at a shorter wavelength. In these molecules, there is no degeneracy in the excited states so that the Faraday *B*-terms are expected, theoretically, to be associated with each absorption peak. Considering that the tendency towards cofacial aggregation is much more significant for larger Ncs than Pcs,[11] that the cofacial aggregation produces a broad Q absorption band as seen at ca. 600−750 nm in Figure 2, and that the Q band MCD of cofacial Pc analogues does not reflect the molecular symmetry of the constituting molecules,[12] the dispersion type Faraday *A*-term like MCD signal corresponding to the Q absorption band at shorter wavelength may imply that the species in Figure 2 contains

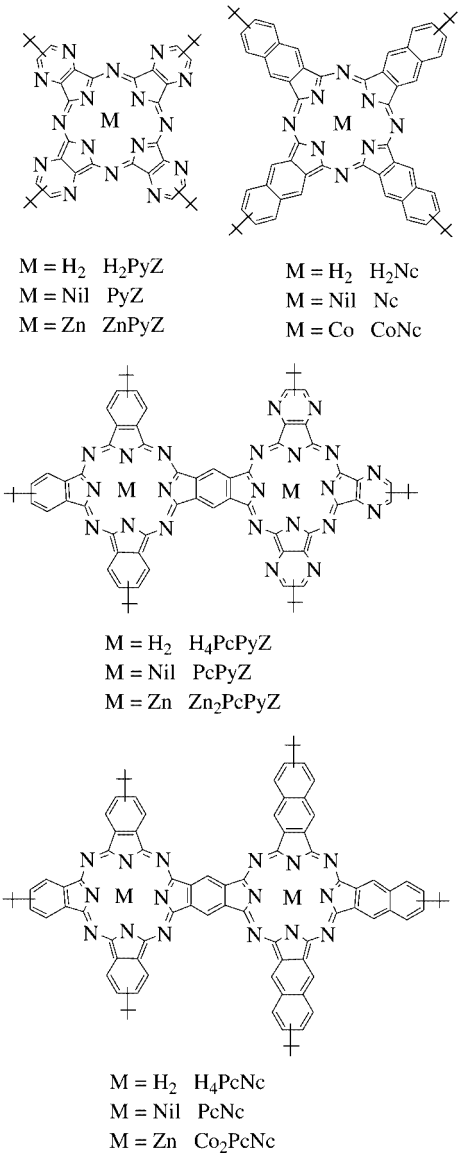

Figure 1. Structures and abbreviations of the compounds in this study

a certain amount of cofacially aggregated species. However, from our previous data[5m] in which the two Q_{00} bands of the homodinuclear planar Pc lie ca.1600−1800 cm^{-1} apart, together with the results of MO calculations on the compounds in the present study which will be discussed below, it is not unreasonable to expect the second Q_{00} band to appear at ca. 640−690 nm, since the other Q_{00} band lies at ca. 800−850 nm. Positive envelopes of the Faraday *B*-term superimposed with the pseudo Faraday *A*-terms at ca. 630−680 nm support this speculation. Another possibility for the interpretation of the dispersion type MCD curves at around 650−720 nm is that these are produced by two closely lying transitions, since MO calculations indicate two transitions in this region, differing from the case of the homodinuclear planar species [see section (iii)].

The apparent absorption coefficient of the B band of the Pc analogues is generally much smaller than that of the Q

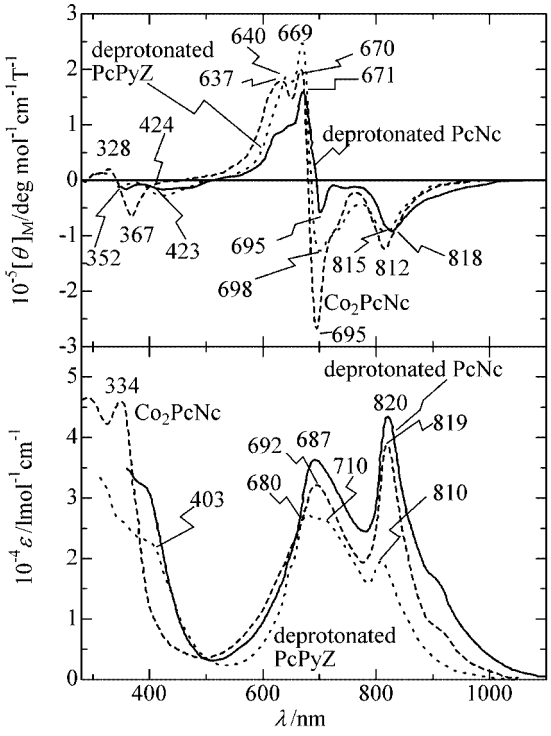

Figure 2. Electronic absorption (bottom) and MCD spectra (top) of (pyrrole proton-deprotonated) PcNc (solid lines), PcPyZ (dotted lines), and Co_2PcNc (broken lines)

band. Although we cannot directly compare the B band spectra of Zn_2PcPyZ and Co_2PcNc, since the central metal is different, the B bands of H_4PcPyZ and H_4PcNc appeared at 337 and 341 nm, and their relative intensity to the Q band is larger than in the monomeric species. When tetraammonium hydroxide was added to these metal-free species to form pyrrole-proton-deprotonated PcPyZ and PcNc, the intensity of the B band decreased and a shoulder appeared at ca. 400 nm for both compounds.

The MCD spectra show that the B band retains the characteristics of the Pc derivatives. Both H_4PcPyZ and H_4PcNc showed a dispersion type, pseudo Faraday *A*-term with a trough and peak at 372 and 320−321 nm, while their intensity was much smaller than that of the Q band, reflecting small angular momentum properties. In PcPyZ and PcNc, two weak pseudo Faraday *A*-terms appeared at around 403 and 366 nm, suggesting that many transitions are included in this region.

(ii) Voltammetry

Figure 3 shows differential pulse voltammograms of Zn_2PcPyZ, Co_2PcNc, and their constituting monomers in *o*-DCB. Unfortunately, we could not unify the type of central metal, since the compound which may be expressed as Co_2PcPyZ fragmented into the PyZ moiety in the cobalt insertion process, while the compound which is described as Zn_2PcNc fragmented during purification by column chromatography. The tetra-*tert*-butylated ZnPc showed two oxidation and reduction couples at 1.01, 0.21, −1.41, and −1.81 V, while ZnPyZ displayed the first oxidation poten-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

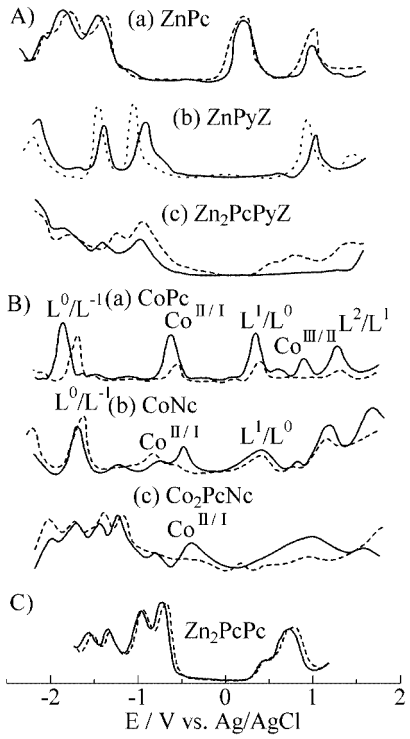

Figure 3. Differential pulse voltammograms of A) (a) ZnPc, (b) ZnPyZ, and (c) Zn_2PcPyZ, B) (a) CoPc, (b) CoNc, and (c) Co_2PcNc, and C) Zn_2PcPc (redrawn from ref.[5f]) in *o*-DCB containing 0.1 M TBAP. The sweep rate was 0.5 mV/s. The solid and broken lines are anodic and cathodic scans, respectively. L^0/L^{-1} and L^1/L^0 are the first reduction and oxidation of the ligand, respectively

tial at 1.03 V and three reduction couples at −0.97, −1.38, and −2.14 V due to the four electron-withdrawing pyrazine rings on the periphery. Zn_2PcPyZ, on the other hand, showed couples at ca. 1.36, 0.76, 0.50, −0.96, −1.34, −1.82, and ca. −2.2 V. Although the voltammograms are not clear, because of the instability of the compound in the positive potential region of the anodic scan, some of the other behavior (amount of current and splitting pattern) is similar to that of homodinuclear planar Pc dimers (voltammograms in C).[5f] That is, it appears as if the couples at 0.76 and 0.50 V correspond to the first oxidation, while those at −0.96 and −1.34, and −1.82 and −2.2 V correspond, respectively, to the first and second reductions of mononuclear species, suggesting that the voltammograms of Zn_2PcPyZ are caused by the interacting dipoles in the Pc and PyZ moieties.

The voltammograms of cobalt Pc derivatives differ from those of, for example, zinc, nickel, and copper derivatives in that they show couples due to the central metal, in addition to those of the ligand. On the basis of previous studies on cobalt Pcs,[13] the redox couples of *tert*-butylated CoPc and CoNc in this figure can be assigned as shown in the voltammograms. The voltammogram of Co_2PcNc is not as clear as that of the mononuclear species because of its low stability and small diffusion coefficient. However, four ligand redox couples characteristic of these types of compounds are explicitly seen at −1.22, −1.43, −1.73, and ca. −2.0 V, in addition to the $Co^{II/I}$ couple(s) which appeared at −0.36 (and −0.80) V, although the positive potential region is more irreversible and more ill-defined. Thus, the four ligand reduction redox couples strongly suggest that the dipoles in the CoPc and CoNc moieties are interacting without significant conjugation through the common benzene ring.

(iii) Molecular Orbital Calculations

In order to enhance our interpretation of the above spectroscopic and electrochemical properties, molecular orbitals (MOs) were calculated using the ZINDO/S Hamiltonian in the HyperChem. R5.1 program,[8] together with those of the constituting mononuclear molecules. The calculated electronic absorption spectra are shown in Figure 4 (all spectra were calculated for the zinc complexes, since Co^{II} in Pc, Nc, and PyZ is paramagnetic), with transition energies, oscillator strengths (*f*), and configurations summarized in Table 1. As detailed in previous publications,[14] in a one-electron description, the Q band of Pc analogues corresponds to a transition from the HOMO to the doubly degenerate LUMO. The B band is associated mainly with a transition from the HOMO-1 to the LUMO at the PPP level of calculations, while this is not clear at the ZINDO/S level of calculation since the B band is actually composed of two bands termed B1 and B2, and there is mixing of many configurations.[14f] For ZnPyZ and ZnPc, the present ZINDO/S calculations indicate the HOMO−LUMO transition and two prominent transitions in the B band region to be at 688 and 307/300 nm, and 699 and 292/278 nm, respectively, which is in approximate agreement with the experimental result (341 and 628 nm for ZnPyZ, and 349 and 671 nm for ZnPc in THF).[6a] This demonstrates the reliability of the calculations. As shown, in the case of mononuclear molecules, the Q band shifts to a longer wavelength in the order ZnPyZ, ZnPc, and ZnNc, with a con-

[a] Excited states with energy less than ca. 3.9 eV and *f* greater than 0.10 are shown.

comitant increase in the absorption coefficient, as has been substantiated by experiments[15] and reproduced by MO calculations[16] using the PPP method.[17] The purity of the Q band also increases in this order, since the configurations of the HOMO−LUMO transition increases.

Turning to the heterodinuclear Pc analogues in this study, the pair of orbitals comprising the lowest unoccupied level in a mononuclear unit split into two levels (Figure 5), so that two split Q bands are calculated at a longer wavelength: 898 and 725 for Zn_2PcPyZ and 964 and 755 nm for Zn_2PcNc (under the same conditions, the Q bands of the homodinuclear Zn_2PcPc were predicted at 931 and 726 nm). The calculated values lie in the correct direction, but fall towards somewhat longer wavelengths compared with the experimental values. In addition, the values indicate that the Q band position depends on that of the constituting units of the dimer. That is, the two Q bands estimated for Zn_2PcPyZ (898 and 725 nm) are at shorter wavelengths than those of Zn_2PcPc (931 and 726 nm), while those of Zn_2PcNc (964 and 755 nm) are calculated at even longer wavelengths. This, however, does not necessarily hold for the Q band intensity. The *f* values for the two Q bands for Zn_2PcPyZ, Zn_2PcPc, and Zn_2PcNc are 2.19 and 0.78, 2.37 and 1.62, and 2.25 and 1.02, respectively (the Q bands at longer wavelengths are always more intense), suggesting that the Q band of the homodimer may be stronger than that of the heterodimers. The values also suggest that in the heterodimers, the Q band of the dimers having larger π conjugation systems may be stronger. As shown by the configurations in Table 1, the calculations predict that for all the planar binucleates, in the one-electron description, the Q band to lower energy corresponds to a transition from the HOMO to LUMO, while that to higher energy is mainly associated with a transition from the HOMO to the LUMO+1. Of these, concerning configurations of the longer wavelength Q band, the contributions of the HOMO−LUMO transition for Zn_2PcPyZ, Zn_2PcPc, and Zn_2PcNc are 88, 89, and 77%, respectively, as for the above *f* values, suggesting that the contribution does not vary systematically with the structure of the constituting units.

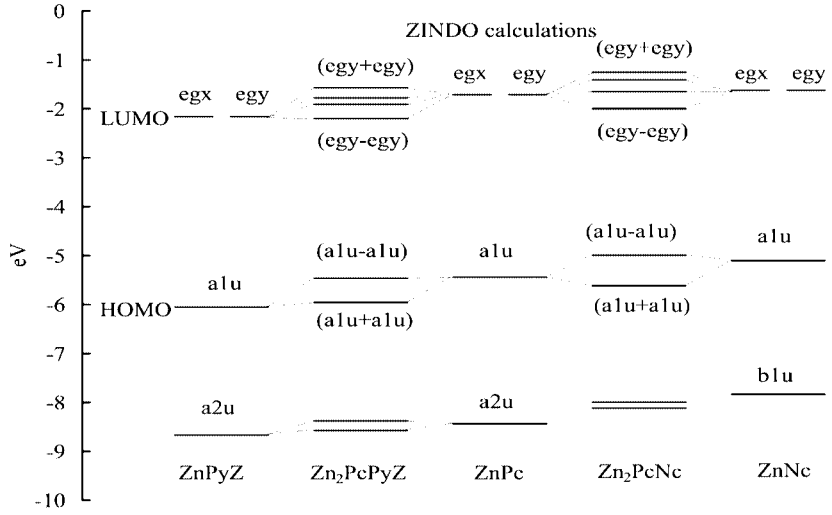

Figure 5. Partial molecular orbital energy diagram for Zn_2PcPyZ and Zn_2PcNc, and for ZnPyZ, ZnPc, and ZnNc, and their mutual relationships. The parentheses near each MO of the dimers indicate the expression of MO by the notation in D_{4h} symmetry, which is used for ZnPyZ, ZnPc, and ZnNc

From the configurational values for the HOMO to LUMO transition (Table 1), the purity of the transition at the longest wavelength of the dimers is similar to that of constituting monomers (88, 87, and 95% for ZnPyZ, ZnPc, and ZnNc, respectively) except for Zn_2PcNc.

Another notable point for the heterodimer spectra is the presence of a third transition lying closely in energy to the second transition (701 nm for Zn_2PcPyZ and 744 nm for Zn_2PcNc). This fairly intense band is ascribed mainly to the HOMO to LUMO+2 transition. It is possible, therefore, to consider that because of this transition, the experimental Q band at a shorter wavelength is much broader than that at a longer wavelength, since two closely lying transitions can produce a broad band due to superimposition. If this is the case, the dispersion type MCD associated with the second Q absorption peak can be considered to be produced by closely lying Faraday *B*-terms of opposite signs.

MO numbers 93, 171, 93, 198, and 129 are the HOMOs for ZnPyZ, Zn_2PcPyZ, ZnPc, Zn_2PcNc, and ZnNc, respectively. The data for the homodinuclear Zn_2PcPc are also shown for comparative purposes.

In the B band region, the calculated data of the constituting compounds are not complicated, particularly for ZnPyZ, although those of ZnNc are more complex because of the involvement of the transitions localized in the naphthalene ring. In contrast, the B band region of the dimers is very complex. The most intense region was predicted at 311 (f = 1.27) and 304 nm (f = 1.20) for Zn_2PcPyZ and 313 (f = 0.97) and 297 nm (f = 0.83) for Zn_2PcNc, implying that the more intense B band region of the two compounds would appear at a similar wavelength, if the two compounds could be prepared (we could not obtain Zn_2PcNc, since it fragmented during column chromatography).

Figure 5 shows how the four frontier orbitals in mononuclear constituting molecules split in the heterodimers. This figure indicates that two monomer orbitals having the same symmetry residing in different constituting units couple and produce two dimer orbitals, and that the extent of the splitting is larger for orbitals having a larger coefficient along the axis connecting the two constituting units (for the shape of orbitals, see Figure 6). That is, of the a_{1u} and a_{2u} orbitals, a_{1u} is larger, while of the e_{gx} and e_{gy} orbitals, the latter is larger. Furthermore, comparison of the orbital energies of the constituting monomers and the resulting dimers suggests that for the HOMO of the dimers the contribution of an electron-richer moiety is larger, while for the LUMO of the dimers the contribution of a more electron-deficient moiety is large. Indeed, if we compare the energy difference between the HOMO of Zn_2PcPyZ and those of ZnPc and ZnPyZ, the difference between Zn_2PcPyZ and ZnPc is much smaller than that between Zn_2PcPyZ and ZnPyZ. Similarly, the energy difference between the HOMO of Zn_2PcNc and ZnNc is much smaller than that between Zn_2PcNc and ZnPc. Accordingly, we can conclude that for the HOMO of Zn_2PcPyZ, the contribution of the Pc moiety is more significant than that of the PyZ moiety. In a similar manner, for the HOMO of Zn_2PcNc, the contribution of the Nc moiety is larger than that of the Pc moiety. In the case of the LUMO, the inverse relationship is observed for the energy difference between the LUMO of constituting monomers and the resultant dimers. Thus, the contribution of the PyZ moiety appears larger than that of the Pc moiety for the LUMO of Zn_2PcPyZ.

We can correlate the experimental redox potentials (Figure 3) with the calculated MO energies from Figure 5. Since relatively clear voltammetric curves were obtained in the negative potential region for all of the compounds, the reduction potentials of the two monomers and the resulting dimer complex can be discussed and compared with data in Figure 5. The first reduction in ZnPc and ZnPyZ corresponds to an addition of an electron to the e_g LUMO. A more negative potential (−1.41 V) is obtained for ZnPc

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

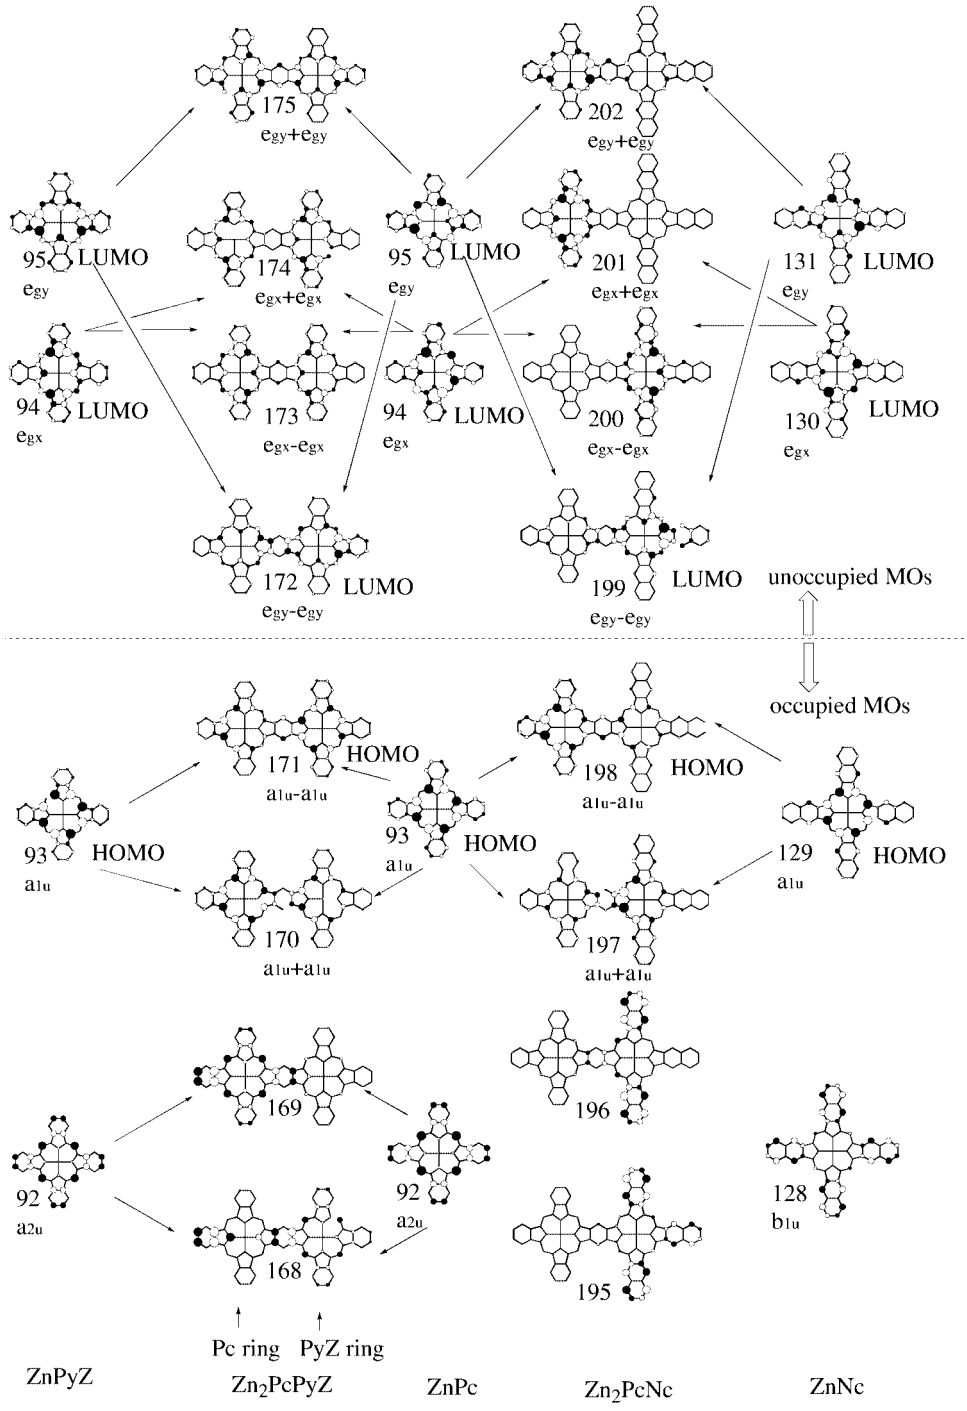

Figure 6. Eight frontier orbitals of Zn_2PcPyZ and Zn_2PcNc and four frontier orbitals of ZnPyZ, ZnPc, and ZnNc. The parentheses under each MO of the dimers indicate the expression of MO by the notation in D_{4h} symmetry, which is used for ZnPyZ, ZnPc, and ZnNc

than (−0.97 V) for ZnPyZ (Figure 3), as a result of the lower electron-density of ZnPyZ due to the electron-withdrawing property of the four peripheral pyrazine rings. Since the e_g orbital of ZnPc sits at a higher energy than that of ZnPyZ (Figure 5), the reduction of ZnPc is expected to require a higher potential. When ZnPc and ZnPyZ are laterally fused to form Zn_2PcPyZ, the calculated LUMO energy is very similar to that of ZnPyZ (Figure 5). As expected, the first reduction potentials of ZnPyZ and Zn_2PcPyZ are found to be very close [Figure 3, curves (b) and (c)]. The calculated LUMO energies of ZnPc and ZnNc are almost identical. The first reduction potentials of these compounds are therefore expected to be very similar. The LUMO energy of the resulting Zn_2PcNc dimer drops substantially, relative to that of ZnPc. As a result, the first reduction step for the Mt_2PcNc dimer occurs at a less negative potential than that of the corresponding MtPc or MtNc monomers. This feature is observed experimentally in the voltammograms of cobalt complexes in Figure 3 (curves in B). There is therefore clearly a close agreement

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

between the calculated LUMO energies and the experimental reduction potentials. The HOMO energies and the oxidation potentials could not be compared in a similar manner, however, since the voltammograms are ill-defined in the positive potential region.

Figure 6 displays the four frontier orbitals of each mononuclear molecule and eight frontier orbitals of the resulting heterodimers. This figure clearly shows that the dimer orbitals are composed of the monomer orbitals with the same symmetry, since the dimer orbitals can be expressed as linear combinations of monomer orbitals of the same symmetry (see the notation below each MO). In addition, supporting the conclusions in Figure 5, for the HOMO of the dimer, the coefficient of the electron-richer moiety is large (i.e. in Zn_2PcPyZ, the coefficients in the Pc moiety are larger than those in the PyZ moiety, and similarly in Zn_2PcNc the coefficients in Nc are larger than those in the Pc moiety). Conversely, in the case of the LUMO, the coefficients in the more electron-deficient moiety is large (the PyZ moiety in Zn_2PcPyZ, and the Pc moiety in Zn_2PcNc).

Conclusion

The electronic absorption and magnetic circular dichroism (MCD) spectra, and differential pulse (DP) voltammograms of planar heterodinuclear phthalocyanine (Pc) dimers consisting of Pc and pyrazinoporphyrazine (PyZ) [Mt_2PcPyZ (Mt = H_2 and Zn)] and Pc and naphthalocyanine (Nc) [Mt_2PcNc (Mt = H_2 and Co)] have been recorded, and their properties interpreted by MO calculations using the ZINDO/S Hamiltonian. These dimers commonly show broad absorption bands between ca. 500 and 1000 nm, while the DP voltammograms suggest that the dimers are unstable to oxidation, and that, in these compounds, two relatively independent chromophore units interact. Dimer orbitals were found to be expressed by linear combinations of the orbitals of the constituting mononuclear orbitals of the same symmetry. It was suggested that for the HOMO of the dimers, the contribution of the electron-richer moiety is large, while, conversely, for the LUMO the contribution of the more electron-deficient moiety is large. The heterodimers showed two intense Q bands experimentally. Our calculations suggested that the position and intensity of these bands were affected by those of the constituting mononucleates. That is, PcPyZ dimers have a split Q band at shorter wavelengths than those of PcNc dimers. Of the two heterodimers, the Q band intensity of the PcNc dimer, i.e. the dimer consisting of larger π conjugation systems, appears larger than that of the PcPyZ dimer, since the calculated Q band of PyZ appears at a shorter wavelength and is weaker than that of Nc.

Experimental Section

(i) Measurements: Mass spectra were obtained with a JEOL JMS-HX110 mass spectrometer using *m*-nitrobenzyl alcohol (NBA) as a matrix (FAB mass). Electronic absorption spectra were recorded with a Hitachi U-3410 spectrophotometer using THF as a solvent. Magnetic circular dichroism (MCD) measurements were made with a JASCO J-725 spectrophotometer equipped with a JASCO electromagnet that produces magnetic fields of up to 1.09 T. Its magnitude was expressed in terms of molar ellipticity per tesla, $[\theta]_M$ (in $deg \cdot mol^{-1} \cdot dm^3 \cdot cm^{-1} \cdot T^{-1}$). The 400 MHz ^{1}H NMR spectral measurements were made with a JEOL-GSX-400 instrument. IR spectra were run on a Shimadzu FTIR-8100M spectrometer using KBr discs. Differential pulse voltammetry (DPV) experiments were carried out with conventional three-electrode cells, in which a platinum wire auxiliary electrode, a glassy carbon working electrode (0.07 cm^2), and an Ag/AgCl wire reference electrode were employed. The solvent for the electrochemical measurements, *o*-dichlorobenzene (*o*-DCB, Nacalai Tesque, specially prepared for HPLC) was used as supplied. Tetrabutylammonium perchlorate (TBAP) was used as an electrolyte. All electrochemical work was carried out under an atmosphere of dry nitrogen. DPV data were recorded with a Yanaco P-1100 polarographic analyzer connected to a Watanabe WX 4401 *XY* recorder.

(ii) Computational Method: MO calculations were performed using HyperChem. software[8] within the ZINDO/S level, in which the overlap weighting factors for σ-σ and π-π were 1.267 and 0.585, respectively. For the configuration interaction (CI) calculations, all singly excited configurations of up to 8 eV were included.

(iii) Materials: Deprotonation of the pyrrole proton in dinuclear metal-free species was affected by adding a small amount of tetra-*n*-butylammonium hydroxide. Tetra-*tert*-butylphthalocyaninatocobalt, CoPc, and tetra-*tert*-butylnaphthalocyaninatocobalt, CoNc, were used as in our previous paper.[9]

Tetra-*tert*-butylpyrazinoporphyrazinatozinc (ZnPyZ): This compound was obtained by zinc insertion using $Zn(OAc)_2$ to metal-free tetra-*tert*-butylpyrazinoporphyrazine[10] in EtOH/1,2-dichloroethane (1:1 v/v), and purified using a basic alumina column and CH_2Cl_2/MeOH as eluent in 71% yield. ^{1}H NMR (400 MHz, $CDCl_3$, TMS, ppm): δ = 9.87−9.67 (s, 4 H, Ar-H), 2.13−1.93 (m, 36 H, *t*Bu). $C_{40}H_{40}N_{16}Zn \cdot 3H_2O$: calcd. C 55.59, H 5.36, N 25.93; found C 55.02, H 5.56, N 25.27.

Tetra-*tert*-butylphthalocyaninatozinc (ZnPc): This compound was also obtained by zinc insertion to metal-free tetra-*tert*-butylphthalocyanine[6b] in EtOH/1,2-dichloroethane (1:1 v/v) in the dark for 15 h, and subsequent purification using a basic alumina and CH_2Cl_2. $C_{48}H_{48}N_8Zn$: calcd. C 71.85, H 6.03, N 13.97; found C 71.23, H 6.50, N 13.34.

Hexa-*tert*-butylphthalocyaninylpyrazinoporphyrazinatodizinc (Zn_2PcPyZ): A mixture of metal-free hexa-*tert*-butylphthalocyaninylpyrazinoporphyrazine,[6a] H_4PcPyZ (5.0 mg, 0.0039 mmol) and $Zn(OAc)_2$ (17 mg, 0.077 mmol) were refluxed in 1,2-dichloroethane/ EtOH (1:1 v/v) in the dark for 15 h, and after evaporating the solvent, the residue was chromatographed over a basic alumina column using a mixture of CH_2Cl_2 and MeOH, to give 5.0 mg (90% yield) of the desired dizinc complex, Zn_2PcPyZ as a blue powder. ^{1}H NMR (400 MHz, $CDCl_3$, TMS, ppm): δ = 9.5−7.0 (br, 14 H, Ar-H), 2.1−1.7 (m, 54 H, *t*Bu). MS (FAB, NBA): *m*/*z*: 1419 [M]. $C_{76}H_{68}N_{22}Zn_2 \cdot 2H_2O$: calcd. C 62.68, H 4.98, N 21.16; found C 62.35, H 5.41, N 20.77.

Hexa-*tert*-butylphthalocyaninylnaphthalocyaninatodicobalt (Co_2PcNc): A mixture of metal-free hexa-*tert*-butylphthalocyaninylnaphthalocyanine[6b] (4.0 mg, 0.0028 mmol) and $CoCl_2$ (7.2 mg, 0.056 mmol) was refluxed in DMF (2.0 mL) for 30 min. After evap-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

oration of the solvent, the residue was purified using a basic alumina column and CH_2Cl_2/MeOH as eluent, to give 3.8 mg (87.5% yield) of the desired Co_2PcNc as a blue powder. MS (FAB, NBA): *m/z*: 1550 [M]. $C_{94}H_{80}Co_2N_{16}{\cdot}H_2O$: calcd. C 71.93, H 5.27, N 14.28; found C 71.29, H 5.46, N 13.80.

Multiproperty Molecular Materials: TTF-Based Conducting and Magnetic Molecular Materials

Lahcène Ouahab*[a] and Toshiaki Enoki[b]

Keywords: Conducting materials / Magnetic properties / Through-space interactions / Through-bond interactions

The chemistry and physics of molecule-based materials are exciting subjects, and due to potential applications this area is being extensively investigated. Considerable effort is currently being made to design and to investigate new materials involving interplay or synergy between multiple physical properties. This microreview examines materials combining magnetism and electrical properties. Some fundamental background material is covered, together with a discussion of constraints on the design of molecular materials with these physical properties. Some examples from the literature are then related, in order to illustrate the achievements in this area.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

1. Introduction

Considerable effort is currently devoted to the synthesis and investigation of new molecule-based materials involving interplay and synergy between multiple physical properties.[1] The construction of molecule-based materials which possess two or more such properties is currently a challenging target. Optical properties in particular are of current interest (especially with respect to natural optical activity), but other combinations of properties have also been targeted both for their fundamental scientific interest and for their potential applications. These kinds of combinations of properties lead either to competition, coexistence, or cooperativity between the desired properties; the latter is much more difficult to achieve than the other two. It should be noted that the construction and control of the self-assembly of the molecular building blocks (so that the resulting supramolecular compound has the desired structure, stability and physical properties) is still a major challenge for synthetic chemists working in this area. Nevertheless, some significant achievements have been obtained, namely:
(i) *Light-induced magnetization*.[2] Direct applications of this technology would be photo-induced magnetic memory devices based on the choice of the laser wavelength. As an

Lahcène Ouahab was born in 1953 in Setif Algeria, and received his Ph.D. from the University of Rennes 1 in 1985. He was Maître de Conférences at the University of Constantine (Algeria) and then associate Professor at the University of Rennes 1 before getting a permanent position in CNRS as "Chargé de Recherche". He is presently a CNRS Director of Research and leads the molecular materials research group. He is the director of the Laboratoire de Chimie du Solide et Inorganique Moléculaire at the Institut de Chimie (Université de Rennes 1). He was awarded the 1998 prize of the Coordination Chemistry Division of the French Chemical Society. His fields of research include molecular materials, and in particular, multifunctional materials, charge transfer complexes, radical ion salts, organic-inorganic hybrids, polymeric coordination complexes and polyoxometalates.

Toshiaki Enoki was born in 1946, and received his Ph.D. in 1974 from Kyoto University, Japan, under the supervision of Prof. Ikuji Tsujikawa. In 1987, he was appointed to the position of Associate Professor in the Department of Chemistry at Tokyo Institute of Technology, and is now a full Professor. His research interests include physical chemistry, especially molecular magnetism. He has been investigating molecular magnets on the basis of organic charge transfer complexes and carbon nano-materials. His pioneering work has contributed to the opening of the field of TTF-based molecular conducting magnets. He has also been leading work on magnetism in nanographites, which have recently been recognized as important spintronics materials.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

example, some very interesting systems have been obtained by Hashimoto and co-workers, for example, a derivative of Prussian blue, namely the cobalt iron cyanide formulated as $K_{0.2}Co_{1.4}[Fe(CN)_6]6.9H_2O$,[2d,2e] which was found to exhibit photo-induced reversible magnetization. The critical temperature increases from 16 to 19 K under illumination with red light, as a result of oxidation state changes for the metal ions [Co^{III} ($S = 0$) and Fe^{II} ($S = 0$) to Co^{II} ($S = 3/2$) and Fe^{III} ($S = 1/2$)].

(ii) *Synergy between spin-crossover and magnetic interactions.*[3] To the best of our knowledge, $Fe(mnt)_2$-rad [or 2-(*para*-*N*-methylpyridinium)-4,4,5,5- tetramethylimidazoline-1-oxyl iron(III) bis(maleonitrile dithiolate)] is the only compound in which evidence has been found for synergy between the spin cross-over effect and intersite magnetic interactions. It was found the $[Fe(mnt)_2]^-$ moiety exhibits a spin cross-over between $S_{Fe} = 3/2$ at high temperature and $S_{Fe} = 1/2$ at low temperature. At the same time, an antiferromagnetic (AF) interaction operates between the spin of the $[rad]^+$ unit ($S = 1/2$) and the spin of the iron atom ($S_{Fe} = 1/2$) at low temperatures, giving rise to a singlet ground state.

(iii) *Electrical conductivity and magnetic interactions.*[4−13] Conducting materials incorporating localized spins are currently a subject of intense investigation. Numerous research groups are involved in this area, and many compounds of this kind have been isolated and characterized. Some important results obtained are the coexistence of paramagnetism and superconductivity,[5a,12] antiferromagnetism and superconductivity,[5c] ferromagnetism and metallic conductivity[5d] and also field-induced ferromagnetism and superconductivity.[12b,12c]

In this microreview, we focus on materials combining magnetic interactions and electrical properties.

2. Background to the Physics of π-d Interactions

Transition metals such as iron are widely known strong ferromagnetic materials. In such metal ferromagnets, the unpaired d-electrons, which stay in the inner shell, behave as localized electrons having magnetic moments, whereas the s- and p-electrons move freely in the crystal, acting as carriers of electrical charge. Thus, the d-electrons in the free electron jellium interact with the charge carriers through an s-d interaction, expressed by the following equation (when a conduction s-electron approaches a d-electron site):

$$2J_{s\text{-}d}\delta(r)\boldsymbol{sS} \quad (1)$$

where s and S are the spin operators for a conduction electron and a localized d-electron, respectively, $\delta(r)$ the delta function, and $J_{s\text{-}d}$ is the coupling constant for the exchange interaction between a conduction s-electron and a localized d-electron, and r is the distance between the conduction electron and the localized d-electron.

The interaction expressed by Equation (1) is termed the s-d interaction. In a crystal where the s-d interaction operates, the conduction carriers mediate the interaction between the magnetic moments of the localized d-electrons. Consequently, the mediation of conduction carriers results in a long-range interaction between localized magnetic moments of the d-electrons, expressed by Equation (2):

$$\frac{3N}{16\pi^2}\frac{J_{s-d}^2}{E_F}I(\boldsymbol{R}_{ij})S_{iz}S_{jz} \quad (2)$$

where R_{ij} is the distance between d-electrons having the z-components of spins S_{iz} at site i and S_{jz} at site j, E_F is the Fermi energy and $I(R_{ij})$ is the decaying function of R_{ij}, with a spatially oscillatory behavior which depends on the Fermi wave number k_F, as given by Equation (3):

$$I(\boldsymbol{R}_{ij}) = \frac{16\pi k_F^3}{(2k_F\boldsymbol{R}_{ij})^4}\left(2k_F\boldsymbol{R}_{ij}\cos 2k_F\boldsymbol{R}_{ij} - \sin 2k_F\boldsymbol{R}_{ij}\right) \quad (3)$$

The exchange interaction between localized magnetic moments in a metallic medium, described in Equation (2), is called the Rudermann−Kittel−Kasuya−Yoshida (RKKY) interaction, which is the origin of strong ferromagnetism in transition metals such as iron.

The RKKY interaction has strategic importance for the development of organic systems with magnetic interactions similar to the s-d interaction, and for the preparation of molecular versions of metal magnets. This could give new insights into phenomena related to the interplay between conduction carriers and localized magnetic moments.

Recently, a large variety of ''organic metal'' complexes and superconductors, modeled on organic charge-transfer complexes,[14] have been developed and their interesting novel properties uncovered. In such organic conductors, the constituent donor/acceptor molecules are planar, so that their π-electron orbitals (which protrude perpendicular to the molecular plane) overlap with each other, giving the π-electrons a small kinetic energy (transfer integral) in the 0.1−1 eV range. Therefore, these π-electrons play a role in the electron transport process, in contrast to conventional metals, in which the s- and p-electrons have a kinetic energy of several eV. In other words, organic conductors can be described as highly correlated electron systems, in which the kinetic energy of the π-electrons is smaller than or similar to the on-site Coulomb interaction. Moreover, one of the important features specific to organic complex crystals, associated with molecular stacking, is the one- or two-dimensionality of their lattices. As a consequence, organic conductors have electronic instabilities, resulting in the appearance of insulating states at low temperatures, such as charge density wave (CDW) and spin density wave states (SDW).[14]

The π-d interaction, which is the organic version of the s-d and s-f interactions, results from the introduction of d-electrons into organic conductors. It can be considered to possess a different nature from the s-d interaction, judging from the specific electronic and structural features men-

tioned above. Here, we present a brief perspective on the magnetism emerging in π-d interaction systems, shown in Figure 1. In this regard, typical π-d based metal magnets appear in the regime where both the transfer integral and the π-d interaction $J_{\pi\text{-}d}$ govern the characteristics of the electronic structures. In the insulating regime, superexchange-mediated π-d composites are expected to provide ferrimagnets, weak ferromagnets or helical magnets, whereas metallic π-d systems only become organic magnetic superconductors if the π-d interaction is not strong enough to bring about pair-breaking against the superconducting state.

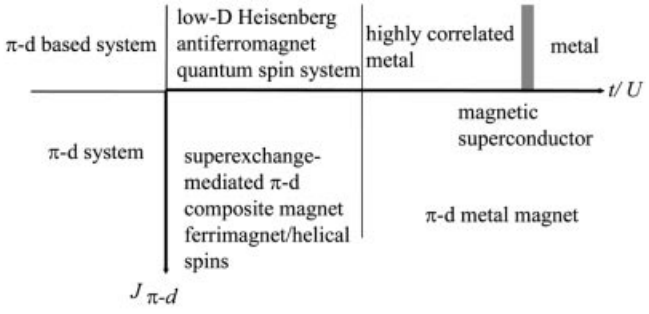

Figure 1. Overview of magnetism appearing in organic charge transfer complexes, depending on t, U and $J_{\pi\text{-d}}$

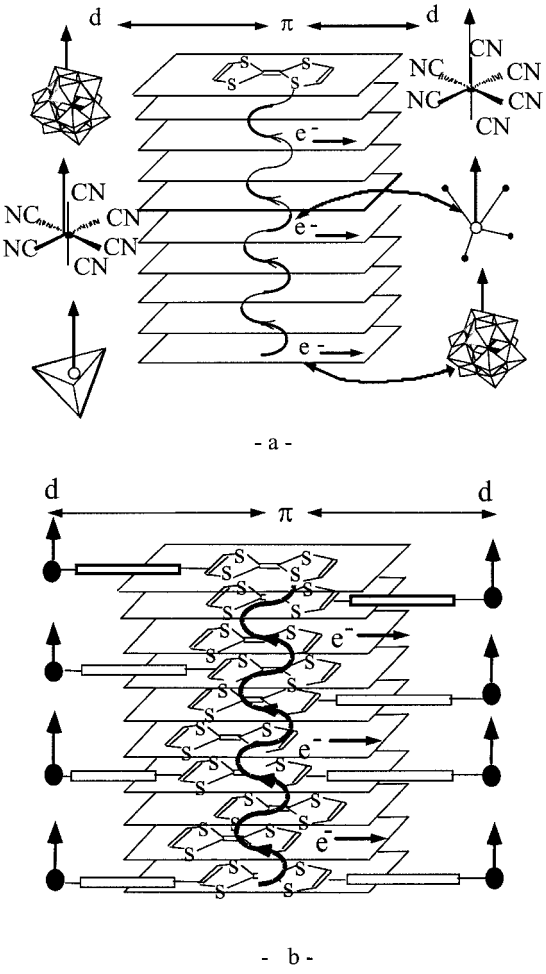
From the perspective of materials design, the π-d system model is based on the synergy between electrical conductivity and magnetic interactions. In this regard, a combination of TTF-based organic donors and magnetic anions having d-electrons could give rise to an interesting family of materials, classified as organic-inorganic hybrids, in which the spins are localized on the transition metals (d-electrons). In these materials, an interesting interplay between electron transport and magnetism could be produced by a long-range magnetic coupling between localized spins through the mobile π-electrons of the conducting networks (Scheme 1).

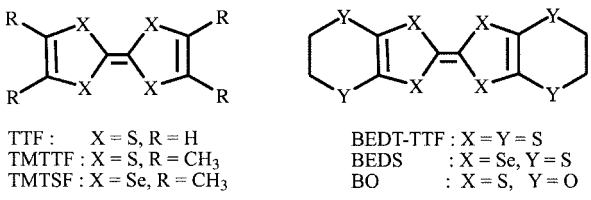
An alternative way of designing a molecule-based magnetic material would be to construct an organic compound in which the localized spins are borne by an organic radical.[11]

3. Conducting and Magnetic Materials

Conducting organic materials incorporating localized spin first appeared in the early 1980s.[4] In particular, (TMTSF)$FeCl_4$ and (TMTTF)$FeCl_4$ [4b] were the first compounds in which it was claimed that the weak antiferromagnetic interactions observed between the localized spins were mediated by the organic system. Since then, many compounds have been synthesized and characterized, but most of these materials show one of the following unfavorable situations between the two properties: (i) Stabilization of the superconducting state with paramagnetic anions, as in (BEDT-TTF)$_4$[$(H_2O)Fe(C_2O_4)_3$]C_6H_5CN (T_c = 8.5 K)[5a] and (BETS)$_2$($FeCl_4$)$_{0.5}$-($GaCl_4$)$_{0.5}$ (T_c = 4.6 K)[12] [BETS = bis(ethylene dithiotetraselenafulvalene)], (ii) Coexistence of two completely independent metallic and ferromagnetic sublattices, as in the recently-reported metal ferromagnets (BEDT-TTF)$_3$[$MnCr(C_2O_4)_3$][5d] and (BO)$_3$[$FeCr(C_2O_4)_3$],[5e] (iii) The presence of magnetic interactions not mediated by the conducting electrons, as found in some insulating salts of TTF derivatives containing $[Cr(NCS)_4(phen)]^-$,[8a] (phen = 1,10-phenanthroline). However, the following interesting examples are worthy of note.



Scheme 1. Representation of the indirect exchange mechanism; (a) through space interaction, (b) through bridge interaction



Scheme 2. Some typical organic donors; TTF = tetrathiafulvalene; TMTTF = tetramethyl-TTF; TMTSF = tetramethyltetraselenafulvalene; BEDT-TTF = bis(ethylenedithio)-TTF; BEDS = bis(ethylenedithio)tetraselenafulvalene; BO = bis(ethylenedioxo)-TTF

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3.1. $(BEDT\text{-}TTF)_3(CuCl_4)H_2O$

This compound was the first BEDT-TTF stable organic metal with a paramagnetic anion;[5f] it is metallic down to very low temperatures (200 mK). No superconductivity was observed under pressure (up to 12 kbar) at temperatures down to 2 K. The product of the susceptibility and the temperature ($\chi_M T$), obtained from ESR measurements, shows a gradual increase at low temperature, indicating short-range ferromagnetic interactions between the Cu^{II} atoms. The Cu···Cu distance was found to be greater than 8.5 Å, resulting in insignificant exchange interactions. A more probable explanation for this behavior is the possibility of indirect exchange through the free electrons of the conducting layer.

3.2. $(BETS)_2(MCl_4)$ ($M = Fe^{III}$, Ga^{III})

A series of BETS conductors with MX_4^- anions [$M = Fe^{III}$ ($S = 5/2$) and Ga^{III} ($S = 0$)] have been reported by Kobayashi et al.[12] These compounds [formulated as $(BETS)_2(MCl_4)$] revealed a rich polymorphism and some interesting properties, including superconductivity in the alloy $(BETS)_2(Fe_{0.5}Ga_{0.5}Cl_4)$. The compounds λ-$(BETS)_2(Fe^{III}Cl_4)$, containing a paramagnetic anion with $S = 5/2$, and its isomorphous salt λ-$(BETS)_2(Ga^{III}Cl_4)$, containing a diamagnetic anion are worthy of discussion. The crystal structures of these two compounds are identical, but their electrical conductivities are very different. Both salts are metallic between 300 K and 8 K, and have almost identical conductivities. But below 8 K, the Ga^{III}-containing salt has a superconducting transition, whereas the Fe^{III}-containing salt has a metal to insulator (MI) transition. It appears that the presence of paramagnetic species strongly influences the electrical conductivity in the donor layers. In agreement with this hypothesis, it was possible to restore the metallic state below 8 K at high magnetic fields.[12b,12c]

3.3 $(DMET)_2FeBr_4$ and $(EDTDM)_2FeBr_4$

These two compounds are isostructural.[15] They consist of alternately stacked donor conducting layers and square-lattice magnetic layers of Fe^{3+} with localized spins ($S = 5/2$). In each donor sheet, donor molecules form 1D chains subjected to weak inter-chain interactions, giving 3/4-filled quasi-1D π-electronic systems. The resistivity shows metallic features down to temperatures of about 40 K and 15 K for $(DMET)_2FeBr_4$ and $(EDTDM)_2FeBr_4$, respectively, below which the insulating SDW emerges. The magnetism is governed mainly by the Fe^{3+} ($S = 5/2$) localized spins. In $(DMET)_2FeBr_4$ and $(EDTDM)_2FeBr_4$, Fe^{3+} spins undergo 3D antiferromagnetic (AF) ordering at $T_N = 3.7$ and 3 K, respectively.

The magnetization curves are anomalous, as shown for $(DMET)_2FeBr_4$ in Figure 2 (a). Application of the external field along the spin-easy axis gives a spin-flop transition when B_{SF} is approximately 2 T. In addition, an anomaly appears around $B_2 \approx 5$ T in the hard axis direction. This feature cannot be explained only by Fe^{3+} spins, suggesting that donor electrons participate in the magnetization.

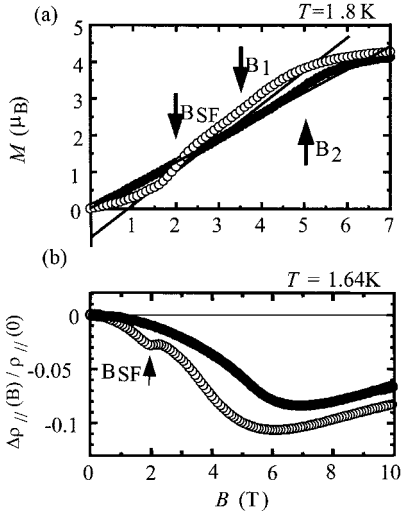


Figure 2. Field dependence of the magnetization; (a) and the in-plane magnetoresistance; (b) for $(DMET)_2FeBr_4$; open and closed circles denote the data for the field applied along the spin-easy and spin-hard axes, respectively; B_{SF} is the field of the spin-flop transition; B_1 and B_2 are the fields at which anomalies appear in the magnetization curves

Figure 2 (b) represents the magnetoresistance (MR) vs. field plot below T_N for the in-plane electron transport of $(DMET)_2FeBr_4$. The MR is negative in the whole field range up to 15 T with a minimum at around 6 T. Interestingly, an anomalous discontinuity exists at B_{SF}, when the field is applied in the spin-easy axis direction. For the field along the hard axis, the MR shows a discontinuity at $B_2 \approx 5$ T, at which the magnetization has an anomaly, as we can see by taking the derivative of the MR with respect to B.

The correlation between the magnetic behavior and the magnetoresistance features can be understood by the formation of SDW in the insulating phase. Below T_{MI}, localized magnetic moments generated in the donor electronic system are spatially ordered. A simple analysis gives the fourfold periodicity in the SDW state along the chain, since the donor is in the 3/4-filled electronic state. In the SDW state, in which the periodicity of the Fe^{3+} AF arrangement is well registered to the SDW, Fe^{3+} spins become antiferromagnetically ordered below T_N. This results in an enhancement of the SDW gap, compared to the case which has no internal magnetic field of Fe^{3+} spins. However, well above the field at which all the Fe^{3+} spins are ferromagnetically arranged, the potential of the Fe^{3+} magnetic lattice does not modify the SDW gap. Therefore, the elevation of the field strength gives negative MR up to the saturation field of Fe^{3+} spins. At fields higher than the field at which the SDW state is destroyed, individual electrons contribute to the transport, resulting in an increase in the MR. The anomaly at B_{SF} in the MR is the consequence of a subtle change in the magnetic energy, which modifies the SDW gap slightly.

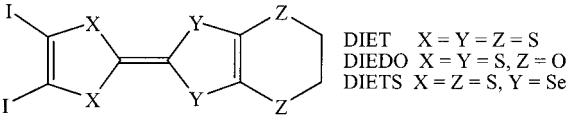
4. Current Developments

In order to establish magnetic or (at least) structural interactions between the organic and inorganic sublattices, some ideas are currently being explored in our groups. The first consists of using halogen-substituted organic donors and polycyanide anions.[5b,7b] The second uses an inorganic anion with π ligands[8] and the third (which is very recent) deals with coordination complexes containing TTF or its derivatives as ligands.[9,10,16]

4.1. Halogen-Substituted Donors

The nitrogen-halogen interaction is known from crystal engineering, and was used to construct the molecular pathway.[17] In our case, we used the unsymmetrical halogen-substituted organic donors DIETS [diiodo (ethylenedithio)-dithiadiselenafulvalene], DIEDO [diiodo(ethylenedioxo)-tetrathiafulvalene] and DIET [diiodo(ethylenedithio)tetrathiafulvalene],[18] which have two terminal iodine atoms with paramagnetic polycyanometalates such as $[M(CN)_6]^{3-}$ [7b] and $[Ni(mnt)_2]^{-}$ [7] as anions (Scheme 3). We describe here two types of compounds containing these anions.



Scheme 3. Organic donors bearing iodine atoms

4.1(a). $(DIETS)_8[Cr(CN)_6]_{0.67}Cl_2 2H_2O$

This compound has a typical layered crystal structure with extremely short Donor···Anion (I···N) contacts.[7b] These distances (in the range 2.722 to 2.825 Å) are slightly shorter than the sum of van der Waals (vdW) separation of ca. 3.65 Å. From the physical properties (Figure 3) we concluded that this compound is semiconducting and paramagnetic. The dc. electrical conductivity measurements over the range 20−300 K show semiconducting behavior, with $\sigma_{RT} \approx 0.2\ Scm^{-1}$ and $E_A = 65$ K. The magnetic susceptibility (Figure 3) obeys the Curie−Weiss law ($C = 1.571$ emu K^{-1} mol^{-1}, $\Theta = -0.2$ K), and there is no magnetic ordering down to 1.7 K. The small Weiss temperature and the absence of any magnetic phase transition shows that the exchange interaction between the magnetic anions is small. The decrease of $\chi_M T$ at low temperature is attributed to AF interactions in the organic layer. Therefore, despite the very short contact attained in this compound, no magnetic interactions were observed between the conduction and magnetic systems.

4.1(b). $(EDO\text{-}TTFI_2)M(mnt)_2$ (M = Ni, Pt): An "Organic Metal" with a Ferromagnetic Interaction

$(EDO\text{-}TTFI_2)M(mnt)_2$ (M = Ni, Pt) complexes feature 1D metal chains (the donor EDO-$TTFI_2$ columns) and 1D magnetic chains [the $M(mnt)_2$ anion columns], which are

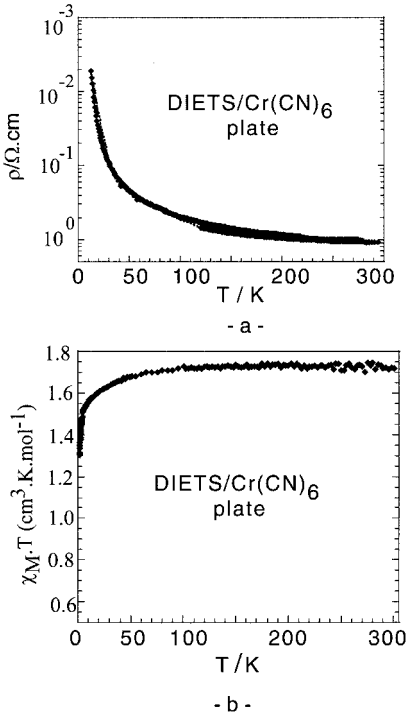


Figure 3. (a) Electrical conductivity and (b) magnetic properties of $(DIETS)_8[Cr(CN)_6]_{0.67}Cl_2 2H_2O$

aligned parallel to each other along the *c*-axis, as shown in Figure 4.[7a] The donor chain has a 3/4-filled state; the metal-insulator transition, T_{MI} = 88 and 96 K for M = Ni and Pt, respectively.

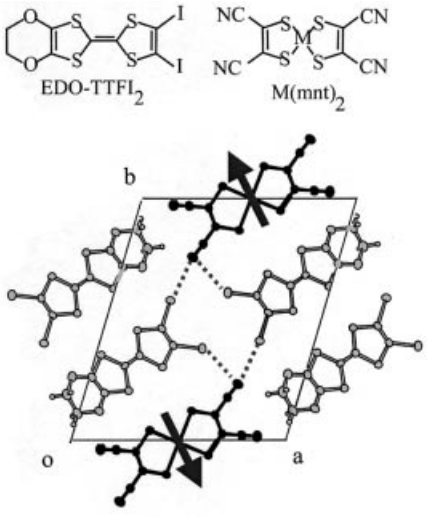

Figure 4. Crystal structure of $(EDO\text{-}TTFI_2)_2M(mnt)_2$ (M = Ni, Pt); dotted lines denote close CN−I atomic contacts between donor and anion; localized spins (S = 1/2) on acceptors are shown with arrows

The anion is in the half-filled state with a localized moment of S = 1/2. The temperature dependence of the magnetic susceptibility is shown in Figure 5. The susceptibility provides evidence for the presence of ferromagnetic interaction, as clearly seen from the increasing trend of χT at low

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

temperatures for M = Ni and Pt. Actually, the observed susceptibility can be satisfactorily explained in terms of the Heisenberg model (for an $S = 1/2$ 1D ferromagnet), with $J = 18$ K for M = Ni, taking into account the absence of anisotropy in the susceptibility as shown in Figure 5 (a). The absence of 3D long-range order is the consequence of the 1D Heisenberg isotropic spin feature. For the Pt complex, the susceptibility has a large anisotropy dependent on the field direction [as shown in Figure 5 (b)], where the fitting is satisfactory with the Ising model (for an $S = 1/2$ 1D ferromagnet), with $J = 20$ K. From the peak in the susceptibility, it is clear that long-range 3D ordering takes place at $T_N = 5.5$ K; the weak inter-chain AF interaction ($J' \approx -0.05$), with the aid of the anisotropy, plays an important role, giving an antiparallel arrangement of ferromagnetic chains.

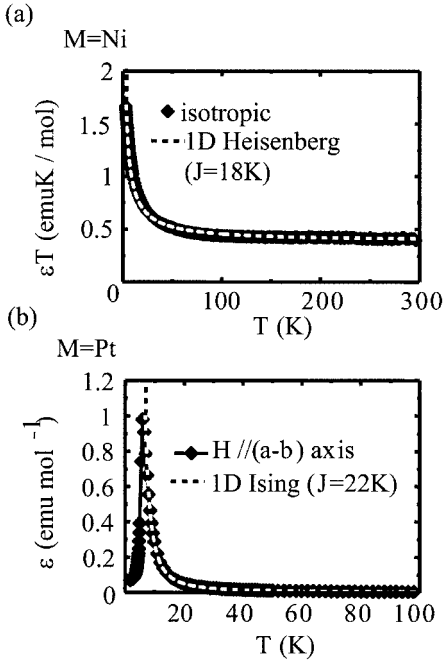

Figure 5. (a) χT vs. T plot for $(EDO\text{-}TTFI_2)_2Ni(mnt)_2$; the dashed line is the theoretical curve for the Heisenberg model (for a $S = 1/2$ 1D ferromagnet) ($J = 18$ K); (b) χ vs. T plot for $(EDO\text{-}TTFI_2)_2Pt(mnt)_2$; the solid line represents the curve for the Ising model (for a S = 1/2 1D ferromagnet) ($J = 20$ K).

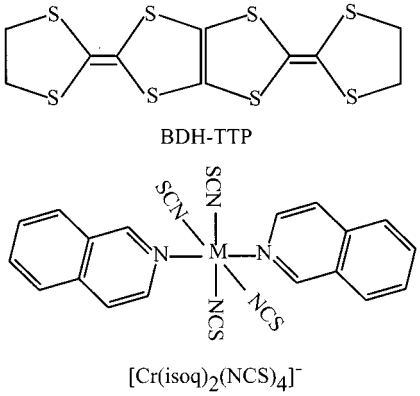
The origin of the ferromagnetic interaction can be explained in terms of McConnell's theory,[19] namely, that the spin polarization effect causes the ferromagnetic interaction. The slipped metal-over-sulfur configuration of $M(mnt)_2$ molecules causes an AF interaction between the small negative spin density on the sulfur atom of an $M(mnt)_2$ unit and a large positive spin density on the metal atom of an adjacent $M(mnt)_2$ unit. Eventually, this local AF configuration produces a ferromagnetic interaction between the large positive spin densities on the metal atoms of adjacent $M(mnt)_2$ molecules.

The interaction between π-conduction carriers and localized spins is an important issue in the development of molecular versions of metal magnets. From this viewpoint, the ESR signal featuring a single Lorentzian shape for M = Ni and the absence of an ESR signal for M = Pt indicate the presence of a considerable interaction between conducting donors and magnetic anions.

4.2. Paramagnetic Anions with π Ligands

Recently, TTF- and TTP- (tetrathiapentalene) derived salts containing $[M(NCS)_4(L)_n]^-$ [where M = Cr^{III}, Fe^{III}, L = 1,10-phenanthroline (phen) or isoquinoline (isoq)] have been reported[8] (Scheme 4). In these compounds, magnetic interactions should be induced by both S···S contacts and π-stacking overlap between the paramagnetic anions and organic radicals. Indeed, a large number of the salts showed long-range ferrimagnetic and weak ferromagnetic order with T_c in the range 4.2−8.9 K.[8]



Scheme 4

As an example, we describe here (BDH-TTP)$[Cr(isoq)_2(NCS)_4]$ (**3**),[8c] where BDH-TTP = 2,5-bis(1,3-dithiolan-2-ylidene)-1,3,4,6-tetrathiapentalene. As shown in Figure 6, the crystal structure consists of one-dimensional chains parallel to the *c*-direction, with remarkably short intermolecular S···S distances (in the range 3.264−3.397 Å, vdW = 3.70 Å). The adjacent chains are connected through the π-π overlap of isoquinoline moieties [interplanar separation, $d = 3.600(5)$ Å] between the anions, and short S···S contacts [S(5)−S(5) = 3.640(2) Å] between the donors. In the [101] direction, neighboring anions are related by the *c*-glide plane, and therefore the orientation of these anions is different; the angle between the molecular axes (defined as isoq−M−isoq) is 6.0(3)°.

As expected from the 1:1 stoichiometry and the alternate stacking of donors and anions, the salt has a low conductivity [$\sigma(300\text{ K}) = 10^{-5}$ S cm^{-1}]. Its magnetic susceptibility [Figure 7 (a)] obeys the Curie−Weiss law above 50 K, with $\Theta = -20.4$ K and $C = 2.19$ emu K mol^{-1}, which is close to the corresponding spin-only value (2.25 emu K mol^{-1}) for non-interacting anion ($S = 3/2$) and donor ($S = 1/2$) spins, assuming $g = 2.0$ for each species. Below 50 K, $\chi_M T$ decreases with the temperature down to 8 K, but then it shows a steep increase at $T_C = 7.6$ K due to a magnetic transition. The insets of Figure 7 (a) present the field-cooled magnetization (FCM) measured at 10 mT, and the

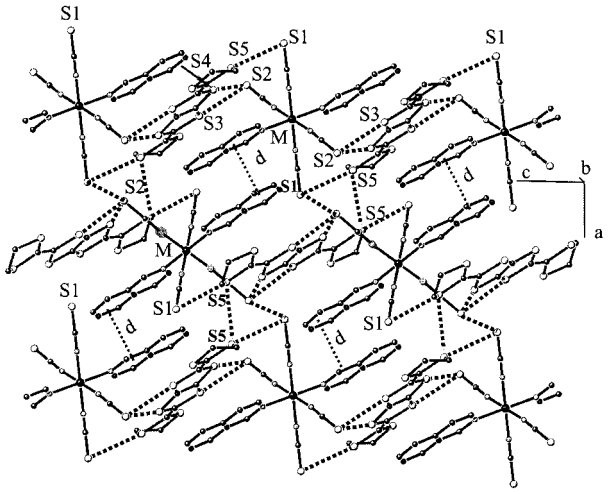

Figure 6. Projection of the crystal structure of (BDH-TTP)[Cr(isoq)$_2$(NCS)$_4$] in the *ac* plane, S···S contacts are shown

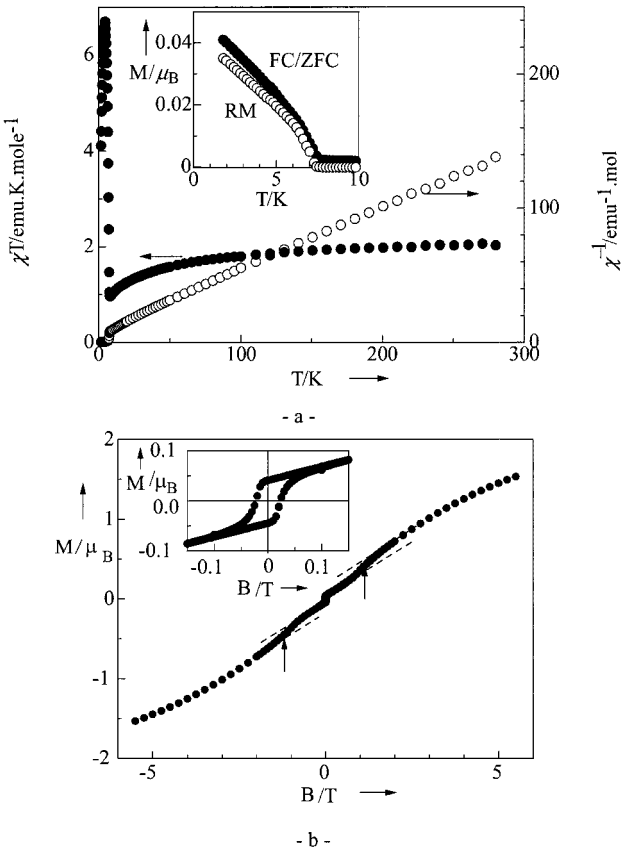

Figure 7. (a) Temperature dependence of $\chi_M T$ (filled circles) and χ_M^{-1} (open circles) for non-oriented samples, measured with an applied field of 10 mT for (BDH-TTP)[Cr(isoq)$_2$(NCS)$_4$]; inset: temperature dependence of the FCM (filled circles) and RM (open circles); (b) magnetization curves at 2 K measured on non-oriented samples; inset: hysteresis loop around B = 0 T

remnant magnetization (RM) observed after the external field of 10 mT is removed at 1.8 K. Below T_C = 7.6 K, the FCMs increase steeply and the RMs also emerge, indicating the presence of spontaneous magnetization. Moreover, in the magnetization curve a hysteresis loop is also observed around B = 0 T [Figure 7 (b)].

This salt has a bulk weak ferromagnetic state, originating from the angled alignment of the one-dimensional ferrimagnetic chains involving d-electrons and π-electrons. The origin of the intra-chain AF coupling are the short intermolecular S···S contacts between donors and anions, whereas the inter-chain coupling comes from the π-π overlap between anions and/or S···S contacts between donors.

4.3. Covalent Links Between Paramagnetic And Conducting Systems

As for the above-described compounds, the strategy commonly used in this area is the assembly of conducting organic sublattices and paramagnetic inorganic sublattices in salts comprising organic ions and paramagnetic inorganic counterions. In general, this yields materials with weak interactions (when they exist at all) between the two systems.

We are currently developing a strategy which consists in preparing new materials where the conducting and magnetic systems are covalently linked through a π-conjugated bridge, as shown in Scheme 1.[9,10] We have therefore synthesized and characterized new paramagnetic coordination complexes containing TTF or BEDT-TTF as ligands, as well as their radical cation salts. We present here as an example [Cu^{II}(hfac)$_2$](TTF-py)$_2$, where hfac = hexafluoroacetylacetonate[10] and TTF-py = 4-(2-tetrathiafulvalenylethenyl) pyridine. Its molecular and crystal structure are shown in Figure 8 (a). The Cu atom is bonded in the equatorial plane to the oxygen atoms of two bidentate hfac anions. The TTF-py ligands occupy the apical positions and are *trans* to each other; they are then bonded to the metal atom through the nitrogen atoms of the pyridyl ring. The crystal structure [Figure 8 (b)], consists of alternate organic (TTF-py) and inorganic [Cu(hfac)$_2$] layers, linked by a conjugated bridge. The two TTF moieties are neutral, and therefore this complex is insulating and paramagnetic, as expected.

The following step of this work was obviously the partial oxidation of these TTF-py ligands to introduce electrical conductivity. A part of this goal has now been achieved by the synthesis and the characterization of the unprecedented radical cation salt [Cu(hfac)$_2$(TTF-py)$_2$][PF$_6$][10] [Figure 9 (a)].

The bond lengths around the Cu atom are very close to those found in the neutral complex, but the central C=C bond length of the TTF-py moiety [1.369(8) Å], which is more sensitive to oxidation, is slightly larger than in the neutral complex [1.317(10) Å]. From the stoichiometry, we can deduce that the charge distribution is [Cu^{2+}(hfac)$_2^{2-}$(TTF-py)$_2^{+}$][PF$_6$]$^-$. This gives rise to a mixed valence state in the [Cu^{2+}(hfac)$_2^{2-}$(TTF-py)$_2^{+}$] radical unit. In the crystal structure [Figure 7 (a)], the TTF units form dimers separated by the PF$_6$ anions [Figure 9 (b)]; the isolated dimers are of course in the mixed valence state. Actually, this structural arrangement is not favorable for electrical conductivity, and therefore further work is needed to achieve electrical conductivity. Studies investiga-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ting systematic changes in anions, metals and ligands are currently underway.

5. Conclusions

In $(DIETS)_8(Et_4N)[Cr(CN)_6]_{0.66}Cl_2 2H_2O$, short I···N contacts were observed between donors and anions. This compound is semiconducting and paramagnetic. However, despite these very short contacts, no magnetic exchange interactions between donor π-electrons and anion d-electrons have been observed. $(EDO\text{-}TTFI_2)M(mnt)_2$ complexes (M = Ni, Pt) are metallic with ferromagnetic interactions, and $(BDH\text{-}TTP)[Cr(isoq)_2(NCS)_4]$ belongs to a series of insulating weak ferromagnets with T_c values in the range 5.8−8.9 K.

Finally, new transition metal complexes and their radical cation salts containing organic donor (TTF-py) as ligands covalently linked through π-conjugated bridges have been presented. These compounds are very promising and constitute a new approach for obtaining π-d interactions in bifunctional conducting and magnetic molecular materials.

From the present results, a combination of TTF-based donors and magnetic anions having d-electrons as building blocks should be expected to produce a large variety of molecular magnets having an unconventional interplay of electron transport and magnetism, owing to the hybrid structure of two components with different functions.

[η^5:η^1-(3,6-*t*Bu$_2$Flu)SiMe$_2$N*t*Bu]Y(η^1-NC$_5$H$_6$)(py)$_2$: A 1,4-Hydride-Addition Product to Pyridine that Provides Evidence for the First Fluorenyl(hydrido)metal (Group 3) Complex

Evgueni Kirillov,[a] Christian W. Lehmann,[b] Abbas Razavi,[c] and Jean-François Carpentier*[a]

Keywords: Fluorenyl / Hydrides / Insertion / Pyridine / Yttrium

Reaction of pyridine with the "constrained geometry" fluorenyl(hydrido)yttrium complex {[(3,6-*t*Bu$_2$Flu)SiMe$_2$N*t*Bu]Y(H)(THF)}$_2$ selectively gives the 1,4-addition product [η^5:η^1-(3,6-*t*Bu$_2$Flu)SiMe$_2$N*t*Bu]Y(η^1-NC$_5$H$_6$)(py)$_2$, which was characterized by single-crystal X-ray diffraction and ^{1}H and ^{13}C NMR spectroscopy.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Activation of C−H bonds by (hydrido)metal (group 3) complexes is well known for a wide variety of substrates, including aromatic heterocycles.[1] In particular, [(C$_5$Me$_5$)$_2$Ln(H)]$_2$ (where Ln = Lu,[2] Sc,[3] Y[4]) and [(C$_5$H$_4$R)$_2$Y(H)(THF)]$_2$ (where R = H, Me)[5] readily react with 1 equiv. of pyridine (py) leading to *ortho*-metalated pyridine complexes, [(C$_5$R$_5$)$_2$Ln(η^2-(*C*,*N*)-C$_5$H$_4$N)]. In the presence of an excess of a strong Lewis base, such as THF or pyridine, the released dihydrogen may initiate the reductive transformation of the 2-pyridyl complexes to 1,2-hydride-addition products, eventually followed by isomerization to the 1,4-addition products upon heating.[4] Polar solvents promote direct addition of Ln−H to the pyridine ring.[5] Several yttrium hydrides bearing non-cyclopentadienyl ligands have been found to undergo such an insertion, giving directly both 1,2- and 1,4-addition products.[6] The structure of the 1,2-addition product, {[6,6′-Me$_2$-(C$_6$H$_3$)$_2$]-(2,2′-NSiMe$_2$*t*Bu)$_2$}Y(η-NC$_5$H$_6$)(py)$_2$, was established by X-ray diffraction.[7] In this contribution, we report the first structurally characterized example of a 1,4-addition pyridine product, which provides indirect evidence for the formation of the first (hydrido)metal (group 3) complex supported by a fluorenyl ligand.

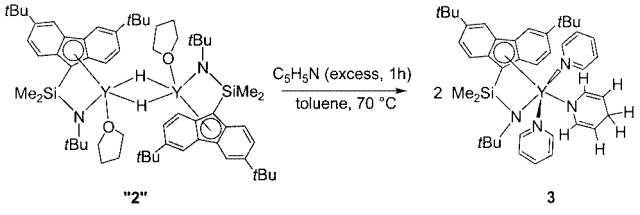
Results and Discussion

Recently we have reported on the synthesis and characterization of the first "constrained geometry" (alkyl)yttrium complex [η^3:η^1-(3,6-*t*Bu$_2$Flu)SiMe$_2$N*t*Bu]Y(CH$_2$SiMe$_3$)(THF)$_2$ (**1**), stabilized by a fluorenyl-amido ligand.[8] In the course of these studies, we found that **1** reacts equally with H_2 or $PhSiH_3$ under ambient conditions (25 °C, 1 atm) to generate a yellow microcrystalline solid in high yield. Considering this reactivity and consistent with elemental analysis, the product was formulated as the putative hydride {[(3,6-*t*Bu$_2$Flu)SiMe$_2$-N*t*Bu]Y(H)(THF)}$_n$ (**2**). However, the surprising insolubility of the latter in common organic solvents (aromatic hydrocarbons, chlorinated solvents, THF), despite the presence of two *tert*-butyl substituents on the fluorenyl ligand, prevented its complete authentication. Complex **2** does not react with an equimolar amount of pyridine after one week at 25 °C but it completely dissolves in a toluene solution at 70 °C after 1 h in the presence of a 20-fold excess of [H$_5$]pyridine (vs. Y) (see Scheme 1). After evaporation of the solution and extraction of the residue with pentane, the new "constrained geometry" (amido)yttrium complex, **3**, was isolated in 69 % yield as an orange-brown crystalline material.



Scheme 1

 DOI: 10.1002/ejic.200300837 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

^{1}H and ^{13}C NMR spectroscopic data establish that **3** is the sole product of the reductive 1,4-addition of pyridine to the hydrido complex **2**. The ^{1}H NMR spectrum of **3** ([D$_6$]benzene, 25 °C) displays one set of sharp resonances consistent with C_v-symmetry that include one singlet and two doublets from the three pairs of equivalent fluorenyl protons, one singlet from the $SiMe_2$ moiety, and one singlet from each of the *tert*-butyl(fluorenyl) and *tert*-butyl(amido) groups. The 1,4-dihydropyridyl fragment is characterized by a doublet for the 2,6-protons (δ = 6.35 ppm, $^3J_{H,H}$ = 6.9 Hz), a multiplet for the 3,5-protons (δ = 4.59 ppm) and a broad singlet for the 4-methylene group (δ = 3.61 ppm).[5] The signals from the coordinated-pyridine molecules are broad at room temperature, which illustrates their fluxional behavior and suggests that they dissociate in solution. On the other hand, there is no evidence for exchange of the coordinated-pyridine molecules with the 1,4-dihydropyridyl fragment, which indicates that the reaction is not reversible at this temperature on the NMR time-scale.

An X-ray-diffraction study confirmed the structure of complex **3** and the coordination of two pyridine molecules in the solid-state (see Figure 1). The formal 18-electron yttrium center is coordinated in a distorted square-pyramidal geometry to four nitrogen atoms and to the centroid of the five-membered ring of the fluorenyl moiety, which occupies the apical position. Complex **3** and the parent alkyl complex **1** have a very similar pseudo-five-coordinate geometry: the THF molecules and the alkyl group in **1** are replaced in **3** by pyridine molecules and by a 1,4-dihydropyridinyl group, respectively. However, the coordination modes of the fluorenyl ligands in the solid-state structures are quite different; that is, in the alkyl complex **1**, the fluorenyl moiety is coordinated in an unusual non-symmetric, exocyclic η^3-coordination mode that involves the bridgehead atom and a neighboring atom of the central five-membered cycle, and the adjacent carbon atom of a phenyl ring.[8] In contrast, the molecular structure of **3** features a symmetric η^5-coordination. This observation is rather surprising considering that pyridine is a stronger base than THF and, therefore, should favor reduced hapticity of the fluorenyl moiety. This difference evidences that the variety of flexible coordination modes of fluorenyl ligands that we recently observed in a series of group 3 metal and lanthanide complexes[8,9] is strikingly dependent on minute electronic and steric factors. The solid-state structure of **3** has a plane of symmetry (non-crystallographic) that embraces the Flu(centroid) and the C(9), N(12), Si(1) and Y(1) atoms as well as the plane of the 1,4-dihydropyridine cycle. The bite angle Flu_{cent}−Y(1)−N(12) is 97.36° and resembles the corresponding Cp_{cent}−Y−N angles (97.1−97.8°) observed in half-sandwich yttrium complexes supported by Cp-amido ligands.[10] The average Y−C (C9, C9a, C8a, C4a, C4b) distance in **3** [2.701(2) Å] is in the range of values 2.646−2.719 Å, observed for other yttrium complexes with silylene-substituted fluorenyl fragments.[11] Similarly, the Y(1)−N(12) bond length of 2.232(2) Å is in the range of 2.208−2.253 Å, found in related "constrained geometry" Cp(amido)yttrium complexes.[10,12] The Y(1)−N(21) bond length between the yttrium and the nitrogen atom of the 1,4-dihydropyridine fragment [2.302(2) Å] is in agreement with the values observed in other yttrium complexes bearing terminal amido groups.[7,13] The bonds in the dihydropyridine fragment (see b in Figure 1) indicate reduction of pyridine via 1,4-insertion,[14] that is, the bond lengths C(22)−C(23) [1.332(3) Å] and C(25)−C(26) [1.338(3) Å] are significantly shorter than the other two C−C bonds in the ring [C(23)−C(24) 1.510(4), C(24)−C(25) 1.484(4) Å]. Also, the angle C(23)−C(24)−C(25) of 108.2(2)° is indicative of the sp^3-hybridization of the C(24) carbon atom.

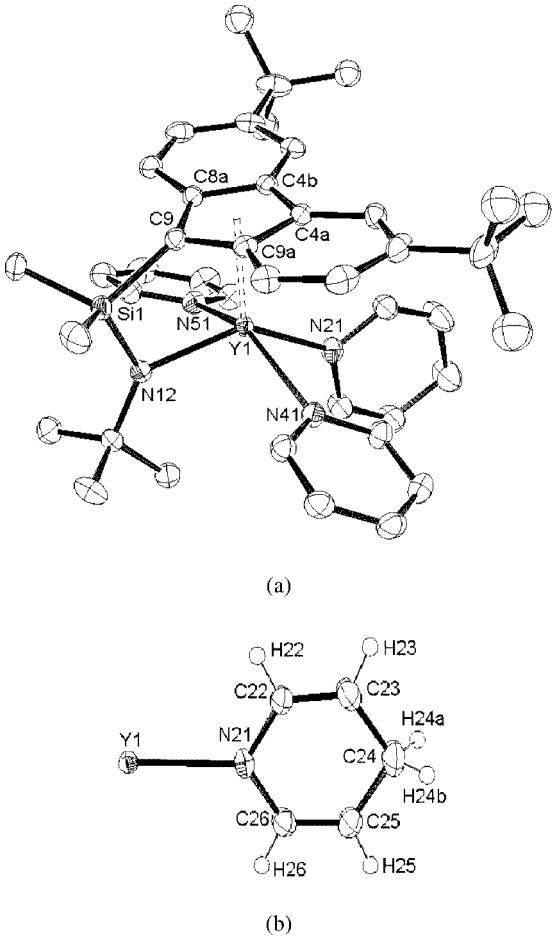


Figure 1. (a) ORTEP drawing of the molecular structure of **3**; thermal ellipsoids are drawn at the 50 % probability level; hydrogen and disordered carbon atoms from *tert*-butyl groups are omitted for the sake of clarity; selected bond lengths (Å) and angles (°) Y(1)−N(12) 2.2319(17), Y(1)−N(21) 2.3015(17), Y(1)−N(41) 2.5325(17), Y(1)−N(51) 2.5383(17), Y(1)−C(9) 2.6021(19), Y(1)−C(9A) 2.6883(18), Y(1)−C(8A) 2.6946(19), Y(1)−C(4B) 2.7588(19), Y(1)−C(4A) 2.7635(18), N(12)−Si(1)−C(9) 99.37(8), N(41)−Y(1)−N(51) 146.28(6), N(21)−Y(1)−N(41) 79.01(6), N(21)−Y(1)−N(51) 78.94(6), N(12)−Y(1)−N(21) 140.10(6); (b) view of the reduced pyridine fragment in **3**; selected bond lengths (Å) and angles (°) N(21)−C(22) 1.381(3), N(21)−C(26) 1.390(3), C(22)−C(23) 1.332(3), C(23)−C(24) 1.510(4), C(24)−C(25) 1.484(4), C(25)−C(26) 1.338(3), C(22)−C(23)−C(24) 123.3(2), C(23)−C(24)−C(25) 108.2(2), C(24)−C(25)−C(26) 123.3(2).

Two possibilities may account for the selective formation of the 1,4-hydride-addition product **3**: (i) although NMR monitoring showed no evidence for the formation of a tran-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sient 1,2-addition product during the reaction course, the latter may rapidly isomerize to **3** due to the enforced conditions, which are required for completion of the reaction;[5,15] (ii) the reaction may involve direct 1,4-addition: nucleophilic attack on both the 2- and 4-positions is well known for pyridine rings.[16]

In conclusion, the isolation of the 1,4-addition product **3** brings indirect evidence of the hydrido nature of the complex formed by hydrogenolysis of the "constrained geometry" (fluorenyl-amido)yttrium alkyl complex **1**. Although its molecular structure and the reasons for its insolubility remain to be determined, complex **1** is, to the best of our knowledge, the first example of a hydrido complex of a group 3 metal supported by a fluorenyl ligand. The scope of this insertion reaction is currently under investigation.

Experimental Section

Crystallographic Data for 3: $C_{42}H_{55}N_4SiY$, M = 732.90, monoclinic, T = 100 K, space group $C2/c$, a = 23.3709(2), b = 13.03550(10), c = 26.4358(2) Å, α = 90, β = 104.75, γ = 90°, V = 7788.33(11) Å^3, Z = 8, D_c = 1.250 g·cm^{-3}, μ(Mo-K_α) = 1.562 mm^{-1}; 65290 reflections collected, 12419 unique (R_{int} = 0.0504), full-matrix least-squares on F^2 refinement, R_1 = 0.0442 [$I > 2\sigma(I)$], wR_2 = 0.1094 (all data). An orange crystal of dimensions 0.32 × 0.30 × 0.13 mm was coated in oil, mounted on a fibre and X-ray-diffraction data were collected using a Nonius−KappaCCD diffractometer employing CCD scans to cover reciprocal space up to 31.03° with 99.7 % completeness. Integration of raw data yielded a total of 65290 reflections, merged into 12412 unique reflections with R_{int} = 0.0504 after applying Lorentz, polarization and absorption correction. The structure was solved by Patterson methods using SHELXS-97.[17] Atomic positions and displacement parameters, on the anisotropic level for all non-hydrogen atoms, were refined using full-matrix least-squares based on F^2 using SHELXL-97.[17] Refinement of 446 parameters using all reflections converged at R_1 = 0.0442, wR_2 = 0.1094, with the highest residual electron-density peak of 1.2 Å^3. CCDC-219360 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge, CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of 3: A solution of pyridine (0.668 g, 8.45 mmol, 20 equiv. vs. Y) in toluene (2 mL) was added to a suspension of **2** (0.240 g, 0.211 mmol of the dimer) in toluene (10 mL). The reaction mixture was stirred at 70 °C until complete dissolution of **2** was achieved (ca. 60 min). The resulting orange solution was evaporated under vacuum to give a brown residue, which was extracted with pentane (3 × 10 mL) to yield complex **3** as brown-orange crystals (0.210 g, 69 %) from combined pentane extracts. ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 8.36 (br. m, 4 H, 2,6-H, py), 8.08 (s, 2 H, 4,5-H, Flu), 7.93 (d, $^3J_{H,H}$ = 8.4 Hz, 2 H, 1,8-H, Flu), 6.88 (d, $^3J_{H,H}$ = 8.3 Hz, 2 H, 2,7-H, Flu), 6.78 (br. m, 2 H, 4-H, py), 6.51 (br. m, 4 H, 3,5-H, py), 6.35 (d, $^3J_{H,H}$ = 6.9 Hz, 2 H, NC*H*CHCH$_2$), 4.59 (m, 2 H, NCHC*H*CH$_2$), 3.61 (s, 2 H, NCHCHC*H*$_2$), 1.35 (s, 9 H, NCC*H*$_3$), 1.31 [s, 18 H, CC*H*$_3$(Flu)], 1.15 (s, 6 H, SiC*H*$_3$) ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]benzene, 25 °C): δ = 150.8 (C-2,6, py), 140.8 (C-3,6, Flu), 137.4 (C-4, py), 135.9 (N*C*HCHCH$_2$), 126.3 (C-10,13, Flu), 123.5 (C-3,5, py), 123.4 (C-2,7, Flu), 123.1 (C-11,12, Flu), 121.8 (C-1,8, Flu), 116.8 (C-4,5, Flu), 94.7 (NCH*C*HCH$_2$), 82.8 (C-9, Flu), 54.3 (N*C*CH$_3$), 35.3 (NC*C*H$_3$), 33.7 (Flu-*C*CH$_3$), 31.9 (Flu-C*C*H$_3$), 24.9 (NCHCH*C*H$_2$), 7.4 (Si*C*H$_3$) ppm. $C_{42}H_{55}N_4SiY$ (732.92): calcd. Pr_6O_{11} Single-Crystal Nanotubes from a Molten-Salt Synthetic Method

Xun Wang,[a] Jing Zhuang,[a] and Yadong Li*[a]

Keywords: Lanthanides / Molten salts / Nanotubes / Three-dimensional structures / X-ray diffraction

Pr_6O_{11} single-crystal nanotubes with a typical 3-D crystal structure in the bulk have been successfully obtained through a template-free molten-salt synthetic method, the formation of which has been attributed to the periodical defect cluster distribution in the Pr_6O_{11} species. It is believed that the synthesis of this new type of 3-D nanotubes will be helpful to explore more rational synthetic methods to nanotubes of 3-D compounds.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Nanotube materials have drawn continuous research attention because of their distinctive structural features combined with novel chemical and physical properties, which are of great research and application interest in electronic, energy and catalyst fields etc.[1−12] Various substances have been processed into nanotubes driven simply by one motivation: what if they are nanotubes?

It is generally believed that nanotubes are only thermodynamically stable when they have a similar layer structure to graphite.[1] Therefore, for many technologically and scientifically important compounds which do not possess layer structures, such as silicon,[5] GaN,[6] and metals,[7] templates are usually needed to confine and stabilize the growth of their nanotubes, including porous membranes,[8] carbon nanotubes,[9] nanorod arrays[5,6] and nanowires.[7] Some syntheses of nanotubes from 3-D compounds, such as ZnO and Te, have been achieved by melting Zn cores[10] or using Te[11] colloidal seeds as self templates, respectively. Meanwhile, stimulated by the possible rolling process in the formation of nanotubes, the thin-solid-film rolling method has been successfully developed by controlled release of polycrystalline layers from substrates.[12] These 3-D compounds, although restricted by large-scale preparation or crystalline quality, have undoubtedly enriched the nanotube categories and given us more inspiration on the exploration of new synthetic methods. Here, we demonstrate that single-crystal Pr_6O_{11} nanotubes, which have a typical 3-D crystal structure in the bulk, can be obtained through a template-free synthetic method. The formation of this nanotube is believed to be related to the periodical defect-cluster distribution in the Pr_6O_{11} species.

Results and Discussion

Our method was based on a molten-salt synthetic process, which has been widely adopted to prepare oxide nanowires by Wang et al.[13,14] and was recently expanded to the preparation of ZnO microtube arrays by us.[15]

The phase purity of the samples has been characterized on a Bruker D8-advance X-ray powder diffractometer with Cu-K_α radiation (λ = 1.5418 Å). As shown in Figure 1, all the reflections of the XRD patterns can be readily indexed to a pure face-centered cubic face of the Pr_6O_{11} crystal with lattice constants a = 5.4678 Å (JC,PDS 42−1121). The 2θ peaks at values of 28.26, 32.81, 47.04, 55.72, 58.46 and 68.64° correspond to the crystal planes of [111], [200], [220], [311], [222] and [400] of the crystalline Pr_6O_{11} species, respectively. The d values at 28.26° are calculated to be approximately 0.318 nm, corresponding to the [111] plane

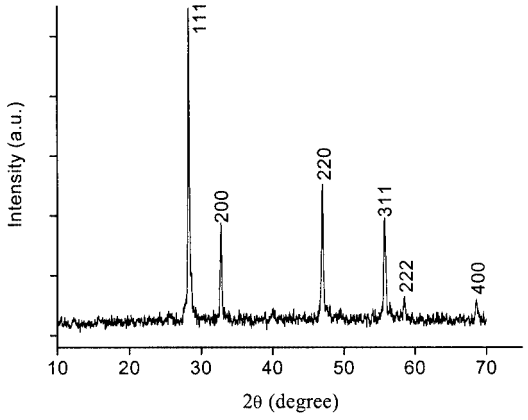

Figure 1. XRD patterns of the Pr_6O_{11} crystal after molten salt thermal treatment

spacing of the Pr_6O_{11} species. All the information from this XRD pattern indicates that the crystal structure of the Pr_6O_{11} species has been maintained after thermal treatment under current experimental conditions.

Thorough TEM analysis (Figure 2, a and b) has indicated that about 30 % of the raw Pr_6O_{11} microparticles have been converted into nanotubes. TEM analysis have shown that these nanotubes usually have diameters of approximately 10−20 nm and lengths of 100−500 nm; all of them have open ends. It is interesting to find that these nanotubes tend to aggregate together around the microparticles, which may serve as evidence for a possible exfoliation process for the formation of these nanotubes from the starting microparticles of the Pr_6O_{11} species.

HRTEM has provided further insight into the microstructure of these Pr_6O_{11} nanotubes. As shown in Figure 2 (c), the HRTEM image of an individual nanotube clearly demonstrates its multi-wall tubular structure with an outer diameter of approximately 20 nm and an inner diameter of about 6 nm; the interlayer spacing can be calculated to be about 0.320 nm, corresponding to the interlayer spacing of the [111] plane of the body-centered cubic Pr_6O_{11} species. The electron diffraction pattern of this nanotube (Figure 2, inset c) revealed its single-crystal nature and can be indexed as that of the [111] zone axis of the face-centered cubic Pr_6O_{11} species. EDS analysis (Figure 2, e) taken from an individual nanotube has indicated that only Pr and O atoms are present; no Na^+ or Cl^- ions were detected, indicating Pr_6O_{11} nanotubes.

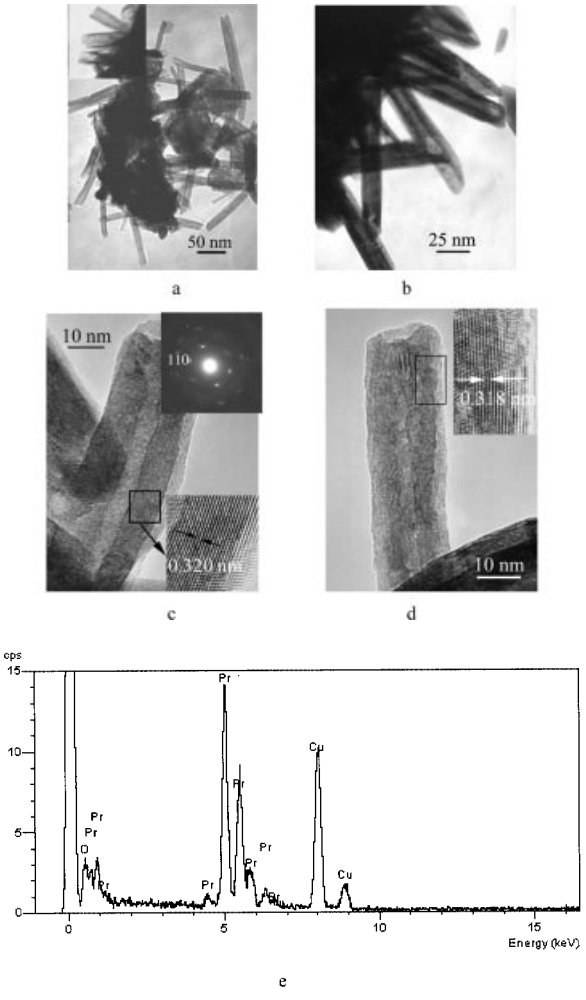

Figure 2. a) TEM images of Pr_6O_{11} nanotubes from NaCl melts; b) TEM images of Pr_6O_{11} nanotubes from KCl melts; c) HRTEM images of a single Pr_6O_{11} nanotube from NaCl melts; inset, electron-diffraction patterns of a single Pr_6O_{11} nanotube; d) HRTEM images of a single Pr_6O_{11} nanotube from KCl melts; e) EDS analysis of a single Pr_6O_{11} nanotube in Figure 2, c)

In contrast to previously reported nanotubes obtained under unrestricted conditions, Pr_6O_{11} nanotubes have no layer structure. Why then are the nanotube structures thermodynamically stable? A further insight into the crystal structure of the Pr_6O_{11} species may help us to illustrate the structure principle of these nanotubes.

The Pr_6O_{11} species is the most thermodynamically stable form of the PrO_x series. X-ray powder diffraction experiments of Pr_6O_{11} nanotubes show that it is related to PrO_2,[16] which has the fluorite structure (Figure 3, a).

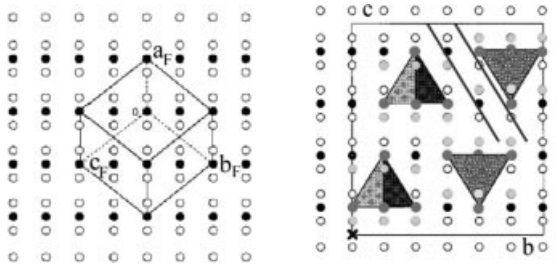

Figure 3. a) Model for the crystal structure of fluorite-type PrO_2; open circles, oxygen atoms; black circles, Pr atoms; b) model for the crystal structure of the Pr_6O_{11} sector viewed along [001] direction; open circles, oxygen atoms; black circles, Pr atoms with an oxidation state of +3; light gray circles, Pr atoms with an oxidation state of +4; dark gray circles, oxygen atoms in Pr_4O_6 vacancy cluster

It is believed that the structures of various intermediate praseodymium oxides are built from a simple basic defect cluster: Pr_4O_6. This defect cluster involves the vacant Pr_4 tetrahedron and its six edge-bridging oxygen atoms and is created when an oxygen atom is extracted from the parent fluorite structure PrO_2,[17,18] which results in two types of Pr cations in the Pr_6O_{11} species: Pr cations participating in the Pr_4O_6 vacancy cluster and those without an oxygen vacancy in their coordination sphere. The formal charge on these two types of Pr ions is +4 and +3, respectively. The result of the cation lattice relaxation is that the intracluster Pr−Pr distances have an average of 4.1 Å, while the intercluster Pr−Pr distances are about 0.4 Å shorter.[19] In other words, the Pr^{3+} ions are crowded into the region between the defect clusters. On the other hand, the dominant chemical force in the rare-earth oxides is ionic in nature, and the electrostatic repulsion between the defect clusters tends to separate them,[19] which may provide the possibility for the exfoliation process of Pr_6O_{11} single-molecule layers from the bulk. Among the different crystal planes of the Pr_6O_{11} structure, the [111] planes have the largest interlayer dis-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tance (0.318 nm) and thus the weakest interaction between layers, so the [111] plane would be the preferred exfoliation direction, and the obtained Pr_6O_{11} nanotubes would grow along [1$\bar{1}$0] axis, which is consistent with our HRTEM and electron-diffraction analysis. Compared with the reported nanotubes of 2-D sheet structures, the interaction between layers is much stronger, so the crystal-lattice images are usually distorted to some extent (Figure 2, c and d).

The conditions of the exfoliation and the further tube-formation process would be critical considering that the following conditions must be met: 1) enough energy must be provided to overcome the strong electrostatic interaction between layers; 2) the provided energy should be moderate enough so that it cannot break all the layers to lead to the formation of irregular particles without a preferred direction; 3) once the layers have been exfoliated, appropriate hindrance should exist to avoid the recombination of the layers. Our experimental results show that NaCl and KCl melts meets these conditions.

Take NaCl as an example, at 840 °C (the melting point of NaCl is about 808 °C) NaCl will melt and ionize into Na^+ and Cl^- ions, which can attack the crowded $[Pr_x^{3+}O_y^{2-}]^{z-}$ anion and the positively charged $[Pr_4O_6]^{4+}$ vacancy cluster along all directions, so that combinations between layers can be loosened to some extent. Since the interaction between [111] layers is the weakest, exfoliation can occur first along the [111] planes, which can be then stabilized by the high viscosity of the NaCl flux and may lead to the formation of nanotubes.

Although the structural analysis is consistent with our experimental results, a thorough theoretical study is still needed to justify its reasonability. Nevertheless, for the first time, single-crystal nanotubes of Pr_6O_{11} with a typical 3-D crystal structure have been successfully obtained through this unrestricted molten-salt method, which we believe may be expanded to the synthesis of nanotubes with similar structures and will greatly encourage materials scientists to explore more rational synthetic methods for the formation of nanotubes from 3-D compounds.

Experimental Section

Synthesis of Pr_6O_{11} Nanotubes: In a typical synthesis procedure, analytical grade NaCl (1 g, or KCl) and Pr_6O_{11} (0.9 g, purity > 99.9 %) were mixed together, and ground in an agate mortar to form a homogeneous mixture, which was then transferred into a crucible, and calcined at 840 °C in air for 3 h. The system was allowed to cool to room temperature. The solidified NaCl-Pr_6O_{11} products obtained were immersed into fresh water for about ten hours to remove NaCl from the Pr_6O_{11} material, during which fresh water was constantly replaced. Aqueous solutions of $AgNO_3$ (0.1 mol/L) and HNO_3 (1 mol/L) were used to detect the remnant Cl^- ions present in the final products. The resultant black powders were filtered, and dried at 80 °C in air.

Microwave-Assisted Synthesis of MPS_3 Materials (M = Mn, Cd) Using a Dewar-Ampoule Device

A. Villanueva,[a] M. C. Morales-Varela,[a] and Eduardo Ruiz-Hitzky*[a]

Keywords: Transition metals / Microwave-assisted reactions / Layered compounds / Synthesis design / Solid-phase synthesis

We report on an easy procedure for the synthesis of inorganic solids such as MPS_3 materials (M = Mn, Cd) which uses a simple device consisting of a silica ampoule that is divided into a Dewar zone (*hot* zone) and a nonisolated part (*cold* zone), which is able to operate inside domestic microwave ovens. This is a rapid and advantageous method applied for the first time to the preparation of inorganic solids. It involves a heat concentration within the Dewar zone that allows the required temperature for the reaction between the components to be reached. In this way, a mixture of S, P, and a transition metal such as Mn or Cd, placed in the Dewar zone gives MPS_3 compounds. The temperature gradient assures the vapor phase transport to the *cold* zone. The resulting MPS_3 crystals are deposited within a few minutes in the *cold* area, in contrast to other conventional procedures requiring long periods of treatment or more complicated procedures for the synthesis of similar products.

Introduction

Microwave-assisted reactions are of increasing interest in different fields of synthetic chemistry to yield both inorganic materials (as in the solid-state synthesis of functional ceramics[1−5]) and organic compounds (as synthesis on supported phases[1,6]). Usually, the reactions developed under microwave (MW) heating show remarkable improvement over those carried out under conventional heating in an extraordinary acceleration of the processes. This is particularly true for solid-state reactions, as for instance, the synthesis of vanadates,[3] chromates,[4] and metal−chalcogenides.[5] In general, the MW treatment of mixtures of pure or combined elements such as metal oxides, nitrates, or carbonates, produces enough heat to induce a rapid transformation of the reagents, to give the corresponding inorganic materials through solid-state reactions, often with excellent yields. A successful control of these reactions depends on the intrinsic properties of the involved solids, mainly related to their conductivity behavior. The energy necessary for the MW-assisted solid-state reactions is given by the absorption of high frequency waves, related to the so-called tangent loss (tan δ), which is the ratio between the dielectric loss (ε′′) and the dielectric constant (ε′) of the material.[7] The tangent loss indicates the efficiency of the solid material towards the conversion of MW energy into thermal energy mainly associated with two mechanisms: dipole rotation and electrical conductivity (either ionic or electronic). In solid-state reactions, no relaxation process except for the conduction process of both electrons and ions, takes place because the molecular dipoles are fixed, leading to high loss tangent values.[1] This has been observed particularly for reactions involving semiconductors or ion-conducting solids, in which the increased temperature produces an increase of the electrical conductivity and therefore gives exponential MW energy absorption and rapid heating, that is, the so-called *thermal runaway.*[2]

Transition-metal phosphorus trisulfides (MPS_3; M = Mn, Cd) are the compounds selected in this paper to show the advantages of using the Dewar ampoule device. This is a family of layered compounds[8] with interesting properties as host lattices for intercalation of organic compounds,[9] and lithium insertion,[10] and is indeed useful as electrodes for lithium-batteries and in nonlinear optical devices. The structure of MPS_3 compounds derives from that of $CdCl_2$, and is closely related to the structure of transition-metal dichalcogenides.[11] Conventional synthesis of MPS_3 materials by ceramic methods needs a heating treatment program at temperatures in the 550−800 °C range, from one to several weeks[12] making the process too long for practical purposes. It is assumed that in these conditions a vapor phase transport mechanism occurs,[13] but the nature of the transported species is so far unknown. MPS_3 compounds can be alternatively prepared by coordination of $[P_2S_6]^{4-}$ anions to M^{2+} cations in aqueous solutions, as in the reaction at room temperature between $MnCl_2$ and sodium hexathiohypophosphate[14] [Equation (1)].

$$2\,MnCl_2 + Na_4P_2S_6 \rightleftarrows 2\,MnPS_3 + 4\,NaCl \quad (1)$$

 DOI: 10.1002/ejic.200300654 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

This procedure is also long and tedious, because the sodium hexathiohypophosphate is a noncommercial product that needs to be prepared in the laboratory by reaction of sodium sulfide and phosphorus trichloride.[15] In addition, the reaction yield is lower than that of the ceramic method (about 67 %, from our experiments).

Results and Discussion

Figure 1. shows the apparatus developed for the MPS_3 synthesis, which essentially consists of a silica (quartz) ampoule with two different zones. One of the zones is furnished with a vacuum thermal barrier [i.e., it is a Dewar container (*hot* zone)], while the other zone is thermally deshielded (*cold* zone). Such a device was inspired by the typical two-zone furnace used to grow single crystals. The novelty of this design is that it operates inside a domestic MW oven, and this configuration allows the temperature to be reached so as to activate certain solid-state reactions. A sufficiently high temperature cannot be obtained in conventional reactors (e.g. standard sealed silica ampoules). For the first time, we have successfully applied this methodology to the preparation of well-crystallized MPS_3 layered solids, selected as an example in view of its difficult synthesis by the classical ceramic process. The attempts to produce these solid-state reactions using small amounts of metals inside conventional silica ampoules (i.e., classical quartz reactors) with MW irradiation always failed. Apparently, in an unshielded ampoule fast heat dissipation precludes the system from reaching a temperature high enough to afford the solid-state reaction. By contrast, the reaction is completed after a few minutes with MW irradiation when the Dewar ampoule apparatus is used, giving almost quantitative amounts of the corresponding metal phosphorus trisulfides. The driving idea to design such a device was to avoid the heat dissipation in the region of the reactor where the components are placed, thus assuring the increase of temperature required to produce the reaction. In our example, the MPS_3 compounds are deposited in the *cold* zone as relatively large crystals due to the temperature gradient that promotes the vapor-phase transport of the synthesized materials.

The nonmetallic elements, sulfur and phosphorus are insulators and practically transparent to MW, although theoretically they could be activated in the presence of a metal incorporated in the form of a fine powder. Under these conditions, the metal simultaneously acts as a reagent and as a MW absorber, because it couples very effectively with microwave radiation. This is the case for the reactions between sulfur and transition metals such as Ta, Cr, Fe, and Mn, which produces the corresponding sulfides.[16] In a similar way, we have tried to prepare MPS_3 compounds (M = Mn and Cd) by MW irradiation of a mixture of their three integrating elements using a conventional reactor (sealed, evacuated, single-quartz ampoule), using the same domestic MW oven. As indicated above, the reactions were always unsuccessful, even after a long time of treatment. It could

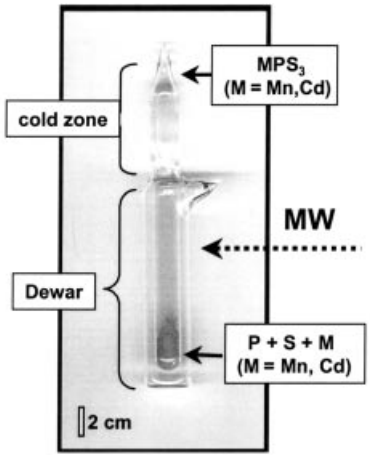

Figure 1. A picture of the Dewar ampoule highlighting its different parts and the process of MPS_3 crystallization

be maintained that under these conditions, the temperature reached is always lower than that required for the activation of the solid-state reaction. We have also unsuccessfully tried to carry out the $MnPS_3$ synthesis using mixtures of manganese metal and P_2S_5, or working under different conditions in a set of experiments involving conventional ampoules. In contrast, the Dewar ampoule offers a way to produce the phosphorus trichalcogenides quickly with excellent yields.

The details for the use of the Dewar ampoule with starting reagent mixtures of sulfur, phosphorus, and the selected transition metal (Mn or Cd), or alternatively mixtures of manganese, sulfur, and P_2S_5 (with stoichiometric MPS_3 ratios) are described in the Exp. Sect. Emission of very intense light of different colors is produced during the reactions, which are completed after 25−40 minutes of MW irradiation.

The MPS_3 resulting materials were characterized by XRD, FTIR spectroscopy and SEM-EDX analyses. Figure 2 shows the XRD patterns of $MnPS_3$ prepared by conventional procedures, that is, either from the ceramic method using a standard furnace (10 days, 700 °C, see A in Figure 2), or from soft conditions through a reaction involving various steps [Equation (1), see B in Figure 2], or by the MW-assisted synthesis using the Dewar ampoule (Figure 2, C and D). The XRD diagram of the reaction product obtained from the aqueous solution method [Equation (1)] corresponds to an ill-crystallized solid in view of the broad and low intensity *hkl* reflections attributed to $MnPS_3$ materials. All the diffraction peaks of the compound prepared by the ceramic method (Figure 2 A) fit very well with the corresponding ASTM file (No. 33−903), the diffractogram being very similar to the sample resulting from 25 minutes of MW irradiation of stoichiometric mixtures of Mn, P, and S (see D in Figure 2). Small differences in the relative intensities of the reflections of the two materials are attributed to preferred orientation effects: the [00 l] reflections of $MnPS_3$ (in particular for $l = 2$) are increased with respect to other reflections in the sample prepared by conventional techniques, while in the material prepared by

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the method reported here other reflections are relatively enhanced (like the [$\bar{1}$30] and [200] reflections, see Figure 2). The sample prepared from 30 minutes MW irradiation of Mn, P_2S_5, and S stoichiometric mixtures shows additional low intensity peaks identified as P_2S_5, MnP_4, and other by-products of variable P, S, and Mn composition.

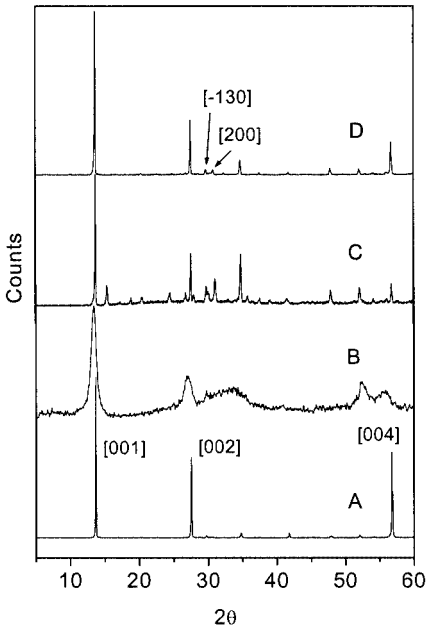

Figure 2. XRD diffraction patterns of $MnPS_3$ synthesized by: A) conventional heating of Mn + P + 3S (700 °C, 10 days); B) reaction of $Na_4P_2S_6$ with $MnCl_2$ in aqueous solution; C) MW-assisted reaction of 2Mn + P_2S_5 + S (30 min); D) MW-assisted reaction of Mn + P + 3S (25 min); traces A and D correspond to pure and highly crystalline $MnPS_3$, the differences between them being related to preferred orientations

Figure 3 shows the IR spectra (800−400 cm^{-1} region) of the reaction products obtained by the two methods that give the best results, that is, conventional heating and MW-assisted reactions involving the Mn + P + 3S mixture. The similarity between the compounds prepared by the two procedures is again evidenced by their coincidence in frequency and intensity of the IR absorption bands, the most characteristic of them appearing in the 700−400 cm^{-1} spectral region. According to Mathey and co-workers,[17] and Joy and Vasudevan,[18] the strong intensity band that appears at 573 cm^{-1} is attributed to P−S stretching vibrations $\nu_{P-S}(PS_3)$, whereas the ν_{P-P} vibration band appears at 440 cm^{-1}.

SEM images of the $MnPS_3$ products obtained by both procedures, the conventional ceramic method, and MW-assisted reactions show crystals of lamellar shape and average particle sizes of about 100 and 20 μm, respectively (Figure 4). The differences in the crystal size can be attributed to the different nucleation and crystal growth rates achieved by MW or conventional heating.

The method of preparation of $MnPS_3$ compounds, with MW's and the Dewar ampoule reported above has also been successfully applied to the synthesis of $CdPS_3$ materials. This result indicates the ability to extend the procedure to other members of the MPS_3 family.

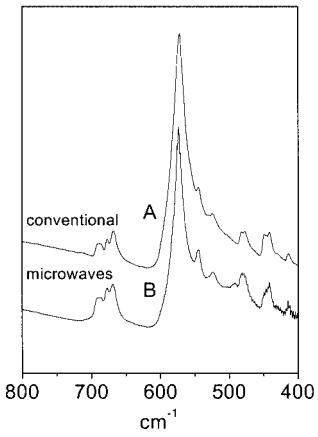

Figure 3. IR spectra (800−400 cm^{-1} region) of $MnPS_3$ obtained by: A) conventional heating of Mn + P + 3S (700 °C, 10 days); B) MW-assisted reaction of Mn + P + 3S (25 min)

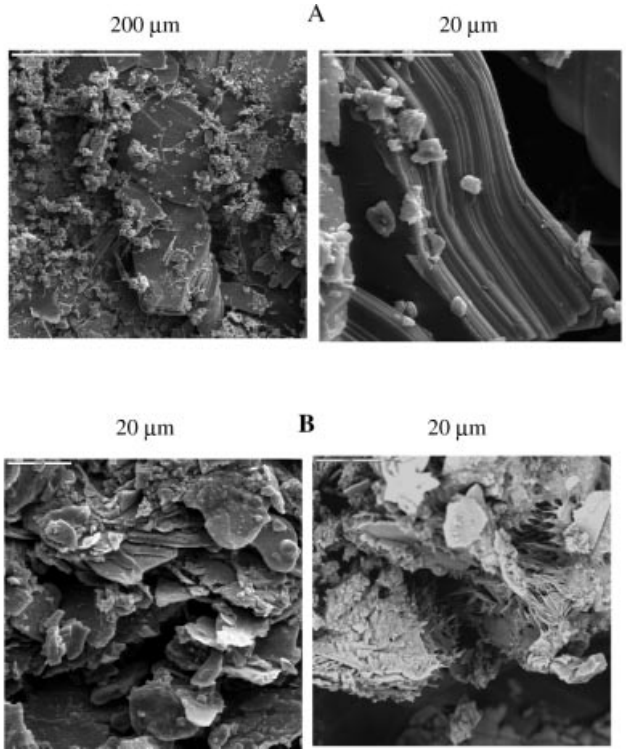

Figure 4. SEM images of $MnPS_3$ obtained by: A) conventional heating of Mn + P + 3S (700 °C, 10 days); B) MW-assisted reaction of Mn + P + 3S (25 min)

Conclusions

We have shown that a simple device such as the Dewar ampoule reported here, when used with an unmodified MW domestic oven, offers a new procedure to reach suitable temperatures(at least when small amounts of powdered metals are used) to allow the efficient and rapid synthesis of solids that are difficult to prepare by other routes, as it is the case of the MPS_3 compounds.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 1. MW synthesis of MPS_3 compounds (M = Mn, Cd) under different experimental conditions

Reactor	Starting reagents	Resulting products	Irradiation time	Emitted light
Conventional ampoule	Mn + P + 3 S	no reaction	1−60 min	no emission
Conventional ampoule	Cd + P + 3 S	no reaction	1−60 min	no emission
Conventional ampoule	2 Mn + P_2S_5 + S	no reaction	1−60 min	no emission
Dewar ampoule	Mn + P + 3 S	$MnPS_3$	25 min	purple-blue
Dewar ampoule	2 Mn + P_2S_5 + S	$MnPS_3$	30 min	pink-orange
Dewar ampoule	Cd + P + 3 S	$CdPS_3$	40 min	white-yellow

In addition, the method developed here could be extended to the preparation of other materials with similar synthetic problems, that is, in the cases where the dielectric component prevails over the metallic or semiconducting elements involved in the starting mixture lowering the efficiency of microwave-assisted procedures. This could be the case of different metal oxides, nitrides, carbides, etc.

Experimental Section

General: Conventional ceramic syntheses of MPS_3 materials were carried out as follows: a mixture of S, P and the transition-metal elements was ground in an glove box (Ar) and sealed in a classical quartz ampoule under a vacuum of 10^{-2} Torr. The ampoule was heated to 700 °C at 1 °C/min and maintained at this temperature for 10 days.[12]

Synthesis of MPS_3 Compounds: MPS_3 (M = Mn, Cd) crystals were also prepared by the Dewar ampoule method as follows: 0.3 g of the starting reagents, either as Mn (Aldrich, 99.9 %) or Cd (Aldrich, 99.5 %), P (Aldrich, 99.99 %) and S [(Aldrich) sublimed, 100 mesh, mixture, or as Mn, P_2S_5 (Aldrich, 99 %)] and S were thoroughly mixed in 1:1:3 or 2:1:1 molar ratios, respectively. The mixture was then transferred to the Dewar zone inside a glove box (Ar atmosphere). After vacuum degassing and hermetic flame sealing, the reactor was surrounded by quartz wool to provide insulation for high temperatures and protection against possible explosions (CAUTION!). In this manner, the mixture was MW-treated in a Moulinex Optiquick model (900 W, 2.45 GHz) during various periods of time (from 5 to 40 minutes) by steps of 1−2 minutes to avoid overheating effects that could produce damage. During the reaction, flashes of very intense visible light are produced, their color depending on the nature of the starting reagents (Table 1). The end of the reaction, which occurs after about 25−40 minutes, is clearly indicated by the extinction of the emitted light. At this time, only traces of residual reagents remain coating the bottom of the hot zone of the Dewar ampoule. The resulting MPS_3 compounds were characterized by X-ray diffraction (Siemens D-500 instrument with a Cu anode and Ni filter), IR spectroscopy (Nicolet 20SXC spectrophotometer), and electron microscopy (SEM) (ZEISS DSM-960 microscope working at 20 kV).

Acknowledgments

The financial support from the CICYT, Spain, (MAT2000−1585-C03−01) is gratefully acknowledged. We would like to express our gratitude to Tomás García-Somolinos for his helpful technical assistance in the Dewar ampoule development. We are indebted to Dr. M. A. Camblor for his helpful discussion and comments incorporated to this article.

A Novel Open-Framework Zinc Phosphite, $Zn_3(HPO_3)_4{\cdot}Ni(en)_2(H_2O)_2$, Templated by a Transition-Metal Complex

Zhi-En Lin,[a] Jie Zhang,[a] Shou-Tian Zheng,[a] and Guo-Yu Yang*[a]

Keywords: Open framework / Inorganic solid / Zinc / Nickel / Template synthesis

A new three-dimensional zinc phosphite, $Zn_3(HPO_3)_4{\cdot}Ni(en)_2(H_2O)_2$, which is the first example of an open-framework metal phosphite templated by a transition-metal complex, was hydrothermally synthesized. The connectivity of the strictly alternating ZnO_4 and HPO_3 units results in a three-dimensional framework with intersecting 8-ring and 12-ring channels, in which the transition-metal complexes reside.

Introduction

The research in the area of inorganic solids with regular-pore architectures is very intense due to the potential applications of these materials in ion-exchange, separation and catalysis.[1] Since the discovery of crystalline aluminophosphate molecular sieves in 1982,[2] much interest has been focused on open-framework metal phosphates because of their compositional diversity and rich structural chemistry.[3] The replacement of the tetrahedral phosphate group by a pyramidal phosphite unit has resulted in the preparation of a new class of compounds with interesting architectures, such as clusters,[4] chains, ladders,[5,6] or layers[7−9] and three-dimensional frameworks.[10−13] Clearfield reported $ZnCa(HPO_3)_2(H_2O)_2$ and $ZnSr(HPO_3)_2(H_2O)_2$ as the first members of open-framework metal phosphites.[14] Harrison reported the synthesis and structure of $[NH_2(CH_2)_2NH_2]_{0.5}{\cdot}ZnHPO_3$, which possesses an unprecedented architecture of two interpenetrated, independent, mixed inorganic-organic networks.[15] Very recently, a ladderlike chromium phosphite, $(C_2H_{10}N_2)[Cr(HPO_3)F_3]$, which is the first organically templated M−P−O compound containing Cr^{III}, has been successfully isolated by Rojo and co-workers.[16] Generally, these materials are synthesized from organic templates under mild hydrothermal conditions to avoid the formation of dense phases.

The employment of metal complexes as structure-directing agents is promising for the design and synthesis of new open-framework compounds with unusual architectures. Compared with organic molecules, metal complexes possess several unique features. First, they can adopt conformations that are difficult to achieve with organic molecules. Second, the wide range of oxidation states of metal ions endows the complexes with properties that are not found in organic molecules. In addition, the use of a chiral metal complex as a templating agent may give rise to a chiral open-framework compound. However, open-framework solids templated by metal complexes are rare.[17−26] This is in part due to the inadequate stability of metal complexes under the hydrothermal conditions needed for framework synthesis. Here we describe the synthesis and structure of a novel open-framework zinc phosphite, $Zn_3(HPO_3)_4{\cdot}Ni(en)_2(H_2O)_2$ (denoted FJ-8; FJ: Fujian Institute of Research on the Structure of Matter), which is the first example of an open-framework metal phosphite templated by a metal complex.

Results and Discussion

FJ-8 was synthesized under hydrothermal conditions in the presence of $Ni(en)_3^{2+}$ complexes as structure-directing agents. Single-crystal X-ray analysis indicates that FJ-8 possesses a three-dimensional open framework containing 8-ring and 12-ring channels along the [101] and [010] directions, respectively. The asymmetric unit of FJ-8 contains 30 non-hydrogen atoms, of which 19 belong to the host network and 11 to the guest-metal complex (see Figure 1). There are three crystallographically distinct Zn atoms and four crystallographically distinct P atoms. The zinc atoms are tetrahedrally coordinated by oxygen atoms with Zn−O bond lengths in the range of 1.905(6)−1.965(6) Å. The O−Zn−O angles are in the range of 96.9(3)−116.5(3)°. Each phosphorus atom shares three oxygen atoms with adjacent Zn atoms [P−O: 1.485(7)−1.529(6) Å] and the fourth ligand is a terminal P−H bond. The existence of

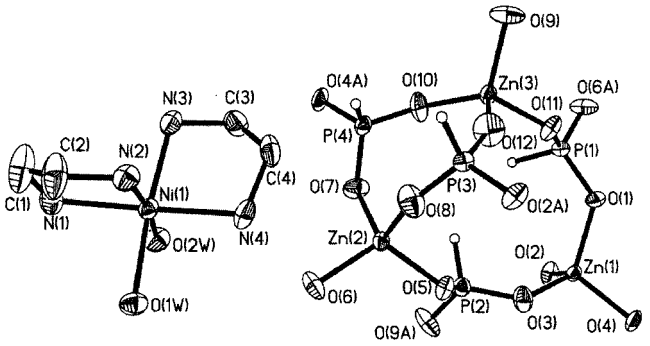

Figure 1. ORTEP view of the asymmetric unit of FJ-8, showing the labeling scheme and the 50 % probability displacement ellipsoids; atom labels with "A" refer to symmetry-generated atoms

P−H bonds is also confirmed by the band in the IR spectrum, which is characteristic of phosphite groups [ν(H−P) 2380 cm^{-1}]. The stoichiometry of $[Zn_3(HPO_3)_4]$ results in a net charge of −2, which is balanced by one $[Ni(en)_2(H_2O)_2]^{2+}$ cation.

The structure of FJ-8 is constructed from strictly alternating ZnO_4 tetrahedra and HPO_3 pseudopyramids that form a three-dimensional framework. There are two types of intersecting channels with different ring-aperture. The smaller one has an eight-membered ring and runs along the [101] direction with a diameter of 6.1 × 7.5 Å (see Figure 2). This channel is intersected by a larger channel with a 12-membered ring. The 12-membered window is somewhat puckered and the diameter of the channel is nearly 8.1 × 9.9 Å (see Figure 3).

The "openness" of a structure is defined in terms of its polyhedral-atom density (framework density, FD), defined as the number of polyhedral atoms per 1000 $Å^3$. The FD value in the structure of FJ-8 is 13.2, which indicates that the openness of this structure is similar to aluminosilicate molecular sieves such as ZSM-3 and ZSM-20.[27]

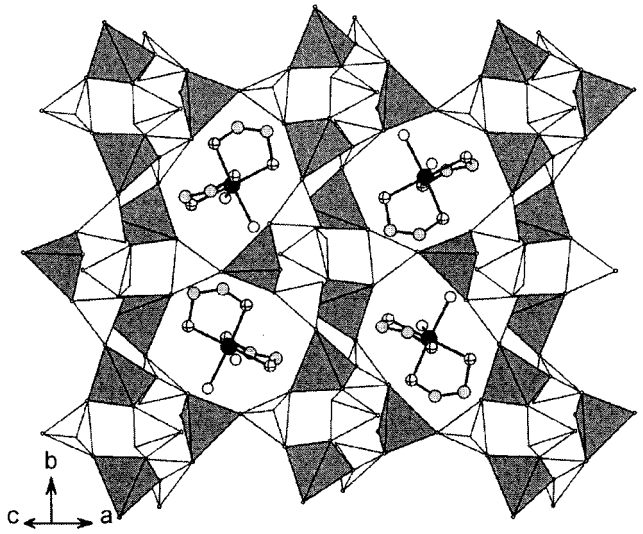

Figure 2. Polyhedral view of the structure of FJ-8 along the [101] direction showing the 8-ring channels; ZnO_4, medium-gray tetrahedra; HPO_3, white pseudopyramids

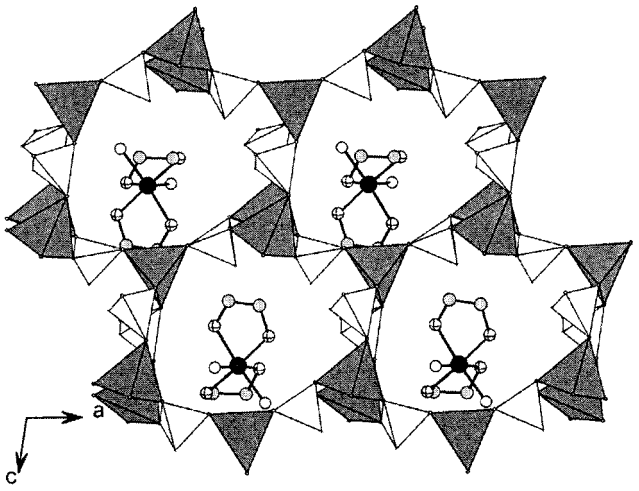

Figure 3. Polyhedral view of the structure of FJ-8 along the [010] direction showing the 12-ring channels; ZnO_4, medium gray tetrahedra; HPO_3, whitepseudo pyramids

The $[Ni(en)_2(H_2O)_2]^{2+}$ cations reside in the "free" space of the intersecting channels. This nickel complex is formed under hydrothermal conditions by the replacing one ethylenediamine ligand in $[Ni(en)3]^{2+}$ with two water molecules. Interestingly, the $[Ni(en)_2(H_2O)_2]^{2+}$ complex possesses two kinds of ligands: ethylenediamine and water. This structural feature is quite different from that of other metal complexes used in the synthesis of open-framework phosphates, as the latter contain only one type of ligand in a particular structure. There is extensive hydrogen bonding in the structure. The complex cations interact with the inorganic framework through strong H-bonds such as O(1 W)-H(5)···O(5) 2.24 Å, O(1 W)-H(6)···O(2) 2.17 Å, O(2 W)-H(7)···O(7) 2.23 Å, O(2 W)-H(8)···O(1) 2.08 Å, N(1)-H(9)···O(9) 2.61 Å, N(2)-H(12)···O(4) 2.30 Å, N(3)-H(13)···O(11) 2.17 Å, N(3)-H(14)···O(4) 2.48 Å, and N(4)-H(16)···O(6) 2.22 Å.

The initial thermogravimetric analysis, performed under flowing N_2, shows a three-step weight loss. The initial weight loss, between 160 and 230 °C, corresponds to the release of water ligands (observed 4.83 %; expected 4.92 %). The second step, occurring between 300 and 500 °C, is due to the partial departure of the ethylenediamine ligands (observed 9.62 %; expected 16.44 %). The lower value is probably due to the retention of ethylenediamine molecules in the solid residue. The last step, at 760 °C, with a mass loss of 7.18 %, is assigned to the removal of the residual ethylenediamine species. To examine the thermal stability of FJ-8 in the absence of water ligands, a sample of FJ-8 was heated in a thermal gravimetric apparatus at 230 °C for 1 h. Powder X-ray diffraction measurements for the dehydrated product showed that the structure collapsed and an unidentified phase was formed.

Conclusion

The hydrothermal synthesis of a novel three-dimensional open-framework zinc phosphite with the formula

$Zn_3(HPO_3)_4{\cdot}Ni(en)_2(H_2O)_2$ and its crystal structure were described. The structure consists of ZnO_4 and HPO_3 units, which are linked through their vertices to form a three-dimensional framework with intersecting 8-ring and 12-ring channels, in which the structure-directing agents reside. This compound is unusual because it is the first instance of an open-framework metal phosphite templated by a transition-metal complex. The use of other transition-metal complexes, such as $[Co(en)_3]^{2+}$ and $[Ni(1,3\text{-}DAP)_3]^{2+}$, in similar hydrothermal systems may result in other novel open-framework metal phosphites. Further work on this subject is in progress.

Experimental Section

Synthesis and Initial Characterization: FJ-8 was hydrothermally synthesized under autogenous pressure. In a typical synthesis, a mixture of ZnO (0.093 g, 1.14 mmol), H_3PO_3 (0.3 mL, 50 wt %), $Ni(en)_3Cl_2{\cdot}2H_2O$ (0.395 g, 1.14 mmol) and H_2O (2.5 mL) in a molar ratio of 1·2·1·130 was stirred under ambient conditions. The resulting gel was sealed in a Teflon-lined steel autoclave and heated at 160 °C for 7 days and then cooled to room temperature. The resulting product, consisting of single crystals in the form of light-purple prisms, was recovered by filtration, washed with distilled water and air-dried. Yield: 0.064 g, (23 % yield based on ZnO). The XRD powder pattern is in accord with the structure simulated on the basis of the single-crystal X-ray analysis, indicating phase purity. Inductively coupled plasma (ICP) spectrometric analysis gave the contents of Zn (calcd. 26.83 wt %; found 25.17 wt %), P (calcd. 16.95 wt %; found 15.41 wt %) and Ni (calcd. 8.03 wt %; found 7.86 wt %) and indicated a Zn:P:Ni ratio of 3:4:1. $C_4H_{24}N_4NiO_{14}P_4Zn_3$ (731.0): calcd. C 6.57, H 3.31, N 7.66; found C 6.48, H 3.26, N 7.61. IR (KBr): $\tilde{\nu}$ = 3345 s, 3280 s, 3274 s, 2960 m, 2890 m, 2380 s, 1680 m, 1605 m, 1465 m, 1095 s, 1020 s, 617 m, 590 m, 518 w cm^{-1}.

X-ray Crystallography: $C_4H_{24}N_4NiO_{14}P_4Zn_3$ (= FJ-8), M = 730.97, monoclinic, space group $P2_1/n$ (no.14), a = 9.9144(3), b = 14.4414(4), c = 14.9785(3) Å, β = 98.8870(10)°, V = 2118.84(10) $Å^3$, Z = 4, d = 2.291 g cm^{-3}, μ = 4.603 mm^{-1}, Mo-K_α radiation, λ = 0.71073 Å, 1.97 < θ < 25.09°. Crystal structure determination by X-ray diffraction was performed on a Siemens SMART CCD diffractometer with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation in the ω and φ scanning mode at room temperature. An empirical absorption correction was applied using the SADABS program. The structure was solved by direct methods using the SHELXL-97 software package and refined with full-matrix least-squares, leading to a convergence with final $R1$ = 0.0557, $wR2$ = 0.1186 and S = 1.152 for 287 parameters and 3713 unique reflections with $I \geq 2\sigma(I)$ [R(int) = 0.0336].

A Blue Photoluminescent 2-D Coordination Polymer Constructed by Dinuclear Zinc(II) Subunits $[Zn_2(oz)_2]$ [Hoz = 2-(2′-Hydroxyphenyl)-2-oxazoline] and Dicyanamide

Jing Zhang,[a,b] Song Gao,*[a] and Chi-Ming Che*[b]

Keywords: Zinc / Photoluminescence / Dinuclear subunit / Polymer / Thermal stability

Substitution of the terminal oz group of the dinuclear $[Zn(oz)_2]_2$ complex (**1**) with dicyanamide [where Hoz = 2-(2′-Hydroxyphenyl)-2-oxazoline] results in the formation of a 2-D coordination polymer $[Zn(oz)N(CN)_2]_n$ (**2**) based on $[Zn_2(oz)_2]$ subunits. Both compounds exhibit strong blue photoluminescence but the coordination polymer **2** has greater thermal stability than the dinuclear complex **1**.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Blue luminescent compounds have received considerable attention in recent years because of their potential applications in electroluminescent (EL) devices or light-emitting diodes (LED).[1] Since the realization of blue electroluminescence using poly(9,9-dihexylfluorene)[3a][3b] and poly(*p*-phenylene),[3c] intensive research in this area has been reported.[3d] Most of the reported examples are aromatic organic molecules, conjugated organic polymers,[1,2] organometallic compounds or metal−chelate compounds of Al^{III}, B(III), Zn^{II} or Cd^{II} based on 8-hydroxyquinoline,[4] methylquinolin-8-ol,[5] azomethine,[6] azaindole,[7] oxadiazole[8] and bipyridyl[9] ligands, while cases of condensed coordination polymers exhibiting blue luminescence are still rare. With the advantages of high thermal stability, good mechanical properties, versatile structures and relatively high emitting intensity (with respect to pure organic materials), blue luminescent coordination polymers have recently attracted significant interest.[10] Inspired by the electroluminescence research on the mononuclear complex of bis[2-(2-hydroxyphenyl)benzothiazolate]zinc $[Zn(BTZ)_2]$,[8a] we started using the ligand 2-(2′-hydroxyphenyl)-2-oxazoline, (Hoz), and dicyanamide anions as structural motifs to develop new blue luminescent coordination-polymers. Hoz has a smaller conjugated system than 2-(2-hydroxyphenyl)benzothiazolate, which may shift the emission wavelength of complexes with such a ligand to blue luminescence since fluorescent emission is dominated by the coordinated ligand. We herein describe the preparation, structural characterization and preliminary luminescence study of a dinuclear zinc complex $[Zn(oz)_2]_2$ (**1**) and a 2-D coordination polymer $[Zn(oz)N(CN)_2]_n$ (**2**) with the dinuclear $[Zn_2(oz)_2]$ fragment as subunit. The two dimer-based compounds may provide a model for studying the influence of the polymerization process upon luminescence and thermal stability.

Results and Discussion

Complex **1** was prepared by mixing $Zn(ClO_4)_2$, Hoz, and triethylamine in methanol in a 1:2:2 molar ratio. Colorless single crystals were obtained after the reaction solution was left to stand overnight at room temperature. Complex **2** was prepared by dissolving equimolar amounts of sodium dicyanamide, Hoz and triethylamine in methanol (20 mL) and then adding $Zn(ClO_4)_2$ in methanol (5 mL) to the solution. The reaction mixture was filtered and after one week colorless crystals appeared in the filtrate. The ORTEP drawing of **1** is shown in Figure 1. Complex **1** is dimeric with two discrete molecules per unit cell. The zinc atom is five-coordinate with three oxygen and two nitrogen atoms. One chelated terminal ligand provides one oxygen and one nitrogen atom, and the two bridging ligands provide a total of two oxygen and one nitrogen atom. The coordination sphere can be described as distorted trigonal-bipyramidal. The two zinc atoms in a discrete molecule are symmetrically related and connected by the O1 atoms of the bridging ligands. Compared with the previously reported mononuclear com-

plex $Zn(BTZ)_2$,[8a] the formation of the dinuclear motif in **1** may be caused by the smaller oz ligand and the existence of oxygen atoms acting as μ_2 bridges.

The zinc atoms in **2** display trigonal-bipyramidal geometry, as in **1**, with three nitrogen atoms, two of which are provided by terminal N atoms of different $[N(CN)_2]^-$ ligands and the other by the chelating oz ligand, and two oxygen atoms from two oz ligands. Hence, two oxygen atoms from two ligands bridging two symmetrically related zinc atoms form the dinuclear subunit. The ORTEP drawing of the dinuclear subunit is shown in Figure 2. Each subunit is further linked to four subunits through $\mu_{1,5}$ bridges of $[N(CN)_2]^-$ and each $[N(CN)_2]^-$ moiety acts as a bidentate spacer to coordinate to two zinc atoms with two nitrile nitrogen atoms. If the dinuclear units are viewed as connecting points, the structure can be simplified into a 2-D square-grid network (see **a** in Figure 3). Each square grid shares four $\mu_{1,5}$ $[N(CN)_2]^-$ groups as rhombic sides and four dimers as connecting nodes. The average distance between two parallel ligands from adjacent layers is 3.54 Å, indicating the existence of π−π stacking in the 3-D supramolecular architecture (see **b** in Figure 3).

The two complexes were further studied by thermogravimetric analysis, which showed that **1** began to lose weight at around 320 °C (see **a** in Figure 4) while **2** exhibited a higher decomposition temperature at 374 °C (see **b** in Figure 4).

The absorption spectrum of **1** in methanol at 298 K shows an intense low-energy band at λ_{max} = 337 nm, which is similar in energy to the absorption band (λ_{max} = 323 nm) of the deprotonated ligand oz^- in a KOH/MeOH solution (ca. 0.2 M; see Figure 5). Complex **1** is highly luminescent in methanol solution at 298 K and the emission maximum and quantum yield are 404 nm and 0.28 (quinine sulfate in

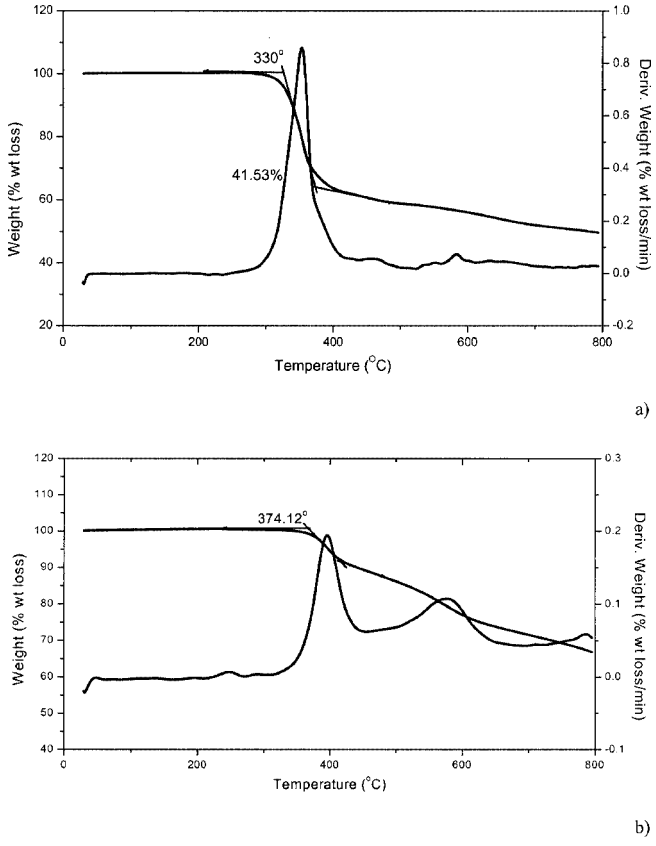

Figure 4. (a) TGA and DTGA curves of complex **1**; (b) TGA and DTGA curves of **2**

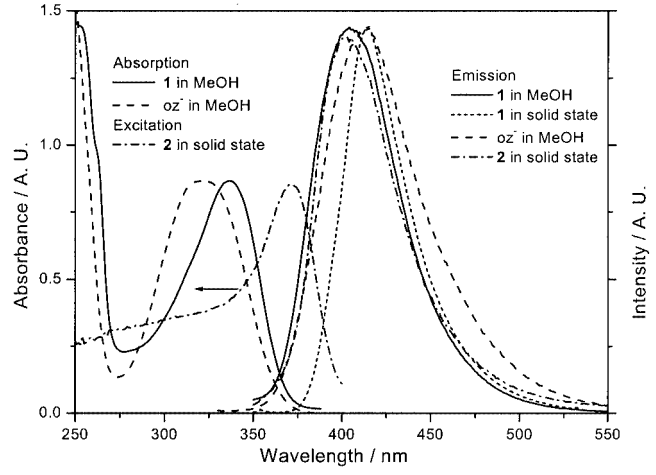

Figure 5. Absorption of the deprotonated oz^- ligand (λ_{ex} = 325 nm) and **1**, excitation of **2** (λ_{ex} = 430 nm) (left, the low-energy bands are normalized for comparison), and normalized emission (right) of the deprotonated oz^- ligand and **1** and **2** at 298 K (λ_{ex} = 325 nm)

similar in energy to that (emission maximum 415 nm, quantum yield 0.09) recorded for the deprotonated ligand oz^- in a KOH/MeOH solution (ca. 0.2 M; see Figure 5) but with a significantly higher quantum yield. These results indicate that the emission from complex **1** originates from the oz^- ligand and an intraligand charge-transfer excited-state is tentatively assigned. The emission enhancement from oz^- to complex **1** could be attributed to the coordination at the zinc atom, which presumably increases the structural rigidity and hence reduces the non-radiative decay-pathway for the excited state. The solid-state emission spectra of dimeric **1** and polymeric **2** (which is not soluble in common organic solvents) have also been recorded at 298 K and depicted in Figure 5. The emission energies (λ_{max} = 415 nm for **1** and 402 nm for **2**) are similar to that recorded for **1** in methanol solution at 298 K, suggesting that no new emissive species such as a $\pi-\pi^*$ excimer or exciplex are formed in the solid states.

Conclusion

Herein we reported the synthesis and photoluminescence study of a dinuclear zinc complex and a 2-D zinc coordination polymer containing dinuclear subunits. The two complexes exhibit similar ligand-centered fluorescence in the blue region. Incorporation of the dinuclear $[Zn_2(oz)_2]$ unit into a coordination polymer appears to improve the thermal stability while luminescence properties are not significantly modified.

Experimental Section

Colorless single crystals were obtained after the reaction solution was left to stand overnight at room temperature. $C_{36}H_{32}N_4O_8Zn_2$ (779.40): calcd. C 55.48, H 7.19, N 4.14; found C 55.24, H 7.25, N 4.17. IR (KBr): 2978(w), 2907(w), 1624(s), 1535(m), 1469(m), 1390(m), 1359(m), 1324(m), 1241(s), 1157(m), 1073(m), 951(m), 930(m), 847(m), 757(m), 689(m), 575(w), 535(w), 433(w) cm^{-1}.

Synthesis of $[Zn(oz)N(CN)_2]_n$ (2): Equimolar amounts of sodium dicyanamide, Hoz and triethylamine were dissolved in methanol (20 mL) and then $Zn(ClO_4)_2$ in methanol (5 mL) was added and the solution was filtered. After the filtrate was left at room temperature for one week, colorless crystals appeared. $C_{11}H_8N_4O_2Zn$ (293.58): calcd. C 45.00, H 2.75, N 19.08; found C 44.89, H 2.84, N 19.01. IR (KBr): 2977 (w), 2907 (w), 2339 (m), 2267 (m), 2198 (s), 1639 (s), 1555 (m), 1483 (s), 1384 (m), 1371 (m), 1323 (m), 1242 (s), 1159 (m), 1067 (m), 944 (m), 930 (m), 840 (m), 758 (m), 688 (m), 575 (w), 508 (w), 433 (w) cm^{-1}.

X-ray Crystallographic Determinations of 1 and 2: All the data collections were carried out on a Nonius Kappa CCD diffractometer with graphite-monochromated Mo-K_α radiation (0.71073 Å) at 293 K. Empirical absorption correction was applied to both cases. The structures were solved by direct methods and refined by a full-matrix least-squares technique based on F^2 using the SHELXL 97 program. All non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed by calculation positions and refined isotropically (see Table 1).

CCDC-221016 (**1**) and CCDC-221015 (**2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

On the Use of the Bis(diiodine) Adduct of 1,4-Dimethylperhydro-1,4-diazepine-2,3-dithione (Me_2dazdt) to Recover Liquid Mercury Producing [Hg(Me_2dazdt)I_2] in a One-Step Reaction

Francesco Bigoli,[a] Maria Cristina Cabras,[b] Paola Deplano,*[b] Maria Laura Mercuri,[b] Luciano Marchiò,[a] Angela Serpe,[b] and Emanuele F. Trogu[b]

Keywords: Mercury / S ligands / Iodine / Adducts / Oxidation

Diiodine adducts with cyclic dithio-oxamides, where complexing and oxidising properties coexist in the same molecule, have been shown to be powerful oxidising reagents towards selected metals. Here we describe the reaction of Me_2dazdt·$2I_2$ [Me_2dazdt = 1,4-dimethylperhydro-1,4-diazepine-2,3-dithione (**1**)] with highly toxic liquid mercury which gives the complex [Hg(Me_2dazdt)I_2] (**2**) in a one-step reaction. X-rays analysis of **2** shows that the Hg^{II} centre is coordinated by two sulfur atoms of the chelating ligand and by two iodine atoms in a distorted tetrahedral geometry. The molecule is asymmetric and crystallizes in the chiral space group $P2_12_12_1$. In the unit cell only the M enantiomer is present [τ (S1–C1–C2–S2) = –61.1(5)°].

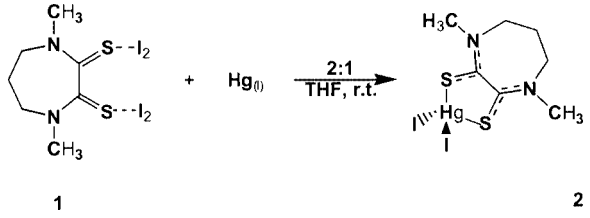
Introduction

Many efforts are currently devoted to find safe, non-polluting reagents which are effective for the dissolution of noble and heavy metals. The recovery of these metals has both environmental and economic relevance because of waste accumulation and simultaneous decrease of raw materials due to their extensive usage in novel technologies.[1] Diiodine adducts with appropriate donors, where complexing and oxidizing properties coexist in the same molecule, have a high potential to dissolve the above-cited metals under mild conditions.[2–4] Successful results have been obtained by our group using the bis(diiodine) adduct of 1,4-dimethylperhydro-1,4-diazepine-2,3-dithione [Me_2dazdt·$2I_2$ = (**1**)] to dissolve elemental gold in a one-step reaction, under mild conditions and in a short time.[5] Moreover, it is inert towards air and moisture and does not exhibit cytotoxicity.[6] These properties make this reagent an optimal candidate for such applications.[7] We are now employing this dissolution method towards highly toxic and heavy metals, with the view to remove them from waste from electronic equipment before disposal in order to prevent the metal dispersion into the soil. In this paper we show the reactivity of **1** towards liquid mercury which exhibits extremely high toxicity,[8] as well as great affinity for sulfur-donors.

Results and Discussion

[Hg(Me_2dazdt)I_2]

Me_2dazdt·$2I_2$ (**1**)[5] has been reacted with liquid mercury according to Scheme 1. Liquid mercury (24 mg) was consumed under the experimental conditions shown in Scheme 1 (2:1 adduct excess, room temperature, THF solvent) in approximately two hours. By Et_2O diffusion into the THF solution, well-formed, shiny, pale-yellow crystals precipitated in an almost quantitative yield.



1 2

Scheme 1

These crystals have been isolated and characterised as [Hg(Me_2dazdt)I_2] (**2**). The use of Me_2dazdt·$2I_2$ has allowed the oxidation and complexation of liquid mercury producing **2** in a very easy and convenient route, under mild conditions and through a one-step reaction. An X-ray dif-

[a] Symmetry = $-x + 1$, $y - 1/2$, $-z + 1/2$.

The mercury atom is in a severely distorted tetrahedral environment, coordinated by two iodine and two sulfur atoms of the chelating ligand. However, the Hg−S interatomic distances are significantly different [Hg−S1 = 2.554(1), Hg−S2 = 2.776(1) Å] as a consequence of a long contact between the metal and an iodine atom of an adjacent molecule [Hg−I1′ = 3.8188(5) Å] that renders the overall coordination geometry nearly trigonal bipyramidal with the equatorial positions occupied by the S1, I1 and I2 atoms. The lengthening of the Hg−S2 bond length is in accordance with the apical position occupied by S2 and by the *trans* influence of the iodine atom I1′. The I1′−Hg−S2 angle is significantly bent [150.07(3)°] and the S1−Hg−S2 angle is forced to be 82.37(4)° due to ligand chelation. The metal lies out of the S1−I1−I2 plane by 0.322(1) Å and is directed toward the S2 atom (cf. 0 Å for trigonal bipyramidal geometry and ca. 0.9 Å for tetrahedral coordination with average Hg−X bond lengths of ca. 2.7 Å). These main structural features are similar to those found in the complex $[Hg(bzimtH_2)_2I_2]$ ($bzimtH_2$ = benzo-1,3-imidazole-2-thione) where the mercury atom is similarly coordinated but the two sulfur atoms belong to two monothionic donors.[9] In other similarly coordinated complexes with heterocyclic thiones, shorter Hg−S interatomic distances and longer Hg−I interatomic distances were found and explained by considering the existence of different intermolecular interactions.[10,11] In the case of complex $[Hg(bzimtH_2)_2I_2]$, the long Hg−S interatomic distances were ascribed to the presence of NH···S interactions which were absent in complexes with shorter Hg−S interatomic distances.

In complex **2**, the C−S and the C−N interatomic distances of the two NCS fragments (Table 1) are in agreement with a strong electron delocalisation inside the thioamidic moieties as has been reported for similar systems.[12−15] Furthermore, no extension of the electron delocalization between the two planar thioamide groups is observed [C1−C2 1.507(6) Å]. The molecule is asymmetric and is therefore chiral. The S1−C1−C2−S2 torsion angle [−61.1(5)°] can be used to define the chirality of the molecular entity.[16]

The IR and Raman bands that are most significant in investigating the coordination mode of the Me_2dazdt ligand are ν(CN) and ν(C=S). In fact, sulfur donation should be accompanied by a shift to lower frequencies of ν(C=S) and simultaneously to higher frequencies of ν(CN).[17] Conflicting literature assignments of ν(C=S)[18−20] reflect difficulty in identifying this vibration, which may be extensively coupled with other vibrations and in several cases, this peak is not very sensitive to coordination.[21] Instead, the assignment of the ν(CN) is well established and can give useful information on the coordination of the ligand. Accordingly, the strong peak at $\tilde{\nu}$ = 1532 cm^{-1} in **2** ($\tilde{\nu}$ = 1530 cm^{-1} in **1**, 1493 cm^{-1} in the free ligand) is assigned to the ν(CN) vibration. A medium weak band ($\tilde{\nu}$ = 826 cm^{-1}) in **2** ($\tilde{\nu}$ = 824 cm^{-1} in **1**, 836 cm^{-1} in the free ligand) is tentatively assigned to ν(C=S). Thus, in accordance with X-ray results, vibrational spectroscopy shows that mesomeric forms involving CN double bonds contribute more than in the free ligand to the description of the structure of Me_2dazdt both in the adduct [ν(CN) = 1532 cm^{-1}] and in **2**. Therefore, when the sulfur atoms function as donors, the polar form of Me_2dazdt is favoured. Also, this contribution is very similar in the adduct and in the complex. Vibrational spectra of **2** in the Far-IR region are shown in Figure 2.

In **2**, a broad, very strong band centred ($\tilde{\nu}$ = 139 cm^{-1}) with shoulders (ca. $\tilde{\nu}$ = 150 and 125 cm^{-1}) appears in the Raman spectrum and in the IR spectrum ($\tilde{\nu}$ = 150 with a shoulder at 139 cm^{-1}). These overlapping bands are assigned to Hg−I vibrations (ν_{as} = 150 and 139 cm^{-1} and

ν_s = 125 cm^{-1}; Figure 2, a).[22] The two weak Raman peaks ($\tilde{\nu}$ = 333 and 318 cm^{-1}; the spectrum is dominated by very strong Hg−I vibrations) which appear in the Far-IR spectrum as a broad peak ($\tilde{\nu}$ = 332 cm^{-1} with a shoulder at 318 cm^{-1}) and are not present in the free ligand's spectrum, (Figure 2, b) are tentatively assigned to Hg−S vibrations.

Conclusion

Me$_2$dazdt·2I$_2$, [the bis(diiodine) adduct of 1,4-dimethylperhydro-1,4-diazepine-2,3-dithione] was shown to be a valuable reagent towards liquid mercury, capable of dissolving the highly polluting metal in a one-step reaction to form the complex [Hg(Me$_2$dazdt)I$_2$] under mild conditions and has been fully characterised. The effectiveness and ease of the reaction coupled with the low environmental impact of the reagent and the extremely high toxicity of the metal make the reported dissolution technique relevance to Hg-recovery.

Experimental Section

General: Reagents and solvents of reagent grade quality were used as furnished by Aldrich. The adduct Me$_2$dazdt·2I$_2$ (**1**) and the ligand Me$_2$dazdt were prepared according to literature procedures.[23,4]

Synthesis of [Hg(Me$_2$dazdt)I$_2$]: A Me$_2$dazdt·2I$_2$ solution (0.170 g, 0.24 mmol in 100 mL of THF) and liquid mercury (0.024 g, 0.12 mmol; 2:1 molar ratio) were mixed in a heterogeneous phase and allowed to react while stirring at room temperature for 2 h. The red-brown solution of the adduct developed into a clear orange-yellow solution. Shiny yellow crystals of [Hg(Me$_2$dazdt)I$_2$], suitable for X-ray analysis, were obtained by slow crystallization from THF/Et$_2$O, with quantitative yield referred to Hg. $C_7H_{12}HgI_2N_2S_2$ (642.7): calcd. C 13.08, H 1.88, N 4.36, S 9.98; found C 13.42, H 1.62, N 4.40, S 9.86. Mid-IR (KBr pellets, cm^{-1}): $\tilde{\nu}$ = 2955 vw, 2923 w, 2852 vw, 1532 vs, 1458 ms, 1440 w, 1398 s, 1358 w, 1331 w, 1287 ms, 1278 s, 1255 m, 1212 vw, 1184 w, 1118 s, 1074 w, 1028 w, 967 w, 826 w, 751 w, 695 vw, 613 mw, 591 w, 538 vw, 417 vw. Far-IR (Polyethylene pellets, cm^{-1}): $\tilde{\nu}$ = 418 ms, 406 ms, 383 mw, 377 mw, 332 ms, 296 w, 273 w, 234 w, 203 w, 170 m, 150 vs, 142 vs, 96 vw, 83 w, 56 m. Raman (cm^{-1}): $\tilde{\nu}$ = 2983 w, 2926 mw, 1526 mw, 1458 w, 1439 vw, 1400 mw, 1358 w, 1287 w, 1256 w, 1213 vw, 1184 vw, 1108 vw, 887 vw, 696 vw, 614 vw, 540 mw, 419 w, 334 w, 283 w, 164 sh, 150 sh, 139 vs, 127 sh, 121 sh, 86 m, 75 mw. UV-Vis (ε = L·mol^{-1}·cm^{-1}): λ = 290 sh (ca. 600) nm, 340 sh (ca. 500).

Measurements: Microanalyses were performed on a Carlo−Erba CHNS elemental analyser model EA1108. IR spectra (4000−50 cm^{-1}) were recorded as KBr (Mid-IR) and polyethylene (Far-IR) pellets with a spectrometer Bruker Equinox-55 (resolution 4 cm^{-1}). FT-Raman spectra were recorded on a Bruker RFS100/S FT-spectrometer, fitted with an InGaAs detector (room temperature) and operating with an excitation frequency of 1064 nm (Nd:YAG laser). The power level of the laser source was 100 mW. The solid samples were introduced into a capillary tube and then fitted into the compartment designed for a 180° scattering geometry (resolution 4 cm^{-1}). No sample decomposition was observed during data collection. Electronic spectra (1500−300 nm) were recorded on a Cary 5 spectrophotometer by using CH_3CN solvent. Polarimetric measurements were performed on a Polax-D instrument using a 10 cm cell.

X-ray Crystallographic Study: A summary of data collection and structure refinement for **2** are reported in Table 2. Single-crystal data were collected with a Bruker AXS Smart 1000 area detector diffractometer (Mo-K_α, λ = 0.71073 Å). Cell parameters were refined from the observed setting angles and detector positions of selected strong reflections. Intensities were integrated from several series of exposure frames covering a hemisphere of reciprocal space.[24] No crystal decay was observed. Absorption correction using the program SADABS[25] was applied and resulted in transmission factors ranging from 0.408−1.000. The space group ($P2_12_12_1$) was chosen on the basis of the systematic extinction and intensity statistics, the absolute configuration has been confirmed at the 3σ level of the Flack parameter [−0.012(4)].[26] The structure was solved by direct methods (SIR97)[27] and refined with full-matrix least-squares (SHELXL-97),[28] using the Wingx software package.[29] Non-hydrogen atoms were refined anisotropically; hydrogen atoms were placed at their calculated positions. The maximum and minimum peaks on the final difference Fourier maps corresponded to 0.806 and −1.040 e·Å^{-3}. The programs Parst [30,31] and ORTEP3 for Windows[32] were also used. CCDC-199303 con-

Synthesis of a Metallamacrocyclic $Re(CO)_3$ Complex Using a Tridentate Bridging Ligand

Thomas Brasey,[a] Andrey Buryak,[a] Rosario Scopelliti,[a] and Kay Severin*[a]

Keywords: Host−guest chemistry / Metallamacrocycles / Rhenium / Silver

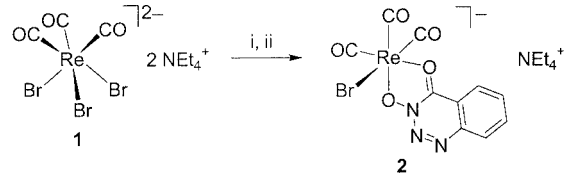
The reaction of $[ReBr_3(CO)_3][NEt_4]_2$ with 3-hydroxy-1,2,3-benzotriazine-4(3*H*)-one in the presence of base gave the ionic rhenium complex $[ReBr(C_7H_4N_3O_2)(CO)_3][NEt_4]$ (**2**) which was crystallographically characterized. A neutral metallamacrocycle **3** was obtained upon abstraction of $[NEt_4]Br$ from complex **2**. This complex cocrystallizes with an unusual C_3-symmetric $[Ag(\eta^2\text{-benzene})_3(OH_2)][BF_4]$ complex as evidenced by single-crystal X-ray diffraction.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The *fac*-$Re^I(CO)_3$ fragment has frequently been used as a building block for the construction of self-assembled metallomacrocycles,[1] some of which have found applications in the field of sensing[2] or catalysis.[3] For the synthesis of these macrocycles, bidentate ligands with N-heterocycles as donor groups were employed almost exclusively. We have recently shown that simple tridentate ligands with N,O,O′-donor atoms such 2,3-dihydroxypyridine[4] or 3,4-dihydroxy-2-methyl-pyridine[5] are well suited for the assembly of organometallic half-sandwich complexes of Ru^{II}, Rh^{III} and Ir^{III}.[6] In continuation of these studies, we have investigated the reaction of $[ReBr_3(CO)_3][NEt_4]_2$[7] (**1**) with 3-hydroxy-1,2,3-benzotriazine-4(3*H*)-one. Complex **1** was chosen as the starting material because the three bromo ligands can easily be replaced. When **1** is dissolved in water, for example, the thermodynamically stable[8] but kinetically labile[9] aqua complex $[Re(CO)_3(OH_2)_3]^+$ is formed. The benzotriazine derivative appeared to be a suitable reaction partner for the construction of a neutral metallamacrocycle because it can occupy the three available coordination sites by acting as a monoanionic, bridging chelate ligand.

Results and Discussion

A mixture of complex **1**, the ligand 3-hydroxy-1,2,3-benzotriazine-4(3*H*)-one and one equivalent of KOH was dissolved in methanol. After 12 h, the solvent was evaporated and the product was separated from the bromide salts by Soxhlet extraction with benzene. In this way we were able to obtain the adduct **2** in 72 % yield (Scheme 1). The infrared spectrum of **2** was characteristic of a $Re(CO)_3$ complex with strong bands in the carbonyl region at ν_{CO} = 2007 and 1855 cm^{-1}. The NMR spectra of **2** confirmed the presence of the benzotriazine ligand and the tetraethylammonium cation.



1 2

Scheme 1. Synthesis of complex **2**; (i) 3-hydroxy-1,2,3-benzotriazine-4(3*H*)-one, KOH (1 equiv.), MeOH, 12 h, r.t.; (ii) evaporation of MeOH and extraction with benzene

The structure of **2** was established by single-crystal X-ray analysis. The deprotonated benzotriazine derivative is coordinated by the two oxygen atoms to the Re atom (Figure 1). This is different from what has been observed for Ru- and Os-carbonyl complexes with this ligand; here a N−N′- or a N−O-coordination mode was found.[10] The third coordination site in **2** is still occupied by one bromo ligand, which is positioned *trans* to a carbonyl ligand, resulting in a negatively charged $Re(CO)_3$ complex. Due to the small bite angle of the chelate ligand, the octahedral geometry around the Re atom is slightly distorted.

In order to induce macrocyclization, the remaining bromo ligand of complex **2** was abstracted with $AgBF_4$ in methanol (Scheme 2). After crystallization from benzene/pentane, a product of the empirical formula $[Re(CO)_3(C_7H_4N_3O_2)]_n$ (**3**) was obtained. An alternative and simpler way to synthesize this complex is by suspending **2** in water followed by extraction of the product with diethyl ether (NEt_4Br remains in the aqueous phase).

The presence of the $Re(CO)_3$ fragment was confirmed by IR spectroscopy (ν_{CO} = 2026 and 1882 cm^{-1}). ^1H NMR

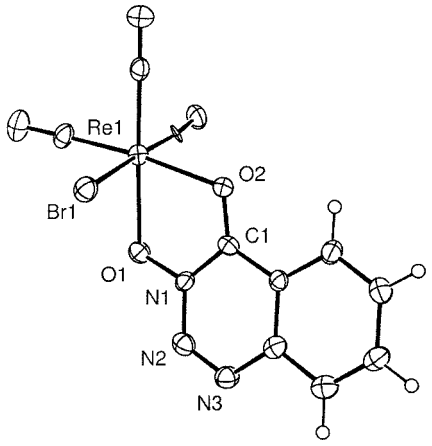

Figure 1. Molecular structure of complex **2** in the crystal; the $[NEt_4]^+$ cation and the CH_2Cl_2 molecule are not shown for clarity; selected bond lengths [Å] and angles [°]: Re1−O1 2.168(10), Re1−O2 2.163(9), Re1−Br1 2.6544(15), N1−O1 1.359(14), C1−O2 1.251(16); O1−Re1−O2 75.2(4), Br1−Re1−O1 83.9(3), Br1−Re1−O2 83.6(3)

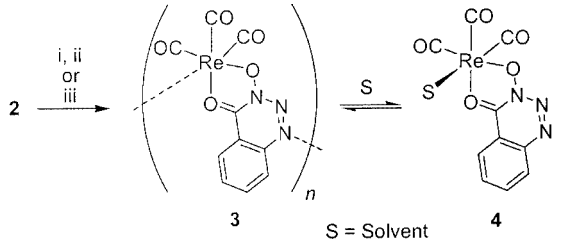

Scheme 2. Synthesis of the metallamacrocycle **3**; (i) $AgBF_4$ (1.1 equiv.), MeOH, 1 h, r.t.; (ii) crystallization from benzene/pentane; alternatively: (iii) separation with Et_2O/H_2O (yield: 80 %); in polar solvents such as methanol, the monomeric adducts **4** are formed

spectroscopic investigations in C_6D_6 were indicative of a highly symmetrical structure due to the presence of only one set of signals for the ligand. Unfortunately, we were not able to determine unequivocally the aggregation number of **3** with either mass spectrometry or single-crystal X-ray analysis, but based on the coordinate vectors of the benzotriazine ligand, a trimeric (see below) or tetrameric macrocycle seemed to be the most likely geometry.

When complex **3** is dissolved in coordinating polar solvents, both the NMR spectra as well as the UV-Vis spectroscopic data change substantially. In benzene, the macrocyclic complex **3** displays a maximum at $\lambda = 426$ nm, whereas in methanol the value is shifted to $\lambda = 373$ nm. A similar value is found in acetonitrile ($\lambda = 376$ nm). In C_6D_6, the signals for the benzotriazine ligand range from $\delta = 6.62-8.68$ ppm, whereas in CD_3OD the signals are confined to a region between $\delta = 7.92$ and 8.31 ppm (CD_3CN: 7.88−8.25 ppm). A plausible explanation of this data is that in coordinating solvents, we generate the monomeric solvent adducts **4** (Scheme 2). Such behaviour is not unprecedented: a solvent-dependent equilibrium between a dimer and a monomer has been described for $Re(CO)_3$ complexes with chelating $[NO]^-$ ligands.[11]

As a side product of the reaction between **2** and $AgBF_4$ (2 equiv.), we were able to isolate crystals of the macrocyclic compound **5** (ca. 5 % yield). As evidenced by X-ray crystallography, complex **5** contains an unusual C_3-symmetric $[Ag(\eta^2\text{-benzene})_3(OH_2)][BF_4]$ guest. A graphical representation of the structure is shown in Figure 2. The Re complex forms a trimeric metallamacrocycle. The $Re(CO)_3$ fragments are connected by the two O-atoms and the N1-atom of the benzotriazine ligand with the metal atoms being 7.066(2) Å apart from each other. To the best of our knowledge, this is the first structurally characterized macrocyclic $Re(CO)_3$ complex built with a tridentate chelate ligand. The noncovalent interactions with the guest molecule are of special interest. The metallamacrocycle forms a slightly concave cavity which has exactly the right size and symmetry to encapsulate the $[BF_4]^-$ anion.[12] On the other side of the macrocycle — and well shielded from the $[BF_4]^-$ anion — a $[Ag(\eta^2\text{-}C_6H_6)_3(OH_2)]^+$ complex is located. This cation represents one of the rare cases in which a $[Ag]^+$ ion is bound to three free arene ligands.[13] There are several examples of complexes containing the $[Ag(\eta^{1/2}\text{-arene})_3]^+$ structural motif, but here, chelating arene ligands such as cyclophane-type macrocycles were used to increase the stability of the complex.[14] The compound $[Ag(C_6H_6)_3][BF_4]$ on the other hand, is highly unstable: out of solution, it decomposes instantaneously even in an inert atmosphere (Figure 2).[13a]

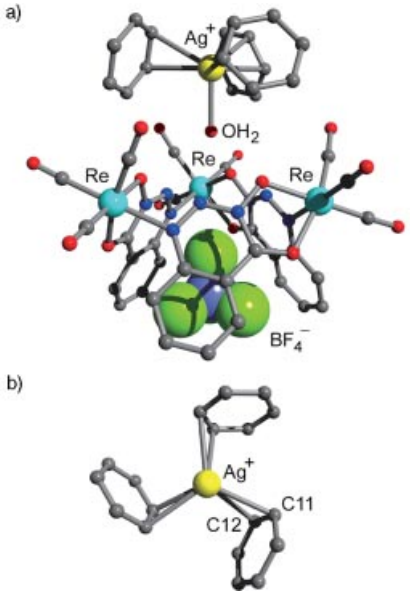

Figure 2. a) Graphic representation of the molecular structure of **5** in the crystal; the hydrogen atoms and a cocrystallized benzene molecule are not shown for clarity; b) view along the C_3-symmetry axis on the $[Ag(\eta^2\text{-benzene})_3]^+$ complex

The $[Ag]^+$ ion in complex **5** is situated on the symmetry axis and is thus coordinated to three benzene solvent molecules in a highly symmetrical fashion (Figure 2 b). In this context, it is interesting to note that the threefold symmetry was claimed to be unfavorable for $Ag(arene)_3$ coordination.[15] In view of our results, this statement appears to

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

be questionable. At least the energy difference between a symmetrical and a distorted geometry must be small since there are only weak packing effects, which can influence the geometry of the $[Ag]^+$ complex in **5**. The Ag−C distances found for **5** are within the expected range [Ag−C11: 2.623(18); Ag−C12: 2.612(17) Å]. A water molecule is bound to the fourth coordination site of the silver ion [Ag−O: 2.297(3) Å]. It is within expected hydrogen-bond lengths to the oxo-groups of the bridging benzotriazine ligand [O···O′: 3.112(18) Å] thereby connecting the silver complex with the $Re(CO)_3$-macrocycle.

Conclusions

In summary, we have described the synthesis and the structure of a new $Re(CO)_3$-containing metallamacrocycle which is able to act as a host for the unusual silver complex $[Ag(\eta^2\text{-}C_6H_6)_3(OH_2)][BF_4]$. In elaboration of previous approaches to construct $Re(CO)_3$ macrocycles, an anionic, tridentate chelate ligand was used to bridge the rhenium centers. It seems likely that this synthetic concept can be expanded by employing other organometallic fragments such as *fac*-$[M^{II}(allyl)(CO)_2]$ (M = Mo, W) or *fac*-$[Pt^{IV}(CH_3)_3]$ and/or by using structurally related anionic ligands. The synthesis and the host-guest chemistry of such complexes is currently being investigated in our laboratory.

Experimental Section

General: All reactions were performed under dry dinitrogen, using standard Schlenk techniques. Complex $[ReBr_3(CO)_3][NEt_4]_2$ (**1**) was prepared according to a literature procedure.[7] The ^1H and ^{13}C spectra were recorded on a Bruker Advance DPX 400 or a Bruker Advance 200 spectrometer with the residual protonated solvents (^1H, ^{13}C) as internal standards. All spectra were recorded at room temperature.

Synthesis of Complex 2: Complex $[ReBr_3(CO)_3][NEt_4]_2$ (770 mg, 1.0 mmol) was added to a solution of the ligand 3-hydroxy-1,2,3-benzotriazine-4(3*H*)-one (163 mg, 1.0 mmol) and KOH (2.0 mL of 0.496 M, 1.0 mmol) in methanol (25 mL). After 12 h, the solvent was removed under reduced pressure and the product was separated by Soxhlet extraction with benzene. Evaporation of the solvent gave 465 mg of complex **2** (72 %). IR: $\tilde{\nu}$ = 2007 (CO), 1855 (CO) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.30 (t, ^3J = 7 Hz, 12 H, CH_3, NEt_4), 3.32 (q, ^3J = 7 Hz, 8 H, CH_2, NEt_4), 7.68 (t, ^3J = 8 Hz, 1 H, aromatic CH), 7.78 (t, ^3J = 8 Hz, 1 H, aromatic CH), 8.08 (d, ^3J = 8 Hz, 1 H, aromatic CH), 8.24 (d, ^3J = 8 Hz, 1 H, aromatic CH) ppm. ^{13}C NMR ($CDCl_3$): δ = 10.7 (CH_3), 55.7 (CH_2), 121.4, 126.0, 130.8, 135.4, 137.0, 146.5, 157.8 (aromatic carbon atoms), 194.2, 198.6, 198.8 (CO) ppm. Crystals were obtained by slow diffusion of pentane into a solution of **2** in CH_2Cl_2. $C_{18}H_{24}BrN_4O_5Re{\cdot}1/3\ C_6H_6$ (668.56 g·mol^{-1}): calcd. C 35.93, H 3.92, N 8.38; found C 35.69, H 4.69, N 7.91.

Synthesis of Complex 3. Method A: A mixture of complex **2** (50 mg, 78 μmol) and $AgBF_4$ (17 mg, 88 μmol) was stirred in methanol (10 mL). After 1 h, the precipitate was filtered off and the solvent was evaporated. The product was then extracted with benzene. After evaporation of the solvent, the product was dried in vacuo (21 mg, 63 %). Crystals of complex **5** were obtained as a side product from benzene/pentane in reactions using a twofold excess of $AgBF_4$ with respect to complex **2**.

Method B: Complex **2** (50 mg, 78 μmol) is dissolved in a mixture of diethyl ether (10 mL) and H_2O (10 mL). The Et_2O phase was separated and washed two more times with H_2O (10 mL). After evaporation of the organic phase, the product was dried in vacuo (27 mg, 80 %). IR: $\tilde{\nu}$ = 2026 (CO) cm^{-1}, 1882 (CO). ^1H NMR (C_6D_6): δ = 6.62 (t, ^3J = 8 Hz, 1 H, aromatic CH), 6.82 (t, ^3J = 8 Hz, 1 H, aromatic CH), 7.63 (d, ^3J = 8 Hz, 1 H, aromatic CH), 8.68 (d, ^3J = 8 Hz, 1 H, aromatic CH) ppm. ^{13}C NMR ($C_6D_5CD_3$): δ = 122.12, 129.07, 130.03, 135.12, 138.09, 148.65 (aromatic carbon atoms; CO: n.o.) ppm. $C_{30}H_{12}N_9O_{15}Re_3{\cdot}H_2O{\cdot}Et_2O$ (1389.23 g·mol^{-1}): calcd. C 29.40, H 1.74, N 9.07; found C 29.13, H 2.04, N 9.14.

Crystallographic Data: Complex **2** × 0.5 CH_2Cl_2: $C_{18.5}H_{25}BrClN_4O_5Re$, M_r = 684.98 g·mol^{-1}, monoclinic, space group $P2_1/c$, a = 12.2500(8), b = 10.3793(5), c = 18.3764(14) Å; β = 96.137(6)°, V = 2323.1(3) Å^3, T = 140(2) K, Z = 4, μ = 7.102 mm^{-1}, λ = 0.71073 Å, 12362 measured reflections, 3865 independent reflections, R_{int} = 0.0499, R_1 [$I > 2\sigma(I)$] = 0.0697, wR_2 (all data) = 0.1662. Complex **5** × 3 C_6H_6: $C_{66}H_{50}AgBF_4N_9O_{16}Re_3$, M_r = 1978.43 g·mol^{-1}, rhombohedral, space group $R3c$, a = 20.8533(16), c = 26.492(3) Å, V = 9976.8(15) Å^3, T = 140(2) K, Z = 6, μ = 5.819 mm^{-1}, λ = 0.71073 Å, 19101 measured reflections, 3875 independent reflections, R_{int} = 0.1648, R_1 [$I > 2\sigma(I)$] = 0.0662, wR_2 (all data) = 0.1542. The benzene molecules have been constrained to regular hexagons with d(C−C) = 1.39 Å. Diffraction data were collected at 140 K, using Mo-K_α radiation and a Oxford Diffraction diffractometer with a kappa geometry and equipped with a Sapphire CCD detector. Data reduction was performed with CrysAlis RED 1.6.9.[16] Absorption correction was applied to all data sets using an empirical method (DIFABS).[17] Structure solutions were determined with ab initio direct methods.[18] All structures were refined using the full-matrix least-squares on F^2 with all non-H atoms anisotropically defined. The hydrogen atoms were placed in calculated positions using the "riding model" with $U_{iso} = a{\cdot}U_{eq}$(C) (where a is 1.5 for methyl hydrogen atoms and 1.2 for others, C is the parent carbon atom). Space group determination, structure refinement and geometrical calculations were carried out on all structures with the SHELXTL software package, release 5.1.[19] The graphical representation of the molecular structures of **2** was generated with the program ORTEP.[20] CCDC-216353 (for **2**) and -216354 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/const/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; Fax: (internat.) + 44-1223-336-033; or deposit@ccdc.cam.ac.uk).

Reactivity of Organoelement Subhalides of Gallium and Indium — Ga−Ga and In−In Bonds Bridged by Carboxylato Ligands

Werner Uhl*[a] and Abdelhakim El-Hamdan[a]

Keywords: Carboxylate ligands / Gallium / Indium / Subvalent compounds

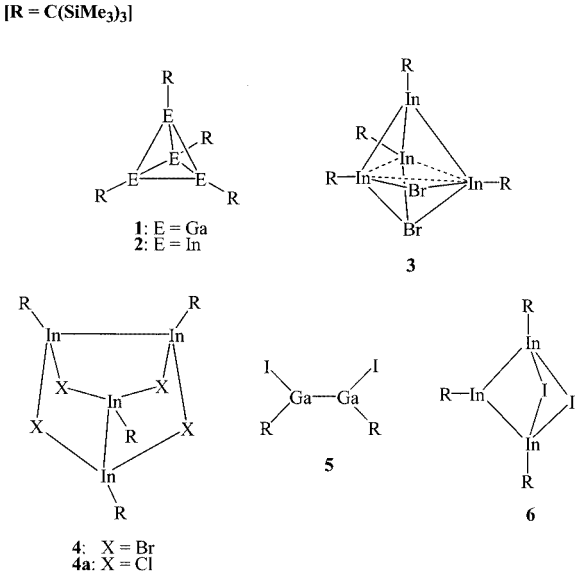
The organoelement subhalides $R_2Ga_2I_2$ (**5**) and $R_3In_3I_2$ [**6**; R = $C(SiMe_3)_3$] reacted with silver benzoate $AgOOCC_6H_5$ to yield the dicarboxylato dielement compounds $R_2E_2(\mu\text{-}OOCC_6H_5\text{-}O,O')_2$ (**7**, E = Ga; **8**, E = In). Both compounds possess E–E single bonds bridged by the chelating carboxylato ligands. The chelating groups are arranged perpendicular to one another. Owing to the small bite of the carboxylato group very short E–E bond lengths of 240.5 pm (Ga–Ga) and 265.4 pm (In–In) were observed.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Careful oxidation of the tetrahedral tetraelement clusters $Ga_4[C(SiMe_3)_3]_4$ (**1**)[1] and $In_4[C(SiMe_3)_3]_4$ (**2**)[2] (Scheme 1) with halogens or organic halogen donors yielded the corresponding subhalides still containing the elements gallium and indium in low oxidation states. The transfer of only one bromine molecule by the reaction of **2** with 1,2-dibromoethane gave the tetraindium compound **3** (Scheme 1), in which the overall tetrahedral arrangement of the In atoms is retained.[3] One face of the tetrahedron is bridged by a μ_3-Br atom, while the second Br atom is located above an edge of that particular face. Reaction with hexachloroethane, or mixtures of $AlBr_3$ and Br_2, yielded the diindium(II) compounds **4**, which contain localized In−In single bonds and form dimers through chlorine or bromine bridges.[3,4] The corresponding digallium(II) compound **5** was obtained by the reaction of **1** with ICl in the presence of AlI_3.[5] In contrast to the diindium compounds **4** it remains monomeric, even in the solid state. An average oxidation state of +1.66 was found for the central atoms of the triindium compound **6**, which possesses a chain of three In atoms connected by In−In single bonds and was obtained by the treatment of **2** with I_2/AlI_3.[6]

These subhalides should be suitable starting compounds for the generation of secondary products by salt-elimination reactions. In a first investigation, which is described here in detail, we employed silver benzoate as a reagent. The driving force of silver halide formation should favor these reactions, and the chelating carboxylato ligand should stabilize any secondary product by coordinative saturation of the Ga or In atoms. Dicarboxylatodigallium compounds containing a Ga−Ga single bond should result from the use of **5**.



Scheme 1

Similar products have previously been obtained in our group by another route when we treated tetraalkyldigallane(4) $R_2Ga-GaR_2$ [R = $CH(SiMe_3)_2$] with carboxylic acids. Two equivalents of bis(trimethylsilyl)methane were released in the course of these reactions, and two alkyl substituents were replaced by the chelating acid residues.[7,8] In contrast, similar diindium dicarboxylates are not accessible by such a reaction, which instead resulted in the quantitative cleavage of the In−In bond by oxidation of the In atoms.[9] Owing to the singular structure of the digallium compounds, which is discussed in detail below, the synthesis and characterization of the corresponding diindium derivatives was of particular interest. Indium subhalides seemed to be suitable starting compounds for their generation.

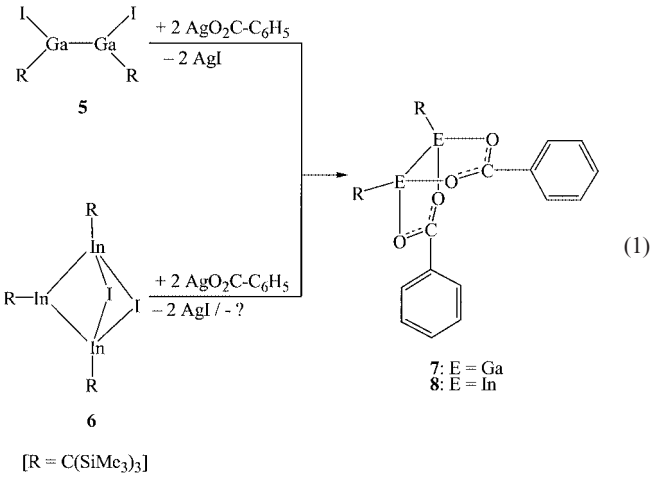
Results and Discussion

Syntheses of the Dicarboxylatodigallium and -diindium Compounds 7 and 8

Treatment of the digallium(II) diiodide $R_2Ga_2I_2$ (**5**) with a suspension of silver benzoate in toluene at low temperature yielded colorless crystals of **7**, after recrystallization of the crude product from cyclopentane, in an almost quantitative yield. The integration ratio of the ^1H NMR spectrum showed one phenyl group per alkyl substituent, as expected for the complete replacement of both iodine atoms by benzoato groups. The resonance of the methyl protons appears at $\delta = 0.52$ ppm, which is in the characteristic range of compounds containing a Ga−Ga single bond. The molecular structure of **7**, possessing an intact Ga−Ga bond, was verified by an X-ray crystal-structure determination (see below) and is shown schematically in Equation (1). Compound **7** is thermally rather stable, with a melting point of 222 °C.



(1)

We hoped to synthesize the corresponding diindium(II) carboxylate **8** by the treatment of the dimeric subhalide $(R_2In_2Br_2)_2$ (**4**) with silver benzoate under similar reaction conditions. However, elemental indium precipitated, and the course of the reaction was more complicated. Crystals of the colorless product **8** could be obtained in very small quantities only. Interestingly, the diindium dicarboxylate **8** was finally isolated in 74% yield when we treated the triindium diiodide $R_3In_3I_2$ (**6**) with silver benzoate at low temperature [Equation (1)]. The silver iodide precipitate became black even at low temperature and in the dark, which may be caused by the formation of elemental indium as a by-product. However, tris(trimethylsilyl)methane, a possible second product of a disproportionation reaction, could not be detected by NMR spectroscopy. Formation of the tetraindium cluster **2** as another possible side product could not be verified by NMR spectroscopy or its characteristic violet color, either. The crude product of the reaction shows two further $SiMe_3$ resonances at $\delta = 0.45$ and 0.41 ppm, which may result from secondary products of the disproportionation but could not be assigned unambiguously. Compound **8** is less stable than its digallium analogue and decomposes already at 158 °C with the formation of a red-brown solid.

Molecular Structures

Compounds **7** and **8** (Figure 1 and 2, respectively) contain a Ga−Ga or an In−In single bond terminally coordinated by two tris(trimethylsilyl)methyl groups and bridged by two carboxylato ligands. The bridging of metal-metal bonds by carboxylato groups is a quite common structural motif in transition metal compounds,[10] however, it is extraordinarily rare in main-group chemistry.[11] While Ga−Ga bonds bridged by carboxylato groups have been reported by our group previously,[7,8] the bridging of an In−In bond is observed for the first time in compound **8**. Owing to the relatively long In−In bonds compared to Ga−Ga distances, and the small bite of the chelating ligand, such a structure was totally unexpected. According to quantum-chemical calculations the terminal coordination of carboxylato groups is very unfavorable because of the rather high energy required for the deformation of the inner OCO angle.[8] Because of this inflexibility, a terminal arrangement, with the coordination of only one metal atom, leads to a relatively short distance between the inner carbon atom of the chelate and the Ga or In atoms, which results in considerable steric and electrostatic repulsion.

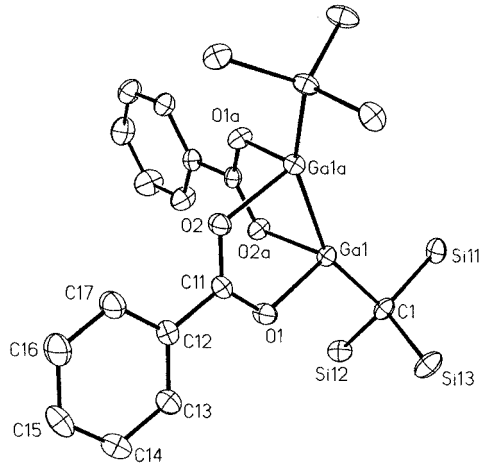


Figure 1. Molecular structure and numbering scheme of compound **7**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups are omitted for clarity; selected bond lengths (pm) and angles (°): Ga1−Ga1′ 240.48(7), Ga1−C1 198.9(2), Ga1−O1 200.6(1), Ga1−O2′ 202.9(1); C1−Ga1−Ga1′ 156.38(6), O1−Ga1−O2′ 91.90(6), O1−Ga1−Ga1′ 88.95(4), O2′−Ga1−Ga1′ 85.95(4); Ga1′ and O2′ generated by $-x, y, -z + 3/2$

The rigidity of the CO_2 backbone results in almost indistinguishable C−O bond lengths [127.1 pm (**7**) and 126.8 pm (**8**), on average] and O−C−O bond angles [124.7° (**7**) and 124.9° (**8**)]. Thus, the bite of the carboxylato ligands [225.2 pm (**7**) and 224.9 pm (av., **8**)] is almost the same in both compounds despite the very different covalent radii of gallium and indium. A strong strain must result, which causes short E−E bond lengths. While that of the digallium compound **7** (240.5 pm) is in the lower range of Ga−Ga single-

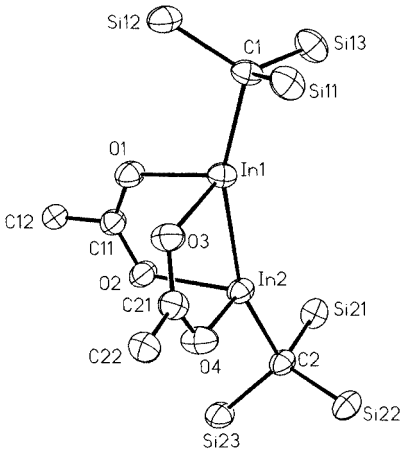

Figure 2. Molecular structure and numbering scheme of compound **8**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups are omitted for clarity; only the *ipso*-carbon atoms of the phenyl groups are shown; selected bond lengths (pm) and angles (°) [the atoms In3, In4, C3, C4, O5, O6, O7 and O8 belong to the second independent molecule not shown here]: In1−In2 265.44(9), In3−In4 265.38(8), In1−C1 217.2(2), In2−C2 216.7(2), In3−C3 217.0(2), In4−C4 216.9(2), In1−O1 222.8(2), In1−O3 222.8(2), In2−O2 221.6(2), In2−O4 221.1(2), In3−O5 221.4(2), In3−O7 222.8(2), In4−O6 222.4(2), In4−O8 221.3(2); C1−In1−In2 158.74(6), C2−In2−In1 161.07(6), C3−In3−In4 160.43(6), C4−In4−In3 160.50(6), O1−In1−O3 89.93(6), O2−In2−O4 90.77(7), O5−In3−O7 90.38(7), O6−In4−O8 90.79(7), O1−In1−In2 85.13(4), O3−In1−In2 83.58(4), O2−In2−In1 83.99(4), O4−In2−In1 85.53(5), O5−In3−In4 85.15(4), O7−In3−In4 83.41(4), O6−In4−In3 84.01(4), O8−In4−In3 85.63(5)

bond lengths reported for digallium(II) halides $Ga_2X_4(L)_2$,[12] for instance, and is similar to that of the starting subhalide **5** (240.1 pm), the bridging of the In−In bond forces a very close In−In contact in **8** of 265.4 pm, which, to the best of our knowledge, is the shortest value reported so far.[13] The In−In single bonds in the starting subhalides **4** and **6** (Scheme 1) are considerably longer (282 pm on average).[3,6] The longer E−E bond in **8** compared to **7** causes slightly more acute E−E−O angles of 84.6° (versus 87.5° in **7**) and larger E−O−C angles of 122.3° (119.3° in **7**). The carboxylato ligands of both compounds are arranged almost ideally perpendicular to one another (O−E−O 91.9° and 90.5°, respectively). In accordance with the almost linear C−E−E groups (156.4° and 160.2°), the particular bonding situation of these compounds is described by sp-hybridized Ga or In atoms[8] so that both E−O bonds are mainly formed by two *p*-orbitals of each central atom. The phenyl substituents in both compounds are almost ideally co-planar with the carboxylato groups (angles between the normals of the corresponding planes 2.1° in **7** and 1.4 to 6.9° in **8**).

