COVER PICTURE

The cover picture shows a view in perspective of a novel phosphovanadate layered structure intercalated by 4,4′-bipyridinium cations which act as hydrogen-bonded pillars between adjacent layers. These inorganic layers are constructed by an unprecendented secondary tetrametallic V^V building unit exhibiting a distorted cubane-type structural motif. Details are discussed in the article by J. Rocha et al. on p. 3031 ff.

Hydroxamic Acids − An Intriguing Family of Enzyme Inhibitors and Biomedical Ligands

Celine J. Marmion,*[a] Darren Griffith,[a] and Kevin B. Nolan*[a]

Keywords: Hydroxamic acids / Chelates / Siderophores / Enzyme inhibitors / Nitric oxide donors / Cyclooxygenase

This review on hydroxamic acids deals with their efficacy as inhibitors of enzymes including cyclooxygenases, their synthesis, the complexity and structural diversity of their metal complexes, and their ability to act as effective nitric oxide donors.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

1. Introduction

Hydroxamic acids, RCONR′OH, have been known since 1869 with the discovery of oxalohydroxamic acid by Lossen.[1] Despite this, research on these compounds was lacking until the 1980's, after which an enormous amount of information has accumulated with respect to their biomedical applications, their synthesis and the synthesis and structures of their metal complexes. As a result, these weak acids, whether naturally occurring or synthetic, constitute one of the most important families of organic bioligands.

One of the first physiological roles of hydroxamic acids was associated with their use as siderophores, a class of low molecular-weight iron-sequestering agents. In the early stages of life, iron, an essential element required by proteins for electron transport, oxygen transport and other life sustaining processes, was in much demand but in poor supply, mainly due to its insolubility under physiological conditions. To circumvent this, organisms, mainly microbial and bacterial, developed a method of effectively assimilating iron in soluble form by synthesising and utilising siderophores.[2,3] These compounds possess either hydroxamate or catecholate groups that are capable of coordinating to iron(III) to give water-soluble, very stable, high-spin octahedral complexes. The desferrioxamine B (a trishydroxamate siderophore, Figure 1) complex of iron(III), for example, has a formation constant log $\beta \approx 30.4$.[4] Complexes

Celine J. Marmion graduated with a BSc. degree in 1990 and a Ph.D. in 1994 from the University of Surrey. She carried out her Ph.D. under the supervision of Prof. L. F. Larkworthy and Prof. G. J. Leigh. She held a lecturing position in chemistry (1994−1995) in St. Mary's College, Strawberry Hill and then graduated with a Postgraduate Certificate in Education from the University of Kingston in 1996. She took up a lecturing position in chemistry at the Royal College of Surgeons in Ireland in 1997 and was promoted to senior lecturer in 2003. Her current research interests include the role of hydroxamic acids as nitric oxide donors, the structural diversity of hydroxamate complexes and the synthesis of metal-based anti-cancer complexes.

Darren Griffith graduated with a BSc degree from University College Dublin in 2000 and obtained his Ph.D. under the supervision of Dr. C. J. Marmion at the Royal College of Surgeons in Ireland in 2004. Research interests include the coordination modes of hydroxamic acids, and the role that hydroxamic acids can play in enhancing the activity of ruthenium and platinum anti-cancer complexes.

Kevin B. Nolan graduated with a BSc degree from University College Galway in 1969 and obtained his Ph.D. under the supervision of Prof. Sean O'Cinneide from the same University in 1972. He carried out post-doctoral research with Prof. R. W. Hay at the University of Stirling and held lecturing positions at University College London (1974−1975) and the University of Surrey (1975−1987) before taking up his present appointment as Professor of Chemistry at the Royal College of Surgeons in Ireland in 1987. His current research interests are in the design and synthesis of hydroxamic acid inhibitors of cyclooxygenase, in the structures of hydroxamate complexes and in the synthesis of metal-based drugs.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

of iron(II) with hydroxamate ligands are much less stable than those of iron(III), e.g. the desferrioxamine-iron(II) complex has a log $\beta \approx 10$.[5] Even under anaerobic conditions, above pH 4, in the iron(II)-desferrioxamine B system, oxidation of iron(II) to iron(III) by hydroxamate occurs to give the iron(III)-desferrioxamine B complex and desferrioxamine B monoamide.[5] The iron siderophore complex, once inside the cell, undergoes reduction, releasing iron and making it accessible to metabolic demands within the cell.[6] A remarkable feature of siderophores, which is crucial to their function, is their ability to selectively bind iron(III) over other metal ions, which may be "poisonous". Siderophores also have high affinities for other tripositive metal ions such as aluminium(III), but their complexes are less stable than those of iron(III).[7]

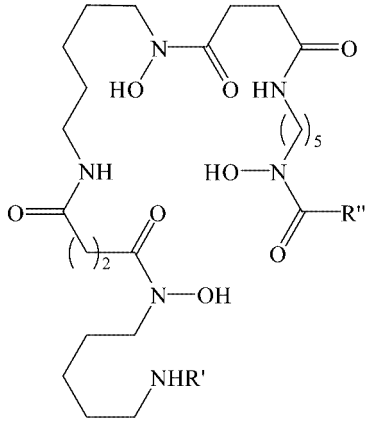

Figure 1. Hydroxamate siderophore, Desferrioxamine B

Siderophores and their analogues have vast therapeutic potential, yet few practical applications of siderophores have been realised. One example is the use of the trishydroxamate siderophore desferrioxamine B (Desferal) to deal with iron-overload in transfusion-dependent patients such as those suffering from thalassaemia.

Thalassaemia, an inherited disease affecting 100,000 babies annually, is characterized by an abnormality in one or more of the globin genes resulting in the inability to synthesise haemoglobin properly, and the patients becoming anaemic.[8] Thalassaemic patients have regular blood transfusions to supplement their haemoglobin levels but this can result in a toxic buildup of iron in the blood, and its accumulation in the heart, liver, endocrine glands and other vital organs eventually resulting in death. Desferrioxamine B, which is administered by prolonged subcutaneous infusion 3 to 7 times per week or by daily intramuscular injections due to its instability in stomach acid, forms a water-soluble iron(III) complex at physiological pH, which is readily excreted in bile and urine. Whilst treatment of thalassaemic patients with regular blood transfusions prolongs their life expectancy by about 20 years, treatment of the resulting iron overload with desferrioxamine B dramatically increases their life expectancy as shown in Figure 2.[9]

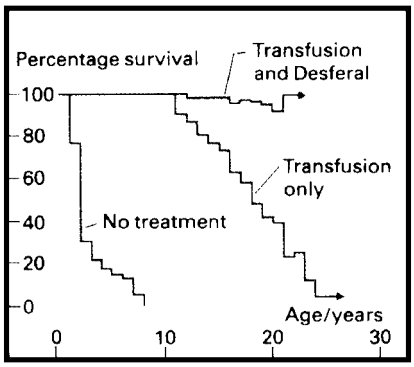

Figure 2. Patient survival rate for treatment of thallasaemia by transfusion only and by both transfusion and administration of desferrioxamine B; taken from ref.[9], reproduced by permission of The Royal Society of Chemistry

The major disadvantage of desferrioxamine B, which has over the past 30 years been the most widely used iron chelator in haematology, is that it is orally inactive.[10] Analogues of desferrioxamine B and a family of compounds known as *N*-hydroxypyrid-2-ones, which are considered to be aromatic hydroxamates are stable in acid and orally active, and are currently being considered as viable alternatives to desferrioxamine B.[11] A related compound deferiprone (not a hydroxamate but a hydroxypyrid-4-one) has been developed as an orally active iron chelator[12,13] but its efficacy has been challenged, and this has resulted in well-publicised acrimony and indeed lawsuits. Analogues of deferiprone are currently under investigation.[11]

Another more recent and potentially powerful application of hydroxamate-containing siderophores is the development of bioconjugates, which are synthesised by covalently linking siderophores with antimicrobial agents. Because microbes have a unique ability to distinguish and employ only certain siderophores, such conjugates could be utilised as carriers to selectively deliver antimicrobial prodrugs to their site of action. The scientific methodology and subsequent syntheses of a number of siderophores, including aerobactin, arthrobactin, schizokinen, a mycobactin, foroxymithine, all of the components of pseudobactin and several analogues, has recently been reported by Miller et al.[14] This group is currently devoting its efforts towards the syntheses and investigation of siderophore antimicrobial agent conjugates in a programme designed to develop iron transport-mediated selective drug delivery systems such as those shown in Figure 3.

This alternative approach to drug delivery may lead to the development of a novel class of selective antimicrobial agents based on active transport of an essential nutrient. The synthesis of such bioconjugates may in addition revitalise old drugs that relied on passive diffusion, and to which resistance has developed. Interestingly, preliminary studies of some of the synthetic siderophore analogues developed by Miller et al. indicate that they have considerable potential as nontoxic, organ selective magnetic resonance imaging (MRI) contrast agents.

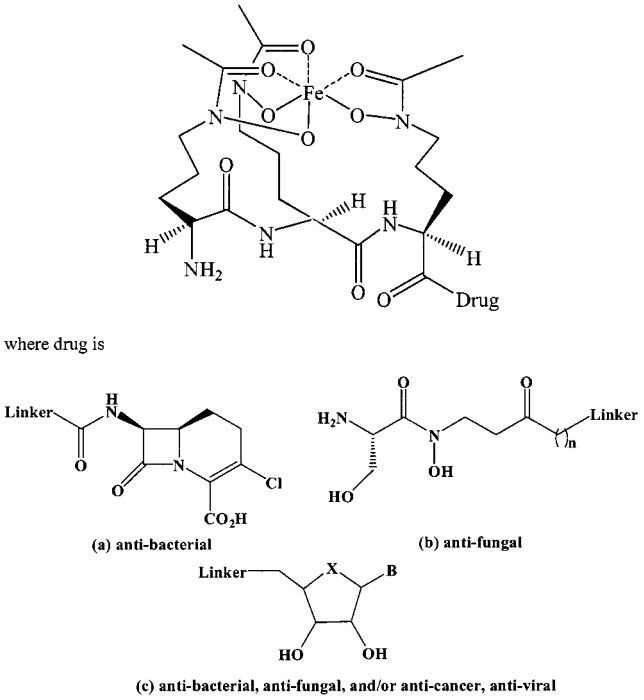

Figure 3. Representative siderophore antimicrobial/anticancer/antiviral agent conjugates as potential iron transport-mediated selective drug delivery systems

The biomedical applications of hydroxamic acids are no longer solely associated with the uptake or removal of iron from the body. In recent years, there has been increasing interest in their roles as potent and selective inhibitors of a range of enzymes including matrix metalloproteases,[15−19] peroxidases,[20−22] hydrolases,[23,24] ureases,[25−28] lipoxygenases,[15] cyclooxygenases[29,30] and peptide deformilases.[31] The basic medicinal chemistry and pharmacology of hydroxamic acid derivatives that act as enzyme inhibitors has recently been the subject of two reviews by Williamson et al.[15] and Lou et al.[32] Hydroxamic acids also represent a wide spectrum of bioactive compounds that have hypotensive,[33] anti-cancer,[16,34−37] anti-malarial,[38−42] anti-tuberculosis and antifungal properties,[43] and have been identified as key functional groups of potential chemotherapeutics targeting cardiovascular diseases, HIV and Alzheimer's disease.[44,45]

Our interest in hydroxamic acids lies in their versatility as ligands, their ability to act as effective nitric oxide donors, and in their potential as specific inhibitors of a class of enzymes known as cyclooxygenases.

2. Syntheses and Structures

Hydroxamic acids are generally considered to be derivatives of hydroxylamine and carboxylic acids, although their metal chelating ability is significantly stronger than the corresponding carboxylic acids. Typically, reaction between hydroxylamine or *O*/*N*-protected hydroxylamines (generated in situ by the addition of base to the hydrochlorides) and an activated acyl group (such as an ester, acid halide, amide) results in the formation of the corresponding hydroxamic acid, Equation (1).

$$RCOX + NH_2OH \rightarrow RCONHOH + HX \quad (1)$$

Recently, a convenient two-step procedure for the parallel synthesis of low molecular-weight hydroxamic acids from carboxylic acids and hydroxylamine with the use of polymer-supported 1-hydroxybenzotriazole has been reported (Figure 4).[46]

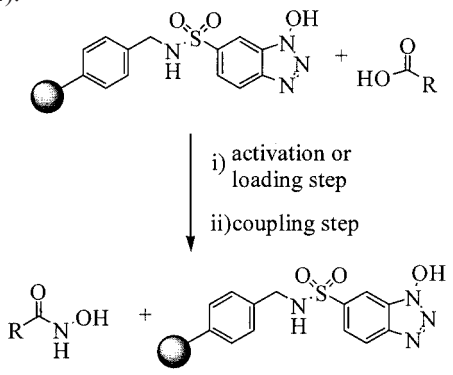

Figure 4. Parallel synthesis of low molecular-weight hydroxamic acids from carboxylic acids and hydroxylamine; reagents and conditions: i. PS-HOBt (1 equiv.), carboxylic acid (1.5 equiv.), DIC (4.5 equiv.), DMAP (0.6 equiv.), DCM/DMF (1:1), 3 h; ii: hydroxylamine (0.6−0.8 equiv.), THF, 5 h

Variations of these methods have been reported and are summarised in a recent paper that describes a simple one-pot method for the syntheses of hydroxamic acids in high yields.[47] The formation of hydroxamic acids and bioactive hydroxamate-containing compounds in both solution and solid phase has also recently been the subject of a comprehensive review by Lou et al.[48]

Two possible hydroxamic acid tautomers exist (Figure 5); the keto tautomer, which is predominant under acidic conditions, and the enol form, which is more stable in alkaline media.[49] Furthermore, NMR spectroscopic studies have shown that each tautomer can exist as (*E*) and (*Z*) isomers (Figure 5), further extending their structural diversity.[50] The conformational preferences of some hydroxamic acids have recently been investigated by density functional and empirical methods.[51]

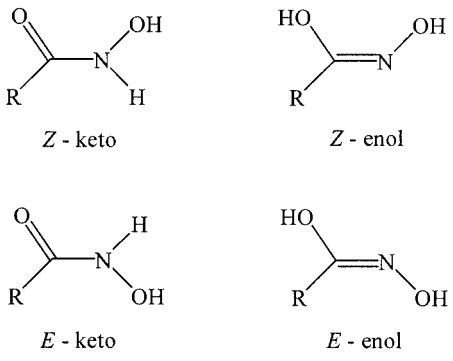

Figure 5. Tautomeric forms of hydroxamic acids

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The acid−base equilibria and associated tautomeric forms have also been extensively described.[52−54] Semi-quantitative comparisons of the acidities of hydroxamic acids, amides and carboxylic acids have recently been reported.[55]

3. Complexation Behaviour

Hydroxamate ligands show a diversity of coordination behaviour that results in a rich array of metal complex structures. The complexing behaviour of hydroxamic acids and, in particular, aminohydroxamic acids has been comprehensively reviewed.[56]

3.1 Bidentate Coordination

It is hardly surprising that many biomedical applications of hydroxamic acids arise as a result of the strong chelating ability of the hydroxamate group. By far the most common mode of metal binding is through the deprotonated hydroxamate and carbonyl oxygen atoms (Figure 6), forming very stable five-membered chelates.

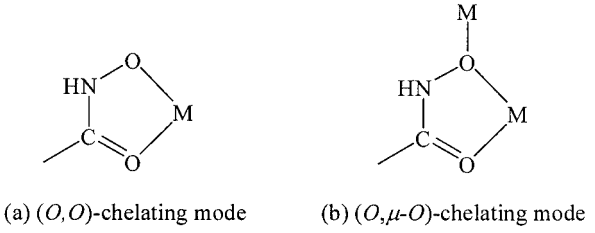

Figure 6. Modes of hydroxamate binding

The hydroxamato(1−) mode of coordination arises from the first deprotonation step involving coordination of the NHO^- moiety. Further metal-induced deprotonation of the NHO^- group leads to hydroximato(2−) complexes.[57]

Furthermore, the hydroxamate moiety possesses several sites for potential hydrogen-bond interactions with, for example, the backbone of enzymes, and these can be critical to their selectivity as enzyme inhibitors (Figure 7).

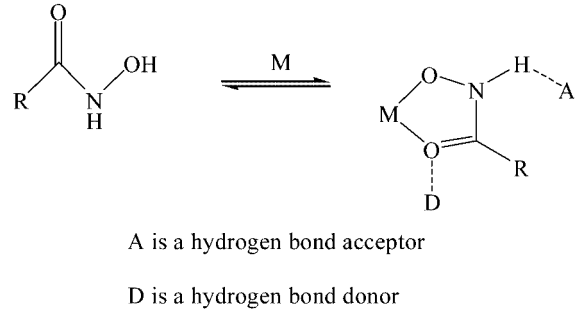

Figure 7. Sites for potential hydrogen-bonding interactions

Bidentate coordination of monohydroxamic acids to a number of transition-metal ions such as iron(III), cobalt(II) and nickel(II) generally results in the ready formation of 3:1 octahedral complexes,[58−60] while in the case of copper(II), 2:1 tetragonal complexes that have two additional monodentate ligands is the preferred geometry.[56,61]

3.2 Monodentate Coordination

Other modes of coordination, including monodentate binding through the deprotonated nitrogen or oxygen atom, have also been reported but these require specially designed coordination environments to provide additional stabilisation. The monodentate *N*-bonded trifluoroacetohydroxamate complex of carbonic anhydrase (a mimic of the hydrogen carbonate−enzyme product complex) is stabilised by hydrogen bonding with Thr-199 and by a weak F to Zn^{II} interaction (2.8 Å) [Figure 8 (a)].[62] A similar complex of acetohydroxamate has also been characterised. The reaction of the octaethylporphyrin (OEP) complex Fe(OEP)Cl, which does not contain two adjacent vacant coordination sites to accommodate normal bidentate coordination, with benzohydroxamic acid gave [Fe(OEP)PhCONHO]·

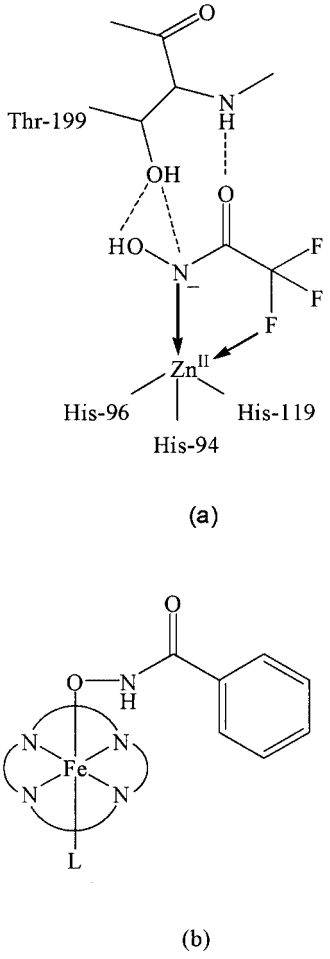

Figure 8. (a) Monodentate *N*-bonded trifluoroacetohydroxamate complex of carbonic anhydrase (a mimic of the hydrogen carbonate−enzyme product complex); (b) monodentate *O*-bonded benzohydroxamate in [Fe(OEP)PhCONHO]·PhCONHOH

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

PhCONHOH, which contains monodentate *O*-bonded hydroxamate stabilised by hydrogen bonding with free benzohydroxamic acid in the lattice [Figure 8 (b)].[63]

3.3 Hydroxamate Ligands with Other Coordinating Groups; Metallacrowns

The coordination behaviour of the hydroxamate group can be dramatically enriched by the incorporation of secondary coordinating groups at adjacent sites in the molecule. Dinuclear copper(II) complexes of α-aminohydroxamic acids that exhibit two modes of hydroxamate coordination (Figure 9), both giving five-membered rings, have been characterised. Under alkaline conditions, *N*,*N*- over *O*,*O*-coordination by copper(II) for α-aminohydroxamate ligands is preferred.[64,65]

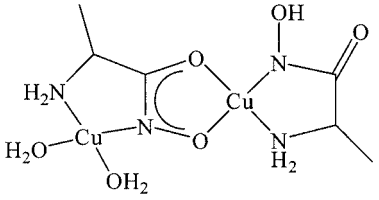

Figure 9. Two distinct bidentate binding modes observed in some complexes of α-aminohydroxamic acids

In the case of nickel(II), α-aminohydroxamate ligands produce bis *N*,*N*-bidentate square-planar complexes[59,66] rather than octahedral complexes containing *O*,*O*-bonded hydroxamates. With these ligands, the cobalt(III) complex forms tris complexes that have *N*,*N*-bidentate coordination.

The coordination properties of β-aminohydroxamic acids are, in general, similar to those of the α derivatives. Whilst β-aminohydroxamic acids can act as *N*,*N*-donors, this involves a six-membered ring, and *O*,*O*-bidentate coordination is generally preferred. A remarkable complex with the general formula $[Cu_5(LH_{-1})_4]$ was reported to be formed from the reaction of copper(II) salts with β-alaninehydroxamic acid (HL).[67] This complex, which is the major species in solution at pH 4.5−9, contains a twelve-membered ring made up of four metal ions linked in pairs by doubly deprotonated NO groups of hydroxamate ligands and another metal ion in a central cavity bonded by the four hydroxamate oxygen atoms. The amino nitrogen atom of one ligand and the carbonyl oxygen atom of another complete basal coordination around each outer copper ion, with the axial coordination of an oxygen atom (from water, perchlorate or a vicinal aminohydroximato ligand) completing the square-pyramidal coordination (Figure 10). This complex is the prototype for a remarkable family of compounds called metallacrowns subsequently developed by Pecoraro and co-workers.[68]

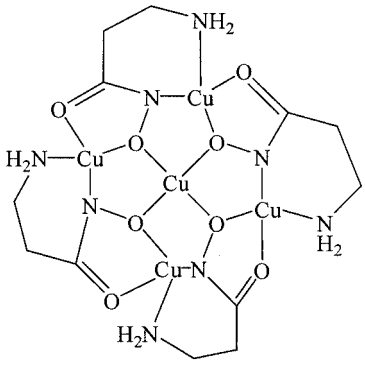

Figure 10. Structure of the copper(II) β-alaninehydroxamic acid complex displaying both *N*,*N*- and *O*,*O*-bidentate coordination through the hydroxamate

Following this, metallacrowns emerged as a new family of molecular recognition agents where hydroxamic acid ligands provided the structural support upon which the supramolecular metallacrown was constructed.[68−71] Salicylhydroxamic acid [Figure 11 (a)], which contains both hydroximato and phenolate donor atoms, is particularly well suited to the synthesis of metallacrowns because (i) three binding sites that are capable of stabilising high valent metal ions are available in the triply deprotonated ligand, and (ii) it is a dinucleating agent with all four heteroatoms as potential metal binding sites [Figure 11 (b)].

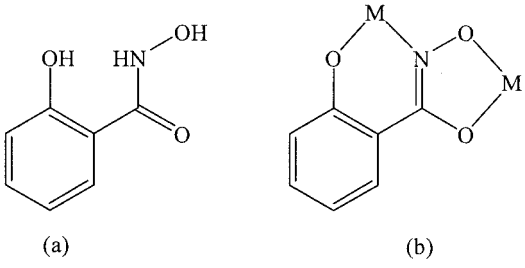

Figure 11. (a) Salicylhydroxamic acid; (b) salicylhydroxamic acid as a dinucleating agent with all four heteroatoms as potential metal binding sites

The ability of salicylhydroxamic acid to form a five-membered chelate ring with one metal through the hydroximate group and a six-membered ring to another metal through the substituted iminophenolate ring facilitates the formation of metal clusters with $M_A-N-O-M_B$ networks that link the ring metals [Figure 11 (b)]. The synthesis of most metallacrowns utilizes base to facilitate deprotonation of the ligand and counterions for charge balance in addition to metal salt and ligand.[68] Replacement of the phenolic group of salicylhydroxamic acid by an amino group affords a family of 2-aminophenylhydroxamic acid (anthranilic hydroxamic acid) metallacrowns. Other scaffolds such as 2-pyridylacetohydroxamic acid and 3-hydroxy-2-naphthohydroxamic acid have also been used in metallacrown synthesis. Although there is a change in charge from −3 to −2 on going from salicylhydroximato to anthranilic hydroximato

ligands, this does not have a pronounced impact on the resulting metallacrown structures but does result in the complex being uncharged. Recent work involving planar ligands such as picolinehydroxamic acid (picha) or nonplanar α-aminohydroxamic acids, e.g. glycinehydroxamic acid (glyha), afforded a new family of metallacrowns that are capable of accommodating a series of lanthanides in their cavities. The reaction of the appropriate hydroxamic acid with copper acetate and 1/5 equivalent of gadolinium(III) or europium(III) nitrates, for example, afforded $Gd(NO_3)_3$[15-MCCu^{II}N(picha)-5], $Eu(NO_3)_3$[15-MCCu^{II}N(picha)-5], and $Eu(NO_3)_3$[15-MC$_{Cu^{II}N(glyha)}$-5], all of which have been structurally characterized. Several other 15-metallacrown-5 complexes were synthesized with (i) Cu^{II} or Ni^{II} in the peripheral ring metal position, (ii) various lanthanides, La^{III}, Nd^{III}, Sm^{III}, Eu^{III}, Gd^{III}, Dy(III), Ho^{III}, Er^{III}, and Yb^{III}, encapsulated in the center of the ring, and (iii) chiral α-aminohydroxamic acids, e.g. phenylalaninehydroxamic acid, leucinehydroxamic acid and tyrosinehydroxamic acid as scaffolding. The complexes containing Cu^{II} ions have the ring metals either in square-planar environments, bound to two hydroximato ligands, or in square-pyramidal geometries with solvent coordinated. The Ni^{II} complexes appear to be either five- or six-coordinate. The encapsulated lanthanides are generally pentagonal bipyramidal, with five oxygen donors from the metallacrown ring, and solvent or bidentate nitrate ions in the axial positions. These complexes exhibit interesting magnetic behaviour due to the circular arrangement of ions. With Dy(III) encapsulated in the center of the ring, for example, a magnetic moment as high as 10.9 BM is achieved.[72]

Originally it was thought that metallacrowns could only be obtained from β-aminohydroxamic acids but a recent study has shown that in aqueous solution α-aminohydroxamic acids are also capable of forming metallacrowns, but these are less stable.[71]

3.3.1 Aminophenylhydroxamic Acid Complexes

As illustrated by the above structures the diversity of hydroxamate coordination modes can be enriched by the presence of secondary donor groups in the ligand. The influence of the position of these donors relative to the hydroxamate on the resulting structures is illustrated by the copper(II) complexes of isomeric aminophenylhydroxamic acids AphaH, which we recently reported.[73] The structures include a novel helical polymer formed by 3-AphaH, a dimeric copper(II)-metallacrown formed by 2-AphaH, and a simple mononuclear complex formed by 4-AphaH.

Reaction of $CuSO_4{\cdot}5H_2O$ with 3-AphaH in aqueous solution gave a helical polymer with the formula $[Cu_3(3\text{-Aphha})_4(H_2O)SO_4]_n{\cdot}8H_2O$ (Figure 12), the monomeric unit of which has three interlinked unique copper(II) sites. These are the neutral square-planar complex $Cu(3\text{-Apha})_2$, the anionic square-pyramidal complex $[Cu(3\text{-Apha})SO_4(NH_2)(\cdots NH_2)]^-$ and the cationic square-pyramidal complex $[Cu(3\text{-Apha})(H_2O)(NH_2)(\cdots NH_2)]^+$, where NH_2 represents amino groups from neighbouring molecules forming both normal and elongated (···) bonds. The Cu(2)−Cu(3) helical backbones are connected by Cu^I square-planar sites. An extensive network of hydrogen bonds involving hydroxamate nitrogen and oxygen atoms, sulfate oxygen atoms, and both coordinated and lattice waters link the polymer chains. The copper(II) ions in this complex are magnetically independent.

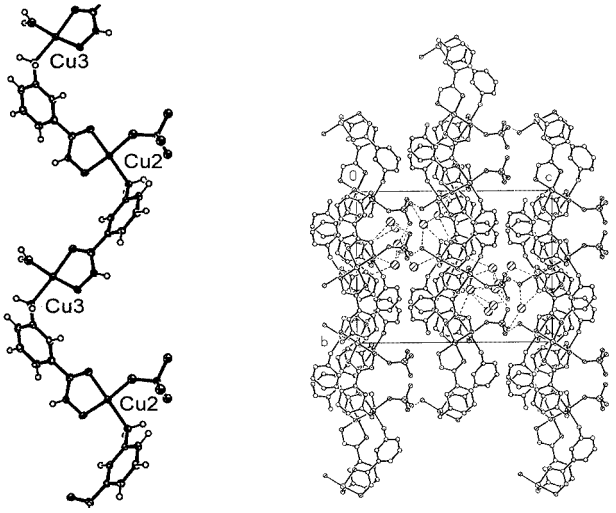

Figure 12. Molecular structure of $[Cu_3(3\text{-Aphha})_4(H_2O)SO_4]_n{\cdot}8H_2O$

The dimeric copper(II)-metallacrown complex $[Cu_5(2\text{-AphaH}_{-1})_4(\mu\text{-}SO_4)(H_2O)_2]_2{\cdot}10H_2O$ (Figure 13) was obtained by reaction of $CuSO_4{\cdot}5H_2O$ and 2-AphaH in aqueous solution. In this case, each monomeric unit contains a square of copper(II) ions, Cu1−4, linked by doubly deprotonated hydroximate ligands 2-AphaH_{-1} and a central copper(II) ion Cu5, which is coordinated by four hydroxamate oxygen atoms and the oxygen atom of a bridging sulfate that is also weakly bonded to Cu4. Pecoraro et al. reported a similar monomeric metallacrown structure, synthesised from $Cu(OAc)_2$.[74] The structure of $[Cu_5(2\text{-AphaH}_{-1})_4(\mu\text{-}SO_4)(H_2O)_2]_2{\cdot}10H_2O$, however, differs from that reported by Pecoraro et al. It is a fused dimeric metallacrown that has a novel "clam-like' structure, the closed end of which arises from the binding of ring copper atoms Cu2 and Cu2A in two metallacrown units to oxygen atoms O2A and O2, respectively, in adjacent units, and the open end of which accommodates bridging sulfate ligands. The external faces of the metallacrown dimer are involved in hydrogen bonding with other metallacrown units through hydroxamate nitrogen and oxygen atoms, resulting in intermolecular Cu−Cu bond lengths of approximately 3.9 Å. The complex is strongly antiferromagnetic. The only other reported dimeric metallacrown is that of a nickel(II) complex in which the metallacrown rings are parallel.[75]

In contrast to the above structures, reaction of 4-AphaH with $CuSO_4{\cdot}5H_2O$ resulted in the formation of a simple mononuclear complex $Cu(4\text{-Apha})_2{\cdot}H_2O$ (Figure 14). An extensive hydrogen-bonding network leads to an overall stacked structure containing internal cavities.

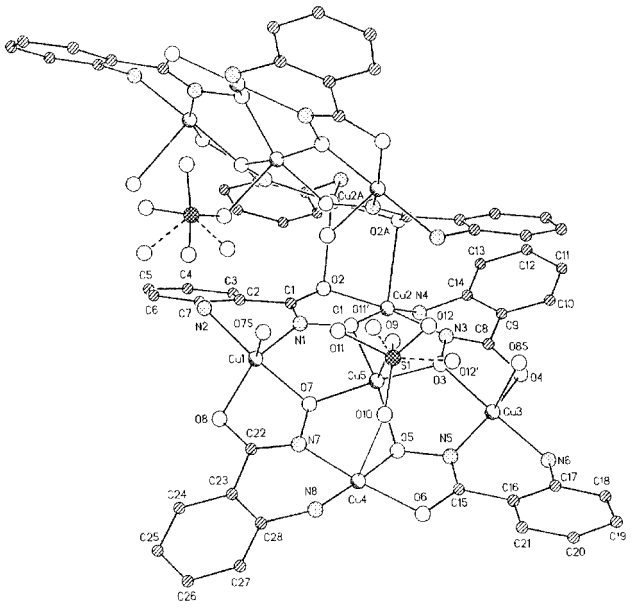

Figure 13. A novel dimeric copper(II)-metallacrown type complex $[Cu_5(2\text{-}AphaH_{-1})_4(\mu\text{-}SO_4)(H_2O)_2]_2\cdot 10H_2O$

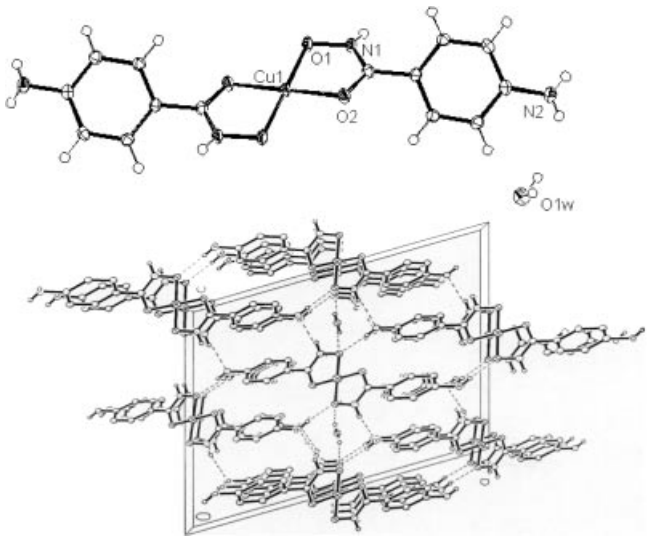

Figure 14. Mononuclear $Cu(4\text{-}Apha)_2\cdot H_2O$ exhibiting an extensive hydrogen-bonding network that leads to an overall stacked structure, which contains internal cavities

An intriguing heptanuclear nickel(II) complex that uniquely exhibits four distinct hydroxamate binding modes, two of which are novel, and which shows both antiferromagnetic and ferromagnetic interactions has also recently been reported by us.[76] Reaction of 2-(dimethylamino)-phenylhydroxamic acid (2-dmAphaH) with $NiSO_4\cdot 6H_2O$ results in the formation of $[Ni_7(2\text{-}dmAphaH_{-1})_2(2\text{-}dmApha)_8(H_2O)_2]SO_4\cdot 15H_2O$ (Figure 15), which contains a trigonal-bipyramidal array of nickel(II) ions with another two nickel(II) ions annexed to the apical sites. This complex in which each nickel ion is octahedrally coordinated contains monodeprotonated 2-dmApha and doubly deprotonated 2-dmAphaH$_{-1}$ hydroxamate ligands.

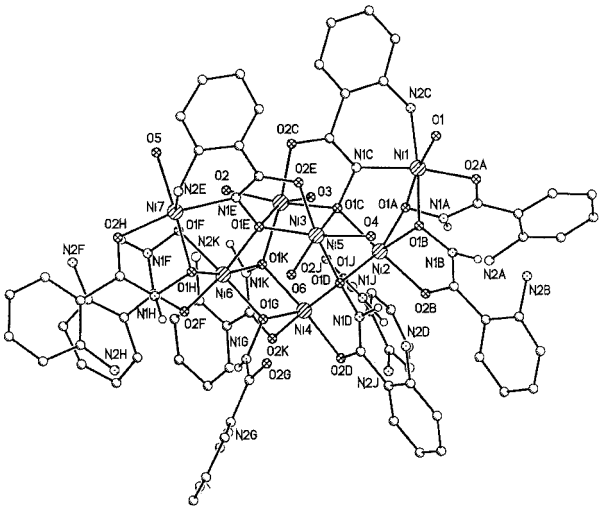

Figure 15. Molecular structure of $[Ni_7(2\text{-}dmAphaH_{-1})_2(2\text{-}dmApha)_8(H_2O)_2]SO_4\cdot 15H_2O$

The hydroxamate binding modes may be categorised as follows. One of the doubly deprotonated hydroxamate ligands C (Figure 15−17) is doubly bidentate with respect to nickel ions, Ni1/Ni3 when all of its donor atoms are involved, and is triply bridging to Ni2/Ni5/Ni3, when the hydroxamate oxygen atom is involved (Figure 17). Ligand E is similarly bonded to Ni5/Ni7 and Ni6/Ni3/Ni5. The remaining eight hydroxamate ligands are singly deprotonated and are coordinated through the hydroxamate group only. Ligand D is bidentate with respect to Ni4 and triply bridging through the hydroxamate oxygen atom with respect to Ni4/Ni2/Ni5. Ligand K is similarly coordinated to Ni4 and Ni4/Ni6/Ni3. Ligand G bridges Ni4 and Ni6 through the hydroxamate oxygen atom, while ligand J is similarly coordinated to Ni2 and Ni4. The four remaining hydroxamate

ligands coordinate pairs of Ni ions in a bidentate bridging manner. Ligands A and B are bidentate with respect to Ni1 and Ni2, respectively, and both ligands bridge these Ni ions through the hydroxamate oxygen atom. Ligands F and H exhibit the same coordination towards Ni6 and Ni7, respectively. The two binding modes observed for ligands D/K and G/J had not previously been reported for hydroxamate ligands, whilst a similar binding mode for ligands C/E, which involves an additional coordinating group, had only once previously been reported (for a nickel(II) metallacrown with salicylhydroxamic acid).[77] The double hydroxamate bridging of Ni1−Ni2 and Ni6−Ni7 by ligands A and B and F and H, respectively, is similar to that observed in some dinickel model systems for urease inhibition,[28,78] which also contain two hydroxamate bridges and for which inter nickel distances of 3.016 and 3.005 Å have been reported. These values are very similar to the values of 2.958(3) and 2.944(2) Å in the present case.

Figure 17. Binding modes of hydroxamate ligands (2-dmApahaH$_{-1}$ and 2-dmApha) in [Ni$_7$(2-dmAphaH$_{-1}$)$_2$(2-dmApha)$_8$(H$_2$O)$_2$]-SO$_4$·15H$_2$O

In contrast to the nickel product, reaction of 2-dmAphaH with CuSO$_4$·5H$_2$O gave the metallacrown [Cu$_5$(2-dmAphaH$_{-1}$)$_4$(HSO$_4$)$_2$(MeOH)$_2$]·2MeOH.[68] The presence of the methyl substituents preclude the formation of a dimeric metallacrown analogous to [Cu$_5$(2-AphaH$_{-1}$)$_4$(μ-SO$_4$)(H$_2$O)$_2$]$_2$·10H$_2$O, which we previously reported for 2-aminophenylhydroxamic acid (Figure 18).[73]

3.6 Hydroxamate Complexes of Ruthenium(III), Platinum(II), Palladium(II), Rhodium(I) and Rhodium(III)

Hydroxamate complexes of ruthenium(III), platinum(II) and palladium(II) were recently reported for the first time.[79−81] The fact that no ruthenium(III) hydroxamates had previously been reported is surprising in view of the extensive library of known iron(III) hydroxamates, and this is probably due to nitrosyl abstraction from hydroxamic acids by ruthenium(III) to give ruthenium(II)-nitrosyls as described in section 4. We have recently reported the structure of the first ruthenium(III) hydroxamate complex Ru(H$_2$edta)(2-OMepha) (Figure 19) from the reaction of NH$_4$[Ru(Hedta)Cl] with 2-methoxyphenylhydroxamic acid (2-OmephaH), and the synthesis and characterisation of several other complexes.

Upon addition of base, the hydroxamate ligand in this complex undergoes further deprotonation to give the hydroximato complex [Ru(edta)(2-OMephaH$_{-1}$)]$^{3-}$, Equation (2).

$$[Ru(edta)(2\text{-}OMephaH)]^{2-} \rightleftharpoons [Ru(edta)(2\text{-}OMephaH_{-1})]^{3-} \quad (2)$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

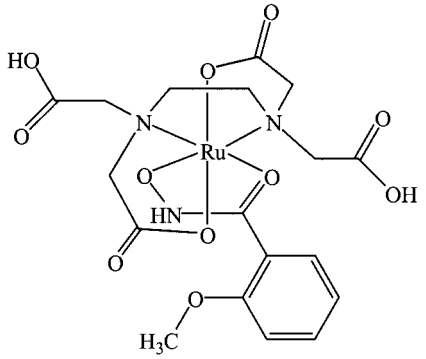

Figure 19. Structure of Ru(H_2edta)(2-OMepha)

The formation of hydroximato complexes, although common in metallacrown chemistry, has been reported in only a few cases for mononuclear complexes.[82−84] The affinity of phenylhydroxamic acid for $[Ru^{III}(edta)(H_2O)]^-$ (hexacoordinate) was found to be much greater than for $[Fe^{III}(edta)(H_2O)]^-$ (heptacoordinate), but this was largely due to differences in charge and coordination numbers of the immediate metal coordination environments rather than intrinsic affinity differences between ruthenium(III) and iron(III) for hydroxamate ligands. The stability of ruthenium(III)-hydroxamate complexes is dependent on the substituent on the aryl ring.

Hydroxamic acid complexes of platinum(II) and palladium(II) have also recently been reported. It was revealed by ^{1}H NMR spectroscopic studies that salicylhydroxamic acid (shaH) does not coordinate to chloro complexes of platinum(II) but can form complexes of the type $[Pt(shaH_{-1})(PPh_3)_2]$, the crystal structure of which was determined. In this complex, $shaH_{-1}$ binds through an (*O*,*O*) coordination mode in its hydroximate form, and the phenolic group remains protonated. Stabilisation of hydroximate binding to platinum is facilitated by the presence of soft ligands. In contrast, the palladium complex $[Pd(sha)_2]$ is readily synthesized and crystallizes as $[Pd(sha)_2](DMF)_4$, with the unexpected (*N*,*O*) binding mode of the salicylhydroxamate ligand.[80] Two novel platinum(II)-diamine benzohydroxamate complexes were reported, namely $[\{Pt(en)\}_2(\mu\text{-bha})]ClO_4\cdot H_2O$ (en = ethane-1,2-diamine, bha = benzohydroxamic acid) (Figure 20), and $[\{Pt(RRchxn)\}_2(\mu\text{-bha})]\cdot 2H_2O$ (chxn = cyclohexane-1,2-diamine) in which Pt−C bonds are present in the dinuclear structures. The two Pt centres are linked through the bha via (*O*,*O*) and (*C*,*N*) coordination modes, the latter involving formation of a Pt−C(*ortho*) bond. Both dinuclear complexes are less cytotoxic than their corresponding dichloro parent complexes. While the mechanism of action of the dinuclear species remains unclear, it has been suggested that the platinum(amine) moieties affect the activity but the presence of the hydroxamate bridge alters the rate of aquation and DNA binding of these species.[81] From these studies, it appears that only aryl hydroxamates readily bind to Pt^{II}. Furthermore, the hydroximate form of the ligand in these complexes appears to be stabilized by the binding of the second platinum centre bridged through the benzohydroximato ligand.

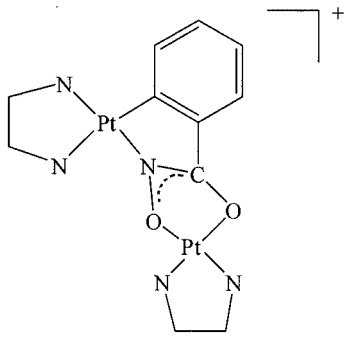

Figure 20. Structure of $[\{Pt(en)\}_2(\mu\text{-bha})]ClO_4\cdot H_2O$ (en = ethane-1,2-diamine, bha = benzohydroxamic acid)

A recent study involving the reaction of *N*-phenylbenzohydroxamic acids with rhodium showed that the oxidation state of the metal ion dictated the type of reaction involved. For rhodium(I), the *N*-phenylbenzohydroxamic acids serve as oxidizing agents and oxidise rhodium(I) to rhodium(III), and are themselves reduced to the corresponding amides. In the presence of rhodium(III), the same hydroxamic acids undergo typical bidentate hydroxamate coordination.[85] Interestingly, an unusual transformation of *N*-arylbenzohydroxamic acids, mediated by osmium(II), affords a family of cyclometalates in which the transformed hydroxamic acids are coordinated as doubly deprotonated benzanilides of osmium(III).[86]

4. Hydroxamic Acids as Nitric Oxide Donors

While some of the physiological roles of hydroxamic acids are undoubtedly due to the chelating ability of the hydroxamate group, others such as their hypotensive effects[33] (a known nitric oxide property) may be due to their ability to release nitric oxide (NO), a view strengthened by the now established importance of NO in many physiological processes. In fact, it is now well recognised that there are probably few pathological conditions where NO does not play an important role.[87−89]

Ruthenium(III) readily forms nitrosyls and there are more known nitrosyl complexes of ruthenium than any other metal.[90] The Ru−NO bond is generally very stable and is easily detected by infrared spectroscopy, ν(NO) at about 1880 cm^{-1}. We have recently shown that hydroxamic acids are effective NO donors by virtue of the fact that they readily transfer NO to ruthenium(III) forming highly stable ruthenium(II)-nitrosyls and by their ability to cause vascular relaxation of rat aorta by NO-mediated activation of the iron(II) haem-containing enzyme guanylate cyclase.[91] In doing so, we effectively used ruthenium(III) as a tool to abstract NO from hydroxamic acids. A similar reaction of hydroxamic acids with $K_3[Fe(CN)_6]$ to give $[Fe(CN)_5NO]^{3-}$ was reported independently at the same time.[92]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Reaction of the well-characterised $K[Ru(Hedta)Cl]\cdot 2H_2O$ with benzohydroxamic acid in aqueous solution at room temperature resulted in the unambiguous formation of a ruthenium nitrosyl complex. The microanalysis, IR, mass and ^1H NMR spectra are consistent with the formation of $K_2[Ru(edta)(NO)Cl]$, containing a linear, diamagnetic $Ru^{2+}-NO^+$ group (distinctive ν_{NO} at 1880 cm^{-1}) and no absorption at 1730 cm^{-1}, which confirms fully deprotonated edta. This complex is similar to the previously reported six-coordinate $Ru(H_2edta)(NO)Cl\cdot 2H_2O$,[93] but contains fully deprotonated tetradentate edta with two pendant carboxylate groups. A related complex $[Ru(edta)NO]^-$ was formed in solution by reaction of NO with K[Ru(Hedta)Cl].[94] Similar reactions of $K[Ru(Hedta)Cl]\cdot 2H_2O$ with acetohydroxamic acid and salicylhydroxamic acid also gave the same product in high yields. The products of the denitrosylation reactions were shown to be the corresponding carboxylic acids, Equation (3).

$$[Ru(Hedta)Cl]^- + RCONHOH \rightarrow [Ru(edta)(NO)Cl]^{2-} + RCOOH \quad (3)$$

Reaction of $RuCl_3\cdot xH_2O$ with aceto-, benzo-, salicyl- and anthranilic hydroxamic acids in ethanol, followed by purification on Sephadex LH 20 columns also gave ruthenium(II) nitrosyl complexes, all of which have very distinctive ν_{NO} bands at approximately 1885 cm^{-1}.

The ability of hydroxamic acids to release nitric oxide in simple biological systems was shown by vascular relaxation of endothelium-denuded rings (to remove endogenous nitric oxide) of rat aorta. These were set up in organ baths for isometric tension recording. Rings were contracted with the α-1-adrenoreceptor agonist phenylephrine (1μM), and the ability of increasing concentrations of hydroxamic acid derivatives to produce relaxation was examined (the results are shown in Figure 21). Of the hydroxamic acids investigated, benzohydroxamic acid proved most effective, causing approximately 45% relaxation of rat aorta at a concentration of 300 μM. Although this value is higher than that quoted for the well-known NO donor 3-morpholinosydnonimine, SIN-1 (1 μM), it compares favourably with that of another NO donor 4-(3-butoxy-4-methoxybenzo)-2-imidazolidilone, Ro-20−1724 (100 μM). Relaxation occurred by activation of the enzyme guanylate cyclase (a definitive receptor for NO) as shown by the fact that methylene blue (10μM), a known inhibitor of this enzyme, prevented the relaxation (e.g. relaxation to 300μM acetohydroxamic acid: vehicle treated, 31.4 ± 10.9% relaxation; methylene blue treated, 6.4 ± 3.1% relaxation, $n = 4$, $P < 0.05$).

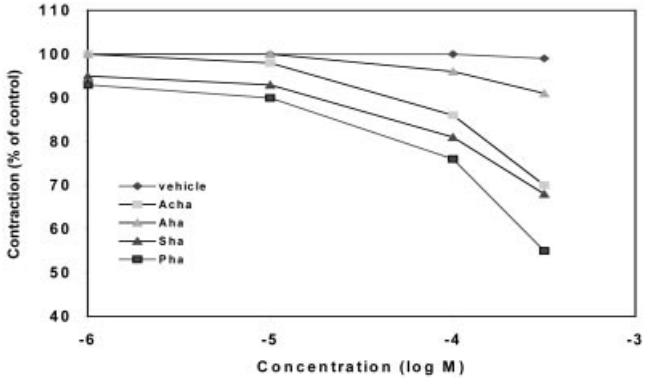

Figure 21. The effects of hydroxamic acids on relaxation of rat aorta

We have therefore shown conclusively that hydroxamic acids can act as effective NO donors by virtue of the fact that they can readily transfer NO to ruthenium(III). Furthermore, hydroxamic acids can cause vascular relaxation in rat aorta by NO-mediated activation of the iron-containing enzyme guanylate cyclase, thus confirming the biological relevance of our novel results.

5. Hydroxamic Acids as Inhibitors of Cyclooxygenase

Cyclooxygenase (COX) is the enzyme responsible for the generation of prostaglandins (Figure 22), bioactive lipids that are involved in many pathophysiological processes including vascular thrombosis, nocioception and temperature control.[95−97]

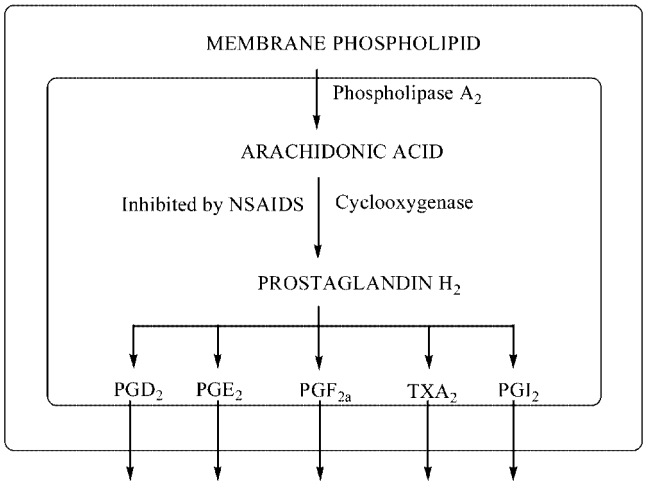

Figure 22. Production of prostaglandins by COX

Two isoforms of the enzyme have been identified: COX-1, which is expressed ubiquitously and is the only form in platelets where it generates thromboxane, a potent platelet activator; and COX-2, which was initially thought to be rare in normal tissue, but expressed at sites of inflammation, in tumours and in response to tissue injury. Both isoforms of COX are inhibited by nonsteroidal anti-inflammatory drugs (NSAIDs)[98] such as aspirin, which were initially thought to have beneficial therapeutic effects due to COX-2 inhibition and side effects due to inhibition of COX-1. There has therefore been intense interest in the development of selective COX-2 inhibitors on the basis that prostaglandins that contribute to inflammation are produced by COX-2, while prostaglandins essential for normal

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

physiological processes are produced by COX-1. Several selective COX-2 inhibitors have resulted, including Celecoxib, Nimesulide and a range of modified NSAIDs such as aspirin analogues that have *o*-alkynyl ether or thioether substituents.[99] Aspirin (acetylsalicylic acid) is unique amongst the NSAIDs in that it covalently modifies the enzyme, irreversibly acetylating a serine residue in the substrate channel.[100]

Aspirin and other NSAIDS do not influence the peroxidase site of the enzyme. Therefore, after NSAID treatment, peroxidase (POX) activity can continue to generate damaging free radical species. There is therefore a need for dual COX and POX site inhibition. The hydroxamic acid Tepoxalin is such an inhibitor (Figure 23).[101]

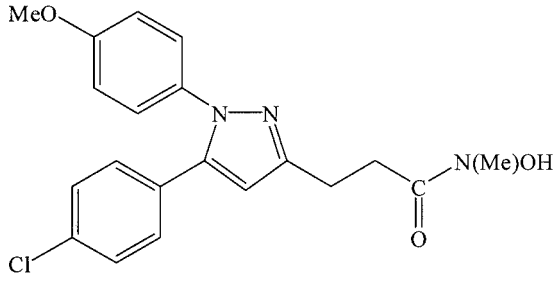

Figure 23. Structure of Tepoxalin

The rationale for the synthesis of selective COX-2 inhibitors has recently been thrown into doubt as it has been shown that COX-2 is expressed constitutively in many tissues and has important physiological roles, and that indeed COX-1 contributes to inflammatory processes. Therefore, it now appears that a combination of selective COX-1 and COX-2 inhibitors may possess greater efficacy than selective COX-2 inhibitors alone.[102]

We decided to investigate hydroxamic acid analogues of aspirin as COX inhibitors for the reasons that: (i) the hydroxamic acid group is less acidic than the carboxylic acid group and should cause less topical irritation; (ii) acetylated hydroxamic acid should, like aspirin, inhibit the COX site by acetylation of Ser-529; (iii) the acetylated hydroxamic acid should also inhibit the POX site since hydroxamic acids are known to inhibit peroxidases; (iv) since we showed that hydroxamic acids are potential NO donors, their aspirin analogues could behave like previously described NO-aspirins with anti-inflammatory effects but devoid of topical irritation, nonulcerogenic, and protective of the stomach.[103,104]

Acetylation of salicylhydroxamic acid with acetyl chloride afforded not the aspirin analogue but instead *O*-acetylsalicylhydroxamic acid, AcSHA, (Figure 24) in which the hydroxamic acid rather than the phenolic group was acetylated. This product was found, however, to be almost as potent as aspirin in the inhibition of cyclooxygenase and was found to require Arg-119 and Ser-529 for activity since the S529A and R119Q mutants were found to be inactive. A crystal structure of the inhibitor-COX-1 complex confirms that acetylation of Ser-529 had occurred, but that instead of the salicylhydroxamate metabolite being trapped in the active site, as was found in the case of bromoaspirin, a fresh molecule of inhibitor is found in this position. This is probably due to the fact that the active site pocket is positively charged and attracts the negatively charged acetylsalicylhydroxamate (i.e. a fresh molecule of inhibitor) with the exclusion of the neutral salicylhydroxamic acid. A mechanism of enzyme inhibition is shown in Figure 25.

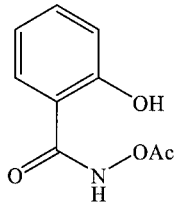

Figure 24. Structure of acetylsalicylhydroxamic acid

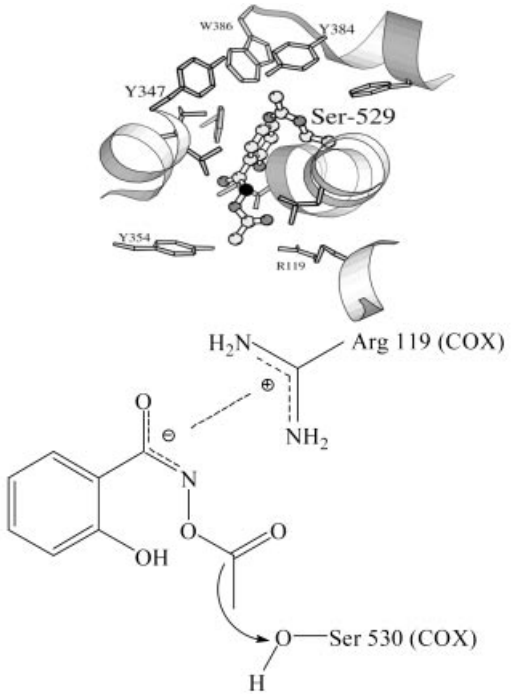

Figure 25. Structure of the COX-1 AcSHA complex, and the mechanism of inhibition of cyclooxygenase

Based on the results obtained with *O*-acetylsalicylhydroxamic acid (AcSHA), we synthesised triacetylsalicylhydroxamic acid (TriAcSHA) (Figure 26), and this was found to be much more effective than both aspirin (ASA) and AcSHA in inactivating both COX-1 and COX-2.[105,106] Hence, preincubation of COX-1 with inhibitor for 5 minutes yielded IC_{50} values of 18 μM for TriAcSHA, and 60 μM for ASA. As with aspirin, mutation of serine-530 of COX-1 to an alanine abolished the activity of TriAcSHA. Mutation of arginine-119 to a glutamine markedly reduced the sensitivity towards TriAcSHA, therefore suggesting that this residue was necessary for interaction with the enzyme. Tri-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

AcSHA was also more effective than aspirin as an inhibitor of platelet aggregation induced by arachidonic acid. The related diacetylated phenylhydroxamates, *N*-methyl-*O*,*O*-diacetylsalicylhydroxamic acid, *N*,*O*-diacetylbenzohydroxamic acid and 2-methyl-*O*,*N*-diacetylbenzohydroxamic acid showed reduced or absent activity against COX-1 (Figure 26). These data together suggest a mechanism of activity which involves Arg-119-assisted *N*-deacetylation of TriAcSha, followed by acetyl group transfer from the phenolate group of the inhibitor to Ser-529, possibly intramolecularly assisted by the anionic deacetylated nitrogen atom (Figure 26).

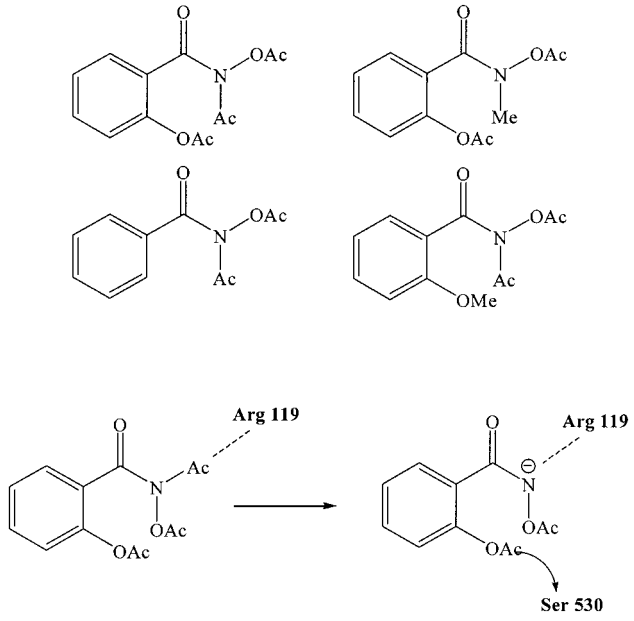

Figure 26. Acetylated salicylhydroxamic acid inhibitors of cyclooxygenase

We synthesized a series of triacylsalicylhydroxamic acids with progressively longer acyl groups (3−6 carbon atoms) (Figure 27). All of the compounds inhibited COX-1 and demonstrated progressively greater COX-1 selectivity with increasing number of carbon atoms (Figure 27). Hence, salicylhydroxamic acid provides a versatile backbone for the generation of a family of acylating inhibitors of COX.

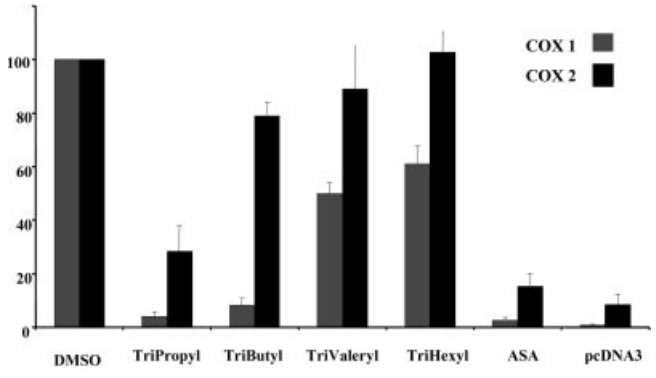

Figure 27. Triacyl derivatives of SHA are selective for COX-1

5. Conclusion

Hydroxamic acids are versatile ligands that give rise to a diverse range of metal complex structures, particularly if there are other metal binding groups present in the molecule. Their biomedical applications, once confined to treatment of metal overload conditions, have been extended to cover inhibition of a wide range of enzymes.

Heat- and Light-Induced Spin Transition of an Iron(II) Polymer Containing the 1,2,4,5-Tetrakis(diphenylphosphanyl)benzene Ligand

Patrick Rosa,[a] Amy Debay,[a] Laurence Capes,[b] Guillaume Chastanet,[a] Azzedine Bousseksou,[c] Pascal Le Floch,[d] and Jean-François Létard*[a]

Dedicated to Philipp Gütlich in the occasion of his 70th birthday

Keywords: Spin crossover / Phosphane ligands / Iron / Photomagnetism / Coordination polymers

A new iron(II) spin-crossover compound containing a phosphane ligand has been synthesized and characterized by magnetic susceptibility, Mössbauer spectroscopy, and heat capacity and photomagnetic experiments. The $[Fe(tppb)Br_2]$ complex [tppb = 1,2,4,5-tetrakis(diphenylphosphanyl)benzene] exhibits a gradual spin conversion at $T_{1/2}$ = 184 K, and displays at low temperature a partial photoconversion of the low-spin (LS) state into the metastable high-spin (HS) state by irradiating the sample at 530 nm.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Iron(II) spin-crossover (SC) compounds have numerous potential applications as display devices, optical switches, and magneto-optical storage systems, since heat- and light-induced spin transitions occur in the solid state without any fatigue.[1] The possibility to convert the spin state by irradiating with light is now reported in a large number of spin-crossover complexes. The major drawback of this process up to now is that optical switching requires that it be carried out at very low temperatures. Nevertheless, it has been theoretically predicted and experimentally confirmed that HS → LS relaxation rates k_{HL} can at least be controlled by the energy difference $\Delta E_{HL}°$ between the lowest vibrational levels of HS and of LS states, and by the change of the metal−ligand bond length Δr_{HL}.[2] In this particular context, iron(II) spin-crossover compounds containing phosphorus atoms are very attractive since a large Δr_{HL} is expected. Unfortunately, to date, spin transition has only been reported for solvated $[FeX_2(dppen)_2]\cdot n$S compounds with dppen = *cis*-1,2-bis(diphenylphosphanyl)ethylene, X = Cl or Br, and solvent molecules (S) = $CHCl_3$, CH_2Cl_2, or $(CH_3)_2CO$.[3−7] In the particular case of $[Fe(dppen)_2Cl_2]\cdot 2(CH_3)_2CO$, single-crystal structures determined both in HS and LS states showed a large Δr_{HL}(Fe−P) variation (0.3 Å),[4] and relaxation kinetics of the HS → LS conversion that occurs after the LIESST effect were slower than for classical FeN_6 complexes.[7]

In this work, we report the preparation of a new iron(II) spin-crossover complex containing phosphorus atoms with the 1,2,4,5-tetrakis(diphenylphosphanyl)benzene (tppb) ligand (Figure 1). The thermal spin-crossover properties were studied by magnetic susceptibility measurements,

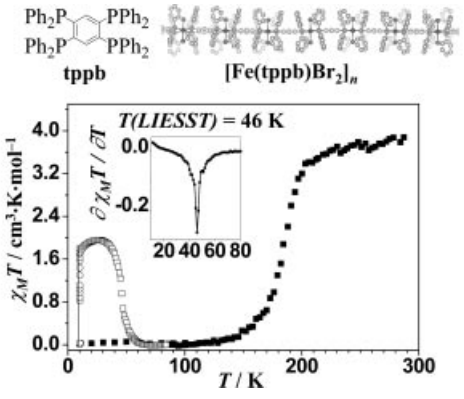

Figure 1. Top left: schematic view of ligand tppb; top right: optimized structure[8] of complex $[Fe(tppb)Br_2]_n$; bottow: molar magnetic susceptibility χ_M vs. temperature T before (filled squares), during (unfilled circles) and after (unfilled squares) light irradiation

Mössbauer spectroscopy, and heat capacity experiments. Photomagnetic investigations are also reported.

Results and Discussion

Complex $[Fe(tppb)Br_2]_n$ was obtained by mixing equimolar amounts of $FeBr_2$ and tppb in a mixture of chloroform and absolute ethanol (see Exp. Sect.). The elemental analysis (C, H, Cl and Fe) was consistent with the expected composition of a polymeric structure. Crystallization was attempted several times by slow diffusion of solutions of $FeBr_2$ and tppb in ethanol into an H-shaped double-tube glass. An amorphous powder was always obtained, certainly due to the expected low solubility of the polymeric structure. Figure 1 shows a polymeric model built up with the CERIUS 4.0 program.[8] Energy minimization suggests at first a linear organization of the iron(II) atoms along the polymeric chain, with Fe−P bond lengths of 2.5 Å, which are within the 2.3−2.6 Å range reported for $[Fe(dppen)_2Br_2]\cdot 2CHCl_3$ by X-ray diffraction.[4] It also shows that the Fe−Fe distance along the polymer chain is 9 Å, which is longer than that in iron(II)−triazole polymers (3.6 Å[9,10]) since the bridging phosphorus atoms are kept apart by the rigid phenylene structure.

The magnetic properties of $[Fe(tppb)Br_2]_n$ are presented in Figure 1. The value of the molar magnetic susceptibility product with temperature ($\chi_M T$) varies from 3.8 $cm^3\cdot K\cdot mol^{-1}$ at room temperature to nearly 0 $cm^3\cdot K\cdot mol^{-1}$ at 80 K. The room-temperature value is consistent with a high-spin Fe^{II} complex with a $^5T_2$ quintet (assuming octahedral symmetry) ground state. At low temperature, the $\chi_M T$ value corresponds to a low-spin Fe^{II} complex with a $^1A_1$ singlet ground state. The $\chi_M T$ curves recorded in the cooling and warming modes are identical, and no hysteresis is detected. The temperature at which there are equal amounts of HS and LS complexes $T_{1/2}$ is 184 K.

Figure 2 displays the Mössbauer spectra recorded at temperatures of 293 K, 180 K and 80 K. This series of data confirms the occurrence of a temperature-controlled singlet/quintet equilibrium with complete conversion. The single doublet recorded at room temperature is typical of iron(II) in the HS (S = 2) ground state with a quadrupole splitting of $\Delta E_Q = 2.773 \pm 0.007\ mm\cdot s^{-1}$ and an isomer shift of $\delta = 0.663 \pm 0.004\ mm\cdot s^{-1}$ relative to natural iron ($-0.13\ mm\cdot s^{-1}$). In contrast, at 80 K, the unique doublet found with $\Delta E_Q = 0.740 \pm 0.002\ mm\cdot s^{-1}$ and $\delta = 0.396 \pm 0.001\ mm\cdot s^{-1}$ is typical of iron(II) in the LS (S = 0) ground state. At an intermediate temperature (180 K), the inner and outer doublets are observed, as expected. This thermal spin transition was also investigated by DSC techniques. The temperature dependence of the molar heat capacity C_p in the cooling and warming modes was examined in the 120−290 K temperature range. The enthalpy variation associated with the spin transition is $\Delta H = 5.6\ kJ\cdot mol^{-1}$, and the entropy change is $\Delta S = 31\ J\cdot mol^{-1}.K^{-1}$. The value for ΔS is smaller than those obtained in strongly cooperative compounds ($50-80\ J\cdot mol^{-1}\cdot K^{-1}$)[11]. Since it is very close to the electronic-only value (ΔS_{el}) of 13.4 $J\cdot mol^{-1}\ K^{-1}$,[1] the weakness of the vibrational component ΔS_{vib} supports the poorly cooperative behavior of $[Fe(tppb)Br_2]_n$.

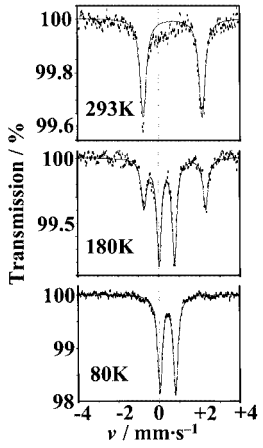

Figure 2. ^{57}Fe Mössbauer spectra for a powder sample of complex **2**; an HS doublet is observed at 293 K, whereas cooling the sample to 80 K gives an LS doublet; at 180 K, both doublets are present with 37% of the HS state

Photomagnetic properties were investigated by irradiating the sample in a SQUID cavity coupled to a Krypton Laser through an optical fiber. The compound was first slowly cooled in the dark from room temperature to 10 K, then irradiated for 1 h. The magnetic response was found to increase rapidly until a value of about 1.8 $cm^3\cdot K\cdot mol^{-1}$ was reached (Figure 1). This indicates a partial conversion (50%) of the LS state into the metastable HS state according to the Light-Induced Excited-Spin-State Trapping (LIESST) process.[12] To increase the level of photoexcitation different experiments were performed: an increase in the irradiation time, an increase in the power (up to $30\ mW\cdot cm^{-2}$), and/or a change in the excitation wavelength (488.0−514.5 nm, 647.1−676.4 nm, 752.5−799.3 nm). Unfortunately, the highest photoinduced LS → HS conversion rate remained at around 50%. The light irradiation was then switched off and the critical LIESST temperature value *T(LIESST)* was recorded.[13] In fact, we recently proposed that the capacity of a compound to retain the light-induced HS information may be estimated through the determination of the *T(LIESST)* value.[14] With this procedure, $\chi_M T$ was found to remain constant at low temperature (tunneling domain) and to drop within a few Kelvin when the thermally activated region was reached. The value of *T(LIESST)*, determined as the minimum of the derivative $\partial\chi_M T/\partial T$, was estimated as 46 K (Figure 1). Such a value, in comparison to the other iron(II) spin-crossover complexes from our database,[14] is unfortunately not exceptional. A study of the kinetics in the vicinity of *T(LIESST)* showed that the relaxation curves strongly deviate from single exponentials, with a fast initial decay and a long tail with a much slower decay, typical of a relaxation following a stretched exponential law. This behavior has, in fact, been reported in many other noncooperative spin-crossover complexes and has been attributed to a distribution of activation energies due to some local inhomogeneity of the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

iron(II) surroundings.[15] In our case, this finding is in good agreement with the gradual character of the thermal spin transition and proves once more the absence of significant cooperativity in the $[Fe(tppb)Br_2]_n$ polymer, certainly because of the long Fe−Fe distances along the chain.

Conclusion

In this work, we have reported the heat- and light-induced spin-crossover properties of a new iron(II) polymeric complex based on a tetraphosphane. This polymer represents an important step towards the design of polynuclear systems combining magnetic interaction and spin conversion under light irradiation. Moreover, it is also a new example of a spin-crossover material involving phosphorus atoms. Synthetic efforts are currently under way to investigate the properties of other complexes based on di- and tetraphosphane ligands.

Experimental Section

General Remarks: All reactions and manipulations were carried out under dry nitrogen. Magnetic susceptibility measurements were carried out by using a MPMS-55 Quantum Design SQUID magnetometer operating at approximately 2 Tesla in the 2−300 K temperature range. Irradiation in the SQUID cavity was done with a 530.9 nm wavelength krypton laser, and the power on the sample was adjusted to 5 $mW{\cdot}cm^{-2}$. Bulk attenuation of light intensity was limited by the preparation of a thin layer of the compound. Its weight was obtained by comparing its thermal spin-crossover curve with the curve recorded with a heavier sample of the same compound. The heat capacities were measured with a Perkin−Elmer DSC-7 calorimeter, and the cell was cooled to the velocity of 2 $K{\cdot}min^{-1}$. Elemental analyses were performed by the Service Central d'Analyse (CNRS) in Vernaison, France.

1,2,3,4-Tetrakis(diphenylphosphanyl)benzene: The synthesis of tppb[16] was modified as follows. Ph_2PNa was obtained starting from Ph_2PCl (6 mL, 32 mmol) in THF (50 mL) and Na (1.5 g, 65.2 mmol) while monitoring by ^{31}P NMR spectroscopy. After 10 h at room temperature, the excess sodium was removed and 1,2,4,5-tetrafluorobenzene (0.71 mL, 6.4 mmol) was added. After 1 h at 70 °C and one night at room temperature, ^{31}P NMR spectroscopic data showed completion of the reaction. A few drops of MeOH were then added, the solvent was removed, and the solid extracted with dichloromethane and water. The organic layer was dried with $MgSO_4$, filtered and concentrated. Recrystallization at −18 °C with the addition of a minimum amount of methanol yielded 2.5 g (47%) of the white product, identified by NMR spectroscopy as tppb.[16]

$\{[Fe(tppb)Br_2]{\cdot}0.16CHCl_3\}_n$: The complex was prepared from a solution of tppb (0.1 g, 0.12 mmol) in $CHCl_3$ (20 mL), which was slowly added to a solution of $FeBr_2$ (0.026 g, 0.12 mmol) in warm (45 °C) absolute ethanol (10 mL) in the presence of a few crystals of ascorbic acid (to prevent oxidation of Fe^{II} to Fe^{III}). Upon addition of the ligand, the reaction mixture changed immediately from an orange color to a cloudy mixture, which yielded a yellow precipitate. The powder was then filtered off, washed with a few milliliters of absolute ethanol, and dried under a stream of nitrogen (yield 106 mg, 84%). $C_{54.16}H_{42.16}Br_2Cl_{0.48}FeP_4$ (1049.56): calcd. C 61.98, H 4.05, Cl 1.62, Fe 5.32; found C 61.86, H 4.11, Cl 1.55, Fe 4.93.

Microwave-Assisted Generation of Lanthanide(II) Halides in THF and Simple Quantitative Determination

Anders Dahlén[a] and Göran Hilmersson*[a]

Keywords: Microwave-assisted reactions / Lanthanides / Halides / Titrations / Quantitative determinations

Lanthanide(II) reagents (SmI_2, $SmBr_2$, YbI_2, EuI_2) have been prepared rapidly in high yields using microwave-assisted heating. Samarium diiodide is obtained as a saturated solution in THF (0.13 M) within 5 min and ytterbium diiodide (0.065 M) after 45 min. A simple method for quantitative determination of LnX_2 in THF is also described by utilizing the instantaneous reaction with ketones in the presence of an amine and water. This method establishes the concentration of the active single-electron-donor species, i.e. Ln^{2+}.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The introduction of the versatile and highly selective single-electron-transfer reagent SmI_2 has had a great impact on the development of organic chemistry during the last 10−15 years.[1−4] The reduction potential of SmI_2 is in the range of −1.3 to −2.2 V,[5] depending on solvents and ligands, which makes SmI_2 particularly useful for selective reduction and various coupling reactions.[6,7] Since SmI_2 has become commercially available, the development of SmI_2-mediated reactions has rapidly entered different areas of organic synthesis. Recently, there have also been reports on the use of other anions (Br^- and amides)[8−10] and lanthanides (Yb, Nd and Dy)[11−13] for various selective reduction reactions. However, reagents such as $SmBr_2$, YbI_2, EuI_2 and ThI_2 are still far from being widely used, much due to the lack of simple methods and long reaction times needed for their preparation. Recent progress in microwave-assisted synthesis is particularly attractive due to dramatically shorter reaction times and higher yields relative to conventional reaction conditions.[14,15]

We have realised that research groups that currently explore the chemistry mediated by e.g. SmI_2 are lacking a reliable method for a simple, rapid and quantitative determination of the concentration of the reducing reagent itself. It is important that the concentration of the reducing reagent is known before the success of a new SmI_2-mediated reaction can be fully evaluated. The concentration of the commercially available SmI_2 reagent (0.1 M) has been found to vary from 0.05 to 0.10 M. (Evaluating the concentrations from several different batches from commercial sources showed that the concentration of SmI_2 varied dramatically.) Today there are only a few volumetric titration methods known for e.g. SmI_2; however, these methods only establish the total concentration of I^- or Sm^{2+} and Sm^{3+} (i.e. they also measure inactive reagents such as SmI_3).[16−18] There is, to the best of our knowledge, no method known for a direct and quantitative method for the titration of the single-electron-transfer reagent Ln^{2+} itself. Recently, we reported on the SmI_2/amine/water instantaneous reduction of ketones.[19] This reaction constitutes a key for quantitative determination of the concentration of various LnX_2 solutions, since the reduction of simple ketones is very clean and proceeds extremely fast. Furthermore, the progress of the reaction may be monitored by the disappearance of the characteristic dark blue colour of SmI_2 in THF (Scheme 1).

$$2\ SmI_2\ (dark\ blue) + R_2C{=}O \xrightarrow[-R_3N{\cdot}HI]{R_3N/H_2O} 2\ Sm(OH)_3\ (white) + R_2CHOH$$

Scheme 1. The colour changes from dark blue to white during the reduction of ketones

Results and Discussion

Generation of LnX_2

Microwave-assisted heating of THF mixtures of samarium metal and iodine, iodoform or diiodoethane for 5 min (at 180 °C) results in rapid formation of dark blue solutions of SmI_2. The resulting SmI_2 solutions are of similar quality whether they are made from iodine, iodoform or diiodoethane. However, the use of iodine is preferred since this source of I^- does not involve the generation of gaseous

by-products (i.e. acetylene or ethene)[20,21] that may cause the maximum pressure allowed in the microwave reaction vessel to be exceeded during heating. Crystals of iodine are also more easily handled inside the glove box. There is a significant difference in the rate of SmI_2 formation from samarium metal if it is used as chunks or as a powder. The formation of SmI_2 using powder of mesh −40 is rapid; the reaction is complete within 3−5 min, while chunks require about 20−30 min. When SmI_2 is generated from more than the necessary amount of I_2 and Sm, the excess SmI_2 precipitates leaving a saturated THF solution. After centrifugation of excess undissolved SmI_2, the maximum concentration of SmI_2 in THF is 0.13 M. The UV/Vis spectrum of the microwave-generated SmI_2 was identical to that previously reported (Supporting Information; for Supporting Information see also the footnote on the first page of this article).[22]

Ytterbium diiodide (YbI_2) has not been used much in organic synthesis since the first report by Kagan.[21] This is in part due to its reported low solubility in THF (0.040 M) and lower reactivity than that of SmI_2. In contrast to the large number of reports on SmI_2-mediated reactions, the development of YbI_2 as a single-electron-transfer reagent is still in its infancy. It was, therefore, with great interest that we prepared YbI_2 from ytterbium metal and iodine crystals using microwave-assisted heating. The saturated clear yellow THF solution of YbI_2 (maximum solubility 0.065 M in THF) is formed in less than 45 min under microwave heating at 180 °C, which results in a pressure of 13 bar. YbI_2 can be stored for extended periods of time inside the glove box without any observable change in colour, concentration or reactivity, as long as there is a slight excess of ytterbium metal present. The UV/Vis spectrum of the microwave-generated YbI_2 is identical to that previously reported (Supporting Information).[22]

We were also interested in the preparation of $SmBr_2$ since it is known to have a considerably larger oxidation potential (−2.07 V) than SmI_2 in THF.[23] Recently, Namy and co-workers reported on the preparation of $SmBr_2$ from tetrabromoethane.[10] We found that the predicted concentration of $SmBr_2$ has to be significantly higher than that of SmI_2, otherwise the preparation failed; the use of approximately 0.45 mmol of $SmBr_2$ per mL of THF gives reproducible results. The samarium bromide could be prepared in a microwave oven from samarium powder and either bromine or tetrabromoethane. However, we recommend preparation of $SmBr_2$ from tetrabromoethane since it gives somewhat cleaner reactions relative to $SmBr_2$ prepared from bromine. (The GC chromatograms of reduced 2-heptanone with $SmBr_2$/triethylamine/water shows no impurities for tetrabromoethane-generated $SmBr_2$, while $SmBr_2$ generated from bromine gives several smaller, unidentified peaks.) In agreement with previous studies we conclude that the solubility of $SmBr_2$ is very low in THF, and it exists predominantly as a suspension. The UV/Vis spectrum agrees with the spectrum for $SmBr_2$ prepared from SmI_2 and LiBr previously reported by Flowers and co-workers (Supporting Information).[23]

[a] The starting materials were mixed inside a glove box. YbI_2 was microwave-irradiated for 45 min, and SmI_2 and $SmBr_2$ for 5 min. $[LnX_2]$ was titrated according to the method described below to yield the concentration with an error of approximately ±2%. [b] Prepared in ultrasonic bath for 2−4 h. [c] Suspension, maximum solubility is exceeded, and the given value is an expected concentration provided that all reagents would dissolve. [d] Prepared inside a glove box with magnetic stirring for at least 15 h.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The use of microwave heating was also explored in the preparation of EuI_2. We found that EuI_2 is prepared within 45 min (this reaction time was not optimised) to yield a clear, light yellow solution. The UV/Vis spectrum is identical to that previously reported (Supporting Information).[22]

Volumetric Titration of SmI_2 Solutions

The reduction of 2-heptanone has been studied using mixtures of SmI_2, amine and water. There is no side-reaction, thus two molecules of SmI_2 are consumed for every reduced molecule of ketone. An excess of I^-, I_2, Sm^0 or Sm^{3+} is not capable of reducing even trace amounts of ketone, hence the reduction of the ketone proceeds only by reaction with the single-electron-transfer reagent SmI_2, and the amount of reduced ketone is directly proportional to the molar concentration of SmI_2 in THF according to Equation (1).

$$R_2C{=}O + 2\,SmI_2 + 6\,H_2O + 4\,R_3N \rightleftharpoons R_2CH_2OH + 2\,Sm(OH)_3 + 4\,R_3N{\cdot}HI \quad (1)$$

Triethylamine (approximately 3 equiv.) and water (approximately 4 equiv.) were added to a solution of unknown concentration of SmI_2 in THF (10−130 mM). The resulting mixture of unknown concentration of the single-electron-transfer reagent SmI_2 was volumetrically titrated with a ketone (2-heptanone) dissolved in THF until the end point, i.e. when the characteristic dark blue colour of SmI_2 had disappeared and a white precipitate and colourless liquid remained. The reduction is instantaneous, even when there is excess precipitated SmI_2 present, which therefore allows rapid titration. The titrant reacts immediately, and there is no delay time during the titration. The added titrant volume was read when the colour changed from light green to white (Table 2).

Table 2. Comparison of volumetric titration with GC-based determinations of $[SmI_2]$[a]

$[SmI_2]_{Volumetric\ titration}$ [M][b]	$[SmI_2]_{Conversion}$ [M][c]	$[SmI_2]_{Internal\ standard}$ [M][d]
0.077	0.075	0.074
0.077	0.076	0.075
0.074	0.074	0.075
0.074	0.075	0.074

[a] SmI_2 (5 mL) was added to a dry Schlenk tube, then Et_3N (3 equiv.) and water (4 equiv.) were added by syringe. [b] 2-heptanone was dissolved in dry THF (0.070 M) and added dropwise to the SmI_2/H_2O/amine mixture. The colour of the solution changed from dark blue to green and finally white. The added titrant volume was noted when the colour changed from light green to white. $[SmI_2]$ was calculated according to the balanced Equation (1). [c] The determined $[SmI_2]$ calculated from the conversion of 2-heptanone to 2-heptanol after integration of the separate peaks of the GC chromatogram. [d] The determined $[SmI_2]$ based on the concentration of unreduced 2-heptanone relative to an internal standard (1-hexanol) after integration of the separate peaks of the GC chromatogram.

It may be argued that SmI_2 decomposes rapidly in the presence of excess water and amine. The stability of the reagent mixture of SmI_2 with excess water and amine in THF was therefore also studied (Figure 1). There is an observed decomposition of a 0.075 M solution of SmI_2 in THF in the presence of 4 equiv. of water and 3 equiv. of amine. However, the decomposition of SmI_2 after 1 h is only about 5%. We therefore conclude that the decomposition of SmI_2 is only of marginal consequence for the analysis. The volumetric addition of the ketone to the THF solution should only require approximately 1−2 min, which corresponds to a maximum error of about 1% in the analysis.

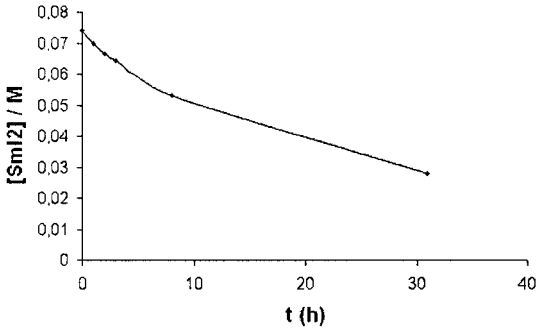

Figure 1. Decomposition of SmI_2 in the presence of triethylamine (3 equiv.) and water (4 equiv.) over an extended period of time (30 h)

GC-Based Titration of SmI_2 and YbI_2

Since the other lanthanide(II) halides do not have such a characteristic colour as SmI_2, another method for the determination of their concentrations was developed. Triethylamine (3 equiv.), water (4 equiv.) and 2-heptanone (1 equiv.) were added to a 5 mL solution or suspension of SmI_2 or YbI_2 in THF (10−400 mM). Provided that the amount of ketone is more than half of the actual amount of LnX_2, the instantaneous reaction of the excess ketone with SmI_2/amine/water results in a mixture of 2-heptanol and 2-heptanone (Scheme 2). Analysis of the amounts of 2-heptanol and 2-heptanone by GC chromatography (verified by an internal standard) yields the initial concentration of LnX_2 (Tables 1 and 2).

$$2\,LnX_2 + R_2C{=}O \xrightarrow[-R_3N{\cdot}HX]{R_3N/H_2O} 2\,Ln(OH)_3 + R_2CHOH$$

Scheme 4. Unbalanced formula for the LnX_2/amine/H_2O reductions

GC-Based Titration of Suspensions of $SmBr_2$, SmI_2 and YbI_2

Initially, we did not expect to be able to determine the amount of precipitated SmI_2 or $SmBr_2$ utilizing the reduction of 2-heptanone in the presence of amine and water. On the contrary, the reduction of the ketone is extremely fast (instantaneous), even with suspensions of YbI_2, SmI_2 and $SmBr_2$; this allows the quantitative titration of suspen-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sions of up to at least 0.4 M (Table 1). These results also indicate that suspensions of either YbI_2, SmI_2 or $SmBr_2$ can be used as single-electron-transfer reagents in the instantaneous reduction of, for example, ketones by the amine/water method.

Titration of EuI_2

Titrations of EuI_2 in THF were unsuccessful. Apparently, the oxidation potential of Eu^{2+} is too low to mediate the reduction of, for example, 2-heptanone in the presence of triethylamine and water.

Conclusion

There should be numerous reduction reactions for which the oxidation potential of SmI_2 is nonideal, and in which other lanthanide halides and also samarium with different counter anions may play a crucial role. We believe that the exploration of the chemistry mediated by these reagents is dependent on simple methods for their preparation. Due to the very low oxidation potential of EuI_2 its synthetic utility as a single-electron-reagent is somewhat limited, nevertheless its use may increase once this rapid and reliable method of preparation is known. Microwave-assisted generation of LnX_2 from metal (Ln = Sm, Yb and Eu) and halides (I_2 and Br_2) appear to be a viable alternative to the recently reported fast sonication technique.[20] Preliminary results indicate that LnX_2 reagents can be prepared in situ in the presence of reducible substrates. In an ideal situation that would allow the use of less solvent as the actual concentration of LnX_2 could be kept low during the reaction.

The direct method of determining the concentration of LnX_2 solutions by utilizing the instantaneous reaction between, for example, SmI_2 and ketones in the presence of excess amine and water has proven to be a very powerful and reliable method. The major advantage with this method is that the determination is made only on the active single-electron-donor species, i.e. LnX_2. Previously reported methods also include inactive species such as LnX_3 and therefore tend to overestimate the concentration of the reagent. This simple method of determining accurate concentrations of LnX_2 will therefore become useful among those working with single-electron-transfer reagents.

Experimental Section

Generation of SmI_2: Samarium powder (113 mg, 0.75 mmol, 1.5 equiv.) and iodine (127 mg, 0.5 mmol, 1 equiv.) were weighed and diluted with dried THF (5 mL) in a microwave-approved vessel inside a glove box under nitrogen. A magnetic stirrer bar was added, and the vessel was sealed. The mixture was inserted in the microwave oven and irradiated at 180 °C for 5 min to yield a dark blue solution of SmI_2 in THF, which could be used without further purification.

Volumetric Titration of SmI_2: SmI_2 was centrifuged, and the solution (5 mL) was added to a test tube containing a magnetic stirrer bar, located inside a glove box and fitted with a septum. Triethylamine (approximately 3 equiv.) and water (approximately 4 equiv.) were then added to the SmI_2 solution by syringe. While vigorously stirring, 2-heptanone diluted in THF (0.07 M) was added dropwise until the dark blue solution turned colourless with the formation of a white suspension, and the volume of added 2-heptanone was read. The final calculation of [SmI_2] could then be carried out using the balanced formula [Equation (1)].

General GC-Based Determination of the Active Amount of $SmBr_2$, SmI_2 and YbI_2: A solution or suspension of SmI_2 (5 mL) was added to a test tube containing a magnetic stirrer bar, located inside a glove box and fitted with a septum. Triethylamine (approximately 3 equiv.) and water (approximately 4 equiv.) were added into the SmI_2 solution by syringe. While vigorously stirring, excess 2-heptanone diluted in THF (0.070 M) (i.e. more ketone than would be possible to reduce with the estimated amount of the prepared lanthanide reagent) was added in one portion, which caused the solution to decolourise. With the use of gas chromatography, the amount of consumed 2-heptanone was determined with an internal standard added, e.g. 1-hexanol. The final calculation of [SmI_2] could then be performed according to Equation (1).

Supporting Information Available (see also the footnote on the first page of this article): UV/Vis spectra of THF solutions of SmI_2, YbI_2, $SmBr_2$ and EuI_2. Further experimental details are also included.

Acknowledgments

We thank the Swedish Research Council (Vetenskapsrådet) for financial support, and Knut and Alice Wallenberg for funding of the glove box. We also thank Personal Chemistry AB and AstraZeneca R&D in Mölndal for the microwave equipment.

Stabilization of a Copper(II) Complex by Hydrogen Bonds between the Axial Tetrafluoroborate Anion and the Ammonium Group from the Coordinated Cationic Ligand Bis(imidazol-2-yl)methyl(isopropyl)ammonium

Yufei Song,[a] Chiara Massera,[b] Patrick Gamez,[a] Anna Maria Manotti Lanfredi,[b] and Jan Reedijk*[a]

Keywords: Hydrogen bonds / Copper / EPR / N ligands

A new mononuclear copper complex [Cu(HIm-*i*Pr)$_2$(BF$_4$)$_2$](BF$_4$)$_2$·2CH$_3$OH {where Im-*i*Pr is [bis(imidazol-2-yl)methyl](isopropyl)amine} has been obtained by diethyl ether diffusion into a methanol solution of Im-*i*Pr and Cu(BF$_4$)$_2$. The complex has been characterized by X-ray analysis, UV/Vis, IR and EPR spectroscopy. Its crystal structure is built up by centrosymmetric [Cu(HIm-*i*Pr)$_2$(BF$_4$)$_2$]$^{2+}$ complex cations, BF$_4^-$ counterions and methanol lattice molecules. In the cation, the Cu atom exhibits a distorted octahedral CuN$_4$F$_2$ chromophore coordinated by two axial BF$_4^-$ ions and by four equatorial imidazole nitrogen atoms from two cationic HIm-*i*Pr ligands. The complex is stabilized by two intramolecular pseudo-chelate hydrogen bonds between the axial BF$_4^-$ ions and the ammonium nitrogen atoms of the HIm-*i*Pr ligand [N5···F8 = 2.761(5) Å].

Introduction

Copper ions, as centers of the active site of various metalloproteins, play an essential role in biological processes such as electron transfer, oxidation catalysis and dioxygen transport.[1] All copper proteins studied so far, except for the copper(I) metallothioneins, contain one or more imidazole residues of histidine, coordinated to the copper ions.[2] In the active site of the type-3 copper proteins, each copper ion is coordinated by three imidazole nitrogen atoms.[3]

Considerable progress in modeling the features of copper centers of type-3 copper proteins has been made, especially with the characterization of synthetic copper−dioxygen complexes.[4] In bioinorganic modeling studies frequently used ligand systems are based on pyridine, pyrazole,[5] and benzimidazole moieties.[6] Since side-chain imidazole coordination derived from histidine is very common in the active-site chemistry of copper proteins,[7] and imidazole-based ligand systems are relatively less reported,[8,9] there has recently been a great deal of interest in polyimidazole copper chemistry.

In the course of our research, [bis(imidazol-2-yl)methyl](isopropyl)amine (Im-*i*Pr, Figure 1), a bulky ligand with one amine and four imidazole nitrogen atoms, was synthesized by reaction of isopropylamine with the intermediate bis(imidazol-2-yl)nitromethane unit.[10] This potential tridentate ligand has been designed to investigate the coordination behavior and the binding properties of the bis(imidazol-2-yl) unit, which is present in most of the designed polyimidazole ligands.[11,12] Furthermore, the electronic effects of replacing aromatic rings like pyridine or imidazole with a short aliphatic chain such as isopropyl can be examined. All these studies are likely to provide important information for dioxygen binding chemistry. In this study, the crystal structure of the copper complex [Cu(HIm-*i*Pr)$_2$(BF$_4$)$_2$](BF$_4$)$_2$·2CH$_3$OH is presented. The complex is stabilized by hydrogen bonding between the axial BF$_4^-$ ions and the ammonium group from the cationic HIm-*i*Pr ligands that is thought to be the driving force for the formation of this unusual copper complex.

Results and Discussion

X-ray Crystal Structure Studies

The mononuclear copper complex with the formula $[Cu(HIm\text{-}iPr)_2(BF_4)_2](BF_4)_2{\cdot}2CH_3OH$ was obtained by reaction of 1 equiv. of Im-*i*Pr with 1 equiv. of $Cu(BF_4)_2$ in methanol. Diethyl ether diffusion into the methanolic solution led to the formation of blue crystals suitable for X-ray diffraction analysis. The structure formally contains two units of HBF_4. A molecular plot representing the complex, together with the atom-labeling scheme is shown in Figure 2.

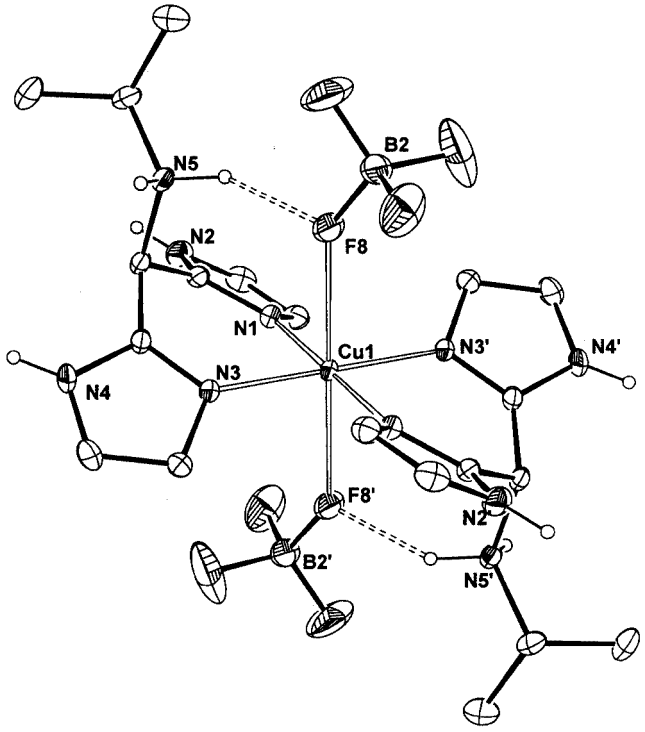

Figure 2. Thermal ellipsoid plot (20% probability level) of the mononuclear copper complex $[Cu(HIm\text{-}iPr)_2(BF_4)_2](BF_4)_2{\cdot}2CH_3OH$ showing the crystallographic numbering scheme; the hydrogen atoms at the C atoms, the non-coordinating BF_4^- ions and the methanol molecules have been omitted for clarity; selected bond lengths [Å] and angles [°]: Cu1−F8 2.493(3), Cu1−N1 2.011(3), Cu1−N3 1.995(3), N5···F8 2.761(5) (hydrogen bond); F8−Cu1−N1 91.4(1), F8−Cu1−N3 86.7(1), N1−Cu1−N3 86.4(1), N1−Cu1−N3a 93.56(11)

Its crystal structure consists of the $[Cu(HIm\text{-}iPr)_2(BF_4)_2]^{2+}$ cation (the −NH group of the Im-*i*Pr ligand is protonated in the course of the reaction to become an ammonium ion), free BF_4^- anions, and crystallization methanol molecules. The Cu^{II} ion, which in the $[Cu(HIm\text{-}iPr)_2(BF_4)_2]^{2+}$ moiety occupies the inversion center, is equatorially coordinated by four imidazole nitrogen atoms (N1, N3, N1′ and N3′) from two organic ligands [Cu1−N1 2.011(3), Cu1−N3 1.995(3) Å]. The coordination sphere is completed by coordination of two BF_4^- anions with a copper−fluoride distance of 2.493(3) Å, which is in good agreement with other values found in the literature,[13] to give a distorted octahedral environment. The complex is stabilized by two intramolecular interactions. The N5−H and N5′−H groups of the ammonium ions are in fact involved in pseudo-chelate hydrogen bonds with fluoride ions from the coordinated BF_4^- anions [N5···F8 2.761(4), H5···F8 1.94(4) Å; N5−H5···F8 144(3)°]. The cationic complexes are packed by weak intermolecular hydrogen bonds involving NH or CH groups from the cations, BF_4^- ions and methanol molecules. Also stacking interactions between the imidazole rings are present. The distance of the centroids between two least-squares imidazole planes is 3.532 Å.

The neutral ligand Im-*i*Pr has been designed to provide new information (for instance the coordinating behavior) in the field of the dioxygen binding chemistry. A general feature that is present in some imidazole-based ligands studied by our group is the [bis(imidazol-2-yl)methyl]amine unit; some examples are 1,1-bis(imidazol-2-yl)-4-(imidazol-4-yl)-2-azabutane (biib), 1,1-bis(imidazol-2-yl)-4-(pyrazol-1-yl)-2-azabutane (bipab), and 1,1-bis(imidazol-2-yl)-4-(pyridine-2-yl)-2-azabutane (bipyb).[9,11] With the potentially tetradentate ligands biib, bipab, and bipyb, dinuclear copper(II) complexes were formed by the sharing of two ligands between two Cu^{II} ions.[11] Due to steric effects, none of these tetradentate ligands can coordinate to a single Cu^{II} ion, but upon dimerization of the complexes, all four nitrogen donors of the ligands are able to coordinate to the copper atoms in a square-planar fashion. This coordination behavior, i.e. ligand sharing, is not observed with the present complex. Im-*i*Pr coordinates to the copper(II) ions in a bidentate fashion. The characteristic of the title complex $[Cu(HIm\text{-}iPr)_2(BF_4)_2](BF_4)_2{\cdot}2CH_3OH$ is that it contains a double intramolecular hydrogen-bond system, which is believed to be the driving force for the formation of the mononuclear copper complex.

Electronic Properties, EPR Spectra, ESI-MS and Conductivity Measurements

The UV/Vis spectrum of the complex in a methanol solution shows absorption bands centered at approximately 365 nm (ε = 2070 M^{-1} cm^{-1}) and 675 nm (ε = 460 M^{-1} cm^{-1}) in the range 300−800 nm. The absorption band at 365 nm is assigned to the charge-transfer transition from the imidazole nitrogen atoms to Cu^{II},[14] while the very weak absorption peak at 675 nm in the visible region of the electronic spectrum of the complex is assigned to d−d transitions of the Cu^{II} octahedral species.[15,16]

The EPR spectrum of a polycrystalline powder of the complex recorded at room temperature shows a typical axial spectrum with $g_{\|}$ = 2.22, $g_{\perp}$ = 2.07, and $A_{\|}$ = 200 G. The signals become sharper upon cooling to 77 K, but the hyperfine signals have not all been resolved.

The EPR analysis of the complex in a frozen solution of MeOH/DMSO (8:2) at 77 K shows a well-resolved axial spectrum with superhyperfine splitting superimposed on the equatorial absorption. The spectrum of the complex is redrawn in Figure 3 with $g_{\|}$ = 2.33, $g_{\perp}$ = 2.06, and $A_{\|}$ = 160 G as the dominant signals; the larger $g_{\|}$ values and the smaller $A_{\|}$ value already indicate a species different from

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that in the solid state. Further, not all nine expected superhyperfine lines with $A_{N\perp}$ = 15 G are resolved, not even at high dilution; this strongly suggests that the copper complex partly dissociates in the MeOH solution. At high dilution, the characteristic EPR lines for the Cu^{2+}−MeOH species ($g_{\|}$ = 2.42, $A_{\|}$ = 115 G)[15] become visible. The fact that the $g_{\|}$ value in the solid state is lower and the $A_{\|}$ value is larger than those in solution may suggest that two axially coordinated BF_4^- anions are dissociated in the methanol solution of the complex, as further confirmed by the ESI-MS and conductivity measurements.

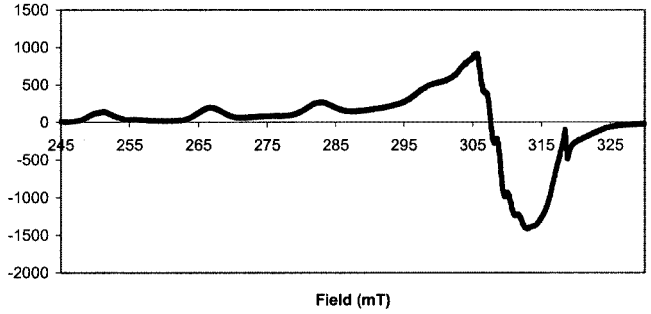

Figure 3. The EPR spectrum of the complex in a frozen solution of MeOH/DMSO (8:2) at 77 K

The conductivity measurement was performed at 25 °C on a 1 mM solution of the complex in MeOH. The value for the equivalent conductivity of the complex was found to be 275 $S{\cdot}cm^2{\cdot}mol^{-1}$, which agrees with a 3:1 type electrolyte in MeOH as the solvent.[17] The result indicates that at least one of the two axially coordinated BF_4^- anions are dissociated from the copper ion in the MeOH solution to form the 3:1 electrolyte (two non-coordinated BF_4^- anions in the crystal lattice of the complex already would have resulted in a 2:1 electrolyte).

The ESI mass spectrum of the complex was measured in MeOH. The most intensive peak at m/z = 206 corresponds to the free ligand Im-*i*Pr. Other major peaks observed at m/z = 450, 419, 391, and 325 correspond to the $[Cu(Im\text{-}iPr)(BF_4)(MeOH)_3]^+$, $[Cu(Im\text{-}iPr)(BF_4)(MeOH)_2]^+$, $[Cu(Im\text{-}iPr)(BF_4)(H_2O)_2]^+$, and $[Cu(HIm\text{-}iPr)_2(BF_4)_2]^{2+}$ cations, respectively; in fact the experimentally observed isotopic pattern is in very good agreement with the theoretical result of the isotope pattern calculation. The ESI mass spectrum of a mixture of the free ligand and $Cu(BF_4)_2$ gave very similar results. It seems that several species are present in the methanolic solution, which may arise from the electrochemical reduction of the copper complex during the electrospray process. Due to the very low solubility of the complex in non-coordinating solvents such as CH_2Cl_2, no information could be obtained with our experimental setup. Extensive studies would be needed to give more detailed information about the solution chemistry of the complex.

Conclusion

In summary, a new mononuclear copper complex has been obtained from the ligand Im-*i*Pr and $Cu(BF_4)_2$. The protonated cationic ligands HIm-*i*Pr coordinate to the copper(II) ion in a bidentate fashion, while two BF_4^- groups complete the distorted octahedral geometry around the metal atom. The complex is stabilized by intramolecular hydrogen bonds formed between the axially coordinated BF_4^- anions and the ammonium group of the ligand HIm-*i*Pr. The frozen-solution EPR spectrum of the complex in MeOH shows dissociation of the tetrafluoroborate anions. The higher $g_{\|}$ value in the solid state than in solution agrees with at least partial dissociation of the BF_4^- anions from the copper ion of the complex in MeOH, which is supported by solution conductivity data. Further studies on the dioxygen binding properties of the corresponding Cu^I complex are currently being carried out in our laboratories.

Experimental Section

General Remarks: All reagents and solvents were purchased from commercial sources and used as received. C, H, N analyses were carried out with a Perkin−Elmer 2400 series II analyzer. IR spectra were recorded with a Perkin−Elmer Paragon 1000 spectrophotometer equipped with a Golden Gate Diamond ATR device, using the diffuse reflectance technique. X-band EPR spectra were recorded at room temperature and at 77 K with a Jeol RE2X ESR spectrometer with DPPH (g = 2.0036) as a standard. The UV/Vis spectrum of the compound was recorded in the 250−800 nm range with a Cary 50 Varian UV/Vis/NIR spectrometer. Electrospray ionization mass spectra (ESI-MS, positive ion) in a methanol solution was recorded with a Thermo Finnigan AQA apparatus. The conductivity measurement was performed with a Philips PW 9526 digital conductivity meter and PW 9551/60 measuring cell with a 1 mM solution of the complex in methanol.

Synthesis of [Bis(imidazol-2-yl)methyl](isopropyl)amine (Im-*i*Pr): Isopropylamine (0.26 g, 4.36 mmol) was added to a solution of the hydrochloride salt of bis(imidazol-2-yl)nitromethane[10] (1.0 g, 4.36 mmol) in sodium hydroxide (10 mL of a 2.0 M of solution). The solution was stirred at 80 °C for more than 2 h and then cooled to room temperature. A white product precipitated from the solution. The precipitate was filtered, and the desired product was washed with small amounts of ethanol and diethyl ether. Yield: 40% (0.36 g). ^1H NMR (200 MHz, CD_3OD, 25 °C, 0−10 ppm): δ = 7.10 (s, 4 H, Im-H), 5.28 (s, 1 H, CH), 2.66 (m, 1 H, CH), 1.10 (d, 6 H, CH_3) ppm. ESI-MS: m/z = 206.1 $[M + H]^+$.

Preparation of the Copper Complex $[Cu(HIm\text{-}iPr)_2(BF_4)_2]\cdot(BF_4)_2\cdot 2CH_3OH$: A solution of the ligand Im-*i*Pr (16.4 mg, 0.08 mmol) in MeOH (5 mL) was added to a solution of $Cu(BF_4)_2\cdot 6H_2O$ (27.6 mg, 0.08 mmol) in MeOH (5 mL). The reaction mixture was stirred for 15 min until the solution was completely clear, then it was filtered. Slow diethyl ether diffusion into the filtrate for several days led to the formation of blue crystals suitable for X-ray analysis. Yield: 30% (10.6 mg). $C_{22}H_{40}B_4CuF_{16}N_{10}O_2$ (887.42): calcd. C 29.8, H 4.5, N 15.8; found

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

C 30.2, H 4.9, N 15.3. IR (solid): $\tilde{\nu}$ = 3339.9, 1569.5, 1471.3, 1393.7, 1009.6, 764.3, 697.1, 519.8, 442.2 cm^{-1}.

X-ray Crystallographic Study: The molecular structure of $[Cu(HIm\text{-}iPr)_2(BF_4)_2](BF_4)_2\cdot 2CH_3OH$ was determined by single-crystal X-ray diffraction methods. Crystallographic and experimental details for the structure are summarized in Table 1. Intensity data and cell parameters were recorded at room temperature (25 °C) with a Philips PW 1100 single-crystal diffractometer using graphite-monochromated Mo-K_α radiation and the θ/2θ scan technique. A correction for absorption was made (maximum and minimum value for the transmission coefficient was 1.000 and 0.5472).[18] The structure was solved by Direct Methods using the SIR97 program[19] and refined on F_o^2 by full-matrix least-squares procedures, with the SHELXL-97 program.[20] All non-hydrogen atoms were refined with anisotropic atomic displacements. The hydrogen atoms were included in the refinement at idealized geometry (C−H 0.95 Å) and refined "riding" on the corresponding parent atoms, with the exception of H4, H5NA, H5NB, H8, and H1S, which were located in the difference Fourier map. The weighting scheme used in the last cycle of refinement was $w = 1/[\sigma^2F_o^2 + (0.1758P)^2]$ [where $P = (F_o^2 + 2F_c^2)/3$]. Molecular geometry calculations were carried out with the PARST97 program[21]. Drawings were obtained by ORTEP3 in the WinGX suite.[22] All calculations were carried out with a DIGITAL Alpha Station 255 computer. CCDC-235117 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Novel Phosphovanadate Layered Structure Assembled from a Tetrametallic Cubane-Like V^V Cluster

Fa-Nian Shi,[a] Filipe A. Almeida Paz,[b] João Rocha,*[a] Jacek Klinowski,[b] and Tito Trindade[a]

Keywords: Organic-inorganic hybrid / Hydrothermal synthesis / Oxo ligands / Vanadium

A novel phosphovanadate layered structure intercalated by 4,4′-bipyridinium cations, $(C_{10}H_{10}N_2)[(VO_2)_4(PO_4)_2]$, was synthesised under hydrothermal conditions and its crystal structure determined using single-crystal X-ray diffraction. The anionic $[(VO_2)_4(PO_4)_2]_n^{2n-}$ perforated layers are strongly hydrogen bonded to the interlayer 4,4′-bipyridinium cations and are assembled by an unprecedented secondary tetrametallic V^V building unit constructed from a distorted cubane-like $\{V_4O_4\}$ cluster. The compound was further characterised by IR, Raman, ^1H, ^1H-^{13}C, ^{31}P and ^{51}V MAS NMR spectroscopy, and by thermal and elemental analysis.

Introduction

Much attention has been given to the synthesis of organic-inorganic hybrid compounds given their ability to combine features from both organic and inorganic building units, leading to novel materials with interesting architectures and potential applications. Vanadium, one of the most versatile transition metals through the combination of its three distinct oxidation states with the several possible coordination geometries,[1] has been extensively used as one of the primary building blocks in transition metal phosphates, which can be employed in functional materials due to their unusual catalytic, magnetic, electrical and optical properties.[2] Solvothermal synthetic conditions provide a versatile route for the synthesis of such materials; organic molecules are usually added to the reactive mixtures. These molecules can coordinate to the metal centres,[3] or act as structure-directing agents, templates, counterions or simply as space-filling molecules.[1,4] In this context, special interest has been given to layered structures and their intercalation by a variety of guest molecules.[1]

Following our interest in hybrid materials containing bridging organic ligands[5,6] and, in particular, vanadium centres,[6,7] we wish to report the preparation and structural characterisation of a novel phosphovanadate layered structure intercalated by 4,4′-bipyridinium cations, $(C_{10}H_{10}N_2)[(VO_2)_4(PO_4)_2]$ (**I**). The anionic layers are assembled by an unprecedented secondary tetrametallic V^V building unit that exhibits a distorted cubane-type structural motif. Other tetrametallic vanadium cores of the $\{V_4O_4\}$ type have already been investigated: those that exhibit the boat conformation (involving two pairs of edge-sharing octahedra connected by two corner-sharing oxygen atoms) or the chair conformation (where each VO_6 octahedron is edge-shared by two neighbouring octahedra).[8] Although the formation of cubane-type clusters is a characteristic structural motif in the coordination chemistry of many different metal centres,[9] only vanadium thiocubane clusters $\{V_4S_4\}$ have been described.[10] Thus, to the best of our knowledge, compound **I** is the first material containing such a structural motif assembled by VO_6 octahedra that are further bridged by phosphate groups (Scheme 1).

Results and Discussion

Crystal Description

The product of the hydrothermal reaction between vanadium(v) oxide, phosphoric acid and 4,4′-bipyridine (4,4′-bpy; see Exp. Sect.) was analysed by single-crystal X-ray diffraction (Table 1) and elemental analysis, and formulated as $(C_{10}H_{10}N_2)[(VO_2)_4(PO_4)_2]$ (**I**) (where $C_{10}H_{10}N_2^{2+}$ = 4,4′-$bpyH_2^{2+}$ = 4,4′-bipyridinium). A direct comparison between the experimental powder X-ray diffraction (PXRD) pattern and a simulation based on single-crystal data confirms phase purity and homogeneity of the bulk sample, despite the presence of a few reflections attributed to strong preferential orientation of the compound.

	$wR2$ = 0.1022
Largest diff. peak and hole	0.641 and −0.666 e·Å^{-3}

The compound contains four crystallographically unique V^V centres distributed along two independent, but topologically identical, tetrametallic secondary building units (SBUs, {V(1),V(4)} and {V(2),V(3)}) that exhibit a distorted cubane-type structural motif (Figure 1) in which each VO_6 octahedron shares edges (belonging to the same face) with the three neighbouring octahedra (Figure 2). In these clusters, formed by twofold rotation axes perpendicu-

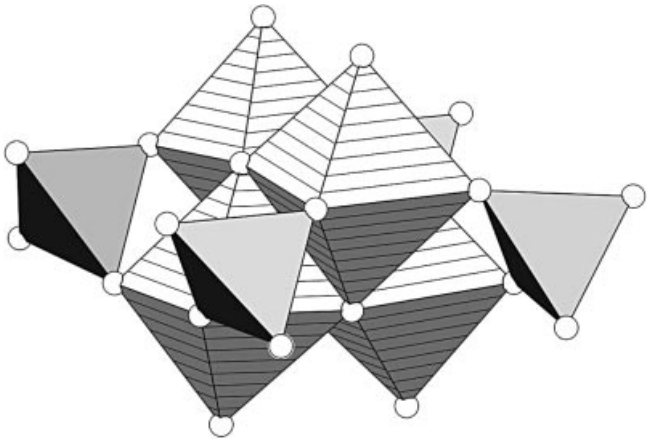

Figure 2. Polyhedral representation of a $\{(V_4O_8)(PO_4)_4\}$ secondary building unit; each VO_6 octahedron is edge-shared (from the same face) with the three neighbouring octahedra, leading to a tetrametallic tetrahedral V^V core

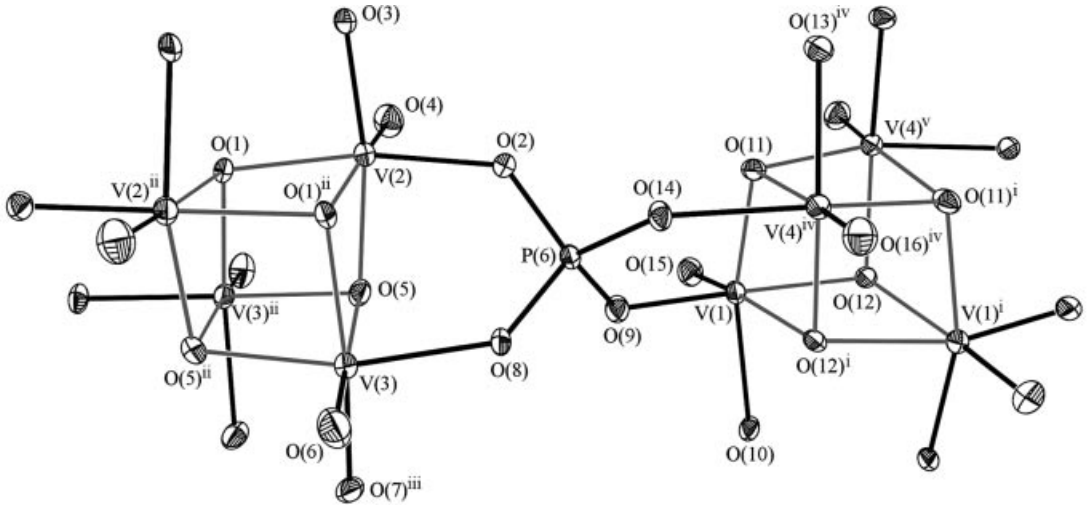

Figure 1. Tetrametallic secondary building units {V(1),V(4)} and {V(2),V(3)}, which form the two-dimensional perforated $[(VO_2)_4(PO_4)_2]_n^{2n-}$ anionic layer; atoms are represented as ellipsoids drawn at the 50% probability level; V···V distances within each SBU: V(1)···V(1)^i 3.3619(18) Å, V(1)···V(4)^{iv} 3.3593(12) Å, V(1)···V(4)^v 2.8031(11) Å, V(4)^{iv}···V(4)^v 3.3758(16) Å, V(2)···V(2)^{ii} 3.3543(16) Å, V(2)···V(3) 3.3322(11) Å, V(2)···V(3)^{ii} 2.8162(11) Å, V(3)···V(3)^{ii} 3.3628(18) Å; for bond lengths and angles see Tables 2 and 3; symmetry codes used to generate equivalent atoms: (i) 1 − *x*, *y*, 1/2 − *z*, (ii) −*x*, *y*, 1/2 − *z*, (iii) *x*, −1 + *y*, *z*, (iv) 1 − *x*, 1 + *y*, 1/2 − *z*, (v) *x*, 1 + *y*, *z*

lar to the *ac* plane, the coordination environment of each V^V centre resembles the typical 1+4+1 coordination type described by Boudin et al., with the observed short, intermediate and long (V−O) bonds within the expected ranges reported by the same authors (Table 2 and Table 3).[11] The core of each cluster consists of a tetrametallic V_4 tetrahedron: each face is capped by a μ_3−O ligand that is equatorially coordinated to two octahedra, $O_{equatorial}$, and also occupies the *trans* position to the oxo group of a third octahedron, O_{trans} (Figure 1). The registered V···V, V−$O_{equatorial}$ and V−O_{trans} distances are within the ranges, 2.8031(11)−3.3758(16) Å, 1.841(3)−1.933(3) Å and 2.426(3)−2.462(3) Å, respectively (Table 2; see caption of Figure 1 for detailed V···V distances). Phosphate groups appear with two distinct structural functions: on the one hand, within each SBU, they link adjacent V^V centres along the edges of the V_4 tetrahedra (Scheme 1, Figures 1 and 2); on the other hand, they establish physical links between adjacent V_4 tetrahedra. In fact, the parallel linking in the *ab* plane through the phosphate groups of the two previously mentioned SBUs leads to a two-dimensional (2D) anionic $[(VO_2)_4(PO_4)_2]_n^{2n-}$ layer, topologically described as a distorted (4,4) net,[12] which is further perforated by eight-membered rings to form pores with an effective cross-section of ca. 2.5 × 2.5 Å (Figure 3).

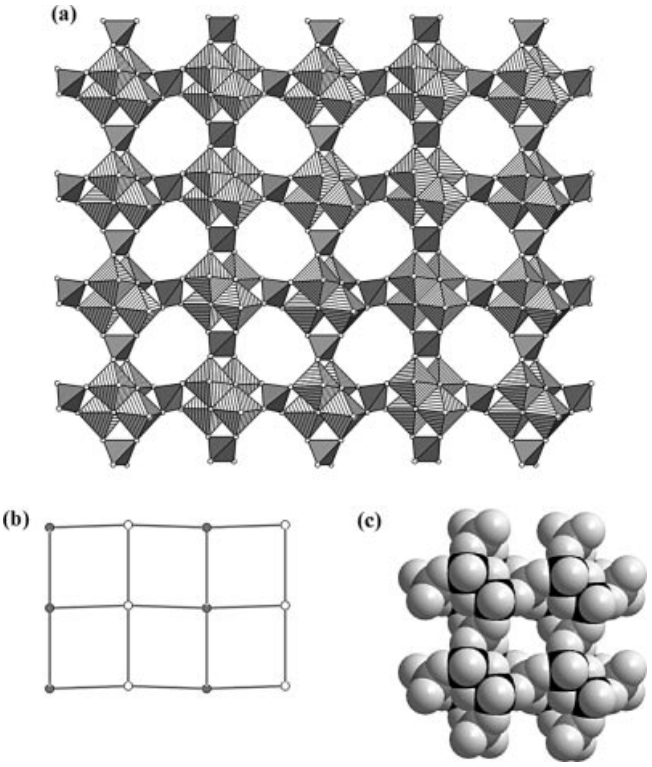

Figure 3. (a) View along the *c* direction of a polyhedral representation of the $[(VO_2)_4(PO_4)_2]_n^{2n-}$ anionic layer, (b) topological representation of the anionic layer which describes a typical (4,4) net (the grey- and white-filled nodes represent the two distinct tetrametallic SBUs), (c) space-fill representation of a portion of the anionic layer showing the pores which have a cross-section of about 2.5 × 2.5 Å

Charge-balancing and space-filling 4,4′-bipyridinium cations are positioned above and below the anionic $[(VO_2)_4(PO_4)_2]_n^{2n-}$ layers, just over the previously mentioned pores (Figure 4). These cations are further connected to the layers through two very strong and highly directional N^+−H···O hydrogen bonds, thus acting as a hydrogen-bonded pillar. The caption of Figure 5 contains further details of the hydrogen-bonding geometry.

Solid-State MAS NMR Spectroscopy

The ^1H, ^{13}C, ^{31}P and ^{51}V NMR spectra fully support the crystal structure. Fast (30 kHz) sample spinning averages out the $^1H-^1H$ dipolar interaction, leading to a highly resolved ^1H MAS NMR spectrum (Figure 6a). The 4,4′-bipyridinium cation contains three magnetically nonequivalent ^1H nuclei, labelled H_a, H_b and H_c, which resonate at ca. 15.5, 9.3 (shoulder) and 8.8 ppm, respectively. The $(H_b + H_c)/H_a$ intensity ratio is 4, in accordance to the expected site populations. The ^{13}C CP/MAS NMR spectrum exhibits peaks at ca. 150.6, 145.0 and 124.7 ppm, which are assigned to C_a, C_b and C_c, respectively (Figure 6b). Together, the ^1H and ^{13}C NMR spectra confirm the integrity of the 4,4′-bipyridinium cation.

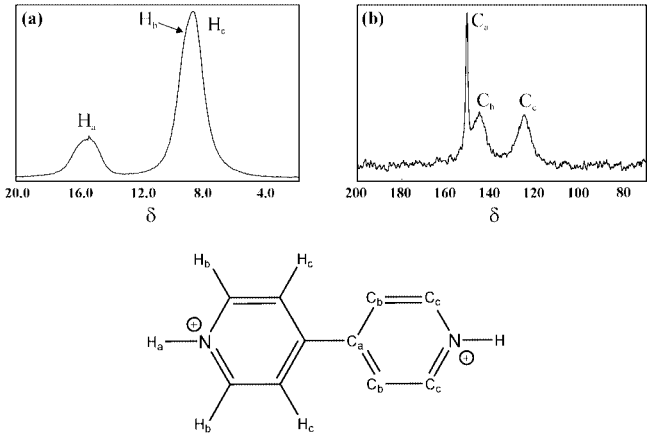

Figure 6. (a) ^1H MAS and (b) ^1H-^{13}C CP MAS NMR spectra, showing the assignment of ^1H and ^{13}C resonances

The ^{31}P MAS NMR spectrum consists of a single peak centred at about −5.2 ppm with a shoulder at about −6.8 ppm which was deconvoluted into three resonances at −6.4, −5.5 and −4.5 in a 1:2:1 intensity ratio, respectively. This is in good agreement with the crystal structure (Figure 7).

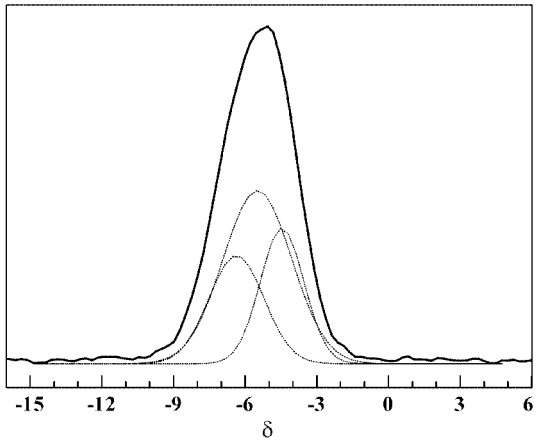

Figure 7. Experimental and simulated ^{31}P MAS NMR spectra

Because of relatively large chemical shift anisotropy, the ^{51}V MAS NMR spectrum exhibits strong spinning sidebands even with MAS at 30 kHz. Three peaks are observed at −580.1, −593.4 and −599.2 ppm in a 2:1:1 intensity ratio, respectively. Since the crystal structure calls for the presence of four nonequivalent V sites, we assume that the peak

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

at δ = −579.9 ppm consists of two overlapping resonances (Figure 8).

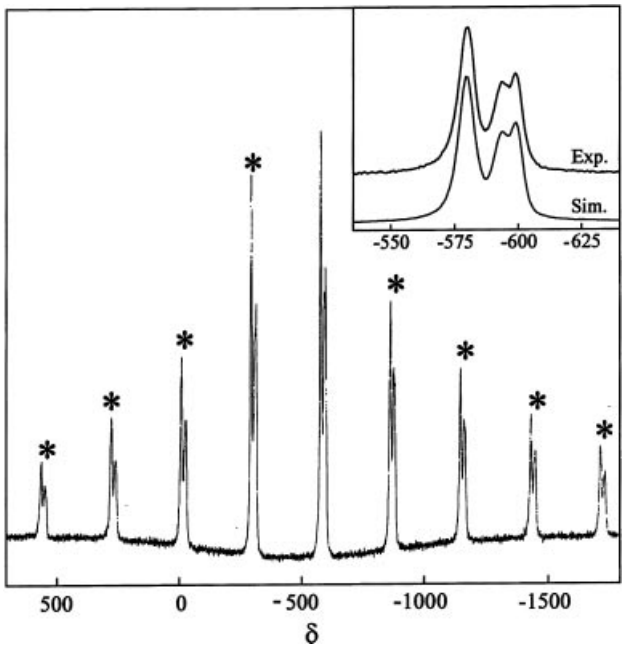

Figure 8. ^{51}V MAS NMR spectrum; the inset shows a magnification of the isotropic peaks (top) and a simulation (bottom) performed with Lorentzian-Gaussian lines (a fair assumption because the second-order quadrupole effects are not significant); asterisks depict spinning sidebands

Thermal Analysis

Thermal treatment reveals that **I** is stable up to ca. 370 °C, as no weight losses were registered. In the 370−800 °C temperature range, the compound undergoes thermal decomposition through five distinct and well-defined steps (as observed in the derivative thermogravimetric analysis), with a total weight loss of 28.3%. This decomposition is attributed to the simultaneous oxidation of the organic component and reduction of half of the V^V centres, leading to the formation of an intermediate inorganic $(V^{IV}_2V^V_2)O_{14}P_2$ phase that contains mixed-valence vanadium centres [72.0% calculated and 71.7% observed residues; Equation (1)]. Between 800 and 900 °C, a continuous weight increase of ca. 1.3% clearly indicates the occurrence of an oxidative process. Indeed, as usually observed in related compounds, traces of oxygen within the apparatus promotes partial oxidation of some V^{IV} centres from the $(V^{IV}_2V^V_2)O_{14}P_2$ intermediate phase, leading to a new mixed-valence phase formulated as $(V^{IV}V^V_3)O_{14.5}P_2$ [73.0% calculated and 73.2% observed residues; Equation (2)].

$$(C_{10}H_{10}N_2)\left[(VO_2)_4(PO_4)_2\right] \xrightarrow[(decomposition\ in\ 5\ steps)]{\Delta} (V^{IV}_2V^V_2)O_{14}P_2 \quad (1)$$

$$(V^{IV}_2V^V_2)O_{14}P_2 \xrightarrow[traces\ of\ O_2]{\Delta} (V^{IV}V^V_3)O_{14.5}P_2 \quad (2)$$

Vibrational Spectroscopy

The IR and Raman spectra contain the most significant diagnostic bands associated with the primary building units of $(C_{10}H_{10}N_2)[(VO_2)_4(PO_4)_2]$. On the one hand, strong bands centred at 990, 970 and 943 cm^{-1} in the IR spectrum (in 976 and 991 in the Raman spectrum) are due to the typical stretching vibrational mode of terminal $V^V{=}O$ double bonds; on the other, bands at 1088 and 1061 cm^{-1} are assigned to the PO_4^{3-} antisymmetric stretching vibrational modes, while those found at 856 and 839 cm^{-1} can be attributed to the related PO_4^{3-} symmetric stretching modes. Several bands observed in the 650−500 cm^{-1} region are also associated with V−O−V stretching vibrational modes, and several intense bands between 1300 and 1640 cm^{-1} arise from the presence of the 4,4′-bipyridinium cations that occupy the interlayer spaces.

Conclusion

A new structure containing 2D anionic $[(VO_2)_4(PO_4)_2]_n^{2n-}$ layers intercalated by 4,4′-bpyH_2^{2+} cations was synthesised by the hydrothermal method and characterised structurally using a variety of techniques. This intercalated phosphovanadate is an important addition to vanadium coordination chemistry as it constitutes the first report of typical $\{V_4O_4\}$ cubane-like clusters. We are currently investigating the intercalation reactions of this compound, particularly the possibility of replacing the 4,4′-bpyH_2^{2+} cations by other organic molecules, and the corresponding structural modifications.

Experimental Section

General: Chemicals were readily available from commercial sources and were used as received without further purification. Syntheses were carried out in PTFE-lined stainless steel reaction vessels (40 cm^3), under autogenous pressure and static conditions in a preheated oven at 140 °C. Reactions took place over a period of 3 days, after which the vessels were removed from the oven and left to cool to ambient temperature before opening. Compounds proved to be air- and light-stable, and insoluble in water and common organic solvents.

Preparation and Structural Characterisation of $(C_{10}H_{10}N_2)[(VO_2)_4(PO_4)_2]$ (I): A yellow suspension containing V_2O_5 (0.140 g, Aldrich), H_3PO_4 (0.450 g, min. 85% Merck) and 4,4′-bipyridine (0.120 g, Fluka) in distilled water (ca. 10 g) was stirred thoroughly for 30 minutes at ambient temperature. The suspension, with a molar composition of ca. 1.0:6.0:1.0:722, respectively, was transferred to the reaction vessel, which was then placed inside the preheated oven. After reacting, the vessel was allowed to cool slowly to ambient temperature to yield a large amount of yellow blocks, which were manually harvested, air-dried for X-ray diffraction analysis and identified as **I**, and a small amount of an unknown pale-green microcrystalline powder. The two phases were readily ultrasonically separated (for 10 minutes), followed by vacuum filtration and washing with copious amounts of distilled water. $C_{10}H_{10}N_2O_{16}P_2V_4$ (based on single-crystal data, 679.90): calcd. H 1.48; found C 18.07, N 4.26, H 1.49. TGA data (weight losses and increases) and derivative thermogravimetric peaks (DTG; in parenthesis): 370−450 °C, −8.4% (425 °C); 450−800 °C, −19.9% (540, 621, 661 and 771 °C); 800−900 °C, +1.3% (849 °C).

Selected IR and Raman data in cm^{-1}): 1639 vs (1645), 1620 vs (1623), 1488 s, 1459 m, 1417 m, 1375 s (1367), 1340 m, 1088 vs (1074), 1061 vs, 990 vs, 970 vs, 943 s, 856 m, 839 m, 793 s, 654 m, 622 s, 610 m, 590 m, 503 vs.

Characterisation: Elemental analyses for C, H and N were performed on an Exeter Analytical CE-440 Elemental Analyser (University of Cambridge). Samples were combusted under oxygen at 975 °C, with He as the purge gas.
FT-IR spectra were measured from KBr disks (Aldrich, 99%+, FT-IR grade) on a Matson 700 FTIR spectrometer, and FT-Raman spectra were collected on a Bruker RFS 100 with a Nd:YAG coherent laser (λ = 1064 nm).
Thermogravimetric analyses (TGA) were carried out on Shimadzu TGA-50, with a heating rate of 10 °C/min, under nitrogen with a flow rate of 20 cm^3/min.
Powder X-ray diffraction patterns were recorded at room temperature on a Philips X'Pert diffractometer, operating with a monochromated Cu-K_α radiation source at 40 kV and 50 mA. Simulated powder patterns were based on single-crystal data, and calculated with the STOE Win XPOW software package.[13]
^{1}H, ^{13}C, ^{31}P and ^{51}V solid-state NMR spectra were recorded at 400.12, 100.61, 160.0 and 105.24 MHz, respectively, on a Bruker Avance 400 spectrometer. ^{1}H and ^{31}P MAS NMR spectra were recorded with a 30 kHz spinning rate, 40° rf pulses and recycle delays of 6 and 70 s, respectively. ^{1}H- ^{13}C cross-polarisation (CP) MAS NMR spectra were acquired with 4 μs ^{1}H 90° pulses, a contact time of 2 ms and a recycle delay of 5 s. ^{51}V MAS NMR spectra were recorded with short, 0.6 μs (equivalent to 10°), pulses and a recycle delay of 5 s. Chemical shifts are quoted in ppm from TMS (^{1}H and ^{13}C), 85% H_3PO_4 (^{31}P) and $VOCl_3$ (^{51}V).

X-ray Crystallographic Studies: Suitable single crystals were mounted on a glass fibre using perfluoropolyether oil.[14] Data were collected at 180(2) K on a Nonius Kappa charge-coupled device (CCD) area-detector diffractometer (Mo-K_α graphite-monochromated radiation, λ = 0.7107 Å) equipped with an Oxford Cryosystems cryostream and controlled by the Collect software package.[15] Images were processed with the software packages Denzo and Scalepack,[16] and the data were corrected for absorption by the empirical method employed in Sortav.[17] The structure was solved by the direct methods of SHELXS-97[18] and refined by full-matrix least-squares on F^2 using SHELXL-97.[19]

All non-hydrogen atoms were directly located from difference Fourier maps and refined with anisotropic displacement parameters. The crystallographically unique H-atoms associated with the 4-pyridinium groups were also located from difference Fourier maps, and refined with independent isotropic displacement parameters and a common N−H distance restrained to 0.98(1) Å. Hydrogen atoms attached to carbon were located at their idealised positions using the HFIX 43 instruction in SHELXL, and included in the refinement in riding-motion approximation with an isotropic thermal displacement parameter fixed at 1.2 times U_{eq} of the atom to which they are attached. The last difference Fourier map synthesis shows the highest peak (0.641 e·Å^{-3}) located at 1.42 Å from O(11), and the deepest hole (−0.666 e·Å^{-3}) at 0.79 Å from V(2). Cavity dimensions were calculated by overlapping rigid spheres with van der Waals radii for each element: O 1.52 Å, P 1.8 Å and V 2.0 Å. CCDC-221172 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Theoretical Studies of a Double Helical Complex with the Ligand 4′,4′′′-Bis(ferrocenyl)-2,2′:6′,2′′:6′′,2′′′:6′′′,2′′′′-quinquepyridine

Javier E. Aguado,[a] Maria José Calhorda,[b] Paulo J. Costa,[b] Olga Crespo,[a] Vitor Félix,[c] M. Concepción Gimeno,[a] Peter G. Jones,[d] and Antonio Laguna*[a]

Keywords: Quinquepyridine / Silver / Helical complexes / Ferrocenyl derivatives / Theoretical studies

4′,4′′′-Bis(ferrocenyl)-2,2′:6′,2′′:6′′,2′′′:6′′′,2′′′′-quinquepyridine (Fc_2qpy) reacts with AgOTf (OTf = trifluoromethylsulfonate) to give a complex of stoichiometry [Ag(Fc2qpy)]-OTf. The crystal structure reveals a dinuclear arrangement among the cations with an Ag···Ag close contact of 3.089(2) Å. The ligands are wrapped around the silver atoms in a double helical array. Further hydrogen bonding between triflate units and the protons of the ferrocene or pyridine moieties results in a supramolecular structure. Theoretical studies confirm the existence of a weak Ag–Ag bond, and show that the dinuclear form can be more stable than the mononuclear one, when there is a favorable balance between the reorganization energy of the two quinquepyridine chains and the energy released by the formation of stronger Ag–N bonds and the new Ag–Ag interaction in the helix.

Introduction

The construction of inorganic supramolecular arrays based on covalent interactions, hydrogen bonding, or other intermolecular interactions is a very interesting area of functional materials.[1−6] Oligopyridines have been used as building blocks for the self-assembly of double helical transition-metal complexes.[3−6] The close proximity between the bipyridine or terpyridine units, which is essential for the formation of the double helical complexes, leads to substantial π-π interactions, but also to some constraints upon complex formation. 2,2′:6′,2′′:6′′,2′′′:6′′′,2′′′′-quinquepyridine (qpy) has a rich transition metal coordination chemistry because of its ability to promote tetrahedral, square planar or octahedral geometries.[7−31] There are several coordination modes, the important ones in the formation of metal helicates being those which lead to the partitioning of the ligand into bidentate and tridentate units. This happens, for example, with several first row transition metals. For metals that have no electronic preference for geometry, the assembly is dictated by the size of the metal ion and the available bonding cavity. For the quinquepyridine ligand in a planar configuration, Constable et al. have shown that the five nitrogen atoms form an effective hole-size ca. of 2.45 Å which corresponds to a pentagonal-planar geometry for metals with an ionic radius 1.0 ± 0.1 Å, and such a geometry has been demonstrated for silver(I) in the complex [Ag(qpy)]PF_6.[7] The introduction of sterically demanding substituents to the quinquepyridine can be expected to increase the effective hole-size of the bonding cavity. Consequently, silver(I) is too small to be accommodated by the ligand in a planar pentadentate mode, and supramolecular helical structures can then be achieved. There are few examples of doubly helical silver complexes with quinquepyridine ligands. In the complex $[Ag_2(dmpqpy)_2](ClO_4)_2 \cdot 2H_2O$ (dmpqpy = 6,6′′′′-dimethyl-4′,4′′′-diphenyl-2,2′:6′,2′′:6′′,2′′′:6′′′,2′′′′-quinquepyridine)[31] the ligand acts as tetradentate donor, and the central pyridine nitrogen atoms play the role of rigid spacers, rather than of donor atoms. The silver center is also tetracoordinate in the heterodinuclear derivative $[AgCo(qpy)_2]^{3+}$.[19] Pentacoordinated silver atoms are present in $[Ag_2(dmqpy)_2](ClO_4)_2$ (dmqpy = 6,6′′′′-dimethyl-2,2′:6′,2′′:6′′,2′′′:6′′′,2′′′′-quinquepyridine).[31]

Here we report on the synthesis of the Ag^I complex of the 4′,4′′′-bis(ferrocenyl)-2,2′:6′,2′′:6′′,2′′′:6′′′,2′′′′-quin-

quepyridine ligand. The crystal structure of the silver(I) derivative shows a double helical arrangement with a short Ag···Ag interaction. Both silver(I) atoms have slightly different geometries. One can be considered as pentacoordinate with an elongated trigonal bipyramidal geometry, and the other as tetracoordinate with a tetrahedral geometry. Theoretical studies have been carried out addressing the formation of the silver(I)-silver(I) interaction as well as the difference in energy between the mononuclear and the dinuclear complexes.

Results and Discussion

Synthesis

The ligand 4′,4′′′-bis(ferrocenyl)-2,2′:6′,2′′:6′′,2′′′:6′′′,2′′′′-quinquepyridine (Fc_2qpy) reacts with AgOTf to give a deep-red solution, from which a complex of stoichiometry [Ag(Fc_2qpy)]OTf was isolated. The X-ray structure confirms that the complex is in fact dimeric with a double helical structure [Equation (1)].

The positive liquid secondary-ion mass spectrum (LSIMS+) exhibits a peak at m/z = 863 (100%), which can be assigned to the cationic molecular peak $[Ag(Fc_2qpy)]^+$. No peaks corresponding to the dinuclear species $[Ag_2(Fc_2qpy)_2]^{2+}$ or $[Ag_2(Fc_2qpy)_2(OTf)]^+$ were detected. The ^{1}H NMR spectrum of [Ag(Fc_2qpy)]OTf shows the signals arising from the protons of the ferrocenyl moieties at δ = 4.12, 4.63, and 4.95 ppm in a ratio 10:4:4. This corresponds to the unsubstituted cyclopentadienyl, and to the α and β protons of the substituted cyclopentadienyl groups, respectively. Five multiplets arise from the quinquepyridine protons, although some of them are overlapping.

Crystal Structure of [Ag(Fc_2qpy)]OTf

The crystal structure of $[Ag\{Fc_2(qpy)\}]_2(OTf)_2 \cdot 3CH_2Cl_2$ has been determined by X-ray diffraction (Figure 1). A selection of bond lengths and angles appears in Table 1. The cation displays a double-helical arrangement, achieved by a series of twists. The dihedral angles between adjacent pyridine planes 8 and 7 (9.5°), 7 and 6 (28.4°), 6 and 9 (38.6°), and 9 and 10 (5°) in one ligand, and between planes 5 and 4 (3.5°), 4 and 1 (32°), 1 and 2 (35.5°), and 2 and 3 (14.2°) in the other (planes are numbered after the nitrogen atoms they contain) confirm that the major twisting in each ligand occurs between the central pyridyl ring and the 2,2′-bipyridyl fragments.

The twisting can be seen more clearly from the space-filling diagram (Figure 2). The helical radius is about a/3,

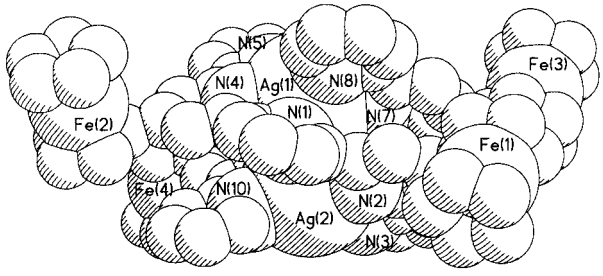

Figure 2. Space filling diagram of the cation in $[Ag_2(Fcqpy)_2](OTf)_2$

4.5 Å and the pitch height about *a*/2, 7 Å. A very distorted trigonal bipyramidal disposition results for one silver atom, upon coordination to three nitrogen atoms of one [Fc_2qpy] ligand, and two from the other [equatorial Ag−N distances 2.323(9), 2.341(9), 2.395(11) Å, axial 2.516(11), 2.550(10) Å]. The atoms N4, N5, N7, and Ag1 lie in the same plane, and the angle between this plane and the plane N8, N6, N7, Ag1 is 60.2°. The other silver atom is bonded to two nitrogen atoms from each ligand. This four-coordinate metal center [Ag−N distances 2.329(9)−2.418(11) Å] shows a very irregular geometry. The dihedral angle between planes N9−Ag2−N10 and N2−Ag2−N3 is 55.3°. This points to a geometry intermediate between tetrahedral and square planar. Thus, in this complex, the two silver(I) atoms exhibit different coordination modes to the quinquepyridine moieties. This is unprecedented since, in metal complexes with this type of ligand, the same coordination has always been observed for both metal ions, for example in $[M_2X(qpy)]^{3+}$ (M = Cu, Co, Ru),[9,10,13,20] or $[M_2X\{(SMe)_2qpy\}_2]^{3+}$ (M = Cu, Ni),[28,29] where the metallic centers are hexacoordinate. Only in complexes which contain two metals in different oxidation states, such as in $[Cu_2(R_2qpy)_2]^{3+}$ (R = SMe, Ph),[28,30] is it possible to find different geometries. Here Cu^{I} is tetrahedral, whereas Cu^{II} is octahedral.

Despite the covalence of the bonding to each silver atom in the compound, the Ag−N distances are within the expected range. The Ag(1)···Ag(2) contact of 3.089(2) Å in $[Ag_2(Fc_2qpy)_2](OTf)_2$ is shorter than in the related examples with qpy derivatives, i.e. 3.48 Å in $[Ag(dmqpy)_2](ClO_4)_2$,[31] and 3.22 Å in $[Ag(dmpqpy)_2](ClO_4)_2\cdot 2H_2O$,[31] but close to those found in complexes with ligands based on terpyridine (terpy) or quaterpyridine (qtpy) units, e.g. $[Ag_2(qtpy)_2](BF_4)_2$ [3.107(2) Å],[34] and $[Ag_2(terpy)_2](PF_6)_2$ (2.914−2.940 Å in each double helical di-silver unit, Ag···Ag contacts of 3.107, 3.156 Å with a second dinuclear unit to form tetranuclear blocks).[33] The distances of the silver atoms Ag1 or Ag2 to the same silver atoms of different units are 7.47 and 6.57 Å, respectively. In $[Ag_2(Fc_2qpy)_2](OTf)_2$ the twisting angles are smaller than in the silver derivatives $[Ag_2(dmqpy)_2](ClO_4)_2$,[31] (major twist angle 47.2°, between terpyridyl and bipyridyl fragments) or $[Ag(dmpqpy)_2](ClO_4)_2\cdot 2H_2O$ (major twist angles 36.8°, 36.1°, in this case between the two bipyridyl fragments and the central ring).[31] These values are in accordance with a shorter silver···silver contact. It has been suggested that it is the steric effect of the terminal groups in flexible ligands with various donor atoms that forces the ligand to adopt a double helical disposition, since the planar configuration is not possible. Four factors seem to govern the formation of a double helical complex, namely the ligand donor set, the coordination geometry of the metal ion, the metal-ion radius, and the substituent effects. These three helical complexes allow an analysis of the effect of the substituents, since the ligand (qpy) and the metal ion (Ag^+) are common to all. The bulkier ferrocene moiety affords the smallest twist angles and, thus, the shortest silver···silver interaction. The presence of four substituents (methyl and phenyl) in qpy, in the 6,6′′′′ and 4′,4′′′ positions, produces a milder effect in the twisting of the ligand than the case with only two ferrocene substituents in the 4′,4′′′ positions.

Stacking interactions between the planar parts of the ligands, reminiscent of the base-pair stacking of nucleic acids, are usual in these helical geometries, sometimes as marked interactions. In $[Ag_2(Fc_2qpy)_2](OTf)_2$ the rings that contain the nitrogen atoms N7 and N2 are almost coplanar (angle between planes 7°), and one lies approximately above the other. The same situation can be observed for the planes that contain N9 and N4 (angle between the planes = 5.6°). The distances between the ring centroids are 3.43 Å and 3.98 Å, respectively. The shorter distance is similar to the stacking distances in $[Ag_2(dmqpy)_2](ClO_4)_2$ (3.38−3.42 Å), and the larger distance is similar to those between di-silver units in the same compound (3.70 Å).[31] No such interactions were observed between di-silver units, since the rings of those which are adjacent are not coplanar. These interactions between di-units are not present in $[Ag(dmpqpy)_2](ClO_4)_2\cdot 2H_2O$, probably due to the presence of the bulky substituents.

Helices are chiral although, normally, a mixture of both enantiomers is obtained, and only the presence of a chiral substituent makes it possible to obtain only one enantiomer. In $[Ag_2(Fc_2qpy)_2](OTf)_2$, the two enantiomers are alternately (Figure 3) disposed. The presence of C−H···O and C−H···F hydrogen bonds (Table 2) results in a supramolecular structure.

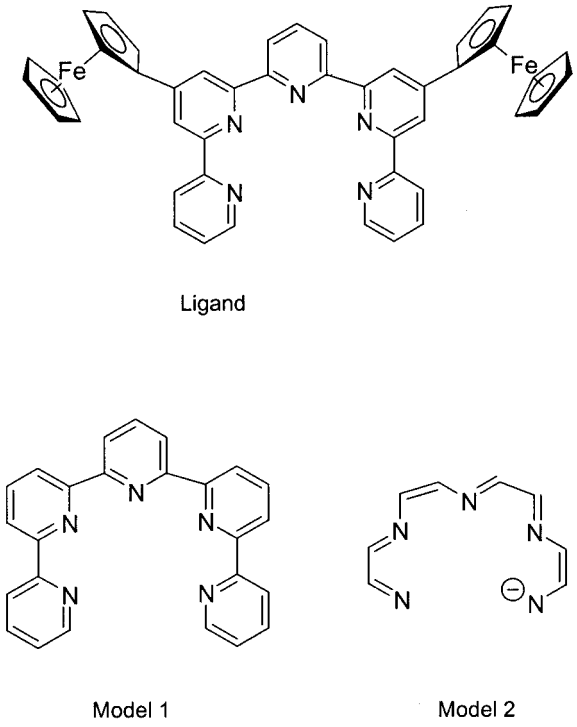

Scheme 1. Theoretical models

Electrochemistry

The electrochemical behavior of the silver complex has been studied by cyclic voltammetry at a platinum electrode in CH_2Cl_2. It shows two oxidation waves. The first is a quasi-reversible two-electron oxidation wave at +0.6 V based on the ferrocene units, a potential slightly higher than that of the free ferrocene (0.47 V). The second is an irreversible oxidation wave at +1.1 V attributable to the oxidation of the silver(I) to silver(II). These reduction waves overlap at around +0.4 V.

Theoretical Studies

Theoretical calculations were performed in order to understand the factors leading to the helical structure observed, and to establish the nature of the Ag···Ag interaction. Several approaches were used, taking into account the size of the system and the adequacy of the method. Geometry optimizations were mainly performed using DFT[34] methods (ADF program[35]), although HF (Gaussian 98[36]) was also tested. Single point MP2[37] calculations were carried out in order to account for correlation effects in the Ag···Ag interactions. The complete structure consists of a large number of atoms, so that models had to be built in such a way as to preserve the features of the experimental structure. For instance, the ferrocenyl units are directed toward the outside of the helices, and were therefore removed. The pyridines were also simplified, keeping the same bonding modes, which implied changing the charge. These models are shown in Scheme 1.

Model 1 was used in a molecular dynamics study of the isolated ligands, aimed at measuring the tendency of the two ligands to preserve the helical arrangement even in the absence of the metal. Model 2 was used in all the quantum calculations.

The quality of the model was addressed first. The structure with two chains and two silver atoms was fully optimized (ADF program; for details see Exp. Sect.). In Figure 4,

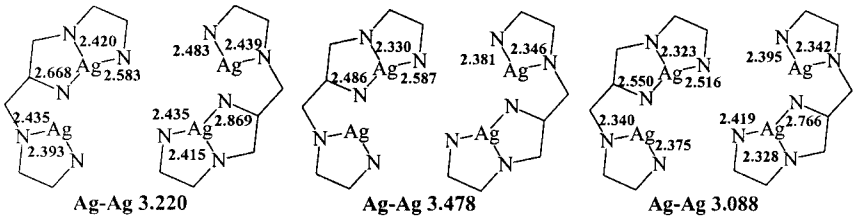

Figure 4. Ag−N distances (Å): calculated using DFT methods (left); in the X-ray structure of $[Ag_2(Fc_2qpy)_2]^{2+}$ (center); in the X-ray structure of $[Ag_2(dmqpy)_2]^{2+}$ (right)

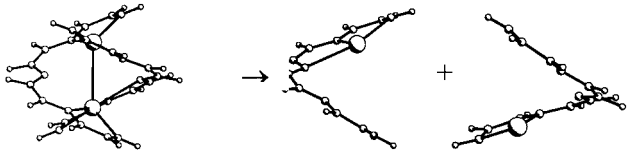
we show a comparison of the calculated Ag−Ag and Ag−N distances (Å) with those found in the corresponding section of the experimental structure of the $[Ag_2(Fc_2qpy)_2]^{2+}$ helix (notice that for clarity, silver atoms are represented twice, as each chain binds two silvers), and also of the $[Ag_2(dmqpy)_2]^{2+}$ complex (owing to symmetry, only one set of distances is given).[31]

Although the Ag−Ag distance is either slightly too long or too short, depending on the structure considered, some Ag−N distances compare relatively well. Each helix binds two different Ag atoms, using three N atoms for the first Ag, and two N atoms for the second. One of the Ag−N distances in each chain is too long for a bond (2.869, 2.668 Å, and 2.766, 2.550 Å, respectively, for the calculated and experimental distances of $[Ag_2(Fc_2qpy)_2]^{2+}$). A similar binding mode was found in the $[Ag_2(dmqpy)_2]^{2+}$ complex (TEPDUN; there is another complex with the same stoichiometry but a less similar environment). The agreement with respect to distances appears acceptable. The helical arrangement is also retained in this simple model, as can be seen in Figure S1 (See Supporting Information, for Supp. Inf. see also the footnote on the first page of this article).

In the following step, we separated the two chains from the original structure, as shown in Scheme 2, and allowed each fragment to relax in order to optimize the structure.



Scheme 2. Separation of the two fragments

The optimized structure consists of an almost flat pentacoordinate Ag complex of the qpy ligand, very similar to the X-ray structure of $[Agqpy]^+$, and is shown in Figure 5.

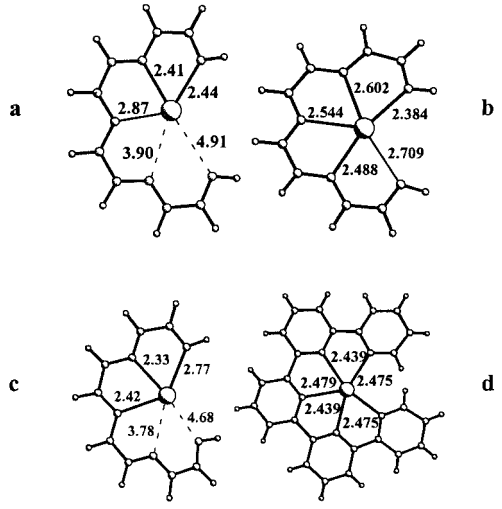


Figure 5. Structures containing one ligand chain and one silver atom: optimized in the helical structure of $[Ag_2(Fc_2qpy)_2]^{2+}$ (a), optimized alone (b), cut from the X-ray structure of the $[Ag_2(Fc_2qpy)_2]^{2+}$ helix (c), X-ray structure of the $[Agqpy]^+$ complex (d).

The Ag−N bond lengths are quite different from those in the helix, also shown in Figure 5, but very close to the distances in the $[Agqpy]^+$ complex, with the exception of one very long bond. Both in the calculated and the experimental helices, there are two Ag−N distances outside the bonding range (3.62, 4.65, or 3.90, 4.91, in the X-ray and calculated structures, respectively). Silver forms extra bonds with nitrogen atoms from the second chain. When the second chain is absent, the five possible Ag−N bonds are formed, and the energy decreases significantly (166 kcal mol^{-1}). How does the formation of the helical structure compete with the formation of two pentacoordinate monomers? Using the ADF optimized structures, we also performed single point HF and MP2 calculations on the monomer, the dimer, and the observed structure. The binding energy of the helical species relative to the sum of the energies of the single chains with the structure they have in the helix (see a in Figure 5) is represented by ΔE_1, and follows directly from Scheme 2. ΔE_2 represents the binding energy relative to two optimized single chains (see b in Figure 5). The difference between these two terms reflects the reorganization energy of each chain from flat to helical, and will be discussed again later. These binding energies are shown in Table 3.

Table 3. Binding energies (kcal·mol^{-1}) of the optimized helical structures relative to the monomer with the geometry in the optimized helical structure (ΔE_1) and the optimized AgL monomer (ΔE_2)

	DFT(ADF)	HF	MP2
ΔE_1	−51.1	−40.4	−90.4
ΔE_2	−5.9	8.5	−26.8

The ΔE_1 values are less relevant, since they give us the interaction energy for adding together the two chains shown in Scheme 2. They are always negative indicating that the formation of the four extra Ag−N bonds (each chain makes two bonds to the second silver atom), and eventually the new Ag−Ag bond, is an exothermic process. ΔE_2 values are much more interesting, because they include the reorganization energy of going from the flat pentacoordinate complex to a helix. This energy may be compensated for by stronger Ag−N bonds (same number, but organized differently) and a new Ag−Ag interaction. HF values give a positive energy, meaning that the helical structure is not favorable. On the other hand, both DFT and MP2 results agree on the higher stability of the double helix relative to the flat monomer, the interaction energy being larger in the MP2 calculation. This indicates that there is some weak Ag−Ag interaction, which relies on correlation and other effects, which are not all described by HF methods, but are fully taken into account by MP2, and only partly by the DFT functionals used. In the absence of this Ag−Ag interaction, the double helix is not favored, which follows from the HF data. Introduction of correlation (DFT) leads to the detection of the Ag−Ag interaction. A better description of cor-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

relation by MP2 increases the exothermiticity of the process.

The existence of the Ag−Ag interaction can be further probed by indicators of bond strength, such as overlap populations or related indices. The experimental distance is relatively long (3.09 Å). Therefore, we performed a natural population analysis,[38] and calculated Wiberg[39] and Mayer[40,41] indices. The Wiberg index, calculated with the MP2 method, was 0.022 for both the optimized structure (model 2) and the $[Ag_2(Fc_2qpy)_2]^{2+}$ helix, indicating a weak bond. The Mayer index, a generalization of the Wiberg index calculated by the ADF program, led to values of 0.066 and 0.086 for the optimized structure and the helix, respectively. These results are all consistent with the existence of a weak Ag···Ag interaction. We may therefore conclude that the helical structure can become energetically more favorable than the existence of monomers, owing to the strong Ag−N bonds that can also be formed in this arrangement, and the extra development of a metal−metal interaction. There is a balance between these terms and the reorganization energy of each chain, which opposes helix formation.

After analyzing the preferences of silver, we address the preferences of the chain in the absence of silver, by means of molecular mechanics and dynamics simulations using the Universal Force Field,[42] within the Cerius2 software package.[43]

A conformational analysis of a single qpy chain (model 1) was undertaken following quench dynamics techniques at 3000 K. The five pyridine rings can adopt *cis* or *trans* arrangements, depending of values of the N−C−C−N torsion angles between adjacent pyridine rings. When the two nitrogen atoms of two contiguous pyridines are opposite to each other, with an almost co-planar arrangement of the aromatic rings, the N−C−C−N torsion angle is near 180°, and the configuration is *trans* (*t*). If they are on the same side, the N−C−C−N torsion angle is near 0°, and the configuration is *cis* (*c*). Apart from changes in the signs of the torsion angles, there are ten unique possible conformations, which are listed in Table 4 together with their energies.

Table 4. The unique MM energy conformations for one qpy chain (torsion angles are listed successively, starting at a terminal pyridine ring)

Conformer	Energy (kcal·mol^{-1})	N−C−C−N torsion angles (°)			
tttt	114.76	180.0	179.9	180.0	180.0

tcct	116.37	−178.0	10.8	10.8	−178.0
tctc	117.99	−178.9	−23.3	−179.2	22.1
ttcc	118.76	−179.4	178.7	22.7	−20.6
cttc	119.75	−19.9	179.4	−179.4	19.9
cccc	124.89	−21.1	−19.8	14.0	−21.0

The results show that the steric energy increases with the number of *cis* torsion angles present in each conformation. Thus, the lowest energy conformation has an energy of 114.76 kcal·mol^{-1}, and exhibits a *tttt* conformation. In the crystal structure of $[H_2(qpy)][PF_6]_2$,[14] the qpy chain (model 1) exhibits a *cttc* conformation with N−C−C−N torsion angles of 3.5, 177.8, 174.5, and 6.9°. This conformation has an energy of 119.77 kcal·mol^{-1} in the gas phase but, in the crystal, two symmetry related $[H_2(qpy)]^{2+}$ cations are assembled face to face through a π-stacking arrangement with an interplanar distance ca. 3.89 Å, and by hydrogen bonding interactions involving the PF_6^- counterions and N−H groups. Therefore, the observed conformation is probably stabilized by these intermolecular interactions and avoids the low energy *tttt* conformation.

In the structure of $[Ag(qpy)][PF_6]$,[7] the qpy ligand adopts a helical shape, with four N−C−C−N torsion angles of −19.7, 1.1, 1.1, and −19.7° defining a *cccc* conformation. An energy of 125.20 kcal mol^{-1} and N−C−C−N torsion angles of −21.1, −19.8, 14.0, and −21.0° were calculated for this conformation, which is the highest energy conformation, and is forced by the binding of silver to the five nitrogen donors.

Having established the structural preferences of the monomeric chain, we then evaluated the stability of a dimeric model involving the self-assembling of two chains of qpy. The energy minimization of the supramolecular aggregate composed of two $[Fc_2(qpy)]$ units, from the X-ray structure of $[Ag_2(Fc_2qpy)_2]^{2+}$ after removing the two silver atoms, was first attempted in the Universal Force Field, parameterized for the full periodic table, using the default parameters available for $FeCp_2$ fragments. Since convergence was not achieved, a model was created by replacing the two ferrocenyl units with hydrogen atoms. This model structure was subsequently minimized by molecular mechanics calculations, and submitted to a dynamics simulation at room temperature (300 K) during 500 ps. Conformational changes were observed with torsion angles varying from −60 to 60°. Surprisingly, the two chains retained the double helical arrangement, and no *cis* to *trans* isomerization was observed. The overall conformation remained *cisoid*. The simulation was repeated for longer simulation periods of 800 and 1000 ps, respectively, and the chains kept their helical topology in both runs. This was only lost when the temperature was raised above 400 K. The changes of N−C−C−N torsion angles with time are given in Figure 6, for a simulation carried out at 500 K, together with snapshots of the most relevant structures. After the first 144.5 ps, two terminal pyridine rings from different chains experienced a conformational change from *cis* to *trans*, but the double-helix structure was retained. Subsequently, during a period of ca. 42 ps, further conformational changes occurred, until the two chains unfolded completely, adopting an almost parallel arrangement, which remained until the end of the simulation. During this period, the arrangement of the two chains changed from *ctttcttt* → *tttttttt* → *tttttttct*, but the *transoid* conformation of the eight torsion angles was retained for a considerable time. In order to evaluate the steric stability of the different arrangements observed in the molecular dynamics simulation, all the

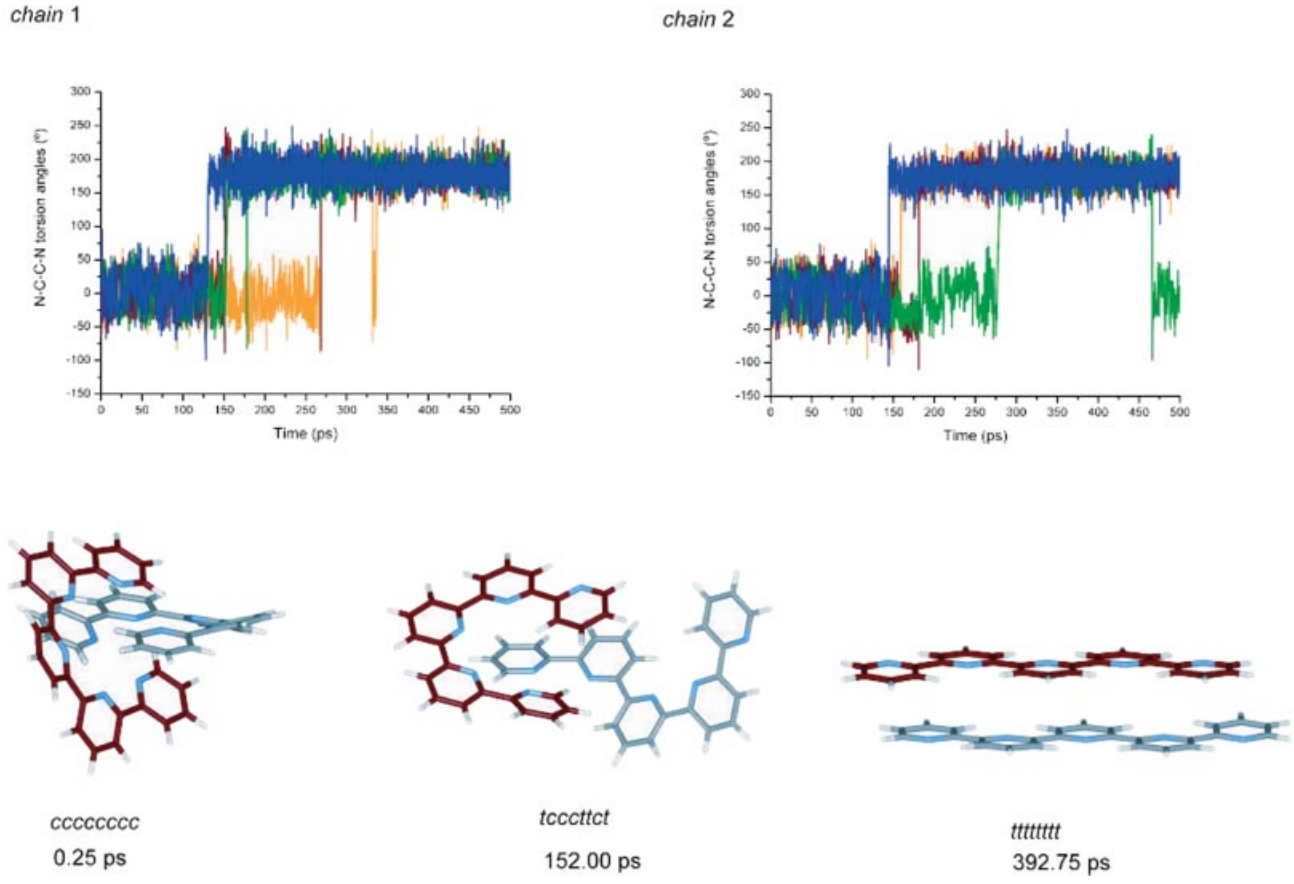

Figure 6. Changes in the N−C−C−N torsion angles during the 500 ps simulation at 500 K, with relevant snapshots showing the unfolding process of the dimeric qpy chain; the yellow, red, green, and blue curves represent the torsion angles from 2,2′, 6,2′, 6′′,2′′′, and 6′′′′, 2′′′′ C−C interannular bonds, respectively; carbon atoms of chains 1 and 2 are red and gray, respectively

frames collected were subsequently minimized by molecular mechanics (MM).

The lowest energy structure (215.94 kcal·mol^{-1}) corresponds to a *tttttttt* conformation, in which the pyridine rings of both chains are π-stacked, with the nitrogen atoms in a *trans* arrangement. In fact, the two terminal pyridine rings subtend a dihedral angle of 4.3°, and the chains are separated by a distance of ca. 3.732 Å. In other words, this supramolecular dimer is stabilized by π-π interactions.

In contrast, the double helix structure *cccccccc*, with torsion angles of −22.8, 22.1, −24.9, −18.9, −22.8, 22.1, −24.9, and −18.9°, is among those with the highest energies (223.97 kcal·mol^{-1}), as reported for the monomer. This conformation was observed in the solid state for $[Ag_2(Fc_2qpy)_2](OTf)_2$ with torsion angles of −1.8 −23.9 −35.9 −3.9 −4.8 −40.2, −28.5, and −1.8°. Therefore, in spite of the apparent stability shown by the double-helix *cccccccc* conformer in the gas phase, dynamics and mechanics results suggest that the silver atoms are, apparently, crucial for this conformational preference.

Selected geometric arrangements of the dimeric qpy chain were also optimized by DFT calculations, the results

being similar to those discussed above. The *ttttttt* conformation is again the most stable, with an energy lower than that of the *cccccccc* conformer by 44.13 kcal·mol^{-1}. The resultant structures together with their relative energies are given in Table 6.

Conclusions

Although silver helical complexes of the type described here have been known for some years, no previous theoretical evaluation has, to the best of our knowledge, been carried out. DFT calculations were performed with a relatively small model, required by the large size of the real system, but were still able to reveal the main patterns. Optimized DFT geometries were very close to those observed experimentally, both in the case of the monomeric species, and of the double helical chain complex with two silver atoms. In our model, the optimized monomer (Figure 5, b) was found to be more stable than a related complex with a helical structure (Figure 5, a). Molecular dynamics and molecular mechanics also showed that the two chains in the helix (experimental structure or DFT optimized) exhibit a high energy conformation, while the planar arrangement of two chains is stabilized by π-π stacking interactions between the aromatic rings, and it is the lowest energy one. Thus, the preference for a dimeric structure depends on the balance between the reorganization energy of the two chains, i.e. between the preferred *tttt* conformation and the high energy *cccc*, and the energy released by the formation of globally stronger Ag−N bonds and the new Ag−Ag bond. The balance of these terms, accompanied by subtle factors not considered in our models, such as packing effects or π-π stacking, will strongly depend on the substituents.

Experimental Section

Instrumentation: Infrared spectra were recorded in the range 4000−200 cm^{-1} with a Perkin−Elmer 883 spectrophotometer using nujol mulls between polyethylene sheets. Conductivities were measured in ca. 5×10^{-4} mol·dm^{-3} solutions with a Philips 9509 conductimeter. C, N, and S analyses were carried out with a Perkin−Elmer 2400 microanalyzer. Mass spectra were recorded with a VG Autospec instrument with the liquid secondary-ion mass spectra (LSIMS) technique, using nitrobenzyl alcohol as matrix. NMR spectra were recorded with a Varian Unity 300 spectrometer or a Bruker ARX 300 spectrometer in CD_2Cl_2. Chemical shifts are cited relative to $SiMe_4$ (^{1}H, external). Cyclic voltammetric experiments were performed by employing an EG&PARC model 273 potentiostat. A three-electrode system was used, which consists of a platinum disk working electrode. The measurements were carried out in CH_2Cl_2 solutions with 0.1 mol·dm^{-3} Bu_4NPF_6 as a supporting electrolyte. Under the present experimental conditions, the ferrocenium/ferrocene couple was located at 0.47 V relative to the SCE.

Synthesis of $[Ag_2(Fc_2qpy)_2](OTf)_2$: To a solution of 4′,4‴-bis-(ferrocenyl)-2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (0.075 g, 0.1 mmol) in dichloromethane (20 mL) was added AgOTf (0.026 g, 0.1 mmol), and the mixture was stirred for 1 h. Evaporation of the solvent to ca. 5 mL, and addition of hexane gave $[Ag_2(Fc_2qpy)_2](OTf)_2$ as an orange-red solid. Yield 89 %. Δ_M 110 Ω^{-1} cm^2·mol^{-1}. $C_{92}H_{66}Ag_2F_6Fe_4N_{10}O_6S_2$ (2024.836): calcd. C 54.57, H 3.28, N 6.91, S 3.16; found C 54.19, H 3.14, N 6.85, S 3.09. ^{1}H NMR: δ = 4.12 (br. m, 10 H, C_5H_5), 4.63 (br. m, 4 H, C_5H_4), 4.95 (br. m, 4 H, C_5H_4), 6.89 (m, 2 H, 5 and 5⁗ of qpy), 7.15 (m, 2 H, 4 and 4⁗ pd qpy), 7.33 (m, 1 H, 4″), 7.6−8.8 (br. m, 10 H, qpy) ppm.

Crystal Data for $[Ag_2(Fc_2qpy)_2](OTf)_2·3CH_2Cl_2$: Empirical formula $C_{95}H_{72}Ag_2Cl_6F_6Fe_4N_{10}O_6S_2$, M = 2279.59, triclinic, space group $P(-1)$, a = 14.917(3), b = 16.205(3), c = 20.572(4) Å, α = 99.71(2), β = 105.46(2), γ = 103.86(2)°, U = 4507.4(15) Å^3, Z = 2, $D_{calcd.}$ = 1.680 Mg·m^{-3}, λ(Mo-K_α) = 0.07173 Å, μ = 1.351 mm^{-1}, F(000) = 2292, T = −130 °C, orange prism, 0.35 × 0.20 × 0.20 mm. 12234 intensities were recorded to $2\theta_{max.}$ 45° (Siemens P4 diffractometer), of which 11739 were unique (R_{int} = 0.0589) after absorption corrections using SHELXA. The structure was solved by heavy-atom methods, and subjected to full-matrix least-squares refinement on F^2 (program SHELXL-97).[44] All non-hydrogen atoms were refined anisotropically. H atoms were included using a riding model. Refinement proceeded to $wR(F^2)$ 0.2101, conventional $R(F)$ 0.0743 for 1180 parameters and 2254 restraints (to light atom U values and local ring geometry), $S(F^2)$ = 0.827; maximum Δρ = 1.384 e·Å^{-3}. CCDC-218940 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details: Density functional calculations[34] were carried out with the Amsterdam Density Functional program (ADF-2000).[35] The Local Spin Density (LSD) exchange correlation potential was used with the Local Density Approximation of the correlation energy (Vosko, Wilk and Nusair's).[45] Gradient corrected geometry optimizations,[46] without symmetry constrains, were performed using the Generalized Gradient Approximation (Becke's non-local exchange[47] and Perdew's correlation corrections).[48] A triple-ζ Slater-type orbital (STO) basis set was used for all atoms, augmented by one polarization function. A frozen core approximation was used to treat the core electrons: (1s) for N and C; ([1−3]s [2−3]p 3d) for Ag.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Single point calculations at the Hartree−Fock (HF)[49] and second order Møller−Plesset (MP2)[37] levels were performed on the ADF optimized geometries using Gaussian 98.[36] The standard LanL2DZ basis set was used for all atoms.[50] A Natural Population (NPA) analysis,[38] and the evaluation of the Wiberg indices[39] (using the MP2 density) were used as bond strength indicators. Mayer indices were calculated with the ADF densities.[40,41]

HF structure optimizations were also performed, but the agreement between calculated and experimental data was worse than that obtained with the DFT methods (longer distances, especially Ag···Ag). They were, therefore, not considered in further single point energy calculations.

The molecular dynamics simulations and mechanics calculations were carried out using the Cerius2 software[43] with parameters from the Universal Force Field.[42] The atomic charges were calculated with the Qeq method implemented in Cerius2. The conformational analysis of model 1 was performed via quench dynamics techniques. A molecular dynamics run was carried out using a time step of 1 fs and 2000 conformations were generated at 0.25 ps intervals at 3000 K. Concomitantly, the generated conformations were minimized by molecular mechanics calculations. The dynamics simulations with model 2 were carried out at temperatures of 300, 400, and 500 K, respectively, using a time step of 1fs, and a set of atomic positions were saved every 0.25 ps over the entire period of the simulation of 500 ps. The simulation runs at 300 and 400 K were repeated for 800 and 1000 ps. An NVT thermostat was used for all simulations. The structures collected in dynamics run at 500 K were subsequently minimized by molecular mechanics.

Synthesis and Characterization of the First Examples of Dicationic Dihydrogen Complexes of Iron and Ruthenium with the PF_3 Ligand

H. V. Nanishankar,[a] Munirathinam Nethaji,[a] and Balaji R. Jagirdar*[a]

Keywords: Dihydrogen complexes / H−H activation / Hydride ligands / Iron / Phosphane ligands / Ruthenium

New dicationic dihydrogen complexes of the type *trans*-$[M(\eta^2\text{-}H_2)(PF_3)(diphosphane)_2]^{2+}$ [M = Ru, diphosphane = dppm ($Ph_2PCH_2PPh_2$); M = Fe, Ru, diphosphane = dppe ($Ph_2PCH_2CH_2PPh_2$)] have been prepared from the precursor hydrides *trans*-$[M(H)(PF_3)(diphosphane)_2]^+$ upon reaction with HOTf. In the case of dppm, in addition to the *trans*-dihydrogen complex *cis*-$[Ru(\eta^2\text{-}H_2)(PF_3)(dppm)_2]^{2+}$ was also obtained in the protonation reaction. The intact nature of the H–H bond in these derivatives has been established using the spin–lattice relaxation time measurements (short T_1 values) and the large $J_{H,D}$ coupling constant of the H–D isotopomers. The H–H bond lengths and the stabilities of the dihydrogen complexes are discussed in terms of the π-acidity of the PF_3 ligand and compared with other systems possessing *trans* CO and CNH ligands. The *trans*-$[Ru(\eta^2\text{-}H_2)(PF_3)(dppe)_2]^{2+}$ complex was found to be remarkably stable with respect to the loss of bound H_2 for a period of about 16 h. The H–D isotopomer of this complex exhibits small temperature variations in the $J_{H,D}$ coupling constant. The X-ray crystal structure of *trans*-$[Ru(H)(PF_3)(dppm)_2][BF_4]$ has been determined.

Introduction

The heterolytic activation of molecular hydrogen by transition metal centers to give a proton and a metal hydride is one of the most intriguing reactions of dihydrogen complexes. Highly electrophilic metal centers have been found to greatly promote heterolysis of dihydrogen.[1,2] This activation pathway leads to interesting reactivity, including catalysis and selective proton transfer to an ancillary ligand.[3,4] The ligand *trans* to the $\eta^2\text{-}H_2$ moiety has a significant role in dictating the properties of the dihydrogen complex, including the heterolytic cleavage of the bound dihydrogen.

We have been interested in preparing systems that are capable of activating H_2 in a heterolytic fashion. Toward this goal, we have reported certain dicationic dihydrogen complexes of iron and ruthenium bearing *trans*-phosphite, phosphane,[5−7] and nitrile[8] ligands that were found to be quite acidic. Numerous examples of highly acidic $\eta^2\text{-}H_2$ complexes have been reported in the literature.[9−14] Rocchini et al.[12] have reported two highly acidic dihydrogen complexes *trans*-$[M(\eta^2\text{-}H_2)(CO)(dppp)_2]^{2+}$ [M = Ru, Os; dppp = 1,3-bis(diphenylphosphanyl)propane]. The ruthenium derivative was found to be stable only at low temperatures whereas the osmium complex is stable even at room temperature. The strong π-accepting tendency of the CO ligand *trans* to the H_2 imparts the high acidity to the dihydrogen ligand. Morris and co-workers have reported an iron dihydrogen complex *trans*-$[Fe(\eta^2\text{-}H_2)(CO)(dppe)_2]^{2+}$ that was found to be quite acidic.[14] In addition to this species, they also prepared a highly acidic dicationic dihydrogen complex, *trans*-$[Ru(\eta^2\text{-}H_2)(CNH)(dppe)_2]^{2+}$ that was found to be stable with respect to the loss of protons or H_2 under strongly acidic conditions (excess triflic acid).[13] A ligand that has similar π acidity to both CO and CNH is PF_3. Dihydrogen complexes with the PF_3 ligand are limited to only one example, the rhenium complex *fac*-$[Re(H_2)(PPh_3)(PF_3)(dien)]^+$.[15,16] As yet there are no reports in the literature of dicationic dihydrogen complexes of transition metals with the PF_3 ligand. Therefore, in continuation of our investigations on the heterolytic activation of molecular hydrogen we report here the first examples of dicationic dihydrogen complexes of iron and ruthenium with a *trans*-PF_3 ligand *trans*-$[M(\eta^2\text{-}H_2)(PF_3)(diphosphane)_2]^{2+}$ (M = Fe, diphosphane = dppe; M = Ru, diphosphane = dppm, dppe).

Results and Discussion

Preparation and Properties of the Hydride Complexes

The new hydride complexes *trans*-$[M(H)(PF_3)(diphosphane)_2][BF_4]$ (M = Fe, diphosphane = dppe **1**; M = Ru, diphosphane = dppm **2**, dppe **3**) were prepared by substitution of the bound H_2 ligand in *trans*-$[M(H)(\eta^2\text{-}H_2)(diphosphane)_2][BF_4]$ with excess PF_3 gas [Equation (1)]. The

The ^1H NMR spectra of the hydride complexes show a doublet of multiplets pattern for the hydride moiety due to coupling with the phosphorus (*trans* and *cis*) and fluorine nuclei. The $J_{H,P_{trans}}$ coupling constants were found to be 155.6 and 171.9 Hz whereas the $J_{H,P_{cis}}$ coupling constants were found to be 21.0 and 19.1 Hz for **2** and **3**, respectively. The $^1H\{^{31}P\}$ NMR spectra gave a quadruplet in the hydride region due to H, F coupling, with $J_{H,F}$ equal to 33.1 and 34.4 Hz for **2** and **3**, respectively. In the case of **1**, a multiplet at $\delta = -7.06$ ppm in the ^1H NMR spectrum with an average $J_{H,P}$ coupling constant (H,P_{trans} and H,P_{cis}) of 50.0 Hz was observed. The $^{31}P\{^1H\}$ NMR spectrum consists of one doublet for the dppe P nuclei coupled to the PF_3 ligand and a quadruplet of quintets for the PF_3 moiety coupled to three fluorine and the four dppe P nuclei. The $J_{P,F}$ coupling constant was found to be in the range 1267.0−1307.9 Hz, which is typical for compounds having direct P−F bonds.[17−20] The ^{19}F NMR spectra of the hydride complexes consist of a doublet of doublets for the PF_3 ligand and a broad singlet for the BF_4^- counterion. The NMR spectroscopic data for these complexes are summarized in Table 1. In order to get an insight into the structural aspects, we carried out an X-ray crystallographic study of **2**.

Structure of *trans*-[Ru(H)(PF_3)(dppm)$_2$][BF_4] (2)

The ORTEP diagram of the *trans*-$[Ru(H)(PF_3)(dppm)_2]^+$ cation is shown in Figure 1. In addition to a discrete BF_4^- counterion, two molecules of H_2O were also found (the source of these water molecules could be the solvent used for crystallization because strict measures were not taken to exclude the moisture). The structure is a highly distorted square pyramid defined by the four nearly coplanar dppm phosphorus atoms, with the PF_3 group almost perpendicular to this plane. The hydride ligand that occupies the sixth coordination site on the metal was not located, although its presence was confirmed by ^1H NMR spectroscopy. The Ru−P(dppm) bond lengths vary from 2.3302(18) to

2.352(2) Å whereas the Ru−P(PF_3) distance was found to be 2.206(2) Å. The bond lengths of certain analogous ruthenium derivatives fall in the following order: 2.3153(17) Å {Ru−P($OMe)_3$ in *trans*-[Ru(H){P($OMe)_3$}($dppm)_2$][BF_4]}[7] > 2.264(2) Å {Ru−P($OMe)_2$ in *trans*-[Ru(H){P($OMe)_2$}($dppe)_2$][BF_4]}[5] > 2.206(2) Å {Ru−PF_3 in *trans*-[Ru(H)(PF_3)($dppm)_2$][BF_4]}. This order is a combined effect of the progressive increase in the π-accepting ability as well as the decrease in the steric crowding due to the reduction in the cone angles[21,22] of the *trans*-phosphorus ligands. The dppm bite angles P(1)−Ru(1)−P(2) and P(3)−Ru(1)−P(4) are 71.87(6)° and 70.48(5)°, respectively. The P(1)−C(25)−P(2) and P(3)−C(50)−P(4) bond angles are 96.6(3)° and 94.4(3)°, respectively, falling at the lower end of the range of P−C−P angles (92−133°) that the dppm ligand exhibits in its complexes. The crystallographic data are given in the Exp. Sect. and selected bond lengths and angles are summarized in Table 2.

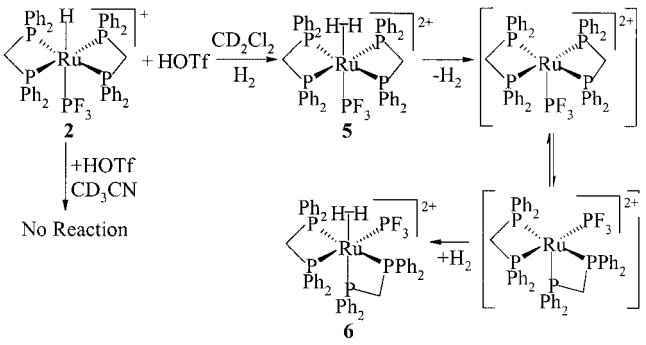
Protonation Reactions of *trans*-[Fe(H)(PF_3)($dppe)_2$][BF_4] and *trans*-[Ru(H)(PF_3)($dppm)_2$][BF_4].

The protonation of the hydrides with HOTf in CD_3CN or with HBF_4·Et_2O in CD_2Cl_2 did not afford the dihydrogen complexes; even with large excesses of the acid, no reaction took place. These experiments indicate that the pK_a of the protonating agent must be less than −2.4 in order to obtain the dihydrogen complexes since the pK_a of HOTf in CH_3CN is 2.6[23] and that of HBF_4·Et_2O is −2.4.[24] When the hydrides were protonated with excess triflic acid under H_2 atmosphere in CD_2Cl_2 at room temperature, the corresponding dihydrogen complexes *trans*-[Fe(η^2-H_2)(PF_3)($dppe)_2$]$^{2+}$ (**4**) and *trans*-[Ru(η^2-H_2)(PF_3)($dppm)_2$]$^{2+}$ (**5**) were presumably formed, although we found that they lose the H_2 ligand quite rapidly thus precluding the NMR spectroscopic characterization of these complexes. The singlet at δ = 4.6 ppm in the ^{1}H NMR spectrum due to free H_2 grew in intensity in these experiments. In the case of protonation of **1**, the resulting mixture gave NMR signals that were extensively broadened upon loss of H_2 due to the generation of some Fe^{III} species, amongst others. In an attempt to observe the dihydrogen complexes spectroscopically, the addition of the protonating agent was done at liquid N_2 temperature and then the mixture was slowly warmed up to 0 °C; the NMR spectral studies were also carried out at this temperature. Under these conditions, we observed signals corresponding to the dihydrogen complexes only in the case of **2**.

The protonation of **2** with HOTf under an atmosphere of H_2 resulted in a mixture of *trans*-[Ru(η^2-H_2)(PF_3)($dppm)_2$]$^{2+}$ (**5**) and *cis*-[Ru(η^2-H_2)(PF_3)($dppm)_2$]$^{2+}$ (**6**) in a ratio of 1:3. We have previously observed a similar behavior in certain analogous ruthenium complexes with *trans* phosphite ligands.[7] The complexes of the type *trans*-[Ru(H)[P($OR)_3$]($dppm)_2$][BF_4] isomerize under thermal conditions (in the presence of small amounts of acid impurities in the solvent) to give a mixture of the *trans* and the *cis* hydride phosphite derivatives. We traced the origin of this isomerization to the lability of the *trans* phosphite ligand. The addition of acid accelerated the isomerization reaction in those derivatives resulting in the corresponding *trans* and *cis* dihydrogen complexes *trans*/*cis*-[Ru(η^2-H_2)[P($OR)_3$]($dppm)_2$][BF_4]$_2$.[7] The mechanism of the isomerization in the current work, however, seems to be different. The PF_3 ligand was not found to be labile; refluxing solutions containing the starting *trans* hydride complexes did not give any isomerized species, thus suggesting that the isomerization occurs only upon addition of the acid. We monitored the loss of the bound H_2 ligand and found that it was faster in the case of **5** than **6**. A plausible mechanism could involve the loss of H_2 ligand from the *trans* dihydrogen complex, rearrangement of the five-coordinate species, followed by the re-binding of the H_2 *cis* to the PF_3 moiety. When the protonation was carried out under an Ar atmosphere, we found no evidence of isomerization except for the loss of H_2 ligand from **5**; a singlet at δ = 4.6 ppm due to free H_2 was observed in the ^{1}H NMR spectrum in this case. This suggests that the isomerization is effected upon loss of H_2 from the *trans* dihydrogen complex followed by the rebinding of H_2 *cis* to PF_3 only when there is excess H_2. The mechanism is illustrated in Scheme 1.

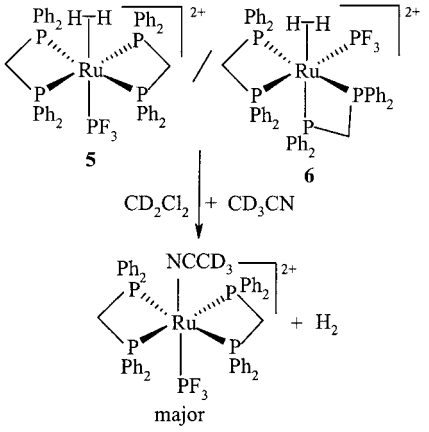


Scheme 1

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Another possible mechanism for the isomerization could involve the protonation of one of the dppm P atoms, opening up of the chelate arms to give Ru−(η^1-dppmH$^+$), followed by the isomerization. The dppmH$^+$ could then protonate the hydride ligand and close its arm. The pK_{a1} of dppmH$^+$ has been reported to be 3.81.[25] The protonated dppm P ([$Ph_2PCH_2PHPh_2$]$^+$) undergoes a dramatic downfield shift with respect to the bound dppm P chemical shifts in the ^{31}P NMR spectroscopy, as has been observed by Rottink and Angelici earlier.[26] We did not find any evidence for a dangling dppmH$^+$ in our ^{31}P NMR spectral studies. In addition, since the pK_a of the protonating agent needs to be lower than −2.4 in order to obtain the dihydrogen complexes, we can rule out this mechanism.

The protonation of **2** in CD_2Cl_2 followed by the addition of CD_3CN gave *trans*-[Ru(CD_3CN)(PF_3)(dppm)$_2$]$^{2+}$ (major product)[27] and the precursor hydride **2** (minor product). The observation of a small amount of the precursor hydride could be due to a part of **2** remaining unchanged under these conditions. These results are summarized in Scheme 2.



Scheme 2

trans-[Ru(η^2-H_2)(PF_3)(dppm)$_2$]$^{2+}$ (**5**) gives a broad doublet at δ = −1.75 ppm in the ^{1}H NMR spectrum for the bound H_2 ligand coupled to the *trans*-PF_3 ligand ($J_{H_2,P_{trans}}$ = 56.4 Hz). We have observed such strong couplings in the past.[5−7] The ^{31}P{^{1}H} NMR spectrum displays a single signal for all the four dppm phosphorus atoms indicating that they are coplanar. On the other hand, *cis*-[Ru(η^2-H_2)(PF_3)(dppm)$_2$]$^{2+}$ (**6**) shows a broad singlet at δ −4.86 ppm for the bound H_2 ligand in the ^{1}H NMR spectrum and two multiplets for the dppm P atoms in the ^{31}P{^{1}H} NMR spectrum. The NMR spectroscopic data for these derivatives are summarized in Table 3.

Protonation Reaction of *trans*-[Ru(H)(PF_3)(dppe)$_2$][BF_4]

The protonation of **3** was attempted with various protonating agents such as HCl, HBr, HI, CF_3COOH, and HBF_4·Et_2O; once again, the behavior of this hydride was similar to that of **1** and **2**. The dihydrogen complex *trans*-[Ru(η^2-H_2)(PF_3)(dppe)$_2$]$^{2+}$ (**7**) was obtained upon protonation with excess triflic acid. Titration of the hydride complex with triflic acid revealed that it requires 50 equivalents of the acid for the complete conversion of the hydride to the dihydrogen complex. This suggests that the pK_a of **7** must be much less than −5 since the aqueous pK_a of HOTf has been estimated to be about −5.[12]

Basallote and co-workers[28] obtained similar results in the protonation of CpRuHL complexes (L = dppm, dppe, $2PPh_3$) with various acids. They suggested that the lack of formation of the dihydrogen complexes in the presence of a large excess of HCl, HBr, or CF_3COOH was unlikely to be due to kinetic reasons because they observed protonation of certain other metal hydrides with these acids to be usually faster than with HBF_4·Et_2O. The failure of the protonation was related to the thermodynamics of the process. There have been other reports in the literature of the formation of dihydrogen complexes upon protonation of the hydrides with both strong and weak acids.[29,30] The fact that protonation of our hydride complexes failed with all acids except HOTf, and that the complete conversion of the hydrides to the corresponding η^2-H_2 derivatives requires large excesses of the acid (HOTf), indicates that our dihydrogen complexes are extremely strong acids, being roughly similar to HOTf.[31] It is intriguing to note that **7** was found to be stable at room temperature under H_2 atmosphere for about

16 h after which time it begins to decompose. We found evidence for some dppeH$^+$ in the ^{31}P NMR spectrum (singlet at δ = 10.0 ppm).[14] We attempted to isolate **7** by precipitation with Et_2O; our attempts, however, failed, and only the starting hydride complex **3** was recovered. In this case, the dihydrogen complex **7** protonates the Et_2O to give Et_2OH^+.

The NMR spectral features of **7** (Table 3) are quite similar to those of **5**; the $J_{H_2,P_{trans}}$ coupling constant of 63.0 Hz is even larger than the values (49−51 Hz) we found earlier in the cases of *trans*-[Ru(η^2-H$_2$)(P)(diphosphane)$_2$]$^{2+}$ complexes [diphosphane = dppe, P = PF(OR)$_2$; diphosphane = dppm, P = P(OR)$_3$, PF(OR)$_2$].[5−7] This stronger coupling could be due to the presence of the more electronegative F substituents in the PF_3 complex, which results in an enormous enhancement of the "s" character of the bonding orbitals in comparison to the PF(OR)$_2$ complexes if it is assumed that the coupling is dominated by the Fermi contact term.[32] No observable H$_2$−F couplings were observed. In an attempt to look for H$_2$−F couplings in the ^{1}H NMR spectrum, we decoupled all the P nuclei and obtained a broad singlet, indicating that the $J_{H_2,F}$ coupling constant is smaller than the line-width of the signal.

Rate Constant for the Decomposition of *trans*-[Ru(η^2-H$_2$)(PF$_3$)(dppe)$_2$]$^{2+}$ (7)

We studied the kinetics of the decomposition of **7** by monitoring the decrease in the integrals of the dihydrogen complex for the η^2-H$_2$ ligand in the ^{1}H NMR spectrum and the dppe phosphorus in the ^{31}P{gated ^{1}H} NMR spectrum. From the kinetics data, the pseudo-first-order rate constant was found to be 4×10^{-5} s^{-1} with a half-life of about 4.45 h. The residual material in the NMR tube after 16 h consisted of dppeH$^+$ (ca. 46%), *trans*-[RuCl(PF$_3$)(dppe)$_2$]$^+$ (**8**; ca. 36%), and *trans*-[Ru(OTf)(PF$_3$)(dppe)$_2$]$^+$ (**9**; <5%) along with certain other unidentifiable Ru^{III} species. The source of the chloride in **8** is the solvent, CD_2Cl_2.

Variable Temperature Spin−Lattice Relaxation Time Measurements.

The variable temperature spin−lattice relaxation times (T_1) for the η^2-H$_2$ moiety were determined; the data are summarized in Table 4. T_1 minima of 10.1, 7.2, and 13.0 ms (at 400 MHz and 273 K) were obtained for **5**, **6**, and **7**, respectively. The H−H distances for the slow- and fast-rotation regimes thus calculated[33] from the T_1 minima are tabulated in Table 5.

HD Isotopomers

In an attempt to prepare the HD isotopomers of **5**, **6**, and **7**, we purged the respective CD_2Cl_2 solutions containing the H_2 complexes with HD gas (generated from NaH and D_2O). Despite purging with HD for a considerable period of time, no observable HD isotopomer was obtained. Therefore, we reacted the starting hydride complexes **2** and **3** with excess F_3CSO_3D in CD_2Cl_2 to obtain the *trans*-[Ru(η^2-HD)(PF$_3$)(dppm)$_2$]$^{2+}$ **5-D$_1$**, *cis*-[Ru(η^2-HD)(PF$_3$)-(dppm)$_2$]$^{2+}$ **6-D$_1$**, and *trans*-[Ru(η^2-HD)(PF$_3$)(dppe)$_2$]$^{2+}$ **7-D$_1$** derivatives, respectively. The ^{1}H NMR spectrum of the hydride region of **5-D$_1$** and **7-D$_1$** is expected to show a doublet of 1:1:1 triplets pattern: the doublet due to the coupling of H with the *trans* phosphorus, and 1:1:1 triplet from the coupling of the proton with deuterium. Figure 2a displays this pattern in the case of **7-D$_1$**. An overlap of the signals is the cause of the poor resolution of the six lines. Upon decoupling the phosphorus atoms, the ^{1}H NMR spectrum shows an approximate 1:1:1 triplet pattern due to

Table 4. Variable-temperature spin−lattice relaxation times (T_1, ms; 400 MHz) of the dihydrogen ligand in [M(η^2-H$_2$)(PF$_3$)-(diphosphane)$_2$]$^{2+}$ complexes in CD_2Cl_2[a]

H−D coupling (Figure 2b). The complex **6-D$_1$** exhibits only a 1:1:1 triplet pattern due to the presence of a *trans* phosphane that is not as strong an acceptor as PF_3. The $J_{H,D}$ coupling constants were found to be 27.0, 28.0, and 30.0 Hz at 273 K for **5-D$_1$**, **6-D$_1$**, and **7-D$_1$**, respectively. The H−H distances calculated from the H−D coupling constant[34,35] are 0.97, 0.96, and 0.92 Å for **5-D$_1$**, **6-D$_1$**, and **7-D$_1$**, respectively. In addition, we carried out variable temperature $J_{H,D}$ measurements for **7-D$_1$**; the data are summarized in Table 6 and show an interesting temperature dependence.

Table 6. Temperature dependence of $J_{H,D}$ for *trans*-[Ru(η^2-H_2)(PF_3)(dppe)$_2$]$^{2+}$ in CD_2Cl_2

T (K)	$J_{H,D}$	d_{HH} (Å)

273	30.0	0.919
258	30.4	0.912
243	31.0	0.902
228	31.4	0.895
213	32.0	0.885

There have been a few reports on the unusual temperature dependence of $J_{H,D}$ coupling in the case of elongated dihydrogen complexes, for example [RuCp*(H···D)(dppm)]$^+$,[36] *trans*-[Os(H)(H···D)(dppe)$_2$]$^+$,[37] *trans*-[Os(Cl)(H···D)(dppe)$_2$]$^+$,[36] and [RuCp/Cp*(H···D/T)(PP)]$^+$.[38] Based on the theoretical studies by Gelabert et al.,[39] it was interpreted that the varying thermal population of the vibrational excited states of the M-H_2 unit results in the unusual temperature dependence of $J_{H,D}$ of the elongated dihydrogen complexes. The data presented in Table 6 show that the variations in $J_{H,D}$ with temperature are small and close to the error in the determination of the H−D coupling constant.

H−H Distances and the Stabilities of the Dihydrogen Complexes

The H−H distances obtained from the T_1(min) data fall in the range 1.03−0.75 Å (see Table 5) for the slow- and the fast-rotation regimes. A correlation between the H−H distances calculated from $J_{H,D}$ and T_1(min) and $\Delta G^{\ddagger}$ for the loss of the H_2 ligand from the metal center has been reported by Gusev et al.[40] The d_{HH} values calculated from $J_{H,D}$ in the current work are of the order of 0.92−0.97 Å (273 K) which are intermediate between the values of 1.03 and 0.75 Å obtained using the slow- and the fast-spinning approximations of H_2. Morris and Wittebort[33] have suggested that H−H distances obtained from $J_{H,D}$ that are intermediate between those derived from the T_1(min) data indicate that librational motion significantly influences the H_2 relaxation process. In addition to these complexes, several examples have been reported earlier where such a situation has been observed.[33]

The effect of the ligand *trans* to H_2 on the properties of the dihydrogen complex, for example d_{HH} and stability, can be interpreted in terms of the σ donation (η^2-H_2 → empty metal d orbital) and the back-donation (filled metal d orbital → σ* orbital of η^2-H_2) components. Woska et al.[41] have determined the stereoelectronic parameters of a series of phosphorus ligands and concluded that PF_3 is the weakest σ donor and the strongest π acid. Thus, the *trans*-PF_3 ligand exerts a high *trans* influence due to its strong π-acidity; in addition, it is also expected to stabilize the metal d orbitals resulting in reduced overlap with the antibonding orbitals of the H_2. Consequently, a strengthening of the H−H bond and a weakening of the M−H_2 interaction occurs giving rise to dihydrogen complexes with short d_{HH} values. The dihydrogen complexes **5**, **6**, and **7** show H−H distances of 0.97, 0.96, and 0.92 Å, respectively, at 273 K. These distances, rather surprisingly, are not appreciably short. We have also measured the $J_{H,D}$ coupling constant of **7-d$_1$** at various temperatures and obtained a d_{HH} of 0.88 Å at 213 K. This distance is similar to the H−H distance found in the case of *trans*-[Ru(η^2-H_2)(CO)(dppp)$_2$]$^{2+}$ (0.85 Å) reported by Rocchini et al.[12] and *trans*-[Ru(η^2-H_2)(CNH)(dppm)$_2$]$^{2+}$ (0.88 Å) reported by Morris and coworkers.[13] Both of these compounds are unstable with respect to the loss of H_2. Since **7** loses H_2 as noted earlier, we attempted to determine the equilibrium constant for the substitution of the bound H_2 with CH_3CN as this could provide insight into the relative M−H_2 bond strength for the complexes prepared in this study. However, we found that CH_3CN substitutes H_2 completely even under stoichiometric conditions (1:1 molar ratio, complex:CH_3CN) thus precluding the measurement of the equilibrium constant. We earlier found that the H_2 ligand in complexes of the type *trans*-[Ru(η^2-H_2)[P(OR)$_3$](dppm)$_2$]$^{2+}$ and *cis*-[Ru(η^2-H_2)[PF(OR)$_2$](dppm)$_2$]$^{2+}$ is labile; however, upon loss of the H_2 ligand (typically loss of H_2 starts to occur after 24−36 h), the dihydrogen complex could be recovered by purging the solutions containing the five-coordinate species with H_2 gas.[7] Considering the greater π-acidity of the PF_3 ligand in comparison to P(OR)$_3$ or PF(OR)$_2$, it is not surprising to find that **7** is stable only for about 16 h before it starts to decompose. Thus, the π-acidities of the CO, CNH, and PF_3 ligands account for the trend in the stability of the M−H_2 bond for the above three complexes, which increases in the order CO ≤ CNH < PF_3. We found that the protonation of **1** with HOTf resulted in extensive broadening of the ^{1}H NMR signals due to the presence of Fe^{III} species that are generated quite rapidly from a highly unstable iron dihydrogen complex. We believe that the origin of the Fe^{III} species is a dihydrogen complex since, upon its (Fe^{III} species) generation, a singlet at δ = 4.6 ppm was observed, indicating the evolution of H_2. This observation further supports the earlier suggestion that the M−H_2 interaction becomes stronger on going down the group, as has been found earlier.[12,42] We speculate that a compound of formula *trans*-[Os(η^2-H_2)(PF_3)(diphosphane)$_2$]$^{2+}$, if realized, could be isolable. Efforts toward this goal are in progress in our laboratories.

Conclusion

The complexes *trans*-[Ru(η^2-H_2)(PF_3)(dppm)$_2$]$^{2+}$ (**5**), *cis*-[Ru(η^2-H_2)(PF_3)(dppm)$_2$]$^{2+}$ (**6**), and *trans*-[Ru(η^2-H_2)(PF_3)(dppe)$_2$]$^{2+}$ (**7**) are formulated as dihydrogen complexes based on their short T_1 values and the observation of substantial H−D coupling in the corresponding HD isotopomers. *trans*-[Ru(η^2-HD)(PF_3)(dppe)$_2$]$^{2+}$ shows a temperature-dependent $J_{H,D}$ coupling, although this effect is only small. All of these derivatives, including *trans*-[Fe(η^2-H_2)(PF_3)(dppe)$_2$]$^{2+}$ (**4**), are unstable at room temperature. The dihydrogen complexes are formed only upon addition of excess HOTf to the precursor hydrides and they protonate Et_2O in solution, indicating the high acidities of these derivatives.

Experimental Section

General Remarks: All reactions were carried out under N_2 at room temperature using standard Schlenk[43,44] and inert atmosphere techniques unless otherwise noted. Solvents used for the preparation of dihydrogen complexes were thoroughly saturated with either H_2 or Ar just before use. The ^{1}H, ^{31}P, and ^{19}F NMR spectroscopic data were obtained using AMX Bruker 400 MHz or Avance Bruker 400 MHz instruments. The shift of the residual protons of the deuterated solvent was used as an internal reference. Variable-temperature proton T_1 measurements were carried out at 400 MHz using the inversion recovery method (180°-τ-90° pulse sequence at each temperature)[45] and the data are summarized in Table 4; the d_{HH} values obtained from the T_1 minima are given in Table 5. All ^{31}P NMR spectra were proton decoupled, unless otherwise specified. ^{31}P NMR chemical shifts were measured relative to 85% H_3PO_4 (as an aqueous solution, external reference) in CD_2Cl_2. ^{19}F NMR spectra were recorded with respect to $CFCl_3$ (external reference) in CD_2Cl_2. Satisfactory elemental analysis data for the samples could not be obtained because of the formation of non-combustible metal fluorides during combustion. The mass spectral studies of the compounds were carried out using a Micromass Q-TOF instrument. 1,2-Bis(diphenylphosphanyl)ethane[46] (dppe), bis(diphenylphosphanyl)methane[47] (dppm), *trans*-[Fe(H)(η^2-H_2)(dppe)$_2$][BF_4], *trans*-[Ru(H)(η^2-H_2)(dppe)$_2$][BF_4],[48] *trans*-[Ru(H)(η^2-H_2)(dppm)$_2$][BF_4],[7] and PF_3 [49] were prepared according to literature procedures.

Preparation of *trans*-[Fe(H)(PF_3)(dppe)$_2$][BF_4] (1): *trans*-[Fe(H)(η^2-H_2)(dppe)$_2$][BF_4] (0.100 g, 0.1 mmol) was dissolved in CH_2Cl_2 (8 mL) under an atmosphere of H_2. PF_3 gas was then purged through this solution at a steady rate for about 10 min after which time it was stirred for 2 h. Concentration of the reaction mixture to about 2 mL and addition of Et_2O (20 mL) caused the complete precipitation of a cream-colored product of **1**. The product was dried in vacuo and recrystallized from a CH_2Cl_2 solution by slow diffusion of Et_2O over a period of several days. Yield 0.082 g (75%). ES-MS: m/z = 941 [$M^+ - BF_4$], 853 [$M^+ - PF_3 + BF_4$]. The NMR spectroscopic data of **1** are summarized in Table 1.

Preparation of *trans*-[Ru(H)(PF_3)(diphosphane)$_2$][BF_4] (diphosphane = dppm 2, dppe 3): These compounds were prepared in a similar manner to that of **1** starting from *trans*-[Ru(H)(η^2-H_2)(diphosphane)$_2$][BF_4]. Yields of **2** and **3** were 0.075 g (69%) and 0.080 g (73%), respectively. ES-MS of **2**: m/z = 871 [$M^+ - PF_3 + BF_4$]. ES-MS of **3**: m/z = 897 [$M^+ - PF_3 + HBF_4$]. The NMR spectroscopic data of **2** and **3** are given in Table 1.

Attempt to Prepare *trans*-[Fe(η^2-H_2)(PF_3)(dppe)$_2$]$^{2+}$ (4): A sample of *trans*-[Fe(H)(PF_3)(dppe)$_2$][BF_4] (15 mg) was placed in a 5 mm NMR tube capped with a septum. The tube was then evacuated and filled with H_2 in three cycles. The hydride complex was then dissolved in 0.6 mL of CD_2Cl_2 and the solution was frozen in a liquid-nitrogen bath. About 20 μL (16 equiv.) of triflic acid (HOTf) was added and the tube was warmed up to 273 K slowly. It was then transferred to the NMR probe precooled to 273 K. ^{1}H NMR spectroscopy revealed a decrease in the intensity of the hydride resonances, whereas the ^{31}P{^{1}H} NMR spectrum showed the appearance of an intense signal at δ = 10.0 ppm due to dppeH$^+$. At the same time, the lock signal deteriorated, signaling the formation of some Fe^{III} species. No evidence of the formation of a dihydrogen complex was apparent, although the singlet at δ = 4.6 ppm due to free H_2 increased in intensity. Upon addition of a further 10 μL (8 equiv.) of HOTf, the lock signal deteriorated further and all the ^{1}H NMR signals broadened. The intensity of the dppeH$^+$ in the ^{31}P NMR spectrum increased significantly.

Preparation of *trans*- and *cis*-[Ru(η^2-H_2)(PF_3)(dppm)$_2$]$^{2+}$ (5 and 6): The preparation of these two complexes was carried out as described above. Upon addition of 30 μL (60 equiv.) of HOTf the tube was warmed up to 273 K and then transferred to the NMR probe precooled to 273 K. The dihydrogen complexes formed were observed by NMR spectroscopy. The NMR spectroscopic data of **5** and **6** are summarized in Table 3.

Preparation of *trans*-[Ru(η^2-H_2)(PF_3)(dppe)$_2$]$^{2+}$ (7): The dihydrogen complex **7** was prepared as described above starting from *trans*-[Ru(H)(PF_3)(dppe)$_2$][BF_4], except that the protonation was carried out at room temperature and a large excess of HOTf (100 μL, 80 equiv.) was used. The resulting solution was analyzed by NMR spectroscopy. The NMR spectroscopic data of **7** are summarized in Table 3.

Attempted Protonation of *trans*-[Ru(H)(PF_3)(dppe)$_2$][BF_4] with HCl/HBr/HI/CF_3CO_2H: The protonation of *trans*-[Ru(H)(PF_3)(dppe)$_2$][BF_4] was attempted with various other acids such as HCl, HBr, HI, and CF_3CO_2H in addition to HOTf as described above. The corresponding dihydrogen complex *trans*-[Ru(η^2-H_2)(PF_3)(dppe)$_2$]$^{2+}$ (**7**) was obtained only in the case of HOTf, whereas only the starting hydride was recovered with the other acids. The addition of a large excess of acid (HCl, HBr, HI, and CF_3CO_2H) also did not afford the corresponding dihydrogen complex.

Attempt to Isolate *trans*-[Ru(η^2-H_2)(PF_3)(dppe)$_2$]$^{2+}$ (7): The dihydrogen complex **7** was prepared as described above. NMR spectroscopy revealed the complete conversion of the starting hydride into the dihydrogen complex. In an attempt to isolate it, excess Et_2O was added to the reaction mixture to precipitate the colorless dihydrogen complex. The supernatant solution was carefully removed with a syringe and the precipitate was washed a few times with Et_2O and then dried under a stream of H_2 gas. The NMR spectrum revealed the presence of only the starting hydride complex *trans*-[Ru(H)(PF_3)(dppe)$_2$][BF_4] and no other species, suggesting that complete deprotonation had taken place upon addition of Et_2O. The dihydrogen complex was found to be stable with respect to deprotonation only in the presence of a large excess of acid.

Measurement of the Rate Constant for the Decomposition of *trans*-[Ru(η^2-H_2)(PF_3)(dppe)$_2$]$^{2+}$ (7): A sample of *trans*-[Ru(H)(PF_3)(dppe)$_2$][BF_4] (6 mg) was placed in a 5 mm NMR tube

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

capped with a septum. The tube was evacuated and filled with dihydrogen gas in three cycles. The hydride complex was then dissolved in CD_2Cl_2 (0.6 mL). Excess HOTf (15 μL, 30 equiv.) was added and the tube was transferred immediately to the NMR probe. The ^1H and the $^{31}P\{gated\ ^1H\}$ NMR spectra were recorded at intervals of 30 min. The rate constant for the decomposition of *trans*-$[Ru(\eta^2\text{-}H_2)(PF_3)(dppe)_2]^{2+}$ was determined from the integrals of the η^2-H_2 signal with respect to the residual $CDHCl_2$ resonance (δ = 5.32 ppm) in the ^1H NMR spectra and those of the dppe P signal with respect to externally added $[Ph_3PH][OTf]$ (δ = 7.11 ppm) in the $^{31}P\{gated\ ^1H\}$ NMR spectra. After about 16 h, the NMR spectra showed the formation of $dppeH^+$ (ca. 40%), *trans*-$[Ru(Cl)(PF_3)(dppe)_2]^+$ (**8**; ca. 36%), and *trans*-$[Ru(OTf)(PF_3)(dppe)_2]^+$ (**9**; <5%).

8: ^1H NMR (CD_2Cl_2): δ = 3.01 (m, 4 H, $Ph_2PCH_2CH_2PPh_2$), 6.81−7.91 (m, 40 H, $PhPCH_2CH_2PPh_2$) ppm. ^{19}F NMR (CD_2Cl_2): δ = −18.57 (d, PF_3) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 64.3 (d, $J_{P,P}$ = 41.0 Hz, $Ph_2PCH_2CH_2PPh_2$), 127.9 (q quint, $J_{P,F}$ = 1308.0 Hz, PF_3) ppm.

9: ^1H NMR (CD_2Cl_2): δ = 2.94 (m, 2 H, $Ph_2PCH_2CH_2PPh_2$), 3.13 (m, 2 H, $Ph_2PCH_2CH_2PPh_2$), 6.81−7.91 (m, 40 H, $PhPCH_2CH_2PPh_2$) ppm. ^{19}F NMR (CD_2Cl_2): δ = −21.81 (d, PF_3), −75.70 (br. s, OTf − coordinated) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 46.6 (d, $J_{P,P}$ = 41.3 Hz, $Ph_2PCH_2CH_2PPh_2$), 132.1 (q quint, $J_{P,F}$ = 1312.0 Hz, PF_3) ppm.

Attempt to Determine the Equilibrium Constant for the Substitution of η^2-H_2 with CH_3CN in *trans*-$[Ru(\eta^2\text{-}H_2)(PF_3)(dppe)_2]^{2+}$: The dihydrogen complex *trans*-$[Ru(\eta^2\text{-}H_2)(PF_3)(dppe)_2]^{2+}$ was prepared starting from *trans*-$[Ru(H)(PF_3)(dppe)_2][BF_4]$ (20 mg) and HOTf (50 μL, 30 equiv.) as described above. After ensuring that the starting hydride complex had been completely converted into the dihydrogen complex, the solution was frozen in a liquid-nitrogen bath. Then, CH_3CN (1 μL, 1 equiv.) was added and the NMR tube was slowly warmed up to 253 K. It was then transferred to the NMR probe precooled to 253 K. NMR spectroscopy revealed the complete disappearance of the resonances due to the dihydrogen complex and the appearance of signals due to the nitrile complex *trans*-$[Ru(CH_3CN)(PF_3)(dppe)_2]^{2+}$ (**10**) thus precluding the measurement of the equilibrium constant for the substitution of the coordinated H_2 ligand with CH_3CN.

10: ^1H NMR (CD_2Cl_2): δ = 1.45 (s, 3 H, CH_3CN), 3.05 (m, 4 H, $Ph_2PCH_2CH_2PPh_2$), 6.91−7.91 (m, 40 H, $PhPCH_2CH_2PPh_2$) ppm. ^{19}F NMR (CD_2Cl_2): δ = −13.51 (d, PF_3), −91.03 (br. s, OTf), −144.62 (br. s, BF_4) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 38.2 (d, $J_{P,P}$ = 42.5 Hz, $Ph_2PCH_2CH_2PPh_2$), 132.8 (q quint, $J_{P,F}$ = 1258.0 Hz, PF_3) ppm.

Observation of the HD Isotopomers, *trans*-$[Ru(\eta^2\text{-}HD)(PF_3)(dppm)_2]^{2+}$ (5-D_1), *cis*-$[Ru(\eta^2\text{-}HD)(PF_3)(dppm)_2]^{2+}$ (6-D_1), and *trans*-$[Ru(\eta^2\text{-}HD)(PF_3)(dppe)_2]^{2+}$ (7-D_1): The HD isotopomers were prepared using similar procedures as the corresponding H_2 complexes except that appropriate quantities of DOTf were used. The HD isotopomers formed were observed by NMR spectroscopy. The temperature dependent $J_{H,D}$ data for *trans*-$[Ru(\eta^2\text{-}H_2)(PF_3)(dppe)_2]^{2+}$ are summarized in Table 6.

X-ray Crystallographic Study: Colorless crystals were obtained by slow diffusion of Et_2O into a CH_2Cl_2 solution of *trans*-$[Ru(H)(PF_3)(dppm)_2][BF_4]$ (**2**) in an H-tube at room temperature. The unit-cell parameters and intensity data were collected on a Bruker SMART APEX CCD diffractometer equipped with a fine-focus Mo-K_α X-ray source. The SMART software was used for data acquisition and the SAINT software for data abstraction.[50] Absorption corrections were made using the psi-scans method.[51] The structure was solved and refined using the SHELX program suite.[52] The Ru atom position was located from the Patterson map and the non-hydrogen atoms were located from successive difference-Fourier maps and were refined anisotropically. All other hydrogen atoms were fixed in idealized positions and refined in a riding model. Additional details of data collection and structure refinements are listed in Table 7.

Table 7. Crystallographic data for *trans*-$[Ru(H)(PF_3)(dppm)_2][BF_4]$ (**2**)

Formula	$C_{50}H_{48}BF_7O_2P_5Ru$

Synthesis and Polymerization Performance of Pd^{II} Complexes of New 2-Hydroxyethyl-Substituted Diphosphane Ligands

Uwe W. Meier,[a] Ulf Thewalt,[b] Tony Debaerdemaeker,[b] and Bernhard Rieger*[a]

Keywords: Homogeneous catalysis / Palladium / Phosphane ligand / Polyketone / Polymerization

We have synthesized a new diphosphane ligand, 1,3-bis[(2-hydroxyethyl)(phenyl)phosphanyl]propane (**2***) (*****: mixture of *meso*- and racemic diastereoisomers), and its corresponding neutral dichloro palladium(II) (**3***), diiodo palladium(II) (**4***), and dicationic diacetonitrile palladium(II) ditetrafluoroborate (**5***) complexes. Separation of the **4** ***rac*** and **4** ***meso*** diastereoisomers was achieved by column chromatography and subsequent crystallization. Assignments of the particular complex geometries of **3** ***meso*** and **4** ***rac*** were facilitated by single-crystal X-ray diffraction analysis. After activation with MAO, complex **3*** exhibits superior activity in the homopolymerization of 2-norbornene relative to that of the dichloro Pd^{II} derivative of 1,3-bis(diphenylphosphanyl)propane (dppp). Compound **5*** and the dppp-analogue possess similar catalytic potentials in ethylene/CO copolymerization experiments. Applying complex **5*** to propylene/CO copolymerization leads to highly regio- and predominantly stereoregular polyketone materials.

Introduction

Bridged bisphosphane ligands play an important role in homogeneous catalysis. The variety of tools available for tailoring their structures makes these ligands ideal platforms upon which to design selective, molecularly defined catalysts for small-molecule transformations and for polymerization reactions.[1] Until now, the functionalities that have been attached, such as oxygen-containing or fluorinated substituents, have been used primarily to impart particular steric and electronic properties to the ligands, as well as solubility properties of the complexes.[2] A novel approach for further developments is the introduction of suitable functional groups that help to open up selective reaction channels by reversible interactions with either the metal center, the incoming substrate, or the growing polymer chain. In this paper we report the synthesis and structural characterization of Pd^{II} complexes of a new bisphosphane ligand, which bears (2-hydroxyethyl)(phenyl)phosphane units (Scheme 1). We have performed 2-norbornene homopolymerizations, as well as ethylene/CO and propylene/CO copolymerization experiments, to investigate the catalytic potential of these novel complex structures.

Results and Discussion

Ligand and Complex Synthesis

Nucleophilic attack of the dilithium diphosphide, which is accessible from 1,3-bis(phenylphosphanyl)propane (**1**) by deprotonation with 2 equiv. of *n*BuLi, on ethylene oxide[3] gave, after aqueous workup, the desired bisphosphane **2*** (Scheme 2). We obtained the ligand as a mixture of the racemic (*R*,*R*;*S*,*S*) and *meso* (*R*,*S*) components in a 1:1.3 ratio (^{31}P NMR: $\delta_{rac} = -32.50$, $\delta_{meso} = -32.64$ ppm).

Complexation of **2*** with $(COD)PdCl_2$ in CH_2Cl_2 gave the corresponding neutral dichloro palladium(II) complex (**3***) in the expected ratio of diastereoisomers (1:1.3, Scheme 3). Extraction of the mixture **3*** with DMSO and subsequent crystallization from DMSO/CH_2Cl_2 gave pure **3** ***meso***. Replacement of the chloro ligands in **3*** by treat-

ment with sodium iodide in DMSO affords the corresponding diiodo palladium(II) compounds **4***. Separation into pure racemic (**4** ***rac***) and *meso* fractions (**4** ***meso***) was performed by crystallization and subsequent chromatography over silica (CH_2Cl_2/acetone).[4] The dicationic complex **5*** was obtained from **3*** by halide abstraction using $AgBF_4$ in acetonitrile.

Single crystals of **3** ***meso*** (Figure 1, left) were grown from a DMSO extract of **3*** after treatment with CH_2Cl_2. Suitable crystals of **4** ***rac*** (Figure 1, right) were obtained by slow evaporation of the solvent from a CH_2Cl_2/acetone (1:1) solution. The coordination geometry around the Pd^{II} center is nearly square planar, as expected for palladium complexes of non-rigid diphosphanes. Both complexes show Pd−P and Pd−Hal bond lengths (Table 1) that resemble those of the symmetric [1,3-bis(diphenylphosphanyl)propane]$PdCl_2$ (Pd−P: 2.244(1)/2.249(2) Å; Pd−Cl: 2.351(1)/2.358(2) Å] and [1,2-bis(diphenylphosphanyl)ethane]PdI_2 (Pd−P: 2.2608(14)/2.2756(12) Å; Pd−I: 2.6649(8)/2.6446(10) Å] analogues.[5,6] The corresponding bond angles at the Pd centers of the complexes **3** ***meso*** and **4** ***rac*** are similar, i.e., they are independent of the nature of the chloro or iodo ligands, but the bond angle X−Pd−X is slightly enlarged in case of X = Cl [91.24(5)°] relative to X = I [90.46(2)°]. The orientation of the hydroxyethyl substituents is fixed in the solid state by intermolecular hydrogen bonding between neighboring complexes. Pairs of two

complex molecules are bridged by two hydrogen bonds in the unit cell of **3** ***meso***. The intermolecular oxygen−oxygen distance is 2.754 Å. In **4** ***rac***, one molecule is bridged by hydrogen bonding with two other complex units, which, thus, forms a linear polymeric chain. The intermolecular oxygen−oxygen distance in **4** ***rac*** (2.853 Å) is slightly enlarged relative to that in **3** ***meso***.

Homo- and Copolymerization Experiments

The use of bulky, substituted chelating ligands is a prerequisite for achieving polymeric products in late transition metal catalyzed ethylene polymerization reactions.[7] Therefore, we chose 2-norbornene to be the first monomer we applied to verify the homopolymerization capabilities of these new complexes. In addition, chain termination induced by β-hydride elimination is thermodynamically unfavorable when using this monomer.[8] The active complex species was obtained by treating the dichloropalladium(II) compound **3*** with MAO in toluene. As expected, polymerization of 2-norbornene resulted in a completely insoluble poly(norbornene) material[9] (Table 2). The monomer conversion is more than twice as high as that obtained when using the structurally related dichloro(dppp)palladium(II) complex, under analogous experimental conditions.

Table 2. Results of 2-norbornene and ethylene homopolymerization experiments using **3*** and the reference dpppPd^{II}Cl$_2$ after activation with MAO in toluene

The dicationic complex **5*** shows a satisfying activity in the alternating copolymerization of ethylene and carbon monoxide after activation with methanol; it is similar to the results obtained when using the standard polyketone catalyst [(dppp)Pd(NCCH$_3$)$_2$](BF$_4$)$_2$ (Table 3). In the propylene/CO copolymerization reaction, complex **5*** shows a completely different behavior than that of the dppp-ligated catalyst, which is known to produce regio-irregular polyketones.[10] In contrast, the propylene/CO material resulting from **5*** is brittle and insoluble in common solvents, which we attribute to a polyspiroketal chain structure. ^{13}C NMR spectroscopy investigations in [D$_2$]hexafluoro-2-propanol (HFIP) proved that the product has high regioregularity (head−tail sequences >97%; Figure 2). Interestingly, the methyl area is dominated by a single resonance,[11] which indicates a stereoregular, isotactic microstructure. This finding is supported by the relatively high melting transition temperature (T_m = 169 °C).[12]

One reason for the observed regioregular microstructure could be the alkyl substitution on the phosphorus moieties, which is known to produce regioregular polyketones.[13] We have no genuine explanation for the high stereoregularity of the propylene/CO copolymer material (PCO). The chiral cage, formed by the phenyl- and 2-hydroxyethyl P-substituents around the Pd^{II} center is not significantly pronounced to explain the isotacticity of the PCO product. One possible explanation is that the C_2-symmetric *rac*-catalyst species

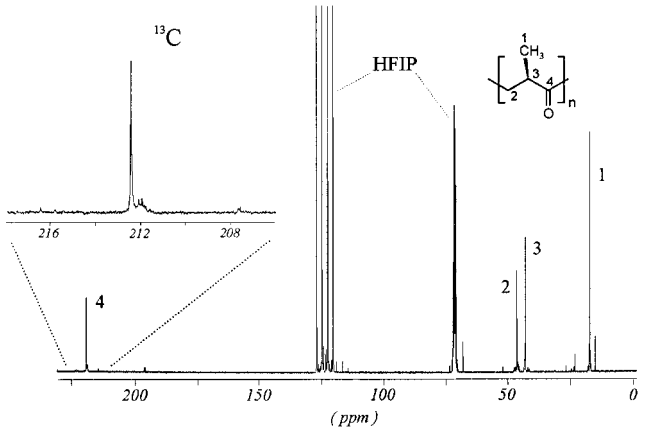

Figure 2. ^{13}C NMR spectrum ([D_2]HFIP) of a propylene/CO-copolymer resulting from the use of **5*** in methanol

has a higher activity than the *meso* complex and leads to the observed isotacticity through interaction of the 2-hydroxy ethyl substituents with the Pd^{II} dicationic metal center (O-coordination). This situation would afford the reversible formation of a chiral and stereorigid metallacycle that might lead to an effective enantiofacial differentiation of the incoming propylene monomer. A second explanation involves reversible interactions of the same OH groups with the coordinated acyl species after CO insertion. Further work toward gaining a deeper insight into these mechanisms is underway.

Conclusion

Our research on multifunctional chelating ligands resulted in the preparation of a 2-hydroxyethyl-substituted bisphosphane **2*** that is accessible by nucleophilic attack of the corresponding dilithium bisphosphide on ethylene oxide. The new ligand exists as a mixture of racemic and *meso* diastereoisomers in a 1:1.3 ratio. Separation of the diastereoisomeric compounds was performed by crystallization and column chromatography of the diiodo Pd^{II} complexes **4***. The neutral dichloro **3*** and the dicationic diacetonitrile Pd^{II} ditetrafluoroborate complexes **5*** are active for the homopolymerization of norbornene and CO/olefins, respectively. Interestingly, the application of complex **5*** affords isotactic propylene/CO copolymers. Elucidating the different polymerization behavior of the *rac* and *meso* isomers and studying the influence of the 2-hydroxyethyl P-substituents will be the subjects of further investigations.

Experimental Section

General: Reactions were performed under argon using standard Schlenk techniques. Solvents were dried by distillation from CaH_2 (dichloromethane) and $LiAlH_4$ (diethyl ether, *n*-pentane). Dry acetonitrile was received from Roth, deoxygenated in vacuo, and stored over molecular sieves (3 Å). H_2O was deoxygenated in vacuo and saturated with argon. 1,3-Bis(phenylphosphanyl)propane (**1**; Strem Chemicals), ethylene oxide (Fluka), $AgBF_4$ and (dppp)$PdCl_2$ (Aldrich), and 2-norbornene (Merck) were used as received. (COD)$PdCl_2$ [14] and $(CH_3CN)_2$(dppp)$Pd(BF_4)_2$ [15] were prepared according to literature procedures. ^1H, ^{13}C, ^{19}F, and ^{31}P NMR spectra were recorded on either a Bruker DRX 400 or an AMX 500 spectrometer. TMS was used as internal standard for the ^1H and ^{13}C spectra. ^{31}P NMR spectroscopic shifts were referenced to the external standard H_3PO_4 (85%). ^{19}F NMR spectra were calibrated to CCl_3F as the internal standard. Mass spectra were acquired using Varian MAT 711 and Finnigan TSQ 7000 instruments. X-Ray structural analyses were performed as described. MAO (in toluene) was supplied by WITCO. Ethylene (2.7), propylene (2.6), and carbon monoxide (2.0) were used without further purification as received from BASF.

1,3-Bis[(2-hydroxyethyl)(phenyl)phosphanyl]propane (2*): 1,3-Bis(phenylphosphanyl)propane (**1**) (11.3 g, 43.4 mmol) was dissolved in THF (400 mL) and cooled to −78 °C. Subsequently, 1.6 M *n*-butyllithium in hexane (53.4 mL, 86.8 mmol) was added to the mixture, which was warmed to room temperature overnight. The orange solution was then cooled to −18 °C and ethylene oxide (7.63 g, 174 mmol, 2 equiv.) was condensed into the reaction mixture. After stirring the resulting white suspension for 1 h at room temperature, all the solvents are removed in vacuo. The residue was hydrolyzed with water and deoxygenated 1 M hydrochloric acid was added, to pH 1, to protonate the bisphosphane. The aqueous solution was extracted with CH_2Cl_2 to remove impurities. Subsequently, after adding CH_2Cl_2 (100 mL) to the resulting acidic water phase, the mixture was adjusted to pH 7, to deprotonate the bisphosphane, by adding deoxygenated aqueous NaOH. The mixture was extracted with CH_2Cl_2 and the combined organic layers were dried over Na_2SO_4. Evaporation of the solvent in vacuo gave ligand **2*** as a colorless, highly viscous oil. Yield 12.2 g (82%). ^1H NMR ($CDCl_3$): δ = 7.47−7.39 (m, 4 H, Ph), 7.33−7.25 (m, 6 H, Ph), 3.68−3.59 (m, 4 H, CH_2O), 2.30−2.15 (br. s, 2 H, OH), 2.01−1.88 (m, 4 H, PCH_2), 1.87−1.72 (m, 4 H, PCH_2, bridge), 1.52−1.39 (m, 2 H, CH_2, bridge) ppm. ^{13}C NMR ($CDCl_3$): δ = 137.7−137.4 (2 × d, *rac*/*meso*, *ipso* Ph), 132.4−132.1 (2 × d, *rac*/*meso*, *ortho* Ph), 128.9 (s, *para* Ph), 128.5−128.3 (2 × d, *rac*/*meso*, *meta* Ph), 60.0 (d, CH_2-OH), 32.0 (vt, *rac*/*meso*, PCH_2), 29.5 (vt, PCH_2, bridge), 22.4−22.1 (m, CH_2, bridge) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −32.50 (s, *rac*), −32.64 (s, *meso*) ppm; ratio *rac*:*meso* = 1:1.3. IR (film): $\tilde{\nu}$ = 3344 cm^{-1} (br., OH). MS (FD): *m*/*z* (%) = 348 (100) $[M]^+$, 303 (5) $[M - CH_2CH_2OH]^+$. $C_{19}H_{26}O_2P_2$ (348.4): calcd. C 65.51, H 7.52; found C 65.23, H 7.35.

Dichloro{1,3-Bis[(2-hydroxyethyl)(phenyl)phosphanyl]propane}-palladium(II) (3*): Ligand **2*** (9.42 g, 27.1 mmol) was dissolved in CH_2Cl_2 (50 mL) and then added to a solution of (COD)$PdCl_2$ (7.72 g, 27.1 mmol) in CH_2Cl_2 (450 mL). After stirring the mixture for 1 h, the precipitated product was separated. Washing with CH_2Cl_2 and pentane and then drying in vacuo gave complex **3*** as a yellow solid. Yield:13.5 g (95%). Extraction of compound **3*** with a small amount of DMSO, followed by crystallization from the DMSO extract by the addition of CH_2Cl_2, gave the pure *meso* complex (**3** ***meso***) containing single-crystals suitable for X-ray diffraction analysis. ^1H NMR ([D_6]DMSO): δ = 8.00−7.91 [m, 4H (*rac*) +4H (*meso*), Ph], 7.55−7.39 [m, 6H (*rac*) + 6H (*meso*), Ph], 5.10 (t, 2 H, *rac*, OH), 5.05 (t, 2 H, *meso*, OH), 4.08−3.85 [m, 4H (*rac*) + 4H (*meso*), CH_2O], 2.91−2.78 (m, 2 H, *rac*), 2.77−2.64 (m, 2 H, *meso*), 2.64−2.40 [m, 2H (*rac*) + 2H (*meso*)], 2.40−2.26 (m, 2 H, *meso*), 2.22−2.07 [m, 2H (*rac*) + 3H (*meso*)], 2.07−1.90 (m, 2 H, *rac*), 1.88−1.70 (m, 2 H, *rac*), 1.20−0.96 (m, 1 H, *meso*) ppm. $^{31}P\{^1H\}$ NMR ([D_6]DMSO): δ = 17.0 (s, *rac*), 13.6 (s, *meso*) ppm;

ratio *rac*:*meso* = 1:1.3. IR (KI): $\tilde{\nu}$ = 3422 cm^{-1} (br., OH). MS (FAB): *m*/*z* (%) = 491 (76) $[M - Cl]^+$, 453 (100) $[M - 2Cl]^+$. $C_{19}H_{26}Cl_2O_2P_2Pd$ (525.7): calcd. C 43.41, H 4.99; found C 43.30, H 4.93.

{1,3-Bis[(2-hydroxyethyl)(phenyl)phosphanyl]propane}diiodopalladium(II) (4*) and Its Separation into 4 *meso* and 4 *rac*: The following procedure was performed using solvents as supplied without further purification. Complex **3*** (7.0 g, 13.3 mmol) was dissolved in DMSO (200 mL). After adding NaI (7.97 g, 53.2 mmol), the reaction mixture was stirred for 15 h at room temperature. The DMSO was separated from the crude product by successive extraction with ether and removal of the resulting DMSO-containing ether layers. Extracting of the resulting solid with CH_2Cl_2 and acetone, followed by crystallization, led to an enrichment of the two diastereoisomers in different product fractions. Complete separation and purification of the diastereoisomers was performed by chromatography over silica (CH_2Cl_2/acetone, 1:2) and subsequent crystallization.

(Al:Pd = 1000), and stirred 2 min to form the active species. 2-Norbornene (5 g) was then added to the solution. The polymerization reaction was quenched after 10 min by pouring the mixture into a glass beaker containing MeOH (500 mL)/conc. hydrochloric acid (5 mL). Separation and drying in vacuo at 80 °C gave the polymer as a white powder.

Ethylene/CO Copolymerization Experiments: The corresponding dicationic diacetonitrile palladium(II) ditetrafluoroborate complex was dissolved in a mixture of CH_2Cl_2 (40 mL) and MeOH (1 mL). The activated catalyst solution was transferred into a 100-mL steel autoclave equipped with a magnetic stirring bar. After pressurizing with ethylene (40 bar) for 5 min, the reactor was charged with carbon monoxide at 80 bar. Following a polymerization time of 3 h, the remaining gases were vented off and the reaction mixture was poured into MeOH. The copolymer was isolated by filtration and then it was dried in vacuo at 60 °C.

Propylene/CO Copolymerization Experiments: The catalyst solution was prepared and transferred into the autoclave as described above for the ethylene/CO copolymerization experiments. The reactor was saturated with propene (30 min) and charged with carbon monoxide at 60 bar. The remaining gases were vented off after a reaction time of 19 h at 25 °C. The resulting reaction mixture was diluted with CH_2Cl_2 and stirred with water for 2 h. The organic phase was separated, the solvent evaporated in vacuo, and the copolymer dried in vacuo at 60 °C.

X-ray Crystallography of 3 *meso* and 4 *rac*: The crystals used in this study were mounted onto the ends of a glass fiber. X-Ray diffraction data were collected on a STOE IPDS unit (Imaging Plate Diffraction System) at 20 °C. Graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å) was used. Crystal data are listed in Table 4 together with refinement details. An absorption correction (analytical method) was applied. The structure of **3** ***meso*** was solved by direct methods using XMY93[16] and that of **4** ***rac*** by the Patterson method. The atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined using the SHELXL-97 program[17] (full-matrix method on F^2 data). Hydrogen atoms, except those attached to oxygen atoms, were included at their calculated positions in the final refinement cycles. The riding model was used to locate the other hydrogen atoms.

CCDC-224744 (for **3** ***meso***) and -224402 (for **4** ***rac***) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Syntheses and Reactions of a Stable 1,2-Dichloro-1,2-diborolane and Aromatic Tetraboranes

Carsten Präsang,[a] Yüksel Sahin,[a] Matthias Hofmann,[b] Gertraud Geiseler,[a] Werner Massa,[a] and Armin Berndt*[a]

Keywords: Aromatics / Boranes / Carbanions / Cyclizations / Heterocycles / Rearrangements

The 1,2-dichloro-1,2-diborolane **1b** was isolated in good yield after the reaction of the 1,2-bis(dimethylamino)-1,2-diborolane **2c** with BCl_3. We prepared **2c** from 1,2-bis(dimethylamino)-1,2-dichlorodiborane(4) (**3**) and TMEDA-free [1,3-bis(trimethylsilyl)allyl]lithium (**5a·Li**), which is accessible by deprotonation of 1,3-bis(trimethylsilyl)propene (**4a**) with *n*-butyllithium in diethyl ether. Upon its reaction with lithium in THF, the 1-allyl-2-chlorodiborane(4) **6a** obtained in the first step undergoes an unprecedented ring closure with 1,2-migration of a trimethylsilyl substituent to yield the boron-stabilized carbanion **7a**. Reaction of **7a** with either chlorotrimethylsilane or HCl gives **2c** or **2d**, respectively. The latter compound cannot be transformed into an isolable 1,2-dichloro-1,2-diborolane; this observation demonstrates that a trimethylsilyl substituent next to each boron atom is essential for the stability of 1,2-dichloro-1,2-diborolanes. Compound **1b** is a versatile starting material, inter alia for the syntheses of the aromatic tetraboranes(6) *cis*-**11** and *trans*-**13** and the aromatic tetraborane(4) *cis*-**12**. The isomerization *cis*-**11** → *trans*-**13** can be explained on the basis of reactions occurring under the conservation of two-electron aromaticity.

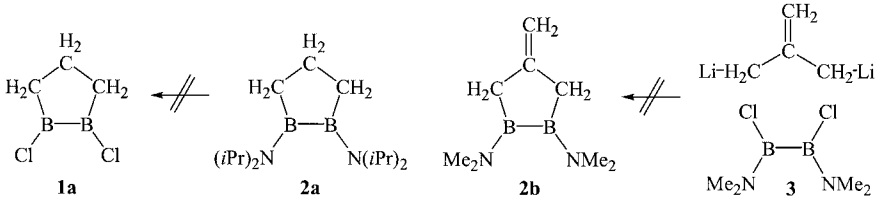
Introduction

1,2-Dichloro-1,2-diborolanes appear to be versatile starting materials for the syntheses of 1,2-diborolanes that lack strong donor substituents at the boron centers, but only 1,2-diborolanes possessing such donors, i.e., 1,2-diamino-1,2-diborolanes, are known experimentally.[1−3] Computations have revealed a strong tendency for the unsubstituted 1,2-diborolane to isomerize to nonclassical forms that have two-electron homoaromatic structures.[4] Attempts to prepare 1,2-dichloro-1,2-diborolane (**1a**) by reaction of the 1,2-diamino-1,2-diborolane **2a** with BCl_3 were unsuccessful,[2] as were efforts to obtain **2b** by reaction of 1,2-dichloro-1,2-bis(dimethylamino)diborane(4) (**3**) with 1,3-dilithio-2-methylenepropane (Scheme 1).[3]

In this paper we describe the synthesis of the stable 1,2-dichloro-1,2-diborolane **1b** (Scheme 3) via the new 1,2-diamino-1,2-diborolane **2c** (Scheme 2). Compound **1b** turned out to be a versatile starting material, inter alia for the syntheses of the aromatic tetraboranes *cis*-**11**,[5] *cis*-**12**,[6] and *trans*-**13**[5] as well as for triboracyclopropanates[7] and a pentaborane(7).[6]

Syntheses

The TMEDA-free allyllithium compounds **5a·Li** and **5b·Li** were prepared by deprotonation of 1,3-bis(silyl)propenes **4a**[8,9] and **4b**[10] with *n*-butyllithium in diethyl ether at room temperature. Compound **4b** was synthesized from 3-[dimethyl(phenyl)silyl]propene,[11] which was deprotonated in the same way and then treated with chlorodimethyl(phenyl)silane.



Scheme 1

The bis(trimethylsilyl)propene **4a** is deprotonated usually in the presence of *N*,*N*,*N*,*N*-tetramethylethylenediamine (TMEDA), THF, or HMPA.[8,12−14] The deprotonation

with *n*-butyllithium in diethyl ether requires a reaction time of 8 d, but the workup of the products obtained after the reaction of lithiopropene **5a·Li** with 1,2-dichloro-1,2-bis(dimethylamino)diborane(4) (**3**) is considerably easier and yields of allylchlorodiboranes(4) **6a,b** are much higher than they are when using the lithium salts of **5a**,**b** containing TMEDA. The 1-allyl-2-chlorodiboranes(4) **6a**,**b** thus obtained are mixtures of (*E*) and (*Z*) stereoisomers, which could not be separated by distillation. The constitutions of (*E*/*Z*)-**6a**,**b** were deduced from their ^1H and ^{13}C NMR spectra and confirmed by the X-ray crystal structure analysis of the product obtained by reaction of the former with lithium in THF (see below). Nearly identical coupling constants $J(^1H,^1H)$ of the alkene moieties of the isomers prevented assignments of configurations by means of ^1H NMR spectroscopy. Probably, the main products (**6a**: 85%; **6b**: 90%) are the (*E*) isomers because of their lower degree of steric hindrance when compared to the (*Z*) isomers.

Reaction of (*E*/*Z*)-**6a** with lithium powder in THF at room temperature yielded 1,2-diborolan-3-ide **7a** as the sole product. This ring-closing reaction was not observed with **6b** even when stoichiometric amounts of lithium naphthalenide were used. The constitution of **7a** is in agreement with all the NMR spectroscopic data and was confirmed definitely by an X-ray crystal structure analysis (see below). While the methyl groups of the dimethylamino substituent of the uncharged boron atom of **7a** show two signals in the ^1H and ^{13}C NMR spectra (300 K, 300/75 MHz), those of the charged boron atom are averaged, which indicates a less hindered rotation.

During the formation of **7a** from (*E*/*Z*)-**6a**, a C−B bond, as well as a boron-stabilized carbanion, is formed, and a trimethylsilyl group must migrate from a carbon atom to the neighboring carbon atom, which, for **6a**, does not possess a silyl substituent. A mechanism for this unprecedented ring closure is proposed below.

The reaction of the anion **7a** with either chlorotrimethylsilane or HCl gave 1,2-diborolanes **2c** and **2d**, respectively. Their constitutions and stereochemistries are in agreement with all of their NMR spectroscopic data. The ^1H NMR spectrum of **2c** exhibits two signals for the silyl groups (2:1), the aminomethyl groups (1:1), and the ring protons (2:1; d

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and t, respectively). The crude product of **2c** was used for subsequent reactions without further purification because it contained very few impurities after removal of the volatile components and filtration.

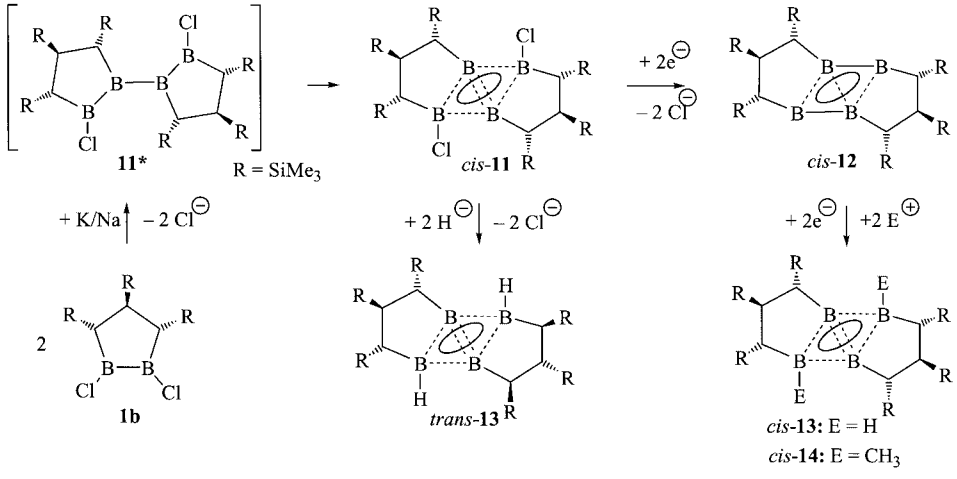
Reaction of **7a** with 1,1,1-trifluoro-2-iodoethane did not yield the expected 3-iodo-1,2-diborolane after warming to room temperature, but, instead, the elimination product diboracyclopentene **8**. The constitution of compound **8** was derived from its one- and two-dimensional ^{1}H, ^{11}B, and ^{13}C NMR spectra.

After the addition of ca. 4 equiv. of neat boron trichloride to a solution of **2c** in *n*-pentane at −78 °C, the solution was warmed to ambient temperature during which time both amino groups were replaced cleanly by chlorine atoms. While small-scale experiments yielded nearly pure **1b**, the crude products of experiments starting with > 10 g of **2c** had to be crystallized from *n*-pentane at −30 °C to obtain satisfactory yields (ca. 68%) of pure **1b**. Diborolane **2d**, which lacks one trimethylsilyl group when compared to **2c**, could not be chlorinated in a similar manner. Reaction with BCl_3 resulted in the recovery of **2d** or led to an inseparable mixture of products containing varying amounts of starting material.

The diborolane **1b** reacts with bis(trimethylsilyl)ethyne at room temperature to form the 3,7-diboracycloheptene **9**. Its constitution was confirmed by NMR spectroscopy experiments. Compound **9** displays three signals for the trimethylsilyl groups (ratio: 2:1:2) and two for the methylene groups (2:1; d and t). Formation of the isomeric 1-methylene-2,6-diboracyclohexane, i.e., the product of the often observed 1,1-diborylation of bis(trimethylsilyl)ethyne,[15,16] was ruled out by $^{13}C\{^{11}B\}$ NMR spectroscopy experiments. The signals of the boron-bound carbon atoms at δ = 181.2 and 34.8 ppm sharpened considerably, but no sharp signal appears for a tricoordinated carbon atom that is not bound to boron atoms (i.e., for an $Si_2C{=}CB_2$ moiety). Similar 1,2-diborylations of ethynes are known to occur from 1,2-diamino-1,2-diborolanes, which, however, require $BF_3{\cdot}OEt_2$ as catalyst and elevated temperatures.[1]

One or both chlorine atoms in **1b** can be exchanged with amino groups by adding stoichiometric amounts of silylamines. In this way, we synthesized the monoaminodiborolanes **10a**,**b** and the diaminodiborolanes **2c**,**e**,**f**. Reaction of **10a** with lithium powder in diethyl ether did not yield a tetraborane(6) by dimerization,[5] but gave the 1,2-diborolan-3-ide **7b**, as proven by its X-ray structural analysis. This transformation, like that of **6a** to **7a**, requires the 1,2-migration of a trimethylsilyl substituent (here to a neighboring boron atom) and the generation of a boron-stabilized carbanion. The NMR spectroscopic data of **7b** are similar to those of **7a**, but some of the chemical shifts differ distinctly. The stronger acceptor in **7b** [$B(SiMe_3)$], when compared to $B(NMe_2)$ in **7a**, causes a downfield shift of the signals of the sp^2-hybridized carbon atom and its proton relative to those signals for **7a** (^{13}C: δ = 149.2 vs. 109.0 ppm; ^{1}H: δ = 6.57 vs. 4.58 ppm). The boron atom bearing the trimethylsilyl group, however, is more shielded (δ = 33 vs. 38 ppm), even though it lacks a second π-donating group. Attempts to let **7b** react with electrophiles (MeI, Me_3SiCl, Me_3SnCl) to yield a *B*-trimethylsilyldiborolane were unsuccessful. The mixtures of products obtained obviously contained no compounds featuring a $B{-}B(SiMe_3)C$ moiety, which would result in a ^{11}B NMR signal for a strongly deshielded boron center.[17]

Reactions of **1b** with $K_{2.8}Na$ in *n*-pentane at room temperature yielded the nonclassical dichlorotetraborane(6) *cis*-**11** (Scheme 4).[5,18,19] As seen from its classical isomer **11***, there are only six electrons to connect the four centers of the B_4 ring of *cis*-**11**. Four of them are used for two three-center two-electron (3c2e) σ-bonds and the remaining two for a 4c2e π-bond.[5] Thus, *cis*-**11** is a 2e-aromatic system having a nonclassical σ-skeleton. Computations for model molecules show the energetic advantage of 2e-aromatic compounds of type **11** over orthogonal classical isomers, which benefit only from twofold B−B hyperconjugation (see below). The aromatic tetraborane(4) *cis*-**12** was obtained by reaction of *cis*-**11** with 2 equiv. of lithium naphthalenide at low temperatures.[6] Reduction of *cis*-**12** to its



Scheme 4

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dianion and a subsequent reaction with either HCl or methyl iodide leads to the tetraborane(6) *cis*-**13** or *cis*-**14**, respectively.[20] Surprisingly, the stereoisomer *trans*-**13** was obtained by exchange of the Cl atoms of *cis*-**11** for hydrogen by use of sodium triethylhydroborate.[5] A reasonable mechanism for this stereoisomerization is presented below.

Crystal Structures

The lithium cations of all the derivatives of allyllithium analyzed by crystal structure determination so far are coordinated by ligands like TMEDA or diethyl ether.[14,21–24] The structure of **5b·Li** is the first one of a solvent-free allyllithium derivative. Attempts to obtain single crystals of **5a·Li** were unsuccessful: it is insoluble, even in boiling *para*-xylene, and it decomposed in boiling mesitylene.

The **5b·Li** complex exhibits a polymeric structure in the solid state with two independent spiral Li−allyl−Li chains parallel to the *c* axis (Figure 1). According to the space group $I4_1$, one spiral chain with Li1 turns around clockwise (4_1 screw axis at 1/4, 1/4, *z*, 90° rotation of subsequent allyl groups); the second one with Li2 turns anticlockwise (4_3 screw axis at 3/4, 1/4, *z*). By the twofold axis in 0.5,0.5,*z*, a second pair of equivalent chains is generated in 3/4,1/4,*z* (Li2) and 3/4,3/4,*z* (Li1) leading to a tetragonal chain packing of alternating 4_1 and 4_3 spirals (Figure 2). Figure 1 displays a section of the Li1 chain that indicates the η^3-connection of the allyl moieties; the C_3 planes are located at an angle of 60.4(3)° [61.7(3)° for the Li2 chain] with respect to the chain axis. In contrast, the structure of (1,3-diphenylallyl)lithium·OEt_2 [22] possesses chains having 2_1-symmetry (180° rotation of subsequent allyl groups); the inclination of the allyl planes to the chain axis is similar (60°).

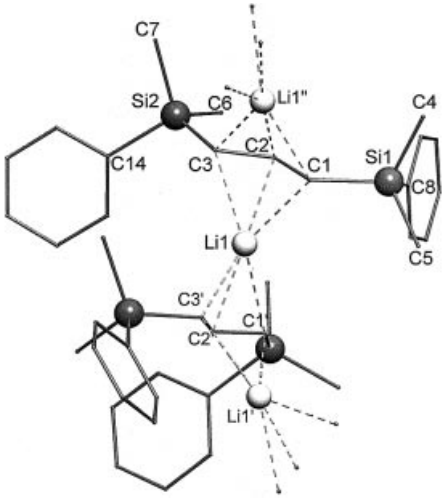


Figure 1. Section of the spiral chain with Li1 in the crystal structure of **5b·Li**; selected bond lengths [pm] and angles [°], the corresponding values for the second spiral chain with Li2 are provided in brackets (same e.s.d.s): C1−C2 140.6(4) [140.2], C2−C3 140.0(4) [139.9], C1−Li1 231.4(6) [233.9], C2−Li1 215.8(6) [215.6], C3−Li1 231.8(6) [228.7], C1′−Li1 228.8(6) [229.7], C2′−Li1 219.3(6) [216.2], C3′−Li1 235.3(6) [229.7]; C1−C2−C3 129.9(3) [128.9], C2−C1−Si1 123.2(2) [124.4], C2−C3−Si2 123.8(2) [123.5], Si1−C1−C2−C3 −176.1(2) [177.9]

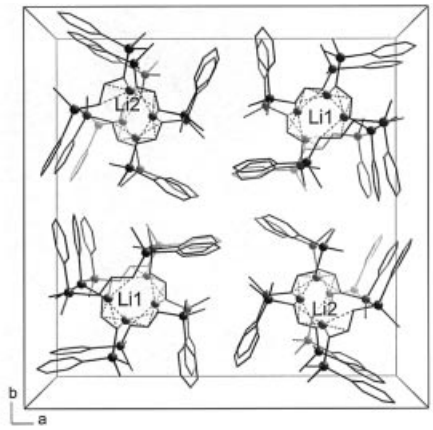

Figure 2. Perspective view along the *c* axis of the unit cell of **5b·Li** having alternating clockwise (Li1) and anticlockwise (Li2) spiral chains

While the differences in the C_3 moieties are not worth mentioning, the absence of an additional ligand coordinating the cation in **5b·Li** has a distinct effect, unsurprisingly, on the C−Li distances. In (1,3-diphenylallyl)lithium·OEt_2, the cation is ca. 10 to 20 pm more remote from the carbon atoms [C−Li: 230(3), 232(3), 248(3), 240(3), 250(3), 252(3) pm].

Compound **7a**·Li[THF]$_2$ forms a contact ion pair; the cation is coordinated by N1, B1−C1, C1−H1, and two molecules of THF, one of which shows disorder. The bond B1−C1 [146.6(3) pm] is significantly shorter than the B2−C3 bond [160.8(3) pm] because of its double bond character. This situation results in a long N1−B1 bond [153.1(2) pm] while the N2−B2 distance [140.8(2) pm] is in the typical range of N−B bonds having a strong π-interaction.

Like **7a**·Li[THF]$_2$, compound **7b**·Li[Et_2O]$_2$ forms a contact ion pair: the cation is coordinated by C1−B1 and two molecules of diethyl ether in this case. The unit cell contains two independent molecules of **7b**·Li[Et_2O]$_2$ with only slightly different bond lengths and bond angles (the second set of data is given in brackets in the following discussion). Complexes **7a**·Li[THF]$_2$ and **7b**·Li[Et_2O]$_2$ are similar with regard to their B_2C_3 rings (see Figures 3 and 4); while the Li cation of the latter is placed approximately above the C−B double bond {B1−Li1: 238.9(5) pm [238.3(4)]; C1−Li1: 239.7(5) pm [243.1(4)]; B2−B1−C1−Li1: 101.9(2)° [101.0(2)°]}, the cation in **7a**·Li[THF]$_2$ is located nearer to the ring plain because of the coordination to the amino group [Li1−C1−B1−B2 146.5 (2)].

In the structure of **1b** (Figure 5), the B−B [169.2(4) pm] and B−Cl [175.9(3), 176.0(3) pm] bond lengths are quite similar to those found in 1,2-dichloro-1,2-dimesityldiborane(4)[25] [168.0(6), 177.0(5) and 177.4(4) pm, respectively]. Compound **1b** deviates from C_s symmetry in the solid state mainly because the orientations of the $SiMe_3$ groups at C1 and C3 break the symmetry of a mirror plane, but also because of slight nonplanarity around the B−B moiety [Cl1−B1−B2−Cl2: 5.8(3)°] and the inequivalent B−C and

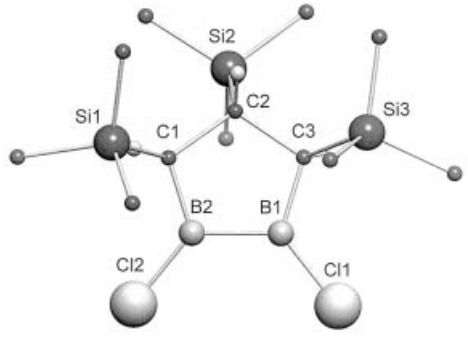

Figure 5. Structure of **1b** in the crystal; selected bond lengths [pm] and angles [°]: B1−B2 169.2(4), B2−C1 150.1(4), C1−C2 156.0(3), C2−C3 157.7(3), C3−B1 151.6(3), B1−Cl1 176.0(3), B2−Cl2 175.9(3), C1−Si1 193.0(2), C2−Si2 189.9(2), C3−Si3 192.5(2); B1−B2−C1 107.2(2), B1−B2−Cl2 128.3(2), B2−B1−C3 106.4(2), B2−B1−Cl1 128.3(2), B1−C3−C2 107.4(2), C3−C2−C1 109.8(2), C2−C1−B2 107.5(2), C1−B2−B1−C3 4.5(2)

C−C bond lengths (see caption to Figure 5). The short B−C [B2−C1: 150.1(4) pm; B1−C3: 151.6(3) pm; usually 158−160 pm] and long C−Si bonds [C1−Si1 193.0(2) pm; C3−Si3 192.5(2) pm; usually 186−187 pm] are mainly the result of C−Si hyperconjugation of the boron atoms with the C−Si bonds.

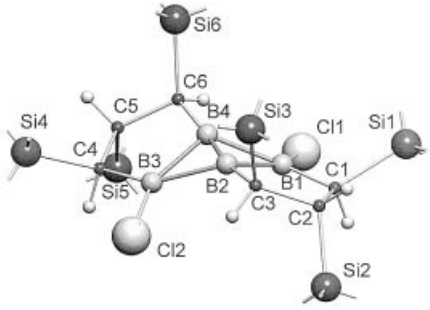

Figure 6. Structure of *cis*-**11** in the crystal; selected bond lengths [pm] and angles [°]: B1−B2 182.6(2), B2−B3 186.3(2), B3−B4 182.2(2), B4−B1 186.0(2), B2−B4 150.2(2), B1−Cl1 179.8(2), B3−Cl2 179.8(2), B1−C1 157.1(2), C1−C2 155.6(2), C2−C3 157.1(2), C3−B2 156.4(2); Cl1−B1−C1 112.1(1), Cl2−B3−C4 112.0(1), C3−B2−B4 169.4(1), C6−B4−B2 170.1(1), B1−B2−B4−B3 135.2(1)

Compound *cis*-**11** (Figure 6) possesses a folded [135.2(1)°] diamond-like structure that has a remarkably short diagonal of only 150.2(2) pm. The edges of this diamond are considerably longer [182.2(2) to 186.3(2) pm] than the B−B bond in **1b** [169.2(4) pm], which indicates multicenter bonding. The boron centers that carry chloro substituents show an approximately planar surrounding by their four neighbors [Cl1−B1−B4−B2: 174.1(1)°; Cl2−B3−B2−B4: 176.7(1)°]. All trimethylsilyl substituents at carbon atoms bound to boron atoms lie on the same side of the B_4 ring. We refer to this stereochemistry as "*cis*" in this text.

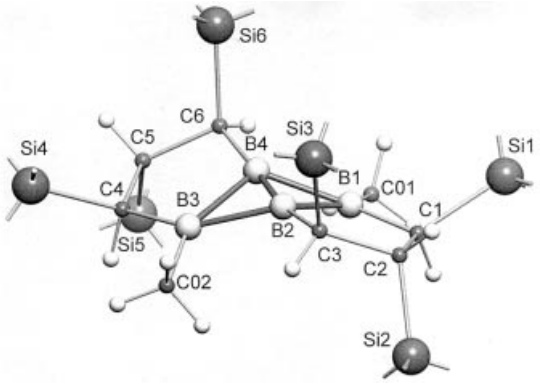

Figure 7. Structure of *cis*-**14** in the crystal; selected bond lengths [pm] and angles [°]: B1−B2 179.9(3) B2−B3 183.0(3), B3−B4 180.2(3), B4−B1 183.5(3), B2−B4 150.1(3), B1−C01 164.8(3), B3−C02 160.9(3), B1−C1 159.6(2), C1−C2 156.1(2), C2−C3 157.0(2), C3−B2 158.0(2); C01−B1−C1 112.0(2), C02−B3−C4 113.0(2), C3−B2−B4 169.4(2), C6−B4−B2 170.1(2), B1−B2−B4−B3 140.2(1)

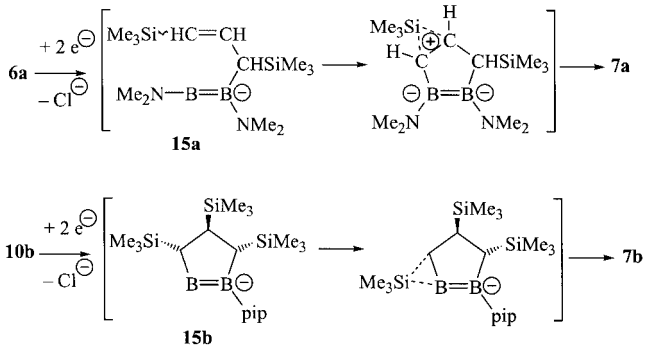
Compound *cis*-**14** (Figure 7) is isostructural to *cis*-**11** and has a similar folding angle of 140.2(1)° for the B_4 diamond. Its diagonal is short [150.1(3) pm], and the edges of the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

diamond are a bit shorter [179.9(3) to 183.5(3) pm] than those in *cis*-**11**. The boron centers that carry methyl substituents are almost planar-tetracoordinate (max. deviations from best planes: B1,B2,B4,C01,C1, 9.9(2) pm; B2,B3,B4,C02,C4, 5.3(2) pm].

Discussion

The ring closure, accompanied by an 1,2-migration of a trimethylsilyl group, which takes place upon reaction of **6a** with lithium metal and leads to the boron-stabilized carbanion **7a**, is unprecedented to the best of our knowledge. It may be explained, however, by analogy to reactions of carbon electrophiles with allylsilanes,[26] by invoking the borylborenate **15a** as an intermediate (Scheme 5). Since borylborenates are isoelectronic with methyleneboranes[27] and vinyl cations, their dicoordinate boron center can be expected to react intramolecularly as a strong electrophile with the allylsilane moiety to generate a carbocation in the β-position relative to a silyl substituent. 1,2-Migration of silyl substituents in cations of this type are well-known processes in the chemistry of allylsilanes.[26]



Scheme 5

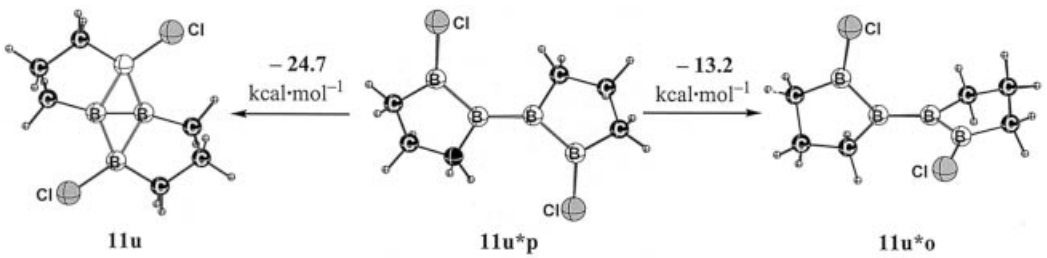
By analogy, the formation of the boron-stabilized carbanion **7b** upon reaction of **10b** with lithium metal can be rationalized by assuming that the borylborenate **15b** is the intermediate. In this case, the silyl substituent migrates to the neighboring electrophilic dicoordinate boron center.

Obviously, the first 1,2-dichloro-1,2-diborolane, **1b**, owes its persistence to the trimethylsilyl substituents at all of the carbon atoms. All attempts to generate a derivative lacking this substituent next to one of the boron centers were unsuccessful. This result explains the failure of earlier efforts to prepare **1a** lacking any substituents.[2]

So far, reaction of metals with 1,2-dichloro-1,2-diboranes(4) having appropriate substituents, like sterically demanding amino or *tert*-butyl substituents, have led to the elimination of both chlorine atoms and generation of folded or tetrahedral tetraboranes(4).[28,29] The reductive dimerization of **1b** to *cis*-**11** is the first example where only one chlorine atom of each 1,2-dichloro-1,2-diborane(4) is eliminated. The dichlorotetraborane(6) *cis*-**11** is a 2e-aromatic tetraborane(6) that has a nonclassical σ-skeleton. Computations (B3LYP/6-311+G**//B3LYP/6-31G*+ZPE)[30] of model molecules lacking silyl substituents show that the aromatic folded diamond **11u** is preferred over the classical planar **11u*p** by 24.7 kcal·mol^{-1}. The orthogonal **11u*o** (Scheme 6), which benefits from twofold B–B hyperconjugation, is only 13.2 kcal·mol^{-1} lower in energy than **11u*p**.

While the *cis* configuration is retained during the transformations of *cis*-**11** to *cis*-**13** and *cis*-**14** via *cis*-**12** and its dianion,[20] the stereoisomer *trans*-**13** is obtained upon reaction of *cis*-**11** with 2 equiv. of sodium triethylhydroborate. All transformations leading to *cis*-**13** occur with conservation of 2e-aromaticity and retention of the stereochemistry in the four-membered rings. The inversion of the stereochemistry of three adjacent centers during the formation of *trans*-**13** requires opening of one ring and then reclosure after inversion at these three centers. This process is possible without loss of 2e-aromaticity by formation of three-membered aromatic systems as intermediates. The initially formed *cis*-**17** can open to *syn*-**18** with conservation of 2e-aromaticity. Rotation about the B–C bond marked with a curved arrow in Scheme 7 in *syn*-**18** leads to *anti*-**18** in which three trimethylsilyl substituents pointing in opposite directions relative to those in *syn*-**18**. This stereochemistry is locked by the reaction to form *trans*-**13**; thus, the transformation of *cis*-**11** into *trans*-**13** occurs with conservation of 2e-aromaticity in all steps. Our mechanism is supported by computations that show that the prototype molecules **17u** and **18u** are low-energy minima.[31] In addition, attack of electrophiles at the 2c2e B–B bond of triboracyclopropanates **18**, like that which occurs during the transformation of *anti*-**18** into *trans*-**13**, are well known experimentally.[7]

Our assumption that the stereoisomerization does not take place during the substitution of the *first* chloride by



Scheme 6

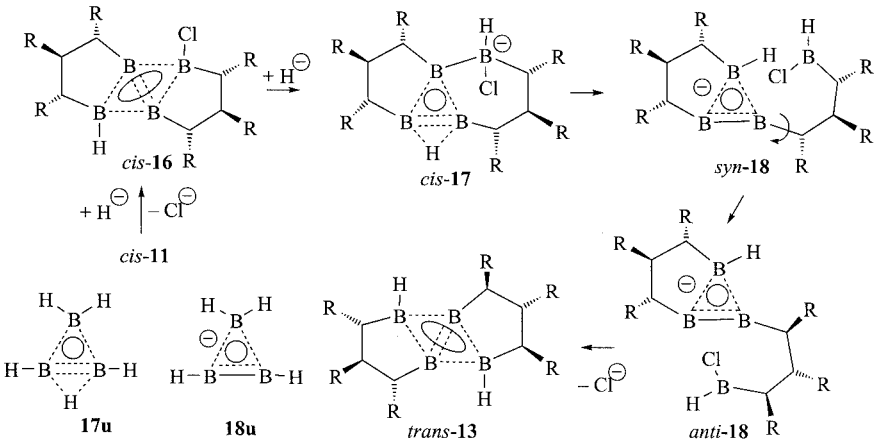

Scheme 7

hydride, but requires a hydrogen atom for the transformation *cis*-**17** → *syn*-**18** to be easy, is supported by the following observation. Substitution of one chloride in *cis*-**11** for CH_2SiMe_3, by reaction with $LiCH_2SiMe_3$, occurs with conservation of the *cis* configuration, as is evidenced by the X-ray structure determination of the obtained monochlorotetraborane(6).[32]

Transformation of the versatile **1b** into 1,2-diorganyl-1,2-diborolanes and their spontaneous and thermally induced reactions will be described in a forthcoming paper.

Experimental Section

General: All reactions were carried out under argon, using standard Schlenk techniques. Solvents were dried, distilled, and saturated with argon. Glassware was dried using a heat gun under high vacuum. ^1H, ^{11}B, and ^{13}C NMR: Bruker ARX 300 and AMX 500 spectrometers. NMR references: Me_4Si, $BF_3{\cdot}OEt_2$.

(*E*)-1,3-Bis[dimethyl(phenyl)silyl]propene (4b): *n*-Butyllithium solution (1.6 N in hexanes, 73.1 mL 117 mmol) was added to a solution of 3-(dimethylphenylsilyl)propene (20.6 g, 116.9 mmol) in *n*-pentane/diethyl ether (1:1, 100 mL) at 0 °C within 2 h. After the solution had been stirred at room temperature for 3 d, chlorodimethyl(phenyl)silane (20.5 g, 120 mmol) was added at −78 °C and the mixture was warmed to room temperature. The organic layer was washed with water (2 × 200 mL), dried with $MgSO_4$, and distilled at 1 × 10^{-3} mbar. Yield: 29.8 g (82%); colorless oil (b.p. 98 °C). For spectroscopic data, see ref.[10]

[1,3-Bis(trimethylsilyl)allyl]lithium (5a·Li): *n*-Butyllithium solution (1.6 N in hexanes, 45 mL 72 mmol) was added at 0 °C to a solution of **4a** (11.9 g, 64.0 mmol) in *n*-pentane/diethyl ether (1:1, 100 mL). After the solution had been stirred at room temperature for 8 d, all volatile components were evaporated in vacuo and the residue was suspended in *n*-pentane (100 mL) and stirred for 2 h. Insoluble **5a·Li** was separated using a reverse glass frit and washed with *n*-pentane (2 × 30 mL). Yield: 9.6 g (78%); colorless, pyrophoric powder. ^1H NMR (200 MHz, [D_8]THF, 300 K): δ = −0.11 (s, 18 H, $SiMe_3$), 2.64 (d, $^3J_{H,H}$ = 16 Hz, 2 H, CHSi), 6.57 (t, $^3J_{H,H}$ = 16 Hz, 1 H, C_2CH) ppm. ^{13}C NMR (75 MHz, [D_8]THF, 300 K): δ = 2.1 (q, $SiMe_3$), 67.3 (d, $^1J_{C,H}$ = 128 Hz, CHSi), 154.3 (d, $^1J_{C,H}$ = 137 Hz, C_2CH) ppm.

1,3-Bis[dimethyl(phenyl)silyl]allyllithium (5b·Li): In a similar reaction to the preparation of **5a·Li**, **4b** (12.0 g, 38.6 mmol) was treated with *n*-butyllithium solution (1.6 N in hexanes, 26.3 mL 42.1 mmol) for 4 d. After workup, **5b·Li** (8.56 g, 70%) was obtained as a slightly yellow, pyrophoric powder. ^1H NMR (300 MHz, [D_8]THF, 300 K): δ = 0.20 (s, 12 H, SiMe), 2.95 (d, $^3J_{H,H}$ = 16 Hz, 2 H, CHSi), 6.77 (t, $^3J_{H,H}$ = 16 Hz, 1 H, C_2CH), 7.15−7.65 (m, 10 H, Ph) ppm.

(*E*/*Z*)-1-[1,3-Bis(trimethylsilyl)allyl]-2-chloro-1,2-bis(dimethylamino)diborane(4) (6a): 1,2-Dichloro-1,2-bis(dimethylamino)diborane(4) (**3**)[33] (17.2 g, 95.0 mmol) was added dropwise to a solution of [1,3-bis(trimethylsilyl)allyl]lithium (**5a·Li**) (18.0 g, 93.6 mmol) in diethyl ether (150 mL) at −78 °C. The mixture was warmed to room temperature and all volatile compounds were evaporated in vacuo. After filtration and washing the residue with *n*-pentane (2 × 50 mL), the filtrate was distilled at 1 × 10^{-1} mbar to yield allyldiborane(4) (*E*/*Z*)-**6a** (29.4 g, 95% relative to **3**; 85:15) as a colorless oil (b.p. 68−72 °C). **(*E*)-6a:** ^1H NMR (300 MHz, $CDCl_3$, 300 K): δ = −0.01, 0.02 (each s, each 9 H, $SiMe_3$), 2.00 (d, $^3J_{H,H}$ = 11 Hz, 1 H, BCHSi), 2.68, 2.69, 2.77, 2.88 (each s, each 3 H, NMe), 5.20 (d, $^3J_{H,H}$ = 18 Hz, 1 H, C=CHSi), 6.09 (dd, $^3J_{H,H}$ = 18, 11 Hz, 1 H, C*H*=CHSi) ppm. ^{11}B NMR (96 MHz, $CDCl_3$, 300 K): δ = 42, 46 ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 300 K): δ = −1.1, −0.8 (each q, $SiMe_3$), 41.2 (br. d, $^1J_{C,H}$ = 94 Hz, BCHSi), 37.6, 39.3, 42.2, 44.6 (each q, NMe), 123.3 (d, $^1J_{C,H}$ = 132 Hz, CH=*C*HSi), 149.3 (d, $^1J_{C,H}$ = 148 Hz, *C*H=CHSi) ppm.

(*E*/*Z*)-1-{1,3-Bis[dimethyl(phenyl)silyl]allyl}-2-chloro-1,2-bis(dimethylamino)diborane(4) (6b): (*E*/*Z*)-**6b** was synthesized by a similar procedure to that of (*E*/*Z*)-**6a** from **3** (4.42 g, 24.44 mmol) and {1,3-bis[dimethyl(phenyl)silyl]allyl}lithium (**5b·Li**, 6.9 g, 22.2 mmol). Distillation at 1 × 10^{-3} mbar yielded (*E*/*Z*)-**6b** (8.29 g, 82% relative to **3**; 9:1) as a colorless oil (b.p. 105−110 °C). **(*E*)-6b:** ^1H NMR (300 MHz, $CDCl_3$, 300 K): δ = 0.27, 0.29, 0.37 (each s, total 12 H, SiMe), 2.28 (d, $^3J_{H,H}$ = 11 Hz, 1 H, BCHSi), 2.35, 2.62, 2.71, 2.85 (each s, each 3 H, NMe), 5.29 (d, $^3J_{H,H}$ = 18 Hz, 1 H, CH=C*H*Si), 6.24 (dd, $^3J_{H,H}$ = 18, 11 Hz, 1 H, C*H*=CHSi), 7.25−7.60 (m, 10 H, Ph) ppm. ^{11}B NMR (96 MHz, $CDCl_3$, 300 K): δ = 42 ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 300 K): δ = −3.4, −2.5, −2.2, −2.1 (each q, SiMe), 40.9 (br. d, $^1J_{C,H}$ = 126 Hz, BCHSi), 37.6, 39.0, 42.1, 44.5 (each q, NMe), 122.2 (d, $^1J_{C,H}$ = 136 Hz, CH=*C*HSi), 127.3, 127.6, 128.6, 128.6, 133.8, 134.0 (each d, *o*-, *m*-, *p*-C), 139.6, 139.9 (each s, *i*-C), 150.9 (d, $^1J_{C,H}$ = 150 Hz, *C*H=CHSi) ppm.

Lithium 1,2-Bis(dimethylamino)-4,5-bis(trimethylsilyl)diborolan-3-ide (7a·Li): Naphthalene (ca. 10 mg) was added to a mixture of lithium powder (600 mg, 86.4 mmol) in THF (150 mL) and then the suspension was stirred until it turned dark-green (5−30 min). The flask was then placed in a big water bath and allyldiborane(4) **6a** (12.0 g, 36.3 mmol) was added within 2 min. After the mixture had been stirred overnight, all volatile compounds were evaporated in vacuo and the residue was suspended in *n*-pentane (150 mL). After filtration, a stable solution of **7a** was obtained, which was used for further syntheses. Crystallization from *n*-pentane at −30 °C yielded **7a**·Li[THF]$_2$ (8.76 g, 50%) as colorless crystals (m.p. 43 °C). ^{1}H NMR (300 MHz, C_6D_6, 300 K): δ = 0.31, 0.33 (each s, each 9 H, $SiMe_3$), 1.20 (s, 1 H, BCHSi), 1.41 (m, 8 H, THF), 2.08 (d, $^3J_{H,H}$ = 3 Hz, 1 H, C_2CHSi), 2.78, 3.03, 3.25 (each s, total 12 H, NMe), 3.48 (m, 8 H, THF), 4.58 (d, $^3J_{H,H}$ = 3 Hz, 1 H, B=CH) ppm. ^{11}B NMR (96 MHz, C_6D_6, 300 K): δ = 38, 52 ppm. ^{13}C NMR (75 MHz, C_6D_6, 300 K): δ = −2.5, 0.8 (each q, $SiMe_3$), 25.4 (t, THF), 30.4 (br. d, $^1J_{C,H}$ = 109 Hz, BCHSi), 33.6 (d, $^1J_{C,H}$ = 115 Hz, C_2*C*HSi), 42.5, 46.5, 46.8 (each q, NMe), 68.5 (t, THF), 109.0 (br. d, $^1J_{C,H}$ = 118 Hz, B=CH) ppm.

3,4-Bis(dimethylamino)-5-(trimethylsilyl)-3,4-diboracyclopentene (8): 1,1,1-Trifluoro-2-iodoethane (8.19 g, 39.0 mmol) was added to a solution of **7a** (prepared from 12.9 g **6a**) in diethyl ether (100 mL) at −78 °C. The mixture was warmed to room temperature within 10 min by using a water bath and then distilled at 20 mbar to yield **8** (4.33 g) as colorless liquid (b.p. 60−62 °C). ^{1}H NMR (300 MHz, $CDCl_3$, 300 K): δ = −0.08 (s, 9 H, $SiMe_3$), 1.45 (d, $^3J_{H,H}$ = 3 Hz, 1 H, BCHSi), 2.78, 2.87, 2.95, 2.99 (each s, each 3 H, NMe), 6.13 (d, $^3J_{H,H}$ = 9 Hz, 1 H, BCH), 7.01 (dd, $^3J_{H,H}$ = 9, 3 Hz, 1 H, C_2CH) ppm. ^{11}B NMR (96 MHz, $CDCl_3$, 300 K): δ = 46, 51 ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 300 K): δ = −1.3 (q, $SiMe_3$), 34.4 (br. d, $^1J_{C,H}$ = 112 Hz, BCHSi), 41.2, 41.4, 44.9, 45.5 (each q, NMe), 137.1 (br. d, $^1J_{C,H}$ = 149 Hz, BCH), 159.5 (d, $^1J_{C,H}$ = 152 Hz, C_2*C*H) ppm.

1,2-Bis(dimethylamino)-3,4,5-tris(trimethylsilyl)-1,2-diborolane (2c): A solution of **7a·Li** [prepared from **6a** (12.0 g, 36.3 mmol)] in *n*-pentane/diethyl ether (2:1, 150 mL) was cooled to −78 °C and mixed with 1.1 equiv. of chlorotrimethylsilane (4.34 g, 39.9 mmol). After warming to room temperature, all volatile components were evaporated in vacuo and the residue was suspended in *n*-pentane (100 mL). Filtration and evaporation of the solvent yielded **2c** (12.43 g, 93% relative to **6a**) as a highly viscous oil that crystallized overnight (m.p. 42 °C). Usually, the *n*-pentane solutions were used for the synthesis of **1b** without further workup. ^{1}H NMR (300 MHz, $CDCl_3$, 300 K): δ = −0.15, 0.04 (each s, total 27 H, $SiMe_3$), 0.64 (d, $^3J_{H,H}$ = 3 Hz, 2 H, BCHSi), 1.46 (t, $^3J_{H,H}$ = 3 Hz, 1 H, C_2CHSi), 2.82, 2.90 (each s, each 6 H, NMe) ppm. ^{11}B NMR (96 MHz, $CDCl_3$, 300 K): δ = 54 ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 300 K): δ = −3.3, 1.5 (each s, $SiMe_3$), 23.6 (br. d, $^1J_{C,H}$ = 123 Hz, BCHSi; d, $^1J_{C,H}$ = 123 Hz, C_2*C*HSi), 42.7, 45.5 (each q, NMe) ppm.

1,2-Bis(dimethylamino)-3,4-bis(trimethylsilyl)-1,2-diborolane (2d): Starting from **6a** (12.2 g), **2d** was synthesized by a similar procedure to that of **2c** from **7a** and 6 N HCl (1 equiv., diethyl ether). Distillation (10 mbar, 65−70 °C) yielded **2d** (8.53 g, 78%) as a colorless liquid. ^{1}H NMR (300 MHz, $CDCl_3$, 300 K): δ = −0.15, 0.13 (each s, each 9 H, $SiMe_3$), 0.76 (s, 1 H, BCHSi), 0.77 (dd, $^2J_{H,H}$ = 17, $^3J_{H,H}$ = 4 Hz, 1 H, BCH*H′*), 1.05 (dd, $^2J_{H,H}$ = 17, $^3J_{H,H}$ = 10 Hz, 1 H, BC*H*H′), 1.17 (dd, $^3J_{H,H}$ = 10, 4 Hz, 1 H, C_2CHSi), 2.75, 2.79, 2.89, 2.91 (each s, each 3 H, NMe) ppm. ^{11}B NMR (96 MHz, $CDCl_3$, 300 K): δ = 53 ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 300 K): δ = −3.3, −0.9 (each q, $SiMe_3$), 20.5 (br. pseudo t, $^1J_{C,H}$ = 117 Hz, BCH_2), 20.9 (d, $^1J_{C,H}$ = 120 Hz, C_2*C*HSi), 27.0 (br. d, $^1J_{C,H}$ = 109 Hz, BCHSi), 40.7, 40.9, 45.1, 45.6 (each q, NMe) ppm.

1,2-Dichloro-3,4,5-tris(trimethylsilyl)-1,2-diborolane (1b): A solution of **2c** (6.8 g, 18.5 mmol) in *n*-pentane (150 mL) was mixed with neat BCl_3 (8.67 g, 74 mmol, 4.4 equiv.) at −78 °C and then warmed to 0 °C within 3 h. All volatile components were evaporated at this temperature and then the residue was warmed to room temperature in vacuo and evacuation was continued for 2 h. The residue was treated with *n*-pentane (50 mL) and the insoluble byproducts were filtered off. Evaporation of the solvent yielded **1b** (6.2 g, 96%) as a highly viscous oil, which was essentially pure based on its ^{1}H NMR spectra. Crystallization from *n*-pentane (necessary for reactions starting with more than 10 g of **2c**) at −30 °C gave light-yellow crystals [68%; m.p. 44 °C (decomposition)]. ^{1}H NMR (300 MHz, $CDCl_3$, 300 K): δ = −0.15, 0.16 (each s, total 27 H, $SiMe_3$), 1.92 (t, $^3J_{H,H}$ = 1 Hz, 1 H, C_2CHSi), 2.13 (d, $^3J_{H,H}$ = 2 Hz, 2 H, BCHSi) ppm. ^{11}B NMR (96 MHz, $CDCl_3$, 300 K): δ = 84 ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 300 K): δ = −3.4, 1.0 (each q, $SiMe_3$), 28.4 (d, $^1J_{C,H}$ = 124 Hz, C_2*C*HSi), 53.2 (br. d, $^1J_{C,H}$ = 117 Hz, BCHSi) ppm.

3,7-Dichloro-1,2,4,5,6-pentakis(trimethylsilyl)-3,7-diboracycloheptene (9): **1b** (ca. 4.5 g, 12.8 mmol) dissolved in *n*-pentane (50 mL) was treated with bis(trimethylsilyl)ethyne (3.27 g, 19.2 mmol, 1.5 equiv.) at 0 °C. After warming to room temperature, all volatile components were evaporated in vacuo, to yield **9** (6.35 g, 95%) as a highly viscous oil that contained some minor impurities. ^{1}H NMR (300 MHz, $CDCl_3$, 300 K): δ = 0.10, 0.18, 0.33 (each s, total 45 H, $SiMe_3$), 1.26 (t, $^3J_{H,H}$ = 7 Hz, 1 H, C_2CHSi), 1.43 (d, $^3J_{H,H}$ = 7 Hz, 2 H, BCHSi) ppm. ^{11}B NMR (96 MHz, $CDCl_3$, 300 K): δ = 67 ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 300 K): δ = 0.7, 1.6, 3.0 (each q, $SiMe_3$), 18.4 (d, $^1J_{C,H}$ = 127 Hz, C_2*C*HSi), 34.8 (br. d, $^1J_{C,H}$ = 112 Hz, BCHSi), 181.2 (br. s, BCSi) ppm.

1,2-Dipiperidino-3,4,5-tris(trimethylsilyl)-1,2-diborolane (2e): *N*-(Trimethylsilyl)piperidine (ca. 4 equiv.) was added to a stirred solution of **2c** (2.2 g, 6.27 mmol) in *n*-pentane (50 mL) at room temperature. After 24 h, all volatile components were evaporated in vacuo to yield **2e** (2.64 g, 94%) as a slightly yellow solid. ^{1}H NMR (300 MHz, C_6D_6, 300 K): δ = 0.26, 0.43 (each s, total 27 H, $SiMe_3$), 1.00 (d, $^3J_{H,H}$ = 5 Hz, 2 H, BCHSi), 1.5−1.7 (m, 12 H, pip), 1.91 (t, $^3J_{H,H}$ = 5 Hz, 1 H, C_2*C*HSi), 3.3−3.5 (m, 8 H, pip) ppm. ^{11}B NMR (96 MHz, C_6D_6, 300 K): δ = 53 ppm. ^{13}C NMR (75 MHz, C_6D_6, 300 K): δ = −2.6, 2.0 ($SiMe_3$), 22.7 (br., BCHSi), 24.3 (C_2*C*HSi), 25.3, 27.8, 28.2, 51.9, 53.9 (pip) ppm.

1,2-Bis(diethylamino)-3,4,5-tris(trimethylsilyl)-1,2-diborolane (2f): By a procedure analogous to that for the preparation of **2e**, **2f** was synthesized from **2c** (4.0 g, 11.39 mmol) and diethyl(trimethylsilyl)amine (4 equiv.) to yield **2f** (4.59 g, 95%) as a slightly yellow solid. ^{1}H NMR (300 MHz, $CDCl_3$, 300 K): δ = −0.14, 0.03 (each s, total 27 H, $SiMe_3$), 0.65 (d, $^3J_{H,H}$ = 3 Hz, 2 H, BCHSi), 1.05 (t, 12 H, NCH_2CH_3), 1.47 (t, $^3J_{H,H}$ = 3 Hz, 1 H, C_2CHSi), 3.22 (q, 8 H, NCH_2CH_3) ppm. ^{11}B NMR (96 MHz, $CDCl_3$, 300 K): δ = 54 ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 300 K): δ = −2.8, 1.5 (each q, $SiMe_3$), 14.6, 15.0 (each q, NCH_2CH_3), 22.8 (br. d, $^1J_{C,H}$ = 110 Hz, BCHSi), 23.8 (d, $^1J_{C,H}$ = 122 Hz, C_2*C*HSi), 43.2, 45.8 (each t, NCH_2CH_3) ppm.

1-Chloro-2-(dimethylamino)-3,4,5-tris(trimethylsilyl)-1,2-diborolane (10a): Dimethyl(trimethylsilyl)amine (530 mg, 4.52 mmol) was added to a solution of **1b** (1.6 g, 4.56 mmol) in *n*-pentane (50 mL) at room temperature. After the mixture had been stirred overnight, all the volatile components were evaporated in vacuo and the residue was treated with *n*-pentane (25 mL) and filtered. Crystalliza-

tion from *n*-pentane (5 mL) at −30 °C yielded **10a** (990 mg, 60%) as slightly yellow crystals [m.p. 52 °C (some decomposition)]. ^{1}H NMR (300 MHz, C_6D_6, 300 K): δ = −0.05, 0.25, 0.31 (each s, each 9 H, $SiMe_3$), 1.29 (s, 1 H, NBCHSi), 1.67 (d, $^3J_{H,H}$ = 2 Hz, 1 H, ClBCHSi), 1.79 (d, $^3J_{H,H}$ = 2 Hz, 1 H, C_2CHSi), 2.62, 3.04 (each s, each 3 H, NMe) ppm. ^{11}B NMR (96 MHz, C_6D_6, 300 K): δ = 48, 91 ppm. ^{13}C NMR (75 MHz, C_6D_6, 300 K): δ = −4.6, 0.1, 0.2 ($SiMe_3$), 24.4 (C_2*C*HSi), 27.9 (br., NBCHSi), 40.7, 41.4 (NMe), 46.8 (br., ClBCHSi) ppm.

1-Chloro-2-piperidino-3,4,5-tris(trimethylsilyl)-1,2-diborolane (10b): *N*-(Trimethylsilyl)piperidine (2.62 g, 16.7 mmol) was added to a solution of **1b** (5.85 g, 16.7 mmol) in *n*-pentane (50 mL) at −78 °C. After warming to room temperature, the mixture was stirred for an additional 18 h and then all the volatile components were evaporated in vacuo. Crystallization of the residue from *n*-pentane (15 mL) at −30 °C yielded **10b** (4.86 g, 73%) as colorless crystals [m.p. 72 °C (some decomposition)]. ^{1}H NMR (300 MHz, $CDCl_3$, 300 K): δ = −0.15, 0.01, 0.13 (each s, each 9 H, $SiMe_3$), 1.21 (d, $^3J_{H,H}$ = 2 Hz, 1 H, BCHSi), 1.43 (d, $^3J_{H,H}$ = 2 Hz, 1 H, BCHSi), 1.62 (dd, $^3J_{H,H}$ = 3, 2 Hz, 1 H, C_2CHSi), 1.32−1.75 [m, 6 H, $N(CH_2)_5$], 3.06, 3.29, 3.95 [each m, total 4 H, $N(CH_2)_5$] ppm. ^{11}B NMR (96 MHz, $CDCl_3$, 300 K): δ = 47, 92 ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 300 K): δ = −3.4, 1.1, 1.3 (each q, $SiMe_3$), 25.1 (d, $^1J_{C,H}$ = 123 Hz, C_2*C*HSi), 27.9 (br. d, $^1J_{C,H}$ = 123 Hz, NBCHSi), 47.3 (br. d, $^1J_{C,H}$ = 104 Hz, ClBCHSi), 25.1, 28.1, 28.6, 51.1, 51.7 [each d, $N(CH_2)_5$] ppm.

Lithium 1-Piperidino-2,4,5-tris(trimethylsilyl)-1,2-diborolan-3-ide (7b·Li): A solution of **10b** (2.42 g, 6.1 mmol) in diethyl ether (25 mL) was added to a suspension of lithium powder (ca. 500 mg) in diethyl ether (25 mL) at room temperature. After the mixture had been stirred for 2 h, all the volatile components were evaporated in vacuo. The residue was treated with *n*-pentane (50 mL) and the excess lithium powder and LiCl were filtered off. Crystallization from *n*-pentane (20 mL) at −30 °C yielded **7b**·Li[Et_2O]$_2$ (1.67 g, 62%) as colorless crystals (m.p. 93 °C). ^{1}H NMR (400 MHz, C_6D_6, 300 K): δ = 0.15, 0.23, 0.45 (each s, each 9 H, $SiMe_3$), 0.86 (t, 6 H, Et_2O), 1.26 (s, 1 H, BCHSi), 1.55−1.87 [m, 6 H, $N(CH_2)_5$], 2.33 (d, $^3J_{H,H}$ = 3 Hz, 1 H, C_2CHSi), 3.01 (q, 4 H, Et_2O), 3.13, 3.42, 3.66, 4.21 [each m, each 1 H, $N(CH_2)_5$], 6.57 (d, $^3J_{H,H}$ = 3 Hz, 1 H, BCH) ppm. ^{11}B NMR (96 MHz, C_6D_6, 300 K): δ = 33, 58 ppm. ^{13}C NMR (75 MHz, C_6D_6, 300 K): δ = −2.5, 0.3, 3.2 (each q, $SiMe_3$), 14.4 (q, Et_2O), 27.5 (br., BCHSi), 26.3, 28.8, 29.3, [each t, $N(CH_2)_5$], 42.3 (d, $^1J_{C,H}$ = 119 Hz, C_2*C*HSi), 51.8, 56.2 [each t, $N(CH_2)_5$], 66.1 (t, Et_2O), 149.2 (br. d, $^1J_{C,H}$ = 122 Hz, BCH) ppm.

Dichlorotetraborane(6) (*cis*-11): $K_{2.8}Na$ (3 mL) was added to a solution of **1b** (5.92 g, 16.9 mmol) in *n*-pentane (150 mL; water bath, reflux condensor) at room temperature. After the reaction started (reflux, precipitation of a deep-blue salt), the mixture was stirred for an additional 30 min. The insoluble components were filtered off and washed with *n*-pentane (3 × 50 mL). Removal of the solvent yielded *cis*-**11** (5.11 g, 96%) as a yellow solid, essentially pure based on its ^{1}H NMR spectra. The use of larger quantities (> 10 g) of **1b** in this reaction caused the formation of some impurities. In this case, crystallization from *n*-pentane at −30 °C yielded **1b** (ca. 75%) as yellow crystals. Spectroscopic data: see ref.[5]

Tetraborane(6) (*trans*-13): $NaBEt_3H$ solution (1.0 N in toluene, 6 mL, 6 mmol) was added to a solution of *cis*-**11** (1.9 g, 3 mmol) in diethyl ether (50 mL) at −78 °C. The mixture was warmed slowly (12 h) to room temperature and then all the volatile components were evaporated in vacuo. The residue was treated with *n*-pentane (50 mL) and then the solution was separated from the solids using a pipette. After washing the solids with additional *n*-pentane (25 mL), the combined solutions were reduced to a volume of 20 mL. Crystallization at −30 °C yielded *trans*-**13** (1.02 g, 60%) in three fractions. Spectroscopic data: see ref.[5]

Tetraborane(4) (*cis*-12): Lithium naphthalenide solution (1.0 N, 26.7 mL, 26.7 mmol) was added to a suspension of *cis*-**11** (8.4 g, 13.3 mmol) in diethyl ether (150 mL) at −100 °C. After warming to room temperature, all of the volatile components were evaporated in vacuo and the naphthalene was sublimed (60 °C/1 × 10^{-3} mbar). The residue was treated with *n*-pentane (120 mL) and the insoluble solids were filtered off. Crystallization at −30 °C yielded *cis*-**12** (7.08 g, 95%) as a yellow solid. Spectroscopic data: see ref.[6]

Dimethyltetraborane(6) (*cis*-14): A solution of *cis*-**12** (1.9 g, 3.39 mmol) in THF (25 mL) was treated with lithium naphthalenide (2 equiv.), followed by iodomethane (0.95 g, 6.79 mmol), at −100 °C. After warming to room temperature, all of the volatile compounds were evaporated in vacuo, the residue was treated with *n*-pentane, and the insoluble material was filtered off. Crystallization from *n*-pentane (10 mL) at −30 °C yielded *cis*-**14** (1.60 g, 80%) as yellow crystals [m.p. 125 °C (decomposition)]. Spectroscopic data: see ref.[20]

Tetraborane(6) (*cis*-13): A solution of *cis*-**12** (1.1 g, 1.96 mmol) in THF (25 mL) was treated with lithium naphthalenide (2 equiv.) followed by HCl solution (2 N in diethyl ether, 0.99 mL, 1.98 mmol). After warming to room temperature and evaporation of the volatile compounds in vacuo, the naphthalene was separated by sublimation (60 °C/1 × 10^{-3} mbar). The residue was treated with *n*-pentane and the insoluble compounds were filtered off. *cis*-**13** of only 95% parity was obtained by crystallization from *n*-pentane at −30 °C. Yield (^{1}H NMR spectroscopy): 90%. ^{1}H NMR (300 MHz, C_6D_6, 300 K): δ = 0.07, 0.24, 0.28 (each s, each 18 H, $SiMe_3$), 1.74 (pseudo t, $^3J_{H,H}$ = 4 Hz, 2 H, C_2CHSi), 1.93 (d, $^3J_{H,H}$ = 4 Hz, 2 H, B_3BCHSi), 2.23 (m, 2 H, HBC*H*Si), 7.01 (very br. s, 2 H, BH) ppm. ^{11}B NMR (96 MHz, C_6D_6, 300 K): δ = 27, 51 ppm. ^{13}C NMR (75 MHz, C_6D_6, 300 K): δ = −3.6, 0.4, 0.5 ($SiMe_3$), 28.9 (d, $^1J_{C,H}$ = 123 Hz, C_2*C*HSi), 30 (br., BCHSi), 41.6 (br. d, $^1J_{C,H}$ = 110 Hz, BCHSi) ppm.

Crystal Structure Determinations: All single-crystal diffraction experiments were performed with an image plate area detector system (IPDS, Stoe) using an Mo-K_α radiation source equipped with a graphite monochromator. Crystals were selected from dry inert paraffin oil, mounted on top of a quartz capillary, and measured with φ scans. All crystal and experimental data of the six structure determinations are listed in Table 1. The structures were all solved by direct methods using the SHELXS program[34] and refined by the full-matrix least-squares method against all F^2 data.[35] "Interesting" hydrogen atoms at the nuclei of the structures were localized from difference Fourier maps and refined using individual isotropic displacement parameters; those of peripheral moieties, like the $SiMe_3$ groups, were treated as riding on idealized calculated positions. Their displacement parameters were fixed to 1.2- or (for methyl groups) 1.5-times the U_{eq} values of their bonding partners. All heavier atoms were refined using anisotropic displacement parameters. Images of the structure were drawn using DIAMOND.[36] Crystals of **1b** suitable for X-ray analysis were grown from an *n*-pentane solution at −30 °C. Single crystals of **5b·Li** were obtained by dissolving **5b·Li** (ca. 2 g) in boiling toluene (80 mL) and then keeping the solution at 95 °C for 18 h. The diffraction pattern of the very sensitive crystal showed weak powder rings, which probably caused the somewhat reduced quality of the results, especially

the relatively high residual electron density of 0.69 e/Å^3. The absolute structure could not be determined clearly because of the absence of suitably strong anomalous scatters [Flack parameter $x = 0.21(11)$]. Possible twinning by merohedry could be excluded. Crystals of **7a**·Li[THF]$_2$ suitable for X-ray analysis were grown from an *n*-pentane solution at −30 °C. In its structure, one of the THF molecules coordinated to lithium shows disorder: C15 has two alternative positions (1:1) above and below the plane of the remaining atoms. A single crystal of **7b**·Li[Et$_2$O]$_2$ was obtained from an *n*-pentane/diethyl ether (1:1) solution at −30 °C. Crystals of the isostructural compounds *cis*-**11** and *cis*-**14** were grown from an *n*-pentane solution at −30 °C. CCDC-225331 (**1b**), -225332 (**5b·Li**), -225333 (**7a·Li[THF]$_2$**), -225334 (**7a·Li[Et$_2$O]$_2$**), -225335 (*cis*-**11**), and -225336 (*cis*-**14**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Studies Related to the Chloro Titanium and Zirconium Complexes with [η^5-Cyclopentadienyldi(silylamido)] Ligands

María Sudupe,[a] Jesús Cano,[a] Pascual Royo,*[a] and Eberhardt Herdtweck[b]

Dedicated to Professor José Vicente on the occasion of his 60th birthday

Keywords: Zirconium / Titanium / Silylamido / Cyclopentadienyl-N ligands

Trichloro complexes [M{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)]$_2$}Cl_3] [M = Zr (**2**), Ti (**3**)] have been synthesized by reaction of the corresponding chlorides MCl_4 with the lithium salt LiC_5H_3[$SiMe_2$(NH*t*Bu)]$_2$ (**1**). Complexes **2** and **3** react with 2 equiv. of $TiCl_4$ in toluene at 110°C to afford the di(chlorosilyl) derivatives [M{η^5-C_5H_3($SiMe_2Cl$)$_2$}Cl_3] [M = Ti (**5**), Zr (**8**)]. Intermediate formation of [Ti{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)]($SiMe_2Cl$)}Cl_3] (**4**) has been proven by NMR spectroscopy. Reaction of **1** with $TiCl_4$ (2 equiv.) in toluene at 110 °C in the presence of excess NEt_3 has yielded the chloro-silyl complex [Ti{η^5-C_5H_3($SiMe_2Cl$)($SiMe_2$-η^1-N*t*Bu)}Cl_2] (**7**) through the intermediate formation of the amino-silyl derivative [Ti{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)] ($SiMe_2$-η^1-N*t*Bu)}Cl_2] (**6**). Reactions of di-*ansa*-[M{η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)$_2$}R] and *ansa*-[M{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)] ($SiMe_2$-η^1-N*t*Bu)}R_2] (M = Ti, Zr; R = NMe_2, CH_2Ph) complexes with NEt_3·HCl have afforded the dichloro derivatives [M{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)] ($SiMe_2$-η^1-N*t*Bu)}-Cl_2] [M = Ti (**6**), Zr (**12**)], the amine-coordinated zirconium compound [Zr{η^5-C_5H_3 [$SiMe_2$(NH*t*Bu)]($SiMe_2$-η^1-N*t*Bu)} Cl_2(NMe_2H)] (**9**) and the chloro-benzyl titanium complex [Ti{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)]($SiMe_2$-η^1-N*t*Bu)}Cl-(CH_2Ph)] (**11**). Formation of the mono-substituted chloro-amido zirconium complex [Zr{η^5-C_5H_3[$SiMe_2$ (NH*t*Bu)]-($SiMe_2$-η^1-N*t*Bu)}Cl(NMe_2)] (**10**) by the reaction of [Zr{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)] ($SiMe_2$-η^1-N*t*Bu)}(NMe_2)$_2$] with $SiClMe_3$ has been monitored in C_6D_6 by NMR spectroscopy. All of the new chloro complexes have been characterized by elemental analyses and NMR spectroscopy and the X-ray crystal structure of [Ti(η^5-C_5H_3{$SiMe_2$(NH*t*Bu)}$_2$)Cl_3] (**3**) has been studied by diffraction methods.

Introduction

Alkylamido-dimethylsilyl-cyclopentadienyl and indenyl group 4 metal complexes and their catalytic applications in olefin polymerization processes have been widely studied.[1−3] The most efficient method of synthesizing these compounds uses the dimetallated anion [$CpSiMe_2$(NR)]$^{2-}$ to transfer the (η^5-Cp-η^1-N) bidentate ligand by reaction with metal chlorides MCl_4 or $MCl_2(NR_2)_2$ to give the dichloro[1a] and diamido[4] derivatives, respectively. However, this method is not recommended in several particular cases and such anion transfers cannot be used when tridentate η^5-Cp(η^1-N)$_2$ ligands are involved in the isolation of cyclopentadienyl-bis(silyl-η^1-amido) metal compounds of the type reported[5] by our group.

An alternative route, avoiding the metathesis step, uses the direct double deprotonation of the amino-dimethylsilyl-cyclopentadiene [$C_5H_5SiMe_2NHR$] with group 4 metal compounds containing strongly basic substituents. Accordingly, metal tetraamides $M(NR_2)_4$ have been extensively used[6] to deprotonate cyclopentadienes,[7] amino-alkyl and -silylcyclopentadienes and different protonated ligands[8] with amine elimination to give amido-silyl ring-closed diamido complexes. The double deprotonation of the cyclopentadiene and the aminosilyl groups may take place in either one or two steps, depending on the acidity of the proton bound to the functional group.[9,10] Similar reactions using metal tetraalkyls[11,12] afford the corresponding dialkyl compounds and are even more useful due to their higher basicity and irreversible elimination of the resulting alkane. However, the use of these deprotonating reagents requires further metathesis of the diamido and dialkyl compounds to access the more versatile dichloro compounds.

We have reported[13] the synthesis of two types of amido and benzyl titanium and zirconium derivatives (Scheme 1), containing the bidentate η^5-C_5H_3[$SiMe_2$(NH*t*Bu)]($SiMe_2$-η^1-N*t*Bu) (**II**) and tridentate η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)$_2$ (**I**) ligands, by deprotonation of the bis(aminosilyl)cyclopentadiene C_5H_4[$SiMe_2$(NH*t*Bu)]$_2$ with metal amides $M(NMe_2)_4$

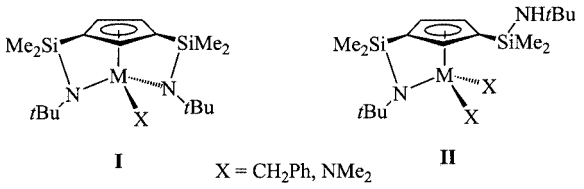
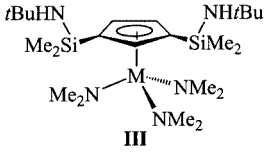
and benzyls $M(CH_2Ph)_4$ (M = Ti, Zr). To access the related chloro compounds, it is convenient to prepare a new type of monocyclopentadienyl compound **III** that may interconvert **I** − **II** − **III** by ring-closing and ring-opening reactions of the M-amidosilyl-Cp system and to compare its reactivity with complexes containing M−Cl, M−NMe_2 and M−CH_2Ph bonds.





Scheme 1

Halogenation of M−NMe_2 bonds in [M(η5-$C_5H_4SiMe_2$-η1-N*t*Bu)$(NMe_2)_2$] complexes with NMe_2H·HCl is reported[9c] to afford the dichloro zirconium derivative, leaving the silyl-η1-amido bridge unaltered, whereas partial simultaneous halogenation of the Si−N bond yields the corresponding chlorosilyl-η5-cyclopentadienyl dichloro-amido titanium complex with amine elimination. In both cases, the liberated amine NMe_2H remained coordinated to the metal centre. Similar behaviour has also been observed for related cyclopentadienyl-alkyl-η1-NR zirconium and hafnium diamides[9a] and for cyclopentadienyl-Si-O-alkyl-η1-NR zirconium diamides.[10a] Alternatively, $SiClMe_3$[14,15] and $SiCl_2Me_2$[16] are efficient chlorinating agents that do not modify the Cp-silyl-η1-amido chelate.

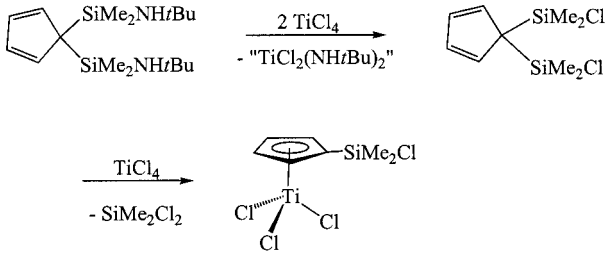
Conversion of M-alkyl into M-halide bonds in group 4 [M{η5-$C_5H_4SiMe_2$(N*t*Bu)}R_2] complexes without alteration of the Cp-silyl-η1-amido chelate is easily achieved in high yields by reactions with protic acids[17] and I_2.[18]

We describe here the results of our aim to isolate new chloro derivatives of the mono- and di-(η1-amidosilyl)cyclopentadienyl titanium and zirconium complexes. We report the synthesis and structural characterization of a new type of monocyclopentadienyl trichloro complex, [M{η5-C_5H_3[$SiMe_2$(NH*t*Bu)]$_2$}Cl_3] (M = Ti, Zr), and studies related to its ring-closing reactions in order to coordinate the silyl-amido arms to the metal centre. We also report the transformation of the reported[5,13] *ansa*-[M{η5-C_5H_3[$SiMe_2$(NH*t*Bu)](SiMe2-η1-N*t*Bu)}R_2] and di-*ansa*-[M{η5-C_5H_3($SiMe_2$-η1-N*t*Bu)$_2$}R] (R = NMe_2, CH_2Ph) complexes into the chloro compounds by reaction with chlorinating agents.

Results and Discussion

Reactions of the bis(aminosilyl)cyclopentadiene C_5H_4[$SiMe_2$(NH*t*Bu)]$_2$ with metal halides MCl_4 follow different reaction pathways to those reported[13] with metal amides $M(NMe_2)_4$ and benzyls $M(CH_2Ph)_4$ (M = Ti, Zr). Group 4 metal halides MCl_4 behave as dehalosilylating agents[19] that can cleave the sp^3-C(Cp)−SiR_3 bonds with the elimination of the halosilane $ClSiR_3$, and $TiCl_4$ is also a useful deamidating reagent for amidosilane derivatives.[20]

The addition of 2 equiv. of $TiCl_4$ to a dichloromethane solution of the bis(aminosilyl)cyclopentadiene produced simultaneous deamidation of the Si−NH*t*Bu bonds and dehalosilylation with elimination of $SiMe_2Cl_2$ to afford a mixture containing C_5H_4[($SiMe_2Cl$)$_2$][21] and [Ti(η5-$C_5H_4SiMe_2Cl$)Cl_3][22] as major products, together with other unidentified minor components, according to ^1H NMR data (Scheme 2).



Scheme 2

Reactions with the [M{η5-C_5H_3[$SiMe_2$(NHtBu)]$_2$}Cl_3] (M = Ti, Zr) Complexes

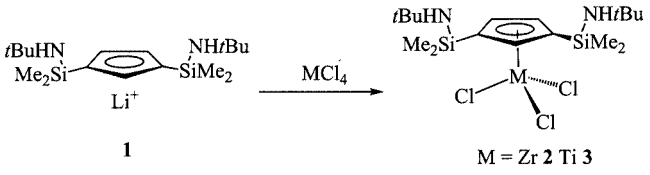
We were first interested in isolating the trichloro [M{η5-C_5H_3[$SiMe_2$(NH*t*Bu)]$_2$}Cl_3] (M = Ti, Zr) complexes to study the possible ring-closing reactions of one or both silyl-amido-metal systems that could give the dichloro(η5-cyclopentadienylsilyl-η1-amido) [M{η5-C_5H_3[$SiMe_2$(NH*t*Bu)](SiMe2-η1-N*t*Bu)}Cl_2] and chloro[η5-cyclopentadienyl bis(silyl-η1-amido)] [M{η5-C_5H_3($SiMe_2$-η1-N*t*Bu)$_2$}Cl] metal complexes, respectively.

With this aim, the higher acidic character of the cyclopentadiene ring proton was used to isolate the required lithium salt LiC_5H_3[$SiMe_2$(NH*t*Bu)]$_2$ (**1**) by selective metallation of the bis(aminosilyl)cyclopentadiene with 1 equiv. of *n*BuLi in hexane−THF for 12 h. Compound **1** was isolated as a white solid and characterized by elemental analysis and NMR spectroscopy (see Exp. Sect.).

Reaction of a toluene suspension of the lithium salt **1** with $ZrCl_4$.2THF afforded the trichloro complex [Zr{η5-C_5H_3[$SiMe_2$(NH*t*Bu)]$_2$}Cl_3] (**2**), which was isolated as a yellow solid in almost quantitative yield and characterized by elemental analysis and NMR spectroscopy. However, a similar reaction of **1** with $TiCl_4$ afforded mixtures of different products depending on the solvent, the molar ratio of both reagents and the reaction conditions (time and temperature). A hexane suspension of the lithium salt **1** reacted

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with $TiCl_4$ (1 equiv.) at room temperature to afford the trichloro derivative [Ti{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)]$_2$}Cl_3] (**3**) as the unique reaction product. Complex **3** was isolated as an orange solid in 70% yield after purification and characterized by elemental analysis and NMR spectroscopy (Scheme 3). ^1H and ^{13}C NMR spectra of complexes **2** and **3** show the behaviour expected for C_s symmetric molecules with two equivalent aminosilyl groups and ring protons. Consequently, two singlets (^1H) and two resonances (^{13}C) for the diastereotopic $SiMe_2$ methyl groups and one singlet (^1H) and two resonances (^{13}C) for the *tert*-butylamino substituents were observed in the NMR spectra of **2** and **3**. In addition, one doublet and one triplet ($J_{H,H}$ = 2.0 Hz) (^1H) are observed for the A_2B spin system of the cyclopentadienyl ring protons and, consistently, three ring carbon resonances appear in the ^{13}C NMR spectra. Recrystallization of **3** using pentane gave crystals appropriate for an X-ray structure determination. The molecular structure of **3** is shown in Figure 1, and selected bond lengths and angles are listed in Table 1.



Scheme 3

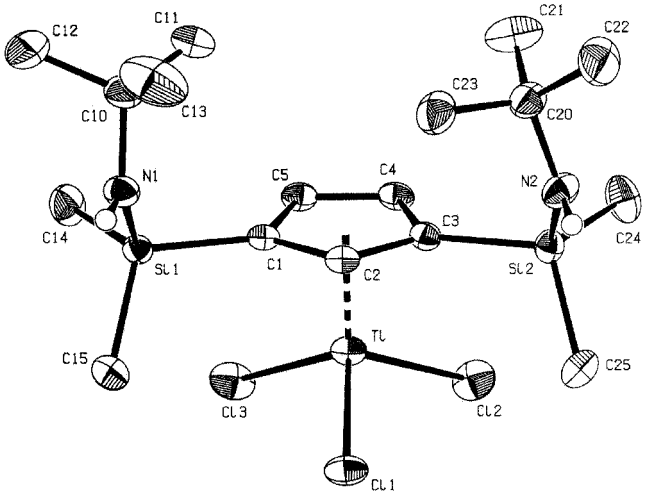


Figure 1. ORTEP drawing of the solid-state molecular structure of **3**; thermal ellipsoids drawn at the 50% probability level and hydrogen atoms are omitted for clarity except for those located at the nitrogen atoms

Complex **3** shows the titanium atom in the well-known pseudo-tetrahedral geometry defined by the centroid of the cyclopentadienyl ring and three coordinated chloro ligands, as reported for many group 4 metal monocyclopentadienyl complexes [Ti(η^5-C_5H_4R)Cl_3] (R = H,[23] Me,[24] $CHPh_2$, CMe_2Ph, $SiMe_2Ph$,[25]), [Ti(η^5-C_5Me_4R)Cl_3] (R = *t*Bu,[26] CH_2CH_2Ph,[27] SiMeClH, $SiMe_3$,[20] [Ti(η^5-1,3-$R_2C_5H_3$)Cl_3] (R = $SiMe_3$,[28] *t*Bu[29]). The Cp ring in an η^5-coordination mode is not distorted, although the C4−C5 distance [1.403(2)] Å is slightly shorter than the other C−C distances of 1.420(2)−1.430(2) Å. Ti−Cl bond lengths (2.23−2.24 Å) and the Cl−Ti−Cl angles (102−104°) are in the typical range for compounds of this type. Si−N bond lengths (1.70−1.71Å) are also in the range known for terminal amino−silyl bonds. Most significantly, the metal fragment and $SiMe_2NH$*t*Bu substituents are at opposite faces of the cyclopentadienyl ring, adopting a conformation that minimizes interaction with the chloro ligands and prevents the nitrogen atoms acting as σ-donor ligands, which would elongate the Ti−Cl bonds and close the Cl−Ti−Cl bond angles, as with [Ti(η^5-C_5H_4R)Cl_3] compounds containing *O*- and *N*-functionalized R groups.[30] In addition, this structural disposition also prevents possible bridging hydrogen-bond interactions between Cl and the NH groups.

Table 1. Characteristic bond lengths (Å) and angles (°) for [Ti(η^5-C_5H_3{$SiMe_2$(NH*t*Bu)}$_2$)Cl_3] (**3**)

Bond lengths		Bond angles	
Ti−Cl1	2.2366(5)	Cl1−Ti−Cl2	102.69(2)
Ti−Cl2	2.2416(6)	Cl1−Ti−Cl3	103.64(2)
Ti−Cl3	2.2396(6)	Cl2−Ti−Cl3	102.45(2)
Si1−N1	1.702(2)	N1−Si1−C1	108.72(7)
Si2−N2	1.707(2)	N2−Si2−C3	110.15(8)
C1−C2	1.420(2)	Si1−N1−C10	131.96(15)
C1−C5	1.430(2)	Si2−N2−C20	133.15(14)
C2−C3	1.420(2)		
C3−C4	1.427(2)		
C4−C5	1.403(2)		

The same reaction of the lithium salt **1** with 1 equiv. of $TiCl_4$ in hexane at 45 °C gave, after 1 h, the bis(chlorosilyl) derivative [Ti{η^5-C_5H_3($SiMe_2Cl$)$_2$}Cl_3] (**5**) as the main reaction product together with a mixture containing various unidentifiable species. The presence in this mixture of the (aminosilyl)(chlorosilyl)cyclopentadienyl titanium complex [Ti{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)]($SiMe_2Cl$)}Cl_3] (**4**) (Scheme 4) could not be verified.4

Pure complex **5** could be isolated from this mixture as a light brown solid in very low yield (10%) after repeated recrystallizations; it was characterized by elemental analysis and NMR spectroscopy. These results demonstrate that complex **3** reacted with unchanged $TiCl_4$ immediately after its formation, when the hexane solution was heated to 45 °C, producing deamidation of both amido-silane groups. Under these conditions, the preferential deamidation of complex **3** prevented the ring-closing formation of *ansa*-cyclopentadienylsilyl-η^1-amido compounds.

Similar behaviour occurs for the same reaction with 1 equiv. of $TiCl_4$ when using a toluene suspension of **1** at room temperature (Scheme 4). The resulting reaction product was a mixture containing almost equal molar proportions of the trichloro complexes **3**−**5**, although in this case formation of small but significant amounts of the also deamidated *ansa*-silyl-η^1-amido complex [Ti{η^5-C_5H_3(SiMe_2Cl)($SiMe_2$-η^1-N*t*Bu)}Cl_2] (**7**) was also observed and

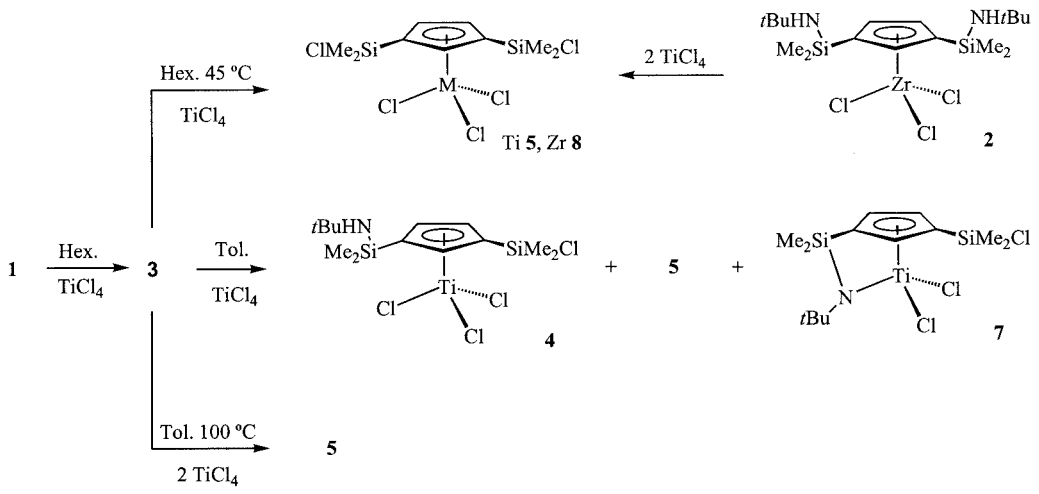

Scheme 4

identified by NMR spectroscopy (see below). The formation of complex **4**, which could not be isolated, was confirmed by a low intensity set of signals in the ^{1}H NMR spectrum, which includes four singlets for the methyl protons of two different $SiMe_2Cl$ and $SiMe_2(NHtBu)$ groups, one singlet for the $NHtBu$ substituent and three multiplets for the non-equivalent ring protons of an asymmetric molecule (see Exp. Sect.). When this mixture containing complexes **3**−**5** and **7** was heated in a Teflon-sealed Schlenk tube at 100 °C for 5 h, compound **3** disappeared completely to give a mixture containing **7** as the major component together with **5** and traces of **4**.

To check the deamidating role of the starting $TiCl_4$ a toluene solution of the isolated complex **3** was reacted with 2 equiv. of $TiCl_4$, heating the solution at 100 °C for 8 h to give an insoluble green product and a solution containing **5**, which was isolated in 65% yield after purification (Scheme 4). Under similar conditions, the zirconium complex **2** did not react with excess $ZrCl_4$ but an almost quantitative deamidation reaction occurred when its toluene solution was heated to 110 °C for 8 h with 2 equiv. of $TiCl_4$. The resulting complex $[Zr\{\eta^5\text{-}C_5H_3(SiMe_2Cl)_2\}Cl_3]$ (**8**) was isolated as a yellow solid in 69% yield and was characterized by elemental analysis and NMR spectroscopy. The ^{1}H NMR spectra of complexes **5** and **8** correspond to molecules with C_s symmetry and show two $SiMe_2$ singlets corresponding to diastereotopic methyl groups of two equivalent chlorosilyl substituents and one doublet and one triplet with relative intensity 2:1, corresponding to the A_2B spin system of the ring protons. Consistently, two $SiMe_2$ and three ring carbon resonances appear in the ^{13}C NMR spectrum (see Exp. Sect.).

$TiCl_4$ is, therefore, the deamidating agent responsible for the transformation of **3** into, successively, **4** and **5**. Moreover, in the presence of excess $TiCl_4$, formation of the *ansa* complexes is totally inhibited.

The thermal behaviour of **2** and **3** in the absence of $TiCl_4$ is also important. Complex **2** is thermally stable, remaining unaltered after heating for 6 h at 125 °C in a Teflon-sealed Schlenk tube. This is consistent with the known high stability of Zr−Cl bonds. However, monitoring the ^{1}H NMR spectrum of a sample of **3**, in a Teflon-sealed NMR tube in C_6D_6 at room temperature, revealed a very slow transformation that gave increasing amounts of a mixture containing one new major compound and a small amount of a second new derivative, along with traces of other components. According to ^{1}H NMR data in the highfield $SiMe_2$ region, the new compounds could be formulated as complexes $[Ti\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}Cl_2]$ (**6**), and $[Ti\{\eta^5\text{-}C_5H_3(SiMe_2Cl)(SiMe_2\text{-}\eta^1\text{-}NtBu)\}Cl_2]$ (**7**) as the major and minor components, respectively (Scheme 5). This suggests that, in the absence of $TiCl_4$, partial formation of *ansa* complexes takes place with elimination of HCl, which, under these conditions, protonates the free amino Si-$NHtBu$ group of **6** to give the Si−Cl group of **7**. Some of the HCl generated in the previous reaction has to be used to neutralize the eliminated NH_2tBu, otherwise only compound **7** should be observed. After 2 days, this transformation afforded, according to ^{1}H NMR data, an approximately 2:1:1 molar ratio of **6**:**3**:**7**. These data confirmed that formation of the first silyl-η^1-amido bridge occurs at room temperature albeit it is very slowly.

To favour the formation of the *ansa* compounds we studied the same reaction, heating a toluene suspension of the lithium salt **1** with 1 equiv. of $TiCl_4$ at 110 °C in the presence of NEt_3 (3 equiv.) (Scheme 5). Under these conditions no deamidation of complex **3** was observed − instead a mixture was obtained that contained the *ansa* complexes **7** and **6** in a molar ratio 3:1, from which complex **7** was isolated after extraction into pentane, as a yellow solid in 60% yield. Better results were obtained for the same reaction using 2 equiv. of $TiCl_4$ because further deamidation of **6** afforded pure complex **7** as the unique reaction product. Complex **7** is a disymmetric molecule due to the enantioface of the cyclopentadienyl ring. Its ^{1}H NMR spectrum shows the expected four singlets for the $SiMe_2$ groups, one

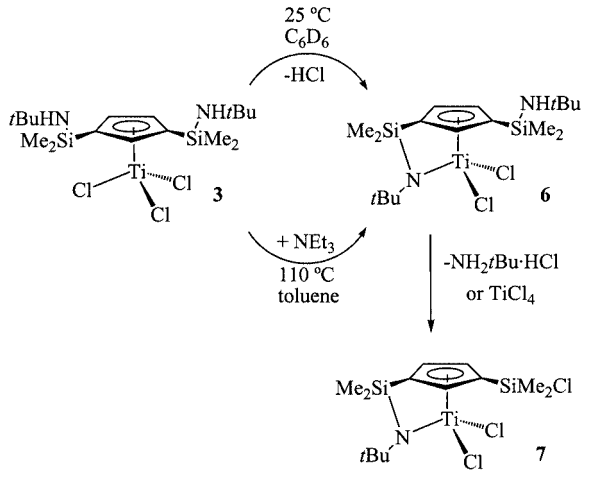


Scheme 5

singlet for the *tert*-butyl substituent and three low-field multiplets for the ring protons. Consistently, four $SiMe_2$ resonances, two N*t*Bu signals and five ring carbon resonances appear in the ^{13}C NMR spectrum of **7** (see Exp. Sect.). Pure samples of complex **6** could not be isolated from the sticky residue, in which it was the minor component. However, complex **6** was identified by its ^1H NMR spectrum, which shows the expected four $SiMe_2$, two *t*Bu singlets and three Cp ring proton multiplets, consistent with its proposed formulation and coincident with those of the pure complex isolated by an alternative method (see below).

Therefore, reactions in the presence of excess NEt_3 yielded the *ansa* complexes, preventing deamidation of complex **3**, even when excess $TiCl_4$ was used to favour the total deamidation of *ansa* complex **6**. However, NEt_3 did not prevent protonation and deamination of the Si−NH*t*Bu group. Indeed, a mixture of **7** and **6** in a molar ratio 1:1 was formed when a toluene suspension of **3** was heated to 110 °C in the presence of 5 equiv. excess NEt_3.

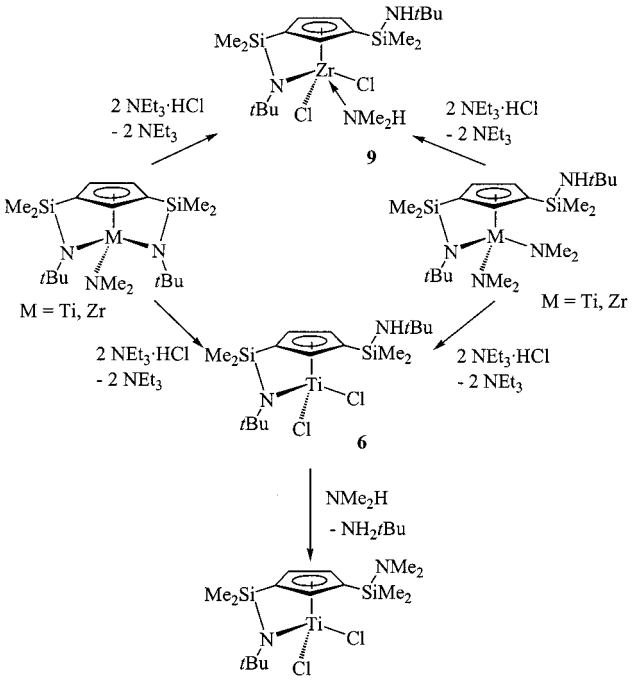
All these results suggest the following sequence of reactions: initially the reaction of $TiCl_4$ with the lithium salt **1** gives the trichloro complex **3**, which is deamidated by excess $TiCl_4$ to give, successively, complexes **4** and **5**. However, ring-closing reactions to give *ansa* complexes require elimination of HCl, this being favoured in the presence of NEt_3, which prevents the deamidation of complex **3** to give **6**. Complex **6** is also deamidated by excess $TiCl_4$, to afford pure complex **7**.

In summary, the ring-closing reaction of the first silyl-η^1-amido arm of the trichloro complex **3** is a selective reaction in the presence of excess NEt_3, although under these conditions simultaneous deamidation of the remaining amido-silane system gives the mono-silyl-η^1-amido complex **7**, preventing the formation of the second silyl-η^1-amido bridge. In contrast, deamidation of both amido-silane groups of complex **3** is a selective reaction in the presence of excess $TiCl_4$, giving the bis(chlorosilyl) derivative **5** while suppressing the formation of silyl-η^1-amido bridges.

Reactions with the [M{η^5-C_5H_3($SiMe_2$-η^1-NtBu)$_2$}R] and [M{η^5-C_5H_3[$SiMe_2$(NHtBu)]($SiMe_2$-η^1-NtBu)}R_2] (M = Ti, Zr; R = NMe_2, CH_2Ph) Complexes

The amido zirconium compound [Zr{η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)$_2$}(NMe_2)][13] reacted with 1 equiv. of NEt_3·HCl in toluene at 70 °C to produce the simultaneous protonation of both the terminal Zr−NMe_2 and one of the bridging Zr−N*t*Bu−Si bonds, affording a mixture that contained half of the unchanged starting compound and a new zirconium complex.

The starting bis(silyl-η^1-amido) compound was completely transformed into the new zirconium derivative, with elimination of NEt_3, when a second equiv. of NEt_3·HCl was added (Scheme 6), giving an 82% yield of a light brown solid that was characterized by elemental analysis and NMR spectroscopy as the dichloro compound [Zr{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)]($SiMe_2$-η^1-N*t*Bu)}Cl_2(NMe_2H)] (**9**). Compound **9**, which contains the amine coordinated to the metal, was also obtained when the same reaction was carried out with one equiv. of NEt_3·HCl and the diamido compound [Zr{η^5-C_5H_3[$SiMe_2$(NH*t*Bu)]($SiMe_2$-η^1-N*t*Bu)}-(NMe_2)$_2$].[13] The simultaneous reaction of both Zr−NMe_2 bonds also occurred, leaving half of the starting complex unaltered, although one of the two amido groups could be sterically protected by the uncoordinated aminosilyl group. Probably, the increased acidity of the metal centre in the resulting chloro-amido intermediate favours the coordination of chloride with protonation and displacement of the second amido group. The reaction was complete after addition of a second equivalent of NEt_3·HCl, affording pure **9**.



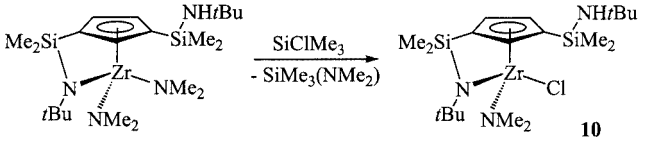
Scheme 6

Similar behaviour was observed for the titanium derivatives [Ti{η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)$_2$}(NMe_2)] and [Ti{η^5-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

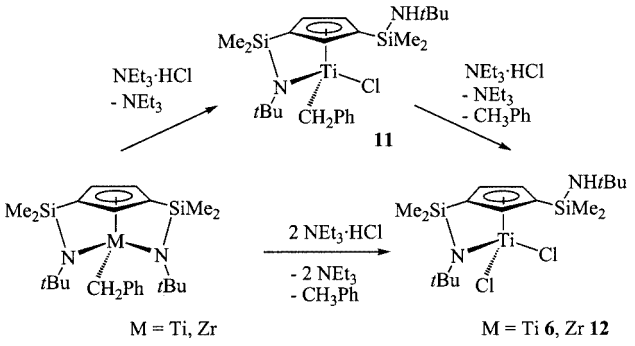
$C_5H_3[SiMe_2(NHtBu)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}(NMe_2)_2]$.[13] However, the resulting product, $[Ti(\eta^5\text{-}C_5H_3\{SiMe_2(NHtBu)\}\text{-}\{SiMe_2(\eta^1\text{-}NtBu)\})Cl_2]$ (**6**), did not contain coordinated amine, and it was always accompanied by variable, small amounts of a second component that could not be isolated but was identified by NMR spectroscopy as $[Ti\{\eta^5\text{-}C_5H_3[SiMe_2(NMe_2)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}Cl_2]$. This last compound resulted from a simultaneous exchange reaction between the amino-silyl Si-NH*t*Bu group of **6** and the liberated amine $NHMe_2$. Complex **6** was isolated as a red solid and characterized by elemental analysis and NMR spectroscopy (see Exp. Sect.).

Reactions with $SiClMe_3$ are reported[14,15] to be a convenient method of converting metal−amido into metal−chloro bonds. The reaction of the diamido zirconium complex $[Zr\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}(NMe_2)_2]$ with one equivalent of $SiClMe_3$ was monitored by ^1H NMR spectroscopy in C_6D_6 at room temperature (Scheme 7). After 1 h, formation of the chloro-amido derivative $[Zr\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}\text{-}Cl(NMe_2)]$ (**10**) with elimination of $SiMe_3(NMe_2)$ was confirmed by ^1H and ^{13}C NMR. Addition of a second equiv. of $SiClMe_3$ produced a very slow reaction, which after 4 d afforded a mixture of unidentified reaction products in which $SiMe_3$-NH*t*Bu (δ_{SiMe} = 0.11 ppm; δ_{NHtBu} = 1.09 ppm) and $SiMe_3-NMe_2$ (δ_{SiMe} = 0.04 ppm; δ_{NMe} = 2.37 ppm) were observed in the ^1H NMR spectrum. This suggests that, probably, the first substitution is a fast diastereoselective reaction at the amido ligand unprotected by the noncoordinated silyl-amino group, which gives one single diastereomer (see below). However, the second substitution at the sterically protected amido ligand is very slow and exchange takes place between the amino groups bound to the silylcyclopentadienyl ligand CpSi−NH*t*Bu of **10** and the trimethylsilyl fragment of the liberated silane $Me_3Si-NMe_2$. Similar studies could not be extended to the related diamido titanium derivative as it was always accompanied by variable amounts of the monoamido complex.



Scheme 7

The reactivity of the benzyl derivatives was also studied (Scheme 8). When 1 equiv. of NEt_3·HCl was added to a toluene solution of the benzyl titanium complex $[Ti\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}NtBu)_2\}(CH_2Ph)]$,[13] one of the silyl-amido arms was protonated to afford the chloro-benzyl derivative $[Ti\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}Cl(CH_2Ph)]$ (**11**), which was isolated as a red solid (77% yield) and characterized by elemental analysis and NMR spectroscopy. In this reaction the benzyl−titanium bond was unaltered although it could also be protonated with elimination of toluene when the same reaction was carried out using 2 equiv. of NEt_3·HCl, at 80 °C for 12 h, to afford the dichloro derivative $[Ti(\eta^5\text{-}C_5H_3\{SiMe_2(NHtBu)\}\text{-}\{SiMe_2(\eta^1\text{-}NtBu)\})Cl_2]$ (**6**) described above. Reaction of the related zirconium complex $[Zr\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}NtBu)_2\}(CH_2Ph)]$[13] was not selective; simultaneous protonation of the η^1-amido and benzyl ligands required the addition of 2 equiv. of NEt_3·HCl, in toluene at 70 °C, to give the dichloro complex $[Zr\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)]\text{-}(SiMe_2\text{-}\eta^1\text{-}NtBu)\}Cl_2]$ (**12**), which is similar to **9** but without coordinated amine. Compound **12** was isolated as a brown solid and characterized by NMR spectroscopy. In the light of these results, the reactivity of related dibenzyl complexes $[M\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}\text{-}(CH_2Ph)_2]$ (M = Ti, Zr) was not studied.



Scheme 8

The new complexes **6** and **9**−**12** belong to the well-known type of *ansa*-cylopentadienylsilyl-η^1-amido compounds with one additional noncoordinated silyl-amino substituent, which makes the face of the cyclopentadienyl ring enantiotopic. Therefore, the dichloro complexes $[M\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}Cl_2]$ [M = Ti (**6**), Zr (**12**)], and the amine-coordinated zirconium derivative $[Zr\{\eta^5\text{-}C_5H_3\ [SiMe_2(NHtBu)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}\text{-}Cl_2(NMe_2H)]$ (**9**) are disymmetric molecules, in agreement with the observed ^1H and ^{13}C NMR spectra (see Exp. Sect.). The chloro-amido $[Zr\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)]\text{-}(SiMe_2\text{-}\eta^1\text{-}NtBu)\}Cl(NMe_2)]$ (**10**) and -benzyl $[Ti\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}Cl(CH_2Ph)]$ (**11**) complexes exhibit one additional stereogenic centre at the metal, although only one isomer was formed in the diastereoselective reactions discussed above. Accordingly, the NMR spectra of **10** and **11** show the expected four Si-Me signals (^1H, ^{13}C), two singlets (^1H) and four signals (^{13}C) for the N*t*Bu groups, and three (^1H) or five signals (^{13}C) for the cyclopentadienyl ring proton and carbon atoms respectively, along with the typical diastereotopic CH_2Ph doublets for **11**.

All these *ansa* complexes exhibit a ^{13}C signal due to the ring C_{ipso} that is shifted upfield with respect to the other ring-carbon signals,[31] and the metal−amido π-bonding contribution is evidenced by $\Delta(\delta C_{tert} - \delta C_{Me})$[32] of 22.8 (**10**)−30.0 (**6**) compared with those of the Si-NH*t*Bu group [15.9 (**10**)−18.5 (**9**)].

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Conclusion

Monolithium salt $LiC_5H_3[SiMe_2(NHtBu)]_2$ (**1**) reacts with the corresponding tetrachlorides MCl_4 in a straightforward method of synthesizing bis(dimethylsilylamino) monocyclopentadienyl titanium and zirconium complexes $[M\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)]_2\}Cl_3]$ (M = Ti, Zr). However, simultaneous reaction of the titanium derivative with the starting $TiCl_4$ produces partial conversion of one or both Si-NH*t*Bu into Si−Cl groups. This is a quantitative transformation when the isolated titanium and zirconium complexes are treated with 2 equiv. of $TiCl_4$.

Ring-closing coordination of one of the silyl-amido arms to the metal by elimination of HCl is very slow at room temperature for the titanium complex and does not occur for the zirconium one. However, this reaction is complete when the titanium compound is heated in toluene to 110 °C in the presence of excess NEt_3, although simultaneous partial conversion of the free Si−NH*t*Bu into Si−Cl is unavoidable. Under these conditions, addition of $TiCl_4$ gives the chloro-silyl complex $[Ti\{\eta^5\text{-}C_5H_3(SiMe_2Cl)(SiMe_2\text{-}\eta^1\text{-}NtBu)\}Cl_2]$ in quantitative yield.

Ring-closing coordination of the second silyl-amido arm was never observed, which is consistent with the very easy ring-opening de-coordination that takes place by protonation with $NEt_3{\cdot}HCl$ of one of the silyl-η^1-amido−titanium and zirconium bonds of the cyclopentadienyl bis(silyl-η^1-amido) di-*ansa*-$[M\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}NtBu)_2\}R]$ (R = NMe_2, CH_2Ph) complexes. In contrast, the single silyl-η^1-amido-titanium system of the *ansa*-$[M\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}(NMe_2)_2]$ (M = Ti, Zr) derivatives remains unaltered in these protonation reactions.

Alternative methods to synthesize the elusive di-*ansa*-$[M\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}NtBu)_2\}Cl]$ complex and its alkyl derivatives are being studied and will be reported in a future paper.

Experimental Section

General Remarks: All manipulations were performed under an inert atmosphere of argon using standard Schlenk techniques or a dry box. Solvents were dried and freshly distilled under argon before use: tetrahydrofuran from sodium benzophenone ketyl; toluene from sodium; hexane from sodium-potassium amalgam. Unless otherwise stated, reagents were obtained from commercial sources and used as received. $C_5H_4[SiMe_2(NHtBu)]_2$, $[M\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}NtBu)_2\}R]$ and $[M\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)](SiMe_2\text{-}\eta^1\text{-}NtBu)\}R_2]$ (M = Ti, Zr; R = CH_2Ph, NMe_2) were prepared by previously reported methods.[13] ^1H and ^{13}C NMR spectra were recorded on a Varian Unity VXR-300 or Varian Unity 500 Plus. Chemical shifts, in ppm, are relative to residual ^1H and ^{13}C resonances for C_6D_6 used as solvent: 7.15 (^1H) and 128.0 (^{13}C), and coupling constants are in Hz. C, H and N analyses were carried out with a Perkin-Elmer 240 C analyzer.

$LiC_5H_3[SiMe_2(NHtBu)]_2$ (1): A hexane solution (1.6 M) of *n*BuLi (11.0 mL, 17.6 mmol) was added dropwise to a yellow solution of $C_5H_4[SiMe_2(NHtBu)]_2$ (5.80 g, 17.6 mmol) in a mixture of hexane (150 mL) and THF (25 mL) at −78 °C. This reaction mixture was then warmed to room temperature and stirred for 12 h. The volatiles were then removed under vacuum to give **1** as a white solid, which was washed with hexane and dried under vacuum (5.72 g, 17.30 mmol, 98%). $C_{17}H_{35}LiN_2Si_2$ (330.6): calcd. C 61.76, H 10.67, N 8.47; found C 61.02, H 10.46, N 8.27. ^1H NMR (C_6D_6/NC_6D_5, 20 °C): δ = 0.49 (s, 12 H, SiMe_2), 0.88 (br. s, 2 H, NH*t*Bu), 1.21 (s, 18 H, NHCMe_3), 6.75 (d, $J_{H,H}$ = 2.0 Hz, 2 H, C_5H_3), 6.90 (t, $J_{H,H}$ = 2.0 Hz, 1 H, C_5H_3) ppm. ^{13}C NMR (C_6D_6/NC_6H_5, 20°): δ = 4.2 (SiMe_2), 34.1 (NHCMe_3), 49.4 (NH*C*Me$_3$), 115.2 (C_5H_3), 115.8 (C_5H_{3ipso}), 120.4 (C_5H_3) ppm.

$[Zr\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)]_2\}Cl_3]$ (2): Toluene (100 mL) was added to a mixture of $ZrCl_4{\cdot}2THF$ (2.08 g, 5.52 mmol) and the lithium salt **1** (1.82 g, 5.52 mmol) at room temperature. The reaction mixture was subsequently stirred for a further 12 h. The solvent of the resulting white suspension was then removed under vacuum and the residue extracted into hexane (2 × 50 mL). After filtration and removal of the solvent, complex **2** was isolated as a light yellow solid (2.46 g, 4.33 mmol, 86%). $C_{17}H_{35}Cl_3N_2Si_2Zr$ (521.2): calcd. C 39.17, H 6.77, N 5.37; found C 39.03, H 6.72, N 5.34. ^1H NMR ($CDCl_3$, 20 °C): δ = 0.35 (s, 6 H, SiMe_2), 0.39 (s, 6 H, SiMe_2), 1.02 (br. s, 2 H, NH*t*Bu), 1.08 (s, 18 H, NHCMe_3), 6.52 (d, $J_{H,H}$ = 1.6 Hz, 2 H, C_5H_3), 7.16 (t, $J_{H,H}$ = 1.6 Hz, 1 H, C_5H_3) ppm. ^{13}C NMR ($CDCl_3$, 20 °C): δ = 1.99 (SiMe_2), 3.43 (SiMe_2), 33.6 (NHCMe_3), 49.6 (NH*C*Me$_3$), 120.5 (C_5H_3), 129.3 (C_5H_{3ipso}), 145.1 (C_5H_3) ppm.

$[Ti\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)]_2\}Cl_3]$ (3): A colourless solution of $TiCl_4$ (0.76 mL, 6.99 mmol) in hexane (15 mL) was cooled to −78 °C and added to a cooled (−78 °C) stirred suspension of the lithium salt **1** (2.31 g, 6.99 mmol) in the same solvent (75 mL). The reaction mixture was then warmed slowly to room temperature and stirred for 12 h. The resulting light brown suspension was then filtered and, after removal of the solvent, complex **3** was isolated as an orange solid (2.33 g, 4.87 mmol, 70%). $C_{17}H_{35}Cl_3N_2Si_2Ti$ (477.8): calcd. C 42.73, H 7.38, N 5.86; found C 41.92, H 7.30, N 5.73. ^1H NMR ($CDCl_3$, 20 °C): δ = 0.39 (s, 6 H, SiMe_2), 0.48 (s, 6 H, SiMe_2), 0.84 (br. s, 2 H, NH*t*Bu), 0.94 (s, 18 H, NHCMe_3), 6.89 (d, $J_{H,H}$ = 2.0 Hz, 2 H, C_5H_3), 7.57 (t, $J_{H,H}$ = 2.0 Hz, 1 H, C_5H_3) ppm. ^{13}C NMR ($CDCl_3$, 20 °C): δ = 1.25 (SiMe_2), 1.41 (SiMe_2), 33.7 (NHCMe_3), 49.8 (NH*C*Me$_3$), 132.2 (C_5H_3), 136.6 (C_5H_3), 149.2 (C_5H_{3ipso}) ppm.

$[Ti\{\eta^5\text{-}C_5H_3[SiMe_2(NHtBu)](SiMe_2Cl)\}Cl_3]$ (4): An orange solution of $TiCl_4$ (0.17 mL, 1.55 mmol) in toluene (15 mL) was cooled to −78 °C and added to a cooled (−78 °C) stirred suspension of the lithium salt **1** (0.51 g, 1.55 mmol) in the same solvent (75 mL). The reaction mixture was warmed slowly to room temperature and stirred for a further 12 h. The solvent was then removed under vacuum and the residue extracted into hexane (50 mL). After filtration and removal of the solvent, an unresolvable mixture of **3**−**5** and **7** was obtained. The presence of **4** was detected by NMR spectroscopy. **4**: ^1H NMR (C_6D_6, 20 °C): δ = 0.31 (s, 3 H, SiMe_2), 0.39 (s, 3 H, SiMe_2), 0.54 (s, 3 H, SiMe_2), 0.58 (s, 3 H, SiMe_2), 0.92 (s, 9 H, NHCMe_3), 6.70 (m, 1 H, C_5H_3), 6.84 (m, 1 H, C_5H_3), 7.47 (m, 1 H, C_5H_3) ppm.

$[Ti\{\eta^5\text{-}C_5H_3(SiMe_2Cl)_2\}Cl_3]$ (5) − Method A: In a Teflon-sealed Schlenk tube, $TiCl_4$ (0.055 mL, 0.50 mmol) was added by syringe to an orange solution of **3** (0.12 g, 0.25 mmol) in toluene (30 mL) cooled to −78 °C. The reaction mixture was then warmed slowly to room temperature, and subsequently heated for 12 h to 110 °C. The volatiles were then removed under vacuum and the residue was extracted into hexane to give **5** as a light brown solid (0.089 g,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

0.22 mmol, 65%). $C_9H_{15}Cl_5Si_2Ti$ (404.5): calcd. C 26.72, H 3.74; found C 27.00, H 3.73. ^{1}H NMR ($CDCl_3$, 20 °C): δ = 0.76 (s, 6 H, Si*Me*$_2$), 0.82 (s, 6 H, Si*Me*$_2$), 7.33 (d, $J_{H,H}$ = 1.8 Hz, 2 H, C_5H_3), 7.56 (t, $J_{H,H}$ = 1.8 Hz, 1 H, C_5H_3) ppm. ^{13}C NMR ($CDCl_3$, 20 °C): δ = 2.36 (Si*Me*$_2$), 2.81 (Si*Me*$_2$), 131.2 (C_5H_3), 135.0 (C_5H_3), 139.3 (C_5H_{3ipso}) ppm.

Method B: In a sealed Schlenk tube, an orange solution of $TiCl_4$ (0.55 mL, 4.99 mmol) in toluene (15 mL) was cooled to −78 °C and added to a cooled (−78 °C) stirred suspension of the lithium salt **1** (0.55 g, 1.66 mmol) in the same solvent (50 mL). The reaction mixture was then warmed slowly to room temperature and then heated for 12 h to 110 °C. Volatiles were then removed under vacuum and the residue extracted into hexane to give **5** (0.66 g, 1.63 mmol, 60%).

Method C: Following the same procedure as method B, the similar reaction of **1** with $TiCl_4$ in hexane (15 mL), heating to 45 °C for 1 h, gave **5** in low yield (10%) after repeated extractions into hexane.

[Ti{η5-C5H3[SiMe2(NHtBu)](SiMe2-η1-NtBu)}Cl2] (6). − Method A: A solution of [Ti{η5-C_5H_3[SiMe_2(NH*t*Bu)](SiMe_2-η1-N*t*Bu)}-(NMe_2)2] (0.60 g, 1.30 mmol) in toluene (40 mL) was added to a suspension of NEt_3·HCl (0.35 g, 2.60 mmol) in the same solvent. The mixture was then stirred for 12 h to 80 °C. After subsequent removal of the solvent under vacuum, the residue was extracted into pentane (70 mL). Following filtration and removal of the solvent, complex **6** was then isolated as a red solid (0.54 g, 1.22 mmol, 94%). $C_{17}H_{34}Cl_2N_2Si_2Ti$ (441.4): calcd. C 46.26, H 7.76, N 6.35; found C 46.52, H 7.68, N 6.13. ^{1}H NMR (C_6D_6, 20 °C): δ = 0.24 (s, 3 H, Si*Me*$_2$), 0.26 (s, 3 H, Si*Me*$_2$), 0.45 (s, 3 H, Si*Me*$_2$), 0.56 (s, 3 H, Si*Me*$_2$), 1.05 (s, 9 H, NHC*Me*$_3$), 1.38 (s, 9 H, NC*Me*$_3$), 6.35 (m, 1 H, C_5H_3), 6.57 (m, 1 H, C_5H_3), 7.17 (m, 1 H, C_5H_3) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = −0.1 (Si*Me*$_2$), 0.6 (Si*Me*$_2$), 1.5 (Si*Me*$_2$), 1.8 (Si*Me*$_2$), 32.3 (NHC*Me*$_3$), 33.9 (NC*Me*$_3$), 49.8 (NH*C*Me$_3$), 63.9 (N*C*Me$_3$), 112.6 (C_5H_{3ipso}), 126.1 (C_5H_3), 129.4 (C_5H_3), 129.5 (C_5H_{3ipso}), 130.9 (C_5H_3) ppm.

Method B: A solution of [Ti{η5-C_5H_3(SiMe_2-η1-N*t*Bu)2}(CH_2Ph)] (0.58 g, 1.25 mmol) in toluene (40 mL) was added to a suspension of NEt_3·HCl (0.34 g, 2.50 mmol) in the same solvent. The mixture was then stirred for 12 h at 80 °C. The solvent was then removed under vacuum and the residue extracted into hexane (40 mL). After filtration and removal of the solvent, complex **6** was then isolated as a red solid (0.31 g, 0.70 mmol, 70%).

Method C: 6 was formed when the method described below to prepare **7** was followed, using 1 equiv. of $TiCl_4$. The resulting mixture contained **6** and **7** in a 1:3 molar ratio. Pure **6** could not be isolated from this mixture.

[Ti{η5-C5H3(SiMe2Cl)(SiMe2-η1-NtBu)}Cl2] (7): In a sealed Schlenk tube, an orange solution of $TiCl_4$ (0.32 mL, 2.97 mmol) in toluene (50 mL) was cooled to −78 °C and added to a cooled (−78 °C) stirred suspension of the lithium salt **1** (0.49 g, 1.48 mmol) in the same solvent (50 mL). NEt_3 (0.62 mL, 4.45 mmol) was added to this mixture, and finally, it was warmed to room temperature and heated for 12 h to 110 °C. The volatiles were removed under vacuum and the residue was extracted into hexane. After filtration and removal of the solvent complex **7** was isolated as a yellow solid (0.44 g, 1.10 mmol, 75%). $C_{13}H_{24}Cl_3NSi_2Ti$ (404.7): calcd. C 38.58, H 5.98, N 3.46; found C 39.07, H 6.16, N 3.46. ^{1}H NMR ($CDCl_3$, 20 °C): δ = 0.60 (s, 3 H, Si*Me*$_2$), 0.62 (s, 3 H, Si*Me*$_2$), 0.70 (s, 3 H, Si*Me*$_2$), 0.79 (s, 3 H, Si*Me*$_2$), 1.43 (s, 9 H, NC*Me*$_3$), 6.53 (m, 1 H, C_5H_3), 6.63 (m, 1 H, C_5H_3), 7.25 (m, 1 H, C_5H_3) ppm. ^{13}C NMR ($CDCl_3$, 20 °C): δ = 0.13 (Si*Me*$_2$), 0.64 (Si*Me*$_2$), 1.65 (Si*Me*$_2$), 2.65 (Si*Me*$_2$), 32.1 (NC*Me*$_3$), 64.6 (N*C*Me$_3$), 113.1 (C_5H_{3ipso}), 129.4 (C_5H_3), 130.6 (C_5H_3), 132.1 (C_5H_3), 135.5 (C_5H_{3ipso}) ppm.

[Zr{η5-C5H3(SiMe2Cl)2}Cl3] (8): In a sealed Schlenk tube, $TiCl_4$ (0.18 mL, 1.65 mmol) was added by syringe to a cooled (−78 °C) light yellow solution of complex **2** (0.43 g, 0.82 mmol) in toluene (70 mL). The reaction mixture was then warmed to room temperature, followed by heating for 12 h to 110 °C. Volatiles were then removed under vacuum and the residue extracted into hexane. After filtration and removal of the solvent, complex **8** was isolated as a light yellow solid (0.25 g, 0.56 mmol, 69%). $C_9H_{15}Cl_5Si_2Zr$ (447.9): calcd. C 24.14, H 3.38; found C 24.01, H 3.30. ^{1}H NMR ($CDCl_3$, 20 °C): δ = 0.70 (s, 6 H, Si*Me*$_2$), 0.75 (s, 6 H, Si*Me*$_2$), 6.76 (d, $J_{H,H}$ = 1.8 Hz, 2 H, C_5H_3), 7.19 (t, $J_{H,H}$ = 1.8 Hz, 1 H, C_5H_3) ppm. ^{13}C NMR($CDCl_3$, 20 °C): δ = 2.65 (Si*Me*$_2$), 3.83 (Si*Me*$_2$), 121.4 (C_5H_3), 126.6 (C_5H_{3ipso}), 141.8 (C_5H_3) ppm.

[Zr{η5-C5H3 [SiMe2(NHtBu)](SiMe2-η1-NtBu)}Cl2(NMe2H)] (9): A solution of [Zr{η5-C_5H_3 (SiMe_2-η1-N*t*Bu)2}(NMe_2)] (0.74 g, 1.46 mmol) in toluene (40 mL) was added to a suspension of NEt_3·HCl (0.40 g, 2.92 mmol) in the same solvent. The resultant mixture was then stirred for 2 h at 70 °C. The solvent was then removed under vacuum and the residue extracted into pentane (40 mL). After filtration and removal of the solvent, complex **9** was isolated as an ochre microcrystalline solid (0.64 g, 1.21 mmol, 82%). $C_{19}H_{41}Cl_2N_3Si_2Zr$ (529.8): calcd. C 43.07, H 7.80, N 7.93; found C 42.46, H 7.58, N 7.60. ^{1}H NMR (C_6D_6, 20 °C): δ = 0.27 (s, 3 H, Si*Me*$_2$), 0.28 (s, 3 H, Si*Me*$_2$), 0.5 (s, 3 H, Si*Me*$_2$), 0.52 (s, 3 H, Si*Me*$_2$), 1.06 (s, 9 H, NHC*Me*$_3$), 1.50 (s, 9 H, NC*Me*$_3$), 2.25 (s, 3 H, N*Me*$_2$H), 2.27 (s, 3 H, N*Me*$_2$H), 3.58 (s br, 1 H, NMe$_2$*H*), 6.43 (m, 1 H, C_5H_3), 6.81 (m, 1 H, C_5H_3), 6.91 (m, 1 H, C_5H_3) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 1.1 (Si*Me*$_2$), 1.4 (Si*Me*$_2$), 1.9 (Si*Me*$_2$), 4.2 (Si*Me*$_2$), 31.6 (NHC*Me*$_3$), 33.6 (NC*Me*$_3$), 39.3 (br., N*Me*$_2$H), 50.1 (NH*C*Me$_3$), 58.3 (N*C*Me$_3$), 114.6 (C_5H_{3ipso}), 123.9 (C_5H_3), 126.3 (C_5H_3), 127.9 (C_5H_{3ipso}), 129.4 (C_5H_3) ppm.

[Zr{η5-C5H3[SiMe2(NHtBu)](SiMe2-η1-NtBu)}Cl(NMe2)] (10): $SiClMe_3$ (15.2 μL, 0.12 mmol) was added by syringe to a solution of [Zr{η5-C_5H_3[SiMe_2(NH*t*Bu)](SiMe_2-η1-N*t*Bu)}(NMe_2)2] (0.059 g, 0.12 mmol) in C_6D_6. The ^{1}H NMR spectrum of this solution was recorded after 1 h of reaction to confirm that **10** was the unique product. ^{1}H NMR (C_6D_6, 20 °C): δ = 0.30 (s, 3 H, Si*Me*$_2$), 0.32 (s, 3 H, Si*Me*$_2$), 0.44 (s, 3 H, Si*Me*$_2$), 0.46 (s, 3 H, Si*Me*$_2$), 1.04 (s, 9 H, NHC*Me*$_3$), 1.27 (s, 9 H, NC*Me*$_3$), 2.75 (d, 6 H, ZrN*Me*$_2$), 6.28 (m, 1 H, C_5H_3), 6.52 (m, 1 H, C_5H_3), 7.02 (m, 1 H, C_5H_3) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 2.0 (Si*Me*$_2$), 2.0 (Si*Me*$_2$), 2.1 (Si*Me*$_2$), 2.1 (Si*Me*$_2$), 33.8 (NHC*Me*$_3$), 34.1 (NC*Me*$_3$), 43.3 (N*Me*$_2$), 49.7 (NH*C*Me$_3$), 56.9 (N*C*Me$_3$), 111.6 (C_5H_{3ipso}), 122.6 (C_5H_{3ipso}), 122.9 (C_5H_3), 125.9(C_5H_3), 127.4 (C_5H_3) ppm.

[Ti{η5-C5H3[SiMe2(NHtBu)](SiMe2-η1-NtBu)}Cl(CH2Ph)] (11): A solution of [Ti{η5-C_5H_3(SiMe_2-η1-N*t*Bu)2}(CH_2Ph)] (0.58 g, 1.25 mmol) in toluene (40 mL) was added to a suspension of NEt_3·HCl (0.17 g, 1.25 mmol) in the same solvent. The resultant mixture was stirred for 2 h at 70 °C. The solvent was then removed under vacuum and the residue was extracted into pentane (40 mL). After filtration and removal of the solvent, complex **11** was isolated as a red solid (0.48 g, 0.96 mmol, 77%). $C_{24}H_{41}ClN_2Si_2Ti$ (497.1): calcd. C 57.99, H 8.31, N 5.64; found C 58.10, H 8.03, N 5.77. ^{1}H NMR (C_6D_6, 20 °C): δ = 0.25 (s, 3 H, Si*Me*$_2$), 0.30 (s, 3 H, Si*Me*$_2$), 0.40 (s, 3 H, Si*Me*$_2$), 0.48 (s, 3 H, Si*Me*$_2$), 1.04 (s, 9 H, NHC*Me*$_3$), 1.48 (s, 9 H, NC*Me*$_3$), 2.92 (d, $J_{H,H}$ = 9.6 Hz, 1 H, C*H*$_2$Ph), 3.1 (d, 1 H, C*H*$_2$Ph), 5.91 (m, 1 H, C_5H_3), 6.39 (m, 1 H, C_5H_3), 6.49 (m, 1 H, C_5H_3), 6.88 (m, 1 H, C_6H_5), 6.97 (m, 2 H, C_6H_5), 7.18

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(m, 2 H, C_6H_5) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 0.4 (SiMe_2), 0.6 (SiMe_2), 1.4 (SiMe_2), 1.5 (SiMe_2), 33.7 (NHCMe_3), 33.8 (NCMe_3), 49.6 (NHCMe$_3$), 62.3 (NCMe_3), 79.7 (CH$_2$Ph), 111.4 (C_5H_{3ipso}), 122.5 (C_5H_3), 126.1 (C_5H_{3ipso}), 127.0 (C_5H_3), 128.7 (C_5H_4) 128.8 (C_6H_5), 133.1 (C_6H_5), 139.2 (C_6H_5), 149.5 (C_6H_{5ipso}) ppm.

[Zr{η^5-C$_5$H$_3$[SiMe$_2$(NH*t*Bu)](SiMe$_2$-η^1-N*t*Bu)}Cl$_2$] (12): A solution of [Zr{η^5-C$_5$H$_3$(SiMe$_2$-η^1-N*t*Bu)$_2$}(CH$_2$Ph)] (0.32 g, 0.63 mmol) in toluene (40 mL) was added to a suspension of NEt$_3$·HCl (0.17 g, 1.26 mmol) in the same solvent. The resultant mixture was stirred for 12 h at 70 °C. The solvent was then removed under vacuum and the residue extracted into pentane (70 mL). After filtration and removal of the solvent, complex **12** was isolated as a light brown solid (0.27 g, 0.58 mmol, 88%). ^{1}H NMR (C_6D_6, 20 °C): δ = 0.27 (2s, 6 H, SiMe_2), 0.43 (s, 3 H, SiMe_2), 0.53 (s, 3 H, SiMe_2), 1.05 (s, 9 H, NHCMe_3), 1.30 (s, 9 H, NCMe_3), 6.41 (m, 1 H, C_5H_3), 6.60 (m, 1 H, C_5H_3), 6.97 (m, 1 H, C_5H_3) ppm. ^{13}C NMR (C_6D_6, 20 °C): δ = 0.8 (SiMe_2), 1.4 (SiMe_2), 1.9 (SiMe_2), 33.0 (NHCMe_3), 33.9 (NCMe_3), 49.8 (NHCMe$_3$), 57.6 (NCMe$_3$), 112.6 (C_5H_{3ipso}), 120.9 (C_5H_3), 126.7 (C_5H_{3ipso}), 128.3 (C_5H_3) ppm.

X-ray Crystallographic Study: Crystal data and details of the structure determination (Table 2) and bond lengths and bond angles (Table 1) are given here. Suitable single crystals for X-ray diffraction were grown from a saturated solution of **3** in pentane by standard cooling techniques. A clear orange fragment (0.41 × 0.43 × 0.48 mm) was stored under perfluorinated ether, transferred to a Lindemann capillary, fixed and sealed. Preliminary examination and data collection were carried out on an area detecting system (NONIUS, MACH3 κ-CCD) at the window of a rotating anode (NONIUS, FR591) and graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Unit cell parameters were obtained by full-matrix least-squares refinement of 2450 reflections. Data collection was performed at 153 K within a Θ-range of 2.77−25.35°. Nine data sets were measured in rotation scan modus with Δφ/ΔΩ = 1.0° controlled by the COLLECT software package.[33] A total of 30285 intensities were integrated. Raw data were corrected for Lorentz, polarization, and during the scaling procedure for latent decay and absorption effects. After merging (R_{int} = 0.043), a sum of 4654 (all data) and 4560 [$I > 2\sigma(I)$] remained and all data were used.[34] The structure was solved by a combination of direct methods[35] and difference Fourier syntheses.[36] All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were found in the final difference Fourier maps and allowed to refine freely with isotropic displacement parameters. Full-matrix least-squares refinements with 366 parameters were carried out by minimizing $\Sigma w(F_o^2-F_c^2)^2$ with the SHELXL-97 weighting scheme and stopped at shift/err < 0.001. The correct enantiomer was proved by Flack's parameter ε = 0.02(2). Final residual electron density maps showed no remarkable features. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from *International Tables for Crystallography*.[37] CCDC-229361 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

1,3,5-Triazapentanediene, A Novel Tridentate Ligand that Bridges Two Metal Ions in a $\kappa^1N:\kappa^2N$ Bridging Mode with C_2 Symmetry

Takashi Kajiwara*[a] and Tasuku Ito[a]

Keywords: Chelates / Coordination modes / N ligands / Nickel

The new mononuclear complexes $[Ni(Htap)_2](ClO_4)_2$ (**1**) and $[Ni(tap)(Htap)]ClO_4$ (**2**) were synthesized by the reaction of nickel(II) perchlorate and 1,3,5-triazine (Htap = 1,3,5-triazapentanediene). In **1** and **2**, neutral Htap and a monoanionic tap^- coordinate in a square-planar mode to the nickel(II) ions (low-spin state) in a bidentate, chelating fashion. Using the central N of tap^- of **2** as a donor atom, multinuclear complexes $[\{Cu(tren)\}_2\{Ni(tap)_2\}](ClO_4)_4$ (**3**) and $[Ni(Htap)_2]_2$-$[Ni\{Ni(tap)(Htap)\}_2(NCS)_4][Ni\{Ni(tap)(Htap)\}(NCS)_5]_2$ (**4**) were synthesized. In both complexes, tap^- binds two metal ions in a $\kappa^1N:\kappa^2N$ bridging mode, with C_2 symmetry along the Ni–Cu axis for **3** and Ni–Ni axis for **4**.

Introduction

Metal-containing ligands[1] are useful building blocks for making metal-assembled complexes with direct or indirect metal−metal interactions. In our recent studies, we have focused on a metal-containing ligand derived from 1,3,5-tris(2-pyridyl)-2,4,6-triazine (tptz). Upon refluxing, tptz can be converted into bis(2-pyridylcarbonyl)amine (Hpbca, Figure 1) or 2,4-bis(2-pyridyl)-1,3,5-triazapentanediene (Hbptap) in the presence of copper(II) ions; they were isolated as their copper(II) complexes (Scheme 1).[2−4,9] Hbpca was easily obtained as the free ligand,[2] and a variety of metal complexes were synthesized for use as metal-containing ligands.[2,5−8] We have shown that complexes such as $[M(bpca)_2]$,[2,5−7] $[Fe_3(\mu_3\text{-}O)(bpca)_4(OEt)_2Cl_4]^-$,[8] and $[Cu(bptap)_2]$[9,10] potentially act as ligands to build metal-assembled complexes. In the resulting complexes, the two adjacent metal ions are bridged in a $\kappa^1N:\kappa^2O$ mode for $bpca^-$ or $\kappa^1N:\kappa^2N$ mode for $bptap^-$, with local C_2 symmetry along the metal−metal axis (Figure 2). When the two metal ions have dσ spins, this bridging mode causes the dσ orbitals to have different symmetry and thus makes them orthogonal to each other.[2,9,10] As a result, a ferromagnetic interaction occurs between the metal ions. While this coordination mode promotes ferromagnetic interactions, only a few reports have been published concerning either $\kappa^1N:\kappa^2O$ or $\kappa^1N:\kappa^2N$ modes.[11]

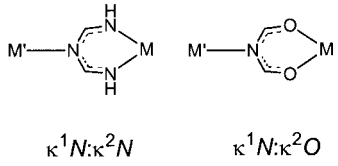

Figure 2. The κ^1N: κ^2N and κ^1N: κ^2O coordination mode with local C_2 symmetry found in complexes of $bpca^-$ and $bptap^-$

This study describes the simplest ligand in the series, 1,3,5-triazapentanediene (Htap, Figure 1), and its metal complexes. This ligand, like Hbptap, can link metals in a $\kappa^1N:\kappa^2N$ mode. Unlike tptz, which requires severe con-

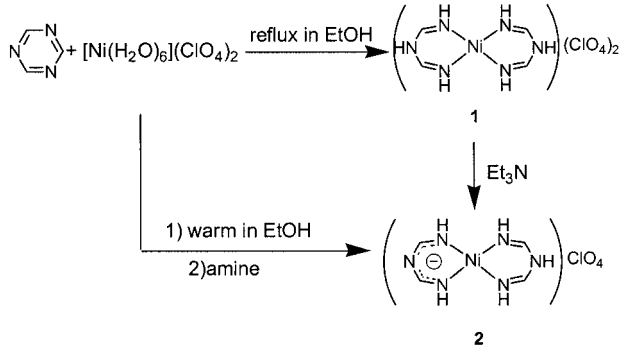
ditions to decompose, 1,3,5-triazine decomposes easily and Htap was first obtained as $[Cu(Htap)_2](ClO_4)_2$.[12] However, this copper(II) complex is not suitable as a metal-containing ligand since it decomposes under basic conditions. We found that 1,3,5-triazine is also converted into Htap in the presence of nickel(II) ions. Herein we report the syntheses of the new nickel(II) complexes $[Ni(Htap)_2](ClO_4)_2$ (**1**) and $[Ni(tap)(Htap)]ClO_4$ (**2**). The syntheses and structures of multinuclear complexes constructed with the complexed ligands, $[\{Cu(tren)\}_2\{Ni(tap)_2\}](ClO_4)_4$ (**3**) and $[Ni(Htap)_2]_2[Ni\{Ni(tap)(Htap)\}_2(NCS)_4][Ni\{Ni(tap)(Htap)\}(NCS)_5]_2$ (**4**), are also described.

Results and Discussion

Synthesis of Complexed Ligands 1 and 2

Unlike tptz, which forms stable metal complexes at room temperature, 1,3,5-triazine readily decomposes in the presence of metal ions to form Htap. At room temperature, the decomposition takes longer with nickel(II) than with copper(II), but upon heating to near reflux it was possible to prepare a new nickel(II) Htap complex, $[Ni(Htap)_2](ClO_4)_2$ (**1**) (Scheme 2).



Scheme 2

The mixed-ligand complex $[Ni(tap)(Htap)]ClO_4$ (**2**) was synthesized by controlling the basicity of the solution with ethylenediamine during the decomposition of 1,3,5-triazine. Slow diffusion of triethylamine into an alcoholic solution of **1** also gave the same product.

In order to obtain a pK_a value for **1**, ^1H NMR spectra of **1** and **2** in D_2O were measured. Both complexes have very broad signals at around $\delta = 9.38$ ppm for **1** and $\delta = 8.40$ ppm for **2**, which were not assigned. These broad peaks are indicative of a fast equilibrium between low-spin four-coordinate and high-spin six-coordinate geometries in aqueous solution, and therefore we could not determine a pK_a value for **1**.

Synthesis of Multinuclear Complexes 3 and 4

Complex **2** has a strong ability to act as a complexed ligand through the amide nitrogen atom of tap^-, and the trinuclear complex $[\{Cu(tren)\}_2\{Ni(tap)_2\}](ClO_4)_4$ (**3**) was easily synthesized by the reaction of **2** and $[Cu(tren)](ClO_4)_2$ in $EtOH/H_2O$. In this compound, a neutral $\{Ni(tap)_2\}$ moiety bridges two copper(II) ions to form a linear trinuclear complex acting as a bis-monodentate ligand (see below).

Addition of strong donor ions such as SCN^- to a solution of **2** resulted in the decomposition of **2** to give $\{Ni(NCS)_4\}^{2-}$ and $\{Ni(NCS)_5\}^{3-}$, and by controlling the reaction stoichiometry, a multinuclear complex $[Ni(Htap)_2]_2[Ni\{Ni(tap)(Htap)\}_2(NCS)_4][Ni\{Ni(tap)(Htap)\}(NCS)_5]_2$ (**4**) was obtained as crystals.

Structures of 1 and 2

The structures of complexes **1** and **2** are shown in Figures 3 and 4, respectively. In **1**, the nickel(II) ion is located on a crystallographic inversion center and the two Htap ligands in each molecule are equivalent. Both Htap ligands occupy four coordination sites of the square-planar nickel(II) ion in a bidentate chelating fashion with short Ni−N distances of 1.859(2) Å and 1.8554(18) Å, which results in the nickel(II) ion being in a low-spin state. The central nitrogen atom of the ligand (N2) is protonated, dividing the conjugated π-system, and, as a result, the terminal C−N bonds (C1−N1 and C2−N3) have a double bond character [C−N = 1.278(3) and 1.280(3) Å, respectively]. Each nitrogen atom in Htap is bound to oxygen atom(s) from ClO_4^- by hydrogen bonding(s) [O···N = 2.983(3)−3.136(2) Å].

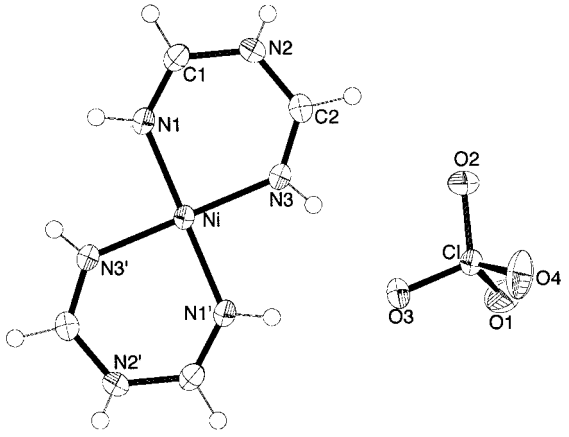


Figure 3. An ORTEP diagram of complex **1** with 50% displacement ellipsoids; relevant bond lengths (Å) and angles (°): Ni−N(1) 1.8554(18), Ni−N(3) 1.859(2), N(1)−C(1) 1.278 (3), C(1)−N(2) 1.348(3), N(2)−C(2) 1.356(3), C(2)−N(3) 1.280(3); N(3)−Ni−N(1) 90.08(9), N(1)−Ni−N(3′) 89.92(9); symmetry transformations used to generate equivalent atoms: ′ $-x, -y + 1, -z$

In **2**, two crystallographically independent cations are present in the unit cell. They have similar structures and are abbreviated as complex **2a** [including Ni(1)] and complex **2b** [including Ni(2)]. $[Ni(tap)(Htap)]^+$ contains both a protonated Htap and a deprotonated tap^-. The structures of the Htap ligands in **2a** and **2b** are similar to that in **1**; however, tap^- shows slight differences from Htap, reflecting the differences in the electronic structures. The minus charge of tap^- is delocalized over the $N_{terminal}-C-N_{central}-C-N_{terminal}$ π-system, and, as a result, the double-bond character of the terminal C−N bonds is reduced and the

bond lengths are slightly elongated [for Htap the $C-N_{terminal}$ bond lengths are in the range between 1.276(4) and 1.285(4) Å; for tap$^-$ the distances are 1.306(4) and 1.297(4) Å for complex **2a** and 1.302(4) and 1.293(4) Å for complex **2b**); see also Table 1]. Both Htap and tap$^-$ coordinate to the nickel(II) ion, with slightly shorter $Ni-N_{terminal}$ bonds for tap$^-$ [1.837(3)−1.843(3) Å] than for Htap [1.860(3)−1.871(3) Å] due to the presence of the negative charge. Because of the strong ligand field, the nickel(II) ions are in a low-spin state. Each of **2a** and **2b** is aligned in a liner manner along the *a* axis and adjoining $N_{central}$(tap) and $N_{central}$(Htap) are connected by a hydrogen bonding [N(2)···N(5)* = 2.775(4) and N8···N(11)* = 2.791(4) Å].

Structure of Trinuclear complex 3

Figure 5 shows the crystal structure of trinuclear [{Cu(tren)}$_2${Ni(tap)$_2$}](ClO$_4$)$_4$ (**3**). Complex **3** consists of two terminal copper(II) units and a neutral {Ni(tap)$_2$} moiety acting as a bis-monodentate bridging ligand to form a linear structure. The central nickel(II) ion is on an inversion center. In **3**, the tap$^-$ ligands bind to two metal ions in a $\kappa^1N:\kappa^2N$ bridging mode with local C_2 symmetry along the Ni−Cu axis. The nickel(II) ion is surrounded by four nitrogens from two tap$^-$ ligands, with Ni−N distances of 1.842(2) and 1.852(2) Å (Table 2), which are slightly longer than the values for tap$^-$ in **2** [1.837(3)−1.845(3) Å] and close to those of Htap in **1**. The Cu^{II} ions are in a trigonal-bipyramidal environment and the apical position of each Cu atom is occupied by the tertiary nitrogen from tren and $N_{central}$ from the tap$^-$ ligand, with a distance of 2.009(2) Å for the latter. The minus charge of each tap$^-$ ligand is localized on this nitrogen to bind the Cu atom, and, again, the terminal C−N bonds in the tap$^-$ ligands have double-bond character, with shorter distances [1.283(3) and 1.287(3) Å]. This charge localization causes a slight elongation of the Ni−N distances compared to those of the tap$^-$ ligands of **2a** and **2b**. Each $N_{terminal}$ is bound to an oxygen atom from a perchlorate ion by a hydrogen bonding [N(1)···O(8)′ = 2.987(3) and N(3)···O(7)′′ = 3.017(3) Å].

cationic $[Ni(Htap)_2]^{2+}$, including Ni1 (complex $\mathbf{4a^{2+}}$), dianionic dinuclear $[Ni(NCS)_5\{Ni(tap)(Htap)\}]^{2-}$, including Ni2 and Ni3 (complex $\mathbf{4b^{2-}}$), and neutral trinuclear $[Ni(NCS)_4\{Ni(tap)(Htap)\}_2]$, with Ni4 and Ni5 (complex **4c**). Ni5 in **4c** is located on a crystallographic inversion center, therefore complex **4** is formulated as **$(4a)_2(4b)_2(4c)$**. The structure of dicationic $\mathbf{4a^{2+}}$ is similar to **1**, with longer Ni−N distances of 1.842(4)−1.858(4) Å and shorter $C-N_{terminal}$ distances of 1.250(6)−1.277(6) Å showing the double-bonding character of $C-N_{terminal}$ (Table 3). In $\mathbf{4b^{2-}}$, the complexed ligand $\{Ni(tap)(Htap)\}^+$ coordinates to an $\{Ni(NCS)_5\}^{3-}$ moiety through the $N_{central}$ of tap^- (N8) with a bond length of 2.086(3) Å. The $C-N_{terminal}$ distances are short [1.257(6)−1.286(5) Å] due to the localization of the negative charge on $N_{central}$. Trinuclear **4c** consists of an anionic $\{Ni(NCS)_4\}^{2-}$ and two complexed ligands coordinating through N19, with a distance of 2.1048(19) Å. The complexed ligands in **4c** show similar structural features to those in $\mathbf{4b^{2-}}$. Non-coordinating $\mathbf{4a^{2+}}$ and two $\{Ni(tap)(Htap)\}^+$ units from $\mathbf{4b^{2-}}$ and **4c** are arranged almost parallel to each other with close Ni···Ni contacts of 3.7764(10) Å from $\mathbf{4a^{2+}}$ to $\mathbf{4b^{2-}}$ and 3.3328(10) Å from $\mathbf{4b^{2-}}$ to **4c**. The positive charge repulsion between $Ni^{II}\cdots Ni^{II}$ centers is slightly diminished for the **4c**/$\mathbf{4b^{2-}}$ couple compared with $\mathbf{4a^{2+}}$/$\mathbf{4b^{2-}}$.

Conclusion

We have reported the decomposition reaction of triazine in the presence of nickel(II) to give Htap and tap^- complexes. $[Ni(Htap)_2]^{2+}$ and its deprotonated derivatives $[Ni(tap)(Htap)]^+$ and $[Ni(tap)_2]$ were obtained as mononuclear complexes for the former two and as complexed ligands for the latter two species. Two multinuclear complexes **3** and **4** contain the complexed ligands $[Ni(tap)_2]$ and $[Ni(tap)(Htap)]^+$ acting as a bridging ligand and as a terminal ligand, respectively. As expected, the tap^- ligand bridges two metal ions in a $\kappa^1N{:}\kappa^2N$ mode with local C_2 symmetry. The formation of a new complexed ligand should be possible with Htap, which can act as a ferromagnetic coupler like $[Cu(bptap)_2]$. Such investigations are now in progress in our laboratory.

Experimental Section

Synthesis of $[Ni(Htap)_2](ClO_4)_2$ (1): A solution of nickel(II) perchlorate hexahydrate in ethanol (0.1 M, 5 mL) and triazine in methanol (0.2 M, 5 mL) were mixed and the resulting pale-green solution was heated to 50 °C for 2 hours, during which time the solution turned yellow. Upon standing overnight, yellow crystals formed. Yield 130 mg (65%). $C_4H_{10}Cl_2N_6NiO_8$ (399.8): calcd. C 12.02, H 2.52, N 21.02; found C 12.17, H 2.71, N 20.87.

Synthesis of $[Ni(tap)(Htap)]ClO_4\cdot H_2O$ ($\mathbf{2}\cdot H_2O$): Three 0.2 M solutions of nickel(II) perchlorate/EtOH (1 mL), ethylenediamine/EtOH (2 mL), and triazine/MeOH (1 mL) were mixed and the resulting blue solution was heated to 70 °C for 1 hour to afford a blue solution. The yellow fraction isolated by column chromatography (Sephadex LH-20/EtOH) was dried. The resulting compound was recrystallized from EtOH/H_2O (1:1, v/v) to give yellow crystals of $\mathbf{2}\cdot H_2O$. Yield 11 mg (35%). $C_4H_{11}ClN_6NiO_5$ (317.3): calcd. C 15.14, H 3.49, N 26.48; found C 15.18, H 3.46, N 26.37.

Synthesis of $[\{Cu(tren)\}_2\{Ni(tap)_2\}](ClO_4)_4$ (3): A yellow suspension of $\mathbf{2}\cdot H_2O$ (3.4 mg, 0.011 mmol) in EtOH/H_2O (1:1, v/v; 1 mL) was added to $[Cu(tren)]ClO_4$ (8.2 mg, 0.027 mmol) in EtOH/H_2O (1:1, v/v; 1 mL). The mixture was stirred to afford a blue-green solution. Blue-green crystals of **3** were obtained from this solution after several days. Yield 6.7 mg (60%). $C_{16}H_{44}Cl_4Cu_2N_{14}NiO_{16}$ (1016.2): calcd. C 18.91, H 4.36, N 19.30; found C 19.10, H 4.45, N 19.21.

Synthesis of $[Ni(Htap)_2]_2[Ni(2)_2(NCS)_4][Ni(2)(NCS)_5]_2\cdot 8H_2O$ ($\mathbf{4}\cdot 8H_2O$): A solution of $\mathbf{2}\cdot H_2O$ (12 mg, 0.038 mmol) in EtOH/ H_2O (1:1, v/v; 1 mL) was added to 0.2 mL of 0.1 M nickel(II) perchlorate/EtOH solution and 0.8 mL of a 0.1 M NH_4SCN/MeOH solution,

and the resulting yellow solution was allowed to evaporate slowly in air. After a week, green crystals of **4**·4H_2O were obtained which were collected by filtration and dried in vacuo. Yield 4.2 mg (30%). $C_{38}H_{56}N_{50}Ni_9S_{14}$ (2190.3): calcd. C 20.90, H 2.59, N 32.09; found C 20.76, H 2.67, N 32.33.

X-ray Crystallography: Data for all the compounds were collected on a Bruker SMART APEX diffractometer employing graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at low temperature (200−233 K). The data integration and reduction were undertaken with SAINT and XPREP.[13] An empirical absorption correction determined with SADABS[14] was applied to each data set. The structures were solved by direct methods using SHELXS-97[15] and refined using least-squares methods on F^2 with SHELXL-97.[15] Non-hydrogen atoms were modelled with anisotropic displacement parameters, and hydrogen atoms were placed by difference Fourier syntheses and refined isotropically. Further details can be found in Table 4.

(Pyrazole)silver(I) and -gold(I) Complexes with Strong and Weak Hydrogen-Bonding Interactions as the Basis of One- or Two-Dimensional Structures

M. Luz Gallego,[a] Paloma Ovejero,[a] Mercedes Cano,*[a] José V. Heras,[a] José A. Campo,[a] Elena Pinilla,[a,b] and M. Rosario Torres[b]

Dedicated to Professor José Vicente on the occasion of his 60th birthday

Keywords: : Gold / Hydrogen bonds / N ligands / Silver / Supramolecular chemistry

New Au^I/Ag^I complexes containing one or two substituted pyrazole ligands $[Au(Hpz^{bp2})(PPh_3)](p\text{-}CH_3C_6H_4SO_3)$ [Hpz^{bp2} = 3,5-bis(4-*n*-butoxyphenyl)pyrazole] (**1**) and $[M(Hpz^{R2})_2]_nX$ [Hpz^{R2} = Hpz^{bp2}, M = Au, *n* = 1, X = *p*-$CH_3C_6H_4SO_3$ (**2**), NO_3^- (**3**); *n* = 2, X = 1,5-naphthalenedisulfonate (1,5nds) (**4**); Hpz^{R2} = Hpz^{bp2}, M = Ag, *n* = 1, X = BF_4^- (**5**), $CF_3SO_3^-$ (**6**); Hpz^{R2} = Hpz^{NO2} (3,5-dimethyl-4-nitropyrazole), M = Ag, *n* = 1, X = BF_4^- (**7**), $CF_3SO_3^-$ (**8**)], have been prepared and characterized. Compounds **1**, **2**, **5** and **8** have been proved to be useful for supramolecular assembly from their single X-ray diffraction analysis. In all cases strong hydrogen bonds maintain the cationic units bonded to their corresponding counterions. The crystal packing arrangement of **1**, **2** and **5** is, however, determined by weak C–H···O/F hydrogen-bonding interactions involving the remaining O/F atoms of the counterion. By contrast, for **8** a two-dimensional layer-type polymeric network is formed by π···π (NO_2···NO_2) and coordinative Ag···O interactions in which the NO_2 substituent on the pyrazole is implicated.

Introduction

Supramolecular architectures derived from metallic complexes as building blocks are an attractive focus of current research. In this context coordinative interactions and/or hydrogen bonds have been extensively used to produce supramolecular one-, two- or three-dimensional polymeric structures.[1] However, although self-assembly has been well documented,[2] much work remains to extend the knowledge of relevant structures. The nature of the metal, counterions or ligands are factors that can be modulated to determine the molecular assembly.

The silver(I) ion is a favourable building block because of its various potential coordination modes such as linear,[3] trigonal[4] or tetrahedral,[5] and its affinity for hard donor atoms such as nitrogen or oxygen. In addition, some silver(I) derivatives have also been determined to present experimental evidence for an argentophilic attraction[6] and therefore with potential applications for self-assembled nets. In the same context, gold(I) complexes are promising for the construction of supramolecular structures based on the aurophilic nature of gold.[6b,7] Furthermore, experimental evidence from structures of Au/Ag-containing cationic complexes indicates the relevant role of the counterion in the molecular architecture.[2b,6c,8]

It has been postulated that the control and manipulation of weak interactions could be used as the key to tune the properties of the bulk materials. In addition to the classical O/N−H···X (X = O, N or F atoms) hydrogen-bonding interactions, other weaker C−H···X (X = O, N or F atoms) interactions have been shown to control the molecular packing in the solid.[1g,9]

In previous work from our lab we have made use of hydrogen-bonding interactions produced between cationic metal complexes containing pyrazole ligands and the corresponding counterions. Although the strong NH···X (X = O or F atoms from NO_3^- or BF_4^- counterions) hydrogen bonds are the predominant force driving the structure, other different intermolecular interactions, such as C−H···O/F, are also considered to be important for the molecular assembly.[10]

We have now extended these results to the use of new silver(I) and gold(I) pyrazole derivatives of the type $[M(Hpz^{R2})_2]^+$ [Hpz^{R2} = 3,5-bis(4-*n*-butoxyphenyl)pyrazole, Hpz^{bp2}; 3,5-dimethyl-4-nitropyrazole, Hpz^{NO2}) containing different counterions, as well as different substituents on the pyrazole rings. The related complex containing only one

pyrazole ligand, [Au(Hpz^{bp2})(PPh$_3$)](*p*-CH$_3$C$_6$H$_4$SO$_3$), has also been prepared and studied (Scheme 1). We report herein how the presence of strong or weak N−H···O/F and C−H···O/F inter- and intramolecular hydrogen-bonding interactions, supported by the different counterions, are responsible for the molecular arrangement in the solid for complexes containing the Hpz^{bp2} ligand. In contrast, the molecular packing of those complexes with Hpz^{NO2} is dominated by interactions through the NO_2 substituents on the ligands.