Experimental Section

General: All procedures were carried out under purified argon in dried solvents (toluene and diisopropyl ether over Na/benzophenone; cyclopentane over $LiAlH_4$). The compounds $R_2Ga_2I_2$ (**5**)[5] and $R_3In_3I_2$ (**6**)[6] were synthesized according to literature procedures. Commercially available silver benzoate (99%; Aldrich) was employed without further purification.

Synthesis of $R_2Ga_2(\mu\text{-}O_2CC_6H_5\text{-}O,O')_2$ [7; R = $C(SiMe_3)_3$]: A suspension of silver benzoate (69 mg, 0.301 mmol) in 20 mL of toluene was cooled to −90 °C and treated with a solution of the diiodide **5** (129 mg, 0.151 mmol) in 10 mL of toluene. The mixture was stirred and slowly warmed to −65 °C. The precipitate was filtered off at −70 °C, and subsequently the solvent was removed in vacuo at room temperature. The yellowish solid residue was recrystallized from cyclopentane, cooling from 20 to −15 °C. Yield: 124 mg (97%), colorless crystals, m.p. (argon, sealed capillary): 222 °C. ^{1}H NMR (C_6D_6, 400 MHz, 298 K): δ = 0.52 (s, 27 H, $SiMe_3$), 6.99 (m, 3 H, phenyl), 8.30 (m, 2 H, phenyl) ppm. ^{13}C NMR (C_6D_6, 100.6 MHz, 298 K): δ = 5.0 (GaC), 5.5 ($SiMe_3$), 128.7 and 130.8 (*m*- and *p*-C of phenyl), 131.4 and 133.7 (*ipso*- and *p*-C of phenyl), 177.6 (CO_2) ppm. IR (CsBr, nujol): $\tilde{\nu}$ = 1597 w phenyl; 1526 m νCO_2; 1462 vs. paraffin; 1411 s δCH_3; 1377 vs. paraffin; 1306 w, 1260 s δCH_3; 1174 vw, 1126 m, 1096 s, 1025 s δCH, νCC; 858 vs, 805 s, 754 vw, 718 m ρCH_3(Si); 699 w, 684 w ν_{as}SiC; 639 vw, 625 vw ν_sSiC; 513 w, 468 w, 373 vw νGaC, νGaO.

Synthesis of $R_2In_2(\mu\text{-}O_2CC_6H_5\text{-}O,O')_2$ [8; R = $C(SiMe_3)_3$]: Silver benzoate (50 mg, 0.218 mmol) was suspended in 20 mL of toluene and cooled to −90 °C. The suspension was treated with a solution of the triindium diiodide **6** (138 mg, 0.107 mmol) in 15 mL of toluene. A black precipitate was formed immediately, which was filtered off at −70 °C. The solvent was removed in vacuo at room temperature. The colorless residue was recrystallized from diisopropyl ether, cooling from 20 to 8 °C. Yield: 82 mg (74%; **8**·O*i*Pr_2); colorless crystals which include up to one molecule of diisopropyl ether per formula unit of **8**; m.p. (argon, sealed capillary): 158 °C (dec.). ^{1}H NMR (C_6D_6, 400 MHz, 298 K): δ = 0.49 (s, 27 H, $SiMe_3$), 1.06 (d, $^3J_{H,H}$ = 6 Hz, 6 H, Me of *i*Pr_2O), 3.43 (sept, $^3J_{H,H}$ = 6 Hz, 1 H, CH of *i*Pr_2O), 7.03 (m, 3 H, phenyl), 8.33 (m, 2 H, phenyl) ppm. ^{13}C NMR (C_6D_6, 100.6 MHz, 298 K): δ = 5.6 ($SiMe_3$), 15.5 (InC), 23.0 (Me of *i*Pr_2O), 68.1 (CH of *i*Pr_2O), 128.5 and 130.6 (*m*- and *p*-C of phenyl), 132.8 and 133.1 (*ipso*- and *p*-C of phenyl), 176.6 (CO_2) ppm. IR (CsBr, paraffin): $\tilde{\nu}$ = 1592 w phenyl; 1528 m νCO_2; 1460 vs. paraffin; 1377 vs. paraffin; 1306 vw, 1260 s δCH_3; 1124 m, 1086 m, 1025 s δCH, νCC; 859 vs, 843 s, 804 m, 718 m ρCH_3(Si); 699 w, 680 w ν_{as}SiC; 654 vw, 614 vw ν_sSiC; 515 w, 460 m νGaC, νGaO.

Crystal-Structure Determinations: Single crystals of compounds **7** and **8** were obtained by cooling solutions in cyclopentane (−15 °C, **7**) or diisopropyl ether (8 °C, **8**). Crystal data and structure-refinement parameters are given in Table 1. The molecules of compound **7** reside on a crystallographic twofold rotation axis. They crystallize with two cyclopentane molecules per formula unit, which can easily be removed on evacuation. A slight disorder was observed for the $C(SiMe_3)_3$ group; owing to the small occupation factor of 0.055, only the silicon atoms were refined on split positions. Compound **8** crystallizes with two independent molecules in the asymmetric unit, which further comprises two diisopropyl ether molecules. A disorder was observed for the $C(SiMe_3)_3$ group at C4, all atoms were refined at split positions with occupation factors of 0.76 and 0.24. A minor disorder was further detected for the $C(SiMe_3)_3$ group at C2; owing to the small occupation of the second position (0.07), only the silicon atoms of the minor component were refined.

CCDC-218887 (**7**) and -218888 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cam-

Hybrid Cyclic Dimers of Divacant Heteropolyanions: Synthesis, Mass Spectrometry (MALDI-TOF and ESI-MS) and NMR Multinuclear Characterisation

Cédric R. Mayer,*[a] Maryline Hervé,[a] Hélène Lavanant,[c] Jean-Claude Blais,[b] and Francis Sécheresse[a]

Keywords: Polyoxometalates / Bridging ligands / Mass spectrometry / Organic-inorganic hybrid composites

In the field of organic-inorganic hybrid composites, functionalized polyoxometalates constitute a special class of inorganic nanobuilding blocks (NBBs). This study represents a first approach related to the formation of new oligomeric hybrid species based on the reaction of bis(electrophilic) groups with a divacant heteropolyanion as the NBB. Bis(phosphonates) such as *para*-$H_2O_3PCH_2(C_6H_4)_nCH_2PO_3H_2$ (n = 1 or 2) have been treated with the divacant heteropolyanion $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ to form the hybrid cyclic dimer $[H_2\{(SiW_{10}O_{36})(O{=}PCH_2(C_6H_4)_nCH_2P{=}O)\}_2]^{6-}$. MALDI-TOF and ESI mass spectrometry have been used as essential analytical techniques for the characterization of such composite systems.

Introduction

"Hybrid organic-inorganic" is an old concept but still represents a current challenge because it allows combination of the specific properties of organic and inorganic components in a unique system.[1] This concept has experienced a notable expansion, especially since soft inorganic chemistry processes have been applied to new inorganic nanobuilding blocks (NBBs) such as oligosilsesquioxane derivatives,[2] organotin−oxo clusters,[3] transition metal−oxo clusters,[4] functionalized polyoxometalates and functionalized nanoparticles.[5] These NBBs have been chosen to cover a large domain of sizes and structures. The degree of organization and properties that can be obtained for such composites closely depends on the synergy between and the chemical nature of the organic and inorganic moieties. Thus, these hybrids can be categorized into two main classes depending on the nature of the interface and interactions shared by both components.[6] Class I corresponds to systems where no covalent or iono-covalent bonds exist between the inorganic and organic moieties, and class II refers to systems linked through strong chemical bonds (covalent bonds). For both classes, the chemical strategy depends largely on the functionalization of the NBBs.

Among these inorganic NBBs, polyoxometalates (POMs) based on Mo or W constitute a special class. In fact, these metallic oxo clusters play a great role in important areas such as catalysis, electro- and photochromism, magnetism, and medicine. Recently, the development of ordered assemblies of POMs within hybrid organic-inorganic materials has undergone considerable expansion, due to a large variety of electronic, magnetic, redox and photonic properties.[7] The main hybrid materials described in the literature belong to class I, being of anionic character and most of them are derived from Keggin heteropolyanions.[8] On the other hand, the materials of class II have appeared only very recently.[9] Indeed, their synthesis requires a prior covalent functionalization. Three different methods can be used to functionalize POM blocks. The first one proceeds by surface activation of POMs, resulting in the localization of the charge density at the oxygen atoms on the surface which permits covalent bonding with organometallic fragments.[10] In the second method, (organoimido)polyoxometalates[11] are used while the last one is based on multivacant polyoxotungstates showing an increased anionic charge density at the oxygen atoms on the lacunary surface. The highly nucleophilic character of the oxygen atoms permits

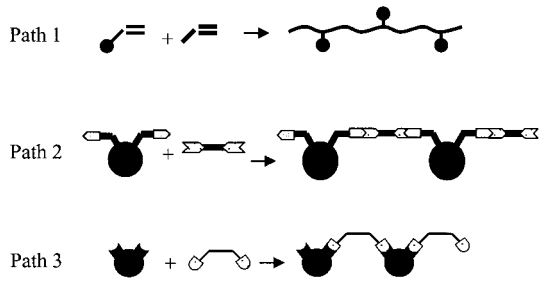
the covalent binding of electrophilic groups such as organotin groups[12] or organophosphorus groups.[13] A few hybrid materials have recently been described in class II by Maatta and co-workers who have reported (organoimido)-POMs as polystyrene pendants by co-polymerization of the monofunctional $[Mo_6O_{18}(NC_6H_4CH{=}CH_2)]^{2-}$ with a styrene monomer.[14] Mayer et al. have described the covalent entrapment in an organic matrix of [γ-$SiW_{10}O_{36}$(OSi−propyl methacrylate)$_4$]$^{4-}$ by radical co-polymerization resulting in the formation of a hybrid gel.[15]

This work is focused on the formation of a new cyclic hybrid POM by reaction of the divacant heteropolyanion $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ with two bis(phosphonate) groups, *para*-$H_2O_3PCH_2(C_6H_4)_nCH_2PO_3H_2$, where n = 1, 2. These systems have been characterized by a combination of multinuclear NMR spectroscopy (^{183}W, ^{29}Si and ^{31}P) and mass spectrometry (MALDI-TOF and ESI-MS).

Results and Discussion

Linear or cyclic hybrid polymers can be obtained in three main ways as shown in Scheme 1. The first path is the most commonly used and corresponds to the radical co-polymerization of monofunctional inorganic NBBs with an organic monomer. The second way concerns the polycondensation of bifunctional inorganic NBBs with a bifunctional organic precursor. A third possibility could be to treat an inorganic NBB containing two nucleophilic sites with a bis(electrophilic) group.



Scheme 1. Schematic structure of polymer hybrids: Path 1: radical co-polymerization of monofunctional inorganic NBBs with an organic monomer; Path 2: polycondensation of bifunctional inorganic NBBs with a bifunctional organic precursor; Path 3: reaction of an inorganic NBB containing two nucleophilic sites with a bis-electrophilic group

We have focused our attention on the last method, starting from the divacant heteropolyanion $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ and two types of bis(phosphonates). The choice of divacant POM was motivated by the ability of the four oxygen atoms of the vacancy to react with electrophilic phosphonate groups. This reaction was expected to lead to only one bifunctionalized POM.[16] Moreover, in recent works, this POM has been shown to be a good inorganic NBB precursor.[17,18] The choice of two bis(phosphonate) precursors, *para*-xylylenebis(phosphonate) (**LI**) and the homologue with a supplementary aromatic group (**LII**), was selected in order to check the influence of their organic chain lengths and to prevent the attachment of the two ending {$-PO_3$} groups to the same POM. The synthesis of these bis(phosphonates) proceeds through an Arbuzov reaction, the two terminal halide ligands are first transformed into {$-PO_3Et_2$} groups,[19] then hydrolyzed into acid functions. Hybrid systems have been obtained from the reaction of 1 equiv. of $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ suspended in acetonitrile with 1 equiv. of bis(phosphonate) previously dissolved in a mixture of dimethylformamide and hydrochloric acid. Tetrabutylammonium bromide was used as transfer agent. After subsequent purification, the oligomer was characterized by several techniques including multinuclear NMR spectroscopy (^{183}W, ^{29}Si and ^{31}P) and mass spectrometry (MALDI-TOF and ESI-MS). Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF), in particular, has been already used with success for the characterization of two organosilyl derivatives of POMs.[20] To the best of our knowledge, however, electrospray ionization mass spectrometry (ESI-MS) has never been performed on these types of inorganic NBBs although it has recently been utilized for lacunary Keggin-type POMs.[21]

Upon proton decoupling each ^{31}P NMR spectrum showed only one resonance attributable to the RPO groups. These single lines display satellites corresponding to the heteronuclear couplings $^2J(^{183}W\text{-}^{31}P)$ = 10.1 Hz for **LI** and 10.3 Hz for **LII**, respectively, as expected for the symmetric attachment of phosphonates groups to the polyanionic surface. No free phosphonate ligands were observed in the solution NMR spectra. The ^{183}W NMR spectra each exhibit three lines with relative intensities of 1:2:2 (Figure 1). The most shielded resonances appear as doublets due to the heteronuclear phosphorus-tungsten couplings $^2J(^{183}W\text{-}^{31}P)$ = 10.2 Hz (for **LI**) and 10.8 Hz (for **LII**), respectively, as already observed in the ^{31}P NMR spectra. These features confirm that the $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ framework has retained its original C_{2v} symmetry after two organophosphonate units have been attached to the surface. Moreover, the shifting of the lines is quite close to that already observed for [γ-$SiW_{10}O_{36}(RPO)_2]^{4-}$ species.[16] Homonuclear tungsten-tungsten couplings were also observed and are presented in

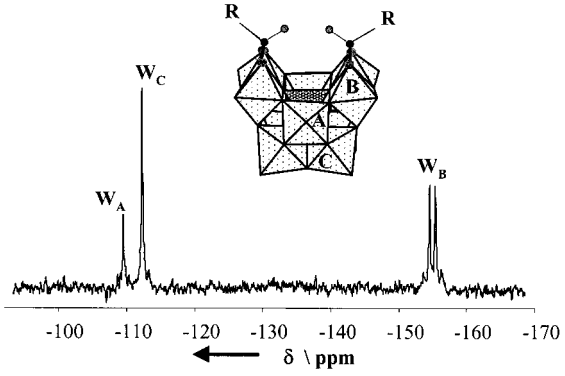


Figure 1. ^{183}W NMR (12.5 MHz) spectrum of **DII**, with a polyhedral representation of the polytungstate framework showing the three types of equivalent tungsten atoms

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the Exp. Sect. Here, for simplification purposes, we use the symbolism used in previous works for these types of functionalized POMs, as illustrated in Figure 1.[16,20] The line with a relative intensity of 1 was assigned to the W(C) atoms, the most shielded line with heteronuclear coupling to the W(B) atoms and the last line to W(A) atoms. ^{31}P and ^{183}W NMR spectroscopic data suggest that a cyclic species has been obtained, containing at least two POMs interlinked by bis(phosphonate) ligands. Thus, two RPO groups could be covalently attached on the lacunary surface through P−O−W bridges, the C_{2v} symmetry of the starting POM being conserved. At this stage, however, nothing is known about the degree of oligomerization of the hybrid.

In order to check whether ESI-MS could be used reliably to determine the structures of the composites, we first performed analyses on $[Bu_4N]_3[\gamma\text{-}SiW_{10}O_{36}(PhPO)_2]$ (noted **$[H(NBu_4)_3M]$**) used as a standard since it has already been fully characterized by X-ray diffraction methods.[16] The mass spectrum obtained from a 10^{-4} M solution in acetonitrile in the negative ion mode is shown in Figure 2 (a). Two signals have been detected at *m*/*z* = 896.7 and 1468.6 which have been attributed to **$[HM]^{3-}$** (calcd. *m*/*z* = 897.2) and **$[H(NBu_4)_1M]^{2-}$** (calcd. *m*/*z* = 1467.1), respectively. Although the presence of many tungsten atoms leads to a wide isotopic distribution with a Gaussian shape, in our case the resolution of the mass analyzer did not allow this distribution to be resolved and only rather large peaks representing an envelope of this distribution could be detected. The *m*/*z* values measured thus correspond to the centroid of the distribution which roughly amounts to an average molecular weight. Noticeably, no M^{4-} species were detected since a proton seemed to be strongly bound, probably through a P−O−H−O−P bridge between two terminal oxygen atoms of two {−P=O} groups. The presence of such a bound proton was also deduced from X-ray diffraction data.[16] It is quite usual in ESI-MS to detect a collection of multiply charged ions of different charge states corresponding to the attachment of various counterions. Here, the presence of two signals confirms the charge states as well as a double determination of the mass of the compound analyzed. In fact, in spite of the multiplicity of the signals, the interpretation of the mass spectrum remained straightforward, particularly since no fragmentation was observed.

The negative ion mass spectrum of the oligomer synthesized in this study is presented in Figure 2 (b), showing for the system based on **LII** three peaks at *m*/*z* = 905.5, 1135.5 and 1481.7. These signals were attributed to **$[H_2D]^{6-}$** (exp. *m*/*z* = 905.5, calcd. *m*/*z* = 905.9), **$[H_2(NBu_4)_1D]^{5-}$** (exp. *m*/*z* = 1135.5, calcd. *m*/*z* = 1135.6) and **$[H_2(NBu_4)_2D]^{4-}$** (exp. *m*/*z* = 1481.7, calcd. *m*/*z* = 1480.1), respectively, where D corresponds to the dimeric anion $[\{(SiW_{10}O_{36})[O=PCH_2(C_6H_4)_2CH_2P=O]\}_2]^{8-}$. The highest charge state detected was 6−, *two* protons are necessarily bound to the polyanion. The sterically improbable monomeric ions **$[HM]^{3-}$** and **$[H_2(NBu_4)M]^{2-}$**, where M is $\{(SiW_{10}O_{36})[O=PCH_2(C_6H_4)_2CH_2P=O]\}^{4-}$, would have the same *m*/*z* values of 905.5 and 1480.1, respectively. The presence of a peak at *m*/*z* = 1135.5 undoubtedly confirms the charge states to be from 6− to 4− rather than 3− and 2−.

MALDI-TOF mass spectrometry was also performed to seek confirmation of the dimerization as it usually yields mostly singly-charged species. The mass spectrum obtained in the positive ion mode presents several peaks in the region of *m*/*z* = 6000−8000 [Figure 3 (a) and (b)], regularly spaced with 242.5 u, corresponding to the mass of the Bu_4N^+ counterion. These peaks were therefore assigned to the cationic entities $[D + x\ Bu_4N + (8 - x)\ H]^+$, with D corresponding to the mass of *two* $\{SiW_{10}O_{36}\}$ units and *two* $\{O=PCH_2(C_6H_4)_nCH_2P=O\}$ units (*n* = 1, 2). These observed experimental values are consistent, within the experimental accuracy estimated as ±2 u in the *m*/*z* = 6000−8000 range, with the calculated masses for the different cations as shown

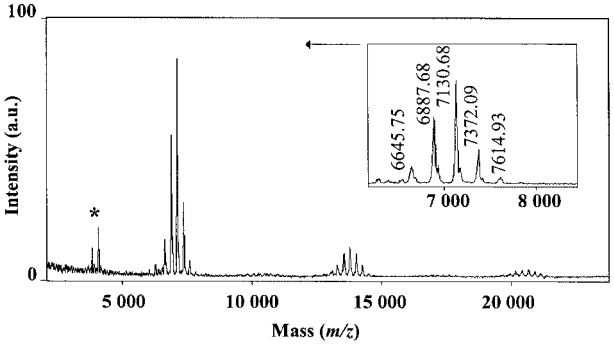

Figure 3. Positive ion MALDI-TOF mass spectra of **DII** and expansion of the *m*/*z* = 6000−8000 region, the asterisk indicates $[SiW_{12}O_{40}]^{4-}$ impurity

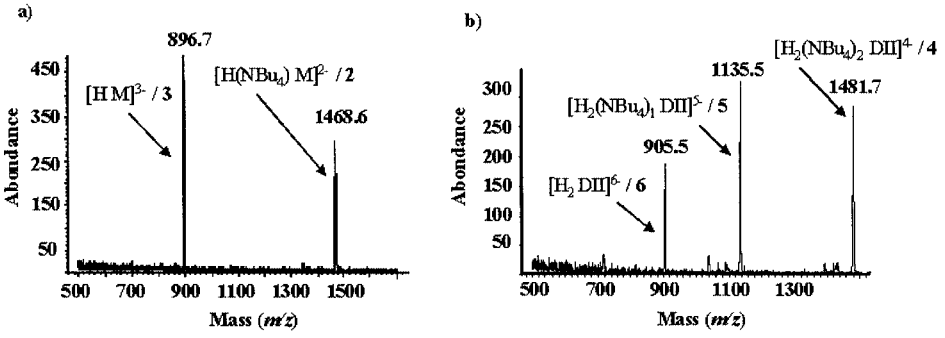

Figure 2. Negative ESI mass spectra of a) $[H\{\gamma\text{-}SiW_{10}O_{36}(PhPO)_2\}]^{3-}$ (**$[HM]^{3-}$**) and b) $[H_2\{(SiW_{10}O_{36})[O=PCH_2(C_6H_4)_2CH_2P=O]\}_2]^{6-}$ (**$[H_2DII]^{6-}$**)

Observed value	6249.4	6494.8	6734.7	6978.2	7220.4	7461.6
Calculated value	6251.2	6493.7	6736.1	6978.6	7221.1	7463.5
DII						
Observed value	–	6645.7	6887.7	7130.7	7372.1	7614.9
Calculated value	6403.4	6645.9	6888.3	7130.8	7373.3	7615.7

in Table 1. Other less intense signals were detected at higher *m*/*z* values (*m*/*z* = 12000−15000 and 19000−21000) as shown in Figure 3. These signals were most probably non-specific noncovalent aggregates of the dimeric compound D which are often produced during the desorption process in MALDI-TOF mass spectrometry.

Both the MALDI-TOF and ESI-MS results undoubtedly point to the presence of cyclic species and indicate the degree of oligomerization, in this case dimeric species are indicated.

Conclusion

The synthesis of hybrid oligomers from inorganic NBBs has undergone considerable developments in the last few years. In this context, the $[\{(SiW_{10}O_{36})[O{=}PCH_2(C_6H_4)_nCH_2P{=}O]\}_2]^{8-}$ (n = 1, 2) species, as represented in Figure 4, constitute an alternative approach for obtaining hybrids with a high degree of oligomerization. Moreover, this work has shown that mass spectrometry (combination of MALDI-TOF and ESI-MS) was more than just an alternative tool, but an essential technique in the characterization of these hybrid systems. Other bis(phosphonates) with larger sizes and different topologies are in preparation and their reactivity towards POMs will be reported very shortly.

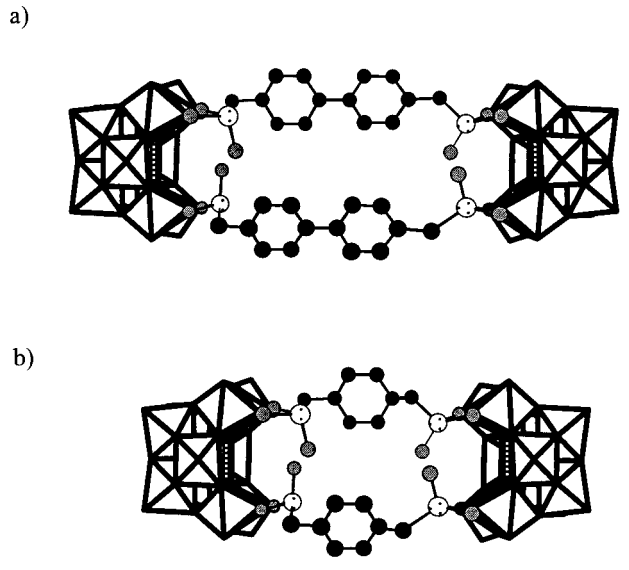

Figure 4. Proposed structures of a) $[H_2\{(SiW_{10}O_{36})[O{=}PCH_2(C_6H_4)_2CH_2P{=}O]\}_2]^{6-}$ and b) $[H_2\{(SiW_{10}O_{36})[O{=}PCH_2(C_6H_4)_1CH_2P{=}O]\}_2]^{6-}$

Experimental Section

General Procedures and Chemicals: $K_8[\gamma\text{-}SiW_{10}O_{36}]\cdot 12H_2O$ was prepared according to ref.[22] Other reagents and solvents were purchased from Aldrich and used as received. IR spectra (4000−250 cm^{-1}) were recorded with a Nicolet Magna 550 spectrometer in KBr pellets.

ESI-MS: The measurements were carried out using an HP 5989B single quadrupole mass spectrometer equipped with an electrospray source from Analytica of Branford. The instrument was operated in the negative ion mode. Source parameters were as follows: U_{needle} = 0 V, $U_{cyl.}$ = 3500 V, $U_{end.}$ = 3000 V, $U_{cap.}$ = 3500 V. Purified air was used as the nebulizing and drying gas, the presence of oxygen helping to prevent corona discharge which is often a problem during negative ion operation. The pressures of the nebulizing and drying gases were 0.34 and 1.70 bar, respectively, the nebulizing gas was heated to approximately 100 °C. Mass spectra were obtained by direct infusion with a Harvard Apparatus syringe pump of 10^{-4}, 5×10^{-5}, or 10^{-5} M sample solutions in pure distilled acetonitrile at a flow rate of 5 μL min^{-1}. The cone voltage U_c was varied, but was mostly set at low values of 10−40 V relative to the capillary exit voltage. Raising the cone voltage improves the ion transmission through the analyzer. It also increases the kinetic energy, which in turn enhances the formation of daughter ions by collisions with solvent and gas molecules within the region of primary stage pumping between the capillary exit and the sampling cone. The mass spectra shown are the result of approximately 20 scans summed from *m*/*z* = 50 to 1650. The mass axis was calibrated using the cluster ions observed from a 50 ng/μL solution of SDS (sodium dodecylsulfate) in acetonitrile.

MALDI-TOF MS: The spectra were recorded using a Voyager Elite Time-of-Flight Mass Spectrometer (PerSeptive Biosystems, Boston, MA, USA). In this apparatus, the pulsed N_2 laser beam (337 nm, 3 ns pulse duration, repetition rate 2 Hz) was focused onto the target with an angle of incidence of 45°. In all experiments the mass spectrometer was tuned in the linear mode using delayed extraction and a beam wire guide. The target voltage was set to +20 kV. The extraction delay and pulse voltage were adjusted to obtain the best mass resolution and the wire guide voltage was adjusted to obtain the best transmission. All mass spectra were recorded and averaged over 256 laser shots with a Tektronix TDS 520 oscilloscope (Beaverton, OR, USA). The samples were prepared as follows: the com-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pound (2 mg) was dissolved in acetonitrile (500 μL; solution A), and dithranol (12 mg) was dissolved in CH_2Cl_2 (500 μL; matrix solution). 1 μL of solution A was then added to 50 μL of the matrix solution. An external calibration of the instrument with a POE 5000 standard was used.

NMR: The ^1H (300 MHz) NMR spectra were obtained at room temperature in 5-mm (o.d.) tubes with a Bruker AC 300 spectrometer equipped with a QNP probe head. Chemical shifts are given according to the IUPAC convention with respect to $SiMe_4$. The 12.5 MHz ^{183}W NMR spectra were recorded at 300 K in almost saturated DMF/CD_3CN (90:10, v/v) solutions in 10-mm (o.d.) tubes with the same spectrometer equipped with a low-frequency special VSP probe head. Chemical shifts are given with respect to 2 M aqueous Na_2WO_4 and were determined by the substitution method using a saturated D_2O solution of tungstosilicic acid $H_4SiW_{12}O_{40}$ as secondary standard (δ = −103.8 ppm).

***para*-Xylylenebis(phosphonic acid) (LI):** α,α′-Dibromo-*p*-xylene (2.084 g, $7.9.10^{-3}$ mol) was suspended in deaerated triethyl phosphite (25 mL) and the mixture was heated to reflux at 138 °C with stirring for 3 h. The unreacted triethyl phosphite was removed in vacuo at 80 °C. Crystalline products were obtained by dissolving the yellow oil in diethyl ether and cooling to −35 °C overnight. *para*-Xylylenebis(diethyl phosphonate) (1 g, $2.64.10^{-3}$ mol) was then dissolved in HCl (60 mL, 12 M) and heated to reflux overnight. The pure phosphonic acid was obtained by removing hydrochloric acid with a rotary evaporator. Yield: 0.65 g, 31%. ^1H NMR (300.13 MHz, [D_6]DMSO, TMS): δ = 2.90 (d, 2 H), 7.14 (s, 2 $H_{arom.}$) ppm. ^{31}P NMR (121.5 MHz, [D_6]DMSO, H_3PO_4): δ = 22.57 ppm.

1,1′-Biphenylene-4,4′-bis(methylene)bis(phosphonic acid) (LII): The procedure was similar except that the starting material was 4,4′-bis(chloromethyl)-1,1′-biphenyl (0.6 g, $2.39.10^{-3}$ mol). Yield: 0.33 g, 40.3%. ^1H NMR (300.13 MHz, [D_6]DMSO, TMS): δ = 2.97 (d, 2 H), 7.31 (d, 2 $H_{arom.}$), 7.54 (d, 2 $H_{arom.}$) ppm. ^{31}P NMR (121.5 MHz, [D_6]DMSO, H_3PO_4): δ = 22.38 ppm.

$(NBu_4)_6H_2[\{(SiW_{10}O_{36})[O{=}PCH_2(C_6H_4)CH_2P{=}O]\}_2]$ (DI): A homogeneous mixture of **LI** (0.089 g, 0.333 mmol) and 12 M hydrochloric acid (0.35 mL) in dimethylformamide (2 mL) was added dropwise to a suspension of solid $K_8[\gamma\text{-}SiW_{10}O_{36}]\cdot 12H_2O$ (1 g, 0.333 mmol) and Bu_4NBr (0.35 g, 1 mmol) in acetonitrile (30 mL). The resultant mixture was heated to reflux with stirring overnight. Acetonitrile was then removed by evaporation, and the crude product was precipitated from the dimethylformamide solution by diffusion of diethyl ether through the gas phase. The precipitate was filtered and washed with ethanol and diethyl ether. Yield: 1.3 g (0.180 mmol, 54%). ^{31}P NMR (121.5 MHz, DMF/CD_3CN, H_3PO_4): δ = 23.23 [$^2J(^{183}W,^{31}P)$ = 10.1 Hz] ppm. ^{183}W NMR (12.5 MHz, DMF/CD_3CN, Na_2WO_4): δ = −109.1 [s, 2 W, $^2J(^{183}W,^{183}W)$ = 21.6, 12.1 Hz], −113.0 [s, 4 W, $^2J(^{183}W,^{183}W)$ = 12.7, 16.5 Hz], −155.3 [d, 4 W, $^2J(^{183}W,^{183}W)$ = 21.35, 16.5, $^2J(^{183}W,^{31}P)$ = 10.2 Hz] ppm. IR (KBr): $\tilde{\nu}$ = 1160 (vw), 1060 (vw), 1006 (vw), 975 (s), 939 (m), 907 (vs), 885 (vs), 835 (m), 763 (vs), 552 (vw), 363 (w), 331 (w) cm^{-1}.

$(NBu_4)_6H_2[\{(SiW_{10}O_{36})[O{=}PCH_2(C_6H_4)_2CH_2P{=}O]\}_2]$ (DII): The synthesis followed the same procedure, using **LII** (0.114 g, 0.333 mmol). Yield: 1.5 g (0.203 mmol, 61.1%). ^{31}P NMR (121.5 MHz, DMF/CD_3CN, H_3PO_4): δ = 22.80 [$^2J(^{183}W,^{31}P)$ = 10.3 Hz] ppm. ^{183}W NMR (12.5 MHz, DMF/CD_3CN, Na_2WO_4): δ = −109.6 [s, 2 W, $^2J(^{183}W,^{183}W)$ = 7, 21.6 Hz], −112.3 [s, 4 W, $^2J(^{183}W,^{183}W)$ = 7, 20.3 Hz], −155.0 [d, 4 W, $^2J(^{183}W,^{183}W)$ = 20.35, 21.6, $^2J(^{183}W,^{31}P)$ = 10.8 Hz] ppm. IR (KBr): $\tilde{\nu}$ = 1160 (vw), 1060 (vw), 1006 (vw), 975 (s), 939 (m), 907 (vs), 885 (vs), 835 (m), 763 (vs), 552 (vw), 363 (w), 331 (w) cm^{-1}.

Fast, High-Yielding Syntheses of Silsesquioxanes Using Acetonitrile as a Reactive Solvent

Paolo P. Pescarmona,[a] Jan C. van der Waal,[a] and Thomas Maschmeyer*[a]

Keywords: Silsesquioxanes / NMR spectroscopy / Mass spectrometry / Solvent effects

New and efficient methods for the synthesis of cyclopentyl- and cyclohexylsilsesquioxanes are described. In the case of cyclopentylsilsesquioxane, pure trisilanol $(c\text{-}C_5H_9)_7Si_7O_9(OH)_3$ was obtained selectively within 18 h in an isolated yield of 64%. The synthesis of cyclohexylsilsesquioxanes also gives high yields, but it is not selective towards a particular structural type [main products: $(c\text{-}C_6H_{11})_6Si_6O_9$, $(c\text{-}C_6H_{11})_6Si_6O_8(OH)_2$, $(c\text{-}C_6H_{11})_7Si_7O_{10}OH$ and $(c\text{-}C_6H_{11})_7Si_7O_9(OH)_3$]. We discuss the crucial role of acetonitrile as a reactive solvent in these syntheses.

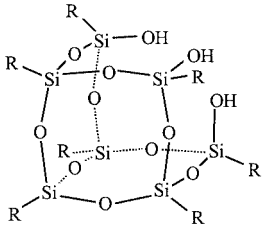
Introduction

Silsesquioxanes are hybrid inorganic/organic compounds that have an increasing number of applications in the field of catalysis[1,2] and materials science.[3,4] In particular, the incompletely condensed silsesquioxanes $R_7Si_7O_9(OH)_3$ (where R is an organic group, commonly cyclopentyl or cyclohexyl, cf. Figure 1) have been used both as soluble model compounds for silica surface sites and as precursors for active homogeneous catalysts.[5−9] The synthesis of this silsesquioxane was first reported by Brown and Vogt;[10] more recently it was optimised and studied in detail by Feher et al.[11,12] The trisilanol $R_7Si_7O_9(OH)_3$ [structural coding *a*7*b*3, cf. Equations (1) and (2)] can be obtained by the slow hydrolytic condensation of the corresponding trichlorosilane $RSiCl_3$ with acetone as the solvent [Equation (1), Equation (2) with $a + b = 2n$, where a, b and n are integers ($a = 1, 2, 3, \ldots$; $b = 0, 1, 2, 3, \ldots$; $n = 1, 2, 3, \ldots$) and $b \leq a + 2$].

$$RSiCl_3 + 3\,H_2O \rightarrow RSi(OH)_3 + 3\,HCl \quad (1)$$

$$a\,RSi(OH)_3 \rightleftarrows (RSiO_{1.5})_a(H_2O)_{0.5b} + (1.5a - 0.5b)\,H_2O \quad (2)$$



*a*7*b*3

Figure 1. Silsesquioxane *a*7*b*3 [R = cyclopentyl, cyclohexyl]

In the case of R = cyclopentyl, silsesquioxane *a*7*b*3 was the only product of the hydrolytic condensation and was obtained after 3 d of reaction in a yield of 29%.[12] When R = cyclohexyl, the hydrolytic condensation proceeded more slowly and produced a mixture of three silsesquioxanes: *a*6*b*0, *a*7*b*3 and *a*8*b*2.[11] Silsesquioxane *a*7*b*3 was the main product, but in a low yield (8% after a reaction of 12 weeks).

Recently, we reported a study of the synthesis of silsesquioxanes as precursors for Ti catalysts that are active in the epoxidation of alkenes, which we realised by means of High-Speed Experimentation (HSE) techniques.[13,14] We investigated the effects of the various parameters that influence the hydrolytic condensation and identified some general trends. Since one of our purposes was to find a faster way to prepare silsesquioxane precursors suitable for active catalysts, the reaction time was set at 18 h, which is a much shorter time than is required usually for the synthesis of silsesquioxanes. The best catalysts were obtained with R = cyclopentyl and cyclohexyl, using acetonitrile as the solvent. In this article, we report a follow-up study of these HSE leads by means of conventional laboratory techniques

with the aim of fully characterising the silsesquioxane products and understanding the role of the solvent.

Results and Discussion

Synthesis of Cyclopentylsilsesquioxanes

The hydrolytic condensation of trichloro(cyclopentyl)silane in acetonitrile in the presence of an excess of water led to the formation of a white precipitate. After a reaction time of 18 h at 50 °C, a crude precipitate was obtained in 54% yield,[15] which contained mainly silsesquioxane *a*7*b*3 [$(c\text{-}C_5H_9)_7Si_7O_9(OH)_3$], as determined on the basis of ^{29}Si NMR and MS analyses. Small amounts of impurities were present in the precipitate, predominantly the cubic, completely condensed silsesquioxane ($c\text{-}C_5H_9)_8Si_8O_{12}$ [structural code *a*8*b*0, cf. Equations (1) and (2)]. If the reaction time was extended from 18 h to 2 weeks,[14] the yield of precipitated silsesquioxanes was nearly quantitative with the main fraction still being silsesquioxane *a*7*b*3. The synthesis was further optimised, on the basis of the observation of Feher et al., that the yield of the synthesis of cyclopentylsilsesquioxane *a*7*b*3 in acetone can be significantly improved by heating the reaction mixture under reflux.[12] Therefore, we modified our synthetic method by increasing the reaction temperature from 50 °C to reflux conditions. This modification led to an increase in the yield to 81% after a reaction time of 18 h and the high selectivity towards silsesquioxane *a*7*b*3 was preserved. Silsesquioxane *a*7*b*3 was then purified by extraction with pyridine[11,12] and the pure compound (as determined by ^{29}Si NMR spectroscopy, cf. Figure 2) was isolated in an overall yield of 64%, which is a significant improvement over the previously reported yield of 29% after 3 d of reaction.[12]

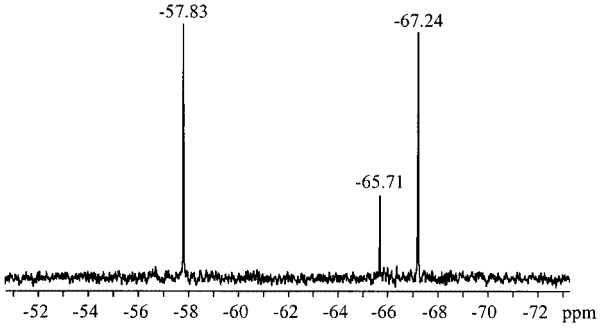

Figure 2. ^{29}Si NMR spectrum of cyclopentylsilsesquioxane *a*7*b*3

This improved synthetic procedure differs from that reported by Feher et al.[12] in regard to a number of parameters: the lower initial trichlorosilane concentration, the higher solvent/water ratio and, above all, the nature of the solvent (acetonitrile), which proved to be a dominant parameter that influences the synthesis of silsesquioxanes.[1,13,14]

After the hydrolytic condensation had proceeded for 18 h under reflux, the reaction mixture separated into two layers: a water phase (bottom) and an acetonitrile phase (top). This liquid-liquid phase separation is related to the hydrolysis of acetonitrile, a side reaction that is favoured by the presence of an acid [cf. Equation (3)],[16,17] which, in this case, was the hydrochloric acid produced during the hydrolysis of $(c\text{-}C_5H_9)SiCl_3$ [see Equation (3)].

$$CH_3CN + 2\,H_2O + HCl \rightarrow CH_3COOH + NH_4Cl \quad (3)$$

The ammonium chloride obtained is much more soluble in water than it is in acetonitrile, which causes the phase separation [only 0.41 g of ammonium chloride is necessary to induce phase separation of a mixture of water (12.5 mL) and acetonitrile (37.5 mL)]. The preferential solvation of ammonium chloride by water, relative to that of silsesquioxanes or acetonitrile, drives the reaction according to Equation (2) more towards the formation of condensed species. This effect is very pronounced towards the end of the experiment, i.e., when phase separation is actually observed. At the same time, the hydrolysis of acetonitrile in the presence of an acid plays an important role in that the formation of ammonium chloride (partially) neutralises the reaction mixture. A detrimental effect of the acidity of the solution has already been observed in the synthesis of silsesquioxane as Ti catalyst precursors.[13] Since silsesquioxanes undergo fast hydrolysis/condensation reactions under acidic conditions,[1] the species formed might be partially decomposed or further condensed before they begin to precipitate from the solution. Partial neutralisation of the reaction mixture could have the effect of slowing down the rates of the hydrolysis/condensation reactions and, thus, favour the precipitation of species that are only poorly soluble in this medium, like the incompletely condensed silsesquioxane *a*7*b*3.[18]

A further contributing factor regarding the improved yield when using acetonitrile as the solvent is its higher polarity relative to acetone, the solvent reported in the literature for the synthesis of silsesquioxane *a*7*b*3.[12] A highly polar solvent can better stabilise the incompletely condensed species by its interactions with their silanol groups, which, therefore, favours the synthesis of these silsesquioxanes over the completely condensed structures. Moreover, it has been proposed that the activation barrier for the condensation reactions towards the formation of silsesquioxanes is reduced in the presence of a polar molecule and that, therefore, the rate of product formation is increased.[19,20]

In this context, it is also relevant to note that acetonitrile has a higher boiling point than acetone (82 °C vs. 56 °C). Since the reaction is performed under reflux, the synthesis is accelerated further.

Synthesis of Cyclohexyl Silsesquioxanes

The hydrolytic condensation of trichloro(cyclohexyl)-silane in acetonitrile, in the presence of an excess of water, produced a white precipitate in 42% yield[15] after a reaction time of 18 h at 50 °C. The crude precipitate contained a mixture of silsesquioxane species, as determined by ^{29}Si NMR spectroscopy. The formation of the precipitate was

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

accelerated by performing the synthesis under reflux, by analogy to the synthesis of cyclopentylsilsesquioxanes. This modification caused an increase of the yield to 79% after a reaction time of 18 h, with the precipitate still being a complex mixture of silsesquioxanes (see Figure 3 for the ^{29}Si NMR spectrum and the MS plot). MS analysis indicated that the silsesquioxanes present in the mixture mainly constituted 6, 7 or 8 siloxane units [$6 < a < 8$, cf. Equations (1) and (2)]. The most-intense peak in the ^{29}Si NMR spectrum ($\delta = -56.72$ ppm, 40% of the crude precipitate)[21] belongs to the completely condensed silsesquioxane (c-$C_6H_{11})_6Si_6O_9$ (*a6b*0, see Figure 4), which can be separated readily from the incompletely condensed species by extraction with pyridine, in which only the latter silsesquioxanes are soluble.[11] The main species present in the remaining mixture of incompletely condensed silsesquioxanes were assigned by combining ^{29}Si NMR spectroscopic and MS data: (c-$C_6H_{11})_6Si_6O_8(OH)_2$ (*a6b*2, 11% of the crude precipitate,[21] see Figure 4), (c-$C_6H_{11})_7Si_7O_{10}OH$ (*a7b*1, 29%, see Figure 4) and (c-$C_6H_{11})_7Si_7O_9(OH)_3$ (*a7b*3, 7%, see Figure 1). Silsesquioxane *a7b*3 can be separated by precipitation from a THF solution of the incompletely condensed silsesquioxane mixture by the slow addition of acetonitrile, in which it has a very low solubility. Silsesquioxane *a6b*2 is, on the other hand, the compound having the highest solubility in acetonitrile among those present in the mixture. Therefore, it can be separated by adding more acetonitrile slowly to the THF/acetonitrile solution, which, thus, induces the precipitation of all the other silsesquioxane structures. The solid obtained after removing silsesquioxanes *a6b*2 and *a7b*3 still contained a mixture of incompletely condensed silsesquioxanes that have very similar solubilities in many organic solvents and, therefore, resisted all attempts of further purification. The main component of this mixture was assigned to an *a7b*1 silsesquioxane structure (two isomers are possible for this silsesquioxane, see Figure 4).

The assignments were confirmed by silylation of the silanol groups of the incompletely condensed silsesquioxanes by means of their reaction with chlorotrimethylsilane $(CH_3)_3SiCl$.[22] The mixture of incompletely condensed structures obtained after separation of silsesquioxane *a6b*0 was treated with an excess of $(CH_3)_3SiCl$. The MS analysis of the products of the silylation reaction clearly shows the presence of four main species: disilylated *a6b*2, monosilylated *a7b*1, disilylated *a7b*3 and disilylated *a8b*2 (Figure 5). The monosilylated *a7b*1 was the species present in the highest concentration. On the basis of these experiments, the assignment of *a7b*1 as the main incompletely condensed species appears unequivocal. The ^{29}Si NMR spectroscopic peaks belonging to this silsesquioxane *a7b*1, both silylated or not, did not, however, correspond to those of the analogous silsesquioxane reported in the literature.[11] The peaks corresponding to the silylated *a7b*1 reported by Feher were present in the ^{29}Si NMR spectrum only as the second main species. This observation suggests that the two isomers of silsesquioxane *a7b*1 (Figure 4) were formed by our synthetic method, with the one known from the literature being the less abundant ($\alpha/\beta = 1:2$). The two isomers differ only in the spatial orientations of their silanol groups. They are both possible products of the hydrolytic condensation of trichloro(cyclohexyl)silane, while only the α-isomer of sil-

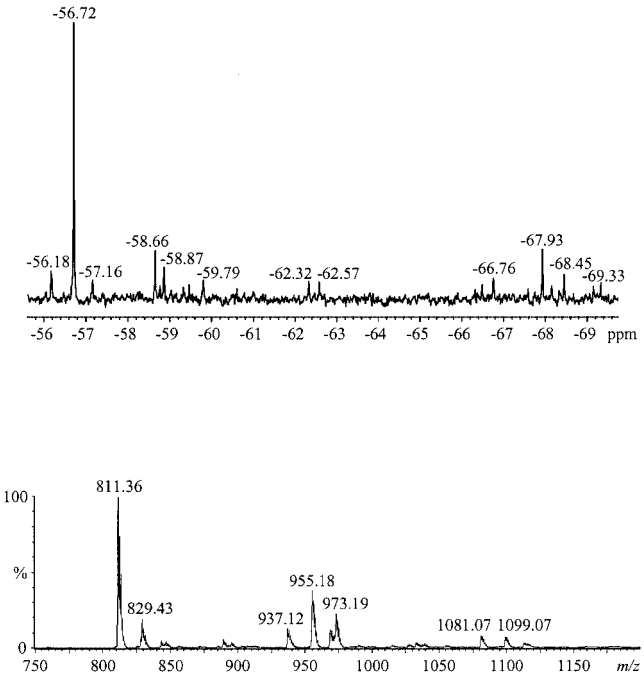

Figure 3. ^{29}Si NMR spectrum (top) and MS plot (bottom) of the cyclohexylsilsesquioxane mixture obtained after the hydrolytic condensation of trichloro(cyclohexyl)silane in acetonitrile

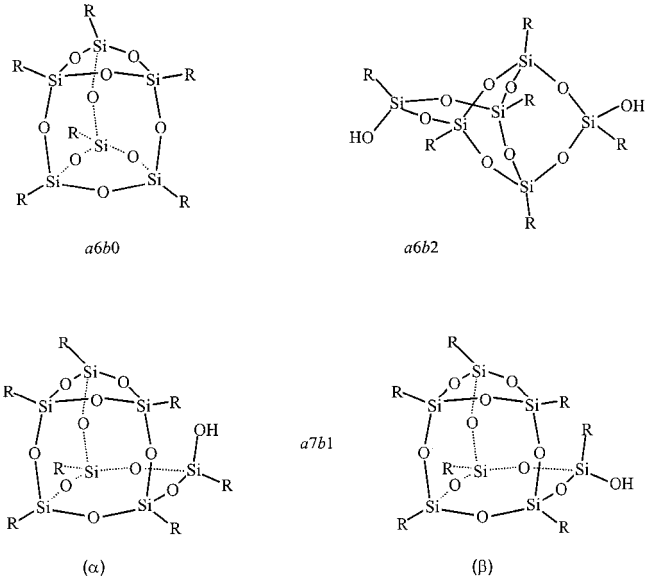

Figure 4. Silsesquioxanes *a6b*0, *a6b*2 and *a7b*1 (α and β isomers) (R = cyclohexyl)

sesquioxane *a7b*1 is obtained by the dehydration of silsesquioxane *a7b*3 reported by Feher.[11]

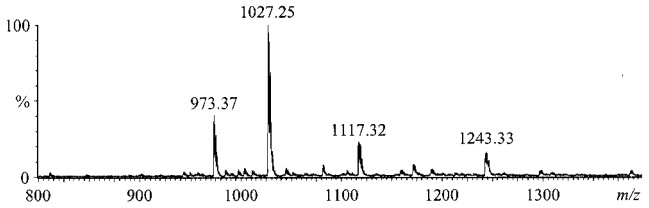

Figure 5. MS analysis of the incompletely condensed cyclohexylsilsesquioxanes, after silylation with $(CH_3)_3SiCl$

After hydrolytic condensation for 18 h under reflux and removal of the precipitate, the reaction was left at room temperature for 20 weeks: more white precipitate was formed (additional 10% yield).[15] The crude product was a mixture of three silsesquioxane species, with some impurities, as determined by ^{29}Si NMR spectroscopy: *a6b*0 (21%),[21] *a6b*2 (27%) and *a7b*3 (51%). Feher et al. have reported a similar increase in the ratio of silsesquioxane *a7b*3 among the products as the reaction time is increased.[11]

The synthesis procedure described here is the first reported method for obtaining silsesquioxanes *a6b*2 and *a7b*1 (both isomers) by the hydrolytic condensation of trichloro(cyclohexyl)silane. Cyclohexylsilsesquioxane *a6b*2 has been synthesised previously by the acid-mediated cleavage and rearrangement of silsesquioxane *a6b*0.[23] The α-isomer of cyclohexylsilsesquioxane *a7b*1 has been obtained formerly by dehydration of silsesquioxane *a7b*3.[11] The synthesis also afforded cyclohexylsilsesquioxane *a7b*3 in significant yields, although its separation from the rest of the mixture is not straightforward. This new method presents a number of differences from those reported previously,[11] namely: the solvent (acetonitrile), the lower initial trichlorosilane concentration and the higher solvent/water ratio. Additionally, performing the reaction under reflux caused a noticeable increase in yield of precipitate in our synthesis, while the rate of silsesquioxane formation could not be improved for the reaction reported in literature. Comparing the two synthetic methods, it is evident that the formation of silsesquioxanes is much faster with the new method, albeit less selective. Such an increase in the rate of formation of silsesquioxanes suggests that the conditions for the precipitation of silsesquioxanes are met more readily and for a larger number of different structures. This fact points to the relevance of using acetonitrile as the solvent, in agreement with the situation observed for the synthesis of cyclopentylsilsesquioxanes (vide supra). Analogously, after a reaction time of 18 h under reflux, the hydrolysis of acetonitrile and the consequent formation of NH_4Cl caused a liquid-liquid phase separation of the reaction mixture. To further study the effect of the presence of NH_4Cl, two additional experiments were performed:

1) Some NH_4Cl (0.073 M) was added to the starting mixture and led, after a reaction time of 18 h under reflux, to a silsesquioxane precipitate in a yield of 82%.[15] ^{29}Si NMR spectroscopic analysis showed that the amount of *a6b*0 increased relative to the other (incompletely condensed) silsesquioxanes. Thus, the addition of NH_4Cl not only increased the yield, but also drove the reaction towards the completely condensed species, which confirms the influence that the preferential solvation of NH_4Cl by water has on the silsesquioxane synthesis.

2) The hydrolytic condensation of trichloro(cyclohexyl)silane was performed in acetone (the solvent used by Brown[10] and Feher[11]) in the presence of NH_4Cl (0.15 M) as an additive: no precipitate was formed after a reaction time of 18 h under reflux (as is the case when no NH_4Cl is added). This finding indicates that the preferential solvation of NH_4Cl by water alone is not sufficient to accelerate the formation of silsesquioxanes.

The lower selectivity of the synthesis of cyclohexylsilsesquioxanes relative to that of cyclopentylsilsesquioxanes seems to be connected to the nature of the organic group.[1] The relatively larger steric hindrance of a cyclohexyl unit might account for the formation of the completely condensed silsesquioxane *a6b*0. The Si−O framework of this molecule is more strained than in the case of silsesquioxane *a7b*3 and, therefore, its formation might be expected to be unfavourable. On the other hand, the organic groups on the silicon atoms in this structure point away from each other: this arrangement may favour the formation of this molecule for bulkier organic groups, like cyclohexyl. Another effect of the organic group is to influence the solubility of the silsesquioxanes.[1] Cyclohexylsilsesquioxane *a7b*3 has been reported to be more soluble in organic solvents than cyclopentylsilsesquioxane *a7b*3.[11,12] The lower solubility of the cyclopentyl structure can account for its selective formation as a precipitate.

Conclusions

New methods for the synthesis of cyclopentyl- and cyclohexylsilsesquioxanes have been developed. In both cases, acetonitrile plays a strong role in accelerating the formation of a silsesquioxane precipitate. The influence of the hydrolysis of acetonitrile on the synthesis has been ascertained.

In the case of cyclopentylsilsesquioxanes, the synthesis is very selective towards the formation of structure *a7b*3, which can be obtained in 64% yield after a reaction time of 18 h. This fast and high-yielding method for preparing silsesquioxane *a7b*3, therefore, makes this compound more readily available for its many applications.

In the case of the synthesis of cyclohexylsilsesquioxanes, four silsesquioxane structures were produced in significant yields: *a6b*0, *a6b*2, *a7b*1 (both isomers) and *a7b*3. This method offers a facile way to synthesise the silsesquioxane structures *a6b*2 and *a7b*1, which are not readily accessible. The lower selectivity of this reaction seems to be connected to the higher solubility of cyclohexylsilsesquioxanes relative to that of cyclopentylsilsesquioxanes.

Experimental Section

General: ^{29}Si NMR spectroscopic characterisation of the silsesquioxanes was performed with a Varian VXR-400S (79.5 MHz, ^{1}H-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

decoupled, 25 °C) and with a Varian Inova-300 (59.6 MHz, ^{1}H-decoupled, 25 °C); pulse width = 30°; pulse delay = 10 s; ^{1}H decoupling during acquisition only. The positions of the silsesquioxanes' peaks in the ^{29}Si NMR spectra are influenced by the solvent in which they are dissolved. Spectra were recorded in THF and $CDCl_3$, with TMS as a reference. Mass spectrometric characterisation of the silsesquioxanes was performed with a Micromass Quattro LC-MS using ESI+ and APCI+ as ionisation techniques. Mass spectrometric analysis allows the identification of the number of siloxane units constituting the silsesquioxane structures (i.e., the value of *a*), but not their level of condensation (i.e., the value of *b*); this phenomenon is due to the fact that silsesquioxanes can coordinate or lose water molecules during the ionisation process.

Synthesis of Cyclopentyl Silsesquioxanes: Typically, deionised water (37.5 mL) was added carefully into a 500-mL round-bottom flask containing a solution of trichloro(cyclopentyl)silane (97% purity, 5.6 mL, 3.3×10^{-2} mol) in acetonitrile/water (4:1, v/v; 150 mL). This homogeneous solution was then heated to 50 °C or under reflux while stirring vigorously for 18 h; a white precipitate formed. The crude precipitate was dissolved in 20 times its weight of pyridine and stirred overnight. Next, the solution was filtered to remove the insoluble completely condensed species (traces) and poured into an equal volume of ice-cold aqueous HCl (37%); a white precipitate formed. The solid was filtered, carefully washed with water and dried overnight at 45 °C. An NMR spectrum of pure cyclopentylsilsesquioxane *a7b3* was obtained. ^{29}Si{^{1}H} NMR (THF): δ = −57.83 [s, 3 Si, (*c*-C_5H_9)SiO(OH)], −65.71 [s, 1 Si, (*c*-C_5H_9)$SiO_{1.5}$], −67.24 [s, 3 Si, (*c*-C_5H_9)$SiO_{1.5}$] ppm. MS (ESI+, cone voltage = 60 V, THF 78%, CH_3CN 20%, HCO_2H 0.1 M, 2%): *m/z* (%) = 875.04 [*a7b3* + H]$^+$ (100), 839.00 [*a7b3* − 2 H_2O + H]$^+$ (41), 897.08 [*a7b3* + Na]$^+$ (16), 911.09 [*a7b3* + 2 H_2O + H]$^+$ (16), 857.03 [*a7b3* − H_2O + H]$^+$ (11).

Synthesis of Cyclohexyl Silsesquioxanes: Typically, deionised water (125 mL) was added carefully into a 1-L round-bottom flask containing a solution of trichloro(cyclohexyl)silane (97% purity, 15 mL, 8.2×10^{-2} mol) in acetonitrile/water (4:1, v/v; 500 mL). This homogeneous solution was then heated to 50 °C or under reflux while stirring vigorously for 18 h.[24] The crude precipitate formed was dissolved in 20 times its weight of pyridine and stirred overnight. The solution was then filtered to remove the insoluble completely condensed species (*a6b0*) and poured into an equal volume of ice-cold aqueous HCl (37%) to precipitate the incompletely condensed silsesquioxanes. The solid mixture of silsesquioxanes was filtered, carefully washed with water and dried overnight at 45 °C. Silsesquioxane *a7b3* was separated by dissolving the mixture of incompletely condensed species in 5 times its weight of THF and then by slowly layering an equal weight of acetonitrile over the THF solution. Under these conditions, a white precipitate was obtained that mainly constituted silsesquioxane *a7b3*. The remaining solution was partially dried under reduced pressure and more acetonitrile was added slowly until a precipitate deposited. The solid was separated by filtration and the solution dried under reduced pressure to afford silsesquioxane *a6b2*. The silylation of the mixture of incompletely condensed silsesquioxanes was performed by adding chlorotrimethylsilane (200 μL) to a solution of the silsesquioxanes (0.3 g) in toluene (30 mL) and triethylamine (1.5 mL). The turbid solution was stirred overnight at room temperature. Next, the solvent and triethylamine were evaporated under reduced pressure to afford a white solid. The solid was extracted with pentane, the solution was filtered to remove the insoluble $(C_2H_5)_3N{\cdot}HCl$ and then concentrated under reduced pressure to give a solid containing the silylated silsesquioxanes. ^{29}Si{^{1}H} NMR: *a6b0* (THF): δ = −56.72 [s, 6 Si, (*c*-C_6H_{11})$SiO_{1.5}$] ppm; *a6b2* (THF): δ = −57.16 [s, 2 Si, (*c*-C_6H_{11})SiO(OH)], −62.32 [s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −62.57 [s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$] ppm; ($CDCl_3$): δ = −55.20 [s, 2 Si, (*c*-C_6H_{11})SiO(OH)], −61.72 [s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −61.92 [s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$]; *a7b1* (THF): δ = −56.18 [s, 1 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −58.66 [s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −58.87 [s, 1 Si, (*c*-C_6H_{11})SiO(OH)], −66.76 [s, 1 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −67.93 [s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$] ppm; ($CDCl_3$): δ = −56.23 [s, 1 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −57.95 [s, 1 Si, (*c*-C_6H_{11})SiO(OH)], −58.58 [s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −66.82 [s, 1 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −67.66 [(s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$)] ppm; silylated *a7b1* isomers ($CDCl_3$): (α): δ = 9.06 [s, 1 Si, $(CH_3)_3SiO_{0.5}$], −56.32 [s, 1 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −59.02 [s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −66.67 [s, 1 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −68.74 {s, 1 Si, (*c*-C_6H_{11})SiO[OSi$(CH_3)_3$]}, −68.83 [s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$] ppm; (β): δ = 8.20 [s, 1 Si, $(CH_3)_3SiO_{0.5}$], −56.28 [s, 1 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −58.70 [s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −66.89 [s, 1 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −67.35 {s, 1 Si, (*c*-C_6H_{11})Si[OSi$(CH_3)_3$]}, −68.14 [s, 2 Si, (*c*-C_6H_{11})$SiO_{1.5}$] ppm; *a7b3* (THF): δ = −59.79 [s, 3 Si, (*c*-C_6H_{11})SiO(OH)], −67.86 [s, 1 Si, (*c*-C_6H_{11})$SiO_{1.5}$], −69.33 [s, 3 Si, (*c*-C_6H_{11})$SiO_{1.5}$] ppm. MS of crude precipitate (APCI+, cone voltage = 15 V, CH_2Cl_2; see Figure 3), for *a* = 6: *m/z* (%) = 811.36 [*a6b0* + H]$^+$ (100), 829.43 [*a6b2* + H]$^+$ (20); for *a* = 7: *m/z* (%) = 937.12 [*a7b1* − H_2O + H]$^+$ (14), 955.18 [*a7b1* + H]$^+$ (38), 973.19 [*a7b3* + H]$^+$ (23); for *a* = 8: *m/z* (%) = 1081.07 [*a8b0* + H]$^+$ (8), 1099.07 [*a8b2* + H]$^+$ (7); silylated incompletely condensed silsesquioxanes (APCI+, cone voltage = 15 V, toluene/acetonitrile, 2:1, few drops of CH_3CO_2H; see Figure 5): *m/z* (%) = 973.37 [disilylated *a6b2* + H]$^+$ (40), 1027.25 [monosilylated *a7b1* + H]$^+$ (100), 1117.32 [disilylated *a7b3* + H]$^+$ (22), 1243.33 [disilylated *a8b2* + H]$^+$ (15).

Acknowledgments

Anton Sinnema and Kristina Djanashvili are kindly acknowledged for the measurement of the NMR spectra.

[18] While the partial neutralisation of the HCl formed during the hydrolysis of trichlorosilanes might have a role in accelerating the formation of silsesquioxane precipitates, complete neutralisation is detrimental. A decrease of the yield (from 79 to 44%, as crude precipitate) was observed by performing the synthesis of cyclohexylsilsesquioxanes in the presence of triethylamine. This result indicates that the hydrolysis/condensation reactions in the absence of HCl are significantly slowed down from the beginning of the synthesis.

Asymmetric Heterodinuclear $Fe^{III}M^{II}$ (M = Zn, Cu, Ni, Fe, Mn), $Co^{III}Fe^{II}$ and $Fe^{II}Co^{III}$ Species: Synthesis, Structure, Redox Behavior, and Magnetism

Sylvia Ross,[a] Thomas Weyhermüller,[a] Eckhard Bill,[a] Eberhard Bothe,[a] Ulrich Flörke,[b] Karl Wieghardt,[a] and Phalguni Chaudhuri*[a]

Keywords: Electrochemistry / Heterodinuclear complexes / Iron / Magnetic properties / Pyridine-2-aldoxime

Reactions of an LFe^{III} unit with an $M(PyA)_3^{n-}$ ion prepared in situ, where L represents 1,4,7-trimethyl-1,4,7-triazacyclononane and PyA^- is the monoanion of pyridin-2-aldoxime, yield heterodinuclear cations of the general formula $[LFe^{III}(PyA)_3M]^{2+}$, where M = Zn^{II} (**1**), Cu^{II} (**2**), Ni^{II} (**3**), low-spin Fe^{II} (**4**) and Mn^{II} (**5**). Additionally, we also prepared the diamagnetic species $[LCo^{III}(PyA)_3Fe^{II}]^{2+}$ (**6**). The $Fe^{III}Co^{II}$ species could not be isolated because a facile intramolecular electron transfer leads to complex **7**, $[LFe^{II}(PyA)_3Co^{III}]^{2+}$. Compounds **1**–**7** contain three oximato anions as bridging ligands and are isostructural in the sense that they all contain a terminal metal(III) ion in a distorted octahedral environment (e.g., FeN_3O_3) and a second six-coordinate metal ion M in a mostly trigonal-prismatic MN_6 geometry. Complexes **1**–**7** were characterized on the basis of elemental analyses, mass spectrometry, IR, UV/Vis, Mössbauer, and EPR spectroscopy, and variable-temperature (2–295 K) magnetic susceptibility measurements. The solid-state structures of **1**–**7** have also been determined by X-ray crystallography. The cyclic voltammograms of the complexes reveal both ligand-centered and metal-centered redox processes. Analysis of the susceptibility data indicates the presence of antiferromagnetic exchange interactions that decrease in the following order: $Fe^{III}Cu^{II}$ (**2**) > $Fe^{III}Ni^{II}$ (**3**) > $Fe^{III}Mn^{II}$ (**5**), as is expected. We have used X-band EPR spectroscopy of **3** ($Fe^{III}Ni^{II}$) at 2–6 K to establish the electronic ground state in great detail and to complement the magnetic susceptibility measurements.

Introduction

The field of research on heteropolynuclear complexes having different paramagnetic centers is still limited today by the small number of known and structurally fully characterized compounds and by the relative difficulty in synthesizing new compounds. Hence, the preparation of heteropolymetallic complexes has been a challenge for coordination chemists for many years.[1−3] Exchange-coupled heterometallic complexes are relevant to many different research areas, ranging from chemistry to solid-state physics and biology, because of their potential impact in material science, catalysis, and metallobiochemistry. Such exchange interactions in metalloproteins that involve more than one metal center have elicited the interest of bioinorganic chemists.[4−8]

We have adopted a synthetic strategy of using metal oximates as ligands for paramagnetic centers to increase the nuclearity and to synthesize heterometallic complexes. Thus, we have described a series of oximato-bridged (diatomic N,O-bridging) symmetrical and asymmetrical cores: M_AM_B,[9] $M_AM_BM_A$,[10] and $M_AM_BM_BM_A$[11] (M_A, M_B being two different metal ions). In addition, we have synthesized asymmetric heterotrinuclear complexes with cores $M_AM_BM_C$[12] and butterfly cores[13] $(M_A)_2(\mu\text{-}O)_2(M_B)_2$. Thus, we have synthesized linear heterotrinuclear complexes of general formula **A** and asymmetric dinuclear motifs $Cr^{III}\mu(O-N)_3M^{II}$ by using [tris(pyridinealdoximato)-metallate]$^-$ anions, $[M^{II}(PyA)_3]^-$, as ligands for the LCr^{III} unit, where L represents the tridentate cyclic amine 1,4,7-trimethyl-1,4,7-triazacyclononane.[9,10]

M_t = Fe^{III}, Mn^{III}, Mn^{IV}, Cr^{III}, Co^{III}

M_c = Zn^{II}, Cu^{II}, Ni^{II}, Fe^{II}, Mn^{II}

O−N N−O represents dioximate dianion

In this paper, we explore the effects of using Fe^{III} as the LM^{III} unit, i.e., $[LFe^{III}(PyA)_3M^{II}]^{2+}$ complex cations that are isostructural with the $[LCr^{III}(PyA)_3M^{II}]^{2+}$ centers. We

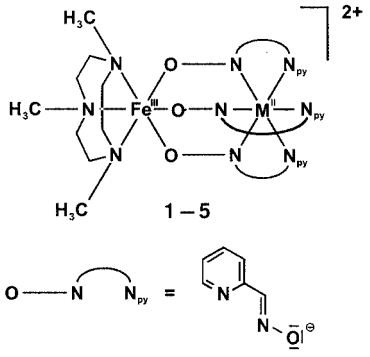
report the synthesis, magnetic, spectroscopic, and other physical properties of the following compounds, where M = Zn (**1**), Cu (**2**), Ni (**3**), Fe (**4**) and Mn (**5**).



Additionally, we report the preparation and structural characterization of complexes $[LCo^{III}(PyA)_3Fe^{II}]^{2+}$ (**6**) and $[LFe^{II}(PyA)_3Co^{III}]^{2+}$ (**7**). Throughout this paper the compounds **1**–**7** are denoted by their metal centers only. Such isostructural series are not available for any other bridging ligands.

Results and Discussion

We utilized the high thermodynamic stability of the complex between Fe^{III} and the macrocycle 1,4,7-trimethyl-1,4,7-triazacyclononane together with the lability of the first transition series divalent metal ions to synthesize $Fe^{III}M^{II}$ dinuclear complexes. It is interesting to note that isolation of the intermediates $[M(PyA)_3]^-$ was not necessary during this synthetic route. Although no scrambling was observed, all attempts to strictly synthesize the cation $[LFe^{III}(PyA)_3Co^{II}]^{2+}$ under argon led to the isolation of **7**, $[LFe^{II}(PyA)_3Co^{III}]^{2+}$, as a result of facile intramolecular electron transfer. On the other hand, complex **6**, $[LCo^{III}(PyA)_3Fe^{II}]^{2+}$, was readily isolated starting from its respective materials. The colors of the heterometal dinuclear complexes **1**–**7** are light-to-deep-red/brown and they are air-stable in the solid state and also in solution for a few days, except for **7**.

Since the relevant bands in the IR spectra of comparable oxime-containing heteronuclear $Cr^{III}M^{II}$ complexes have been described earlier,[9] and the spectra of complexes **1**–**7** are also very similar, we refrain from discussing them in detail. The bands, together with their tentative assignments, are given in the Exp. Sect.

The electronic spectral results indicate that the complexes **1**–**7** are stable and retain their discrete dinuclear entities also in acetonitrile solution. Only complexes **3** and **7** exhibit lowest-energy spin-allowed d–d transitions at the Ni^{II} and Co^{III} centers, respectively. On the basis of their high extinction coefficients and transitions similar to those reported in the literature,[14] all bands below 350 nm (see Exp. Sect.) for complexes **1**–**7** are assigned to $\pi\rightarrow\pi^*$ transitions of the oxime ligand, whereas the bands above 400 nm, except at ca. 628, 729, and 891 nm for **3** and at 925 nm for **7**, are assigned to the MLCT and LMCT transitions indicating strong interactions of d orbitals with the conjugated π system of the oxime.[15] Judged on the basis of their low extinction coefficients, we tentatively ascribe the bands at ca. 628, 729, and 891 nm for **3** (Ni^{II}) and 925 nm for **7** (Co^{III}) to d–d transitions at the Ni^{II} and Co^{III} centers, respectively.

Electrospray-ionization mass spectrometry (ESI-MS) in the positive-ion mode proved to be a very useful analytical tool for characterizing complexes **1**–**7**. The major peaks are listed in the Exp. Sect. The ESI-MS results for **1**–**7** are very similar and show that, in most cases, there are only two peaks, which correspond to the monocation $[LFe(PyA)_3M(ClO_4)]^+$ and the dication $[LFe(PyA)_3M]^{2+}$. Interestingly, all the complexes show the doubly charged species $[LFe(PyA)_3M]^{2+}$ as the base peak (100%). There is practically no indication in the spectra for ligand fragmentation or cleavage of the dimer, which indicates the robustness of the clathrochelates,[16] i.e., multicyclic ligand systems that completely encapsulate a metal ion, derived from the pyridinealdoxime and the iron-containing capping agent. The data summarized in the Exp. Sect. show that mass spectrometry of the complexes demonstrates the nuclearity of all the complexes unambiguously and also provides a means for identification of the metal centers and the composition of the complexes. Complexes **1**–**7** are not fragile and can withstand the conditions of the ESI(pos)-MS ionization.[17]

Electrochemistry

Cyclic voltammograms (CV) of complexes **1**–**7** were measured at a glassy-carbon working electrode at ambient

Table 1. Cyclic voltammetric data in CH_3CN solutions: the reversible metal-centered oxidations and reductions of $[LM_A(PyA)_3M_B](ClO_4)_2$ **1**–**7**

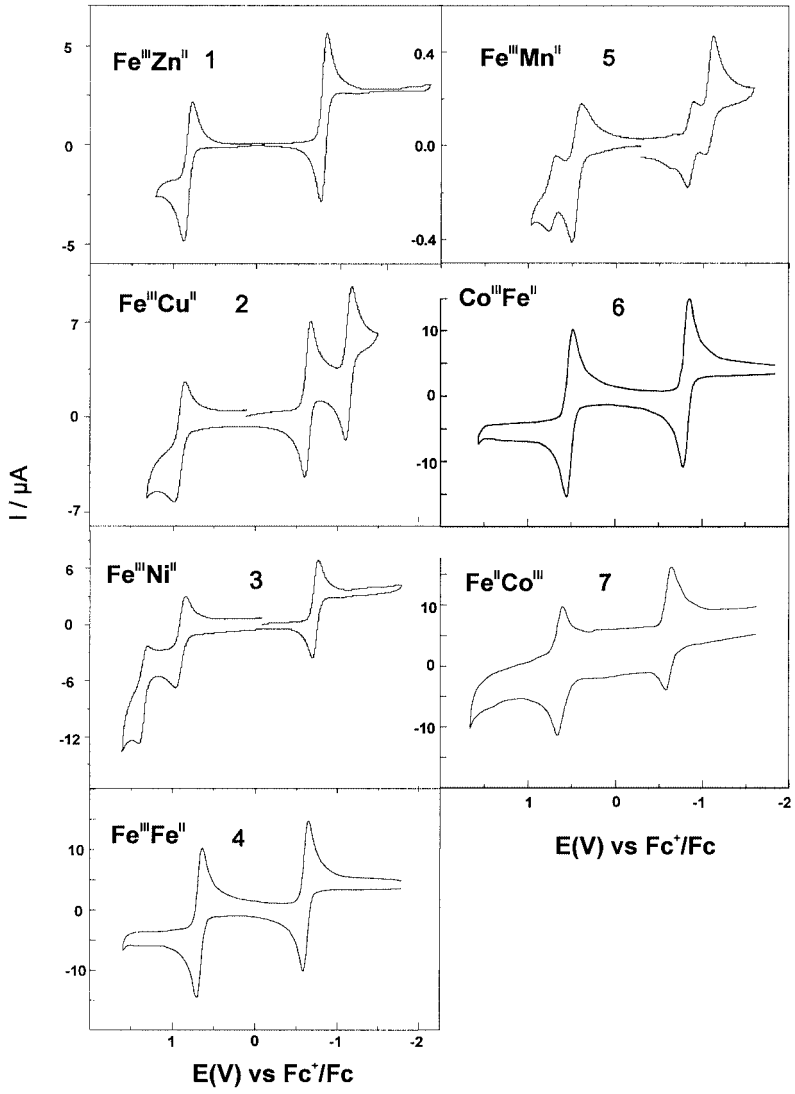

Figure 1. Cyclic voltammograms showing the reversible redox waves of complexes **1**−**7** in CH_3CN solutions containing 0.1 M nBu_4NPF_6; scan rates are 0.1 V/s, except for **5** where a scan rate of 1 V/s was used to achieve full reversibility of the first oxidative wave; working electrode: 2-mm glassy carbon or Pt disk; counter electrode: Pt; reference electrode: Ag/0.01 M $AgNO_3$ and referenced vs. Fc^+/Fc, added as an internal standard after each set of measurements

temperature in CH_3CN containing 0.1 M tetrabutylammonium hexafluorophosphate as the supporting electrolyte. The results are summarized in Table 1 and Figure 1. All redox potentials are referenced in V versus the ferrocenium/ferrocene couple (Fc^+/Fc) used as an internal standard, which is usually located at 0.09 V vs. Ag/0.01 M $AgNO_3$.

Each of the cyclic voltammograms of **1**−**7** (Figure 1) exhibits two reversible waves: one for an oxidation (in the range from +0.53 to +0.93 V) and one for a reduction (in the range from −0.62 to −0.85). The CV of **5** displays a particular feature: the oxidation and reduction are both split symmetrically into two components of unequal heights that are practically independent of the scan rate (0.3−3 V/s). The reason for this behavior is presently unknown. Apart from this exception, the heights of the peaks for oxidation and reduction of each complex are the same. Therefore, we conclude that they represent one-electron redox processes, since simultaneous, reversible two-electron oxidation *and* reduction of a mononuclear complex is not feasible. The two redox potentials for each complex, obtained from the voltammograms, are compiled in Table 1.

The reversible reductions observed for **1**−**7** in a relatively narrow potential range are assigned to the reduction of Fe^{III} (with **1**−**5**) or Co^{III} (with **6** and **7**) metal ions to their respective M^{II} forms. Complex **2** displays, in addition, a further reversible reduction wave at −1.14 V, which we assign to the Cu^{II}/Cu^{I} couple. At more negative potentials (ca. −2.0 V), further (irreversible) reductions occur for **3** and **5** (results not shown). These processes are assigned to ligand-centered reduction processes at the pyridin-2-aldoxime ligand in accordance with earlier observations[18] and results obtained with the analogous $Co^{III}Zn^{II}$ complex,[9] which exhibits *three* reversible reductions, with the one hav-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing the lowest reduction potential (−1.83 V) being ligand-centered.

The reversible oxidations could be due either to oxidation of the M^{II} metal ions (M_B for **1**−**6** and M_A for **7**) to their M^{III} forms or to ligand oxidation. Clearly with complex **1**, which bears the "redox-inactive" metal ion $M_B = Zn^{II}$, the oxidation must be ligand-centered. The similarity of the redox potentials for all complexes **1**−**7**, irrespective of the nature of the M^{II} metal ions, could suggest that this phenomenon applies to all the complexes **1**−**7**. Nevertheless, we assign these reversible oxidations to the oxidations of the M^{II} metal ions M_B (for **2**−**6**) or M_A (for **7**) to their respective M^{III} forms, since ligand oxidation was observed only at potentials higher than +1.1 V for the analogous $Co^{III}M^{II}$, $Mn^{III}M^{II}$, and $Cr^{III}M^{II}$ complexes,[9] after metal-centered oxidation. Also, irreversible oxidation of this ligand in Ni^{II} complexes has been described in the literature,[18] again at potentials > 1.0 V. With **3** and **5**, we also observed such oxidation peaks at more positive potentials — at +1.42 and +1.36 V for **3** and **5**, respectively — and these processes are indeed assignable to oxidation of the pyridin-2-aldoxime ligand.

Mössbauer Isomer Shifts and Quadrupole Splittings

The Mössbauer spectra for **1**−**7** were measured at 80 K in zero field to determine the spin and oxidation states of the iron centers. The iron coordination environments are also different, i.e., $Fe^{III}N_3O_3$ for **1**−**5**, $Fe^{II}N_6$ for **4** and **6**, and $Fe^{II}N_3O_3$ for **7**. Each spectrum, except for that of **4**, was fitted with a single quadrupole split doublet, whose isomer shifts (δ_{Fe}) and quadrupole splitting (ΔE_Q) values are listed in Table 2. Mössbauer results, except for **4**, indicate a single quadrupole splitting in accordance with only one type of iron coordination sphere in the solid-state structure, namely the iron site coordinated to the cyclic amine, 1,4,7-trimethyl-1,4,7-triazacyclononane. An isomer shift of δ_{Fe} = 1.07 mm·s^{-1} and a quadrupole splitting of ΔE_Q = 3.66 mm·s^{-1} for **7** are consistent with those observed for high-spin iron(II) ions in octahedral and distorted octahedral environments.[19] The spectrum of **4** is a best fit to two equal-area doublets, which imply two iron sites having different coordination spheres, in agreement with the molecular structure of **4**, and, thus, they are assigned to the Fe^{III} and Fe^{II} ions. A comparison of the Mössbauer data for **1**−**5** with those for **6** and **7** indicates clearly the d^5 high-spin electron configuration for the iron centers coordinated to the cyclic amine. This assignment is also confirmed by the X-ray structures of **1**−**7**. The Mössbauer parameters of complexes **4** and **6** containing the $Fe^{II}N_6$ core are completely in agreement with those observed for low-spin iron(II) ions in octahedral and distorted octahedral environments. Summarily, the Mössbauer spectra[19] show unambiguously the high-spin nature of the Fe^{III} centers in complexes **1**−**5** and of the Fe^{II} center in complex **7**, containing FeN_3O_3 coordination environments, and the low-spin character of the Fe^{II} centers bonded to the nitrogen donor atoms of pyridin-2-aldoxime in complexes **4** and **6**.

Table 2. Mössbauer parameters at 80 K in zero-field

Molecular Structures of $[LFe^{III}(PyA)_3M^{II}](ClO_4)_2$ [M = Zn (1), Cu (2), Ni (3), Fe (4), Mn(5)]

The X-ray structures confirm that mixed-metal $Fe^{III}M^{II}$ complexes have indeed been formed with geometries in which two pseudooctahedral polyhedra are joined by three oximato N−O groups. The coordinated ligand L exhibits no unexpected features.[10,20] The N−O (average 1.355 ± 0.008 Å) and C=N_{ox} (average 1.287 ± 0.017 Å) bond lengths and C−N−O bond angle (average 117.8 ± 1.6°) of the bridging pyridinaldoximate ligand are very similar to those of other comparable structures.[9,21−24] Figure 2 illustrates the thermal ellipsoid plot of the $N_3Fe(O-N_{ox})_3M(N_{py})_3$ core for the $Fe^{III}Ni^{II}$ compound **3**. Table 3 lists bond lengths of the first coordination sphere of the $Fe^{III}M^{II}$ compounds **1**−**5**. As expected, the donor atoms for the metal ions of the cations in **1**−**5** are identical [FeN_3O_3 and $M^{II}(N_{ox})_3(N_{py})$], but the coordination geometry of the divalent metal centers are not. Perspective views of the cations are shown in Figure 3 for **1** and **2** and in Figure 4 for **3**, **4**, and **5**.

The iron coordination geometry is distorted octahedral with three nitrogen atoms, N(1), N(2), and N(3), from the facially coordinated tridentate macrocyclic amine L and three oxygen atoms, O(1), O(2), and O(3), from the bridging oximate group (Figure 2). The Fe−N (average 2.197 ±

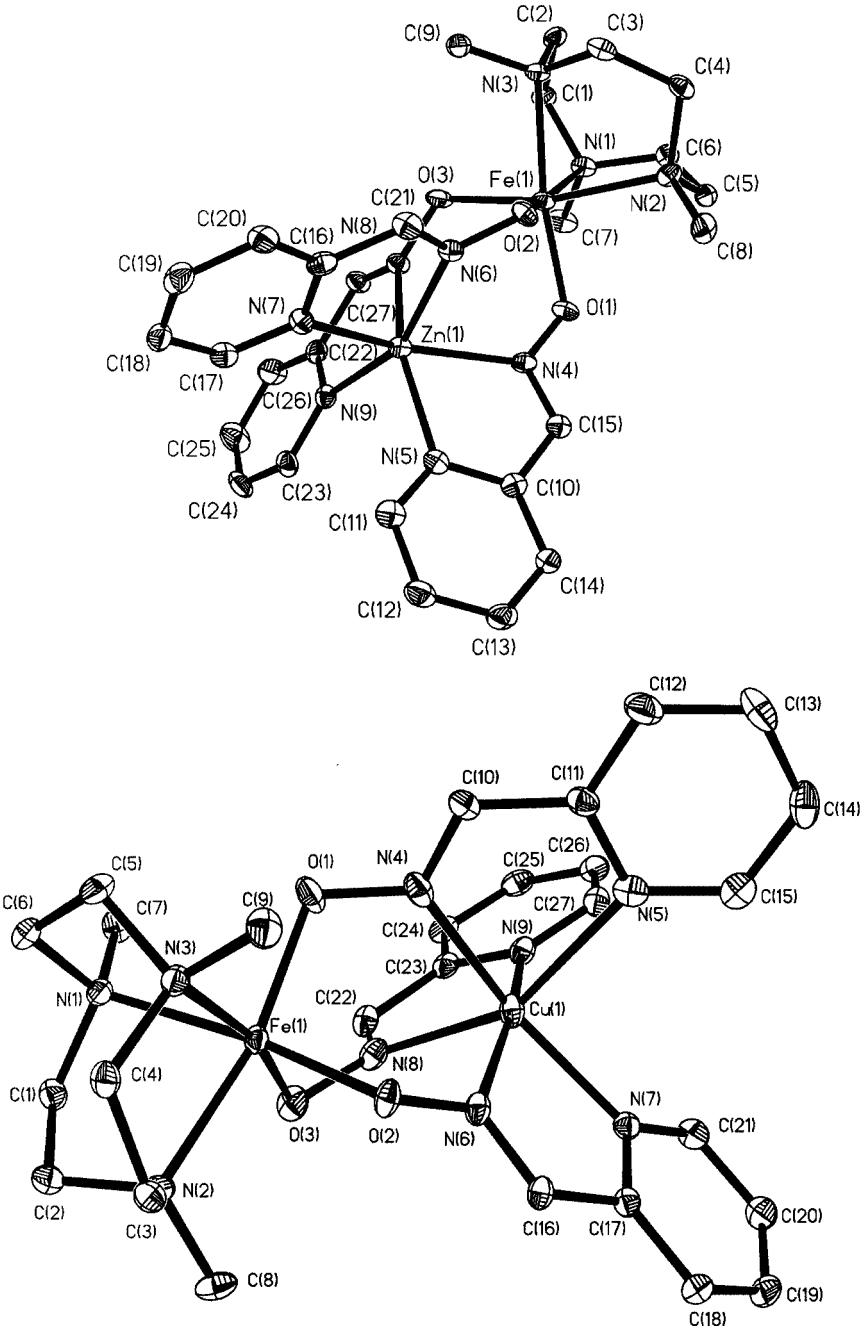

Figure 3. Molecular structures of the dications $Fe^{III}Zn^{II}$ in **1** (top) and $Fe^{III}Cu^{II}$ in **2** (bottom)

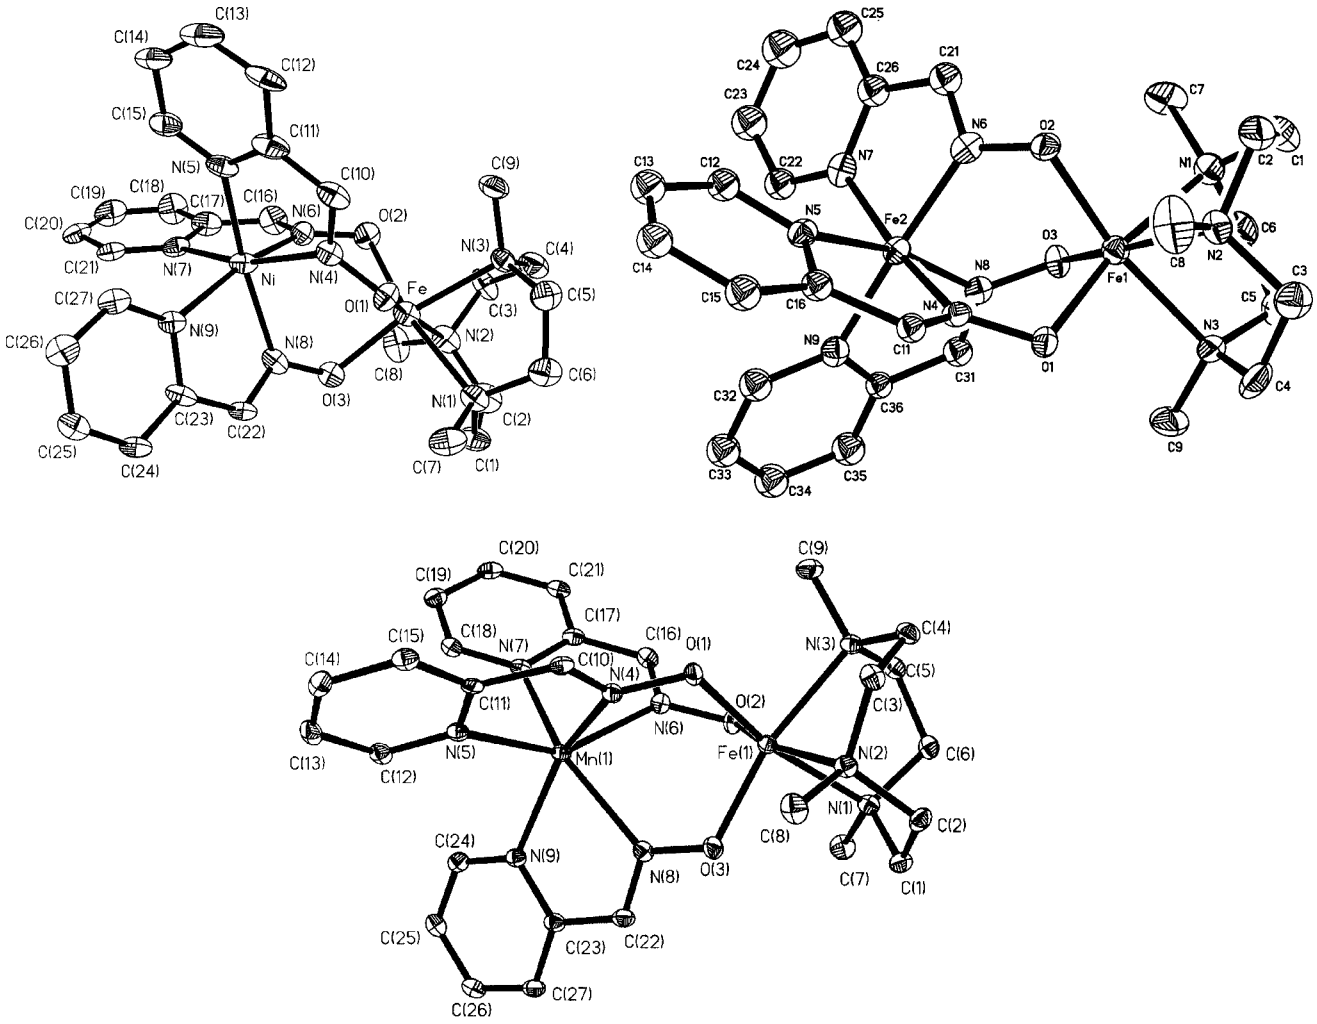

Figure 4. ORTEP diagrams of the complex cations showing the atom labeling schemes for $Fe^{III}Ni^{II}$ (**3**) (top, left), $Fe^{III}Fe^{II}$ (**4**) (top, right), and $Fe^{III}Mn^{II}$ (**5**) (bottom)

0.021 Å) and Fe−O (average 1.968 ± 0.020 Å) distances for complexes **1**−**5** correspond to those of known values[20,23] for Fe^{III} complexes with this macrocyclic amine, and are in agreement with a d^5 high-spin electronic configuration of the Fe^{III} centers, which is in complete agreement with the Mössbauer results. The largest deviation from the idealized 90° interbond angles is 12°, which occurs within the six-membered O−Fe−O chelate rings, the O−Fe−O angles ranging between 101.8(2) and 95.3(2)°, whereas the N−Fe−N angles fall between 78.95(5) and 81.1(3)°. The divalent second metal atom, which is separated from the ferric center at a distance 3.36−3.67 Å, does not affect the geometry of the ferric center. A similar observation has been made earlier for the analogous series of complexes featuring Cr^{III} ions.[9]

The crystal structure of complex **1** ($Fe^{III}Zn^{II}$) indicates the presence of two independent molecules crystallized with two molecules of solvent (methanol), which are hydrogen-bonded to two oxygen atoms of a perchlorate anion with O···O distances of 2.852 and 3.107 Å. We have found no substantial differences in the metrical parameters for the two independent molecules of **1**.

The second metal center, either Zn^{II}, Cu^{II}, Ni^{II}, Fe^{II}, or Mn^{II}, is also sixfold coordinated, yielding an MN_6 core. Coordination occurs facially through pyridine nitrogen atoms, $N_{py}(5)$, $N_{py}(7)$, and $N_{py}(9)$, and three azomethine nitrogen atoms, $N_{ox}(4)$, $N_{ox}(6)$, and $N_{ox}(8)$, from the pyridinaldoxime (PyA) ligand (Figure 2). The average M−N bond lengths fall within the ranges that are considered as normal covalent bonds for M^{II} centers with a high-spin configuration for Mn^{II} (d^5) (**5**), Ni^{II} (d^8) (**3**), and Cu^{II} (d^9) (**2**) and a d^6 low-spin electronic configuration for Fe^{II} (**4**). The low-spin electronic state of Fe^{II} in **4** has also been confirmed by the Mössbauer data.

The Cu−N distances and the angles N−Cu−N for **2** indicate that the resultant coordination sphere around the copper center in $Fe^{III}Cu^{II}$ is highly distorted. The smallest acute bite angle for *cis*-N−Cu−N occurs for the N(4)−Cu(1)−N(5) unit [73.3(1)°], where N(4) and N(5) atoms represent the oxime and pyridine nitrogen atoms, respectively, of the same pyridin-2-aldoximato ligand. On the other hand, the nitrogen atoms of the N(8)−Cu(1)−N(5) unit [154.3(1)°] belong to two different pyridinaldoximato ligands and the angle is the smallest

Table 4. Selected structural parameters for complexes **1**−**7**

Complex	$Fe^{III}\cdots M^{II}$ or $Co^{III}\cdots Fe^{II}$ or $Fe^{II}\cdots Co^{III}$ [Å]	Av. twist angle φ [°][a]	Dihedral angle θ [°][b]
1 $Fe^{III}Zn^{II}$	3.593(1)	30.3	34.9/39.4/35.4
2 $Fe^{III}Cu^{II}$	3.507(1)	35.2	40.0/34.4/43.9
3 $Fe^{III}Ni^{II}$	3.476(1)	39.2	43.5/37.4/37.5
4 $Fe^{III}Fe^{II}$	3.359(2)	46.3	39.6/43.7/43.9
5 $Fe^{III}Mn^{II}$	3.665(1)	22.3	28.7/36.2/31.3
6 $Co^{III}Fe^{II}$	3.389(1)	45.7	45.0/46.3/41.0
7 $Fe^{II}Co^{III}$	3.389(2)	50.4	50.8/51.1/49.9

[a] The trigonal twist angle φ is the angle between the triangular faces comprising N(4)N(6)N(8) and N(5)N(7)N(9) (Figure 2) and has been calculated as the mean of the Newman projection angles viewed along the centroids of focus. For an ideal trigonal prismatic arrangement, φ is 0° and 60° for an octahedron (or trigonal-antiprismatic arrangement). [b] That the core Fe(O−N)M is not linear is shown by the dihedral angles θ between the planes comprising Fe(O−N) and M(N−O) atoms.

among the *trans*-N−Cu−N angles, which indicates the severe deviation of the copper geometry from octahedral. No substantial differences in bond lengths and angles are found between the two crystallographically independent molecules of **2**.

For comparison, the important structural parameters are given in Table 4. It is clear from the data in Table 4 that the geometries of the metal ions Mn^{II} (**5**), Fe^{II} (**4**), Ni^{II} (**3**), Cu^{II} (**2**), and Zn^{II} (**1**) are distorted from octahedra toward trigonal prisms, as is evident from the twist angles; these distortions can be ascribed to both electronic (LFSE) and size effects, as has been discussed earlier.[9,10,25]

Molecular Structures of $[LCo^{III}(PyA)_3Fe^{II}](ClO_4)_2$ (6) and $[LFe^{II}(PyA)_3Co^{III}](PF_6)_2$ (7)

Figure 5 displays two perspective views of the cations in **6** and **7** and their atom labeling schemes. Selected bond lengths and angles are listed in Tables 5 and 6. The structural data concerning the ligand parts of the complex are in good agreement with the findings of previous studies dealing with compounds having the same ligands and do not warrant any additional comments. The X-ray structures confirm that the heterodinuclear complexes **6** and **7** have indeed been formed with a Co···Fe distance of 3.389 Å. The cobalt center in **6** and the iron center in **7** are distorted octahedra coordinated with three nitrogen atoms from the facially coordinated tridentate macrocyclic amine L and three oxygen atoms from the bridging oximate groups. The distances Co−N [average 2.011(3) Å] and Co−O [average 1.942(4) Å] in **6** and Fe−N [average 2.178(12) Å] and Fe−O [average 2.101(1) Å] in **7** correspond well with literature values for low-spin Co^{III} and high-spin Fe^{II} complexes, respectively.[20,26] The high-spin d^6 electronic configuration of the iron(II) center in **7** has also been confirmed by the Mössbauer and susceptibility measurements.

The second metal center, iron in **6** or cobalt in **7**, is also sixfold coordinated yielding an MN_6 core. Coordination occurs through three pyridine nitrogen atoms and three azomethine nitrogen atoms (Figure 5). The Fe−N (in **6**) and Co−N (in **7**) bond lengths (Tables 5 and 6) are consistent with a d^6 low-spin electron configuration for the metal centers, which was confirmed also by the magnetochemical measurements. Some pertinent structural parameters are listed in Table 4.

Magnetic Susceptibility and EPR Measurements

Magnetic susceptibility data for polycrystalline samples of the complexes were collected in the temperature range 2−290 K in an applied magnetic field of 1 T. We use the Heisenberg spin Hamiltonian in the form $H = -2J\cdot S_{Fe}\cdot S_M$ for an isotropic exchange coupling with $S_{Fe} = {}^5/_2$ and $S_M = 0$ for Zn^{II} (**1**), low-spin Fe^{II} (**4**), $S_M = {}^1/_2$ for Cu^{II} (**2**), $S_M = 1$ for Ni^{II} (**3**), and $S_M = {}^5/_2$ for Mn^{II} (**5**); for complex **7**, the spin states used are $S_{Fe} = {}^4/_2$ for a high-spin Fe^{II} ion and $S_{Co} = 0$ for a low-spin d^6 Co^{III} ion. The experimental data for **2**, **3**, and **5** for the effective magnetic moments (μ_{eff}) versus temperature (T) are displayed in Figure 6. The experimental magnetic data for the complexes (**1**−**5** and **7**) were simulated using a least-squares fitting program and the solid lines in Figure 6 represent the simulations for **2**, **3**, and **5**. Table 7 summarizes selected magnetic parameters with the observed spin ground states.

Complex **6** is diamagnetic indicating that both the cobalt and iron centers are in low-spin d^6 electron configurations, which is a finding that is also in full accord with the Mössbauer and structural parameters. Above $T \approx 25$ K, complexes **1** and **4**, which are magnetically mononuclear, exhibit essentially temperature-independent μ_{eff} values of 5.90 ± 0.02 and 5.80 ± 0.05 μ_B, respectively. Simulations of the experimental magnetic moment data yield g_{Fe} values of 2.0 for **1** and 1.96 for **4** with $S_{Fe} = {}^5/_2$ and $S_M = 0$. We note that the value of $g_{Fe} = 1.96$ for a high-spin ferric ion is comparatively low.

The magnetic moment μ_{eff}/molecule for **7**, Fe^{II}(h.s.)-Co^{III}(l.s.), of 5.30 μ_B ($\chi_M\cdot T = 3.517$ $cm^3\cdot K\cdot mol^{-1}$) at 290 K decreases monotonically with decreasing temperature until it reaches a value of 4.90 μ_B ($\chi_M\cdot T = 3.002$ $cm^3\cdot K\cdot mol^{-1}$) at 30 K and then starts to further decrease rapidly and reaches a value of 2.57 μ_B ($\chi_M\cdot T = 0.827$ $cm^3\cdot K\cdot mol^{-1}$) at 2 K. This temperature dependence is in agreement with a high-spin ferrous ion having an orbital T ground term. A least-squares fit results in a g_{Fe} value of 2.12.

The experimental magnetic moment for **2**, Fe^{III}(h.s.)Cu^{II}, is 5.55 μ_B ($\chi_M\cdot T = 3.853$ $cm^3\cdot K\cdot mol^{-1}$) at 290 K, which is

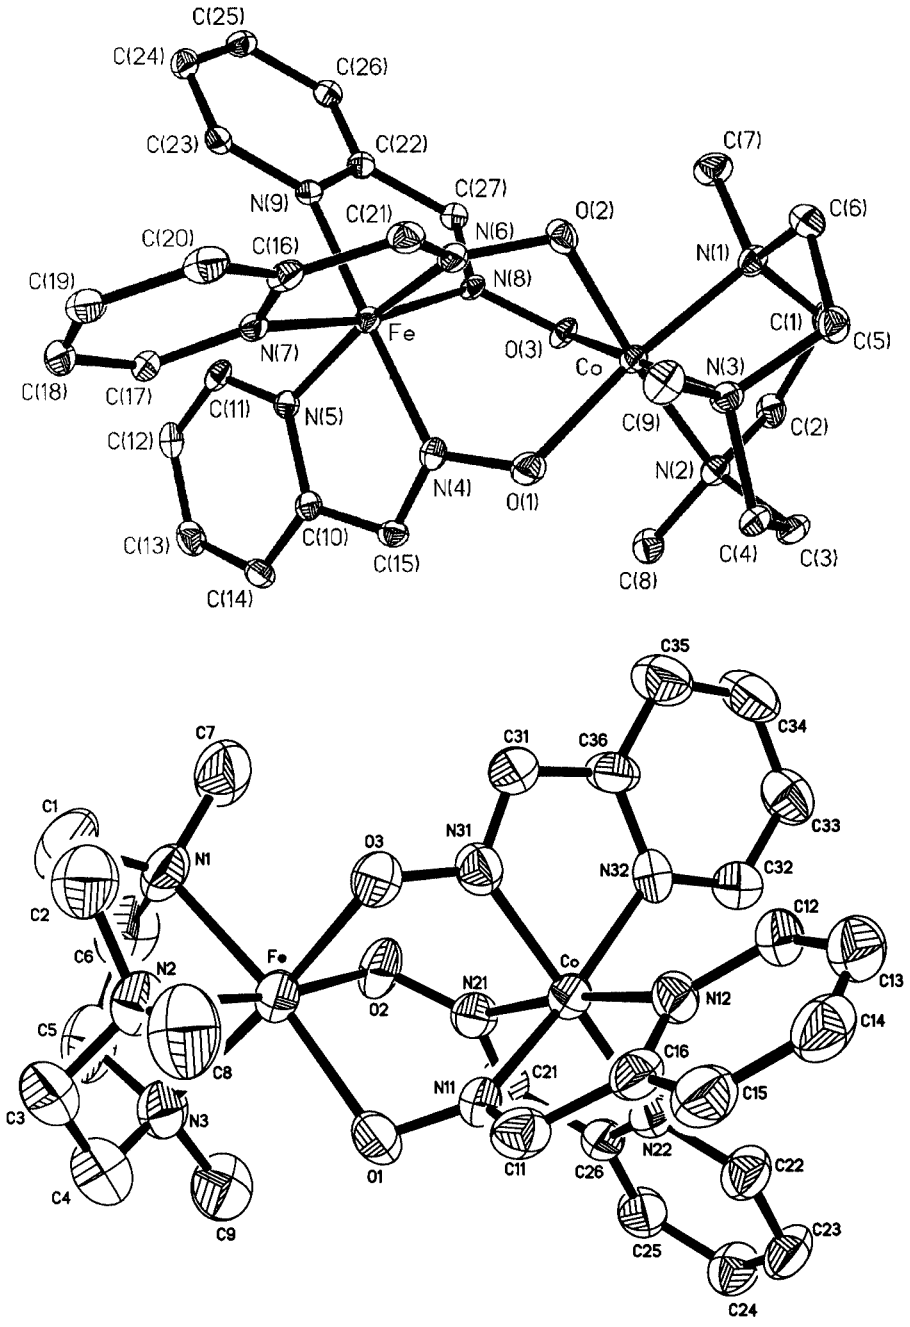

Figure 5. Perspective views of the cations in **6** ($Co^{III}Fe^{II}$) (top) and in **7** [Fe^{II}(h.s.)Co^{III}] (bottom)

significantly smaller than the theoretical value of μ_{eff} = 6.168 μ_B for two uncoupled spins of $S_{Fe} = {}^5/_2$ and $S_{Cu} = {}^1/_2$ with $g = 2.0$. Upon lowering the temperature, μ_{eff} decreases until a plateau is reached in the temperature range 80−40 K with a μ_{eff} value of ca. 4.88 μ_B ($\chi_M{\cdot}T$ = 2.974 $cm^3{\cdot}K{\cdot}mol^{-1}$), which is very close to the theoretical "spin-only" value of 4.90 μ_B for $S = 2$ expected as the ground state for an antiferromagnetically coupled $Fe^{III}Cu^{II}$ compound. Below 40 K, there is a decrease in μ_{eff} reaching a value of 3.27 μ_B ($\chi_M{\cdot}T$ = 1.341 $cm^3{\cdot}K{\cdot}mol^{-1}$) at 2 K. This deviation from the theoretical value is attributable to either zero-field splitting of the ground state $S_t = 2$ and/or intermolecular interactions. We have modeled this decrease with respect to the Weiss constant, θ. The least-squares fitting, shown as the solid line in Figure 6, of the experimental data leads to $J = -42.5\ cm^{-1}$, $g_{Fe} = 2.00$, $g_{Cu} = 2.05$, and θ = −0.4 K. The observed antiferromagnetic coupling ($J = -42.5\ cm^{-1}$) agrees well with the comparable exchange coupling constants reported earlier.[27]

The magnetic behavior of **3**, $Fe^{III}Ni^{II}$, is characteristic of an antiferromagnetically coupled dinuclear complex. At 290 K, the μ_{eff} value of 5.46 μ_B ($\chi_M{\cdot}T$ = 3.729 $cm^3{\cdot}K{\cdot}mol^{-1}$) decreases monotonically with decreasing temperature until it reaches a value of 3.53 μ_B ($\chi_M{\cdot}T$ =

1.561 $cm^3 \cdot K \cdot mol^{-1}$) at 10 K. A plateau in $\mu_{eff}(T)$ observed at 10−50 K indicates the presence of an energetically isolated ground state with total spin $S_t = {}^3/_2$ (spin-only value $\mu_{eff} = 3.87\ \mu_B$) according to a dominating exchange interaction between Fe^{III} ($S_{Fe} = {}^5/_2$) and Ni^{II} ($S_{Ni} = 1$). Below 10 K, there is a further decrease in μ_{eff} beyond what is expected from usual saturation due to zero-field splitting of the ground-state quadruplet. Magnetic susceptibility data were analyzed on the basis of a spin-Hamiltonian description of the electronic ground state of the single ions and their exchange interaction according to Equation (1), where $\mathbf{S}_i$ ($i = 1, 2$) are the spins of the metal ions in the dimers, D_i, E/D_i, and g_i are the local axial and rhombic zero-field parameters and g values, respectively, and J represents the exchange coupling constant.

$$H = \Sigma\{D_i[S_{z,i}^2 - S_i(S_i + 1)/3 + (E/D_i)(S_{x,i}^2 - S_{y,i}^2)] + \mu_B\mathbf{B}\cdot g_i\cdot\mathbf{S}_i\} - 2J\, S_1\cdot S_2 \quad (1)$$

The temperature dependence of μ_{eff} was well simulated by Equation (1) with parameters $J_{FeNi} = -34\ cm^{-1}$, $g_{Fe} = 2.0$ (fixed), $g_{Ni} = 2.12$ (fixed), $D_{Fe} = -1.1\ cm^{-1}$, $D_{Ni} = 5\ cm^{-1}$ (fixed), and 5.8% paramagnetic impurity with $S = {}^1/_2$. In the corresponding fitting procedure, the axial zfs parameter for nickel D_{Ni} was fixed to the value obtained from an isostructural $Co^{III}Ni^{II}$ complex having diamagnetic Co^{III} (not shown)[9] and the sign of D_{Fe}, as well as the value for g_{Ni}, was fixed according to the constraints derived from the EPR data (see below).

Solutions of compound **3** in BuCN/toluene (75:25, 0.4 mM) show resolved X-band EPR spectra (Figure 7). The derivative lines at $g \approx 4$ and 2 are typical of $S_t = {}^3/_2$ with strong axial zero-field splitting ($D_t > h\nu$) and low rhombicity ($0 > E/D_t > 0.1$). The presence of a distinct sharp peak at $g \approx 6$, which increases at lower temperatures, indicates the $|m_s = \pm{}^3/_2 >$ Kramers doublet to be the ground

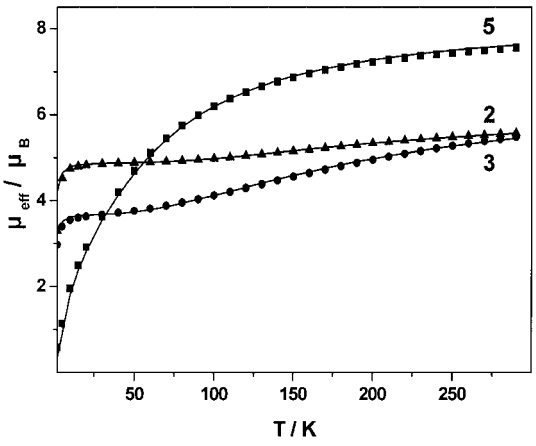

Figure 6. Plots of μ_{eff} vs. T for solid **2**, **3**, and **5**; the solid lines represent the best fit of the data to the Heisenberg−Dirac−van Vleck model (see text)

Table 7. Selected magnetic parameters for heterodinuclear complexes **1**−**7**

Complex	J [cm^{-1}]	g_{Fe}	g_M	Ground state (S_t)
1 $Fe^{III}Zn^{II}$	5.90 ± 0.02 μ_B	2.00	−	$S_t = {}^5/_2$
2 $Fe^{III}Cu^{II}$	−42.5	2.00	2.05	$S_t = 2$
3 $Fe^{III}Ni^{II}$ [a]	−34.0	2.00	2.12	$S_t = {}^3/_2$
4 $Fe^{III}Fe^{II}$(l.s.)	5.80 ± 0.05 μ_B	1.96	−	$S_t = {}^5/_2$
5 $Fe^{III}Mn^{II}$(h.s.)	−6.1	2.00	2.00	$S_t = 0$
6 Co^{III}(l.s.)Fe^{II}(l.s.)	diamagnetic			
7 Fe^{II}(h.s.)Co^{III}(l.s.)	5.1 ± 0.20 μ_B	2.12	−	$S_t = 2$

[a] $D_t = -1.8\ cm^{-1}$ (EPR), $D_t = -1.7\ cm^{-1}$ (susceptibility).

state, as a result of the negative zfs parameter D_t. The spectrum could be simulated reasonably well by using Equation (2) (see Exp. Sect.) for total spin $S_t = {}^3/_2$ with parameters $D_t = -1.8\ cm^{-1}$, $E/D_t = 0.078$, $g_t = (1.954, 1.954, 1.95)$, and isotropic g value $g_{t,iso} = 1.953$. The characteristic line shape of the powder spectrum was achieved by using a Gaussian distribution of the rhombicity parameter with a half-width $\sigma(E/D) = 0.078$.

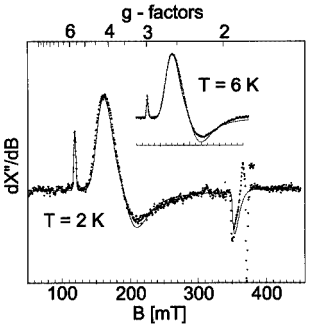

Figure 7. X-band EPR spectra of the $Fe^{III}Ni^{II}$ dimer **3** in BuCN/toluene solution recorded at 2 and 6 K (inset); experimental parameters: frequency = 9.4775 GHz, power = 2 μW (2 K)/20 μW (6 K), modulation = 1 mT/100 kHz; the solid lines are spin Hamiltonian simulations obtained using Equation (2) for total spin $S_t = {}^3/_2$ with parameters $D_t = -1.8\ cm^{-1}$, $E/D_t = 0.078$, $\sigma(E/D) = 0.078$, and $g_t = (1.954, 1.954, 1.95)$

The EPR parameter complements the interpretation of the magnetic data as given above. According to the spin projection properties, the ground-state parameters of complex **3** are related to the local single-ion values for iron and nickel by $D_t = (28/15)D_{Fe} + (1/15)D_{Ni}$ (neglecting dipolar contributions) and $g_t = 7/5\ g_{Fe} - 2/5\ g_{Ni}$. This finding indicates the dominant influence of the iron on the properties of the ground-state spin quadruplet. With the zfs value $D_{Fe} = -1.1\ cm^{-1}$ derived from the magnetic data (using fixed $D_{Ni} = 5\ cm^{-1}$), one obtains for the spin quadruplet $D_t = -1.7\ cm^{-1}$, which is strikingly close to the experimental value obtained from the EPR simulations ($-1.8\ cm^{-1}$). Hence, the complementary EPR and magnetic measurements determine the electronic properties of iron(III) and nickel(II) in **3** in great detail.

The μ_{eff} value for **5**, $Fe^{III}Mn^{II}$, decreases continuously from 7.64 μ_B ($\chi_M \cdot T = 7.299\ cm^3 \cdot K \cdot mol^{-1}$) at 290 K to 1.63 μ_B ($\chi_M \cdot T = 0.3304\ cm^3 \cdot K \cdot mol^{-1}$) at 2 K; this temperature dependence of μ_{eff} is a clear indication of an antiferromagnetic exchange coupling between two paramagnetic centers Fe^{III} ($S = {}^5/_2$) and Mn^{II} ($S = {}^5/_2$) with a resulting singlet ($S_t = 0$) ground state. Simulation of the experimental data (solid line in Figure 5) results in $J = -6.1\ cm^{-1}$, $g_{Fe} = g_{Mn} = 2.00$, and a paramagnetic impurity PI ($S = {}^5/_2$) = 0.3%.

Because a qualitative rationale for the trend of the antiferromagnetic exchange interactions between the spin carriers in the $Fe^{III}M^{II}$ pairs [M = Cu (**2**), Ni (**3**), and Mn (**5**)], on the basis of the established Goodenough−Kanamori rules[28] for superexchange as presented concisely by Ginsberg[29] and later by Kahn,[7] has been reported earlier,[3] we refrain from discussing it again in detail. Qualitatively, it can be said that the strength of exchange interactions increases upon decreasing the number of unpaired electrons, i.e., $Fe^{III}Mn^{II}$ (**5**) < $Fe^{III}Ni^{II}$ (**3**) < $Fe^{III}Cu^{II}$ (**2**), as the number of ferromagnetic paths operating in the interacting spin system decreases along the series shown above.

Several examples of structurally similar heterodimetallic complexes $Fe^{III}M^{II}$ (M = Zn, Cu, Ni, Co, or Mn) containing (μ-OR)bis(μ-carboxylato)-bridging ligands have been described in the literature[30−34] as models for dinuclear metal centers in proteins. Although the present exchange-coupled complexes **2**, **3**, and **5** having diatomic (−N−O) oximato bridges differ from the reported complexes,[30−34] it would be appropriate here to make a comparison of the efficacy of different bridging ligands with regard to the nature and magnitude of exchange couplings in the $Fe^{III}M^{II}$ pairs. The doubly or triply bridged $Fe^{III}M^{II}$ complexes exhibit exchange coupling varying from weakly ferromagnetic ($+4.2\ cm^{-1}$) to moderately antiferromagnetic ($-25\ cm^{-1}$). The bridging angle Fe−O(R)−M has been invoked[31] to rationalize this wide variation. In contrast, the tris(oximato)-bridged complexes **2**, **3**, and **5** are antiferromagnetically coupled, irrespective of the nature of the divalent metal center,[3,23,35] and, for comparable metal centers, they exhibit stronger exchange coupling than those reported in the literature,[31−35] although the Fe···M distances are significantly longer (ca. 0.2 Å) for the present complexes, which indicates that the oximato bridge is a better spin-coupler than either phenoxo or alkoxo groups.

Conclusions

In summary, we have synthesized and structurally characterized triply oximato-bridged heterodimetallic $Fe^{III}M^{II}$ complexes by using tris(pyridinaldoximato)metalates as ligands. This study confirms the essentially σ nature of the exchange interaction and applicability of the Goodenough−Kanamori rules in general to predict the nature of exchange interactions for different heterometal compounds containing the ferric ion in high-spin state. The strength of the antiferromagnetic interaction decreases in the following order: $Fe^{III}Cu^{II} > Fe^{III}Ni^{II} > Fe^{III}Mn^{II}$, as is expected.

The $Fe^{III}Co^{II}$ species could not be isolated because of facile intramolecular electron transfer leading to complex **7** ($Fe^{II}Co^{III}$). This finding is also in agreement with the cyclic voltammetric data.

The observation of the doubly charged species $[LFe(PyA)_3M]^{2+}$ as the base peak in each ESI-MS (positive) for all the complexes studied allowed the unambiguous characterization of these heterodimetal complexes.

Experimental Section

Materials and Physical Measurements: Reagent- or analytical-grade materials were obtained from commercial suppliers and used without further purification, except those for electrochemical measurements. Elemental analyses (C, H, N) were performed by the Micro-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

analytical Laboratory, Dornis & Kolbe, Mülheim, Germany. Quantitative determination of manganese, iron, and cobalt was performed spectrophotometrically as their dipicolinic acid complexes.[36] Copper and nickel were determined gravimetrically by using *N*-benzoyl-*N*-phenylhydroxylamine and dimethylglyoxime, respectively. The perchlorate anion was determined gravimetrically as tetraphenylarsonium perchlorate. Fourier transform IR spectra of the samples in KBr disks were recorded with a Perkin−Elmer 2000 FT-IR instrument. Electronic absorption spectra in solution were measured with a Perkin−Elmer Lambda 19 spectrophotometer. Magnetic susceptibilities of powdered samples were recorded with a SQUID magnetometer in the temperature range 2−295 K with an applied field of 1 T. Experimental susceptibility data were corrected for the underlying diamagnetism using Pascal's constants and for the TIP contributions. Cyclic voltammetric and coulometric measurements were performed using EG & G equipment (potentiostat/galvanostat model 273A). Mass spectra were recorded with either a Finnigan MAT 8200 (electron ionization, EIMS) or a MAT 95 (electrospray, ESI-MS) instrument. A Bruker DRX 400 instrument was used for NMR spectroscopy. The Mössbauer spectrometer worked in the conventional constant-acceleration mode with a ^{57}Co/Rh source. Isomer shifts are given relative to α-Fe at room temperature. X-band EPR spectra were recorded with a Bruker ELEXSYS E500 spectrometer equipped with a helium flow cryostat (Oxford Instruments ESR 910). The spectra were simulated on the basis of a spin Hamiltonian description of the spin ground state manifold of the dimer molecules according to Equation (2), where S_t is the manifold and D_t and E/D_t are the axial and rhombic zero-field parameters.

$$H_e = D[S_{t,z}^2 - S_t(S_t+1)/3 + (E/D)(S_{t,x}^2 - S_{t,y}^2)] + \mu_B \mathbf{B}\cdot g\cdot \mathbf{S}_t \qquad (2)$$

The simulation program was developed from the $S = {}^5/_2$ routines of Gaffney and Silverstone and specifically makes use of the calculation of transition fields based on a Newton−Raphson iterative method as described.[38]

Preparations

$LFeCl_3$: This complex was prepared as described previously.[37]

$[LFe^{III}(PyA)_3M^{II}](ClO_4)_2$ [M^{II} = Zn (1), Ni (3), Fe (4), Mn (5)]: As complexes **1** and **3**−**6** were prepared in very similar manners, only a representative method is described. An argon-scrubbed solution of *syn*-pyridin-2-aldoxime (0.36 g, 3 mmol) in methanol (75 mL) was stirred with $M(ClO_4)_2\cdot 6H_2O$ (1 mmol) and triethylamine (0.5 mL) under argon for 0.5 h. Solid $LFeCl_3$ (0.33 g, 1 mmol) was added to the resulting solution and the stirring was continued under argon for a further 1 h before the mixture was filtered to remove any solid particles. The volume of the filtrate was reduced by passing argon over the surface of the solution until crystals began to separate. The crystals were collected by filtration and washed with diethyl ether.

Complex 1, $Fe^{III}Zn^{II}$: Red-violet crystals. Yield 0.33 g (39%). $C_{27}H_{36}Cl_2FeN_9O_{11}Zn$ (854.8): calcd. C 37.94, H 4.25, N 14.75, Fe 6.53, ClO_4 23.16; found: C 39.1, H 4.4, N 15.1, Fe 6.7, ClO_4 23.4. IR (KBr): $\tilde{\nu}$ = 1636 (CN), 1005 (NO), 1605, 1554, 1480, 1441 (pyridine) cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 257 (25720), 303 (27300), 390 sh (ca. 4500) nm ($M^{-1}\cdot cm^{-1}$). ESI-MS: *m*/*z* (%) = 753, 654, 327 (100).

Complex 3, $Fe^{III}Ni^{II}$: Red-brown crystals. Yield 0.36 g (42%). $C_{27}H_{36}Cl_2FeN_9NiO_{11}$ (848.1): calcd. C 38.07, H 4.26, N 14.81, Fe 6.56, Ni 6.90, ClO_4 23.37; found C 38.0, H 4.2, N 14.7, Fe 6.7, Ni 6.8, ClO_4 23.5. IR (KBr): $\tilde{\nu}$ = 1636 (CN), 1007 (NO), 1605, 1584 1476, 1444 (pyridine) cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 220 (33600), 255 (31910), 305 (29910), 513 sh (ca. 2100), 628 sh (ca. 102), 729 (40) nm ($M^{-1}\cdot cm^{-1}$). ESI-MS: *m*/*z* (%) = 747, 324 (100).

Complex 4, $Fe^{III}Fe^{II}$: Deep-red crystals. Yield 0.35 g (40%). $C_{27}H_{36}Cl_2Fe_2N_9O_{11}$ (845.2): calcd. C 38.37, H 4.29, N 14.91, Fe 13.21, ClO_4 23.43; found C 38.6, H 4.3, N 14.8, Fe 13.6, ClO_4 23.6. IR (KBr): $\tilde{\nu}$ = 1635 (CN), 1006 (NO), 1604, 1563 1467, 1435 (pyridine) cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 202 (35660), 252 (23660), 294 (27550), 512 (8280) nm ($M^{-1}\cdot cm^{-1}$). ESI-MS: *m*/*z* (%) = 745, 323 (100).

Complex 5, $Fe^{III}Mn^{II}$: Deep-red crystals. Yield 0.34 g (40%). $C_{27}H_{36}Cl_2FeMnN_9O_{11}$ (844.3): calcd. C 38.41, H 4.30, N 14.93, Fe 6.61, Mn 6.51, ClO_4 23.56; found C 38.8, H 4.3, N 14.8, Fe 6.7, Mn 6.6, ClO_4 23.7. IR (KBr): $\tilde{\nu}$ = 1636 (CN), 1007 (NO), 1601, 1549 1466, 1437 (pyridine) cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 257 (44670), 306 (43750), 393 (ca. 10880), 515 sh (ca. 2750) nm ($M^{-1}\cdot cm^{-1}$). ESI-MS: *m*/*z* (%) = 744, 322.5 (100).

$[LFe^{III}(PyA)_3Cu](ClO_4)_2$ (2): A sample of anhydrous copper(II) chloride (0.14 g, 1 mmol) and triethylamine (0.5 mL) was added with stirring under argon to a degassed solution of methanol (75 mL) containing *syn*-pyridin-2-aldoxime (0.36 g, 3 mmol). After 0.5 h, the stirred solution was charged with solid $LFeCl_3$ (0.33 g, 1 mmol) and the stirring was continued at ambient temperature for a further 1 h. After addition of $NaClO_4\cdot H_2O$ (0.75 g, 6 mmol), the volume of the solution was reduced by passing argon over the surface of the solution. The brown-red microcrystalline product was collected by filtration. X-ray-quality crystals were obtained from an acetonitrile solution. Yield 0.5 g (59%). $C_{27}H_{36}Cl_2CuFeN_9O_{11}$ (852.9): calcd. C 38.02, H 4.25, N 14.78, Fe 6.55, Cu 7.45, ClO_4 23.32; found C 38.1, H 4.4, N 14.6, Fe 6.6, Cu 7.6, ClO_4 23.5. IR (KBr): $\tilde{\nu}$ = 1635 (CN), 1006 (NO), 1606, 1583 1475, 1444 (pyridine) cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 207 (31930), 240 (30390), 302 (26960), 525 sh (ca. 1640) nm ($M^{-1}\cdot cm^{-1}$). ESI-MS: *m*/*z* (%) = 752, 326.5 (100).

$[LCo^{III}(PyA)_3Fe^{II}](ClO_4)_2$ (6): Solid $Co(CH_3COO)_2\cdot 4H_2O$ (0.25 g, 1 mmol) was added to a degassed methanolic solution (25 mL) of 1,4,7-trimethyl-1,4,7-triazacyclononane (0.17 g, 1 mmol) under argon; the solution was stirred further for 1 h. A methanolic solution (50 mL) of (0.36 g, 3 mmol) of *syn*-pyridin-2-aldoxime and $Fe(ClO_4)_2\cdot 6H_2O$ (0.36 g, 1 mmol) was added to the cobalt-containing solution and then stirred at room temperature for 0.5 h. The precipitated black-violet microcrystalline substance was collected by filtration. X-ray-quality crystals were obtained by recrystallization from CH_3CN. Yield 0.42 g (50%). $C_{27}H_{36}Cl_2CoFeN_9O_{11}$ (848.3): calcd. C 38.23, H 4.28, N 14.86, Co 6.95, Fe 6.58, ClO_4 23.45; found C 38.2, H 4.1, N 14.5, Co 6.7, Fe 7.0, ClO_4 23.6. IR (KBr): $\tilde{\nu}$ = 1636 (CN), 1016 (NO), 1602, 1563 1467, 1434 (pyridine) cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 209 (46500), 247 (42900), 270 sh (ca. 32400), 326 (23400), 527 (4100) nm ($M^{-1}\cdot cm^{-1}$). ESI-MS: *m*/*z* (%) = 748, 324.5 (100).

$[LFe^{II}(PyA)_3Co^{III}](ClO_4)_2$ (7): Methanol (25 mL) containing Et_3N (0.5 mL) was degassed at room temperature. Solid $Co(CH_3COO)_2\cdot 4H_2O$ (0.25 g, 1 mmol) and *syn*-pyridin-2-aldoxime (0.36 g, 3 mmol) were added to the methanol solution with continuous stirring over 0.5 h. $LFeCl_3$ (0.33 g, 1 mmol) was added to this clear solution and the stirring was continued for a further 1 h. Addition of $NaClO_4\cdot H_2O$ (0.5 g, 4 mmol) afforded a deep-red microcrystalline solid, which was collected by filtration and washed with diethyl ether. Yield 0.31 g (37%). $C_{27}H_{36}Cl_2CoFeN_9O_{11}$ (848.3): C 38.23, H 4.28, N 14.86, Fe 6.58, Co 6.95, ClO_4 23.45; found C 38.2,

H 4.3, N 14.8, Fe 6.7, Co 7.0, ClO_4 23.6. IR (KBr): $\tilde{\nu}$ = 1620 (CN), 1010 (NO), 1602, 1560 1470, 1444 (pyridine) cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 208 (37900), 243 (29370), 317 (16050), 516 (1710), 925 (20) nm ($M^{-1}\cdot cm^{-1}$). ESI-MS: *m*/*z* (%) = 748, 324.5 (100). X-ray-quality crystals of $[LFe(PyA)_3Co](PF_6)_2$ were obtained by addition of $NaPF_6$ as the anion source, instead of $NaClO_4$, from a methanolic solution.

CAUTION: Although we experienced no difficulties with the compounds isolated as their perchlorate salts, the unpredictable behavior of perchlorate salts necessitates extreme caution in their handling.

X-Ray Crystallographic Data Collection and Refinement of the Structures: The crystallographic data for **1**−**7** are summarized in Tables 8 and 9. Graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used throughout. X-ray diffraction data were collected at 293(2) K using a Siemens R3m/V diffractometer for **4** and **7**. Dark-red/brown to red crystals of **1**, **2**, **3**, **5**, and **6** were fixed with perfluoropolyether onto glass fibers and mounted on a Siemens SMART diffractometer (CAD 4 for **2**) equipped with a cryogenic nitrogen cold stream, and intensity data were collected at 100(2) K. Final cell constants were obtained from a least-squares fit of the setting angles of several strong reflections. Intensity data were corrected for Lorentz and polarization effects. An empirical absorption correction by ψ scans was applied for **4** and **7**. The data set for **2** was not corrected for absorption. The program SADABS (G. M. Sheldrick, Universität Göttingen, **1994**) was used for absorption corrections on data sets for **1**, **3**, **5**, and **6**. The Siemens ShelXTL software package (G. M. Sheldrick, Universität Göttingen) was used for solution, refinement, and artwork of the structures; the neutral atom scattering factors of the program were used. All structures were solved and refined by direct methods and difference Fourier techniques. Non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters. For **4**, the aldoximic carbon atoms were refined isotropically. The methanol molecule and a perchlorate anion in **1** were found to be disordered and, therefore, a split-atom model was used. The two positions of the oxygen atom of the methanol molecule, O(70), were refined with two occupancies; O(70)/O(70X) = 0.8:0.2. CCDC-214728 (**1**), -214729 (**2**), -214730 (**3**), -214731 (**5**), -214732 (**6**), -212949 (**4**), and -212950 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This work was initiated in Bochum. Our thanks are due to M. Winter (Bochum), H. Schucht, P. Höfer, A. Göbels, and B. Mienert for their skilful technical assistance. Support from the Max Planck Society and Fonds der Chemischen Industrie is gratefully acknowledged.

Systematic Investigation of PPV Analogue Oligomers Incorporating Low-Coordinate Phosphorus Centres

Rhett C. Smith[a] and John D. Protasiewicz*[a]

Keywords: Oligomers / Phosphorus / Phosphaalkenes

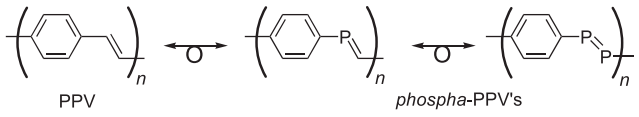
Sterically-encumbered ligands tethered to conjugated segments have been developed and employed in concert with existing bulky ligands to prepare a series of *phospha*-PPV oligomers. A study of the variation of $\lambda_{\pi\text{-}\pi^*}$ values along this series indicates that low-coordinate phosphorus centres can support conjugation across extended systems, and generally confirms the expected red shift across the series from all-carbon oligomers to phosphaalkenes to diphosphenes. These findings provide experimental evidence that low-coordinate phosphorus centres are in fact capable of supporting electronic communication across extended π conjugated systems.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Since the discovery that selected polymers featuring extended π conjugation may exhibit conductivity[1] and other fascinating properties and the subsequent integration of such materials into devices such as OLEDs,[2] an explosion of research has emerged in the search for new systems with specifically desired properties.[3] Efforts in this area have focused particularly on tuning the band gap (and therefore absorption and emission wavelengths and conductivity) by varying substitution patterns or exploring different conjugated linkers along the conjugated polymer chain.[4] One of the most technologically promising classes of conjugated polymers are poly(*p*-phenylenevinylene)s (PPV)s.[3] Hence, numerous efforts have been undertaken to create new polymers that incorporate the basic PPV framework with other conjugated linkers. However, comparatively little work has been carried out in this area in which heavier main group elements have been incorporated along the main chain, despite the success that has been achieved with polythiophene and polyaniline, in which accessible lone pairs may participate in π conjugation (n−pπ interactions) giving rise to unique properties compared with their all carbon analogues.[3d]

The success of PPV's and variations thereof, along with the established analogy between the chemistry of carbon and phosphorus (phosphorus is often referred to as a "carbon copy"[5]) and the predicted π conjugative ability of phosphorus[6] led to our interest in the synthesis and study of "*phospha*-PPV's" in which olefinic bonds are replaced by P=C or P=P bonds to yield main group pπ−pπ conjugated materials. Such substitution may have a significant impact on the properties of the polymers. The recent synthesis of the first poly(*p*-phenylenephosphaalkene), **P1**, did indeed provide evidence for π-conjugation involving P=C functional groups in a polymer.[7]



Another poly(*p*-phenylenephosphaalkene), **P2**, not only showed evidence for conjugation, but also revealed that such systems may also exhibit fluorescence,[8] a property critical for LEDs. Particularly noteworthy is the very exciting breakthrough that phosphole-containing oligomers have been successfully used in LEDs.[9] Several other investigations related to the incorporation of phosphorus into materials featuring possible π conjugation (in which phosphorus may contribute via n−pπ interactions) have also been reported.[10] Examples include polyarylphosphanes,[11] blue emitting polymers incorporating phosphole units,[12] poly(ferrocenylphosphanes),[13,14] and oligomers incorporating phosphirenes[15] or phospholes.[16−18]

Substitution of the sp^2 carbon atoms along the path of conjugation in PPV's by heavier elements such as phosphorus thus has a significant impact on the properties of polymers. For example, simple differences in polarizability and electron affinity will effect the hole and electron transport properties. In addition, the HOMO−LUMO gaps may become increasingly smaller upon substitution with low-coordinate (formally sp^2) P atoms along the path of conjugation. One approach to gaining a fuller understanding of how molecular properties affect properties displayed by polymeric systems is the so-called "oligomer approach" that has been used for studying PPV and related organic

[a] Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106-7078, USA

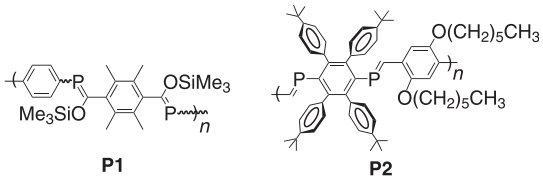
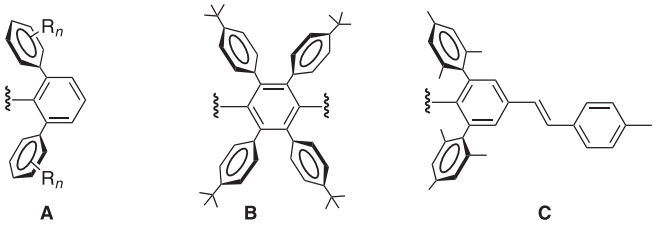
conjugated materials.[19] In this approach studies of discrete model oligomers of increasing size can yield correlations between small molecules and polymers.



P1 **P2**

Some work has been carried out towards developing such an analogy for phosphaalkenes and diphosphenes, and towards drawing parallels between them and their all-carbon analogues. For example, discrete phosphaalkenes and diphosphenes are more easily reduced than olefin analogues. Studies of the reduction of bifunctional conjugated phosphaalkenes and diphosphenes have already revealed the additional possibilities of producing high-spin materials[20] and even molecular switches.[21] Further extensions of these studies require oligomers having longer conjugation paths and an increased phosphorus content. The longest π conjugated PPV-like molecules featuring phosphaalkene or diphosphene units reported prior to this particular investigation were analogues of distyrylbenzene[22,23] and stilbene.[24,25]



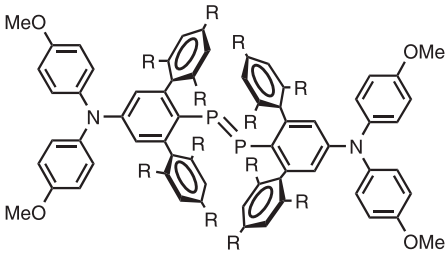
A **B** **C**

The absence of more (pπ−pπ conjugated) extended systems with (P=P) and (P=C) linkages can possibly be attributed to difficulties associated with the synthesis of suitably bulky ligands required to prevent the redistribution reactions that phosphaalkenes and diphosphenes are susceptible to in the absence of steric protection.[26] The extent of steric bulk required can be illustrated by the fact that it was not until the 2,4,6-tri-*tert*-butylphenyl (Mes*) ligand was employed that the first isolable diphosphene (Mes*P=PMes*) was reported.[25] More recently, *m*-terphenyl ligands **A** have also been extensively employed in the steric shielding of multiple bonds between heavier main group elements.[27]

In this report, routes to *m*-terphenyl ligands with conjugated groups tethered to the position *para* to the steric cleft (**C**) are detailed. These ligands, along with the existing ligands **A** and **B**, have enabled the preparation of a series of *phospha*-PPV oligomers as models for polymeric systems. The synthesis of this series of oligomers has allowed us to begin a systematic study of the effect of conjugation length and phosphorus for carbon substitution in PPV oligomers, the results of which are reported herein.

Results and Discussion

The protection of main group multiple bonds with *m*-terphenyl ligands featuring substitution *para* to the steric cleft is an underdeveloped area. Only a few 4-substituted 2,6-diarylphenyl ligands have been developed for use in low-coordinate phosphorus chemistry. Two relevant molecules bearing novel ligands have been pioneered by the Yoshifuji group.[28] While compound **D** could not be fully purified, diphosphene **E**, having a greater degree of steric protection, was isolated in 11 % yield.



R = Me, **D**
λ = 446, 504 nm

R = *i*Pr, **E**
λ = 460, 530 nm

Both of these materials display impressive red shifts in their absorption spectra with data for **E** showing λ_{max} = 460 and 530 nm for the π−π* and n−π* bands, respectively. The approach to the amino functionalized terphenyl ligands was based upon introduction of the diarylamino functionality into preformed 1,4-diiodo-2,6-diarylbenzenes by a copper coupling step.

Our approach to functionalised terphenyls introduces functionality earlier in the synthesis. Specifically, 1,3-dichlorobenzene, the starting material for the simplest route to *m*-terphenyls (Scheme 1, top),[29] was replaced with substituted 1,3-dichlorobenzenes (**v**, **xi**, Scheme 1).

These materials should enable common access to terphenyl ligands bearing different aromatic groups on the periphery of the ligand. Synthesis of precursor **v** has been previously reported and we have been able to effect its synthesis in an overall yield of 71 % in 4 steps from the commercially available 1,3-dichlorobenzoyl chloride.[30,31] The more extended precursor **xi** could be prepared from the known intermediate phosphonium salt in an overall yield of 22 % in 6 steps starting with *p*-*tert*-butyltoluene.[32,33] The syntheses of **v** and **xi** are summarized in Scheme 2.

The substituted 1,3-dichloroarenes were thus employed for the synthesis of Dmp′I (Scheme 1, middle) and Dmp′′I (Scheme 1, bottom) using essentially the same conditions employed in the synthesis of the DmpI ligand (Scheme 1, top), although yields became increasingly lower as the length of the conjugated tether was increased. The decrease in yield with increased conjugation length may be due to decreased reactivity of the intermediate arynes. Alternatively, aryne formation may be inhibited due to an increase in stability of the 2-chlorolithio (or magnesio) benzene and subsequent difficulty of metal halide elimination. Longer reaction times for Dmp′I and Dmp′′I (10 and 16 hours, respectively) relative to DmpI (4 hours, ca. 60 % yield) partially compensate for less reactive substrates. Further increases in reaction times, however, did not provide increased

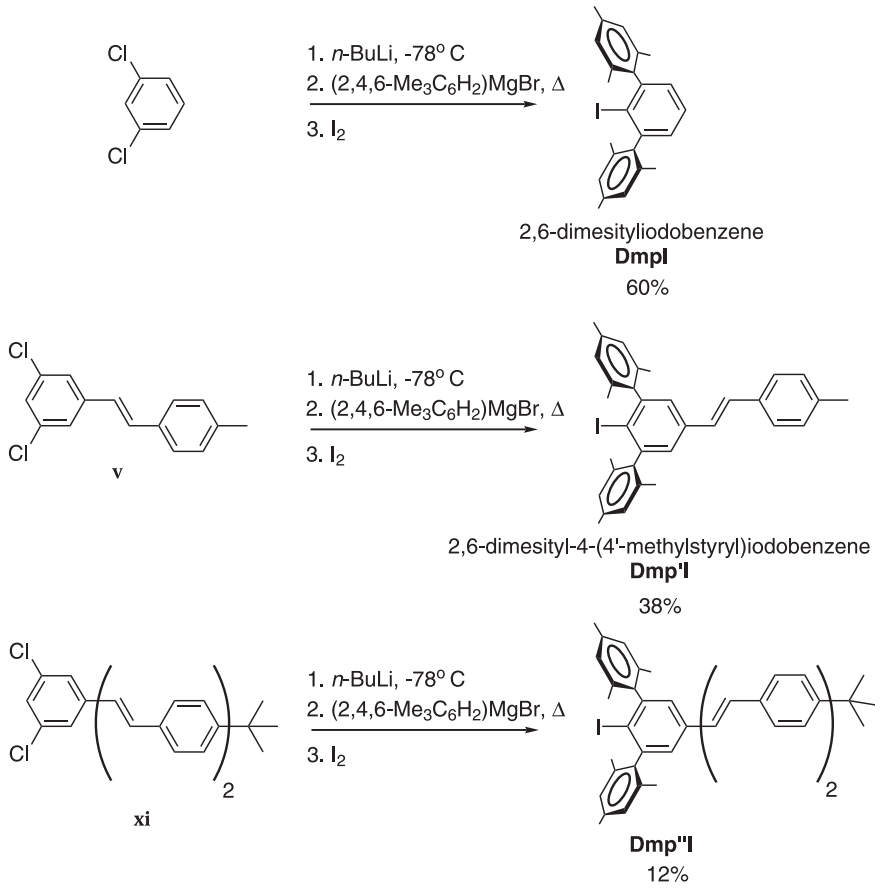
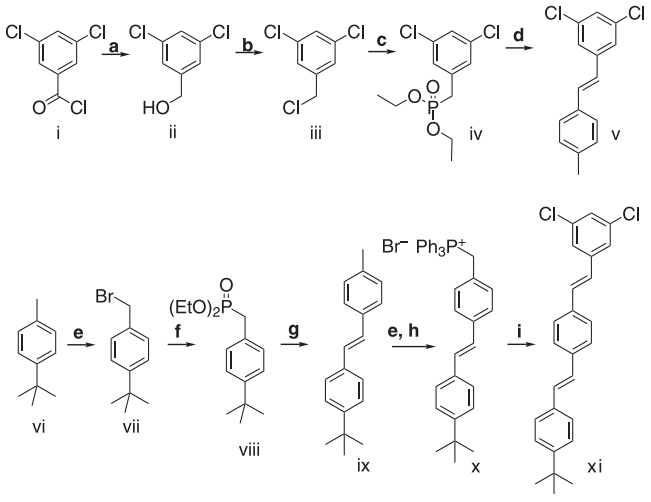


Scheme 1



Scheme 2. Reagents and conditions: a) 1. $LiAlH_4$, 0 °C, 2. H^+; b) $SOCl_2$; c) $P(OEt)_3$, 160 °C; d) *p*-tolualdehyde, KO*t*Bu; e) NBS, BPO, reflux, 3 h; f) $P(OEt)_3$, 160 °C; g) *p*-tolualdehyde, KO*t*Bu; h) PPh_3, toluene, reflux; i) 3,5-dichlorobenzene, KO*t*Bu

yields for Dmp′ and Dmp′′I beyond 38 % and 12 %, respectively. Due to the significant decrease in yield and time consuming preparation of more complex starting materials required to access Dmp′′I compared with Dmp′I (Schemes 1 and 2), only the latter material has been pursued for utility in the current study.

The olefinic units in precursor materials (Scheme 2) were either prepared in the *E* form directly (via the Horner−Wittig reaction) or isomerized to the all-(*E*) conformation subsequent to synthesis. The retention of the all-(*E*) form in the course of the *m*-terphenyl synthesis and all subsequent steps was confirmed by the characteristic chemical shifts and coupling constants in ^{1}H NMR spectra. These diagnostic features were not resolved in the ^{1}H NMR spectrum of compound **9** (vide infra), however. Therefore the structural assignment of **9** was deduced using the known orientation of the starting material and the fact that a single species was observed in both ^{1}H and ^{31}P NMR spectra. The *E* forms were highly desired for a useful comparison with organic PPV oligomers and derivatives in which the *E* forms are technologically far more relevant than corresponding *Z* isomeric materials.[3]

Some differences in the general properties of Dmp′ derivatives compared with those of known Dmp analogues are of note. For example, the conjugated segment tethered to the Dmp′ ligand affords much greater solubility compared with analogous compounds featuring the simple Dmp ligand. Interesting colour differences can also be observed not only in the *phospha*-PPV oligomers that are the focus of the current study (vide infra), but also in the precursors. For example, while DmpLi is a white material,[34] Dmp′Li is a red-brown colour, probably indicating that the

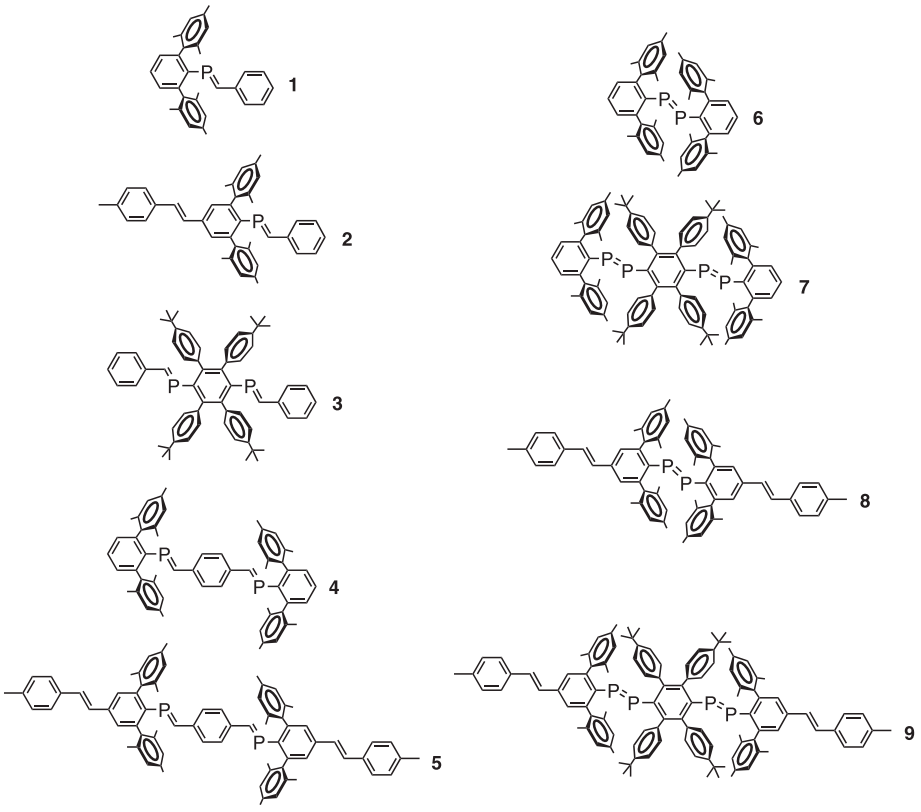
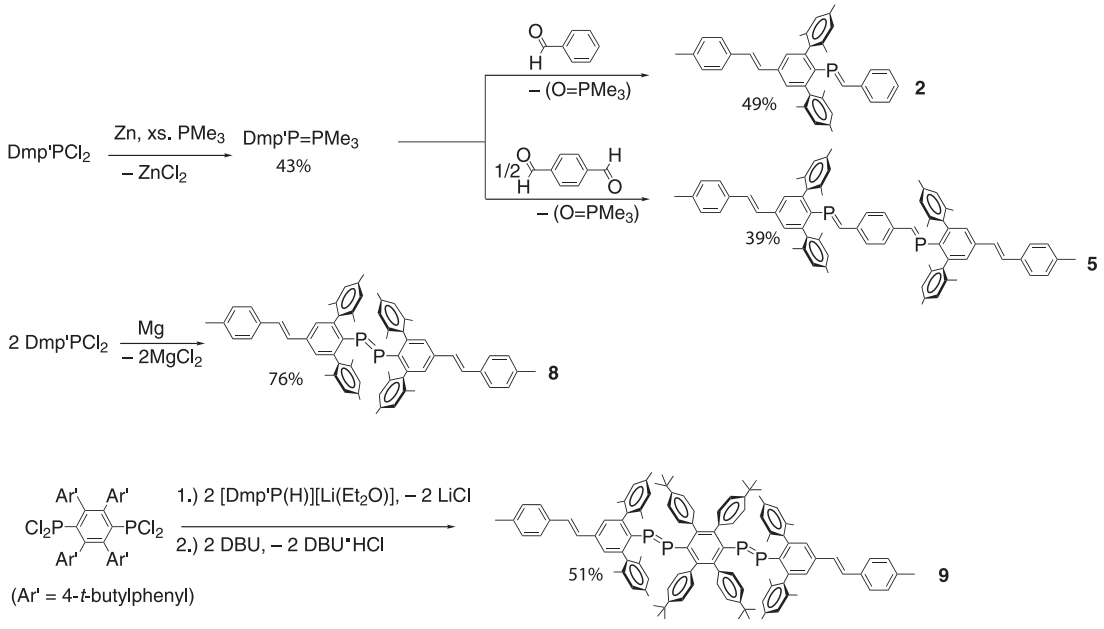


Scheme 3



Scheme 4

extended conjugated system allows for delocalization of the anionic charge or possibly an ionic or charge separated structure. $DmpPCl_2$ (white) and $Dmp'PCl_2$ (pale yellow) (prepared from ArLi by known methods[45]), however, differ only slightly in colour. Interestingly, a notable colour change is noted for the air- and moisture-sensitive phospha-Wittig reagents $ArP{=}PMe_3$. Whereas $DmpP{=}PMe_3$ is yellow (λ = 348 nm, ε = 6021 $M^{-1}cm^{-1}$; λ = 390 nm, ε = 2998 $M^{-1}cm^{-1}$), $Dmp'P{=}PMe_3$ is deep red (λ = 332 nm, ε = 34,800 $M^{-1}cm^{-1}$; λ = 432 nm, ε = 10,600 $M^{-1}cm^{-1}$).

The Dmp′ ligand was thus used to produce a series of (P=C)- (Scheme 3, left) and (P=P)- (Scheme 3, right) containing *phospha*-PPV oligomers via the routes summarised in Scheme 4. These materials exhibit diagnostic bands in

their visible absorption spectra. Phosphaalkenes commonly display a single characteristic absorption in the visible region normally assigned to a π−π* transition.[5,6] Diphosphenes exhibit similar bands due to π−π* transitions but these are accompanied by a second absorption band of significantly lower intensity at higher wavelengths that have been assigned to n−π* transitions.[24,25] The n−π* transition should be forbidden and therefore less intense. Following this convention, assignments of bands for **1**−**9** were made as summarized in Table 1. In accord with previous reports, the higher wavelength n−π* transitions for diphosphenes **6**−**9** have absorptivities approximately one order of magnitude lower than those of the corresponding π−π* transitions. This specific ordering has been the subject of some discussion, however.[24,35] The most recent experimental (electron density deformation) and computational results (DFT) give most credence to the above ordering, that is, the HOMO of a diphosphenes is more than likely the phosphorus lone pair orbital and the HOMO-1 is the π bond.[36]

The set of diphosphene oligomers **6**−**9** enables one to test this ordering in a different fashion. Figure 1 portrays two qualitative models for how the energies of pertinent frontier molecular orbitals should vary with increasing conjugation length. For the first model (Figure 1, left), the HOMO is assumed to be the π orbital and in the second model (Figure 1, right), the HOMO is assumed to be the phosphorus lone pair (n_+ combination). For both models the difference between the π and π* orbitals is diminished with increasing conjugation length and the lone pairs are assumed to be relatively unaffected. The first model predicts that as the conjugation length increases, the HOMO−HOMO−1 gap (described by Δ in Figure 1) should increase. The second model predicts the exact opposite. The very crude model given in the right of Figure 1 fits the observed trends for compounds **6**−**9** nicely, as well as agreeing with the most recent computational and experimental data for simple diphosphenes.[36]

A simple comparison of the absorption maxima ($\lambda_{\pi\text{-}\pi^*}$) for the all-carbon oligomers **M1**−**M4**, phosphaalkenes **1**−**5**, and diphosphenes **6**−**9** with central π-conjugated cores of equal length (Table 1) generally demonstrates the intended red shifts for the electronic transitions as either the phosphorus content or maximum conjugation length in-

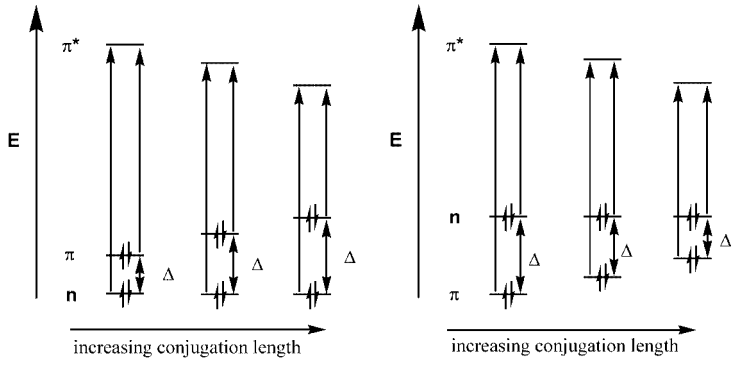

Figure 1. Simple MO diagrams for conjugated materials assuming the HOMO involves P=E π bonds (left) or n orbitals (right)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

creases. A more detailed evaluation, however, reveals some discrepancies in these general trends. For example, although the $\lambda_{\pi\text{-}\pi^*}$ values for compounds **2** and **3** are consistent with the anticipated red shift with increasing P content (one P=C in **2** versus two P=C units in **3**), the values might also be expected to be red shifted with respect to the all-carbon analogue, distyrylbenzene (**M2**). The $\lambda_{\pi\text{-}\pi^*}$ values for compounds **2** and **3** are actually *blue* shifted by 13 nm and 5 nm, respectively, relative to distyrylbenzene. Compound **4**, however, which is also of the same geometric conjugation length, is quite significantly red shifted by 57 nm. These large differences exhibited by molecules of equal conjugation length demonstrate the striking effects that steric influences can produce. Specifically, such deviations can be attributed to deflections of some portions of the conjugated system out of ideal coplanarity with one another in response to steric clashes. In this manner, the *effective* conjugation length is lowered relative to that expected for an entirely coplanar conjugated core. A simple example of this effect is the observed 33 nm blue shift in the $\lambda_{\pi\text{-}\pi^*}$ value of (*E*)-2,6-dimethylstilbene with respect to (*E*)-stilbene.[37]

Steric disruptions to coplanarity have in fact been intentionally incorporated into organic conjugated polymers and have been observed to provide a significant enhancement of electroluminescent efficiency.[38] In other cases, steric distortions induced by binding events along conjugated polymer backbones have led to significant changes in absorption maxima, a property routinely taken advantage of in the design of molecular sensors.[39] Such steric effects were also discussed in the analysis of the properties of a poly(*p*-phenylenephosphaalkene),[7] and we have previously observed this effect (at least in the solid state) by X-ray crystallographic analysis of diphosphene **7** and phosphaalkene **3**.[22]

The effect of such sterically-induced noncoplanarity may not have as great an impact on the $\lambda_{\pi\text{-}\pi^*}$ of **4** since, in that case, the steric bulk is located on the outer rings rather than on the central ring such that the latter may easily maintain conjugation with at least the two flanking P=C units without steric interference. A direct comparison of **4** can also be made with 1,4-[Mes*P=C(H)]$_2$C$_6$H$_4$ (Mes* = 2,4,6-tri-*tert*-butylphenyl),[40] in which the only difference is the replacement of Dmp with Mes* ligands. The Mes*-containing system has a $\lambda_{\pi\text{-}\pi^*}$ of only 326 nm, closer to that of stilbene than the all-carbon analogue, distyrylbenzene. Distortions of the phosphorus centre from the plane of the attached phenyl ring in the Mes* components are common due to the extreme steric pressure in such systems[41] and such distortions may complicate comparisons of the type made here. Regardless of the explanation, similar large differences can be observed when comparing $\lambda_{\pi\text{-}\pi^*}$ values for other materials featuring the two sets of ligands such as **6** (372 nm) with Mes*P=PMes* (340 nm) or **1** (334 nm) with Mes*P=C(H)Ph (259 nm).[38]

Another example of steric effects on effective conjugation is evident from the observed $\lambda_{\pi\text{-}\pi^*}$ value in **7**. Whereas a red shift of **7** with respect to **2**, **3**, or **4** might be expected, the observed value is actually within the range spanned by these three materials (390 nm for **7**, compared with 341 nm, 349 nm, and 411 nm for **2**, **3**, and **4**, respectively). This observation may not be altogether surprising in light of the much greater steric bulk about the P=P units in **7** compared with that about the P=C units in **2**–**4**.

Such minor and explainable deviations do not, however, detract from the overall trend observed when comparing systems with comparable steric positioning. For example, a comparison of **1** with **2**, **4** with **5**, **6** with **8** or **7** with **9**, where the pairs of compounds differ only by the addition of simple styryl units, all exhibit red shifts with increased conjugation length (15, 6, 35, and 32 nm, respectively). These data indicate that the incorporation of low-coordinate phosphorus centres into conjugated materials is a viable strategy for accessing materials featuring smaller band gaps than those observed in all-carbon analogues. Indeed, the $\lambda_{\pi\text{-}\pi^*}$ of 426 nm observed for simple (*E*)-PPV[42] is practically equalled by the comparatively small (P=P)-containing analogue **9** ($\lambda_{\pi\text{-}\pi^*}$ = 422 nm) despite steric influences.

In addition to changes in $\lambda_{\pi\text{-}\pi^*}$ with increasing length or P content, observed differences in absorptivity (given as logε, Table 1) are also noteworthy. For instance, while ε for **1** is similar to that of stilbene, the diphosphene analogue **6** has a value approximately eight times lower, and whereas ε increases uniformly with oligomer length for the organic models, the same trend does not hold for *phospha*-PPV analogues. These observations may again be due to steric factors. The sterically-induced perturbations from coplanarity which lead to a truncated effective conjugation length, as previously discussed, are synonymous with decreasing the cross section of the chromophore responsible for the $\pi-\pi^*$ transition, and the molar absorptivity of the band associated with this transition will therefore diminish (in the event that all else is held fairly constant). This proposition is supported by previously reported data on 2,6-disubstituted stilbenes.[37] For example, simple 2,6-dimethyl substitution leads to approximately half as much absorptivity as unsubstituted stilbene, along with the aforementioned blue shift in the absorption maximum. Even a single bulky subsistent, as in (*E*)-2-*tert*-butylstilbene ($\lambda_{\pi\text{-}\pi^*}$ = 285 nm, ε = 22,650 $M^{-1}cm^{-1}$), has a significant impact.[43] Clearly such an effect would be more pronounced in diphosphenes **6**–**9** than in phosphaalkenes **1**–**5** due to the greater steric crowding in the former. Based on such a steric argument, it would also be expected that for molecules of the same approximate *geometric* size there should be a correlation between $\lambda_{\pi\text{-}\pi^*}$ and ε. This premise is qualitatively demonstrated by the series of phosphaalkene distyrylbenzene analogues **2**–**4** in which $\lambda_{\pi\text{-}\pi^*}$ and ε both increase across from **2**–**4**. Certainly many more complex factors, such as polarity/polarizability and solvation effects of both ground and excited states (to mention a few), are involved in determining the absorptivity of a given system as well. Although the perhaps oversimplified steric arguments presented here are merely qualitative assessments based on rational conjecture, they seem in line with data on substituted stilbenes.

In summary, we have developed novel sterically-encumbered ligands tethered to conjugated segments and have employed these ligands in concert with existing bulky ligands

to prepare a series of *phospha*-PPV oligomers. A study of the variation of $\lambda_{\pi\text{-}\pi^*}$ values along this series indicates that low-coordinate phosphorus centres can support conjugation across extended systems, and generally confirms the expected red shift across the series from carbon oligomers **M1**−**M4** (Table 1) to phosphaalkenes **1**−**5** to diphosphenes **6**−**9**. Importantly, these findings provide experimental evidence that such low-coordinate phosphorus centres are in fact capable of supporting electronic communication across extended π conjugated systems, a criterion required of any moiety viable in the type of materials of interest in the current investigation. Some noteworthy differences between the optical properties of these *phospha*-PPV oligomers and those of related organic systems may be explainable in terms of their inherent steric bulk.

Experimental Section

All manipulations were carried out in a dry box under an atmosphere of N_2. Acetonitrile was distilled from CaH_2 under nitrogen and all other solvents were distilled from sodium benzophenone ketyl prior to use. Compounds **1** and **4**,[44] **3** and **7**,[22] and **6**[45] were prepared as previously reported. Absorption spectra were carried out in degassed HPLC grade $CHCl_3$ on a Lambda 25 spectrophotometer. NMR spectra were recorded on a Varian Gemini instrument operating at 300 MHz for proton and 121.5 MHz for phosphorus. Proton and phosphorus spectra are referenced to residual solvent signals and 85 % phosphoric acid, respectively.

(*E*)-3,5-Dichloro-4′-methylstilbene (v): To a suspension of potassium *tert*-butoxide (18.7 g, 165 mmol) and 18-crown-6 (ca. 0.4 g) in THF (150 mL) was added dropwise over 30 minutes a solution of diethyl(3,5-dichlorobenzyl)phosphonate (44.6 g, 150 mmol) and 4-tolualdehyde (18.0 g, 150 mmol) in THF (300 mL). The mixture was then stirred for 24 hours at room temperature, after which time the reaction was quenched by pouring into 10 % methanolic HCl (500 mL). The mixture was filtered and diethyl ether (300 mL) and water (300 mL) were added to the filtrate. The organic layer that separated was washed with water (2 × 300 mL aliquots), neutralized (determined using pH paper) by addition of 5 % sodium hydrogencarbonate solution then rinsed with water (300 mL). Removal of volatiles from the organic solution yielded a sticky yellow solid. Triturating this solid in hexanes followed by filtration and drying of the solid in vacuo yielded the product as a pale yellow powder (30.2 g, 76.4 %). ^{1}H NMR ($CDCl_3$, ppm): δ = 2.36 (s, 3 H), 6.88 (d, *J* = 16 Hz, 1 H), 7.07 (d, *J* = 16 Hz, 1 H), 7.17 (d, *J* = 8 Hz, 2 H), 7.20 (t, *J* = 2 Hz, 1 H), 7.34 (d, *J* = 2 Hz, 2 H), 7.38 (d, *J* = 8 Hz, 2 H); m.p. 78−80 °C (ref.[30] 80−82 °C).

(*E*)-4-Iodo-3,5-dimesityl-4′-methylstilbene (Dmp′I): A solution of (*E*)-3,5-dichloro-4′-methylstilbene (**v**) (10.0 g, 38.0 mmol) in THF (125 mL) was cooled to −78 °C whereupon *n*-butyllithium (16.0 mL, 2.5 M in hexanes, 39.9 mmol) was added dropwise via cannula. After 1 hour of stirring at −78 °C, a solution of mesitylmagnesium bromide [prepared by the reaction of 2-bromomesitylene (26.5 g, 133 mmol) and Mg turnings (4.26 g, 190 mmol) in THF (150 mL)] was added dropwise via cannula at −78 °C. After warming to room temperature over a 3 hour period, the solution was heated to reflux for an additional 10 hours. After cooling to room temperature, the flask was placed in an ice bath and iodine (19.3 g, 76.0 mmol) was added in 5 g portions. After the exothermic reaction was complete and the characteristic iodine colour persisted in solution for 15 minutes, 5 % Na_2SO_3 (250 mL) was added to quench excess iodine and the solution became yellow. The organic layer was extracted with diethyl ether (250 mL), rinsed with water (2 × 250 mL aliquots) and volatiles removed to yield a sticky solid. The solid was dissolved in boiling hexanes and precipitated at −7 °C to yield the product as an off-white powder (8.15 g, 38.5 %). ^{1}H NMR ($CDCl_3$, ppm): δ = 2.12 (s, 3 H), 2.14 (s, 12 H), 2.23 (s, 6 H), 6.85 (d, *J* = 16 Hz, 1 H), 6.92 (s, 4 H), 6.97 (d, *J* = 16 Hz, 1 H), 6.98 (d, *J* = 8 Hz, 2 H), 7.13 (s, 2 H), 7.27 (d, *J* = 8 Hz, 2 H); m.p. 165−168 °C. HRMS(FAB, *m*/*z*): calcd. for $C_{33}H_{33}I$, 556.1627; found, 556.1628.

Dmp′PCl$_2$: A solution of Dmp′I (4.0 g, 7.2 mmol) in THF (125 mL) was cooled to −78 °C whereupon *n*-butyllithium (3.0 mL, 2.5 M in hexanes, 7.5 mmol) was added dropwise via cannula. After 1 hour of stirring at −78 °C, PCl_3 (1.9 mL, 22 mmol) was added rapidly with a syringe. After the resultant solution was allowed to warm to room temperature over three hours, volatiles were removed in vacuo. The resultant orange solid was stirred with acetonitrile (150 mL) for 15 minutes and filtered. Removal of volatiles in vacuo gave a yellow solid which was dissolved in diethyl ether and filtered to remove salts. Removal of the diethyl ether in vacuo gave the product as a pale yellow powder (0.93 g, 24 %). ^{1}H NMR ($CDCl_3$, ppm): δ = 2.01 (s, 12 H), 2.09 (s, 6 H), 2.36 (s, 3 H), 6.96 (s, 4 H), 7.03 (d, *J* = 16 Hz, 1 H), 7.13 (d, *J* = 16 Hz, 1 H), 7.17 (d, *J* = 8 Hz, 2 H), 7.25 (d, 2 H, $^4J_{H,P}$ = 3 Hz), 7.39 (d, *J* = 8 Hz, 2 H). ^{31}P NMR ($CDCl_3$, ppm): δ = 162.0.

Dmp′P=PDmp′ (8): Magnesium turnings (15 mg, 0.62 mmol) were added to a solution of Dmp′PCl_2 (0.30 g, 0.56 mmol) and the resultant mixture sonicated for approximately 3 hours during which time the solution became an orange-red colour. The solution was decanted from a small amount of remaining magnesium and volatiles were removed in vacuo. The crude solid was extracted with hexanes and filtered. Removal of the solvent in vacuo gave the product as a red-orange powder (0.26 g, 76 %). ^{1}H NMR ($CDCl_3$, ppm): δ = 1.73 (s, 24 H), 2.33 (s, 18 H), 6.77 (s, 8 H), 6.95 (d, *J* = 16 Hz, 2 H), 7.07 (d, *J* = 16 Hz, 2 H), 7.09 (s, 4 H), 7.13 (d, *J* = 8 Hz, 4 H), 7.33 (d, *J* = 8 Hz, 4 H). ^{31}P NMR ($CDCl_3$, ppm): δ = 490.8. HRMS (FAB, *m*/*z*): calcd. for $C_{66}H_{67}P_2$, 921.4718; found, 921.4672.

Dmp′P=PMe$_3$: To a stirred suspension of zinc dust (0.030 g, 0.46 mmol) and Dmp′PCl_2 (0.20 g, 0.38 mmol) was added trimethylphosphane (0.11 g, 1.4 mmol). The mixture was stirred for 3 hours during which time a red colour developed. The mixture was filtered, volatiles removed in vacuo and the crude solid dissolved in hexanes. The solution was then filtered and solvent removed in vacuo. The product was precipitated from a saturated *n*-pentane solution at −35 °C as a red solid (0.087 g, 43 %). ^{1}H NMR ($CDCl_3$, ppm): δ = 1.07 (d, 9 H, *J* = 12 Hz), 2.08 (s, 12 H), 2.34 (s, 9 H), 6.95 (s, 4 H), 6.94 (d, *J* = 16 Hz, 1 H), 7.01 (d, *J* = 16 Hz, 1 H), 7.05 (s, 2 H), 7.12 (d, *J* = 8 Hz, 2 H), 7.32 (d, *J* = 8 Hz, 2 H). ^{31}P NMR ($CDCl_3$, ppm): δ = −0.7 (d, *J* = 560 Hz), −110.4 (d, *J* = 560 Hz).

Dmp′P=C(H)Ph (2): Trimethylphosphane (0.11 g, 1.4 mmol) was added to a mixture of zinc dust (0.03 g, 0.46 mmol), Dmp′PCl_2 (0.20 g, 0.38 mmol) and benzaldehyde (0.042 g, 40 mmol). A yellow colour developed almost immediately and after stirring for 6 hours the mixture was filtered and the solvent removed in vacuo. The crude solid was dissolved in hexanes, filtered and the solvent removed from the filtrate in vacuo. The product was precipitated from a saturated *n*-pentane solution at −35 °C as a yellow solid (0.10 g, 49 %). ^{1}H NMR ($CDCl_3$, ppm): δ = 2.03 (s, 12 H), 2.21

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(s, 6 H), 2.28 (s, 3 H), 6.81 (s, 4 H), 6.97 (d, J = 16 Hz, 1 H), 6.81 (d, J = 16 Hz, 1 H), 7.04 (m, 5 H), 7.08 (d, J = 8 Hz, 2 H), 7.18 (s, 2 H), 7.31 (d, J = 8 Hz, 2 H), 8.59 (d, 1 H, $J_{H,P}$ = 25 Hz). ^{31}P NMR ($CDCl_3$, ppm): δ = 239.2 ppm. HRMS (FAB, MH^+, m/z): calcd. for $C_{40}H_{40}P$, 551.2868; found, 551.2864.

1,4-[Dmp′P=C(H)]$_2$C$_6$H$_4$ (5): Trimethylphosphane (0.17 g, 2.3 mmol) was added to a mixture of zinc dust (0.074 g, 1.1 mmol), Dmp′PCl_2 (0.30 g, 0.56 mmol), and terephthalaldehyde (0.038 g, 0.28 mmol). A yellow-orange colour developed almost immediately and after stirring for 10 hours the mixture was filtered and the solvent removed in vacuo. The crude solid was dissolved in boiling hexanes, filtered, and the solvent removed in vacuo. The resultant solid was then rinsed with a small amount of warm acetonitrile and the final product was precipitated from diethyl ether/hexanes solution at −35 °C as a yellow-orange solid (0.11 g, 39 %). ^{1}H NMR ($CDCl_3$, ppm): δ = 1.98 (s, 24 H), 2.18 (s, 12 H), 2.26 (s, 6 H), 6.77 (s, 8 H), 6.94 (d, J = 16 Hz, 2 H), 7.02−7.08 (m, 10 H), 7.15 (s, 4 H), 7.29 (d, J = 8 Hz, 4 H), 8.40 (d, 2 H, $J_{H,P}$ = 19 Hz). ^{31}P NMR ($CDCl_3$, ppm): δ = 242.3. MS (FAB, MH^+, m/z): calcd. for $C_{74}H_{73}P_2$, 1024; found, 1024.

Dmp′PH$_2$: To a stirred suspension of $LiAlH_4$ (0.18 g, 4.7 mmol) in THF (25 mL) was added solid Dmp′PCl_2 (1.2 g, 2.3 mmol) in small portions over 5 minutes. After stirring for 6 hours the mixture was filtered and volatiles removed in vacuo to give an off-white solid. This material was then dissolved in diethyl ether and filtered through alumina twice. Removal of volatiles in vacuo gave the product as an off-white powder (0.89 g, 85 %). ^{1}H NMR (C_6D_6, ppm): δ = 2.12 (s, 3 H), 2.14 (s, 12 H), 2.23 (s, 6 H), 3.31 (d, 2 H, J_{PH} = 212 Hz), 6.92 (s, 4 H), 6.98 (d, J = 7 Hz, 2 H), 7.02 (d, J = 16 Hz, 1 H), 7.16 (d, J = 16 Hz, 1 H), 7.18 (d, 2 H, $^4J_{H,P}$ = 2 Hz), 7.28 (d, J = 7 Hz, 2 H). ^{31}P NMR (C_6D_6, ppm): δ = −146.3 (t, J = 212 Hz).

1,4-[Dmp′P=P]$_2$C$_6$Ar$_4$ (Ar = 4-*tert*-butylphenyl) (9): A solution of [Li(Et_2O)][P(H)Dmp′][45] (0.19 g, 0.35 mmol) in diethyl ether (20 mL) was added at room temperature to a rapidly stirred suspension of Cl_2P-(p-C_6Ar_4)-PCl_2[22] (0.14 g, 0.17 mmol) in diethyl ether (20 mL) over a 10 min period. During this time a fine white precipitate formed. The solvent was reduced in volume to 20 mL and a solution of DBU (0.053 g, 0.35 mmol) in diethyl ether (5 mL) was added. Upon addition, the solution became orange and eventually nearly red over a 1 h period after which time the reaction mixture was filtered and the solvent removed in vacuo. The solid material was precipitated from n-pentane at −35 °C to give 0.18 g of red powder (51 %). ^{1}H NMR (C_6D_6, ppm): δ = 1.13 (s, 36 H), 1.93 (s, 24 H), 2.09 (s, 6 H), 2.33 (s, 12 H), 6.65 (d, J = 8 Hz, 8 H), 6.86 (d, J = 8 Hz, 8 H), 6.91−6.95 (m, 16 H), 7.11 (s, 4 H), 7.20 (d, J = 8 Hz, 4 H). ^{31}P NMR ($CDCl_3$, ppm): δ = 479.7 (d, J = 570 Hz), 524.8 (d, J = 570 Hz).

(*E*,*E*)-3,5-Dichloro-4′-(4-*tert*-butylstyryl)stilbene (xi): A solution of (*E*)-4-bromomethyl-4′-*tert*-butylstilbene (29.6 g, 89.9 mmol)[32] and triphenylphosphane (25.8 g, 98.2 mmol) was heated to reflux in toluene (200 mL) for four hours. The resultant suspension was cooled to room temperature and the fine white precipitate collected by filtration. The solid was rinsed with n-pentane and dried, giving 49.9 g (67.4 %) (*E*)-4-(4-*tert*-butylstyryl)benzyltriphenylphosphonium bromide. A suspension of this material (35.0 g, 59.2 mmol) and 3,5-dichlorobenzaldehyde (11.4 g, 65.1 mmol) in THF (200 mL) was added over 30 minutes to a THF (50 mL) solution of tBuOK (7.36 g, 65.1 mmol) containing 18-crown-6 (0.160 g, 0.605 mmol). The mixture was then stirred for 12 hours, and quenched by pouring into an equal volume of 10 % methanolic HCl, upon which a pale yellow solid precipitated. The precipitate was collected by filtration, rinsed with ethanol and dried. Proton NMR spectroscopic analysis of the crude solid indicated a mixture of *E* and *Z* isomers. Complete isomerization to the *E* form was successfully carried out by heating a toluene solution of the crude solid to reflux for 3 hours in the presence of a crystal of iodine, followed by rinsing with 5 % Na_2SO_3 and removal of volatiles in vacuo. Compound **xi** was isolated as a yellow powder (12.5 g, 51.9 %). ^{1}H NMR ($CDCl_3$, ppm): δ = 1.34 (s, 9 H), 6.95, d, 1 H, J = 16 Hz), 7.05 (d, J = 16 Hz, 1 H),7.09 (d, J = 16 Hz, 1 H), 7.14 (d, J = 16 Hz, 1 H), 7.22 (s, 1 H), 7.36−7.40 (m, 4 H), 7.45−7.52 (m, 6 H); m.p. 139−141 °C.

(*E*,*E*)-4-Iodo-3,5-dimesityl-4′-(4-*tert*-butylstyryl)stilbene (Dmp′′I): A solution of (*E*,*E*)-3,5-dichloro-4′-(4-*tert*-butylstyryl)stilbene (**xi**) (10.0 g, 24.5 mmol) in THF (125 mL) was cooled to −78 °C and n-butyllithium (10.3 mL, 2.5 M in hexanes, 25.8 mmol) was added dropwise via cannula. After 1 hour of stirring at −78 °C, a solution of mesitylmagnesium bromide [prepared by reaction of 2-bromomesitylene (17.1 g, 85.9 mmol) and Mg turnings (2.98 g, 123 mmol) in THF (85 mL)] was added dropwise via cannula at −78 °C. After warming to room temperature over a 3 hour period, the solution was then heated to reflux for an additional 10 hours. After cooling to room temperature the flask was placed in an ice bath and iodine (15.6 g, 61.4 mmol) was added in 3 g portions. After the exothermic reaction was complete and the characteristic iodine colour persisted in solution for 15 minutes, 5 % Na_2SO_3 (200 mL) was added to quench excess iodine and the solution became yellow. The organic layer was extracted with diethyl ether (200 mL), rinsed with water (2 × 200 mL aliquots) and volatiles removed to yield a viscous oil. Three precipitations of the material from a boiling ethanol solution subsequently cooled to −7 °C gave the product as a pale yellow powder (2.05 g, 11.8 %). ^{1}H NMR ($CDCl_3$, ppm): δ 1.35 (s, 9 H), 2.05 (s, 12 H), 2.39 (s, 6 H), 6.90 (s, 4 H), 7.03−7.14 (m, 4 H), 7.39−7.42 (m, 4 H), 7.46−7.52 (m, 6 H).

One-Dimensional Magnetism in New, Layered Structures: Piperazine-Linked Copper and Nickel Oxalate Chains

Tony D. Keene,[a] Helen R. Ogilvie,[a] Michael B. Hursthouse,[a] and Daniel J. Price*[a]

Keywords: Magnetic properties / Layered compounds / Hydrothermal synthesis / Coordination networks

Two new coordination network materials with the composition M(pip)(ox) (pip = piperazine; ox = oxalate; M = Ni, Cu) have been synthesised under ambient and hydrothermal conditions. These compounds adopt related structures, both consisting of intersecting $[M(pip)]_\infty$ and $[M(ox)]_\infty$ chains, which result in layered structures. The nickel compound crystallises in $P\bar{1}$. The metal ions are octahedrally coordinated and are linked by symmetric chelating bridging oxalate ions. In contrast, the copper compound crystallises in the chiral space group $P2_12_12_1$. Here the copper atom displays square pyramidal coordination geometry and the oxalate ions bridge metals in an unsymmetric fashion resulting in a polar metal-oxalate chain structure. The magnetic behaviour is determined by the nature of the exchange-coupled network. Only the antiferromagnetic interaction mediated by the bridging oxalate group is significant and the compounds are well modelled as 1-D antiferromagnetically coupled chains. For the copper compound ($S = {}^1/_2$) we determined J/k_B to be −25.9 K, while the nickel compound ($S = 1$) shows a larger exchange coupling ($J/k_B = -42.2$ K). In the nickel compound we see a significant deviation between the observed and calculated magnetic susceptibilities at the lowest experimental temperatures. This may be due either to the formation of a Haldane quantum antiferromagnetic ground state or to single-ion zero-field splitting effects.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Structurally, the oxalate anion is well-known for its chelating coordination mode and for its symmetric bis-chelating bridging mode. The prevalence of this linking mode provides a degree of predictability with regard to the structural motifs and the architectures found in oxalate coordination networks.[1] Electronically, the oxalate anion is very good at mediating an exchange interaction between bridged paramagnetic metal ions. Consequently, many 1-D,[2] 2-D[3] and 3-D[4] magnetic networks have been characterised that contain just this bridging mode.

Magnetostructural correlations in oxalate-bridged homometallic Ni^{II} [5] and Cu^{II} [6] compounds are well-known. For Ni^{II}, the most common geometry; octahedral coordination and a symmetric bis-chelating oxalate bridge, results in antiferromagnetic coupling interactions in the range;(J/k_B = −32 to −56 K). The variation can be correlated with the coordination environment of the nickel ion. By comparison, oxalate-bridged copper-containing compounds show a greater range of coupling constants (0 to −500 K). Here the d^9 configuration means that only one magnetic orbital on each metal is involved in the coupling interaction. Thus, the symmetry of the crystal field and the relative orientations of the local crystal field axis of neighbouring metals to the bridging group orbitals are the key in determining the sign and magnitude of the magnetic interaction. The range of coupling constants is related to the variety of coordination geometries adopted by Cu^{II} ions.

In terms of structure, while many dinuclear oxalate-bridged nickel compounds are known, relatively few infinite chain structures have been reported.[7] This may be in part due to the difficulty in crystallising low solubility network materials. Similarly, symmetrically bridged dinuclear copper compounds are much more prevalent than other mono or polynuclear complexes. However, there are many more extended copper oxalate chain structures than analogous nickel structures.[8] In addition we see examples of 2-D networks[9] in solid-state copper oxalate chemistry. Although the symmetric bridging mode is dominant, there is a much greater variability in the oxalate coordination by copper, resulting in a greater range of oxalate bridging modes.

We have initiated a program of research to use structure-directing amines and ammonium cations in the synthesis of new oxalate network structures. Here we present the synthesis, structure and magnetic properties of two new compounds both with the composition M(pip)(ox) (e.g. where M is either Ni (**1**) or Cu (**2**), pip is the neutral cyclic diamine, piperazine and ox is the oxalate dianion. Our choice of oxalate and piperazine as distinct types of predominantly linear bridging ligands result in straight-forward network topologies in **1** and **2**. Despite the similarity in composition and overall structure, **1** and **2** crystallise in different space

groups with different structures and very different metal and oxalate coordination environments.

Results and Discussion

Crystal Structures

Crystallographic data for both compounds are given in Table 1. The asymmetric unit of **1** (Figure 1) contains one half of a nickel atom, one half of a piperazine molecule and one half of an oxalate dianion. All of these components lie on crystallographic inversion centres. The nickel ion is approximately octahedrally coordinated with a *trans*-N_2O_4 coordination sphere. The oxalate ions chelate and bridge adjacent nickel ions in a normal fashion resulting in linear chains of metal oxalate running parallel to the *a*-axis [Figure 2 (a)]; thus the Ni···Ni separation in these chains is the *a*-parameter [5.3613(11) Å]. Two nickel ions are linked by a piperazine molecule, in the low-energy chair form, with bonds to the equatorial position. Thus the nickel ions and the piperazines form another 1-D motif, this time running parallel to the [01$\bar{1}$] direction with a Ni···Ni separation of 7.225(41) Å. Together the bridging oxalate and piperazine groups connect the nickel ions into a 2-D net in the (011) plane [Figure 2 (b)]. While the shortest Ni···Ni separation

[a] $-x, -y, -z$). [b] $(-x, -y, 1-z)$. [c] $(-x, -1-y, -z)$. [d] $(-1/2+x, 1/2-y, -z)$. [e] $(-x, 1/2+y, 1/2-z)$. [f] $(-1/2-x, 1-y, 1/2+z)$.

is through the bridging oxalate group, the next shortest Ni···Ni distances connect nickel ions in neighbouring layers along the *b* and *c* directions [5.9848(14) and 6.4997(16) Å, respectively]. The packing of these layers is shown in Figure 2 (c). There are several short C−H···O and N−H···O contacts between adjacent layers of Ni(pip)(ox) (Table 2). However, the very significant deviation from linearity of the N−H···O interaction and the fact that there are shorter C−H···O contacts suggests that hydrogen bonding to the amine proton is not significant in determining the overall structure of **1**.

The crystal structure of **2** contains one copper atom, one oxalate anion and one piperazine molecule in the asymmetric unit (Figure 3). The Cu^{II} cations are five-coordinate with a *trans*-N_2O_2 + O donor set in a square pyramidal geometry. The apical atom, O3, shows an elongated Cu−O bond of 2.413(3) Å, while the copper−ligand distances in the square base range from 1.954(3) to 2.060(4) Å. The oxalate anion bridges two neighbouring Cu atoms in an unsymmetrical manner, with one side of the oxalate unit in chelating mode through O1 (basal) and O3 (apical) while the other side is monodentate coordinating to a neighbouring copper atom through a basal site in a *syn*-geometry. This leaves one oxygen atom (O2) on the oxalate unit that is not involved in copper coordination. This oxalate bridging results in a polar ribbon of coplanar copper and oxalate ions running along the *c*-axis [Figure 4 (a)]. Within this ribbon, the copper ions form a zigzag chain with a Cu···Cu separation of 5.414(1) Å and a Cu−Cu−Cu angle of 158°. The piperazine molecule again adopts the low energy chair conformation with the hydrogen atoms on both nitrogen atoms, in an axial conformation. The piperazine groups also link neighbouring Cu atoms coordinating through *trans* sites on the square base of the pyramid to form a linear chain running parallel to the *a*-axis. Here the Cu···Cu separation is the *a*-parameter [6.8678(3) Å]. Together these two bridging units link copper ions into a 2-D array in the *ac*-plane [Figure 4 (b)]. Within a given layer all the $[Cu(ox)]_\infty$ chains have the same polarity, but between adjacent layers this polarity is reversed. Each amine proton is involved in hydrogen bonding to the oxygen atom O2 (not involved in copper coordination). In addition there are a large number of short C−H···O contacts (Table 2). The packing of these layers is shown in Figure 4 (c).