Compound	Formula
1	[Au(Hpz^{bp2})(PPh$_3$)](*p*-CH$_3$C$_6$H$_4$SO$_3$)
2	[Au(Hpz^{bp2})$_2$](*p*-CH$_3$C$_6$H$_4$SO$_3$)
3	[Au(Hpz^{bp2})$_2$](NO$_3$)
4	[Au(Hpz^{bp2})$_2$]$_2$(1,5nds)[a]
5	[Ag(Hpz^{bp2})$_2$](BF$_4$)
6	[Ag(Hpz^{bp2})$_2$](CF$_3$SO$_3$)
7	[Ag(Hpz^{NO2})$_2$](BF$_4$)
8	[Ag(Hpz^{NO2})$_2$](CF$_3$SO$_3$)

Hpz^{bp2} = 3,5-bis(4-*n*-butoxyphenyl)pyrazole

Hpz^{NO2} = 3,5-dimethyl-4-nitropyrazole

[a] 1,5nds = 1,5-naphthalenedisulfonate ($O_3SC_{10}H_6SO_3$)

Scheme 1

Results and Discussion

Synthetic and Characterization Studies

Complex **1**, containing triphenylphosphane, was obtained from the reaction of [Au(*p*-CH$_3$C$_6$H$_4$SO$_3$)(PPh$_3$)] (prepared by a literature procedure)[8d] and one equivalent of Hpz^{bp2} in dry THF (Scheme 2). Compounds **2**−**4** were prepared by reaction of [AuCl(THT)] (THT = tetrahydrothiophene)[11] with two equivalents of Hpz^{bp2} and one equivalent of the corresponding silver salt in dry THF (Scheme 3). The related silver(I) derivatives **5**−**8** were synthesized by treatment of two equivalents of the corresponding pyrazole ligand with one equivalent of the silver salt in dry THF or acetonitrile (Scheme 4).

$$[Au(p\text{-}CH_3C_6H_4SO_3)(PPh_3)] + Hpz^{bp2} \longrightarrow$$

$$[Au(Hpz^{bp2})(PPh_3)](p\text{-}CH_3C_6H_4SO_3) \quad (\mathbf{1})$$

Scheme 2

$$[AuCl(THT)] + 2\ Hpz^{bp2} + AgX \longrightarrow [Au(Hpz^{bp2})_2]_nX \quad (\mathbf{2}\text{–}\mathbf{4})$$

Scheme 3

$$AgX + 2\ Hpz^{R2} \longrightarrow [Ag(Hpz^{R2})_2]X$$

$$Hpz^{R2} = Hpz^{bp2} \quad (\mathbf{5}\text{–}\mathbf{6})$$
$$Hpz^{R2} = Hpz^{NO2} \quad (\mathbf{7}\text{–}\mathbf{8})$$

Scheme 4

All compounds are air-stable white solids and they were characterized by elemental analysis and IR and ^{1}H NMR spectroscopy. In addition, ^{31}P NMR spectroscopy was also used for **1**. All data are listed in the Exp. Sect. The IR spectra show, amongst others, the characteristic bands of the pyrazole ligands, ν(C=N) + ν(C=C) at ca. 1600 cm^{-1} and ν(N−H) in the range 3112−3308 cm^{-1}, as well as those from the corresponding counterions.[8d,12]

The ^{1}H NMR spectra in $CDCl_3$ solution at room temperature show the expected signals of the ligands. It is interesting to note that the ^{1}H NMR spectra of **5**−**8** at room temperature are consistent with the presence of two equivalent coordinated pyrazole ligands, each of them having two equivalent substituents at the 3- and 5-positions. A related equivalence of the substituents has also been observed for **1**. Thus, it is possible to suggest a metallotropic equilibrium to explain the above behaviour similar to that previously found for related complexes.[13] Lowering the temperature slows down the dynamic process, resulting in the non-equivalence of the substituents, as observed for **5** and **6** at −40 °C by the well-defined signals for the aromatic and alkyl-

chain protons of the butoxyphenyl substituents. A similar feature is also present in the gold derivatives **2**−**4**, which exhibit the non-equivalence of the butoxyphenyl substituents at room temperature. The protons at the 4-positions of the pyrazole rings of **2** and **3** show an unusual coupling with the NH proton, which was confirmed by homonuclear decoupling techniques. This situation has also been observed in some metal complexes containing related pyrazole ligands.[14] The ^{31}P NMR spectrum of **1** at room temperature in $CDCl_3$ shows a single resonance at $\delta = 31.06$ ppm in the characteristic region of gold-phosphane complexes.[15]

The photoluminescence study of **1**−**3** in the solid state shows that, under 325−330 nm UV irradiation, all of them emit luminescence in the 440−510 nm range. For **1** this emission occurs both at room temperature and 77 K, while for **2** and **3** this behaviour is only observed at low temperature. The maximum-emission wavelengths are red-shifted by ca. 100 nm relative to the free pyrazole ligands.

Crystal Structure of 1

The molecular structure of [Au(Hpz^{bp2})(PPh$_3$)](*p*-CH$_3$C$_6$H$_4$SO$_3$) (**1**) is depicted in Figure 1a, which also shows the numbering scheme. Selected bond lengths and angles and the hydrogen-bond parameters for all compounds crystallographically characterized in this work are collected in Table 1 and 2, respectively.

The structure of **1** consists of *p*-toluenesulfonate anions and cationic units where the gold(I) atom is two-coordinate. The coordinative environment (shape, Au−P and Au−N distances, and P−Au−N angles) are, as expected, similar to those of the complex [Au(Hpz^{bp2})(PPh$_3$)](NO$_3$) (**A**), previously reported by us,[10b] which contains the same cationic fragment and NO_3^- as counterion [Au1−P1, Au1−N1 and P1−Au1−N1 bond parameters are 2.243(2), 2.069(5) Å and 177.1(2)° in **1**, and 2.239(2), 2.077(5) Å and 178.1(2)° in **A**]. In addition, the cationic unit in both **1** and **A** is bonded to the corresponding counterion by a strong hydrogen bond, with N···O distances of 2.701(7) Å (Table 2) and 2.764(9) Å, respectively.

Table 2. Hydrogen bond geometries for **1**, **2**, **5** and **8** (lengths in Å and angles in degrees)

However, when considering the packing arrangement in the solid several differences are observed. A two-dimensional structure was envisaged for **A** from weak intermolecular C−H···O interactions of 3.31−3.38 Å involving two of the oxygen atoms of the counterion, which were not implicated in the previous hydrogen bond.[10b] In contrast, in **1**

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the *p*-toluenesulfonate counterion forms a weak C−H···O interaction at 3.39(1) Å (Table 2) to produce a columnar one-dimensional arrangement along the *a* axis (see b in Figure 1). These columns are also reinforced by the presence of a new C−H···O interaction between the O2 atom of the substituent on the pyrazole ligand and the C31 atom of the PPh_3 ligand of a neighbouring molecule (Table 2). Throughout this one-dimensional distribution the gold atoms are in a zig-zag disposition at a distance of 5.58(1) Å, which excludes the presence of intermetallic interactions.

The above differences in the supramolecular architectures are clearly dependent on the counterions. It can therefore be suggested that the driving force of the reorientation of cationic entities when the planar NO_3^- is substituted by the bulkier *p*-toluenesulfonate could be related to the pseudo-tetrahedral geometry of the SO_3 group; interactions through this group appear to preclude a layer-like distribution.

However, this result does not exclude the possibility of new contacts involving the remaining free oxygen atom of the SO_3 group (which was not used in the previous interactions). In fact, the columns in **1** are connected to each other by very weak C−H···O interactions at 3.43(1) Å (Table 2).

At this point, it is important to mention that similar weak C−H···O contacts observed in a large variety of compounds have been considered as support of the supramolecular network.[9,16] On these basis, we propose for **1** that the strong N−H···O hydrogen bonds as well as the weak C−H···O inter- and intramolecular contacts through the SO_3 group of the counterion stabilize the crystal structure in the solid state forming a two-dimensional network.

Crystal Structures of 2 and 5

The molecular structures of complexes **2** and **5** are represented in parts a of Figure 2 and 3, respectively. The structures of the mononuclear cations $[M(Hpz^{bp2})_2]^+$ [M = Au (**2**), Ag (**5**)] show similar features. In both cases an angular molecular shape is formed by the two 3,5-disubstituted pyrazole groups bonded through the pyridinic nitrogen to the metal centre. In addition, each cationic unit has both heterocycles in a *cis*-orientation and is bonded to its corresponding counterion by two strong hydrogen bonds using both NH groups and two of the oxygen or fluorine atoms of the counterion, forming an eight-membered metallacycle (O−N−N−Au−N−N−O−S and F−N−N−Ag−N−N−F−B in **2** and **5**, respectively). The molecules have a quasi-linear N−M−N atomic sequence [176.3(4) in **2** and 170.1(1)° in **5**] and the average Au−N (2.02 Å) and Ag−N (2.12 Å) lengths (Table 1) in **2** and **5**, respectively, are similar to those found for related complexes containing pyrazole-type ligands.[10b,15b,15d,17−19] The main difference in the molecular structure of **2** and **5** is related to the orientation of the two pyrazole rings; they are almost parallel in **2** [dihedral angle of 4.5(5)°] but slightly tilted in **5** [dihedral angle of 24.6(1)°]. Other dihedral angles are collected in Table 3.

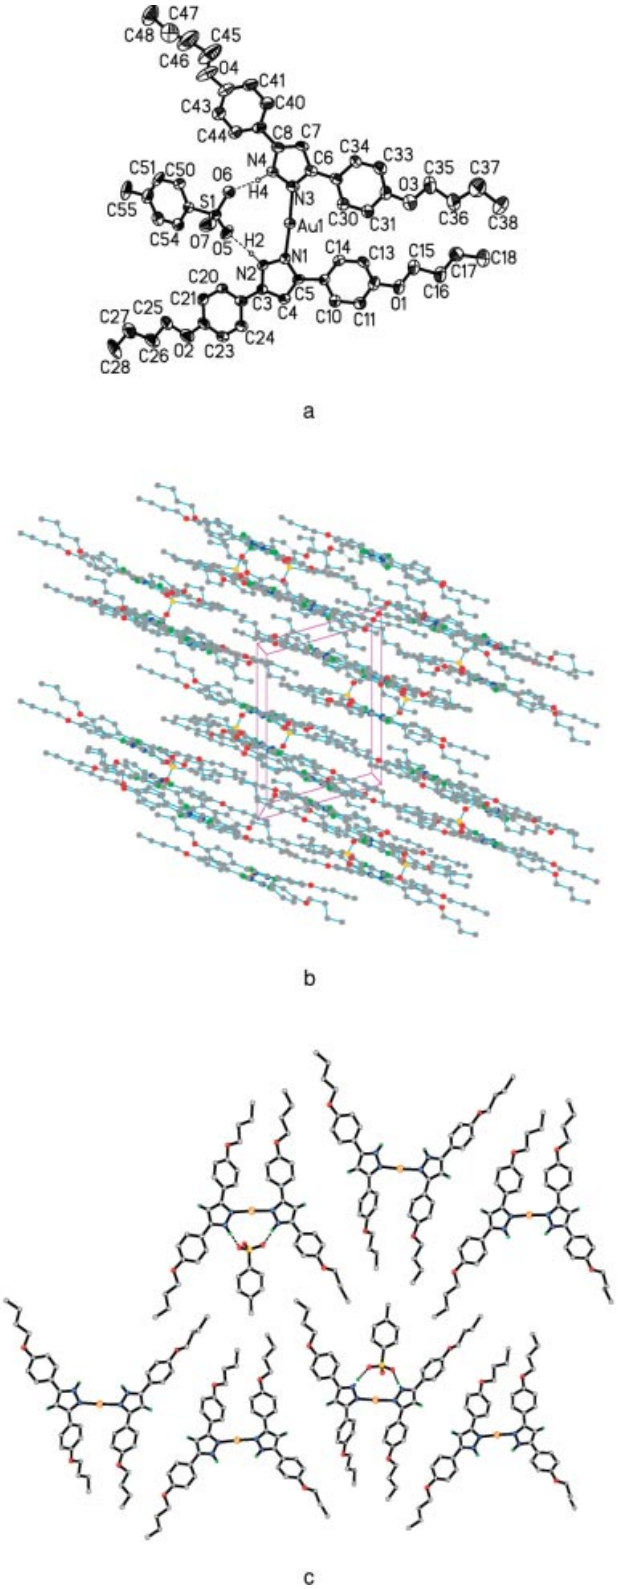

Figure 2. a) ORTEP plot of **2** at the 30% probability level; hydrogen atoms, except H2 and H4, and the labelling of some atoms have been omitted for clarity; b) view of the packing along the *b* axis showing the layer-like arrangement in the (1 0 $\bar{2}$) direction; c) view of the distribution in a layer

The crystal packing of **2** can be defined as layer-like (see b in Figure 2), with the sheet containing the cationic bis(pyrazole)gold units bonded to its corresponding counterion. The layers are situated in the (1 0 $\bar{2}$) direction. The cationic

2−6	20.1(5)	3.6(2)
5−6	12.9(4)	29.1(2)

[a] Plane 1: N1−N2−C3−C4−C5; plane 2: N3−N4−C6−C7−C8; plane 3: C9−C10−C11−C12−C13−C14; plane 4: C19−C20−C21−C22−C23−C24; plane 5: C29−C30−C31−C32−C33−C34; plane 6: C39−C40−C41−C42−C43−C44.

entities in the layer adopt a head-to-tail alignment with no short contacts between them (see c in Figure 2). However, weak C−H···O interactions between the layers are observed which involve the free O7 atom of the counterion in a bifurcated form [C4···O7 ($-x + 2, -y + 1, -z + 1$) of 3.39(2) Å; C34···O7 ($x - 1/2, -y + 1/2, z - 1/2$) of 3.42(2) Å] (Table 2). These weak intermolecular contacts form a one-dimensional framework.

The crystal packing of **5** also presents similar characteristics, the layers being oriented in the (1 1 $\bar{4}$) direction (see b and c in Figure 3). Weak inter-layer interactions involving the BF_4^- counterion are also observed for this complex. These C−H···F interactions [C7···F3 ($-x, -y + 1, -z$) of 3.40(1) Å] (Table 2) also form a one-dimensional framework.

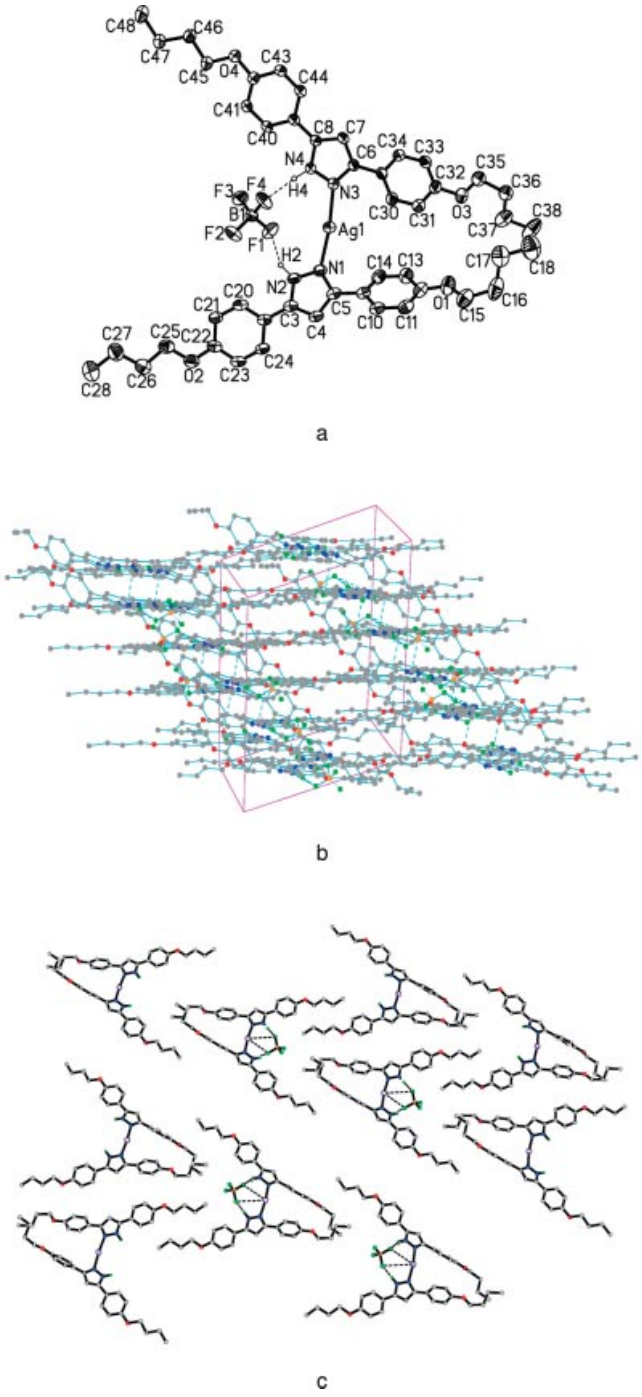

Figure 3. a) ORTEP plot of **5** at the 30% probability level; hydrogen atoms, except H2 and H4, and the labelling of some atoms have been omitted for clarity; b) view of the layer-like packing in the (1 1 $\bar{4}$) direction; c) view of the distribution in a layer

Crystal Structure of 8

The most relevant structure of complexes of the type $[M(Hpz^R)_2]X$ is that of complex **8**, where the pyrazole ligand is 3,5-dimethyl-4-nitropyrazole (Hpz^{NO2}) and X is $CF_3SO_3^-$. The structure of the cation $[Ag(Hpz^{NO2})_2]^+$ is shown in Figure 4 (see part a). The silver atom is coordinated to the two pyridinic nitrogen atoms of the heterocyclic ligands at ca. 2.17 Å (Table 1). The geometry around the metal is distorted lineal with an N1−Ag1−N4 angle of 163.67(9)°. Both pyrazole rings are almost parallel [angle of 4.8(1)°]. They show a *cis* orientation and are bonded through strong hydrogen bonds to the counterion [N2···O6: 2.771(3) Å; N5···O7: 2.852(4) Å] (Table 2). The nitro groups at the 4-position of the heterocyclic rings are almost coplanar with their own pyrazole planes [dihedral angles of 5.1(2) °and 6.3(4)°]; as a consequence the molecule shows a high planarity.

The structure built by the strongest interactions can be considered as that formed by dimers involving coordinative interactions Ag1···O5($-x + 1, -y + 1, -z + 1$) of 2.821(3) Å between the oxygen atom of the counterion (not implicated in the above hydrogen bond) and the silver centre of each molecule, giving rise to a closest distance of the metallic centres in the dimer of 3.7841(4) Å (b in Figure 4).

The next step in the packing is due to π···π contacts between dimers to form columns. The distances between atoms of the nitro groups from two neighbouring molecules, which are not implicated in the same dimer, are 3.268(4) Å [N6···N6($-x + 2, -y + 1, -z + 2$)] and 3.168(6) Å [O3···O3($-x + 2, -y + 1, -z + 2$)]. These are remarkably short distances and show the existence of a π···π interaction between those NO_2 groups,[16e−16g] which are situated in an alternating fashion. This mode of interaction

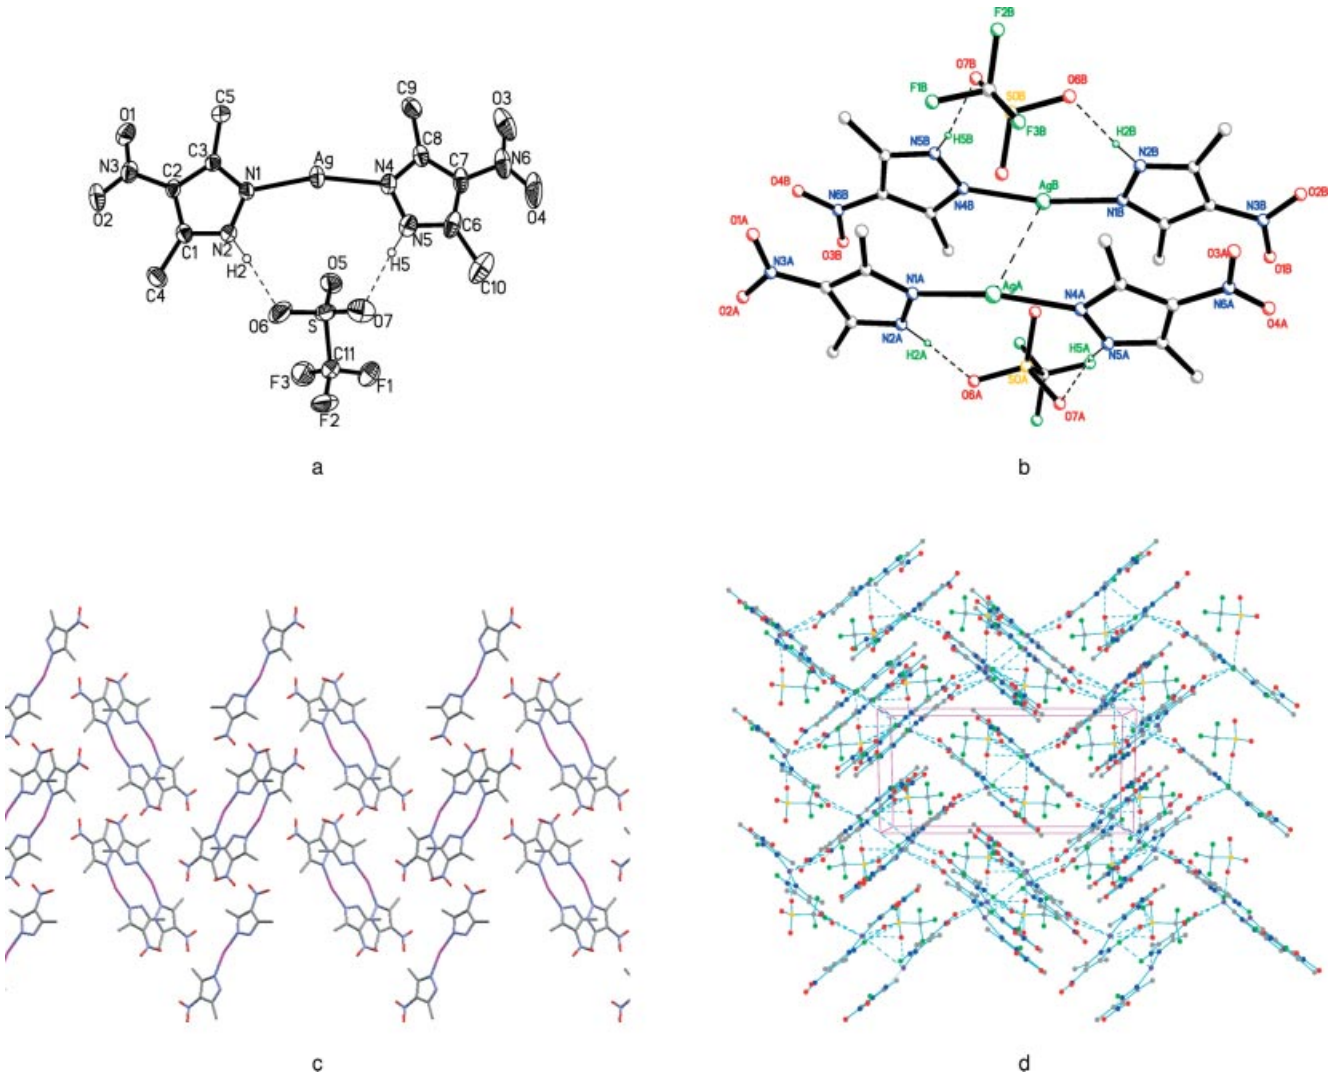

Figure 4. a) ORTEP plot of **8** at the 30% probability level; hydrogen atoms, except H2 and H4, and the labelling of some atoms have been omitted for clarity. b) View of the "dimeric unit" showing the close intermetallic approach. c) View of the two-dimensional network. d) View of the packing along the *c* axis showing the herringbone-type distribution

gives rise to the formation of columns along the (1 0 1) direction.

Finally, the columns are bonded each other to give a two-dimensional network which is extended parallel to the plane (1 0 $\bar{1}$) by long-range coordinative Ag1···O1(x + 1/2, $-y$ + 1/2, z + 1/2) interactions at 2.978(3) Å, produced between an oxygen atom of a NO_2 group, which is not implicated in the previously described π···π interactions, and the metal centre of neighbouring columns (c in Figure 4). This layer-like supramolecular structure can also be described as a herringbone-type arrangement of dimers connected through coordinative Ag···O interactions (d in Figure 4), the dimers being almost orthogonal to the layer as deduced by the angle defined between the C2−C7 line and the *a* axis of 77.01(3)°. No short interlayer distances are observed.

Concluding Remarks

The present work shows that Au/Ag complexes containing pyrazole-type ligands are efficient in constructing one- or two-dimensional networks. Complex **1** is formed by self-assembly of cationic $[Au(Hpz^{bp2})(PPh_3)]^+$ units and *p*-toluenesulfonate counterions, providing linear polymeric chains through N−H···O−S−O···H−C bridges containing both strong and weak hydrogen-bonding interactions. The geometry of the *p*-toluenesulfonate counterion appears to be responsible for the one-dimensional chain, which is different to the two-dimensional network produced by related interactions with the planar NO_3^- counterion. Therefore for cationic complexes containing one pyrazole ligand the one-dimensional supramolecular arrangement appears to be determined not only by the hydrogen-bonding interactions but also by the geometry of the counterion.

For complexes **2**, **5** and **8**, on the basis of the interactions between the counterion and the two NH-pyrazolic groups of each cationic unit, a polymeric chain was expected. However, the molecular conformation is responsible for a different assembly. In fact, in contrast to the observed *trans* disposition of the pyrazole groups found in the $[Ag(Hpz^{R2})_2]^+$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compounds (Hpz^{R2} = pyrazole, 3,5-dimethylpyrazole),[17] complexes **2**, **5** and **8** present a *cis* orientation, which gives rise to $[M(Hpz^{R2})_2]X$ unities containing the A−N−N−M−N−N−A−B metallacycle (A = donor atom of the counterion; B = central atom of the counterion). The molecular assembly in **2** and **5** is therefore determined by new, weak, intermolecular C−H···O/F contacts through the remaining O/F atoms of the counterion, its geometry being responsible for the polymeric one-dimensional network. Alternatively, an embracing effect of the cations around the anions could also be considered as driving force for encapsulation.

A special behaviour has been found for **8**. The presence of the nitro group on the pyrazoles plays the most relevant role in the formation of its polymeric architecture, which adopts a two-dimensional, herringbone-type structure involving both coordinative Ag···O and π···π interactions. The extensive hydrogen-bonds between the counterions and the cationic unities only determine the formation of dimers.

From the above results we can deduce that, in the absence of coordinative NO_2 groups as substituents on the pyrazole rings, which appear to be determinant for supramolecular interactions, the conformations of the complexes as well as intermolecular orientations between them and the counterions are responsible for the hydrogen-bonding contacts involved in the molecular assembly.

Experimental Section

Materials and Instrumentation: All commercial reagents were used as supplied. The ligands 3,5-bis(4-*n*-butoxyphenyl)pyrazole (Hpz^{bp2})[20] and 3,5-dimethyl-4-nitropyrazole (Hpz^{NO2})[21] as well as the starting gold(I) derivatives [AuCl(THT))][11] and [Au(*p*-$CH_3C_6H_4SO_3$)(PPh_3)][8d] were prepared by literature procedures. Commercial solvents were dried prior to use. Elemental analyses for carbon, hydrogen and nitrogen were carried out by the Microanalytical Service of the Complutense University. IR spectra were performed on a FTIR Nicolet Magna-550 spectrophotometer with samples as KBr pellets in the 4000−400 cm^{-1} region. ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on Varian VXR-300 or Bruker DPX-300 spectrophotometers of the NMR Service of the Complutense University, from solutions in $CDCl_3$. Chemicals shifts δ(H) are given in ppm relative to $SiMe_4$, with the signal of the deuterated solvent as reference, and δ(P) in ppm relative to 85% H_3PO_4. Coupling constants (*J*) are in Hz. The ^1H and ^{31}P chemical shifts and coupling constants are accurate to ±0.01 ppm and ±0.3 Hz, respectively. Excitation and emission spectra of solid samples placed in capillary tubes were recorded on a Perkin−Elmer LS-55 luminescence spectrometer equipped with a R928 photomultiplier tube.

Synthesis of [Au(Hpz^{bp2})(PPh_3)](*p*-$CH_3C_6H_4SO_3$) (1): Hpz^{bp2} (18 mg, 0.05 mmol) was added to a solution of [Au(*p*-$CH_3C_6H_4SO_3$)(PPh_3)] (30 mg, 0.05 mmol) in freshly distilled THF (20 mL) and stirred for 24 h. The solvent was then removed in vacuo and the product was precipitated by addition of hexane/diethyl ether. Slow diffusion of diethyl ether into a dichloromethane/diethyl ether solution of this product gave colourless crystals suitable for crystallographic studies. $C_{48}H_{50}AuN_2O_5PS$ (994.90): calcd. C 57.95, H 5.02, N 2.82; found C 57.90, H 5.05, N 2.79. IR (KBr): $\tilde{\nu}$ = 3113 cm^{-1} ν(N−H), 1614 ν(C=N) + ν(C=C), 1174, 1162 and 1119 $\nu_d(SO_3)$, 1007 $\nu_s(SO_3)$. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.00 (t, 6 H, CH_3 Hpz^{bp2}), 1.48−1.56 (m, 4 H, CH_2 Hpz^{bp2}), 1.75−1.82 (m, 4 H, CH_2 Hpz^{bp2}), 2.27 (s, 3 H, *p*-$CH_3C_6H_4SO_3$), 3.97 (t, $^3J_{H,H}$ = 6.6 Hz, 4 H, OCH_2 Hpz^{bp2}) 6.71 (s, 1 H, H4 Hpz^{bp2}), 6.86 (d, $^3J_{H,H}$ = 8.5 Hz, 4 H, H_m Hpz^{bp2}), 6.95 (d, $^3J_{H,H}$ = 7.9 Hz, 2 H, *p*-$CH_3C_6H_4SO_3$), 7.60−7.48 (m, 15 H, PPh_3), 7.74 (d, $^3J_{H,H}$ = 7.9 Hz, 2 H, *p*-$CH_3C_6H_4SO_3$), 7.79 (d, $^3J_{H,H}$ = 8.5 Hz, 4 H, H_o Hpz^{bp2}) ppm. ^{31}P NMR (121.49 MHz, $CDCl_3$, 25 °C): δ = 31.06 (s) ppm.

Synthesis of [Au(Hpz^{bp2})$_2$](*p*-$CH_3C_6H_4SO_3$) (2): A THF solution (20 mL) of Hpz^{bp2} (116 mg, 0.32 mmol) was added to a solution of [AuCl(THT)] (50 mg, 0.16 mmol) in dry THF (15 mL), and finally a solution of silver(I) *p*-toluenesulfonate (44 mg, 0.16 mmol) in dry THF (15 mL) was also added. After 24 h of stirring, the resulting mixture was filtered through a plug of Celite and the obtained colourless clear filtrate was evaporated to dryness. The residue was dissolved in dichloromethane and precipitated with hexane. X-ray quality crystals were obtained by slow diffusion of hexane into a dichloromethane solution of the product. $C_{53}H_{63}AuN_4O_7S$ (1097.1): calcd. C 58.02, H 5.79, N 5.11; found C 58.00, H 5.68, N 5.03. IR (KBr): $\tilde{\nu}$ = 3112 cm^{-1} ν(N−H), 1613 ν(C=N) + ν(C=C), 1221, 1174 and 1124 $\nu_d(SO_3)$, 1037 $\nu_s(SO_3)$. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.01 (m, 12 H, CH_3 Hpz^{bp2}). 1.46−1.60 (m, 8 H, CH_2 Hpz^{bp2}), 1.75−1.86 (m, 8 H, CH_2 Hpz^{bp2}), 2.38 (s, 3 H, *p*-$CH_3C_6H_4SO_3$), 3.98 (t, $^3J_{H,H}$ = 6.5 Hz, 8 H, OCH_2 Hpz^{bp2}), 4.01 (t, $^3J_{H,H}$ = 6.5 Hz, 8 H, OCH_2 Hpz^{bp2}), 6.71 (d, $^4J_{H,H}$ = 2.0 Hz, 2 H, H4 Hpz^{bp2}), 6.79 (d, $^3J_{H,H}$ = 8.7 Hz, 4 H, H_m Hpz^{bp2}), 6.96 (d, $^3J_{H,H}$ = 8.7 Hz, 4 H, H_m Hpz^{bp2}), 7.21 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, *p*-$CH_3C_6H_4SO_3$), 7.76 (d, $^3J_{H,H}$ = 8.7 Hz, 4 H, H_o Hpz^{bp2}), 7.79 (d, $^3J_{H,H}$ = 8.7 Hz, 4 H, H_o Hpz^{bp2}), 7.96 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, *p*-$CH_3C_6H_4SO_3$), 14.54 (br. s, 2 H, NH Hpz^{bp2}) ppm.

Synthesis of [Au(Hpz^{bp2})$_2$](NO_3) (3): This compound was prepared by the same method previously described for **2**, from [AuCl(THT)] (50 mg, 0.16 mmol), $AgNO_3$ (27 mg, 0.16 mmol) and Hpz^{bp2} (116 mg, 0.32 mmol). $C_{46}H_{56}AuN_5O_7$ (987.96): calcd. C 55.92, H 5.71, N 7.09; found C 55.97, H 5.56, N 7.10. IR (KBr): $\tilde{\nu}$ = 3213 and 3141 cm^{-1} ν(N−H), 1614 ν(C=N) + ν(C=C), 1302 $\nu_{as}(NO_3)$. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.02 (m, 12 H, CH_3 Hpz^{bp2}), 1.46−1.60 (m, 8 H, CH_2 Hpz^{bp2}), 1.78−1.83 (m, 8 H, CH_2 Hpz^{bp2}), 3.99 (t, $^3J_{H,H}$ = 6.5 Hz, 4 H, OCH_2 Hpz^{bp2}), 4.03 (t, $^3J_{H,H}$ = 6.5 Hz, 4 H, OCH_2 Hpz^{bp2}), 6.75 (d, $^4J_{H,H}$ = 1.9 Hz, 2 H, H4 Hpz^{bp2}), 6.84 (d, $^3J_{H,H}$ = 8.9 Hz, 4 H, H_m Hpz^{bp2}), 7.02 (d, $^3J_{H,H}$ = 8.9 Hz, 4 H, H_m Hpz^{bp2}), 7.77 (d, $^3J_{H,H}$ = 8.9 Hz, 4 H, H_o Hpz^{bp2}), 7.80 (d, $^3J_{H,H}$ = 8.9 Hz, 4 H, H_o Hpz^{bp2}), 13.70 (br. s, 2 H, NH Hpz^{bp2}) ppm.

Synthesis of [Au(Hpz^{bp2})$_2$]$_2$(1,5nds) (1,5nds = 1,5-naphthalenedisulfonate) (4): Ag_2O (32 mg, 0.14 mmol) was added to an aqueous solution (25 mL) of 1,5-naphthalenedisulfonic acid (50 mg, 0.14 mmol) with constant stirring until all the solids had dissolved. Acetone was then added to this solution and the resulting white precipitate was filtered off, dried and identified as silver 1,5-naphthalenedisulfonate.

Compound **4** was obtained by the same procedure described for **2**, from [AuCl(THT)] (38 mg, 0.12 mmol), silver 1,5-naphthalenedisulfonate (60 mg, 0.12 mmol) and Hpz^{bp2} (87 mg, 0.24 mmol). $C_{102}H_{118}Au_2N_8O_{14}S_2$ (2138.2): calcd. C 57.30, H 5.56, N 5.24; found C 57.29, H 5.39, N 5.19. IR (KBr): $\tilde{\nu}$ = 3115 cm^{-1} ν(N−H), 1612 ν(C=N) + ν(C=C), 1178 $\nu_d(SO_3)$, 1031 $\nu_s(SO_3)$, 607 $\delta_s(SO_3)$. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.93 (t, $^3J_{H,H}$ = 7.3 Hz, 12 H, CH_3 Hpz^{bp2}), 1.02 (t, $^3J_{H,H}$ = 7.3 Hz, 12 H, CH_3 Hpz^{bp2}),

1.41−1.58 (m, 16 H, CH_2 Hpz^{bp2}), 1.69−1.84 (m, 16 H, CH_2 Hpz^{bp2}), 3.91 (t, $^3J_{H,H}$ = 6.5 Hz, 8 H, OCH_2 Hpz^{bp2}), 3.97 (t, $^3J_{H,H}$ = 6.5 Hz, 8 H, OCH_2 Hpz^{bp2}), 6.70 (s, 4 H, H4 Hpz^{bp2}), 6.79 (d, $^3J_{H,H}$ = 8.7 Hz, 8 H, H_m Hpz^{bp2}), 6.82 (d, $^3J_{H,H}$ = 8.7 Hz, 8 H, H_m Hpz^{bp2}), 7.47 (t, 2 H, 1,5nds), 7.72 (d, $^3J_{H,H}$ = 8.7 Hz, 8 H, H_o Hpz^{bp2}), 7.77 (d, $^3J_{H,H}$ = 8.7 Hz, 8 H, H_o Hpz^{bp2}), 8.44 (d, $^3J_{H,H}$ = 6.5 Hz, 2 H, 1,5nds), 9.30 (d, $^3J_{H,H}$ = 8.7 Hz, 2 H, 1,5nds), 14.53 (s, 4 H, NH Hpz^{bp2}) ppm.

Synthesis of $[Ag(Hpz^{bp2})_2](BF_4)$ (5): $AgBF_4$ (19 mg, 0.10 mmol) was added under nitrogen to a solution of Hpz^{bp2} (71 mg, 0.20 mmol) in dry THF (10 mL). After 24 h of stirring, the solvent was removed in vacuo, giving rise to an oil from which a white solid was isolated after addition of dichloromethane and pentane. This product was crystallized by diffusion of hexane into a dichloromethane solution. $C_{46}H_{56}AgBF_4N_4O_4$ (923.63): calcd. C 59.83, H 6.11, N 6.07; found C 59.64, H 6.10, N 5.94. IR (KBr): $\tilde{\nu}$ = 3308 cm^{-1} ν(N−H), 1614 ν(C=N) + ν(C=C), 1067 and 1037 ν(BF). ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.00 (t, $^3J_{H,H}$ = 7.3 Hz, 12 H, CH_3 Hpz^{bp2}), 1.40−1.60 (m, 8 H, CH_2 Hpz^{bp2}), 1.70−1.90 (m, 8 H, CH_2 Hpz^{bp2}), 3.99 (t, $^3J_{H,H}$ = 6.6 Hz, 8 H, OCH_2 Hpz^{bp2}), 6.69 (s, 2 H, H4 Hpz^{bp2}), 6.70−7.00 (br. s, 8 H, H_m Hpz^{bp2}), 7.62 (d, $^3J_{H,H}$ = 8.8 Hz, 8 H, H_o Hpz^{bp2}), 11.95 (s, 2 H, NH Hpz^{bp2}) ppm. ^1H NMR (300 MHz, $CDCl_3$, −40 °C): δ = 0.95 ppm (t, $^3J_{H,H}$ = 7.2 Hz, 6 H, CH_3 Hpz^{bp2}), 0.96 (t, $^3J_{H,H}$ = 7.2 Hz, 6 H, CH_3 Hpz^{bp2}), 1.40−1.51 (m, 8 H, CH_2 Hpz^{bp2}), 1.68−1.80 (m, 8 H, CH_2 Hpz^{bp2}), 3.86 (t, $^3J_{H,H}$ = 6.6 Hz, 4 H, OCH_2 Hpz^{bp2}), 3.94 (t, $^3J_{H,H}$ = 6.6 Hz, 4 H, OCH_2 Hpz^{bp2}), 6.67 (s, 2 H, H4 Hpz^{bp2}), 6.72 (d, $^3J_{H,H}$ = 8.4 Hz, 4 H, H_m Hpz^{bp2}), 6.95 (d, $^3J_{H,H}$ = 8.7 Hz, 4 H, H_m Hpz^{bp2}), 7.53 (d, $^3J_{H,H}$ = 8.7 Hz, 4 H, H_o Hpz^{bp2}), 7.60 (d, $^3J_{H,H}$ = 8.4 Hz, 4 H, H_o Hpz^{bp2}), 11.86 (s, 2 H, NH Hpz^{bp2}) ppm.

Synthesis of $[Ag(Hpz^{bp2})_2](CF_3SO_3)$ (6): This compound was prepared in a similar way to **5**, from $AgCF_3SO_3$ (21 mg, 0.08 mmol) and Hpz^{bp2} (60 mg, 0.16 mmol). The resulting white solid was purified by washing with dichloromethane. $C_{47}H_{56}AgF_3N_4O_7S$ (985.92): calcd. C 57.26, H 5.73, N 5.68; found C 57.58, H 5.73, N 5.62. IR (KBr): $\tilde{\nu}$ = 3227 cm^{-1} ν(N−H), 1615 ν(C=N) + ν(C=C), 1226 $\nu_s(CF_3)$, 1028 $\nu_s(SO_3)$. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.00 (t, $^3J_{H,H}$ = 7.3 Hz, 12 H, CH_3 Hpz^{bp2}), 1.43−1.61 (m, 8 H, CH_2 Hpz^{bp2}), 1.73−1.87 (m, 8 H, CH_2 Hpz^{bp2}), 3.98 (br. s, 8 H, OCH_2 Hpz^{bp2}), 6.69 (s, 2 H, H4 Hpz^{bp2}), 6.70−7.00 (br. s, 8 H, H_m Hpz^{bp2}), 7.63 (d, $^3J_{H,H}$ = 8.0 Hz, 8 H, H_o Hpz^{bp2}), 12.66 (s, 2 H, NH Hpz^{bp2}) ppm. ^1H NMR (300 MHz, $CDCl_3$, −40 °C): δ = 0.95 (t, $^3J_{H,H}$ = 6.9 Hz, 12 H, CH_3 Hpz^{bp2}), 1.39−1.51 (m, 8 H, CH_2 Hpz^{bp2}), 1.69−1.80 (m, 8 H, CH_2 Hpz^{bp2}), 3.83 (t, $^3J_{H,H}$ = 5.1 Hz, 4 H, OCH_2 Hpz^{bp2}), 3.95 (t, $^3J_{H,H}$ = 5.4 Hz, 4 H, OCH_2 Hpz^{bp2}), 6.67 (s, 2 H, H4 Hpz^{bp2}), 6.69 (d, $^3J_{H,H}$ = 8.7 Hz, 4 H, H_m Hpz^{bp2}), 6.95 (d, $^3J_{H,H}$ = 8.7 Hz, 4 H, H_m Hpz^{bp2}), 7.53 (d, $^3J_{H,H}$ = 8.4 Hz, 4 H, H_o Hpz^{bp2}), 7.61 (d, $^3J_{H,H}$ = 8.4 Hz, 4 H, H_o Hpz^{bp2}), 12.54 (s, 2 H, NH Hpz^{bp2}) ppm.

Synthesis of $[Ag(Hpz^{NO2})_2](BF_4)$ (7): $AgBF_4$ (35 mg, 0.18 mmol) was added under nitrogen to a solution of Hpz^{NO2} (131 mg, 0.36 mmol) in dry acetonitrile (25 mL). After stirring for 24 h, the solvent was removed under vacuum to give an oil from which a white solid was isolated after addition of dichloromethane and pentane. $C_{10}H_{14}AgBF_4N_6O_4$ (476.93): calcd. C 25.18, H 2.96, N 17.62; found C 25.34, H 2.97, N 17.72. IR (KBr): $\tilde{\nu}$ = 3175 cm^{-1} ν(N−H), 1595 ν(C=N) + ν(C=C), 1506 $\nu_{as}(NO)$, 1363 $\nu_s(NO)$, 1034 ν(BF). ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 2.71 (s, 12 H, CH_3 Hpz^{NO2}), 11.67 (s, 2 H, NH Hpz^{NO2}) ppm.

Synthesis of $[Ag(Hpz^{NO2})_2](CF_3SO_3)$ (8): The synthetic procedure for **8** was analogous to that used for **5** from $AgCF_3SO_3$ (46 mg, 0.18 mmol) and Hpz^{NO2} (51 mg, 0.36 mmol). Crystals were obtained by the slow diffusion of hexane into a dichloromethane solution of the compound. $C_{11}H_{14}AgF_3N_6O_7S$ (539.21): calcd. C 24.50, H 2.62, N 15.59; found C 24.57, H 2.59, N 15.57. IR (KBr): $\tilde{\nu}$ = 3205 and 3128 cm^{-1} ν(N−H), 1600 ν(C=N) + ν(C=C), 1509 ν_{as}(NO), 1366 ν_s(NO), 1252 $\nu_d(SO_3)$, 1230 $\nu_s(CF_3)$, 1040 $\nu_s(SO_3)$. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 2.70 (s, 12 H, CH_3 Hpz^{NO2}), 12.50 (s, 2 H, NH Hpz^{NO2}) ppm.

X-Ray Structure Determinations: Crystals suitable for X-ray experiments were obtained from dichloromethane/diethyl ether for **1** or dichloromethane/hexane for **2**, **5** and **8**. Data collection was carried out at room temperature on a Bruker Smart CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) operating at 50 kV and 20 mA. In all cases data were collected over a hemisphere of the reciprocal space by combination of three exposure sets. Each exposure covered 0.3 in ω. The cell parameters were determined and refined by least-squares fit of all reflections collected. The first 50 frames were recollected at the end of the data collection to monitor crystal decay; no appreciable decay was observed. A summary of the fundamental crystal and refinement data is given in Table 4.

The structures were solved by direct methods and refined by full-matrix least-squares methods on F^2.[22] All non-hydrogen atoms were refined anisotropically, with some exceptions due to the thermal and non-resolvable positional disorder found for some atoms. For the C47 atom in **2**, only its coordinates were refined. The fluorine and oxygen atoms in **8** were refined anisotropically over two cycles and in the subsequent cycles their thermal parameters were kept constant. Additionally, for **2** and **5** some carbon atoms of the butoxy chain were refined with geometrical restraints and a variable common carbon−carbon distance. For **5** the BF_4^- group was also refined with geometrical restraints and a variable common boron−fluorine distance. Hydrogen atoms bonded to the nitrogen atoms were located in a Fourier synthesis, included and their coordinates fixed or refined. The remaining hydrogen atoms were included in calculated positions and refined as riding on their respective carbon atoms and the thermal parameters related to the bonded atoms. The largest residual peaks in the final difference map are located close to the metal atoms.

CCDC-226053−226056 (for compounds **1**, **2**, **5** and **8**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44 (0)1223 336033; E-mail: deposit@ccdc.cam.ac.uk].

A Theoretical Investigation of the Donor Ability of [M(R,R′timdt)$_2$] Dithiolene Complexes towards Molecular Diiodine (M = Ni, Pd, Pt; R,R′timdt = Formally Monoreduced Disubstituted Imidazolidine-2,4,5-trithione)

Keywords: Charge transfer / Density functional calculations / Dithiolenes / Iodine / Raman spectroscopy / X-ray diffraction

The σ-type charge-transfer (CT) interaction between [M(R,R′timdt)$_2$] donors (M = Ni, Pd, Pt; R,R′timdt = formally monoreduced disubstituted imidazolidine-2,4,5-trithione) and diiodine has been thoroughly investigated by a large set of theoretical calculations at different levels of theory (HF, pure and hybrid-DFT with different functionals and basis sets) on I_2 (and for the sake of comparison on IBr and Br_2), on the model donor dithiolene complexes [M(H_2timdt)$_2$], and on the adducts [M(H_2timdt)$_2$]·I_2 (M = Ni, Pd, Pt). The computations have accounted for the ability of adducts to assume different stoichiometries and to make up polymeric networks based on sulfur–iodine contacts, as in the case of [Ni(Me,*i*Pr-timdt)$_2$]·I_2, which was also characterised by single-crystal X-ray diffraction. In addition, the strength of the donor–acceptor interaction has been evaluated through the calculated vibrational features of the model adducts, compared with the experimental FT-Raman spectra recorded on the adducts between [M(Et_2timdt)$_2$] and [M(Me,*i*Pr-timdt)$_2$] (M = Ni, Pd, Pt) and diiodine. The frontier-orbital composition, the NBO-charge distribution and bond orders indicate a medium-weak donor ability for the dithiolene donors, which depends only slightly on the nature of the central metal ion, and decreases on passing from M = Ni to M = Pd and Pt, in agreement with the values of the experimental frequencies of the FT-Raman-active I–I stretching vibrations in the adducts [M(Et_2timdt)$_2$]·2I_2 (M = Ni, Pd, Pt). The ZPE- and CP BSSE-corrected binding energy for [Ni(H_2timdt)$_2$]·I_2 has been evaluated as −11 kcal/mol.

Introduction

Since the pioneering work by Schrauzer and co-workers,[1] the scientific community has become increasingly interested in metal dithiolene complexes.[2] This is justified not only by the essential role of dithiolene ligands in the chemistry of enzymes[3−5] and by the great potential for exploiting these complexes in fields as diverse as nonlinear optics[6,7] and superconductivity,[8] but also by their fascinating electronic structures.[9] In particular, dithiolene complexes containing d^8 metal ions (namely Ni, Pd, and Pt) feature an extended π-electron delocalization involving the organic framework as well as the metal centre.[10] The electronic features are reflected in peculiar molecular properties, such as high thermal and photochemical stabilities, electrochromism,[10] and the ability to undergo multi-step reversible redox processes.[11,12] Square-planar neutral bisdithiolenes feature a peculiar very intense Vis/NIR absorption, which falls at 720, 785, and 680 nm for the simplest [M(edt)$_2$] neutral complexes [edt = ethylenedithiolato; M = Ni (**1**), Pd (**2**), and Pt (**3**), respectively].[1,13] This absorption has been ascribed to a HOMO−LUMO π-π* transition, based on theoretical calculations carried out at several levels of theory, ranging from EHT to TD-DFT.[14,15] The donor ability of the ligand towards the metal centre is tunable through structural modifications of the substituents at the carbon atoms of the dithiolene system, and affects both the Vis/NIR optical properties and the order of the relative stabilities of the available oxidation states (typically dianionic, monoanionic, and neutral).

Since 1995 we have been investigating neutral Ni, Pd, and Pt dithiolene complexes derived from the R,R′timdt ligand (R,R′timdt = formally monoreduced disubstituted imid-

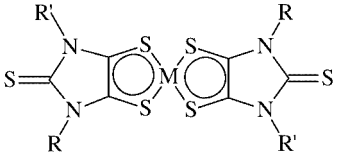
azolidine-2,4,5-trithione), which differs from the very well-known dmit dithiolenes [dmit = $C_3S_5^{2-}$, 1,3-dithiole-2-thione-4,5-dithiolate;[8] M = Ni (**4**), Pd (**5**), Pt (**6**)] in having NR groups instead of sulfurs in the pentaatomic ligand (Scheme 1).[16−24] Hybrid-DFT[18,19,23] and very recent TD-DFT calculations[21,24] confirmed that the tight HOMO−LUMO energy gap is responsible for the low-energy NIR transition falling at about 1000 nm (extinction coefficients as high as 120000 $M^{-1}\cdot cm^{-1}$ in toluene).[23] In addition, contrary to most dithiolene complexes, and in particular to their dmit analogues, neutral [M(R,R′timdt)$_2$] complexes behave as donors towards molecular acceptors, and some of the authors of this paper have reported the reaction between [Ni(*i*Pr$_2$timdt)$_2$] (**7**) and molecular diiodine, leading to the CT adducts **7**·2I$_2$ and **7**·2I$_2$·1/2I$_2$, and to the mixed-valence complex [Ni(*i*Pr$_2$timdt)$_2$]·2I$_2$·[Ni(I)$_2$(*i*Pr$_2$timdt)$_2$]·3I$_2$.[17] Among Pd complexes, only the CT adduct **8**·I$_2$·CHCl$_3$ (**8** = [Pd(Et$_2$timdt)$_2$]) has been reported,[18] while the reactivity of Pt dithiolene complexes towards diiodine has not been explored to date. In order to rationalize the donor ability of neutral [M(R,R′timdt)$_2$] complexes, we have now carried out a study on the products of the reactions between [M(Et$_2$timdt)$_2$] and [M(Me,*i*Pr-timdt)$_2$] (M = Ni, Pd, Pt) and molecular I$_2$ in several molar ratios (Scheme 1).



R	R'	M	Dithiolene:I$_2$ reaction ratio			
			1:1	1:2	1:5	1:10
Et	Et	Ni	1:1	1:2	1:2	1:3
		Pd	2:1	2:1	1:2	1:2
		Pt	1:1	1:1	2:3	1:2
Me	i-Pr	Ni	1:1	1:1	1:1	1:4
		Pd	2:5	1:2	1:2	1:2
		Pt	1:3	1:4	1:5	1:5

Scheme 1

Theoretical calculations have recently been proved to be a very valuable tool in interpreting the interactions between chalcogenone donors and molecular halogens,[25] although it seems that the number of papers on complexes containing iodine is limited. Thus, with the aim of understanding the nature of the CT interaction and investigating the effect of the central metal ion and of the substituents on the reactivity of the metal dithiolene complexes [M(R,R′timdt)$_2$] towards molecular diiodine, we performed a large set of theoretical calculations on [M(H$_2$timdt)$_2$]·I$_2$ model adducts.

Results and Discussion

Synthesis

Since the low solubility of neutral [M(R,R′timdt)$_2$] complexes prevents them from reaching the concentrations needed to study their equilibria with iodine in solution,[26] neutral [M(R,R′timdt)$_2$] complexes (M = Ni, Pd, Pt), both symmetrically (R = R′ = Et) and unsymmetrically (R = Me; R′ = *i*Pr) substituted, were reacted with molecular iodine in closed pressure-tubes (to avoid halogen losses) in dithiolene/iodine molar ratios ranging between 1:1 and 1:10, in order to achieve CT adducts with different stoichiometries. Unfortunately, conventional solid-state spectroscopic techniques (such as FT-Raman, FT-IR, and CP MAS ^{13}C NMR) are not useful in clarifying the nature of the final products, which can be only ascertained by elemental analysis and, when possible, by X-ray diffraction. Although the composition of the final products cannot be ascertained clearly in all cases (especially when R = Me, R′ = *i*Pr), an examination of the dithiolene/I$_2$ molar ratios in the adducts (Scheme 1) shows that the halogen content in the final products increases on increasing the starting molar ratio, and that the nature both of the central metal and of the substituents is crucial in determining the final product. It is worthy of note that all the Pt complexes were found to react with I$_2$ yielding reaction products with dithiolene/halogen ratios ranging between 1:0.5 and 1:5 depending on the substituents. The isolation of several adducts with dithiolene/I$_2$ ratios higher than 1:2 suggests that the terminal iodine units of [M(R,R′timdt)$_2$]·2I$_2$ adducts should be able to behave as donors towards further diiodine molecules.

X-ray Diffraction Studies

Crystals having a 1:1 dithiolene/I$_2$ ratio, suitable for X-ray diffraction studies, were obtained by reacting [Ni(Me,-*i*Pr-timdt)$_2$] (**9**) and I$_2$ in molar ratios ranging between 1:1 and 1:5. A perspective view of the 1:1 CT adduct **9**·I$_2$ is depicted in Figure 1. The nickel atom of the [Ni(Me,*i*Pr-timdt)$_2$] molecule is located on a crystallographic inversion centre at 0,0,0 whereas the diiodine molecule lies across a different crystallographic centre at 0, 1/2, 1/2. As expected based on the few previously reported structures of CT adducts between [M(R,R′timdt)$_2$] complexes and diiodine,[17,18] the dithiolene coordinates the iodine molecule through its terminal thiocarbonyl groups with an S(3)···I(1) interaction of 3.098(2) Å. A view of the crystal packing of **9**·I$_2$ (Figure 2) shows the polymeric nature of the adduct. The packing consists of zig-zag polymeric chains made up of complex molecules symmetrically linked by iodine units bridging the terminal sulfur atoms [S(3)] of different molecules. The diiodine moieties are essentially perpendicular to the dithiolene molecular plane and the S(3)···I(1)−I(1)′′···S(3)′′ system is linear. Similar S···I−I···S systems have been isolated in several CT adducts between thioether macrocycles and diiodine.[27] In these systems, which structurally recall the I_4^{2-} anion ($^-$I···I−I···I$^-$),[28]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the bridging iodine molecule is less elongated than in the corresponding 1:1 CT adducts. Chains of alternating dithiolene and diiodine units are packed by dithiolene stacking interactions analogous to those described for **9**,[19] with the nickel atom sandwiched between two imidazolidine rings of parallel adjacent dithiolene molecules, the distances between each nickel ion and the imidazolidine centroid being 3.72 and 3.77 Å in **9** and **9**·I_2, respectively. A comparison with the crystal structure of **9**[19] shows that the terminal thiocarbonyl group involved in the CT interaction is slightly elongated with respect to the free donor [C(3)−S(3) = 1.644(5) in **9**, 1.674(6) Å in **9**·I_2], in agreement with the situation generally found for CT adducts between thiocarboxyl donors and iodine.[29] However, this lengthening is small and is compatible with a weak sulfur−iodine interaction. The rest of the complex molecule displays bond lengths and angles close to those found in complex **9** [C(1)−C(2), C(1)−S(1), and C(2)−S(2) 1.396(6), 1.682(5), and 1.681(5) Å in **9**; 1.380(7), 1.719(6), and 1.688(5) Å in **9**·I_2]. Due to the bridging role of the halogen in **9**·I_2, the interaction between the metal complex and the diiodine units [S(3)···I 3.098(2) Å] is weaker than that observed in the case of either **7**·2I_2·1/2I_2 [2.825(6) Å] or **8**·I_2·$CHCl_3$ [2.815(3) Å].[17,18] Accordingly, the elongation of the I−I distance due to the CT interaction [2.790(1) Å in **9**·I_2; I−I = 2.715 Å for iodine in the solid state][30] is less than that found for the adducts **7**·2I_2·1/2I_2 and **8**·I_2·$CHCl_3$ [I−I distances 2.815(3) and 2.811(2) Å, respectively].

FT-Raman Spectroscopy

Because of the resonance Raman effect with the broad NIR absorption at about 1000 nm, the FT-Raman spectra of neutral [M(R,R′timdt)$_2$] complexes recorded with spectrometers based on a Nd:YAG laser (λ_{exc} = 1064 nm) allow us to identify the vibrations due to the MS_4 system.[19] The spectra show only two very intense peaks in the 500−50 cm^{-1} region. The former falls at average values of 435, 427, and 425 cm^{-1} for the Ni, Pd, and Pt complexes, respectively; the latter, which falls at 380 and 340 cm^{-1} for the Ni and Pd complexes, respectively, was not observed for the Pt complex.[19] These peaks have been attributed to the a_g or b_{1g} bending and to the a_g stretching modes of the MS_4C_4 dithiolene system, respectively.[19,24] Analogous peaks also appear in the solid-state FT-Raman spectra of the synthesized CT adducts at frequencies very close to those recorded for the starting dithiolenes. In weak and medium-weak CT adducts, the lengthening of the inter-iodine bond length due to the CT interaction has been correlated to the lowering of the corresponding stretching vibration, which occurs at 180 cm^{-1} for solid iodine, and is shifted towards lower frequencies in CT adducts (140−180 cm^{-1}).[29,31] Unfortunately, when using Nd:YAG FT-Raman spectrometers, the Raman enhancement of the metal-sulfur vibrations makes the peaks due to the I−I stretching mode barely visible. Nonetheless, in the cases of the adducts of the complexes [M(Et_2timdt)$_2$] (M = Ni, Pd, Pt), the peak due to the I−I stretching mode is clearly visible at 139,[32] 153, and 155 cm^{-1}, for M = Ni, Pd, and Pt, respectively (see Figure 3 for [M(Et_2timdt)$_2$]·2I_2 adducts). The position of the peaks indicates a medium-weak interaction between [M(R,R′timdt)$_2$] and I_2, whose strength decreases on passing from Ni to Pt. Unfortunately, the peak due to the I−I vibration is completely absent in the adducts of [M(Me,*i*Pr-timdt)$_2$] dithiolenes.

Theoretical Calculations

A few years ago, we reported[18,19,23] DFT[33,34] calculations performed with the Gaussian 98 package[35] on [M(H_2timdt)$_2$] model complexes [M = Ni (**10**), Pd (**11**), Pt (**12**); R = R′ = H in Scheme 1] using the three-parameter[36] hybrid B3LYP functional (based on the gradient-corrected Becke exchange functional[37] along with the Lee, Yang and Parr correlation functional[38]), and the LanL2DZ basis set (BS) with Effective Core Potentials (ECP)[39] for the central metal ion. With the results of these calculations it was possible to explain the trend in the NIR absorption maxima experimentally found on changing the central metal ion [λ_{max} (Ni) ≈ λ_{max} (Pt) < λ_{max} (Pd)], and the electrochemical behaviour of [M(R,R′timdt)$_2$] complexes compared to other neutral dithiolenes, such as **1**−**3** and **4**−**6**. In fact, TD-DFT calculations showed that the NIR excitation energy is well-represented by an almost pure HOMO−LUMO transition.[21,24] It has been proved that Kohn−Sham (KS) one-electron energies $-\varepsilon$ of occupied orbitals can be interpreted as approximate relaxed vertical ionisation potentials.[40] Thus, the energy of the NIR transition can be estimated as the one-electron energy difference $\Delta\varepsilon$ between the HOMO and the LUMO.[18,19,21,23,24] At any rate, although the previous calculations accounted nicely for the spectroscopic and electrochemical properties of the title dithiolene complexes, the M−S bond lengths were systematically overestimated. Subsequently, we reported relativistic TD-DFT calculations which highlighted how the trend in the metal−sulfur distances is affected by relativistic effects.[21,24] Now, in order to find the best level of theory to deal with adduct formation, new HF and DFT calculations with different basis sets and, in the case of DFT, different functionals of the electron density, were performed on **10**−**12**, on I_2, and, for the sake of comparison, on Br_2 and IBr. The results of the calculations performed separately on **10**−**12** and on I_2 were used to find a suitable theoretical level to approach the donor−acceptor interaction leading to the model CT adducts **10**·I_2, **11**·I_2, and **12**·I_2. As regards DFT calculations, pure (BLYP[37,38] and BPW91[37,41]) and hybrid (mPW1PW[42] and B3LYP)[36−38] functionals were used. The PBE0 GGA functional[43] was not considered, since we have found recently that it gives results close to those obtained at the B3LYP level on the model dithiolene complexes **4** and **10**.[24] For all calculations, the Schafer, Horn and Ahlrichs pVDZ basis sets[44] were used for the organic framework, while for the central metal we tested the LanL2DZ,[39] SBKJC,[45] Stuttgart,[46] CRENBS[47] and CRENBL[47,48] basis sets with the corresponding effective core potential (ECP) sets. For halogens, the all-electron 6-311G**[49] and MIDI![50] and the sets LanL2DZ,[39] SBKJC,[45] and Stuttgart[46] with ECPs were used. Based on the results separately obtained on the interacting molecular units **10**−**12** and I_2,[51,52] the calculations on 1:1 adducts were performed on the model complexes **10**·I_2, **11**·I_2, and **12**·I_2 at the DFT level, using the mPW1PW functional and the LanL2DZ BSs with ECPs both for the central metal ion M and for iodine (see Supporting Information). A comparison between the optimised geometries of the adducts between **10**−**12** and I_2 shows a good agreement between the experimental bond lengths and angles reported previously[17,18] and those of the corresponding calculated values (Table 1). As an example, Figure 4 compares the bond lengths optimised for **11**·I_2 with those determined by X-ray diffraction[18] for **8**·I_2·$CHCl_3$.

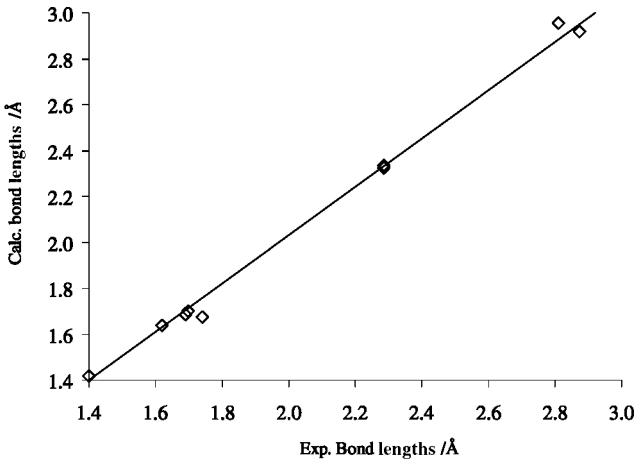

Figure 4. Bond lengths calculated for **11**·I_2 compared with the average structural bond lengths of **8**·I_2·$CHCl_3$ [18]

An interaction diagram (Figure 5 for **10**·I_2) between the molecular orbitals of the dithiolenes **10**−**12** (D_{2h} point group) and those of molecular diiodine ($D_{\infty h}$ point group) shows that the Kohn−Sham HOMO and LUMO in the adducts, depicted in Figure 6 for **10**·I_2, derive from the σ-interaction of the b_{1u} HOMO and b_{2g} LUMO of the dithiolene with the $p\sigma_u$* LUMO of the I_2 molecule, whose energy is just intermediate between those of the two molecular orbitals of the complex. As expected from a qualitative fragment molecular orbital (FMO) interpretation of the donor−acceptor interaction,[53] the electron donation from the filled HOMO of the dithiolene to the antibonding LUMO of diiodine weakens the I−I bond. Due to the compositions of the HOMOs calculated for **10**−**12**, which are very similar in energy and do not contain significant contributions from the central metals, the donor−acceptor interaction between [M(H_2timdt)$_2$] and iodine is not expected to be strongly dependent on M. In fact, the calculated lengthening in the I−I bond length of coordinated diiodine depends only slightly on the nature of the donor dithiolene complex (I−I: 2.830 Å for free I_2; 2.970, 2.957 and 2.955 Å in **10**·I_2, **11**·I_2, and **12**·I_2, respectively). The I−I elongation with respect to free I_2 is small (4.7%, 4.3%, and 4.2% for **10**·I_2, **11**·I_2, and **12**·I_2, respectively) in agreement with the structural results (3.6% and 3.5% for **7**·2I_2·1/2I_2, and **8**·I_2, respectively). As regards the metal dithiolene units, in agreement with the experimental results only very slight modifications are found in the metal−sulfur bond lengths compared to the optimised geometries of the dithiolenes **10**−**12**, which mainly regard the ligand unit interacting with the halogen (M−S = 2.189, 2.313, and 2.328 Å for **10**, **11**, and **12**, respectively, and 2.186, 2.324, and 2.324 Å for **10**·I_2, **11**·I_2, and **12**·I_2, respectively). An examination of all the other bond lengths within the dithiolene ligands shows that an intramolecular charge transfer is induced from the non-interacting H_2timdt moiety to the interacting one, and then to the halogen molecule (intramolecular charge transfer). Thus, the non-interacting unit has a slightly higher trithione character than the interacting one (testified by a slight shortening of all C−S bond lengths, mainly in the terminal one, and a lengthening of the C−C bond length with respect to the other H_2timdt ligand unit interacting with diiodine and to the free dithiolene). On the contrary, in agreement with the structures of **9**·I_2 and **8**·I_2·$CHCl_3$, the C−C bond lengths in the ligand unit interacting with iodine are calculated to be slightly shorter than in the free dithiolene. As expected, the terminal C(3)−S(3) bond interacting with diiodine is the most affected (1.637, 1.637, and 1.645 Å in

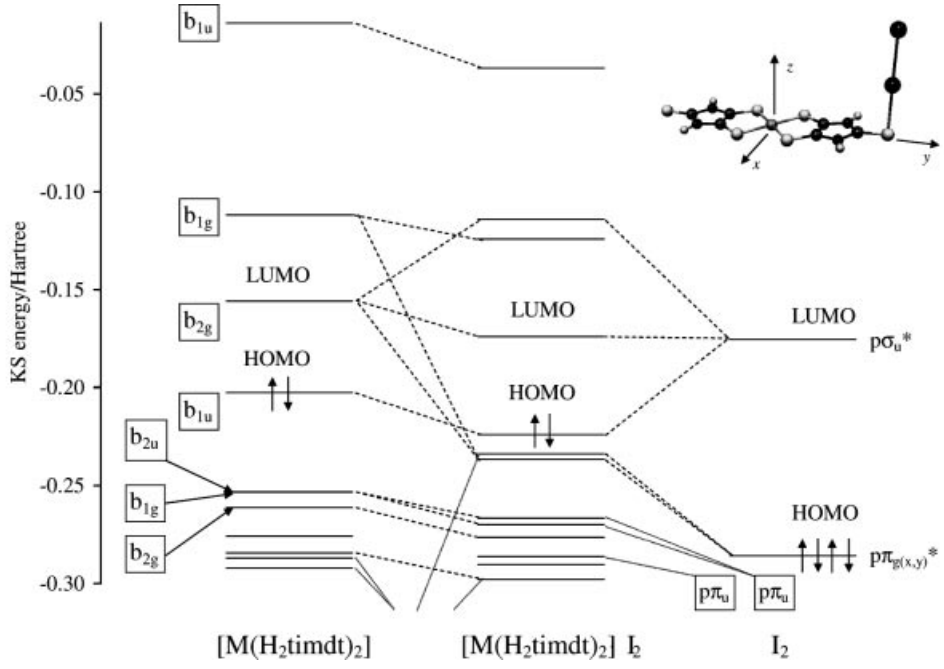

Figure 5. MO diagram showing the interaction between **10** and I_2; symmetry labels are referred to the D_{2h} space group (with the dithiolene on the *xy* plane) for **10** and $D_{\infty h}$ for I_2

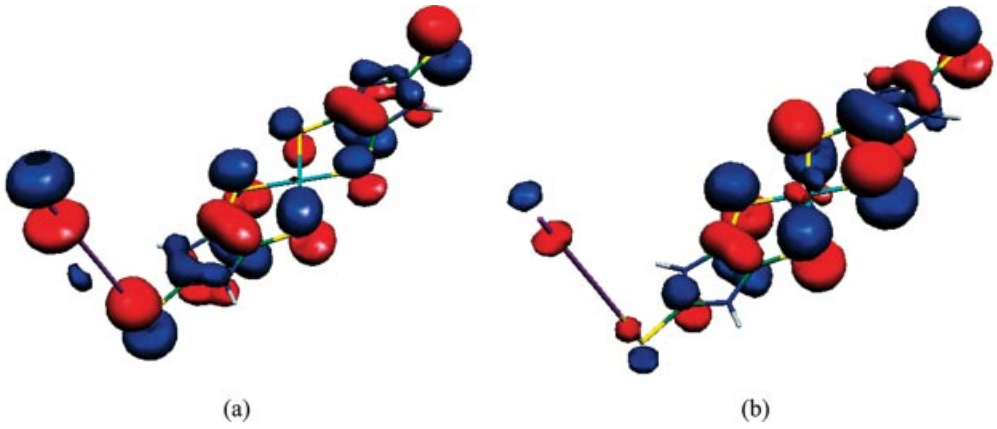

Figure 6. Drawings of Kohn−Sham HOMO (a) and LUMO (b) calculated for **10**·I_2

10, **11**, and **12**; 1.669, 1.675, and 1.676 Å in the interacting unit of **10**·I_2, **11**·I_2, and **12**·I_2, respectively). The strength of the interaction between the dithiolene donors and I_2 is reflected in the Wiberg bond indexes calculated for the involved groups. Thus, bond indexes of 0.287, 0.260, and 0.260 were calculated between the interacting terminal sulfurs and iodine in **10**·I_2, **11**·I_2, and **12**·I_2, respectively. Accordingly, the bond indexes of the interacting terminal thione groups (1.146, 1.391, and 1.388 for **10**·I_2, **11**·I_2, and **12**·I_2, respectively) are smaller than those of the free thione groups (1.639, 1.627, and 1.623 for **10**·I_2, **11**·I_2, and **12**·I_2, respectively), while the I−I bond order assumes fractional values in the three adducts (0.679, 0.702, and 0.704 for **10**·I_2, **11**·I_2, and **12**·I_2, respectively). The overall NBO-charge distribution in the three adducts (Table 2) confirms that the interaction between **10**−**12** and I_2 determines a charge transfer from the dithiolenes to the dihalogen, which depends only very slightly on the central metal ion, and is greater in the case of **10**·I_2 (charge on diiodine −0.295, −0.281, and −0.282 electrons for **10**·I_2, **11**·I_2, and **12**·I_2, respectively). In addition, the most negative charge in the adduct resides on the terminal iodine atom (−0.233, −0.212, and −0.213 for **10**·I_2, **11**·I_2, and **12**·I_2, respectively), which is available for interacting with other iodine molecules. Accordingly, I−I···I−I contacts have been found in the crystal structures of **7**·2I_2·1/2I_2 and **8**·I_2·$CHCl_3$. This type of interaction could also account for the isolation of adducts having dithiolene/I_2 molar ratios higher than 1:2. The partial positive charge remaining on the dithiolene molecule is unevenly distributed over the two ligand units — the most positive being the non-interacting one — in agreement with the differences in the bond lengths described for the two ligands (the charge on the ligand interacting with diiodine is 0.130, 0.120, and 0.123 electrons and that on the non-interacting ligand is 0.166, 0.156, and 0.153 electrons for **10**·I_2, **11**·I_2, and **12**·I_2, respectively). Interestingly, the free terminal sulfur atom of the dithiolene carries a small residual negative charge, which allows for further interaction with a second diiodine molecule to give 1:2 adducts.

The coherent trends in the I−I bond lengths, in the charge transfer from the donor dithiolenes to iodine, and in the S−I and I−I bond indexes, calculated for **10**·I_2, **11**·I_2, and **12**·I_2, clearly indicate that the entity of the donor−acceptor interaction is almost constant on passing from **10**·I_2 to **12**·I_2, and is only slightly higher in the case

of the nickel-dithiolene adduct. This is in agreement with the trend in the wavenumbers of FT-Raman-active stretching I−I frequencies measured for the adducts [M(Et$_2$timdt)$_2$]·2I$_2$. We therefore performed a calculation of the binding energy ΔE between **10** and I$_2$. In order to evaluate this energy, the renowned basis set superposition error (BSSE) has to be taken into account. This occurs when calculating the energy of an assembly of interacting monomers: each unit "borrows" Gaussian basis functions from the other components in order to describe its own electronic structure more accurately.[54] This results in an artificial overestimation of the interaction energies. Due to the computational effort required for these calculations, this correction has only been computed so far for small interacting systems, especially when geometrical deformations are to be taken into account.[54,55]

The BSSE in **10**·I$_2$ has been estimated by adapting the Boys−Bernardi full counterpoise (CP) correction scheme:[56]

$$\Delta E_{BSSE}(\mathbf{10}\cdot I_2) = [E(\mathbf{10}\cdot I_2) - E_{fin}(\mathbf{10})^G - E_{fin}(I_2)^G] + [E_{str}(\mathbf{10}) + E_{str}(I_2) - E(\mathbf{10}) - E(I_2)] = [E(\mathbf{10}\cdot I_2) - E(\mathbf{10}) - E(I_2)] + [E_{str}(\mathbf{10}) + E_{str}(I_2)] - [E_{fin}(\mathbf{10})^G + E_{fin}(I_2)^G] = \Delta E_{unc} + E_{str}(\mathbf{10} + I_2) - E_{fin}(\mathbf{10} + I_2)^G = \Delta E_{unc} + \delta\Delta E_{BSSE}$$

so that the CP-corrected binding energy ΔE_{BSSE} is calculated from the uncorrected value ΔE_{unc} obtained from the total electronic energies calculated for **10**, I$_2$, and **10**·I$_2$ in their optimised geometries, [E(**10**), E(I$_2$) and E(**10**·I$_2$), respectively], adding a BSSE correction term, $\delta\Delta E_{BSSE}$, calculated from the electronic energies computed for **10** and I$_2$ with [E_{fin}(**10** + I$_2$)^G = E_{fin}(**10**)^G + E_{fin}(I$_2$)^G] and without [E_{str}(**10** + I$_2$) = E_{str}(**10**) + E_{str}(I$_2$)], which are the "ghost" electronic functions of iodine and of the dithiolene atoms, respectively, calculated at the "strained" equilibrium geometry assumed in the adduct. Finally, upon adding the Zero Point Energy (ZPE) correction, in order to account for the effects of molecular vibrations at 0 K, a CT-interaction energy $\Delta E_{ZPE,BSSE}$ of −10.94 kcal·mol^{-1} can be evaluated for **10**·I$_2$ (Table 3). It is worth noting that, since large basis sets are used for the organic framework and effective core potentials are used for the central metal and for the halogen atoms, the BSSE correction is small (1.235 kcal·mol^{-1}) compared to the CT-interaction energy. The calculated $\Delta E_{ZPE,BSSE}$ value confirms that the interaction between the dithiolene-complex donor and diiodine is weaker than those of similar systems, such as the CT adduct between imidazoline-2-thione and iodine (ΔE_{unc} = −18.554; $\delta\Delta E_{ZPE}$ = 0.860; $\delta\Delta E_{BSSE}$ = 1.477; $\Delta E_{ZPE,BSSE}$ = −16.216 kcal·mol^{-1}).

Table 3. Electronic energy (E) and electronic energy with ZPE correction (E_{ZPE}) for **10**, I$_2$, and **10**·I$_2$ (Hartree); electronic energy at the adduct geometry with (E_{fin}^G) and without (E_{str}) ghost electronic functions, calculated for **10** and I$_2$ (Hartree); uncorrected interaction energy ΔE_{unc}, ZPE correction $\delta\Delta E_{ZPE}$, BSSE correction $\delta\Delta E_{BSSE}$, and corrected CT-interaction energy $\Delta E_{ZPE,BSSE}$ for **10**·I$_2$ (mHartree and kcal mol^{-1})[a]

Finally, although the complete assignment of the Raman spectra recorded for the adducts between [M(R,R′timdt)$_2$] and diiodine is beyond the scope of this work, the DFT calculations help us to understand the nature and type of the vibrational FT-Raman peaks. As described above, three groups of Raman peaks are found for all adducts in the far-IR region (500−50 cm^{-1}), although when using an FT-Raman spectrometer exploiting Nd:YAG lasers the lowest-energy peak can only rarely be observed experimentally because of the resonance Raman effect. As regards the two groups of peaks at higher wavenumbers (whose maxima for **10**·I$_2$, **11**·I$_2$, and **12**·I$_2$ are calculated at 450, 508, and 438 cm^{-1} for the first group and 328, 345, and 372 cm^{-1} for the second, respectively), the calculated assignments do not differ from those previously reported for **10**−**12**.[17] Most importantly, the third group of peaks arises from the coupling between the I−I stretching and a waving vibration of the dithiolene complexes, resulting in two overlapping intense peaks, calculated at 146 and 156, 139 and 154, and 151 and 155 cm^{-1} for **10**·I$_2$, **11**·I$_2$, and **12**·I$_2$, respectively. As an example, Figure 7 shows a comparison between the experimental FT-Raman spectrum recorded for **8**·2I$_2$ and the spectrum simulated for **11**·I$_2$. In this case, the two overlapping peaks involving the I−I stretching vibration result in a single peak with a maximum at 155 cm^{-1}, in perfect agreement with the experimental values recorded for the adducts of [Pd(Et$_2$timdt)$_2$].

Conclusions

The interaction between the neutral Ni, Pd, and Pt dithiolene complexes belonging to the general class [M(R,R′timdt)$_2$] and diiodine has been investigated in depth from both an experimental and theoretical point of view. The donor ability of these dithiolenes, previously ascertained for Ni and Pd complexes, has now been confirmed also for Pt complexes. The characterisation of the reaction products has shown that different dithiolene/halogen molar ratios can be reached, depending on the nature of both the central metal ion and of the substituents R and R′. Among the synthesized adducts, [Ni(Me,*i*Pr-timdt)$_2$]·I$_2$ was characterised by X-ray diffraction on a single crystal, showing an unprecedented supramolecular network based on soft S···I interactions and due to the ability of diiodine to bridge different dithiolene stacks. A large set of preliminary calculations proved DFT to be more reliable than HFT in describing the structural and spectroscopic features of the model complexes [M(H$_2$timdt)$_2$] (M = Ni, Pd, Pt) and of dihalogen and interhalogen molecules, such as I$_2$, Br$_2$, and IBr. The mPW1PW functional along with the LanL2DZ basis set adopted for the heaviest atoms have been used to investigate the model CT adducts [M(H$_2$timdt)$_2$]·I$_2$. The computations are in very good agreement with structural and spectroscopic features. DFT calculations have shown that the soft-soft CT interaction involves σ-donation from the HOMO of the dithiolene donor to the LUMO of diiodine. In all cases, the DFT calculations indicate that the title dithiolene complexes are medium-weak donors towards molecular iodine. In accordance with the composition of the Kohn−Sham HOMOs calculated for [M(H$_2$timdt)$_2$], the I−I lengthening with respect to free I$_2$, the change in the Wiberg bond indexes, and the charge transfer calculated on the basis of the NBO-charge distribution, clarify that the donor ability of [M(H$_2$timdt)$_2$] dithiolene complexes depends only marginally on the metal; it is only slightly higher in the case of M = Ni, in agreement with FT-Raman evidence. Thus, a binding energy of −10.83 kcal·mol^{-1} for the adduct [Ni(H$_2$timdt)$_2$]·I$_2$ has been calculated from the electronic energies of the adduct and of the separated synthons, corrected both for ZPE and for BSSE according to the CP scheme.

Experimental Section

Materials and Methods: All solvents, reagents, and pressure tubes were purchased from Aldrich. All operations were carried out under a dry nitrogen atmosphere. The degree of purity of each compound was checked by CHNS and TLC analyses. Elemental analyses were performed on a FISONS EA-1108 CHNS-O instrument. Characterisation of all synthesized compounds was carried out as described previously.[17]

Synthesis of [M(R,R′timdt)$_2$]·*n*I$_2$ Adducts: The dithiolene complexes [M(R,R′timdt)$_2$] (M = Ni, Pd, Pt; R = R′ = Et; R = Me, R′ = *i*Pr) were synthesised as reported previously.[18,19,23] They (15−30 mg) were then reacted with weighed amounts of diiodine in 1:1, 1:2, 1:5, and 1:10 molar ratios, in 30 mL of CHCl$_3$/hexane mixtures (1:3 v/v) according to the procedure described previously for the reaction between **8** and Br$_2$.[22] The stoichiometric ratios of the final products summarised in Scheme 1 were calculated on the basis of the elemental analyses.

Crystal Data for 9·I$_2$: $C_{14}H_{20}I_2N_4NiS_6$, triclinic, space group $P\bar{1}$ (no. 2), a = 5.519(1), b = 8.667(2), c = 13.685(3) Å, α = 85.30(3)°, β = 80.34(3)°, γ = 72.70(3)°, U = 615.8(7) Å^3, Z = 1, T = 293(2) K, μ = 38.12 cm^{-1}. A needle crystal was mounted on a glass fiber in a random orientation on a Siemens SMART CCD area-detector diffractometer. Graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) was used with the generator working at 45 kV and 40 mA. Cell parameters and orientation matrix were obtained from least-squares refinement on reflections measured in three different sets of 20 frames each in the range $0 < \theta < 28°$. 7082 Intensity data were collected in the full sphere (ω scan method), 2838 of which were unique. 2100 Frames (30 seconds per frame, $\Delta\omega$ = 0.3°) were collected and the first 100 frames recollected to provide crystal decay monitoring, which was not observed. An absorption correction was applied using the SADABS routine.[57] The structure was solved by direct methods (SIR-97)[58] and refined on F^2 using the SHELX-97[59] program implemented in the WINGX suite.[60] Anisotropic displacement parameters were assigned to all non-hydrogen atoms. The hydrogen atoms were included in the structure model riding on their C atoms. The final values for $R1$ and $wR2$ were 0.041 and 0.084, respectively, for 1641 observed reflections [$I > 2\sigma(I)$] and 127 parameters. The maximum and minimum electron-density residual in the final ΔF map were 0.94 and −0.99 e·Å^{-3}, respectively. CCDC-224813 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: +44 (0)1223 336033; E-mail: deposit@ccdc.cam.ac.uk].

Theoretical Calculations: Our aim was to compare the structures and energetics of model metal-dithiolene complexes **10**−**12**, iodine, and their CT adducts. Therefore, computations were carried out in such a way that the results could be compared reliably. Quantum chemical calculations were carried out on all compounds using the commercially available suite of programs Gaussian 98.[35] Although the use of all-electron basis sets provides better accuracy and efficiency, pseudopotential techniques are useful when relativistic effects have to be taken into account. Thus, the Schafer, Horn, and Ahlrichs all-electron pVDZ basis[44] was used for all calculations for C, N, and S. For Br and I the full-electron 6-311G**[49] and the MIDI![50] BS's, designed as a modification of the MIDI Huzinaga Split Valence basis,[61] and the LanL2DZ,[39] SBKJC,[45] and Stuttgart[46] BSs with effective core potentials (ECPs) were used.[62] For Ni, Pd, and Pt the LanL2DZ,[39] SBKJC,[45] Stuttgart,[46] CRENBS[47] and CRENBL[47,48] BSs were tested.[62] For DFT calculations on **10**−**12** and on the dihalogens Cl_2, Br_2 and I_2, the pure functionals BLYP,[34,36] BPW91,[34,41] and the hybrid ones mPW1PW[42] and B3LYP[36−38] were tested. All geometry optimisations for complexes **10**−**12** were performed starting from the previously reported geometries (D_{2h} point group), computed with the B3LYP functional.[17] Due to a wrong default electronic initial guess, alteration of the initial ground state configurations of dithiolenes **10**−**12** (involving swapping of LUMO, HOMO, and HOMO−1) was needed in some cases. In particular, for HF calculations the "alter" option was used for **11** (SBKJC and Stuttgart BSs for Pd) and **12** (all BSs for Pt). For DFT calculations, the same problems were encountered when the functionals B3LYP (M = Ni, Pd, Pt with all BSs), BLYP (M = Pd with CRENBS, SBKJC and Stuttgart BS; Pt with all BSs), BPW91 (M = Pd with SBKJC BS; Pt with all BSs), and mPW1PW (M = Pd with SBKJC and Stuttgart BSs; M = Pt with all BSs) were used. Interestingly, in the case of **10** and **11**, the removal of the inversion centre in the starting geometries allows the optimisation to converge to slightly lower energies. For the dithiolenes **4**−**6**, for the CT adducts **10·**I$_2$, **11·**I$_2$, and **12·**I$_2$, for imidazoline-2-thione, and for its 1:1 iodine adduct, DFT calculations were performed using the B3LYP and mPW1PW functionals and the LanL2DZ BS's with ECPs for the central metal ion and, if necessary, for halogen atoms. For all molecules, normal mode frequency calculations and NBO[63] charge distributions were calculated at the optimised geometries. The binding energies $\Delta E_{ZPE,BSSE}$, corrected for BSSE and ZPE, were calculated for the CT adducts between either **10** or imidazoline-2-thione and iodine as described above. All calculations were performed on an SGI Origin 3800 equipped with 128 Gb of RAM. The program Molekel 4.3 was used to investigate the shape of the calculated Kohn−Sham orbitals.[64] In order to simulate vibrational IR and Raman spectra starting from Gaussian output files, the program GaussFreq 2003[65] was developed using the RapidQ language. All spectra were simulated as superimposed Gaussian curves with a fixed halfbandwidth of 15 cm^{-1} starting from the calculated unscaled frequencies.

Supporting Information: Details on the criteria followed for choosing the computational level, calculated bond lengths and angles, and KS-orbital energies for dithiolenes **10**−**12**, bond lengths and normal mode frequencies of Br_2, I_2, and IBr have been deposited as Electronic Supporting Information (see also footnote on the first page of this article).

Acknowledgments

CINECA and Dr. Sigismondo Boschi are gratefully acknowledged for the computational resources and continuous help, Prof. Giuseppe Saba for the very useful discussions, and MIUR (Ministero dell'Istruzione, dell'Università e della Ricerca; Fondo Integrativo Speciale per la Ricerca) for funding.

[51] It is worthy of note that the very narrow HOMO−LUMO gap classifies these dithiolene complexes as soft donors (Hardness = 0.674, 0.604, and 0.636 eV, for **10, 11**, and **12**, respectively). In addition, the NBO charge distribution on **10−12** at the optimised geometries shows a negative charge on the terminal sulfur atoms. On the contrary, the charges on the terminal sulfur atoms of neutral dithiolenes **4−6**, calculated at the same level of theory, assume very small positive values. This difference in the charge distributions calculated in the two classes of complexes is in agreement with the donor ability towards halogens found for $[M(R,R'timdt)_2]$ and never reported for dmit metal complexes.
[52] As expected on the basis of the HSAB theory, the hardness estimated from the HOMO and LUMO eigenvalues increases on passing from I_2 to Br_2 (hardness = 1.504, 1.625, and 1.760 eV for I_2, IBr, and Br_2, respectively, at mPW1PW/LanL2DZ level).

Supramolecular Hydrogen-Bond Structures and Magnetic Interactions in Basal-Apical, Dinuclear, Azide-Bridged Copper(II) Complexes

Mau Sinha Ray,[a] Ashutosh Ghosh,*[a] Siddhartha Chaudhuri,[b] Michael G. B. Drew,[c] and Joan Ribas*[d]

Keywords: Azides / Copper / Hydrogen bonds / Magnetic properties / N,O ligands / Schiff bases

The synthesis, characterisation, X-ray single crystal structures and magnetic properties of three new basal-apical μ_2-1,1-azide-bridged complexes $[CuL^1N_3]_2$ (**1**), $[CuL^2N_3]_2$ (**2**) and $[CuL^3N_3]_2$ (**3**) with very similar tridentate Schiff-base blocking ligands {HL^1 = *N*-[2-(ethylamino)ethyl]salicylaldimine; HL^2 = 7-(ethylamino)-4-methyl-5-azahept-3-en-2-one; HL^3 = 7-amino-4-methyl-5-azaoct-3-en-2-one} have been reported [complex **1**: monoclinic, $P2_1/c$, a = 8.390(2), b = 7.512(2), c = 19.822(6) Å, β = 91.45(5)°; complex **2**: monoclinic, $P2_1/c$, a = 8.070(9), b = 9.787(12), c = 15.743(17) Å, β = 98.467(10)°; complex **3**: monoclinic, $P2_1/n$, a = 5.884(7), b = 16.147(18), c = 11.901(12) Å, β = 90.050(10)°]. The structures consist of neutral dinuclear entities resulting from the pairing of two mononuclear units through end-on azide bridges connecting an equatorial position of one copper centre to an axial position of the other. The copper ions adopt a (4+1) square-based geometry in all the complexes. In complex **2**, there is no inter-dimer hydrogen-bonding. However, complexes **1** and **3** form two different supramolecular structures in which the dinuclear entities are linked by H-bonds giving one-dimensional systems. Variable temperature (300–2 K) magnetic-susceptibility measurements and magnetisation measurements at 2 K reveal that all three complexes have antiferromagnetic coupling. Magneto-structural correlations have been made taking into consideration both the azido bridging ligands and the existence of intermolecular hydrogen bonds.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The development of supramolecular structures created by hydrogen bonds is a new challenge for the synthesis of non-serendipitous species in order to study their magnetic behaviour;[1,2] control of these hydrogen bonds seems to be very important for synthesising new supramolecular systems. The role played by hydrogen bonds in the transmission of magnetic interactions is still not fully understood. For many years, hydrogen bonds were thought to propagate essentially antiferromagnetic interactions between metal centres,[3] but the number of ferromagnetically coupled hydrogen-bonded systems is growing.[1a,4] A variety of ligands have been employed for preparation of these systems. The azido group is one of the most widely used versatile bridges, which is able to create strong hydrogen bonds between itself and OH or NH_2 of the blocking ligands. As a result, azide-bridged complexes, especially those with copper(II), are one of the most fascinating subjects for studying the magnetic interactions.[5–16] However, there are some misapplications of the magneto-structural correlation for the basal-apical, end-on azide-bridged copper(II) complexes. For example, it is well established that when the azido ligand bridges two Cu^{II} ions in an end-on manner, the nature of the exchange coupling changes from ferromagnetic to antiferromagnetic when the Cu–N–Cu angle is around 108°.[17] This correlation, in principle, is valid only for basal-basal coordination, although it has also sometimes been applied to the basal-apical coordination mode. To understand the controlling factors in such systems it is essential to study dinuclear copper(II) compounds. However, among numerous examples of azide-bridged copper(II) complexes, end-on bridged, basal-apical dimers are rare.[6,10,13] Recently, we found that a group of tridentate Schiff-base blocking ligands, formed by the half condensation of diamines with salicylaldehyde or 2,4-pentandione, provide the desired dimeric species.[18] We have also shown that for basal-apical coordination, the Cu–N–Cu angle is not indicative of the magnetic interaction, nor does it have any controlling structural parameters; instead the supramolecular

H-bonding networks between the dinuclear entities play a very important role in magneto-structural correlations.

In order to obtain more insight into the possible control of the H-bonding network and its effect on the magnetism of such systems we have synthesised three new complexes. In this paper we report the synthesis, X-ray crystal-structure analysis, and variable-temperature magnetic behaviour of these basal-apical, dinuclear μ_2-1,1-N_3 copper(II) complexes with three different tridentate Schiff-base blocking ligands (Scheme 1). We found that very subtle differences in the H-bonding network and structural parameters could be responsible for the drastic changes in magnetic behaviour.

Results and Discussion

Infrared Spectra

The coordination mode of azide to transition metal is usually detected by the intense IR band due to $\nu_{as}(N_3)$ which occurs above 2000 cm^{-1}. In general, it appears above 2055 cm^{-1} for μ_2-1,1-azide bridges. However, this generalisation is valid only for symmetric end-on azide bridges where the difference between the two N−N distances ($\Delta d'$) of the azide group is relatively large. In basal-apical-type bridges $\Delta d'$ is smaller and, consequently, ν_{as} appears at lower frequencies.[13,18] All three complexes (**1**, **2** and **3**) that are reported in this paper show only a single absorption band, consistent with the presence of only one type of azide bridge in the structures, and all of them appear at lower frequencies, viz. 2041, 2053 and 2043 cm^{-1} respectively, in agreement with the basal-apical bridging.

Complexes **1** and **2** display a single sharp band at 3239 and 3241 cm^{-1}, respectively, due to the N−H stretching vibration whereas complex **3** shows two bands at 3292 and 3247 cm^{-1} characteristic of the NH_2 group. The band corresponding to the azomethine (C=N) group is distinct in all the three complexes; it occurs at 1630, 1594 and 1593 cm^{-1} for complexes **1**, **2** and **3**, respectively

Description of Structures of Complexes 1, 2 and 3

The structure determination reveals that all the three azido complexes consist of neutral dinuclear entities. Each of them results from the pairing of two mononuclear units related by a crystallographic centre of symmetry. A view of the dinuclear species is given in Figure 1 for complex **1** (complexes **2** and **3** have very similar molecular structures; see Figures S1 and S2 in the Supporting Information). For all three complexes, two centrosymmetrically related Cu^{II} centres are bridged by azide ions in an asymmetric end-on fashion leading to relatively small Cu···Cu distances (Table 1). Within these dimeric units, each of the two trigonally distorted square pyramidal copper(II) centres is coordinated equatorially by three ligating atoms [O(1), N(1) and N(2)] of the corresponding tridentate Schiff-base ligand and a nitrogen atom, N(11), of one of the bridging azides; this comprises the basal plane. A second nitrogen atom, N(11)′, from the centrosymmetrically related bridging azide coordinates axially at a rather long distance [Cu−N(11)′: 2.550(8), 2.447(6), 2.443(9) Å for **1**, **2** and **3** respectively] furnishing

an elongated square-pyramidal (4+1) geometry for each copper(II) centre in all three complexes.

The four basal donor atoms [O(1), N(1), N(2) and N(11)] deviate from the mean coordination plane through them by 0.06(1), −0.10(1), 0.09(1) and −0.05(1) Å, respectively, in complex **1**, 0.08(1), −0.12(1), 0.12(1) and −0.13(1) Å, respectively, in complex **2**, and 0.11(1), −0.14(1), 0.16(1) and −0.12(1) Å, respectively, in complex **3**. The copper atom is slightly pulled out of this plane towards the apical donor atom N(11)′ at a distance 0.125(1), 0.097(1) and 0.108(1) Å in complexes **1**, **2** and **3**, respectively. The distortions of the coordination polyhedron from the square pyramid to the trigonal bipyramid have been calculated by the Addison parameter (τ)[19] as an indication of the degree of trigonality. τ is defined as $(\beta - \alpha)/60$, where β and α are the two trans-basal angles. For a perfectly square pyramidal geometry τ is equal to zero, while it becomes unity for a perfectly trigonal-bipyramidal geometry. The τ values for complexes **1**, **2** and **3** are 0.13, 0.23 and 0.21, respectively.

The five-membered chelate ring Cu−N1−C8−C9−N2 in complex **1** has a half-chair conformation, twisted around C(8)−C(9), with puckering parameters[20] q_2 = 0.383(16) Å and φ_2 = 54.4(2)°. The closest pucker[21] conformation of the five-membered chelate rings Cu−N1−C4−C5−N2 in complexes **2** and **3** is an envelope on C(5); the puckering parameters[20] are q_2 = 0.426(6) Å and φ_2 = 115.3(7)° in the former and q_2 = 0.292(13) Å and φ_2= 71.7(2)° in the latter.

The bridging Cu_2N_2 network is exactly planar as dictated by symmetry. Due to the formation of basal-apical μ_2-1,1-N_3 bridging, the bridging Cu−N bond lengths are significantly different (Δd = 0.46, 0.46 and 0.53 Å for **1**, **2** and **3**, respectively). The bridging N_3^- anions are quasi-linear; the N(11)−N(12)−N(13) angles are 177.5(15)°, 176.8 (7)° and 178.4 (10)° in **1**, **2** and **3**, respectively. The angles subtended at the metal in the coordination sphere are very similar in the three structures. There is, however, a significant difference between the Cu−N(11)−N(12) angles for the axial azide [122.3(9)° in **1**, 115.4(6)° in **2** and 131.9(6)° in **3**].

The three crystal structures exhibit different hydrogen-bonding patterns (Table 2). There is one hydrogen atom, H2a, in each of the complexes **1** and **2** available for hydrogen-bond formation, and two hydrogen atoms, H2a and H2b, in complex **3**. H2a in each of the three complexes is involved in strong intra-dimer N−H···O hydrogen bonding with the ligating oxygen O1 of the corresponding tridentate Schiff-base ligand (Figure 1 and Figures S1 and S2 in the Supporting Information). In addition, in complex **1** a second direct connection is established between the two

Table 2. Hydrogen-bonding distances (Å) and angles (°) for complexes **1**, **2** and **3**

halves of the dinuclear entity through strong intra-dimer N−H···N hydrogen bonding with the middle centrosymmetrically related bridging azido nitrogen N12 (Figure 1).

The inter-dimer interaction is significantly different in complexes **1**, **2** and **3** (Table 2). H2b in complex **3** bridges the symmetry-related dimers through an N2−H2b···N11 [N2···N11:3.285(13) Å] hydrogen bond in a one-dimensional supramolecular entity (Figure 2). H2a in complex **1** is similarly involved in a somewhat weaker N2−H2a···N13 [N2···N13:3.533(19) Å] hydrogen bond-like contact with a neighbouring dimer (Figure 3). Complex **2** does not show any important intermolecular hydrogen bond in the "one-dimensional" net.

Magnetic Properties

Before reporting the experimental data, it is important to underline which are the magnetic pathways in the three complexes, according to the structural data discussed above. Complex **1** can be considered as a dinuclear complex in which the Cu ions are linked by two azido bridging ligands in an end-on equatorial-apical fashion (μ-1,1) through the N11 atom. There are also two short intramolecular hydrogen bonds [O1−H2a(N2): 2.613 Å; N12−H2a(N2): 2.621 Å]. The same H2a(N2) is linked by a weak, hydrogen bond-like contact to N13 (terminal nitrogen of the azido bridging ligand) of another dinuclear complex at 2.934 Å, thus giving a pseudo-one-dimensional supramolecular entity (Figure 3). Complex **2** shows the same intramolecular pathway [Cu−(μ-1,1-N_3)$_2$−Cu]. There is also a short intramolecular hydrogen bond [O1−H2a(N2): 2.37 Å], but in this case there is no appreciable hydrogen bond between adjacent dimers. The shortest H2a(N2) distances are 5.5 Å to N11 and 6.13 Å to O1 of a neighbouring dinuclear entity. Thus, complex **2** can be considered as an isolated dinuclear complex. Complex **3** shows the same intramolecular pathway [Cu−(μ-1,1-N_3)$_2$−Cu] through the N11 atom. There is also a short intramolecular hydrogen bond [O1−H2a(N2): 2.452 Å]. The H2b(N2) atom is linked by a weak hydrogen bond to N11 (first nitrogen of the azido bridging ligand) of another dinuclear complex at 2.673 Å, thus giving a pseudo-one-dimensional supramolecular entity (Figure 2). In this one-dimensional structure H2b(N2) links the O1 of an adjacent unit at 3.063 Å, with H2a···H2a at 3.091 Å and H2a···H2b at 3.323 Å.

Complexes 1 and 2

The magnetic properties of complexes **1** and **2** are very simple and correspond to almost isolated dinuclear entities from the magnetic point of view, at least down to 2 K. A $\chi_m T$ versus T plot (χ_m is the molar magnetic susceptibility for two Cu^{II} ions) for complex **1** is shown in Figure 4 [for the analogous complex **2** the corresponding figure is given in the Supporting Information (Figure S3)]. The value of $\chi_m T$ for **1** at 300 K is 0.83 $cm^3 \cdot mol^{-1} \cdot K$, which is as expected for two magnetically quasi-isolated spin doublets ($g > 2.00$). The $\chi_m T$ values decrease smoothly from 0.83 to 0.35 $cm^3 \cdot mol^{-1} \cdot K$ at 2 K. This global feature is characteristic of very weak antiferromagnetic coupling. Considering the possible interactions through the dinuclear entities as nil, the Bleaney−Bowers formula for a dinuclear $S = 1/2$ system was used.[22] The Hamiltonian employed is $H = -JS_1S_2$. The best-fit parameters were: $J = -2.63 \pm 0.01$ cm^{-1}, $g = 2.11$ and $R = 2.1 \times 10^{-5}$ for **1** and $J = -1.79 \pm 0.01$ cm^{-1}, $g = 2.13$ and $R = 12.1 \times 10^{-5}$ for **2** {R is the agreement factor defined as $\Sigma_i[(\chi_m T)_{obsd.} - (\chi_m T)_{calcd.}]^2 / \Sigma_i[(\chi_m T)_{obsd.}]$, the temperature-independent paramagnetism

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(TIP) was taken as 120×10^{-6} cm^3·mol^{-1}}.[22b] All attempts to improve the fits by introducing a small percentage of mononuclear impurities or a possible intermolecular J' (molecular-field approximation) did not improve the R values, and the intramolecular J values were left unmodified. The reduced molar magnetisation tends to 1.7 $N\beta$ for both **1** and **2** when the fields approach 5 T (see inset in Figure 4 and Figure S3), and they do not follow the de Brillouin formula for two isolated Cu^{II} ions. This feature is also indicative of the small antiferromagnetic coupling in both compounds.

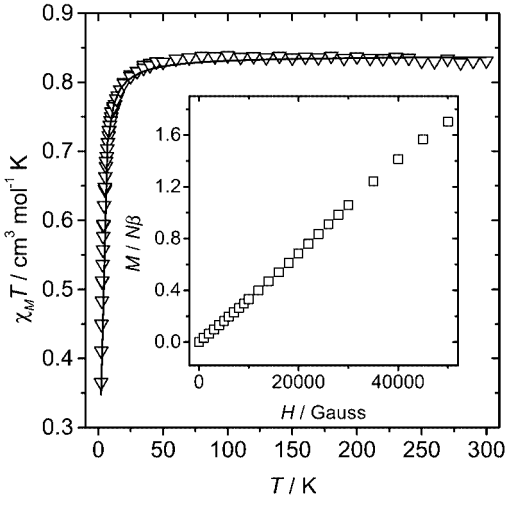

Figure 4. Plot of $\chi_M T$ vs. T for complex **1**; the solid lines represent the best fit and the points the experimental data; inset: plot of $M/N\beta$ vs. H at 2 K for complex **1**

Complex 3

The magnetic properties of complex **3** are different from those of complexes **1** and **2**. The $\chi_m T$ versus T plot (χ_m is the molar magnetic susceptibility for two Cu^{II} ions) is shown in Figure 5. The value of $\chi_m T$ at 300 K is 0.85 cm^3·mol^{-1}·K, which is as expected for two magnetically quasi-isolated spin doublets ($g > 2.00$). The $\chi_m T$ values smoothly decrease from 0.85 to 0.1 cm^3·mol^{-1}·K at 2 K. The global feature is characteristic of weak antiferromagnetic coupling. Considering the possible interactions through the dinuclear entities as nil, all attempts to fit the experimental data with only one $J_{intramolecular}$ value were unsuccessful.[22] The J value was of the order of $4-5$ cm^{-1} but with an unsatisfactory R value. As indicated above, complex **3** is a one-dimensional system formed by dinuclear entities linked by hydrogen bonds. This gives an alternating $S = 1/2$ system (J_1 for azido bridging ligand and J_2 for hydrogen bond). The fit of the magnetic data has been carried out with the Clumag program using a ring of twelve copper(II) ions which is the best way to represent the infinite character of the chain.[23] The best-fit parameters obtained with this computing model are: $J_1 = -5.37 \pm 0.06$ cm^{-1}, $J_2 = -3.97 \pm 0.08$ cm^{-1}, $g = 2.14$ and $R = 0.5 \times 10^{-5}$ (TIP was taken as 60×10^{-6} cm^3 mol^{-1} for the copper ion).[22b] The reduced molar magnetisation (see inset in Figure 5) clearly indicates that the global coupling is more antiferromagnetic than that for complexes **1** and **2**. For **3** the $M/N\beta$ value at 5 T tends to 0.7 $N\beta$, which is very far from the expected value for two isolated copper(II) ions. The shape of the curve formed by the experimental point does not follow the de Brillouin formula, and its convexity is more pronounced than in **1** and **2**. Thus, the global antiferromagnetic coupling is greater than for **1** and **2**.

Magneto-Structural Correlations

Intramolecular Interactions (J_1) through End-On Azido Bridging Ligands

Complexes **1**, **2** and **3** show antiferromagnetic coupling. For complex **3** it is impossible to state if the J value for the azido bridging ligand is -5.38 cm^{-1} or -3.97 cm^{-1} but it seems logical to assume that the intramolecular azido coupling would be greater than the intermolecular hydrogen-bond coupling. In any case both are negative and of the same order of magnitude. When the azido bridge is in a basal-basal position, either the experimental values or the theoretical calculations demonstrate that J can be antiferromagnetic or ferromagnetic depending mainly on the Cu−N_3−Cu angle.[17] This reasoning is not valid when the azido bridges are in basal-apical coordination (such as in **1**, **2** and **3**), although too many papers devoted to this kind of coupling try to relate this angle with the J parameter. The literature data indicate a total dispersion of the J values with regard to the Cu−N−Cu angles.[6−16,18] In equatorial-axial complexes (such as in **1**, **2** and **3**), the distortion parameter τ (square-pyramidal to trigonal bipyramidal)[19] could be important from a magnetic point of view. However, experimentally, the maximum value of τ gives, surprisingly, the minimum value of J. The variations in J are small and, consequently, it would be difficult to establish clear trends connecting theoretical parameters to variations in J.

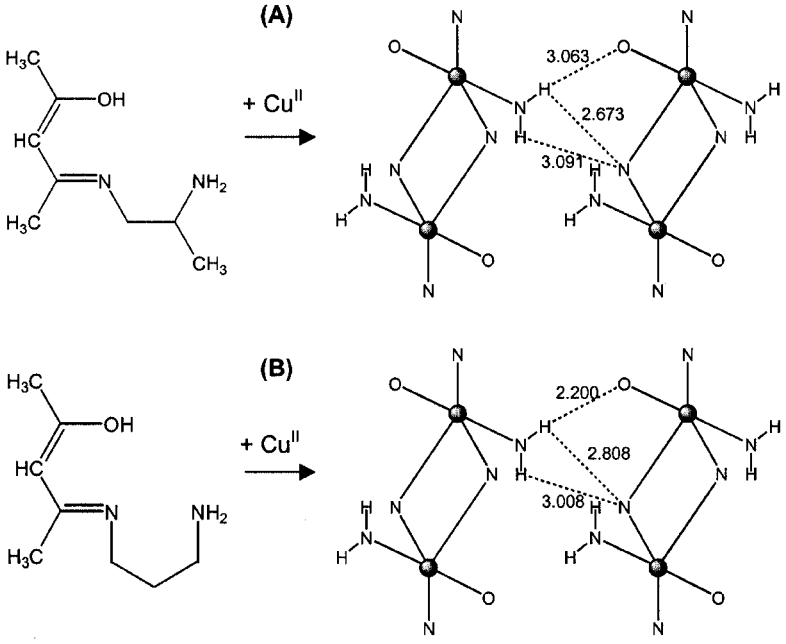

Figure 6. Scheme of the ligands and complex **3** (A) (antiferromagnetically coupled) and complex reported by the authors in ref.[18] (B) (ferromagnetically coupled)

The main structural parameters for the three complexes are gathered in Table 1.

Intermolecular Hydrogen Bonds in Complex 3 − Small Subtleties That Modify the Magnetism

It is well know that the role played by hydrogen bonds in the transmission of magnetic interactions is still not fully understood. For many years, hydrogen bonds were thought to propagate essentially antiferromagnetic interactions between metal centres,[3] but the number of ferromagnetically coupled hydrogen-bonded systems is growing.[1a,4] We decided to compare two very similar complexes, complex **3** and the other one previously reported by us;[18] the ligands and their main structural parameters are schematized in Figure 6. Although the ligands are very similar and the packing of the two complexes is analogous, subtle differences can be found: in **3** the shorter intermolecular hydrogen bond length is N−H···N(azido) (rather long) while in the previous complex,[18] the stronger hydrogen-bond length is N−H···O (very short). The experimental result is that complex **3** clearly shows intermolecular antiferromagnetic coupling while its analogue shows intermolecular ferromagnetic coupling.[18] Although J_{inter} is large, close to -4 cm^{-1} (see above), other much greater J values are reported in literature, such as $J = -90$ cm^{-1} (Cu dimer with O−H···O distance of 2.32 Å).[24] Even for other metals, like chromium(III), considerable large J values are also reported.[3a,25]

Concluding Remarks

Three very similar blocking ligands have been used to synthesise three new, basal-apical, end-on azide-bridged, dinuclear Cu^{II} complexes. The dinuclear entities of all three complexes are very similar but the H-bonding network among the dinuclear entities and consequently their relative orientation in the one dimensional net are very different. From a magnetic point of view, it is important to emphasise that for basal-apical coordination neither the Cu−N−Cu angle nor the τ distortions are clearly indicative of the magnetic interaction.

The difference between the antiferromagnetic character (intra and inter) in **3** with regard to the ferromagnetic character in its homologue[18] is a challenge for experimental and theoretical chemists to synthesise new similar complexes and to try to interpret the subtle differences that cause the drastic change in the magnetic behaviour.

Experimental Section

Caution! *Azido complexes of metal perchlorates in the presence of organic ligands are potentially explosive. Only a small amount of material should be prepared, and it should be handled with care.*

Physical Measurements: Elemental analyses (carbon, hydrogen and nitrogen) were performed using a Perkin−Elmer 240C elemental analyzer and the copper contents in all the complexes were estimated spectrophotometrically.[26] IR spectra of the complexes in KBr (4500−500 cm^{-1}) were recorded using a Perkin−Elmer RXI FT-IR spectrophotometer. Electronic spectra of the complexes in methanol (1200−350 nm) were recorded on a Hitachi U-3501spectrophotometer. The crystallographic data of complex **1** were collected on a Bruker Nonius MACH3 diffractometer and for complexes **2** and **3** were collected on a MAResearch Image Plate system. Magnetic measurements were carried out in the "Servei de Magnetoquímica (Universitat de Barcelona)" on polycrystalline samples (30 mg) with a Quantum Design MPMS XL-5 SQUID susceptometer operating

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

at a magnetic field of 0.1 T between 2 and 300 K. The diamagnetic corrections were evaluated from Pascal's constants.

Materials: All the chemicals were of reagent grade and used without further purification. The three monocondensed ligands were synthesised as described below.

Preparation of HL^1 {*N*-[2-Ethylamino)ethyl]salicylaldimine} and HL^2 (7-Ethylamino-4-methyl-5-azahept-3-en-2-one): Both HL^1 and HL^2 were prepared by condensation of the NH_2 group of *N*-ethyl-1,2-ethanediamine (0.45 mL, 5 mmol) with salicylaldehyde (0.53 mL, 5 mmol) and 2,4-pentanedione (0.55 mL, 5 mmol), respectively, in methanol (30 mL) under reflux for 3 h.

Preparation of 7-Amino-4-methyl-5-azaoct-3-en-2-one (HL^3): This ligand was prepared by following a similar method to that adopted for the half condensation of 1,2-ethanediamine or 1,3-propanediamine with 2,4-pentanedione as reported earlier.[27] A solution of 2,4-pentanedione (1.1 mL, 10 mmol) in chloroform (50 mL) was added dropwise to a solution of 1,2-propanediamine (0.80 mL, 10 mmol) in chloroform (50 mL) at ambient temperature. After completion of the addition, the solution was stirred for an additional 3 h and the chloroform was then evaporated under reduced pressure. The resultant viscous oil was collected and dissolved in methanol (30 mL).

Synthesis of $[CuL^1N_3]_2$ (1), $[CuL^2N_3]_2$ (2) and $[CuL^3N_3]_2$ (3): Direct synthesis of the complexes from methanolic solutions of $Cu(ClO_4)_2{\cdot}6H_2O$, NaN_3 and the respective ligands did not allow the formation of sufficiently pure desired products. A mixture of hydrolysed products as well as a small amount of the respective complexes was formed. It was very difficult to separate the mixture. Therefore, to prepare good quality crystalline compounds, we adopted the following procedure.

Addition of copper(II) perchlorate hexahydrate to a methanolic solution of HL^1, HL^2 or HL^3, followed by addition of a stoichiometric amount of triethylamine, gave the dinuclear complex $[(CuL^1)_2](ClO_4)_2$ and the trinuclear complexes $[(CuL^2)_3(OH)](ClO_4)_2{\cdot}H_2O$ and $[(CuL^3)_3(OH)](ClO_4)_2$, respectively, as reported previously for similar compounds.[28]

A methanol/water solution (9:1, v/v) of sodium azide, (0.13 g, 2 mmol) was added to a methanolic solution (30 mL) of $[(CuL^1)_2](ClO_4)_2$ (0.35 g, 0.5 mmol), $[(CuL^2)_3(OH)](ClO_4)_2{\cdot}H_2O$ (0.47 g, 0.5 mmol) or $[(CuL^3)_3(OH)](ClO_4)_2$ (0.44 g, 0.5 mmol) and the mixture was stirred for 30 min. There was no immediate separation of any compounds. The clear solutions were therefore left to stand in a refrigerator overnight. Dark-green plate-shaped single crystals of **1** and blue parallelepiped-shaped single crystals of **2** and **3** suitable for X-ray diffraction were obtained.

Complex 1: Yield: 0.20 g (65%). $C_{22}H_{30}Cu_2N_{10}O_2$ (593.66): calcd. C 44.5, H 5.1, N 23.6, Cu 21.4; found C 44.5, H 5.2, N 23.7, Cu 21.1. UV/Vis (methanol): λ_{max} (ε_{max}) = 613 nm (287 $dm^3{\cdot}mol^{-1}{\cdot}cm^{-1}$). IR: 3239 cm^{-1} ν(N−H); 1630 ν(C=N).

Complex 2: Yield: 0.35 g (80%). $C_{18}H_{34}Cu_2N_{10}O_2$ (549.65): calcd. C 39.3, H 6.2, N 25.5, Cu 23.1; found C 39.2, H 6.0, N 25.6, Cu 22.8. UV/Vis (methanol): λ_{max} (ε_{max}) = 595 nm (334 $dm^3{\cdot}mol^{-1}{\cdot}cm^{-1}$). IR: 3241 cm^{-1} ν(N−H); 1594 ν(C=N).

Complex 3: Yield: 0.27 g (70%). $C_{16}H_{30}Cu_2N_{10}O_2$ (521.60): calcd. C 36.8, H 5.8, N 26.8, Cu 24.3; found C 36.7, H 5.9, N 26.7, Cu 24.0. UV/Vis (methanol): λ_{max} (ε_{max}) = 591 nm (226 $dm^3{\cdot}mol^{-1}{\cdot}cm^{-1}$). IR: 3245 and 3292 cm^{-1} ν(N−H); 1592 ν(C=N).

Crystallographic Studies: The crystallographic data of complex **1** were collected on a Bruker-Nonius MACH3 diffractometer using the ω-2θ scan mode in the θ range 2−25°; a maximum of 60 s were allowed per reflection. The data for complexes **2** and **3** were collected on a MAResearch Image Plate System with the crystals positioned at 70 mm from the plate; 100 frames were measured at 2° intervals with a counting time of 2 min per frame. Mo-K_α radiation was used in all three cases.

The raw intensity data for complex **1** were processed for Lorentz and polarisation effects using the XCAD4 program in the WinGX suite and empirical absorption correction was carried out using ψ-scan data.[29] The data for complexes **2** and **3** were processed using the XDS[30] program and empirical absorption corrections were applied using DIFABS.[31] The number of independent reflections for complexes **1**, **2** and **3** were 2119, 2174 and 1940, respectively.

The structures were solved by direct methods with the SHELXS-97 program.[32] Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms bonded to carbon and nitrogen atoms were included in geometric positions and given thermal parameters equivalent to 1.2-times those of the atom to which they are attached. The crystals of **3** were twinned (*hkl*, *hk*−*l*)

Preparation, Structure Determination and Cytotoxicity of the Pd^{II}·Bleomycin A2 Complex

Athanasios Papakyriakou,[a] Ioannis Bratsos,[a] Maria Katsarou,[a] and Nikos Katsaros*[a]

Keywords: Bleomycin / Palladium / Molecular modelling / Cytotoxicity

The solution structure of the Pd^{II}·bleomycin A2 complex was resolved by NMR spectroscopy in combination with molecular modelling. The preparation of the complex in 1.0 M NaCl aqueous solutions leads to the formation of a major compound, which is very stable at ambient temperature. Our NMR spectroscopic data demonstrate that bleomycin is coordinated through the β-aminoalanine secondary amine, the pyrimidine ring N1, the deprotonated histidyl amide and the imidazole N1, in contrast to an earlier study that proposed coordination of the valerate amide. 2D NMR spectroscopic data were used as distance constraints in simulated annealing molecular-dynamics calculations and the first solution structure of a square-planar metallo-bleomycin is reported. In order to assess the toxicity of Pd^{II}·bleomycin, cytotoxicity measurements were performed in U937 and K562 leukemia cell lines using two methods. In both cell lines the free drug and the complex exhibit similar toxicity as a function of time.

Introduction

Bleomycins are a group of antibiotics with clinical use as anticancer drugs.[1−3] The commercial preparation, Bleocin or Blenoxane, consists predominantly of bleomycins A2 and B2 (Scheme 1). Their efficacy is mainly attributed to their ability to mediate cleavage of the DNA backbone by attacking at the deoxyribose 4′-H position and causing single- and double-strand cleavage and base release.[4−8] A number of putative pathways have been proposed to initiate DNA oxidation.[10,11] The drug is activated in the presence of iron and oxygen species as cofactors. Other metals can also facilitate DNA cleavage by bleomycin in vitro, even though their reactions are less well characterized.[12]

Umezawa and co-workers were the first to isolate bleomycins from the culture medium of *Streptomyces verticillus* and to propose the most likely metal-binding sites.[13] The X-ray crystal structure of Cu^{II}·P3A,[14,15] a biosynthetic intermediate of bleomycins lacking the linker, C-terminus and carbohydrate domains, revealed a five-coordinate square-pyramidal complex with five nitrogen donors. Only recently, Suguiyama et al.[16] obtained the X-ray crystal structures of both apo and Cu^{II}·bleomycin A2 bound with a protein and established the proposed metal-binding mode. The equatorial plane comprises the secondary amine of aminoalanine, the pyrimidine N1, the histidine amide and the imidazole N1, while the aminoalanine primary amine occupies the apical position (see Scheme 1). These structures were found to be consistent with the NMR models proposed by Stubbe et al. for the two Co^{III}·bleomycin adducts.[17−19] Among them, HO_2·Co^{III}·bleomycin is considered to be a robust structural analogue of the biologically relevant Fe·bleomycin.[20,21] Although Ga^{III} and In^{III}·bleomycins are not able to mediate DNA degradation, their solution structures were recently shown to bear strong resemblance to these models.[22,23] On the other hand, structural NMR studies on iron species have been carried out for the low-spin CO·Fe^{II}·bleomycin [24] and the paramagnetic Fe^{II}·bleomycin,[25] which exhibited contradictory results. Other direct structural studies on metallo-bleomycins have been performed with manganese,[26−28] ruthenium,[29,30] vanadyl,[31,32] zinc,[33−36] cadmium,[37] nickel,[38,39] calcium and trivalent lanthanides,[40] as well as the paramagnetic Co^{II}·bleomycin complex.[41,42]

In view of the fact that bleomycins are often administered in combination with cisplatin [*cis*-$PtCl_2(NH_3)_2$] for the treatment of malignant tumors,[43] Garnier-Suillerot and Albertini have carried out an investigation on the interaction between the two compounds.[44] Apart from cisplatin, *cis*-$PdCl_2(NH_3)_2$, $PdCl_2$(ethylenediamine) and $PdCl_4^{2-}$ were also used in this study. The final species, resulting from the interaction of these compounds with bleomycin, were suggested to be similar, albeit different reaction rates and formation constants were observed. Spectroscopic and potentiometric data have led the authors to propose a binding mode, which differs from the equatorial plane of most metallo-bleomycins. Instead of the imidazole ring N1, the valerate peptide nitrogen was proposed to be a donor atom of bleomycin, independent of the starting complex.

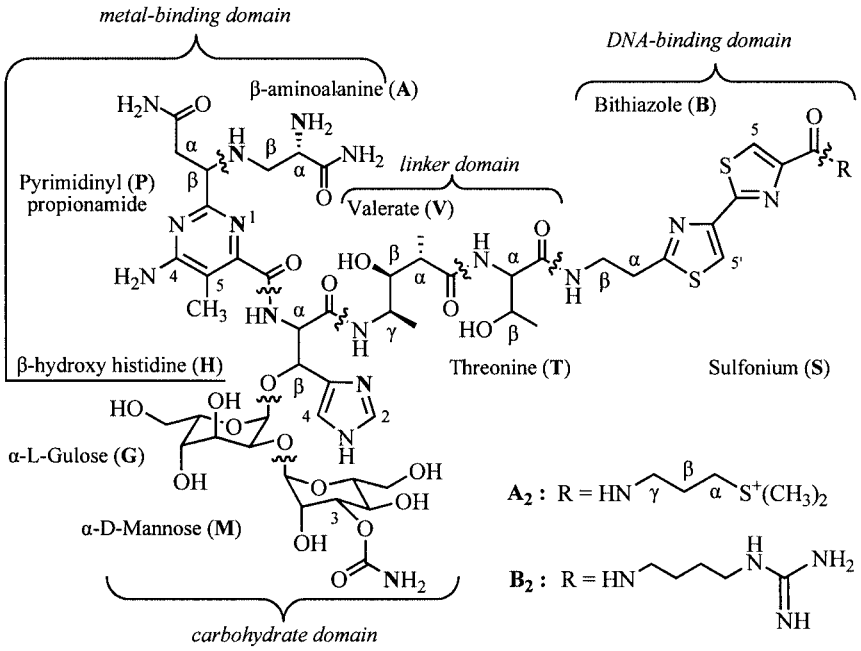

Scheme 1. Structure of bleomycins A2 and B2; the functional groups are separated by wavy lines and the potential N ligands are marked in bold

We have undertaken the preparation and structural characterization of Pd^{II}·bleomycin A2 with the aim to obtain its detailed solution structure through a combined use of NMR spectroscopy and molecular modelling. Our NMR spectroscopic data indicate that bleomycin binds strongly to Pd^{II} and forms a 1:1 adduct through four nitrogen donors, which comprise the equatorial plane of nearly all metallobleomycins. The combination of proton−proton distance constraints obtained by 2D NOESY experiments at low temperature, along with a suitable molecular mechanics force field for the modelling of Pd^{II}·bleomycin A2, have been used in determining its solution structure. Since no cytotoxicity results were reported for Pd^{II}·bleomycin and in pursuing a comparison with a cisplatin−bleomycin complex, we have performed cytotoxicity measurements in two leukemia cell lines using two methods. While complexation of bleomycin and cisplatin results in the decrease of their activity,[44] our data evidences that Pd^{II}·bleomycin exhibits comparable cytotoxicity with that of apo-bleomycin.

Results and Discussion

Interaction of Pd^{II} with Bleomycin

The first step in the structural characterization procedure of Pd^{II}·bleomycin was to prepare a pure and stable complex in aqueous media. Since Pd^{II} tends to undergo hydrolysis reactions,[45,46] addition of a twofold excess of K_2PdCl_4 in bleomycin solutions (1−10 mM concentrations) immediately produced a yellow, fine aggregate. Most likely, the insoluble product consists of hydroxo-bridged polynuclear Pd^{II} species. Even though mixing equimolar amounts of K_2PdCl_4 and bleomycin did not readily result in precipitation, a variety of compounds were formed, even at low pH (< 2). This was evident from the ^1H NMR spectra recorded immediately after mixing, which reveal the presence of at least three different species. Higher pH values and longer periods of time give rise to precipitation or formation of more complex mixtures.

Based on speciation studies of several Pd^{II} compounds analogous to cisplatin as a function of their concentration, pH and $[Cl^-]$,[47−50] we carried out the complex preparation in 1.0 M NaCl, so as to restrict the presence of aqua and/or hydroxo Pd^{II} species. As shown in Figure 1, under these

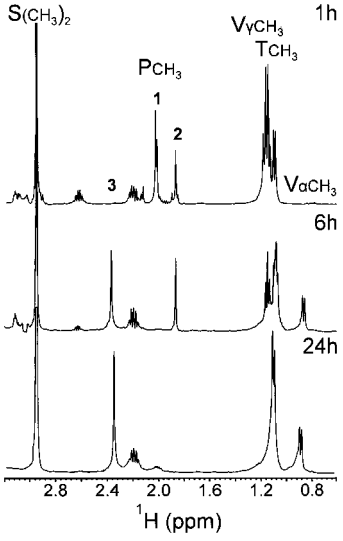

Figure 1. ^1H NMR spectral region of the Pd^{II}·bleomycin A2 system in 1.0 M NaCl at 298 K as a function of time; the resonances of the pyrimidine ring methyl protons ($P-CH_3$) reveal a three-step reaction and are indicated by the numbers 1, 2 and 3

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

conditions the ^{1}H NMR spectra indicate a multi-step reaction that occurrs during the first hours after mixing equimolar amounts of K_2PdCl_4 and bleomycin, which eventually leads to a major compound after 24 h at 40 °C. The complex formed is stable over a long period of several months, in neutral aqueous solutions (pH 6.7) of 10 mM concentration and at room temperature. This has allowed us to perform 2D NMR experiments and proceed to the structural determination of Pd^{II}·bleomycin A2.

Assignment and Analysis of the NMR Spectra

A strategy for the assignment of the non-exchangeable protons of bleomycin A2 has been previously presented in detail.[17,24] Combined use of heteronuclear and homonuclear experiments plays a key role in this procedure. A dispersion in the carbon dimension of the HMQC spectra (Figure S1 in the Supporting Information) in combination with the long-range couplings detected in the HMBC and TOCSY experiments have enabled us to assign the signals, especially the crowded disaccharide signals. ^{1}H and ^{13}C chemical shift values of Pd^{II}·bleomycin A2 are given in Tables S1 and S2 of the Supporting Information, in comparison with those reported for the metal-free bleomycin A2.[24,51]

Coordination of bleomycin to Pd^{II} through the pyrimidine and imidazole aromatic rings is readily detected by the changes in the **P**−CH_3 and **H**−C2H chemical shifts. In particular, the former signal appears at considerably lower field regions ($\Delta\delta$ = 0.4 ppm), which indicates a strong electron-withdrawing effect by the metal ion (see Figure 1). Despite the fact that both the ^{1}H and ^{13}C chemical shifts of the histidine **H**−Cα are not significantly affected upon complexation, the deprotonation of the histidine amide nitrogen is evident from the disappearance of its NH resonance. This is a strong indication for the coordination of the amide nitrogen to Pd^{II}, which was also the case for other metallo-bleomycins.[17,19,22−24,33−36] On the other hand, coordination of the β-aminoalanine secondary amine is reflected by the perturbation of the chemical shifts at **P**−CβH ($\Delta\delta$ = 0.4 ppm) and at the two **A**−$CβH_2$ ($\Delta\delta$ = 0.2−0.3 ppm).

Apart from the histidine amide proton, all the others were detected and assigned by observation of scalar couplings with their vicinal protons. Therefore, participation of any other amide nitrogen into the coordination sphere of Pd^{II}, rather than the deprotonated histidine amide, can be excluded. This is also true for the **V**−NH group (δ = 8.01), which has been proposed as a ligand for Pt^{II} and Pd^{II}·bleomycin.[44] The primary amine protons of β-aminoalanine exhibit a single resonance (δ = 6.39) strongly coupled to **A**−CαH. Their degeneration owning to the fast rotation around the C−N bond indicates that the primary amine is not coordinated, in contrast to Ga^{III} and In^{III}·bleomycins for which two strongly coupled signals had been detected.[22,23] Additionally, four pair of signals strongly coupled to each other were assigned to the pyrimidine ring **P**−NH_2 (δ = 7.51, 7.60), **P**−$CONH_2$ (δ = 7.08, 7.69), **A**−$CONH_2$ (δ = 6.93, 7.21) and **M**−$CONH_2$ (δ = 6.16, 6.61). The pyrimidine amine exhibits only medium-size NOEs with the neighbouring methyl group, in accordance with previous NMR studies.[17−19,22,23] **P**−$CONH_2$ and **A**−$CONH_2$ were assigned by virtue of their NOEs with the Cα and Cβ protons of the pyrimidinyl and aminoalanine moieties (see Figure 2). The remaining couple of fast exchanging protons was assigned to **M**−$CONH_2$, which did not show any cross-peak with other protons.

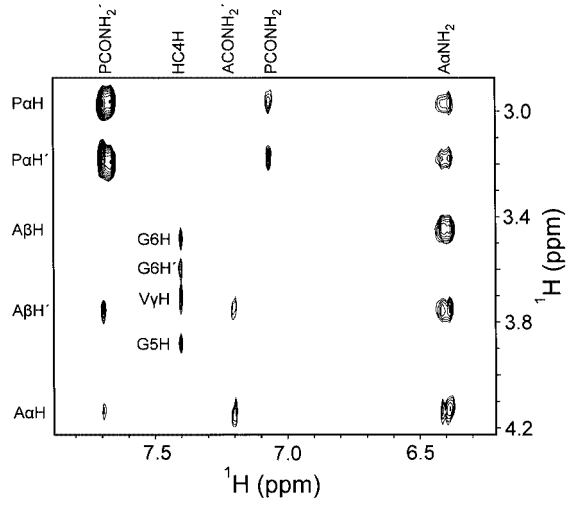

Figure 2. Expanded region from the NOESY spectrum of Pd^{II}·bleomycin A2 in H_2O (10% D_2O), 1.0 M NaCl, pH 6.7 at 278 K; the cross peaks shown are supporting the assignment of the exchangeable primary amine and amide protons

NOESY experiments were performed at 278 K and not only assisted in the assignment procedure, but also provided a wealth of structural information through distance constraints (Table S3 of the Supporting Information). Some common characteristics of metallo-bleomycins, such as the folding of the linker domain under the imidazole ring, were also exhibited by the Pd^{II}·bleomycin adduct. This is indicated by a number of NOEs between the aromatic protons of imidazole and the linker domain, especially by two medium intensity cross-peaks for **H**−C2H···**V**−CαH and **H**−C2H···**T**−CH_3. As a result of shielding by the imidazole ring current, **V**−CαH and **V**−αCH_3 proton signals appear at higher field compared with the metal-free bleomycin. Similarly, **M**−C3H is found to be shielded by the pyrimidine ring current, as the sugars move toward the metal-binding domain. In earlier NMR studies, the even higher upfield shift of the **M**−C3H signal ($\Delta\delta$ > 0.5 ppm) has been used as evidence for the coordination of the 3-*O*-carbamoyl nitrogen,[24] but it was disputed later.[17,19] Such stacking of the carbamoyl moiety over the pyrimidine ring has also been observed in the crystal structure of Cu^{II}·bleomycin A2.[16] Finally, the bithiazole and sulfonium

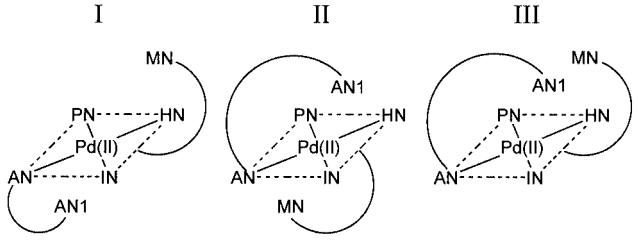
moieties of Pd^{II}·bleomycin lack any long-range NOEs with other domains, thus demonstrating a conformational flexibility.

Molecular Modelling and Structure Determination

Having established that the four common nitrogen ligands are involved in Pd^{II}·bleomycin and given that the square-planar geometry is the most favourable, three isomer models were constructed (see Scheme 2). To facilitate more extensive sampling of the conformational space, the disaccharide and β-aminoalanine moieties were placed at different orientations. In models I and II they were placed at opposite sides of the coordination plane, whereas in model III they both share the same side. Models I and II were based on the coordinates of the NMR structure of Co^{II}·bleomycin A2 (PDB code 1DEY),[41] while model III was based on the X-ray crystal structure of Cu^{II}·bleomycin A2 (PDB code 1JIF).[16]



Scheme 2. Starting models employed in the molecular dynamics calculations; the ligands are designated as β-aminoalanine secondary amine (AN), pyrimidine N1 (PN), β-hydroxyhistidine amide (HN) and imidazole N1 (IN); the β-aminoalanine primary amine (AN1) and the mannose carbamoyl nitrogen (MN) occupy different sides of the equatorial plane in models I, II and the same side in model III

Each model was subjected to 20 runs of a simulated annealing calculation following the same protocol as that described for the structural determination of Ga^{III} and In^{III}·bleomycins.[22,23] After minimizing the energy of the initial models without any constraints, a molecular dynamics run was performed while increasing the temperature from 300 to 1000 K. The distance constraints were then gradually introduced and after allowing the system to overcome any potential energy minima, the temperature was decreased to 300 K. From the final 20 ps of the molecular dynamics run (at 300 K with distance constraints) 100 structures were collected and were superimposed by mass-weighted rms fittings of all heavy atoms excluding the bithiazole and C-terminal groups. Their coordinates were averaged and the final model was subjected to energy minimization until the rms gradient became less than 0.01.

The structural and energy statistics of the ten best structures for each model, by virtue of the lowest potential energy and lowest deviation from the restraints, are given in Table 1. Models I and III were found to be more consistent with the NMR constraints and they exhibited the lowest energy structures. Model II resulted in higher strain-energy structures in order to satisfy the restraints and can be readily excluded. Despite the different starting position of β-aminoalanine in models I and III, their final structures were quite similar. As a result, all structures of the isomers I and III exhibit minimal energy differences in comparison with those obtained by model II. Nevertheless, model III exhibits the most favourable results with minor restraint violations and the lowest total potential energy.

The solution structure of Pd^{II}·bleomycin A2 (see Figure 3) resulted by averaging the ten best structures of model III and by minimizing its strain energy. Selected structural data of the coordination plane are presented in Figure S2 (see Supporting Information). Some of the above-mentioned structural features of metallo-bleomycins were also identified in the Pd^{II} adduct. The linker domain of the two Co^{III}·bleomycin complexes is folded under the equatorial plane from the side of the imidazole. The basis of this folding has been related to the interaction of the hydroperoxide or hydroxide axial ligand with the linker backbone.[17,19] In our case, a similar folding of the linker domain can be attri-

Table 1. Structural and energy statistics for the three Pd^{II}·bleomycin A2 models, which were obtained from the simulated annealing molecular dynamics calculations; for each model, ten structures were obtained by mass-weighted rms fitting and averaging the coordinates from the last 20 ps of the trajectory (100 snapshots); statistics were obtained after energy minimization was performed with all the distance restraints applied

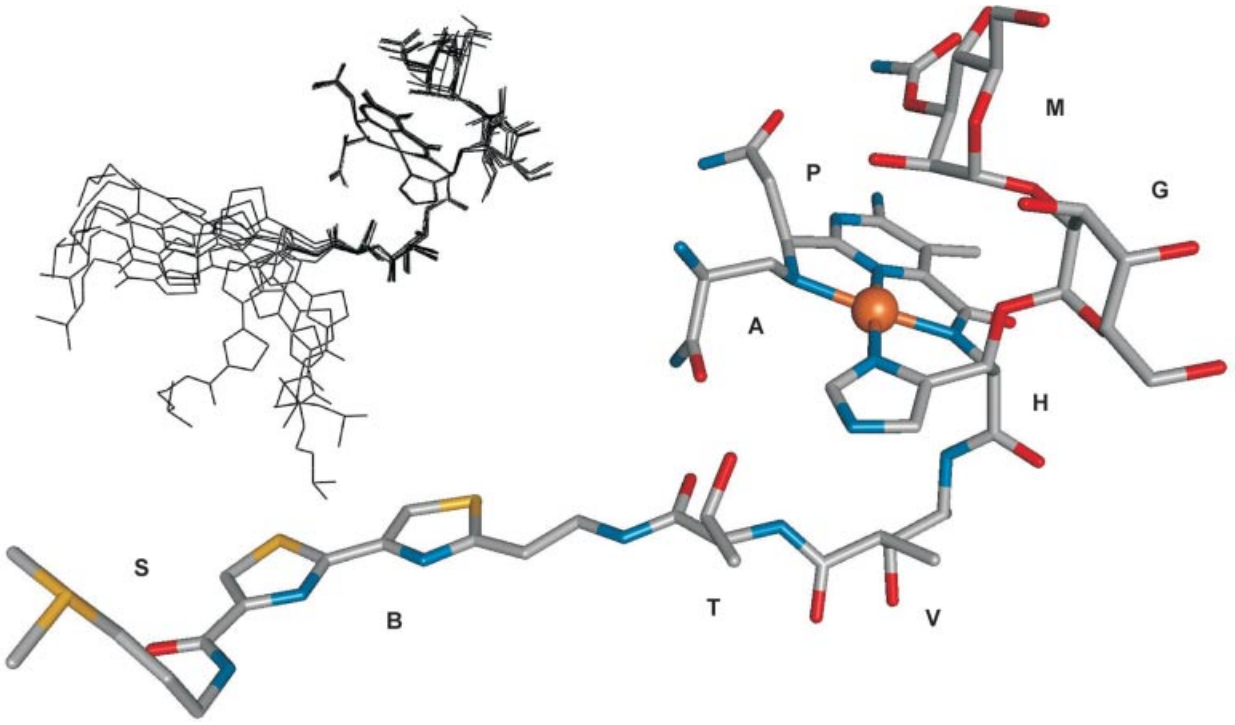

Figure 3. Structure of Pd^{II}·bleomycin A2 calculated from the averaged coordinates of the ten best models of III (shown in the inset) after energy minimization with all the constraints applied; atom colours are grey for C, blue for N, red for O, yellow for S and orange for Pd

buted to the H bonds, which were exhibited between the threonine and aminoalanine moieties (**T**−O−H···O=C−**A** and **T**−C=O···H−N−**A**). Their geometric characteristics indicate a strong interaction, which can account for the folding observed (Figures S3 and S4 in the Supporting Information). This interaction is supported by the strong chemical shift perturbation of **A**−$CONH_2$ protons (Table S1) and by a medium and a weak NOE between the two **A**−$CONH_2$ protons and **T**−NH (Table S3).

The disaccharide moiety of bleomycin is found to be positioned over the plane, which can be due to an additional H bond between the propionamide and carbamoyl moieties (**P**−C=O···H−N−**M**). But since the **P**−$CONH_2$ and **M**−$CONH_2$ signals are marginally perturbed upon complexation (Table S1 in Supporting Information) this interaction cannot be explicitly defined. In addition, it is also possible that water molecules mediate H-bonding interactions between mannose and propionamide domains, an interaction that cannot be simulated without explicit treatment of the solvent. As shown in Figure 3, the aminoalanine moiety is located away from the metal ion. If **A**−αNH_2 occupied the initial position over the metal, then it would be expected to participate in an axial Pd···H−N interaction. This would contradict our NMR spectroscopic data, since one of the degenerate resonances from the interacting amine proton should be shifted to lower field. Indeed, examination of the final model revealed that axial Pd···H−X (X = calcd. C, O, N) interactions are absent. Finally, the thiazolium rings are shown in the *cis* conformation, by virtue of a quite weak NOE detected between their two aromatic protons (not used as distance constraint).

Antitumor Activity

The cytotoxicity of the Pd^{II}·bleomycin A2 complex was screened in two leukemia cell lines, human chronic myeloid leukemia (K562) and human histiocytic lymphoma (U937). K562 cells were incubated with higher concentrations of the drugs (100 and 300 μg/ml) than U937 cells (10 and 100 μg/ml), since the former are less sensitive to several anticancer agents. Incubation times were 6 to 48 hours. Two different methods were used, in order to assess the percentage of total alive cells (MTT) and the number of necrotic cells (Trypan Blue). The MTT assay is based on an enzymatic reaction and is therefore more sensitive and accurate. Since MTT is absorbed by the mitochondria, it is transformed into formazan by the enzyme succinic dehydrogenase. By assessing the activity of the mitochondrial dehydrogenases, the activity of viable cells is screened. The results obtained by both methods are presented in Table S4 (see Supporting Information).

The results obtained using the MTT assay, which are illustrated in Figure 4, show that the cytotoxicity exhibited by Pd^{II}·bleomycin is similar to that of the free drug. For both cell lines, the toxicity of the complex was measured as being 10 % lower than that of bleomycin, following the same trend as a function of time. A plausible explanation for the toxicity demonstrated by Pd^{II}·bleomycin is that the complex dissociates under cellular conditions. By virtue of its lack of redox activity and inability to mediate DNA-strand scission, the cytotoxicity is most probably due to the free drug released into the cells. Based on this hypothesis, the percentage of lower toxicity of Pd^{II}·bleomycin can be

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

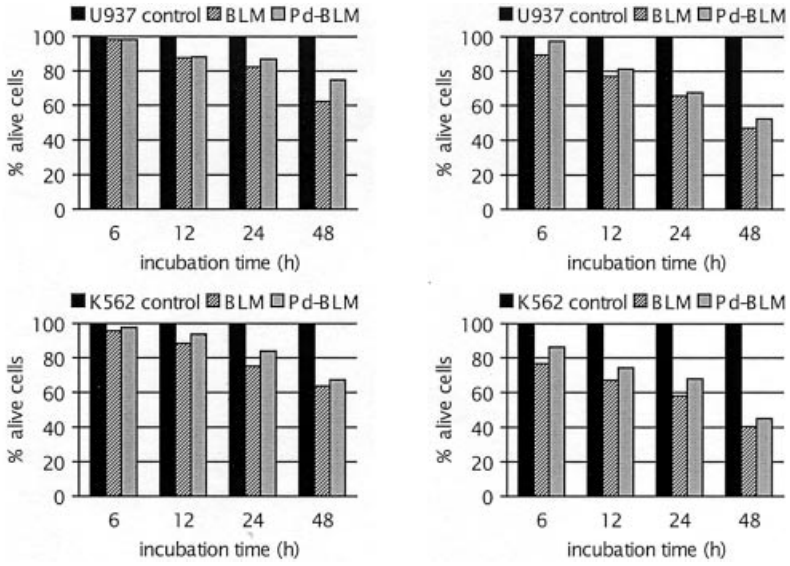

Figure 4. Antitumor activity of the Pd^{II}·bleomycin A2 complex (Pd-BLM) in comparison with that exhibited by the metal-free drug (BLM) as a function of time; the upper diagrams illustrate the results obtained by the MTT assay for U937 cells, after incubation with 10 μg/ml (left) and 100 μg/ml (right) of drugs; the lower diagrams were obtained by the same method as for K562 cells, after incubation with 100 μg/ml (left) and 300 μg/ml (right) of drugs

attributed to the presence of an equilibrium between the metal-bound and the apo-form of bleomycin. It is possible that the stability of the complex observed does not correspond to the same stability under cellular conditions, which are quite different to those of the NMR experiments.

In order to obtain more information on the stability of the complex, we performed NMR and circular dichroism (CD) studies on Pd^{II}·bleomycin in lower salt concentrations. For this reason we diluted a stock 10 mM solution of the complex (1.0 M NaCl, pH = 6.7) in H_2O, so that the final salt concentration was 4−150 mM, while the drug concentration was 0.04−1.5 mM. The pH was adjusted to 7.2 using aliquots from dilute NaOH and the solutions were incubated at 37 °C. All spectra were recorded at room temperature starting one hour after each dilution and lasting up to three days. Seeing that no changes occur either in the CD spectra (solutions with [drug] < 0.5 mM), or the NMR spectra (solutions with [drug] > 0.5 mM), we cannot support the hypothesis that Pd^{II}·bleomycin dissociates under cellular conditions.

On the other hand, we cannot rule out the possibility that Pd^{II}·bleomycin mediates the cytotoxicity observed, without requiring the redox activation of oxygen. Based on observations in vitro that the complex is not only able to bind strongly to DNA, but it can also displace Fe^{III} from its coordination site,[44] the cytotoxicity of Pd^{II}·bleomycin could be attributed to its DNA-binding ability or any other mechanism that may lead to the cell death (such as apoptosis). But taking into consideration that Pt^{II}·bleomycin exhibits a strong affinity for DNA and that the complexation of bleomycin and cisplatin gives rise to a decrease in the cytotoxicity of both drugs,[44] albeit screened in different cell lines, the hypothesis that Pd^{II}·bleomycin dissociates under cellular conditions seems more plausible. Still, further investigations should be carried out, in order to elucidate the mechanism of cytotoxicity. A related paradigm is the case of Cu·bleomycin, which was initially considered as an inhibitor of DNA cleavage.[52] However, later findings have suggested that it may assist in generating an active Fe·bleomycin species in vivo, a mechanism that still remains a puzzle.[12]

Conclusion

Following the procedure described herein, we prepared the Pd^{II}·bleomycin A2 complex in aqueous media and determined its solution structure using NMR spectroscopy in combination with molecular dynamics calculations. Our data reveal that bleomycin binds to Pd^{II} adopting a conformation similar to most of the models proposed either by NMR or X-ray crystallography. The same N ligands involved in the equatorial planes of Cu^{II}, Fe^{II}, Co^{II} and Co^{III}, Ga^{III} and In^{III} metallo-bleomycins are shown to be arranged in a square-planar geometry around Pd^{II}. Cytotoxicity measurements in two leukemia cell lines demonstrate that Pd^{II}·bleomycin is almost as toxic as the free drug, in contrast to Pt^{II}·bleomycin, which was found to have lower toxicity than apo-bleomycin.

Experimental Section

Sample Preparation: Bleocin and pure bleomycin A2 sulfate were a kind offer from Nippon Kayaku Co. Ltd. and were used without further purification. The complex was prepared by mixing equimolar amounts of K_2PdCl_4 (100 mM) and bleomycin (10 mM) in aqueous solutions containing NaCl (1.0 M). The pH of the solution, which immediately dropped below 2.0, was slowly increased to 3.5 using aliquots of dilute NaOH (1.0 M). After heating the mixture at 40 °C for 2 h, its pH, which continuously dropped, was then

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

increased to 5.0. This procedure was repeated twice before the pH was finally increased to 7.0. The mixture was then heated at 40 °C for 24 h, so as to assure complete formation of the complex and the pH was finally readjusted to 6.7. Its stability over a period of several months at room temperature is demonstrated by the fact that no changes were detected in the ^{1}H NMR spectra. Using the same procedure, Pd^{II}·bleomycin was also prepared in Millipore water for the cytotoxicity measurements.

NMR Experiments: Samples for the NMR experiments were prepared either in H_2O (10% D_2O) or D_2O 99.99%. All spectra were recorded on a Bruker Avance NMR spectrometer operating at proton frequency of 500.13 MHz. X-WIN NMR 2.6 (Bruker Analytik GmbH) was used to process the spectra and SPARKY 3.1,[53] running on a Linux PC, was used for the assignment and analysis of the 2D spectra. ^{1}H and ^{13}C chemical shift values were referenced to an internal standard, sodium 3-(trimethylsilyl)-1-propanesulfonate (TSP).

Two-dimensional NOESY (100, 200 and 400 ms mixing times), DQF COSY,[54] and TOCSY (MLEV-17 sequence with 35 and 70 ms mixing times)[55] experiments were performed at 278 and 298 K in H_2O and D_2O. Data sets with 2048 × 512 complex points were acquired with 7 KHz-sweep widths in both dimensions and 32 scans per t_1 increment. ^{1}H{^{13}C} HMQC[56] and HMBC[57] spectra were recorded at 278 and 298 K in H_2O and D_2O. Data sets with 1024 × 256 points were collected with 32 or 64 scans per t_1 increment and spectral widths of 6 KHz in the proton and 25 kHz in the carbon dimension. Solvent suppression for the H_2O samples was performed using excitation sculpting with gradients,[58] while for the D_2O samples a pre-saturation pulse was applied during the relaxation delay of 2.0 s. The indirect dimension was zero-filled up to 1024 data points and the FIDs were processed with either a combination of exponential and Gaussian weighting functions or a 90°-shifted sine-bell function.

Force Field Parameters: All molecular modelling calculations were performed with AMBER 6.[59] In order to accurately represent the bleomycin complex, the AMBER-94 force field was modified according to the guidelines of its authors.[60] Standard atom types were assigned to the atoms of bleomycin by analogy with their chemical environment. For the sugar atoms, we used parameters from the GLYCAM force field for modelling carbohydrates.[61] A new atom type was created for Pd^{II} using the van der Waals parameters R^* = 1.65 Å and ε = 0.20 kcal mol^{-1}, based on the crystallographic data of Bondi.[62] According to the calculations of Hambley,[63] these parameters reproduce quite well the metal−ligand separations in molecular mechanics force fields. The bond, angle and dihedral angle parameters of bleomycin were also chosen upon their analogy with existing parameters of AMBER, while those involving Pd^{II} were adapted from parameters developed for platinum compounds.[64] Equilibrium Pd−N bond lengths were set to R_o of 2.01 Å using a relatively low force constant of 100 kcal mol^{-1} Å^{-2}. For the N−Pd−N angles, θ_o of 90° or 180° with 40 kcal mol^{-1} rad^{-2} force constants were used, while dihedral angles involving the metal were set with zero force constants.

The atom-centred point charges of the complex were generated from the electrostatic potential of its molecular fragments. The equatorial plane of Pd^{II}·bleomycin comprising β-aminoalanine, pyrimidinyl propionamide and histidyl moieties was fitted as a whole. For the other domains we used the charges, which had been previously calculated for Ga^{III}·bleomycin.[22] Spin-restricted DFT calculations using Becke's three-parameter-hybrid functional with the correlation functional of Lee, Yang, and Parr (B3LYP)[65−67] were performed using the program package GAMESS.[68] The Los Alamos effective core potentials were applied on palladium,[69−71] and the 6−31G(d) basis set on all other atoms. The point charges were fitted to reproduce the electrostatic potential using the RESP method,[72] a two-stage approach where the equivalent methyl and methylene hydrogen atoms are restrained to have the same charge. In order to reassemble the charges of the entire molecule, the H-neutralization method was used.[73]

Restrained Molecular Dynamics: NOE signals from the NOESY spectrum (200 ms mixing time at 278 K, pH 6.7) were classified as strong, medium and weak by visual inspection of the cross-peak intensities and the constraints were set to an upper distance limit of 3.0, 4.0 and 5.0 Å, respectively. An additional 1.0 Å was allowed for NOEs involving methyl groups and ambiguous methylene protons. A total of 76 distance constraints were applied with a 50 kcal mol^{-1} Å^{-2} force constant, using a square-bottom-well function with parabolic sides out to 0.5 Å and then linear sides beyond that. Molecular dynamics calculations in vacuo were carried out at a time step of 1 fs with the distance-dependent dielectric constant algorithm of AMBER. The cut-off distance was set to 16.0 Å and the non-bonded pair list was updated every ten steps. Temperature regulation was performed using the Berendsen algorithm. For the heating and cooling stages, a bath coupling constant of 0.1−0.5 ps was applied, in order to assure a tighter coupling to the heat bath, while for the equilibration stages it was increased up to 2.0 ps, so as to allow sampling of more natural trajectories. Starting models were energy minimized prior to the simulated annealing calculations without restraints for 500 steps of the steepest descent method, followed by the conjugate gradient method until the rms gradient became less than 0.1.

Each model was subjected to 20 individual runs, while changing the initial velocities assigned. The annealing protocol consisted of five stages: (1) heating the system from 5 K up to 1000 K during the first 20 ps, (2) gradual application of the constraints for a period of 10 ps, (3) high-temperature equilibration for 20 ps, (4) slow cooling down to 300 K during the next 20 ps and (5) final dynamics run for 50 ps at 300 K. A final model from each iteration was generated by mass-weighted rms fitting and averaging the coordinates from the last 20 ps of the trajectory (100 structures). Energy minimization with restraints was performed as above but until the rms gradient became less than 0.01. The results presented in Table 1 were derived from the ten best structures, which were favoured by their low potential energy and minimal deviations from the NMR constraints.

Cell Lines and Cytotoxicity Assays: RPMI 1640, Fetal Bovine Serum (FBS), penicillin, streptomycin, Phosphate Buffered Saline (PBS) and HEPES buffer were purchased from BIOCHROM. L-Glutamine was purchased from AppliChem. Trypan Blue, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT), sodium dodecyl sulfate (SDS), formamide and $NaHCO_3$ were purchased from Sigma−Aldrich. Two human cell lines routinely maintained in the Biology department of NCSR "Demokritos" were used in this study. Chronic myelogenic leukemia (K562) and human promyelocytic cell line (U937) were maintained in RPMI 1640 medium containing 10% (v/v) FBS, 2 mM L-glutamine, 0.85 g/l $NaHCO_3$, 25 mM HEPES, 200 U/ml penicillin and 100 μg/ml streptomycin at 37 C in a 5% CO_2 atmosphere. The pH of the medium was adjusted to 7.3. In all experiments, cells were cultured to the logarithmic phase growth over a period of 48 h, starting from a culture density of 3−5 × 10^5 cells/ml.

The viability of the cells was determined by the Trypan Blue dye-exclusion method and cytotoxicity was assessed by the MTT assay.[74−77] Briefly, logarithmically grown cells were plated in 25-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mL flasks and treated with two concentrations of each drug. Untreated cells were used as a negative control. Incubation was carried out at 37 °C for different time periods, starting from a 6 h incubation up to 50 h. After drug incubation for various time periods at 37 °C, MTT (50 µl, 10 mg/ml) was added to each well, followed by a 4 h incubation at 37 C. The reaction results in the reduction of MTT by the mitochondrial dehydrogenases of viable cells to a purple formazan product. Cells were lysed using DMF solution (55 mL H_2O + 12.5 g SDS + 45 mL formamide, pH 4.7) and left overnight at 37 °C. After centrifugation, 200 µL of each sample were placed in 96-well microtiter plates in duplicate and $OD_{550\ nm}$ was determined in an ELISA plate reader. The results are expressed as the percentage of alive cells, calculated from MTT reduction and it is assumed that the absorbance of control cells is 100%. In addition, cell viability in U937 and K562 cell lines was assessed by the method of Trypan Blue exclusion. Trypan blue (0.2%, 2 µl) was added to aliquots of cell-containing media (18 µl) and the percentage of viable cells was determined by counting the number of cells able to exclude the dye on an hemocytometer. All of the above experiments were performed in duplicate.

Supporting Information (see also the footnote on the first page of this article): Two tables giving the ^1H and ^{13}C chemical shift values of Pd^{II}·bleomycin A2 in comparison with those obtained for the metal-free bleomycin A2, a table with the categorized NOE intensities, a table with all the results from the cytotoxicity measurements, a figure showing an expanded region of the $^1H\{^{13}C\}$ HMQC spectrum and three figures illustrating the solution structure of Pd^{II}·bleomycin A2 along with selected structural data of the coordination sphere, potential intramolecular H-bonds and a comparison with the crystal structure of Cu^{II}·bleomycin.

Acknowledgments

We are grateful to Prof. Ivano Bertini for his hospitality at the University of Florence (CERM) in the framework of the European Large Scale Research Infrastructure. We thank Prof. Enzo Alessio for his critical comments on the manuscript. This work has been supported with a grant by the General Secretariat for Research and Technology of Greece.

Oxidation of *N*-(4-Chlorophenyl)-*N*′-hydroxyguanidine to *N*-(4-Chlorophenyl)urea and Nitric Oxide by Photoexcited Iron Porphyrins

Andrea Maldotti,*[a] Alessandra Molinari,[a] Irene Vitali,[a] Elena Ganzaroli,[a] Pierrette Battioni,[b] Delphine Mathieu,[b] and Daniel Mansuy[b]

Keywords: O−O activation / Nitric oxide / Photooxidation / Porphyrins / Protein models

Photochemical excitation ($\lambda > 350$ nm) of chloro[*meso*-tetrakis(2,6-dichlorophenyl)porphyrin]iron(III) [Fe^{III}(TDCPP)Cl] and chloro[*meso*-tetra(α,α,α,α-pivalamidophenyl)porphyrin]-iron(III) [Fe^{III}(TpivPP)Cl] induces the oxidation of coordinated *N*-(4-chlorophenyl)-*N*′-hydroxyguanidine (**1**) by molecular oxygen, to give iminoxyl radicals and the $Fe^{II}(O_2)$ [or $Fe^{III}(O_2^{\cdot})$] adduct. This complex can be accumulated in significant amounts using [Fe^{III}(TpivPP)Cl]. The primary photoproducts give rise to secondary reactions that lead to the formation of *N*-(4-chlorophenyl)urea (**2**) as the main end-product of **1**. The conversion of **1** into **2** is accompanied by the formation of NO, as revealed both by an ESR spin-trapping technique and in the form of its stable end-products NO_2^- and NO_3^-. The presence of 1-methyl imidazole (1-MeIm) coordinated in axial position has a significant positive effect on the photoinduced production of **2** and NO from the hydroxyguanidine **1**. The observation that radical scavengers inhibit the photooxidation process strongly supports the possibility that the reaction pathway resembles a radical-type autoxidation mechanism, where the very fast reaction of O_2 with the ferrous porphyrin in the presence of the photogenerated iminoxyl radical should yield an iron-peroxo intermediate as precursor of the urea **2** and NO.

Introduction

The photochemical excitation of iron porphyrin complexes [Fe^{III}(P)] is an important tool for obtaining biomimetic model systems of interest in oxygenase-like catalytic oxidation.[1] All these systems are characterized by common primary photoprocesses. Irradiation in axial ligand (L) to metal charge-transfer bands (λ = 300−400 nm) induces a homolytic cleavage of the Fe^{III}(L) bond, which causes oxidation and detachment of L$^{\cdot}$ as a radical species and reduction of Fe^{III} to Fe^{II} [Equation (1)]. It has been demonstrated that O_2 is able to effectively react with the ferrous intermediate, thus inhibiting solvent-cage effects [back reaction in Equation (1)]. A peculiar aspect of this process is that a monoelectronic reductive activation of O_2 occurs through the formation of a dioxyiron complex $Fe^{II}(P)(O_2)$ or $Fe^{III}(P)(O_2^{\cdot})$ according to Equation (2). A two-electron reduction of O_2 may also be achieved when the described photochemical process is carried out in the presence of suitable hydrocarbons (RH). Under these conditions, alkyl radicals (R$^{\cdot}$) may be formed as a consequence of the reaction between the photogenerated L$^{\cdot}$ radicals and RH. The extremely fast subsequent reaction of O_2 with Fe^{II}(P) in the presence of R$^{\cdot}$ may lead to the formation of alkyl-peroxo complexes according to Equation (3).[2] In all cases, the photoassisted activation of O_2 occurs in a catalytic manner, since the starting iron porphyrin is restored after its reoxidation and after coordination of a new equivalent of axial ligand.

(3)

Chloro[*meso*-tetrakis(2,6-dichlorophenyl)porphyrin]-iron(III) [Fe^{III}(TDCPP)Cl] has been often employed in the photocatalytic activation of O_2 as the bulky chlorine atoms in its *meso*-aryl groups prevent the well-known bimolecular

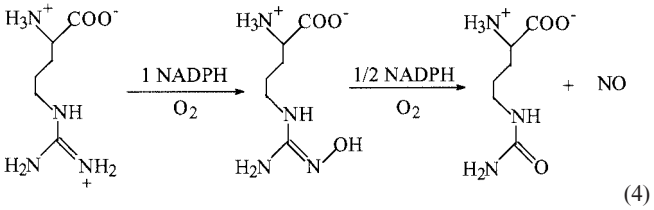
reaction of the Fe^{II}dioxy complex to give μ-oxo dimers as the final product.[3] Moreover, they provide a steric protection of the porphyrin ring against its radical-induced oxidative degradation.[4]

One intriguing and up-to-date aspect of the photocatalytic processes described above is their possibility to generate reactive intermediates such as $Fe^{III}(P)(O_2^{\cdot})$, $Fe^{III}(P)$-(OOR) and radical species that might be relevant also to the mechanism of nitric oxide synthases (NOSs), as explained below.

All the three NOS isoforms in mammals catalyse the stepwise oxidation of L-arginine to nitric oxide (NO) by O_2 and NADPH.[5] This process occurs in the NOS oxygenase domain, which contains heme and tetrahydrobiopterin (usually indicated as BH_4) as cofactors.[6] The NO synthesis mechanism is complex and not completely understood. A first step is likely a classical monooxygenation of L-arginine to give *N*-hydroxy-L-arginine, which occurs with the consumption of one mol of O_2 and one mol of NADPH [first step in Equation (4)]. The generally accepted P450 reaction mechanism can account for the stoichiometry and the product formation.[7] Reduction of ferric heme is followed by the formation of a Fe^{II}dioxy complex that accepts a second electron from NADPH to form an iron-peroxo intermediate. The subsequent O−O bond scission yields a presumed iron-oxo species that is able to hydroxylate a guanidinic nitrogen of L-arginine.



(4)

The second step involves an oxidative cleavage of the C=NOH bond of *N*-hydroxy-L-arginine to give the final products NO and L-citrulline through the consumption of one mol of O_2 and only one electron coming from 0.5 mol of NADPH [second step in Equation (4)].[8] A monoelectronic reduction of ferric heme enables O_2 binding and forms an iron-dioxy complex [$Fe^{II}(P)(O_2)$ or $Fe^{III}(P)(O_2^{\cdot})$]. A number of experimental results are consistent with BH_4 having a redox function in the second step of NO synthesis. Stuehr et al.[9] have proposed that the cofactor BH_4 may be able to provide a second electron to $Fe^{III}(P)(O_2^{\cdot})$ to yield an iron-peroxo intermediate as ultimate oxidant able to react with bound *N*-hydroxy-L-arginine according to Scheme 1 (steps a and b). The subsequent back electron transfer to the $BH_4^{+\cdot}$ radical should yield the final products NO and L-citrulline together with BH_4 and $Fe^{III}(P)$ in their starting conditions (step c).

The formation of radical intermediates has been proposed by Groves et al.[5d,10] for model systems that mimic many important properties of the NOS-catalysed oxidation of *N*-hydroxy-L-arginine. This mechanism, summarized in Scheme 2, involves the oxidation of *N*-hydroxy-L-arginine to the corresponding iminoxyl radical with the simultaneous reduction of $Fe^{III}(P)$ to $Fe^{II}(P)$ (step a). The insertion of O_2 between the ferrous porphyrin and the radical in its α-nitroso form would generate an iron-peroxo intermediate (steps b and c). The subsequent homolytic cleavage of its O−O bond may lead to the formation of NO, L-citrulline and $Fe^{IV}(P)(O)$ (step d), which can immediately undergo a single-electron reduction with, possibly, the involvement of BH_4 (step e).

The very limited number of substrates for NOSs known so far suggests that highly specific structural features are required for NO generation by these enzymes. However, it has been recently shown that NOSs are also able to catalyse the oxidation of some analogues of *N*-hydroxy-L-arginine.[11] In particular, it has been found that mixtures of *N*-arylurea, *N*-arylcyanamide and NO are formed when several *N*-aryl-*N*′-hydroxyguanidines are incubated in the presence of NOS. These substrates are of particular interest in mechanistic studies with model systems since, contrary to *N*-hydroxy-L-arginine, their oxidation products are relatively stable and easy to analyse.

In this work, we have used as oxidizable substrate a simple *N*-aryl-*N*′-hydroxyguanidine: *N*-(4-chlorophenyl)-*N*′-hydroxyguanidine (**1**, see Scheme 3). We have investigated its redox reactivity in the presence of photoexcited iron porphyrins with the aim of inducing the reductive activation of O_2 in order to obtain intermediates analogous to those involved in the NOS-dependent oxidation of *N*-hydroxyarginine. The possibility that the photoinduced redox processes may be affected by the presence of *N*-methyl imidazole (1-MeIm) has also been evaluated.

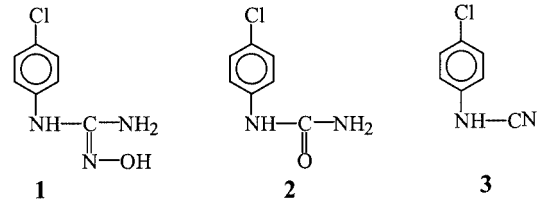

Scheme 3. *N*-(4-Chlorophenyl)-*N*′-hydroxyguanidine (**1**), *N*-(4-chlorophenyl)urea (**2**) and *N*-(4-chlorophenyl)cyanamide (**3**)

The iron porphyrins employed are shown in Figure 1. [Fe^{III}(TDCPP)Cl] has been chosen because of its stability under photocatalytic conditions. The chloro[*meso*-tetra(α,α,α,α-pivalamidophenyl)porphyrin]iron(III) [Fe^{III}(TpivPP)Cl] is expected to give important information about the possible formation and reactivity of $Fe^{II}(P)(O_2)$ adducts as it has a protective enclosure for binding oxygen on one side of the porphyrin ring and it is able to form a stable adduct with O_2.[12]

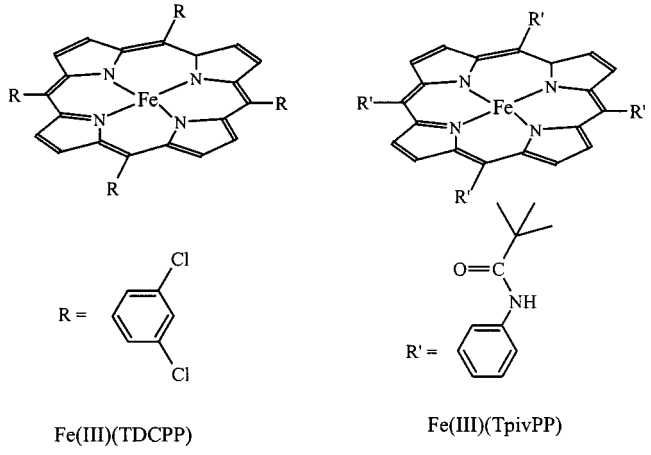

Figure 1. Structure of the investigated iron porphyrins

Results and Discussion

Biomimetic Photooxidation of *N*-(4-Chlorophenyl)-*N*′-hydroxyguanidine (1)

The photochemical experiments described below were carried out by irradiating CH_3CN solutions of [Fe^{III}(TDCPP)Cl] (1×10^{-5} M) and **1** (1×10^{-3} M) in the presence of 1-MeIm, (5×10^{-5} M) [Fe^{III}(TDCPP)Cl/**1**/1-MeIm system] or without 1-MeIm [Fe^{III}(TDCPP)Cl/**1** system] with light of wavelength higher than 350 nm. First of all, we report some UV/Vis results shedding light on the nature of the main light-absorbing species present in these systems. More specifically, we were interested in defining the nature of the iron porphyrin axial ligand that may be involved in the primary photochemical process in Equation (1).

It has been reported previously that numerous *N*-hydroxyguanidines such as **1** are able to bind through their oxygen atom to the ferric heme group of both microperoxidase-8 and NOS itself.[13] The consequent formation of stable, low-spin complexes is accompanied by significant changes in the UV/Vis spectra. In particular, the coordination of *N*-hydroxyguanidines causes red shifts of the Soret peak. Table 1 (runs a and b) provides evidence that the addition of **1** to a [Fe^{III}(TDCPP)Cl] solution induces an analogous shift of the Soret band from 412 nm to 422 nm, thus indicating that **1** is coordinated in the axial position to the metal centre to give the complex [Fe^{III}(TDCPP)(**1**)Cl]. Table 1 (run c) and Figure 2 show that different spectral variations were obtained when both **1** and 1-MeIm were added to [Fe^{III}(TDCPP)Cl]. This result, together with the observation that addition of 1-MeIm alone causes other spectral changes (run d) allows us to infer that solution equilibria in the [Fe^{III}(TDCPP)Cl]/**1**/1-MeIm system lead mainly to the formation of a porphyrin complex that contains hydroxyguanidine and 1-MeIm bound in the two axial positions (step a in Scheme 4).

Table 1. UV/Vis spectroscopic data of [Fe^{III}(TDCPP)Cl]

Run	System[a]	Absorption maxima (nm)
a	Fe^{III}(TDCPP)Cl	325, 412, 570
b	Fe^{III}(TDCPP)Cl/**1**	422, 541
c	Fe^{III}(TDCPP)Cl/**1**/1-MeIm	426, 535
d	Fe^{III}(TDCPP)Cl/1-MeIm	327, 413, 569
e	Fe^{III}(TDCPP)Cl/**1**/1-MeIm/hν	416, 505, 546

[a] [Fe^{III}(TDCPP)Cl] (CH_3CN): 1×10^{-5} M; [**1**]: 1×10^{-3} M; [1-MeIm]: 5×10^{-5} M. Irradiation in run e was carried out at 22 ± 1 °C in the presence of 760 Torr of oxygen; excitation wavelength: $\lambda > 350$ nm; irradiation time: 30 min.

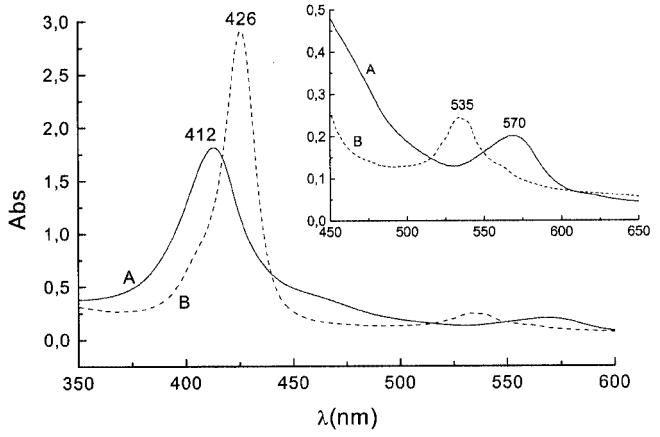

Figure 2. A) UV/Vis spectrum of a CH_3CN solution of [Fe^{III}(TDCPP)Cl] (1×10^{-5} M); B) UV/Vis spectrum of a CH_3CN solution of [Fe^{III}(TDCPP)Cl] (1×10^{-5} M) in the presence of **1** (1×10^{-3} M), and 1-MeIm (5×10^{-5} M)

The [Fe^{III}(TDCPP)Cl]/**1**/1-MeIm system was irradiated for 30 minutes in the presence of 760 torr of O_2. HPLC analyses revealed the formation of both *N*-(4-chlorophenyl)urea (**2**) and *N*-(4-chlorophenyl)cyanamide (**3**; Scheme 3), by comparison of their retention times with those of authentic samples, and by co-injection with the authentic compounds.

Table 2 reports the yields of the described photoprocess in terms of amount of detected products. The first row of this table provides evidence that the urea **2** is the main end-product of the hydroxyguanidine **1**. In agreement with an NOS-like oxidation mechanism, the conversion of **1** to **2** approximately matches the formation of NO, which was revealed in the form of its stable end-products NO_2^- and NO_3^-. Table 2 shows that the cyanamide **3** is a second minor photoproduct. Literature data show that the oxidation of the hydroxyguanidine **1** to the corresponding cyanamide is accompanied by the formation of NO^- instead of NO.[14] This intermediate, after dimerization, protonation and dehydration would release gaseous N_2O without the formation of NO_2^- and NO_3^-.

Control experiments indicated that the formation of **2**, **3**, NO_2^- and NO_3^- from **1** did not occur in appreciable amounts in the dark or in the absence of either [Fe^{III}(TDCPP)Cl] or O_2. We also verified that the photoexciting wavelengths employed here did not cause any appreciable degradation of **2** and **3**. Finally, we found UV/Vis evidence that neither **2** nor **3** competes with **1** in binding the metal centre at the concentrations that they typically reach during the photochemical experiment.

[Fe^{III}(TDCPP)Cl] underwent significant spectral changes when irradiated in the presence of **1** and 1-MeIm. As shown in Table 1 (compare runs c and e), we observed a blue shift

Table 2. Oxidation of **1** by photoexcited [Fe^{III}(TDCPP)Cl] and by the [Fe^{III}(TpivPP)($O_2^{\cdot}$)(1-MeIm)] adduct

System	Products[a] (μM) Urea **2**	Cyanamide **3**	NO_2^-	NO_3^-
Fe^{III}(TDCPP)Cl/**1**/1-MeIm[b]	6.6 ± 0.6	1.5 ± 0.1	2.2 ± 0.2	2.7 ± 0.2
Fe^{III}(TDCPP)Cl/**1**[b]	1.6 ± 0.1	1.5 ± 0.1	<0.6	<0.6
Fe^{III}(TDCPP)Cl/**1**/1-MeIm/PBN[b]	3.5 ± 0.3	1.5 ± 0.1	1.2 ± 0.2	1.3 ± 0.2
Fe^{III}(TpivPP)($O_2^{\cdot}$)/**1**/1-MeIm[c]	1 ± 0.1	<0.2	<0.6	<0.6

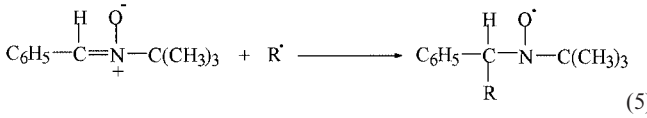
[a] Results are expressed in μmol dm^{-3} of products formed and are averages (± standard deviation) of between three and five experiments. [b] Irradiations were carried out at 22 ± 1 °C in the presence of 760 Torr of oxygen. Excitation wavelength: $\lambda > 350$ nm. Irradiation time: 30 minutes. [Fe^{III}(P)]: 1×10^{-5} M; [**1**]: 1×10^{-3} M; [1-MeIm]: 5×10^{-5} M; [PBN]: 1×10^{-4} M. [c] The [Fe^{III}(TpivPP)($O_2^{\cdot}$)]/1-MeIm adduct was obtained by dissolving [Fe^{III}(TpivPP)Cl] (1×10^{-5} M) in a mixture of acetone and ethanol (95:5, v/v) in the presence of 1-MeIm (5×10^{-5} M). The solution was degassed (less than 1×10^{-5} Torr), irradiated (90 s) and put in contact with O_2 at low temperature (−5 to −8 °C). Then, **1** (1×10^{-3} M) was added to the obtained sample.

of the porphyrin Soret band from 426 nm to 416 nm, as well as the formation of two new bands at 505 and 546 nm. These spectral variations may be ascribed to axial coordination of the end-product NO_2^- anion on the basis of literature data concerning the effect of binding of this anion on the spectroscopic properties of iron porphyrin complexes[15] and by the observation that progressive addition of $NaNO_2$ to the [Fe^{III}(TDCPP)]/**1**/1-MeIm system induced analogous spectral variations.

The data reported in the second line of Table 2 show that the photoinduced oxidation of **1** occurred to some extent also in the absence of 1-MeIm. On the other hand, a significant reduction in the production of **2** and NO was observed in this case, indicating the main role of coordinated 1-MeIm in the photoinduced formation of these products.

Spin-Trapping Investigation and Proposed Reaction Pathways

Evidence for the oxidation of bound *N*-hydroxyguanidine (**1**) to radical species was provided by an ESR spin-trapping investigation. This technique is a powerful tool for detecting the formation of short-lived radicals[16] and has been fruitfully employed in photochemical studies on iron porphyrins.[2a,4] It is based on the ability of some molecules, such as α-phenyl-*N*-*tert*-butylnitrone (PBN), to trap radicals ($R^{\cdot}$) and give paramagnetic nitroxides stable enough to be studied by ESR spectroscopy [Equation (5)].



(5)

The [Fe^{III}(TDCPP)Cl]/**1**/1-MeIm system was irradiated in the presence of PBN (5×10^{-3} M) directly in the cavity of an ESR spectrometer. Figure 3 shows that the spectrum obtained consists of a triplet of doublets, with hyperfine splitting constants $a_N = 14.75$ G and $a_H = 2.77$ G. This signal may be ascribed to the trapping of a radical species originating from the photooxidation of the bound hydroxyguanidine **1** according to step b in Scheme 4. In line with this statement, blank experiments carried out without **1** did not give any ESR signal.

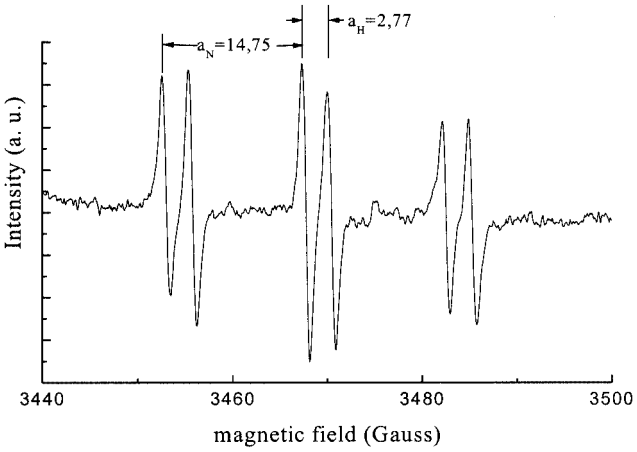


Figure 3. ESR spin-trapping spectrum obtained during irradiation of a CH_3CN solution of [Fe^{III}(TDCPP)Cl] (1×10^{-5} M) in the presence of **1** (1×10^{-3} M), 1-MeIm (5×10^{-5} M) and PBN (5×10^{-3} M)

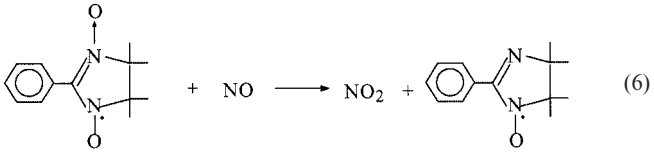
Row 3 in Table 2 reports the concentration of **2**, **3**, NO_2^- and NO_3^- after 30 minutes irradiation of the [Fe^{III}(TDCPP)Cl]/**1**/1-MeIm system carried out in the presence of PBN (1×10^{-4} M). The radical scavenger did not affect at all the formation of the cyanamide **3**, while it partially inhibited the production of the urea **2**, NO_2^- and NO_3^-.

The above results are consistent with a reaction pathway for the light-induced oxidation of the hydroxyguanidine **1** by [Fe^{III}(TDCPP)Cl] that resembles the radical-type autoxidation mechanism mentioned in the introduction.[5d,10] In line with the general mechanism shown in Equations (1)−(3), peroxidic intermediates should be formed as a consequence of the very fast reaction of O_2 with the photogenerated ferrous porphyrin in the presence of iminoxyl radicals (steps c and d in Scheme 4). The formation of the urea **2** and NO likely occurs as a consequence of a homolytic cleavage of the O−O bond according to steps e and f. The possibility that photogenerated alkyl hydroperoxides may decompose by the above reactions has been reported previously.[1c,2] It seems likely that the well-known ability of

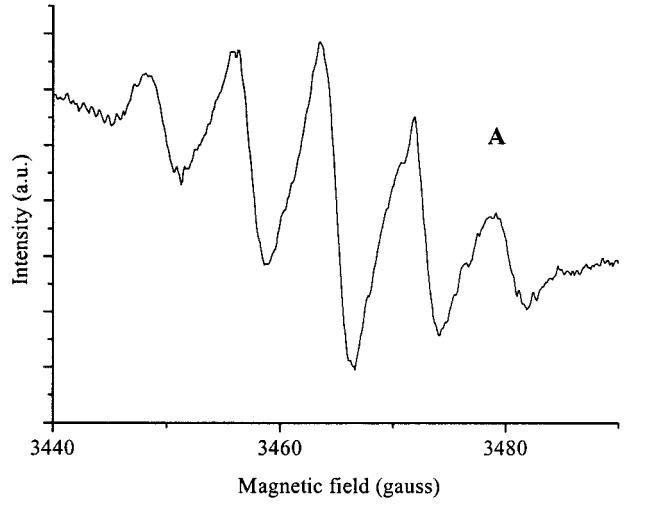
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bound 1-MeIm to stabilize this photogenerated ferrous-dioxy intermediate $Fe^{III}(O_2^{\cdot})$[12b] may be the reason for the observed positive effect of this nitrogen base on the final product yields.

An additional possibility to take into account is that oxidation of **1** may occur as a consequence of its reaction with $O_2^{\cdot -}$, which could originate from $Fe^{III}(O_2^{\cdot})$ dissociation (steps g and h). Indeed, it has been already demonstrated that $O_2^{\cdot -}$ can react with **1** to give the cyanamide **3** as the major product.[17] The low yield of this product indicates that this possibility is only a minor process in the photoinduced oxidation of **1** described here.



(6)



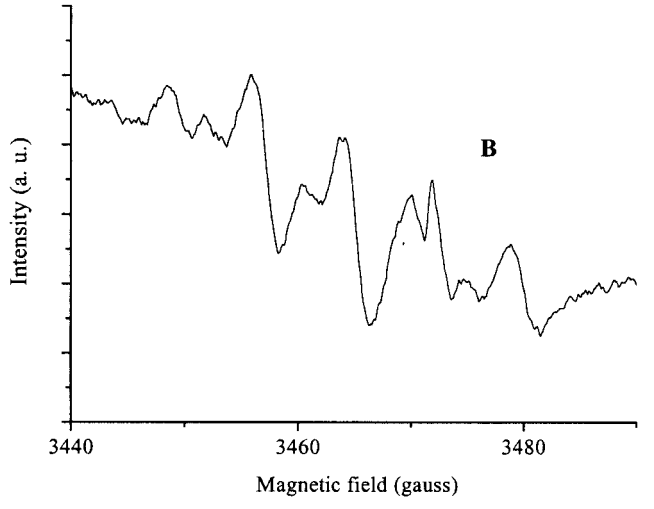


Figure 4. A) ESR spectrum of PTIO (2×10^{-6} M) in a CH_3CN solution containing **1** (1×10^{-3} M), [Fe^{III}(TDCPP)Cl] (1×10^{-5} M) and 1-MeIm (5×10^{-5} M); B) curve A after ten minutes irradiation

The ESR spin-trapping technique was also used to obtain direct evidence for the formation of NO. We employed 2-phenyl-4,4,5,5-tetramethylimidazoline-1-oxyl 3-oxide (PTIO) as an NO-specific reactant.[18] The ESR spectrum of PTIO consists of a 1:2:3:2:1 quintet due to the interaction of one unpaired electron with two equivalent nitrogen atoms (a_N = 8.2 G). Nitric oxide reacts with this compound according to Equation (6) to give an imino-nitroxide (PTI), in which two different nitrogen atoms generate a different and more complex spectrum with nine lines (a_N^1 = 9.8 G and a_N^2 = 4.4 G).

Curve A in Figure 4 shows the five-line ESR spectrum of PTIO (2×10^{-6} M) in the presence of **1** (1×10^{-3} M), [Fe^{III}(TDCPP)Cl] (1×10^{-5} M) and 1-MeIm (5×10^{-5} M). The same signals were obtained when **1** or [Fe^{III}-(TDCPP)Cl] or 1-MeIm were omitted from the reaction mixture. Ten-minute photoexcitation led to a decrease of the intensity of this spectrum together with the growth of new signals, as shown by Curve B in Figure 4. The position of these signals corresponds very well to that expected for the nitroxide PTI.[17] Negligible spectral changes were observed in the dark when the photochemical experiment was carried out in the absence of [Fe^{III}(TDCPP)Cl] or **1**.

Reactivity of Photogenerated [Fe^{II}(TpivPP)(O_2)(1-MeIm)]

Irradiation of [Fe^{III}(TpivPP)Cl] in the presence of **1**, 1-MeIm and O_2 gave results very similar to those obtained with the [Fe^{III}(TDCPP)Cl]/**1**/1-MeIm system from a qualitative point of view. However, experiments carried out with this porphyrin allowed us to accumulate only traces of the end-products, because it undergoes a very fast degradation under aerobic photochemical conditions to give small colourless fragments. This instability may be ascribed to the lack of hindered groups able to protect the *meso* positions from oxidative attacks.

In spite of this limitation, which forced us to limit the photocatalytic characterization previously described to [Fe^{III}(TDCPP)Cl], with [Fe^{III}(TpivPP)Cl] we could obtain direct experimental evidence of the photoinduced formation of a [Fe^{II}(TpivPP)(O_2)(1-MeIm)] adduct, which, in the previous discussion, has only been supposed for [Fe^{III}-(TDCPP)Cl].

The first step for obtaining the [Fe^{II}(TpivPP)(O_2)(1-MeIm)] adduct was the photoinduced reduction of the ferric porphyrin under anaerobic conditions. This result was obtained by irradiating (for 90 s, $\lambda > 350$ nm) deoxygenated solutions of [Fe^{III}(TpivPP)Cl] (1×10^{-5} M) containing 1-MeIm (5×10^{-5} M). We decided to use an acetone/ethanol (95:5) mixture as solvent knowing that, in these conditions, ethanol works as coordinating solvent and that the primary photochemical process is expected to be the reduction of Fe^{III} to Fe^{II} by the bound ethanolate, in line with the general mechanism shown in Equation (1).[2,4] Accordingly, the UV/Vis spectrum observed after irradiation (Curve A in Figure 5) presents the typical absorption at 567 nm of the ferrous porphyrin. The spectral changes (Curve B) that accompany the subsequent oxygenation of the sample at low temperature (−5 to −8 °C) are consistent with the forma-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion of [Fe^{II}(TpivPP)(O_2)(1-MeIm)] or [Fe^{III}(TpivPP)-(O_2·)(1-MeIm)] adduct.[12]

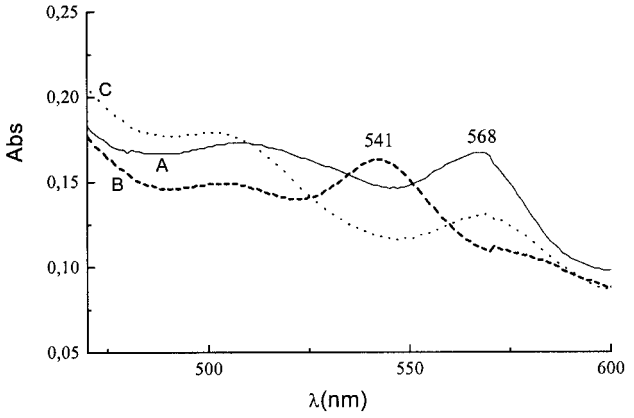

Figure 5. A) UV/Vis spectrum of an acetone/ethanol (95:5) solution of [Fe^{III}(TpivPP)Cl] (1×10^{-5} M) and 1-MeIm (5×10^{-5} M) after 90 s irradiation under anaerobic conditions; B) curve A after subsequent oxygenation of the sample at −8 °C; C) curve B after a second deoxygenation

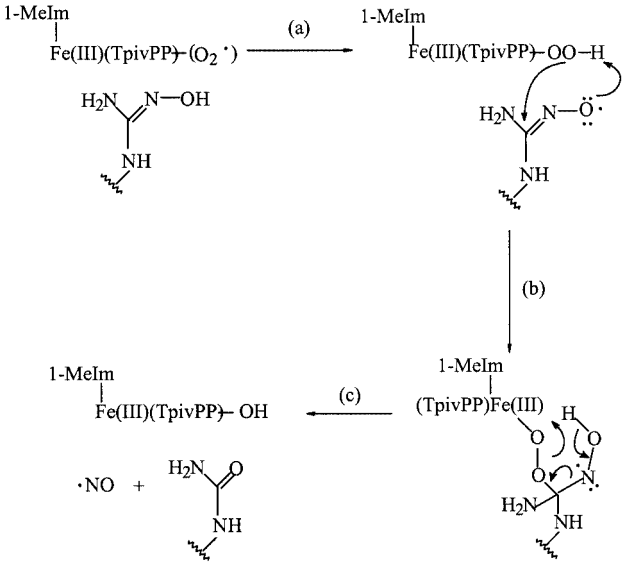

Scheme 5. Oxidation of **1** by the [Fe^{III}(TpivPP)(O_2·)(1-MeIm)] adduct

A second deoxygenation of this solution regenerated the spectrum of the ferrous porphyrin deprived of O_2. Figure 5 shows that this oxygenation/deoxygenation cycle is not completely reversible, probably due to irreversible oxidation of the porphyrin ring. The O_2 binding reversibility to Fe^{II}-(TpivPP) has been demonstrated and discussed in depth by Collman in previous fundamental papers.[12] The novelty of this work is that we observe the same binding reversibility using light rather than chemical reducing agents.

The possibility of accumulating significant amounts of the [Fe^{II}(TpivPP)(O_2)(1-MeIm)] adduct enabled us to investigate its possible reactivity towards the hydroxyguanidine **1**. In fact, it should be taken into account that the [Fe^{II}(TpivPP)(O_2)(1-MeIm)] species might undergo reduction by **1** to give an iron-peroxo intermediate,[19] although a number of results seem to argue against a reaction between the Fe^{III}(P)(O_2·) of NOS and *N*-hydroxy-L-arginine.[9a,9b,20]

Table 2 shows that the addition of **1** to the photogenerated [Fe^{III}(TpivPP)(O_2·)(1-MeIm)] led to a detectable amount of urea **2** with a yield of 80% with respect to the sum of **2** and **3**. A possible reaction pathway explaining this result is given in Scheme 5. The [Fe^{III}(TpivPP)(O_2·)-(1-MeIm)] intermediate might abstract the hydrogen atom of the hydroxyguanidine hydroxy group to furnish a hydroperoxo complex (step a), whose well-known nucleophilicity should allow it to react with the iminoxy radical (step b).[19,21] Finally, a subsequent pericyclic reaction of the peroxy intermediate is expected to form NO and **2** according to step c. The possibility that the conversion of **1** to **2** and NO upon irradiation of the [Fe^{III}(TDCPP)Cl]/**1**/1-MeIm system may also occur, at least in part, through the described mechanism cannot be ruled out.

The formation of urea as a major product of the reaction between [Fe^{II}(TpivPP)(O_2)(1-MeIm)] and **1** was confirmed by an additional experiment where the [Fe^{II}(TpivPP)(O_2)(1-MeIm)] adduct was prepared with a chemical reducing agent according to previous work (see Exp. Sect.).[12b] Addition of the hydroxyguanidine **1** to the chemically obtained [Fe^{II}(TpivPP)(O_2)(1-MeIm)] led to the formation of a detectable amount of the urea **2** with a yield of about the 65% with respect to the sum of **2** and **3**. This chemoselectivity in the production of urea is in line with that obtained using light to form [Fe^{II}(TpivPP)(O_2)(1-MeIm)]. The observed small differences of the **2**:**3** concentration ratios may be ascribed to the experimental error inherent in the HPLC analysis and to the different experimental conditions that we were forced to employ in the two approaches.

Conclusion

The aforementioned results show that photochemical excitation of iron porphyrins is a suitable means of inducing the oxidation of the hydroxyguanidine **1**. This reaction presents important similarities with the oxidation of the endogenous *N*-hydroxy-L-arginine by heme-containing metalloenzyme nitric oxide synthases (NOSs) and their model systems.

Coordinated hydroxyguanidine **1** presents a photoreactivity that typically characterizes many axial ligands, undergoing oxidation to radical species. The simultaneous formation of Fe^{III}(O_2·) is a key point for the oxidation of **1**.

The two iron porphyrin complexes employed here have provided complementary results. Photochemical excitation of [Fe^{III}(TDCPP)Cl] in the presence of O_2 and 1-MeIm revealed that the urea **2** is the main end-product of **1**. In agreement with an NOS-like oxidation mechanism, the conversion of **1** to **2** approximately matches the formation of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

NO, as revealed by both ESR spin-trapping experiments, and in the form of its stable end-products NO_2^- and NO_3^-. A significant reduction in the production of **2** and NO was observed in the absence of 1-MeIm, due to the main role of coordinated 1-MeIm in stabilizing the $Fe^{III}(O_2^{\cdot})$ intermediate.

The ability of radical scavengers to inhibit the production of both the urea **2** and NO strongly supports the possibility that the reaction pathway resembles a radical-type autoxidation mechanism, where the very fast reaction of O_2 with the ferrous porphyrin in the presence of the photogenerated iminoxyl radical should yield an iron-peroxo intermediate as precursor of **2** and NO.

The use of [Fe^{III}(TpivPP)Cl] provides the first experimental evidence for the photoinduced formation of an iron-dioxy adduct. Moreover, the observed reactivity of the [Fe^{II}(TpivPP)(O_2)(1-MeIm)] complex indicates that iron-peroxo species able to generate the urea **2** may be also formed as a consequence of the reduction of the $Fe^{III}(O_2^{-\cdot})$ intermediate by the hydroxyguanidine **1** itself.

The described results give important indications about the reactivity of iron-dioxy complexes that are in good agreement with current opinion on the second step of NOS catalysis. In particular, our results are in line with the hypothesis that the formation of iron-peroxo intermediates is essential for the oxidation of *N*-hydroxy-L-arginine to L-citrulline and NO.

Experimental Section

Materials: The complexes [Fe^{III}(TDCPP)Cl] and [Fe^{III}(TpivPP)Cl] were prepared and purified as described elsewhere.[22,12b] The hydroxyguanidine **1**, the urea **2** and the cianamide **3** were synthesized following previous procedures.[11a] *N*-Methyl imidazole (1-MeIm), α-phenyl-*N*-*tert*-butylnitrone (PBN) and $NaNO_2$ were commercial products (Aldrich), 2-phenyl-4,4,5,5-tetramethylimidazoline-1-oxyl 3-oxide (PTIO) was purchased from Alexis Biochemicals. They were all used as received. Acetonitrile, acetone and ethanol were spectroscopic-grade solvents.

Apparatus: UV/Vis spectra were recorded with a Kontron Model Uvikon 943 spectrophotometer and X-Band electron spin resonance (ESR) spectra with a Bruker 220 SE spectrometer that was calibrated with α,α′-diphenylpicrylhydrazyl. HPLC analysis was carried out with a Thermo Quest instrument, equipped with a UV detector, using a Discovery HS PEG column (Supelco, 25 cm × 4.6 mm, 5 μm).

Irradiation was carried out with a medium-pressure Hanau Q 400 mercury lamp (15 mW/cm^2). The required wavelength interval was selected by using cut-off filters. When necessary, solutions were degassed to less than 1×10^{-5} Torr by means of five vacuum-line freeze-pump-thaw cycles. Low temperature experiments were performed in a Julabo F12 (MP) cryostat.

Photooxidation of *N*-(4-Chlorophenyl)-*N*′-hydroxyguanidine (1): [Fe^{III}(TDCPP)Cl] or [Fe^{III}(TpivPP)Cl] (1×10^{-5} M) was dissolved in a CH_3CN solution (3 mL) containing **1** (1×10^{-3} M), with or without 1-MeIm (5×10^{-5} M). When necessary PBN (1×10^{-4} M) was also added. The solutions thus obtained were irradiated for 30 minutes with wavelengths higher than 350 nm in the presence of 760 Torr of O_2. UV/Vis spectra were recorded during the preparation of the solutions after the addition of each component and at the end of the irradiation. HPLC analysis was performed on the irradiated sample. Separation and detection of **1**, **2** and **3** was achieved by eluting with a mixture of H_2O and CH_3CN (85:15) in the presence of $CH_3COO\,NH_4$ buffer (10 mM), while HPLC analysis of NO_2^- and NO_3^- was realised using a water solution of acetic acid (pH 3) for elution. In both cases the flow rate was 1 mL/min. Compounds **1**, **2** and **3** were identified by injection of authentic samples. Quantitative analysis was performed using calibration curves obtained from the authentic compounds. Control HPLC experiments were carried out in order to verify that no reaction occurred when irradiation was carried out in the absence of [Fe^{III}(TDCPP)Cl] or O_2. Moreover, we verified that no thermal reaction occurred when the reaction mixture was kept in the dark for several hours.

ESR Spin-Trapping: CH_3CN solutions of [Fe^{III}(TDCPP)Cl] (1×10^{-5} M) containing **1** (1×10^{-3} M), 1-MeIm (5×10^{-5} M) and PBN (5×10^{-3} M) were irradiated ($\lambda > 350$ nm, room temperature) inside the ESR cavity using a flat quartz cell. No ESR signal was obtained when performing the described experiment in the absence of **1**.

For NO detection experiments, CH_3CN solutions of [Fe^{III}(TDCPP)Cl] (1×10^{-5} M), 1-MeIm (5×10^{-5} M) and PTIO (2×10^{-6} M) with and without **1** (1×10^{-3} M) were irradiated ($\lambda > 360$ nm) inside the ESR cavity for some minutes.

Preparation of the [Fe^{II}(TpivPP)(O_2)(1-MeIm)] Adduct: [Fe^{III}(TpivPP)Cl] (1×10^{-5} M) dissolved in a mixture of acetone and ethanol (95:5, v/v) in the presence of 1-MeIm (5×10^{-5} M) was degassed to less than 1×10^{-5} Torr by means of five vacuum-line freeze-pump-thaw cycles. Subsequently, it was irradiated (for 90 s) at low temperature (−5 to −8 °C) at wavelengths higher than 350 nm. After irradiation, the solution was put in contact with O_2 at the same low temperature. Finally, a new deoxygenation cycle was carried out. UV/Vis spectra were recorded after each step of the procedure. HPLC analysis was carried out in order to investigate the reactivity of the hydroxyguanidine **1** (1×10^{-3} M) with the Fe^{II}(TpivPP)(O_2) adduct.

The Fe^{II}(TpivPP)(O_2) adduct was also chemically prepared starting from [Fe^{III}(TpivPP)(Br)] and following the procedure already reported by Collman et al.[12b] Here, we employed zinc amalgam as a reducing agent instead of $[Cr(acac)_2]_2$. [Fe^{III}(TpivPP)(Br)] (1×10^{-3} M) and 1-MeIm (3×10^{-3} M) dissolved in acetone were degassed by means of three vacuum-line freeze-pump-thaw cycles. A drop of zinc amalgam was then introduced into the solution kept under argon atmosphere. After a while, the solution became red in colour and the appearance of an intense band at 535 nm was indicative of the formation of the [Fe^{II}(TpivPP)(1-MeIm)$_2$] complex. The solution containing the ferrous complex, separated from the zinc amalgam, in a bath of ethanol/liquid nitrogen at −60 °C was put in contact with O_2. Evidence for the formation of the [Fe^{II}(TpivPP)(O_2)(1-MeIm)] complex was obtained at room temperature by UV/Vis spectroscopy (observation of a new band at 548 nm). Addition of the hydroxyguanidine **1** (2×10^{-2} M) to an acetone solution of [Fe^{II}(TpivPP)(O_2)(1-MeIm)] (1×10^{-3} M) was carried in an ice bath at 0 °C. The reaction mixture was stirred and kept at the same temperature for 30 min before the HPLC analysis.

Ruthenium(II) and Ruthenium(III) Complexes Containing the $[pyS_4]^{2-}$ Ligand [pyS_4^{2-} = 2,6-Bis(2-mercaptophenylthio)dimethylpyridine(2−)][‡]

Dieter Sellmann,[†][a] Kinga Hein,*[a] and Frank W. Heinemann[a]

Keywords: Ruthenium / S ligands / Oxidation reactions

In the search for complexes, having sulfur-dominated coordination spheres, that potentially bind, activate, or stabilize nitrogenase-relevant small molecules, we have synthesized several ruthenium–sulfur complexes of the type $[Ru(L)(pyS_4)]$ starting from the labile acetonitrile complex $[Ru(NCMe)(pyS_4)]$ (**2**). Complex **2** was obtained from the reduction of $[Ru(NO)(pyS_4)]Br$ (**1**) by $N_2H_4{\cdot}H_2O$ in the presence of MeCN. The acetonitrile ligand in **2** could be exchanged for the soft σ–π ligand CO to give $[Ru(CO)(pyS_4)]$ (**3**). Attempts to coordinate N_2 to the pyS_4^{2-} fragment of **2** gave $[\{Ru(pyS_4)\}_2]$ (**4**). Complex **2** reacts also with hard σ-ligands, such as N_2H_4, NH_3, pyridine, and pyrazine, to afford mononuclear $[Ru(N_2H_4)(pyS_4)]$ (**5**), $[Ru(NH_3)(pyS_4)]$ (**6**), $[Ru(py)(pyS_4)]$ (**7**), and $[Ru(pyr)(pyS_4)]$ (**8**), respectively. Reaction of **2** with NEt_4N_3 resulted in the formation of $NEt_4[Ru(N_3)(pyS_4)]$ (**9**). The oxidation of **2** with I_2 afforded $[Ru(I)(pyS_4)]$ (**10**). The protonated and alkylated species $[Ru(NCMe)(pyS_4\text{-}H)]BF_4$ (**11**), $[Ru(NCMe)(pyS_4\text{-}Et)]BF_4$ (**12**), and $[\{Ru(pyS_4\text{-}Et)\}_2](BF_4)_2$ (**13**) were obtained from **2** by its treatment with HBF_4 or Et_3OBF_4. The N_2H_4 ligand in **5** could not be oxidized to N_2H_2: the oxidation of the Ru^{II} center to Ru^{III} takes place instead. Attempts to oxidize **5** using either $[FeCp_2]PF_6$ or I_2 gave $[\{Ru^{II/III}(pyS_4)\}_2](PF_6)$ (**14**) and $[Ru^{III}(NH_3)(pyS_4)]X$ (X = PF_6, I) (**15**, **16**). The oxidation of **3** and **6** by $NOBF_4$ gave Ru^{III} species of $[Ru^{III}(CO)(pyS_4)]BF_4$ (**17**) and $[Ru^{III}(NH_3)(pyS_4)]BF_4$ (**18**). The oxidation of **5** and **6** with H_2O_2 afforded $[\{Ru^{II}(pyS_4{-}O_3)\}_2]$ (**19**), $[\{Ru^{II}(pyS_4{-}O_4)\}_2]$ (**20**) and $[Ru^{II}(NH_3)(pyS_4{-}O_4)]$ (**21**). All complexes were characterized by spectroscopic methods and by elemental analysis. The molecular structures of **4**, **6**, **10**, **14**, **15**, **19**, and **20** were determined by X-ray crystallographic analyses.

Introduction

Transition metals in sulfur-dominated coordination spheres exhibit rich coordination chemistry.[1] Sulfur coordination of transition metals is characteristic of the active sites of metal sulfur oxidoreductases, such as nitrogenases[2] and the nitrile hydratase.[3] To create model compounds, different multidentate organosulfur ligands and their transition metal complexes have been synthesized and investigated.[4] The previously reported $[M(N_HS_4)]$ fragment [$N_HS_4^{2-}$ = 2,2′-bis(2-mercaptophenylthio)diethylamine-(2−)] binds a number of nitrogenase-relevant molecules, such as CO, NO, N_2H_2, N_2H_4, and NH_3, but with the exception of N_2.[5] Moreover, in the case of ruthenium, the diastereoisomerism of the $[M(N_HS_4)]$ fragments leads to the formation of inseparable mixtures of $[Ru(L)(N_HS_4)]$ species. To overcome this problem, the flexible $N(C_2H_4)_2$ bridge was replaced by the rigid $py(CH_2Br)_2$ bridge, which yielded exclusively *trans*-alkylated species. The synthesis of many iron,[6,7c,7e] but only a few ruthenium complexes containing the $[M(pyS_4)]$ fragment have been described.[7a,7b] The extreme lability of important nitrogenase-relevant intermediates, such as $[Fe(N_2H_4)(pyS_4)]$ and $[\mu\text{-}N_2H_2\{Fe(pyS_4)\}_2]$,[8] prompted us to examine the coordination behavior of the pyS_4 ligand towards ruthenium − a homologue of the nitrogenase-dominating iron systems. In the case of ruthenium, the syntheses of $[Ru(L)(pyS_4)]$ complexes, e.g., $[Ru(CO)(pyS_4)]$, require very drastic conditions.[7a] The previous reports have also illustrated the difficulties in finding complexes with labile ligands L. Therefore, our primary aim was to find $[Ru(L)(pyS_4)]$ complexes with labile ligands which are capable of coordinating nitrogenase-relevant small molecules under mild conditions. In this context, we investigated the chemistry of $[Ru(L)(pyS_4)]$ complexes. Herein, we describe the synthesis of labile $[Ru(NCMe)(pyS_4)]$ (**2**) and its reactivity towards various nitrogenase-relevant molecules, such as CO and N_2H_4. We prove also the possibility of coordinating the σ ligands NH_3 and N_3^- to the $[Ru(pyS_4)]$ fragment; these ligands do not coordinate to the Fe analogue.[8] Attempts to oxidize coordinated hydrazine to diazene units led either to the oxidation of Ru^{II} to Ru^{III} or to the oxidation of thiolate donors in the pyS_4 ligand to sulfinates/sulfenates. This is a new observation when compared to the behavior

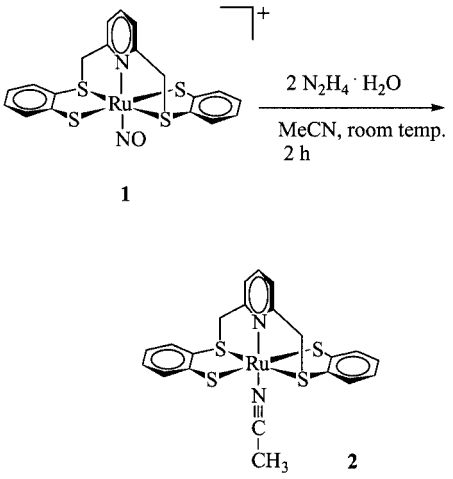
of other ruthenium sulfur hydrazine complexes, such as $[Ru(N_2H_4)(PPh_3)(tpS_4)]$,[9] $[Ru(N_2H_4)(P\mathit{i}Pr_3)(S_4)]$, $[Ru(N_2H_4)(PCy_3)(S_4)]$,[10] and $[Ru(N_2H_4)(PPh_3)(^{bu}S_4)]$.[11]

Results

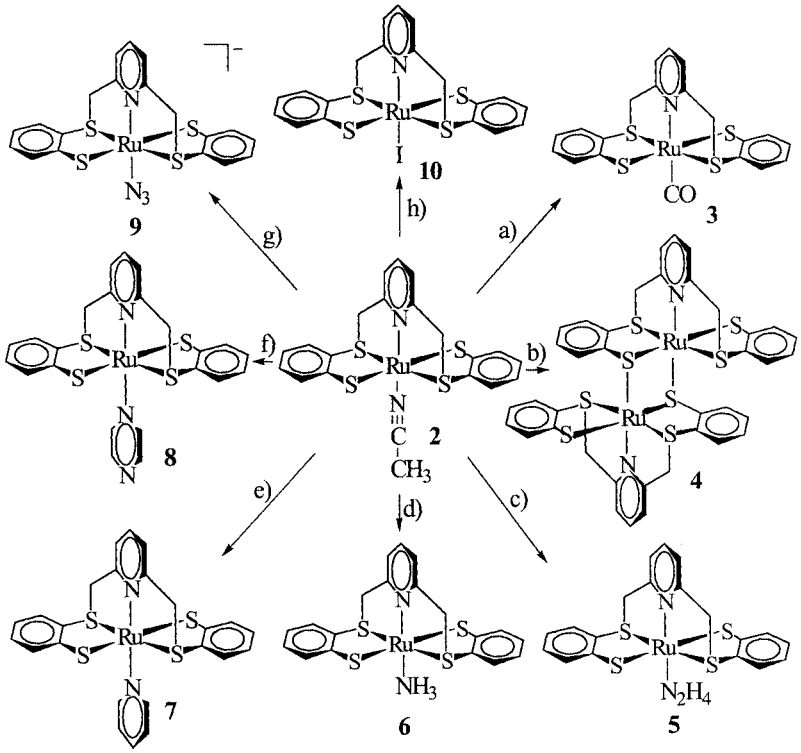
Earlier attempts to synthesize the acetonitrile complex **2** directly from $[RuCl_2(CH_3CN)_4]$ and Li_2pyS_4 were unsuccessful.[7a] Now, we have found that **2** can be synthesized from $[Ru(NO)(pyS_4)]Br$ (**1**) by reductive elimination of the NO^+ ligand. Treatment of **1** with two equiv. of $N_2H_4{\cdot}H_2O$ in acetonitrile afforded the target complex **2** (Scheme 1).



Scheme 1. Synthesis of $[Ru(NCMe)(pyS_4)]$ (**2**)

The NO^+ ligand in **1** is reduced by $N_2H_4{\cdot}H_2O$, giving probably the highly reactive and unstable 19-VE $[Ru(NO)(pyS_4)]^0$ intermediate, which releases NO and coordinates MeCN to afford **2**. The acetonitrile complex **2** is soluble in CH_2Cl_2 and THF, but it is insoluble in MeOH and Et_2O. ^1H and ^{13}C NMR spectra indicate that **2** exhibits C_2 symmetry in solution. In the solid state, **2** can be stored at room temp. for a couple of weeks, but it decomposes in solution over the course of 48 h. Complex **2** is an excellent starting material for the synthesis of numerous complexes that had been inaccessible previously. The reactivity of **2** towards various nucleophiles is depicted in Scheme 2.

Complex **2** reacts with CO instantaneously to give the CO complex **3**; this process indicates the lability of **2**. Attempts to exchange the acetonitrile ligand in **2** by N_2 led to the formation of the stable, dinuclear $[\{Ru(pyS_4)\}_2]$ (**4**). Complex **4** could be obtained in better yield when **2** was heated under reflux in THF for a few days. When **2** was treated with $N_2H_4{\cdot}H_2O$, a mononuclear hydrazine complex formed: $[Ru(N_2H_4)(pyS_4)]$ (**5**). Complex **5** is stable in solution for only a few hours and all attempts to obtain single crystals suitable for X-ray analysis resulted in the formation of crystals of **4**. Although one of the decomposition products of **5** was identified as $[Ru(NH_3)(pyS_4)]$ (**6**), formation of an N_2H_2 complex, resulting from disproportionation, has never been observed. Attempts to synthesize a diazene complex directly from **2** and N_2H_2, generated in situ by hydrolysis of $K_2N_2(CO_2)_2$ with acetic acid, were unsuccessful. Complex **6** could be prepared very simply from **2** in a reaction with gaseous NH_3 under ambient conditions. In contrast to the $[Fe(pyS_4)]$ fragment, which does not coordinate



Scheme 2. Reactivity of **2** towards nitrogenase-relevant molecules: a) CO, THF, room temp.; b) N_2, THF, 100 bar; c) $N_2H_4{\cdot}H_2O$, THF, 15 h, room temp.; d) NH_3(g), THF, 2 h, room temp.; e) pyridine, 5 min, reflux; f) pyrazine, 15 min, reflux; g) NEt_4N_3, acetone, 50 °C; h) 0.5 I_2, THF, 30 min, room temp.

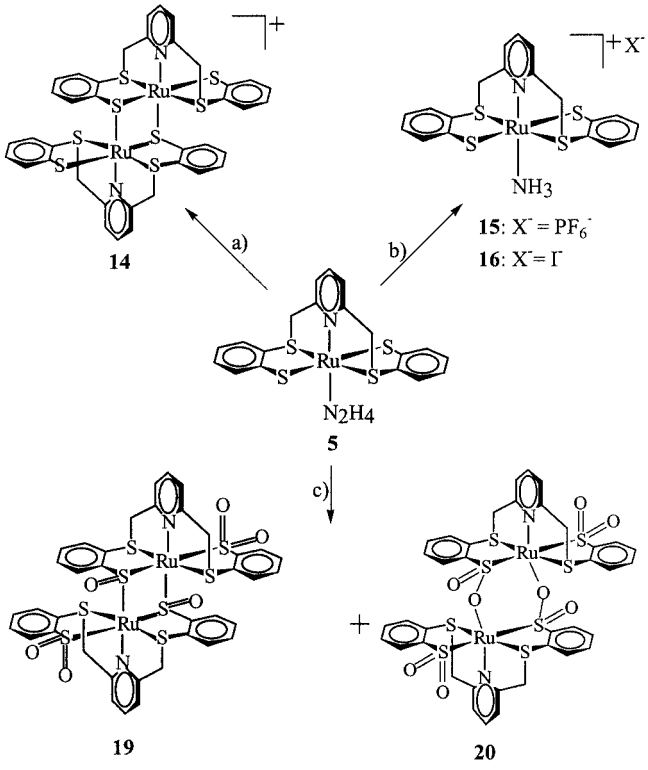
σ ligands at all, the NH_3 ligand in **6** proved to be very inert. The CO exchange reaction takes place very slowly and requires ca. 72 h to reach completion. For that reason, **6** did not afford a dinitrogen complex either. Attempts to exchange NH_3 for N_2 were unsuccessful, even under very drastic conditions, e.g., 100 bar/50 °C. Treatment of **2** with other hard σ ligands, such as pyridine and pyrazine, led to the formation of [Ru(py)(pyS_4)] (**7**) and [Ru(pyr)(pyS_4)] (**8**), respectively. To drive the reactions to completion, the solutions were usually heated under reflux for a short period of time. Azide complexes are used for the preparation of dinitrogen complexes that are not accessible by direct coordination of gaseous nitrogen.[12] Treatment of **2** in acetone with NEt_4N_3 afforded the extremely unstable azide complex NEt_4[Ru(N_3)(pyS_4)] (**9**) whose formation can be ascertained only by IR spectroscopy, which shows a characteristic ν(N_3) absorption at 2026 cm^{-1}. This absorption is in good agreement with those of other [Ru(N_3)(L)]$^-$ complexes, e.g., NEt_4[Ru(N_3)(PPh_3)(tpS_4)] (2029 cm^{-1}),[9] NEt_4[Ru(N_3)(PPh_3)($^{bu}S_4$)] (2034 cm^{-1}),[11] and NEt_4[Ru(N_3)(PCy_3)(S_4)] (2028 cm^{-1}).[13] This reaction took place only when the mixture was heated briefly at 50 °C. The azide complex proved to be too labile to obtain reasonable ^{1}H NMR spectra, and elemental analysis proved also to be very erratic. This situation most certainly is due to the inherent instability of the azide ligand, which proved to be very labile: the compound decomposed when it was dried in vacuo.

Oxidation of **2** with 0.5 equiv. of I_2 in THF led to a color change from orange-red to violet. Addition of *n*-hexane to the filtrate precipitated a violet solid, which we characterized by elemental analysis, mass spectrometry, and X-ray crystallography to be [Ru(I)(pyS_4)] (**10**). Addition of an excess of I_2 to a filtrate after preparation of **10** led to the formation of single crystals, which we identified with the help of an X-ray analysis to be [Ru^{III}(pyS_4)]$_2$(I_3)$_2$ (**22**). In the presence of an excess of iodine, the iodide ligand in **10** dissociates in solution and then two [Ru(pyS_4)] fragments dimerize to form **22**.

We performed protonation and alkylation experiments to further explore the reactivity of [Ru(NCMe)(pyS_4)] (**2**). When **2** was treated with 1 equiv. of HBF_4 at −78 °C, the protonated [Ru(NCMe)(pyS_4-H)]BF_4 (**11**) complex formed; it has a characteristic ν(CN) absorption at 2273 cm^{-1}. Addition of 1 equiv. of Et_3OBF_4 to **2** led to the formation of the monoalkylated species [Ru(NCMe)(pyS_4-Et)]BF_4 (**12**), which has a ν(CN) frequency at 2282 cm^{-1}. To prove the possibility that **2** can be dialkylated, we added an excess (5 equiv.) of Et_3OBF_4 to **2**. In the course of 2 days, the dinuclear complex [{Ru(pyS_4-Et)}$_2$](BF_4)$_2$ (**13**) formed. These observations regarding the reactivity of the [Ru(pyS_4)] acetonitrile complex confirm its wide applicability to the synthesis of other [Ru(L)(pyS_4)] complexes, but only when the entering ligand L is competitive enough to form the desired [Ru(L)(pyS_4)] species.

Our unsuccessful attempts to obtain a [Ru(pyS_4)] dinitrogen complex from its acetonitrile, ammonia, or azide precursors prompted us to return to the hydrazine complex **5** as a starting point. The oxidation of **5** by other oxidants gave unexpected, but interesting, results, which are summarized in Scheme 3.



Scheme 3. Oxidation of [Ru(N_2H_4)(pyS_4)] (**5**) with different oxidants: a) [$FeCp_2$]PF_6, LiOMe; b) [$FeCp_2$]PF_6 or I_2; c) H_2O_2

When **5** was treated with 2 equiv. of [$FeCp_2$]PF_6 and 1 equiv. of LiOMe, red microcrystals formed which were identified as **4**. The red solid that precipitated from the filtrate, upon the addition of Et_2O, was separated and characterized as [{$Ru^{II/III}$(pyS_4)}$_2$](PF_6) (**14**). The hydrazine ligand in **5** dissociates in solution and then the resulting two [Ru(pyS_4)] fragments dimerize to form **4**. Overnight, a slow oxidation of the metal centers took place in the mother liquor to produce the mixed-valence species **14**. Treatment of **5** with an excess of either [$FeCp_2$]PF_6 or I_2 gave [Ru^{III}(NH_3)(pyS_4)]X (X = PF_6, I) (**15**, **16**). To gain some understanding of the formation of these stable ammonia complexes (**15**, **16**), we performed some additional oxidation experiments of **3** and **6** using $NOBF_4$. As expected, in both cases [Ru^{III}(CO)(pyS_4)]BF_4 (**17**) and [Ru^{III}(NH_3)(pyS_4)]BF_4 (**18**) formed; these complexes could be isolated and characterized. These results indicate the facility of the oxidation of the Ru center in the [Ru(pyS_4)] fragment when using oxidants such as [$FeCp_2$]PF_6, I_2, and $NOBF_4$. In the case of $NOBF_4$, the oxidation takes place without decoordination of the NH_3 and CO ligands. The formation of stable ammonia complexes, **15** and **16**, from the hydrazine complex **5** is in agreement with the observed decomposition of the hydrazine ligand in **5** to ammonia, and other compounds, mentioned above. A possible explanation for the oxidation

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of **5** to **15** and **16** might be the decomposition of hydrazine to ammonia in the first step and then oxidation of Ru^{II} to Ru^{III} in the resulting ammonia complex — an intermediate species — in the second. The oxidation of **5** and **6** with H_2O_2 leads to oxidation of the thiolate donors. When H_2O_2 is added to a solution of **5** in THF, the initial red color turns to yellow and the formation of a mixture of $[\{Ru(pyS_4-O_3)\}_2]$ (**19**) and $[\{Ru(pyS_4-O_4)\}_2]$ (**20**) is observed. This yellow solid exhibits two new IR bands at 1141 and 1042 cm^{-1} that indicate the oxidation of thiolato sulfur to sulfenato/sulfinato (**19**) and sulfinato groups (**20**).[14] Several examples of the oxidation of thiolate donors in transition metal complexes appear in the literature. Although thiolates are normally oxidized to disulfides, it is known that metal-bound thiolates can be oxidized to sulfinates and sulfenates.[15,16] The X-ray crystallographic structural determination of **19** confirms the formation of dinuclear Ru^{II} species, wherein two $[Ru(pyS_4-O_3)]$ fragments are bridged by the S atom of a sulfenato group. In the case of **20**, two $[Ru(pyS_4-O_3)]$ fragments are bridged by two O atoms. Treatment of **6** with H_2O_2 led also, as in the case of **5**, to the oxidation of the thiolate donors. The elemental analysis of the isolated product was in agreement with the formation of mononuclear $[Ru(NH_3)(pyS_4-O_4)]$ (**21**). The ammonia ligand did not decoordinate during this reaction; this result is in line with our observations, discussed above, on the different stabilities of the ammonia and hydrazine ligands in the $[Ru(pyS_4)]$ fragment.

The various results of the chemical oxidation experiments of the $[Ru(pyS_4)]$ fragment prompted us to undertake electrochemical investigations using the Ru^{II} complexes **2**, **3**, **5**, **6**, **7**, and **8** and the Ru^{III} complexes **15** and **17**. The results support the hypothesis that the metal center is easy oxidized in the $[Ru(pyS_4)]$ fragment. The Ru^{II} CO complex **3** displays one quasireversible redox wave at 0.58 V, which we assign to the redox couple $[Ru(CO)(pyS_4)]^{+/2+}$. The possible chemical oxidation of thiolate donors, which we commented on above, is now corroborated by the results of the electrochemical investigations. $[Ru(NH_3)(pyS_4)]$ (**6**) exhibits an irreversible wave at 0.88 V, which we ascribe to the oxidation of thiolate donors in the pyS_4 ligand. A similar wave at 0.8 V appears in the cyclic voltammogram of the Ru^{III} ammonia complex **15**. The second reversible wave observed for **15** at 0.32 V is assigned to the $[Ru(NH_3)(pyS_4)]^{+/2+}$ redox couple. The cyclic voltammogram of **15** also exhibits one reversible wave in the cathodic region (−0.24 V); it is compatible with the reversible reduction of **15** to the Ru^{II} ammonia complex and can be assigned to the redox couple $[Ru(NH_3)(pyS_4)]^{+/0}$. The cyclic voltammograms of **2**, **7**, and **8** exhibit reversible redox waves in the anodic region that are typical of $[Ru(L)(pyS_4)]$ (L = MeCN, py, pyr): at 0.07, 0.06, and 0.12 V, respectively. In the case of **2**, we also observed a reversible redox wave in the cathodic region at −0.2 V, which we assign to the redox couple $[Ru(NCMe)(pyS_4)]^{0/-1}$. The difficulties in oxidizing the hydrazine complex **5** to a diazene complex are in good agreement with the electrochemical properties of **5**. No redox waves were observable in the anodic region of the voltammogram of **5**. One quasireversible redox wave at −0.13 V is assigned to the redox couple Ru^{II}/Ru^{I}.

Characterization of $[Ru(L)(pyS_4)]$ Complexes

As far as possible, we characterized all of the complexes by elemental analyses and IR, NMR, and mass spectra. The molecular structures of **4**, **6**, **10**, **14**, **15**, **19**, **20**, **22**, **23**, and **24** were determined by X-ray crystallographic analyses. The Ru^{II} complexes (including **6** and **7**) are soluble in CH_2Cl_2, THF, DMF, and DMSO, but they are insoluble in MeOH, Et_2O, and hexane. Complexes **6** and **7** are soluble in all common solvents. The Ru^{III} complexes display better solubility in MeOH and are rather sparingly soluble in CH_2Cl_2 and THF. All Ru^{II} complexes proved to be diamagnetic, while the Ru^{III} complexes are paramagnetic, as indicated by their ^1H NMR spectra. The ^1H NMR spectra of $[Ru^{II}(L)(pyS_4)]$ complexes exhibit a typical set of four or five multiplets for the 11 aromatic protons ($\delta \approx 9-6$ ppm) and two typical patterns for an AB spin system representing the diastereotopic methylene protons ($\delta \approx 5.5-4.5$ ppm). In the case of **20**, all of the pairs of methylene protons of the oxidized pyS_4 ligand are diastereotopic because of the stereogenic center at the S atom of the bridging sulfinic group. Typically, we observed a characteristic triplet that is due to the pyridine H_γ protons. The ^1H NMR spectra of **2**, **6**, and **21** exhibit characteristic singlets at $\delta = 2.16$, 1.54, and 1.52 ppm, respectively, that indicate the coordination of acetonitrile and ammonia ligands. The hydrazine complex **5** gave rise to two singlets at $\delta = 4.86$ and 4.01 ppm, which we assign to the Ru-bound NH_2 group and terminal NH_2 group. In the $^{13}C\{^1H\}$ NMR spectra, the 17 aromatic and 2 aliphatic carbon atoms of the $[Ru(pyS_4)]$ fragments resulted in 10 signals (9 and 1, respectively). The electronic absorption spectra of **5** and **6** in DMF each consist of two strong bands with maxima at 347 and 504 nm; **7** and **8** exhibit absorptions at ca. 400 and 509 nm (for **7**) and 557 nm (for **8**). Absorption at > 500 nm arises from thiolate-to-ruthenium(II) charge-transfer transitions. The blue shift of the pyrazine complex **8** is compatible with its deep violet color compared to the red pyridine complex **7**. The presence of the pyridine unit in the pyS_4 ligand is associated with an absorption at ca. 400 nm. Complex **15** displays absorptions at 596 and 822 nm.

X-ray Structural Analyses

X-ray structural analyses corroborated the spectroscopic results for several of the complexes. Figure 1−3 depict the molecular structures of $[\{Ru(pyS_4)\}_2]\cdot 2$toluene (**4**·2-toluene), $[Ru(NH_3)(pyS_4)]$(**6**), $[Ru(I)(pyS_4)]\cdot 1.5CH_2Cl_2$ (**10**·$1.5CH_2Cl_2$), $[\{Ru(pyS_4)\}_2](PF_6)\cdot CD_2Cl_2$ (**14**·CD_2Cl_2), $[Ru(NH_3)(pyS_4)]PF_6\cdot CH_2Cl_2$ (**15**·CH_2Cl_2), and $0.68[\{Ru(pyS_4-O_3)\}_2]\cdot 0.32[\{Ru(pyS_4-O_4)\}_2]\cdot 2MeOH$ (0.68 **19**·0.32 **20**·2MeOH). We also report the structures of $[\{Ru(pyS_4)\}_2](I_3)_2\cdot 1.8THF$ (**22**·1.8THF), $[\{Ru(pyS_4\text{-}Et)\}_2](BF_4)_2(B_2F_7)\cdot 3CD_2Cl_2$ (**23**·$3CD_2Cl_2$), and $[\{Ru(pyS_4)\}_2](BF_4)(B_2F_7)\cdot 3CH_2Cl_2$ (**24**·$3CH_2Cl_2$), which we only characterized by X-ray crystallography.

Molecular structures of [{Ru(pyS$_4$)}$_2$]·2 toluene (**4**·2toluene), [Ru(NH$_3$)(pyS$_4$)] (**6**), [Ru(I)(pyS$_4$)]·1.5 CH_2Cl_2 (**10**·1.5CH_2Cl_2), and [{Ru(pyS$_4$)}$_2$](I$_3$)$_2$·1.8THF (**22**·1.8THF); 50% probability ellipsoids, H atoms, solvent molecules, and I_3^- anions omitted

Table 1−3 list selected distances and angles of these complexes.

In all of the complexes, the ruthenium centers exhibit pseudo-octahedral coordination. Thiolate and thioether donors always adopt *trans* positions in the [RuS$_4$] cores. This observation proves the steric rigidity of the py(CH$_2$)$_2$ backbone. In the mononuclear complexes **6**, **10**, and **15**, the Ru centers are coordinated by one N and four S donors of the pentadentate pyS_4^{2-} ligand and a sixth ligand (NH$_3$ or I), while in the dinuclear complexes **4**, **14**, **19**, **20**, **22**, **23**, and **24** the sixth ligand is a thiolate donor of the second [Ru(pyS$_4$)] unit. In mono- and dinuclear Ru^{II} complexes, the Ru−S (thiolate) distances are slightly longer than the Ru−S (thioether) distances, but all the Ru−S distances in the Ru^{III} complexes are of similar length. The Ru−N (pyridine) distances in all the Ru^{II} complexes are slightly shorter (by ca. 4 pm) than in the Ru^{III} complexes.

In the case of **19** and **20**, two different orientations were refined for the oxygen atoms, with an occupancy of 68% for O1, O3, and O4 and 32% for O1′, O2′, O3, and O4. The ethyl groups in **23** are situated at the S atoms S4 and S4A that are *trans* to the bridging S donors S1 and S1A, respectively. The dimer **4** that has two Ru^{II} centers possesses crystallographically imposed C_i symmetry. The mixed-valence complex **14** exhibits approximate C_2 symmetry. The two

Ru^{III} fragments in dimeric **22** are connected by a crystallographic inversion center. The dinuclear complex **23** contains one *R* and one *S* [Ru(pyS$_4$-Et)] enantiomer, while in the mixed-valence complex **24** always two identical enantiomers [(*R*,*R*) or (*S*,*S*)] occurred.

Conclusion

The aim of this work was the synthesis of new labile $[Ru(L)(pyS_4)]$ complexes. We have found that $[Ru(MeCN)(pyS_4)]$ (**2**) is a good precursor for other complexes. This complex allows the synthesis of $[Ru(CO)(pyS_4)]$ (**3**), $[Ru(N_2H_4)(pyS_4)]$ (**5**), and $[Ru(NH_3)(pyS_4)]$ (**6**), which contain nitrogenase-relevant ligands. The $[Ru(pyS_4)]$ fragment can bind a further σ ligand, such as N_3^-, in contrasting to the $[Fe(pyS_4)]$ fragment, which does not coordinate NH_3 and N_3^- ligands. Moreover, the coordination of the nitrogenase-relevant molecules takes place under rather mild conditions. The replacement of the flexible NH(dialkyl)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bridge of the former NHS_4^{2-} ligand with the sterically more rigid dialkyl methyl pyridine bridge in the pyS_4^{2-} ligand successfully enforces a *trans*-thiolate configuration in [Ru(L)(pyS_4)] complexes. The synthesis of complexes such as [Ru^{III}(NH_3)(pyS_4)]X (X = PF_6, I, BF_4) (**15**, **16**, **18**) and [Ru^{III}(CO)(pyS_4)]BF_4 (**17**) proves that the oxidation of Ru^{II} to Ru^{III} centers occurs readily in the [Ru(pyS_4)] fragment. Interestingly, both [Ru(N_2H_4)(pyS_4)] (**5**) and [Ru(NH_3)(pyS_4)] (**6**) can be converted readily into the corresponding sulfinato species upon reaction with H_2O_2. We have proven the different lability of hydrazine and ammonia ligands in [Ru(pyS_4)] fragments by studying their reactivity towards a range of oxidants.

Experimental Section

General Methods: Unless noted otherwise, all reactions and operations were carried out under nitrogen and at room temp. using standard Schlenk techniques and absolute solvents. As far as possible, reactions were monitored by IR and NMR spectroscopy. Spectra were recorded using the following instruments: IR (KBr disks or CaF_2 cuvettes, solvent bands were compensated): Perkin−Elmer 16 PC FT IR. NMR: JEOL FT-JNM-GX 270, EX 270, and Lambda LA 400; spectra are referenced to residual protiosolvent signals; chemical shifts are quoted on the δ scale (downfield shifts are positive) relative to tetramethylsilane (^{1}H, ^{13}C{^{1}H} NMR); spectra were recorded at 25 °C. Mass spectra: JEOL JMS 700 spectrometer. UV-Vis-NIR: Varian Cary 50, quartz cuvettes (hellma, d = 1 cm). Elemental Analysis: Carlo−Erba EA 1106 and 1108 analyzer. Cyclic voltammetry was performed with a PAR 264A potentiostat using a three-electrode cell with glassy carbon ROTEL A working, Pt reference, and Pt counter electrodes. The concentration of each complex was 10^{-3} M. NBu_4PF_6 (10^{-1} M) was used as the conducting electrolyte. Potentials are referenced to the NHE via Fc/Fc^+ as internal standard (E = +0.41 V vs. NHE).[17] Reagents (N_2H_4·H_2O, pyridine, pyrazine, LiOMe, Et_3OBF_4, HBF_4/Et_2O, $NOBF_4$, and H_2O_2) were purchased from Merck, Fluka, Aldrich, and Acros. [Ru(NO)(pyS_4)]Br (**1**) was prepared as described in the literature.[7b]

[Ru(NCMe)(pyS_4)] (2): N_2H_4·H_2O (0.034 mL, 0.704 mmol) was added to a brown-violet suspension of **1** (210 mg, 0.352 mmol) in MeCN (20 mL). The color of the suspension turned to carrot-orange. The suspension was stirred for 2 h, during the course of which time an orange solid formed; this solid was filtered, washed with MeOH (2 × 20 mL) and Et_2O (20 mL), and dried in vacuo. Yield: 155 mg of **2** (80%). $C_{21}H_{18}N_2RuS_4$ (527.67): calcd. C 47.80, H 3.43, N 5.31, S 24.31; found C 47.35, H 3.59, N 5.87, S 23.30. IR (KBr): $\tilde{\nu}$ = 2262 cm^{-1} (ν_{CN}). ^{1}H NMR (269.6 MHz, CD_2Cl_2/CD_3CN): δ = 7.63−7.56 (m, 2 H, C_6H_4), 7.41−7.35 (m, 2 H, C_6H_4), 7.11 (t, 1 H, C_5H_3N), 6.93 (d, 2 H, C_5H_3N), 6.88−6.77 (m, 4 H, C_6H_4), 4.64 (d, $^3J_{H,H}$ = 17.8 Hz, 2 H, CH_2), 4.44 (d, $^3J_{H,H}$ = 17.8 Hz, 2 H, CH_2), 2.16 (s, 3 H, CH_3) ppm. ^{13}C{^{1}H} NMR (67.7 MHz, CD_2Cl_2): δ = 158.7, 157.1, 132.2, 131.8, 131.2, 130.2, 127.4, 120.6, 120.1 (C_6H_4), 116.5 (MeCN), 55.6(CH_2) ppm.

[Ru(CO)(pyS_4)] (3): CO gas was bubbled through a red-orange suspension of **2** (200 mg, 0.38 mmol) in THF (20 mL). Instantly, the color of the suspension changed to yellow. After stirring for 24 h under an atmosphere of CO, the resulting yellow suspension was filtered. The filtrate was evaporated to dryness and the resulting yellow powder was washed with MeOH (20 mL) and dried in vacuo. Yield: 178.2 mg of **3**·MeOH (86%). $C_{21}H_{19}NO_2RuS_4$ (546.70): calcd. C 46.14, H 3.50, N 2.56, S 23.46, found C 45.84, H 3.84, N 2.45, S 23.10. IR (KBr): $\tilde{\nu}$ = 1959.4 cm^{-1} (ν_{CO}). ^{1}H NMR (269.6 MHz, CD_2Cl_2): δ = 7.67−7.62 (m, 2 H, C_6H_4), 7.49−7.42, (m, 4 H, C_6H_4), 7.23 (d, $J_{H,H}$ = 13.5 Hz, 2 H, C_5H_3N), 7.03−6.95 (m, 4 H, C_6H_4/C_5H_3N), 5.12 (d, 2 H, CH_2), 5.07 (d, 2 H, CH_2) ppm. ^{13}C{^{1}H} NMR (67.7 MHz, CD_2Cl_2): δ = 201.7 (CO), 156.3, 155.9, 136.8, 132.5, 131.1, 131.0, 129.16, 122.6, 122.0 (C_6H_4) 58.2 (CH_2) ppm. MS (FD, CH_2Cl_2, ^{102}Ru): m/z = 515 [Ru(CO)(pyS_4)]$^+$.

[{Ru(pyS_4)}$_2$] (4): An orange suspension of **2** (250 mg, 0.47 mmol) in THF (30 mL) was heated under reflux for 4 days to give a red-brown suspension. The solid was filtered, washed with Et_2O (2 × 10 mL), and dried in vacuo. Yield: 156 mg of **4** (68%). $C_{38}H_{30}N_2Ru_2S_8$ (973.34): calcd. C 46.89, H 3.11, N 2.88, S 26.36; found C 45.38, H 2.76, N 2.91, S 25.44. MS (FD, DMSO, ^{102}Ru): m/z = 973 [{Ru(pyS_4)}$_2$]$^+$.

[Ru(N_2H_4)(pyS_4)] (5): An excess of N_2H_4·H_2O (0.55 mL, 11.4 mmol) was added to a suspension of **2** (300 mg, 0.57 mmol) in THF (30 mL). After 15 h, the red precipitate was separated, washed with MeOH (3 × 30 mL), and dried in vacuo. Yield: 295 mg of **5** (83%). $C_{19}H_{19}N_3RuS_4$ (518.69): calcd. C 44.00, H 3.69, N 8.10, S 24.72; found C 44.19, H 3.29, N 7.34, S 24.64. IR (KBr): $\tilde{\nu}$ = 3335, 3207, 3102 cm^{-1} (ν_{NH}). ^{1}H NMR (269.6 MHz, [D$_7$]DMF): δ = 7.75−7.72 (m, 2 H, C_6H_4), 7.45−7.42 (m, 2 H, C_6H_4), 7.12−7.06 (t, 3 H, C_5H_3N), 6.91−6.81 (m, 4 H, C_6H_4), 4.86 (s, 2 H, −N*H*$_2$−NH$_2$), 4.72 (d, $^3J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 4.52 (d, $^3J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 4.01 (s, 2 H, −NH$_2$−N*H*$_2$) ppm. ^{13}C{^{1}H} NMR (67.7 MHz, CD_2Cl_2): δ = 159.1, 156.7, 132.5, 132.2, 131.5, 131.2, 128.1, 121.6, 120.5 (C_6H_4), 54.6 (CH_2) ppm. MS (FD, DMF, ^{102}Ru): m/z = 973 [{Ru(pyS_4)}$_2$]$^+$.

[Ru(NH_3)(pyS_4)] (6): NH_3 was bubbled through a suspension of **2** (600 mg, 1.14 mmol) in THF (100 mL) for 15 min. The resulting red suspension was stirred under an NH_3 gas for additional 2 h and then filtered. Addition of *n*-hexane (100 mL) to the red filtrate precipitated a red powder, which was separated, washed with *n*-hexane (3 × 20 mL), and dried in vacuo. Yield: 493 mg of **6** (86%). $C_{19}H_{18}N_2RuS_4$ (503.68): calcd. C 45.31, H 3.60, N 5.56, S 25.46; found C 45.43, H 3.55, N 5.14, S 24.49. IR (KBr): $\tilde{\nu}$ = 3362, 3242, 3161 cm^{-1} (ν_{NH}). ^{1}H NMR (269.6 MHz, CD_2Cl_2): δ = 7.67−7.64 (m, 2 H, C_6H_4), 7.52−7.46 (m, 2 H, C_6H_4), 7.10−7.06 (t, 3 H, C_5H_3N), 6.93−6.88 (m, 4 H, C_6H_4), 4.65 (d, $^3J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 4.46 (d, $^3J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 1.54 (s, 3 H, −NH_3) ppm. MS (FD, CH_2Cl_2, ^{102}Ru): m/z = 973 [{Ru(pyS_4)}$_2$]$^+$, 504 [Ru(NH_3)(pyS_4)]$^+$.

[Ru(py)(pyS_4)] (7): A suspension of **2** (340 mg, 0.64 mmol) in pyridine (25 mL) was heated under reflux for 5 min. The resulting red solution was evaporated to yield a red solid. Yield: 340 mg of **7**·py (82.38%). $C_{29}H_{25}N_3RuS_4$ (644.85): calcd. C 54.02, H 3.91, N 6.52, S 19.89; found C 54.04, H 4.51, N 6.50, S 20.19. ^{1}H NMR (269.6 MHz, CD_2Cl_2): δ = 8.58 (d, $J_{H,H}$ = 5.4 Hz, 2 H, C_5H_5N) 8.41−8.38 (m, 2 H, C_6H_4), 7.69−7.65 (m, 2 H, C_6H_4), 7.52 (d, $J_{H,H}$ = 8.1 Hz, 2 H, C_5H_3N), 7.46−7.40 (t, 1 H, C_5H_5N), 7.31−7.26 (m, 2 H, C_5H_5N), 7.10−7.04 (t, 1 H, C_5H_3N), 6.95−6.89 (m, 4 H, C_6H_4), 4.77 (d, $^3J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 4.47 (d, $^3J_{H,H}$ = 16.2 Hz, 2 H, CH_2) ppm. ^{13}C{^{1}H} NMR (67.7 MHz, CD_2Cl_2): δ = 159.38, 156.74, 150.05, 136.01, 134.82, 132.54, 132.24, 131.55, 128.10, 123.91, 123.77, 120.62 (C_6H_4), 56.5 (CH_2) ppm. MS (FD, CH_2Cl_2, ^{102}Ru): m/z = 973 [{Ru(pyS_4)}$_2$]$^+$.

[Ru(pyrazine)(pyS_4)] (8): An excess of pyrazine (4.0 g, 49 mmol) was added to a suspension of **2** (340 mg, 0.64 mmol) in THF (40 mL).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The reaction mixture was heated under reflux for 15 min. The resulting deep-violet solution was evaporated to yield a violet powder, which was washed with *n*-hexane (5 × 30 mL) and dried in vacuo. Yield: 210 mg of **8**·0.25 pyrazine (54.22%). $C_{29}H_{25}N_3RuS_4$ (586.78): calcd. C 49.13, H 3.44, N 7.75, S 21.86; found C 48.09, H 3.60, N 7.86, S 20.76. ^{1}H NMR (269.6 MHz, CD_2Cl_2): δ = 8.56 (s, free pyrazine), 8.38 (d, $J_{H,H}$ = 5.4 Hz, 2 H, C_4H_4), 8.07 (d, $J_{H,H}$ = 5.4 Hz, 2 H, C_4H_4), 7.69 (d, $J_{H,H}$ = 16.2 Hz, 2 H, C_6H_4) 7.52 (d, $J_{H,H}$ = 10.8 Hz, 2 H, C_5H_3N), 7.21−7.15 (t, 1 H, C_5H_3N), 6.99−6.88 (m, 6 H, C_6H_4), 4.80 (d, $^3J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 4.50 (d, $^3J_{H,H}$ = 13.5 Hz, 2 H, CH_2) ppm. $^{13}C\{^1H\}$ NMR (67.7 MHz, CD_2Cl_2): δ = 159.14, 156.94, 152.20, 145.40 (free pyrazine), 144.05, 133.14, 132.63, 131.12, 131.00, 121.81, 120.93 (C_6H_4), 56.46 (CH_2) ppm. MS (FD, CH_2Cl_2, ^{102}Ru): *m*/*z* = 973 $[\{Ru(pyS_4)\}_2]^+$, 567 $[Ru(pyr)(pyS_4)]^+$.

[Ru(I)(pyS$_4$)] (10): I_2 (0.27 g, 1.08 mmol) was added to a suspension of **2** (1.15 g, 2.16 mmol) in THF (50 mL). The resulting violet suspension was stirred for 30 min and then filtered. *n*-Hexane (100 mL) was added to the filtrate. After 30 min, the violet precipitate was filtered, washed with *n*-hexane (2 × 20 mL) and Et_2O (2 × 20 mL), and dried in vacuo for 1 h. Yield: 0.65 g of **10** (48.9%). $C_{19}H_{15}NRuS_4I$ (613.55). MS (FD, THF, ^{102}Ru): *m*/*z* = 614 $[Ru(I)(pyS_4)]^+$, 973 $[\{Ru(pyS_4)\}_2]^+$.

[Ru(NCMe)(pyS$_4$-H)]BF$_4$ (11): HBF_4 (0.11 mL, 54% solution in Et_2O, 0.77 mmol) was added to a suspension of **2** (406 mg, 0.77 mmol) in CH_2Cl_2 (20 mL) at −78 °C. The color of the suspension changed to yellow-green. The reaction mixture was stirred for 2 h at −78 °C and then filtered. *n*-Hexane (50 mL) was added to the green filtrate. The green precipitate was separated by filtration and dried in vacuo for 15 min. IR (KBr): $\tilde{\nu}$ = 2472 (ν_{SH}), 2273 (ν_{CN}), 1055 (ν_{BF}) cm^{-1}. MS (FD, DMF, ^{102}Ru): *m*/*z* = 976 $[\{Ru(pyS_4\text{-}H)\}_2]^+$.

[Ru(NCMe)(pyS$_4$-Et)]BF$_4$ (12): Et_3OBF_4 (1.19 mL, 1 M solution in CH_2Cl_2, 1.19 mmol) was added to a suspension of **2** (627 mg, 1.19 mmol) in CH_2Cl_2 (30 mL). The color changed to yellow-brown and, after 2 h, the brown solid was separated by filtration. *n*-Hexane (70 mL) was added to the deep yellow-brown filtrate. The yellow precipitate was filtered, washed with *n*-hexane (20 mL), and dried in vacuo. $C_{23}H_{23}N_2RuS_4BF_4$ (643.56). IR (KBr): $\tilde{\nu}$ = 2282 (ν_{CN}), 1048 (ν_{BF}) cm^{-1}. ^{1}H NMR (269.6 MHz, CD_2Cl_2): δ = 8.25 (d, $J_{H,H}$ = 5.4 Hz, 2 H, C_5H_3N), 7.77−6.93 (m, 9 H, aryl), 5.00, 4.85, 4.73, 4.55 (4 × d, 8 H, CH_2), 3.18 (m, 2 H, CH_2), 2.39 (s, 3 H, coord. CH_3CN), 2.23 (s, 3 H, free CH_3CN), 1.50 (t, 3 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (67.7 MHz, CD_2Cl_2): δ = 159.2, 155.0, 138.15, 135.6, 134.8, 133.7, 133.5, 133.3, 133.0, 132.9, 132.4, 131.9, 131.6, 130.4, 122.9, 122.3 (C_6H_5), 123.9 (CH_3CN), 55.7 (CH_2), 55.5 (CH_2), 38.1 (CH_2), 13.0 (CH_3), 4.6 (CH_3CN) ppm. MS (FD, CH_2Cl_2, ^{102}Ru): *m*/*z* = 516 $[Ru(pyS_4\text{-}Et)]^+$.

[{Ru(pyS$_4$-Et)}$_2$](BF$_4$)$_2$ (13): Et_3OBF_4 (5.16 mL, 1 M solution in CH_2Cl_2, 6.35 mmol) was added to a suspension of **2** (670 mg, 1.27 mmol) in CH_2Cl_2 (30 mL) and then the mixture was stirred for 2 days. During this period of time, the mixture became a yellow-green solution. Upon addition of Et_2O (20 mL) and THF (30 mL), a yellow solid precipitated; it was filtered and dried in vacuo. $C_{42}H_{40}N_2Ru_2S_8B_2F_8$ (1205.02). IR (KBr): $\tilde{\nu}$ = 1060 cm^{-1} (ν_{BF}). ^{1}H NMR (399.65 MHz, CD_2Cl_2): δ = 8.23 (d, $J_{H,H}$ = 8.1 Hz, 2 H), 7.78−7.25 (m, 9 H, C_6H_5), 5.01 (d, $^3J_{H,H}$ = 24.0 Hz, 2 H, CH_2), 4.84 (d, $^3J_{H,H}$ = 28.0 Hz, 2 H, CH_2), 3.24 (m, 4 H, CH), 2.39 (s, 3 H, free CH_3CN), 1.53 (t, 6 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (67.7 MHz, CD_2Cl_2): δ = 159.4, 138.3, 134.9, 134.5, 133.4, 133.2, 133.1, 132.5, 130.5 [C_6H_5], 124.0 (free CH_3CN), 55.2 (CH_2), 38.1 (CH_2), 13.0 (CH_3), 4.5 (free CH_3CN) ppm. MS (FD, CH_2Cl_2, ^{102}Ru): *m*/*z* = 585 $[Ru(pyS_4-Et_2)(MeCN)]^{2+}$, 1033 $[\{Ru(pyS_4-Et_2)\}_2]^+$.

[{Ru$^{II/III}$(pyS$_4$)}$_2$](PF$_6$) (14): LiOMe (0.77 mL, 1 M MeOH solution) and $[FeCp_2]PF_6$ (255 mg, 0.77 mmol) were added sequentially to a red solution of **5** (200 mg, 0.386 mmol) in DMF (20 mL) and then the mixture was stirred overnight. During this period of time, red microcrystals formed; they were isolated by filtration and identified as dimeric **4** (ca. 25 mg). Crystals grew from the deep-red filtrate; they were identified by an X-ray structural analysis to be **14**·CD_2Cl_2.

[Ru(NH$_3$)(pyS$_4$)](PF$_6$) (15). From 6: $[FeCp_2]PF_6$ (a small spatula's worth) was added to a red suspension of **6** (80 mg, 0.16 mmol) in THF (10 mL). The resulting green suspension was filtered and Et_2O (30 mL) was added to the green filtrate. The green precipitate was filtered, washed with Et_2O (2 × 10 mL), and dried in vacuo. Yield: 40 mg of **15** (32%). $C_{23}H_{26}F_6N_2OPRuS_4$ (**15**·THF) (720.75): calcd. C 38.33, H 3.89, N 3.64, S 17.79; found C 37.45, H 3.36, N 3.64, S 17.13. IR (KBr): $\tilde{\nu}$ = 3356, 3283, 3187 (ν_{NH}) cm^{-1}. MS (FD, CH_2Cl_2, ^{102}Ru): *m*/*z* = 973 $[\{Ru(pyS_4)\}_2]^+$, 504 $[Ru(NH_3)(pyS_4)]^+$.

From 5: $[FeCp_2]PF_6$ (a small spatula's worth) was added to a red suspension of **5** (230 mg, 0.44 mmol) in THF (30 mL). The resulting green suspension was filtered and then Et_2O (60 mL) was added to the green filtrate. The green precipitate was filtered, washed with Et_2O (2 × 20 mL), and dried in vacuo. Yield: 49 mg of **15** (59%).

[Ru(NH$_3$)(pyS$_4$)](I) (16): I_2 (225 mg, 0.9 mmol) was added to a red suspension of **5** (465 mg, 0.9 mmol) in THF (20 mL) and then the mixture was stirred for 30 min. The resulting yellow-brown solid was separated by filtration, washed with THF (3 × 20 mL), and dried in vacuo. Yield: 140 mg of **15** (47%). $C_{21}H_{22}IN_2O_{0.5}RuS_4$ (**16**·0.5THF) (666.64): calcd. C 37.84, H 3.33, N 4.20, S 19.24; found C 37.84, H 2.89, N 3.99, S 18.44.

[Ru(CO)(pyS$_4$)](BF$_4$) (17): $NOBF_4$ (20.54 mg, 0.17 mmol) was added at 0 °C to a yellow solution of **3** (90 mg, 0.17 mmol) in CH_2Cl_2 (30 mL). The reaction mixture was stirred at room temp. until a green solution formed (ca. 1 h); it was evaporated to yield a green solid. $C_{20.5}H_{16}BCl_2F_4NORuS_4$ (**17**·0.5CH_2Cl_2) (643.93): calcd. C 38.24, H 2.50, N 2.17, S 19.92; found C 35.93, H 2.33, N 2.40, S 18.73. IR (KBr): $\tilde{\nu}$ = 2004.5 cm^{-1}(ν_{CO}).

[Ru(NH$_3$)(pyS$_4$)](BF$_4$) (18): A red solution of **6** (325 mg, 0.65 mmol) in CH_2Cl_2 (30 mL) was combined with $NOBF_4$ (78.54 mg, 0.65 mmol) at 0 °C. The solution was stirred for 1 h at 0 °C and then for an additional 1 h at room temp. until its color had changed to green. Evaporation of the solvent gave a violet oil, which was redissolved in MeOH (30 mL). Et_2O (40 mL) was added to the resulting violet-brown solution. The green precipitate was separated and dried in vacuo. Yield: 130 mg of **18**·CH_2Cl_2 (30%). $C_{23}H_{26}F_6N_2OPRuS_4$ (675.87): calcd. C 35.54, H 2.98, N 4.15, S 18.98; found C 34.55, H 2.70, N 4.17, S 19.05.

[{Ru(pyS$_4$−O$_3$)}$_2$]/[{Ru(pyS$_4$−O$_4$)}$_2$] (19/20): H_2O_2 (1 mL) was added at room temp. to a red suspension of **5** (220 mg, 0.42 mmol) in THF (30 mL) and then the mixture was stirred for 30 min. During this period of time the color of the suspension changed to yellow. The yellow solid was separated by filtration and dried in vacuo. $C_{38}H_{30}N_2O_{8.64}Ru_2S_8$ (0.68[{Ru(pyS$_4$−O$_3$)}$_2$] × 0.32[{Ru(pyS$_4$−O$_4$)}$_2$]) (1143.65). IR (KBr): $\tilde{\nu}$ = 1141, 1042 (ν_{SO}) cm^{-1}. ^{1}H NMR (269.6 MHz, MeOD): δ = 8.09−8.00 (m, 4 H, C_6H_4 × 2),

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

7.84−7.77 (m, 8 H, C_6H_4), 7.59−7.47 (m, 16 H, C_6H_4), 7.35−7.23 (m, 4 H, C_5H_3N), 7.14−7.06 (m, 8 H, C_5H_3N), 5.41 (d, $J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 5.40 (d, $J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 4.68 (d, $J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 4.67 (d, $J_{H,H}$ = 18.9 Hz, 2 H, CH_2) ppm. MS (FD, MeOH, ^{102}Ru): *m*/*z* = 1101 $[\{Ru(pyS_4{-}O_4)\}_2]^+$, 1068 $[\{Ru(pyS_4{-}O_3)\}_2]^+$, 974 $[\{Ru(pyS_4)\}_2]^+$, 486 $[Ru(pyS_4)]^+$.

[Ru(NH$_3$)(pyS$_4$−O$_4$)] (21): A red solution of **6** (205 mg, 0.41 mmol) in THF (50 mL) was combined with H_2O_2 (1 mL) at room temp. The resulting yellow precipitate was stirred for 1 h, then filtered, washed with THF (30 mL), and dried in vacuo. Yield: 201.54 mg of **21**·0.5THF (82%). $C_{21}H_{22}N_2RuS_4O_{4.5}$ (603.73): calcd. C 41.78, H 3.67, N 4.64, S 21.24; found C 38.99, H 3.55, N 4.37, S 20.81. IR (KBr): $\tilde{\nu}$ = 3353, 3301, 3188 (ν_{NH}), 1134, 1013 (ν_{SO}) cm^{-1}. ^{1}H NMR (269.6 MHz, CD_2Cl_2): δ = 7.92−7.84 (m, 4 H, C_6H_4), 7.53−7.49 (m, 4 H, C_6H_4), 7.33−7.27 (t, 3 H, C_5H_3N), 7.08 (d, $J_{H,H}$ = 8.1 Hz, 2 H, C_6H_4), 5.82 (d, $J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 4.47 (d, $J_{H,H}$ = 16.2 Hz, 2 H, CH_2), 1.52 (s, 3 H, $-NH_3$) ppm. ^{13}C{^{1}H} NMR (67.7 MHz, CD_3OD): δ = 161.4, 159.7, 136.7, 133.3, 132.5, 132.2, 128.8, 123.8, 122.5 (C_6H_5), 54.9 (CH_2) ppm.

[{Ru(pyS$_4$)}$_2$](I$_3$)$_2$ (22): Black single crystals of **22**·1.8THF that were suitable for X-ray structural analysis were grown from the filtrate after preparation of **10** in the presence of an excess of I_2.

[{Ru(pyS$_4$-Et)}$_2$](BF$_4$)$_2$(B$_2$F$_7$) (23): The single crystals of **23**·3CD_2Cl_2 were obtained during attempts to recrystallize **13** from CD_2Cl_2; spontaneously dealkylation and oxidation of the two Ru centers were observed to occur in the CD_2Cl_2 medium.

[{Ru(pyS$_4$)}$_2$](BF$_4$)(B$_2$F$_7$) (24): The single crystals of **24**·3CH_2Cl_2 were obtained during attempts to recrystallize **13** from CH_2Cl_2; spontaneously dealkylation and oxidation of one of the Ru centers were observed to occur in the CH_2Cl_2 medium.

X-ray Structural Determination of [{Ru(pyS$_4$)}$_2$]·2toluene (4·2toluene), [Ru(NH$_3$)(pyS$_4$)] (6), [Ru(I)(pyS$_4$)]·1.5CH_2Cl_2 (10·1.5CH_2Cl_2), [{Ru(pyS$_4$)}$_2$](PF$_6$)·CD_2Cl_2 (14·CD_2Cl_2), [Ru(NH$_3$)(pyS$_4$)]PF$_6$·CH_2Cl_2 (15·CH_2Cl_2), 0.68[{Ru(pyS$_4$−O$_3$)}$_2$]·0.32[{Ru(pyS$_4$−O$_4$)}$_2$]·2MeOH (0.68 19·0.32 20·2MeOH), [{Ru(pyS$_4$)}$_2$](I$_3$)$_2$·1.8THF (22·1.8THF), [{Ru(pyS$_4$−Et)}$_2$](BF$_4$)$_2$(B$_2$F$_7$)·3CD_2Cl_2 (23·3CD_2Cl_2), and [{Ru(pyS$_4$)}$_2$](BF$_4$)(B$_2$F$_7$)·3CH_2Cl_2 (24·3CH_2Cl_2): Orange rhombs of **4**·2toluene were obtained by recrystallization of a saturated solution of **4** in toluene. Red irregular-shaped crystals of **6** were grown from a saturated H_2O solution of **6**. Black rhombs of **10**·1.5CH_2Cl_2 crystallized from a saturated solution of **10** in CH_2Cl_2. Black blocks of **14**·CD_2Cl_2 were obtained within 10 days from a CD_2Cl_2 solution at room temp. Green fragments of **15**·CH_2Cl_2 formed from a saturated solution of **15** in CH_2Cl_2. Orange prisms of **19/20**·2MeOH formed upon layering a MeOH solution of **19/20** with *n*-hexane. Black crystals of **22**·1.8THF were grown from the filtrate after preparation of **10**. Brown fragments of **23**·3CD_2Cl_2 formed from **13** in a 1:1 mixture of CD_2Cl_2/THF, which was layered with Et_2O. Dark-green platelets of **24**·3CH_2Cl_2 crystallized from a saturated CH_2Cl_2 solution of **13**. Data were collected on a Bruker−Nonius KappaCCD diffractometer using Mo-K_α radiation (λ = 71.073 pm) and a graphite monochromator. Lorentz and polarization corrections were applied for all data sets. A numeric absorption correction was used for **10**·1.5CH_2Cl_2 (Gauss integration).[18] A semiempirical absorption correction has been applied for **14**·CD_2Cl_2 (SORTAV).[19] A semiempirical absorption correction (SADABS)[20] was used for **4**·2toluene, **6**, **15**·CH_2Cl_2, **19/20**·2MeOH, **22**·1.8THF, and **24**·3CH_2Cl_2. All structures were solved by direct methods and refined using full-matrix least-squares procedures on F^2 (SHELXTL NT 6.12).[21] All non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were either taken from the

difference Fourier synthesis and refined with a common isotropic displacement parameter (**6**, **10**·1.5CH_2Cl_2, and **24**·3CH_2Cl_2) or were positioned geometrically with isotropic displacement parameters fixed at 1.2 or 1.5 times the value of *U*(eq) of the preceding carbon atom (**4**·2toluene, **14**·CD_2Cl_2, **15**·CH_2Cl_2, **19/20**·2MeOH, **22**·1.8THF, and **23**·3CD_2Cl_2). Complex **4** crystallized with two toluene molecules per formula unit. Four significant residual electron density maxima are found in close vicinity to the central Ru atom. Complex **10** crystallizes with 1.5 molecules of CH_2Cl_2, which are disordered about the crystallographic inversion center. In the case of **22**·1.8THF, the I_3^- anion is disordered on two alternative sites and the solvate THF molecule is disordered on four different sites. Four significant residual electron density maxima are found in close vicinity of the disordered I_3^-/THF units. The $B_2F_7^-$ anion in the structure of **23**·3CD_2Cl_2 is situated on a crystallographic inversion centre and shares its site with one solvate CD_2Cl_2 molecule, with an occupancy of 50% each. The $B_2F_7^-$ anion in the structure of **24**·3CH_2Cl_2 is disordered on two different sites having occupancies of 78(2)% (for C22, C23) and 22(2)% (for C22′, C23′). The CD_2Cl_2 solvent molecule in **14**·CD_2Cl_2 is disordered on a crystallographic C_2 axis. In the case of **15**·CH_2Cl_2, the CH_2Cl_2 solvate molecule is disordered on two different sites having occupancies of 92.1(4)% and 7.9(4)%, respectively. Two different molecules in **19/20**·2MeOH share a single site on a crystallographic inversion center with occupancies of 68(2)% for [{Ru(pS_4−O_3)}$_2$] (**19**) and 32(2)% for [{Ru(pS_4−O_4)}$_2$] (**20**). The solvate MeOH molecules are also disordered. Selected crystallographic data are summarized in Table 4−6.[22]

Acknowledgments

We thank Prof. Dr. Horst Kisch for valuable discussions of many aspects of this work and the Deutsche Forschungsgemeinschaft (SFB 583 "Redoxaktive Metallkomplexe") for financial support.

Synthesis and Characterization of Cubane-Like Cr_4E_4 (E = S, Se) Clusters − Molecular Structures of $(\eta^5\text{-}RC_5H_4)_4Cr_4E_4$ (E = S, R = MeCO, MeO_2C, EtO_2C; E = Se, R = H)

Li-Cheng Song,*[a] Hua-Wei Cheng,[a] Xin Chen,[a] and Qing-Mei Hu[a]

Keywords: Clusters compounds / Chromium / Selenium / Cp ligands / Cluster-forming reactions

Treatment of the Cr–Cr singly-bonded dimers $[\eta^5\text{-}RC_5H_4Cr(CO)_3]_2$ (**1**, R = MeCO; **2**, R = MeO_2C; **3**, R = EtO_2C) with excess sulfur in refluxing THF gave the cubane Cr_4S_4 clusters $(\eta^5\text{-}RC_5H_4)_4Cr_4S_4$ (**4**, R = MeCO; **5**, R = MeO_2C; **6**, R = EtO_2C). The cubane Cr_4S_4 cluster **4** reacted with excess 2,4-dinitrophenylhydrazine to produce the hydrazone derivative $[\eta^5\text{–}2,4\text{-}(NO_2)_2C_6H_3NHN{=}C(Me)C_5H_4]_4Cr_4S_4$ (**7**). The singly-bonded dimers of $[\eta^5\text{-}RC_5H_4Cr(CO)_3]_2$ (**8**, R = Me; **9**, R = EtO_2C), in the presence of excess selenium, reacted similarly to the linear Cr_2Se complexes $[\eta^5\text{-}RC_5H_4Cr(CO)_2]_2Se$ (**10**, R = Me; **11**, R = EtO_2C), which reacted with an equimolar quantity of selenium to afford the cubane Cr_4Se_4 clusters $(\eta^5\text{-}RC_5H_4)_4Cr_4Se_4$ (**12**, R = Me; **13**, R = EtO_2C). A particularly interesting phenomenon is the cross-assembled reaction of the linear Cr_2Se complexes $[\eta^5\text{-}MeC(O)C_5H_4Cr(CO)_2]_2Se$ (**14**) and $[CpCr(CO)_2]_2Se$ (**15**) in the presence of excess selenium in THF that gave rise to a series of cubane Cr_4Se_4 clusters $[\eta^5\text{-}MeC(O)C_5H_4]_nCp_{4-n}Cr_4Se_4$ (**16**, n = 0; **17**, n = 1; **18**, n = 2; **19**, n = 3; **20**, n = 4). The possible pathway for the cross-assembled reaction is suggested. Furthermore the new clusters were characterized by elemental analysis and spectroscopy, and in the case of **4**–**6** and **16** also by X-ray diffraction techniques.

Introduction

Transition-metal cubane-like cluster complexes containing μ_3-E chalcogen elements (where E = S, Se) have attracted much attention, largely due to their unique structures and novel properties,[1−4] and particularly because of the biological functions played by cubane subclusters, such as Fe_4S_4 and $MoFe_3S_4$, in metalloenzymes of nitrogenase and [Fe]-only hydrogenase.[5−8] Among these transition metal clusters, the Cr_4E_4 cluster complexes (where E = μ_3-S, μ_3-Se) have been studied to a smaller extent, although the parent clusters and the Me-substituted Cp derivatives $Cp_4Cr_4E_4$ (where E = S,[3] E = Se[9]) and $(\eta^5\text{-}MeC_5H_4)_4Cr_4E_4$ (where E = S,[10] E = Se[11]) have been known for many years. In this paper we report the synthesis and spectroscopic characterization of a series of cubane Cr_4E_4 clusters (E = S, Se), $(\eta^5\text{-}RC_5H_4)_4Cr_4S_4$ [where R = MeCO, MeO_2C, EtO_2C, 2,4-$(NO_2)_2C_6H_3NHN{=}CMe$], $(\eta^5\text{-}RC_5H_4)_4Cr_4Se_4$ (where R = Me, EtO_2C) and $[\eta^5\text{-}MeC(O)C_5H_4]_nCp_{4-n}Cr_4Se_4$ (n = 0−4), along with the crystal structures of cubane clusters $(\eta^5\text{-}RC_5H_4)_4Cr_4S_4$ (where R = MeCO, MeO_2C, EtO_2C) and $Cp_4Cr_4Se_4$.

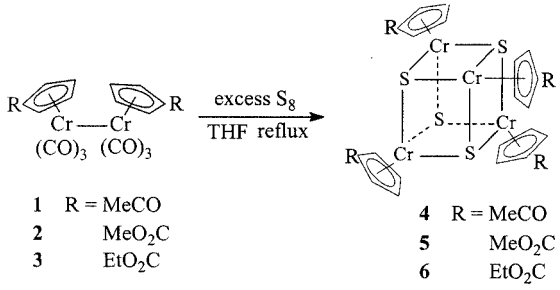
Results and Discussion

Synthesis and Characterization of $(\eta^5\text{-}RC_5H_4)_4Cr_4S_4$ [4, R = MeCO; 5, R = MeO_2C; 6, R = EtO_2C; 7, R = 2,4-$(NO_2)_2C_6H_3NHN{=}CMe$]

The Cr−Cr singly-bonded dimers $[\eta^5\text{-}RC_5H_4Cr(CO)_3]_2$ (**1**, R = MeCO;[12] **2**, R = MeO_2C;[12] **3**, R = EtO_2C[13]) were found to react with an excess amount of elemental sulfur in THF at reflux for 12 h to give cubane clusters **4**−**6** in 81−95 % yields (see Scheme 1), while the functional transformation reaction of cubane cluster **4** with excess 2,4-dinitrophenylhydrazine in CH_2Cl_2 at room temperature for 24 h afforded the phenylhydrazone derivative **7** in 63 % yield (see Scheme 2).

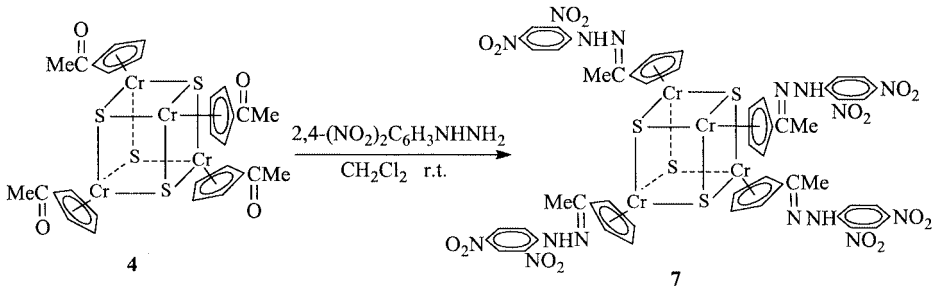
For the above preparations, it is worth pointing out that (i) although clusters **4** and **5** have been previously prepared



1 R = MeCO
2 MeO_2C
3 EtO_2C

4 R = MeCO
5 MeO_2C
6 EtO_2C

Scheme 1



Scheme 2

by another method, the yields were rather low (29 % and 42 %, respectively) and their structures were characterized by combustion analysis and spectroscopy, but not confirmed by X-ray diffraction analysis;[14] and (ii) cluster **7** was the solely isolated product during the course of our study on the functional transformation reactions of the acetyl groups in cluster **4**. The other attempted functional transformation reactions, such as with $NaBH_4$ and with Grignard reagents followed by hydrolysis, led to serious decomposition of the starting cluster **4** and no corresponding hydroxy-containing cluster derivatives were isolated.

The new clusters **6** and **7** were characterized by combustion analysis, IR and ^1H NMR spectroscopy and the structures of clusters **4**−**6** were further confirmed by X-ray crystallographic studies. Similarly to clusters **4** and **5**,[14] the IR spectra of **6** and **7** showed one absorption band at 1708 and 1616 cm^{-1} for the ester C=O and hydrazone C=N groups, while the ^1H NMR spectra of **6** and **7** displayed two singlets at lower and higher fields, attributed respectively to H^2/H^5 and H^3/H^4 protons in the functionally substituted Cp rings.[15]

The ORTEP drawings of **4**−**6** are shown in Figures 1−3, while the selected bond lengths and angles are presented in Table 1.

Figures 1−3 show the molecular structures of clusters **4**−**6**, which are similar to those of the methyl analogs $(\eta^5\text{-}MeC_5H_4)_4Cr_4S_4$,[10] in which the cubane-like Cr_4S_4 cluster core carries four substituted Cp ligands coordinated in an η^5-manner to four chromium atoms. The bond lengths of Cr−Cr are 2.8042−2.8298 Å for **4**, 2.8214−2.8589 Å for **5** and 2.7946−2.8337 Å for **6**, whereas those of Cr−S are 2.2390−2.2540 Å for **4**, 2.2584−2.2747 Å for **5** and 2.2347−2.2478 Å for **6**. The bond angles of Cr−S−Cr are 77.27−78.08° for **4**, 77.03−78.21° for **5** and 77.02−78.49° for **6**, while those of S−Cr−S are 100.69−101.39° for **4**, 100.21−101.95° for **5** and 100.5−101.89° for **6**. The C(1)−C(6) bond of **4** [1.483(11) Å], the C(5)−C(6) bond of **5** [1.494(6) Å] and the C(1)−C(6) bond of **6** [1.477(9) Å] are all shorter than a normal C−C single bond, presumably due to conjugation between the π-electron systems of the functional substituents and the cyclopentadienyl rings.

Synthesis and Characterization of $(\eta^5\text{-}RC_5H_4)_4Cr_4Se_4$ (12, R = Me; 13, R = EtO_2C) and $[\eta^5\text{-}MeC(O)C_5H_4]_nCp_{4-n}Cr_4Se$ (16, *n* = 0; 17, *n* = 1;18, *n* = 2; 19, *n* = 3; 20, *n* = 4)

When the Cr−Cr singly-bonded dimers $[\eta^5\text{-}RC_5H_4Cr(CO)_3]_2$ (**8**, R = Me;[16] **9**, R = EtO_2C[13]) were refluxed with an equimolar amount of elemental selenium in THF for 8 h or when the linear complexes $[\eta^5\text{-}RC_5H_4Cr(CO)_2]_2Se$ (**10**, R = Me;[17] **11**, R = EtO_2C[17]) were treated with an equimolar quantity of selenium in refluxing THF for 8 h, the corresponding cubane Cr_4Se_4 clusters **12** and **13** were obtained in excellent yield (see Scheme 3).

More interestingly, when an equimolar mixture of the linear acetyl-substituted complex $[\eta^5\text{-}MeC(O)C_5H_4Cr(CO)_2]_2Se$ (**14**)[4] and its parent complex $[CpCr(CO)_2]_2Se$ (**15**)[18] were treated with elemental selenium in refluxing THF for 8 h, a series of Cr_4Se_4 cubane clusters with the general formula $[\eta^5\text{-}MeC(O)C_5H_4]_nCp_{4-n}Cr_4Se_4$ (**16**−**20**, *n* = 0−4) were produced in total 97 % yield (see Scheme 4).

At present, we do not know how clusters **16**−**20** are formed from the reaction described in Scheme 4. We initially thought that the complicated reaction might be similar to that of the linear complexes **10** or **11** with selenium and that cubane clusters **16** and **20** were formed from the corresponding reaction of complexes **14** or **15** with selenium, and clusters **17**−**19** were then produced by ligand exchange between **16** and **20**. However, our experiment showed that the attempted reaction between **16** and **20** in THF at reflux did not afford any cubane clusters bearing mixed-Cp ligands. Therefore, we further suggested that clusters **16**−**20** could possibly be formed by self-tetramerization and cross-tetramerization of the highly unsaturated species η^5-$MeC(O)C_5H_4CrSe$ and CpCrSe, generated in situ from the thermolysis of the mixture of **14**, **15** and elemental selenium. This is because the molar ratio of the five products **16**−**20** is approximately 1:4:6:4:1, which is consistent with the combinatory rule of tetramerization of the two highly unsaturated fragments η^5-$MeC(O)C_5H_4CrSe$ and CpCrSe. However, this pathway is mainly speculative and the detailed mechanism for the cross-assembled reaction needs to be further studied. This cross-assembled reaction is particularly interesting, since it provides evidence for the mechanism for the production of the cubane Cr_4Se_4 clusters[19] and it can also furnish the novel cubane clusters with mixed-Cp ligands.

While the cubane clusters **12**,[11] **16**[9] and **20**[4] have been previously prepared by other methods, clusters **13**, **17**−**19** are new and were characterized by combustion analysis, IR, ^1H NMR spectroscopy and ^{77}Se NMR spectroscopy. The IR spectra of **13** and **17**−**19** display one absorption band

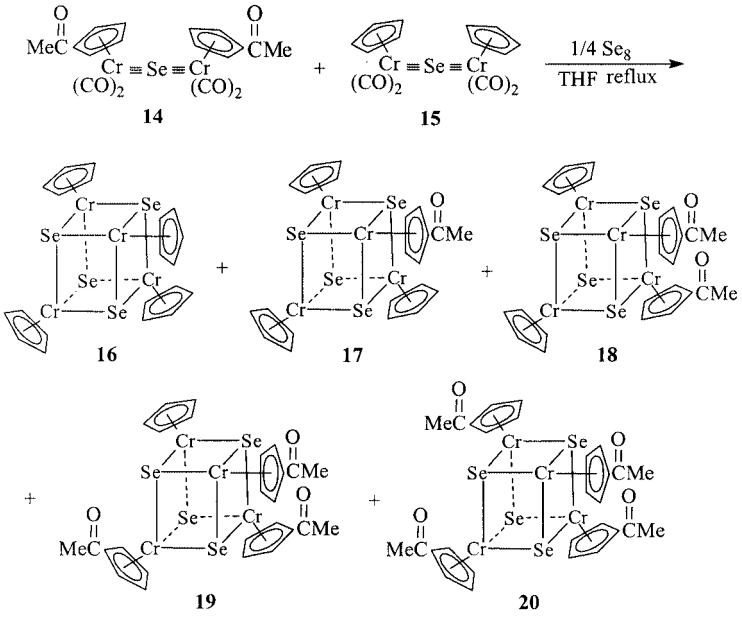

Scheme 4

in the region 1666−1668 cm^{-1} for the ketone carbonyls. The ^1H NMR spectra of **13** and **17−19** show one singlet for the five protons of each Cp ring and two singlets for the H^2/H^5 and H^3/H^4 protons of each substituted Cp ring.[15] It is worthy of note that the ^1H NMR signals of the mixed-Cp cluster **18** appear in the normal range, whereas the signals displayed by **17** and **19** are in the low-field region (12−28 ppm), probably due to traces of paramagnetic species, such as $(CpCr)_mSe_n$ and $(RCpCr)_mSe_n$, generated from the decomposition of the corresponding cubane clusters.

^{77}Se NMR spectroscopy is an important tool for characterizing Se-containing complexes.[20] To examine the influence of different Cp ligands upon ^{77}Se NMR behavior, the ^{77}Se NMR spectra of **12**, **13** and **17−19** were determined. Only one singlet in the range 1009−1241 ppm, which corresponds to the μ_3-Se atoms, was observed. This means that the magnetic environments around the four μ_3-Se atoms in each of the cubane clusters are basically the same, even for the mixed-Cp clusters **17−19**. The ^{77}Se chemical shifts of these clusters are in the order **12** < **17** < **18** < **19** < **13**, which is consistent with the electron-releasing effect of the methyl group and the electron-withdrawing effects of the acetyl and ethoxycarbonyl groups.

Although cluster **16** has been previously prepared,[9] we were the first to confirm its structure by using X-ray crystal-diffraction techniques. This is probably due to its low solubility in common solvents for crystal growing. Figure 4

shows the ORTEP drawing of cluster **16** and Table 2 lists selected bond lengths and angles. Similarly to the methyl derivative,[11] cluster **16** comprises a cubane Cr_4Se_4 cluster core that carries four Cp ligands coordinated in an η^5-fashion to four Cr atoms. The Cr−Cr and Cr−Se bond lengths and the Cr−Se−Cr and Se−Cr−Se bond angles are 2.9683 Å, 2.3957−2.4055 Å, 76.32−79.50° and 98.48−103.12°, respectively. Thus, the cubane Cr_4Se_4 cluster core is just slightly distorted. This molecule has an alternating fourfold axis of symmetry.

Experimental Section

General: All reactions were carried out under an atmosphere of highly purified nitrogen gas using standard Schlenk or vacuum-line techniques. Solvents for preparative use were dried and distilled under nitrogen from Na/benzophenone ketyl or CaH_2 prior to use. Commercial sulfur powder, selenium powder, and 2,4-dinitrophenylhydrazine were used as received. [η^5-$RC_5H_4Cr(CO)_3]_2$ (where R = Me,[16] MeCO,[12] MeO_2C,[12] EtO_2C[13]), [$CpCr(CO)_2]_2Se$[18] and [η^5-$MeC(O)C_5H_4Cr(CO)_2]_2Se$[4] were prepared according to literature procedures. All reactions were monitored by thin layer chromatography (TLC) at intervals. The preparative TLC was carried out on a glass column (2 × 10 cm) packed with silica gel G and glass plates (25 × 20 × 0.25 cm) coated with silica gel H (10−40 μm). Samples for characterization were recrystallized from mixed dichloromethane and hexane. IR spectra were recorded on a Bruker Vector 22 infrared spectrophotometer. While ^{1}H NMR spectra were recorded on a Bruker AC-P 200 NMR spectrometer, ^{77}Se NMR spectra were taken from a Varian Unity-Plus 400 NMR spectrometer with Ph_2Se_2 as external standard and chemical shifts were referenced to Me_2Se (δ = 0 ppm). Elemental analysis was performed on an Elementar Vario EL analyzer. Melting points were determined on a Yanaco MP-500 apparatus.

Preparation of (η^5-$MeCOC_5H_4)_4Cr_4S_4$ (4): A 100-mL Schlenk flask equipped with a magnetic stir bar was charged with [η^5-$MeCOC_5H_4Cr(CO)_3]_2$ (0.423 g, 0.87 mmol), sulfur powder (0.070 g, 2.19 mmol) and THF (20 mL). The mixture was stirred at reflux for 12 h. The solvent was removed under vacuum and the residue was extracted in a minimum volume of dichloromethane, which was then subjected to TLC separation using acetone/petroleum ether (v/v, 1:2) as eluent. Compound **4** (0.287 g, 86 %) was obtained as a black solid from the green band and it was identified by comparing its melting point, ^{1}H NMR and IR spectra with those of the spectroscopically characterized sample.[14]

Preparation of (η^5-$MeO_2CC_5H_4)_4Cr_4S_4$ (5): The same procedure as for the preparation of **4** was followed, but [η^5-$MeO_2CC_5H_4Cr(CO)_3]_2$ (0.450 g, 0.87 mmol) was employed to give **5** (0.342 g, 95 %) as a black solid, which was also identified by comparing its melting point, ^{1}H NMR and IR spectra with those of the spectroscopically characterized sample.[14]

Preparation of (η^5-$EtO_2CC_5H_4)_4Cr_4S_4$ (6): The same procedure as for the preparation of **4** was followed, but [η^5-$EtO_2CC_5H_4Cr(CO)_3]_2$ (0.490 g, 0.90 mmol) was employed to give **6** (0.321 g, 81 %) as a black solid. M.p. 186−188 °C. ^{1}H NMR ($CDCl_3$): δ = 1.32 (t, *J* = 8.0 Hz, 12 H, 4 CH_3), 4.24 (q, *J* = 8.0 Hz, 8 H, 4 CH_2), 4.76 (s, 8 H, 4 H^3, 4 H^4), 5.28 (s, 8 H, 4 H^2, 4 H^5). IR (KBr disk): $\tilde{\nu}$ = 1708 (s) (C=O) cm^{-1}. $C_{32}H_{36}Cr_4O_8S_4$ (884.85): calcd. C 43.44, H 4.10; found C 42.85, H 4.13.

Preparation of [η^5−2,4-$(NO_2)_2C_6H_3NHN{=}CMeC_5H_4]_4Cr_4S_4$ (7): A 2,4-dinitrophenylhydrazine solution (2 mL, ca. 4 mmol), which was prepared by dissolving 1.0 g of 2,4-dinitrophenylhydrazine in 5 mL of 98 % H_2SO_4, 10 mL of H_2O and 35 mL of 95% EtOH, was added to a solution of **4** (0.382 g, 0.50 mmol) in CH_2Cl_2 (10 mL). The mixture was stirred at room temperature for 24 h. The solvent was removed under reduced pressure and the residue was washed carefully by anhydrous ethyl alcohol and was then extracted with a minimum volume of CH_2Cl_2. This extract was subjected to TLC separation using CH_2Cl_2 as eluent. Compound **7** (0.467 g, 63 %) was obtained as a black solid from the main band. M.p. 242−244 °C. ^{1}H NMR ($CDCl_3$): δ = 1.53 (s, 12 H, 4 CH_3), 4.93 (s, 8 H, 4 H^3, 4 H^4), 5.64 (s, 8 H, 4 H^2, 4 H^5), 7.80 (m, 4 H, 4 H^6 of benzene ring), 8.20−8.50 (m, 4 H, 4 H^5 of benzene ring), 9.14 (s, 4 H, 4 H^3 of benzene ring), 11.20 (s, 4 H, 4 NH) ppm. IR (KBr disk): $\tilde{\nu}$ = 3312 (vs) (N−H), 1616 (s) (C=N) cm^{-1}. $C_{52}H_{44}Cr_4N_{16}O_{16}S_4$ (1485.24): calcd. C 42.05, H 2.99, N 15.32; found C 41.74, H 3.51, N 15.09.

Preparation of (η^5-$MeC_5H_4)_4Cr_4Se_4$ (12). Method (i): A mixture of [η^5-$MeC_5H_4Cr(CO)_3]_2$ (0.215 g, 0.50 mmol), selenium powder (0.079 g, 1.00 mmol) and THF (20 mL) was refluxed for 8 h, causing a color change from brown red to dark green. The solvent was removed under vacuum and the residue was extracted with CH_2Cl_2. CH_2Cl_2 was removed under vacuum and the residue was recrystallized from a mixed CH_2Cl_2/hexane solvent to give 0.202 g (96%) of **12** as a black solid. M.p. 179−180 °C. ^{1}H NMR ($CDCl_3$): δ = 2.57 (s, 12 H, 4 CH_3), 30.07 (s, 8 H, 4 H^2, 4 H^5), 30.45 (s, 8 H, 4 H^3, 4 H^4) ppm. ^{77}Se NMR ($CDCl_3$): δ = 1009 (s) ppm. IR (KBr disk): $\tilde{\nu}$ = 1630 (m), 1490 (m), 1449 (s), 1371 (m), 1038 (m), 1024 (s), 802 (vs) cm^{-1}. $C_{24}H_{28}Cr_4Se_4$ (840.30): calcd. C 34.30, H 3.36; found C 34.18, H 3.31. **Method (ii):** A mixture of [η^5-$MeC_5H_4Cr(CO)_2]_2Se$ (0.227 g, 0.50 mmol), selenium powder (0.040 g, 0.50 mmol) and THF (20 mL) was refluxed for 8 h. The same workup as that described in method (i) gave 0.200 g (95%) of **12**.

Preparation of (η^5-$EtO_2CC_5H_4)_4Cr_4Se_4$ (13). Method (i): The same procedure as Method (i) for **12** was followed, but [η^5-$EtO_2CC_5H_4Cr(CO)_3]_2$ (0.273 g, 0.50 mmol) was utilized to give 0.260 g (97%) of **13** as a black solid. M.p. 169−170 °C. ^{1}H NMR ($CDCl_3$): δ = 1.32 (t, *J* = 7.0 Hz, 12 H, 4 CH_3), 4.14 (q, *J* = 7.0 Hz, 8 H, 4 CH_2), 4.95 (s, 8 H, 4 H^3, 4 H^4), 5.83 (s, 8 H, 4 H^2, 4 H^5) ppm. ^{77}Se NMR ($CDCl_3$): δ = 1241 (s) ppm. IR (KBr disk): $\tilde{\nu}$ = 1705 (s) (C=O) cm^{-1}. $C_{32}H_{36}Cr_4O_8Se_4$ (1072.45): calcd. C 35.84, H 3.38; found C 35.41, H 3.16. **Method (ii):** The same procedure as Method (ii) for **12** was followed, but [η^5-$EtO_2CC_5H_4Cr(CO)_2]_2Se$ (0.285 g, 0.50 mmol) was used to afford 0.257 g (96%) of **13**.

Preparation of [η^5-$MeC(O)CC_5H_4]_nCp_{4-n}Cr_4Se_4$ (*n* = 0, 16; *n* = 1, 17; *n* = 2, 18; *n* = 3, 19; *n* = 4, 20): A 100-mL Schlenk flask was charged with [$CpCr(CO)_2]_2Se$ (0.212 g, 0.50 mmol), [η^5-$MeC(O)C_5H_4Cr(CO)_2]_2Se$ (0.255 g, 0.50 mmol), selenium powder (0.158 g, 2 mmol) and THF (30 mL). The mixture was stirred at reflux for 8 h, resulting in a color change from brown red to dark green. The mixture was centrifuged to give a clear centrifugate, which was concentrated to ca. 10 mL and was then subjected to TLC separation using acetone/CH_2Cl_2/petroleum ether (v/v/v, 1:3:3) as eluent to develop four brown-green bands.

[η^5-$MeC(O)C_5H_4]Cp_3Cr_4Se_4$ (17): Compound **17** (0.096 g, 23 %) was obtained from the first band (R_f = 0.81) as a black solid. M.p. 202−203 °C. ^{1}H NMR ($CDCl_3$): δ = 2.17 (s, 3 H, CH_3), 12.27 (s, 2 H, H^3, H^4), 13.17 (s, 15 H, 3 C_5H_5), 15.20 (s, 2 H, H^2, H^5) ppm.

^{77}Se NMR ($CDCl_3$): δ = 1148(s) ppm. IR (KBr disk): ṽ = 1667 (s) (C=O) cm^{-1}. $C_{22}H_{22}Cr_4OSe_4$ (826.24): calcd. C 31.98, H 2.68; found C 31.93, H 2.54.

[η^5-MeC(O)C$_5$H$_4$]$_2$Cp$_2$Cr$_4$Se$_4$ (18): Compound **18** (0.158 g, 36 %) was obtained from the second band (R_f = 0.72) as a black solid. M.p. 214−215 °C. ^{1}H NMR ($CDCl_3$): δ = 2.19 (s, 6 H, 2 CH_3), 5.27 (s, 4 H, 2 H^3, 2 H^4), 5.33 (s, 10 H, 2 C_5H_5), 6.13 (s, 4 H, 2 H^2, 2 H^5) ppm. ^{77}Se NMR ($CDCl_3$): δ = 1178 (s) ppm. IR (KBr disk): ṽ = 1668 (s) (C=O) cm^{-1}. $C_{24}H_{24}Cr_4O_2Se_4$ (868.28): calcd. C 33.20, H 2.79; found C 33.21, H 2.76.

[η^5-MeC(O)C$_5$H$_4$]$_3$CpCr$_4$Se$_4$ (19): Compound **19** (0.112 g, 25 %) was obtained from the third band (R_f = 0.60) as a black solid. M.p. 188−189 °C. ^{1}H NMR ($CDCl_3$): δ = 2.18 (s, 9 H, 3CH_3), 22.17 (s, 6 H, 3 H^3, 3 H^4), 23.75 (s, 5 H, C_5H_5), 27.22 (s, 6 H, 3 H^2, 3 H^5) ppm. ^{77}Se NMR ($CDCl_3$): δ = 1224 (s) ppm. IR (KBr disk): ṽ = 1666 (s) (C=O) cm^{-1}. $C_{26}H_{26}Cr_4O_3Se_4$ (910.31): calcd. C 34.31, H 2.88; found C 34.33, H 2.77.

[η^5-MeC(O)C$_5$H$_4$]$_4$Cr$_4$Se$_4$ (20): Compound **20** (0.031 g, 7 %) was obtained from the fourth band (R_f = 0.45) identified by comparing its IR and ^{1}H NMR spectra with those of the fully characterized sample.[4] The immovable base band was collected and refluxed with 10 mL of bromobenzene for 10 min. Once it had cooled to room temperature, the mixture was filtered and the filtrate was centrifuged to give a clear centrifugate, from which $Cp_4Cr_4Se_4$ (**16**)[9] (0.025 g, 6 %) was obtained.

Attempted Cp/η^5-MeC(O)C$_5$H$_4$ Ligand Exchange Between Cp$_4$Cr$_4$Se$_4$ and [η^5-MeC(O)C$_5$H$_4$]$_4$Cr$_4$Se$_4$: A mixture consisting of $Cp_4Cr_4Se_4$ (0.078 g, 0.10 mmol) and **20** (0.095 g, 0.10 mmol) in THF (20 mL) was stirred at reflux for 10 h. The resulting mixture was concentrated to ca. 5 mL and was subjected to TLC separation using acetone/CH_2Cl_2/petroleum ether (v/v/v, 1:3:3) as eluent to develop only one brown-green band. Compound **20** (0.079 g, 82 %) was recovered from this band, while $Cp_4Cr_4Se_4$ (0.052 g, 67 %) was recovered from the immovable band. No ligand exchange products of [η^5-MeC(O)CC_5H_4]$_n$Cp$_{4-n}$Cr$_4$Se$_4$ (n = 1−3, **17**−**19**) were produced.

Crystal Structure Determination of 4−6 and 16: Single crystals of **4**−**6** and **16**, suitable for X-ray diffraction analysis, were grown by slow evaporation of an acetone/hexane solution at room temperature. Each single crystal was glued to a glass fiber and mounted on a Bruker SMART 1000 automated diffractometer. Data were collected at room temperature, using graphite monochromator Mo-K_α radiation (λ = 0.71073 Å) in the ω-2θ scanning mode. Absorption correction was performed using the SADABS method. The structure was solved by direct methods using the SHELXS-97[21a] program and refined by full-matrix least-squares techniques (SHELXL-97[21b]) on F^2. Hydrogen atoms were located by using the geometric method. The crystal data and structural refinement details are listed in Table 3. The calculations were performed using the TEXSAN crystallographic software package of Molecular Structure Corporation.[22] CCDC-228444, -228445, -228446 and -228990 contain the supplementary crystallographic data for this paper. Dedicated to Professor José Vicente Soler on the occasion of his 60th birthday

Keywords: Cyclopentadienyl ligands / N ligands / Olefin polymerization / Titanium

The synthesis of *N*,*N*′-alkyl 1,2-phenylenediamines 1,2-$C_6H_4(NHR)_2$ [R = $CH_2CH_2CH_3$ (*n*Pr), CH_2tBu (Np)] was carried out in three steps by lithiation of the primary 1,2-phenylenediamine, reaction with the appropriate acyl chloride and reduction with $LiAlH_4$. The addition of *n*BuLi to a stirred solution of *N*,*N*′-alkyl diamines in cold hexane resulted in the immediate deposition of the corresponding lithium salts, which react with [$MCp^{R'}Cl_3$] to give the diamidochloro(η^5-cyclopentadienyl)titanium and -zirconium complexes [$MCp^{R'}$\{1,2-$C_6H_4(NR)_2$\}Cl] (**4**–**10**) [M = Ti, Zr; $Cp^{R'}$ = η^5-C_5H_5, η^5-$C_5(CH_3)_5$, η^5-$C_5H_4(SiMe_3)$; R = *n*Pr, Np]. The compound [Ti(η^5-C_5H_5){1,2-C_6H_4(N*n*Pr)$_2$}Cl] (**3**) was obtained by treatment of [Ti(η^5-C_5H_5)Cl_3] with 1,2-C_6H_4(NH*n*Pr)$_2$ in the presence of NEt_3 in toluene. All the reported compounds were characterized by the usual analytical and NMR spectroscopic methods. The molecular structures of **3** and **7** were determined by single-crystal X-ray crystallography. The compounds described here were further investigated as potential olefin polymerization catalysts.

Introduction

The organometallic chemistry of group 4 transition metals is based largely on η^5-cyclopentadienyl (Cp) complexes, for example [MCp_2R_2] and [$MCpR_3$] derivatives, which doubtless figure among the best known organometallic systems.[1] Chelating diamido ligands are gaining increasing interest in early transition metal chemistry.[2] Bidentate (N^-,N^-) and tridentate (N^-,N^-,X; X = O,N) diamido ligands have been used as alternatives to η^5-cyclopentadienyl-based fragments, and non-η^5-cyclopentadienyl Group 4 metal complexes containing these ligands have been investigated as precursors for living α-olefin polymerization processes.[3] Descriptions of titanium and zirconium derivatives combining η^5-cyclopentadienyl and diamido groups are limited, but they show an interesting chemical reactivity.[4] The well-known amido(η^5-cyclopentadienyl)[5] and the more recently reported diamido(η^5-cyclopentadienyl)[6] derivatives are attracting increasing interest in the context of α-olefin polymerization processes. The vast majority of group 4 metallocene and related complexes used as olefin polymerization precatalysts typically have two or more abstractable or insertable alkyl (or halide) groups attached to the metal. Examples of precatalysts containing only one such group that can be actived for olefin polymerization are scarce.[5h,6,7] This paper expands this class of compounds by reporting monochlorotitanium and -zirconium complexes supported by Cp and chelating diamido ligands which are of potential interest in the context of single-site olefin polymerization catalysis.

We are interested in the synthesis and chemical behaviour of [MCp′(LL)X] derivatives (Cp′ = substituted or unsubstituted η^5-cyclopentadienyl ring; LL = chelating diamido and dialkoxo[7] ligands) and describe herein the synthesis and characterization of new chlorodiamido complexes of titanium and zirconium [$MCp^{R'}$\{1,2-$C_6H_4(NR)_2$\}Cl] [M = Ti, Zr; $Cp^{R'}$ = η^5-C_5H_5, η^5-$C_5(CH_3)_5$, η^5-$C_5H_4(SiMe_3)$; R = *n*Pr, Np]. The X-ray molecular structures of [Ti(η^5-C_5H_5){1,2-C_6H_4(N*n*Pr)$_2$}Cl] and [Ti{η^5-$C_5H_4(SiMe_3)$}{1,2-C_6H_4(N*n*Pr)$_2$}Cl] are also described. All synthesized complexes were tested as potential catalysts for ethylene and styrene polymerization after activation with MAO.

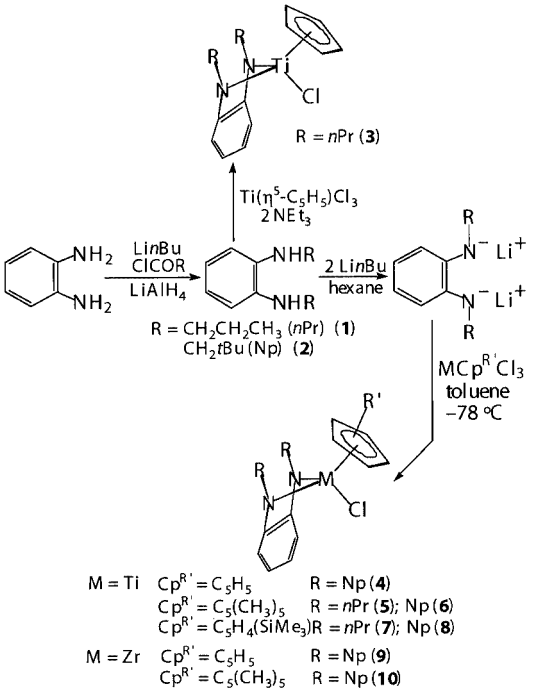
Results and Discussion

The *N*,*N*′-alkyl-1,2-phenylenediamines 1,2-$C_6H_4(NHR)_2$ [R = *n*Pr (**1**), Np (**2**)] were synthesized in good yield from 1,2-diaminobenzene by successive *N*,*N*′-dilithiation, reaction with propionyl or trimethylacetyl chloride to give the corresponding diamide derivative, and reduction with $LiAlH_4$.[8] The propylamine was obtained as a brown oil and the neopentylamine as an orange solid. The synthesis of *N*,*N*′-bis(neopentyl)-1,2-phenylenediamine has been described previously and it has been used in the synthesis of 1,2-phenylenediaminotin(II) complexes through a transamination process.[9] The amines were spectroscopically and analytically characterized. As it was obtained as an oil, compound **1** could not be recrystallized or subjected to elemental analysis. The phenyl protons and the substituents on the nitrogen atoms exhibit a characteristic set of ^1H and $^{13}C\{^1H\}$ NMR resonances[10] (see Exp. Sect.).

The titanium and zirconium chelating diamido derivatives were synthesized by the usual approach based on the metathetical reaction of the dilithium salts of 1,2-phenylenediamines with the appropriate metal halide. Treatment of **1** and **2**, at −78 °C, successively with *n*BuLi in hexane and the appropriate titanium or zirconium compound $[MCp^{R'}Cl_3]$ in toluene gave the corresponding mono-cyclopentadienyl chlorodiamido titanium and zirconium complexes $[MCp^{R'}\{1,2\text{-}C_6H_4(NR)_2\}Cl]$ (**4**−**10**) [M = Ti, Zr; $Cp^{R'}$ = η^5-C_5H_5, η^5-$C_5(CH_3)_5$, η^5-$C_5H_4(SiMe_3)$; R = *n*Pr, Np] (Scheme 1). Similar attempts to obtain *N*,*N*′-dipropyl-1,2-phenylenediamidozirconium derivatives were unsuccessful, which may be attributed to the larger size of zirconium compared with titanium, favouring β-elimination decomposition pathways. The compound $[Ti(\eta^5\text{-}C_5H_5)\{1,2\text{-}C_6H_4(NnPr)_2\}Cl]$ (**3**) was synthesized by reaction of $[Ti(\eta^5\text{-}C_5H_5)Cl_3]$ with 1,2-$C_6H_4(NHnPr)_2$ in the presence of NEt_3 in toluene. Group 4 metal phenylenediamido complexes of the non-cyclopentadienyl type[2d,9] $M(NN)X_2$ and monocyclopentadienyl[4c] type MCp′′(NN)X have recently been reported.



Scheme 1

Complexes **3**−**10** were obtained as black or red-brown solids, soluble in aromatic hydrocarbons, dichloromethane, chloroform, diethyl ether and alkanes (hexane and pentane). Their purification was difficult, as they are highly soluble in alkanes and polar solvents. They are both air and moisture sensitive in solution and in the solid state, although they can be stored unaltered for weeks under an inert atmosphere. The complexes were characterized by the usual analytical and spectroscopic methods. The elemental analysis values found for **8** were inaccurate due to the presence of a small amount of LiCl in the mixture, which could not be removed.

Most importantly in this type of complexes, the diamido ligand can adopt different coordination modes[4e,11] and has two possible conformations (*supine* or*prone*)[12] relative to the cyclopentadienyl ring. The ^1H NMR spectra (C_6D_6 and $CDCl_3$, room temperature) show the presence of only one species, ruling out a mixture of the two rotamers (*supine*-*prone* automerization) observed in solutions of similar monocyclopentadienyl diene complexes.[4d,4e] The spectra show the expected resonances for the cyclopentadienyl rings: one singlet for the C_5H_5 and the C_5Me_5 protons and two sets of pseudo triplets for the $C_5H_4(SiMe_3)$ ring protons, corresponding to an AA′BB′ spin system. The ^1H NMR resonances of the cyclopentadienyl protons appear as signals at δ = 6.20−6.30 ppm for Cp, δ = 6.40−6.73 ppm for $CpSiMe_3$ and δ = 1.65−1.75 ppm for C_5Me_5. Such shifts suggest that the cyclopentadienyl protons are not influenced by phenylene magnetic anisotropy[13] and lead us to propose that the phenylenediamido ligand adopts a *supine* conformation.[4c] The methyl protons of the $SiMe_3$ group exhibit one singlet (δ = 0.25−0.26 ppm). The spectra for compounds **3** and **7** show sets of multiplet, multiplet and triplet for the N-CH_2-CH_2-CH_3 fragment protons, respectively, while two multiplets for the N−CH_2 protons are observed in the spectrum of the pentamethylcyclopentadienyl derivative **5**. These data indicate the diastereotopic nature of the methylene protons bonded to the nitrogen atom. In the spectra of compounds **4**, **6**, and **8**−**10** in C_6D_6, the neopentyl groups show a singlet for the methyl protons and a doublet of doublets corresponding to the diastereotopic methylene protons. Similar spectroscopic features indicate that the neopentyl-group signals in the spectra of compounds **4**, **6**, **8** and **9** in $CDCl_3$ exhibit a diastereotopic behaviour for the N−CH_2 protons, while the spectrum of **10** in $CDCl_3$ shows only one singlet assignable to these protons. Characteristic low-field chemical shift trends are observed for the N−CH_2 protons on going from free diamine (δ = 2.6 ppm for **1** and δ = 2.8 ppm for **2**) to an amido coordination mode to the Lewis acid titanium atom in complexes **3**−**10** (δ = 4−3.5 ppm). The phenyl protons appear as two multiplets in the usual range.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In the ^{13}C NMR spectra of the free diamines **1** and **2** the signals of the imine C-atoms are observed at δ = 138 and 138.9 ppm, respectively. The corresponding resonances for the titanium and zirconium complexes are found at higher field, at around δ = 125 ppm and δ = 137 ppm for the neopentyl and propyl derivatives, respectively. These spectroscopic data are in agreement with C_s symmetry, consistent with the presence of a mirror plane containing the Ti and Cl atoms and bisecting the N−Ti−N angle of the chelate diamido ligand.

A nuclear Overhauser enhancement (NOE) study of the complexes[12c,12d] containing the Cp ligand confirms this proposal. Irradiation of the Cp signal of the propyl derivative **3** results in a significant NOE enhancement of the CH_2 signals, while irradiation of the Cp signal of the neopentyl derivative **4** results in significant NOE enhancements in the *t*Bu and the CH_2 signals. Irradiation of the Cp signals of **3** and **4** does not cause NOE enhancements in the phenyl signals. These observations suggest that the propyl and neopentyl groups are in close proximity to the Cp ring, with the diamido ligand adopting a *supine* conformation, consistent with the disposition found in the solid state from the X-ray structural analysis of **3** and **7**.

Crystal Structure of [Ti(η^5-C_5H_5){1,2-C_6H_4(N*n*Pr)$_2$}Cl] (3) and [Ti{η^5-C_5H_4(SiMe$_3$)}{1,2-C_6H_4(N*n*Pr)$_2$}Cl] (7)

In order to establish the solid-state molecular geometry for compounds of this type, X-ray crystal-structure analyses of **3** and **7** were carried out. Single crystals of **3** and **7** obtained by slow recrystallization from hexane solution were of good enough quality to be analyzed by X-ray diffraction. The crystal structure of **3** is shown in Figure 1 and Table 1 summarizes selected bond lengths and angles.

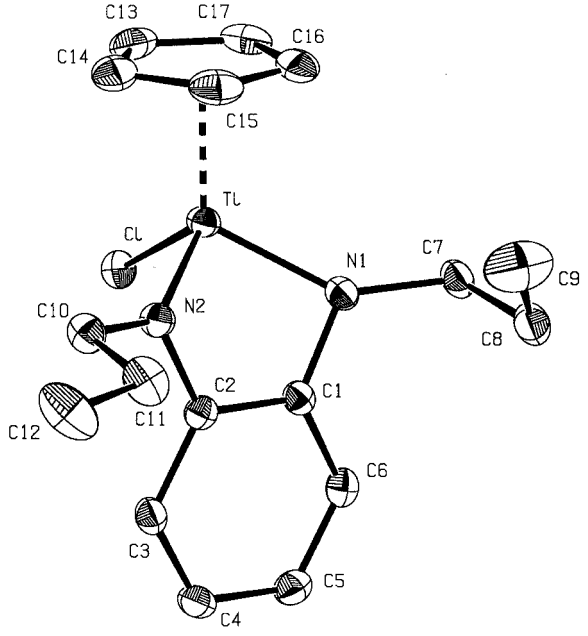


Figure 1. ORTEP representation of [Ti(η^5-C_5H_5){1,2-C_6H_4(NCH$_2$CH$_2$CH$_3$)2}Cl] (**3**) in the solid state; thermal ellipsoids are drawn at the 50% probability level; hydrogen atoms are omitted for clarity

[a] Cg denotes the centroid of the Cp ligand.

The compound is monomeric with a tetrahedral coordination geometry around the titanium atom which coordinated by an η^5-cyclopentadienyl ring, a chloride ligand and the two nitrogen atoms of the symmetrically chelated diamido ligand. The structure contains a non-crystallographic plane of symmetry containing the cyclopentadienyl and phenylene ring centroids, the metal centre and the chlorine atom. As expected from the NMR spectroscopic data (solution studies), the phenylenediamido ligand adopts a *supine* conformation in the solid state, which minimizes the steric interaction with the Cp ring, although a *prone* conformation of the amido ligand in analogous monocyclopentadienyl diazadiene group 4 and 5 metal complexes has also been observed.[4d,4e] The nature of the alkyl substituents in the nitrogen atom seems to have a dramatic effect on the conformation geometry that the diene ligands adopt in half-sandwich complexes. In the literature, the *supine* conformation preferred for the *n*Pr substituents and the *prone* conformation preferred for the *t*Bu substituents have been found.[12d,14] Unfortunately, we were not successful in preparing crystals of the Np derivatives suitable for X-ray diffraction studies, although we propose that, as in compound **3**, a *supine* conformation can also be expected for Np derivatives in the solid state.

The titanium atom is located out of the plane defined by Cl and the nitrogen atoms [distance from Ti to N(1)−N(2)−Cl plane of 0.923(1) Å] which is almost parallel to the cyclopentadienyl ring with an interplanar angle of 4.6(1)°. The trigonal-planar geometry of the nitrogen atom, corresponding to sp^2 hybridization, is evidenced by the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sums of the angles at N(1) (358.4°) and N(2) (358.8°) and the comparatively short Ti−N bond lengths of 1.9018(14) and 1.9014(13) Å, which point to a significant pπ-dπ interaction and are in agreement with reported values for related titanium amido[2d,2e,15] complexes. The N−Ti−N angle is 89.69(5)°. The Ti−C(1) and Ti−C(2) distances [2.4600(15) and 2.4635(15) Å] are long enough to allow donation of electron density from the C(1)−C(2) bond to the titanium atom. The phenylene ring shows a marked deformation. Thus, the C(1)−C(2) [1.427(2) Å] distance is significantly elongated with respect to the rest of the C−C distances in the ring (average 1.390 Å). These Ti−C and C(1)−C(2) bond lengths are longer and shorter, respectively, than similar distances reported for related diazadiene complexes[4d,4e] in which a π interaction between the double diene C−C bond and the metal centre is observed. The N−C bond lengths are 1.396(2) and 1.399(2) Å for N(1)−C(1) and N(2)−C(2), respectively, showing slight double-bond character,[16] while the N−C(Pr) bond lengths of 1.461(2) for N(1)−C(7) and 1.456(2) for N(2)−C(10) are consistent with single bonds.

The five-membered chelate ring is not planar and the phenylenediamido ligand is folded along the N(1)···N(2) vector with a fold angle, Θ, of 49.77(7)°. Similar folding has previously been interpreted in terms of κ^4-σ^2(N,N),π(C=C) bonding.[2e,4c,17] However, our results indicate this situation to be unlikely here.[9b]

The titanium-chlorine bond length is 2.3270(5) Å, slightly longer that those found for related monocyclopentadienyl- and dicyclopentadienyl-type chloride complexes.

The crystal structure of **7** is shown in Figure 2 and Table 1 summarizes selected bond lengths and angles. The structural parameters in the Ti-core of **7** are similar to those observed in compound **3**. The Cp ligand is oriented such that the $SiMe_3$ group is located in the plane bisecting the N−Ti−N angle and in a *trans* position with respect to the phenylene ligand.

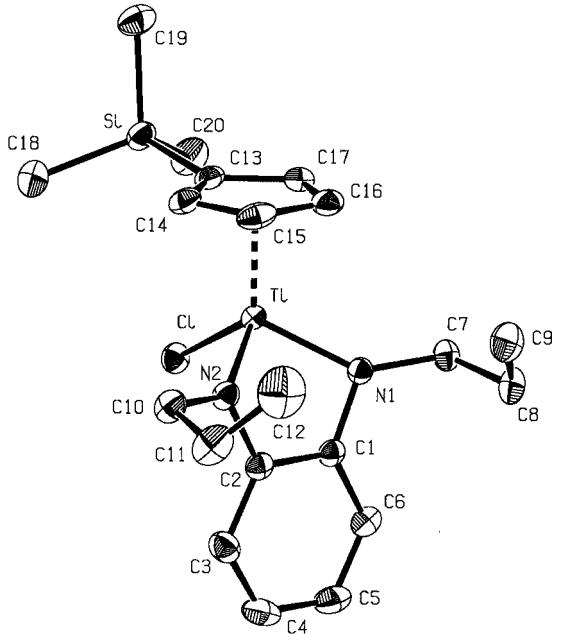

Figure 2. ORTEP representation of [Ti{η^5-$C_5H_4(SiMe_3)$}{1,2-$C_6H_4(NCH_2CH_2CH_3)_2$}Cl] (**7**) in the solid state; thermal ellipsoids are drawn at the 50% probability level; hydrogen atoms are omitted for clarity

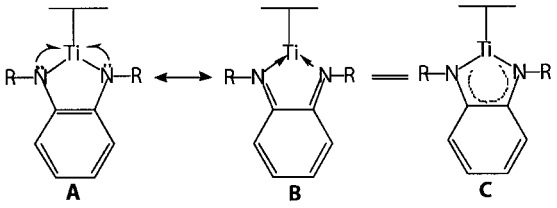
Various coordination modes[11] [from η^1-N to η^4-N_2C_2 (σ^2,π)] can be proposed for the diamido ligands, where the N substituents regulate the steric demands at the metal centre. The bonding of the phenylenediamido ligand in compounds **3**−**10** can be best described by a σ^2,*N*,*N* bond with a partial pπ-dπ nitrogen interaction (form **A** in Scheme 2) and electronic density delocalization through the N−C−C−N bond system (form **B** in Scheme 2) consistent with the resonance hybrid form **C**, and such a ligand can therefore produce more electronically saturated complexes, consistent with a dianionic moiety that can donate between four and six electrons to the metal centre. The phenylenediamido ligand can therefore be considered as a σ^2,π-enediamide group structure in which the π-component is mainly contributed by the two nitrogen lone pairs.[18]



Scheme 2

Olefin Polymerization

Complexes **3**−**8** were studied as α-olefin polymerization pre-catalysts with methylalumoxane (MAO) as cocatalyst.

Ethylene polymerization was investigated using 50 mL total volume of toluene with 10−20 μmol of catalyst, with a Al/Ti molar ratio of 1000 at 25 °C and 1 atm pressure. The results are summarized in Table 2. Only traces of polymer or no polymerization were found when the reaction was carried out with propylene. Polymerization runs with the *n*Pr complexes resulted in moderate[19] activity (approx. 100 g of PE/mmol of Ti·atm·h) of PE with activity increasing in the order **7** < **5** < **3**. This result indicates that the activity is

influenced greatly by the nature of the cyclopentadienyl substituents. A lower activity was observed for the Np derivatives. The activities of these chloro pre-catalyst systems are lower[20] than those found for the well-known non-cyclopentadienyl group 4 complexes containing chelating diamido ligands;[2c,2i,3a,3b,3d,20] rapid deactivation pathways[15d,21] of these chloro compounds after the reaction with MAO or TMA (present in MAO) could be a possible explanation for this behaviour.

The PE polymer samples obtained had melting points of 130−135 °C, characteristic of high density polyethylene, and remarkable differences in the ΔH enthalpy values. The degree of crystallinity (α) found for these PEs was lower than that expected for commercial HDPE, suggesting that chain branching occurs during the polymerization process.[22]

Styrene polymerization was studied using 35 mL total volume of toluene and 5 mL of monomer; the results are summarized in Table 3. For the *n*Pr derivatives, the activity for **3**/MAO was higher than for the system **7**/MAO; a lower activity was found for **5**/MAO (runs 1, 5 and 3, Table 3), indicating that the cyclopentadienyl ligands exert a strong influence on the activity of the catalyst and the order of activity is lower than that obtained for [$CpTiCl_3$] (used as a reference point) under similar conditions.[23] The polymers were precipitated in acidified MeOH, and syndiotactic polystyrene was obtained, as evidenced by NMR spectroscopic analysis and the melting point values.[24]

It is a general observation that the complexes containing the *n*Pr amido ligand show higher polymerization activities than the Np derivatives, suggesting that the activity is highly influenced by the steric effect[25] at the titanium centre caused by *n*-propyl or neopentyl substituents at the nitrogen atom of the diamido ligand. Similar examples of the influence of bulky substituents on catalytic polymerization activity have been observed for related amidinate complexes.[26]

Attempts to copolymerize styrene/ethylene were unsuccessful and afforded a mixture of the two homopolymers.

The precatalyst complexes **3**−**8** have only one chloro ligand. We assume that initially the MAO cocatalyst reacts with these complexes by methyl−halide exchange to afford Ti−Me derivatives, followed by cleavage of one of the Ti−N bonds by the $AlMe_3$ component in the MAO cocatalyst to generate active cationic alkyl species in a Ziegler−Natta olefin polymerization model.[27]

Conclusions

In this contribution we have described the synthesis and the characterization of new chloro mono(η^5-cyclopentadienyl)phenylenediamidotitanium and -zirconium complexes. X-ray diffraction studies confirm that compounds with *n*Pr substituted at the nitrogen atom adopt a *supine* conformation in the solid state which is maintained in solution, as deduced from the NMR spectroscopic data. The phenylenediamido ligand is bonded to the metal centre as a dianionic ligand showing a σ^2,π structure in which the π-component is mainly contributed by the two nitrogen lone pairs. NMR spectroscopic studies indicate that in solution at room temperature only one species is present, with a *supine* conformation, and no *supine-prone* automerization (flipping of the titanium-diamido framework) is observed. The catalytic activity of these compounds for olefin polymerization, when activated with MAO, was tested and studied. The steric effect of the *n*-propyl or neopentyl substituents at the nitrogen atom of the diamido ligand, and the nature of the cyclopentadienyl ring, strongly influenced catalytic polymerization activity.

Experimental Section

General Considerations: All manipulations were performed under argon using Schlenk and high-vacuum-line techniques or in a glove box model MO40-2. The solvents were purified by distillation under argon before use by employing the appropriate drying/deoxygenated agent. Deuterated solvents were stored over activated 4-Å molecular sieves and degassed by several freeze-thaw cycles. 1,2-Diphenylamine, *n*BuLi, $ClCOCH_2CH_3$, $ClCOC(CH_3)_3$, $LiAlH_4$ and $MgSO_4$ (Aldrich) were purchased from commercial sources and used without further purification. NEt_3 (Aldrich) was distilled before use and stored over 4 Å molecular sieves. [$Ti(\eta^5\text{-}C_5H_5)Cl_3$],[28] [$Ti(\eta^5\text{-}C_5Me_5)Cl_3$],[29] [$Ti(\eta^5\text{-}C_5H_4SiMe_3)Cl_3$],[30] [$Zr(\eta^5\text{-}C_5H_5)Cl_3$]·DME[31] and [$Zr(\eta^5\text{-}C_5Me_5)Cl_3$][32] were prepared by known procedures.

Polymerization-grade ethylene was used as received. Reagent grade styrene (Aldrich) was distilled under reduced pressure from calcium hydride and stored in a refrigerator under argon. The polymerization solvent (toluene) was dried by refluxing over sodium-benzophenone and distilled before used in an inert atmosphere. MAO (Witco 10%) was used as a solution in toluene.

C, H and N microanalyses were performed on a Perkin−Elmer 2400 microanalyzer. The analytical data found for **8** deviated from expected values since LiCl could not be completely removed from the mixture. NMR spectra, measured at 25 °C were recorded on a Varian Unity FT-300 (^{1}H NMR at 300 MHz, ^{13}C NMR at 75 MHz) spectrometer and chemical shifts were referenced to residual solvent protons.

1,2-$C_6H_4(NHCH_2CH_2CH_3)_2$ (1): *n*BuLi (100 mL of a 1.6 M solution, 160 mmol) was added dropwise to a solution of 1,2-pheny-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lenediamine (8.6 g, 79.27 mmol) in 100 mL of THF at −78 °C. After stirring the reaction mixture for 12 hours, $ClCOCH_2CH_3$ (13.85 mL, 160 mmol) was added and the mixture stirred for an additional 4 h. The reaction mixture was slowly warmed to room temperature to give an orange solution and a white precipitate. After filtration, the solvent was reduced to half of its original volume under vacuum and a suspension of $LiAlH_4$ (10.0 g, 260 mmol) in 50 mL of diethyl ether was added dropwise. After stirring the solution for 12 h at 40 °C, excess $LiAlH_4$ was destroyed by addition of a saturated solution of Na_2SO_4. The solid precipitate was removed by filtration and the solution dried with $MgSO_4$. Removal of the solvent under vacuum gave a brown oil characterized as **1** (1.24 g, 8%). The compound was obtained as an oil that could not be recrystallized, preventing us from obtaining accurate elemental analysis data. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 6.96 (m, 2 H, Ph), 6.72 (m, 2 H, Ph), 2.98 (broad, 2 H, NH), 2.78 (t, 4 H, N−CH_2), 1.34 (m, 4 H, CH_2), 0.78 (t, 6 H, CH_3) ppm. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 6.78 (m, 2 H, Ph), 6.70 (m, 2 H, Ph), 3.24 (broad, 2 H, NH), 3.07 (t, 4 H, N−CH_2), 1.70 (m, 4 H, CH_2), 1.03 (t, 6 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 138.0 (*ipso*-Ph), 119.7−112.2 (Ph), 46.5 (CH_2), 23.2 (CH_2), 11.9 (CH_3) ppm.

1,2-C_6H_4($NHCH_2tBu$)$_2$ (2): The amine *o*-C_6H_4($NHCH_2CtBu$)$_2$ (**2**) was obtained as an orange solid (7.98 g, 32.15 mmol, 41%) following the procedure described for **1**, from *n*BuLi (100 mL, 160 mmol), 1,2-phenylenediamine (8.6 g, 79.0 mmol), $ClCOC(CH_3)_3$ (19.53 mL, 160 mmol) and $LiAlH_4$ (10.0 g, 260 mmol). $C_{16}H_{28}N_2$ (248.16): calcd. C 77.43, H 11.28, N 11.28; found C 76.72, H 11.53, N 11.34. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.00 (m, 2 H, Ph), 6.74 (m, 2 H, Ph), 3.27 (broad, 2 H, NH), 2.67 (s, 4 H, N−CH_2), 0.88 (s, 18 H, *t*Bu) ppm. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 6.74 (m, 2 H, Ph), 6.69 (m, 2 H, Ph), 3.30 (broad, 2 H, NH), 2.82 (s, 4 H, N−CH_2), 1.02 (s, 18 H, *t*Bu) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 138.9 (*ipso*-Ph), 119.9−113.0 (Ph), 56.6 (CH_2), 31.5 (*ipso*-*t*Bu), 27.9 (*t*Bu) ppm.

[Ti(η^5-C_5H_5){1,2-C_6H_4($NHCH_2CH_2CH_3$)$_2$}Cl] (3): A toluene solution (30 mL) of *o*-C_6H_4($NHPr$)$_2$ (0.84 g, 4.37 mmol) and NEt_3 (1.22 mL, 8.74 mmol) was added to a yellow solution of [Ti(η^5-C_5H_5)Cl_3] (0.96 g, 4.37 mmol) in toluene (60 mL) at −78 °C. The cooling bath was removed and the reaction mixture was allowed to warm to room temperature with stirring for 12 h. The solid formed was collected by filtration and the toluene removed under vacuum. The residue was extracted with pentane (2 × 30 mL). The filtrate was dried and the solid obtained recrystallized from cold pentane to give **3** as a black solid (1.16 g, 3.43 mmol, 78%). $C_{17}H_{23}ClN_2Ti$ (338.49): calcd. C 60.32, H 6.80, N 8.27; found C 60.02, H 6.72, N 8.03. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.36 (m, 2 H, Ph), 6.97 (m, 2 H, Ph), 6.23 (s, 5 H, C_5H_5), 3.70 (t, 4 H, CH_2), 1.32 (m, 4 H, CH_2), 0.58 (t, 6 H, CH_3) ppm. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.48 (m, 2 H, Ph), 7.11 (m, 2 H, Ph), 6.55 (s, 5 H, C_5H_5), 4.05 (t, 4 H, CH_2), 1.50 (m, 4 H, CH_2), 0.81 (t, 6 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 137.8 (*ipso*-Ph), 127.0, 116.1 (Ph), 114.8 (C_5H_5), 58.9 (N−CH_2), 24.6 (CH_2), 11.6 (CH_3) ppm.

[Ti(η^5-C_5H_5){1,2-C_6H_4(NCH_2tBu)$_2$}Cl] (4): *n*BuLi (4.50 mL of an 1.6 M solution, 7.26 mmol) was added dropwise to a stirred solution of *o*-C_6H_4($NHCH_2tBu$)$_2$ (0.90 g, 3.63 mmol) in 50 mL of hexane at −78 °C. After the addition was complete, the reaction mixture was stirred for 6 hours and then slowly warmed to room temperature; a white precipitate formed. This suspension was cooled to −78 °C and a solution of [Ti(η^5-C_5H_5)Cl_3] (0.80 g, 3.63 mmol) in 50 mL of toluene was added. The reaction mixture was slowly warmed to room temperature and stirred for 12 h. After filtration, the solvent was removed under vacuum to give a red-brown oil which was recrystallized from cold hexane. A red-brown solid was collected which was characterized as **4** (0.64 g, 1.66 mmol, 45%). $C_{21}H_{31}ClN_2Ti$ (394.58): calcd. C 63.92, H 7.86, N 7.10; found C 63.55, H 7.97, N 7.10. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.33 (m, 2 H, Ph), 7.25 (m, 2 H, Ph), 6.31 (s, 5 H, C_5H_5), 3.88 (dd, 4 H, CH_2), 0.63 (s, 18 H, *t*Bu) ppm. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.48 (m, 2 H, Ph), 7.41 (m, 2 H, Ph), 6.51 (s, 5 H, C_5H_5), 4.17 (dd, 4 H, CH_2), 0.75 (s, 18 H, *t*Bu) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 127.8, 119.2 (Ph), 122.3 (*ipso*-Ph), 115.1 (C_5H_5), 67.2 (CH_2), 35.7 (*ipso*-*t*Bu), 28.8 (*t*Bu) ppm.

[Ti(η^5-C_5Me_5){1,2-C_6H_4($NCH_2CH_2CH_3$)$_2$}Cl] (5): Compound **5** was prepared from the reaction of the *o*-C_6H_4($NHPr$)$_2$ amine (0.81 g, 4.22 mmol), 8.44 mmol of *n*BuLi and [Ti(η^5-C_5Me_5)Cl_3] (1.22 g, 4.22 mmol) by the procedure described for **4**, and obtained as a black oil (1.59 g, 3.90 mmol, 92%). $C_{22}H_{33}ClN_2Ti$ (408.54): calcd. C 64.67, H 8.08, N 6.85; found C 64.80, H 8.76, N 6.30. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.30 (m, 2 H, Ph), 6.89 (m, 2 H, Ph), 3.88 (m, 1 H, N−CH_2), 3.57 (m, 1 H, N−CH_2), 1.75 (s, 15 H, C_5Me_5), 1.64 (m, 4 H, CH_2), 0.80 (t, 6 H, CH_3) ppm. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.26 (m, 2 H, Ph), 7.01 (m, 2 H, Ph), 4.00 (m, 1 H, N−CH_2), 3.81 (m, 1 H, N−CH_2), 1.93 (s, 15 H, C_5Me_5), 1.59 (m, 4 H, CH_2), 0.88 (t, 6 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 124.5, 114.1 (Ph), 122.9 (*ipso*- C_5Me_5), 54.5 (N−CH_2), 23.5 (CH_2), 12.5 (CH_3), 11.4 (C_5Me_5) ppm; the signal for *ipso* Ph was not observed

[Ti(η^5-C_5Me_5){1,2-C_6H_4(NCH_2tBu)$_2$}Cl] (6): Compound **6** was prepared by reacting of the *o*-C_6H_4($NHCH_2tBu$)$_2$ amine (0.85 g, 3.42 mmol), 6.85 mmol of *n*BuLi and [Ti(η^5-C_5Me_5)Cl_3] (1.00 g, 3.45 mmol) by the procedure described for **4**, and obtained as a red-brown oil (0.90 g, 1.94 mmol, 56%). $C_{26}H_{41}ClN_2Ti$ (464.58): calcd. C 67.21, H 8.89, N 6.02; found C 67.26, H 8.84, N 6.17. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.23 (m, 2 H, Ph), 7.19 (m, 2 H, Ph), 3.97 (dd, 4 H, CH_2), 1.63 (s, 15 H, C_5Me_5), 0.90 (s, 18 H, *t*Bu) ppm. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.38 (m, 2 H, Ph), 7.36 (m, 2 H, Ph), 3.96 (dd, 4 H, CH_2), 1.65 (s, 15 H, C_5Me_5), 0.75 (s, 18 H, *t*Bu) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 125.0, 117.4 (Ph), 122.7 (*ipso*-Ph), 121.0 (*ipso*-C_5Me_5), 62.1 (N−CH_2), 37.6 (*ipso*-*t*Bu), 29.6 (*t*Bu), 11.1 (C_5Me_5) ppm.

[Ti{η^5-C_5H_4($SiMe_3$)}{1,2-C_6H_4($NCH_2CH_2CH_3$)$_2$}Cl] (7): Compound **7** was prepared by reacting the *o*-C_6H_4($NHPr$)$_2$ amine (1.7 g, 8.85 mmol), 17.70 mmol of *n*BuLi and [Ti{η^5-C_5H_4($SiMe_3$)}Cl_3] (2.50 g, 8.85 mmol) by the procedure described for **4**, and obtained as a black oil (2.5 g, 6.09 mmol, 69%). $C_{20}H_{31}ClN_2SiTi$ (410.52): calcd. C 58.51, H 7.98, N 6.82; found C 58.61, H 7.98, N 6.26. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.34 (m, 2 H, Ph), 6.96 (m, 2 H, Ph), 6.57, 6.40 (2 H, 2 H, AA′BB′ spin system, C_5H_4), 3.82 (m, 4 H, CH_2), 1.33 (m, 4 H, CH_2), 0.60 (t, 6 H, CH_3), 0.32 (s, 6 H, $SiMe_3$) ppm. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.43 (m, 2 H, Ph), 7.08 (m, 2 H, Ph), 6.66, 6.65 (2 H, 2 H, AA′BB′ spin system, C_5H_4), 4.08 (m, 4 H, CH_2), 1.46 (m, 4 H, CH_2), 0.78 (t, 6 H, CH_3), 0.25 (s, 6 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 137.8 (*ipso*-Ph), 125.6 (*ipso*-C_5H_4), 127.0, 116.7 (Ph), 121.8, 116.4 (C_5H_4), 59.3 (CH_2), 24.4 (CH_2), 11.7 (CH_3), −0.04 ($SiMe_3$) ppm.

[Ti{η^5-C_5H_4($SiMe_3$)}{1,2-C_6H_4(NCH_2tBu)$_2$}Cl] (8): Compound **8** was prepared by reacting the *o*-C_6H_4($NHCH_2tBu$)$_2$ amine (0.50 g, 2.00 mmol), 4.03 mmol of *n*BuLi and [Ti{η^5-C_5H_4($SiMe_3$)}Cl_3] (0.59 g, 2.00 mmol) by the procedure described for **4**, and obtained as a red-brown oil (0.60 g, 1.28 mmol, 64%). The isolated oil con-

sisted mainly of **8**, but it contained some unremovable LiCl as an impurity and therefore correct elemental analysis data could not be obtained, although satisfactory spectroscopic data were obtained. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.31 (m, 2 H, Ph), 7.24 (m, 2 H, Ph), 6.73, 6.38 (2 H, 2 H, AA′BB′ spin system, C_5H_4), 4.02 (dd, 4 H,, CH_2), 0.68 (s, 18 H, *t*Bu), 0.37 (s, 9 H, $SiMe_3$) ppm. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.47 (m, 2 H, Ph), 7.40 (m, 2 H, Ph), 6.69, 6.55 (2 H, 2 H, AA′BB′ spin system, C_5H_4), 4.25, 4.11 (2 H, CH_2), 0.77 (s, 18 H, *t*Bu), 0.26 (s, 9 H, $SiMe_3$) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = 122.5 (*ipso*-Ph), not observed (*ipso*-C_5H_4), 127.8, 119.1 (Ph), 123.0, 116.3 (C_5H_4), 67.6 (CH_2), 35.9 (*ipso*-*t*Bu), 28.9 (*t*Bu), 0.14 ($SiMe_3$) ppm.

[Zr(η^5-C_5H_5){1,2-C_6H_4(NCH_2tBu)$_2$}Cl] (9): *n*BuLi (5.04 mL of an 1.6 M solution, 8.06 mmol) was added dropwise to a stirred solution of *o*-C_6H_4($NHCH_2t$Bu)$_2$ (1.0 g, 4.03 mmol) in 50 mL of hexane at −78 °C. After the addition was complete, the reaction mixture was stirred for 6 hours and then slowly warmed to room temperature. The white solid formed was filtered and washed with cold hexane. This solid was added to a solution of [Zr(η^5-C_5H_5)Cl_3]·DME (1.4 g, 4.03 mmol) in 50 mL of toluene at −78 °C. The cooling bath was removed and the reaction mixture was allowed to warm to room temperature with stirring for 12 h. The solid formed was insoluble in hexane which made its characterization difficult. Complex **9** was obtained as a yellow solid (0.27 g, 0.62 mmol, 15.4%). $C_{21}H_{31}ClN_2Zr$ (437.67): calcd. C 57.58, H 7.08, N 6.40; found C 57.32, H 8.22, N 6.40. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.39 (m, 2 H, Ph), 7.18 (m, 2 H, Ph), 5.98 (s, 5 H, C_5H_5), 3.80 (dd, 4 H, CH_2), 0.78 (s, 18 H, *t*Bu) ppm. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.32 (m, 2 H, Ph), 7.17 (m, 2 H, Ph), 5.82 (s, 5 H, Cp), 3.70 (dd, 4 H, CH_2), 0.72 (s, 18 H, *t*Bu) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = 123.5−120.1 (Ph), 124.5 (*ipso*-Ph), 114.0 (C_5H_5), 63.2 (CH_2), 35.4 (*ipso*-*t*Bu), 28.8 (*t*Bu) ppm.

Synthesis of [Zr(η^5-C_5Me_5){1,2-C_6H_4(NCH_2tBu)$_2$}Cl] (10): Compound **10** was prepared by reacting the *o*-C_6H_4($NHCH_2t$Bu)$_2$ amine (1.0 g, 4.03 mmol), 8.06 mmol of *n*BuLi and [Zr(η^5-C_5Me_5)Cl_3] (1.34 g, 4.03 mmol) by the procedure described for **5** and obtained as a black solid (1.66 g, 3.27 mmol, 81%). $C_{26}H_{41}N_2ZrCl$ (507.93): calcd. C 61.48, H 8.07, N 5.51; found C 61.56, H 8.69, N 5.64. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.09 (m, 2 H, Ph), 7.02 (m, 2 H, Ph), 3.65 (dd, 4 H, CH_2), 1.66 (s, 15 H, C_5Me_5), 0.97 (s, 18 H, *t*Bu) ppm. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.28 (m, 4 H, Ph), 3.63 (s, 4 H, CH_2), 1.72 (s, 15 H, C_5Me_5), 0.87 (s, 18 H, *t*Bu) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = 122.5, 117.2 (Ph), 117.8 (*ipso*- C_5Me_5), 62.1 (CH_2), 34.9 (*ipso*-*t*Bu), 28.9 (*t*Bu), 10.0 (C_5Me_5) ppm; *ipso*-Ph signal not observed.

Polymerization Procedure: Ethylene polymerization was carried out in 100 mL Schlenk flasks with magnetic stirring. Polymerization was carried out as follows: toluene and MAO were injected into the Schlenk flask with magnetic stirring at the desired temperature (25 °C). The solution was then saturated with 1 atmosphere of ethylene, and the monomer pressure was kept constant over the polymerization runs. Polymerization begins with the addition of a toluene solution of the titanium compound into the flask. After the desired reaction time was reached, polymerization was terminated by venting the ethylene gas and quenching with a small volume of a solution of MeOH/HCl. The polymers were isolated by filtration, washed with MeOH, and then dried in vacuo at 50 °C.
Polymerization of styrene was performed in toluene at 50 °C. Polymerization was carried out as follows: toluene (30 mL), styrene (5 mL), and MAO were injected into the Schlenk flasks with magnetic stirring at the desired temperature. The titanium compound dissolved in toluene (5 mL) was added last. All manipulations were performed under an argon atmosphere. The reaction was stopped after 15 minutes by addition of MeOH/HCl, and the polymer prod-

uct was coagulated with a large excess of acidified methanol and recovered by filtration.

Characterization of Polymers: The thermal properties of the samples were studied in a Du Pont 2920 MDSC instrument calibrated by measuring the melting point of indium. 5−10 mg each of the dried polymer were fused into standard aluminium pans and measured using the following temperature program for polyethylene samples: first a heating phase (10 °C/min) from 50 to 200 °C, followed by a cooling phase (−10 °C/min) to 50 °C. The peak maximum of the second heating curve was taken as the melting point (T_m). To determinate the degree of crystallinity (α) the relationship $\Delta H_m/\Delta H°_m$ was used. ΔH_m was derived from the data of the second heating course of the DSC, and $\Delta H°_m$ was assumed to be the fusion enthalpy[33] (290 J/g) for 100% crystalline polyethylene.
Polystyrene samples were subjected to the following steps: heating at 10 °C/min from 30 to 270 °C and then cooling at 10 °C/min from this temperature to 30 °C, followed by heating at 10 °C/min from 30 to 270 °C to obtain the melting peak temperature (T_m).
The NMR samples were prepared by dissolving the polystyrene sample in tetrachloro-1,2-dideuterioethane. The spectra were recorded at 25 °C.

X-ray Structure Determination of 3 and 7: Details of the X-ray experiment, data reduction, and final structure refinement calculations are summarized in Table 4. Crystals of complex **3** (**7**) suitable for an X-ray single crystal structure determination were obtained from hexane. Preliminary examination and data collection were carried out on a kappa-CCD device (Nonius) at the window of a rotating anode (NONIUS FR591; 50 kV; 60 mA; 3.0 kW) and graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å).[34] The unit-cell parameters were obtained by full-matrix least-squares refinement of 3274 (3935) reflections. Data collection was performed at 123 (153) K with an exposure time of 60 (80) s per frame, 7 (7) sets; 501 (335) frames; phi and omega scans; 2.0° (2.0°) scan-width. A total number of 36764 (15832) reflections were integrated. Raw data were corrected for Lorentz and polarization effects. If necessary, corrections for absorption and decay effects were applied during the scaling procedure.[35] After merging, a sum of 3131 (3989) independent reflections remained and used for all calculations. The structure was solved by a combination of direct methods[36] and difference-Fourier syntheses.[37] All non-hydrogen atoms of the asymmetric unit were refined with anisotropic thermal displacement parameters. All hydrogen atoms were found in the final Fourier maps and refined with isotropic displacement. Full-matrix least-squares refinements were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ with the SHELXL-97 weighting scheme and stopped at maximum shift/err < 0.001. Neutral-atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International Tables for Crystallography.[38] All other calculations (including ORTEP graphics) were carried out with the program PLATON.[39]
CCDC-206875 (for **3**) and -206874 (for **7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Financial support for this research by DGICYT (Project MAT2001-1309) is gratefully acknowledged. We are also grateful to Professor Alfonso Grassi (Universtity of Salerno) for facilities to carry out the polymerization experiments.

Mechanistic Tuning of Hydrocarbon Oxidations with H_2O_2, Catalyzed by Hexacoordinate Ferrous Complexes

Yasmina Mekmouche,[a] Stéphane Ménage,*[a] Jacques Pécaut,[b] Colette Lebrun,[b] Lee Reilly,[c] Volker Schuenemann,[c] Alfred Trautwein,[c] and Marc Fontecave[a]

Keywords: Iron catalysts / Hydrogen peroxide / Oxidation / Non-heme iron / Monooxygenase

A comparison of the catalytic properties of a series of $Fe^{II}LXY$ complexes on oxidation reactions with H_2O_2, [L = *N*,*N*′-bis(pyridin-2-yl-methyl)-*N*,*N*′-bis(3,4,5-trimethoxybenzyl)-ethane-1,2-diamine] indicates that the lability of the X and Y ligands (Cl^- or CH_3CN) determines the nature of the oxidation pathway. The absence of a labile site in the complex, i.e. when X = Y = Cl^-, causes the reaction to proceed via a Fenton pathway (generation of hydroxyl radicals, exclusively). The presence of two labile CH_3CN ligands (X = Y = CH_3CN) allows the catalysis to proceed through a metal-based mechanism, whereas in the case of a complex with only one labile ligand (X = Cl^- and Y = CH_3CN), the reaction is less controlled by the metal. We wish to emphasize that the cleavage of the O–O bond in the Fe–OOH moeity, a key intermediate in the reaction, is different in the last two cases.

Introduction

Synthetic non-heme ferrous complexes have been extensively studied due to their ability to mimic some structural and functional properties of non-heme iron monooxygenases or oxygen activating enzymes.[1] Some of the ligands used, mainly polydentate nitrogen-based, are shown in Scheme 1. These complexes have been found to be efficient catalysts for alkane oxidation using hydroperoxides or oxygen-donating reagents.[2] Few catalytic systems, however, allow selective oxidation of alkanes to the corresponding alcohol without formation of secondary products.[3] In the case of Fe and Mn porphyrins, such a selective reaction has been attributed to the involvement of a metal-oxo intermediate as the active species for the hydroxylation.[4] The question of the formation and the stabilization of such a species in non-heme systems has been the subject of extensive studies, and recently an Fe^{IV}=O system has been fully characterized.[5] Nevertheless, as soon as hydrogen peroxide is involved in the catalytic reaction as the oxidant, the nature of the reaction pathway is controversial. It usually alternates between a free radical (Fenton chemistry) or a metal based mechanism.[6] The identification of the essential stereoelectronic parameters, which control the reactivity of the active species, is still an important challenge. In particular, we demonstrated the importance of a labile site on the iron complex in order to allow the oxidant to bind, and to be activated.[7] Here, we will show from the reactivity pattern of a series of six-coordinate iron complexes $[Fe^{II}LXY](ClO_4)_n$ (L designating a tetradentate nitrogen based ligand and X, Y a monodentate ligand) that two labile sites are absolutely required for selective catalysis of alkane oxidation. The ligand L has been designed to serve as a substrate for probing the reaction mechanism. Indeed, L contains sites such as the methylene groups and the phenyl rings from benzylic moieties, which are vulnerable to oxidation. The latter are known to be very reactive towards hydroxyl radicals, leading to the formation of phenol.[8] Three hexacoordinate ferrous complexes, containing the tetradentate ligand L, [L = *N*,*N*′-bis(pyridin-2-yl-methyl)-*N*,*N*′-bis(3,4,5-trimethoxybenzyl)ethane-1,2-diamine],[8] the two remaining coordination sites being occupied either by a solvent molecule (known to be a labile ligand) or a chloride anion (known to be less exchangeable), have also been synthesized and fully characterized (Scheme 1).

The structure and catalytic properties of $FeLCl_2$ (**1**) and $FeL(CH_3CN)_2(ClO_4)_2$ (**2**) have been partly described previously.[9] In this paper they are compared, in more detail, with the structural, spectroscopic, and catalytic properties of a third new complex $FeLCl(CH_3CN)(ClO_4)$ (**3**), containing only one labile site. This complex completes the series.

Results

Syntheses of Complexes

The syntheses of complexes **1** and **2** are straightforward. Solid products were obtained by simply mixing equimolar amounts of ligand L and $FeCl_2{\cdot}4H_2O$ or $Fe(ClO_4)_2{\cdot}4H_2O$, respectively, in methanol under an inert atmosphere and at room temperature.[9] Complex **3** was synthesized via a two step procedure. When stoichiometric amounts of complexes **1** and **2** were mixed together in CH_2Cl_2 or $CHCl_3$ under argon, a light yellow microcrystalline powder was obtained. The reaction was quantitative, and the complex formed was identified, based on ESI/MS (see Exp. Sect.), as a dinuclear ferrous complex $[Fe_2L_2Cl_2](ClO_4)_2$. When the dinuclear complex was dissolved in acetonitrile it dissociated quantitatively into two identical $FeL(Cl)(CH_3CN)(ClO_4)$ units, i.e. complex **3**, which crystallizes in quantitative yield upon diffusion of ether into the mother liquor.

X-ray Structures of Complexes 1, 2, and 3

The structure of the cation present in the three complexes is represented in Figure 1. The Fe^{II} ion is in a pseudo-octahedral environment with the tetradentate ligand L wrapped around the metal ion. The two remaining coordination sites are filled by two chloride ions for **1**, two acetonitrile molecules for **2**, and one chloride and one acetonitrile for **3**. The topology consists of a *cis* α configuration for the monodentate ligands in each complex. Each one is *trans* with respect to one amine nitrogen atom and the pyridine ligands are *trans* to each other.

The Fe−ligand distances decrease as the number of CH_3CN ligands increases, reflecting the increase in ligand field strength in the following order: **1** < **3** < **2**. Accordingly, the shorter Fe−N distances (1.942−2.060 Å) are found in **2**, consistent with a low-spin configuration for its ferrous ion in the crystalline state, whereas the Fe−N distances (2.212−2.3272 Å) in **1** are longer than in **3** (2.1708−2.2787 Å), a range of distances is in agreement with a high-spin configuration for the ferrous ion in both complexes (see Table 1). Moreover, the $Fe-NCCH_3$ distance is longer in complex **3** [2.1730(8) Å] than in complex **2** [1.942(4) Å], and the Fe−Cl distance is shorter in complex **3** than in complex **1** [2.3383(3) compared with 2.4080(2)−2.4260(2) Å].

The presence of chloride anions is responsible for a distortion from the ideal octahedral geometry as shown by the more acute $N_{pyridine}-Fe-N_{pyridine}$ and $N_{amine}-Fe-N_{amine}$ angles in **1** and **3** compared with those in complex **2**. Accordingly, the presence of two Cl^- ions in a *cis* geometry leads to a larger X−Fe−Y angle [102.274(8) in **1** compared with 96.6(2) in the case of complex **3**].

The structural parameters of the $[Fe^{II}LXY]$ series are similar to those of the previously described $Fe(N_2Py_2)$ family represented, for example, by $[Fe(bpmen)(CH_3CN)_2]^{2+}$ or $(LBzl_2)FeCl_2$ [bpmen = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-pyridyl-

methyl)ethylene-1,2-diamine (Scheme 1), and $LBzl_2$ = *N*,*N*′-dibenzyl-*N*,*N*′-bis(2-pyridylmethyl)ethylene-1,2-diamine].[3b,10]

Spectroscopic Characterization of Complexes 1−3

Solid-state (powder) Mössbauer spectroscopy (77 K) showed a doublet with comparable isomer shifts at about $\delta = 1.1$ mm·s^{-1} for each of the complexes, in accordance with a high spin state for the ferrous ions. Significantly different quadrupole splitting values ΔE_q were observed, however (Table 2).[11] The highest ΔE_q value was found for **3**, in agreement with the lower degree of symmetry resulting from two different monodentate ligands in the iron coordination sphere (see Table 2). It has to be noted that in the solid-state, the spin state of complex **2** differs from that in the crystal, revealing the importance of the packing in the crystal, and suggesting the involvement of a network of hydrogen bonds between the anions. This behavior is characteristic of related spin crossover systems.[12]

The complexes retained their structure in solution as they remained all monomeric in acetonitrile solution as indicated by their ESI/MS spectrum (Table 2). The UV/Visible spectra of acetonitrile solutions exhibit only one intense band in each case at around 400 nm, attributable to a MLCT band from Fe^{II} "t_{2g}" orbitals to π* orbitals of the pyridine ligands. Interestingly, it has been previously shown that the value of the extinction coefficient can be correlated with the ligand field strength.[13] The trend observed here, confirmed the order of the series found in the solid state.

Cl−Fe−N_{amine}	90.40(2) 161.82(2)	95.43(18)	

The three complexes were also characterized by ^{1}H NMR spectroscopy at room temperature in CD_3CN solutions (Figure 2). The spectra show proton resonances between −20 and 140 ppm, a range typical for high spin ferrous (S = 2) complexes. A comparison of ^{1}H NMR spectra showed that the three complexes have different structures in solution. Proton assignments have been carried out from a comparison with related complexes, integrations, and T_1 values (see Table 3).[14] The pyridyl resonances are subject to large isotropic shifts in the following order α > β> γ based on the fact that the paramagnetic contact shifts are governed by σ-delocalization effects, so that the shifts increase with closer proximity to the ferrous ion.[15]

Thus, the α-pyridyl protons were assigned to the resonance at lower field, i.e. above δ = 130 ppm. Moreover, the β-pyridyl proton resonances, easily recognizable as they are usually assigned to two close sharp resonances at around δ = 50 ppm, shifted from 59/53 (β/β′) ppm for complex **1** to 52/44 and 48/40 ppm for complexes **3** and **2**, respectively.[14] Finally, the γ-H resonances were observed at δ = 21 ppm for **1**, and were found upfield for **2** and **3** at δ = 10 ppm and −8 ppm, respectively. The methylene CH_2 resonances can be assigned to the broader resonances spread throughout the spectra (see for example spectrum 2 in Figure 2). The number of these resonances signify the distinction between the two protons of the methylene moieties, a fact which is related to their position with regard to the metal ion. The methylene protons of CH_2−Pyr were tentatively attributed to the broad resonances in the 120−40 ppm region by comparison with the TPA complexes.[14] The methylene protons of the diamino and benzyl moieties of the ligand were less shifted, and were sensitive to the nature of the monodentate ligand set trans to the aliphatic amine.

We have tentatively attributed the upfield shift of the α,β,γ− pyridyl protons and the methylene protons in complex **2** to a lower paramagnetism compared with in **1** and **3**. It should be noted that the resonances of the protons of the trimethoxyphenyl moieties could not be assigned due to the presence of several overlapping peaks in the diamagnetic region of the spectra.

Remarkably, the spectra of **2** and **3** display broader resonances, suggesting ligand exchange in solution. This was confirmed when the NMR spectra were recorded in a non-coordinating solvent, i.e. CD_2Cl_2. Only the spectra of complexes **2** and **3** were different in terms of isomeric shifts and the broadness of the peaks. This is in agreement with the solvent ligand (CH_3CN) being more labile than the coordinated chloride. Conversely, this confirms that the chloride anions in complexes **1** and **3** remain iron-bound in acetonitrile solution, and that solutions of **3** do not contain a mixture of **1** and **2**.

Finally, Table 2 also shows that, as expected, the three complexes have different Fe^{III}/Fe^{II} potentials in acetonitrile. The cyclic voltammograms in CH_3CN/TBAP 0.1 M display one quasi-reversible process (ΔE = 100 mV) for **1** and **2**, whereas two systems of waves were observed on the reverse scan in the case of **3**. The presence of these two reduction peaks was attributed to an EC process, which has been assigned to the minor formation of $[FeLCl_2]^+$ (less than 10%) during the one-electron oxidation process of **3**. Accordingly, the location of the reducing wave of this minor electroactive

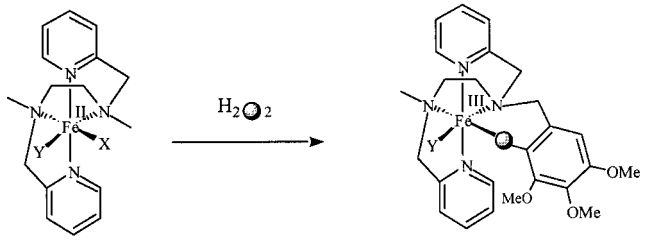
species was observed close to that observed for **1**. As expected, the easier system to oxidize is **1**, followed by **3** then **2**. The presence of chloride anions in the coordination sphere implicates a decrease in oxidation potential of about 500 mV per anion.

To conclude, the three complexes have different structures in solution. We have thus obtained and fully characterized a series of complexes containing the same tetradentate ligand, and various combinations of chloride and acetonitrile ligands. These complexes can be used to study the effect of the nature of monodentate ligands and the number of labile sites on their ability to catalyze alkane oxidations. It should be noted that they retain their structures during redox processes. These results are presented in the next section.

Ligand Oxidation − A Probe for Hydroxyl Radical Generation

The reaction of complex **1** with hydrogen peroxide in the absence of an external substrate led to the formation of a new chromophore.[9] This chromophore has been characterized as a phenolato complex $[Fe^{III}LOCl]^+$, and resulted from hydroxylation, at the *ortho* position, of one phenyl moiety of the ligand L (Scheme 2). No such species could be observed during reaction of complex **2** with H_2O_2 under the same conditions. On the other hand, in the presence of 10 equivalents of H_2O_2 in acetonitrile, complex **3** was partly converted into this chromophore as shown by ESI-MS with a molecular ion peak at m/z = 708. When $H_2{}^{18}O_2$ was used, only one peak at m/z = 710, corresponding to the $[Fe^{III}(L^{18}O)Cl]^+$ fragment, was present. This signifies that the inserted oxygen came exclusively from the oxidant.



Scheme 2. Chemical transformation of ferrous complexes **1** and **3** using hydrogen peroxide

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

However, the yield of ligand hydroxylation was found to be much lower than in the case of **1**. Ligand extraction from the mother liquor confirmed the ligand oxidation, and quantitative analysis showed that the oxidized ligand LOH was preferentially formed with complex **1** (yield = 60%), in contrast to the result with complex **3** (15%) (see Table 4). With all complexes, minor formation of ligand L1, *N*,*N*′-bis(pyridin-2-ylmethyl)-*N*-(3,4,5-trimethoxybenzyl)ethane-1,2-diamine, was detected (<15%).[9] L1 results from an *N*-dealkylation of the ligand L following hydroxylation at one of the benzylic positions.

Table 4. Comparison of the oxidizing properties of complex **1**, **2**, and **3** (experimental conditions: CH_3CN, room temp., Ar; [complex] = 1 mM; [complex]/substrate/H_2O_2, 1:100:10

Complex	**1**	**3**	**2**

2-cyclohexene-1-one	0	6	1

[a] Only the three major products analyzed by HPLC have been reported. [b] Yield based on the oxidant. [c] ol/one corresponds to the ratio of cyclohexanol over cyclohexanone. [d] % RC = 100 × (*cis*-OH-*trans*-OH)/(*cis*-OH + *trans*-OH) with an error estimated to be ± 5%; *cis*-OH = (1*R*,2*R*- or 1*S*,2*S*)-1,2-dimethylcyclohexanol. *trans*-OH = (1*R*,2*S*- or 1*S*,2*R*)-1,2-dimethylcyclohexanol.

OH radicals are excellent agents for aromatic hydroxylation.[6] Thus the formation of LOH from the oxidation of L by H_2O_2 was used here as a probe for the presence of $OH^{\cdot}$ radicals derived from H_2O_2. Our results thus show a dramatic difference between **2**, on the one hand, and **1** and **3**, on the other hand, in terms of generation of $OH^{\cdot}$ radicals. Only complex **2** was unable to convert H_2O_2 into $OH^{\cdot}$. It is also important to note that in the case of **3**, LOH is a minor product whereas in the case of **1**, L is extensively converted into LOH, indicating a more significant involvement of $OH^{\cdot}$ radicals in reactions catalyzed by **1**. This is supported by the observations reported below.

Hydrocarbon Oxidation

In a typical reaction, 2 μmol of complex $[FeLXY](ClO_4)_n$ [n = 0 for complex **1**, 1 for **3** and 2 for **2**] in acetonitrile (final volume = 2 mL) was treated with 20 μmol of H_2O_2 (10 equiv.) in the presence of 1100 equiv. of the alkane in acetonitrile at room temperature under argon. All the reactions were complete after 10 minutes by which time the oxidant was completely consumed. No oxidation occurred in the absence of the iron complex. Complex **2** was found to be the most active catalyst during oxidation of cyclohexane with a 30% total yield based on the oxidant, followed by complex **3** (13%), and **1** (4%). The same pattern was observed when the selectivity of the hydroxylation was considered with an alcohol/ketone ratio above 9 for complex **2** (Table 4), whereas much less selectivity was observed with complexes **3** and **1**.

Furthermore, only complex **2** could catalyze stereoselective hydroxylations (Table 4). For example, oxidation of *cis*-1,2-dimethylcyclohexane gave *cis*-1,2-dimethylcyclohexanol (1*R*,2*R* or 1*S*,2*S*) as the major product (%RC over 70%) showing that hydroxylation proceeds preferentially with retention of configuration at C-1, thus excluding a pure radical mechanism. Much less stereoselectivity was observed with complexes **3** and **1** (%RC = 40% and 20%, respectively).

Ligand hydroxylation and alkane oxidation reactions clearly make it possible, therefore, to distinguish **2** from **1** and **3**, but not **1** from **3**. In contrast, alkene epoxidation, as discussed below, provides a convenient reaction probe to make this distinction. Indeed, whereas epoxides are formed during oxidation of cyclohexene and cyclooctene by H_2O_2 in the presence of **2** and **3**, no epoxide could be detected with complex **1** as the catalyst. In the latter case, only very little allylic alcohol could be detected with cyclohexene as the substrate. Here, epoxidation is used as a probe for the involvement of metal-oxo intermediate active species.[16] Thus, these results suggest the presence of such species in reactions catalyzed by **2** or **3**, but not in reactions catalyzed by **1**. The involvement of a $[Fe{=}O]^{n+}$ species is further supported by the observation of ^{18}O labeled cyclohexanol during cyclohexane oxidation by H_2O_2 in the presence of 1000 equivalents of $H_2{}^{18}O$ (complex **2**: 47%, complex **3**: 5%). This is due to the ability of (per)ferryl complexes to exchange O atoms with H_2O.[17] The presence of products labeled with O atoms from both water and the oxidant has already been observed in oxidations dependent on non-heme iron complexes.[18]

Evidence for Iron-Hydroperoxo Complexes During the Reaction

Iron hydroperoxo complexes have been extensively studied during the last decade.[1,19,20] They are usually characterized by a LMCT band in the visible region, from which a resonance Raman spectrum dominated by O−O and Fe−O vibrations may be observed.[21] Using a previously described methodology,[22] which consists of low temperature mixing of the oxidant and the catalyst, we were able to detect such an Fe−OOH species by ESI-MS in some cases. Firstly, fast mixing of complex **3** with 10 equivalents of H_2O_2 resulted in the detection of a new peak at m/z = 726, which we assigned to the $[FeLOOHCl]^+$ fragment, with excellent agreement between its observed and theoretical isotopic patterns (see Supporting Information S1). The assign-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ment was confirmed, during an MS/MS experiment, by the loss of a fragment of $m/z = 33$ corresponding to the OOH fragment. A corresponding shift of +4 in the parent peak was observed when $H_2{}^{18}O_2$ was used. In contrast, with complex **1**, no Fe−OO(H) could be detected, whereas with complex **2** different fragments were observed at $m/z = 790$ and 345.5. These were assigned to $[FeLOOHClO_4]^+$ and $[FeLOOH]^{2+}$, respectively (Supporting Information S2). The fact that this fragment was absent in the mass spectrum of **3**/H_2O_2 indicates that complex **2** was not a contaminant in solutions of complex **3**.

The presence of a hydroperoxo ferric complex $[X-Fe^{III}-OOH]^{n+}$ in the case of **2** and **3** but not **1**, strongly suggests a distinct reaction pathways in systems dependent on **1** and **3**.

Discussion

Using a variety of reaction probes we have clearly demonstrated that the three complexes under study have very different catalytic properties during oxidation by hydrogen peroxide, even though they contain the same tetradentate nitrogen-based ligand L.

In the case of complex **1**, the extensive conversion of L to LOH by aromatic hydroxylation, the low alcohol/ketone ratio, the low stereoselectivity during alkane oxidation, and the lack of epoxide formation during alkene oxidation suggest that freely diffusing hydroxyl radicals are the active species.[23]

In contrast, in the case of complex **2**, the lack of LOH formation, the high alcohol/ketone ratio, the large stereoselectivity, the fact that oxygens from exogenous water molecules are incorporated into the products, and its ability to epoxidize alkenes are in agreement with a selective metal-based mechanism.

Complex **3** displays some of the properties of complex **1** (formation of LOH, low stereoselectivity), and some of those of complex **2** (epoxidation, formation of an Fe-hydroperoxo complex, and cyclohexanol labeling with $H_2{}^{18}O$). This, then, suggests a third type of mechanism involving both [Fe=O] and OH radical species.

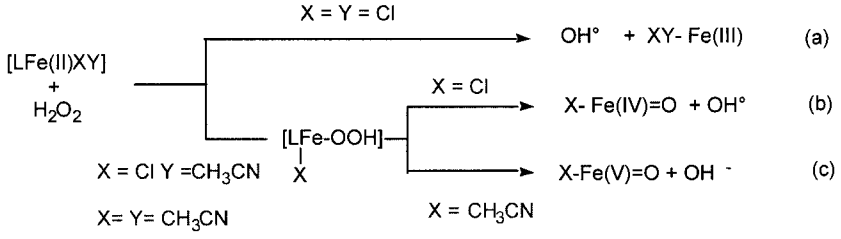
What differentiates complexes **1**−**3** from each other is the number of labile coordination sites. We have shown that in solution, Cl^- ligands are not exchangeable with the solvent even when the iron center is in the ferrous state. In contrast CH_3CN ligands are exchangeable. As a consequence, complex **1** has no exchangeable ligand, complex **3** has one, and complex **2** has two. We thus propose that the number of labile coordination sites defines the type of reaction mechanism, namely the type of active species responsible for substrate activation and oxygen atom insertion (Scheme 3).

In the case of complex **1**, H_2O_2 cannot bind to iron, in agreement with the fact that no Fe−OOH species could be detected. This iron reacts with H_2O_2 via an outer sphere one-electron redox process generating OH radicals with good aromatic hydroxylation and poor epoxidation power. In the case of complex **2**, H_2O_2 can bind to iron to form an intermediate Fe−OOH complex, as shown by ESI-MS. It is proposed that the latter proceeds by heterolytic O−O cleavage to generate an active $[Fe^V=O]$ species, allowing a more selective metal-based oxo transfer process.

In the case of complex **3**, with a single exchangeable coordination site, H_2O_2 can also bind to iron. Indeed an Fe−OOH complex has also been detected in this case by ESI-MS. It can be proposed, however, that the latter proceeds by homolytic (and not heterolytic) cleavage of the O−O bond thus generating both $[Fe^{IV}=O]$ and $OH^{\cdot}$ species, in agreement with the properties of the oxidation reaction catalyzed by **3**.

The question thus arises, whether the rather drastic difference between **2** and **3** results only from the difference in terms of labile sites or for an additional reason. Studies by L. Que Jr. and co-workers have shown the importance of the presence of two labile sites for promoting heterolytic cleavage.[18] In particular, the possibility for the terminal oxygen of the Fe−OOH species to interact with iron via binding to the second site provides a major driving force for the heterolytic cleavage of the O−O bond. A second possibility comes from the binding of a molecule of H_2O to the second site, which can thus promote O−O heterolytic cleavage by donating a proton.

In the case of complex **3**, a Cl−Fe−OOH species is formed, and there is no such driving force for heterolytic cleavage because of the presence of a non-exchangeable Cl ligand. As a consequence, only a homolytic cleavage takes place. We have thus shown here, from a detailed comparison of **2** and **3**, that the number of labile sites has a great impact on the outcome of the oxidation reactions involving Fe−OOH intermediates. Previous studies by Que Jr. and Feringa and co-workers have raised a similar issue. They did it on the basis of the comparison of $[Fe(TPA)(CH_3CN)_2]^{2+}$ complexes with diverse ligand sub-



Scheme 3. The three reaction pathways for iron/H_2O_2 systems as a function of the ligands X and Y

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

stitutions − which are catalysts of oxidation reactions proceeding by metal-based mechanisms −, with the $[Fe(N4py)(CH_3CN)]^{2+}$ complex, in which N4py is a pentadentate ligand related to TPA (Scheme 1).[18,24] The latter has only one exchangeable site, and is not able to catalyze the epoxidation of alkenes by H_2O_2.

On the other hand, it should be recalled that in the case of reactions of Fe-porphyrins with *m*-chloroperbenzoic acid (*m*CPBA), cleavage of the O−O bond within the intermediate Fe−OOC(O)R complex is dependent on the nature of the axial ligand trans to the acylperoxo ligand.[25] The cleavage is homolytic when this ligand is Cl^-, and heterolytic with less electron donating anions such as ClO_4^-. In the case of **2** and **3**, we might also consider that, rather than the exchangeability of the sites, it is the electronic properties of the ligands (Cl^- vs. CH_3CN) which influence the cleavage of the O−O bond of the X−Fe−OOH species. Further experiments are needed to better establish the importance of such electronic effects in these catalysts.

Conclusion

The structural parameters required for efficient iron catalysts for selective oxidations using hydrogen peroxide as the oxidant have been elucidated. The presence of neutral nitrogen ligands (allowing a high Lewis acidity for the metal for H_2O_2 activation), and the presence of two labile sites (to favor the heterolytic cleavage of the O−O bond) are required for selective and efficient catalysis of alkane hydroxylation. The control of the O−O bond cleavage by anions needs to be better understood, and the charge on the X ligand is probably an important parameter to consider. So far, complex **2** represents one of the more efficient catalyst in its category.

Experimental Section

General: Most of the reagents were of the best commercial grade, and were used without further purification. The synthesis of ligand L has been described previously.[8]

Synthesis of Complex 1: In a glove box, $FeCl_2{\cdot}4H_2O$ (150 μmol) was added to a methanolic solution (8 mL) of ligand L (150 μmol). The solution rapidly turned yellow, and was stirred for two hours under an inert atmosphere at room temperature. The resultant powder was filtered, and washed with diethyl ether. Crystals suitable for X-ray crystallography were obtained by diffusion of diethyl ether into an acetonitrile solution of complex **1**. The powder was found to be stable under aerobic conditions.

Synthesis of Complex 2: In a glove box, $Fe(ClO4)_2{\cdot}4H_2O$ (150 μmol) was added to a methanolic solution (8 mL) of ligand L (150 μmol). The solution was stirred until complete precipitation of a pale yellow powder. After filtration, the powder was washed twice with diethyl ether. Purple crystals of complex **2** were obtained from diffusion of diethyl ether into an acetonitrile solution but the crystals were unsuitable for X-ray crystallography. X-ray quality crystals for **2** were obtained after a metathesis of ClO_4 for PF_6 anions. The powder was found to be less stable in air than complex **1**.

Synthesis of Complex 3: Complex **2** (32 mg, 36 μmol) was added to a $CHCl_3$ or CH_2Cl_2 solution of complex **1** (27 mg, 36 μmol) under an Ar atmosphere, and stirred for 1 h. A light yellow powder progressively appeared (yield >90%). The solid was washed with diethyl ether, and analyzed by ESI-MS and ^{1}H NMR spectroscopy. The spectroscopic data are consistent with the description of the complex as a dinuclear compound $[Fe_2L_2Cl_2(ClO_4)_2]$. The presence of two chloro bridges led, in this case, to a small ferromagnetic coupling as indicated by a CH_2Cl_2 X-band EPR (parallel mode) signal (g = 16, T = 4 K). This is a characteristic signature for an integral spin ground state (data not shown).[26] This was also corroborated by the larger range for the proton resonances observed by ^{1}H NMR spectroscopy in the dinuclear complex, compared with those in complexes **1** and **2** (for example, the α-H resonance of the bound pyridine moieties was observed at δ = 180 ppm, whereas it was found at around δ = 140 ppm in **1** and **2**). Solid-state Mössbauer parameters are in agreement with the high-spin configuration of the two identical ferrous atoms of the dinuclear unit (δ = 1.10 mm·s^{-1} and δ = 1.28 mm·s^{-1}). ESI-MS: m/z = 1485 (50%), $[Fe_2L_2Cl_2ClO_4]^+$: m/z = 1421 (100%) $[Fe_2L_2Cl_3]^+$. ^{1}H NMR (CD_2Cl_2): δ = 180.2 (α-H py); 49.0, 46.5 (β-H py). 155.1, 50.3 (CH_2-py). 31.0, 24.7(CH_2−Et). 70.0, 51.0 [(CH_2−Bz), 10.2 (Ar−O−*Me*), 11.4 (*p*-*H*-Benzyl), −7.2 (γ-*H*-py) ppm.
To obtain complex **3**, the yellow powder was dissolved in acetonitrile, and crystals were grown by diffusion of ether into this acetonitrile solution.

Crystallographic Studies: Data collection and analyses of complexes **1**-**3** were conducted on a Bruker SMART CCD system at the crystallography service of the SCIB laboratory (CEA-Grenoble). Experimental conditions for complex **3**: **3**·0.5$(C_2H_5)_2O$·0.5H_2O ($C_{38}H_{51}Cl_2FeN_5O_{11}$): M = 880.59 g mol^{-1}, yellow plate, triclinic, collection temperature 223 K, space group $P\bar{1}$, a = 10.9451(7) Å, b = 13.3551(8) Å, c = 15.746 (1) Å, α = 94.719 (1)°, β = 105.831(1)°, γ = 97.859(1)°, V = 2176.5(2) Å^3, Z = 2, $R1$ = 0.0515 [I = 2σ(I)]. Pertinent crystallographic data are reported in Table 1, full data can be obtained from the Cambridge Crystallographic Data Centre. The structures were solved by direct methods using the SHELXTL 5.03 software package. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in ideal positions, and refined as riding atoms with individual (or group) isotropic displacements. CCDC-146454, -146455, and -226070 contain the supplementary crystallographic data for **1**, **2**, and **3**, respectively. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Physical Studies: 300-MHz ^{1}H-NMR spectra were recorded on a DPX300 Bruker spectrometer, and the shifts referred to the residual solvent peak. Visible absorption spectra were recorded on Varian Cary1Bio and HP 8453 diode array spectrophotometers. Gas chromatography (GC) was performed on a Perkin−Elmer Autosystem instrument with a FID detector, using an SE 30 column coupled to a Perkin−Elmer Turbomass EI spectrometer. Mössbauer spectra were recorded in 400 μL cups containing the complex as a solid with a conventional constant acceleration spectrometer using a ^{57}Co source in a Rh matrix (1.85 Gbq). ESI-MS spectra were obtained on an LCQ ion trap spectrometer. Cyclic voltammetry experiments were performed using a PAR model 273 potentiostat/galvanostat. The working electrode was a platinum disc.

Ligand Extraction and Titration of the Products After Oxidation Reactions: After the completion of the reaction between the com-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

plex and hydrogen peroxide followed by UV/visible spectroscopy the solvent was removed, and water was added until a concentration of 5 mM, based on starting iron concentration, was reached. Excess dithionite was then added, and 5 equivalents of bathophenanthroline were added. The total complexation of iron by the dinitrogen ligand was followed by UV/Visible spectroscopy (ε_{535nm} = 22140 $M^{-1}\cdot cm^{-1}$) and, when complete, the organic products were extracted with dichloromethane. The products were analyzed by ^1H and ^{13}C NMR spectroscopy and ESI-MS. Quantitative analysis of the components of the mixture was performed using HPLC based on the titration curves of pure samples. The total content never reached 100% due to the presence of minor products observed on the HPLC chromatogram.

Oxidation Reactions: In a typical reaction, 10 equivalents of H_2O_2 were added to a 1 mM solution of complex containing 1100 equivalents of cyclohexane (or 600 equiv. of 1,2-dimethylcyclohexane) or alcene in a glove box. The reaction was complete after 15 minutes, and the oxidation products were analyzed by GC/MS chromatography using benzophenone or acetophenone as an internal standard. The products were identified by ESI-MS, and titration curves were performed using pure samples to enable a quantitative analysis of the products.

Supporting Information: ESI/MS spectrum of **2**/H_2O_2 (S1) and ESI/MS spectrum of **3**/H_2O_2 (S2).

An Attempt to Programme the Orientation of Bis(heterocyclic) Azine Heterotopic Sequences around Ag^{I}, Cu^{I} and Zn^{II} Metal Centres

Julien Mathieu,[b] Noureddine Ghermani,[a] Nouzha Bouhmaida,[c] Bernard Fenet,[d] and Alain Marsura*[b]

Keywords: Self-assembly / Self-recognition / Heterocyclic bidentate sequences / Cu^{I}, Ag^{I}, Zn^{II} metal complexes

Four novel bis(heterocyclic) sequences, which incorporate a 2,2′-bipyridine system with the 2,2′-bithiazole, 4,4′-bithiazole, 2,2′-bipyrazine or 4,4′-bipyrimidine units, have been synthesized. In the presence of stoichiometric amounts of Cu^{I}, Ag^{I} or Zn^{II} cations, fully oriented discrete head-to-head (H-H) or head-to-tail (H-T) species have been observed by NMR and X-ray crystallography. The orientation of the ligands in the Ag^{I}, Cu^{I} or Zn^{II} dinuclear complexes during the self-assembly process appears to be under the control of electronic factors relating to the electronic configuration of the different bis(heterocyclic) sequences.

Introduction

The design and study of double- and triple-stranded helical complexes obtained by self-assembly of two or three ligand strands with metal ions has been the subject of several recent detailed investigations and literature reviews.[1,2] Architectural information is expressed in the matching between the ligand binding sites and the stereochemical preferences of the metal ion.

Of the numerous helical structures already published, the spontaneous formation of double-stranded homodimetallic[2a−2e] or heterodimetallic[2f−2i] helicates has been studied extensively. The formation of helicates depends on the nature of the metal ions and ligands and sometimes on additional factors introduced by appropriate templating.[3] Some years ago, a first event was observed in the case of Ga^{III} and Ti^{V} aminophenolate/catecholate complexes where the phenolic protons were abstracted allowing the formation of the corresponding dinuclear oriented triple-stranded helicates.[4] The selectivity of these assemblies in discriminating between a nitrogen (amine) and an oxygen (hydroxy) atom of a biphenylene structure was obviously influenced by the difference of reactivity between the two coordinating centres.

Recently, we described another kind of strongly induced selectivity in the case of a Cu^{I} double-stranded head-to-tail (H-T) spontaneous assembly obtained from a bipyridine-bipyrazine sequence.[5] In that case, the final complex was formed solely by the coordination of Cu^{I} to the imino nitrogen lone pairs of the heterocycles without the need for external hindered factors or other stereochemical requirements. Additionally, we have reported ab initio theoretical calculations dealing with the probable origin of the observed selectivity.[6] According to the stereochemistry found in the helicate, an electron back-donating effect was found to be responsible for the better stability of the heterotopic complexes (bipyridine−Cu−bipyrazine) compared to the homotopic ones[6] This feature clearly suggests that the aromatic nature of the heterocycles themselves could play a decisive role on orientation within the final helicate.

In order to verify the generality of this assumption for other ligands, we have prepared four novel bis(heterocyclic) heterotopic saturated sequences, which incorporate a 2,2′-bipyridine nucleus together with a 2,2′-bithiazole, 4,4′-bithiazole, 2,2′-bipyrazine or 4,4′-bipyrimidine bis(heterocyclic) unit. The formation of the corresponding Ag^{I}, Zn^{II}

and Cu^I complexes with these ligands and the X-ray structure analysis of the Cu^I and Ag^I dinuclear helicates revealed a fully selective H-T and H-H orientation of the strands within the helicates.

Results and Discussion

Synthesis of Ligands 9 to 12

In order to explore the scope and limitations of a possible programming of oriented double-stranded helicates from discrete bis(heterocyclic) azines, we prepared the new ligands **9**−**12** containing a 2,2′-bithiazole, a 4,4′-bithiazole, a 2,2′-bipyrazine or a 4,4′-bipyrimidine unit, respectively, together with a common 2,2′-bipyridine nucleus. These ligands were designed in order that the non-identical bis(heterocyclic) components present two identical bis(diimine) coordinating centres connected by an oxopropylene bridge. Therefore, in the presence of geometrically tetrahedral coordinating cations, there are two possible orientations for the ligands around the metal atom in a dinuclear complex: H-H (head-to-head) or H-T (head-to-tail) (Figure 1).

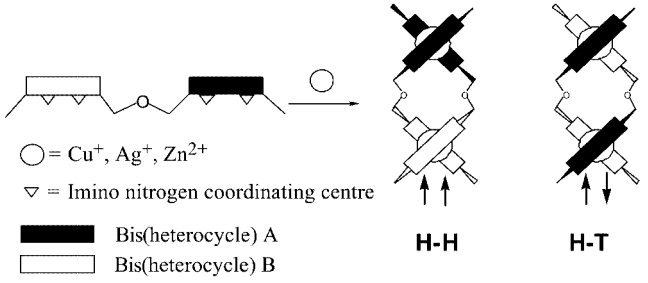

Figure 1. Graphical illustration of the self-assembly strategy

Ligand **9** (Scheme 1) was prepared from the dimethyl-2,2′-bithiazole **1**,[7] ligand **10** from the dimethyl-4,4′-bithiazole **3**,[8] ligand **11** from 2,2′-dimethyl-4,4′-bipyrimidine (**5**)[9] and ligand **12** from 6,6′-dimethyl-2,2′-bipyrazine by a previously reported method[5] The bis(heterocycles) were transformed into 6-(monobromomethyl) **2**, **4** and **6** derivatives or 6-(monohydroxymethyl) derivatives **7** and **8**, respectively. The final ligands were obtained in good yields (70−83%) after Williamson condensation of the (monobromomethyl)bithiazoles, -bipyrimidine or -bipyridine with 6-(hydroxymethyl)-6′-methyl-2,2′-bipyridine[10] or 6-(hydroxymethyl)-6′-methyl-2,2′-bipyrazine,[5] respectively. Addition of previously prepared $[Cu(CH_3CN)_4]PF_6$ or commercially available $Ag(PF_6)$ to solutions of **9**−**12** in anhydrous acetonitrile or addition of $Zn(OTf)_2$ to solutions of the ligands in MeOH affords the corresponding copper, silver or zinc dinuclear complexes (Scheme 2). Addition of the

metal ion solutions resulted in instant colour changes from colourless to deep-red or deep-orange in the case of Cu^{I} or colourless to pale yellow in the case of the Ag^{I} and Zn^{II} indicating the effective formation of the complexes. A thin layer chromatographic control showed that the free ligand was totally consumed in the reaction. The crude materials were recrystallized by slow diffusion of diethyl ether into acetonitrile or acetone solutions (copper and silver complexes) or by slow concentration of a methanolic solution in the case of zinc complexes (see Exp. Sect.). The deep red crystals with Cu^{I} and the pale yellow crystals with Ag^{I} and Zn^{II} are stable in air. In each case, the ligands form the expected dinuclear double-stranded helical structures as observed by X-ray diffraction analyses.

Thermodynamic Self-Assembly Processes of Ligands 9−12 with Cu^{I}, Ag^{I} and Zn^{II}

The formation of the double-helical metal complexes **13**−**23** was followed by UV/Vis spectrophotometric titration of ligands **9**−**12** with $Cu[CH_3CN]_4[PF_6]$, $AgPF_6$ in CH_3CN or $Zn(OTf)_2$ in MeOH. Titrations of ligand **9** with $Cu[CH_3CN]_4[PF_6]$ (Figure 2) and ligand **11** with $Zn(OTf)_2$ (Figure 3) are presented as typical examples (see Supporting Information for other titration data; see the footnote on the first page of this article). Spectra obtained during titration of ligand **9** display two sharp isosbestic points between 250 and 600 nm over the duration of the titration. The colourless solution of **9** becomes red instantly upon addition of $Cu[CH_3CN]_4[PF_6]$ owing to the appearance of an MLCT band at $\lambda_{max.}$ = 450 nm (ε = 1700) and indicating coordination of the Cu^{I} atoms. The titration plot (see B in Figure 2) indicates that the species formed has a composition of ca. 1 Cu atom for 1 equiv. of **9** in agreement with the stoichiometry expected for the double-stranded helicate $[Cu_2(\mathbf{9})_2][PF_6]_2$ (**13**). Conversely, the titration spectra of ligand **11** display, on addition of $Zn(OTf)_2$, the successive appearance of two strong and distinct absorptions at $\lambda_{max.}$ = 304 nm (ε = 17650) and $\lambda_{max.}$ = 316 nm (ε = 18970) indicating the effective coordination of the Zn^{II} atoms. The titration plot (B in Figure 3) reveals that the species formed has a composition of ca. 1 Zn atom for 1 equiv. of **11** in agreement with the expected stoichiometry of **21**. A similar difference is observed in the formation of complex **18** containing Zn^{II} but not with the formation of the other zinc complexes or the other metal complexes investigated. This suggests that the two zinc ions were complexed in a different environment in the other species.

Analysis of titration data provides the thermodynamic parameters of dihelicate formation. Factor analysis points to the existence of five absorbing species (L, ML, M_2L, ML_2, M_2L_2) and the spectrophotometric data can be fitted to the equilibria given below [Equations (1) and (2)], which characterize the assembly process and are described by stability constants (β_{ml}). Using the SPECFIT program,[11] the binding constants $\log(\beta_{ml})$ for each species M_mL_l have been calculated (Table 1).

$$M + L \rightleftarrows ML \quad \log \beta_{11} \tag{1}$$

$$ML_2 + M \rightleftarrows M_2L_2 \quad \log \beta_{22} \tag{2}$$

The species M_2L and ML_2 were neglected because they

were present only in negligible quantities under the experimental conditions used here.

Positive-mode ESI-MS spectra of all the complexes contained doubly charged ions except for the Zn^{II} complexes in which quadruply charged ions were detected. For illustration, mass spectra of the copper and zinc complexes **13** and **15** (Figure 4) reveal the $[Cu_2(\mathbf{9})_2]^{2+}$ doubly charged ion (m/z = 457 a.m.u.) (peak separated by 0.5 a.m.u.) and the $[Cu_2(\mathbf{9})_2\ (PF)_6]^+$ singly charged ion (m/z = 1059 a.m.u.), while for the zinc complex the $[Zn_2(\mathbf{9})_2]^{4+}$ quadruply charged ion (m/z = 229 a.m.u.) (peak separated by 0.25 a.m.u.) and the $[Zn_2(\mathbf{9})_2(OTf)_3]^+$ singly charged ion (m/z = 1364 a.m.u.) are observed. These results are only compatible with the formation of double-stranded helicates.[12] Similar results were obtained with the other complexes.[13]

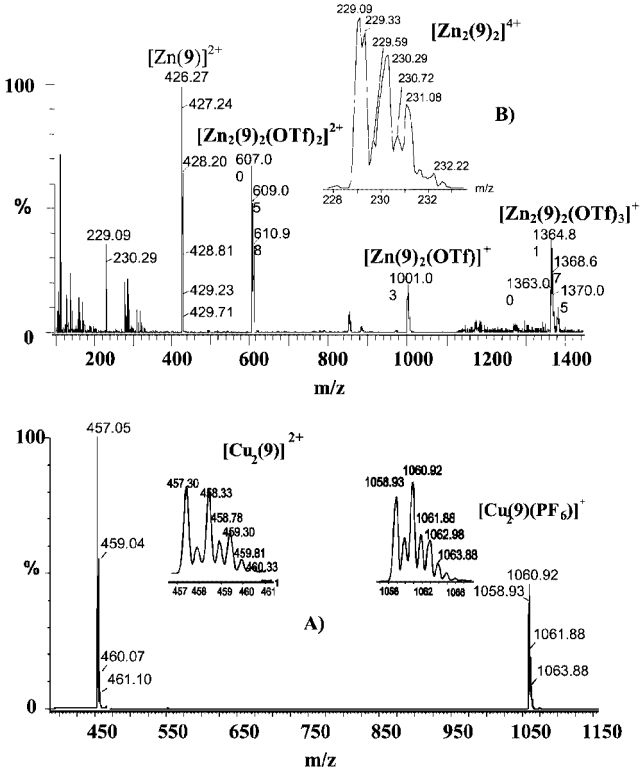

Figure 4. Positive-ion ESI mass spectra of complexes: A) **13** and B) **15**

NMR Analysis

The ^1H NMR spectra of the free ligands **9**−**12** give resolved first-order spectra and each proton of each bis(heterocycle) in the ligand was assigned on the basis of COSY-LR NMR experiments. Complexation of metal ions by the ligand causes upfield or downfield shifts of all the ligand proton ^1H NMR signals indicating the effective formation of the complexes (see for example Figure 5).

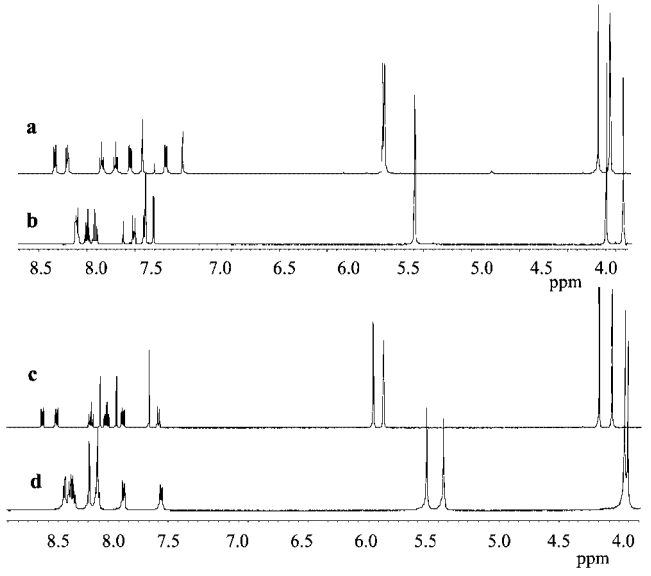

Figure 5. ^1H NMR spectra (400 MHz, 298 K, $CDCl_3/CD_3CN$) of a) ligand **9**; b) $[Ag_2(\mathbf{9})_2][PF_6]_2$ (**14**); c) ligand **10**; d) $[Ag_2(\mathbf{10})_2][PF_6]_2$ (**17**)

Significant shifts of the signals in the ^1H and ^{13}C NMR spectra were observed. Identical spectra were observed from in situ prepared solutions of the complexes by addition of stoichiometric amounts of the metal compound to the free ligand or from redissolution of crystals of the corresponding crystallized metal complex. At room temperature, sharp signals were observed in spectra of the silver and zinc complexes indicating the effective formation of discrete species rather than oligomeric structures. The spectra of the silver complexes **14** and **17** (Figure 5) and **20** and **22** (not shown) obtained from the 2,2′-bithiazolyl and 4,4′-bithiazolyl ligands **9**, **10** and from bipyrimidine and bipyrazine ligands **11**, **12**, respectively, show that only one species is present in solution at room temperature. The methylene protons of the oxopropylene bridges display two A_2 patterns (Figure 5) in place of two AB patterns, which should normally be observed for diastereotopic methylene protons in a chiral heterotopic double-helical structure.[14] This is almost certainly because of a rapid exchange under these experimental conditions as has been reported already for silver helicates.[15] ^1H NMR spectra of the complexes in CD_3CN remain unchanged during a decrease in temperature from 333 to 233 K, and only a negligible broadening of all the signals of the whole spectrum was observed at the lowest temperature with no splitting of the methylene proton resonance into an AB pattern. In the absence of the corresponding X-ray structures for the two (bithiazolyl)silver complexes, no conclusions can be drawn from the above NMR results regarding the conformational preference of these complexes (H-H or H-T). However, variable-temperature results obtained from solutions were compatible with a side-by-side nonhelical achiral structure for these two complexes in solution although a fast exchange between chiral structures cannot be excluded because we did not observe any true line broadening in these experiments. The X-ray structures of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the silver complexes with bipyrimidyl (**20**) and bipyrazyl (**22**) ligands (see Figures 15 and 16) better corroborated the hypothesis of the existence of a chiral structure undergoing a fast exchange since they reveal that the structures of $[Ag_2(\mathbf{11})_2]^{2+}$ (**20**) and $[Ag_2(\mathbf{12})_2]^{2+}$ (**22**) contain double-stranded helical cations. In each case, only one species is present in the crystals having exclusively an H-H or an H-T conformation, respectively.

As previously observed for the $[Cu_2(\mathbf{12})_2][PF_6]_2$ complex,[5] the NMR signals for compounds $[Cu_2(\mathbf{9})_2][PF_6]_2$ (**13**), $[Cu_2(\mathbf{10})_2][PF_6]_2$ (**16**) and $[Cu_2(\mathbf{11})_2][PF_6]_2$ (**19**) in acetonitrile are broad and poorly resolved at room temperature[16] and display line shapes typical of exchange at moderate rate on the NMR time scale (Figure 6a). Gradually lowering the temperature of the solutions to 233 K gives resolved spectra (Figures b and 7a,b) but which are not identical with the two typical perfect AB patterns previously observed for the $[Cu_2(\mathbf{12})_2][PF_6]_2$ double-stranded helical complex.[5] The spectra observed here display doubling of all signals indicating the presence of two species in solution at 233 K as revealed by the four different signals of methyl protons, AB and A_2 patterns of oxopropylene bridge methylene protons and supplementary signals in the aromatic part of the spectrum (Figures 6b and 7a,b). Increasing the temperature results in the coalescence of the AB spin systems of the methylene protons into two A_2 spin systems. This strongly indicates a loss of chirality during the exchange mechanism[16] so that only one achiral species composes the cations **16** and **19** at 353 K (see Figure 7a,b). Alternatively, there is a fast exchange between chiral structures, as proposed above in the case of the silver complexes.

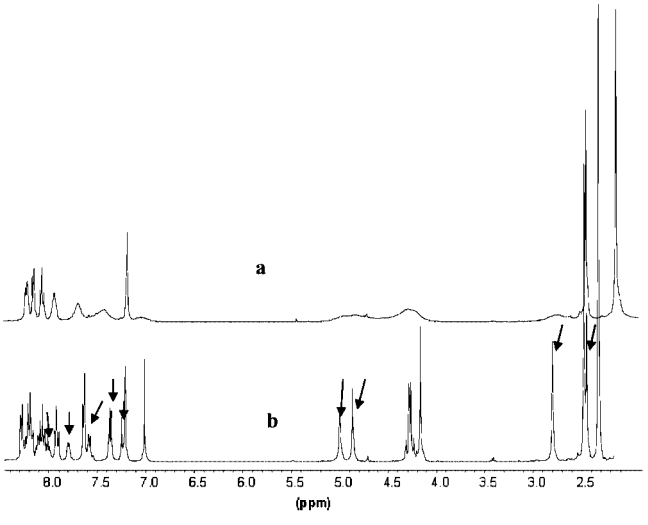

Figure 6. ^1H NMR spectra (400 MHz, CD_3CN) of $[Cu_2(\mathbf{9})_2][PF_6]_2$ (**13**); a) 298 K, b) 233 K (arrows indicate the second species)

A deeper analysis of ^1H NMR data of the Cu^I complexes suggested a dynamic interconversion exchange of enantiomeric helicates should occur at room temperature [dinuclear right-handed (*P*) to dinuclear left-handed (*M*)] on the NMR timescale (unresolved, large methylene proton signals) as observed for the $[Cu_2(\mathbf{12})_2][PF_6]_2$ complex.[5] This

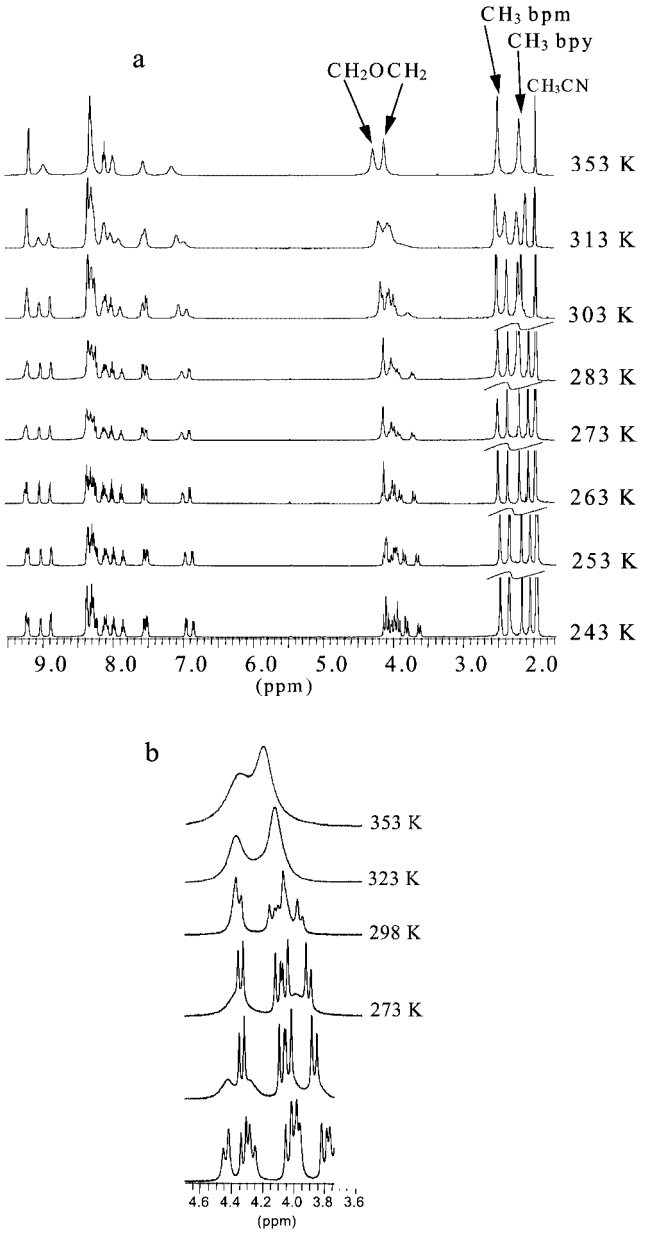

Figure 7. Variable-temperature ^1H NMR spectra of a) $[Cu_2(\mathbf{11})_2][PF_6]_2$ (**19**) (full spectra); b) $[Cu_2(\mathbf{10})_2][PF_6]_2$ (**16**) (selected region of oxapropylene bridges) between 353 and 233 K

was confirmed by recording spectra at different temperatures (down to 233 K) revealing a sharpening of signals and a shifting and characteristic splitting of the signal of the diastereotopic methylene protons of the oxopropylene bridges. Unfortunately, this phenomenon is concomitant with the appearance of supplementary signals (methyl, oxomethylene and aromatic) which correspond to the appearance of a second species in solution. At this stage, two explanations may be advanced.