Although **1** and **2** have the same generic composition — M(pip)(ox) — the different stereoelectronic preferences of d^8 and d^9 configurations result in different metal coordination geometries and a change in the bridging mode of the oxalate. Despite these substantial local differences in the vicinity of the metal ions the overall structures show remarkable similarity. In both cases we can view the structures as intersecting chains of $[M(ox)]_\infty$ and $[M(pip)]_\infty$ resulting in a 2-D approximately "square" lattice of metal ions. These electrically neutral layers are then held together through a combination of Van der Waals and weak hydrogen bonding interactions.

Only three other nickel oxalate compounds display a linear chain motif; $[Ni(C_2O_4)(H_2O)_2]$,[7a−7c] [Ni(4-aminopyridine)$_2$(ox)][7d] and [Ni(4,4′-bipy)(ox)].[7e] The latter material

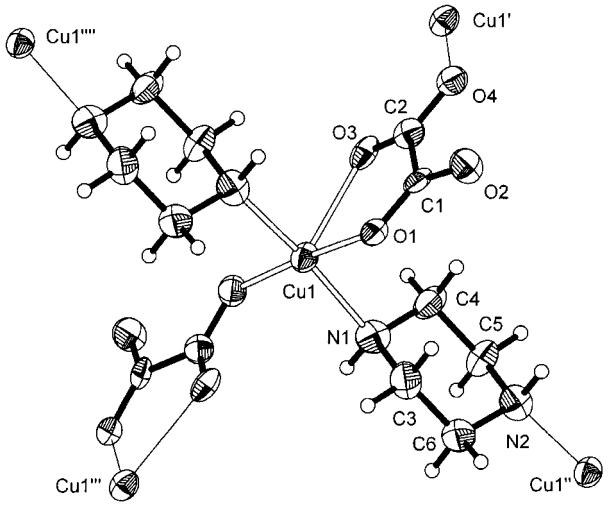

Figure 3. The asymmetric unit and selected symmetry equivalents of Cu(pip)(ox) (**2**) showing the copper coordination sphere and the bridging modes of both ligands; thermal ellipsoids are at the 90 % probability level; selected bond lengths (Å) and angles (°): Cu1−N1 2.058(4), Cu1−O1 1.954(3), Cu1−O3 2.413(3), Cu1′′−N2 2.043(4), Cu1′−O4 1.959(3), C1−C2 1.573(6), C1−O1 1.263(5), C1−O2 1.237(6), C2−O3 1.240(5), C2−O4 1.273(5) Å; N1−Cu1−O1 89.30(14), N1−Cu1−O4′′′′ 89.52(14), N2′′′′−Cu1−O4′′′ 90.65(14), N2′′′′−Cu1−O1 89.92(14), O3−Cu1−N1 99.55(15), O3−Cu1−O1 75.78(12), O3−Cu1−N2′′′′ 86.68(15), O3−Cu1−O4′′′ 109.54(12)°; symmetry codes: ′ ($^1/_2 - z$, $1 - y$, $-^1/_2 + z$); ′′ ($-1 + x$, y, z); ′′′ ($^1/_2 - x$, $1 - y$, $^1/_2 + z$); ′′′′ ($1 + x$, y, z).

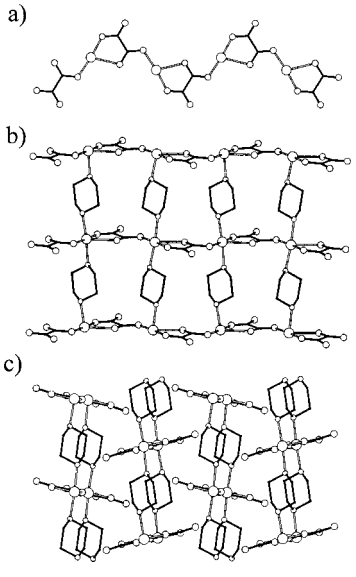

Figure 4. a) The unsymmetric oxalate bridging mode in **2**, resulting in a polar copper oxalate chain structure; b) the bridging mode of the oxalate ions and the linking of these chains by piperazine to form a 2-D net in **2**; view from just off the *b*-axis; c) the 3-D structure showing how layers pack together, viewed along the *c*-axis (hydrogen atoms omitted for clarity)

displays remarkable structural similarity to **1** with essentially the same 2-D network topology. Other chain-containing materials are known where the oxalate ions coordinate to the nickel atom with *cis* geometry resulting in a zigzag chain structure.[7d,7f,7g] As with nickel, the majority of known compounds containing copper(II), oxalate and alkyl or aryl-amine ligands form dinuclear structures in which the oxalate-bridge metal ions in a symmetric bis-chelating fashion. However, there are a significant number of chain structures, which again contain bridging symmetric bis-chelating oxalate ions. Different amines have been used to stabilise linear chains[8a] (with *trans*-amine coordination), and zigzag chains[8b] (through *cis* coordination of the amine). Few copper(II) oxalate chain structures with a similar asymmetric oxalate bridging mode are known.[8c−8e] In all these cases the monodentate oxalate mode forms an axial coordination to the copper ion, resulting in a noncoplanar copper oxalate chain.

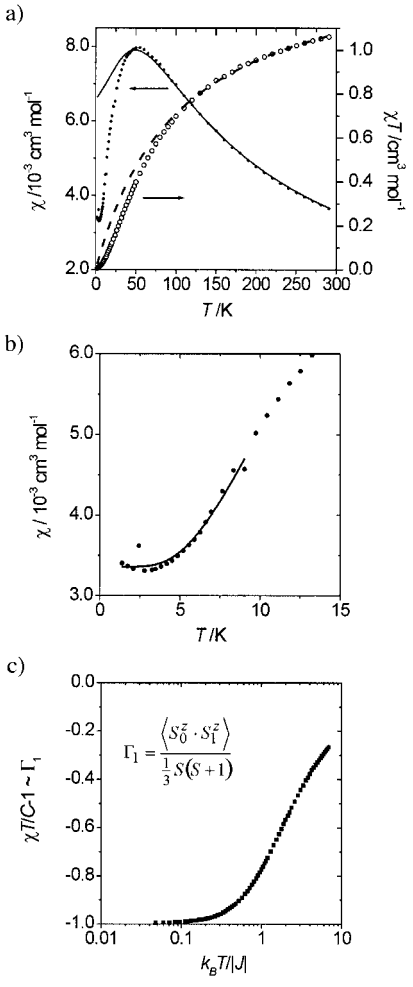

Figure 5. a) The thermal variation in the susceptibility (filled circles) of **1** and the best fit for an isotropic 1-D, (S = 1) model using Weng's equation for the data between 26 and 290 K; also shown in the product χT (open circles) and the Curie−Weiss fit to this data; b) fit of the low temperature data of **1** to an exponential function [Equation (3)] to estimate the energy gap; c) the nearest neighbour pair correlation function, Γ_1, derived from the susceptibility data plotted on a normalised axis scales

Electronic and Magnetic Properties

The approximately octahedral coordination of the Ni^{II} ion in **1** results in a $^3A_{1g}$ ground state, and the electronic spectra of **1** is consistent with this. We determined the crystal field splitting parameter, Δ_{oct} = 9440 cm^{-1}, the energy of the higher lying ^3P term to be at 11450 cm^{-1}, which results in β° = 27.7 %. We note also the presence of a spin-forbidden transition to a ^1E_g state at 14400 cm^{-1}. The enhanced intensity of this transition is due to mixing with the nearby $^3T_{1g}(F)$ state.

The magnetic susceptibility of **1** follows a Curie−Weiss law for data above 100 K [C = 1.446(7) $cm^3 \cdot K \cdot mol^{-1}$ and θ = −104(1) K]. A plot of $\mu_{eff}(T)$ shows the moment to increase monotonically on heating. It is clear that at the highest experimental temperature (290 K), the observed moment of 2.91 μ_B has not reached the asymptotic limit. A plot of $\chi(T)$ shows a broad maximum at 53(1) K with $\chi(T_{max})$ = 7.99(2) × $10^{-3} \cdot cm^3 \cdot mol^{-1}$ [Figure 5 (a)], on further cooling $\chi(T)$ tends to a value of 3.3(1) × 10^{-3} $cm^3 \cdot mol^{-1}$ as T approaches 0 K. The decrease in $\mu_{eff}(T)$ on cooling and the large negative Weiss constant suggest a significant antiferromagnetic exchange interaction between neighbouring nickel ions. From the crystallographic structure of **1** we expect the system to be well described as a 1-D "chain" of antiferromagnetically interacting spin moments. While typically spin-orbit coupling of the ground term to the low lying $^3T_{2g}$ state raises the g-value to about 2.25, g-values for Ni^{II} are usually isotropic, thus the system may be described by a Heisenberg Hamiltonian [Equation (1)]. The behaviour of an antiferromagnetically coupled chain of quantum spins was calculated by Weng,[10] and can be modelled by a polynomial approximation[11] [Equation (2)].

$$\hat{H} = -J \sum_i \mathbf{S}_i \cdot \mathbf{S}_{i+1} \tag{1}$$

$$\chi = \frac{N\mu_B^2 g^2}{k_B T}\left(\frac{A + Bx^2}{C + Dx + Ex^3}\right) \tag{2}$$

where $x = |J| / k_B T$

For $S = {}^1/_2$: A = 0.2500, B = 0.045743, C = 1.000, D = 0.77335, E = 0.43038

For S = 1: A = 0.6667, B = 0.64558, C = 1.000, D = 1.8018, E = 4.9448.

Least-squares fitting of the data over the whole of the measured temperature range (2−290 K) does not give a satisfactory agreement. The model underestimates the data at high temperatures and overestimates in the low temperature regime. If this model is applied to data over the limited region from 26 to 290 K a vastly improved fit is obtained [Equation (2); g = 2.31(1) and J/k_B = −42.2(3) K; Figure 5 (a)]. These couplings are in good agreement with reported values for a similarly bridged nickel oxalate compounds.[5,12]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The discrepancy between the observed and calculated susceptibility at low temperatures may have one of several origins. Most likely either: a) the zero-field-splitting commonly observed in octahedral Ni^{II} complexes may be responsible; or b) we are seeing the formation of a "Haldane" quantum antiferromagnetic state. It is well-known that integer-spin chains are theoretically expected to display a gap[13] (known as the Haldane gap) immediately above a nonmagnetic ground state with novel quantum order. Theoretically this would result in an exponential increase in χ as T is increased from 0 K. In fact the low temperature susceptibility of **1** can be fitted to just such a model[14] [Equation (3); Figure 5 (b)] that results in a gap [Eg/k_B = 32(3) K]. This is in reasonable agreement with the expectation[15] that Eg is approximately $0.4|J|$ and is directly comparable to values reported for similarly coupled Ni^{II} chains.[16] We can use the measured susceptibility to derive an approximate value for the nearest-neighbour pair correlation function, Γ_1, from the susceptibility measurement.[17] The thermal evolution of Γ_1, which is proportional to the magnetic energy of the system, is shown in Figure 5 (c). For $\Gamma_1 = 0$ there is no correlation between neighbouring moments, while $\Gamma_1 = -1$ corresponds to perfect antiparallel alignment.

$$\chi = \chi_0 + C\exp\left(-\frac{Eg}{k_B T}\right) \tag{3}$$

The measured magnetic susceptibility of **2** shows a broad feature centred at about 13(2) K (determined by the derivative curve) although at the lowest experimental temperatures the susceptibility is seen to increase just as in a non-coupled paramagnetic material (Figure 6). A plot of reciprocal susceptibility vs. temperature showed approximately linear behaviour for data above 50 K. This could be fit to a Curie−Weiss law giving $C = 0.418(2)$ $cm^3 \cdot K \cdot mol^{-1}$ and $\theta = -44(1)$ K. The negative value for the Weiss constant θ, suggests a significant antiferromagnetic exchange interaction between neighbouring copper ions. From a plot of $\mu_{eff}(T)$, we can see that μ_{eff} increases on heating and by room temperature, the observed moment of 1.71(1) μ_B has not yet reached the asymptotic limit.

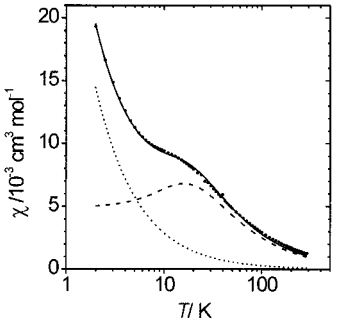

Figure 6. The thermal variation in the susceptibility (filled circles) of **2** and the best fit (solid line) for an isotropic 1-D, ($S = {}^1/_2$) model using Weng's equation plus a component due to a paramagnetic impurity (a logarithmic scale is used to highlight the good fit over a wide range of temperatures); each of these components is shown separately: contribution for **2** (dashed line), contribution due to paramagnetic impurity (dotted line)

Although consideration of the Cu···Cu separations suggests a 3-D network, the only likely magnetic superexchange pathway is through the bridging oxalate anion; thus we may anticipate 1-D magnetic behaviour. The observed broad maximum in the susceptibility at low temperature is consistent with this expectation. As with **1**, the magnetic interactions in compound **2** can be described by the Heisenberg Hamiltonian [Equation (1)], for which approximate solutions are known. Fitting the data to the quantum model[10,11] [Equation (2); Figure 6], plus a contribution due to a paramagnetic impurity gives a good fit [J/k_B = −25.9(1) K, g = 1.9 and 5.3 % paramagnetic impurity]. However, since the model clearly underestimates the high-temperature data it is likely that here g has been underestimated.

The coupling interaction between paramagnetic copper(II) ions is particularly well-studied, because the d^9 configuration always provides a simple spin ($S = {}^1/_2$) moment, free from orbital contributions and zero-field splitting effects which always complicate the analysis. Furthermore, the overwhelming tendency of Cu^{II} ions to form tetragonally elongated octahedra, square pyramid or square-planar coordination geometries results in a $d_{x^2-y^2}$ magnetic orbital and a clearly defined set of crystal field axis. The magnitude of the exchange coupling between Cu^{II} ions bridged by an oxalate ion depends crucially on the relative orientations of the magnetic $d_{x^2-y^2}$ orbitals of neighbouring cations and on the relative orientation of the oxalate group. Two different orbital orientations for the common symmetric bis-chelating mode are shown in Figure 7 (a and b).

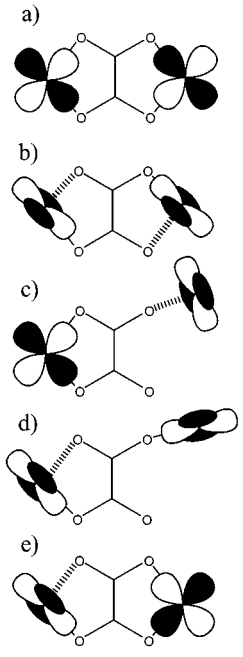

Figure 7. Some of the possible orbital topologies found in oxalato-bridged copper(II) compounds, see main text for details

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

These different orbital topologies have antiferromagnetic couplings of approximately −500 and −9 K, respectively.[6,18] The unsymmetric μ-1,2,3-oxalato bridging mode is much less common[19] and in all previously reported compounds it appears that the magnetic orbital adopts the relative geometry shown in Figure 7 (c). This configuration supports exchange couplings in the range −0.50 to −3.9 K. To the best of our knowledge the disposition of the magnetic orbitals in **2** [Figure 7 (d)] is unique. This mode is related to an orbital topology seen occasionally in bis-chelating coordination geometries[8a,20] [Figure 7 (e)]. The larger exchange coupling observed in **2** compared to other unsymmetric μ-1,2,3 oxalato bridging modes is easily reconciled with the better spatial overlap of both metal $d_{x^2-y^2}$ orbitals and the oxalate orbitals.

Thermal Analysis

Thermogravimetric analysis of **1** under an O_2 atmosphere shows a single-stage decomposition at 400 °C to give a dark grey powder. The corresponding mass loss of 66.6 % agrees well with that expected upon formation of NiO. Compound **2** follows a similar single-step decomposition at about 220 °C with an observed weight loss of 38.9 %, consistent with the formation of CuO.

Conclusions

We have used two distinct bridging ligands to form a network with a topology that may have been anticipated. The difference in the structures of the Ni^{II} **1** and Cu^{II} **2** derivatives can be wholly attributed to the different stereoelectronic preferences of the d^8 and d^9 configurations. Both materials display 1-D antiferromagnetic behaviour consistent with the 1-D metal-oxalate structure. While the coupling constant in **1** is as expected the small value for **2** is due to the unusual orientations of the $d_{x^2-y^2}$ orbital on neighbouring metal ions relative to the oxalate bridge. The low temperature magnetism of **1** is consistent with the formation of a Haldane state, predicted for such a 1-D ($S = 1$) Heisenberg quantum antiferromagnet. However, these preliminary measurements do not rule out similar effects from zero-field splitting. If the low temperature state is a Haldane phase then **1** is an excellent material for further physical study. The fact that there is only one single spin carrier and one single coupling pathway per unit cell, and that both of these lie on crystallographic inversion centres greatly simplifies the interpretation of more sophisticated magnetic measurements. We are currently engaged in more detailed studies to better understand the magnetism of this ($S = 1$) material.

Experimental Section

Reagents: Nickel(II) hydroxide (97 %), oxalic acid (99 %), potassium oxalate monohydrate (99 %), and tetramethoxysilane (98 %) were all purchased from Aldrich, piperazine (99 %) from Acros, copper(I) chloride (96 %) from Fisher and copper(II) sulfate pentahydrate (99.5 %) from BDH. All used without further purification.

Physical Measurements: IR spectra were recorded on a Perkin−Elmer Spectrum One FT-IR machine as diffuse reflectance measurements between 4000 and 400 cm^{-1} using a KBr matrix. Elemental analysis for, C H and N was carried out commercially by Medac Ltd. UV-Vis/NIR spectra were recorded on a Perkin−Elmer Lambda 19 spectrometer in diffuse reflectance mode with the samples embedded in a $BaSO_4$ matrix. Thermogravimetric analysis was performed on a Metller Toledo TGA/SDTA851^e equipped with a T50800GCI gas control system and a T50801RD sample robot. Measurements were carried out under an atmosphere of approximately 60 % O_2 between 30 and 600 °C with a heating rate of 10 °C·min^{-1}. Single-crystal X-ray data was collected with monochromated Mo-K_α radiation (λ = 0. 71073 Å) on an Enraf−Nonius−Kappa CCD area detector as φ and ω scans to fill the Ewald sphere. Data collection and cell refinement were managed by DENZO,[21] absorption corrections were applied using SORTAV,[22] structure solution and refinement by SHELXS-97[23] and SHELXL-97[24] in the WinGX environment (Table 1).[25] CCDC-213878 **1** and CCDC-213879 **2** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Powder X-ray diffraction using a Siemens D5000 diffractometer was performed to confirm the purity and identity of all microcrystalline samples. Field-cooled magnetisation measurements were made between 2 and 290 K using a Quantum Design MPMS SQUID magnetometer in applied fields of 200 G. The powdered samples were held in an eicosane matrix to prevent reorientation effects. A diamagnetic correction of -119×10^{-6} cm^3·mol^{-2} was determined from Pascal's constants[26] and applied to both samples.

Synthesis of Ni(pip)(ox) (1): Nickel hydroxide (100 mg, 1.07 mmol), oxalic acid dihydrate (254 mg, 2.25 mmol), piperazine (689 mg, 8.00 mmol) and distilled water (10 mL) were placed into a 23 mL capacity Teflon lined autoclave and heated to 180 °C under autogenous pressure for 72 h. The green microcrystalline product was collected by filtration and dried in air (30 mg, 12 %). $C_6H_{10}N_2NiO_4$ (232.9): C 30.95, H 4.33, N 12.03; found C 31.23, H 4.61, N 12.08. IR: $\tilde{\nu}$ = 3250 cm^{-1} m, 3108 w, 3072 w, 3004 m, 2975 w, 2918 m, 2880 m, 2825 w, 2679 w, 2554 w, 2509 w, 2420 w, 2420 w, 2274 w, 2031 w, 1972 w, 1895 w, 1619 s, 1457 s, 1439 m, 1420 s, 1362 m, 1342 m, 1314 s, 1249 m, 1098 m, 1069 s, 1019 s, 992 s, 905 m, 881 s, 804 s, 647 m, 488 s, 414 s. UV-Vis: λ_{max} /cm^{-1} (ε/relative) = 9500 (0.423) $^3A_{2g} \rightarrow {}^3T_{2g}$(F), 14400 (0.315) $\rightarrow {}^1E_g$, 15600 (0.292) $\rightarrow {}^3T_{1g}$(F), 24700 (0.162) $\rightarrow {}^3T_{2g}$(P), 37900 (1.000).

Synthesis of Cu(pip)(ox) (2): A mixture of copper(I) chloride (1.000 g, 10.10 mmol), potassium oxalate monohydrate (2.000 g, 10.86 mmol), piperazine (1.000 g, 11.61 mmol) and distilled water (15 mL) was allowed to react in air for a period of 6 days. During the course of the reaction Cu^I both disproportionates and is slowly oxidised by air to Cu^{II}. The product is formed as a purple precipitate. The major contaminant $K_2Cu(ox)_2$·$2H_2O$ is removed by dissolution in H_2O and the product is collected by filtration. Yield 85 %. $C_6H_{10}CuN_2O_4$ (237.7): calcd. C 30.32, H 4.24, N 11.78; found C 28.54, H 4.44, N 10.81. IR: $\tilde{\nu}$ = 3189 cm^{-1} s, 3167 s, 2996 m, 2950 m, 2884 m, 2798 m, 2379 w, 2191 w, 1657 s, 1631 s, 1606 s, 1443 m, 1372 m, 1347 m, 1306 s, 1239 m, 1151 s, 1092 s, 1028 m, 1008 m, 892 s, 833 m, 789 s, 675 m, 596 m, 517 s, 421 m. UV-Vis: λ_{max} /cm^{-1} (ε/relative) = 14700 (0.684), 17500 (0.772), 27000 (0.930), 29100 (0.965), 33800 (1.000).

Crystallisation of 2: Single crystals of **2** were obtained by a gel crystallisation method. Tetramethoxysilane (2 mL) was added to a solution of piperazine (0.500 g, 5.81 mmol) and potassium oxalate monohydrate (1.00 g, 5.43 mmol) in distilled water (18 mL), and the mixture allowed to react. This gel was transferred to a test tube. A solution of copper sulfate pentahydrate (1.25 g, 4.81 mmol) in distilled water (5 mL) was added to the top and allowed to diffuse slowly into the gel. After three days small, purple crystals of **2** formed.

Acknowledgments

We are grateful to Dr. H. J. Blythe (The University of Sheffield) for assistance with the magnetisation measurements and Dr. A. L. Hector (University of Southampton) for measurement of the TGA data. D. J. P. thanks the EPSRC for the award of an Advanced Research Fellowship.

Synthesis, Structural Characterization and Fluorescence Properties of Organoselenium Compounds Bearing a Ligand Containing Both Bulky and Nonbonding Groups − The First Observation of Both Intramolecular Se···N and Se···O Interactions in a Diselenide Structure

Karuppasamy Kandasamy,[a] Sangit Kumar,[a] Harkesh B. Singh,*[a] Ray J. Butcher,[b] and K. Travis Holman[c]

Keywords: Selenium / Intramolecular coordination / X-ray diffraction / Fluorescence

The synthesis of bis[3-(4,5-dihydro-4,4-dimethyl-1,3-oxazol-2-yl)-4-(3,5-dimethylphenyl)-2-naphthyl] diselenide, R_2Se_2 (**4**), was achieved by a facile ortholithiation route. Further reaction of the diselenide with a stoichiometric amount of SO_2Cl_2 or Br_2 afforded the corresponding selenenyl halides RSeX [X = Cl (**5**), X = Br (**6**)]. The novel selenenyl iodide RSeI (**7**), in which the selenium and iodine are covalently bonded to each other, was obtained by treatment of the diselenide with an equimolar amount of iodine. The stable aryl benzyl selenide **8** was prepared by the reaction of benzyl chloride with lithium areneselenolate (**3**) at low temperature. Surprisingly, the reaction of the diselenide with 1,2-dibromo-*o*-xylene gave the selenenyl bromide (**6**) instead of the arylselenium derivative **9**. Elemental analysis, multinuclear (^1H, ^{13}C, ^{77}Se) NMR spectroscopic and mass spectrometric techniques were used for the identification of products. Compounds **4**, **6**, **7**, and **8** were also characterized by single-crystal X-ray diffraction studies.

Introduction

In recent years organoselenium chemistry has been receiving much attention from the whole chemical community because of its potential applications in various fields. Selenium reagents have been extensively used in a variety of organic reactions.[1] Other major applications are: i) ligand chemistry,[2] ii) precursors for the preparation of thin films in metal-organic chemical vapor deposition (MOCVD),[3] and iii) biochemistry.[4] Nevertheless, organoselenium compounds are known to be very unstable, highly reactive and very difficult to synthesize. Recent studies show that the use of sterically more hindered groups and intramolecularly coordinating groups has been successful in synthesizing some stable organoselenium compounds. Arnold et al.[5] and Bochmann et al.[6] have used sterically more hindered groups to stabilize unstable organoselenium compounds. Intramolecular Se···X (X = H,[7] S,[8] O,[9] F,[10] N,[4i,11] Cl and Br[10b,12]) interactions have also been successfully used for the same purpose. Ramasubbu et al.,[13] Goldstein et al.,[14] and Barton et al.[15] have analyzed the nature of the intramolecular interactions, and the electronic structure around the selenium atom has been interpreted in terms of a three center, four electron X···Se−R bond (hypervalent bond). These interactions are also expected to be responsible for the specific redox reactivity of organoselenium compounds[16] as well as stabilization of selenenic acid, the key intermediate in the glutathione peroxidase catalytic cycle.[4]

Although intramolecular coordination and steric effects have been employed individually for the synthesis of stable organoselenium compounds, to the best of our knowledge there are no reports of their combined use for the stabilisation of organoselenium compounds. The use of (4,4-dimethyl-2-phenyl)oxazoline for the preparation of some novel organoselenium compounds has been reported recently by our group.[11d] Metal thiolates[17] and selenolates[2k] incorporating the same substrate have also been synthesized and characterized. In zinc thiolate and selenolate complexes, chirality was observed as a result of the diastereotopic methylene protons of the oxazoline ring, which arises from the strong "hard-hard" interactions between the zinc and the imine nitrogen atoms. However, attempts to

obtain crystals of group 12 tellurolates[18] were unsuccessful due to the facile decomposition of the complexes in common solvents. In this context, we thought it worthwhile to use a ligand that can induce both steric and intramolecular coordination effects together as it could provide greater stability than ligands having either an *o*-chelating group or a sterically more demanding group. This would also provide an opportunity to study Se···N interactions in the presence of sterically more demanding group.

We report here the synthesis and characterization of some novel organoselenium complexes of 2-[1-(3,5-dimethylphenyl)-2-naphthyl]-4,5-dihydro-4,4-dimethyl-1,3-oxazole. This substrate has been synthesized as one of the intermediates in the preparation of mevanolactones, which are used as inhibitors in cholesterol biosynthesis.[19] A comparison of structural and spectroscopic properties with similar compounds derived from the sterically less hindered 4,4-dimethyl-2-phenyloxazoline and other ligands is also described.

Results and Discussion

Synthesis

The synthesis of the synthetically important diselenide **4** was achieved by an ortholithiation route. The lithium areneselenolate **3** was prepared by the direct metalation of 2-[1-(3,5-dimethylphenyl)-2-naphthyl]-4,5-dihydro-4,4-dimethyl-1,3-oxazole (**1**) with a 1.6 M solution of *n*BuLi in hexane followed by the addition of finely ground selenium powder. Oxidative work up gave the desired diselenide. Treatment of the diselenide with sulfuryl chloride gave the stable selenenyl chloride **5**. The stable bromo derivative **6** was obtained as a yellow crystalline solid by the reaction of diselenide with a stoichiometric amount of bromine. Isolation of the stable binary compounds containing selenium and iodine was difficult because of their similar electronegativity and their tendency to form charge-transfer adducts.[20] Although isolation has been possible using more hindered groups, like the 2,4,6-tri-*tert*-butylphenyl group,[21] a slight

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reduction of their steric bulkiness again led to the formation of the charge-transfer adduct.[22] However, our group has succeeded in isolating stable binary compounds containing selenium and iodine using ligands such as 4,4-dimethyl-2-phenyl-1,3-oxazoline,[11d] *N*,*N*-dimethylbenzylamine,[11e] and *N*,*N*-dimethylnaphthylamine.[11c] Here also, the reaction of the diselenide with stoichiometric amounts of iodine led to the formation of the novel mono-iodide **7**. This consistent isolation of stable Se−I bonded compounds regardless of bulkiness proves that the intramolecular approach is a more effective method for the isolation of unstable compounds than the steric approach. In general, aryl benzyl and allyl aryl selenides are unstable and decompose readily to give coupled hydrocarbon products and free selenium.[23] Treatment of the lithium areneselenolate **3** with equimolar amounts of benzyl chloride gave the stable benzylselenium derivative **8**. All these reactions are shown in Scheme 1.

The treatment of α,α-dibromo-*o*-xylene with the lithium areneselenolate **3** gave, unexpectedly, the selenenyl bromide **6** instead of the expected compound **9**. The reaction of $Se(dtc)_2$ with the lithiated product **2** was expected to give a stable symmetrical selenide. The yellow-colored product formed in this reaction decomposed immediately to give the starting material. It is worth mentioning that the reaction of 4,4-dimethyl-2-phenyl-1,3-oxazoline with $Se(dtc)_2$ afforded the expected bis(4,4-dimethyl-2-phenyl-1,3-oxazolin-2-yl) selenide.[24] Hence, the decomposition may be due to the steric crowding around the selenium atom. All attempts to synthesize a stable bis{2-[1-(3,5-dimethylphenyl)-2-naphthyl]-4,5-dihydro-4,4-dimethyl-1,3-oxazol-2-yl} selenide, lithium selenolate and selenol were unsuccessful.

Spectroscopic Studies

The ^{1}H NMR spectra of the diselenide **4** and aryl benzyl selenide **8** are not particularly informative as the peaks are only shifted slightly downfield (ca. 0.09 ppm) from those in the free ligand **1**, thus indicating the presence of a weak Se···N interaction. However, much larger downfield shifts (ca. 0.7 ppm for the methylene proton and ca. 0.4 ppm for the methyl protons) were observed for the selenenyl halides **5**, **6**, and **8**. This indicates a strong Se···N interaction. These ^{1}H NMR chemical shifts are in good agreement with those in other intramolecularly stabilized organoselenium compounds.[11c−11e]

The ^{77}Se NMR chemical shifts are quite informative about the Se···N nonbonding interactions. The ^{77}Se NMR spectrum of **4** exhibits a single peak at δ = 450 ppm, which is more downfield shifted than systems having sp^3 nitrogen atoms.[11c,11e] However, it is close to the diselenide of 4,4-dimethyl-2-phenyl-1,3-oxazoline.[11d] Interestingly, the crystal structure of the diselenide reveals that only one of the nitrogen atoms interacts with the Se atom, with the other being much further away (vide infra). The ^{77}Se NMR chemical shift of compound **8** lies upfield (δ = 351 ppm) from that of the corresponding diselenide (**4**; δ = 450 ppm). This may be due to the presence of the benzyl group, which cannot accept electron density from the selenium; the Se···N interaction may also be very weak. The crystal structure of **8** confirmed this very weak Se···N interaction (vide infra). The ^{77}Se NMR chemical shifts of compounds **5**, **6**, and **7** are very close to each other and downfield of the diselenide. This shows that their Se···N interactions are almost equal and stronger than Se···N interaction of **4**. This is also confirmed by the crystal structures of **6** and **7** (vide infra).

In the IR spectra, the $\nu_{C=N}$ vibrations for compounds **4**−**8** are found in the range 1670−1760 cm^{-1} and are shifted by 20−100 cm^{-1} to higher frequency relative to the free ligand, indicating that the nitrogen of the oxazoline ring is coordinated to the selenium atom. These shifts to higher frequencies may be due to the presence of negative hyperconjugation between the selenium and the nitrogen atom. The $\nu_{C=N}$ frequencies of compounds **5** and **6** are observed at higher frequencies than compounds **4** and **8**, indicating the stronger coordination of nitrogen in the selenenyl halides than in the diselenide or benzyl selenide.

Compounds **4**, **6**, **7**, and **8** exhibit similar absorption spectra, with a strong peak in the 280−310 nm region and an absorption maximum at 295 nm due to the ligand core. Fluorescence emission spectra for compounds **4**, **5**, **6**, **8**, and free ligand **1** were recorded to probe their fluorescence emission properties in methanol at an excitation wavelength of 285 nm. The quantum yield of fluorescence emission was determined with naphthalene (Φ_f = 0.23) as a standard.[25] From the quantum yield of the fluorescence emission of selenium derivatives **4** (Φ_f = 0.038), **5** (Φ_f = 0.018), **6** (Φ_f = 0.021), and **8** (Φ_f = 0.043) compared to the fluorescence emission of free ligand **1** (Φ_f = 0.067) it is clear that the fluorescence emissions are quenched in the selenium compounds compared to the ligand **1** due to the substitution of heavy metal atoms.[26]

Mass spectra were recorded for compounds **4**−**6**, and **8** to identify the constitution of the product under mass spectrometric conditions. The presence of seven isotopes of selenium leads to a highly characteristic group of selenium fragments. Molecular ion peaks were observed in low intensities for all compounds. In all cases except **5**, the base peaks observed at *m*/*z* = 402−412 with high intensity can be assigned to RSe^+ fragments. This strongly suggests a weakening of the Se−X (X = SeR, Br, CH_2Ph) bond *trans* to the Se···N fragment.

X-ray Crystallographic Studies

The significant bond lengths and bond angles of compounds **4**, **6**, **7**, and **8** are listed in Table 1.

Molecular Structure of 4

The X-ray crystal structure of **4** is shown in Figure 1. The coordination geometry around the selenium atom is distorted T-shaped with each selenium atom bonded to selenium, carbon and a nitrogen/oxygen atom. The most interesting feature of the structure is the existence of both Se···N and Se···O interactions between selenium and nitrogen/oxygen in the same molecule. This is the first structure, to the best of our knowledge, to be reported where both intramolecular Se···N and Se···O interactions exist in the same mol-

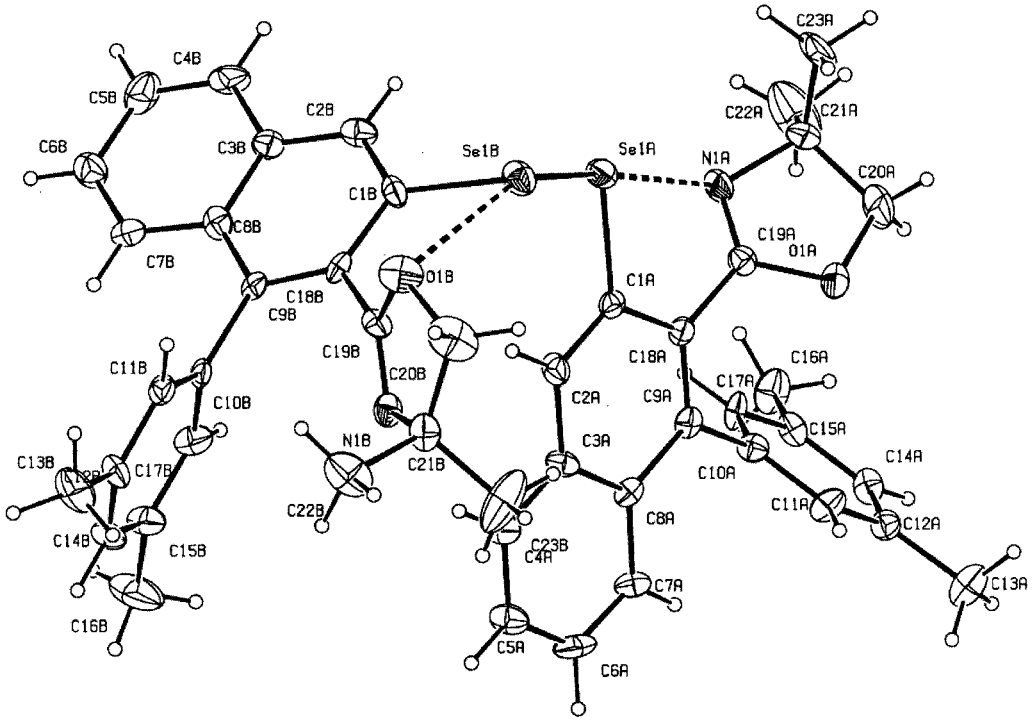

Figure 1. Molecular structure of **4**

ecule. Several structures of selenium compounds incorporating 4,4-dimethyl-2-phenyloxazoline,[2k,4i,17,18,24,27] have been reported by our group. In all cases only Se···N interactions were observed. Thus, the unusual observation of an intramolecular Se···O interaction in the structure of **4** may be explained by the orientation of the oxazoline rings.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

These rings are twisted about the C(18)−C(19) axis in opposite orientations such that in one oxazoline ring the nitrogen atom is directed towards the selenium [C(1A)−C(18A)−C(19A)−N(1A) = −48.27(14)° vs. C(1A)−C(18A)−C(19A)−O(1A) = 131.72(8)°], whereas in the other ring the oxygen atom is directed towards the selenium [C(1A)−C(18A)−C(19A)−O(1A) = 53.69(12)° vs. C(1A)−C(18A)−C(19A)−N(1A) = −127.58(10)°]. The orientation of the oxazoline rings may be due to the influence of steric crowding imposed by the sterically bulkier substituents present in the system. The Se(1A)···N(1A) [2.976(8) Å] and Se(1B)···O(1B) [2.9815 Å)] distances are similar to the respective distances in other related diselenides.[4i,28] The observed Se−Se distance [2.3216(16) Å] is also shorter than in bis(4,4-dimethyl-2-phenyl-1,3-oxazolin-2-yl) diselenide [2.354(8) Å],[11d] bis{2-[(dimethylamino)methyl]-phenyl} diselenide [2.357(1) Å][11e] and bis[2-(dimethylamino)naphthyl] diselenide[11c] [2.383(2) Å]. Another interesting feature in this structure is the "*cisoid*" conformation of the diselenide. Sandman et al.[29] have reported the crystal structures of two conformational polymorphs of bis(2-naphthyl) ditelluride. The "*cisoid*" conformations have a C−Se−Se−C torsion angle of less than 90° and the "*transoid*" conformations have a C−Se−Se−C torsion angle greater than 90°. In the case of **4** the C(1A)−Se(1A)−Se(1B)−C(1B) torsion angle is 81.42° and thus has a "*cisoid*" conformation. From the unusual intramolecular Se···N and Se···O interactions, the shorter Se−Se distance, and the "*cisoid*" conformation it may be concluded that the Se−Se and Se···N bond lengths are lengthened to minimize the steric crowding imposed by the sterically more demanding group present in this system. There are no significant intermolecular Se···Se contacts. The shortest intermolecular Se···Se distance [8.618 Å] is much longer than the sum of the van der Waals radii (3.8 Å). However, intermolecular Se···H [Se1A···H13AA: 3.1096 Å; Se1A···H2BA: 3.2678 Å; Se1B···H2AA: 2.7981 Å; Se1B···H13BB: 2.8697 Å] contacts exist that are much shorter than the sum of the van der Waals radii (3.35 Å). These short Se···H contacts may be a result of optimized dense packing of the molecules.

Molecular Structure of 6

An ORTEP view of **6** is shown in Figure 2. The geometry around Se is T-shaped and the methyl groups attached to the oxazoline are disordered. The strong nonbonded Se···N interaction [2.052(3) Å] is very close to the corresponding distance in [2-(4,4-dimethyl-1,3-oxazolin-2-yl)phenyl]selenium bromide [2.063(3) Å][11d] and shorter than in {2-[(dimethylamino)methyl]phenyl}selenium bromide [2.143(6) Å].[11e] The Se−Br bond length [2.6485(7) Å] is longer than the sum of the single-bond covalent radii of Se and Br (2.31 Å). The lengthening of the Se−Br bond length can be attri-

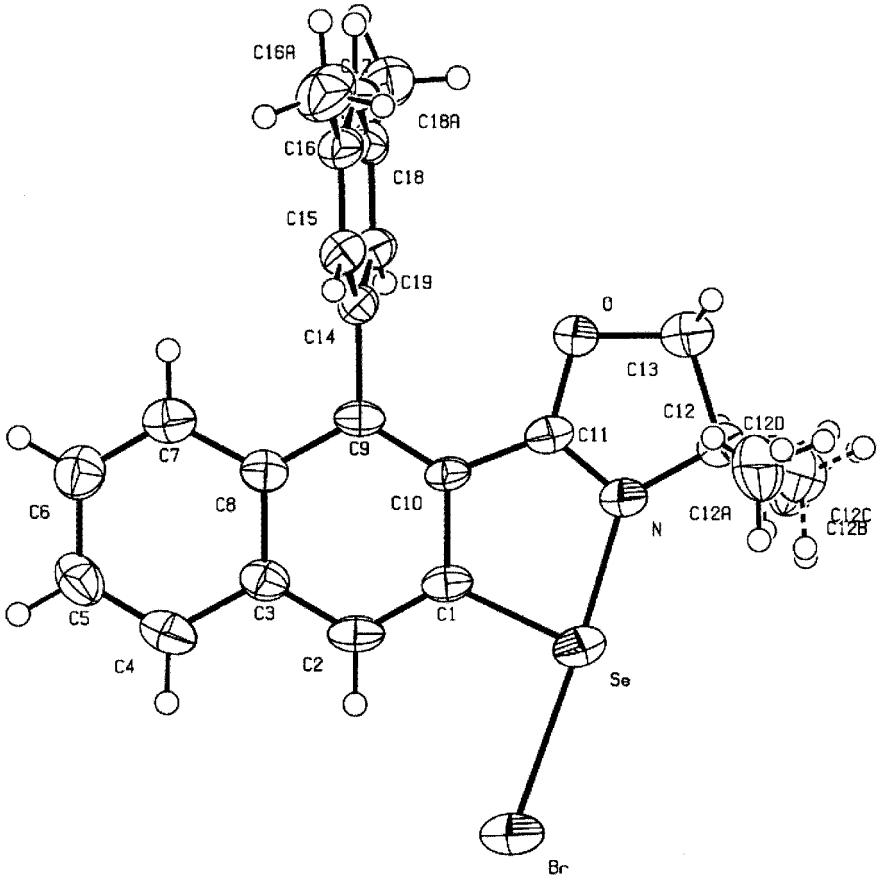

Figure 2. Molecular structure of **6**

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

buted to the strong *trans* influence of the Se···N interaction. A similar observation has been made for the molecular structure of 2-formylbenzeneselenenyl bromide.[30] The Se−Br bond length in **6** [2.6485(7) Å] is also similar to the reported values for [2-(4,4-dimethyl-1,3-oxazolin-2-yl)phenyl]selenium bromide [2.631(9) Å] and {2-[(dimethylamino)methyl]phenyl}selenium bromide [2.634(1) Å]. The Se···N−Br angle [175.16 (10)°] is close to linear. From the C(1)−Se−Br [95.91(12)°] and C(1)−Se···N [81.03(15)°] bond angles the coordination around selenium can be regarded as trigonal bipyramidal if the lone pairs are taken into account. However, the packing pattern of this structure is significantly different from the other intramolecularly stabilized organoselenium bromides, including [2-(4,4-dimethyl-2-phenyloxazolinyl)phenyl]selenium bromide. In all the organoselenium bromides the formation of weak dimers by intermolecular interactions between selenium and bromine were observed.[11c−11e,31] However, in the case of **6** such intermolecular Se···Br interactions are absent. The shortest intermolecular Se···Br contact [4.8914 Å] is greater than the sum of the van der Waals radii (3.9 Å). The absence of intermolecular Se···Br interactions clearly suggests that the sterically more demanding group present in this system prevents the formation of weak dimers and thus confirms the formation of a truly monomeric selenium bromide. Intermolecular Br···H (Br···H2A: 2.7190 Å; Br···H19Aa: 3.1953 Å; Br···H4Ab: 3.1463 Å; Br···H5Ab: 3.0838 Å) and Se···H12C (3.1405 Å) contacts are observed in the packing diagram. The Br···H and Se···H distances are shorter than the sum of their van der Waals radii, at 3.45 Å and 3.35 Å, respectively. The short Se···H contacts may be a result of optimized dense packing of molecules as for the above structure.

Molecular Structure of 7

The molecular structure of **7** is given in Figure 3. This is isostructural with **6**. In this structure the methyl groups attached to the oxazoline rings are disordered. The observed intramolecular Se···N distance [2.059(5) Å] is considerably shorter than the corresponding distances in [2-(4,4-dimethyl-2-oxazoline)phenyl]selenium iodide [2.133(4) Å],[11d] and [8-(dimethylamino)-1-naphthyl]selenium iodide [2.242(5) Å],[11c] whereas the Se−I distance [2.8297(8) Å] is considerably longer than the corresponding distance in [2-(4,4-dimethyl-1,3-oxazolin-2-yl)phenyl]selenium iodide [2.7773(7) Å] and [8-(dimethylamino)-1-naphthyl]selenium iodide [2.742(9) Å]. The Se−I distance is also longer than in 2,4,6-tri-*tert*-butylphenyl iodo selenide [2.529(1) Å].[21] The elongation of the Se−I bond length may be attributed to the presence of a shorter (strong) Se···N interaction *trans* to the Se−I fragment. The N···Se−I bond angle

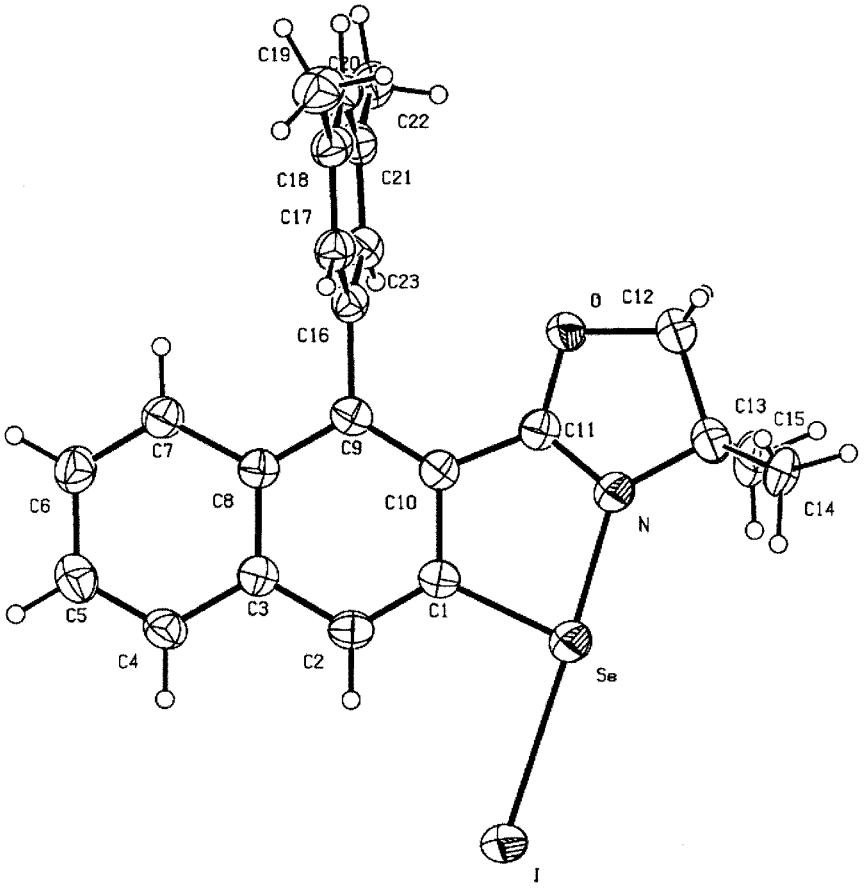

Figure 3. Molecular structure of **7**

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

[175.26(14)°] is close to linear. In the packing diagram of **7** the shortest intermolecular contact between the selenium and iodine is 4.811 Å, about 0.8 Å greater than the sum of the van der Waals radii (4.02 Å). Intermolecular Se···H and Se···H contacts are also observed here that are shorter than the sum of the van der Waals radii, which may be due to the optimized dense packing of the molecules.

Molecular Structure of 8

The molecular structure of **8** is shown in Figure 4 as an ORTEP view. This compound crystallizes in the monoclinic system with four symmetry-independent molecules in the asymmetric unit cell. The geometry around the selenium atom is V-shaped. The selenium atom is bonded to two carbon atoms derived from two different organic substituents. It is worth noting that the C(1)−Se(1) [C(1A)−Se(1A): 1.916(5) Å; C(1B)−Se(1B): 1.903(6) Å; C(1C)−Se(1C): 1.918(5) Å; C(1D)−Se(1D): 1.935(5) Å] and C(24)−Se(1) [C(24A)−Se(1A): 1.979(7) Å; C(24B)−Se(1B): 1.952(7) Å; C(24C)−Se(1C): 1.911(7) Å; C(1D)−Se(1D): 1.944(7) Å] bond lengths, and the C(1)−Se(1)−C(24) [C(1A)−Se(1A)−C(24A): 98.0(2)°; C(1B)−Se(1B)−C(24B): 98.4(3)°; C(1C)−Se(1C)−C(24C): 98.1(3)°; C(1D)−Se(1D)−C(24D): 98.0(2)°] bond angle are significantly different for all four independent molecules. The Se−C(Ph) and Se−CH_2Ph bond lengths are in good agreement with the corresponding distances reported for the related systems.[11d,32] One of the interesting features is the longer Se−CH_2Ph [Se(1A)−C(24A): 1.979(7) Å] distance compared to that in the sterically less hindered benzyl 2-(4,4-dimethyl-1,3-oxazolin-2-yl)phenyl selenide [1.966(3) Å], even though the intramolecular Se···N interaction (3.3842 Å) was found to be much weaker than in the latter case [2.798(3) Å]. The lengthening of the Se−CH_2Ph distance even in the presence of a weak Se···N interaction suggests that the sterically more demanding group present in the system plays an important role. The very weak Se···N interaction may be a result of the perpendicular orientation of the oxazoline ring, which is twisted about the C(10)−C(11) bond axis such that the nitrogen atom is slightly away from the selenium. Figure 4 shows that Se and N atoms lie in a different plane, in contrast to the benzyl (4,4-dimethyl-1,3-oxazolin-2-yl)phenyl selenide where both the selenium and nitrogen are in same plane.

Conclusion

Novel organoselenium compounds, including a diselenide, with both intramolecular Se···N and Se···O interactions, incorporating a ligand with steric and intramolecularly coordinating groups, have been prepared and characterized. From the current results and their comparison with intramolecularly stabilized organoselenium compounds derived from sterically less-hindered ligands, it is apparent that the strength of the Se···N interaction also depends on the nature of the substituents (steric groups) present in the system, in addition to the nature of the nitrogen atom used as an *ortho* chelating group and the electronegativity of the group attached to the selenium atom. The Se···N nonbonding interactions are considerably stronger than in organoselenium

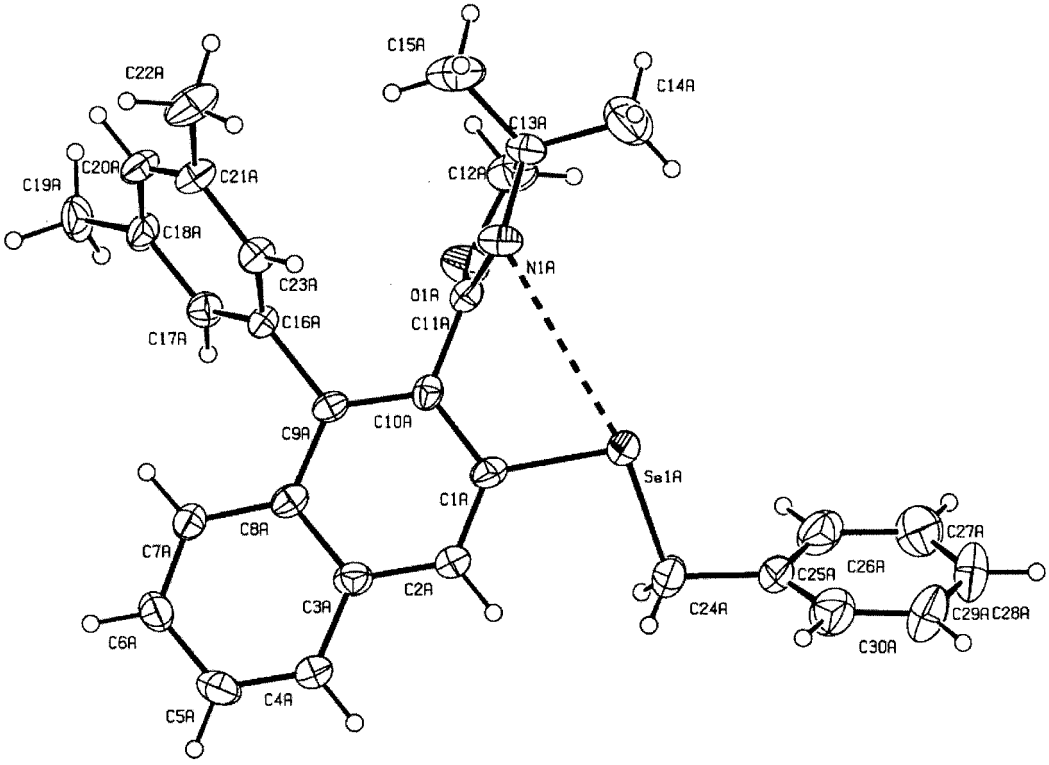

Figure 4. Molecular structure of **8**

compounds derived from the sterically less-hindered ligands. The Se···N nonbonding interactions lengthen the Se···X bond (X = −Se, Br, I, or CH_2) and enhance the possibility of nucleophilic attack at the selenium atom. The intermolecular Se···X (X = Cl, Br, I) interactions generally observed in the other reported organoselenium halides are absent, possibly due to the presence of the sterically more-demanding group. Thus, selenium halides derived from this substrate can be considered as true monomers in the solid state. Although the intermolecular Se···X interactions of the organoselenium halides described here are not within the sum of the van der Waals radii, the intermolecular Se···X contacts decrease (strong interaction) as the size of the halogen atom increases. This may be attributed to the decrease of ligand-ligand repulsions (steric repulsions) as the size of the atom increases.

Experimental Section

General: All reactions were carried out in an inert atmosphere using nitrogen or argon with standard vacuum-line techniques. All solvents were purified by following the literature method and freshly distilled prior to use.[33] 2-[1-(3,5-Dimethylphenyl)-2-naphthyl]-4,5-dihydro-4,4-dimethyloxazole (Aldrich) and *n*-butyllithium (E. Merck) were reagent grade and used as received. $Se(dtc)_2$ was prepared by a reported procedure.[34] Melting points were recorded in capillary tubes and are uncorrected. ^1H, ^{13}C and ^{77}Se NMR were obtained at 300, 75.42 and 57.22 MHz, respectively, in $CDCl_3$ on a Varian VXR 300S spectrometer. Chemical shifts are cited with respect to $SiMe_4$ as internal (^1H and ^{13}C) and Me_2Se (^{77}Se) as external standard. Elemental analyses were determined with a Carlo−Erba model EA 1112 CHNS analyzer. Infrared spectra were recorded in the range of 4000−400 cm^{-1} on a Nicolet Impact 400 FT-IR spectrometer. UV/Vis spectra were recorded on a Shimadzu UV-160A spectrophotometer and fluorescence spectra on a Perkin−Elmer LS-55 Luminescence spectrometer. Fast atomic bombardment (FAB) mass spectra were recorded at room temperature on a JEOL SX 102/DA-6000 mass spectrometer/data system with xenon (6 kV, 10 mV) as the bombarding gas. The accelerating voltage was 10 kV. *m*-Nitrobenzyl alcohol was used as the matrix with cation detection. For isotopes the value given is for the most intense peak.

Synthesis of Diselenide 4: Addition of 1.6 M solution of *n*BuLi in hexane (3.45 mL, 5.5 mmol) to a diethyl ether (50 mL) solution of 2-[1-(3,5-dimethylphenyl)-2-naphthyl]-4,5-dihydro-4,4-dimethyloxazole (1.647 g, 5 mmol) under N_2 at 0 °C resulted in a dark brown solution of the lithiated compound. After 2 hours, finely ground selenium powder (0.4 g, 5 mmol) was added at 0 °C and the temperature maintained for 2 hours to give the lithium areneselenolate. The reaction mixture was then poured into a beaker containing cold aqueous $NaHCO_3$ and O_2 was passed at a moderate rate for 30 min and the mixture extracted with diethyl ether (50 mL). The organic phase was washed with water, and dried over Na_2SO_4. The filtrate was concentrated to give a yellow oil, which solidified upon addition of hexane. The compound was recrystallized from a hexane/dichloromethane (4:1) mixture to give yellow crystals of **4**. Yield: 0.97 g, 25%. M.p. 196−198 °C. $C_{46}H_{44}N_2O_2Se_2$ (816.2): calcd. C 67.83, H 5.44, N 3.44; found C 67.52, H 5.41, N 3.22. UV/Vis (dichloromethane): λ_{max} (ε) = 303.5 nm (18000 dm^3 mol^{-1} cm^{-1}), 350 (8000). ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = 1.29 (s), 2.37 (s), 3.78 (s), 1.29 (s), 2.37 (s), 3.78 (s), 7.05 (s), 7.35 (t), 7.65 (t), 7.75 (t), 8.3 (s) ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 298 K): δ = 21.2, 28.0, 68.1, 79.4, 126.1, 127.0, 127.6, 127.8, 128.0, 129.0, 129.4, 131.2, 134.6, 137.1, 137.6, 140.9, 160.1 ppm. ^{77}Se NMR (300 MHz, $CDCl_3$, 298 K): δ = 450 ppm. IR (KBr): $\tilde{\nu}$ = 1670 cm^{-1} ν(C=N). FAB-MS: *m*/*z* = 816 [M^+].

Synthesis of Selenenyl Chloride 5: Treatment of a solution of the diselenide (0.16 g, 0.2 mmol) in carbon tetrachloride (25 mL) with a carbon tetrachloride solution of SO_2Cl_2 (0.6 mL of 2.1 g, 50 mL, 0.2 mmol) at room temperature gave a yellow precipitate after 1 hour. The mixture was evaporated to dryness under vacuum in order to give the desired compound. The yellow crystalline product was obtained after recrystallization from methanol/chloroform (2:1). Yield: 0.083 g, 93%. M.p. (decomp.) > 200 °C. $C_{23}H_{22}ClNOSe$ (443.05): calcd. C 62.39, H 5.01, N 3.16; found C 62.33, H 5.33, N 3.23. ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = 1.63 (s), 2.39 (s), 4.45 (s), 6.92 (s), 7.13 (s), 7.45 (t), 7.59 (d), 7.7 (t), 8.05 (d), 9.36 (s) ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 298 K): δ = 21.3, 27.9, 65.3, 84.9, 115.8, 126.4, 127.4, 127.6, 128.2, 129.0, 129.9, 131.0, 134.9, 135.8, 137.2, 141.9, 143.8, 167.1 ppm. ^{77}Se NMR (300 MHz, $CDCl_3$, 298 K): δ = 839 ppm. IR (KBr): $\tilde{\nu}$ = 1755 cm^{-1} ν(C=N). FAB-MS: *m*/*z* = 443 [M^+].

Synthesis of Selenenyl Bromide 6: The procedure followed was the same as that used for the preparation of compound **5**, except the addition of Br_2/CCl_4 was carried out for 4 hour at 0 °C. The compound was recrystallized from a dichloromethane/hexane mixture to give yellow crystals. Yield: 0.06 g, 68%. M.p. (decomp.) > 216 °C. $C_{23}H_{22}BrNOSe$ (487.0): calcd. C 56.70, H 4.55, N 2.87; found C 56.51, H 4.39, N 2.70. UV/Vis (dichloromethane): λ_{max} (ε) = 399.5 nm (9540 dm^3 mol^{-1} cm^{-1}), 303.5 (11950). ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = 1.64 (s), 2.39 (s), 4.47 (s), 6.9 (s), 7.13 (s), 7.43 (t), 7.53 (d), 7.63 (t), 8.01 (d), 9.4 (s) ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 298 K): δ = 21.3, 27.9, 65.2, 84.7, 115.9, 126.4, 127.6, 128.2, 129.1, 129.5, 129.8, 131.2, 134.9, 135.9, 137.2, 139.7, 143.8, 166.7 ppm. ^{77}Se NMR (300 MHz, $CDCl_3$, 298 K): δ = 836 ppm. IR (KBr): $\tilde{\nu}$ = 1660 cm^{-1} ν(C=N). FAB-MS: *m*/*z* = 488 [M + 1]$^+$, 487 [M^+].

Synthesis of Selenenyl Iodide 7: Here the procedure used for the preparation of compound **6** was also followed, with the addition of I_2 instead of SO_2Cl_2. The solution obtained was concentrated to give a yellow crystalline product. The compound was recystallized from a dichloromethane/hexane mixture (1:2). Yield: 0.42 g, 79%. M.p. (decomp.) > 240 °C. $C_{23}H_{22}INOSe$ (535.0): calcd. C 51.71, H 4.15, N 2.62; found C 51.68, H 4.12, N 2.46. UV/Vis (dichloromethane): λ_{max} (ε) = 400 nm (7890 dm^3 mol^{-1} cm^{-1}), 303 (17760). ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = 1.59 (s), 2.4 (s), 3.8 (s), 4.3 (s), 6.9 (s), 7.4 (m), 7.6 (m), 7.72 (d), 8.0 (d), 9.31 (s) ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 298 K): δ = 21.6, 28.4, 65.4, 84.2, 117.0, 126.4, 127.5, 127.7, 127.9, 128.8, 129.7, 131.6, 132.3, 134.9, 136.2, 137.1, 143.5 ppm. ^{77}Se NMR (300 MHz, $CDCl_3$, 298 K): δ = 782 ppm.

Synthesis of Aryl Benzyl Selenide 8: The benzyl chloride (0.635 mL, 5 mmol) was added to the lithium selenolate at 0 °C and stirring continued for 2 hours. The usual work up followed by evaporation under reduced pressure gave the desired yellow compound, which was recrystallized from an acetonitrile/dichloromethane mixture (2:1). Yield: 0.7 g, 28%, M.p. 158−160 °C. $C_{30}H_{29}NOSe$ (500.2): calcd. C 72.29, H 5.86, N 2.81; found C 72.59, H 5.95, N 2.66. UV/Vis (dichloromethane): λ_{max} (ε) = 350 nm (3000 dm^3 mol^{-1} cm^{-1}), 303.5 (18420). ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = 1.12 (s), 2.35 (s), 3.83 (s), 4.22 (s), 7.02 (s), 7.39 (t), 7.6−7.49 (t),

[a] $R(F_o) = ||F_o| - |F_c||/|F_o|$ and $wR(F_o^2) = \{[w(F_o^2 - F_c^2)^2]/[w(F_c^2)^2]\}^{1/2}$.

7.72 (d), 7.87 (s) ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 298 K): δ = 21.2, 27.7, 67.9, 126.4, 126.7, 127.4, 128.2, 129.0, 130.4, 131.4, 133.3, 134.0, 137.0, 137.5, 138.3, 141.1, 161.7 ppm. ^{77}Se NMR (300 MHz, $CDCl_3$, 298 K): δ = 351 ppm. IR (KBr): $\tilde{\nu}$ = 1670 cm^{-1} ν(C=N). FAB-MS: m/z = 500 [M$^+$].

Attempted Synthesis of 9: A solution of α,α-dibromo-*o*-xylene (2.5 mmol) in 5 mL of diethyl ether was added dropwise at 0 °C to a diethyl ether solution of arenelithium selenolate (5 mmol). The mixture was stirred at 0 °C for 2 hours. The resulting mixture was washed with water, dried and the solvents evaporated to give a yellow solid which was characterized as the selenenyl bromide **6**.

X-ray Crystallography: The diffraction measurements for compounds **4**, **6**, and **7** were performed on a Siemens R3m/V diffractometer and compound **8** on a Bruker SMART diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.7170 Å). The structures were determined by routine heavy-atom and Fourier methods using SHELXS-86[35] and refined by full-matrix least-squares with the non-hydrogen atoms anisotropic and hydrogens with fixed isotropic thermal parameters of 0.07 Å^2 by means of the SHELXL-97 program.[36] Hydrogens were partially located from difference electron-density maps and the rest were fixed at predetermined positions. Scattering factors were from common sources. Some details of the structural refinement are given in Table 2.
CCDC-217082 to -217085 (**4**, **6**, **7**, and **8**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structure and Photoluminescent Studies of a Novel Supramolecular [Ag(phen)(CN)]·(phen) Complex

Xiao-Chun Huang,[a,b] Shao-Liang Zheng,[a] Jie-Peng Zhang,[a] and Xiao-Ming Chen*[a]

Keywords: Density functional calculations / N ligands / Pi interactions / Photoluminescence / Silver

A novel Ag^{I} complex [Ag(phen)(CN)]·(phen) (phen = 1,10-phenanthroline) has been solvothermally synthesized and characterized by X-ray diffraction. The crystal packing reveals unprecedented threefold interpenetrating three-dimensional four-connected networks self-assembled through C-H···N hydrogen bonds and π···π stacking interactions, which are stabilized by strong C-H···π interactions between the three independent networks. The photoluminescent properties have been investigated by molecular orbital (MO) calculations, showing that the luminescent properties of the complex in the solid state are due to both a $\pi_L \rightarrow \pi_L^*$ transition of the uncoordinated phen species and metal-to-ligand charge transfer (MLCT), admixed with the cyanide-to-ligand charge transfer (XLCT) of the [Ag(phen)(CN)] species.

Introduction

In the field of crystal engineering, many attempts have been made to control the molecular arrangement in a crystal using hydrogen bonds and π···π stacking interactions. The unique strength and direction of these interactions play important roles in the generation of a variety of molecular architectures.[1−8] Non-conventional hydrogen bonds with weak proton donor C-H groups are of great theoretical interest, especially for C-H···N hydrogen bonding interactions.[9−12] Many novel supramolecular structures have been constructed using these weak interactions, such as the supramolecular graphyne-like network structure of 2,4,6-triethynyl-1,3,5-triazine.[6]

1,10-Phenanthroline (phen) is a suitable ligand to study these supramolecular interactions since it contains a large π-system and rich C−H donors. Various novel structures have been constructed with phen and such interactions in our previous work.[13,14] Phen and its derivatives have also been widely used for synthesizing materials with interesting photoluminescence properties. Over the past two decades the photochemical and photophysical properties of d^{10} metal-phen complexes have been extensively investigated.[15−17] Most reported d^{10} metal-phen complexes are cationic, whereas their neutral complexes are rarely documented.[18] Recently, we have synthesized a variety of neutral d^{10} complexes with an unsymmetrical hydroxylated phen ligand; molecular orbital (MO) calculations of these compounds give an effectual proof in the analysis of their interesting photoluminescent mechanism.[19] Herein we describe the synthesis and crystal structure of a novel molecular adduct of a neutral silver(I) complex with a solvate phen molecule, [Ag(phen)(CN)]·(phen) (**1**), which exhibits interesting supramolecular interactions in the solid state. The photoluminescent properties of complex **1** have been investigated and the mechanisms have also been validated by MO calculations on the experimental geometries.

Results and Discussion

Synthesis and Characterization

Complex **1** was prepared by a solvothermal reaction from silver oxide and excess phen in a concentrated aqueous ammonia and acetonitrile mixture. The existence of a cyanide group in complex **1** may be due to the decomposition of acetonitrile at the relatively high temperature (140 °C) and autogenous pressure of the reaction, which is somewhat similar to the process of acetonitrile decomposition under physiological conditions.[20] The formation of the stable mononuclear species [Ag(phen)(CN)] may be ascribed to the slow release of the cyanide ligand from acetonitrile and the multiple weak interactions between [Ag(phen)(CN)] and excess phen ligand, since direct addition of the cyanide salt usually yielded polymeric products.[21]

The IR spectrum of complex **1** shows one band at 2128 cm^{-1}, which can be assigned to the ν(CN) stretching vibration of the terminal CN^- species, taking into account that it is close to the recorded value for $K[Ag(CN)_2]$ (2140

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200300616

cm^{-1}).[22] The ν(CN) stretching vibration for terminally bound CN^- complexes shifts to higher energy than that (2080 cm^{-1})[23] of free cyanide ion in water due to the strong σ donation of the weakly anti-bonding lone pair on CN^- to the metal, but to lower energy than those found for linear M−CN−M complexes such as $[Ag_2(L^2)_2(\mu\text{-}CN)][BF_4]$ [L^2 = 4,7-bis(2-cyanomethyl)-1-thia-4,7-diazacyclononane] (2150 cm^{-1})[24] where the two metal centres are coupled.

Crystal Structure

The X-ray single-crystal structure analysis shows that complex **1** is a 1:1 molecular adduct of mononuclear [Ag(phen)(CN)] and an uncoordinated phen ligand. The [Ag(phen)(CN)] molecule is bisected by a crystallographic mirror plane. The silver(I) atom assumes a Y-shaped planar geometry in which the metal ion is ligated by two nitrogen atoms of a phen and one carbon atom of the terminal cyanide, as shown in Figure 1. The Ag(1)−N(2) distance is 2.301(2) Å, while the Ag(1)−C(1) bond length is 2.026(5) Å. The observed Ag−N distances are similar to the corresponding values [2.283(6) and 2.300(5) Å] found for $Ag(dmp)NO_3{\cdot}2H_2O$ (dmp = 2,9-dimethyl-1,10-phenanthroline),[25] while the Ag−C distance is typical of silver cyanide, and is shorter than that [2.083(2) Å] found for $[Ag_2(L^2)_2(\mu\text{-}CN)][BF_4]$ [L^2 = 4,7-bis(2-cyanomethyl)-1-thia-4,7-diazacyclononane].[24] In complex **1**, the N(2)−Ag(1)−C(1) bond angle is 143.4(1)°, whereas the N(2)−Ag(1)−N(2A) angle is 73.3(1)°.

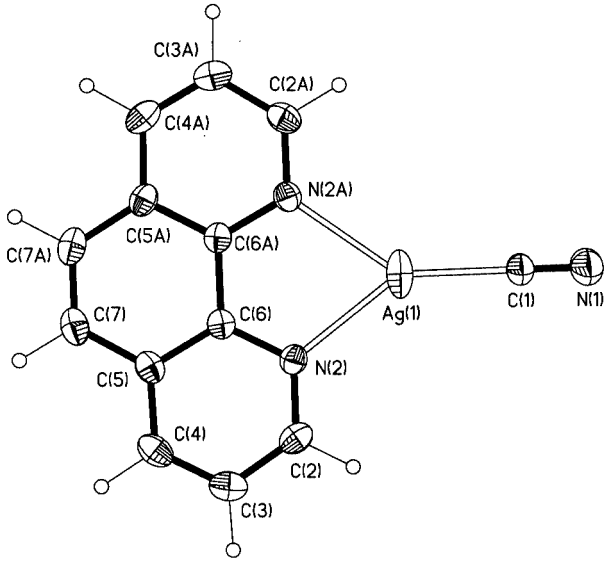

Figure 1. Perspective view of [Ag(phen)(CN)] (30 % thermal ellipsoids) with atom-numbering scheme; selected bond lengths (Å) and bond angles (°): Ag(1)−N(2) 2.301(2); Ag(1)−C(1) 2.026(5); N(2)−Ag(1)−C(1) 143.4(1); N(2)−Ag(1)−N(2A) 73.3(1); symmetry code: A) 1/2 − *x*, *y*, *z*

Cyanometallates are useful building blocks for the construction of supramolecular structures. Such supramolecular assemblies are usually achieved through bridging linear covalent M−CN−M bonding interactions.[23] In contrast, successful attempts to use a cyanide as a terminal ligand, especially for a hydrogen-bond acceptor, are rare.[26] The most intriguing feature in the structure of complex **1** is its unusual supramolecular interactions, including C-H···N hydrogen bonds, π···π stacking and C-H···π interactions involving the terminal cyanide and phen ligands, generating a unique supramolecular architecture in the solid state (Figure 2).

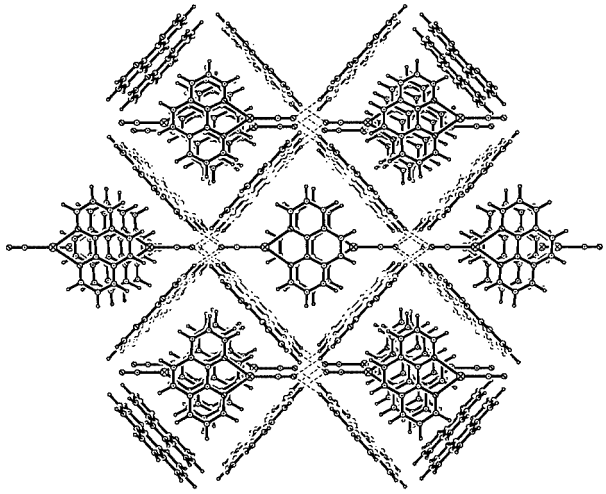

Figure 2. Crystal packing pattern of **1** viewed along the *a* axis

Adjacent [Ag(phen)(CN)] molecules in complex **1** are stacked in an inverse fashion through strong offset π···π aromatic stacking interactions, with a face-to-face distance of about 3.40 Å, forming a one-dimensional array (Figure 3, top),[3] whereas the uncoordinated phen molecules are arranged to give extended one-dimensional ribbons with relatively long C-H···N(phen) contacts (C···N 3.61 Å, H···N 2.60 Å, C-H···N 155°; Figure 3, bottom), where the H···N distance is still shorter than the van der Waals radii sum of 2.75 Å.[27] It is very interesting that the arrays and the ribbons are extended into a novel three-dimensional structure by strong C-H···N(CN) hydrogen bonds (C···N 3.41 Å, H···N 2.35 Å, C-H···N 164.4°). There are a few reported networks built from both weak C-H···X hydrogen bonds and π···π interactions.[13,14,28,29] A noteworthy example is the diamondoid network made up of C-H···O hydrogen bonds and π···π interactions in the structure of tetrakis(4-nitrophenyl)methane·G (G = THF, dioxane, nitrobenzene, 4-bromoanisole, anisole, ethoxybenzene, *p*-xylene, chlorobenzene).[28] The C-H···N hydrogen bonds are consistent with the previous report of this type of interactions, for example, the short C-H···N hydrogen bonds (C···N 3.27 Å, H···N 2.31 Å, C-H···N 180° and C···N 3.30 Å, H···N 2.34 Å, C-H···N 172.1°) in the structure of 2,4,6-triethynyl-1,3,5-triazine.[6] It should be noted that the acidity of $C_{(phen)}$−H is significantly weaker than $C_{(sp)}$−H or Cl_3C-H, which are

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

involved in the most reported short and linear C-H···N hydrogen bonds.[5]

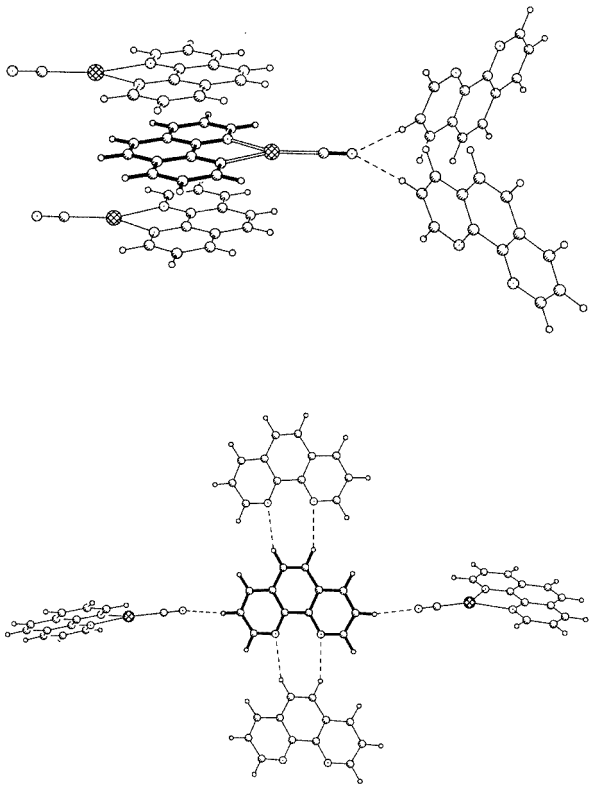

Figure 3. (top) The tetrahedral node defined by an [Ag(phen)(CN)] molecule connected to two other [Ag(phen)(CN)] molecules by π···π stacking interactions and two uncoordinated phen molecules by C-H···N hydrogen bonds; (bottom) the square-planar node defined by an uncoordinated phen molecule connected to two [Ag(phen)(CN)] moieties and two uncoordinated phen molecules by C-H···N hydrogen bonds

As shown in Figure 3, each [Ag(phen)(CN)] molecule forms hydrogen bonds and π···π interactions with its adjacent molecules in a tetrahedral arrangement (Figure 3, top), which can be regarded as a tetrahedral node; each uncoordinated phen molecule forms hydrogen bonds with its adjacent molecules in a square-planar arrangement, which can be regarded as a square-planar node (Figure 3, bottom). The three-dimensional structure of complex **1** linked by hydrogen bonds and π···π interactions can therefore be rationalized to contain equal numbers of tetrahedral nodes and square-planar nodes, where every node is connected to two nodes of the same type and two nodes of the other type (Figure 4, top). The resulting unprecedented binodal four-connected $(5^5 6)(5^4 8^2)$ topology is related to the well-known PtS net since it contains equal numbers of tetrahedral and square-planar nodes. However, the nodes of the PtS net are arranged in such a way that every node is connected to four nodes of the other type, in contrast to the topology found in complex **1**.[30] There is threefold interpenetration, with the networks being linked through edge-to-face C-H···π interactions between the coordinated ligands and uncoordinated phen molecules of the three nets, as illustrated in Figure 4 (bottom). Other examples of interpenetrating three-dimensional hydrogen-bonding networks linked by weak interactions include the structures of 4-(carboxamindo)-1-cubanecarboxylic acid, $[Zn(Him)_2(tpa)]\cdot H_2O$ (Him = imidazole, tpa = terephthalate) and $NH_4(bpedo)_2PF_6\cdot 3H_2O$ [bpedo = *trans*-bis(4-pyridyl)ethylene dioxide].[31–33] The pattern of C-H···π hydrogen bonds is very interesting in **1**, as there are two sets of contacts, with the short one having an H···π interaction of about 2.39 Å (C-H···π ca. 163°) and the longer one an H···π interaction of about 2.82 Å (C-H···π ca. 163°), which results in every coordinated phen species containing four C−H donors and every uncoordinated phen species being an acceptor for four C−H donors from two coordinated phen ligands (Figure 5).

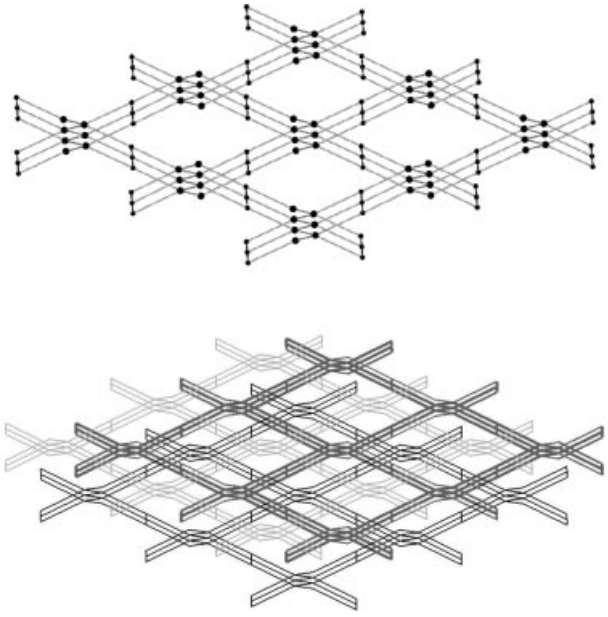

Figure 4. (top) The four-connected net constructed by the tetrahedral ([Ag(phen)(CN)], larger spheres) and square-planar (phen, smaller spheres) nodes, as well as (bottom) the threefold interpenetrating nets in **1**

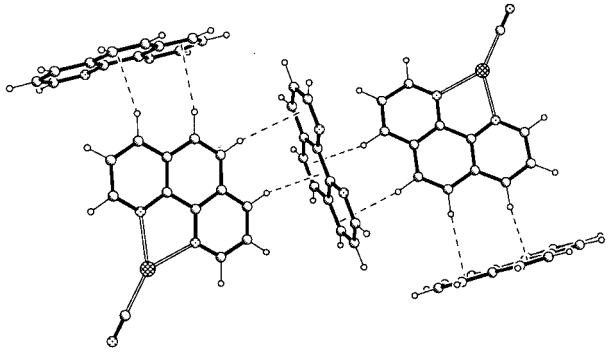

Figure 5. Perspective view of the C-H···π interactions

Luminescent Properties

Most luminescent Ag^I compounds exhibit emission at low temperature. Some important examples are organometallic silver(I) compounds containing bridging acetylide ligands,[34] silver(I) diisocyanide[35] and other silver(I) cyan-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ide compounds.[36] Only a few monomeric and polymeric Ag^I complexes exhibit luminescence at room temperature.[37−41] Interestingly, solid **1** is luminescent at ambient temperature. Upon excitation at 325 nm, complex **1** displays an intense blue photoluminescence with three emission maxima at 406, 420 and 529 nm. The first two emission bands resemble the π-π* transition bands (385 and 403 nm) observed for solid phen (see Figure 6) due to the presence of uncoordinated phen molecules in **1**.

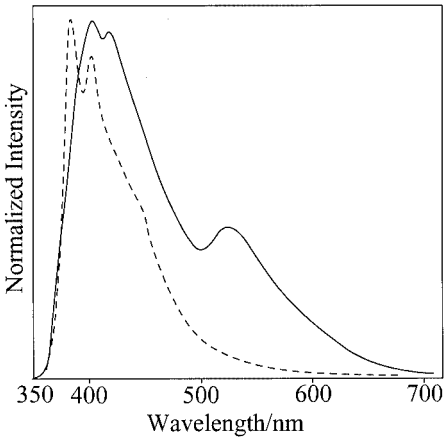

Figure 6. Photoluminescent spectra of solid **1** (−) and phen (---) (excited at 325 nm) in the solid state at room temperature

It has been suggested that the emission bands in the reported silver(I) complexes originate from dσ*-pσ or 4d−5s transitions, the excited states of a metal-to-ligand charge transfer (MLCT), or have an MMLCT character.[42−45] To assign the emission bands, we carried out molecular orbital (MO) calculations on the mononuclear [Ag(phen)(CN)] species and the phen molecule with the experimental geometries. The relevant HOMOs and LUMOs for [Ag(phen)(CN)] and phen, together with the orbital energies, are shown in the contour plots in Figure 7. For uncoordinated phen, the HOMOs are associated with the π-bonding orbital from the phen rings, while the LUMOs are mainly associated with the π-antibonding orbital; for [Ag(phen)(CN)], the HOMOs are mainly composed of σ(Ag−C≡N) orbitals, localized more on the metal center (namely the d_z^2 orbit), while the LUMOs are mainly composed of the π-antibonding orbital from the phen rings. There are deviations between the HOMO−LUMO analysis derived from our calculations (HOMO−LUMO gaps for [Ag(phen)(CN)] 3.74 eV; for phen 4.84 eV) and the experimentally measured emission energy (ca. 2.34 and 3.10 eV), since only the ground states were taken into consideration in the MO calculations. Moreover, extensive transverse interactions, such as π···π stacking, C−H···π interactions and C−H···N hydrogen bonds, exist in the real solid state and play an essential role in decreasing the HOMO−LUMO gaps.[19,46,47] These supramolecular interactions may also account for the decrease of the HOMO−LUMO gap of the phen groups in complex **1** compared to that of solid phen, resulting in a red-shift of the higher energy emission bands for complex **1**. Moreover, it is worthy to mention that the trend derived from the calculations is in accordance with the experimental results. As a characteristic of large heterocyclic aromatic ligands, the conjugated system can effectively decrease the π*-orbital energies, therefore the LUMO may not be contributed by the metal atom, as demonstrated by the MO calculation results of [Ag(phen)(CN)]. The ligation of a d^{10} metal atom to the heterocyclic aromatic ligand will further decrease the LUMO energy contributed by the π*-orbital, resulting in a much lower-energy emission band for the [Ag(phen)(CN)] species in complex **1**. It can therefore be concluded from the MO calculations that, for the adduct compound **1** in the solid state, the high-energy emission bands can mainly be assigned to the $\pi_L \rightarrow \pi_L^*$ transition of the uncoordinated phen molecules, whereas the low-energy transition is expected to be the metal-to-ligand charge transfer (MLCT), admixed with the cyanide-to-ligand charge transfer (XLCT) band.

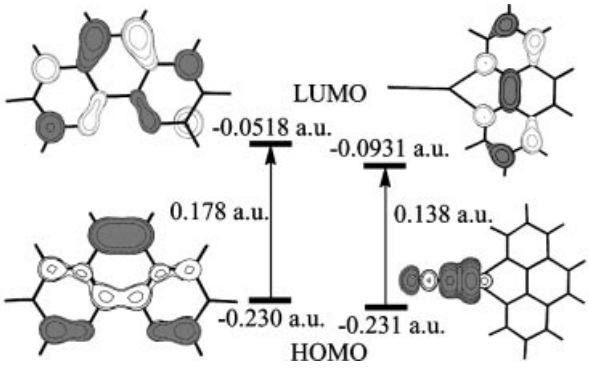

Figure 7. Contour plots and orbital energies of the HOMOs and LUMOs for phen (left) and [Ag(phen)(CN)] (right)

Conclusion

In summary, complex **1** shows an unprecedented four-connected three-dimensional network through cooperative π···π stacking interactions and C-H···N hydrogen bonds; the threefold interpenetrating net is connected by C-H···π interactions between the coordinated phen and uncoordinated phen species. The photoluminescence mechanism of **1** has been studied by molecular orbital calculations, showing that the photoluminescent properties are due to both the $\pi_L \rightarrow \pi_L^*$ transition of the uncoordinated phen molecule and metal-to-ligand charge transfer (MLCT), admixed with the cyanide-to-ligand charge transfer (XLCT) of the [Ag(phen)(CN)] molecule.

Experimental Section

General Remarks: The reagents and solvents employed are commercially available and were used as received without further purification. The C, H, and N microanalyses were carried out with a Perkin−Elmer 240 elemental analyser. The FT-IR spectra were recorded from KBr pellets in the range 4000−400 cm^{-1} on a Nicolet Magna 750 FT-IR spectrometer. The emission spectra were re-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

corded on a Perkin−Elmer LS50B fluorescence spectrophotometer, and the excitation source used was the 325 nm line of He-Cd laser (Kimmon IK5352R-D) with maximum power of 4 mW.

Synthesis of [Ag(phen)(CN)]·(phen) (1): Single crystals of complex **1** were obtained by a solvothermal method. In a typical procedure, silver oxide (0.5 mmol, 0.116 g), phen (2 mmol, 0.400 g), concentrated aqueous ammonia (5 mL) and acetonitrile (5 mL) were mixed sufficiently with stirring and placed into a 25-mL Teflon-lined steel autoclave and heated at 140 °C for 72 h, then cooled to 5 °C/h to 80 °C and held at that temperature for 10 h, followed by slow cooling to room temperature. Pale-yellow crystals (0.101 g) were collected in 20 % yield based on Ag_2O. $C_{25}H_{16}AgN_5$ (494.30): calcd. C 60.75, H 3.26, N 14.17; found C 60.43, H 3.78, N 14.15. FT-IR (KBr): $\tilde{\nu}$ = 3415 cm^{-1} (br. s), 3044 (m), 2925 (m), 2128 (m), 1683 (w), 1646 (m), 1618 (m), 1565 (m), 1503 (s), 1417 (s), 1136 (m), 1091 (m), 837 (m), 792 (w), 723 (m), 621 (w), 461 (w), 433 (w).

X-ray Crystallographic Study: A pale-yellow crystal (0.40 × 0.30 × 0.30 mm^3) of complex **1** suitable for X-ray analysis was selected and data collection was performed at 21 °C on a Bruker Smart Apex CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Data were corrected for Lorentz and polarization effects and empirical absorption corrections were applied using the SADABS program.[48] The structure was solved by direct methods and refined with full-matrix least-squares technique using the SHELXTL software suite.[49] Anisotropic thermal parameters were applied to all non-hydrogen atoms. The organic hydrogen atoms were generated geometrically with a restricted bond length (C−H 1.083 Å). The crystallographic data are listed in Table 1.
CCDC-216802 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Limiting indices	$-8 \le h \le 8$, $-22 \le k \le 17$, $-17 \le l \le 18$
Reflections collected/unique	10063/1990 [R_{int} = 0.033]
Completeness to θ = 26.00°	99.5 %
Absorption correction	Semi-empirical from equivalents
Max. and min. transmission	0.7502 and 0.6866
Refinement method	Full-matrix least-squares on F^2
Data/restraints/parameters	1990/0/143
Goodness-of-fit on F^2	1.068
Final *R* indices [$I > 2\sigma(I)$]	R_1 = 0.0410, wR_2 = 0.1004
R indices (all data)	R_1 = 0.0542, wR_2 = 0.1079
Extinction coefficient	0.0005(4)
Largest diff. peak and hole (*e*·Å^{-3})	0.380 and −0.425

Calculational Details: Density functional calculations were performed with the Gaussian 98 suite of programs,[50] at the B3LYP level. The basis set used for C, O, N and H atoms was 6−31G while effective core potentials with a LanL2DZ basis set were employed for transition metals. The contour plots of MOs were obtained with the Molden 3.5 graphic program.[51]

Acknowledgments

Epoxidation versus Baeyer−Villiger Oxidation: The Possible Role of Lewis Acidity in the Control of Selectivity in Catalysis by Transition Metal Complexes

Agostino Brunetta[a] and Giorgio Strukul*[a]

Keywords: Lewis acids / Homogeneous catalysis / Oxidation / Peroxides

The synthesis of a series of cationic complexes of Pt^{II} containing triphos or triphosPO and either a solvent, a hydroxo or a hydroperoxo as the fourth ligand is reported. The complexes are characterized by IR and $^{31}P\{^1H\}$ NMR spectroscopy and by molar conductivity data, and their Lewis acid characteristics determined by NMR techniques. All complexes are good catalysts for the epoxidation of olefins and the Baeyer–Villiger oxidation of ketones under mild conditions using hydrogen peroxide as oxidant. The latter reaction is more Lewis-acid demanding in terms of the electronic characteristics of the catalysts. The use of Lewis-acidic metal centers allows the selective oxidation of unsaturated ketones to the corresponding unsaturated esters without oxidation of the carbon-carbon double bond, indicating that a strong Lewis-acid character of the catalyst can be an important feature in the design of catalysts capable of separating the two processes.

Introduction

In transition metal chemistry, the idea of Lewis acidity is generally associated with electron-deficient metal centers such as the early metals in their highest oxidation state or the first row late metals such as Cu^{II} and Zn^{II}. This simple notion is supported by a huge number of applications in organic synthesis.[1] Within this framework, the idea of associating Lewis acidity with electron-rich metal centers like Pd^{II} and Pt^{II} for catalytic applications is a relatively recent one, the necessary condition to exploit the Lewis acidity of the latter systems being the presence of at least one positive charge on the complex. In the past few years, the number of applications of these systems in catalysis has been increasing, although, among the examples reported,[2] none refers to oxidation reactions.

Several years ago we reported the first example of transition metal catalysis in the Baeyer−Villiger (BV) oxidation of ketones, with H_2O_2 as the oxidant, and using a cationic complex of Pt^{II} as the catalyst.[3] The mechanism of the reaction[3b] (Figure 1) clearly indicates that, having no role in the activation of the oxidant, the major function of Pt in the catalytic cycle is to behave as a Lewis acid for the activation of the ketone. This view is strengthened by the analogies (Figure 1) between the quasi-peroxymetallacyclic intermediate **1** and the Criegee intermediate involved in the purely organic reaction using peracids (Pt replaces H^+). More recently, typical Lewis acids such as Al^{III},[4] Mg^{II},[5] and Sn^{IV} [6] have also been reported in the BV oxidation of ketones, emphasizing the importance of having a Lewis-acid center to promote the reaction by activation of the ketone.

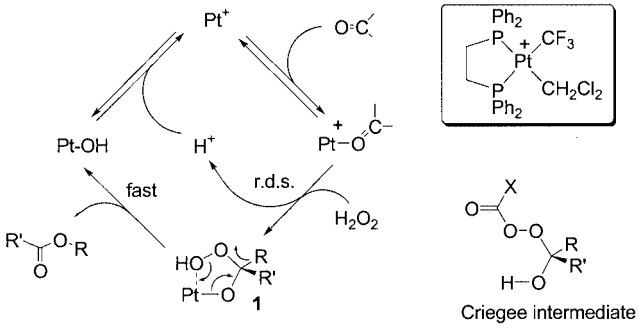

Figure 1. Reaction mechanism for the Baeyer−Villiger oxidation of ketones with hydrogen peroxide catalyzed by $[Pt(CF_3)(P\text{-}P)(solv)]^+$-type complexes

The same complex reported in Figure 1 was also recognized to be an efficient catalyst for the epoxidation of olefins with H_2O_2 under mild conditions,[7] although in this case the mechanism of the reaction (Figure 2) indicates that the function of the catalyst is more complex[7d] as it activates both the olefin towards nucleophilic attack and, at the

same time, hydrogen peroxide, increasing its nucleophilicity by coordination.

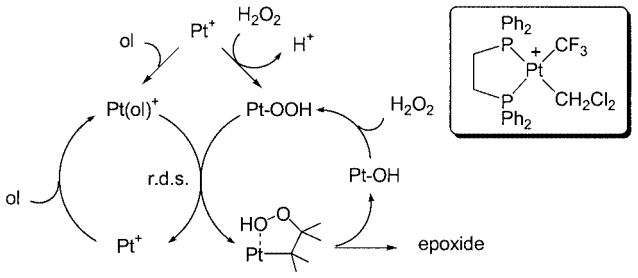

Figure 2. Reaction mechanism for the epoxidation of olefins with hydrogen peroxide catalyzed by $[Pt(CF_3)(P\text{-}P)(solv)]^+$-type complexes

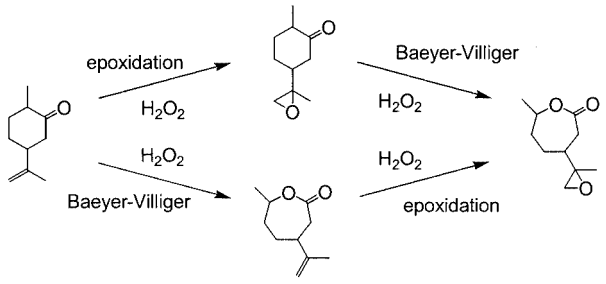
Platinum complexes are the only catalysts known in the literature that catalyze both the BV and the epoxidation reactions with high activity. Moreover, they do so using hydrogen peroxide as the oxidant, i.e. a cheap, environmentally friendly oxidant, but also an elusive one for selective, non-radical-type oxidations. The versatility of these systems offers a unique opportunity to investigate in more detail the electronic properties of the metal center that allow us to separate the BV reaction from the epoxidation reaction. This aspect is crucial for selectivity whenever a bifunctional molecule is oxidized, and may have an important impact in organic synthesis, as both the BV and the epoxidation reactions are widely used as intermediate steps in complex synthetic procedures, leading to the preparation of pharma, agro and fine chemicals. As an example, Scheme 1 shows the theoretical case of dihydrocarvone where both parallel and consecutive reactions are possible leading to the unselective formation of the epoxy lactone. The aim of the present work is to establish whether the Lewis acidity of the metal center is of importance for controlling the relative rates of the BV and epoxidation reactions.



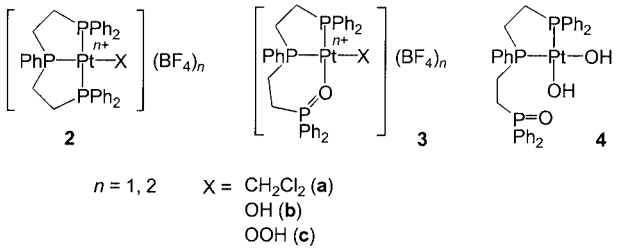
Scheme 1

Results and Discussion

Synthesis of Complexes

To address the problem exposed above, one has to design a class of cationic homologous complexes of platinum(II) with very similar geometric constraints, but differing in the electron density of the metal. Since the presence of a coordinated diphosphane seems to be a crucial requirement to promote the activity of these complexes,[3,7,8] to achieve this goal we chose tridentate ligands of the type P-P-P and P-P-P=O, bearing, respectively, three P donors and two P and one O donors. This would ensure the formation of bis-cationic complexes possessing, in principle, a significant Lewis acidity.

Square planar Pt^{II} complexes such as **2** and **3** containing tridentate ligands (Scheme 2) were synthesized following the procedure outlined in Scheme 3. This was already published for solvento complexes by Bergamini et al.[9] although the species were characterized in situ (NMR evidence) but never isolated. The isolation of the hydroxo and hydroperoxo complexes of **2** could be easily accomplished by addition of, respectively, OH^- to the corresponding solvento complex or H_2O_2 to the hydroxo complex. Conversely, in the case of **3**, given the lability of the oxygen donor, the same procedure led to the formation of a different species that was characterized in situ by NMR spectroscopy. Attempts to isolate this species synthetically using the procedure adopted for **2b** (i.e. addition of a stoichiometric amount of OH^- in acetone/H_2O) led to the formation of a complex mixture showing a different NMR spectrum. Isolation of a species (albeit in moderate yield) with the same NMR spectrum as observed in the in situ experiment could be accomplished in CH_2Cl_2 by adding an excess of OH^- in water. This species is most likely a neutral bis-hydroxo complex of the type $[Pt(OH)_2(P\text{-}P\text{-}P{=}O)]$ (**4**) as seems to be indicated by the full spectroscopic characterization (see below).



Scheme 2

Characterization of Complexes

All complexes were characterized by IR and $^{31}P\{^1H\}$ NMR spectroscopy, and molar conductivity measurements. A summary of the characterization data is reported in Table 1. For the purpose of simplicity, and with reference to Scheme 2, in reporting the NMR spectroscopic data P_a refers to the phosphorus *trans* to P (or to O in complexes **3**), P_b to the phosphorus *trans* to X and (only in complexes **3**) P_c to the oxidized phosphorus. As shown in Table 1, in the IR spectrum all complexes display the broad band characteristic of non-coordinated BF_4^- in the 1100−960 cm^{-1} range. Additionally, complexes **2b** and **2c** show typical weak O−H stretching frequencies at 3620 and 3483 cm^{-1}, respectively, in agreement with previously reported hydroxo

[a] IR in nujol; NMR in [D_6]acetone at 25 °C; molar conductivity: 10^{-3} M solution in EtOH. [b] NMR spectrum recorded in CD_2Cl_2. [c] In 1,2-dichloroethane solution. [d] NMR spectra recorded in acetone at −70 °C.

and hydroperoxo complexes of Pt^{II}.[7e,10] Similarly, in complex **3a** the P=O stretching frequency of the oxygen-coordinated ligand is observed at 1124 cm^{-1}.[11]

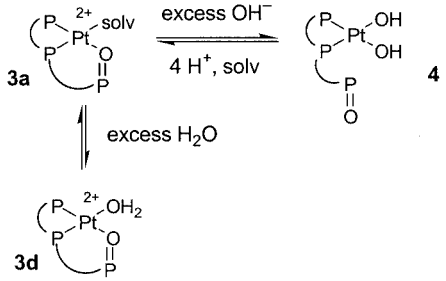
The NMR spectroscopic data were taken in [D_6]acetone. Complexes **2a** and **3a** give very broad signals in CD_2Cl_2 so a more coordinating solvent was necessary in order to observe a relatively static spectrum at room temperature. The signals are moderately broad so that P–P coupling constants cannot be determined. In general, P_b when it is *trans* to a solvent (as in **2a** and **3a**), displays higher P–Pt coupling constants. The same happens to P_a in **3a** where it is *trans* to the labile oxygen ligand. It should be noted that the P_b–Pt coupling constants for **2b** and **2c** are significantly smaller than in the case of mononuclear diphosphane complexes of platinum[7e,10a,12] where they fall in the 3000–3400 Hz range, reflecting the moderate *trans* effect of the -OH (-OOH) ligand, as was suggested by Appleton and Bennett.[12] The data reported for **2a**, **2b** and **3a** are identical to those observed in situ by Bergamini et al.[9]

Conductivity data for **2a**, **3a**, and **2b**, **2c** taken in 10^{-3} M MeOH solutions are in the range generally accepted for 1:2 and 1:1 electrolytes, respectively.[13]

At variance with the NMR spectra mentioned above, the addition of an excess of OH^- to **3a** results in the formation of a more static species (**4**) in which P–P coupling constants can be observed. The signal assigned to P_c is strongly shifted (about 20 ppm) to higher fields with respect to the parent compound, indicating that the O donor is probably no longer in the coordination sphere of the metal. This view seems to be confirmed by the observation that in the IR spectrum of the isolated species the P=O stretching frequency shifts from 1124 cm^{-1} in **3a** to 1178 cm^{-1} in **4**.[11] Additionally, the P_a–Pt and P_b–Pt coupling constants are practically identical (3477 and 3480 Hz respectively). The IR spectrum of **4** in dichloroethane solution also shows a weak band at 3599 cm^{-1}, typical of hydroxo complexes of Pt^{II}.[7d,7e,8a,10a] On this basis two possibilities are possible, both in agreement with the NMR spectroscopic data but neither corresponding to **3b**: the complex might be either a mononuclear bis-hydroxo complex or a dinuclear μ-hydroxo complex. The latter class of complexes is very stable and is relatively common in the literature in the case of Pt^{II}.[14] A possible formulation of **4** as a dinuclear μ-hydroxo complex might be supported by the values of the $^1J_{P,Pt}$ coupling con-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

stants that fall in the 3200−3600 Hz range typical for this class of complexes.[14] Addition of an excess (4:1) of HBF_4 in Et_2O (Scheme 4) allows us to observe the corresponding solvento complex **3a**, while the further addition of an excess of water leads to the formation of the aquo complex (see below and **3d** in Table 1). These observations would be consistent with **4** being both a bis-hydroxo complex (as formulated in Scheme 4) and also a dinuclear μ-hydroxo complex. Conclusive evidence for the nature of **4** as a mononuclear bis-hydroxo complex comes from IR spectroscopy, where the broad strong BF_4^- band is not observed, and from molar conductivity data. As shown in Table 1, the conductivity of a 10^{-3} M solution of **4** in MeOH is practically negligible, indicating that the complex is neutral.



Scheme 4

Acidity Measurements

A critical point for the purpose of the present work is the determination of the Lewis acid characteristics of the homologous complexes **2a** and **3a**. This was initially investigated by IR spectroscopy, following addition to solutions of **2a** and **3a** of CO, acetonitrile and 2,6-dimethylphenyl isocyanide, all of which can easily displace the CH_2Cl_2 from the coordination sphere of the metal. It is well-known that both the CO, CN and NC stretching frequencies of the above coordinated molecules are sensitive to the electron density of the metal[14] and hence might be a valuable tool for understanding the Lewis acid nature of the metal center. Experiments were carried out in 1,2-dichloroethane (DCE). In the case of CO, solutions of the complexes were saturated with the gas prior to recording the IR spectrum, while with acetonitrile or 2,6-dimethylphenyl isocyanide variable amounts of reactant could be added. This allowed us to distinguish between the free and coordinated ligand. Table 2 summarizes the results obtained. As can be seen, in all cases the coordinated ligand vibrates at higher frequencies with respect to the free ligand (CO 2143 cm^{-1}; MeCN 2255 cm^{-1}; 2,6-dimethylphenyl isocyanide 2121 cm^{-1}), which is a good indication that the complexes are indeed Lewis acids. However, the addition of CO or CH_3CN results in negligible differences between the complexes, only with 2,6-dimethylphenyl isocyanide could a 5 cm^{-1} shift to higher frequency be observed in the case of **3b**. It has to be pointed out that with the latter complex the addition of an excess of isocyanide determines a further shift of the band maximum to higher frequencies as a result of the formation of a shoulder at about 2225 cm^{-1}, indicative of the presence of a second ligand in the coordination sphere of the metal causing the likely displacement of the labile O donor. Since the above IR data did not provide a clear answer as to which of the complexes was more Lewis acidic (common chemical sense would indicate **3a**) it was decided to turn to a different technique.

Table 2. IR data of **2a** and **3a** after reaction with CO, acetonitrile or 2,6-dimethylphenyl isocyanide[a]

Complex	ν(CO) (cm^{-1})	ν(CN) (cm^{-1})	ν(NC) (cm^{-1})
2a	2150	2295, 2324	2204
2b	2152	2296, 2326	2209

[a] In DCE solution; resolution 0.5 cm^{-1}.

Recently, Zhong et al.[16] have faced a similar problem in the study of a homologous series of cationic bis(aryl)diimine-ligated methyl complexes of Pt^{II} where the substituents on the aromatic rings were varied systematically. The aim of these authors was to determine the electronic effects of the ligands on the metal center and possibly find a correlation with respect to their properties in the C−H activation of alkanes. The problem was addressed by studying the equilibrium shown in Scheme 5 by ^1H NMR spectroscopy, where water is used as a Lewis base. The extent of this equilibrium can be taken as a measure of the Lewis acidity of the metal center. Although this method was developed for a different class of homologous complexes of Pt^{II}, it seems reasonable to apply it, at least semi-quantitatively, also to the present case. The ratio between Pt-solv and $Pt-OH_2$ complexes can be easily determined by $^{31}P\{^1H\}$ NMR spectroscopy at −70 °C {NMR spectroscopic data for $[Pt(H_2O)(P\text{-}P\text{-}P)](BF_4)_2$ (**2d**) and $[Pt(H_2O)(P\text{-}P\text{-}P{=}O)](BF_4)_2$ (**3d**) are reported in Table 1}. By applying mass balance to Pt and H_2O one can easily solve a four-equation system, which allows us to calculate the equilibrium constant (Scheme 5). This was found to be 110 for **2a** and 1400 for **3a** indicating that the latter is considerably more Lewis acidic than the former. Indeed, as the NMR experiments were carried out in acetone the solvento species are not exactly **2a** and **3a**, as in Scheme 2, but more correctly the corresponding acetone derivatives. The limitations of these

$$\text{Pt-solv} + H_2O \underset{-70\,^\circ C}{\overset{K_a}{\rightleftharpoons}} \text{Pt-OH}_2 + \text{solv}$$

solv = [D$_6$]acetone

$$\begin{cases} [Pt(H_2O)] / [Pt(solv)] = n \\ [H_2O] + [Pt(H_2O)] = C^\circ_b \\ [Pt(H_2O)] + [Pt(solv)] = C^\circ_a \\ [solv] = 15.2\ M \end{cases}$$

$$K_a = \frac{[Pt(H_2O)]\,[solv]}{[Pt(solv)]\,[H_2O]}$$

$$K_a = \frac{n\,(n+1)\,[solv]}{n\,(C^\circ_b - C^\circ_a) + C^\circ_b}$$

NMR experiments when used for the interpretation of the catalytic reactions that will be considered below are numerous: (i) the technique was developed for a different class of complexes, although the principle is quite general; (ii) the equilibrium constants are determined at −70 °C, while the catalysis is carried out at higher temperatures; (iii) the solvento complexes considered are actually Pt(acetone) instead of Pt(dichloromethane). Even with these limitations we believe that the overall meaning of the experiment is quite clear, i.e. **3a** is more acidic than **2a**.

Catalytic Activity

Having ascertained that **2a** and **3a** differ significantly in their Lewis acidity, their activity in the BV oxidation and in the epoxidation of olefins with hydrogen peroxide was compared. 2-Methylcyclohexanone and cyclooctene were chosen as prototype substrates and a substrate/H_2O_2/catalyst ratio equal to 100:100:1 was chosen. Reactions were carried out in DCE.

In both processes **2a** was found to be inactive at 20 °C, whereas at 70 °C a moderate activity was observed. In Figure 3 a comparison between **2a**, **2b** and **2c** in the epoxidation of cyclooctene is reported. As can be seen the homologous complexes display a very similar catalytic behavior: their maximum activity (expressed as zero-order rate constant) is essentially the same: a very short induction time is observed with **2b** and **2c**, indicating a relatively quick conversion into the catalytically active species, and only the amount of epoxide formed seems to differ markedly. The reactions are in any case very selective as the epoxide was the only product observed, with no evidence for glycol or further oxidation products. It has to be pointed out that under these experimental conditions a certain degree of irreproducibility was observed (approximately ±10% of the maximum activity and ±25% of the maximum conversion) as the result of a deactivation process that will be considered more thoroughly below. Similar results (Table 3) were observed for the oxidation of 2-methylcyclohexanone (2-heptalactone was the only oxidation product) both in terms of activity and conversion. Like in epoxidation, the reaction must be carried out at 70 °C, and deactivation of the catalyst is evident.

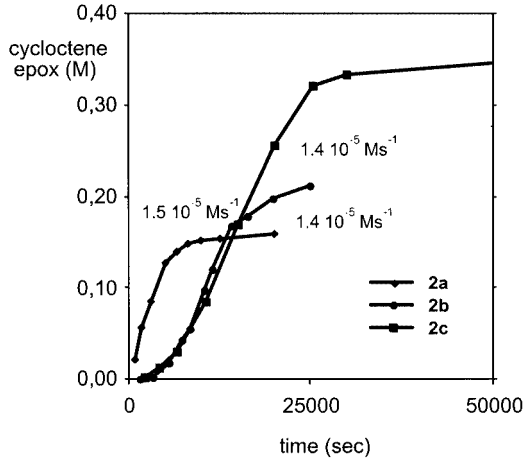

Figure 3. Reaction profiles for the epoxidation of cyclooctene with hydrogen peroxide catalyzed by homologous Pt^{II} complexes: [(triphos)Pt(solv)]$^{2+}$ (**2a**), diamonds; [(triphos)Pt(OH)]$^{+}$ (**2b**), circles; [(triphos)Pt(OOH)]$^{+}$ (**2c**), squares; numbers on the curves indicate the rate expressed as a zero-order rate constant; reaction conditions: catalyst 0.017 mmol; substrate 1.7 mmol; 35% H_2O_2 1.7 mmol; DCE 3 ml; N_2 1 atm.

The activity of **3a** is significantly different, although the reaction profile has the same shape as that shown for **2a** in Figure 3. As can be seen from Table 3, this catalyst is already active at 20 °C especially in the oxidation of 2-methylcyclohexanone, while the activity is very poor in the epoxidation of cyclooctene. At 70 °C it is approximately as active as **2a** in the epoxidation reaction and more active in the BV oxidation (Table 3), but seems to deactivate more quickly.

The reactivity shown by **2a** with respect to cyclooctene is observed also in the epoxidation of other olefins (Table 4). Even in this case a similar activity between **2a** and **2b** is observed. However, by the end of the epoxidation reactions, some epoxide hydrolysis occurs with formation of the corresponding glycol, probably promoted by the acid catalyst and due to the lower stability of these epoxides with respect to cyclooctene epoxide. Internal olefins are epoxidized more efficiently than terminal olefins (1-octene) and this contrasts with the behavior observed for other cationic Pt^{II} complexes {e.g. [Pt(CF_3)(P-P)(solv)]$^{+}$}, which are specific for the epoxidation of terminal olefins.[7] The α,β-unsatu-

Table 3. Catalytic activity of complexes **2** and **3** in the epoxidation of cyclooctene and the Baeyer−Villiger oxidation of methylcyclohexanone[a]

Catalyst	Substrate	Temp. (°C)	10^5 × max. rate (Ms^{-1})	Max. conv. (%)
2a	cyclooctene	70	1.5	20
2b		70	1.4	40
2c		70	1.4	25
2a	2-methylcyclohexanone	70	1.5	11
2b		70	1.6	13
3a	cyclooctene	20	0.05	2
3a		70	1.2	11
3a	2-methylcyclohexanone	20	2.0	40
3a		70	7.0	25

Table 4. Catalytic activity of complexes **2** and **3** in the oxidation of other substrates[a]

Catalyst	Substrate	Temp. (°C)	$10^5 \times$ max. rate (Ms^{-1})	Max. conv. (%)
2a	cyclohexene	70	1.0	20
2b		70	1.3	20
2a	1-octene	70	0.3	10
2b		70	0.4	15
2b	4-methyl-2-pentene	70	1.0	10
2a	2-cyclohexen-1-one	70	2.0	15
2b		70	1.5	12
3a	cyclopentanone	20	0.5	5
3a		70	4.5	15
3a	cyclohexanone	20	0.5	5
3a		70	6.2	11
3a	3,3-dimethyl-2-butanone	20	0.2	5
3a		70	5	6
3a	2-allylcyclohexanone	20	0.8	11

[a] Experimental conditions: catalyst 0.017 mmol; substrate 1.7 mmol; 35% H_2O_2 1.7 mmol; DCE 3 ml; N_2 1 atm.

rated ketone 2-cyclohexen-1-one is selectively epoxidized in agrement with previous findings with Pt^{II} complexes.[17]

Complex **3a** is less effective than **2a** in the epoxidation of olefins, but far more efficient in the BV oxidation of ketones (Table 4). Notably, the oxidation of open-chain ketones is also possible, a unique ability among the BV oxidation catalysts known in the literature, that is shared only with $[Pt(\mu\text{-}OH)(P\text{-}P)]_2^{2+}$ complexes.[8a]

Competition Reactions and the Possible Role of Lewis Acidity

The overall picture that emerges from an analysis of the catalytic activity of **2a** and **3a** is that the latter is far more active in the BV oxidation, whereas **2a** is probably a better epoxidation catalyst, although in this case the differences are less evident. This seems to confirm the considerations made in the Introduction, where the reactions were compared mechanistically and indicate that the BV oxidation is more Lewis acid demanding as far as the catalyst properties are concerned.

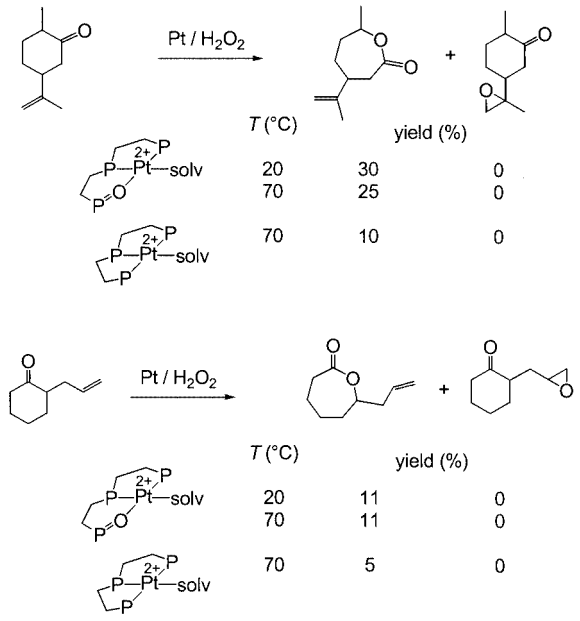
To clarify this point and possibly answer the main question raised — "can we exploit the Lewis acidity of the catalyst to control the selectivity of the reaction?" — some competition experiments and reactions on bifunctional substrates were carried out.

Table 5. Competition experiments in the oxidation of a mixture of cyclooctene and 2-methylcyclohexanone[a]

Catalyst	Product	Temp. (°C)	$10^5 \times$ max. rate (Ms^{-1})	Max. conv. (%)
2a	cyclooctene epoxide	20	–	–
	2-heptalactone			
2a	cyclooctene epoxide	70	0.8	20
	2-heptalactone		1.5	20
3a	cyclooctene epoxide	20	0.05	2
	2-heptalactone		1.5	30
3a	cyclooctene epoxide	70	1.0	10
	2-heptalactone		7.0	25

[a] Experimental conditions: catalyst 0.017 mmol; substrates 0.85 +0.85 mmol; 35% H_2O_2 1.7 mmol; DCE 3 ml; N_2 1 atm.

Initially, **2a** and **3a** were tested in the oxidation of a 1:1 mixture of cyclooctene and 2-methylcyclohexanone; the results are collected in Table 5. As can be seen, in the case of **3a** the reactivity observed seems to be simply the addition of the results observed in the reactions with the individual substrates. Conversely, the behavior of **2a** is somehow surprising and in contrast to the results observed with the individual substrates. In fact, some preference for the BV reaction seems to be evident at 70 °C. This trend becomes quite clear in the oxidation of unsaturated ketones. Scheme 6 summarizes the results observed with dihydrocarvone and 2-allylcyclohexanone. In both cases the exclusive product is the lactone, independently of the catalyst used. This might



Scheme 6

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

be partly due to the moderate activity of **2a** observed with terminal olefins. However, we believe that other factors might cooperate to explain the results of this competitive experiment. For example, if the complex is sufficiently Lewis acidic, even a metal center like Pt^{II} becomes more oxophilic and, in the presence of a molecule containing a C=C double bond and a C=O double bond, it becomes more prone to interact with a simple donor like oxygen and more reluctant to undergo back-bonding to the olefin. In other words, the discrimination may arise both from the intrinsic catalytic activity and from the coordinating ability of the metal, both properties being determined by the Lewis acidity of the central metal atom.

Deactivation of the Catalyst

As was mentioned above, a deactivation process is evident when reactions are carried out at 70 °C. This limits significantly the reproducibility of the catalytic experiments and seems to be independent both of the catalyst and of the oxidation reaction studied. When the metal species are isolated at the end of a catalytic reaction they can be recognized either as [PtCl(P-P-P)](BF_4) (from **2a**) or, at least partly, as [$PtCl_2$(P-P-P=O)] (from **3a**). In the case of **3a** the situation is more complex as some free, fully oxidized phosphane is also observed in the $^{31}P\{^1H\}$ NMR spectrum of the isolated material and therefore some phosphorus-free Pt species must also be formed. The most likely source of chloride is the solvent and it was demonstrated that the same chloro derivatives could be obtained by simply boiling the starting complexes in DCE, $CHCl_3$ or CH_2Cl_2. In the case of **3a** the observation that only the chloro complex is formed is a good indication that the other decomposed species are most likely generated in the catalytic reactions by hydrogen peroxide, which is responsible for the full oxidation of the phosphane. These observations imply that during the catalytic processes there is a parallel reaction between the catalyst and the solvent that leads to the complete conversion into catalytically inactive chloro derivatives. The inactivity of the chloro complexes was demonstrated by blank catalytic tests. The moderate stability of boiling DCE or chloroform and their tendency to form traces of HCl, which would explain our results, are quite well-known, although we have used DCE as solvent in Pt^{II}-catalyzed oxidations with hydrogen peroxide for the past 20 years and never observed such problems. The case of dichloromethane is less straightforward as this solvent boils at 42 °C and is recognized to be quite stable. We may speculate that a possible explanation for the above behavior may rely on a direct attack on the C−Cl bond by the strongly Lewis acidic Pt^{2+} metal centers.

Conclusions

In this work we have synthesized two classes of homologous cationic complexes of Pt^{II} containing tridentate ligands and bearing only one potentially vacant coordination site: one class contains three phosphorus donors while the other contains two phosphorus and one oxygen donors. Spectroscopic characterization indicates that the solvento derivative of the latter class of complexes (**3a**) is a stronger Lewis acid than its counterpart **2a**, although both are rather strong. Their use as catalysts in the BV oxidation of ketones and in the epoxidation of olefins has shown that the former reaction is quite Lewis-acid demanding with respect to the properties of the catalyst. This has allowed the complete control of the parallel oxidation processes in the oxidation of bifunctional substrates such as dihydrocarvone or 2-allylcyclohexanone, where the exclusive formation of the BV oxidation product was observed. The views presented in this work may probably be generalized and could be of help in the design of a new generation of selective, more active catalysts.

Experimental Section

Apparatus: IR spectra were recorded on a Nicolet 750 spectrophotometer either in nujol mulls using KBr plates or in CH_2Cl_2 solution using CaF_2 windows. $^{31}P\{^1H\}$ and ^1H NMR spectra were recorded on a Bruker AC200 spectrometer, operating in FT mode, using as external reference 85% H_3PO_4 and TMS, respectively. Negative chemical shifts are upfield from the reference. GLC measurements were taken on a Hewlett−Packard 5890A gas chromatograph equipped with a FID detector (gas carrier He). Identification of products was made by GLC by comparison with authentic samples. Molar conductivity measurements were made on 10^{-3} M solutions in MeOH with a CDM 83 Radiometer Copenhagen instrument, equipped with a CDC 334 immersion cell.

Materials: Solvents were dried and purified according to standard methods. Substrates were purified by passing through neutral alumina and stored in the dark at low temperature. Hydrogen peroxide (35% Fluka), triphos (Aldrich), HBF_4 (54% in diethyl ether; Aldrich) are commercial products and were used without purification.

The following compounds were prepared according to literature procedures: [$PtCl_2$(COD)],[18] [$PtMe_2$(COD)],[19] [$PtMe_2$(triphos)],[9] [$PtMe_2$(triphosPO)].[9] The preparation of new complexes was performed under dry N_2 by using Schlenk techniques, although all of them were found to be air stable once isolated.

Preparation of Complexes: Some of the complexes reported here were previously observed by in situ NMR spectroscopy, but never isolated and fully characterised.

[(triphos)Pt(CH_2Cl_2)](BF_4)$_2$ (2a): Triphos (0.3 g, 0.56 mmol) was dissolved in dry N_2-saturated CH_2Cl_2 (5 mL) and a solution of [$PtMe_2$(COD)] (0.19 g, 0.57 mmol) in dry N_2-saturated CH_2Cl_2 (5 mL) was added to this solution. The mixture was stirred for 2 hours under N_2 and then 200 μL of 54% HBF_4 was slowly added to the solution. This was stirred for 20 minutes, during which time rapid CH_4 evolution was observed. Water was added to the solution to eliminate traces of acid, the two phases were separated and the organic one was dried with anhydrous Na_2CO_3. The solvents were slowly evaporated from the solution in vacuo to give a white-yellow solid. This was recrystallized from CH_2Cl_2/Et_2O (0.46 g, yield 82%). $C_{35}H_{35}B_2Cl_2F_8P_3Pt$: calcd. C 42.54, H 3.57; found C 42.27, H 3.39.

[(triphosPO)Pt(CH_2Cl_2)](BF_4)$_2$ (3a): Triphos (0.80 g, 1.50 mmol) was dissolved in dry N_2-saturated CH_2Cl_2 (10 mL) and a solution

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of $[PtMe_2(COD)]$ (0.48 g, 1.44 mmol) in dry N_2-saturated CH_2Cl_2 (5 mL) was added to this solution. The mixture was stirred for 2 hours under N_2 and then a 3% solution of H_2O_2 (5 mL, 2 mmol) was added; after vigorously stirring for one hour the mixture was filtered. The two phases were separated and the organic phase was washed with water and dried with anhydrous Na_2CO_3, filtered and reduced to a small volume. 500 μL of 54% HBF_4 was then slowly added to the solution. This was stirred for 20 minutes during which rapid time CH_4 evolution was observed. Water was added to the solution to eliminate traces of acid, the two phases were separated and the organic one was dried with anhydrous Na_2CO_3. The solvents were slowly evaporated from the solution in vacuo to obtain a white-yellow solid. This was recrystallized from CH_2Cl_2/Et_2O (1.15 g, yield 80%). $C_{35}H_{35}B_2Cl_2F_8OP_3Pt$: calcd. C 41.86, H 3.51; found C 41.57, H 3.42.

[(triphos)Pt(OH)]BF_4 (2b): Compound **2a** (0.50 g, 0.51 mmol) was suspended in $CDCl_3$ (15 mL). A solution of NaOH (0.1 M) was added (15 mL) and the mixture was vigorously stirred for 30 minutes. The organic phase was separated, washed with water and dried with anhydrous Na_2CO_3, filtered and slowly evaporated in vacuo to obtained a white solid. This was recrystallized from CH_2Cl_2/Et_2O (0.37 g, yield 87%). $C_{34}H_{34}BF_4OP_3Pt$: calcd. C 49.00, H 4.11; found C 49.17, H 4.03.

[(triphos)Pt(OOH)]BF_4 (2c): Compound **2b** (0.62 g, 0.74 mmol) was suspended in $CDCl_3$ (5 mL). A 3.5% solution of H_2O_2 (1.5 mL, 1.5 mmol) was added and the mixture was vigorously stirred for 30 minutes. The white precipitate obtained was filtered off, washed with Et_2O and recrystallized from CH_2Cl_2/Et_2O (0.35 g, yield 55%). $C_{34}H_{34}BF_4O_2P_3Pt$: calcd. C 48.07, H 4.03; found C 48.15, H 4.11.

[(triphosPO)Pt$(OH)_2$] (4): Compound **3a** (0.30 g, 0.30 mmol) was dissolved in CH_2Cl_2 (4 mL) under N_2. A 4 M solution of NaOH (3 mL) in water was added and the mixture was stirred for one hour. The organic phase was separated, washed with water and dried with anhydrous Na_2CO_3. The solvents were slowly evaporated from the solution in vacuo to obtain a white solid. This was redissolved in warm acetone and kept at −15 °C for 24 hours. The white solid obtained was washed with diethyl ether and dried (0.070 g, yield 30%). $C_{34}H_{35}O_3P_3Pt$: calcd. C 52.38, H 4.52; found C 52.12, H 4.33.

Determination of the Acidity of the Complexes. NMR Method: In these experiments **1a** and **2a** were generated in an NMR tube from a known amount of precursor. The use of the isolated complexes **2a** and **3a** was found to be less reproducible as they contain traces of water. Typically 4.5×10^{-5} mol of $[PtMe_2(triphos)]$ or $[PtMe_2(triphosPO)]$ were dissolved in dry $[D_6]$acetone (0.7 mL). A stoichiometric quantity of 54% HBF_4 (12 μL, 0.9×10^{-4} mol) was added and, after evolution of methane, the $^{31}P\{^1H\}$ NMR spectrum was registered at −70 °C. Then, increasing volumes of H_2O (1, 1.5, 2, 3 μL) were introduced into the tube, and the $^{31}P\{^1H\}$ NMR spectrum at −70 °C was registered each time. A new species formed (**2d** or **3d**). By comparing the intensity of the signals at δ = 56 (**3a**, at −70 °C the signal shifts to lower fields) and 55 ppm (**3d**) and at δ = 51 (**2a**) and 48.5 ppm (**2d**) the equilibrium constant could be calculated as shown in Scheme 5.

Catalytic Reactions: These were carried out in a 10 mL round-bottomed flask equipped with a stopcock for vacuum/N_2 operations and a sidearm fitted with a screw-capped silicone septum to allow sampling. Stirring was performed by a Teflon-coated bar driven externally by a magnetic stirrer. Reactions at 70 °C were carried out using an oil bath connected with a thermostat. The concentration of the commercial 35% H_2O_2 solution was checked iodometrically prior to use.

The following general procedure was followed: the required amount of catalyst was placed in solid form (0.017 mmol) in the reactor, which was evacuated and filled with N_2. Purified, N_2-saturated olefin/ketone was added under N_2 flow, followed by the required amount of 1,2-dichloroethane (3 mL). After thermostating at the required temperature for a few minutes, the H_2O_2 solution in the appropriate amount was injected through the septum and the time was started.

All reactions were monitored by GLC by direct injection of samples taken periodically from the reaction mixtures with a microsyringe. Separation of the products was performed on a 25 m HP-5 capillary column using a flame ionization detector. The maximum rate was expressed as a zero-order rate constant from analysis of conversion vs. time curves.

Determination of the Solvothermal Synthesis Mechanism of Metal Imidazolates by X-ray Single-Crystal Studies of a Photoluminescent Cadmium(II) Imidazolate and Its Intermediate Involving Piperazine

Yun-Qi Tian,*[a,b] Li Xu,[a] Chen-Xin Cai,[a] Ji-Chong Wei,[a] Yi-Zhi Li,[a] and Xiao-Zeng You*[a]

Keywords: Cadmium / Crystal engineering / Fluorescence / Nitrogen heterocycles / Zeolite analogues

Cadmium(II) imidazolate (**3**), with a twofold interpenetrating diamondoid net, was obtained in a manner similar to cobalt(II) imidazolate. In the process, a crystallized intermediate involving piperazine (**2**), which was suitable for X-ray single crystal study, was isolated. Based on the composition of **2**, a mechanism for the solvothermal synthesis of metal imidazolates was proposed. **3**: a = 9.931(2), b = 10.739(2), c = 14.622(3) Å, $\alpha = \beta = \gamma = 90°$, orthorhombic, *Pcab*; **2**: a = 8.243(2), b = 9.883(2), c = 12.471(3) Å, α = 107.89(3)°, β = 92.56(3)°, γ = 100.87(3)°, triclinic, $P\bar{1}$. Both compounds are photoluminescent with λ_{max} = 459 nm for **3** and 444 nm for **2**; they also display quenching of the fluorescence with $\tau \approx 5$ ns. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2002)

Introduction

The search for crystalline solids with unusual electrochemical, magnetic, photophysical and porous properties[1] has attracted an increasing amount of attention from materials scientists and has made the subjects of molecular design and crystal engineering grow almost exponentially in recent years.[2] Because of this, polymorphism, or supramolecular isomerism, has been found to be more general than was previously expected according to the Cambridge Structural Database (CSD).[3] Nevertheless, the phenomenon of extended polymorphism[4] is still rare, although it has been demonstrated that the frequency of occurrence of polymorphic modifications is not necessarily uniform in all categories of substances and it is probably more common in molecules that have conformational flexibility and/or multiple groups capable of hydrogen bonding or coordination.[2]

More recently, in our investigations of metal-organic frameworks with zeolitic topologies, we have found that extended polymorphism also exists in cobalt(II) imidazolate frameworks that show zeolite-like flexibility with variable T−T−T angles.[5] Unlike the flexibility mentioned above, the flexibility of the T−T−T angles can allow extended polymorphism in many zeolite varieties. Because of this we believe that there should be even more supramolecular isomers (or framework polymorphs) of cobalt(II) imidazolate than we have so far obtained. Although cobalt(II) imidazolate isomers have been prepared by a solvothermal method, an apparently successful synthetic strategy,[5] to create more isomers other synthetic strategies have to be developed. In order to do this, however, more details of the mechanism of the formation of cobalt(II) imidazolates are needed. In the synthesis of cobalt(II) imidazolate we noticed that piperazine plays a more important role than other organic bases, such as trialkylamines.[5b] Therefore, it is essential to understand the effect of the piperazine in the solvothermal synthesis in order to determine the synthetic mechanism.

According to the IR spectrum and the element analysis of the intermediate of cobalt(II) imidazolate involving piperazine, which separated as a powder after 12 h reaction at room temperature, and X-ray single crystal studies on the final solvothermal product of cobalt(II) imidazolates, a mechanism for the solvothermal synthesis of cobalt(II) imidazolates was proposed (Scheme 1), in which the piperazine serves not only as a base to deprotonate the imidazole, but also as a ligand that can coordinate to the metal center in cooperation with the imidazolate. Nevertheless, this is only a proposal since the intermediate is formed at room temperature while the nature of the relevant species under solvothermal conditions are still unknown.

Fortunately, during the synthesis of cadmium(II) imidazolate, besides the intermediate involving piperazine (Pz), $[Cd(OAc)_2(Pz)(im\text{-}H)]_n$ (**1**), which is similar to the cobalt(II) imidazolate intermediate that separated at room tempera-

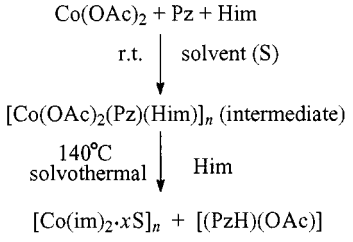

Scheme 1. Proposed reaction scheme for the solvothermal formation of cobalt imidazolate polymers

ture, we also obtained another compound with piperazine, $[Cd_2(OAc)_3(Pz)(im)]_n$ (**2**), which was obtained as single crystals under solvothermal conditions. To prepare the piperazine-free polymer, $[Cd(im)_2]_\infty$ (**3**), an even higher solvothermal temperature has to be used. Therefore, the solvothermal synthesis of the cadmium(II) imidazolate could be suitable for demonstrating the effect of the piperazine, and also for determining the solvothermal synthetic mechanism of metal imidazolates. In this paper, we present the crystal structures and photoluminescent properties of the cadmium imidazolate (**3**) and its intermediate(**2**), which are used to support the supposed solvothermal synthetic mechanism of cadmium(II) imidazolate and its cobalt analogues.

Results and Discussion

X-ray Crystal Structures

X-ray single crystal studies showed that **2** is a 2D quaternary coordination polymer (i.e., one with four different chemical components). In the asymmetric unit (Figure 1, top) of **2**, there are two Cd^{II} atoms, three acetates, two halves of different piperazine molecules and one imidazolate; the Cd1···Cd2 distance is 4.39 Å. In order to understand this complicated crystal structure easily, we can view the 2D coordination polymer as an assembly of cadmium(II) acetate chains (Figure 1, bottom) with piperazine and imidazolates. The chains are composed of two different cadmium-acetate links: (i) $[(OAc)Cd1(\mu\text{-}OAc)_2Cd1'(OAc)]$ (simplified as link A−A′, in which each cadmium is chelated by two acetates; Cd1 and Cd1′, separated by 3.74 Å, are doubly bridged by two oxygen atoms of the two inner acetates), and (ii) $[Cd2(\mu\text{-}OAc)_2Cd2']$ (simplified as link B−B′, in which each cadmium is chelated by one acetate; the two cadmiums Cd2 and Cd2′ are separated by a distance of 3.87 Å and doubly bridged by two oxygen atoms of the carboxylic groups). Subsequently, the two kinds of links, A−A′ and B−B′, are alternately connected to each other by the single oxygen bridges of the outside carboxylic groups of the A−A′ links in the [1 0 −1] direction. In the chains, the carboxylic oxygen atoms are all coordinated to the equatorial positions of the cadmium ions, while the axial positions of the metals are occupied alternately by imidazolate and piperazine within the chains along the [1 0 −1] axis and between the chains along the [3 0 1] axis, forming a 2D sheet that parallels the (0 1 0) plane (Figure 2, top).

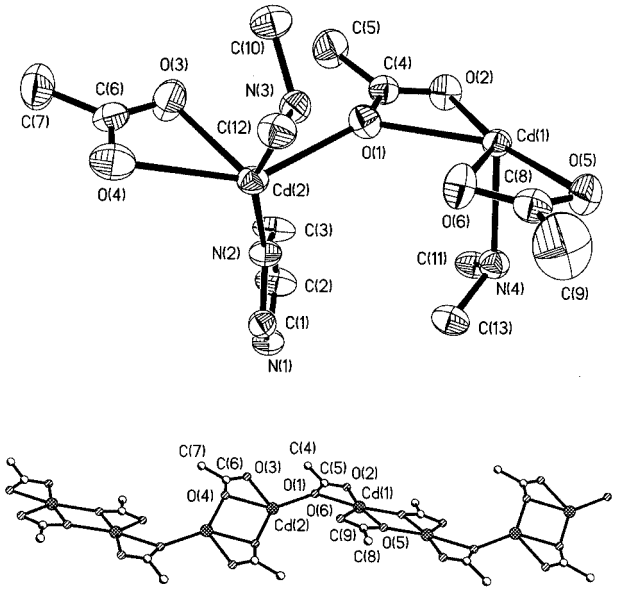

Figure 1. Top: ORTEP drawing of the asymmetric unit of **2** with thermal ellipsoids at 50% probability; bottom: ball and stick diagram of **2** showing the cadmium acetate chain of alternate connected links A−A′ ($[(OAc)Cd1(\mu\text{-}OAc)_2Cd1'O(OAc)]$) and B−B′ ($[Cd2(\mu\text{-}OAc)_2\ Cd2']$)

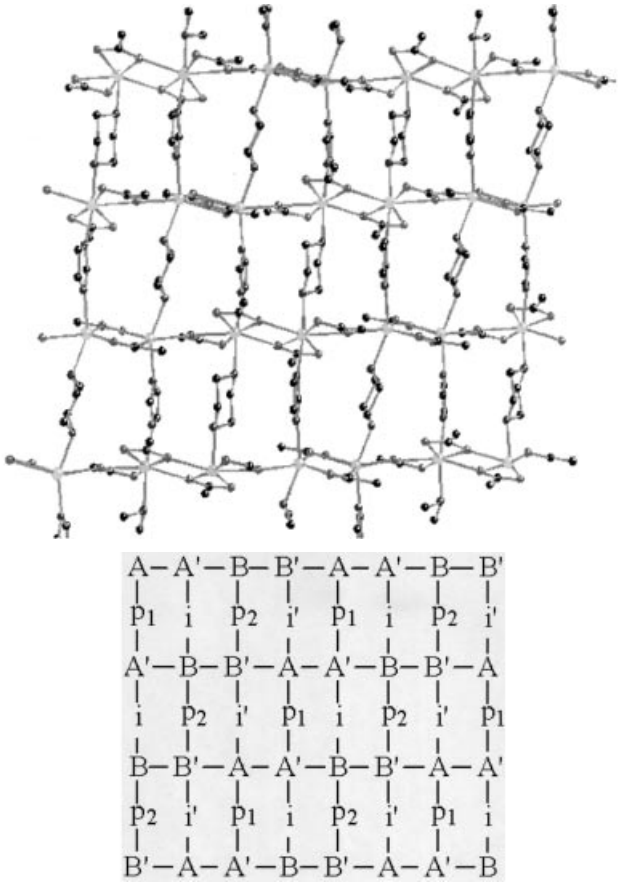

Figure 2. Top: View of the 2D structural layer of compound **2** along the [0 1 0] axis; top: ball and stick diagram of **2** (the hydrogen atoms are omitted for clarity); bottom: symbolized representation of the supramolecular 2D assembly of the quaternary coordination polymer (p = piperazine, i = imidazolate, A to A′, B to B′ and i to i′ are symmetry-related)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Thus, the Cd^{II} ions in A−A′ are seven coordinate while the Cd^{II} ions in links B−B′ are six coordinate. For a distinct view of the supramolecular assembly of compound **2**, a 2D structure of symbolized components is illustrated as Figure 2, bottom. In the crystal of **2** such sheets are stacked parallel to the (010) plane with an interlayer distance of 9.883 Å, equal to the value of the crystal unit-cell parameter *b*.

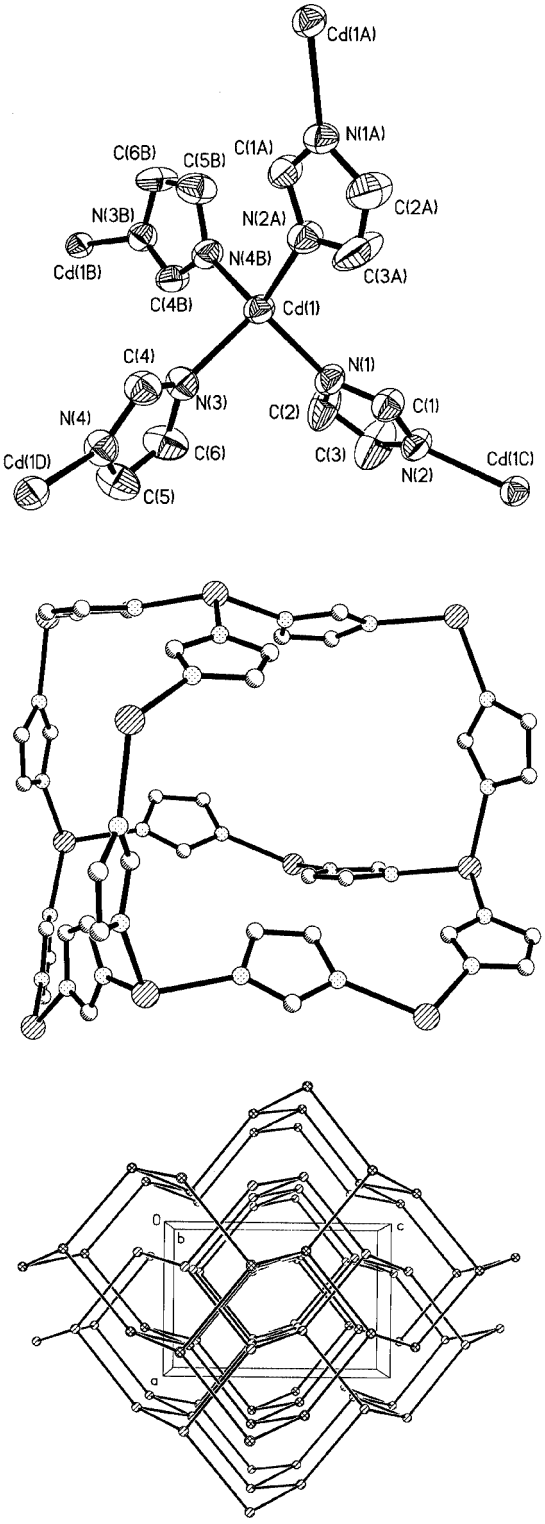

Figure 3. Top: ORTEP drawing of the Cd coordination environment in **3**, with thermal ellipsoids of 50% probability; middle: ball and stick diagram of the diamondoid-cage unit of **3**; bottom: ball and stick representation of the twofold parallel interpenetrating nets of **3** (ball = Cd^{II}, stick = imidazolate)

X-ray single-crystal studies on compound **3** show that this compound contains one Cd^{II} atom and two imidazolates in its asymmetric unit. In the structure, the Cd^{II} is four coordinate (Figure 3, top) like Co^{II} in all of the cobalt imidazolate isomers.[5b] The MN_4 tetrahedra exhibit almost the same deviations from a regular tetrahedron as those in $[Co_5(im)_{10}\cdot 2MB]_\infty$.[5a] However, the deviation of the T−T−T angles from a regular tetrahedron are much smaller than those in any of the cobalt(II) imidazolate isomers prepared so far (Table 1). It is known that a 3D net with regular tetrahedral nodes is likely to have a diamondoid structure,[6] and $[Cd(im)_2]_\infty$ indeed forms such a net with a cristobalite-like structure (Figure 3, middle). As an expanded diamondoid framework, compound **3** exhibits a "normal" mode[7] of twofold interpenetrating nets (Figure 3, bottom), in each of which the shortest Cd···Cd distance is ca. 6.4 Å. Compound **3** is, to the best of our knowledge, the first structurally characterized cadmium imidazolate homopolymer and is also the only metal imidazolate with a diamondoid topology that responds to the problem raised by Masciocchi et al.[4] The preparation of other structures of cadmium imidazolate has not yet been successful. The absence of polymorphism for this substance might be due to the limited flexibility of the Cd···Cd···Cd angles, which suffer from restrained Cd−N bond rotation.

Photoluminescent Properties

The diffuse-reflectance absorption and photoluminescence spectra of pure compounds **2** and **3** in the solid state at room temperature are shown in Figure 4. Compound **2** displays an intense photoluminescence emission at 444 nm (22523 cm^{-1}) that is red-shifted by about 1630 cm^{-1} from the 0−0 transition band (414 nm, 24155 cm^{-1}), while that of **3** is found at 459 nm (21786 cm^{-1}) and is red-shifted by about 1800 cm^{-1} from the 0−0 transition band (424 nm, 23585 cm^{-1}). It is well-known that the lowest excited state of imidazole is an n→π* transition that displays no photoluminescence;[8] therefore the increase in the rigidity of the imidazolate ligand upon forming the polymeric complexes should not cause the fluorescent emission of these compounds, especially considering that $[Zn(im)_2]_n$ displays almost no photoluminescence. It has also been shown that $[Cd(Him)_6](NO_3)_2$ and the intermediate $[Cd(OAc)_2(Pz)(imH)]$ (**1**) are also not photoluminescent. All this evidence suggests that the fluorescence must be due to the deprotonated imidazoles and/or the cadmium(II) centers. Therefore the fluorescent emissions in the two compounds are proposed to be ligand-to-metal charge-transfer (LMCT) in

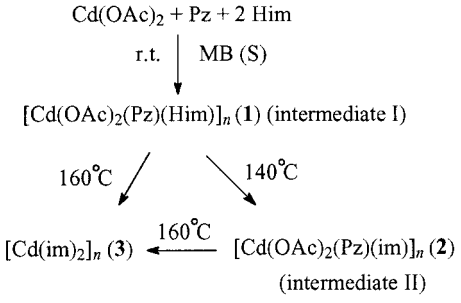
The Coordination Buffering Effect of Piperazine

In the hydrothermal synthesis of inorganic zeolites, the organic amines play very important roles[9] in (i) structure-direction or templation, (ii) gel modification, and (iii) gel-PH alteration or buffering. Although organic amines are also necessary for the solvothermal synthesis of metal imidazolates, they are seemingly restricted to amines that are able to coordinate to metals. Nevertheless, the coordinating ability of the amines to metals should not be so strong that they cannot be replaced by imidazolates, and their basicity should not be so low that they are unable to deprotonate the imidazoles under solvothermal conditions. Our experiments show that piperazine is an ideal amine to act as both the ligand and the base (Scheme 1). Although we had managed to isolate a single crystal of the intermediate, a cobalt imidazolate involving piperazine formed at a lower solvothermal temperature, to support this proposed mechanism, all our attempts to isolate such an intermediate under the experimental conditions were in vain. However, in the cadmium imidazolate (**3**) synthesis, such a mass crystalline intermediate $[Cd_2(OAc)_3(Pz)(im)]_\infty$ (**2**), the intermediate II in Scheme 2, was separated and showed a different composition from $[Cd(OAc)_2(Pz)(im\text{-}H)]_n$ (**1**), the intermediate I, separated after 24 hours reaction at room temperature (the composition of **1** was determined according to the IR and elemental analyses as well as the charge balance principle. Although the mass spectrum was measured, no significant mass signals were observed due to the insolubility of the polymeric substances).

In order to confirm **2** as a real intermediate of **3**, we separated **2** and then allowed it to react with imidazole in a ratio of 1:3 under the same solvothermal conditions for another 24 hours. As expected, the product was as same as that of the one-pot reaction at 160 °C. Therefore, the solvothermal synthetic route of cadmium(II) imidazolate could be as depicted in Scheme 2, similar to that of the cobalt(II) imidazolate. However, in the latter case, the intermediate under solvothermal conditions is still unknown and it may not be the same as that of the cadmium imidazolate, although the fact that piperazine has taken part in the intermediate formation is undeniable. It is the buffering effect on the concentration of free metal ions by piperazine under solvothermal conditions that gives the template solvent enough time to direct the metal imidazolate to the default or the non-default structures[11] and allows the substance to crystallize with sufficient crystal size. So far, there have been six different topological structures[5,10] of cobalt imidazolates prepared by using piperazine as organic base and buffering ligand.



Scheme 2. Solvothermal synthetic route of cadmium(II) imidazolate

NB: During the writing of this paper the structure of **3** was published.[12] However, as the powdery product resulted from a different synthetic procedure, its structure had to be determined by an ab initio XRPD method.

Conclusion

The solvothermal synthesis of metal imidazolates is regarded as similar to the hydrothermal synthesis of inorganic

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

zeolites or molecular sieves. However, depending on the effects of the organic bases in both of the above mentioned syntheses, the reaction mechanism of metal imidazolates should be different from that of zeolites or molecular sieves:[9] An amine with a certain coordinating ability can form coordination compounds with metals at room temperature and then release the metals steadily under the solvothermal conditions, thus facilitating the crystallization of porous structures of metal imidazolates. Therefore, it is understandable why the trialkylamines commonly used in the hydrothermal synthesis of zeolites are useless for the synthesis of metal imidazolates. As for an amine with strong coordinating ability, such as ethylenediamine, the use of such an organic base in the synthesis of metal imidazolates may lead to the need for a higher solvothermal temperature that will not facilitate a porous structure, or sometimes, due to the high stability of the metal-amine complexes, the metal imidazolate polymers may even not be realizable. Although the use of piperazine as the organic base was initially a random choice, it should now be seen as inevitable, although the search for other suitable organic amines, as synthetic variables is encouraged.

Experimental Section

General Remarks: Imidazole, cadmium acetate dihydrate and anhydrous piperazine were obtained from commercial sources and used without further purification. Elemental analyses for C, H and N were performed at the Materials Analysis Center of Nanjing University with a Perkin−Elmer 240 analyzer. Fourier Transform Infrared (FT-IR) Spectra were measured from KBr pellets by using a Nicolet FT-IR 17SX. The diffuse-reflection absorption UV/Vis spectra were performed on a Perkin−Elmer Lambda35 UV/Vis Spectrometer (No. 101N1102201). The fluorescence spectroscopic studies were conducted on an AMINCO Bowman Series 2 Luminescence Spectrometer, whilst the fluorescent quenching was measured on an SLM48000DSCF System.

$[Cd(OAc)_2(Pz)(Him)]$ (1): $Cd(OAc)_2{\cdot}2H_2O$ (1.33 g, 5 mmol), anhydrous piperazine (0.43 g, 5 mmol) and imidazole (0.68 g, 10 mmol) were added to 30 mL of 3-methyl-1-butanol, and this heterogeneous mixture was then stirred at room temperature for 24 h. The resulting powder was separated by filtration, washed with ethanol and diethyl ether, and dried in vacuo to give 1.34 g of **1**; yield ca. 70%. $C_{11}H_{20}CdN_4O_4$ (384.4): calcd. C 34.34, H 5.20, N 14.57; found C 35.01, H 5.86, N 13.27. IR (KBr pellet): $\tilde{\nu}$ = 3117 (vs, sh), 3059 (m), 2952 (m), 2885 (m), 2849 (m), 1579 (vs), 1464 (s), 1417 (vs), 1338 (m), 1329 (m), 1076 (s), 1058 (s), 941 (m), 835 (m), 791 (s), 667−621 (s) cm^{-1}.

$[Cd_2(OAc)_3(Pz)(im)]_\infty$ (2): $Cd(OAc)_2{\cdot}2H_2O$ (1.33 g, 5 mmol), anhydrous piperazine (0.43 g, 5 mmol) and imidazole (0.68 g, 10 mmol) were added to 30 mL of 3-methyl-1-butanol, and after being stirred at room temperature for 12 h, this heterogeneous mixture was placed into a Teflon-lined autoclave (34 mL). The autoclave was then sealed and heated at 140 °C for 24 hours. After cooling to room temperature, colorless crystals were collected and washed with 3 × 15 mL of ethanol and dried in vacuo to give 0.83 g of **2**; yield ca. 60%. $C_{13}H_{22}Cd_2N_4O_6$ (554.8): calcd. C 28.14, H 3.96, N 10.09; found C 27.89, H 3.68, N 9.67. IR (KBr pellet): $\tilde{\nu}$ = 3227 (s, sh), 3136 (m, sh), 3112 (m, sh), 3058 (m), 2967 (m), 2858 (m), 1562 (vs), 1498 (m), 1411 (s), 1340 (m), 1329 (m), 1073 (s), 1015 (m), 943 (m), 882 (s), 822 (m), 772 (m), 670−621 (m) cm^{-1}.

$[Cd(im)_2]_\infty$ (3): $Cd(OAc)_2{\cdot}2H_2O$ (1.33 g, 5 mmol), anhydrous piperazine (0.43 g, 5 mmol) and imidazole (0.68 g, 10 mmol) were added to 30 mL of 3-methyl-1-butanol, and after being stirred at room temperature for 12 h, this heterogeneous mixture was placed into a Teflon-lined autoclave (34 mL). The autoclave was sealed and heated at 160 °C for 24 hours. After cooling to room temperature, colorless crystals were collected and washed with 3 × 15 mL of ethanol and dried in vacuo to give 0.50 g of **3**; yield 40%. $C_6H_6CdN_4$ (246.4): calcd. C 29.22, H 2.44, N 22.73; found C 29.60, H 2.20, N 22.38. IR (KBr pellet): $\tilde{\nu}$ = 3130 (w), 1586 (w), 1482 (vs, sh), 145 (s, sh), 1315 (m), 1244 (s, sh), 1164 (m, sh), 1087 (vs, sh), 943 (s, sh), 818 (m), 756 (s, sh), 746 (s, sh), 664 (vs, sh) cm^{-1}.

X-ray Crystallographic Study: The X-ray single-crystal structure determination was carried out using an Enraf Nonius-CAD4SDP44 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The unit-cell parameters were based on 25 carefully centered reflections in the range $4.42° < 2\theta < 51.96°$. An absorption correction was applied using ψ-scan data. The structures were solved by direct methods and refined by full-matrix least-squares on F^2 using SHELXS-97 (version 5.1).[13] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated and included in the structure-factor calculations with assigned isotropic thermal parameters but were not refined. For the full-matrix least-squares refinements [$I > 2\sigma(I)$], the unweighted and weighted agreement factors $R = (||F_o| - |F_c||)/|F_o|$ and $wR = \{w[(|F_o|^2 - |F_c|^2)^2]/w[(|F_o|^2)^2]\}^{1/2}$ $\{w = 1/[\sigma^2(|F_o|^2) + (aP)^2 + bP]$, where $P = (|F_o|^2 + 2|F_c|^2)/3\}$ were used. The crystallographic data are summarized in Table 2, and selected bond lengths and bond angles of the compound **2** and **3** are listed in Table 3. CCDC-149555 (**2**) and -212355 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Dinuclear Potassium-Chromium and Potassium-Tungsten Carbonyl Complexes

Vladimir Kirin[a] and Peter W. Roesky*[a]

Keywords: Chromium / Coordination chemistry / N Ligands / Potassium / Tungsten

The tetracarbonyl complexes $[M(CO)_4\{\eta^2\text{-}(Ph_2P)_2NH\}]$ [M = Cr (**1a**), W (**1b**)] have been synthesised by reaction of $M(CO)_6$, $Me_3NO{\cdot}2H_2O$, and $(Ph_2P)_2NH$. Subsequent treatment of complexes **1a**,**b** with an excess of KH in THF at room temperature yields the potassium salts $[Cr(CO)_4\{\eta^2\text{-}(Ph_2P)_2N\}K(THF)_3]_n$ (**2a**) and $[W(CO)_4\{\eta^2\text{-}(Ph_2P)_2N\}K(THF)_2]_n$ (**2b**), respectively, in almost quantitative yields. The ionic compounds **2a**,**b** are stable at room temperature. All four compounds **1a**,**b** and **2a**,**b** were characterised by single-crystal X-ray diffraction. Compounds **2a**,**b** form infinite chains via isocarbonyl bridges in the solid state.

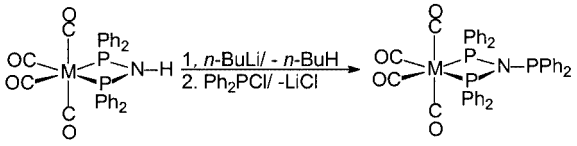
Introduction

Anionic P−N systems such as phosphinimides (R_2PNR'),[1,2] diphosphinoamides $[(Ph_2P)_2N]$,[3−6] phosphoraneiminates (R_3PN),[7−9] phosphiniminomethanides $[(RNPR'_2)CH]$,[10] phosphiniminomethandiides $[(RNPR'_2)C]$[11] and diiminophoshphinates $[(R_2P(NR'))]$[12] have been known for a long time and their chemistry has been intensively studied over the years. Today there are numerous papers describing the synthesis, structure and reactivity of these anions.[13] The P−N anions are frequently used as ligands in main group and transition metal chemistry.[7,14−16] Even sodium and potassium have sometimes been used as counterions for the P−N anions, although the vast majority of these compounds are lithium salts. These alkali-metal salts are generally generated by deprotonation of the corresponding neutral P−N system, for example an aminophosphane, with butyllithium,[1] sodium[4] or potassium hydride,[6] KO*t*Bu,[5] or by other methods.[8] Ellermann et al. have reported the deprotonation of a neutral P−N ligand that is coordinated to a transition metal fragment.[17,18] This work was performed in situ by deprotonation of bis(diphenylphosphanyl)aminechromium, -molybdenum or -tungsten tetracarbonyl, $[M(CO)_4\{\eta^2\text{-}(Ph_2P)_2NH\}]$ (M = Cr, Mo, W) with *n*-butyllithium. Due to its high sensitivity towards moisture and air the obtained intermediate was not isolated or characterised but further reacted at dry-ice temperature with, for example, chlorophosphanes (Scheme 1). A similar reaction has been performed on metal clusters having the $(Ph_2P)_2NH$ ligand in the coordination sphere.[19] Again, the corresponding alkali metal species was not isolated. Other groups have reported the deprotonation of cationic complexes ligated by $(Ph_2P)_2NH$, which led to zwitterionic compounds.[20]



Scheme 1

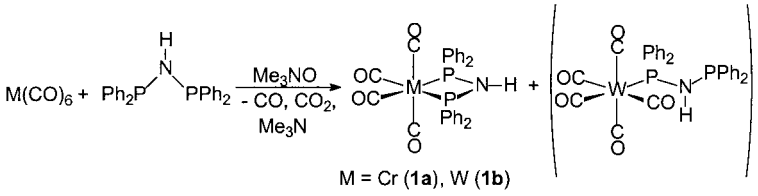
In this article we report on the synthesis and structural characterisation of bis(diphenylphosphanyl)aminechromium and -tungsten tetracarbonyl, $[M(CO)_4\{\eta^2\text{-}(Ph_2P)_2NH\}]$ [M = Cr (**1a**), W (**1b**)], along with details of further reactions of these complexes with potassium hydride. These reactions lead, in a deprotonation reaction, to the corresponding amidopotassium compounds $[M(CO)_4\{\eta^2\text{-}(Ph_2P)_2N\}K(THF)_x]_n$ [M = Cr (**2a**), W (**2b**); x = 2, 3], which have been isolated and fully characterised by standard analytical/spectroscopic techniques. The structures of **2a**,**b** have been confirmed by single-crystal X-ray diffraction in the solid state. Compounds **2a**,**b** form infinite chains via isocarbonyl bridges in the solid state.

Results and Discussion

Synthesis

The tetracarbonyl complexes $[M(CO)_4\{\eta^2\text{-}(Ph_2P)_2NH\}]$ [M = Cr (**1a**), W (**1b**)] have been synthesised previously by reaction of $M(CO)_6$ with $(Ph_2P)_2NH$ in boiling dodecane.[18,21] We made compounds **1a**,**b** by reaction of $M(CO)_6$, $Me_3NO{\cdot}2H_2O$, and $(Ph_2P)_2NH$ in good yield at room temperature (Scheme 2). Compound **1a** was obtained without significant amounts of by-product, whereas the synthesis of **1b** also yielded the pentacarbonyl complex $[W(CO)_5\{\eta^1\text{-}(PhP_2)_2NH\}]$. Both **1a** and **1b** were character-

[a] Institut für Chemie, Freie Universität Berlin, Fabeckstraße 34−36, 14195 Berlin, Germany

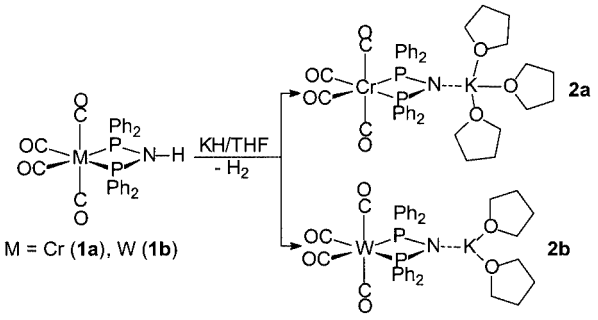


Scheme 2

ised by standard spectroscopic techniques. The observed chemical shifts in the NMR spectra are in good agreement with the literature data.[18,21]

The solid-state structures of both compounds were established by single-crystal X-ray diffraction in order to learn how further reactions at the ligand alter the complex framework.

The potassium salts $[Cr(CO)_4\{\eta^2\text{-}(Ph_2P)_2N\}K(THF)_3]_n$ (**2a**) and $[W(CO)_4\{\eta^2\text{-}(Ph_2P)_2N\}K(THF)_2]_n$ (**2b**) were obtained in almost quantitative yield by treatment of the neutral complexes **1a**,**b** with an excess of KH in THF at room temperature (Scheme 3). The ionic compounds **2a**,**b** are stable at room temperature even after several weeks the only sign of decomposition in the solid state is the loss of THF from the crystals. In solution we did not observe a possible intermolecular reaction of the amido group with the carbonyl ligand.



Scheme 3

Compounds **2a** and **2b** were characterised by Raman, ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectroscopy and elemental analysis. The $^{31}P\{^1H\}$ NMR resonances of **2a**,**b** [δ = 58.7 ppm (**2a**), 8.07 ppm (**2b**)] are significantly shifted upfield relative to **1a**,**b** [δ = 96.9 ppm (**1a**), 46.1 ppm (**1b**)]. Furthermore, an expected $^1J_{P,W}$ coupling in **2b** of 168.7 Hz is observed, which is about 40 Hz smaller than in **1b**. Based on earlier measurements of $(Ph_2P)_2CH_2$ and $[M(CO)_4\{\eta^2\text{-}(Ph_2P)_2CH_2\}]$ the signals in the $^{13}C\{^1H\}$ NMR spectra could be clearly assigned in the phenyl and in the carbonyl region.[22]

Solid-State Structures

The solid-state structures of **1a**,**b** (Figures 1 and 2, respectively) and **2a**,**b** (Figures 3 and 4, respectively) were established by single-crystal X-ray diffraction. The bond lengths and angles of **1a**,**b** are in the expected range. The complex framework is similar to the structurally characterised molybdenum compound $[Mo(CO)_4\{\eta^2\text{-}(Ph_2P)_2NH\}]\cdot CH_3CN$.[23] In contrast to compound **1a**, in **1b** one molecule of acetone is bound via a hydrogen bond to the N−H function of the ligand.

The ionic complexes **2a**,**b** show some surprising aspects in the solid state. Both complexes form polymeric one-dimensional chains in the crystal. In Figure 5 a cutout of the infinite chain of **2a** is shown. The potassium cations are bound to the amido nitrogen atom of one anion and to the oxygen atom of a carbonyl group of a neighbouring anion. Thus, a potassium isocarbonyl compound is formed. The K−N bond lengths are 271.1(2) pm (**2a**) and 273.6(3) pm (**2b**) and the K−O bond lengths are 264.9(2) pm (**2a**) and 270.2(3) pm (**2b**). There are no other structurally characterised K−W and only a few K−Cr isocarbonyl complexes

reported in the literature.[24] Furthermore, in **2a** the potassium atom is coordinated by three THF molecules and no π-coordination of the phenyl rings is observed. In contrast, the potassium atom of compound **2b** is surrounded by only two THF molecules. Due to the vacant coordination sites π-coordination of one phenyl ring of the $(Ph_2P)_2N$ group is seen. The different coordination modes of the potassium atoms in **2a** and **2b** cause significantly different O−K−N bond angles [130.54(8)° (**2a**) and 92.24(10)° (**2b**)] in both compounds. Furthermore, the M−C and the C−O bond

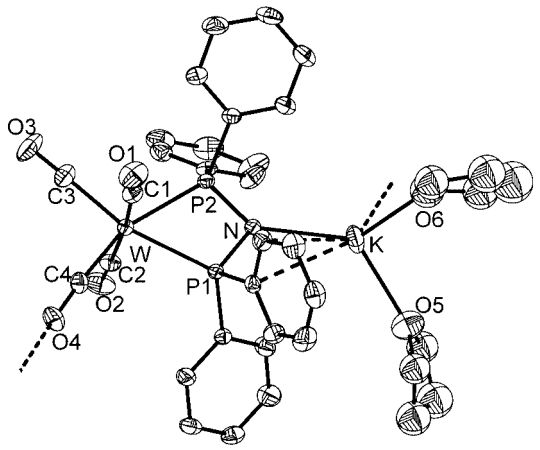

Figure 4. Perspective ORTEP view of the molecular structure of **2b**; thermal ellipsoids are drawn to encompass 50% probability; hydrogen atoms are omitted for clarity; selected distances [pm] and angles [°]: W−C1 202.3(4), W−C2 202.0(4), W−C3 200.2(4), W−C4 196.0(4), W−P1 251.80(8), W−P2 254.20(9), P1−N 166.0(3), P2−N 167.1(3), C1−O1 114.5(5), C2−O2 114.2(5), C3−O3 113.9(5), C4−O4 117.3(5), K−N1 273.6(3), K−O4′ 270.2(3), K−O5 260.4(6), K−O6 255.0(7); C1−W−C2 174.16(15), C1−W−C3 87.0(2), C1−W−C4 89.7(2), C2−W−C3 90.03(2), C2−W−C4 85.56(15), C3−W−C4 94.5(2), C1−W−P1 94.23(12), C2−W−P1 89.99(12), C3−W−P1 164.14(14), C4−W−P1 101.34(11), C1−W−P2 96.49(12), C2−W−P2 89.10(11), C3−W−P2 103.78(14), C4−W−P2 160.99(11), P1−W−P2 60.37(3), O4′−K−O5 94.85(15), O4′−K−O6 82.4(2), O4′−K−N 92.24(10), P1−N−P2 99.62(14), P1−N−K 107.04(12), P2−N−K 142.99(15)

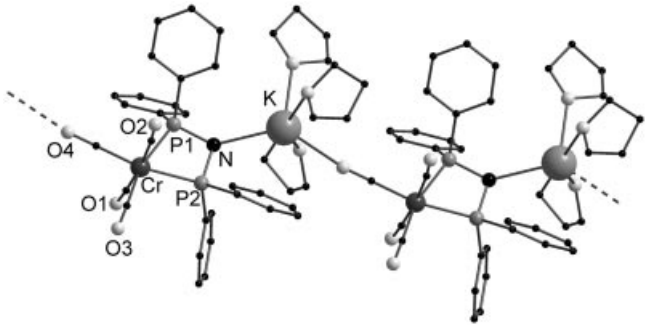

Figure 5. Solid-state structure of **2a** showing the atom labelling scheme, omitting hydrogen atoms; two units of infinite chain are shown

lengths are also influenced. In the CO group (C4O4) that forms the isocarbonyl bridge in **2a**,**b**, the M−C bond lengths are shortened, whereas the C−O bond lengths are lengthened [M−C: 186.4(2) pm (**1a**), 201.4(15) pm (**1b**), 182.2(2) pm (**2a**), 196.0(4) pm (**2b**); C−O: 115.0(2) pm (**1a**), 114(2) pm (**1b**), 116.4(3) pm (**2a**), 117.3(5) pm (**2b**)].

Due to the deprotonation of the $(Ph_2P)_2NH$ ligand in **2a**,**b** the geometry of the $(Ph_2P)_2N$ group is significantly different to that in **1a**,**b**. The P−N−P angles of **2a**,**b** [97.30(9)° (**2a**) and 99.62(14)° (**2b**)] are narrower than in $(Ph_2P)_2NH$ [118.9(2)°][25] and **1a**,**b** [103.24(9)° (**1a**) and 105.7(9)° (**1b**)]. The P−N distances of **2a**,**b** [166.4(2) pm, 167.3(2) pm (**2a**); 166.0(3) pm 167.1(3) pm (**2b**)], are slightly shorter than those observed in **1a,b** [169.6(2) pm, 168.8(2) pm (**1a**); 167.3(10) pm (**1b**)] and $(Ph_2P)_2NH$ (168.2 pm). All

the P−N distances indicate a partial P−N multiple-bond character.[1a] Since the deprotonation does not significantly influence the P−N bond length we suggest that the negative charge in **2a**,**b** is basically located on the nitrogen atom. This is supported by the N−K contact in the solid state. To the best of our knowledge only three other structurally characterised heterobimetallic transition metal−alkali metal P−N complexes have been reported in the literature,[26] and none of them was generated by deprotonation of the corresponding phosphinoamine compound.

The Raman spectra of compounds **1a**,**b** and **2a**,**b** were recorded in the solid state. The spectrum of **1b** (without acetone) has been reported previously.[18] For **1b** we observe the same number of vibration modes, but at slightly different wavenumbers. This may be a result of the additional molecule of acetone. Based on earlier measurements on $[M(CO)_4\{\eta^2\text{-}(Ph_2P)_2CH_2\}]$ (M = Cr, W) the vibration modes could be clearly assigned.[27] For the C−O stretching vibration in **2a**,**b** a noticeable shift to lower wavenumbers is seen. This effect is especially noticeable for the symmetric and asymmetric stretching vibration of the equatorial CO groups (up to 56 cm^{-1} for **2a**). The weakening of the C−O bond observed in the Raman spectra is in agreement with the data of the single-crystal X-ray structures.

Conclusions

The $(Ph_2P)_2N^-$ anion, which was previously generated by a deprotonation reaction of $(Ph_2P)_2NH$, has been used to build alkali metal[3−6] titanium,[28] lanthanide,[6] and late transition metal complexes and clusters.[19,20] Now we have shown that the deprotonation of the tetracarbonyl complexes $[M(CO)_4\{\eta^2\text{-}(Ph_2P)_2NH\}]$ (M = Cr, W) with potassium hydride leads to bimetallic amidopotassium−isocarbonyl complexes $[Cr(CO)_4\{\eta^2\text{-}(Ph_2P)_2N\}K(THF)_3]_n$ (**2a**) and $[W(CO)_4\{\eta^2\text{-}(Ph_2P)_2N\}K(THF)_2]_n$ (**2b**), in which the transition metal is bound to the phosphorous atom and the alkali metal is coordinated to the nitrogen atom. Complexes **2a**,**b** form polymeric one-dimensional chains in the solid state. The new amido compounds are stable at room temperature and no intermolecular reaction of the amido function with carbonyl group is observed. Based on the results of the single-crystal X-ray structures we suggest that the negative charge is basically localised on the nitrogen atom.

Experimental Section

General: All manipulations of air-sensitive materials were performed with the rigorous exclusion of oxygen and moisture in flame-dried Schlenk-type glassware either on a dual manifold Schlenk line, interfaced to a high vacuum (10^{-3} Torr) line, or in an argon-filled M. Braun glove box. Ether solvents (tetrahydrofuran and diethyl ether) were predried over Na wire and distilled under nitrogen from Na/K alloy benzophenone ketyl prior to use. Hydrocarbon solvents (toluene and *n*-pentane) were distilled under nitrogen from $LiAlH_4$. All solvents for vacuum-line manipulations were stored in vacuo over $LiAlH_4$ in resealable flasks. CH_2Cl_2 and CH_3CN were distilled from over P_2O_5. Deuterated solvents were obtained from Aldrich Inc. (all 99 atom% D). NMR spectra were recorded on a Jeol JNM-LA 400 FT NMR spectrometer. Chemical shifts are referenced to internal solvent resonances and are reported relative to tetramethylsilane (^1H and ^{13}C) or 85% phosphoric acid (^{31}P NMR). Raman spectra were performed on a Bruker RFS 100. Elemental analyses were carried out with an Elementar vario EL. $(Ph_2P)_2NH$ was prepared according to a literature procedure.[29]

$[Cr(CO)_4\{\eta^2\text{-}(Ph_2P)_2NH\}]$ (1a): a) A solution of $Me_3NO{\cdot}2H_2O$ (1.14 g) in 11 mL of MeOH was added dropwise over 3 h to a suspension of $(Ph_2P)_2NH$ (1.78 g, 4.62 mmol) and $Cr(CO)_6$ (1.08 g, 4.91 mmol) in 25 mL of CH_2Cl_2. After this time the reaction mixture was stirred at room temperature for 18 h, filtered through silica gel and the solvents evaporated under reduced pressure. The solid residue was crystallised from hexane/CH_2Cl_2 mixture. Yield: 2.15 g (84.6%).

b) Upon addition of $Me_3NO{\cdot}2H_2O$ (0.23 g, 2.07 mmol) to a suspension of $Cr(CO)_6$ (0.42 g, 1.9 mmol) in 30 mL of MeCN at 0 °C, a yellow colour steadily developed. After 10 min of vigorous stirring, solid $(Ph_2P)_2NH$ (0.75 g; 1.95 mmol) was added to the reaction mixture. The resulting solution was stirred for 18 h at room temperature and then at 70 °C for 5 h. The solvent was removed under reduced pressure and the residue was chromatographed on silica gel using hexane/acetone (4:1) as eluent. The bright-yellow fraction ($R_f \approx 0.3$) was isolated and recrystallised from hexane/CH_2Cl_2 mixture. Yield: 0.63 g (60.3%). Raman (solid): $\tilde{\nu}$ = 3323 cm^{-1} (w, νN−H), 3058 (m, νC=C-*H*), 2018 (m, νCO_{ax}), 1915 (m, $\nu_{sym}CO_{eq}$), 1859 (m, $\nu_{asym}CO_{eq}$), 1583 (w, νC=C), 998 (s, νPC), 644 (w, δCO), 470 (m, νMC), 415 (m, νMC), 187 (s, νMP). ^1H NMR ($CDCl_3$, 400 MHz, 25 °C): δ = 7.51−7.23 (m, 20 H, Ph), 4.88 (t, $^2J_{P,H}$ = 6.9 Hz, 1 H, NH) ppm. ^{13}C NMR (C_6D_6, 100.4 MHz, 25 °C): δ = 228.8 (t, $^2J_{P,C}$ = 8.7 Hz, CO_{ax}), 221.7 (t, $^2J_{P,C}$ = 13.2 Hz, CO_{eq}), 139.3 (m, $J_{P,C}$ = 19.9 Hz, C_{ipso}), 130.5 (s, C_{para}), 130.3 (m, $^2J_{P,C}$ = 6.6 Hz, C_{ortho}), 128.7 (m, $J_{P,C}$ = 4.9 Hz, C_{meta}) ppm. ^{31}P NMR ($CDCl_3$, 161.7 MHz, 25 °C): δ = 96.9 ppm. $C_{28}H_{21}CrNO_4P_2$ (549.47) C 61.21, H 3.85, N 2.55; found C 60.99, H 3.80, N 2.43.

$[W(CO)_4\{\eta^2\text{-}(Ph_2P)_2NH\}]$ (1b) and $[W(CO)_5\{\eta^1\text{-}(Ph_2P)_2NH\}]$: A mixture of $W(CO)_6$ (2.7 g, 7.67 mmol), $Me_3NO{\cdot}2H_2O$ (0.86 g, 7.75 mmol), and $(Ph_2P)_2NH$ (2.86 g, 7.43 mmol) in 100 mL of MeCN was stirred at room temperature for 20 h and then heated at 60 °C for 18 h. The resulting yellow-green solution was evaporated to dryness and the residue was chromatographed on silica gel using hexane/acetone/ethyl acetate (4:1:1) as eluent. The colourless ($R_f \approx 0.7$) and bright-yellow ($R_f \approx 0.7$) fractions were isolated. Recrystallisation of the first fraction from hexane/acetone gave $[W(CO)_5\{\eta^1\text{-}(Ph_2P)_2NH\}]{\cdot}Me_2CO$ (0.9 g, 17.1%). A second fraction was recrystallised from hexane/ethyl acetate. The obtained crystals were dissolved in toluene and the solution was evaporated in vacuo to give $[W(CO)_4\{\eta^2\text{-}(Ph_2P)_2NH\}]$.

1b: Yield: 2.52 g (49.8%). Raman (solid, **1b**·acetone): $\tilde{\nu}$ = 3054 cm^{-1} (m, νC=C-*H*), 2018 (m, νCO_{ax}), 2923 (m, νCH), 1896 (m, νCO), 1884 (m, νCO), 1872 (m, νCO), 1859 (m, νCO), 1699 (m, νCO), 1586 (w, νC=C), 998 (s, νPC), 456 (sh νMC), 441 (sh, νMC), 180 (s, νMP). ^1H NMR (C_6D_6, 400 MHz, 25 °C): δ = 7.46 (m, 8 H), 6.95 (m, 12 H, Ph), 5.13 (t, $^2J_{P,H}$ = 5 Hz, 1 H, NH) ppm. ^{13}C NMR (C_6D_6, 100.4 MHz, 25 °C): δ = 210.7 (dd, $^2J_{P,C}$ = 22.7 Hz and 7.0 Hz, CO_{eq}), 202.7 (t, $^2J_{P,C}$ = 7.0 Hz, CO_{eq}), 138.6 (dd, $^1J_{P,C}$ = 38.2 Hz; $^3J_{P,C}$ = 6.8 Hz, C_{ipso}), 130.7 (d, $^2J_{P,C}$ = 15.6 Hz, C_{ortho}), 130.6 (s, C_{para}), 128.7 ($^2J_{P,C}$ = 4.9 Hz, C_{meta}) ppm. ^{31}P NMR (C_6D_6, 161.7 MHz, 25 °C): δ = 46.1 (s, $^1J_{P,W}$ = 208.1 Hz) ppm.

$[W(CO)_4\{\eta^2\text{-}(Ph_2P)_2N\}K(THF)_2]$ (2b): Solid **1b** (2.5 g; 3.67 mmol) was added to a suspension of KH (237 mg, 5.92 mmol) in 50 mL THF. After stirring at room temperature for 4 h the solvent was removed in vacuo and the resulting yellow powder was crystallised from THF/*n*-pentane (1:4). After one day yellow crystals were obtained. Yield: 2.98 g (94%). Raman (solid): $\tilde{\nu}$ = 3055 cm^{-1} (m, νC=C-*H*), 2983 (w, νCH), 2877 (w, νCH), 1997 (m, νCO_{ax}), 1877 (m, $\nu_{sym}CO_{eq}$), 1802 (m, $\nu_{asym}CO_{eq}$), 1584 (w, νC=C), 997 (s, νPC), 918 (w, νC−C), 483 (w, νMC), 442 (m, νMC), 184 (m, νMP). ^{1}H NMR ([D$_8$]THF, 400 MHz, 25 °C): δ = 7.69 (m, 8 H, Ph), 7.18 (m, 8 H, Ph) 7.08 (m, 4 H, Ph), 3.61 (m, 4 H, THF), 1.76 (m, 4 H, THF) ppm. ^{13}C NMR (C_6D_6, 100.4 MHz, 25 °C): δ = 228.5 (CO_{ax}), 221.63 (CO_{eq}), 148.8 (m, $J_{P,C}$ = 23.09 Hz, C_{ipso}), 127.9 (s, C_{para}), 130.8 (m, $J_{P,C}$ = 6.4 Hz, C_{ortho}), 127.7 (m, $J_{P,C}$ = 5.2 Hz, C_{meta}), 68.2 (s, THF), 26.4 (s, THF). ^{31}P NMR ([D$_8$]THF, 161.7 MHz, 25 °C): δ = 8.07 ($^1J_{P,W}$ = 168.7 Hz) ppm. $C_{36}H_{36}KNO_6P_2W$ (863.58): calcd. C 50.07, H 4.20, N 1.62; found C 49.95, H 4.17, N 1.54.

X-ray Crystallographic Studies of 1a, 1b, 2a and 2b: Crystals of **1a** and **1b** were obtained from hexane/CH_2Cl_2 and hexane/acetone, respectively. Crystals of **2a** and **2b** were grown from THF/*n*-pentane (1:4). A suitable crystal was covered in mineral oil (Aldrich) and mounted onto a glass fibre. The crystal was transferred directly to the −73 °C cold N_2 stream of a Stoe IPDS or a Bruker CCD SMART 1000 diffractometer. Subsequent computations were carried out on an Intel Pentium III PC.

Data Collection and Refinement: SHELXS-97,[30] SHELXL-97.[31]

Hydrothermal Synthesis and Characterization of a Novel Sinusoidal Layer Structure Constructed From Polyoxometalates and Coordination Complex Fragments

Xiao-Bing Cui,[a,b] Ji-Qing Xu,*[a] Yong Li,[a] Ying-Hua Sun,[a] and Guo-Yu Yang*[b]

Keywords: Hydrothermal synthesis / Magnetic properties / Polyoxometalates / X-ray diffraction

A novel polyoxometalate compound, $[As_8V_{14}O_{42}(SO_4)][Ni(en)_2]_3{\cdot}4.5H_2O$ (**1**), has been synthesized by a hydrothermal method and characterized by X-ray crystallography, showing that the compound **1** is the first example of a sinusoidal layer structure constructed from polyoxometalates and coordination complex fragments.

Introduction

Polyoxometalates (POMs) are a fascinating class of metal-oxygen cluster compounds with a wide structural variety and interesting properties, which are of use in fields as diverse as catalysis, sorption, molecular electronics, and medicine, amongst others.[1−3] Despite the fundamental and practical importance of polyoxometalates, the preparation of these complexes still remains elusive and is often described as self-assembly. Recently, a novel approach to the synthesis of polyoxometalate chemistry has been to find some novel units as building blocks and then to connect them up into one-, two-, or even three-dimensional extended solid frameworks in appropriate ways. This method is quite attractive and appears to hold the key to the development of a rational synthesis for tailor-made materials based on polyoxometalates with desirable features. The crucial requirement for the success of this approach is to find suitable polyoxometalates that could be readily assembled. Polyoxometalates and their derivatives provide an exciting opportunity to explore the potential of this approach. Hydrothermal synthesis techniques, in combination with organic templates, have been demonstrated to be useful in the preparation of metal oxide materials.[4,5] A number of extended solid framework materials based on polyoxometalates as building blocks have been synthesized hydrothermally.[6−17]

Arsenic-vanadium clusters, one of the most important subclasses of polyoxometalates, have been thoroughly investigated, and typical examples include $[As_8V_{14}O_{42}(X)]^{6-}$ ($X = SO_3^{2-}$ or SO_4^{2-}),[18] $[N(Me)_4]_4[As_8V_{14}O_{42}(H_2O)_{0.5}$ [18] and $K_6[As_6V_{15}O_{42}(H_2O)]{\cdot}8H_2O$.[18] Most of them exhibit discrete cluster structures and are able to function as building blocks. However, compared with the abundance of compounds based on the $[V_{18}O_{42}]$ cluster,[8−11,14] the linking of arsenic-vanadium clusters into one-, two-, and three-dimensional structures remains relatively unexplored.[12,13] We have therefore extended our search for solid framework complexes by exploiting arsenic-vanadium clusters as building blocks — the successful use of the $[As_8V_{14}O_{42}(SO_4)]^{6-}$ [18] cluster results in the formation of a two-dimensional structural compound $[As_8V_{14}O_{42}(SO_4)][Ni(en)_2]_3{\cdot}4.5H_2O$ (**1**), which is the first example of a two-dimensional sinusoidal layer structure constructed from polyoxometalates and coordination complex fragments.

Results and Discussion

A novel metal-oxygen cluster polymer, $[As_8V_{14}O_{42}(SO_4)][Ni(en)_2]_3{\cdot}4.5H_2O$, has been hydrothermally synthesized and structurally characterized. Selected bond lengths for **1** are given in Table 1. It crystallizes in the triclinic space group $P\bar{1}$ with a unit cell containing two units. There are four crystallographically independent nickel atoms in an asymmetric unit, Ni(2) and Ni(3) are located on inversion centers with occupancy factors of 0.5, and all other atoms are at general positions.

The X-ray crystal structural analysis suggests that compound **1** is a novel, sinusoidal layered compound containing $[As_8V_{14}O_{42}(SO_4)]^{6-}$ clusters, $[Ni(en)_2]^{2+}$ cations and waters of crystallization. The building block unit, shown in Figure 1, consists of fourteen distorted VO_5 square pyramids and eight AsO_3 triangular units, with a disordered SO_4^{2-} anion at its center. Every two AsO_3 groups are joined to-

gether by an oxygen bridge, forming a handle-like As_2O_5 moiety. In the cluster, eight vanadium [V(1), V(2), V(4), V(5), V(9), V(10), V(13) and V(14)] oxygen square pyramids are linked to one another into a ring by sharing edges. In addition, three vanadium [V(6), V(11) and V(12)] oxygen square pyramids form a trimer by sharing edges. This trimer is connected across the ring by sharing edges with V(13)- and V(14)-containing square pyramids. Vanadium[V(3), V(7) and V(8)] oxygen square pyramids form another trimer by sharing edges, and this trimer is similarly connected on the opposite side of the ring to V(4)- and V(10)-containing square pyramids. Therefore, fourteen VO_5 square pyramids are arranged to form a cage, the overall chemical composition of which is $[(VO)_{14}O_{24}]$. Clearly there are twenty-four oxygen atoms occupying the vertices of the cage, which has a total of eighteen square faces. Fourteen of them are formed by the bases of the VO_5 square pyramids, and the remaining square faces are formed by the bases of the As_2O_5 units to give a total composition of $[As_8V_{14}O_{42}]^{4-}$. The V−O and the As−O distances are all similar to those in reported compounds.[18]

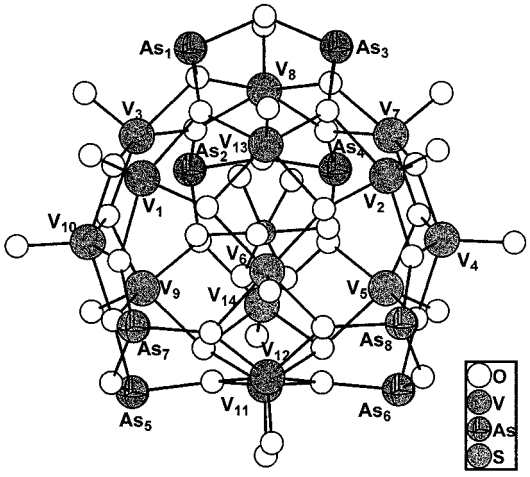

Figure 1. Ball-and-stick representation of the $[As_8V_{14}O_{42}(SO_4)]^{6-}$ cluster

There are two different types of $[Ni(en)_2]^{2+}$ cations in **1**. The first type contains $[Ni(2)(en)_2]^{2+}$, $[Ni(3)(en)_2]^{2+}$ and $[Ni(4)(en)_2]^{2+}$ cations, in which each octahedrally coordinated nickel atom bridges two clusters. The nickel site is defined by four nitrogen donors from two en ligands and *trans*-oxo atoms from two adjacent clusters, and these nickel atoms exhibit very strong covalent attachments to adjacent clusters, with Ni−O distances in the range 2.082(10)−2.110(10) Å. Four surface oxygen atoms of one cluster coordinate to four bridging nickel atoms [Ni(2), Ni(3) and two Ni(4)], so each cluster is connected to four neighboring ones into a two-dimensional network of $[-\{As_8V_{14}O_{42}(SO_4)\}-\{Ni(en)_2\}-\{As_8V_{14}O_{42}(SO_4)\}-]_n$ arrays, as shown in Figure 2 (a). This layer is arranged parallel to the crystallographic *ab* plane. In the layer, through the connection of each Ni(4) atom, the clusters are linked to one another along the $a - b$ axis into a novel straight chain, as shown in Figure 2 (b), while through the connections alternatively at Ni(2) and Ni(3), each chain is connected with the adjacent ones along the $a + b$ axis, forming a novel sinusoidal layer. Figure 2c clearly shows that the layer displays a beautiful sinusoidal ruffling look, with an amplitude of about 20.8 Å, which is larger than those in $[M(bpy)_2]_2V_6O_{17}$ (M = Zn, Ni, about 13 Å)[19,20] and $[Ni(Phen)_2]_2V_4O_{11}$ (about 18.5 Å),[21] whereas the period (about 25.9 Å) is also far larger than those in $[M(bpy)_2]_2V_6O_{17}$ (M = Zn, Ni, about 15 Å)[19,20] and $[Ni(Phen)_2]_2V_4O_{11}$ (about 9.7 Å).[21] These differences clearly originate from the fact that the layer of compound **1** is constructed from coordination complexes and bulky sphere-like $[As_8V_{14}O_{42}(SO_4)]^{6-}$ clusters, which makes the amplitude and period larger. The structure of compound **1**

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

can be described as being built up from $[As_8V_{14}O_{42}(SO_4)]^{6-}$ clusters linked into a two-dimensional sinusoidal layer structure. It is the most unusual feature of compound **1**, and, to the best of our knowledge, such a feature has not been found in any other structures of polyoxometalates.

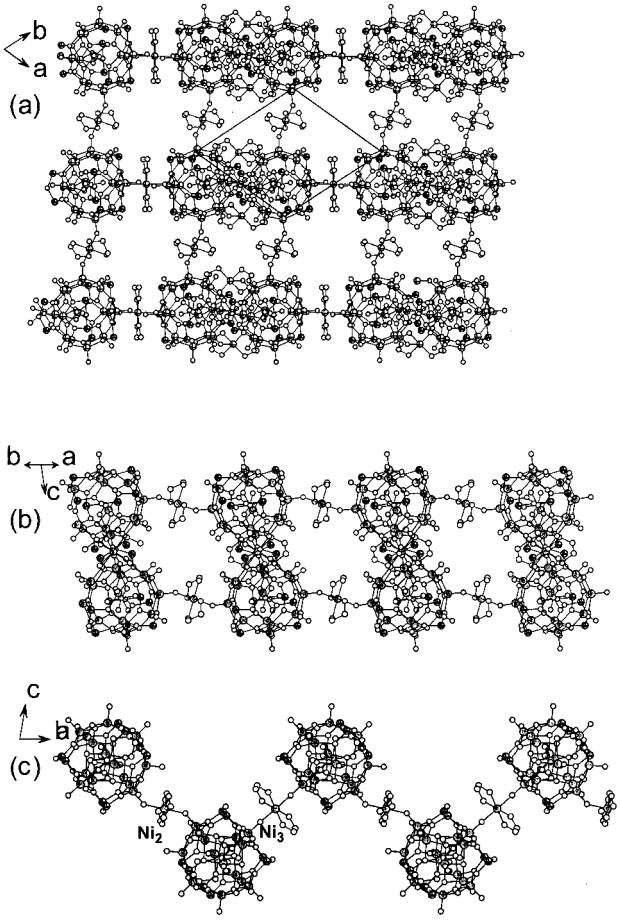

Figure 2. (a) A view of the sinusoidal layer of compound **1** down the *c* axis; (b) the sinusoidal layer of compound **1** extending along the $a - b$ axis; (c) the sinusoidal layer of compound **1** extending along the $a + b$ axis

The $[Ni(1)(en)_2]^{2+}$ cation is the second type of Ni atom, and it serves as a charge-compensating component. The $[Ni(en)_2]^{2+}$ cations of this type occupy the regions between the adjacent sinusoidal layers. In contrast to the bridging $[Ni(en)_2]^{2+}$ cations of the first group, the nickel atoms of the second group exhibit only weak interactions with the clusters, with Ni···O distances of 2.852(11)−3.145(11) Å.

The assignments of the oxidation states for the vanadium and arsenic atoms are consistent with the electric charge and confirmed by bond valence sum (BVS) calculations.[22] The BVS values for vanadium and arsenic atoms vary from 3.767 to 4.237 and from 2.997 to 3.240, respectively, indicating that the oxidation state for each vanadium atom and each arsenic atom is +4 and +3, respectively. The oxidation states of the vanadium atoms and the arsenic atoms are consistent with the formula of compound **1**.

Preliminary magnetic studies have been performed on a powered sample of **1** in the range 2−300 K. Plots of χ_m^{-1} and μ_{eff} vs. T for **1** are shown in Figure 3. The product μ_{eff} decreases continuously as the temperature is lowered, indicating the presence of an antiferromagnetic exchange interaction. The room-temperature value ($\mu_{eff} = 6.84\ \mu_B$) is smaller than the expected value ($\mu_{eff} = 7.83\ \mu_B$) for the 14 uncoupled $S = 1/2$ spins of the V^{4+} atoms and the two uncoupled $S = 1$ spins of the Ni^{2+} atoms (two nickel atoms of the first type are octahedrally coordinated, with $S = 1$, and the nickel atom of the second type displays a square-planar environment, with $S = 0$, assuming $g = 2.0$ for V^{4+} and $g = 2.20$ for Ni^{2+}), indicative of antiferromagnetic coupling. These antiferromagnetic coupling interactions are related to electron delocalization of high-nuclearity metal clusters.[23] Unfortunately, it is too difficult to fit the experimental magnetic data of this two-dimensional heteropolymetallic spin system using a suitable theoretical model.[24] However, the magnetic data of **1** obey the Curie−Weiss law in the high-temperature regions, and the fitting in the range 80−300 K gives values of $C = 5.26$ emu·mol^{-1}·K and $\theta = -1.11$ K, characteristic of an overall antiferromagnetic interaction.

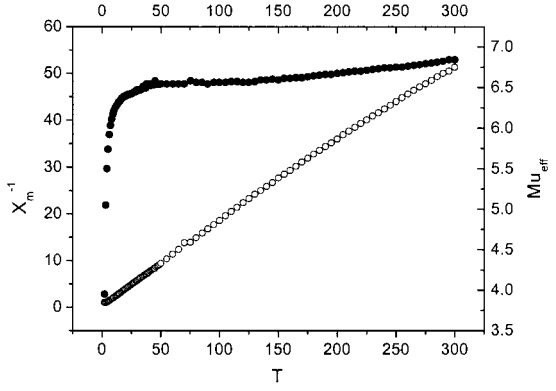

Figure 3. The effective magnetic moment μ_{eff} (filled circles) and inverse molar susceptibility (open circles) vs. temperature for **1**

The ESR spectrum of **1** at room temperature shows no signals for V^{4+}. This lack of signals indicates that the electrons of the cluster are spin-spin coupled. Figure 4 (a) shows the XPS[25] spectrum of **1** in the V 2p region, with the peak at 516.2 eV being ascribed to V^{4+}. Figure 4 (b) shows the spectrum of **1** in the As 3d region, with the peak at 45 eV being attributed to As^{3+}. The XPS estimation of the valence-state values seems to be in reasonable agreement with those calculated from the bond valence sum calculations. These results further confirm the valences of the arsenic and vanadium atoms.

Conclusion

Complex **1** is synthesized from V_2O_5 by exploiting the reducing ability of $H_2C_2O_4{\cdot}2H_2O$ and en. The presence of $H_2C_2O_4{\cdot}2H_2O$ and en is absolutely essential to the product formation. The successful synthesis of compound **1** provides another example of connecting arsenic-vanadium

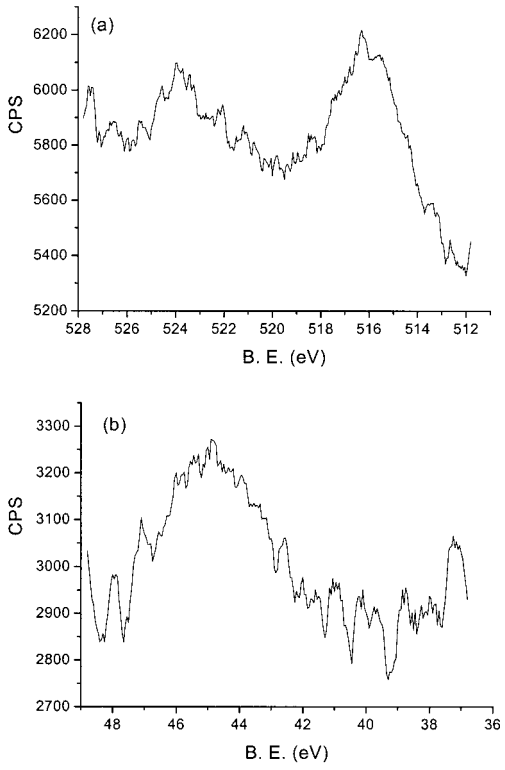

Figure 4. (a) XPS spectrum of V $2p_{3/2}$ for compound **1**; (b) XPS spectrum of As $3d_{5/2}$ for compound **1**

clusters by transition metal coordination complexes. It suggests that further condensation of clusters into higher dimensional solids through the linkage of the coordination complexes could be feasible. The bridging center may be replaced by other metal ions (Cu, Co, Mn etc.), and the building block clusters may be substituted by other arsenic-vanadium clusters, such as $[As_8V_{14}O_{42}(H_2O)_{0.5}]^{4-}$ [18] and $[As_6V_{15}O_{42}(H_2O)]^{6-}$.[18]

Experimental Section

General Remarks: All reagents were purchased commercially and used without further purification. The content of vanadium, nickel and arsenic was determined on a Perkin−Elmer Optima 3300DV spectrometer. Elemental analyses (C, H and N) were performed on a Perkin−Elmer 2400 Series II CHNS/O elemental analyzer. The infrared spectrum was obtained on an Perkin−Elmer spectrophotometer in the 200−4000 cm^{-1} region with pressed KBr pellet. Measurement of the electron-spin resonance (ESR) spectrum carried out on a Bruker ER 200D-SRC diffractometer. XPS measurements were performed on single crystals with an Escalab Mark II apparatus, using Mg-K_α X-ray radiation as the excitation source ($E_{Mg\text{-}K_\alpha}$ = 1253.6 eV). Variable-temperature magnetic susceptibility measurements for **1** were performed on a MPMS-XL magnetometer over the range 2−300 K.

Synthesis of 1: Compound **1** was hydrothermally synthesized in 73% yield (based on V). A mixture of As_2O_3 (0.40 g), V_2O_5 (0.36 g), $H_2C_2O_4{\cdot}2H_2O$ (0.25 g), en (0.24 g), $NiSO_4{\cdot}6H_2O$ (0.53 g), and distilled water (21.6 mL) in a molar ratio of 1:1:1:2:1:600 was stirred for ca. 10 min and then transferred to a Teflon-lined reactor and heated at 160 °C for three days. $H_2C_2O_4{\cdot}2H_2O$ was used as reducing agent and it was necessary to maintain the pH value of the reaction system. After cooling to room temperature, black block crystals were isolated. The compound **1** is stable to air in water, and in acetone. Elemental analysis (%): calcd. As 22.21, V 26.43, S 1.19, Ni 6.53, C 5.34, H 2.13, N 6.23; found As 22.18, V 26.41, S 1.14, Ni 6.54, C 5.33, H 2.07, N 6.21. IR: 3451(w) cm^{-1}, 2925(w), 1587(m), 1139(m), 1016(m), 969(s), 704(s).

X-ray Crystallographic Study: $C_{12}H_{57}As_8N_{12}Ni_3O_{50}SV_{14}$ (**1**), M_r = 2698.41, triclinic space group $P\bar{1}$, a = 12.9318(6) Å, b = 13.4441(7) Å, c = 21.2885(13) Å, α = 87.260(3)°, β = 77.637(2)°, γ = 68.699(3)°, V = 3366.5(3) $Å^3$, Z = 2, ρ = 2.662 $mg{\cdot}m^{-1}$, μ(Mo-K_α) = 6.704 mm^{-1}, $F(000)$ = 2606, R [$I \geq 2\sigma(I)$] = 0.0707, $wR2$ = 0.2161 for all reflections, goodness-of-fit = 0.883.
A black crystal (dimensions 0.447 × 0.367 × 0.273 mm^3) was carefully chosen from the batch sample and mounted on a glass fiber for data collection at 293 K on a Rigaku RAXIS-RAPID diffractometer equipped with Mo-K_α radiation. A total of 16168 reflections were measured, 9572 of which were unique. Structure solution was performed with SHELXS-97 by direct methods. All atoms except C(1) were refined anisotropically. The Ni(1) atom is disordered over two positions, with occupancy factors of 0.63 and 0.37, respectively. The hydrogen atoms were positioned with an idealized geometry and refined with fixed isotropic-displacement parameters using a riding model.
CCDC-210956 (**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Electronic Interactions in Dinuclear Platinum and Palladium Ethynylferrocene and Ferrocenylvinylidene Complexes

John H. K. Yip,*[a] Jianguo Wu,[a] Kwok-Yin Wong,*[b] Kam Piu Ho,[b] Lip Lin Koh,[a] and Jagadese J. Vittal[a]

Keywords: Platinum / Palladium / Ferrocene / Alkenes

The complex $[Pd_2(dppm)_2(\mu\text{-}\eta^1{:}\eta^1\text{-}H\text{–}C{=}C\text{–}Fc)Cl_2]$ (**2**) and its vinylidene isomer $[Pd_2(dppm)_2(\mu\text{-}C{=}CH\text{–}Fc)Cl_2]$ (**3**) [dppm = bis(diphenylphosphanyl)methane, Fc = ferrocenyl unit, $CpFeC_5H_4$] have been synthesized and characterized by single-crystal X-ray diffraction. Both **2** and **3** are A-frame structures with long Pd–Pd distances of 3.2055(9) Å (**2**) and 3.1002(2) Å (**3**), respectively, and square-planar metal coordination. The cyclic voltammograms (CV) of the complexes are measured and compared with that of $[Pt_2(dppm)_2(\mu\text{-}\eta^1{:}\eta^1\text{-}H\text{–}C{=}C\text{–}Fc)Cl_2]$ (**1**). The CV of **2** and **3** consist of a nearly reversible Fc-oxidation, an irreversible oxidation and a small reversible couple. The $E_{1/2}$ values (vs. Cp_2Fe^+/Cp_2Fe) of the Fc-groups in complexes **1**–**3** follow the order **2** (–75±8 mV) > **1** (–108±10 mV) > **3** (–124±8 mV). The difference in the $E_{1/2}$ values is explained by the orbital interactions between the acetylene and vinylidene groups with Pt_2 and Pd_2 cores. Our analysis shows that the metal-to-ligand π back-bonding and ligand-to-metal σ-donation have determining effects on the electronic interactions between the dimetallic centers and the bridgehead ligands.

Introduction

Understanding ligand-mediated electronic interactions is pertinent to the design of organometallic-based advanced materials. Special attention has been given to alkynyl (−C≡C−) and polynyl ligands because of the potential applications of their metal complexes in areas such as molecular electronics and photonic materials.[1] While many complexes containing acetylene (R−C≡C−R′)[2] and vinylidene (C=CRR′)[3] have been synthesized, the emphasis of the studies is mostly on the reactivity and structures of the compounds and the knowledge of the electronic interactions in these metal complexes is rather limited. Similar to the alkynyl group, acetylene and vinylidene can participate in π-conjugation with metal centers. However, there are differences between metal−acetylene/−vinylidene bonding and the metal−alkynyl bonding, which is expected to have pronounced effects on the electronic interactions mediated by these ligands. Apparently, a better understanding of the electronic interactions between the metal and the two organic linkages is essential for the exploitation of metal−acetylene and −vinylidene complexes in organometallic materials.

Dinuclear d^9−d^9 $[M_2(L)_2(L')_2]$ complexes (M = Ir^0, Rh^0, Pd^I, Pt^I; L = bridging diphosphane or diarsane, L′ = terminal ligands) are known to react with various groups (X) i.e. CO, acetylene, isocyandide, halides to form the so-called A-frame complexes $[M_2(L)_2(L')_2(\mu\text{-}X)]$ in which the two metal atoms are bridged by the X group in the apical position.[4] The complexes have been studied intensively, mainly for their intriguing structures and reactivity.[4,5] The first comprehensive theoretical study of the bonding of A-frame complexes was given by Hoffmann.[6] The optical spectroscopy and electronic structures of a series of A-frame vinylidene $[Ni_2(dppm)_2(\mu\text{-}C{=}CH_2)X_2]$ (X = Cl, Br, SCN)[7] and the luminescent properties of the distorted A-frame $[Pt_2(\mu\text{-}AuCl)(dppm)_2Cl_2]$ were reported.[8] In view of their structural simplicity and the theoretical underpinning, it is believed that the A-frame acetylene and vinylidene complexes could serve as models in probing the electronic communications mediated by the two unsaturated groups. Our recent study showed that the redox-active ethynylferrocene can be anchored onto an A-frame complex $[Pt_2(dppm)_2(\mu\text{-}\eta^1\text{-}\eta^1\text{-}HC{=}C{-}Fc)Cl_2]$ (**1**) (Fc = ferrocenyl $CpFeC_5H_4$) via the oxidative addition reaction with $[Pt^I{}_2(dppm)_2Cl_2]$.[9] The cyclic voltammogram (CV) of the complex shows a cathodic shift of the reduction potential of the Fc^+/Fc couple, indicating the existence of electronic interactions between the Fc group and the Pt_2 center. In order to further elucidate the electronic interactions between the dimetallic

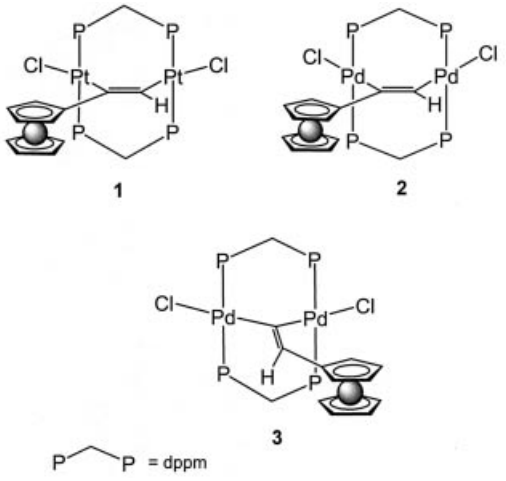
center and Fc group, we prepared the palladium analog of compound **1**, $[Pd_2(dppm)_2(\mu\text{-}\eta^1\text{-}\eta^1\text{-}HC{=}C{-}Fc)Cl_2]$ (**2**), and its vinylidene isomer $[Pd_2(dppm)_2(\mu\text{-}C{\equiv}CH{-}Fc)Cl_2]$ (**3**) (Scheme 1). Apart from showing the effects of the metal ion and the bridging ligand on the electronic interactions, our results also provide insights into the metal−acetylene and −vinylidene bonding.

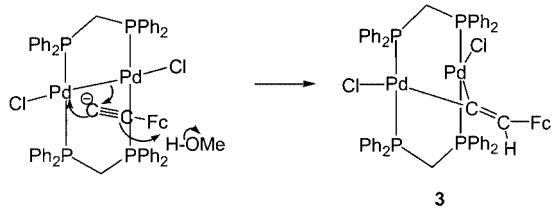


Scheme 1

Results and Discussion

Synthesis and Structures

Like other A-frame dipalladium-acetylene complexes,[10] $[Pd_2(dppm)_2(\mu_2\text{-}\eta^1{:}\eta^1\text{-}H{-}C{\equiv}C{-}Fc)Cl_2]$ (**2**) was synthesized from a reaction between $[Pd_2(dppm)_2Cl_2]$ and ethynylferrocene. The synthesis of the vinylidene complex $[Pd_2(dppm)_2(\mu\text{-}C{\equiv}CH{-}Fc)Cl_2]$ (**3**) is different from the conventional method which involves acid catalyzed isomerization of the dipalladium-acetylene complex[11] or reaction of $[Pd_2(dppm)_2Cl_2]$ with diiodoalkenes.[12] Refluxing a methanol solution of compound **2** with HBF_4 failed to transform complex 2 into its vinylidene isomer. We discovered that the vinylidene complex can be synthesized in moderate yield by the reaction between $[Pd_2(dppm)_2Cl_2]$ and ferrocenylacetylide ($Fc{-}C{\equiv}C^-$), which was generated from the deprotonation of $Fc{-}C{\equiv}C{-}H$ by NaOMe generated in situ. The formation of complex **3** may involve the reduction of $Fc{-}C{\equiv}C^-$ by the Pd−Pd bond (Scheme 2).



Scheme 2

The Pt-vinylidene complex, $[Pt_2(dppm)_2(\mu\text{-}C{=}CHFc)Cl_2]$, cannot by synthesized by this method or acid-catalyzed isomerization of compound **1**. As reported earlier, the reaction between $[Pt_2(dppm)_2Cl_2]$ and $FcC{\equiv}C^-$ led to the formation of $[Pt_2(dppm)_2(C{\equiv}C{-}Fc)_2]$.[13]

The complex **2** is isostructural to its Pt analog $[Pt_2(dppm)_2(\mu_2\text{-}\eta^1{:}\eta^1\text{-}H{-}C{\equiv}C{-}Fc)Cl_2]$, the structure of which was recently reported by us.[9] The X-ray crystal structure of compound **2** shows two nearly square-planar Pd ions bridged by two *trans* oriented dppm groups and one ethynylferrocene (Figure 1 and Table 1). Two chloride ions are coordinated *trans* to the two acetylene carbon atoms [C(1)−Pd(1)−Cl(1) = 170.1(3)°, C(2)−Pd(2)−Cl(2) 171.4(3)°]. As observed in many other dppm-bridged dinuclear compounds, the $Pd_2(P{-}C{-}P)_2$ metallocycle in **2** adopts a boat conformation. The Pd−P and Pd−Cl bond lengths are normal.[10,11,12] The Pd−C bond lengths, which are slightly different [Pd(1)−C(1) = 2.010(1) Å and Pd(2)−C(2) = 2.038(1) Å], are similar to the ones found in similar complexes such as $[Pd_2(dppm)_2(\mu_2\text{-}\eta^1{:}\eta^1\text{-}F_3C{-}C{=}C{-}CF_3)Cl_2]$ [Pd−C = 1.994(12) and 2.014(12) Å].[10] The long Pd−Pd distance of 3.2055(9) Å indicates the absence of a metal−metal bond; in other words, the two d^9 Pd^I ions in $[Pd_2(dppm)_2Cl_2]$ are formally oxidized to d^8 Pd^{II} ions in **2**. The distorted square-planar coordination geometry of the Pd ions is characteristic of d^8 metals. Accordingly the bridging ligand should be regarded as a dianionic ethylene $(H{-}C{=}C{-}Fc)^{2-}$, as suggested by the theoretical study.[6] In line with the assignment of the bridging acetylene as a dianionic ethylene $(H{-}C{=}C{-}Fc)^{2-}$ is the acetylene C(1)−C(2) bond length [1.309(14) Å], which is significantly longer than the averaged C≡C bond length (1.19 Å) but falls into the range of an average C=C bond. In addition, the angles between the bridging acetylene and the Pd atoms [Pd(1)−C(1)−C(2) = 117.2(8)° and Pd(2)−C(2)−C(1) = 118.4(8)°] are close to 120° expected for an sp^2 carbon. Similar bond angles and acetylene C−C distances are found in complex **1** [Pt−C−C = 120.4(7)° and 116.8(7)°, C−C = 1.293(1) Å]. The angles θ, which measure the deviation of

the Pd−Cl bonds from the Pd−Pd vector (Scheme 3), are 52.74(9)° and 69.83(9)°. Similar angles θ [53.30(9)°, 69.44(9)°] were observed in the complex **1**. The $^{31}P\{^{1}H\}$ NMR spectrum of the complex is second-order showing two multiplets (AA′BB′)[10] at δ = 4.80 and 10.58.

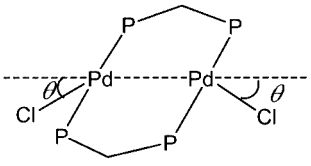

Scheme 3

The X-ray crystal structure $[Pd_2(dppm)_2(\mu\text{-}C{\equiv}CH{-}Fc)Cl_2]$ (**3**) (Figure 2 and Table 2) features a $[Pd_2(dppm)_2Cl_2]$ core similar to that of complex **2**. The two metal ions are bridged by the α-carbon atom of the ferrocenylvinylidene. The Fc group is disordered over two positions (50% occupancy for each position) which are symmetric with respect to the two Pd atoms. The α-carbon atom is equidistant from the two metal ions [Pd(1)−C(2) = 19.18(11) Å]. Although the Pd−Pd distance [3.1002(17) Å] is shorter than those reported in other A-frame Pd_2−vinylidene complexes, it is still too long to assign any formal bonding between the metal ions; accordingly, the Pd and the bridging ligand should be formulated as Pd^{II} and $Fc{-}CH{=}C^{2-}$, respectively. The bridging angle, Pd(1)−C(1)−Pd(1A), 107.8(9)°, is smaller than the 120° of an sp^2 carbon. This is by no means unique to the present complex, as a similar bridging angle is found in related compounds, i.e. $[Pd_2(dppm)_2(\mu\text{-}C{=}CH_2)Cl_2]$ [Pd−C−Pd = 109.2(8)°]. Due to their high thermal parameters, the distance between the two vinylidene carbon atoms C(2)−C(3) cannot be determined accurately. The angle θ, 38.16(2)°, is smaller than that in complex **2**. No ν(C≡C) vibration is observed in the IR spectrum of **3**. The $^{31}P\{^{1}H\}$ NMR spectrum is in accordance with the molecular structure of the complex as it shows two second-order multiplets centered at δ 13.5 which display a splitting pattern ascribable to the AA′BB′ system.[10]

Electrochemistry of the Complexes

The electrochemical data of the complexes **1**−**3** are summarized in Table 3. Our previous study showed that, at room temperature, the cyclic voltammogram (CV) of **1** shows a reversible Fc^+/Fc-couple (ΔE_p = 60 mV, i_c/i_a = 1) at −108±10 mV vs. Cp_2Fe^+/Cp_2Fe.[9] There is an irreversible oxidation at 583±10 mV attributable to the oxidation of the Pt metal center. The corresponding Pt reduction occurs at 343±10 mV. No reduction wave was observed when the initial scan direction was made towards the cathodic side.

The CV of **2** measured in CH_2Cl_2 at room temperature (Figure 3) displays a reversible couple at $E_{1/2}$ = −75±8 mV (vs. Cp_2Fe^+/Cp_2Fe, $i_{pc}/i_{pa} \approx 1$, ΔE_p = 77 mV), an irreversible oxidation peak II at +487±8 mV, and a reversible couple III at $E_{1/2}$ = +833±8 mV ($i_{pc}/i_{pa} \approx 1$). Couple I at $E_{1/2}$ = −75±8 mV is attributable to the one-electron oxidation of the Fc group as its reduction potential is close to the Fc^+/Fc-couple of **1**. The peak-to-peak splitting (ΔE_p) of 77 mV is slightly larger than the 60 mV expected for a reversible one-electron couple. This is likely to be caused by the resistance of the dichloromethane electrolyte and the liquid junction potential between the reference electrode and the electrolyte. The reversible oxidation of the Fc group is followed by an irreversible oxidation wave II at +487±8 mV. The size of this irreversible oxidation wave is close to that of the Fc^+/Fc-couple, indicating that it too is a one-electron process. Reversing the voltammetric scan at 550 mV did not

Table 3. Electrochemical data of compounds **1**, **2**, and **3**[a]

Complex[a]	Fc^+/Fc-couple I[b] $E_{1/2}$	Irreversible oxidation peak II[b] (reduction peak)	Reversible couple III[b] $E_{1/2}$
1	−108±10	+583±10 (343±10)	
2	−75±8	+487±8 (+330±8)	+833±8
3	−124±8	+679±8 (+623±8)	+969±8

[a] Measured in CH_2Cl_2 (0.1 M nBu_4NPF_6), working electrode: glassy carbon electrode (0.07 cm^2), reference electrode: $Ag/AgNO_3$ (0.1 M in CH_3CN), counter electrode: platinum wire. [b] mV vs. Cp_2Fe^+/Cp_2Fe.

result in the observation of the corresponding reduction wave for this oxidation. A small reduction peak, however, was observed at +311±8 mV in the reverse scan. This indicates that **2**, once oxidized at this potential, rapidly undergoes an irreversible 'chemical reaction'. Theoretical calculations on the isoelectronic and isostructural A-frame Rh^I_2(μ-acetylene) showed that the HOMO of the complex is mostly metal-based.[6] This suggests that the oxidation process at 487±8 mV could correspond to the one-electron oxidation of $Pd^{II}Pd^{II}$ to $Pd^{II}Pd^{III}$. Since Pd^{III} and Pd^{II} ions prefer different coordination geometries, the oxidation brings about drastic structural changes, which could account for the 'chemical reaction' following the electron transfer. The small reduction wave at 311±8 mV could be due to the product after the structural rearrangement has occurred. The irreversible oxidation at 487±8 mV is followed by a smaller but reversible couple III at $E_{1/2}$ = +833±8 mV. The smaller size of this couple compared to the Fc^+/Fc-couple is consistent with the structural rearrangement of the complex preceding the electron transfer. Tentatively the couple is assigned to the oxidation of $Pd^{III}Pd^{II}$ to $Pd^{III}Pd^{III}$.

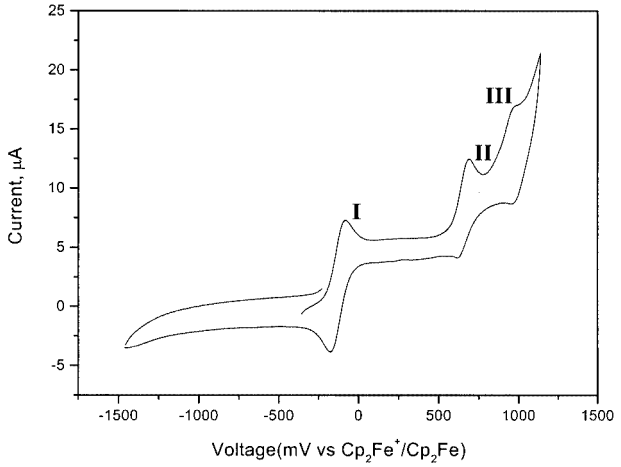

Figure 3. CV of **2** measured in CH_2Cl_2 (0.1 M nBu_4NPF_6), working electrode: glassy carbon electrode (0.07 cm^2), reference electrode: $Ag/AgNO_3$ (0.1 M in CH_3CN), counter electrode: platinum wire, concentration of complex = 1.2 mM, scan rate = 10 mV/s

Similar to compound **2**, the CV of the vinylidene complex **3** (Figure 4) exhibits a reversible couple I at $E_{1/2}$ = −124 ± 8 mV ($i_{p,c}/i_{p,a} \approx 1$; ΔE_p = 74 mV), an irreversible oxidation peak II at +679±8 mV and a smaller reversible couple at $E_{1/2}$ = +969±8 mV ($i_{p,c}/i_{p,a} \approx 1$). The reversible couple I $E_{1/2}$ = −124 mV is assigned to the Fc^+/Fc-couple. The size of the irreversible wave II at +679±8 mV is similar to that of the Fc^+/Fc-couple and is therefore assigned to the one-electron oxidation of Pd^{II} Pd^{II} to $Pd^{II}Pd^{III}$. A small reduction peak appeared at +623±8 mV, which is attributed to reduction of the rearranged product after the oxidation process has occurred. The smaller reversible couple III at +969±8 mV could be due to the oxidation of $Pd^{II}Pd^{III}$ to $Pd^{III}Pd^{III}$.

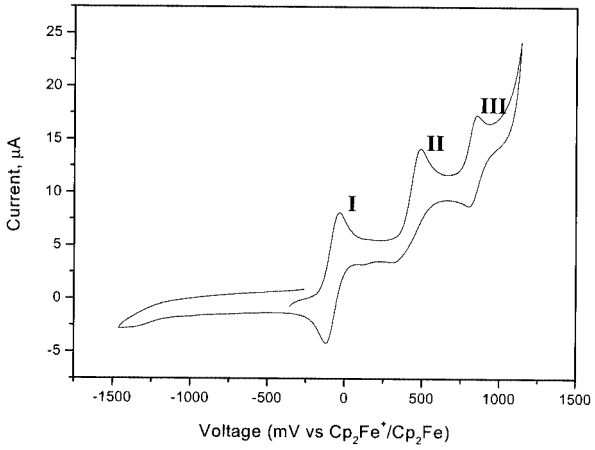

Figure 4. CV of **3** measured in: CH_2Cl_2 (0.1 M nBu_4NPF_6), working electrode: glassy carbon electrode (0.07 cm^2), reference electrode: $Ag/AgNO_3$ (0.1 M in CH_3CN), counter electrode: platinum wire, concentration of complex = 1.2 mM, scan rate = 10 mV/s

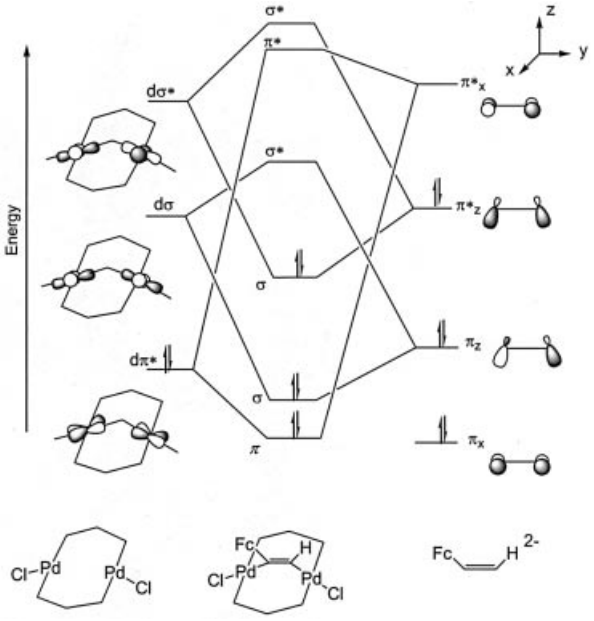
Electronic Interactions

A common electrochemical feature of the complexes is the low $E_{1/2}$ of their Fc^+/Fc-couples in comparison with the reported $E_{1/2}$ of ethynylferrocene (Fc^+−C≡CH/Fc−C≡CH = +254 mV vs. Cp_2Fe^+/Cp_2Fe).[14] In other words, the Fc groups in the three dinuclear complexes are more reducing or electron-rich than the one in the uncomplexed Fc−C≡C−H. This is consistent with the formal assignment of the bridgehead ligands as the dianionic $(H-C=C-Fc)^{2-}$ and $Fc-CH=C^{2-}$ species. Since the Fc groups in these complexes are connected to the acetylene and vinylidene groups via σ- and π-bonds, transfer of electron density from the dimetallic cores onto the linkage would lower the potential of the Fc^+/Fc-couple via π-conjugation and an inductive effect.

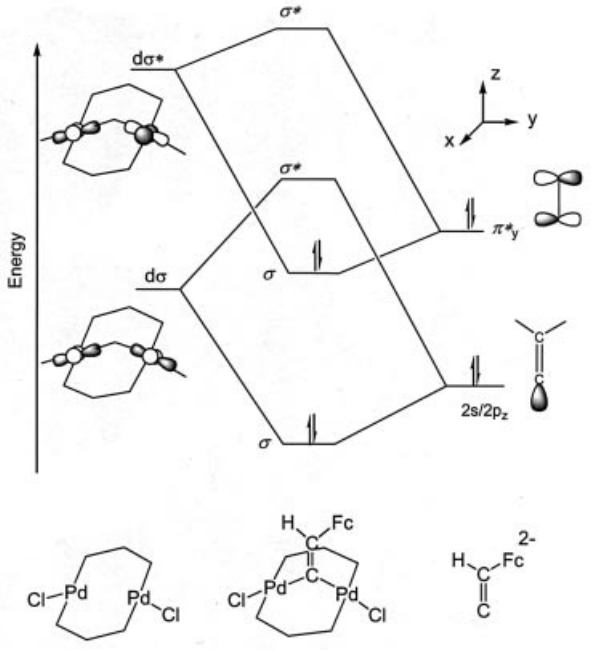
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Comparing the $E_{1/2}$ of the Fc^+/Fc-couples of the isostructural compounds **1** and **2** shows that the Fc group in the Pd_2 complex (−75±8 mV) is less reducing than the one in the Pt_2 complex (−108±10 mV). The interactions between the dianionic $(H-C{\equiv}C-Fc)^{2-}$ and the dinuclear M_2 centers (M = Pd^{II} and Pt^{II}) consist of σ- and π-donations from the ligand π-orbitals and the metal-to-ligand π back-bonding (Scheme 4). The bending of the $(H-C{\equiv}C-Fc)^{2-}$ unit lifts the degeneracy of the π- and π*-orbitals, with the energy in the order: $\pi_x^2 < \pi_z^2 < \pi^*_z{}^2 < \pi^*_x$ (*x* axis is parallel to the meridian of the complex).[6] In addition, the π_z- and π_z*-orbitals are hybridized with the 2s-orbital. The ligand(π_x)-to-metal π-donation is secondary as there is no low-lying accepting orbital in the metals to interact with the deep-seated π_x-orbital. In first-order approximation, the ligand-to-metal σ-donation involves, primarily, interactions between the filled bonding π_z- and antibonding π_z*-orbitals of $(H-C{\equiv}C-Fc)^{2-}$ and the empty dσ- and dσ*-orbitals, respectively. The latter orbitals arise from the bonding and antibonding combinations of the two $nd_{x^2-y^2}$-orbitals (*n* = 4 for M = Pd and 5 for M = Pt). While electron density drifts from $(H-C{\equiv}C-Fc)^{2-}$ to the M_2 core as a result of σ-donation, the metal-to-ligand π back-bonding, which involves the nd_{xy}-orbitals of M_2 and the π_x*-orbital of $(H-C{\equiv}C-Fc)^{2-}$, transfers electron density from the metal to the $(H-C{\equiv}C-Fc)^{2-}$ unit. The importance of the ligand-to-metal σ-donation in the interactions is obvious but the significance of the metal-to-ligand π back-bonding in the electronic interactions is rather uncertain. In view of the general conception that third row transition metals form stronger π back-bonding than their second row congeners, one would expect the $Pt_2 \rightarrow (H-C{\equiv}C-Fc)^{2-}$ π back-bonding to be stronger than the $Pd_2 \rightarrow (H-C{\equiv}C-Fc)^{2-}$ π back-bonding. This is consistent with the $E_{1/2}$ values of the Fc^+/Fc-couples in **1** and **2**.

The $E_{1/2}$ of the Fc^+/Fc-couple of the vinylidene complex (−124±8 mV) is lower than the corresponding $E_{1/2}$ of its acetylene isomer **2** (−75±8 mV). The Fc group of **3** is even more reducing than that of **1**, which suggests the metal-to-ligand π back-bonding is not the main cause for the low reduction potential. We believe that this difference in the reduction potentials could be interpreted as a weaker $Fc-CH{=}C^{2-} \rightarrow Pd_2$ σ-donation in complex **3**. Notably, the peak potential of the irreversible metal oxidation of complex **2** (+487±8 mV) is lower than that of complex **3** (+679±8 mV), suggesting that Pd_2 in **2** is more electron-rich than that in **3**. This is consistent with the argument that the $(H-C{\equiv}C-Fc)^{2-} \rightarrow Pd_2$ donation is stronger than the $Fc-CH{=}C^{2-} \rightarrow Pd_2$ donation. The σ-bonding in complex **3** involves the interactions between (i) the filled antibonding π*-orbital (vinylidene) and the dσ*-orbital (Pd_2) and (ii) an admixture of 2s- and $2p_y$-orbitals (vinylidene) and the dσ-orbital (Pd_2) (Scheme 5). The splitting of the dσ- and dσ*-orbitals would be increased by a better overlap of the two $d_{x^2-y^2}$-orbitals.[6] This can be achieved by shortening the Pd−Pd distance or reducing the angle θ. Comparing the structures of the two isomers shows that the Pd−Pd distance [3.1002(17) Å] and the angle θ [38.16(2)°] are shorter and smaller than the ones in complex **2** [Pd−Pd = 3.2055(9) Å; θ = 52.74(9)°, 69.83(9)°]. These structural features suggest that the dσ*-orbital in complex **3** is more destabilized than the one in complex **2**. The larger energy separation between the π_y*- and dσ*-orbitals weaken the σ-donation. On the other hand, one would expect the 2s/2p−dσ interaction to be enhanced as the dσ-orbital is now more stabilized. Nonetheless, the $E_{1/2}$ of the Fc group should be determined mainly by the π_y*−dσ* interaction since the π_y*-orbital is higher in energy than it is in π-conjugation with the Cp-ring of the Fc group. Another possibility for the poorer σ-donation in complex **3** is the relatively in-



Scheme 4



Scheme 5

sufficient overlap between the apical carbon sp^2-hybridized orbital and the metal orbitals; suggested by the fact that the bridging angle Pd−C−Pd [107.8(9)°] is smaller than 120°. On the other hand, the orbital overlap between $(H-C{=}C-Fc)^{2-}$ and Pd_2 in complex **2** is better as the Pd(1)−C(1)−C(2) and Pd(2)−C(2)−C(1) angles [117.2(8)° and 118.4(8)°] are close to the ideal angle of an sp^2-hybridized carbon atom. This poor σ-donation would retain more electron density in the vinylidene from which the inductive effect would be transmitted via the σ-bonds to the ferrocenyl group, leading to a lower Fc^+/Fc potential as observed.

Concluding Remarks

In summary, our work demonstrated the presence of electronic interactions between the ferrocenyl group and the metal centers in the complexes $[Pd_2(dppm)_2(\mu\text{-}\eta^1{:}\eta^1\text{-}H-C{=}C-Fc)Cl_2]$ and $[Pd_2(dppm)_2(\mu\text{-}C{=}CH-Fc)Cl_2]$. Comparing the $E_{1/2}$ of the Fc^+/Fc-couples of $[Pd_2(dppm)_2(\mu\text{-}\eta^1{:}\eta^1\text{-}H-C{=}C-Fc)Cl_2]$ and its Pt-analog shows that the Pt has stronger metal-to-ligand π backbonding than the Pd. It is rather unexpected that the ligand-to-metal σ-donation in the Pd_2−μ-vinylidene complex is weaker than the one in the acetylene isomer. This is attributed to the destabilization of the dσ*-orbital and the poor orbital overlap between the bridging vinylidene and the metal ions.

Experimental Section

General Methods: All syntheses were carried out using standard Schlenk techniques. All solvents used in syntheses and electrochemical measurements were purified according to the literature methods. The supporting electrolyte $n\text{Bu}_4\text{NPF}_6$ (TBAH) obtained from Aldrich was recrystallized from ethanol and dried at 100 °C for 24 h before being used. Ethynylferrocene[15] and $[Pd_2(dppm)_2Cl_2]$[16] were prepared according to reported procedures. Dichloromethane used for the voltammetric measurements was distilled over P_2O_5.

Physical Measurements: NMR spectra were recorded at 25 °C on a Bruker ACF 300 spectrometer. Elemental analyses of the complexes were carried out in the microanalysis laboratory in the department of chemistry, the National University of Singapore. Solution infrared spectra of the complexes were recorded on a Bio-Rad TFS 156 spectrometer. A Bioanalytical Systems (BAS) model 100 W electrochemical analyzer was used in all electrochemical measurements. $n\text{Bu}_4\text{NPF}_6$ (0.1 M) was used as the supporting electrolyte unless otherwise stated. Cyclic voltammetry was performed in a conventional two-compartment electrochemical cell. The platinum disc working electrode (area 0.02 cm^2) was treated by polishing it with 0.05 μm alumina using a microcloth and then sonicated for 5 minutes in deionized water followed by rinsing with the solvent used in the electrochemical studies. An $Ag/AgNO_3$ (0.1 M in CH_3CN) electrode was used as reference electrode. The potential of the $Ag/AgNO_3$ reference electrode was calibrated against the $Cp_2Fe^{+/0}$ couple before and after each set of experiments to ensure the accuracy of the potential measured;[17] the $E_{1/2}$ of $Cp_2Fe^{+/0}$ was found to be 0.06±0.01 V vs. the $Ag/AgNO_3$ reference. The $E_{1/2}$ values are the average of the cathodic and anodic peak potentials for the oxidative and reductive waves of reversible couples.[18]

Synthesis of $[Pd_2(dppm)_2(\mu\text{-}\eta^1{:}\eta^1\text{-}HC{=}C-Fc)Cl_2]\cdot CH_2Cl_2$ ($2\cdot CH_2Cl_2$): A methanol suspension of $[Pd_2(dppm)_2Cl_2]$ (0.3 g, 0.29 mmol) and ethynylferrocene (0.06 g, 0.29 mmol) was stirred at room temperature for 24 h and the orange precipitate that formed was filtered. The solid was dissolved in dichloromethane and filtered. Excess diethyl ether was added to the filtrate to precipitate the product as an orange solid. The product was purified by diffusing diethyl ether into a dichloromethane solution. Yield 59%. $C_{63}H_{56}Cl_4FeP_4Pd_2$: calcd. C 56.11, H 4.16; found C 56.00, H 4.12 (%). ^{1}H NMR (300 MHz, CD_2Cl_2, δ/ppm): 5.42 (m, 1 H, H−C=), 3.06 (m, 2 H, PCH_2P), 3.41 (s, 5 H, C_5H_5), 3.41 (s, 4 H, C_5H_4), 3.25 (m, 2 H, PCH_2P), 6.94−7.98 (m, 40 H, Ph). $^{31}P\{^1H\}$ NMR (300 MHz, CD_2Cl_2, δ/ppm): 4.80 (m, 2 P), 10.58 (m, 2 P).

Synthesis of $[Pd_2(dppm)_2(\mu\text{-}C{\equiv}CH-Fc)Cl_2]$ (3): Sodium (0.02 g, 0.855 mmol) was added to a methanol solution (10 mL) of ethynylferrocene (0.18 g, 0.86 mmol). After 20 min of stirring hexane (60 mL) was introduced, followed by the addition of $[Pd_2(dppm)_2Cl_2]$ (0.30 g, 0.29 mmol). The mixture was stirred at room temperature for 12 h and then filtered. The solid was dissolved in dichloromethane and filtered. Excess diethyl ether was added to the filtrate to precipitate the product as an orange solid. The product was purified by diffusing diethyl ether into a dichloromethane solution. Yield 45%. $C_{62}H_{54}Cl_2FeP_4Pd_2$: calcd. C 58.93, H 4.28; found C 58.46, H 4.12 (%). ^{1}H NMR (300 MHz, CD_2Cl_2, δ/ppm): 5.56 (m, 1 H, H−C=C), 2.60 (m, 2 H, PCH_2P), 3.67 (s, 5 H, C_5H_5), 4.02 (s, 4 H, C_5H_4), 3.10 (m, 2 H, PCH_2P), 6.95−7.92 (m, 40 H, Ph). $^{31}P\{^1H\}$ NMR (300 MHz, CD_2Cl_2, δ/ppm): 12.7−14.5 (m).

X-ray Crystallography: The diffraction experiments were carried out on a Bruker AXS SMART CCD 3-circle diffractometer at T = 223 K, 2θ−ω scan with a sealed tube using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The following software was used: SMART[19] for collecting frames of data, indexing reflection and determination of lattice parameters; SAINT[19] for integration of intensity of reflections and scaling; SADABS[20] for empirical absorption correction; and SHELXTL[21] for space group determination, structure solution and least-squares refinements on $|F|^2$. The crystals were mounted at the end of glass fibers. Anisotropic thermal parameters were refined for the non-hydrogen atoms. The hydrogen atoms were placed in their ideal positions. A brief summary of crystal data and experimental details are given in Table 4. Crystallographic data for (i) **$[Pd_2(dppm)_2(\mu\text{-}\eta^1{:}\eta^1\text{-}HC{=}CFc)Cl_2]\cdot CH_2Cl_2$** ($2\cdot CH_2Cl_2$): of the 16441 reflections collected, 10837 were independent (R_{int} = 0.0466). Index range: $-15 \le h \le 17$, $-17 \le k \le 16$, $-21 \le l \le 19$. Refinement of F^2 converged with R_1 = 0.0982 for $I > 2\sigma(I)$ and wR_2 = 0.2672. The residual electron density is 3.142 and −2.392 e·Å^{-3}, (ii) **$[Pd_2(dppm)_2(\mu\text{-}C{=}CH-Fc)Cl_2]$ (3)**: of the 25934 reflections collected, 5298 were independent (R_{int} = 0.0747). Index range: $-19 \le h \le 18$, $-18 \le k \le 18$, $-24 \le l \le 15$. Refinement of F^2 converged with R_1 = 0.0611 for $I > 2\sigma(I)$ and wR_2 = 0.1648. The residual electron density is 0.394 and −0.239 e·Å^{-3}. The ferrocenyl unit is disordered over two positions with 50% occupancy. One of the phenyl groups is disordered and is modeled with two orientations, each with 50% occupancy.

Keywords: Ruthenium / Tungsten / Molybdenum / Cluster compounds / Selenium

The open-triangular, *nido* clusters of the type $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(L)_2]$ (L = PPh_3, $PPh_2(OMe)$, $PPh_2(Me)$, $P(p\text{-}MeOC_6H_4)_3$] react at room temperature with $[W(CO)_3(MeCN)_3]$ to give the dimetallic *closo* clusters $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(L)_2]$. When L is $P(CH_2Ph)Ph_2$ the donor-acceptor adduct $[(CO)_5W(\mu_4\text{-}Se)Ru_3(\mu_3\text{-}Se)(CO)_7\{P(CH_2Ph)Ph_2\}_2]$ is obtained where the *nido* cluster $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(L)_2]$ interacts with the fragment $W(CO)_5$ through a selenido ligand. DFT calculations, performed on the model species $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(PH_3)_2]$ and $[(CO)_5W(\mu_4\text{-}Se)Ru_3(\mu_3\text{-}Se)(CO)_7(PH_3)_2]$, showed that the computed total energy of the latter is 1.1 eV lower than that of the former.

Introduction

In recent years we have carried out systematic investigations on the selenium-transfer reactions of tertiary phosphane and diphosphane selenides with carbonyl clusters $M'_3(CO)_{12}$ (M′ = Fe or Ru).[1−9] These reactions take advantage of the frailty of the P=Se bond and provide a simple, sometimes selective,[2] synthetic route to phosphane-substituted, mono- and diselenido clusters. When the starting phosphane contains heterocyclic groups, such as the 2-pyridyl and 2-thienyl moieties, P−C bond cleavage is observed, affording selenido-phosphido clusters coordinating to heterocyclic fragments.[5−7]

The synthesis of phosphane-substituted mixed-metal selenido clusters has also been investigated as the presence of different metals can influence the selectivity of certain processes,[8,9] leading to the formation of compounds with new and not always easily predictable structures. For the synthesis of dimetallic substituted selenido-carbonyl clusters two different synthetic strategies have been developed: (a) M′M + PSe, i.e. reactions between preformed dimetallic clusters and tertiary phosphane selenides,[10] and (b) M′Se + M, i.e. cluster growth reactions between preformed chalcogenide metal clusters and suitable organometallic fragments.

As regards route (b), selenido clusters $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(L)_2]$ were considered to be ideal candidates for growth reactions. These starting compounds are open-triangular, *nido* clusters with seven skeletal electron pairs (SEPs), according to the requirements of the polyhedral skeletal electron pair (PSEP) theory. As a consequence they could be prone to add a zero SEP fragment, such as $M(CO)_3$, derived from $[M(CO)_3(CH_3CN)_3]$ (M = Mo or W), giving the corresponding *closo* clusters $[MRu_3(\mu_4\text{-}Se)_2(CO)_{10}(L)_2]$. In this regard Adams[11] and co-workers obtained the monophosphane sulfur derivative of formula $[WRu_3(\mu_4\text{-}S)_2(CO)_{11}(PMe_2Ph)]$ upon irradiating a solution of $[Ru_3(\mu_3\text{-}S)_2(CO)_9]$ and $[W(CO)_5(PMe_2Ph)]$.

In a preliminary communication,[12] the products of the reactions between $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(PPh_3)_2]$ and $[M(CO)_3(CH_3CN)_3]$ were erroneously identified as the unexpected, centrosymmetric *closo* clusters $[M_2Ru_2(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(PPh_3)_2]$ (M = W or Mo) on the basis of misinterpreted X-ray structural analyses. However, preliminary MO calculations, mass spectral and accurate elemental analysis data stimulated further crystallographic studies, which revealed that a disorder exists in the crystals of these compounds involving the mutually opposite Ru and W atoms of the *closo* core of the cluster. This results in a disordered $Ru_3M(\mu_4\text{-}Se)_2$ cluster core instead of a centrosymmetric $M_2Ru_2(\mu_4\text{-}Se)_2$ one. Definitive evidence for this was provided by the solution of the crystal structure of $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6\{P(OMe)Ph_2\}_2]$ which does not

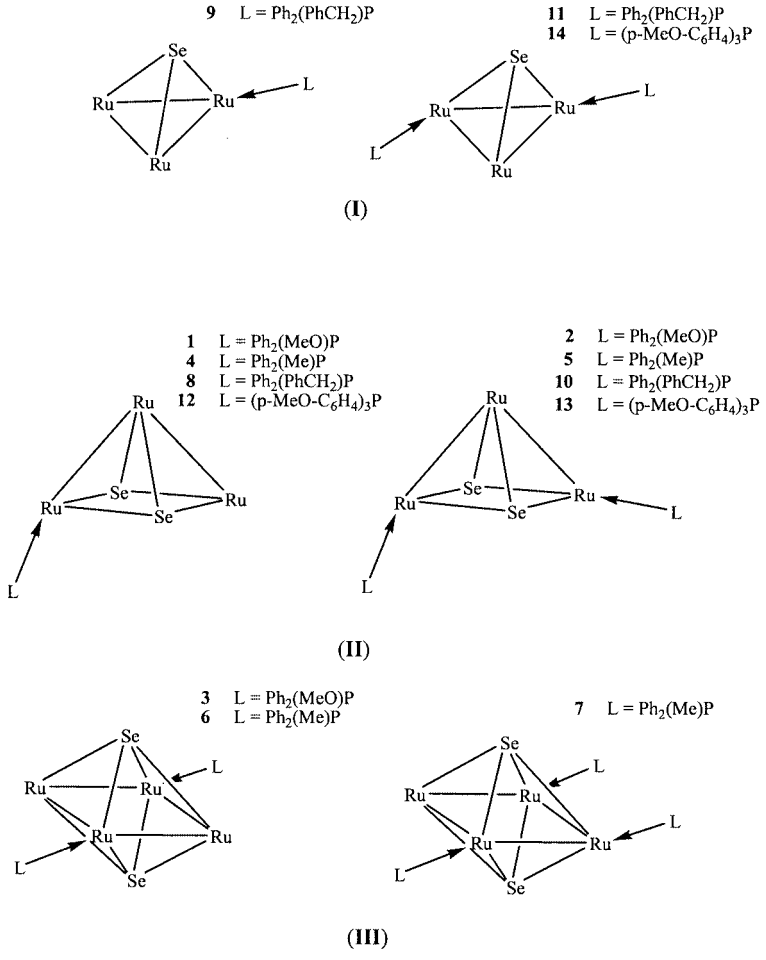

Scheme 1. (Carbonyl groups omitted)

exhibit the disorder described above. Consequently, this paper deals with the synthesis of five $[MRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(L)_2]$ clusters [M = Mo, L = PPh_3; M = W, L = $PPh_2(Me)$, $PPh_2(OMe)$, $P(p\text{-}MeO\text{-}C_6H_4)_3$] and the structural characterisation of four of them. In the case of the reaction involving $P(CH_2Ph)Ph_2$, we obtained $[(CO)_5W(\mu_4\text{-}Se)Ru_3(\mu_3\text{-}Se)(CO)_7\{P(CH_2Ph)Ph_2\}_2]$, which can be considered as the product of a donor-acceptor interaction between $[Ru_3(\mu_3\text{-}Se)_2(CO)_7\{P(CH_2Ph)Ph_2\}_2]$ and the $W(CO)_5$ fragment through a selenido ligand. Moreover, DFT calculations have been performed on the model compounds $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(PH_3)_2]$ and $[(CO)_5W(\mu_4\text{-}Se)Ru_3(\mu_3\text{-}Se)(CO)_7(PH_3)_2]$. Besides these major results, some new phosphane selenides have been characterised, and used to produce the selenido clusters shown in Scheme 1. They can be grouped in three different families according to the cluster cores: Ru_3Se (I), Ru_3Se_2 (II) and Ru_4Se_2 (III). The crystal structures of two of them, $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(L)_2]$ [L = $PPh_2(OMe)$ or $P(CH_2Ph)Ph_2$], have been determined by X-ray methods.

Results and Discussion

The new tertiary phosphane selenides $Ph_2(Me)PSe$, $Ph_2(MeO)PSe$, $(p\text{-}MeOC_5H_4)_3PSe$ and $Ph_2(PhCH_2)PSe$ were obtained in quantitative yield by selenium transfer from elemental Se to the parent phosphane. They exhibit a characteristic P=Se IR stretching band in the range 520−530 cm^{-1} and a ^{31}P NMR signal with ^{77}Se satellites, $^1J_{P,Se}$ being in the range 710−740 Hz as normally found in similar species.[13]

The reaction between $[Ru_3(CO)_{12}]$ and the tertiary phosphane selenides in hot toluene and in the presence of Me_3NO gave a number of substituted selenidoruthenium carbonyl clusters (some of them, **8**−**14**, already known) belonging to three different families: the monoselenido trinuclear species with a $Ru_3(\mu_3\text{-}Se)$ core (**9**, **11**, **14**; type I), the diselenido trinuclear species with a $Ru_3(\mu_3\text{-}Se)_2$ core (**1**, **2**, **4**, **5**, **8**, **10**, **12**, **13**; type II), and the diselenido tetranuclear species with a $Ru_4(\mu_4\text{-}Se)_2$ core (**3**, **6**, **7**; type III. See Scheme 1). As the reaction conditions are the same for all phosphanes, it appears that the product distribution is influenced by the nature of the phosphane.

Clusters belonging to the type I family could be regarded as the primary product of the attack of one molecule of the phosphane selenide on the starting reagent $[Ru_3(CO)_{12}]$, resulting in the transfer of a selenium atom to the metal triangle and the substitution of one or two carbonyl groups. These clusters undergo a second attack by another phos-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

phane selenide molecule affording, under appropriate conditions, the corresponding diselenido derivatives (clusters of type II). Mono- and disubstituted diselenido species are always present even if the starting Ru_3/PSe molar ratio is 1:1. Type II clusters can be described as square pyramids with two ruthenium and two selenium atoms alternating in the basal plane and the third ruthenium atom at the apex of the pyramid. Mono- and disubstitution by phosphanes occurs only at the base of the pyramid.

Type III clusters belong to the family of tetranuclear *closo* clusters with seven SEPs. They can be described as octahedral clusters with four ruthenium atoms in the equatorial plane and two selenium atoms at the apices. Two (**3**, **6**) or three (**7**) phosphane ligands substitute the same number of carbonyl groups. The coordination around each ruthenium atom is completed by carbonyl groups.

Slow crystallisation of compounds **2** and **10** from dichloromethane solutions afforded well-formed crystals suitable for an X-ray diffraction analysis. ORTEP views of **2** and **10** are shown in Figure 1 and 2, respectively. The most important bond lengths and angles are given in Table 1 together with those of a cluster of formula $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(PPh_3)_2]$.[2]

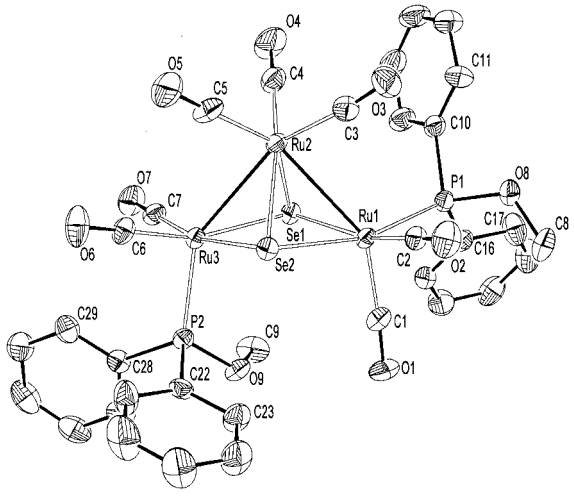

Figure 1. View (ORTEP, 30% probability level) of the molecular structure of **2** with the atom numbering scheme

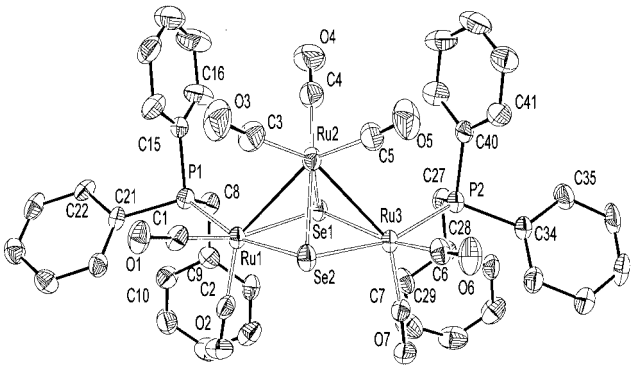

Figure 2. View (ORTEP, 30% probability level) of the molecular structure of **10** with the atom numbering scheme

The cluster cores are similar to that of the analogous compound $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(PPh_3)_2]$[2] in which the Ru−Ru bond lengths are 2.801(2) and 2.855(2) Å; those of the six Ru−Se bonds range from 2.491(1) to 2.536(2) Å. The Ru−Ru bond lengths are 2.831(2) and 2.847(2) Å in **2** and 2.799(2) and 2.806(2) Å in **10**, whereas the Ru−Se bond lengths range from 2.485(1) to 2.529(2) Å in **2** and from 2.449(2) to 2.500(2) Å in **10**. In **10** the two diphenylbenzylphosphane ligands coordinate to two ruthenium atoms, substituting two carbonyl groups in *pseudo*-equatorial positions [the P1−Ru1 and P2−Ru3 bond lengths are 2.309(2) and 2.306(3) Å]. In **2** the two diphenylmethoxyphosphane ligands substitute two carbonyls in a *pseudo*-equatorial and *pseudo*-axial position. The P1−Ru1 and P2−Ru3 bond lengths [2.327(2) and 2.274(3) Å] differ remarkably because of the different *trans* influence of the Ru−Ru and Ru−Se bonds.

Clusters **2** and **10** show the same NMR behaviour in solution despite the different coordination of the phos-

phane ligands in the solid state (eq-ax and eq-eq respectively). The room temperature ^{31}P NMR spectra of clusters **2** and **10**, as well as **5** and **13**, show two broad peaks which collapse at a temperature higher than 40 °C, together with two sharp singlets (see Figure 3 for **13**).

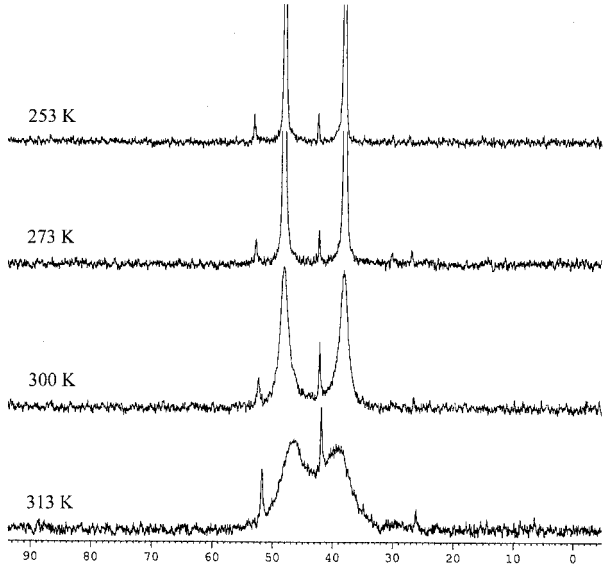

Figure 3. $^{31}P\{^{1}H\}$ NMR spectra of compound **13** recorded at different temperatures evidencing the incipient coalescence of the broad signals due to the different coordination modes of the phosphane ligands; the presence of four signals confirms the existence of the two isomeric forms A (broad peaks) and B (sharp peaks) depicted in Scheme 2

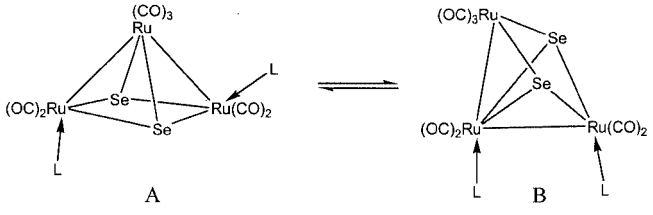
The two sets of peaks suggest the existence of two isomers A and B, indicated below in Scheme 2, as observed for $[Ru_3(\mu_3\text{-}Se)_2(CO)_7(\mu\text{-dppm})]$ (dppm = $Ph_2PCH_2PPh_2$).[14] They should be involved in an exchange process as occurs for the dppm derivative, consisting of the migration of a Ru−Ru bond from one side of the open Ru_3 triangle to the basal plane of the square pyramid (see Scheme 2). For all these complexes, an equilibrium takes place in solution starting from pure crystals of isomers A. The prevalence of isomer A (broader peaks) in solution is suggested by the fact that the basal metal sites are the preferred ones for phosphane substitution.[1] For both isomers the presence of two peaks suggests that the two P ligands are not equivalent. In fact, in B the two phosphanes occupy two different Ru sites, whereas in A (where the two Ru sites are equivalent) the presence of two peaks is probably the consequence of the fact that one phosphane ligand is coordinated in an axial position and the other in an equatorial position. As one ligand moves from the axial to the equatorial position, the other moves from equatorial to axial. This concerted movement of both ligands is responsible for the observed broadening of the major peaks.



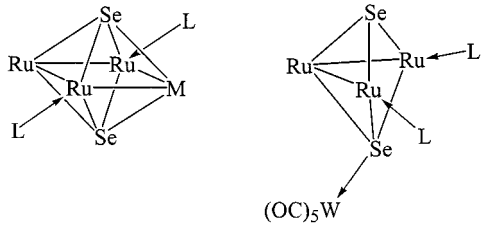
Scheme 2

Cluster Growth Reactions

Type II compounds are open-triangular, *nido* clusters with seven SEPs, according to the PSEP rules. As a consequence they could be prone to add a zero SEP fragment, such as $M(CO)_3$ (M = Mo or W), giving the *closo* clusters $MRu_3(\mu_4\text{-}Se)_2(CO)_{10}(L)_2$. We reacted clusters **2**, **5**, **10** and **13** with an excess of $W(CO)_3(CH_3CN)_3$ in dichloromethane. The reactions take place in a few hours, at room temperature, giving compounds $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6\{P(OMe)Ph_2\}_2]$ (**15**), $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6\{P(Me)Ph_2\}_2]$ (**16**), $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6\{P(p\text{-}MeO\text{-}C_6H_4)_3\}_2]$ (**17**) and $[(CO)_5W(\mu_4\text{-}Se)Ru_3(\mu_3\text{-}Se)(CO)_7\{P(CH_2Ph)Ph_2\}_2]$ (**20**) as the only isolable products. The IR spectra of **15**−**17**, in the carbonyl region are superimposable with $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(PPh_3)_2]$ (**18**) and $[MoRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(PPh_3)_2]$ (**19**), suggesting the same molecular structure for all five compounds.

Clusters **15**, **17**, **18** and **19** were unequivocally identified by X-ray diffraction methods (**18** and **19** are isomorphous). Three of these clusters, namely **17**, **18** and **19**, show a crystallographically imposed C_i symmetry, so the mutually opposite Ru and M (M = W or Mo) atoms of the *closo* core of the cluster must be disordered and distributed in the two positions with the same occupancy factor in such a way that a disordered $[Ru_3M(\mu_4\text{-}Se)_2]$ cluster core forms instead of a centrosymmetric $[M_2Ru_2(\mu_4\text{-}Se)_2]$ core. Differently from the clusters **17**, **18** and **19**, cluster **15** does not show this type of disorder.

The structural diagrams of clusters **15**−**20** are shown in Scheme 3.



15 L = $P(OMe)Ph_2$ M = W
16 L = $P(Me)Ph_2$ M = W
17 L = $P(p\text{-}MeO\text{-}C_6H_4)_3$ M = W
18 L = PPh_3 M = W
19 L = PPh_3 M = Mo
20 L = $P(CH_2Ph)Ph_2$

Scheme 3. (Carbonyl groups omitted)

Because of the disorder, compounds **18** and **19** were previously identified as the six SEP species $[M_2Ru_2(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(L)_2]$ (M = W or Mo).[12] According to the PSEP theory, the observed *closo* arrangement is predicted to be unstable for electron-deficient species. This was con-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

firmed by DFT calculations on the isoelectronic models $[Mo_2Ru_2(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(L)_2]$ (L = CO, PH_3) assuming the observed *closo* architecture (geometry optimisation carried out assuming C_{2h} and C_i symmetry for L = CO and PH_3, respectively). Indeed, small HOMO-LUMO gaps were computed for these models (0.24 and 0.44 eV for L = CO and PH_3, respectively). Consistently, the excited triplet state was found to lie close to the singlet ground state (by 0.12 eV and 0.26 eV for L = CO and PH_3, respectively). All these results are indicative of a thermal and kinetic instability for $[M_2Ru_2(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(L)_2]$ (M = W or Mo), a result at variance with the behaviour of **18** and **19**. On the other hand, calculations on $[Mo_2Ru_2(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(L)_2]^{2-}$ and $[Mo_2Ru_2(\mu_4\text{-}SeH)_2(\mu\text{-}CO)_4(CO)_6(L)_2]$ (L = CO, PH_3) indicated thermal stability for the regular seven SEP count (HOMO-LUMO gap 1.92 eV (L = CO) and 1.81 eV (L = PH_3) for the former and 1.69 eV (L = CO) and 1.61 eV (L = PH_3) for the latter). Consistently, further crystallographic studies revealed that the correct formula for **18** and **19** is $[MRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(L)_2]$ (M = W or Mo).

ORTEP views of **15**, **17**, **18** and **19** are shown in Figure 4, 5, 6 and 7, respectively. The most important bond lengths and angles are given in Table 2 together with those calculated for the complex $[WRu_3(\mu_3\text{-}Se)_2(CO)_{10}(PH_3)_2]$.

The four *closo* seven SEP complexes can be described as distorted octahedra in which the three ruthenium and the M atoms lie in the basal plane with two selenium atoms at the apices. The Ru−Ru bond lengths span from 2.676(7) to 2.835(1) Å. The M−Ru bond lengths range from 2.852(6) to 2.939(2) Å for M = W and from 2.938(8) to 3.027(5) Å for M = Mo. Two phosphane ligands coordinate two nonbonded rutheniums through the phosphorus atoms. Four carbonyls asymmetrically bridge the Ru−Ru and Ru−M edges. The coordination around each metal atom is completed by terminal carbonyl groups.

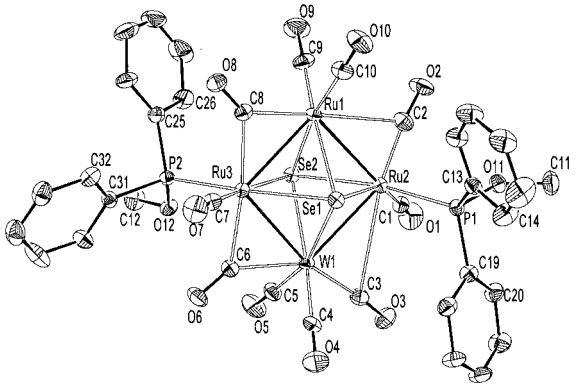


Figure 4. View (ORTEP, 30% probability level) of the molecular structure of **15** with the atom numbering scheme

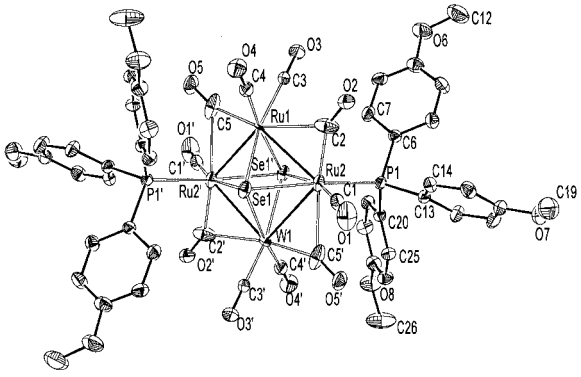

Figure 5. View (ORTEP, 30% probability level) of the molecular structure of one of the two disordered complexes **17** with the atom numbering scheme

DFT calculations on the $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(PH_3)_2]$ model (assuming C_1 symmetry) lead to a large HOMO-LUMO gap (1.65 eV), as expected for a *closo*

Table 2. Comparison of selected bond lengths (Å) and angles (°) found for compounds **15**, **17**, **18**, **19** and calculated for complex $[WRu_3(\mu_3\text{-}Se)_2(CO)_{10}(PH_3)_2]$

seven SEP species. The major optimised bond lengths and angles are given in Table 2. Taking into account that such calculations are known to overestimate the bond lengths between heavy atoms by approximately 2−6%,[15] the optimised geometry of $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(PH_3)_2]$ is in good agreement with the X-ray structures of **15**, **18** and **19**.

Surprisingly, in the case of the reaction between $[W(CO)_3(MeCN)_3]$ and **4**, we obtained the compound $[(CO)_5W(\mu_4\text{-}Se)Ru_3(\mu_3\text{-}Se)(CO)_7\{P(CH_2Ph)Ph_2\}_2]$ (**20**) as the only isolable product identified by X-ray diffraction methods. It could be considered as the product of a donor-acceptor interaction between a $W(CO)_5$ fragment and a selenido ligand of **10**. The presence of similar products is detectable on the preparative TLC plates in all the growth reactions described above, as red bands attributable to adducts (which decompose during elution) are always observed. In the case of $PPh_2(OMe)$, it was even possible to isolate and recognize, by FT-IR spectroscopy, a cluster analogous to **20**, which, however, rapidly decomposed. The decomposition product was identified as the starting disubstituted *nido* cluster **2**.

A view of cluster **20** is given in Figure 8. A list of the most important bond lengths and angles are given in Table 3.

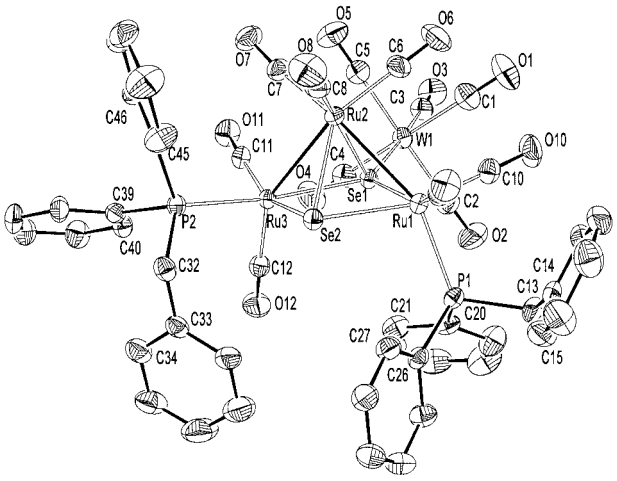

Figure 8. View (ORTEP, 30% probability level) of the molecular structure of **20** with the atom numbering scheme

Table 3. Selected bond lengths (Å) and angles (°) found for compound **20** compared with those calculated for the complex $[(CO)_5W(\mu_4\text{-}Se)Ru_3(\mu_3\text{-}Se)(CO)_7(PH_3)_2]$

	20	$[(CO)_5W(\mu_4\text{-}Se)Ru_3(\mu_3\text{-}Se)(CO)_7(PH_3)_2]$
Ru(1)−Ru(2)	2.802(2)	2.907
Ru(2)−Ru(3)	2.8526(13)	2.902

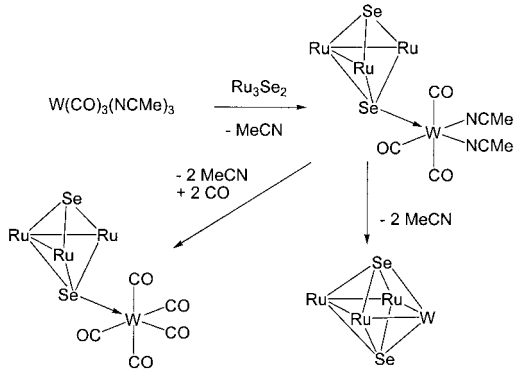
Ru(2)−Se(1)	2.5390(12)	2.698
Ru(3)−Se(2)	2.4950(13)	2.618
Ru(3)−Se(1)	2.5203(15)	2.649
Ru(1)−Ru(2)−Ru(3)	87.01(6)	87
Ru(1)−Se(1)−Ru(3)	101.09(5)	100
Ru(1)−Se(2)−Ru(3)	102.38(5)	100
Se(1)−Ru(1)−Se(2)	77.13(5)	81
Se(1)−Ru(3)−Se(2)	78.25(5)	80

It consists of a $[Ru_3(\mu_3\text{-}Se)_2(CO)_7\{P(CH_2Ph)Ph_2\}_2]$ moiety linked to a $W(CO)_5$ unit through a coordinative interaction between a selenido ligand and the tungsten atoms [Se1−W1 = 2.685(1) Å]. The $[Ru_3(\mu_3\text{-}Se)_2]$ core unit, described as a square pyramid with two ruthenium and two selenium atoms at the base of the pyramid and a ruthenium atom at the apex, is similar to those of **10** and **2** with similar Ru−Ru [2.802(2) and 2.853(1) Å], and Ru−Se bond lengths [ranging from 2.495(1) to 2.539(1) Å]. The two diphenylbenzylphosphane ligands substitute two ruthenium atoms at the base of the pyramid in a *pseudo*-equatorial and *pseudo*-axial position [P1−Ru1 and P2−Ru3 bond lengths of 2.315(1) and 2.345(2) Å]. The quadruply bridging selenido ligand (μ_4-Se) acts as a six-electron donor, two of which serve to attain an 18-electron configuration at the tungsten

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

atom. An analogous unsubstituted compound of formula $[Os_3(\mu_3\text{-}S)(\mu_4\text{-}S)(CO)_9W(CO)_5]$ was previously reported by Adams et al.[16] In contrast to this osmium derivative, the heptacoordinate Ru2 atom is bound to a carbonyl group essentially *trans* with respect to the (μ_4-Se) ligand [Se1−Ru2−C8 176.9(2)°]. In the parent Os compound the carbonyl group is almost *trans* to the (μ_3-S) ligand [S−Os−C 166.4(2)°] and in that case the better donor character of the μ_3-ligand with respect to the μ_4-ligand has been invoked. In the case of **20** the steric hindrance of the two phosphane ligands predominates over the electronic factors and forces the system to be disposed in the observed way.

As regards the mechanism for the production of **20**, we are far from a unique solution, but it could involve a labile intermediate of formula $[Ru_3(\mu_3\text{-}Se)(\mu_4\text{-}Se)(CO)_7\{P(CH_2Ph)Ph_2\}_2W(CO)_3(CH_3CN)_2]$, formed from $[W(CO)_3(MeCN)_3]$ by loss of one acetonitrile ligand. Subsequently, two MeCN ligands could be substituted by two carbonyls. On the other hand, if the labile intermediate loses two acetonitrile ligands, the anchored $W(CO)_3$ fragment can approach the Ru_2Se_2 basal plane of the pyramid (i.e. the cavity of the *nido* polyhedron), leading to the previously described *closo* clusters. These reaction sequences are depicted in Scheme 4. In the case of $PPh_2(CH_2Ph)$, the corresponding dimetallic *closo* cluster has not been obtained, probably because of the steric hindrance of the benzyl group, which does not facilitate the approach of the $W(CO)_3$ moiety.



Scheme 4. (Carbonyl groups omitted)

DFT calculations on the $[(CO)_5W(\mu_4\text{-}Se)Ru_3(\mu_3\text{-}Se)(CO)_7(PH_3)_2]$ model (assuming C_1 symmetry) lead to the optimised bond lengths and angles given in Table 3. They are consistent with those computed for $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(PH_3)_2]$. It is noteworthy that the computed total energy of $[(CO)_5W(\mu_4\text{-}Se)Ru_3(\mu_3\text{-}Se)(CO)_7(PH_3)_2]$ is 1.1 eV lower than that of $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(PH_3)_2]$ + 2CO. Although this value has to be considered as a rough approximation of the enthalpy of the reaction $[(CO)_5W(\mu_4\text{-}Se)Ru_3(\mu_3\text{-}Se)(CO)_7(PH_3)_2] \rightarrow [WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6(PH_3)_2]$ + 2CO it is indicative of thermal stability of **20**. However, the adduct compounds are labile and prone to decompose over silica gel in the air in such a way that they cannot be obtained by TLC as mentioned above. Only in the case of $P(CH_2Ph)Ph_2$ were we able to isolate and characterise the corresponding adduct **20**. Moreover, the yield of these adducts, which does not exceed 40%, is influenced by the scarcity of free CO, which could be the limiting factor in the process of formation of the adduct molecules. Adams et al. observed that these adduct species can be prepared by UV irradiation of solutions of $[Os_3(CO)_9(\mu_3\text{-}S)_2]$ and $W(CO)_6$, giving $[Os_3(CO)_9(\mu_3\text{-}S)(\mu_4\text{-}S)\{W(CO)_5\}]$ in 70% yield.[16] This could be a more convenient route to obtain higher yields of similar adducts.

Experimental Section

General Procedures: The starting reagents $[Ru_3(CO)_{12}]$, elemental selenium, phosphanes and Me_3NO are pure commercial products (Aldrich and Fluka) and were used as received. The solvents (C. Erba) were dried and distilled by standard techniques before use. $[Ru_3Se_2(CO)_7(PPh_3)_2]$[2] $M(CO)_3(CH_3CN)_3$ (M = W or Mo)[17] and clusters **8**−**14**[18] were prepared according to literature procedures. All manipulations (prior to the TLC separations) were carried out under dry nitrogen by means of standard Schlenk-tube techniques. Elemental (C, H) analyses were performed with a Carlo Erba EA 1108 automated analyzer. IR spectra (KBr discs or CH_2Cl_2 solutions) were recorded on a Nicolet "Nexus" spectrometer. ^1H (300 MHz) and ^{31}P (162.0 MHz, 85% H_3PO_4 as external reference) NMR spectra ($CDCl_3$ solutions) were recorded on Bruker instruments, AC 300 (^1H) and AMX 400 (^{31}P). NICI Mass spectra (Negative-Ion Chemical Impact) were recorded on a Fennigan MAT SSQ710; *m*/*z* values are reported as the average of the isotopic distributions.

Synthesis of the Phosphane Selenides: The phosphane selenides were obtained as white powders by reacting the corresponding phosphanes with elemental selenium (in excess) in toluene at 90 °C with vigorous stirring. The solutions were dried in vacuo and the residues were extracted with dichloromethane. All products gave satisfactory elemental analysis. Their purity was checked by ^1H NMR spectroscopy.

$Ph_2(PhCH_2)PSe$: Yield 95%. FT-IR (KBr) $\nu_{(P=Se)}$: 526s cm^{-1}. ^{31}P NMR ($CDCl_3$): δ = 34.3 ppm (s, with ^{77}Se satellites, $^1J_{P,Se}$ = 715 Hz).

$Ph_2(MeO)PSe$: Yield 93%. FT-IR (KBr) $\nu_{(P=Se)}$: 520s cm^{-1}. ^{31}P NMR ($CDCl_3$): δ = 88.0 ppm (s, with ^{77}Se satellites, $^1J_{P,Se}$ = 715 Hz).

(p-MeO-$C_6H_4)_3PSe$: Yield 97%. FT-IR (KBr) $\nu_{(P=Se)}$: 526s cm^{-1}. ^{31}P NMR ($CDCl_3$): δ = 31.5 ppm (s, with ^{77}Se satellites, $^1J_{P,Se}$ = 718 Hz).

$Ph_2(Me)PSe$: Yield 97%. FT-IR (KBr) $\nu_{(P=Se)}$: 528s cm^{-1}. ^{31}P NMR ($CDCl_3$): δ = 23.3 ppm (s, with ^{77}Se satellites, $^1J_{P,Se}$ = 731 Hz).

Reaction of Phosphane Selenides with $[Ru_3(CO)_{12}]$

Reaction with $Ph_2(MeO)PSe$: $[Ru_3(CO)_{12}]$ (300 mg, 0.47 mmol) was reacted in a 1:2 ratio with $Ph_2(MeO)PSe$ (277 mg, 0.94 mmol) in toluene at 70 °C for 1.5 h in the presence of Me_3NO (35 mg, 0.47 mmol) until the solution turned deep reddish brown. The solvents were evaporated to dryness and the residue was redissolved in a small amount of dichloromethane. TLC separation on silica, using a 2:1 dichloromethane/hexane as eluent, yielded three bands

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

together with some minor decomposition. The three bands contained clusters $[Ru_3(\mu_3\text{-}Se)_2(CO)_8\{P(OMe)Ph_2\}]$ (orange, **1**; yield 15%), $[Ru_3(\mu_3\text{-}Se)_2(CO)_7\{P(OMe)Ph_2\}_2]$ (red, **2**; yield 30%) and $[Ru_4(\mu_4\text{-}Se)_2(\mu\text{-}CO)_2(CO)_7\{P(OMe)Ph_2\}_2]$ (deep red, **3**; yield 25%) in order of elution.

3: FT-IR (CH_2Cl_2): ν(CO): 2041w, 2012vs, 2000s, 1966m, 1844w, 1807w cm^{-1}. ^1H NMR ($CDCl_3$, 298 K): δ = 3.58 and 3.66 (d, $^2J_{H,P}$ = 13.2 Hz, 6 H, CH_3), 7.26−7.64 (m, 20 H, 4Ph). $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ = 139 (s) ppm. $C_{35}H_{26}O_{11}P_2Ru_4Se_2$: calcd. C 33.8, H 2.11; found C 33.5, H 2.12.

Reaction with $Ph_2(Me)PSe$: $[Ru_3(CO)_{12}]$ (300 mg, 0.47 mmol) was reacted in a 1:2 ratio with $Ph_2(Me)PSe$ (260 mg, 0.94 mmol) in toluene at 70 °C for 2 h in the presence of Me_3NO (35 mg, 0.47 mmol) until the solution turned deep reddish brown. The solvents were evaporated to dryness and the residue was redissolved in a small amount of dichloromethane. TLC separation on silica gel, using 3:1 dichloromethane/hexane as eluent, yielded four bands: an orange, a red, a brown and a deep red one in order of elution. The four bands contained compounds $[Ru_3(\mu_3\text{-}Se)_2(CO)_8\{P(Me)Ph_2\}]$ (**4**; yield 15%), $[Ru_3(\mu_3\text{-}Se)_2(CO)_7\{P(Me)Ph_2\}_2]$ (**5**; yield 30%), $[Ru_4(\mu_4\text{-}Se)_2(\mu\text{-}CO)_2(CO)_7\{P(Me)Ph_2\}_2]$ (**6**; yield 10%) and $[Ru_4(\mu_4\text{-}Se)_2(\mu\text{-}CO)(CO)_7\{P(Me)Ph_2\}_3]$ (**7**; yield 25%).

4: FT-IR (CH_2Cl_2): ν(CO): 2077s, 2043vs, 2025s, 2066s, 1975m cm^{-1}. ^1H NMR ($CDCl_3$, 298 K): δ = 2.49 (br., 3 H, CH_3), 7.4−7.8 (m, 10 H, 2Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ = 37.2 (s) ppm. $C_{21}H_{13}O_8PRu_3Se_2$: calcd. C 28.6, H 1.48; found C 28.6, H 1.47.

5: FT-IR (CH_2Cl_2): ν(CO): 2045vs, 2009vs, 1967m, 1946w cm^{-1}. ^1H NMR ($CDCl_3$, 298 K): δ = 2.20 (br), 2.32 (d) and 2.52 (d, $^2J_{H,P}$ = 9.3 Hz, 6 H, CH_3), 7.3−7.7 (m, 20 H, 4Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ = 52 (s), 43 (s) (isomer B); 47 (br), 40 (br) (isomer A) ppm. $C_{33}H_{26}O_7P_2Ru_3Se_2$: calcd. C 37.6, H 2.48; found C 37.3, H 2.41.

6: FT-IR (CH_2Cl_2): ν(CO): 2056w, 2038w, 2010vs, 1992sh, 1961sh, 1839w, 1800w cm^{-1}. ^1H NMR ($CDCl_3$, 298 K): δ = 2.07 (d) and 2.12 (d, $^2J_{H,P}$ = 9 Hz, 6 H, CH_3), 7.3−7.6 (m, 20 H, 4Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ = 35.15 (s), 25.1 (s) (3:2). $C_{35}H_{26}O_9P_2Ru_4Se_2$: calcd. C 34.7, H 2.16; found C 34.5, H 2.14.

7: FT-IR (CH_2Cl_2): ν(CO): 2017s, 1995vs, 1984s, 1955m, 1789w cm^{-1}. ^1H NMR ($CDCl_3$, 298 K): δ = 2.02 (d) and 2.30 (d, $^2J_{H,P}$ = 8.4 Hz, 9 H, CH_3), 7.2−7.9 (m, 30 H, 6Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ = 23.3 (s), 30.0 (s) (2:1). $C_{47}H_{39}O_8P_3Ru_4Se_2$: calcd. C 40.8, H 2.84; found C 40.3, H 2.81.

Synthesis of $[WRu_3(\mu_4\text{-}Se)_2(\mu\text{-}CO)_4(CO)_6\{P(OMe)Ph_2\}_2]$ (15): Compound **2** (50 mg, 0.089 mmol) and $[W(CO)_3(CH_3CN)_3]$ (50 mg, 0.128 mmol) were stirred in dry CH_2Cl_2 for 1 h at room temperature under N_2. The resulting dark solution was evaporated to dryness and the residue was dissolved in CH_2Cl_2 (10 mL). The product (cluster **15**, yield 40%) was separated and purified by TLC on silica gel, using diethyl ether/light petroleum (b.p. 40−60 °C) (2:1) as eluent mixture. FT-IR (CH_2Cl_2): ν(CO): 2043m, 2007vs, 1987vs, 1894m, 1910m, 1831w, 1799w cm^{-1}. ^1H NMR ($CDCl_3$, 298 K): δ = 3.49 (d), 3.58 (d), 3.66 (d) and 3.73 (d, 6 H, $^3J_{H,P}$ = 13.5 Hz, CH_3) (8:4:1:1); 7.10−7.80 (m, 20 H, 4Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ = 130.0 (s) ppm. MS (NICI): *m/z* (%) = 1356 (95) $[Ru_3W(\mu_4\text{-}Se)_2(CO)_{10}\{P(OMe)Ph_2\}_2]^+$, 1300 (100) $[Ru_3W(\mu_4\text{-}Se)_2(CO)_8\{P(OMe)Ph_2\}_2]^+$, 1272 (42) $[Ru_3W(\mu_4\text{-}Se)_2(CO)_7\{P(OMe)Ph_2\}_2]^+$, 1244 (15) $[Ru_3W(\mu_4\text{-}Se)_2(CO)_6\{P(OMe)Ph_2\}_2]^+$, 1216 (21) $[Ru_3W(\mu_4\text{-}Se)_2(CO)_5\{P(OMe)Ph_2\}_2]^+$, 1188 (16) $[Ru_3W(\mu_4\text{-}Se)_2(CO)_4\{P(OMe)Ph_2\}_2]^+$, 1160 (28) $[Ru_3W(\mu_4\text{-}Se)_2(CO)_3\{P(OMe)Ph_2\}_2]^+$, 1104 (25) $[Ru_3W(\mu_4\text{-}Se)_2(CO)\{P(OMe)Ph_2\}_2]^+$, 1076 (10) $[Ru_3W(\mu_4\text{-}Se)_2\{P(OMe)Ph_2\}_2]^+$. $C_{36}H_{26}O_{12}P_2Ru_3Se_2W$: calcd. Crystal Structure Determination of 2, 10, 15, 17, 18, 19 and 20·2CH$_2$Cl$_2$: Suitable crystals for the X-ray analysis for all complexes were obtained by layering methanol on dichloromethane solutions. The intensity data, at room temperature, of **2**, **10** and **20·2CH$_2$Cl$_2$** were collected on a Bruker AXS Smart 1000 single crystal diffractometer (equipped with an area detector using a graphite monochromated Mo-K_α radiation, λ = 0.71073 Å), those of **15**, **17**, and **18** on a Philips PW 1100 single-crystal diffractometer (graphite monochromated Mo-K_α radiation, λ = 0.71073 Å) and those of **19** on an Enraf Nonius CAD 4 single-crystal diffractometer (graphite monochromated Cu-K_α radiation, λ = 1.54184 Å). Crystallographic and experimental details for the structures are summarised in Table 4. An empirical correction for absorption was made for **15**, **17**, **18** and **19** [maximum and minimum value for the transmission coefficient was 1.000 and 0.7262 (**15**), 1.000 and 0.6872 (**17**), 1.000 and 0.5947 (**18**) and 1.000 and 0.460 (**19**)].[19a,19b] For complexes **2**, **10** and **20·2CH$_2$Cl$_2$** [maximum and minimum effective transmission value was 1.000 and 1.000 (**2**), 1.000 and 0.8532 (**10**) and 1.000 and 0.5104 (**20·2CH$_2$Cl$_2$**)] the raw frame data were processed using SAINT and SADABS to yield the reflection data file and the Bruker software was used for the absorption correction.[19c−19e] The structures were solved by Patterson and Fourier methods and refined by full-matrix least-squares procedures (based on F_o^2) (SHELX-97)[20] first with isotropic thermal parameters and then with anisotropic thermal parameters in the last cycles of refinement for all the non-hydrogen atoms. In the crystals of **20** dichloromethane molecules of solvation were found. The hydrogen atoms were introduced into the geometrically calculated positions and refined as riding on the corresponding parent atoms.

In the crystals of **17**, **18** and **19** a disorder exists which involves the mutually opposite Ru and W atoms of the *closo* core of the cluster, resulting in a disordered $[Ru_3M(\mu_4\text{-}Se)_2]$ core, distributed in two positions with the same occupancy factor, instead of the centrosymmetric $[M_2Ru_2(\mu_4\text{-}Se)_2]$ core.

CCDC-208915 (**2**), -208916 (**10**), -208917 (**15**), -208920 (**17**), -208918 (**18**), -208919 (**19**) and -208921 (**20·2CH$_2$Cl$_2$**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details: Density functional theory (DFT) calculations were carried out using the Amsterdam density functional (ADF) program[21] developed by Baerends and co-workers.[22] The Vosko−Wilk−Nusair parameterization[23] was used for the local density approximation (LDA) with gradient correction for exchange (Becke88)[24] and correlation (Perdew86).[25] Relativistic corrections were added using the ZORA (Zeroth Order Regular Approximation) scalar Hamiltonian.[26] The atom electronic configurations were described by a triple-ξ Slater-type orbital (STO) basis set for H 1s, C, O 2s and 2p, P 3s and 3p and Se 4s and 4p augmented with a 3d single-ξ polarisation function for C, O, P, with a 2p single-ξ polarisation function for H and 4d single-ξ polarisation function for Se. A triple-ξ STO basis set was used for Mo, Ru 4d and 5s and for W 5d and 6s augmented with a single-ξ 5p for Mo and Ru and 6p for W. A double-ξ STO basis set was used for W 5s and 5p. A frozen-core approximation was used to treat the core electrons of C, O, P, Se, Mo, Ru and W.

Synthesis and Characterization of a Series of (Diphenyldipyrazolylmethane)copper Complexes as Possible Precursors to Type I Blue Copper Protein Active Site Models

Janet L. Shaw,[a] Thomas B. Cardon,[b] Gary A. Lorigan,[b] and Christopher J. Ziegler*[a]

Keywords: Copper / N ligands / Pyrazolylmethanes / Scorpionates

A series of copper complexes employing the neutral, bidentate, pyrazole-based ligand diphenyldipyrazolylmethane was synthesized and fully characterized by various techniques, including elemental analysis, EPR, and structure elucidation by single-crystal X-ray diffraction. The structures of compounds **3**–**8** reveal variable coordination environments at the copper center, ranging from square pyramidal to tetrahedral, depending on the steric bulk at the pyrazole periphery and on the identity of the counterion. Cyclic voltammetry data on these compounds show a positively shifted reduction potential as compared to those observed employing the negatively charged pyrazolylborates or β-diketiminates. These results indicate that these compounds may lead to (thiol)copper complexes that more accurately reproduce the reduction potentials observed during electron-transfer processes in blue copper proteins.

Introduction

Small models of the active sites of metalloenzymes remain important for understanding the structure−function relationships that exist between immediate metal-ion coordination environments and activities such as electron transport or dioxygen activation. Scorpionate ligands, such as the sterically hindered pyrazolylborates (see Figure 1), have been successful in mimicking many of the coordination geometries observed in the active sites of metalloproteins.[1−3] In addition to numerous zinc complexes,[4−6] pyrazolylborates have been employed for generating models of both type I blue copper proteins[7−10] and type III dicopper proteins,[11] such as plastocyanin and hemocyanin, respectively.[12−13] The ease of synthesis, the ability to add additional bulk to the pyrazole moieties, and the favorable multidentate binding mode are all responsible for the continued interest in pyrazolylborates as ligands for small model complexes. However, pyrazolyborates are negatively charged and can lead to complexes with higher oxidation states than those of the metal sites in native proteins.[14] Therefore, work continues toward the development of model complexes that can more accurately model the geometry and electronic structure of metal ions in proteins.

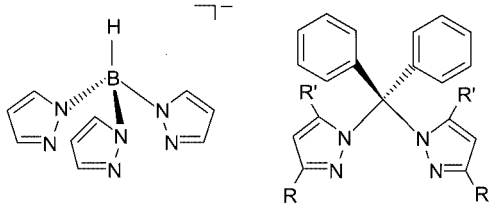

Figure 1. Schematic drawings of the ligands tris(pyrazolyl)borate (left) and diphenyldipyrazolylmethane (right) where R = R′ = H (**1**), R = R′ = CH_3 (**2**) and R = CH_3, R′ = H (**3**)

We have begun to explore the synthesis of active site models for copper proteins using the ligand diphenyldipyrazolylmethane, shown in Figure 1. Synthesized previously for use in polymerization catalysis,[15−16] this ligand is neutral and contains two pyrazole moieties available for bidentate metal-ion coordination. Like the pyrazolylborates, the pyrazole rings may be functionalized to incorporate more steric bulk around the copper center. This can be exploited to enforce desired geometries, inhibit the formation of bridging species, or promote low-coordination-number end products. Once synthesized, these compounds may be useful as starting materials in reactions with thiol or carboxylate-containing ligands to produce small model complexes of copper-enzyme active sites. Since these models incorporate a neutral ligand, we believe that they will exhibit redox potentials that more closely resemble those observed in nature

for type I blue copper proteins. Here we report our results on the synthesis and characterization of some (diphenyldipyrazolylmethane)copper complexes including crystal structures, cyclic voltammetry, and electron paramagnetic resonance spectra. We observe high potentials for the Cu^{II}/Cu^{I} redox couple, and increased steric bulk at the periphery of the pyrazole ring enforces lower coordination numbers.

Results and Discussion

The diphenyldipyrazolylmethanes (Figure 1, right) were synthesized using a modified procedure reported by Trofimenko that involves the generation of a pyrazolide ion and subsequent reaction with a dihalomethane.[17] These ligands have previously been employed in molybdenum[15] and palladium[16] complexes for use as catalysts. Figure 2 shows the crystal structures elucidated for ligands **1** and **2**. The C(1)−N(1,3) bond lengths in **1** are 1.490(4) Å and 1.484(4) Å, respectively, while in **2** they are 1.4753(17) Å and 1.4754(16) Å. The angle formed by N3−C1−N1 in **1** is 108.0(2)°, while in **2** it is 104.85(10)°. Based on their structural characteristics, these ligands should act as bidentate chelators. A comparison of the bond angles and lengths for these two ligands can be found in Table 1.

The copper complexes were synthesized by a reaction of either copper(II) nitrate or copper(I) chloride with the appropriate ligand in a number of organic solvents. In most cases the final product remained soluble throughout the reaction and was isolated by recrystallization from the appropriate solvent. All reactions produce X-ray quality crystals with little purification required.

A survey of the literature uncovers few examples of 1:1 complexes forming between dipyrazolyalkanes and either copper(I) or copper(II),[18−21] with the preference instead being 2:1 ligand-to-metal complexation.[22−23] Of these, less crystallographic information is available and the compounds have instead been characterized by other techniques such as IR spectroscopy, magnetic susceptibility, EPR, and ^{1}H NMR spectroscopy. The stoichiometry of the observed final products in the literature appears to depend on the starting copper salt (chloride salt vs. nitrate salt) and the degree of steric hindrance at the pyrazole periphery.

Unlike in the dipyrazolylalkane complexes, the majority of the compounds reported here form 1:1 complexes. The geometries of compounds **4**−**8** range from square pyramidal to tetrahedral, depending on the steric bulk at the pyrazole periphery and the counterion identity. Table 2 and Table 3 present relevant bond lengths and angles and the crystallographic data for compounds **4**−**8**, respectively. Compound **4** (see Figure 3) is best described as having a distorted square-pyramidal geometry. The copper(II) center is ligated by one bidentate **1** ligand, two nitrates and one water molecule in the axial position. The methanol employed in this reaction was not dried prior to use, and the

ligated water molecule may have come from residual water in the reaction solvent. The nitrates bind in a monodentate fashion with Cu−O distances of 1.971(3) Å and 1.975(3) Å. Within the literature, the modes of nitrate bonding can vary. For example, in the similar compound $Cu(bmpp)(NO_3)_2$ the two nitrates coordinate to the copper in an unsymmetrical bidentate fashion with Cu−O distances of 2.026(2) Å.[24] The Cu−O distance for the coordinating water molecule is 2.256(4) Å and the Cu−N bond lengths are both around 1.986(4) Å.

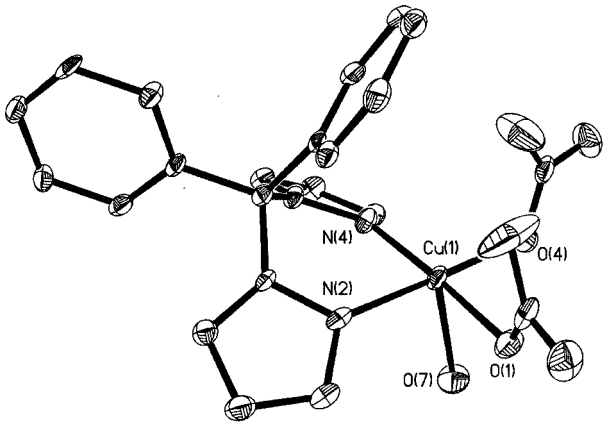

Figure 3. Structure of compound **4** with hydrogens omitted for clarity and thermal ellipsoids drawn at 50 % probability

Compound **5** (Figure 4) exhibits a similar geometry to complex **4**, but the water molecule in the coordination sphere is absent and one of the nitrates binds in a bidentate fashion with Cu−O distances of 1.9959(16) Å and 2.0110(19) Å. These distances are somewhat longer than those seen in **4** for the nitrates bound in a monodentate fashion. The lack of a coordinating water molecule may be due to the increase in steric bulk at the 3 position of the pyrazole ring in **5**. The coordination sphere of **5** is completed with a bidentate **3** ligand [Cu−N4 1.9344(18) and Cu−N2 1.9610(18)] and one monodentate nitrate group [Cu−O1 2.1361(17) Å]. Increasing the steric bulk at the pyrazole periphery in compound **5** alters the geometry from square pyramidal to pseudotetrahedral. In addition, the coordination geometry at the copper center is affected by the binding mode of the nitrate counterion. Whereas in compound **4** both nitrates ligate in a monodentate fashion, in compound **5** one nitrate is bidentate and the other is monodentate. This variable coordination mode of the nitrate counterion is not uncommon.

Unlike the Cu^{II} compounds, the Cu^{I} compound **7**, shown in Figure 5, forms a product with a 2:1 ratio of ligand to metal ion. The copper ion is in a distorted tetrahedral environment with two bidentate **1** ligands with Cu−N distances ranging from 2.007(3) Å to 2.045(3) Å and with N−Cu−N angles ranging from 91.38(10)° to 128.05(10)°. The intraligand N−Cu−N angles are closer to 90° while the interligand N−Cu−N angles are both near 120°. The bond lengths compare nicely to those reported for other 2:1 complexes $[Cu(bpp)_2](BF_4)$ (about 2.031 Å)[23] and $[CuL_2](ClO_4)$ (about 2.037 Å), where L = bis[2,2′-bis(2-imidazolyl)-biphenyl].[25] The bond angles in compound **7** show a slight compression along the intraligand axes. These bond angles compare well with those observed in the copper(II) complexes α- and β-$[Cu(bpp)_2](BF_4)_2$ (95.23−127.20° and 91.34−135.66°, respectively).[23] It is unclear as to why **7** exists as a 2:1 complex, but similar results have been observed in the literature: the ligand-to-metal ratio was found to depend not only on the steric bulk at the pyrazole periphery but also on the identity of the counterion.[21,26]

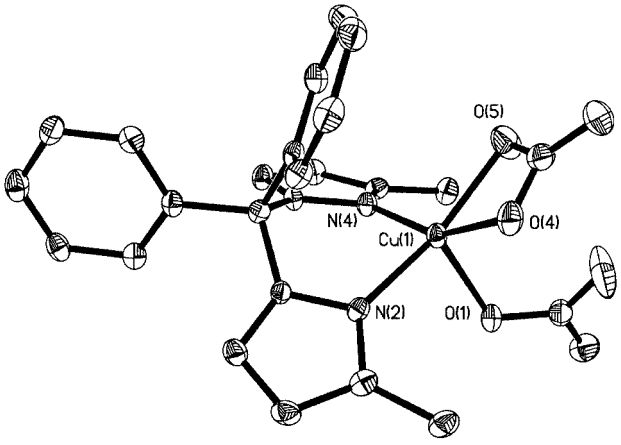

Figure 4. Structure of compound **5** with hydrogens omitted for clarity and thermal ellipsoids drawn at 50 % probability

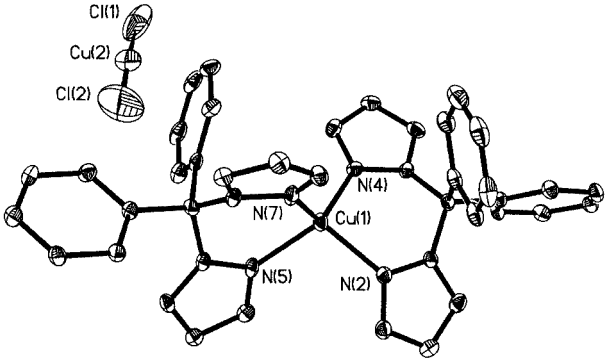

Figure 5. Structure of compound **7** with hydrogens omitted for clarity and thermal ellipsoids drawn at 50 % probability

Exposing an acetonitrile solution of compound **7** to air causes the clear solution to turn green over a 12 hour period. This color change is due to the oxidation of the d^{10} copper(I) compound (**7**) to the d^9 copper(II) compound (**8**). Crystals of the green solid **8** (see Figure 6) were grown from the air-exposed product by layering a solution of CH_2Cl_2 with hexane at room temperature. The crystal structure was elucidated and was found to contain a Cu^{II} ion in a tetrahedral-coordination environment with one bidentate **1** ligand and two ligated chloride ions. The average Cu−N and Cu−Cl bond lengths are 1.986(4) Å and 2.223(16) Å, respectively. These lengths are in close agreement with those reported for the tetrahedral complex Cu(bdpp)Cl_2, where bdpp is 1,3-bis(3′,5′-dimethylpyrazol-1′-yl)propane.[24] The N−Cu−N bond angle is 88.72(16)° and the N−Cu−Cl bond angles range from 91.36(12)−153.99(12)°, thus exhibiting a distorted tetrahedral environment at the copper center.

Unlike in the synthesis of compounds **4**−**8**, something unanticipated occurs upon reacting **2** with copper nitrate: the ligand decomposes. The product that forms (compound **6**) is a five-coordinate, distorted, square-pyramidal copper(II) complex with three ligating 3,5-dimethylpyrazole moieties and two monodentate nitrates (Figure 7). Relevant bond angles and lengths are listed in Table 2. The Cu−N bond-length values compare nicely to those reported for the polymeric $[Cu(pyrazole)_2]_x$ complex [1.992(6) Å vs. 1.957(2) Å].[27]

Similar examples have been documented in the literature for the decomposition of pyrazole-based ligands upon reac-

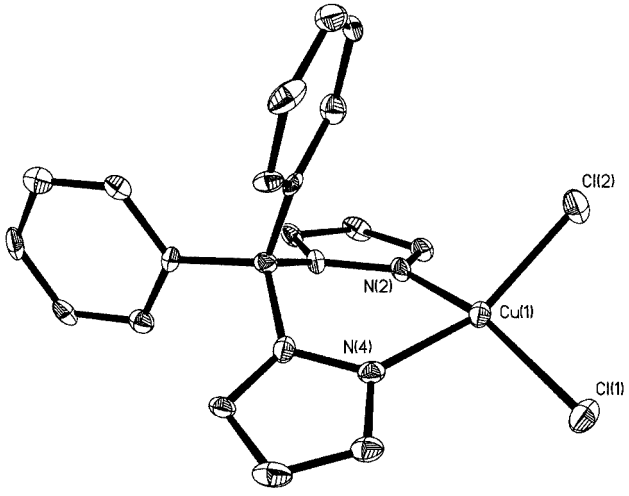

Figure 6. Structure of compound **8** with hydrogens omitted for clarity and thermal ellipsoids drawn at 50 % probability

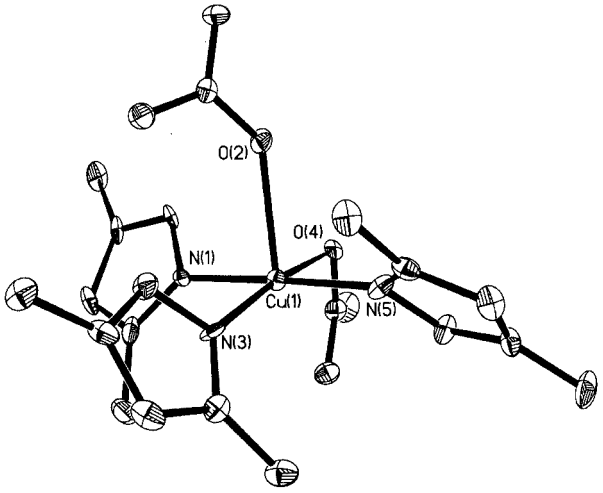

Figure 7. Structure of compound **6** with hydrogens omitted for clarity and thermal ellipsoids drawn at 50 % probability

tion with metal salts.[28,29] The proposed mechanism involves metal-mediated cleavage of the pyrazole nitrogen−X bond, where X may be boron, as is the case with pyrazolylborates, or carbon, as is the case in this report. We do not believe that compound **6** is a product of pyrazole impurity from the previous ligand synthesis because complete characterization of the Pz''_2CPh_2 ligand, prior to use in this metallation reaction, indicates purity. Attempts are currently under way to synthesize the $Cu(Pz''_2CPh_2)$ derivative under anaerobic conditions using dry solvents.

The low-temperature solution state EPR spectra of compounds **4**, **5**, **6** and **8** are shown in Figure 8. Changes in the features of such spectra result from the coordinated ligands, the compound geometry, and the compound charge, in decreasing order of importance.[30,31] Because the ligands used here are nearly identical, varying only by one methyl substituent, and because the coordination geometry of each complex is similar, as seen in Figures 3 4, 5 and 6, one would expect little change in the EPR spectrum of each compound, as is seen in Figure 8. Calculated $g_{\|}$, $g\perp$ and $A_{\|}$ values are shown in Table 4 and these values are similar to those recorded in the literature for compounds with similar structures.[24,32−34] The hyperfine splitting pattern for a Cu 3/2 spin is observed but there are no observable superhyperfine interactions. Calculated $A_{\|}$ values for **5** reveal a slight compression in this region of the spectra.

Table 4. Selected EPR parameters for **4**, **5**, **6** and **8**

	$g_{\|}$	$g_{\perp}$	$A_{\|}$
4	2.492	2.074	160 G
5	2.312	2.079	149 G
6	2.298	2.063	158 G
8	2.287	2.068	164 G

The cyclic voltammogram of **4** is shown in Figure 9. The quasi-reversible wave at 0.55 V vs. SCE (E_{pc} at 0.48 V, E_{pa} at 0.62 V, 0.31 V vs. NHE) is attributed to the Cu^{II}/Cu^{I} redox couple. A scan rate of 50 mv/s afforded optimal reversible behavior. A cyclic voltammogram was also acquired for compound **5** and is shown in Figure 9. The reversible wave at 0.63 V vs. SCE (E_{pc} at 0.55 V, and E_{pa} at 0.71 V, 0.39 V vs. NHE) is also ascribed to the Cu^{II}/Cu^{I} redox pair and is shifted by +0.1 V as compared to that observed for **4**. Once again, the best spectra resulted when

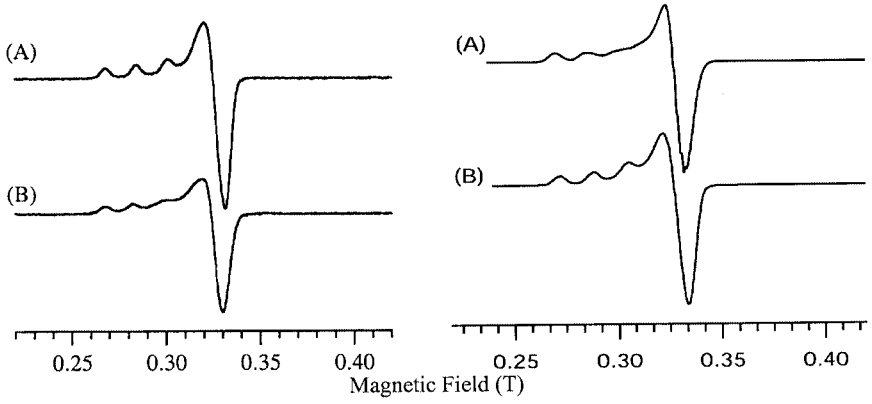

Figure 8. EPR spectra of compounds **4** (top, left), **5** (bottom, left), **6** (top, right) and **8** (bottom, right) (9.42 GHz) in MeOH at 120 K

a scan rate of 50 mv/s was used. Altering this scan speed resulted in a decreased intensity of the voltammogram half-wave features.

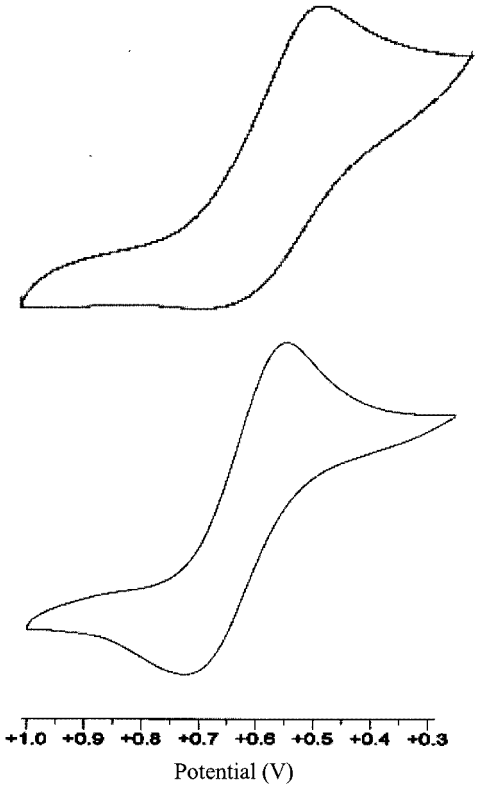

Figure 9. Cyclic voltammograms of compounds **4** (top) and **5** (bottom) at a scan rate of 50 mV/s in CH_3CN with 0.1 M $[Bu_4N]BF_4$ vs. SCE; y-axis is current measured in uA

These potentials are more positive than those of other copper-model complexes in the literature. For instance, in the β-diketiminate copper complex, LCuCl, where L is 2,4-bis(2,6-diisopropylphenylimido)pentane, a half-potential of −0.78 V vs. ferrocene (0.02 V vs. NHE) was reported in CH_2Cl_2.[33] This shift to a more negative potential results, in part, from the negative charge on the diketiminate ligand. The charge shifts the preference toward a +2 oxidation state at the copper center, thus resulting in a more negative potential for the Cu^{II}/Cu^{I} redox couple. Subsequent thiol complexes that incorporate either the above mentioned β-diketiminate or the popular tris(pyrazolyl)borate ligands also have reduction potentials that are significantly lower than those observed in copper-active sites in biology.[7,14]

Attempts were made to isolate thiol complexes by reacting complexes **3** and **4** with bulky aryl thiols such as triphenylmethanethiol or bidentate thiols such as 1,2-benzenedithiol. Each time decomposition occurs forming a reduced metal compound, indicative of colorless copper(I), and the disulfide. A reaction of compound **5** with 1,2-benzenedithiol did lead to a stable green complex in DMF, but crystals were not of X-ray quality. Further work is being done to determine the identity of this product. In addition, attempts are currently under way to further protect the copper ion from reduction chemistry, by increasing the steric bulk at the pyrazole periphery from a methyl to a *tert*-butyl group.

Conclusion

Diphenyldipyrazolylmethane reacts with commercially available copper salts to form low-coordination-number copper complexes. Reactions with copper(II) nitrate produce 1:1 complexes, while the reaction with copper(I) chloride yields a 2:1 complex. Similar compounds presented in the literature, employing dipyrazolylalkanes, produce mainly 2:1 complexes and it is therefore believed that the phenyl rings employed here provide additional protection to the copper ion. Also, the ability of the nitrate counterion to coordinate in different modes (monodentate or bidentate) influences the coordination environment of the copper ion. Additional counterions may be studied in order to affect changes in the copper ion-coordination environment. The geometry of these compounds in the solution state can be further studied by performing conductivity experiments in alcoholic solutions.

We hope that the diphenyldipyrazolyl ligands will produce more biologically relevant model complexes than those that currently exist in the literature because the neutrality of our ligand produces copper complexes with more positive reduction potentials than those observed employing negatively charged ligands, such as the pyrazolylborates. We find that increasing the steric bulk on the pyrazole ring, from compound **4** to compound **5**, leads to a slight preference for copper(I) rather than copper(II), based on the reduction potentials, because of the nearly tetrahedral geometry supported by this ligand. A delicate balance between these two oxidation states is necessary in order to adequately replicate the redox behavior observed in biology in type I blue copper proteins.

Experimental Section

All solvents and starting materials were obtained from commercially available sources and were used without further purification. Mass spectra were recorded using an ES MS Bruker Esquire-LC ion-trap mass spectrometer. ^{1}H NMR spectra were measured on a Gemini 300 MHz spectrometer. The elemental analysis was performed on a CE440 analyzer at the School of Chemical Sciences Microanalysis Laboratory at the University of Illinois at Urbana-Champaign. EPR data were collected at the University of Miami in Ohio. UV/Visible spectra were obtained using a Hitachi U-3010 instrument.

Synthesis of Diphenyldipyrazolylmethane Pz_2CPh_2 (1): All three ligands were synthesized using a slight modification of the procedure by Trofimenko.[17] After isolation of the yellow solid, the ligand was washed with hexanes to yield 1.13 g of white solid (47.7 % yield). Recrystallization by slow evaporation of a saturated toluene solution yielded crystals suitable for single-crystal X-ray diffraction. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.65 (d, 2 H, 3-pz), 7.52 (d, 2 H, 5-pz), 7.43−7.33 (m, 6 H, ph), 7.06−7.03 (m, 4 H, ph), 6.31 (dd, 2 H, 4-pz). ES MS (+ ion, MeOH) 323.1 *m*/*z* [M +

Na]. $C_{19}H_{16}N_4$ (300.36): calcd. C 75.97, H 5.38, N 18.64; found C 75.04, H 5.30, N 18.20.

Synthesis of Diphenylbis(3,5-dimethylpyrazolyl)methane Pz''_2CPh_2 (2): Ligand **2** was prepared similarly to ligand **1**. After workup, 1.06 g of yellow solid (43.0 % yield) were obtained. Crystals suitable for X-ray structural elucidation were grown from a THF/CH_3CN solvent mixture. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.30−7.20 (m, 6 H, ph), 7.05−6.95 (m, 4 H, ph), 6.01 (s, 2 H, 4-pz), 2.22 (s, 6 H, 3-methyl), 1.58 (s, 6 H, 5-methyl). ES MS (+ ion, $CHCl_3$/MeOH) 379.2 *m*/*z* [M + Na]. $C_{23}H_{24}N_4$ (356.46): calcd. C 77.49, H 6.80, N 15.71; found C 77.04, H 6.75, N 15.45.

Synthesis of Diphenylbis(3-methylpyrazolyl)methane Pz'_2CPh_2 (3): Ligand **3** was prepared similarly to ligands **1** and **2**. The resulting yellow-orange solution was filtered and reduced under vacuum to afford a yellow oil. Hexanes were added to precipitate out a small amount of brown solid. A yellow solid resulted upon evaporation of the hexanes. This was washed with hexanes and deionized water to yield 1.70 g of a light yellow solid (58.7 %). ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.4 (s, 2 H, 5-pz), 7.4−7.3 (m, 6 H, ph), 7.2−7.1 (m, 4 H, ph), 6.05 (d, 2 H, 4-pz), 2.3 (s, 6 H, 3-methyl). ES MS (+ ion, $CHCl_3$/MeOH) 351.2 *m*/*z* [M + Na]. $C_{21}H_{20}N_4$ (328.41): calcd. C 76.80, H 6.15, N 17.05; found C 76.79, H 6.17, N 16.43.

Synthesis of $Cu(Pz_2CPh_2)(NO_3)_2\ H_2O$ (4): $Cu(NO_3)_2$ (0.082 g, 0.44 mmol) in MeOH (10 mL) was combined with a methanol solution of **1** (0.131 g, 0.44 mmol). The blue copper solution darkened upon combining the two reagents. The reaction was allowed to stir for 2 hours at room temperature. This solution was then reduced under vacuum to yield a blue solid. Recrystallization by layering of CH_2Cl_2 and hexane at −42 °C yielded crystals suitable for single-crystal X-ray diffraction (79.1 % yield). UV/Vis (CH_2Cl_2), λ (ε) = 716.0 nm (68 $M^{-1}cm^{-1}$). ES MS (+ ion, MeOH) 425.0 *m*/*z* [M − NO_3]. $C_{19}H_{16}CuN_6O_6$ (505.93): calcd. C 46.77, H 3.31, N 17.22; found C 46.38, H 3.18, N 16.85. $E_{1/2}$ (CH_3CN) 0.55 V vs. SCE (E_{pc} at 0.48 V, E_{pa} at 0.62 V).

Synthesis of $Cu(Pz'_2CPh_2)(NO_3)_2$ (5): $Cu(NO_3)_2$ (0.106 g, 0.56 mmol) dissolved in THF (10 mL) was added to a solution of **3** (0.185 g, 0.56 mmol) in THF (10 mL). The resulting green solution was stirred for 2 hours at room temperature. This solution was then reduced under vacuum to yield a green-blue solid. Crystals were obtained by layering CH_2Cl_2 with hexane at room temperature (75.3 % yield). Two crystal morphologies of this compound formed: blue needles that do not diffract X-rays well, and green blocks that were suitable for single-crystal X-ray diffraction. UV/Vis (CH_2Cl_2), λ (ε) = 779.0 nm (70 $M^{-1}cm^{-1}$). ES MS (+ ion, THF/MeOH) 453.0 *m*/*z* [M − NO_3]. $C_{21}H_{20}CuN_6O_6$ (515.97): calcd. C 48.89, H 3.92, N 16.28; found C 49.61, H 4.11, N 15.94. $E_{1/2}$ (CH_3CN) 0.63 V vs. SCE (E_{pc} at 0.55 V, and E_{pa} at 0.71 V).

Synthesis of $Cu(Pz'')_3(NO_3)_2$ (6): $Cu(NO_3)_2$ (0.264 g, 1.4 mmol) in MeOH (10 mL) was combined with a methanol solution of **2** (0.501 g, 1.4 mmol). The ligand was only partially soluble in methanol. The murky reaction was stirred for 12 hours and then allowed to evaporate down to afford a bluish-green solid. The solid was redissolved in CH_2Cl_2 and filtered to yield two products: a green solid and a blue solid (63.2 % yield crude product). Crystals of the blue solid were grown by layering CH_2Cl_2 and hexane at −42 °C. UV/Vis (CH_2Cl_2), λ (ε) = 633.0 nm (56 $M^{-1}cm^{-1}$). ES MS (+ ion, THF/MeOH) 317.1 *m*/*z* [M − NO_3 − Pz″]. $C_{15}H_{24}CuN_8O_6$ (475.96): calcd. C 37.86, H 5.09, N 23.53; found C 37.99, H 4.95, N 22.59. $E_{1/2}$ (CH_3CN) 0.70 V vs. SCE (E_{pc} at 0.63 V, E_{pa} at 0.77 V).

Syntheses of $[Cu(Pz_2CPh_2)_2]CuCl_2$ (7) and $Cu(Pz_2CPh_2)Cl_2$ (8): In a dry box with a nitrogen atmosphere, CuCl (0.052 g, 0.52 mmol) and **1** (0.155 g, 0.52 mmol) were combined in CH_3CN (10 mL). The resultant clear solution was left to stir for 6 hours. Slow evaporation of the reaction solution yielded clear crystals of compound **7** suitable for single-crystal X-ray diffraction (quantitative yield). The crystal structure was solved in the *Cc* space group. The literature reports that this space group can be problematic[35,36] so attempts were also made to solve the structure using the suggested *C*2/*c* space group, which incorporates a center of symmetry. However, refinement using *C*2/*c* was poor (R_1 ca. 20 %) as compared to *Cc* (R_1 = 3.83 %) and it was determined that the correct space group for structural elucidation was, in fact, *Cc*. In addition, the structure solved using *Cc* has C−C phenyl ring bond lengths [1.373(5)−1.404(4) Å] closer to the literature value of 1.397 Å, as compared to those for the elucidated structure in *C*2/*c* (1.305−1.434 Å). ES MS (+ ion, MeOH) 663.3 *m*/*z* [M − $CuCl_2$]. $C_{38}H_{32}Cl_2Cu_2N_8$ (798.70): calcd. C 57.14, H 4.05, N 14.02; found C 57.22, H 3.91, N 14.22.

A portion of compound **7** was redissolved in CH_3CN and exposed to air. The white solution of **7** gradually turned green over a 12 hour period. Crystals of the final oxidized green product (**8**) were grown by layering CH_2Cl_2 and hexane at room temperature. Additionally, compound **8** was synthesized by the reaction of $CuCl_2$ (0.158 g, 1.1 mmol) in THF (5 mL) with a THF solution of **1** (0.352 g, 1.2 mmol). Upon combining the two solutions a green precipitate formed immediately. The precipitate was removed via filtration and washed with additional THF (59.9 % yield). UV/Vis (CH_2Cl_2), λ (ε) = 417.0 nm (644 $M^{-1}cm^{-1}$), 677.0 (86 $M^{-1}cm^{-1}$). ES MS (+ ion, $CHCl_3$) 398.2 *m*/*z* [M − Cl]. $C_{19}H_{16}Cl_2CuN_4$ (434.80): calcd. C 52.47, H 3.72, N 12.88; found C 52.10, H 3.72, N 12.37. $E_{1/2}$ (CH_3CN) 0.37 V vs. SCE (E_{pc} at 0.26 V, E_{pa} at 0.47 V).

X-ray crystallography: X-ray intensity data were measured at 100 K (Bruker KRYO-FLEX) on a Bruker SMART APEX CCD-based X-ray diffractometer system equipped with a Mo-target X-ray tube (λ = 0.71073 Å) operated at 2000 watts power. Crystals were mounted on a cryoloop using Paratone N-Exxon oil and placed under a stream of nitrogen. The detector was placed at a distance of 5.009 cm from the crystals. Analyses of the data sets showed negligible decay during data collection. The data were corrected for absorption with the SADABS program. The structures were refined using the Bruker SHELXTL Software Package (Version 6.1), and were solved by direct methods until the final anisotropic full-matrix, least-squares refinement of F^2 converged.[37] Experimental details for all of the structures are provided in Table 3.

EPR experiments on compounds were carried out using a Bruker EMX X-band CW-EPR spectrometer consisting of an ER 041XG microwave bridge and a TE102 cavity coupled with a BVT 3000 nitrogen gas temperature controller (temperature stability of 0.2 K). EPR spectra were acquired by taking a 168 s field-swept scan with the center field set to 3200 G, a sweep width of 2000 G, a microwave frequency of 9.42 GHz, the modulation frequency was set to 100 kHz, and a modulations amplitude of 10.0 G. The spectra were acquired at a temperature of 120 K. The samples were dissolved in methanol to a final concentration of 1 mg/mL and transferred to 4 mm 707-SQ-250M fused quartz EPR tubes (Wilmad, Buena, NJ).

Cyclic voltammetry measurements were carried out on compounds **4**, **5**, **6** and **8** using a BAS 100B/W electrochemical workstation from Bioanalytical Systems, Inc. in West Lafayette, Indiana. HPLC grade acetonitrile (< 0.02 % H_2O) was used without further purification. A three-electrode setup with a platinum working electrode, a platinum wire electrode, and a saturated calomel reference elec-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trode was employed. Copper complexes were prepared at 1 mM concentration using 0.1 M tetrabutylammonium tetrafluoroborate as the supporting electrolyte in CH_3CN. A scan rate of 50 mV/s afforded optimal reversible behavior. Solutions were degassed with nitrogen prior to use and all experiments were run under a blanket of inert gas.

CCDC-216892 to -216898 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ad.uk/conts/retrieving.html [or from the Cambridge Crystllographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Allylpalladium(II) Complexes with Aminophosphane Ligands: Solution Behaviour and X-ray Structure of *cis*-[Pd(η^3-$CH_2CHCHPh$)-{$Ph_2PCH_2CHPhNH(2,6\text{-}C_6H_3iPr_2)$}][$PF_6$]

Keywords: Allyl ligands / N,P ligands / *syn-anti* exchange / Palladium

A new β-aminophosphane L^2 [$Ph_2PCH_2CH(Ph)NH(2,6\text{-}C_6H_3iPr_2)$], bearing an asymmetric carbon atom and a vicinal prochiral nitrogen centre and (η^3-allyl)palladium complexes of general formula [Pd(η^3-C_3H_4R){η^2-$Ph_2PCH_2CH(Ph)NHAr$}][PF_6] (**1**–**6**) (R = H, Me or Ph and Ar = Ph or 2,6-$C_6H_3iPr_2$) have been synthesised. NMR spectroscopic studies and a crystal structure analysis of complex **6** (R = Ph, Ar = 2,6-$C_6H_3iPr_2$) confirmed the highly diastereoselective coordination of the nitrogen atom. Because of the allyl fluxionality and the presence of asymmetric centres, all the complexes exist in solution as mixtures of up to four diastereomers. For the monosubstituted allyl complexes [Pd(η^3-C_3H_4R){$Ph_2PCH_2CH(Ph)NHAr$}][PF_6] (**3**–**6**, R = Me or Ph) only *cis*/*trans*-P and *endo*/*exo* isomers with *syn*-oriented allyl substituents have been observed in solution. The diastereomeric distribution is subject to a steric control since a modification of the steric bulk of the allyl substituents and/or N-aryl groups strongly affect the isomers ratio. An X-ray diffraction study of compound **6** reveals a mixture of *endo* and *exo cis*-P *syn* isomers and corresponds to the first *cis*-P isomer crystal structure for an N,P-ligand allyl complex. A phase-sensitive 2-D NOESY NMR analysis showed that complex **1** undergoes a selective *syn-anti* exchange isomerisation, involving exclusively a *trans*-P opening of the η^3-allyl moiety. Therefore, η^3-η^1-η^3 rearrangements in allylic complexes **1**–**6** were assumed to occur via the regioselective formation of a σ-allyl intermediate.

Introduction

Palladium-catalysed allylic substitution is a powerful methodology for the formation of new C−C or C−N bonds, with the potential to achieve high levels of enantioselectivity in the presence of chiral ligands.[1−4] In particular, the use of N,P-ligands provides very high enantioselectivities in the allylic alkylation of 1,3-diphenylpropenyl substrates.[5−10] One major advantage of hybrid ligands over ditopic ligands consists in the electronic differentiation of the coordinating atoms, inducing a nucleophilicity discrimination of the terminal allylic carbon atoms. Therefore, other chiral hybrid ligands such as O,P,[11,12] P,S[13,14] or N,S[15,16] have been studied in order to benefit from these electronic effects. Cationic allylic [Pd(η^3-allyl)L_2]$^+$ complexes with bidentate L_2 ligands are thought to be the key intermediate in the catalytic cycle and there is a growing interest in understanding their dynamic behaviour in solution and in elucidating mechanistic details related to the enantiocontrol.[17−19] For complexes containing ditopic N,P-ligands, the nucleophilic attack is assumed to occur at the carbon atom *trans* to the phosphorus[17,27,28] and the selectivities strongly depend on the relative abundance of diastereomeric allylic complexes. In comparison to extensive investigations of complexes with symmetric allyl ligands, few studies have been devoted to monosubstituted allyl complexes.[17,20−26] In the case of the allylic alkylation of asymmetric substrates, such as cinnamyl acetate or crotyl acetate, only the *trans*-P diastereomers lead to the product containing the new chiral centre; the *cis*-P isomers lead to achiral linear *Z* or *E* products (see Figure 1). The enantiocontrol is therefore subordinate to the regiocontrol.

In a previous contribution, we have described the synthesis and the coordinative behaviour of a chiral aminophosphane $Ph_2PCH_2CH(Ph)NHPh$ (L^1), in allylpalladium(II) complexes.[29] This study highlighted a diastereoselective N-coordination in the cationic complex [Pd(η^3-C_3H_5)(L^1)]+, and an N−H···Cl−M intramolecular interaction involving the dangling N−H moiety for the neutral complex [PdCl(η^3-C_3H_5)(κ1:P,L^1)]+ (see Figure 2) which is a feature of P-coordinated aminophosphanes with a secondary amine function.[30]

We report here the extension of our synthetic procedure to a new β-aminophosphane and to its cationic allylpalladium complexes, including ones with asymmetric mono-

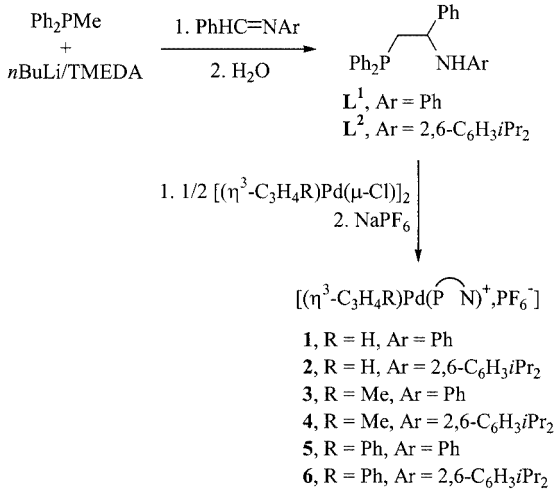
substituted allyl ligands, as well as a detailed 2-D NOESY NMR investigation of the mechanism of interconversion of the various diastereomers. The diastereomeric ratio is strongly dependent on the steric bulk of the allyl N-substituents. The first X-ray structure of a *cis*-P allyl complex is also presented.

Results and Discussion

Synthesis of the Aminophosphane Ligand L^2 and Cationic Allylpalladium Complexes

The new aminophosphane ligand L^2 was synthesised by the same one-step procedure previously described for ligand L^1 (Scheme 1).[29] It consists of the nucleophilic attack of an imine moiety by the diphenylphosphinomethyl anion. After hydrolysis and workup, the aminophosphane was isolated in good yield as a light-yellow, microcrystalline powder and was characterised by ^1H, ^{13}C and ^{31}P NMR spectroscopy and by elemental analysis (see Exp. Sect.). The ^{31}P NMR spectroscopic data are in agreement with those of other β-N,P ligands bearing an sp^3 nitrogen centre and an ethylenic backbone linking the heteroatoms.[29,31,32]



Scheme 1

The cationic allyl complexes **1**−**6** were synthesised by treatment of the chloro-bridged allylpalladium dimer with the appropriate ligand in the presence of an excess of the halide-scavenger $NaPF_6$ in dichloromethane. They were obtained in high yields as air-stable, white or yellow powders that are soluble in organic solvents, except alkanes and Et_2O. The ^{31}P NMR chemical shifts for compounds **1**−**6** are characteristic of the aminophosphane bidentate coordination. Since the ligands contain an asymmetric centre, the complexes may exist as different diastereomers arising from the different face coordination (*endo* or *exo*) of the allyl moiety with respect to the ligand. The *endo* isomer is defined as having the C−H bond of the internal allylic carbon atom pointing in the same direction as the N−H bond (see Scheme 2). For the monosubstituted allyl complexes, the allyl substituents can be in a *cis*-P or *trans*-P position and can be positioned *syn* or *anti* with respect to the internal allyl proton. Furthermore, the nitrogen atom becomes a new asymmetric centre upon coordination. However, because of the induction by the vicinal chiral carbon atom, its coordination is expected to be highly diastereoselective, as previously reported.[29,33] Therefore, only eight different diastereomers may arise, in principle, from the possible orientations of the allyl fragment. The diastereomeric distribution in solution at room temperature was determined in each case by NMR spectroscopy (except for **1**, which has already been reported[29]) and is presented below.

NMR Spectroscopic Studies on Allylic Compounds 1 and 2

The $^{31}P\{^1H\}$ NMR spectra of complexes **1** and **2** display two singlets in a 1:1 and 6.8:3.2 ratio, respectively. Because of the diastereoselective *N*-coordination and the allyl symmetry, compounds **1** and **2** may only afford two diastereomers (*endo* and *exo*, see Scheme 2). The diastereomeric ratio was confirmed by integration of the ^1H NMR spectra. The steric bulk of the N-substituents affects the isomeric proportion, as observed for other allyl compounds (see below). This seems to be an important key for the enantiocontrol in allylic substitution of 1,3-propenyl acetate derivatives.[8,18,19,34] For allylic complexes, the *endo*/*exo* ratio can be tuned by adjusting the steric constraints either around the donor atoms or on the allyl moiety.[14,19,35] You et al. have observed that, for a complex containing the 2-(phenylthio)-1-(4-*tert*-butyloxazolinyl)ferrocene ligand, an inversion of the configuration of the oxazoline ring asymmetric carbon slightly affects the *endo*/*exo* ratio (3.1:1 vs. 2.1:1), whereas introducing two benzylic groups at the 4-position of the oxazoline ring strongly displaces the equilibrium in favour of the *endo* diastereomer.[36]

The preferential nucleophilic attack at one specific allyl carbon atom is another way to achieve high enantioselectivity. The difference between the ^{13}C NMR chemical shifts of the external allyl carbon atoms ($\Delta\delta = \delta C_1 - \delta C_3$) is a measure of the difference between their electronic environments.[14,23,28,37] For complexes **1** and **2**, $\Delta\delta$ lies between 35.7 and 27.2 ppm depending on the isomer (see Table 1). Such a high $\Delta\delta$ is usual for N,P ligands, given the very different *trans* influence of the phosphorus and nitrogen atoms,[26] and reveals a higher electrophilicity for the C-1 atom (*trans*-P) than for the C-3 atom (*cis*-P; see Scheme 2). This feature has also been observed in the solid state, since the Pd−C distances are longer for $C_{trans\text{P}}$ than those for $C_{cis\text{P}}$.[19,38−40] It should be noted that the orientation of the allyl fragment induces slight differences in $\Delta\delta$ (35.7:32.5 for **1** and 29.9:27.2 for **2**). This feature probably arises from the steric hindrance caused by the N-substituents onto the allylic *trans*-P carbon atom, affecting its electrophilicity. Similar observations have been made for allylic complexes with phosphinoxazoline ligands.[41] Therefore, there is a close relation between the bulk of the N-substituents and (*i*) the *endo*/*exo* ratio, and (*ii*) the electrophilicity of the external carbon atoms.

	$\delta^{13}C$ ($^2J_{H,P}$ in Hz) C-1 *trans*P	C-2	C-3 *cis*P	$\Delta\delta^{13}C$ (δC-1 − δC-3)
1a	87.1 (27)	120.6	51.4	35.7
1b	84.6 (28)	123.0	52.1	32.5
2a	82.3 (27)	120.3 (5)	52.4	29.9
2b	80.6 (29)	122.2 (5)	53.4	27.2

NMR Characterisation of Monosubstituted Allylic Compounds 3−6

As detailed above, the introduction of one substituent at an external allyl carbon atom increases the number of possible isomers from two to eight. NMR investigations for complexes **3**−**6** revealed that all of them exist as mixtures of four diastereomers in solution in different equilibrium ratios. The coupling constants and chemical shifts for the allyl moieties are reported in Table 2. The $^3J_{H,P}$, $^2J_{C,P}$ and $\delta^{13}C$ values are helpful for the assignment of each isomer as *trans*-P or *cis*-P, since the coupling constants to the phosphorus nucleus are greater for the *trans* than for the *cis*

nuclei.[26,42] For the 1-butenyl complexes, the coupling constants involving the external methyl moiety, $^4J_{H,P}$ and $^3J_{C,P}$, enable the establishment of the *cis*-P/*trans*-P ratio, whereas δ^1_H is not diagnostic of the relative orientation. Indeed, for 1-butenyl (R = Me) complexes based on other types of N,P ligands, van Leeuwen has proposed that the signal for the methyl group should be found at $\delta > 1.3$ ppm when in the *trans*-P position and at $\delta < 0.6$ ppm when in the *cis*-P position.[43] However, several ^{1}H NMR resonances for the methyl substituents in complexes **3**−**6** and other known allyl complexes transgress this "rule".[19,20,44] For instance, the isomers of complexes **3** show resonances at δ = 0.66, 1.04, 1.09 and 1.46 ppm (Figure 3). In spite of this difficulty, the *cis*/*trans*-P orientation could be established unambiguously from other NMR characteristics.

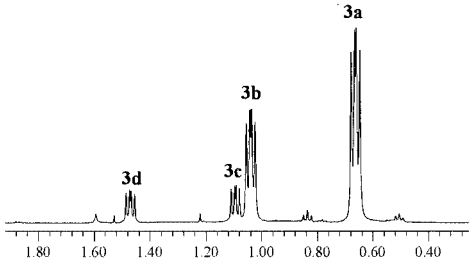

Figure 3. High field ^{1}H NMR spectrum ($CDCl_3$, 500 MHz, 283 K) of the CH_3 terminal group of complex **3**, showing the presence of four isomers

The analysis of the $^3J_{H_2,H_1}$ coupling constants allowed us to determine the relative positions of each allyl proton, revealing the exclusive presence of the *syn* isomers, i.e. having the protons 1-H and 2-H in *anti* positions. This contrasts with 1,3-disubstituted allylic complexes, for which minor amounts of isomers with the allylic substituents in the *anti* position are present in solution.[28,45] The *syn*/*anti* ratio could be affected by tuning the steric bulk between the ligand substituents and the allyl moiety.[18,19,43] The four isomers and their relative proportions are depicted in Figure 4. Compounds **3** and **4** have been identified as 53:30:11:6 and 78:9:9:4 mixtures, respectively, with the two major isomers (a and b) having a *syn trans*-P orientation. The two minor isomers were assigned to the *syn cis*-P diastereomers (c and d). Concerning the *trans*-P isomers, it can be observed that

	endo/*exo syn trans*-P (**a**/**b** or **b**/**a**)	*endo*/*exo syn cis*-P (**c**/**d** or **d**/**c**)
3	53/30	11/6
4	78/9	9/4
5	55/22	12/11
6	9/7	62/22

Figure 4. Schematic representation and distribution of complexes **3**−**6** isomers

the greater steric bulk introduced by the addition of the two isopropyl groups at the *ortho* positions of the *N*-phenyl substituent induces a strong variation of the *endo*/*exo* (or *exo*/*endo*) ratio (from 53:30 for **3** to 78:9 for **4**), whereas the global *cis*/*trans*-P ratio is only slightly affected (around 85:15). The geometry of the least abundant isomer of **4** (4% relative abundance) could not be unambiguously elucidated because of its very low concentration, coupled with the partial overlap of its resonances with those of the other isomers. Therefore, it was assumed to correspond to the second *cis*-P isomer of the **c**/**d** couple.

An influence of the steric bulk on the diastereomeric proportion is also present for the 1-phenylpropenyl complexes **5** and **6**, which were observed as 55:22:12:11 and 62:22:9:7 isomeric mixtures in solution, respectively. Contrary to the observations for compounds **3** and **4**, introducing a bulky N-substituent leads to a strong variation of the *cis*/*trans*-P ratio, whereas the global *endo*/*exo* ratio is only slightly affected. Nevertheless, the most remarkable observation is that the major isomer in solution is a *cis*-P isomer for complex **6**. Indeed, the major isomers for most[47] monosubstituted allyl complexes reported in the literature present a

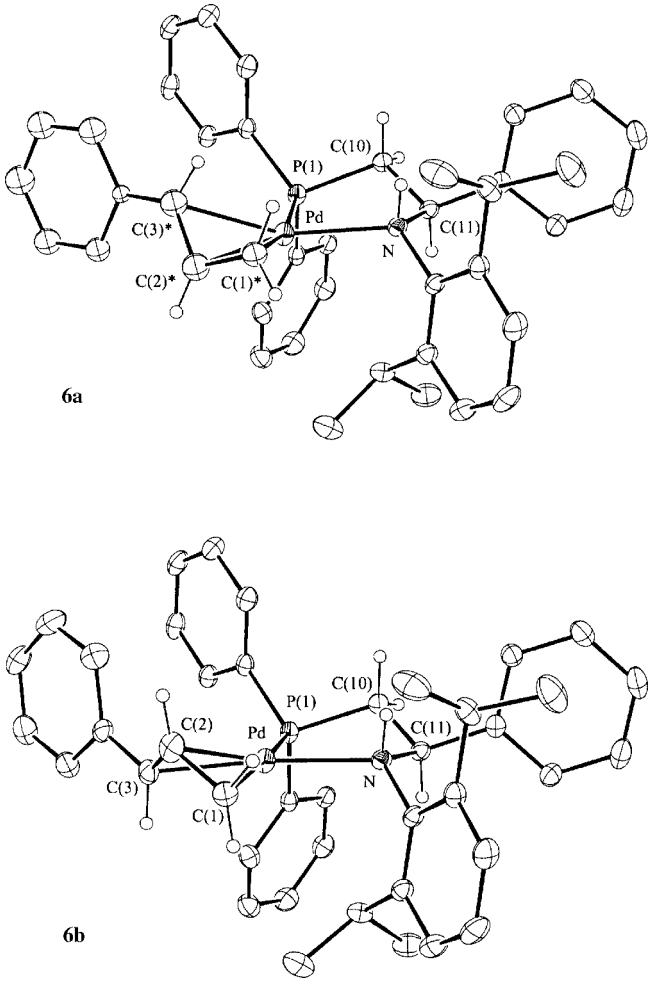

Figure 5. ORTEP views of the *exo*-**6c** and *endo*-**6d** isomers; only relevant hydrogen atoms are shown; for clarity, the CH_2Cl_2 solvent and the hexafluorophosphate anion are omitted.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trans-P orientation.[17,20,23,43,44,46] To confirm this unexpected observation, suitable crystals were therefore grown and used for an X-ray crystallographic study.

The solid-state structure (discussed in more detail later) highlights the *cis*-P orientation of the phenyl group and corresponds to a solid solution of both *endo* and *exo* isomers in a 78:22 ratio (see Figure 5). To the best of our knowledge, this represents the first solid-state structural determination of an allylic complex with an N,P ligand in a *cis*-P position. The crystals were redissolved in $CDCl_3$ and the resulting solution was monitored by ^{31}P NMR spectroscopy (see Figure 6). The spectrum displays four singlets whose relative intensities evolved slowly from a 7:9:55:21 ratio (5 min) to the equilibrium 7:9:22:62 ratio after 24 hours. Therefore, the configuration of the two major isomers is completely established: the major isomer in the solid state (*endo cis*-P, **6d**) displays the ^{31}P NMR resonance at $\delta = 29.68$ ppm, whereas the major one in solution (^{31}P resonance at $\delta = 21.85$ ppm, **6c**) corresponds to the *exo cis*-P species.

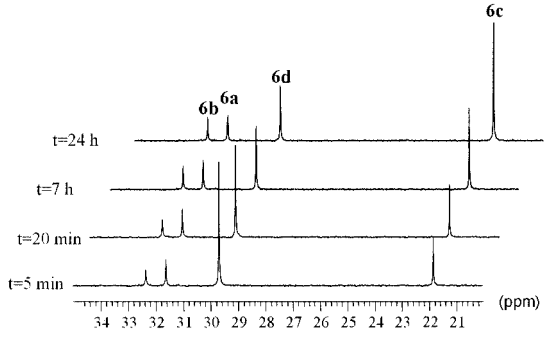

Figure 6. Kinetic ^{31}P NMR monitoring of crystals of **6** dissolved in $CDCl_3$

As already shown for complexes **3** and **4**, the addition of *i*Pr groups to the aryl *ortho* positions induces dramatic changes in the isomeric ratios on going from **5** to **6**, since it approximately inverts the *trans*-P/*cis*-P ratio from 77:23 to 16:84. The free rotation around the $C_{Ar}-N$ bond and the sterically demanding *i*Pr group destabilize the *trans*-P orientation of the allylic phenyl substituents. A similar behaviour was already observed by Helmchen and co-workers.[17,19,27] Therefore the subtle combination of steric repulsions between the allyl substituent and the N group allows a higher discrimination between the diastereomers. For the 1-butenyl complexes **3** and **4**, the *N*-isopropyl groups favour the *endo* isomer over the *exo* (or vice versa) and destabilize the *cis*-P vs. the *trans*-P isomers. The trend of tuning the *endo*/*exo* ratio has been reported mainly for symmetrically disubstituted allyl complexes, while very few papers have mentioned *cis*/*trans* control.[17,23,43] All the complexes studied in this paper provide evidence of the influence of the steric bulkiness of the nitrogen substituent on the diastereomeric ratio.

Crystal Structure of $[Pd(\eta^3\text{-}CH_2CHCHPh)\{Ph_2PCH_2\text{-}CHPhNH(2,6\text{-}C_6H_3iPr_2)\}][PF_6]$ (6)

Yellow crystals of compound **6** were grown from dichloromethane/pentane. As already mentioned above, the structure is quite interesting because it exhibits a solid mixture of two different *cis*-P diastereomeric cations within the same unit cell. Indeed, due to disorder around the allyl carbon atoms, accompanied by a slight tilting of the phenyl substituent, both *endo* and *exo cis*-P isomers have been identified in the solid state and their relative occupancies refined to afford a 78:22 ratio in favour of the *endo* isomer (**6d**, see Figure 5). Such a cocrystallisation phenomenon has many literature precedents for asymmetric allyl complexes[17,41,48–51] and allowed us to fully determine the major diastereomers not only in the solid state but also in solution, as detailed in the previous section. An ORTEP view of the *endo* and *exo* diastereomers and selected bond lengths and angles are reported in Figure 5 and Table 3, respectively. Both isomers **6c** and **6d** exhibit a typical distorted square-planar arrangement of the (η^3-allyl)Pd-P,N moiety.[17–19,28,41] The P–Pd–N bite angle of 84.89(6)° falls in the range observed for other compounds with five-membered rings containing N,P ligands and the Pd–P [2.284(1) Å] and Pd–N [2.165(2) Å] bond lengths are similar to other reported values.[44,52–55] As a result of the different *trans* influence of the N and P atoms, the Pd–C(1) bond [2.187(4) Å] is longer than the Pd–C(3) bond [2.156(4) Å]. The tilt angle α between the C(1)–C(2)–C(3) and P–Pd–N planes is 107.6°, which is in the wide range (100–120°) reported for other allylic compounds. The envelope conformation of the five-membered chelate ring is characteristic of this kind of ligand in the solid state.[29,33,56]

NMR NOESY Studies of the Dynamic Behaviour of Complex 1

The fluxional behaviour of the isomeric forms of $[Pd(\eta^3\text{-allyl})(L\text{-}L')]^+$ complexes in solution has been established as

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a consequence of different possible allyl isomerisation pathways or of the dissociation of the L-L′ ligand.[4] The existence of a dynamic equilibrium between the two diastereomers of complex **1** in a 1:1 ratio has already been reported by us[29] and we then wished to clarify the allyl isomerisation pathway by recurring to 2-D NMR experiments. Therefore, a phase-sensitive 2-D NOESY experiment was carried out in $CDCl_3$ solution. Similar experiments have previously been described for related compounds.[37,41,57] Figure 7 shows the results of this experiment and the most relevant exchange cross-peaks are labelled from *a* to *d*. The allyl ^1H NMR resonances are labelled on the 1D spectrum for isomers **a** (*endo*) and **b** (*exo*) following the nomenclature of Scheme 2, the primed labels corresponding to the *exo* isomer.

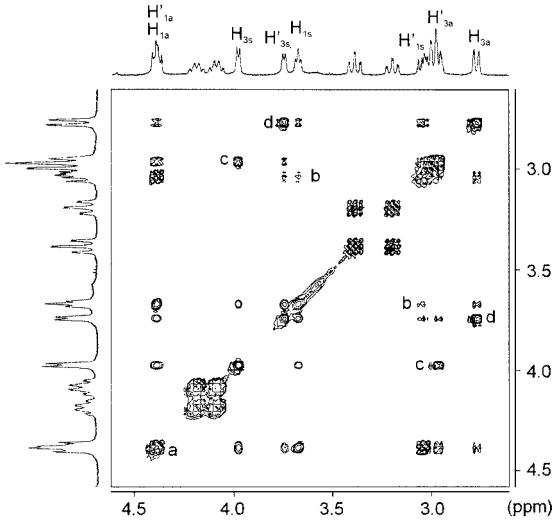

Figure 7. The ^1H-^1H phase-sensitive NOESY spectrum ($CDCl_3$, 500 MHz, 293 K) of complex **1**, showing the exchange cross-peaks (labelled *a* to *d*) in the isomers **1a** and **1b**

The spectrum shows exchange cross-peaks for all the external allylic protons belonging to the *same* C atom, indicating an η^3-η^1-η^3 isomerisation pathway. No exchange was observed between the H atoms on C_1 (*trans* to P) in **1a** and those on C_3 (*trans* to N) in **1b**, or vice versa, thereby excluding an apparent allyl rotation. At the C_1 position, the H_{1s} proton in **1a** exchanges with the H'_{1s} proton in **1b** (Figure 8). Correspondingly, the H_{1a} proton in **1a** exchanges with the H'_{1a} proton in **1b**. Thus, each terminal allyl proton *trans* to P keeps its relative position with respect to the internal allyl proton during the epimerisation process. At the C_3 position, on the other hand, cross-peaks between the 3-H_s (and 3-H_a) proton in **1a** and 3-H'_a (and 3-H'_s) proton in **1b** are observed. Thus, only the two terminal allyl protons *trans* to N trade places in the process. These two latter observations are in agreement with a *syn-anti* exchange, which implies the formation of an η^1-allyl intermediate by selective decoordination at the position *trans* to the phosphorus donor atom, followed by a C−C bond rotation and recoordination of the η^1-allyl double bond (see Scheme 3). This is consistent with the absence of any *anti cis*-P isomers for the monosubstituted complexes **3**−**6**. Other exchange cross-peaks were not observed. Notably, exchange peaks between 3-H_s and 3-H'_s and between 3-H_a and 3-H'_a are clearly absent. Because of the extensive overlap between the 1-H_a and 1-H'_a resonances, the absence of cross peaks between 1-H_a and 1-H'_s or between 1-H_s and 1-H'_a could not be unambiguously established, because any peak of this kind would be masked by the NOE peaks. However, we trust that we have sufficient evidence to conclude that a site-selective *syn-anti* exchange occurs at the C-3 atom.

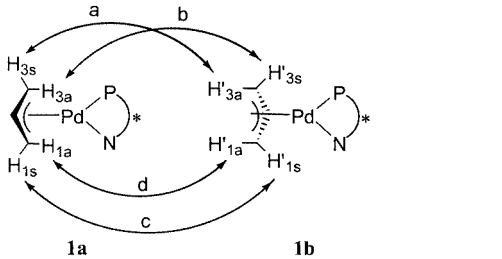

Figure 8. Exchange allyl protons between isomers **1a** and **1b**

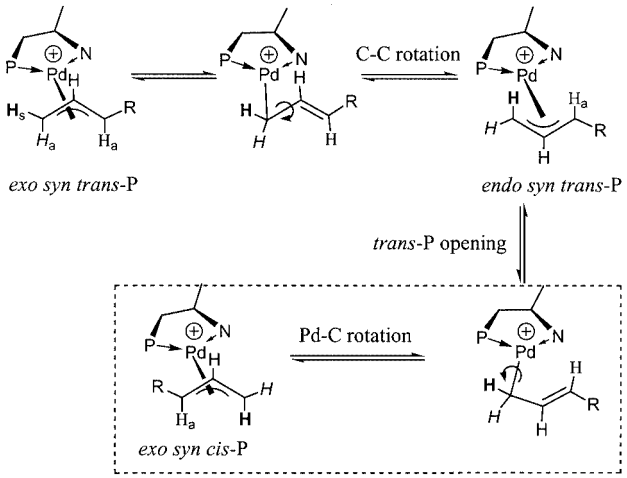

Scheme 3. η^3-η^1-η^3 isomerisation pathways involving a selective *trans*-P opening; dotted square: only for substituted allyl complexes **3**−**6**

Therefore, we can conclude that a selective opening of the η^3-allyl *trans* to the phosphorus atom occurs that leads exclusively to a *cis*-P σ-allyl intermediate during the η^3-η^1-η^3 isomerisation process. Such a selective process has already been described for chiral allyl complexes with P-based hybrid ligands resulting from the stronger *trans* influence of the P donor atom.[8,19,39,44] The only exception to this rule seems to involve a *cis*-P opening for a P,S ligand system.[14] For the other complexes reported here (**2**−**6**), we can as-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sume a similar η^3-η^1-η^3 rearrangement by an exclusive *trans*-P opening. For the monosubstituted allyl compounds **3**−**6**, a second isomerisation pathway is necessary in order to interconvert the *cis*-P and *trans*-P isomers and this could involve an apparent allyl rotation. It seems likely that this pathway involves a Pd−C bond rotation after the selective *trans*-P opening (see Scheme 3). The same proposal was made by Krishnamurthy et al. to explain the *cis*/*trans* isomerisation of the minor isomers in [Pd(η^3-1-PhC_3H_4){$Ph_2PN(iPr)PPh(3,5\text{-}N_2C_3HMe_2)$}] complexes.[20]

Conclusion

The β-aminophosphane ligands $Ph_2PCH_2CH(Ph)NHAr$ [Ar = Ph L^1, (2,6-$C_6H_4iPr_2$) L^2] bearing a prochiral nitrogen atom display a bidentate coordination mode in allylpalladium complexes. Because of the presence of an asymmetric centre vicinal to the weakly basic amine function, the metal coordination is highly diastereoselective. Different (η^3-allyl)palladium complexes of formula [Pd(η^3-1-C_3H_4R)L][PF_6] (R = H, Me, Ph; L = L^1, L^2) have been synthesised and characterised in solution and in the solid state. In solution, they display a dynamic behaviour between the diastereomers because of a regioselective η^3-η^1-η^3 isomerisation of the allyl moiety interconverting *endo*/*exo* (for **1**−**6**) and *cis*/*trans*-P (for **3**−**6**) isomers. Complexes **3**−**6** show exclusively the *syn* orientation of the allylic substituents and therefore give rise to a mixture of four diastereomers. The isomeric proportion depends on the steric bulk of the allylic and/or N-substituents. The dynamic behaviour of **1** was studied by 2-D NOESY experiments. These prove that the *syn*-*anti* exchange process occurs via a regioselective η^3-allyl opening *trans* to the phosphorus position. On the basis of these results, the exclusive formation of *cis*-P η^1-allyl intermediates was assumed to occur by an apparent allyl rotation which equilibrates the *cis* and *trans*-P isomers for the monosubstituted allyl complexes **3**−**6**. Work aimed at obtaining enantiomerically pure forms of these aminophosphane ligands is in progress permitting the study of palladium-catalysed allylic alkylation of monosubstituted 1-propenyl substrates in order to correlate (or not) the regio-, stereo- and enantioselectivities with the observations described herein.

Experimental Section

All reactions were performed in Schlenk-type flasks under an argon atmosphere and solvents were purified and dried by conventional methods and distilled under argon. The ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were recorded in $CDCl_3$ on a Bruker 300 Advance or a Bruker 500 DRX instrument. Complete assignment was achieved by use of COSY, DEPT and HMQC experiments. All chemical shifts are relative to $SiMe_4$ (^1H and ^{13}C NMR) or 85% H_3PO_4 (^{31}P NMR) and are given in ppm. Numbering scheme used for the L^2 ligand: H^a, H^b and H^c are the non-equivalent PCH_2 and the NCH protons, respectively. Numbering scheme used for the allyl ligand: C^1, C^2 and C^3 are *trans* to P atom, central carbon and *cis* to P atom, respectively, and H^s and H^a are in the *syn* and *anti* positions, respectively, relative to the internal proton H^2. For complexes **1** and **2**, the carbon and proton chemical shifts are noted C, H and C′, H′ respectively, for the *endo* and *exo* diastereomers (see Scheme 2). The elemental analyses were performed on a Fisons EA 1108 apparatus at the L.S.E.O. in Dijon. The reagents *n*BuLi (1.6 M in hexane), Ph_2PCH_3 and $NaPF_6$ are commercial products from Aldrich, and were used as received. *N*-benzylidene-2,6-diisopropylaniline[58] and the chloro-bridged allylpalladium dimers[59] [Pd(η^3-C_3H_5)(μ-Cl)]$_2$, [Pd(η^3-MeC_3H_4)(μ-Cl)]$_2$, [Pd(η^3-PhC_3H_4)(μ-Cl)]$_2$ were prepared as described previously. Compound **1** and the ligand L^1 have already been described in a previous publication.[29]

Synthesis of Ligand L^2: According to Peterson's method,[60] 5.0 mL of *n*BuLi (1.6 M in hexane, 8 mmol) was slowly added to 1.2 mL of TMEDA (8 mmol) and the mixture was stirred at room temperature for 20 minutes. Methyldiphenylphosphane (1.5 mL, 8 mmol) was then slowly added. The mixture was stirred further leading within 30 minutes to a bright yellow precipitate, which was dissolved by addition of a few mililiters of THF. The solution was further stirred for half an hour and a solution of *N*-benzylidene-2,6-diisopropylaniline (1.65 g, 6.2 mmol) in 10 mL of THF was slowly added. The mixture was then stirred overnight, followed by hydrolysis with 20 mL of water. The water phase was separated and extracted three times with 20 mL of Et_2O. The combined organic phases were dried over $MgSO_4$ and the solvents were removed in vacuo. The product was recrystallised from ethanol and yellowish needles were isolated by filtration and dried in vacuo. Yield: 1.59 g (59%). $C_{32}H_{36}NP$ (465.6): calcd. C 82.55, H 7.79, N 3.01; found C 82.25, H 8.05, N 3.48. ^1H NMR ($CDCl_3$, 300.13 MHz): δ = 0.89 [d, $^3J_{H,H}$ = 6.5 Hz, 6 H, CH-(CH_3)$_2$], 1.02 [d, $^3J_{H,H}$ = 6.5 Hz, 6 H, CH-(CH_3)$_2$], 2.77 (ddd, $^2J_{H,P}$ = 1.0, $^3J_{H,H}$ = 8.0, $^2J_{H,H}$ = 13.5 Hz, 1 H, PCH^a), 2.91 (ddd, $^2J_{H,P}$ = 1.0, $^3J_{H,H}$ = 8.0, $^2J_{H,H}$ = 13.5 Hz, 1 H, PCH^b), 3.00 [septet, $^3J_{H,H}$ = 6.7 Hz, 2 H, CH-(CH$_3$)$_2$], 3.44 (broad s, 1 H, exchange with D_2O, NH), 3.93 (dt, $^3J_{H,H}$ = $^3J_{H,H}$ = 6.7, $^3J_{H,P}$ = 8.2 Hz, 1 H, NCH), 7.00 (m, 3 H, $H_{m,p}$ N-*Ph*), 7.14 (dd, $^4J_{H,H}$ = 1.4, $^3J_{H,H}$ = 7.9 Hz, 2 H, H_m C-*Ph*), 7.25−7.35 (m, 15 H, H_{arom}), 7.40 (dt, $^4J_{H,H}$ = 1.8, $^3J_{H,H}$ = 7.0 Hz, 1 H, H_o P-*Ph*), 7.45 (dt, $^4J_{H,H}$ = 1.8, $^3J_{H,H}$ = 7.0 Hz, 1 H, H_o P-*Ph*) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CDCl_3$): δ = 24.3 [2C, 2 CH(CH_3)$_2$], 24.5 [2C, 2 CH(CH_3)$_2$], 28.2 [2C, 2 CH(CH$_3$)$_2$], 36.1 (d, $^2J_{C,P}$ = 14 Hz, PCH_2), 62.7 (d, $^3J_{C,P}$ = 17 Hz, NCH), 123.7 (2C, 2 C_m N-*Ph*), 124.0 (C_p N-*Ph*), 127.5 (2C, 2 C_m C-*Ph*), 127.9 (C_p C-*Ph*), 128.75 (2C, 2 C_o C-*Ph*), 128.85 (2C, 2 C_m P-*Ph*), 128.9 (2C, 2 C_m P-*Ph*), 129.0 (C_p P-*Ph*), 129.2 (C_p P-*Ph*), 132.9 (d, $^2J_{C,P}$ = 19 Hz, 2 C, 2 C_o P-*Ph*), 133.5 (d, $^2J_{C,P}$ = 21 Hz, 2 C, 2 C_o P-*Ph*), 138.9 (d, $^2J_{C,P}$ = 12 Hz, 1 C, 2 C_i P-*Ph*), 139.0 (d, $^2J_{C,P}$ = 12 Hz, 1 C, 2 C_i P-*Ph*), 141.1 (C_i C-*Ph*), 143.0 (2C, C_o N-*Ph*), 143.1 (C_i N-*Ph*) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$): δ = −23.2 ppm.

[Pd(η^3-C_3H_5){$Ph_2PCH_2CHPhNH(2,6\text{-}C_6H_3iPr_2)$}][$PF_6$] (2): A dichloromethane solution (5 mL) of ligand L^2 (0.202 g, 0.53 mmol) was progressively added to a solution of [Pd(η^3-C_3H_5)Cl]$_2$ (97 mg, 0.26 mmol) in 5 mL of dichloromethane. The solution was stirred for 30 minutes at room temperature and then added to a suspension of $NaPF_6$ (0.223 g, 1.3 mmol) in 2 mL of dichloromethane. The mixture was stirred for a further 2 hours and filtered through Celite. The resulting yellow filtrate was concentrated in vacuo to ca. 1 mL. Addition of 15 mL of pentane caused the precipitation of the product, which was washed with pentane (2 × 20 mL). The white powder was filtered and dried under vacuum. Yield: 0.315 g (89%). $C_{35}H_{41}F_6NP_2Pd$ (758.1): calcd. C 55.45, H 5.45, N 1.84; found C 55.34, H 5.70, N, 2.11. Major isomer (**2a**, 68%): ^1H NMR

Crystal Structure Determination for 6: Crystal and refinement data are reported in Table 4. The data set was collected on an Enraf−Nonius KappaCCD diffractometer at 110 K using Mo-K_α radiation. The structure was solved with a Patterson search program[61] and refined with full-matrix least-squares methods[62] based on $|F^2|$ with the aid of the WINGX program.[63] The allylic fragment (CH_2···CH···CHPh) was found to be disordered with two different orientations (*endo*/*exo*). The occupation factors refined to m1 = 0.78 (*endo* isomer) and m2 = 1 − m1 = 0.22 (*exo* isomer).

All non-hydrogen atoms were refined with anisotropic thermal parameters except for the atoms belonging to the minor allylic fragment (*exo*) and the terminal carbon atom, C(1), of the major allylic fragment. The positions of the hydrogen atoms were either calculated or located in final Fourier difference maps and refined, after idealisation, with a riding model with isotropic temperature factors fixed to 1.5- or 1.2-times those of the corresponding parent atoms. CCDC-218899 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to the Ministère de la Recherche et de la Technologie for support and for a PhD fellowship (to J.-M. C.), the Centre National de la Recherche Scientifique (C.N.R.S.) and the Conseil Régional de Bourgogne for financial support of this work. We thank Dr. Bernard Hanquet (L.S.E.O.) for his assistance with the NOESY NMR experiments and Mr. Cédric Balan for technical assistance.

Hydroxo and Oxo Complexes of Platinum(II) Stabilized by Phosphanes: Synthesis and Characterization − X-ray Structures of *cis*-$[L_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ (L = PMe_2Ph, $PMePh_2$) and $[\{cis\text{-}(PMe_2Ph)_2Pt\}_3(\mu\text{-}O)_2]Cl_2$

Bruno Longato,*[a,c] Giuliano Bandoli,[b] and Alessandro Dolmella[b]

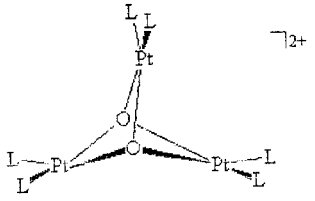
Keywords: Platinum / Oxo and hydroxo ligands / X-ray diffraction / Deprotonation reactions

The dinuclear hydroxo complexes *cis*-$[L_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ (L = PMe_2Ph and $PMePh_2$) have been characterized by single-crystal X-ray analysis, and their reactivity towards chloride ions has been investigated. Reaction of *cis*-$[L_2Pt(\mu\text{-}OH)]_2X_2$ (L = PMe_3, PMe_2Ph; X = NO_3^-, ClO_4^-) with $(NEt_4)Cl\cdot H_2O$ or $(AsPh_4)Cl$, in a 1:2 molar ratio, afforded a mixture of *cis*-$[L_2PtCl_2]$ and $[\{cis\text{-}L_2Pt\}_3(\mu\text{-}O)_2]^{2+}$ in ca. equimolar amounts. The trinuclear oxo compounds, separated by fractional crystallization of the reaction mixtures, were fully characterized by spectroscopic techniques, and the derivative $[\{cis\text{-}(PMe_2Ph)_2Pt\}_3(\mu\text{-}O)_2]Cl_2$ was also characterized by X-ray diffraction methods. Under the same experimental conditions, the structurally analogous hydroxo complex, stabilized by the less basic and more hindered $PMePh_2$ ligand, reacted with Cl^- to give *cis*-$[(PMePh_2)_2PtCl_2]$ as the only isolable species. The ^{31}P NMR spectroscopic analysis of the reaction mixtures allowed the detection of a moderately stable product, which is most likely to be the neutral hydroxo complex *cis*-$[L_2PtCl(OH)]$.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2002)

Introduction

Oxo complexes of platinum(II) stabilized by phosphanes of the type $[L_2Pt(\mu\text{-}O)]_2$ (L = PPh_3, PMe_2Ph; L_2 = bidentate phosphanes) have recently been described by P. R. Sharp.[1] They were obtained by deprotonation of the corresponding hydroxo bridged complexes $[L_2Pt(\mu\text{-}OH)]_2^{2+}$ with strong bases such as $LiN(SiMe_3)_2$. A common feature of the bridging oxo ligands, and their chalcogenide analogues,[2] is the ability to bind ions such as Li^+, Ag^+, Cu^+, and other metal centers, thus affording stable and well-characterized heteropolymetallic complexes. An exception is represented by the adduct $[cis\text{-}L_2Pt(\mu\text{-}O)]_2\cdot 2LiBF_4$ (L = PMe_2Ph), which decomposes in THF to give $[\{cis\text{-}L_2Pt\}_3(\mu\text{-}O)_2](BF_4)_2$ (Scheme 1), the trinuclear species in which each oxygen atom is symmetrically coordinated to three $[L_2Pt]^{2+}$ units.[3]



Scheme 1

We have now found that oxo complexes of this type are also formed when the hydroxo complexes *cis*-$[L_2Pt(\mu\text{-}OH)]_2^{2+}$ (L = PMe_3 and PMe_2Ph) react with chloride ions in aprotic solvents. The nucleophilic attack of Cl^- at the metal center affords a mixture of the mononuclear dichloro *cis*-$[L_2PtCl_2]$ species and the trinuclear $[\{cis\text{-}L_2Pt\}_3(\mu\text{-}O)_2]^{2+}$ species in which the relative quantity of the two compounds is strongly dependent on the amount of added chloride. A large excess of Cl^- ions leads to the formation of *cis*-$[L_2PtCl_2]$ as the main product, whereas relatively good yields of the oxo complex are formed when the molar ratio $n_{(Cl^-)}/n_{(\text{hydroxo complex})}$ approaches the value of 2:1. This finding contrasts the observations reported by Bushnell for the strictly related hydroxo complex stabilized by PEt_3.[4] In that case, addition of LiCl to a solution of $[cis\text{-}(PEt_3)_2Pt(\mu\text{-}OH)]_2^{2+}$, in a 2:1 molar ratio, gave the substitution product *cis*-$[(PEt_3)_2PtCl_2]$ and about half of the starting hydroxo complex remained unreacted.

In this paper, in addition to the X-ray structures of *cis*-$[L_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ (L = PMe_2Ph, $PMePh_2$), we report on the details of the reaction of this class of dinuclear compounds with chloride ions. The facile deprotonation of the bridging hydroxo ligands, induced by the presence of the nucleophile Cl^-, offers an alternative route for the synthesis of the oxo compounds $[\{cis\text{-}L_2Pt\}_3(\mu\text{-}O)_2]^{2+}$ (L = PMe_2Ph, and PMe_3), one of which has not previously been described. The products have been isolated as pure compounds and characterized by spectroscopic methods, and the species $[\{cis\text{-}(PMe_2Ph)_2Pt\}_3(\mu\text{-}O)_2]Cl_2$ has also been characterized by single-crystal X-ray diffraction analysis. Moreover, the study of the reaction by ^{31}P NMR spectroscopy allowed the detection of unstable products, which are tentatively attributed to the mononuclear complexes *cis*-$[L_2PtCl(OH)]$ (L = PMe_3, PMe_2Ph, $PMePh_2$).

Results and Discussion

Synthesis and Characterization of the Hydroxo Complexes *cis*-$[(PMe_2Ph)_2Pt(\mu\text{-}OH)]_2X_2$ [X = NO_3^- (1a), ClO_4^- (1b)] and *cis*-$[(PMePh_2)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ (2)

We have already shown that the removal of the chloride ligands from the trimethylphosphane complex *cis*-$[(PMe_3)_2PtCl_2]$ with $AgNO_3$, followed by neutralization of the resulting solution, afforded the hydroxo compound *cis*-$[L_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ (L = PMe_3). This compound is a dinuclear cationic complex, which is very soluble in water when the anion is the nitrate group.[5] More recently, we have prepared the complex *cis*-$[(PMe_2Ph)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ (**1a**) using the same procedure. This compound is still moderately soluble in water.[6] As previously observed for the PMe_3 analogue, the conversion of **1a** into the perchlorate salt results in a drastic decrease in the solubility. The compound *cis*-$[(PMe_2Ph)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ (**1b**) can be obtained in a quantitative yield from **1a** by metathetical exchange. The complex *cis*-$[(PMePh_2)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ (**2**), which was prepared in a good yield using a slightly modified procedure, is virtually insoluble in water.

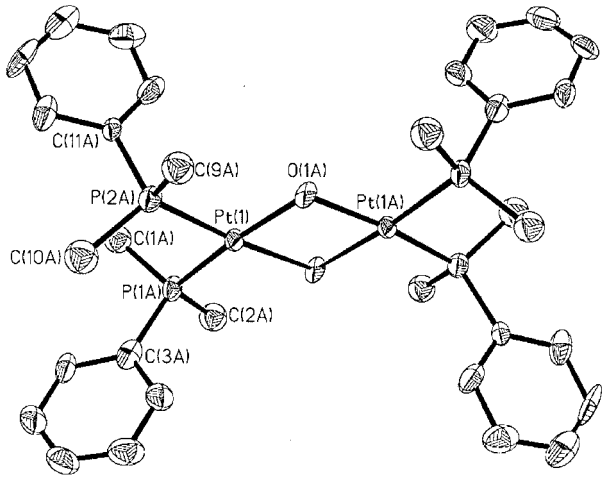

Figure 1. ORTEP drawing of **1a** showing 40% probability thermal ellipsoids and the essential atom numbering scheme; for clarity, the nitrate anions are omitted and only unit **I** is shown

The dinuclear nature of **1a** and **2** has been confirmed by single-crystal X-ray analysis. The ORTEP drawings of the two cations, *cis*-$[L_2Pt(\mu\text{-}OH)]_2^{2+}$, are shown in Figures 1 and 2, while the relevant bond lengths and angles are reported in Table 1. The unit cell of **1a** comprises two moieties denoted as **I** and **II**.

[a] At *x*, *y*, 1 − *z* in **1a**; at *x*, 1 − *y*, *z* in **2**.

The $P_4Pt_2O_2$ skeleton is essentially planar, within 0.03, 0.04, and 0.05 Å in **1a**−**I**, **1a**−**II**, and **2**, respectively. Comparison of the structural parameters of **1a** and **2** with those of the PMe_3 analogue shows only minor differences. In particular, the P−Pt−P and O−Pt−O angles are 93.6(2) and 77.5(4), 94.9(2) and 78.5(4), and 96.5(1)° and 79.4(4)° in **1a**−**I**, **1a**−**II**, and **2**, respectively, while the corresponding values in the PMe_3 analogue are 95.4(1) and 75.9(4)°. However, more significant changes are observed in the O···O and Pt···Pt distances. The O···O distance is relatively short in the PMe_3 derivative (2.54 Å), however, this distance is longer in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1a and **2**, 2.61 Å and 2.64 Å, respectively; the latter value is the same as that observed for the structurally analogous complex that is stabilized by NH_3 ligands,[7] and only slightly shorter than that found in the PPh_3 derivative (2.66 Å).[3] An increase in the O···O separation is accompanied by a decrease in the Pt···Pt distance; 3.222 Å (average) in **1a**, 3.174(1) Å in **2** and 3.261 Å in the PMe_3 complex. This trend probably reflects the different repulsion effects at the metal centers due to the diverse basicity of the PR_3 ligands.[3]

As found in the PMe_3 analogue, in **1a** the hydroxo ligands interact via hydrogen-bonding with the nitrate anions. In particular, the atoms that are involved in this hydrogen-bonding interaction are O(6) (at x, y, $1 - z$) in unit **I** (O···O separation of 2.74 Å and an O−H···O angle of 167°) and O(2) (at x, $y + 1$, z) in unit **II** (separation of 2.79 Å and an angle of 178°). This hydrogen-bonding system is not present in the crystal packing of **2**, where the shortest O···O distance is 3.18 Å.

The spectroscopic characterization of compounds **1** and **2** has been carried out in [D_6]DMSO. In the ^{1}H NMR spectra, the OH resonances are observed as broad singlets at $\delta = 4.11$ (L = PMe_2Ph) and 3.53 (L = $PMePh_2$), values similar to that observed for the PMe_3 analogue ($\delta = 3.46$).[5] The ^{31}P NMR spectra, obtained at 36.23 MHz, exhibit a singlet flanked by the typical pattern due to the ^{195}Pt satellites. Each component of the doublet, which is assigned to the isotopomer $[L_2{}^{195}Pt(OH)_2PtL_2]^{2+}$ ($^1J_{P,Pt} = 3457$ Hz for **1** and 3571 Hz for **2**), is flanked by a couple of very weak resonances, separated by 304 Hz for **1** and 232 Hz for **2**, due to the contribution of the less abundant isotopomer $[L_2{}^{195}Pt(OH)_2{}^{195}PtL_2]^{2+}$ (relative abundance 11.4%). As previously noticed for *cis*-$[(PMe_2Ph)_2Pt(\mu\text{-}OH)]_2(BF_4)_2$,[3] the main resonance does not show resolved satellites, which are assigned to the $^3J_{P,Pt}$ coupling, indicating that the magnetic interaction between the ^{31}P and ^{195}Pt nuclei through three bonds is presumably too small to be observed.

Lability of the Bridging Hydroxo Ligands in *cis*-$[L_2Pt(\mu\text{-}OH)]_2^{2+}$ (L = PMe_3, PMe_2Ph, and $PMePh_2$)

The ^{1}H and ^{31}P NMR spectroscopic parameters of **1** and **2** do not exhibit appreciable changes with the concentration (in the 10^{-2} to 10^{-3} M range), suggesting that these dinuclear hydroxo-bridged complexes do not dissociate significantly in DMSO solution. However, the lability of the Pt−O bonds becomes evident when solutions of **1** and **2** are mixed. The ^{31}P NMR spectrum of a freshly prepared mixture shows, after a few minutes, the growth of two new singlets, symmetrically flanked by ^{195}Pt satellites at $\delta = -5.15$ ($^1J_{P,Pt} = 3541$ Hz) and −16.15 ($^1J_{P,Pt} = 3478$ Hz). These values for the chemical shifts and the coupling constants are intermediate between those found for the pure compounds (Table 2), and are consistent with the formation of the mixed complex *cis*-$[(PMe_2Ph)_2Pt(\mu\text{-}OH)_2Pt(PMePh_2)_2]^{2+}$. A similar exchange also occurs when **1** or **2** are mixed with *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$.

Table 2. ^{1}H and ^{31}P NMR spectroscopic data for *cis*-$[L_2Pt(\mu\text{-}OH)_2PtL'_2](NO_3)_2$ in [D_6]DMSO at 27 °C

L,L	δ_p [ppm]	$^1J_{P,Pt}$ [Hz]	δ_{OH} [ppm]
L = L′ = PMe_3	−24.5	3358	3.46
L = L′ = PMe_2Ph	−15.5	3457	4.11
L = L′ = $PMePh_2$	−5.32	3571	3.53
L = PMe_3 L′ = PMe_2Ph	−24.30 −15.73	3363 3446	3.40
L = PMe_3 L′ = $PMePh_2$	−24.87 −4.94	3377 3522	4.01
L = PMe_2Ph L′ = $PMePh_2$	−16.15 −5.15	3478 3541	3.90

In all the cases, the NMR spectrum of the resulting mixture shows the resonances of the starting complexes and two new singlets which are assigned to the species *cis*-$[L_2Pt(\mu\text{-}OH)_2PtL'_2]^{2+}$ (L = PMe_3, L′ = PMe_2Ph or $PMePh_2$). After a few hours at room temperature, the relative intensities of the signals due to the mixed complexes are approximately the same as those expected for a statistical distribution of the *cis*-$[L_2Pt(OH)]^+$ units according to the equilibrium reaction [Equation (1)].

$$cis\text{-}[L_2Pt(\mu\text{-}OH)]_2{}^{2+} + cis\text{-}[L'_2Pt(\mu\text{-}OH)]_2{}^{2+} \rightleftarrows 2\ cis\text{-}[L_2Pt(\mu\text{-}OH)_2PtL'_2]^{2+} \quad (1)$$

This exchange reaction is followed by a further redistribution of the neutral ligands around the metal center as indicated by the appearance of additional doublets due to the {*cis*-LL′Pt} moieties in the ^{31}P NMR spectra.[8] The lability of the bridging hydroxo ligands has previously been observed in the structurally related Ni^{II} complexes $[NiR(PMe_3)(\mu\text{-}OH)]_2$ (R= CH_2Ph; CH_2CMe_2Ph).[9]

Synthesis and Characterization of the Oxo Complexes [{*cis*-$L_2Pt\}_3(\mu\text{-}O)_2]X_2$ (L = PMe_3, X= ClO_4^-, 3; L = PMe_2Ph, X = Cl^-, 4)

When chloride ions were added to solutions of *cis*-$[L_2Pt(\mu\text{-}OH)]_2X_2$ (X = NO_3^-, ClO_4^-; L = PMe_3, PMe_2Ph) in DMSO or CH_2Cl_2/DMSO, at room temperature, a mixture of the species *cis*-$[L_2PtCl_2]$ and $[\{cis\text{-}L_2Pt\}_3(\mu\text{-}O)_2]^{2+}$ (L = PMe_3, **3**; PMe_2Ph, **4**) was formed. {^{1}H}^{31}P NMR analysis of the resulting pale yellow solutions shows that the relative quantity of the two products is strongly dependent on the stoichiometric ratio of the reactants. A large excess of Cl^- ions (molar ratio > 10), added as solid $(NEt_4)Cl{\cdot}H_2O$ or $(PPh_4)Cl$, affords the corresponding *cis*-$[L_2PtCl_2]$ as the only detectable species. At lower concentrations of the chloride ions, the solutions contain increasing amounts of the oxo complexes $[\{cis\text{-}L_2Pt\}_3(\mu\text{-}O)_2]^{2+}$.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

When the molar ratio $n_{(Cl^-)}/n_{(Pt\ complex)}$ is in the range 1−2, the relative intensity of the ^{31}P resonances which are assigned to the dichloro and oxo complexes approach the value expected from the following reaction [Equation (2)].

$$2\ cis\text{-}[L_2Pt(\mu\text{-}OH)]_2^{2+} + 2\ Cl^- \rightleftarrows cis\text{-}[L_2PtCl_2] + [\{cis\text{-}L_2Pt\}_3(\mu\text{-}O)_2]^{2+} + 2\ H_2O \quad (2)$$

The trinuclear complexes were obtained as pure compounds (^{31}P NMR spectroscopy) after precipitation with Et_2O, followed by fractional crystallization. The elemental analysis of the product isolated from the reaction of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ with $(NEt_4)Cl$ was consistent with the separation of the oxo species as the perchlorate salt, $[\{cis\text{-}(PMe_3)_2Pt\}_3(\mu\text{-}O)_2](ClO_4)_2$ (**3**). The presence of the ClO_4^- ion was clearly evidenced by the typical absorption at 1093 cm^{-1} in the IR spectrum of the solid.