The first case entails the presence of a mixture of helical and side-by-side double-stranded dinuclear copper complexes, while the second case has a mixture of H-H and H-T conformers undergoing a rapid exchange. It should be kept in mind that the second situation can exist only by a

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

total and rapid decomplexation of the components, which allows inversion of the strand orientation. Additionally, it should be mentioned that, for the first hypothesis, a side-by-side complex would be observed in solution during the (*P*) ⇄ (*M*) interconversion process upon depression of the temperature. This might be considered as an intermediate conformer in the exchange mechanism between the two enantiomeric (*P*) and (*M*) helicates. In such a situation, a rapid decomplexation-recomplexation of only one helicate extremity would be sufficient. The first proposal is supported by Harding[17] and later by Greenwald[18] who made similar observations. Despite this, ^{63}Cu NMR spectra of the $[Cu_2(\mathbf{9})_2][PF_6]_2$ (**13**), $[Cu_2(\mathbf{10})_2][PF_6]_2$ (**16**) and the homotopic Cu^I complex were investigated in order to confirm one of the two proposals (see ref.[13] for details). The ^{63}Cu NMR spectra of **13** and **16** exhibit a single resonance at $\delta \approx 0$ ppm, indicating a similar environment for the copper atoms within these helicates. For **13**, this situation is consistent with only an (H-T) orientation of the ligands as was also found in its crystal structure. However, for **16**, we should theoretically observe two resonances with reference to an expected (H−H) orientation as observed in its crystal structure. In any case, these results are obviously not in agreement with the presence of a mixture of (H−H) and (H-T) conformers in which three resonances are normally expected. Considering this, we decided to perform low-temperature ^{1}H NMR ROESY experiments (233 K) on the copper dications **13**, **16**, silver dications **14**, **20** and zinc dication **23**.

In the case of zinc complex **23**, two inter-strand correlations were detected in the (298 K) ^{1}H NMR ROESY spectrum (Figure 8): one between the methyl protons of the bipyrazine unit and 7-H of the bipyridine unit and a second between methyl protons of the bipyridine unit and 1-H of the bipyrazine unit indicating a selective (H-T) orientation of the ligands in this complex. Unfortunately, in the case of the complexes **13**, **16** (copper), **14**, **20** (silver) and **18**, **21** (zinc), we were unable to freeze out the systems, because of a rapid exchange, which operated even at low temperature. Under these conditions, no correlation between terminal methyl protons of one heterocyclic unit and the aromatic protons of the opposite heterocyclic unit were observed by NMR spectroscopy.

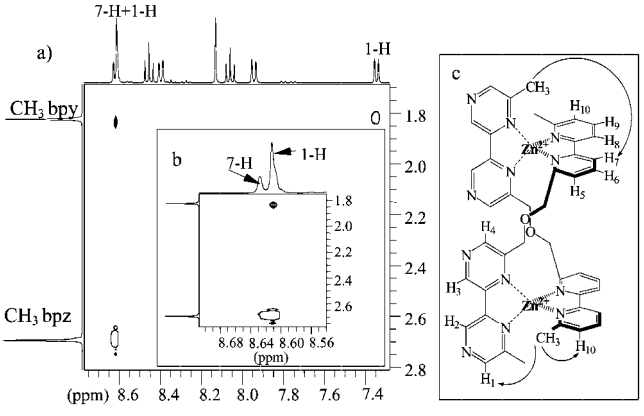

Figure 8. a) ^{1}H NMR ROESY of $[Zn_2(\mathbf{12})_2][OTf]_4$ (**23**) in CD_3OD at 298 K (selected region); b) zoom on correlations between methyl and aromatic protons; c) scheme of the resulting double-stranded helicate structure (arrows indicate specific interactions)

X-ray Structure Analysis

Finally, crystallized helicates $[Ag_2(\mathbf{11})_2][PF_6]_2$ (**20**) and $[Ag_2(\mathbf{12})_2]][PF_6]_2$ (**22**) were obtained by slow diffusion of diethyl ether into acetonitrile solutions of the complexes (see Exp. Sect.) giving light yellow crystals suitable for X-ray crystallography. The two compounds both occupy the centrosymmetric $P\bar{1}$ space group with two PF_6^- counterions in the asymmetric unit. An acetonitrile (C_2H_3N) solvent molecule was found in the asymmetric unit of **20**. However, the presence of PF_6 counterions induces, some disorder in the crystal packing and during the refinements.

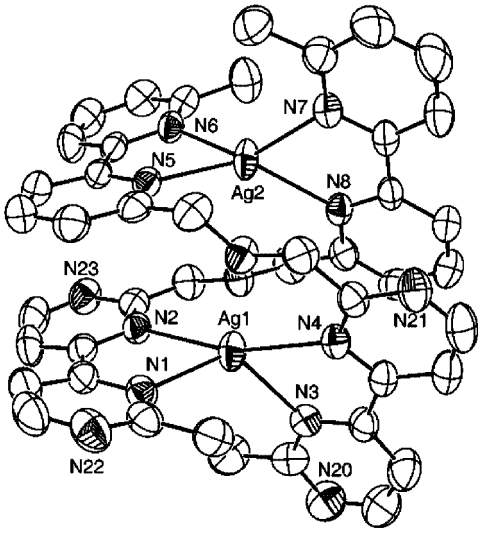

Figure 9. ORTEP drawing of the asymmetric unit of the silver complex $[Ag_2(\mathbf{11})_2][PF_6]_2$ (**20**) (counterions and solvent molecules omitted); thermal ellipsoids are at 50% probability level

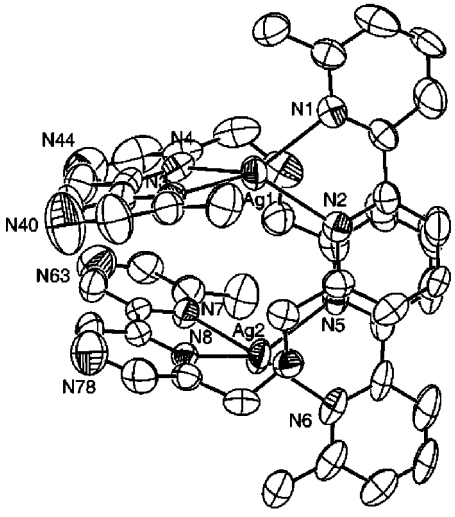

Figure 10. ORTEP drawing of the asymmetric unit of the silver complex $[Ag_2(\mathbf{12})_2][PF_6]_2$ **22** (counterions omitted); thermal ellipsoids are at 50% probability level

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The ORTEP[19] views of the two dinuclear Ag^I complexes **20** and **22** are shown in Figures 9 and 10, respectively. As usual in the case of a chemical system with a large number of heavy atoms, it was impossible to observe all the hydrogen atoms in the Fourier difference maps. This made it particularly difficult to differentiate between N atoms and CH groups of the ligand nuclei without a careful inspection of C−C and C−N bond lengths and thermal displacements, which was done in this case. The complexes **20** and **22** are double-stranded helicates where each Ag^I cation is in tetrahedral coordination involving the nitrogen atoms of the bipyrimidine (bpm), bipyrazine (bpz) and bipyridine (bpy) ligands. However, the complex **20** occupies an (H-H) conformation whereas the complex **22** is in an (H-T) conformation as shown in Figures 9 and 10. The intramolecular Ag−Ag distances are 4.14 and 6.13 Å for the complexes **20** and **22**, respectively. This large difference of 2 Å in the metal−metal spacing of the two helicates can be explained by the π-electronic interactions between the facing heteroatomic rings (bpm−bpy in complex **20** and bpz−bpz in complex **22**), which differ between the two complexes.

In the bpm−bpy interactions in **20**, the nitrogen atoms can avoid a close approach to the opposing π-electronic system.

More precisely, the nucleophilicity of the nitrogen atoms makes the N−N and the N−π-electron repulsions highly involved and favour or disfavour the close approach of the heteroatomic nuclei and the attraction occurred. Conversely, electrostatic repulsion is dominant in the bpz−bpz facing heterocycles in **22**, especially because of the similar positions of the nitrogen atoms in the two facing rings. As a consequence of these interactions, the AgN_4 tetrahedra present distorted geometries as previously reported in our copper helicate studies.[5] The interatomic bond lengths and angles are given.[13] The average values of the Ag−N bond lengths for compound **20** are 2.406(5) Å [$Ag(bpm)_2$], 2.339(5) Å [$Ag(bpy)_2$] and are significantly longer than those in compound **22**, 2.321(7) Å [Ag(bpz−bpy)], 2.317(8) Å [Ag(bpz−bpy)], respectively. All N−Ag−N bond angles are within the range 70−140° except N2−Ag1−N4 = 163° found for the bpm interligand connection. Figures 11 and 12 depict the space-filling representations (MOLEKEL[20]

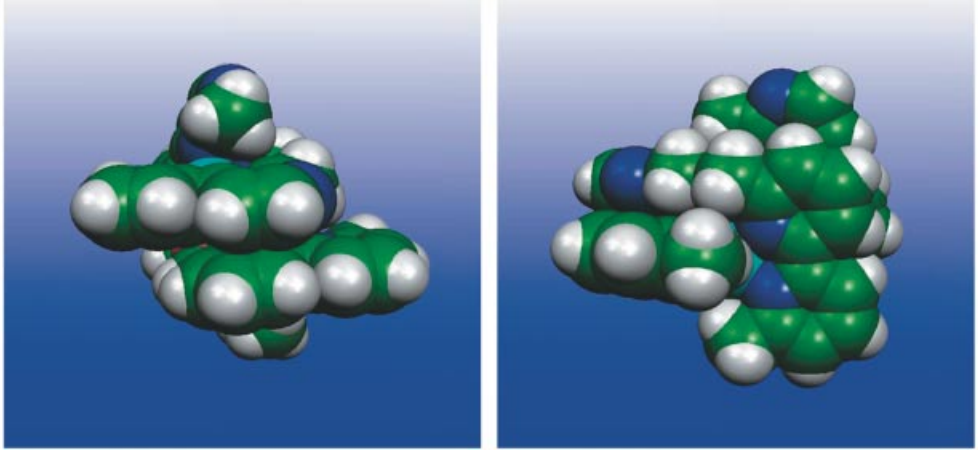

Figure 11. Two views of the space-filling representation of the silver helicate $[Ag_2(\mathbf{11})_2][PF_6]_2$ (**20**) (N atoms blue)

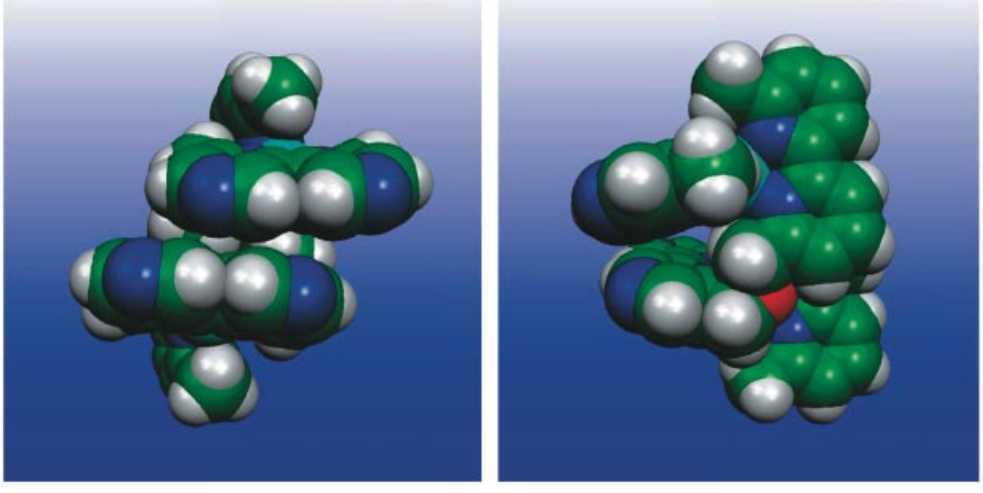

Figure 12. Two views of the space-filling representation of the silver helicate $[Ag_2(\mathbf{12})_2][PF_6]_2$ (**22**) (N atoms blue, O atoms red)

visualization program) of the structures of **20** and **22** showing the interactions of heteroatomic ring packing and the N−N and N−π-electron repulsions. In Figure 12, the bpm−bpy facing rings are close to each other. The stabilization of the facing rings imposes mutually transverse displacements.

The two helicates $[Cu_2(\mathbf{9})_2][PF_6]_2$ (**13**) and $[Cu_2(\mathbf{10})_2][PF_6]_2$ (**16**), were crystallized by slow diffusion of diethyl ether into acetonitrile or acetone solutions of the complexes (see Exp. Sect.). The resulting crystals were deep-red and fragile. The structures of the copper complexes **13** and **16** were determined from difficult X-ray single-crystal experiments (see Exp. Sect.) because of the poor quality of the crystals. Both compounds crystallized in the triclinic setting and the centrosymmetric $P\bar{1}$ space group. Attempts to resolve and refine the structures in the $P1$ space group did not improve their figures of merit and yielded high R values (see Exp. Sect.), which are expected for such disordered materials especially in the presence of PF_6^- counterions. Twinning was also considered but it was not observed in our samples. However, the helicate structures and conformations could be observed despite the complete disordering of the PF_6^- counterions in the crystal lattices. The asymmetric unit of **13** contains one dinuclear Cu^I complex, two PF_6^- counterions and one residual acetone (C_3H_6O) solvent molecule. The complex **16** contains two dicopper(I) complexes and four PF_6^- counterions in the crystal asymmetric unit. The respective ORTEP[19] views of the two compounds are depicted in Figures 13 and , respectively.

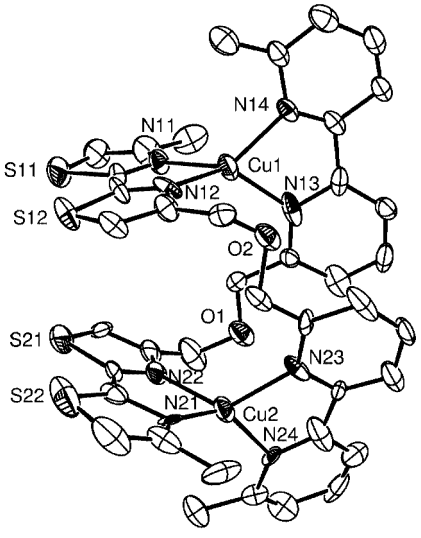

Figure 13. ORTEP drawing of the asymmetric unit of the copper complex $[Cu_2(\mathbf{9})_2][PF_6]_2$ (**13**) (counterions and solvent molecules omitted); thermal ellipsoids are at 50% probability level

The intramolecular Cu−Cu distances are 5.95 Å (complex **13**) and 6.28 (helix **16a**) and 6.24 Å (helix **16b**). The dimetallic cations are double-stranded helicates yielding left- and right-handed units in the crystal because of the presence of the centre of inversion ($P\bar{1}$ space group). It is worth noting that for complex **16**, both dinuclear **16a** and

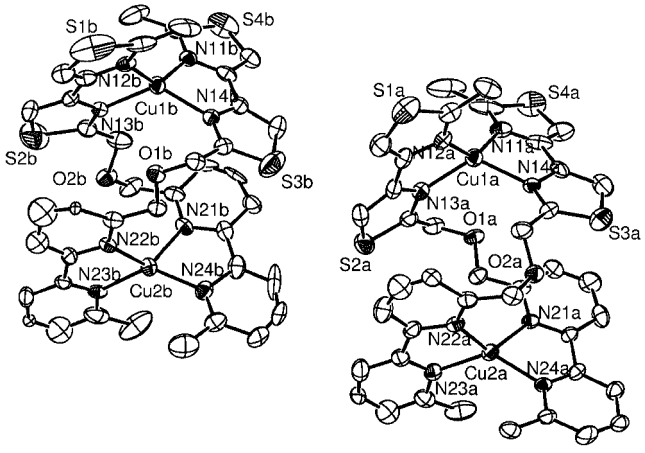

Figure 14. ORTEP drawing of the asymmetric unit contents of the copper complex $[Cu_2(\mathbf{10})][PF_6]_2$ (**16**) (counterions and solvent molecules omitted); thermal ellipsoids are at 50% probability level

16b helices in the asymmetric unit have the same handedness (Figure 14). In the complexes **13** and **16**, the copper ions occupy a distorted tetrahedral coordination involving the nitrogen atoms of the bipyridine and bithiazole heterocyclic ligands. However, the position of the connecting carbon atoms (C-2 or -4) in the bithiazole rings is found to yield to either hetero-ligand (**13**) or homo-ligand (**16**) coordinations of the copper atom as shown in Figures 13 and 14. Consequently, a different ring stacking is obtained as shown in Figures 15 (**13**) and 16 (**16**) generated by the MOLEKEL[20] program. This stacking is due to the π−π and electrostatic interactions between the heterocyclic ligands. Figures 15 and 16 indicate that these interactions are stronger when sulfur atoms are involved: the interactions become attractive. Both transverse and longitudinal displacements of facing heterocyclic ligand planes are observed. This obviously implies CuN_4 distorted tetrahedral geometry especially when the copper atom is connected to one or two bithiazole ligands. These features were also reported in our previous study of the (bipyrazine−bipyridine)copper complex.[5] It is worth noting that the disorder of the PF_6^- counterions results in poor quality structure refinements and has an influence on the precision of the atomic bond lengths and angles in the organic part of the helicates. It can also distort the planarity of the ligand nuclei.

On the other hand, the geometry of the copper environment is much more stable because of the heavy metal contribution to the X-ray diffracting power of the samples. Atomic bond lengths and angles for copper coordination in compounds **13** and **16** are given in the Supporting Information.[13] All Cu−N bond lengths are approximately equal to 2 Å within the estimated error intervals. Similar bond angles in the range from 80 (intra-ligand angles) to 137° (interligand angles) are also found for the two compounds. We note that these structural values do not correlate with the nature of the heterocyclic ligand.

The X-ray structural analyses showed unambiguously that the discrete dinuclear copper helicates **13** and **16** were

formed and adopt an (H-T) conformation with the bipyridine-2,2′-bithiazole heterotopic ligand and an (H-H) conformation with the bipyridine-4,4′-bithiazole heterotopic ligand. Both metal centres in the helicates are coordinated to the heterocyclic nitrogen atoms by a distorted tetrahedral geometry.

In unison with experimental[5] and theoretical[6] results obtained previously for the heterotopic bipyrazine−bipyridine ligand self-assembly process with Cu^I, an H-T conformation has also been obtained for this sequence with Ag^I and Zn^{II}. This "programming" was assigned to the electronic properties of the heterocycles on the basis of Cu^I orbital contributions to the HOMO and on the basis of a metal→ligand back-bonding phenomenon,[6] which enhances the stability of the hetero complex (bpz−bpy). Similar reasoning can be applied to the Ag^I and Zn^{II} metal complexes. Conversely, the bipyrimidine−bipyridine sequence **11** exhibits an H-H conformation. The only difference between the bipyrimidine and bipyrazine units lies in the heterocycle electronic configurations. As reported earlier by us,[24,25] both the reactivity and experimental electron density distribution of bipyrazine indicate its less aromatic character compared to other diazines such as bipyrimidine[26] and probably also to other diazines such as bipyridine or phenanthroline. Notably, the topological analysis of the electron density[24] allowed a comparison of the coordination scheme of the inner and outer nitrogen atoms of the bipyrazine and the 4,4′-bipyrimidine rings, respectively,[26] revealing a participation of the outer nitrogen atoms in the coordination of Cu^I only in the bipyrimidine ring. Unfortunately, ab initio DFT calculations on the 4,4′-bipyrimidine homo- and hetero-Cu^I complexes failed and no data could be presented regarding this.

Conclusion

In conclusion, we have demonstrated in this study that four different tetradentate heterotopic ligands containing 2,2-bipyrazine, 2,2′- or 4,4′-bithiazole or 4,4′-bipyrimidine fragments connected to a bipyridine nucleus are very effective for the spontaneous formation of new double-stranded head-to-head (H-H) or head-to-tail (H-T) fully oriented dinuclear helicates in the solid state. Analysis of the spectrophotometric UV/Vis titrations indicate that all the complexes are formed quantitatively at M/L = 1.0 stoichi-

ometry and that the self-assembly process of the dinuclear double-stranded helicates is driven to completion by positive cooperativity.

However, it was not possible to ascertain the precise nature of the second species which appears in solution at lower temperature (especially in the cases of the silver and copper complexes) because of a very rapid dynamic interconversion equilibrium between conformers. Nevertheless, the structure of one zinc complex **23** with an H-T orientation was fully characterized, which indicates that the helical structures of the dinuclear metal complexes studied may persist in solution. This observation was made possible by the lack of exchange in that particular case.

Considering the X-ray structures of the four complexes, extensive heteroaromatic ring π-stacking and the overlap of near parallel fragments of adjacent ligands govern the metal−metal distance, modulate the pitch and bending of the helix shape and strongly stabilize the molecule. As a direct consequence of this, there is a remarkable and uncommon Ag^{I} cation distorted tetrahedral geometry in the corresponding helicate.

Finally, it is considered that "programming" oriented helicate self-assemblies could be achieved with a high efficiency by the design of heterotopic strands composed only of bis(heterocycles) with different electronic configurations in their structure. Projected investigations include: a) study of the role of the counter-anion in the formation and stability of helicates, b) study of the presented ligands' complexation with hexacoordinating metal atoms. Further work is also in progress to use this property for the construction of other ligands and heterotopic sequences in order to programme novel supramolecularly oriented systems.

Experimental Section

General Remarks: ^{1}H and ^{13}C NMR spectra were recorded with a Bruker DRX 400 spectrometer and ^{63}Cu NMR spectra with a Bruker DRX 500 at −10 °C, UV/Vis spectra were recorded with a Uvmc2 Safas spectrophotometer. Mass spectra (ES) were taken with a Micromass Platform spectrometer. Elemental analyses were obtained with a Perkin−Elmer 240C CHN-O-S analyzer. Solvents were purified by standard methods.

2-(Bromomethyl)-2′-methyl-4,4′-bithiazole (4): NBS (998 mg, 5.61 mmol) was added to a solution of 6,6′-dimethyl-4,4′-bithiazole [9] (1 g, 5.10 mmol) in CCl_4 (100 mL) under Ar. The mixture was refluxed for 30 min, then benzoyl peroxide (85 mg) was added. The mixture was refluxed and irradiated with a tungsten lamp (100 W) for 45 min. The resulting mixture was cooled to 0 °C and the precipitate was filtered, washed with CH_2Cl_2, and the solvent was removed in vacuo. The crude product was purified by chromatography on silica gel (elution: CH_2Cl_2/acetone, 95:5). Yield: 708 mg (50%). M.p. 128 °C. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 7.78 (s, 1 H_{Ar}), 7.62 (s, 1 H_{Ar}), 4.77 (s, 2 H), 2.76 (s, 3 H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): δ = 166.4 (q), 165.8 (q), 150.8 (q), 149.6 (q), 116.9 (CH_{Ar}), 115.2 (CH_{Ar}), 26.6 (CH_2Br), 19.2 (CH_3) ppm. $C_8H_7BrN_2S_2$ (275.19): calcd. C 34.92, H 2.56, N 10.18; found C 34.9, H 2.54, N 10.12.

2-(Bromomethyl)-2′-methyl-4,4′-bipyrimidine (6): NBS (688 mg, 3.86 mmol) and AIBN were added to a solution of 2,2′-dimethyl-4,4′-bipyrimidine (1.2 g, 6.44 mmol) in CCl_4 (50 mL) under Ar. The mixture was refluxed and irradiated with a tungsten lamp (100 W) for 4 h. The resulting precipitate was filtered, washed with CH_2Cl_2, and the solvent was removed in vacuo. The crude product was purified by chromatography on silica gel (elution: CH_2Cl_2/Et_2O, 75:25), which gave **6** as a white powder. Yield: 480 mg (28%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 8.94 (d, ^{3}J = 5.1 Hz, 1 H_{Ar}), 8.85 (d, ^{3}J = 4.9 Hz, 1 H_{Ar}), 8.32 (d, ^{3}J = 5.1 Hz, 1 H_{Ar}), 8.24 (d, ^{3}J = 5.2 Hz, 1 H_{Ar}), 4.69 (s, 2 H, CH_2Br), 2.83 (s, 3 H, CH_3) ppm. ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): δ = 168.5 (q), 166.4 (q), 161.9 (q), 160.4(q), 159.3 (CH_{Ar}), 158.7 (CH_{Ar}), 116.1 (CH_{Ar}), 114.8 (CH_{Ar}), 33.6 (CH_2Br), 26.1 (CH_3) ppm.

6′-Methyl-6-{[(4′-methyl-2,2′-bithiazol-4-yl)methoxy]methyl}-2,2′-bipyridine (9): 6-(Hydroxymethyl)-6′-methyl-2, 2′-bipyridine (300 mg, 1.50 mmol) in THF (10 mL) was added to a suspension of NaH (72 mg, 3.00 mmol) in anhydrous THF (5 mL) under Ar at 0 °C. The mixture was stirred at 0 °C for 1 h, then 6-(bromomethyl)-6′-methyl-2, 2′-bithiazole (413 mg, 1.50 mmol) in THF (10 mL) was added, and the mixture was warmed to room temperature. The mixture was stirred at 40 °C for 4 h. After cooling to room temperature, H_2O (10 mL) was added to the mixture and the phases were separated. The aqueous layer was extracted with CH_2Cl_2 (3 × 30 mL). The combined organic phases were dried with $MgSO_4$ and the solvent was removed in vacuo. The solid was purified by chromatography on silica gel (elution: CH_2Cl_2). Yield: 490 mg (83%). M.p. 118 °C. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 8.32 (d, ^{3}J = 7.8 Hz, 1 H_{Ar}, bpy), 8.19 (d, ^{3}J = 7.6 Hz, 1 H_{Ar}, bpy), 7.83 (t, ^{3}J = 7.8 Hz, 1 H_{Ar}, bpy), 7.69 (t, ^{3}J = 7.6 Hz, 1 H_{Ar}, bpy), 7.53 (d, ^{3}J = 7.6 Hz, 1 H_{Ar}, bpy), 7.41 (s, 1 H_{Ar}, btz), 7.16 (d, ^{3}J = 7.6 Hz, 1 H_{Ar}, bpy), 6.98 (s, 1 H_{Ar}, btz), 4.89 (s, 2 H, CH_2, btz), 4.87 (s, 2 H, CH_2, bpy), 2.63 (s, 3 H, CH_3, bpy), 2.51 (s, 3 H, CH_3, btz) ppm. ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): δ = 161.6 (q, bpy), 160.4 (q, bpy), 157.8 (q, bpy), 157.5 (q, bpy), 155.8 (q, btz), 155.5 (q, btz), 155.0 (q, btz), 154.1 (q, btz), 137.4 (CH_{Ar}, bpy), 137.0 (CH_{Ar}, bpy), 123.2 (CH_{Ar}, bpy), 121.1 (CH_{Ar}, bpy), 119.8 (CH_{Ar}, bpy), 118.1 (CH_{Ar}, bpy), 117.6 (CH_{Ar}, btz), 115.7 (CH_{Ar}, btz), 73.8 (CH_2, btz), 68.6 (CH_2, bpy), 24.6 (CH_3, bpy), 17.1 (CH_3, btz) ppm. UV/Vis (CH_3CN): $\lambda_{max.}$ ($\varepsilon_{max.}$) = 290 (19500), 328 (14450) nm. $C_{20}H_{18}N_4OS_2 \cdot 0.25CH_2Cl_2$ (415.74): calcd. C 58.50, H 4.49, N 13.48; found C 58.31, H 4.47, N 13.26.

6′-Methyl-6-{[(2′-methyl-4,4′-bithiazol-2-yl)methoxy]methyl}-2,2′-bipyridine (10): 6-(Hydroxymethyl)-6′-methyl-2,2′-bipyridine (268 mg, 1.34 mmol) in THF (10 mL) was added to a suspension of NaH (65 mg, 2.68 mmol) in anhydrous THF (5 mL) under Ar at 0 °C. The mixture was stirred at 0 °C for 1 h, then 6-(bromomethyl)-6′-methyl-4,4′-bithiazole (369 mg, 1.34 mmol) in THF (10 mL) was added, and the mixture was allowed to warm to room temperature. The mixture was stirred at 40 °C for 4 h. After cooling to room temperature, H_2O (10 mL) was added to the mixture and the phases were separated. The aqueous layer was extracted with CH_2Cl_2 (3 × 30 mL). The combined organic phases were dried with $MgSO_4$ and the solvent was removed in vacuo. The solid was purified by chromatography on silica gel (elution: CH_2Cl_2). Yield: 437 mg (83%). M.p. 156 °C. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 8.34 (d, ^{3}J = 7.4 Hz, 1 H_{Ar}, bpy), 8.19 (d, ^{3}J = 7.4 Hz, 1 H_{Ar}, bpy), 7.84 (t, ^{3}J = 7.6 Hz, 1 H_{Ar}, bpy), 7.76 (s, 1 H_{Ar}, btz), 7.68 (d, ^{3}J = 7.2 Hz, 1 H_{Ar}, bpy), 7.60 (s, 1 H_{Ar}, btz), 7.53 (d, ^{3}J = 7.2 Hz, 1 H_{Ar}, bpy), 7.16 (d, ^{3}J = 7.2 Hz, 1 H_{Ar}, bpy), 5.03 (s, 2 H, CH_2, btz), 4.92 (s, 2 H, CH_2, btz), 2.76 (s, 3 H, CH_3, btz), 2.64 (s, 3 H, CH_3, bpy) ppm. ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): δ = 168.8

X-ray Crystallographic Study: The crystal structures of $[Ag(C_{22}H_{20}N_6O)]_2[PF_6]_2[CH_3N]$ (**20**) [$\rho_{calcd.}$ = 1.70 Mg·m^{-3}, μ (Mo-K_α) = 0.924 mm^{-1}] and $[Ag(C_{22}H_{20}N_6O)]_2[PF_6]_2$ (**22**) [$\rho_{calcd.}$ = 1.74 Mg·m^{-3}, μ (Mo-K_α) = 0.926 mm^{-1}] were determined from single-crystal X-ray diffraction experiments using Mo-K_α X-ray radiation (λ = 0.71073 Å) with a Siemens Smart CCD diffractometer. Both compounds crystallized in the triclinic $P\bar{1}$ space group, Z = 2. The cell parameters for complex **20** are a = 13.705(2), b = 14.010(2), c = 14.277(3) Å, α = 90.47(1), β = 96.31(1), γ = 109.83(1)°, V = 2560.1(2) Å^3. The cell parameters for complex **22** are a = 12.019 (1), b = 15.153(2), c = 15.186(2) Å, α = 75.08(1), β = 70.89(1), γ = 71.13(1)°, V = 2437.0(1) Å^3. 11193 and 10720 reflections were collected up to $\theta_{max.}$ = 23.4° for complexes **20** and **22**, respectively. The structures were solved by semi-invariant methods using the SIR92 module in the WINGX package.[21].The structures were refined by the full-matrix least-squares method based on F^2 using the SHELX97[23] program. Thermal displacements of non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at their idealized positions but not refined. For complex **20**, the final statistical factors were found equal to $R1$(all observed data) = 0.058, $wR2$ = 0.130 for 7349 data and 695 parameters, $R1[F^2 > 2\sigma(I)]$ = 0.050 for 6374 data with $F^2 > 2\sigma(I)$. The final residual densities in the unit cell were +0.81 and −0.58 e·Å^{-3}. For complex **22**, the final statistical factors were found equal to $R1$(all observed data) = 0.095, $wR2$ = 0.170 for 7009 data and 667 parameters, $R1[F^2 > 2\sigma(I)]$ = 0.073 for 5541 data with $F^2 > 2\sigma(I)$. The final residual densities in the unit cell were +0.92 and −0.64 e·Å^{-3}. The crystal structures of $[Cu_2(C_{20}H_{18}N_4OS_2)_2(C_3H_6O)][PF_6]_2$ (**13**) [$\rho_{calcd.}$ = 1.62 g·cm^{-3}, μ (Mo-K_α) = 1.13 mm^{-1}] and $[Cu(C_{20}H_{18}N_4OS_2)]_2[PF_6]_2$ (**16**) [$\rho_{calcd.}$ = 1.55 g·cm^{-3}, μ (Mo-K_α) = 1.13 mm^{-1}], were determined from single-crystal X-ray diffraction experiments performed with an Enraf−Nonius CAD-4F diffractometer at room temperature. Large crystal samples (**13**: red, 0.6 × 0.5 × 0.3 mm; **16**: orange, 0.9 × 0.6 × 0.5 mm) were chosen for the experiments using Mo-K_α X-ray radiation (λ = 0.71073 Å). Both compounds crystallized in the triclinic $P\bar{1}$ space group, Z = 2 (**13**) and 4 (**16**). The unit cell parameters were obtained by least-squares fit to setting angles of 25 reflections in the range 8° < 2θ < 36° (**13**) and 12° < 2θ < 40° (**16**). The cell parameters are a = 13.336(5), b = 13.437(4), c = 15.874(5) Å, α = 90.63(2), β = 98.82(3), γ = 111.96(2)°, V = 2599(2) Å^3 (**13**) and a = 12.682(5), b = 19.688(5), c = 21.624(5) Å, α = 100.810(5), β = 97.364(5), γ = 99.628(5)°, V = 5157(3) Å^3 (**16**). The ω-2θ scan mode was used to record the diffracted intensities. Three standard reflections were monitored every 2 h in order to control the intensity decay, which did not occur significantly. 8485 and 25719 reflections were collected up to $2\theta_{max.}$ = 55.3 (**13**) and 59.9° (**16**). Lorentz-polarisation corrections and data reduction were performed using the WINGX package[26] for CAD4-collected intensities. The structures were solved by direct methods using the SIR92 program[22] and refined by the full-matrix least-squares method based on F^2 using the SHELX97[23] program. Thermal displacements of non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at their idealized positions. In the last cycles of refinement, the best results were obtained with empirical absorption corrections using the XABS2 (**13**) and DIFABS (**16**) programs in the WINGX package.[21] For the complex **13**, the final statistical factors were found equal to $R1$(all data) = 0.261, $wR2$ = 0.498 for 8485 data and 668 parameters, $R1[F^2 > 2\sigma(I)]$ = 0.183 for 3790 data with $F^2 > 2\sigma(I)$ and the final residual densities in the unit cell were +1.14 and −1.51 e·Å^{-3}. For the complex **16**, the results were $R1$(all data) = 0.258, $wR2$ = 0.419 for 23950 data and 1231 parameters, $R1[F^2 > 2\sigma(I)]$ = 0.122 for 9291 data with $F^2 > 2\sigma(I)$ and the final residual densities in the unit cell were +1.95 and −0.86 e·Å^{-3}. CCDC-205779 (**20**), -205780 (**22**), -201694 (**13**) and -201695 (**16**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

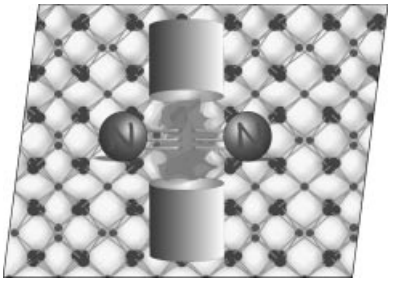
COVER PICTURE

The cover picture shows symbolically the activation of an N_2 molecule by igniting a plasma discharge in nitrogen gas. The crystal structure of a new tantalum nitride obtained by the plasma-enhanced CVD method is seen in the background. Details are discussed in the article by G. V. Vajenine et al. on p. 3233 ff. We thank the Alexander von Humboldt Foundation for support through a Sofia Kovalevskaja Research Award.

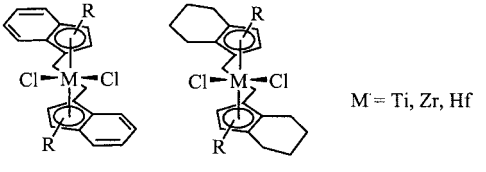


MICROREVIEW

Contents

3201 **R. Leino,* P. Lehmus, A. Lehtonen**

Heteroatom-Substituted Group 4 Bis(indenyl)-metallocenes



Keywords: Indene / Metallocenes / Zirconium / Olefin polymerization

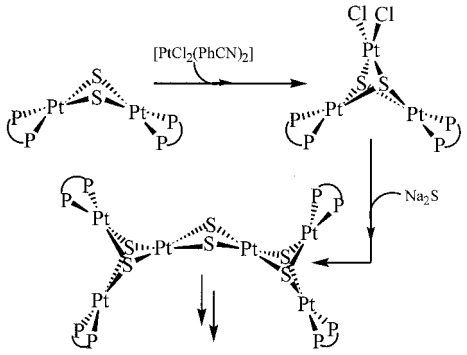
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

SHORT COMMUNICATIONS

3223 **R. Mas-Ballesté, W. Clegg, A. Lledós,* P. González-Duarte***

A Novel Route to Multinuclear d^8 Metal–Chalcogen Compounds with Nuclearity Control

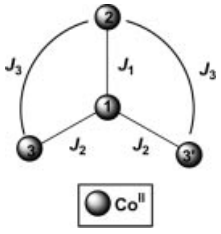
Keywords: Cluster compounds / Platinum / Metalloligands / Self-assembly / Sulfur



3228 **M. Du, Y.-M. Guo, X.-H. Bu,* J. Ribas**

First Tetranuclear Co^{II} Cluster with Planar Triangular Pattern: Crystal Structure and Ferromagnetic Behavior

Keywords: Carboxylic-functionalized diazamesocyclic ligands / Cobalt / Crystal structure / Magnetic properties / Tetranuclear clusters

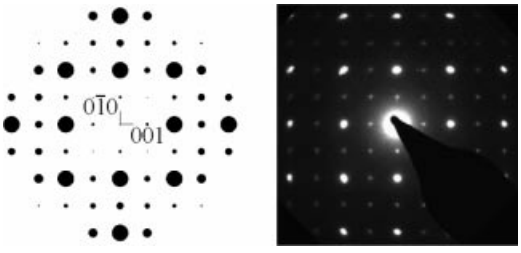


FULL PAPERS

3233 **A. Yu. Ganin, L. Kienle, G. V. Vajenine***

Plasma-Enhanced CVD Synthesis and Structural Characterization of Ta_2N_3

Keywords: Tantalum / Nitrides / Plasma-enhanced chemical vapor deposition / X-ray diffraction / Electron microscopy



3240 **M. Mehring**

Two- and Three-Dimensional Hydrogen-Bonded Networks Built from 1,3,5-$[(HO)_2(O)P]_3C_6H_3$ and 4-(Dimethylamino)pyridine

Keywords: Phosphonic acid / Hydrogen bonds / Crystal engineering / Supramolecular chemistry

Heteroatom-Substituted Group 4 Bis(indenyl)metallocenes

Reko Leino,*[a] Petri Lehmus,[b] and Ari Lehtonen[c]

Keywords: Indene / Metallocenes / Zirconium / Olefin polymerization

The synthesis, characterization and applications of heteroatom-substituted group 4 bis(indenyl)metallocene complexes is reviewed. In recent years, an increasing number of group 4 metallocenes with electronically modified cyclopentadienyl ligands have been reported with, in some cases, considerably altered catalytic properties. This microreview focuses on bis(indenyl) complexes of titanium, zirconium and hafnium that contain nitrogen, oxygen and sulfur atoms directly bonded to the five- or six-membered rings of the indenyl ligand framework. The catalytic performance is briefly reviewed, with emphasis on catalytic olefin polymerization.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The past decades have witnessed an impressive growth in the application of group 4 metallocene complexes in homogeneous catalysis. Of particular significance is the ability of appropriately substituted bridged and unbridged bis(indenyl)-ligated complexes to stereoselectively control the microstructure of poly-α-olefins produced when activated with methylaluminoxane (MAO) or other cocatalysts.[1−6] In enantioselective synthesis, chiral group 4 bis(indenyl)metallocenes are being employed as reagents or catalysts for various applications ranging from enantioselective cyclopolymerization[7] to carbon−carbon, carbon−hydrogen, and carbon−oxygen bond formation in small molecule syntheses.[8,9] Prototypical chiral bis(indenyl) complexes are the now classic ethylene-bridged *ansa*-metallocenes **1**−**3** and their hydrogenated tetrahydroindenyl congeners **4**−**6** (Figure 1) originally described by Brintzinger and co-

Reko Leino was born in Turku, Finland in 1969. He received his PhD (Doctor of Science in Technology) at Åbo Akademi University in 1998 with Professor Jan H. Näsman, in the field of organometallic synthesis and catalytic olefin polymerization. After a post-doctoral year at Stanford University with Professor Robert M. Waymouth in 1998-1999 working on stereocontrol in syndiospecific propylene polymerization, he briefly returned to the Laboratory of Polymer Technology, Åbo Akademi University to work on polymer-supported chiral catalysts, then for 18 months during 2001-2002 joined the Biopharmaceutical company Carbion Ltd. (later merged with Biotie Therapies Corp.) focusing on the development of carbohydrate-based pharmaceuticals. Since January 2003 he is Professor of Organic Chemistry at Åbo Akademi University with research interests ranging from synthetic organic and organometallic chemistry to polymer synthesis with current focus on stereoselective catalysis, bioorganometallic and carbohydrate chemistry.

Petri Lehmus was born in Helsinki, Finland in 1970. His interest in the polymerization behavior of single-site catalysts was inspired by his studies at Helsinki University of Technology, where he graduated as Doctor of Science in Technology from the research group of Professor Jukka V. Seppälä. Parts of his Ph.D. work were conducted in the group of Professor Bernhard Rieger at the University of Ulm, Germany. In 2000 he joined Borealis Polymers where he currently acts as research manager for Single Site Technology.

Ari Lehtonen was born in 1966. He obtained his MSc in Chemistry in 1990 from the University of Turku and his Doctorate in 1995, also at the University of Turku. During 1999 he worked as a post-doctoral fellow with Prof. Bohumil Štíbr at the Institute of Inorganic Chemistry, Academy of Sciences of the Czech Republic. Presently, he is a lecturer at the University of Turku. His current research interests include coordination chemistry of catalytically interesting high-valent metal compounds, especially molybdenum and tungsten phenoxides.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

workers 20 years ago.[10−13] In the synthesis, the ethylene-bridged C_2-symmetric complexes, together with an unwanted *meso* diastereomer, are formed as racemates, which in an optimal case may be resolved through diastereomeric derivatives to afford the individual (*R*,*R*) and (*S*,*S*) enantiomers.[10,12,14−16] Since the initial reports, a huge number of substituted chiral and achiral group 4 bis(indenyl) complexes have been prepared and studied, and the structure-property relationships, especially in catalytic olefin polymerization, are now relatively well understood.[3,17−20] An excellent review is available covering the synthesis of chiral titanocene and zirconocene dichlorides and their ligand precursors,[21] including those of the bis(indenyl) type, although, with the exclusion of heteroatom-substituted ligands and complexes. An obvious attractive feature of these catalysts is the relative ease with which variations in the ligand-substitution pattern can be carried out using standard synthetic methodology, although the catalytic performance is very often a complicated and, in many cases, inseparable combination of steric as well as electronic effects.

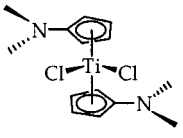
Figure 1. Racemic ethylene-bridged bis(indenyl) and bis(tetrahydroindenyl) group 4 *ansa*-metallocenes **1**−**6**; only one enantiomer of the racemic pair is shown

Despite the imminent possibilities, the influence of electronic modification of these systems by direct heteroatom ligand substitution has, until recently, remained less explored. This reluctance may, in part, be due to the anticipated problems associated with the combination of highly electrophilic early transition metals with heteroatom-containing substituents. In recent years, however, a large number of group 4 bis(indenyl) complexes containing oxygen, sulfur as well as nitrogen donor atoms directly bonded to the five- or six-membered rings of the indenyl ligand framework have been reported in the literature; in some cases, the catalytic properties are significantly altered. The purpose of this microreview is to cover the recent synthetic efforts towards these complexes, as well as some of their catalytic applications, with the main focus on olefin polymerization. The emphasis lies on bis(indenyl) and bis(tetrahydroindenyl) complexes of the group 4 metals (Ti, Zr, Hf) that contain N, O and S atoms directly linked to the indenyl ligand. Excluded thus from detailed discussion are complexes containing substituted or unsubstituted cyclopentadienyl, fluorenyl and related ligands, complexes with pendant heteroatom substitution where the functional group is separated from the ligand by an inert linker,[22−25] as well as complexes with directly bonded phosphorus,[26] boron,[27−29] and other heteroatom substituents. The so-called constrained-geometry linked amido-cyclopentadienyl and amido-indenyl complexes,[30,31] as well as cyclopentadienyl complexes containing fused heterocyclic ring systems[32−36] that mimic those of indenyl compounds, are excluded as well. The references have been, with a few exceptions, drawn from the authors' own work in the area and the open scientific literature.

Complex Synthesis and Characterization

Amino-Substituted Group 4 Bis(indenyl)metallocenes

An early example of an amino-substituted group 4 metallocene is the 1,1′-bis(dimethylamino)titanocene dichloride **7** reported by Boche and co-workers in 1984 (Figure 2).[37] Since the first reports by Brintzinger,[38] Näsman,[39] and Plenio groups[40] in 1996, a number of 2-amino-substituted bis(indenyl) complexes of titanium and zirconium have been described and characterized (complexes **8**−**16**).[41−45] Selected compounds have been collected in Figure 3. The numbering system of indene is displayed in Figure 4. Related recently reported complexes include the mixed-ligand titanocene dichloride **17** that incorporates one 2-(dimethylamino)indenyl ligand as described by Bochmann and co-workers,[46] as well as the (aminofluorenyl)zirconium complexes of Miller and Bercaw.[47] Aminocyclopentadienyl compounds have also been incorporated into the donor/acceptor group 4 metallocenes of Ostoja Starzewski, catalyst technology designed for production of thermoplastic elastomers.[48] In addition, a number of mono- and bis(2-aminoindenyl) complexes of manganese, cobalt and iron,[49−52] lithium,[53] and ruthenium[54] have been reported in recent years. Heteroatom-substituted, constrained-geometry titanium complexes including those derived from 2- and 3-aminoindenes have also been described.[55] De Rosa, Resconi and co-workers have recently reported the preparation of a series of silyl-bridged constrained-geometry *tert*-butylamido-indenyl complexes of titanium in which the indenyl ligand has a nitrogen- or sulfur-containing heterocycle condensed onto the five-membered indenyl ring.[56,57]



7

Figure 2. 1,1′-Bis(dimethylamino)titanocene dichloride (**7**)

Syntheses of the 2-amino-substituted indenes generally follow the original procedures of Edlund,[58−61] which involve the enamine reaction of 2-indanone with a secondary amine in methanol or toluene to produce the corresponding 2-aminoindenes, typically in excellent yields (Scheme 1).[38−40,42−45,49−53] The reaction is applicable to substituted cyclopentenones and also provides access to a

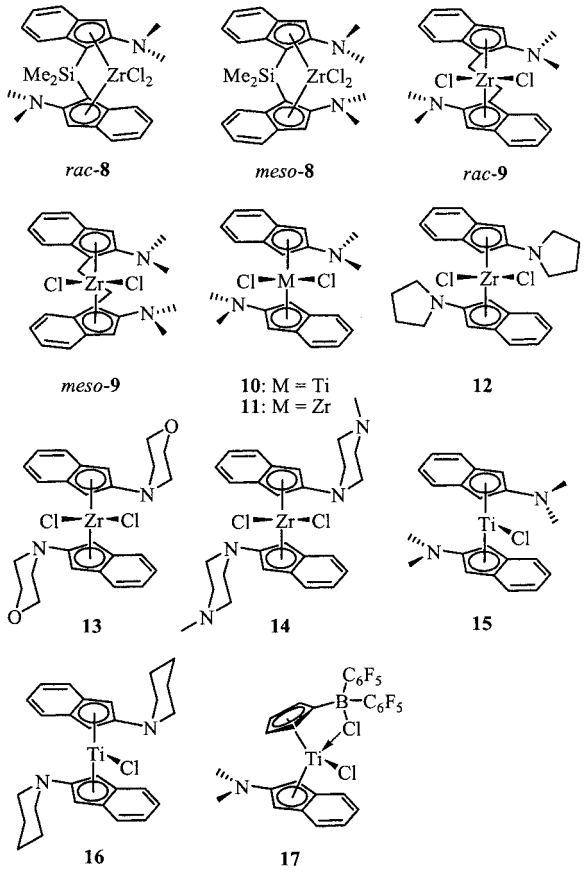

Figure 3. 2-Amino-substituted indenyl complexes of titanium and zirconium described in the literature; for racemic complexes, only one enantiomer of the racemic pair is shown

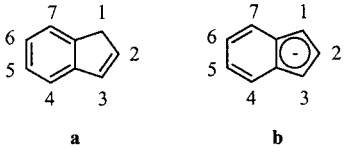

Figure 4. Numbering system for indene (**a**) and the corresponding indenyl anion (**b**)

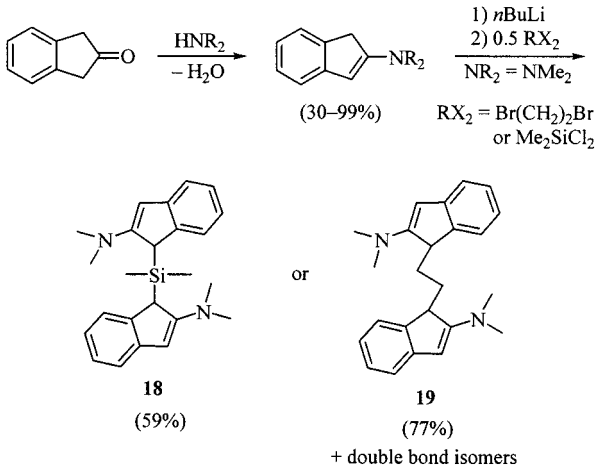
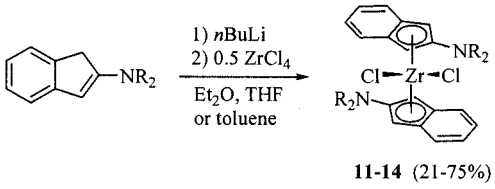
series of amino-substituted cyclopentadienes.[40,44,49,52] For 2-(dimethylamino)indene, the synthesis of both dimethylsilylene-[38] and ethylene-bridged[39] bis(indenyl) analogues **18** and **19** in good yields (59 and 77%, respectively) has been described that employs standard deprotonation/alkylation and deprotonation/silylation procedures in THF or diethyl ether solution (Scheme 1). The synthesis of 3-aminoindenes by enamine reaction of 1-indanone with secondary amines has also been reported.[55,62,63]

The syntheses of the unbridged bis(2-aminoindenyl)zirconocene dichlorides **11**−**14** proceed in 21−75% yields by reaction of the corresponding 2-aminoindenyllithium salts with $ZrCl_4$ in Et_2O, THF or toluene (Scheme 2) followed by standard workup and crystallization procedures.[38−40,44,45] In terms of metallation yield, toluene appears to be the preferred solvent. The bis(2-dimethylamino)indenyl)titanocene dichloride analogue **10** was obtained in a nearly quantitative yield by oxidation of the corresponding titanium(III) monochloride **15**, which in turn was prepared in over 90% yield by reaction of the 2-(dimethylamino)indenyllithium salt with $TiCl_3$·3THF.[43] The piperidinoindenyl analogue **16** was obtained in 70% yield according to a similar procedure.[64] All zirconium complexes **11**−**14** have been characterized crystallographically (vide infra). The titanium(III) chlorides **15** and **16** reported by Stryker and co-workers have been further converted into a series of (η^3-allyl)titanium and titanacyclobutane complexes, several of which were characterized crystallographically[42,43] and applied in the synthesis of cyclobutanones[64] and substituted cyclobutanimines.[65]



Scheme 1. Synthesis of 2-aminoindenes and the corresponding bridged bis(indenes)

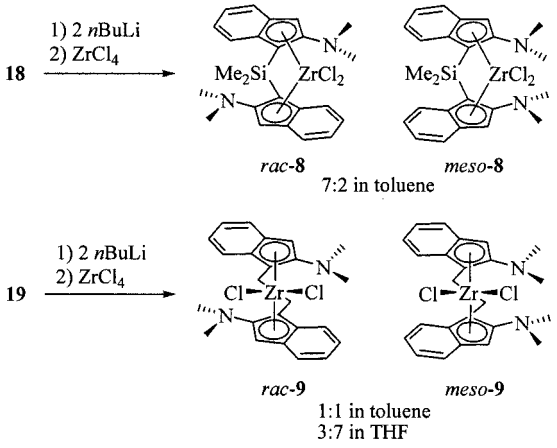


Scheme 2. Synthesis of the unbridged bis(2-aminoindenyl)zirconium dichlorides **11**−**14**

The dimethylsilylene- and ethylene-bridged bis(indenes) **18** and **19** yield, after deprotonation with *n*BuLi and subsequent reactions of the dilithium salts with $ZrCl_4$ in toluene or THF, the corresponding *ansa*-metallocene complexes **8** and **9** (see Figure 3) as mixtures of the racemic and *meso* diastereomers (Scheme 3). In the case of the dimethylsilylene-bridged complex **8**, the reaction in toluene gives a 7:2 *rac*/*meso* mixture in an overall yield of 57%, from which the pure racemic diastereomer *rac*-**8** was obtained in 30% yield by recrystallization, and was characterized crystallographically.[38] The ethylene-bridged analogue **9** in turn shows an unusual case of solvent-dependent *meso* diastereoselectivity in the metallation step, to yield a 1:1 *rac*/*meso* ratio in tolu-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

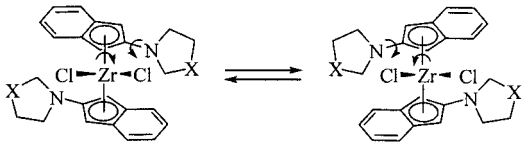
ene, from which *rac*-**9** was isolated after fractional crystallization in 33% yield.[39] However, when the metallation was carried out in THF, a 3:7 *rac*/*meso* ratio was obtained from which the pure *meso* diastereomer was isolated in 38% yield.[41] Both diastereomers of **9** have been characterized crystallographically.



Scheme 3. Synthesis of the *ansa*-bis[2-(dimethylamino)indenyl]zirconocenes **8** and **9**; only one enantiomer of the racemic pair is shown

The ^{1}H and ^{13}C NMR spectra of all unbridged zirconium complexes **11**−**14** show time-averaged molecular C_{2v} symmetry at room temperature, consistent with rapid rotation of the aminoindenyl ligands around the Cp(centroid)−Zr axis. The ^{1}H NMR resonances of the 1-H/3-H protons in the five-membered indenyl ring range from δ = 4.42 (complex **12**) to 4.86 ppm (complex **14**); these protons are considerably shielded relative to those of the 2-hydrocarbon-substituted analogues (commonly δ ≈ 6.0−6.5 ppm), indicating increased electron density in the Cp ring induced by the electron-donating amino substituent. For the complexes **12** and **13**, a detailed 600 MHz ^{1}H NMR spectroscopic study in [D$_8$]toluene by Erker and co-workers reveals two different dynamic processes, which freeze on the NMR timescale when the monitoring temperature is lowered (Scheme 4).[44] For complex **12**, a C−N rotational barrier of $\Delta G^{\ddagger}_{(\text{CN-rot})}$ (338 K) = 16.4 ± 0.2 kcal·mol^{-1} and an activation energy for the rotation about the zirconium−Cp(indenyl) vector of $\Delta G^{\ddagger}_{(\text{Ind-rot})}$ (198 K) = 9.1 ± 0.5 kcal·mol^{-1} was determined. For the 2-morpholinoindenyl complex **13**, the corresponding values were measured as $\Delta G^{\ddagger}_{(\text{CN-rot})}$ (268 K) = 12.9 ± 0.2 kcal·mol^{-1} and $\Delta G^{\ddagger}_{(\text{Ind-rot})}$ (178 K) = 7.6 ± 0.5 kcal·mol^{-1}, indicating that, for both of these complexes, a single metallocene rotamer is present in solution at low temperature within the limits of the ^{1}H NMR detection.

In solution, racemic C_2-symmetric ethylene-bridged bis(indenyl)zirconocenes commonly rapidly interconvert between two limiting conformations, indenyl-forward (Π) and indenyl-backward (Y), which arise from the conformational freedom of the five-membered metallacycle formed by the central metal atom, bridgehead carbon atoms, and the carbon atoms of the ethylene bridge (Scheme 5).[66−68] Simi-



Scheme 4. Dynamic processes in unbridged bis(2-aminoindenyl)zirconium dichlorides

larly, for the *meso* diastereomers, two chiral C_1-symmetric, equienergetic, staggered, mirror-image-limiting conformations exist that interconvert in solution through a completely eclipsed conformation (Scheme 6). Bis(indenyl) complexes having one-membered silicon or carbon bridges are considerably more rigid due to the restricted conformational freedom of the four-membered metallacycle formed by the metal atom, bridgehead carbon atoms, and the bridge.

The ^{1}H NMR spectra of both *rac*- and *meso*-ethylene-bridged 2-dimethylamino-substituted bis(indenyl)zirconocenes *rac*-**9** and *meso*-**9** show at room temperature only one set of highly symmetric ligand resonances, which indicate rapid interconversion between the limiting conformations on the NMR time scale.[39,41] For both diastereomers, only one single resonance is observed for the aminomethyl groups indicating rapid rotation around the η^5-C−N bond as well. The β-protons in the five-membered indenyl rings of both *rac*-**9** (δ = 5.99 ppm) and *meso*-**9** (δ = 5.85 ppm) are considerably shielded relative to those of the racemic and *meso* diastereomers of the unsubstituted bis(indenyl) analogue **2** (δ = 6.58 and 6.70 ppm, respectively);[66] this is consistent with donation of electron density from the amino substituent to the Cp ring. Similarly, the β-H of the dimethylsilylene-bridged analogue *rac*-**8** (δ = 6.4 ppm) is strongly shielded relative to that of the unsubstituted racemic parent complex dimethylsilylenebis(indenyl)zirconium dichloride (δ = 6.90 ppm).[69]

Brintzinger and co-workers have reported cyclic voltammograms of the dimethylamino-substituted complexes *rac*-**8** and **11**.[38] In comparison with the unsubstituted analogues *rac*-dimethylsilylenebis(indenyl)zirconium dichloride and bis(indenyl)zirconium dichloride, an additional irreversible oxidation peak was observed at $E_{1/2} \approx 0$ V, indicating instability against oxidation. The Zr^{IV}/Zr^{III} reduction peaks of these complexes, recorded at $E_{1/2} = -2.48$ V (*rac*-**8**) and −2.42 V (**11**), respectively, are shifted to more negative potentials by 0.28 and 0.43 V relative to the unsubstituted analogues, indicating noticeable increase in the electron density at the Zr centers of the amino-substituted complexes. The electrochemical potentials were measured at a platinum electrode against an Ag/AgNO$_3$ (satd.) reference electrode at 25 °C, with full compensation of the internal resistance (*IR*) of the electrolyte solution, and referenced against the standard potential of the ferrocene/ferrocenium couple ($E_{1/2} = -0.12$ vs. Ag/AgNO$_3$).

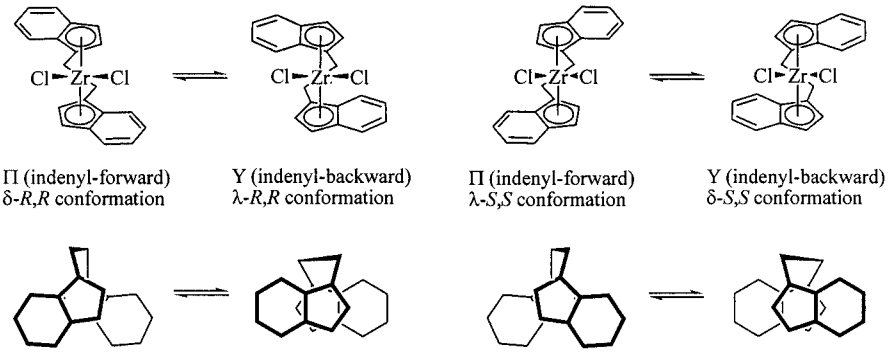
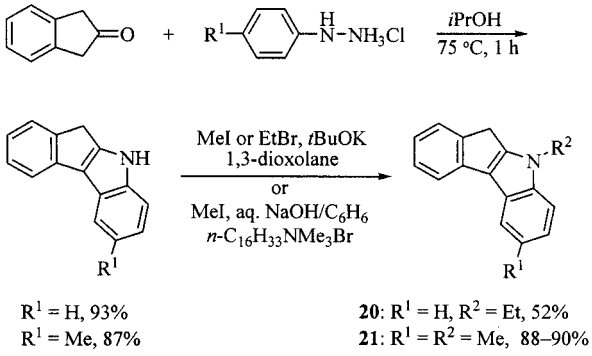


Scheme 5. Schematic presentation of the indenyl-forward/indenyl-backward interconversion for both enantiomers of the racemic ethylene-bis(indenyl)zirconium dichloride **2**

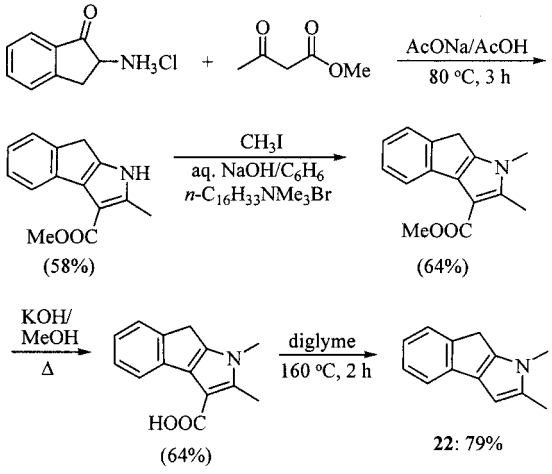
Scheme 6. Conformational freedom in the *meso* diastereomer of ethylene-bridged bis(indenyl)metallocenes

The synthesis of the indenoindole and indenopyrrole ligand precursors **20**–**22** for constrained-geometry type titanium complexes described by Resconi and co-workers are displayed in Schemes 7 and 8, respectively. The indenoindoles **20** and **21** were prepared in high yields by the acid-catalyzed Fischer condensation of 2-indanone with arylhydrazines (Scheme 7). The amines obtained were then alkylated in good yields using methyl iodide or bromoethane.[57]



Scheme 7. Synthesis of the indenoindole ligand precursors **20** and **21**

The *N*,2-dimethyldihydroindeno[2,1-*b*]pyrrole ligand precursor **22** was obtained in 25% overall yield (4 steps) by Knorr condensation between 2-aminoindanone hydrochloride and acetoacetic ester followed by *N*-alkylation, hydrolysis, and decarboxylation of carboxylic acid (Scheme 8).[57]



Scheme 8. Synthesis of the indenopyrrole ligand precursor **22**

Alkoxy-Substituted Group 4 Bis(indenyl)metallocenes

Alkoxy-substituted group 4 indenyl complexes **23**–**32** are collected in Figure 5. Detailed information on bis(indenyl) group 4 metallocenes containing direct alkoxy substitution in the five-membered Cp rings has only appeared in the patent literature. The racemic ethylene-bridged 2- and 3-methoxy-substituted zirconium complexes *rac*-**23** and *rac*-**24**[70] displayed in Figure 5 were obtained by recrystallization of the corresponding 1:1 *rac*/*meso* mixtures from toluene.[71] The 1:1 *rac*/*meso* mixtures had been obtained in 35 and 31% yields, respectively, by treating the lithiated ethylene-bridged ligand precursors with $ZrCl_4$ in THF. The syntheses of 2- and 3-methoxyindenes **33** and **34** are displayed in Scheme 9. Reaction of 1-indanone with trimethyl orthoformate in a mixture of methanol, benzene and a small amount of methanol saturated with dry hydrogen chloride yielded, after workup and distillation, a 59% yield of 3-methoxyindene.[72] A similar reaction of 2-indanone with trimethyl orthoformate in methanolic *p*-toluenesulfonic acid solution reportedly yielded 2-methoxyindene

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

after purification by preparative GLPC, although the yield of the reaction was not described.[73][74] Subsequent deprotonation with *n*BuLi and reaction with 0.5 equiv. of dibromoethane in THF then gave the corresponding bis(methoxyindenyl)ethanes in 45 and 64% yields, respectively.[71] For the 2- and 3-methoxy-substituted zirconocene dichlorides, the five-membered ring β-protons of **23** (*rac*/*meso* mixture: 6.0/6.1 ppm) and the α-protons of **24** (*rac*/*meso* mixture: δ = 5.7/5.9 ppm) are shielded considerably relative to the corresponding β- and α-protons of the unsubstituted ethylene-bridged *rac*/*meso*-**2** (δ = 6.58/6.70 and 6.20/6.55 ppm, respectively);[66] this is consistent with increased electron density in the η^5-Cp rings. In addition to these, dimethylsilylene-bridged constrained-geometry *tert*-butylamidoindenyl complexes of titanium incorporating both 3-methoxy- and 2-ethoxyindenyl ligands have been reported in the open literature.[55] Synthesis of 2-ethoxyindene in 86% yield by reaction of 2-indanone with ethyl orthoformate in a manner similar to those reported for the 2- and 3-methoxyindenes has been described.[75]

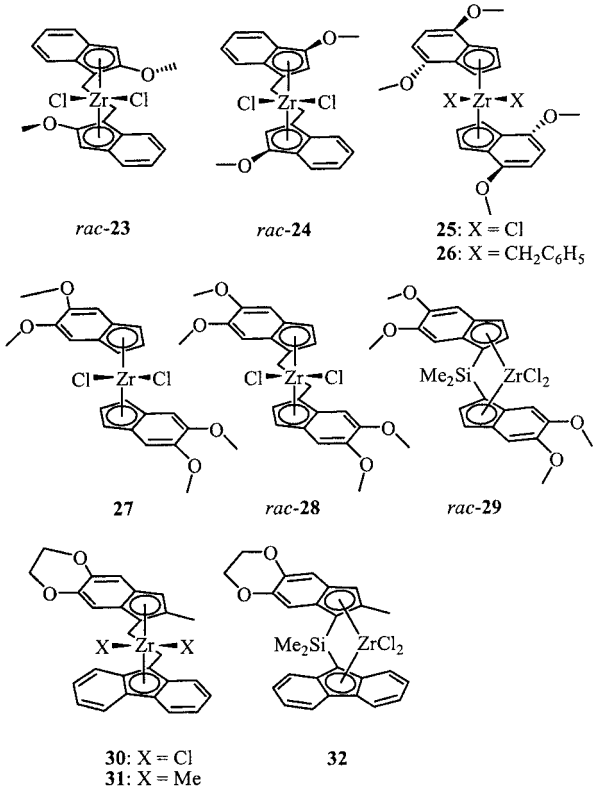


Figure 5. Alkoxy-substituted indenyl complexes of zirconium described in the literature; for racemic complexes only one enantiomer of the racemic pair is shown

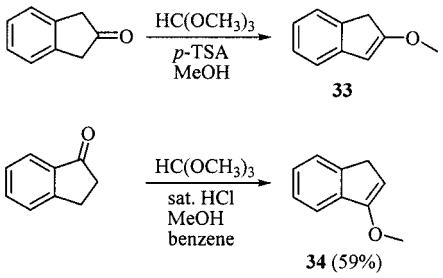
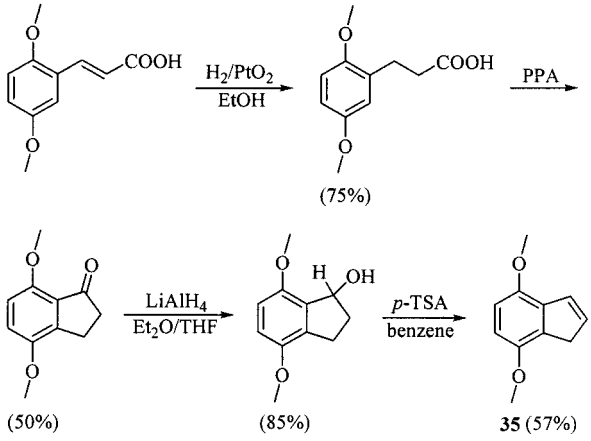
Bis(indenyl)zirconium complexes containing alkoxy substitution in the six-membered rings of the indenyl ligand system have been reported in both the open and patent literature (complexes **25**−**29** in Figure 5).[71,76,77] Consiglio and co-workers have described the synthesis of 4,7-dimethoxyindene (**35**) in four steps and in 18% overall yield from *trans*-3-(2,5-dimethoxyphenyl)propanoic acid



Scheme 9. Synthesis of 2- and 3-methoxyindenes (**33** and **34**)

(Scheme 10),[76] according to a modified literature procedure.[78,79] Deprotonation of **35** with *n*BuLi and subsequent reaction with $ZrCl_4$ in THF then gave, after workup and crystallization from toluene/hexane, a 40% yield of the 4,7-dimethoxy-substituted unbridged bis(indenyl)zirconium dichloride **25**.[76] The benzyl analogue **26** was prepared in 68% yield by reaction of **25** with benzylmagnesium chloride in Et_2O followed by crystallization from toluene/hexane.

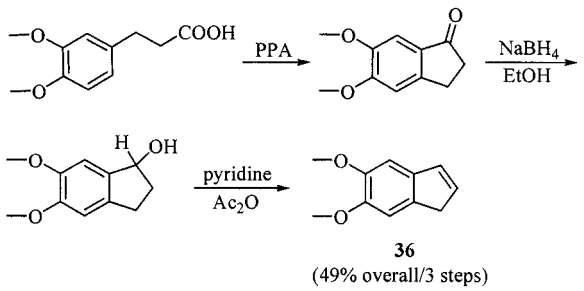


Scheme 10. Synthesis of 4,7-dimethoxyindene (**35**)

Collins and co-workers have reported the synthesis of the unbridged bis(5,6-dimethoxyindenyl)zirconium dichloride (**27**) in 35% yield by deprotonation of 5,6-dimethoxyindene (**36**) with *n*BuLi in THF followed by reaction with $ZrCl_4$ and subsequent workup and crystallization from toluene.[77] The synthesis of **36** is analogous to that of the 4,7-dimethoxy derivative **35**, which involves cyclization of 3-(3,4-dimethoxyphenyl)propanoic acid with polyphosphoric acid to the corresponding 1-indanone followed by reduction and dehydration steps to yield **36** in 49% overall yield (Scheme 11).[80] The ethylene-bridged ligand derivative was then prepared in 56% yield by reaction of the lithium derivative of **36** with dibromoethane in THF/HMPA solution.[77] Subsequent deprotonation with *n*BuLi and reaction with $ZrCl_4$ in THF gave, after workup and washing with

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

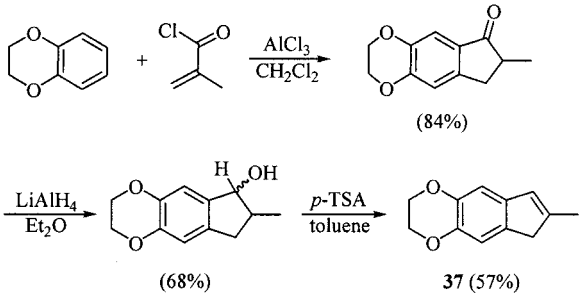
toluene, the racemic ethylenebis(5,6-dimethoxyindenyl)zirconium dichloride (*rac*-**28**) in 24% yield.



Scheme 11. Synthesis of 5,6-dimethoxyindene (**36**)

The dimethylsilylene-bridged analogue *rac*-**29** has been reported in the patent literature only. It was obtained by deprotonation of the dimethylsilylene-bridged ligand precursor with *n*BuLi and subsequent reaction of the isolated dilithium salt with $ZrCl_4$ in CH_2Cl_2 to give, after workup and crystallization from the same solvent, a 3:1 *rac*/*meso* mixture in 35% yield.[71] The pure racemate was then obtained by recrystallization. The dimethylsilylene-bridged ligand was prepared in 55% yield according to standard procedures by lithiation of **36** with *n*BuLi followed by reaction with dichlorodimethylsilane in THF.

In a recent study, Rieger and co-workers have described a series of C_1-symmetric mixed-ligand *ansa*-zirconium complexes **30**−**32**, which incorporate one 2-methylindenyl ligand with a fused 5,6-ethylenedioxy substituent.[81] The 5,6-(ethylenedioxy)-2-methylindene (**37**) employed was prepared in three steps and 32% overall yield by reaction of 1,2-(ethylenedioxy)benzene with methacryloyl chloride and $AlCl_3$ followed by subsequent reduction and dehydration steps (Scheme 12). The mixed ligand complexes form, upon activation with suitable cocatalysts, active catalyst systems for production of medium-tacticity polypropylenes. A detailed discussion is outside the scope of this review.



Scheme 12. Synthesis of 5,6-(ethylenedioxy)-2-methylindene (**37**)

All unbridged methoxy-substituted zirconium complexes **25**−**27** give, at room temperature, ^{1}H NMR spectra consistent with time-averaged molecular C_{2v} symmetry and unhindered ligand rotation around the Cp(centroid)−Zr axis. The η^5-Cp ring protons of the dichloride complexes **25** (1-H/3-H: δ = 6.11 ppm; 2-H: δ = 6.30 ppm) and **24** (1-H/3-H: δ = 5.91 ppm; 2-H: δ = 6.15 ppm) are considerably less shielded relative to unsubstituted bis(indenyl)zirconium dichloride (1-H/3-H: δ = 6.20 ppm; 2-H: δ = 6.45 ppm)[76,82] than those of the unbridged 2-amino-substituted complexes **11**−**14** (vide supra). Likewise, the racemic ethylene- and dimethylsilylene-bridged complexes **28** and **29** containing methoxy substituents in the six-membered indenyl rings give resonances in their ^{1}H NMR spectra that indicate that the α-H (δ = 5.98 and 5.82 ppm, respectively) and β-H (δ = 6.45 and 6.75 ppm, respectively) atoms are less shielded than the corresponding H atoms in the 2-aminoindenyl analogues, relative to those of the unsubstituted analogues *rac*-ethylenebis(indenyl)zirconium dichloride (**2**)[66] and *rac*-dimethylsilylenebis(indenyl)zirconium dichloride[69] (α-H: δ = 6.20 and 6.08 ppm; β-H: δ = 6.58 and 6.90 ppm, respectively). In the five-membered ring, however, the electron-releasing effect of the methoxy substituent is similar to that of the amino group, as can be seen by the η^5-Cp ring proton resonances of *rac*/*meso*-**23** (β-H: δ = 6.0/6.1 ppm) and *rac*/*meso*-**24** (α-H: δ = 5.7/5.9 ppm).

In addition to alkoxy groups, sterically hindered ester groups have been incorporated at both the 2- and 3-positions of indene by some of us and others (Figure 6).[83,84] All compounds **38**−**41** can be deprotonated with *n*BuLi to generate the corresponding indenyl anions. In all cases the anions were successfully trapped by addition of chlorotrimethylsilane or iodomethane. Complexation of the ester-functionalized ligands with transition metals has, however, not been described.

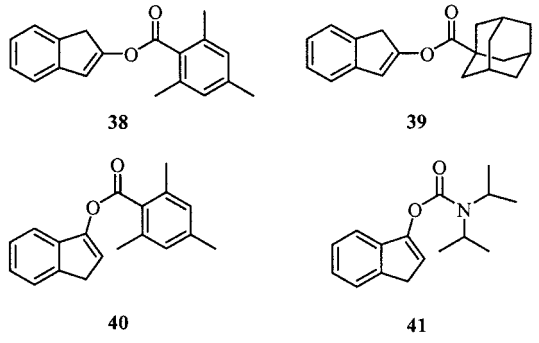


Figure 6. Ester-substituted indenes that can be deprotonated with butyllithium

Siloxy-Substituted Group 4 Bis(indenyl)metallocenes

A series of 1-(3-) and 2-trialkylsiloxy-substituted bis(indenyl) and bis(tetrahydroindenyl) complexes of zirconium and hafnium were reported by Leino, Luttikhedde, Näsman and co-workers between 1996 and 2000, with focus on the electronic effects in catalytic olefin polymerization (Figures 7 and 8).[85−97] Parts of this work have been briefly reviewed previously.[98] Prior to our work, both 2- and 3-trimethylsilylindenes had been reported in the literature;[73,99−103] however, the complexation of silyl ether substituted indenyl ligands with transition metals was undisclosed. Instead of the acid-labile and sterically less shielded trimethylsiloxy group, our initial attempts were focused on the use of the more stable *tert*-butyldimethylsilyl

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ether and its analogues as electron-donating indenyl ligand substituents.[104][105] The synthesis of 2-trialkyl/arylsiloxy-substituted indenes utilizing the keto-enol tautomerism of 2-indanone[73] is shown in Scheme 13. Thus, reaction of 2-indanone with *tert*-butylchlorodimethylsilane,[85] chlorodimethyl(thexyl)silane,[93] chlorotriisopropylsilane,[90] chloro(cyclohexyl)dimethylsilane,[106] and *tert*-butylchlorodiphenylsilane using the base/solvent combinations of DMF/imidazole or DBU/benzene gave the corresponding 2-siloxyindenes **64**−**68** as distillable oils in 69−90% yields. The six-membered ring substituted ligand analogues 2-(*tert*-butyldimethylsiloxy)-4,7-dimethylindene (**69**)[91] (distillable oil) and 2-(*tert*-butyldimethylsiloxy)cyclopenta[*l*]phenanthrene (**70**)[89] (powderous solid) were prepared in 85 and 72% yields, respectively, by reaction of 4,7-dimethyl-2-indanone[91] and 1,3-dihydro-2-oxocyclopenta[*l*]phenanthrene[107,108] (Scheme 14) with *tert*-butylchlorodimethylsilane/DBU in benzene. Analogously, the reaction of 1-indanone with *tert*-butylchlorodimethylsilane[92] and chlorotriisopropylsilane[90] using DBU/dichloromethane gave the corresponding 3-siloxyindenes **72** and **73** in 92 and 70% yields, respectively (Scheme 15). The 2-methyl-substituted analogue 3-(*tert*-butyldimethylsiloxy)-2-methylindene (**73**)[105] was prepared from 2-methyl-1-indanone[109] in 81% yield according to a similar procedure.[110]

The synthesis of the unbridged 2-siloxy-substituted bis(indenyl)zirconium dichlorides **48**,[90] **51**[91] and **52**[89] was carried out using standard procedures involving deprotonation of the indenyl ligand precursor with *n*BuLi in Et_2O or THF followed by metallation with $ZrCl_4$ in the same solvent or toluene (Scheme 16). The unbridged metallocenes were isolated after workup and crystallization in 32−42% yields. Of these, complex **51** was characterized crystallographically (vide infra). Attempts to prepare the analogous unbridged zirconium complexes from 2-(*tert*-butyldimethylsiloxy)indene (**64**) and 2-[dimethyl(thexyl)-siloxy]indene (**65**) likewise resulted in the formation of the desired metallocenes, as evidenced by EIMS, and ^1H and ^{13}C NMR analyses. Due to their extremely high solubilities in all common organic solvents, these complexes were, however, always obtained as inseparable powderous 5:3−5:2 mixtures containing also the unchanged indenyl ligand precursor as the minor component.[110] Obviously, a bulkier substitution pattern, as in complexes **48**, **51** and **52**, is required for obtaining unbridged 2-siloxy-substituted complexes in pure crystalline form.

The unbridged 2-siloxy-substituted zirconocene dichlorides **48**, **51** and **52** show at room temperature highly symmetric ^1H and ^{13}C NMR spectra consistent with time-averaged molecular C_{2v} symmetry and rapid rotation of the siloxyindenyl ligands around the Cp(centroid)−Zr axis. For example, in the ^1H NMR spectrum of complex **51** at ambient temperature five singlets are observed at δ = 6.84, 5.83, 2.32, 1.08 and 0.34 ppm in a 2:2:6:9:6 ratio assigned to the

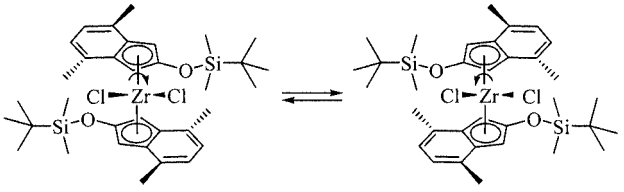
aromatic methine CH, five ring CH, the methyl groups of the aromatic ring, silicon-bound *tert*-butyl and methyl groups, respectively. The 1-H/3-H protons in the five-membered indenyl rings of complexes **48** (δ = 5.51 ppm)[90] and **51** (δ = 5.83 ppm)[91] are considerably more shielded than those observed for the 2-hydrocarbon-substituted analogues (commonly $\delta \approx 6.0-6.5$ ppm), indicating increased electron density in the Cp ring induced by the electron-donating siloxy substituent. In complex **52**, the observed deshielding of this proton resonance (δ = 6.24 ppm)[89] is apparently caused by the increased π-electron delocalization induced by the fused benzo substituents.

Variable-temperature NMR spectroscopic measurements were carried out on both complexes **51**[91] and **52**, and indicate dynamic behavior upon lowering the monitoring temperature. For **51**, the ^{1}H NMR resonance of the methyl sig-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nal at δ = 2.32 ppm becomes appreciably broadened at 218−198 K, and below coalescence (T_c = 193−190 K) two resonances of equal intensities are observed. In a similar fashion, the methyl signal at δ = 0.34 ppm and the methine signals at δ = 6.84 and 5.83 ppm show considerable broadening at 218−188 K, and split into two resonances below 178 K. Finally, at 173 K a 6.3 Hz ^3J coupling was observed for the methine protons of the six-membered ring. Similar splitting was observed for most of the ^{13}C NMR signals of **51** recorded at 173 K. Analogous to the amino-substituted zirconocenes **12** and **13** described by Erker and co-workers, and discussed earlier in this microreview (vide supra),[44] the signal splitting indicates a single C_2-symmetric bent-metallocene conformation that is detected when the equilibration of **51** with its nonsuperimposable mirror image becomes frozen on the NMR time scale (Scheme 17).[111] The calculated activation barrier for **51**, $\Delta G^{\ddagger}_{(\text{Ind-rot})}$ (190−193 K) = 9.1−9.3 kcal·mol^{-1}, is of similar magnitude to those observed by Erker and co-workers for the amino-substituted complexes,[44] and by Waymouth et al. for dibenzylbis(2-phenylindenyl)zirconium for which $\Delta G^{\ddagger}_{(\text{Ind-rot})}$ (203 K) = 10.7 kcal·mol^{-1} has been reported.[112] For complex **52**, a coalescence temperature of T_c = 173−174 K was estimated from the extensive broadening of the ^{1}H NMR signals at 173 K.[113] An activation barrier $\Delta G^{\ddagger}_{(\text{Ind-rot})}$ (173 K) = 8.91 kcal·mol^{-1} was calculated using the splitting of the ^{13}C NMR Si−CH_3 resonance at this temperature.



Scheme 17. Dynamic behavior in bis[2-(*tert*-butyldimethylsiloxy)-4,7-dimethylindenyl]zirconium dichloride (**51**)

The 3-(*tert*-butyldimethylsiloxy)indenes **71** and **73** were likewise converted into the corresponding bis(indenyl)zirconium dichlorides **60** and **61** by deprotonation with *n*BuLi in Et_2O followed by reaction of the isolated lithium salts with 0.5 equiv. of $ZrCl_4$ in toluene (Scheme 18). In contrast to 2-substituted indenyl complexes, the presence of a 3-(or 1-)indenyl substituent renders the ligand system prochiral. The attachment of the metal atom can occur from either enantiotopic face of the five-membered ring system, thus resulting in diastereomeric metallocene complexes consisting of a pair of racemic-like enantiomers **A** and **B**, and their *meso*-like diastereomer **C** (Figure 9).[114−116] In the case of complex **60**, workup and crystallization from Et_2O provided a first crop of a diastereomerically pure bright yellow powder in 15% yield, possibly corresponding to the enantiomeric **60a/b** mixture. Further concentration and cooling of the mother liquor then provided the other diastereomer (tentatively **60c**) in 12% yield, contaminated with traces of the other diastereomer.[117] As both diastereomers give highly symmetrical NMR spectra and similar EIMS fragmentation patterns, assignment of the diastereomers is not possible based on the spectroscopic data of the dichlorides only. Similar types of complexes have previously been assigned by Erker and co-workers based on conversion of the dichloride complexes to dimethylzirconium compounds where the *rac*-type isomer exhibits only one ^{1}H NMR resonance, whereas two resonances in a 1:1 ratio are observed for the *meso*-like diastereomer.[116] In the case of the sterically more hindered ligand precursor **73** that contains an additional 2-methyl substituent in the indenyl fragment, the ^{1}H NMR spectrum of the crude product indicates an approximately 1:1 mixture of two metallocene diastereomers. From a crude yield of 40%, diastereomerically pure complex **61** (tentatively the racemic-like isomer) was isolated in 13% yield after recrystallization from toluene. Complex **61** was further hydrogenated to yield the corresponding tetrahydroindenyl complex **62** in 65% isolated yield.[110] Despite several attempts, crystals suitable for X-ray structure determination were not obtained from any of the complexes **60**−**62**.

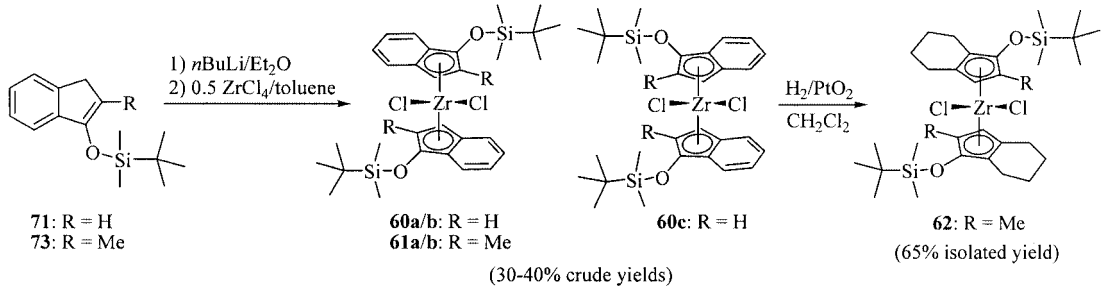

Scheme 18. Synthesis of unbridged 1-siloxy-substituted bis(indenyl) and bis(tetrahydroindenyl)zirconium dichlorides **60**−**62**; for racemic complexes only one enantiomer of the racemic pair is shown

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The synthesis of bridged 2,2′- and 3,3′-siloxy-substituted bis(indenyl) ligands was carried out according to standard procedures. Thus, all 2-siloxy-substituted indenes **64**−**68** were successfully converted into the corresponding ethylene-bridged bis(indenyl) derivatives **74**−**78** in 28−58% yields (crystalline solids) by lithiation with *n*BuLi followed by reaction with 0.5 equiv. of dibromoethane in THF, subsequent workup and purification by crystallization (Scheme 19). In contrast to bis(indenyl)ethane for which the 3,3′-indenyl-bridged isomer predominates,[10,66,118] all siloxy-substituted indenes yield exclusively the 1,1′-bridged product.[85,90,93,106] Only in the case of the six-membered ring substituted 2-siloxyindenes **69**[91] and **70**[106] were the yields for the ethylene-bridged bis(indenyl) ligands **79** and **80** (Figure 10) low (4.8 and 3.9%, respectively), which resulted from the nearly exclusive predomination of the spirocyclopropane adducts formed by intramolecular bis(alkylation) reactions of the substituted indene.[8,67,77,119] Both 2-(*tert*-butyldimethylsiloxy)indene (**64**) and 2-[dimethyl(thexyl)siloxy]indene (**65**) were further converted into the dimethylsilylene-bridged bis(indenyl) ligand analogues **81** and **82** in high yields by deprotonation with *n*BuLi followed by reaction with 0.5 equiv. of dichlorodimethylsilane.[106] The racemic diastereomers of the dimethylsilylene-bridged ligands were obtained as crystalline solids in 42 and 30% yields, respectively, and the *meso* diastereomers were isolated as oils in similar yields after exhaustive washing of the mother liquor with cold pentane. The benzo-fused dimethylsilylene-bridged bis[2-(*tert*-butyldimethylsiloxy)cyclopenta[*l*]phenanthryl] ligand (**83**, Figure 10) was prepared from **70** according to a similar procedure and isolated as a high-melting solid (m.p. 273−274 °C) in 25% yield.[89]

All 3-siloxy-substituted indenes **71**−**73** were converted into the corresponding ethylene-bridged bis(indenyl) analogues **84**,[92] **85**[90] and **86**[110] in variable yields ranging from 14% (compound **86**) to nearly quantitative (compound **85**) by deprotonation with *n*BuLi followed by reaction with dibromoethane in THF (Scheme 20).

The ethylene-bridged bis(2-siloxyindenes) **74**−**76** yield, after deprotonation with *n*BuLi and subsequent reactions of the dilithium salts with $ZrCl_4$ in THF, the corresponding *ansa*-zirconocene complexes **42**, **47** and **49** (Scheme 21).[85,90,93,97] The bulkiness of the siloxy group in the α-position to the ethylene bridge influences the *rac*/*meso* ratio of the metallocenes formed. In the case of the 2-*tert*-butyldimethylsiloxy-substituted complex **42**, metallation with $ZrCl_4$ in THF initially produces a *rac*/*meso* ratio of 14:1 as determined by ^1H NMR spectroscopic analysis of the crude product, whereas an entirely *rac*-selective metall-

Scheme 21. Synthesis of the ethylene-bridged 2-siloxy-substituted bis(indenyl)- and bis(tetrahydroindenyl)metallocene complexes **42**, **43**, **45**−**47**, **49** and **50**; for racemic complexes only one enantiomer of the racemic pair is shown

ation was observed for the 2-triisopropylsiloxy-substituted analogue **49**. Pure *rac*-**42** was obtained in 21−26% yield after crystallization/recrystallization from dichloromethane,[85,97] and pure *meso*-**42** after repeated recrystallization from a large-scale synthesis of **42**.[97] The analogous hafnium complex *rac*-**43** was isolated in 13% yield according to a similar procedure.[86] The racemic 2-[dimethyl(thexyl)-siloxy]-[93] and 2-triisopropylsiloxy-substituted[90] zirconium complexes *rac*-**47** and *rac*-**49** were isolated in 22 and 28% yields, respectively, after crystallization from dichloromethane or toluene. All attempts to metallate the dilithium salts of the ligand precursors **77**−**79** failed. The ethylene-bridged benzo-fused ligand precursor **80** was, however, successfully deprotonated with *n*BuLi, and treated with $ZrCl_4$ in THF. Workup and washing of the residue with toluene and hexane provided in total 22 mg of the corresponding metallocene *rac*-**54** (Figure 7) in 7% yield, tentatively assigned as the racemic diastereomer based on the highly isotactic polypropylene obtained upon activation of this complex with MAO and subsequent exposure to gaseous propylene.[113]

The racemic zirconium complexes *rac*-**42** and *rac*-**49** were further hydrogenated to yield the corresponding tetrahydroindenyl analogues *rac*-**45** and *rac*-**50**, isolated in 80% and 67% yields, respectively.[86][90] A small amount of pure *meso*-**45** was isolated after repeated recrystallization of the product obtained from hydrogenation of a *rac*/*meso*-**42** mixture.[120] Hydrogenation of the hafnium complex *rac*-**43** provided the corresponding tetrahydroindenyl complex *rac*-**46** in 75% isolated yield.[121] All of the ethylene-bridged 2-siloxy-substituted bis(indenyl)- and bis(tetrahydroindenyl)-metallocene complexes, with the exception of the bis(indenyl)hafnocene *rac*-**43**, are remarkably stable in air and towards moisture. The 2-siloxy-substituted bis(indenyl) complexes are generally soluble in cyclohexane, diethyl ether, toluene and dichloromethane. The hydrogenated congeners also dissolve readily in aliphatic solvents such as pentane and hexane. The increased stability in polar solvents is exemplified by complex *rac*-**42**, which is readily recrystallized from acetone.

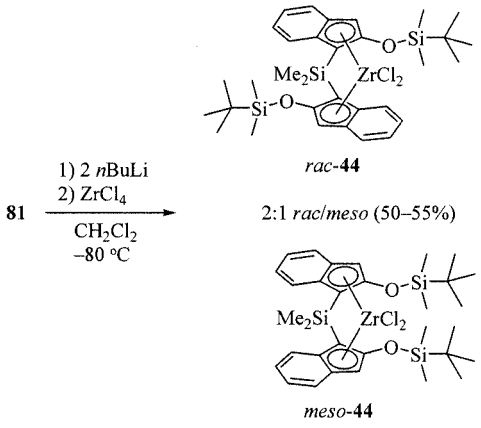
The X-ray crystal structures of complexes *rac*-**42**,[85] *rac*-**45**,[87] *rac*-**46**,[121] *rac*-**47**,[93] *rac*-**49**,[90] *rac*-**50**[90] and *meso*-**45**[120] were determined and are discussed separately (vide infra).

The ^{1}H NMR spectra of all ethylene-bridged racemic and *meso*-2-siloxy-substituted bis(indenyl)- and bis(tetrahydroindenyl)metallocene dichlorides show, at ambient temperature, one set of highly symmetrical ligand resonances indicating rapid interconversion between the limiting ligand conformers on the NMR time scale. The interconversion is analogous to that discussed earlier in this microreview for the 2-dimethylamino-substituted complexes *rac*/*meso*-**9** (Schemes 5 and 6), and by Resconi and co-workers for *rac*/*meso*-ethylenebis(indenyl)zirconium dichloride **2** and its 4,7-dimethyl-substituted analogue.[66,67] Likewise, analogous to the 2-amino-substituted complexes *rac*- and *meso*-**9**, the β-protons in the five-membered rings of all ethylene-bridged *rac*- and *meso*-2-siloxy-substituted bis(indenyl) complexes **42**, **43**, **47** and **49** are shielded and the signals shifted by 0.6−0.7 ppm to a higher field relative to the corresponding resonances of the 2-alkyl or unsubstituted analogues. Similar effects are observed in the ^{13}C NMR spectra for the chemical shifts of the β-carbon atoms of the five-membered rings. The only exception in this series is the benzo-fused complex *rac*-**54**, for which a ^{1}H NMR β-H resonance of δ = 6.51 ppm, similar to that observed for the unsubstituted parent complex *rac*-ethylenebis(indenyl)zirconium dichloride *rac*-**2** (δ = 6.58 ppm),[66][118] was detected.[113] The observed shielding effects are consistent with increased electron densities in the five-membered rings induced by the electron-donating siloxy substituents. For the benzo-fused complex *rac*-**54** the observed deshielding is apparently a consequence of the increased π-electron delocalization, as observed also for its unbridged congener **52** (vide supra). In the ^{29}Si NMR spectrum of the 2-*tert*-butyldimethylsiloxy-substituted ethylene-bridged ligand precursor **74**, the Me_2Si resonance is observed at δ = 22.45 ppm; however, in the corresponding racemic bis(indenyl)- and bis(tetrahydroindenyl)zirconium complexes *rac*-**42** and *rac*-**45**, lower field ^{29}Si NMR resonances of δ = 26.64 and 25.21 ppm, respectively, are observed, which are possibly influenced by electron donation to the aromatic five-membered rings and the Lewis-acidic zirconium atoms.[98] The subsequent decrease in the local electron densities of the oxygen atoms of the metallocene complexes then result in inductive electron withdrawal from the silicon to the oxygen atom, thus contributing to the lower field ^{29}Si NMR resonances.

The dimethysilylene-bridged ligand precursor **81** gave, upon deprotonation and reaction of the dilithium salt with $ZrCl_4$ in CH_2Cl_2 and subsequent workup and crystallization from the same solvent, a 2:1 mixture of fairly pure *rac*-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and *meso*-dimethylsilylenebis[2-(*tert*-butyldimethylsiloxy)indenyl]zirconium dichlorides (**44**) in approximately 50−55% yield (Scheme 22).[98,106] Surprisingly, in contrast to the ethylene-bridged complexes, the silylene-bridged analogue is highly sensitive towards air and moisture, and only a small sample of fairly pure racemic diastereomer *rac*-**44** was obtained after tedious recrystallization from Et_2O. Likewise, the diastereocontrol in favor of the racemic isomer in the metallation step is inferior to that observed for the ethylene-bridged analogues. The ^1H NMR chemical shift of β-H in *rac*-**44** (δ = 6.22 ppm) is of the same magnitude as that observed for the 2-dimethylamino-substituted analogue *rac*-**8** (δ = 6.4 ppm)[38] (vide supra) and strongly shielded relative to that observed for the parent *rac*-dimethylsilylenebis(-indenyl)zirconium dichloride (δ = 6.90 ppm).[69] The benzo-fused dimethylsilylene-bridged ligand **83** gave after deprotonation with *n*BuLi and subsequent reaction with $ZrCl_4$ in toluene a 1:9 *rac*/*meso* mixture of the corresponding zirconium complex **53**, as indicated by ^1H NMR spectroscopic analysis of the crude product.[89] Both diastereomers of **53** decompose rapidly in common organic solvents; the racemic isomer is the more unstable one. After rapid workup and crystallization from dichloromethane, pure *meso*-**53** was, however, obtained in 40% isolated yield.



Scheme 22. Synthesis of the dimethylsilylene-bridged 2-*tert*-butyldimethylsiloxy-substituted bis(indenyl) complex **44**; only one enantiomer of the racemic pair is shown

The ethylene-bridged 3-siloxy-substituted ligand precursors **84**−**86** were likewise deprotonated with *n*BuLi in Et_2O or THF, and the obtained dilithium salts reacted with $ZrCl_4$ (ligands **84**−**86**)[90][92][110] and $HfCl_4$ (ligand **84**) in THF or dichloromethane to yield the corresponding 1-(3-)siloxy-substituted *ansa*-metallocene complexes **55**, **56**, **58** and **63** as mixtures of the *rac* and *meso* diastereomers (Scheme 23). In the case of the 1-*tert*-butyldimethylsiloxy-substituted zirconium and hafnium complexes **55** and **56**, metallation of the dilithiated ligand precursor with MCl_4 (M = Zr, Hf) initially produces a 5:1 mixture of the corresponding *rac* and *meso* diastereomers, isolated after workup and crystallization from Et_2O in 20 and 15% yields, respectively. A small amount of analytically pure racemic zirconium complex *rac*-**55** was obtained after tedious recrystallization from toluene.[92] Recrystallization of the *rac*/*meso*-hafnocene mixture from Et_2O finally provided a 28:1 mixture of *rac*-**56**/*meso*-**56** used for characterization of the racemic hafnium complex.[110] Pure *meso* diastereomers *meso*-**55** and *meso*-**56** were obtained in 4 and 8% isolated yields, respectively, after tedious recrystallization from dichloromethane or toluene. Crystals suitable for X-ray structure determination were obtained from the *meso*-zirconocene **55**.[92] Separation of the diastereomers of the *tert*-butyldimethylsiloxy-substituted complexes **55** and **56** is hampered by the *slightly lower solubilities* of the minor *meso* diastereomers in common crystallization solvents such as Et_2O and toluene. An inverse order for the solubilities was observed for the 1-(3-)triisopropylsiloxy-substituted congeners *rac*- and *meso*-**58**, of which the fairly pure racemic diastereomer was obtained in 44% yield by simply washing the crude product with Et_2O.[90] Analytically pure *rac*-**58** was then obtained by recrystallization from toluene. Recrystallization of the Et_2O extracts from hexane provided pure *meso*-**58** in 6% isolated yield. The more highly substituted 1-*tert*-butyldimethylsiloxy-2-methyl-substituted zirconium complex **63** was obtained, after workup and crystallization from hexane, as an inseparable 18:1 mixture of the *rac* and *meso* diastereomers in 7% yield.[110] A 9:1 *rac*/*meso*-**55** mixture and the pure racemic diastereomer of **58** were further hydrogenated to yield the corresponding tetrahydroindenyl complexes **57** and *rac*-**59** in 84 and 67% isolated yields, respectively. The *tert*-butyldimethylsiloxy-substituted tetrahydroindenyl complex was obtained, after crystallization from hexane, as the initial 9:1 *rac*/*meso* mixture. Samples of pure *rac*-**57** were then obtained after careful recrystallization from the same solvent and characterized crystallographically.[92]

The ^1H NMR chemical shifts of the α-protons in the five-membered rings of the racemic 1-siloxy-substituted bis(indenyl)zirconium complexes *rac*-**55** (δ = 5.60 ppm)[92] and *rac*-**58** (δ = 5.63 ppm)[90] are shielded in comparison with those observed for *rac*-ethylenebis(indenyl)zirconium dichloride (**2**) (δ = 6.20 ppm)[66] and *rac*-ethylenebis(1-trimethylsilylindenyl)zirconium dichloride (δ = 6.10 ppm),[70] consistent with electron donation from the siloxy substituent to the aromatic five-membered ring. Similarly, for the tetrahydroindenyl complexes *rac*-**57** (δ = 4.96 ppm)[92] and *rac*-**59** (δ = 5.01 ppm),[90] the α-Hs are shielded relative to that of *rac*-**5** (δ = 5.61 ppm).[118]

In addition to the siloxy-substituted group 4 bis(indenyl) complexes reported by us, a series of siloxy-substituted mono- and bis(cyclopentadienyl) complexes of iron, manganese, tungsten, titanium and zirconium have been described by Plenio and co-workers.[122−125]

Thio-Substituted Group 4 Bis(indenyl)metallocenes

To the best of our knowledge, the only examples of thio-substituted group 4 bis(indenyl)metallocene complexes are those claimed in the patent literature (Figure 11).[126] Explicit yields for the metallation step were not given, characterization data for the ligands and metallocenes were also not given. Complexes **87**−**90** were claimed to be catalysts

Scheme 23. Synthesis of the ethylene-bridged 1-siloxy-substituted bis(indenyl)- and bis(tetrahydroindenyl)metallocene complexes **55**−**59** and **63**; for racemic complexes only one enantiomer of the racemic pair is shown

both in solution homopolymerization of ethylene, as well as copolymerization of ethylene and propylene, with few details of polymer characterization given in the patent application.

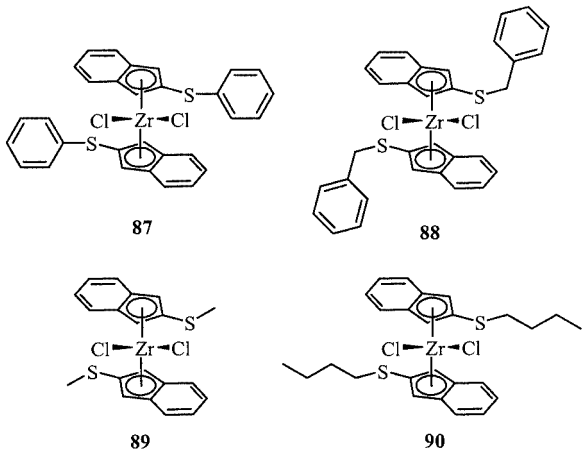

Figure 11. Thio-substituted bis(indenyl)zirconium complexes **87**−**90** reported in the patent literature

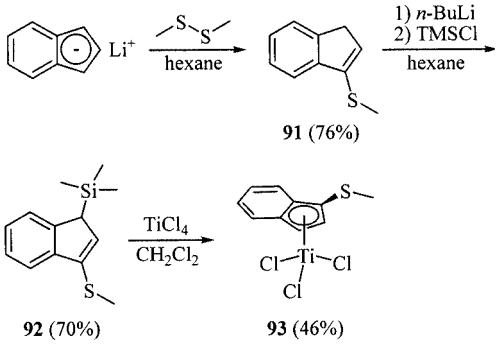
Related to these, Rausch and co-workers have reported the synthesis of the monoindenylmetallocene trichloro[1-(thiomethyl)indenyl]titanium (**93**) and its application in the syndiospecific polymerization of styrene (Scheme 24).[127] The 3-(methylthio)indene (**91**) employed as ligand precursor was prepared from indenyllithium and dimethyl disulfide in 76% yield according to the procedure of Hartke.[128] Subsequent deprotonation with *n*BuLi and reaction with chlorotrimethylsilane gave the TMS adduct **92** in 70% yield, which upon reaction with $TiCl_4$ in dichloromethane eliminates TMSCl to form the half-sandwich titanocene **93** in 46% yield after crystallization from toluene. Introduction of the methylthio group appears to have a detrimental effect on the styrene polymerization activity, presumably due to interaction of the sulfur lone pairs with the MAO cocatalyst.



Scheme 24. Synthesis of 3-(methylthio)indene (**91**) and the corresponding half-sandwich titanium dichloride complex **93**

Preparation of C_1-symmetric, mixed-ligand ethylene-bridged group 4 *ansa*-metallocenes (Zr, Hf) **94**−**97** containing one benzothiophene-fused indenyl ligand and one fluorenyl ligand was recently described by Rieger (Figure 12).[129] The 2-methyl-1-*H*-benzo[*b*]indeno[4,5-*d*]thiophene (**98**) precursor was prepared in good yield by Friedel−Crafts acylation of dibenzothiophene with methacrylic chloride in a manner similar to that described for the 5,6-ethylenedioxy-fused ligand (Scheme 10), followed by subsequent Nazarov cyclization, ketone reduction and water elimination (Scheme 25). The mixed-ligand complexes, upon activation with MAO, form high-performance catalysts for production of controlled tacticity polypropylenes. A detailed discussion is outside the scope of this review.

The related indenyl ligand precursor 2-methyl-8*H*-indeno[2,1-*b*]thiophene (**99**), having a sulfur-containing heterocycle condensed to the indenyl *five-membered ring* and reported by Resconi and co-workers for use in constrained-geometry titanium complexes, was prepared from 4-bromo-2-methylthiophene in 30% overall yield (three steps), as displayed in Scheme 26.[57] The 2-methyl-4-phenylthiophene was obtained in 70% yield after reaction of the bromo compound with phenylmagnesium bromide. Additionally, a few examples of bis(cyclopentadienyl) group 4 metallocenes containing phenylthio-[130] and propylthio-substituted[131,132] Cp ligands have been reported in the literature.

Theoretical Studies

Pakkanen and co-workers have studied the geometry prediction of a large set of bridged zirconocene dichloride complexes by ab initio Hartree−Fock, MP2, BLYP and B3LYP methods; with basis sets range from 3-21G* to 6-311G**.[133] Selected calculated geometrical parameters of close to 60 zirconocene dichloride complexes, including several amino- and siloxy-substituted bis(indenyl) and bis(tetrahydroindenyl)zirconocenes, were compared with the experimentally determined crystal structures. The least expensive HF/3-21G* method was verified to be notably accurate for such predictions by a comprehensive data set of 62 bridged zirconocene dichlorides. In a separate study by the same authors,[134] factors controlling the accessibility of cationic metal sites in zirconocene polymerization catalysts was investigated by the ab initio Hartree−Fock method at the 3-21G* level. Special emphasis was laid on the influence of the electronic effects and the ligand structure on the accessibility, stabilization and destabilization of the active center. Several heteroatom-substituted indenyl complexes, including both amino and siloxy substitution, were modeled successfully. A detailed description is outside the scope of this microreview.

In yet another study by Pakkanen et al., conformational preferences of racemic ethylene-bridged bis(indenyl)zirconocenes were investigated using the ab initio Hartree−Fock method with emphasis on the influence of the ligand-substitution pattern on the relative stabilities of the limiting indenyl-backward (Y) and indenyl-forward (Π) conformations (Scheme 5) and their interconversion.[135] Conformational interconversion of several ethylene-bridged methyl- and 1- or 2-trialkylsiloxy-substituted bis(indenyl)- and bis(tetrahydroindenyl)zirconium dichlorides was evaluated as part of this investigation.

Solid-State Structures

Table 1 presents selected bonding parameters for several unbridged, ethylene-bridged and silicon-bridged bis(indenyl) group 4 metallocene dichlorides and their hydrogenated congeners.[38−41,44,45,6,85,86,88,90,92,93,120,121,136−139] Each studied molecule represents the closely related overall structure of the metal-centered unit, i.e. bent-sandwich geometry around the pseudotetrahedrally coordinated metal ion.

Of the unbridged zirconium complexes, the parent bis(indenyl)zirconium dichloride $(Ind)_2ZrCl_2$ displays a staggered conformation in the solid state,[136] whereas the 2-amino-substituted analogues **11**−**14** all crystallize in an *anti* conformation having a crystallographically imposed C_2-axial symmetry. Crystallization of the unbridged 2-siloxy-substituted zirconium complex bis[2-(*tert*-butyldimethylsiloxy)-4,7-dimethylindenyl]zirconium dichloride (**51**) arranges two rotamers in the asymmetric unit corresponding to a C_1-symmetric, "central/lateral:*gauche*" conformation and a C_2-symmetric, "bis(central):*syn*" conformation, respectively.[114] In both rotamers the metallocene C_5 rings are nearly eclipsed.

The combination of ethylene bridge with bis(indenyl)-based ancillary ligands results in the potential formation of *meso* and *rac* diastereomers. All of the crystallographically characterized *meso* isomers display a chiral C_1-symmetric conformation due to the staggered placement of the two indenyl ligand moieties (Scheme 6). The racemic ethylene-bridged bis(indenyl) and bis(tetrahydroindenyl)metallocenes show the ordinary C_2-symmetric bent-metallocene structure adopting one of the two limiting conformations,

indenyl-forward (Π) and indenyl-backward (Y), as discussed previously in this microreview (vide supra). Representative examples of ethylene-bridged parent and heteroatom-substituted bis(indenyl) and bis(tetrahydroindenyl) complexes are displayed in Figures 8 and 9, respectively.

In most cases, racemic ethylene-bridged bis(indenyl)-type metallocenes crystallize in the Π conformation. However, nearly all of the racemic 2-siloxy-substituted complexes crystallize in the less common Y conformation, apparently resulting from the diminished repulsion between the bridge and the 2-substituent of the indenyl ring.[135] As an exception, *rac*-ethylenebis(2-triisopropylsiloxyindenyl)zirconium dichloride *rac*-**49** crystallizes in the indenyl-forward conformation; however, its hydrogenated congener *rac*-**50** again adopts the indenyl-backward conformation in the solid state (Figure 15).[90] Complexes with large equatorial substituents favor the Y conformation, albeit the energy differences between the Π and Y conformations appear to be

small.[66,67,135] In addition to the siloxy-substituted complexes, the indenyl-backward conformation has also been observed in the solid state by Brintzinger and co-workers for the racemic ethylenebis(4,5,6,7-tetrahydroindenyl)titanium[*O*-acetyl-(*R*)-mandelate],[12,140] by Jordan et al. for the racemic ethylenebis(4,5,6,7-tetrahydroindenyl)zirconium(η^2-CH_2Ph)(CH_3CN)$^+$ cation[141] and racemic ethylenebis(indenyl)hafnium(NMe_2)$_2$,[142] and by Kaminsky and co-workers for racemic ethylenebis(2,4,7-trimethylindenyl)-zirconium dichloride.[68]

X-ray crystal structures of the silicon-bridged bis(indenyl)metallocene derivatives display mainly racemic, C_2-symmetric molecules. The coordination sites are surrounded in an equal fashion, in accordance with the conditions for equivalent enantiofacial coordination of prochiral ligands. Structure determinations of the unbridged, amino-substituted complexes reveal that the amino groups are approximately planar.[38−40,44,45] The short C−N bond lengths of about 1.35 Å indicate that the nitrogen lone pair is considerably delocalized into the indenyl five-membered ring. Even so, related planar amino groups and short N−C distances are not found in the silicon- or ethylene-bridged bis(aminoindenyl)zirconium complexes due to the steric interaction of the amino groups with the interannular bridges.[39,41] The nitrogen−chlorine distances are typically slightly shorter than the sum of their van der Waals radii (3.3 Å), and there is no significant bonding. Aforementioned electron donation from the nitrogen atom may result in adequate electron deficiency that allows these short intermolecular distances. For the C_2-symmetric ethylene-bridged 2-siloxy-substituted complexes, the indenyl-backward conformation brings the chlorine and oxygen atoms in closer contact (3.53−3.85 Å) than in the indenyl-forward conformation (4.06 Å).[85,86,90,93,121] In the unbridged 2-siloxy-substituted complex **51**, the Cl−O distance is even shorter (3.141 Å), being shorter than the sum of their relevant van der Waals radii (3.20 Å).[91] Similar short contacts (3.15−3.30 Å) are also found for 1-siloxy-substituted complexes.[92] Then again, the electron donation from the heteroatom to the zirconocene center can result in a sufficient electron shortage that permits the short intramolecular distances.

UV/Vis Spectroscopic Studies

Recently, Mäkelä-Vaarne and co-workers have utilized UV/Vis spectroscopy to study the activation of siloxy-substituted bis(indenyl) complexes with MAO.[143−145] Interestingly, the position of the siloxy substituent was found to have a drastic influence on the activation behavior of the complex. The activation of 2-siloxy-substituted and unsubstituted bis(indenyl) complexes was observed to proceed relatively quickly, contrary to the slow activation of a 1-siloxy-substituted complex, which showed in the UV/Vis spectrum a sequence of three time-consuming reaction steps. With the aid of molecular modeling studies, the reason for the slow activation of the 1-siloxy-substituted complex was interpreted as resulting from an interaction between the oxygen donor atom of the siloxy group and the electron-deficient zirconium atom. According to UV/Vis studies at ambient temperature, to overcome this interaction took several hours, while formation of the final active species occurred for the 2-siloxy-substituted complex in less than a minute.[145]

On increasing the [Al]/[Zr] ratio for the 1-siloxy-substituted bis(indenyl) complex, the UV/Vis spectrum showed an LMCT band shift to higher energies. This shift is indicative of an interaction between the cocatalyst and the siloxy substituent, the net result of which is a decrease in the cata-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lytic activity. At low [Al]/[Zr] ratios this band shift was not observed, which can be correlated with the optimum polymerization performance under such conditions in terms of activity and shortened induction times.[86,95,146]

Polymerization Catalysis

Polymerization catalysis will be discussed here with focus on polymerization activity, molecular weight control and copolymerization ability. Optimally, heteroatom substitution can be utilized to tune the electronic properties of catalyst precursors to stabilize the active cationic species by electron donation, which improves the polymerization activity. Noteworthy, it is to a large extent the interaction of the cocatalyst and the functional groups of the catalyst precursor that determine the net result of the electronic effect on the active cationic center.

Olefin Homopolymerization

To study the electronic effects of ligand substituents, Piccolrovazzi et al.[76] and Collins et al.[77] introduced methoxy groups in the 4,7- and 5,6-positions, respectively, of indenyl ligands. Activation with MAO led to a drastic decrease in the polymerization activity relative to the unsubstituted complexes. This was explained by interaction of MAO with the methoxy groups, which resulted in net electron withdrawal and destabilization of the active center. A similar reasoning can also be used to explain the low activities reported for 2-methoxy-substituted bis(indenyl)zirconocenes.[71] Introduction of 2-amino groups into an indenyl ligand framework was found by Brintzinger et al.[38] and Näsman and co-workers[39] to result in modest activity after an induction period of several hours. The induction time was explained to result from inhibition of the reaction generating the active species, probably again as a consequence of an unfavorable interaction of the donor substituents with the cocatalyst MAO. A similar induction period was reported for a 1-siloxy-substituted bis(indenyl) complex,[95,146] and recently explained to be, in addition to an unfavorable interaction with the cocatalyst, a consequence of an interaction between the donor oxygen atom and the electron-deficient zitconium atom.[145]

Increasing the temperature from 40 to 80 °C or adding triisobutylaluminum to the reaction medium was found to shorten the induction period.[95,146] In contrast to 1-siloxy-substituted bis(indenyl) complexes, 2-siloxy-substituted complexes have been reported not to suffer from such induction periods, which according to molecular modeling studies was explained to result from a weaker O(siloxy)−Zr and a weaker (MAO)Al−O(siloxy) interaction of the latter complexes.[145]

Overall, both 1- and 2-siloxy-substituted bis(indenyl) complexes show a considerable increase in ethylene polymerization activity at low [Al]/[Zr] ratios relative to their unsubstituted analogues. Thus, the polymerization behavior of siloxy-substituted bis(indenyl) systems has been extensively studied.[85−89,91,93−98] It was shown that the optimal catalyst activity for siloxy-substituted bis(indenyl) complexes in homogeneous olefin polymerization is achieved at a remarkably low [Al]/[Zr] ratio of 250. A similar low [Al]/[Zr] ratio for the optimal activity was recently reported by Rieger and co-workers for the heteroatom-substituted C_1-symmetric complexes **30** and **32**.[81] Several reasons for the increased polymerization activity at low [Al]/[Zr] ratios have been suggested.[81,85,86,95] Sufficiently shielded heteroatoms, such as oxygen in trialkylated siloxy substituents or oxygen atoms embedded in a dioxane ring, can be understood to be protected against the attack by the Lewis-acidic aluminum cocatalyst. As a result, the heteroatoms preserve their electron-donating nature in the presence of low amounts of MAO, which facilitates the formation of the active site and stabilizes the cationic metal center. In addition, the weaker bonding of the counterion to the cationic alkylmetallocene might increase the rate of monomer insertion into the metal−alkyl bond and thus the chain propagation rate. One further reason could simply be that the polar oxygen substituents promote the approach of the Lewis-acidic aluminum cocatalyst towards the complex and thus promote the activation reaction in the apolar polymerization medium.

Facilitated activation has also been reported by Kallio and co-workers, who showed that siloxy-substituted bis(indenyl) complexes are more readily activated by higher aluminoxanes, such as hexaisobutylaluminoxane than their unsubstituted analogues.[147]

Besides the polymerization activity, the ability to produce sufficiently high-molecular weight polymers is a key factor when evaluating the performance of an olefin polymerization catalyst. Siloxy substitution[85,86,95] and dioxane substitution[81] were found to enhance the probability of chain transfer to aluminum, which was the dominant mechanism for chain termination in propylene polymerization and resulted in rather low polypropylene molecular weights. Chain termination to aluminum has also been reported for 2-amino-substituted complexes in propylene polymeri zation.[38] Rieger et al. reported that borate activation of the dimethylated complex **31** doubled the molecular weight compared with MAO activation of the dichloride.[81] Contrary to propylene polymerization, in ethylene polymerization chain transfer to aluminum has been found to be insignificant for the siloxy-substituted complexes. At 80 °C and with a moderate ethylene concentration of 0.2 mol/dm^3 chain transfer to monomer was found to be the dominant termination mechanism for siloxy-substituted bis(indenyl) complexes, resulting in a number-average molecular weight of 40 kg/mol. For the hydrogenated analogues, chain transfer to monomer was present but less pronounced, and also transfer of β-H to the Zr atom became significant. The number-average molecular weight, 110 kg/mol, was higher than that found for the bis(indenyl) system.[95]

Olefin Copolymerization

Finally, the ability to incorporate comonomers is important when considering the usefulness of a complex to produce linear low-density polyethylene. Table 2 compares the effect of siloxy substituents on the 1-hexene copolymeri-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

zation ability in ethylene polymerization for bis(indenyl)- and bis(tetrahydroindenyl)zirconium complexes.[95,97] Siloxy substitution in the 1-position of the indenyl ligand was found to markedly improve the α-olefin copolymerization ability, reducing the reactivity ratio of ethylene from 48 to 19 for bis(indenyl) complexes, and from 71 to 30 for the corresponding hydrogenated complexes. The reason for the improved copolymerization ability of 1-siloxy-substituted complexes was explained by their increased coordination gap aperture, which is a parameter generally known to affect comonomer accessibility. Replacing the methyl groups at the silicon atom by isopropyl groups has been reported to further improve the copolymerization ability.[94] In contrast to 1-siloxy substitution, 1-*tert*-butyldimethylsilyl substitution, as reported by Ekholm and co-workers for *rac*-ethylenebis(1-*tert*-butyldimethylsilylindenyl)zirconium dichloride (**100**) (Figure 16), clearly reduced the copolymerization ability and resulted in low molecular weight polymers due to excessive chain transfer after primary comonomer insertion, probably as a consequence of the extensive steric hindrance in the vicinity of the active site.[146] Siloxy substitution in the 2-indenyl position resulted in a slightly reduced copolymerization ability relative to that of the unsubstituted complex.[95]

Conclusions and Outlook

As shown above, modification of group 4 metallocene complexes with electron-donating heteroatom substituents provides an efficient means for modulating the steric as well as electronic features of this class of organometallic compounds. In most cases, the synthesis of such complexes is straightforward employing conventional organic and organometallic synthesis methods for both ligand and metallocene construction. For example, broad varieties of both 2- and 3-amino-, as well as 2- and 3-siloxyindenes, are obtained in high yields in a single reaction step from 2- and 1-indanones and the corresponding secondary amines or chlorosilanes. Accordingly, a large number of bis(indenyl) group 4 complexes, in particular zirconocenes, containing nitrogen and oxygen atoms directly linked to the indenyl ligand have appeared in the literature in recent years. Most recently, while this microreview was being finalized for publication, Erker and co-workers disclosed the synthesis of 4,7-bis(dimethylamino)indene and zirconocene complexes derived thereof.[149]

In terms of the catalytic applications, remarkable effects have been observed in catalytic olefin polymerization where properly shielded electron-donating substituents on the indenyl ligand can be used to control the electron density of the active metal center and thus its ability to control the formation of the cationic active species, monomer-coordination and chain-termination events in the homo- or copolymerization reaction. For example, the siloxy-substituted bis(indenyl)zirconium complexes reach their maximum activities in the polymerizations of ethylene and propylene at significantly reduced concentrations of the expensive MAO cocatalyst, most likely due to the efficient shielding of the donor atoms from unfavorable coordination of alkylaluminum compounds, allowing them to retain the electron-donating character, which in turn facilitates the formation of the active species. Considering the various promising applications of chiral group 4 metallocenes in stereo- and enantioselective organic synthesis, interesting applications for the electronically modified analogues may be anticipated in these areas as well, while such applications hitherto have remained virtually unexplored.

Acknowledgments

Co-authors of our original publications are gratefully acknowledged for their contributions. R. L. wishes to express his sincerest gratitude to his mentor, Professor Jan H. Näsman (1955−2000), whose contribution in the development of the authors' own work reported in this microreview was most influential and whose untimely death a deep loss.

A Novel Route to Multinuclear d^8 Metal−Chalcogen Compounds with Nuclearity Control

Rubén Mas-Ballesté,[a] William Clegg,[b] Agustí Lledós,*[a] and Pilar González-Duarte*[a]

Keywords: Cluster compounds / Platinum / Metalloligands / Self-assembly / Sulfur

We have designed a new synthetic procedure to obtain multinuclear aggregates containing a $\{Pt_2S_2\}_n$ core. The synthetic strategy involves the reaction of [(dppp)Pt(μ-S)$_2$Pt(dppp)] with [PtCl$_2$(PhCN)$_2$] and thus the expansion of the $\{Pt_2S_2\}$ ring to a $[\{Pt_2S_2\}PtCl_2]$ fragment. The lability of the chloride anions allows their replacement by bridging sulfide ligands, thus affording a new $[\{Pt_2(\mu_3\text{-}S)_2\}\{Pt_2(\mu\text{-}S)_2\}\{Pt_2(\mu_3\text{-}S)_2\}]$ core. Its subsequent evolution to $[\{Pt_2S_2\}_3PtCl_2]$ lays the foundation for a new cycle.

Introduction

Preparation of novel structures in good yields by systematic approaches is relevant in transition-metal sulfide chemistry in view of the current interest and economic importance of these compounds in industrial uses.[1] Although novel approaches to the synthesis of high nuclearity platinum complexes have been reported recently,[2] the chemistry of noble-metal−sulfido clusters has been neglected compared with that of aggregates containing the first transition series metals and molybdenum.[3] Here we report a novel synthetic route based on the behavior of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds as metalloligands, which leads to multinuclear aggregates containing a $\{Pt_2S_2\}_n$ core. The synthetic strategy allows control of the nuclearity of the cluster and can be extended to other metals with square-planar coordination.

The outstanding nucleophilicity of the sulfur atoms in the $\{Pt_2S_2\}$ core accounts for the significant number of known homo- and heterometallic derivatives of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ (L = phosphane) identified to date,[4] as well as for its reaction with organic electrophiles[5] and protons.[6] On the basis of the ability of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ to act as a ligand to metal centers, we now address the use of these compounds for building up multinuclear aggregates containing a $\{Pt_2S_2\}_n$ core. The synthetic strategy involves first expansion of the $\{Pt_2S_2\}$ rings to $[\{Pt_2S_2\}PtL'_2]$ fragments containing labile terminal L′ ligands, which are then replaced by bridging sulfide ligands. As a result, the PtL'_2 fragment evolves to a $\{Pt_2S_2\}$ linking unit between two $\{Pt_2S_2\}$ rings, thus affording a new $[\{Pt_2S_2\}_2\{Pt_2S_2\}]$ core. Its subsequent evolution to $[\{Pt_2S_2\}_3PtL'_2]$ lays the foundation for a new cycle. In this work we present the synthesis and characterization of three complexes derived from $[Pt_2(\mu\text{-}S)_2(dppp)_2]$ (**1**; Scheme 1) and provide evidence for the lability of chloride ligands in the $[\{Pt_2S_2\}PtCl_2]$ fragment.

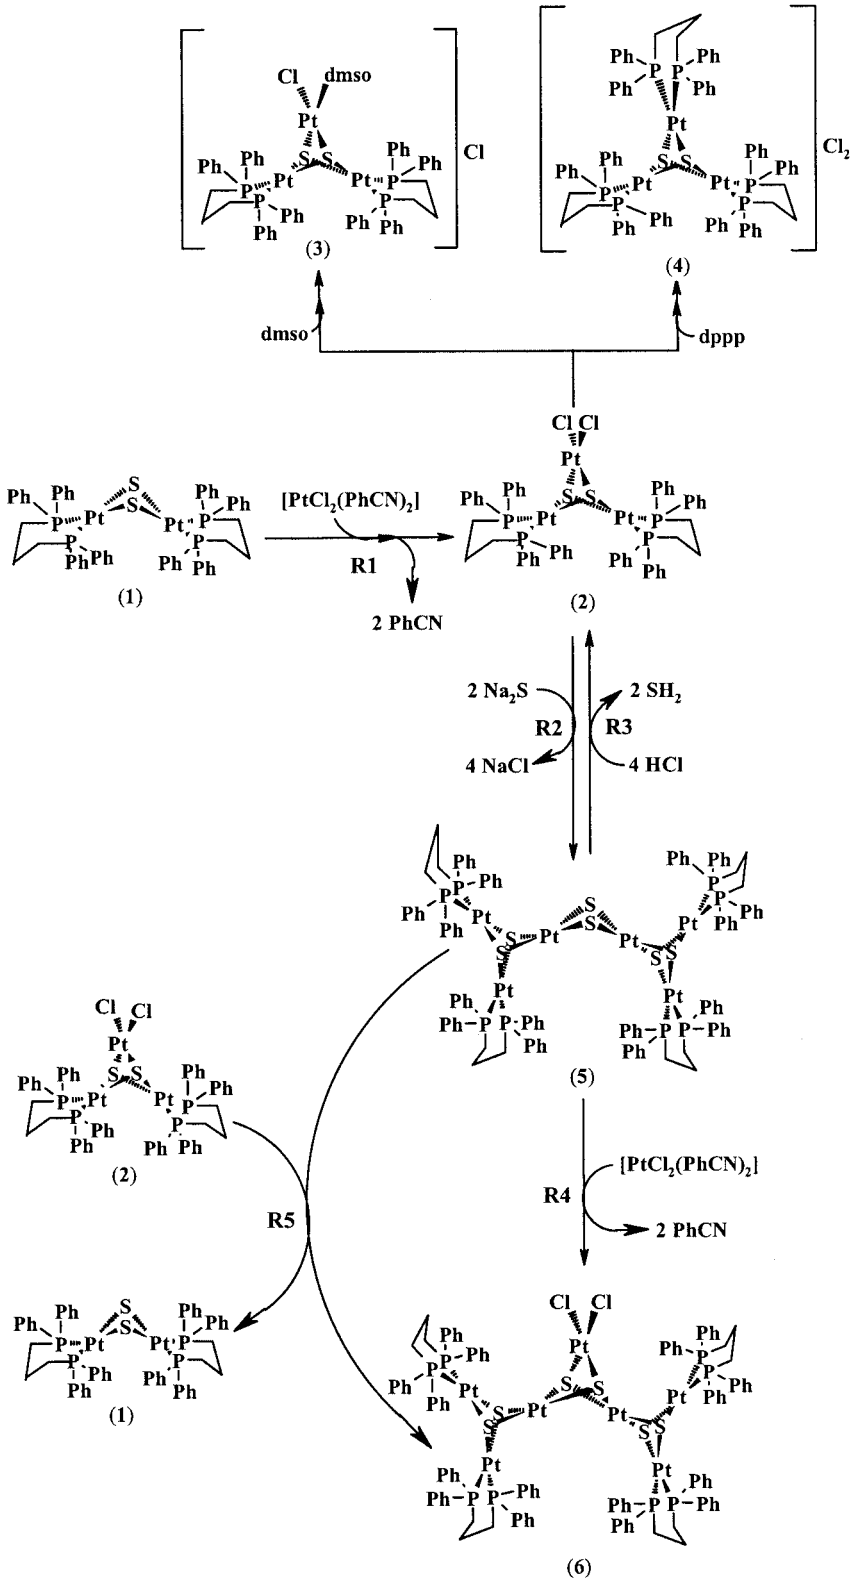
Results and Discussion

The reaction of equimolar quantities of $[Pt_2(\mu\text{-}S)_2(dppp)_2]$ (**1**) and $[PtCl_2(PhCN)_2]$ gave the compound $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}PtCl_2]$ (**2**) in good yield. The X-ray crystal structure of this complex consists of discrete trinuclear species and solvent molecules. Although the latter show disorder, the structure of the complex (Figure 1) has been unequivocally determined. Thus, the central Pt_3S_2 unit consists of a nonequilateral triangle of platinum atoms capped above and below by two sulfur atoms, thus forming a trigonal bipyramid. Each platinum atom has approximate square-planar coordination. Significantly, among the wide family of derivatives obtained from $[L_2Pt(\mu\text{-}S)_2PtL_2]$ metalloligands (L = phosphane) no previous example of the $P_4Cl_2Pt_3S_2$ core observed in **2** has been observed by X-ray diffraction. Thus, in the absence of X-ray data, three different alternatives have been proposed as a result of synthetic strategies similar to that followed for the synthesis of **2** (reaction R1). These are: formation of a mixture of hexanuclear $[\{Pt_2(\mu_3\text{-}S)_2[P(tolyl)_3]_4\}M_2(\mu\text{-}Cl)_2\{Pt_2(\mu_3\text{-}S)_2\text{-}[P(tolyl)_3]_4\}]^{2+}$ and trinuclear $[\{Pt_2(\mu_3\text{-}S)_2[P(tolyl)_3]_4\}MCl_2]$ (M = Pd, Pt) species,[7] or formation of only a hexanuclear $[\{Pt_2(\mu_3\text{-}S)_2(PPh_3)_4\}Pd_2(\mu\text{-}Cl)_2\{Pt_2(\mu_3\text{-}S)_2(PPh_3)_4\}]^{2+}$,[8] or a trinuclear $[\{Pt_2(\mu_3\text{-}S)_2(PPh_3)_4\}PtCl_2]$[9] complex. The $^{31}P\{^1H\}$ NMR spectrum of **2** in $CDCl_3$ shows only one signal centered at $\delta = -8.08$ ppm with $^1J_{Pt,P} = 2978$ Hz, thus indicating that the ^{31}P nuclei are equivalent in solution, in agreement with the solid-state structure.



Scheme 1

The lability of the chloro ligands in **2** becomes apparent in the characterization of this compound by ESI-MS. Thus, depending on the recording conditions and on the solvent used to obtain mass data, the following cationic species have been identified: $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}PtCl]^+$ (m/z = 1509.5), $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}PtCl(CH_3CN)]^+$ (m/z = 1550.8), $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}Pt(CH_3CN)_2]^{2+}$ (m/z = 778.2), or $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}PtCl(CH_3OH)]^+$ (m/z = 1541.6).

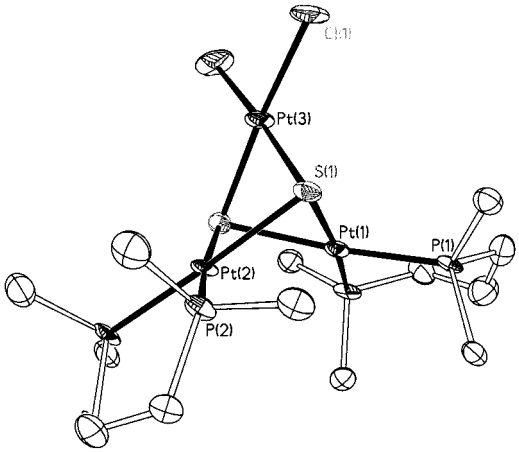

Figure 1. Molecular structure of **2** with the key atoms labeled and 50% probability ellipsoids; H atoms, phenyl rings and CH_2Cl_2 solvent molecules have been omitted; selected structural parameters [Å, °]: Pt−Cl 2.330(7), Pt(1)−S 2.381(7), Pt(2)−S 2.357(6), Pt(3)−S 2.287(6), Pt(1)−P(1) 2.237(7), Pt(2)−P(2) 2.256(7), Pt(1)···Pt(2) 3.124(2), Pt(1)···Pt(3) 2.942(2), Pt(2)···Pt(3) 3.277(2), S···S 2.981; Cl−Pt(3)−Cl 91.1(4), P−Pt(1)−P 93.6(4), P−Pt(2)−P 93.1(3), S−Pt(1)−S 77.5(3), S−Pt(2)−S 78.5(3), S−Pt(3)−S 81.4(3); dihedral (hinge) angles between PtS_2 planes: Pt(1)/Pt(2) 116.0, Pt(1)/Pt(3) 110.1, Pt(2)/Pt(3) 134.0

For the three species a good match between experimental and theoretical isotope distribution has been observed, the above *m*/*z* values corresponding to the major intensity peak. Additional evidence for this lability is provided by the fact that a solution of **2** in DMSO yields the unprecedented complex [{$Pt_2(\mu_3\text{-}S)_2(dppp)_2$}PtCl(dmso)]Cl (**3**), whose synthesis and characterization is reported here. Moreover, the addition of a stoichiometric amount of dppp to **2** affords complex [$Pt_3(\mu_3\text{-}S)_2(dppp)_3$]$Cl_2$ (**4**), already obtained from a different synthetic procedure.[6a]

On the basis of its ability to exchange the chloride ions, the synthesis of [{$Pt_2(\mu_3\text{-}S)_2(dppp)_2$}$_2${$Pt_2(\mu\text{-}S)_2$}] (**5**) was carried out by treating complex **2** with a stoichiometric amount of $Na_2S{\cdot}9H_2O$. The $^{31}P\{^1H\}$ NMR spectrum of **5** in [D_6]DMSO shows a broad signal centered at $\delta = -7.9$ ppm with a $^1J_{Pt,P}$ value of ca. 3000 Hz, and the ^{195}Pt NMR spectrum in the same solvent consists of two signals, one singlet at $\delta = -3524$ ppm (PtS_4) and one triplet centered at $\delta = -4425$ ppm (S_2PtP_2) with $^1J_{Pt,P} = 3002$ Hz. Further evidence for the hexanuclear nature of **5** was provided by the MALDI-TOF mass spectrum, which shows a complex isotope-pattern distribution with a major peak at *m*/*z* = 3013.5. As shown in Figure 2, both features are consistent with the molecular mass of the cation [{$Pt_2(\mu_3\text{-}S)_2(dppp)_2$}Pt(μ-S)(μ-SH)Pt{$Pt_2(\mu_3\text{-}S)_2(dppp)_2$}]$^+$, and thus with the nature of complex **5**.

Comparison of the nucleophilicity of the {Pt_2S_2} core in complexes **5** and **1** was established by determination of their basic character. Thus, titration of **1** and **5** with HCl was monitored by $^{31}P\{^1H\}$ NMR spectroscopy. The addition of a stoichiometric amount of HCl to **5** leads to **2** quantitatively, while formation of [$PtCl_2$(dppp)] from **1** requires a significant excess of HCl.[6a] Additional evidence for the greater basicity of the {Pt_2S_2} core in **5** than in **1** comes

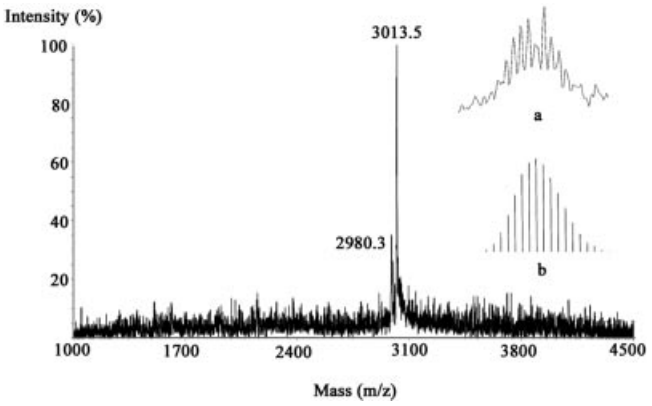

Figure 2. MALDI-TOF spectrum of **5** showing the major intensity peak at *m*/*z* = 3013.5 corresponding to [**5** + H]$^+$; experimental (a) and simulated (b) isotope-distribution patterns are included; the peak at *m*/*z* = 2980 corresponds to [**5** − S]$^+$

from the ability of the former to displace the {$PtCl_2$} fragment from **2** to afford **1** and [{$Pt_2(\mu_3\text{-}S)_2(dppp)_2$}$Pt_2(\mu_3\text{-}S)_2PtCl_2${$Pt_2(\mu_3\text{-}S)_2(dppp)_2$}] (**6**), as indicated in Scheme 1. An alternative way to obtain **6** is by treating **5** with a stoichiometric amount of [$PtCl_2(PhCN)_2$].

Complex **6** was characterized by mass spectrometry and NMR spectroscopy. The MALDI-TOF spectrum has a major signal at *m*/*z* = 1640.2, which can be assigned to the [**6** + 2 H]$^{2+}$ cation (for the major peak, theoretical *m*/*z* = 1640). Comparison of the experimental and theoretical isotope-distribution patterns is given in Figure 3. $^{31}P\{^1H\}$ NMR measurements of **6** in [D_6]DMSO show a broad signal centered at $\delta = -9.3$ ppm with $^1J_{Pt,P}$ of about 3000 Hz. The broadness of this signal, which does not allow us to distinguish the nonequivalence of the phosphorus nuclei, can be attributed to the high number of possible couplings between magnetically active platinum and phosphorus nuclei in **6**. The ^{195}Pt NMR spectrum consists of two singlets ($\delta = -3519$, -3418 ppm) corresponding to the platinum nuclei in the PtS_4 and $PtCl_2S_2$ fragments, respectively, and

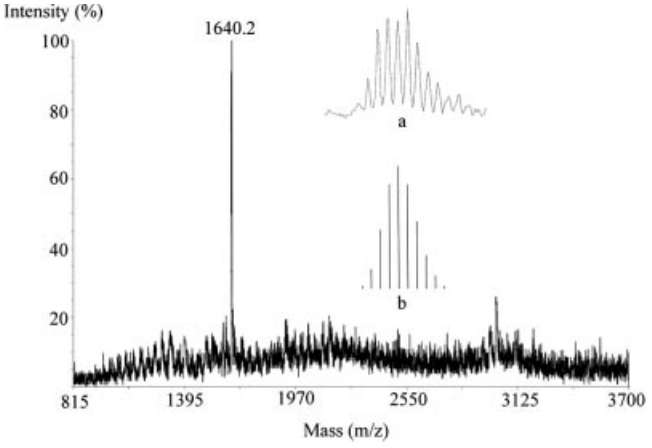

Figure 3. MALDI-TOF spectrum of **6** showing the major intensity peak at *m*/*z* = 1640.3 corresponding to [**6** + 2 H]$^{2+}$; experimental (a) and simulated (b) isotope-distribution patterns are included

two triplets — $\delta = -4403$ ppm ($^1J_{Pt,P} = 2997$ Hz) and $\delta = -4420$ ppm ($^1J_{Pt,P} = 2970$ Hz) — which can be assigned to the two different platinum nuclei present as S_2PtP_2 in **6**.

The thermodynamic feasibility of the reactions given in Scheme 1 has been corroborated by means of density functional calculations performed for complexes **1**, **2**, **5** and **6**, where dppp is modeled by two PH_3 ligands. The calculated reaction energies are given in Table 1. Geometry optimization of **1t**, **2t**, **5t** and **6t** affords their structural data, that of **2t** being in good agreement with the crystallographically determined data for **2**. As regards the HOMO orbitals of **1t** and **5t**, they essentially consist of an antibonding combination of p_π orbitals of the sulfur atoms pointing outwards from the hinged $\{Pt_2S_2\}$ ring, thus accounting for the observed coordinating ability of the sulfur atoms. Interestingly, the energy level of the HOMO for **5t** (−2.46 eV) is 1.95 eV higher than for **1t** (−4.41 eV), which is in agreement with the greater basicity found experimentally for the $\{Pt_2S_2\}$ core in **5** than in **1**.

Table 1. B3LYP reaction energies in the gas phase

Reaction	R1	R3	R4	R5
Energy [kcal/mol]	−8.3	−41.2	−49.7	−40.4

Conclusion

In this work, we have provided a new insight into the chemistry of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds that goes beyond their usual behavior as metalloligands towards a wide range of transition metals. The synthetic route used demonstrates that the nucleophilicity of the $\{Pt_2S_2\}$ core can be driven to build nuclearity-controlled multinuclear aggregates containing a $\{Pt_2S_2\}_n$ core. This strategy requires replacement of the terminal X ligands in $[\{Pt_2S_2\}_nPtX_2]$ fragments. For X = Cl, this has been achieved by reaction with sodium sulfide.

Characterization of the high nuclearity complexes here obtained has required several spectroscopic techniques, among which MALDI-TOF mass spectrometry has proved very valuable despite its scarce use in coordination chemistry studies.

Finally, on the basis of these results it can be concluded that a similar reaction scheme should be suitable for obtaining macromolecular complexes containing a $\{M_2(\mu\text{-}S)_2\}_n$ core provided M has a preference for square-planar coordination environments.

Experimental Section

General Remarks: All reactions were carried out under pure dinitrogen, and conventionally dried and degassed solvents were used throughout. Complex $[PtCl_2(dppp)]$ was prepared according to published methods.[10] The synthesis of $[(dppp)Pt(\mu\text{-}S)_2Pt(dppp)]$ has already been reported.[5] ^1H, $^{13}C\{^1H\}$ $^{31}P\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR spectra were recorded from samples in $(CD_3)_2SO$ solution at room temperature, using a Bruker 250 spectrometer. ^1H and ^{13}C chemical shifts are relative to $SiMe_4$, ^{31}P chemical shifts to external 85% H_3PO_4 and ^{195}Pt chemical shifts to external H_2PtCl_6. The ESI-MS measurements were performed with a VG Quattro Micromass Instrument. Experimental conditions are given elsewhere.[5] MALDI mass spectra were obtained with a Voyager DE-RP (PerSeptive Biosystems, Framighan) time-of-flight (TOF) mass spectrometer equipped with a nitrogen laser (337 nm, 3 ns pulse). The accelerating voltage in the ion source was 20 kV. Data were acquired in the reflector mode operation with a delay time of 60 ns. Experiments were performed using the matrix 2,5-dihydroxybenzoic acid (DHB; Aldrich). Matrix solutions were prepared by dissolving 10 mg of DHB in 10 mL of CH_3CN/H_2O 50% (v/v). Equal volumes (1 μL + 1 μL) of matrix solution and diluted samples (10^{-2} M in CH_3CN) were mixed and spotted onto the stainless-steel sample plate. The mixture was dried in air before being introduced into the mass spectrometer. Microanalytical data have been omitted because those referring to the carbon content were unsatisfactory, as already reported in some related (phosphane)platinum complexes.[5][6a][6b]

Synthesis of $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}PtCl_2]$ (2): The reaction of equimolar quantities of $[Pt_2(\mu\text{-}S)_2(dppp)_2]$ (**1**; 500 mg, 0.39 mmol) and $[PtCl_2(PhCN)_2]$ (184 mg, 0.39 mmol) in benzene (80 mL) at room temperature for 6 h gave $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}PtCl_2]$ (**2**) as an orange solid, which was filtered off and washed with diethyl ether (532 mg, yield 82%). Slow evaporation of the solvent from a solution of **2** in CH_2Cl_2 afforded yellow X-ray-quality crystals. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta = -8.1$ ppm ($^1J_{Pt,P} = 2978$ Hz). ESI-MS: $m/z = 1509.5$ $[M - Cl]^+$.

Synthesis of $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}PtCl(dmso)]Cl$ (3): Complex **2** (300 mg, 0.19 mmol) was dissolved in the minimum amount of DMSO (1 mL). Addition of diethyl ether caused precipitation of complex **3** as a yellowish solid, which was filtered off and washed with diethyl ether (206 mg, yield 67%). $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta_A = -7.1$ ppm ($^1J_{Pt,P_A} = 3022$ Hz); $\delta_B = -7.8$ ppm ($^1J_{Pt,P_B} = 3051$ Hz). ^1H NMR ($CDCl_3$): $\delta = 2.85$ ppm (coordinated dmso). ^{13}C NMR ($CDCl_3$): $\delta = 44.4$ ppm (coordinated dmso). ESI-MS: $m/z = 1587.7$ $[M]^+$.

Synthesis of $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}Pt_2(\mu\text{-}S)_2\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}]$ (5): A suspension of complex **2** (400 mg, 0.25 mmol) in methanol (50 mL) was allowed to react with a stoichiometric amount of $Na_2S{\cdot}9H_2O$ (61 mg, 0.25 mmol) at room temperature for 1 h. Concentration of the filtered orange solution thus obtained, followed by addition of diethyl ether, allowed isolation and characterization of the title compound (229 mg, yield 61%). $^{31}P\{^1H\}$ NMR ([D$_6$]DMSO): $\delta = -7.9$ ppm. ^{195}Pt NMR ([D$_6$]DMSO): $\delta = -3524$, -4425 ppm ($^1J_{Pt,P} = 3000$ Hz). MALDI: $m/z = 3013.5$ $[M + H]^+$.

Synthesis of $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}Pt_2(\mu_3\text{-}S)_2PtCl_2\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}]$ (6): A solution of **5** (200 mg, 0.07 mmol) in acetonitrile (50 mL) containing a stoichiometric amount of $[PtCl_2(PhCN)_2]$ (32 mg, 0.07 mmol) was left to react at room temperature for 3 h. The red solution was filtered and the resulting filtrate concentrated. The title compound was isolated after addition of diethyl ether (123 mg, yield 54%). $^{31}P\{^1H\}$ NMR ([D$_6$]DMSO): $\delta = -9.3$ ppm. ^{195}Pt NMR ([D$_6$]DMSO): $\delta = -3519$, -3418, -4403 ppm ($^1J_{Pt,P} = 2997$ Hz), -4420 ($^1J_{Pt,P} = 2970$ Hz) ppm; MALDI: $m/z = 1640.2$ $[M + 2H]^{2+}$.

X-ray Crystallographic Study of Complex 2: $C_{54}H_{52}Cl_2P_4Pt_3S_2{\cdot}6CH_2Cl_2$, M = 2054.7, orthorhombic, *Pnma*, a = 19.982(3), b = 18.607(2), c = 19.372(2) Å, V = 7202.5(16) Å^3, Z = 4, T = 160 K, R = 0.091. The molecule lies in a crystallographic mirror plane, as do some of the chloroform solvent molecules, while others are in general positions. High displacement parameters suggest possible disorder of the solvent molecules, but this could be resolved only for one, in which one chlorine atom occupies alternative sites on either side of a mirror plane while the carbon atom and the other chlorine atom are in the plane. Restraints on geometry and displacement parameters were used to aid the refinement. The crystallographic analysis was further complicated by the probable occurrence of multiple twinning by exchange among the unit cell axes, all three of which are similar in length; this was indicated by an analysis of the agreement of observed and calculated intensities, but it was not possible to find a simple model for the twinning. This leads to the relatively high R factor. CCDC-221226 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details: Gas-phase DFT calculations with the B3LYP functional were carried out using the Gaussian 98 suite of programs.[11] Effective core potentials and their related double-ζ basis set known as LANL2DZ were used for Pt, P, Cl and S atoms, supplemented with polarization functions for P, Cl and S atoms. The 6-31G basis set was used for H, C and N atoms with the addition of polarization functions for the N atom. A thermodynamic consideration for the R2 reaction requires taking into account the solvent effects. However, PCM calculation for compound **5** was hindered by the size of the system and thus the reaction energy for R2 could not be obtained.

Acknowledgments

Thanks are due to Prof. O. Rossell and I. Angurell for their assistance in the recording of the ^{195}Pt NMR spectra. Financial support from the Ministerio de Ciencia y Tecnología of Spain (projects BQU2001-1976 and BQU2002-04110-CO2-02) and the EPSRC (UK) is gratefully acknowledged. R. M. First Tetranuclear Co^{II} Cluster with Planar Triangular Pattern: Crystal Structure and Ferromagnetic Behavior

Miao Du,[a,b] Ya-Mei Guo,[a] Xian-He Bu,*[a] and Joan Ribas[c]

Keywords: Carboxylic-functionalized diazamesocyclic ligands / Cobalt / Crystal structure / Magnetic properties / Tetranuclear clusters

The preparation, crystal structure and magnetic properties of the first tetrameric Co^{II} cluster with a unique planar triangular motif, $[Co_4L_3(H_2O)_2](ClO_4)_2{\cdot}2H_2O$ (**1**), based on a carboxylic-functionalized 1,5-diazacyclooctane (DACO) bridging ligand [1,5-bis(2-carboxyethyl)-DACO], are reported.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The development of routes and strategies for the design and preparation of polynuclear clusters of 3d metals in moderate oxidation states is of great importance in bioinorganic chemistry, magnetochemistry, material chemistry and solid-state chemistry.[1] Tetranuclear systems have attracted particular interest since it was discovered that they are also the smallest aggregates that show single molecular magnet (SMM) behavior.[2] Of the relatively small number of reported tetracobalt(II) compounds, the majority have a dicubane/cubane rather than a square/rhombus-like core.[3] As described by us and others, diazamesocycles, especially 1,5-diazacyclooctane (DACO), modified by suitable functional pendants can be used as building blocks for constructing polymeric systems with unique structures and properties.[4,5] Very recently we have made an attempt to incorporate the carboxylic group, a versatile ligand with various coordination modes, on the backbone of DACO, and some fascinating chemistry of such ligands under self-assembly with metal ions were successfully achieved.[6] In the present contribution, we describe the preparation, crystal structure and magnetic properties of the first tetranuclear Co^{II} cluster $[Co_4L_3(H_2O)_2](ClO_4)_2{\cdot}2H_2O$ (**1**) [H_2L = 1,5-bis(2-carboxyethyl)-DACO; Scheme 1] exhibiting a unique planar-triangular Co_4 topology.

Scheme 1

Results and Discussion

The crystal-structure determination of **1** reveals that it is a spontaneously resolved chiral crystal (each individual crystal is a single enantiomer).[7] Four Co^{II} centres are located on an exactly trigonal plane (see Figure 1) with a crystallographic twofold axis passing through Co1 and Co2. Three crystallographically independent Co^{II} ions have different octahedral coordination environments: the central Co1 bonds to six carboxylic oxygen donors, and the vertex Co^{II} ions are coordinated by DACO with unusual *chair*/*chair* configuration,[4] and four $O_{carboxylic}$ (for Co2), and three $O_{carboxylic}$ and one aqua ligand (for Co3). The carboxylato groups bridge the Co^{II} ions in two modes: μ-O,O-μ-O,O′$_{syn}$ (O5−C13−O6 and O3−C12−O4) and μ-O,O (O1−C1−O2) with Co···Co distances of 3.004(5) Å (Co1···Co2), 3.192(6) Å (Co1···Co3) and 4.939(3) Å (Co2···Co3), and Co−O−Co bridging angles of 99.9(2)° (Co1−O1−Co3), 89.3(1)° (Co1−O6−Co2) and 95.3(1)° (Co3−O3−Co1). The Co3···Co3A distance is 6.147(4) Å. The tetramers are well isolated, with the intermolecular contacts between the Co^{II} atoms above 7 Å.

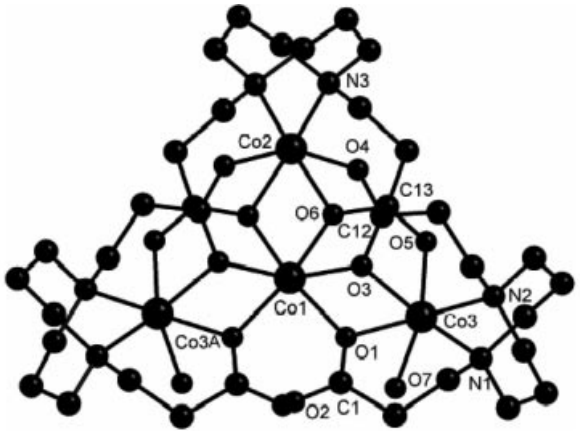

Figure 1. View of the $[Co_4L_3(H_2O)_2]^{2+}$ cation (H atoms omitted for clarity); symmetry code: $-x+1, y, -z+2$; selected bond lengths and angles: Co1−O1 2.070(4), Co1−O3 2.176(4), Co1−O6 2.109(4), Co2−N3 2.097(5), Co2−O4 2.099(4), Co2−O6 2.166(4), Co3−O5 2.119(4), Co3−N1 2.104(5), Co3−O7 2.102(5), Co3−O1 2.101(4), Co3−N2 2.127(5), Co3−O3 2.143(4), Co1−O(1)−Co3 99.9(2), Co1−O(3)−Co3 95.3(1), Co1−O(6)−Co2 89.3(1)

The magnetic properties of **1** in the form of $\chi_M T$ versus T plots (χ_M is the molar magnetic susceptibility for four Co^{II} ions) are shown in Figure 2 (A). The $\chi_M T$ value at 300 K is 11.87 $cm^3 \cdot mol^{-1} \cdot K$, which is larger than the spin-only value for four isolated Co^{II} ions (7.5 $cm^3 \cdot mol^{-1} \cdot K$, assuming artificially $g = 2.00$), indicating an important contribution from the orbital angular momentum typical for the $^4T_{1g}$ ground term. From 300 to 50 K the $\chi_M T$ value is almost constant (close to 12 $cm^3 \cdot mol^{-1} \cdot K$), and from 50 to 2 K it continuously increases (16.2 $cm^3 \cdot mol^{-1} \cdot K$ at 2.0 K). The shape of this curve indicates significant ferromagnetic interactions, because in the presence of spin-orbit interactions the $\chi_M T$ values for any Co^{II} ion tend to decrease with decreasing temperature.[8]

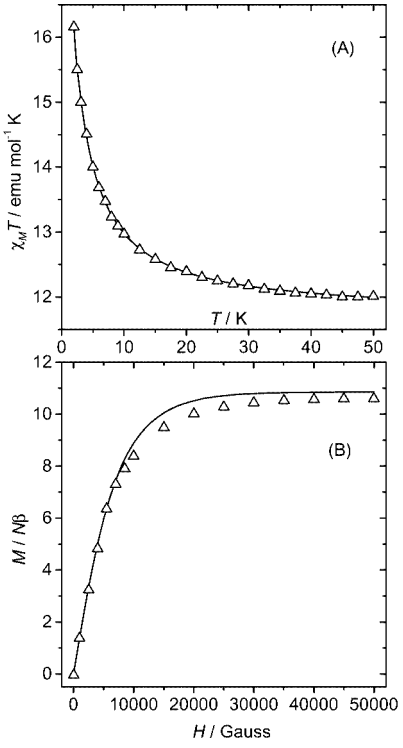

Figure 2. (A) Plot of the $\chi_M T$ vs. T from 50 to 2 K for **1** (the solid line is the best simulation with the following parameters: $J_1 = 2.15 \pm 0.08$ cm^{-1}, $J_2 = 0.40 \pm 0.03$ cm^{-1}, $J_3 = 0.12 \pm 0.02$ cm^{-1}, $g_{\parallel} = 7.3 \pm 0.2$ and $g_{\perp} = 3.5 \pm 0.1$; (B) plot of the reduced magnetisation at 2 K (the solid line is the simulation with J and g values obtained from the $\chi_M T$ vs. T curve)

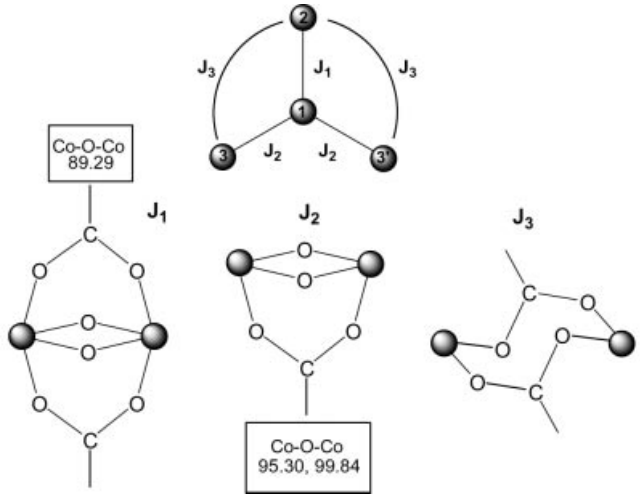
For the interpretation of the magnetic measurements, the importance of the spin-orbit coupling of Co^{II} must be emphasized. The degeneracy of the $^4T_{1g}$ ground state of the octahedral Co^{II} ion prevents any possible fit in the whole temperature range, except for dinuclear complexes.[9] In the low-temperature region, the overall effect of low-symmetry crystal-field components and spin-orbit coupling produces up to six Kramers doublets and leads to a doublet ground state,[8] which should result in an anisotropic exchange coupling. This anisotropy has been clearly shown by inelastic neutron scattering (INS) studies in many polynuclear Co^{II} systems.[3b,10] For this reason, at low temperature ($< 40-50$ K), Co^{II} systems may be described as having an effective spin of 1/2 with large anisotropy. Thus, for not too complicated systems, it is possible to fit the low-temperature zone with special computational methods, such as the MAGPACK program,[11] as previously done for several di- to pentanuclear Co^{II} systems.[3b,10]

The exchange pathway connecting the Co^{II} ions is depicted in Scheme 2. In the case of tetramer **1**, the exchange Hamiltonian that describes the exchange interactions between the effective $S = 1/2$ spins is:

$$H = -2 \sum_{i=x,y,z} [J_{1i} S_{1i} S_{2i} + J_{2i}(S_{1i} S_{3i} + S_{1i} S_{3'i}) + J_{3i}(S_{2i} S_{3i} + S_{2i} S_{3'i})$$



Scheme 2. Spin topology for **1** assuming different J values

When the number of J values is only 1 or 2, it is possible to take into account axial anisotropy of J, since the number of final parameters is still sufficiently small. However, we had to assume here (even artificially) that $J_{x,y} = J_z$, simulat-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing with an average J value, such as in an isotropic case. On the other hand, we assumed that $g_{\parallel}$ and $g_{\perp}$ for all four Co^{II} ions were equal. With this hypothesis, the best simulation was obtained with the following parameters: $J_1 = 2.15 \pm 0.08\ cm^{-1}$, $J_2 = 0.40 \pm 0.03\ cm^{-1}$, $J_3 = 0.12 \pm 0.02\ cm^{-1}$, $g_{\parallel} = 7.3 \pm 0.2$ and $g_{\perp} = 3.5 \pm 0.1$. The found g values are very reasonable for Co^{II} sites with distorted octahedral coordination.[12] Moreover, we have obtained the magnetisation vs. H curve at 2 K. At 5 T the $M/N\beta$ (reduced magnetisation) is 10.7. The simulation of the reduced magnetisation vs. H, with J and g values calculated from the susceptibility data, using the same MAGPACK program[11], is given in Figure 2 (B). There is reasonable agreement with the experimental curve.

Taking into account the difficulties for determining the exact J values, it will be interesting to compare this Co_4 cluster with the isostructural Ni_4 analogue.[6a] In the Ni^{II} case the J parameters were: $J_1 = 5.12\ cm^{-1}$, $J_2 = 0.35\ cm^{-1}$, $J_3 = 0.23\ cm^{-1}$ and $g = 2.17$. It was necessary to introduce the D parameter ($7.7\ cm^{-1}$) to explain the magnetic behavior at low temperatures. Thus, it is important to point out that in both cases the three J parameters are ferromagnetic and of the same order of magnitude: $J_1 >> J_2 > J_3$. As in the Ni_4 cluster, in **1** the Co−Co interactions between the corresponding spins are transmitted through the oxo and carboxylato bridges. From the magnetic point of view it is important to distinguish between these pathways. *Co−O−Co angles:* These angles lie close to 90° for J_1 and 95−100° for J_2; they are in the range in which ferromagnetic exchange pathways are dominant (90−100°); large superexchange angles lead to antiferromagnetic interactions while smaller ones induce ferromagnetic coupling.[13] *Acetato bridges*: The effect of the *syn*/*syn* acetato bridge is antiferromagnetic for Co^{II} and, actually, for any metal.[14] Thus, these bridges can mediate an additional exchange pathway and *significantly reduce* the ferromagnetic contribution from μ-oxo ligands. This effect has also been observed in the Ni_4 complex. *Comparison between J_1 and J_2*: J_1 is given by a planar Co−O−Co−O fragment (Scheme 2) with a Co−O−Co angle of 90°. This angle enhances the ferromagnetic coupling, but the presence of *two* carboxylato ligands (*syn*/*syn*) reduces this coupling. On the other hand, J_2 is given by a nonplanar Co−O−Co−O entity, with greater Co−O−Co angles, thus creating low ferromagnetic coupling, which is reduced by the presence of only *one* carboxylato group. Experimentally, both contributions are quasi-balanced, giving a J value that is positive but $< 1\ cm^{-1}$. *Study of J_3*: The carboxylato ligand bridges two Co^{II} ions in a *syn*/*anti* configuration; low antiferro- or ferromagnetic coupling is expected for this kind of coordination mode.[15] To the best of our knowledge, no magnetic studies for *syn*/*anti* carboxylato-bridged Co^{II} complexes have been reported so far.

Experimental Section

Materials and General Methods: H_2L was prepared by a literature method.[6] Other commercially available chemical reagents and solvents were of analytical grade and purified by standard procedures prior to use. FT-IR spectra were recorded with a 170SX (Nicolet) spectrometer at room temperature, and electronic absorption spectra were taken with a Hitachi UV-3010 spectrophotometer. Elemental analyses were carried out with a Perkin−Elmer 240C analyser. TG-DTA experiments were carried out with a Dupont thermal analyser from room temperature to 800 °C under N_2 at a heating rate of 10 °C/min. The variable-temperature magnetic susceptibilities were measured in the "Servei de Magnetoquímica (Universitat de Barcelona)" with a Quantum Design MPMS SQUID susceptometer operating at a magnetic field of 0.1 T between 2 and 300 K. The diamagnetic corrections were evaluated from Pascal's constants for all the constituent atoms.

Preparation of 1: Purple block crystals were obtained in 78% yield (199 mg) by slow concentration of the water solution containing $Co(ClO_4)_2 \cdot 6H_2O$ (300 mg, 0.8 mmol) and $H_2L \cdot 2HCl$ (200 mg, 0.6 mmol) in a 4:3 molar ratio by adjusting the pH to 5−6 with KOH. IR (cm^{-1}): $\tilde{\nu}$ = 1606 vs $\nu_{as}(COO^-)$, 1390 vs $\nu_s(COO^-)$, 1120 vs, 1108 vs and 625 s $\nu(ClO_4^-)$. $C_{36}H_{68}Cl_2Co_4N_6O_{24}$ (1275.6): calcd. C 33.90, H 5.37, N 6.59; found C 33.77, H 5.43, N 6.58. DTA (peak positions): 115, 293, 386 and 545 °C. UV (H_2O): $\lambda_{max.} = 491$ nm.

Crystallographic Study: $C_{36}H_{68}Cl_2Co_4N_6O_{24}$ (**1**), $M_r = 1275.58$, monoclinic, space group C_2, $a = 24.411(5)$, $b = 12.260(2)$, $c = 8.351(2)$ Å, $\beta = 98.738(4)°$, $V = 2470.4(8)$ Å^3, $F(000) = 1320$, $Z = 2$, $\mu = 1.518\ mm^{-1}$, $D_{calcd.} = 1.715\ g \cdot cm^{-3}$, Flack parameter = 0, 2989 reflections measured, 2669 unique ($R_{int} = 0.0186$). Final R, wR and S values are 0.0342, 0.0949 and 1.052, respectively. CCDC-176943 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/cons/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Plasma-Enhanced CVD Synthesis and Structural Characterization of Ta_2N_3

Alexei Yu. Ganin,[a] Lorenz Kienle,[a] and Grigori V. Vajenine*[a,b]

Dedicated to Professor Francis J. DiSalvo on the occasion of his 60th birthday

Keywords: Tantalum / Nitrides / Plasma-enhanced chemical vapor deposition / X-ray diffraction / Electron microscopy

Microcrystalline tantalum nitride films were prepared on various substrates from $TaCl_5$ precursor and nitrogen gas using the plasma-enhanced chemical vapor deposition (PECVD) method. Syntheses carried out at 600–650 °C led to single-phase samples of the tantalum nitride Ta_2N_3 with a defect fluorite-type structure. The anion vacancies were found to order resulting in a $2 \times 2 \times 2$ cubic superstructure of the C-Ln_2O_3 type (space group $Ia\bar{3}$, $Z = 16$) with a = 9.8205(4) Å according to a Rietveld refinement of the X-ray powder diffraction data. At higher deposition temperatures (650–700 °C) formation of highly textured orthorhombic Ta_3N_5 was observed. The samples were additionally studied by high-resolution transmission electron microscopy (HRTEM) and selected-area electron diffraction (SAED). The details of the new crystal structure for Ta_2N_3 as well as a possible nitrogen nonstoichiometry are discussed.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The binary Ta−N system is quite rich in compounds with well-defined and variable stoichiometries. The formal oxidation state of tantalum covers the whole range from nearly zero to the maximum of +5. These compounds can be divided into four groups: solid solutions of nitrogen in tantalum, the phase with the approximate stoichiometry Ta_2N, three phases with a nearly 1:1 composition, and nitrogen-rich nitrides. A few comprehensive reviews of tantalum nitride structural chemistry are available.[1−3] Results of the previous structural studies in this binary system are summarized in Table 1.

Up to 5 at.% of nitrogen can be dissolved in the body-centered cubic lattice of elemental tantalum, for example by heating of Ta powder in ammonia at 600−700 °C.[3] The lattice constant of such solid solutions increases slightly to 3.315−3.369 Å compared to that of the pure metal (a = 3.311 Å). Observation of additional weak reflections suggests a cubic superstructure with the unit cell tripled in all directions and with $a_\beta = 3a_\alpha = 10.11$ Å.[1,13]

The γ-phase with the composition range $TaN_{0.41-0.5}$, also denoted as β-Ta_2N,[4] crystallizes with a hexagonal unit cell.[1−4] Its crystal structure can be described as a hexagonal close packing of the tantalum atoms with the nitrogen atoms filling half of the octahedral interstices. While the earlier studies suggested a statistical distribution,[1,2] electron-[3] and neutron-diffraction[4] investigations revealed a trigonal $P\bar{3}1m$ supercell with $a' = \sqrt{3}a$, isostructural to β-Nb_2N[14] and of the anti-Li_2ZrF_6-type.[15] The γ-phase can be obtained by nitriding of tantalum powder in gaseous ammonia at 800−900 °C or from the elements at 2000 °C.[1,3]

The hexagonal ε-phase was proposed by Schoenberg[1] to have a B35 CoSn-type structure with the composition $TaN_{1.00}$; the same description was given by Brauer and Zapp.[2] In this structure type the nitrogen atoms are at the center of slightly distorted tantalum octahedra. Later, Christensen and Lebech[5] showed that the nitrogen atoms are displaced from these ideal positions reducing their coordination sphere to a square pyramid. The unit cell determined by Christensen and Lebech[5] (a = 5.196 Å, c = 2.911 Å) is quite similar to that given by the other authors.[1−3] The ε-phase can be obtained as a product of nitriding of Ta powder at temperatures at > 1100 °C.[1]

Another modification of tantalum mononitride, the δ-phase with a face-centered cubic B1 NaCl-type structure, was observed by Gerstenberg and Calbick[16] in thin films; it was also recently synthesized from the ε-phase by shock compression.[7] The lattice parameter (a = 4.337 Å) for this

Ta_5N_6	hexagonal, Nb_5N_6-type	Ta_5N_6	5.175	10.307	[3]
TaN_x	cubic, CaF_2-type	TaN_x	5.02		[11]
	CaF_2-type with a body-centered tetragonal superstructure	TaN_x	5.77	5.01	[12]

nitride obtained by Gatterer et al.[6] from the elements at 2000 °C and a pressure of 40 bar, and that obtained by Mashimo et al.[7] (a = 4.336 Å), are almost identical.

Finally, the θ-phase crystallizes hexagonal in the Bh WC-type structure type with a simple hexagonal stacking of the metal layers. The nitrogen atoms center the trigonal prisms formed by the tantalum atoms. The unit cell observed for this hexagonal phase (a = 2.936 Å, c = 2.885 Å) by Brauer et al.[8] is rather similar to that obtained by Mashimo and Tashiro[9] (a = 2.938 Å, c = 2.868 Å). The hexagonal ε-TaN phase transforms into θ-TaN at pressures of 20−100 kbar and at 800−960 °C, or under mechanical alloying conditions.[8,9]

Ta_3N_5, the nitrogen-richest phase, has a pseudobrookite (Fe_2TiO_5)-type[17] structure. This structure contains octahedrally coordinated tantalum atoms, while the nitrogen atoms are both three- and four-coordinate. The TaN_6 octahedra are linked together by sharing edges and corners. Though Brauer and Weidlein[18] reported a tetragonal unit cell, it was later refined as orthorhombic[19] (a = 3.893 Å, b = 10.264 Å, c = 10.264 Å) and monoclinic[20] (a = 10.229 Å, b = 3.875 Å, c = 10.229 Å, β = 90.0°). Brese et al.[10] have shown that both structural models are valid within the accuracy of the data. Ta_3N_5 can be obtained by nitriding of Ta_2O_5 in an ammonia flow at 860−920 °C,[18] for example.

Upon heating in argon or ammonia, Ta_3N_5 decomposes yielding the nitrides Ta_4N_5 and Ta_5N_6.[21] The tetragonal Ta_4N_5[3] phase is isostructural to Nb_4N_5,[22] a defect variant of the NaCl-type structure. The hexagonal Ta_5N_6[3] is isostructural to Nb_5N_6;[22] it is built up from the tantalum atom layers in the stacking ABACABAC.

Yet another binary tantalum nitride, TaN_x, has been reported, although its stoichiometry and crystal structure have not been established reliably. It was first observed in reactive sputtering experiments by Buvinger[11] and appeared to have an fcc-type crystal structure with a = 5.02 Å, which is notably larger than that of the NaCl-type δ-phase (a = 4.34 Å). Coyne and Tauber[12] confirmed the lattice parameter range of 4.98−5.05 Å and proposed a fluorite-type structure for this nitride. Additional reflections led the authors to postulate a body-centered tetragonal supercell with a = 5.77 Å and c = 5.01 Å.

Except for the latter phase, all the above-mentioned tantalum nitrides can be prepared by conventional synthetic routes. In the last few years interest in tantalum nitride films has been sparked by a combination of their mechanical stability, chemical inertness and resistive behavior of these phases. Possible applications in microelectronics as Cu diffusion barriers, for example, has stimulated application of novel techniques such as reactive sputtering,[23,24] rapid thermal processing,[25] and ion-beam-assisted deposition (IBAD)[26] to the synthesis of tantalum nitrides. Another approach, the plasma-enhanced chemical vapor deposition (PECVD) method proved to be useful for the preparation of the cubic δ-phase, for example.[27,28] This contribution describes the application of PECVD to the synthesis of Ta_2N_3, previously known as the "bct-TaN_x" phase, and its structural characterization.

Results and Discussion

Tantalum nitride powder coatings were grown in a PECVD reactor by passing a mixture of nitrogen gas and $TaCl_5$ precursor in the plasma region over the substrate in the temperature range of 600−700 °C. Deposition experiments were carried out on silicon, copper, and quartz glass

substrates. Representative deposition conditions are listed in Table 2.

The phase composition of the coatings varies with the deposition temperature, according to the powder X-ray diffraction investigations. While at higher temperatures of 650−700 °C the orthorhombic Ta_3N_5 phase was predominantly formed, the experiments at lower temperature (600−650 °C) yielded another phase with the strongest reflections corresponding to an fcc lattice with $a \approx 5.0$ Å. This value, which is similar to that observed for the "bct-TaN_x" phase, suggested a nitrogen-rich phase of the fluorite (CaF_2) type. However, the ideal composition "TaN_2" is implausible due to the requirement of the formal oxidation state Ta^{6+}. Indeed, a closer inspection of the additional weak reflections indicated a cubic $2 \times 2 \times 2$ superstructure. The analogy to the well-known bixbyite- or C-Ln_2O_3-type phases[29,30] (space group $Ia\bar{3}$) led us to postulate the same structure and the Ta_2N_3 composition for this tantalum nitride. It was mentioned above that a similar fluorite-based TaN_x phase has been identified by electron diffraction in samples obtained in sputtering experiments.[12] Weak superstructure reflections were observed there as well, but a different body-centered tetragonal supercell with $a = 5.77$ Å and $c = 5.01$ Å was proposed without further structural study.[12] However, these superstructure reflections appear to be identical to those observed in our study; moreover, the c/a ratio of the proposed bct cell is $0.867 \approx \sqrt{3}/2$, indicating the equivalence of the $(200)_{bct}$ and $(111)_{fluorite}$ reflections according to the cell choices of the phases. This would imply non-orthogonality of the proposed a_{bct} and c_{bct} axes, thus making the bct superstructure inadequate.

The product composition was determined by energy-dispersive X-ray spectroscopy (EDXS). Although the formation of nitrogen-rich products could be established, more accurate determination of the composition was not possible. Chlorine contamination was found to be below the detection limit of EDXS (2−3 at.%), whereas the oxygen content did not exceed 5 at.%.

In order to test the proposed structural model for Ta_2N_3, sample A was investigated by HRTEM and was additionally studied with the internal EDX. As before, only a small amount of oxygen (less then 4 at.%) was found in the sample; no other impurities could be detected. Such oxygen content typically results from the surface contamination of thin crystallites. Sample A contains irregular, roundish particles with sizes in the range of 50−500 nm (Figure 1a). Electron-diffraction patterns recorded on aggregates of particles show Bragg intensities located on concentric rings around 000. The d values derived from these patterns are consistent with the metrics of the cubic Ta_2N_3 phase. Applying selected-area electron diffraction (SAED), the larger roundish particles of the sample could be identified as microcrystals of Ta_2N_3. SAED patterns were recorded along different zone axes on these crystallites in order to compare them with simulated patterns. Some crystallites of sample A were sufficiently large and could be tilted in several zone axis orientations. The tilt angles, α, are consistent with the expected cubic metrics, for example with those for the zone axes $[100]_{cubic}$ and $[311]_{cubic}$ ($\alpha = 25.2°$), $[311]_{cubic}$ and $[211]_{cubic}$ ($\alpha = 10°$), and $[111]_{cubic}$ and $[313]_{cubic}$ ($\alpha = 22°$). For all analyzed orientations, we observed a convincing agreement between the simulated and experimental patterns (see Figure 1b for $[100]_{cubic}$).

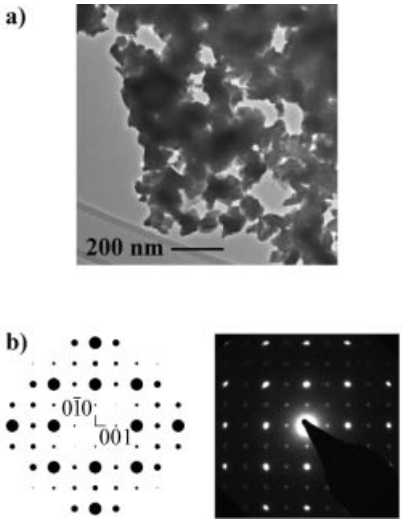

Figure 1. High resolution transmission electron microscopy (HRTEM) micrographs of deposited tantalum nitride: (a) roundish shape of Ta_2N_3 crystallites; (b) simulated and observed selected-area electron diffraction patterns along the [100] axis

Through-focus HRTEM images, for instance in [110] orientations, are in good agreement with simulated micrographs based on the assumed structure of Ta_2N_3. However, details of the real structure concerning the precise arrangement of the nitrogen atoms cannot be derived from HRTEM micrographs.

The C-Ln_2O_3 structure type is an ordered-defect variant of the fluorite structure. Aside from doubling of the unit cell in all directions, a quarter of the anion positions remain empty. When local coordination of the Ta atoms is considered, this corresponds to removing two of eight nitrogen atoms in the first coordination sphere on going from the ideal TaN_2 composition to the stoichiometry Ta_2N_3. Two types of Ta positions result, as shown in Figure 2a: while two opposing nitrogen atoms of a TaN_8 cube are removed around Ta(1), two nitrogen positions connected by a face diagonal of the cube remain empty for Ta(2). After a relaxation of the crystal structure, Ta(1) occupies the 8*b* position (1/4,1/4,1/4), Ta(2) is shifted to the 24*d* site (*x*,0,1/4), and the nitrogen atoms take the general 48*e* position with $x \approx z \approx 3/8$ and $y \approx 1/8$ (see Table 3). The missing nitrogen atoms would occupy the 16*c* (*x*,*x*,*x*) site with $x \approx 1/8$ in this space group. Partial filling of the latter position is indeed observed in the $U_2N_{3+\delta}$ series, in which both end members, U_2N_3 and UN_2, are known as well.[31]

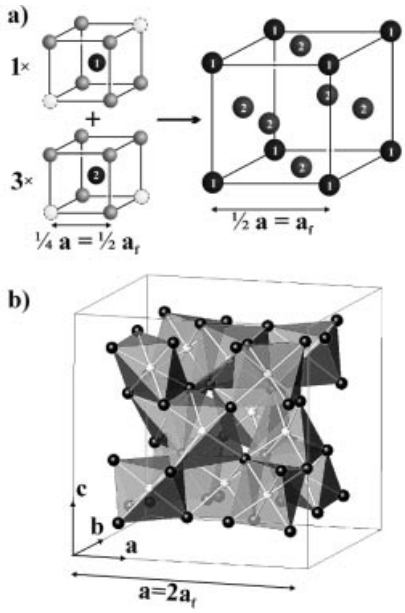

Figure 2. Crystal structure of Ta_2N_3: (a) analogy between the fluorite and Ta_2N_3 structures ["1" and "2" stand for the Ta(1) and Ta(2) positions, respectively]; (b) TaN_6 coordination polyhedra inside the unit cell of Ta_2N_3

While the TEM and SAED investigations confirmed qualitatively the C-Ln_2O_3-type structure for this tantalum nitride, a Rietveld refinement of the powder diffraction data from sample C was carried out in order to elucidate the structural details. It was possible to refine the atomic positions for all atoms; these are shown in Table 3, in comparison with those in related phases.

Table 3. Atomic positions in Ta_2N_3 compared to those in related compounds

	x(24*d*)	*x*(48*e*)	*y*(48*e*)	*z*(48*e*)
Ta_2N_3	−0.0280(3)	0.377(4)	0.153(3)	0.377(6)
Ta_2N_3 model	−0.02686	0.38366	0.14472	0.38061
U_2N_3 [31]	−0.018	0.38	0.167	0.398

Ideal fluorite	0	3/8	1/8	3/8

The refinement of the occupation of the 16*c* position was not successful due to the low quality of the powder diffraction data; this position was left empty in the further refinements. The resulting crystal structure of Ta_2N_3 is shown in Figure 2. The structure is built from octants, which have tantalum atoms in their centers. These form a face-centered cubic lattice and are coordinated by distorted octahedra of nitrogen atoms. The TaN_6 units are linked together by sharing edges and corners. The Ta−N distances in two different Ta coordination polyhedron types vary between 2.01(5) and 2.17(4) Å. Similar Ta−N distances were found in the nitrides Ta_3N_5 (1.955−2.240 Å), ε-TaN (2.041−2.163 Å), δ-TaN (2.165 Å), and θ-TaN (2.23 Å). In the Ta(1)N_6 trigonal antiprisms all Ta(1)−N distances are equal to 2.01(5) Å and the bond angles [78(2)−108(2) and 180°] approach those in an ideal octahedron. The Ta(2)N_6 polyhedron is less symmetrical: there are three pairs of Ta(2)−N distances [2 × 2.13(4), 2 × 2.13(5), and 2 × 2.17(4) Å] and the bond angles fall into the ranges 72(2)−116(2) and 129(2)−170(2)°. The coordination of nitrogen atoms remains nearly tetrahedral, as in the parent fluorite structure, with the Ta−N−Ta bond angles ranging from 100(2) to 125(2)°.

Due to a relatively large uncertainty in the nitrogen position, a simple model structure was introduced. First, for each value of $x_{Ta(2)}$, a nitrogen position equidistant from the four tantalum neighbors was calculated. The resulting Ta−N distance was then plotted as a function of $x_{Ta(2)}$ (Figure 3). Remarkably, this function was found to reach a minimum at $x_{Ta(2)} = -0.02686$ with a corresponding Ta−N distance of 2.109 Å. The resulting model structure may be taken as the first approximation to a crystal structure involving chemically similar Ta(1) and Ta(2) atoms. As Table 3 shows, this model reproduces well the observed Ta_2N_3 structure: the corresponding structural parameters compare well with the refined ones, when the respective standard deviations are taken into account.

The question of the exact stoichiometry of Ta_2N_3 remains open: a partial occupation of the 16*c* position, as in $U_2N_{3+\delta}$, leading to $Ta_2N_{3+\delta}$ cannot be excluded. Since the highest formal oxidation state of tantalum is +5, the values of δ from 0 to 1/3 are possible. The EDXS method is not sensitive enough to detect such a small variation of the composition and sufficiently large amounts of Ta_2N_3 for an accurate chemical analysis cannot yet be prepared. Larger

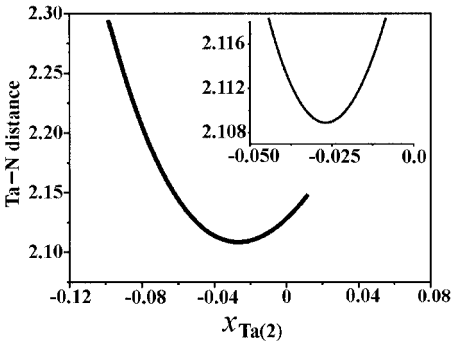

Figure 3. The Ta−N bond length in a Ta_2N_3 model structure in Å as a function of the Ta(2) *x*-coordinate assuming the equality of all Ta−N distances

samples would also be required for accurate measurements of resistivity and magnetic susceptibility. Interestingly, the "bct-TaN_x" phase[12] was found to be conducting, with a ρ(T) behavior corresponding to $\Delta E \approx 0.1-0.3$ eV and with an optical bandgap of 2.0−2.6 eV. Two indirect indications suggest that the formal oxidation state of tantalum in $Ta_2N_{3+\delta}$ is lower than +5. Firstly, the color of the compound (black metallic) compared to that of Ta_3N_5 (red-brown) supports this idea. Secondly, annealing $Ta_2N_{3+\delta}$ samples in vacuo at 700 °C led to an apparent disproportionation to fcc δ-TaN and Ta_3N_5 (see also Table 2), thus also suggesting a lower tantalum oxidation state. Therefore, we designate this phase as Ta_2N_3, keeping the possible nitrogen nonstoichiometry in mind.

In sample B, which contains Ta_3N_5 with a small fraction of Ta_2N_3, nanorods (see Figure 4a) with typical dimensions

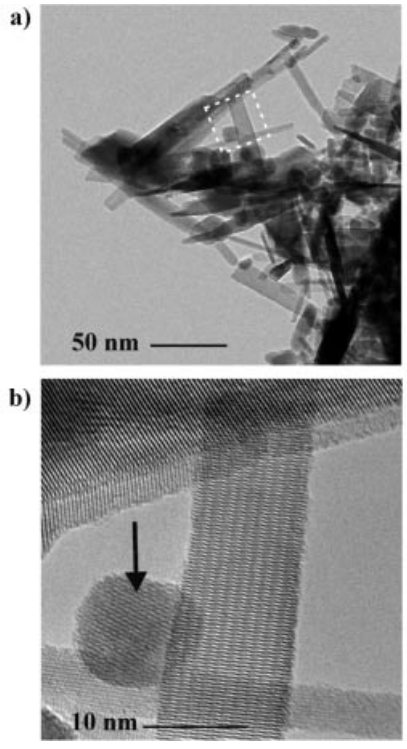

Figure 4. (a) Nanorods of Ta_3N_5; (b) enlarged section: a crystallite of Ta_2N_3 (see arrow) bordered by the Ta_3N_5 nanorods

of 10 nm × 100 nm were observed by HRTEM. In the diffraction patterns of these nanorods strong intensities occur in the positions expected for the orthorhombic Ta_3N_5 phase. All nanorods are highly crystalline (Figure 4b). These microcrystals of Ta_3N_5 exhibit additional features of the micro- and nanostructure which both originate from a lamellar assembly of $(010)_{ortho}$ layers.

Conclusion

Microcrystalline films of a binary tantalum nitride with the composition Ta_2N_3 have been obtained in an RF plasma from $TaCl_5$ and nitrogen gas at 600−650 °C using the PECVD technique. According to X-ray and electron diffraction data, the compound crystallizes in the cubic C-Ln_2O_3 structure type, an ordered defect 2 × 2 × 2 superstructure of the fluorite type. This nitride is thought to be identical with the previously reported "bct-TaN_x" phase obtained in sputtering experiments. Notably, this binary tantalum nitride could not be prepared by conventional synthetic routes so far; plasma activation of the nitrogen gas appears to be essential for the successful synthesis.

Experimental Section

Synthesis: Syntheses were performed in a custom-designed PECVD (Plasma Enhanced Chemical Vapor Deposition) experimental setup, which is schematically illustrated in Figure 5. It consists of a nitrogen gas delivery line, a precursor handling system, and a reactor.

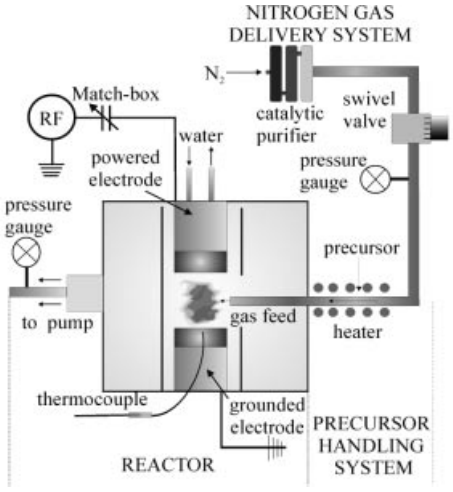

Figure 5. Scheme of the experimental PECVD setup

Nitrogen Gas Delivery Line: Nitrogen gas (Westfalen AG, 99.999%) was further purified by passing it through three separate catalytic columns (silica gel, molecular sieves, and an oxysorb catalyst[35]), in order to remove traces of oxygen and moisture from the nitrogen stream.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Precursor Handling System: The $TaCl_5$ precursor was loaded in a argon dry box into a glass tube, which was then connected to the setup under nitrogen flow. The precursor was then dropped down into the heated delivery line. Throughout the deposition process the temperature of the precursor handling system was maintained at 70−80 °C by means of a hot air gun in order to prevent the condensation of the precursor.

Reactor: Deposition occurred in a plasma region inside of a quartz tube between two parallel electrodes. This setup was placed in an evacuated glass vessel. The upper of the electrodes was connected to the 13.56 MHz 1000 W RF (radio frequency) source (Hüttinger, PFG-RF1000) through a match box (Hüttinger, PFM 1500A), while the lower electrode was grounded. Substrates were loaded on the lower electrode, the upper electrode was water-cooled. An NiCr/NiAl thermocouple was inserted into the lower electrode for temperature monitoring as shown in Figure 5.

Deposition: Before every deposition, the reactor with a loaded substrate was baked in plasma at 400 °C in the nitrogen gas flow for 1 h. Afterwards, the reactor was cooled and heated up to the deposition temperature by igniting the plasma. Nitrogen carrier gas was mixed with the $TaCl_5$ precursor evaporated at 70−80 °C and delivered into the gap between the two electrodes. The pressure in the system was measured by means of two pressure gauges at the inlet and the outlet of the setup. The deposition time varied depending on the evaporation rate of the $TaCl_5$ precursor. A typical experiment took 2−6 h at an RF power of 500−700 W. The reaction progress could also be monitored by the color change of the plasma from light green to yellow-orange as the precursor was consumed. The conditions of the deposition experiments are summarized in Table 2.

Substrates: Silicon wafer (100), copper (Alfa Aesar, 99.9%), and quartz glass substrates (Heraeus) were used. Their sizes varied from 5 × 10 to 10 × 20 mm. The substrates were prepared for deposition by washing with ethanol in a sonic bath and then rinsing with deionized water and acetone.

Precursor Preparation: Tantalum(v) chloride (Alfa Aesar, 99.99% metals basis) was purified by sublimation. The observed X-ray diffraction pattern of the product matched that of the monoclinic phase reported in the literature.[36]

Scanning Electron Microscopy Analysis: Investigations were performed with a TESCAN 5120MM scanning electron microscope. Quantitative analysis of the samples was done by EDXS with an Oxford Si-detector with an electron-beam energy of 10 keV, and signal accumulation time of 60−120 s.

Transmission Electron Microscopy: Samples A (Ta_2N_3) and B (Ta_3N_5) were crushed in an agate mortar and suspended in *n*-butanol. A perforated carbon/copper net was covered with the suspension, leaving wedge-shaped crystallites in random orientations after drying. HRTEM and SAED investigations were performed with a Philips CM30ST instrument (300 kV, LaB_6 cathode, C_S = 1.15 mm). Computer simulations of the HRTEM images (multislice formalism) and SAED patterns (kinematical approximation) were carried out with the EMS program package[37] (spread of defocus: 70 Å, illumination semiangle: 1.2 mrad). All images were collected with a Multiscan CCD Camera [software Digital Micrograph 3.6.1 (Gatan)].

Sample Appearance: The deposits of Ta_2N_3 were black with a metallic shine; growth of red-brown Ta_3N_5 was also observed in some experiments. Adhesion of all samples to the substrate material was rather low, as evidenced by the "scotch test": the microcrystalline products could be removed from the substrates by a scotch tape.

Annealing: Sample I (Ta_2N_3) was annealed at 700 °C in vacuo (5.0×10^{-8} Torr) for 50 h. X-ray analysis of the sample was carried out before and after the annealing.

X-ray Crystallographic Study: The powder diffraction data were collected with a STADI-P STOE diffractometer using Cu-$K_{\alpha 1}$ radiation at room temperature. The results of the phase analysis are presented in Table 2. The powder diffraction pattern of the single phase sample C is shown in Figure 6, where the reflections corresponding to the 2 × 2 × 2 superstructure of the fluorite unit cell are clearly visible. These data were used for a Rietveld refinement using the CSD package.[38] The C-Ln_2O_3 structure type (space group $Ia\bar{3}$) was chosen as the starting model for Ta_2N_3. The unit cell constant and the atomic positional parameters were refined, while the isotropic temperature displacement factor had to be fixed for the nitrogen atom position; pseudo-Voigt functions were employed to model the reflection profiles. The background was fitted by a parabolic form, and an absorption correction was introduced. Additionally, texture effects along the [100] axis had to be taken into account. Crystal data for the investigated sample are summarized in Table 4. Further details of the crystal structure investigation may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-413802.