The crystallization of the product obtained from the reaction of *cis*-$[(PMe_2Ph)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ with Cl^- gave crystals of $[\{cis\text{-}(PMe_2Ph)_2Pt\}_3(\mu\text{-}O)_2]Cl_2$ (**4**), i.e. the chloride salt of the oxo species, as established by single-crystal X-ray analysis. The structure of the dication of **4** is shown in Figures 3 and 4, while the relevant data are presented in Table 3.

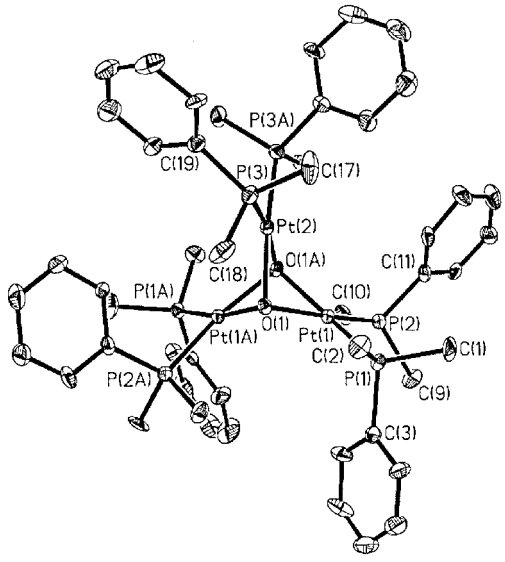

Figure 3. ORTEP drawing of **4** showing 35% probability thermal ellipsoids and the essential atom numbering scheme; for clarity, the chloride anions are omitted

The oxygen atoms cap a triangle formed by three $(PMe_2Ph)_2Pt$ units in which the average Pt···Pt distance is 2.884 Å. Comparison of this structure with that containing BF_4^- as the counterion[3] does not reveal any significant differences. For example, the Pt−O distances and the angles around the oxygen atoms are almost equal, averaging 2.087(5) Å and 87.4(2)° in **4** and 2.083(8) Å and 87.4(3)° in that previously determined. The three dihedral angles formed by the three P_2PtO_2 mean planes are 61.3, 58.7, and 61.3° in **4** and compare with the values of 61.8, 59.1, and 59.5° in the BF_4^- derivative.

[a] At $1/2 - x$, $y - 1/2$, $1/2 - z$.

Attempts to determine the structure of **3** by X-ray analysis were unsuccessful. However the ^{31}P NMR spectrum of this complex shows a pattern that is very similar to that shown in the spectrum of **4**. Both complexes are characterized by a singlet (at $\delta = -30.3$ and −19.5 ppm for **3** and **4**, respectively, in $[D_6]DMSO$) that is symmetrically flanked by satellites which can be assigned to the $^3J_{P,Pt}$ (ca. 13 Hz) and $^1J_{P,Pt}$ couplings (in the range 3356−3396 Hz for **3** and 3410−3460 Hz for **4**).

Dinuclear oxo complexes of platinum(II) stabilized by phosphanes are obtained by reacting the corresponding hydroxo compounds with strong bases [Equation (3)].

$$cis\text{-}[L_2Pt(\mu\text{-}OH)]_2(BF_4)_2 + 2\ LiNR_2 \rightleftarrows [cis\text{-}L_2Pt(\mu\text{-}O)]_2{\cdot}2LiBF_4 + 2\ HNR_2 \quad (3)$$

The bridging oxo ligands generally associate one or two molecules of $LiBF_4$, depending on the type of phosphane used. In solution, when L is PMe_2Ph, the dinuclear oxo complex decomposes to form the stable species $[\{cis\text{-}(PMe_2Ph)_2Pt\}_3(\mu\text{-}O)_2](BF_4)_2$ in a high yield.[3] In the reaction of **1**, and its PMe_3 analogue, with Cl^- ions [Equa-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion (2)], the ^{31}P NMR spectra obtained immediately after the addition of the chloride ions do not show signals which can be assigned to the dinuclear oxo complex. The formation of *cis*-$[L_2PtCl_2]$ and $[\{cis\text{-}L_2Pt\}_3(\mu\text{-}O)_2]^{2+}$ instead is accompanied by the formation of a relatively stable species; it has tentatively been suggested that this species is the mixed complex *cis*-$[L_2PtCl(OH)]$, although a dinuclear species of the type $[\{cis\text{-}L_2Pt\}_2(\mu\text{-}Cl)(\mu\text{-}OH)]^{2+}$ cannot be ruled out.[10] In a typical experiment, increasing amounts of $(AsPh_4)Cl$ as a solid were added to a CD_2Cl_2 solution of **1a** and the ^{31}P NMR spectrum of the resulting solution immediately obtained. Figure 5(a) shows the spectrum that is observed when the molar ratio $n_{(\mathbf{1a})}/n_{(Cl^-)}$ is 1.0. The main resonance signal is the singlet, whose chemical shift and coupling constant are very similar to those of unchanged **1a**. The signals of the oxo species (at $\delta = -19.5$) and the dichloro complex (at $\delta = -14.4$) exhibit relative intensities of 5.6:1, whereas the resonances assigned to *cis*-$[L_2PtCl(OH)]$, characterized by an AX multiplet, (at ca. $\delta = -12$ and -24 ppm; $^2J_{P,P} = 24$ Hz) are only just detectable.

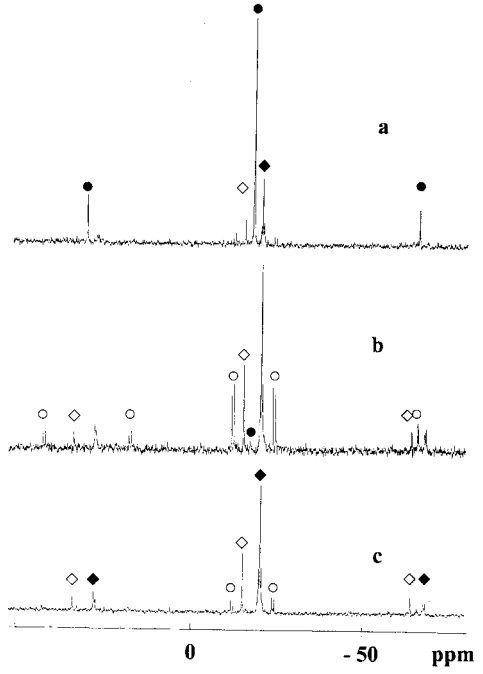

Figure 5. $\{^1H\}^{31}P$ NMR spectrum (at 36.23 MHz) of a solution ($3.73\cdot10^{-2}$ M) of **1a** in CD_2Cl_2 at 27 °C: (**a**) immediately after the addition of $(AsPh_4)Cl$ (molar ratio **1a**/Cl^- = 1:1); the labels (solid circle and solid diamond) refer to the complexes *cis*-$[(PMe_2Ph)_2Pt(\mu\text{-}OH)]_2^{2+}$ and *cis*-$[\{(PMe_2Ph)_2Pt\}_3(\mu\text{-}O)_2]^{2+}$, respectively; (**b**) ca. half an hour after (a), following the addition of a further amount of $(AsPh_4)Cl$ (molar ratio **1a**/Cl^- = 1:2); (**c**) after 12 h at 33 °C); the labels (open circle and open diamond) refer to the complexes *cis*-$[(PMe_2Ph)_2PtCl_2]$ and *cis*-$[(PMe_2Ph)_2PtCl(OH)]$, respectively

The further addition of chloride ions ($n_{(\mathbf{1a})}/n_{(Cl^-)}$ = 1:2), carried out after ca. 0.5 h, leads to the almost complete disappearance of the resonances due to the starting complex, whereas the AX multiplet became more intense to allow the detection of the platinum-195 satellites (Figure 5, b). The doublet at lower field ($\delta = -11.97$, $^1J_{P,Pt}$ 3930 Hz) is assigned to the PMe_2Ph molecule *trans* to the chloride ion, and the resonance at -23.86 ppm, with a lower P−Pt coupling constant (3020 Hz), is assigned to the phosphane *trans* to the hydroxo ligand. The intensities of these signals slowly decrease, whereas the relative intensities of the signals at $\delta = -19.5$ and -14.4 ppm remain apparently unchanged as shown in Figure 5(c), which represents the spectrum of the same solution left for 12 h at 33 °C.

A similar behavior was observed with the hydroxo complex stabilized by PMe_3. The spectrum of a mixture containing *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2X_2$ and Cl^- in a 1:2 molar ratio shows, in addition to the resonances assigned to the oxo complex **3** (52% of relative intensity) and *cis*-$[(PMe_3)_2PtCl_2]$ (relative intensity 20%), an AX multiplet ($^2J_{P,P}$ = 20 Hz) at $\delta = -21.0$ and -34.0 ppm which disappears after 24 h. These results lead to conclusion that the species responsible for the AX multiplet, the mononuclear hydroxo complex *cis*-$[(PMe_3)_2PtCl(OH)]$, slowly decomposes leaving a pale yellow solution in which the only detectable resonances are those of the colorless species *cis*-$[L_2PtCl_2]$ and $[\{cis\text{-}L_2Pt\}_3(\mu\text{-}O)_2]^{2+}$.

Once formed, the species $[\{cis\text{-}L_2Pt\}_3(\mu\text{-}O)_2]^{2+}$ are unreactive towards an excess of Cl^- ions. In fact, the ^{31}P NMR spectrum of the isolated complex **3** (in **4**) in DMSO is unaffected by the addition of $AsPh_4Cl$ (molar ratio 1:3), after several days at room temperature. The stability of the Pt−O bonds in these trinuclear oxo complexes is confirmed by the observation that they do not undergo intermolecular exchange. Unlike their hydroxo precursors, when mixed in DMSO, **3** and **4** maintain their structure as is observed by the absence of new resonances in the ^{31}P NMR spectrum of the resulting mixture.

Reactivity of *cis*-$[(PMePh_2)_2Pt(\mu\text{-}OH)]_2^{2+}$ with Cl^-

Under the same conditions as those used for the PMe_3 and PMe_2Ph analogues, complex **2** does not form stable oxo species when treated with Cl^-. The ^{31}P NMR spectrum of a solution of **2** in $CDCl_3$ (or CH_2Cl_2/[D_6]DMSO mixtures) containing $(NEt_4)Cl\cdot H_2O$ (or $AsPh_4Cl$) in a 1:2 molar ratio, exhibit an intense singlet at $\delta = -1.08$ ($^1J_{P,Pt}$ = 3634 Hz) and an AX multiplet (δ = 1.97, $^1J_{P,Pt}$ = 4030 Hz and -9.03 ppm, $^1J_{P,Pt}$ = 3100 Hz, with $^2J_{P,P}$ = 23 Hz) as the main resonance signals. These signals are assigned to *cis*-$[(PMePh_2)_2PtCl_2]$ and to the neutral complex *cis*-$[(PMePh_2)_2PtCl(OH)]$. Two relatively weak signals are seen at $\delta = -8.85$ (singlet, $^1J_{P,Pt}$ = 3602 Hz) and at $\delta = -5.72$ (broad singlet). After 12 h at room temperature, the AX multiplet disappears, the resonance at $\delta = -5.72$ ppm also disappears and is replaced by a very weak singlet at $\delta = -5.92$ due to unchanged complex **2**. A further change in the ^{31}P NMR spectrum occurs after several days, leading to the complete disappearance of the resonance at $\delta = -8.85$. The low concentration and the moderate stability of the species responsible for this singlet prevents better characterization. The absence of the fine structure observed for **3** and **4**, however, seems to exclude the formation of the anal-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ogous trinuclear species *cis*-$[\{(PMePh_2)_2Pt\}_3(\mu\text{-}O)_2]^{2+}$. On the other hand, the formation of a mononuclear species of the type *cis*-$[(PMePh_2)_2Pt(OH)_2]$, (the analogue *cis*-$[(PMe_3)_2Pt(OH)_2]$ (known to be unstable in chlorinated solvents) as has been seen before),[11] is not supported by the value of $^1J_{P,Pt}$ coupling constant. The observed value (3602 Hz), in fact, is only slightly lower than that of the dichloro complex, *cis*-$[(PMePh_2)_2PtCl_2]$ ($^1J_{P,Pt}$ = 3627 Hz); however, the difference between the observed value and those for *cis*-$[(PMe_3)_2Pt(OH)_2]$ (3254 Hz, in CD_2Cl_2) and *cis*-$[(PMe_3)_2PtCl_2]$ (3470 Hz) is large.[11] Similar considerations seem to exclude the formation of *cis*-$[(PMePh_2)_2Pt(\mu\text{-}O)]_2$ since such oxo species should have a $^1J_{P,Pt}$ value that is much lower than that of the precursor hydroxo complex.[3]

Conclusions

The structures of complexes **1** and **2** reported here represent further examples of the preference for the $\{L_2Pt(OH)\}^+$ moiety (L = phosphanes or diphosphanes) to form dinuclear species. This feature is in common with most of the monohydroxo complexes of Pt^{II} with N-donor ligands, although examples of the formation of hydroxo complexes with higher nuclearity from some diamines are known.[12]

An interesting feature of the phosphano-based complexes *cis*-$[L_2Pt(\mu\text{-}OH)]_2^{2+}$ (L = PMe_3, PMe_2Ph, and $PMePh_2$) is their reactivity towards Cl^- ions. Unlike the isostructural hydroxo compounds containing the chelate ligands 2,2′-bipyridine or phenanthroline, which are inert towards LiCl even at 100 °C,[13] they react with Cl^- ions under very mild conditions. When an excess of chloride ions is used, the substitution of the OH^- ligands, to give *cis*-$[L_2PtCl_2]$, is the predominant process. At lower concentrations of Cl^- ions, however, other reaction pathways become competitive, leading to the concomitant formation of the stable complexes $[\{cis\text{-}L_2Pt\}_3(\mu\text{-}O)_2]^{2+}$ when L is PMe_3 or PMe_2Ph, but an unstable and not yet fully characterized species when L is $PMePh_2$.

Experimental Section

Reagent and Chemicals: Reagent grade chemicals $(NEt_4)Cl\cdot H_2O$ (Ega-Chemie) and $(AsPh_4)Cl$ (Fluka) were used as received. The complexes *cis*-$[(PMePh_2)_2PtCl_2]$,[14] *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2X_2$ (X = NO_3,[5] ClO_4),[15] and *cis*-$[(PMe_2Ph)_2Pt(\mu\text{-}OH)]_2(NO_3,)_2$ [6] were synthesized as previously reported.

Instrumentation: ^1H and $\{^1H\}^{31}P$ spectra were obtained with JEOL 90Q and/or Bruker 300AVANCE spectrometers. ^1H chemical shifts are referred to the residual peak of the deuterated solvent ($[D_6]$DMSO), whereas the external reference for ^{31}P is H_3PO_4 (85% w/w in H_2O). IR spectra in the range 4000−400 cm^{-1} were recorded as KBr pellets with a Perkin−Elmer 283 spectrophotometer.

Syntheses of the Complexes

Preparation of *cis*-$[(PMe_2Ph)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ (1b): A solution of $AgNO_3$ (1.15 g, 6.77 mmol) in H_2O (20 mL) was added to a suspension of *cis*-$[(PMe_2Ph)_2PtCl_2]$ (1.84 g, 3.38 mmol) in H_2O (200 mL). The AgCl precipitate formed immediately was removed by filtration, and the resulting solution was neutralized with NaOH (0.092 M). Addition of $NaClO_4\cdot H_2O$ (0.48 g, 3.4 mmol) led to the immediate precipitation of a white microcrystalline solid, which was collected by filtration, washed with H_2O, EtOH, and Et_2O. The yield of the dry product **1b** was 1.29 g (92%). $C_{16}H_{23}ClO_5P_2Pt$ (587.8): calcd. C 32.69, H 3.94; found C 32.41, H 4.01. ^1H NMR at 89.55 MHz in $[D_6]$DMSO: δ = 7.5−7.7 (5 H, Ph), 4.09 (broad s, 1 H, OH), 1.54 (apparent doublet, J_{PH} = 11.7, $^3J_{PtH}$ = 35.6 Hz, 6 H, CH_3) ppm. $\{^1H\}^{31}P$ NMR at 36.23 MHz in $[D_6]$DMSO: δ = −14.50 (s, $^1J_{P,Pt}$ = 3456 Hz; $^2J_{Pt,Pt}$ = 304 Hz) ppm.

Caution*: *The above perchlorate is a potential explosive!

Preparation of *cis*-$[(PMePh_2)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ (2): A solution of $AgNO_3$ (0.794 g, 4.67 mmol) in EtOH (10 mL) and H_2O (2 mL) was added to a solution of *cis*-$[(PMePh_2)_2PtCl_2]$ (1.56 g, 2.34 mmol) in CH_2Cl_2 (20 mL). The AgCl precipitate formed immediately was filtered, and an aqueous solution (25.4 mL) of NaOH (0.092 M) was added to the resulting solution. The solution was concentrated under vacuum, and a white precipitate was obtained, which was recovered by filtration, washed twice with H_2O (10 mL) and dried under vacuum. The yield of the pure product **2** was 1.11 g (70%). $C_{26}H_{27}NO_4P_2Pt$ (674.5): calcd. C 46.29, H 4.03, N 2.08; found C 45.73, H 3.96, N 1.99. ^1H NMR at 89.55 MHz in $[D_6]$DMSO: δ = 7.5−7.8 (10 H, Ph), 3.53 (s broad, 1 H, OH), 1.62 [apparent doublet, J_{PH} = 10.7 Hz, 3 H, CH_3] ppm. $\{^1H\}^{31}P$ NMR in $[D_6]$DMSO: δ = −5.32 (s, $^1J_{P,Pt}$ = 3578, $^2J_{Pt,Pt}$ = 232 Hz) ppm.

Preparation of $[\{cis\text{-}(PMe_3)_2Pt\}_3(\mu\text{-}O)_2](ClO_4)_2$ (3): A solution of $(NEt_4)Cl\cdot H_2O$ (228 mg, 1.24 mmol) in CH_2Cl_2 (20 mL) was added to a stirred solution of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ (576 mg, 0.62 mmol) in DMSO (15 mL), and the resulting pale yellow solution was left at room temperature for 18 h. Addition of Et_2O (100 mL) afforded a white precipitate which was recovered by filtration, dissolved in a minimum amount of CH_2Cl_2 and precipitated by addition of Et_2O. The crude solid (265 mg) was further purified from CH_2Cl_2/Et_2O, and a microcrystalline product was obtained which was recovered by filtration, washed with EtOH and dried under vacuum. The yield of the pure compound **3** was 91 mg [23%, based on Equation (2)]. $C_{18}H_{54}Cl_2O_{10}P_6Pt_3$ (1272): calcd. C 16.99, H 4.28; found C 16.78, H 4.16. ^1H NMR in $[D_6]$DMSO: δ = 1.59 (d, $J_{H,P}$ = 10.3, $^3J_{H,Pt}$ = 34 Hz) ppm. $\{^1H\}^{31}P$ NMR in CD_2Cl_2 (at 36.23 MHz): δ = −31.7 ($^1J_{P,Pt}$ = 3376−3406 Hz) ppm. Crystallization of the solid from $CH_2Cl_2/CHCl_3$ (1:1) gave needle-shaped colorless crystals unsuitable for X-ray diffraction analysis.

Preparation of $[\{cis\text{-}(PMe_2Ph)_2Pt\}_3(\mu\text{-}O)_2]Cl_2$ (4): A solution of $(NEt_4)Cl\cdot H_2O$ (166 mg, 0.90 mmol) in CH_2Cl_2 (10 mL) was added dropwise to a stirred solution of **1b** (533 mg, 0.49 mmol) in DMSO (6 mL). The resulting pale yellow solution was left at ca. 20 °C for 24 h. Addition of Et_2O (120 mL) gave a waxy solid which was rapidly washed with H_2O and then with Et_2O. The dried solid (360 mg) was purified twice by dissolution in CH_2Cl_2 and precipitation with toluene. The yield of **4**, free of the perchlorate salt, was 126 mg [yield 34%, based on Equation (2)]. $C_{48}H_{66}Cl_2O_2P_6Pt_3$ (1517.0): calcd. C 38.00, H 4.38; found C 37.85, H 4.29. ^1H NMR in $[D_6]$DMSO: δ = 7.96−7.53 (complex multiplets, 5 H, Ph), 1.52 (d, $J_{H,P}$ = 10.2 Hz with unresolved ^{195}Pt satellites) ppm. $\{^1H\}^{31}P$ NMR in CD_2Cl_2: δ = −20.1 ($^1J_{P,Pt}$ = 3460−3487 Hz) ppm.

[a] $R(F) = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR(F^2) = [\Sigma w(|F_o|^2 - |F_c|^2)^2/\Sigma w(|F_o|^2)^2]^{1/2}$. [c] GOF $= [\Sigma w(|F_o|^2 - |F_c|^2)^2/(n - p)]^{1/2}$.

X-ray Data Collection, Structure Solution and Refinement of 1a, 2, and 4:[16] The X-ray data collections were performed at room temperature with a Nicolet−Siemens four-circle R3m/V diffractometer on single-crystals mounted in thin-walled glass capillaries with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å).

Crystals of **1a** and **2** were obtained by slow diffusion of vapors of Et_2O into a saturated solution of the corresponding compound in ethanol, whereas crystals of **4** were obtained by slow evaporation of a $CH_2Cl_2/C_6H_5CH_3$ solution of the complex, at room temperature.

A summary of the X-ray analyses carried out on the complexes is listed in Table 4. The cell dimensions for the complexes were determined from the setting angles of 50 centered reflections. Intensity data were collected for unique portions of reciprocal space to the limit of observable diffraction. Corrections for X-ray absorption effects were applied on the basis of azimuthal scan data.[17] The absorption effects have been noticeable only in complex **4**, the transmission factors ranging from 0.637 to 0.996.

The unit cell of **1a** comprises two moieties denoted as **I** and **II**. The structures were solved by heavy-atom methods and refined by full-matrix least-squares against F^2. Pt, P, and phenyl C atoms of **1a** and all non-hydrogen atoms of **2** and **4** were assigned anisotropic displacement parameters. As expected, the nitrate groups of **1a** and **2** endure high thermal motions and they have been treated isotropically.

Final difference syntheses showed no chemically significant features, the largest maxima being close to the platinum. Refinements converged smoothly to residuals given in Table 4. All calculations were made with programs of the SHELXTL/PC[18] system and SHELXL-93[19] program.

Binary and Ternary Cluster Complexes Containing Gold-Selenium, Gold-Indium-Selenium and Gold-Gallium-Tellurium − Synthesis and Structures of $[Au_5Se_2(PPh_3)_4]Cl$, $[(Au_3Se)_2\{Ph_2P(CH_2)_6PPh_2\}_3]Cl_2$, $[Au_{10}Se_4\{Ph_2P(CH_2)_5PPh_2\}_4]InCl_5$, $[Au_4(SeInCl_3)_2\{Ph_2P(CH_2)_5PPh_2\}_2]$, $[Au_2(TeGaCl_3)\{Ph_2P(CH_2)_6PPh_2\}]_2$ and $[Au_8Se_4In\{Ph_2P(CH_2)_2PPh_2\}_4](InCl_4)_3$

Keywords: Cluster compounds / Gallium / Gold / Indium / Selenium / Tellurium

Reactions of gold phosphane complexes $[(AuX)(PR_3)]$ (X = Cl, Br, I; R = organic moiety) with $Se(SiMe_3)_2$ lead to the formation of gold complexes with chalcogenide bridges. The reaction of the complex $[Ph_3PAuCl]$ and *t*BuSe($SiMe_3$) gives the cluster $[Au_5Se_2(PPh_3)_4]Cl$ (**1**). The in situ preparation of the complex $[(AuCl)_2dpph]$ [dpph = $Ph_2P(CH_2)_6PPh_2$] by reaction of dpph with $[Me_2SAuCl]$, and subsequent reaction with $Se(SiMe_3)_2$, leads to the formation of $[(Au_3Se)_2(dpph)_3]Cl_2$ (**2**). Reactions of the gold(I) complex $[(AuCl)_2dpppe]$ [dpppe = $Ph_2P(CH_2)_5PPh_2$] with $Se(SiMe_3)_2$ and $InCl_3$ in different molar ratios lead to the formation of $[Au_{10}Se_4(dpppe)_4]InCl_5$ (**3**) and $[Au_4(SeInCl_3)_2(dpppe)_2]$ (**4**). The reaction of $[(AuCl)_2dpph]$ with $Te(SiMe_3)_2$ and $GaCl_3$ produces the isostructural cluster compound $[Au_4(TeGaCl_3)_2(dpph)_2]$ (**5**). From the reaction of $Se(SiMe_3)_2$ with $[(AuCl)_2dppe]$ [dppe = $Ph_2P(CH_2)_2PPh_2$] and $InCl_3$ $[Au_8Se_4In(dppe)_4](InCl_4)_3$ **6** can be isolated. The structures of **1**–**6** were determined by X-ray diffraction.

Introduction

Due to the important photophysical and photochemical properties of gold(I) complexes, many investigations have been undertaken towards the synthesis and structural analysis of gold complexes and clusters.[1−5] However, only a few examples of gold complexes with selenium or tellurium bridges are known.[2,6]

For the preparation of this kind of cluster complex, a reaction has been developed using metal halides MX_n (M = metal; X = Cl, Br, I) and silylated main group element derivatives, R−E−$SiMe_3$ (R = organic group, $SiMe_3$; E = S, Se, Te), in the presence of a tertiary phosphane PR_3. The driving force of this reaction is the formation of the corresponding trimethylsilyl halide, $XSiMe_3$.[7] The phosphane ligands stabilize the metal cluster complex and avoid theformation of the binary phases.[8] The first results in this kind of preparations, using silylated derivatives of S, Se and Te, were reported by Abel et al. and Schmidbaur et al.[9]

The use of polyphosphanes leads to the formation of large cluster complexes containing copper[10] and silver[11] atoms bridged by chalcogenides. Polyphosphanes were also successfully applied in analogous reactions with gold(I) salts, resulting in the formation of several gold cluster complexes which have been characterized, for example $[Au_{18}Se_8(dppe)_6]Br_2$,[12] $[Au_{10}Se_4(dpppe)_4]Br_2$,[13] $[Au_{34}Se_{14}(tpep)_6(tpep^{Se})_2]Cl_6$ [tpep = $P(PCH_2CH_2PPh_3)_3$ and $tpep^{Se}$ = $Ph_2P(Se)CH_2CH_2P(PCH_2CH_2PPh_3)_2$].[14] Some have been found to have luminescent properties, for example $[Au_{10}Se_4(dpppe)_4]Br_2$,[13] $[Au_{10}(\mu_3\text{-}S)_4(PNP)_4][PF_6]_2$ [PNP = $Ph_2PN(Pr)PPh_2$][15] and $[Au_{12}Se_4(dppm)_6](PF_6)_4$ (dppm = $Ph_2PCH_2PPh_2$).[16]

In contrast to the well-known binary chalcogenide cluster complexes of group 11 metals,[17,18] ternary chalcogenide compounds containing metals of group 11 and 13 are rare and of special interest due to their promising properties. For example, the ternary compounds $CuInSe_2$ or $CuGaSe_2$ have important potential in thin film technology for solar cells.[19] Recently, some ternary cluster compounds, for example $[Cu_{11}In_{15}Se_{16}(SePh)_{24}(PPh_3)_4]$,[20] $[Cu_6In_8S_{13}Cl_4(PEt_3)_{12}]$[21] and $[Ag_6In_8S_{13}Cl_4(PPh_3)_{12}]$[22] have been synthesized. Ternary In-Au and Ga-Au chalcogenide cluster

Scheme 1. Preparation reactions of compounds **1**−**6**

compounds have, to the best of our knowledge, not yet been prepared.

In this work we report the preparation and X-ray characterization of some Au-chalcogenide, In-Au and Ga-Au chalcogenide cluster compounds.

Results and Discussion

Compounds **1**−**6** were prepared as shown in Scheme 1. From the reaction of $[Ph_3PAuCl]$ with tBuSe($SiMe_3$) in CH_2Cl_2 at room temperature a pale yellow solution was obtained. Layering of the solution with *n*-pentane produced yellow crystals of $[Au_5Se_2(PPh_3)_4]Cl$ (**1**). Crystals of the compound $[(Au_3Se)_2(dpph)_3]Cl_2$ [**2**; dpph = $Ph_2P(CH_2)_6PPh_2$] were obtained from the reaction of the corresponding phosphane ligand with $[Me_2SAuCl]$ and $Se(SiMe_3)_2$ in CH_2Cl_2. The final yellow solution was layered with *n*-pentane and, after a few days, yellow crystals were isolated.

Reaction of the gold(I) complex $[(AuCl)_2dpppe]$ [dpppe = $Ph_2P(CH_2)_5PPh_2$][23] with two equivalents of $Se(SiMe_3)_2$ and one equivalent of $InCl_3$ in CH_2Cl_2/THF gave the formation of small yellow crystals of **3**. If the reaction is carried out using an Se:In molar ratio of 1:2, cubic crystals of **4** are formed. Colorless crystals of the isostructural cluster compound **5** were obtained from the reaction of $[(AuCl)_2dpph]$ with $Te(SiMe_3)_2$ and $GaCl_3$ in CH_2Cl_2/THF, and from the reaction of $Se(SiMe_3)_2$ with $[(AuCl)_2dppe]$ [dppe = $Ph_2P(CH_2)_2PPh_2$] and $InCl_3$ (1:1:1) in CH_2Cl_2/THF colorless needles of **6** could be isolated.

The structures of the six compounds were determined by single-crystal X-ray crystallography.

$[Au_5Se_2(PPh_3)_4]Cl$ (1)

Complex **1** crystallizes in the triclinic space group $P\bar{1}$ with four molecules per unit cell and two molecules per asymmetric unit (Figure 1). These are identical within the standard deviations therefore only one of them will be discussed. Two molecules of dichloromethane are present as lattice-bound solvent in the crystal.

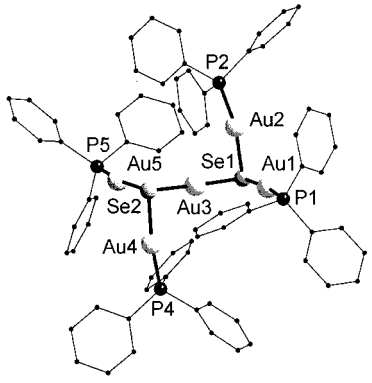

Figure 1. Crystal structure of the cation in **1**; selected distances (pm) and angles (°): Au1−Au2 305.94(9), Au2−Au3 299.56(10), Au3−Au4 304.87(10), Au3−Au5 327.04(11), Au1−Se1 245.17(12), Au2−Se1 245.58(14), Au3−Se1 246.43(12), Au3−Se2 245.75(12), Au4−Se2 243.48(14), Au5−Se2 243.83(12), Au1−P1 227.4(2), Au2−P2 226.6(3), Au4−P4 226.4(3), Au5−P5 226.6(3); Au1−Se1−Au2 77.13(4), Au1−Se1−Au3 78.64(4), Au2−Se1−Au3 75.01(4), Au4−Se2−Au5 79.89(4), Au4−Se2−Au3 77.09(4), Au5−Se2−Au3 83.82(4), Se2−Au3−Se1 177.87(4), P1−Au1−Se1 171.15(7), P2−Au2−Se1 167.65(7), P4−Au4−Se2 170.93(7), P5−Au5−Se2 170.27(7)

The Au_5Se_2 units in **1** are composed of two Au_3Se tetrahedra which share a corner; there are no bonds between the gold atoms inside the Au_5Se_2 unit (see Figure 1). The observed Au−Au distances are within the range 299.56(10)−327.04(11) pm. All selenium atoms act as μ_3-bridges above and below the plane defined by the gold atoms Au1 to Au5, with Au−Se−Au angles between 75.01(4)° and 83.82(4)°. Au−Se distances range from 243.48(14) to 246.43(12) pm, and are within the range of commonly observed distances in other Au−Se cluster complexes.[12−16]

The central gold atom has an almost linear coordination to two selenium atoms (Se1, Se2) with an angle of 177.87(4)°. The peripheral gold atoms also show a linear

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

coordination geometry. The Se−Au−P angles are between 167.65(7) and 171.15(7)°, and the Au−P distances range from 226.4(3) to 227.4(2) pm. An isostructural compound $[Au\{S(AuPPh_3)_2\}_2][(CH_3)_3SnCl_2]$, prepared using a different procedure, has already been reported by Jones et al.[24]

Au_5Se_2 units are known building blocks in other Au−Se cluster cations. Some examples are $[Au_{10}Se_4(dppm)_4]^{2+}$, $[Au_{10}Se_4(dpppe)_4]^{2+}$ and $[Au_{10}Se_4(depe)_4]^{2+}$ [depe = $Et_2P(CH_2)_2PEt_2$].[13,14] In these cases, the complex cations are formed by two Au_5Se_2 units bridged by the phosphane ligands. In the complexes containing dppm and depe, the phosphane carbon chains are shorter, resulting in the formation of more-distorted Au_3Se tetrahedra. In the case of dpppe, the phosphane bridge is longer, resulting in an almost regular Au_3Se tetrahedron. In **1**, however, where a monodentate phosphane ligand was used for the preparation, almost regular Au_3Se tetrahedra are observed as there is no distortion due to the formation of bridges (see above).

$[(Au_3Se)_2(dpph)_3]Cl_2$ (2)

Complex **2** crystallizes in the monoclinic space group $P2_1/c$ with four molecules per unit cell. One molecule of *n*-pentane and one of dichloromethane are present as lattice-bound solvent in the crystal. The bond lengths and angles are within the expected range.[12−16] The cation $[(Au_3Se)_2(dpph)_3]^{2+}$ is composed of two Au_3Se tetrahedra bridged by dpph ligands (see Figure 2).

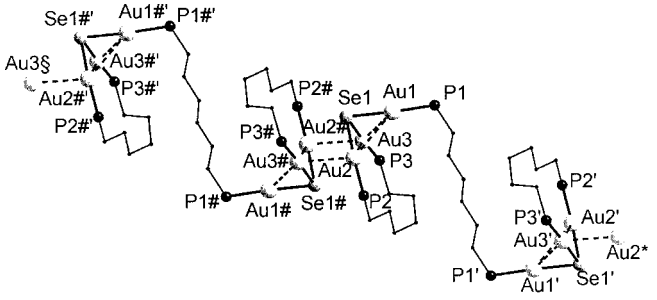

Figure 2. Crystal structure showing two cations in **2**; phenyl rings are omitted for clarity; symmetry transformations for the generation of equivalent atoms: $-x + 1, -y + 1, -z + 1$; selected distances (pm) and angles (°): Au1−Au2 326.19(10), Au1−Au3 301.66(8) Au2−Au3# 304.27(7), Au3−Au2# 304.27(7), Au1−Se1 242.47(10), Au2−Se1 245.38(11), Au3−Se1 247.35(11), Au1−P1 226.2(2), Au2−P2 227.6(3), Au3−P3 227.3(2); P1−Au1−Se1 175.10(7), P2−Au2−Se1 176.10(9), P3−Au3−Se1 177.58(7), Au1−Se1−Au3 76.02(3), Au2−Se1−Au3 82.58(3), Au3−Au2−Au1 55.18(2), Au3−Au1−Au2 62.23(2), Au3#−Au2−Au3 84.98(2), Au3#−Au2−Au1 124.55(1), Au1−Au3−Au2# 135.04(2), Au2#−Au3−Au2 95.02(2)

Selenium atoms act as μ_3-bridges to three gold atoms, building slightly distorted Au_3Se tetrahedra. The Se−Au distances are between 242.47(10) and 247.35(11) pm, and the Au−Se−Au angles range from 76.02(3) to 82.58(3)°.

All gold atoms exhibit an almost linear coordination geometry and are coordinated by a phosphorus and a selenium atom. The P−Au−Se angles are within the range 175.10(7)−177.58(7)° and the Au−P distances are between 226.2(2) and 227.6(3) pm.

Within the Au_3Se tetrahedra, the non-bonding Au−Au distances range from 301.66(8) to 326.19(10) pm. The intermolecular Au−Au distances between two Au_3Se units are relatively short, with a value of 304.27(7) pm. This shows that the short interactions, probably due to the "aurophilic attraction", lead to the formation of a polymeric chain of cations in the solid state.[25] Other examples of gold cluster complexes with secondary Au−Au bonding and solid-state polymers can be found in the literature.[14,26,27]

$[Au_{10}Se_4(dpppe)_4]InCl_5$ (3)

Complex **3** crystallizes in the monoclinic space group $C2/c$ with four molecules per unit cell. The Au_5Se_2 units within the cation of **3** are bridged by dpppe ligands (see Figure 3). The Au−Au distances between the Au_5Se_2 units are 312.3(2) and 333.2(2) pm. The Au_5Se_2 units consist of two Au_3Se tetrahedra sharing a corner (see above). In these tetrahedra, the selenium atoms are acting as μ_3-bridges to three gold atoms, being placed above and below the plane formed by the gold atoms (Au1−Au5 and symmetry equivalents) with Au−Se−Au angles of 74.02(9)° and 82.61(8)°. The Au−Se distances range between 245.2(3) and 247.4(3) pm (Figure 3).

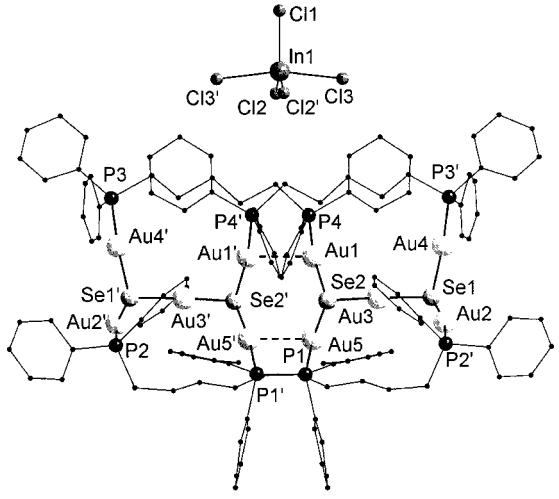

Figure 3. Crystal structure of **3**; symmetry transformations for the generation of equivalent atoms: $-x + 1, y, -z + 1/2$; selected distances (pm) and angles (°): Au1−Se2 244.9(3), Au1−Au3 302.32(16), Au1−Au1′ 312.3(2), Au1−Au5 323.47(19), Au2−Se1 247.4(3), Au2−Au3 294.72(14), Au3−Se1 242.2(3), Au3−Se2 242.7(3), Au3−Au5 306.18(15), Au3−Au4 328.29(16), Au4−P3′ 225.6(8), Au4−Se1 244.5(3), Au4−Au2′ 314.27(18), Au5−P1 226.4(7), Au5−Se2 245.2(3), Au5−Au5′ 333.2(2); P4−Au1−Se2 171.9(2), P4−Au1−Au1′ 108.9(2), Se2−Au1−Au1′ 78.70(7), Au3−Au1−Au1′ 130.03(4), P4−Au1−Au5 132.0(2), Se2−Au1−Au5 48.73(7), Au3−Au1−Au5 58.47(4), Au3−Au2−Au4 64.92(4), Se1−Au3−Se2 175.17(9), Au2−Au3−Au1 160.88(5), P1−Au5−Au1 131.6(2), Se2−Au5−Au1 48.66(8), Au3−Au5−Au1 57.31(4), Au3−Se1−Au2 74.02(9), Au1−Se2−Au5 82.61(8)

A distorted linear coordination geometry is found for the central gold atom (Au3 and symmetry equivalents), bonded to two selenium atoms with an Se−Au−Se angle of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

175.17(9)° and Au−Se distances of 242.2(3) and 242.7(3) pm. All non-central gold atoms also display a linear geometry and are coordinated to a selenium and a phosphorus atom, with Au−P bond lengths between 225.6(8) and 227.7(7) pm and P−Au−Se angles ranging from 169.06(8)° to 175.28(19)°.

An isostructural cation was found in the complex $[Au_{10}Se_4(dpppe)_4]Br_2$.[13,14] However, the Au−Au distances between the Au_5Se_2 units in **3** [312.3(2) and 333.2(2) pm] are longer than those in $[Au_{10}Se_4(dpppe)_4]Br_2$ [300.2(3) and 326.0(4) pm]. The Au−Au distances within the Au_5Se_2 units are shorter in **3** [range from 294.7(30) to 328.3(8) pm] than the ones found in the isostructural cluster $[Au_{10}Se_4(dpppe)_4]Br_2$ [298.0(3) to 334.1(3) pm].

$[Au_2(SeInCl_3)dpppe]_2$ (4)

Cluster **4** crystallizes in the triclinic space group $P\bar{1}$ with two molecules per unit cell. In **4** two gold atoms (Au1, Au2′) are coordinated to a selenium atom (Se1) and two phosphorous atoms (P1′, P2) of the bidentate phosphane ligand (see Figure 4), leading to a distorted linear coordination at gold (P−Au−Se from 173.59(4)° to 178.39(4)°]. The μ_3-Se^{2-} ligand is also coordinated to an In atom (In1) of an $InCl_3$ molecule. In the crystal lattice, two $[Au_2(SeInCl_3)dpppe]$ units form a dimer by inversion symmetry, with a planar square of gold atoms (Au1′−Au2−Au1 83.94(3) and Au2′−Au1−Au2 96.06(3)°]. The Au−Au distances within the Au_2Se units [Au1−Au2′ 320.88(9) pm] are slightly longer than the ones found between both Au_2Se-units [(Au1−Au2 311.67(10) pm]. Related Au_4 arrangements have been observed before in the ionic complex $[(PPh_3Au)_2(SCH_2Ph)](NO_3)$, with values of 307.7 and 319.4 pm for the non-bridged Au−Au distances and distances of 307.7 and 314.2 pm for the bridged ones,[28] and also in $[(PPh_3Au)_2(SC_6H_4CH_3)_2](PF_6)$, which has Au−Au distances of 317.3 pm for the free edges and 315.2 pm for the sulfur-bridged ones.[28] In analogy to these sulfur-bridged complexes, the selenium atoms in **4** are placed above and below the plane of the four-membered ring of gold atoms (Au1−Au2−Au1′−Au2′) with an Au1′−Se1′−Au2 angle of 78.83(3)°. With the $InCl_3$ directly bonded to the selenium atom, compound **4** represents the first step in the build-up of ternary gold indium chalcogenide complexes.

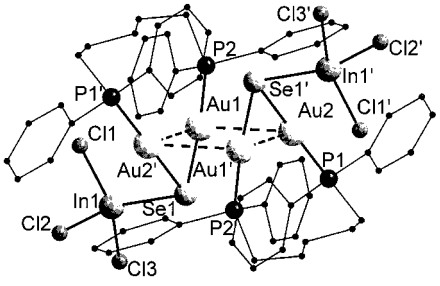

Figure 4. Crystal structure of **4**; symmetry transformations for the generation of equivalent atoms: $-x + 2, -y + 1, -z$; selected distances (pm) and angles (°): In1−Se1 254.74(11), Se1−Au1 244.60(8), Se1−Au2′ 244.95(8), Au1−P2 226.07(16), Au1−Au2 311.67(10), Au1−Au2′ 320.88(9), Au2−Se1′ 244.95(8); Au1−Se1−Au2′ 81.91(3), Au1−Se1−In1 93.95(4), P2−Au1−Se1 173.59(4), P2−Au1−Au2 100.64(5), Se1−Au1−Au2 85.61(4), Se1−Au1−Au2′ 49.09(2), Au2−Au1−Au2′ 96.06(3), P1−Au2−Se1′ 178.39(4), P1−Au2−Au1′ 130.20(4), Au1−Au2−Au1′ 83.94(3)

$[Au_2(TeGaCl_3)dpph]_2$ (5)

Compound **5** crystallizes in the monoclinic space group $P2_1/c$ with two molecules per unit cell. This cluster shows the same structural motif as **4**, with a central arrangement of four gold atoms, bridged by tellurium atoms, which are also coordinated to a $GaCl_3$ molecule (see Figure 5). A distorted linear geometry at each of the gold atoms is observed, with P−Au−Te angles ranging from 171.45(4)° to 176.42(4)°. The μ_3-Te^{2-} ligands are also coordinated to a Ga atom (Ga1, Ga1′) of a $GaCl_3$ molecule. The Au−Au distances are Au1−Au2 305.03(9) and Au2−Au1′ 340.8(1) pm with Au1−Au2−Au1′ and Au2′−Au1′−Au2 angles of 92.10(1)° and 87.90(1)°, respectively.

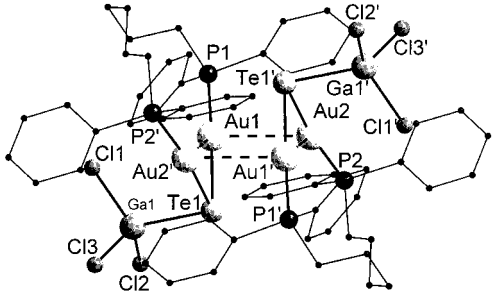

Figure 5. Molecular structure **5**; symmetry transformations for the generation of equivalent atoms: $-x + 1, -y + 1, -z$; selected distances (pm) and angles (°): Ga1−Te1 258.92(12), Te1−Au1 259.43(6), Te1−Au2′ 260.69(6), Au1−Au2 305.03(9), Au2−P2 228.66(14), Au2−Te1′ 260.69(6); Ga1−Te1−Au1 93.96(3), Ga1−Te1−Au2′ 88.89(2), Au1−Te1−Au2′ 81.87(2), P1−Au1−Te1 171.45(4), P1−Au1−Au2 107.21(4), Te1−Au1−Au2 81.34(2), P2−Au2−Te1′ 176.42(4), P2−Au2−Au1 98.32(4), Te1′−Au2−Au1 84.145(19)

$[Au_8Se_4In(dppe)_4](InCl_4)_3$ (6)

Compound **6** crystallizes in the monoclinic space group $C2/c$ (Figure 6). The hydrogen atoms were not calculated for this crystal structure. One molecule of dichloromethane is present as lattice-bound solvent in the crystal. The cation consists of a central indium atom (In1) enclosed within a distorted tetrahedron of four selenium atoms (Se1, Se2, Se1′, Se2′). The In−Se distances range from 258.5(3) to 259.5(3) pm with Se−In−Se angles ranging between 107.10(14)° and 110.85(8)°. Each of these μ_3-Se atoms coordinates to two Au atoms (Au1−Au4 and symmetry equivalent atoms) forming four Au_2Se units with Au−Se bond lengths ranging from 244.7(3) to 244.8(3) pm and Au−Se−Au angles within the range 77.12(7)−78.29(8)°. All the bidentate phosphane ligands (P1−P4 and symmetry equivalent atoms) bridge two Au atoms belonging to two different Au_2Se units, resulting in a distorted linear coordination environment for all Au atoms. Each gold atom is

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

coordinated by one Se and one P atom [Se−Au−P: 167.52(9)−177.75(18)°; Au−P: 226.7(6)−228.2(7) pm]. A distorted eight-membered ring in the boat conformation is formed by the Au atoms, with Au−Au distances ranging from 301.41(15) (Au3−Au4) to 309.04(17) pm (Au4−Au1′). A similar Au−Au distance of 305.1(1) pm is found in $[(PPh_3Au)_2Se]$.[29] The structure of the cation in **3** can be rationalized as an In atom tetrahedrally coordinated by four $dppeAu_2Se$ units, where phosphane ligands connect neighbouring Au_2Se units. Similar Au_2Se units have been stabilized and crystallized before by the use of either monodentate phosphane ligands like PPh_3 in monomeric $[(PPh_3Au)_2Se]$[21] or bidentate phosphanes, such as $Ph_2PC_6H_4PPh_2$ (dppbe), in the polymeric $[Au_2Se(dppbe)]_\infty$.[14]

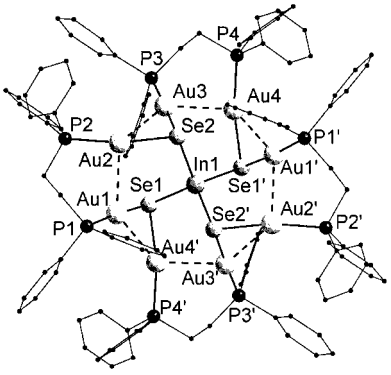

Figure 6. Molecular structure of the cation in **6**; symmetry transformations for the generation of equivalent atoms: $-x + 1$, y, $-z + 0.5$; selected distances (pm) and angles (°): Au1−P1 228.2(7), Au1−Se1 244.8(3), Au1−Au4′ 309.04(17), Au2−P2 226.7(6), Au2−Se2 244.7(3), Au2−Au3 305.06(15), Au3−P3 227.9(7), Au3−Se2 244.7(3), Au3−Au4 301.41(15), Au4−P4 227.4(8), In1−Se1 258.5(3), In1−Se2 259.5(3); P1−Au1−Se1 175.7(2), P1−Au1−Au2 92.62(19), Se1−Au1−Au2 91.61(7), P1−Au1−Au4′ 125.01(19), Se1−Au1−Au4′ 50.85(7) Au2−Au1−Au4′ 137.92(5), P2−Au2−Se2 167.52(19), P2−Au2−Au1 92.49(18), Se1−In1−Se2 110.85(8), Se2−In1−Se2′ 107.10(14), Au4′−Se1−Au1 78.29(8), Au4′−Se1−In1 97.73(9)

Experimental Section

All experiments with chalcogenide ligands were carried out under a dry nitrogen atmosphere. THF was dried over sodium-benzophenone, and CH_2Cl_2 over P_2O_5 followed by distillation of the solvents under nitrogen. Anhydrous $InCl_3$ was obtained from Aldrich.

Preparation of $[Ph_3PAuCl]$: A solution of [Au(thiodiglycol)Cl][30] (0.51 g Au, 2.59 mmol) in MeOH (5 mL) was added to a solution of PPh_3 (0.68 g, 2.59 mmol) in CH_2Cl_2 (20 mL). The mixture was stirred for 2 hours. The volume was reduced to a few milliliters and water (50 mL) was added to produce a white solid. The solid was filtered off, washed with water and dried in vacuo. Yield 85% (1.09 g).

Preparation of $[(AuCl)_2(phosphane)]$:[23,26] A solution of [Au(thiodiglycol)Cl][30] (0.40 g Au, 2.04 mmol) in MeOH (5 mL) was added to a solution of phosphane (phosphane = dppe, dpppe, dppph; 1.02 mmol) in CH_2Cl_2 (10 mL). The final mixture was stirred for 24 hours. The solvents were removed in vacuo and water (50 mL) added. The white precipitate was filtered off, washed with water and Et_2O, and dried in vacuo. Yield 70−85% (dppe 0.62 g, dpppe 0.74 g, dpph 0.80 g).

Preparation of $[Au_5Se_2(PPh_3)_4]Cl$ (1): tBuSe($SiMe_3$) (0.02 mL, 0.022 g, 0.107 mmol) was added at room temperature to a solution of $[Ph_3PAuCl]$ (0.10 g, 0.21 mmol) in CH_2Cl_2 (10 mL),. The final mixture was stirred for 14 hours to give a light yellow solution. This solution was layered with n-pentane and, after a few days, light yellow crystals of **1** had formed (see Table 1). Yield 60% (0.06 g). $C_{74}H_{48}Au_5Cl_5P_4Se_2$ (2396.6): calcd. C 37.05, H 2.67; found C 37.17, H 2.71.

Preparation of $[(Au_3Se)_2(dpph)_3]Cl_2$ (2): A solution of $[Me_2SAuCl]$ (19) (0.1 g, 0.35 mmol) in CH_2Cl_2 (5 mL) was added to a solution of dpph (0.08 g, 0.18 mmol) in CH_2Cl_2 (5 mL). The solutions were stirred for 30 minutes and $Se(SiMe_3)_2$ (0.04 mL, 0.039 g, 0.18 mmol) was added to give a yellow solution. This solution was layered with n-pentane and, a few days later, crystals of **2** had formed (see Table 1). Yield 40% (0.07 g). $C_{102}H_{96}Au_6Cl_2P_6Se_2$ (2916.9): calcd. C 41.96, H 3.29; found C 41.82, H 3.25.

Preparation of $[Au_{10}Se_4(dpppe)_4]InCl_5$ (3): $Se(SiMe_3)_2$ (0.10 mL, 0.44 mmol) was added to a solution of $[(AuCl)_2dpppe]$ (0.20 g, 0.22 mmol) in CH_2Cl_2 (25 mL) to give a yellow solution. A solution of $InCl_3$ (0.05 g, 0.22 mmol) in THF (2 mL) was added and a yellow precipitate was formed. The solid was filtered off and a few days later small yellow crystals of **3** were isolated (see Table 1). Yield 10% (0.02 g). $C_{116}H_{120}Au_{10}Cl_5InP_8Se_4$ (4339.6): calcd. C 32.11, H 2.79; found C 29.96, H 2.78.

Preparation of $[Au_4(SeInCl_3)_2(dpppe)_2]$ (4): $Se(SiMe_3)_2$ (0.05 mL, 0.22 mmol) was added to a solution of $[(AuCl)_2dpppe]$ (0.20 g, 0.22 mmol) in CH_2Cl_2 (25 mL). The solution became yellow. After five days $InCl_3$ (0.10 g, 0.44 mmol) in THF (2 mL) was added to the former solution, to produce colourless cubic crystals of **4** (see Table 1). Yield 65% (0.16 g). $C_{58}H_{60}Au_4Cl_6In_2P_4Se_2$ (2269.2): calcd. C 30.70, H 2.67; found C 29.56, H 2.48.

Preparation of $[Au_4(TeGaCl_3)_2(dpph)_2]$ (5): $Te(SiMe_3)_2$ (0.05 mL, 0.21 mmol) was added to a solution of $[(AuCl)_2dpph]$ (0.19 g, 0.21 mmol) in CH_2Cl_2 (25 mL). A solution of $GaCl_3$ (0.04 g, 0.22 mmol) in THF (2 mL) was then added to the resultant dark brown mixture After a few days colourless crystals of **5** had formed (see Table 1). Yield 40% (0.10 g). $C_{60}H_{64}Au_4Cl_6Ga_2P_4Te_2$ (2304.3): calcd. C 31.27, H 2.80; found C 30.48, H 2.75.

Preparation of $[Au_8Se_4In(dppe)_4](InCl_4)_3$ (6): A solution of $InCl_3$ (0.03 g, 0.12 mmol) in THF (2 mL) was added to a suspension of $[(AuCl)_2dppe]$ (0.10 g, 0.12 mmol) in CH_2Cl_2 (25 mL). $Se(SiMe_3)_2$ (0.03 mL, 0.12 mmol) was added. The mixture was stirred for 2 hours. After 2 days colourless needles of **6** started to grow in the flask (see Table 1). Complete crystallization was achieved by reducing the volume in vacuo. Yield 85% (0.09 g). $C_{104}H_{96}Au_8Cl_{12}In_4P_8Se_4$ (4370.0): calcd. C 28.58, H 2.21; found C 28.15, H 2.21.

X-ray Analyses: STOE-IPDS II (Mo-K_α); data collection and refinement (SHELXTL-97).[31] CCDC-214542 to -214547 (for **1**−**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Tellurated Schiff Bases Formed from {2-[(4-Methoxyphenyl)telluro]ethyl}amine and Bis(2-aminoethyl) Telluride with *o*-Hydroxyacetophenone: Synthesis and Complexation Reactions with Hg^{II}, Pd^{II} and Ru^{II} − Crystal Structures of the Ligands, $[Ru(p\text{-cymene})Cl\{H_2NCH_2CH_2TeC_6H_4\text{-}4\text{-}OCH_3\}]Cl\cdot H_2O$ and $[RuCl\{4\text{-}MeOC_6H_4TeCH_2CH_2NHCH(CH_3)C_6H_4\text{-}2\text{-}O^-\}]$

{2-[(4-Methoxyphenyl)telluro]ethyl}amine and bis(2-aminoethyl) telluride on treatment with *o*-hydroxyacetophenone gave the Schiff bases 4-$MeOC_6H_4TeCH_2CH_2N{=}C(CH_3)C_6H_4$-2-OH (**L¹**) and 2-$HOC_6H_4(CH_3)C{=}NCH_2CH_2TeCH_2CH_2N{=}C(CH_3)C_6H_4$-2-OH (**L³**), respectively. The reduction of **L¹** and **L³** with $NaBH_4$ resulted in 4-$MeOC_6H_4TeCH_2CH_2NHCH(CH_3)C_6H_4$-2-OH (**L²**) and 2-$HOC_6H_4(CH_3)CHNHCH_2CH_2TeCH_2CH_2NHCH(CH_3)C_6H_4$-2-OH (**L⁴**), respectively, which have 1 or 2 chiral centers. The ^1H and ^{13}C NMR spectra of **L¹** to **L⁴** were found to be characteristic. Treatment of **L¹** with $[Ru(p\text{-cymene})Cl_2]_2$ resulted in $[Ru(p\text{-cymene})(4\text{-}MeOC_6H_4TeCH_2CH_2NH_2)Cl]Cl\cdot H_2O$ (**1**) whereas in the reaction of **L²** with $[Ru(p\text{-cymene})Cl_2]_2$, the *p*-cymene ligand is lost resulting in [RuCl(**L²**-H)] (**4**). The reactions of **L¹**, **L³** and **L⁴** with $HgBr_2$ resulted in complexes of the type $[HgBr_2\cdot(\mathbf{L})_2]$ while Na_2PdCl_4 reacted with **L¹** to give [PdCl(**L¹**-H)]. The solid-state structures of **L¹**, **L³**, **1** and **4** were determined by single-crystal X-ray diffraction studies. The very swift formation of the tellurated amine from a tellurated Schiff base (**L¹**) by hydrolysis has been observed for the first time and has resulted in **1**. The Ru–N and Ru–Te bond lengths in **1** are 2.142(3) and 2.6371 (4) Å, respectively. The replacement of the *p*-cymene ligand with a hybrid organotellurium ligand (**L²**-H), resulting in **4**, is also a first example of its kind. The Ru center in **4** has a square-planar geometry, with the Ru–N, Ru–Te, Ru–O and Ru–Cl bond lengths being 2.041(6), 2.4983(8), 2.058(5) and 2.308(2) Å, respectively. In the crystals of **4** there are secondary intermolecular Te···Cl interactions and intermolecular N–H···O hydrogen bonds. This is the first example in which coordinated Te in a complex is engaged in two intermolecular secondary interactions.

Introduction

Schiff bases have been studied extensively as ligands but known tellurated Schiff bases are rare.[1] Some important tellurated Schiff bases reported so far are 1,6-bis[2-(butyltelluro)phenyl]-2,5-diazahexa-1,5-diene,[2] Schiff bases derived by treating bis(*o*-formylphenyl) telluride and *o*-(butyltelluro)-benzaldehyde with chiral amines (*R*)-(+)-[(1-phenylethyl)-amine] and (1*R*,2*S*)-(−)-norephedrine, respectively,[3] and macrocyclic Schiff bases.[4]

In all three instances the tellurated aldehydes were treated with amines to prepare Schiff bases. If a tellurated amine is treated with aldehydes or ketones then a wider range of Schiff-base ligands may be designed by varying the carbonyl group containing compound. We have designed $NH_2CH_2CH_2TeAr$[5] and $NH_2CH_2CH_2TeCH_2CH_2NH_2$,[6] which may be used for this purpose and it was therefore thought worthwhile to synthesize the series **L¹** to **L⁴**. Their metal complexes, in which a metal−tellurium bond is formed, are of interest and so the reactivity of these ligands with species containing Hg^{II}, Pd^{II} and Ru^{II} has been studied. Tellurium being a very "soft" donor does not coordinate with common species of the 3d transition metals. The reaction of **L¹** with $[Ru(p\text{-cymene})Cl_2]_2$ (*p*-cymene = 1-methyl-4-isopropylbenzene) resulted in $[RuCl_2(H_2NCH_2CH_2TeC_6H_4OCH_3)]Cl\cdot H_2O$ (**1**), in which the ligand seems to have been generated by hydrolysis of the Schiff base **L¹**. This is the first example of very easy hydrolysis of a tellurated Schiff base effected by traces of water present in organic solvents. The reaction of $[Ru(p\text{-cymene})Cl_2]_2$ with **L²** resulted in a complex [RuCl(**L²**-H)] (**4**) by loss of a *p*-cymene ligand. This is also the first example where *p*-cymene is replaced by a hybrid organotellurium ligand. **L¹**, **L²**, **1** and **4** have been characterized by single-crystal X-ray dif-

fraction studies. The results of these investigations are reported in this paper.

Results and Discussion

All the tellurated Schiff bases and their reduction products $\mathbf{L^1}$ to $\mathbf{L^4}$ are stable and can be stored under ambient conditions up to 6 months. They have good solubility in $CHCl_3$, CH_2Cl_2, CH_3CN, EtOH and acetone. In MeOH the solubility is moderate for $\mathbf{L^3}$ but good for the other three ligands. In hexane all four ligands either are partially soluble or insoluble. Complexes **1** and **4** are stable under ambient conditions and soluble in $CHCl_3$, CH_2Cl_2, CH_3CN, EtOH, MeOH and acetone but insoluble in hexane. Complex **2** and the mercury complexes of $\mathbf{L^1}$ and $\mathbf{L^3}$ are poorly soluble in $CHCl_3$ and CH_2Cl_2 and insoluble in hexane, acetone, and acetonitrile. $[HgBr_2{\cdot}(\mathbf{L^4})_2]$ is soluble in $CHCl_3$, CH_2Cl_2 and acetonitrile. All the mercury complexes, however, decompose in DMSO. All the ligands as well as **4** are non-electrolytes. The molecular weights were found to be consistent with the monomeric nature of $\mathbf{L^1}$ and $\mathbf{L^2}$. The molar conductivity of **1** was found to be lower than that of a 1:1 electrolyte probably due to association in the solution. **4** is a non-electrolyte but molecular weight measurement suggests intermolecular association in solution. The IR spectra of $\mathbf{L^1}$ and $\mathbf{L^3}$ are characteristic and show >C=N stretching vibrations at 1612 cm^{-1}, which are absent in the spectra of $\mathbf{L^2}$ and $\mathbf{L^4}$. The Te−C(alkyl) vibrations are observed in the IR spectra at 513 to 518 cm^{-1}, whereas Te−C(aryl) vibrations appear at 292 cm^{-1}. In all mercury complexes the potentially polydentate ligands appear to coordinate through the tellurium atom alone since the $-TeCH_2$ signal is deshielded ($\delta \approx 0.4-0.5$ ppm). The ν(Hg−Br) resonance appears in the IR spectra at 278 or 288 cm^{-1}. In complex **2**, the palladium atom appears to be coordinated to a monoanionic tridentate $\mathbf{L^1}$ since both $-TeCH_2$ and $-NCH_2$ are deshielded ($\delta \approx 0.36$ and 0.25 ppm, respectively) and the protons *ortho* and *para* to the oxygen atom are shielded ($\delta \approx 0.2$ ppm). This is corroborated by the $^{13}C\{^1H\}$ NMR spectrum of **2** and a red shift (ca. 17 cm^{-1}) in the >C=N− stretching frequency. Unfortunately, crystals of complexes **2**, **3**, **5** and **6** suitable for X-ray diffraction could not be obtained. In the course of the reaction of $\mathbf{L^1}$ with $[Ru(p\text{-cymene})Cl_2]_2$; the ligand is first hydrolyzed by traces of water present in the solvents resulting in $NH_2CH_2CH_2TeC_6H_4$-4-OMe, which generates complex **1**. This hydrolysis appears to be catalyzed by metallic species since in their absence it was not observed. This is the first example where a tellurated Schiff base is hydrolyzed by traces of water present in the solvent so rapidly and this is probably induced by the metal. Such metal-induced hydrolysis has also been reported earlier for common Schiff-base ligands.[7] The reaction of $\mathbf{L^2}$ with $[Ru(p\text{-cymene})Cl_2]_2$ resulted in the replacement of the *p*-cymene ring with the Te,N,O ligand. So far no hyrbrid organotellurium ligand has been able to displace this ring[1,8] and this is the first example of such behaviour. However, the replacement of the *p*-cymene ring in $[Ru(p\text{-cymene})Cl_2]_2$ has been reported earlier with some polydentate hybrid phosphanes.[9] The reactions of $\mathbf{L^3}$ and $\mathbf{L^4}$ with $[Ru(p\text{-cymene})Cl_2]_2$ and $[Ru(DMSO)_4Cl_2]$ gave intricate mixtures which are very difficult to separate.

Molecular Structures of $\mathbf{L^1}$ and $\mathbf{L^3}$

The structures of $\mathbf{L^1}$ and $\mathbf{L^3}$ are shown in Figures 1 and 2 with selected bond lengths and angles given in Table 1. In $\mathbf{L^1}$, Te−C(11) [2.111(3) Å] is shorter than Te−C(10) [2.142(3) Å]. For $\mathbf{L^3}$, Te−C(10A) and Te−C(10B) are 2.143(4) and 2.148(4) Å, respectively. These values are closer to that of Te−C(10) in $\mathbf{L^1}$ and consistent with the earlier reports that Te−C(aryl) bonds are shorter than Te−C(alkyl) bonds.[10] In $\mathbf{L^1}$ the angle C(11)−Te(1)−C(10) is 94.29(11)° which is consistent with the

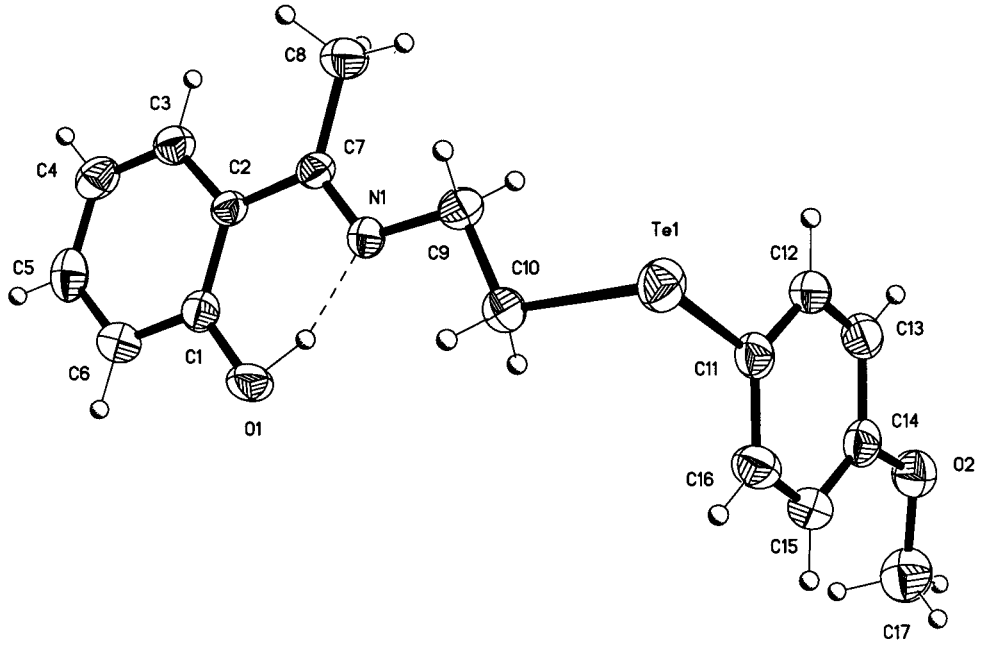

Figure 1. Molecular structure of **L**[1]

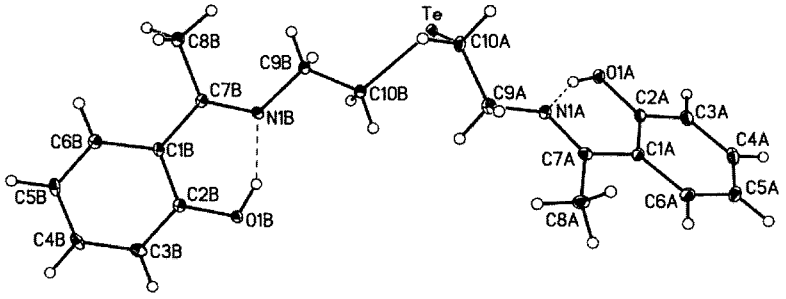

Figure 2. Molecular structure of **L**[3]

C(10A)−Te−C(10B) angle of 94.88(14)° in **L**[3] as well as other related values reported in the literature.[10] The molecules of both these ligands have intramolecular hydrogen bonding. The azomethine bond length is nearly the same in both ligands, N(1)−C(7) is 1.284(3) Å, with N(1B)−C(7B) and N(1A)−C(7A) both being 1.287(4) Å.

Molecular Structures of 1 and 4

The molecular structure of **1** is shown in Figure 3 and selected bond lengths and angles are given in Table 1. In the lattice of **1** there is one water molecule per molecule of the complex. The Ru−N bond length is 2.142(3) Å (sum of covalent radii ca. 1.95 Å) and consistent with literature reports of 2.056(6) Å in $[Ru(bipy)_3][PF_6]_2$,[11] 2.042(5)−2.154(6) Å in Ru^{II} complexes of 2-(arylazo)pyridines,[12] 1.990(3)−2.087(5) Å for Ru^{II} complexes of tetradentate ligands based on 2,6-bis(pyrazol-1-yl)pyridine,[13] 2.060(5) and 2.079(4) Å for [Ru(*p*-cymene)Cl{2,3-bis(2-pyridyl)pyrazine}]BF_4 [14] and 2.077(3)−2.113(3) for Ru^{II} complexes of oxazoline-based ligands. The Ru−Te bond length is 2.6371(4) Å which is consistent with earlier reports [2.619(8)−2.656(8) Å] of Ru^{II} complexes of hybrid organotellurium ligands.[15] The bond angles at the Ru center are normal. The bond angles at Te and the coordinating N atom are consistent with their nearly trigonal-pyramidal [92.28(11)−106.82(9)°] and tetrahedral [120.0(2)°] geometries, respectively.

The molecular structure of **4** is shown in Figure 4 and selected bond lengths and angles are given in Table 1. The Ru−N bond length is 2.041(6) Å which is shorter than that of **1** but consistent with the literature reports mentioned above. The Ru−Te bond length 2.4983(8) Å is significantly shorter than that of **1** and also shorter than the sum of covalent radii of 2.62 Å. The Ru−O bond length is 2.058(5) Å (sum of covalent radii ca. 1.91 Å) and agrees with the values of 2.034(5)−2.232(5) Å reported for complexes of Ru^{II} with a variety of ligands.[16] The Ru−Cl bond length of 2.308(2) Å (sum of covalent radii ca. 2.24 Å) is somewhat shorter than the reported range of 2.404(3)−2.434(1) Å for complexes of the [Ru(*p*-cymene)Cl_2] moiety with hybrid organotellurium ligands.[15] There are two interesting features of the structure of **4**. The first is the intermolecular second-

ary interactions between each Te and two Cl atoms of neighboring molecules [Te···Cl distances of 3.322(2)−3.805(2) Å are less than the sum of van der Waals radii of 4.0 Å], which makes the geometry around the Te center distorted pseudo-octahedral. The second feature of interest is the intermolecular N−H···O hydrogen bond. The bond angles at Ru (Table 1) suggest that the N, O, Te and Cl centers are arranged around it in an almost square-planar

geometry. The Te···Cl secondary interaction observed in **4** has not been reported so far for coordinated Te in any complex of Te ligands. The present one is the first example of its kind.

Conclusion

Tellurated Schiff bases have been synthesized from tellurated amines and characterized structurally. This route has been rarely used, however. The reactions of 4-$MeOC_6H_4$-$TeCH_2CH_2N{=}C(CH_3)C_6H_4$-2-OH (**$L^1$**) with [Ru(*p*-cymene)$Cl_2$]$_2$ first results in the hydrolysis of **L^1** which appears to be metal-promoted. Thereafter, the tellurated amine, (4-$MeOC_6H_4TeCH_2CH_2NH_2$) forms complexes with the Ru^{II} moiety. The reaction of 4-$MeOC_6H_4TeCH_2CH_2$-$NHCH(CH_3)C_6H_4$-2-OH (**L^2**) with [Ru(*p*-cymene)Cl_2]$_2$ resulted in loss of a *p*-cymene ring. So far, in the reaction of [Ru(*p*-cymene)Cl_2]$_2$ with Te ligands, this has never been reported and the present example is the first of its kind. The Te···Cl secondary interaction observed in **4** has not been reported so far for coordinated Te in any complex of Te-based ligands and the present one is the first example.

Experimental Section

General: C and H analyses were carried out with a Perkin−Elmer elemental analyzer 240 C. Tellurium contents were estimated by atomic absorption spectroscopy. The ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded with a Bruker Spectrospin DPX-300 NMR spectrometer operating at 300.13 and 75.47 MHz, respectively. IR spectra in the range of 4000−250 cm^{-1} were recorded with a Nicolet Protége 460 FT-IR spectrometer as KBr or CsI pellets. The conductivity measurements were carried out in acetonitrile (concentration ca. 1 mM) using an ORION conductivity meter model 162. The molecular masses (concentration ca. 5 mM) in chloroform were determined with a Knauer vapor pressure osmometer model A0280. The melting points determined in open capillary are reported as such. {2-[(4-Methoxyphenyl)telluro]ethyl}amine[5] and bis(2-aminoethyl) telluride[6] were prepared by the reported methods.

X-ray Diffraction Analyses: X-ray diffraction data for **L^3**, **1** and **4** were collected with a Bruker Smart APEX CCD diffractometer, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 293(2) K. An analytical face-indexed absorption correction was applied. The structures where solved by direct methods. Refinement was carried out using full-matrix least-squares analyses with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were placed in calculated positions and refined using a riding model with fixed isotropic thermal parameters. Calculations were carried out with SMART software for data collection and data reduction and SHELXTL for solution and refinement.[17] A summary of relevant crystallographic results appears in Table 2. For **L^1**, the data were collected with a Bruker SMART 1K CCD diffractometer using X-rays of wavelength 0.71073 Å (Mo-K_α source). A semiempirical absorption correction was applied.[18] Cell refinement was done with the SMART and SAINT programs.[19] The structure was solved in a similar manner to those of **L^3**, **1** and **2** using SHELXTL.[20] CCDC-214420 (**1**), -214421 (**L^1**), -214422 (**4**) and -214423 (**L^3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at

Synthesis of L^1: {2-[(4-Methoxyphenyl)telluro]ethyl}amine (1.39 g, 5.0 mmol) was stirred in dry ethanol (20 mL) at room temperature for 0.5 h. *o*-Hydroxyacetophenone (0.68 g, 5.0 mmol), dissolved in dry ethanol (20 mL), was added to the above solution dropwise with stirring. The mixture was stirred at room temp. for a further 2 h. The solvent was evaporated in a rotary evaporator resulting in a yellow precipitate. The precipitate, on recrystallization from chloroform/hexane (1:1), afforded yellow single-crystals of L^1. Yield 1.61 g (85%); m.p. 82−83 °C. Λ_M = 0.9 cm^2·mol^{-1}·ohm^{-1}. $C_{17}H_{19}NO_2Te$ (396.9): calcd. C 51.44, H, 4.82, N 3.53, Te 32.15; found C 51.26, H 4.81, N 3.16, Te 31.86. Molecular mass: calcd. 396.6; found 399.0. ^{1}H NMR ($CDCl_3$, TMS, 25 °C): δ = 2.27 (s, 3 H, CH_3), 3.13 (t, 2 H, 2-H), 3.81 (s, 3 H, OCH_3), 3.92 (t, 2 H, 1-H), 6.76−6.82 (m, 3 H, ArH *m* to Te and 7-H), 6.945 (d, J = 8.4 Hz, 1 H, 9-H), 7.30−7.32, (m, 1 H, 8-H), 7.505 (d, J = 8.1 Hz, 1 H, 6-H), 7.745 (d, J = 8.4 Hz, 2 H, ArH *o* to Te), 16.00 (br. s, 1 H, OH) ppm. ^{13}C{1H} NMR ($CDCl_3$, 25 °C, TMS): δ = 8.32 (CH_3), 14.54 (C-2), 50.87 (C-1), 55.11 (OCH_3), 99.67 (ArCTe), 115.21 (ArC *m* to Te), 117.11 (C-6), 118.63 (C-8), 119.10 (C-4), 127.97 (C-9), 132.40 (C-7), 141.34 (ArC *o* to Te), 159.90 (Ar-$COCH_3$), 163.53 (C-5), 171.38 (C-3) ppm.

Synthesis of [Ru(*p*-cymene)Cl($H_2NCH_2CH_2TeC_6H_4$-4-OCH_3)]-Cl·H_2O (1): $[RuCl_2(p\text{-cymene})]_2$ (0.62 g, 1 mmol) was dissolved in dichloromethane (10 mL). A solution of L^1 (0.79 g, 2 mmol), prepared in dichloromethane (20 mL), was added with vigorous stirring. The mixture was stirred for a further 3 h. The solvent was removed in a rotary evaporator under reduced pressure. The resultant precipitate was recrystallized from chloroform/hexane (1:1). The dark-red crystals of **1** were washed immediately with dichloromethane and recrystallized again to give dark-orange single crystals. Yield ca. 0.85 g (ca. 60%); m.p. 160 °C (dec.). Λ_M = 43.0 cm^2·mol^{-1}·ohm^{-1}. Molecular mass: calcd. 603; found 648. $C_{19}H_{27}Cl_2NORuTe{\cdot}H_2O$ (603): calcd. C 39.01, H 4.65, N 2.39, Te 21.81; found C 38.97, H 4.83, N 2.56, Te, 21.22. ^{1}H NMR ($CDCl_3$, 25 °C, TMS): δ = 1.22 (d, J = 6.6 Hz, 3 H, CH_3 of *i*Pr), 1.315 (d, J = 6.6 Hz, 3 H, CH_3 of *i*Pr), 2.27 (s, 3 H, CH_3 *p* to *i*Pr), 2.69−2.74 (sept, 1 H, CH of *i*Pr), 2.69−2.72 (t, 2 H, $TeCH_2$), 3.53−3.56 (t, 2 H, NCH_2), 3.83 (s, 3 H, OCH_3), 5.13−5.96 (m, 4 H, ArH of *p*-cymene), 7.045 (d, J = 8.4 Hz, 2 H, ArH *m* to Te), 8.005 (d, J = 8.7 Hz, 2 H, ArH *o* to Te), 8.46 (br. s, 2 H, NH_2) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C, TMS): δ = 17.28 ($TeCH_2$), 18.89 (*p*-cymene CH_3), 24.69 and 25.73 (CH_3 of *i*Pr of *p*-cymene), 30.75, 31.41 (CH of *i*Pr of *p*-cymene), 42.55 (NCH_2), 55.36 (OCH_3), 76.58−85.13 (ArC of *p*-cymene *m* and *o* to *i*Pr), 101.51 (ArCTe), 104.75 ($ArCCH_3$ of *p*-cymene), 105.88 (ArC-*i*Pr of *p*-cymene), 115.15−116.34 (ArC *m* to Te), 138.09 (ArC *o* to Te), 161.69 (Ar-$COCH_3$) ppm. IR (KBr): nu(tilde) = 361 ν(Ru−Cl), 440 ν(Ru−N) cm^{-1}.

Synthesis of [PdCl(L^1-H)] (2): $Na_2[PdCl_4]$ (0.294 g, 1 mmol) was dissolved in water (5 mL). A solution of L^1 (0.397 g, 1 mmol) prepared in acetone (10 mL) was added with vigorous stirring. An orange precipitate of **2** was immediately obtained which was filtered and dried. The orange solid was recrystallized from chloroform/methanol/hexane to give crystals of **2**. Yield ca. 0.37 g (ca.72%); m.p. 162 °C. $C_{17}H_{18}ClNO_2PdTe$ (533.8): calcd. C 37.97, H 3.37, N 2.60, Te 23.80; found C 39.48, H 3.47, N 2.43, Te 23.65. ^{1}H NMR ($CDCl_3$, 25 °C, TMS): δ = 2.39 (s, 3 H, CH_3), 3.49 (t, 2 H, 2-H), 3.82 (s, 3 H, OCH_3), 4.17 (t, 2 H, 1-H), 6.61−6.66 (m, 3 H,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ArH *m* to Te and 7-H), 6.915 (d, J = 8.7 Hz, 1 H, 9-H), 7.12−7.14, (m, 1 H, 8-H), 7.335 (d, J = 9.0 Hz, 1 H, 6-H), 8.065 (d, J = 9.0 Hz, 2 H, ArH *o* to Te) ppm. $^{13}C\{1H\}$ NMR ($CDCl_3$, 25 °C, TMS): δ = 13.38 (CH_3), 19.29 (C-2), 62.76 (C-1), 55.01 (OCH_3), 102 (ArCTe), 115.38 (ArC *m* to Te), 115.71 (C-6), 120.86 (C-8), 125.01 (C-4), 127.68 (C-9), 130.86 (C-7), 138.58 (ArC *o* to Te), 159.90 ($ArCOCH_3$), 163.53 (C-5), 171.38 (C-3) ppm. IR (KBr): $\tilde{\nu}$ = 306 ν(Pd−Cl), 486 ν(Pd−N) cm^{-1}.

Synthesis of $[HgBr_2{\cdot}(L^1)_2]$ (3): $HgBr_2$ (0.720 g, 2 mmol) was dissolved in acetone (5 mL). A solution of $\mathbf{L^1}$ (1.588 g, 4 mmol), prepared in chloroform (10 mL), was added with stirring. The mixture was stirred for a further 0.5 h. A yellow solid separated out which was filtered, washed with acetone and dried. Yield 1.66 g (ca. 85%); m.p. 138 °C. $C_{34}H_{38}Br_2HgN_2O_2Te_2$ (1154): calcd. Te 22.8; found Te 21.6. ^1H NMR ($CDCl_3$, 25 °C, TMS): δ = 2.38 (s, 6 H, CH_3), 3.56 (t, 4 H, 2-H), 3.82 (s, 6 H, OCH_3), 4.04 (t, 4 H, 1-H), 6.80−6.83 (m, 3 H, ArH *m* to Te and 7-H), 6.925 (d, J = 9.0 Hz 1 H, 9-H), 7.505 (d, J = 7.8 Hz, 1 H, 6-H), 7.745 (d, J = 8.7 Hz, 2 H, ArH *o* to Te) ppm; signal due to 8-H merged with that of chloroform (δ = 7.26 ppm).

Synthesis of L^2: $\mathbf{L^1}$ (0.40 g, 1 mmol) and $NaBH_4$ (0.38 g, 10 mmol) were heated to reflux in dry ethanol (100 mL) for 24 h. The solution was cooled and the solvent was evaporated in vacuo. The ligand was extracted with dichloromethane and the extract dried with sodium sulfate. The solvent was removed in vacuo. $\mathbf{L^2}$ was obtained as highly viscous pale yellow oil. Yield 0.28 g (70%); Λ_M = 0.4 $cm^2{\cdot}mol^{-1}{\cdot}ohm^{-1}$. $C_{17}H_{21}NO_2Te$ (399): calcd. Te 31.98; found Te 31.31. ^1H NMR ($CDCl_3$, 25 °C, TMS): δ = 1.38 (d, J = 6.6 Hz, 3 H, CH_3), 1.87−1.97 (br. s, 1 H, NH), 2.83−2.98 (m, 4 H, 1-H + 2-H), 3.78 (s, 3 H, OCH_3), 3.83−3.88 (m, 1 H, CH), 6.71−6.79 (m, 4 H, ArH *m* to Te and 7-H + 9-H), 6.885 (d, J = 7.5 Hz, 1 H, 6-H), 7.09−7.14 (m, 1 H, 8-H), 7.655 (d, J = 8.7 Hz, 2 H, ArH *o* to Te), 11.40 (very br. s, OH) ppm. $^{13}C\{1H\}$ ($CDCl_3$, 25 °C, TMS): δ = 8.83 (C-1), 22.27 (CH_3), 47.65 (C-1), 55.09 (OCH_3), 58.19 (C-3) 99.67 (ArCTe), 115.29 116.67 (ArC *m* to Te), 118.95 (C-6), 120.20 (C-8), 126.50 (C-4), 127.90 (C-9), 128.26 (C-7), 140.23−141.07 (ArC *o* to Te), 157.12 ($ArCOCH_3$), 159.91 (C-5) ppm.

Synthesis of $[RuCl(L^2\text{-}H)]$ (4): $[RuCl_2(p\text{-cymene})]_2$ (0.62 g, 1 mmol) was dissolved in dichloromethane (10 mL). A solution of $\mathbf{L^2}$ (0.80 g, 2 mmol), prepared in dichloromethane (20 mL), was added with vigorous stirring. The mixture was stirred for a further 3 h. The solvent was removed in a rotary evaporator under reduced pressure. The dark orange single crystals of **4** were grown from chloroform/hexane (1:1). Yield 0.72 g (67%); m.p. 100 °C (dec.). Molecular mass: calcd. 535.41; found 1037. Λ_M = 0.9 $cm^2{\cdot}mol^{-1}{\cdot}ohm^{-1}$. $C_{17}H_{20}ClNO_2RuTe$ (534.4): calcd. C 38.21, H 3.77, N 2.62, Te 23.88; found C 39.01, H 4.20, N 2.22, Te 23.16. IR (KBr): $\tilde{\nu}$ = 361 ν(Ru−Cl), 450 ν(Ru−N) cm^{-1}.

Synthesis of L^3: Bis(2-aminoethyl) telluride (1.13 g, 2.5 mmol) was stirred at room temperature in dry ethanol (20 mL) for 0.5 h. 2-Hydroxyacetophenone (0.68 g, 5 mmol), dissolved in dry ethanol (20 mL), was added to the above solution dropwise with stirring. The mixture was stirred at room temp. for a further 6 h, was then kept at 0−5 °C for 24 h. $\mathbf{L^3}$ separated as a yellow precipitate. The precipitate was recrystallized at 0−5 °C from chloroform/hexane (1:1) to give yellow single crystals of $\mathbf{L^3}$. Yield 1.13 g (80%); m.p. 95−96 °C. Λ_M = 0.86 $cm^2{\cdot}mol^{-1}{\cdot}ohm^{-1}$. Molecular mass: calcd. 452; found 444.5. $C_{20}H_{24}N_2O_2Te$ (452): calcd. C 53.14, H, 5.35, N 6.20, Te 28.23; found C 52.52, H 5.42, N 6.74, Te 27.66. ^1H NMR ($CDCl_3$, 25 °C, TMS): δ = 2.32 (s, 6 H, CH_3), 3.02−3.07 (t, 4 H, $TeCH_2$), 3.94−3.99 (t, 4 H, 1-H), 6.75−6.80 (m, 2 H, 8-H), 6.915 (d, J = 8.1 Hz, 2 H, 9-H) 7.26−7.30 (t, 2 H, 7-H), 7.502 (d, J = 8.1 Hz, 2 H, 6-H), 15.93 (br. s, 1 H, OH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25 °C, TMS): δ = 3.49 (C-2), 14.73 (CH_3), 51.64 (NCH_2), 117.27 (C-6), 118.57 (C-8), 119.36 (C-4), 128.06 (C-9), 132.43 (C-7), 163.32 (C-5), 171.60 (C-3) ppm.

Synthesis of $[HgBr_2(L^3)_2]$ (5): $HgBr_2$ (0.360 g, 1 mmol) was dissolved in acetone (5 mL). A solution of $\mathbf{L^3}$ (0.904 g, 2 mmol), prepared in chloroform (10 mL), was added with stirring. The mixture was stirred for a further 1 h. A yellow solid separated out which was filtered, washed with acetone and dried. Yield 1.01 g (80%); m.p. 142 °C. $C_{34}H_{38}Br_2HgN_2O_2Te_2$ (1264): calcd. Te 20.25; found Te 19.88. ^1H NMR ($CDCl_3$, 25 °C, TMS): δ = 2.29 (s, 12 H, CH_3), 3.49−3.53 (t, 8 H, 2-H), 4.07−4.11 (t, 8 H, 1-H), 6.75−6.80 (t, 4 H, 8-H), 6.873 (d, J = 8.1 Hz, 4 H, 9-H), 7.22−7.27 (m, 4 H, 7-H), 7.48 (d, J = 6.9 Hz, 4 H, 6-H), 15.13 (br. s, OH) ppm.

Synthesis of L^4: $\mathbf{L^3}$ (0.452 g, 1 mmol) and $NaBH_4$ (0.38 g, 10 mmol) were heated to reflux in dry ethanol (100 mL) for 24 h. The solution was cooled and the solvent was evaporated in vacuo. The ligand was extracted with dichloromethane and the extract dried with sodium sulfate. The solvent was removed in vacuo affording $\mathbf{L^4}$ as a highly viscous pale yellow oil. Yield 0.31 g (67%); Λ_M = 0.90 $ohm^{-1}{\cdot}cm^2{\cdot}mol^{-1}$. $C_{17}H_{21}NO_2Te$ (456): calcd. Te 25.52; found Te 24.93. ^1H NMR ($CDCl_3$, 25 °C, TMS): δ = 1.361, 1.365 (2 d, J = 6.6, 9.9 Hz, 6 H, CH_3), 2.54−2.75 (m, 8 H, 1-H + 2-H), 3.83−3.84 (m, 2 H, CH), 6.67−6.74 (m, 4 H, 7-H + 9-H), 6.86 (d, J = 7.2 Hz, 2 H, 6-H), 7.03−7.08 (m, 2 H, 8-H), 11.40 (very br. s, OH) ppm.

Synthesis of $[HgBr_2(L^4)_2]$ (6): $HgBr_2$ (0.360 g, 1 mmol) was dissolved in acetone (5 mL). A solution of $\mathbf{L^4}$ (0.904 g, 2 mmol), prepared in chloroform (10 mL), was added with stirring. The mixture was stirred for a further 1 h. A yellow solid separated out which was filtered, washed with acetone and dried. Yield 1.02 g (ca.80%); m.p. 105 °C. $C_{34}H_{38}Br_2HgN_2O_2Te_2$ (1272): calcd. Te 20.12; found Te 19.35. ^1H NMR ($CDCl_3$, 25 °C, TMS): δ = 2.16 (s, 12 H, CH_3), 2.81 (br. s, 8 H, 1-H), 3.10 (br. s, 8 H, 2-H), 3.99 (m, 2 H, CH), 6.77−6.79 (m, 4 H, 7-H + 9-H), 6.99 (d, J = 6 Hz, 2 H, 6-H), 7.09−7.11 (m, 2 H, 8-H) ppm.

Sodium Hydro(isothiocyanato)borates: Synthesis and Structures[‡]

Heinrich Nöth*[a] and Marcus Warchhold[a]

Dedicated to Prof. Dr. B. Krebs on the occasion of his 65th birthday

Keywords: Crown compounds / Sodium / NMR spectroscopy / Borates

Sodium thiocyanate reacts in THF solution with 18-crown-6 to give the molecular compound Na(18-crown-6)(THF)NCS (**3**) with the N atom of the NCS anion oriented towards Na^+. The same reaction with 15-crown-5 yields the ion pair Na(15-crown-5)NCS (**4**). In contrast, $Na(NCS)(py)_4$, obtained by treating a solution of $Na(H_3BNCS)$ in THF with pyridine, yields $Na(py)_4(NCS)$ (**5**), which has a chain structure with hexacoordinate Na atoms coordinated to five N atoms and an S atom. Na(NCS) in THF adds 1 equiv. of BH_3 to give $Na(H_3BNCS)\cdot n$THF. Addition of 18-crown-6 to this solution yields crystals of the salt $[Na(18\text{-crown-6})(THF)_2][H_3BNCS]$ (**1**), as shown by X-ray crystallography. Both the cation and the anion show site disorder. However, when 15-crown-5 is used for complexation, the salt $[Na(15\text{-crown-5})(THF)][H_3BNCS]$ (**2**) can be isolated. Its anion shows an almost linear B–N–C–S unit. Only a mixture of (catecholato)-(isothiocyanato)borates results on treating Na(NCS) in THF with catecholborane. However, the borate $Na[catB(NCS)_2]$ is readily formed by adding Na(NCS) to *B*-(isothiocyanato)catecholborane. Single crystals of this compound were obtained as the salt $[Na(18\text{-crown-6})(THF)_2][catB(NCS)_2]$ (**6**). On the other hand, the reaction of Na(NCS) with 9-borabicyclo[3.3.1]nonane (9-BBN) in THF yields Na[(9-BBN)NCS)]·*n*THF, and, on addition of 18-crown-6, the complex $[Na(18\text{-crown-6})(THF)_2][(9\text{-BBN})NCS]$ was isolated. Suitable crystals for X-ray structure determination were, however, only obtained by crystallization from tetrahydropyran. This solvate has the rather unusual structure $[Na(18\text{-crown-6})(thp)_2][\{(9\text{-BBN})NCS\}_2Na(thp)_4]$ (**8**). The sodiate anion has an Na atom coordinated by two S and four O atoms. DFT calculations support these experimental results: The (isothiocyanato)borates are more stable than the thiocyanato isomers. For the latter a bent structure of the B–S–C–N unit with a B–S–C bond angle of 105.7° is predicted.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

It is well known that the reducing power of alkali metal tetrahydroborates can be influenced by introducing various substituents at the boron atom.[2] In general, there are two routes to these "mixed" hydroborates: (i) reactions of MBH_4 (M = Li, Na, K) with protic reagents HX (X = CN, RCOO, RO), or (ii) addition of the BH_3 component of $H_3B{\cdot}L$ (L = THF, Me_2S, NR_3) to a nucleophilic anion X^- (X = R, NR_2, OR, CN, NCS). The action of $BH_3{\cdot}$THF on MSCN was first reported by Aftandilian et al.[3] They concluded from IR data that the BH_3 unit is attached to the S atom of the thiocyanate anion to give $(H_3B{-}SCN)^-$. Klanberg et al.,[4] however, showed that $Li[B(NCS)_4]$ contains isothiocyanate substituents. About 18 years later, Hui analyzed the IR spectra again[5] and came to the conclusion that the adduct of BH_3 with NCS^- is better formulated as the isomer $(H_3B{-}NCS)^-$. Moreover, NMR spectroscopic data also favored the isothiocyanato structure.[6] In order to finally settle the question of isomerism we studied several borate complexes containing the NCS anion by X-ray crystallography.

Results

Crown Ether Complexes of Na(NCS) and Na($H_3B{-}NCS$)

The compound $Na(H_3B{-}NCS)$, was prepared as shown in Equation (1) and precipitated as the 18-crown-6 solvate **1** by adding the ligand to its THF solution. In previously reported reactions the salt $Na(H_3B{-}NCS)$ was precipitated as a dioxane solvate.[2,4]

$$NaSCN + BH_3{\cdot}THF \xrightarrow[THF]{\text{18-crown-6}} \underset{\mathbf{1}}{Na(H_3B\text{-}NCS){\cdot}THF{\cdot}18\text{-crown-6}} \quad (1)$$

Table 1 summarizes some information on the IR data of H_3BNCS^- salts, some of our experimental results as well as results obtained by DFT[7] calculations. In addition IR data for Na(SCN)(15-crown-5) and MeNCS[8] are included.

Table 1. IR bands [cm^{-1}] reported for $(H_3B-NCS)^-$ compared with Na(NCS)(15-crown-5), MeNCS and DFT calculation (for NCS^-)

	Ref.[2]	Ref.[5]	Ref.[5]	**1**	Na(NCS)(14-crown-4)[9]	MeNCS[8]	$(H_3BNCS)^-$, DFT calcd.
νBH	2380−2300	2380, 2330, 2290	2334, 2295, 2260	2365, 2325	–	–	2358, 2355, 2354
νNCS	2175, 2085	2180, 2080	2158, 2055	2172, 2050	2045	2129	2149

We found in most samples of **1** an IR band at 2050 cm^{-1} with different intensities (weak to medium), in addition to a strong band at 2172 cm^{-1}. The band at 2050 cm^{-1} is most likely due to the presence of NCS^-, as can be deduced from the band found at 2045 cm^{-1} observed in Na(NCS)(15-crown-5).[9] In order to make reliable assignments we performed DFT calculations at the B3LYP/6-311**G(d,p) level. There should be two IR-active B−H stretching frequencies at 2355 and 2358 cm^{-1}. Because the calculations were also performed for C_1 symmetry, the degeneracy for ν_{as} (2355 cm^{-1}) is removed, but the third vibration is close to the degenerate band and probably was not resolved experimentally. Moreover, the BH vibrations couple with the CN vibration, for which only one band is predicted at 2149 cm^{-1}, in acceptable agreement with experimental values. The IR data for **1** and MeNCS suggest that the H_3B group is *N*-coordinated to the NCS anion.

Another argument for the presence of a B−N bond in **1** comes from ^{14}N and ^{13}C NMR spectroscopic data. $\delta^{14}N$ for **1** is observed at $\delta = -244$ ppm; the ^{14}N resonance for MeNCS is found at $\delta = -290$ ppm.[10]

The ^{13}C NMR signal is split into a 1:1:1 triplet due to C−N coupling ($^1J_{^{13}C^{14}N} = 24$ Hz), which is also found for isocyanides.[11,12] In contrast, the ^{11}B NMR spectroscopic data for **1** ($\delta = -27$ ppm, $^1J_{^{11}B^1H} = 96$ Hz) do not allow a distinction between B−N or B−S bonding. For instance, the ^{11}B NMR signal of $(H_3BSH)^-$ is found at $\delta = -25$ ppm[13] and that of $(H_3BNC)^-$ at $\delta = -27$ ppm.[14]

Recrystallization of the 18-crown-6 solvate of $Na(H_3B-NCS)$ from THF always caused the formation of Na(NCS)(18-crown-6). This also happened when 15-crown-5 was used. All attempts to obtain single crystals of $Na(H_3B-NCS)$(18-crown-6) from THF solutions failed. When crystallization of $Na(H_3B-NCS)$ was performed in an excess of BH_3·THF in the presence of the 18-crown-6 ligand then suitable crystals for an X-ray structure determination were obtained. However, these showed site disorder for the anion and for THF molecules in the [Na(18-crown-6)$(THF)_2$] cation (see below). In contrast, when 15-crown-5 was used as a ligand then single crystals of compound **2** were obtained without disorder, due to the lower symmetry of the cation $[Na(15\text{-crown-5})(THF)]^+$ [Equation (2)].

$$\mathrm{Na[NCS] \xrightarrow{+BH_3\cdot THF} Na[H_3B\text{-}NCS]\cdot THF \xrightarrow{+\ 15\text{-crown-5}} \underset{\mathbf{2}}{Na[H_3B\text{-}NCS]\cdot 15\text{-crown-5}}} \quad (2)$$

In THF solution $Na(H_3B-NCS)$ shows a slight tendency to rearrange according to Equation (3). The solutions are fairly stable at room temperature. On heating a 0.1 M solution for 4 d under reflux only 40% of $Na(H_3B-NCS)$ decomposed.

$$2\ Na(H_3B-NCS) \rightarrow Na(BH_4) + Na[H_2B(NCS)_2] \quad (3)$$

In order to have a solid basis for comparing the IR spectra of the H_3B-NCS anion with the Na(NCS) complexes this salt was treated with 18-crown-6 and 15-crown-5 in THF solution; compounds **3** and **4** were isolated as single crystals. On the other hand, when $Na(H_3B-NCS)$ was treated in THF solution with an excess of pyridine, crystals of the compound Na(NCS)·4.5py (**5**) were obtained. Thus, pyridine removes the BH_3 group from $Na(H_3B-NCS)$ in THF solution.

Structures

Compounds **3** and **4** are tight ion pairs, with Na coordinated to the N atom of the NCS groups (Figures 1 and 2) while **5** is a coordination polymer with a chain structure in which the Na ions are hexacoordinate, with four py molecules in equatorial positions and an N and S atom of two different NCS anions in *trans* positions (Figure 3). Compound **3** contains an octacoordinate Na ion which sits in the center of the crown ligand. The coordination sphere is completed by a THF molecule and an *N*-bonded NCS anion. In contrast, compound **4** contains a hexacoordinate Na ion, which is present in a distorted pentagonal-pyramidal environment. The Na−N bond lengths increase in the series **3** to **5**. Within the errors of standard deviations one can consider the N−C bond lengths as equal, and this holds also for the C−S bond lengths. The average Na−O distance in **3** is significantly longer than in **4**, while the Na−O distance to the THF molecule in **3** is about 0.3 Å shorter than the distances to the O atoms of the crown ether. Selected molecular parameters are summarized in Table 2, others are found in the captions to the figures.

The trihydro(isothiocyanato)borate **1** crystallizes in the triclinic space group $P\bar{1}$ with $Z = 1$. The compound is ionic with formula $[Na(18\text{-crown-6})(THF)_2]^+[H_3B-NCS]^-$ (see Figure 4). Because the Na ion occupies a crystallographic

inversion center the THF molecules are present in *trans* positions. The structure of this cation has been observed already in several $[Na(18\text{-crown-6})(THF)_2]^+$ complexes with various anions.[15−18] Moreover, the two orientations of the anion result from a crystallographic inversion center in the middle of the two N−C bonds (equal 1:1 occupancy). Therefore, there are large errors regarding the bond lengths of the linear B−N−C−S unit.

In contrast, no disorder problem was associated with compound **2**, which is also ionic. It crystallizes in the orthorhombic space group $P2_12_12_1$. Figure 5 shows the two ions. The cation closely resembles compound **4** whose NCS ligand has been replaced by a THF molecule. The

H_3B-NCS anion has an almost linear B−N−C−S skeleton [bond angles B−N−C = 178.7(4)° and N−C−S = 178.9(4)°]. The B−N bond is comparatively long [1.575(5) Å] for a tetrahedral boron atom bound to a two-coordinate N atom. On the other hand, the C−N bond is very short [1.150(5) Å], and corresponds to a C−N triple bond. However, the short C−S bond [1.613(4) Å] is indicative of a double bond. With these structure determinations it is proved that the reaction of borane·THF with Na(NCS) results exclusively in formation of the trihydro(isothiocyanato)borate anion. This seems logical considering the strengths of the B−N and B−S bonds.

Calculations

In order to support the experimental bonding parameters of the [H_3B-NCS]$^-$ ion we performed MO calculations on this anion at the B3LYP and MP2(fc) level of theory with the basis set 6-311++G(d,p). These calculations were started with C_1 symmetry for the anion as found experimentally (however, it should be noted that the determined B−H bond lengths have high e.s.d.s), but resulted in C_{3v} symmetry for both methods. Table 3 shows the calculated values; it also contains the experimental data.

Except for the C−S bond lengths all data are in good agreement with those found for compound **2**. Due to the disorder in the anion of compound **1** as well as of [Bu_4N][H_3B-NCS][6] these data are too inaccurate to use them for comparison.

In order to also obtain information on the structure of the isomeric trihydro(thiocyanato)borate and its stability we performed analogous calculations for [H_3B-SCN]$^-$ (see Table 4). One can see that the C−N bond length is practically the same whether the BH_3 group is *N*- or *S*-coordinated but the C−S bond is to be expected to be longer in the trihydro(thiocyanato)borate than in the trihydro(isothiocyanato)borate. More importantly, the B−S−C−N unit is not linear, and a B−S−C bond angle of about 104° is to be expected. In each case the trihydro(isothiocyanato)borate is more stable than its isomer by −27 kJ/mol or −57 kJ/mol, respectively, depending on the level of theory (Table 4). This is reflected also in the calculation of the reaction energies as shown in Equations (4)−(6).

$$BH_3{\cdot}THF + NCS^- \rightarrow H_3B-NCS^- + THF;\ \Delta E = -96\ kJ \quad (4)$$

$$BH_3{\cdot}THF + SCN^- \rightarrow H_3B-SCN^- + THF;\ \Delta E = -38\ kJ \quad (5)$$

$$2\ BH_3{\cdot}THF + NCS^- \rightarrow H_3B-NCS-BH_3^- + 2\ THF;\ \Delta E = -109\ kJ \quad (6)$$

All these reactions are exothermic. The trihydro(thiocyanato)borate is less favored. However, a thiocyanatobis(trihydroborate) [Equation (6)] should also be stable but we were unable to detect this anion, even in concentrated solutions.

Further (Isothiocyanato)borates

In principle, many more (isothiocyanato)borates may be accessible simply by addition of NCS^- as nucleophile to a sufficiently Lewis-acidic boron center. We have studied two of them. In the first case we allowed catecholborane, catBH, to react with Na(NCS), and in the second case we used 9-borabicyclo[3.3.1]nonane (9-BBN).

The ^{11}B NMR spectra recorded for the reaction mixture of catecholborane with Na(NCS) revealed that several borate anions are formed. Table 5 shows the product distribution. We could not separate the mixture by fractional crystallization or separate Na[cat$B(NCS)_2$] (**6**) by adding di-

Table 5. Product distribution resulting in the reaction of catecholborane with Na(NCS) in THF monitored by ^{11}B NMR spectroscopy

	$\delta^{11}B$ [ppm]; $^1J_{B,H}$ [Hz]	Amount
catBH	23.0 (d); 190	7%
$Na[B(cat)_2]$	12.3 (s)	58%
$Na[catB(NCS)_2]$	−0.1 (quint); 24 $^1J_{B,N}$	8%
$Na[H_2B(NCS)_2]$	−19.5 (t); 115	27%

oxane. There is, however, an unusual feature in the proton-decoupled ^{11}B NMR spectrum of the products formed in solution, because the quintuplet at $\delta = -0.1$ ppm does not vanish. Therefore, this signal excludes the presence of B−H bonds. Moreover, the chemical shift excludes a BH_4 anion ($\delta^{11}B = -41$ ppm).[19] This is also revealed by the fact that the intensity of the five signals is 1:2:3:2:1 while BH_4^- requires a 1:4:6:4:1 intensity. However, the observed coupling pattern corresponds to the coupling of the boron nucleus with two nuclei of spin $I = 1$. Therefore, the observed coupling is due to $^1J_{^{11}B^{14}N}$. Such a coupling has already been detected for ^{15}N-enriched (isothiocyanato)borates $B(NCS)_{4-n}X_n^-$ (X = F, Cl; n = 1, 2, 3)[20] which have, however, not been isolated as alkali metal salts. The observed coupling constant $^1J_{^{11}B^{14}N}$ corresponds to those found for these species (21−28 Hz). Usually it is difficult to observe $^1J_{^{11}B^{14}N}$ couplings because of rapid quadrupole relaxation as both nuclei have strong quadrupole moments which generally leads to broad unresolved signals. For instance, no such coupling is observed for diazido(catecholato)borate whose structure is very similar to that of **6**.[21]

The synthesis of pure sodium catecholatobis(isothiocyanato)borate can be readily achieved by the reaction sequence shown in Equation (7).

Compound **6** not only shows a well-resolved 1:2:3:2:1 quintuplet in the ^{11}B NMR spectrum but also a 1:1:1:1 quadruplet in the ^{14}N NMR spectrum. Moreover, in concentrated THF solutions of **6** the ^{13}C resonance for the isothiocyanato group can also be detected as a broad signal at $\delta = 131$ ppm.

Single crystals of **6** separated from the THF solution after addition of 18-crown-6. They have the composition $[Na(18\text{-crown-6})(THF)_2][catB(NCS)_2]$. The crystals are triclinic, space group $P\bar{1}$, $Z = 2$. Figure 6 shows the structures of the two ions. The anion has almost C_{2v} symmetry, which by calculation is shown to be an energy minimum.

Table 6 contains selected experimentally determined and calculated data for the $[catB(NCS)_2]$ anion. There is good agreement between both except that the experimentally determined B−N−C bond angle is 12.3° smaller than calculated. The N−B bonds are shorter than in (H_3B-NCS). Moreover, the C−S bond is shorter than in free NCS^- (0.04 Å) and shorter by 0.023 Å than in $(H_3B-NCS)^-$. The calculated vibrational frequencies fit well with experimental values if multiplied by a factor of 0.96.[22] Calculation predicts 2150 cm^{-1} for the A_1 vibration of the NCS group and 2112 cm^{-1} for the B_1 vibration. These were found in the IR spectrum at 2150 and 2115 cm^{-1} and in the Raman spectrum at 2144 and 2108 cm^{-1}, respectively.

[a] B3LYP/6-311*G(d) level of theory.

When Na(NCS) is treated with 9-borabicyclo[3.3.1]nonane (9-BBN) in THF, the solution shows a single doublet in the ^{11}B NMR spectrum at $\delta = -11.4$ ppm, $^1J_{^{11}B^1H} = 100$ Hz. This is compatible with the presence of an *N*-bonded NCS anion in Na[(9-BBN)NCS] (**7**).

Addition of 18-crown-6 to the solution of **7** precipitates the crown ether complex, which, after drying followed by dissolution in THF, leads to two ^{11}B NMR signals at $\delta = -6.3$ and 31.0 ppm. None of them shows any multiplicity due to B,H coupling. The signal at $\delta = 31.0$ ppm may be due to a 9-BBN(NCS)·THF solvate [9-BBN(NMe$_2$): $\delta^{11}_B = 47.7$ ppm;[23] Ph$_2$BBr·OEt$_2$: $\delta^{11}_B = 33.4$ ppm[24]] and the latter could be due to its dimer. But this interpretation is speculative.

The crown ether complex of **7** can be crystallized from THF solution. Its crystals have the composition Na(18-crown-6)(THF)$_2$[(9-BBN)NCS]. Although a good data set could be collected for the monoclinic crystals, the structure could not be resolved satisfactorily. However, crystallization of **7** from tetrahydropyran (thp) produced single crystals of [Na(18-crown-6)(thp)$_3$][(9-BBN)NCS] which proved to be [Na(18-crown-6)(thp)$_2$][Na(thp)$_4${(9-BBN)NCS}$_2$] (**8**) in the solid state. As shown in Figure 7 the cation is similar in structure to [Na(18-crown-6)(THF)$_2$]$^+$ [15−18] with two thp molecules in *trans* positions. In the anionic part of the compound the sodium cation is surrounded by four thp molecules and two sulfur atoms which are supplied by two (9-BBN)NCS anions. The S1−Na1−S2 bond angle is 174.47(6)°, and the O1−Na1−O2 and O3−Na1−O4 bond angles are 177.4(1) and 176.4(1)°, respectively. This results in an averaged S1−Na1−O bond angle of 88.5°, and an averaged S2−Na1−O bond angle of 91.5°. Interestingly, the two Na−S bond lengths are significantly different, with Na1−S1 3.254(2) and Na1−S2 3.045(2) Å. Also, the Na−O bonds differ, spanning a range from 2.302(3) to 2.377(3) Å. However, the bonding parameters for the two 9-BBN units are rather similar as shown, for instance, by the two B−N bond lengths, which are 1.564(5) and 1.568(5) Å.

Discussion

It is now well established from previous results and those presented here that the NCS^- anion coordinates to the boron atom of BH_3 through its N atom. Although this was already deduced from spectroscopic data[3−5] this is now ascertained by X-ray structural results for the solid state. From a chemical point of view this seems logical because the B−N bond is much stronger than the B−S bond; therefore, (isothiocyanato)borates should be favored over (thiocyanato)borates, and this is supported by DFT calculations. This argument is valid also for borane derivatives.

In general, the addition of the NCS^- anion to a borane unit (BH_3, catecholborane, 9-BBN) is not necessarily the best preparative route, in particular not for BH_3 and catecholborane because the (isothiocyanato)borates formed can react with the borane by hydrogen exchange giving rise ultimately to the formation of tetrahydroborate. This kind of behavior is particularly noticeable for reactions of alkali metal alkoxides with BH_3 in THF,[7] but also for catecholborane, which, on addition of a nucleophile, gives an organyloxoborate in analogy to the BH_3/OR^- reaction. In the case of 9-BBN we did not observe this behavior: there was a straightforward reaction to the borate **7** without any by-products. Most likely this is due to the bulky R_2B group of the 9-borabicyclo[3.3.1]nonyl group.

The ligand distribution reaction can be retarded or even prevented when an (isothiocyanato)borane is treated with NCS^- as shown for (isothiocyanato)catecholborane, which leads to the bis(isothiocyanato)borate **6**.

Although a series of (isothiocyanato)borates $B(NCS)_{4-n}X_n^-$ is known,[19] no crystal structures of their salts have been reported. This is also the case for the (thiocyanato)hexaborate $B_6H_5(SCN)^{2-}$ where it is deduced from vibrational spectroscopy that the NCS group is *S*-bonded.[25] In $B_6H_5(SeCN)^{2-}$ the presence of the B−Se bond has been established.[26] Obviously the B_6H_5 unit acts as a soft acid.

On average, the B−N bonds of the (isothiocyanato)borates are longer [1.542(5)−1.575(5) Å] than in tetrakis(dihydropyridino)borate [1.546(2) Å].[27] One would have expected the opposite because the N atom of the isothiocyanate ion is sp-hybridized while in the (dihydropyridinato)borate the N atom resides in a planar environment and, therefore, is sp^2-hybridized. Obviously the B−N bond of the investigated (isothiocyanato)borates is weaker than in the aminoborate derivative.

While crown ether complexes of the alkali metal thiocyanates have been investigated in the early days of the polyether complexes[28] the only compound which is akin to **4** is the dicyclohexano-15-crown-5 complex of Na(NCS) whose bonding parameters resemble those of **4**.[29] As shown, the two crown ether complexes **3** and **4** have molecular structures. In the case of the 18-crown-6 complex the sodium ion is octacoordinate. The Na−N bond is shorter than the Na−O bond to the coordinated THF molecule while all bonds to the O atoms of the crown are more than 0.3 Å longer. On the other hand, in the crown ether compound **4** the Na−N bond is somewhat longer than in complex **3** in spite of the fact that the sodium ion is only hexacoordinate, and has the geometry of a distorted pentagonal pyramid; the Na−N bond in $[Na(15\text{-crown-5})(NCMe)]^+$ is even longer.[29] Moreover, the crown ether in this cation is less symmetrically bonded than in **4**, which has a mirror plane through the atoms S, C, N, Na and O1. In contrast, the hexacoordinate Na ion in the pyridine complex **5** approaches an octahedral geometry. Moreover, the Na−N bond in the acetonitrile adduct [2.960(7) Å] is longer than in **4**. This is not unusual. The Na−N bond of the NaNCMe unit is even longer than in **4** and only about 0.1 Å shorter than the Na−N bonds to the pyridine molecules. In this case the octahedral coordination site is filled by a sulfur atom, and this leads to a zig-zag arrangement of the building blocks. Na−S bonds are also present in the anion of **8**. In this case, the NCS anion behaves similarly to the pyridine complex of Na(SCN) except for the fact that in **5** each Na ion is *N*- and *S*-coordinated as a consequence of the *B*-bonded NCS group in **8**. From this point of view it is surprising that there is no Na−S coordination in compounds **1** and **2** nor in the 18-crown-6·THF complex of **6** where the S atom of the *B*-bonded NCS anion is not able to replace a THF molecule coordinated to Na.

In the anion of the catecholatoborate **6** both the O−B−O and the N−B−N bond angles are smaller than the ideal tetrahedral bond angle. However, in the bis(catecholato)borate anion the O−B−O bond angles are even more acute by 3°.[30] Moreover, the B−O bonds in **6** are shorter than those found for comparable (catecholato)boranes such as catecholborane−oxazolidine [B−O, 1.479(2), 1.481(2) Å],[31] bis(catechol)diborane−lutidine [B−O 1.489(2), 1.498(2) Å][32] as well as in the bis(catechol)borate anion [B−O 1.470−1.485(9) Å].[30] Also, the B−N bonds are shorter in **6** than in catecholborane−oxazolidine [1.541(2) and 1.548(2) Å] or the lutidine adduct [1.659(2) Å]. The structural parameters of **6**, therefore, show the inductive effect of the isothiocanate group.

Compound **8** has an unusual and unexpected structure. It is one of the rare examples of a complexed sodium sodiate. The cation, $[Na(18\text{-crown-6})(thp)_2]^+$, is rather similar to $[Na(18\text{-crown-6})(THF)_2]^+$. Obviously, the anion $[(9\text{-BBN})NCS]^-$ is a fairly good base as it coordinates twice to a sodium ion through Na−S bonds. Its coordination sphere is completed by the addition of four thp molecules. A relationship with the so-called "ate complexes" is noticeable.

It follows from the present study that the NCS^- ion coordinates to boron centers through its N atoms favoring (isothiocyanato)borate structures. The study of substituted hydroborates offers interesting insights into the coordination chemistry of their alkali metal salts. It seems that small effects of the ligands determine their structure. So, neither the sulfur atom nor the BH_3 hydrogen atoms of H_3B-NCS^- are able to replace a THF molecule from $[Na(18\text{-crown-6})(THF)_2]^+$ in contrast to the sulfur atom of $(9\text{-BBN})NCS^-$ in the presence of tetrahydropyran.

Experimental Section

General: All experiments were conducted under anhydrous conditions (N_2 blanket or vacuum). Commercial grade chemicals were used, and solvents dried by conventional procedures. NMR spectroscopic data were recorded with a Jeol 400 instrument, and IR data were taken with a Nicolet FT 20 instrument. Raman spectra were recorded with a Perkin−Elmer 2000 NIR FT spectrometer operated with an Nd-YAG laser at 1064 nm. For X-ray structure determinations a Siemens P4 diffractometer equipped with a CCD detector and an LT 2 low-temperature device and Mo-K_α radiation was used. Microchemical analyses were performed at the departmental microanalytical laboratory.

Crown Ether Complexes of Na(NCS): Na(SCN) was dissolved in THF and an equimolar amount of the crown ether (18-crown-6, 15-crown-5) added. After partial removal of the solvent, the solution was kept in the refrigerator. The crystals which formed within a few days were isolated and used for X-ray structure determination. The yield was not determined and no analysis performed.

Sodium Trihydro(isothiocyanato)borates. a) A solution of BH_3 in THF (2.12 mmol, 50 mL) was added with vigorous stirring to a suspension of Na(NCS) (0.508 g, 6.27 mmol) in THF (50 mL). The suspension turned rapidly into a clear solution. ^{11}B NMR spectroscopy showed that more than 90% of the borane had been consumed. Then, a solution of 18-crown-6 (1.925 g, 7.28 mmol) in 10 mL of THF was added followed by the addition of methylcyclohexane. This produced a white precipitate which was isolated by filtration and, after drying in vacuo, was found to have the composition Na(18-crown-6)(H_3B-NCS). Yield: 1.7 g (74%). From the filtrate, which was kept at 8 °C, a few single crystals of [Na(18-crown-6)$(THF)_2$][H_3B-NCS] (**1**) separated after several days; m.p. 155 °C (dec.). $C_{13}H_{27}BNNaO_6S$ (359.15): calcd. C 43.37, H 7.58, N 3.90, S 8.92; found C 43.28, H 7.48, N 3.77, S 8.93. ^{11}B NMR (THF): δ = −27.3 (q, $^1J^1_H{}^{11}_B$ = 96 Hz) ppm. ^{13}C NMR: δ = 128.4 (t, $^1J^{13}_C{}^{14}_N$ = 24 Hz) ppm. ^{14}N NMR: δ = 128.4 ($^1J^{11}_B{}^{14}_N$ = 25 Hz) ppm. IR: $\tilde{\nu}$ = 2365 m, 2325 m, 2172 st, 1353 m, 1248 m, 1155 m, 1109 st, 969 st, 840 m cm^{-1}. Raman (crystals): $\tilde{\nu}$ = 2918 st, 2833 st, 2361 w, 2331 w, 2150 m, 1477 m, 1281 m, 1264 m, 1244 m, 863 st cm^{-1}. **b)** The complex [Na(15-crown-5)][H_3B-NCS] (**2**) was prepared in a similar manner. No precipitate formed after addition of methylcyclohexane. Single crystals separated from the solution at 8 °C. These were isolated by filtration. X-ray structure determination showed them to be [Na(15-crown-5)THF]-[H_3B-NCS]. The compound was isolated from the filtrate after partial evaporation of the solvents. After drying in vacuo, it was found to have the composition Na(15-crown-5)(H_3B-NCS). Yield: 676 mg (85%); m.p. 168 °C (dec.). $C_{16}H_{34}BNNaO_5S$ (375.13): calcd. C 41.60, H 7.25, N 3.73, S 8.54; found C 41.80, H 6.92, N 3.72, S 8.28. IR: $\tilde{\nu}$ = 2365 m, 2307 m, 2161 st, 1349 m, 1248 m, 1154 m, 1105 st, 963 st, 839 m cm^{-1}.

***B*-(Isothiocyanato)catecholborane:** Trimethylsilylisothiocyanate (2.0 mL, 1.80 g, 14.2 mmol) was added to a solution of *B*-bromocatecholborane (1.722 g, 8.699 mmol) in toluene (10 mL). After refluxing the solution for 24 h, the ^{11}B NMR spectrum showed a quantitative reaction. All volatile components were removed in vacuo (1 Torr). The residue (1.22 g of a brown oil) was heated to 100 °C in vacuo. From the gas phase a solid separated as a colorless powder which, on storing, turned slowly orange. The product quickly hydrolyzes in moist air. Yield: 1.16 g (75%); m.p. 146−148 °C (dec.). $C_7H_4BNO_2S$ (177.01): calcd. C 47.51, H 2.28, N 7.91, S 18.11; found C 48.89, H 2.63, N 7.97, S 17.31. ^{1}H NMR ($CDCl_3$): δ = 7.1−7.2 (m) ppm. ^{11}B NMR: δ = 18.1 ppm. ^{13}C NMR: δ = 112.8 (C-2/5), 123.7 (C-3/4), 147.4 (C-1/6), 143.1 (br., NCS) ppm. ^{14}N NMR: δ = −280 ppm. IR: $\tilde{\nu}$ = 2074 m, 1625 m, 1473 st, 1440 st, 1351 st, 1349 st, 1096 st, 808 st, 741 w cm^{-1}. Raman: $\tilde{\nu}$ = 3071 m, 2092 w, 1627 m, 1440 m, 1399 st, 1231 st, 1142 w, 1006 m, 810 m, 612 w cm^{-1}.

Sodium Catecholatobis(isothiocyanato)borate (6): A solution of Na(NCS) (0.194 g, 2.39 mmol) in THF (10 mL) was added with stirring to a solution of *B*-(isothiocyanato)catecholborane (0.429 g, 2.42 mmol) in THF (5 mL). Stirring was continued at 0 °C for 1 h, then 18-crown-6 (0.91 g, 3.4 mmol) was added. After addition of methylcyclohexane (10 mL), the clear solution turned turbid. Insoluble material was removed by filtration and the filtrate kept at −20 °C. Within 1 d [Na(18-crown-6)$(THF)_2$][catB$(NCS)_2$] separated as colorless prisms (used for X-ray structure determination) which, on drying in vacuo, lost THF and became opaque. Yield 1.04 g of [Na(18-crown-6)][catB$(NCS)_2$] (65%); m.p. 51−54 °C. $C_{20}H_{28}BN_2NaO_8S_2$ (522.13): calcd. C 45.99, H 5.40, N 5.36, S. 12.27; found C 46.88, H 5.64, N 4.76, S 11.80. ^{1}H NMR ([D$_8$]THF): δ = 6.4−5.5 (m) ppm. ^{11}B NMR: δ = −0.1 (quint, $^1J^{11}_B{}^{14}_N$ = 24 Hz) ppm. ^{13}C NMR: δ = 108.7 (C-2/5), 118.5 (C-3/4), 151.1 (C-1/6), 130.9 (br., NCS) ppm. ^{14}N NMR: δ = −248 (1:2:3:2:1 quint, $^1J^{13}_C{}^{14}_N$ = 24 Hz) ppm.

Sodium (Isothiocyanato)-9-boratabicyclo[3.3.1]nonane: A solution of Na(NCS) (0.530 g, 6.54 mmol) in THF (35 mL) was added at 0 °C with stirring to a solution of 9-BBN (0.803 g, 6.59 mmol) in THF (15 mL). After warming to ambient temperature, 18-crown-6 was added (2.00 g, 7.57 mmol) followed, after some time, by methylcyclohexane (10 mL). A precipitate formed which was isolated by filtration. After drying in vacuo, the product was practically free of THF. Cooling the filtrate to −20 °C afforded small amounts of clear needles which were highly intergrown. They were used for X-ray crystal structure determination. NMR spectroscopic data were obtained from a freshly prepared solution in THF (without adding the crown ether). Single crystals suitable for an X-ray structure determination were obtained by recrystallization of the crystals from tetrahydropyran. Yield (from THF): 2.84 g (71%); m.p. 98−102 °C (dec.). $C_{21}H_{39}BNNaO_6S$ (467.25): calcd. C 53.96, H 8.41, N 3.00, S 6.86; found C 49.88, H 8.21, N 2.97, S 6.75. ^{11}B NMR (THF): δ = −11.4 (d, $^1J^{11}_B{}^1_H$ = 100 Hz) ppm. ^{13}C NMR: δ = 26.1, 26.3 ($CH_2CH_2CH_2$), 31.2, 34.5 ($CHCH_2CH_2$), 125.8 (NCS) ppm. ^{14}N NMR: δ = −224 ($h_{1/2}$ = 75 Hz) ppm. IR (nujol): $\tilde{\nu}$ = 2301, 2271 w, 2231 w, 2138 st, 2069 st, BH, 1472 m, 1352 st, 1248 m, 1112 st, 1058 m, 967 st, 671 m cm^{-1}.

X-ray Structure Determinations: Suitable crystals were selected from the solution, in most cases at −20 °C, and covered with perfluoro ether oil. The selected crystal was mounted on a glass fiber and put rapidly on the goniometer head which was flushed with cold nitrogen gas. The size of the unit cell was determined from the data of five sets of 15 frames taken at different orientations, using the program SMART.[33] Data collection was performed with the program SMART[33] and data from 1250 frames were used for data reduction (program SAINT[33]). Structure solutions were performed by direct methods in SHELX 97.[34] Non-hydrogen atoms were refined anisotropically, hydrogen positions on C atoms were in most cases observed, but were put in calculated positions. The BH hydrogen atoms were found in the Fourier map and were freely refined using isotropic thermal parameters. Table 7 shows relevant crystallographic parameters and data related to structure solution and refinement. In Figures 1−7 the thermal ellipsoids are depicted at a 25% probability level. CCDC-217263 to -217269 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retriev-

Nitrogen Trifluoride as a Bifunctional Lewis Base: Implications for the Adsorption of NF_3 on Solid Surfaces

Paola Antoniotti,[a] Stefano Borocci,[b] and Felice Grandinetti*[b]

Keywords: Ab initio calculations / Nitrogen trifluoride / Lewis bases / Isomeric structures

The structure, stability, and thermochemistry of isomeric adducts between NF_3 and the Lewis acids $BH_{3-n}F_n$ (n = 0–3) have been investigated at the coupled-cluster and at the Gaussian-3 (G3) level of theory. At the CCD/cc-pVDZ level both the nitrogen- and the fluorine-coordinated structures of all $BH_{3-n}F_n$–(NF_3) (n = 0–3) adducts were characterized as true minima on the potential energy surface, thus providing the first theoretical evidence for the behavior of NF_3 as a bifunctional Lewis base when interacting with neutral Lewis acids. At the G3 level, and 298.15 K, including the contribution of the entropy term, the H_3B–NF_3 adduct is predicted to be more stable than H_3B–F–NF_2 by 4.3 kcal mol^{-1}; this free energy difference is 3.7 kcal mol^{-1} at the CCSD(T)/cc-pVTZ//CCD/cc-pVDZ level of theory. Conversely, at the latter computational level, the fluorine-coordinated isomers of the BH_2F–(NF_3), BHF_2–(NF_3), and BF_3–(NF_3) adducts are practically degenerate with the nitrogen-coordinated ones. $BH_{3-n}F_n$–(NF_3) (n = 0–3) complexes feature typical bond dissociation energies of ca. 1–2 kcal mol^{-1}, and are predicted to be thermodynamically stable only at low temperatures. However, the appreciable influence of the basis set superposition error (BSSE) prevents a quantitative assessment of these small computed dissociation energies. Finally, we briefly discuss the implications of our calculations for the adsorption of NF_3 on solid surfaces.

Introduction

Nitrogen trifluoride, NF_3 (gas), is extensively used by the electronic industry in etching and cleaning processes,[1,2] e.g. to remove contaminant residues from chemical vapor deposition chambers and in plasma etching and reactive-ion etching of various materials.[3–8] Compared with more traditional fluorinated gases such as CF_4 and C_2F_6, NF_3 offers advantages of a shorter atmospheric lifetime and avoids carbon contamination residues, thereby boosting productivity by > 30% and decreasing effluent emissions by ca. 90%.[1,2] Thus, the recent industrial use of NF_3 has increased remarkably, stimulating considerable experimental and theoretical interest in the interaction of NF_3 and NF_3-based plasmas with material surfaces.[9–22] In particular, a complete understanding of the etching process requires details of the geometric and electronic structure of NF_3 adsorbed on a solid surface. When interacting with Si(001), NF_3 undergoes slow dissociative chemisorption, with spontaneous and competitive formation of Si–N and Si–F bonds.[11,20a,21] Similarly, the interaction of NF_3 with Ru(0001) leads, at least partially, to molecular decomposition on the surface, leaving F, NF or NF_2 fragments, and it has been suggested that all the NF_x moieties (x = 1–3) are oriented exclusively with their nitrogen end toward the metal.[3] Conversely, an investigation[17] on the thermal, electron, and photon-stimulated chemistries of NF_3 adsorbed on Pt(111) at low temperature revealed that adsorption and thermal desorption of NF_3 is molecular, with no evidence for dissociation. This suggests that NF_3 is very weakly held and behaves like a physisorbed species. Interestingly, the available experimental evidence points to different positions of NF_3 and orientations of its dipole moment with respect to the surface and the neighboring molecules. Thus, details of the possible orientation of NF_3 with respect to a metal surface still pose stimulating experimental and theoretical questions. From the fundamental point of view, a first step is to investigate the still unexplored behavior of NF_3 as a bifunctional Lewis base when interacting with a *neutral* Lewis acid. Experimental and theoretical investigations on the ligation of NF_3 to ionic Lewis acids such as H^+,[23,24] Li^+,[25,26] CH_3^+,[27,28] and NF_2^+ [29,30] clearly indicate that both the M–NF_3^+ and MF–NF_2^+ isomeric structures (M = H, Li, CH_3, and NF_2) can, in principle, exist as distinguishable species in the gas phase, and that the nature of the M^+ electrophile has a substantial effect on both the relative stability of the two isomers and on the their energy difference. Conversely, experimental and theor-

etical studies performed on complexes between NF_3 and neutral Lewis acids, such as BH_3,[31−34] BH_2F,[34] BHF_2,[34] BF_3,[31,33−36] BCl_3,[36] AlH_3,[37] $Ga(CH_3)_3$,[38] HF,[39] and ClF,[40] have invariably assumed that nitrogen trifluoride behaves exclusively as a nitrogen donor that can form adducts such as H_3B-NF_3, F_3B-NF_3, and H_3Al-NF_3. However, in keeping with the behavior of bifunctional base toward ionic Lewis acids, NF_3 could also interact with neutral Lewis acids as a fluorine base, forming adducts such as $H_3B-F-NF_2$, $F_3B-F-NF_2$, and $H_3Al-F-NF_2$. The structure and stability of such complexes appears to be unexplored. Therefore, stimulated by our continuing experimental and theoretical interest in the chemistry of nitrogen trifluoride and closely related neutral and ionic species,[24,26,28,30,41−51] we undertook a detailed theoretical investigation on the structure and stability of the isomeric adducts arising from the ligation of NF_3 to BH_3, BH_2F, BHF_2 and BF_3. The results discussed here confirm the expectation that, even with neutral Lewis acids, NF_3 can behave not only as a nitrogen but also as a fluorine base, forming isomeric structures of comparable stability. Concerning the interaction with solid surfaces, these findings support the suggestion that the molecular physisorption of NF_3 may occur by different orientations, and that this adsorption could be critically affected by the nature of the surface and the strength of the interaction.

Computational Details

Quantum chemical calculations have been performed using the Unix versions of the GAUSSIAN 98[52] and MOLPRO 2000.1[53] sets of programs installed on an Alphaserver 1200 and a DS20E Compaq machine.

Geometries of the investigated species have been optimised by analytical-gradient techniques at the coupled-cluster level of theory,[54,55] including the contribution from double substitutions (CCD), using the Dunning's correlation consistent double-zeta basis set (cc-pVDZ).[56] The located structures were unambiguously characterized as true minima on the surface by computing the corresponding CCD/cc-pVDZ harmonic frequencies, obtained by numerical differentiation of the analytical first derivatives of the CCD/cc-pVDZ total energies. The CCD/cc-pVDZ numerical force constants of the $BH_3-(NF_3)$ and the $BF_3-(NF_3)$ adducts were subsequently used to refine their geometries at the CCSD/cc-pVDZ level. For all investigated species, CCD/cc-pVDZ optimised geometries were used to perform single-point calculations at the coupled cluster level of theory, including the contribution from single and double substitutions and an estimate of connected triples, CCSD(T), using the cc-pVTZ basis set. The CCD/cc-pVDZ unscaled frequencies were used to calculate the zero-point vibrational energies (ZPE) of the investigated species and the vibrational contribution to their thermal correction (TC), obtained at 298.15 K by standard statistical mechanics formulas.[57] The overall TC term was finally obtained by adding the translational (1.5 *RT*) and rotational (*RT* or 1.5 *RT* for linear and non-linear species, respectively) contributions at this temperature. Total entropies at 298.15 K of the investigated species were obtained using the CCD/cc-pVDZ unscaled frequencies and moments of inertia. The influence of the basis set superposition error (BSSE) on the dissociation energies calculated at the CCSD(T)/cc-pVTZ//CCD/cc-pVDZ level was estimated using the full counterpoise method by Boys and Bernardi.[58]

Total energies of the $BH_3-(NF_3)$ complexes were also obtained using the G3 procedure of Pople and co-workers.[59] This composite method consists of a sequence of well-defined single-point calculations, at the MP2(fc), MP4(fc), and QCISD(T) levels of theory, used to calculate, according to an additivity scheme, the total energy of a species at its MP2(full)/6-31G(d) optimised geometry ("full" and "fc" denote the inclusion or not of the valence electrons for the calculation of the correlation energies). A small higher-level empirical term is also included, which depends on the number of valence electron pairs. The ZPE is calculated at the HF/6-31G(d) level and scaled by 0.8929, and the G3 energies at 0 K, G3(0 K), corrected at 298.15 K by adding the thermal contribution calculated using the scaled HF/6-31G(d) frequencies for the vibrations in the harmonic approximation and the classical approximation

for translation (1.5 *RT*) and rotation (*RT* or 1.5 *RT* for linear and non-linear species, respectively). A further *RT* term is added to convert the G3(298.15 K) total energies into G3 enthalpies. The 6-31G(d), 6-31+G(d), and 6-31G(2df,p) basis sets standard in Gaussian 98 were used with six Cartesian d-functions, while the G3large basis set, downloaded from the website suggested in ref.[59], uses five "pure" d-functions. Both the 6-31G(2df,p) and the G3large basis sets use a set of "pure" seven f-functions.

Results and Discussion

Structure, Stability, and Thermochemistry of the $BH_{3-n}F_n-(NF_3)$ ($n = 0-3$) Isomeric Structures

To investigate the conceivable behavior of nitrogen trifluoride as a bifunctional Lewis base when interacting with neutral Lewis acids we searched for distinct isomeric structures arising from the ligation of $BH_{3-n}F_n$ ($n = 0-3$) to the N and the F atom(s) of NF_3. Starting from different initial geometries, we located the $BH_{3-n}F_n-NF_3$ and $BH_{3-n}F_n-F-NF_2$ complexes **1a** and **1b** ($n = 0$), **2a** and **2b** ($n = 1$), **3a** and **3b** ($n = 2$), and **4a** and **4b** ($n = 3$) as true energy minima on the CCD/cc-pVDZ potential energy surface. Their optimised structures (Figure 1) and absolute and relative energies, at the CCSD(T)/cc-pVTZ//CCD/cc-pVDZ level of theory, (Table 1) are given here. The energy, enthalpy and free energy changes of the reaction in Equation (1) for the various isomeric structures are reported in Table 2.

$$BH_{3-n}F_n-(NF_3) \rightarrow BH_{3-n}F_n + NF_3\ (n = 0\text{-}3) \quad (1)$$

For comparative purposes, the geometries of the complexes **1a**, **1b**, **4a**, and **4b** were refined at the CCSD/cc-pVDZ level, but we found only negligible differences with respect to the CCD/cc-pVDZ optimised structures. The geometries of **1a** and **1b** were also optimised at the CCD/aug-cc-pVDZ level of theory, but, with respect to the CCD/cc-pVDZ parameters, the largest variations were only about 0.5° in the bond angles and about 0.05 Å in the bond lengths.

Table 2. CCSD(T)/cc-pVTZ//CCD/cc-pVDZ dissociation energies (ΔE), enthalpies (ΔH), and free energies (ΔG) of $BH_{3-n}F_n-(NF_3)$ isomeric structures into $BH_{3-n}F_n$ and NF_3 ($n = 0-3$) [kcal mol^{-1}] (for connectivities of the species, see Figure 1)

Species	ΔE (0 K)[a][b]	ΔH (298.15 K)[a][b]	ΔG (298.15 K)[a][b]	BSSE
1a	8.7 (9.4)	9.9 (10.6)	−2.4 (−0.7)	3.5
1b	1.2 (1.2)	1.1 (0.9)	−6.0 (−5.0)	2.0
2a	1.0	0.6	−6.1	1.2
2b	1.2	0.7	−5.7	1.9
3a	1.2	0.5	−5.9	1.1
3b	1.5	0.8	−6.5	2.0
4a	1.8	1.1	−6.3	1.4
4b	2.0	1.3	−6.8	2.3

[a] Not including the BSSE. [b] G3 values given in parentheses.

As with all previous theoretical investigations on the geometric and electronic structure of the H_3B-NF_3 complex **1a**,[31−34] the CCD/cc-pVDZ optimised geometry points to an n-donor−p-acceptor complex, with partial electron transfer from the N atom of NF_3 to the B atom of BH_3. The N−F bond length of free NF_3, computed as 1.368 Å at the CCD/cc-pVDZ level of theory (experimental value is 1.365 Å[60]), reduces by 0.019 Å, whereas the B−H distance of free BH_3, computed as 1.207 Å at the CCD/cc-pVDZ level of theory, increases by 0.006 Å. In addition, the $-BH_3$ moiety of **1a** deviates slightly from planarity, and the F−*N*−F angle is larger than that of free NF_3 by 1.7°. At the CCSD(T)/cc-pVTZ//CCD/cc-pVDZ level, the energy changes obtained at 0 K and the enthalpy change at 298.15 K of the reaction according to Equation (1) are, for isomer **1a**, 8.7 and 9.9 kcal mol^{-1}, respectively. The inclusion of the appreciable contribution of the entropy term leads to a free-energy change at 298.15 K of −2.4 kcal mol^{-1}, and the still experimentally unobserved complex **1a**

Table 1. CCSD(T)/cc-pVTZ total energies [atomic units], thermal corrections [atomic units], and total entropies [cal mol^{-1} K^{-1}] of the $BH_{3-n}F_n-(NF_3)$ ($n = 0-3$) isomeric structures (for connectivities of the species, see Figure 1)

is predicted to dominate the mixture at equilibrium below ca. −33°C. The energy, enthalpy, and free-energy change of the reaction according to Equation (1) for isomer **1a** were also calculated using the G3 procedure. This method usually furnishes thermochemical data that are as accurate as ca. 2 kcal mol^{-1}.[59] However, the absence of compounds similar to those studied here in the G3 data-base suggests caution in assuming that this "standard" level of accuracy will be obtained here. However, the G3 data agree well with those obtained at the CCSD(T)/cc-pVTZ//CCD/cc-pVDZ level of theory (Table 2), and so we used only the latter approach to calculate the thermochemistry of the more complex $BH_{3-n}F_n-(NF_3)$ ($n = 1-3$) isomeric structures. We note also that, for isomer **1a**, both the CCSD(T)/cc-pVTZ//CCD/cc-pVDZ and the G3 values of ΔE at 0 K of the reaction according to Equation (1) are in good agreement with those previously obtained[33] at the MP2/6-31G(d) and at the B3LYP/6-31G(d) computational levels (8.9 and 9.9 kcal mol^{-1}, respectively).

The C_1-symmetry structure **1b** arises from the ligation of the boron atom of BH_3 with one of the fluorine atoms of NF_3 and its characterization as a true energy minimum on the CCD/cc-pVDZ potential energy surface provides the first theoretical evidence for the behavior of NF_3 as a bifunctional Lewis base when interacting with a *neutral* Lewis acid. Compared with the nitrogen-coordinated isomer **1a**, the optimised geometry of **1b** suggests a much weaker interaction between the two BH_3 and NF_3 building moieties. Thus, the B−F bond length results as large as 2.581 Å, and the other optimised parameters, are quite similar to those predicted for free BH_3 and NF_3. Consistently, from Table 2, the CCSD(T)/cc-pVTZ//CCD/cc-pVDZ energy change at 0 K and the enthalpy change at 298.15 K of the reaction according to Equation (1) are obtained for isomer **1b** as 1.2 and 1.1 kcal mol^{-1}, respectively, and the corresponding free energy change at 298.15 K results as −6.0 kcal mol^{-1}. Therefore, this complex is predicted to be dominant in the equilibrium mixture at temperatures lower than ca. −227 °C. At 0 K, isomer **1a** is predicted to be more stable than **1b** by 7.5 kcal mol^{-1} at the CCSD(T)/cc-pVTZ//CCD/cc-pVDZ level of theory and by 8.2 kcal mol^{-1} at the G3 level. However, consistent with the character of loosely bound species of **1b**, at 298.15 K the free energy difference with **1a** reduces to 3.7 kcal mol^{-1} at the CCSD(T)/cc-pVTZ//CCD/cc-pVDZ level of theory, and to 4.3 kcal mol^{-1} at the G3 level.

The nitrogen-coordinated isomers **2a**, **3a**, and **4a** and the fluorine-coordinated isomers **2b**, **3b**, and **4b** of the adducts between NF_3 and the fluorinated Lewis acids BH_2F, BHF_2, and BF_3 reveal minima on the CCD/cc-pVDZ potential energy surface, which is consistent with the results for $BH_3-(NF_3)$ complexes. This provides additional positive evidence for NF_3 having the character of a bifunctional Lewis base when interacting with neutral Lewis acids. In addition, Figure 1 and Tables 1 and 2 clearly indicate that, on passing from BH_3 to BH_2F, BHF_2, and BF_3, the structure and stability of the $BH_{3-n}F_n-(NF_3)$ ($n = 1-3$) complexes are appreciably affected. Thus, the nitrogen-coordinated structures **2a**, **3a**, and **4a** feature B−N distances that are remarkably longer than for **1a**, and the parameters of the BH_2F, BHF_2, BF_3, and NF_3 moieties are practically coincident with the geometries computed for the free molecules.[61] This is consistent with the weak interaction energies computed between the BH_2F, BHF_2, BF_3, and NF_3 building blocks. At the CCSD(T)/cc-pVTZ//CCD/cc-pVDZ level, ΔE at 0 K for the reaction according to Equation (1) is 1.0, 1.2 and 1.8 kcal mol^{-1} for complexes **2a**, **3a** and **4a**, respectively. The value for **4a** has been computed as 3.0 kcal mol^{-1} at the MP2/6-31G(d) level of theory[33,35] and 1.3 kcal mol^{-1} at the B3LYP/6-31G(d) level.[33] Therefore, passing from BH_3 to BH_2F, BHF_2, and BF_3, the stability of the nitrogen-coordinated isomers of $BH_{3-n}F_n-(NF_3)$ ($n = 0-3$) complexes is drastically reduced. Figure 1 and Table 2 indicate, however, that, on passing from $H_3B-F-NF_2$ isomer **1b** to the analogous fluorine-coordinated structures **2b**, **3b**, and **4b**, the B−F bond lengths are only slightly elongated, and the geometry of the $-NF_3$ moiety remains essentially unaltered. The stability of the four complexes is consistently quite similar and, in particular, at the CCSD(T)/cc-pVTZ//CCD/cc-pVDZ level of theory, ΔE at 0 K for the reaction according to Equation (1), computes as 1.2 kcal mol^{-1} for complexes **1b** and **2b**, 1.5 kcal mol^{-1} for **3b**, and 2.0 kcal mol^{-1} for **4b**. Therefore, whereas the nitrogen-coordinated isomer **1a** of the $BH_3-(NF_3)$ complex is appreciably more stable than the fluorine-coordinated isomer **1b**, the energy difference between the nitrogen- and the fluorine-coordinated isomers of the $BH_2F-(NF_3)$, $BHF_2-(NF_3)$, and $BF_3-(NF_3)$ adducts is considerably smaller. In particular (Table 1), the fluorine-coordinated structures **2b**, **3b**, and **4b** are predicted to be practically degenerate with the nitrogen-coordinated structures **2a**, **3a**, and **4a**. This conclusion is not essentially affected by inclusion of the thermal and entropy contributions at room temperature. Therefore, the present calculations indicate not only that NF_3 could behave as a bifunctional Lewis base when interacting with a neutral Lewis acid, but also that the fluorine-coordinated isomer could be degenerate or even thermodynamically more stable than the nitrogen-coordinated one.

Generally speaking, the interaction between NF_3 and the boranes is very weak and the computed energy changes of the reaction according to Equation (1) could be, in principle, significantly affected by the BSSE. Although the use of the counterpoise method is not undisputed,[62] we employed it to appreciate the influence of the BSSE on our CCSD(T)/cc-pVTZ//CCD/cc-pVDZ interaction energies. The obtained values (Table 2) amount to 3.5 kcal mol^{-1} for isomer **1a** and range around 1.5 kcal mol^{-1} for the other $BH_{3-n}F_n-(NF_3)$ adducts ($n = 0-3$). This confirms that, at least in percentage terms, the BSSE should significantly affect the computed interaction energies of our complexes. Nevertheless, it does not alter the essential conclusions from our calculations, although it suggests caution in the quantitative assessment of our computed interaction energies.

None of the presently investigated $BH_{3-n}F_n-(NF_3)$ adducts ($n = 1-3$) has been experimentally observed. From

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 2, the free energy change of the reaction according to Equation (1) for complexes **2a**−**4a** and **2b**−**4b** is invariably predicted to be around −6 kcal mol^{-1}, and all these species should dominate the equilibrium mixtures at well below −200 °C. Interestingly, it has been reported[36] that NF_3 and BF_3 undergo weak association below −125 °C, but the heat of dissociation was so small that a true equilibrium expression was unobtainable.

Nitrogen trifluoride is firmly established as a much weaker Lewis base than ammonia.[63] Comparison of our results on $BH_{3-n}F_n$−(NF_3) adducts (n = 0−3) with the previously investigated $BH_{3-n}F_n$−NH_3 complexes (n = 0−3)[32−34,64] fully confirms this expectation. We note in particular that, at the MP2/TZ2P level of theory,[64] the B−N distance of the F_3B−NH_3 complex is 1.678 Å, which is much shorter than the F_3B−NF_3 of complex **4a**, and the bond energy of F_3B−NH_3 amounts to more than 20 kcal mol^{-1}.

Implications for the Adsorption of NF_3 on Solid Surfaces

As noted in the Introduction, the present theoretical investigation on the conceivable behavior of NF_3 as a bifunctional Lewis base was stimulated by a study on the thermal, electron, and photon-stimulated chemistry of nitrogen trifluoride adsorbed on solid Pt(111).[17] All the peaks observed in the temperature-programmed desorption spectra of adsorbed NF_3 lie below 70 K − suggesting that this molecule is very weakly held and behaves like a physisorbed species. In addition, the available experimental evidence points to different positions of NF_3 and orientations of its dipole moment with respect to the surface and the neighboring molecules. Our calculations provide supporting, although indirect, evidence for conceivably different orientations of NF_3 ligated to a solid surface. Thus, when interacting with the neutral Lewis acids $BH_{3-n}F_n$ (n = 0−3), NF_3 may undergo not only ligation by nitrogen but also by fluorine, leading to isomeric structures that are practically degenerate, especially for the weakest Lewis acids, BH_2F, BHF_2, and BF_3. Although our investigated $BH_{3-n}F_n$−(NF_3) complexes (n = 0−3) are much too simple to be effective models to mimic the interaction of NF_3 with a solid surface, if one perceives the fixation of NF_3 to Pt(111) as an interaction as weak as that occurring in our investigated adducts, it is reasonable to assume that it occurs not only by the nitrogen but also by the fluorine atom(s). Of course, for solids other than platinum, the possible molecular adsorption of NF_3 by different orientations should be critically affected not only by the nature of the surface but also by the strength of the interaction. Due to the widespread industrial use of nitrogen trifluoride in the treatment of solid surfaces, a more detailed investigation of these aspects could be of experimental and theoretical interest.

Acknowledgments

COVER PICTURE

The cover picture shows the results of modelling the diffusion of phthalodinitrile through the zeolite pores. Once inside, phthalodinitrile reacts to form a large phthalocyanine guest that remains entrapped inside the zeolite cavity. The resulting zeolite–guest chemistry resembles at molecular level a ship in a bottle that is a typical souvenir in many harbour cities. The zeolite-encapsulated guest shows many promising applications as discussed in the Microreview by A. Corma and H. Garcia on p. 1143 ff.

Supramolecular Host-Guest Systems in Zeolites Prepared by Ship-in-a-Bottle Synthesis

Avelino Corma*[a] and Hermenegildo Garcia*[a]

Keywords: Host-guest systems / Phthalocyanines / Ship-in-a-bottle synthesis / Supramolecular chemistry / Zeolites / Zeozymes

Zeolites have a microporous system defining large cavities interconnected by smaller windows. These cages can accommodate large molecules whose size, however, can be too big to cross the windows. The most important examples of these tridirectional zeolites are faujasites X and Y, but examples of other suitable zeolites are Beta, EMT and MCM-22. The inclusion of large guests inside the cavities starts from smaller precursors that can diffuse through the zeolite pores and then react inside the cavities to form the target guest. This microreview discusses the special characterisation techniques necessary to study these systems, differentiating those that serve to assess the identity and purity of the guests from those that address the internal vs. external location of the guests with respect to the zeolite host. It is organized by grouping the examples of ship-in-a-bottle synthesis according to the potential application of the system as catalysts, photocatalysts, sensors, in molecular machines, etc. Although proper credit is given to the pioneering reports on ship-in-a-bottle synthesis, the emphasis is placed on the most recent examples of the literature covering up to mid 2003.

A. General Aspects

1. Introduction

Zeolites owe their importance to their use as catalysts in gas-phase, large-scale petrochemical processes such as catalytic cracking, Friedel−Crafts alkylation and alkylaromatic isomerisation or disproportionation.[1−6] Zeolites are easy to separate from the reaction products, thereby offering convenient reactor design and allowing continuous-flow operation. Because they are thermally stable and chemically robust, zeolites can be almost completely regenerated by calcination in air when they become deactivated by the presence of large organic products that remain adsorbed.

The promising results of gas-phase reactions in zeolites have triggered an intense research effort aimed at

Avelino Corma Canos was born in Moncófar, Spain. He was a postdoc in the Department of Chemical Engineering at Queen's University (Canada, 1977−1979). He is director of the Instituto de Tecnología Química (UPV-CSIC) at the Universidad Politécnica de Valencia since 1990. His current research field is structured nanomaterials and molecular sieves as catalysts, covering aspects of synthesis, characterisation and reactivity. Avelino Corma has written about 500 articles on these subjects in international journals, three books, and a number of reviews and book chapters. He is co-author of more than 80 patents, six of them being commercialised. He is the recipient of numerous awards, including the Dupont Award on New Materials (1995), the Ciapetta and Houdry Awards from the ACS, the F. Gault Award of the European Catalysis Society and the Spain National Award on Science and Technology.

Hermenegildo García (Herme) was born in Canals (Spain) in June of 1957 and studied chemistry at the Faculty of Science of the Universidad de Valencia (Spain) where he graduated in 1979 with Honors. He did his PhD on preparative organic photochemistry under the guidance of Prof. Miguel A. Miranda and this was awarded, also with Honors by the Universidad de Valencia in 1983. Then, he moved to the Technical University of Valencia where he initiated his career in 1983 first as Assistant Professor, becoming finally Full Professor in 1996. In 1991 he was appointed member of the Institute of Chemical Technology, a joint centre depending on the Spanish National Research Council (CSIC) and the Technical University of Valencia that was founded in that year. He stayed as a postdoc at the Chemistry Department of the University of Reading (U.K.) with Prof. Andrew Gilbert in 1987, and later took three periods of sabbatical leave in 1992−1993 (one year), 1995 (six months) and 2000 (three months) at the University of Ottawa joining the Laser Flash Photolysis group led by Prof. J. C. (Tito) Scaiano. He has co-authored over 200 papers most of them dealing with the application of zeolites as hosts of organic guests and as solid catalysts. He holds three international patents. His main current interests are in supramolecular photochemistry and photocatalysis, the development of photoactive nanoscopic materials and heterogeneous catalysis.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

developing the potential of zeolites as acid-base and redox catalysts for the production of chemicals and fine chemicals.[7,8] As a result of these studies, heterogeneous catalysis of organic reactions by zeolites can be considered a mature field, and the industrial applications of zeolites for membranes, adsorption-separation and in the production of fine and specialty chemicals are expected to grow in the near future.

In addition to the current importance of zeolites in heterogeneous catalysis, it is likely that these solids will also attract interest in materials science for the development of functional materials, and in nanotechnology.[9] For these applications, zeolites provide a rigid matrix in which some active component or components can be included. Enantioselective catalysis, sensors, solid lasers, intelligent switches, membranes, waveguides and solar cells are emerging fields in which zeolites can be applied. The main problem to be solved for the application in nanotechnology is the preparation of submillimeter films in which the pores are oriented with respect to the substrate. Progress on film preparation has been made by "in situ" crystallisation of gels or the covalent attachment of zeolite particles to the substrate.[10−13]

A system that has vast potential for application in catalysis as well as for nanotechnology is that in which a functional guest is incarcerated inside the zeolite supercages without the possibility of diffusing out of the particle. In the field of catalysis, there are a number of reviews summarising the use of encapsulated coordination complexes as oxidation catalysts[14,15] and the possible strategies for the preparation of zeolite ship-in-a-bottle complexes, including the use of flexible ligands and zeolite synthesis around the complexes.[16] The generation of organic carbocations entrapped within the zeolite during a chemical reaction in the liquid phase has also been reviewed.[17] Considering the zeolites as catalysts, these carbocations are generally undesired species that poison and block the catalytic site, but in other cases their preparation has been purposely achieved.[17−19] This microreview focuses on the preparation, characterisation and properties of such supramolecular guest-zeolite materials, with special emphasis on their applications. Firstly, we will comment briefly on the main characteristics of zeolites as hosts. Then, we will describe adsorption procedures and the ship-in-a-bottle synthesis. We will cover characterisation techniques of encapsulated guests and how to address the internal vs. external location of the guest. The main body of the microreview describes the examples reported of ship-in-a-bottle synthesis. We have classified them according to the potential application that these host-guest systems can have.

2. Zeolites: Composition and Chemical Structure

Zeolites are crystalline aluminosilicates whose structure is formed by an array of corner-sharing SiO_4^{4-} or AlO_4^{5-} tetrahedra.[20−22] These building blocks become arranged in a periodic way to form channels and cages on a nano- and subnanometer scale of strictly regular dimensions, named micropores. The pores of the zeolites are open to the exterior and to the surrounding medium, thus allowing diffusion of molecules from the exterior to the interior of the zeolite particle. The existence of these accessible micropores ranks zeolites at the top of the list of solids exhibiting large specific surface areas, typically above 300 $m^2 \cdot g^{-1}$ with an internal void volume above 0.1 $cm^3 \cdot g^{-1}$.

A zeolite framework containing exclusively oxygen-sharing SiO_4^{4-} tetrahedra is neutral. Al is a near neighbour of Si in the periodic table, both elements having similar ionic radii. When an Al atom replaces an Si atom isomorphically in the framework, this becomes negatively charged, one negative charge being introduced by each AlO_4^{5-} tetrahedron. The overall negative charge of these aluminosilicates requires the presence of organic or inorganic cations to maintain the electroneutrality of the solid.

Although there are natural zeolites, most of the over 100 zeolites known are synthetic. The first synthesis of zeolite Y by Barrer in the mid 1950s was an attempt to mimic the conditions under which natural zeolites were supposed to have formed on the Earth.[23−32] This synthesis has been widely recognized as one of the most important advances in the chemistry of the last century. Zeolites are obtained in the laboratory by crystallisation (either static or under continuous agitation) of gels containing alumina and silica in an aqueous medium at temperatures in the range of 100−190 °C and autogenous pressure, for several days or weeks.[33] Besides silica and alumina, the gel can be prepared from other sources of Al, Si and some other metals, and it may also contain quaternary ammonium cations to direct the crystallisation of a given crystal structure.

Zeolites are classified based on the symmetry of their unit cell, each structure being denoted by three capital letters.[34] An alternative classification that is more convenient here is according to the dimensions of the micropores (Scheme 1). In this regard the zeolites can be classified as having a small, medium or large pore size depending on whether the number of oxygen atoms and Si plus Al atoms is 8, 10 or 12, respectively.[35] The number of oxygen atoms defining the minimum ring of a pore determines roughly the dimension of the pores, which are approximately 3, 5 and 7 Å for the small-, medium- and large-pore zeolites, respectively. Recently, new structures containing pores of different dimensions have been reported.[36−39]

There has been an intense search for extra-large-pore zeolites (those having pores with more than 12-membered rings), but the success has been limited in the sense that, although some extra-large-pore zeolites or zeotypes have been synthesised, the resulting pores are not spherical and the minimum axis and structure are not much different from those of large-pore zeolites.[40,41]

Another aspect of importance regarding the micropore system of zeolites is the geometry of the pores. In this regard zeolites can be classified as uni-, bi- and tridirectional zeolites, depending on whether the channel system is arranged along one, two or the three Cartesian axes. The directionality of the zeolite pore system is relevant with respect to the ability of zeolites to include guests inside the micropores. Diffusion coefficients in unidirectional zeolites

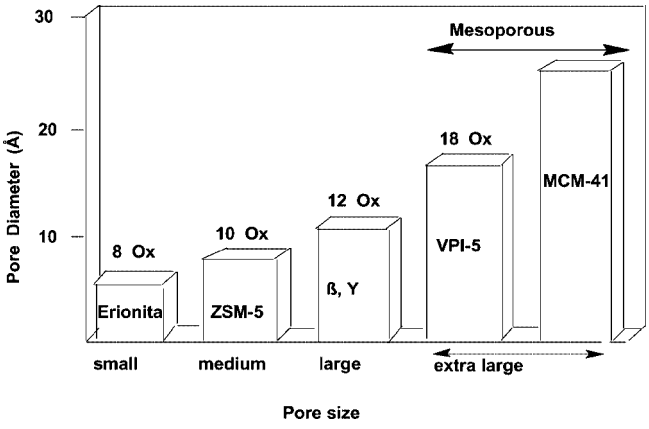


Scheme 1

are typically smaller than those of tridirectional zeolites, which contain a much more open pore system.[42]

The phenomenon of inclusion of a molecule inside the rigid pores defined by the zeolite framework is commonly denoted with terms like adsorption, incorporation, inclusion or encapsulation. The latter three terms are used when the residence time inside the pores is indefinitely long, while in catalysis in which the access of the reagents and substrates to the internal sites is a necessary step in the mechanism and the products have to migrate away from the sites, the terms adsorption and desorption are the preferred ones.

The ability of zeolites to include organic or inorganic guests in their interior gives rise to a supramolecular chemistry in which the properties of the guest-zeolite assembly differs from the molecular properties of the guest in solution.[43] The control of the molecular properties by the zeolite may arise basically by the combination of any of at least five main factors including: (i) restriction of the mobility and conformational flexibility of the guest; (ii) shape-selectivity effects in which the molecular size of the reactants, transition states and products relative to the dimensions of the pores play a decisive role; (iii) compartmentalisation of the reaction cavity favouring geminate recombination and disfavouring escape effects; (iv) polarity of the zeolite internal voids promoting and stabilizing charged species; and (v) the presence of cooperating active sites in close proximity to the encapsulated species. Here we will provide examples that illustrate how incorporation into a zeolite can alter the *intrinsic molecular properties* of the included guest.

Different terms have been coined to refer to the zeolite adsorption-encapsulation chemistry. For instance, zeolites were initially defined by Barrer as molecular sieves to denote that certain molecules can access the interior of the pores, while others are too large and are size-excluded from the interior, the zeolites behaving as sieves of molecular dimensions.[20] In fact, zeolites commercially available from Aldrich are still indicated in the catalogue as molecular sieves instead of the three-letter code applied by the International Zeolite Association to classify any zeolite. Kochi coined the term *molecular pocket* to describe the effective protection of reactive guests occurring by encapsulation inside the rigid matrix defined by zeolite inert crystal structure.[44] The most general descriptor, *reaction cavity*, refers to the importance of certain properties of the environment surrounding reacting molecules such as flexibility and deformability, dimensions, and polarity among others.[45]

3. Adsorption Procedures

Guests can gain access to the interior of the zeolite particles through the micropores following different adsorption protocols which depend on the Coulombic charge of the guest, its diffusion coefficient, its stability and persistence. The simplest adsorption procedure for neutral guests that can diffuse into the pores consists of dissolving them in an inert solvent, preferably apolar, and placing the solution in contact with thermally dehydrated zeolite samples. Adsorption can be carried out by stirring the solid in the solution at room temperature or by heating. Due to the activation energy for diffusion within the micropores, mild heating can have a very large effect facilitating the adsorption.

It has to be remarked that the pores of hydrophilic zeolites are filled by co-adsorbed water, and this water has to be desorbed before proceeding to the inclusion of any guest. Typically, co-adsorbed water can be evacuated by heating the zeolite at temperatures above 100 °C under reduced pressure or by heating at higher temperatures under atmospheric pressure. After dehydration, water can be regained partially or completely very quickly upon exposure to the ambient moisture.

For guest adsorption from solutions, the nature of the solvent has a large influence. This effect is generally rationalised in terms of competition between guest or solvent adsorption. If a solvent is strongly adsorbed within the zeolite then the co-adsorption of the guest is impeded. On the other hand, if the interaction of the solvent and the zeolite is weak then solute adsorption is favoured. The interaction of the zeolite with solvents and simple guests can be discussed quantitatively by means of calorimetry, measuring the specific heat of adsorption. In the case of polar zeolites, it can be said that, in general, apolar, aprotic solvents promote adsorption of larger amounts of the guests than protic solvents.

Incorporation of guests inside the zeolite micropores can also be accomplished in the gas phase in those cases where the vapour pressure of the guests is sufficiently high at room temperature or when the substrate to be adsorbed can be heated to appropriate temperatures. Chemical vapour deposition chambers can be used for this purpose. The absence of solvent in vapour-phase adsorption facilitates the inclusion of the guest and, in addition, the resulting samples are free of contamination from adventitious presence of residual solvent molecules.

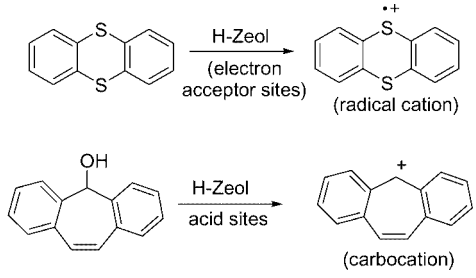
For cationic compounds, incorporation of the cation requires the exchange with the charge-balancing cation. This is easily done when the counterbalance cation is an alkali or alkaline earth cation. The ion exchange is normally carried out in water as solvent. A single ion exchange normally leads to partial cation replacement, the percentage of ex-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

change depending on the initial solution concentration. The ion exchange is usually repeated two or three times increasing the initial solution concentration of the cationic guest to achieve a high level of ion exchange. Given that there are different positions where the charge-balancing cations can be located with respect to the zeolite framework, it can occur that, depending on the relative size of the cation being introduced with respect to the existing one, normally Na^+ or another alkali metal ion, not all the families of pre-existing cations can be exchanged. A prototypical case are faujasites in which the type-I and -II cations located inside the sodalite cages or hexagonal prisms are difficult to exchange.[20−22]

4. Ship-in-a-Bottle Synthesis

Besides incorporation of a guest from the exterior into the interior of the zeolite particle, a particular case is the in situ formation of species by adsorbing suitable precursors that will be transformed into the final guest. The zeolite may play an active role in the generation of the species by containing active sites that would interact with the guest precursor, promoting the transformation. Typically, the zeolite can have acidic or basic sites, but metallic centres can also be present. The type of transformations used to generate a trapped species can be elimination, substitution or a redox process. An example of the above reactions is the generation of organic radical cations by adsorbing the neutral precursor and abstracting a single electron. Another example is the generation of a carbocation by protonation and dehydration of an alcohol (Scheme 2).



Scheme 2

In most cases in which an immediate precursor is adsorbed, this compound contains most of the bonds of the final species and there is not a large difference in the size of the precursor and the final species. However, in some cases the final species that is formed in the zeolite arises from the coupling of several precursors and there is a notable increase in the number of atoms and size of the final guest.

For this situation and using tridirectional zeolites as hosts a possibility can be envisioned in which, due to the large molecular size of the resulting guest, it remains imprisoned inside the zeolite structure after its synthesis with an impeded diffusion. The internal voids of tridirectional zeolites have a geometry encompassing large cavities interconnected only by smaller windows. The most frequent cases are faujasites X and Y, whose internal voids are formed by almost spherical cavities of 13 Å diameter, called supercages, tetrahedrally interconnected through 12-membered-ring windows of only 7.4 Å diameter. Also, zeolite Beta has oval cages (7.4 × 11 Å) defined by the crossing of two perpendicular 12-membered-ring channels (ca. 7.4 Å) whose axes are slightly shifted. For these topologies, a situation can occur in which a guest has a molecular size that, on one hand, allows it to be accommodated inside the cages but, on the other, is too big to cross the smaller cavity windows. These guests will remain immobilized by the rigid zeolite framework but they can still interact with small substrates able to diffuse through the micropores.

The term ship-in-a-bottle was most probably coined by Herron, whilst working at the R&D centre of Dupont at Wilmington, who reported the synthesis of several types of metallic complexes encapsulated within zeolites.[46] The term ship-in-a-bottle alludes to the similarity of the resulting complex imprisoned within the zeolite framework with the artistic bottles containing a ship larger than the bottle neck. However, even before this term was coined other researchers had most probably already used this methodology. Thus, as an example, Romanovskii, publishing in Russian[47−49] and Schulz-Ekloff[50,51] independently synthesised metallic phthalocyanines inside faujasite X by treating *o*-phthalodinitrile with a transition-metal-exchanged faujasite at temperatures above 200 °C, a reaction that is archetypical of a ship-in-a-bottle synthesis.

Normally, the reactions employed in a ship-in-a-bottle synthesis also work well in solution. In those cases in which a homogeneous catalyst is needed in solution, the ship-in-a-bottle synthesis requires the presence of active sites in the micropores of the zeolites. These sites can be acidic, basic or metal atoms. Reactions suitable for a ship-in-a-bottle synthesis should start from precursors of suitable size and should give high product yields, or the by-products should be small enough to be separated by solid-liquid extraction. In fact, the only purification treatment applicable to the ship-in-a-bottle synthesis is solid-liquid extraction as this treatment is based on the desorption of starting material and by-products.

An alternative and complementary procedure to the ship-in-a-bottle synthesis is to build the bottle around the ship. This consists in performing the crystallisation of the zeolite from a gel that contains the preformed guest. Two obvious limitations of this methodology is that the guest has to survive the relatively harsh conditions of the zeolite synthesis in terms of pH and temperatures for long periods, and the zeolite crystal structure should still be formed in the presence of the guest. The ease of crystallisation explains why the build-the-bottle-around-the-ship approach has been employed almost exclusively for faujasites X and Y.

An approach worthy of being explored more systematically would be exactly the reverse of a ship-in-a-bottle synthesis, the target being the synthesis of new zeolite structures by using large guests molecules that could act, in principle, as templates or structure-directing agents for the crystallisation of the aluminosilicate. A precedent of this is the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

synthesis of extra-large-pore UTD-10 using a Co^{II} complex of 1,8-bis(trimethylammonio)-3,6,10,13,16,19-hexaazabicyclo[6.6.6]icosane reported by Balkus, Jr.[16,52]

After a successful ship-in-a-bottle synthesis the main feature of the resulting zeolite containing a big organic guest inside the cavities is that the guest becomes immobilized and imprisoned inside the cages without the possibility of diffusing out of the particle. In the field of supramolecular chemistry of rotaxanes and catenanes, Stoddart has coined the term "mechanical immobilisation" to describe a situation in which one of the components of a supramolecular assembly cannot diffuse independently from the other and both of which are held in place by physical forces without the existence of a covalent bond between them.[53,54] According to this definition, the same term will apply to the system comprising a big guest encapsulated within a tridirectional zeolite since, despite the fact that there is no covalent bond connecting both entities, the guest remains entrapped, without the possibility of escape, due to physical (forbidden van der Waals atomic overlapping) forces.

Also useful when dealing with ship-in-a-bottle synthesis is Turro's "@" notation used to indicate that the guest is assumed to be located inside the particle and not exclusively or predominantly on the external surface.[55]

5. Characterisation Techniques

When performing a ship-in-a-bottle synthesis there are two crucial issues that need to be addressed independently. These two questions are the identity and purity of the encapsulated species and the location of the guests with respect to the zeolite particle.

The techniques to study the nature of the guest differ if we are dealing with a completely inorganic guest, such as metal clusters, or an organic species. In the case of purely inorganic guests X-ray diffraction, EXAFS, XANES and electron microscopy are the most important tools, together with some particular techniques such as diffuse reflectance UV/Vis, Raman and Mössbauer spectroscopy. The dispersion and size distribution of the clusters for heavy atoms can be determined by X-ray diffraction and can also be observed by electron-microscopic techniques. Even UV/Vis spectroscopy can be useful for this purpose since some typical inorganic clusters absorb visible light, the λ_{max} of the band being related to the average cluster size. IR and Raman spectroscopy on the other hand can also provide some information about the nature of the guest and, by means of probe molecules, can indirectly report on the ability of the clusters to interact with adsorbates. CO, NH_3 and pyridine are among the favourite probe molecules for Lewis-acid clusters.[56]

Spectroscopy,[57] including UV/Vis,[58] IR,[59−61] Raman[62] and multinuclear solid-state NMR,[63] is also one of the favourite techniques to determine the nature of metallic complexes or organic guests incorporated inside the zeolite pores.[64] It is worth noting that in these techniques either the zeolite framework does not give any signal or, in the worst case, at only certain spectral wavelengths. For instance, zeolites composed of silicon and not containing any other heteroatom are transparent in the UV/Vis spectrum at wavelengths longer than 220 nm. It has been reported that highly pure zeolites absorb exclusively in the vacuum UV region ($\lambda < 200$ nm). Since UV/Vis radiation penetrates deep inside the zeolite particle, it is possible to record the optical spectrum of a guest that is occluded inside the zeolite grain without interference of the zeolite framework, in a similar way as the optical spectra of organic guests are recorded in other matrices. Perhaps the major peculiarity is that diffuse reflectance techniques,[65] rather than the transmission techniques typically used for solutions, are used to record the UV/Vis spectrum.

Also, in IR spectroscopy zeolites are transparent at most IR wavelengths and, importantly, in the 3400−1300 cm^{-1} zone characteristic of the principal organic functional groups.[60] Zeolites possess a strong absorption due to the T−O bonds at around 1000 cm^{-1}, accompanied by weaker framework O−H stretching bands in the 3700−3500 cm^{-1} zone. Apart from these localised regions, the zeolite framework does not interfere in the IR absorption of the incorporated guests.

Solid-state ^{13}C NMR spectroscopy can also be used for identification purposes.[63] However, the low sensitivity of this technique makes it not very useful unless isotopically ^{13}C-labelled compounds are used or the guest loading is sufficiently high. Other nuclei such as ^{19}F, ^{29}Si, ^{31}P, etc. can be important in some particular cases.

One of the most useful approaches to determine the nature of the species resulting after the ship-in-a-bottle synthesis is to compare the reported spectroscopic properties of a species in solution with that recorded for the zeolite sample. Caution should be exercised when comparing the spectra, since some other species or by-products may have also similar properties. Particularly important as identity criteria are IR and Raman spectra taken as fingerprints due to the large number of peaks with various intensities appearing in these spectra. However, there are some cases in which the spectra of the species in other media are not available or the spectroscopic features are too general to be attributed unambiguously to a single species. One common reason for this is the instability of the species in other media. In these cases, or in general as a complementary strategy to the analysis of the spectroscopic data, one approach to determine the nature of the incorporated guest consists in dissolving the zeolite framework with concentrated hydrofluoric acid or with a mixture of HF and HNO_3 and extract the guest or the products derived from it that can thus be analysed. The limitation of this approach is the instability of the guest to this aggressive treatment. However, it is worth mentioning that some organic groups can survive HF treatment and, when this occurs, the method becomes useful. On the other hand, given the large amount of inorganic salts present in the liquor resulting after dissolving the zeolite, extraction of the guest from these solutions is problematic. High loading and low polarity of the guest facilitates the extraction.

A good practice when performing the ship-in-a-bottle synthesis is to analyse the extractable products. In principle,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

it is logical to assume that the products observed in solution, if bulky enough, will also be trapped inside the zeolite pores since it is expected that it will be formed equally outside and inside the zeolite grain. If, on the other hand, the recoverable products are not bulky enough to remain entrapped inside the zeolite, they can give a useful information on the operating reaction mechanism and their formation has to be compatible with the overall reaction scheme.

6. Evidence to Support the Internal Location of Encapsulated Guests

Once the nature of the species is known, a different question that requires specific techniques to be answered is the location (internal vs. external) of the guests. The fact that a synthesis has succeeded does not guarantee that the guest is located predominantly in the interior of the grains. In fact it would be reasonable to assume that during the synthesis a distribution of guests between the external surface and the internal pores occurs. Since the total surface area in a zeolite is predominantly internal (over one order of magnitude larger than the external surface), it is logical to consider that most of the guests are located internally, particularly when dealing with high loading samples.

However, ship-in-a-bottle syntheses conducted using amorphous silicas have demonstrated in some cases that the product can also be formed on these non-porous solids. Likewise, in the case of small- or medium-pore-size zeolites in which large guests cannot be accommodated within the interior of the micropores, the synthesis can also succeed. For these solids (either non-porous or small-pore-size zeolites) there is no doubt that the product formed has to be located exclusively on the external surface. Therefore, the formation of the product (as assessed by spectroscopic means) in a tridirectional zeolite can never be taken as evidence per se of its location.

Direct evidence of the internal location of guests can be obtained when the guests are heavy metal atoms by means of high-resolution X-ray diffraction, neutron scattering or high-resolution transmission electron microscopy. These techniques have been applied in fact to the study of zeolites devoid of any guest to address the crystallographic position of the charge-balancing cations. However, organic compounds do not normally give a clear signal or image with these techniques due to the low atomic weight of carbon. Nevertheless Baerlocher et al. have reported direct evidence of organic guest location by high-resolution X-ray diffraction.[66] Thus, the location of organic guests has to be addressed indirectly and generally by a combination of several techniques since each of them have serious limitations that can induce errors if no special precautions are taken.

It is frequently assumed that exhaustive solid-liquid extraction can be a proof of the internal location of bulky guests. Molecules small enough to diffuse through the internal pores should be recoverable by solid-liquid extraction even if they are adsorbed internally. However, this assumption has to be proved and supported by appropriate blank controls. Thus, known amounts of a compound can be adsorbed on a zeolite and then extracted to determine the efficiency of the extraction protocol. On the other hand, large guests supported on amorphous silicas can also be submitted to solid-liquid extraction to determine the efficiency of the recovery when these guests are deposited on the external surface. In any case, it can be stated that, although exhaustive solid-liquid extractions are a necessary workup in a ship-in-a-bottle synthesis, the fact that the zeolite still contains some guest after this treatment is only a weak indication of its internal location, particularly for low residual loading of the guest.

An indirect technique used to address the location of a guest in a zeolite is isothermal gas adsorption. Surface area and pore volume measurements should reflect a decrease in the specific values due to the presence of the guest occupying the internal void. However, in order to provide meaningful data isothermal gas adsorption requires prior evacuation of co-adsorbed water by thermal desorption under reduced pressure. Thermal treatment must be then carefully performed since mild desorption conditions could still leave some residual water adsorbed on strong sites and a more severe treatment may lead to the decomposition of the organic guest. Since most organic compounds start to degrade at temperatures above 300 °C, this is approximately the common limit for pre-treatment of these surface area measurements. For certain zeolites, particularly those having strongly acidic sites, 300 °C may not be sufficient to desorb all the adsorbed water completely and the porosity measurements will therefore be disguised. On the other hand, a labile organic guest may not resist prolonged heating at high temperature.

XPS provides an elemental analysis of a shallow layer (approx. 20 nm depth for soft X-rays) of the zeolite grain. XPS analysis can be quantitative by integrating the area of the peak corresponding to each element and calibrating the response of each atom using standards. A technique that is used in materials science to determine the depth of a metal corrosion is to combine XPS analysis and fast atom bombardment that produces the disappearance and ablation of the outermost layer exposed to the high-energy sputtering. The Ar^+ ion can be used for this purpose. If the combination of XPS and Ar^+ ion sputtering is applied to zeolites, a map of the elemental composition vs. the time of exposure to the Ar^+ beam is obtained. The time of the Ar^+ sputtering can be related to the depth of penetration from the external surface to the interior of the zeolite particle due to the destruction and evacuation of the exposed zeolite framework. Therefore, a plot of the percentage of a given element vs. penetration depth can be obtained. If the percentage of C atoms with respect to the total of other atoms (O + Si + Al) increases along the distance from the particle surface, this can indicate that the guest is located predominantly in the interior of the grains. Figure 1 shows a reported example of the use of XPS/sputtering for the purpose of mapping out the C composition along the particle radius.

The limitation of the XPS combined with fast atom sputtering technique may arise from the texture and mor-

phology of the zeolite samples. While for continuous and flat surfaces, such as those of metals, the above technique really provides a map of the composition along the penetration in the material, when working with powders composed of individual particles of micrometer size the situation is more complicated. Depending on the sample preparation and how the powder is presented, the differences in the composition along the time of sputtering may not really reflect differences along the zeolite particle depth, but rather differences from particle to particle. Differences in the packing of the particles, sedimentation and other aspects related to the agglomeration of a multitude of particles, rather than penetration inside an individual zeolite particle, can also be responsible for differences in the XPS upon Ar^+ sputtering.

For many zeolites, the location of charge-balancing cations in as-synthesised, highly crystalline samples has been conclusively demonstrated by high-resolution X-ray diffraction and neutron scattering. If a guest is replacing a significant fraction of these structural cations, it can be assumed that they will occupy the initial positions of the original cations. Even if the crystallographic positions are not exactly the same for the initial cation and the replacing guest, it is reasonable to assume that the positions have to be as close as possible in order to minimize the electrostatic energy. Thus, if a large fraction of a cation located internally is replaced by a bulky guest, the guest has to be also within the micropores.

A related case is that of protonic zeolites having acidic hydroxy ≡Si−(OH)−Al≡ bridges. In IR spectroscopy, different framework hydroxy groups may exhibit different absorptions. In particular, for fully protonic HY zeolite there are distinctive IR hydroxy bands related to external silanols (3740 cm^{-1}), acidic bridged OH inside the sodalite cage (3670 cm^{-1}), OH in the supercage (3650 cm^{-1}), and OH in the sodalite hexagonal prisms (ca. 3550 cm^{-1}).[56] These peaks appear as sharp absorption bands in the spectra of dehydrated HY samples, and some other OH groups can also be present depending on the type of sample and the presence or not of non-framework Al. If as a result of a ship-in-a-bottle synthesis a bulky guest is located in the Y supercage replacing these protons totally or partially, then quantification of the peak corresponding to the vibration of this type of hydroxy groups in the IR spectra for exactly the same weight of the zeolite before and after the ship-in-a-bottle synthesis should reflect the decrease in the population of these acidic OH groups. Since the location of these groups is known, their replacement requires that the formed guest occupies a position close to the original OH.

However, also in this case there are some artifacts that can influence the intensity of the OH groups without being actually replaced. Since these OH groups are acidic, the presence of residual amounts of solvents, reactant, or by-products may broaden the acidic OH peak considerably, giving the impression that its intensity has decreased or making the peak integration inexact. In order for these measurements to be valid, the spectrum of the sample after the ship-in-a-bottle synthesis has to be recorded under conditions in which nothing alters the OH groups. Blank controls in which a zeolite sample is submitted to an analogous ship-in-a-bottle treatment but without a necessary reagent to form the entrapped guest is also a good practice to compare the IR spectra with and without guest.

B. Applications of Zeolite-Embedded Guest Systems Obtained by Ship-in-a-Bottle Synthesis

1. Ship-in-a-Bottle Systems as "Zeozymes"

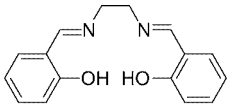
There are some enzymes in which a metallic complex is embedded with the tridimensional structure of a protein. The metallic complex acts as the catalytic site while the access of the substrate to the site is controlled by the surrounding protein skeleton. Other properties such as solubility and the micropolarity of the environment site isolation are also determined by the protein. Inspired by the enzyme constitution, it is possible to imagine an analogous system comprising a catalytically active metallic complex but embedded within an inorganic matrix. The term "zeozyme" was constructed by the combination of the words *zeolite* and *enzyme* and refers to the latter possibility.[15,68,69] There is no doubt that this application of ship-in-a-bottle synthesis will attract a renewed interest in coming years motivated by the understanding of new enzymatic systems.

In this context, probably the first example of a synthesis termed as a ship-in-a-bottle synthesis was a Co^{II}−salen complex that was prepared by adsorbing the flexible salen ligand into a Co^{II}-ion-exchanged zeolite.[46]

Transition metal complexes of salen are widely used as catalysts in homogeneous solution for a large number of reactions such as epoxidation of alkenes, epoxide ring aperture, nucleophilic additions to carbonyl and imine groups, CO_2 fixation, etc.[70−74] The term *salen* for the ligand is the acronym standing for bis(salicylidene)ethylenediamine. These salen complexes are a particular case of Schiff-base

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complexes, since one of the coordination bonds between the metal atom and the ligand occurs through the imine group that is known in organic chemistry as the Schiff base.



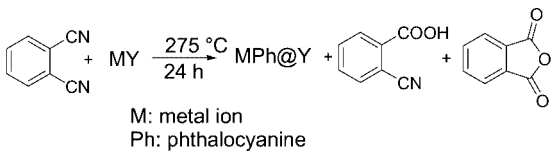
salen

In contrast to the flexibility of the salen ligand (particularly through the ethylene bridge), the resulting metal complex is rigid and becomes entrapped inside the zeolite cavities.[46] Encapsulated Co^{II}−salen complex shows affinity for O_2, forming a 1:1 adduct exhibiting a somewhat lower binding equilibrium than in solution, but an excellent resistance to undergo autooxidation even at elevated temperatures.[46] This system has a resemblance to that of hemoglobin, the Co^{II}−salen acting as a prosthetic group binding oxygen reversibly and the zeolite behaving as an "*inorganic*" protein. This example developed by *bioinspiration* is the origin of the word *zeozymes*.

Since Co^{II}−salen many other transition-metal−salen complexes, such as those of $V{=}O^{2+}$ [75] and iron,[76] have been reported. The influence of the preparation procedure and reaction temperature on the efficiency of the complex formation has been studied for Rh^{III}−salen encapsulated in zeolites X and Y.[77,78]

Jacobs has used a biomimetic approach to design encapsulated mono- and polynuclear iron catalysts with activity similar to *monooxygenase* metalloproteins that catalyse the incorporation of oxygen atoms from dioxygen into organic substrates.[79]

Metallophthalocyanines can also be entrapped inside faujasites X and Y by a ship-in-a-bottle synthesis starting from *o*-phthalodinitrile and the transition-metal-exchanged zeolite or by a build-the-bottle-around-the-ship strategy. Balkus, Jr. has made significant contributions in this area and has written several reviews on the preparation and catalytic activity of encapsulated metallophthalocyanines.[75,80] As mentioned earlier in the introductory sections, after the pioneer work of Romanovskii and Schulz-Ekloff, Herron coined the term ship-in-a-bottle synthesis and, as well as the first metallic complexes, he also prepared iron−phthalocyanine inside faujasites X and Y by thermal tetramerisation of *o*-phthalodinitrile templated by iron ions (Scheme 3).[81] His idea was to mimic the activity of cytochrome P 450, which is able to oxidize alkanes with molecular oxygen, but replacing the flexible, but labile protein surrounding the prosthetic iron centre by the rigid and robust zeolite framework.



Scheme 3

The molecular size of the flat, relaxed geometry of the phthalocyanine macrocycle (about 14 Å of diameter) is too large to be accommodated inside the supercages of faujasites, whose free volume is also a function of the nature of the charge-balancing cations occupying site-III positions in the supercage. Since it is a fact that the ship-in-a-bottle synthesis of phthalocyanines is feasible, it has been proposed that the heteroaromatic macrocycle adopts a roof-like, rather than a flat, conformation to fit inside the cavities. Figure 2 shows a molecular modelling of Cu^{II}−phthalocyanine inside an ideal all-silica faujasite. Furthermore, in an interesting report, the synthesis of much bulkier iron−tetra-*tert*-butylphthalocyanine (estimated diameter of 19 Å) has been successfully accomplished starting from pre-encapsulated $[HFe_3(CO)_{11}]$ iron−carbonyl clusters and 4-*tert*-butyldicyanobenzene inside NaY.[82] Based on the characterisation by EXAFS, Mössbauer, FT-IR and diffuse-reflectance UV/Vis spectroscopy, the authors propose that the tetra-*tert*-butylphthalocyanine is located inside the zeolite supercage in a conformation far from planar.[82] Due to the steric compression compared to the parent iron−phthalocyanine, the tetra-*tert*-butyl derivative exhibits higher activity and selectivity toward terminal hydroxylation of *n*-hexane and *trans*-epoxidation of stilbenes with PhIO. This higher regioselectivity indicates a preferential attack of oxygen in the active Fe=O species on the terminal carbon atoms of the substrate. It would be of interest to gain a deeper understanding of the conformation, strain and location of this very large phthalocyanine complex.

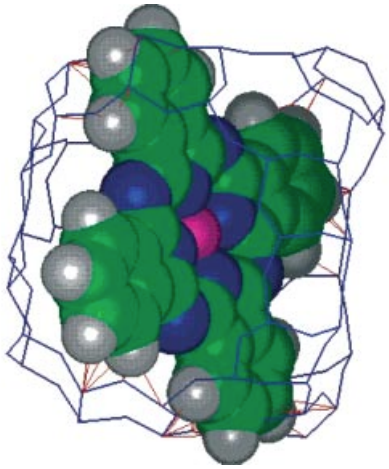


Figure 2. Molecular model showing copper−phthalocyanine encapsulated inside the supercage of zeolite Y (see also ref.[83])

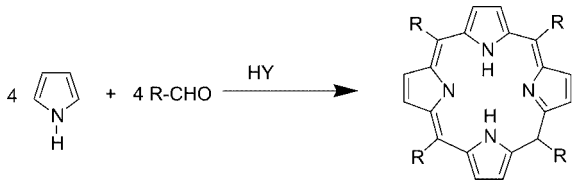
An approach to avoid forcing the steric compression of phthalocyanine has been to use novel zeotypes with pore sizes larger than those of conventional faujasites. Co^{II}−phthalocyanine has been encapsulated in the large cavities of zeolite EMT at a loading of one complex for every six supercages.[84] The resulting Co−phthalocyanine@EMT exhibits a turnover number for the oxidation of ethylbenzene with molecular oxygen of about 22000. Likewise, Jacobs and co-workers have reported the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

encapsulation of iron−phthalocyanine inside large-pore-size VPI-5, which is a monodirectional aluminophosphate of extra-large pore size.[85−87] The VPI-5-occluded iron−phthalocyanine acts as a catalyst for alkane oxygenation using iodosobenzene. Jacobs has also reported an interesting further elaboration of the encapsulated phthalocyanine by preparing a composite in which the fibres of a partially crosslinked poly(dimethylsiloxane) polymer holds the zeolite containing the phthalocyanine complex.[88] This poly(dimethylsiloxane)/zeolite composite acts as a membrane at the interphase between aqueous hydrogen peroxide and hydrophobic cycloalkene and can promote the catalytic oxidation of alkenes, mimicking again the activity of cytochrome P 450.[88]

In an attempt to increase the stability and the turnover numbers of the encapsulated metallophthalocyanines, Balkus, Jr. described the synthesis of Ru^{II}−perchloro-[89] and -perfluorophthalocyanine[75,90−92] inside zeolite X. The methodology followed in this case was to build the bottle around the ship.[91] These perhalophthalocyanines show activity for the oxidation of cyclohexane with *tert*-butyl hydroperoxide and cyclohexene and stilbene with oxygen.[92] The perfluorinated phthalocyanine shows no signs of deactivation, in contrast to the nonfluorinated analogues.[91]

Related to encapsulated metallophthalocyanines are the attempts of ship-in-a-bottle synthesis of *meso*-tetrasubstituted porphyrins that formally possess the same aromatic macrocycle. This synthesis has been attempted by condensation of pyrrole with aldehydes (Scheme 4).[93] Although porphyrins are expected to be more flexible than phthalocyanines, and porphyrins are among the products observed in the solution during the ship-in-a-bottle synthesis, spectroscopic characterisation reveals that it is a precursor of the protoporphyrin type that is present inside the zeolite. It has been assumed that the lower thermodynamic stability of porphyrins as compared to phthalocyanines makes their ship-in-a-bottle synthesis unsuccessful, particularly the last oxidative aromatisation step that requires the achievement of planarity. In this context, and given the number of enzymes having metalloporphyrins and their interesting catalytic activity, it would be of interest for the development of the zeozyme concept to explore other zeolites with larger pores as hosts for porphyrins.



Scheme 4

There are metalloporphyrins, however, that can be encapsulated within faujasite by using the build-the-bottle-around-the-ship approach, crystallising the zeolite gel around the porphyrin. One example is the preparation of the metallotetrakis(*N*,*N*,*N*-trimethylanilinium)porphyrin cation entrapped in faujasite Y that was used as a catalyst for the oxidation of cyclohexene.[94] The latter strategy of crystallising the zeolite around the guest may work well for faujasites for which no structure-directing agent is required. In this case, the metallic complex has to be sufficiently robust to resist the hydrothermal zeolite crystallisation (typically above 100 °C and alkaline pH for at least a few hours) and has to have a relatively high solubility in water.

2. Ship-in-a-Bottle Systems as Catalysts

Moving further from the initial zeozyme concept to the broader use in catalysis, one general methodology to transform a successful homogeneous catalyst into a heterogeneous one consists in immobilizing it onto a large-surface-area support. Immobilisation of the homogeneous catalyst permits its recovery from the reaction mixture and its reuse in consecutive runs. Immobilisation also allows the design of continuous flow reactors in which the catalyst is in a different phase than the reactants and products. In this context, the ship-in-a-bottle methodology has been used since the early days to prepare efficient solid catalysts.

a. Hydrogenation

Carbonylmetal clusters have been synthesised in zeolites, and remain trapped in the cages, by the ship-in-a-bottle methodology.[95,96] Thus, neutral carbonyl clusters of Pd, Rh and Ir have been synthesised in the α cages of Y zeolite. The general procedure involves an ion-exchange process of amine complexes such as $[Pt(NH_3)_4]^{2+}$, $[Pd(NH_3)_4]^{2+}$, $[Rh(NH_3)_5Cl]^{2+}$, $[Ir(NH_3)_5Cl]^{2+}$, and even an $[Rh(H_2O)_6]^{3+}$ complex, with NaY zeolite, followed by calcination, reduction and CO treatment under different reaction conditions. In this way, the ship-in-a-bottle synthesis of $Pd_{13}(CO)_x$, $Rh_6(CO)_{16}$, and $Ir(CO)_3Cl$ has been successfully achieved.[97−100] When a more basic faujasite zeolite (NaX) is used, anionic carbonylmetal clusters of platinum $\{[Pt_{15}(CO)_{30}]^{2-}\}$, rhodium $\{[Rh_6(CO)_{15}]^{2-}\}$, and dimetallic Pt−Rh $\{[PtRh_5(CO)_{15}]^{-}\}$, and Fe−Rh $\{[Fe_2Rh_4(CO)_{16}]^{2-}\}$ can also be prepared inside the supercavities.[101−104]

Some mononuclear Ir species can migrate through the channels and cavities of the zeolites when heated. After CO treatment they give either neutral carbonyl clusters such as $[Ir_4(CO)_{12}]$ or $[Ir(CO)_{16}]$ when using zeolite NaY,[105−108] or anionic clusters when zeolite NaX is used.

Encapsulated metal−salen complexes have also been used as catalysts for reactions different from those catalysed by enzymes. Hölderich and co-workers have prepared Pd^{II}− and chiral Co^{II}−salen complexes encapsulated within zeolites and used them as carbonyl hydrogenation catalysts.[109] Encapsulated Pd^{II}−salen is able to promote the hydrogenation of methyl pyruvate with complete selectivity at conversions higher than 70% and that of methyl acetoacetate with a product selectivity of 92% at about 50% conversion, while bulkier substrates such as isopropyl and *tert*-butyl pyruvate gave less or no conversion.[109]

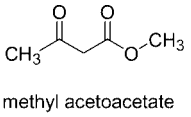
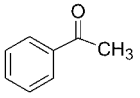
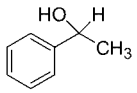
alkyl pyruvate



methyl acetoacetate



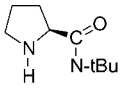
acetophenone



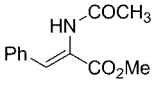
1-phenylethanol

In the case of the chiral Co^{II}–salen complex, although the selectivity for the conversion of acetophenone to 1-phenylethanol using the encapsulated Co complex was complete, the enantiomeric excesses at 25 °C were very low (8%) although higher than those of the homogeneous complex at lower temperatures (−10 °C). In agreement with the work on Mn^{III}–salen complexes, which will be mentioned shortly, the presence of large substituents on the ligand also precludes the ship-in-a-bottle synthesis of the Co complex and the resulting complex is located exclusively on the external surface, leading to enantiomeric excesses lower than those achieved with the same complex in homogeneous phase.[109]

Heterogeneous hydrogenation catalysts based on incarcerated metallic complexes other than salen have also been widely used. A complex of (cyclooctadiene)Rh^{I} and prolinamide or *N-tert*-butylprolinamide has been prepared inside zeolite, the resulting solids exhibiting a higher specific activity for the hydrogenation of alkenes than their homogeneous counterparts.[110] For the enantioselective hydrogenation of methyl (*Z*)-2-acetamido-3-phenylacrylate the enantiomeric excess was much higher with the heterogenized catalyst than with the homogeneous complex.



N-tert-butylprolinamide



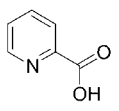
methyl (*Z*)-2-acetamido-3-phenylacrylate

b. Acid Catalysis

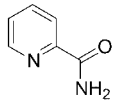
The heteropolyacid $H_3PW_{12}O_{40}$ is an almost spherical cluster of about 8 Å diameter. Its Keggin structure, with a central tetrahedral PO_4 core and internal tungsten atoms, makes this compound very rigid and undeformable preventing it from crossing the 7.4 Å windows of faujasites. One important property of phosphotungstic acid is its strong acidity, even higher than that exhibited by pure sulfuric acid due to the negative charge delocalisation through the outer oxygen layer of the structure. In spite of this superacidity, phosphotungstic acid has been synthesised inside the cavities of zeolite Y without destroying the crystal structure. ^{31}P MAS NMR spectroscopy shows a broad signal at $\delta = -14.4$ ppm that is assigned to the Keggin heteropolyacid interacting with the zeolite Al atoms. The encapsulated heteropolyacid exhibits high activity for *m*-xylene isomerisation and disproportionation.[111]

c. Oxidation Catalysis

Picolinic acid as a ligand for Fe^{III} was used successfully by Barton for the oxidation of cyclohexane by hydrogen peroxide.[112] Garcia and co-workers reported the encapsulation of iron picolinate inside a series of zeolites and found that the zeolites containing the encapsulated picolinate complex are efficient and reusable heterogeneous catalysts for the oxidation of cyclohexane to cyclohexyl hydroperoxide, cyclohexanol and cyclohexanone.[113] Mordenite was found to be the best host for this purpose.[113] Analogously, vanadyl picolinate encapsulated within NaY is also active for the oxidation of alkanes, alcohols and benzene with hydrogen peroxide.[114,115] Jacobs has also reported the ship-in-a-bottle synthesis of an iron complex of a tetradentate N_4 ligand derived from 2-pyridinecarboxamide that is able to effect the oxidation of cyclohexane to cyclohexyl hydroperoxide as well as cyclohexanol and cyclohexanone.[116] In most of these iron oxidations it is widely assumed that the catalytically active species is a high-valent $Fe^{IV}=O$ species.

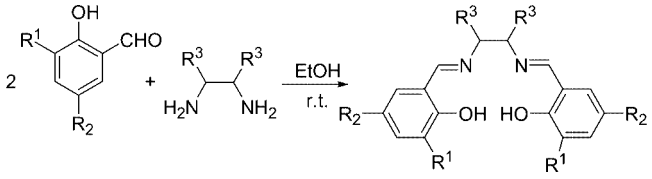


picolinic acid



2-pyridinecarboxamide

Many related ligands can be easily derived from salen by modifying the ethylenediamine bridge or by introducing substituents in the salicylidene aromatic moiety and they can be easily obtained by the condensation of a primary diamine with salicylaldehyde. This reaction is normally carried out by stirring an ethanolic solution of the salicylaldehyde and the diamine at room temperature until the product has formed (Scheme 5).



Scheme 5

Chiral salen ligands can be easily obtained if one uses a single enantiomer of a chiral diamine, as has been reported in solution. In fact the most important application of salen complexes is as asymmetric catalysts for the enantioselective epoxidation of alkenes using the manganese complex of bis(2,4-di-*tert*-butylsalicylidene)-1,2-cyclohexanediamine that is commonly known as the Katsuki–Jacobsen catalyst.[117,118]

In 1997, and almost simultaneously, two independent communications reported the ship-in-a-bottle synthesis of a chiral manganese Schiff-base complex inside faujasite and

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

EMT zeolites and used them as enantioselective catalysts for the heterogeneous epoxidation of alkenes.[119] (*Z*)-Methylstyrene and indene are two favourite substrates for the study of the enantioselectivity of asymmetric epoxidation. The enantiomeric excesses obtained with these zeolite-bound Mn^{III}−salen complexes were only modest (about 60%), particularly compared to the enantiomeric excesses that can be achieved in solution for the bis(2,4-di-*tert*-butylsalicylidene) derivative. It has to be noted, however, that due to steric restrictions the actual chiral salen ligand encapsulated within the Y zeolite cages lack the bulky *tert*-butyl substituents. Molecular modelling predicts that the tetra-*tert*-butyl-substituted salen ligand is too large to be accommodated inside the zeolite Y supercage. Figure 3 shows a visualisation of the Mn^{III}−salen complex obtained by freezing the geometry of zeolite Y devoid of framework Al to the crystallographic positions and optimising the geometry of the complex at the semiempirical MNDO level. A recent report, however, has challenged this modelling by claiming the preparation of the tetra-*tert*-butylsalen derivative inside the supercages of zeolite Y.[120] The authors have claimed to be able to prepare the encapsulated complex by adsorbing the preformed bulky ligand into the zeolite pores, something that molecular modelling predicts should not be possible. Recently, chiral vanadyl−di-*tert*-butylsalen complexes have been grafted in the walls of MCM-41.[121]

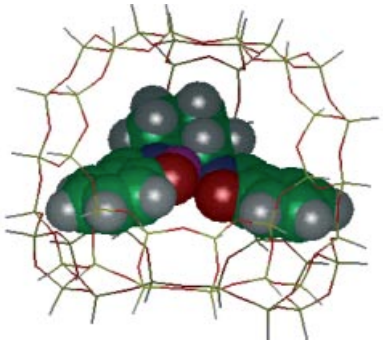


Figure 3. Molecular model of chiral Schiff-base Mn^{III}−bis(salicylidene)cyclohexanediamine lacking *tert*-butyl groups encapsulated within zeolite Y

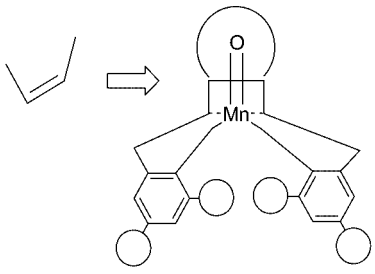
The low enantiomeric excesses obtained using zeolite-encapsulated complexes can be rationalised considering that the asymmetric induction requires, as determined in solution, a precise "*side-on*" approach of the alkene to the oxomanganese epoxidation centre, the role of the bulky *tert*-butyl substituents being to impede the approach from other directions (Scheme 6). This process is completely disrupted when the complex is encapsulated in the zeolite, the geometry of the voids being the main factor dictating the possible approaches between the guest and the alkene. In addition, the presence of other Mn species in the solid, particularly as Mn^{II}, that can act as unselective epoxidation centres, has also been determined by EPR spectroscopy and electrochemistry.[122,123]



side-on approach of the alkene to the encumbered Mn=O bond

Scheme 6

A Co^{II}−Schiff-base complex derived from *N*,*N*′-bis(salicylidene)-1,2-diphenylethylenediamine has also been encapsulated within zeolite by the template method and studied as co-catalyst for the ruthenium-catalysed oxidation of benzylic alcohols.[124] The resulting zeolite-bound complex shows several distinctive facts with respect to the same complex in solution including: (i) higher reaction rates due to site isolation; (ii) no need for triphenylphosphane as axial ligand; and (iii) relative lack of influence of the solvent in which the reaction is carried out.[124]

3. Ship-in-a-Bottle Systems as Photocatalysts

Besides being catalysts for thermal reactions, zeolite-embedded guests prepared by ship-in-a-bottle synthesis have also been widely used as photocatalysts. In this latter case, the solid absorbs light and converts it into chemical energy by generating a highly reactive species. The photocatalytic generation of the $^{\cdot}OH$ radical from O_2, H_2O_2 or other sources is an emblematic example of conversion of light into chemical energy. Photocatalysis is obviously less developed than catalysis but is showing great promise for air and water purification.

In the following sections we will describe examples of ship-in-a-bottle-prepared systems whose use as a photocatalyst has been described.

a. Transition Metal Complexes

i) Tris(bipyridyl)ruthenium and Related Poly(pyridyl) Complexes

Tris(bipyridyl)ruthenium was one of the first large guests for which a ship-in-a-bottle synthesis was reported. The initial synthetic procedure by Lundsford et al.[125] was later improved by Dutta.[126] The method consists of the initial introduction of $[Ru(NH_3)_4]^{3+}$ followed by addition of an excess of 2,2′-bipyridine and prolonged heating at 220 °C. The excess of ligand is removed by continuous solid-liquid extraction. Calzaferri has shown that the purity of the encapsulated $[Ru(bpy)_3]^{2+}$ complex decreases upon increasing the loading of the complex due to diffusion problems.[127]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Other species present as impurities have an $[Ru(bpy)_n(NH_3)_{6-2n}]^{2+}$ ($n < 3$) stoichiometry. However, essentially pure samples of included $[Ru(bpy)_3]^{2+}$ can be obtained for loadings lower than one complex for every two supercages.[127]

Tris(bipyridyl)ruthenium is a complex that exhibits a high phosphorescence quantum yield. Since this phosphorescence is quenched by oxygen, a sensor based on this ruthenium complex has been developed.[128] $[Ru(bpy)_3]^{2+}$ has also been a favourite probe molecule for studies dealing with photoinduced electron transfer as well as in basic studies on long charge storage.[125,126,129,130] These studies rely on the easy emission detection in opaque powders.

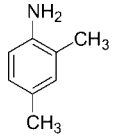
In an attempt to increase the efficiency of the charge separation, Dutta and co-workers reported the ship-in-a-bottle synthesis of tris(bipyridyl)ruthenium in nanometric zeolite X.[139] Caution has to be taken in this case to avoid acid formation during each step of the ship-in-a-bottle synthesis, since otherwise the crystallinity of the nanoscopic X zeolite is considerably reduced and the advantages of the use of nanocrystals disappear. Under conditions in which 90% of the crystallinity is preserved, it was observed that the photoinduced electron transfer between $[Ru(bpy)_3]^{2+}$ and methylviologen is about a factor of two more efficient in nanocrystals than in conventional micrometer-sized crystallites.[139]

Besides tris(bipyridyl)ruthenium(II) other metal−polypyridyl complexes such as $[Co(bpy)_3]^{2+}$,[140] $[V{=}O(bpy)_2]^{2+}$,[141] and $[Fe^{II}(bpy)_3]^{2+}$ [79,142] have also been synthesised. In the case of $[Fe^{II}(bpy)_3]^{2+}$, Bossmann, Braun and co-workers have studied the use of the resulting solid as a heterogeneous photo-Fenton catalyst.[142] In the Fenton reaction, aggressive ·OH radicals are formed by reaction of Fe^{II} with hydrogen peroxide [Equation (1)]. Then, this ·OH radical can initiate the oxidative degradation of the vast majority of organic molecules either by C−H hydrogen abstraction, nucleophilic addition to unsaturated multiple bonds or by single-electron oxidation. The Fenton reaction requires a stoichiometric amount of iron(II) with respect to the ·OH radical. A variant of this Fenton process that only requires catalytic amounts of Fe is the photo-Fenton reaction in which the Fe^{III} formed in Equation (1) is reduced back to Fe^{II} by light, with the additional generation of a second ·OH radical. One problem of this photochemical reaction is that the aquated iron ion has a low extinction coefficient in the visible region and therefore UV light is required. The advantage of the use of the $[Fe^{II}(bpy)_3]^{2+}$ complex is that it absorbs visible light with a high molar absorptivity, thus increasing the efficiency and practicality of Equation (2).

$$Fe^{2+} + H\text{-}OO\text{-}H \longrightarrow Fe(OH)^{2+} + {\bullet}OH \quad (1)$$

$$Fe^{3+} + H_2O \xrightarrow{h\nu} Fe^{2+} + H^+ + {\bullet}OH \quad (2)$$

In a further refinement, these authors have co-doped the encapsulated $[Fe^{II}(bpy)_3]^{2+}$ with TiO_2 clusters that have been prepared after the ship-in-a-bottle synthesis of $[Fe^{II}(bpy)_3]^{2+}$ by hydrolysis of $TiCl_3$.[142] Apparently, the presence of TiO_2 enhances the photocatalytic activity of the iron complex by acting as an electron relay from the donor to the iron(III) complex. The photocalytic activity of this $[Fe^{II}(bpy)_3]^{2+}$ system in acidic aqueous solutions has been studied in the presence and absence of H_2O_2 using 2,4-xylidine, a recalcitrant non-biodegradable pollutant, as model compound.



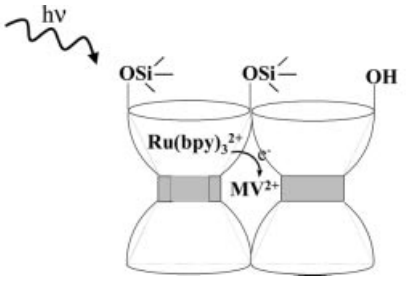
2,4-xylidine

Fundamental studies on electron transfer within the zeolite matrix have been done by using metal−polypyridyl complexes. For instance, Fukuzumi and co-workers have also synthesised $[Fe(bpy)_3]^{2+}$ encapsulated inside NaY at a loading of one molecule per 10 supercages and converted it into $[Fe(bpy)_3]^{3+}$ by chemical oxidation with chlorine.[143] Observation of an extremely slow reaction between ferrocene and encapsulated $[Fe(bpy)_3]^{3+}$ has led to the suggestion of the occurrence of a long-range electron transfer through the zeolite framework.[143] An analogous *through-framework* electron transfer between tris(bipyridyl)ruthenium and methylviologen has been demonstrated using ITQ-2 as zeolite (Scheme 7).[130] In this case, the zeolite defines a topology comprising external cups and internal 10-membered channels. The (polypyridyl)ruthenium complex is located in the open cups of the zeolite while viologen as electron acceptor is incorporated inside the 10-membered-ring channels of the zeolite. Upon photoexcitation of $[Ru(bpy)_3]^{2+}$, an electron transfer to encapsulated MV^{++} occurs.

b. Organic Cations

i) Pyrylium and Derivatives

The first ship-in-a-bottle syntheses in zeolites were used to prepare encapsulated metallic complexes. In most of these early cases, the key feature in the encapsulation was



Scheme 7

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the formation of a coordinative bond between a metal ion and a heteroatom having lone electron pairs.

In contrast to this, the hallmark of organic synthesis is the formation of new C−C bonds by coupling of nucleophilic and electrophilic reagents in the absence of a metal. In this regard, one of the first ship-in-a-bottle *organic* (as opposed to coordination chemistry) synthesis was the encapsulation by Corma, Garcia and Miranda of the 2,4,6-triphenylpyrylium ion inside zeolite HY.[144] This pyrylium ion is obtained in solution by treating 2 equiv. of chalcone with acetophenone in the presence of strong liquid Brönsted acids, such as perchloric or tetrafluoroboric acid.[145] The reaction mechanism involves the aldol reaction of chalcone and acetophenone, followed by aromatisation by hydrogen transfer. By emulating this solution reaction successfully, but using the Brönsted acid sites of microporous HY zeolite instead of a liquid acid, it was possible to obtain the encapsulated 2,4,6-triphenylpyrylium (Scheme 8). Alternatively, the chalcone can be synthesised in situ catalysed by the same HY zeolite by allowing acetophenone and benzaldehyde to react.

The above procedure requires HY samples of sufficient acidity to promote the aldolic condensation. Recently, Miranda, Braun and Bossmann have reported[146] a more simple procedure to perform the ship-in-a-bottle synthesis of 2,4,6-triphenylpyrylium. This recent process has the advantage of starting from the commercial HSO_4^- salt of 2,4,6-triphenylpyrylium and commercial NaY in aqueous suspension to achieve the encapsulation of the dye. Formally, the whole process is a true ion exchange in aqueous solution of a bulky, size-excluded 2,4,6-triphenylpyrylium ion by internal Na^+. All the available information indicates that under these conditions the pyrylium ion undergoes a hydrolytic ring opening and the more flexible 1,3,5-triphenyl-2-pentene-1,5-dione migrates inside the zeolite supercage (Scheme 9). Once inside, dehydration by mild baking of the solid reforms the pyrylium heterocycle. Among the many advantages of this improved procedure, the major ones are the purity reproducibility of the encapsulated 2,4,6-triphenylpyrylium, the use of neutral, commercial NaY and the possibility to control the loading of the pyrylium cation in a reproducible way to achieve essentially a complete filling of one dye molecule per supercage. Concerning reproducibility, the crucial step is the baking of the zeolite to accomplish the complete cyclisation of the pentenedione.

2,4,6-Triphenylpyrylium salts such as those with BF_4^-, HSO_4^- and ClO_4^- are soluble in organic solvents such as CH_2Cl_2, CH_3CN and alcohols. These salts of 2,4,6-triphenylpyrylium are well-known electron-transfer photosensitizers in organic solvents.[147] Analogously, 2,4,6-triphenylpyrylium@Y is a solid photocatalyst that is able to promote photoinduced electron-transfer processes in organic solvents, such as one-way (*Z*)/(*E*) isomerisation of stilbene[148,149] and Diels−Alder cyclodimerisation of 1,4-cyclohexadiene.[150] Moreover, 2,4,6-triphenylpyrylium@Y can also be an effective photocatalyst in aqueous solution while, as mentioned above, simple salts of TP^+ cannot be used in water at neutral or basic pH due to the hydrolytic ring opening. Thus, one interesting feature of the encapsulation is that the occluded 2,4,6-triphenylpyrylium becomes persistent in water and can be used as a solid photocatalyst in water.[151] When encapsulated inside zeolites, 2,4,6-triphenylpyrylium has been found to be an efficient photocatalyst for the degradation and partial mineralisation of pesticides in water upon solar light irradiation. Some of the pesticides that can be degraded by the photocatalytic irradiation of encapsulated 2,4,6-triphenylpyrylium are phenol, aniline, 4-chlorophenoxyacetic acid,[152] methylparathion,[153] fenvalerate[154] and propoxur.[155] The case of 2,4,6-triphenylpyrylium@Y constitutes an example of the opportunities of encapsulated guests in photocatalysis.

Evidence supports the proposition that the photocatalytic mechanism involves the generation of ·OH radicals formed through photoinduced electron transfer from water

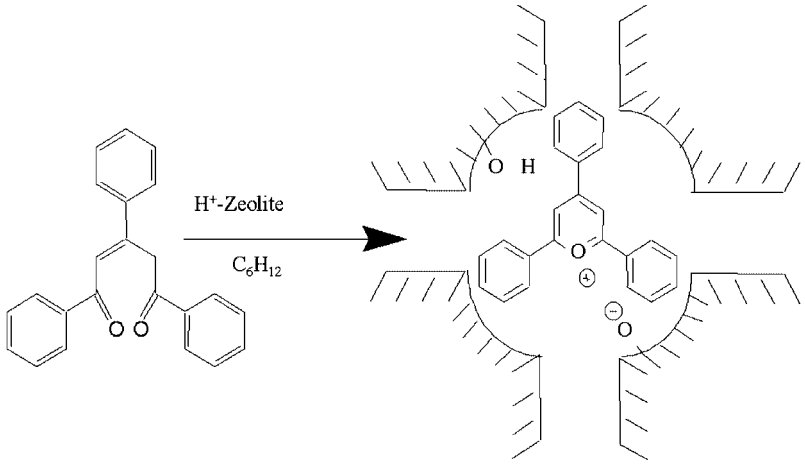
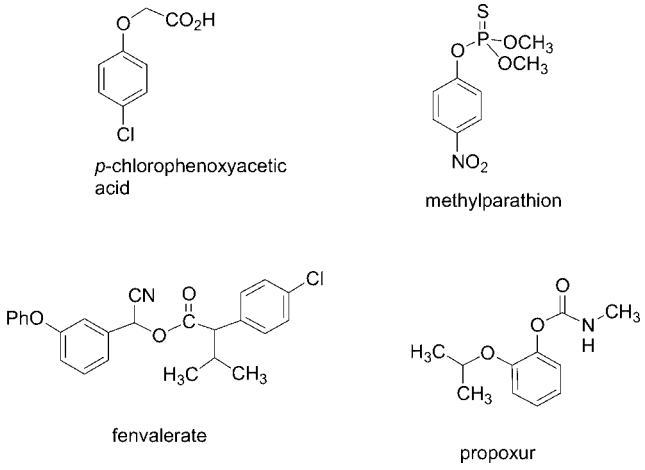


Scheme 9



to the dye in its excited state.[151] Interestingly, encapsulation also protects the dye from self-degradation by ·OH. Even irradiation of a suspension of 2,4,6-triphenylpyrylium encapsulated within zeolites in distilled water produces the build-up of a 10^{-2} to 10^{-3} M concentration of H_2O_2.[151] This lack of self-degradation has been rationalised based on the molecular modelling that indicates that the zeolite framework binds the 2,4,6-triphenylpyrylium tightly and it does not allow the size increase required in the nucleophilic attack (Scheme 10).[151] Self-degradation is a common phenomenon that precludes the use of organic photosensitizers as photocatalysts. This conformational immobilisation of 2,4,6-triphenylpyrylium is also responsible for the observation of room-temperature phosphorescence.[156]

After the initial synthesis of 2,4,6-triphenylpyrylium and in an effort to improve its photocatalytic activity and stability, the ship-in-a-bottle synthesis of some derivatives was successfully accomplished. Thus, 2,4,6-triphenylthiapyrylium has been obtained encapsulated in zeolites Y and Beta by allowing acetophenone and benzaldehyde dissolved in cyclohexane to react in the presence of acid zeolites, wherein the solvent and zeolites have been previously saturated with H_2S (Scheme 11).[157] Compared to oxygen, the lower electronegativity of the S atom, similar to carbon, increases the aromaticity of the thiapyrylium ring and therefore its thermal stability. Also, the photocatalytic activity of 2,4,6-triphenylthiapyrylium is superior to that of the pyrylium analogue (Figure 4), 2,4,6-triphenylthiapyrylium encapsulated within zeolites Y and Beta exhibiting in addition a much higher photostability thus making possible its reuse.

Tetraphenylbipyrylium is a bulky molecule that requires not one but two neighbouring supercages for it to be accommodated, thus making its ship-in-a-bottle synthesis especially challenging. The preparation of this dication inside the pores of zeolite Y has been accomplished employing the same reaction type as that followed for the synthesis of triphenylpyrylium, but using terephthaldehyde instead of

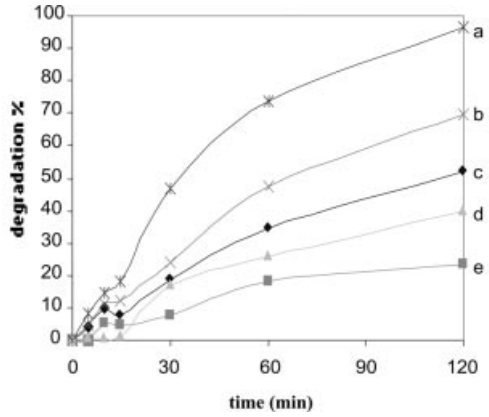

Figure 4. Plot of the phenol disappearance vs. time upon irradiation of an aqueous solution (20 mL) of phenol (δ = 40 ppm) in the presence of solid photocatalysts (30 mg) under identical conditions; a: 2,4,6-triphenylthiapyrylium@HBeta; b: 2,4,6-triphenylthiapyrylium@HY; c: P-25 TiO_2 standard; d: 2,4,6-triphenylpyrylium@HBeta; e: 2,4,6-triphenylpyrylium@HY

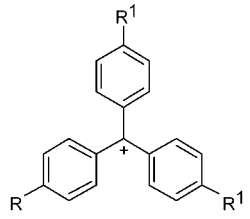
benzaldehyde.[158] Figure 5 provides a view of the model showing the tetraphenylbipyrylium occupying two zeolite Y supercages. However, although bipyrylium encapsulated within zeolite Y also exhibits the photocatalytic activity characteristic of 2,4,6-triphenylpyrylium, its efficiency is somewhat lower.

ii) Trityl Cations and Derivatives

Carbocations derived from the parent trityl cation are among the most stable in solution due to charge delocalisation through the aryl rings. Under appropriate conditions and in the absence of nucleophiles and moisture the parent trityl cation becomes indefinitely persistent in solution. Obviously, the presence of electron-donor substituents on the aryl rings stabilizes the carbocation further. One property of these trityl ions is the colour, which changes from the yellow of the unsubstituted trityl to orange, following the Woodward rules of additivity, according to the nature of the substituent. Some of these cations find application as dyes or pigments, malachite green and rose aniline being two examples among many others.[159]



Trityl cations

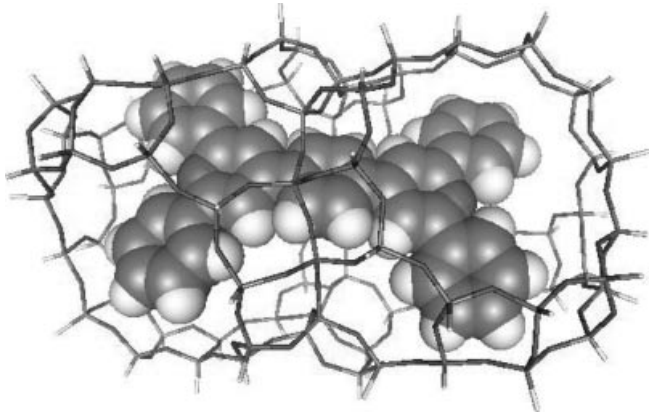


Figure 5. Model of tetraphenylbipyrylium showing the occupancy of two neighbour supercages (taken from ref.[158])

These trityl dyes have been prepared inside zeolite Y and Beta in their H^+ or La^{3+} forms by treating an aromatic aldehyde with electron-rich benzene derivatives such as anisole or *N*,*N*-dimethylaniline, as indicated in Scheme 12.[67,156] Evidence in support of the internal location of the dyes was obtained by the good fitting between the experimental high-resolution X-ray diffraction and the Rietveld refinement of a model in which the zeolite Y supercage contained the dye at one third of cage occupancy (Figure 6).[67] The resulting encapsulated dyes showed activity as heterogeneous photosensitizers to promote the radical-cation-mediated dimerisation of 1,3-cyclohexadiene.

Maciel and co-workers have followed a different strategy to form these encapsulated trityl cations consisting in the reaction of CCl_4 with benzene using the HY zeolite as catalyst. By using ^{13}C MAS NMR spectroscopy, isotopically labelled $^{13}CCl_4$ and studying the reaction of $Ph_3{}^{13}C^+$ with bulky nucleophiles, they reached the conclusion that the product was located predominantly in the internal cavities of the zeolites, in contrast to the simple adsorption of Ph_3CCl in HY that leads to the deposition of the bulky cation exclusively on the external surface of the particles.[160]

4. Ship-in-a-Bottle Systems as Electrocatalysts

Electrochemistry is a convenient tool to study the population of an electroactive guest located at the outermost supercages or subsurface zones since the electrochemical oxidation or reduction process has to be accompanied by the concomitant diffusion of a charge-balancing electrolyte. This diffusion limits the depth in which electrochemistry occurs in the particle.

One interesting application of zeolite-embedded guests is in electrocatalysis[161,162] and the development of selective electrodes.[163,164] In this case the electrode, normally a metallic conductor, is modified by depositing a film of a zeolite-

encapsulated guest that increases the electrochemical response towards an analyte or promotes an electrochemical process.

Most of the transition metal complexes have a characteristic electrochemical response due to the changes in the metal oxidation number. By means of electrochemistry, Bedioui, Balkus and co-workers have provided experimental evidence of the site isolation arising from the encapsulation of a large guest in a single zeolite supercage. Thus, Rh^{III}−phthalocyanine@NaY exhibits a reversible reduction peak interpreted as the transition between Rh^{III}−phthalocyanine/Rh^{II}−phthalocyanine, while in solution this reversible reduction peak is not observed due to dimerisation/dismutation of the Rh^{II} species.[165]

Balkus, Jr. and Bedioui have prepared zeolite-encapsulated metal−salen compounds and studied their electrochemical response.[166] Apparently, the electrochemical behaviour of the encapsulated complexes is similar to that in solution and the redox potential peaks of the zeolite-encapsulated complexes appear at similar values as in homogeneous solution. In this context, an interesting controversy is how deep in the particle the electrochemical techniques can probe and if the electrochemical response is purely extrazeolitic, due to zeolite-bound complexes, or really intrazeolitic.[167−169]

Organic guests can also exhibit an electrochemical response.[123,170−172] 2,4,6-Triphenylpyrilium encapsulated inside zeolites has been shown to promote the electrochemical response of dopamine, norepinephrine and other catecholamine neurotransmitters by a factor of up to 20. This can serve to develop electrodes that allow the detection of smaller concentrations of analytes that exhibit a selective response for a substrate.

5. Ship-in-a-Bottle Systems as Sensors and Photochromic Systems

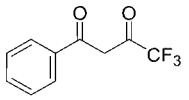
The large surface area, the porosity and even the shape-selective adsorption of zeolites are also very interesting for the development of solid sensors in which a zeolite-entrapped guest can report on the presence of certain analytes.

As mentioned earlier, metal−polypyridyl complexes such as $[Ru(bpy)_3]^{2+}$ are strongly photoluminescent either in solution or when encapsulated within zeolites. The actual emission decay kinetics is sensitive to the environment of the complex and to the presence of quencher molecules such as oxygen.

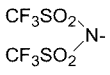
Rare-earth cations are also strongly luminescent, but in contrast to normal emission from organic lumophores, the atomic emission may consist of sharp atomic lines rather than broad emission bands. Luminescent rare-earth complexes have also been used as sensors.[173−176] However, atomic photoluminescence presents, in general, two problems. On one hand, the excitation of the atomic orbital of the cation is difficult since rare-earth cations do not absorb in the visible or even in the UV and light absorption is a prerequisite for the emission. On the other hand, the presence of water and other ligands containing O−H groups coordinating the rare-earth cation thwarts the emission by providing an efficient radiationless deactivation pathway consisting in the vibration of the O−H group in resonance with the decay of the excited atomic electronic state. Both problems can be overcome by complexation of the rare-earth cation. Formation of a suitable rare-earth complex prevents the quenching of water and at the same time it

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

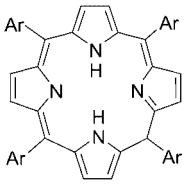
introduces new ligand-to-metal transition bands in the visible that allows easy excitation of the rare-earth cation. Encapsulation of these luminescent complexes within zeolites can serve to obtain a highly luminescent solid in which site isolation and compartmentalisation provided by the zeolite framework reduces the self-quenching and emission reabsorption that occurs in pure crystals of the complex. Photoluminescent Eu^{3+},[177] Nd^{3+} [178] and Tb^{3+} [179] complexes with trifluoroacetylacetophenone, bis(perfluoromethanesulfonyl)aminate or tetrarylporphyrinate have been prepared by ship-in-a-bottle synthesis within a series of zeolites.



4,4,4-trifluoro-1-phenyl-butane-1,3-dione



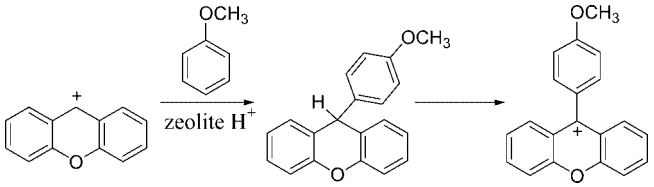
bis(trifluoromethyl-sulfon)amidate



tetraarylporphyrin

9-(4-Methoxyphenyl)xanthylium has also been prepared by a ship-in-a-bottle synthesis inside the cavities of zeolites Y and Beta by electrophilic attack of preformed xanthylium cation[180] on electron-rich anisole (Scheme 13).[181] The resulting 9-arylxanthylium remains entrapped inside the zeolite supercages, molecular modelling indicating that the conformational rotation of the anisyl substituent over the xanthylium cores is impeded by the encapsulation (Figure 7). An interesting consequence of the conformational freezing in 9-(4-methoxyphenyl)xanthylium@HY is the observation of fluorescence. In solution these dyes do not emit at room temperature due to the efficient radiationless deactivation mechanism consisting in the flipping of the electron-rich anisyl group around the electron-poor xanthylium moiety, the observation of room-temperature emission for 9-(4-methoxyphenyl)xanthylium@HY is taken as an experimental confirmation of the molecular model of the 9-anisylxanthylium encapsulated within zeolite Y supercages. In a certain sense, encapsulation has the same effect as decreasing the temperature, both methodologies diminishing the conformational mobility. Photoluminescence from encapsulated 9-(4-anisyl)xanthylium is quenched by nucleophiles and this quenching can be the basis for the development of sensing systems.

Spiropyrans with a chromene substructure are typical photochromic compounds in solution.[182] Upon illumination of the colourless spiro form, ring opening with formation of the merocyanine isomer leads to the development of colour, depending on the actual substitution of the spiropyran (Scheme 14). Upon standing in the dark, the thermodynamically unstable open merocyanine isomer undergoes



Scheme 13

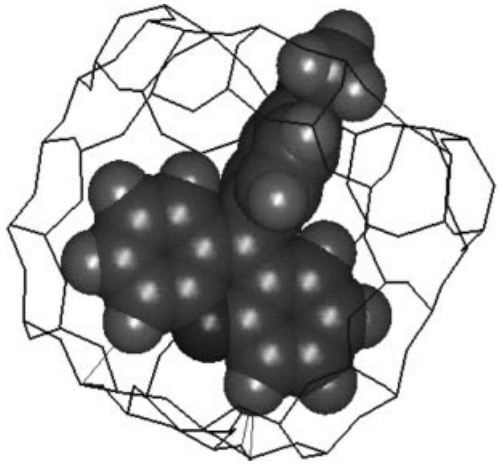


Figure 7. Molecular model of the 9-(4-methoxyphenyl)xanthylium cation encapsulated within an *all-silica* zeolite Y supercage (taken from ref.[181]; reprinted with permission; © 1996 American Chemical Society)

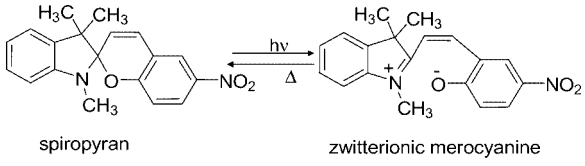
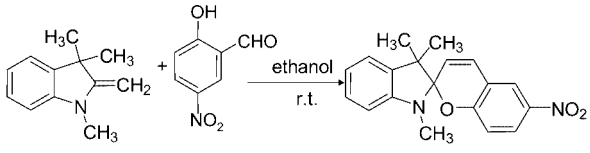
thermal ring-closure back to the spiropyran form (Scheme 14).



Scheme 14

For some applications as photochromic pigments it would be of interest to support spiropyrans on a solid. The molecular size and the conformational rigidity of the spiro form precludes adsorption of these chromotropic compounds inside the cavities of faujasite, and a ship-in-a-bottle synthesis is required. This has been accomplished by Garcia et al. by treating 1,3,3-trimethylindoline with 4-nitrosalicylaldehyde in the presence of zeolite NaY (Scheme 15).[183] In contrast, spiropyran can be adsorbed on mesoporous MCM-41[184] without requiring any synthesis.



Scheme 15

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

However, although in situ spectroscopic characterisation and product studies have demonstrated the formation of encapsulated spiropyran, it appears that the reversibility of the ring opening and closure is strongly modified by the polar environment of the zeolite supercage and/or the presence of weak acid sites as compared to ethanol solution. As a consequence, in a few irradiation/dark cycles the zeolite-containing spiropyran becomes strongly coloured and this colour does not disappear upon standing in the dark. These facts have been interpreted as indicating that in the zeolite the open merocyanine form tends to become stabilized, protonated and (*Z*)/(*E*)-isomerized, in contrast to the rapid and selective cyclisation observed in solution (Scheme 14).

Azo dyes such as methyl orange adsorbed in mesoporous Y zeolites have been prepared by coupling of *N*,*N*-dimethylaniline with diazonium cations.[185] Apparently, the dimensions of the transition states are too large to fit inside the supercages of regular dimensions and as result the azo dyes are not formed in the cages, but in the mesopores formed by defects in the crystal structure of the zeolite. Zeolite Y can be specially treated with citric acid and similar strongly complexing organic hydroxy acids to promote the formation of mesopores by damaging partially the crystal structure. The resulting azo dye incorporated inside the zeolite can act as a pigment and fluorescent solid.

6. Ship-in-a-Bottle Systems in Molecular Switches

As mentioned in the Introduction, one of the novel potential applications of zeolite-encapsulated guests is as functional materials in nanotechnology. One of the current strategies in nanotechnology is the "*bottom-up*" approach in which a molecule comprising several subunits is designed on purpose to produce a given effect upon external stimulus. These functional molecules are frequently termed as molecular devices since they perform certain actions at the molecular level that are characteristic of common mechanical devices. One type of such molecular devices are the so-called molecular machines in which one unit of the molecule is able to perform a cyclic movement emulating, at the simplest level, a machine.[53,186,187] While many of these molecular machines have been synthesised and the proof of principle at the molecular level has been sufficiently demonstrated, one general problem in this area is how to organize and assemble the individual molecular machines so that a coherent and co-operative response can be obtained from the assembly. In this regard, zeolites may provide a compartmentalized and organized space in which the molecular machines can be entrapped and held in place on the surface of a given support.

A preliminary step towards the direction of assembling molecular machines is their synthesis inside the zeolite micropores. One of the most common components in molecular machinery is the so-called "blue box", which is a bipyridinium macroring that acts as an electron-poor moiety forming charge-transfer complexes with electron-rich subunits in rotaxanes and catenanes.[188] Figure 8 shows a model of this blue-box encapsulated within zeolites.

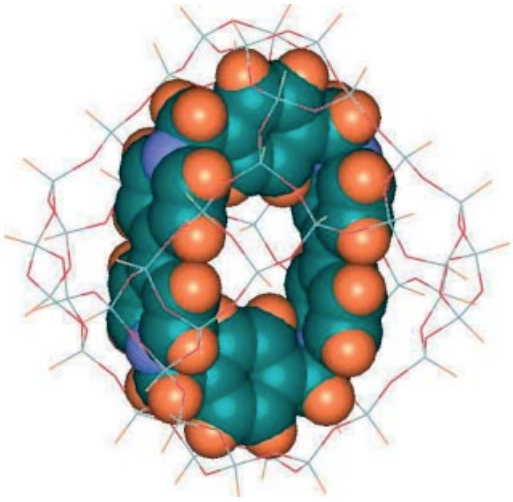


Figure 8. Molecular modelling of the bis(bipyridinium)cyclophane macrocycle inside the zeolite Y supercages

Besides spectroscopic characterisation, formation of the bipyridinium macrocycle was confirmed by dissolving the zeolite with HF and recovering the macrocycle from the solution.[188] The key factor in the success of the ship-in-a-bottle synthesis is the "*templating*" effect of the zeolite cavity approaching the distant pyridine N atoms in the open intermediate (Figure 9). The shape of the cage and the position of the positive charges in the same cage are responsible for the larger yield for cyclophane macrocycle formation inside zeolite Y than in solution, where the yield of cyclisation is only about 3%.

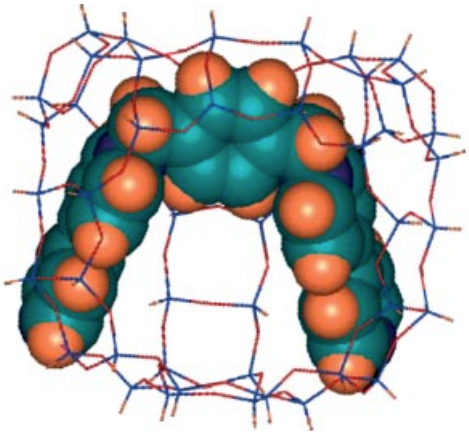

Figure 9. Molecular model of the open dicationic precursor of the blue box encapsulated within the supercage of zeolite Y; note the distance between the terminal N atoms (taken from ref.[188a]; reprinted with permission; © 2002 American Chemical Society)

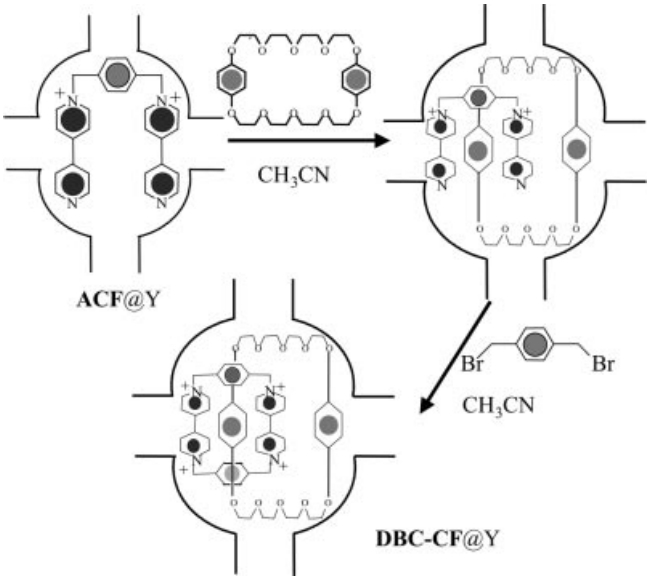
A further development has been the ship-in-a-bottle synthesis of a [2]catenane comprising the *blue box* interlocked with a hydroquinolyl polyether macrocycle. The ship-in-a-bottle synthesis parallels the route followed in solution for

this [2]catenane, initiating the procedure by ion-exchanging the precursor in the zeolite (Scheme 16).



Scheme 16

Upon photochemical excitation at the charge-transfer band of the [2]catenane an electron transfer and a corresponding charge separation occur (Figure 10). The most important effect of the encapsulation of the catenane inside the zeolite has been the observation of a dramatic enhancement of the lifetime of the viologen radical cation. In solution the geminate radical ion pair generated instantaneously upon excitation of the charge-transfer complex lives in the picosecond time regime and this short lifetime makes the operation of any co-conformational[189] and atomic movement that could occur in the state of charge separation generated as a consequence of the photoinduced electron transfer impossible. Co-conformational changes would occur in the microsecond or longer timescale. In this regard, the above results have demonstrated that encapsulation of these molecular switches inside the zeolite would increase the lifetime of the radical cation sufficiently to allow movements of the interlocked rings, but the actual occurrence of these co-conformational changes is yet to be demonstrated.

7. Ship-in-a-Bottle Synthesis of Conducting Polymers

Conducting organic polymers such as polyacetylenes, polyanilines and polypyrrols have promising applications in the field of charge storage, as antistatic coatings and in electronics. A general problem associated with conducting polymers is their degradability upon exposure of the charged polymer to the atmosphere. A way to circumvent this decomposition is to encapsulate the polymers within the pores of zeolites that will protect them from the attack of external reagents. The field of encapsulated polymers has been subjected to periodic reviews.[190−193] Among the most recent contributions are the preparation of parent polyacetylene by polymerisation of acetylene in Ni-exchanged zeolites, essentially filling the void volume.[194,195] Electrochemical

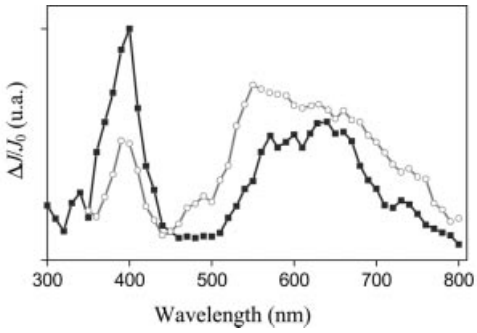


Figure 10. Diffuse reflectance UV/Vis transient spectra recorded for the catenane (circles) and for the bipyridinium cyclophane (squares) encapsulated within the supercages of zeolite Y (data taken from ref.[188b]; reproduced by permission of The Royal Society of Chemistry)

measurements indicate that the polymer can be charged, but the polymer becomes degraded in the first use.[196] The spontaneous formation of polarons has also been reported.[197] Spange has recently reviewed the cationic polymerisation of vinyl ether, furan and other polymers within MCM-41.[198−200]

C. Concluding Remarks

Since the initial, seminal work of Herron and Schulz-Ekloff on the ship-in-a-bottle synthesis of metal complexes, a considerable number of examples of this and other types of guests have been reported. These reports have continued to explore the application of zeolites containing encapsulated guests as catalysts and zeozymes, but other fields like photocatalysis, electrocatalysis, sensors and development of functional materials have also benefited from ship-in-a-bottle methodologies. In the near future, and given the current impetus in nanotechnology, it can be anticipated that the systems based on the ship-in-a-bottle synthesis will attract renewed interest in order to develop active components for photonics (laser cavities, harmonic generators, light switches, wave guides, etc.) and as intelligent devices such as activable membranes, chromotropic layers. Also, the ship-in-a-bottle synthesis could find applications in molecular machines as a way to assemble and modify the properties of supramolecular systems.

The special properties of zeolites as hosts in terms of site isolation, space compartmentalisation, polarity and the presence of acidic and other sites are very interesting and can contribute to the operation and design of these hybrid solids. This field will also benefit from the continuous advances in the characterisation techniques, some of which have become routine, allowing a safer and firmer determination of the encapsulated material as well as from the preparation of zeolite films on substrates.[201,202]

Synthesis and Magnetic Properties of Single-Crystals of $MnFe_2O_4$ Nanorods

Jun Wang,[a] Qianwang Chen,*[a] Binyang Hou,[a] and Zhenmeng Peng[a]

Keywords: Iron / Magnetic properties / Nanorods / Nanowires / X-ray diffraction

Single-crystals of $MnFe_2O_4$ nanorods with an average diameter of 20 nm and length of 250 nm were synthesized by a hydrothermal process at 180 °C after 12 h. High-resolution transmission electron microscopy (HRTEM) and electron diffraction (ED) analysis revealed that the nanorods grow along the [110] axis, which is one of the easy magnetization axes of the material $MnFe_2O_4$. It was found that the nanorods exhibited a saturation magnetization (*Ms*) of 68.02 emu/g, which is much higher than that of quasi-spherical particles of $MnFe_2O_4$, prepared by other approaches such as solid-state reaction methods (*Ms* = 36.7 emu/g), and coprecipitation processes followed by annealing in vacuo at 400 °C (*Ms* = 24.4 emu/g). The oriented growth along the easy magnetization axis of $MnFe_2O_4$ was suggested to be responsible for the improvement of magnetic properties of $MnFe_2O_4$ nanorods.

Introduction

In the nanoscale regime, magnetic nanoparticles have been a subject of increasing interest from both fundamental and technological points of view.[1] It has been shown that the shape of magnetic particles strongly influences their magnetic properties.[2,3] Nanorods and nanowires not only exhibit unique magnetic properties but are also key components for ultrahigh-density magnetic recording media.[4] Many efforts have been made to synthesize nanorods and nanowires of magnetic materials.[5,6] For example, Chaudret et al.[7,8] prepared magnetic nanorods of cobalt by thermal decomposition. Iron nanorods were synthesized through controlled coalescence of spherical iron nanoparticles protected by trioctylphosphane oxide (TOPO).[9] Acicular iron particles were prepared by reduction of ferrous ions with sodium borohydride in tubular lecithin.[10]

The substance $MnFe_2O_4$, one of the most important magnetic materials, has been widely used in electronic applications[11,12] and contrast-enhancement agents in magnetic resonance imaging (MRI) technology,[13−16] in addition to recording media. Several techniques have been developed to synthesize $MnFe_2O_4$ nanoparticles, such as solid-phase reactions,[17] mechanical ball-milling,[18,19] thermal decomposition,[20] and coprecipitation methods.[13,14,21,22] However, the synthesis of $MnFe_2O_4$ nanorods has seldom been reported. The coprecipitation process can provide a quick and easy way to prepare $MnFe_2O_4$ nanoparticles; however, it usually yields nanoparticles with large size-distributions and less well-defined crystals. The rapid formation process is also very disadvantageous to synthesize single-crystal nanorods or nanowires as the product is formed far from equilibrium conditions. The hydrothermal process is one of the more successful ways to grow crystals of many different materials such as quartz and malachite. This technique has also been used to grow dislocation-free single-crystals; grains formed in this process could have a better crystallinity than those from other processes.

Our aim was to develop a low-temperature hydrothermal process for the preparation of $MnFe_2O_4$ nanorods that might find applications in perpendicular recording media.

Results and Discussion

X-ray diffraction (XRD) patterns for the samples obtained at different reaction conditions, which are compatible with cubic $MnFe_2O_4$ crystals (JCPDS card No. 73−1964), are shown in Figures 1 and 2. They revealed that the samples were pure $MnFe_2O_4$ crystals without impurity phases. From Figure 1, one can see that the reflection peaks become sharper and stronger on increasing the hydrothermal temperature and the time period, indicating that crystallinity tends to improve. For example, the crystallinity of the sample prepared at 180 °C (see A in Figure 1) was better after 6 h than after 3 h (see B in Figure 1). The dimensions and shapes of the particles were found to depend strongly on reaction conditions such as temperature, time, and the pH of the reaction system. Uniform $MnFe_2O_4$ nanorods were synthesized at 180 °C after 12 h. Lower temperatures and shorter time periods were favorable for the formation of quasi-spherical particles. For example, the products were dominated by quasi-spherical particles when the reaction was carried out at 140 °C (see A in Figure 3); when the

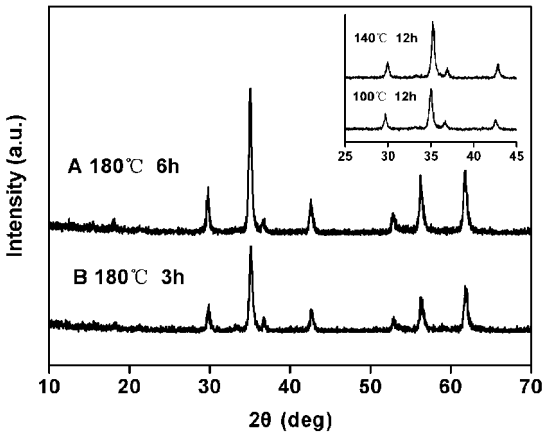

Figure 1. The XRD patterns of the samples prepared at 180 °C after 6 h (A) and 3 h (B); the inset shows XRD patterns of the samples formed at 140 °C and 100 °C after 12 h

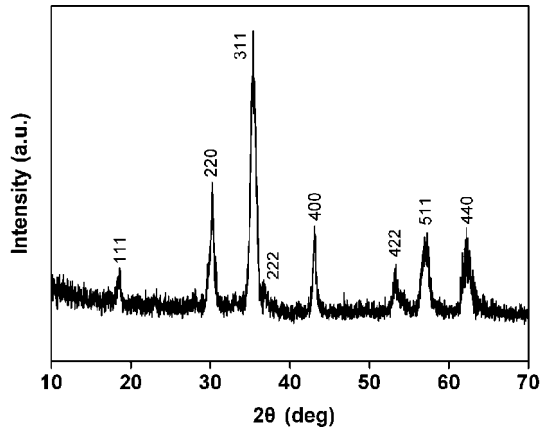

Figure 2. The XRD pattern of the sample prepared at 180 °C after 12 h

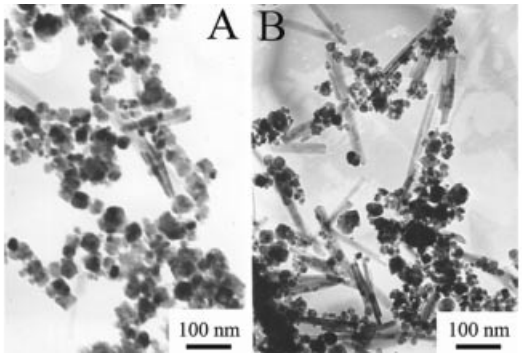

Figure 3. TEM images of the samples obtained at 140 °C after 12 h (A) and at 180 °C after 6 h (B)

temperature was increased to 180 °C, nanorods formed as the major product of the reaction (see A in Figure 4). At 180 °C, as the reaction time was reduced to 6 h, the product was also dominated by quasi-spherical particles (see B in Figure 3). It should be noted that the initial pH of the system had to be higher than 11, otherwise quasi-spherical particles were obtained.

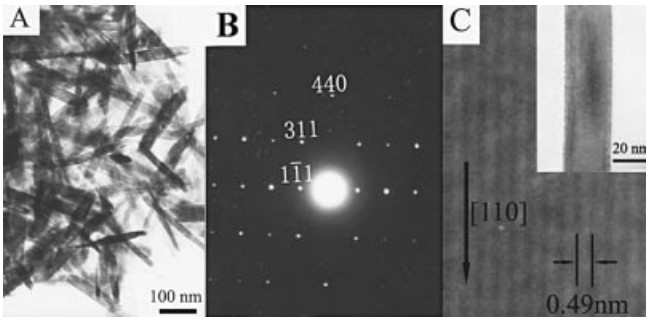

Figure 4. Representative TEM image of $MnFe_2O_4$ nanorods (A), ED pattern of a single-crystals of a nanorod (B) and HRTEM image of the nanorod in the inset (C); the inset in C is a magnified image of one individual $MnFe_2O_4$ nanorod shown in A; the sample was obtained after 12 h at 180 °C.

As shown in Figure 4 (see A), uniform nanorods with an average length of 250 nm and a width of 20 nm were produced at 180 °C after 12 h. From the XRD pattern of the sample shown in Figure 2, we found that the ratio between the intensities of the (220) and (311) diffraction peaks was higher than the conventional value (0.5 versus 0.28), indicating the oriented growth of the nanoparticles. Figure 4 (see B) shows the electron diffraction (ED) patterns obtained from one typical nanorod. The diffraction spots suggest that the nanorod was a single crystal. The high-resolution transmission electron microscopy (HRTEM) image further supports the existence of these $MnFe_2O_4$ nanorods as single crystals (see C in Figure 4). The lattice fringes (ca. 0.49 nm) observed in this image agree well with the separation between the [111] lattice planes. Combined with the result from ED, it was confirmed that the nanorods grew along the [110] plane, which is one of the easy magnetization axes of the $MnFe_2O_4$ nanorods.[23,24]

Indeed, single-crystals of nanorods and nanowires are formed because the relative growth rates of the various faces favor oriented growth along one crystal direction. The experimental conditions such as temperature, time, and pH influence the relative growth rates and can then be used to control the morphology and dimensions of the nanoparticles.

The magnetic properties of the Mn-ferrite samples obtained at 180 °C (see A in Figure 5) and 140 °C (see B in Figure 5) after 12 h were evaluated by a vibrating sample magnetometer. The hysteresis loops of the samples measured at room temperature (Figure 5) show ferromagnetic behavior with a saturation magnetization of 68.02 emu/g, which is slightly smaller than the corresponding bulk material (80 emu/g).[13,25] The reason may mainly depend on the nature of ultrafine particles: surface disorder, cation distribution, and defects etc. For example, a surface-disordered layer could serve as a nonmagnetic layer and decrease saturation magnetization. However, the saturation magnetization of the nanorods is much higher than that for $MnFe_2O_4$ quasi-spherical nanoparticles synthesized by other methods, such as solid-state reactions at 1200 °C (Ms = 36.7 emu/g),[26] coprecipitation followed by annealing in vacuo at 400 °C (Ms = 24.4 emu/g),[25] and is

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

also higher than that of our sample (see B in Figure 5) that was hydrothermally prepared at 140 °C after 12 h (*Ms* = 55.8 emu/g), in which quasi-spherical particles are the major products. It is, therefore, reasonable to suggest that the growth along the easy magnetic axis could improve the magnetic properties of the nanorods. During the measurement process, the $MnFe_2O_4$ nanorods tend to align along the magnetic line of force, which makes the easy magnetization axis correspond to the magnetic line of force. Magnetization makes all the net magnetic moments of the $MnFe_2O_4$ nanorods orientate themselves along the magnetic line of force. As a result, the saturation magnetization can be improved. It is, therefore, reasonable to suggest that in addition to the nonmagnetic layer on the surface of the nanoparticles, the morphology could also be an important factor determining the magnetic properties; growth of nanorods along the easy magnetization axis is a way to improve the magnetic properties of nanosized materials.

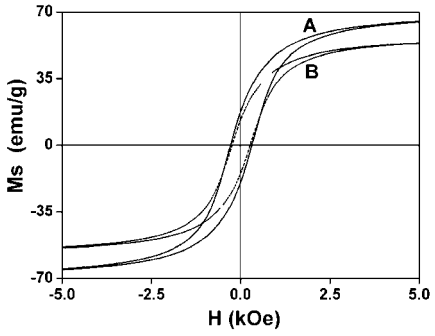

Figure 5. Magnetic hysteresis curves of $MnFe_2O_4$ samples hydrothermally obtained at 180 °C (A) and at 140 °C (B) after 12 h; the measurements were carried out at room temperature

Conclusions

Single crystals of $MnFe_2O_4$ nanorods were synthesized by a hydrothermal process at 180 °C after 12 h. The nanorods (average diameter of 20 nm and length of 250 nm) were found to grow along the easy magnetization axis [110] of the $MnFe_2O_4$ nanoparticles. The saturation magnetization of the nanorods (*Ms* = 68 emu/g) increases significantly to that of quasi-spherical particles prepared by other methods, which indicates that the controlled growth of nanorods along the easy magnetization axis of magnetic materials is a way to improve their magnetic properties. This process might be of general interest for the synthesis of nanorods and other ferrite materials in order to improve their magnetic properties.

Experimental Section

General: The chemical reagents used in this work were iron(III) chloride ($FeCl_3 \cdot 6\,H_2O$), manganese(II) chloride ($MnCl_2 \cdot 4H_2O$), and sodium hydroxide (NaOH). All chemicals were of analytical grade. The reaction is described by Equation (1):

$$MnCl_2 + 2\,FeCl_3 + 8\,NaOH \rightleftarrows MnFe_2O_4 + 4\,H_2O + 8\,NaCl \quad (1)$$

$MnCl_2 \cdot 4H_2O$ and $FeCl_3 \cdot 6\,H_2O$ were dissolved in water at concentrations of 0.05 M and 0.1 M, respectively, ($[Fe^{3+}]/[Mn^{2+}]$ = 2:1. 35 mL). The metal-ion solution mixture was put into a Teflon™-lined stainless autoclave. Sodium hydroxide (0.880 g) dissolved with 5.0 mL distilled water was slowly added dropwise into the Teflon-lined stainless autoclave. A brown precipitate formed immediately. The autoclave was placed into an oven and kept at 180 °C for 12 hours, then allowed to cool to room temperature. The product was washed several times with distilled water and absolute ethanol. The products were finally dried in oven at 60 °C for 12 hours.

X-ray diffraction was performed on a Rigaku X-ray diffractometer with high-strength Cu-K_α radiation. Transmission electron microscope (TEM) images were taken with a Hitachi model H-800 with an accelerating voltage of 200 kV. High-resolution transmission electron microscopy (HRTEM) images were recorded on JEOL-2010 with an accelerating voltage of 200 kV. Their magnetic properties were evaluated on a BHV-55 vibrating sample magnetometer (VSM).

Towards 3-D Spherical Self-Assembly by Ternary Surfactant Combinations: The Case of Magnetite Nanoparticles

Yanglong Hou,[a,b] Song Gao,*[a] Toshiaki Ohta,[b] and Hiroshi Kondoh[b]

Keywords: Self-assembly / Magnetic properties / Magnetite / Nanoparticles / Super paramagnet

Here we report on a facile one-step route to assemble magnetite nanoparticles into 3D-spherical aggregates with an average diameter of 100 nm. The self-assembly approach was achieved in a solvothermal reduction reaction with a ternary surfactant combination comprising trioctylphosphane oxide (TOPO), polyvinylpyrrolidone (PVP), and oleic acid as the "mortar". Transmission electron microscopy (TEM) investigations indicated that the spherical aggregates were composed of magnetite nanoparticles. The mean size of the individual magnetite particles was estimated to be 6 nm, calculated by the Scherrer equation with the powder X-ray diffraction (XRD) data. The formation mechanism of magnetite spheres can be attributed to the cooperation of the ternary surfactants described above. Magnetic measurements performed by a Quantum Design SQUID magnetometer on the nanoparticles exhibited superparamagnetic behavior above liquid-nitrogen temperatures. Fourier-transform infrared spectroscopy (FTIR), inductively coupled plasma-atomic emission spectrometer (ICP-AE) and X-ray photoelectron spectroscopy (XPS) were also used in the characterization of the assembled magnetite spheres.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

In recent years, the assembled nanostructures have attracted much interest because of their potential for application in magnetic recording, molecular recognition, biological labeling, and electronic devices.[1−10] The development of simple routes for the fabrication of ordered nanostructures is indispensable for producing new nanodevices. A number of techniques have been exploited in assembly approaches to nanoparticles, such as aerosol-assisted, thiol-modified, DNA-directed, electrostatic-interaction-assisted, and recognition-mediated synthesis.[11−14] The construction of organized metal nanoparticles has recently been a major issue.[15−18] An efficient approach to build self-assembled structures is to harness the spontaneous control of noncovalent interactions between the building blocks, including van der Waals forces,[19,20] π−π interactions,[21] electrostatic forces,[22,23] and hydrogen bonding.[24−26] These molecular interactions are usually constructed through polymer functionalization of nanoscale materials, after which such polymer-functionalized nanoparticles are used as building blocks to fabricate an assembled structure system. For example, Rotello and co-workers reported that monolayer polymer-protected gold nanoparticles self-assembled into spherical aggregates through hydrogen-bonding interactions.[26] The self-assembly of 2-caroxyterthiophene (TTP-COOH) coated Fe_3O_4 aggregates was also achieved by π−π interactions.[21] However, the preparation of ordered nanostructures for applications has been more challenging.

Herein, we report an intriguing finding of self-assembly magnetic particles into spherical aggregates. Our strategy is to use a ternary surfactant combination such as trioctylphosphane oxide (TOPO), polyvinylpyrrolidone (PVP), and oleic acid for the assembly of magnetite nanoparticles. In the presence of these surfactants, the spherical aggregates of magnetite were obtained by a solvothermal reduction of iron(III) acetylacetonate with hydrazine in ethylene glycol. Note that the spherical aggregates of magnetite nanoparticles formed spontaneously without any external force.

Results and Discussion

Powder XRD and TEM measurements were employed to study the structure and the morphology of the obtained products. The XRD pattern of the sample (Figure 1) reveals the characteristic diffraction peaks of magnetite (JCPDS file, 19−629). The broad nature of the peaks results from nanosized magnetite aggregates. The average size of the individual magnetite particles is about 6 nm, calculated by the

Scherrer equation.[27] In addition, far-IR and XPS spectra were applied to confirm the formation of magnetite rather than hematite. The far-FTIR spectrum of the sample is in good agreement with that of commercially available magnetite powder (Alfa catalog No 44120, see Supporting Information Figure S1), suggesting the formation of magnetite. Furthermore, as shown in the XPS spectra (Figure S2, see Supporting Information), the binding energy of Fe $2p_{3/2}$ is 711.4 eV, which is very close to that of magnetite. TEM images (Figure 2) show that the mean size of the spherical aggregates is about 100 nm. The selected-area electron diffraction (SAED) pattern of the sample indicates the crystalline characteristics of magnetite aggregates (see c in Figure 2). The formation process of assembled magnetite aggregates is illustrated in Scheme 1. It is well-known that the dipole−dipole interaction between magnetic nanoparticles strongly affects their shape and properties. However, this magnetic interaction scarcely contributes to the formation of spherical nanostructures of magnetite nanoparticles; similar behavior has also been observed in the TTP-COOH-coated Fe_3O_4 nanoparticle system.[21] In the present system, the key factor that directs the assembly of spheres is considered to be the combination of ternary surfactants on the surface of the magnetite nanoparticles, although the interaction between magnetite nanoparticles and surfactants is not fully understood. When only PVP was used in the reaction, iron nanoparticles (ca. 60 nm) without spherical aggregation were obtained,[28] whereas the similar systems with PVP and oleic acid produced magnetite nanoparticles where the size could be controlled.[29,30] It was supposed that the process to produce assembled spherical nanostructures was controlled by the diffusion growth,[31] that is, a number of nanoparticles aggregated around a single nanoparticle automatically forming spherical aggregates, which have the lowest surface energy. As the reaction progresses, magnetite nanoparticles coated with surfactants were initially produced. This is followed by the assembly of the individual surfactant-coated magnetite nanoparticles into spherical structures with the help of intermolecular interactions, which result from the cooperation of TOPO, oleic acid, and PVP.[31,32] The total content of the surfactants was 54.4 wt-%, estimated by ICP measurements. As shown in the FTIR pattern (Figure S3, see Supporting Information), the characteristic peak of PVP in the sample ($\tilde{\nu}$ = 3398 cm^{-1}) has a small blue-shift, relative to that of neat

PVP, while the peak intensities of TOPO and oleic acid are obviously weakened, which is most likely ascribed to the interaction of the surfactants with the nanoparticles. This result also confirms the above description on the formation process of nanoparticle aggregates. Further studies are required to characterize the structural features and the interaction between the nanoparticles and the surfactants in the assembled magnetite aggregates.

The magnetization curves were measured as a function of temperature with an applied field of 100 Oe between 5 and 300 K using field-cooling (FC) and zero-field-cooling (ZFC) procedures. When the sample is cooled to the zero magnetic field temperature, the total magnetization of the particles will be zero since the magnetic moments of individual particles are randomly oriented. An external magnetic field energetically favors the reorientation of the moments of the individual particles along the applied field at low temperatures. As the temperature increases, more and more particles reorient their magnetization with the external field and the total magnetization increases, and reaches the maximum at the blocking temperature (T_B = 70 K), shown in Figure 3. At this temperature, the thermal energy becomes similar to the energy gained by aligning the particle magnetic vectors in the weak field; the transition from ferromagnetic to superparamagnetic behavior is observed. At temperatures higher than T_B, one can see that the magnetization decreases and follows a Curie−Weiss law corresponding to the superparamagnetic behavior, also suggesting the absence of strong dipole−dipole interactions. Such behavior has been reported for several particle systems, in agreement with theoretical predictions.[33] In the case of field cooling, magnetization monotonously increases as the temperature decreases. Below T_B, the field-cooling curve splits from the zero-field-cooling curve.

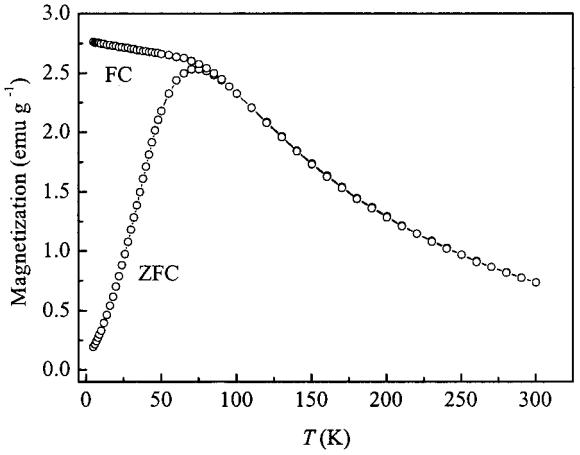

Figure 3. ZFC and FC curves of self-assembled magnetite spherical aggregates measured with a field of 100 Oe

The divergence of magnetization below T_B in ZFC-FC procedures is attributed to the existence of the magnetic anisotropy barriers. The derivative of the magnetization decay plot, $f(T)$ represents the distribution of anisotropy energy barriers.[34]

$$f(T) = \frac{d}{dT}\left(\frac{M_{ZFC}}{M_{FC}}\right) \quad (1)$$

This is represented by Equation (1) where M_{ZFC} denotes only the contribution of nanoparticles, for which the energy barriers are overcome by the thermal energy at the measurement; while M_{FC} represents the contribution of all the nanoparticles. The calculated magnetic anisotropy distribution of 6 nm spherical Fe_3O_4 aggregates is shown in Figure 4 and fitted by the Gauss function. The center and width values are 33.0 K and 40.7 K, respectively. The narrow distribution indicates that the nanoparticles have a uniform size. For superparamagnetic particles, $T_B = KV/25k$, where T_B is the blocking temperature, K denotes the magnetic anisotropy constant, k the Boltzmann's constant, and V the volume of the particles; below T_B the free movement ($\mu_p = Ms \cdot V$) is blocked by the anisotropy, where Ms represents the saturation magnetization. Above T_B, kT activates the magnetic moment so that the system appears to have the characteristics of a superparamagnet. The anisotropy constant can be estimated by referring to the experimental data of the blocking temperature. In the present system, the anisotropy constant of the assembled magnetite nanoparticle with a size of 6 nm is 2.14×10^6 erg·cm^{-3}.

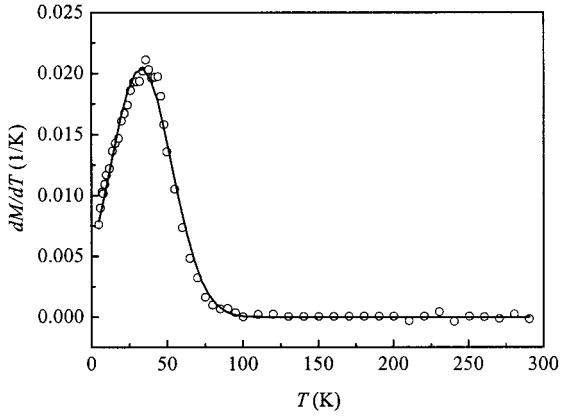

Figure 4. The energy barrier distribution of magnetic anisotropy in the self-assembled magnetite aggregates

A representative hysteresis loop of assembled Fe_3O_4 spheres is shown in Figure 5. At 300 K, the saturation magnetization of the assembled Fe_3O_4 particles is 83 emu/g at 30 kOe, while that of the commercial magnetic liquid is 123 emu/g(Fe).[35] The decrease of the saturation magnetization is most likely attributed to the existence of surfactants on the surface of the Fe_3O_4 nanoparticles. Some studies suggested that the noncollinear spin structure, which originated from pinning the surface spins and coated surfactants to the iron oxide interface, results in the reduction of the magnetic moment in such nanoparticles.[36] The coercive force of self-assembled spheres is 292 Oe at 5 K (as shown

by the inset in Figure 5), while the coercivity at room temperature is almost negligible, which is a characteristic of superparamagnetic materials.[37,38]

Conclusion

In this work, a facile and effective route has been developed to build 3D, spherical aggregates of nanoparticles with ternary surfactants as the "mortar". The results reveal that the self-assembly strategy is an efficient way to create novel nanostructured systems. The magnetic behavior of spherical magnetite aggregates shows superparamagnetic characteristics above liquid-nitrogen temperatures. The magnetic anisotropy distribution of the spherical magnetite aggregates has also been deduced from magnetic data.

Experimental Section

General: The synthesis and assembly of magnetite spheres was performed by a one-step procedure, in which $Fe(acac)_3$ (acac = acetylacetonate) was partially reduced by a mixture of hydrazine and ethylene glycol and spontaneously assembled into spherical nanostructures in the presence of a combination of surfactants including TOPO, PVP, and oleic acid. In a typical procedure, a solution of 70 mL was first prepared by dissolving $Fe(acac)_3$ (0.2 g), TOPO (99 %, 0.2 g), PVP (M_r = 55,000, 0.2 g), and oleic acid (0.1 mL) in ethylene glycol, after which 10 % $N_2H_4{\cdot}H_2O$ (2 mL) was added. The mixture was transferred into an autoclave and heated to 180 °C for 12 h and then allowed to cool to room temperature. The black products deposited onto the bottom of the autoclave indicated the formation of magnetite. The final product was collected and washed with methanol/$CHCl_3$ (1:1) and distilled water to remove possible excess surfactants, $N_2H_4{\cdot}H_2O$, and by-products. The black product was then dried in vacuo at 60 °C for 12 h. Powder XRD patterns of the sample were obtained on a Rigaku Dmax/2000 diffractometer with Cu-K_α radiation. TEM images to determine the size and morphology of the product were collected with a HITACHI H-800 electron microscope (200 kV). IR spectra (KBr pellets) were recorded on a NICOLET Magna-IR 750 spectrophotometer. X-ray photoelectron spectroscopy (XPS) data were collected on a ESCA-lab5. The content of magnetite in the product was determined on an inductively coupled plasma-atomic emission spectrometer (ICP). Magnetic studies were carried out by using a Quantum Design SQUID magnetometer.

(μ-Methylene)bis(methylzirconocene): Preparation, Molecular Structure, and Thermal Disproportionation

Marijke Hogenbirk,[a,b] Gerrit Schat,[a] Otto S. Akkerman,[a] Friedrich Bickelhaupt,*[a] Jörg Schottek,[c] Markus Albrecht,[c] Roland Fröhlich,[c][‡] Gerald Kehr,[c] Gerhard Erker,*[c] Huub Kooijman,[d] and Anthony L. Spek[d][‡]

Keywords: Magnesium / Metallocenes / Zirconium / Configuration at carbon

The title compound $[(\mu\text{-}CH_2)(ZrCp_2Me)_2]$ (**4**) was prepared by the reaction of $[Cp_2Zr(Cl)Me]$ (**6**) with $CH_2(MgBr)_2$ (**5**) or $(CH_2Mg)_n$ (**7**). It had been expected that the carbon atom bridging the two zirconium atoms of **4** might be a candidate for a planar tetracoordinate carbon atom, but the X-ray crystal structures of two different modifications (crystals 1 and 2) showed it to be non-planar; however, the widened Zr–C–Zr angle of 132.7(1) and 134.0(3)°, respectively, and an unsymmetrical coordination of the central μ-CH_2 group (average: Zr1–CH_2 2.225 Å, Zr2–CH_2 2.242 Å) indicates a tendency towards planarity. While **4** is relatively stable in THF solution, it disproportionates in toluene solution to give the 1,3-dizirconacyclobutane $(Cp_2ZrCH_2)_2$ (**8**) and $[Cp_2ZrMe_2]$ (**9**), especially in the presence of magnesium salts; a tentative mechanism is presented. Reaction of **4** with $B(C_6F_5)_3$ yielded the methyl-bridged cationic complex **17**, which, on treatment with trityl chloride, was transformed into the corresponding chloro complex **18**; the latter was characterized by an X-ray crystal structure determination. With THF and tetrahydrothiophene, **17** formed the unsymmetrical adducts **19a** and **19b**, respectively; NMR spectroscopic data revealed dynamic symmetrization due to methyl-group exchange at 280 and 213 K, respectively.

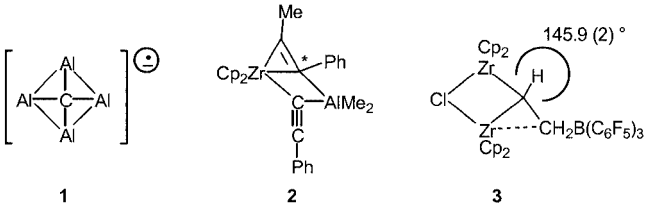
Introduction

Tetracoordinate carbon centers strongly prefer a tetrahedral geometry, as is common knowledge since the early work of van't Hoff and Le Bel.[1] Two strategies have been applied to stabilize the unfavorable planar geometry: one of them uses strain to force the carbon atom into planarity, the other stabilizes the planar carbon atom electronically by di- or polysubstitution with metal atoms.[2−5]

Thus, in the gas phase, the Al_4C^- ion (**1**; Scheme 1) has been shown by PES spectroscopy and by calculation to have a planar D_{4h} symmetry.[4] Erker et al. have been successful in preparing stable compounds involving a planar tetracoordinate carbon atom incorporated into a π- or an aromatic system such as **2**; the asterisk marks the planar carbon atom.[6] Another example of such a dimetallic compound is **3**. In this case the planarity around the carbon atom was not effected, but a widening of the Zr−CH−CH_2 angle approaching local C_{2v} symmetry, as indicated in Scheme 1, shows the incipient tendency of this carbon atom to become severely distorted as well.[7]



1 2 3

Scheme 1

It remains a challenge to try and prepare a stable planar tetracoordinate saturated carbon atom. In this context, we investigated the possibility that the methylene carbon atom in $[(\mu\text{-}CH_2)(Cp_2ZrMe)_2]$ (**4**) might be a candidate.

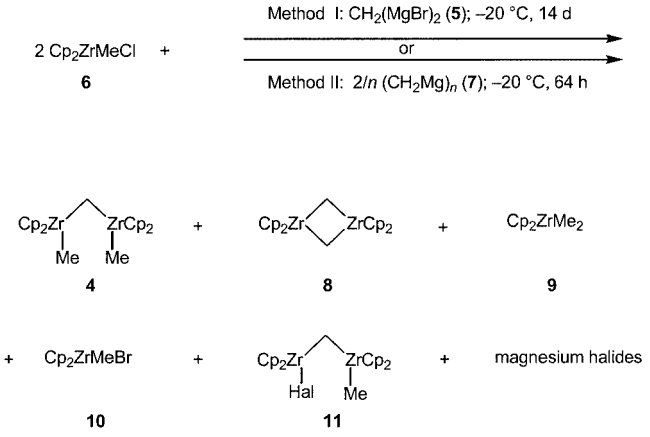
Results and Discussion

Synthesis of [(μ-CH_2)($Cp_2ZrMe)_2$] (4)

The methylene di-Grignard reagent $CH_2(MgBr)_2$ (**5**)[9−11] seemed to be a promising starting material; reaction of **5** with 2 equiv. of chloro(methyl)zirconocene (**6**)[12] is expected to yield the desired **4** (Method I, Scheme 2). Methylenemagnesium $(CH_2Mg)_n$ (**7**)[9] is potentially an alternative synthon for this purpose (Method II); originally, it was considered less attractive because it is obtained via **5**, but at a later stage **7** turned out to offer certain advantages (vide infra).



Scheme 2

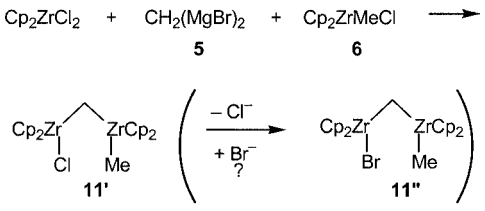
According to Method I, **5** (in benzene/diethyl ether) and **6** (in toluene) were treated at low temperatures and during longer periods. After removal of the solvents, the residue was extracted with pentane and subsequently with benzene. Table 1 shows the relative amounts of the products **4**, **8**, **9**, **10**, and **11** in the pentane and the benzene extract, respectively. The compounds were identified by ^1H NMR spectroscopy, the signals of **8**[12] and **9**[13] being in agreement with literature data, and those of **10** showing a great similarity to those of **6**. Furthermore, the structure of **4** (containing a small amount of impurity, presumably **11**) was established by X-ray crystal structure determination (vide infra).

Table 1. Formation of **4** and of by-products from **6**[a]

Reactant	Extract	**4**	**8**	**9**	**6/10**	**11**
5	pentane	16	8	37	37[b]	2
5	benzene	68	7	6	10[b]	9
7	pentane	14	14	14	53[c]	5
7	benzene	66	4	4	21[c]	5

[a] Relative amounts (%). [b] **10** only. [c] **6** + **10**.

We assume that **8** and **9** are formed by disproportionation of **4**; this reaction will be discussed later. Compound **10** is formed from **6** by halogen exchange with the bromide ion derived from **5**, while **11** probably results from the reaction of **5** with **6** and Cp_2ZrCl_2 (Scheme 3), present as an impurity in the starting material **6** (about 10%). The structural assignment of **11** as a minor side-product is only tentative and this holds, in particular, for the halogen involved. An argument for the halogen being chlorine (**11′**) might be derived from the observation (vide infra) that when the bromine-deficient **7**, instead of **5**, was treated with **6**, the chlorine atom in the latter was not fully replaced to give **10**, whereas **11** remained unchanged. Furthermore, the crystal structure analysis of **4** (vide infra) indicates the presence of (some) bromine as an impurity at this position (**11"**).



Scheme 3

From the composition of the extracts with benzene as compared to those with pentane, it is obvious that a certain degree of purification of **4** was accomplished by sequential extraction. Hydrolysis of the residues that were insoluble in both solvents, followed by titration (Mg^{2+} with EDTA and OH^- with HCl),[14] indicated that about 10% of the di-Grignard reagent **5** had not reacted. An exact determination of the yields is difficult and has not been attempted. However, from a preparative point of view, this route to **4** appears to be an attractive one, as was concluded from the results of the titration and, after evaporation of the solvent, from the visual observation that the pentane extract contained only a very small amount of material while the benzene extract, containing a substantial amount of material, consisted of nearly 70% of **4**.

The reaction of **5** with **6** was performed under a variety of conditions; a reaction temperature of −20 °C and a relatively long reaction time of 14 d appeared to provide the best results. The extraction with benzene had to be performed quickly and at 5 °C (around the melting point of benzene) because at room temperature the proportion of the side products **8** and **9** increased significantly. After the workup procedure (extraction with pentane and benzene), the extracts contained fewer magnesium salts than the original reaction mixture. This is presumably due to the low solubility of such salts in hydrocarbons, which is only slightly increased by the presence of diethyl ether; this diethyl ether is introduced with the solvent of **5** (vide supra) and successively depleted during the extraction. As disproportionation of **4** now occurred at a lower rate than before workup (**8** can be readily recognized by its red color), we speculated that magnesium halides might play a role in this disproportionation process.

To test this hypothesis, we investigated the formation of **4** from **6** and **7** (Method II), because in this case the amount of magnesium salts in the final product is strongly reduced. Unfortunately, it is not possible to obtain **7** completely bro-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mide-free.[9] The amount of residual salts depends on the intensity of extraction of $MgBr_2$ from **7** with THF, two to four extractions being a compromise between purity and yield of **7**.[9] In our case, titration after hydrolysis of **7** showed that the Mg^{2+}/OH^- ratio was 1:1.6 (instead of 1:2 as required for pure **7**), indicating a formal **7**/$MgBr_2$ ratio of 80:20 (in reality this product consists of a mixture of various oligomeric combinations of the two formal constituents).[9] Nevertheless, it is obvious that the amount of magnesium halides present after formation of **4** should be reduced considerably. Now, as expected, short periods at temperatures higher than −20 °C did not immediately lead to formation of side products; after about 10 min at 5 °C, the red color of **5** was not observed. In the product mixture, some starting material **6** was identified (^{1}H NMR spectroscopy). As **7** contained much less (magnesium) bromide than **5**, complete halogen exchange transforming **6** to **10** did not occur; instead, a mixture of both **6** and **10** was formed.

The absolute yield of **4** from **7** was determined by ^{1}H NMR spectroscopy with cyclopentane as internal standard and found to be 56% (in a ratio of 53:3 for the benzene and the pentane extract, respectively). According to ^{1}H NMR spectroscopy, **4** obtained by this procedure was converted into **8** and **9** much more slowly, confirming our assumption that magnesium halides promote the disproportionation.

Another attractive aspect of Method II is that the reaction with **7** is much faster than with **5** (64 h versus 14 d, see Scheme 2).

Structural Characterization of 4

After several attempts, yellow-orange crystals of **4**, suitable for an X-ray crystal-structure determination, were isolated from a product mixture obtained from Method II by dissolving the material in toluene/heptane (5:1) and repeated crystallizations at −80 °C. At room temperature, the crystals were quickly transferred into Lindemann glass capillaries in a glovebox under nitrogen and afterwards kept at −20 °C. The structure (**4**, crystal 1) is shown in Figure 1; selected bond lengths and angles are presented in Table 2.

A second single crystal of **4** was obtained from the reaction of **5** with **6** that was carried out in toluene (0 °C to room temperature). After workup and removal of the magnesium halides, pentane was added. From the toluene/pentane (5:2) solution bright yellow crystals of **4** were obtained at −30 °C. A second X-ray crystal structure analysis was performed with these crystals, which turned out to be of a second polymorph of **4** (**4**, crystal 2). They contained a disordered impurity that is possibly **11**′′ [$(Cp_2ZrBr)CH_2(Cp_2ZrMe)$]. Aside from this crystallographic complication, the two independent structure determinations of **4** gave practically identical results as far as the molecular structure of **4** is concerned, even though the crystal packing is completely different, as is reflected by the space group symmetry: $P2_12_12_1$ (orthorhombic) for crystal 1 versus $P\bar{1}$ (triclinic) for crystal 2. Table 2 gives a comparison of selected structural parameters of **4** obtained by these two independent X-ray crystal-structure analyses.

Table 2. Selected bond lengths and angles for **4**

	Crystal 1[a]	Crystal 2[b]	Average
Zr1−C11	2.368(3)	2.334(6)	2.351
Zr2−C23	2.294(4)	2.332(7)	−
Zr1−C12	2.225(3)	2.225(6)	2.225
Zr2−C12	2.247(3)	2.236(5)	2.242
Zr1−C12−Zr2	132.7(1)	134.0(3)	133.4
C11−Zr1−C12	101.2(1)	101.3(2)	101.3
C12−Zr2−C23	93.8(1)	92.9(2)	93.4
C11−Zr1−C12−Zr2	−0.6(3)	1.6(5)	1.1
Zr1−C12−Zr2−C23	175.7(3)	−178.7(5)	−177.2

[a] Determined in Utrecht. [b] Determined in Münster.

In the solid state, **4** is unsymmetrical. It crystallizes in an "antiperiplanar" conformation in which the methyl groups are on opposite sides of the molecule with (averaged) dihedral angles C11−Zr1−C12−Zr2 = 1.1° and Zr1−C12−Zr2−C23 = −177.2°. This specific orientation may be steric in origin, although related μ-oxozirconocene complexes usually favor a bisected (i.e. perpendicular) allene-type conformational orientation. Thus, in $[(Cp_2ZrMe)_2O]$ (**12**)[15] and related systems,[16] the Zr−O−Zr angle is close to linear [**12**: 174.1(3)°] and the Me−Zr···Zr−Me dihedral angle is close to 90°. In contrast, complex **4** favors an almost coplanar arrangement of the Zr−C σ-vectors. In the analogous and sterically rather crowded methylene-bridged complex $[(Cp^*)(C_2B_9H_{11})Zr]_2(\mu\text{-}CH_2)$ (**13**),[17] the bulky dicarbollide ligands at the zirconium atom are *trans*-oriented, too.

Of special interest is the wide bond angle at the methylene carbon atom: Zr−C12−Zr (133.4°). While the geometry around C12 is clearly not planar, it shows a pro-

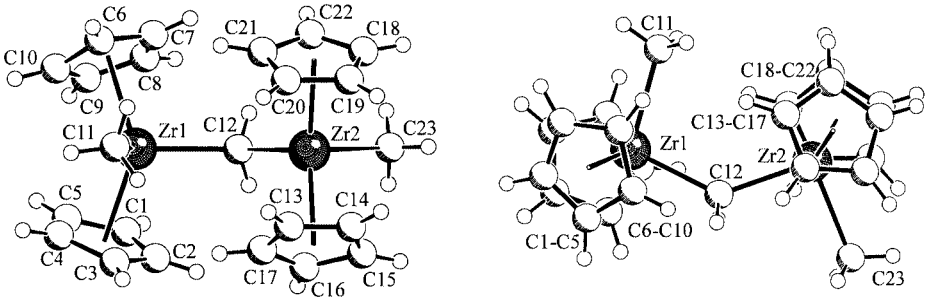


Figure 1. Two views of the molecular structure of **4** (crystal 1)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nounced tendency of flattening in the direction of D_{2h} symmetry. This may be compared with several related structures. Compound **3**[7] has a much smaller Zr1−C1−Zr2 angle [101.86(10)°], but this is due to the fact that it is incorporated into a four-membered ring (involving a chlorine atom); in this case, it is the external angle Zr2−C1−C2 [145.9 (2)°] that is opened up. In **13**, the angles around the methylene carbon atom are rather normal [Zr−CH_2−Zr (119.14°) and H−C−H (108.74°)]; the Zr−CH_2 bond lengths [2.187(6) and 2.176(7) Å] are slightly shorter than those in **4** (2.225 and 2.242 Å). These shorter bonds may signal more s-character in the Zr−CH_2 bond of **13**, although a stabilizing bridging Zr···H−B interaction has also been considered.[17] The wider bond angles in **4** might also be considered as indicators for more s-contribution to the Zr−CH_2 bonds. Apparently, a number of different effects with a complicated interplay are involved. The Zr−CH_3 σ-bonds are in the expected range (see Table 2).[15,17] It must be noted, however, that the Zr1/2−C12 linkages are different from each other. While the Zr2−C12 bond (average 2.242 Å) is in the typical range for zirconium−carbon σ-bonds, the Zr1−C12 bond is shorter at (averaged) 2.225 Å. The latter value is close to the Zr−CH_2 bond lengths observed in the (μ-methylene)zirconocene system **13**.[17] The Zr−C(Cp) bond lengths of **4** lie in a range between 2.491 and 2.570 Å.

In general, the NMR spectroscopic data (Table 3) are in line with the crystal structure. A major difference is that, in solution, the structure is symmetrical, as the two methyl groups and the four cyclopentadienyl groups show only one signal each. Even at −100 °C, only one signal is observed for the methyl groups, which means that the conformational equilibrium in **4** has a very low barrier.

Table 3. NMR spectroscopic data for **4** (δ in ppm)

Group	δ(^{1}H)[a]	δ(^{1}H)[b]	δ(^{13}C)[a]	δ(^{13}C)[b]
Cp	5.73	6.11	109.1 (170.7)[c]	109.8 (171.5)[c]
CH_2	3.68	3.76	146.4 (107.2)[c]	145.8 (106.5)[c]
CH_3	−0.32	−0.46	22.5 (115.9)[c]	22.0 (117.6)[c]

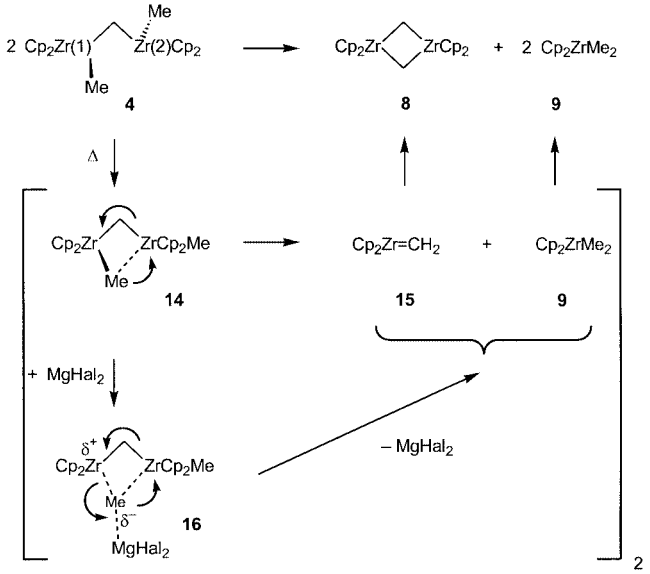
[a] In [D_8]toluene. [b] In [D_8]THF. [c] $^1J_{C,H}$ [Hz] in parentheses.

The deshielded ^{13}C NMR chemical shift of δ= 146 ppm and the small $^1J_{C,H}$ coupling constant of 107 Hz are typical for a methylene group bridging between two metal atoms. Methylene groups in 1,3-dimetallacyclobutanes are even more deshielded,[10,18] as exemplified by the value of δ = 173 ppm for **8**. For methylene groups bridging between two transition metal atoms, such as manganese or rhodium, metal−metal bonding has been invoked,[18] but in **4**, the Zr−Zr distance of 4.10 Å clearly excludes such interactions, as the Zr−Zr distance in the metal is 3.2 Å.[19]

As discussed above, the large Zr−CH_2−Zr angle of 133.4° may be an indication of a relatively high s-character of these bonds, which facilitates the accommodation of electron density released from the metal atoms towards the carbon atom. As a consequence, less s-character is left for the C−H bonds, which explains the small $^1J_{C,H}$ value of 107 Hz (cf. $^1J_{C,H}$ = 117 Hz for the methyl groups) because in the latter, the carbon atom is bonded to only *one* metal atom.

Thermal Disproportionation of 4

In order to further investigate the disproportionation of **4** to **8** and **9**, as mentioned above, the benzene extract of a mixture obtained by Method I containing approximately 70% of **4** was subjected to a kinetic analysis. For this purpose, the solution was kept at 5 °C (cold room) while the solvent was removed by distillation under vacuum into a vessel cooled by liquid nitrogen, followed by high-vacuum pumping. A sample of the residue was dissolved in [D_8]toluene and transferred into an NMR tube, which was subsequently sealed. In the NMR spectrometer, the tube was warmed to 55 °C and the ^{1}H NMR spectrum was recorded. As determination of the absolute concentration of the components was not possible, their relative concentration was derived from the ratio between the intensity of their signals (per proton) and that of the solvent. The sum of the integrals of all cyclopentadienyl signals remained unchanged, which means that decomposition to insoluble products had not occurred. Taking into account the low initial concentrations of **8** and **9** formed during the synthesis of **4** (see Table 1), the two products were newly formed in a ratio of 1:2 as required by stoichiometry (Scheme 4).



Scheme 4

The disproportionation of **4** follows roughly first-order kinetics with $k = 19 \times 10^{-5}$ s^{-1}. A conceivable mechanism is presented in Scheme 4. In the transition state, **14**, of the first and rate-determining step, a methyl group migrates from Zr1 to Zr2, while, simultaneously, the Zr2−CH_2 bond starts to cleave. This produces **9** and the carbene complex **15** which, being highly unstable, immediately dimerizes to form **8**. However, several observations suggest that this

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mechanism may be too simple. In the first place, it does not explain the strong influence of magnesium salts mentioned above. Secondly, when an identical sample of **4** obtained by Method I was dissolved in [D_8]THF instead of [D_8]toluene, the stability increased considerably: at 55 °C, only a small percentage of **4** had undergone disproportion after 64 h, and after 9.5 months at room temperature, the intensity of the signals of **4** had decreased by only 35%. This may be tentatively explained by the strong coordination of $MgHal_2$ by THF, which "inactivates" the salt.

This is supported by two other experiments with a sample of **4** that had been purified and made (practically) salt-free by repeated crystallization from toluene/heptane (5:1), followed by ^{1}H NMR spectroscopy in [D_8]toluene. After heating the solution at 60 °C, 50% of **4** had survived after one month; again, kinetic order (first order) and product formation (**8**/**9** = 1:2) were unchanged. However, when an excess of $MgBr_2$ was added to this salt-free toluene solution, disproportionation occurred within a few hours, although in this case product formation was less straightforward: initially, signals of **9** and **10** were observed while those of **8** appeared only later and in a ratio smaller than 1:2; in addition, unidentified products were formed (singlets at δ = 5.78, 5.76, 0.30, −0.10 ppm).

Thus, it is obvious that magnesium salts do play an important role. From the fact that the reaction is of first order, it follows that they act as catalysts; a tentative rationalization is shown in Scheme 4. One can imagine that in an apolar medium, $MgHal_2$ coordinates to **4**, presumably at the "external" methyl group at Zr1 (Figure 1) as shown in **16**. This will accelerate the cleavage of the Me−Zr2 bond and thus promote migration of the methyl group and the ensuing cleavage process.

Cation Formation

Dimethylzirconocene reacts with the strong Lewis acid $B(C_6F_5)_3$ and a variety of related reagents with abstraction of a methyl anion equivalent to form the respective methylzirconocene cation.[20] A similar reaction was observed when **4** was treated with $B(C_6F_5)_3$ in dichloromethane at low temperature: a methyl group was transferred from a zirconium to a boron atom to yield **17** (Scheme 5). The dimetallic cation of **17** is characterized by a single Cp resonance in the ^{1}H NMR spectrum at δ = 6.60 ppm, integrating for 20 protons (δ(^{13}C) = 114.5 ppm), in addition to ^{1}H NMR resonances of the CH_2 group at δ = 8.01 ppm (**4**: δ = 3.77 ppm) and of the bridging methyl group at δ = −1.05 ppm. The ^{13}C NMR methylene resonance is markedly different from that of its neutral precursor **4** [**17**: δ = 186.6 ppm ($^1J_{C,H}$ = 124 Hz); **4**: δ = 145.1 ppm ($^1J_{C,H}$ = 107 Hz)]. The ^{13}C NMR resonance of the bridging CH_3 group of **17** occurs at δ = 47.4 ppm [$^1J_{C,H}$ = 109 Hz; cf. δ = 22.7 ppm ($^1J_{C,H}$ = 118 Hz) for **4**].

Complex **17** is not stable in dichloromethane solution for a prolonged time at ambient temperature as it reacts with this solvent to yield the chloride-bridged complex **18**. On a preparative scale, it was synthesized by treatment of **17** with trityl chloride to cleanly furnish **18** [CH_2: δ(^{1}H) = 8.53 ppm; δ(^{13}C) = 193.7 ppm ($^1J_{C,H}$ = 124 Hz)] and 1,1,1-triphenylethane. Single crystals of **18** were obtained from a concentrated CD_2Cl_2 solution in an NMR tube. The X-ray crystal structure analysis (Figure 2) shows the formation of the four-membered metallacycle, although a 1:1 disorder of the μ-Cl and μ-CH_2 groups allows the calculation of average Zr−Cl/CH_2 bond lengths and angles only inside the framework of **18**.

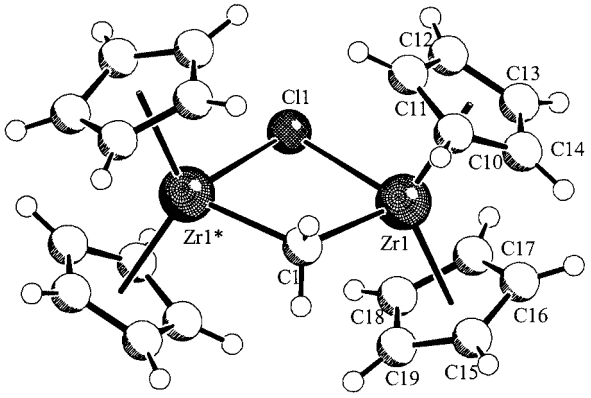


Figure 2. View of the molecular structure of **18** (the counterion has been omitted for clarity)

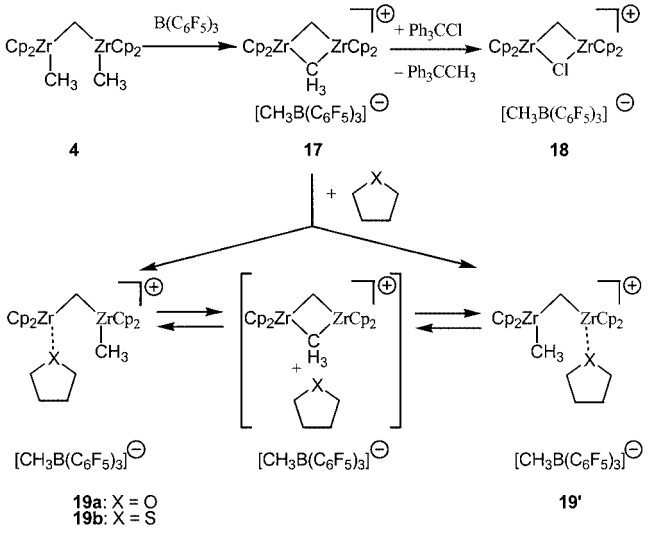
The addition of 1 equiv. of tetrahydrofuran to **17** opens the μ-CH_3 bridge with formation of the unsymmetrically substituted (μ-methylene)dizirconocene cation **19a** [μ-CH_2: δ(^{1}H) = 5.13 ppm; δ(^{13}C) = 163.4 ppm ($^1J_{C,H}$ = 106 Hz); Scheme 5]. The THF-stabilized cation shows dynamic NMR spectra. At room temperature and above it exhibits a single Cp resonance (in CD_2Cl_2, 600 MHz) which decoalesces below 280 K into an equal intensity pair of C_5H_5 singlets (δ = 6.38 and 6.17 ppm at 218 K). This probably indicates a process where THF is readily removed from the dinuclear complex to re-form the C_s-symmetric methyl-bridged cation **17**. Attack of THF can then occur at either side of the dimetallic complex, which leads to the observed



Scheme 5

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

equilibration process (Scheme 5). From the dynamic ^1H NMR spectra of **19a**, a Gibbs activation energy of $\Delta G^{\neq}(280\ K) = 13.1 \pm 0.5$ kcal mol^{-1} was estimated.

Tetrahydrothiophene (THT) reacts similarly with **17** to form the unsymmetrical THT adduct **19b** (Scheme 5). It shows a pair of Cp ligand signals (1:1 intensity) at very low temperature in CD_2Cl_2 (193 K: $\delta(^1H)$ = 6.35, 6.17 ppm; $\delta(^{13}C)$ = 111.5, 110.5 ppm) in addition to a μ-CH_3 singlet at $\delta(^1H) = -0.53$ ppm ($\delta(^{13}C)$ = 10.2 ppm) and a μ-CH_2 resonance at $\delta(^1H)$ = 5.59 ppm and $\delta(^{13}C)$ = 169.2 ppm ($^1J_{C,H}$ = 107 Hz) in addition to the THT ligand and the $[CH_3B(C_6F_5)_3]^-$ anion resonances. Warming of the sample in the NMR spectrometer rapidly leads to coalescence of the Cp signals. From the dynamic ^1H NMR spectra a barrier of $\Delta G^{\neq}(213\ K) = 9.9 \pm 0.5$ kcal mol^{-1} was obtained for the dynamic equilibration process of **19b**.

Conclusion

The title compound [(μ-CH_2)($Cp_2ZrMe)_2$] (**4**) was obtained from [Cp_2Zr(Cl)Me] (**6**) and the two methylenedimagnesium reagents $CH_2(MgBr)_2$ (**5**) or $(CH_2Mg)_n$ (**7**). The X-ray crystal structure of **4** showed that the carbon atom of the central methylene group is non-planar, but a widened Zr−C−Zr angle of 133.4° indicates the tendency of this carbon atom to become planar. On first inspection, **4** may just be regarded as a methane derivative where the central methylene group bears two very bulky (Cp_2ZrMe) substituents. These have a tendency to become oriented far away from each other, thereby leading to an increased metal−CH_2−metal angle.

However, there are some noteworthy features of **4** which may be caused by factors other than simply by steric strain. Planarization of methane derivatives eventually would result in a transition from sp^3- to sp^2-hybridization of the central carbon atom.[2] By this type of re-hybridization, a doubly occupied p-orbital would develop which is oriented perpendicular to the plane of the σ-bonds. One must note that in complex **4** the electrophilic Cp_2ZrCH_3 substituents are both oriented such that their available acceptor orbitals[21] could, in principle, interact with this developing p-orbital at the bridging carbon atom and potentially stabilize it. In the observed unsymmetrical situation, it appears that the metallocene group at Zr1 (see Figure 1) could just have started to profit from such a developing electronic interaction. This might be the reason why the corresponding Zr1−C12 bond is slightly shorter than its adjacent Zr2−C12 neighbor. This is probably only a small energetic effect, but it seems that **4** represents a system where the bonding features of the central methylene carbon atom are just in the initial stage of being distorted from the common pseudo-tetrahedral coordination environment of tetracoordinate carbon toward its unusual planar-tetracoordinate isomer. This unusual structural feature may actually bear some relevance to its chemical behavior: **4** turned out to be relatively stable in THF solution, but it disproportionates in toluene solution to give the 1,3-dizirconacyclobutane [($Cp_2ZrCH_2)_2$] (**8**) and dimethylzirconocene [Cp_2ZrMe_2] (**9**). This reaction appears to be catalyzed by magnesium salts.

Reaction of **4** with $B(C_6F_5)_3$ yielded the methyl-bridged cationic complex **17** which, on treatment with trityl chloride, was transformed into the corresponding chloro complex **18**. The latter has been characterized by X-ray crystal structure determination. With THF and tetrahydrothiophene, **17** formed the adducts **19a** and **19b**, respectively, which are unsymmetrical in solution at low temperatures.

Experimental Section

General Remarks: Most of the experiments were performed using a high-vacuum sealed-glass apparatus,[11,14] in Schlenk-type glassware or in a glove box. Solvents were dried before use by distillation from liquid NaK alloy under argon. Magnesium was triply sublimed. For the determination of some NMR spectra, the solution obtained from a reaction was concentrated to dryness by distilling off the solvent under vacuum into a vessel cooled by liquid nitrogen, followed by pumping under high vacuum; subsequently, the sample was redissolved in a deuterated solvent in a high vacuum system and finally the NMR tube was sealed. NMR spectra were measured with a Bruker WH 90, AC 200, WM 250 or a Varian Unity Plus (^1H: 600 MHz) spectrometer. GCMS analysis was performed with a Hewlett Packard 5890 GC/5970 MS combination with a 50-m Chrompack CP Sil 5 column.

CCDC-221605 (**4**, crystal 1), -221381 (**4**, crystal 2) and -221380 (**18**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

(μ-Methylene)bis[dicyclopentadienyl(methyl)zirconium] (4)

Method I: At −20 °C, a solution of **6**[12] (185.2 mg, 0.68 mmol) in toluene (20 mL) was added to a solution of **5** (0.34 mmol) in diethyl ether/benzene (1:1; 12.4 mL). The reaction mixture was stirred at −20 °C for 14 d, after which time the mixture had become yellow-orange and homogeneous. The solution was kept at 5 °C (cold room) while the solvent was removed by distillation under vacuum

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

into a vessel cooled by liquid nitrogen followed by high vacuum pumping, and the solid residue was extracted with pentane (10 mL, 5 times) and benzene (10 mL), and filtered. Hydrolysis and titration[11] of the residue in the reaction vessel showed that about 10% of **5** had not reacted (a small part may be lost during the workup procedure as well). Titration with EDTA revealed that some of the magnesium salts dissolved in the benzene extract. The yield of **4** was about 60% as determined by ^{1}H NMR spectroscopy with cyclopentane as internal standard. The ratios of products in the pentane and in the benzene extract are reported in Table 1. The NMR spectroscopic data for **4** are presented in Table 3. ^{1}H NMR spectroscopic data for by-products (200 MHz, [D_8]toluene, reference [D_7]toluene at δ = 2.03 ppm). **8:** δ = 6.27 (s, 4 H, CH_2), 6.09 (s, 20 H, Cp) ppm; the data are in agreement with those reported previously.[10] **9:** δ = 5.64 (s, 10 H, Cp), −0.25 (s, 6 H, Me) ppm; the data are similar to those reported previously.[13] **10:** δ = 5.68 (s, 10 H, Cp), 0.15 (s, 3 H, Me) ppm. **11:** δ = 5.89 (s, 10 H, Cp), 5.82 (s, 10 H, Cp), 4.37 (s, 2 H, CH_2), −0.15 (s, 3 H, Me) ppm.

Method II: At −20 °C, a solution of **6** (92.9 mg, 0.34 mmol) in toluene (10 mL) was added to a suspension of **7**[9,11] (0.17 mmol of **7**; see general text for the composition of the reagent) in THF (6.2 mL). The mixture was stirred at −20 °C for 64 h; this was followed by stirring at 5 °C for 2 h and at room temperature for 2 h while the solvents were removed by distillation under vacuum into a vessel cooled by liquid nitrogen followed by high vacuum pumping. The reaction vessel was evacuated at room temperature for 2 h. At room temperature, the residue was extracted with pentane (10 mL), filtered, and subsequently extracted with benzene (10 mL). Analysis by ^{1}H NMR spectroscopy with cyclopentane as internal standard showed that the total yield of **4** was 56% (53% in the benzene extract; 3% in the pentane extract). The composition of the extracts is reported in Table 1. Compound **4** was purified by crystallization from a toluene/heptane (5:1) solution at −80 °C. At room temperature, the crystals were quickly transferred into Lindemann capillaries in a glove box under nitrogen and afterwards kept at −20 °C.

X-ray Crystal Structure of 4 (Crystal 1): $C_{23}H_{28}Zr_2$, M_r = 486.91, orange crystal, 0.2 × 0.2 × 0.3 mm, orthorhombic, space group $P2_12_12_1$ (no. 19) with a = 10.0234(14), b = 13.8914(6), c = 14.3841(18) Å, V = 2002.8(4) Å^3, Z = 4, $\rho_{calcd.}$ = 1.615 g cm^{-3}, $F(000)$ = 984, $\mu_{Mo\text{-}K\alpha}$ = 1.03 mm^{-1}. 6884 reflections measured with an Enraf−Nonius CAD4-T diffractometer with a rotating anode ($\lambda_{Mo\text{-}K\alpha}$ = 0.71073 Å, T = 100 K, θ_{max} = 34.9°), 6358 unique (R_{int} = 0.027), 5063 observed [$I > 2.5\sigma(I)$]. Structure solved with SHELXS-86. 305 parameters refined with SHELX-76, R = 0.0355, R_w = 0.0358, S = 1.61, residual density in the range −1.00, 1.40 e$^-$/Å^3. Hydrogen atom coordinates, with exception of the methyl moieties, were refined. The low value of the displacement parameters of methyl group C11 in comparison with the other methyl group might be explained as substitutional disorder with Br. However, no satisfactory disorder model could be refined, suggesting that, if any, only a very small fraction of Br is present.

Method III: The single crystals used for the X-ray crystal structure analysis in Münster (Table 2, crystal 2) were obtained as follows: A solution of **6** (0.63 g, 2.32 mmol) in toluene (10 mL) was cooled to 0 °C. Then, a solution of **5** [diethyl ether/benzene (1:1), 50 mL, 0.025 M, 1.25 mmol of **5**) was added. The ice bath was removed and the mixture stirred at room temperature for 1 h. Dioxane (2.5 mL) was added and the mixture stirred for 15 min. The solvent was then removed in vacuo. The residue was suspended in toluene (15 mL), the magnesium halide precipitate was removed by filtration, and the clear solution concentrated to about 5 mL. Pentane (2 mL) was added and the solution cooled to −30 °C to yield bright yellow crystals of **4** (0.37 g, 65%).

X-ray Crystal-Structure Analysis of 4 (Crystal 2): $C_{23}H_{28}Zr_2{\cdot}1/2$ correctly represents composition of crystal ($C_{22.86}H_{27.58}Br_{0.14}Zr_2$), M = 734.88, yellow crystal 0.40 × 0.40 × 0.05 mm, a = 10.787(1), b = 13.028(1), c = 13.066(1) Å, α = 63.55(1), β = 69.77(1), γ = 80.83(1)°, V = 1542.6(2) Å^3, $\rho_{calcd.}$ = 1.582 g cm^{-3}, μ = 11.06 cm^{-1}, empirical absorption correction with ψ-scan data (0.666 ≤ T ≤ 0.947), Z = 2, triclinic, space group $P\bar{1}$ (no. 2), λ = 0.71073 Å, T = 223 K, ω/2θ scans, 6565 reflections collected (±h, +k, ±l), [(sinθ)/λ] = 0.62 Å^{-1}, 6275 independent (R_{int} = 0.031) and 4199 observed reflections [$I \geq 2\sigma(I)$], 356 refined parameters, R = 0.049, wR^2 = 0.129, max. residual electron density 0.68 (−1.20) e$^-$/Å^3, hydrogen atoms calculated and refined as riding atoms, in the second independent molecule 7% of the terminal CH_3 group is substituted by Br, in addition the bridging CH_2 group is split over two positions due to symmetry.

Synthesis of 17: Solid **4** (120 mg, 0.25 mmol) was mixed with solid $B(C_6F_5)_3$ (126 mg, 0.25 mmol). Toluene (10 mL) was then slowly added at −78 °C. The mixture was stirred at −78 °C for 20 min and then allowed to warm to room temperature. The toluene phase was decanted from the precipitated oil. The remaining product was washed twice with pentane to give **17** as a yellow powder (70 mg, 28%). $C_{41}H_{28}BF_{15}Zr_2$ (998.9): calcd. C 49.30, H 2.83; found C 48.72, H 3.04. ^{1}H NMR (CD_2Cl_2, 360 MHz, 213 K): δ = 8.01 (s, 2 H, CH_2), 6.60 (s, 20 H, Cp), 0.36 (br., 3 H, CH_3−[B]), −1.05 (s, 3 H, Zr−CH_3) ppm. ^{13}C NMR (CD_2Cl_2, 90.6 MHz, 213 K): δ = 186.6 (t, $^1J_{C,H}$ = 124 Hz, CH_2), 147.4 [d, $^1J_{C,F}$ = 236 Hz, *o*-$B(C_6F_5)_3$], 136.4 [d, $^1J_{C,F}$ = 246 Hz, *p*-$B(C_6F_5)_3$], 135.5 [d, $^1J_{C,F}$ = 243 Hz, *m*-$B(C_6F_5)_3$], 127.8 [s, *ipso*-$B(C_6F_5)_3$], 114.5 (d, $^1J_{C,H}$ = 174 Hz, Cp), 47.4 (q, $^1J_{C,H}$ = 109 Hz, μ-CH_3), 9.2 (br., CH_3−[B]) ppm.

Synthesis of 18

Method I: A solution of $B(C_6F_5)_3$ (0.14 g, 2.74 mmol) in CH_2Cl_2 (10 mL) was added dropwise to a solution of **4** (0.14 g, 2.90 mmol) in CH_2Cl_2 (15 mL) at −78 °C. The reaction mixture was stirred at −78 °C for 2 h and then at room temperature for 12 h. Pentane (5 mL) was then added. Cooling to −45 °C gave a red precipitate that was isolated and dried in vacuo to yield **18** (55 mg, 19%). ^{1}H NMR (CD_2Cl_2, 360 MHz, 300 K): δ = 8.53 (s, 2 H, CH_2), 6.69 (s, 20 H, Cp), 0.49 (br., 3 H, CH_3−[B]) ppm. ^{11}B NMR (CD_2Cl_2, 64.2 MHz, 300 K): δ = −15.1 ppm. ^{13}C NMR (CD_2Cl_2, 90.6 MHz, 300 K): δ = 193.5 (t, $^1J_{C,H}$ = 124 Hz, CH_2), 148.0 [d, $^1J_{C,F}$ = 233 Hz, *o*-$B(C_6F_5)_3$], 138.9 [d, $^1J_{C,F}$ = 246 Hz, *p*-$B(C_6F_5)_3$], 136.1 [d, $^1J_{C,F}$ = 242 Hz, *m*-$B(C_6F_5)_3$], 129.3 [s, *ipso*-$B(C_6F_5)_3$], 115.5 (d, $^1J_{C,H}$ = 175 Hz, Cp), 11.7 (br., CH_3−[B]) ppm. ^{19}F NMR (CD_2Cl_2, 282.2 MHz, 300 K): δ = −126.1, −162.9, −165.4 [*o*-, *p*-, *m*-$B(C_6F_5)_3$] ppm. Single crystals of **18** were obtained by slow evaporation of the solvent from a solution of the complex in CD_2Cl_2.

X-ray Crystal-Structure Analysis of 18: $C_{21}H_{22}ClZr_2{\cdot}CH_3B(C_6F_5)_3$, M = 1019.30, red crystal 0.40 × 0.25 × 0.15 mm, a = 10.768(1), b = 11.305(1), c = 16.283(1) Å, α = 71.93(1), β = 86.31(1), γ = 88.91(1)°, V = 1880.5(3) Å^3, ρ = 1.800 g cm^{-3}, μ = 7.31 cm^{-1}, empirical absorption correction with ψ-scan data (0.759 ≤ T ≤ 0.898), Z = 2, triclinic, space group $P\bar{1}$ (no. 2), λ = 0.71073 Å, T = 223 K, ω/2θ scans, 6979 reflections collected (±h, −k, ±l), [(sinθ)/λ] = 0.59 Å^{-1}, 6612 independent (R_{int} = 0.033) and 3880 observed reflections [$I \geq 2\sigma(I)$], 551 refined parameters, R = 0.038, wR^2 = 0.071, max. residual electron density 0.59 (−0.41) e$^-$/Å^3, hydrogen atoms calculated and refined as riding atoms, the bridg-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing CH_2 and Cl groups are split over two positions due to symmetry.

Method II: Complex **4** (50 mg, 0.10 mmol) was mixed with solid $B(C_6F_5)_3$ (53 mg, 0.10 mmol). Toluene (10 mL) was added slowly at −78 °C. The mixture was stirred at −78 °C for 20 min. A precooled solution (−78 °C) of trityl chloride (30 mg, 0.10 mmol) in toluene (10 mL) was then added. The mixture was warmed to room temperature and then stirred for another 10 min. The toluene phase was separated from the precipitated oil of the organometallic product **18** (see above) and washed twice with pentane. From the combined organic phases 1,1,1-triphenylethane[22] was recovered as a white powder (34 mg 35%). M.p. 95 °C.

Reaction of 17 with THF

Formation of 19a: Compound **4** (20 mg, 41 μmol) was dissolved in 0.5 mL of CD_2Cl_2. A solution of $B(C_6F_5)_3$ (21 mg, 41 μmol) in CD_2Cl_2 (0.5 mL) was added at −78 °C. After 10 min, THF (3 mg, 43 μmol) in $CD_2Cl_2$was added. The solution was flame-sealed in an NMR tube and the temperature-dependent NMR spectra of the resulting complex **19a** were recorded. ^{1}H NMR (600 MHz, CD_2Cl_2, 218 K): δ = 6.38 (s, 10 H, Cp), 6.17 (s, 10 H, Cp), 5.34 (s, 2 H, CH_2), 3.58 (m, THF), 1.61 (m, THF), 0.42 (br., 3 H, CH_3−[B]), −0.43 (s, 3 H, Zr−CH_3) ppm. ^{1}H NMR (600 MHz, CD_2Cl_2, 300 K): δ = 6.34 (s, 20 H, Cp), 5.13 (s, 2 H, CH_2), 3.58 (m, THF), 1.69 (m, THF), 0.62 (br., 3 H, CH_3−[B]), −0.22 (s, 3 H, Zr−CH_3) ppm. Coalescence of the Cp signals at 280 K, Δν (at the limiting low temperature) is 126 Hz, $\Delta G^{\neq}$ (280 K) = 13.1 ± 0.5 kcal mol^{-1}. ^{13}C NMR (150.6 MHz, [D$_8$]THF, 218 K): δ = 163.4 (t, $^1J_{C,H}$ = 106 Hz, CH_2), 150.4 [d, $^1J_{C,F}$ = 236 Hz, *o*-$B(C_6F_5)_3$], 138.4 [d, $^1J_{C,F}$ = 246 Hz, *p*-$B(C_6F_5)_3$], 136.8 [d, $^1J_{C,F}$ = 243 Hz, *m*-$B(C_6F_5)_3$], 130.8 [s, *ipso*-$B(C_6F_5)_3$], 117.5 (d, $^1J_{C,H}$ = 174 Hz, Cp), 114.5 (d, $^1J_{C,H}$ = 174 Hz, Cp), 43.5 (q, $^1J_{C,H}$ = 122 Hz, Zr-CH_3), 11.2 (br., CH_3−[B]) ppm.

Reaction of 17 with Tetrahydrothiophene (THT)

Formation of 19b: As described above, **4** (40 mg, 82 μmol) was treated in CD_2Cl_2 first with $B(C_6F_5)_3$ (42 mg, 82 μmol) and then with tetrahydrothiophene (7 mg, 85 μmol) at −78 °C to form **19b**. A sample of the solution was flame-sealed in an NMR tube for spectroscopic characterization. ^{1}H NMR (600 MHz, CD_2Cl_2, 183 K): δ = 6.35 (s, 10 H, Cp), 6.17 (s, 10 H, Cp), 5.59 (s, 2 H, CH_2), 3.08 (br., free THT), 2.82 (br., coordin. THT), 1.83 (br., coordin. THT), 1.68 (br., free THT), 0.40 (br., 3 H, CH_3−[B]), −0.53 (s, 3 H, Zr−CH_3) ppm. ^{1}H NMR (600 MHz, CD_2Cl_2, 300 K): δ = 6.29 (s, 20 H, Cp), 5.59 (s, 2 H, CH_2), 3.02 (m, THT), 1.87 (m, THT), 0.41 (br., 3 H, CH_3−[B]), −0.50 (s, 3 H, Zr−CH_3) ppm. Coalescence of the Cp signals at 213 K, Δν (lower limit) = 109 Hz, $\Delta G^{\neq}$ (213 K) = 9.9 ± 0.5 kcal mol^{-1}. ^{13}C NMR (150.6 MHz, CD_2Cl_2, 183 K): δ = 169.2 (t, $^1J_{C,H}$ = 107 Hz, CH_2), 147.5 [d, $^1J_{C,F}$ = 237 Hz, *o*-$B(C_6F_5)_3$], 137.5 [d, $^1J_{C,F}$ = 246 Hz, *p*-$B(C_6F_5)_3$], 135.5 [d, $^1J_{C,F}$ = 243 Hz, *m*-$B(C_6F_5)_3$], 127.8 [s, *ipso*-$B(C_6F_5)_3$], 111.5 (d, $^1J_{C,H}$ = 175 Hz, Cp), 110.5 (d, $^1J_{C,H}$ = 175 Hz, Cp), 42.5 (m, α-THT), 32.5 (m, β-THT), 26.5 (q, $^1J_{C,H}$ = 110 Hz, Zr−CH_3), 10.2 (br., CH_3−[B]) ppm.

The Predicted Structures of the New Pnictides HfMQ in Contrast to ZrMQ (M = Ti, V; Q = P, As)

Shahab Derakhshan,[a] Enkhtsetseg Dashjav,[a] and Holger Kleinke*[a]

Keywords: Structure map / X-ray diffraction / Electronic structure / Phosphides / Arsenides

The new pnictides HfTiP, HfTiAs and HfVAs have been prepared through arc-melting. These arsenides form the predicted structures with (distorted) $TiAs_4$ and VAs_4 tetrahedra, while the structures of both Zr analogs (ZrTiAs and ZrVAs) are comprised of $TiAs_4$ and VAs_4 square planes, respectively. These differences stem from significant differences in the metal atom substructures. On the other hand, HfTiP and ZrTiP are isostructural. These variations were predicted by utilizing a structure map for metal-rich pnictides and chalcogenides M_2Q (M = valence-electron poor transition metal, Q = pnicogen or chalcogen) presented in the year 2000. The HfMQ structure is stabilized by strong Hf–Q, M–Q and M–M bonds, and to a minor extent by Hf–Hf and Hf–M bonding interactions. All three new $Hf_{1-\delta}M_{1+\delta}Q$ phases exhibit significant phase ranges.

Introduction

The ternary equiatomic early transition-metal pnictides MM′Q (M, M′: element of groups 3−5; Q: P, As, Sb) typically occur in one of two common crystal structures. These structures differ in the metal−nonmetal coordination spheres (but with the same coordination numbers) as well as in the metal−metal bonding, while the nonmetal atoms are always surrounded by nine metal atoms in form of a tricapped trigonal prism, and the larger M atoms are situated in a square pyramid formed by five Q atoms. In the first variant, the Co_2Si type (ordered variant: TiNiSi[1]), the smaller M′ atoms are tetrahedrally coordinated by four Q atoms, whereas in the second variant, the La_2Sb type (ordered variant: CeScSi[2]), the $M'Q_4$ polyhedra are best described as square planes.

These differences may be understood to stem from different metal atom substructures, which contain stronger M−M and M−M′ bonds in case of the Co_2Si structures. As shown earlier,[3] the major structure determining factors for such metal-rich pnictides and chalcogenides are the valence-electron concentration of M, the relative extension of the d orbitals of M (reflected in the principal quantum number), the radius ratio r_M/r_Q, and the electron deficit of the Q atoms. As for the metal atoms, higher valence-electron concentration, larger d orbitals and larger atomic radii all facilitate stronger M−M bonding. On the other hand, larger atomic sizes and larger electron deficits of the Q atoms would lead to larger coordination numbers for the Q atoms. Given the fact that the known structure types all have comparable packing efficiencies, more M−M bonds occur with smaller coordination numbers of the Q atoms. Obviously these factors can cancel each other, one example being Zr_2S and Hf_2P that are isostructural.

All these factors were summarized empirically in the power product $\mathbf{f} = vec_M \times n_M^2 \times (r_M/r_Q)/(8 - e_Q)^2$, wherein vec_M equals the valence-electron concentration per M atom after (formally) reducing the Q atoms, n_M the main quantum number of the M atoms, (r_M/r_Q) the radius ratios based on the Slater radii,[4] and $(8 - e_Q)$ the electron deficit of the Q atoms in their neutral state − in analogy to the $(8 - N)$ rule. Plotting the averaged coordination number of the Q atoms <C.N.(Q)> of all M_2Q pnictides and chalcogenides, including the ternaries with two different M atoms as well as two different Q atoms, against **f** gave a structure map with distinct domains of the (then) eleven different structure types of this family.[3]

For all of the factors contributing to the power product **f** are readily available, **f** may be calculated for all hypothetical, still uncovered M_2Q binaries as well as $M_{1-\delta}M'_{1+\delta}Q$ and $M_2Q_{1-\delta}Q'_\delta$ ternaries. Then, the domain and thus the structure type can be predicted, unless the compound in question either does not exist or forms a new type. However, unlike well-known structure maps such as Pettifor's[5] or Villars',[6] this approach even suggests information about unknown types, namely the averaged coordination number of the Q atoms.

The (in part systematic) subsequent recovery of new members of this M_2Q family proved the usability of this structure map: the ternary arsenide, $Zr_{1-\delta}Ti_{1+\delta}As$, was postulated to form the La_2Sb type, which was subsequently proven to be correct.[7] $Zr_{1-\delta}V_{1+\delta}As$[8] is at the border be-

E-mail: kleinke@uwaterloo.ca

tween the Co_2Si and La_2Sb representatives of this family, depending on the exact Zr:V ratio, and always forms the La_2Sb structure. Harbrecht et al. uncovered with Zr_6STe_2 ($\equiv Zr_2S_{0.33}Te_{0.67}$)[9] the first example of a new compound in this family that occurs in a new type, and its <C.N.(Q)> value is indeed eight − thus a nice fit in the structure map. Furthermore, an extension to other stoichiometries is possible, as demonstrated by us for the M_5Q_3 compounds.[10,11]

This work deals with the new hafnium phosphides and arsenides $Hf_{1-\delta}Ti_{1+\delta}P$, $Hf_{1-\delta}Ti_{1+\delta}As$, and $Hf_{1-\delta}V_{1+\delta}As$. As illustrated in Table 1, the power product **f** clearly places these three new materials into the Co_2Si domain, together with ZrTiP,[12] ZrVP and HfVP,[13] ZrNbP and HfNbP,[14] and V_2P[15] and in contrast to ZrTiAs and ZrVAs (as well as La_2Sb[16] and Zr_2Sb[17]). Our investigations confirmed the Co_2Si type in all three new cases introduced.

Table 1. Overview of M_2Q compounds in the Co_2Si and La_2Sb types. Hypothetical compounds are in italic

Compound	f	Structure	Reference
HfNbP	15.1	Co_2Si	[14]
TaVP	13.6	Co_2Si	[12]
ZrNbP	12.5	Co_2Si	[14]
HfVP	12.1	Co_2Si	[13]
HfVAs	10.5	Co_2Si	this work
HfTiP	10.2	Co_2Si	this work
ZrVP	9.8	Co_2Si	[13]
HfTiAs	8.9	Co_2Si	this work
V_2P	8.4	Co_2Si	[15]
ZrTiP	8.3	Co_2Si	[12]
ZrVAs	8.5	La_2Sb	[8]
La_2Sb	8.1	La_2Sb	[16]
Zr_2Sb	7.4	La_2Sb	[17]
ZrTiAs	7.2	La_2Sb	[7]
HfTiSb	7.1	predicted La_2Sb	hypothetical
ZrTiSb	5.7	predicted La_2Sb	hypothetical

Results and Discussion

Structure Map

Several ternary phosphides, arsenides and antimonides of Zr and Hf form the Co_2Si type. Typically, the second metal is a late transition-metal atom, as in ZrMP (M = Fe, Co),[18,19] HfMP (M = Fe, Co, Ni),[20] ZrMAs and HfMAs (M = Fe, Co, Ni),[21] and ZrMSb and HfMSb (M = Fe, Ni).[22,23] With the exception of ZrNiP (Ni_2In type)[24] and HfNiP, these Zr and Hf compounds are always isostructural. Only few examples are known with Zr or Hf and a second early transition metal, namely the phosphides ZrTiP,[12] ZrVP and HfVP,[13] ZrNbP and HfNbP[14] (all Co_2Si type), while the arsenides known to date form the La_2Sb type (i.e. ZrTiAs and ZrVAs[7,8]). Furthermore, no such antimonides were uncovered to date.

Employing the structure map for M_2Q compounds, the hitherto unknown pnictides HfTiP, HfTiAs and HfVAs were predicted to form the Co_2Si type (cf. the overview in Table 1).[7,8] Our investigations presented here prove this to be correct. Knowledge of the structures of related pnictides published before could not be used for this prediction, as ZrTiAs and ZrVAs both occur only in the La_2Sb type, while ZrTiP crystallizes (like HfTiP) in the Co_2Si type.

In particular, one might have correctly assumed HfTiP to be isostructural with ZrTiP, but following this logic, HfTiAs should be isostructural with ZrTiAs, which is not the case. A thorough theoretical investigation of ternary phosphides MM′P, with M and M′ being an early transition-metal element,[25] was based on Extended Hückel calculations,[26,27] using the atomic parameters of Zr and Nb. This work analyzed four different possible structure types, namely Cu_2Sb, Co_2Si, Fe_2P and Ni_2In. For 14 valence-electrons, the Co_2Si type was calculated to be electronically preferred, which is the case for MNbP, MVP and MVAs with M = Zr, Hf. Similar compounds with 13 valence-electrons − explicitly mentioned was HfTiP in that article − were predicted to form the Cu_2Sb type, which exhibits a M atom substructure related to that of the La_2Sb type. To summarize, the latter method, which exclusively used valence-electron concentrations for rationalizing structural trends, correctly identified ZrVP, HfVP and HfVAs, but failed to foresee correctly ZrTiAs, ZrVAs, HfTiP and HfTiAs.

Crystal Structure

Since the Co_2Si type (*anti*-$PbCl_2$) is a well-known structure type, its description may be kept short here. We are therefore concentrating on the differences to the La_2Sb type, for ZrTiAs and ZrVAs adopt the latter, and HfTiAs and HfVAs the former type. In the following, we will discuss the differences between HfVAs and ZrVAs, whose structures are shown in Figure 1.

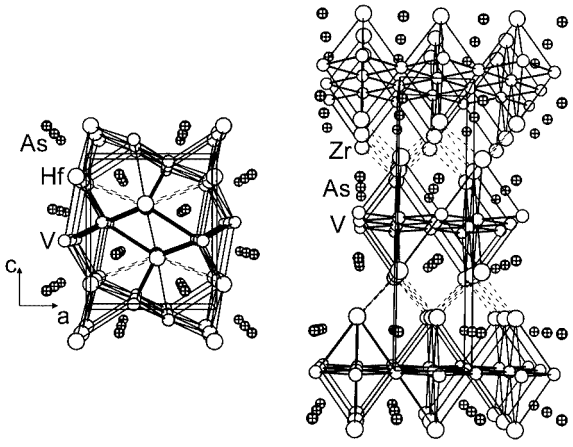

Figure 1. Crystal structures of HfVAs (left) and ZrVAs (right)

Both structures comprise three atomic positions, one As, one M(1) (mainly the group 4 element, i.e. Zr or Hf) and one M(2) (mainly V) site. Depending on the exact M:V ratio of $Zr_{1-\delta}V_{1+\delta}As$ and $Hf_{1-\delta}V_{1+\delta}As$, the M(1) site may exhibit up to 15% V in ZrVAs and 9% V in HfVAs, and the M(2) site up to 43% Zr in ZrVAs and 2% Hf in HfVAs. It is noted that in the case of MTiAs, the M(2) site cannot

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

include any Zr of Hf contributions, but M(1) up to 42% Ti in ZrTiAs and 40% Ti in HfTiAs.

In both structures, ZrVAs and HfVAs, the As atom is surrounded by nine transition-metal atoms forming a (distorted) tri-capped trigonal prism (deltahedral tetrakaidecahedron), namely five M(1) and four M(2) atoms. Furthermore, the M(1) atoms are located in (distorted) As_5 square pyramids in both structures, but the V atom in a (distorted) As_4 tetrahedron in HfVAs and in an As_4 planar "square" (more precisely: rectangle) in ZrVAs. These coordination polyhedra are depicted in Figure 2.

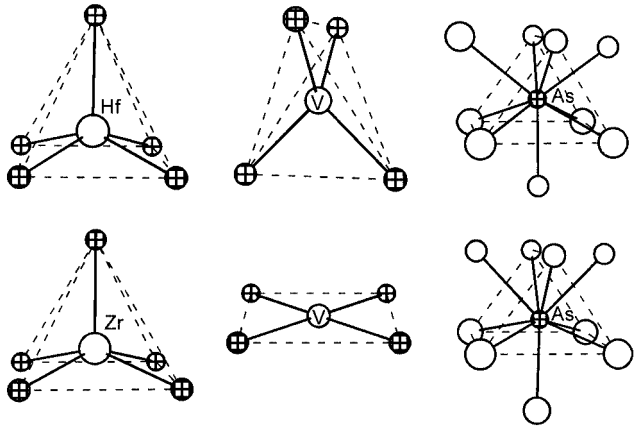

Figure 2. Coordination polyhedra of HfVAs (top) and ZrVAs (bottom)

The different coordination numbers of M(1) and M(2) reflect a likely reason why the smaller V atom prefers the M(2) site in both cases. As well, the coordination number of four inhibits an incorporation of the group 4 element to some extent; only in the case of ZrVAs may the M(2) site exhibit significant amounts of it.

Of particular interest are the differences in metal−metal bonding in these structures, for the only (yet obvious) difference between the formulas ZrVAs and HfVAs is the main quantum number of the group 4 metal atoms. Size and electronegativity of Zr and Hf atoms are virtually equivalent. ZrVAs comprises sheets of corner-sharing Zr_2V_4 octahedra (tetragonally elongated, i.e. of D_{4h} symmetry), wherein the apices are occupied by Zr atoms. Then, the V atoms form planar square nets, whose interatomic distances are much shorter than the Zr−V distances, namely 268 pm vs. 326 pm in $Zr_{0.85}V_{1.15}As$ (each 4 × per V atom). Additional M−M bonding occurs between the sheets of octahedra in form of Zr−Zr bonds of 341 pm.

More complex, and truly three-dimensional, is the bonding situation in HfVAs. V−V zigzag chains with short interatomic distances of 266 pm (in $Hf_{0.97}V_{1.03}As$) run along the *b* axis. While that bond length is similar to the V−V bonds in ZrVAs, the multitude is smaller, with two bonds per V atom in HfVAs, compared to four bonds per V atom in ZrVAs. Each V atom in HfVAs is additionally connected to Hf atoms at rather short distances of 2 × 298 pm and 2 × 308 pm, and longer ones of 321 pm and 334 pm. The Hf−Hf distances vary between 329 pm and 363 pm.

The four Hf−V distances between 298 pm and 308 pm and the six Hf−Hf between 329 and 363 pm stand against the four Zr−V at 326 pm and four Zr−Zr distances at 340 pm of ZrVAs. It is evident that the Hf atoms in HfVAs participate in more and shorter M−M bonds than the Zr atoms in ZrVAs. Remembering that the radii of the Zr and Hf atoms are virtually equivalent (e.g., Slater radii: 155 pm for both atoms, Pauling's single bond radii: 145 pm for Zr and 144 pm for Hf[28]), the reason behind this cannot be of steric nature. Since the relative extension of the *d* orbitals is higher in case of the *5d* elements, they principally tend to form more and stronger M−M bonds than the *4d* elements. This fact was used to explain the site preferences of the Ta atoms in ternary niobium tantalum sulfides,[29,30] as well as the differences between the structures of ZrNiP and HfNiP.[20] Similarly, the different main quantum numbers of Zr and Hf led to the different power factors **f** of ZrVAs and HfVAs, which ultimately results in the occurrence in different structure domains in our structure map, namely the La_2Sb and Co_2Si domains, respectively.

The differences in bond lengths (Table 2) between $Hf_{0.97}V_{1.03}As$ and $Hf_{0.92}V_{1.08}As$ stem from size differences between Hf and V (Slater radius of V: 135 pm). The same is true for $Hf_{0.84}Ti_{1.16}As$ and $Hf_{0.60}Ti_{1.40}As$. Although the latter two compounds are less Hf-rich, their unit cell volumes and bond lengths are larger than those of the V compounds, because of the larger size of Ti, compared to V (140 pm vs. 135 pm).

Table 2. Selected interatomic distances [pm]

Bond	No.	*d*[a]	*d*[b]	*d*[c]	*d*[d]

Mixed Occupancies

All four structures analyzed here exhibit mixed occupancies on at least one metal atom site, that is, Hf/Ti and Hf/V mixtures. The same is true for $Zr_{0.58}Ti_{1.42}As$, $Zr_{1.43}V_{0.57}As$ and $Zr_{0.85}V_{1.15}As$, but not for ZrTiAs at the exact 1:1 ratio of Zr:Ti. The latter indicates a strong preference for ordering, for the two available atom sites as well as atom kinds are quite different. Hf/Ti mixed occupancies were observed in $(Hf,Ti)_7Sb_4$ [31] with almost no differences

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

between the metal atom sites, and Zr/V and Zr/Ti mixed occupancies with intermediate ordering in $(Zr,V)_{13}Sb_{10}$,[32] $(Zr,V)_{11}Sb_8$,[33] and (Zr,Ti)Sb.[34] All of these observations may be explained with the various extents of the differences between the metal atom sites of the respective structures.

Electronic Structure

To further characterize HfMAs and to gain more insight into the differences between ZrMAs and HfMAs, we analyze the band structures of HfTiAs and HfVAs, as ZrVAs and ZrTiAs were investigated before. The Densities Of States (DOS) and selected Crystal Orbital Hamilton Populations (COHP)[35] curves, each cumulated over the whole unit cell, are shown in Figure 3 (HfTiAs) and Figure 4 (HfVAs). The facts, that the structures are isotypic and the constituent elements similar, are reflected in comparable, yet not equivalent, shapes of the DOS curves. As a consequence of the different valence-electron concentration, due to Ti being a 4th and V a 5th group element, the DOS of HfVAs is shifted up by more than 0.5 eV with respect to HfTiAs, with both Fermi levels fixed at 0 eV. In both cases, the energy windows shown exclude the As-*s* dominated peak, which occurs well below −7 eV. A pseudo gap (at −2.0 eV in the Ti and −2.7 eV in the V case) separates the As-*p* peak from the metal-centered states.

Hf, Ti and V contributions below −2.0 eV and −2.7 eV, respectively, are indicative of covalent M−As bonding character. As may be seen in the COHP curves on the right sides of the Figure 3 and 4, all M−As interactions are strong, and only bonding states are filled. Virtually no M−As states are found in the vicinity of the Fermi level. The same statements can be made in the cases of ZrTiAs and ZrVAs.

A second pseudo gap is located within the M-*d* peak, separating bonding M(2)−M(2) interactions from the antibonding ones. The Fermi level is found slightly below this local minimum in HfTiAs, and slightly above it in HfVAs. In both cases the Fermi level is located in the midst of the metal *d* states, emphasizing the importance of the *d* states for the bonding and thus crystal structure. The V−V bonds are optimized in HfVAs, that is, the transition from bonding to antibonding character takes place directly at the Fermi level. The Ti−Ti bonds in HfTiAs would gain bonding character by an increase of valence-electrons, because empty bonding states are found up to 1 eV above the Fermi level.

That Hf is the most electropositive element here, and thus the higher oxidized M atom, reflects itself in fewer filled Hf−Hf bonding states, compared to both Ti−Ti and V−V states. Therefore, the Hf−Hf interactions are less dominant,

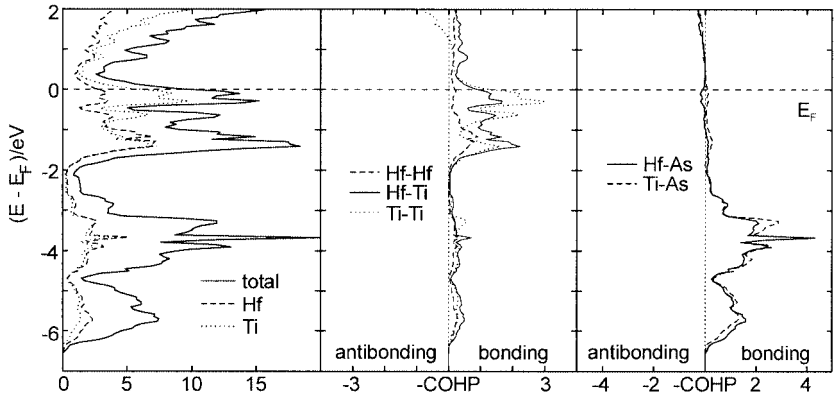

Figure 3. Densities of states (left) and selected cumulated COHP curves for HfTiAs

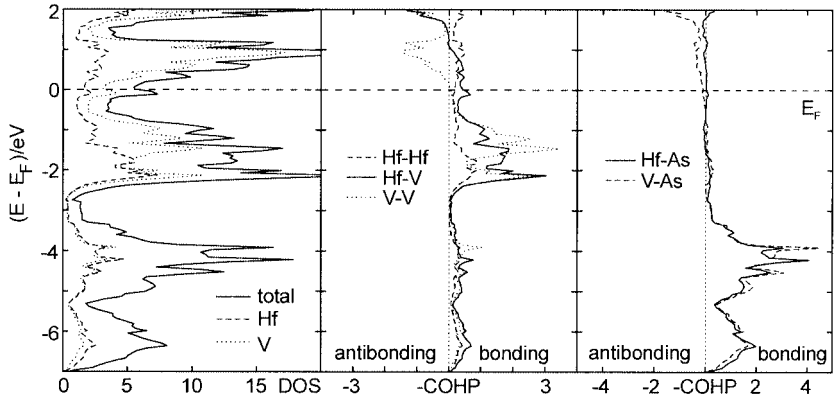

Figure 4. Densities of states (left) and selected cumulated COHP curves for HfVAs

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and they exhibit exclusively bonding states within the depicted energy window. The latter is also true for the Hf−Ti interactions in HfTiAs, but not for the Hf−V interactions in HfVAs. The latter turn into antibonding character about 1 eV above the Fermi level.

The most striking difference between the M−M COHP curves of the Zr and Hf arsenides under consideration is the relative importance of the Ti−Ti and V−V interactions, in relation to the other kinds. While they seem to be the strongest in all cases, they are less dominant in the Hf cases, particularly compared to the Hf−Ti and Hf−V bonds, respectively. In turn, the Hf−M′ bonds are thus more important in the HfM′As structures than the Zr−M′ bonds in ZrM′As. This observation is in tune with the assumption that Hf may form stronger metal−metal bonds than Zr because of the larger extension of its *5d* orbitals, as all the metal−metal interactions rely almost exclusively on the *d* states.

Conclusion

Three new compounds, all with significant phase ranges, have been introduced: $Hf_{1-\delta}Ti_{1+\delta}P$, $Hf_{1-\delta}Ti_{1+\delta}As$, and $Hf_{1-\delta}V_{1+\delta}As$, all crystallizing in the Co_2Si type. This completes the series of ternary Zr/Hf − Ti/V phosphides and arsenides that form either the Co_2Si or the La_2Sb type. Evidently all these compounds fit into the recently published M_2Q structure map based on the power product $\mathbf{f} = vec_M \times n_M^2 \times (r_M/r_Q)/(8 - e_Q)^2$ − higher **f** values are indicative of more M−M bonding. On the other hand, electron counting or basic analogy considerations failed to explain the respective crystal structures, as for both structure variants examples exist with 13 as well as 14 valence-electrons, and seemingly analogous compounds such as ZrTiAs and HfTiAs occur in different types, while ZrTiP and HfTiP are isostructural.

While all kinds of M−M bonding occur in both types, the Hf−Hf and Hf−Ti/V bonds of HfTiAs and HfVAs are shorter than the respective Zr-containing bonds in ZrTiAs and ZrVAs (the latter both La_2Sb type). That difference may be understood based on the different main quantum numbers n_{Zr} and n_{Hf}, considering that higher quantum numbers enable the metal atom to form stronger M−M bonds (cf. n_M in the power product **f**).

Experimental Section

Syntheses of HfMP and HfMAs

All experiments started from the elements as purchased in microcrystalline form from Aldrich, with purities above 99.5%. The first steps were the syntheses of the monopnictides HfP, HfAs, TiP, TiAs, and VAs as starting materials, which were necessary to minimize mass losses due to vaporization of phosphorus or arsenic during arc-melting and tube attacks during annealing in tantalum containers, respectively. The monoarsenides were prepared starting from the elements in the stoichiometric 1:1 ratios in evacuated fused silica tubes at 800 °C, and TiP was synthesized at 400 °C under addition of trace amounts of iodine. Then, more metal was added to reach the target ratio of metal/pnicogen of 2:1. These mixtures were thoroughly ground, pressed into pellets and then arc-melted twice under a flow of Argon. This procedure led to the synthesis of HfTiP, HfTiAs and HfVAs in yields of 80−90%, as estimated based on the powder diagrams obtained using an X-ray powder diffractometer with position-sensitive detector (Inel). Higher yields were obtained in the HfTiP system by annealing the mixtures in sealed tantalum containers at 1400 °C over a period of several days (without prior arc-melting).

Phase Ranges of $Hf_{1-\delta}Ti_{1+\delta}P$ and $Hf_{1-\delta}M_{1+\delta}As$

$Zr_{1-\delta}Ti_{1+\delta}As$ and $Zr_{1-\delta}V_{1+\delta}As$ (both La_2Sb type) exhibit significant phase ranges, with $0 \le \delta \le 0.42(1)$ and $-0.43(4) \le \delta \le 0.15(1)$, respectively.[7,8] $Zr_{1-\delta}V_{1+\delta}P$ and $Hf_{1-\delta}V_{1+\delta}P$ (both Co_2Si type) were reported to have significant phase widths as well ($0 \le \delta \le 0.40$ and $0 \le \delta \le 0.55$).[13] Therefore, we varied the Hf:M ratios to determine the phase ranges of $Hf_{1-\delta}Ti_{1+\delta}P$ and $Hf_{1-\delta}M_{1+\delta}As$. These investigations were started with arc-melting different mixtures in the arsenic system:

$HfAs + Ti \rightarrow Hf_{1-\delta}Ti_{1+\delta}As + Hf_3As + ?$ (**I**)

$0.75\ Hf + 0.25\ Ti + TiAs \rightarrow Hf_{1-\delta}Ti_{1+\delta}As + ?$ (**II**)

$0.5\ Hf + 0.5\ Ti + TiAs \rightarrow Hf_{1-\delta}Ti_{1+\delta}As + Ti_3As + ?$ (**III**)

$0.25\ Hf + HfAs + 0.75\ V \rightarrow Hf_{1-\delta}V_{1+\delta}As + Hf_3As + ?$ (**IV**)

$HfAs + V \rightarrow Hf_{1-\delta}V_{1+\delta}As + ?$(**V**)

$0.75\ Hf + 0.25\ V + VAs \rightarrow Hf_{1-\delta}V_{1+\delta}As + V_3As + ?$ (**VI**)

The products of the reactions (**I**) − (**VI**), as determined by X-ray powder diffraction, indicate different phase ranges for the Ti- and V-containing Hf arsenides, namely $0 < \delta < 0.5$ for $Hf_{1-\delta}Ti_{1+\delta}As$ and $-0.25 < \delta < 0.25$ for $Hf_{1-\delta}V_{1+\delta}As$. The symbol "?" implies the presence of unidentified compounds in small yields.

Analogous investigations in the Hf−Ti−P system were carried out at 1400 °C, for arc-melting proved to be more difficult, most likely due to phosphorus vaporization. Reactions aiming at $Hf_{1-\delta}Ti_{1+\delta}P$ were carried out with δ varying between −0.5 and +0.5, and $Hf_{1-\delta}Ti_{1+\delta}P$ was formed as the main product when $-0.2 \le \delta \le 0.5$. The lattice dimensions of the Co_2Si type phases were determined from their X-ray powder diagrams by least-square refinements (assuming orthorhombic symmetry). EDS analyses (LEO, 1530, with integrated EDAX Pegasus 1200) on several selected crystals of the Co_2Si phases did not reveal any incorporation of impurity elements, such as Si or oxygen stemming from the silica tube or Ta coming from the tantalum container, or iodine from the synthesis of TiP. According to the averaged values of these analyses (summarized in Table 3), $Hf_{1-\delta}Ti_{1+\delta}P$ exists between $Hf_{0.6}Ti_{1.4}P$ and $Hf_{1.2}Ti_{0.8}P$ (i.e. $-0.2 \le \delta \le 0.4$). An increasing Hf content is reflected in larger cell volumes, for Hf atoms are larger than Ti atoms (e.g., Slater radii: 155 pm vs. 140 pm).

Crystal Structure Studies of $Hf_{1-\delta}M_{1+\delta}As$

From each of the reactions (**I**), (**III**), (**IV**), and (**VI**), one single crystal was selected for structure refinements, to prove the formation of the Co_2Si type and to analyze the occupancy factors. Based on the powder data, the products were at the phase range borders; thus, determining their Hf/M ratios will give the phase width.

A Smart Apex CCD diffractometer (Bruker) using Mo-K_α radiation was employed for the data collections. In all four cases, 606 frames were collected with 0.3° scans in ω for exposure times of 60 seconds per frame. The data were corrected for Lorentz and Polarization effects. The unit cell dimensions and the systematic absences were consistent with the space group *Pnma* (and its noncentrosymmetric subgroup $Pn2_1a$), which is the space group of the Co_2Si type. This was subsequently confirmed by the successful structure refinements using SHELXL[36] yielding satisfying residual factors. Refining the structures in the noncentrosymmetric subgroup $Pn2_1a$ did not yield significant changes, but instead resulted in high correlations.

The Co_2Si type comprises three crystallographically independent atom sites (all on a mirror plane, Wyckoff notation 4*c*). The Si site was treated as the As site, and the two metal atom sites [denoted as M(1) and M(2)] were refined as being mixed occupied by Hf and M (Ti and V, respectively), with the sums of the occupancy factors fixed at 100%. M(1) is the Ti site in TiNiSi, and the Hf site in isostructural HfCoAs.[21]

In each case investigated here, the M(1) site was mainly occupied with Hf atoms, but exhibited always some Ti or V content. The M(2) site was either mixed occupied (with Hf as the minor component), or solely a Ti/V site, namely on the Hf-poor side of the phase range. Furthermore, the Hf contents of M(2) on the Hf-rich side [0.022(5) and 0.018(5)] may be regarded as insignificant. The refined formulas were $Hf_{0.84(1)}Ti_{1.16}As$, $Hf_{0.602(5)}Ti_{1.40}As$, $Hf_{0.97(2)}V_{1.03}As$, and $Hf_{0.916(6)}V_{1.084}As$, respectively. Crystallographic details are given in the Table 4. Atomic positions, occupancy factors, and displacement parameters are listed in Table 5. Further details of the crystal structure investigations can be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository numbers CSD-413262, -413263, -413264 and -413265.

Electronic Structure Calculations

The band structures were calculated employing the self-consistent tight-binding *first principles* LMTO approximations (LMTO = linear muffin tin orbitals[37,38]). In the LMTO approach, the density functional theory is used with the local density approximation (LDA).[39] The integration in *k* space was performed by an improved tetrahedron method[40] on grids of 462 irreducible *k* points of the first Brillouin zone. Void space was filled with four so-called empty spheres. As structure models, we chose the structural parameters obtained from the refinements of $Hf_{0.84}Ti_{1.16}As$ and $Hf_{0.97}V_{1.03}As$ (using Hf parameters for M(1) and Ti and V parameters for M(2), respectively).

Eu^{III} Luminescence in a Hygroscopic Ionic Liquid: Effect of Water and Evidence for a Complexation Process

Isabelle Billard,*[a] Soufiane Mekki,[a] Clotilde Gaillard,[a] Peter Hesemann,[b] Gilles Moutiers,[c] Clarisse Mariet,[c] Alexandre Labet,[c] and Jean-Claude G. Bünzli[d]

Keywords: Ionic liquids / Lanthanides / Europium / Luminescence / Complexation

The spectroscopic characteristics (excitation, emission and lifetime) of Eu^{III} dissolved in 1-methyl-3-butylimidazolium bis(trifluoromethanesulfon)imide (BumimTf_2N) are reported. In a first series of experiments, the effect of the presence of water in BumimTf_2N was examined. It appears that non-degassed solutions are most probably inhomogeneous, displaying large water clusters leading to an intense diffusion of the red light of an He:Ne laser. In these samples, the Eu emission spectrum is close to that observed in slightly acidic aqueous solutions. In contrast, when the samples were degassed the solution appeared homogeneous and water can be considered as a competitive ligand for the first coordination sphere of Eu. In a subsequent series of experiments, tetrabutylammonium chloride (TBACl) was added to the solution and the resultant species investigated. The ensuing enhancement in the metal-centered luminescence has been interpreted in terms of changes in the inner coordination sphere of the Eu^{III} ion and possible structures are discussed. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Room-temperature ionic liquids (RTIL) appear as "multi-purpose liquids" able to replace usual organic solvents in almost every field of chemistry (e.g. catalysis, synthesis, electrochemistry).[1] Both the cationic and the anionic components of these liquids can be easily varied, and they can therefore be tailored for particular applications or to have specific sets of properties. As a consequence, RTILs represent a green alternative to volatile organic solvents, offering environmentally safe processes.

In particular, in the field of nuclear waste reprocessing, there is still a need for improved routes for the actinide/lanthanide separation/extraction. In addition to promising studies on the use of ionic liquids for liquid/liquid extraction,[2] a recent study has shown that some ionic liquids display reasonable stability under α and γ irradiation,[3] thus reinforcing their potential interest for the nuclear fuel industry. However, despite the increasing number of publications devoted to ionic liquids, the solvation effects, the solute-solvent and solvent-solvent interactions as well as the general structural organization of these solvents are still hardly known. These fundamental aspects are of tremendous importance for understanding the solvating properties of these new solvents, thus limiting their applications for liquid/liquid extraction. In order to gain a better insight into these questions, we have undertaken a spectroscopic investigation on the solvation of Eu^{III} in 1-methyl-3-butylimidazolium bis(trifluoromethanesulfon)imide (BumimTf_2N, see Scheme 1). This ionic liquid has been chosen because it can be used, among others, for biphasic separations such as liquid extraction in view of its hydrophobic properties. Eu^{III} has been chosen as a representative lanthanide ion and as a good homologue of Am^{III}, an actinide of great interest in the nuclear fuel cycle. In this work, we take advantage of the specific properties of Eu^{III} to investigate its solvation in BuminTf_2N by means of luminescence measurements. Specific attention has been paid to the role

of water (considered as a solute) in the luminescence properties of Eu^{III} and the effect of added tetrabutylammonium chloride has also been investigated.

Results and Discussion

Effect of Water on the Spectroscopic Characteristics of Eu^{III}

Results

Europium triflate (5×10^{-3} M) in $BumimTf_2N$ turns to a slight brownish color after degassing (procedure II, see Exp. Sect.) and a very weak absorption band located at 394 nm can be observed corresponding to the transition with the largest oscillator strength in the Eu^{III} spectrum namely the $^5L_6 \leftarrow {}^7F_{0,1}$ transition (Figure 1). The spectrum of a more concentrated and degassed solution (4×10^{-2} M) is displayed in Figure 2, from which a molar absorption coefficient of 0.8 $M^{-1}\cdot cm^{-1}$ (λ = 394 nm) could be estimated. This value is of the same order of magnitude as that reported for Eu^{III}(aq) i.e. 2.4 $M^{-1}\cdot cm^{-1}$.[4] In two previous studies,[5,6] various lanthanide triflates were dissolved in RTILs, particularly in $BumimPF_6$, at concentrations far below the maximum concentration obtained by us. This may be due in part to the use, in these studies, of anhydrous lanthanide salts.

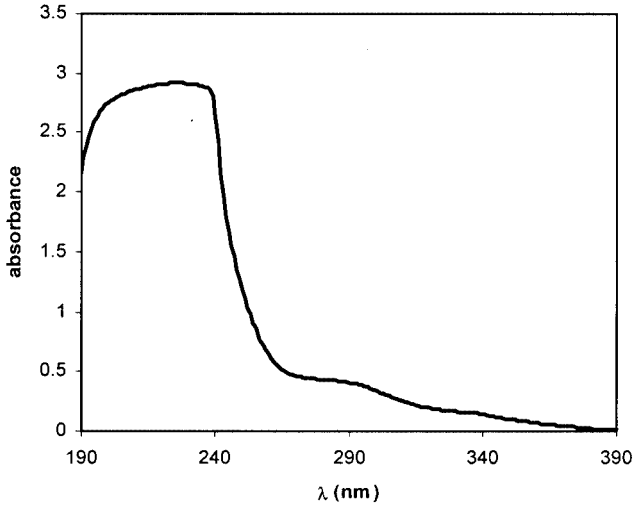

Figure 1. Absorption spectrum of the $BumimTf_2N$ batch used in this work (non-degassed)

RTILs are known to be hygroscopic[1,7,8] and previous studies have provided insight into the dependence of the kinetics of water absorption by RTILs upon experimental conditions.[7–9] In order to obtain a deeper understanding of the influence of water on europium luminescence in $BumimTf_2N$, a solution was submitted to cycles combining various degassing procedures and storage durations during which the solution was simply kept in the quartz cuvette with a Teflon cap. Table 1 summarizes these cycles and displays the decay behavior (either mono- or biexponential),

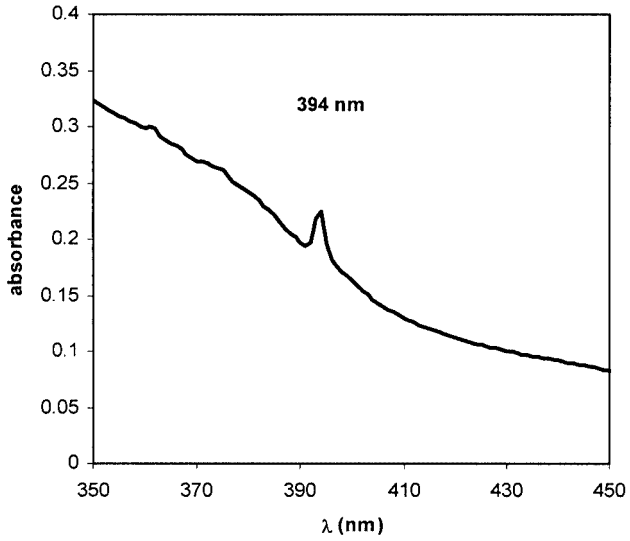

Figure 2. Absorption spectrum of the Eu^{III} triflate salt 4×10^{-2} M in $BumimTf_2N$

the corresponding lifetimes and relative intensities during the cycles. In this table, $t = 0$ corresponds to the end of the first degassing procedure and positive t values indicate the time elapsed since $t = 0$, when the data (decay profile and emission/excitation spectra) were recorded. By definition, the notation $t = -1$ means that the measurement was performed *before* this first degassing procedure when the ionic liquid water content was constant with time (see section "water contents"). Note that a lifetime decay could be obtained for the non-degassed (probably heterogeneous) sample, since no fluctuations of the luminescence intensity were observed. Figure 3 presents the excitation spectra obtained at times equal to −1, 0, and 13 d of the cycle, while emission spectra are displayed in two separate figures (Figure 4, a and b) in view of the large differences in emission intensities. For t = 25 d, the excitation and emission spectra are very similar to those for t = 13 d and are therefore not shown.

Table 1. Decay behavior, lifetime values (μs), relative intensities (%) and $R_{612/589}$ values for the Eu^{III} triflate salt in $BumimTf_2N$ along the degassing/storage cycle (see text)

t [d]	Procedure	Decay characteristics	$R_{612/589}$
−1	no degassing	monoexponential τ = 159 μs	< 1
0	degassing (I)	biexponential τ_1 = 643 μs (19%) τ_2 = 1596 μs (81%)	3.4
6	storage	monoexponential τ = 350 μs	n. d.
13	degassing (II)	biexponential τ_1 = 689 μs (85%) τ_2 = 2556 μs (15%)	3.4
20	storage	monoexponential τ = 681 μs	n. d.
25	storage	monoexponential τ = 545 μs	3.4

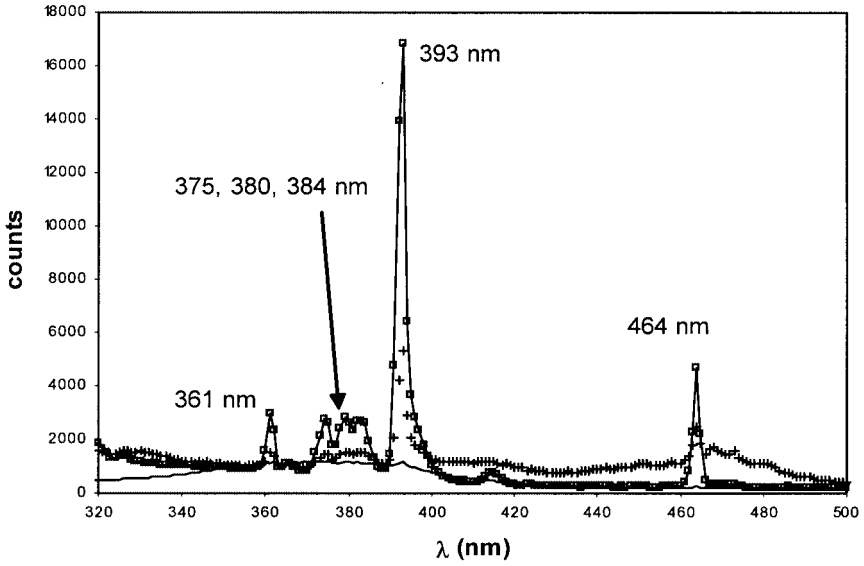

Figure 3. Excitation spectra of the Eu^{III} triflate salt 5×10^{-3} M in $BumimTf_2N$ during the degassing cycle; emission wavelength: $\lambda = 609$ nm; solid line: $t = -1$ d; open squares: $t = 0$ d (procedure I); +++: $t = 13$ d (procedure II)

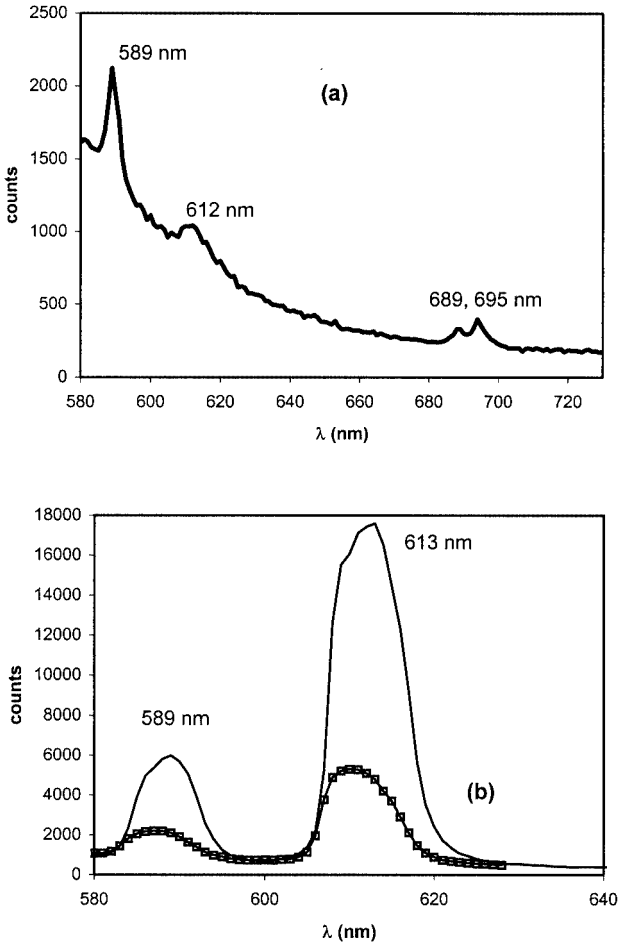

Figure 4. a: Emission of the Eu^{III} triflate salt 5×10^{-3} M in $BumimTf_2N$ at $t = -1$ d (see text and Table 1); excitation wavelength: $\lambda = 394$ nm; b: emission of the Eu^{III} triflate salt 5×10^{-3} M in $BumimTf_2N$ in function of the degassing procedure (see text and Table 1); excitation wavelength: $\lambda = 393$ nm; solid line: $t = 0$ d (procedure I); open squares: $t = 13$ d (procedure II)

For all samples the excitation spectra essentially display f-f transitions, indicating no antenna effect from the ionic liquid. The energies of these transitions do not vary which is in contrast to their intensities which substantially decrease over time after the first degassing procedure. Similar behavior was observed for the emission spectra and lifetimes. Using excitation at other wavelengths (data not shown), the emission was similar in shape and the intensity change reflects the relative intensities observed in the excitation spectra. The lifetimes exhibit peculiar behavior: a single exponential decay was measured for the non-degassed solution with a short lifetime of 0.159 ms, which became biexponential upon degassing, with much longer lifetimes of 0.64 and 1.6 ms. After 6 d of storage, the decay was again characterized by a single exponential but this again became biexponential after the second degassing. For the air- and water-tight solution, biexponential behavior was still observed more than 12 d after degassing and the lifetime values were perfectly stable.

Discussion

The intense diffusion of the He:Ne laser light by the non-degassed europium solution compared with almost zero diffusion for pure non-degassed $BumimTf_2N$ points to the presence of large aggregates (clusters) in the former. Hence the non-degassed europium solution, which contains approximately 80 H_2O molecules per Eu^{III} ion, should be better considered as being an emulsion. The emission spectrum of the non-degassed sample (Figure 4, a) is very similar to the one obtained for $Eu^{3+}{}_{aq}$ in slightly acidic aqueous solution,[4,10] although the corresponding lifetime is larger (0.159 ms compared with 0.111 ms for $Eu^{3+}{}_{aq}$, see Table 1). The presence of high-energy O−H oscillators in the inner coordination sphere of Eu^{III} is known to induce a severe quenching of the luminescence.[11] The short lifetime measured for the ionic liquid solution suggests that Eu^{III} is heav-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ily hydrated, possibly to the same extent as in an aqueous solution. Indeed, triflate is only slightly more coordinating than perchlorate[12] and should not bind to the Eu^{III} ion in water. In contrast, no data are available on the coordinating strength of Tf_2N^- but since it is present in large excess in the solutions, inner-sphere coordination cannot be excluded. The longer lifetime measured in the RTIL could be due to the limited amount of water in $BumimTf_2N$ leading to a decreased inner-sphere hydration number n and/or a decreased outer sphere hydration number m in the $\{[Eu(A^-)_x(H_2O)_n]^{(3-x)+}(H_2O)_m(A^-)_{(3-x)}\}$ aggregates (A^- stands for an anion). In water, n is fractional (and x is essentially equal to zero), reflecting a fast equilibrium between 8- and 9-coordinate species,[13] while both nona- octa- and hexahydrated Ln^{III} ions have been evidenced in the solid state. The contribution of second-sphere oscillators to the luminescence decay is not well known, but in the case of Eu^{III} complexes with cyclen derivatives, it has been estimated to be 0.25 ms^{-1}.[14]

In contrast, the degassed sample at the beginning of the cycle ($t = 0$) exhibited completely different Eu^{III} spectroscopic properties, indicating a large loss of inner-sphere water molecules. This is illustrated by the increased intensity of the hypersensitive transition ($^5D_0 \rightarrow {}^7F_2$) at ca. 613 nm by a factor > 3 (see Figure 4, b). The relative broadness of the bands and their lack of crystal-field fine structure may indicate that Eu^{III} is imbedded into a medium with properties similar to those of a glass. The degassing procedure drastically decreases the total water amount but some water remains. A water content of 50 ppm still corresponds to one molecule of water per Eu^{III} ion.

No information can be gained on which form of water is better extracted in the degassing procedure[9] whether already accommodated in the solvent prior to solution preparation or introduced with the europium salt. As a matter of fact, the absence of laser light diffusion after degassing is evidence for a homogeneous solution and the changes in the emission spectra show that europium is now solvated in the RTIL and no longer in "water clusters". The biexponential behavior of the luminescence decay either in the air- and water-tight cuvette or at the beginning of the storage can be considered to reflect the presence of two different Eu^{III} species in solution. One explanation could be the formation of inner-sphere complexes with the counterions [Equations (1) and (2)].

$$\{[Eu(H_2O)_n]^{3+}(H_2O)_m\} \rightleftarrows [Eu(H_2O)_n]^{3+} + m\,H_2O \rightleftarrows [Eu(H_2O)_x]^{3+} + (m + n - x)\,H_2O \quad (1)$$

$$[Eu(H_2O)_x]^{3+} + y\,A^- \rightleftarrows [Eu(A)_y(H_2O)_{x-y}]^{3-y)+} + y\,H_2O \quad (2)$$

In Equation (2), A^- has been taken as being a monodentate anion, but the triflate could also be bidentate or even act as bridging moiety. The latter assumption is, however, not very probable in view of the relatively high dilution of the solutions. In water, phenomenological calibration curves have been reported which relate the number of inner-sphere water molecules to the lifetimes measured in water and deuterated water.[11,15] In the absence of structural information on the solvated species in RTILs, and because these phenomenological correlations cannot be easily transposed from one solvent to another, no such relationship is available and therefore an estimate of x is not within reach with the present lifetime data. We note, however, that 1.6 ms is a rather long lifetime [cf. 2.10 ms for $Eu(ClO_4)$ in anhydrous acetonitrile][16] and since the RTIL medium is not dielectrically too different from an organic solvent, the associated species probably contains, on average, less than one water molecule. The subsequent transformation of the decay into a single exponential curve, with a concomitant decrease in lifetime after few days of storage reflects a rehydration of the Eu^{III} ion, although not completely, since both the lifetime and the $R_{612/589}$ ratio remain substantially larger than in the non-degassed solution. We have interpreted this in terms of several different hydrated species being in equilibrium. When several water molecules are coordinated in the inner sphere, their lifetimes become comparable. This makes a mathematical resolution of the decays difficult. Moreover, fast water exchange reactions lead to an averaging of the species on the time scale of the luminescence experiment (ms).

After applying degassing procedure II (see Exp. Sect.), the solution again contained two Eu^{III} species, one having a relatively short lifetime (which corresponds to the short lifetime measured after procedure I was applied), while the other featured a much longer lifetime than the long lifetime of the previous sample. This clearly demonstrates that further dehydration has occurred. The value of this lifetime, 2.56 ms, probably implies that an anhydrous species has been formed but again, this assessment will need to be confirmed by determining the exact nature of the species in solution. When re-hydration occurred, the decay turned again into a single exponential curve with a lifetime intermediate between the ones obtained after the first and the second degassing procedures.

The results presented above are of great practical interest and show that, for luminescence measurements, caution should be paid to the degassing procedure and to the water intake by the sample. It should be stressed, however, that luminescence measurements can be performed with reasonable confidence (i.e. results are reproducible) because, as can be seen from Table 1, the absorption of water under our experimental conditions was slow. These slow kinetics compared with those observed by Seddon and co-workers[8] or by Tran and co-workers[9] are mainly due to the absence of vigorous stirring and to the use of a cap for the cuvettes in our case.

Spectroscopy in the Presence of Tetrabutylammonium Chloride (TBACl)

Results

The data presented in Figures 5−8 were recorded immediately after the end of the degassing procedure. Figures 5 and 6 display the excitation and emission spectra for

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ratios r = [TBACl]/[Eu] = 4.5, 6 and 9. Compared with Figures 3 and 4, the main difference is the strong band centered around 330 nm seen in the excitation spectra and the well-defined structure in the Eu emission spectra. For comparison, a solution containing only TBACl in $BumimTf_2N$ displays a single very broad band of very low intensity centered at 375 nm.

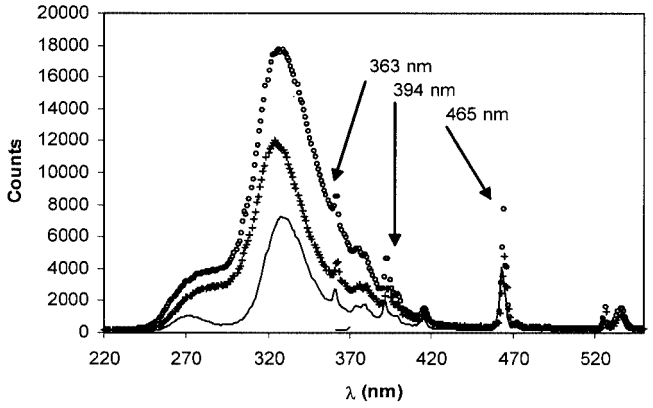

Figure 5. Excitation of the Eu^{III} triflate salt 5×10^{-3} M in $BumimTf_2N$ containing TBACl; emission at λ = 608 nm; solid line: r = 9; +++: r = 6; open circles: r = 4.5

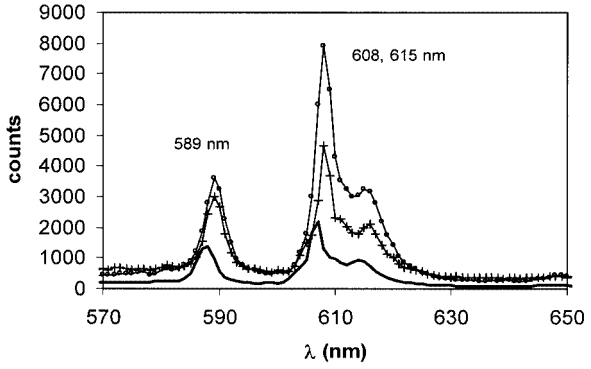

Figure 6. Emission of Eu^{III} triflate salt 5×10^{-3} M in $BumimTf_2N$ containing TBACl; excitation wavelength: λ = 464 nm; solid line: r = 9; +++: r = 6; open circles: r = 4.5

The total excitation intensity decreases as a function of r, as does the total emission intensity. For all the samples, in contrast to what was obtained without TBACl, the luminescence decays are single exponential curves, even after the degassing procedure. The Eu^{III} lifetime values as a function of the total TBACl amount are displayed in Table 2. Although incomplete dissolution occurs for $r < 4.5$, a lifetime value could be obtained.

Table 2. Lifetime values for the solutions of the Eu^{III} triflate salt containing added TBACl

r = [TBACl]/[Eu]	τ [μs]
3.5	2038
4.5	2060
6	2560
9	2760

The excitation and emission spectra of the Eu^{III}/TBA-triflate/$BumimTf_2N$ solution (r = 6) are displayed in Figures 7 and 8, together with the data for TBACl for the sake of comparison. Compared with the addition of chloride, the emission intensity was lower when the triflate was added and the bands were much broader.