Two- and Three-Dimensional Hydrogen-Bonded Networks Built from 1,3,5-$[(HO)_2(O)P]_3C_6H_3$ and 4-(Dimethylamino)pyridine

Michael Mehring[a]

Keywords: Phosphonic acid / Hydrogen bonds / Crystal engineering / Supramolecular chemistry

Crystallisation of 3,5-bis(phosphonophenyl)phosphonic acid, 1,3,5-$[(HO)_2(O)P]_3C_6H_3$, from $MeOH/H_2O$ in the presence of 4-(dimethylamino)pyridine, 4-$(Me_2N)C_5H_4N$, gave $[1\text{-}\{(HO)_2(O)P\}\text{-}3,5\text{-}\{(HO)(O)_2P\}_2C_6H_3]^{2-}[\{4\text{-}(Me_2N)C_5H_4NH\}^+]_2$ (**2**) and $[1,3\text{-}\{(HO)_2(O)P\}_2\text{-}5\text{-}\{(HO)(O)_2P\}C_6H_3]^-[4\text{-}(Me_2N)\text{-}C_5H_4NH]^+$ (**3**). Single-crystal X-ray diffraction analyses revealed a two- and a three-dimensional hydrogen-bonded network for compounds **2** and **3**, respectively. Compound **2** is composed of layers which are formed by hydrogen-bonded motifs of the type R2,2(8) and R4,4(16). These motifs are connected within the layer by additional hydrogen bonds and the benzene spacer. The cation $[4\text{-}(Me_2N)C_5H_4NH]^+$ is located between the layers and determines the interlayer separation of approximately 6.5 Å. In compound **3** a layered network of the hydrogen-bonded building units R2,3(10) was observed. These units are interconnected by four additional hydrogen bonds within the network. The benzene spacer links the adjacent layers to give a three-dimensional structure. Within this network, channels with internal dimensions of ca. 8.5 × 11.3 $Å^2$ which are occupied by the $[4\text{-}(Me_2N)C_5H_4NH]^+$ cations were observed.

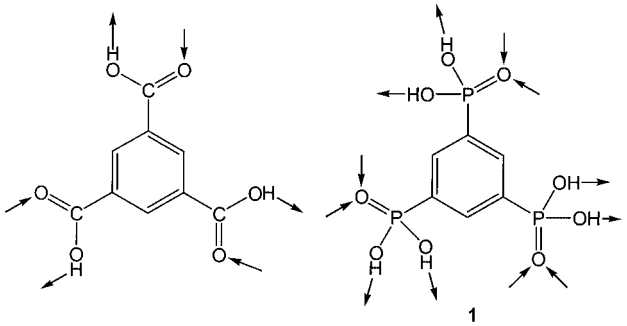
Introduction

In the last three decades there has been a tremendous interest in the development of new metal phosphonates due to their great potential for applications based on ion exchangers, catalysts, selective adsorbents, sensors, photochemically active materials, proton conductors and materials for non-linear optics.[1,2] Most of the metal phosphonates based on non-functionalised mono(phosphonic acids), RPO_3H_2, and bis(phosphonic acids), $H_2O_3P-R-PO_3H_2$, adopt layered and pillared-layered structures. Recently, a growing interest in metal phosphonate clusters has emerged as well.[3−13] In contrast to the intensive studies of metal phosphonates, little attention was drawn to the structure and properties of simple phosphonic acids. Their crystal structures are characterised by the formation of hydrogen bonds of the type P−O−H···O=P which results in a diverse structural chemistry ranging from hydrogen-bonded clusters[14] to two- and three-dimensional polymers.[15−24] However, the prediction of structures even in the case of non-functionalised mono(phosphonic acids) is far from simple because each phosphonic acid moiety might serve as a hydrogen bond acceptor for one or even two hydrogen bond donors through its P=O group and as a double hydrogen bond donor through its two P−O−H groups. In contrast to crystal engineering approaches to organic solids using phosphonic acids, much effort has been made in the development of organic hydrogen-bonded materials using the carboxylic acid dimer motif. One of the most popular organic acids in this context is trimesic acid, 1,3,5-$(HO_2C)_3C_6H_3$, and a large number of studies based on this carboxylic acid have been reported.[25] Surprisingly, its phosphorus-containing counterpart, the triphosphonic acid 1,3,5-$[(HO)_2(O)P]_3C_6H_3$, has not been the subject of crystal engineering studies. This triphosphonic acid might function as a robust synthon for the construction of two- and three-dimensional networks through the formation of strong hydrogen bonds. The only report on 1,3,5-$[(HO)_2(O)P]_3C_6H_3$ stems from 2002 and deals solely with its synthesis.[26]



1

A drawback of functional organic solids is often their low thermal stability but it was shown recently that the co-crystallisation of nitrilotri(methylphosphonic acid) with various amines produces aggregates showing thermal stability similar to that obtained for metal phosphonates.[27,28]

Studies of the crystallisation of phosphonic acids in the presence of amines have shown that a proton is transferred from the phosphonic acid to the amine to give anions of the type $[RP(O)_2OH]^-$.[29−35] As result of their self-assembly through strong hydrogen bonds of the type P−O−H···$^-$O−P and the cooperative effect operating within the hydrogen-bonded network, very robust crystalline solids are produced. In a combined theoretical and experimental work on *tert*-butylphosphonic acid we have shown previously that by removal of a proton the hydrogen bond strength in the dimer is increased from ca. 43 kJ·mol^{-1} calculated for $[t\text{BuP(O)(OH)}_2]_2$ to ca. 83 kJ·mol^{-1} calculated for $[\{t\text{BuP(O)}_2\text{(OH)}\}\{t\text{BuP(O)(OH)}_2\}]^-$.[14]

Here we report on the synthesis and characterisation of hydrogen-bonded aggregates of the triphosphonic acid 1,3,5-$[(HO)_2(O)P]_3C_6H_3$ (**1**) with 4-(dimethylamino)pyridine. The phosphonic acid was crystallised in the presence of the amine to give $[1\text{-}\{(HO)_2(O)P\}\text{-}3,5\text{-}\{(HO)(O)_2P\}_2\text{-}C_6H_3]^{2-}[\{4\text{-}(Me_2N)C_5H_4NH\}^+]_2$ (**2**) and $[1,3\text{-}\{(HO)_2\text{-}(O)P\}_2\text{-}5\text{-}\{(HO)(O)_2P\}C_6H_3]^-[4\text{-}(Me_2N)C_5H_4NH]^+$ (**3**). The single-crystal X-ray structure analyses of both compounds as well as their thermal stability are discussed.

Results and Discussion

The triphosphonic acid 1,3,5-$[(HO)_2(O)P]_3C_6H_3$ (**1**) was prepared from the corresponding arylphosphonic ester 1,3,5-$[(i\text{PrO})_2(O)P]_3C_6H_3$[36] by reaction with Me_3SiBr and subsequent reaction with methanol. The ester was prepared by an Ni-mediated variant of the Arbuzov reaction starting from 1,3,5-tribromobenzene in 80% yield. The recently described synthesis of 1,3,5-$[(MeO)_2(O)P]_3C_6H_3$ starting from 1,3,5-trichlorobenzene and trimethyl phosphite under UV irradiation for three weeks was reported to give a mixture of products from which 1,3,5-$[(MeO)_2(O)P]_3C_6H_3$ was isolated in moderate yield and subsequently hydrolysed to give the corresponding triphosphonic acid.[26]

So far, all of our attempts to crystallise the phosphonic acid **1** without the aid of a template have been unsuccessful. However, co-crystallisation of **1** with 4-(dimethylamino)-pyridine from water/methanol gave the 1:2 adduct $[1\text{-}\{(HO)_2(O)P\}\text{-}3,5\text{-}\{(HO)(O)_2P\}_2C_6H_3]^{2-}[\{4\text{-}(Me_2N)C_5H_4NH\}^+]_2$ (**2**) and the 1:1 adduct $[1,3\text{-}\{(HO)_2(O)P\}_2\text{-}5\text{-}\{(HO)(O)_2P\}C_6H_3]^-[4\text{-}(Me_2N)C_5H_4NH]^+$ (**3**). Both salts are soluble in water, but poorly soluble in solvents such as $CHCl_3$, acetone and DMSO. A proton transfer from the phosphonic acid moieties to 4-(dimethylamino)pyridine is observed and thus, in addition to neutral O−H···O hydrogen bonds, ionic hydrogen bonds of the type O−H···O$^-$ and O···H−N$^+$ are formed. Selected bond lengths and angles are given in Table 1. The asymmetric unit of **2** is shown in Figure 1.

Table 1. Hydrogen bond parameters [Å, °] of compounds **2** and **3**

	D−H	H···A	D···A	D−H···A
2				
O(1)−H···O(8A)	0.85(3)	1.70(3)	2.541(2)	172(3)
N(2)−H···O(8A)	0.84(3)	1.99(3)	2.782(3)	158(3)
O(4)−H···O(6A)	0.83(3)	1.72(3)	2.546(3)	174(3)
N(4)−H···O(3A)	0.96(3)	1.71(3)	2.653(3)	167(3)
O(5)−H···O(9A)	1.05(3)	1.39(3)	2.431(2)	170(3)
O(7)−H···O(2A)	0.90(3)	1.55(3)	2.448(2)	179(4)
3				
N(1)−H···O(5)	0.89(2)	1.90(2)	2.778(2)	172(2)
O(2)−H···O(4A)	0.80(2)	1.76(2)	2.568(2)	175(3)
O(3)−H···O(7A)	0.94(3)	1.56(3)	2.495(2)	172(2)
O(5)−H···O(8A)	0.89(3)	1.64(3)	2.523(2)	176(3)
O(6)−H···O(1A)	0.93(2)	1.57(2)	2.496(2)	171(2)
O(9)−H···O(4A)	0.99(3)	1.55(3)	2.536(2)	175(2)

Both amines act as proton acceptors through their pyridine nitrogen atoms to give the cation $[4\text{-}(Me_2N)C_5H_4NH]^+$. It is noteworthy that the oxygen atom O(8) is involved in hydrogen bonds to N(2) and O(1A) with X···O (X = N, O) bond lengths of 2.782(3) and 2.541(2) Å, respectively, thus acting as a double hydrogen bond acceptor. In contrast, the oxygen atom O(3) exclusively forms an O···H−N$^+$ hydrogen bond of 2.653(3) Å with its neighbouring cation $[4\text{-}(Me_2N)C_5H_4NH]^+$. The remaining oxygen atoms form single hydrogen bonds resulting in a total number of eight O−H···O/O−H···O$^-$ hydrogen bonds for each triphosphonic acid molecule. Four of the latter are related by symmetry and the O···O distances range from 2.431(2) to 2.546(3) Å. The dianion $[1\text{-}\{(HO)_2(O)P\}\text{-}3,5\text{-}\{(HO)(O)_2P\}_2C_6H_3]^{2-}$ self-assembles through these hydrogen bonds to give a layered structure with the cations [4-

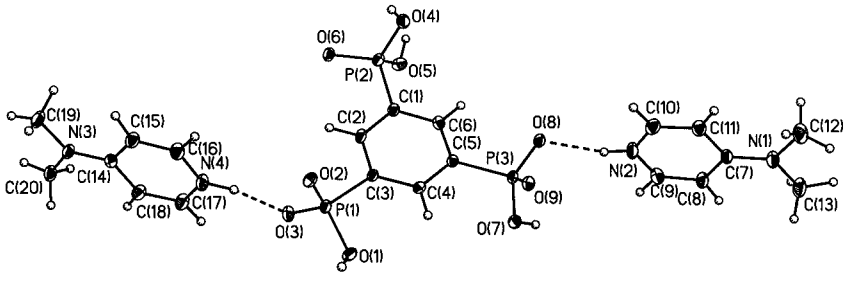

Figure 1. Molecular structure of $[1\text{-}\{(HO)_2(O)P\}\text{-}3,5\text{-}\{(HO)(O)_2P\}_2C_6H_3]^{2-}[\{4\text{-}(Me_2N)C_5H_4NH\}^+]_2$ (**2**): view of the building unit of **2** showing the labeling scheme and the thermal ellipsoids drawn at 30% of probability level; selected bond lengths: P(1)−O(1) 1.570(2) Å, P(1)−O(2) 1.519(2) Å, P(1)−O(3) 1.495(2) Å, P(2)−O(4) 1.552(2) Å, P(2)−O(5) 1.522(2) Å, P(2)−O(6) 1.500(2) Å, P(3)−O(7) 1.538(2) Å, P(3)−O(8) 1.508(2) Å, P(3)−O(9) 1.524(2) Å

$(Me_2N)C_5H_4NH]^+$ sandwiched between the layers, giving rise to an interlayer distance of ca. 6.5 Å (see Figure 2).

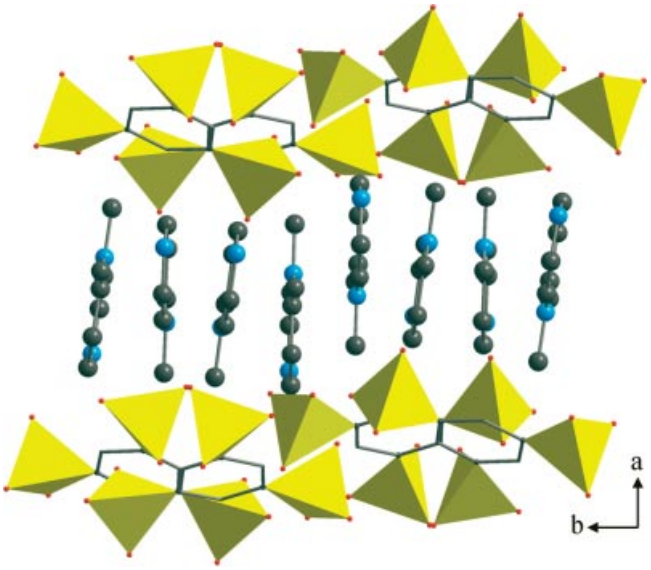

Figure 2. View of the crystal packing diagram of **2** down the *c* axis showing the layered structure; the cations $[4\text{-}(Me_2N)C_5H_4NH]^+$ are intercalated between hydrogen-bonded layers (tetrahedron: PO_3C; phosphorus: yellow; carbon: dark grey; nitrogen: blue; oxygen: red)

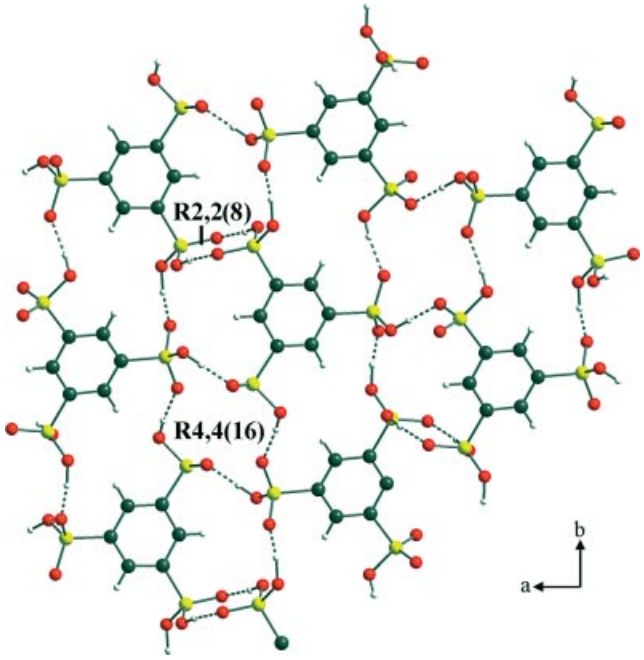

Figure 3. View of the hydrogen-bonded 2-D network in the *b*,*c* plane of **2**; the main structural motifs are dimers having the R2,2(8) notation and tetramers having the R4,4(16) notation; these motifs are linked through an additional hydrogen bond and the benzene spacers within the layer (carbon: dark grey; phosphorus: yellow; oxygen: red; hydrogen: light grey)

The layer shown in Figure 3 is best described as being composed of two hydrogen-bonded ring motifs which are assigned to R2,2(8) and R4,4(16) using the graphset theory (see general remarks).[37] Connecting both ring types with the benzene spacer and an additional hydrogen bond results in the two-dimensional network with the amines stacked above and below the *b*,*c* plane.

The asymmetric unit of compound **3** is shown in Figure 4. Similar to **2**, the cation $[4\text{-}(Me_2N)C_5H_4NH]^+$ is observed as a result of a proton transfer from **1** to the pyridine nitrogen atom of 4-(dimethylamino)pyridine; the N(1)···O(5) distance amounts to 2.778(2) Å. In addition, O(5) is linked to O(8A) showing an intermolecular distance of 2.523(2) Å. The oxygen atom O(4) is involved in two hydrogen bonds to O(2A) and O(9A) with distances of 2.568(2) and 2.536(2) Å, respectively. The remaining oxygen atoms show single O−H···O hydrogen bonds of 2.495(2) Å [O(3)−O(7A)] and 2.496(2) Å [O(6)−O(1A)]. A total of ten O−H···O/O−H···O^- hydrogen bonds for each triphosphonic acid molecule are observed, of which five are related by symmetry. In contrast to the layered structure of **2**, the monoanionic moieties $[1,3\text{-}\{(HO)_2(O)P\}_2\text{-}5\text{-}\{(HO)(O)_2P\}\text{-}C_6H_3]^-$ self-assemble to give a three-dimensional hydrogen-bonded network. This network is composed of layers which are formed by extensive hydrogen bonding (see Figure 5) and which are connected through benzene spacers along the *a* axis.

The main structural feature of the layers is the R2,3(10) ring motif shown in Figure 5. Of note is that this motif was also observed as a structure-directing motif in neutral and anionic clusters of *tert*-butylphosphonic acid.[14] The outer sphere of the R2,3(10) unit is composed of two hydrogen

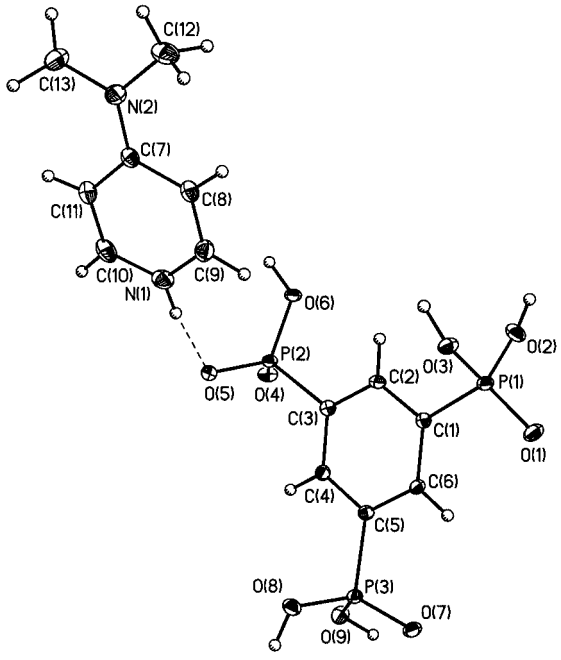

Figure 4. Molecular structure of $[1,3\text{-}\{(HO)_2(O)P\}_2\text{-}5\text{-}\{(HO)(O)_2P\}C_6H_3]^-[4\text{-}(Me_2N)C_5H_4NH]^+$ (**3**): view of the building unit of **3** showing the labeling scheme and the thermal ellipsoids drawn at 30% of probability level; selected bond lengths: P(1)−O(1) 1.481(1) Å, P(1)−O(2) 1.552(2) Å, P(1)−O(3) 1.551(1) Å, P(2)−O(4) 1.514(1) Å, P(2)−O(5) 1.512(1) Å, P(2)−O(6) 1.553(1) Å, P(3)−O(7) 1.495(1) Å, P(3)−O(8) 1.542(1) Å, P(3)−O(9) 1.549(1) Å

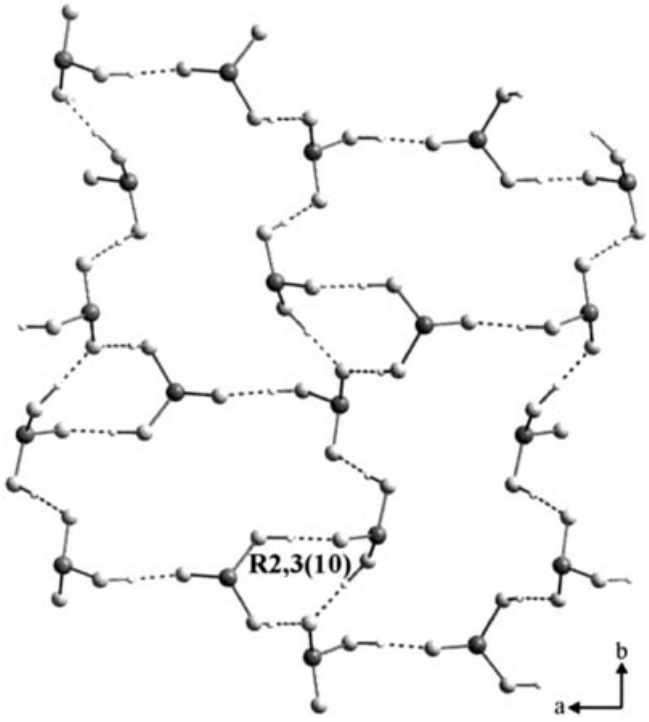

Figure 5. The hydrogen bonded 2-D network of **3**; view of the *a*,*b* plane; the benzene spacer and 4-(dimethylamino)pyridine molecules are omitted for clarity; the main structural motif is a 10-membered ring having the R2,3(10) notation; additional hydrogen bonds link these motifs within the layer; the layers are connected through the benzene spacer along the *c* axis; (phosphorus: grey; oxygen and hydrogen: light grey)

bond acceptors and two hydrogen bond donors. Thus, the R2,3(10) motifs are linked by symmetry-related hydrogen bonds to give the network shown in Figure 5.

The three-dimensional network of compound **3** is illustrated in Figure 6. Large channels with internal dimensions of ca. 8.5 × 11.3 $Å^2$ run along the *a* axis. These channels are occupied by the $[4\text{-}(Me_2N)C_5H_4NH]^+$ cations which are bonded to the triphosphonic acid framework through hydrogen bonds. Interestingly, supramolecular aggregates prepared from nitrilotri(methylphosphonic acid) with various amines were recently reported to give three-dimensional hexagonal structures with channel dimensions close to the values found for compound **3**.[27] A closer look at the structures of compounds **2** and **3** reveals an interesting relationship. Both are composed of similar staircase-type layers as a result of the planar stacking of the benzene rings (Figure 6). In compound **3** hydrogen bonds connect these layers to give the 3-D structure whereas in compound **2** the additional cations prevent the interconnection, resulting in the 2-D structure.

As a result of the proton transfer from the phosphonic acid to 4-(dimethylamino)pyridine, negative charge is introduced into the hydrogen-bonded network resulting in a very robust framework. The hydrogen bond energy of anionic O−H···O^- bonds in phosphonic acids is significantly increased compared with that of the corresponding O−H···O bond and consequently the O−H···O^- bonds are markedly shorter.[14] In agreement with this observation, the average O(H)···O distances in compounds **2** and **3** are 2.492 and 2.523 Å, respectively. Both distances are significantly shorter than the average O(H)···O distance of 2.607 Å calculated for the most stable gas-phase monoanion of *tert*-butylphosphonic acid, $[\{t\text{BuP(O)}_2\text{(OH)}\}\{t\text{BuP(O)(OH)}_2\}_2]^-$.[14] In the solid state typical P−O(H)···O−P distances in the range 2.45−2.60 Å were reported for organic ammonium salts of phosphonic acids. To the best of our knowledge the lower limit is determined by a distance of 2.413 Å reported for an aggregate of nitrilotri(methylphosphonic acid) with phenanthroline.[27,28] The shortest O(H)···O distance in compound **2** amounts to 2.431(2) Å.

The IR spectrum of the triphosphonic acid **1** shows a broad absorption band centred at 3360 cm^{-1}. In contrast, distinct absorption bands at 3240, 3110, 3107 and 2977 cm^{-1} are observed in compound **3** which are red-shifted to

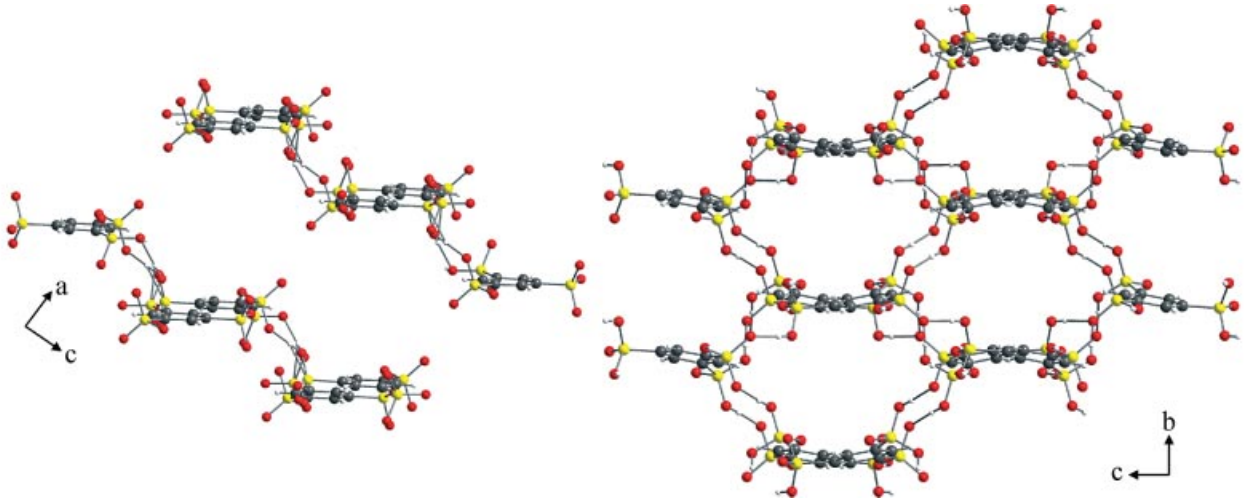

Figure 6. View of the 2-D structure of **2** (left) and the 3-D structure of **3** (right); the cations $[4\text{-}(Me_2N)C_5H_4NH]^+$ are omitted for clarity (carbon: dark grey; phosphorus: yellow; oxygen: red; hydrogen: light grey)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3213, 3100, 3065 and 2938 cm^{-1} in compound **2**. The bands at 3240 cm^{-1} (**3**) and 3213 cm^{-1} (**2**) are assigned to the O−H stretching of a phosphonic acid moiety. No assignment is made for the bands in the region 2938−3110 cm^{-1} which are associated with the O−H vibration as well as with the C−H vibration of 4-(dimethylamino)pyridine.

The thermal stability of compounds **2** and **3** is increased compared to that of the triphosphonic acid **1**. The latter decomposes at 248 °C. The DTA-TG measurements show that **3** starts to melt at 265 °C; an exothermic peak at 365 °C is indicative of its decomposition. The 1:2 adduct **2** starts to decompose at 319 °C without prior melting at lower temperatures.

Conclusion

The co-crystallisation of 1,3,5-$[(HO)_2(O)P]_3C_6H_3$ and 4-(dimethylamino)pyridine gives a two-dimensional structure for the 1:2 adduct **2** and a three-dimensional network for the 1:1 adduct **3**. Although both compounds **2** and **3** are composed of a large number of different hydrogen bond patterns, their structures are best described by the assembly of simple hydrogen-bonded motifs using the graphset theory. In adduct **2** the motifs R2,2(8) and R4,4(16) are interconnected to give a one-dimensional ribbon and the benzene spacer connects these ribbons to give a layered structure. In adduct **3** the R2,3(10) motif is observed solely. Hydrogen bonding connects the motif into a layer and the benzene spacer connects the layers to give a three-dimensional network. This network contains hexagonal channels which are occupied by 4-(dimethylamino)pyridinium cations, $[4\text{-}(Me_2N)C_5H_4NH]^+$. Our results demonstrate that the phosphorus counterpart of 1,3,5-$(HO_2C)_3C_6H_3$ (H_3TMA), the triphosphonic acid 1,3,5-$[(HO)_2(O)P]_3C_6H_3$ (**1**), is a promising building unit in the growing field of supramolecular chemistry and crystal engineering. In contrast to H_3TMA, it allows the design of 3-D networks. The extension of the reported work to other amines will add to the fundamental understanding of the self-assembly process of phosphonic acids and represents a step towards the rational design of 3-D hydrogen-bonded frameworks. Furthermore, the triphosphonic acid **1** holds potential for the preparation of novel three-dimensional metal phosphonates.

Experimental Section

General Remarks: Solvents were distilled from appropriate drying agents prior to use. Elemental analyses were performed with an instrument from Carlo Erba Strumentzione (model 1106). Thermal analyses were recorded using a vacuum thermoanalyser TA1 from Mettler Instrumente AG. The DTA-TG measurements were performed at a heating rate of 6 °C min^{-1} to a maximum temperature of 700 °C in flowing nitrogen using Al_2O_3 as the reference material. ^1H and ^{31}P NMR spectra were recorded at 200.13 MHz (^1H) and 80.02 MHz (^{31}P) at room temperature. Chemical shifts δ are given in ppm and were referenced against Me_4Si (^1H) and 85% H_3PO_4 (^{31}P). IR spectra were obtained with a Bruker FTIR IFS 113v spectrometer and run as KBr discs. Electrospray ionisation mass spectrometric analyses (ESI-MS) were recorded in the positive and the negative mode with a Thermoquest-Finnigan instrument using MeOH/H_2O (1:1) as the mobile phase. The compounds were dissolved in MeOH/H_2O and then diluted with the mobile phase to give solutions of approximate concentration 0.1 mM. The samples were introduced with a syringe pump operating at 10 μL/min. The capillary voltage was kept at 4.5 kV, while the cone-skimmer voltage was varied in the positive mode between 50 and 110 V, and in the negative mode between −70 and −80 V. The ion source temperature was kept at 280 °C. The *m*/*z* values reported correspond to those of the most intense peaks in the corresponding isotope pattern. Similar ESI-MS spectra of compounds **1**−**3** were obtained in the negative mode. In the positive mode the ESI-MS spectra of compounds **2** and **3** are dominated by the 4-(dimethylamino)pyridinium cation $[4\text{-}(Me_2N)C_5H_4NH]^+$ (*m*/*z* = 122.6), but show a similar peak pattern in the range *m*/*z* = 200−1000 as observed for compound **1**.

Graphset Theory:[37] Graphset descriptors indicate the hydrogen bond motif by the general form *Ga*,*d*(*n*). *G* describes the structural unit: C for a chain, D for a finite dimeric system, R for a cyclic system, S for intramolecular hydrogen bonds. The symbols *d* and *a* define the numbers of hydrogen bond donors and acceptors, respectively. The symbol *n* defines the total number of atoms in a motif.

1,3,5-$[(HO)_2(O)P]_3C_6H_3$ (1): Bromotrimethylsilane (27.9 g, 182.03 mmol) was added with a syringe to a solution of 1,3,5-$[(i\text{Pr}\text{-}O)_2(O)P]_3C_6H_3$ [36] (10.0 g, 18.20 mmol) in 150 mL of CH_2Cl_2 at 0 °C. The solution was stirred at room temperature for 12 h and after the addition of 250 mL of MeOH, the solution was heated at reflux for 4 h. The solvent was removed in vacuo to give a brownish solid. Addition of 100 mL of acetonitrile gave a suspension. The solid material was filtered off and crystallised from water to give **1** (3.5 g, 61%) as a colourless solid which decomposes at 248 °C. $C_6H_9O_9P_3$ (318.1): calcd. C 22.7, H 2.9; found C 22.3, H 2.8. ^1H NMR (200.13 MHz, [D$_4$]MeOH): δ = 8.25−8.47 (m) ppm. ^{31}P NMR (81.02 MHz, [D$_4$]MeOH): δ = 14.1 ppm. ESI-MS (positive mode, 101 V): *m*/*z* (%) = 318.9 (13) $[1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 + H]^+$, 336.6 (8) $[1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 + H_2O + H]^+$, 350.8 (24) $[1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 + CH_3OH + H]^+$, 636.8 (100) $[2 \times 1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 + H]^+$, 954.8 (14) $[3 \times 1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 + H]^+$, 1272.9 (6) $[4 \times 1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 + H]^+$. ESI-MS (negative mode, −71 V): *m*/*z* (%) = 280.7 (3) $[1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 - 2\,H_2O - H]^-$, 289.9 (12) $[2 \times 1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 - 3\,H_2O - 2\,H]^{2-}$, 298.7 (22) $[1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 - H_2O - H]^-$, 316.8 (100) $[1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 - H]^-$, 330.8 (17) $[1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 - H_2O + CH_3CN - H]^-$, 348.8 (8) $[1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 + CH_3CN - H]^-$, 616.8 (4) $[2 \times 1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 - H_2O - H]^-$, 634.9 (46) $[2 \times 1,3,5\text{-}\{(HO)_2(O)P\}_3C_6H_3 - H]^-$. IR (KBr): $\tilde{\nu}$ = 278 (w), 303 (w), 360 (w), 470 (m), 537 (m), 580 (w), 606 (w), 693 (m), 740 (w), 805 (w), 890 (m), 916 (m), 947 (m), 995 (s), 1166 (s, br.), 1400 (w), 1655 (s, br.), 2325 (s, br.), 3360 (vs, br.) cm^{-1}.

X-ray Crystallographic Study: Intensity data for the colourless crystals were collected with a Nonius KappaCCD diffractometer with graphite-monochromated Mo-K_α radiation at 173 K. The data collection covered almost the whole sphere of reciprocal space with two (**2**) and four sets (**3**) at different κ angles and 79 (**2**) and 248 (**3**) frames by ω-rotation (Δ/ω = 1°) at two times 110 (**2**) and 30 s (**3**) per frame. The crystal−detector distance was 3.4 cm. Crystal decay was monitored by repeating the initial frames at the end of data collection. Analysis of the duplicate reflections gave no indication of any decay. The structure was solved by direct methods SHELXS-97[38] and successive difference Fourier syntheses. Refinement applied full-matrix least-squares methods (SHELXL-97).[39] The H atoms were located in the difference Fourier map and refined isotropically. Atomic scattering factors for neutral atoms and real and imaginary dispersion terms were taken from *International Tables for X-ray Crystallography*. The figures were created by SHELXTL.[40] Crystallographic data are given in Table 2. CCDC-223048 and -223049 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Binary Neodymium Alkoxide/Dialkylmagnesium Polymerization Systems: Studies on the Nature of the Reaction Intermediates and Active Species

Jérôme Gromada,[a] André Mortreux,[a] Guy Nowogrocki,[b] Frédéric Leising,[c] Thomas Mathivet,[c] and Jean-François Carpentier*[d]

Keywords: Alkoxides / Alkyl complexes / Homogeneous catalysis / Magnesium / Neodymium / Polymerization

Attempts to identify the intermediates and/or active species generated from binary combinations of a lanthanide alk(aryl)-oxide with a dialkylmagnesium reagent, which behave as efficient olefin polymerization systems, are reported. The well-defined trinuclear complex $[Nd_3(\mu_3\text{-}O\textit{t}Bu)_2(\mu_2\text{-}O\textit{t}Bu)_3(\mu\text{-}O\textit{t}Bu)_4(THF)_2]$ (**1**) and the monomeric precursor $[Nd(OC_6H_2\textit{t}Bu_2\text{-}2,6\text{-}Me\text{-}4)_3(THF)]$ (**2**) were used in association with $[Mg(CH_2SiMe_3)_2(Et_2O)]$ (**3**). The new heterodimetallic complex $[(THF)Nd(\mu_3\text{-}O\textit{t}Bu)_2(\mu_2\text{-}O\textit{t}Bu)_2(O\textit{t}Bu)Mg_2(CH_2TMS)_2]$ (**4**) and the alkyllanthanide complex $[Nd(OC_6H_2\textit{t}Bu_2\text{-}2,6\text{-}Me\text{-}4)_2(CH_2SiMe_3)(THF)_2]$ (**5**) have been isolated and characterized in the solid state and in solution. Complex **4** is proposed to be a reaction intermediate in the active species formation, while complex **5** is the first alkyllanthanide species isolated from an "$Ln(OR)_3$"/MgR_2 mixture, consistent with the observed behavior of these combinations in olefin polymerization.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

We have recently described new versatile polymerization systems based on combinations of a neodymium alk(aryl)-oxide and a dialkylmagnesium reagent that enable the synthesis of original materials such as high molecular weight poly(ethylene-*b*-methyl methacrylate)[1] and poly(butadiene-*b*-glycidyl methacrylate)[2] diblock copolymers. For this purpose, the well-defined trinuclear complex $[Nd_3(\mu_3\text{-}O\textit{t}Bu)_2(\mu_2\text{-}O\textit{t}Bu)_3(\mu\text{-}O\textit{t}Bu)_4(THF)_2]$ (**1**) and the monomeric precursor $[Nd(OC_6H_2\textit{t}Bu_2\text{-}2,6\text{-}Me\text{-}4)_3(THF)]$ (**2**) were employed.

The active species formed in situ from these combinations act either as initiators with lanthanidocene-like properties, for example for ethylene[1] and methyl methacrylate (MMA)[3] controlled homopolymerizations, or as catalysts for 1,3-diene polymerization[2] along with a fast, reversible transfer reaction to the magnesium centers. From this polymerization behavior, we anticipated that the active species is likely to be a homonuclear alkyllanthanide, or a related mixed alkyl-bridged lanthanide-magnesium species.[1b,1c] Variable-temperature ^1H NMR monitoring experiments of mixtures of a dialkylmagnesium, for example $Mg(n\text{-}Hex)_2$ or *n*BuMgEt, with **1** or **2** showed that fast reactions take place in the absence of monomer.[1b] Complete conversion of the initial alk(aryl)oxides to unidentified species was observed at −70 °C, followed upon raising of the temperature by the appearance of the corresponding 1-alkene (1-hexene, 1-butene; ethylene was immediately polymerized in situ), presumably arising from β-hydride elimination of a putative alkylneodymium species. The release of 1-alkene was observed at temperatures as low as −60 °C with the *tert*-butoxide precursor **1** while a higher temperature, typically 0−20 °C, was required for the aryloxide precursor **2**. As a consequence of this ready decomposition, a reaction product could only be isolated and fully characterized in the case of the **2**/$Mg(n\text{-}Hex)_2$ combination — the alkylmagnesium aryloxide compound $[(n\text{-}Hex)Mg(OC_6H_2\textit{t}Bu_2\text{-}2,6\text{-}Me\text{-}4)]_2$, consistent with the envisioned transmetallation process.[1b] Herein we report further studies of these binary polymerization systems, using $[Mg(CH_2SiMe_3)_2(Et_2O)]$ (**3**) as a co-reagent, and the isolation and structural characterization of two intermediate alkyllanthanide alk(aryl)oxide complexes.

Results and Discussion

To obtain a better understanding of these binary catalyst systems, we decided to concentrate our efforts on the iso-

lation of the reaction intermediates and active species. For this purpose, the typical co-reagent Mg(*n*-Hex)$_2$ used for polymerization and initial mechanistic studies was replaced by [Mg(CH$_2$SiMe$_3$)$_2$(Et$_2$O)] (**3**). The latter reagent, in combination with **1** or **2**, has been shown to also generate active polymerization systems towards ethylene, MMA and 1,3-dienes, with properties similar to those of combinations based on Mg(*n*-Hex)$_2$, although somewhat less active.[1b,2] The dialkylmagnesium **3** was selected to stabilize the corresponding alkyllanthanide species, in particular by avoiding β-H elimination reactions.[4] Another potential advantage of **3** over Mg(*n*-Hex)$_2$ and higher long-chain dialkylmagnesium reagents is the better propensity of the CH$_2$SiMe$_3$ moiety for crystallization.

Combinations of [Nd$_3$(OtBu)$_9$(THF)$_2$] and [Mg(CH$_2$SiMe$_3$)$_2$(Et$_2$O)]

Toluene solutions of **1** and **3** in various ratios were prepared and stored at low temperature (−30 °C). When the reaction was performed in a 1:3 molar ratio (i.e. Nd/Mg = 1), as optimized for polymerization purposes, in the absence of additive, it was not possible to isolate any species from the resulting dark-brown solution. On the other hand, in the presence of THF (10 equiv. vs. Nd), the solution remained clear and blue. The ^{1}H NMR spectrum of the blue crystals grown from this solution is identical to the starting trinuclear alkoxide **1**, indicating that an excess of THF prevents the alkylation reaction from taking place. This fact is in direct line with the observed inactivity of the **1**/Mg(*n*-Hex)$_2$ system in the presence of minute amounts of THF for ethylene polymerization.[1b] Evans et al. have observed a similar phenomenon with their [Y(O*t*Bu)$_7$Cl$_2$]/AlMe$_3$ systems and assigned this lack of reactivity to the formation of the unreactive [AlMe$_3$(THF)].[5]

Given the successful isolation by Yasuda et al. of an intermediate in lanthanidocene-based MMA polymerization[6] and the efficient controlled syndiotactic polymerization of this monomer achieved with **1**/Mg(*n*-Hex)$_2$,[3] MMA (0.03 equiv. vs. Nd) was added to some crystallization experiments. Under those conditions, colorless crystals of [(Me$_3$SiCH$_2$)Mg(O*t*Bu)(THF)] (**5**) formed rapidly (15−20% isolated yield vs. Mg) in a reproducible manner, followed after a few weeks by pale-blue crystals of a neodymium complex (**4**; 30−40% yield vs. **1**) [Equation (1)]. As established by NMR spectroscopy and an X-ray diffraction analysis (Figure 1, Table 1), the product **4** corresponds to the new heterodimetallic complex [(THF)Nd(μ$_3$-O*t*Bu)$_2$(μ$_2$-O*t*Bu)$_2$(O*t*Bu)Mg$_2$(CH$_2$SiMe$_3$)$_2$], which obviously, however, does not contain any MMA. The neodymium center in **4** is hexacoordinate, as are most *tert*-butoxyneodymium derivatives,[7] with six oxygen atoms in its environment, one terminal *tert*-butoxy ligand and a THF molecule. Doubly and triply bridging *t*BuO groups link the neodymium atom to the two tetracoordinate magnesium atoms, each of which bears an alkyl chain. Such segregation of the alkoxide and alkyl ligands in complex **4** can be correlated with the higher oxophilicity of Nd vs. Mg (bond disruption energies: Nd−O, 703 ± 13 kJ·mol^{-1}; Mg−O, 363 ± 13 kJ·mol^{-1}).[8]

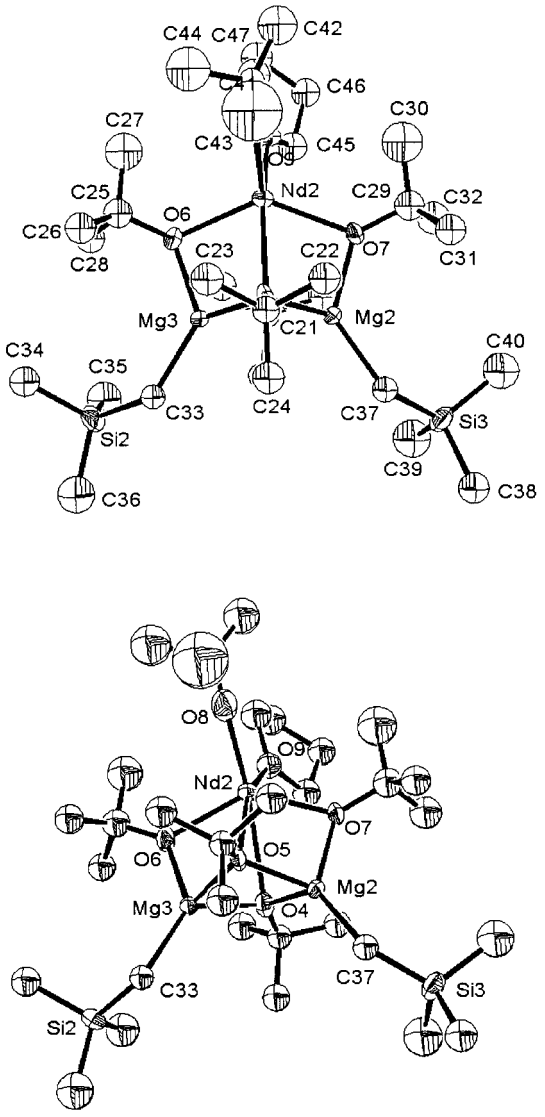

Figure 1. Two views of the molecular structure of [Nd(THF)(μ$_3$-O*t*Bu)$_2$(μ$_2$-O*t*Bu)$_2$(O*t*Bu)Mg$_2$(CH$_2$SiMe$_3$)$_2$] (**4**); ellipsoids are drawn at the 40% probability level and hydrogen atoms omitted for clarity

Several well-characterized aluminium-lanthanide alkyl-alk(aryl)oxide complexes have been described previously, most of which were prepared from the interaction of lanthanide alk(aryl)oxides with AlR$_3$.[9] Examples of heterodimetallic organometallic Ln-Mg complexes are much rarer and none of them contain alk(aryl)oxide ligands as in **4**.[10]

O(5)−Mg(2)−C(37)	121.1(2)	Mg(2)−O(7)−Nd(2)	95.4(1)

In the solid state, complex **4** has basically the same structural framework as the starting trinuclear alkoxide **1**, except that the [Nd(O*t*Bu)(THF)] and [Nd(O*t*Bu)$_2$] moieties have been replaced by two [Mg(O*t*Bu)(CH$_2$SiMe$_3$)] units. It is therefore interesting to compare the geometric features of both structures. The Nd−O distance of the terminal *tert*-butoxide ligand in **4** [Nd(2)−O(8): 2.241(6) Å] is somewhat longer than those found in **1** [2.147(4)−2.163(3) Å],[1b] while the Nd−O(THF) distance is significantly shorter [2.350(5) Å vs. 2.661(4) Å]. It is worthwhile mentioning that these THF and terminal O*t*Bu ligands are statistically disordered (see Exp. Sect.), which may lead to averaged values. The doubly bridging Nd−O distances are, as expected, longer than those for the terminal alkoxide ligand [Nd(2)−O(7): 2.304(3); Nd(2)−O(6): 2.307(4) Å], and slightly shorter than those measured in **1** [2.333(3)−2.458(3) Å]. Also, the nonequivalent triply bridging Nd−O bonds [Nd(2)−O(4): 2.762(4); Nd(2)−O(5): 2.600(4) Å] are the longest ones observed in the structure and longer than the corresponding values in **1** [2.624(3) and 2.409(3) Å],[1b] showing that the Nd atom is highly distorted from an ideal octahedral geometry. The angles around the neodymium center are similar to those observed in **1** except for the O(μ_3)−Nd−O(μ_3) angle, which is smaller in the heterodimetallic complex [55.3(1)° in **4** vs. 66.0(1)° in **1**]. This difference may be ascribed to the asymmetry in the complex caused by the shorter Mg−O bonds compared to the Nd−O ones. The equivalent magnesium atoms are four-coordinate, showing a distorted tetrahedral geometry. This geometry has been observed previously in some mixed alkoxy-amido complexes such as [(CMeNC$_6$H$_3$*i*Pr$_2$-2,6)Mg(μ_2-O*t*Bu)(THF)] and [(CMeNC$_6$H$_3$*i*Pr$_2$-2,6)Mg(μ_2-OC$_6$H$_9$)].[11] The doubly bridging Mg−O distances [Mg(2)−O(7): 1.984(4); Mg(3)−O(6): 1.974(4) Å] and Mg−O−Nd angles [Mg(2)−O(7)−Nd(2): 95.4(1); Mg(3)−O(6)−Nd(2): 95.6(1)°] compare well with the corresponding values observed in [(CMeNC$_6$H$_3$*i*Pr$_2$-2,6)Mg(μ_2-O*t*Bu)(THF)] [Mg−O: 1.997(2) and 1.994(2) Å; Mg−O−Mg: 98.56(6)°].[11]

The solution structure of complex **4** was briefly studied by ^{1}H NMR spectroscopy in [D$_8$]toluene. As shown in Figure 2, interpretation of the variable-temperature NMR spectra is complicated by the high fluxionality of the molecule and, above all, the paramagnetic Nd center, which broadens signals and affects intensity measurements. Thus, the correlation between chemical shift and coordination mode of the alkoxide groups previously noted in diamagnetic yttrium and lanthanum complexes of this type — increased bridging is associated with lower-field shifts[12] — cannot be applied to determine the geometry of **4** in solution unambiguously. Minimal overlapping of the resonances is observed in the NMR spectrum at −80 °C (Figure 2), which features eight major singlet-like resonances **A**−**H** with relative integrations 9:9:18:2:18:4:9:4 (from high field to low field). This pattern is consistent with the structure observed in the solid state, considering that both 18 H singlets **C** and **D** correspond to the μ_3-O*t*Bu and μ_2-O*t*Bu groups, which are magnetically equivalent on the NMR timescale at this low temperature,[12] and that the CH$_2$SiMe$_3$ groups are nonequivalent, one of the methylene resonance being obscured by residual solvent resonances (e.g. **I**) or a stronger intensity signal.

Complex **4** was exposed to ethylene (1 bar) in toluene solution. At room temperature, even after a long time period (48 h), the formation of polyethylene was not observed. This was not unexpected considering that **4** does not contain any Nd−C bond susceptible to insert ethylene. Addition of a slight excess of **3** to **4** under ethylene led to an effective polymerization. We can therefore hypothesize that **4** is an intermediate in the formation of the real active species in **1**/MgR$_2$ systems for ethylene polymerization. On the other hand, the 1:1 Nd/Mg stoichiometry imposed for the reaction between **1** and **3** was not recovered in the final complex **4**, and we cannot discard the potential catalytic activity of other products remaining in the mother solution and so far unidentified, such as species of the type [(*t*BuO)$_2$Nd−R]$_n$.

Combinations of [Nd(OC$_6$H$_2$*t*Bu$_2$-2,6-Me-4)$_3$(THF)] and [Mg(CH$_2$SiMe$_3$)$_2$(Et$_2$O)]

We focused next on [Nd(OC$_6$H$_2$*t*Bu$_2$-2,6-Me-4)$_3$(THF)] (**2**). This precursor, thanks to its bulky and readily displaceable ligand commonly used in the chemistry of group 1−4 metals, might lead to more stable and/or more easily crystallizable complexes, as evidenced by the isolation of [Mg(OC$_6$H$_2$*t*Bu$_2$-2,6-Me-4)(*n*-Hex)]$_2$ from a **2**/Mg(*n*-Hex)$_2$ (1:1) mixture in toluene.[1b] The quantitative formation of the latter compound is in agreement with the assumed in situ formation of a bis(aryloxy)alkylneodymium complex. However, the latter could not be isolated either from Mg(*n*-Hex)$_2$ or upon using the dialkylmagnesium compound **3** in pure toluene, despite repeated efforts. On the other hand,

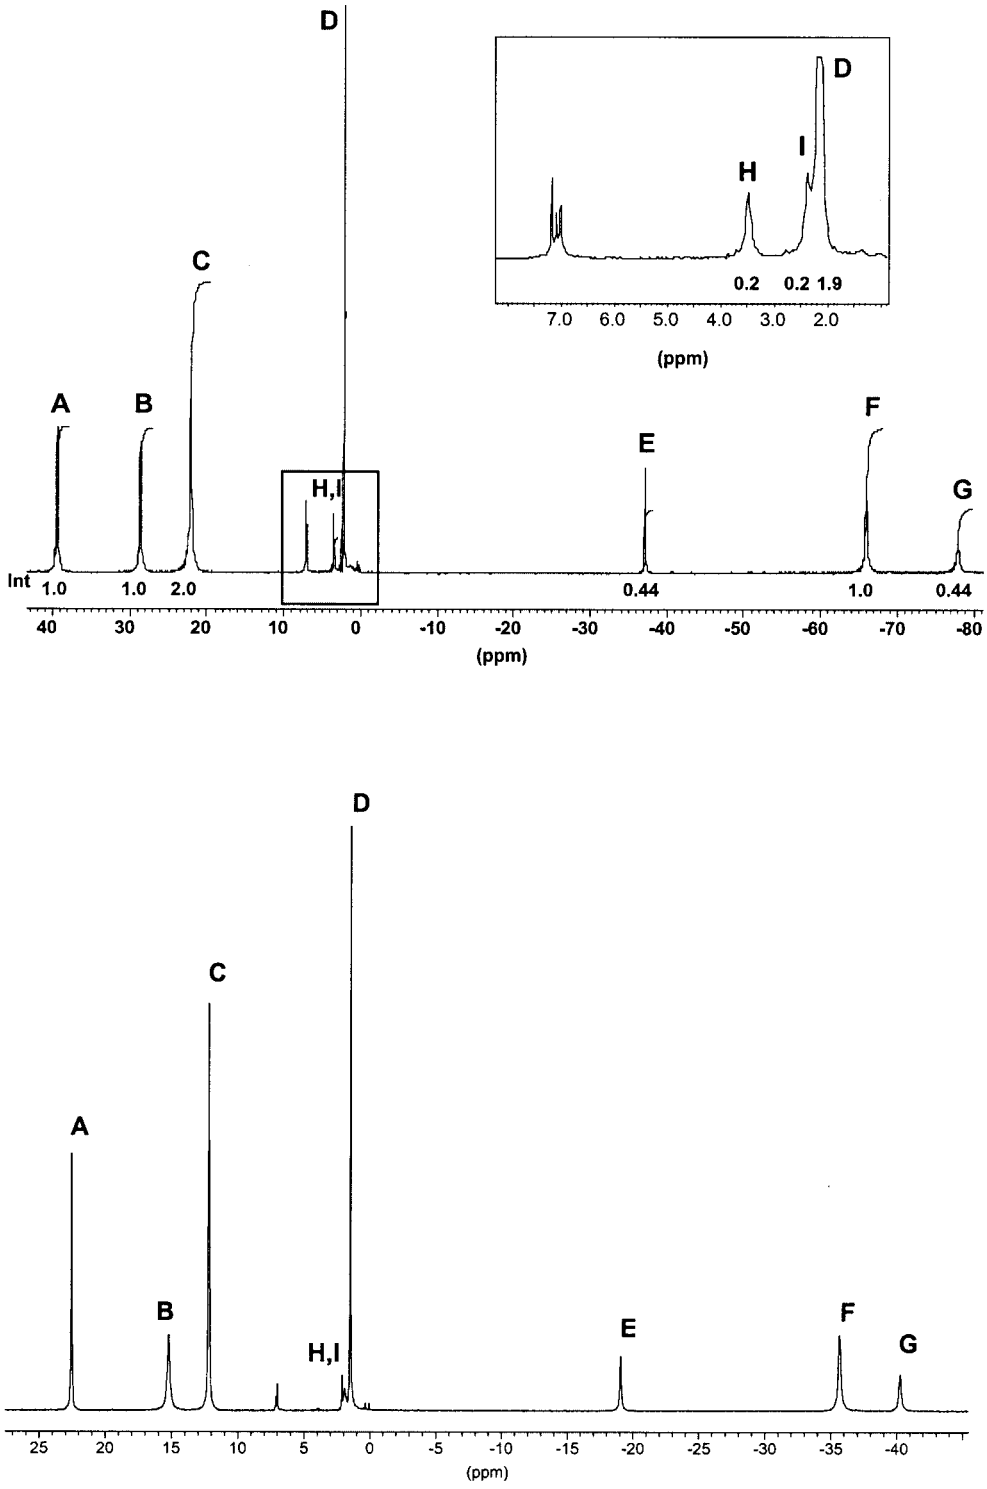

Figure 2. Representative variable-temperature ^{1}H NMR spectra of [Nd(μ_3-O*t*Bu)$_2$(μ_2-O*t*Bu)$_2$(O*t*Bu)Mg$_2$(CH$_2$SiMe$_3$)$_2$(THF)] (**4**) in [D$_8$]-toluene; top: −80 °C; bottom: 0 °C (**I** denotes residual toluene resonance and/or a signal from **4**)

the addition of THF (10 equiv. vs. Nd) to a mixture of **2** and **3** (1:1) enabled the ready crystallization of the pentacoordinate complex [(4-Me-2,6-*t*Bu$_2$C$_6$H$_2$O)$_2$Nd(CH$_2$SiMe$_3$)(THF)$_2$] (**6**) along with [(4-Me-2,6-*t*Bu$_2$C$_6$H$_2$O)Mg(CH$_2$SiMe$_3$)]$_2$ (**7**), isolated in 34% and 39% yields, respectively [Equation (2)].

(2)

The solid-state structure of **6** features the metal center coordinated in a slightly distorted trigonal-bipyramidal mode by one equatorial methyltrimethylsilyl and two aryloxy groups (sum of the angles around Nd = 359.49°), and two axial THF ligands (Figure 3, Table 2). A plane of symmetry (noncrystallographic) embraces the Nd, both O(THF) and the C(CH_2SiMe_3) atoms. Similar trigonal-bipyramidal coordination has been observed previously in $Ln(OR)_3L_2$ complexes such as $[Nd(OCtBu_3)_3(CH_3CN)_2]$,[13] as well as in mixed halogen-aryloxide complexes, such as $[SmI(OAr)_2(THF)_2]$ and $[(4\text{-Me-}2,6\text{-}tBu_2C_6H_2\text{-}O)_2LnCl(THF)_2]$ (Ln = Er, Yb),[14] and in the mixed aryl-halogen complex $[(2,6\text{-dimesitylphenyl})YbCl_2(THF)_2]$,[15] in which the chlorine atoms occupy the axial positions. The O(1A)−Nd(1)−O(1B) angle [146.2(1)°] in **6** is much larger than 120°, reflecting the larger steric requirement of the aryloxide ligands compared to the CH_2TMS group. The bulkiness of the equatorial ligands affects the geometry of the axial ligands, with a lower (THF)O−Nd−O(THF) angle [165.46(9)°] than the theoretical value (180°). The increase in coordination number from the four-coordinate, distorted tetrahedral tris(aryloxide) precursor **2** to pentacoordinate complex **6** also likely stems from the decreasing steric requirement of CH_2SiMe_3 compared to the very bulky aryloxide. We assume that this may be the reason why it was not possible to isolate a putative alkyl complex, such as $[(ArO)_2Nd(CH_2SiMe_3)]$, in the absence of THF. The necessary addition of a Lewis base for crystallization has also been claimed in the case of $[Nd(\mu_2\text{-}OAr)(OAr)_2(py)_2]_2$.[9h]

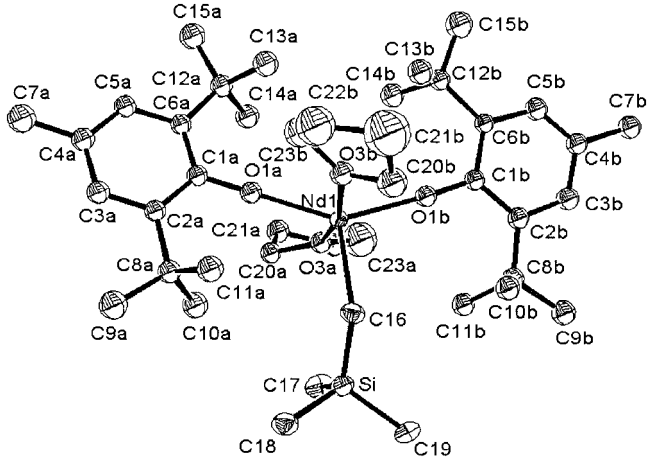

Figure 3. Molecular structure of $[(4\text{-Me-}2,6\text{-}tBu_2C_6H_2O)_3Nd(CH_2SiMe_3)(THF)_2]$ (**6**); ellipsoids are drawn at the 50% probability level and hydrogen atoms omitted for clarity

Table 2. Selected bond lengths [Å] and angles [°] for **6**

Nd(1)−O(1A)	2.235(3)	O(1A)−Nd(1)−O(1B)	146.21(10)
Nd(1)−O(1B)	2.227(3)	O(1A)−Nd(1)−O(3B)	83.70(10)
Nd(1)−O(3A)	2.500(3)	O(1B)−Nd(1)−O(3B)	91.69(10)
Nd(1)−O(3B)	2.487(3)	O(1A)−Nd(1)−C(16)	113.02(12)
Nd(1)−C(16)	2.482(4)	O(1B)−Nd(1)−C(16)	100.26(12)
O(1A)−C(1A)	1.352(5)	O(3B)−Nd(1)−C(16)	88.54(12)
O(1B)−C(1B)	1.355(5)	O(1A)−Nd(1)−O(3A)	84.40(9)
C(16)−Si	1.843(4)	O(1B)−Nd(1)−O(3A)	93.56(10)
C(16)−Nd(1)−O(3A)	103.82(12)	O(3B)−Nd(1)−O(3A)	165.46(9)

The Nd−O(Ar) distances are nearly identical for both ligand units [2.227(3), 2.235(3) Å] and are somewhat longer than those in **2**, but similar to those observed in related complexes.[16] Also, the Nd−O(THF) distances [2.487(3), 2.500(3) Å] are within the range of values reported for Nd−THF complexes.[17] The Nd−C distance of 2.482(4) Å can be compared to the terminal Sm−C distance of 2.45(1) Å in $[Sm(OAr)_3(CH_2SiMe_3)_2][Li(THF)]_2$ (Ar = 2,6-$iPr_2C_6H_3$), reflecting the minimal 2.6% difference in the ionic radii.[18] It is, however, much lower than that of 2.68(1) Å in $[\{1,1'\text{-}(3,5\text{-}tBu_2\text{-}2\text{-}C_6H_2O)_2\}La\{CH(SiMe_3)_2\}(THF)_3]$ due to the larger ionic radius of lanthanum,[18] its hexacoordination and the bulkiness of both aryloxide and alkyl groups.[19]

The characterization of **6** in solution by ^1H NMR spectroscopy was unambiguous and indicated a symmetric structure on the NMR time scale, as observed in the solid state. Complex **6** exhibits the same pattern as **2** for the equivalent aryloxide ligands — narrow signals for the aromatic and Me protons and a broad singlet for the *tert*-butyl groups at higher field. The signals assigned to the alkyl group appear at $\delta = -1.25$ and -7.15 ppm for the methylene and trimethylsilyl groups, respectively, while the two equivalent coordinated THF molecules give broad resonances at $\delta = -6.90$ and -9.66 ppm.

As expected, despite the presence of an Nd−C bond, complex **6** does not initiate ethylene polymerization under the conditions used for catalytic combinations of **2** and **3** (1 atm, 0−80 °C). This is, of course, due to the presence of the two coordinated THF molecules that "block" the active site for the weaker Lewis base ethylene.

In conclusion, some reaction products of the combinations of neodymium alk(aryl)oxides **1** and **2** with $[Mg(CH_2SiMe_3)_2(Et_2O)]$ (**3**) have been isolated and fully characterized. The new heterodimetallic complex **4**, obtained from the association of **1** with **3**, appears to be a plausible intermediate towards the species active in ethylene and methyl methacrylate (co)polymerizations. Indeed, although inert towards ethylene, complex **4** can be further activated upon MgR_2 addition, eventually yielding species that are active in polymerization. The alkylneodymium complex **5** is also inert towards olefins despite its reactive Nd−C bond. The isolation of this complex is, however,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

noteworthy in this area since it is the first example of an alkyl complex prepared from a neodymium alk(aryl)oxide/dialkylmagnesium mixture. Formation of **5** is the strongest evidence to date corroborating that an alkyllanthanide could be the active species in olefin polymerizations initiated by these new binary catalytic systems.

Experimental Section

General: All operations were performed in a glove box under nitrogen. Solvents and deuterated solvents were freshly distilled from sodium-potassium amalgam under argon and degassed prior to use. NMR spectra were recorded in Teflon-valved NMR tubes with a Bruker AC-200 spectrometer. ^{1}H (200 MHz) and ^{13}C{^{1}H} (50 MHz) chemical shifts are expressed in ppm vs. $SiMe_4$ and are referenced to the residual solvent peaks. The complexes [$Nd_3(O\mathit{t}Bu)_9(THF)_2$],[1b] [$Nd(OC_6H_2\mathit{t}Bu_2$-2,6-Me-4)$_3$(THF)],[20] and [$Mg(CH_2SiMe_3)_2(OEt_2)$][21] were prepared according to the reported procedures. Methyl methacrylate (99%, Aldrich) was vacuum-distilled from CaH_2 and stored at −20 °C under argon.

Reaction of [$Nd_3(\mu_3$-O*t*Bu)$_2(\mu_2$-O*t*Bu)$_3(\mu$-O*t*Bu)$_4$(THF)$_2$] (1) with [$Mg(CH_2SiMe_3)_2(Et_2O)$] (3)]. Synthesis of [$Nd(\mu_3$-O*t*Bu)$_2(\mu_2$-O*t*Bu)$_2(\mu$-O*t*Bu)$Mg_2(CH_2SiMe_3)_2$(THF)] (4) and [(Me_3SiCH_2)-Mg(O*t*Bu)(THF)] (5): [$Nd_3(O\mathit{t}Bu)_9(THF)_2$] (**1**; 0.124 g, 0.10 mmol) was dissolved in a minimal amount of toluene (ca. 0.25 ml). Methyl methacrylate (10 μL, 0.010 mmol) and [$Mg(CH_2SiMe_3)_2(OEt_2)$] (**3**; 0.084 g, 0.33 mmol) were then added at room temperature to the resulting deep-blue solution. The solution turned green after addition of the magnesium reagent and was immediately cooled to −30 °C. After 2 d, colorless crystals of [(Me_3SiCH_2)Mg(O*t*-Bu)(THF)] (**5**) were removed from the solution (0.015 g, 17%) and after typically about 10 d, pale-blue crystals of **4** had grown from the dark-green solution (0.027 g, 37%), which proved suitable for X-ray diffraction.

4: ^{1}H NMR (200 MHz, [D$_8$]toluene, 23 °C): δ = 19.56 (s, 1 H), 12.82 (br. s, 0.6 H), 10.40 (s, 2 H), 1.37 (s, 2 H), −15.87 (s, 0.4 H), −30.11 (br. s, 0.7 H), −33.43 (br. s, 0.4 H) ppm. ^{1}H NMR (200 MHz, [D$_8$]toluene, −35 °C): δ = 27.54 (s, 1 H), 19.09 (s, 1 H), 15.16 (s, 2 H), 2.25 (s, 0.2 H), 2.10 (s, 0.1 H), 1.69 (s, 1.5 H), −24.53 (s, 0.4 H), −44.86 (s, 1 H), −51.62 (s, 0.4 H) ppm. ^{1}H NMR (200 MHz, [D$_8$]toluene, −80 °C): δ = 39.38 (s, 9 H), 28.60 (s, 9 H), 22.06 (s, 18 H), 3.48 (s, 2 H), 2.37 (s, 2 H), 2.15 (s, 18 H), −37.21 (s, 4 H), −66.03 (s, 9 H), −78.01 (s, 4 H) ppm. $C_{32}H_{75}Mg_2NdO_6Si_2$ (804.96): calcd. C 47.75, H 9.39; found C 47.1, H 9.11.

5: ^{1}H NMR (200 MHz, [D$_6$]benzene, 23 °C): δ = 3.68 (m, 4 H, THF), 1.29 (s, 9 H, *t*Bu), 1.24 (m, 4 H, THF), 0.41 (s, 9 H, $SiMe_3$), −1.33 (s, 2 H, CH_2) ppm. ^{13}C{^{1}H} NMR (50 MHz, [D$_6$]benzene, 23 °C): δ = 69.7 (*C*H$_2$O, THF), 67.8 (C_q, *t*Bu), 35.3 (*C*H$_3$, *t*Bu), 25.5 (*C*H$_2$, THF), 5.6 [Si(*C*H$_3$)], −6.0 (*C*H$_2$Mg) ppm. $C_{12}H_{28}MgO_2Si$ (256.74): calcd. C 56.14, H 10.99; found C 55.86, H 10.53.

Reaction of [$Nd(OC_6H_2\mathit{t}Bu_2$-2,6-Me-4)$_3$(THF)] (2) with [$Mg(CH_2SiMe_3)_2(Et_2O)$] (3). Synthesis of [$Nd(OC_6H_2\mathit{t}Bu_2$-2,6-Me-4)$_2(CH_2SiMe_3)$(THF)$_2$] (6) and [(4-Me-2,6-*t*Bu$_2$C$_6$H$_2$O)Mg(CH$_2$S-iMe$_3$)]$_2$ (7): [$Nd(OC_6H_2\mathit{t}Bu_2$-2,6-Me-4)$_3$(THF)] (**2**) (0.087 g, 0.10 mmol) was dissolved in a mixture of toluene (0.140 g, 0.16 mL) and THF (0.050 g, 0.70 mmol) THF was weighted to introduce an exact amount. [$Mg(CH_2SiMe_3)_2(Et_2O)$] (**3**) (0.027 g; 0.10 mmol) was added at room temperature to the resulting purple solution, and the mixture was immediately cooled to −30 °C. After a few days, colorless crystals of [(4-Me-2,6-*t*Bu$_2$C$_6$H$_2$O)Mg(CH$_2$S-iMe$_3$)]$_2$ (**7**) were removed from the solution (0.013 g, 39%) and blue crystals of **6** suitable for X-ray analysis were obtained from the blue solution after a month (0.025 g, 34%).

6: ^{1}H NMR (200 MHz, [D$_6$]benzene, 23 °C): δ = 21.36 (s, 2 H, Ar), 10.47 (s, 3 H, Me), 7.99 (br. s, 18 H, *t*Bu), −1.25 (s, 2 H, CH_2), −6.90 (br. s, THF), −7.15 (s, $SiMe_3$), −9.66 (br. s, THF) ppm. $C_{42}H_{73}NdO_4Si$ (814.35): calcd. C 61.94, H 9.04; found C 60.45, H 8.96.

7: ^{1}H NMR (200 MHz, [D$_6$]benzene, 23 °C): δ = 7.19 (s, 2 H, Ar), 2.29 (s, 3 H, Me), 1.59 (s, 18 H, *t*Bu), 0.06 (s, 9 H, $SiMe_3$), −1.16 (s, 2 H, CH_2) ppm. ^{13}C{^{1}H} NMR (50 MHz, C_6D_6, 23 °C): δ = 159.4 (C_{Ar}), 139.8 (C_{Ar}), 128.9 (C_{Ar}), 127.6 (C_{Ar}), 35.7 (C_q, *t*Bu), 33.9 (*C*H$_3$, *t*Bu), 21.9 (*C*H$_3$), 4.1 [Si(*C*H$_3$)], −6.2 (*C*H$_2$-Mg) ppm. $C_{19}H_{34}MgOSi$ (330.86): calcd. C 68.97, H 10.36; found C 68.4, H 9.82.

X-ray Crystal-Structure Determination of 4: A pale-blue crystal of approximate dimensions 0.30 × 0.25 × 0.10 mm was mounted on a glass fiber. X-ray data were collected with a Bruker SMART CCD area-detector diffractometer with Mo-K_α radiation (λ = 0.71073 Å) at T = 100 K. Crystal data: monoclinic, *Cc*; a = 26.312(5), b = 11.595(2), c = 22.888(5) Å; β = 109.127(3)°; V = 6597(2) Å^3; formula unit: $C_{32}H_{75}O_6Mg_2NdSi_2$ with Z = 6; molecular weight: 804.96; calculated density = 1.216 g·cm^{-3}; F(000) = 2562; μ(Mo-K_α) = 1.297 mm^{-1}. 22487 reflections collected (2.27° < Θ < 25.00°). The structure was solved by direct methods.[22] Of the six neodymium atoms in the cell, two are on the twofold axis and the four others are in general positions. The resolution was complicated by the disorder between the monodentate O*t*Bu ions and THF molecules, which had to be refined as independent parts. Hydrogen-atom positions were calculated on a geometrical basis. Full-matrix least-squares refinement on F^2 based on 11197 independent reflections converged with 620 variable parameters and three restraints. $R1$ = 0.0360 [for 10265 data with $I > 2\sigma(I)$]; $wR2$ = 0.0864; GoF (F^2) = 1.057. $\Delta\rho_{max}$ = 1.776 and −0.851 e·Å^{-3}.

X-ray Crystal Structure Determination of 6: A pale-blue crystal of approximate dimensions 0.45 × 0.25 × 0.12 mm was mounted on a glass fiber. X-ray data were collected with a Bruker SMART CCD area-detector diffractometer with Mo-K_α radiation (λ = 0.71073 Å) at T = 100 K. Crystal data: orthorhombic, *Pca2*$_1$; a = 23.732(5), b = 9.799(2), c = 18.902(4) Å; V = 4395.7(16) Å^3; formula unit: $C_{42}H_{73}O_4SiNd$ with Z = 4; molecular weight: 814.33; calculated density = 1.119 g·cm^{-3}; F(000) = 1724; μ(Mo-K_α) = 1.244 mm^{-1}. 30722 reflections collected (2.15° > Θ > 28.04°). The structure was solved by direct methods.[22] Hydrogen-atom coordinates were generated by geometrical calculations. Full-matrix least-squares refinement on F^2 based on 9437 independent reflections converged with 450 variable parameters and one restraint. $R1$ = 0.0339 [for 7321 data with $I > 2\sigma(I)$]; $wR2$ = 0.0637; GoF (F^2) = 1.010. $\Delta\rho_{max}$ = 2.015 and −0.808 e·Å^{-3}. The largest residuals are close to one of the THF molecule and are probably due to some orientational disorder.

CCDC-228005 (**4**) and -228006 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK; Fax: (internat.) + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

[4] It should be pointed out, as commented by a referee, that numerous *n*-alkyllanthanide complexes, including active polymerization catalysts, are known, which indicates that β-H elimination is not necessarily a problem. Also, β-H elimination is not the only possible decomposition process in the lanthanide *tert*-butoxide/MgR_2 systems described in this paper. When the R alkyl group, transferred from the magnesium to the neodymium atom, does not undergo β-H elimination, a second pathway can take place that involves decomposition of the *tert*-butoxy ligand into isobutene to give the corresponding alkane (RH) and lanthanide oxide. See ref.[1b]

Synthesis and Reactions of Alkynyl Oligosilanes

Christian Mechtler,[a] Michaela Zirngast,[a] Judith Baumgartner,[a] and Christoph Marschner*[a]

Keywords: Alkynes / Anions / Silanes / Polyanions

Synthesis, properties, and reactions of various alkynyl oligosilanes, and their potassium derivatives are described. A series of tris(trimethylsilyl)silylalkynes have been prepared. Their reaction with potassium *tert*-butoxide leads to the corresponding potassium derivatives, which can be subjected to further derivatization. X-ray structures of three oligosilylalkynes are reported.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Over the last five years we have developed an interest in the chemistry of silyl anions which permits the synthesis of both larger oligosilanes and metal silyl compounds.[1] Besides the advancements in this field it is still desirable to enhance the number of compatible functional groups which can be used. Hence, we decided to study alkynylsilanes. Alkynes can be further functionalized by employing addition and substitution reactions and in the case of metal silyl compounds the triple bond exhibits a charge-stabilizing effect.

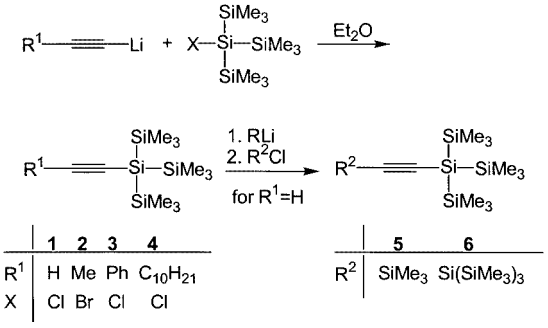
Alkynylsilanes are commonly prepared by the reaction of silyl halides or triflates with metal alkynyl compounds in organic solvents.[2−4] However, surprisingly few alkynyl-substituted oligosilanes are known[5] to date and the corresponding anions are almost completely unknown.[1b]

In connection with this we report on the selective synthesis of oligosilyl alkynes and their reactions with potassium *tert*-butoxide to form mono- or di-anions along with the further reactions that they are involved in.

Results and Discussion

Synthesis of Alkynylsilanes

The most convenient method for the synthesis of alkynylsilanes makes use of the reaction of silyl halides with metallated alkynes such as Grignard compounds.[6] Our preferred route was that of the lithiated alkynes. Although a two step synthesis was employed avoiding the use of dilithiated acetylene an excellent yield of over 80% was obtained for **6,** compared with the 5% reported.[7] The nature of the lithium alkyl used for the metallation of the alkyne was not important with the exception of the case of lithiation of phenylated alkynes where the use of methyllithium was found to be crucial. The reacting silanes were usually chlorosilanes, only for the 1-propinyl compound **2,** and also **10**, were the more reactive bromosilanes used (Scheme 1).



Scheme 1. General scheme for the synthesis of alkynylsilanes

Reaction of propargyl tosylate with potassium tris(trimethylsilyl)silane[1] affords propargylsilane **7** in a yield of 80%. Astonishingly deprotonation of the alkyne by the highly basic silyl anion was not a significant side reaction. Reaction towards the bissilylated compound **8** was easily achieved by lithiation of **7** and reaction with chlorotris(trimethylsilyl)silane (Scheme 2).

In order to obtain a compound bearing two alkynyl groups we treated 2,2-dibromohexamethyltrisilane with two equivalents of lithiated phenylacetylene (Scheme 3).

In an attempt to prepare a higher alkynyl oligosilane, bromopentakis(trimethylsilyl)disilane was treated with phenyl acetylide (Scheme 4).

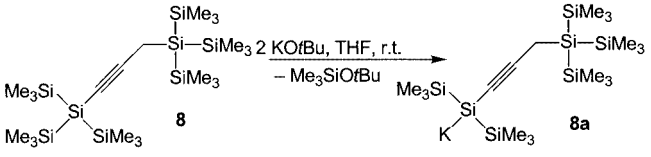
Preparation of Alkynyl Silyl Anions

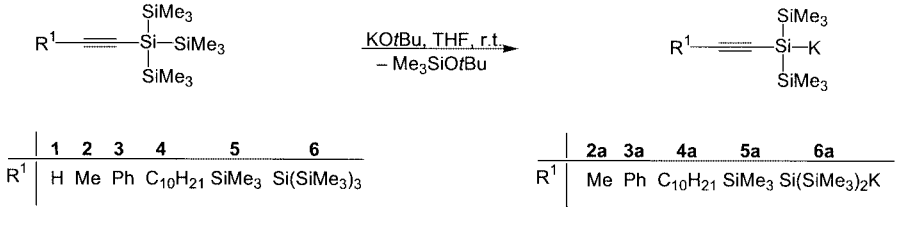
Recently, we described the reaction of oligosilanes with one or two molar equivalents of potassium *tert*-butoxide to give the respective mono-[1,16] or dianions[1b] and a silyl ether. Monoanions were formed in THF at ambient temperature, the formation of dianions, however, required a temperature of about 60 °C and reaction times of a few days. The use of benzene or toluene as a solvent and the addition of 18-crown-6 facilitated the formation of dianions so that complete conversion within a few hours at room temperature could be achieved. The alkynylsilanes discussed here proved to be considerably more reactive than the silanes studied so far. The conversion into the respective mono- or dianions proceeded smoothly at room temperature within minutes and even at −20 °C it proceeded within an hour. The alkynyl group seems to enhance reactivity towards the potassium alkoxide significantly. The effect is so pronounced that it is not possible to achieve clean mono metallation for the case of the alkynylidene-bridged compound **6**. Only a mixture of starting material, mono- and dianion could be detected upon reaction with one equivalent of potassium *tert*-butoxide. As already observed for the reactions with other oligosilanes, conversion only occurs in THF, DME or even more polar ethereal solvents. No conversion, even with the more reactive alkynylsilanes occurred in diethyl ether, benzene or toluene.

The metallations of compounds **2**, **3**, **4** and **5** proceeded as expected from our experience gained thus far. A trimethylsilyl group was formally replaced by a negative charge. All reactions were faster than the conversion with tetrakis(trimethylsilyl)silane,[1] with compound **3** being the most reactive. In THF the conversion of **3** at ambient temperature was completed within less than five minutes. Interestingly the reaction of tris(trimethylsilyl)silylacetylene (**1**) with potassium *tert*-butoxide did not yield the expected anion, instead the only product detected was the rearrangement product **5a** which can also be obtained from **5** (Scheme 5). The nature of the rearrangement is still unclear. It is, however, likely that a reaction of the initially formed compound **1a** with *tert*-butyltrimethylsilyl ether occurs.

Tris(trimethylsilyl)propargylsilane (**7**) underwent another unexpected rearrangement. The result of its reaction with potassium *tert*-butoxide was compound **2a**. A closer look at the reaction revealed an initial base catalyzed rearrangement of **7** to **2,** which then was followed by conversion into **2a**. In contrast to the rapid and exclusive reaction of **6** towards the dianion compound **6a**, **8** was showing very different behavior. Addition of one equivalent of potassium *tert*-butoxide did not effect the formation of the expected monoanion **8a**. A second equivalent of the alkoxide eventually resulted in the fast formation of **8a** but even after 72 h no dianion could be observed and complete decomposition had occurred (Scheme 6).



Scheme 6. Monometallation of **8**

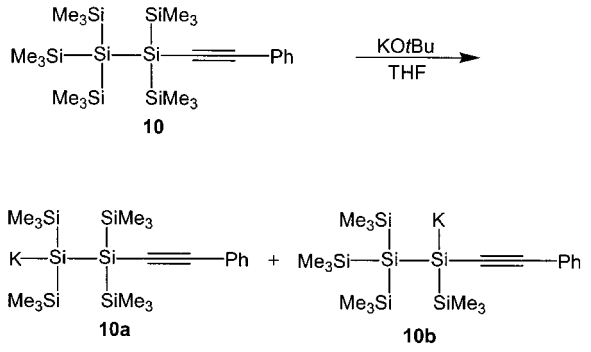


Scheme 5. Synthesis of potassium alkynylsilanes

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The reaction of the dialkyne **9** with potassium *tert*-butoxide did not give a dialkynyl(trimethylsilyl)silyl anion. Although a vigorous and clearly exothermic reaction occurred no soluble silicon containing product was obtained. The brown insoluble material, which could be isolated, seemed to indicate a polymerization reaction. An early and isolated example by Gilman et al.[8] reported addition of two equivalents of triphenylsilyllithium across diphenylacetylene. Besides the addition product almost 90% of polymeric material was obtained. An anionic addition polymerization process may account for the course of reaction in both cases.

The behavior of starting material **10** in its reaction with potassium *tert*-butoxide was of special interest. In the analogous reaction with pentakis(trimethylsilyl)phenyldisilane we have observed a perfect regioselectivity for the cleavage of a trimethylsilyl group in the β-position to the phenyl group. However, for the case of **10** a mixture of the two possible anions **10a** to **10b** was found in a ratio of about 2 to 1 (Scheme 7).



Scheme 7. Reaction of **10** with potassium *tert*-butoxide

NMR Spectroscopy

^{29}Si NMR spectroscopy is most useful for the chemistry of oligosilanes. While the resonances for the tertiary silicon atom of alkylated tris(trimethylsilyl)silanes can be found at around −80 ppm, the alkynyl substituent causes a high-field shift to δ = −101 ppm. Replacement of one trimethylsilyl group by potassium causes another shift to approximately δ = −155 ppm. This behavior is in accordance with our previous observations on other silyl potassium compounds.[1]

Table 1. Increments for the calculation of ^{13}C NMR shifts of substituted alkynes[9,10,16]

Group	α	β
Me	+8.5	−3.6
*n*Bu	+11.1	−5.9
Ph	+12.7	−6.4
$SiMe_3$	+17.4	+21.8
$Si(SiMe_3)_3$	+11.5	+24.9
$CH_2Si(SiMe_3)_3$	+13.0	−4.3

In the case of alkynylsilanes ^{13}C NMR spectroscopy is also of some interest. As acetylenes have only two substituents it is easy to study their influence on the ^{13}C NMR shift. Using acetylene as a parent compound α- and β-shift effects can be observed upon replacement of a proton by another substituent.[9] While alkyl groups cause the α-carbon to resonate at a lower and the β-carbon at a higher field, phenyl groups effect both signals at a lower field with the β-shift being smaller. The trimethylsilyl group again gives rise to a shift to a lower field but the magnitude of the influence is reversed compared to the phenyl group.[10] The tris(trimethylsilyl)silyl group has a similar but even more pronounced influence (Table 1). This plain increment system can also be used advantageously for a rough estimate of disubstituted alkynes, as seen from Table 2, where the observed ^{13}C shift values for the tris(trimethylsilyl)silylated alkynes can be compared to those obtained by simple increment addition to the base value of δ = 71.9 ppm for acetylene.

Table 2. ^{13}C NMR shifts of $(Me_3Si)_3Si-C(A)=C(B)-R$ in ppm; incremental values in brackets

Group R	δ C(A)	δ C(B)
Me	73.1 (79.8)	105.2 (105.3)
$C_{10}H_{19}$	76.5 (77.5)	113.9 (107.9)
Ph	76.5 (89.8)	111.3 (109.5)
$SiMe_3$	107.9 (105.2)	117.7 (114.2)
$Si(SiMe_3)_3$	109.6 (108.3)	109.6 (108.3)
$CH_2Si(SiMe_3)_3$	73.4 (79.1)	110.8 (109.8)

X-ray Crystallography

As has already been mentioned only a few oligosilylacetylenes have been synthesized to date. It is therefore not completely surprising that no crystal structures of tertiary silylacetylenes have been reported so far. Even for secondary silylacetylenes only two examples can be found.[2,11] One reason for this obvious lack of structural investigations may be difficulties in obtaining good quality crystals. Most compounds investigated by us were either oils or solids with melting points close to room temperature. Nevertheless, we were able to determine the first examples of crystal structures of isotetrasilanylacetylenes. Compounds **3**, **6**, and **9** could be subjected to structure analysis (Table 3, Figures 1−3). The structural features of all three compounds are within the ranges of what is expected. Examples of the acetylenic triple bond length of alkynylsilanes range from 1.16 Å to 1.22 Å.[12] **3** [1.185(5) Å], **6** [1.217(6) Å] and **9** [1.205(5), 1.204(5) Å] fit into this range with **6** exhibiting the longest bond, probably reflecting the two bulky silyl groups. The tetrahedral bond angles around the central silicon atoms are clearly a function of the spatial demand of the substituents. This can be observed best for the diacetylene compound **9**, where the two trimethylsilyl groups open up at an angle of 117.4°. Deviations from the expected 180° for the CCSi angle are comparatively small for **3** [176.5(4)°] and **6** [178.9(4)°] and only for **9** [178.7(4), 173.3(3)°] was a

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

very slight bending observed. The two tris(trimethylsilyl)silyl groups of **6** exhibit an almost perfectly staggered conformation with respect to each other (Figure 2).

Figure 1. Conclusion

A number of alkyne substituted oligosilanes have been prepared mainly by the reaction of lithiated alkynes with chloro- or bromooligosilanes. Reaction of these compounds with potassium *tert*-butoxide showed considerably enhanced reactivity compared to silyl or alkyl-substituted oligosilanes. Usually within minutes formation of a silyl potassium compound and *tert*-butyltrimethylsilyl ether was complete. Phenylacetylene derived compounds (**3, 10**) are the most reactive among all investigated materials. Reaction with a compound possessing two alkynyl substituents (**9**) led to a vigorous and strongly colored reaction which did not yield soluble silicon containing material. The reaction of a propargylsilane (**7**) with the potassium alkoxide gave an initial rearrangement to the propynylsilane (**2**) followed by the formation of a propynylsilyl potassium compound (**2a**). An alkynylidene-bridged bisoligosilyl compound (**6**) could be used to obtain an oligosilyl dianion (**6a**) by means of a smooth reaction. With a similar propargylidene bridged compound (**8**) only mono-metallation could be achieved.

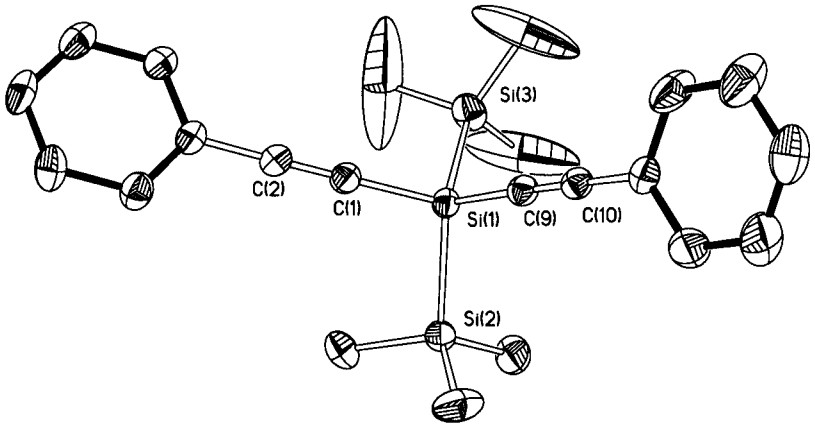

Figure 3. The molecular structure and numbering of **9** with 30% probability thermal ellipsoids; all hydrogen atoms have been omitted for clarity; selected bond lengths (Å) and bond angles (°) with estimated standard deviations: Si(1)−C(9) 1.843(4), Si(1)−C(1) 1.846(4), Si(1)−Si(3) 2.3501(16), Si(1)−Si(2) 2.3539(15), C(1)−C(2) 1.205(5), C(9)−C(10) 1.204(5), C(9)−Si(1)−C(1) 107.70(16), C(9)−Si(1)−Si(3) 109.34(13), C(1)−Si(1)−Si(3) 106.21(13), C(9)−Si(1)−Si(2) 109.38(12), C(1)−Si(1)−Si(2) 106.30(13), Si(3)−Si(1)−Si(2) 117.45(6), Si(1)−C(1)−C(2) 173.3(3), Si(1)−C(9)−C(10) 178.7(3)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In summary it can be concluded that alkynyl substituents substantially enhance the reactivity of oligosilanes towards potassium alkoxide attack. Given all the possible derivatization reactions of the alkynyl group, its introduction into oligosilyl anions considerably extends the scope of this chemistry.

Experimental Section

General Remarks: All reactions involving air-sensitive compounds were carried out under an atmosphere of nitrogen or argon using either Schlenk techniques or a glovebox. All solvents besides $CDCl_3$ were dried over sodium/potassium alloy under nitrogen and were freshly distilled prior to use. Potassium *tert*-butoxide was purchased from Merck. Other chemicals were obtained from different chemical suppliers and used as received.

Aqueous workup was performed by adding the reaction mixture to 2 M H_2SO_4 followed by separation of the layers. Subsequently, the aqueous layer was extracted twice with the indicated solvent. The combined organic layers were washed with a saturated aqueous sodium hydrogen carbonate solution and then dried over sodium sulfate.

^1H (300 MHz), ^{13}C (75.4 MHz), and ^{29}Si (59.3 MHz) NMR spectra were recorded on a Varian INOVA 300 spectrometer. Samples for ^{29}Si NMR spectra were either dissolved in deuterated benzene or chloroform, or the reaction samples were measured in the presence of a D_2O capillary in order to provide an external lock frequency signal. To compensate for the low isotopic abundance of ^{29}Si the INEPT pulse sequence was used to amplify the signal.[13]

GC analyses were carried out on an HP 5890 series II equipped with capillary column HP-1ms (25 m × 0.251 mm; 0.33 μm) and an HP 5971 mass spectrometer.

GC/MS samples of derivatized silyl anions were obtained by adding a solution of the nucleophile to a mixture of 10% ethyl bromide in diethyl ether or to the organic layer of a mixture of diethyl ether/2 M H_2SO_4 to give the corresponding ethylated or protonated silane species in a very rapid, clean and quantitative reaction.

Elementary analyses were carried out using a Heraeus Vario Elementar. Tetrakis(trimethylsilyl)silane,[14] tris(trimethylsilyl)silane,[1a] chlorotris(trimethylsilyl)silane,[15] tris(trimethylsilyl)silylpotassium,[1,16] propargyltosylate,[17] tris(trimethylsilyl)silylethyne (**1**),[1b] bis[tris(trimethylsilyl)silyl]ethyne (**6**),[1b] and bis[potassiobis(trimethylsilyl)silyl]ethyne (**6a**)[1b] were prepared according to literature procedures.

Propynyltris(trimethylsilyl)silane (2)

Bromotris(trimethylsilyl)silane: Tris(trimethylsilyl)silane (24.0 g, 97.0 mmol) was dissolved at room temperature in bromoform (100 mL). After 16 h the solution was heated to 70 °C for 1 h. After complete conversion (reaction control by GC) bromoform and methylenebromide were distilled off leaving bromotris(trimethylsilyl)silane (28.9 g, 91%) as colorless, deliquescent crystals. ^1H NMR (C_6D_6): δ = 0.29 (s, 27 H) ppm. ^{13}C NMR (C_6D_6): δ = 1.7 ppm. ^{29}Si NMR (THF, D_2O): δ = −12.7, −24.0 ppm. MS: *m*/*z* (%) = 326 (4), 328 (5) [M^+], 313 (6), 311 (5) [M^+ − Me], 174 (93) [Si_3Me_6], 159 (48) [Si_3Me_5], 73 (100) [$SiMe_3$].

Synthesis of 2: A 1-L round-bottomed flask was evacuated and then filled with propyne (approx. 41 mmol). The gas was condensed on diethyl ether (20 mL) at −70 °C in a flask equipped with a dropping funnel. At the same temperature *n*-butyllithium (21 mL, 42 mmol, 2 M in pentane) was added dropwise. The temperature was raised to −50 °C and bromotris(trimethylsilyl)silane (13.1 g, 40.0 mmol) in diethyl ether (20 mL) was added. The mixture was allowed to reach room temperature and was stirred for a further 16 h. Aqueous workup, evaporation of the solvent and distillation (100 °C, 0.05 mbar) yielded **2** (8.51 g, 75%) as a yellowish oil. ^1H NMR (C_6D_6): δ = 1.67 (s, 3 H), 0.44 (s, 27 H) ppm. ^{13}C NMR (C_6D_6): δ = 105.2, 73.1, 5.2, 0.5 ppm. ^{29}Si NMR (THF, D_2O): δ = −11.7, −100.5 ppm. MS: *m*/*z* = 286 (9) [M^+], 271 (20) [M^+ − Me], 213 (18) [M^+ − $SiMe_3$], 174 (75) [$Si(SiMe_3)_2$], 73 (100) [$SiMe_3$].

Tris(trimethylsilyl)silylphenylacetylene (3): Synthesis according to literature.[18] ^1H NMR ($CDCl_3$): δ = 7.46 (m, 2 H), 7.32 (m, 3 H), 0.23 (s, 27 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 132.0, 128.4, 127.9, 124.9, 108.6, 88.4, 0.7 ppm. ^{29}Si NMR ($CDCl_3$): δ = −11.5, −100.5 ppm. MS: *m*/*z* = 348 (13) [M^+], 275 (19) [M^+ − $SiMe_3$], 174 (70) [$Si(SiMe_3)_2$], 135 (25) [$PhSiMe_2$], 129 (26) [Si_3Me_3], 73 (100) [$SiMe_3$].

Dodecynyltris(trimethylsilyl)silane (4): In a 100-mL Schlenk flask equipped with a rubber septum and stirring bar, dodecyne (0.850 g, 5.11 mmol) was dissolved in diethyl ether (30 mL) and methyllithium (3.70 mL, 5.88 mmol, solution, 1.6 M in diethyl ether) was added dropwise via a syringe at −70 °C. After 20 min the temperature was raised to −20 °C followed by addition of chlorotris(trimethylsilyl)silane (1.70 g, 6.00 mmol) in diethyl ether (20 mL). The mixture was then stirred for 16 h at room temperature. Aqueous workup and evaporation of the solvent gave a brown oily solid, which was extracted with pentane (50 mL). Evaporation of the solvent and removal of the volatiles in vacuo (20 °C, 0.05 mbar) yielded **4** (1.84 g, 87%) as a yellow oil. ^1H NMR (C_6D_6): δ = 1.26 (broad signal, 16 H), 0.98 (m, 5 H), 0.32 (s, 27 H) ppm. ^{13}C NMR (C_6D_6): δ = 111.3, 76.5, 32.7, 30.5, 30.4, 30.2, 29.9 (2 ×), 29.4, 23.5, 21.1, 14.8, 1.0 ppm. ^{29}Si NMR (C_6D_6): δ = −11.7, −100.7 ppm. MS: *m*/*z* = 412 (14) [M^+], 339 (10) [M^+ − $SiMe_3$], 174 (100) [$Si(SiMe_3)_2$], 159 (16) [$Si(SiMe_3)_2$ − Me], 73 (100) [$SiMe_3$].

1-Trimethysilyl-2-[tris(trimethylsily)silyl]ethyne (5): Similar procedure as for compound **4** using **1** (1.00 g, 3.67 mmol), methyllithium (2.6 mL, 4.2 mmol, 1.6 M in diethyl ether), and chlorotrimethylsilane (0.33 g, 4.07 mmol) to yield **5** (1.10 g, 87%) as a colorless oil.[19] ^{29}Si NMR (C_6D_6): δ = −12.2, −20.3, −101.2 ppm. MS: *m*/*z* (%) = 344 (26) [M^+], 329 (16) [M^+ − Me], 271 (12) [M^+ − $SiMe_3$], 174 (54) [$Si(SiMe_3)_2$], 73 (100) [$SiMe_3$].

3-Propinyltris(trimethylsilyl)silane (7): Tris(trimethylsilyl)silylpotassium (4.24 mmol) in toluene (20 mL) was added to a solution of propargyltosylate (0.89 g, 4.24 mmol) in toluene (20 mL) at −50 °C. The solution was allowed to reach room temperature and was stirred for a further 16 h before the reaction was subjected to an extractive workup procedure. The residue was filtered through Celite yielding **7** (0.98 g, 81%) as a light yellow oil. ^1H NMR (C_6D_6): δ = 1.68 (t, *J* = 3.0 Hz, 1 H), 1.55 (d, *J* = 3.0 Hz, 2 H), 0.22 (s, 27 H), ppm. ^{13}C NMR (C_6D_6): δ = 84.9, 67.6, 0.8, −3.9 ppm. ^{29}Si NMR (C_6D_6): δ = −12.4, −78.0 ppm. MS: *m*/*z* (%) = 286 (2) [M^+], 271 (19) [M^+ − Me], 213 (100) [M^+ − $SiMe_3$], 197 (26) [$(C_3H_2)Si_3Me_5$], 129 (27) [Si_3Me_3], 73 (100) [$SiMe_3$].

1,3-Bis[tris(trimethylsilyl)silyl]propyne (8): Similar procedure as for the synthesis of **4** employing **7** (3.49 g, 12.3 mmol), butyllithium (7.7 mL, 12.3 mmol, 1.6 M in hexane), and chlorotris(trimethylsilyl)-silane (3.49 g, 12.3 mmol) to give a mixture of **8** and starting materials. Removal of the volatile products by Kugelrohr distillation leaves **8** (3.02 g, 46%) as a yellow oil. ^1H NMR (C_6D_6): δ = 1.80

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(s, 2 H), 0.35 (s, 27 H), 0.24 (s, 27 H) ppm. ^{13}C NMR (C_6D_6): δ = 110.8, 73.4, 0.9, 0.7, −1.3 ppm. ^{29}Si NMR (C_6D_6): δ = −12.3, −12.5, −80.2, −100.4 ppm. MS: *m*/*z* (%) = 532 (2) [M^+], 285 (100) [$(C_3H_2)Si(SiMe_3)_3$], 197 (11) [$(C_3H_2)Si_3Me_5$], 73 (44) [$SiMe_3$].

Hexamethyl-2,2-bis(phenylethynyl)trisilane (9)

2,2-Dibromohexamethyltrisilane: On hexamethyl-2,2-diphenyltrisilane[20] (7.2 g, 21.9 mmol) hydrogen bromide (approx. 20 mL) was condensed at −80 °C. A reflux condenser cooled to −80 °C was put on the flask, the bath removed and the hydrogen bromide was refluxed for 2 h. Subsequently the remaining hydrogen bromide and all volatiles were condensed into a liquid nitrogen cooled trap. The whole procedure was repeated once to ensure complete conversion. The dibromide was obtained as deliquescent crystals at room temperature (7.15 g, 98%). ^{1}H NMR ($CDCl_3$): δ = 0.34 (s, 18 H) ppm. ^{13}C NMR (C_6D_6): δ = −3.0 ppm. ^{29}Si NMR ($CDCl_3$): δ = 23.7, −10.0 ppm. MS: *m*/*z* (%) = 332/334 (8) [M^+], 180/182 (25) [Me_3Si-SiBr], 73 (100) [$SiMe_3$].

Synthesis of 9: Similar procedure as for the synthesis of **4** using phenylacetylene (3.57 g, 35.0 mmol), *n*-butyllithium (22.0 mL, 35.2 mmol, 1.6 M in hexane), and 2,2-dibromohexamethyltrisilane (5.00 g, 15.0 mmol) to give **9** (2.76 g, 49%) as a colorless oil. B.p. 135−142 °C (0.1 bar). ^{1}H NMR (C_6D_6): δ = 7.41 (m, 4 H), 6.91 (m, 6 H), 0.39 (s, 18 H) ppm. ^{13}C NMR (C_6D_6): δ = 132.1, 128.5, 128.4, 123.8, 110.2, 86.9, −1.4 ppm. ^{29}Si NMR ($CDCl_3$): δ = −13.7, −80.8 ppm.

Pentakis(trimethylsilyl)(phenylethynyl)disilane (10)

Bromopentakis(trimethylsilyl)disilane: Pentakis(trimethylsilyl)phenylsilane[16,21] (3.40 g, 6.83 mmol) was treated as described above for the synthesis of 2,2-dibromohexamethyltrisilane. At room temperature colorless, deliquescent crystals (3.30 g, 97%) of the bromo compound were obtained. ^{1}H NMR (C_6D_6): δ = 0.34 (s, 27 H), 0.28 (s, 18 H) ppm. ^{13}C NMR (C_6D_6): δ = 3.9, 2.9 ppm. ^{29}Si NMR ($CDCl_3$): δ = −9.4, −12.5, −69.1, −128.2 ppm.

Synthesis of 10: Similar procedure as for the synthesis of compound **4** using phenylacetylene (1.5 g, 3.48 mmol), methyllithium (9.25 mL, 14.8 mmol, 1.6 M in diethyl ether), and bromopentakis(-trimethylsilyl)disilane (2.20 g, 4.21 mmol) to give **10** (1.11 g, 51%) as colorless crystals. M.p. 75−84 °C. ^{1}H NMR (C_6D_6): δ = 7.68 (m, 1 H), 7.43 (m, 2 H), 6.96 (m, 2 H), 0.41 (s, 18 H), 0.38 (s, 27 H) ppm. ^{13}C NMR (C_6D_6): δ = 137.7, 131.6, 128.4, 124.8, 110.1, 90.9, 3.6, 1.9 ppm. ^{29}Si NMR (C_6D_6): δ = −9.4, −10.4, −98.0, −129.3 ppm.

General Procedure for the Synthesis of Potassium Silyls: In a nitrogen filled glove box the respective silane and potassium *tert*-butoxide (1.05 equiv. for mono-, and 2.10 equiv. for the dipotassium compounds) were dissolved in THF. The solution immediately turned yellow and after some time dark brown. Complete conversion was controlled by ^{29}Si NMR spectroscopy of a small aliquot. Yields were not easily determined by removal of the solvent because different ratios of THF coordinate to the anions. Derivatization reactions with sulfuric acid or ethyl bromide, which were analyzed by GC/MS, showed that formation of the anions was almost quantitative within the limits of detection.

[Propynylbis(trimethylsilyl)silyl]potassium (2a): ^{1}H NMR (C_6D_6): δ = 1.75 (s, 3 H), 0.15 (s, 18 H) ppm. ^{13}C NMR (C_6D_6): δ = 99.6, 95.2, 36.9, 3.4 ppm. ^{29}Si NMR (C_6D_6): δ = −6.8, −155.3 ppm. MS (ethyl bromide quench): *m*/*z* (%) = 242 (31) [M^+], 213 (24) [M^+ − Et], 169 (11) [M^+ − $SiMe_3$], 130 (100) [$Me_3SiSiEt$], 102 (51) [$HSiSiMe_3$], 73 (56) [$SiMe_3$].

[Bis(trimethylsilyl)silylphenylacetylene]potassium (3a): ^{1}H NMR (C_6D_6): δ = 7.00 (m, 2 H), 6.92 (m, 2 H), 6.77 (m, 1 H), 0.04 (s, 18 H) ppm. ^{13}C NMR (C_6D_6): δ = 129.8, 128.7, 127.5, 123.4, 115.2, 106.2, 3.3 ppm. ^{29}Si NMR (C_6D_6): δ = −7.0, −155.1 ppm.

[Dodecynylbis(trimethylsilyl)silyl]potassium (4a): ^{1}H NMR (C_6D_6): δ = 2.1 (m, 2 H), 1.35 (br. s, 4 H), 1.17 (br. s, 12 H), 0.77 (t, 3 H), 0.07 (s, 18 H) ppm. ^{13}C NMR (C_6D_6): δ = 103.7, 96.8, 32.0, 30.8, 29.9, 29.8, 29.6, 29.5, 29.0, 22.7, 21.5, 13.7, 3.4 ppm. ^{29}Si NMR (C_6D_6): δ = −7.3, −156.2 ppm. MS (ethyl bromide quench): *m*/*z* (%) = 368 (22) [M^+], 130 (90) [Si_2Me_3Et], 73 (100) [$SiMe_3$].

{1-Trimethysilyl-2-[bis(trimethylsily)silyl]acetylene}potassium (5a): ^{1}H NMR (C_6D_6): δ = −0.01 (s, 18 H), −0.04 (s, 9 H) ppm. ^{13}C NMR (C_6D_6): δ = 138.0, 109.9, 3.4, 1.1 ppm. ^{29}Si NMR (C_6D_6): δ = −7.6, −27.4, −159.6 ppm. MS (ethyl bromide quench): *m*/*z* (%) = 300 (20) [M^+], 227 (21) [M^+ − $SiMe_3$], 199 (40) [$(Me_3Si)_2$-Si(CC)H], 130 (37) [$Me_3SiSiEt$], 73 (100) [$SiMe_3$].

{1-Bis[bis(trimethylsilyl)silyl]-3-[tris(trimethylsily)silyl]propyne}-potassium (8a): ^{29}Si NMR (C_6D_6): δ = −8.1, −12.7, −82.0, −149.6 ppm.

[1,1,2,2-Tetrakis(trimethylsilyl)-1-(phenylethynyl)disilyl]potassium (10a): ^{29}Si NMR (C_6D_6): δ = −8.0, −13.2, −93.1, −188.9 ppm.

[1,1,1,2-Tetrakis(trimethylsilyl)-1-(phenylethynyl)disilyl]potassium (10b): ^{29}Si NMR (C_6D_6): δ = −6.0, −10.1, −128.4, −151.4 ppm.

Bis[bis(trimethylsilyl)methylsilyl]ethyne (6b): To the dipotassium compound **6a** (0.37 mmol) in diethyl ether (2 mL) dimethylsulfate (0.10 mL, 1.05 mmol) was added at 0 °C. The solution was stirred for 16 h at room temperature before it was subjected to an extractive workup. A colorless oil of **6b** (140 mg, 95%) was obtained. ^{1}H NMR (C_6D_6): δ = 0.26 (s, 6 H), 0.24 (s, 36 H) ppm. ^{13}C NMR (C_6D_6): δ = 114.2, −1.5, −7.8 ppm. ^{29}Si NMR (C_6D_6): δ = −15.6, −65.3 ppm. MS: *m*/*z* (%) = 402 (5) [M^+], 329 (29) [M^+ − $SiMe_3$], 232 (40) [Si − $(SiMe_3)_3$] − Me], 73 (100) [$SiMe_3$].

Bis[bis(trimethylsilyl)silyl]ethyne (6c): 6a (0.39 mmol) was added to a vigorously stirred mixture of H_2SO_4 (2 M, 5 mL) and diethyl ether (5 mL). After 10 min the aqueous layer was removed, the organic residue diluted twice with toluene and the solvent removed under reduced pressure. A colorless oil of **6c** (123 mg, 85%) was obtained. ^{1}H NMR (C_6D_6): δ = 3.83 (s, 2 H), 0.26 (s, 36 H) ppm. ^{13}C NMR (C_6D_6): δ = 110.3, −0.6 ppm. ^{29}Si NMR (C_6D_6): δ = −14.3, −91.0 ppm. MS: *m*/*z* (%) = 374 (5) [M^+], 301 (18) [M^+ − $SiMe_3$], 285 (99) [M^+ − $SiMe_3$ − CH_4], 241 (31) [$Me_3Si(Me)SiC{=}CSiSiMe_3$], 227 (36) [$Me_3Si(H)SiC{=}CSiSiMe_3$], 73 (100) [$SiMe_3$].

X-ray Crystallographic Studies: Measurements were carried out on a Bruker SMART Apex diffractometer with Mo-K_α radiation. The data were reduced to F_o^2 and corrected for absorption effects with SAINT[22] and SADABS,[23] respectively (Table 3). The structures were solved by direct methods and refined by full-matrix least-squares method (SHELXL-97).[24] All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were located in calculated positions to correspond to standard bond lengths and angles.

Acknowledgments

This study was carried out within the START project *Chiral polysilanes* (Y120) funded by the Austrian ministry of education, science and culture.

New Porous Lanthanide-Organic Frameworks: Synthesis, Characterization, and Properties of Lanthanide 2,6-Naphthalenedicarboxylates

Xiangjun Zheng,[a] Changyan Sun,[a] Shaozhe Lu,[b] Fuhui Liao,[c] Song Gao,[c] and Linpei Jin*[a]

Keywords: Carboxylate ligands / Coordination polymers / Hydrothermal synthesis / Lanthanides / X-ray diffraction

Three porous, 3-D coordination polymers $[Pr_4(NDC)_6(H_2O)_6]\cdot 2H_2O$ (**1**), $[Eu_4(NDC)_6(H_2O)_5]\cdot 3H_2O$ (**2**) and $[Yb_2(NDC)_3(H_2O)]\cdot H_2O$ (**3**) based on lanthanide 2,6-naphthalenedicarboxylates (NDC) were synthesized by hydrothermal reactions of lanthanide chlorides with NDC and their properties were investigated. Polymers **1**, **2** and **3** differ in the coordination environment of the Ln^{III} ions. Their 3-D networks are reminiscent of the shape of a compressed honeycomb, showing 1-D open channels. The guest water molecules and coordinating water molecules are enclathrated in the channels. The photophysical properties of the Eu^{3+} complex were investigated by high-resolution luminescence spectroscopy. The results indicate that there are four Eu^{III} ion sites in complex **2**, which is in accordance with the results of the single-crystal X-ray diffraction studies. Thermogravimetric and variable-temperature powder X-ray diffraction analyses show that the porous frameworks of this series of complexes are relatively stable. The framework remained even when the guest molecules were lost and did not collapse until the temperature reached 430 °C. The magnetic properties of **2** were also investigated.

Introduction

The assembly of porous networks has been an intriguing field for their potential applications in catalysis,[1,2] adsorption and separation processes,[3−9] ion exchange,[10,11] and sensor technology.[12,13] Many molecular-based porous materials constructed by coordination polymers have been reported.[6−9,14−17] These open-framework coordination polymers possess unprecedented pore size, shape and function. However, the main problem encountered in designing such coordination polymers is the interpenetration of networks or collapse of the framework upon removal of the guest molecules enclathrated in the cavities.[9] The modification of the ligand and the selection of the metal ions are the key points to avoid the interpenetration of networks. Thus far, porous coordination polymers have centered on the assembly of carboxylates and d-block metal ions such as Zn^{II},[9] Cu^{II},[14] and Co^{II} [17,18] as d-block metal ions have low coordination numbers and the coordination sites of d-block metal ions are easily occupied by the carboxylates, therefore interpenetration of the framework is less likely to occur. Lanthanide ions have higher coordination numbers, and it is more difficult to predict or control the coordination frameworks of lanthanide ions than their d-block analogues. The interpenetration of frameworks can frequently be seen in lanthanide coordination polymers because many coordination sites are accessible for the bridging ligand. However, incorporation of ancillary ligands (such as water molecules) into lanthanide coordination networks is also more feasible, and these ancillary ligands can occupy some coordination sites and prevent the frameworks from interpenetrating. At the same time, they may be removed without collapse of the lanthanide-organic framework, thereby generating porous solids with coordinatively unsaturated and Lewis-acidic lanthanide ions that have potential catalytic activity.[19,20] Additionally, the inherent flexibility of their coordination geometry is particularly attractive for the preparation of new network types as this greater structural ambivalence will lead to the synthesis of unprecedented structures. Based on the fact that lanthanide ions have a high affinity for oxygen-containing ligands, we selected a rigid linear ligand, 2,6-naphthalenedicarboxylate, to construct lanthanide coordination polymers. In the present case, we report the synthesis and structure of lanthanide naphthalenedicarboxylates; their properties were inves-

tigated systematically. They are porous and quite thermally stable because they have channels with incorporated solvents, which may be removed without the collapse of the framework.

Results and Discussion

Syntheses and Structures

Dipotassium 2,6-naphthalenedicarboxylate easily forms a precipitate upon the addition of lanthanide chloride, therefore in the preparation of the coordination polymers, the 2,6-naphthalenedicarboxylate was acidified first to facilitate the growth of crystals. 1,10-Phenanthroline (phen), which is a mild organic base, was also added to promote the hydrothermal reaction. Klinowski et al. have reported the crystal structure of $[Yb_2(NDC)_3(H_2O)]\cdot 2H_2O$ from the reaction of $YbCl_3\cdot 6H_2O$, 2,6-naphthalenedicarboxylic acid and triethylamine.[21] The difference between $[Yb_2(NDC)_3(H_2O)]\cdot 2H_2O$ and complex **3** is a lattice water molecule, which cannot have a significant effect on the crystal structure. Therefore, only the structures of complexes **1** and **2** will be discussed here.

There are four crystallographically independent Ln^{III} cations and six NDC anions in the unit cells of **1** and **2**, while for **3** there are only two Yb^{III} ions and three NDC anions in the asymmetric unit. In **1**, **2** and **3**, the Ln^{III} ions are all coordinated to oxygen atoms, with Ln−O distances in the range 2.357(9)−2.745(12) Å for **1**, 2.302(16)−2.625(15) Å for **2** and 2.169(9)−2.323(19) Å for **3**, characteristic of the lanthanide contraction. The NDC ligand adopts a bis(bidentate bridging) coordination mode where every NDC ligand bridges four Ln^{III} cations.

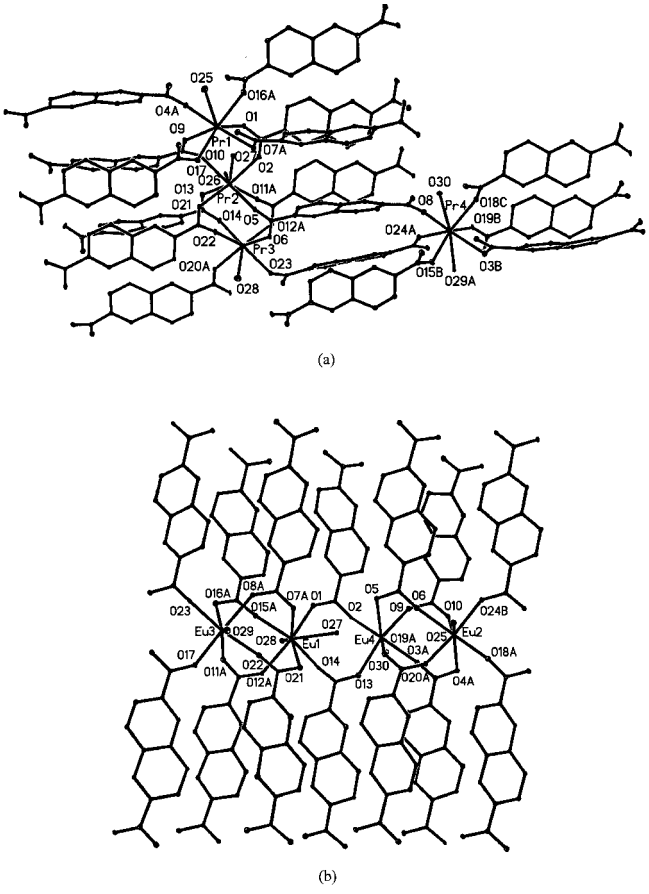

Figure 1. Coordination environment of **1** (a) and **2** (b); lattice water molecules and all hydrogen atoms have been omitted for clarity; thermal ellipsoids are shown at 10% probability

There are four Pr^{III} ions, six NDC anions, six coordinated water molecules and two lattice water molecules in the asymmetric unit of **1**. Pr1 and Pr3 are both sevenfold coordinated, with six oxygen atoms from six NDC ligands and one oxygen atom from a water molecule, while Pr2 and Pr4 are both eightfold coordinated, with six oxygen atoms from six NDC ligands and two oxygen atoms from two water molecules [see (a) in Figure 1]. Pr1 and Pr2 are connected by two μ_2-carboxylates from two NDC ligands. Pr2 and Pr3 are connected by four μ_2-carboxylates from four NDC ligands; Pr4 is connected to Pr2 and Pr3 through the bridging of two NDC ligands. The Pr^{3+} ions along the *a*-axis are bridged together, resulting in an infinite zigzag chain with the order Pr3···Pr2···Pr1···Pr4A···Pr3A···, with Pr···Pr distances of 4.133(2), 4.196(2), 4.131(2) and 5.001(2) Å, respectively. The chains may be viewed as secondary building blocks that are further cross-linked by the $C_{10}H_4$ spacers of the NDC anions. when viewed along the *a*-axis, the resulting 3-D network of **1** is reminiscent of the shape of a compressed honeycomb, showing 1-D open channels (Figure 2). The guest water molecules and coordinated water molecules are enclathrated in the channels.

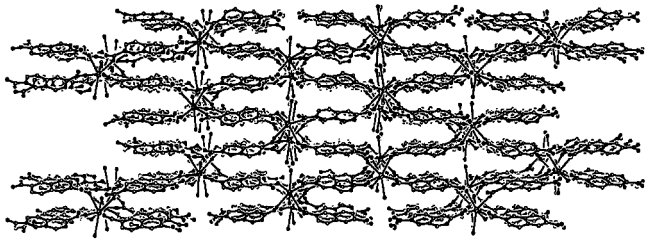

Figure 2. 3-D open-framework of **1** containing 1-D channels viewed along the *a*-axis; all hydrogen atoms and lattice water molecules have been omitted for clarity

There are four Eu^{III} ions, six NDC anions, five coordinated water molecules and three lattice water molecules in the asymmetric unit of **2**. Eu2, Eu3 and Eu4 have a sevencoordinate environment [see (b) in Figure 1] like Pr1 and Pr3 in **1**, while Eu1 is located in an eight-coordinate environment like Pr2 and Pr4 in **1**. Eu1 and Eu3 are connected by four μ_2-carboxylates from four NDC ligands. This is also the case for Eu2 and Eu4; Eu1 and Eu4 are linked by two μ_2-carboxylates from two NDC ligands. The Eu^{3+} ions along the *a*-axis are arranged in the order Eu3···Eu1···Eu4···Eu2···Eu3A···, with Eu···Eu distances of 4.997(2), 4.073(2), 4.805(2) and 4.064(2) Å, respectively. When viewed along the *a*-axis, this complex exhibits the same porous honeycomb-like architecture as **1**. Removing all hydrogen atoms, the coordinated and guest water mol-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ecules from the crystal structure of **2** gives the ball-and-stick model and the space-filling model shown in Figure 3. The ball-and-stick model shows a quite large opening in the cross section of the open channel, but the space-filling model shows that only the middle part of this is an effective cavity, with dimensions of about 5.0 × 2.1 Å^2.

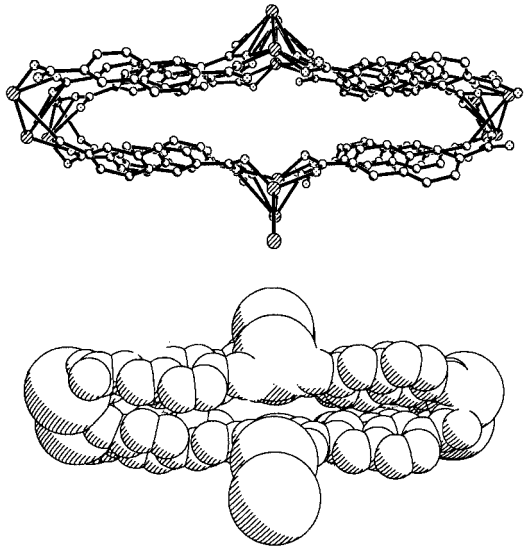

Figure 3. Cross-section of the open channel in **2** (all hydrogen atoms and water molecules have been omitted): ball-and-stick model (top), space-filling model (bottom)

These results show that **1**, **2** and **3** are different in the coordination environment of Ln^{III} ions, but they nevertheless form similar 3-D porous coordination polymers with the same topology. The sizes of the pores are also similar. When viewed along the *b*-axis, the coordination polymers of **1**, **2** and **3** can exhibit 3-D inorganic-organic hybrid architectures (Figure 4). The inorganic sheets are composed of Ln^{3+} ions, and the organic sheets are composed of NDC ligands; the two sheets alternate. The adjacent sheets are linked together through $Ln-O_{COO^-}$ coordination bonds.

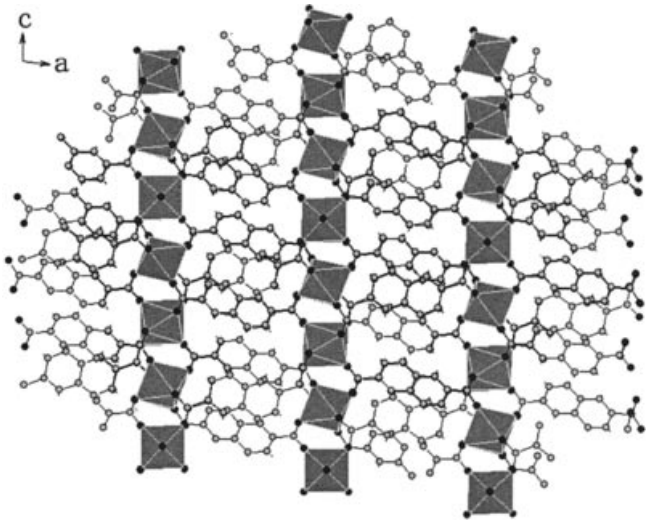

Figure 4. The inorganic-organic hybrid structure of **2**

Photophysical Properties of 2

The Eu^{III} ion is frequently used as a structural probe to investigate local symmetry.[22] The lowest emission level, $^5D_0$, and the ground state, $^7F_0$, are both nondegenerate, therefore the number of excitation peaks corresponding to the $^7F_0 \rightarrow {}^5D_0$ transition will reveal the number of Eu^{3+} ions with different coordination environments in the compound. The high-resolution emission spectrum of **2** corresponding to $^5D_0 \rightarrow {}^7F_J$ (J = 0−4) transitions excited at a wavelength of 355 nm at 77 K is shown in Figure 5. The most intense transition is $^5D_0 \rightarrow {}^7F_2$, which implies red emission light of **2**. No obvious and direct information about the Eu^{3+} ion sites can be obtained from Figure 5, but from the time-resolved spectra (Figure 6) corresponding to $^5D_0 \rightarrow {}^7F_J$ (J = 1, 2) transitions, it can be seen that both the shape and number of the emission peaks change. It can be concluded that there is more than one Eu^{3+} ion site in **2**. Selective excitation techniques were applied to further probe the number of Eu^{3+} ion sites in **2**. With 16107 and 16232 cm^{-1} as the monitoring wavenumbers, and scanning in the range 17280−17229.5 cm^{-1} ($^7F_0 \rightarrow {}^5D_0$), the excitation spectra shown in Figure 7 (a and b) were obtained. There are obviously three groups of peaks located at 17260.7, 17255.4 and 17249.1 cm^{-1}, respectively. Although a broadened $^7F_0 \rightarrow {}^5D_0$ excitation band is often seen in europium coordination polymers, it is worthy of note that there is a shoulder at the peak located at 17253.3 cm^{-1}. The average Eu−O bond lengths for Eu1, Eu2, Eu3 and Eu4 are 2.412, 2.372, 2.372 and 2.391 Å, respectively. However, around Eu2 there is a lattice water molecule, O26, and the distance between Eu2 and O26 [2.80(2) Å] suggests a weak coordination interaction, making the coordination bonds around Eu2 more ionic than those around Eu3. The longer a bond is, the more ionic character the bond possesses and the higher the energy needed to excite the europium ion. Therefore the four peaks at 17260.7, 17255.4, 17253.3 and 17249.1 cm^{-1} in Figure 7a can be ascribed to the $^5D_0$ levels of Eu1, Eu4, Eu2 and Eu3, respectively, confirming that

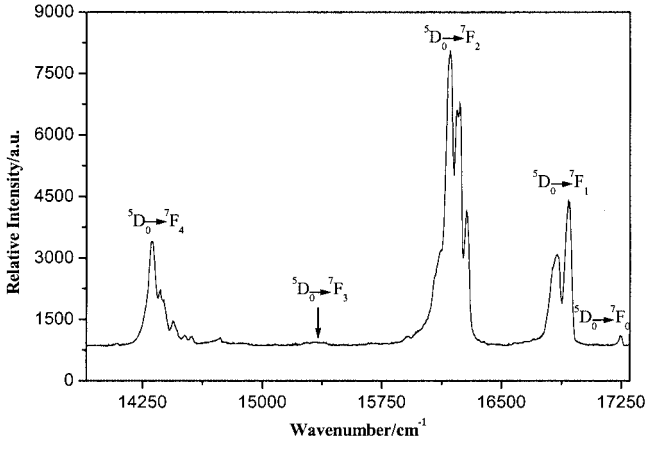

Figure 5. Emission spectrum of **2** corresponding to $^5D_0 \rightarrow {}^7F_J$ (J = 0 ~ 4) transitions at 77 K (λ_{exc} = 355 nm)

four Eu^{3+} ion sites exist in **2**, which is in agreement with the X-ray diffraction results.

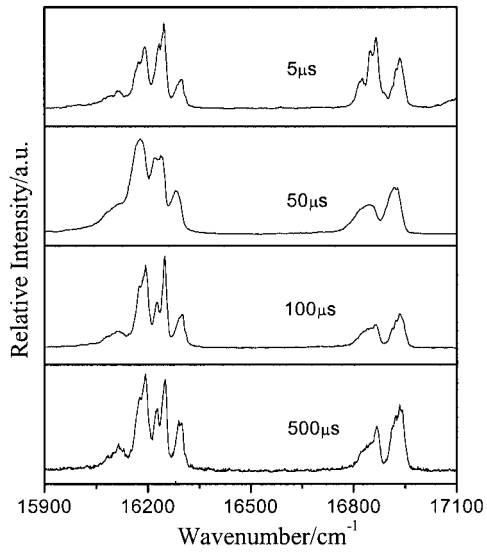

Figure 6. Time-resolved spectra of **2** at 77 K in the range 17100−15900 cm^{-1}; delay time: 5 μs, 50 μs, 100 μs and 500 μs; λ_{exc} = 355 nm

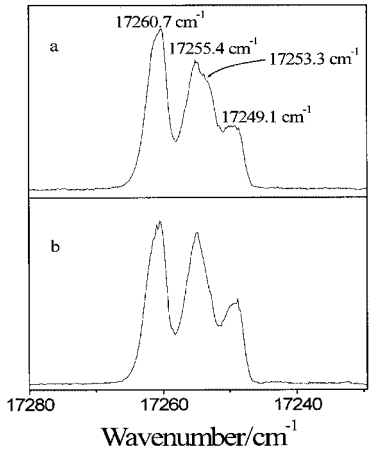

Figure 7. Excitation spectra of **2**; analyzing wavenumbers: a 16107 cm^{-1}; b 16232 cm^{-1}

Thermal Stability Analysis of 2

TG analysis of **2** is consistent with the crystallographic observations. The first weight loss of 5.06% from 103 °C to 186 °C (Figure 8) corresponds to the loss of three lattice water molecules and three coordinated water molecules (calculated: 5.31%), leaving a framework of $[Eu_4(NDC)_6 \cdot 2H_2O]$. Between 271 °C and 308 °C, the sample undergoes a second weight loss of 1.31%. During this process the two coordinated water molecules that have a stronger interaction with the Eu^{3+} ions [Eu1−O28: 2.474(15) Å; Eu2−O25: 2.451(15) Å] and are also involved in hydrogen bonding with carboxylate oxygen atoms [O25···O14 ($-x + 1/2$, $y + 1/2$, $-z + 1/2$) 2.758 Å; O28···O18 ($-x + 3/2$, $y - 1/2$, $-z + 1/2$) 2.844 Å] are removed (calculated: 1.77%), leaving a framework of $[Eu_4(NDC)_6]$. $[Eu_4(NDC)_6]$ remains stable up to 430 °C at which temperature it begins to decompose.

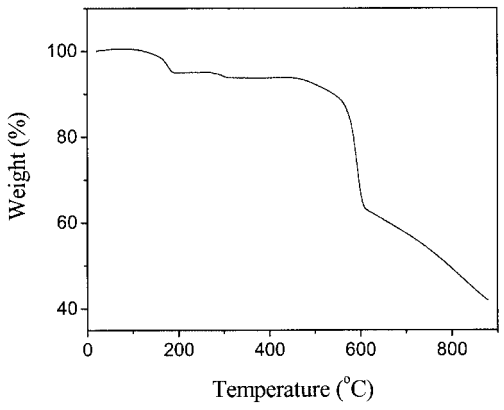

Figure 8. TG curve of **2**

To further test the thermal stability of **2**, powder samples were examined by powder X-ray diffraction analysis. Corresponding to the TG analysis, powder XRD patterns (Figure 9) were recorded at 27, 200, 250, 300, 350, 400, 450, 500 and 700 °C. It can be seen from Figure 9 that the XRD pattern at 200 °C is different from that at room temperature. The major peaks shift a little to higher 2θ value, indicating that a distortion of the structure has occurred, although this does not affect the existence of the framework. From 200 °C to 400 °C the major peaks in the XRD patterns at five different temperatures show no change in their position, indicating that the framework is able to survive the heat treatment and is thermally stable despite the removal of the water molecules. Above 450 °C the XRD pattern changes significantly, revealing the collapse of the framework, which is in accordance with the result of thermogravimetric analysis.

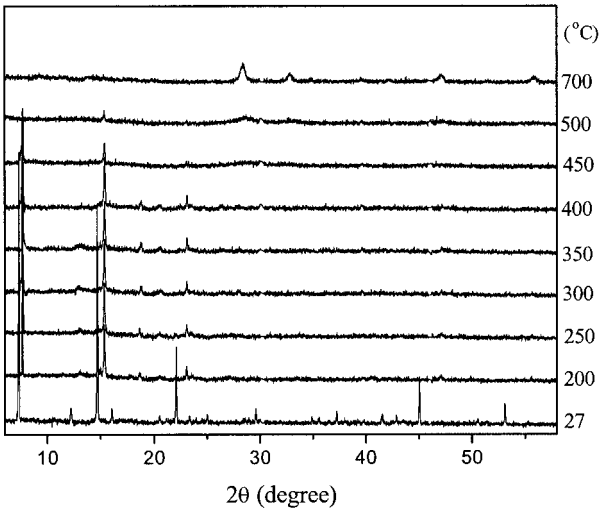

Figure 9. Powder X-ray diffraction patterns of **2** at different temperatures

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The results of thermogravimetric analyses for **1** and **3** show a similar stability to **2**.

Magnetic Properties of 2

The variable temperature magnetic susceptibility of **2** was measured in the range 2−304 K. The plot of $\chi_M T$ vs. T is shown in Figure 10, where χ_M is the corrected molar magnetic susceptibility per $[Eu]_4$ unit. The observed $\chi_M T$ at room temperature is 5.0 $cm^3 \cdot mol^{-1} \cdot K$, less than the value 6.0 for four Eu^{III} ions calculated from the van Vleck equation allowing for population of the lower excited state of ^7F_J (Eu^{3+}) in **2** at 293 K. As the temperature is lowered, $\chi_M T$ decreases continuously due to the depopulation of the Stark levels for a single Eu^{III} ion. At the lowest temperature, $\chi_M T$ is close to zero, indicating a $J = 0$ ground state of the Eu^{III} ion ($^7F_0$). The magnetic susceptibility above 150 K follows the Curie−Weiss law due to the presence of thermally populated excited states.

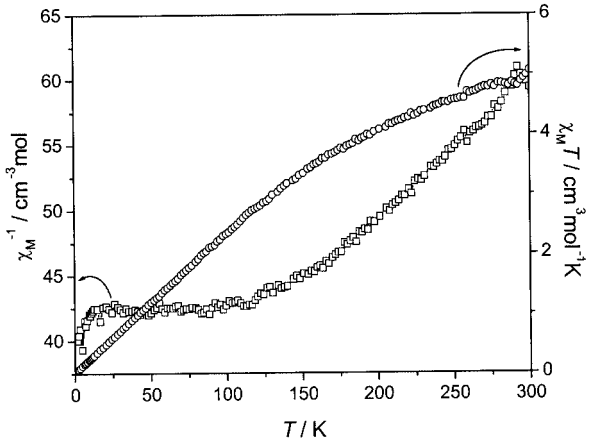

Figure 10. Plot of the temperature dependence of $\chi_M T$ (O) and χ_M^{-1} (□) for the title complex (per $[Eu]_4$unit)

Experimental Section

General: $PrCl_3 \cdot 6H_2O$, $EuCl_3 \cdot 6H_2O$ and $YbCl_3 \cdot 6H_2O$ were prepared by dissolving their oxides in concentrated hydrochloric acid and then evaporating the solvents dryness. All the other reagents are commercially available and were used without further purification. Elemental analyses were obtained on an Elementar Vario EL analyzer. The IR spectra were recorded with a Nicolet Avatar 360 FT-IR spectrometer using the KBr pellet technique. Thermogravimetric analyses were performed with a TGA: 951 Thermogravimetric Analyzer. The magnetic susceptibilities were obtained on a crystalline sample using an Oxford MagLab System 2000 magnetometer. The experimental susceptibilities were corrected for the sample holder and the diamagnetism contributions estimated from Pascal's constants. The powder X-ray diffraction patterns were recorded on a Bruker AXS D8 ADVANCE diffractometer.

$[Pr_4(NDC)_6(H_2O)_6] \cdot 2H_2O$ (1): Two drops of hydrochloric acid (1.65 $mol \cdot L^{-1}$) were added to a mixture of dipotassium 2,6-naphthalenedicarboxylate (0.044 g, 0.15 mmol) and H_2O (3 mL) and the mixture was stirred. $PrCl_3 \cdot 6H_2O$ (0.036 g, 0.1 mmol) and phen·H_2O (0.02 g, 0.1 mmol) were then added. The mixture was sealed in a 25 mL stainless steel reactor with Teflon liner and heated at 200 °C for 72 h. Green crystals of **1** were obtained in 76.3% yield (0.038 g). $C_{72}H_{52}O_{32}Pr_4$ (1992.8): calcd. C 43.40, H 2.63; found C 43.86, H 2.61. IR data (KBr pellet): $\tilde{\nu}$ = 3446 s, 2970 m, 1602 m, 1542 s, 1408 s, 1352 s, 1196 m, 924 m, 797 m, 560 m, 493 m cm^{-1}.

$[Eu_4(NDC)_6(H_2O)_5] \cdot 3H_2O$ (2): Two drops of hydrochloric acid (1.65 $mol \cdot L^{-1}$) were added to a mixture of dipotassium 2,6-naphthalenedicarboxylate (0.044 g, 0.15 mmol) and H_2O (3 mL) and the mixture was stirred. $EuCl_3 \cdot 6H_2O$ (0.037 g, 0.1 mmol) and phen·H_2O (0.04 g, 0.2 mmol) were then added. The mixture was sealed in a 25 mL stainless steel reactor with Teflon liner and heated at 200 °C for 72 h. Light-yellow crystals of **2** were obtained in 78.4% yield (0.04 g). $C_{72}H_{52}Eu_4O_{32}$ (2037.0): calcd. C 42.45, H 2.57; found C 42.99, H 2.24. IR data (KBr pellet): $\tilde{\nu}$ = 3508 m, 1602 m, 1547 s, 1491 s, 1412 s, 1353 s, 1199 m, 927 m, 795 s, 564 m, 492 m cm^{-1}.

$[Yb_2(NDC)_3(H_2O)] \cdot H_2O$ (3): Two drops of hydrochloric acid (1.65 $mol \cdot L^{-1}$) were added to a mixture of dipotassium 2,6-naphthalene-

dicarboxylate (0.044 g, 0.15 mmol) and H_2O (15 mL) and the mixture was stirred. $YbCl_3 \cdot 6H_2O$ (0.039 g, 0.1 mmol) was then added. The mixture was sealed in a 50 mL stainless steel reactor with Teflon liner and heated at 180 °C for 72 h. Light-yellow crystals of **3** were obtained in 29.3% yield (0.015 g). $C_{36}H_{22}O_{14}Yb_2$ (1024.6): calcd. C 42.20, H 2.16; found C 42.08, H 2.31. IR data (KBr pellet): $\tilde{\nu}$ = 3447 m, 2977 m, 1693 s, 1602 s, 1574 s, 1423 s, 1293 s, 1193 m, 775 m, 452 m cm^{-1}.

Measurement of the High-Resolution Luminescence Spectra: The excitation light source was a YAG:Nd laser which emits at 1.064 μm, and the excitation wavelength was 355 nm. The sample was placed in a dewar and cooled with liquid nitrogen. The fluorescence data were collected at right angles through a Spex 1403 monochromator with a photomultiplier tube, then averaged with a Boxcar integrator and finally transferred to a computer.

X-ray Crystallographic Study: The X-ray single-crystal data collection for complexes **1**, **2** and **3** was performed on a Bruker Smart 1000 CCD diffractometer, using graphite-monochromated Mo-K_α radiation (λ = 0.71073Å). Semiempirical absorption corrections were applied using the SADABS program. The structures were solved by direct methods and refined by full-matrix least-squares on F^2 using the SHELXTL-97 program.[23] All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were generated geometrically and treated by a mixture of independent and constrained refinement. Experimental details for X-ray data collection of **1**, **2** and **3** are presented in Table 1, while selected bond lengths for **1**, **2** and **3** are listed in Table 2.

CCDC-228787−228789 (for **1**−**3**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Ru^{II} Complexes of Bis(1,10-phenanthrolin-2-yl)diazines

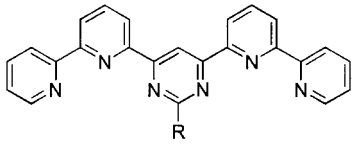
Darren Brown,[a] Ruifa Zong,[a] and Randolph P. Thummel*[a]

Keywords: Bridging ligands / Ruthenium / Phenanthrolines / Diazines

A series of three bis-tridentate bridging ligands has been prepared in which two 1,10-phenanthroline units have been symmetrically appended to a central pyridazine, pyrimidine, or pyrazine ring. These ligands have been treated with [Ru(tpy-d_{11})Cl_3] to afford both mono- and dinuclear complexes whose photo- and electrochemical properties have been evaluated (tpy = 2,2′:6′,2′′-terpyridine). A structural comparison is made between [(tpy)Ru(**3**)Ru(tpy)]$(PF_6)_4$ and a previously reported complex involving 2,2′-bipyridines in place of phenanthrolines on the bridging ligand and surprisingly little difference is found.

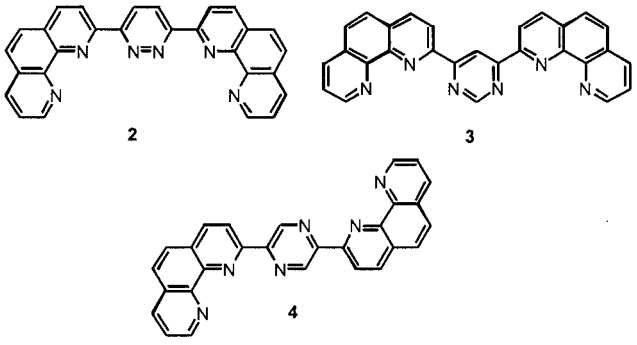
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Lehn and co-workers have constructed an elegant series of bis-terdentate ligands (**1**) based on a central pyrimidine ring with the intent of using these systems as bridging ligands for the formation of rack-type polynuclear complexes.[1] An important aspect of constructing such rack systems is the ability to arrange the bridging units in a parallel array to preserve a rectangular rack.[2] They found that the spatial relationship between two bound Ru(tpy) units was governed by the nature of the central substituent R, which was varied between hydrogen, methyl, phenyl, and 9-anthracenyl. When R = H, the planes of the two Ru-bound terpyridines defined a convergence angle of 36.3°, where a parallel arrangement (angle = 0°) was desired for optimum rack formation. This deformation results from a pinching of the ligand which causes the two outer pyridine groups to move closer to one another. We reasoned that further constraining the ligating portion of the system by substituting 1,10-phenanthroline (phen) for the 2,2′-bipyridine (bpy) subunits might offset this pinching effect and result in a more parallel arrayed system.



1

In an earlier work we have reported the preparation and Ru^{II} complexation of a series of diphen-substituted diazines **2**−**4**.[3] All three ligands formed mononuclear heteroleptic complexes [Ru(tpy-d_{11})(L)]$^{2+}$ (tpy-d_{11} = perdeuterio-2,2′:6′,2′′-terpyridine), while **3** and **4** also formed dinuclear complexes [(tpy-d_{11})Ru(L)Ru(tpy-d_{11})]$^{4+}$. The use of tpy-d_{11} in place of the protio-analogue greatly facilitated analysis of the NMR spectra. The chemical shifts of the protons on the central pyrimidine or pyrazine ring indicated that these resonances were consistent with the additivity of deshielding effects due to the attached phens with shielding effects from the coordinated tpys. In this paper we report on the structural properties of [(tpy)Ru(**3**)Ru(tpy)]$^{4+}$, as well as on the electronic and photophysical properties of the Ru^{II} complexes of **2**−**4**.



2 **3** **4**

A crystal of [(tpy)Ru(**3**)Ru(tpy)]$(PF_6)_4$ suitable for X-ray analysis was grown from acetonitrile/acetone. In this instance the use of protio-tpy as the auxiliary ligand was preferred. An ORTEP plot showing the structure of the cation is illustrated in Figure 1, and selected structural data is summarized in Table 1 along with the corresponding data from the reported structure for [(tpy)Ru(**1**)Ru(tpy)]$(PF_6)_4$, where R=H.[1] We were quite surprised by the close similarity of the two structures. The central benzo-ring of the phen subunits in **3** pulls C5 and C8 closer by 0.20 Å, and this may straighten out the ligand somewhat. However, this

[a] Department of Chemistry, 136 Fleming Building, University of Houston,
Houston, Texas 77204-5003, USA

change is more than compensated by a lengthening of the C10−C17 bond. The bond angles beyond the chelate rings are found to decrease on the phen side of **3** by about 4.2°, while they increase on the side that pyrazine is coordinated by 1.9°. The overall pinching angle of the molecule actually increases from 25.6° to 30.8° in the complex of **3**. These changes in ligand geometry in going from **1** to **3** are moderated by small adjustments in the Ru−N bond lengths - the Ru−N12 distance is shortened by 0.013 Å and Ru−N15 by 0.015 Å so that the convergence angle remains essentially the same.

[a] Numbering pattern from Figure 1 with the same relative atom positions for both complexes.

It is interesting to note that the bridging ligand is slightly bent in both complexes, with a larger bend for the complex of **3**. Figure 2 shows how this relatively small deformation is amplified by the tpy ligands which are splayed much farther apart on one side of the complex. On the closer side, the carbon atoms C34 and C34′ are separated by 3.55 Å, while C28 and C28′ are 3.35 Å apart so that some π-stacking effects may be important. On the further side, C22 and C22′ are separated by 7.73 Å. In the complex of **1**, the "open" side of tpy is occupied by a molecule of acetone solvent; this feature is not observed for the complex of **3**. However, the crystal packings are remarkably similar in both cases. It appears that the distortions from ideal octahedral geometry around Ru^{II} caused by tridentate complexation with tpy dictate the shape of the complex, and these effects cannot be greatly influenced by structural modification of the bridging bis-tridentate moiety. The ability of these ligands to participate in rack-type polynuclear structures involving octahedral centers is therefore somewhat compromised.

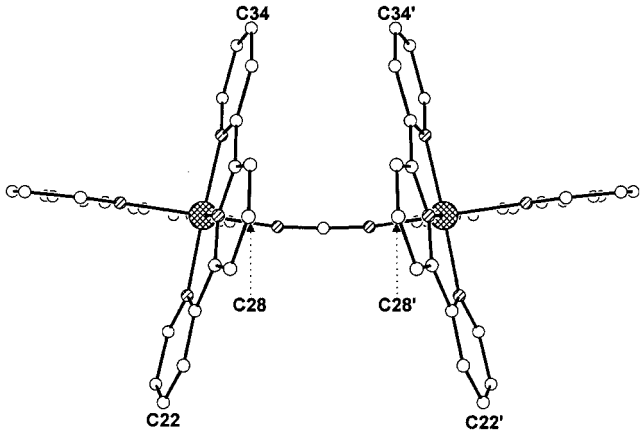

Figure 2. Side view of the cation of [(tpy)Ru(**3**)Ru(tpy)]$(PF_6)_4$

The electronic absorption and emission properties of the mono- and dinuclear complexes of **2**−**4** are summarized in Table 2, and the spectra involving **3** and **4** are illustrated in Figure 3. The mono- and dinuclear complexes all show long wavelength absorption bands that may be attributed to a metal-to-ligand charge-transfer (MLCT) state typically associated with such Ru^{II} polypyridine complexes.[4] This state involves the photoexcitation of an electron from the HOMO, which is a metal-centered d orbital, to the LUMO, which is a π*-orbital localized on one of the ligands. In the cases of the heteroleptic mononuclear complexes of **2**−**4**, the MLCT state consists of two components, one involving the more electronegative and more delocalized bridging diazine and the other involving the tpy-d_{11} ligand. This latter component shows a fairly consistent absorption at higher energy (445−451 nm), reflecting the higher energy of the π*-state for tpy. The lower energy component involving the diazine decreases in energy in the order **2** (522 nm), **4** (530 nm), **3** (538 nm). The energy difference may partly be associated with the disposition of the uncoordinated phen ring. For the complex of **3**, this ring is relatively unhindered in either planar conformation, while the complexes of **4** and **2** show increasing steric hindrance to ligand planarity. The allowed transitions also follows the same trend as can be seen by looking at the ratios of the molar absorptivities for

$[(tpy\text{-}d_{11})Ru(\mathbf{3})Ru(tpy\text{-}d_{11})]^{4+}$	647 (10500), 569 (10360) 444 (24040)	842	2.4×10^{-5}	+1.38, +1.56	−0.33, −0.83, −1.56
$[(tpy\text{-}d_{11})Ru(\mathbf{4})Ru(tpy\text{-}d_{11})]^{4+}$	636 (15300), 586sh (6010), 447 (14520)	839	1.1×10^{-4}	+1.36, +1.56	−0.35, −0.76, −1.37

[a] 5×10^{-5} M in CH3CN at 25 °C. [b] Solutions were 0.1 M TBAP in CH_3CN; the sweep rate was 200 mV/s. [c] Referenced to $[Ru(bpy)_3]Cl_2$ in air-equilibrated water (Φ = 0.028).

the two bands for each mononuclear complex. The ratio of the molar absorptivities for the MLCT bands for the tpy vs. the diazine moiety is 1.56 for the complex of **2**, 1.09 for **4**, and 0.84 for **3** which is the most planar.

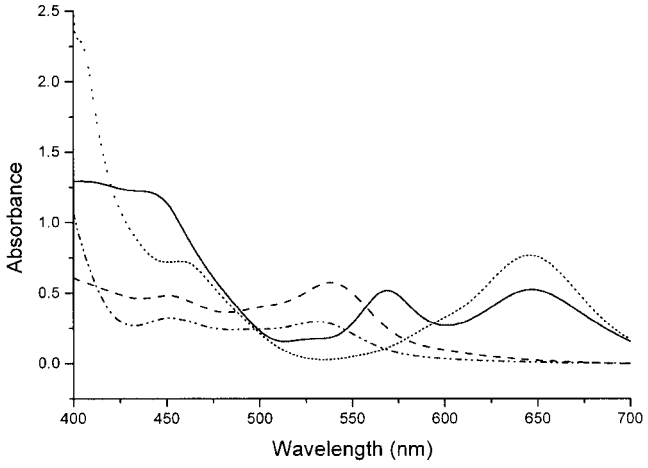

Figure 3. Electronic absorption spectra for Ru^{II} complexes of **3** and **4** in CH_3CN (5×10^{-5} M): $[Ru(\mathbf{3})(tpy\text{-}d_{11})]^{2+}$ (— —), $[Ru(\mathbf{4})(tpy\text{-}d_{11})]^{2+}$ (·· —·· —), $[(tpy\text{-}d_{11})Ru(\mathbf{3})Ru(tpy\text{-}d_{11})]^{4+}$ (—), $[(tpy\text{-}d_{11})Ru(\mathbf{4})Ru(tpy\text{-}d_{11})]^{4+}$ (····)

The dinuclear complexes of **3** and **4** both show enhanced MLCT bands associated with the two auxiliary tpy-d_{11} ligands that are very roughly double their mononuclear counterparts. The longer wavelength components are shifted to much lower energies, hence, the color is green. As has been observed earlier for other diazine-bridged dinuclear Ru^{II} complexes,[4] two bands are seen at longer wavelength. The spectrum for the pyrimidine system shows bands at 647 and 569 nm, whereas that of the pyrazine system shows a strong band at 636 with a shoulder at 586 nm.

All five complexes show weak to medium emission bands when excited at their long wavelength absorption maximum. These emissions follow the expected trend based on the absorptions of the mononuclear complex so that the Stokes shifts remain almost constant at 213−215 nm. The dinuclear complexes show weaker emissions at lower energies, which may be due to quenching by the second metal center.

The redox properties are also consistent and well behaved (reported in Table 2). All five complexes show metal-based Ru^{II}/Ru^{III} oxidations in the range of 1.36−1.40 V. For the dinuclear complexes a second wave at 1.56 V is observed for oxidation of the second metal. This second wave is separated by 0.18−0.20 V from the first wave, indicating a strong interaction between the two metal centers. As observed previously, the interaction is stronger when the metal centers communicate through a pyrazine as opposed to a pyrimidine bridge. Reductions are typically ligand based. For the mononuclear complexes, the first two reductions lie in the range of −0.72 to −0.84 V and −1.18 to −1.26 V, and are associated with the complexed diphen−diazine ligand. The third reduction for these systems is assigned to the tpy-d_{11} ligand (−1.55 to −1.62 V). For the dinuclear complexes, complexation by a second metal increases the reduction potentials associated with the bridging diazine ligand by about +0.4 V.

Experimental Section

The preparation of the ligands **2−4** and their Ru^{II} complexes has been reported.[3] Electronic spectra were obtained on a Perkin−Elmer Lambda 3B spectrophotometer. Emission spectra were obtained on a Perkin−Elmer LS-50 luminescence spectrometer. Cyclic voltammetry was carried out in a conventional three-electrode cell with a BAS-27 voltammeter and a Houston Instruments model 100 X-Y recorder according to a previously described procedure.[5]

X-ray Determination: All measurements were made with a Siemens SMART platform diffractometer equipped with a 1 K CCD area detector. A hemisphere of data (1271 frames at 5 cm detector distance) was collected using a narrow-frame method with scan widths of 0.30° in omega and an exposure time of 30 s/frame. The first 50 frames were remeasured at the end of data collection to monitor instrument and crystal stability, and the maximum correction on I was <1%. The data were integrated using the Siemens SAINT program, and the intensities corrected for Lorentz factor, polarization, air absorption, and absorption due to variation in the path length through the detector faceplate. A psi scan absorption correction was applied based on the entire data set. Redundant reflections were averaged. Final cell constants were refined using 3854 reflections having $I > 10\sigma(I)$, and these, along with other information pertinent to data collection and refinement, are listed in Table 3. The Laue symmetry was determined to be mmm, and from the

systematic absences noted, the space group was shown to be either *Pna*2(1) or *Pnma*. The asymmetric unit consists of one-half of the Ru_2 tetracation situated about a mirror plane, one PF_6 anion in a general position, two half PF_6 anions situated on mirror planes, a solvent molecule of acetone in a general position, and one-half molecule of acetonitrile on a mirror plane. One of the anions and the acetone are disordered over two slightly different orientations. The acetone had to be treated as an ideal rigid body in order to facilitate refinement. Additionally, the hydrogens on acetonitrile are disordered.

The Redox Chemistry of SbF_6^- Ion

Maja Ponikvar,*[a][‡] Joel F. Liebman,*[b][‡‡] and H. Donald B. Jenkins*[c][‡‡‡]

Keywords: SbF_6^- / Reduction / Redox chemistry / XeF_2 / Stabilisation

Chemical analysis of Sb in coordination compounds requires quantitative reduction of Sb^V in the form of SbF_6^- (and its related fluoro-hydroxy species) to Sb^{III}. This process, although thermodynamically favoured, appears to be kinetically hindered. The experimentally observed stabilisation of SbF_6^- towards reduction, as happens when the associated metal counterion is complexed by XeF_2 (generally regarded as being an oxidizing agent), is also discussed.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Various coordination compounds have been isolated from MF_q / PnF_5 / anhydrous HF systems (where M = metal in the oxidation state $q+$; PnF_5 = Lewis acid, Pn = P, As, Sb, Bi) because they are interesting as independent products in their own right and because new approaches to the syntheses of these compounds have been established. Such compounds can be further used as starting materials for the syntheses of coordination compounds with fluoro ligands, such as XeF_2 or AsF_3, coordinated to the metal centre. [1−5]

Estimation of the elemental composition of such compounds remains, despite the availability of numerous state-of-the-art, instrumental analytical techniques, still within the domain of classical analysis.[6] Diverse, classical analytical methods are available for the determination of the amounts of total Pn in different oxidation states, usually III or V. Usually, a prior reduction or oxidation of the element being determined has to be initially performed.[7] Problems associated with the determination of the total elemental composition of these compounds, including analytical methods for the determination of the amount of total respectively free fluoride (F_t^- and F_f^-) and the amounts of Pn, were resolved only recently.[8−10] Additional knowledge concerning the chemistry and properties of these compounds in aqueous media[11,12] was gained from the introduction and development of these analytical methods.

The aim of this paper is to explain the tendency shown towards reduction of coordination compounds of the type $M(SbF_6)_2$ (where M = Mg, Ca, Sr, Ba) in relation to their analogues having XeF_2 molecules coordinated in the form $M(SbF_6)_2{\cdot}nXeF_2$ (n = 2−5), as is observed during the process of total chemical analysis employing these compounds. We also examine the thermodynamics of the redox chemistry of SbF_6^- and show that such chemistry may be subject to kinetic rather than thermodynamic barriers.

Results and Discussion

Prior to determination of antimony within coordination compounds containing SbF_6^-, the procedure followed is to quantitatively reduce the Sb^V in the SbF_6^- ion [and the hydrolytically derived Sb(v)-fluoro-hydroxo species] to Sb^{III}. Initially, reduction experiments were conducted according to the standard procedure for the conversion of Sb^V to Sb^{III}, as reported by Hillebrand and Lundell[13] using hydrazine and Na_2SO_3 in acidic (HCl) media. However, the results revealed that hydrazine was completely ineffective as a reductant for the transformation of Sb^V to Sb^{III} in all of the compounds studied, because no Sb^{III} was detected in the sample using redox titration methods once the process of reduction was completed. When the process of reduction of the compounds under study *was* repeated using Na_2SO_3 as a reductant, it was found that Na_2SO_3 was effective for reduction of Sb^V to Sb^{III} in $KSbF_6$ and also in $M(SbF_6)_2$ compounds (where M is Sr or Ba). We can conjecture that the ease of reduction could be related to the nature of the

M−F bonding. The compounds having a more ionic M−F interaction, that is, $KSbF_6$ and $M(SbF_6)_2$ (where M = Sr, Ba) are reduced more readily than $NaSbF_6$ or than those having M = Mg, Ca with a more significant contribution of covalent fluorine-bridged structures. The M−F bond in $KSbF_6$ is more ionic than in $NaSbF_6$ because the charge−volume ratio of sodium is smaller [$V(Na^+)$ = 0.00394 nm^3 [14]] than the charge−volume ratio of potassium [$V(K^+)$ = 0.00986 nm^3 [14]]. So the Na−F bond is stronger than the K−F bond. As we descend the metal-cation group, the compounds should have an increased contribution to the ionic bond.

In addition, the analogous $M(SbF_6)_2$ compounds with an XeF_2 coordinated to the metal centre M were also examined with respect to their ease of reduction compared to those not having XeF_2 coordinated.

We further report that the reduction of Sb^V in the $M(SbF_6)_2$ compounds (M = Mg or Ca) using 50 mg of metallic Al powder in acid (HCl) media had to be initiated by a gentle heating of the suspension (at approximately 40−50 °C).[9] In contrast, for the compounds where XeF_2 was coordinated as a ligand to the metal centre M, more rigorous conditions were required in order to complete the reduction process: (1) heating to boiling whilst under reflux was required to initiate the reaction and (2) the procedure had to be repeated by one or two subsequent additions of 50 mg of metallic Al.

The tendency of the SbF_6^- ion towards reduction would be more easily rationalized were redox potentials of SbF_6^-/Sb^{III} or $Sb_2F_{11}^-/Sb^{III}$ couples or the other hexafluoropnictates(v) couples listed in the literature. Such is not the case. An alternative understanding of the thermochemistry of the redox chemistry of SbF_6^- and of the apparent resistance of SbF_6^- to reduction by XeF_2 complexation is therefore sought. The aim of the present work is to provide such a rationalisation.

The results of total chemical analysis of the compounds used in this work are presented in Table 1.

These results verify that the analyzed compounds were greater than 99% pure (although their stoichiometry was not always exact).

Conclusion

The Thermochemistry of the Redox Chemistry of SbF_6^-

The likely thermodynamics of three alternative reduction scenarios are considered below. Aqueous N_2H_4, an aqueous SO_3^{2-} salt and metallic Al powder were individually investigated as reducing agents for the purpose of the reduction of Sb^V in the SbF_6^- ion to Sb^{III}, with the assumption that their reaction products are N_2, aqueous SO_4^{2-} and aqueous Al^{III}, respectively. We consider the example of the K^+ salts in reactions (1) − (3), chosen because the relevant thermodynamic data can be estimated. To the extent that hexafluoroantimonate salts are strong electrolytes, the actual choice of counterion is irrelevant since the enthalpy and Gibbs energy of formation of the aqueous salt is the sum of the corresponding quantities for the component ions, in other words, the enthalpy of formation of aqueous K_2SO_3 is the sum of twice the aqueous enthalpies of formation of K^+, and that of SO_3^{2-}. Only enthalpies are discussed in the current study. The three redox reactions are:

$$2\,KSbF_6(aq) + N_2H_4(aq) + 6\,H_2O(l) \rightarrow 2\,Sb(OH)_3(aq) + N_2(g) + 2\,KF(aq) + 10\,HF(aq) \quad (1)$$

$$2\,KSbF_6(aq) + K_2SO_3(aq) + 6\,H_2O(l) \rightarrow 2\,Sb(OH)_3(aq) + K_2SO_4(aq) + 2\,KF(aq) + 10\,HF(aq) \quad (2)$$

$$3\,KSbF_6(aq) + 2\,Al(s) + 3\,H_2O(l) \rightarrow 3\,Sb(OH)_3(aq) + 2\,AlF_3(aq) + 3\,KF(aq) + 6\,HF(aq) \quad (3)$$

All of the desired enthalpy of formation data is available from the archival literature[15] except for that of the standard enthalpy of formation of the aqueous salt containing our anion of interest, that is, $\Delta_fH^0(KSbF_6, aq)$.

Recently, one of us reported a thermochemical study in which the gas-phase enthalpy of formation for SbF_6^-, $\Delta_fH^0(SbF_6^-, g)$, was derived.[16] Taking the standard enthalpy of formation for the solid $KSbF_6$ salt, $\Delta_fH^0(KSbF_6, s) = -2089 \pm 3$ kJ·mol^{-1} (the average value from the refer-

ences[17,18] cited therein), in order to estimate $\Delta_f H^0(KSbF_6, aq)$, we then require the corresponding enthalpy of solution for the salt, $\Delta_{soln.}H^0(KSbF_6, s)$. From the data in ref.[15], although we can derive a value of $\Delta_{soln.}H^0(KPF_6, s) = 44\ kJ{\cdot}mol^{-1}$ for the valence isoelectronic KPF_6, in this source we find no additional data for any hexafluoropnictate salt or any other hexafluorometallate salt. The justification for the comparison made is that KPF_6 and $KSbF_6$ are both KEF_6 salts. Further support comes from the fact that a roughly "universal" value for $\Delta_{soln.}H^0(KEO_4, s)$ of about $54 \pm 10\ kJ{\cdot}mol^{-1}$ is found for a set of KEO_4 salts (where E = Cl, Br, I, Mn, Tc, Re) and yet another "universal" value of $\Delta_{soln.}H^0(K_2EO_4, s)$ of about 11 ± 12 kJ/mol for K_2EO_4 salts (where E = S, Se, Cr, Mo, W), where it appears that changing the central metal, E, has a minimal effect on the thermochemical behaviour of these compounds when going into solution. Accordingly, we derive an enthalpy of formation of aqueous $KSbF_6$, $\Delta_f H^0(KSbF_6, aq)$, of about $-2045 \pm 3\ kJ{\cdot}mol^{-1}$ whereupon we find that ΔH for reaction (1) (as written) is exothermic by about 273 kJ, ΔH for reaction (2) by about 513 kJ and ΔH for reaction (3) by 2141 kJ. The uncertainties, although large, indicate that nonetheless these reactions remain unequivocally exothermic and since ΔS for all of them is likely to be positive, they are thermodynamically favoured. We can only conclude that the reduction reactions must be subject to a kinetic barrier. This confirms the long-held view that SbF_6^- is generally an "unreactive" ion.

Stabilization of SbF_6^- to Reduction by XeF_2 Complexation

From the experiments described above, we deduce that aqueous SbF_6^- is stabilized (i.e. more resistant to reduction) when the associated metal counterion is complexed by XeF_2. This is surprising. XeF_2 is generally regarded as being an oxidizing agent, although with the hitherto documented existence of highly stable, higher valence xenon-containing species in aqueous media [both Xe(VII) and Xe(VIII), $HXeO_4^-$ and various protonated forms of XeO_6^{4-}][19] XeF_2 can conceivably also serve as a reducing agent. However, for the counterions we employed for this SbF_6^- study no redox chemistry of any type was seen in the synthesis of the salts (no redox active metal was studied), and so none is expected here. So, why is there any effect at all on the ease of reduction of SbF_6^-? We showed earlier that AsF_6^-, a lighter valence isoelectronic analogue of SbF_6^-, is destabilized with regard to hydrolysis by multiply-charged cations.[12] The same destabilization mechanism may also apply to reduction processes. From elementary chemistry courses, we recall that these multiply-charged, aqueous cations should not be considered as M^{q+} but rather as $[M(H_2O)_n]^{q+}$. Although this is in the absence of XeF_2 as a ligand, we could postulate a similar $[M(H_2O)_w(XeF_2)_x]^{q+}$ ion where w and x are left intentionally unstated because of our admitted ignorance of the constitution of such complex ions in solution. It is clear that the complexing hydrogens are partially positive and so can assist in the decomposition of the anion much as the positive, bare metal cation might be expected to do. There is no reason to doubt that XeF_2 complexes the metal using one of its fluorine atoms whilst the other F atom faces the water molecules: these fluorines are partially negative and the 180° F−Xe−F angle precludes chelation using them both. As such, the metal cation is likely to have a neutral, if not partially negative, exterior and this will not assist in the hydrolytic decomposition of the anion. Indeed, that the exterior of the cationic metal is at least partially fluorinated, as is the anion, suggests they will avoid each other. Such avoidance is documented: Greenberg, Liebman and Van Vechten used similar logic as part of the theoretical interpretation of "the Perfluoroalkyl (R_f) effect" on the thermodynamic and kinetic stability of substituted highly strained organic molecules,[20] a phenomenon first enunciated in an experimental study made by Lemal and Dunlap.[21] Relatedly, where the negative charge on the anion is lessened, as with ion pairing that would arise with the smaller and less electropositive cations Na, Mg and Ca, reduction is also less likely.

Experimental Section

All reagents were of analytical grade and all solutions were prepared using double-distilled water.

Sample Preparation: Except $NaSbF_6$ (tech., Aldrich) and $KSbF_6$ (99%, Aldrich) that are not moisture sensitive, the analyzed coordination compounds are sensitive to traces of moisture. Therefore, the test samples for determination of each constituent were prepared by weighing in a dry box, with a precision of ± 0.05 mg into air and moisture tight Teflon containers. The containers were cooled in liquid nitrogen in order to moderate the subsequent reaction with water (20 mL) during suspension in a closed Erlenmeyer flask.[9]

Analyses: Both accurate and precise results of chemical analyses having an absolute error of less than 0.2−0.3% were obtained using classical analytical methods. A modified analytical technique, involving the use of a fluoride-ion-selective electrode enabled that us to achieve an absolute error of analysis of less than 0.3%, was applied to the determination of fluoride.

The amounts of antimony were determined after reductive decomposition of the acidic (HCl) sample by addition of metallic Al powder (50 mg).[9] If necessary, the sample was either gently heated to approximately 40−50 °C to initiate the reaction or further Al powder (50 mg) was added to the suspension whilst heating to boiling point under reflux to prevent losses of volatile SbF_3. The amount of Sb^{III} obtained was determined by potentiometric titration with $KBrO_3$ after dissolution of the antimony precipitate. The amount of F_t^- was determined after total reductive decomposition of the sample using Devarda alloy in alkaline (KOH) media.[8] The amounts of F_f^- were estimated in aqueous suspensions of the samples. The latter analyses were performed by direct potentiometry using a fluoride-ion-selective electrode.[8] The amounts of other metals (except alkaline metals) were determined using a corresponding complexometric titration with EDTA.[22]

Syntheses and Molecular Structures of Novel Alkali Metal Tetraorganylcyclopentaphosphanides and Tetraorganyltetraphosphane-1,4-diides[‡]

Robert Wolf,[a] Andrea Schisler,[a] Peter Lönnecke,[a] Cameron Jones,[b] and Evamarie Hey-Hawkins*[a]

In memoriam Professor Marianne Baudler

Keywords: Alkali metals / Phosphorus / P ligands / ^{31}P NMR spectroscopy / Tetraphosphane-1,4-diides

The reaction of sodium with $RPCl_2$ and PCl_3 (12:4:1) in THF gives Na[*cyclo*-(P_5R_4)] [R = *i*Pr (**1**), Ph (**2**)], while four equivalents of $RPCl_2$ [R = Ph, 2,4,6-$Me_3C_6H_2$ (Mes), *t*Bu] react with ten equivalents of sodium sand or elemental potassium in refluxing THF to yield the compounds [$Na_2(THF)_5(P_4Ph_4)$] (**3**), [$Na_2(THF)_4(P_4Mes_4)$] (**4**), and [$Na_2(THF)_4(P_4tBu_4)$] (**5**), or the potassium salt [$K_2(THF)_6(P_4Mes_4)$] (**6**). Recrystallizing **6** from 1,4-dioxane/pentane (1:3) also led to [{$K(L)_2$}$_2${$K(L)$}$_6$(P_4Mes_4)$_4$·0.5THF]$_\infty$ (L = 1,4-dioxane) (**7**). In the solid state, compounds **3**–**6** exist as isolated ion-contact complexes, in which the P_4 chain of the $(P_4R_4)^{2-}$ ligand has a *syn* arrangement, while a polymeric helical arrangement was observed for **7**. A minor product, [{K(pmdeta)(HP_3Mes_3)}$_2${K_2(P_4Mes_4)}]·0.25hexane (**8**), was isolated from the reaction of $MesPCl_2$ and K (1:2.5). Compound **8** contains the first structurally characterized example of a triphosphanide anion, $(HP_3Mes_3)^-$, besides $K_2(P_4Mes_4)$.

Introduction

Cyclooligophosphanes *cyclo*-$(PR)_n$,[1] which are isolobal with cycloalkanes have attracted the interest of chemists for a long time. Whereas the first example of this class of compounds, *cyclo*-$(PPh)_5$, was synthesized as early as 1877,[2] the first cyclooligophosphanide anions *cyclo*-$(P_nR_{n-1})^-$ were only reported approximately 100 years later.[3,4] Even today, the number of compounds readily accessible in pure form is still small.[5] Thus, the alkali metal compounds K[*cyclo*-(P_3tBu_2)],[3] K[*cyclo*-(P_5Ph_4)],[5] and Li[*cyclo*-(P_ntBu_{n-1})] ($n = 3-5$)[6,7] were only obtained as inseparable mixtures, and characterized by ^{31}P NMR spectroscopy. Only recently, we reported the targeted high-yield synthesis of Na[*cyclo*-(P_5tBu_4)] as well as preliminary results of its use in coordination chemistry.[8]

We have now employed the same synthetic approach for the preparation of other cyclopentaphosphanide anions Na[*cyclo*-(P_5R_4)], starting from *i*PrPCl$_2$, PhPCl$_2$ or MesPCl$_2$ (Mes = 2,4,6-$Me_3C_6H_2$), PCl$_3$, and Na (4:1:12). While Na[*cyclo*-(P_5R_4)] [R = *i*Pr (**1**), Ph (**2**)] are obtained, the tetraphosphane-1,4-diides $Na_2(P_4R_4)$ are the major products for R = Ph (**3**) and R = Mes (**4**).

While a large number of alkali metal phosphanides M(PRR′) (R, R′ = alkyl, aryl, H) have been synthesized and structurally characterized, their structures in solution are largely unknown.[9] In this respect, oligophosphanediides of the general formula $M_2(P_4R_4)$ (M = Li, Na, K; R = Me, Et, Cy, *t*Bu, Ph), which were first obtained by Issleib et al. by reduction of cyclooligophosphanes, *cyclo*-$(PR)_n$, with Li, Na, and K, are of special interest.[10] In contrast to alkali metal phosphanides, M(PRR′),[9] these compounds have been extensively studied by ^{31}P NMR spectroscopy, and their molecular structures in solution were proposed on the basis of the complex spin systems observed.[11] Independently from our own work, the solid-state structures of complexes of the general composition $Na_2(P_nPh_n)$ ($n = 2-4$), which were obtained from the reaction of PhPCl$_2$ and Na, were recently reported.[12]

Although linear and cyclic oligophosphanides are of interest as ligands in main group and transition metal

chemistry, there are only a few reports where linear oligophosphanide ligands $(P_nR_n)^{2-}$ have been employed in coordination chemistry. These include the synthesis of metallocene triphosphane-1,3-diyl complexes $[Cp_2M(P_3R_3)]$ (M = Ti, Zr, Hf; R = Me, Et, Ph, *t*Bu),[13] a nickel tetraphosphane-1,4-diyl complex $[Ni(\eta^2\text{-}P_2tBu_2)(P_4tBu_4)]$,[14] the germatetraphospholanes[15] *cyclo*-$(P_4tBu_4GeR_2)$ (R = Et, Ph) and *cyclo*-$\{P_4tBu_4Ge(\eta^2\text{-}P_2tBu_2)\}$, and the stannatetraphospholanes[16] *cyclo*-$(P_4tBu_4SnR_2)$ (R = *t*Bu, *n*Bu, Ph) and *cyclo*-$\{P_4tBu_4Sn(Cl)nBu\}$. In addition, we have shown, that the cyclic oligophosphanide anion *cyclo*-$(P_5tBu_4)^-$ exhibits a rich and unprecedented chemistry.[8,17]

We now report the syntheses of the sodium cyclopentaphosphanides Na[*cyclo*-(P_5R_4)] [R = *i*Pr (**1**), Ph (**2**)], and improved syntheses of the alkali metal tetraphosphane-1,4-diides $[Na_2(THF)_5(P_4Ph_4)]$ (**3**), $[Na_2(THF)_4(P_4Mes_4)]$ (**4**), and $[Na_2(THF)_4(P_4tBu_4)]$ (**5**), and the potassium salts $[K_2(THF)_6(P_4Mes_4)]$ (**6**) and $[\{K(L)_2\}_2\{K(L)\}_6(P_4Mes_4)_4\cdot 0.5THF]_\infty$ (L = 1,4-dioxane) (**7**). The structures of **3**−**6** in solution were established from ^{31}P NMR spectroscopic studies, and were compared with the solid-state structures.

A minor product from the reaction of $MesPCl_2$ and K (1:2.5) with an excess of pmdeta (pmdeta = pentamethyldiethylentriamine) and hexane, namely $[\{K(pmdeta)(HP_3Mes_3)\}_2\{K_2(P_4Mes_4)\}]\cdot 0.25$hexane (**8**), was isolated and structurally characterized. Compound **8** contains the first structurally characterized example of a triphosphanide anion, $(HP_3Mes_3)^-$, besides $K_2(P_4Mes_4)$.

Results and Discussion

Synthesis and Spectroscopic Properties of Na[*cyclo*-(P_5R_4)] [R = *i*Pr (1), Ph (2)]

The reaction of sodium with $RPCl_2$ and PCl_3 (12:4:1) in THF gives Na[*cyclo*-(P_5R_4)] (R = *i*Pr (**1**), Ph (**2**)] in an amount of conversion of 61 and 32%, respectively (as determined by ^{31}P NMR spectroscopy). Besides **1** and **2**, signals of *cyclo*-$(PiPr)_4$,[18] $iPrPH_2$,[19] and $Na_2(P_2iPr_2)$[20] (for **1**) or $Na_2(P_4Ph_4)$ (**3**),[11] Na{PPhP(H)Ph},[20] $Na_2(P_3Ph_3)$,[11] and $Na_2(P_2Ph_2)$[20] (for **2**) were observed in the ^{31}P NMR spectra of the reaction mixtures. Compounds **1** and **2** are very air-sensitive, and even pyrophoric as finely divided powders. They dissolve readily in ethers, aliphatic, and aromatic organic solvents.

In the $^{31}P\{^1H\}$ NMR spectra, **1** and **2** exhibit signals for an ABB′CC′ spin system.[21] Only one conformational isomer was observed, which we propose to be the *all-trans* isomer by comparison with Na[*cyclo*-(P_5tBu_4)].[8] This is also in agreement with the observed coupling constants (Table 1).[5,11c,22]

Table 1. $^{31}P\{^1H\}$ NMR parameters (C_6D_6, 25 °C, δ in ppm, *J* in Hz) of Na[*cyclo*-(P_5R_4)] (R = *i*Pr (**1**), Ph (**2**) or *t*Bu[8])

	*i*Pr	Ph	*t*Bu[8]

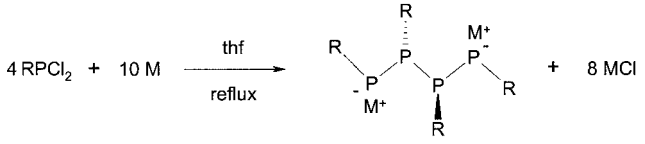
Synthesis, Molecular Structures, and Spectroscopic Properties of $[Na_2(THF)_5(P_4Ph_4)]$ (3), $[Na_2(THF)_4(P_4Mes_4)]$ (4), $[Na_2(THF)_4(P_4tBu_4)]$ (5), $[K_2(THF)_6(P_4Mes_4)]$ (6), and $[\{K(L)_2\}_2\{K(L)\}_6(P_4Mes_4)_4\cdot 0.5THF]_\infty$ (L = 1,4-Dioxane) (7)

The reaction of four equivalents of $PhPCl_2$ (**3**), $MesPCl_2$ (**4** and **6**), or $tBuPCl_2$ (**5**) with ten equivalents of sodium sand (**3**−**5**) or elemental potassium (**6**) in refluxing THF yields the compounds **3**−**6** in high purity and moderate yields (27 to 43%, Scheme 1). Compound **7** can be obtained upon recrystallization of **6** from dioxane/pentane (1:3).



Scheme 1. Synthesis of **3**−**6** [M = Na, R = Ph (**3**), Mes (**4**), *t*Bu (**5**); M = K, R = Mes (**6**)]

In the solid state **3**, **4**, **5**, and **6** exist as isolated ion-contact complexes, in which the P_4 chain of the $(P_4R_4)^{2-}$ ligand has a *syn* arrangement [torsion angles between the planes P1−P2−P3 and P2−P3−P4 or P1−P2−P2′ and P2−P2′−P1′: 32.1° (**3**), 72.7° (**4**), 8.8° (**5**), and 75.1° (**6**)], and is coordinated to two alkali metal cations (Figures 1−5). The coordination spheres of the alkali metal cations are completed by two (**4** and **5**) or three (**3** and **6**) THF molecules. In **3**, a bridging THF molecule can be observed [*d*(Na1−O3) = 301.3(8) pm]. This is a rare situation,[23] and has only been observed twice in the structures of alkali metal phosphanides.[24] Bridging THF molecules were also observed in the molecular structure of the tetrameric sodium and potassium fluorenone ketyls $[Na_4(OC_{13}H_8)_2(THF)_2(\mu_2\text{-}THF)_2(OC_{13}H_8)_4]$ [*d*(Na−O) = 239.1(7)−260.6(7) pm] and $[K_4(hmpa)_4(\mu_2\text{-}THF)(OC_{13}H_8)_4]$ (hmpa = $OP(NMe_2)_3$].[23] The P−P bond lengths, which range from 216.6(1)−226.2(2) pm, are in the typical range for single bond lengths.[25] In spite of these general similarities, there are significant differences between the coordination modes of

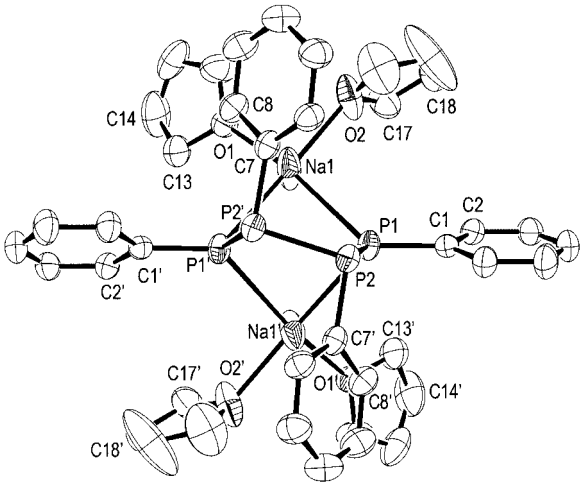


Figure 1. Molecular structure of $[Na_2(THF)_5(P_4Ph_4)]$ (**3**); the bridging THF molecule has been omitted for clarity

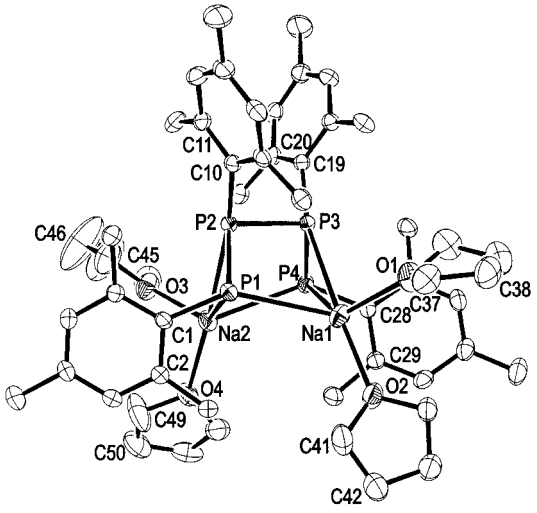

Figure 2. Molecular structure of $[Na_2(THF)_4(P_4Mes_4)]$ (**4**)

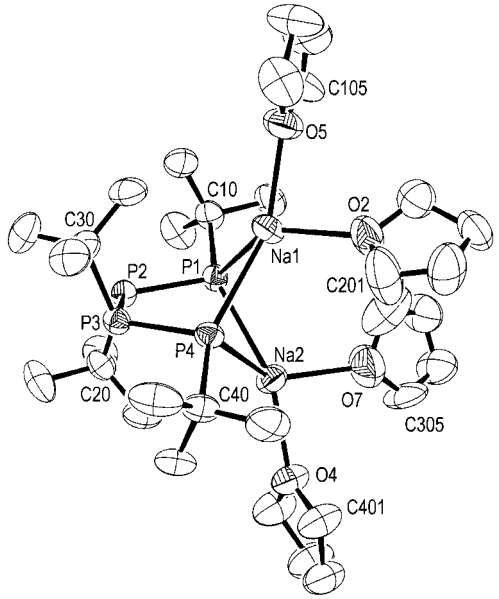

Figure 3. Molecular structure of $[Na_2(THF)_4(P_4tBu_4)]$ (**5**)

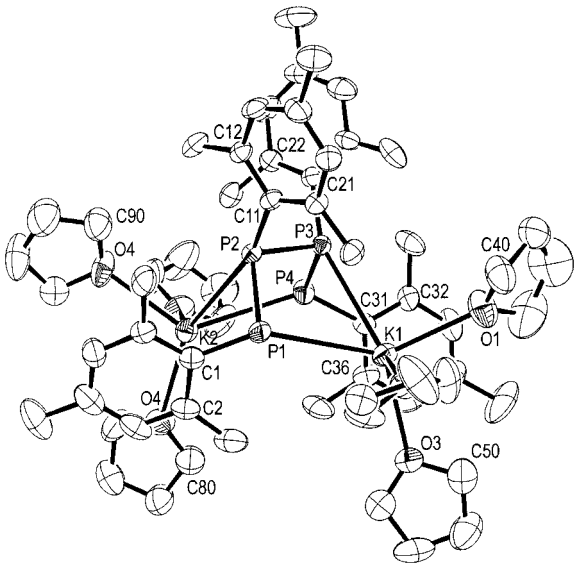

Figure 4. Molecular structure of $[K_2(THF)_6(P_4Mes_4)]$ (**6**)

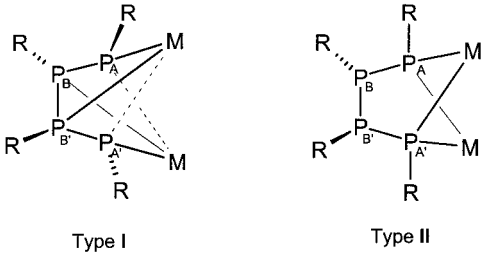

Figure 5. The two structural arrangements observed in the solid-state structures of **3** and **5** (type **II**), and **4** and **6** (type **I**)

Na and K. Whereas for **4** and **6** the phosphorus alkali metal distances are in the typical range for related sodium and potassium phosphanides[9] *both* for the internal and terminal phosphorus atoms of the chain [**4**: *d*(Na1−P1,P3), *d*(Na2−P2,P4) = 289.6(2)−316.6(1) pm, **6**: *d*(K1−P1,P3), *d*(K2−P2,P4) = 331.4(3)−359.8(2) pm], in **3** and **5** the Na cations are exclusively coordinated by the terminal phosphorus atoms [**3**: *d*(Na1−P1) = 290.1(2) pm, *d*(Na1−P1′) = 289.2(2) pm, **5**: *d*(Na1−P1,P4) = 281.9(1)−291.1(1) pm, *d*(Na2−P1,P4) = 284.0(1)−290.1(1) pm] (Figure 5). Thus, for **4** and **6**, the phosphorus atoms in the 1,3 positions coordinate and four-membered MP_3 chelate rings are formed. Additionally, longer contacts can be observed between the alkali metal and the second terminal phosphorus atom [**4**: *d*(Na1−P4) = 331.6(2), *d*(Na2−P1) = 317.3(2) pm, **6**: *d*(K1−P4) = 382.3(3) pm, *d*(K2−P1) = 385.1(2) pm]. The strong interaction with the inner phosphorus atoms is also reflected in the larger torsion angle of the $(P_4R_4)^{2-}$ chain (see above). Solvation of Na and K is completed by short contacts to carbon atoms of the mesityl substituents [**4**: d[Na(1)−C28,C29), *d*(Na2−C1,C2) = 289.6(3)−306.6(3) pm, **6**: *d*(K1−C31,C36), *d*(K2−C1,C2) = 314.2(5)−321.5(6) pm], indicating η^2 interactions of the aryl rings. Interestingly, short K−C contacts were not observed for the phenyl rings of **3**, whereas π coordi-

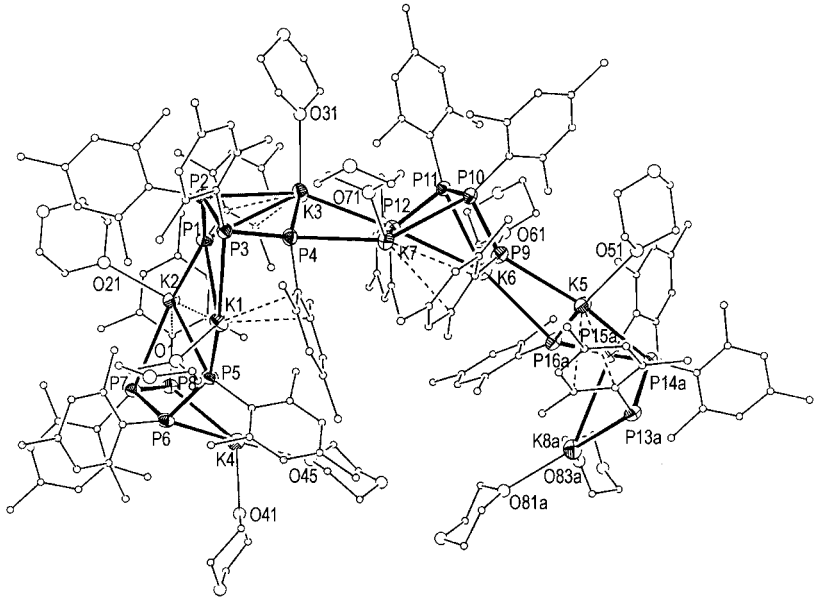

Figure 6. Molecular structure of $[\{K(L)_2\}_2\{K(L)\}_6(P_4Mes_4)_4 \cdot 0.5THF]_\infty$ (L = 1,4-dioxane) (**7**); only one tetrameric unit is shown; the THF solvate molecule has been omitted for clarity; only K−P distances up to 363 pm are shown

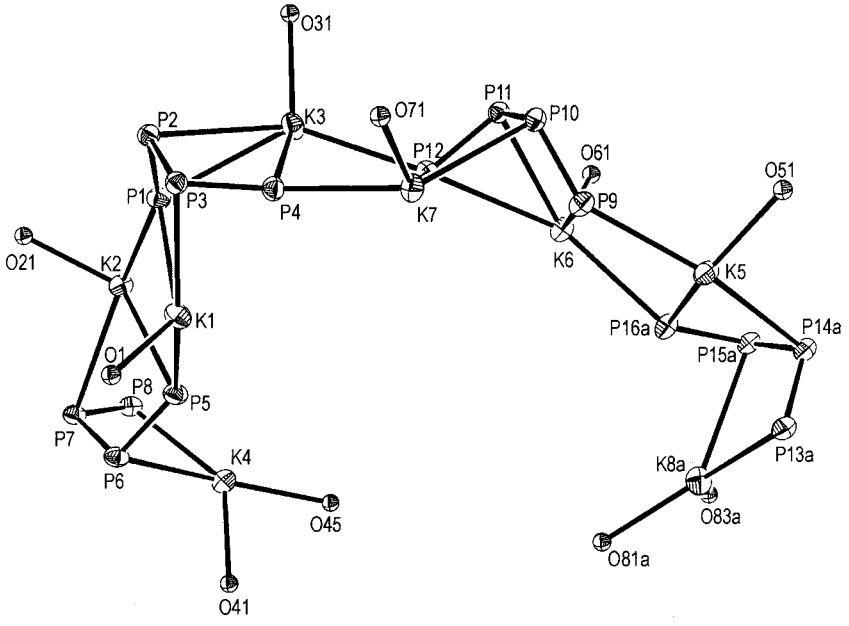

Figure 7. Molecular structure of the tetrameric unit in $[\{K(L)_2\}_2\{K(L)\}_6(P_4Mes_4)_4 \cdot 0.5THF]_\infty$ (L = 1,4-dioxane) (**7**); only the central K, P, O framework and K−P distances up to 363 pm are shown

nation of arene ligands to potassium[26−30] and the heavier alkali metals[31] has often been observed.[32]

When $[K_2(THF)_6(P_4Mes_4)]$ (**6**) was recrystallized from a mixture of 1,4-dioxane and *n*-pentane (1:3), the orange crystalline compound $[\{K(L)_2\}_2\{K(L)\}_6(P_4Mes_4)_4 \cdot 0.5THF]_\infty$ (L = 1,4-dioxane) (**7**) was formed. An X-ray crystal structure analysis revealed, that the asymmetric unit of **7** consists of two crystallographically independent units, $\{K_2(L)_3(P_4Mes_4)\}$ and $\{K_2(L)_2(P_4Mes_4)\}$, both of which are associated *via* K−P interactions. Thus, a tetrameric arrangement is formed in the solid state (Figure 6 and Figure 7), which aggregates *via* further K−P interactions to form a helical, 1-D coordination polymer (Figure 8).

Interestingly, the coordinative arrangement within the monomeric building blocks $\{K_2(L)_3(P_4Mes_4)\}$ and $\{K_2(L)_2(P_4Mes_4)\}$ of the polymeric chain resembles the pattern found in the monomeric THF adduct $[K_2(THF)_6(P_4Mes_4)]$ (**6**). Thus, the K−P distances between one terminal and one internal phosphorus atom are generally significantly shorter [*d*(K5−P16a,P14a;K8a−P15a,P13a) = 324.4(2)−358.9(2) pm, *d*(K6−P9,P11;K7−P10,P12) = 330.8(2)−345.6(2) pm, *d*(K1−P1,P3;K3−P2,P4) = 327.1(2)−355.1(2) pm, *d*(K2−

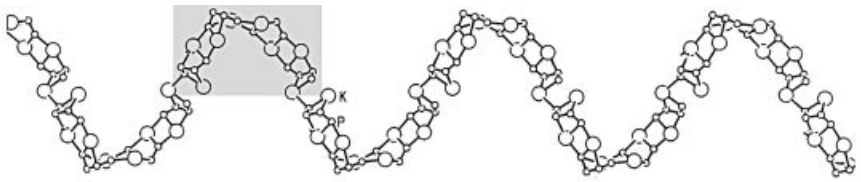

Figure 8. Polymeric helical arrangement in $[\{K(L)_2\}_2\{K(L)\}_6(P_4Mes_4)_4 \cdot 0.5THF]_\infty$ (L = 1,4-dioxane) (**7**); the tetrameric unit is underlain in grey; only K−P distances up to 363 pm are shown

P5,P7;K4−P6,P8) = 323.6(2)−355.8(2) pm] than the K−P distance to the second terminal phosphorus atom [*d*(K8a−P16a;K5−P13a;K4−P5;K2−P8) = 346.5(2)−406.8 pm, *d*(K6−P12;K7−P9;K3−P1;K1−P4) = 360.8(2)−401.3(2) pm]. The torsion angles in the $(P_4Mes_4)^{2-}$ chains are in a range similar to those observed in **4** and **6** [torsion angles between the planes P5−P6−P7 and P6−P7−P8: 70.8°, P1−P2−P3 and P2−P3−P4: 74.4°, P9−P10−P11 and P10−P11−P12: 74.3°, P13a−P14a−P15a and P14a−P15a−P16a: 68.7°]. This seems to indicate the formation of four-membered chelate rings of the dianionic $(P_4Mes_4)^{2-}$ ligands with potassium, a situation that is analogous to the structures of **4** and **6**, and may be described as predominant coordination of the alkali metal by the phosphorus atoms in the 1,3 positions of the chain with additional (weaker) interactions bearing a further phosphorus atom in the terminal position of the chain. The monomeric $\{K_2(L)_3(P_4Mes_4)\}$ and $\{K_2(L)_2(P_4Mes_4)\}$ units are associated *via* a four-membered K_2P_2 ring motif displaying K−P interactions, which are close to the short contacts observed in the monomers themselves [*d*(K5,K6−P16a,P9) = 325.8(2)−340.7(2) pm, *d*(K7,K3−P4,P12) = 324.3(2)−345.6(2) pm, *d*(K1,K2−P1,P5) = 328.6(2)−338.2(2) pm]. In contrast, aggregation of the tetrameric units proceeds through only two K−P interactions [*d*(K8a−P8) = 360.4(2) pm, *d*(K4−P13) = 376.1(2) pm], which are in the upper range of the distances generally observed in related potassium phosphanides.[9] Six potassium atoms within the tetrameric framework are each solvated by one dioxane ligand, whereas the two potassium atoms at the termini of the tetramer are each coordinated by two dioxane ligands. It is noteworthy, that in all the dioxane molecules only *one* oxygen atom coordinates to potassium. Solvation is completed by additional close contacts of some of the potassium cations with the aromatic rings of the mesityl substituents, which may be described as η^2-interactions [(K1−C41,C46) = 308.4(5)−321.7(5) pm, *d*(K3−C11, C12) = 305.8(5)−309.6(5) pm, *d*(K7−C91,C92) = 312.6(5)−316.2(5) pm, *d*(K5−C131a,C132a) = 302.7(5)−309.5(5) pm, *d*(K2−C81,C86) = 302.7(5)−312.1(5) pm].[26−30]

Orange crystals of $[\{K(pmdeta)(HP_3Mes_3)\}_2\{K_2(P_4Mes_4)\}] \cdot 0.25$ hexane (**8**) were obtained from the concentrated reaction mixture of $MesPCl_2$ and K (1:2.5), which also contained an excess of pmdeta and hexane. The crystal structure of this compound displays a co-complex, containing a $[K_2(P_4Mes_4)]$ unit, which is in contact with two $(HP_3Mes_3)^-$ ligands and two K cations, the latter being additionally solvated in each case by one pmdeta ligand (Figure 9 and Fig-

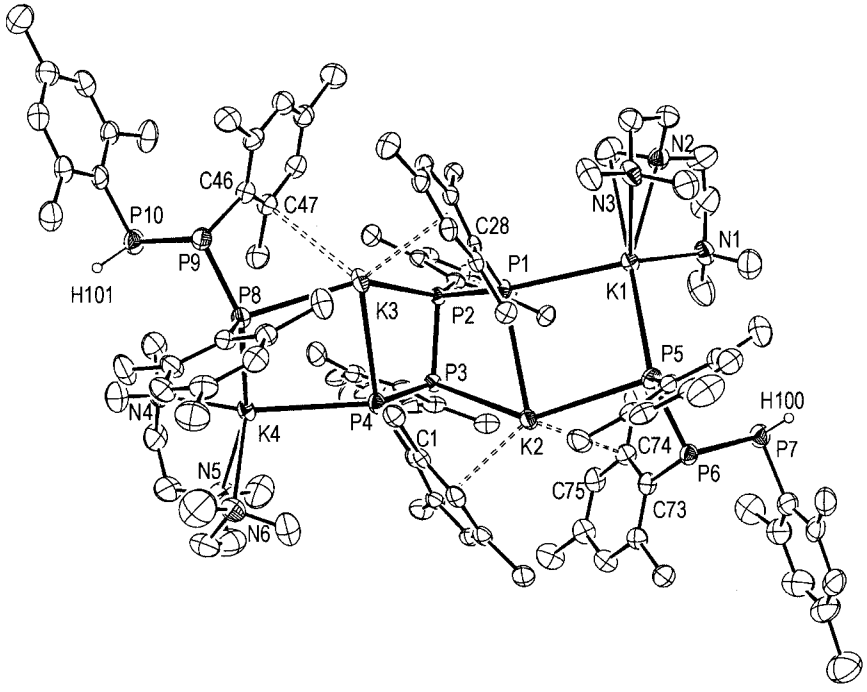

Figure 9. Molecular structure of $[\{K(pmdeta)(HP_3Mes_3)\}_2\{K_2(P_4Mes_4)\}] \cdot 0.25$hexane (**8**) (hexane not shown)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

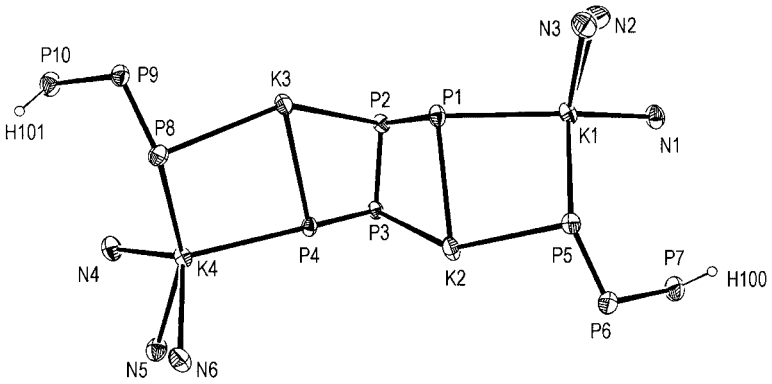

Figure 10. Molecular structure of $[\{K(pmdeta)(HP_3Mes_3)\}_2\{K_2(P_4Mes_4)\}]\cdot 0.25$hexane (**8**); only the central K,P,N framework and the P−H hydrogen atoms are shown.

ure 10). In spite of minor differences, the overall structural arrangement of the $[K_2(P_4Mes_4)]$ core in **8** is similar to those observed in the related compounds **4**, **6**, and **7**: the central $(P_4Mes_4)^{2-}$ dianion is in a *syn* arrangement with a slightly larger torsion angle than in the former structures [torsion angle between the planes P1−P2−P3 and P2−P3−P4: 91.1°]. The K−P distances are short between one terminal and one internal phosphorus atom of the chain and each potassium cation [*d*(K2−P1,P3) = 341.0(2)−342.5(2) pm, *d*(K3−P2,P4) = 339.4(2)−348.3(2) pm], but longer to the second terminal phosphorus atom [*d*(K2−P4) = 385.9(2), *d*(K3−P1) = 393.1(2) pm], indicating the formation of three-membered chelate rings (Figure 10). Additional solvation of the two central potassium cations by the aromatic substituents is indicated by short K−C contacts [*d*(K2−C28,C29,C30,C31,C32,C33) = 297.2(4)−342.3(5) pm, *d*(K2−C47) = 323.3 pm, *d*(K3−C1,C2,C3,C4,C5,C6) = 304.2(5)−334.9(5) pm, *d*(K3−C79) = 312.6 pm].[26−30]

The $[K_2(P_4Mes_4)]$ unit and the two $[K(pmdeta)(HP_3Mes_3]$ units are associated via four-membered K_2P_2 rings with short K−P interactions [*d*(K1,K2−P1,P5) = 321.7(2)−342.5(2) pm, *d*(K3,K4−P4,P8) = 328.5(2)−344.8(2) pm] (Figure 10). The catenated $(HP_3Mes_3)^-$ ligands coordinate to two potassium atoms (K1, K2 and K3, K8, respectively) through the anionic terminal phosphorus atom (P5 or P8), whereas the second terminal phosphorus atom (P7 or P10), which bears the proton of the chain, is uncoordinated. The bond angles about the internal phosphorus atom indicate sp^3 hybridization [angle P5−P6−P7: 107.41(9)°, angle P8−P9−P10: 108.20(8)°], and the P−P bond lengths within the anion are unremarkable [*d*(P5−P6), *d*(P6−P7), *d*(P8−P9), *d*(P9−P10) = 214.5(2)−224.6(2) pm].

The surprising observation of a three-membered monoprotonated $(HP_3Mes_3)^-$ anion in the structure of **8** may be explained by the fact that small amounts of the hitherto unknown compound $K_2(P_3Mes_3)$ were observed as a by-product in the synthesis of **6** when the stoichiometry of the reaction was slightly inaccurate. The anion $(HP_3Mes_3)^-$ may, therefore, have formed by reaction of the $(P_3Mes_3)^{2-}$ dianion with traces of water fortuitously present in the reaction mixture. Unfortunately, complete characterization of **8** was hampered by the impure nature of the isolated solid. Only further investigations will show if **8** can also be produced in a rational fashion.

A comparison of the structures **3**−**8** enables two different structural types to be distinguished: A "quasicyclic" arrangement, in which the ligands form five-membered chelate rings with the alkali metals, was observed for the structures of **3** and **5** (structural type **II**, Table 2 and Figure 5) − an arrangement, which has already been proposed by Baudler et al.[11a,11c] for **3** and related species, on the basis of their $^{31}P\{^1H\}$ NMR spectra (see below). In contrast, a different structural arrangement is present in **4**, **6**, **7**, and **8**, in which coordination occurs through both the internal and the terminal phosphorus atoms of the chain, and four-membered MP_3 chelate rings (M = Na, K) are the predominant structural features (structural type **I**, Table 2 and Figure 5).

While the $^{31}P\{^1H\}$ NMR spectra of **4**−**6** display well resolved AA′BB′ spin systems at room temperature, the $^{31}P\{^1H\}$ NMR spectrum of **3** exhibits broad signals. Only at −83 °C do signals showing the characteristic AA′BB′ spin system (ca. 80% intensity) appear. These signals compare well with the literature values.[11b] In addition, there are also resonances, which indicate the presence of a second species (δ = −25 to −30, −70; ca. 20% intensity). Since these multiplets were not well resolved, the nature of these

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

species could not be confidently ascertained. It seems likely, however, that these signals can be attributed to an ion-separated species $[Na(THF)_n][Na(THF)_m(P_4Ph_4)]$, which is in equilibrium with the ion-contact complex **3**.[12]

Nevertheless, the presence of only one AA′BB′ spin system for **3**−**6** clearly indicates the existence of only one diastereomer in solution. A summary of the chemical shifts and coupling constants of **3**−**6** is displayed in Table 2. While the chemical shifts of these species are in a similar range, a remarkable trend is observed for the coupling constants. Thus, whereas the $^3J(A,A')$ coupling constants (the coupling constants between the two terminal phosphorus atoms of the chain P_A and $P_{A'}$) of **4** and **6** are in the usual range expected for such long-range couplings, the corresponding coupling constants are dramatically larger for **3** and **5**. This unexpected strong coupling between the terminal phosphorus atoms, which has already been noted by Baudler et al. for **3** and related compounds, may indeed be explained by the presence of bridging alkali metal cations in a structure such as **II**, which may mediate an alternative pathway for coupling between the two terminal phosphorus atoms.[11a,11c] This, however, may not only be the case for an ion-contact structure such as **II**, but may also be consistent with alternative structures, such as an ion-separated cyclic arrangement with one bridging alkali metal cation, as suggested by Hoffmann and Caulton.[11b] To distinguish between these different possibilities, the $^2J(A,B')$ coupling constants are particularly informative. Interestingly, Baudler et al. noted that for related five-membered heterocycles *cyclo*-(P_4R_4X) (X = CH_2, R = Me, Cy, *t*Bu, Ph; X = S, Se, R = Ph; X = $P(CF_3)$, R = CF_3) a strict dependence of the $^2J_{P,P}$ coupling constant on structural features may be observed. If the substituents on the respective phosphorus atoms are in a *cisoid* arrangement, the coupling constants appear to attain significantly more positive values than if the substituents on the respective phosphorus atoms are in a *transoid* arrangement[11c] (a relationship, which is also valid for related sila-, stanna- and germatetraphospholanes).[15,16,33] A comparison of the $^2J(A,B')$ coupling constants in **3**−**6** revealed that **3** and **5** display similar negative $^2J(A,B')$ values. In contrast, the $^2J(A,B')$ coupling constants for **4** and **6** are significantly more positive. Hence, assuming that this rule is also valid for the related alkali metal complexes **3**−**6**, the different values for the $^2J(A,B')$ coupling constants may be due to different orientations of the organic substituents on the respective phosphorus atoms. A comparison of the solid-state structures of these compounds shows that a defined *cisoid* orientation of the Mes substituents of the internal and the terminal phosphorus atoms (i.e. between P_A,$P_{B'}$ and $P_{A'}$,P_B respectively) is indeed present in **4**, **6**, **7**, and **8**. However, the substituents on the terminal phosphorus atoms (P_A and $P_{A'}$) of **3** and **5** are approximately coplanar, with an almost coplanar arrangement of the four phosphorus atoms of the $(P_4R_4)^{2-}$ ligand. Thus, a proper *cis*/*trans* relationship between the substituents of P_A,$P_{B'}$ and $P_{A'}$,P_B was not observed for these structures. This characteristic feature of the solid-state structures of **3** and **5** may well be the underlying reason for the smaller values of the $^2J(A,B')$ coupling constants of these compounds in solution.

In general, the main features of the solid-state structures of **3**−**6** appear to reflect the trends observed for the P−P coupling constants of these species in solution quite clearly. This indicates, that the basic structural arrangements in the solid state are indeed retained in solution.

Interestingly, the ^{1}H NMR spectra of **4** and **6** [in C_6D_6 (**4**) and C_7D_8/[D_8]THF, 2:1, (**6**)] exhibit dynamic behavior. At room temperature, the resonances for the *ortho*-methyl groups of the Mes substituents of the terminal phosphorus atoms are inequivalent [**4**: δ = 2.47 (br) and 3.31 (br); **6**: δ = 2.36 and 3.22]. Upon warming the samples to 67 °C (**4**) and 60 °C (**6**), the broad, inequivalent peaks coalesce into a single broad resonance at ca. δ = 2.9 for **4**, while for **6** the previously sharp signals broaden severely, indicating that coalescence apparently requires a higher temperature. The inequivalence and the temperature dependence of the *o*-Me resonances may be the result of hindered rotation of the respective Mes groups in solution. Although a purely steric effect cannot be excluded on the basis of the NMR spectroscopic data alone, this might be caused by the presence of alkali metal-aryl interactions, which were also observed in the solid-state structures of these species.

Conclusions

Investigations of the reactions of *i*PrPCl$_2$, PhPCl$_2$ or MesPCl$_2$ with PCl$_3$ and Na (4:1:12) revealed that the cyclopentaphosphanide salts Na[*cyclo*-(P_5R_4)] [R = *i*Pr (**1**), Ph (**2**)] are formed in yields of 61% and 32%, respectively. In the reactions with PhPCl$_2$ and MesPCl$_2$, however, the catenated tetraphosphanediide salts $[Na_2(THF)_5(P_4Ph_4)]$ (**3**) and $[Na_2(THF)_4(P_4Mes_4)]$ (**4**) were obtained as the major products. Compounds **3**, **4**, $[Na_2(THF)_4(P_4tBu_4)]$ (**5**), and $[K_2(THF)_6(P_4Mes_4)]$ (**6**) were obtained more conveniently in a one-pot reaction of RPCl$_2$ (R = *t*Bu, Ph, Mes) with Na and K (1:2.5), and this represents a general, simplified route to tetraphosphanediide salts $[M_2(P_4R_4)]$.

In the solid state, two different types of coordination of the alkali metals were observed for **3**−**6**. All four phosphorus atoms are employed in the coordination of the alkali metal in **4** and **6**, whereas in **3** and **5**, coordination of Na occurs exclusively through the terminal phosphorus atoms of the chain. Recrystallization of **6** from 1,4-dioxane/pentane and pmdeta/THF/hexane solutions resulted in the isolation of $[\{K(L)_2\}_2\{K(L)\}_6(P_4Mes_4)_4\cdot 0.5THF]_\infty$ (L = 1,4-dioxane) (**7**) and $[\{K(pmdeta)(HP_3Mes_3)\}_2\{K_2(P_4Mes_4)\}]\cdot 0.25$hexane (**8**). The polymeric arrangement of **7** indicates that such compounds may also associate in the solid state, but the basic structural arrangement of the $[K_2(P_4Mes_4)]$ units, displaying four-membered KP_3 chelate rings, is preserved. This is also the case for the structure of **8**, in which one $[K_2(P_4Mes_4)]$ unit is associated with two [K(pmdeta)-(HP_3Mes_3)] moieties. A comparison of the structures of **3**−**8** and of the related compounds $[Na_2(tmeda)_2(P_4Ph_4)]$ and $[Na_2(dme)_3(P_4Ph_4)]$[12] indicates that the M_2P_4 frame-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

works are structurally rather robust, even in the presence of chelating donors and for different modes of association.

The ABB′CC′ (for **1** and **2**) and the AA′BB′ coupling patterns in the ^{31}P NMR spectra of **3**−**6** were analyzed. A comparison of the resultant coupling constants of the latter indicates that the basic structural features of these species are preserved not only in the solid state, but also in solution.

Future investigations will focus on the further elaboration of the structural chemistry of alkali metal oligophosphanediides and on the use of these compounds in the synthesis of phosphorus-rich metal complexes.

Experimental Section

General Methods: All procedures were performed under an inert atmosphere of pure argon with vigorous exclusion of air and moisture. The NMR spectra were recorded with a Bruker AVANCE DRX 400 spectrometer. ^1H NMR (400.13 MHz), internal standard: solvent, external standard: TMS. ^{31}P NMR (161.9 MHz), external standard: 85% H_3PO_4. ^{13}C NMR (100.16 MHz), internal standard: solvent, external standard: TMS. The solvents were saturated with argon and stored over potassium mirrors. *i*PrPCl$_2$,[34] *t*BuPCl$_2$,[34] MesPCl$_2$[35] were prepared by literature methods. PhPCl$_2$ and PCl$_3$ are commercially available and were freshly distilled before use. Elemental analyses were performed on a Heraeus VARIO EL instrument. The melting points were determined in sealed capillaries under argon and are uncorrected.

Data Collection and Structural Refinements of 3−8: Data [λ(Mo-K_α) = 0.71073 Å] were collected with a Siemens CCD (SMART) diffractometer (for **3**−**6**), on a STOE IPDS (**7**) or on a Nonius Kappa CCD (for **8**). All observed reflections were used in the refinements (SAINT) of the unit-cell parameters. Empirical absorption corrections were carried out with SADABS (**3**−**6**) and SORTAV (**8**).[36] The structures were solved by direct methods (**3**−**7**: SHELXTL PLUS. **8**: SHELX-97).[37] Na, K, P, N O, and C atoms were refined anisotropically. Some C atoms of disordered solvent molecules were refined isotropically. H atoms were located using difference maps and refined isotropically. Table 3 lists crystallographic details. The thermal ellipsoids of the molecular structures in Figures 1−4 and 6−10 are shown at the 30% probability level. CCDC-222008 (for **3**), -222009 (for **4**), -222005 (for **5**), -222007 (for **6**), -222006 (for **7**), and -222004 (for **8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax (internat.): +44-1223-336-033 or E-mail: deposit@ccdc.cam.uk].

Na[*cyclo*-(P$_5$*i*Pr$_4$)] (1) and Na[*cyclo*-(P$_5$Ph$_4$)] (2): PCl$_3$ (2.51 g, 18.2 mmol, 1.6 mL) and Na (5.04 g, 219.0 mmol) were carefully added to *i*PrPCl$_2$ (10.6 g, 73.1 mmol) or PhPCl$_2$ (13.04 g, 72.6 mmol), respectively, in THF (150 mL). The mixture was heated to reflux for 5 days. After 1 day the initially colorless solution had become yellow-green, and after 2 days, dark brown. The solvent was removed under reduced pressure, and the dark brown residue extracted with *n*-pentane (250 mL). The solvent was re-

moved under reduced pressure, and **1** and **2** were characterized by ^{31}P NMR spectroscopy (cf. Table 1).

$[Na_2(THF)_5(P_4Ph_4)]$ (3): $PhPCl_2$ (3.83 g, 21.4 mmol) was dissolved in THF (ca. 50 mL), and added to freshly prepared sodium sand (1.23 g, 53.5 mmol, prepared from Na in boiling toluene). The mixture was heated to reflux for 3 days. An orange suspension was formed that contained ca. 75% of **4**. Filtration and concentration of the THF solution to ca. 30 mL gave yellow crystals upon storage at −20 °C overnight. The yellow crystals were isolated and dried in vacuo for 45 min. Yield 1.97 g (48% ref. to **3**-THF); m.p. 101−103 °C. ^1H NMR (C_7D_8): δ = 1.32 (m, 16 H, THF), 3.36 (m, 16 H, THF), 6.38 (br., 2 H, *p*-H), 6.62 (br., 4 H, *m*-H), 6.78 (br., 2 H, *p*-H), 6.91 (br., 4 H, *o*-H), 7.29 (br., 4 H, *m*-H), 7.86 (br., 4 H, *o*-H). $^{13}C\{^1H,^{31}P\}$ NMR (C_6D_6): δ = 25.27 (THF), 67.55 (THF), 120.69 (4-C in Ph), 125.89 (4-C in Ph), 130.54 (2,6-C in Ph), 132.42 (2,6-C in Ph), 146.1 (1-C in Ph), 151.60 (1-C in Ph) (no P−C coupling observed, signals of 3,5-C overlap with solvent resonances at ca. 127 ppm). $^{31}P\{^1H\}$ NMR (C_7D_8, +25 °C): δ ≈ −23.0 (br), −74.6 (br), −88.0 (br). $^{31}P\{^1H\}$ NMR (C_7D_8, −83 °C): δ ≈ −25 to −30 (m, 2P), −26.5 (B part of an AA′BB′ spin system, 8P), ca. −70 (m, 2P), −90.7 (A part of an AA′BB′ spin system), cf. Table 2. $C_{40}H_{52}Na_2O_4P_4$ (766.72): calcd. C 62.7, H 6.80, P 16.2; found C 60.0, H 6.55, P 16.5.

$[Na_2(THF)_4(P_4Mes_4)]$ (4): $MesPCl_2$ (1.31 g, 5.9 mmol) was dissolved in THF (ca. 50 mL) and added to freshly prepared sodium sand (0.33 g, 14.5 mmol, prepared from Na in boiling toluene). The mixture was heated to reflux for 2.5 days. A red suspension was formed which was filtered. The solvent was completely removed, and the remaining yellow solid recrystallized from THF/hexane, 1:2. Yield 0.31 g (27% ref. to **4**−2THF); m.p. 238 °C decomp. to a brown solid. ^1H NMR (C_6D_6): δ = 1.51 (m, 8 H, THF), 2.04 (s, 6 H, *p*-CH_3 in Mes), 2.16 (s, 6 H, *p*-CH_3 in Mes), 2.47 (br., 6 H, *o*-CH_3 in Mes), 2.70 (s, 12 H, *o*-CH_3 in Mes), 3.31 (br., 6 H, *o*-CH_3 in Mes), 3.57 (m, 8 H, THF), 6.61 (br., 4 H, 3,5-H in Mes), 6.81 (br., 4 H, 3,5-H in Mes). $^{13}C\{^1H,^{31}P\}$ NMR (C_6D_6): δ = 20.43 (*p*-CH_3 in Mes), 20.56 (*p*-CH_3 in Mes), 23.56 (*o*-CH_3 in Mes), 24.47 (THF), 26.17 (*o*-CH_3 in Mes), 66.60 (THF), 128.13 (3,5-C in Mes at P_B), 129.41 (3,5-C in Mes at P_A), 135.03 (4-C in Mes at P_A), 137.34 (1-C in Mes at P_A), 141.43 (4-C in Mes at P_B), 141.89 (2,6-C in Mes at P_A), 145.09 (2,6-C in Mes at P_B), 150.40 (1-C in Mes at P_B) (no P−C coupling observed). $^{31}P\{^1H\}$ NMR (C_6D_6): cf. Table 2. $C_{52}H_{76}Na_2O_4P_4$ (935.05): calcd. C 66.80, H 8.20, O 6.80; found C 65.50, H 6.69, O 7.01.

$[Na_2(THF)_4(P_4tBu_4)]$ (5): $tBuPCl_2$ (5.71 g, 35.9 mmol) was dissolved in THF (ca. 50 mL), and added to freshly prepared sodium sand (2.10 g, 90.0 mmol, prepared from Na in boiling toluene). The mixture was heated to reflux for 5 days. A dark-green suspension formed, which contained ca. 53% of **5**. This was filtered, the filtrate reduced to ca. 10 mL, and layered with 20 mL of pentane. Light yellow crystals formed on storage at −20 °C and were isolated. The crystals still contained ca. 15% *cyclo*-$[Na(THF)_4(P_5tBu_4)]$ and were recrystallized from THF/hexane, 1:2 to give **5** in 95% purity. Yield 1.23 g (40% ref. to **5**-4THF); m.p. 240 °C decomp. to a brown solid. ^1H NMR (C_7D_8/[D_8]THF, 2:1): δ = 1.51 (br., 36 H, *t*Bu). $^{13}C\{^1H,^{31}P\}$ NMR (C_7D_8/[D_8]THF, 2:1): δ = 28.64 [2 $C(CH_3)_3$], 29.06 [2 $C(CH_3)_3$], 30.84 (6 CH_3 in *t*Bu), 37.81 (6 CH_3 in *t*Bu). $^{31}P\{^1H\}$ NMR (C_7D_8/[D_8]THF, 2:1): cf. Table 2.

$[K_2(THF)_6(P_4Mes_4)]$ (6): Potassium (1.12 g, 28.30 mmol) was added to a solution of $MesPCl_2$ (2.55 g, 11.51 mmol) in THF (40 mL). The mixture was heated to reflux for 3 h. The resultant dark red suspension was filtered, and the filtrate reduced to ca. 5 mL. A yellow precipitate formed, which redissolved on heating the solution. Dark-orange crystals formed on storing the saturated solution of **6** at ambient temperature. The orange-red, crystalline solid was isolated and dried in vacuo for 2 h. Yield 0.84 g (43% ref. to **6**−6THF); m.p. 200−201 °C. ^1H NMR (C_7D_8/[D_8]THF, 2:1): δ = 2.06 (s, 6 H, *p*-CH_3 in Mes), 2.11 (s, 6 H, *p*-CH_3 in Mes), 2.36 (s, 6 H, *o*-CH_3 in Mes), 2.62 (s, 12 H, *o*-CH_3 in Mes), 3.22 (s, 6 H, *o*-CH_3 in Mes), 6.41 (br., 4 H, 3,5-H in Mes), ca. 6.7 (br., 4 H, 3,5-H in Mes). $^{13}C\{^1H,^{31}P\}$ NMR (C_7D_8/[D_8]THF, 2:1): δ = 19.8 (*p*-CH_3 in Mes), 20.0 (*p*-CH_3 in Mes), 23.15 (*o*-CH_3 in Mes), 25.41 (*o*-CH_3 in Mes), 26.30 (*o*-CH_3 in Mes), 127.6 (3,5-C in Mes at P_A), 128.6 (3,5-C in Mes at P_B), 134.31 (4-C in Mes at P_A), 138.6 (1-C in Mes at P_A), 141.48 (2,6-C in Mes at P_A), ca. 141.4 (4-C in Mes at P_B), 144.68 (2,6-C in Mes at P_B), 153.5 (1-C in Mes at P_B) (no P−C coupling observed). $^{31}P\{^1H\}$ NMR (C_7D_8/[D_8]THF, 2:1): cf. Table 2.

$[\{K(L)_2\}_2\{K(L)\}_6(P_4Mes_4)_4\cdot 0.5THF]_\infty$ (L = 1,4-Dioxane) (7): A solution of **6** (0.21 g, 0.31 mmol) in 1,4-dioxane (5 mL) was layered with *n*-pentane (15 mL) and stored for 2 weeks at room temperature. Large orange crystalline plates formed, which were isolated and dried in vacuo for 1 h. Yield 0.15 g; m.p. 175−177 °C; the compound is insoluble in hydrocarbon solvents, but shows signs of decomposition when dissolved in THF (cf. ^{31}P NMR spectroscopic data). ^{31}P NMR ([D_8]THF): δ = −10.3 (br. m, 2P), −14.4 (B part of an AA′BB′ spin system of $(P_4Mes_4)^{2-}$, 4P), −83.6 (br., 4P), −85.3 [dd, 2P, $^1J_{P,P}$ = 376.3, $^1J_{P,H}$ = 204.4 Hz, MesPH of $K(HP_2Mes_2)$], −106.2 (br. m, 4P), −109.7 [A part of an AA′BB′ spin system of $(P_4Mes_4)^{2-}$, 4 P], −136.2 [d, 2 P, $^1J_{P,P}$ = 376.3 Hz, $MesP^-$ of $K(HP_2Mes_2)$], −143.2 [d, 1 P, $^1J_{P,H}$ = 163 Hz, K(HPMes)[28]].

Tris(pyrazolyl)methane Ligands: Syntheses and Structures of Monometallic and Metallodendritic Complexes

Alberto Sánchez-Méndez,[a] Gustavo F. Silvestri,[a] Ernesto de Jesús,[a] F. Javier de la Mata,[a] Juan C. Flores,*[a] Rafael Gómez,[a] and Pilar Gómez-Sal[a]

Keywords: N ligands / Titanium / Palladium / Molybdenum / Dendrimers

The substituted ligands $Me_3SiC(pz)_3$ (**1**) and $Me_3SiOCH_2C(pz)_3$ (**2**) have been prepared starting from $HC(pz)_3$ and $HOCH_2C(pz)_3$. The molecular structure of compound **1** has been determined by X-ray diffraction studies, which show a propeller-like conformation of the pyrazolyl rings. Compound **2** has been found to be useful for the synthesis of $[Mo(CO)_3\{Me_3SiOCH_2C(pz)_3\}]$ (**3**), $[TiCl_2(N\mathit{t}Bu)\{Me_3SiOCH_2C(pz)_3\}]$ (**4**), and $[PdCl_2\{Me_3SiOCH_2C(pz)_3\}]$ (**5**), through ligand exchange reactions. The characterization of the new complexes is compatible with a tridentate coordination of the ligands in complexes **3** and **4**, and a bidentate coordination in **5** as confirmed by an X-ray analysis carried out with the palladium complex. The procedure has been extended for the synthesis of the carbosilane G1–$[OCH_2C(pz)_3]_4$ (**6**) and the tetrametallic compound G1–$[OCH_2C(pz)_3Mo(CO)_3]_4$ (**7**) (G1 = $Si(CH_2CH_2CH_2Me_2Si)_4$–).

Introduction

Since their introduction by Trofimenko's pioneering work,[1] tris(pyrazolyl)-borates, or scorpionates, have become a very important class of tripodal nitrogen-donating ligands in modern coordination chemistry. These versatile family of substituted and non substituted ligands have been used to synthesize complexes of most metals of the periodic table, some of which have useful applications in a wide range of areas.[2] The isoelectronic and isosteric tris(pyrazolyl)methane ligands have received much less attention until the significant improvement of their synthetic procedures.[3] Subsequently, this area of chemistry has rapidly developed new modified ligands and complexes, including those functionalized at the methine central carbon atom of tris(pyrazoly)methane[4–7] and related systems.[5] The substitution of the reactive methine proton by other functional groups have led, for instance, to the preparation of ligands and complexes soluble and stable in water,[6] and offered the opportunity to synthesize multitopic ligands and polynuclear compounds by linking tris(pyrazolyl)methane units in a molecular core.[7]

In the last few years we have focused our research work into the chemistry of carbosilane dendrimers containing early transition metal complexes, located at the dendritic periphery or at the focal point, and usually bonded through O- or N-donor anchoring ligands.[8] Since poly(pyrazolyl)-methanes can be functionalized with different groups at the central carbon atom while coordinated to metallic moieties at the other side, we decided to evaluate the possible application of this type of neutral ligands in the field of carbosilane metallodendritic chemistry.

This paper describes our results using silyl and siloxy derivatives of tris(1-pyrazolyl)methane and -ethane for the synthesis of early and late transition metal complexes. In addition, the preparation and characterization of a molybdenum tetranuclear compound with a carbosilane core is presented.

Results and Discussion

Synthesis of Ligands

$Me_3SiC(pz)_3$ (**1**) was prepared by the deprotonation reaction of tris(pyrazolyl)methane with LiMe in THF, followed by the addition of chlorotrimethylsilane in the same solvent (Scheme 1). The preparation of compound **1** with *n*-butyllithium as a base has been reported during the course of this work; **1** was described as an orange yellow solid, which was characterized by ^1H NMR spectroscopy, and the molecular peak observed by MS.[4] The procedure used here, including the isolation and purification of the intermediate $LiC(pz)_3$ (**I**, see Scheme 1 and the Exp. Sect.), allows for the synthesis of **1** in 75% yield as an analytically pure white solid. The product is stable in air and soluble in all common organic solvents. Single crystal of **1** suitable for X-ray structure determinations were obtained by recrystallization from pentane.

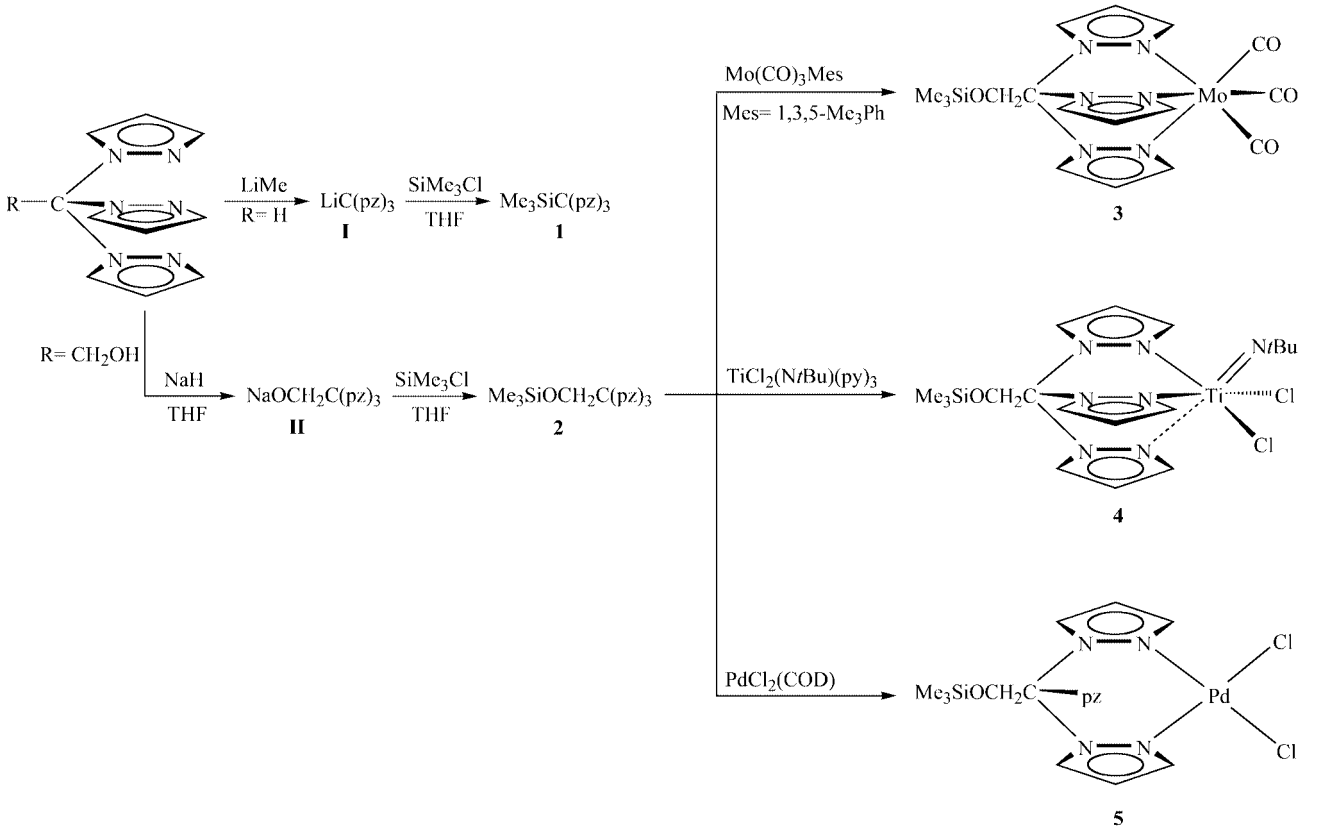

Scheme 1

A computer molecular modeling study of this compound shows several close contacts between the atoms in the 5-position of the pyrazolyl rings (C and H) and the $SiMe_3$ fragment. Maximum interaction occurs when the three rings are parallel to the C_3 axis (Figure 1a) in the tripodal arrangement expected in coordination complexes, and this steric hindrance minimizes by rotation of the pyrazolyl rings about the N−C(methine) bond (Figure 1b). These results are confirmed in the solid-state structure determined by X-ray diffraction studies, and in solution by the chemical behavior found for compound **1** (vide infra). At this point it is worth mentioning that our attempts to functionalize the central carbon atom of $HC(3,5\text{-}Me_2pz)_3$ failed, as was also noted by Reger who explained that the methyl groups in the 5-position block the reaction at that carbon atom.[4]

The reaction of 2,2,2-tris(pyrazolyl)ethanol with NaH in THF at room temperature resulted in the quantitative formation of the alkoxide **II** as an intermediate (Scheme 1), which was isolated as a hygroscopic white solid and characterized spectroscopically.[9] Subsequent addition of $SiMe_3Cl$ in THF gave $Me_3SiOCH_2C(pz)_3$ (**2**) in 80% yield after workup. Compound **2** was isolated as a colorless oil, which is stable in air and very soluble in all common organic solvents. Molecular modeling of the siloxy derivative **2** reveals a much more relaxed structure. Only some close contacts are observed between the 5-position atoms and the CH_2O-$SiMe_3$ moiety, if the tripodal arrangement is in the eclipsed conformation along the $(pz)_3C-CH_2O$ bond (Figure 1c).

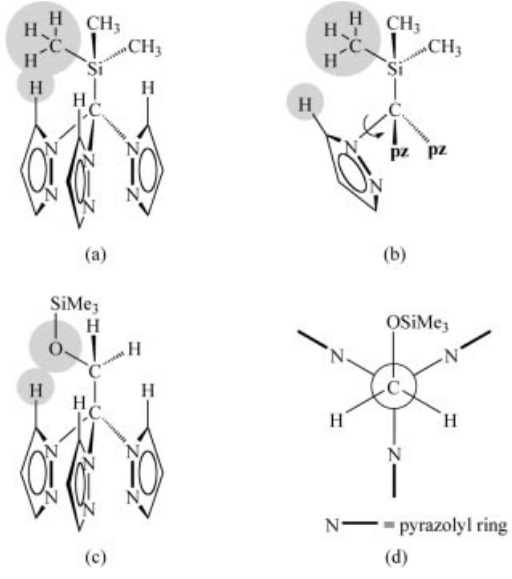

Figure 1. Representations of close contacts in compound **1** (a) and a more relaxed disposition (b); representations of close contacts in compound **2** (c) and the staggered conformation (d)

These interactions become negligible for the staggered conformation (Figure 1d) or by rotation of the pyrazolyl ring. The latter is in agreement with the small rotation barrier along the central $C-CH_2OR$ bond proposed by Reger in related rhenium compounds.[7b]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The NMR spectra of compounds **1** and **2** confirm the presence of three equivalent pyrazolyl rings in each molecule. The ^1H and $^{13}C\{^1H\}$ NMR spectroscopic data for both compounds are almost the same for the atoms in the 3- and 4-position of the rings. However, those in the 5-position are assigned more up field for compound **1** (δ = 6.63 and 128.5 ppm, proton and carbon, respectively) than for **2** (δ = 7.44 and 131.0 ppm), an effect probably related to the significant steric hindrance discussed above between the pyrazolyl rings and the $SiMe_3$ group in compound **1**. Both derivatives show an IR band $\nu_{C=N}$ around 1515 cm^{-1} in the usual range for free pyrazolyl rings.

Complexes Syntheses

The labile ligand substitution in $[Mo(CO)_3\{1,3,5\text{-}(CH_3)_3C_6H_3\}]$, $[TiCl_2(NtBu)(py)_3]$, and $[PdCl_2(COD)]$ by ligand **2**, leads to the formation of $[Mo(CO)_3\{Me_3SiOCH_2C(pz)_3\}]$ (**3**), $[TiCl_2(NtBu)\{Me_3SiOCH_2C(pz)_3\}]$ (**4**), and $[PdCl_2\{Me_3SiOCH_2C(pz)_3\}]$ (**5**), respectively, in high yields (see Scheme 1, and the Exp. Sect.). The formation of the molybdenum compound **3** required the use of a polar solvent such as THF or acetonitrile, whereas no reaction was observed in toluene. Instead, compounds **4** and **5** were readily prepared in toluene under reflux conditions. They are found to be stable (**5**), or moderately sensitive as a solid (**3**), or very sensitive to air (**4**). They are insoluble in alkanes, complex **3** is only soluble in polar solvents (THF, CH_3CN, acetone), compound **4** in chlorinated solvents, and complex **5** in aromatic solvents.

Similar attempts that use compound **1** as the entering ligand resulted in a mixture of the starting materials for the titanium and palladium compounds, and an untreatable insoluble greenish solid for the reaction with $[Mo(CO)_3$(mesitylene)]. The different chemical behavior showed by compounds **1** and **2** in these reactions can arise as a result of the important steric interaction between the $SiMe_3$ fragment and the pyrazolyl rings in compound **1**. Its tripodal arrangement to form complexes analogous to **3** or **4**, or the bidentate coordination as in **5** are hindered probably because the molecule minimizes the steric hindrance, thus positioning the three pyrazolyl rings in a three-bladed propeller conformation similar to that observed in the solid state (vide infra).

A number of tricarbonyl tris(pyrazolyl)methane metal complexes have been described,[3a,7] including molybdenum compounds[10] with tris(pyrazolyl)silane ligands.[11] The titanium examples are much more limited,[12] although some interesting heteroscorpionate-like complexes have recently been reported.[13] In the case of palladium(II), bis(pyrazolyl)methane as well as tris(pyrazolyl)methane compounds have been described.[14,15]

Complexes **3**–**5** were characterized by NMR and IR spectroscopy and elemental analysis, and the molecular structure of compound **5** has been determined by X-ray diffraction studies.

The ^1H NMR spectrum of complex **3** at room temperature exhibits one set of three multiplets for the pyrazolyl protons, whereas at lower temperature each type of pyrazolyl proton gives two resonances in the ratio 2:1. This finding is consistent with a staggered conformation of the ligand, as represented in Figure 1d, with a small rotation barrier along the central C–CH_2OR bond, as earlier proposed by Reger for dinuclear rhenium compounds.[7b]

The ^1H NMR spectra of complexes **4** and **5** are simple at 50 °C because at this temperature their different conformers rapidly interconvert on the NMR time-scale. Only one type of pyrazolyl ring is observed for compound **4**, and two are observed for **5** in a 2:1 ratio due to the bidentate coordination of ligand **2** to the palladium atom. On cooling the NMR samples, the spectra become more complicated, indicating the presence of conformational isomers in both complexes.

Thus, the spectra for the imide complex **4** at −80 °C in CD_2Cl_2 exhibits ten resonances in the range δ = 7.60–8.40 ppm assigned to the pyrazolyl protons H^3 and H^5, and two singlets assigned to the Me_3Si- (δ = 0.36 and 0.41 ppm) and to the Me_3C groups (δ = 0.90 and 0.97 ppm), indicating the presence of two conformers in a 1:1.25 ratio, with a total of five different pyrazolyl environments. Mixtures of conformers have also been described for related titanium compounds with tridentate N-donor ligands.[16] For the current case (**4**), the observation of two conformers can be attributed to the presence of the *tert*-butyl imide group with an important *trans* influence and to the presumable rotation barrier for the Me_3SiOCH_2 moiety (see conformers A and B in Figure 2).

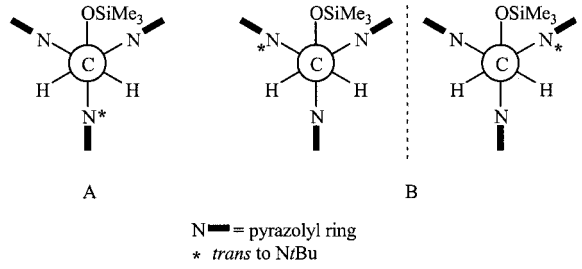

Figure 2. Conformer projections for compound **4**

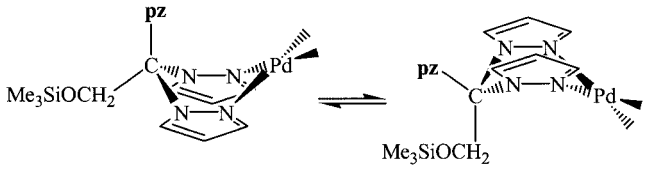
The ^1H NMR spectra of derivative **5** at −50 °C in $CDCl_3$ shows twelve resonances for the pyrazolyl protons (δ = 6.40–8.40 ppm) and two singlets for the Me_3Si group (δ = 0.06 and 0.28 ppm). The splitting of these resonances and their relative intensities are in agreement with the presence of two conformers in an approximate ratio of 1:3, each with two equivalent pyrazolyl rings. These data are interpreted as the result of a boat-to-boat conformational exchange between the isomers depicted in Scheme 2,[14,15] which are observable at low temperature in an unequal population because of the different natures of the substituents in the axial position on the methine carbon (pz or Me_3SiOCH_2). It is worth noting that the exchange process between the non-coordinated and the coordinated pyrazolyl rings, a feature described as a "tumbling" process[1a] and commonly found in related complexes,[15,17] was not observed for compound **5** below 50 °C. A similar result has been reported for some

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

palladium(II) complexes containing the rigid ligand 2-pyridyl-bis(3,5-dimethylpyrazolyl)methane, in which the pyridine group remains uncoordinated.[14a] However, the tris(pyrazolyl)methane ligand in compound **5** is flexible as demonstrated by the observation of the boat-to-boat inversion. The effect, nevertheless, could be ascribed to the presence of the Me_3SiOCH_2 substituent, which might hinder the ability of the free-pyrazolyl ring to coordinate to the metal center and, therefore, preclude the formation of the pentacoordinate intermediate involved during the tumbling process.



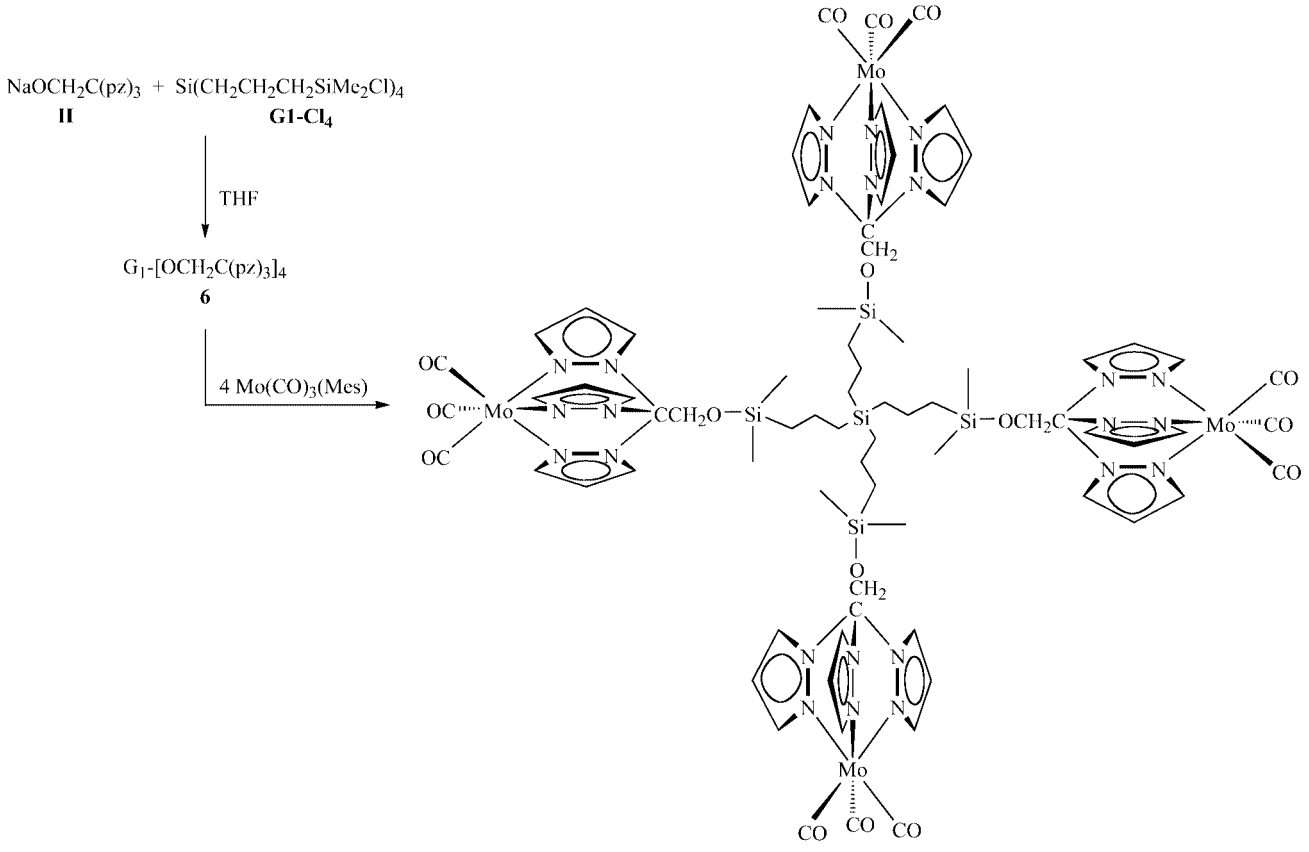
Scheme 2

The $^{13}C\{^1H\}$ NMR spectroscopic data for derivatives **3**–**5** are in agreement with a tripodal coordination of the tris(pyrazolyl)methane ligand in compounds **3** and **4**, and a bidentate *cis* coordination in a square-planar geometry for **5**. The spectra for **3** and **4** show one set of pyrazolyl resonances, whereas the spectrum for **5** shows the presence of nonequivalent rings in a 2:1 ratio; no mixtures of conformers are detected by $^{13}C\{^1H\}$ NMR spectroscopy at room temperature.

The IR spectra of compounds **3** and **5**, obtained as KBr pellets, show a band $\nu_{C=N}$ at around 1519 cm^{-1} not far from the absorption observed in the free ligand. In addition, the spectrum for the molybdenum complex shows two strong absorptions in the carbonyl region at 1901 cm^{-1} (a_1 mode) and 1764 cm^{-1} (e mode), as expected for a C_{3v} symmetry in an octahedral tricarbonyl complex. The observed ν_{CO} values are similar to those reported for related group 6 metal complexes.[11]

Synthesis of Dendritic Molecules

The methodology described above for the preparation of ligand **2** and compound **3** was extended to synthesize $G1-[OCH_2C(pz)_3]_4$ (**6**) and $G1-[OCH_2C(pz)_3Mo(CO)_3]_4$ (**7**) (Scheme 3), whereas attempts to prepare the corresponding tetrametallic analogues of compounds **4** and **5** yielded untreatable mixtures of insoluble solids. Thus, the reaction of chloro-containing carbosilane $G1-Cl_4$[18] with the sodium salt **II** in THF results in the formation of $G1-[OCH_2C(pz)_3]_4$ (**6**) as a colorless oil in a 76% yield. Subsequent treatment with $[Mo(CO)_3(mesitylene)]$ in refluxing THF leads to the dendritic compound **7**. Compounds **6** and **7** are found to be fairly stable in air. The



Scheme 3

organic compound is soluble in all common organic solvent, whereas the tetra-molybdenum complex is only slightly soluble in polar solvents such us acetone. The latter fact is relevant since it severely limits the preparation of higher generations of this type of metallodendrimers.

^1H and $^{13}C\{^1H\}$ NMR chemical shifts of the terminal $-OCH_2C(pz)_3$ groups for **6** are similar to those for **2**; the spectra are also quite similar, with additional signals for the methylene groups of the $SiCH_2CH_2CH_2Si$ chains in **6**. The most significant difference in the NMR spectroscopic data of **6** relative to that of the starting material G1−Cl_4, is the shift of the $SiMe_2$ resonances form $\delta = 0.38$ (^1H) and 0.2 (^{13}C) to 0.00 (^1H) and −2.4 (^{13}C) for **6**. The ^1H and $^{13}C\{^1H\}$ NMR spectra for compound **7** are consistent with the structure depicted in Scheme 3, and the peripheral organometallic units are in an electronic environment like that described for the mononuclear complex **3**.

The IR spectra of compounds **6** and **7** show a band $\nu_{C=N}$ at around 1518 cm^{-1}, and two strong ν_{CO} bands at 1906 cm^{-1} and 1757 cm^{-1} in the case of **7**.

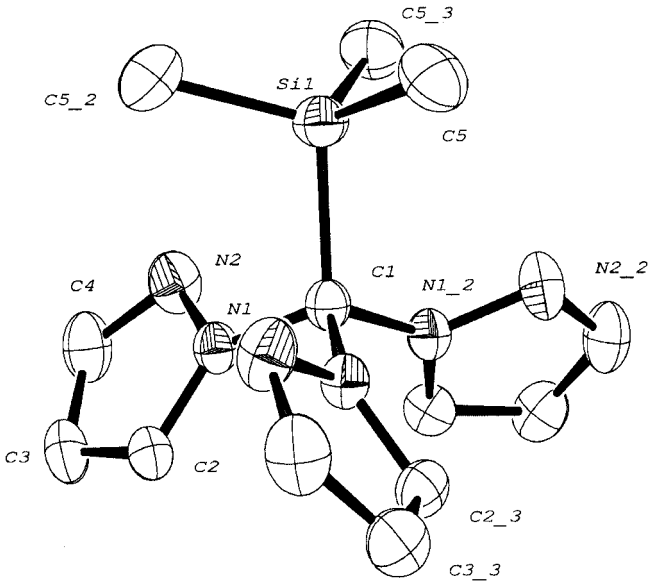

Figure 3. Molecular structure of compound **1**

Structures of $Me_3SiC(pz)_3$ (1) and $[PdCl_2\{Me_3SiOCH_2C(pz)_3\}]$ (5)

The molecular structures of both compounds have been determined by single-crystal X-ray diffraction studies. Figure 3 and Figure 4 show ORTEP representations of them, and Table 1 and Table 2 summarize their relevant structural data.

The molecular structure of **1** consists of discrete molecules and provides the first reported structure containing a tris(pyrazolyl)methane−Si linkage. The C−Si bond lies on a threefold axis in the *R*-3 space group, and only one third of the molecule appears in the asymmetric part of the unit cell. The geometry around the silicon atom is tetrahedral, but the Si(1)−C(1) bond length is clearly longer [1.968(3) Å] than the other Si−C bond lengths [1.858(3) Å]. The geometry around C(1) is distorted tetrahedral as shown by the Si(1)−C(1)−N(1) angle [111.5(1)°]. The three methyl groups bonded to the Si atom are located in a staggered configuration with respect to the C−N(pyrazolyl) bonds. The pyrazolyl rings are tilted with respect to the threefold axis to give the molecule a propeller-like shape. The Si−C−N−N torsion angle [46.4(2)°] provides a measure of this twist.

This shape is similar to that found in other molecules such as tris(3,5-dimethylpyrazol-1-yl)methane[19] and tris(3,5-dimethylpyrazol-1-yl)silane.[20] However, it is worth mentioning that only one of the possible conformers is present in the crystal of **1**; the isomer with the N(2) and the Si

atom located on the same side of the plane defined by the three nitrogen atoms bonded to the central carbon atom. Obviously, this arrangement found in the solid state is incompatible with a bi- or tridentate coordination of compound **1** to a metal center.

The molecular structure of compound **5** consists of discrete molecules with one Pd atom with a *cis* configuration in a square-planar environment. The metal atom is bonded to two chlorine and two nitrogen atoms from the tris(pyrazolyl)methane ligand, whereas one of the pyrazolyl rings remains uncoordinated. The asymmetric part of the unit cell comprises two molecules. Both molecules are very similar, except for the position of the Me_3SiOCH_2 moiety, whose orientations differ with respect to the rest of the structure in such a way that the two molecules are enantiomers.

Two examples of palladium complexes containing the tris(pyrazolyl)methane ligand have been described and structurally characterized. The octahedral palladium(IV) complex $[PdMe_3\{HC(pz)_3\}]I$[21] and the square-planar Pd^{II} species $[Pd\{HC(pz)_3\}_2][BF_4]_2$,[15a] both cationic compounds, show the κ^3-and the κ^2-mode of coordination of the ligand, respectively. The neutral compound **5** is also a Pd^{II} square-planar complex, with Pd−N bond lengths [ranging from 2.003(4) Å to 2.027(4) Å] and N−Pd−N angle [87.41(1)°] very similar to those found in $[Pd\{HC(pz)_3\}_2][BF_4]_2$.[15a]

In contrast with the other examples, the two coordinated rings in both molecules of the asymmetric unit have different inclinations with respect to the coordination plane of the metal. The dihedral angle of this plane with the pyrazolyl ring closer to the Me_3SiOCH_2 moiety is 36.0(1)° [rings with N(3)−N(4) and N(9)−N(10)], whereas the angle with the other pyrazolyl ring is 29.3(1)° [rings with N(1)−N(2) and N(7)−N(8)]. This structural feature is probably caused by the orientation of the siloxy group and the different steric interactions over the coordinated pyrazolyl rings in the solid state.

In both molecules, the non-coordinated pyrazolyl ring is oriented towards the palladium coordination plane with an angle between the planes of 57.1°. The distances between the N apical and Pd atoms are 3.180 Å in Pd(1)−N(5) and 3.195 Å in Pd(2)−N(11), and the Pd(1)−N(6) and Pd(2)−N(12) distances are 3.738 Å and 3.762 Å, respectively. The donor nitrogen atoms N(6) and N(12) are pointing to the opposite side of the Me_3SiOCH_2 moieties.

Conclusion

Tris(pyrazolyl)methane compounds substituted at the methine carbon atom have been prepared and characterized. Their ability as coordination ligands is greatly affected by the substituent. Thus, $Me_3SiOCH_2C(pz)_3$ (**2**) allows the straightforward preparation of transition metal complexes **3**−**5**, whereas similar attempts using $Me_3SiC(pz)_3$ (**1**) all failed. The result is interpreted as a consequence of the "steric pressure" of the Me_3Si group over the pyrazolyl rings in **1**, which blocks their ability to coordinate. Ligand **2** is tridentately coordinated in $[Mo(CO)_3\{Me_3SiOCH_2C(pz)_3\}]$ (**3**) and $[TiCl_2(NtBu)\{Me_3SiOCH_2C(pz)_3\}]$ (**4**), and bidentately coordinated in $[PdCl_2\{Me_3SiOCH_2C(pz)_3\}]$ (**5**). The dynamic behavior of these complexes in solution is consistent with a staggered conformation of ligand **2** in complexes **3** and **4** at low temperature. In addition, the absence of chemical exchange between the free and the coordinated pyrazolyl rings in compound **5** is explained in terms of the steric effect exerted by the Me_3SiOCH_2 group over the tris(pyrazolyl)methane ligand. The preparation of poly(pyrazolyl)methane complexes can be readily extended to polymetallic systems as demonstrated by the synthesis of the carbosilane precursor **6**, and the tetramolybdenum complex **7**. However, modification of the ligand will be required to reduce its steric crowding and to obtain more soluble compounds, in order to apply this methodology in dendrimer chemistry. Further work along these lines is currently underway.

Experimental Section

General Remarks: All operations were performed under an argon atmosphere using Schlenk or dry-box techniques. Unless otherwise stated, reagents were obtained from commercial sources and used as received. $[TiCl_2(NtBu)(py)_3]$,[22] $[PdCl_2(COD)]$,[23] $[Mo(CO)_3\{1,3,5\text{-}(CH_3)_3C_6H_3\}]$,[24] carbosilane $G1\text{−}Cl_4$,[18] $HC(pz)_3$, and $HOCH_2C(pz)_3$[3a] were prepared according to literature procedures. Solvents were previously dried and distilled under argon as described elsewhere.[25] NMR spectra were recorded on Varian Unity 500+, VR-300 or 200 NMR spectrometers. Chemical shifts (δ) are reported in ppm referenced to $SiMe_4$ for ^1H and ^{13}C. IR spectra were recorded on a Perkin−Elmer FT-IR Spectrum-2000 spectrophotometer. Elemental analyses were performed by Microanalytical Laboratories of the University of Alcalá on a Heraeus CHN-O-Rapid mycroanalyzer. Molecular modeling was carried out using CambridgeSoft Chem. 3D Pro 5.0 for Mac and MM2 force field computations.

Preparation of (Trimethylsilyl)tris(1-pyrazolyl)methane (1): LiMe (3.0 mL, 1.6 M in diethyl ether, 4.80 mmol) was slowly added with a funnel equipped with a bubbler to a solution of $HC(pz)_3$ (1.00 g, 4.67 mmol) in THF (20 mL) at −78 °C, and the reaction mixture was stirred overnight and allowed to warm up to room temperature. Removal of the solvent under vacuum led to intermediate **I** as an off-white solid that was washed with pentane (10 mL). Solid **I** was dissolved in THF (20 mL), treated with an excess of $SiMe_3Cl$ (1.0 mL, 7.88 mmol) at 0 °C, and the resulting solution stirred for 4 h. The volatiles were removed in vacuo and the residue extracted into hexane (2 × 10 mL). Compound **1** was isolated as a white solid by evaporation of the filtrates under vacuum to dryness, and recrystallized from pentane. Yield: 1.00 g (75%). $C_{13}H_{18}N_6Si$ (286.41): calcd. C 54.52, H 6.33, N 29.34; found C 54.65, H 6.64, N 29.73%. ^1H NMR ($CDCl_3$): δ = 0.29 (s, 9 H, $SiMe_3$), 6.28 (dd, 3 H, $J_{H,H}$ = 1.5, 2.6 Hz, pz−H^4), 6.63 (d, $J_{H,H}$ = 2.6 Hz, 3 H, pz−H^5), 7.65 (d, $J_{H,H}$ = 1.5 Hz, 3 H, pz−H^3) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = −0.6 ($SiMe_3$), 105.9 (pz−C^4), 128.5 (pz−C^5), 140.6 (pz−C^3) ppm, $C(pz)_3$ not observed. IR (KBr): $\tilde{\nu}$ = 1510 cm^{-1} (s, C=N).

Preparation of 1-(Trimethylsiloxy)tris-2,2,2-(1-pyrazolyl)ethane (2): A solution of $HOCH_2C(pz)_3$ (1.00 g, 4.09 mmol) in THF (15 mL)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was added to NaH (0.17 g, 60% dispersion in mineral oil, 4.25 mmol) previously washed with hexane and suspended in THF (15 mL). When the evolution of H_2 ceased, the solvent was removed under vacuum to lead to intermediate **II** as a white solid, which was washed with pentane (10 mL).[9] The solid was then dissolved in THF (20 mL), $SiMe_3Cl$ (0.6 mL, 4.73 mmol) was added at 0 °C, and the resulting solution stirred for 2 h at room temperature. The volatiles were removed in vacuo, and the residue extracted into hexane (2 × 10 mL) to give **2** as a colorless oil. Yield: 1.03 g (80%). $C_{14}H_{20}N_6OSi$ (316.44): calcd. C 53.14, H 6.37, N 26.56; found C 53.64, H 6.33, N 26.05%. ^1H NMR ($CDCl_3$): δ = 0.02 (s, 9 H, $SiMe_3$), 5.19 (s, 2 H, CH_2O), 6.29 (dd, 3 H, $J_{H,H}$ = 1.7, 2.7 Hz, pz−H^4), 7.44 (d, $J_{H,H}$ = 2.7 Hz, 3 H, pz−H^5), 7.62 (d, $J_{H,H}$ = 1.7 Hz, 3 H, pz−H^3) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = −0.7 ($SiMe_3$), 66.9 (CH_2O), 90.3 [$C(pz)_3$], 106.2 (pz−C^4), 131.0 (pz−C^5), 141.1 (pz−C^3) ppm. IR (CsI/Nujol): $\tilde{\nu}$ = 1518 cm^{-1} (s, C=N).

Preparation of $[Mo(CO)_3\{Me_3SiOCH_2C(pz)_3\}]$ (3): In a Schlenk, $[Mo(CO)_3\{1,3,5\text{-}(CH_3)_3C_6H_3\}]$ (95 mg, 0.32 mmol) was added to a solution of **2** (100 mg, 0.32 mmol) in acetonitrile or THF (15 mL) at room temperature. The yellow solution was stirred overnight and evaporated to dryness, and the yellow solid was washed with hexane and recrystallized form THF. Yield: 143 mg (90%). $C_{17}H_{20}N_6O_4SiMo$ (496.41): calcd. C 41.13, H 4.06, N 16.93; found C 41.27, H 3.89, N 16.46%. ^1H NMR ([D_6]acetone): δ = 0.44 (s, 9 H, $SiMe_3$), 5.99 (s, 2 H, CH_2O), 6.49 (m, 3 H, pz−H^4), 8.02 (m, 3 H, pz−H^5), 8.33 (m, 3 H, pz−H^3) ppm. $^{13}C\{^1H\}$ NMR ([D_6]acetone): δ = −0.7 ($SiMe_3$), 63.0 (CH_2O), 85.6 [$C(pz)_3$], 107.5 (pz−C^4), 133.3 (pz−C^5), 146.0 (pz−C^3), 229.8 (CO)ppm. IR (KBr): $\tilde{\nu}$ = 1901 and 1764 cm^{-1} (s, CO), 1518 cm^{-1} (m, C=N).

Preparation of $[TiCl_2(N\mathit{t}Bu)\{Me_3SiOCH_2C(pz)_3\}]$ (4): $[TiCl_2(N\mathit{t}Bu)(py)_3]$ (452 mg, 1.06 mmol), **2** (335 mg, 1.06 mmol), and toluene (15 mL) were placed into a glass ampoule equipped with a high vacuum greaseless stopcock. The mixture was kept at reduced pressure, evacuating the vapors regularly through the stopcock, and heated at 100 °C for 24 h. The resulting salmon-color solid was filtered and washed with pentane (2 × 10 mL). Yield: 385 mg (72%). $C_{18}H_{29}N_7OSiTiCl_2$ (506.33): calcd. C 42.70, H 5.77, N 19.36; found C 43.17, H 5.36, N 18.82%. ^1H NMR ($CDCl_3$, 50 °C): δ = 0.47 (s, 9 H, $SiMe_3$), 1.06 (s, 9 H, NtBu), 5.45 (s, 2 H, CH_2O), 6.28 (m, 3 H, pz−H^4), 7.85 (m, 3 H, pz−H^5), 8.19 (m, 3 H, pz−H^3) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = −0.3 ($SiMe_3$), 30.6 (CMe_3), 62.2 (CH_2O), 69.4 (CMe_3), 83.3 [$C(pz)_3$], 106.8 (pz−C^4), 129.8 (pz−C^5), 145.9 (pz−C^3) ppm.

Preparation of $[PdCl_2\{Me_3SiOCH_2C(pz)_3\}]$ (5): $[PdCl_2(COD)]$ (81 mg, 0.28 mmol) was added to a solution of compound **2** (90 mg, 0.28 mmol) in toluene (15 mL), and the mixture was refluxed for 1.5 h. The solvent was evaporated, and the yellow-orange residue was washed with hexane (2 × 10 mL) and recrystallized from acetone to afford **5** as orange crystals suitable for X-ray analysis. Yield: 130 mg (94%). $C_{14}H_{20}N_6OSiPdCl_2$ (493.76): calcd. C 34.06, H 4.08, N 17.02; found C 34.42, H 4.05, N 16.58%. ^1H NMR ($CDCl_3$, 50 °C): δ = 0.15 (s, 9 H, $SiMe_3$), 5.48 (s, 2 H, CH_2O), 6.40, 6.63 (m, m, 2 H, 1 H, pz−H^4), 6.96, 7.89 (m, m, 2 H, 1 H,

pz−H^5), 8.01, 8.49 (m, m, 1 H, 2 H, pz−H^3) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = −0.5 ($SiMe_3$), 66.5 (CH_2O), 107.4, 108.9 and 146.0 (coord. pz−C^{4,5,3}) 109.1, 134.1 and 144.0 (non coord. pz−C^{4,5,3}) ppm. IR (KBr): $\tilde{\nu}$ = 1519 cm^{-1} (m, C=N).

Preparation of G1−[OCH$_2$C(pz)$_3$]$_4$ (6): This compound was prepared according to the procedure described above for **2**, from NaOCH$_2$C(pz)$_3$ (**II**, 1.288 g, 4.84 mmol) and carbosilane G1−Cl$_4$ (0.690 g, 1.21 mmol) in THF (20 mL). The resulting oil was dissolved in pentane (20 mL), washed with water, and the organic layer dried with $MgSO_4$. The solvent was removed under vacuum giving compound **6** as a colorless oil. Yield: 1.29 g (76%). $C_{64}H_{92}N_{24}O_4Si_5$ (1402.02): calcd. C 54.83, H 6.61, N 23.98; found C 53.89, H 6.82, N 23.57%. ^1H NMR ($CDCl_3$): δ = 0.00 (s, 6 H, $SiMe_2$), 0.44 (m, 2 H, Si*CH*$_2$), 0.56 (m, 2 H, *CH*$_2$SiMe$_2$), 1.24 (m, 2 H,CH$_2$*CH*$_2$CH$_2$), 5.19 (s, 2 H, CH_2O), 6.29 (dd, 3 H, $J_{H,H}$ = 1.4, 2.3 Hz, pz−H^4), 7.43 (d, $J_{H,H}$ = 2.3 Hz, 3 H, pz−H^5), 7.61 (d, $J_{H,H}$ = 1.4 Hz, 3 H, pz−H^3) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = −2.4 ($SiMe_2$), 16.8 (CH_2), 17.5 (CH_2), 20.8 (CH_2), 66.8 (CH_2O), 90.1 [C(pz)$_3$], 106.1 (pz−C^4), 130.8 (pz−C^5), 140.9 (pz−C^3) ppm. IR (CsI/Nujol): $\tilde{\nu}$ = 1517 cm^{-1} (m, C=N).

Preparation of G1−[OCH$_2$C(pz)$_3$Mo(CO)$_3$]$_4$ (7): A yellow solution of [Mo(CO)$_3${1,3,5-(CH$_3$)$_3$C$_6$H$_3$}] (137 mg, 0.46 mmol) and compound **6** (160 mg, 0.11 mmol) in THF (20 mL) was refluxed for 1.5 h. At room temperature, a greenish precipitate was filtered, washed with hexane (2 × 5 mL), and recrystallized from acetone to afford **7** as a mustard-yellow solid. Yield: 143 mg (61%). $C_{76}H_{92}N_{24}O_{16}Si_5Mo_4$ (2121.91): calcd. C 43.02, H 4.37, N 15.84; found C 42.62, H 4.72, N 15.75%. ^1H NMR ([D$_6$]acetone): δ = 0.41 (s, 6 H, $SiMe_2$), 0.58 (m, 2 H, Si*CH*$_2$), 0.89 (m, 2 H, *CH*$_2$SiMe$_2$), 1.35 (m, 2 H, CH$_2$*CH*$_2$CH$_2$), 5.98 (s, 2 H, CH_2O), 6.46 (m, 3 H, pz−H^4), 8.01 (m, 3 H, pz−H^3), 8.27 (m, 3 H, pz−H^5) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]acetone): δ = −1.9 ($SiMe_2$), 17.6 (CH_2), 18.6 (CH_2), 27.7 (CH_2), 63.5 (CH_2O), 107.0 (pz−C^4), 131.7 (pz−C^5), 146.0 (pz−C^3) ppm, C(pz)$_3$ and CO not observed. IR (KBr): $\tilde{\nu}$ = 1906 and 1757 cm^{-1} (s, CO), 1519 cm^{-1} (m, C=N).

X-ray Crystallography Studies: Suitable monocrystals of **1** and **5** were obtained from a saturated solution in pentane at −30 °C, and by slow evaporation of acetone at room temperature. A summary of crystal data, data collection, and refinement parameters for the structure analysis of both compounds is given in Table 3. A colorless (**1**) or yellow (**5**) crystal was glued to a glass fiber and mounted on Kappa-CCD Bruker-Nonius diffractometer with area detector, and data were collected with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). For compound **1**, data were collected at room temperature, with an exposure time of 30 s per frame (five sets; 224 frames; phi and omega scans 2° scan-width). For compound, **5** data collection was performed at 150 K, with an exposure time of 10 s per frame (12 sets; 510 frames; phi and omega scans 2° scan-width). Raw data were corrected for Lorenz and polarization effects.

Structures were solved by direct methods, completed by subsequent difference Fourier techniques, and refined by full-matrix least-squares on F^2(SHELXL-97).[26] Anisotropic thermal parameters were used in the last cycles of refinement for the non hydrogen atoms in both structures. Hydrogen atoms were found in the final Fourier maps and were refined with isotropic thermal displacement parameters.

All the calculations were made with the WINGX system.[27]

CCDC-232262 and -232263 contains the supplementary crystallographic data for compounds **1** and **5**, respectively. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We gratefully acknowledge Prof. Reger for the useful information related to the synthesis and purification of the pyrazolylmethane precursors. We also thank the DGI-Ministerio de Ciencia y Tecnología (project BQU2001−1160) for financial support.

Lithium and Potassium Amides of Sterically Demanding Aminopyridines

Natalie M. Scott,[a] Thomas Schareina,[b] Oleg Tok,[a] and Rhett Kempe*[a]

Keywords: Amido ligands / Coordination polymers / Lithium / N ligands / Potassium

The reaction of Grignard compounds of 1-bromo-2,4,6-diisopropylbenzene (**1**) or 1-bromo-2,6-dimethylbenzene (**2**), formed in situ, with 2,6-dibromopyridine in the presence of a catalytic amount of [(dme)$NiBr_2$] (dme = 1,2-dimethoxyethane) and tricyclohexylphosphane (1:2 ratio) leads to the corresponding monoarylated bromopyridines. These bromopyridines undergo Pd-catalysed aryl amination (Buchwald–Hartwig amination) with 2,6-diisopropylaniline giving rise to (2,6-diisopropylphenyl)[6-(2,4,6-triisopropylphenyl)pyridin-2-yl]amine (Ap*H) and (2,6-diisopropylphenyl)[6-(2,6-dimethylphenyl)pyridin-2-yl]amine (Ap′H) (Ap = aminopyridinate). Deprotonation of Ap*H in diethyl ether using BuLi results (after workup in hexane) in a colourless crystalline material. X-ray structural analysis reveals it to be a monomeric three-coordinate lithium aminopyridinate. In toluene solution, an equilibrium between [$(Ap^*Li)_2$] (in excess at room temperature) and [$Ap^*Li(OEt_2)$] (prominent at low temperature) is observed. Reaction of Ap′H with BuLi in diethyl ether gives rise to [Ap*LiAp*$Li(OEt_2)$]. Deprotonation of Ap*H and Ap′H using KH leads to $[Ap^*K]_n$ and $[Ap'K]_\infty$, respectively. $[Ap'K]_\infty$ is a rare example of a crystalline organometallic polymer, as determined by X-ray analysis.

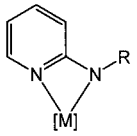
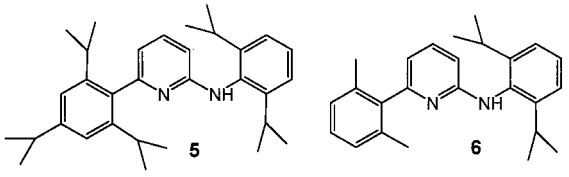
Introduction

During the renaissance[1] of (amido)metal[2] chemistry, aminopyridinato ligands[3] have been used extensively to stabilise early transition metal and lanthanide ions (Scheme 1).



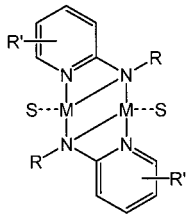
Scheme 1. Aminopyridinato ligand ([M] = early transition metal moiety; R = aryl, silyl or alkyl substituent)

The aminopyridinato ligands used thus far have exhibited a relatively low steric demand, especially in the plane perpendicular to the pyridine moiety. This characteristic has restricted the chemistry of the corresponding metal complexes so far, leading to the formation of "ate" species, for example.[3,4] In order to minimise this feature, we became interested in designing bulkier aminopyridinato ligands by the introduction of 2,6-alkylphenyl (alkyl = methyl or isopropyl) substituents at the amido N atom as well as the 6-position of the pyridine ring. Here, we report on the synthesis and structure of the lithium and potassium amides of Ap*H and Ap′H (Scheme 2).



Scheme 2. Ap*H (**5**) and Ap′H (**6**)

The syntheses and structures of alkali metal aminopyridinates were described first by Clegg and Snaith et al.[5] These compounds are remarkable examples of the diversity metal amides can show in terms of binding and aggregation modes.[6] One of the most common structures observed is a dimer containing two coordinated solvent molecules (Scheme 3).[7]



Scheme 3. The dimeric bis(solvent)-coordinated structure motive (M = alkali metal; R, R′ = alkyl, aryl or silyl substituent; S = mono- or bidentate donor solvent molecule)

Furthermore, structurally diverse alkali metal aminopyridinates have been found in aminopyridinato "ate" complexes[8] and in main group amides.[9]

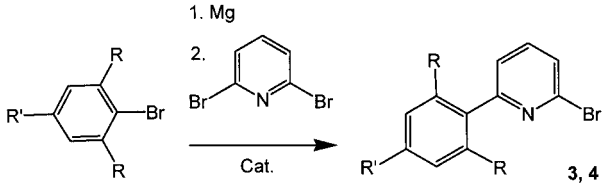
Results and Discussion

Synthesis of the Ligands

The reaction of in situ formed Grignard compounds of 1-bromo-2,4,6-diisopropylphenyl or 1-bromo-2,6-dimethylphenyl (**1**, **2**) with 2,6-dibromopyridine in the presence of a catalytic amount of [(dme)$NiBr_2$] and tricyclohexylphosphane (1:2 ratio) leads to the bromopyridines **3** and **4** (Scheme 4). The catalyst system was chosen on the basis of results of parallel screening experiments with various phosphane/group 10 metal combinations. The best combination also turned out to be optimal in terms of material availability (both components can be obtained commercially), selectivity and activity.[10]



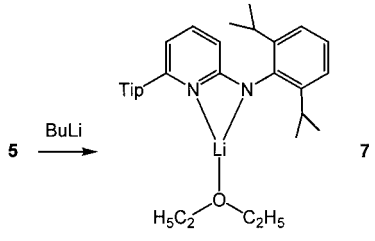
Scheme 4. Synthesis of **3** and **4** (**3** with R, R′ = *i*Pr; **4** with R = CH_3, R′ = H)

Compounds **3** and **4** undergo Pd-catalysed aryl amination (Buchwald–Hartwig amination) with 2,6-diisopropylaniline giving rise to **5** and **6**, respectively.[11] Despite the steric demands of the reactants, good yields have been observed for these two reactions.

Synthesis, Structure and Dynamic Behaviour of the Aminopyridinates

Deprotonation of **5** in diethyl ether using BuLi gave rise (after workup in hexane) to a colourless crystalline material (compound **7**) in about 80% yield (Scheme 5). X-ray crystal structure analysis of **7** revealed it to be a monomeric three-coordinated lithium aminopyridinate in the solid state (Figure 1).

The nearly equivalent Li–N distances [Li–N1 1.987(5), Li–N2 2.020(5) Å] indicate a delocalised binding mode.[12] The coordination of the lithium ion is approximately trigonal-planar (sum of angles = 353°; deviation of Li out of the plane N1–N2–O = 0.26 Å). The steric demand of deprotonated **5** is large. The maximum atom–atom distances of deprotonated **5** in **7** are a = 15 Å (Scheme 6) and, approximately perpendicular to it, b = 8 Å (Scheme 6). Comparison of these distances with those of the bulky, η^5-coordinated Cp* ligand[13] (Cp* = pentamethylcyclopentadienyl), which has a distance of $a = b$ = 6.2 Å for both directions, indicates that deprotonated **5** should be effective for the protection of large metal ions.



Scheme 5. Synthesis of **7** (Tip = 2,4,6-triisopropylphenyl)

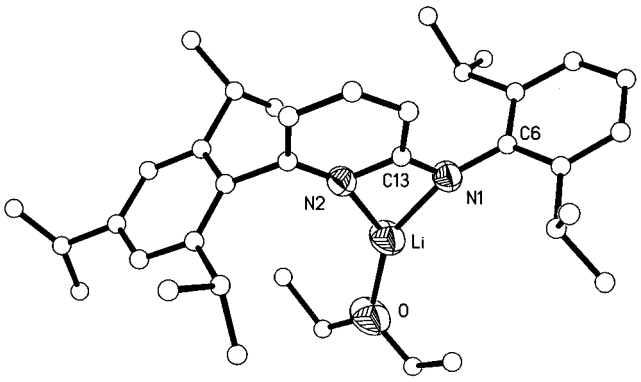


Figure 1. Molecular structure of **7** (ellipsoids correspond to the 50% probability level); selected bond lengths [Å] and angles [°]: Li–O 1.903(5), Li–N1 1.987(5), Li–N2 2.020(5); O–Li–N1 150.4(3), O–Li–N2 132.9(3), N1–Li–N2 69.28(16)

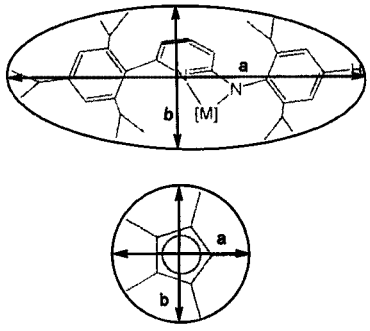

Scheme 6. Description of the steric demand of deprotonated **5**

^{1}H NMR spectroscopy of **7** at room temperature revealed it to be dynamic (Figure 2). One possibility is that the isopropyl groups of the aniline moiety and the pyridine substituent have restricted rotation due to the strained η^2-coordination mode [angle N1–Li–N2 = 69.28(16)°]. Alternatively, two different compounds (e.g. isomers) could exist in solution. Cooling of the NMR sample resulted in the formation of signals from a second compound (Figure 2). A characteristic of this "room-temperature compound" (**7a**) is that ether coordination is not observed as evidenced by the matching of the well-resolved ether signals to those of "free ether" in C_7D_8. In accordance with the structure of **8** (see discussion below) we propose a "solvent-free" dimeric structure for **7a** (Scheme 7)

Cooling down to −30 °C results in a change in the ratio of **7**/**7a** from 2:1 to 3:1. Precipitation of **7** starts at −50 °C (broad signals). Signal resolution occurs with the addition

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

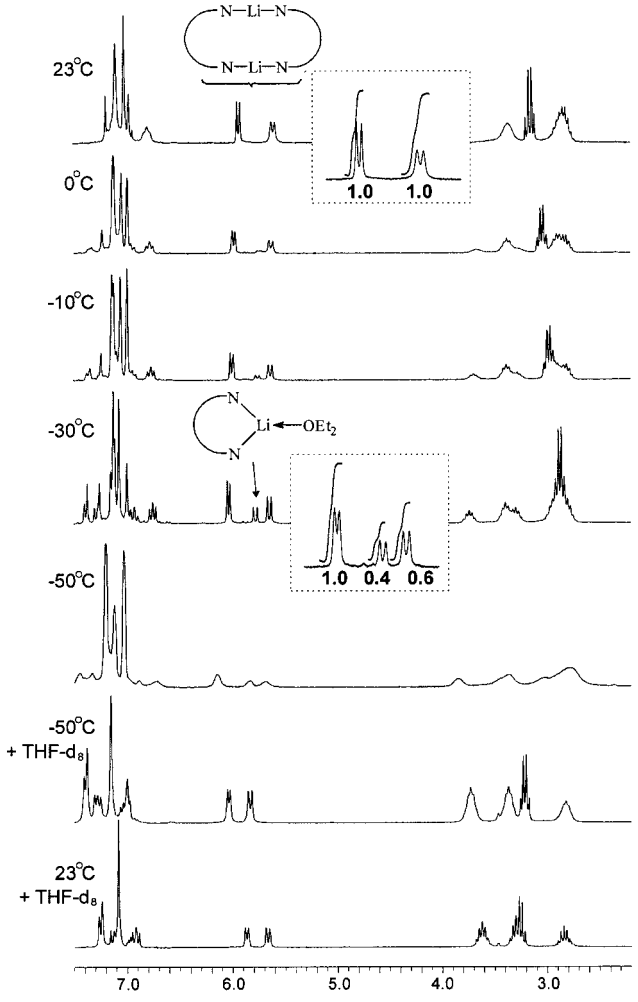

Figure 2. ^{1}H NMR of **7** in C_7D_8 at different temperatures; the two last spectra show signals after addition of $[D_8]$THF

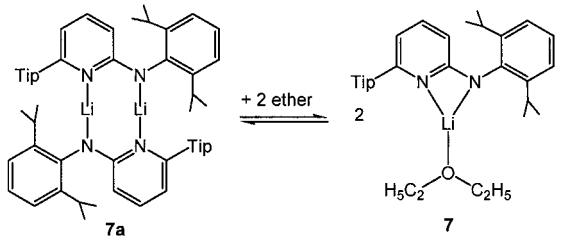
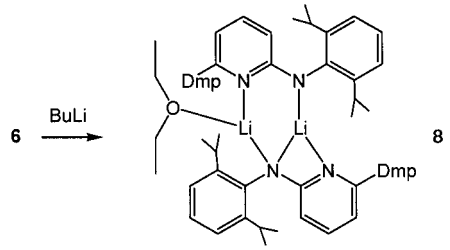


Scheme 7. Equilibrium between **7a** (dominant at room temperature) and **7** (low-temperature ether adduct)

of an excess of $[D_8]$THF at this temperature with the formation of a THF adduct analogous to **7**. This is indicated by a new, third signal set accompanied by the signals of "free ether". Raising the temperature to 25 °C causes only marginal changes of the signal set, which is in accordance with the expected temperature dependence. Furthermore, the signals observed for the pyridine protons suggest a delocalised binding mode in solution for both **7** and **7a**.[12]

Reaction of **6** with BuLi in diethyl ether gave (after work up in hexane) a crystalline material (**8**) in good yield (Scheme 8).



Scheme 8. Synthesis of **8** (Dmp = 2,6-dimethylphenyl)

X-ray crystal structure analysis of **8** revealed a dimeric structure in the solid state (Figure 3). Both Li atoms are coordinated in an almost trigonal-planar manner. The deviations of the lithium atoms out of the coordination planes are 0.43 Å (Li1) and 0.23 Å (Li2). One of the two Ap′ ligands acts as a bridge (bridging binding mode) with a significantly longer $N_{pyridine}-Li$ than $N_{amido}-Li$ bond, indicative of a localisation of the anionic charge of this ligand at the amido nitrogen atom. The second Ap′ ligand binds one of the lithium atoms in the strained η^2-binding mode [N4−Li2−N3 65.82(14)°] whereas the N_{amido} lone pair acts as a bridge to the second lithium atom. The steric demands of this new ligand can be described as mentioned above for Ap* (Scheme 6). The maximum atom−atom distances are a = 13 Å and, perpendicular to it, b = 8 Å. NMR studies reveal a similar dimeric structure in toluene solution as found in the solid state.

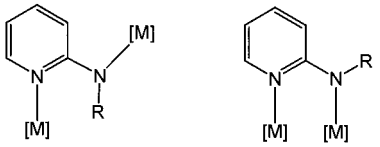
Figure 3. Figure 4. Part of the molecular structure of **10** (ellipsoids correspond to the 50% probability level); selected bond lengths [Å] and angles [°]: C1−K1 3.125(9), C2−K1 3.218(10), C3−K1 3.260(10), C4−K1 3.260(10), C5−K1 3.187(9), C6−K1 3.137(9), C12−K1 3.292(9), C17−K1 3.341(9), N3−K1 2.815(7), N4−K1 2.739(7); N4−K1−N3 157.2(2)

suitable for X-ray analysis were grown from diethyl ether (crystal structure: Figure 4).

The structure of **10** is best described as a coordinative one-dimensional polymer. (The amidoaryl groups appear on the same side in successive "monomer residues" − pseudo-isotactic.) The amido N atom coordinates one potassium atom and the pyridine function binds the next. The coordination thus can be described as a *transoid*-bridging binding mode (Scheme 10).



Scheme 10. *transoid*- (left) and *cisoid*-bridging binding (right) mode of aminopyridinato ligands ([M] metal moiety)

The binding situation observed for **10** might be helpful in explaining the mechanism of polymeric by-product formation found during aminopyridinato early transition metal complex syntheses.[3] The *transoid*-bridging binding mode formed by a two-coordinate potassium ion would be unstable without the π-coordination of the electron-rich phenyl substituents which coordinatively saturate the system. From an alternative viewpoint it could be said that the electron-rich arene functions of **5** and **6** are ideal for coordinatively saturating the potassium atoms and owing to geometric restrictions, the *transoid*-bridging binding mode is favoured. A detailed discussion of bond lengths and angles of **10** is precluded by the high disorder in the X-ray structure and grown-together twinned crystals. Despite the fact that a potassium−arene interaction is a common phenomenon, polymeric structures based on these are rarely observed[14] and homoleptic systems are almost unknown.[15]

Conclusions

Grignard coupling and palladium-catalysed aryl amination are efficient methods for the preparation of sterically encumbered aminopyridines. The steric coverage of deprotonated aminopyridines (aminopyridinato ligands) approaches the nanometer range and the cover area is about 3.3 and 2.8 times larger for deprotonated **5** and deprotonated **6**, respectively, than for Cp*. The structural and dynamic behaviour of the lithium and potassium amides in solution differ significantly. Compound **10** is a rare example of an Ap complex exhibiting the *transoid*-bridging binding mode.

Experimental Section

General Procedures: All reactions and manipulations with air-sensitive compounds were performed under dry argon, using standard Schlenk and drybox techniques. Solvents were distilled from sodium benzophenone ketyl. Deuterated solvents were obtained from Cambridge Isotope Laboratories and were degassed, dried (CaH_2) and distilled prior to use. NMR spectra were obtained using either a Bruker ARX 250 or Bruker DRX 500 spectrometer. Chemical shifts are reported in ppm relative to the deuterated solvent. *n*BuLi, KH, 1-bromo-2,4,6-triisopropylbenzene, 1-bromo-2,6-dimethylbenzene, $NiBr_2$(dme), tricyclohexylphosphane, 2,6-diisopropylaniline, 3-bis(diphenylphosphanyl)propane, sodium *tert*-butoxide, 1,2-dibromoethane and tris(dibenzylideneacetone)dipalladium(0) were purchased from commercial suppliers. X-ray crystal structure analyses were performed by using a STOE-IPDS I or II equipped with an Oxford Cryostream low-temperature unit. Structure solution and refinement were accomplished using SIR97,[16] SHELXL-97[17] and WinGX.[18] Crystallographic details are summarised in Table 1. CCDC-231858 (for **10**), -231859 (for **8**) and -231860 (for **7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk]

Preparation of 1-MgBr-[2,4,6-(*i*Pr)$_3$C$_6$H$_2$] (1): THF (30 mL) was added to magnesium turnings (0.94 g, 38.7 mmol). 1-Br-2,4,6-(*i*Pr)$_3$C$_6$H$_2$ (35.2 mmol, 9.97 g, 8.86 mL) was then added and the resulting suspension stirred and activated using 1,2-dibromoethane. An exothermic reaction took place and an ice bath was used to cool the reaction mixture when the reaction became too vigorous. After 1 h, the cooled reaction mixture was stirred at 50 °C overnight. The reaction mixture was filtered and the filtrate directly used in the preparation of **3**.

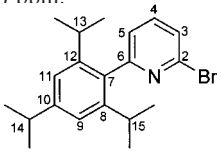
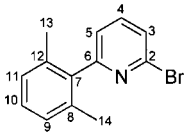
Preparation of 1-MgBr-[2,6-(Me)$_2$C$_6$H$_3$] (2): THF (30 mL) was added to magnesium turnings (0.94 g, 38.7 mmol). 1-Br-2,6-Me$_2$C$_6$H$_3$ (35.2 mmol, 6.50 g, 4.69 mL) was then added and the resulting suspension stirred. The reaction mixture was activated using 1,2-dibromoethane (approx. 0.4 mL). An exothermic reaction took place and an ice bath was used to cool the reaction mixture when the reaction became too vigorous. After 2 h, the cooled reaction mixture was stirred at 50 °C for 12 h. The reaction mixture was filtered and the filtrate directly used in the preparation of **4**.

Preparation of 3: 2,6-Dibromopyridine (7.91 g, 33.4 mmol), dioxane (35 mL), tricyclohexylphosphane [0.075 mmol, 1.5 mL (0.05 M in THF)] and [NiBr$_2$(dme)] (0.012 g, 0.0375 mmol) were added together in a Schlenk flask under argon; **1** was then added to the stirred suspension resulting in a beige precipitate. The reaction mixture was warmed to 50 °C and stirred for 72 h. Water and $CHCl_3$ were added and the resulting suspension transferred to a 2-L separating funnel. The organic phase was collected and the inorganic phase washed with $CHCl_3$ and extracted. The combined organic phases were washed with a saturated sodium chloride solution and dried with Na_2SO_4. The solvent was removed to afford a white precipitate. The precipitate was recrystallised from hot *n*-octane and washed with *n*-pentane (20 mL). Yield 7.05 g (58%). M.p. 232–233 °C $C_{20}H_{26}BrN$ (360.3): calcd. C 66.67, H 7.27, N 3.89; found C 67.56, H 7.48, N 3.78. ^{1}H NMR (250 MHz, $CDCl_3$, 298 K): δ = 1.00–1.30 [m, 18 H, CH(C*H*$_3$)$_2$], 2.44 [sept, 2 H, C*H*(CH$_3$)$_2$], 2.88 [sept, 1 H, C*H*(CH$_3$)$_2$], 7.02 (s, 2 H, 9,11-H), 7.21 (d, 1 H, 3-H), 7.45 (d, 1 H, 5-H), 7.59 (br. dd, 1 H, 4-H) ppm. ^{13}C NMR (250 MHz, $CDCl_3$, 298 K): δ = 23.85 [2 CH$_3$, (*C*H$_3$)$_2$CH], 24.06 [2 CH$_3$, (*C*H$_3$)$_2$CH], 24.17 [2 CH$_3$, (*C*H$_3$)$_2$CH], 30.41 [*C*H(CH$_3$)$_2$, C-13,-15], 34.44 [*C*H(CH$_3$)$_2$, C-14], 120.76 (CH, C-9,11), 123.94 (CH, C-3/5), 125.90 (CH, C-3/5), 134.88 (C, C-7), 137.93 (CH, C-4), 141.46 (C, C-2), 146.12 (C, C-8,12), 149.29 (C, C-10), 161.30 (C, C-6) ppm.



Preparation of 4: 2,6-Dibromopyridine (7.91 g, 33.4 mmol), dioxane (35 mL), tricyclohexylphosphane (0.075 mmol, 1.5 mL (0.05 M in THF) and [NiBr$_2$(dme)] (0.012 g, 0.0375 mmol) were combined in a Schlenk flask and cooled to 0 °C. Compound **2** was then slowly added dropwise to the cooled, stirred suspension. A beige precipitate resulted and the resulting mixture was then warmed to room temperature where a moderate exothermic reaction took place. Once the reaction mixture was cooled to room temperature, it was stirred and after 1 h heated to 50 °C for 72 h. Water (50 mL) and CH_2Cl_2 (50 mL) were added and the resulting suspension transferred to a 2-L separating funnel. The organic phase was collected and the inorganic phase washed with CH_2Cl_2 and extracted. The combined organic phases were washed with a saturated sodium chloride solution and dried with Na_2SO_4. The organic phase was concentrated to dryness under vacuum resulting in a red-orange oily product. The reddish oil was purified using silica chromatography (dichloromethane) and then crystallised from pentane at –20 °C. Yield 7.80 g (89%). M.p. 62–63 °C. $C_{13}H_{12}BrN$ (262.1): calcd. C 59.56, H 4.61, N 5.34; found C 60.30, H 4.74, N 5.28. ^{1}H NMR (250 MHz, $CDCl_3$, 298 K): δ = 1.91 (s, 6 H, CH$_3$), 6.92 (s, 2 H, 9,11-H), 6.86–7.35 (m, 3 H, Ar, 3,5,10-H), 7.44 (br. dd, 1 H, 4-H) ppm. ^{13}C NMR (250 MHz, $CDCl_3$, 298 K): δ = 20.17 (2 CH$_3$, C-13,14), 123.41 (CH, C-3/5), 126.03 (CH, C-3/5), 127.52 (CH, C-9,11), 128.21 (C, C-10), 135.64 (C, C-8,12), 138.91 (CH, C-4), 140.73 (C, C-2/7), 141.71 (C, C-2/7), 160.88 (C, C-6) ppm.



Preparation of Ap*H (5): In a drybox the solids **3** (4.00 g, 11.12 mmol), 1,3-bis(diphenylphosphanyl)propane (0.115 g, 0.279 mmol), tris(dibenzylideneacetone)dipalladium(0) (0.126 g, 0.139 mmol) and sodium *tert*-butoxide (0.90 g, 3.10 mmol) were combined in a Schlenk flask. 2,6-Diisopropylaniline (11.12 mmol, 1.97 g, 2.10 mL) and toluene (40 mL) were added to the flask. The

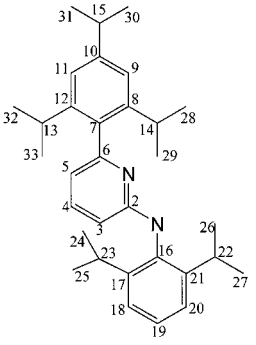
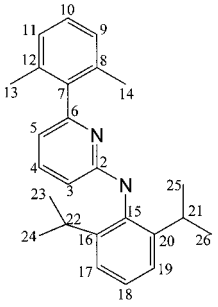
resulting mixture was heated at 95 °C for 48 h. The reaction mixture was cooled to room temperature, and water (50 mL) and diethyl ether (50 mL) were added. The organic phase was extracted and the remaining inorganic phase was washed with diethyl ether (3 × 20 mL). The combined organic phases were washed with a saturated sodium chloride solution and the organic phase was dried with sodium sulfate. The solvent was removed under reduced pressure and the resulting red-orange solid was purified using silica chromatography (dichloromethane). Yield 5.00 g (89%). M.p. 162−163 °C. $C_{32}H_{44}N_2$ (456.7): calcd. C 84.16, H 9.71, N 6.13; found C 83.94, H 9.75, N 5.71. ^{1}H NMR (250 MHz, $CDCl_3$, 298 K): δ = 1.00−1.27 [m, 30 H, CH(CH_3)$_2$], 2.70 [sept, 2 H, CH(CH$_3$)$_2$], 2.90 [sept, 1 H, CH(CH$_3$)$_2$], 3.25 [sept, 2 H, CH(CH$_3$)$_2$], 3.72 (br. s, 1 H, NH), 5.91 (br. d, ^1J = 8.30 Hz, 1 H, 3-H), 5.97 (br. s, 1 H, 4-H), 6.61 (br. d, ^1J = 7.2 Hz, 1 H, 5-H), 7.03−7.40 (m, Ar, 5 H, 9,11,18,19,20-H) ppm. ^{13}C NMR (250 MHz, $CDCl_3$, 298 K): δ = 22.43 [CH(CH$_3$)$_2$, C-22,23], 23.95 [2 CH(CH$_3$)$_2$, C-32,33/28,29/30,31], 24.14 [2 CH(CH$_3$)$_2$, C-32,33/28,29/30,31], 24.51 [2 CH(CH$_3$)$_2$, C-32,33/28,29/30,31], 28.47 [CH(CH$_3$)$_2$, C-24,25,26,27], 30.33 [CH(CH$_3$)$_2$, C-13,14], 34.47 [CH(CH$_3$)$_2$, C-15], 103.64 (CH, C-3), 114.89 (CH, C-5), 120.74 (CH, C-9,11), 123.92 (CH, C-18,20), 127.90 (CH, C-19), 134.51 (C, C-16), 136.61 (C, C-7), 137.35 (CH, C-4), 146.01 (C, C-8,12), 148.01 (C, C-17,21), 148.45 (C, C-10), 158.54 (C, C-2/6), 159.08 (C, C-2/6) ppm.



Preparation of Ap′H (6): In a drybox the solids **4** (2.00 g, 7.63 mmol), 1,3-bis(diphenylphosphanyl)propane (0.115 g, 0.279 mmol), tris(dibenzylideneacetone)dipalladium(0) (0.126 g, 0.139 mmol) and sodium *tert*-butoxide (0.83 g, 8.6 mmol) were combined in a Schlenk flask. 2,6-Diisopropylaniline (7.63 mmol, 1.35 g, 1.43 mL) and toluene (30 mL) were added to the flask. The resulting mixture was heated at 95 °C for 72 h. The reaction mixture was cooled to room temperature, and water (50 mL) and diethyl ether (50 mL) were added. The organic phase was extracted and the remaining inorganic phase washed with diethyl ether (3 × 20 mL). The combined organic phases were washed with a saturated sodium chloride solution and the organic phase was dried with sodium sulfate. The solvent was removed under reduced pressure and the resulting red solid was then purified using column chromatography (dichloromethane) and crystallised at −20 °C from pentane to afford a white crystalline material. Yield 2.10 g (77%). M.p. 106−107 °C. $C_{25}H_{30}N_2$ (358.5): calcd. C 83.75, H 8.43, N 7.81; found C 83.37, H 8.54, N 7.72. ^{1}H NMR (250 MHz, $CDCl_3$, 298 K): δ = 0.88−1.20 [m, 12 H, CH(CH_3)$_2$], 2.09 (s, 6 H, CH_3), 3.25 [sept, 2 H, CH(CH$_3$)$_2$], 3.76 (v. br. s, 1 H, NH), 5.86 (br. d, ^1J = 8.30 Hz, 1 H, 3-H), 5.98 (br. s, 1 H, 4-H), 6.49 (br. d, ^1J = 7.2 Hz, 1 H, 5-H), 7.03−7.35 (m, Ar, 6 H, 9,10,11,17,18,19-H) ppm. ^{13}C NMR (250 MHz, $CDCl_3$, 298 K): δ = 20.10 (CH$_3$, C-13,14), 23.75 [CH(CH$_3$)$_2$, C-21,22], 28.44 [CH(CH$_3$)$_2$, C-23,24,25,26], 103.73 (CH, C-3), 114.08 (CH, C-5), 124.06 (CH, C-17,19), 127.56 (CH, C-9,11), 127.70 (CH, C-10/18), 128.00 (CH, C-10/18), 134.18 (C, C-15), 135.75 (C, C-8,12), 138.04 (CH, C-4), 140.74 (C, C-7), 148.01 (C, C-16,20), 158.43 (C, C-2/6), 159.37 (C, C-2/6) ppm.



Preparation of 7: *n*BuLi (1.38 mL, 1.6 M, 2.20 mmol) was slowly added to a stirred solution of Ap*H (1.00 g, 2.20 mmol) in diethyl ether (40 mL) at 0 °C. After complete addition, the mixture was stirred and warmed to room temperature (ca. 1 h). The reaction mixture was concentrated to dryness and hexane (20 mL) added. The solvent volume was reduced to ca. 2 mL in vacuo, and on standing colourless crystals of the title complex formed. Yield 0.96 g (82%). $C_{36}H_{53}LiN_2O$ (536.8): calcd. C 80.56, H 9.95, N 5.22; found C 79.85, H 9.66, N 4.90. ^{1}H NMR (250 MHz, C_7D_8, 298 K): δ = 0.89 (br. m, 6 H, CH$_3$, OEt$_2$), 0.98−1.40 [m, 30 H, CH(CH_3)$_2$], 2.83 [br. m, 3 H, CH(CH$_3$)$_2$] 3.11 (m, 4 H, CH$_2$, OEt$_2$), 3.25 [br. m, 2 H, CH(CH$_3$)$_2$], 5.61 (br. d, ^1J = 8.05 Hz, 1 H, 3-H), 5.92 (d, ^1J = 6.90 Hz, 1 H, 5-H), 6.95 (br. dd, 1 H, 4-H), 6.98−7.32 (m, Ar, 5 H, 9,11,18,19,20-H) ppm. ^{13}C NMR (250 MHz, C_7D_8, 298 K): δ = 14.99 (2 CH$_3$, Et$_2$O), 24.37 [CH(CH$_3$)$_2$, C-22,23], 24.47 [CH(CH$_3$)$_2$, C-28,29,32,33], 24.88 [CH(CH$_3$)$_2$, C-30,31], 28.42 [CH(CH$_3$)$_2$, C-24,25,26,27], 30.66 [br., CH(CH$_3$)$_2$, C-13,14], 34.94 [br., CH(CH$_3$)$_2$, C-15], 66.17 (2 CH$_2$, Et$_2$O), 107.15 (br. Preparation of 8: *n*BuLi (0.63 mL, 1.6 M, 1.00 mmol) was slowly added to a stirred solution of Ap′H (0.36 g, 1.00 mmol) in diethyl ether (40 mL) at 0 °C. After complete addition, the mixture was stirred and warmed to room temperature (ca. 1 h). The reaction mixture was reduced to dryness and hexane (20 mL) added. The solvent volume was reduced to ca. 10 mL in vacuo, and on standing colourless crystals of the title complex formed. Yield 0.35 g (88%). $C_{54}H_{68}Li_2N_4O$ (803.0): calcd. C 80.76, H 8.53, N 6.98; found C 79.18, H 8.20, N 6.95; the slightly too low C value is due to removal of the coordinated ether during the drying process. ^{1}H NMR (500 MHz, C_7D_8, 298 K): δ = 0.99 (br. m, 6 H, CH_3, OEt_2), 0.92−1.10 [m, 24 H, CH(CH_3)$_2$], 1.92 (s, 12 H, CH_3), 3.19 (m, 4 H, CH_2, OEt_2), 3.27 [sept, 4 H, CH(CH$_3$)$_2$], 5.58 (br. d, ^1J = 8.05 Hz, 2 H, 3-H), 5.76 (d, ^1J = 6.90 Hz, 2 H, 5-H), 6.83 (br. dd, 2 H, 4-H), 6.98−7.10 (m, Ar, 12 H, 9,10,11,17,18,19-H) ppm. ^{13}C NMR (250 MHz, C_7D_8, 298 K): δ = 15.32 (2 CH_3, Et_2O), 20.08 (2 CH_3, C-13,14), 24.18 [2 CH$_3$, CH(CH$_3$)$_2$, C-23,25/24,26], 24.58 [2 CH_3, CH(CH$_3$)$_2$, C-23,25/24,26], 28.44 [2 CH_3, CH(CH$_3$)$_2$, C-23,25/24,26], 65.88 (2 CH_2, Et_2O), 106.19 (CH, C-3/5), 107.46 (CH, C-3/5), 124.90 (CH, C-17,19), 127.30−128.40 (CH, C-9,10,11,18), 135.78 (C, C-8,12), 138.53 (CH, C-4), 141.13 (C, C-7), 143.86 (C, C-15), 144.89 (C, C-16,20), 157.16 (C, C-6), 169.19 (C, C-2) ppm.

Preparation of 9: Diethyl ether (50 mL) was added to the solids KH (0.09 g 2.19 mmol) and Ap*H (1.00 g, 2.19 mmol) and the reaction mixture stirred for 12 h. The mixture was filtered and the filtrate concentrated to dryness under vacuum. The resulting off-white residue was washed with hexane (30 mL) and the resulting white precipitate dried under vacuum. Yield 0.86 g (79%). $[C_{32}H_{43}KN_2]_n$: calcd. C 77.68, H 8.76, N 5.66; found C 77.39, H 8.94, N 5.34. ^{1}H NMR (250 MHz, C_6D_6, 298 K): δ = 1.10−1.30 [m, 30 H, CH(CH_3)$_2$], 2.85 [sept, 1 H, CH(CH$_3$)$_2$], 3.18 [sept, 2 H, CH(CH$_3$)$_2$], 3.33 [sept, 2 H, CH(CH$_3$)$_2$], 5.76 (v. br. d, 1 H, 3-H), 5.92 (br. d, ^1J = 6.80 Hz, 1 H, 5-H), 6.93 (br. dd, 1 H, 4-H), 6.90−7.21 (m, Ar, 5 H, 9,11,18,19,20-H) ppm. ^{13}C NMR (250 MHz, C_6D_6, 298 K): δ = 24.15 [CH(CH$_3$)$_2$, C-28,29,32,33], 24.46 [CH(CH$_3$)$_2$, C-30,31], 25.11 [CH(CH$_3$)$_2$, C-22,23], 28.38 [CH(CH$_3$)$_2$, C-13,14], 30.44 [CH(CH$_3$)$_2$, C-24,25,26,27], 34.93 [CH(CH$_3$)$_2$, C-15], 106.58 (CH, C-3), 120.73 (CH, C-9,11), 121.93 (CH, C-5), 123.82 (CH, C-18,20), 125.84 (CH, C-19), 136.26 (CH, C-4), 139.96 (C, C-7), 143.49 (C, C-16), 146.54 (C, C-8,12), 146.77 (C, C-10), 147.99 (C, C-17,21), 154.05 (C, C-6), 157.81 (C, C-2) ppm.

Preparation of 10: Diethyl ether (50 mL) was added to the solids KH (0.09 g 2.19 mmol) and Ap′H (1.00 g, 2.19 mmol) and the reaction mixture stirred for 12 h. The mixture was filtered and the filtrate concentrated to dryness under vacuum. The resulting off-white residue was washed with hexane (30 mL) and the resulting white precipitate dried under vacuum. Yield 0.86 (79%). Crystals of **6** were grown from diethyl ether. $C_{25}H_{29}KN_2$ (396.6): calcd. C 75.71, H 7.37, N 7.06; found C 75.45, H 7.63, N 6.63. ^{1}H NMR (250 MHz, C_6D_6, 298 K): δ = 1.11−1.16 [m, 12 H, CH(CH_3)$_2$], 2.25 (s, 6 H, CH_3), 3.32 [m, 2 H, CH(CH$_3$)$_2$], 5.85 (v. br. d, 1 H, 3-H), 6.23 (br. d, 1 H, 5-H), 7.00−7.45 (m, Ar, 7 H, 4,9,10,11,17,18,19-H) ppm. ^{13}C NMR (250 MHz, C_6D_6, 298 K): δ = 20.47 (CH_3, C-13,14), 24.11 [CH(CH$_3$)$_2$, C-23,24,25,26], 28.53 [CH, CH(CH$_3$)$_2$, C-21,22], 121.42 (1 CH, C-3/4/5), 123.09, 123.97 (CH, C-17,19), 124.40, 127.26 (CH, C-9,11), 135.65, 135.83 (C, C-8,12), 137.07 (1 CH, C-3/4/5), 150.07 (C, C-16,20) ppm. ^{1}H NMR (250 MHz, C_4D_8O, 298 K): δ = 1.08−1.12 [m, 12 H, CH(CH_3)$_2$], 2.20 (s, 6 H, CH_3), 3.39 [m, 2 H, CH(CH$_3$)$_2$], 5.34 (v. br. d, 1 H, 3-H), 5.51 (br. d, 1 H, 5-H), 6.76 (br. dd, 1 H, 4-H), 6.95−7.02 (m, Ar, 6 H, 9,10,11,17,18,19-H) ppm. ^{13}C NMR (250 MHz, C_4D_8O, 298 K): δ = 20.45 (CH_3, C-13,14), 24.51 [CH(CH$_3$)$_2$, C-23,24,25,26], 28.90 [CH, CH(CH$_3$)$_2$, C-21,22,], 101.92 (v. br., 1 CH, C-3/4/5), 104.21 (1 CH, C-3/4/5), 119.77 (v. br., 1 CH, C-3/4/5), 122.58 (CH, C-17,19), 126.29 (CH, C-10), 126.79 (CH, C-9,11), 135.03 (CH, C-18), 135.50 (C, C-8,12), 142.82 (v. br., C, C-16,20), 144.82 (br., C, C-7), 157.74 (C, C-6), 165.71 (v. br., C, C-2) ppm; C-15 signal could not be observed.

Acknowledgments

We thank Wolfgang Milius for his support in the X-ray laboratory and Elena Klimkina for her help with the assignment of the NMR spectroscopic data. Financial support from the Alexander von Humboldt Stiftung (N. M. S.), the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm 1166 "Lanthanoidspezifische Funktionalitäten in Molekül und Material") and the Fonds der Chemischen Industrie is gratefully acknowledged.

Synthesis and Structural Characterization of Novel Oxorhenium(v) Complexes Containing N-Heterocyclic Carbenes

Beatriz Royo,*[a] Eberhardt Herdtweck,[b] and Carlos C. Romão[a]

Keywords: Carbene ligands / Oxo ligands / Rhenium

Reaction of $[ReOCl_3(PPh_3)_2]$ with 2 equiv. of 1,3-diisopropylimidazol-2-ylidene (*i*Pr-carbene) affords $[ReOCl_3(i\text{Pr-carbene})_2]$ (**1**). When an excess of free carbene is used, the dicationic species $[ReOCl(i\text{Pr-carbene})_4][Cl]_2$ (**2**) is isolated. The cationic dioxorhenium complex $[ReO_2(i\text{Pr-carbene})_4]^+$ has been isolated as its I^- (**3**) and ReO_4^- (**4**) salts by different reactions. Treatment of $[ReO_2I(PPh_3)_2]$ with an excess of 1,3-diisopropylimidazol-2-ylidene yields compound **3** in quantitative yield. The cationic species is also isolated as an ReO_4^- salt from the reaction of $[ReO_2Me(PhCCPh)]$ with 1,3-diisopropylimidazol-2-ylidene. The molecular structures of $[ReOCl_3(i\text{Pr-carbene})_2]$ (**1**) and $[ReO_2(i\text{Pr-carbene})_4][ReO_4]$ (**4**) have been determined by single-crystal X-ray diffraction.

Introduction

Since the first isolation and X-ray structural characterization of free stable Wanzlick carbenes[1] by Arduengo,[2] a new area of transition metal complexes with these imidazolylidene-type carbenes as ligands has developed.[3]

Acting as strong Lewis bases, N-heterocyclic carbenes (NHC) are promising alternatives for the well-established phosphane ligands in organometallic catalysis. A rich variety of transition metal complexes with this type of ligand is known. However, few examples of oxometal complexes containing N-heterocyclic carbenes have been reported. Indeed, the first example of an oxometal−NHC derivative $[ReO_3Me{\cdot}NHC]$ was published in 1994 by Herrmann et al., although no structural characterization was possible.[5] To the best of our knowledge, the X-ray diffraction studies of $[TiCl_3(1,3\text{-diisopropyl-4,5-dimethylimidazol-2-ylidene})(\mu\text{-}O)]_2$,[6] $[VOCl_3(1,3\text{-dimesitylimidazol-2-ylidene})]$[7] and $[UO_2Cl_2(1,3\text{-dimesitylimidazol-2-ylidene})_2]$[8] are the only examples of oxo transition metal and actinide derivatives containing NHCs that have been reported in the literature. During the preparation of this manuscript the X-ray diffraction studies of the cationic dioxorhenium(v) and -technetium(v) complexes $[ReO_2(1,3\text{-diisopropyl-4,5-dimethylimidazol-2-ylidene})_4][PF_6]$ and $[TcO_2(1,3\text{-diisopropyl-4,5-dimethylimidazol-2-ylidene})_4][TcO_4]{\cdot}2.5THF$ were reported.[9]

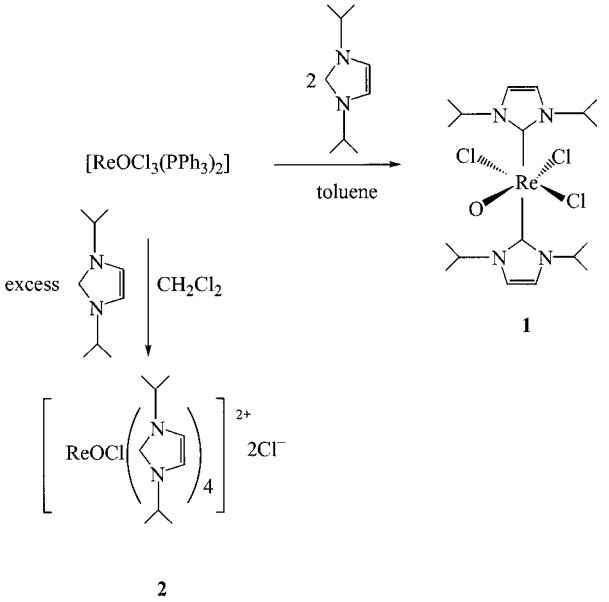
In the present study we describe the synthesis of oxorhenium derivatives containing an NHC ligand and the first X-ray molecular structure of a chlorooxorhenium(v)−NHC complex.

Results and Discussion

Reaction of $[ReOCl_3(PPh_3)_2]$ with 2 equiv. of 1,3-diisopropylimidazol-2-ylidene in toluene at room temperature affords $[ReOCl_3(i\text{Pr-carbene})_2]$ (**1**; *i*Pr-carbene = 1,3-diisopropylimidazol-2-ylidene), which was isolated as a green



Scheme 1. Synthesis of $[ReOCl_3(i\text{Pr-carbene})_2]$ (**1**) and $[ReOCl(i\text{Pr-carbene})_4][Cl]_2$ (**2**)

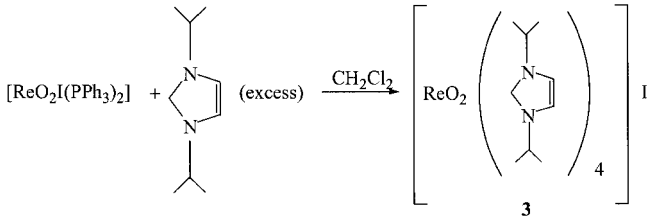
crystalline solid. Double substitution of the triphenylphosphane is preferred since treatment of $[ReOCl_3(PPh_3)_2]$ with 1 equiv. of 1,3-diisopropylimidazol-2-ylidene yields a mixture of compound **1** and unchanged starting material. The reaction of $[ReOCl_3(PPh_3)_2]$ with an excess of free carbene in dichloromethane gives the green dicationic complex $[ReOCl(i\text{Pr-carbene})_4][Cl]_2$ (**2**). Compound **2** is the result of the displacement of two chloride ions and both triphenylphosphane ligands by the imidazol-2-ylidene ligand (Scheme 1).

The ^{1}H NMR spectrum of **1** displays a doublet at δ = 1.40 ppm for the methyl protons of the isopropyl group, a multiplet at δ = 5.75 ppm for the CH proton of the isopropyl group and a singlet at δ = 7.10 ppm for the olefinic protons of the carbene ligand. In contrast, two signal groups of the carbene ligands can be observed for **2**, indicating two inequivalent sets of *i*Pr substituents. This is in agreement with an approximate octahedral environment for the rhenium atom in **2**, with the oxygen and chlorine atoms *trans* to each other. The ^{1}H NMR spectrum of **2** shows two doublets at δ = 2.63 and 2.94 ppm for the methyl protons of the isopropyl group, two multiplets at δ = 4.92 and 5.35 ppm for the CH proton of the isopropyl group and two multiplets at δ = 8.52 and 8.43 ppm for the olefinic protons of the carbene ligand. The ^{13}C NMR signal of the metal-coordinated carbene C atom is shifted by about 85 ppm to higher field upon complexation of the ligand to the metal atom (δ = 175 ppm for **1** compared with δ = 260 ppm for the free ligand). The IR spectra of **1** and **2** show strong ν(ReO) absorptions at 972 and 989 cm^{-1}, respectively. The mass spectrum of **2** gives the molecular ion *m*/*z* (%) = 423 (100). The main fragment corresponds to the loss of one carbene ligand.

Solid samples of compounds **1** and **2** showed no decomposition in air when exposed for shorts periods of time, but solutions of **1** and **2** are moisture-sensitive; traces of water lead to formation of $[ReO_2(i\text{Pr-carbene})_4][ReO_4]$.[9] Compound **1** is soluble in aromatic hydrocarbons such as benzene or toluene, while compound **2** is insoluble in toluene, dichloromethane, tetrahydrofuran or diethyl ether, and slightly soluble in acetonitrile.

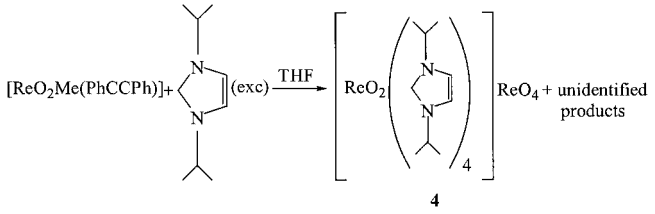
Crystals of **1** suitable for an X-ray structure analysis were grown from toluene at −20 °C and its molecular structure was determined by single-crystal X-ray diffraction.

The reaction of $[ReO_2I(PPh_3)_2]$ with excess of 1,3-diisopropylimidazol-2-ylidene in dichloromethane at −20 °C affords $[ReO_2(i\text{Pr-carbene})_4][I]$ (**3**) [Equation (1)]. The displacement of the iodine atom and both triphenylphosphane ligands in $[ReO_2I(PPh_3)_2]$ by a carbene affords the monocationic species **3**. A similar displacement has been observed previously upon treatment of $[ReO_2I(PPh_3)_2]$ with 2 equiv. of dppe yielding $[ReO_2(dppe)_2][I]$.[10] Compound **3** was isolated as a brown solid, soluble in dichloromethane and insoluble in hexane or diethyl ether. Its ^{1}H NMR spectrum shows two resonances for the methyl protons of the isopropyl group, a doublet at δ = 0.70 ppm and a doublet at δ = 1.18 ppm, indicating a hindered rotation of the isopropyl groups, a multiplet for the CH proton of the isopropyl group at δ = 5.74 ppm, and a singlet at δ = 7.09 ppm for the olefinic protons of the carbene. The resonance of the metal-coordinated C atom appears at δ = 172.6 ppm which compares well with other rhenium−carbene complexes such as $[Re(1,3\text{-dimethylimidazol-2-ylidene})_2I(CO)_3]$ (δ = 175.1 ppm)[11] and $[ReO_3Me(1,3\text{-dimethylimidazol-2-ylidene})_2]$ (δ = 176.7 ppm).[5] The mass spectrum of $\mathbf{3}^+$ gives the molecular ion *m*/*z* (%) = 827 (100). The Re=O vibration of the central dioxorhenium(v) unit appears at 782 cm^{-1}. Similar values have been reported for the Re=O vibration in $[ReO_2(1,3\text{-diisopropyl-4,5-dimethylimidazol-2-ylidene})_4][PF_6]$,[9] and in $[ReO_2(dppe)_2][I]$.[10]



(1)

The $[ReO_2(i\text{Pr-carbene})_4]^+$ cation is also formed by reaction of $[ReO_2Me(PhCCPh)]$ with an excess of 1,3-diisopropylimidazol-2-ylidene in tetrahydrofuran [Equation (2)]. When a solution of $[ReO_2Me(PhCCPh)]$ in THF was treated with an excess of 1,3-diisopropylimidazol-2-ylidene, a brown solution was obtained. After removal of the solvent, the residue was extracted into toluene and the solution was cooled to −20 °C. Light-yellow crystals separated from the solution. On the basis of elemental analysis, spectroscopic evidence and X-ray crystallography, the yellow crystals were formulated as $[ReO_2(i\text{Pr-carbene})_4][ReO_4]$ (**4**). The ^{1}H NMR spectrum of the toluene-insoluble brown residue shows a mixture of complexes which could not be separated by recrystallisation. It seems reasonable to explain the formation of **4** as the result of the reaction of adventitious water.



(2)

Crystallographic Studies

A single crystal of the carbene complex **1** was obtained from toluene by standard cooling techniques and its molecular structure was determined by single-crystal X-ray diffraction. Figure 1 shows an ORTEP-style plot of the monomeric neutral molecule. Selected bond lengths and bond angles are reported in Table 1. The asymmetric unit shows two crystallographically independent molecules A and B,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

each of which is located around a center of inversion, and one solvent molecule (toluene). The intrinsic symmetry of the carbene moiety implies a 50:50 disorder of one chlorine atom and of the oxo ligand. As expected from NMR and IR spectroscopic data, the rhenium atom is coordinated by two carbene ligands in the apical positions of the octahedral coordination sphere. Three chloro and one oxo ligand complete the octahedron in the equatorial plane.

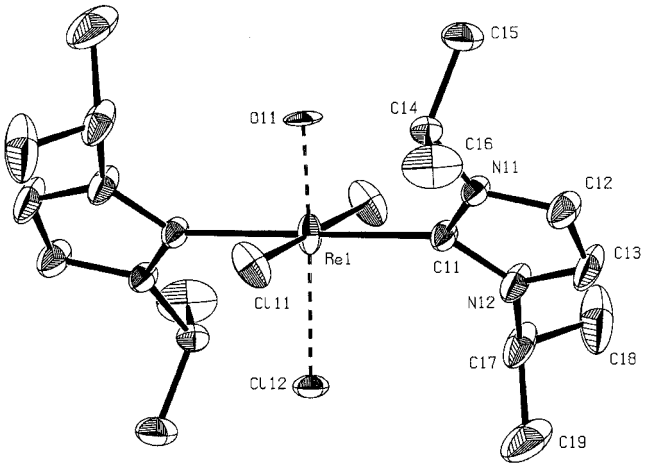


Figure 1. ORTEP representation of compound **1**·toluene (molecule A) in the solid state; thermal ellipsoids are at the 50% probability level; hydrogen atoms are omitted for clarity; dashed lines indicate a disorder (see Exp. Sect.)

Table 1. Selected interatomic distances [Å] and angles [°] for [$ReOCl_3$(*i*Pr-carbene)$_2$(toluene)] (**1**·toluene) and [ReO_2(*i*Pr-carbene)$_4$][ReO_4] (THF) (**4**·THF)

	1·toluene	**4**·THF
Re1−Cl11	2.3943(12)	
Re1−Cl12	2.298(3)	
Re1−O1/O11	1.770(8)	1.796(4)
Re1−O2		1.798(4)
Re1−C11	2.181(4)	2.185(5)
Re1−C21		2.184(3)
Re1−C31		2.208(5)
Re1−C41		2.207(5)
Cl11−Re1−Cl12	83.83(10)	
Cl11−Re1−O11	90.1(3)	
Cl11−Re1−C11	89.63(11)	
O1−Re1−O2		178.92(15)
C11−Re1−C21		89.9(2)
C11−Re1−C41		89.5(2)
C21−Re1−C31		89.9(2)
C31−Re1−C41		90.7(2)

All bond lengths and bond angles of the N-heterocyclic carbene ligand lie within the typical ranges. The very short Re1−Cl12 distance [2.298(3) Å] and the very long Re1=O11 double bond [1.770(8) Å] in comparison to the statistical range given by the CCDC[12a] are caused by the disorder, and therefore have to be regarded as artificial effects. With 2.3943(12) Å, the Re−Cl11 distance fits the mean value of 2.376[12a] Å very well. The dihedral angles N11−C11−Re1−Cl11 and N11−C11−Re1−O11 are −50.5(4)° and 39.4(5)°, respectively. Thus, the carbene moiety defined by N11−C11−N12 is staggered with respect to the planar $ReCl_3O$ unit.

Cooling of a saturated THF solution of **4** to −20 °C for several days yielded clear yellow crystals suitable for X-ray analysis. Figure 2 shows an ORTEP-style plot of the monomeric cationic part of compound **4**. Selected bond lengths and bond angles are reported in Table 1. The asymmetric unit shows one cationic tetrakis(carbene)dioxorhenium moiety, one perrhenate anion, and one solvent molecule (THF). As expected from NMR and IR spectroscopic data, the rhenium atom is coordinated by two oxo ligands in the apical positions and four carbene groups in the basal plane of the octahedral coordination sphere. All bond lengths and bond angles of the N-heterocyclic carbene ligand lie within the typical ranges. The Re1=O11 double-bond lengths [1.796(4) Å and 1.798(4) Å] represent the upper end in the statistical range given by the CCDC.[12b] The dihedral angles N11−C11−Re1−O1, N21−C21−Re1−O1, N31−C31−Re1−O1, and N41−C41−Re1−O1 are 143.6(4)°, 147.5(4)°, 142.0(4)°, and 149.5(5)°, respectively. Thus, the four carbene species are arranged in a propeller mode around the central linear O=Re=O moiety fitting an approximate D_4 symmetry in the solid state.

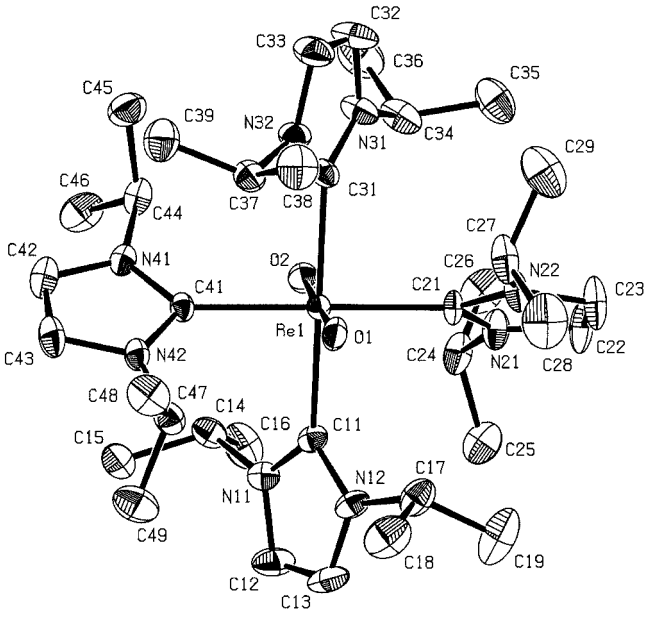

Figure 2. ORTEP representation of the cationic part of compound **4**·THF in the solid state; thermal ellipsoids are at the 50% probability level; hydrogen atoms omitted for clarity

Conclusions

A series of oxorhenium(v) derivatives containing the N-heterocyclic carbene 1,3-diisopropylimidazol-2-ylidene have been prepared. The strong Lewis base carbene easily re-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

places the triphenylphosphane and halide ligands to give neutral and cationic oxorhenium−carbene complexes.

Experimental Section

General Remarks: All manipulations were carried out under dinitrogen using standard Schlenk-line and glovebox techniques. Solvents were purified by conventional methods and distilled under nitrogen prior to use. NMR spectra were recorded with a Bruker AMX 300 spectrometer. Infrared spectra were recorded with a Unicam Mattson Model 7000 FTIR spectrophotometer using KBr pellets. Electrospray mass spectrometric experiments were performed with a Bruker Daltonic esquire 3000 plus spectrometer. Elemental analyses were performed in our laboratories (ITQB). 1,3-Diisopropylimidazolin-2-ylidene,[13] $[ReOCl_3(PPh_3)_2]$,[14] $[ReO_2I(PPh_3)_2]$,[15] and $[ReO_2Me(PhCCPh)]$[16] were prepared according to literature procedures.

Trichlorobis(1,3-diisopropylimidazol-2-ylidene)oxorhenium(v) (1): 1,3-Diisopropylimidazolin-2-ylidene (4.82 mL of a 0.34 M solution in THF, 1.64 mmol) was added to a suspension of $[ReOCl_3(PPh_3)_2]$ (0.68 g, 0.80 mmol) in toluene (0.40 mL) at −20 °C and the reaction mixture was stirred for 30 min. The mixture was then allowed to warm up to room temperature and was stirred for a further 16 h. The toluene solution was filtered and the volume of the filtrate was reduced in vacuo to about 10 mL. Cooling to −20 °C yielded green crystals of **1**. Yield: 0.30 g (65%). $C_{18}H_{32}Cl_3N_4ORe$ (613.05): calcd. C 35.27, H 5.26, N 9.14; found C 35.37, H 5.32, N 9.25. Selected IR data (KBr): ν(ReO) = 972 vs cm^{-1}. ^1H NMR (300 MHz, CD_2Cl_2): δ = 7.10 (s, 2 H, C*H*C*H*), 5.75 (m, 2 H, C*H*Me$_2$), 1.40 (d, $J_{H,H}$ = 6 Hz, 12 H, CH*Me*) ppm. ^{13}C NMR (75 MHz, CD_2Cl_2): δ = 174.9 (Re*C*$_{carbene}$), 119 (*CH*C*H*), 49 (*C*HMe$_2$), 23 (CH*Me*$_2$) ppm.

Chlorotetrakis(1,3-diisopropylimidazol-2-ylidene)oxorhenium(v) Dichloride (2): 1,3-Diisopropylimidazolin-2-ylidene (15.23 mL of a 0.34 M solution in THF, 5.18 mmol) was added at −20 °C to a suspension of $[ReOCl_3(PPh_3)_2]$ (1 g, 1.29 mmol) in dichloromethane (30 mL). When the addition was completed, the mixture was allowed to warm up to room temperature and was then stirred for a further 20 h. The dichloromethane solution was then filtered, the filtrate was concentrated in vacuo to about 10 mL and was cooled to −20 °C, giving deep-green crystals of **2**. Yield: 0.82 g (72%). $C_{36}H_{64}Cl_3N_8ORe$ (917.53): calcd. C 47.13, H 7.03, N 12.21; found C 46.98, H 6.82, N 12.02. Selected IR data (KBr): ν(ReO) = 989 vs cm^{-1}. ^1H NMR (300 MHz, NCMe): δ = 8.52 (m, 2 H, C*H*C*H*), 8.43 (m, 2 H, C*H*C), 5.35 (q, $J_{H,H}$ = 6 Hz, 2 H, C*H*Me$_2$), 4.92 (q, $J_{H,H}$ = 6 Hz, 2 H, C*H*Me$_2$), 2.94 (d, $J_{H,H}$ = 6 Hz, 12 H, CH*Me*$_2$), 2.63 (d, $J_{H,H}$ = 6 Hz, 12 H, CH*Me*$_2$) ppm. MS (ES): *m*/*z* (%) = 423/422 (100) [M^+].

Tetrakis(1,3-diisopropylimidazol-2-ylidene)dioxorhenium(v) Iodide (3): 1,3-Diisopropylimidazolin-2-ylidene (14.70 mL of a 0.34 M solution in THF, 5 mmol) was added at room temperature to a solution of $[ReO_2I(PPh_3)_2]$ (1 g, 1.14 mmol) in dichloromethane (20 mL). The reaction mixture was stirred for 16 h and was then concentrated in vacuo to about 8 mL. Cooling of the dichloromethane solution to −20 °C afforded the title compound **3**, which was isolated as a brown solid. Yield: 0.84 g (78%). $C_{36}H_{64}IN_8O_2Re$ (954.07): calcd.C 45.32, H 6.76, N 11.74; found C 45.03, H 6.69, N 11.65. Selected IR data (KBr): ν(ReO) = 782 vs cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 7.09 (s, 2 H, C*H*C*H*), 5.74 (m, 2 H, C*H*Me$_2$), 1.18 (d, $J_{H,H}$ = 6 Hz, 12 H, CH*Me*$_2$), 0.70 (d, $J_{H,H}$ = 6 Hz, 12 H, CH*Me*$_2$) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 172.6 (Re-C$_{carbene}$), 117.9 (*CH*C*H*), 49.8 (*C*HMe$_2$), 23.2(CH*Me*$_2$) ppm.

Tetrakis(1,3-diisopropylimidazol-2-ylidene)dioxorhenium(v) Perrhenate (4): 1,3-Diisopropylimidazolin-2-ylidene (5.5 mL of a 0.14 M solution in THF, 0.77 mmol) was added to a solution of $[ReO_2Me(PhCCPh)]$ (0.32 g, 0.77 mmol) in tetrahydrofuran (20 mL) at −30 °C. The mixture was stirred at low temperature for 20 min and at room temperature for 2 h. All the volatiles were removed under vacuum and the residue was extracted into toluene. The volume of the toluene solution was reduced in vacuo to about 10 mL and was kept in a refrigerator at −20 °C to yield the title compound **4** as light-yellow crystals. Yield: 0.28 g (47%). $C_{36}H_{64}N_8O_6Re_2$ (1077.4): calcd. C 40.13, H 5.99, N 10.40; found C 39.89, H 5.86, N 10.35. Selected IR (KBr): ν(ReO) = 910vs cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 7.09 (s, 2 H, C*H*C*H*), 5.74 (m, 2 H, C*H*Me$_2$), 1.18 (d, $J_{H,H}$ = 6 Hz, 12 H, CH*Me*$_2$), 0.70 (d, $J_{H,H}$ = 6 Hz,12 H, CH*Me*$_2$) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 172.6 (Re-C$_{carbene}$), 117.9 (*CH*C*H*), 49.8 (*C*HMe$_2$), 23.2(CH*Me*$_2$) ppm. MS (ES): *m*/*z* (%) = 827/825 (100) [M^+].

Crystal Structure Determination of 1 and 4: Details of the X-ray experiment, data reduction, and final structure refinement calculations are summarized in Table 2. Crystals of complex **1** (or **4**) suitable for X-ray structure determination were grown from a toluene (THF) solution, fixed with perfluorinated ether in a glass capillary and transferred to the diffractometer. Preliminary examination and data collection were carried out on a Kappa-CCD device (Nonius Mach3) at the window of a rotating anode (Nonius Fr591; 50 kV; 60 mA; 3.0 kW) and graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Data collection was performed at 123 (153) K with an exposure time of 30 (15) s per frame [φ- and ω-scans, rotation modus, Δφ/Δω = 2.0° (1.0°)]. A total number of 66812

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(48058) reflections were collected.[17a] After merging, a sum of 5391 (8550) independent reflections remained and was used for all calculations. Data were corrected for Lorentz and polarization effects. Corrections for absorption and/or decay effects were applied during the scaling procedure. The unit-cell parameters were obtained by full-matrix least-squares refinements of 5725 (4535) reflections with the program SCALEPACK.[17b] The structures were solved by a combination of direct methods and difference-Fourier syntheses.[17c] All non-hydrogen atoms of the asymmetric unit were refined with anisotropic thermal displacement parameters. All hydrogen atoms were calculated in ideal positions riding on the parent carbon atom. Full-matrix least-squares refinements were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ with the SHELXL-97 weighting scheme and stopped at a maximum shift/err value < 0.001.[17d] Neutral-atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International Tables for Crystallography.[17e] All other calculations (including ORTEP graphics) were done with the program PLATON.[17f] Compound **1**·toluene crystallizes with two crystallographically independent molecules A and B in the asymmetric unit. Each of them is located around a center of inversion. This implies a 50:50 disorder of one chlorine ligand and the oxygen atom. Compound **4**·THF appears to be a twin. Twin refinement ends with Flack's parameter at $\varepsilon = 0.443(6)$. Despite the virtual symmetry of the molecule there is no way to transform the coordinates into the centrosymmetric space group *C*2/*c*. Attempts to solve and to refine the experimental data in *C*2/*c* failed. CCDC-229836 (**1**) and -229837 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Structural and Dynamic Studies of Zinc, Gallium, and Cadmium Complexes of a Dicarboxylate Pendant-Armed Cross-Bridged Cyclen

Weijun Niu,[a] Edward H. Wong,*[a] Gary R. Weisman,*[a] Yijie Peng,[a] Carolyn J. Anderson,[b] Lev N. Zakharov,[c] James A. Golen,[c][‡] and Arnold L. Rheingold[c]

Keywords: Zinc / Gallium / Cadmium / Cyclen / Cross-bridged ligand / Pendant arms

Zn^{II}, Ga^{III}, and Cd^{II} complexes of a dicarboxylate pendant-armed derivative of an important new cross-bridged cyclen ligand were prepared and characterized spectrally. Crystal structures of the Zn^{II} and Ga^{III} complexes both feature pseudo-octahedral metal centers, fully enveloped by the ligand's *cis*-N_4O_2 donor set with the zinc coordination sphere less distorted. All Ga–N and Ga–O bonds are significantly shorter than the corresponding values in the zinc structure. Solution NMR spectral studies revealed dynamic enantiomerization for the Zn^{II} complex with $\Delta G^{\neq}$ = 12.3(1) kcal/mol (24 °C). By contrast, the Ga^{III} complex gave only slow-exchange limit spectra up to the highest temperature measured [87(2) °C; $\Delta G^{\neq} > 21.1(2)$ kcal/mol].

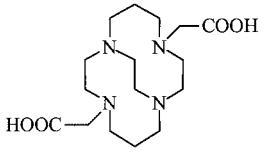
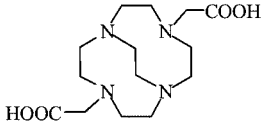
Introduction

The enhanced kinetic inertness imparted to metal complexes formed by cross-bridged cyclam and cyclen ligands has generated interest in the catalytic as well as radiopharmaceutical potentials of these ligands.[1−4] This superior inertness towards decomplexation even under highly acidic or oxidizing conditions, which discourages common decomplexation pathways, is a consequence of our ligand design.[5−7] While the importance of accessible, ancillary *cis*-coordination sites for catalytic or biomimetic applications has been noted[8−10] for carriers of radiometals such as ^{64}Cu, ^{67}Ga, and ^{111}In, complete envelopment of such cations within the chelator is desirable to ensure even more inert complexes.[11−13] *N*-Functionalization of the parent ligands with pendant arms containing additional donor sites is an effective way to attain this goal. We have already reported a dicarboxylate-armed cyclam ligand, CB-H_2TE2A, and its copper(II) complex, Cu-CB-TE2A, as well as its cyclen analogue, Cu-CB-DO2A.[2,7] Their in vivo behavior using ^{64}Cu labelling has also been investigated.[1,2] Herein, we report the syntheses and spectral characterizations of the zinc(II), gallium(III), and cadmium(II) complexes of the dicarboxylate pendant-armed cross-bridged cyclen CB-H_2DO2A (ligand H_2 **1**).[14,15] Their diamagnetic nature makes solution NMR spectral studies possible. X-ray structures of both the Zn^{II} and Ga^{III} complexes were determined. These d^{10}-cations are without ligand-field stabilization factors and offer the opportunity to compare charge and size effects on coordination preferences.



CB-H_2TE2A



CB-H_2**1**DO2A

Results and Discussion

Synthesis

In the presence of a stoichiometric amount of aqueous NaOH, cross-bridged ligand H_2 **1** and hydrated $Zn(ClO_4)_2$ or $Cd(ClO_4)_2$ formed a cloudy solution in methanol after refluxing. Upon filtration to remove a small amount of white precipitate and ether diffusion into the supernatant,

in each case, pure crystals of the neutral complexes co-crystallized with sodium perchlorate, [Zn·**1**]$(NaClO_4)_{1.5}$ and [Cd·**1**]$(NaClO_4)$, were obtained as revealed by both IR spectral and analytical data. To synthesize the gallium complex, equivalent amounts of the ligand and $Ga(NO_3)_3$ with sodium acetate as the base were refluxed in methanol. The resulting white precipitate was redissolved in aqueous methanol and diffusion of a mixture of diethyl ether and methanol into this solution yielded clear crystals of the complex [Ga·**1**]NO_3.

Infrared Data

The solid-state IR spectra of all isolated complexes contained strong carboxylate stretches and those of the Zn^{II} and Cd^{II} complexes occur between 1595 and 1645 cm^{-1}. By contrast, the Ga^{III} complex has its carboxylate bands at significantly higher frequencies (1672 and 1692 cm^{-1}). In addition, strong stretching bands are also observed for the nitrate (1284−1363 cm^{-1}) or perchlorate (1091−1107 cm^{-1}) anion in the respective complex.

NMR Spectral Data

The ^1H NMR spectrum of Zn·**1** in CD_3OD (or D_2O) is indicative of time-averaged C_{2v} symmetry. This is most clearly shown by the downfield singlet resonance of the pendant-arm methylene protons (see Figure 1, top).

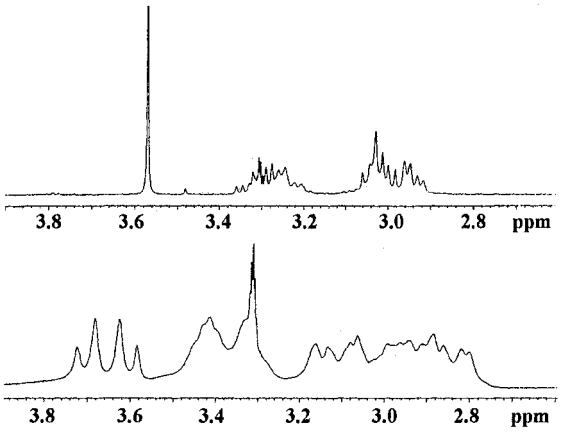

Figure 1. Variable-temperature 400 MHz ^1H NMR spectra of Zn-CB-DO2A in CD_3OD at 24 °C (top) and at −80 °C (bottom)

Likewise, the $^{13}C\{^1H\}$ NMR spectrum exhibits only four methylene ^{13}C resonances (two broad), in keeping with C_{2v} symmetry (see Figure 2, top). These data are in contrast to the solid-state X-ray structure, which approximates C_2 symmetry (vide infra) and suggest onset of a dynamic solution enantiomerization (see Figure 3). This was confirmed by the low-temperature NMR spectra in CD_3OD at −80 °C. While this proton spectrum contains broad and poorly resolved resonances in the upfield region, the pendant-arm CH_2 signal is clearly resolved into the AB pattern of diastereotopic methylene protons expected for C_2 symmetry (see Figure 1, bottom). Similarly, two of the four methylene ^{13}C resonances are resolved into two separate signals each at low temperature (see Figure 2, bottom). Complete lineshape analysis of the broadest carbon resonance at 24(2) °C (see Exp. Sect.), which is in intermediate fast exchange, allows us to calculate a free energy of activation of 12.3(1) kcal/mol for the enantiomerization. Either a dissociative process involving detachment of pendant arms or a nondissociative pseudorotation mechanism is consistent with the observed dynamic behavior.

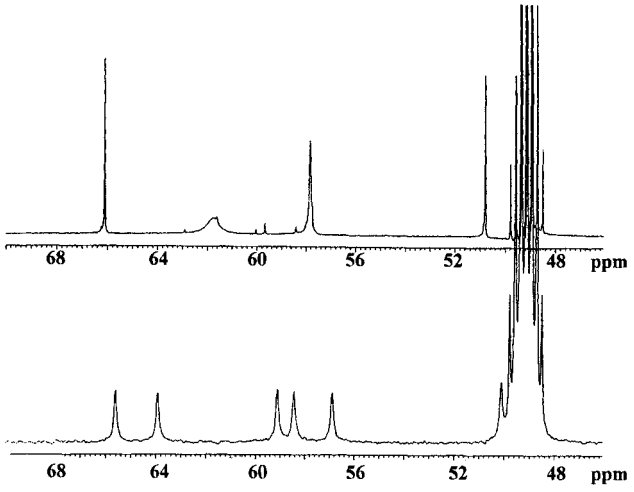

Figure 2. Variable-temperature 100 MHz $^{13}C\{^1H\}$ NMR spectra of Zn-CB-DO2A in CD_3OD at 24 °C (top) and at −80 °C (bottom)

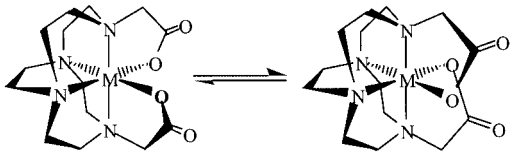

Figure 3. Enantiomerization of the zinc(II) complex of CB-DO2A

Both the proton and $^{13}C\{^1H\}$ NMR spectra of [Cd·**1**] at room temperature in D_2O (see Exp. Sect.) are similar to the Zn^{II} complex data, again indicative of averaged C_{2v} solution symmetry on the NMR timescale. In addition, satellites due to $^{111,113}Cd$ coupling can also be observed in several of the ^1H as well as ^{13}C resonances. These attest to the integrity of the complex in solution since such couplings would be lost upon facile ligand exchange.

Unlike the zinc and cadmium complexes, at ambient temperature [Ga·**1**]NO_3 in D_2O gave proton and $^{13}C\{^1H\}$ NMR spectra consistent with a solution structure of C_2 symmetry (see Figure 4 and Exp. Sect.) in agreement with its X-ray structure (vide infra). The pendant-arm CH_2 protons exhibit an AB pattern with an additional W-long-range doublet coupling to the B portion of the subspectrum (apparent AB of ABX, although even this is an oversimplification since the X proton must be further coupled as well). Six signals having no dynamic broadening are observed in the methylene region of the $^{13}C\{^1H\}$ spectrum. Thus, enantiomerization is in the slow exchange limit on

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

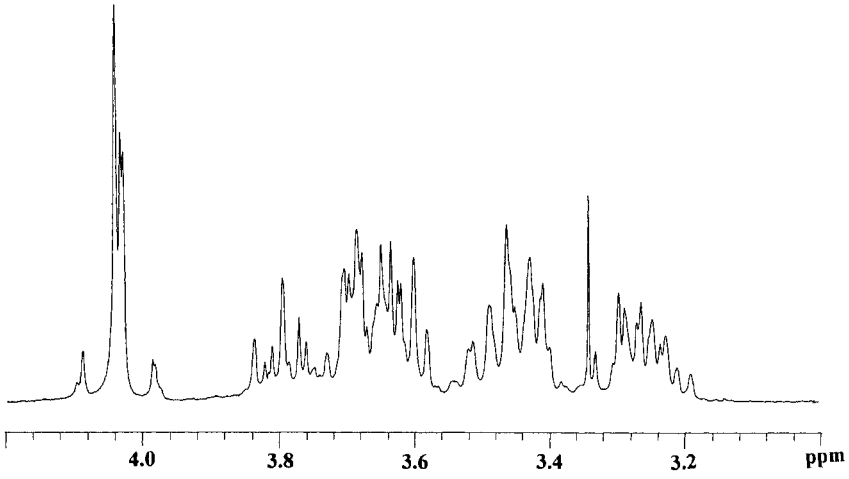

Figure 4. 360 MHz ^{1}H NMR spectrum of [Ga-CB-DO2A]NO_3 in D_2O

the ^{1}H and ^{13}C NMR timescales in solution at room temperature. High-temperature ^{1}H NMR spectra up to 87(2) °C show no dynamic broadening of the AB portion of the pendant-arm *AB*X multiplet. (Interestingly, the integration of this multiplet decreases over time, indicating significant H/D exchange.) Complete lineshape simulations of AB → BA dynamic exchange of the apparent *AB*X subspectrum of the pendant-arm CH_2 protons allow us to place a lower limit of 21.0(2) kcal/mol on the enantiomerization barrier at 87(2) °C. This dramatic increase in going from Zn·**1** to [Ga·**1**]$^+$ may be attributed to the higher cationic charge at the Ga^{III} center and stronger metal−ligand bonds, which may inhibit any dissociative process involving the coordinated carboxylate pendant arms. The X-ray solid-state structural comparison between [Zn·**1**] and [Ga·**1**]$^+$ in the next section lends support to this premise. Since this gallium complex does not rapidly enantiomerize, we can further conjecture that pendant-arm dissociation rather than non-dissociative pseudorotation is most likely the relevant dynamic process.

X-ray Structural Data

The core structure of the zinc complex [Zn·**1**] is shown in Figure 5. The Zn^{II} cation is fully enveloped within the *cis*-N_4O_2 donor set of the cross-bridged ligand in a near-octahedral geometry. The axial N(2)−Zn(1)−N(4) angle of 178.32(6) [176.07(6)]° (structural data for a second independent molecule are given in brackets) is close to linearity, showing an unusually good fit for Zn^{II} within the cross-bridged cyclen cavity. Previous structural data of zinc complexes of the cross-bridged cyclen and its derivatives have shown the cation significantly distended from the ligand cavity with much more distorted axial N−Zn−N angles of between 148 and 159°.[16−18] Another manifestation of these distortions can also be seen in their longer axial N−Zn bonds (2.17−2.26 Å) compared to the average of 2.12 Å found in Zn·**1**. The near-octahedral coordination geometry around Zn(1) here can also be seen in the N(1)−Zn(1)−O(3) angle of 172.30(6) [170.20(6)]° and the N(3)−Zn(1)−O(1) angle of 173.95(6) [174.18(6)]°. Indeed, all Zn−N and Zn−O bond lengths are within a relatively narrow range of 2.067−2.177 Å. Selected bond lengths and angles are shown in Table 1. An X-ray structure of a DOTA complex of zinc(II) featuring a related *cis*-N_4O_2 ligand coordination mode has been reported.[19] This has an axial N−Zn−N angle of 153.9°, an axial Zn−N distance of 2.232 Å, an equatorial Zn−N distance of 2.171Å, and a shorter Zn−O distance of 2.037 Å. However, without the cross-bridging ethylene, the equatorial N−Zn−N angle is opened up to 107.8° [compared to the 83.84(6)° for N(1)−Zn(1)−N(3) here]. Also, in the reported structure the coordinated carboxylate pendant arms are on the equatorial macrocyclic nitrogen atoms rather than the axial ones and the DOTA structure is thus close to C_{2v} symmetry.

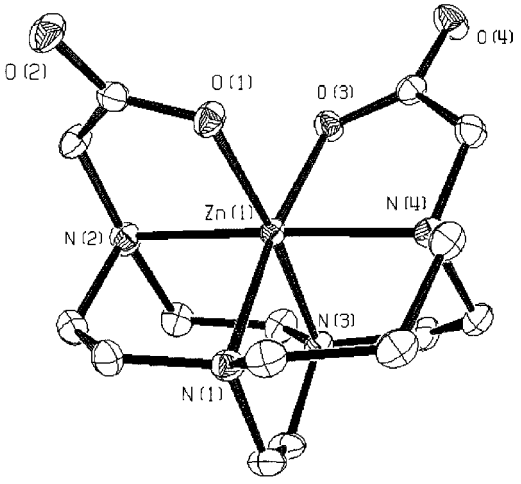

Figure 5. Molecular structure of Zn-CB-DO2A·$NaClO_4$; hydrogen atoms and sodium perchlorate have been omitted for clarity

The X-ray structure of [Ga·**1**]NO_3 also reveals a fully enveloped Ga^{III} cation within the ligand's cleft (see Figure 6). The distortion from an idealized octahedral geometry is more pronounced here with an axial N(2)−Ga(1)−N(2A)

		N(3)−Zn(1)−N(4)	86.48(7), 86.70(7)

angle of 164.6(1)°. In accord with the higher charge of this cation, all Ga−N and Ga−O bonds are significantly shorter than the corresponding ones in the zinc(II) structure, with Ga(1)−N(1) at 2.046(2) Å, Ga(1)−N(2) at 2.078(2) Å, and especially Ga(1)−O(1) at 1.942(1) Å. Another noteworthy difference is the disparate carboxylate C−O distances here: 1.298(2) Å for the Ga-coordinated C(7)−O(1) versus 1.227(2) Å for the uncoordinated C(7)−O(2). In the zinc structure, these average to very similar values of 1.26 Å and 1.25 Å, respectively, most likely due to further coordination of the carbonyl oxygen atoms to sodium cations in the crystal lattice. Selected bond lengths and angles for this structure are listed in Table 2. The X-ray structure of a related gallium(III) complex of a DOTA derivative is in the published literature.[13] A *cis*-N_4O_2 donor set is also found here with an axial N−Ga−N angle of 156.3°, Ga−N distances of 2.12−2.16 Å, and short Ga−O distances of 1.90−1.93 Å. Again, the coordinated carboxylate pendant arms are attached to the equatorial instead of axial cyclen nitrogen atoms. In the absence of the ethylene cross-bridge, the equatorial N−Ga−N angle opens up to 105.6°.

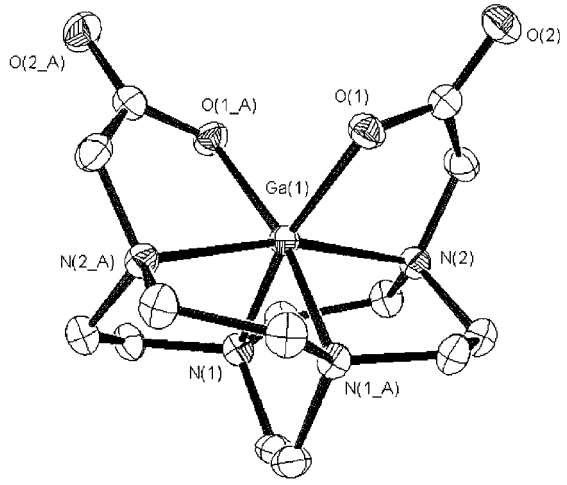

Figure 6. Molecular structure of [Ga-CB-DO2A]NO_3; hydrogen atoms and nitrate have been omitted for clarity

Conclusion

Under basic conditions, Zn^{II}, Ga^{III}, and Cd^{II} complexes of the dicarboxylate pendant-armed cross-bridged cyclen H_2**1** were prepared. In solution, both the Zn^{II} and Cd^{II} complexes were found by NMR spectroscopy to exhibit fast dynamic enantiomerization at room temperature; the Zn^{II} complex has a $\Delta G^{\neq}$ barrier of 12.3(1) kcal/mol at 24(2) °C. In contrast, the Ga^{III} complex exhibits C_2 symmetry consistent with its solid-state structure with no dynamic broadening on either the ^1H or ^{13}C NMR timescales. X-ray structures confirm full ligand envelopment of both the Zn^{II} and Ga^{III} cations with significantly shorter Ga−N and Ga−O bonds. A dissociative enantiomerization mechanism is in agreement with the dramatically higher barrier of the Ga complex. These data, taken as a whole, infer that such pendant-armed ligand complexes of Ga^{III} will exhibit even greater kinetic stability than the parent cross-bridged complexes. Future kinetic inertness studies are clearly warranted.

Experimental Section

CAUTION: *Although we did not encounter any problems, perchlorate salts of metal complexes containing organic ligands and solvents are potentially explosive and should be handled only in small quantities and with great caution!*

General Methods and Materials: ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded with a Bruker AM-360 or Varian Inova-400 instrument and referenced to TMS. Acetonitrile was used as an internal reference in D_2O with the methyl proton resonance set at δ = 2.06 ppm and ^{13}C resonance at δ = 1.70 ppm. Low-temperature ^{1}H and ^{13}C NMR spectral studies were carried out with the Varian Inova-400. A methanol chemical shift thermometer (0.03% concd. HCl in MeOH) was used to monitor the probe temperature.[20] High-temperature spectra were recorded with the Bruker AM-360 and the probe temperature calculated from the chemical shift difference between the proton signals of neat ethylene glycol.[21] Complete lineshape analysis of the two-site mutual exchange broadening exhibited by the δ = 61.77 ppm room temperature [24(2) °C] ^{13}C{^{1}H} resonance of [Zn·**1**] in CD_3OD (fast intermediate exchange) was carried out using the program WINDNMR-Pro version 7.1.5 (Hans J. Reich, University of Wisconsin, Madison, WI, USA, **2001**),[22] which is based on the modified Bloch equations as expressed by Rogers and Woodbrey;[23] Δν (484 Hz) was determined from the anisotropically broadened, slow-exchange limit spectrum (CD_3OD at −80 °C). The simulations gave a rate constant k (forward = reverse) of 6.0(5) × 10^3 s^{-1}. The $\Delta G^{\neq}$ at 24(2) °C was calculated using the Eyring equation with K = 1. A lower limit was placed upon the enantiomerization barrier of [Ga·**1**]$^+$ in D_2O through comparison of the experimental proton *AB*X subspectrum of the pendant-arm CH_2 protons with simulated spectra (WINDNMR-Pro) allowing exchange of A and B nuclei. For k = 1.5 s^{-1}, calculated broadening is significantly greater than that observed experimentally at 87(2) °C.

IR spectra were recorded as KBr pellets with a Nicolet MX-1 FT Spectrophotometer. Elemental analyses were obtained from Atlantic Microlab. Inc., Norcross, GA, USA. Reactions were run under nitrogen with magnetic stirring in standard Schlenk glassware. Bulk solvent removal was by rotary evaporation under reduced pressure and trace volatile removal from solids was by vacuum pump. Solvents were used as purchased. Cross-bridged ligand **1**[14,15] was prepared as a trifluoroacetate salt by a modification of published methods.[6]

[Zn·1](NaClO$_4$)$_{1.5}$: An aqueous solution of NaOH (0.970 N) (0.818 mL) was added to a MeOH solution (10 mL) of H_2**1**·(CF_3COOH)·(H_2O) (113 mg, 0.265 mmol) to form a clear solution. A MeOH solution (6 mL) of $Zn(ClO_4)_2$·$6H_2O$ (100 mg, 0.270 mmol) was then added into this solution. After refluxing for 2 d and cooling to room termperature, this MeOH solution was centrifuged off from a small amount of precipitate. Et_2O vapor diffusion into the supernatant yielded 106 mg (71.2%) of a white crystalline solid. IR (KBr): $\tilde{\nu}$ = 1617 cm^{-1} (broad) (ν_{COO}). ^{1}H NMR (360.13 MHz, D_2O): δ = 3.63 (s, 4 H, CH_2COO), 3.20−3.37 (m, 8 H), 3.03 (s, 4 H, cross-bridging CH_2CH_2), 2.89−3.08 (m, 8 H) ppm. ^{1}H NMR (400 MHz, CD_3OD): δ = 3.61 (s, 4 H, CH_2COO), 3.20−3.41 (m, 8 H), 3.07 (s, 4 H, cross-bridging CH_2CH_2), 2.91−3.15 (m, 8 H) ppm. ^{1}H NMR (400 MHz, CD_3OD, −80 °C): δ = 3.72 (AB, CH_2COO, J = 16.4 Hz, 4 H), 3.24−3.48 (m, 8 H), 2.72−3.19 (m, 12 H) ppm. ^{13}C{^{1}H} (D_2O): δ = 179.03, 64.94, 61.10, 56.83, 49.95 ppm. ^{13}C{^{1}H} NMR (100 MHz, CD_3OD): δ = 177.85, 66.11, 61.77 (br.), 57.85, 50.80 ppm. ^{13}C{^{1}H} NMR (100 MHz, CD_3OD, −80 °C): δ = 178.59, 65.62, 63.93, 59.12, 58.44, 56.89, 50.12 ppm. $C_{14}H_{24}Cl_{1.5}N_4Na_{1.5}O_{10}Zn$ (561.41): calcd. C 29.95, H 4.31, N 9.98; found C 30.05, H 4.68, N 9.81. X-ray quality crystals were grown by ether diffusion into a sample dissolved in 95% ethanol solution. These have a composition of [Zn·**1**](NaClO$_4$)(C_2H_5OH)(H_2O)$_{0.5}$.

[Cd·1](NaClO$_4$)(H$_2$O)$_{1.5}$: An aqueous solution of NaOH (0.970 N) (0.64 mL) was added to a clear solution of H_2**1**·(CF_3COOH)·(H_2O) (89.0 mg, 0.208 mmol) and $Cd(ClO_4)_2$·$6H_2O$ (94.8 mg, 0.226 mmol) in 15 mL MeOH to form a cloudy solution. The reaction mixture was refluxed for 7 h, cooled, and some white precipitate was centrifuged off. Et_2O vapor diffusion into the supernatant yielded 73.0 mg (61.1%) of a white crystalline solid. IR (KBr): $\tilde{\nu}$ = 1615, 1595 cm^{-1} (ν_{COO}). ^{1}H NMR (360.13 MHz, D_2O):

δ = 3.48 (s, 4 H, CH_2COO, ^{111}Cd, ^{113}Cd satellites, J = 11.6 Hz), 2.94−3.26 (m, 12 H), 2.89 (s, 4 H, cross-bridging CH_2CH_2, ^{111}Cd, ^{113}Cd satellites, J = 13.7 Hz), 2.81 (br. dd, 4 H, J = 12.1, 4.4 Hz) ppm. $^{13}C\{^1H\}$ NMR (90.55 MHz, D_2O): δ = 179.23 (^{111}Cd,^{113}Cd satellites, J = 11.3 Hz), 64.95 (^{111}Cd, ^{113}Cd satellites, J = 6.0 Hz), 60.58, 57.32, 47.63 (^{111}Cd, ^{113}Cd satellites, J = 15.3 Hz) ppm. $C_{14}H_{27}CdClN_4NaO_{9.5}$ (574.24): calcd. C 29.28, H 4.74, N 9.76, Cl 6.17; found C 29.31, H 4.70, N 9.65, Cl 5.96.

[Ga·1](NO$_3$)$_3$: A solution of $Ga(NO_3)$ hydrate (38.6 mg, ca. 0.15 mmol) in MeOH (6 mL) was added to an MeOH solution (14 mL) of H_2**1**·(CF_3COOH)·(H_2O) (66.4 mg, 0.155 mmol) to form a clear solution. Anhydrous NaOAc (46.3 mg, 0.564 mmol) in MeOH (7 mL) was then added in two portions. The reaction mixture was refluxed for 2 d, after which time a white precipitate was isolated by centrifugation. The resulting white precipitate was dried to give the product complex (41.9 mg, 62.9%). This was redissolved in a H_2O (2.6 mL)/MeOH (3.2 mL) mixture followed by Et_2O/MeOH (1:1) vapor diffusion into this solution to yield crystals suitable for X-ray analyses. IR (KBr): $\tilde{\nu}$ = 1692 (s), 1672 (s) cm^{-1} (ν_{COO}), 1363 (s), 1351 (s), 1339 (s), 1299 (s), 1284 (s) cm^{-1} (broad) (ν_{NO3}). ^1H NMR (360.13 MHz, D_2O): δ = 4.03 and 4.06 (AB of apparent ABX, CH_2COO, J_{AB} = 16.8, $J_{BX} \approx$ 1.5 Hz, 4 H), 3.57−3.85 (m, 10 H), 3.38−3.54 (m, 6 H), 3.18−3.31 (m, 4 H, cross-bridging CH_2CH_2) ppm. $^{13}C\{^1H\}$ NMR (90.55 MHz, D_2O): δ = 174.89, 64.07, 63.67, 57.11, 57.09, 54.87, 51.78 ppm. $^{13}C\{^1H\}$ NMR (90.55 MHz, [D_6]DMSO): δ = 169.92, 63.65, 61.92, 56.21, 55.35, 54.06, 50.25 ppm. $C_{14}H_{24}GaN_5O_7$ (444.10): calcd. C 37.86, H 5.45, N 15.77; found C 37.82, H 5.45, N 15.75.

X-ray Crystallography: Diffraction intensity data were collected with Bruker Smart Apex CCD {[Zn·**1**]($NaClO_4$)} and Siemens P4 CCD ([Ga·**1**]NO_3) diffractometers. Crystal data collection, and refinement parameters are given in Table 3. The structures were solved using direct methods, completed by subsequent difference Fourier syntheses, and refined by full-matrix least-squares procedures on F^2. SADABS absorption corrections were applied to both sets of data {$T_{min.}/T_{max.}$= 0.917 and 0.724 for [Zn·**1**]($NaClO_4$) and [Ga·**1**]NO_3, respectively}. In both structures all non-hydrogen atoms were refined with anisotropic displacement coefficients. Hydrogen atoms were treated as idealized contributions except the H atoms of solvent water molecules in [Zn·**1**]($NaClO_4$) involved in H-bonds which were located on the F-map and refined with isotropic thermal parameters. The Flack parameter for [Ga·**1**]NO_3 is 0.014(11). All software and sources of scattering factors are contained in the SHELXTL (5.10) program package (G. Sheldrick, Bruker XRD, Madison, WI, USA). CCDC-229393 {[Zn·**1**]($NaClO_4$)} and -229394 ([Ga·**1**]NO_3) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structure and Magnetic Properties of a Series of Novel Isophthalate-Bridged Manganese(II) Polymers with Double-Layer or Double-Chain Structures

Chengbing Ma,[a,d] Changneng Chen,[a] Qiutian Liu,*[a] Feng Chen,[a] Daizheng Liao,[b] Licun Li,[b] and Licheng Sun[c]

Keywords: Manganese / Crystal structure / Isophthalic acid / Magnetic properties / Structural topology

Four isophthalate-bridged manganese(II) coordination polymers, $[Mn_4(ip)_4(H_2O)_2(Him)_4]_n$ (**1**), $[Mn(ip)(Him)_2]_n$ (**2**), $[Mn(ip)(dpe)]_n{\cdot}0.5ndpe\cdot n H_2O$ (**3**) and $[Mn_2(ip)_2(bpy)_2]_n$ (**4**) [ip = isophthalate, Him = imidazole, bpy = 2,2′-bipyridine and dpe = (*E*)-1,2-bis(4-pyridyl)ethene], have been rationally synthesized and characterized by single-crystal X-ray structure determinations and magnetic studies. Both **1** and **3** are two-dimensional (2D) double-layer polymers. In **1**, novel Mn_4 entities are linked by ip ligands, while **3** is made of $[Mn(ip)]_n$ parallel double chains cross-linked by the μ-dpe ligands. Both **2** and **4** are one-dimensional (1D) double-chain polymers, where **2** is composed of $[Mn(ip)]_n$ parallel double chains capped by the Him ligands, while **4** is made of $[Mn_2(ip)_2]_n$ helical double chains capped by the chelating bpy ligands. Variable-temperature magnetic susceptibility measurements revealed weak antiferromagnetic exchange interactions between the adjacent Mn^{II} ions of the four coordination polymers. The data of **2**–**4** were fitted to the homonuclear alternating chain model to give magnetic coupling parameters of $J_1 = -0.71(4)$ to $-1.01(3)$ cm^{-1} and $J_2 = -0.02(2)$ to $-0.46(2)$ cm^{-1}. In the case of **1**, the fitting of magnetic data considering only the interactions within the Mn_4 moiety led to $J = -2.17(1)$ cm^{-1} and $zJ' = -0.01(5)$ cm^{-1}, using a combination of a dimeric model and a mean molecular field approximation model.

Introduction

Currently, there is great interest in metal-organic hybrid materials containing paramagnetic metal ions within extended structures. This is driven to a large extent by their fascinating network topologies and potential application in the field of molecular magnetism.[1,2] The low-dimensional (1D chain-like or 2D layer-like) extended structures have attracted special interest on account of their specific structural features and unusual nonlinear optical and magnetic properties.[3] Therefore, rational design and construction of new materials with specific network structures and investigation of their properties have become a particularly important and topical subject. One commonly used strategy to construct such extended networks is to select appropriate bridging ligands which can transmit magnetic interactions in addition to binding several metal ions in a specific coordination geometry. Accordingly, polycarboxylic acid ligands are good candidates for this purpose. The three isomeric benzenedicarboxylic acids, i.e. phthalic acid, isopthalic acid and terephthalic acid, are especially suitable since they can bind metal ions in a variety of modes and can provide various superexchange pathways, which transmit magnetic interactions between metal ions through either the carboxylate group or the benzene ring of the ligand. Among these three isomeric dicarboxylates, major studies performed using terephthalate resulted in a rich variety of complexes with interesting structures and various magnetic properties.[4] The other two isomers have not been studied extensively for this purpose.[5,6]

On the other hand, the manganese(II) carboxylate complexes have long been of special interest since they are known to exist at the active sites of some metalloenzymes.[7] As part of our ongoing work on manganese complexation by dicarboxylic acids,[8] we have explored the reaction systems containing the Mn^{2+} ion and the isomeric benzenedicarboxylic acids as primary bridging ligand, paying par-

ticular attention to rational design of the magnetically coupled complexes with specific polymeric frameworks. Concurrently, introduction into the reaction systems of diimine chelating ligands, such as 2,2′-bipyridine and 1,10-phenanthroline, imidazole or linear ditopic ligands, such as 4,4′-bipyridine and (*E*)-1,2-bis(4-pyridyl)ethene, as ancillary ligands, was expected to inhibit the expansion of polymeric frameworks in order to obtain the desired low-dimensional polymers, or to induce the evolution of novel structures.

In this work, we report a novel family of Mn^{2+} coordination polymers **1**−**4**. They were isolated by treatment of an Mn^{2+} salt with isophthalic acid in the presence of selected ancillary ligands − imidazole, (*E*)-1,2-bis(4-pyridyl)ethene and 2,2′-bipyridine, under different crystallization conditions (Scheme 1). Single-crystal X-ray diffraction analyses revealed either double-chain structures or double-layer structures, which differ substantially from those of several metal isophthalate polymeric compounds reported previously.[5,9] The isophthalate ligands display various coordination modes (Scheme 2) and mediate overall antiferromagnetic exchange interactions between Mn^{2+} ions in these coordination polymers.

Results and Discussion

Preparation of the Complexes and IR Spectroscopy

When compared with the manganese complexes containing monocarboxylate ligands such as acetate, benzoate and their derivatives, the structural information for manganese dicarboxylate complexes is relatively scarce. This is mainly because of the insolubility of the polymeric materials resulted from the reaction of a dicarboxylate with an Mn^{2+} salt under ambient conditions. The reaction of isophthalate with Mn^{2+} salts in the presence of imidazole is an exception, resulting in a clear solution. Cosolvent methanol was added in order to promote crystallization of **1**. As indicated in the structural description of **1** given below, only three of the four carboxyl O atoms in the isophthalate ligand (see b in Scheme 2) are coordinated and there is a relatively rare aqua coordination to the metal ion. The unexpected ancillary ligation by water often results in poor control over the framework of the final product. The fact that hydrothermal reaction can enhance metal−ligand interactions rather than metal−water coordination has been clearly demonstrated in several cases.[10] Further study of the reaction of **1** in an H_2O/CH_3OH solvent mixture under hydrothermal conditions led to deposition of **2**, in which metal−water coordination was blocked and all of the carboxyl O atoms take part in coordination (see c in Scheme 2). Taking into account that formation of higher dimensionality systems is prevented by the axially capping imidazole ligands in the 1D chain structure of **2**, the coordination polymer **3**, possessing a 2D layer structure, was expected with confidence when the linear *exo*-bidentate (*E*)-1,2-bis(4-pyridyl)ethene ligand was used in place of the axial imidazole ligands. The near parallel double-chain of $[Mn(ip)]_n$ in **2** was modified to a distorted double-helical chain of $[Mn_2(ip)_2]_n$ in **4** by means of *cis* chelation of the rigid 2,2′-bipyridine ligand used in place of the imidazole ligand.

IR spectra of the coordination polymers offer some valuable information about both the presence of isophthalate and the coordination modes of the carboxylates. The absence of any strong absorptions around 1700 cm^{-1} indicates that all carboxyl groups in **1**−**4** are deprotonated. Of three strong characteristic peaks at 1566, 1448 and 1394 cm^{-1} for **1**, the one at 1566 cm^{-1} is attributed to $\nu_{as}(COO)$ of all the carboxylate groups, while the peaks at 1448 cm^{-1} and 1394 cm^{-1} may be assigned to $\nu_s(COO)$ of the bidentate carboxylate group and the monodentate carboxylate group, respectively, since it is known that the difference $\Delta = \nu_{as} - \nu_s$ is smaller in the former (118 cm^{-1}) than in the latter (172

cm^{-1}).[11] Amongst the four strong absorptions at 1557, 1541, 1444, 1390 cm^{-1} for **2** (1568, 1547, 1429 and 1394 cm^{-1} for **3**, and 1572, 1556, 1439 and 1394 cm^{-1} for **4**), the peaks at 1557 and 1541 cm $^{-1}$ for **2** (1568 and 1547 cm^{-1} for **3**, and 1572 and 1556 cm^{-1} for **4**) are attributed to ν_{as}(COO) of the three complexes. The splitting of the ν_{as}(COO) peak indicates that both carboxylate groups of the ip ligand are in two different coordination modes,[11b] which is consistent with their respective crystal structures. The other two peaks at 1444 and 1390 cm^{-1} for **2** (1429 and 1394 cm^{-1} for **3**, and 1439 and 1394 cm^{-1} for **4**) correspond to ν_s(COO) of the bidentate chelating carboxylate group and the bidentate bridging carboxylate group, respectively.

Description of the Crystal Structures

The X-ray structure determination revealed a novel and complex covalently bonded 2D network for **1**, containing two crystallographically independent manganese(II) ions of different octahedral geometry. As shown in Figure 1 for compound **1**, the ip ligands are of two types: A and B [as shown in Scheme 2 (a) and (b), respectively]. The two crystallographically independent Mn atoms (Mn1 and Mn2), with an interatomic distance of 3.476(2) Å, are bridged by one μ-aqua (Ow), one $\mu_{1,3}$-OCO and one $\mu_{1,1}$-OCO bridge. To the best of our knowledge, this type of triply bridged Mn dimeric core is unique, although three examples containing one μ-aqua and two $\mu_{1,3}$-OCO bridges were previously reported.[12] The bond valence sum (BVS) calculations[13] give the values of 2.00 and 2.11 for Mn1 and Mn2, respectively, indicating that the Mn centers are of +2 oxidation state. In order to maintain the electroneutrality of the compound, the Ow is assigned as a neutral water ligand. Additionally, the absence of characteristic IR absorptions around 1700 cm^{-1} expected for the vibration of protonated carboxyl groups (COOH), indicates that all carboxyl groups in **1** are deprotonated. Furthermore, the Mn−Ow distances of 2.229(2) and 2.331(2) Å fall in the normal range found in other Mn complexes,[12,14] which also suggests that the bridging ligand is water. The Mn1 and Mn2 atoms are coordinated by one N atom of Him, one bridging Ow atom, and two bridging O atoms from the μ_4-ip ligands. Two O atoms of the μ_3-ip ligand chelate to Mn1 and coordinate monodentately to Mn2, respectively, completing the distorted octahedral geometries (Table 1) of the two Mn ions. The Mn_2 unit is further dimerized through two *syn*/*anti*-carboxylate bridges from symmetry-related μ_4-ip ligands to form a novel nonplanar cyclic Mn tetramer containing four Mn octahedra and two carboxylate groups with Mn1···Mn2A = 5.309(2) Å. The most remarkable structural feature of **1** is that each Mn tetramer connects eight ip ligands to form an infinite 2D coordination framework featuring an unprecedented puckered rhombic grid-like $[Mn_{16}(ip)_8(H_2O)_8(Him)_{16}]$ as the basic building block (Figure 2). Each apex of the grid is occupied by a Mn_4 clus-

ter which is surrounded by ip ligands in bridging bis(bidentate) μ_4, bridging/chelating bidentate and monodentate μ_3 modes.

The structure of **2** differs from the structure of **1** since the coordination of water to Mn was completely precluded. Each ip ligand coordinates to three Mn atoms through two carboxylate groups in an interesting bridging and chelating bis(bidentate) μ_3 mode [Scheme 2 (c)] resulting in an infinite 1D polymer. Figure 3 illustrates the distorted octahedral geometry of the Mn^{2+} center (Table 2) with four O atoms from three ip ligands in the equatorial plane, and with two Him N atoms occupying the *trans*-axial positions. One pair of symmetry-related Mn atoms (Mn and MnA) with an interatomic distance of 4.480(2) Å is bridged by two carboxylate groups to produce a four-membered (two octahedra and two carboxylate groups) ring (**A**), whereas the other pair of symmetry-related Mn atoms (Mn and MnB) with an interatomic distance of 7.098(2) Å are bridged by two extended ip ligands to produce another four-membered (two octahedra and two isophthalate groups) ring (**B**). The two types of subrings, **A** and **B**, alternately interlock through Mn−O−C edge-sharing to produce a 1D parallel double chain of $[Mn(ip)]_n$ (with respect to the Mn atoms) in the *c* direction. Interestingly, the capping Him ligands are located at both sides of the double chain (Figure 4), thus preventing a 2D structure for **2**. It is reasonable to expect that a 2D double-layer framework will be created if the Him ligands are replaced by bidentate linear linkers such as 4,4′-bipyridine or (*E*)-1,2-bis(4-pyridyl)ethene.

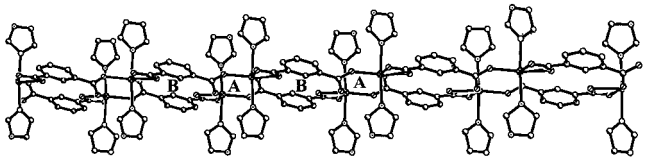

Figure 4. A view of the double-chain framework of **2** showing alternate interlocking of the two types of subrings (**A** and **B**) into parallel double chains of $[Mn(ip)]_n$

Complex **3** was obtained when (*E*)-1,2-bis(4-pyridyl)-ethene (dpe) was used instead of Him in the reaction. As expected, the structure of **3** is an infinite 2D double-layer polymer. The solvate dpe molecule is distorted within the crystal lattice but its presence was confirmed by elemental analysis. However, the neutral polymeric framework is clearly defined. As shown in Figure 5, the coordination mode of the ip ligand is identical to that found in **2**. Again, three ip ligands coordinate equatorially to one Mn atom through four carboxyl O atoms [Mn−O = 2.113(5)−2.329(5) Å] (Table 3), forming a 1D parallel double chain of $[Mn(ip)]_n$ almost the same as that contained in **2**. One remarkable structural feature of **3** is that the adjacent double chains of $[Mn(ip)]_n$ are cross-linked by linear μ-dpe ligands in the axial directions of the Mn octahedra [Mn−N1 = 2.263(5), Mn−N2C = 2.266(6) Å] giving a novel 2D double-layer framework with large open rectangular cavities (Figure 6). The intracavity Mn···Mn separation, bridged through the dpe, the ip and the μ_2-bridging carboxylate group, is 13.919 × 10.178 × 4.028 Å. These layers stack along the crystallographic *a* axis, generating large rectangular channels, which in turn accommodate solvate dpe and water molecules in the crystal lattice (Figure 7).

When 2,2′-bipyridine (bpy) was used instead of Him, complex **4** was obtained. The X-ray structure determination reveals that **4** is a 1D chain-like polymer constructed from $[Mn_2(ip)_2(bpy)_2]$ units. As shown in Figure 8, two symmetry-unrelated ip ligands exhibit two types of coordination mode [shown in Scheme 2 (c) and (d)]. The latter is a bridging bidentate and monodentate μ_3 mode. Several differences in the coordination environments of the two crystallographically distinct Mn^{2+} atoms can be observed (Table 4). The Mn2 atom has a distorted octahedral geometry coordinated by two N and four O atoms, whereas the Mn1 atom is in distorted trigonal-bipyramidal geometry, being coordinated by two N and three O atoms. However, the Mn1···O6 distance of 2.528(5) Å indicates a

weak interaction, which may be described as a semichelating coordination mode of the monodentate carboxylate group.[15] Similarly to **2** and **3**, every three ip ligands coordinate to one Mn atom to produce a 1D double chain of $[Mn_2(ip)_2]_n$ (Figure 9). It is worth noting that the $[Mn_2(ip)_2]_n$ motif, featuring a double-helix chain with a long pitch of about 10 Å, is more distorted than those of $[Mn(ip)]_n$ in **2** and **3** due to *cis* chelation of the rigid bpy ligand to an Mn center. The double chain also differs structurally from that reported previously in an isomeric complex containing an $[Mn(ip)(bpy)]_n$ core,[16] where all Mn atoms were symmetry-dependent, and all carboxyl O atoms were coordinated to Mn centers with all of the Mn−O bond lengths in the usual range [2.111(2)−2.284(3) Å]. Interestingly, the adjacent double-helical chains of **4** were intercalated in a zipper style to form 2D supramolecular layers through the π-π stacking interactions between the

Magnetic Susceptibility Study of Compounds

The magnetic behavior of complex **1** is plotted in Figure 11. At room temperature, the experimental effective magnetic moment (μ_{eff}) is 7.93μ_B, which is slightly smaller than the value of 8.37μ_B expected for two uncoupled Mn^{2+} ions (S1 = S2 = 5/2). Upon cooling from room temperature to 80 K, the value of μ_{eff} remains essentially constant, then gradually decreases to 4.24 μ_B at 5 K, indicative of an overall antiferromagnetic coupling between the Mn^{2+} centers.

As indicated in the structure description, **1** is a 2D double-layer polymer built from Mn_4 entities linked by ip ligands. No appropriate analytical expressions were available for calculation of the interaction parameters for this double-layer system. However, magnetic coupling between Mn tetramers through the extended ip bridging ligands and between the mixed water/carboxyl-bridged Mn dimers through the *syn*/*anti*-bridging carboxylate groups are all expected to be very weak. Thus, a simplified analysis of this coupling system can be accomplished by either of two approaches:

(i) The first approach neglects the Mn intertetramer magnetic interactions through the extended ip-bridging ligands. The observed magnetic behavior was simulated using modified Equation (1), which was obtained by combining the dimer model of $S = 5/2$ spins ($\boldsymbol{H} = -2J\boldsymbol{S}_1\boldsymbol{S}_2$)[17] with the Mn interdimeric interactions (zJ') under the molecular field approximation[18] [see inset of Figure 11 (a)].

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

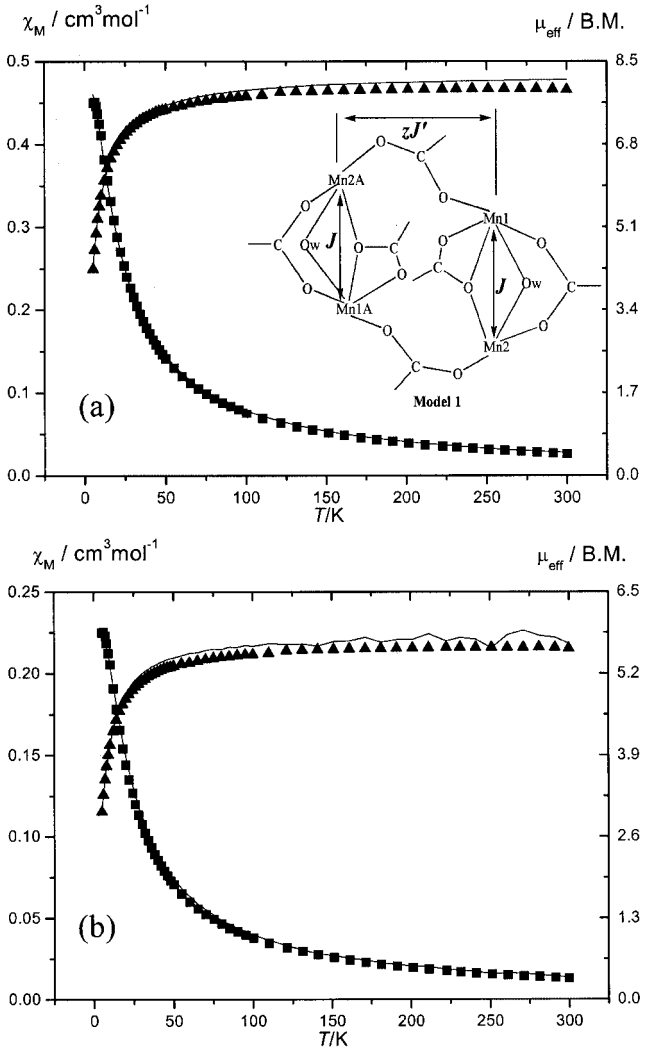

Figure 11. Experimental magnetic susceptibilities (χ_M, marked as square) and effective magnetic moment (μ_{eff}, marked as triangle) as a function of temperature for complex **1**; the solid lines represent the calculated values

$$\chi_M = \chi_{bi}/\left(1 - zJ'\chi_{bi}/Ng^2\beta^2\right)$$

where

$$\chi_{bi} = \frac{2Ng^2\beta^2}{kT}\left[\frac{55+30\exp(-10J/kT)+14\exp(-18J/kT)+5\exp(-24J/kT)+\exp(-28J/kT)}{11+9\exp(-10J/kT)+7\exp(-18J/kT)+5\exp(-24J/kT)+3\exp(-28J/kT)+\exp(-30J/kT)}\right] \quad (1)$$

A best-fit result with parameters $J = -2.16(8)$ cm^{-1}, $zJ' = -0.01(4)$ cm^{-1}, $g = 1.96(9)$, and the agreement factor R [defined as $R = \Sigma[(\chi_M T)_{calcd.} - (\chi_M T)_{obsd.}]^2/[\Sigma(\chi_M T)_{obsd.}]^2 = 1.73 \times 10^{-4}$ was obtained over the temperature range studied.

The small negative zJ' value agrees well with the notion that the *syn*/*anti*-carboxylate bridge always mediates very weak magnetic couplings due to the expanded metallic core and the mismatch in the orientation of magnetic orbitals.[19] The small zJ'/J ratio (ca. 0.006) validates the use of the mean molecular field approximation model.[20]

(ii) In the second approach the magnetic interactions through the *syn*/*anti*-carboxylate bridges were ignored, and the magnetic behavior of **1** was simulated using the analytical expression according to Equation (2) based on the homonuclear alternating chain structure,[21] where $u_i = \coth[J_iS(S+1)/kT] - kT/[J_iS(S+1)]$ $(i = 1, 2)$.

$$\chi = \frac{Ng^2S(S+1)\mu_B^2}{3kT}\left(\frac{1+u_1+u_2+u_1u_2}{1-u_1u_2}\right) \quad (2)$$

The best fit gives the parameters $J_1 = -1.48(4)$ cm^{-1}, $J_2 = -0.01(9)$ cm^{-1}, $g = 1.96(5)$ and $R = 7.99 \times 10^{-4}$ over the temperature range studied.

Although the latter simulation is mathematically logical, the theoretical curve is not smooth in the high-temperature range (100−300 K), which can be seen from Figure 11 (b). On the basis of this, the result derived from the first simulation seems to be more exact for compound **1**.

Complexes **2**, **3** and **4** have similar magnetic properties and the plots of the effective magnetic moment (μ_{eff}) vs. T are shown in Figure 12. At room temperature, the values of μ_{eff} were 5.90 μ_B, 5.88 μ_B and 5.83 μ_B per one Mn^{2+} ion for **2**, **3** and **4**, respectively. These values are close to, or slightly lower than, the value of 5.91 μ_B expected for an "isolated" Mn^{2+} ion ($S = 5/2$). As the temperature is lowered, the μ_{eff} values remain essentially constant in the regions 300−60 K, 300−80 K, and 300−100 K for **2**, **3**, and **4**, respectively. When the temperature is further lowered, the μ_{eff} values decrease continuously down to 4.15 μ_B, 3.54 μ_B and 3.67 μ_B at 5 K for **2**, **3** and **4**, respectively, indicating overall antiferromagnetic couplings between Mn^{2+} centers for the three complexes. Considering that the magnetic interaction between two Mn centers separated by > 14 Å through μ-dpe in **3** is very weak, the analytical expression according to

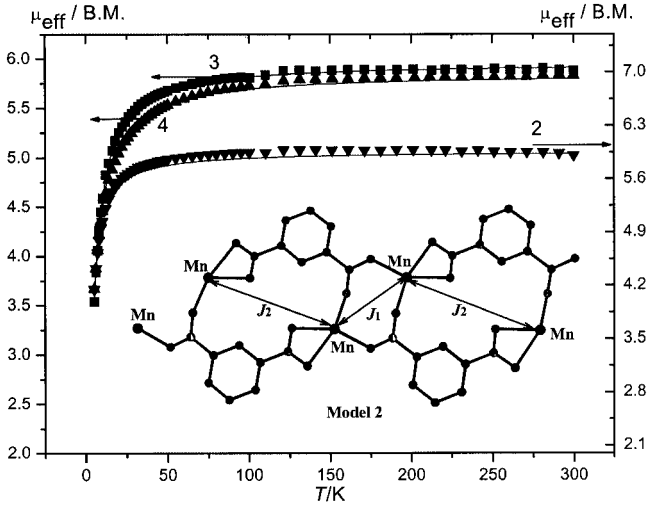

Figure 12. Experimental effective magnetic moment (μ_{eff}) as a function of temperature for complexes **2**−**4**; the solid lines represent the calculated values

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Equation (2) for the homonuclear alternating chain structure (see inset of Figure 12) can be adopted to simulate the magnetic behavior of the three complexes.

The least-squares fitting of the experimental data over the full temperature range led to $J_1 = -0.71(4)$ cm^{-1}, $J_2 = -0.02(2)$ cm^{-1}, $g = 2.02(2)$ and the agreement factor $R = 2.10 \times 10^{-4}$ for **2**, $J_1 = -1.01(3)$ cm^{-1}, $J_2 = -0.09(1)$ cm^{-1}, $g = 2.01(1)$ and $R = 6.0 \times 10^{-5}$ for **3**, and $J_1 = -0.80(1)$ cm^{-1}, $J_2 = -0.46(2)$ cm^{-1}, $g = 1.98(2)$ and $R = 8.1 \times 10^{-4}$ for **4**.

All these negative J_1 values fall in the range (-0.7 to -1.84 cm^{-1}) expected for doubly bridged Mn^{2+} carboxylate compounds,[22] and the differences in them [J_1(**3**) > J_1(**4**) > J_1(**2**)] agree well with the inter-Mn distance (4.028 Å for **3**, 4.322 Å for **4** and 4.480 Å for **2**). Shorter separation of paramagnetic centers allows more effective magnetic coupling. For all of the complexes, the smaller negative J_2 value can be attributed to a very weak antiferromagnetic interaction through the extended bridging ip ligand pathway. Its low magnitude can be associated with the excessive span (> 7 Å) of the ip ligand bridge, and is logically smaller than the J_1 value mediated by double carboxylate bridges presenting short pathways.

Conclusion

In this paper, four low-dimensional coordination polymers **1**−**4** have been synthesized by treatment of an Mn^{2+} salt with isophthalic acid and with the participation of selected ancillary ligands − Him, dpe and bpy − under different crystallization conditions. The evolution of structure of these compounds was as expected. Under ambient conditions, the spontaneous assembly of ip and Mn^{2+} salt with the participation of Him ligand yielded the novel 2D double-layer framework **1**. Hydrothermal conditions inhibited coordination of water to the metal atom, as expected, and led to the formation of **2**, which consists of an interesting double-chain framework. Polymer **3**, with a 2D double-layer framework, was rationally induced by the use of secondary μ-dpe ligands as axial connectors of Mn octahedra in double chains of $[Mn(ip)]_n$. The parallel $[Mn(ip)]_n$ double-chain moiety was further modified to the helical double-chain framework in **4** by introduction of the steric constraint caused by *cis* chelation of the rigid bpy ligand. The results show that metal-organic coordination polymers with a specific architecture may be elaborated by the judicious choice of the organic spacer and ancillary ligand, along with careful manipulation of various reaction conditions such as the reaction temperature and solvent. The magnetic properties of these compounds revealed overall weak antiferromagnetic exchange interactions between Mn^{2+} ions through the bridging carboxylate group of the ip ligand or through the extended ip ligand bridge. The coupling interactions, as well as the differences in them, were explained briefly according to the structural parameters and their variations.

Experimental Section

General Remarks: All chemicals were of reagent grade and used as received. Elemental analyses were performed with a Vario EL-III element analyzer. IR spectra of KBr pellets (4000−400 cm^{-1}) were recorded with an FTS-40 spectrophotometer. Variable-temperature magnetic susceptibilities were measured over the temperature range 5−300 K on crystalline samples mounted in a capsule using a model CF-1 superconducting magnetometer. Diamagnetic corrections were estimated with Pascal's constants for all the complexes: -2.50×10^{-4} c.g.s. for **1**, -1.68×10^{-4} c.g.s. for **2**, -2.56×10^{-4} c.g.s. for **3** and -3.55×10^{-4} c.g.s. for **4**.