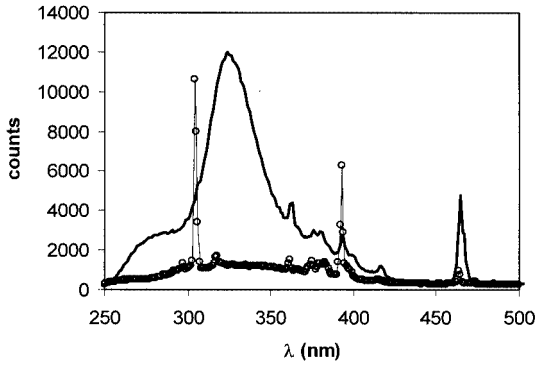

Figure 7. Excitation spectra of solutions of the Eu^{III} triflate salt 5×10^{-3} M in $BumimTf_2N$ (λ_{em} = 608 nm); solid line: with TBACl, r = 6; open circles: with TBA-triflate, r = 6; the sharp peak at 304 nm is due to the excitation light (608 nm is the second harmonic)

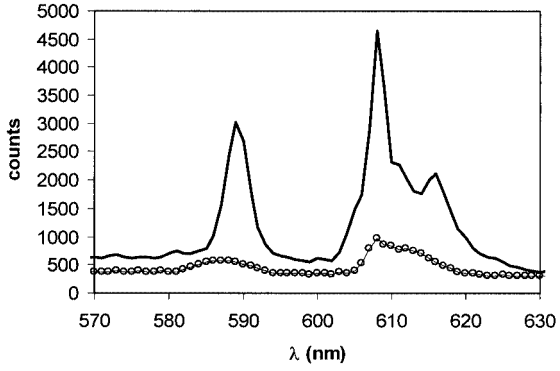

Figure 8. Emission spectra of solutions of the Eu^{III} triflate salt 5×10^{-3} M in $BumimTf_2N$ (λ_{ex} = 464 nm); solid line: with TBACl, r = 6; open circles: with TBA-triflate, r = 6

The effect of progressive water absorption by $BumimTf_2N$ as a function of time has also been studied. In the case of TBACl, and in contrast to the solutions to which no TBA salt was added, the increasing amount of water had no effect at all on the Eu^{III} lifetime and decay behavior for r = 9. Even after 22 d of storage, the lifetime changed by less than 10 μs. On the other hand, the lifetime of the solution to which TBA triflate had been added decreased as a function of time (from τ = 1180 μs after degassing to 492 μs after 3 d of storage).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Discussion

There is no physical evidence for stating that the introduction of TBACl strongly modifies the course of the degassing procedure. Therefore, the single exponential behavior of the decays after the degassing procedure shows that the Eu^{III} coordination sphere is strongly modified compared with the solution without TBACl. This is also illustrated by the changes observed in the excitation and emission spectra as a function of *r*. In comparison with what is known about europium luminescence in other solvents,[16−18] these changes can be ascribed to a complexation process. Slight changes can be observed in the emission spectra at $r = 3$ and 9, especially in the value of $R_{612/589}$. This experimental fact, together with the reduced solubility observed for $r < 4.5$ would indicate that at least two different complexes are present in solution, depending on *r*. TBACl is a 1:1 electrolyte, but it is not clear from our experiments whether it is entirely dissociated in $BumimTf_2N$. Although a detailed symmetry analysis is not possible due to the relative broadness of the emission bands, we note that $^5D_0 \rightarrow {}^7F_1$ generates one symmetrical band while 2−3 components can be seen for the $^5D_0 \rightarrow {}^7F_2$ transition, indicating a relatively high symmetry around the Eu^{III} ion. Trivalent europium is known to form a stable hexachloride with an elpasolite structure and O_h symmetry.[19] In ethanol solution, this species either dissociates or reacts with the solvent to give a species with D_2 symmetry.[20] It is noteworthy that the $^5D_0 \rightarrow {}^7F_2$ spectrum reported for the latter species is very similar to the one reported in Figure 6 for $r = 6$ and so are the spectra for $[Cl^-]/[Eu] = 26$ (in ethanol)[20] and $r = 9$ (Figure 6). Therefore we may safely conclude that upon addition of TBACl, polychloro species are formed in RTIL solution.

The implications of single exponential behavior of the decays of the emission spectra and the lifetime values changing as a function of the ligand concentration (TBACl case) have been discussed long ago[21] and have been revisited recently.[22] Both papers agree that such experimental facts point to a photochemically induced complexation reaction occurring in the solution. It was also agreed that the excitation and emission data collected for $r = 9$ (lifetime plateau value, see Table 2) are those of the higher complex obtained with a lifetime of 2760 μs.

The luminescence enhancement observed could be explained in two ways: (i) the interaction of chloride ions in the inner coordination sphere results in a ligand-to-metal transfer state reflected in the excitation spectrum (Figure 7) and energy transfer takes place between this state and Eu^{III}. Such a state is observed around 33 000 cm^{-1} [23] for $[EuCl_6]^{3-}$ in the solid state and excitation in such states may result in metal-centered luminescence when they lie at relatively high energy, which is the case here. Moreover, the spectrum displayed in Figure 8 (top) matches perfectly well the one published earlier for $[EuCl_6]^{3-}$ in ethanol.[20] (ii) The inner-sphere chloride ions act as relays between the metal ion and the $Bumim^+$ or TBA^+ cations in the second solvation shell, allowing a through-bond energy transfer.

Finally, the quite different spectroscopic properties observed upon addition of TBA triflate, in particular the absence of luminescence enhancement, point to a much weaker interaction between the added anions and the metal ion so that competition with water molecules easily leads to hydrated species with quenched luminescence.

Conclusion

For the first time, a spectroscopic investigation of Eu^{III} dissolved in $BumimTf_2N$ has been conducted particularly with respect to the effect of water and added TBA chloride. The results pinpoint the importance of degassing procedures and storage conditions, in view of the highly hygroscopic nature of the solvent. A complexation process between Eu^{III} and the added TBA salts has been evidenced and some insight into the species in equilibrium and the composition of the inner coordination sphere of Eu^{III} has been obtained. A first conclusion is that the behavior of the Eu^{III} ion in degassed $BumimTf_2N$ displays trends similar to that exhibited in other organic hygroscopic solvents (e.g. acetonitrile or ethanol), with respect to both its coordination and spectroscopic properties. On the other hand, non-degassed solutions exhibit a highly inhomogeneous nature. In view of the evaluation of RTILs for use in future lanthanide/actinide extraction processes it is essential that basic data on the solvation of metal ions in these liquids be at hand. From this standpoint, the results presented here are very encouraging since they demonstrate that complexation processes analogous to those in common solvents take place in the investigated RTIL, and that they can be monitored by a highly sensitive technique such as time-resolved luminescence. However, some differences have also been unraveled and we are now concentrating our efforts on gathering structural data on these solutions in order to get a much deeper understanding of the nature of the solvated and complexed species in equilibrium.

Experimental Section

Synthesis of $BumimTf_2N$ and Experimental Methods: All chemicals were of the highest reagent grade (Aldrich) and were used without further purification. All aqueous solutions were prepared with deionized water (Millipore de-ionization system, $\omega = 18.3\ M\Omega\ cm^{-1}$). The synthesis of $BumimTf_2N$ was derived from the previously reported synthesis of $BumimPF_6$ [23] and was typically performed as described in the following.

First Step. Synthesis of BumimCl: A three-necked round-bottom flask under argon, equipped with a water refrigerant, was loaded with methylimidazole (1 mol, 82.11 g) and *n*-chlorobutane (1 mol, 92.57 g). The mixture was stirred under argon at 70 °C for 48 h until the appearance of a pale yellow viscous mixture. This was then transferred into a flask and stored at 3−5 °C under argon until quantitative precipitation (ca. 12 h). White crystals were obtained which were washed several times with ethyl acetate and filtered each time with a Büchner apparatus. The crystals were transferred to a dry box containing phosphorus pentoxide and placed

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

under vacuum. A fine white powder of BumimCl was obtained. Yields were typically around 80%.

Second Step. Synthesis of BumimTf$_2$N: A solution of BumimCl (110 g) in water (150 mL) was added to a solution of LiTf$_2$N (200 g) in water (300 mL) and the resultant mixture was stirred at 70 °C for 16 h. Two phases were obtained and the upper layer (aqueous) was decanted. The lower phase (BumimTf$_2$N) was washed several times with de-ionized water (10 × 350 mL). BumimTf$_2$N, as a transparent and slightly viscous liquid, was transferred and stored in a dry box under vacuum containing phosphorus pentoxide. Typical yields: ca. 80%. The water content of the samples was determined by Karl Fischer titration, using standard procedures (Mettler DL18 titrator, hydranal composite 5 (Fluka) and analytical grade methanol). Absorption spectra in the range 190−900 nm were recorded with a Uvikon 930 (Kontron) spectrometer with 1-cm quartz cuvettes. In all cases, the reference was an empty quartz cuvette. No precaution was taken for the storage of the samples which were simply left in the quartz cuvettes (with Teflon cap), so that the water content may have changed with time (see the relevant study in the text). Emission and excitation spectra were recorded with a classical spectrofluorimeter (Photon Technology International) which does not allow for time-resolution but was corrected for gain efficiency of the detector. Data are also presented as $R_{612/589}$, the ratio of the intensity of the $^5D_0 \rightarrow {}^7F_2$ transition (around 612 nm) with that of the $^5D_0 \rightarrow {}^7F_1$ transition (around 589 nm) for an excitation at λ_{exc} = 394 nm. The uncertainty on the value of $R_{612/589}$ is in the range of ±10%. The time-resolved emission spectroscopy (TRES) apparatus has been described in detail elsewhere.[24,25] Briefly, for decay measurements, the excitation wavelength was set to 266 nm and the decays were recorded at λ = 612 or 589 nm, depending on the transition efficiency. As is usual for time-resolved experiments of this kind, the data analysis was performed by systematically excluding the first 10 μs of each decay, for which the intense short-lived luminescence of the pure BumimTf$_2$N dominates and thus precludes any detection of the long-lived europium species. Therefore, in the following, the discussion of the decay behavior only corresponds to lifetimes ascribable to Eu^{III}. The importance of the decay behavior (either mono- or multiexponential) has been stressed in other papers[22,26] and the quality of the fits was assessed both by the usual χ^2 test and the shape of the residuals (experimental minus calculated values). The error in the lifetime values was of the order of ±3%. Although the measurements of the luminescence spectra and decays are easy to perform under the experimental conditions of this work, they cannot be conducted under optimum conditions for europium assays. For most of the feasible excitation wavelengths, the absorption of the sample was way above the usual 0.05 limit, for which a linear relationship holds between concentration and emission intensity, because of solvent absorption. All experiments were performed at a controlled temperature of 294 K.

Purification and Characterization: The purification procedure previously used for BumimPF$_6$ [27] was also applied to BumimTf$_2$N. However, the absorption band in the range 250−300 nm observed for non-purified BumimPF$_6$,[27] was still present in the absorption spectrum of the purified BumimTf$_2$N (Figure 1). It is probable that some organic impurities still remain. To the best of our knowledge, the absorption spectrum of ultra-pure BumimTf$_2$N is not known, so that comparison with our batch is impossible. On the other hand, repeated measurements of the absorption spectrum showed that the BumimTf$_2$N batch used in this work was stable for more than four months. Due to the synthetic procedure, BumimTf$_2$N contains water even after purification on an alumina column. The presence of water is a common feature of room-temperature ionic liquids[1,7,28,29] and numerous works have pinpointed the large influence of water on various physico-chemical properties of RTILs.[8,30] This very important point will be addressed in this work.

Water Contents and Dissolution of Salts in BumimTf$_2$N: A previous study[8] focused on the effect of water on the properties of various RTILs, such as BumimBF$_4$ or BumimPF$_6$. In particular, it was shown that above a certain water content (around a molar fraction of 0.5), the viscosities and densities of the resultant mixtures became water-like, so that these samples have to be considered as aqueous solutions of RTILs and not as hydrated RTILs. Another study has shown that water absorption by BumimTf$_2$N may be rapid and important.[9] For the BumimTf$_2$N batch used in this work, the amount of water was equal to 5000 ± 50 ppm (i.e. 0.4 M or 0.5% w/w) after purification. This is a consequence of the numerous water washes at the end of the synthesis and the subsequent purification on the alumina column. This batch is thus not water-saturated when compared with values of up to 14000 ppm reported in the literature for BumimTf$_2$N,[1] but nevertheless contains a substantial amount of water. After several months of storage, the water content did not change much as shown by a new determination of the water content of 5100 ± 500 ppm. In order to control the water content of the samples, we degassed them according to two different methods. In procedure I, batches of 5 mL were pumped at room temperature for 18 h and, additionally, at 50 °C for 10 h (residual pressure: 1.8 mbar); the resultant water content was below 100 ppm (i.e. 8×10^{-3} M or 0.01% w/w). In a few cases (see below), samples were further degassed at 70 °C for 48 h (procedure II). Finally, a solution of europium triflate was degassed (procedure I) directly in a quartz cuvette connected to the degassing setup by a quartz-glass tube. In this case, by use of a tap, the solution in the cuvette was air- and water-tight but, due to the bulkiness of the setup, only lifetime measurements could be performed. Europium(III) triflate (Aldrich), tetrabutylammonium chloride (Aldrich) and triflate (Aldrich), and NaCl (Prolabo) were used as received. Hygroscopic salts were kept in a desiccator with P_4O_{10}. Unless otherwise specified, the europium concentration was 5×10^{-3} M. Possible changes in density from one sample to another due to different water contents were not considered in the determination of the concentration. A common value d = 1.43 for the density (non-degassed BumimTf$_2$N) has been assumed for all the BumimTf$_2$N samples in this work. Even though the europium triflate salt contains 4 water molecules per europium unit, the amount of water introduced with the salt is negligible compared with the water already present in the non-degassed solvent. Upon addition of europium triflate to BumimTf$_2$N, a slightly cloudy solution was obtained which indicates either an incomplete dissolution or, more probably, the formation of inhomogeneous clusters. In fact, these samples strongly diffuse the red light of an He:Ne laser. On the other hand, light diffusion was no more clearly observed even after degassing the samples using procedure I (solutions become clear) or II, so that these samples may be considered as being homogeneous (see also discussion). Various amounts of tetrabutylammonium chloride together with europium triflate (r = [TBACl]/[Eu^{III}] = 3−9) were introduced into BumimTf$_2$N. Due to the very slow rate of dissolution, a small amount of CH_3CN (on the order of 0.5 mL), which is totally miscible in BumimTf$_2$N, was also added to the BumimTf$_2$N solutions prior to degassing in order to speed up the process. Considering the vapor pressure, it can be safely assumed that all CH_3CN was removed at the end of the degassing procedure. Despite this modified dissolution procedure, not all the salts dissolve for r < 4.5, even after degassing (procedure I). No attempts were

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

made to determine the exact composition of the undissolved residue. For $r > 4.5$, dissolution was fully achieved after degassing. Finally, a single solution of europium triflate with tetrabutylammonium triflate (TBA-triflate, $r = 6$) was prepared and degassed.

Acknowledgments

This work has been performed with the financial help of the French "Groupement de Recherches" PARIS. We thank Prof. K. R. Seddon for an interesting discussion about degassing procedures. The help of Dr. M. Roynette for the Karl Fischer measurements is greatly acknowledged. J.-C. G. B. is grateful to the Swiss National Science Foundation for financial support.

Long Range Metal-Metal Interactions Along Fe−NC−Ru−CN−Fe Chains

Tianlu Sheng[a] and Heinrich Vahrenkamp*[a]

Keywords: Chain structures / Cyanide complexes / Polynuclear complexes / Metal−metal interactions

Trinuclear complexes with linear Fe^{II}–NC–Ru^{II}–CN–Fe^{II} arrays were obtained by attachment of FeCp(dppe) units to the cyanoruthenium complexes *trans*-[$Ru(CN)_2(Py)_4$] (Py = pyridine, 4-methylpyridine, 4-ethylpyridine) . From their cyclic voltammograms it can be concluded that there are long-range metal–metal interactions between their external iron centers. Partial oxidation led to the isolation of the corresponding mixed-valent Fe^{II}–NC–Ru^{II}–CN–Fe^{III} complexes. For these the long range metal–metal interactions are evident from a broad MMCT band in the NIR spectra. The MMCT properties were quantified by an analysis using the Hush formalism.

Introduction

Cyanide-linked coordination polymers have attractive optical, electrical and magnetic properties.[1−3] The basis of these are metal−metal interactions across the bridging cyanide ligands. For this reason numerous studies have been undertaken on cyanide-bridged low-molecular complexes, with the purpose of elucidating the molecular equivalents of the bulk properties in terms of electron transfer, metal−metal charge transfer and molecular magnetism.[4]

The simplest objects of study in this respect would be chain-like complexes with linear arrays of metals and bridging cyanide ligands. It turns out, however, that long chains of this kind are difficult to synthesize, and until today no such complex with more than three metal atoms has been unambiguously identified in solution or obtained analytically pure. Moreover, proof of long-range metal−metal interactions in trinuclear complexes with M−CN−M′−CN−M arrays, for instance by the typical splitting of the cyclovoltammetric redox waves, has been achieved in only a rather small number of cases.[5,6−8]

Our own investigations in the area of chain-like cyanide-bridged trinuclear complexes have virtually doubled the number of species for which evidence of remote metal−metal interactions exists.[9−14] For the first time we could also subject a group of such complexes to preparative one-electron oxidations and isolate mixed-valent trinuclear complexes with Fe^{II}-(μ-CN)-Pt^{II}-(μ-CN)-Fe^{III} arrays.[9] Yet, despite a wide variation of the building blocks, the supporting ligands, the oxidation states of the metals and the shape of the M−CN−M′−CN−M chains we have not yet found conclusive evidence as to which factors govern the occurrence and the extent of their remote metal−metal interactions.

The present study contributes one such piece of evidence. The complexes under investigation have *trans*-[$Ru^{II}(CN)_2Py_4$] units at the center and FeCp(dppe) units at the external positions which turned out to be favorable for redox reactions and spectroscopic measurements. $RuPy_4(CN)_2$-centered complexes with external $Ru(NH_3)_5$ [7] and $Ru(Py)_4Cl$ units[15] have already been described and subjected to electrochemical and spectroscopic measurements as well as a theoretical treatment of vibronic coupling in them.

Results and Discussion

Preparations and Structures

Previously we have investigated L_nM-(μ-CN)-$M'^{II}(Py)_4$-(μ-CN)-ML_n complexes with M'^{II} ions from the first row of the transition metals at the center.[16] Their octahedral $M'X_2Py_4$ cores are labile, and hence $M'(NC)_2Py_4$ arrangements in the trinuclear complexes could not be prevented, even when starting from $M'(CN)_2Py_4$ complexes (cyanide-isocyanide rearrangement). In contrast, octahedral Ru^{II} complexes are quite inert, and it could be anticipated that the *trans*-[$Ru(CN)_2Py_4$] array would be maintained after the attachment of two organometallic L_nM units. This was expected to be favorable in two respects: first, the attachment of the cyanide's carbon terminus (the π-acceptor orientation of CN^-) to ruthenium should raise the Ru^{II}/Ru^{III} redox potential, and second the attachment of the nitrogen terminus (the σ-donor orientation of CN^-) to the L_nM unit should lower the redox potential of the latter. Hence it would be likely that a partially oxidized (i.e. mixed-valent) species would have the oxidation state M^{II}−NC−Ru^{II}−CN−M^{III}, and that electronic communication between M^{II} and M^{III}

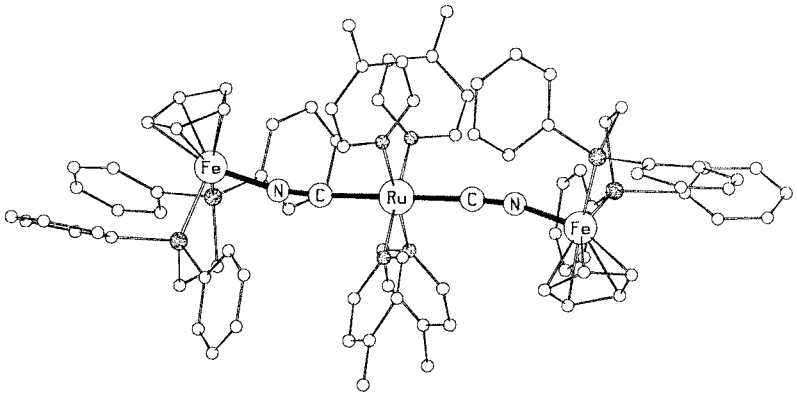

Figure 1. Molecular structure of the trinuclear cation of **2b**

would be facile[9] due to the *trans*-configuration of the central Ru^{II} ion.

The combination of $RuPy_4$ and FeCp(dppe) units confirmed this assumption. [$Ru(CN)_2Py_4$] complexes [Py = pyridine (**1a**), 4-methylpyridine (**1b**) or 4-ethylpyridine (**1c**)] were synthesized in which the variation of the pyridines provided a variation of the electron density at ruthenium. Their treatment with [FeCp(dppe)(CH_3CN)]Br yielded the trinuclear complexes [Cp(dppe)Fe−NC−$RuPy_4$−CN−Fe(dppe)Cp] $(PF_6)_2$ (**2a**−**c**) in a straightforward way. When crystallized with PF_6 counterions, **2a**−**c** are orange, air-stable, crystalline solids.

The identities of **2b** and **2c** were confirmed by crystal structure determinations. Figure 1 shows the structure of **2b** as a representative example. Table 1 lists the relevant bond lengths and angles.

Table 1. Relevant bond lengths (Å) and angles (°) in **2b** and **2c**

	2b	**2c**
Ru−N(Py)	2.086−2.120(7)	2.094−2.099(3)
Ru−C(CN)	2.061(9)	2.034(3)
C−N(CN)	1.16(1)	1.164(4)
Fe−N(CN)	1.911(7)	1.923−1.931(3)
Fe−P	2.185−2.195(3)	2.202−2.206(1)
N−Ru−N	89.2−90.3(3)	86.4−91.7(1)
C−Ru−N	88.0−90.8(3)	88.7−91.7(1)
C−Ru−C	178.3(5)	177.9(1)
Ru−C−N	175.2(7)	176.3−177.5(3)
Fe−N−C	166.6(7)	170.9−174.8(3)

The two structural units of complexes **1**, the $Ru(CN)_2Py_4$ unit and the Cp(dppe)Fe−NC unit, compare favorably with those in related complexes. Various $RuPy_4X_2$ complexes,[17] including $Ru(CN)_2Py_4$,[15] display the close to ideally octahedral coordination of ruthenium and the *trans* arrangement of the two ligands X. The isocyanide-ligated FeCp(dppe) unit is almost superimposable with that in dinuclear Cr−CN−Fe[18] and trinuclear Pt(CN-Fe)$_2$ complexes.[9] The electronic situation of complexes **2** is nicely reflected in the bond lengths and angles along the Ru−C−*N*−Fe arrays. The withdrawal of electron density from the cyanide ligand enhances the Ru→C π-backbonding, thereby making the Ru−C bonds rather short (cf. the Ru−N bonds). Likewise the lack of significant Fe→N π-backdonation results in Fe−N bond lengths that are significantly longer than the Fe−C bonds in related complexes with M−*N*−C−Fe arrays.[9,16,18] The various degrees of π-backdonation also explain a feature which is observed here like in most of our other M−C−*N*−M′ complexes: for the cyanide ligand the M−C−N angle (here Ru−C−N) is always close to 180°, while the M′−*N*−C angle (here Fe−*N*−C) shows significant bending, the average value of which in complexes **2** is 170°.

Redox Chemistry

The cyclic and square-wave voltammograms of **2a**−**c** show three waves in the oxidative range (see Figure 2 and Table 2). The first two of these are a closely spaced pair assignable to the FeCp(dppe) units.[9,18] The third one, at high voltage, belongs to the $RuPy_4$ unit. Characteristically the position of the Ru^{II}/Ru^{III} wave responds to the nature of the pyridine ligands, the more electron-rich of which in **2b** and **2c** facilitate the oxidation. The redox potentials for the FeCp(dppe) units are typically lower than that of Cp(dppe)Fe−CN (0.48 V), reflecting the more electron-rich state of iron due to the attachment of the cyanide's nitrogen.

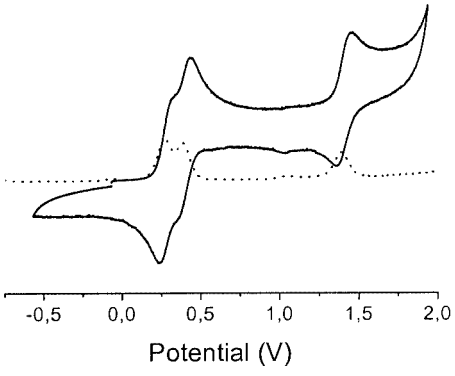

Figure 2. Cyclic (solid line) and square-wave voltammogram (dotted line) of **2b** (in CH_3CN, potentials vs. Ag/AgCl, scan rate 100 mV/s)

Table 2. Cyclovoltammetric data of complexes **2**[a]

	$E_{1/2}$ (1)	$E_{1/2}$ (2)	$E_{1/2}$ (3)
2a	0.29	0.40	1.52
2b	0.28	0.39	1.40
2c	0.27	0.38	1.40

[a] In CH_3CN, potentials (V) against Ag/AgCl, scan rate 100 mV/s.

The occurrence of two redox steps for the Cp(dppe)Fe units is the indicator of electronic communication between them. The potential separation of 110 mV is in the usual range.[9,12,13] Thus, complexes **2** are the third group of complexes synthesized by us for which a low-spin central unit with unfilled e_g orbitals enables electronic interactions between the two terminal redox-active organometallic units.

The potential separation is large enough to enable partial chemical oxidation of the FeCp(dppe) units. After treating **2a−c** with one equivalent of ferrocinium hexafluorophosphate in dichloromethane, the mixed-valent trinuclear complexes
$[Cp(dppe)Fe-NC-RuPy_4-CN-Fe(dppe)Cp](PF_6)_3$
(**3a−c**) could be isolated in good yields. Complexes **3** are only the second group of trinuclear complexes that have been isolated in the mixed-valent state. Prior to our work[9] the mixed-valent species could only be observed spectroscopically as transient species during redox titrations.

The identity of complexes **3** is evident from their analytical composition and from the fact that their voltammograms are identical to those of the corresponding complexes **2**. As before,[9] we failed to obtain crystals of a complex **3** suitable for X-ray analysis. Thus, the structural consequences of mixed valence in this type of complexes are still unknown. However, the spectroscopic data of **3a−c** (see below) clearly identify them as such.

Spectroscopy

The ν(CN) bands of complexes **1−3** (Table 3) provide good evidence for their structure and for their electronic situation. As expected, the symmetrical *trans*-configuration of the $Ru(CN)_2Py_4$ units in **1** and **2** gives rise to only one cyanide band in the IR spectra. Complexes **3**, with two distinctively different FeCp(dppe) units, show two widely separated ν(CN) absorptions.

Table 3. ν(CN) bands (in KBr, cm^{-1}) in the IR spectra

	1	**2**	**3**
a	2060	2071	2020, 2089
b	2055	2070	2014, 2090
c	2058	2070	2007, 2088

The ν(CN) band positions in complexes **2** are slightly raised relative to those in complexes **1**. As discussed by us several times before[9−13,16,18] this indicates that the kinematic effect (impediment of CN vibration due to the attachment of the second metal) is almost completely outbalanced by the π* effect (enhanced π-backdonation from ruthenium due to electron withdrawal by iron).

Complexes **3** provide a rare case of an internal reference for the size of these effects. The ν(CN) band position for the $Ru-C-N-Fe^{III}$ fragment is dramatically lowered because the Fe^{III} center is a much stronger electron acceptor than the Fe^{II} center. This induces a stronger π-backdonation from the Ru^{II} center into the CN-π* orbitals, causing a serious weakening of the C−N bond. We have observed this phenomenon in di- and trinuclear complexes before,[9,18] the most pronounced cases being the $L_nM-C-N-FeCl_3$ complexes with a ν(CN) band shift of −60 to −80 cm^{-1}.[19] The other ν(CN) band of complexes **3**, originating from the $Ru-C-N-Fe^{II}$ fragment, is now at significantly higher wavenumbers than in **1** or **2**. This is consistent with the opposite shift of the first band: there is less π-backdonation available on this side of the ruthenium atom, resulting in a lesser weakening of the C−N bond and hence a more pronounced appearance of the kinematic effect. Thus the IR spectra of complexes **1−3** are a demonstration of the classical *trans* effect observed in the IR spectra of octahedral metal carbonyls.

The absorptions in the electronic spectra of complexes **1−3** are listed in Table 4. Complexes **1** are yellow due to the tailing off of their strong absorption band in the near UV region. Complexes **2** are orange due to a weak absorption in the early visible range which results from the FeCp(dppe) units. Complexes **3** have deeper orange or brown colors which mostly results from an intensification of the latter absorption. This, in turn, results from the fact that the FeCp(dppe) absorption sits on the high-energy tail of a very broad medium-intensity absorption in the NIR. Figure 3 displays this for **3a**.

Table 4. Absorption bands [λ (ε·10^{-3})] in the visible and NIR spectra[a]

	1	**2**	**3**

c	376 (24.1)	368 (23.1), 560 (sh)	342 (21.6), 475 (1.9), 970 (3.6)

[a] Dichloromethane solutions, λ in nm, ε in $M^{-1}cm^{-1}$.

The NIR absorption is a typical MMCT band, and it classifies complexes **3** as class II mixed-valent species according to Robin and Day.[20] We assign it as a long-range $Fe^{II} \rightarrow Fe^{III}$ electron transfer across the *trans*-$Ru(CN)_2$ center, in analogy to such transfers for *trans*-PtL_2-[9] and Fe(Pc)-centered[12] complexes. Alternatively, it might be considered a $Ru^{II} \rightarrow Fe^{III}$ electron transfer across a single cyanide bridge, in analogy to our observations for related $Fe(bpy)_2$-centered complexes.[21] This, however, is unlikely based on the redox potentials observed for the Ru and Fe units (cf. Table 2) and on our observations for short-range MMCT in complexes with similar redox properties.[10,12]

The MMCT bands observed here occur at higher energies than the ones observed by us before for PtL_2-[9] and

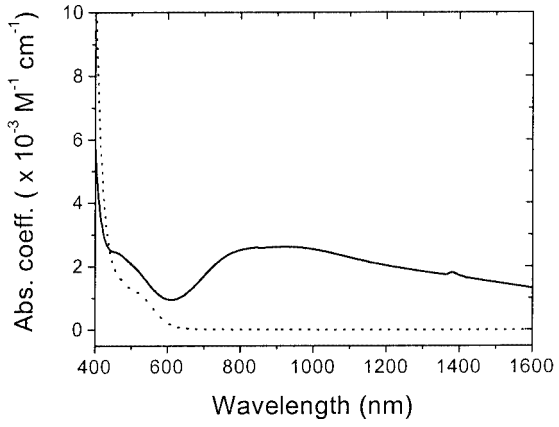

Figure 3. Electronic spectra of **2a** (dotted line) and **3a** (solid line) in dichloromethane

Fe(Pc)-centered[12] complexes with external FeCp(dppe) units. At first glance this might imply that the electronic interaction between the two iron centers is smaller than in the latter complexes. However, the quantitative treatment disproved this. It was done as before[9,12,18] by applying the Hush formalism for non-delocalized mixed-valent species according to Equation (1) and (2).[22]

$$H_{ab} = \tilde{\nu}_{max} a = 2.06 \cdot 10^{-2} (\tilde{\nu}_{max}/d)(\varepsilon_{max}\Delta\nu_{1/2}/\tilde{\nu}_{max})^{1/2} \quad (1)$$

$$a^2 = 4.24 \cdot 10^{-4} (\varepsilon_{max}\Delta\nu_{1/2}/\tilde{\nu}_{max} d^2) \quad (2)$$

For the computations $\tilde{\nu}_{max}$ was taken as 10000 cm^{-1} and $\Delta\nu_{1/2}$ as 6500 cm^{-1}, which is somewhat uncertain due to the large bandwidths of the MMCT bands. The value of d, the Fe−Fe distance, was taken from the structures of **2b** and **2c** as 10.2 Å. With these data the metal−metal interaction parameter, H_{ab}, is about 9000 cm^{-1} and the electron delocalization parameter a^2 about 0.8% for complexes **3**. Both these values are higher than the ones for the mixed-valent species with Fe^{II}−NC−Pt^{II}−CN−Fe^{III} backbones,[9] which indicates that the Fe···Ru···Fe system investigated here is a viable electronic conductor, as proposed in the introduction. In dinuclear species with M−CN−Fe(dppe)Cp arrays the electronic interaction between M and Fe, due to the 50% shorter distance, is naturally much stronger.[18,19]

Conclusions

This work has shown that Ru^{II} units with nitrogen ligands, which are famous as the external redox-active centers in classical mixed-valent dinuclear complexes,[23] are also favorable as the central units in trinuclear mixed-valent complexes. By a suitable choice of ligands on the three metal centers and by the suitable orientation of the bridging cyanide ligands it was ensured that a linear Fe−*N*−C−Ru−C−*N*−Fe array was obtained and that one-electron oxidations take place primarily at the iron centers. The basis for this is the inertness of octahedral Ru^{II}, which allows the unnatural orientation of the cyanide bridges (carbon attached to the electron-poor and nitrogen attached to the electron-rich metal) to persist.

These features have allowed, for the second time, the isolation of partially oxidized mixed-valent trinuclear complexes, i.e. the Fe^{II}−NC−Ru^{II}−CN−Fe^{III} species. Their spectroscopic investigation has identified their localized Fe^{II}/Fe^{III} nature and revealed a low-energy metal−metal charge transfer, which puts the complexes into class II of mixed-valent species according to the classification of Robin and Day. The electron delocalization parameter a^2 is of the order of 1%, which is considerably smaller than in related dinuclear complexes, but compares favorably with the values for other trinuclear complexes.

Among the trinuclear complexes of the type M-(μ-CN)-M′-(μ-CN)-M with organometallic units at the external positions only those with heavy and late transition metals at the center have allowed the detection of mixed valence by cyclic voltammetry and to investigate it by preparative redox chemistry, the prominent examples being those with Au^{I},[24] Pt^{II},[9] and Ru^{II} (this work). Their common feature is the low-spin electronic state with filled d_{xy}, d_{xz} and d_{yz} orbitals, i.e. those orbitals which provide π-interactions with the bridging cyanide ligands. This points to the π-bonding orbitals as the pathway for the metal−metal interactions. However, it is still too early to generalize this observation, and further studies, both preparative and theoretical, are necessary to gain a real understanding of these phenomena.

Experimental Section

For the general experimental and measuring techniques, see ref.[18] The starting materials $[RuCl_2(DMSO)_4]$,[25] $[Ru(CN)_2(pyridine)_4]$,[17] and $[FeCp(dppe)(CH_3CN)]Br$[26] were prepared as published.

1b: A mixture of $[RuCl_2(DMSO)_4]$ (300 mg, 0.62 mmol) and 10 mL of 4-methylpyridine was stirred at 100 °C for 30 min. After cooling to room temp. KCN (150 mg, 2.31 mmol) in 3 mL of water was added. After refluxing for 20 min all volatiles were removed in vacuo at 80 °C. The residue was extracted with 20 mL of dichloromethane. After filtration the extract was evaporated to dryness, leaving behind 230 mg (65%) of **1b** as a yellow powder, m.p. 280 °C (dec.). $C_{26}H_{28}N_6Ru \cdot 0.5CH_2Cl_2$ (525.62 + 42.46): calcd. C 56.03, H 5.15, N 14.79; found C 56.57, H 5.77, N 14.97.

1c: Prepared similarly to **1b** from $[RuCl_2(DMSO)_4]$ (300 mg, 0.62 mmol), 10 mL of 4-ethylpyridine and KCN (210 mg, 3.23 mmol). The dichloromethane extract was evaporated to 3 mL and chromatographed over a 10 × 1.5 cm silica gel column with CH_3CN/CH_2Cl_2 (1:4). A single yellow band was collected. Evaporation to dryness left behind 210 mg (51%) of **1c** as a yellow powder, m.p. 210 °C (dec.). $C_{30}H_{36}N_6Ru \cdot CH_2Cl_2$ (581.72 + 84.93): calcd. 55.85, H 5.75, N 12.61; found C 55.62, H 5.40, N 12.39.

2a: Complex **1a** (94 mg, 0.20 mmol) and $[FeCp(dppe)(CH_3CN)]Br$ (258 mg, 0.40 mmol) in 10 mL of dichloromethane were stirred for 8 h. NH_4PF_6 (68 mg, 0.42 mmol) was then added and the mixture stirred for a further 30 min. After filtration, slow diffusion of diethyl ether into the filtrate led, within one week, to the precipitation of 246 mg (63%) of **2a** as orange crystals, m.p. 180 °C (dec.).

$C_{84}H_{78}F_{12}Fe_2N_6P_6Ru{\cdot}2CH_2Cl_2$ (1798.16 + 169.86): calcd. C 52.49, H 4.20, N 4.27; found C 52.52, H 4.32, N 4.36.

2b: Complex **1b** (114 mg, 0.20 mmol) and [FeCp(dppe)(CH_3CN)]Br (258 mg, 0.40 mmol) in 10 mL of methanol were stirred for 3 days. Addition of NH_4PF_6 (91 mg, 0.56 mmol) produced a red precipitate. This was filtered off and extracted with 6 mL of dichloromethane. After filtration the filtrate was layered with 1 mL of petroleum ether (60−70 °C) and 10 mL of diethyl ether. Within one week 273 mg (67%) of **2b** had precipitated as orange crystals, m.p. 255 °C (dec.). $C_{88}H_{86}F_{12}Fe_2N_6P_6Ru{\cdot}2CH_2Cl_2$ (1854.27 + 169.86): calcd. C 53.40, H 4.48, N 4.15; found C 53.65, H 4.66, N 4.12.

2c: Prepared similarly to **2b** from **1c** (67 mg, 0.10 mmol), [Cp(dppe)-Fe(CH_3CN)]Br (129 mg, 0.20 mmol) and NH_4PF_6 (34 mg, 0.21 mmol). Yield 80 mg (38%) of **2c** as orange crystals, m.p. 230 °C (dec.). $C_{92}H_{94}F_{12}Fe_2N_6P_6Ru{\cdot}2CH_2Cl_2$ (1910.38 + 169.86): calcd. C 54.27, H 4.75, N 4.04; found C 54.31, H 5.04, N 4.07.

3a: [Cp_2Fe]PF_6 (6.6 mg, 0.02 mmol) was added to a solution of **2a** (39 mg, 0.02 mmol) in 6 mL of dichloromethane. After stirring for 1 h the mixture was filtered and the filtrate layered with 10 mL of petroleum ether (60−70 °C). After 3 days 20 mg (51%) of **3a** had separated as brown crystals, m.p. 155 °C (dec.). $C_{84}H_{78}F_{18}Fe_2N_6P_7Ru$ (1943.13): calcd. C 51.92, H 4.05, N 4.32; found C 52.36, H 4.49, N 4.32.

3b: Prepared similarly to **3a** from **2b** (41 mg, 0.20 mmol). Yield: 30 mg (75%) of **3b** as orange crystals, m.p. 250 °C (dec.). $C_{88}H_{86}F_{18}Fe_2N_6P_7Ru$ (1999.23): calcd. 52.87, H 4.34, N 4.20; found C 52.86, H 4.60, N 4.22.

3c: Prepared similarly to **3a** from (42 mg, 0.20 mmol) of **2c**. Yield: 24 mg (58%) of **3c** as orange crystals, m.p. 220 °C (dec.). $C_{92}H_{94}F_{18}Fe_2N_6P_7Ru$ (2055.34): calcd. C 53.76, H 4.61, N 4.09; found C 53.05, H 4.81, N 3.99.

Structure Determinations:[27] Crystals of **2b** were obtained by layering a solution of **2b** in dichloromethane with hexane/diethyl ether, and those of **2c** by slow diffusion of diethyl ether into a solution of **2c** in methanol/dichloromethane. Diffraction data were recorded at −30 °C on a Bruker Smart CCD diffractometer and subjected to empirical absorption corrections. The structures were solved and refined with the SHELX program suite.[28] All hydrogen atoms were included with fixed distances and isotropic temperature factors 1.2-times those of their attached atoms. Parameters were refined against F^2. The *R* values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = [\Sigma\{w(F_o^2 - F_c^2)^2\}/\Sigma\{w(F_o^2)^2\}]^{1/2}$. Drawings were produced with SCHAKAL.[29] Table 5 lists the crystallographic data.

The Electronic Structure of (Diiminopyridine)cobalt(I) Complexes

Quinten Knijnenburg,[a] Dennis Hetterscheid,[a] T. Martijn Kooistra,[a] and Peter H. M. Budzelaar*[a]

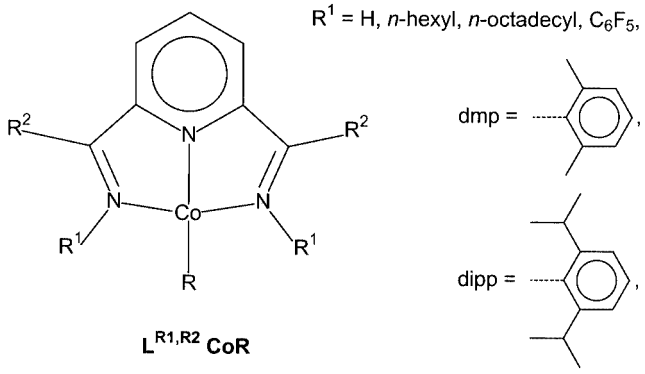
Keywords: Charge transfer / Cobalt / Density functional calculations / NMR spectroscopy / Radicals

DFT calculations show that square-planar $LCo^{I}R$ complexes of a diiminopyridine ligand are best regarded as containing low-spin Co^{II} antiferromagnetically coupled to a ligand radical anion. The lowest triplet state, corresponding to a $3d_{z^2} \rightarrow \pi^*$ excitation, is calculated to be only a few kcal/mol above the ground state, and is thermally accessible. The anomalous ^1H NMR chemical shifts of the LCoR complexes are suggested to be due to thermal population of the triplet state at room temperature.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Diamagnetic square-planar d^8 complexes of Co^{I} are much rarer[1,2] than the corresponding Rh^{I} and Ir^{I} species. Apparently, such Co^{I} species easily "escape" to the high-spin state or to higher oxidation states like Co^{II} or Co^{III}. Nevertheless, this type of Co^{I} complex is of great interest because the resemblance to its heavier Rh^{I} congener might be accompanied by a rich catalytic chemistry similar to that of Rh. Therefore, the recent observation that the diiminopyridine ligand L is able to stabilize Co^{I} in a low-spin, square-planar state,[3] while still leaving a coordination site available for further chemistry, is significant.



The complexes $LCo^{I}X$ (X = halide, alkyl) were reported to have unusual ^1H NMR chemical shifts for the pyridine Hγ and imine methyl groups,[3] when compared to the analogous Rh^{I} and Ir^{I} species.[4,5] The possibility that these unusual shifts might reflect an unusual electronic structure of the Co^{I} complexes prompted us to prepare a few additional Co and Rh complexes and to undertake a theoretical investigation of these species. In the present work, we report that the bonding in the Co^{I} species indeed shows several unexpected features. Diiminopyridine complexes of Co^{II} have been studied theoretically in the context of olefin polymerisation.[6] Experimental[7] and theoretical[8] studies of bis(diiminopyridine) complexes of the first-row transition metals Mn−Zn have revealed the non-innocent character of the ligand and the importance of biradical character in the metal-ligand interaction. The present work shows that biradical character can be even more pronounced in mono(ligand) complexes of cobalt.

Results and Discussion

Synthesis and Characterisation

2,6-Diacetylpyridine, anilines and amines are commercially available. 2,6-Dibenzoylpyridine is easily synthesised by Friedel−Crafts acylation of pyridine-2,6-dicarboxylic acid dichloride and benzene.[9] The diiminopyridine ligands were prepared from the condensation of two equivalents of the appropriate aniline or amine with diacylpyridine. The cobalt dichloride complexes can be synthesised in air. The reduction and subsequent alkylation of the cobalt dichloride complexes to monoalkyl complexes (e.g. $LCoCH_2SiMe_3$) can be achieved in one step using two equivalents of $LiCH_2SiMe_3$, or in two steps via a cobalt monochloride complex, as described earlier.[3] Alkyl complexes [$L^{dipp,Me}CoR$] having the bulky dipp group at R^1 react with hydrogen to form the hydride [$L^{dipp,Me}CoH$]. This complex is very reactive and could not be isolated in pure form, so it was only characterised by NMR spectroscopy. The complexes [LCoR], bearing smaller substituents at R^1 (dmp, alkyl), also react with hydrogen, but after reaction no reson-

ances due to Co complexes could be recognized in the spectra. The chloride complexes [LCoCl] do not react with hydrogen. The rhodium complex [$L^{dipp,Me}$RhCl] can be easily converted into the desired alkyl complex by addition of alkyllithium. This demonstrates the importance of steric shielding of the metal: the analogous but more open complex [$L^{dmp,Me}$RhCl] could only be converted into the alkyl by an elaborate indirect route.[4]

Structures and Lowest-Energy States of [LCoR] Complexes

The Rh and Ir model complexes [$L^{H,Me}$MR] (M = Rh, Ir; R = H, Me, Cl) have normal closed-shell ground states stable to symmetry breaking. In contrast, for all cobalt complexes studied theoretically the restricted DFT (b3lyp) solution is unstable. The unrestricted $m_S = 0$ solution ("U_0") is 10−20 kcal/mol lower in energy, depending on the ligand. At the restricted DFT (RDFT) level, the optimised structures of the hydride and methyl complexes are non-planar, with the hydride or methyl group bent out of the coordination plane by a significant amount (typically around 20°). Re-optimisation at the unrestricted DFT (UDFT) level, however, results in planar or near-planar structures in all cases.[10]

In the optimised geometries, the Co−N (Table 1) and Co−Cl distances are systematically too large by about 0.04

Å, as is evident from a comparison with the X-ray structures shown in Figure 1. The calculated Co−C distance appears to be about right, but this agreement is fortuitous, since the experimental value is for a CH_2SiMe_3 group while the calculated value is for a Me group, which *should* have a shorter Co−C distance.[11] Thus, Co simply appears to be too large in the calculations. Distances *within* the ligand are reproduced satisfactorily.

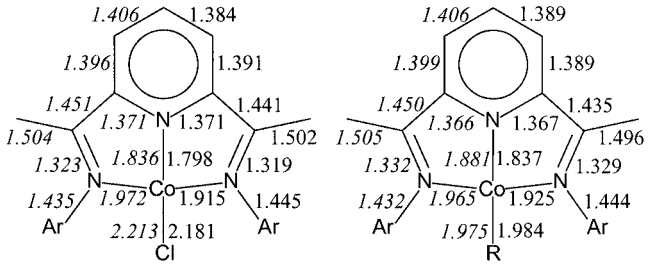

Figure 1. Observed and *calculated* bond lengths for [$L^{dipp,Me}$CoR] complexes: R = Cl[3a] (left) and CH_2SiMe_3 [3b] or *Me* (right)

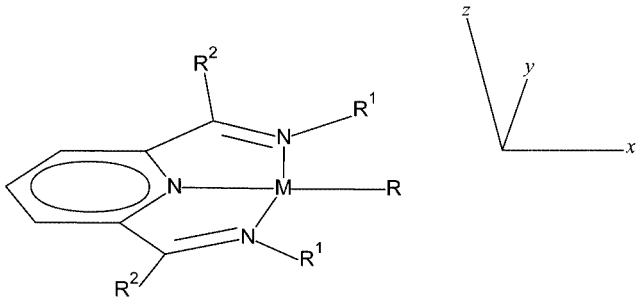

The U_0 wavefunctions have S^2 values of 0.80−1.05.[12a] They have one "pair" of occupied α and β orbitals, corresponding to bonding and antibonding combinations of the metal $3d_{xz}$ and ligand π* orbitals, respectively (Figure 2). The remaining orbitals are all fairly cleanly paired. This means that the U_0 "states" are nearly 50:50 mixtures of singlet and triplet states, where the relevant triplet state corresponds to the $3d_{xz}\rightarrow\pi^*$ excitation of a hypothetical true [$LCo^{I}R$] species. These triplets, indicated here by $U_1(xz)$, were also obtained separately from unrestricted $m_S = 1$ calculations, and they have S^2 values of 2.00−2.10, indicating little spin contamination. The true singlet energies were then estimated from the energies ε_0, ε_1 of the unrestricted solutions U_0, $U_1(xz)$ and their S^2 values by extrapolating the presumed linear relation between energy and S^2 to $S^2 = 0$ [Equation (1)]:[12b,13]

$$\varepsilon_S \approx \frac{S_1^2\varepsilon_0 - S_0^2\varepsilon_1}{S_1^2 - S_0^2} \quad (1)$$

The singlet-triplet separation calculated from this varies between 9 and 13 kcal/mol. These results show that the singlet ground state is best described as a square-planar, low-spin $Co^{II}R$ fragment ($3d_{xz}$ singly occupied) antiferromagnetically coupled to a ligand radical anion. In this respect, these complexes are more extreme than the L_2Co^+ complexes considered in earlier work,[8] where only about half of the 3d→π* transfer of electron density was in the form of unpaired electron density, the remainder being "classical" back-donation. Related to this, complexes [LMnR] have been shown to contain a ligand radical anion antiferromagnetically coupled to a *high-spin* Mn^{II} centre.[14] If the ligand is simply considered as a uni-negative ligand and its unpaired electron is ignored, complexes [LCoR] can be seen as relatives of the (also square-planar) low-spin Co^{II} amido complex [$CoBz\{N(SiMe_2CH_2PPh_2)_2\}$].[15] Thus, reduction of high-spin [$LCoCl_2$] to low-spin [LCoCl][3] actually occurs at the ligand rather than at the metal, but is accompanied by a spin flip at the metal, possibly induced by the higher ligand-field of the ligand radical anion. A related reduction-induced spin flip was observed in L_2Mn^{2+}.[7]

Interestingly, the $U_1(xz)$ triplet is not the lowest-lying triplet state. According to our calculations, the $U_1(z^2)$ ($3d_{z^2}\rightarrow\pi^*$) triplet is the lowest one; this always lies about 3−5 kcal/mol below the $U_1(xz)$ triplet and hence about 4.5−9 kcal/mol above the singlet ground state. The geometries calculated for U_0 and $U_1(z^2)$ are very similar, typically differing by less than 0.01 Å in bond lengths. The clearest exception is the $Co-N_{im}$ bond, which can be up to 0.03 Å longer in the triplet state.

Substituent Effects on the Singlet-Triplet Separation in Co Complexes

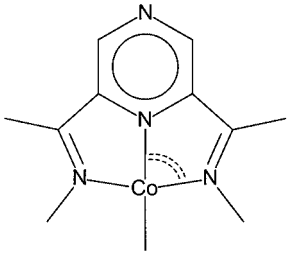
In order to check whether the unusual bonding described above applies not only to simple models but also to "real" systems, we have studied a number of combinations of substituents. Table 1 shows the calculated geometries and singlet-triplet gaps for all systems studied. All values have been calculated at the b3lyp/SV(P) level. For the smallest model system $L^{H,Me}$, we have also calculated energies with the TZVPP basis set. This resulted in somewhat smaller gaps, especially for the hydride. It is likely that basis-set improvement would also lower the gaps for the other systems. However, such calculations are not feasible for the large systems studied here.

The most remarkable result is probably that the singlet-triplet gaps are so insensitive to changes in R, R^1 and R^2. Interpreting the small changes we do see is not so easy, given that they correspond to an excitation from a $3d_{xz}\rightarrow\pi^*$ *singlet* to a $3d_{z^2}\rightarrow\pi^*$ *triplet*. Since, however, we find that the energy difference between the $3d_{xz}\rightarrow\pi^*$ and $3d_{z^2}\rightarrow\pi^*$ triplets is fairly constant, we need only discuss the $3d_{xz}\rightarrow\pi^*$ singlet to $3d_{xz}\rightarrow\pi^*$ triplet gap. This gap, which in the wavefunction picture corresponds to an exchange integral, will be larger if the regions of high electron density of the relevant metal and ligand orbitals (mainly Co $3d_{xz}$ and N $2p_z$) overlap more. Changes in any of the groups R, R^1 and R^2 are therefore expected to affect the gap in two different ways. Steric hindrance at nitrogen will weaken the Co−imine coordination and hence decrease the gap. However, electronic factors that strengthen the pyridine and/or imine coordination will increase the gap.

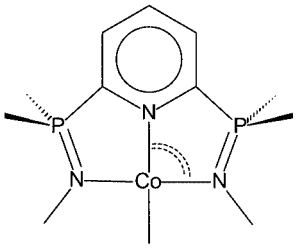
We consistently see an increasing gap when changing R in the order H < Me < Cl, in steps of about 1 kcal/mol. This is presumably a direct electronic effect: in this order, the *trans* effect of the R group decreases and the $Co-N_{py}$ distance decreases (by 0.03−0.04 Å).

Introducing bulky groups at nitrogen (R^1 = *n*-hexyl or dipp, compared to R^1 = H) decreases the gap by about 2 kcal/mol. This is probably a mostly steric effect: the $Co-N_{im}$ distance is 0.04−0.05 Å longer for these *N*-substituted derivatives. Introducing instead the very electron-withdrawing C_6F_5 group at N has very little additional effect, decreasing the gap further by only 0.5 kcal/mol. Since the steric effects of C_6F_5 and dipp should be similar here, it is clear that the electronic effect is rather small. Replacing the backbone (R^2) methyl groups by phenyls has a somewhat larger effect (about 1 kcal/mol for $L^{dmp,Ph}$ relative to $L^{dipp,Me}$). This is most likely due to increased delocalisation of the ligand π*-orbital. The effect is modest because the phenyls cannot become coplanar with the ligand skeleton for steric reasons. Surprisingly, replacing the backbone methyls by CF_3 groups results in an *increase* of the gap by about 1 kcal/mol. At the same time, the Co−imine distance decreases by about 0.03 Å, indicating that the CF_3 substituents strengthen the Co−imine coordination,[16] which is consistent with the increased gap.

Finally, we have considered two more exotic systems: diiminopyrazine and bis(phosphinimino)pyridine. Complexes of the diiminopyrazine ligand show a singlet-triplet gap that is marginally smaller than that calculated for the diiminopyridine complexes. The Co-ring nitrogen distance is slightly smaller, and the Co−imine distances are slightly larger, due to the replacement of Cγ by the smaller nitrogen atom. It is remarkable that such a major change in the π-acceptor character of the ligand has so little effect on the gap. Perhaps the reason is that the diiminopyridine and diiminopyrazine complexes are all completely biradicals, so the variation in ligand π-acceptor strength does not influence the electronic structure.



diiminepyrazine



bis(phosphinimine)pyridine

The bis(phosphinimine)pyridine system,[17] too, is fully a biradical. For this ligand, we calculate a gap which is smaller by about 2 kcal/mol, i.e. as much as is attainable using substituent effects *within* the diiminopyridine system. The most likely explanation is that here the N−Co−N angles are closer to their ideal value of 90°. The exchange integral determining the gap is reduced because the N $2p_z$ orbitals are now closer to a nodal plane of the $3d_{xz}$ orbital. It looks like bis(phosphinimino)pyridines can be considered as a useful extension (in an electronic sense) of the diiminopyridine ligands.

Correlation with NMR Results

Table 2 contains the observed ^{1}H NMR chemical shifts for a number of LMR complexes, some of which were only generated in situ. We concentrate on the data for $L^{dipp,Me}$, although the other ligands behave similarly. NMR spectroscopic data for several Co^I complexes have already been reported.[3] The shifts for pyridine Hβ are fairly normal. However, for Co the Hγ resonance shows an abnormal low-field shift with increasing ligand field of the group R, from δ = 9.53 ppm for [$L^{dipp,Me}$CoCl] to δ = 10.80 ppm for [$L^{dipp,Me}$CoH]. Even the value for [$L^{dipp,Me}$CoCl] is already high, given that this resonance is found at δ = 7.97 ppm for the free ligand and at δ = 7.80 ppm for [$L^{dipp,Me}$RhCl]. Simultaneous with the low-field shift of the Hγ resonance, the imine methyl (R^2) group shifts from δ = 2.30 ppm (for free $L^{dipp,Me}$) via δ = 0.05 ppm (for [$L^{dipp,Me}$CoCl]) to δ = −1.65 ppm (for [$L^{dipp,Me}$CoH]), while for Rh it never goes below δ = +0.7 ppm. The magnitudes of these curious shifts are emphasised in Table 3, where for Hβ, Hγ and imine Me the values for Co are given relative to the corresponding Rh values.

Table 3. Estimated "anomalous" shifts ($\Delta\delta = \delta_{LCoX} - \delta_{LRhX}$) of $L^{dipp,Me}$ complexes

Complex	Pyridine Hβ	Hγ	Imine CH_3
LCoCl	−0.06	+1.73	−1.02
$LCoCH_2SiMe_3$	+0.41	+1.83	−1.72
LCoBz	+0.62	+2.35	−2.12
LCoMe	+0.62	+2.09	−1.87
LCoH[a]	+0.36	+2.70	−2.37

[a] Using LRhMe as reference.

It is tempting to correlate these NMR shifts with the remarkable electronic structures of the LCoR complexes. The biradical character of singlet LCoR should not, by itself, result in anomalous NMR shifts. However, the calculated singlet-triplet gaps for the "real" systems are rather small (5−8 kcal/mol) and are expected to become smaller with larger basis sets: a decrease of 1.8 kcal/mol is calculated for the model system [$L^{H,Me}$CoH] on going from SV(P) to TZVPP (Table 1). Thus, the extrapolated gap for [$L^{dipp,Me}$CoH] at the b3lyp/TZVPP level is only 3.8 kcal/mol. Allowing for an error of only a few kcal/mol in the gaps we could already have a sizeable thermal population of the triplet state. Rapid spin-flip would then result in averaged shifts containing a contribution of the triplet-state paramagnetic shift. With an estimated Fermi contact term *a* of −1.5 G for Hγ[18] and an anomalous NMR shift of about 2 ppm, the fraction, *f*, of triplet population of [$L^{dipp,Me}$CoMe] calculated from Equation (2) should be about 2%, corresponding to a singlet-triplet gap of about 2 kcal/mol.

$$\Delta\delta \approx f\frac{a\gamma_e^2\eta}{4\gamma_H kT} \qquad (2)$$

At present, we have no way of verifying this hypothesis. At room temperature, no triplet EPR signal is observed, but this would not be expected anyway because of rapid relaxation. At 4 K, where a signal should normally be observable, the triplet population would be so small as to escape detection. Temperature-dependent ^{1}H NMR studies are hampered by solubility and (especially for the more interesting alkyls) stability problems.

The anomalous shifts increase with decreasing singlet-triplet gap, which agrees with the above hypothesis. However, the changes in observed shifts suggest that the triplet population changes only by a factor of about two over the whole range of Cl···H, corresponding to a gap change of about 0.3 kcal/mol, smaller than our calculated change of about 2 kcal/mol.

Conclusions

[$LCo^{I}X$] complexes have a diamagnetic ground state with a square-planar coordination geometry. In contrast to their heavier Rh^{I} and Ir^{I} analogues, they are best regarded as containing low-spin Co^{II} antiferromagnetically coupled to a ligand radical anion. The lowest-lying triplet state, corresponding to a $3d_{z^2}\rightarrow\pi^*$ excitation, lies only a few kcal/mol above the ground state. The singlet-triplet separation decreases with increasing ligand-field strength of the group X at Co. We suggest that the anomalous ^{1}H NMR shifts observed for these Co complexes, but not for their Rh and Ir analogues, are due to thermal population of the triplet state at room temperature. The triplet state is so low in energy that it can certainly be involved in chemical reactions. Obviously, the availability of both a singlet biradical and a triplet state multiplies the number of reaction paths accessible to the complex. Whether this is relevant to polymerisation catalysis of LCo complexes remains to be established.

Experimental Section

General Remarks: All manipulations were carried out under an atmosphere of argon using standard Schlenk techniques or in a con-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ventional nitrogen-filled glove box. Solvents were refluxed over an appropriate drying agent and distilled under nitrogen prior to use. NMR spectra were recorded on Varian and Bruker spectrometers at ambient temperature. Commercially available chemicals were used as received. The starting material 2,6-dibenzoylpyridine,[9] the ligands $L^{dmp,Me}$ and $L^{dipp,Me}$ [19] and the complexes $[L^{dipp,Me}Rh^{I}Cl]$,[20] $[L^{dipp,Me}Co^{II}Cl_2]$, $[L^{dmp,Me}Co^{II}Cl_2]$,[19] $[L^{dipp,Me}Co^{I}Cl]$, $[L^{dipp,Me}Co^{I}CH_3]$, $[L^{dipp,Me}Co^{I}Bz]$ and $[L^{dipp,Me}Co^{I}CH_2SiMe_3]$[3] were synthesised according to literature procedures.

Methods: All calculations were carried out with the Turbomole program[21] coupled to the PQS Baker optimiser.[22] Geometries were fully optimised at the unrestricted ("singlet" or "triplet") b3-lyp level[23] level using the Turbomole SV(P) basis set on all atoms (pseudopotential basis on Co). For the smallest model system, improved final energies were then obtained from single-point calculations using a TZVPP basis and a fine ("m4") integration grid. Zero-point energy (ZPE) and thermal corrections were not included. Orbital plots were prepared using Molden.[24] For triplet states of a minimal model system ($R^1 = R^2 = H$, R = Cl, Me, H) Fermi contact terms were estimated using the Gaussian 98 package,[25] a LANL2DZ basis[26] for the metal atom, and the 6-31G* basis[27] for the ligand atoms.

$L^{dmp,Ph}$: 2,6-Dibenzoylpyridine (1.50 g, 5.23 mmol) and dimethylaniline (0.60 g, 4.96 mmol; 0.95 equiv.) were dissolved in benzene (50 mL). After the addition of a small amount of camphorsulfonic acid, the solution was refluxed overnight, using a Dean−Stark water trap. The solution was placed in the dark for a week over molecular sieves. Recrystallisation from hot methanol offered 0.30 g of yellow needles, which, according to GC analysis, consisted of 82% of the desired product together with 18% of the monocondensed product.

$L^{hex,Me}$: 2,6-Diacetylpyridine (1.00 g, 6.13 mmol) and *n*-hexylamine (1.245 g, 12.27 mmol, 2.0 equiv.) were dissolved in benzene (50 mL). After the addition of a small amount of camphorsulfonic acid, the solution was refluxed overnight, using a Dean−Stark water trap. The solvent was removed in vacuo, and 1.83 g (90.9%) of product was obtained as a yellow oil. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.96 (d, $^3J_{H,H}$ = 7.7 Hz, 2 H, Py *H*β), 7.59 (t, $^3J_{H,H}$ = 7.7 Hz, 1 H, Py *H*γ), 3.42 (t, $^3J_{H,H}$ = 7.2 Hz, 4 H, hex *H*α), 2.29 (s, 6 H, N=C*Me*), 1.64 (quint, 4 H, $^3J_{H,H}$ = 7.2 Hz, hex *H*β), 1.26 (m, 12 H, hex *H*γδε), 0.80 (t, $^3J_{H,H}$ = 7.2 Hz, 6 H, hex *H*ζ) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 166.33 (N=*C*), 156.26 (Py *C*α), 136.45 (Py *C*γ), 120.85 (Py *C*β), 52.57 (hex *C*α), 31.77, 30.81, 27.39, 22.65 (hex *C*β−ε), 14.05 (hex *C*ζ), 13.61 (N=C*Me*) ppm.

$L^{octadec,Me}$: 2,6-Diacetylpyridine (1.00 g, 6.13 mmol) and *n*-octadecylamine (3.30 g, 12.26 mmol, 2 equiv.) were dissolved in benzene (50 mL). After the addition of a small amount of acetic acid, the solution was refluxed overnight, using a Dean−Stark water trap. The solvent was removed in vacuo yielding a yellow oil, which solidified upon cooling with ice. The yield was 3.88 g (95%). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.98 (d, $^3J_{H,H}$ = 7.7 Hz, 2 H, Py *H*β), 7.59 (t, $^3J_{H,H}$ = 7.7 Hz, 1 H, Py *H*γ), 3.43 (t, $^3J_{H,H}$ = 7.2 Hz, 4 H, octadec *H*α), 2.28 (s, 6 H, N=C*Me*), 1.66 (quint, 4 H, $^3J_{H,H}$ = 7.1 Hz, octadec *H*β), 1.25−0.90 (m, 60 H, octadec *H*γ-ρ), 0.80 (t, $^3J_{H,H}$ = 6.8 Hz, 6 H, octadec *H*ς) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 167.0 (N=*C*), 156.9 (Py *C*α), 137.1 (Py *C*γ), 121.6 (Py *C*β), 53.3 (octadec *C*α), 32.6, 31.5, 30.4 (several), 30.1, 28.4, 23.3, 14.8 (octadec *C*β−ς), 14.3 (N=C*Me*) ppm.

$[L^{dmp,Ph}Co^{II}Cl_2]$: Part of the mixture of mono- and dicondensed dibenzoylpyridine (0.30 g containing 499 μmol of $L^{dmp,Ph}$) and $CoCl_2{\cdot}6H_2O$ (0.15 g, 630 mmol, 1.26 equiv.) were dissolved in 10 mL of THF. Almost immediately a colour change could be observed and a golden brown solid precipitated. After stirring for an additional hour at room temperature, this solid was filtered off, washed twice with THF (5 mL) and dried in vacuo. The yield was 0.195 g (63.8%). ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 108.80 (2 H, Py *H*β), 37.45 (1 H, Py *H*γ), 6.04, 5.74, −1.37 (3 × 4 H, Ph $H_{o,m}$, dmp H_m), 3.20 (2 H, Ph H_p), −11.62 (2 H, dmp H_p), −26.99 (12 H, dmp *Me*) ppm.

$[L^{hex,Me}Co^{II}Cl_2]$: $L^{hex,Me}$ (2.16 g, 6.55 mmol) and $CoCl_2{\cdot}6H_2O$ (1.16 g, 4.87 mmol; 0.74 equiv.) were dissolved in 50 mL of THF and stirred for 15 min. The solvent was removed in vacuo, leaving 2.83 g (102%, presumably containing some residual THF) of the red-brown product. ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 104.14 (2 H, Py *H*β), 71.35 (4 H, hex *H*α), 13.90 (1 H, Py *H*γ), −1.55 (6 H, hex *H*ζ), −3.25 (4 H, hex *H*ε), −5.12 (6 H, N=C*Me*), −7.12 (4 H, hex *H*δ), −12.88 (4 H, hex *H*γ), −39.74 (4 H, hex *H*β) ppm.

$[L^{octadec,Me}Co^{II}Cl_2]$: $L^{octadec,Me}$ (1.10 g, 1.65 mmol) and $CoCl_2{\cdot}6H_2O$ (0.39 g, 1.64 mmol, 1.0 equiv.) were dissolved in 20 mL of THF and stirred for an hour. The solvent was removed in vacuo, leaving 1.21 g (93%) of the red-brown product. ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 106.0 (2 H, Py *H*β), 71.7 (4 H, octadec *H*α), 14.1 (1 H, Py *H*γ), −5.6 (6 H, N=C*Me*), 1.7, 1.4−0.8 (several), 0.5, 0.2, −1.6, −3.6, −7.1, −13.4, −41.1 (68 H, octadec, *H*β-ς) ppm.

$[L^{dipp,Me}Co^{I}H]$: This complex was generated in situ by addition of 2 mL of H_2 to an NMR sample of $[L^{dipp,Me}Co^{I}CH_2SiMe_3]$. ^{1}H NMR (300 MHz, C_6D_6): δ = 10.80 (t, $^3J_{H,H}$ = 7.8 Hz, 1 H, Py *H*γ), 7.60 (m, 4 H, Py *H*β, dipp H_p), 7.46 (d, $^3J_{H,H}$ = 7.8 Hz, 4 H, dipp H_m), 3.41 (sept, 4 H, $^3J_{H,H}$ = 6.9 Hz, C*H*Me$_2$), 1.31 and 0.29 (d, 12H each, $^3J_{H,H}$ = 6.9 Hz, CH*Me*$_2$), −1.65 (s, 6 H, N=C*Me*) ppm. ^{13}C NMR (100 MHz, C_6D_6): δ = 168.5 (N=*C*), 160.1 (dipp C_i), 156.5 (Py *C*α), 140.2 (dipp C_o), 126.3 (dipp C_p), 124.1 (dipp C_m), 123.6 (Py *C*β), 117.8 (Py *C*γ), 28.6 (*C*HMe$_2$), 25.4 (N=C*Me*), 23.3 and 22.5 (CH*Me*$_2$) ppm.

$[L^{dipp,Me}Co^{I}Et]$: This complex was generated in situ by addition of 2 mL of ethene to an NMR sample of $[L^{dipp,Me}Co^{I}H]$. ^{1}H NMR (300 MHz, C_6D_6): δ = 10.25 (t, $^3J_{H,H}$ = 7.5 Hz, 1 H, Py *H*γ), 7.99 (d, $^3J_{H,H}$ = 7.5 Hz, 2 H, Py *H*β), 7.52 (t, $^3J_{H,H}$ = 7.5 Hz, 2 H, dipp H_p), 7.39 (d, $^3J_{H,H}$ = 7.5 Hz, 4 H, dipp H_m), 3.13 (sept, 4 H, $^3J_{H,H}$ = 6.7 Hz, C*H*Me$_2$), 1.51 (q, 2 H, $^3J_{H,H}$ = 7.5 Hz, Co*CH*$_2$CH$_3$), 1.17 and 0.75 (d, 12H each, $^3J_{H,H}$ = 6.7 Hz, CH*Me*$_2$), −1.19 (t, $^3J_{H,H}$ = 7.5 Hz, 3 H, CoCH$_2$C*H*$_3$) −1.33 (s, 6 H, N=C*Me*) ppm. ^{13}C NMR (100 MHz, C_6D_6): δ = 165.3 (N=*C*), 157.9 (dipp C_i), 154.9 (Py *C*α), 140.9 (dipp C_o), 126.6 (dipp C_p), 124.1 (dipp C_m), 122.6 (Py *C*β), 117.6 (Py *C*γ), 28.3 (*C*HMe$_2$), 26.1 (N=C*Me*), 24.2 and 23.1 (CH*Me*$_2$) 12.8 CoCH$_2$*C*H$_3$ ppm. The signal for Co*C*H$_2$ was not observed.

$[L^{dmp,Me}Co^{I}CH_2SiMe_3]$: $[L^{dmp,Me}Co^{II}Cl_2]$ (0.276 g, 553 μmol) was added to a solution of $LiCH_2SiMe_3$ (0.115 g, 1.21 mmol; 2 equiv.) in 8 mL of hexane. The mixture was stirred for one hour, after which it was filtered. The filtrate was evaporated to dryness; the yield was not determined. ^{1}H NMR (200 MHz, C_6D_6): δ = 10.06 (t, $^3J_{H,H}$ = 7.8 Hz, 1 H, Py *H*γ), 7.71 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, Py *H*β), 7.34 (d, $^3J_{H,H}$ = 6.2 Hz, 2 H, dmp H_p), 7.26 (d, $^3J_{H,H}$ = 6.2 Hz, 4 H, dmp H_m), 0.80 (s, 2 H, Co*CH*$_2$), −0.63 (s, 9 H, Si*Me*$_3$), −1.28 (s, 6H N=C*Me*) ppm. The addition of H_2 to the NMR sample resulted in a colour change from deep red-purple to green and disappearance of all the complex-related ^{1}H NMR signals.

$[L^{dmp,Ph}Co^{I}CH_2SiMe_3]$: $[L^{dmp,Ph}Co^{II}Cl_2]$ (0.195 g, 313 μmol) was added to a solution of $LiCH_2SiMe_3$ (0.065 g, 684 μmol, 2.2 equiv.)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in 5 mL of hexane. An immediate colour change to green was observed. After 2 h the mixture was filtered, and the filtrate was evaporated to dryness, yielding a green powder (yield not determined). ^{1}H NMR (200 MHz, C_6D_6): δ = 9.91 (t, $^3J_{H,H}$ = 8 Hz, 1 H, Py *H*γ) ppm. The rest of the peaks could not be unambiguously assigned. The addition of H_2 to the NMR sample resulted in disappearance of all the complex-related ^{1}H NMR signals.

[L^{hex,Me}Co^{I}CH$_2$SiMe$_3$]: A 1 M solution of $LiCH_2SiMe_3$ (1.6 mL, 1.60 mmol, 2.0 equiv.) in pentane and 8 mL of hexane were added to [L^{hex,Me}Co^{II}Cl$_2$] (0.45 g, 0.79 mmol). The mixture was stirred for one hour, after which it was filtered. The filtrate was evaporated to dryness, yielding 0.153 g of [L^{hex,Me}Co^{I}CH$_2$SiMe$_3$] (33.8%) as a thick dark-red oil. ^{1}H NMR (200 MHz, C_6D_6): δ = 9.72 (t, $^3J_{H,H}$ = 7.6 Hz, 1 H, Py *H*γ), 7.31 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H, Py *H*β), 5.19 (t, $^3J_{H,H}$ = 7.6 Hz, 4 H, hex *H*α), 2.22 (quint, $^3J_{H,H}$ = 7.6 Hz, 4 H, hex *H*β), 1.54 (quint, $^3J_{H,H}$ = 7.6 Hz, 4 H, hex *H*γ), 1.22 (m, 8 H, hex *H*δ, ε), 0.82 (t, $^3J_{H,H}$ = 7.2 Hz, 6 H, hex *H*ζ), 0.02 (s, 2 H, CoC*H*$_2$), −0.14 (s, 9 H, Si*Me*$_3$), −0.18 (s, 6 H, N=C*Me*) ppm. ^{13}C NMR (75 MHz, C_6D_6): 162.42 (N=*C*), 152.18 (Py *C*α), 122.50 (Py *C*β), 114.01 (Py *C*γ), 59.35 (hex *C*α), 32.20 and 22.89 (hex *C*δ, ε), 29.08 and 27.36 (hex *C*β, γ), 20.39 (N=C*Me*), 14.21 (hex *C*ζ), 3.00 (Si*Me*$_3$) ppm. The signal for Co*C*H$_2$ was not found. The addition of H_2 to the ^{1}H NMR sample resulted in a colour change from dark red to green-brown and a loss of all the complex-related ^{1}H NMR signals.

[L^{octadec,Me}Co^{I}CH$_2$SiMe$_3$]: A 1 M solution of $LiCH_2SiMe_3$ (0.90 mL, 900 μmol, 2.45 equiv.) in pentane and 8 mL of hexane were added to [L^{octadec,Me}Co^{II}Cl$_2$] (0.292 g, 368 μmol). The mixture was stirred for two hours, after which it was filtered, and the solvent was removed in vacuo leaving a deep purple-red product. ^{1}H NMR (400 MHz, C_6D_6): δ = 9.71 (t, $^3J_{H,H}$ = 7.6 Hz, 1 H, Py *H*γ), 7.31 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H, Py *H*β), 5.21 (t, $^3J_{H,H}$ = 7.6 Hz, 4 H, octadec *H*α), 2.26 (quint, $^3J_{H,H}$ = 7.6 Hz, 4 H, octadec *H*β), 1.59 (quint, $^3J_{H,H}$ = 7.2 Hz, 4 H, octadec *H*γ), 1.5−1.1 (m, 56 H, octadec *H*δ−ρ) ppm. octadec *H*ς is presumably obscured by the resonance of traces of hexane. The signals for Co*C*H$_2$, Si*Me*$_3$ and N=C*Me* could not be unambiguously assigned.

[L^{dipp,Me}Rh^{I}CH$_3$]: Toluene (2 mL) was added to a mixture of [L^{dipp,Me}Rh^{I}Cl] (100 mg, 0.16 mmol) and MeLi (7.1 mg, 0.32 mmol, 2 equiv.) and the reaction mixture was stirred for three days. The obtained product was filtered off and the filtrate was evaporated to dryness, yielding 91 mg of [L^{dipp,Me}Rh^{I}CH$_3$] (84%) as a dark green solid. ^{1}H NMR (300 MHz, C_6D_6): δ = 8.19 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H, Py *H*γ), 7.34 (d, $^3J_{H,H}$ = 7.7 Hz, 2 H, Py *H*β), 7.22−7.10 (m, 6 H, dipp *H*$_{m,p}$), 3.19 (sept., 4 H, $^3J_{H,H}$ = 6.8 Hz, *CH*Me$_2$), 2.12 (d, $^2J_{RhH}$ = 1.1 Hz, 3 H, Rh*Me*), 0.99 (m, 24 H, CH*Me*$_2$), 0.73 (s, 6 H, N=C*Me*) ppm. ^{13}C NMR (75 MHz, C_6D_6): δ = 166.8 (N=*C*), 155.3 (d, $^2J_{RhC}$ = 2.7 Hz, Py *C*α), 148.3 (dipp *C*$_i$), 140.6 (Py *C*γ), 140.4 (dipp *C*$_o$), 123.6 (dipp *C*$_m$), 123.1 (Py *C*β), 28.2 (*C*HMe$_2$), 23.9 and 23.6 (CH*Me*$_2$), 18.9 (N=C*Me*), 1.2 (d, $^1J_{RhC}$ = 21.0 Hz, Rh*Me*) ppm. dipp *C*$_p$ is presumably obscured by the resonance of the C_6D_6 solvent.

[L^{dipp,Me}Rh^{I}Bz]: Toluene (2 mL) was added to a mixture of [L^{dipp,Me}Rh^{I}Cl] (100 mg, 0.27 mmol) and Bz_2Mg (41 mg, 0.27 mmol, 1 equiv.). The mixture was stirred for 24 h. The magnesium salts were separated from the reaction products by filtration and the filtrate was evaporated to dryness, yielding a purple powder. Hexane (5 mL) was added, the mixture was filtered and the filtrate was evaporated to dryness, yielding [L^{dipp,Me}Rh^{I}Bz] as a purple powder. ^{1}H NMR (C_6D_6, 200 MHz): δ = 7.97 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H, Py *H*γ), 7.31−7.17 (m, 8 H, dipp *H*$_{m,p}$, Py *H*β), 7.21 (t, $^3J_{H,H}$ = 7.3 Hz, 2 H, Bz *H*$_m$), 6.65 (m, 1 H, Bz *H*$_p$), 5.59 (d, $^3J_{H,H}$ = 6.9 Hz, 2 H, Bz *H*$_o$), 3.69 (d, $^2J_{RhH}$ = 2.6 Hz, 2 H, RhC*H*$_2$), 3.17 (sept., 4 H, $^3J_{H,H}$ = 6.8 Hz, *CH*Me$_2$), 1.01−0.92 (m, 30 H, N=C*Me*, CH*Me*$_2$) ppm. ^{13}C NMR (C_6D_6 75 MHz): δ = 166.8 (d, $^2J_{RhC}$ = 2.3 Hz, N=*C*), 156.2 (d, $^2J_{RhC}$ = 2.9 Hz, Py *C*α), 151.9 (d, $^2J_{RhC}$ = 1.7 Hz, Bz *C*$_i$), 148.4 (dipp *C*$_i$), 141.0 (Py *C*γ), 140.6 (dipp *C*$_o$), 127.3 (Bz *C*$_o$), 127.0 (Bz *C*$_m$), 126.5 (dipp *C*$_p$), 124.2 (dipp *C*$_m$), 123.6 (Py *C*β), 119.6 (Bz *C*$_p$), 28.6 (*C*HMe$_2$), 24.0 and 23.8 (CH*Me*$_2$), 19.5 (d, $^3J_{RhC}$ = 1.7 Hz, N=C*Me*) ppm. The Rh*C*H$_2$ signal was not detected.

[L^{dipp,Me}Rh^{I}CH$_2$SiMe$_3$]: A 1.0 M solution of $LiCH_2SiMe_3$ in pentane (0.54 mL 0.54 mmol, 2 equiv.) and 4 mL of toluene were added to [L^{dipp,Me}Rh^{I}Cl] (170 mg, 0.27 mmol, 1 equiv.). The mixture was stirred for 24 h. The solvent was removed in vacuo, yielding a green-brown powder. Hexane (5 mL) was added, the mixture was filtered and the filtrate was evaporated to dryness, yielding [L^{dipp,Me}Rh^{I}CH$_2$SiMe$_3$] as a green powder. ^{1}H NMR (C_6D_6, 300 MHz): δ = 8.06 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H, Py *H*γ), 7.24 (d, $^3J_{H,H}$ = 8.1 Hz, 2 H, Py *H*β), 7.15−7.03 (m, 6 H, dipp *H*$_{m,p}$), 3.26 (sept., $^3J_{H,H}$ = 6.8 Hz, 4 H, *CH*Me$_2$), 1.87 (d, $^2J_{Rh;H}$ = 2.2 Hz, 2 H, RhC*H*$_2$), 1.28 and 0.97 (2 × d, $^3J_{H,H}$ = 6.6 Hz, 12 H each, CH*Me*$_2$), 0.86 (s, 6 H, N=C*Me*), 0.29 (s, 9 H, Si*Me*$_3$) ppm. ^{13}C NMR (C_6D_6 75 MHz): δ = 165.8 (d, $^2J_{RhC}$ = 0.9 Hz, N=*C*), 156.3 (d, $^2J_{RhC}$ = 3.2 Hz, Py *C*α), 149.4 (dipp *C*$_i$), 141.1 (Py *C*γ), 140.6 (dipp *C*$_o$), 126.7 (dipp *C*$_p$), 124.3 (dipp *C*$_m$), 123.6 (Py *C*β), 28.2 (*C*HMe$_2$), 24.5 and 24.3 (CH*Me*$_2$), 19.9 (d, $^3J_{Rh,C}$ = 2.0 Hz, N=C*Me*), 6.7 (d, $^1J_{Rh,C}$ = 33.0 Hz, Rh*C*H$_2$), 4.0 (Si*Me*$_3$) ppm.

[10] Burger reported that non-planar structures also form easily for Rh and Ir and are sometimes even preferred.[4] However, in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that case they do not become planar when allowed to go unrestricted, and indeed there is no unrestricted solution lower than the restricted one.

[11] Compare for example, $[(dmg)_2Co(CH_2SiMe_3)(py)]$, where Co−C = 2.031 Å: [11a] L. Randaccio, N. Bresciani-Pahor, P. J. Toscano, L. G. Marzilli, *J. Am. Chem. Soc.* **1981**, *103*, 6347; with $[(dmg)_2Co(Me)(im)]$, where Co−C = 1.986 Å: [11b] V. Pattabhi, M. Nethaji, E. J. Gabe, F. L. Lee, Y. le Page, *Acta Crystallogr., Sect. C* **1984**, *40*, 1155.

[12] [12a] Usually, unrestricted solutions with $S^2 = 1$ correspond to small singlet-triplet gaps.[13f] However, if the preference of the "pure" singlet for a biradical structure is strong enough, full mixing (leading to $S^2 \approx 1$) will occur also for larger singlet-triplet separations. Apparently, that is the case here. [12b] Noodleman uses Equation (1′), which is similar to Equation (1) but has $\hat{S}_1^2$ set to the ideal value of 2;[13a−13c] Bachler uses a similar expression.[13d,13e]

$$\varepsilon_S \approx \frac{2\varepsilon_0 - S_0^2\varepsilon_1}{2 - S_0^2} \qquad (1')$$

Spin contamination is always present in both the U_0 and U_1 solutions. Contamination of U_0 skews the result of Equation (1′) towards larger gaps. We prefer Equation (1) because it treats spin contamination in U_0 and U_1 on an equal basis. In any case, results obtained with Equation (1′) would differ only marginally from the ones we calculate with Equation (1).

[16] We tentatively explain this somewhat counterintuitive result as follows. Initially, the diiminopyridine ligand has two low-lying acceptor orbitals, which we here denote π^*_{xz} and π^*_{yz} for their association with the corresponding Co 3d orbitals. π^*_{yz} is slightly higher in energy, but its overlap with Co $3d_{yz}$ is larger. Back-donation to both orbitals is possible. The CF_3 groups stabilize π^*_{yz} because that orbital has a larger density on the imine groups. In the singlet state, this results in more back-donation to π^*_{yz} at the expense of π^*_{xz}. In the triplet state, however, one full electron has already been transferred into π^*_{xz}, so further back-donation into π^*_{yz} is difficult.

Quantum Chemical Studies of Neutral and Ionized DyX, DyX_2, and DyX_3 Species (X = F, Cl, Br, I) and the Implications for the Mass Spectra of Gaseous DyX_3

Julia Saloni,[a,d] Szczepan Roszak,*[a] Klaus Hilpert,[b] Mirosław Miller,[c] and Jerzy Leszczynski[d]

Keywords: Halides / Lanthanides / Mass spectrometry / Quantum chemical calculations / Thermochemistry

The mass spectrum pattern of DyF_3(g) and the appearance potentials for identified ions were measured and compared with the respective data obtained previously for $DyCl_3$, $DyBr_3$, and DyI_3. The structural parameters, total energies, and vibrational frequencies of DyX_3, DyX_2, and DyX (X = F, Cl, Br, I) neutral and single ionized species were determined by quantum-chemical studies. The theoretical appearance potentials of different ions, calculated from energies of gaseous species, are in the good agreement with the experimental data. Fragmentation energies of the DyX_n^+ ion, where n = 1, 2, 3, were computed and compared with the mass spectra patterns of the respective vapour species. A theoretical electron population analysis indicates the involvement of the s and f valence electrons of Dy in the bond formation as well as in the ionization processes. The σ-back donation from halogen atoms to the dysprosium center partially compensates the electron density loss. The ionization strengthens the bonding in the DyX and DyX_2 molecules. The ionization of DyX_3 destroys the C_{3v} symmetrical structure due to the Jahn–Teller effect. Contrary to the other studied systems, the open shell character of DyX_3^+ arises not only from unpaired electrons of dysprosium but also from electron density on halogen atoms.

Introduction

Knudsen effusion mass spectrometric studies of metal halide vapors show evidence for the significant fragmentation of gaseous species due to the electron bombardment used for the ionization. The mechanism of the ionization and fragmentation processes leading to the formation of particular ions recorded in the mass spectra is poorly understood. The molecular structures and the bonding nature of the species taking part in such processes are not directly available experimentally, and supplementary theoretical data is usually scarce. The few combined experimental and theoretical studies (e.g. ref.[1]) that exist allow a discussion of the energetic considerations and a quantitative analysis of fragmentation data.[2,3] Unfortunately, experimental mass spectra for metal halides published in the literature depend, to some extent, on the construction of the ion source of the mass spectrometer and on the energy of the ionising electrons. In order to correlate the theoretical predictions of the mass spectrum patterns with experimental data, the "true" mass spectra, obtained by the integration of peak areas, not by recording their intensities, should be taken into account.[4] In spite of this, mass spectra of gaseous metal halides recorded by different authors show similar characteristic trends for the ion intensities. The highest thermodynamic stability is not necessarily the most important condition for that particular ion to be the most abundant in the mass spectrum. However, the structures, bonding, and the charge distribution of ions formed upon ionization/fragmentation processes should, to some extent, correlate with the mass spectrum. Moreover, as was shown previously,[1,3] the thermochemical stability of neutral species and ions can be used for the elucidation of the fragmentation behavior of gaseous species. The above considerations motivated the analysis of the structural and thermochemical properties of gaseous species obtained by experimental and theoretical approaches for metal halide systems presented in this work. The recent development of quantum chemical methods has resulted in the efficient sup-

port of the theory of mass spectra in organic chemistry (e.g. ref.[5]). To the best of our knowledge, such studies for metal halide vapors are yet to be performed.

In the present study we report an experimental and quantum chemical analysis of neutral and ionic species detected upon studying the vaporization of DyX_3 by Knudsen effusion mass spectrometry. The vaporization of dysprosium halides has been investigated by different methods. Brunetti et al.[6] and Kapala et al.[7] have published a comparison of thermodynamic data reported in the literature. Recently, the vaporization thermodynamics of $DyCl_3$,[7,8] $DyBr_3$,[9] and DyI_3 [10] were investigated by means of Knudsen effusion mass spectrometry using different equipment and experimental conditions. The ion-molecule reactions in the $DyCl_3$ vapors were studied as well.[8] The mass spectrometric analysis of DyF_3 vapors performed in the present work complements our previous investigations.[7,9,10] The vapors of DyX_3 are predominantly monomeric, although mass spectrometric studies show evidence for dimeric,[7−10] trimeric,[8,10] or even tetrameric[8] species. In the past few years several quantum chemical studies have been carried out on gaseous lanthanide halides. The structures of monomeric[7,11−13] and dimeric[7,14] complexes of LnX_3 and other properties, including vibrational modes, have been presented. The results of the calculations were used for the interpretation of experimental infrared spectra of the gaseous phase[12] and for the estimation of the thermodynamic functions of gaseous species required for the third law treatment of equilibrium partial pressures.[7]

In the present work the theoretical structures and vibrational frequencies of DyX_3^+ molecular ions and their fragments (DyX_2^+, DyX^+) are reported. Their ionization potentials and appearance potentials were also calculated and compared with the values determined experimentally. The nature of the chemical bonding was studied applying Mulliken and natural bond orbital (NBO) electron population analysis. This information on structures, stabilities, and dissociation energies of gaseous ions is a significant step toward the better understanding of ionization and fragmentation processes in metal halide vapors and should thereby allow the prediction of their mass spectra.

Results

Mass Spectrometric Investigations

The mass spectrum of the DyF_3 vapors was recorded over a temperature range of 1208−1587 K. Table 1 shows the mass spectral data of gaseous DyF_3 interpolated for 1430 K. The data for gaseous DyX_3, where X = Cl, Br, I; obtained in previous studies are shown in Table 1 as well. The ionization of DyX_3 species by electron bombardment results, in addition to molecular ions, in the formation of DyX_n^+ fragments, where n = 0−2. Such fragmentation paths are generally characteristic for metal halide molecules (e.g. ref.[15]). The increasing fragmentation of gaseous DyX_3 on going from iodide to fluoride can easily be seen from the data in Table 1, despite the fact that they obtained with different spectrometers, at different temperatures, and with different energies of ionizing electrons. The same regularity can be seen for other metal halides.[15]

Table 1. Experimental mass spectra of the gaseous DyX_3 species

Figure 1 shows the ionization efficiency curves (IEC) obtained for the different ions detected in DyF_3 vapors. Table 2 summarizes the appearance potentials obtained from the IEC curves for the ionic species of mass spectra recorded for different DyX_3 compounds. As expected, the ionization potentials of gaseous DyX_3 and the respective appearance potentials of the fragment ions increase on going from dysprosium iodide to dysprosium fluoride. However, the respective values for $DyCl_3$ and $DyBr_3$ are very similar in every case. The ionization and appearance potentials obtained experimentally should only be considered as an upper limit to the adiabatic values.[16]

blue-shift of the stretching vibrations in the cations relative to the parent molecules. Spin-density calculations for DyX indicate four f and one s unpaired electrons on Dy. The ionization removes the nonbonding s electron and leads to an increase in the Coulomb interactions in the cation. Only the single valence electron from the s shell is involved in the Dy−X bond; the ionization removes the second one (Table 6). The charge transfer of 0.703 electrons from Dy to the halogen atom is not affected by the ionization process, indicating that the bond strength is enhanced mostly due to the increase in the ionic contribution.

The bonding in DyX_2 moieties is similar to that observed in DyX; the bond lengths are again shorter in the cations. The increasing strength of the bonds is confirmed by the blue-shifted stretching vibrational modes (Table 4). The polarization of the electronic density of the chemical bonds is similar to that in DyX. The charge transfer in the DyX_2 molecule is approximately double that in DyX. The spin-density analysis in the molecule as well as in the cation indicates the almost exclusive localization of the open-shell electrons on Dy. The ionization removes an electron from the f orbital; however, the loss of electronic density at the metal is compensated by the σ-back-donation of electrons from the halogens to the d and p valence-orbitals of dysprosium. The total atomic charge on the Dy center in $DyCl_2^+$ amounts to only 1.939 electrons (Table 6). The value of the positive charge localized on the central atom is consistent with the first two ionization potentials of Dy (5.927 eV and 11.67 eV).[17] The direct ionization of the f electron would involve about 20 eV (the third ionization potential of Dy is 22.8 eV [17]). A rearrangement of the electronic density on Dy is observed instead, and the loss of valence electrons from the f orbital of Dy is accompanied by σ-back-donation from the halogens.

The DyX_3 molecules follow trends observed in smaller compounds. The structures with C_{3v} symmetry are almost planar (Table 5). The experimental bond lengths are well reproduced by the present calculations.[18−20] The available vibrational frequencies for $DyCl_3$ (58, 85, 328, 340 cm^{-1} [18]) are in excellent agreement with the calculated values (56, 82, 331, 344 cm^{-1}). The Mulliken spin densities indicate the localization of unpaired electrons exclusively on the Dy atom, and the electron transfer from Dy to the halogen atoms is only slightly lower than the values of charge transfers in the DyX and DyX_2 molecules. However, the orbital electronic distribution on Dy is similar to that on the DyX_2^+ cation but not to its neutral precursors DyX and

DyX_2. Two s and one f electrons of Dy are involved in the bond formation. The strong σ-back-donation to the d and p orbitals leads to a total charge of 1.811 electrons on Dy. Contrary to smaller systems the ionization of DyX_3 leads to dramatic changes. The unpaired electrons are no longer localized exclusively on the Dy center. The symmetry of the parent molecule (C_{3v}) is destroyed, and the cation undergoes a Jahn−Teller distortion, leading to C_s symmetry. The atomic charge localized on dysprosium is almost unchanged relative to the molecule, indicating a contribution of electronic density from the halogen atoms to the ionization process (Table 6). The consecutive ionization energies of dysprosium are 5.927, 11.67, and 22.8 eV. The active participation of halogen atoms in the ionization in the DyX_3 molecule is consistent with the increasing consecutive ionization potential of Dy. The third ionization potential (22.8 eV) is significantly higher than those (17.48, 13.01, 11.84, and 10.454 eV for F, Cl, Br, and I, respectively[21]) of the halogens.

For the reasons given in the previous section it was interesting to compare the experimental values of the ionization/fragmentation potentials with those obtained theoretically for adiabatic processes. The calculated ionization and appearance potentials are given in Table 2. The values generally agree with the respective potentials derived from the IEC taking into account the accuracy of experimental values of about ±0.5 eV. In most cases the theoretical values are somewhat smaller than the experimental ones. These differences become clearly larger for DyX^+ and Dy^+ ions in comparison to DyX_3^+ and DyX_2^+, probably due to the larger kinetic energy of two or three X fragments resulting in the fragmentation processes leading to these ions. More importantly, this agreement indicates the correct prediction of the structures of the studied species and validates the discussion concerning the nature of the bonding. In Figure 2 we display the ionization energies and energies of subsequent dissociations of the Dy−X bonds in the charged species obtained from the theoretical AP values in Table 2. The comparatively low dissociation energy of the first bond in the DyX_3^+ species could explain the highest intensity of the DyX_2^+ ions in all the mass spectra of dysprosium halides. The dissociation of subsequent halogen atoms from the ionic fragments becomes energetically less preferable. The tendency of increasing the dissociation energy of the Dy−X bond in going from the DyX_3^+ to the DyX^+ ionic species can be seen for all dysprosium halides with the exception of dysprosium bromide. At present we are not able to offer an explanation for this phenomenon.

Discussion and Conclusions

The mass spectrum patterns of the gaseous DyX_3 species consist of molecular ions and the DyX_2^+, DyX^+, and Dy^+ fragment ions, with DyX_2^+ being the most intense for all dysprosium halides. The ionization and appearance potentials obtained for these ions by quantum chemical methods

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

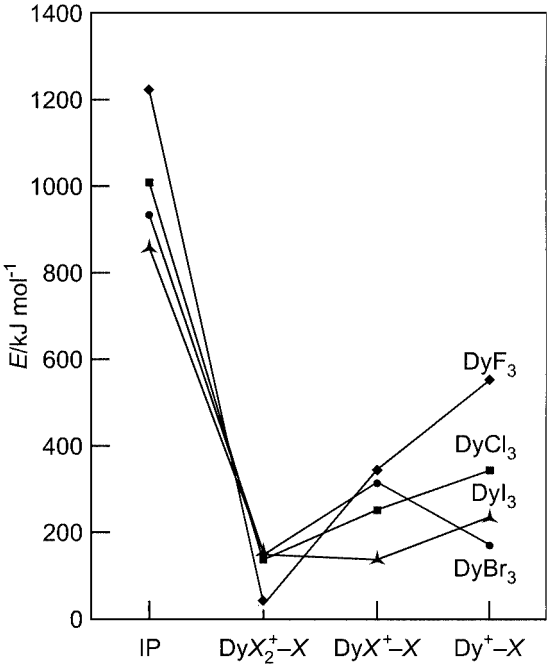

Figure 2. Ionization energies of DyX_3 and fragmentation energies for the DyX_n^+ ions ($n = 1-3$)

in the present study agree well with the experimental values. The thermodynamic meaning of the appearance potentials is the energy of dissociation of the metal−halide bonds in the neutral molecule. For instance, AP(DyF^+) correlates with the energy of the process

$$DyF_3(g) + e \rightarrow DyF^+ + 2F + 2e$$

Combinations of appearance potentials should yield the dissociation energies of the halogen−metal bond in ions. For instance the difference AP(DyF^+) − AP(DyF_2^+) should correlate with the energy of the dissociation process

$$DyF_2^+ \rightarrow DyF^+ + F$$

As already mentioned, the experimental appearance-potentials yield, in fact, upper limits of adiabatic values. Moreover, the accuracy of the AP values, usually reported, is no better than ±0.5 eV. Therefore the determination of the energies of the dissociation/fragmentation processes from experimental appearance potentials is limited.

The available experimental energetic data (ionization and appearance potentials) are reasonably reproduced by the calculated values. More importantly, the calculations reproduce the perturbations in the measured data that originate from the increasing importance of relativistic contributions in heavier halogens. The chemical bonds are formed due to the charge transfer of the electronic density from dysprosium to the halogen atoms. The atomic charge on Dy amounts to 0.702 (DyCl), 1.525 ($DyCl_2$), and 1.811 ($DyCl_3$) leading to a negative charge on chlorine of −0.702, −0.762, and −0.604 electrons, respectively. In the first-order approximation this electron transfer can be considered as an additive process. The increasing positive charge on the metal atom enhances the Coulomb interactions in the cations, leading to a shortening of the Dy−X distance. This charge transfer involves s electrons in DyX and DyX_2. In DyX_3, the f electrons also take part in the bonding (Table 6). The transfer of the f electron is compensated, however, by a similar amount of electronic density due to the σ-back-donation from halogen atoms to the d and p orbitals of Dy. The highest atomic charge in DyX_3 is close to two. This observation is consistent with the Dy values of the two lowest ionization potentials, which are smaller than those of the halogens. The open-shell electrons are localized almost exclusively on the dysprosium atom. The number of electrons confirms the involvement of one s, two s, and two s + one f electrons in the DyX, DyX_2, and DyX_3 bonding, respectively. The atomic charge on the metal atom in DyX_3 disagrees with the established model of the $Dy^{3+}X_3^-$ bonding scheme.[22] It is consistent, however, with the very high value of the third ionization potential of Dy. Due to the σ-back-donation of electrons from the halogens, a more appropriate model for the metallic center in DyX_3 is the Dy^{2+} cation in the excited electronic state, corresponding to an electron excitation from the f to the d orbital. The computations indicate the active participation of the f orbital in the bonding process in DyX_2^+ cations and DyX_3 molecules.

The ionization of DyCl removes the s electron, increasing the charge of Dy from 0.703 to 1.703 electrons. The ionization of $DyCl_2$ corresponds to the removal of the f electron. The charge on Dy increases from 1.525 to 1.939 electrons due to the compensation for electrons involved in the bonding by the σ-back-donation. The unpaired electrons are localized at the Dy center. The removal of the nonbonding f electron from the metal atom increases the Coulomb interactions. However, the ionization process does not affect the charge transfer. The increased contribution of the ionic interactions leads to shorter bonds. The effect of the increased bond strength is confirmed by a blue shift of the corresponding stretching vibrations. The ionization of DyX_3 is more complicated. Ionized $DyCl_3^+$ is subject to the Jahn−Teller effect, and the symmetrical C_{3v} molecules are distorted to the C_s geometry. The total spin-density indicates that open-shell electrons are also localized on the halogen atoms. The above observation agrees with the high values of the third IP of Dy and the preferred ionization of halogen atoms. Such a distribution of electronic density allows the value of the charge on the metallic center to be close to two electrons. The removal of the f electron is again compensated by the σ-back-donation. The bond formation and ionization processes in DyX, DyX^+, DyX_2, DyX_2^+, and DyX_3 lead to the electron loss from the Dy center involving less than two electrons. The primary process of the electron transfer from the metal (including the ionization process) is promptly compensated by the σ-back-donation from halogen atoms. The above processes are consistent with the two lowest IPs of Dy being lower than the first potentials of the halogens. An attempt to remove more electrons from Dy was not successful, and in the DyX_3^+ cation

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the halogen atoms also contribute to the electron-loss process.

Experimental Section

Mass Spectra of Gaseous DyX_3: The mass spectrum of DyF_3 vapors and the ionization efficiency curves for ions identified in the mass spectrum were recorded on a CH5 mass spectrometer (Finnigan MAT, Bremen, Germany)[23] in Julich. Knudsen cells made of Mo with an edged effusion orifice of 0.8 mm diameter were employed in every case. The energy of the ionising electrons, 34 eV, was calibrated with the ionization potentials of Hg, In, and Ag measured prior to the recording of the DyF_3 mass spectra. Mass spectra and appearance potentials for ions present in the mass spectra of $DyCl_3$,[7,8] $DyBr_3$,[9] and DyI_3 [10] were taken from our previous studies. The mass spectrum of $DyCl_3$ [8] and the appearance potentials for ions in the DyI_3 mass spectrum[24] were also taken from the literature.

Theoretical Methods: The quantum-chemical calculations were carried out using the density functional theory (DFT) approach, using Becke's three-parameter functional[25] with Vosko et al.'s local correlation part[26] and Lee et al.'s[27] non-local part (abbreviated as B3LYP). All the calculations were carried out using the relativistic effective core potentials (RECPs) developed by the Stuttgart/Dresden groups that retain the outer $4s^24p^64d^{10}5s^25p^64f^{10}6s^2$ shells of dysprosium and ns^2np^7 of halogen atoms.[28–30] The corresponding basis sets are characterized as the (12s, 11p, 9d,8f) collection contracted to [5s, 5p, 4d, 2f] for Dy and (4s, 4p) contracted to [2s, 3p] for halogen atoms. The basis sets of the halogens were additionally supplemented by two d polarization and a set of sp diffuse functions proposed as part of the SDB-aug-cc-PVTZ and aug-cc-PVTZ basis sets.[31,32] Because of the ionic nature of the chemical bonds in the studied complexes, the validity of the basis sets was checked by the computation of the ionization potential of Dy and electron affinities of halogen atoms. The agreement between the calculated ionization potential of Dy (6.02 eV) and its experimental value (5.927 eV [17]) indicates the reasonable treatment of high-spin electronic states in the Dy atom (sextet) as well as in the Dy^+ cation (quintet) within the applied density functional theory method. The theoretical values of electronic affinities for F (3.33 eV), Cl (3.72 eV), Br (3.51 eV), and I (3.35 eV) agree satisfactorily with the respective experimental data of 3.401, 3.61, 3.36, and 3.059 eV.[21] The availability of unpaired electrons on the f orbitals of dysprosium allows for the rich manifold of electronic states in the studied compounds. The calculations for the studied molecules and cations were performed for the different electronic states allowed by the electronic configurations of the participating atoms, to ensure the location of the proper electronic ground state. Spin-orbit contributions have been neglected in the present calculations. Previous calculations, which estimated such contributions for lanthanide trihalides,[33] indicated that although not negligible, spin-orbit effects constitute only a few percent of the studied properties and do not change the qualitative picture. All geometrical structures were optimized. The location of true minima was confirmed in calculations of vibrational frequencies. The electronic density distributions were studied applying the Mulliken population analysis and the natural bond orbital (NBO) analysis.[34] Because both approaches lead to a similar qualitative picture, the results of the Mulliken populations are discussed in detail in the text. Although differences in electronegativity between halogen atoms lead to some quantitative differences,[34] the qualitative picture of the electron-density distribution is similar and detailed results are illustrated for dysprosium chloride. The calculations were carried out using the Gaussian 98 package of programs.[35]

N,*N*-Dialkylcarbamato Lanthanide Complexes, a Series of Isotypical Coordination Compounds

Ulrich Baisch,[a,b] Daniela Belli Dell'Amico,*[a] Fausto Calderazzo,[a] Luca Labella,[a] Fabio Marchetti,[a] and Alessandra Merigo[a,c]

Keywords: Coordination modes / Lanthanides / Lanthanide contraction

The preparations of the *N*,*N*-dialkylcarbamato complexes with analytical formulae $[Ln(O_2CNR_2)_3]$ (Ln = Pr, Nd, Eu, Gd, Ho, Er, Yb, Lu, R = *i*Pr; Ln = Nd, Eu, Gd, R = Bu; Ln = Nd, R = Et), using $[LnCl_3(ether)_x]$ (ether = THF or dimethoxyethane, DME), NHR_2, and CO_2 are reported. X-ray diffraction of the diisopropylcarbamato derivatives, including a reinvestigation of $[Yb_4(O_2CNiPr_2)_{12}]$, showed these complexes to be tetranuclear and isotypical over a range of 12 atomic numbers. The lanthanide contraction has been evaluated based on the lengths of four different types of Ln–O bond.

Introduction

The synthesis, characterization, and reactivity of *N*,*N*-dialkylcarbamato transition metal complexes have been extensively studied in these laboratories and elsewhere.[1−6] As far as lanthanide (Ln) derivatives are concerned, the structurally characterized examples have resulted from work carried out within this research group,[7,8] with the sole exception of the heteroleptic binuclear complex $[Sm_2(C_5Me_5)_4(THF)\{\mu\text{-}\eta^2\text{-}:\eta^1\text{-}NN(CO_2)Ph_2\}]$, prepared[9] by carbonation of the precursor $[Sm_2(C_5Me_5)_4\{\mu\text{-}\eta^2\text{-}:\eta^1\text{-}NNPh_2\}]$. Moreover, structurally defined homoleptic derivatives of lanthanides with oxygen donors are rather rare. A literature survey has in fact shown that, with these restrictions, even the well-established classes of the β-diketonato[10−12] and carboxylato[13,14,15] complexes are not extensively represented. However, it appears that when bulky coordinated ligands are present, isostructural behavior may be more easily observed. This is evidenced by the synthesis of the isopropoxy μ_5-oxo derivatives of general formula $[Ln_5(\mu_5\text{-}O)(OiPr)_{13}]$ which have been shown to crystallize in the $P2_1/n$ (no. 14) space group for Ln = Nd, Gd, Er, i.e. over a range of nine atomic numbers.[16]

Recently, a preliminary communication from these laboratories showed that the metrical data of the isotypical tetranuclear complexes $[Ln_4(O_2CNiPr_2)_{12}]$ allowed the lanthanide contraction in these complexes to be evaluated in the sequence from neodymium to ytterbium.[17] In this paper, the preparation of the derivatives $[Ln(O_2CNR_2)_3]$ (R = *i*Pr, Ln = Pr, Nd, Eu, Gd, Ho, Er, Lu; R = Et, Ln = Nd; R = Bu, Ln = Nd, Eu, Gd) and the full details of the crystal and molecular structures of the isotypical compounds $[Ln_4(O_2CNiPr_2)_{12}]$ (Ln = Nd, Eu, Gd, Ho, Er, Yb, Lu) are reported.

Results and Discussion

The carbamato complexes $[Ln(O_2CNR_2)_3]$ have been mainly prepared[7,8,17] starting from the derivatives $[LnCl_3(ether)_x]$ (ether = THF or dimethoxyethane, DME),[18] which have a low nuclearity and react promptly with NHR_2 and CO_2 according to Equation (1).

$$[LnCl_3(ether)_x] + 6\,NHR_2 + 3\,CO_2 \rightarrow [Ln(O_2CNR_2)_3] + 3\,[NH_2R_2]Cl + x\,ether \quad (1)$$

As previously reported, in the cases of erbium and ytterbium,[7,8,17] the unsolvated chlorides $LnCl_3$ have been found to be useful starting materials for the synthesis of the carbamato complexes. Consistent with the fact that erbium and ytterbium are late lanthanide elements, and in the hypothesis that the chemical properties of these compounds are mainly governed by the ionic radius of the central metal cation, the preparation of the carbamato derivative was also attempted with lutetium trichloride. This has now been found to react with the $NHiPr_2/CO_2$ system giving the corresponding carbamato derivative in good yield. Conversely, this synthetic route met with failure for the lighter lantha-

nides. The extended structures of the anhydrous lanthanide chlorides could be responsible for their poor or even lack of reactivity. In this context, it is useful to point out that the anhydrous trichlorides have the structure of UCl_3 ($CN = 9$) from lanthanum to gadolinium, while from dysprosium to lutetium the structures are like that of YCl_3 ($CN = 6$).[19] The lower coordination number towards the end of the series, associated with the usual trend towards smaller ionic radii in the same direction, may be responsible for the higher reactivity of the heavier metal halides. In fact, it is reasonable that the primary stage of the reaction sequence towards the formation of the carbamato derivatives is amine association. This is presumably more likely to occur with ytterbium and lutetium with a reduced coordination number, thus initiating the chain of reactions towards the final product.

The yields of the *N*,*N*-dialkylcarbamato complexes (R = *i*Pr, Bu) varied from moderate to good. The workup was rather simple, requiring a preliminary filtration of the reaction mixture to eliminate the dialkylammonium chloride, followed by concentration of the filtrate containing the product.

The solubility of the products in non-polar solvents depends on the nature of the R group. For instance, the *N*,*N*-diethylcarbamato complex of neodymium $[Nd(O_2CNEt_2)_3]$, presumably possessing a polynuclear structure, is only sparingly soluble in hydrocarbons. For this reason it is more conveniently prepared by treatment of the soluble $[Nd(O_2CNBu_2)_3]$ in a hydrocarbon solution with $NHEt_2$ and CO_2 according to an $O_2CNR_2/O_2CNR'_2$ substitution reaction, originally reported for the titanium(III) complexes,[20] and more latterly extended to other metal cations.[5,21]

Table 1. IR spectra of the tetranuclear complexes $[Ln_4(O_2CN{i}Pr_2)_{12}]$ in the 1650−1350 cm^{-1} region

Ln	Medium	Wavenumber[a] (cm^{-1})			
Pr	PCTFE	1591	1527	1518	1353
Nd	Nujol	1593	1515	1479	1354
Eu	PCTFE	1597	1533	1488	1354
Gd	PCTFE	1598	1537	1485	1355
Ho	Nujol	1601	1538	1489	1354
Er	Nujol	1602	1540	1490	1355
Yb	Nujol	1604	1541	1491	1355
Lu	Nujol	1610	1530	1490	1354

[a] Bands at about 1460 and 1380 cm^{-1}, attributable to the CH_3 and CH_2 groups. Bending vibrations are not reported.

The IR spectra of these derivatives show intense and broad bands in the 1650−1350 cm^{-1} region due to the stretching vibrations of the O_2CN moieties (see Table 1, and the Exp. Sect.). As expected for complexes having analogous molecular structures, the spectra of $[Ln_4(O_2CN{i}Pr_2)_{12}]$ are almost identical, except for a shift of the highest frequency band towards higher wavenumbers along the series. Chisholm and Extine[3] studied the effect of isotopic substitution ($^{18}O_2CN$ and $O_2{}^{13}CN$) on the position of the highest frequency band for some dialkyl-carbamato complexes of zirconium, niobium and tantalum. They concluded that for a bidentate group the vibration is mostly NC in character, while for a monodentate arrangement there is a predominant OC contribution. According to this interpretation, the data in Table 1 would tend to suggest an increase of the NC bond order from Pr to Lu. The following data within this paper on the observed trend of Ln−O bond lengths (vide infra) are relevant to this specific point.

Magnetic susceptibility measurements have been carried out on $[Nd_4(O_2CN{i}Pr_2)_{12}]$, $[Eu_4(O_2CN{i}Pr_2)_{12}]$, and $[Gd(O_2CNBu_2)_3]$, see Table 2. The magnetic moments at room temperature agree with the experimental values usually encountered with these paramagnetic centers and, for neodymium and gadolinium, they correspond to the calculated values.[22,23] The europium (III) derivatives frequently show more complicated magnetic behavior as the first excited level is close to the ground state (about 250 cm^{-1} higher) so that it may become thermally populated. Variable temperature studies have been performed for the europium and gadolinium compounds. In the range 70−270 K, the magnetic susceptibility of the gadolinium derivative follows the Curie−Weiss law. On the contrary, the europium compound in the 70−170 K range shows, as expected, a temperature dependent μ value, the magnetic moment becoming independent of temperature above 170 K.

The diisopropyl derivatives can be easily recrystallized from heptane with formation of single crystals suitable for X-ray diffraction studies. They are isotypical and the complete structural determination was performed for the neodymium, europium, gadolinium, holmium, erbium and lu-

Table 2. Magnetic susceptibilities of the $[Ln(O_2CNR_2)_3]$ derivatives

Ln	R[a]	*T* /K	χ_{corr} /cgsu	Diam. Corr,[b]/cgsu	μ_{eff} /BM ($\mu_{calcd.}$)[c]	Ref.
Nd	*i*Pr	297	$5250\cdot10^{-6}$	$-302\cdot10^{-6}$	3.53 (3.62)	this work
Eu[d]	*i*Pr	295	$3210\cdot10^{-6}$	$-302\cdot10^{-6}$	2.76 (0)	this work
Gd[d]	Bu	270	$24400\cdot10^{-6}$	$-373\cdot10^{-6}$	7.28 (7.94)	this work
Er	*i*Pr	295	$35400\cdot10^{-6}$	$-302\cdot10^{-6}$	9.11 (9.58)	[8]
Yb	Et	295	$7645\cdot10^{-6}$	$-231\cdot10^{-6}$	4.23 (4.54)	[8]
Yb	*i*Pr	295	$7576\cdot10^{-6}$	$-302\cdot10^{-6}$	4.21 (4.54)	[8]

[a] The compounds are tetranuclear for R = *i*Pr; the nuclearity of the ethyl and butyl derivatives is unknown. [b] Pascal constants have been used for H, C, N, and O, the diamagnetic correction for Ln^{3+} being $-16\cdot10^{-6}$ cgsu. [c] $\mu_{calcd.} = g[J(J+1)]^{1/2}$; $g = 3/2 + [S(S+1) - L(L+1)]/2J(J+1)$. [d] See text for the variable−temperature measurements.

tetium complexes.[24] Although the ytterbium compound had been previously studied, a new crystallographic determination was carried out in order to have more accurate bond parameters.

The molecules of $[Ln_4(O_2CN\mathit{i}Pr_2)_{12}]$ are slightly prolate spheroids with a maximum diameter of about 16.4 Å. The external shell of the molecules is composed of isopropyl groups, and this accounts for the solubility of these species in hydrocarbons. The crystal packing of these large molecules leaves relatively large cavities which can accommodate solvent molecules such as toluene, heptane, or isooctane. The different nature of the lattice solvent, however, does not affect either the space group or the molecular structure of the compounds, as shown by the smooth trend of the Ln−O distances vs. the number of *f* electrons (Figure 2).

The lanthanide carbamato molecules have C_2 symmetry, the carbamato ligands being situated around four metal atoms as shown in Figure 1. Two metal atoms are related to the other two by a two-fold axis, the quadruplet building a sort of elongated tetrahedron (ditrigon). Three different coordination modes are exhibited by the ligands, which chelate three, two, or one metal atom, labelled **[a]**, **[b]**, and **[c]**, respectively.

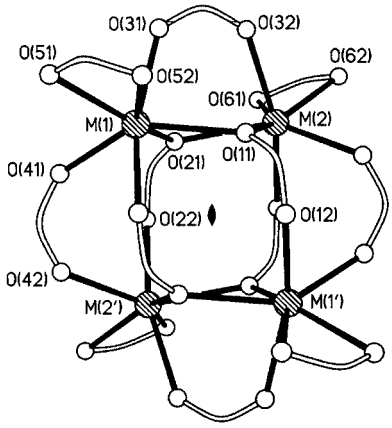

Figure 1. Schematic representation of the $[Ln_4(O_2CN\mathit{i}Pr_2)_{12}]$ core projected down the two-fold axis, showing the metal and oxygen labelling

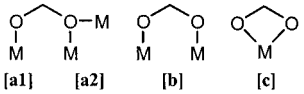

The ligands chelating three metal atoms have a tri-coordinated oxygen atom which shows the longest Ln−O distances and has been indicated as the **[a2]** type and a di-coordinated one, the **[a1]** type. Table 3 shows the Ln−O distances found in the known structures of $[Ln_4(O_2CN\mathit{i}Pr_2)_{12}]$ listed by metal and by ligation type. For each type the weighted means are also reported. The mean values and the standard deviations have been calculated using the expressions below.[25]

$$\bar{x} = \frac{\sum_i \left(\frac{x_i}{\sigma_i^2}\right)}{\sum_i \left(\frac{1}{\sigma_i^2}\right)}$$

$$\sigma(\bar{x}) = \sqrt{\frac{1}{\sum_i \left(\frac{1}{\sigma_i^2}\right)}}$$

The lanthanide is hepta-coordinated and the coordination polyhedra of M(1) and M(2) are almost superimposable. They may be considered as a heavy distortion of a pentagonal bipyramid (idealized symmetry D_{5h}), according to the catalogue of seven-vertex polyhedra proposed by Britton and Dunitz.[26]

Taking into account the mean values of the Ln−O distances of Table 3, the **a2** distance is the longest, being about 6% greater than the **a1** type (see Table 3 for the individual M−O distances). This lengthening is certainly due to the tri-coordination of the oxygen in the **a2** type. In contrast, the Ln−O distances of type **c** are stretched by about 4%, with a small O−Ln−O angle of about 56°. Finally, for each compound the Ln−O distances of types **a1** and **b** are rather similar, the differences being within 1%.

In order to show the trend of the Ln−O distances as a function of the nature of the lanthanide, the mean values of the distances for each bond type (**a1**, **a2**, **b**, and **c**) have been plotted against the number of *f* electrons of the metal cation. Figure 2 shows the result when the distances of each type were fitted with the quadratic function $d(\text{Ln}-\text{O}) = A_0 - A_1 \cdot n + A_2 \cdot n^2$, where *d* is the distance, *n* is the number of *f* electrons and A_0, A_1, and A_2 are the fitting parameters. The curves show rather similar slopes, suggesting that the metal radius contraction should mainly account for the trend. In the case of the Ln−O **a1** distances some adjacent couples, such as Yb/Lu or Ho/Er, do not show a significant contraction. However, the trend along the series is analogous to that found for the other bond types.

As has been underlined in a previous preliminary communication[17] from these laboratories, the trend of the Ln−O bond shortening is parabolic,[27] i.e. the early lanthanides contract their radii slightly more rapidly than the later ones (Figure 2). Since we now add the data for the Eu, Er and Lu derivatives and the more accurate data for the Yb derivative, we further confirm the general trend of the distances. The A_2 parameter of the fitting is $1.71 \cdot 10^{-4}$ for the Ln−O distances of the **b** type compared with a mean value of $4.87 \cdot 10^{-4}$ for the other types. The well−known lanthanide contraction was originally recognized[27b] on the basis of X-ray crystallographic determinations on the oxides and fluorides of the Ln^{3+} ions, which are not isostructural along the whole series. The contraction was evaluated to be 15% from cerium to lutetium, a correction being required for the decreased coordination number along the series. [27c,27d]

The **a1** bonds represent the maximum approach of the oxygen to the metal. The **a1** fitting corresponds to the equa-

[a] ′: $-x$, y, $3/2 - z$.

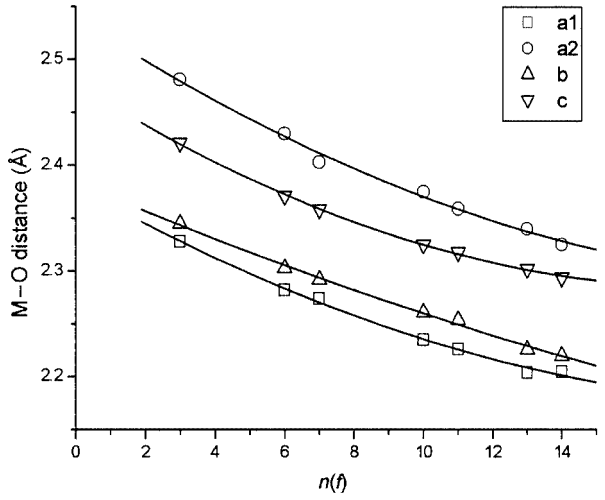

Figure 2. Polynomial fittings of different types of Ln−O distances in the isotypical $[Ln_4(O_2CNiPr_2)_{12}]$ vs. the 4*f* electronic configuration.

tion $d(\text{Ln}-\text{O}) = 2.381 - 0.0188 \cdot n + (4.24 \cdot 10^{-4}) \cdot n^2$. By extrapolation it can be anticipated that 2.381 Å should be shortest La−O distance of this type if the lanthanum carbamato derivative had the same structure as the compounds reported in this paper.

It is remarkable that the cerium(III) derivative $[Ce_4(O_2CNiPr_2)_{12}]$ also turned out to be a tetranuclear species.[28] It shows a less symmetrical molecular structure than the compounds described herein. In the molecule the coordination number is seven for three of the cerium atoms and eight for the fourth one. Because of the different structural arrangement, a comparison of the Ce−O distances with those found in the isotypical species herein described is in general difficult. On the other hand, the unique Ce−O distance of type **a1** involving hepta-coordinated cerium [Ce(3)−O(82)] in this complex is 2.368 Å corresponding to a length increase of 0.04 Å with respect to the neodymium complex.

Conclusions

A class of molecular compounds of the trivalent lanthanides, i.e. the *N*,*N*-dialkylcarbamato complexes, has been exhaustively defined as far as their preparation and characterization are concerned. The *N*,*N*-diisopropyl derivatives from Nd to Lu are isotypical species, consisting of tetranuclear molecules, $[Ln_4(O_2CNiPr_2)_{12}]$, where the metal center is hepta-coordinated. The structural determinations have allowed the lanthanide contraction over a range of 12 atomic numbers to be monitored.

The solubility of these complexes in hydrocarbons can be tuned by varying the nature of the alkyl group, thus allowing these compounds to be used as precursors to other derivatives in slightly polar, non-coordinating solvents.

Experimental Section

All preparations were carried out under a dry atmosphere (N_2 or CO_2). Solvents were freshly distilled from the usual drying agents under nitrogen. In the case of the lutetium derivative, commercially available anhydrous $LuCl_3$ was used as received (Aldrich). Elemental analyses (C,H,N) were carried out at the Laboratorio di Microanalisi della Facoltà di Farmacia, Università di Pisa, with a Carlo Erba mod. 1106 analyzer. IR spectra were measured with a FT-IR Perkin−Elmer mod. 1725X spectrophotometer. Magnetic measurements were performed with a magnetic balance (Faraday method) using $CuSO_4 \cdot 5H_2O$ for calibration. The lanthanide complexes $LnCl_3(ether)_x$ (ether = DME or THF) were prepared as previously reported.[17]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Synthesis of $[Ln_4(O_2CNiPr_2)_{12}]$ (Ln = Pr, Nd, Eu, Gd, Ho, Er, Yb, Lu): The syntheses were carried out by treating the solvated chlorides $[LnCl_3(ether)_x]$ (ether = DME, x = 0.5, Ln = Nd; x = 1, Ln = Pr; x = 2, Ln = Eu, Gd, Ho, Yb; ether = THF, x = 1.5, Ln = Nd; x = 0, Ln = Lu) with $NHiPr_2$ and CO_2 in toluene. Analysis for $C_{21}H_{42}LnN_3O_6$, Ln = Pr, M = 573.49: calcd. Pr 24.6, CO_2 23.0%; found Pr 25.2; CO_2 23.3%. Ln = Nd, M = 576.83: calcd. Nd 25.0, CO_2 22.9%; found Nd 25.2, CO_2 21.5%. Ln = Eu, M = 584.55: calcd. Eu 26.0, CO_2 22.6%; found Eu 25.2, CO_2 22.5%. Ln = Gd, M = 589.84: calcd. Gd 26.7, CO_2 22.4%; found Gd 25.2, CO_2 21.2%. Ln = Ho, M = 597.52: calcd. Ho 27.6, CO_2 22.1%; found Ho 27.5, CO_2 21.7%. Ln = Er, M = 599.85: calcd. Er 27.9, CO_2 22.0%; found Er 27.5, CO_2 21.7%. Ln = Yb, M = 605.63: calcd. Yb 28.6, CO_2 21.8%; found Yb 28.8, CO_2 20.9%. Ln = Lu, M = 607.56: calcd. Lu 28.8, CO_2, 21.7%; found Lu 29.6; CO_2 21.3%.

Colors of the products are: green (Pr), violet (Nd), pale pink (Eu), colorless (Gd, Yb, Lu), yellow-pink (Ho), and pink (Er). The approximate solubility of the tetranuclear ytterbium compound is $6\cdot10^{-3}$ M in toluene. Analyses of the products, once dried in vacuo, were consistent with the formula $[Ln(O_2CNiPr_2)_3]_n$. When obtained as single crystals by recrystallization from hydrocarbons (C_nH_m = heptane, isooctane, or toluene), their compositions corresponded to $Ln_4(O_2CNiPr_2)_{12}\cdot2C_nH_m$ (Ln = Nd, n = 8, m = 18; Ln = Eu, Er, n = 7, m = 8; Ln = Gd, Ho, Yb, Lu, n = 7, m = 16).

Two typical experiments are described below.

a) Europium: A solution of $NHiPr_2$ (16.0 mL, 114.2 mmol) was stirred in a flask under CO_2 until gas absorption was complete. At this point, $[EuCl_3(DME)_2]$ (5.02 g; 11.45 mmol) was added, the suspension was stirred for 23 h and then filtered. The filtrate was evaporated to dryness and the pale-pink residue was treated with heptane (50 mL). The product was recovered by filtration and dried in vacuo (2.75 g, 41% yield).

b) Lutetium: A solution of $NHiPr_2$ (8.0 mL, 57.08 mmol) in toluene (200 mL) was stirred in a flask under CO_2 up to completion of the gas absorption. Anhydrous $LuCl_3$ (1.58 g, 5.62 mmol) was introduced and the suspension was stirred under CO_2 for 2 days. The mixture was filtered and the filtrate was evaporated to dryness in vacuo. The colorless residue was recrystallized from heptane (1.22 g, 36% yield).

Synthesis of $[Ln(O_2CNBu_2)_3]$ (Ln = Nd, Eu, Gd): The syntheses were carried out starting from $[LnCl_3(DME)_x]$ (x = 0.5, Ln = Nd; x = 2, Ln = Eu, Gd). The dimethoxyethane adduct $[LnCl_3(DME)_x]$ was treated with $NHBu_2$ and CO_2 in toluene. Analysis for $C_{27}H_{54}N_3LnO_6$. Ln = Nd, M = 660.99: calcd. C 49.1, H 8.2, N 6.4, Nd, 21.8, CO_2, 20.0%; found C 48.7, H 8.7, N 6.1, Nd, 22.1, CO_2, 20.0%. Ln = Eu, M = 668.71: calcd. Eu, 22.7, CO_2, 19.7%; found Eu, 20.8, CO_2, 17.4%. Ln = Gd, M = 674.00: calcd. Gd, 23.3, CO_2, 19.6%; found Gd, 21.7, CO_2, 18.0%.

A typical experiment is described: A solution of dibutylamine (5.0 mL, 29.67 mmol) in heptane (50 mL) was saturated with CO_2 and $[NdCl_3(DME)_{0.5}]$ (0.74 g, 2.50 mmol) was then added. After 12 h stirring the suspension was filtered and the violet product was obtained by evaporating the filtrate to dryness (1.23 g, 74% yield). IR (1700−1300 cm^{-1}, Nujol mull, cm^{-1}): 1528 s, 1490 s, 1430 s, 1325 s.

Synthesis of $[Nd(O_2CNEt_2)_3]$: $[Nd(O_2CNBu_2)_3]$ (6.77 g, 10.24 mmol) in heptane (100 mL) was treated with $NHEt_2$ (7.0 mL, 67.66 mmol) under CO_2. The violet product precipitated and after 1 h stirring the liquid phase had become colorless. The suspension was filtered and the solid was dried in vacuo (4.36 g, 86% yield). Analysis for $C_{15}H_{30}N_3NdO_6$. M = 492.66: calcd. Nd, 29.3, CO_2, 26.8%; found: Nd, 28.6, CO_2, 26.9%. IR (range 1700−1300 cm^{-1}, PCTFE mull, cm^{-1}): 1610 w, 1545 s, 1493 s, 1457 s, 1436 s, 1313 s.

X-ray Crystallography: Only the structure determination of $Yb_4(O_2CNiPr_2)_{12}\cdot2C_7H_{16}$ is presented in detail, the other determinations being performed in a similar manner. A summary of data collection is in Table 4. The X-ray measurements were carried out with a Bruker P4 diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The crystals, prepared as described before, are colorless prisms. One of them was sealed in a glass capillary under a nitrogen atmosphere saturated with heptane vapor and the unit cell parameters listed in Table 4 were derived from the setting angles of 34 intense reflections. Data were collected in the $\omega/2\theta$ scan mode, and three standard reflections were monitored every 97 measurements for checking crystal decay and equip-

ment stability. Data reduction was carried out using the XSCANS program.[29] A set of 7669 reflections was collected between θ = 2.3 and 25.0° and corrected for Lorentz and polarization effects and for absorption by the ψ−scan method. After merging the equivalent reflections $\{R_{int} = [\Sigma|F_o^2 - F_o^2(mean)|/\Sigma(F_o^2)] = 0.0251\}$, 5848 unique reflections satisfying the condition $I > 2\sigma(I)$ were retained for the following calculations. The systematic absences strongly suggested the space groups *Cc* or *C*2/*c*. The solution was found by direct methods in the centrosymmetric space group and completed through the subsequent difference Fourier maps. Calculations were carried out with the SHELX-97 and SHELXTL programs.[30,31] In the final refinement cycles, based on F^2, anisotropic thermal parameters were used for all non hydrogen atoms. The final reliability factors are listed in Table 4.

Synthesis, Structure and Characterizations in Solid State and Solution of Dinuclear Pentacoordinated Fe^{II} and Mn^{II} Complexes and of a Linear Tetranuclear Fe^{III} Complex Obtained with the Ligand *N*,*N*,*N*′,*N*′-Tetrakis-[(6-methyl-2-pyridyl)methyl]propane-1,3-diamine

Keywords: N ligands / Iron / Manganese / Tetranuclear complexes / Bioinorganic chemistry

Two neutral complexes $[(L_6{}^3{}4M)Fe_2Cl_4]\cdot 2H_2O\cdot 2CHCl_3$ (**1**) and $[(L_6{}^3{}4M)Mn_2Cl_4]\cdot CH_3CN$ (**2**) have been synthesized {$L_6{}^3{}4M$ = *N*,*N*,*N*′,*N*′-tetrakis[(6-methyl-2-pyridyl)methyl]propane-1,3-diamine} and their molecular structures established by X-ray crystallography. Both structures are similar, with each metal center in a trigonal-bipyramidal environment. No magnetic coupling is observed between the metal centers. UV/Vis spectra and cyclic voltammograms were recorded in CH_2Cl_2 and CH_3CN solutions. Both complexes are stable in CH_2Cl_2, whereas only **2** is stable in CH_3CN. On the contrary, **1** is in equilibrium with another Fe^{II} species in CH_3CN. When this last solution is aerated, monocrystals of the neutral linear tetranuclear complex $[(L_6{}^3{}4M)Fe_4(\mu\text{-}O)_3Cl_6]\cdot 2CH_3CN$ (**3**) can be isolated. Its structure is unusual with two Fe^{III} ions pentacoordinate and the two others tetracoordinate with only chloro ligands and oxo bridges. The magnetic properties reveal that two consecutive metal centers are strongly antiferromagnetically coupled.

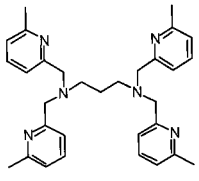
Introduction

Much of the interest in the coordination chemistry of iron and manganese ions has been driven by their involvement in a number of biological systems, and in particular in the active sites of catalytic systems. Dioxygen interaction with heme- or nonheme-iron enzymes is of fundamental importance in aerobic life processes[1], including metabolism.[2,3] Whatever the system considered, interaction between dioxygen and an Fe^{II} ion leads to a superoxo adduct to Fe^{III}. In dioxygen fixation, this reaction is reversible. For substrate oxidations, reduction of the superoxo group leads to a peroxo form which evolves toward a high-valent iron−oxo entity. Often, complexes synthesized with various amine/polypyridine-, amine/polyimidazole- or polypyrazole-based ligands can reproduce the reactivity and transient peroxo motifs observed in the catalytic cycles of natural systems.[4−6]

To synthesize iron complexes, which are functional or spectroscopic models of the transient species formed during the catalytic cycle of natural systems for alkane hydroxylation, we have used a series of amine/pyridine ligands with variable length and a number of functions.[7] We report here the synthesis and structure of a dinuclear Fe^{II} complex $[(L_6{}^3{}4M)Fe_2Cl_4]\cdot 2H_2O\cdot 2CHCl_3$ (**1**) with the new hexadentate ligand *N*,*N*,*N*′,*N*′-tetrakis[(6-methyl-2-pyridyl)methyl]-propane-1,3-diamine ($L_6{}^3{}4M$; Figure 1), which upon reaction with O_2 leads to a linear tetranuclear Fe^{III} complex $[(L_6{}^3{}4M)Fe_4(\mu\text{-}O)_3Cl_6]\cdot 2CH_3CN$, (**3**). Magnetic data in the solid state, and UV/Vis and electrochemical characterizations in solution are also reported.



$L_6{}^3{}4M$

Figure 1. Structure of the ligand *N*,*N*,*N*′,*N*′-tetrakis[(6-methyl-2-pyridyl)methyl]propane-1,3-diamine ($L_6{}^3{}4M$)

Given the importance of Mn^{III} tetranuclear complexes in relation with the oxygen-evolving center[8,9] the previous

result prompted us to prepare the analogous Mn complexes. Indeed, we have prepared $[(L_6{}^34M)Mn_2Cl_4]\cdot CH_3CN$ (**2**). Nevertheless, due to the higher oxidation potential for Mn^{III}/Mn^{II}, no reaction was observed with O_2. Electrochemical properties of **1** are presented and compared to those of **2**.

Results and Discussion

X-ray Crystal Structures

The structures of complexes **1** and **2** are analogous, as shown in Figures 2 and 3, respectively. The crystallographic data are reported in Table 4.

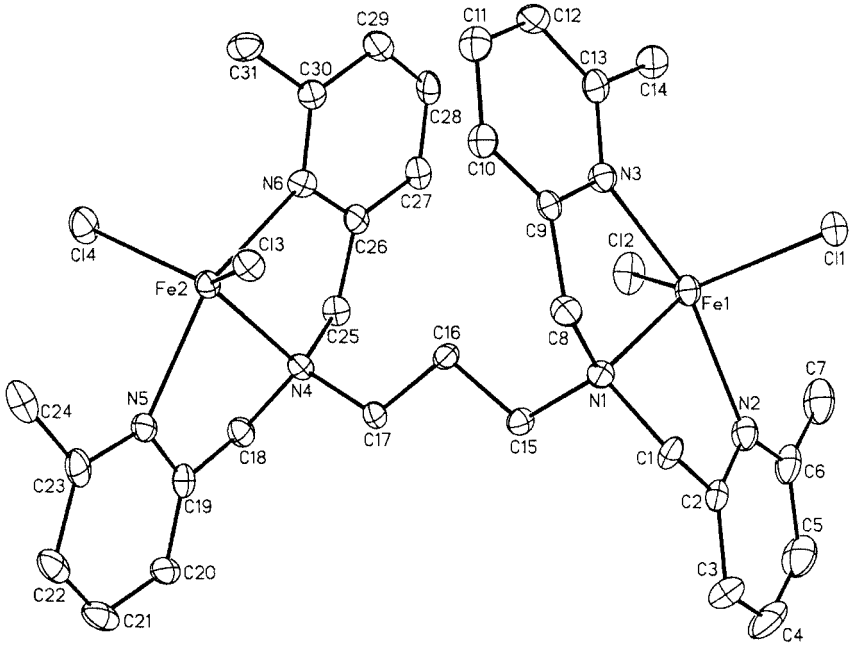

Figure 2. Crystal structure of **1** (2 H_2O and 2 $CHCl_3$ not shown)

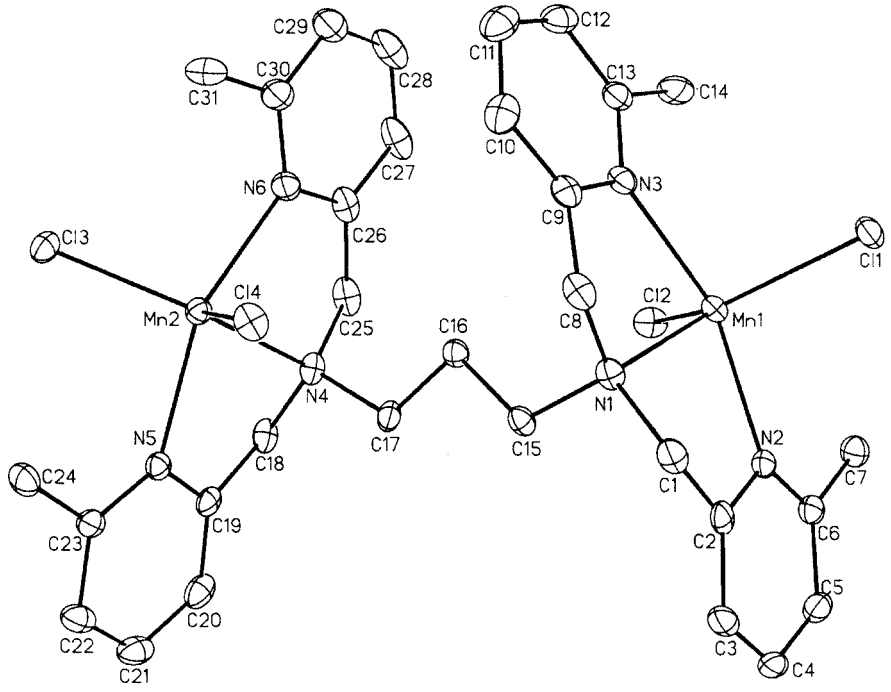

Figure 3. Crystal structure of **2** (CH_3CN not shown)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The metal/ligand ratio is 2:1 for both complexes and they exhibit two similar coordination sites. Each metal ion is surrounded by three nitrogen atoms from the ligand and two chloride ions. The geometries at the metal centers can be described as distorted trigonal bipyramids with the amino nitrogen atom, the metal center and the two chloro ligands defining the equatorial plane. Complexes containing pentacoordinate Fe^{II} ions with a similar geometry have been recently reported by Britovsek et al. with imine/pyridine ligands.[10]

The bond lengths and angles for **1** and **2** are reported in Table 1. For both complexes, the two coordination sites present small variations of the bond lengths and angles. The metal−N distances, 2.2 Å for Fe^{II} and 2.3 Å for Mn^{II}, are indicative of a high-spin state for each metal.[11−13] For complex **2** the shortest Mn−N distance occurs with the pyridine nitrogen atom, as for complexes with similar aminopyridine ligands,[14,15] which accords with a better π-acceptor character of the pyridines. The correlation between the bond lengths and the π-acceptor character of the ligand indicates minimal steric congestion at the metal center. Coordination of the ligand is therefore governed by electronic interactions. Surprisingly, this effect is not observed with the Fe^{II} complex **1**. The $Fe-N_{amino}$ bonds (ca. 2.19 Å) are shorter than the $Fe-N_{pyridine}$ ones (between 2.21 and 2.26 Å). This can be related to an enhanced steric hindrance at the metal centers in **1**. Indeed, contraction of the metal ion from Mn^{II} to Fe^{II} shortens the metal−ligand distances. However, the steric hindrance provided by the methyl groups on the pyridines lengthens the Fe−pyridine bonds.

Table 1. Selected bond lengths [Å] and angles [°] for complexes **1** and **2**

	1	**2**
M1−Cl1	2.3197(11)	2.3784(14)
M1−Cl2	2.3145(11)	2.3899(14)
M2−Cl3	2.2962(10)	2.3817(16)
M2−Cl4	2.3243(12)	2.3788(15)
M1−N1	2.188(3)	2.302(4)
M1−N2	2.253(3)	2.267(4)
M1−N3	2.217(3)	2.280(4)
M2−N4	2.192(3)	2.320(4)
M2−N5	2.256(3)	2.297(4)
M2−N6	2.230(3)	2.278(4)
Cl1−M1−Cl2	126.10(4)	123.61(6)
Cl3−M2−Cl4	128.93(4)	120.93(6)

The same conclusion is suggested by the Cl−M−Cl angles. For **1**, these are 128.93 and 126.10°, which are very similar to those of complexes with related structures.[10] Compared with **1**, the diminution of the angles observed for the Mn complex **2** (123.61 and 120.93°) is accompanied by elongation of the M−Cl bond lengths, which minimizes the repulsion between both chloride ions. Those Mn^{II}−Cl distances (around 2.38 Å) are shorter than those usually found (around 2.42 Å) for hexacoordinate Mn^{II} complexes containing at least one chloride ion. For a pseudo-square-pyramidal high-spin Mn^{II} complex containing one chloride ion, Bucher et al.[13] observed an even shorter Mn−Cl distance (2.331 Å). Therefore, the diminution of the Mn−Cl distance can be related to both the diminution of the metal coordination number and the steric hindrance around the metal center. The structure of complex **3** is represented in Figure 4.

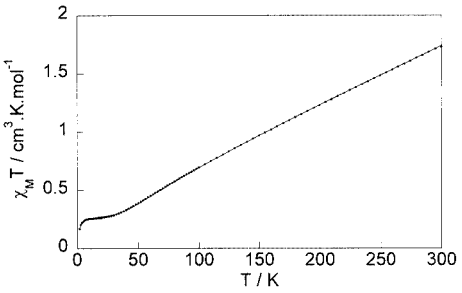

Figure 5. $\chi_M T$ vs. T for **3** (the solid line represents the best fit and the dots represent the experimental data)

The molecule is a neutral tetranuclear Fe^{III} complex, corresponding to the formula $[(L_6{}^3 4M)Fe_4(\mu\text{-}O)_3Cl_6]$. The Fe^{III} ions are in a linear configuration with three single oxo bridges. Selected bond lengths and angles are listed in Table 2.

Several reported tetranuclear Fe^{III} complexes with similar ligands[16−20] all exhibit closed structures with hexacoordinate Fe^{III} ions bridged by oxo and carboxylato groups. With the new ligand $L_6{}^3 4M$, the tetranuclear complex is linear and only two iron centers, Fe(1) and Fe(2), are coordinated to the ligand. As for **1** and **2**, the geometry at those metal centers can be considered as distorted trigonal-bipyramidal since Fe(1) and Fe(2) are surrounded by only three nitrogen atoms from the ligand and two exogeneous ligands: two oxo bridges for Fe(1) and one oxo bridge and one terminal chloride ion for Fe(2). Fe(3) and Fe(4) are not coordinated to the ligand and have tetrahedral geometries. Fe(3) is surrounded by two chloride ions and two bridging oxygen ligands, and Fe(4) by three chloride ions and one bridging oxygen ligand. The Fe(1)/Fe(4) fragment is reminiscent of unsymmetrical diiron(III) complexes.[21−25] As indicated in Table 2, all the Fe−O bond lengths are around 1.8 Å, which is typical of μ-oxo bridges for symmetrical as well as unsymmetrical units.[26] The Fe−O−Fe angles are around 150°, as observed for the other unsymmetrical (μ-oxo)diiron(III) complexes[21−24] with the exception of that reported recently by Raffard−Pons y Moll et al. (ca. 180°).[25]

An unsymmetrical structure, similar to the one of **3**, has been obtained for an $Fe^{III}-Ni^{II}$ complex with diphenylphosphate as bridging and terminal ligands.[27] Thus, the four inorganic centers are the Fe^{III}, the Ni^{II} and the P atoms. However, the structure given here for **3** is, as far as we know, the first reported tetranuclear unsymmetrical unit with only Fe^{III} ions.

Magnetic Properties

The temperature dependence of the magnetic susceptibility was measured for the three complexes in the range 300−5 K.

For complexes **1** and **2** $\chi_M T$ vs. T curves follow a Curie law, indicating no coupling between the metal ions, in agreement with the two independent coordination sites. At room temperature $\chi_M T$ is 6.7 $cm^3 \cdot K \cdot mol^{-1}$ for **1** and 8.9 $cm^3 \cdot K \cdot mol^{-1}$ for **2**. The value obtained for **1** is characteristic of two independent $S = 2$ Fe^{II} ions with $g = 2.11$. For **2**, the two Mn^{II} ions are high spin ($S = 5/2$) with a g of 2.02.

The magnetic susceptibility of the tetranuclear complex **3** as a crystalline powder material was recorded. Experimental data are represented as $\chi_M T$ vs. T in Figure 5, together with the fit.

The data were fitted to the Van Vleck formula,[28] assuming three identical oxo bridges, with full diagonalization of a $6^4 \times 6^4$ matrix. The $\chi_M T$ at 0 K differs from the zero expected and corresponds to a paramagnetic impurity, and the usual Curie−Weiss expression adapted to the high-spin Fe^{II} complex **1** was used to account for this low temperature data. The strong antiferromagnetic coupling obtained is $J = -241$ cm^{-1} and the amount of impurity is 2%. Attempts to fit the curve with three different J values have been made. The quality of the fits obtained was similar to the one reported here. Furthermore, the three J values obtained were of the same order and similar to that found when only one J was considered.

The high antiferromagnetic coupling is quite usual for single oxo-bridged unsymmetrical dinuclear Fe^{III},[21−25] and is reminiscent of the linear tetranuclear Mn^{IV} we obtained previously.[29] When the two central ions (b,c) are strongly antiferromagnetically coupled, the two terminal spins (a,d) appear to be coupled by an antiferromagnetic (AF) effective interaction. In this present case we found that if $IJ_{ab}/J_{bc}\, I << 1$ there is an effective $J_{eff} = 2.5J_{ab}{}^2/J_{bc}$. The lowest spin states are then predicted to be those of an $S_i = 5/2$ pair: $S = 0-5$. The constants obtained here led to first states of $S = 0$ ($E = 0$ cm^{-1}), $S = 1$ ($E = 114$ cm^{-1}), $S = 2$ ($E = 360$ cm^{-1}), $S = 3$ ($E = 760$ cm^{-1}). The next state is not $S = 4$ but $S = 1$ at 1014 cm^{-1}; $S = 4$ is found at $E = 1372$ cm^{-1}. The first states thus obey, qualitatively, the idea proposed, but the agreement is not quantitative since the individual J values do not obey the condition for the validity of the perturbation theory. Qualitatively, we can retain the idea that the two external spins are AF-coupled through an almost diamagnetic system, as explained by Philouze et al.[29]

EPR

The EPR spectrum of complex **2** was recorded as a frozen solution in CH_2Cl_2 at 4 K in the range 500−8000 G (Figure 6). There are no hyperfine transitions, while the broad resonances seen are typical of low-symmetry mononuclear Mn^{II} complexes,[13,30] which is consistent with the independence of the two metal centers. The main derivative line at $g = 4.2$ indicates a rhombic symmetry with E/D close to 1/3. According to this attribution, the spectrum is similar to those obtained by simulation with D between 0.2 and 0.3 cm^{-1}.[31] As far as we know, **2** is the first trigonal-bipyramidal complex with both X-ray structure and EPR characterizations.

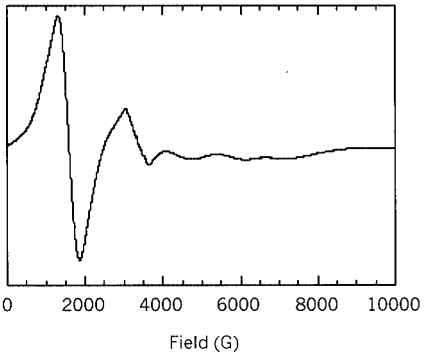

Figure 6. EPR spectra of **2** recorded in CH_2Cl_2 at 4 K at the frequency of 9.38667 GHz

No signal could be detected (at 4 K) for **3** dissolved CH_3CN. The neutral structure characterized for **3** in the solid state remains, therefore, intact in CH_3CN.

UV/Vis

UV/Vis spectra of both **1** and **2**, recorded in CH_2Cl_2, show an intense band at 268 nm that is attributed to pyridine π−π* transitions.

The Fe^{II} complex **1** shows two other bands, at 313 and 390 nm, corresponding to MLCT transitions from Fe^{II} to pyridine π* orbitals. The calculated ε values are 950 and 880 $M^{-1}\cdot cm^{-1}$, respectively. The intensity of those bands is usually around 1000 $M^{-1}\cdot cm^{-1}$ for high-spin Fe^{II} complexes.[32]

For complex **2**, no bands other than the 268 nm one are observed, except for a shoulder at 313 nm with an ε of 400 $M^{-1}\cdot cm^{-1}$.

The UV/Vis spectrum of **3** recorded in CH_3CN (Figure 7) presents three intense bands below 400 nm. The first at 262 nm is attributed to pyridine π−π* transitions with an ε of 29000 $M^{-1}\cdot cm^{-1}$. A large band with several components is observed around 335 nm (ε = 23000 $M^{-1}cm^{-1}$). In this 320−350 nm area, intense $Cl^-\rightarrow Fe^{III}$ charge-transfer bands are expected, as reported previously for dinuclear complexes with $-O-FeCl_3$ fragments,[23,25] and possibly amine-to-metal charge transfer as well.[33,34] The other intense band (381 nm, ε = 20000 $M^{-1}\cdot cm^{-1}$) may be attributed to an oxo→Fe^{III} charge-transfer transition.[35,36] The spectral features reported for μ-oxodiiron(III) complexes with aminopyridine and chloro ligands, which present an intense band around 320 nm and another at about 380 nm,[37,38] are also consistent with these assignments.

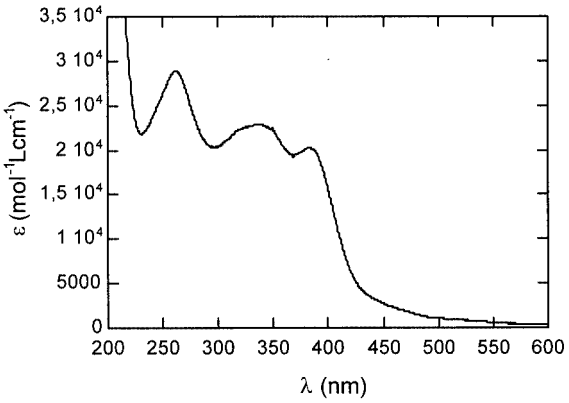

Figure 7. UV/Vis spectrum of the tetranuclear complex **3** in acetonitrile; the extinction coefficients are calculated per one molecule

Electrochemistry

The electrochemical behavior in CH_2Cl_2 of **1** (Figure 8) reveals an oxidation wave at $E_p = 0.63$ V. On the reverse scan, two waves are observed, at 0.53 and 0.04 V. Based on the peak height[39] the wave at 0.63 V is attributed to a two-electron oxidation corresponding to the simultaneous oxidation of the two Fe^{II} sites. The intensity of the cathodic wave at 0.5 V is smaller than the anodic one, thus indicating that the wave is not totally chemically reversible. Indeed, a second cathodic wave is seen on the reverse scan at a less positive potential ($E_p = 0.04$ V). The cyclic voltammogram of **1** can be compared with those reported for several complexes obtained with tetradentate aminopyridine ligand and two chloride ions. The electrochemical potentials for the Fe^{II}/Fe^{III} redox process are observed between 0 and 0.3 V.[12] The much higher potential observed here is related to the pentacoordinate geometry adopted by the iron center, which destabilizes the Fe^{III} species.

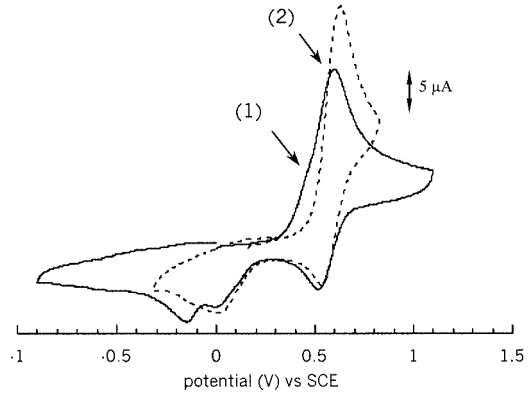

Figure 8. Cyclic voltammogram recorded in CH_2Cl_2 (- - -) and CH_3CN (———) under argon for **1**; concentration 1 mM, scan rate 100 mV s^{-1}, temperature 20 °C

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The cyclic voltammogram recorded at 100 mV·s^{-1} on a CH_2Cl_2 solution of **2** (Figure 9) shows two oxidation waves, at 1.15 and 1.65 V. Reversing the potential scanning at 1.35 V allows the reversibility of the first wave to be observed ($E_{1/2}$ = 1.1 V; ΔE_p = 100 mV). The intensity of the peak indicates a two-electron process, attributed to the oxidation of the two Mn^{II} ions. The characteristic oxidation peak of the free chloride ion at 1.3 V is, notably, not observed, indicating that the two chloride ions both remain coordinated to the Mn^{II} ion and to the generated Mn^{III} center. The second oxidation wave (1.65 V) is totally irreversible, even when the scan rate is increased to 5 V s^{-1}. This second oxidation is attributed to the generation of an Mn^{IV} species − a strong oxidant that readily reacts with any trace of nucleophilic impurity in the solvent − and, therefore, no reversibility of the oxidation wave is seen under the present experimental conditions. Electrochemical data reported for Mn complexes with chloro ligands are listed in Table 3.

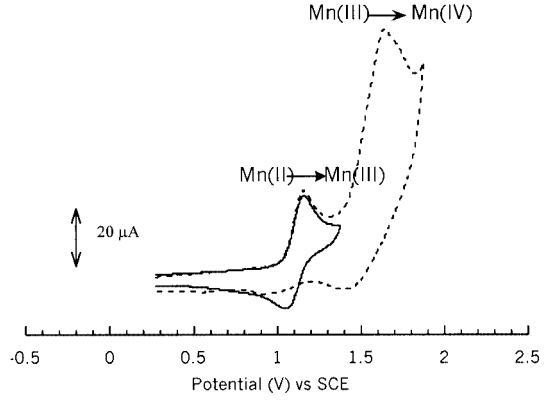

Figure 9. Cyclic voltammogram recorded in CH_2Cl_2 for **2**; concentration 1 mM, scan rate 100 mV s^{-1}, temperature 20°C

The electrochemical potential for the Mn^{II}/Mn^{III} process for **2** is much higher than those reported for mononuclear hexacoordinate Mn^{II} with two chloride ions.[40] However, it is similar to that obtained for a pentacoordinate monochloro−Mn^{II} complex for which $E_{1/2}$ = 1.14V.[13] It is surprising that the $E_{1/2}$ values are so close for both pentacoordinate complexes as the number of chloride ions coordinated is different.

In the electrogenerated $[2]^{2+}$ species the manganese ion is pentacoordinate with two chloride ions. This species was found to be more stable than the pentacoordinate monochloro−Mn^{III} complex obtained by Bucher.[13] Indeed, Bucher et al. observed a reorganization of the Mn^{III} species, leading to an hexacoordinate complex. Moreover, the pentacoordinate $[\mathbf{2}]^{2+}$ species is oxidized at a higher potential (1.65 V) than the hexacoordinate dichloro−Mn^{III} complex obtained by Hubin et al.[40] (1.33 V) and lies in the same range as the hexacoordinate monochloro−Mn^{III} complex reported by Brudenell et al. (1.56 V).[14] Complex **2** was also studied in CH_3CN. The cyclic voltammetry shows potentials identical to the one in CH_2Cl_2 solution.

Conversion of Complex 1 into Complex 3

Complex **1**, which is stable in aerated CH_2Cl_2, reacts upon O_2 exposure in CH_3CN to form complex **3**. To understand the chemical or structural modifications allowing this reactivity, complex **1** was studied in CH_3CN by cyclic voltammetry. Under argon, two anodic signals were observed, at 0.46 and 0.60 V (denoted 1 and 2 in Figure 8). The reverse scan showed three cathodic waves, at 0.5, 0 and −0.15 V. Increasing the scan rate led to the disappearance of wave 1 and the increase of wave 2 (not shown). The intensity of the resulting unique oxidation wave was identical to that observed in CH_2Cl_2 This behavior indicates that the two oxidation waves correspond to two Fe^{II} species in equilibrium. By analogy with the study in CH_2Cl_2, wave 2 is attributed to a two-electron oxidation of the neutral complex **1** and is therefore correlated to the two reduction peaks at 0.5 and 0 V. The first oxidation signal (0.46 V) is completely irreversibile. The relative intensity of waves 1 and 2 indicates that the amount of Fe^{II} species responsible for the anodic process at 0.46 V is very low in solution. Nevertheless, it is very likely that this Fe^{II} species, which forms only in CH_3CN, is responsible for the reactivity of **1** with O_2 in the same solvent. Similar behavior has been observed with a parent Fe^{II} complex,[7,25] for which the reactivity with O_2 was related to its slight instability in CH_3CN.

When the solution was open to air, the intensity of the wave at −0.15 V increased. This wave (−0.15 V) was also observed when the potential was scanned from 0.25 V towards reduction potential, thus indicating the air oxidation of the bulk solution. Concomitantly, UV/Vis spectra

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

were recorded on the same CH_3CN solution of **1**. The spectrum did not show any change under argon. On the contrary, two large absorption bands at 335 and 360 nm appeared when the solution was exposed to air. These new bands are tentatively attributed to the formation in CH_3CN solution of a polynuclear Fe^{III} species with Cl^- ligands and oxo bridges.[23−25] Most likely, this species is responsible for the cathodic wave at −0.15 V.

In the mass spectrum of a CH_3CN solution of **1** under air the peak seen at m/z= 836 is attributed, according to the isotopic distribution, to the $[(L_6{}^34M)Fe_3(\mu\text{-}O)_2Cl_4]^+$ cation (Figure 10). A second peak, at m/z = 621.2, is attributed to the Fe^{II} complex $[(L_6{}^34MH)FeCl_2]^+$. It is attractive to propose that the UV/Vis spectrum with absorption bands at 335 and 360 nm as well as the −0.15 V reduction wave are related to the cation $[(L_6{}^34M)Fe_3(\mu\text{-}O)_2Cl_4]^+$. The ultimate entity isolated from this CH_3CN solution was the structurally characterized tetranuclear complex $[(L_6{}^34M)Fe_4(\mu\text{-}O)_3Cl_6]$, and therefore $[(L_6{}^34M)Fe_3(\mu\text{-}O)_2Cl_4]^+$ can be considered as a precursor of the tetranuclear complex. A possible structure for $[(L_6{}^34M)Fe_3(\mu\text{-}O)_2Cl_4]^+$ is presented in Figure 11.

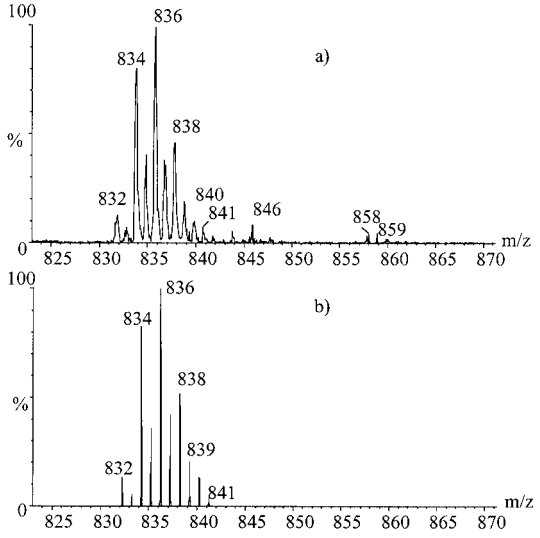

Figure 10. ESI-MS of $[(L_6{}^34M)Fe_3(\mu\text{-}O)_2Cl_4]^+$: (a) experimental spectrum; (b) calculated spectrum

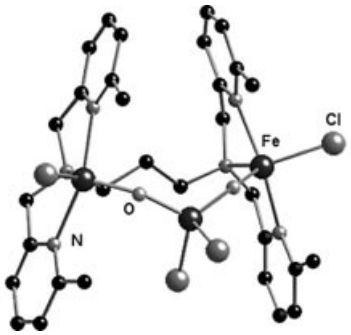

Figure 11. Possible structure for $[(L_6{}^34M)Fe_3(\mu\text{-}O)_2Cl_4]^+$

Conclusion

The neutral complexes **1** and **2** have been obtained and characterized. They present identical structures: each contains high-spin pentacoordinate metal centers in a trigonal-bipyramidal environment. The metal centers are involved in two different coordination sites and present no magnetic coupling. Both complexes are stable in CH_2Cl_2 solution and their neutral structure is retained. However, in CH_3CN, **2** is stable whereas **1** is unstable and transforms partially into a new complex species that equilibrates with **1**, as indicated by cyclic voltammogram. This latter complex is probably responsible for the reactivity of **1** with O_2 in CH_3CN, which leads to the formation of the linear tetradentate neutral complex **3**. The four metal centers are strongly antiferromagnetically coupled by single oxo bridges and exhibit different coordination sites: two are bound to the ligand and pentacoordinate whereas the two others are only tetracoordinate with chloro ligands and oxo bridges in their coordination sphere. This structure is uncommon and is, to the best of our knowledge, the first reported linear tetraferric complex.

Experimental Section

General Methods: All manipulations were carried out by using standard Schlenk techniques. Starting materials were purchased from Acros. Solvents were purchased from Merck and used without further purification.

Physical Methods: Electronic absorption spectra were recorded with a Varian Cary 5E spectrophotometer. FT-IR spectra were recorded with a Perkin−Elmer Spectrum1000 (s = sharp, i = intense, m = medium, w = weak, b = broad). Magnetic data were recorded with an MPMS5 magnetometer (Quantum Design Inc.). The calibration was made at 298 K using a palladium reference sample furnished by Quantum Design Inc. EPR spectra were recorded with an X-band Bruker ESP 300 E. Cyclic voltammograms were measured using an EGG PAR model M270 scanning potentiostat operating at a scan rate of 10−1000 mV s^{-1}. Studies were carried out under argon in acetonitrile or CH_2Cl_2 solutions using 0.2 M tetrabutylammonium perchlorate (puriss. grade, Fluka) as the supporting electrolyte, and 10^{-3} M of the complex. The working electrode was a glassy-carbon disk (0.32 cm^2) polished with 1 μm polishing powder. The reference electrode was $Ag/AgClO_4$ (+0.3 V vs. SCE), which was separated from the rest of the solution by a salt bridge containing the solvent/supporting electrolyte, with a Pt wire as an auxiliary electrode. All potentials are given vs. SCE electrode. The $E_{1/2}$ potentials are calculated as the mid-point between the anodic and the cathodic peak potentials. The mass spectra of ions formed by electrospray were acquired with a Quattro II (Micromass, Manchester, UK) triple quadrupole mass spectrometer. Typical optimized values for the source parameters were: capillary 2.5 kV, counter-electrode 0.49 kV source temperature of 80°C, RF lens 0.5 V, skimmer lens offset 0; cone voltage 20 V. Sample solutions were prepared in CH_3CN. All solutions were infused at a flow rate of 10 μL min^{-1} by a Harvard Apparatus (Southnatic, MA, USA) syringe pump. Crystallographic data were collected with a Nonius Kappa CCD area detector diffractometer[41] using graphite-monochromated Mo-K_α radiation. The lattice parameters were determined from ten images recorded with 2° -scans and later re-

fined on all data. The data were recorded at 123 K. A 180° -range was scanned with 2° steps with a crystal−detector distance fixed at 30 mm. Data were corrected for Lorentz polarization. The structures were solved by direct methods with SHELXS[42] and refined by full-matrix least squares on F^2 with anisotropic thermal parameters for all non-H atoms with SHELXL-97.[43] In complex **1**, one solvent molecule ($CHCl_3$) was disordered on two sites with 0.5 occupancy. H atoms (except H atoms of solvent molecules, CH_3Cl and H_2O in **1**, CH_3CN in **2** and **3**) were introduced at calculated positions as riding atoms with isotropic displacement parameters of 1.2 (CH, and CH_2) or 1.5 (CH_3) times that of the parent atom. Molecular plots were drawn with SHELXTL.[44] All calculations were performed with a Silicon Graphics R10000 workstation. CCDC-199949 (**1**), -199950 (**3**), -199951 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of $L_6^3$4M: *N*,*N*,*N*′,*N*′-Tetrakis[(6-methyl-2-pyridyl)methyl]propane-1,3-diamine. The ligand was synthesized as *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)ethane-1,2-diamine[45] using 2-(chloromethyl)-6-methylpyridine hydrochloride (8 g) and propane-1,3-diamine (835 μL) as starting materials. The product was recrystallized from cyclohexane and obtained as a white powder (4.35 g).

Synthesis of $[(L_6^3$4M)$Fe_2Cl_4]\cdot 2H_2O\cdot 2CHCl_3$ (1): 1 equiv. of ligand (100 mg) in THF (2 mL) was added to a solution of 2 equiv. of $FeCl_2\cdot 2H_2O$ (66 mg) in THF (3 mL) under argon. The mixture was then stirred at room temperature for 30 min and concentrated. After removal of most of the solvent, a yellow solid precipitated, which was filtered off (80 mg, 53% yield). $C_{31}H_{38}Cl_4Fe_2N_6\cdot H_2O$ (766.21): calcd. C 48.60, H 5.26, N 10.97; found C 48.66, H, 5.22, N 10.33. FT-IR: $\tilde{\nu}$ = 1605 (s, i), 1577 (s, m), 1458 (s, i), 1043 (s, w), 1010 (s, m), 841 (s, w), 782 (s, m) cm^{-1}. Crystals of **1** were obtained by slow diffusion of *tert*-butyl methyl ether into a solution of the powder dissolved in $CHCl_3$.

Synthesis of $[(L_6^3$4M)$Mn_2Cl_4]\cdot 2CH_3CN$ (2): 1 equiv. of ligand (50 mg) in THF (2 mL) was added to a solution of 2 equiv. of $MnCl_2\cdot 4H_2O$ (40 mg) in THF (4 mL). The mixture was then stirred at room temperature for 30 min, and the resultant white precipitate was filtered off and collected (56 mg, 74% yield). $C_{31}H_{38}Cl_4Mn_2N_6$ (746.4): calcd. C 49.88, H 5.13, N 11.26; found C 49.19, H, 5.17, N 11.97. FT-IR: $\tilde{\nu}$ = 1607 (s, i), 1578 (s, i), 1454 (s, i), 1043 (s, w), 1010 (s, mi), 860 (s, m), 781 (b, m), 300 (b, m) cm^{-1}. The white powder was dissolved in CH_3CN and crystals of **2** were obtained by slow diffusion of *tert*-butyl methyl ether into the solution. All characterizations of complex **2** were performed with crystals.

Synthesis of $[(L_6^3$4M)$Fe_4(\mu\text{-}O)_3Cl_6]\cdot 2CH_3CN$ (3): Complex **3** was isolated after evolution of a solution of **1** in CH_3CN in air; X-ray quality crystals were obtained by slow evaporation of the solvent CH_3CN. In an alternative method a solution of **1** in CH_3CN was heated under air at 70°C for 24 h. Crystals of **3** were obtained after an additional 24 h, when the solution was allowed to cool to room temperature. $C_{31}H_{38}Cl_6Fe_4N_6O_3$ (978.8): calcd. C 38.04, H 3.91, N 8.58; found C 37.70, H 3.87, N 8.54. FT-IR: $\tilde{\nu}$ = 1610 (s, i), 1578 (s, m), 1469 (s, i), 1456 (s, i), 854 (s, i), 818 (b, i), 790 (s, i), 352 (s, i) cm^{-1}. The three bands around 800 cm^{-1} can be attributed to Fe−O modes, by comparison with other (μ-oxo)diiron(III) complexes.[26]

Synthesis and Carbonylation of Platinum(II) Organometallic Complexes with Bis(phosphanyl) Monosulfides − Crystal Structures of [κ^2*P*,*S*-{$Ph_2CH_2P(S)Ph_2$}Pt(CH_3)(Cl)] and [κ*P*,μ-κ*S*-{$Ph_2CH_2CH_2P(S)Ph_2$}Pt-(CH_3)]$_2$[BF_4]$_2$

Dedicated to Professor Adriano Sacco on the occasion of his 80th birthday

Keywords: Platinum / P,S ligands / Carbonyl ligands / Bridging ligands / Mass spectrometry

The neutral complexes of formula [κ^2*P*,*S*-(dppmS)Pt(CH_3)(Cl)] (**1**) and [κ^2*P*,*S*-(dppeS)Pt(CH_3)(Cl)] (**2**) [dppmS = $Ph_2PCH_2P(S)Ph_2$, dppeS = $Ph_2P(CH_2)_2P(S)Ph_2$] have been synthesised and characterised. Reaction of **1** and **2** with $AgBF_4$ carried out in CH_3CN or CH_3CN/CH_2Cl_2 affords the corresponding monomeric cationic complexes [κ^2*P*,*S*-(dppmS)Pt(CH_3CN)(CH_3)][BF_4] (**3**) and [κ^2*P*,*S*-(dppeS)Pt(CH_3CN)(CH_3)][BF_4] (**4**). Complexes **3** and **4** partially dissociate in CD_2Cl_2, giving, in the case of **3**, the asymmetric dimer {[κ^2*P*,*S*-(dppmS)](CH_3)Pt{κ*P*,μ-κ*S*-(dppmS)}Pt(CH_3)(CH_3CN)][BF_4]$_2$ (**5**), and, in the case of **4**, the symmetrical sulfur-bridged dimer [κ*P*,μ-κ*S*-(dppeS)Pt(CH_3)]$_2$[BF_4]$_2$ (**6**). Pure **6** can be obtained by heating **4** under vacuum. Exposing CD_2Cl_2 solutions of the cationic complexes **3** and **4** to CO at ambient conditions brings about the formation of the monomeric methyl carbonyl complexes [κ^2*P*,*S*-(dppmS)Pt(CO)(CH_3)][BF_4] (CO *trans* to P, **7a**) and [κ^2*P*,*S*-(dppeS)Pt(CO)(CH_3)][BF_4] (CO *trans* to P, **8a**), which slowly transform into their CO *cis* to P isomers **7b** and **8b**, respectively. The single-crystal X-ray diffraction studies of **1**·CD_2Cl_2 and **6**·2CD_2Cl_2 are reported. Mass spectrometric analyses with APCI and ESI interfaces were also performed for all new complexes.

Introduction

Heteroditopic ligands, those ligands that possess at least two types of chemical functionality capable of binding to a metal centre, have been receiving ever-growing attention in the field of coordination and organometallic chemistry. Such ligands, characterised by the stability advantages typical for chelates, may also confer interesting catalytic properties to their metal complexes owing to the generation of very different *trans* effects and, therefore, reactive sites within the same molecule.[1−3]

In this framework P,S bidentate ligands are appealing since the peculiar features of sulfur favour a strong coordination to soft metal centres.[4,5] In particular P,(P)S ligands exhibit a heteroditopic behaviour[6−12]that has been recently exploited in catalysis.[13,14]

Following our studies in the coordination chemistry of heteroditopic ligands,[15−17] we became interested in the synthesis and reactivity of neutral and cationic methyl complexes of platinum(II) with the heteroditopic ligands dppmS and dppeS.

Results and Discussion

The synthesis of the complexes [κ^2*P*,*S*-(dppmS)Pt(CH_3)Cl] (**1**) and [κ^2*P*,*S*-(dppeS)Pt(CH_3)Cl] (**2**) was carried out starting from [(cod)Pt(CH_3)(Cl)] (cod = 1,5-cyclooctadiene) and an equivalent of the appropriate bis(phosphanyl) monosulfide ligand.

Subsequently, the coordinated chlorides of **1** and **2** were removed by reaction with silver tetrafluoroborate in acetonitrile or acetonitrile/dichloromethane. The absence of the IR bands of Pt−Cl stretching at 276 cm^{-1} for **1** and 273 cm^{-1} for **2** is evidence for the effective chloride abstraction.

The vacant coordination site was occupied by the acetonitrile, thus obtaining the cationic complexes [κ^2P,S-(dppmS)Pt(CH_3)(CH_3CN)][BF_4] (**3**) and [κ^2P,S-(dppeS)Pt(CH_3)(CH_3CN)][BF_4] (**4**) (Scheme 1). End-on coordination of the acetonitrile leads to two $\tilde{\nu}_{C\equiv N}$ bands in the IR spectra (at 2325 and 2297 cm^{-1} for **3**, and 2323 and 2295 cm^{-1} for **4**), both blue-shifted with respect to free CH_3CN.

The spectroscopic data both in solution (NMR) and in the solid state (IR) confirm a κ^2P,S coordination for complexes **1**−**4**. A first evidence in this respect is given by the 20−25 cm^{-1} red-shift of the phosphanyl sulfide stretching frequencies in the IR spectrum. The $\tilde{\nu}_{(P=S)}$ bands at 605 cm^{-1} (dppmS) and at 610 cm^{-1} (dppeS) of the free ligands are shifted in the neutral complexes **1** and **2** to 585 cm^{-1} and 591 cm^{-1}, respectively. In the case of cationic complexes **3** and **4** the $\tilde{\nu}_{(P=S)}$ bands are found at 580 cm^{-1} and 586 cm^{-1}, respectively.

Consistently, the $^{31}P\{^1H\}$ NMR signals ascribed to the sulfur-bound phosphorus in **1**−**4** are all flanked by ^{195}Pt satellites due to ^2J[P(S),Pt] (23 Hz for **1**, 58 Hz for **2**, 39 Hz for **3**, and 55 Hz for **4**).

The direct ^1J(P,Pt) values found for **1**−**4**, ranging from 4606 to 4695 Hz (Table 1), are in agreement with a relatively weak *trans* influence of the ligand positioned *trans* to coordinated P,[18] chloride for **1** and **2**, CH_3CN for **3** and **4**.

Moreover the values of the coupling constants for the ^1H and $^{13}C\{^1H\}$ NMR methyl signals of complexes **1**−**4** are entirely in agreement with a configuration in which the methyl group is *cis* with respect to the phosphorus atom directly coordinated to the platinum centre.[18−20] The observed ranges are: ^3J(H,P) = 3.4−4.6, ^2J(H,Pt) = 68−74, ^2J(C,P) = 5.8−8.3 Hz, and ^1J(C,Pt) = 605−650 Hz.

Table 1. $^{31}P\{1H\}$ and $^{195}Pt\{1H\}$ NMR spectroscopic data (δ, ppm, CD_2Cl_2, 298 K) (see Figure 3 for numbering of **5**)

	δ(P)	δ[P(S)]	δ(Pt)	J(P,P) Hz	^1J(P,Pt) Hz	^2J(P,Pt) Hz

		Pt(1_2)−S(1)−Pt(1)	99.59(9)

Pt and its coordinating atoms P(1), S, C(1), and Cl(1) occur with an essentially square-planar geometry. The maximum deviation of a least-squares study occurs for C(1) and amounts to 0.032(6) Å. The platinum coordination is characterised by metal-centred angles between 89.12(17)° and 87.74(6)°. The sum of the four angles on platinum is 360.03(18)°. Interestingly, the different *trans* influence of phosphorus and sulfur can be evidenced by comparison of Pt−Cl and Pt−C bond lengths with similar compounds: for instance, the Pt−C(1) bond length [2.056 (6) Å] is considerably shortened due to the presence of the *trans* sulfur donor atom with respect to a complex in which the methyl group is *trans* to a P^{III} atom as in the bridging complex [$Pt_2Me_4(\mu$-dmpm$)_2$] [dmpm: bis(dimethylphosphanyl)methane] (Table 2).[22] As for the Pt−Cl(1) and Pt−P(1) bond lengths, they are similar to other platinum complexes embodying the *trans* P−Pt−Cl substructure such as complexes of formula {bis[bis(*o*-isopropylphenyl)phosphanyl]-methane}$PtCl_2$ [20] and (P^N)Pt(Me)Cl (P^N: chiral phosphanyl oxazoline).[23]

When the cationic species **3** and **4** are dissolved in CH_2Cl_2, a dissociation equilibrium of CH_3CN takes place as evidenced by the appearance in the IR, ^1H and ^{13}C NMR spectra (CD_2Cl_2 solutions) of free acetonitrile signals.

In the case of **4**, the $^{31}P\{^1H\}$ NMR spectrum in CD_2Cl_2 shows the appearance of ca. 25% of a new species **6**, which gives two broad singlets centred at δ = 16.1 and δ = 38.0 ppm. The signal at δ = 16.1 ppm, ascribable to a P atom directly bound to the platinum centre, is flanked by ^{195}Pt satellites from which a ^1J(P,Pt) of 4331 Hz could be extracted. The signal at δ = 38.0 ppm, ascribable to a P atom bound to a coordinated sulfur atom, only shows broadening at the base which could be due to unresolved ^{195}Pt satellites with a small ^2J(P,Pt) value.

In principle, acetonitrile dissociation which takes place by dissolving **4** in dichloromethane (or CD_2Cl_2) could result in *i*) BF_4^- coordination in the place of CH_3CN; *ii*) CH_2Cl_2 (or CD_2Cl_2) coordination [24] in the place of CH_3CN; *iii*) dimerisation of the coordinatively unsaturated platinum species to give sulfur bridged dimers.

The possible coordination of the tetrafluoroborate in the place of acetonitrile has been ruled out by recording $^{19}F\{^1H\}$ NMR spectra (282 MHz) of **4** in CD_2Cl_2. The only signals present were ascribable to ionic free BF_4^- [δ = −152.98 (s, $^{10}BF_4^-$), δ = −153.02 ppm(s, $^{11}BF_4^-$)].

On the other hand, substitution of dichloromethane for a nitrile group, as already reported in a similar system,[23] should result in a significant increase of the ^1J(P,Pt). In our case, on the contrary, a slight decrease of the ^1J(P,Pt) is observed (Table 1).

The remaining hypothesis *iii*), (formation of the dimers), could be supported by the aforementioned small ^2J(P,Pt) coupling constants which is consistent with a P atom bound to a bridging sulfur and suggests the dimer structure [κ*P*,μ-κ*S*-(dppeS)Pt$(CH_3)]_2[BF_4]_2$ (**6**) (Scheme 1).

The presence of the two sulfur atoms in the coordination sphere of each platinum results in the downfield shift observed in the ^{31}P NMR spectrum for the P atoms directly bound to the Pt centre when comparing **4** with **6**.

In order to shift the dissociation equilibrium between the acetonitrile monomeric complex **4** and **6** to the right, we have heated solid **4** under vacuum. The reaction led quantitatively to the synthesis of **6** that, after crystallisation from CD_2Cl_2, could be submitted for the single-crystal XRD analysis.

The structure of **6** represents the first structurally characterised sulfur bridged bis(phosphanyl) monosulfide dimeric complex. An ORTEP view of its molecular structure in the crystal is given in Figure 2. The crystals contain two molecules of clathrated CD_2Cl_2 per complex molecule.

The asymmetric unit of **6** consists of half a centrosymmetric divalent cation, one tetrafluoroborate anion, and one solvent molecule, CD_2Cl_2. The coordination around platinum is that of a distorted square with angles ranging from 80.4° to 96.3°. Two neighbouring coordination sites are occupied by the two bridging sulfur atoms of the chelat-

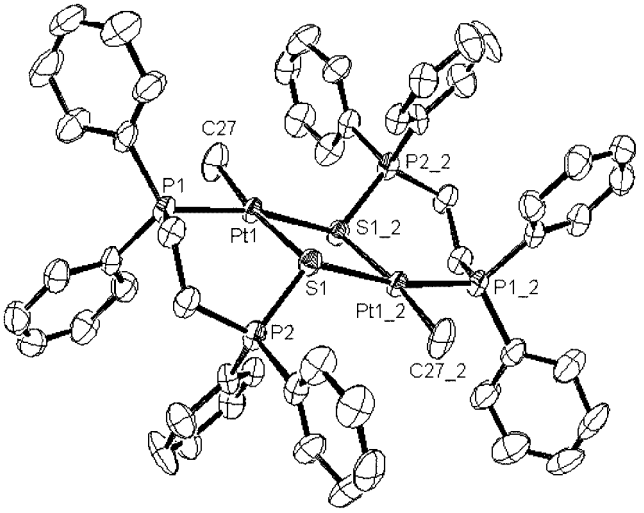

Figure 2. ORTEP drawing of **6**. Solvent molecules and counter anions were omitted for clarity; displacement ellipsoids are scaled to 40% probability

ing ligands; thus a four membered planar Pt_2S_2 ring around the crystallographic inversion centre is formed. The coordination sphere of each metal is completed by the methyl carbon and the donor phosphorus atom of the chelating ligand. The Pt−S bond lengths [2.402(3) and 2.427(3) Å] are similar to those [2.4094(17) Å and 2.4227(17) Å] observed for the related sulfur bridged complex $[Pt(C_6F_5)_2(\mu\text{-}SPPh_2C_5H_5)]_2$ [25] and are similar to that [2.4243(18) Å] observed for the parent complex **2** in which the sulfur atom is terminally bound.

The P−S distances of 2.043(4) Å are intermediate between the expected value for a P=S double bond and a P−S single bond, and the sulfur atoms are pyramidal, as indicated by the sum of the angles at the sulfur atom (320.4°).[25] Dihedral angles between the Pt_2S_2 plane and the phenyl rings range between 60.9(5)° and 76.7(5)°.

Owing to its bridging coordination mode, the P=S band in the IR spectrum was significantly red-shifted with respect to the monomeric cation **4** ($\tilde{\nu}_{(P=S)}$ changed from 586 cm^{-1} for **4** to 532 cm^{-1} for **6**).

In the case of **3**, the NMR spectra recorded in CD_2Cl_2 show the appearance of 45% of a new species different from the expected **6** homologue.

The $^{31}P\{^1H\}$ NMR spectrum of this new species consists of four signals with equal integrals: a doublet of doublets centred at δ = 22.3 and a doublet centred at δ = 52.1 ppm mutually coupled [^2J(P,P) 28 Hz], a doublet centred at δ = 12.8 and a doublet of doublets centred at δ = 52.0 ppm mutually coupled with a ^2J(P,P) 20 Hz. The further splitting observed in the signals at δ = 22.3 and δ = 52.0 corresponds to a mutual coupling of 4 Hz. The signals at δ = 22.3 and δ = 12.8 ppm, flanked by ^{195}Pt satellites from which ^1J(P,Pt) of 4469 Hz and 4724 Hz could be extracted are attributed to two chemically different Pt-bound P atoms. The partially overlapped signals at δ = 52.1 and δ = 52.0 ppm are ascribable to P atoms bound to coordinated sulfur. Both signals show broadening only at the base as unresolved ^{195}Pt satellites with a small ^2J(P,Pt) value. Moreover, the ^1H NMR spectrum shows, together with free CH_3CN (δ = 1.97 ppm) two peaks in the region of coordinated acetonitrile, one belonging to complex **3** at δ = 2.52 ppm and the other (δ = 2.54 ppm), having the same integration of the free CH_3CN, belonging to the new species.

All these spectroscopic features suggest that the species formed by partial CH_3CN dissociation on dissolving **3** in CD_2Cl_2, is the unsymmetrical dimer $[\{\kappa^2P,S\text{-}(dppmS)\}(CH_3)Pt\{\kappa P,\mu\text{-}\kappa S\text{-}(dppmS)\}Pt(CH_3)(CH_3CN)][BF_4]$ (**5**) depicted in Figure 3. The proposed structure is substantiated by ESI-MS analyses (vide infra) and by the observed ^3J(P,P) 4 Hz coupling constant between P^1 (bonded to Pt^1) and P^4 (bonded to the bridging sulfur).

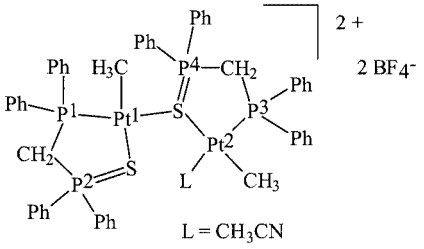

Figure 3. Alleged structure for complex **5**

The two methyl signals for **5** occurred in the ^1H NMR spectrum as doublets (with satellites) centred at δ = 0.74 ppm [^3J(H,P) = 3, ^2J(H,Pt) = 64 Hz, CH_3 *cis* to CH_3CN] and δ = 0.06 ppm [^3J(H,P) = 3.9, ^2J(H,Pt) = 66.9 Hz, CH_3 *cis* to bridging S]. Assignment of ^1H, ^{31}P, ^{13}C, ^{195}Pt NMR spectral features is reported in Table 1 and in the Exp. Sect.

The equilibrium between **3** and **5** or **4** and **6** (Scheme 1) completely shifts towards the acetonitrile species by adding CH_3CN to the $[D_2]$dichloromethane solutions.[26]

Heating solid **3** under vacuum for 8 h resulted in an enrichment of the equilibrium mixture in **5** (the dimer/monomer ratio passed from 0.82 to 3.0, based on total phosphorus, as assessed by ^{31}P NMR spectra in CD_2Cl_2). Attempts to shift the dissociation equilibrium between the acetonitrile monomeric complex **3** and **5** completely to the right, by prolonging the heating for 2.5 days, resulted in a complex mixture of products containing, according to ^{31}P integration data, ca. 43% of **5**.