Synthesis of $[Mn_4(ip)_4(H_2O)_2(Him)_4]_n$ (1): Solid $Mn(OAc)_2{\cdot}4H_2O$ (0.50 g, 2 mmol) was added to an H_2O/MeOH (ca. 4:1, v/v, 20 mL) solvent mixture containing isophthalic acid (H_2ip) (0.34 g, 2 mmol), KOH (0.23 g, 4 mmol) and imidazole (Him) (0.14 g, 2 mmol) with continuous stirring. The solution was stirred at room temperature for 2 h, then filtered. The filtrate was left in a $CaCl_2$ desiccator for approximately one month to produce colorless crystals of **1** in 68% yield (0.41 g). $C_{44}H_{36}Mn_4N_8O_{18}$ (1184.57): calcd. C 44.61, H 3.06, N 9.46; found C 44.69, H 3.14, N 9.44. IR (KBr): $\tilde{\nu}$ = 3320 (br., s), 3080 (m), 1612 (s), 1566 (s), 1520 (m), 1477 (m), 1448 (s), 1394 (s), 1325 (m), 1271(w), 1255 (w), 1157 (w), 1126 (w), 1092 (w), 1070 (m), 1061(s), 935 (w), 906 (w), 856 (w), 837 (w), 820 (m), 744 (s), 712 (s), 704 (s), 658 (s), 619 (m), 538 (w), 459 (w), 434 (m) cm^{-1}.

Synthesis of $[Mn(ip)(Him)_2]_n$ (2): Complex **1** (1.2 g, 1 mmol) was dissolved in an H_2O/MeOH (ca. 4:1, v/v, 15 mL) solvent mixture and was heated at 140 °C in a 20-mL sealed Teflon-lined stainless vessel for 4 d, then cooled to room temperature over a period of 5 h. This gave colorless crystals of **2** in 54% yield (0.77 g). $C_{14}H_{12}MnN_4O_4$ (355.22): calcd. C 47.34, H 3.41, N 15.77; found C 47.37, H 3.49, N 15.72. IR (KBr): $\tilde{\nu}$ = 3064 (m), 1605 (s), 1557 (s), 1541 (s), 1477 (m), 1446 (s), 1444 (s), 1390 (s), 1352 (m), 1311 (w), 1277 (w), 1250 (w), 1178 (w), 1157 (m), 1134 (m), 1119 (s), 1076 (w), 1057 (s), 1041 (s), 939 (m), 908 (m), 877 (m), 827 (w), 816 (w), 780 (s), 746 (s), 715 (s), 658 (w), 611 (m), 573 (w), 532 (w), 451 (w), 432 (m), 408 (m) cm^{-1}.

Synthesis of $[Mn(ip)(dpe)]_n{\cdot}0.5ndpe\cdot nH_2$O (3): $Mn(OAc)_2{\cdot}4H_2O$ (0.25 g, 1 mmol), dissolved in water (10 mL), was mixed with an H_2O/EtOH (ca. 1:1, v/v, 10 mL) solvent mixture containing H_2ip (0.17 g, 1 mmol), KOH (0.11 g, 2 mmol) and dpe (0.28 g, 1.5 mmol) leading to the immediate precipitation of a yellow powder which was filtered. Small yellow crystals of **3**, suitable for X-ray diffraction, were grown from the filtrate upon standing at room temperature for three weeks. Yield: 11% (0.06 g). $C_{26}H_{21}MnN_3O_5$ (510.40): calcd. C 61.18, H 4.15, N 8.23; found C 61.25, H 4.16, N 8.21. IR (KBr): $\tilde{\nu}$ = 3442 (br., s), 3037 (m), 1608 (s), 1568 (s), 1547 (s), 1479 (m), 1429 (s), 1394 (s), 1254 (w), 1217 (m), 1105 (w), 1074 (w), 1014 (s), 972 (m), 912 (w), 827 (s), 746 (s), 719 (s), 660 (w), 552 (s), 509 (w), 424 (m) cm^{-1}.

Synthesis of $[Mn_2(ip)_2(bpy)_2]_n$ (4): 2,2′-bipyridine (bpy) (0.31 g, 2 mmol) in DMF (10 mL) was slowly added to a solution of $Mn(OAc)_2{\cdot}4H_2O$ (0.50 g, 2 mmol), H_2ip (0.34 g, 2 mmol) and NaOH (0.16 g, 4 mmol) in water (25 mL) with continuous stirring, resulting in a yellow suspension. The suspension was transferred into a 50-mL round-bottomed flask and heated to reflux for about a week during which time yellow crystals of **4** deposited in 17% yield (0.13 g). $C_{36}H_{24}Mn_2N_4O_8$ (750.47): calcd. C 57.62, H 3.22, N 7.47; found C 57.69, H 3.17, N 7.38. IR (KBr): $\tilde{\nu}$ = 3053 (m), 1610 (s), 1572 (s), 1556 (s), 1473 (m), 1439 (s), 1394 (s), 1313 (w), 1244

X-ray Crystallographic Study: Intensity data were collected at 293 K with a Siemens SMART CCD diffractometer equipped with a graphite-monochromated Mo-K_α radiation source (λ = 0.71073 Å). Data were corrected for LP factors and empirical absorption correction was applied. Structures were solved by direct methods and refined by full-matrix least-squares refinement on F^2 using the SHELXTL-97 program package.[23] All non-hydrogen atoms were refined anisotropically, and hydrogen atoms were introduced geometrically with the exception of the water hydrogen atoms which were located from the difference Fourier syntheses. The free solvate dpe molecule in **3** was distorted in the lattice because of relatively poor crystal quality and so no attempt was made to refine the hydrogen atoms contained in it. Crystallographic data of **1**−**4** are outlined in Table 5. CCDC-220080 to -220083 contain the supplementary crystallographic data of **1**−**4** for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

NMR Evidence for Major Groove Binding of Both Λ- and Δ-[Ru(bpy)$_2$(pqx)](PF$_6$)$_2$ to the Oligonucleotide d(CGCGAATTCGCG)$_2$

Achilleas Garoufis,*[a] Gerasimos Malandrinos,[a] and Nick Hadjiliadis*[a]

Keywords: Major groove / N ligands / NMR spectroscopy / Oligonucleotides / Ruthenium

The enantiomeric complexes Λ- and Δ-[Ru(bpy)$_2$(pqx)](PF$_6$)$_2$ [pqx = 2-(2′-pyridyl)quinoxaline] were synthesized and characterized by various spectroscopic techniques. Their binding properties to the oligonucleotide duplex d(CGCGAATTCGCG)$_2$ were subsequently studied by NMR spectroscopy. 1D and 2D NMR techniques provided evidence for major-groove binding of both enantiomers with the oligonucleotide. The Δ-[Ru(bpy)$_2$(pqx)](PF$_6$)$_2$ enantiomer binds more deeply enantiomer to the oligonucleotide than the Λone. The quinoxalinic moiety of the pqx ligand faces the major groove in the Δ complex and is oriented at the external side of the adduct in the Λ complex. Both complexes show some affinity for the T8C9 base sequence of the dodecanucleotide helix.

Indroduction

The binding properties of transition metal tris-chelate complexes with DNA have been extensively studied in recent years.[1,2] One of the pioneering works was the report by Barton et al. pointing out the remarkable difference in the binding strength of the enantiomers of [Zn(phen)$_3$]$^{2+}$ with DNA.[3] The interactions between CT-DNA and the enantiomeric ruthenium complexes Λ- and Δ-[Ru(phen)$_3$]$^{2+}$ have been studied by several methods, with controversial conclusions. Several studies led to the conclusion that the Δ-isomer either intercalates between the base pairs,[4−7] or is partially inserted,[8−10] or it binds to DNA in various ways[11,12] (e.g. in the major[8,10] or in the minor groove[13,14]). On the other hand Λ-[Ru(phen)$_3$]$^{2+}$ binds to DNA either by electrostatic forces,[4,5] or surface-bound interactions,[6,12] and with weak binding in the minor[13,14] or the major groove.[8,10] 2,2′-Bipyridine has been used as a ligand less often than 1,10-phenanthroline in tris-chelate complexes of Ru^{II} in studies of interactions with DNA due to the lower affinity of this ligand to bind to the DNA helix. Based on photophysical results, it has been suggested that Δ-[Ru(bpy)$_3$]$^{2+}$ binds weakly with DNA either by intercalation or electrostatic interactions.[4,5,15] It has also been reported that no enantiomeric discrimination is apparent between the binding of Λ- and Δ-[Ru(bpy)$_3$]$^{2+}$ with DNA.[16]

The interaction of the mixed-ligand complex [Ru(bpy)$_2$(phen)]$^{2+}$ with DNA has been studied by linear dichroism spectroscopy with the aim of investigating the role of each ligand involved in the complex. The results indicate that the complex shows a similar binding geometry to [Ru(phen)$_3$]$^{2+}$ in which one phen ligand faces the DNA base pairs, almost as if it were intercalated nearly parallel to them.[9] A similar mixed-ligand complex, [Ru(bpy)$_2$(ppz)]$^{2+}$ (ppz = 4,7-phenanthrolino[6,5-*b*]pyrazine, a non-classical intercalative ligand), which is longer than phen by a six-membered fused ring, shows that both Λ- and Δ-enantiomers bind in the major groove of DNA by partial intercalation of the ppz ligand. The bpy ligands are not capable of inducing intercalation and the enantioselectivity is maintained by the different interactions of the Δ- and Λ-enantiomers with the DNA major groove.[17] In an attempt to contribute to the better understanding of how these mixed-ligand complexes bind to DNA, we have synthesized, characterized and studied the binding properties of the enantiomeric complexes Λ- and Δ-[Ru(bpy)$_2$(pqx)]$^{2+}$ [pqx = 2-(2′-pyridyl)quinoxaline], to the oligonucleotide duplex d(5′-CGCGAATTCGCG-3′)$_2$ mainly by NMR spectroscopy. The ligand pqx was chosen based on the following criteria: (i) it has an asymmetric nature that could be extended to the two bpy ligands of the complex, making them magnetically distinct; (ii) it is more similar to the structure of bpy than phen, even though it contains a six-membered fused aromatic ring on one side of the molecule.

Results and Discussion

Synthesis, Characterization and Solution Structure of the Enantiomers

rac-[Ru(bpy)$_2$(pqx)](PF$_6$)$_2$ has been synthesized previously by a one-step reaction between *cis*-[RuCl$_2$(bpy)$_2$] and pqx,[18] although the enantiomeric resolution by chromatographic techniques was unsuccessful. This is the reason our synthesis of the enantiomers was based on the optically pure precursors Δ- and Λ-[Ru(bpy)$_2$(py)$_2$]A·12H$_2$O (A = *O*,*O*′-dibenzoyltartaric acid), by replacing the two pyridine molecules by the bidentate ligand 2-(2′-pyridyl)quinoxaline (pqx) in ethylene glycol/DMSO (9:1). Since the substitution of the pyridines by pqx requires high temperature (ca. 160 °C), a stream of argon was used to prevent the oxidation of Ru^{II}. Isolation of the final products was achieved after addition of NH_4PF_6.

The CD spectra of Λ- and Δ-[Ru(bpy)$_2$(pqx)](PF$_6$)$_2$ are mirror images of each other and exhibit absorptions at λ_{max} ($\Delta\varepsilon$) = 463.7 nm (−1.6 м$^{-1}$cm^{-1}), 419.2 (+ 9.5), 402.3 (+9.1), 376.2 (−4.2) and 361.6 (-4.8) for the Δ-enantiomer and at 464.2 (+1.6), 419. 5 (−9.4), 403.8 (−9.0), 377.0 (+ 4.2) and 362.4 (+ 4.8) for the Λ-enantiomer (Figure 1). These assignments were made by comparison with similar complexes of known configuration.[19,20]

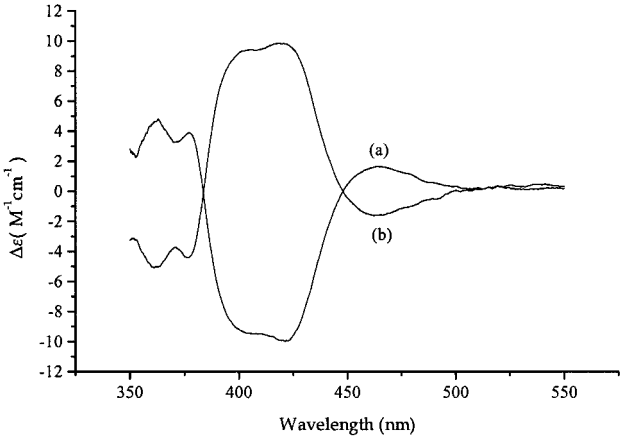

Figure 1. The CD spectra of: (a) Λ-[Ru(bpy)$_2$(pqx)](PF$_6$)$_2$ and (b) Δ-[Ru(bpy)$_2$(pqx)](PF$_6$)$_2$ in the region 350−550 nm

The ^{1}H and ^{13}C NMR resonances of the enantiomers were assigned assisted by 2D [^{1}H,^{1}H] DQF-COSY and 2D [^{1}H,^{13}C] HMBC/HMQC experiments. Figure 2 shows the structures of Λ- and Δ-[Ru(bpy)$_2$(pqx)](PF$_6$)$_2$ with atom labeling. Table 1 and 2 present chemical shift data for the enantiomeric complexes.

The ^{1}H and ^{13}C NMR spectra of both enantiomers show resolved signals for each of the bpy ligands, indicating that they are magnetically inequivalent. In addition, separate signals for the constituents of the bpy ligands (i.e. the pyridine rings) were observed. Sixteen proton and twenty carbon signals were observed in total, corresponding to all the proton and carbon nuclei of the two bpy ligands of each

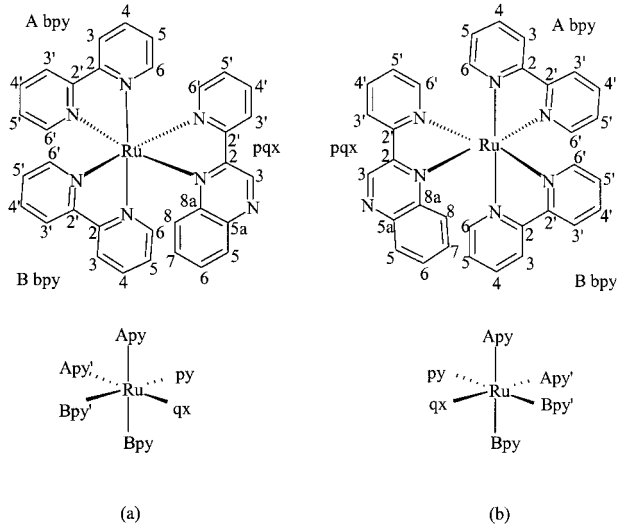

Figure 2. Structures of the enantiomeric complexes Λ- and Δ-[Ru(bpy)$_2$(pqx)]$^{2+}$, including atom numbering

enantiomer, which were fully assigned. This observation shows that the influence of the asymmetric nature of the pqx ligand on the magnetic environment of the two bpy molecules is important, in contrast to what was suggested for other similar complexes.[20−22] Since in the cases of Λ- and Δ-[Ru(bpy)$_2$(pqx)]$^{2+}$ the bpy ligands are magnetically discernible (probably due to the high magnetic field), it is necessary to define the relative location of the two bpy molecules towards pqx. In an attempt to determine the complete assignments of the enantiomers ^{13}C NMR spectroscopy was used to evaluate the Coordination Induced Shifts (CIS = $\delta_{complexed} - \delta_{free}$) and 2D [^{1}H^{1}H] ROE spectroscopy to investigate internuclear distances of less than 5 Å between the ligand protons. In general, the major effects affecting the CIS are: (i) the σ-withdrawal of electron density of the carbon nuclei through the nitrogen lone-pair upon coordination, causing downfield shifts, (ii) the π-back donation from the metal back-bonding to the π* orbitals of the ligand, causing downfield shifts, and (iii) the location of a carbon nucleus close to a high-electron-density area, such as an aromatic ring, causing dramatic upfield shifts. Figure 3 presents the CIS for all carbon atoms of the pyridine rings (py) of the complex Ru(bpy)$_3^{2+}$ together with the CIS of the pyridine rings of the two bpy (Abpy and Bbpy) and the pqx ligand of the complex Δ-[Ru(bpy)$_2$(pqx)]$^{2+}$ (see Figure 2). In the case of Ru(bpy)$_3^{2+}$ all six pyridine rings are magnetically equivalent, with the planes of the bipyridine rings perpendicular to each other. Also, the six pyridine rings are opposite to each other in the coordination sphere of the ruthenium.

As seen in Figure 2, the planes of the pyridine rings of Apy and Bpy, which occupy the axial sites of the complex, are perpendicular to the py and qx moieties of the pqx respectively. Since the quinoxalinic part of pqx is a more extended aromatic system (two fused six-membered aromatic rings) than a single pyridine ring, it is expected to provide a lower electron density to the C$_6$ atom of the per-

[a] NMR spectroscopic data at 600 MHz in $CDCl_3$ at 298 K (in ppm): (i) 2,2′-bipyridine: C2 = 155.45, C3 = 120.51, C4 = 136.73, C5 = 123.73, C6 = 148.92; (ii) ligand pqx: C2 = 149.44, C3 = 144.23, C5a= 141.84, C5 = 129.71, C6 = 130.10, C7 = 130.05, C8 = 129.33, C8a = 142.54, C2′ = 154.51, C3′ = 122.13, C4′ = 137.10, C5′ = 124.60, C6′ = 150.12; (iii) $[Ru(bpy)_3]^{2+}$: C2 = 156.50, C3 = 124.80, C4 = 138.00, C5 = 127.80, C6 = 150.80.

pendicularly located pyridine ring. Consequently, the CIS value of this nucleus differs from those of the other five C_6 and $C_{6'}$ atoms because it is less shielded, causing the higher downfield shift. Indeed, the C_6 of the Bpy ring shifts downfield by 5.60 ppm, about two times more than the C_6 of the other pyridine rings, indicating that Bpy is the one located vertically with respect to the quinoxaline ring system.

The σ- and π-back donations are two factors related to the bond strength that may also affect the CIS of the carbon nuclei of the pyridine rings. For both enantiomers the pyridine rings Apy′ and Bpy′ are located opposite the quinoxaline (qx) and pyridine (py) moieties of pqx, respectively, while the pyridine rings Apy and Bpy are opposite to each other (see Figure 2). Thus, only one of the five (py) rings seems to differ (slightly) from the others with respect to the σ- and π-back donation to the ruthenium coordination sphere. This is the Apy′ opposite to the (qx) moiety of the

pqx. Supposing that the Ru−N(py) bond strength differs from that of Ru−N(qx), the bond opposite to them will also differ. Consequently, the Apy′ with the higher downfield shifts of its carbon atoms (see Table 1) is probably located opposite the qx in the meridian plane of the ruthenium octahedron.

2D (^{1}H,^{1}H) ROESY spectroscopy was also used to confirm the above structure. Figure 4 shows the aromatic region of the ROESY spectrum of Δ-[Ru(bpy)$_2$(pqx)]$^{2+}$ at τ_m = 80 ms at a concentration of 5 mM and a temperature of 298 K. Note that three ROESY spectra were acquired with different mixing times of 60, 80 and 120 ms to select the optimum value for the intramolecular (^{1}H,^{1}H) correlation (r = 5 Å). The low concentration was necessary to avoid intermolecular contacts due to π-π stacking effects between the aromatic rings of the ligands of neighboring ions of the complex Δ-[Ru(bpy)$_2$(pqx)]$^{2+}$.[21]

Many intramolecular cross peaks were observed and were assigned to internuclei spin-spin interactions between the neighboring protons of the aromatic rings of the ligands, together with cross-peaks between the ring protons. A very clear cross-peak appears between H4′ of the pqx ligand and H6 of the Bbpy ligand, showing that these protons are close to each other. Additionally, the observation of an interligand cross-peak between H6 of Abpy and H6 of pqx confirms the structure shown in Figure 2. In this structure the plane of the Bpy′ ring is located perpendicular to the pyridine moiety of the pqx ligand and the Apy ring is also vertically located to the quinoxalinic ring system of the pqx ligand.

Interactions of the Enantiomers with d(CGCGAATTCGCG)$_2$

The addition of the Λ- or Δ-[Ru(bpy)$_2$(pqx)]$^{2+}$ enantiomer to the oligonucleotide duplex d(CGCGAATTCGCG)$_2$ causes changes in the proton chemical shifts of both enantiomers and the oligonucleotide; these are listed in Table 2 and 3.

The ^{1}H NMR spectra of the adduct of the Δ- or Λ-enantiomer to the oligonucleotide duplex at a 0.5:1 and 1:1 molar ratio at 298 K show only one set of resonances, indicating a fast exchange.[22]

A good indicator of which groove of the oligonucleotide the enantiomer binds to is the observed change in the chemical shifts of specific protons of the oligonucleotide duplex. The protons AH8 and GH8, CH6/H5, sugar H2′and H2′′ located in the major groove and AH2 and sugar H1′in the minor groove are mostly affected by this binding. The influence of the high electron density of the ligand aromatic protons causes upfield shifts of these protons. For both the Λ- and the Δ-enantiomer, only very small changes for all these protons (−0.02 to +0.02 ppm) were observed, showing that the stacking between the DNA base rings remains intact keeping the B-DNA structure. A π-type stacking interaction between the bases and the aromatic ligands of the enantiomers has to be excluded due to the

small upfield shifts of the protons of the oligonucleotide bases. Even though the environment of the bases in DNA is already rich in electron density, since they are stacked over the *z* axis itself with a separation of 3.4 Å, intercalators cause upfield shifts of about −0.2 ppm in the base protons by increasing their electron density still further.[23]

Small changes in the chemical shifts for the pqx ligand protons in both the Δ- and Λ-$Ru(bpy)_2(pqx)]^{2+}$ enantiomers, ranging from +0.04 to −0.20 ppm, were also observed, thus excluding any possibility for intercalation. It is known that for an intercalating aromatic ring, which stacks above and below the ring planes of a DNA base-pair, a dramatic upfield shift of −0.5 to −1.0 ppm typically occurs.[24] The magnitude of the upfield shift depends on the relative position of the protons of the intercalating ligand and the center of the base plane. Classical intercalators, like dppz, cause higher upfield shifts of the protons that are located between the DNA bases, by about −0.80 ppm[22] in the complex Δ-$[Ru(phen)_2(dppz)]^{2+}$ and by -0.67 ppm in the complex Δ-$[Ru(Me_2phen)_2(dppz)]^{2+}$.[23] As for the other two bipyridine ligands (Abpy and Bbpy), the most affected protons are H6 and H6′ of Abpy, which shift upfield by -0.32 and -0.38 ppm, respectively, for both the Δ- and the Λ-enantiomer. These values are not large enough to allow us to conclude that this ligand intercalates between the base pairs. Upfield shifts of the order of −0.2 to −0.4 ppm have been observed for the proton signals of ligands that are either partially inserted between the DNA bases,[25,26] or associate to the DNA grooves (e.g. 1,10-phenanthroline). Both Λ- and Δ-$[Ru(phen)_3]^{2+}$ bind to the minor groove of the oligonucleotide[13,14] $d(CGCGATCGCG)_2$ and cause upfield changes of about −0.3 ppm in some of the phen proton signals.[14] It is worth mentioning that in both enantiomers the influence of the binding causes similar changes to the proton chemical shifts.

The intermolecular NOEs observed between the Λ- or Δ-enantiomer and $d(CGCGAATTCGCG)_2$ are listed in Table 4. Figure 5 and 6 show portions of the NOESY spectra of the Λ- or Δ-$[Ru(bpy)_2(pqx)]^{2+}$/$d(CGCGAATTCGCG)_2$ adduct at 298 K.

Table 4. Intermolecular NOEs observed between Δ- and Λ-$[Ru(bpy)_2(pqx)]^{2+}$ and the oligonucleotide duplex $d(CGCGAATTCGCG)_2$ at molar ratio 1:1 and temperature 298 K

	G10H2′′ pqxH5
	C9H6 BbpyH3

In both NOE maps of the adducts the sequential NOEs arising from the inter- and intramolecular contacts between the oligonucleotide protons remain intact, indicating that the B-type conformation is kept upon interaction with Λ- or Δ-$[Ru(bpy)_2(pqx)]^{2+}$. This observation is consistent with a groove or a weak type of binding rather than with an intercalation, as this would cause significant perturbation in the DNA helix. Small differences in the cross-peak intensities of the duplex indicate insignificant changes of the oligonucleotide structure following interaction with the Ru enantiomers.

In the case of the Λ-isomer, a few cross-peaks with weak to medium intensities are observed. In the aromatic region, three intramolecular NOEs appear between the complex protons AbpyH3, BbpyH3 and pqxH6′, and T8H6. Since additional cross-peaks between the aromatic protons of bases C9 and T7 (neighboring to T8) and the enantiomer are not detected, the binding with intercalation above or below the T8 plane must be excluded. Taking into account that two more intermolecular cross-peaks between C9H2′′ and G10H2′′ and pqxH5 are observed, we can propose that

the complex binds in the major groove of the oligonucleotide where all these protons are located. The absence of cross-peaks between the complex protons and the sugar H1′ proton, or the adenine ring protons H2, located in the minor groove support the suggestion of binding in the major groove, close to the base T8. All five observed intermolecular NOEs cannot arise from the same binding state of the complex to the oligonucleotide due to the fast exchange kinetics of the system but, fortunately, they are located in the same part of the oligonucleotide duplex. While binding is unambiguous for the region -T8-C9- of the d(CGCGAATTCGCG)$_2$ complex, it is difficult to suggest which of the three ligands (Abpy, Bbpy, or pqx) binds to the oligonucleotide. All five observed NOEs should belong to different binding states (different ligands) — T8H6 pqxH6 and T8H6 BbpyH3. In an attempt to understand how the enantiomer binds to the oligonucleotide, a binding model generated by manually docking the complex close to the T8 of the major groove of the helix was obtained. Rotation of the complex in the range of ±15° in its *x*, *y*, *z* axis, produced a superimposed structure that satisfied all the observed NOE cross-peaks. In general, the obtained structures show that the complex binds mainly through the ligand Abpy in the major groove of the helix while the pyridine rings Bpy of the ligand Bbpy and py of the ligand pqx, are oriented along the DNA *z* axis. The quinoxaline moiety of the pqx ligand occupies the external side of the Λ- [Ru(bpy)$_2$(pqx)]$^{2+}$/d(CGCGAATTCGCG)$_2$ adduct (Figure 7).

Moreover, with this orientation the complex has an approximate height along the *z* DNA axis of approximately 11.5 Å. This is defined as the distance between the Bbpy H4 and the H4 of the pyridine ring of the pqx ligand, which is closer to the dimensions of the major groove (11.6 Å width × 8.5 Å depth), than those of the minor (6.0 Å width × 8.2 Å depth) in the B-DNA structure.[27] In this way the depth of the insertion is also defined. A ligand (L) with an extended aromatic fused rings' system in its Ru^{II} complexes of general formulae [Ru(phen)$_2$(L)]$^{2+}$, intercalates between the DNA bases with significant perturbation of the DNA structure, thereby affecting the dimentions of the grooves. Such complexes (e.g. Δ-[Ru(Me$_2$phen)$_2$(dppz)]$^{2+}$,[23] Δ-[Ru(phen)$_2$(L)]$^{2+}$ L = dipyrido[3,2-*a*:2′,3′-*c*][6,7,8,9]tetrahydrophenazine,[28] etc.) bind to the minor groove following

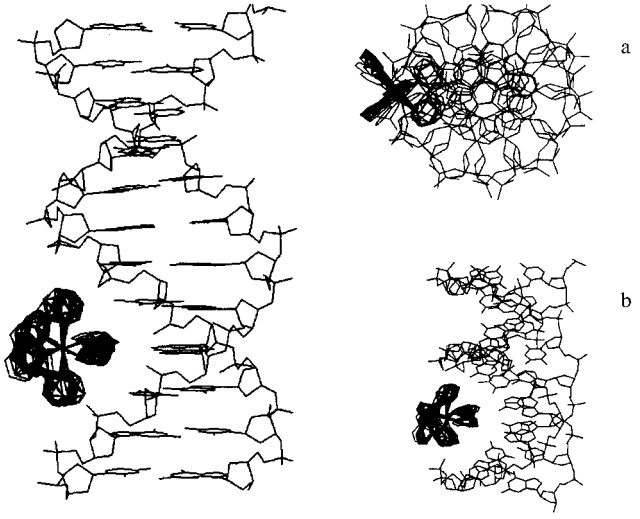

Figure 7. A molecular model of the interactions between Λ-$[Ru(bpy)_2(pqx)]^{2+}$ and $d(CGCGAATTCGCG)_2$ reflects qualitatively the binding of the complex to the oligonucleotide; inset: (a) top view along the *z*-axis showing the complex orientation with only the Abpy ligand facing the oligonucleotide; (b) a view across the major groove showing the complex orientation

the intercalating ligand which prefers the narrow minor groove and is stabilized by van der Waals interactions. On the other hand, complexes without a "leader" intercalative ligand such as $[Ru(bpy)_3]^{2+}$ or $[Ru(phen)_3]^{2+}$ bind without intercalation. Based on photophysical results it has been suggested that $[Ru(bpy)_3]^{2+}$ binds to DNA weakly[15] without intercalation and its electrostatic interactions with the DNA phosphates are ambiguous. Minor-[13,14] or major-groove[8,10] binding has been found for the related complex $[Ru(phen)_3]^{2+}$ for both Λ- and Δ-enantiomers by spectroscopic techniques. Λ-$[Ru(phen)_3]^{2+}$ was found to interact with the DNA minor groove only with one phenanthroline molecule such as in the case of Λ-$[Ru(bpy)_2(pqx)]^{2+}$ that interact only with the Abpy. Hiort et al. have suggested a major-groove binding for both enantiomers of the complex $[Ru(phen)_3]^{2+}$ based on LD studies.[10] Major-groove binding was also observed for both enantiomers of the complex $[Ru(bpy)_2(ppz)]^{2+}$, where the ligand ppz was deeply inserted between the base pairs.[17] In the case of Λ-$[Ru(bpy)_2(pqx)]^{2+}$, which clearly prefers the major groove, the 2,2′-bipyridine ligand seems to have a lower affinity than 1,10-phenanthroline, with van der Waals interactions with the DNA mainly taking place from the minor groove. On the other hand, electrostatic interactions that probably coexist in our case take place through the phosphates in the major groove. Additionally, the bpy ligands provide less steric hindrance than phenanthroline. These are probably the reasons why Λ-$[Ru(bpy)_2(pqx)]^{2+}$ prefers the major groove.

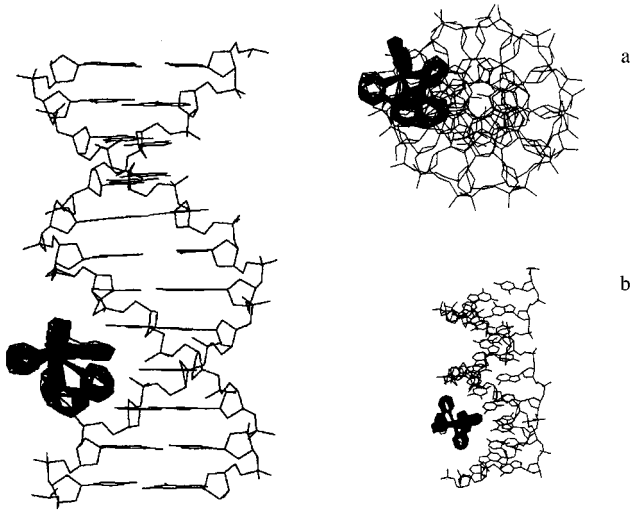

Figure 8. A molecular model of the interactions between Δ-$[Ru(bpy)_2(pqx)]^{2+}$ and $d(CGCGAATTCGCG)_2$ reflects qualitatively the binding of the complex to the oligonucleotide; inset: (a) top view along the *z*-axis showing that the complex inserts both the Bbpy and the pqx ligands into the major groove of the helix; (b) a view across the major groove showing the complex orientation

In the case of the Δ-isomer many more cross-peaks are observed, all of which are located at the same part of the oligonucleotide close to the bases T8 and C9, as in the case of the Λ- isomer. The protons that are involved in these intramolecular NOEs are all located in the major groove of the helix. This observation is in agreement with the results of 1D ^1H NMR spectra where the chemical-shift changes are very similar for both enanatiomers. However, some specific cross-peaks between the Δ-enantiomeric protons and the base ring protons, particularly in neighboring bases (e.g. the pqxH8 with T8H6 and C9H6), indicate that the complex is inserted deeply into the major groove. Due to the fast kinetics of the binding it is not possible to assign all the observed cross-peaks to one binding state, but, as shown in Figure 8, all the generated structures (according to the binding model procedure) place the Bpy of Bbpy and the quinoxalinic part of the pqx ligand close to the bases in the depth of the major groove. The Abpy ligand is located on the external part of the adduct without being in contact with the oligonucleotide helix.

To be consistent with the groove dimentions, this deeper insertion of the Δ- than the Λ-isomer means that the internal *z* axis of the complex is not parallel to the *z* axis of the helix but is slightly bent. In this orientation the complex interacts with the major groove of the oligonucleotide with the two ligands without causing a significant distortion of the DNA structure. Based on intramolecular NOE contacts, it has been suggested that the complex Δ-$[Ru(phen)_3]^{2+}$ binds to $d(CGCGATCGCG)_2$ by insertion of two phenanthroline molecules into the minor groove of the central AT part of the oligonucleotide.[13,14] This suggestion seems to be in contrast with our observation that the complex binds to the major groove. However, the complex $[Ru(bpy)_2(pqx)]^{2+}$ shows an affinity for the oligonucleotide T8C9 base sequence and not for the central AATT region, and this is probably the reason why the approach of the helix is from the major groove. In general, the central AATT region of $d(CGCGAATTCGCG)_2$ is preferred by molecules that bind from the minor groove.[29,30]

Conclusions

In both enantiomers Λ- and Δ-[Ru(bpy)$_2$(pqx)]$^{2+}$ the asymmetric nature of the pqx ligand causes different magnetic environments of the two bpy ligands and allows the distinction of Abpy and Bbpy. The pqx ligand is not a classical intercalator and its DNA binding properties were previously unexplored. The determination of the complete assignment of these complexes allows us to understand better their binding properties with the oligonucleotide d(CGCGAATTCGCG)$_2$. The main conclusions are summarized below:

(i) As indicated by NMR spectroscopy, both enantiomers bind non-intercalatively in the d(CGCGAATTCGCG)$_2$ major groove close to the T8C9 sequence without significant perturbation of the helix structure. Evidence for a similar binding of the enantiomers comes from the similar changes in the proton chemical shifts of the adducts, and the NOE results.

(ii) Δ-[Ru(bpy)$_2$(pqx)]$^{2+}$ binds more deeply than Λ-[Ru(bpy)$_2$(pqx)]$^{2+}$, with two ligands (pqx and Bbpy) facing the DNA groove while the Λ isomer only has one (Abpy).

(iii) The quinoxalinic moiety of the pqx ligand in the case of Δ-[Ru(bpy)$_2$(pqx)]$^{2+}$ contributes to the interaction with the oligonucleotide while in the case of the Λ-enantiomer it is located in the external part of the adduct.

Experimental Section

Materials: All chemicals and solvents were of reagent grade and were used without further purification. The deoxynucleotide d(5′-CGCGAATTCGCG-3′) was purchased from OSWEL DNA Service (University of Southampton, UK) and purified by chromatography on a 120 × 2.5 cm Sephadex G-25 superfine column, using distilled water as eluent and lyophilized to dryness. The complexes *cis*-[RuCl$_2$(bpy)$_2$][31] and Λ- and Δ-[Ru(bpy)$_2$(py)$_2$]A·12H$_2$O (where A = *O*,*O*′-dibenzoyltartaric acid),[32,33] and the ligand 2-(2′-pyridyl)quinoxaline (pqx) were synthesised according to literature procedures.[34]

Instrumentation: Elemental analyses for C, H and N were performed using a Carlo−Erba 1108 apparatus. CD spectra were recorded on a Jasco J-720 spectropolarimeter. A 2-cm path length cuvette was used for the region 350−500 nm. All NMR spectroscopic data were acquired at 150.92 and 201.21 MHz for ^{13}C and 600.13 and 800.13 MHz for ^{1}H transmitter frequencies on AVANCE 600 and 800 MHz Bruker spectrometers. 1D (^{1}H and ^{13}C) spectra for both enantiomers were recorded at 298 K in either $CDCl_3$ or D_2O. In addition 2D (^{1}H,^{1}H) DQF-COSY, 2D (^{1}H,^{13}C) HMBC/HMQC and 2D (^{1}H,^{1}H) ROESY spectra were acquired in $CDCl_3$ on the AVANCE 600 and (^{1}H,^{1}H) DQF-COSY in D_2O on the 800 MHz instrument, at 298 K. In the case of (^{1}H,^{13}C) HMBC/HMQC spectra, a total of 2048 complex points in t_2 were collected for each of 320 t_1 increments. (^{1}H,^{1}H) ROESY spectra were collected at mixing times (τ_m) between 60 and 120 ms with the pulse program roesyetgp.[35,36] 2D (^{1}H,^{13}C) HMBC spectra were obtained using the inv4gplplrnd pulse sequence, optimized for long-range couplings, with a low-pass J-filter to suppress one-bond correlation. The AVANCE 800 instrument was used mainly to acquire the spectra of the [d(CGCGAATTCGCG)$_2$]/[Ru(bpy)$_2$(pqx)]$^{2+}$ adducts in D_2O at 298 K. (^{1}H,^{1}H) DQF-COSY spectra were recorded using the cosydfesgpph26 pulse programe, while the water suppression was achieved using excitation sculpting with gradients allowing for presaturation during relaxation delay in cases of radiation damping phasecycle.[37] The (^{1}H,^{1}H) NOESY spectra were collected in 4096 complex points in t_2 for each of 512 t_1 increments at two mixing times (τ_m) of 350 and 400 ms with the noesyesgpph26 phase-sensitive pulse programme using the TPPI method.[38] Finally the (^{1}H,^{13}C) HMQC spectra were collected in 2048 complex points in t_2 for each of 128 t_1 increments with the pulse sequence inv4prtp with decoupling during acquisition.[39] The NMR spectroscopic data were processed using the Bruker Xwin NMR Ver. 2.6 software.

Sample Preparation: In each oligonucleotide sample the amounts were estimated by weighing and the concentrations were determined from the absorption at 260 nm.[40] In all NMR experiments a 100 mM Na_2HPO_4/NaH_2PO_4, pH 7.00 (uncorrected for isotope effects) buffer was used. The lyophilized samples were dissolved in D_2O (99.9%) and lyophilized again to dryness. These samples were finally dissolved in 0.4 mL of D_2O (99.96%) and transferred to 5 mm NMR tubes. The 1D ^{1}H NMR spectra were recorded on samples with a concentration of about 50 OD_{260} units while the 2D NOE experiments were performed with more-concentrated samples (ca. 200 OD_{260}). No internal chemical-shift reference was added to the samples.

Molecular Modeling: Both Λ- and Δ-[Ru(bpy)$_2$(pqx)](PF$_6$)$_2$ were constructed manually from the X-ray atomic coordinates of the closely related complexes [Ru(bpy)$_2$(py)$_2$]$^{2+}$.[33] Each of the above complexes was docked manually at the major groove of the dodecanucleotide close to bases T8C9. The enantiomers were rotated along the axis *x*, *y*, *z*, to produce superimposed structures. This average structure satisfied all the observed NOE interatomic distances between the protons of the complex and the dodecanucleotide. The DNA helix was in the B-type configuration and was produced by the database of the molecular software program HyperChem. v. 6.0. Graphical outputs were obtained with the RasMol v2.6 software.

Δ-[Ru(bpy)$_2$(pqx)](PF$_6$)$_2$: Δ-[Ru(bpy)$_2$(py)$_2$]A·12H$_2$O (0.1 mmol, 105 mg) was dissolved in 10 mL of a 9:1 mixture of ethylene glycol and DMSO and a solution of pqx (0.4 mmol, 83 mg) in the same solvent (5 mL) was added. The mixture was refluxed for 24 hours under argon (99.999%). After cooling to room temperature, 5 mL of water was added and the mixture filtered to remove the excess of pqx. A saturated solution of NH_4PF_6 (5 mL) was added to the remaining clear solution. A deep-red precipitate was obtained by cooling the solution to 4 °C overnight, and this was filtered and washed with cold water (2 × 5 mL) and diethyl ether (2 × 5 mL). The crude solid was dissolved in MeCN and purified on an activated aluminum oxide column (20 × 1 cm) using MeCN as eluent. The solvent (MeCN) was evaporated from the collected brown-orange band to yield orange needles of Δ-[Ru(bpy)$_2$(pqx)](PF$_6$)$_2$ (yield 65%). $C_{33}H_{25}F_{12}N_7P_2Ru$: calcd. C 43.5, H 2.7, N 10.8; found C 42.9, H 2.9, N 10.7. ^{1}H NMR ($CDCl_3$, 600 MHz, 298 K): δ = 10.19 (s, pqxH$_3$), 9.31 (d, $^{3}J_{H,H}$ = 8.3 Hz, pqxH$_{3'}$), 8.95 (d, $^{3}J_{H,H}$ = 6.7 Hz, AbpyH$_3$), 8.94 (d, $^{3}J_{H,H}$ = 6.7 Hz, AbpyH$_{3'}$), 8.77 (d, $^{3}J_{H,H}$ = 8.1 Hz, BbpyH$_3$), 8.68 (d, $^{3}J_{H,H}$ = 8.1 Hz, BbpyH$_{3'}$), 8.33 (t, $^{3}J_{H,H}$ = 7.8 Hz pqxH$_{4'}$), 8.26 (t, $^{3}J_{H,H}$ = 7.5 Hz, AbpyH$_{4'}$), 8.23 (t, $^{3}J_{H,H}$ = 7.8 Hz, BbpyH$_4$), 8.24 (d, $^{3}J_{H,H}$ = 8.1 Hz pqxH$_8$), 8.23 (t, $^{3}J_{H,H}$ = 7.8 Hz, AbpyH$_4$), 8.13 (d, $^{3}J_{H,H}$ = 5.3 Hz, AbpyH$_6$), 8.09 (t, $^{3}J_{H,H}$ = 7.5 Hz, BbpyH$_{4'}$), 8.00 (d, $^{3}J_{H,H}$ = 5.3 Hz pqxH$_{6'}$), 7.88 (t, $^{3}J_{H,H}$ = 7.5 Hz pqxH$_7$), 7.79 (d, $^{3}J_{H,H}$ = 5.3 Hz, BbpyH$_6$),

Synthesis, Structure and Binding Properties of Nickel and Copper [14]Cyclidene Complexes with Appended Aza Crown Ethers

Bohdan Korybut-Daszkiewicz,*[a] Joanna Taraszewska,*[b] Katarzyna Zięba,[b] Anna Makal,[c] and Krzysztof Woźniak*[c]

Keywords: Cyclidene complexes / Crown ether compounds / Copper / Nickel / Electrochemistry

Copper(II) and nickel(II) cyclidenes linked with one or two 15-azacrown-5 ethers (**3Ni**, **4Ni** and **4Cu**) as well as similar model morpholine-substituted derivatives (**2Cu**, **2Ni**) have been synthesized and characterized using ESI mass-spectrometry, X-ray diffraction, spectroscopic methods and elemental analysis. Cyclic voltammetry of the copper complexes exhibits two reversible redox couples $Cu^{II/III}$ and $Cu^{II/I}$, whereas the nickel complexes show reversible $Ni^{II/III}$ and irreversible $Ni^{II/I}$ redox processes. Cyclic and differential pulse voltammetry have been used to study interactions of metal cations and amino acids with the above complexes. Na^+ and Li^+ interact weakly with the **3Ni** complex. In the presence of Mg^{2+}, the ligand isomerizes from aldehyde to enolate ion, which interacts strongly with Mg^{2+}. The presence of lysine caused a more pronounced shift of the $Cu^{II/III}$ potential in **4Cu** than did leucyne. This suggests that there are interactions between the NH_3^+ group and the crown ether moiety and between the carboxylic group and the Cu^{III} center of the former guest.

Introduction

Redox-active molecular receptors designed to complex and electrochemically recognize charged and neutral guest species have attracted great attention.[1−4] Compounds possessing such properties consist of a redox-active component and a macrocyclic ligand well suited for the complexation of guest species. The redox center in such systems can easily be switched between its oxidized and reduced forms, thus giving two different states with different charges. Each state is expected to behave differently in the binding process with some substrates. Ferrocene crown ethers[1−6] and ferrocene cryptands[7−11] have been the most extensively studied species. However, such electro-active components as cobaltocene[6] quinone, nitrobenzene, and others have also been used.[4] Plenio et al.[8,9] found that efficient electronic communication between the guest coordinated in the macrocyclic cavity and the redox active unit is crucial for the optimum performance of such molecular devices. Some redox switchable host−guest systems have frequently been proposed as the key components of potential molecular devices and sensors.[12,13]

Azamacrocyclic ligands can stabilize unusual oxidation states of coordinated transition metal ions, making them a promising tool for the construction of supramolecular sensors and switches. Rybak-Akimova et al.[14−16] have synthesized a ditopic molecule consisting of 4-formylbenzo-15-crown-5 and a redox-active tetraazamacrocyclic nickel(II) complex as a receptor for $MeNH_3^+$ and β-$AlaH^+$.[14] They also proposed a ditopic receptor for dicarboxylic acids based on a 15-membered tetraazamacrocyclic (cyclidene)-nickel(II) complex conjugated with two cyclic tetraamines (cyclene),[15] and another for the molecular recognition of diammonium cations based on a cyclidene nickel(II) complex bearing two benzocrown ethers.[16] Bernhardt and Hayes[17] applied benzocrown ethers with appended cobalt cyclam as receptors for alkali cations. Fabbrizzi et al.[18] have synthesized luminescent molecular sensors operating through a metal-center redox couple, combining nickel(II) cyclam-like macrocycles or a copper 14-ane-S4 complex with organic fluorophores (mainly anthracene). Previously,[19] we have studied tetraazamacrocyclic nickel(II) complexes functionalized with benzo-15-crown 5 ethers as receptors for group I and II metal cations.

In this paper we describe the synthesis and characterization of 14-member copper(II) and nickel(II) cyclidenes linked with one or two 15-aza-crown-5 ethers (Scheme 1, complexes **3Ni**, **4Ni** and **4Cu**), as potential receptors for alkali, alkaline-earth metal cations and zwitterionic species such as amino acids. Ligands containing binding sites for

both cations and anions should be suitable for studying the recognition of such species. This may be important in understanding many biological and communication processes at the molecular level. Transition metal porphyrins[20] and phthalocyanines[21] bearing crown ethers substituents are among several known ditopic macrocyclic molecules containing transition metal and ammonium ion binding sites. Kimura et al.[22] have shown that a molecule composed of a macrocyclic polyamine covalently linked with benzo-15-crown-5 ether forms stable 1:1 complexes with zwitterionic substrates such as amino acids.

Results and Discussion

Synthesis and Structure

Copper(II) and nickel(II) *O*-methylated [14]cylidene complexes **1Cu** and **1Ni** (Scheme 1) reacted with morpholine as well as with 1-aza-15-crown-5 to form amino-substituted cyclidenes **2Cu, 2Ni** or **4Cu, 4Ni**. When complex **1Ni** was used in excess, the monosubstituted product **3Ni** was isolated by chromatography on an SP Sephadex C25 column. Complexes **3Ni** and **4Cu** gave crystals suitable for X-ray analysis.

Structural Details

Complex **4Cu** (Figure 1) crystallizes in the triclinic $P\bar{1}$ space group, as a salt in which two PF_6^- ions interact with one complexed Cu^{II} cation. The complex occupies a special position, with the central Cu atom located exactly on the crystallographic symmetry center. Therefore, the inner symmetry of the molecule becomes a crystallographic feature and, crystallographically, only half of the molecule is independent. Together with one PF_6^- ion the independent half of the **4Cu** molecule defines the crystallographic asymmetric unit.

The macrocyclic fragment of **4Cu** is nearly planar, except for the part including C(1) and C(2), which is an aliphatic part of the ring. The C(1)−C(2) bond length is 1.519 Å and the carbon atoms are above and below the macrocycle plane accordingly. The valence angles C(2)−N(1)−C(3) and C(1)−N(2)−C(5) are close to 120° − a characteristic of such macrocyclic compounds. The bond lengths between other atoms of the macrocyclic moiety reveal their partial double bond character, thus confirming the aromatic character of the tetraazamacrocyclic compound. N(1) and N(2) bind the Cu^{II} cation at the center of the macrocycle with a bond length that is characteristic of N−Cu^{II} interactions (ca. 1.90 Å). C(6) and N(3) are coplanar with the Cu^{II} cation and the coordinating N(1) and N(2) atoms and both C(4)−C(6) and C(6)−N(3) bonds show partial double character, indicating that the lone electron pair of N(3) contributes to the electron density of the aromatic macrocycle. Important bond lengths and angles are given in Table 1. N(3) is nearly coplanar with C(5) and C(3); the rest of the crown ether is forced to be located at close to 100° with respect to the azamacrocyclic moiety. The conformation of the crown ether in this structure is not the most preferable for the coordination of the cations, with the oxygen atoms O(2) and O(4) directed outside the crown and the carbons C(10) and C(15) pointing inwards. Some weak interactions appear to occur between O(1) and O(3) and the hydrogen atoms connected to C(10) and C(15), although the interatomic distances are too long to be classified as regular hydrogen bonds (Table 1). Some reorganization of the crown must occur prior to, or simultaneously with, the process of possible cation complexation. The average C−C and C−O distances in the crown ether are slightly shorter than the average expected C−C and C−O bond lengths (Table 1) but are consistent with the distances reported in crystallographic databases.

The PF_6^- ion shows standard octahedral geometry (Table 1) and is localized close to the macrocycle ring. F(14) interacts with the Cu^{2+} ion (the two atoms are 3.027 Å apart). Together with the macrocyclic nitrogen atoms, F(14) completes the coordination sphere of the Cu^{2+}, making it roughly octahedral, with N(1)−Cu−F(14) and N(2)−Cu−F(14) of 78.92° and 77.68°, respectively. There

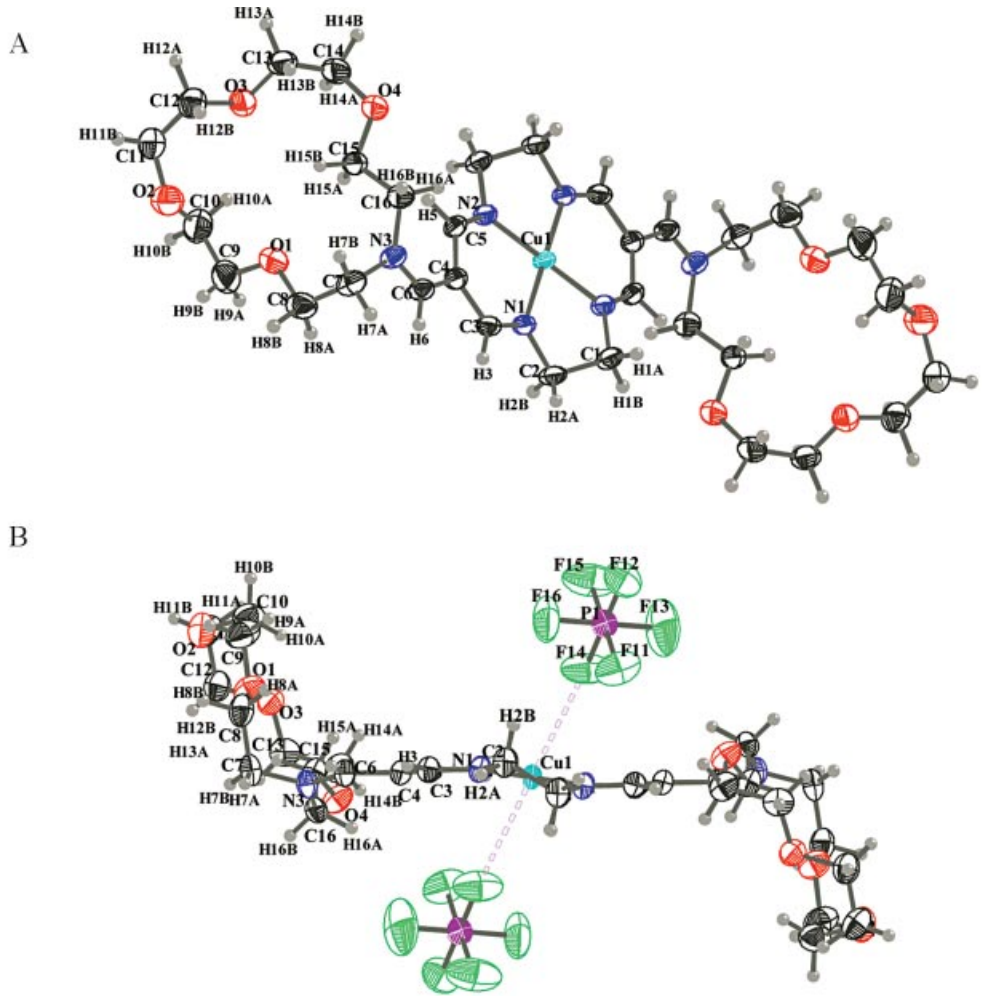

Figure 1. Structure of **4Cu**: (A) with atom labeling, (B) including coordinating PF_6^- molecules

are no other significant interactions between the PF_6^- ion and the macrocyclic Cu complex.

There are also no special intermolecular interactions such as hydrogen bonds that would stabilize the crystal structure of **4Cu**. The packing is rather close and reveals a two-layered structure (Figure 2). The first layer consists of parallel packed macrocyclic moieties and PF_6^- ions while the crown ether compounds build the second layer, forming cages.

3Ni crystallizes in the monoclinic $P2_1/c$ space group, as a salt of one PF_6^- ion interacting with the Ni cation complexed by the macrocyclic compound (Figure 3). The complex occupies a general crystallographic position and together with the PF_6^- ion constitutes the crystallographic asymmetric unit. There are four symmetry related **3Ni** molecules in the unit cell.

The overall structure of the macrocyclic Ni^{II} complex is similar to that in **4Cu**, although there are some differences. The inter-atomic distances between the Ni^{II} ion and the four coordinating nitrogen atoms are slightly shorter than in the **4Cu** structure. This length is characteristic for this type of coordination. The presence of an extra negative charge within the macrocycle ring also has a significant influence. The bonds connecting C(9) with C(8) and C(10)

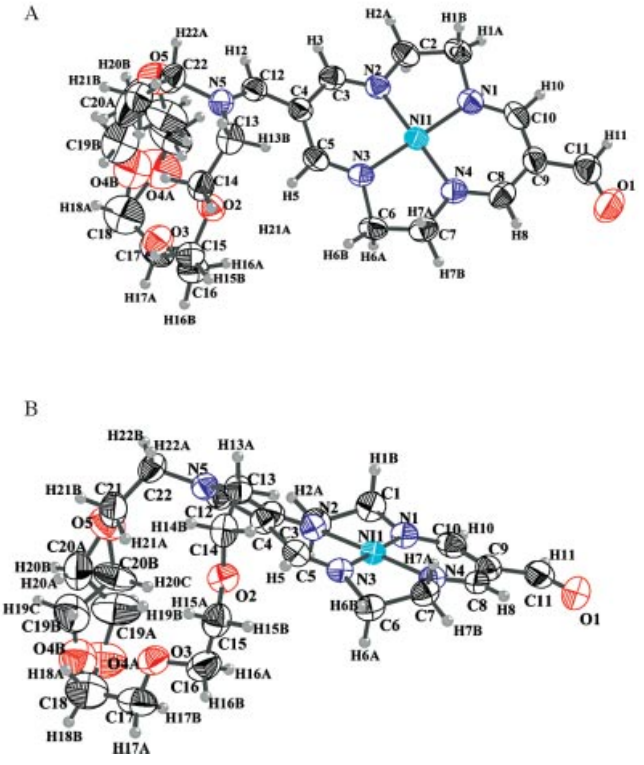

Figure 3. Structure of **3Ni**: (A) view of the macrocyclic compound and (B) presentation of the disorder in the crown ether part

are of equal length and shorter than expected for a typical C−C single bond. This confirms that most of the negative charge is located around C(9), close to the aldehyde group connected with the macrocycle. The exocyclic bond length C(9)−C(11) is typical for a C=C double bond, and the effect is due to both the negative charge on C(9) and the conjugation of the double bond of the carbonyl group with the double bonds of the macrocycle; This is confirmed by the coplanarity of O(1) with C(8) and C(10) (with torsion angles of 1.7° and 179.6°, respectively). The opposite part of the macrocycle is not exactly parallel to the first one, although the atoms that comprise it all lay in one plane and the aromatic character of the compound is confirmed by the bond lengths (Table 2). Similarly to the **4Cu** structure, the lone electron pair of N(5) of the crown ether joins the aromatic system of the macrocycle and, therefore, fixes the location of the crown at the angle with respect to the macrocycle plane. Probably due to the negative charge on C(9), the crown moiety is closer to the macrocycle ring than in **4Cu**, with an angle between the average crown ether plane and the macrocycle of less than 90°. The conformation of the crown is close to that preferable for cation complexation, with only O(5) pointing somewhat outside the ring. The fragment including O(4), C(19) and C(20) atoms proved to be disordered. There are two possible conformations that share nearly the same occupation, designated as A and B. The disorder causes quite large thermal ellipsoids in the structure. The more important bond lengths and angles are reported in Table 2.

The PF_6^- ion does not appear to form close contacts with the complexed Ni^{II} ion or **3Ni** moiety and, not being stabilized in the crystal structure by any well-defined interaction, it seems to rotate freely in the space among the **3Ni** molecules. This may explain the severe disorder in the ion's

structure. At least four possible conformations for the ion may appear.

The packing of the **3Ni** and PF_6^- ions resembles that observed in **4Cu**. Again, there are two different layers, one consisting of the parallel placed macrocycle moieties and another built up by the crown ethers, forming cages of each pair of crown moieties (Figure 4). The PF_6^- ions are located in tunnels formed in bends of the **3Ni** moieties. Again, there are no significant interactions such as hydrogen bond that would stabilize the structure.

Electrochemical Characteristics of Cu and Ni Complexes

Cyclic voltammograms (CV) of the studied complexes recorded in ACN containing 0.1 M $[Bu_4N]BF_4$ are presented in Figure 5. The CV of complexes **2Cu** and **4Cu** exhibit two reversible redox couples, $Cu^{II/I}$ and $Cu^{II/III}$, respectively. Comparison of the corresponding E_fs (Table 3) indicates that the aza crowns facilitate the $Cu^{II/III}$ redox process and

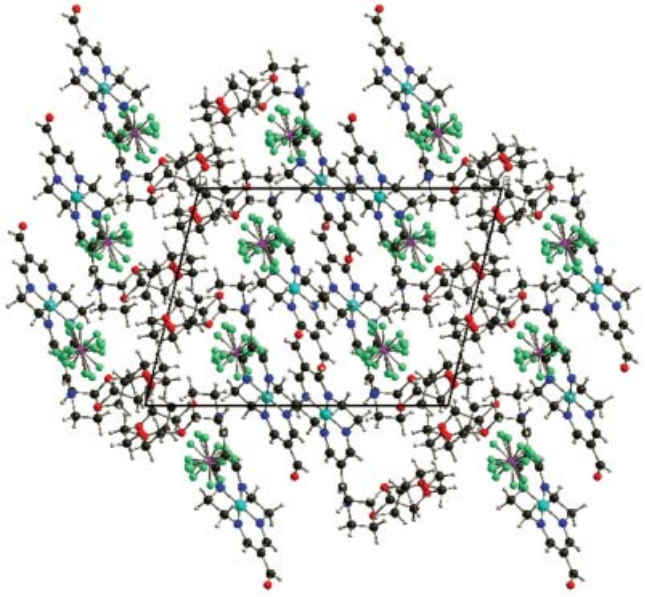

Figure 4. Packing of **3Ni** molecules in the crystal lattice − view along the *y*-axis

make the $Cu^{II/I}$ process more difficult. **3Ni** exhibits a reversible $Ni^{II/III}$ redox process, similar to complex **4Ni**, and an irreversible $Ni^{II/I}$ process.

tial shift of the $Ni^{II/III}$ redox couple and a more pronounced anodic shift of the $Ni^{II/I}$ cathodic wave (Table 4). With further addition of Li^+ and Na^+ cations the $Ni^{II/III}$ redox potential did not change; however, the $Ni^{II/I}$ potential shifted by 70 mV and by about 100 mV in the presence of 10 equiv. of Li^+ and Na^+, respectively. These results indicate that the binding ability of Li^+ and Na^+ cations to the crown ether moiety is significant when Ni^{II} in the azamacrocycle is reduced to Ni^{I}. With Ni^{III} the complexation of both cations is very weak. The addition of K^+ did not change the $Ni^{II/III}$ potential, and changed only slightly (5 mV) the $Ni^{II/I}$ potential.

The addition of 0.25 equiv. of Mg^{2+} cation to the solution of **3Ni** resulted in an anodic shift of the $Ni^{II/III}$ redox potential by 10 mV and the appearance of a new irreversible $Ni^{II/I}$ peak at the potential 200 mV less negative (Table 4). After addition of 0.5 equiv. of Mg^{2+} a new anodic peak *a* appeared at 170 mV more positive (see A in Figure 6). With increasing Mg^{2+} the current of the new anodic peak increased at the expense of the anodic current of the original peak. At higher concentrations of Mg^{2+} two peaks could be still observed on the differential pulse voltammograms. The currents of both peaks vs. the equivalents of Mg^{2+} added are plotted in Figure 7. However, the reduction current corresponding to the first process remained unchanged. In the cathodic region, with increasing Mg^{2+} the height of the new peak at −1.500 V increased at the expense of the original peak

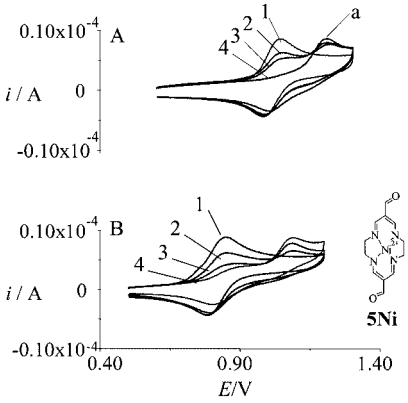

Figure 6. Cyclic voltammograms of 5×10^{-4} M of complexes **3Ni** (A) and **5Ni** (B) upon addition of Mg^{2+} (equiv.): (1) 0; (2) 0.5; (3) 1; (4) 2; inset: structure of **5Ni**

The above effects are explained in Scheme 2.

The small anodic potential shift of E_f after the addition of 0.25 equiv. of Mg^{2+} indicates complexation of this guest

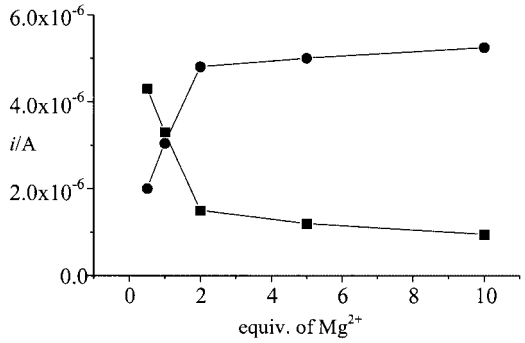

Figure 7. Currents corresponding to the oxidation of Ni^{II} from the aldehyde form of **3Ni** (squares) and from the enolate form (circles) vs. Mg^{2+} added (equiv.)

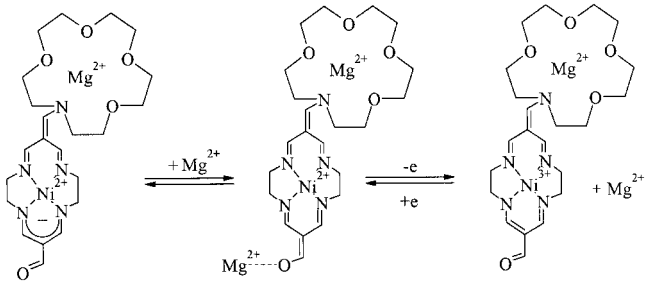

Scheme 2

cation in the crown ether moiety. Further addition of Mg^{2+} forces the charge to shift from the macrocyclic ring to the oxygen of the aldehyde group. This results in the formation of an enolate anion, which interacts with a second Mg^{2+} cation. The second anodic peak corresponds to the oxidation of Ni^{II} from this complex. The so-produced Ni^{III} forces the negative charge to shift again to the macrocyclic ring, with formation of the original complex, which is reduced at about 0.985 V.

To verify the above explanation complex **5Ni** was synthesized.[23] After the addition of Mg^{2+} its electrochemical behavior (Figure 6, B) was similar to that of the **3Ni**. Interaction of an enolate anion with Mg^{2+} was also confirmed by UV/Vis spectroscopy (Figure 8). For both complexes, the absorption band corresponding to Ni^{II} shifts to shorter wavelengths with increasing equivalents of Mg^{2+} cations.

After the addition of 0.25 equiv. of Ba^{2+} the $Ni^{II/III}$ redox potential is shifted towards positive values by 6 mV; however, the second anodic peak at 1.21 V began to appear after the addition of 5 equiv. and increased with the addition of further amounts of Ba^{2+}.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

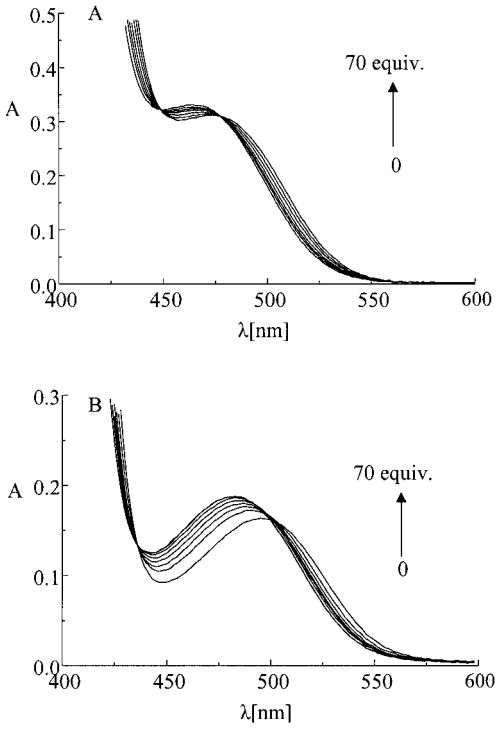

Figure 8. Spectrophotometric titration curves of solutions of **3Ni** (A) and of **5Ni** (B) with $Mg(ClO_4)_2$

The addition of alkali and alkaline earth metal cations to solutions of **4Cu** and **4Ni** had no influence on the E_fs of $Cu^{II/III}$ and $Ni^{II/III}$ redox systems. However, the presence of NH_4^+ exerted a significant influence on the $Cu^{II/I}$ redox process in complex **4Cu**. Figure 9, A, shows the CV of **4Cu** after the addition of 1 equiv. of NH_4^+ cation. The reduction peak *a* at about 200 mV less negative than that of peak *b*, corresponding to the reduction of $Cu^{II/I}$ from complex **4Cu**, is due to the $Cu^{II/I}$ reduction from the part of complex **4Cu** with NH_4^+ cation complexed in the crown ether moiety.

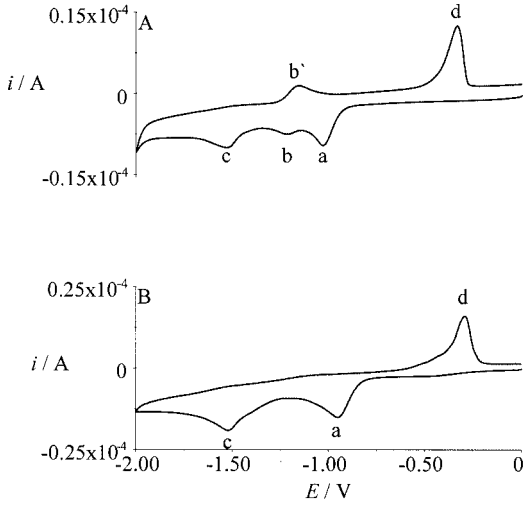

Figure 9. Cyclic voltammograms of complex **4Cu** (5×10^{-4} M) upon addition of (A) 1 equiv. of NH_4^+ and (B) 1 equiv. of Mg^{2+}; scan rate 0.05 Vs^{-1}

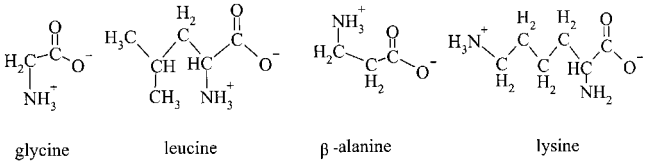
Peak *c*, at ca. −1.520 V, corresponds to the $Cu^{I/0}$ reduction in this complex. The proximity of the positively charged cation to the positive copper center can destabilize the complex (which is usually less stable in the case of Cu^+). The anodic peak *d* at ca. −0.300 V corresponds to the oxidation of copper deposited on the electrode surface (which was confirmed by the experiment with CuCl). Peaks *bb′* correspond to the reversible $Cu^{II/I}$ redox process from the original **4Cu** complex. They disappeared at higher concentrations of NH_4^+.

The addition of Na^+ cation had no influence on the $Cu^{II/I}$ redox potential in complex **4Cu**; however, the irreversible $Ni^{II/I}$ potential in complex **4Ni** is shifted anodically by 25 mV after the addition of 20 equiv. of this cation, suggesting that after formation of Ni^I the Na^+ cation is complexed in the crown ether moiety of complex **4Ni**. After the addition of Mg^{2+} cations to the solution of **4Cu** (Figure 9, B) the $Cu^{II/I}$ reduction peak is shifted anodically by about 280 mV (Figure 9, B; peak *a*) versus the original peak *b*. Peaks *c* and *d* were also recorded. A significant increase in both reduction currents (peaks *a* and *c*) indicates that the proximity of Mg^{2+} in the crown ether moiety to the positive copper center can destabilize the complex on the level of Cu^{II}. Such behavior may also be connected with a relatively high concentration of Mg^{2+} in the double layer region. In such a case, Mg^{2+} may influence the electrochemical behavior of the copper center in the azamacrocycle. The CV curves of complex **4Cu** in the presence of Ca^{2+} were similar.

Recognition of Amino Acids

The two α-amino acids (leucine and glycine), β-alanine and lysine (Scheme 3) were chosen as substrate molecules that might interact with complexes **4Cu** and **4 Ni**. Leucine and glycine may interact only with the crown ether moiety (NH_3^+ group) or with the metal cation in the macrocyclic ring through the formation of a coordination bond with the COO^- group. β-Alanine and, especially, lysine, due to the carboxylic and NH_3^+ groups at C-ω, are expected to undergo two-centered fixation. Studies were carried out in acetonitrile/water, 4:1, due to the insolubility of amino acids in pure aprotic solvent.



Scheme 3

Unfortunately, electrospray ionization mass spectrometry revealed the decomposition of complexes **4Cu** and **4Ni** (more rapidly) in the presence of leucine and lysine. The peak at *m/z* = 220.2 (Figure 10) corresponds to the free, protonated aza crown ether. The decomposition rate in the presence of lysine (pH of the medium 9.3) was faster than in the presence of leucine (pH of the medium 6.2). Therefore, electrochemical measurements were carried over a short time (3 min after addition of amino acids). Figure 11 shows

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the differential pulse voltammogram (DPV) of the **4Cu** complex recorded after the addition of 2 equiv. of leucine or lysine. In both cases the $Cu^{II/III}$ redox peak diminishes and starts to be irreversible. In the presence of leucine, the $Cu^{II/III}$ peak potential is shifted cathodically by 7 mV, and in the presence of lysine by 40 mV. A potential shift of 10 mV was observed after the addition of 2 equiv. of glycine, and of 30 mV after addition of 2 equiv. of β-alanine. A slight cathodic potential shift with leucine and glycine may be due to the interaction of Cu^{III} with the carboxylic group. The presence of the positively charged NH_3^+ group in the immediate vicinity of the COO^- group and of a highly charged Cu^{III} ion may explain the small potential shift and destabilization of the Cu^{III} complex. The more substantial potential shift observed for β-alanine is consistent with a stronger interaction of the carboxylic group with the Cu^{III} center due to the presence of the charged ammonium group at C-β. For lysine, one can expect the two-center interactions − of the carboxylic group with the Cu^{III} center and of the NH_3^+ group at C-ω with the crown ether moiety. In this case the potential shift (40 mV) may be the result of these two effects − the cathodic shift due to the coordination of the carboxylic group, and the anodic potential shift due to complexation of the charged ammonium group. We found that after the addition of 2 equiv. of acetate anion to a solution of complex **6Cu**[24] (Scheme 4) the $Cu^{II/III}$ potential shifted 80 mV towards less positive values.

Crystallographic data indicate that the lone-pair electrons of the crown ether nitrogen atom contribute to the electron density of the cyclidene macrocycle. This may diminish the binding properties of the crown ether moiety towards cat-

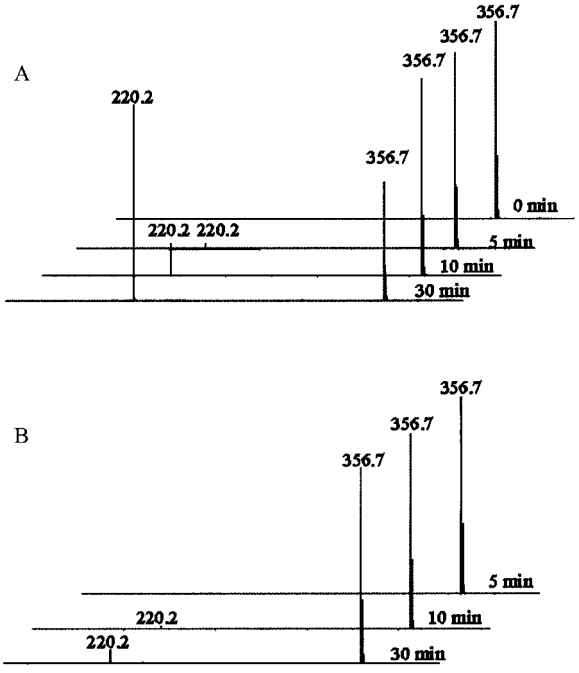


Figure 10. Electrospray ionization mass spectra as a function of time in acetonitrile/H_2O, 4:1, solutions containing 10^{-5} M of complex **4Cu** + 10^{-4} M of the corresponding amino acid: (A) lysine and (B) leucine

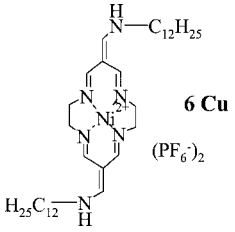

Scheme 4

ions. Conversely, the interaction of the carboxylic group with the central copper ion should reverse this effect and facilitate complexation of the ammonium group in the presence of lysine. Simultaneous binding of carboxylic and ammonium groups with leucine is not possible due to the short distance between them.

Conclusion

Comparison of the E_fs for complexes **4Cu** and **2Cu** indicates that the presence of aza crowns facilitates the $Cu^{II/III}$ redox process and makes the $Cu^{II/I}$ process more difficult.

The interaction of Na^+ and Li^+ with the **3Ni** complex was quite weak. In the presence of Mg^{2+}, the ligand aldehyde isomerizes to enolate ion. Crystallographic data indicate that the lone-pair electrons on the crown ether nitrogen atom contribute to the electron density of the cyclidene macrocycle. This may be one of the reasons why the addition of alkali and alkaline earth metal cations to the solutions of **4Cu** and **4Ni** has no influence on the E_fs of $Cu^{II/III}$ and $Ni^{II/III}$ redox systems. However, the presence of NH_4^+, Mg^{2+} and Ca^{2+} cations influences significantly the $Cu^{II/I}$ redox process in complex **4Cu**.

A more pronounced shift of the $Cu^{II/III}$ potential in **4Cu** in the presence of lysine than with leucine suggests that there is, in the first case, a simultaneous interaction between the NH_3^+ group and the crown ether moiety and between the carboxylic group and the Cu^{III} center.

Experimental Section

Chemicals: All solvents (Merck) were used without further purification. Deionized water from a Milli-Q system (Millipore, Bedford,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

MA, USA), distilled additionally from a quartz still, was used. As supporting electrolyte, electrochemical grade $[Bu_4N]BF_4$ (Fluka) was used. Cations were added as their perchlorate salts.

Instrumentation: Cyclic and differential pulse voltammograms were measured at a glassy carbon (GC-20) electrode with a Pt plate as the counter electrode and an Ag/Ag^+ reference electrode. This was connected to the electrolytic cell via an intermediate vessel filled with the solution under investigation. The Ag/Ag^+ reference electrode contained an internal solution of 0.001 M $AgNO_3$ + 0.10 M $[Bu_4N]BF_4$ in acetonitrile. The potential of this reference electrode was 200 mV vs. 1 M NaCl aqueous calomel electrode (MCE). All potentials in this paper are expressed vs. this reference electrode. Solutions were deaerated by flushing with pure argon. The measuring system was an Autolab (EcoChemie, Netherlands). Electronic spectra were recorded using a Cary 1 (Varian) spectrophotometer. NMR spectra were obtained on a Varian Mercury 400 spectrometer. Signals are reported in ppm relative to residual solvent signal. IR spectra (paraffin oil mulls) were recorded with a Perkin−Elmer Spectrum 2000 FT-IR spectrometer. ESI mass spectra were measured on a Mariner Perseptive Biosystem mass spectrometer.

Synthesis

Syntheses of 5,12-dimethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene diperchlorate and of complexes **1Cu** and **1Ni** have been described elsewhere.[24]

[6,13-Bis(morpholinomethylidene)-1,4,8,11-tetrazacyclotetradeca-4,7,11,14-tetraene]nickel(II) Bis(hexafluorophosphate) (2Ni): Morpholine (0.18 cm^3, 1 mmol) was added to a solution of complex **1Ni** (0.32 g, 0.5 mmol) in dry acetonitrile (25 mL). The mixture was then stirred for 4 h at room temperature, and the resulting solution was applied to a 2 × 20 cm acidic alumina column. The column was then washed with acetonitrile. A fast-moving orange band was collected, evaporated and dissolved in acetonitrile/H_2O, 1:1. Solid NH_4PF_6 (0.2 g) was then added to the solution and the resultant orange crystalline product that precipitated upon evaporation of acetonitrile was filtered off and dried under reduced pressure. Yield 0.29 g, 79%. $C_{20}H_{30}N_6NiO_2{\cdot}(PF_6)_2$ (735.1): calcd. C 32.7, H 4.1, N 11.4; found C 32.9, H 4.1, N 11.4. ^1H NMR (CD_3CN, 400 MHz): δ = 3.54 (s, 8 H, NCH_2CH_2N), 3.69 (b. m, 4 H, morpholine CH_2 groups), 3.70 (b. m, 4 H, morpholine CH_2 groups), 3.82 (b. m, 8 H, morpholine CH_2 groups), 7.58 (s, 2 H, exoc. =CH−N), 7.74 (b. s, 4 H, N=C−H). ^{13}C NMR (CD_3CN, 100 MHz): 51.7, 57.1, 66.1 and 67.2 (morpholine CH_2), 60.1 (b, NCH_2CH_2N), 103.6 (ring-C=), 162.9 (exoc. =CH−N, ring H−C=N signals were not observed due to dynamic line broadening). IR (Nujol): $\tilde{\nu}$ = 1600 and 1568 (ν C=N and C=C), 840 and 558 (PF_6^-) cm^{-1}. UV/Vis (CH_3CN, nm): λ_{max} (ε) = 267 (28980), 380 (52360), 459 (1400). ESI MS: *m*/*z* = 444.2 $[C_{20}H_{30}N_6NiO_2]^{2+}$.

[6,13-Bis(morpholinomethylidene)-1,4,8,11-tetraazacyclotetradeca-4,7,11,14-tetraene]copper(II) Bis(hexafluorophosphate) (2Cu): Complex was synthesized from copper(II) complex **1Cu** following the same procedure as for **2Ni**. Yield 75%. $C_{20}H_{30}CuN_6O_2{\cdot}(PF_6)_2$ (740.0): calcd. C 32.5, H 4.1, N 11.4; found C 32.6, H 4.2, N 11.5. IR (Nujol): $\tilde{\nu}$ = 1599 (ν C=N and C=C), 833 and 533 (PF_6^-) cm^{-1}. UV/Vis (CH_3CN, nm): λ_{max} (ε) = 294 (27370), 347 (65900), 507 (301). ESI MS: *m*/*z* = 224.6 $[C_{20}H_{30}CuN_6O_2]^{2+}$.

{6,13-Bis[(1,4,7,10-tetraoxa-13-azacyclooctadecano-13-yl)methylidene]-1,4,8,11-tetraazacyclotetradeca-4,7,11,14-tetraene}nickel(II) Bis(hexafluorophosphate) (4Ni): 1,4,7,10-Tetraoxa-13-azacyclooctadecane (0.22 g, 1 mmol) was added to a solution of complex **1Ni** (0.315 g, 0.5 mmol) in dry acetonitrile (25 mL). The mixture was then stirred for 4 h at room temperature, and the resulting solution was applied to a 2 × 20 cm acidic alumina column. The column was subsequently washed with acetonitrile. A fast-moving orange band was then collected, evaporated and crystallized from acetonitrile/water. The orange crystalline product that precipitated upon evaporation of acetonitrile was filtered off and dried under reduced pressure. Yield 0.39 g, 78%. $C_{32}H_{54}N_6NiO_8{\cdot}(PF_6)_2$ (999.4): calcd. C 38.5, H 5.5, N 8.4; found C 38.4, H 5.5, N 8.5. ^1H NMR (CD_3CN, 400 MHz): δ = 3.60−3.90(m, 48 H, NCH_2CH_2N and crown ether CH_2 groups), 7.66 (s, 2 H, exocyclic =CH−N), 7.99 (v.b. s, 4 H, ring N=C−H). ^{13}C NMR (CD_3CN, 100 MHz): 55.7, 61.6, 68.0, 69.8, 70.7, 70.8, 70.9, 71.1, 71.2, 71.3 (crown ether CH_2), 60.1 (broad, ring NCH_2-CH_2N), 104.7 (ring =C; ring H−C=N signals were not observed due to dynamic line broadening), 165.3 (exocyclic = CH−N). IR (Nujol): $\tilde{\nu}$ = 1594 vs, 1559 w (ν C=N and C=C), 842 vs and 559 s (PF_6^-) cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 267 (28980), 380 (52360), 459 (1400) nm. ESI MS (CH_3CN, *m*/*z*): 354.2$[C_{32}H_{54}O_8N_6Ni]^{2+}$.

{6-Formyl-13-[(1,4,7,10-tetraoxa-13-azacyclooctadecano-13-yl)methylidene]-1,4,8,11-tetraazacyclotetradeca-4,7,11,14-tetraen}-nickel(II) Hexafluorophosphate (3Ni): 1,4,7,10-Tetraoxa-13-azacyclooctadecane (0.11 g, 0.5 mmol) was added to a solution of complex **1Ni** (0.315 g, 0.5 mmol) in dry acetonitrile (25 mL). The mixture was then stirred for 2 h at room temperature. The resulting solution was diluted with water (25 mL) and applied to the SP Sephadex C25 cation exchange column (25 × 2 cm). The column was then washed with water and eluted with 0.2 M Na_2SO_4 solution. Two resultant orange bands were separated and the products precipitated with an excess NH_4PF_6. After filtration the isolated solid products were dissolved in acetonitrile, diluted with water/ethanol, 1:1, and crystallized upon slow evaporation of solvents. The first fraction contained complex **3Ni** (yield 30%), and the previously described complex **4Ni** was isolated from the second fraction. $C_{22}H_{34}N_5NiO_5{\cdot}PF_6$ (652.2): calcd. C 40.5, H 5.3, N 10.7; found C 40.4, H 5.3, N 10.5. ^1H NMR (CD_3CN, 400 MHz): δ = 3.60−3.90 (m, 28 H, NCH_2CH_2N and crown ether CH_2 groups), 7.57 (s, 1 H, exocyclic =CH−N), 7.50 (v.b. s, 1 H) and 8.37 (v.b. s, 1 H, ring N=C−H crown ether site), 7.50 (b. s, 1 H) and 7.86 (b. s, 1 H, ring N=C−H formyl site), 9.20 (s, 1 H, O=C−H). ^{13}C NMR (CD_3CN, 100 MHz): δ = 55.5, 61.5, 68.2, 70.0, 70.7, 70.8, 71.0, 71.2, 71.2, 71.2 (crown ether CH_2), 58.6, 59.0, 59.3, 60.8 (broad, ring NCH_2-CH_2N), 104.8 (ring =C−CHN), 114.2 (ring =C−CHO, ring H−C=N not observed), 164.5 (=CH−N), 187.3 C=O. IR (Nujol): $\tilde{\nu}$ = 1656 m,1594 vs, 1569 m, 1541 (ν C=O, C=N and C=C), 841 vs and 558 s (PF_6^-) cm^{-1}. UV/Vis (CH_3CN, nm): λ_{max} (ε) = 247 (15900), 281 (26880), 357 (28140), 371 (29040), 474 sh (636). ESI MS (CH_3CN): *m*/*z* = 506.2 $[C_{22}H_{34}N_5NiO_5]^+$.

{6,13-Bis[(1,4,7,10-tetraoxa-13-azacyclooctadecano-13-yl)methylidene]1,4,8,11-tetraazacyclotetradeca-4,7,11,14-tetraene}copper(II) Hexafluorophosphate (4Cu): This complex was synthesized from copper(II) complex **1Cu** following the same procedure as with **4Ni**. Yield 85%, red crystals. $C_{32}H_{54}CuN_6O_8{\cdot}(PF_6)_2$ (1004.3): calcd. C 38.3, H 5.4, N 8.4; found C 38.3, H 5.5, N 8.5. IR (Nujol): $\tilde{\nu}$ = 1646 w, 1599 s, 1587 s (PF_6^-), 841 vs and 558 s (PF_6^-) cm^{-1}. UV/Vis (CH_3CN, nm): λ_{max} (ε) = 290 (17050), 345 (43050), 492 (306). ESI MS (CH_3CN) *m*/*z* =356.7 $[C_{32}H_{54}CuN_6O_8]^{2+}$.

X-ray Crystallographic Study: The structures of **3Ni** and **4Cu** complexes were determined in single-crystal X-ray diffraction experiments. Both measurements were performed on a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo-K_α radi-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ation (λ = 0.71073 A, 45.0 kV, 40.0 mA) at room temperature (293 K). In each experiment the crystal was positioned 62 mm from the KM4CCD camera. Some 600 frames were measured for each crystal at 1.0° intervals with counting times of 33 s for the **3Ni** crystal and 27 s for **4Cu**. A numeric absorption correction was applied to the collected datasets. Data reduction and analysis were carried out with the Kuma Diffraction programs.

The structures were solved by direct methods using the SHELXS-97[25] program and subsequent refinement was also carried out with SHELXL-97.[26] Refinement was based on F^2 for all reflections except those with negative intensities. Weighted R factors, wR and all goodness-of-fit S values were based on F^2, whereas conventional R factors were based on the amplitudes, with F set to zero for negative F^2. The $F_o^2 > 2\sigma(F_o^2)$ criterion was applied only in calculating R factors and was not relevant to the choice of reflections for the refinement. The R factors based on F^2 are, for both structures, about twice as large as those based on F. For the **3Ni** structure some hydrogen atoms were located in idealized geometrical positions. Also, some special constraints were applied to the anisotropic displacement parameters of some atoms; the constraints were necessary due to disorder in the crown-ether compound and PF_6^- ion. Scattering factors were taken from Table 4.2.6.8 and 6.1.1.4 of International Crystallographic Tables Vol. C.[27]

3Ni: $C_{22}H_{34}NiN_5O_5{\cdot}PF_6$, M = 652.22, T = 293(2) K, λ = 0.71073 Å; crystal system, monoclinic; space group, $P2_1/c$; unit cell dimensions, a = 18.454(4) Å, b = 11.406(2) Å, c = 13.642(3) Å, α = 90°, β = 103.93(3)°, γ = 90°; V = 2787.0(10) Å^3; Z = 4; calculated density = 1.554 Mg m^{-3}; absorption coefficient = 0.836 mm^{-1}; F(000) = 1352; crystal size: 0.34 × 0.16 × 0.07 mm; θ range for data collection: 3.41 to 22.50°; index range: $-19 \le h \le 19$, $-12 \le k \le 12$, $-12 \le l \le 14$; reflections collected = 16239; unique reflections = 3637 [R_{int}= 0.0632]; completeness to θ = 22.50°: 99.7%; refinement method, full-matrix least-squares on F^2, data/restraints/parameters: 3637/51/460; goodness-of-fit on F^2 = 1.148; final R int [$I > 2\sigma(I)$]: $R1$ = 0.0445, $wR2$ = 0.1170; R int (all data): $R1$ = 0.0589, $wR2$ = 0.1273; extinction coefficient = 0.0020(7); weight = $1/[\sigma^2(F_o^2) + (0.0712P)^2 + 0.00P]$ where $P = [\max(F_o^2, 0) + 2F_c^2]/3$; largest diffraction peak and hole: 0.604 and −0.348 e·Å^{-3}.

A Study of the Electronic Spin-State Crossover in $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$

Daniel L. Reger,*[a] J. Derek Elgin,[a] Mark D. Smith,[a] Fernande Grandjean,[b] Leila Rebbouh,[b] and Gary J. Long*[c]

Keywords: Iron / N ligands / Spin crossover / Magnetic properties / Mössbauer spectroscopy

The synthesis, structural, magnetic, and Mössbauer spectroscopic properties of $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ are reported. The single-crystal X-ray structure results indicate that at 150 K $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ has a structure which is very similar to that observed at 220 K for the trigonally distorted octahedral, high-spin $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}(BF_4)_2$ complex. Both the magnetic and Mössbauer spectroscopic results indicate that $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ is high spin between 160 and 296 K. Upon cooling, $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ exhibits a complete electronic spin-state crossover from the high-spin to the low-spin state at approximately 110 K and remains completely low spin down to 4.2 K; upon subsequent warming from 4.2 K, the transition from the low-spin to the high-spin state occurs at 148 to 150 K. $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ exhibits a rather large thermal hysteresis of 38 K in its spin-state crossover. Thus, $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ behaves differently from both $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}(BF_4)_2$, which is known to show a unique spin-state crossover of one-half of its iron(II) ions associated with a phase transition, and $Fe[HB(3,4,5\text{-}Me_3pz)_3]_2$, which is known to remain high-spin even upon cooling to 1.7 K.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The various unsubstituted and methyl-substituted tris(pyrazolyl)borate anionic ligands[1] have become very important in coordination chemistry and are known to sometimes provide a crystal-field potential that leads to a spin-state crossover in nominally octahedral high-spin iron(II) complexes.[2−4] This crossover, which involves a change from the paramagnetic $^5T_{2g}$ high-spin state to the diamagnetic $^1A_{1g}$ low-spin state, can be induced by cooling, by optical excitation, or by the application of pressure.[5−9]

The ubiquity of the tris(pyrazolyl)borate ligands in yielding a variety of electronic spin-state behaviors in iron(II) complexes led us to undertake an extensive investigation of the iron(II) complexes formed with the related unsubstituted and methyl-substituted tris(pyrazolyl)methane neutral ligands.[10−17] This work showed different behaviors for $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}(BF_4)_2$ and $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2$: the first complex exhibits[10−13] a unique structural phase transition upon cooling, a phase transition that induces a spin-state crossover to the low-spin state of only one-half of the initially identical high-spin iron(II) ions; in contrast, the second complex exhibits[14−15] the more usual complete spin-state crossover upon cooling and at high-pressure. Interestingly, the low-spin complex, $\{Fe[HC(pz)_3]_2\}(BF_4)_2$, undergoes a gradual spin-state transition[11] to the high-spin state upon heating above 295 K, a transition which is very similar to that observed[7] in the analogous borate complex, $Fe[HB(pz)_3]_2$.

We have undertaken an investigation of $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ (**1**) for two reasons: because $Fe[HB(3,4,5\text{-}Me_3pz)_3]_2$ is known[7] to remain high-spin even upon cooling to 1.7 K and to show a spin-state crossover to the low-spin state at high pressure,[7] and because $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}(BF_4)_2$ has a unique spin-state crossover behavior. Herein we report the synthesis, the single-crystal X-ray structure and magnetic analysis, and Mössbauer spectroscopic studies of this new complex, a complex that does show a complete spin-state crossover from the high-spin to the low-spin state upon cooling.

Results and Discussion

Synthesis

The reaction of $Fe(BF_4)_2\cdot 6H_2O$ and two equivalents of $HC(3,4,5\text{-}Me_3pz)_3$ prepared according to a modified literature procedure[18] in tetrahydrofuran leads to the formation of $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ (**1**), see Scheme 1.

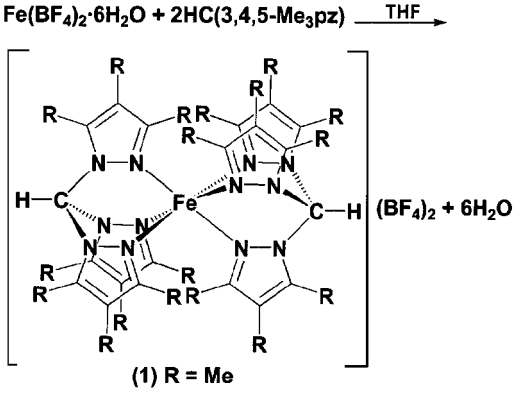
[b] Institute of Physics, B5, University of Liège, 4000 Sart-Tilman, Belgium
[c] Department of Chemistry, University of Missouri-Rolla, Rolla, MO 65409-0010, USA



Scheme 1

$\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ in powder form is white, and its single crystals are colorless indicating that the iron(II) is high-spin at room temperature.[8,11] The solution phase ^1H NMR spectrum is broad with chemical shifts ranging from 41 to −43 ppm, a range that is indicative of a paramagnetic high-spin iron(II) complex.

X-ray Structure

The single-crystal X-ray structure of the iron(II) cation in **1** is shown in Figure 1 and a view down the H−C−Fe−C−H pseudo-threefold axis of the cation is shown in Figure 2. Crystallographic information and selected bond lengths and angles are given in Table 1 and Table 2. The structure of the N_6 coordination environment is that of a distorted octahedron in which the largest structural deviation results from the restrictions imposed by the chelate rings; the intraligand N−Fe−N angles average 84.1°. The average Fe−N bond length is 2.162 Å, a value that is clearly indicative of a high-spin iron(II) complex. In contrast, an average Fe−N bond length of about 1.97 Å is typical of a low-spin iron(II) complex with an N_6 coordination environment.[3] The structure of the cation in **1** is very similar to that in $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}(BF_4)_2$. In this complex the average Fe−N bond length is 2.17 Å and the chelate rings restrict the intraligand N−Fe−N angles to an average of 84.3°.[11]

One interesting difference between the two structures involves the "tilting" of the pyrazolyl rings away from an ideal C_{3v} arrangement. In the absence of tilting the FeN(n1)−N(n2)−C(n1) torsion angles (where n denotes the ring number) would be 180° and the iron(II) ion would reside in the planes defined by the pyrazolyl rings. In general, this torsion angle decreases as the size of the metal ion in-

creases, because the bite size of these ligands is largely fixed, and increasing the tilting is an important way to accommodate larger metal ions.[10] In the fully high-spin structure[11] of {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}(BF$_4$)$_2$ this torsion angle averages 168°, with the range from 167.3 to 172.4°. In contrast, as is shown in Figure 2, in **1** two of the angles [178.92(16) and 179.74(16)°] suggest very little tilting, whereas the third ring shows substantial tilting with an angle of 164.55(15)°; the average value is 174.4°. The size of these angles is important: the angles are approximately 180° in these complexes when the iron(II) is low spin, and the Fe−N bond lengths are about 0.2 Å shorter.[10,13] Unfortunately, we have been unable to obtain the low-temperature crystal structure of **1** in order to follow how these angles change upon spin-state crossover, because the crystals shatter upon cooling to low temperature.

Magnetic Results

The temperature dependence of the molar magnetic susceptibility and the effective magnetic moment, μ_{eff}, of **1** is shown in Figure 3. This figure includes magnetic results for two full cycles of cooling and heating and reveals that the results for the second cooling and heating cycle are identical to those of the first cycle. Between 150 and 295 K the complex is paramagnetic and exhibits Curie law behavior with a Curie constant of 3.136 K/(emu/mol) and a small Weiss temperature of 1.85 K. These values correspond to an effective magnetic moment, μ_{eff}, of 5.01 μ_B between 150 and 295 K, a moment which is typical of high-spin iron(II) with a nominal octahedral $^5T_{2g}$ electronic ground state. Thus, above 150 K **1** is fully high spin.

As is shown in Figure 3, upon cooling below 150 K **1** exhibits a sharp decrease in its molar magnetic susceptibility beginning at about 110 K such that at 100 K and below the complex is essentially diamagnetic as would be expected of a low-spin iron(II) complex with a nominal octahedral $^1A_{1g}$ electronic ground state. Upon subsequent heating from 5 K, the complex remains low spin until, at 138 K, the magnetic susceptibility increases sharply such that at 148 K it is the same as that of the high-spin state. This behavior is typical of an iron(II) spin-state crossover, albeit with a rather large magnetic hysteresis of about 38 K.

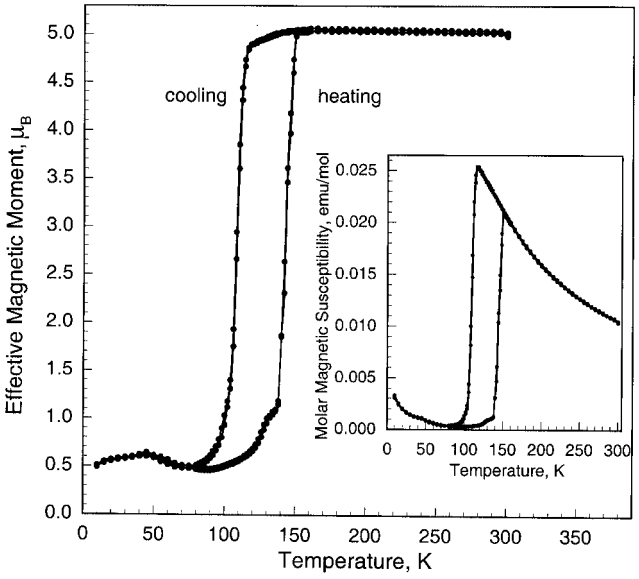

Figure 3. The temperature dependence of the effective magnetic moment of {Fe[HC(3,4,5-Me$_3$pz)$_3$]$_2$}(BF$_4$)$_2$ (**1**); inset: the temperature dependence of the molar magnetic susceptibility of **1**

Below about 60 K the molar magnetic susceptibility of **1** (see Figure 3) shows a small increase, which would be typical of an approximate 0.01 weight percent trace of either a high-spin iron(II) or a high-spin iron(III) impurity. Again, this behavior is typical of a diamagnetic complex whose low temperature magnetic properties are extremely sensitive to the presence of any paramagnetic impurities. Further, as is shown in Figure 3, below about 80 K the effective magnetic moment of **1** is essentially constant at 0.5 μ_B, a value which results partly from the trace impurity and predominately from a second-order Zeeman contribution to the molar magnetic susceptibility, i.e. the temperature-independent paramagnetic contribution to the moment of a diamagnetic complex that has a low-lying excited magnetic state; in this case the $^5T_{2g}$ state is the low-lying excited state at temperatures below the spin-state crossover.

Mössbauer Spectroscopic Results

The Mössbauer spectra of **1** obtained upon cooling from 296 K are shown in Figure 4, and the corresponding spectra obtained upon heating from 4.2 K are shown in Figure 5. In all cases the spectra have been fit with one or two symmetric quadrupole doublets, and selected hyperfine parameters are given in Table 3. The temperature dependence of the observed isomer shifts and quadrupole splittings is shown in Figure 6. The hyperfine parameters of the single quadrupole doublet observed at 160 K and above clearly indicate that **1** is high spin above this temperature.[2,7,11] Further, the hyperfine parameters of the single quadrupole

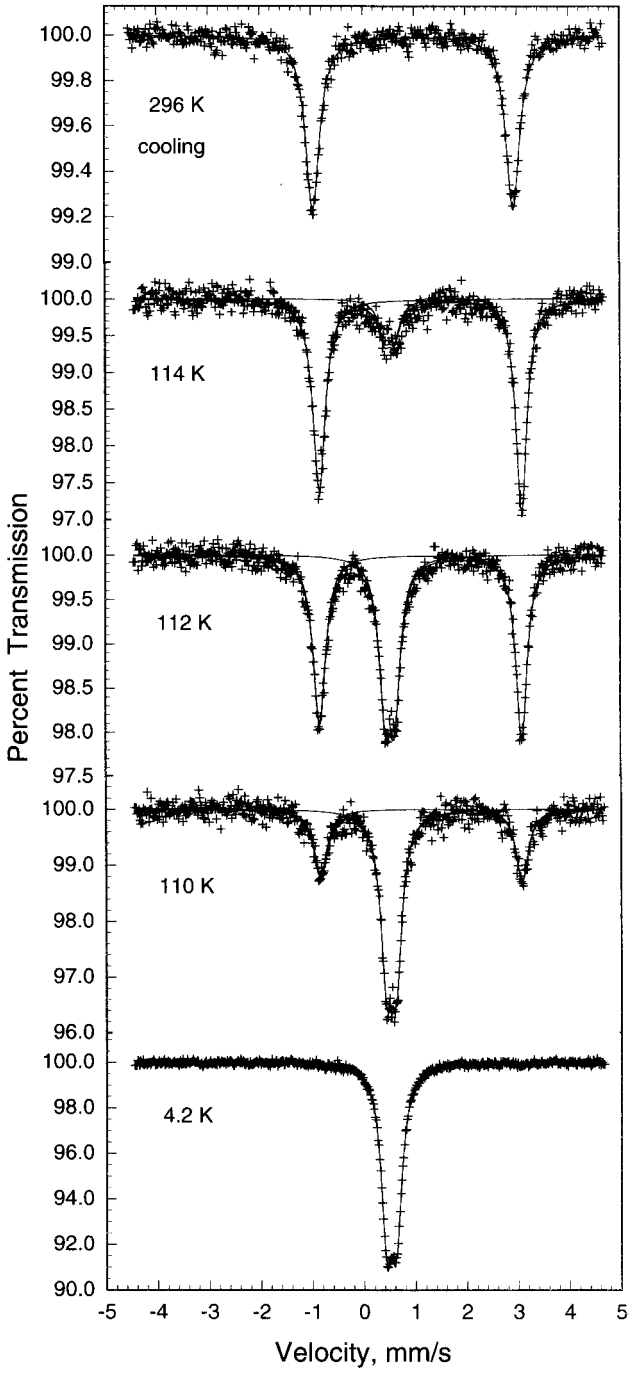

Figure 4. The Mössbauer spectra of {Fe[HC(3,4,5-$Me_3pz)_3]_2$}$(BF_4)_2$ (**1**) obtained at the indicated temperatures upon cooling from 296 K

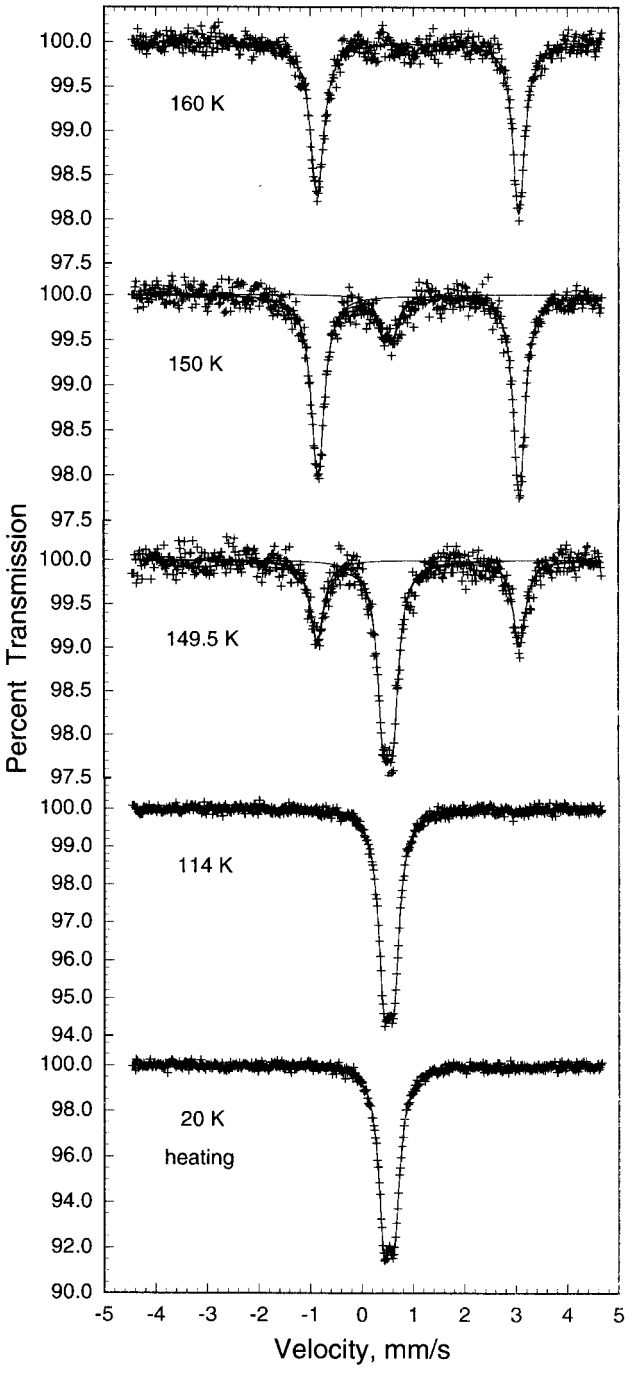

Figure 5. The Mössbauer spectra of {Fe[HC(3,4,5-$Me_3pz)_3]_2$}$(BF_4)_2$ (**1**) obtained at the indicated temperatures upon heating from 4.2 K

doublet observed between 4.2 and 100 K suggest that **1** is low spin at these temperatures. The linear temperature dependence of the high-spin isomer shift observed between 110 and 300 K is expected and, within the high-temperature limit, leads to an effective vibrating mass[19] of 64 g mol^{-1}. In the low-temperature limit, between 4 and 100 K, where the low-spin isomer shift is obtained, almost no temperature dependence of the isomer shift is observed, as expected.

The quadrupole splitting of approximately 3.9 mm s^{-1} observed for high-spin iron(II) is close to the maximum 4 mm s^{-1} expected[20] valence contribution to the quadrupole splitting, whereas the small quadrupole splitting of about 0.2 mm s^{-1} observed for the low-spin iron(II) results from the lattice contribution. The lattice contribution is usually opposite in sign to the valence contribution, and explains the reduction of the high-spin iron(II) quadrupole splitting from 4 to 3.9 mm s^{-1}. As expected, the low-spin quadrupole splitting resulting from the lattice contribution is virtually independent of temperature. Between 110 and 300 K the quadrupole splitting of the high-spin iron(II) does

[a] The isomer shifts are given relative to room temperature α-iron foil. [b] Data obtained upon cooling from 296 K. [c] Data obtained upon heating from 4.2 K. [d] The average values obtained from Ref. 11. [e] Data obtained from Ref. 7.

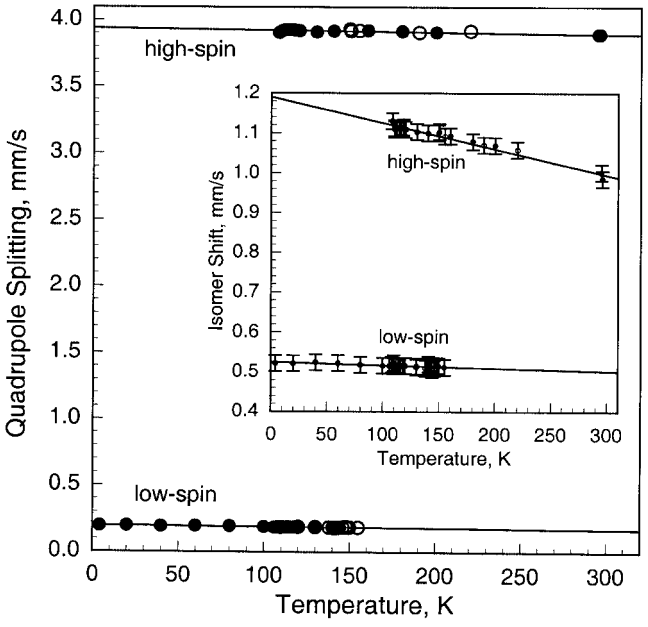

Figure 6. The temperature dependence of the Mössbauer spectroscopic quadrupole splitting of {Fe[HC(3,4,5-Me$_3$pz)$_3$]$_2$}(BF$_4$)$_2$ (**1**); inset: the temperature dependence of the isomer shift of **1**

not vary with temperature. Hence, the excited orbital states must lie at relatively high energy and are not thermally populated.

The population of the iron(II) high-spin state in **1** is shown in Figure 7 as a function of cooling from 295 to 4.2 K and subsequent heating from 4.2 to 240 K. Between 160 and 100 K the Mössbauer spectra of **1** exhibit two quadrupole doublets, which indicate the coexistence of the two electronic spin states at these temperatures. This spin-state coexistence is typical of a complex undergoing a spin-state crossover with a large thermal hysteresis; in this case a hysteresis of about 39 K is obtained, which agrees well with that (38 K) obtained from the magnetic studies (see above). It should be noted that there are both strong similarities and differences between the Mössbauer spectroscopic results for **1** and several related compounds. Although the hyperfine parameters of **1** are virtually identical to those of {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}(BF$_4$)$_2$ **2** (see Table 3), as would be expected on the basis of their very similar crystal structures at 150 and 220 K, respectively (see above), **1** undergoes a complete spin-state crossover with a distinct thermal hysteresis, whereas **2** shows no thermal hysteresis and is only 50 percent converted into the low-spin state, a conversion that is induced by the low-temperature phase transition.

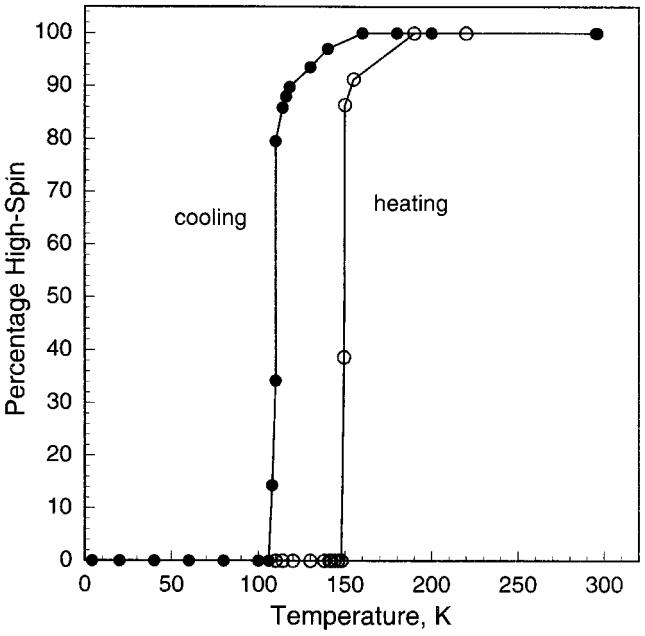

Figure 7. The percentage of high-spin iron(II) observed in the Mössbauer spectra of $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ (**1**) as a function of temperature

Further, the structure of **1** is different from its analogous tris(pyrazolyl)borate complex, $Fe[HB(3,4,5\text{-}Me_3pz)_3]_2$ (**3**); the former shows a complete spin-state crossover upon cooling, whereas the latter does not exhibit any spin-state crossover and remains high-spin[7] even upon cooling to 1.7 K (see Table 3). The single-crystal X-ray structure of **3** has recently been determined,[21] and its structure has been found to be very similar to that of **1**, except that its average Fe−N bond length is 2.19 Å, i.e. it is 0.02 Å longer than that in **1**. This increase in the Fe−N bond length, which reduces the σ-electron density at the iron(II) in **3** relative to that in **1**, accounts for the significantly lower 295 K isomer shift observed in **1** than in $Fe[HB(3,4,5\text{-}Me_3pz)_3]_2$ (**3**) (see Table 3). Further, the distortion of the iron(II) coordination environment in **1** is found to be substantially larger[22,23] than that in **3**. The larger distortion accounts for the substantially larger quadrupole splitting observed in **1** relative to **3**. Finally, it should be noted that the spin-state crossover observed in **1** is similar to that observed in $Fe[HB(3,5\text{-}Me_2pz)_3]_2$ (**4**),[2,6,7] which shows a gradual spin-state crossover between 150 and 220 K, but again, the hyperfine parameters of **1** and **4** are somewhat different.

Because the temperature dependence of the Mössbauer spectra has been measured under identical conditions, i.e. a constant geometry and with a constant energy window, the changes in the spectroscopic absorption area as a function of temperature are directly related to the changes in the iron-57 recoil-free fraction. The logarithm of the total spectral absorption area observed in the Mössbauer spectra of **1** as a function of temperature is shown in Figure 8. The general decrease in ln(area) with increasing temperature is expected, but the jumps and hysteresis at approximately 110 K are unusual and are related to the spin-state crossover. The solid lines shown in Figure 8 correspond to a fit with the Debye model[19] between 4.2 and 100 K and between 150 and 296 K. These fits assume an effective vibrating mass of 57 g mol^{-1} and yield effective Mössbauer temperatures of 156 K for the low-spin state and 139 K for the high-spin state. The accuracy of these temperatures is estimated to be ± 10 K.

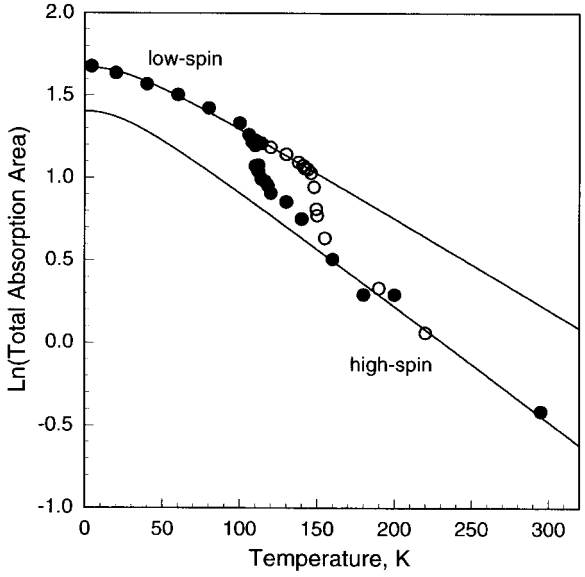

Figure 8. The logarithm of the total spectral absorption area observed in the Mössbauer spectra of $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ (**1**) as a function of temperature; the straight lines correspond to the slope associated with the low-spin data obtained between 4.2 and 100 K and the high-spin data obtained between 160 and 296 K

The high-spin iron(II) ion in **1** has an average iron−nitrogen bond length of 2.162 Å, which is substantially larger than the typical value of 1.97 Å observed[9] for low-spin iron(II) complexes. The shorter average bond length leads to stronger bonding, more effective binding of the iron(II) ion into the lattice site, a higher recoil-free fraction, and a higher effective Mössbauer temperature for the low-spin iron(II) than for the high-spin iron(II) state.

Conclusions

The solid-state structure and color of $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ clearly show that the complex contains high-spin iron(II) at ambient temperature. Both magnetic and Mössbauer studies show that the complex rapidly and completely changes to the low-spin state below 100 K. This behavior shows significant hysteresis upon heating where the change back to high spin does not begin until 138 K. This magnetic behavior is very different from the closely related complex $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}(BF_4)_2$ that exhibits a spin-state crossover to the low-spin state of only one-half of the initially identical high-spin iron(II) ions and shows no hysteresis effects.[10−13] This very different behavior of $\{Fe[HC(3,4,5\text{-}Me_3pz)_3]_2\}(BF_4)_2$ is further evidence to sup-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

port our earlier contention that the unusual spin-state crossover behavior of {Fe[HC(3,5-$Me_2pz)_3]_2$}$(BF_4)_2$ is completely controlled by the phase transition, one which prevents one-half of the initially identical high-spin iron(II) ions from changing to the low-spin form.

Experimental Section

Synthesis and Characterization: All operations were carried out under a nitrogen atmosphere using either standard Schlenk techniques or a dry box. All solvents were dried, degassed, and distilled prior to use. $Fe(BF_4)_2 \cdot 6H_2O$ was purchased from Aldrich. The synthesis of 3,4,5-trimethylpyrazole was performed according to a published method.[24]

Synthesis of tris(3,4,5-trimethylpyrazol-1-yl)methane: A 100 mL round-bottom flask was charged with 3,4,5-trimethylpyrazole (2.2 g, 20 mmol), tetra-*N*-butylammonium bromide (0.32 g, 1.0 mmol) and distilled H_2O (40 mL). Once the materials were dissolved, sodium carbonate (12.7 g, 120 mmol) was slowly added (*Caution: mildly exothermic reaction on addition*). Once the aqueous solution had cooled to near room temperature, chloroform (20 mL) was added to the flask. The flask was equipped with a reflux condenser and heated at a gentle reflux for 3 days, to give in a golden brown emulsion. The mixture was allowed to cool to room temperature, filtered through a Büchner funnel to remove the excess base, and the organic layer separated from the aqueous layer. The organic layer was washed with distilled water (2 × 10 mL) and dried over sodium sulfate. The drying agent was removed by filtration, and the solvent removed by rotary evaporation. The resulting oily, brown solid was flushed through a plug of silica with chloroform (2 × 100 mL) to afford a pale yellow solid (1.4 g, 62%). M.p. 156−157 °C (literature[18]: 156−157 °C). ^{1}H NMR ($CDCl_3$): δ = 186, 1.92 (3,5-CH_3, s, s; 9 H, 9 H,), 2.12 (4-CH_3, s, 9 H), 8.03 (C*H*, s, 1 H) ppm.

Synthesis of {Fe[HC(3,4,5-$Me_3pz)_3]_2$}$(BF_4)_2$: A 50 mL round-bottom Schlenk flask was charged with $Fe(BF_4)_2 \cdot 6H_2O$ (0.200 g, 0.60 mmol) and distilled THF (3 mL) was added with the use of a syringe. A second 50 mL round-bottom Schlenk flask was charged with tris(3,4,5-trimethylpyrazol-1-yl)methane (0.500 g, 1.5 mmol) and distilled THF (6 mL) was added by a syringe. Once the starting materials were dissolved, the ligand/THF solution was added to the metal/THF solution by cannula transfer. The resulting mixture was left to stir overnight, yielding a white powder precipitate. The solvent was removed by cannula filtration, and the solid was washed with distilled hexane and dried under vacuum (0.47 g, 85% yield). M.p.: decomposes above 318 °C. ^{1}H NMR ([D_6]acetone): δ = 41.2, 20.9, 7.4 (18, 18, 18, v. br., br., br., Me_3), −42.8 (2, v. br., *H*−C). TOF MS ES+: *m*/*z* calcd. for {Fe[HC(3,4,5-$Me_3pz)_3]_2$}$(BF_4)^+$: 823.4129; found: 823.4132. Elemental Analysis: calcd. C 49.79, H 6.19, N 18.34; found C 49.21, H 6.21, N 18.43. Crystals for X-ray crystallographic and magnetic analysis, and Mössbauer spectroscopy were grown by layering a saturated acetone solution with hexane.

X-ray Structure Determination of {Fe[HC(3,4,5-$Me_3pz)_3]_2$}$(BF_4)_2 \cdot 0.35H_2O$: A colorless block crystal was mounted onto the end of a thin glass fiber using inert oil. X-ray intensity data covering the full sphere of reciprocal space were obtained at 150(1) K on a Bruker SMART APEX CCD-based diffractometer with Mo-K_α radiation, λ = 0.71073 Å.[25] The raw data frames were integrated with SAINT+,[25] which also corrected for Lorentz polarization effects. The final unit cell parameters are based on the least-squares refinement of 6654 reflections from the data set with $I > 5(\sigma)I$. Analysis of the data showed negligible crystal decay during data collection. An empirical absorption correction, based on the multiple measurement of equivalent reflections, was applied with the program SADABS.[25]

{Fe[HC(3,4,5-$Me_3pz)_3]_2$}$(BF_4)_2 \cdot 0.35H_2O$ crystallizes in the triclinic system and the structure was solved in the $P-1$ space group through a combination of direct methods and difference Fourier syntheses and refined by full-matrix least-squares against F^2 by using the SHELXTL software package.[26] The {Fe[HC(3,4,5-$Me_3pz)_3]_2$}$^{2+}$ cation resides on a center of symmetry and the BF_4^- counterion is rotationally disordered; a model incorporating four distinct orientations of the BF_4^- anion was used in the refinement. A total of 68 restraints were employed to maintain a chemically reasonable geometry for the disordered components. Initially, the site occupation factors for the four components were allowed to refine freely, but were subsequently fixed at the refined values and then adjusted slightly to sum to unity (0.38, 0.39, 0.14, 0.09). Atoms of the two minor components were refined with only isotropic displacement parameters. A significant, isolated electron-density peak present near the end of the refinement was assumed to be a partially occupied water molecule, which refined to a 35% occupancy; its hydrogen atoms were not located or calculated. All non-hydrogen atoms, except for the BF_4^- atoms mentioned above, were refined with anisotropic displacement parameters. Hydrogen atoms were placed in geometrically idealized positions and refined as standard riding atoms.

It was not possible to obtain the single-crystal X-ray structure of {Fe[HC(3,4,5-$Me_3pz)_3]_2$}$(BF_4)_2$ (**1**) in the low-spin state, because the crystals always shattered upon cooling through the spin-state crossover. Further, changes in the magnetic behavior of the compound upon grinding prevented the measurement of the powder diffraction pattern of the complex at low temperature in the low-spin state.

Magnetic Measurements: Magnetic susceptibilities were measured on crystalline samples at 0.5 T by using a Quantum Design MPMS XL SQUID magnetometer. Clear gelatine capsules were used as sample containers for measurements between 5 and 350 K. The very small diamagnetic contribution of the gelatine capsule had a negligible contribution to the overall magnetization which was dominated by the sample. The molar magnetic susceptibilities were corrected for the diamagnetic susceptibility of {Fe[HC(3,4,5-$Me_3pz)_3]_2$}$(BF_4)_2$ by using the value of −0.0004632 emu/mol that was obtained from Pascal's constants.

Mössbauer Spectroscopic Measurements: The Mössbauer spectroscopic absorber contained 50 mg/cm^2 of powder mixed with boron nitride, and the spectra were measured between 4.2 and 295 K on a constant-acceleration spectrometer which utilized a room-temperature rhodium-matrix cobalt-57 source and was calibrated at room temperature with α-iron foil. The estimated absolute errors are ± 0.005 mm/s for the isomer shifts, ± 0.01 mm/s for the quadrupole splittings and line widths, and ± 0.2 percent for the relative spectral absorption areas.

Ruthenium Nitrosyl Complexes of Bis(3,5-dimethylpyrazol-1-yl)methane Oxyanions

Mayreli Ortiz,[a] Alicia Díaz,[a] Roberto Cao,*[a] Reynier Suardíaz,[b] Antonio Otero,[c] Antonio Antiñolo,[c] and Juan Fernández-Baeza[c]

Keywords: Ruthenium nitrosyl complexes / Nitric oxide / NNO Scorpionates / Bis(pyrazolic) ligands

New ruthenium(II) mononitrosyl complexes of general composition $[Ru(NO)LCl_2]$, $[Ru(NO)L(en)]Cl_2$ and $[Ru(NO)L_2]Cl$ have been obtained upon treating $Ru(NO)Cl_3$ with potential κ^3-*N*,*N*,O ligands bis(3,5-dimethylpyrazol-1-yl)methanesulfonate (bdmpzsa) and bis(3,5-dimethylpyrazol-1-yl)acetate (bdmpza) in 1:1 and 1:2 molar ratios. These mononitrosyl complexes have a sharp, intense νNO band in the IR spectra within 1874–1851 cm^{-1}, indicating a linear Ru–NO^+ coordination. For both $[Ru(NO)L_2]Cl$ compounds, a dynamic switch on-off process occurs between the oxyanionic moieties on the apical position *trans* to NO^+ and the pyrazolic ligands on the equatorial plane. A dynamic ^1H NMR experiment of this process gave $\Delta G^{\#}$= 46–48 kJ·mol^{-1} at 218–228 K for the acetate derivative.

Introduction

In the past decade nitric oxide, NO, has been widely studied since it was found to be an essential component in many physiological processes. The physiological functions of NO are various: a killer of invading microorganisms, primary messenger in regulating blood pressure and neurotransmitter. Dysfunction in NO metabolism has been associated with several disease states, such as epilepsy, arthritis, hypertension and septic shock.[1]

Ruthenium(III) complexes coordinate nitric oxide, NO, to form stable Ru^{II} mononitrosyl complexes. This reaction can occur rapidly in aqueous solution.[1b] It is assumed that, generally, a $Ru^{II}-NO^+$ linear bond is formed. The νNO bands (IR) lie within the range 1789−1960 cm^{-1}.[2,3]

However, when a linear Ru^{II} mononitrosyl complex is submitted to a chemical (or electrochemical) one-electron reduction,[4] the stable low-spin d^6 configuration of Ru^{II} apparently remains unaffected while the electron transferred in the reduction process is accepted by NO, by which it is transformed into a radical, NO·. This radical is ESR active with g_x = 1.995; g_y = 2.035, and g_z = 1.883. Under such conditions the NO· radical can easily be released.[4a] The NO· signal can be observed in the ESR spectrum of these Ru^{II} mononitrosyl complexes at 77 K. Some Ru^{II} nitrosyl complexes photochemically dissociate NO·.[5]

Different Ru^{III} complexes with polyaminocarboxylic acids have been studied as NO scavengers.[6] Complexes of Ru^{II} coordinated to NO^+, NO· and NO^- have been obtained by the interaction of NO with $[Ru(hedta)Cl]^-$ [hedta: *N*-(hydroxyethyl)ethylenediaminetriacetate] and further electrochemical reduction.[6b]

The first report on ruthenium nitrosyl complexes with pyrazol-1-yl derivatives included the study of $[TpRuNOCl_2]$, $[pzTpRuNOCl_2]$ and $[Tp^*RuNOCl_2]$ (Tp: trispyrazol-1yl borate; Tp*: 3,5-substituted Tp).[7] Ruthenium nitrosyl complexes with 3,5-dimethylpyrazole have also been reported.[8] These complexes were structurally characterized by single-crystal X-ray diffraction and in all cases the Ru−N−O angle lies between 176.2 and 179.6°, while the νNO band (IR) appears within 1894−1790 cm^{-1}.

Recently, we reported different ruthenium(II) complexes with bis(3,5-dimethylpyrazol-1-yl)methane derivatives: Bis(3,5-dimethylpyrazol-1-yl)methanesulfonate (bdmpzsa, **1**), and bis(3,5-dimethylpyrazol-1-yl)acetate (bdmpza, **2**) (Figure 1).[9] Both ligands lie on the equatorial plane and coordinate as κ^3-*N*,*N*,O scorpionates, but with a weak interaction through the oxyanionic moiety.

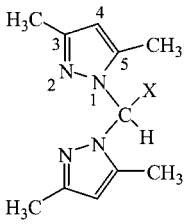

Figure 1. Schematic representation of the studied ligands bis(3,5-dimethylpyrazol-1-yl)methanesulfonate (bdmpzsa, **1**) (X = SO_3^-), and bis(3,5-dimethylpyrazol-1-yl)acetate (bdmpza, **2**) (X = COO^-)

In this paper, we report on Ru^{II} mononitrosyl complexes with ligands **1** and **2**, prepared by the interaction of the ligands with $Ru(NO)Cl_3$.

Results and Discussion

In the synthesized complexes reported previously,[9] the bis(pyrazolic) ligands lie on the equatorial plane − only one set of signals appear in the NMR spectra. Conversely, NO is assumed to be coordinated on an apical position. In compounds **3** and **4**, one bis(pyrazolic) ligand and the two chloride anions lie on the equatorial plane (Figure 2 for **4**). In **5** and **6** both bis(pyrazolic) ligands lie on the equatorial plane, while in **7** and **8** ethylenediamine (en) and the bis(pyrazolic) ligand lie in this plane.

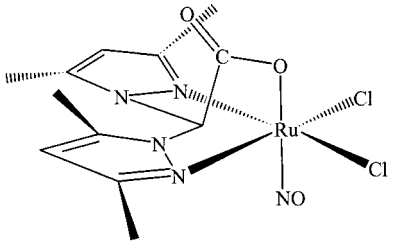

Figure 2. Representation of compound **4**

Very small shifts appear in the NMR signals of the pyrazolic rings upon coordination, as reported previously.[9]

To confirm the earlier ^1H and ^{13}C NMR assignments of the pyrazolic rings the ^1H,^{15}N gs-HMBC (NMR) two-dimensional spectrum of $[Ru(bdmpza)_2(NO)]Cl$ (**6**) was recorded (Figure 3).

This technique permits the correlation of coupling of ^1H and ^{15}N signals of atoms 2−3 bonds apart. Two signals of ^{15}N coupled to ^1H occur: one at δ = 127.5 ppm (N^1) and another at δ = 212.5 ppm (N^2). The former couples through three bonds to the protons of the $CH_3{}^5$, through two bonds to the methylenic (CH) proton, and through three bonds to the protons of the CH group of the pyrazolic ring. The ^{15}N signal at δ = 212.5 ppm (N^2) ppm couples through three bonds to the protons of $CH_3{}^3$, through three bonds to the proton of the methylenic (CH) and through

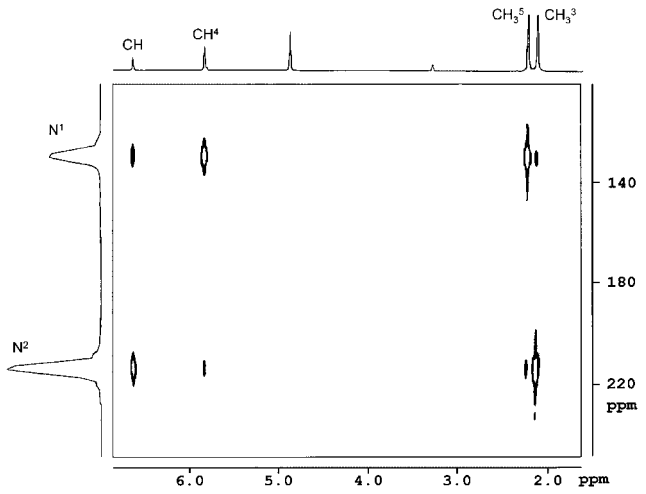

Figure 3. ^1H, ^{15}N gs-HMBC spectrum of $[Ru(bdmpza)_2NO]Cl$ in CD_3OD

three bonds to the proton of the CH group of the pyrazolic ring. Small shifts (Δδ = 2 ppm) were now observed for ^{15}N of N^1 and N^2 of the pyrazolic ring upon coordination. These results confirm the previous assignments.

Coordinated NO could not be detected by this technique since the neighboring protons are too distal. Nevertheless, the small chemical shifts in the spectra of the obtained Ru^{II} nitrosyl complexes indicate that coordinated NO, with a significant *trans* effect, is on an apical position. Only one set of ^{15}N signals are observed, confirming that the bis(pyrazolic) ligands lie on the equatorial plane.

IR stretching bands of the oxyanionic moieties and the methylenic CH signals (^1H and ^{13}C NMR) of the pyrazolic rings shift very slightly upon coordination. This indicates that the oxyanionic moiety is weakly coordinated. In addition, the IR spectra of both $[Ru(NO)L_2]Cl$ complexes (**5** and **6**) present only one asymmetric stretching band for the oxyanionic groups: 1647 [$\nu_{as}(COO^-)$] and 1249 cm^{-1} [$\nu_{as}(SO_3^-)$] respectively, indicating that they are equivalent. Conversely, in the ^1H NMR spectra, δ_H of methylenic CH at room temperature broadens when two bis(pyrazolic) ligands (**1** or **2**) are coordinated. This can be interpreted as a dynamic switch on-off exchange between both oxyanionic groups to coordinate to Ru^{II} at the only vacant site left, since the four positions on the equatorial plane are occupied by the four N atoms of both bis(pyrazolic) rings, plus NO on an apical position.

A dynamic-^1H NMR technique was used to confirm a switch on-off exchange between both groups in $[Ru(NO)L_2]Cl$ (**5**, **6**). With decreasing temperature the proton signal of the methylenic groups of **6** initially broadened further and then, finally, decoalesced into two broad singlets at 193 K (Figure 4).

This latter effect should be because the dynamic exchange is "frozen", such that one oxyanionic group remains near Ru^{II} and the other more distant. From the difference in chemical shifts and the approximately estimated coalescence temperature (218−228 K), the free energy of acti-

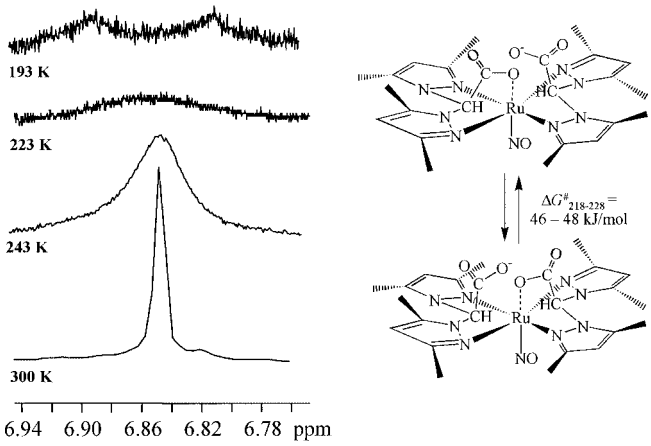

Figure 4. Switch on-off process of carboxylate groups in compound **6** studied by dynamic ^{1}H NMR spectroscopy

vation ($\Delta G^{\#}$) of the process could be evaluated,[10] corresponding to 46−48 kJ·mol^{-1} for [Ru(NO)(bdmpza)$_2$]Cl (**6**). This low value supports the proposed room-temperature dynamic process that causes the observed equivalency between both methylenic groups. For compound **5**, decoalescence takes place below 193 K, indicating an even weaker coordination of the sulfonate group with respect to the carboxylate.

The switch on-off process was modeled by molecular dynamics for complex **6**. Movement of the bonding oxygen atom of one of the carboxylate groups, as time function, indicates a fast motion to and from the proximity of Ru^{II} (Figure 5, a). The steric effect of the CH_3[3] groups in the pyrazolic rings is important in this dynamic process since it restricts the complete approach of the carboxylate groups to Ru^{II} (Figure 5, b).

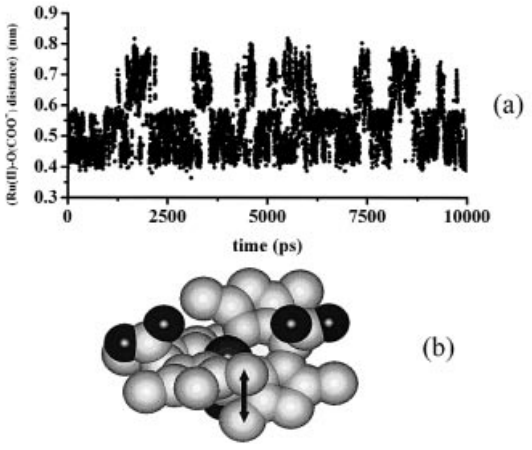

Figure 5. (a) Ru^{II}−OOC− distance as time function obtained by molecular dynamics; (b) schematic representation of complex **6** where both switching oxygen atoms of the carboxylate groups are in black, as is Ru^{II} (a larger sphere); steric repulsion between both CH_3[3] groups is indicated by a double arrow

This prediction agrees with both the low $\Delta G^{\#}$ obtained from ^{1}H NMR studies and the very similar chemical shifts (^{13}C NMR) of the carboxylate group in the free ligand (**2**) and in complex **6**.

We earlier reported that for the complex [Ru(NEt$_3$)(bdmpza)$_2$], formed by treating [Ru(bdmpza)$_2$] with NEt$_3$, the COO$^-$ and CH signals in the ^{13}C NMR spectrum are two well-defined singlets, while the ν_{as}(COO$^-$) band (IR) appears as two peaks at 1660 and 1647 cm^{-1}. A similar result occurs in the ^{13}C NMR spectrum of [Ru(NEt$_3$)(bdmpzsa)$_2$].[9] Comparing these results with those obtained for **5** and **6**, where the switch on-off process is observed, shows that NO$^+$ evidently weakens the *trans* position much more than NEt$_3$. This can be explained by the strong *trans* effect of NO$^+$, which provokes the observed switch on-off process of the oxyanionic groups.

Coordination of NEt$_3$ was also used here to "freeze" the dynamic exchange of both oxyanionic groups in the obtained nitrosyl complexes. For this, the reaction products of [Ru(NO)L$_2$]Cl (**5**, **6**) and NEt$_3$ (1:1 molar ratio) in methanol were isolated and purified. Once NEt$_3$ was coordinated to Ru^{II} *trans* to NO, leaving both oxyanionic groups free, the methylenic protonic signals became sharp and the ^{13}C NMR spectra gave only one set of signals (Supporting Information, Figure S1; for Supporting Informations see also the footnote on the first page of this article).

As expected, the obtained mononitrosyl complexes are ESR silent and completely diamagnetic according to SQUID determinations, which excludes any possible Ru^{III} impurity.

All IR spectra of the mononitrosyl complexes gave a sharp, intense band at 1874−1851 cm^{-1}, and only very slight differences (0−4 cm^{-1}) were observed between the spectra of samples prepared as KBr tablets and those recorded in CH_2Cl_2 solutions. The band, assigned as νNO, indicates a linear coordination to Ru^{II}.

Heating KBr tablets of different samples from 200 up to 400 K resulted in no significant loss in intensity and only slight, reversible, shifts to higher frequencies (3−17 cm^{-1}) in the νNO band. These results indicate that NO is characterized by a stable coordination to Ru^{II} in the studied complexes.

Conclusion

Stable Ru^{II} complexes with a typical Ru^{II}−NO$^+$ bond have been obtained by reacting ligands **1** and **2** with Ru(NO)Cl$_3$. Compounds **5** and **6**, with two pyrazolic ligands, are characterized by a switch on-off process between both oxyanionic groups. This process has been studied by dynamic ^{1}H NMR for complex **6**, for which $\Delta G^{\#}_{218-228K}$ = 46−48 kJ·mol^{-1} was obtained. This process, modeled by molecular dynamics studies, should be enhanced by the *trans* effect of NO over the oxyanionic groups in **5** and **6**.

Experimental Section

Reagents: All chemicals used, including Ru(NO)Cl$_3$, were of high quality and purchased from Aldrich. Solvents were dried and distilled before use.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Spectroscopy: Electronic spectra were recorded with an Ultrospec III spectrophotometer (Pharmacia-LKB) interfaced with a microcomputer for data acquisition. IR spectra were recorded with a Perkin-Elmer 883 FT-IR spectrometer, with samples prepared as KBr tablets and as CH_2Cl_2 solutions in CaF_2 cells. ESR spectra at room temperature were carried out at X-band with a Bruker ESP 300 spectrometer, operating at 100 kHz field modulation. The frequency was measured with a Hewlett−Packard 5352B frequency counter. NMR spectra were obtained with a Bruker AC 250 (62.89 MHz for ^{13}C) equipped with an ASPECT 3000 computer. All samples were dissolved in [D_4]methanol (30 mg/0.4 mL) and recorded at 300 K. Chemical shifts (δ) are expressed in ppm and referred to tetramethylsilane (TMS). The nature of each carbon atom was determined using the DEPT technique with proton pulses at θ = 135°. Quantitative measurements were carried out by recording the ^{13}C NMR spectra using the inverse-gated decoupled technique with a relaxation D_1 = 10 s, to fulfill the condition $D_1 > 5T_1$ (maximum) for hydrogenated carbon atoms. The ^1H NMR dynamic experiment was carried out with a Varian FT-300, using an Oxford Instruments VTC 4 unit, measured by a thermocouple and calibrated with [D_4]methanol, within 300 and 193 K, using [D_6]acetone as solvent. ^1H, ^{15}N gs-HMBC spectra were obtained with a Bruker AV 400 (40.53 MHz for ^{15}N) equipped with a GRASP accessory, using [D_4]methanol as solvent. The chemical shifts (δ, ppm)/CH_3NO_2 of the ^{15}N signals have been converted into the liquid ammonia reference scale. Resonances observed upfield of nitromethane were assigned as negative chemical shifts and those downfield as positive chemical shift for the conversion.

Molecular Dynamics: Molecular dynamics calculations were performed using the Gromos 96 program with additional parameters of ab initio calculus and crystallographic data of similar compounds.[11] One solute molecule and 168 solvent molecules of methanol made up the studied system, confined in a truncate octahedral box of 2.8 nm (300 K, 1 atm). Periodic frontier conditions were used; simulation time of 10 ns with a path of 0.002 ps.

Magnetic Susceptibility Determinations: Magnetic susceptibility measurements (1.8−300 K) were carried out with a Quantum Design SQUID magnetometer under an applied magnetic field of 1 T at high temperature and 100 G at low temperature to avoid any problem of magnetic saturation. The device was calibrated with $(NH_4)_2Mn(SO_4)_2{\cdot}6H_2O$. Corrections for the diamagnetism were estimated from Pascal constants. Experimental susceptibilities were also corrected for the temperature-independent paramagnetism [60 × 106 $cm^3{\cdot}mol^{-1}$ per copper(II) ion] and the magnetization of the sample holder.

The ligand [{Li(bdmpzsa)(H_2O)}$_4$] (**1**) (and, alternatively, the potassium salt) was prepared as reported previously.[9]

[{Li(bdmpza)(H_2O)}$_4$] (2): This ligand was prepared as reported previously.[12]

[Ru(NO)(bdmpzsa)($Cl)_2$] (3): $Ru(NO)Cl_3$ (50 mg, 0.21 mmol) was dissolved in methanol (20 mL) containing ligand **1** (61 mg, 0.21 mmol) and stirred for 12 h in an inert atmosphere. The soformed brownish-red suspension was roto-evaporated and the product dissolved in dichloromethane to separate LiCl by filtration. The solution was then evaporated to dryness under vacuum, and a brownish red hygroscopic solid was obtained. Yield: 75 mg (73.5%). $C_{11}H_{15}Cl_2N_5O_4RuS$ (485.3): calcd. C 27.21, H 3.09, N 14.43; found C 27.18, H 3.12, N 14.41. IR (KBr): $\tilde{\nu}$ = 1874 ν(NO), 1562 ν(C=N), 1175 $\nu_{as}(SO_3^-)$, 1114 $\nu_s(SO_3^-)$, 334 ν(Ru−Cl) cm^{-1}. IR (CH_2Cl_2): $\tilde{\nu}$ = 1874 ν(NO) cm^{-1}. UV/Vis: λ (log ε) = 230 (sh) (π → π*), 457 (2.95, d-d) nm. ^1H NMR (250 MHz, CD_3OD, 298 K): δ = 2.11 (s, 6 H, Me^3), 2.42 (s, 6 H, Me^5), 5.85 (s, 2 H, H^4), 6.82 (s, 1 H, CH) ppm. $^{13}C\{^1H\}$ NMR/DEPT-135° (62.89 MHz, CD_3OD, 298 K): δ = 10.9 (+, Me^5), 13.3 (+, Me^3), 75.2 (+, CH), 105.8 (+, C^4), 141.3 (0, C^5), 147.5 (0, C^3) ppm.

[Ru(NO)(bdmpza)($Cl)_2$] (4): A procedure similar to that described for **3** was used, but with $Ru(NO)Cl_3$ (50.0 mg, 0.21 mmol) and ligand **2** (53.3 mg, 0.21 mmol) to afford a brownish-red hygroscopic solid. Yield: 0.080 g (84.7%). $C_{12}H_{15}Cl_2N_5O_3Ru$ (449.3): calcd. C 32.07, H 3.34, N 15.59; found C 32.04, H 3.37, N 15.61. IR/KBr: $\tilde{\nu}$ = 1872 ν(NO), 1645 $\nu_{as}(CO_2^-)$, 1562 ν(C=N), 1387 $\nu_s(CO_2^-)$, 336 ν(Ru−Cl) cm^{-1}. IR (CH_2Cl_2): $\tilde{\nu}$ = 1868 ν(NO) cm^{-1}. UV/Vis: λ (log ε) = 234 (sh, π → π*), 400 (2.96, d-d) nm. ^1H NMR (250 MHz, CD_3OD, 298 K): δ = 2.15 (s, 6 H, Me^3), 2.24 (s, 6 H, Me^5), 5.86 (s, 2 H, H^4), 6.62 (s, 1 H, CH) ppm. $^{13}C\{^1H\}$ NMR / DEPT-135° (62.89 MHz, CD_3OD, 298 K): δ = 11.2 (+, Me^5) 13.3 (+, $M3^5$), 73.9 (+, CH), 107.3 (+, C^4), 142.4 (0, C^5), 149.5 (0, C^3), 169.7 (0, C=O) ppm.

[Ru(NO)(bdmpzsa)$_2$]Cl (5): A procedure similar to that for **3** was used, but with $Ru(NO)Cl_3$ (50.0 mg, 0.21 mmol) and ligand **1** (122.0 mg, 0.42 mmol) to furnish a brownish red crystalline solid. Yield: 140 mg (91.0%). $C_{22}H_{30}ClN_9O_7RuS_2$ (733.2): calcd. C 36.03, H 4.09, N 17.20; found C 35.99, H 4.12, N 17.18. IR (KBr): $\tilde{\nu}$ = 1865 ν(NO), 1564 ν(C=N), 1249 $\nu_{as}(SO_3^-)$, 1049 $\nu_s(SO_3^-)$ cm^{-1}. IR (CH_2Cl_2): $\tilde{\nu}$ = 1868 ν(NO) cm^{-1}. UV/Vis: λ (log ε) = 251 (sh, π → π*), 374 (sh, MLCT), 455 (2.59, d-d) nm. ^1H NMR (250 MHz, CD_3OD, 298 K): δ = 2.12 (s, 12 H, Me^3), 2.22 (s, 12 H, Me^5), 5.86 (s, 4 H, H^4), 6.67 (s, 2 H, CH) ppm. $^{13}C\{^1H\}$ NMR/ DEPT 135° (62.89 MHz, CD_3OD, 298 K): δ = 11.3 (+, Me^5), 13.2 (+, Me^3), 75.2 (+, CH), 107.4 (+, C^4), 143.0 (0, C^5), 150.1 (0, C^3) ppm.

[Ru(NO)(bdmpza)$_2$]Cl (6): A procedure similar to that for **3** was used, but with $Ru(NO)Cl_3$ (50.0 mg, 0.21 mmol) and ligand **2** (106.6 mg, 0.42 mmol) to give a brownish red crystalline solid. Yield: 134 mg (96.4%). $C_{24}H_{30}ClN_9O_5Ru$ (661.1): calcd. C 43.60, H 4.54, N19.07; found C 43.58, H 4.57, N 19.04. IR (KBr): $\tilde{\nu}$ = 1860 ν(NO), 1647 $\nu_{as}(CO_2^-)$, 1562 ν(C=N), 1385 $\nu_s(CO_2^-)$ cm^{-1}. IR (CH_2Cl_2): $\tilde{\nu}$ = 1862 ν(NO) cm^{-1}. UV/Vis: λ (log ε) = 250 (sh, π → π*), 376 (3.52, MLCT), 564 (2.84, d-d) nm. ^1H NMR (250 MHz, CD_3OD, 298 K): δ = 2.15 (s, 12 H, Me^3), 2.24 (s, 12 H, Me^5), 5.85 (s, 4 H, H^4), 6.61 (s, 2 H, CH) ppm. $^{13}C\{^1H\}$ NMR/DEPT 135° (62.89 MHz, CD_3OD, 298 K): δ = 11.2 (+, Me^5), 13.4 (+, Me^3), 73.9 (+, CH), 107.1 (+, C^4), 142.6 (0, C^5), 149.6 (0, C^3), 169.6 (0, C=O) ppm.

Restricted Phenyl Rotation in Pyridyl Thioether Ligands N,S-Chelated to Congested Diiminoruthenium Cores

Laura Baradello,[a] Sandra Lo Schiavo,[a] Francesco Nicolò,[a] Santo Lanza,[a] Giuseppe Alibrandi,[a] and Giuseppe Tresoldi*[a]

Keywords: Activation barriers / N,S ligands / Restricted rotation / Ruthenium

The thioethers 2-pyridylmethyl *p*-tolyl sulfide (**a**) and *p*-chlorophenyl 2-pyridylmethyl sulfide (**b**) react with the precursors *cis*-[$RuCl_2$(*N*,*N*-diimine)$_2$] [diimine = di-2-pyridyl sulfide (dps), **1**; 2,2′-bis(4-methylpyridyl) sulfide (4mdps), **2**; 2,2′-bis(5-methylpyridyl) sulfide (5mdps), **3**; di-2-pyrimidyl sulfide (dprs), **4**; and 2,2′-bis(5-ethylpyrimidyl) sulfide (5edprs), **5**] in the presence of NH_4PF_6 to give the complexes [Ru(*N*,*N*-diimine)$_2$(*N*,*S*-**a**)][PF_6]$_2$ and [Ru(*N*,*N*-diimine)$_2$(*N*,*S*-**b**)][PF_6]$_2$, respectively. As a consequence of the *N*,*S* chelation all the complexes contain a five-membered RuSCCN(*Ru*–*N*) ring, the sulfur and ruthenium atoms of which are stereogenic centres, with (*R*) and (*S*) and Δ and Λ configurations, respectively. Furthermore, the coordinated thioethers contain anisochronous methylene protons and phenyl protons which are sensor nuclei for pyramidal sulfur inversion and rotation of the pendant phenyl ring, respectively. In the low-temperature ^{1}H NMR spectra of the complexes a single AB system for the methylene protons, in agreement with a fast sulfur inversion, is observed. Well-separated signals of the two *ortho*- as well as the *meta*-phenyl protons, indicating restricted phenyl rotation, are also observed. At higher temperatures the fast exchange of the two halves of the phenyl ring leads to averaged signals for the phenyl protons. The rates and activation energies of this fluxional process were measured by one-dimensional band-shape analysis. Certain trends were immediately apparent. The rotation barrier values ($\Delta G^{\#}_{298}$) of the dps, 4mdps and 5mdps complexes were ca. 4.0 kJ·mol^{-1} lower than those of the dprs and 5edprs complexes. On the contrary, substitution of H^4 or H^5 dps protons with methyl groups and H^5 dprs protons with ethyl groups, as well as substitution of **a** with **b**, leaves the rotation-barrier values practically unchanged. This effect can be correlated to the steric hindrance produced by the two ligands *cis* to the rotating group. The crystal structure of the enantiomeric couple Δ*S*/Λ*R* of [Ru(dps)$_2$(2-pyridymethyl 2-pyridyl sulfide)][PF_6]$_2$ (**1c**), in which the 2-pyrimidylmethyl 2-pyridyl sulfide (**c**) ligand acts in an *N*,*S*-bidentate mode forming a five-membered RuSCCN(*Ru*–*N*) chelate ring, is also reported.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The chemistry of di-2-pyridyl sulfide (dps) is of interest in that the ligand, which usually adopts an *N*,*N*-bidentate coordination,[1−13] can exhibit a variety of bonding modes to metal atoms, for example monodentate,[10−12] and bridging.[11−14] Consequently, dps complexes can exhibit interconversion between different coordination species or fluxional processes.[10−12] The *N*,*N* chelation[15−20] of dps, and similar thioether compounds containing heterocycles, to the ruthenium(II) ion, and a *cis* arrangement[15−17,19,20] around the metal atom, are usually observed, although complexes with a *trans* configuration[18] or which contain a four-membered RuSCN(*Ru*−*N*)[19] ring have also been obtained. As a consequence of the *N*,*S* coordination, the thioether ligand contains a stereogenic sulfur centre [(*R*) and (*S*) configurations] and a pendant ring. The ^{1}H and ^{13}C NMR spectra of the complexes containing *cis*-Ru(*N*,*N*-dprs)$_2$ or *cis*-Ru(*N*,*N*-dps)$_2$ fragments (dprs = di-2-pyrimidyl sulfide) and the *N*,*S*-chelated thioether ligand phpys (phenyl pyridyl sulfide) below 240 K are temperature-dependent due to the restricted rotation of the pendant ring.

The NMR investigation of [Ru(*N*,*N*-diimine)$_2$(*N*,*S*-thioether)][PF_6]$_2$ [20] (diimine = dps or dprs; thioether = pySCH_2R or prSCH_2R, where py = pyridyl, pr = pyrimidyl and R = phenyl derivative) shows the presence of two invertomers as pairs of enantiomers (Δ*R*, Λ*S* and Δ*S*, Λ*R*) due to the Δ and Λ configurations of the ruthenium atom and the (*R*) and (*S*) configurations of the sulfur atom. The sulfur inversion produces the exchange [(*R*) ⇄ (*S*)] whereas the racemization process (Δ ⇄ Λ) was absent and the rotation of the pendant ring fast.

In order to study the effect of the steric hindrance of the Ru(diimine)$_2$ fragment on the phenyl rotation and the effect of the ring size on the sulfur inversion we have selected a series of [$RuCl_2$(diimine)$_2$] precursors and thioethers suitable for *N*,*S* chelation. We report on the dynamic behaviour

of the compounds obtained from 2-pyridylmethyl *p*-tolyl sulfide (**a**) and *p*-chlorophenyl 2-pyridylmethyl sulfide (**b**) with *cis*-[$RuCl_2$(*N*,*N*-diimine)$_2$] compounds [diimine = dps, **1**; 2,2′-bis(4-methylpyridyl) sulfide (4mdps), **2**; 2,2′-bis(5-methylpyridyl) sulfide (5mdps), **3**; dprs, **4** and 2,2′-bis(5-ethylpyrimidyl) sulfide (5edprs) **5**]. The crystal structure of the couple $\Delta S/\Lambda R$ of [Ru(dps)$_2$(2-pyridymethyl 2-pyridyl sulfide)][PF_6]$_2$ (**1c**) is also reported.

Results

Synthesis of the Compounds Containing an N,S-Chelate Ligand

The air-stable compounds **1a**, **3a**−**5a**, **1b**−**5b** and **1c** were obtained by the reactions depicted in Scheme 1. The new precursors [$RuCl_2$(*N*,*N*-4mdps)$_2$] (**2**), [$RuCl_2$(*N*,*N*-5mdps)$_2$] (**3**) and [$RuCl_2$(*N*,*N*-5edprs)$_2$] (**5**) were prepared from $RuCl_3 \cdot 3H_2O$ and 4mdps,[21] 5mdps[21] or the new ligand 5edprs; see Exp. Sect.).

	Ru(*N*,*N*-diimine)$_2$Cl$_2$	*N*,*S* ligand	Complex
1	Ru(dps)$_2$Cl$_2$	**a** (X = CH, R = Me)	**1a**
3	Ru(5mdps)$_2$Cl$_2$	**a**	**3a**
4	Ru(dprs)$_2$Cl$_2$	**a**	**4a**
5	Ru(5edprs)$_2$Cl$_2$	**a**	**5a**
1	Ru(dps)$_2$Cl$_2$	**b** (X = CH, R = Cl)	**1b**
2	Ru(4mdps)$_2$Cl$_2$	**b**	**2b**
3	Ru(5mdps)$_2$Cl$_2$	**b**	**3b**
4	Ru(5edprs)$_2$Cl$_2$	**b**	**4b**
5	Ru(dps)$_2$Cl$_2$	**c** (X = N, R = H)	**1c**

Scheme 1

The complexes are yellow or orange solids that are soluble in acetone or acetonitrile and slightly soluble in methanol, ethanol and water. They were characterised by elemental analysis, conductivity measurements in acetonitrile solution with values characteristic of 1:2 electrolytes (330−300 $S \cdot cm^2 \cdot mol^{-1}$), IR spectroscopy, which shows the bands of PF_6^- (ca. 842 and 558 cm^{-1}) and those characteristic of thioether ligands in the range 1630−1540 cm^{-1}. This indicates that the ligands dps, 4mdps, 5mdps, dprs and 5edprs act as bidentate *N*,*N*-chelate ligands,[8−20] whereas **a**, **b** and **c** are *N*,*S*-chelate ligands.[19,20] These findings were confirmed by subsequent ^1H and ^{13}C NMR spectroscopic studies.

Low-Temperature ^1H NMR Spectra

At low temperatures the NMR spectra of these complexes show well-separated signals of the two *ortho*- (as well as the *meta*-) phenyl protons. The spectrum of **4b** at 218 K in the δ = 8.2−3.7 ppm range is shown in Figure 1; the data are listed in Table 1. Because of the slow phenyl rotation two doublets of doublets are observed in the phenyl region for the *ortho*-protons at δ = 8.09 (partially overlapped with the signal of the H^5 pyrimidine proton) and 5.38 ppm, labelled **M** and **N**, respectively. Furthermore, two doublets of doublets for the *meta*-protons are observed at δ = 7.60 and 6.75 ppm, labelled **O** and **P**, respectively. The coupling constants between **M** and **O** and **N** and **P** are 8.6 Hz and between **M** and **N** and **O** and **P** 2.3 Hz. In the methylene region two doublets appear at δ = 4.65 and 3.87 ppm ($^2J_{H,H}$ = 17.4 Hz).

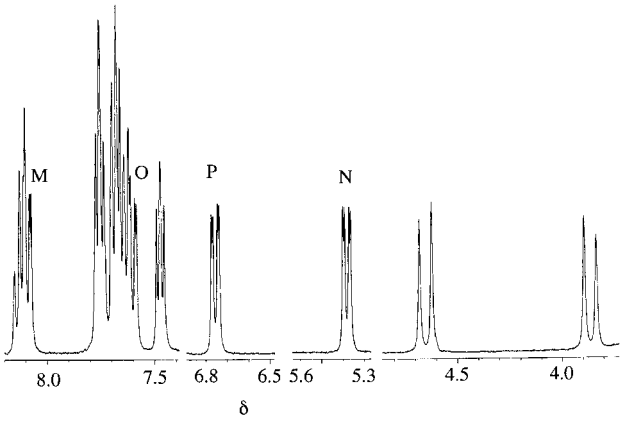

Figure 1. ^1H NMR spectrum of [Ru(*N*,*N*-dprs)$_2$(*N*,*S*-**b**)][PF_6]$_2$ (**4b**) at 218 K in $(CD_3)_2CO$ (range δ = 8.2−3.7 ppm)

The full assignment of the signals and the solution structure was based on 2D COSY, phase-sensitive 2D NOESY, decoupling experiments and one-dimensional ^1H NMR spectra at variable temperatures. In this way the twelve signals, as doublets of doublets due to the protons of the four pyrimidine rings with the coupling constants $J_{4,5} \approx 4.6$, $J_{4,6} \approx 2.1$, $J_{5,6} \approx 6.0$ Hz and the ten signals due to the protons of the pyridine, the phenyl and methylene groups of the **b** ligand, were assigned.

Dynamic NMR Studies

The dynamic behaviour of the complexes was preliminarily examined by phase-sensitive 2D NOESY spectroscopy, which shows the interchanges (positive cross-peaks) and the interactions (negative cross-peaks) between the protons. The phase-sensitive 2D NOESY spectra of the dprs and 5edprs complexes were recorded almost at the same temperature (245−250 K) whereas those of the dps, 4mdps and 5mdps complexes were recorded at lower temperatures as the dynamic process is faster than for the dprs and 5edprs complexes (vide infra).

The spectrum for **4b**, at 248 K, is shown in Figure 2. At this temperature the *ortho*-phenyl signals as well as the *meta* signals are split as the fluxional process that exchanges the two halves of the phenyl ring is slow. Positive cross-peaks, due to chemical exchange of magnetization, are detected between the phenyl protons **M** and **N** (at δ = 8.09 and 5.38

[a] At 300.13 MHz, in [D$_6$]acetone; δ in ppm with respect to TMS, *J* in Hz. [b] Picolyl fragment. [c] Phenyl fragment. [d] Methyl of **a**. [e] Methyl of the *N,N* ligand. [f] Methylene of 5edprs. [g] Pyridyl fragment.

ppm, respectively) and **O** and **P** (at $\delta = 7.60$ and 6.75 ppm, respectively) while the strong NOEs (negative cross peaks) include interactions between the methylene protons, intra-ring interactions in the phenyl ring (**M/O** and **N/P**) and in the pyrimidine ring (H^6/H^5) and, most significantly, the following interactions: methylene proton at $\delta = 4.65$ ppm/H^3 pyridine proton at $\delta = 7.63$ ppm, methylene proton at $\delta = 3.87$ ppm/H^6 pyrimidine proton at $\delta = 9.66$ ppm, H^6 pyrimidine proton at $\delta = 9.46$ ppm/H^6 pyridine proton at $\delta = 9.41$ ppm, H^6 pyrimidine proton at $\delta = 9.46$ ppm and that at $\delta = 9.05$ ppm, H^6 pyrimidine proton at $\delta = 9.66$ ppm and that at $\delta = 8.81$ ppm. If we assume that the sulfur inversion is fast at low temperatures and that the phenyl rotation is slow, the *ortho*-phenyl protons (**M** and **N**) are anisochronous as are the *meta*-protons (**O** and **P**), and the phenyl rotation exchanges protons **M** and **N** and **O** and **P**. Furthermore the negative cross-peaks found in the 2D NOESY spectrum suggest that in the invertomer depicted (Figure 3) the pyrimidine ring labelled C is *cis* to the phenyl ring B and the ring F is *cis* to the pyridine ring A, while ring E is *trans* to the sulfur atom. In the other invertomer (not shown) the phenyl ring should be *cis* to the ring F.

Similar structures for the other complexes at low temperature can be deduced from the data listed in Table 1. The ring and the position of the protons were assigned by the one- and two-dimensional experiments mentioned previously and by comparison of the spectra. In particular, the solution structure depicted in Figure 4 is proposed for an invertomer of **1a**.

Upon warming the solutions, the spectral lines of the phenyl protons broaden and coalesce in the range 255−295 K. At 330 K, the highest temperature reached, averaged signals are observed for the *ortho*- as well the *meta*-phenyl protons of all the complexes (Table 2). For instance,

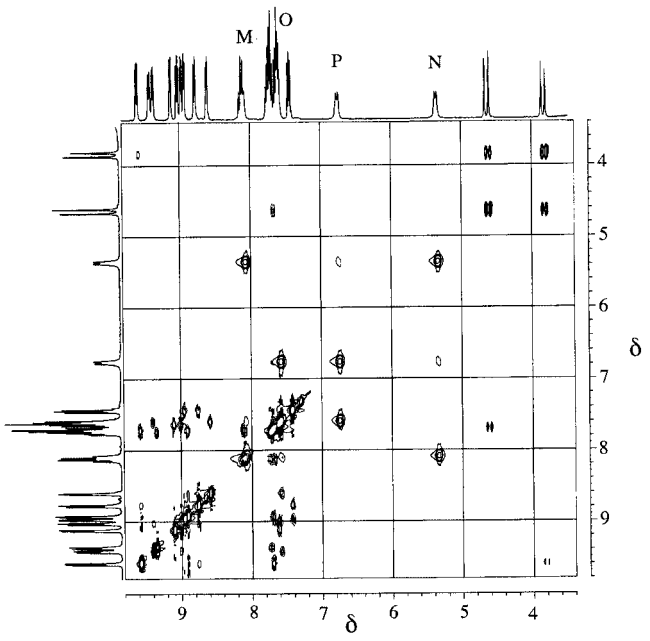

Figure 2. Phase-sensitive 2D NOESY spectrum of **4b** at 248 K in $(CD_3)_2CO$ (range δ = 9.8−3.4 ppm)

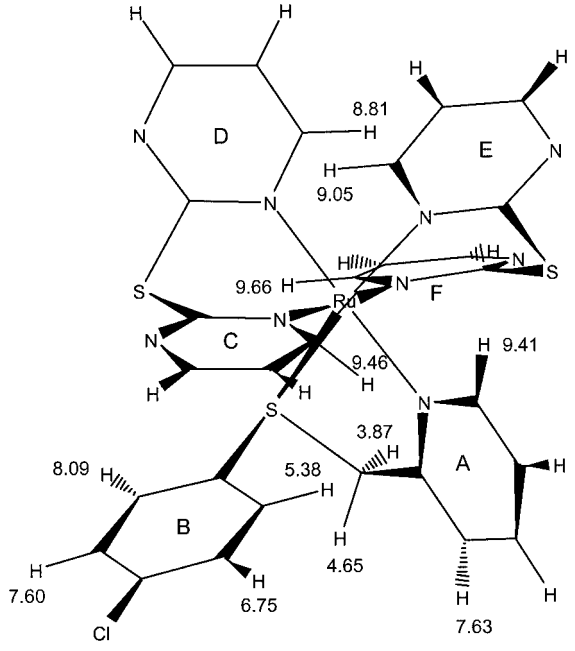

Figure 3. Proposed solution structure of **4b**; the rings are labelled A−F; the following signal assignments, based on 2D NOESY spectra at low temperatures, show vicinal protons at δ = 8.09−7.60, 6.75−5.38, 7.63−4.65, 9.66−3.87, 9.46−9.41, 9.46−9.05, 9.66−8.81 ppm

the *meta*- and the *ortho*-phenyl proton signals of **1a** are observed at δ = 6.83 and 6.50 ppm, respectively, near the statistical average of δ = 6.84 and 6.44 ppm, respectively, as expected for a single dynamic process. Furthermore, the *meta*- and the *ortho*-phenyl proton signals of **4b** are observed at δ = 7.12 and 6.67 ppm, respectively. The last signal in this complex, as well as in other dprs and 5edprs

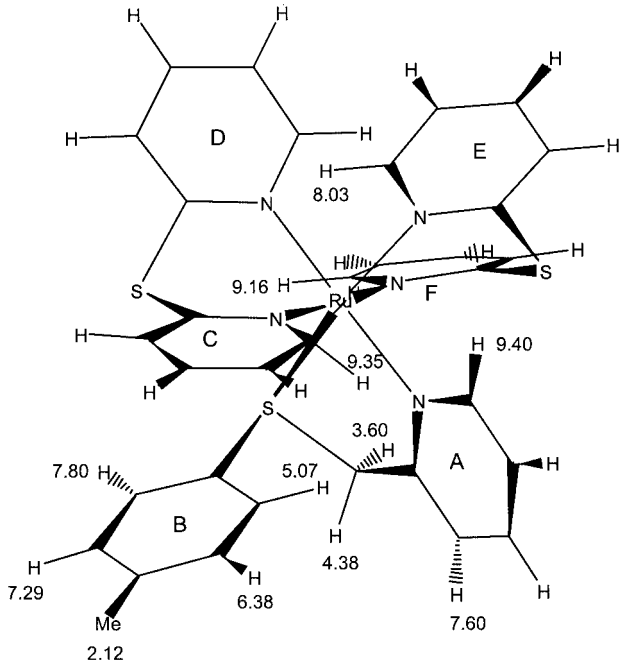

Figure 4. Proposed solution structure of **1a**; the rings are labelled A−F; the following signal assignments, based on 2D NOESY spectra at low temperatures, show vicinal protons at δ = 7.80−7.29, 6.38−5.07, 7.60−4.38, 9.16−3.60, 9.40−9.35, 6.38−2.12, 7.29−2.12, 9.40−8.03 ppm

complexes, is rather broad due to the great chemical-shift differences of the exchanging protons (ca. 2.7 ppm) and the energy-barrier values ($\Delta G^{\#}_{298} \approx$ 54.3 kJ·mol^{-1}, vide infra and Table 3). Although the dynamic behaviour of the complexes in CD_3CN parallels that observed in acetone, decomposition above 340 K is observed. Furthermore solubility problems in other solvents prevent detailed NMR studies at higher temperatures. It is worth noting that this process has a negligible effect on the methylene protons which appear, at all the temperatures, as a single AB system.

COSY and NOESY experiments were also performed at high temperatures allowing the complete assignment of the proton signals. In particular the signals of **4b** at δ = 9.20, 7.71, 8.06 and 7.64 ppm were assigned to the pyridine protons H^6, H^5, H^4 and H^3, respectively, of the *N*,*S*-coordinated ligand (Table 2).

The rates of the process were deduced by band-shape analysis of the phenyl signals. Some experimental and computer-simulated spectra are shown in Figure 5. Activation energy data were calculated from fifteen independent fittings in the temperature range 210−330 K. The activation energy data for the other complexes were obtained by a similar method and are collected in Table 3.

The ^{13}C NMR spectra of the complexes were interpreted easily, at least for the carbon signals of the *N*,*S*-chelate ligand, by comparison of the spectra of the present complexes with those of the free ligands and other complexes containing *N*,*S*-chelate ligands,[19,20] with the help of the jmod pulse sequence. The variable-temperature ^{13}C NMR spectra of **4b** in the range δ = 142−124 ppm are shown in

[a] At 300.13 MHz, in [D_6]acetone, at 298 K unless stated otherwise; δ in ppm with respect to TMS, J in Hz. [b] Picolyl fragment. [c] *ortho*-Phenyl proton. [d] *meta*-Phenyl proton. [e] Methyl proton. [f] Pyridyl fragment. [g] At 330 K. [h] Methylene of 5edprs.

Figure 6. In the ^{13}C NMR spectrum at 208 K the signals of the more deshielded carbon atoms appear at δ = 169.5, 169.2, 168.9 and 168.3 ppm (quaternary pyrimidine carbon atoms), while two overlapped signals for the C^6 pyrimidine carbon atoms appear at δ = 164.6 ppm, the others being well separated (δ = 164.5 and 163.0 ppm). The signal of the more deshielded carbon atom of **b** is observed at δ = 162.40 ppm (quaternary pyridine carbon atoms) while the C^6 pyridine carbon atom (δ = 155.5 ppm) is shielded with respect to the C^4 pyrimidine carbon atoms (δ = 158.6, 158.2, 158.1 and 156.8 ppm). Figure 6 shows the C^4 pyridine signal (δ = 138.6 ppm), the *ortho*-phenyl carbon signals (δ = 135.6 and 128.5 ppm), the *meta*-phenyl carbon signals (δ = 129.4 and 129.3 ppm), the CS signal (δ = 135.5 ppm), the CCl signal (δ = 128.5 ppm) and the signals of the C^3 and C^5 pyridine carbon atoms of **b** at δ = 124.3 and 124.1 ppm. The signals of the C^5 pyrimidine carbon atoms (not shown in Figure 6) are observed at δ = 122.2, 121.6 ppm, with two overlapping signals at δ = 121.3 ppm.

Upon warming the solutions, the signals of the *ortho*- and *meta*-phenyl carbon atoms broadened and then coalesced. The coalescence temperature (T_c) for the *meta*-phe-

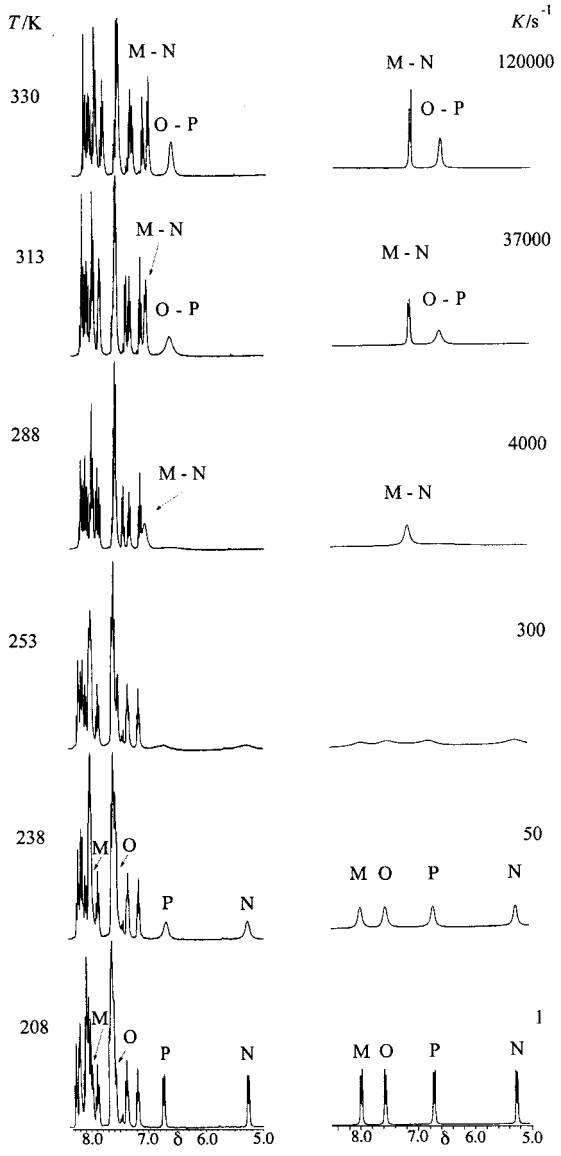

Figure 5. Selected variable-temperature ^{1}H NMR spectra of [Ru(*N*,*N*-dps)$_2$(*N*,*S*-**b**)][PF$_6$]$_2$ (**1b**) in (CD$_3$)$_2$CO (range δ = 8.4−4.8 ppm); simulated spectra on the right

nyl carbon atoms is 255 K. Their chemical-shift difference at 208 K is 12.09 Hz. The value of $\Delta G^{\#}_{255}$ (55.2 kJ·mol^{-1}), calculated from $\Delta G^{\#}_{T_c}$ = 19.14 T_c 10^{-3} (9.97 + logT_c/$\Delta\nu$),

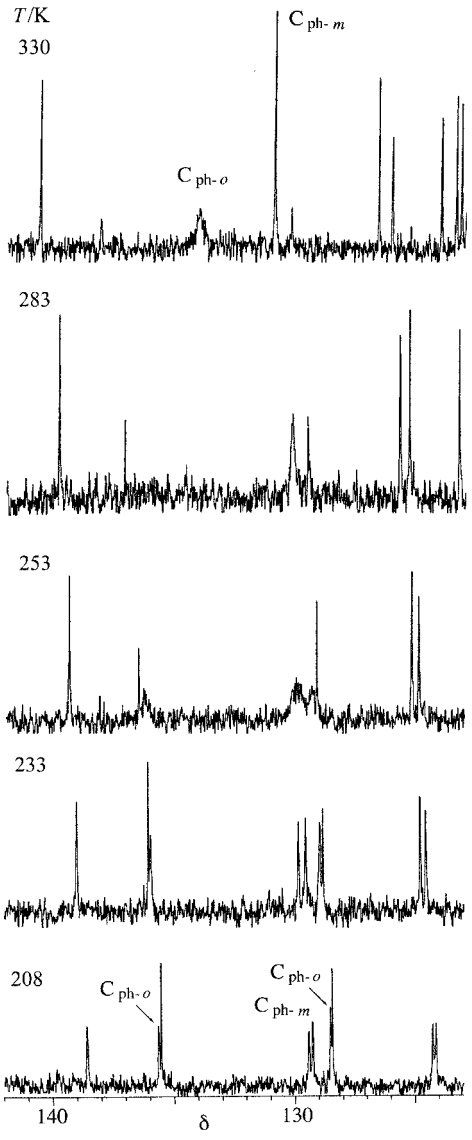

Figure 6. Selected variable-temperature ^{13}C NMR spectra of **4b** in (CD$_3$)$_2$CO (range δ = 141−124 ppm)

is in good agreement with the activation-energy barriers ($\Delta H^{\#}$ = 60.5 kJ·mol^{-1} and $\Delta S^{\#}$ = 20.8 J·K^{-1}·mol^{-1}) listed in Table 3.

In the fast-exchange regime (330 K) averaged signals of the *ortho*-phenyl (δ = 134.1 ppm) and *meta*-phenyl carbon atoms (δ = 131.0 ppm) are observed. Selected ^{13}C NMR spectroscopic data at low and high temperatures are listed in Table 4.

Molecular Structure of [Ru(dps)$_2$(2-pyridyl 2-pyridylmethyl sulfide)][PF$_6$]$_2$·(CH$_3$)$_2$CO (1c·C$_3$H$_6$O)

The complex cation of Ru^{2+} crystallizes in a 1:2 ratio with the hexafluorophosphate anions (both affected by a noticeable rotational disorder) for charge balance and in a 1:1 ratio with a disordered acetone molecule of the solvent. The crystal packing is stabilized by several hydrogen-bond interactions involving the fluorine atoms of the PF_6^-

anions and the oxygen atom of the acetone with the hydrogen atoms of the dps ligands [at a distance of 2.443(5) Å]. The geometry about the ruthenium(II) ion is distorted octahedral (Figure 7), with the coordination polyhedron defined by five nitrogen atoms and one sulfur atom: two *N,N*-chelate dps ligands are *cis* to each other while the molecule of 2-pyridyl 2-pyridylmethyl sulfide is bidentate through S(3) and N(5). The distortion of the geometry is mainly caused by the sulfur atom, with a significantly longer Ru−S(3) distance [2.370(1) Å] than the five similar Ru−N bonds [mean 2.104(5) Å, with a slightly shorter bond to N(2) due to the sulfur *trans* effect]. Despite the different size of the chelating rings (6 atoms for dps and 5 for the 2-pyridylmethyl sulfide), the bite angles of the three bidentate ligands are almost equal and N(5)−Ru−S(3) is only slightly narrower than the other two equal chelating angles corresponding to dps molecules [81.39(9)° vs. 89.3(1)°]. The same Ru^{II} coordination has already been observed in our previous work[19] for the $[Ru(N,N'\text{-dps})_2(N,S\text{-dps})]^{2+}$ cation, where the distortion is more important due to the significantly shorter N···S bite of one dps, which closes the corresponding chelating angle up to 67.8(2)°. The larger steric hindrance for the bigger bite and bulk of 2-pyridyl 2-pyridylmethyl sulfide with respect to the *N,S*-dps chelating ligand might be related to the significant elongation of the Ru−N bonds in the corresponding complex [mean value 2.104(5) vs. 2.078(5) Å, respectively]. Moreover, the elongation of the distance to the N atom in the *trans* position causes a contraction the Ru−S(3) bond [2.370(1) vs. 2.424(2) Å, respectively]. However, the Ru−N bonds are still significantly longer than the analogous distances in the known Ru(bipy) complexes due to the reduction in back bonding when dps replaces bipy ligands, as evidenced in the previous work. The dps ligand adopts a twisted *N,N*-inside "butterfly-like" arrangement and the resulting six-membered chelate rings show the usual boat conformation, as evidenced by the

puckering analysis[22] on the Ru/N1/C1/S1/C6/N2 [Ru/N3/C16/S2/C11/N4] ring: θ = 90.8(2)° [92.4(2)]°, φ = 0.7(7)° [4.6(2)]°, QT = 0.847(5) [0.920(2)] Å and Δ_S(Ru) = 0.008(2) [0.045(2)]. The C and N atoms lie on a plane from which the Ru and S atoms deviate by 0.7516(3) [0.8584(3)] Å and 0.718(1) [0.741(1)] Å on the same side, respectively. The two chiral atoms [Ru and S(3)] in the cation might generate two possible couples of enantiomers of the complex and, due to the presence of a crystallographic centre of symmetry, the crystal packing is a racemic mixture corresponding to the couple $\Delta S/\Lambda R$ (one arbitrary enantiomer of which is represented in Figure 7).

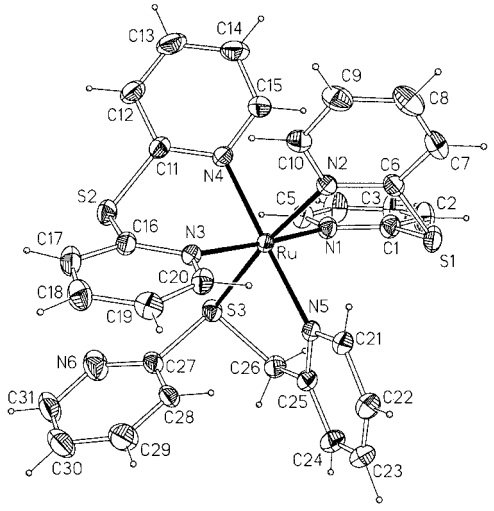

Figure 7. View of the cation **1c**·C_3H_6O showing the labelling scheme; anions and co-crystallized acetone moieties have been omitted for clarity; thermal ellipsoids are drawn at 50% probability while the size of the hydrogen atoms is arbitrary

Discussion

Our previous studies[19] on the dynamic behaviour of [Ru(*N*,*N*-dprs)$_2$(*N*,*S*-phpys)][PF_6]$_2$ and [Ru(*N*,*N*-dps)$_2$(*N*,*S*-phpys)][PF_6]$_2$ (phpys = phenyl pyridyl sulfide), containing a four-membered RuSCN(*Ru*−*N*) ring, showed that, in the range 180−240 K, a restricted rotation of the pendant phenyl ring was operative, affecting only the phenyl proton signals. Above 240 K extensive internal arrangements were invoked to explain the changes in the aromatic region of the ^{1}H NMR spectra at higher temperature.

The ^{1}H NMR spectra of the complexes containing a four-membered RuSCN(*Ru*−*N*) ring — [Ru(*N*,*N*-diimine)(*N*,*S*-pySCH_2R)][PF_6]$_2$ or [Ru(*N*,*N*-diimine)$_2$(*N*,*S*-prSCH_2R)][PF_6]$_2$ [20] — at the lowest temperature reached (190 K) clearly show the presence of two slowly exchanging invertomers, and restricted rotation is not observed. It is likely that restricted rotation of the phenyl group occurs below 190 K but experimental difficulties ruled out the possibility of confirming this proposal. Furthermore, for these complexes, which contain a chiral ruthenium atom (configurations Δ and Λ) and a chiral sulfur atom [configurations (*S*) and (*R*)] the possibility of racemisation ($\Delta \rightleftarrows \Lambda$) was discarded and only the sulfur inversion [(*R*) $\rightleftarrows$ (*S*)] occurred.

In this work owing to the *N*,*S* chelation of the thioethers **a** and **b** and the consequent formation of a five-membered metallacycle, two invertomers, as the enantiomeric couples $\Delta R/\Lambda S$ and $\Delta S/\Lambda R$, are expected and, consequently, two AB systems for the methylene protons in the ^{1}H NMR spectra. However, the spectra only show a single AB system. This can indicate the presence of: (i) only one invertomer, (ii) two invertomers that give superimposed signals, or (iii) two rapidly exchanging invertomers at low temperatures. The presence of only one invertomer or two invertomers that give superimposed signals, should eliminate the possibility of a rotation process exchanging the *ortho*- as well as the *meta*-phenyl protons, whereas the NOESY experiments indicate the exchange of the phenyl protons.

It is important to note at this point that the splitting patterns of the methylene protons (single AB system) and phenyl protons (coupling constants between **M** and **N** as well as **O** and **P)** rule out the possibility of a slow sulfur inversion at low temperatures, while the splitting patterns of the methylene protons at higher temperatures (single AB system) also rule out the possibility of racemisation ($\Delta \rightleftarrows \Lambda$) which should average the environments of the methylene protons. In other words, due to the very fast sulfur inversion even at low temperatures, averaged methylene proton signals as well as averaged phenyl proton signals of the two invertomers were observed, whereas due to the restricted phenyl rotation the two *ortho*- (and *meta*-) phenyl protons are anisochronous. The fast rotation of the phenyl ring at high temperatures makes the averaged environments of the two *ortho*- (and *meta*-) protons equivalent, whereas the methylene protons are practically unaffected.

On the other hand, from literature precedents it is unlikely that the two invertomers have similar resonances. In particular, the methylene proton signals are very sensitive to the sulfur configurations and four doublets are observed in the methylene region when two slowly exchanging invertomers are present.[20,23,24] Furthermore, the H^3 pyridine proton of the *N*,*S*-chelate ligand and the other pyridine and pyrimidine protons gave well-separated signals for the two invertomers at low temperature,[20] whereas for the present compounds only a single signal is present. Thus, two rapidly exchanging invertomers are present. In order to firmly establish this point and other structural features we attempted several crystallizations of the present compounds. None of the complexes containing ligands **a** or **b** gave crystals suitable for X-ray crystallography; however, the reaction of 2-pyridyl 2-pyridylmethyl sulfide (**c**) and [$RuCl_2$(dps)$_2$] in the presence of NH_4PF_6 gave [Ru(*N*,*N*-dps)$_2$(*N*,*S*-**c**)][PF_6]$_2$ (**1c**) which easily formed crystals. The X-ray analysis revealed the enantiomeric couple $\Delta S/\Lambda R$. Moreover, the ^{1}H NMR spectra of this complex are compatible with the presence of two rapidly exchanging invertomers: a single AB system is observed for the methylene protons at low temperatures (Table 1).

For the complexes [*cis*-Ru(*N*,*N*-diimine)(*N*,*S*-pySCH$_2$R)][PF$_6$]$_2$ and [*cis*-Ru(*N*,*N*-diimine)$_2$(*N*,*S*-prSCH$_2$R)][PF$_6$]$_2$ [20] the access to the transition state of sulfur inversion is difficult due to the four-membered chelate ring. However, the relatively high-energy ground state, due to the simultaneous presence of the congested Ru(diimine)$_2$ fragment and the sterically demanding four-membered *N*,*S*-chelate ring, explains the low energy-barrier of the process. In the present complexes the steric demand of the Ru(diimine)$_2$ fragments is similar, whereas the increase of the chelate ring-size decreases the transition-state energy of the inversion, which consequently is fast. Therefore, the only fluxional process observed which exchanges the *ortho*- and *meta*-protons (whereas other protons are practically unchanged) is a phenyl rotation. The possible mechanisms that need to be considered are: (i) a dissociative mechanism with formation of five-coordinate species in which exchange of the two halves of the phenyl ring is operative, (ii) an associative mechanism involving solvent, anion or free ligand with formation of a seven-coordinate species in which restricted rotation of phenyl ring occurs, or (iii) phenyl rotation in the octahedral complexes without any bond rupture. The dissociative mechanism can be discarded on the basis of the following findings: (i) the NMR spectra are temperature-reversible and concentration-independent, (ii) the exchange rates are similar in acetone and acetonitrile, (iii) the steric hindrance to phenyl rotation can be very much diminished by dissociation of the Ru−S or Ru−N bond; and (iv) in the presence of a Ru−S bond dissociation the sulfur inversion and phenyl rotation would occur at the same rate. On the contrary, at low temperatures, sulfur inversion is fast whereas phenyl rotation is slow. An associative mechanism involving solvent, anion or free ligand is also unlikely. In fact, when the free ligand is added, separate signals are observed and the exchange rates are not affected. Addition of chloride or hexafluorophosphate anion does not affect the rate of the process. Therefore, the only mechanism consistent with all the experimental results appears to be the phenyl rotation in the octahedral complexes. This phenyl rotation occurs at higher rates in the complexes containing Ru(dprs)$_2$ or Ru(5edprs)$_2$ fragments than in those containing Ru(dps)$_2$, Ru(4mdps)$_2$ or Ru(5mdps)$_2$ fragments, the differences in the averaged $\Delta G^{\#}_{298}$ values being 4 kJ·mol^{-1} (Table 3); the substitution of dps with 4mdps or 5mdps leaves the magnitude of $\Delta G^{\#}_{298}$ practically unchanged. Similarly, substitution of dprs with 5edprs or **a** with **b** does not affect the values of $\Delta G^{\#}_{298}$. On this basis we suggest that the contribution of electronic effects to the restricted phenyl rotation is negligible while the parameters observed are correlated to the hindrance produced by the two ligands *cis* to the rotating group. Crystallographic data of [Ru(*N*,*N*-dps)$_2$(*N*,*S*-**c**)][PF$_6$]$_2$ and similar complexes[15,18,19] indicate that *N*,*N* chelation is favoured by the combination of the boat conformation for the six-membered metallacycle and a twisted *N*,*N*-inside conformation of dps which corresponds to the best pyridine dihedral angle for chelation to the metal atom. We have no crystallographic data of dprs complexes containing **a** or **b** or other *N*,*S* ligands; however, it is very likely that the conformation of the *N*,*N* chelate dprs is similar. Since the pyridine or pyrimidine rings are inclined the hindrance to rotation is mainly determined by the size of the N atom and, to a lesser extent, by the CH[6] group. In other words, the inclined pyrimidine ring of dprs is somewhat "bulkier" than the inclined pyridine ring of dps, producing enhanced hindrance to the phenyl rotation.

Conclusion

The reactions of a series of thioethers bearing CH$_2$Py groups has allowed us to extend the chemistry of polypyridylruthenium(II) compounds containing *N*,*S*-coordinated ligands with a five-membered chelate ring. The NMR experiments clearly show that the phenyl rotation in the octahedral complexes is the fluxional process that produces the exchange of the *ortho*- and *meta*-phenyl protons. The steric hindrance of the ruthenium substrates appears to play a determinant role for the phenyl rotation which, in the complexes containing dps ligands or methyl derivatives, occurs at lower rates than in those containing dprs or 5edprs; the difference in the averaged $\Delta G^{\#}$ values being 4 kJ·mol^{-1}. The ring size of the *N*,*S*-coordinated thioether ligand plays a determinant role for the sulfur inversion. When the inverting sulfur atom is present in a five-membered *N*,*S*-chelated ring, the process is fast even at low temperatures, whereas in a four-membered ring[20] it is much slower. Further experiments are in progress with the aim of studying the effect of the nature of congested Ru(*N*,*N*-diimine)$_2$ cores and sterically demanding thioethers on the energy barrier of the dynamic processes.

Experimental Section

General Remarks: Di-2-pyridyl sulfide,[25] di-2-pyrimidyl sulfide,[19] 2-pyridylmethyl *p*-tolyl sulfide,[26] *p*-chlorophenyl 2-pyridylmethyl sulfide,[26] 2-pyridyl 2-pyridylmethyl sulfide,[26] [RuCl$_2$(dps)$_2$]·2H$_2$O[15] and [RuCl$_2$(dprs)$_2$]·2H$_2$O[19] were prepared by published methods. Other reagents and solvents were used as received. Conductivity measurements were done with a Radiometer CDM 3 conductivity meter. Infrared spectra were recorded with an FT-IR 1720X spectrophotometer with samples as Nujol mulls placed between KBr plates and the ^{1}H and ^{13}C NMR spectra with a Bruker AMX 300 spectrometer. The following Bruker programs were used: zg, homodecnew, zgpg, jmod, cosy, noesy.pt, invb. Simulations of static and dynamic spectra were performed with the G NMR program. Selected ^{1}H NMR spectroscopic data for the complexes are given in Tables 1 and 2, activation energy data are given in Table 3 and ^{13}C NMR spectroscopic data are given in Table 4.

2,2′-Bis(5-ethylpyrimidyl) Sulfide (5edprs): 2-Chloro-5-ethylpyrimidine (4.85 g, 34.0 mmol) was dissolved in *N*,*N*-dimethylformamide (30 mL), under N$_2$. Na$_2$S (1.37 g, 17.5 mmol) was added. The resulting mixture was heated to reflux with stirring for 4 h. The initial pale-yellow solution gradually turned green, then deep yellow. The solvent was distilled off under reduced pressure and the residue extracted with CH$_2$Cl$_2$. Evaporation of the solvent gave a pale-yellow solid, which was crystallized from CH$_2$Cl$_2$ (30 mL) by care-

ful addition of heptane, washed with pentane and dried in vacuo. Yield 1.26 g (30%). Selected IR data (KBr): $\tilde{\nu}$ = 1607 ms, 1574 s, 1538 vs, 1267 s, 1230 vs, 1142 vs, 1068 s, 938 vs, 820 vs, 790 s, 767 vs, 653 vs, 646 vs 638 vs, 499 vs cm^{-1}. ^1H NMR ([D$_6$]acetone, 298 K): δ = 1.25 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 2.67 (q, 4 H, CH_2), 8.56 (s, 4 H, H^3 and H^6) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]acetone, 298 K): δ = 15.05 (CH_3), 23.45 (CH_2), 158.25 (C^3 and C^6) ppm. $C_{12}H_{14}N_4S$ (246.33): calcd. C 58.51, H 5.73, N 22.74, S 13.01; found C 58.40, H 5.80, N 22.60, S 13.00.

2,2′-Bis(4-methylpyridyl) Sulfide (4mdps):[21] 2-Bromo-4-methylpyridine (9.70 g, 56.4 mmol) was dissolved in *N*,*N*-dimethylformamide (30 mL) under N_2. Na_2S (2.28 g, 29.2 mmol) was added. The resulting mixture was heated to reflux with stirring for 6 h. The initial pale-yellow solution gradually turned green, then yellow. Distillation under reduced pressure gave the solvent at 30−50 °C and the compound as a yellow oil at 150 °C. The oil was kept at −24 °C until it solidified. Selected IR data (KBr): $\tilde{\nu}$ = 1625 s, 1590 vs, 1556 s, 1539 s, 1282 ms, 1233 s, 1221 s, 1119 vs, 1079 vs, 986 s, 869 ms, 849 vs, 823 vs, 700 vs, 539 s, 517 s cm^{-1}. ^1H NMR ([D$_6$]acetone, 298 K): δ = 2.30 (s, 6 H, CH_3), 7.09 (dd, $J_{6,5}$ = 5.0 Hz, $J_{5,3}$ = 1.3 Hz, 2 H, H^5), 7.31 (d, 2 H, H^3), 8.33 (d, 2 H, H^6) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]acetone, 298 K): δ = 20.60 (CH_3), 123.50 (C^5), 126.70 (C^3), 150.30 (C^6) ppm.

2,2′-Bis(5-methylpyridyl) Sulfide (5mdps):[21] The compound was obtained in the same way as above starting from 2-bromo-5-methylpyridine (9.70 g, 56.4 mmol) and Na_2S (1.37 g, 17.5 mmol). Selected IR data (KBr): $\tilde{\nu}$ = 1667 vs, 1586 vs, 1557 vs, 1504 s, 1221 vs, 1102 vs, 1084 s, 1025 vs, 828 vs, 724 s cm^{-1}. ^1H NMR ([D$_6$]acetone, 298 K): δ = 2.30 (s, 6 H, CH_3), 7.32 (d, $J_{4,3}$