It is interesting to note that the homologous cations $[\kappa^2P,S\text{-}(dppmS)Pd(CH_3CN)(CH_3)]^+$ and $[\kappa^2P,S\text{-}(dppeS)Pd(CH_3CN)(CH_3)]^+$, recently prepared by us,[17] are stable in CH_2Cl_2 solution as monomeric acetonitrile complexes.

The difference in behaviour between **3** and **4** observed in dichloromethane, i.e. the formation of the unsymmetrical or symmetrical dimers **5** or **6**, deserves a comment.

Theoretical calculations indicate that Pt_2S_2 rings adopt a planar conformation in Pt^{II} complexes of formulae *trans*-$[Pt_2(\mu\text{-}SR)_2L_2L'_2]$ or $[Pt_2(\mu\text{-}RS)_2L_4]$, and a hinged arrangement in Pt^{II} complexes of formula *cis*-$[Pt_2(\mu\text{-}RS)_2L_2L'_2]$.[27]

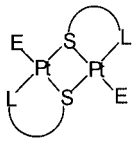
Moreover, given that the sulfur atom usually adopts a pyramidal geometry in bridging ligands like thiolates[28,29] and phosphino sulfides [25] with a Pt−S−Pt angle close to 100°,[30] a bidentate S L ligand must possess some specific structural features in order to form stable Pt^{II} complexes of structure:



In our case, where E = CH_3 and S^L = $Ph_2P(CH_2)_nPPh_2(S)$, the length of the methylene chain might be discriminating for the stability of the symmetrical dimer complexes. It seems, from our experimental data, that in the case of dppmS, only one sulfur bridge can be borne, because closing the Pt_2S_2 core with the second sulfur would result in a hinge distortion unfavourable for these types of compounds.[27]

On the contrary, the more flexible six-membered platinacycles of the symmetric dimer **6** obtained with dppeS, better fit into the geometrical constraints imposed by the planar core structure and the pyramidality of the bridging sulfur atom.

Such a hypothesis seems to be confirmed by studies carried out by Dervisi on Ni^{II}, Pd^{II}, Pt^{II} complexes of the related ligand 1-(diphenylphosphanyl)butane-2-thiolate (PS^-). It was found, in fact, that, under suitable conditions Ni^{II} and Pd^{II} formed sulfur bridged dimeric complexes of formula $[Ni(PS)Cl]_2$ and $[Pd(PS)Cl]_2$, both containing two five-membered metallacycles [31] whereas, attempts to prepare the analogous Pt^{II} complex were unsuccessful, leading only to the $[Pt(PS)_2]$ monomeric species.[32]

When CD_2Cl_2 solutions of **3** and **4** were exposed to an atmospheric pressure of carbon monoxide at room temperature, a fast reaction took place leading to carbonyl complexes **7a** and **8a** (Scheme 2) as evidenced by the appearance, in the IR spectra, of strong $\tilde{\nu}_{CO}$ bands at 2113 and 2112 cm^{-1}, respectively. The corresponding carbonyl resonances of **7a** and **8a** in the $^{13}C\{^1H\}$ NMR spectrum appear as doublets of doublets due to couplings with inequivalent P atoms, and are centred at δ = 177.7 and δ = 176.2 ppm, respectively.

The multinuclear NMR spectra of the reaction solution of **3** under CO ($P_{atm.}$) recorded every 2 days for one week showed the progressive isomerisation of **7a** into **7b** (Scheme 2). In fact the decrease of $^{31}P\{^1H\}$ NMR signals at δ = 25.3 and δ = 59.3 ppm attributed to the coordinated P and P(S) atoms of **7a,** respectively, was observed. Simultaneously new signals at δ = 31.2 and δ = 67.9 ppm [*J*(P,P) 72 Hz] appeared and were attributed to **7b**. The relatively low value of the ^1J(P,Pt) found for **7b** (1556 Hz) strongly supports the structure with the methyl group *trans* to the P atom. Comparable ^1J(P,Pt) are found for coordinated P atoms *trans* to CH_3 groups in complexes of formula $[(P\ P)Pt(Me)CO]^+$ [P P = 1,3-(diphenylphosphanyl)propane, ^1J(P,Pt) = 1593 Hz,[33] P P = BINAP, ^1J(P,Pt) = 1735 Hz .[19]]

The $^{13}C\{^1H\}$ NMR spectra of **7b** and **8b** show the carbonyl resonances at δ = 168.6 and δ = 167.9 ppm, respectively.

Figure 4 shows the $^{13}C\{^1H\}$ and $^{195}Pt\{^1H\}$ spectra of the CD_2Cl_2 reaction solution after carbonylation of **3** at two different times demonstrating the progressive enrichment in **7b**.

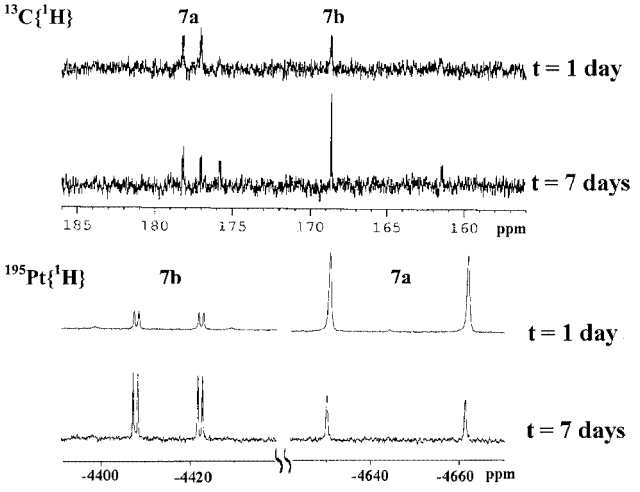


Figure 4. $^{13}C\{^1H\}$ (125 MHz) and $^{195}Pt\{^1H\}$ (107 MHz) NMR spectra (298 K, CD_2Cl_2) of the reaction solutions obtained by carbonylation of **3** recorded after 1 day (top traces) and after 7 days (lower traces)

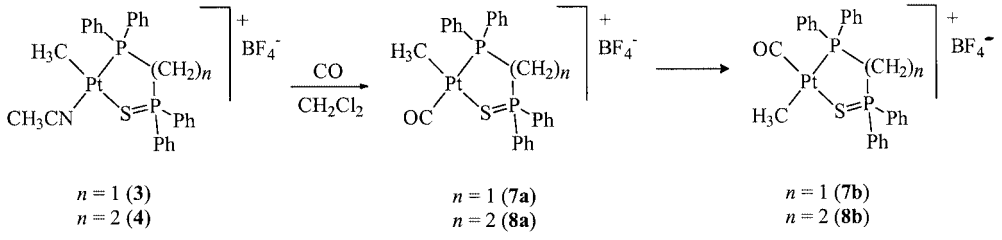
An analogous behaviour was observed in the carbonylation of the cationic complex **4** which results in the immediate formation of **8a** that slowly isomerises into **8b** (Scheme 2). Table 3 summarises selected spectroscopic features of **7a**−**b** and **8a**−**b**.



n = 1 (**3**)
n = 2 (**4**)

Table 3. $^{31}P\{1H\}$ and $^{195}Pt\{1H\}$ NMR spectroscopic data (δ, ppm) of **7a**−**b** and **8a**−**b**

	δ(P)	δ[P(S)]	δ(Pt)	*J*(P,P) Hz	^1J(P,Pt) Hz	^2J(P,Pt) Hz
7a	25.3	59.3	−4646	33	3336	20
7b	31.2	67.9	−4415	72	1556	113
8a	13.8	43.1	−4560	[a]	3372	55
8b	3.6	40.8	−4328	31	1576	105

When acetonitrile solutions of **3** or **4** were exposed to CO at ambient conditions, the CH_3CN excess prevented the carbonylation reaction.

Conclusion

Methyl chloro platinum(II) complexes with the heteroditopic dppmS and dppeS ligands have been prepared and characterised. Chloride abstraction from the neutral complexes carried out in acetonitrile leads to the formation of the solvento species, which have been isolated in the pure state. Loss of acetonitrile, which leads to dimeric species, has been studied both in solution and in the solid state. In the case of the dppeS, the symmetric dimer **6** could be obtained by heating the corresponding acetonitrile complex under vacuum. This reaction represents an interesting example of clean solid state molecular rearrangement. The type of dimer formed in solution by loss of acetonitrile (mono bridged or dibridged) has been found to be strictly related to the number of the methylene groups in the ligand backbone. Carbonyl complexes obtained by substitution of acetonitrile with CO have also been synthesised and their isomerisation reactions, in solution, have been studied.

Experimental Section

General Remarks: All manipulations were carried out using standard Schlenk techniques under nitrogen as inert gas. Acetonitrile, dichloromethane, diethyl ether and *n*-hexane were dried and distilled under nitrogen; $AgBF_4$ and Celite™ were purchased from Fluka. NMR spectra in solution were recorded at 298 K on a Bruker AM 500 or a Bruker Avance DRX500 spectrometer (CARSO) or a Varian Mercury 300; frequencies are referenced to Me_4Si (^1H, ^{13}C), 85% H_3PO_4 (^{31}P), H_2PtCl_6 (^{195}Pt) and $CFCl_3$ (^{19}F). IR spectra were recorded with a Bruker Vector 22 FT instrument. C, H, N and S elemental analyses were carried out on a Eurovector CHNS-O Elemental Analyser. Cl elemental analyses were performed by potentiometric titration using a Metrohm DMS Titrino.

LC-MS analyses were performed with an Agilent HPLC system equipped with DAD, autosampler and MS systems (Agilent 1100 LC-MS SL series). All samples were dissolved in the same HPLC-grade solvent, which was used as eluent. The used interfaces were APCI or ESI for neutral complexes and ESI for cationic complexes. APCI conditions: negative ion mode, flow rate 0.5 mL/min, nitrogen as nebulizing and drying gas, nebulizer pressure 60 psi, vaporizer temperature 350 °C, corona current 25 μA, drying gas flow 5 L/min, drying gas temperature 300 °C (unless otherwise specified), capillary voltage 4000 V. ESI conditions: positive ion mode, flow rate 0.5 mL/min, nitrogen as nebulizing and drying gas, nebulizer pressure 30 psi, drying gas flow 13 L/min, capillary voltage 4000 V. The fragmentor voltage was varied from 0 to 400 V by 50 V increments in order to obtain clean and intense spectra. Other optimal conditions are specified below for each complex. Mass spectrometry data were acquired in the Scan mode (mass range m/z = 50−3000).

The ligands dppmS and dppeS have been prepared by the procedure described in ref.[17]

The complex [(cod)Pt(CH_3)Cl] was synthesised according to ref.[18]

Synthesis of [(P^P(S)Pt(CH_3)(Cl)] 1 and 2: A solution of bis(phosphanyl) monosulfide [hereafter denoted as P^P(S)] in CH_2Cl_2 was added to a CH_2Cl_2 solution containing an equimolar amount of [(cod)Pt(CH_3)Cl], kept under vigorous stirring at room temperature. After 3 h the solvent was evaporated to ca. one fifth of the volume and addition of *n*-hexane caused the precipitation of the desired complexes as white solids. Filtration followed by washings with 3 × 5 mL *n*-hexane and drying in vacuo afforded **1** and **2** in high yield. Scales and analytical data are given below.

Synthesis of [(P^P(S)Pt(CH_3)(CH_3CN)]BF_4 3 and 4: A solution of silver tetrafluoroborate in CH_3CN was added dropwise to a suspension containing an equimolar amount of [(P^P(S)Pt(CH_3)(Cl)] in CH_3CN kept under vigorous stirring at room temp. in the dark. The mixture was stirred for 10 minutes at room temp. and the suspension was then filtered through Celite™, obtaining a colourless solution which was evaporated to dryness in vacuo. The solid was washed with diethyl ether (2 × 10 mL) and dried in vacuo. Scales and analytical data are given below.

Synthesis of *af*-Dimethyl-*bd,ec*-bis{(diphenylphosphanylethyl-κ*P*)-diphenylphosphanyl Sulfide, μ-κ*S*)}diplatinum(II) Bis(tetrafluoroborate) [μ-(dppeS)Pt(CH_3)]$_2$[BF_4]$_2$ (6): Solid **4** (50 mg, 0.065 mmol) was heated under high vacuum in a Schlenk tube at 90 °C for 30 h obtaining a white solid (47 mg) consisting of pure dimer **6**. Crystallisation from slow evaporation of a CD_2Cl_2 solution gave colourless crystals suitable for XRD analysis. M.p. 169 °C (dec.). MS Analyses: All complexes were submitted for LC-MS analyses by using APCI and API-ES sources and positive and negative ionisation modes at different fragmentor voltages. The negative APCI spectrum of **1** in dichloromethane gave a very intense base peak at m/z = 697 [M + Cl]$^-$ (fragmentor voltage: 0 V). Increasing the fragmentor voltage the intensity of the [M + Cl]$^-$ ion decreased with the concomitant appearance of the [M]$^-$ ion (m/z = 661). At 200 V the base peak is represented by [M]$^-$ ion and the [M + Cl]$^-$ ion disappeared. The negative APCI mass spectrum of a dichloromethane solution of **2** displayed the [M + Cl]$^-$ ion (m/z = 710) and [M + Cl − CH_3]$^-$ (m/z = 695) at a fragmentor voltage of 100 V. Using CH_3CN as solvent and the ESI interface (positive ions) at a fragmentor voltage of 120 V the [M − Cl + CH_3CN]$^+$ (m/z = 681) and [M − Cl]$^+$ ions (m/z = 640, 100% relative abundance) were detected.

Complex **3** was first dissolved and analysed in acetonitrile. ESI-MS spectra were acquired in positive ion mode at a drying gas temperature of 300 °C. At a fragmentor voltage of 0 V the spectrum is dominated by a peak at m/z = 667 which corresponds to the cationic part of the complex [M]$^+$$BF_4^-$. A base peak at m/z = 626 was observed at fragmentor 200 V corresponding to the [M − CH_3CN]$^+$ ion due to the loss of a coordinated acetonitrile molecule. The use of dichloromethane as solvent (and eluent) for **3** and a fragmentor voltage of 350 V confirmed the presence of [M]$^+$ and [M − CH_3CN]$^+$ ions and showed the appearance of a new peak at m/z = 1287 attributable to the dimeric cation [2M − 2CH_3CN + Cl]$^+$. The latter ion may arise from complex **5,** which is formed by dissolving **3** in CH_2Cl_2, after substitution of a chloride for the coordinated acetonitrile. The relative abundance of the peak at m/z = 1287 passed from 5.0% to 10.0% lowering the 300 °C drying gas temperature down to 100 °C.

The mass spectrometric behaviour of **4** was similar to that of its homologue **3**. The base peak of ESI-MS spectra of **4** in acetonitrile was the [M]$^+$ ion (m/z = 681) at fragmentor voltages in the range

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

0−100 V. At 150 V the base peak was represented by the $[M - CH_3CN]^+$ ion (m/z = 640). The dichloromethane solution of **4** showed, in the 0−350V fragmentor voltage range, the m/z = 1315 ion corresponding to the cationic part of **6** (which is formed by dissolving **4** in CH_2Cl_2) plus a chloride ion.

The positive ESI-MS spectra of pure **6** were acquired in dichloromethane and were analyzed under the same conditions applied for **4**. The $[M + Cl]^+$ ion (m/z = 1315) was observed in the 0−350V fragmentor voltage range whereas the m/z = 640 peak, corresponding to the monocharged halfed dimer was the most intense peak in the fragmentor voltage range 0−100 V.

Chloride adduct formation is a consequence of the use of dichloromethane. No evidence of doubly charged ions was found: the strong tendency of the dicationic species to form single charged adducts in the presence of the above mentioned negative ions probably represents the optimal ionization pathway.

The positive ESI-MS spectra of dichloromethane solutions of carbonyl species **7** and **8** were acquired under the same conditions reported for **3** and showed intense $[M]^+$ ions (m/z = 654 for **7**, m/z = 668 for **8**) in the fragmentor voltage range 0−200 V. At 250 V the loss of the CO molecule gave the $[M - CO]^+$ ions (m/z = 626 for **7**, m/z = 640 for **8**) as base peaks.

X-ray Structure Determinations of 1·CD_2Cl_2 and 6·2CD_2Cl_2:[34] Single crystals were obtained by slowly evaporating solutions of the compounds in CD_2Cl_2. The stoichiometries of the resulting solvates were **1**·CD_2Cl_2 and **6**·2CD_2Cl_2. Data were collected at room temperature with a Bruker SMART D8 goniometer equipped with an APEX detector. The structures were solved by direct methods.[35] The final structure model with anisotropic displacement parameters for all non-hydrogen atoms and H atoms riding in idealized positions was refined on F^2.[36] Crystal data, parameters of data collection, and convergence results are compiled in Table 4. Table 2 summarises selected bond lengths and angles.

Polymetallated 4-*tert*-Butylcalix[4]arene Complexes of Sodium and Potassium Stabilized by Crown Ethers: Syntheses, Structures and Activation of Carbon Dioxide

Reinald Fischer,[a] Helmar Görls,[a] and Dirk Walther*[a]

Keywords: Alkali metals / Calixarenes / Carbon dioxide fixation / Carboxylation / Crown compounds

4-*tert*-Butylcalix[4]arene and 18-crown-6 react with NaH in THF to form the complex [(18-crown-6)(THF)Na_4(4-*tert*-butylcalix[4]arene-4H)]$_2$·3THF (**1**). Analogously, the reaction with 4-*tert*-butyltetrathiacalix[4]arene in DMF results in the formation of [(18-crown-6)Na(dmf)$_{1.5}$]$_2$[(4-*tert*-butyltetrathiacalix[4]arene-4H)$_2$$Na_6(dmf)_2$] (**2**) The X-ray analysis of **1** shows an Na_6O_6 skeleton consisting of two fused open heterocubanes. Two Na^+ ions are encapsulated in the cavities of the calix[4]arene units. Additionally, two peripheral Na^+ ions, each surrounded by a crown ether and one THF ligand, are connected to the central Na_6O_6 skeleton by one bridging oxygen of the calix[4]arene. In contrast, **2** contains the highly symmetrical anion [(4-*tert*-butyltetrathiacalix[4]arene-4H)$_2$$Na_6(dmf)_2$]$^{2-}$ and crown-ether-stabilized cations. While **1** shows a dynamic process in solution above 40 °C, the structure of the highly symmetrical compound **2** remains stable at higher temperatures. The solid-state structure of the potassium complex [(dibenzo-18-crown-6)K_4(4-*tert*-butylcalix[4]arene-4H)(THF)$_3$]$_2$·4THF (**4**) is similar to **1**; however, the calix[4]arene units in the open heterocubane structure of **4** are shifted less than half a diameter to one another than in the sodium complex **1**. According to the ^{1}H NMR spectra complex **3a**, containing 18-crown-6, has a very similar structure to the related complex **4**. Both **1** and **4** absorb carbon dioxide in THF and are active CO_2-transfer reagents towards 2-fluoropropiophenone; complex **2** is much less active. This clearly demonstrates the subtle influence of the structure of the alkali metal complexes on the CO_2 reactivity in these types of compounds.

Introduction

Calixarenes and their metal complexes have attracted great interest during the last 20 years due to a number of attractive aspects in different areas. A great number of derivatives have been synthesized, structurally characterized and used for application in supramolecular chemistry (especially host-guest complexes), for selective metal coordination, as models for simulating catalytic oxide surfaces, and as catalysts and sensors.[1−7]

Interactions with alkali metal ions have been intensively investigated mainly due to their importance for the separation of the alkali metals and as models for metal-ion transport.[8] The first complex of the monoanion of 4-*tert*-butylcalix[4]arene with Cs^+ was described 1991 by Harrowfield.[9] In 1993 Atwood isolated a monometallated sodium complex in which two oxygens of the calixarene unit chelate to the metal.[10] A number of other alkali metal complexes with monoanionic and dianionic calixarenes are also known.[11−13] Recently, Harrowfield described partially deprotonated thiacalixarene complexes of the Li−Cs series,[14] and in 1995 Bock et al. published the molecular structure of [Li_3(calix[4]arene-3H)(NH_3)]$_2$ the first alkali metal complex of a multiply deprotonated calix[4]arene.[15]

Surprisingly little is known about alkali metal complexes with fully deprotonated calix[4]arenes of the type [M_4(4-*tert*-butylcalix[4]arene-4H)(solv)$_x$]$_2$, which are useful building blocks for the preparation of transition metal complexes. The first complex of this type with Li as the metal center was described by Davidson.[16] Recently, Floriani,[17] and Fromm[18] prepared and structurally elucidated polymetallated alkali metal complexes with Li, Na and K using different synthetic procedures. Partial hydrolysis of the lithium derivative resulted in the formation of the doubly protonated Li complex.[18] Furthermore, the syntheses and structures of dialkylated alkali metal calix[4]arene complexes were recently described, and their reaction with crown ethers in solution investigated by NMR spectroscopy.[19]

It is well-known that alkali-metal phenolates react with carbon dioxide to form complexes of hitherto unknown structures which can undergo self-carboxylation to form salicylic acid or the *para*-hydroxybenzoic acid. Additionally, some alkali-metal phenolates are also able to carboxylate

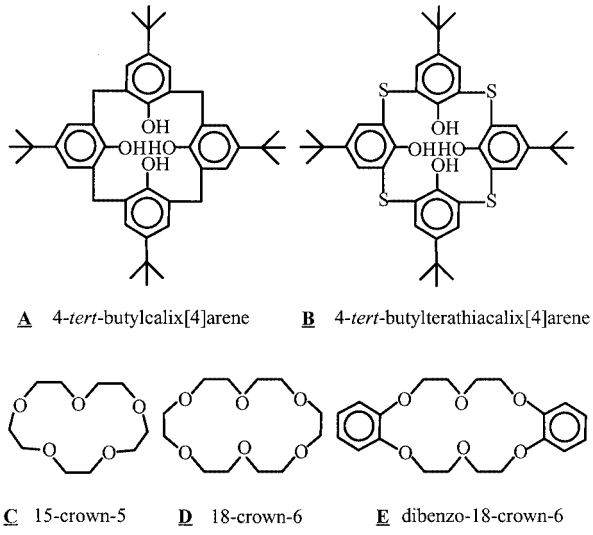
activated aliphatic C−H bonds in dipolar aprotic solvents to form aliphatic carboxylic acids upon hydrolysis.[20−24]

Generally, calixarene alkali metal complexes containing phenolate groups linked in the two *ortho* positions by methylene groups should be of great interest in CO_2 chemistry, especially for the design of metal complexes which could be active in both the fixation and the activation of carbon dioxide. To the best of our knowledge, this aspect of calixarene metal chemistry has been completely ignored so far.

Here we report on the synthesis and molecular structures of new polymetallated sodium and potassium calix[4]arene complexes in combination with crown ethers, which act as competitive ligands. Our aim was to construct soluble systems which would be active in both CO_2 fixation and in carboxylation reactions of activated aliphatic C−H bonds.

Results and Discussion

Scheme 1 displays the starting calix[4]arene **A** and its sulfur-bridged analogue **B**, as well as the three crown ethers used as co-ligands.



Scheme 1. The calix[4]arenes **A** and **B** and the crown ethers **C**−**E** used as ligands

Sodium Complexes with 4-*tert*-Butylcalix[4]arene (1 and 2)

In the absence of traces of water sodium hydride readily reacts with the calix[4]arene **A** in THF to form completely deprotonated products. In the presence of 15-crown-5 (**C**), which is tailor-made for Na^+, the resulting reaction product is insoluble even in polar solvents such as THF, DMF or DMSO. We assume, therefore, that the fully deprotonated calixarene-containing sodium complex consists either of separated ions, which cannot be solvated effectively in organic solvents, or forms a polymeric structure.

However, with 18-crown-6 (**D**) as co-ligand, a crown ether which does not "fit" effectively to Na^+,[25] complex **1** was obtained as a THF-soluble product. From this solution we isolated well-shaped single crystals containing three non-coordinated molecules of THF per dimeric unit [18-crown-6)(THF)Na_4(4-*tert*-butylcalix[4]arene-4H)]$_2$. THF is very easily eliminated from this complex at 0 °C or by bubbling a stream of inert gas through the solution. Complex **1** is formed in a very selective reaction in high yields. Even if an excess of 18-crown-6 was used as a competitor ligand for the calix[4]arene, only complex **1** was formed. This shows that the sodium strongly prefers the charged ligand to the neutral one. Single crystals were grown from THF solution and the structure of **1** was confirmed crystallographically with the molecular structure illustrated in Figure 1.

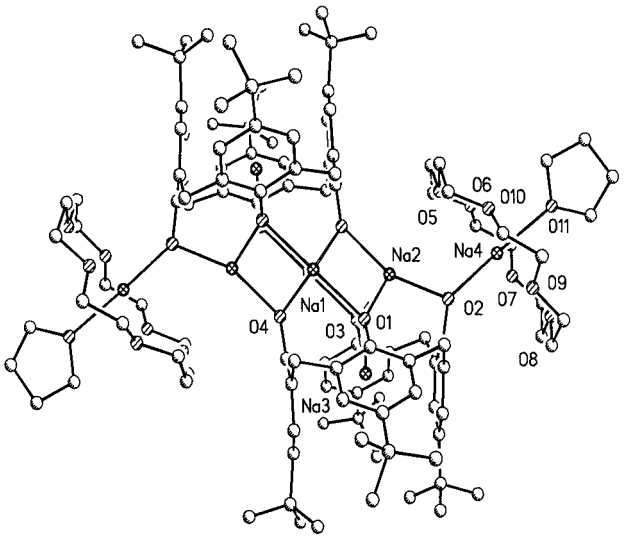


Figure 1. Molecular structure of [(18-crown-6)(THF)Na_4(4-*tert*-butylcalix[4]arene-4 H)]$_2$·3THF (**1**); non-coordinated THF and hydrogen atoms have been omitted for clarity; selected bond lengths (A): Na(1)−O(1) 2.275(3), Na(1)−O(3) 2.281(3), Na(1)−O(4) 2.292(3), Na(2)−O(1) 2.383(3), Na(2)−O(2) 2.199(3), Na(2)−O(3) 2.359(3), Na(2)−O(4A) 2.232(3), Na(3)−O(1) 2.327(3), Na(3)−O(3) 2.356(3), Na(4)−O(2) 2.216(3), Na(4)−O(5) 2.802(4), Na(4)−O(6) 2.805(4), Na(4)−O(7) 2.661(4), Na(4)−O(8) 2.714(4), Na(4)−O(9) 2.672(4), Na(4)−O(10) 2.820(4), Na(4)−O(11) 2.381(4), Na(1)···Na(1A) 2.931(3), Na(1)···Na(2) 3.152(2); selected bond angles (°): O(11)−Na(4)−O(5) 99.60(14), O(11)−Na(4)−O(6) 84.2(2), O(11)- Na(4)−O(7) 86.9(2), O(11)−Na(4)−O(8) 83.13(13), O(11)−Na(4)−O(9) 86.1(2), O(11)−Na(4)−O(10) 81.6(2), (11)−Na(4)−O(2) 177.7(2), O(1)−Na(1)−O(3A) 171.68(12), O(1)−Na(1)−O(4A) 93.73(11), O(1)−Na(1)−O(4) 90.77(10), O(2)−Na(2)−O(4A) 153.33(12), O(2)−Na(2)−O(1) 101.50(11), O(2)−Na(2)−O(3) 102.82(11), O(1)−Na(2)−O(3) 86.91(10), Na(1)−O(1)−Na(3) 118.7(3), Na(1A)−O(3)−Na(3) 117.3(3)

Figure 2 shows the Na_6O_6 skeleton of **1**, with the Na(1)−O(4)−Na(1A)−O(4A)−plane fusing two heterocubane units. Since there are no bonding interactions between Na(3) and O(4) or Na(3A) and O(4A), two "open" heterocubane units result.

Compound **1** can be considered as an intermediate between the fully lithiated compound (with the coordination number 4 for Li)[18] and the potassium compound (open heterocubane structure), reflecting also the intermediate size of the Na cation between Li and K.

Furthermore, in **1** the two calix[4]arene units are shifted by half a diameter with respect to one another. This is different to the reported pyridine-stabilized sodium complex

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

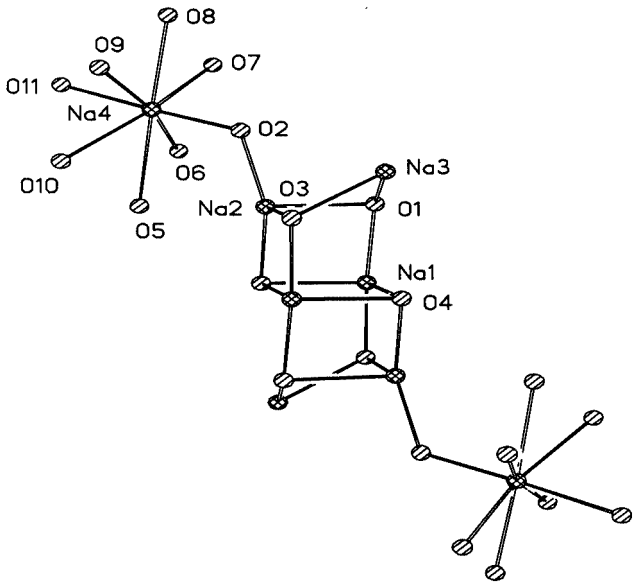

Figure 2. Na_8O_8 cluster core of **1** with the central Na_6O_6 skeleton

[(pyridine)$_4$Na$_4$(4-*tert*-butylcalix[4]arene-4H)]$_2$·THF in which this shift is very small.[10] Consequently, the sodium atoms in the plane fusing the two heterocubanes exhibit coordination numbers of four in **1**, in contrast to the above pyridine complex where these Na^+ ions have a coordination number of five.

In the central Na_6O_6 skeleton the oxygen atoms of the calix[4]arene are situated at the corners of a deformed rhomb, in contrast to their positions in the free calix[4] arene where these oxygens occupy the corners of a square.[26] Na(3) and Na(3A) are encapsulated in the cavities of the calix[4]arenes and are in contact with the aromatic π-systems of two calix[4]arene phenyl rings. These rings are almost parallel to each other and the Na−C bond lengths (between 2.931 and 3.500 Å) are similar to previously reported values.[18,19]

The peripheral Na(4) and Na(4A) atoms, with a coordination number of eight, each surrounded by the six oxygens of 18-crown-6 and one THF oxygen, are linked to the central Na_6O_6 skeleton by only one bridging calixarene phenolate. The six crown ether oxygens adopt almost coplanar positions with the sodium ion out of this plane (deviation from the least-squares plane: 0.15 Å, shifted in the direction of the coordinated phenolate). Furthermore, the coordinated THF and the oxygen of the phenolate group lie *trans* to each other, perpendicular to the plane formed by the crown ether. This type of coordination is, in principle, well-known for symmetric 18-crown-6 sodium complexes of the type [(18-crown-6)NaL$_2$]X (L = THF,[27−30] H_2O[31,32] with different anions; for a review see ref.[33]). Moreover, asymmetric types of the composition [(18-crown-6)Na(X)] (L = THF or 1,3-dioxolane; X = anionic ligand) have recently been found as well.[34−36]

The Na−O(crown) distances in **1** [between 2.661(4) and 2.805(4) Å] are considerably longer than the Na−O(THF) distance [2.381(4) Å]. These values lie in a typical range for the above type of asymmetric compounds. As expected, the Na−O(phenolate) distance [2.216(3) Å] is the shortest Na−O bond due to the anionic nature of the Na_6O_6 skeleton containing the calixarene units.

The ^{1}H NMR spectrum in [D$_8$]THF at room temperature suggests that the structure found in the solid state is also maintained in solution at ambient temperature (Figure 3). As expected for this structure three signals of *tert*-butyl groups in a 2:1:1 ratio (at δ = 0.76, 0.95 and 1.29 ppm), and four signals for the *meta*-protons of the phenolates at δ = 6.27, 6.54, 6.84 and 6.90 ppm are observed at 20 °C. Furthermore, four doublets belonging to the bridging methylene groups at δ = 2.71, 2.82, 3.77 and 4.73 ppm appear.

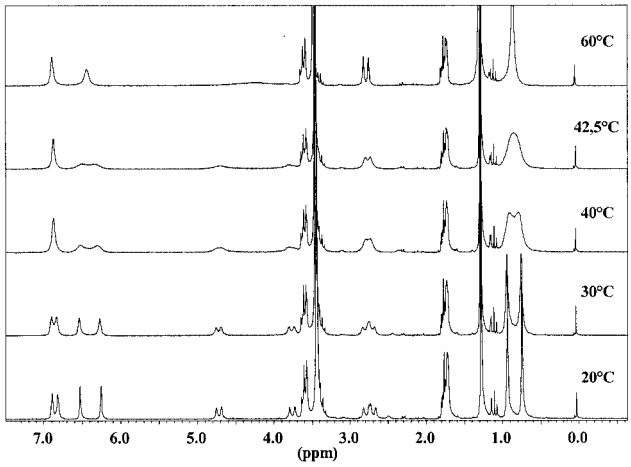

Figure 3. Temperature-dependent ^{1}H NMR spectra of **1** in [D$_8$]THF

Increasing the temperature results in a significant change of the NMR spectra. At 42.5 °C the two signals at higher field coalesce and at higher temperatures only two signals for the *tert*-butyl protons in a ratio of 2:2 (at δ = 0.82 and 1.25 ppm) appear. The signals of the *meta*-protons of the phenolates (at δ = 6.40 and 6.84 ppm) and of the bridging CH_2 (at δ = 2.74 and 4.19 ppm) show the same behavior, indicating that at higher temperature two pairs of equivalent phenolates exist in the molecule.

The reversible nature of the temperature-dependent ^{1}H NMR spectra implies a dynamic process, the activation energy of which (ΔH = 65.0 ± 0.5 kJ·mol^{-1}) can be calculated from the temperature of coalescence and the separation of the signals in the ^{1}H NMR spectra.

One possibility to explain this dynamic behavior would be the dissociation of **1** into the ions [Na(18-crown-6)]$^+$ and [(4-*tert*-calix[4]arene-4H)Na$_3$]$_2^-$. However, this process can be excluded because in this case three different species would exist in solution above 40 °C: the starting compound **1** and the ionic compounds [Na(18-crown-6)]$^+$ and [(4-*tert*-butylcalix[4]arene)Na$_3$]$_2^-$. This is not in agreement with the simple ^{1}H NMR pattern at high temperatures. However, a translation process involving the translation of one calix[4]-arene unit in the direction defined by the Na(2)−Na(2A)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

axis, and the translation of the other calix[4]arene in the opposite direction, could explain the NMR spectroscopic data. Simultaneously, the sodium ions Na(4) and Na(4A) would undergo a 1,3-shift. An alternative process would be the synchronized rotation of both calix[4]arene units in **1** around their central axis. The rhomb of Na(1)−Na(2)−Na(1A)−Na(2A) may be fixed during this process in which **1** would act in solution as a "temperature-dependent molecular slide clutch". A similar process, with an activation enthalpy, ΔH^{Θ}, of 45 kJ·mol^{-1} was recently found for a mononuclear Zn calixarene complex.[37] Although the NMR spectroscopic data do not allow us to distinguish between the translation and the rotation process in **1**, it is reasonable to favor the translation process, since a rotation would require more activation energy than a simple transition process.

The reaction of the sulfur-bridged calix[4]arene **B** with $NaN(SiMe_3)_2$ in the presence of 18-crown-6 in a molecular ratio of 1:4:1 in THF results in an insoluble product. Recrystallization from DMF gives well-shaped single crystals of the composition [(18-crown-6)Na(dmf)$_{1.5}$]$_2$[(4-*tert*-butyltetrathiacalix[4]arene-4H)$_2$Na$_6$(dmf)$_2$] (**2**). Complex **2** contains the same molecular ratio between calix[4]arene, sodium and 18-crown-6 as **1**; however the ^{1}H NMR spectrum of **2** exhibits only a simple pattern indicating a high symmetry of the molecule.

Unfortunately, due to the poor crystal quality only the structural motif could be determined by X-ray analysis. However, the complex is undoubtedly an ionic compound consisting of two [(dmf)$_n$Na$^+$(18-crown-6)]$^+$ (n = 1, 2) cations and the anion [(dmf)$_2$Na$_6$(4-*tert*-butyltetrathiacalix[4]arene$_2$]$^{2-}$. Figure 4 displays the structure motif of the anionic part.

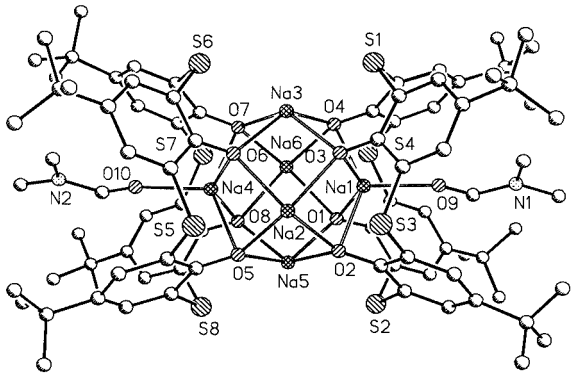

Figure 4. Structural motif of the [(4-*tert*-butyltetrathiacalix[4]arene-4H)$_2$Na$_6$(dmf)$_2$]$^{2-}$ anion of **2**; the counterions [(dmf)$_2$Na(18-crown-6)]$^+$, [(dmf)Na(18-crown-6)]$^+$ and the hydrogen atoms have been omitted for clarity

Complex **2** contains two perpendicular mirror planes, one of which consists of Na(2), Na(3), Na(5) and Na(6), and the other S(1), S(2), S(6) and S(8). The central unit of the structure is an octahedron with Na(1), Na(2), Na(3), Na(4), Na(5) and Na(6) at the corners. Every plane of the octahedron is capped by an oxygen of the phenolate rings. The sodium atoms Na(3), Na(2) Na(5), and Na(6) form square pyramids, with the Na ions at the apex and four oxygens in the base. In addition, the oxygen atoms of the calix[4]arene phenolates are located at the corners of a cube and the 4-*tert*-butyltetrathiacalix[4]arene moieties are in an eclipsed arrangement. There is no interaction of the Na$^+$ ions with the free electron-pairs of the sulfur atoms. In contrast to the sodium-calixarene complex **1**, where a sodium atom is found inside the cavities, the cavities of **2** contain a DMF molecule, which coordinates to Na(1) and Na(4).

The two counterions [(dmf)Na$^+$(18-crown-6)] and [(dmf)$_2$Na$^+$(18-crown-6)] have different coordination environments. In [(dmf)Na$^+$(18-crown-6)] the crown ether oxygens are arranged in a "boat form" with the sodium ion below the plane. The coordination of six oxygens of the crown ether and one DMF molecule results in a coordination number of seven for the sodium ion. This arrangement is similar to that in compound **5** and will be discussed in more detail below.

The structural motif of the other cation [(dmf)$_2$Na$^+$(18-crown-6)] is typical of the above-mentioned group of symmetrical [(18-crown-6)NaL$_2$]$^+$ complexes,[27−33] with a hexagonal-bipyramidal arrangement of the eight oxygen ligands surrounding the sodium ion. The sodium ion is situated in the center of the plane formed by the six oxygens of the crown ether compound. In addition, the two DMF ligands lie *trans* to each other.

The ^{1}H NMR spectrum in [D$_8$]THF is in agreement with this highly symmetrical structure found in the solid state: besides the DMF protons only one singlet for the protons of the *tert*-butyl groups (at δ = 1.14 ppm), one singlet for the *meta* CH groups of the aromatic rings (at δ = 7.42 ppm) and one singlet for the OCH$_2$ groups of the crown ether (at δ = 3.59 ppm), with the expected intensities, were observed. According to the ^{1}H NMR spectrum, this structure is maintained even at higher temperatures.

Potassium Complexes with 4-*tert*-Butylcalix[4]arene and Crown Ethers

The reaction of **A** with KN(SiMe$_3$)$_2$ and 18-crown-6 (**D**) in a molar ratio of 1:4:1 in THF afforded a mixture of the two compounds **3a** and **3b** even if the molecular ratio of **A**/18-crown-6 was varied from 1:1 to 1:2. Complex **3a** crystallized as large, colorless crystals of the composition [(18-crown-6)K$_4$(4-*tert*-butylcalix[4]arene-4H)(THF)$_n$], and **3b** crystallized as fine needles. Separation of **3a** from the reaction mixture was possible by repeated decanting of **3a** from the suspension followed by washing the crystals with THF at −78 °C. According to the ^{1}H NMR spectrum the purity of **3a** was greater than 95%. However, since **3a** could not be isolated as single crystals suitable for X-ray crystallography, we performed a similar reaction with the closely related dibenzo-18-crown-6 instead of 18-crown-6 to get better crystals of this type of compound.

Reaction of ligand **A** with KN(SiMe$_3$)$_2$ and dibenzo-18-crown-6 (**E**) in a molar ratio of 1:4:1 in THF did indeed yield the complex [(dibenzo-18-crown-6)K$_4$(4-*tert*-butylcalix[4]arene-4H)(THF)$_3$]$_2$·4THF (**4**) in a mixture with a second product of the composition [(dibenzo-18-crown-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

6)$_2$K$_4$(4-*tert*-butylcalix[4]arene-4H)] (according to the ^{1}H NMR spectrum of the reaction mixture). Single crystals of compound **4** grown from THF were suitable for X-ray analysis. Figure 5 shows the molecular structure and contains selected bond lengths and bond angles in the figure caption; Figure 6 shows the K_8O_8 core.

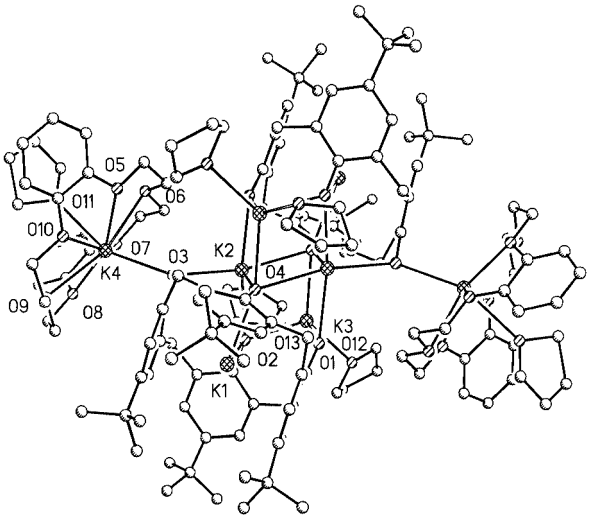

Figure 5. Molecular structure of **4**; non-coordinated THF and hydrogen atoms have been omitted for clarity; selected bond lengths (A): K(1)−O(2) 2.704(4), K(1)−O(4) 2.842(4), K(2)−O(2) 2.619(4), K(2)−O(3) 2.599(4), K(2)−O(4) 2.574(4), K(3)−O(1A) 2.702(4), K(2)−K(2A) 3.477(2), K(3)−O(1) 2.744(4), K(3)−O(2) 2.678(4), K(3)−O(12) 2.776(7), K(3)−O(13) 2.833(6), K(3)−K(2A) 2.6391(18Å, K(4)−O(3) 2.681(4), K(4)−O(5) 2.827(5), K(4)−O(6) 2.779(4), K(4)−O(7) 2.797(5) Å, K(4)−O(8) 2.848(5), K(4)−O(9) 2.812(5), K(4)−O(10) 2.841(5), K(4)−O(11) 2.758(8)

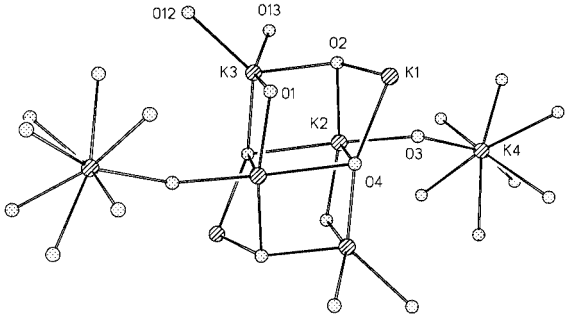

Figure 6. The K_8O_8 core in **4** with the central K_6O_6 skeleton and the two peripheral K^+ ions (each surrounded by the crown ether oxygens and one oxygen of THF) bridged by O(3) and O(3A), respectively

The molecular structure of **4** shows some similarities to the sodium compound **1**. In both complexes the central M_6O_6 moiety consists of two fused open heterocubanes where the corners are occupied alternately by alkali metal cations and oxygens of the calix[4]arenes. However, there are remarkable differences in the details of the structure. In contrast to **1**, the central heterocubane units in **4** are arranged nearly perpendicularly, and the peripheral [(THF)K(4)(dibenzo-18-crown-6)]$^+$ unit interacts with the phenolate oxygen bridge O(3) of the central skeleton and not with O(2) as found in **1**.

The calixarene oxygens coordinate to the central potassium rhomb containing K(2), K(3), K(2A) and K(3A). K(2) and K(2A) have coordination numbers of five, with a distorted square-pyramidal arrangement of the phenolate oxygen atoms. K(3) and K(3A) also have a coordination number of five due to three phenolate oxygen atoms and two coordinated THF molecules.

The two calix[4]arene units are shifted less than half a diameter with respect to one another, therefore the [(THF)K(dibenzo-18-crown-6)]$^+$ moieties are much closer to the central K_6O_6 skeleton.

The structure of **4** is very similar to the reported structures of the complexes [(THF)$_5$K$_4$(4-*tert*-butylcalix[4]arene-4 H)]$_2$·4THF[17] and [(THF)$_5$K$_4$(4-*tert*-butylcalix[4]arene-4 H)]$_2$·THF.[18] The most remarkable difference consists in the different coordination of the peripheral ions K(4) and K(4A), indicating the influence of the crown ether ligand: as they are surrounded by the crown ether oxygens and one THF, both K(4) and K(4A) are only coordinated to one calix[4]arene oxygen bridge, in contrast to the previously described THF-stabilized complexes, where two oxygen bridges link these K^+ ions.

K(1) and K(1A) inside the calix[4]arene cores are bonded to only two oxygen atoms of the phenolates, although they also interact with the π-electron systems of the two nearly parallel phenolates. The K(1)−C_{aromat} distances lie within reported ranges[18] [2.931(3)−3.435(4) Å for the first ring and 3.058(4)−3.152(3) Å for the second ring]. However, there are also contacts to the *ipso* carbon atoms of the other two phenyl rings [K(1)−C_{ipso} = 2.977(3) and 2.964(5) Å].

The structure of the crown ether part is very similar to that in the sodium compound **1**. The coordination number of the potassium ion is eight, and the crown ether oxygens are arranged in an almost coplanar arrangement. The potassium ion lies above this plane, with a deviation of 0.53 Å. This structural motif is known for 18-crown-6 complexes of both sodium and potassium.[38] The K−O(crown) distances in **4** vary between 2.779(4) and 2.848(5) Å. As expected for the coordination of an anionic oxygen ligand, the K−O distance to the bridging calix[4]arene moiety [K(1)−O(3) 2.681(4) Å] is significantly shorter than the other K−O distances.

The ^{1}H NMR spectrum of **4** is in agreement with the structure found in the solid state and is very similar to that of **3a**, which contains 18-crown-6 instead of dibenzo-18-crown-6. Therefore, we assume that **3a** has a similar nonionic cluster-like structure to that of complex **4**.

The temperature-dependent ^{1}H NMR spectra of complex **3a** give evidence for an interesting reversible reaction. At ambient temperature three chemically different *tert*-butyl protons in a molecular ratio 2:1:1 are observed at δ = 1.15, 1.11 and 1.08 ppm. Upon warming, the signals of the *tert*-butyl protons and the *meta* protons of the phenolate groups become more and more equal and, in a simultaneous process, the intensity of the original signals of **3a** disappears, while new signals of a highly symmetric compound appear without coalescence. At 55 °C the ^{1}H NMR spectrum contains only signals for chemically equivalent phenolate

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

groups. Therefore, we assume that a reversible, temperature-dependent dissociation of compound **3a** may proceed according to Equation (1):

$$\mathbf{3a} \rightleftarrows 2\,[K(18\text{-crown-6})(THF)_2]^+ + [K_3(calix[4]arene\text{-}4H)]_2^{2-} \quad (1)$$

Due to the similarities with the ^1H NMR spectrum of the anion of **2** we suggest that the anion $[K_3(calix[4]arene\text{-}4H)]_2^{2-}$ could have a similar molecular structure.

One of the reasons for the different behavior between the sodium complex **1** and the potassium complex **3a** in solution at increasing temperatures may be the different coordinating ability of 18-crown-6 to Na^+ and K^+, which favors the formation of an ionic product for K^+.

Fixation of CO_2 by 1, 2 and 4 and CO_2-Transfer Reaction with 2-Fluoropropiophenone

Sodium phenolate reacts with carbon dioxide to give a product of unknown structure which is able to carboxylate activated aliphatic C−H bonds in dipolar aprotic solvents.[13−17] Therefore it may be expected that some of the above alkali metal calix[4]arene complexes containing four linked phenolate rings should, in principle, be capable of carboxylating activated C−H bonds.

Compound **1** reacts rapidly with CO_2 in THF. If water is not excluded very carefully the resulting products are $NaHCO_3$ and compound **5** [Equation (2)], which could be obtained as single crystals from THF.

$$\mathbf{1} + 3\,CO_2 + 3\,H_2O \rightarrow \underset{\mathbf{5}}{[Na(18\text{-crown-6})][(calix[4]arene\text{-}H)]} + 3\,NaHCO_3$$

The X-ray structure of **5** (Figure 7) shows that the compound contains a single deprotonated $[calix[4]arene\text{-}3H]^-$ anion that is connected to the counterion $[Na(18\text{-crown-6})]^+$ by a phenolate bridge of the calix[4]arene monoanion [Na−O(3) = 2.454(5) Å]. The other three oxygens of the calixarene unit do not coordinate [Na−O distances: Na···O(1) 4.869(5), Na···O(2) 3.507(6), Na···O(4) 3.984(4) Å]. The O···O distances between the calixarene oxygens of O(1)···O(2) [2.932(6) Å], O(1)···O(4) [2.669(6) Å], O(2)···O(3) [2.597(6) Å], and O(3)···O(4) [2.528(6) Å] are typical for intramolecular hydrogen bonds. The much shorter separations between the phenolate oxygen atom O(3) and its neighboring atoms O(2) and O(4) suggests rather strong intramolecular hydrogen bonds between these atoms. In contrast, the other O···O distances are significantly longer, although they are also in the range of hydrogen bonds. A more detailed discussion about the nature of the hydrogen-bond system is, however, not possible, because the hydrogen atoms were not found in the Fourier map. In this connection it is interesting to note that, in the known monometallated sodium compound of **A**,[10] containing methanol as co-ligand, and the tetrathia analogue **B**,[14] with water and THF as co-ligands, the calixarene units also form an intramolecular hydrogen-bond system. However, in these complexes the two calixarene oxygens act as bidentate chelating ligands, in contrast to **5**, where only one oxygen of the calixarene is coordinated. This reflects again the stronger ligand-effect of the crown ether compared with the other ligands in the above complexes. The coordinated 18-crown-6 is folded away from the calix[4]arene moiety, so there is no space for another THF molecule to coordinate to the sodium cation, which has a coordination number of seven. The structure of the crown ether part in **5** is very different from that in complex **1**, where the oxygens form a coplanar arrangement: the crown ether oxygens in **5** form a "distorted boat" with the plane formed by O(6), O(7), O(9), and O(10). The sodium ion lies below this plane, whereas the other two oxygens [O(5) and O(8)] are above the plane, with very different deviations from the least-square plane [1.86 Å for O(5) and 0.80 Å for O(8)]. According to a search of the Cambridge Crystallographic Database a few other 18-crown-6 complexes of sodium exist in which an analogous arrangement has been found.[39,44] It is, however, noteworthy that the six calixarene oxygens in similar sodium complexes can assume a chair form as well.[41,42]

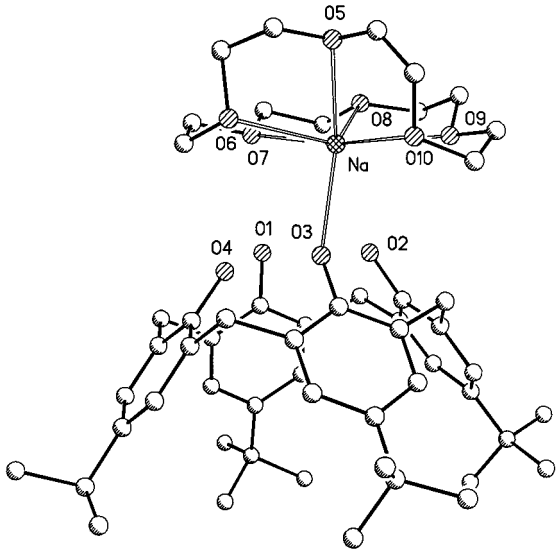

Figure 7. $[Na(18\text{-crown-6})(4\text{-}tert\text{-butylcalix[4]arene-H})]\cdot OEt_2$ (**5**); the non-coordinated ether and the hydrogen atoms have been omitted for clarity; selected bond lengths (Å): Na−O(3) 2.454(4), Na−O(5) 2.522(5), Na−O(6) 2.612(6), Na−O(7) 2.532(5), Na−O(8) 2.574(5), Na−O(9) 2.586(5), Na−O(10) 2.703(6); selected bond angles (°): O(3)−Na−O(5) 148.2(2), O(3)−Na−O(6) 94.8(2), O(3)−Na−O(7) 89.2(2), O(3)−Na−O(8) 113.4(2), O(3)−Na−O(9) 101.6(2), O(3)−Na−O(10) 97.4(2), Na(1)−O(1)−Na(3) 118.7(3)

Compound **5** displays a simple NMR spectrum. In the ^1H NMR spectrum only one singlet is observed for the *tert*-butyl groups (at δ = 1.17 ppm) and for the *meta* protons of the calix[4]arene unit (at δ = 6.87 ppm). The OH protons appear at δ = 13.39 ppm. Furthermore, two doublets of the calix[4]arene CH_2 protons were observed at δ = 3.07 and 5.52 ppm. The crown ether CH_2 protons give a signal at δ = 3.62 ppm. From these data we can conclude that, in solution, the $(18\text{-crown-6})Na^+$ moiety jumps from one phenol oxygen to another.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In contrast to these results, the reaction of **1** with carbon dioxide, with strict exclusion of moisture, proceeds differently. When a solution of **1** in hot THF under an atmosphere of CO_2 is quickly cooled down in a dry ice bath, a clear solution is obtained, although the starting compound is only sparingly soluble in cold THF. This is the first evidence for the formation of a reaction product with CO_2. In the ^1H NMR spectrum the signals of **1** disappear upon uptake of carbon dioxide and a set of new signals appear at δ = 1.17 (s), 3.07 (d), 3.62 (s), 5.52 (d) and 6.87 ppm (br). The CO_2-containing complex could not be isolated because the weakly coordinated CO_2 is easily eliminated during work up. The final product is again the complex **1**. This clearly demonstrates that the CO_2 fixation is a reversible reaction. The same behavior was observed for **2**, meaning that both **1** and **2** are able to act as reversible CO_2 carriers.

To prove that the CO_2 products are capable of transferring their CO_2 to activated aliphatic C−H bonds we investigated the reactions of **1**, **2** and **4** in THF with 2-fluoropropiophenone under an atmosphere of carbon dioxide. After 24 h the reaction mixture was treated with dimethyl sulfate to yield the methyl ester of the unstable 3-ketocarboxylic acid. For comparison, the same reaction was carried out with sodium phenolate, which is known to act as a CO_2-transfer reagent.

Figure 8 shows that in all four reactions 2-benzoyl(2-fluoro)methylpropionate was formed, although in veryy different yields. Whereas sodium phenolate/CO_2 and **2**/CO_2 show very little activity (9% and 8% yield, respectively), the systems **1**/CO_2 and **4**/CO_2 are very efficient CO_2-transfer reagents that form the carboxylation product in a highly selective reaction (about 90%).

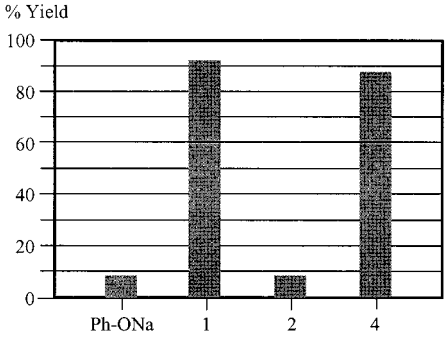

Figure 8. Carboxylation of 2-fluoropropiophenone by the complexes **1**/CO_2, **2**/CO_2, **4**/CO_2 and PhONa/CO_2 (for comparison) in THF at ambient temperature; reaction time: 24 h, molar ratio: 2-fluoropropiophenone/complex = 1:4; the yield was determined by ^{19}F NMR spectroscopy

Although the reasons for the remarkable difference in the carboxylation reactivity are hitherto unknown, the following points attract attention. Generally, CO_2-transfer reactions between NaOPh/CO_2 and substrates containing aliphatic activated C−H bonds such as acetone or acetophenone only proceed efficiently if dipolar aprotic solvents are used as solvent; the activity in THF is very low.[23] The reaction with 2-fluoropropiophenone confirms this (Figure 8). To explain this solvent-dependent activity, we assume that dipolar aprotic solvents (such as DMF, DMSO or *N*-methyl-ε-caprolactam) are stronger ligands than THF and can additionally split the Na−O bonds of the NaOPh oligomer in solution. This could result in more-reactive species which carboxylate activated C−H bonds much better than the "closed" heterocubane system found in complexes of the type (LNaOPh)[23,24] or polymeric NaOPh.[24] In contrast, **1** and **4** are complexes with "open" heterocubane structures in which the Na−O bonds should be more reactive in carboxylation reactions of activated aliphatic C−H bonds. The different structure of **2**, which exhibits a highly symmetrical anionic structure, could then explain why **2** is less active.

Conclusions

Sodium and potassium complexes of calix[4]arenes and crown ethers yield different types of stable molecular structures depending on the diameter of the alkali metal cations, the different size of the cavities of the calix[4]arenes and the different efficiency of the coordination by additional crown ether ligands. Even a relatively small difference of the size in the cavities of **A** (C−CH_2 = 1.516−1.581 Å) and **B** (C−S = 1.777 Å) results in a completely different structure type for complexes **1** and **2**, even though the ratio between 18-crown-6, Na^+ ions and calix[4] arene is the same. While **1** shows a dynamic process in solution above 40 °C, the structure of the highly symmetrical compound **2** remains stable at higher temperatures.

The structure of the potassium compound **4** is also different from the related sodium complex **1**. In **4** the calix[4]arene units are less shifted with respect to the plane fusing the two heterocubane units, and the coordination of the peripheral $[(THF)K(dibenzo\text{-}18\text{-}crown\text{-}6)]^+$ is also different. Temperature-dependent ^1H NMR spectra suggest, in this case, that a dissociation process proceeds resulting in the formation of ionic species.

Compounds **1** and **4**, containing the calix[4]arene **A**, are active CO_2-transfer reagents towards 2-fluoropropiophenone, in contrast to **2**, which contains the calix[4]arene **B**. This clearly demonstrates the subtle influence of the structure of the alkali-metal complexes on the CO_2 reactivity in these types of compounds.

Experimental Section

Due to the sensitivity of the substances to moisture and partly to air all manipulations were carried out under an atmosphere of argon. The solvents DMF and DMSO were dried with molecular sieves and THF with benzophenone/sodium, and freshly distilled before use.

4-*tert*-Butyltetrathiacalix[4]arene was prepared from 4-*tert*-butylphenol and sulfur in a solution of tetraethylene glycol dimethyl ether.[20] 4-*tert*-Butylcalix[4]arene, sodium hydride, $NaN(SiMe_3)_2$, $KN(SiMe_3)_2$, 4-*tert*-butylphenol, dibenzo-18-crown-6, 15-crown-5 and 18-crown-6 were purchased from Aldrich and tetraethylene glycol dimethyl ether from Merck-Schuchardt.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Most of the synthesized complexes contain extremely weakly bound THF in the crystals which is extremely easily released when not in contact with the mother liquor. In addition, THF is very easily eliminated from complex **1** even at −78 °C in a stream of inert gas. The other complexes (except **2** and **5**) eliminate solvent when handled at 0 °C. This resulted in problems in obtaining microanalyses for **1**, **3a**, and **4** from the bulk material. Furthermore, only approximate yields (%) could be calculated on the basis of complex compositions due to loss of non-coordinated volatile solvents. These problems are well-known for alkali metal compounds of calixarenes containing volatile ligands.[12,14,18]

^{1}H and ^{13}C NMR spectra were recorded on a Bruker AC 200 F spectrometer. Mass spectra were recorded on a Finnigan MAT SSQ 710.

[(18-Crown-6)(THF)Na$_4$(4-*tert*-butylcalix[4]arene-4H)]$_2$·3THF (1): 18-Crown-6 (0.33 g, 1.25 mmol) and sodium hydride (0.13 g, 5.42 mmol) were added to a suspension of **A** (0.81 g, 1.25 mmol) in THF (50 mL). The reaction mixture was stirred and heated in a water bath to reflux. Hydrogen gas was liberated while the starting materials gradually dissolved. The hot solution was filtered through a Schlenk frit. Complex **1** crystallized from the filtrate. The colorless crystals lost non-coordinated THF and formed an amorphous powder. Yield: 1.3 g (ca. 95% based on the composition [(18-crown-6)(THF)Na$_4$(4-*tert*-butylcalix[4]arene-4H)]$_2$. ^{1}H NMR (200 MHz, [D$_8$]THF, 20 °C): δ = 0.76 (s, 9 H, *t*Bu), 0.95 (s, 9 H, *t*Bu), 1.29 (s, 18 H, *t*Bu), 2.71 (d, $^2J_{H,H}$ = 13.1 Hz, 2 H, CH$_2$), 2.82 (d, $^2J_{H,H}$ = 13.6 Hz, 2 H, CH$_2$), 3.45 (s, 24 H, CH$_2$O), 3.77 (d, $^2J_{H,H}$ = 13.6 Hz, 2 H, CH$_2$), 4.73 (d, $^2J_{H,H}$ = 13.3 Hz, 2 H, CH$_2$) 6.27 (s, 2 H, *m*-CH), 6.54 (s, 2 H, *m*-CH), 6.84 (s, 2 H, *m*-CH), 6.90 (s, 2 H, *m*-CH) ppm. ^{1}H NMR (200 MHz, [D$_8$]THF, 60 °C): δ = 0.86 (s, 18 H, *t*Bu), 1.25 (s, 18 H, *t*Bu), 2.74 (d, $^2J_{H,H}$ = 13.3 Hz, 4 H, CH$_2$), 3.38 (s, 24 H, OCH$_2$), 4.19 (br., 4 H, CH$_2$), 6.40 (s, 4 H, *m*-CH), 6.84 (s, 4 H, *m*-CH) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, [D$_8$]THF, 60 °C): δ = 32.1, 32.6 (CH$_3$, *t*Bu), 33.9 (CH$_2$), 34.8 (C, *t*Bu), 70.5 (CH$_2$O), 123.6, 134.3 (br., *o*-C), 125.7, 132.1 (*m*-CH), 129.3, 163.7 (*ipso*-C). Well-shaped crystals suitable for the X-ray analysis crystallized from a solution in THF.

[(18-Crown-6)Na(dmf)$_{1.5}$]$_2$[(4-*tert*-butyltetrathiacalix[4]arene-4H)$_2$Na$_6$(dmf)$_2$] (2): 18-Crown-6 (0.33 g, 1.25 mmol) and sodium hydride (0.13 g, 5.42 mmol) were added to a suspension of **B** (0.90 g, 1.25 mmol) in THF (50 mL). The reaction mixture was stirred and heated in a water bath to reflux. Hydrogen gas was liberated during the reaction. The resulting white precipitate was separated from the reaction mixture by filtration through a Schlenk frit. Single crystals for X-ray analysis of **2** were obtained by recrystallization of the precipitate from a solution in DMF. Yield: 2.85 g (91%) of colorless needles of **2**. C$_{119}$H$_{171}$N$_5$Na$_8$O$_{25}$S$_8$: calcd. C 56.90, H 6.86, N 2.79, S 10.21; found C 56.07, H 6.81, N 3.21, S 9.44. ^{1}H NMR (200 MHz, [D$_7$]DMF, 30 °C): δ = 1.14 (s, 36 H, *t*Bu), 3.59 (s, 24 H, OCH$_2$), 7.43 (s, 8 H, *m*-CH) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, [D$_7$]DMF, 30 °C): δ = 32.0 (CH$_3$, *t*Bu), 33.6 (C, *t*Bu), 70.5 (CH$_2$O), 126.3, 134.3, 132.3, 135.9, 171.1 (*ipso*-C) ppm.

[(18-Crown-6)K$_4$(4-*tert*-butylcalix[4]arene-4H)(THF)$_n$] (3a): A suspension of **1** (0.81 g, 1.25 mmol) in THF (50 mL) was reacted with 18-crown-6 (0.33 g, 1.25 mmol) and KN(SiMe$_3$)$_2$ (1.07 g, 5.38 mmol). Large colorless crystals of **3a** were decanted from a suspension of fine needles of **3b**. The crystals of **3a** were washed with THF at −78 °C in order to remove impurities of **3b** from the surface of the crystals. The colorless crystals very easily lost non-coordinated THF when not in contact with the mother liquor and formed an amorphous powder. Yield: 0.04 g of the amorphous product **3a** approximately 3% based on the composition [(18-crown-6)K$_4$(4-*tert*-butylcalix[4]arene-4H)]. According to the ^{1}H NMR spectrum the purity of the product was greater than 95%.
3a: ^{1}H NMR (200 MHz, [D$_8$]THF, 10 °C): δ = 1.08 (s, 9 H, *t*Bu), 1.11 (s, 9 H, *t*Bu), 1.15 (s, 18 H, *t*Bu), 2.67 (br., CH$_2$), 3.45 (s, 24 H, CH$_2$O), 4.44 (br., CH$_2$), 6.63 (s, 4 H, *m*-CH), 6.91 (s, 4 H, *m*-CH) ppm. ^{1}H NMR (200 MHz, [D$_8$]THF, 55 °C): δ = 1.12 (s, 36 H, *t*Bu), 2.67 (br., CH$_2$), 3.46 (s, 24 H, CH$_2$O), 4.44 (br., CH$_2$), 6.82 (s, 8 H, *m*-CH) ppm.
3b: ^{1}H NMR (200 MHz, [D$_8$]THF, 10 °C): δ = 1.11 (s, 36 H, *t*Bu), 2.70 (br., 4 H, CH$_2$), 3.46 (s, 48 H, CH$_2$O), 4.50 (br., 4 H, CH$_2$), 6.66 (s, 8 H, *m*-CH) ppm.

[(Dibenzo-18-crown-6)K$_4$(4-*tert*-butylcalix[4]arene-4 H)(THF)$_3$]$_2$·4THF (4): Dibenzo-18-crown-6 (0.45 g, 1.25 mmol) and KN(SiMe$_3$)$_2$ (1.07 g, 5.38 mmol) were added to a suspension of **1** (0.81 g, 1.25 mmol) in THF (50 mL). The reaction mixture was stirred and heated in a water bath to reflux while the starting materials gradually dissolved. The hot solution was filtered through a Schlenk frit. Compound **4** crystallized from the filtrate as a mixture with "K$_4$(4-*tert*-butylcalix[4]aren-4H)(dibenzo-18-crown-6)$_2$(THF)$_n$". The large colorless crystals of **4** were separated from the fine needles of the by-product by pouring off the suspension. The colorless crystals lost non-coordinated THF and formed an amorphous powder. Yield: 0.44 g of a white amorphous crude product. (ca. 25% based on the composition [(dibenzo-18-crown-6)K$_4$(4-*tert*-butylcalix[4]arene-4H)(THF)$_3$]$_2$. ^{1}H NMR (200 MHz, [D$_8$]THF, 10 °C): δ = 1.09 (s, 9 H, *t*Bu), 1.10 (s, 9 H, *t*Bu), 1.15 (s, 18 H, *t*Bu), 3.00 (d, $^2J_{H,H}$ = 11.7 Hz, 2 H, CH$_2$), 3.92 (br., 8 H, O-CH$_2$), 3.99 (br., 8 H, O-CH$_2$), 4.46 (br., 2 H, CH$_2$), 6.73 (br., 8 H, *m*-CH), 6.82 (br., 8 H, *o*-C$_6$H$_4$) ppm.

[(18-Crown-6)Na](4-*tert*-butylcalix[4]arene-H)·OEt$_2$ (5): Carbon dioxide gas and water (54 μL, 3.0 mmol) were added to a suspension of crude product of **1** (1.07 g, 1.0 mmol) in THF (50 mL). The reaction mixture was then stirred and heated in a water bath to reflux. The hot solution was filtered through a Schlenk frit. The complex **5·THF** crystallized from the clear filtrate. Single crystals of **5·OEt$_2$** suitable for X-ray analysis were obtained by recrystallization of **5·THF** from diethyl ether. Yield: 0.54 g (58%) of colorless **5·THF**. C$_{56}$H$_{79}$NaO$_{10}$: calcd. C 71.92, H 8.52; found C 71.46, H 8.98. ^{1}H NMR (200 MHz, [D$_8$]THF, 25 °C): δ = 1.17 (s, 36 H, *t*Bu), 3.07 (d, $^2J_{H,H}$ = 12.1 Hz, 4 H, CH$_2$), 3.62 (s, 24 H, O-CH$_2$), 5.52 (d, $^2J_{H,H}$ = 12.1 Hz, 4 H, CH$_2$), 6.87 (br., 8 H, *m*-CH), 13.39 (s, 3 H, OH) ppm. ^{13}C{^{1}H} NMR (50.3 MHz, [D$_8$]THF, 25 °C): δ = 32.1 (CH$_3$, *t*Bu), 34.1, 35.1, 70.8 (O-CH$_2$), 124.8, 131.2, 139.4, 154.2 (*ipso*-C) ppm.

Reaction of 1 with CO$_2$: A suspension of **1** (1.0 mmol) in THF (50 mL) under a carbon dioxide atmosphere was refluxed, resulting in a clear solution which was quickly cooled down in a dry ice bath. No precipitation was observed. ^{1}H NMR (200 MHz, [D$_8$]THF, 25 °C): δ = 1.17 (s, 36 H, *t*Bu), 3.07 (d, $^2J_{H,H}$ = 12.0 Hz, 4 H, CH$_2$), 3.62 (s, 24 H, O-CH$_2$), 5.52 (d, $^2J_{H,H}$ = 12.0 Hz, 4 H, CH$_2$), 6.87 (s, 8 H, *m*-CH) ppm. Carbon dioxide was liberated from this product during warming of the solution to reflux under an atmosphere of argon. The NMR spectroscopic data of the resulting precipitate were identical to those of the starting compound **1**.

Carboxylation of 2-Fluoropropiophenone: A suspension of **1** (1.0 mmol), **2** (1.0 mmol) or **4** (1.0 mmol) in THF (30 mL) was warmed to reflux under an atmosphere of carbon dioxide. The solution was then quickly put in a dry ice cooling bath. 2-Fluoropropiophenone (0.152 g, 1.0 mmol) was then added from a syringe. The reaction mixture was shaken for 24 h followed by addition of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dimethyl sulfate (0.69 g, 5.5 mmol) and Na_2CO_3 (0.5 g). The mixture was then shaken for 24 h. Yield of 2-fluoro-2-benzoyl-methylpropionate (as determined by ^{19}F NMR spectroscopy): 92% for **1**/CO_2; 8% for **2**/CO_2; 89% for **4**/CO_2. ^1H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 1.86 (d, $^3J_{H,F}$ = 22.6 Hz, 3 H, CH_3), 3.76 (s, 3 H, $COOCH_3$), 7.42−8.04 (m, 5 H, Ph) ppm. $^{13}C\{^1H\}$ NMR (50.3 MHz $CDCl_3$, 25 °C): δ = 20.9 (d, $^2J_{F,C}$ = 23.3 Hz, CH_3), 53.1 ($COOCH_3$), 97.0 (d, $^1J_{F,C}$ = 195.1 Hz, CF), 20.9 (d, $^2J_{F,C}$ = 23.3 Hz, CH_3), 128.5 (CH), 129.6 (d, $^4J_{F,C}$ = 5.6 Hz, *m*-CH), 130.0 (d, $^3J_{F,C}$ = 20.4 Hz, *i*pso-C), 133.8 (CH), 168.7 (d, $^2J_{F,C}$ = 25.6 Hz, $COOCH_3$), 191.6 (d, $^2J_{F,C}$ = 25.2 Hz, C=O) ppm. ^{19}F NMR (188.3 MHz, $CDCl_3$, $CFCl_3$, 25 °C): δ = −151.9 (q, $^3J_{H,F}$ = 22.6 Hz) ppm. MS (EI): *m*/*z* = 210 [M^+], 179 [$M^+ - OCH_3$], 151 [$M^+ - COOCH_3$], 105 [PhCO]. GC-IR: ν(C=O) = 1777 cm^{-1}, ν($COOCH_3$) = 1712 cm^{-1}.

Carboxylation with **2**/CO_2 yielded the product in very low yield. Upon reaction with dimethyl sulfate, white crystals of 4-*tert*-butyltetrathiacalix[4]arene tetramethyl ether[44] crystallized as the first product from the reaction mixture. ^1H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 1.28 (s, 36 H, *t*Bu), 3.42 (s, 12 H, OCH_3), 7.42 (s, 8 H, *m*-CH) ppm.

Crystal Structure Determination: The intensity data for the compounds were collected on a Nonius KappaCCD diffractometer, using graphite-monochromated Mo-K_α radiation. Data were corrected for Lorentz and polarization effects, but not for absorption effects.[45,46] The structures were solved by direct methods (SHELXS[47]) and refined by full-matrix least-squares techniques against F_o^2 (SHELXL-97[48]). All hydrogen atoms were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[48] The *R*1 values are relatively high, since the compounds are large systems that contain both slightly disordered coordinated and non-coordinated solvent molecules. In addition, *tert*-butyl groups cause high anisotropic displacement parameters. This is typical for a number of similar compounds.[14,18] Very recently the general reasons for the difficulties in obtaining low *R*1 values have been discussed in detail.[14]

Since the quality of the data of both modifications of compound **2** is too low, we will only publish the conformation of the molecule and the crystallographic data. We have not deposited the data with the Cambridge Crystallographic Data Center. Although the *R*1 value for **4** is also high, the estimated standard derivations (e.s.d.) for the bond lengths and angles are small (see Figure 5), therefore the structural data have been deposited. XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations

Crystal Data for 1:[49] $C_{148}H_{224}Na_8O_{29}$, M_r = 1325.60 g·mol^{-1}, colorless prism, size 0.40 × 0.35 × 0.32 mm^3, triclinic, space group $P\bar{1}$, *a* = 16.6116(6), *b* = 17.3483(9), *c* = 17.9319(9) Å, α = 97.769(2)°, β = 105.557(2)°, γ = 115.616(2)°, *V* = 4297.3(3) $Å^3$, *T* = −90 °C, *Z* = 2, $\rho_{calcd.}$ = 1.024 g·cm^{-3}, μ(Mo-K_α) = 0.86 cm^{-1}, *F*(000) = 1432, 11345 reflections in *h*(0/17), *k*(−19/17), *l*(−19/18), measured in the range 4.93° ≤ Θ ≤ 23.31°, completeness Θ_{max} = 91.3%, 11345 independent reflections, 8317 reflections with $F_o > 4\sigma(F_o)$, 946 parameters, 0 restraints, $R1_{obs}$ = 0.087, $wR2_{obs}$ = 0.246, $R1_{all}$ = 0.118, $wR2_{all}$ = 0.2704, GOOF = 1.092, largest difference peak and hole: 0.523/−0.426 e·$Å^{-3}$.

Crystal Data for 2: $C_{108}H_{136}N_{20}Na_8O_5S_8$, M_r = 2234.77 g·mol^{-1}, colorless prism, size 0.04 × 0.03 × 0.03 mm^3, monoclinic, space group $P2_1/n$, *a* = 12.8900(1), *b* = 32.1789(5), *c* = 33.4040(4) Å, β = 94.988(8)°, *V* = 13803.0(3) $Å^3$, *T* = 20 °C, *Z* = 4, $\rho_{calcd.}$ = 1.075 g·cm^{-3}, μ(Mo-K_α) = 2.05 cm^{-1}, *F*(000) = 4720, 77462 reflections in *h*(−15/12), *k*(−38/41), *l*(−32/43), measured in the range 1.22° ≤ Θ ≤ 27.41°, completeness Θ_{max} = 87.3%, 27449 independent reflections.

Crystal Data for 4:[49] $C_{168}H_{232}K_8O_{30}$, M_r = 3044.34 g·mol^{-1}, colorless prism, size 0.32 × 0.28 × 0.20 mm^3, monoclinic, space group $P2_1/n$, *a* = 16.7197(2), *b* = 18.9198(5), *c* = 27.1965(6) Å, β = 97.489(1)°, *V* = 8529.8(3) $Å^3$, *T* = −90 °C, *Z* = 2, $\rho_{calcd.}$ = 1.185 g·cm^{-3}, μ(Mo-K_α) = 2.69 cm^{-1}, *F*(000) = 3264, 62897 reflections in *h*(−21/18), *k*(−24/19), *l*(−34/35), measured in the range 1.31° ≤ Θ ≤ 27.45°, completeness Θ_{max} = 97.5%, 19016 independent reflections, R_{int} = 0.096, 10537 reflections with $F_o > 4\sigma(F_o)$, 803 parameters, 4 restraints, $R1_{obs}$ = 0.132, $wR2_{obs}$ = 0.347, $R1_{all}$ = 0.214, $wR2_{all}$ = 0.395, GOOF = 1.280, largest difference peak and hole: 3.123/−1.179 e·$Å^{-3}$.

Crystal Data for 5:[49] $C_{56}H_{79}NaO_{10}·C_4H_{10}O$, M_r = 1009.30 g·mol^{-1}, colorless prism, size 0.32 × 0.30 × 0.28 mm^3, monoclinic, space group $P2_1$, *a* = 12.6427(5), *b* = 12.7316(3), *c* = 18.4929(6) Å, α = 90.00°, β = 94.233(1)°, γ = 90.00°, *V* = 2968.5(2) $Å^3$, *T* = −90 °C, *Z* = 2, $\rho_{calcd.}$ = 1.129 g·cm^{-3}, μ(Mo-K_α) = 0.82 cm^{-1}, *F*(000) = 1096, 4475 reflections in *h*(0/14), *k*(0/14), *l*(−20/20), measured in the range 2.21° ≤ Θ ≤ 23.26°, completeness Θ_{max} = 99.4%, 4475 independent reflections, 3732 reflections with $F_o > 4\sigma(F_o)$, 648 parameters, 7 restraints, $R1_{obs}$ = 0.068, $wR2_{obs}$ = 0.171, $R1_{all}$ = 0.100, $wR2_{all}$ = 0.201, GOOF = 1.129, Flack-parameter −0.1(9), largest difference peak and hole: 0.544/−0.319 e·$Å^{-3}$.

Alkali-Metal-Directed Hydrolytic Condensation of Trifunctional Phenylalkoxysilanes

Yulia A. Pozdniakova,[a] Konstantin A. Lyssenko,[a] Alexandr A. Korlyukov,[a] Inessa V. Blagodatskikh,[a] Norbert Auner,[b] Dimitris Katsoulis,[c] and Olga I. Shchegolikhina*[a]

Keywords: Hydrolytic condensation / Potassium / Self-assembly / Silanes / Sodium / Template synthesis

The alkali-metal-directed hydrolysis of phenyltrialkoxysilanes, $PhSi(OR)_3$ (R = Me, Et, *n*Bu), was performed under various reaction conditions. The alkali metal ions were used both as templating entities and as structural elements. The crystalline sodium and potassium phenylsiloxanolates (Na-PhS and K-PhS) were obtained in two different molecular compositions based on a *cis*-tetraphenylcyclotetrasiloxanolate, *cis*-$[PhSi(O)O^-]_4$, or on a *cis*-triphenylcyclotrisiloxanolate, *cis*-$[PhSi(O)O^-]_3$, anions assembled into a chain or double-layer supramolecular structure through coordination with alkali cations and hydrogen-bonding contacts. Conditions for selective preparation of crystalline Na-PhS or K-PhS of both structural types were identified. The molecular and crystal structures of $[(Na^+)_3\{PhSi(O)O^-\}_3]\cdot 8H_2O$ (**2**), $[(Na^+)_3\{PhSi(O)O^-\}_3]\cdot 4H_2O\cdot 1EtOH$ (**3**) and $[(K^+)_3\{PhSi(O)O^-\}_3]_2\cdot 7H_2O\cdot 3MeOH$ (**4**) were determined by single-crystal X-ray analysis.

Introduction

The hydrolytic condensation of trifunctional organosilanes [e.g. $RSiCl_3$ or $RSi(OR)_3$], generally used for the preparation of silsesquioxane materials, is a multistep and rather complicated process. Due to a statistical distribution of intermediate components the process is very sensitive to a combination of experimental factors and usually produces a wide range of products, from small oligomers and polyhedral silsesquioxanes to mixtures of resin materials and gels.[1] The purpose of our investigations is to direct a hydrolytic condensation process to the formation of only one desired compound, with a well-defined structure, using a template. The proposed method includes the assembling of silicon-containing species on the template through non-covalent bonding, thus bringing the functional groups attached at the silicon atom into close contact. Such a mutual arrangement will favor the cyclocondensation and, finally, the formation of well-organized architecture. Subsequent removal of the template will give an individual siloxane molecule with a well-defined structure.

At present the template and self-assembly approach to the design of metal-based molecules and supramolecules from oligodentate ligands and appropriate metal ions is one of the most popular and fastest growing areas of experimental chemistry that offers an alternative to the classical organic route. The effectiveness of metal-mediated self-assembly for the construction of one-, two- and three-dimensional structures has been demonstrated in an enormous number of examples published in various articles, reviews and books.[2] As an alternative to the traditional approaches used in siloxane chemistry we have taken advantage of a metal-directed self-assembly strategy to selectively create metallasiloxane molecules with well-defined architectures by hydrolysis of various trifunctional alkoxysilanes in the presence of alkaline and/or transition and lanthanide metal ions.[3]

The focus of our present work is a study of the alkali-metal-directed hydrolytic condensation of phenyltrialkoxysilanes under a wide variety of different experimental conditions. The alkali metal ions were used both as templating entities and as structural elements.

Literature data on the synthesis and structure of alkali metal organosiloxanolates are presented in details in our previous publication[4] and references cited therein.

Results

Reactions of phenyltrialkoxysilanes $PhSi(OR)_3$ (R = *n*Bu, Et, Me) with NaOH or KOH [Si/Na(K) = 1:1] were

performed in the presence of water according to Scheme 1 and the description given in the Exp. Sect. The H_2O/Si ratio was varied within the range 1−12:1. Alcohols (*n*BuOH, EtOH, MeOH) or their mixtures with either aromatic solvents (xylene, toluene, benzene) or with hexane, were used as solvents.

$$PhSi(OR)_3 + MOH + x\,H_2O \xrightarrow{\text{solvent}} [PhSi(O)OM]_n{\cdot}L$$

R = Me, Et, *n*Bu; M = Na, K; x = 1–12, n = 3, 4; L = ROH, H_2O

Scheme 1

From some reaction solutions suitable single crystals were isolated and their molecular and crystal structures were determined by X-ray analysis. Trapping reactions of the bulk samples with Me_3SiCl were used in order to establish a correspondence between one element in the crystal structure (namely the size of the siloxanolate cycle) and the overall crystalline mass composition (Scheme 2). The corresponding trimethylsiloxy-substituted derivatives of alkali metal phenylsiloxanolates were analyzed by NMR spectroscopy and GPC.

$$[PhSi(O)OM]_n{\cdot}L + x\,Me_3SiCl \xrightarrow[-\,n\,MCl,\,-\,py{\cdot}HCl]{\text{solvent, py}} [PhSi(O)OSiMe_3]_n$$

M = Na, K; n = 3, 4

Scheme 2

The analytical data obtained from the above combination of physical methods proved unambiguously that crystalline sodium phenylsiloxanolates (Na-PhS) as well as potassium phenylsiloxanolates (K-PhS) are compounds that contain cyclic phenylsiloxanolate fragments, *cis*-$[PhSi(O)O^-]_n$, surrounded by sodium or potassium ions. Two different molecular structures can be generated based on either a *cis*-tetraphenylcyclotetrasiloxanolate (Figure 1) or on a *cis*-triphenylcyclotrisiloxanolate fragment (Figures 2−4); their specific formation depends on the reaction conditions (see below).

Sodium phenylsiloxanolates of both types crystallize in good yields over a wide range of different reaction conditions (Table 1). Crystalline sodium phenylsiloxanolate, based on a *cis*-tetraphenylcyclotetrasiloxanolate fragment (Na-PhS-4), was selectively produced from the reaction of $PhSi(OnBu)_3$ [4] with sodium hydroxide in *n*BuOH, in the presence of an equimolecular amount of water (molar ratio H_2O/Si = 1:1). Crystalline Na-PhS-4 was isolated in about 80% yield under similar conditions from the reaction of $PhSi(OEt)_3$ in ethanol. A single crystal of *cis*-$[(Na^+)_4\{PhSi(O)O^-\}_4]{\cdot}8n$BuOH (**1**; Figure 1), obtained from $PhSi(OnBu)_3$, was characterized by X-ray crystallography.[4] Treatment of both crystalline bulks with Me_3SiCl yielded *cis*-$[PhSi(O)OSiMe_3]_4$ exclusively.

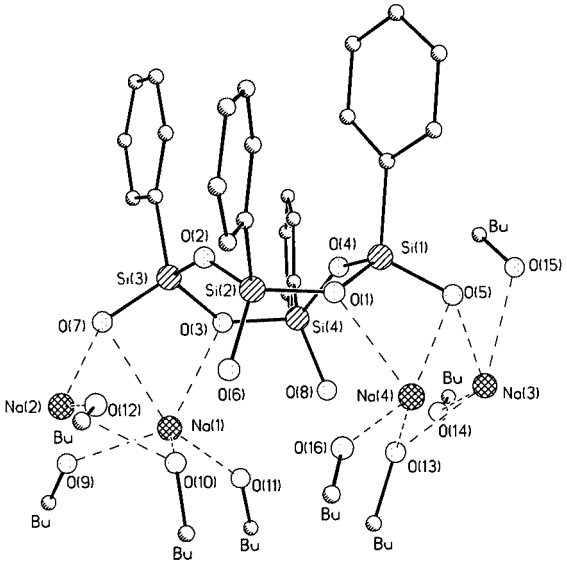

Figure 1. General view of the molecular structure of sodium phenylsiloxanolate **1**[4]

Crystalline sodium phenylsiloxanolate based on a *cis*-triphenylcyclotrisiloxanolate fragment (Na-Ph-3) was synthesized from $PhSi(OEt)_3$ under different reaction conditions. A summary of reactions performed with $PhSi(OEt)_3$ under different conditions is given in Table 1. The formation of the six-membered cycle was promoted by an increase of the H_2O/Si ratio and/or by the addition of a strongly hydrophobic solvent (hexane) to the reaction medium. Reactions performed in pure ethanol solution with a high excess of water (H_2O/Si = 4−12:1; Table 1, Entries 2 and 3) led to the selective formation of Na-PhS-3 as the only crystalline product in yields up to 63%. A single crystal (Table 1, Entry 3; H_2O/Si = 12:1) was characterized as *cis*-$[(Na^+)_3\{PhSi(O)O^-\}_3]{\cdot}8H_2O$ (**2**) by X-ray analysis (Figure 2). The use of an ethanol/hexane mixture as reaction

Table 1. Formation of Na-PhS-3 and/or Na-PhS-4 from $PhSi(OEt)_3$ under different experimental conditions

Entry	H_2O/Si ratio	Solvent	Yield of crystalline Na-PhS[a] (%)	Na-PhS-3/Na-PhS-4 ratio
1	1:1	ethanol	83	−:1
2	4:1	ethanol	42	1:−
3	12:1	ethanol	63	1:−
4	1:1	ethanol/hexane	95	1:1
5	2:1	ethanol/hexane	95	1:−

[a] Amorphous, powder-like by-products add to 100%; their trimethylsiloxy derivatives are the set of oligomers.

medium resulted in the selective formation of Na-PhS-3 in yields up to 95% even at molar H_2O/Si ratios of about 2:1 (Table 1, Entry 5). Derivatization of the crystalline bulk materials (Table 1, Entries 2, 3 and 5) with Me_3SiCl afforded the quantitative formation of *cis*-$[PhSi(O)OSiMe_3]_3$ in all cases.

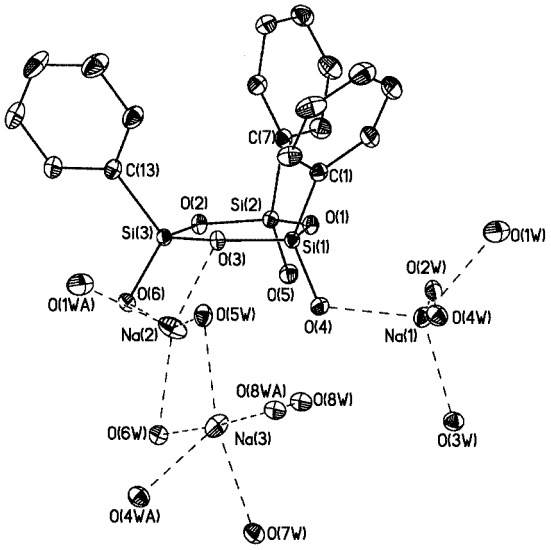

Figure 2. General view of **2** with thermal ellipsoids at 50% probability level

X-ray structure analysis of a single crystal isolated from the hydrolysis of $PhSi(OEt)_3$ in EtOH/hexane solution (molar ratio H_2O/Si = 1:1; Table 1, Entry 4) documents the formation of $[(Na^+)_3\{PhSi(O)O^-\}_3]\cdot 4H_2O\cdot 1EtOH$ (**3**; Figure 3). The molecular structure of **3** differs from that of compound **2** with respect to the coordination sphere of the sodium cations. In **3** one solvate molecule of ethanol replaces four water molecules in the molecular unit. Although the molecular structure of Na-PhS-3 is based on a trisiloxanolate cycle as the main fragment, the trapping reaction of the whole crystalline bulk with Me_3SiCl yielded a mixture of $[PhSi(O)OSiMe_3]_3$ and $[PhSi(O)OSiMe_3]_4$ in a molar ratio of 1:1. Thus, the formation of both structural types occurs under these reaction conditions.

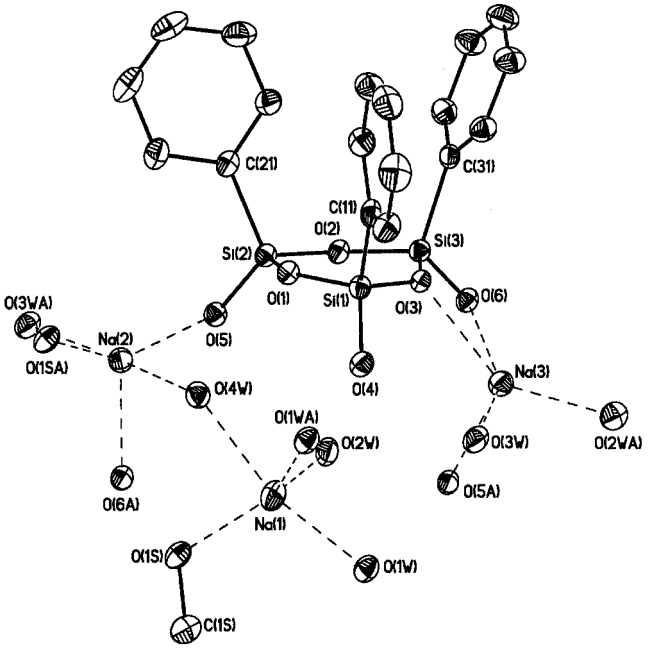

Figure 3. General view of **3** with thermal ellipsoids at 50% probability level

No crystalline products could be isolated from reactions of $PhSi(OMe)_3$ with NaOH in the presence of different amounts of water (H_2O/Si = 1−10:1) and in different solvents (MeOH, MeOH/benzene, MeOH/toluene, MeOH/hexane). The derivatization of the products obtained with Me_3SiCl gave a mixture of oligomers, as proven by GPC analytical methods.

Crystallization of potassium phenylsiloxanolate, unlike the corresponding sodium salt, occurs only under a narrow range of conditions, probably due to a higher solubility of the potassium siloxanolate intermediate compared to its sodium analogue. Thus, the use of a high dielectric constant medium (neat alcohol, excess of water) results in a low yield

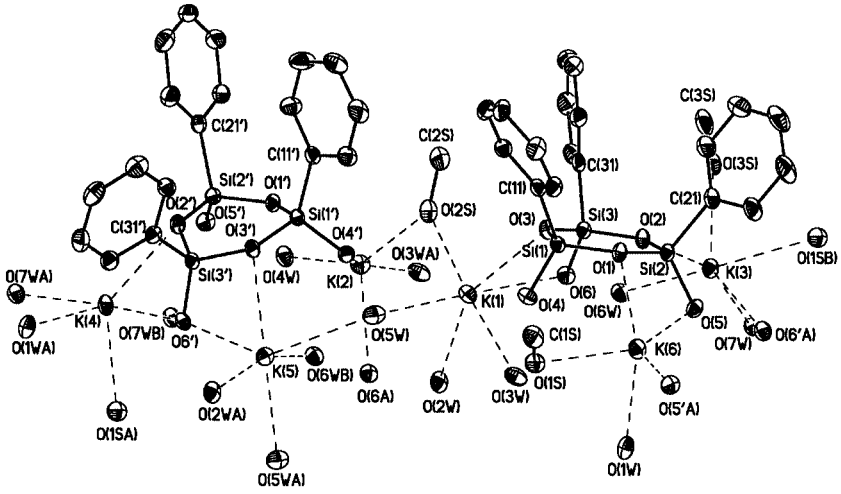

Figure 4. General view of **4** with thermal ellipsoids at 50% probability level

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of crystalline material or even prevents crystallization. A defined molar ratio of H_2O/Si from 1:1 to 1.5:1 is required for a successful crystallization.

The reaction of $PhSi(OMe)_3$ with KOH, even in an equimolar ratio of H_2O/Si in neat MeOH, did not yield any crystalline material. In contrast, reactions of $PhSi(OnBu)_3$ and of $PhSi(OEt)_3$ with KOH using an equimolar ratio of H_2O/Si in pure *n*BuOH or EtOH, respectively, gave crystalline potassium phenylsiloxanolate with a tetraphenylcyclotetrasiloxanolate fragment (K-PhS-4), but only in low yields ranging from 10 to 28%. Although we failed to grow suitable single crystals for X-ray analysis, reactions of the crystalline bulk with Me_3SiCl yielded $[PhSi(O)OSiMe_3]_4$ selectively, proving the formation of a potassium salt based on a tetrasiloxanolate cyclic fragment.

Decreasing the dielectric constant of the reaction medium by addition of non-polar solvent supports the bulk crystallization of potassium triphenylcyclotrisiloxanolate (K-PhS-3). Crystalline materials in high yields (up to 95%) were isolated from phenyltrialkoxysilanes $PhSi(OR)_3$ (R = Me, Et, *n*Bu) used for KOH treatment in mixtures of MeOH/benzene, EtOH/toluene, and of *n*BuOH/xylene. In all cases the derivatization of the crystalline bulk with Me_3SiCl gave exclusively $[PhSi(O)OSiMe_3]_3$. A single crystal suitable for X-ray analysis was obtained from the reaction of $PhSi(OMe)_3$. The molecular structure is shown in Figure 4 and proves the formation of $[(K^+)_3\{PhSi(O)O^-\}_3]_2 \cdot 7H_2O \cdot 3MeOH$ (**4**).

Molecular Structures of 2, 3, and 4

The single-crystal X-ray investigations revealed that the independent unit cells of compounds **2** and **3** contain one triphenylcyclotrisiloxanolate anion, three sodium cations and water (**2**) or water and alcohol molecules (**3**) (Figures 2 and 3, respectively). The peculiarity of the crystal structure of the potassium salt **4** is the presence of two independent siloxanolate anions and, consequently, of six potassium cations (see Table 2, Figure 4) in the unit cell. In all molecular structures the geometry of the siloxanolate anions is characterized by typical bond lengths and angles usually observed for this class of compounds (Tables 3 and 4).[5,6] Thus, the Si−C bonds of the Si−Ph groups are equal to 1.862(2) Å (average value), the cyclic Si−O bonds are significantly elongated [1.639(2)−1.661(1) Å] compared to terminal analogues [1.577(2)−1.596(1) Å]. The six-membered Si−O cycles exhibit an all-*cis* arrangement of the phenyl substituents. Their conformations vary from an approximately planar one in **2** and in **4** (in one of the two independent molecules) to an envelope conformation in **3** [deviation of Si(3) atom], and a distorted boat conformation [deviation of Si(3′) and O(1′) atoms] for the second independent molecule in **4**. This variation of the siloxanolate ring conformations is in line with the high flexibility of the siloxanolate rings.

The coordination sphere of the alkali cations is predominantly determined and formed by the negatively charged siloxanolates oxygen atoms and water (in **2**), and the sur-

rounding siloxanolate oxygen atoms, water and alcohol molecules (ethanol in **3**, and methanol in **4**, respectively). In spite of the differences in the number of solvate molecules in sodium salts **2** and **3**, both are characterized by some common features: only two of the cations are directly connected to the siloxanolate ring's oxygen atoms, while the coordination sphere of the third cation contains only the solvate molecules, and thus can consequently be described as a "bridging cation". An equivalent "bridging sodium" was previously detected in the corresponding salt **1**[4] and therefore is probably a general feature of such sodium salts. In contrast to compounds **1**−**3**, in salt **4** all potassium atoms are linked to the siloxanolate ring's oxygen atoms; this is probably due to the larger van der Waals radius of potassium cations. The number of oxygen atoms coordinated to the potassium or to the sodium cations in **2**−**4** varies between five and six and is dependent mainly on the type of coordinated oxygen atoms (in water or in alcohol molecules). The Na−O and K−O distances are 2.287(3)−2.599(2) Å, and 2.625(3)−3.053(3) Å, respectively, with the shortest contacts to the water molecules. The coordination polyhedra of the alkali metal atoms are distorted trigonal-bipyramidal or octahedral, depending on the coordination number.

The presence of a significant amount of solvate molecules (water and alcohol) leads to the formation of a complicated hydrogen-bonding network, with O···O distances varying from 2.568(1) to 3.037(2) Å. Analysis of the crystal structures of **2**−**4** revealed that, depending on the solvate contents and the nature of the cations, the hydrogen bonds are formed solely between the solvate and Si−O$^-$ (**3**) and/or only between the solvate molecules (**2**, **4**). In general, the hydrogen bonds between solvate and $^-$O−Si are characterized by slightly shorter O···O distances than those between solvate molecules. The maximum number of hydrogen bonds formed by the siloxanolate oxygen atoms is three, with a pseudo-tetrahedral arrangement around the oxygen atom. The number and strength of these hydrogen bonds is mainly dominated by the coordination of the corresponding Si−O$^-$ bond to the alkali metal atom, resulting in a systematic shortening of the hydrogen bond lengths of the centers weakly coordinated or uncoordinated by alkali.

In **2**−**4** the hydrogen-bonding pattern leads to an overall supramolecular architecture: the molecules are assembled into double layers (Figure 5), which have a hydrophilic "filling" (alkali, water and alcohol molecules) and a hydrophobic "coating" (Ph groups).

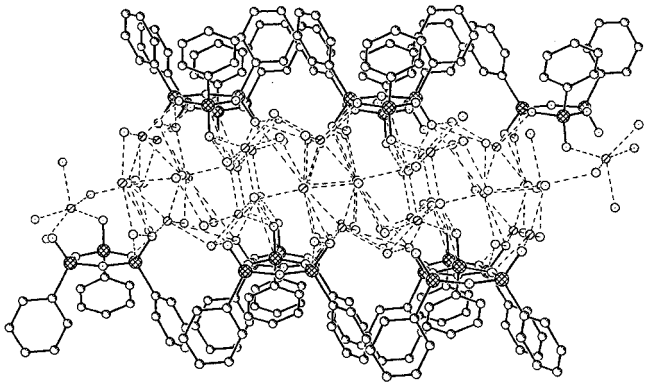

Figure 5. Double-layer structure in **2**−**4**

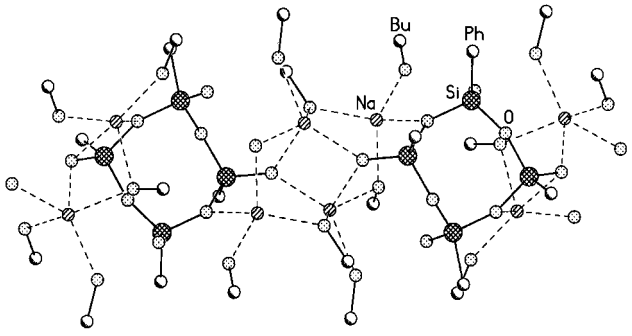

Figure 6. Cyclotetrasiloxanolate tetraanion/tetracation arrangement to form chains in **1**;[4] phenyl groups are omitted for clarity

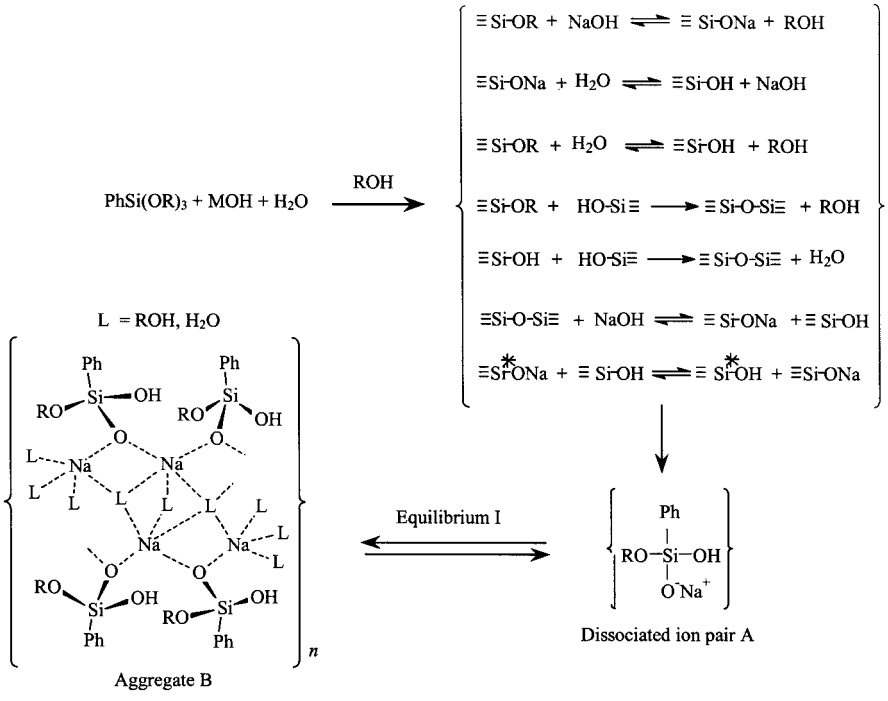
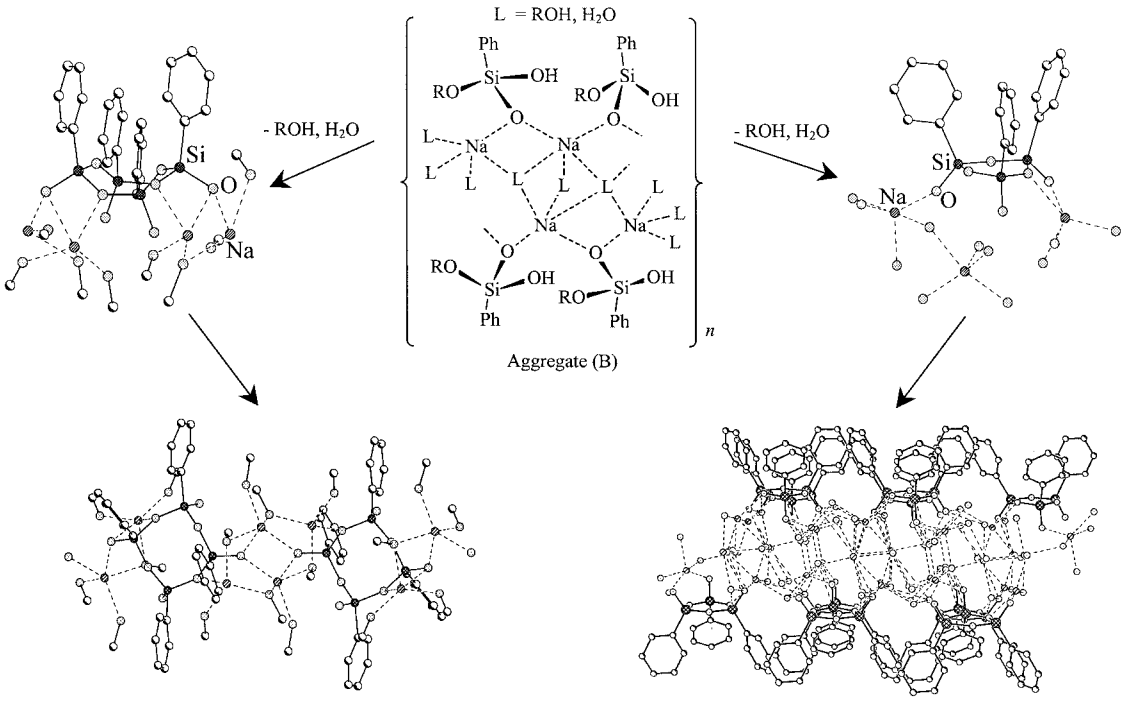
The packing of the sodium phenylsiloxanolates **2** and **3**, based on trisiloxanolate cycles, is different from that of the sodium phenylsiloxanolate based on a tetrasiloxanolate cycle:[4] the molecules of the latter are assembled into a chain-like structure by coordination bonds. Each chain is surrounded by phenyl substituents and solvated alcohol molecules without bridging ions connecting neighboring chains (Figure 6).

Discussion

Several coupled equilibrium reactions must take place when the hydrolysis of trialkoxysilane is performed in an alcoholic medium in the presence of an equimolar amount of the base (e.g. NaOH; Scheme 3. As a result of these reactions, and a rapid proton-cation exchange,[7] the generation of a labile alkaline intermediate, suggested[4] to be [PhSi(OH)(OR)(O^-Na^+)] (A) (Scheme 3), is quite possible. Presumably, these alkaline intermediates, containing solvent-separated ion pairs,[8] tend to associate (equilibrium I),[9] forming complex aggregates (B) in which an ionic part (alkali metal ion, alcohol and water molecules) is surrounded by silicon species containing functional OH and OR groups. These groups can undergo a condensation process with both water and alcohol elimination resulting in the formation of either a mixture of oligomers or cyclic products, depending on the reaction parameters (Scheme 4). The equilibrium I is a function[10] of the charge density of M^+, the solvating ability of the solvent, the nucleophilicity of the anion, and the solvent/salt ratio. Such a complicated and multi-argument process leads to results that are relatively difficult to predict. In the course of our study we found an appropriate set of conditions whereby the condensation process can be selectively directed to the generation of cyclotri- or cyclotetrasiloxanolate anions as-



Scheme 3



Scheme 4

sembled into supramolecular architectures (double layers or chains) through coordination with metal cations and hydrogen bonding.

The high-yield crystallization of sodium phenylsiloxanolate of different structural types in a wide range of conditions can be explained by the possible shift of equilibrium I to the formation of the complex aggregates (B).

In contrast, crystallization of potassium phenylsiloxanolate from an alcohol solution is quite rare. Moreover, an excess of water ($H_2O/Si > 1.5:1$) prevents crystallization. This could be caused by the tendency of potassium phenylsiloxanolate to exist as a solvent-separated ion pair (A). A decrease in the dielectric constant of the reaction medium should shift the equilibrium I to the opposite side and force the crystallization. This is in line with the experimental data — a high-yield crystallization of potassium phenylsiloxanolate was achieved only upon addition of non-polar aromatic solvents.

The *cis* configuration of sodium and potassium phenylsiloxanolates of both structural forms should be governed by the existence of aggregates B as micelles in the reaction solutions. The presence of these micelles was detected in our preliminary investigations of the reaction solutions by a light-scattering method. These results are now under further investigation and will be published elsewhere.

The removal of metal ions by treatment of the crystals obtained with Me_3SiCl gave the corresponding cyclosiloxanes without a change of their size or configuration. It has to be noted that the *cis*-tetraphenyl(trimethylsiloxy)cyclotetrasiloxane obtained exhibits properties of a plastically crystalline (3D) mesophase.[11] The analogous removal of metal ions from Na-PhS-4 by reaction with dilute HCl solution gives *cis*-$[PhSi(O)OH]_4$ in high yield.[3b]

Experimental Section

General: ^1H and ^{29}Si NMR spectra were recorded with a Bruker DRX-500 spectrometer (500 MHz for ^1H and 99 MHz for ^{29}Si) at 20 °C in C_6D_6 or $CDCl_3$ as solvents and with TMS as internal reference standard. GPC was performed with a Waters instrument with an M-600 pump and an M-484 UV detector (wavelength 254 nm) on U-Styragel 500, 1000 Å columns, using a Maxima information processing computer system. Structure-determined[12] crystals of $[PhSi(OSiMe_3)O]_{12}$ (retention time = 16.12 min), $[PhSi(OSiMe_3)O]_6$ (retention time = 16.95 min), $[PhSi(OSiMe_3)O]_4$ (retention time = 17.43 min) and $[PhSi(O)OSiMe_3]_3$ [13] (retention time = 17.79 min) were used as the standards. THF was used as an eluent. Calculations on KOH were made based on the content of KOH (85%, Aldrich). The H_2O/Si ratio in the synthesis with KOH was calculated taking into account the water content in KOH (15% according to Aldrich).

General Synthesis of Na-PhS: A mixture of phenyltrialkoxysilane, sodium hydroxide, water and solvents was stirred vigorously either at room temperature or under reflux conditions until the solution became completely transparent; for completion, the solution was stirred for an additional hour. Within a few hours or days (depending on the alkoxysilane and amount of water) crystals formed and precipitated from the solution. The crystalline bulk was separated by filtration through a Schott filter, washed with hexane and dried in vacuo (10 Torr/40 °C/1 h).

General Synthesis of K-PhS: A mixture of phenyltrialkoxysilane, potassium hydroxide, water and solvents was vigorously stirred at

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

room temperature until a clear solution had formed. For completion, stirring was continued for an additional hour. Most of the solvents (ca. 75%) were removed in a rotary evaporator, and an equal amount of an aromatic solvent was added to the residue. White, tiny needle-like crystals precipitated within 20 h (usually after cooling of the reaction mixture to ca. 10 °C). The crystalline solid was filtered, washed with hexane and dried in vacuo (10 Torr/40 °C/1 h).

General Procedure for the Trimethylsilylation of Alkali Metal Phenylsiloxanolates: Na-PhS or K-PhS was added as a solid to a vigorously stirred mixture of dry hexane, Me_3SiCl and pyridine at room temperature. The mixture was refluxed for 1 h, then cooled to room temperature, filtered and washed with water until it was chloride-free. After drying with Na_2SO_4, the solvent was removed and the residue was dried under vacuum (10 Torr/40 °C/1.5 h). The remaining product was characterized by NMR spectroscopy and GPC.

Na-PhS Obtained from PhSi(O*n*Bu)$_3$ and Trimethylsilylation:[4] $PhSi(OnBu)_3$ (5 g, 15.4 mmol), NaOH (0.62 g, 15.4 mmol), and H_2O (0.28 g, 15.4 mmol) in *n*-butanol (15 mL). Yield of Na-PhS-4: 2.35 g (78%). $[C_6H_5Si(O)ONa]_4\cdot 3nBuOH = C_{36}H_{50}Na_4O_{11}Si_4$ (863): calcd. C 50.10, H 5.84, Na 10.66, Si 13.02; found C 50.43, H 6.14, Na 10.95, Si 12.98. The Na-PhS-4 obtained above (2.35 g, 2.7 mmol), Me_3SiCl (1.17 g, 10.8 mmol) and pyridine (0.64 g, 8.1 mmol) in benzene (40 mL) were allowed to react to give 2.3 g (96%) of a white solid product. GPC (THF): one peak corresponding to $[PhSi(OSiMe_3)O]_4$ (retention time: 17.43 min).

Na-PhS Obtained from PhSi(OEt)$_3$ in Ethanol and Trimethylsilylation: H_2O/Si = 1:1 (Table 1, Entry 1). $PhSi(OEt)_3$ (4.98 g, 20.7 mmol), NaOH (0.83 g, 20.7 mmol), and H_2O (0.37 g, 20.7 mmol) were allowed to react in ethanol (10.5 mL). Yield of Na-PhS-4: 3.18 g (83%). $[C_6H_5Si(O)ONa]_4\cdot 2EtOH = C_{28}H_{32}Na_4O_{10}Si_4$ (733): calcd. C 45.89, H 4.40, Na 12.55, Si 15.33; found C 45.51, H 4.27, Na 12.62, Si 15.13. Na-PhS-4 (3.18 g, 4.3 mmol), Me_3SiCl (5.65 g, 52.0 mmol), and pyridine (3.48 g, 44.0 mmol) were allowed to react in hexane (50 mL) according to the General Procedure. Yield of the white solid product: 2.49 g (74%). GPC (THF): one peak corresponding to $[PhSi(OSiMe_3)O]_4$ (retention time: 17.43 min).

Na-PhS Obtained from PhSi(OEt)$_3$ in Ethanol and Trimethylsilylation: H_2O/Si = 4:1 (Table 1, Entry 2). $PhSi(OEt)_3$ (4.98 g, 20.7 mmol), NaOH (0.83 g, 20.7 mmol), and H_2O (1.49 g, 82.8 mmol) were allowed to react in ethanol (35 mL). Yield of crystalline Na-PhS-3: 1.59 g (42%). $[C_6H_5Si(O)ONa]_3\cdot 3H_2O = C_{18}H_{21}Na_3O_9Si_3$ (535): calcd. C 40.44, H 3.96, Na 12.91, Si 15.76; found C 40.50, H 3.73, Na 12.80, Si 15.63. Na-PhS-3 (1.59 g, 3.0 mmol), Me_3SiCl (3.83 g, 35.2 mmol), and pyridine (1.85 g, 23.4 mmol) were allowed to react in benzene (40 mL). A colorless, transparent liquid was formed: 1.6 g (85%). GPC (THF): one peak corresponding to $[PhSi(OSiMe_3)O]_3$ (retention time 17.79 min).

Na-PhS Obtained from PhSi(OEt)$_3$ in Ethanol and Trimethylsilylation: H_2O/Si = 12:1 (Table 1, Entry 3). $PhSi(OEt)_3$ (4.98 g, 20.7 mmol), NaOH (0.83 g, 20.7 mmol) and H_2O (4.48 g, 248.4 mmol) were allowed to react in ethanol (15 mL). Yield of crystalline Na-PhS-3: 2.33 g (60%). A suitable single crystal was analyzed by X-ray crystallography to give the molecular composition $[(Na^+)_3\{PhSi(O)O^-\}_3]\cdot 8H_2O$ (**3**). $[C_6H_5Si(O)ONa]_3\cdot 4H_2O = C_{18}H_{23}Na_3O_{10}Si_3$ (553): calcd. C 40.54, H 5.04, Na 11.66, Si 16.17; found C 40.12, H 5.20, Na 11.49, Si 16.25. Na-PhS-3 (2.33 g, 4.2 mmol), Me_3SiCl (5.00 g, 46.0 mmol), and pyridine (2.64 g, 33.4 mmol) were allowed to react in benzene (80 mL). A colorless, transparent liquid product was formed: 1.58 g (63%). GPC (THF): one peak corresponding to $[PhSi(OSiMe_3)O]_3$ (retention time. 17.79 min).

Na-PhS Obtained from PhSi(OEt)$_3$ in Ethanol/Hexane and Trimethylsilylation: H_2O/Si = 1:1 (Table 1, Entry 4). $PhSi(OEt)_3$ (4.98 g, 20.7 mmol), NaOH (0.83 g, 20.7 mmol), and H_2O (0.38 g, 20.7 mmol) were allowed to react in a mixture of ethanol (7 mL) and hexane (10 mL) to give two fractions of crystals. Yield of the first fraction: 1.64 g (45%). $[C_6H_5Si(O)ONa]_4\cdot EtOH = C_{26}H_{26}Na_4O_9Si_4$ (687): calcd. C 45.47, H 3.82, Na 13.39, Si 16.36; found C 45.52, H 3.63, Na 12.98, Si 16.19. Yield of the second fraction: 1.82 g (50%). $[C_6H_5Si(O)ONa]_3\cdot 2H_2O = C_{18}H_{19}Na_3O_8Si_3$ (517): calcd. C 41.85, H 3.71, Na 13.36, Si 16.31; found C 41.70, H 4.05, Na 13.17, Si 17.08. A suitable single crystal from the second fraction was analyzed by single-crystal X-ray crystallography, giving the molecular composition $[(Na^+)_3\{PhSi(O)O^-\}_3]\cdot 4H_2O\cdot EtOH$ (**2**). The first fraction of the Na-PhS crystalline compound (1.64 g, 2.4 mmol), Me_3SiCl (2.78 g, 25.6 mmol), and pyridine (1.21 g, 15.3 mmol) were allowed to react in hexane (30 mL) to give 1.28 g (76%) of a white solid product. GPC (THF): one peak corresponding to $[PhSi(OSiMe_3)O]_4$ (retention time: 17.43 min). The second fraction of the Na-PhS crystalline product (1.82 g, 3.5 mmol), Me_3SiCl (2.66 g, 24.5 mmol), and pyridine (1.11 g, 14.0 mmol) were allowed to react in hexane (20 mL). A colorless liquid product was formed: 1.72 g (78%). GPC (THF): one peak corresponding to $[PhSi(OSiMe_3)O]_3$ (retention time: 17.79 min).

Na-PhS Obtained from PhSi(OEt)$_3$ in Ethanol/Hexane and Trimethylsilylation: H_2O/Si = 2:1 (Table 1, Entry 5). $PhSi(OEt)_3$ (4.98 g, 20.7 mmol), NaOH (0.83 g, 20.7 mmol), and H_2O (0.75 g, 41.4 mmol) were allowed to react in a mixture of ethanol (21 mL) and hexane (21 mL). Yield: 3.56 g (95%) of a crystalline solid. $[C_6H_5Si(O)ONa]_3\cdot 3H_2O = C_{18}H_{21}Na_3O_9Si_3$ (535): calcd. C 40.44, H 3.96, Na 12.91, Si 15.76; found C 40.71, H 4.28, Na 13.32, Si 16.01. Na-PhS (3.56 g, 6.6 mmol), Me_3SiCl (6.45 g, 59.3 mmol), and pyridine (3.13 g, 39.6 mmol) were allowed to react in hexane (35 mL). A colorless liquid product was formed: 2.92 g (70%). GPC (THF): one peak corresponding to $[PhSi(OSiMe_3)O]_3$ (retention time: 17.79 min).

K-PhS Obtained from PhSi(O*n*Bu)$_3$ in *n*BuOH (H_2O/Si = 1:1) and Trimethylsilylation: $PhSi(OnBu)_3$ (4.73 g, 14.6 mmol), KOH (0.96 g, 14.6 mmol), and H_2O (0.12 g, 6.6 mmol) in *n*BuOH (5 mL) were allowed to react. Yield: 0.85 g (28.6%) of needle-like crystals. $[C_6H_5Si(O)OK]_4\cdot nBuOH\cdot 2H_2O = C_{28}H_{34}K_4O_{11}Si_4$ (815): calcd. C 41.25, H 4.20, K 19.18, Si 13.78; found C 41.19, H 4.03, K 19.28, Si 13.53. K-PhS-4 (0.85 g, 1 mmol), Me_3SiCl (1.57 g, 14.4 mmol), and pyridine (0.76 g, 9.6 mmol) in hexane (10 mL) were allowed to react to give a white crystalline product: 0.69 g (82%). GPC (THF): one peak corresponding to $[PhSi(O)OSiMe_3]_4$ (retention time: 17.43 min).

K-PhS Obtained from PhSi(OEt)$_3$ in EtOH (H_2O/Si = 1:1) and Trimethylsilylation: $PhSi(OEt)_3$ (4.98 g, 20.7 mmol), KOH (1.37 g, 20.7 mmol), and H_2O (0.17 g, 9.3 mmol) in EtOH (5 mL) were allowed to react to give 0.4 g (10%) of small needle-like crystalline material. $[C_6H_5Si(O)OK]_4\cdot EtOH = C_{26}H_{26}K_4O_9Si_4$ (751): calcd. C 41.57, H 3.49, K 20.82, Si 14.95; found C 41.75, H 3.38, K 20.95, Si 15.07. K-PhS-4 (0.4 g, 0.5 mmol), Me_3SiCl (0.62 g, 5.7 mmol), and pyridine (0.27 g, 3.4 mmol) in hexane (10 mL) were allowed to react to yield a white crystalline product: 0.3 g (67%). GPC (THF): one peak corresponding to $[PhSi(O)OSiMe_3]_4$ (retention time: 17.43 min).

K-PhS Obtained from PhSi(O*n*Bu)$_3$ in *n*BuOH/*o*-Xylene (H_2O/Si = 1.5:1) and Trimethylsilylation: $PhSi(OnBu)_3$ (4.73 g, 14.6 mmol),

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

KOH (0.96 g, 14.6 mmol), and H_2O (0.26 g, 14.6 mmol) were allowed to react in a mixture of butanol (7 mL) and *o*-xylene (28 mL). A crystalline solid product was formed: 2.43 g (72%). $[C_6H_5Si(O)OK]_3{\cdot}3H_2O{\cdot}n$BuOH = $C_{22}H_{31}K_3O_{10}Si_3$ (657): calcd. C 39.14, H 4.93, K 17.38, Si 12.48; found C 38.77, H 4.62, K 17.21, Si 12.83. K-PhS-3 (2.43 g, 3.7 mmol), Me_3SiCl (3.04 g, 28.0 mmol), and pyridine (1.33 g, 16.8 mmol) were allowed to react in hexane (30 mL). A colorless liquid product was formed. Yield 1.53 g (67%). GPC (THF): one peak corresponding to $[PhSi(OSiMe_3)O]_3$ (retention time: 17.79 min).

K-PhS Obtained from $PhSi(OEt)_3$ in EtOH/Toluene (H_2O/Si = 1.5:1) and Trimethylsilylation: $PhSi(OEt)_3$ (4.98 g, 20.7 mmol), KOH (1.37 g, 20.7 mmol), and H_2O (0.37 g, 20.7 mmol) were allowed to react in a mixture of ethanol (7 mL) and toluene (28 mL). Yield of solid K-PhS-3: 3.97 g (92%). $[C_6H_5Si(O)OK]_3{\cdot}5H_2O$ = $C_{18}H_{25}K_3O_{11}Si_3$ (619): calcd. C 35.68, H 4.46, K 17.64, Si 14.02; found C 35.93, H 4.07, K 17.52, Si 13.61. K-PhS-3 (3.97 g, 6.4 mmol), Me_3SiCl (6.12 g, 56.3 mmol), and pyridine (2.67 g, 33.8 mmol) were allowed to react in hexane (100 mL). A colorless liquid product was formed. Yield 3.29 g (81%). GPC (THF): one peak corresponding to $[PhSi(OSiMe_3)O]_3$ (retention time: 17.79 min).

K-PhS Obtained from $PhSi(OMe)_3$ in MeOH/Benzene (H_2O/Si = 1.5:1) and Trimethylsilylation: $PhSi(OMe)_3$ (5.31 g, 26.8 mmol), KOH (1.77 g, 26.8 mmol), and H_2O (0.48 g, 26.8 mmol) were allowed to react in a mixture of methanol (7 mL) and benzene (28 mL). Crystalline K-PhS-3 formed: 5.09 g (95%). $[C_6H_5Si(O)OK]_3{\cdot}MeOH{\cdot}2H_2O$ = $C_{19}H_{23}K_3O_9Si_3$ (597): calcd. C 38.23, H 3.88, K 19.65, Si 14.12; found C 38.01, H 3.69, K 19.61, Si 13.86. A single crystal was analyzed by X-ray crystallography. The molecular composition is $[(K^+)_3\{PhSi(O)O^-\}_3]_2{\cdot}7H_2O{\cdot}3MeOH$ (**4**). K-PhS-3 (5.06 g, 8.5 mmol), Me_3SiCl (7.85 g, 72.2 mmol), and pyridine (3.43 g, 43.4 mmol) were allowed to react in hexane (80 mL). A liquid, colorless product formed. Yield 4.47 g (83%). GPC (THF): one a peak corresponding to $[PhSi(OSiMe_3)O]_3$ (retention time: 17.79 min).

NMR Data for $[PhSi(OSiMe_3)O]_4$: ^{1}H NMR (500 MHz, C_6D_6, 20 °C): δ = 0.21 (s, 9 H, $SiMe_3$), 7.11 (t, ^3J = 7.4 Hz, 2 H, *m*-C_6H_5Si), 7.28 (t, ^3J = 7.4 Hz, 1 H, *p*-C_6H_5Si), 7.33 (d, ^3J = 7.4 Hz, 2 H, *o*-C_6H_5Si) ppm. $^{29}Si\{^1H\}$ NMR (99 MHz, C_6D_6, 20 °C): δ = 10.99 ($OSiMe_3$), −78.49 (O_3SiPh) ppm.

NMR Data for $[PhSi(OSiMe_3)O]_3$: ^{1}H NMR (500 MHz, $CDCl_3$, 20 °C): δ = 0.24 (s, 9 H, $SiMe_3$), 7.25 (t, ^3J = 7.4 Hz, 2 H, *m*-C_6H_5Si), 7.36 (t, ^3J = 7.4 Hz, 1 H, *p*-C_6H_5Si), 7.50 (d, ^3J = 7.4 Hz, 2 H, *o*-C_6H_5Si) ppm. $^{29}Si\{^1H\}$ NMR (99 MHz, C_6D_6, 20 °C): δ = 11.58 ($OSiMe_3$), −69.56 (O_3SiPh) ppm.

X-ray Crystal Structure Determination: Colorless single crystals of compounds **2**, **3**, and **4** were grown from solutions (see above). Details of crystal data, data collection and structure refinement parameters for siloxanolate salts **2**−**4** are given in Table 2. The structures were solved by direct methods and refined by a full-matrix least-squares technique against F^2, with anisotropic temperature factors for all non-hydrogen atoms. All hydrogen atoms in **2**−**4** were located from the Fourier synthesis of electron density and refined in the isotropic approximation. Data reduction and further calculations were performed using SAINT[14] and SHELXTL PLUS 5[15] on an IBM PC AT. CCDC-217730 to -217732 for crystal structures **2**−**4** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Peripherally Metallated Porphyrins: the First Examples of *meso*-η¹-Palladio(II) and -Platinio(II) Complexes with Chelating Diamine Ligands

Regan D. Hartnell[a] and Dennis P. Arnold*[a]

Keywords: N ligands / Palladium / Platinum / Porphyrins

The oxidative addition of bis(dibenzylideneacetone)platinum(0) to *meso*-bromo-5,15-diarylporphyrins in the presence of PPh_3 has been shown to be an effective way of synthesising η¹-organoplatinum porphyrins in high yields. This methodology has been extended to synthesise various palladio- and platinioporphyrins that utilise bidentate nitrogen donor ligands [*N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmeda) and 2,2′-bipyridyl (bpy)] in order to enforce a *cis* configuration at the metal centre. The products were characterised by multinuclear NMR and UV-Vis spectroscopy as well as fast-atom bombardment and high-resolution electrospray ionisation mass spectroscopy.

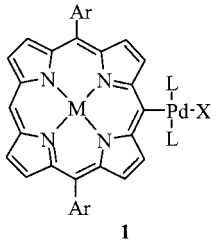
Introduction

There has been considerable interest in the investigation of the synthesis and properties of various types of organometallic porphyrins. Traditionally the "organometallic" fragment of the molecule involves a metal−carbon bond between the metal bound in the central cavity of the porphyrin macrocycle and either an alkyl or aryl moiety that has either σ- or π-bonding character.[1] These investigations have often been directed towards the catalytic activation of small molecules, usually in a biomimetic sense. The recent discovery and investigation of porphyrinoid macrocycles with modified cavities, such as inverted or "N-confused" porphyrins[2] and azuliporphyrins,[3] has somewhat increased the number of examples in this area; however, the centrally coordinated metal is still intimately involved in the organometallic character of the molecule. There are also several examples of porphyrinoid compounds covalently bound to organometallic fragments such as metallocenes,[4] or with one of the porphyrin pyrrole rings participating in an η⁵-pyrrolyl−metal arrangement.[5]

Besides the examples discussed above, there is also a small group of peripherally metallated η¹-organometallic porphyrins. Examples in this area include mercurated porphyrins,[6] *meso*-tellurium trichloride appended porphyrins,[7] porphyrinyl boronates[8] and the recent Grignard-like metalloporphyrin of Therien.[9] Our publications have been the only reports of isolated η¹-organopalladio- and organoplatinioporphyrins[10−13] and these are the only examples with transition metals directly bonded to porphyrin carbons. Compounds of type **1** are involved in the catalytic reactions for the coupling of *meso*-haloporphyrins with simple terminal alkynes, alkynylstannanes or alkynylzincs and alkenylorganometallics.[14−17] The key initial step in these couplings is the oxidative addition of the *meso*-carbon−halogen bond to a zerovalent palladium species, usually a bis(phosphane) moiety. Several years ago, we serendipitously isolated the resulting *meso*-η¹-organopalladium(II) porphyrin from one of these reactions[12] and have recently embarked on a systematic study of this type of palladium compound and their more robust organoplatinum(II) analogues. One possible area of interest in *meso*-η¹-platinioporphyrins relates to the combination of the cytotoxicity of the *cis*-platinum centre and the tumour selectivity and photodynamic effect of the porphyrin.[18−20] In this paper we report our synthesis for the first time of *meso*-η¹-organometallic porphyrins of palladium(II) and platinum(II) with chelating nitrogen ligands, namely *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmeda) and 2,2′-bipyridyl (bpy).



1

Results and Discussion

Syntheses of Palladio- and Platinioporphyrins

As part of our ongoing investigation of η¹-organometallic *meso*-platinio- and palladioporphyrins, we were very

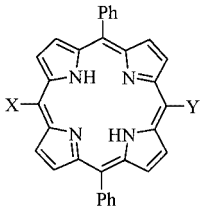
keen to synthesise platinioporphyrins with chelating ligands, in order to enforce a *cis* arrangement of the platinum fragment. This had been achieved for the palladioporphyrins by the use of various diphosphanes, for example, 1,2-bis(diphenylphosphanyl)ethane (dppe), 1,3-bis(diphenylphosphanyl)propane (dppp) and 1,1′-bis(diphenylphosphanyl)ferrocene (dppf).[13] These η^1-organometallic *meso*-palladioporphyrins were readily synthesised by the oxidative addition of a zerovalent palladium species into a 10-bromo-5,15-diarylporphyrin. The zerovalent palladium species is usually prepared in situ by the addition of the convenient palladium precursor, $Pd_2(dba)_3$ (dba = dibenzylideneacetone, 1,5-diphenylpenta-1,4-dien-3-one) to the bidentate phosphane in degassed toluene at 105 °C, to which the bromoporphyrin is later added. Under these conditions, the reaction is usually completed within 30 minutes. After removal of the solvent and recrystallisation, the desired η^1-organometallic *meso*-palladioporphyrin is obtained in high yields (> 80 %).

Having developed this efficient methodology for our palladioporphyrin analogues, we naturally sought to prepare the analogous platinioporphyrin species. After several attempts it was soon apparent that the intervening zerovalent platinum species that is formed in situ from $Pt(dba)_2$ and a diphosphane (dppe or dppp) is too stable to undergo the oxidative addition step with the haloporphyrin. This appears to be because the redistribution of ligands on Pt favours the apparently inert $18e^-$ species [e.g. $Pt(dppe)_2$]. The analogous reaction was also attempted several times with less stable, more sterically hindered zerovalent platinum species prepared from larger bidentate diphosphanes, namely 2,2′-bis(di-*p*-tolylphosphanyl)-1,1′-binaphthyl (tol-BINAP) and dppf. However, these also failed to undergo the oxidative addition step with a haloporphyrin to give the desired platinioporphyrin. In order to ensure that the $Pt(dba)_2$ substance that was being used throughout the investigations above was of high quality and not the cause of problematic side-reactions, we carried out a control reaction between monodentate triphenylphosphane, $Pt(dba)_2$ and a bromoporphyrin **2** (Table 1 shows the structures of compounds **2**−**14**). This reaction proceeded smoothly, as evident from TLC that the $Pt(dba)_2$ was consumed to form either $Pt(PPh_3)_3$ or $Pt(dba)(PPh_3)_2$ in situ and that **2** was being converted into a much more polar compound. Continual TLC analysis showed that the initial more polar compound was slowly being converted into a slightly more mobile product. This observation is in line with previous reports[10,11] that the initially formed product of the oxidative addition step is the *cis* isomer **3**, which with continued heating, isomerises slowly (ca. 6 hours) to the *trans* isomer **4**. This method has the distinct advantage over the previous method[10,11] that it avoids the use of air- and moisture-sensitive $Pt(PPh_3)_3$, which if not freshly prepared may be of doubtful quality.

With the viability of the dba-ligand method proven, as explained above, a different tactic was attempted in order to prepare the desired *cis*-orientated organoplatinum porphyrins. It is well-known that aromatic iodo groups undergo palladium(0)-catalysed coupling reactions at a much greater rate than those of bromo analogues.[21] This has also been shown to be true for 5-bromo-15-iodo-10,20-diarylporphyrins, which are found to undergo palladium(0)-catalysed coupling reactions at the iodo-substituted position preferentially over the bromo-substituted position.[17,22] With this in mind, the oxidative addition reactions of the platinum(0) diphosphane precursors were repeated with a range of iodoporphyrins; unfortunately, these also failed to give the desired η^1-organometallic porphyrins.

Table 1. Correspondence of compound numbers and structures



Compound	X	Y
2	H	Br
3	H	*cis*-$Pt(PPh_3)_2Br$
4	H	*trans*-$Pt(PPh_3)_2Br$
5	H	Pd(tmeda)Br
6	H	Pd(bpy)Br
7	Br	Br
8	Pd(tmeda)Br	Pd(tmeda)Br
9	Ph	I
10	H	H
11	Ph	H
12	Ph	Pt(tmeda)I
13	Ph	Pt(bpy)I
14	Ph	*trans*-$Pt(PPh_3)_2I$

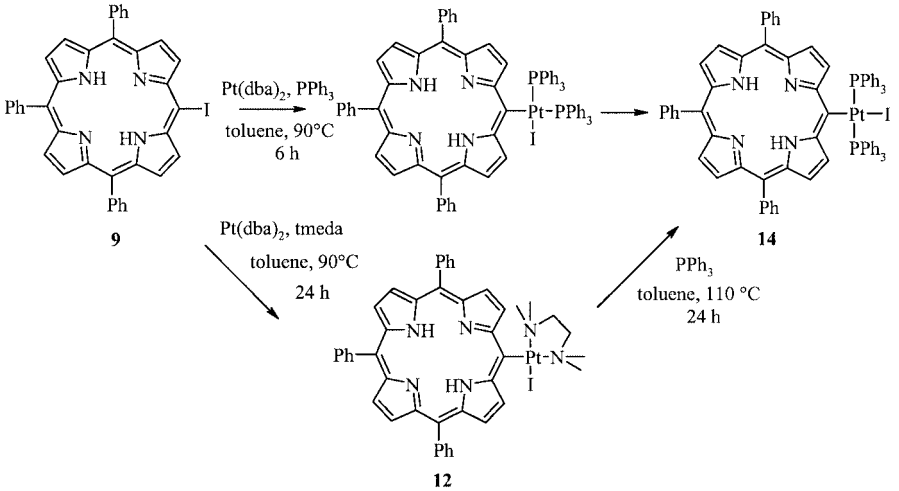
After these disappointing results with bidentate diphosphanes, a new methodology that utilises bidentate nitrogen donor ligands was developed in order to approach the desired *cis*-orientated organoplatinum porphyrins. This reaction was initially attempted with palladium, since it is known to undergo oxidative addition reactions much more readily than platinum analogues. These reactions are well-known from the work of Canty and co-workers, who have used these N-ligands to make interesting Pd^{IV} complexes.[23] Thus, when $Pd_2(dba)_3$ was treated with an excess of tmeda and an equivalent of bromoporphyrin **2** in degassed toluene at 105 °C, it was soon evident that the starting material was being consumed and converted into a much more polar compound. The reaction was completed after approximately one hour and the solution was filtered to remove any palladium metal resulting from decomposition of the Pd^0 precursors. After two recrystallisations from $CHCl_3$/cyclohexane, product **5** was obtained in high yield as an air- and moisture-stable dark purple solid. This procedure was similarly carried out with 2,2′-bipyridine as the nitrogen donor ligand to produce a high yield of the similar η^1-organometallic porphyrin **6**. Unlike the porphyrinyl-palladium bidentate diphosphane analogues,[12,13] it

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was found that these compounds are relatively stable towards silica and thus may be purified by column chromatography if required; as long as efforts are taken to ensure that any solvents used during the purification process are thoroughly free from acid. The reaction was repeated with the dibromoporphyrin species (**7**), tmeda and $Pd_2(dba)_3$ in order to prepare the bis(palladated) species. TLC analysis suggested that the desired double oxidative addition had occurred analogously; however, the product precipitated from the hot toluene solution. The precipitate was collected but it was found to be extremely insoluble in all common organic solvents and thus was not amenable to further purification. Other attempts at producing a bis(palladated) porphyrin system using the more soluble 5,15-bis(3′,5′-di-*tert*-butylphenyl)porphyrin also gave insoluble products that were difficult to purify thoroughly. FAB mass spectra of **8** (see below) indicated that the desired bis(palladium) porphyrin was formed. Initial thoughts were that the bidentate tmeda fragment could be flexible enough to act as a bridging group between two η^1-palladioporphyrin macrocycles, thus forming an oligomeric or polymeric species. However, the same result was seen with the less flexible 2,2′-bipyridine ligand, which suggests that they are not forming oligomers and that these examples of bis(palladiated) porphyrin species with bidentate nitrogen ligands are inherently insoluble.

Attempts at preparing the analogous platinioporphyrin systems with bromoporphyrin **2** failed, so the reactions were repeated with an iodoporphyrin. The iodoporphyrin chosen was 5-iodo-10,15,20-triphenylporphyrin (H_2TrPP-I) (**9**). This porphyrin was chosen due to its ease of synthesis in high yields, from the readily available starting material diphenylporphyrin (H_2DPP) (**10**).[11,24] The one free *meso*-position of triphenylporphyrin (H_2TrPP) (**11**) lends itself ideally to selective iodination.[17,22] This method avoids the tedious chromatographic separation procedures required to remove other iodoporphyrins that would be present if **10** itself were iodinated by similar procedures. Thus, when the more reactive iodoporphyrin **9** was utilised, the desired platinioporphyrins with bidentate nitrogen ligands were formed in good yields. As expected the formation of platinioporphyrins **12** and **13** was somewhat slower than the analogous palladioporphyrins **5** and **6**. The latter were formed in high yields within one hour, whilst **12** and **13** required overnight heating in degassed toluene with an excess of the platinating agent, but were eventually formed in good yields (ca. 80 %). Platinioporphyrins **12** and **13** were purified by column chromatography on silica support in order to remove a trace of the starting iodoporphyrin **9** and no degradation was seen during this procedure. It is important to note that even though these oxidative addition reactions are carried out on the free-base porphyrins, no metallation of the central porphyrin cavity is seen in any of these reactions, even after prolonged heating at 105 °C in toluene. This has been a general observation in all our metallation reactions. Moreover, Pd-catalysed couplings on free base porphyrins are readily carried out, as has been shown by several groups.[15,16,25] Indeed, we have found from qualitative reactivity comparisons of Pt insertions, that the bromo free bases react faster than either Ni^{II} or Zn^{II} substrates.[26] For all of these free-base η^1-organometallic porphyrins, it was found that the addition of a small amount of base (1 % triethylamine) to the mobile phase used during any of the chromatographic procedures greatly improved the tractability of these species. If base was omitted, it was found that the porphyrin macrocycle tended to protonate very readily on the column due to the strong electron donating properties of the η^1-organometallic fragment,[10−13] further enhanced by the electron-donating properties of the bidentate nitrogen ligands.

With metalloporphyrins **12** and **13** in hand, we investigated the substitution of the bidentate nitrogen donor ligands by chelating diphosphane ligands whose coordination to the soft Pt^{II} centre is expected to be favoured.



Scheme 1

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Unfortunately, both **12** and **13** failed to undergo any ligand exchange reactions with a variety of bis(phosphanyl) ligands (dppe, dppp and dppf). It was surprising that the ligand exchange did not occur at all even with excess phosphane ligand, elevated temperatures, and prolonged reaction times. In all cases, the bis(N-donor)-chelated species was quantitatively recovered with no noticeable decomposition detectable by ^{1}H NMR spectroscopy. However, it is encouraging to observe that these species are quite stable and unlikely to decompose under a variety of different solvents and reaction conditions, so their use for the construction of multiporphyrin arrays with Pt^{II} connectors should be possible. The ligand exchange did occur with the simple monophosphane, PPh_3 to yield **14** in approximately 50 % yield, implying that the problems may be steric in origin. However, it was observed that H_2TrPP (**11**) was also produced in an approximately equal amount. Clearly, the organometallic platinioporphyrin **14** is best prepared by using our original, direct oxidative addition of a zerovalent Pt bis(phosphane) species (see Scheme 1), as discussed above.[10−13]

NMR Spectra of Palladio- and Platinioporphyrins

There are several aspects of interest in the NMR spectra of these η^1-organometallic porphyrins. The first observation is the facial asymmetry of the porphyrin due to the favoured, approximately orthogonal disposition of the N−Metal−N plane of the organometallic fragment and the plane of the porphyrin macrocycle. This arrangement gives rise to two different signals for the *o*-hydrogens of the phenyl groups in the 5,15-positions of the porphyrin. The unequal faces of the porphyrin are also clearly evident in the case of **5** where different nonequivalent *m*-hydrogens on the 5,15-phenyl groups are also seen. This feature was less apparent in our previous compounds with bidentate aryl diphosphanes because of overlap of many aryl signals.[12,13] The porphyrin β-hydrogens appear as four doublets (^1J = 4.7 Hz), typical of substituted porphyrins of this symmetry and all peaks are shifted from those encountered in the corresponding parent haloporphyrins. The biggest shifts are understandably experienced by the peaks arising from the 3,7-β-hydrogens adjacent to the organometallic fragment, which are shifted downfield by approximately δ = 0.8 ppm. In the case of **5** and **6**, this peak appears to be shifted even more downfield than the 20-*meso*-proton which is observed as a sharp singlet at about δ = 9.8 ppm. In those species containing a 2,2′-bipyridyl ligand, namely **6** and **13**, the peaks arising from the bipyridine unit appear as a series of eight mutually coupled signals over a δ = 4 ppm range (see Figure 1). The signals from the protons that are above the porphyrin plane are somewhat shielded by the macrocycle and this is demonstrated by large upfield shifts of about δ = 1 ppm from corresponding signals in the free ligand. Interestingly, the signals arising from the 6′-proton of the bipyridine moiety in **6** and **13** are strongly shifted downfield to δ = 9.7 and 10.4 ppm, respectively, demonstrating the effect of the halogen as a neighbouring electronegative centre. In NOESY experiments on **6** and **13**, a strong cross-peak is seen that represents the NOE between the 3,7-β-hydrogens of the porphyrin and the 6′′-proton of the bipyridine fragment. All peaks in these spectra have been assigned by careful examination of the 1-D spectra and a series of DQF-COSY and NOESY 2-D NMR experiments (see Figure 2). Similar spectra are observed for **5** and **12**, with signals for the tmeda fragment appearing in the upfield region between δ = 1.6 and 3.2 ppm. It is clear that the metallo-substituent is rotating slowly on the NMR timescale, mostly orthogonal to the plane of the porphyrin to give two singlets for the methyl groups corresponding to those that are *cis* and those that are *trans* to the porphyrin. A dipolar coupling cross-peak from one of these methyl singlets to the 3,7-β-hydrogens of the porphyrin reveals that the more upfield peak around δ = 1.6 ppm arises from the methyl groups that are *cis* to the porphyrin.

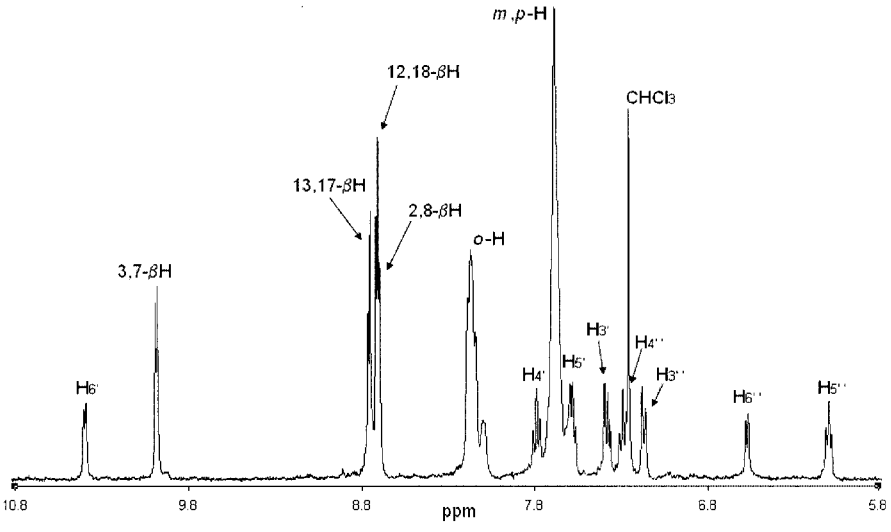


Figure 1. ^{1}H NMR spectrum of [PtI(H_2TrPP)(bpy)] (**13**) in $CDCl_3$ at 293 K

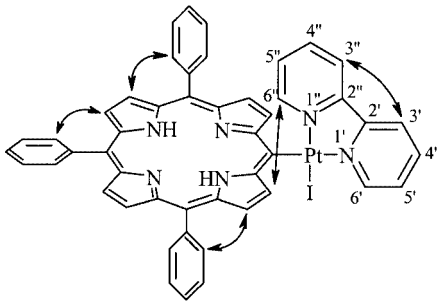

Figure 2. Numbering scheme for the bpy fragment and through-space correlations revealed by the NOESY spectrum of **13**

Mass and UV-Visible Absorption Spectra of Palladio- and Platinioporphyrins

All species gave mass spectra (ESI high-resolution for **5** and **6** and FAB for **12** and **13**) that displayed either the molecular ions of the respective complexes or their halide-exchanged analogues. For example, **6** did not give any molecular ion signal peaking at m/z = 805.0744 for the bromo complex, rather the most abundant peak in the spectrum corresponded extremely well with that for the iodo complex (calculated m/z = 851.0622; found m/z = 851.0722), which indicates that iodide from the NaI internal calibration standard had induced exchange. Also present in the spectra were the analogous chloro complexes from CH_2Cl_2 used in the introduction of the samples into the mass spectrometer. For platinioporphyrins **12** and **13**, the FAB mass spectra displayed the desired molecular ions for the appropriate parent compounds. In line with our observations that the halogen is less labile on the platinioporphyrins than on the palladioporphyrins, **13** displayed only a very small (< 10 %) cluster for the chloro-complex, whilst **12** did not display any analogous peak at all. In all mass spectra, fragmentation occurred and appropriate masses were recognised. These included fragments corresponding to the parent porphyrin macrocycle and fragments after loss of the halide. On the other hand, the MALDI-TOF spectra of all compounds displayed no parent molecular ions, but only clusters representing the porphyrin macrocycle, indicating that considerable fragmentation occurs during laser-induced ionisation. Bis(palladated)porphyrin **8** gave a strong parent molecular ion (calculated m/z = 1065.1; found m/z = 1065.2) as well as peaks corresponding to the loss of either one or both of the organometallic fragments. Peaks for the chloro analogues were also detected.

The UV-Visible spectra of these organometallic porphyrins are quite typical for di- and triphenylporphyrin derivatives. The wavelengths of the principal visible absorption bands for all complexes and the precursors are displayed in Table 2. Some trends can be distinguished, even with this limited number of examples. All groups other than H in the *meso* positions cause a red-shift, which is usual for these and related porphyrinic systems.[15] It can be seen that the *meso*-η^1-organometallic fragment exerts a similar effect on the electronic spectra to that of a simple halo substituent. There is a red-shift of the Soret band of approximately 10−15 nm and similar shifts for the Q bands relative to the base porphyrin macrocycles, after formation of the organometallic species. The nature of the nitrogen-donor ligands has very little effect on the electronic absorption spectrum for similar metallated species, for example, compare **5** and **6** or **12** and **13** to phosphane-ligated species like **14** and those previously reported.[10−13] They all have very similar electronic spectra although the phosphane-coordinated species displays slightly more red-shifted bands. The bis(palladated) species **8** continues the trend seen with mono-(palladated) **5**; the spectrum of **8** displays an even larger red-shift of all bands. This could be a sign of greater macrocycle distortion in order to cope best with the electronic and steric demands of the two organometallic fragments as well as the expected electron donating effect on the energy of the HOMO.

Table 2. Wavelengths for the principal UV-Visible absorption bands for the *meso*-metalloporphyrins and their precursors (in CH_2Cl_2)

Compound	λ_{max} (nm)				
Soret	IV	III	II	I	
2	420	510	545	587	642
5	417	518	551	588	642
6	418	516	550	589	640

9	421	519	554	595	651
10	405	502	535	575	630
11	411	508	542	583	637
12	426	527	564	599	655
13	426	526	563	597	653
14	434	528	567	601	659

Conclusion

The combination of $Pt(dba)_2$ and monodentate phosphane ligands with various haloporphyrins has been shown to be an effective way of synthesising η^1-organoplatinum porphyrins in high yields. An advantage of this method over previous methods is that it avoids the use of unstable Pt^0 phosphane complexes. This method has also been extended for the first time to synthesise various palladio- and platinioporphyrins that utilise bidentate nitrogen donor ligands in order to enforce a *cis* configuration of the metal centre. The availability of these stable *cis*-orientated organometallic porphyrins will allow for variation of architectures when incorporated with other suitable tectons in self-assembled supramolecular systems.

Experimental Section

General Remarks: Syntheses involving zerovalent metal precursors were carried out under high-purity argon using conventional Schlenk techniques. Porphyrin starting materials 10-bromo-5,15-diphenylporphyrin (**2**)[17] and 5,10,15-triphenylporphyrin (**11**)[11] were prepared by literature procedures and $Pt(dba)_2$ by the method of Cherwinski and co-workers.[27] All other reagents and ligands were

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

used as received from Sigma−Aldrich. Toluene was AR grade, stored over sodium wire, and degassed by heating and purging with argon at 105 °C. All other solvents were AR grade, and dichloromethane and chloroform were stored over anhydrous sodium carbonate. Analytical TLC was performed using Merck silica gel 60 F_{254} plates and column chromatography was performed using Merck silica gel (230−400 mesh). NMR spectra were recorded on Bruker Avance 400 MHz or Varian Unity 300 MHz instruments in $CDCl_3$ solutions, using $CHCl_3$ as the internal reference at δ = 7.26 ppm for ^1H spectra, and external 85 % H_3PO_4 as the reference for proton-decoupled $^{31}P\{^1H\}$ spectra. UV-Vis spectra were recorded on a Cary 3 spectrometer in dichloromethane. High resolution ESI mass spectra were recorded on a Bruker BioApex 47e FTMS fitted with an Analytica Electrospray Source. The samples were dissolved in dichloromethane and diluted with either dichloromethane/methanol (1:1) or methanol, and solutions were introduced into the source by direct infusion (syringe pump) at 60 μL/h, with a capillary voltage of 80 V. The instrument was calibrated using internal NaI. Positive ion FAB mass spectra were recorded on a Kratos Concept instrument at the Central Science Laboratory, University of Tasmania. Samples were dissolved in dichloromethane, and dispersed in a 4-nitrobenzyl alcohol matrix. In the data below, masses given are for the strongest observed peak in the molecular ion spectrum. In all compounds, this *m*/*z* value agreed with the predicted molecular mass, although in most cases it represented a mixture of M and M + 1 due to partial protonation of the free base porphyrin. Elemental analyses were carried out by the Microanalytical Service, The University of Queensland.

***trans*-[PtBr(H_2DPP−)(PPh_3)$_2$] (4):** Toluene (25 mL) was added to a Schlenk flask and degassed by bubbling argon through the solution at 90 °C. Bromoporphyrin **2** (20 mg, 0.037 mmol) was added and stirred for 5 min. Pt(dba)$_2$ (29 mg, 0.044 mmol) and triphenylphosphane (35 mg, 0.132 mmol) were added and the solution stirred at 105 °C. TLC analysis (50 % $CHCl_3$/*n*-hexane/1 % Et_3N) of the reaction mixture clearly showed disappearance of the starting material after about 30 min and that the initially formed *cis* isomer was slowly being converted into the *trans* isomer. After about 6 h the isomerisation was considered complete and the reaction mixture was cooled to room temperature and the solvent removed in vacuo. The residue (now air stable) was purified on a SiO_2 column and eluted with 50 % $CHCl_3$/*n*-hexane/1 % Et_3N; the major purple fraction was collected and the solvent removed in vacuo. The residue was recrystallised from $CHCl_3$/*n*-hexane to give **4** as dark purple crystals in 94 % yield. The data (^1H and ^{31}P NMR spectroscopy) of this compound agreed well with those of a genuine sample prepared previously using Pt(PPh_3)$_3$.[13]

General Procedure for the Preparation of Compounds 5, 6 and 8: As an example of this method, tmeda (35 μL, 0.25 mmol) and $Pd_2(dba)_3$ (43 mg, 0.046 mmol) were added sequentially to a stirred solution of bromoporphyrin **2** (25 mg, 0.046 mmol) in dry toluene (15 mL) that had been degassed at 90 °C. The reaction was maintained at 90 °C under an argon atmosphere and monitored by TLC (50 % $CHCl_3$/*n*-hexane/1 % Et_3N). When the reaction was considered to be complete by the total disappearance of starting material; the solution (now air stable) was filtered through a fine glass frit and the solvent removed in vacuo. The residue was recrystallised twice from $CHCl_3$/cyclohexane to give a dark purple solid that was dried thoroughly under high vacuum.

[PdBr(H_2DPP−)(tmeda)] (5): The desired complex **5** (34 mg) was obtained in 93 % yield. ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = −2.78 (br. s, 2 H, NH), 1.50 [s, 6 H, (CH_3)$_2$N], 2.37 (m, 2 H, NCH_2CH$_2$N), 2.43 (m, 2 H, NCH$_2$$CH_2$N), 2.70 [s, 6 H, ($CH_3$)$_2$N], 7.65−7.75 (m, 2 H, one pair *m*-H on 10,20-phenyl), 7.75−7.85 (overlapping m, 4 H, one pair *m*-H on 10,20-phenyl and *p*-H on 10,20-phenyl), 8.05−8.10 (m, 2 H, *o*-H on 10,20-phenyl), 8.25−8.35 (m, 2 H, *o*-H on 10,20-phenyl), 8.82, 8.90, 9.18, 10.04 (each d, $^3J_{H,H}$ = 4.7 Hz, 2 H, β-H), 9.92 (s, 1 H, *meso*-H) ppm. UV-Vis: λ_{max} (ε/10^3 M^{-1}·cm^{-1}) = 417 (356), 518 (16.9), 551 (13.0), 588 (8.6), 642 (11.5) nm. High-resolution ESI MS: $[M]^+$ accurate mass calculated for $C_{38}H_{38}BrN_6Pd(+1)$: 765.1375; found: 765.1385.

[PdBr(H_2DPP−)(bpy)] (6): The desired complex **6** (36 mg) was obtained in 91 % yield. ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = −2.93 (br. s, 2 H, NH), 5.95 (t, $^3J_{H,H}$ = 6.5 Hz, 1 H, 5′′-H), 6.02 (d, $^3J_{H,H}$ = 6.5 Hz, 1 H, 6′′-H), 7.05 (t, $^3J_{H,H}$ = 6.5 Hz, 1 H, 4′′-H), 7.13 (d, $^3J_{H,H}$ = 6.5 Hz, 1 H, 3′′-H), 7.32 (d, $^3J_{H,H}$ = 6.5 Hz, 1 H, 3′-H), 7.48 (t, $^3J_{H,H}$ = 6.5 Hz, 1 H, 5′-H), 7.62 (t, $^3J_{H,H}$ = 6.5 Hz, 1 H, 4′-H), 7.65−7.75 (m, 6 H, *m*,*p*-H on 10,20-phenyl), 8.05−8.15 (m, 2 H, *o*-H on 10,20-phenyl), 8.20−8.25 (m, 2 H, *o*-H on 10,20-phenyl), 8.79, 8.92, 9.17, 10.25 (each d, $^3J_{H,H}$ = 4.7 Hz, 2 H, β-H), 9.70 (d, $^3J_{H,H}$ = 6.5 Hz, 1 H, 6′-H), 9.91 (s, 1 H, *meso*-H) ppm. UV-Vis: λ_{max} (ε/10^3 M^{-1}·cm^{-1}) = 418 (492), 516 (15.2), 550 (9.9), 589 (6.3), 640 (7.0) nm. High-resolution ESI MS: I/Br exchanged product $[M]^+$ accurate mass calculated for $C_{42}H_{30}IN_6Pd(+1)$: 851.0622; found: 851.0722.

Bis(palladio)porphyrin (8): This was prepared by a similar procedure as above, but using dibromoporphyrin (**7**) and the appropriate amounts of tmeda and $Pd_2(dba)_3$. The crude yield was quantitative, however, the product is not sufficiently soluble for further purification and ^1H NMR analysis. UV-Vis: λ_{max} (rel. int.) = 427 (37.8), 529 (3.3), 567 (5.6), 607 (1.0), 665 (4.9) nm. FAB MS: $[M]^+$ mass calculated for $C_{44}H_{52}Br_2N_8Pd_2(+1)$: 1065.2; found: 1065.2.

H_2TrPP-I (9): Pyridine (250 μL), iodine (24 mg, 0.1 mmol) and bis(trifluoroacetoxy)iodobenzene (40 mg, 0.1 mmol) were added to a solution of triphenylporphyrin (**13**) (50 mg, 0.093 mmol) dissolved in $CHCl_3$ (25 mL). The reaction vessel was protected from light and stirred at room temperature. Periodically, the progress of the reaction was checked by TLC (30 % CH_2Cl_2/*n*-hexane). After 36 h it was found that there was total consumption of the starting material and the presence of a faster-moving spot. The solvent was removed in vacuo and the residue purified by column chromatography on SiO_2 and eluted with 50 % CH_2Cl_2/*n*-hexane. The major fraction was collected and the solvent removed and the residue recrystallised from CH_2Cl_2/*n*-pentane. The desired haloporphyrin (**9**) was collected as bright purple crystals in a 97 % yield. ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = −2.71 (br. s, 2 H, NH), 7.7−7.8 (m, 9 H, *m*,*p*-H on 10,15,20-phenyl), 8.1−8.2 (m, 6 H, *o*-H on 10,15,20-phenyl), 8.78, 8.80 (overlapping d), 8.87, 9.68 (each d, $^3J_{H,H}$ = 4.7 Hz, 2 H, β-H) ppm. UV-Vis: λ_{max} (ε/10^3 M^{-1}·cm^{-1}) = 421 (433), 519 (19.7), 554 (11.6), 595 (5.5), 651 (4.9) nm. High-resolution ESI MS: $[M + H]^+$ accurate mass calculated for $C_{38}H_{26}IN_4(+1)$: 665.1202; found: 665.1212. $C_{38}H_{25}IN_4$: calcd. C 68.68, H 3.79, N 8.43; found C 68.54, H 3.70, N 8.27.

General Procedure for the Preparation of Compounds 12 and 13: As an example of this method, tmeda (28 μL, 0.19 mmol) and Pt(dba)$_2$ (125 mg, 0.19 mmol) were added sequentially to a stirred solution of iodoporphyrin (**9**) (25 mg, 0.038 mmol) in dry toluene (15 mL) that had been degassed at 90 °C. The reaction was maintained at 90 °C under an argon atmosphere and monitored by TLC (50 % $CHCl_3$/*n*-hexane/1 % Et_3N). When the reaction was considered complete (after 24 h by the total disappearance of starting material), the solution (now air stable) was filtered through a fine glass frit and the solvent removed in vacuo. The residue was dissolved in $CHCl_3$, loaded onto a SiO_2 column, and eluted with $CHCl_3$/1 %

***trans*-[PtI(H_2TrPP)(PPh_3)$_2$] (14)**

Method A: The phosphane PPh_3 (5.2 mg, 0.02 mmol) was added to a refluxing solution of complex **13** (10 mg, 0.01 mmol) in toluene. The solution was refluxed under argon for 24 h. The solvent was removed in vacuo and the residue purified by column chromatography on SiO_2, and eluted with 50 % $CHCl_3$/*n*-hexane/1 % Et_3N to remove the by-product (**11**). The solvent was removed and the residue recrystallised from toluene/*n*-pentane to give the desired complex **14** in a 52 % yield.

Method B: Toluene (50 mL) was added to a Schlenk flask and degassed by bubbling argon through the solvent at 90 °C. Iodoporphyrin **9** (50 mg, 0.075 mmol) was added and stirred for 5 min. $Pt(dba)_2$ (59 mg, 0.090 mmol) and triphenylphosphane (47 mg, 0.18 mmol) were added and the solution stirred at 90 °C. TLC analysis (50 % $CHCl_3$/*n*-hexane/1 % Et_3N) of the reaction mixture clearly showed disappearance of the starting material after about 30 min and that the initially formed *cis* isomer was slowly being converted into the *trans* isomer. After about 6 h the isomerisation was considered complete; the reaction mixture was cooled to room temperature and the solvent removed in vacuo. The residue (now air stable) was purified by column chromatography and eluted with 50 % $CHCl_3$/*n*-hexane/1 % Et_3N; the major purple fraction was collected and the solvent removed in vacuo. The residue was recrystallised from $CHCl_3$/*n*-pentane to give 90 mg of **14** as dark purple crystals in 87 % yield. Some I/Cl exchange was found to occur when left in chlorinated solvents for extended periods. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = −3.13 (br. s, 2 H, NH), 6.40−6.60 (m, 18 H, PPh_3), 7.20−7.30 (m, 12 H, PPh_3), 7.60−7.70 (m, 9 H, *m*,*p*-H on 10,15,20-phenyl), 8.05−8.15 (m, 4 H, *o*-H on 10,20-phenyl), 8.20−8.25 (m, 2 H, *o*-H on 15-phenyl), 8.26, 8.63, 8.65 (overlapping d), 9.65 (each d, $^3J_{H,H}$ = 4.7 Hz, 2 H, β-H) ppm. ^{31}P NMR: δ = 24.0 (s, $^1J_{Pt-P}$ = 2976 Hz), UV-Vis: λ_{max} (ε/10^3 M^{-1}·cm^{-1}) = 434 (299), 528 (11.0), 567 (13.8), 601 (7.2), 659 (12.4) nm. High-resolution ESI MS: $[M]^+$ accurate mass calculated for $C_{74}H_{55}IN_4P_2Pt(+1)$: 1385.2690; found: 1385.2690.

Novel Layered Lead(II) Aminodiphosphonates with Carboxylate-Sulfonate and 1,3,5-Benzenetricarboxylate Ligands as Pendant Groups or Intercalated Species

Shao-Ming Ying[a] and Jiang-Gao Mao*[a]

Keywords: Hydrothermal synthesis / Layered compounds / Carboxylates / Sulfonates

The hydrothermal reaction of lead(II) carbonate with 3-sulfobenzoic acid, 3-HO_3S–C_6H_4–CO_2H, and isopropylimino-bis(methylenephosphonic acid), $(CH_3)_2CHN(CH_2PO_3H_2)_2$ (H_4L^1), gave a new layered lead(II) carboxylate-phosphonate, $Pb_7(3\text{-}O_3S\text{–}C_6H_4\text{–}CO_2)(L^1)_3(H_2O)_2\cdot 2H_2O$ (**1**), whereas the hydrothermal reaction of lead(II) carbonate with **1**, 3,5-benzenetricarboxylic acid (H_3BTC) and *N*-cyclohexylimino-bis(methylenephosphonic acid), $C_6H_{11}N(CH_2PO_3H_2)_2$ (H_4L^2), afforded a layered complex, $Pb_3(HL^2)(H_2L^2)(H_2BTC)(H_2O)\cdot H_3BTC\cdot H_2O$ (**2**). The structure of complex **1** contains <010> lead(II) carboxylate-phosphonate hybrid layers, with the sulfonate group of the carboxylate-sulfonate ligand as the pendant group. In complex **2**, the lead(II) ions are interconnected through bridging diphosphonate ligands, and results in the formation of a lead(II) diphosphonate slab, which are further interlinked via hydrogen bonds between non-coordinated phosphonate oxygen atoms to form a <001> layer. The doubly protonated H_2BTC anion is bidentately chelated to a lead(II) ion through a carboxylate group, whereas the neutral H_3BTC ligand is intercalated between two layers, forming hydrogen bonds with the non-coordinated carboxylate groups of the H_2BTC anion.

Introduction

Materials with open-framework and microporous structures are a class of very important compounds due to their traditional applications in catalysis, separations, sorbents, and ion exchange. Further, it is expected that these compounds could be used as hybrid composite materials in electro-optical and sensing applications.[1,2] Studies of metal phosphonates have shown that the use of bifunctional or multifunctional anionic units, such as diphosphonates, aminophosphonates or phosphonocarboxylates can lead to new materials with microporous or open-framework structures.[3–6] Recently, we have isolated a microporous Cd^{II} complex with the *N*,*N*′-bis(phosphonomethyl)-1,10-diaza-18-crown ether.[7] Several porous Zr^{IV} complexes with aza-crown ether functionalized phosphonic acids have been synthesized using phosphoric acid as the spacer.[8] The direct use of two types of ligands in the preparation, such as a phosphonic acid and a carboxylic acid, has been found to be another effective method for the exploration of hybrid open-frameworks; however, such reports are still rare.[2,9,10] A 3-D open-framework tin(II) phosphonopropionate oxalate and a layered tin(II) methylphosphonate oxalate have previously been reported by Cheetham and co-workers,[9] and a microporous zinc(II) complex of phosphonopropionic acid and 1,3,5-benzene-tricarboxylic acid (H_3BTC) has been isolated, in which the tricarboxylate moiety remains non-coordinated and is also severely disordered.[2] Recently, we reported two novel porous lead(II) carboxylate-phosphonates in which both types of ligands act as multidentate metal linkers.[10] We have initiated a research program in order to study the intercalation chemistry of the layered lead(II) diphosphonates with various types carboxylic acids and sulfonic acids. Such hybrids may have good proton conductivities, as well as ion-exchange properties, due to the presence of protons with greater acidity. The hydrothermal reaction of lead(II) carbonate with 3-sulfobenzoic acid, 3-$HO_3S-C_6H_4-CO_2H$, and isopropylimino-bis(methylenephosphonic acid), $(CH_3)_2CHN(CH_2PO_3H_2)_2$ (H_4L^1), gave a new layered lead(II) carboxylate-phosphonate, $Pb_7(3\text{-}O_3S-C_6H_4-CO_2)(L^1)_3(H_2O)_2\cdot 2H_2O$ (**1**), whereas the hydrothermal reaction of lead(II) carbonate with **1**, 3,5-benzenetricarboxylic acid (H_3BTC) and *N*-cyclohexylimino-bis(methylenephosphonic acid), $C_6H_{11}N(CH_2PO_3H_2)_2$ (H_4L^2), afforded a layered complex, $Pb_3(HL^2)(H_2L^2)(H_2BTC)(H_2O)\cdot H_3BTC\cdot H_2O$ (**2**). Herein, we report on the syntheses, characterizations and crystal structures of these compounds.

Results and Discussion

The hydrothermal reaction of lead(II) carbonate with 3-sulfobenzoic acid, 3-$HO_3S-C_6H_4-CO_2H$, and isopro-

pylimino-bis(methylenephosphonic acid), $(CH_3)_2CHN(CH_2PO_3H_2)_2$ (H_4L^1), gave a new layered lead(II) carboxylatephosphonate, $Pb_7(3\text{-}O_3S{-}C_6H_4{-}CO_2)(L^1)_3(H_2O)_2{\cdot}2H_2O$ (**1**), whereas the hydrothermal reaction of lead(II) carbonate with **1**, 1,3,5-benzenetricarboxylic acid (H_3BTC) and *N*-cyclohexylimino-bis(methylenephosphonic acid), $C_6H_{11}N(CH_2PO_3H_2)_2$ (H_4L^2), afforded a layered complex, $Pb_3(HL^2)(H_2L^2)(H_2BTC)(H_2O){\cdot}H_3BTC{\cdot}H_2O$ (**2**). We believe that many more new inorganic-organic hybrid materials will be developed using the synthetic technique of mixing two different types of ligands.

$Pb_7(3\text{-}O_3S{-}C_6H_4{-}CO_2)(L^1)_3(H_2O)_2{\cdot}2H_2O$ (**1**) is the first structurally characterized metal phosphonate-sulfonate hybrid. It is composed of seven lead(II) ions, three fully deprotonated L^1 ligands, one $3\text{-}O_3S{-}C_6H_4{-}CO_2$ dianion, two aqua ligands and two lattice water molecules. As shown in Figure 1, Pb1 is six-coordinate and is bonded to a tridentate chelating L^1 anion (N3, O52 and O62), two phosphonate oxygen atoms from two other L^1 anions (O13 and O12), as well as to a carboxylate oxygen atom from a carboxylate-sulfonate ligand. Pb1 exhibits a distorted octahedral coordination geometry. Pb2 is four-coordinate and is bonded to three phosphonate oxygen atoms from three L^1 anions and one carboxylate oxygen atom from a sulfonate ligand. The coordination geometry around Pb2 can be described as a ψ-PbO_4 trigonal bipyramid, with the fifth coordination site occupied by the lone pair of electrons from the Pb^{II} ion. Pb3 is five-coordinate and is bonded to a tridentate chelating L^1 anion (N2, O32, O42) and two phosphonate oxygen atoms from two other L^1 anions; it exhibits a ψ-PbO_5 octahedral geometry, with the sixth coordination site occupied by the lone pair of electrons from the Pb^{II} ion. Pb4, Pb5 and Pb6 have a coordination geometry similar to that exhibited by Pb3; they are all five-coordinate and are bonded to a bidentate chelating L^1 ligand (O51 and O52 for Pb4; O31 and O43 for Pb5; O52 and O63 for Pb6) and three phosphonate oxygen atoms from three other L^1 anions. Pb7 is four-coordinate and is bonded to two phosphonate oxygen atoms from two L^1 anions and two aqua ligands, and exhibits a ψ-PbO_4 trigonal bipyramidal geometry with the fifth coordination site occupied by the lone pair of electrons

from the Pb^{II} ion. The Pb−O distances are in the range 2.287(18) to 2.747(18) Å, and the Pb−N distances range from 2.618(17) to 2.643(19) Å; these distances are similar to those reported for other Pb^{II} aminodiphosphonates.[10−12] The three L^1 anions in complex **1** adopt three different types of coordination modes (see Figure 2). The L^1 anion that contains P1 and P2 chelates Pb6 in a bidentate fashion, and also forms bridges with eight other Pb^{II} ions. Its amine group remains non-coordinated and four phosphonate oxygen atoms act as μ_2 metal linkers. The diphosphonate anion that contains P3 and P4 chelates Pb3 in a tridentate manner (N2, O32 and O42), chelates Pb5 in a bidentate fashion (O31, O43), and forms bridges with five other lead(II) ions. The three phosphonate oxygen atoms are

bidentate. The third L^1 anion is bonded to Pb1 in a tridentate fashion, chelates Pb4 and Pb6 bidentately and also forms bridges with three other lead(II) ions. O52 acts as a μ_3 metal linker, and only O51 is a μ_2 bridging group. This kind of coordination mode has not been reported before. The carboxylate-sulfonate anion is bidentate, forming bridges with two Pb^{II} ions through the carboxylate group. The sulfonate group remains non-coordinated. Based on the requirements of charge balance, both types of ligands have been completely deprotonated.

The interconnection of the above Pb^{II} polyhedra through the diphosphonate L^1 anions, as well as through the carboxylate-sulfonate ligands, results in a <010> hybrid layer. The interlayer distance is approximately 14.9 Å. The sulfonate group acts as a pendant group, hanging between two layers (Figure 3). The lattice water molecules are also located in the middle of the interlayer space, forming hydrogen bonds with the non-coordinated sulfonate groups, as well as with the aqua ligands (Table 1). The O(4 W)···O(4) (symmetry code: x, $1 + y$, z) contact distance is only 2.60(4) Å, indicating that the hydrogen bond between the lattice water molecule and the sulfonate group is very strong.

$Pb_3(HL^2)(H_2L^2)(H_2BTC)(H_2O)\cdot H_3BTC\cdot H_2O$ (**2**) also has a layered structure and contains 1,3,5-benzene-tricarboxylate ligands that behave both as a pendant group and as an intercalated species. As shown in Figure 4, Pb1 is four-coordinate and is bonded to four phosphonate oxygen atoms from three diphosphonate ligands (1 H_2L^2 and 2 HL^2). Its coordination geometry can be described as a ψ-PbO_4 square pyramid with the fifth coordination site occupied by the lone pair of electrons. Pb2 is five-coordinate and is bonded to a bidentate carboxylate group of the H_2BTC anion and three phosphonate oxygen atoms from three diphosphonate ligands (1 H_2L^2 and 2 HL^2). Its coordination geometry can be described as a ψ-PbO_5 octahedron with the sixth site occupied by the lone pair of electrons. The Pb(2)−O(6) bond of 2.766(10) Å is significantly longer than the Pb(2)−O(5) bond [2.584(13) Å]. Pb3 is five-coordinate and is bonded to four phosphonate oxygen atoms from three diphosphonate ligands (1 H_2L^2 and 2 HL^2) and an aqua ligand. It has a ψ-PbO_5 octahedral geometry that is similar to that of Pb2. The Pb−O distances range from 2.407(12) to 2.767(13) Å; these distances are similar to those in complex **1** and those observed in other lead(II) phosphonates,[10−12] as well as to those reported for the lead(II) complex with H_3BTC.[13]

The HL^2 anion that contains P2 and P3 is heptadentate; it chelates Pb1 in a bidentate manner (O21 and O32) and forms bridges with five other lead(II) ions. The O23 and O32 atoms are bidentate metal linkers. Both phosphonate groups are fully deprotonated, but the amine group remains protonated. The H_2L^2 anion containing P4 and P5 is tetradentate; it chelates Pb3 in a bidentate fashion (O41 and O53) and also connects with two other Pb^{II} ions. The O42 atom is a bidentate metal linker. The P4 and P5 phosphonate groups are tridentate and unidentate, respectively. Based on the P−O distance and the charge balance, the P5 phosphonate group should be 1H-protonated, so does the amine group, hence the doubly protonated diphosphonate anion carries two negative charges. The H_2BTC anion in complex **2** is bidentately chelated to Pb2 (O5 and O6) and the other two carboxylate groups remain non-coordinated, while all three carboxylate groups of the neutral H_3BTC ligand in complex **2** are non-coordinated (Figure 4). This is unlike the situation in porous lead(II) phosphonate-carboxylates in which all three carboxylate groups are involved in metal coordination.[10]

The interconnecting lead(II) ions, via bridging amino diphosphonate ligands, leads to the formation of a slab along the *a*-axis. Such slabs are further interlinked via strong hydrogen bonds between the non-coordinated phosphonate oxygen atoms to form a <001> layer (Figure 5). The O(33)···O(52) distance (symmetry code: $-x$, $y - 1$, $-z$) is 2.509(17) Å (Table 2). The non-coordinated dicarboxylate moiety of H_2BTC is orientated towards the interlayer space, and is able to form hydrogen bonds with the carboxylate groups of the neutral H_3BTC ligand (Table 2, Figure 6).

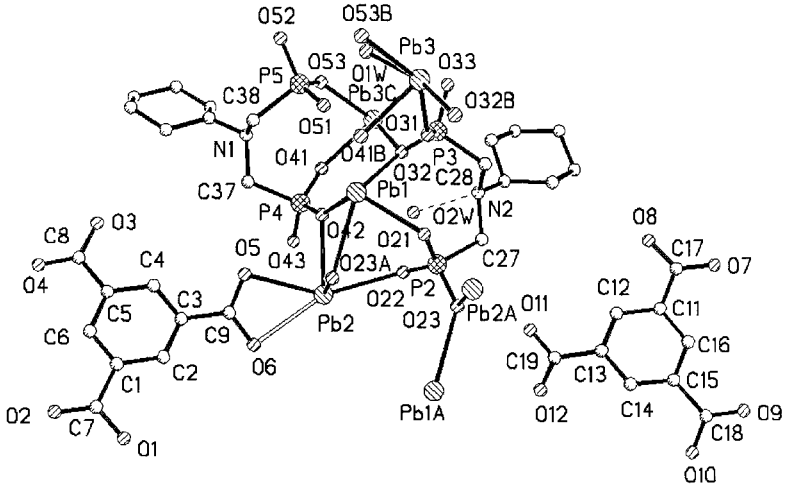

Figure 4. The asymmetric unit of complex **2**. The elongated Pb-O bond is represented by an open line; hydrogen bond is drawn as a dotted line; symmetry codes for the generated atoms: a) $-x$, $-y$, $-z$; b) $x + 1$, y, z; c) $-1 + x$, y, z

Such hydrogen bonding creates a six-membered ring that consists of two carboxylate groups, one from H_3BTC and one from H_2BTC (Figure 6). The aqua ligands are located at the cavities within the 2-D layer, and form hydrogen bonds with the non-coordinated phosphonate oxygen atoms, as well as with the amine groups (Table 2). The interlayer space of about 21.4 Å is much larger than that of complex **1**, mainly due to the intercalation of the H_3BTC molecules.

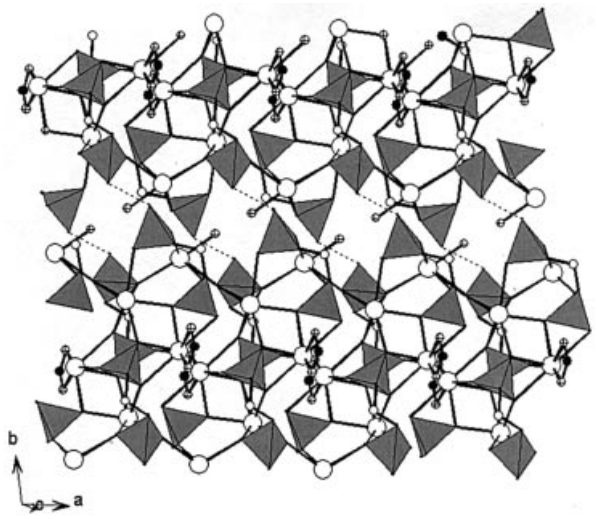

Figure 5. A <001> layer formed by the interconnection of lead(II) ion by bridging diphosphonate ligands in complex **2**; the pendant H_2BTC anions have been omitted for clarity; the $C-PO_3$ tetrahedra are shaded in gray, and Pb, N, O and C atoms are represented by open, octanded, crossed and black circles, respectively

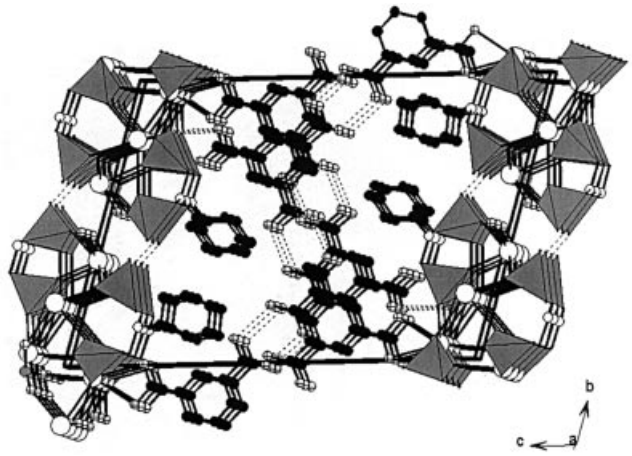

Figure 6. View of the structure of complex **2** down the *a*-axis; the $C-PO_3$ tetrahedra are shaded in gray, and Pb, N, O and C atoms are represented by open, octanded, crossed and black circles, respectively; hydrogen bonds are drawn as dotted lines.

The XRD powder patterns for complexes **1** and **2** were collected on a Philips X′Pert-MPD diffractometer using graphite-monochromated Cu-K_α radiation in the angular range $2\theta = 5-70°$. The powder patterns of **1** and **2** match those calculated from their single-crystal structure data, thus both compounds exist as a single phase.

The IR spectra of complexes **1** and **2** show the asymmetric and symmetric vibrations of the carboxyl group at 1531

and 1419 cm^{-1} for complex **1**, and 1576 and 1454 cm^{-1} for complex **2**, respectively. The differences in $\nu_{as}(COO)$ and $\nu_s(COO)$ are much larger than 95 cm^{-1} in both complexes, indicating the bidentate coordination mode for the carboxylate groups.[14] Complex **2** also exhibits a strong absorption band at 1722 cm^{-1} assigned to the non-coordinating carboxylate groups (COOH). The vibrations of the phosphonic group groups can be seen in the region 900−1100 cm^{-1}.[7] The broad bands at 3406 cm^{-1} (for complex **1**) and 3428 cm^{-1} (for complex **2**) indicate the presence of the water molecules in both compounds. Those frequencies which are characteristic of the fundamental and split $\nu_{as}(S-O)$ stretching modes for complex **1** appear in the range 1200−1000 cm^{-1}.

The TGA curves of complex **1** exhibit two steps corresponding to weight losses. The first step indicates the loss of two lattice water molecules and two aqua ligands, which starts at 55 °C and ends at 210 °C. The observed weight loss of 2.8% is in good agreement with the theoretical weight loss (2.94%). The second weight loss step starts at 375 °C and continues up to 800 °C, and indicates the loss of the aminodiphosphonate and carboxylate-sulfonate ligands. The final products are $Pb_2P_2O_7$ and $PbSO_4$ (in a molar ratio of about 3:1), based on the X-ray power pattern. The total weight loss of 14.2% is similar to that calculated (15.65%). The TGA diagram for complex **2** reveals three main steps corresponding to weight losses. The first step involves the loss of the lattice water molecule and the aqua ligand, which starts at about 90 °C and ends at about 282 °C. The observed weight loss of 2.4% is in good agreement with the calculated value (2.2%). The second step, which covers a temperature range from 282 °C to 345 °C, corresponds to the loss of intercalated H_3BTC. The third step starts at 345 °C and ends at 710 °C, and involves two overlapping processes: the loss of one water molecule formed by the condensation of the hydrogen phosphonate groups, and the loss of the diphosphonate ligand and the H_2BTC anion. The final products are $Pb_2P_2O_7$ and $Pb(PO_3)_2$ (in a molar ratio of 1:1), based on the XRD powder pattern. The total weight loss is 41.3% is similar to that calculated (42.1%).

Conclusion

In summary, two novel layered lead(II) carboxylate-phosphonate hybrids were obtained by the hydrothermal reactions of lead(II) carbonate with amino-diphosphonic acid and 3-sulfobenzoic acid (or, 1,3,5-benzenetricarboxylic acid). In both compounds, the 2-D inorganic-organic layer is formed by the lead(II) ions that are interconnected through the diphosphonate ligands. The sulfonate group of the carboxylate-sulfonate ligand in complex **1** acts as a pendant group between the 2-D layers, whereas the 1,3,5-benzenetricarboxylate ligands in complex **2** act both as a pendant ligand and as the intercalated species between two metal-diphosphonate layers. It is believed that a wide range of novel open-frameworks and microporous materials can be developed using this ligand-hybrid technique.

Experimental Section

Materials and Methods: All chemicals were obtained from commercial sources and used without further purification. Elemental analyses were performed on a Vario EL III elemental analyzer. Thermogravimetric analyses were carried out with a TGA/SBTA851 unit at a heating rate of 15 °C/ min under a nitrogen atmosphere. IR spectra were recorded on a Magna 750 FT-IR spectrometer as KBr pellets in the 4000−400 cm^{-1} range. ^1H and ^{31}P NMR spectra were recorded on a Varian Unity 500 NMR in D_2O. H_3PO_4 (85%) was used as ^{31}P standard reference. The XRD powder patterns were collected on a Philips X′Pert-MPD diffractometer using graphite-monochromated Cu-K_α radiation in the angular range $2\theta = 5-70°$ with a step size of 0.02° and a counting time of 3 seconds per step.

Preparation of H_4L^1 and H_4L^2: H_4L^1 and H_4L^2 were prepared by a Mannich type reaction according to procedures described previously.[11]
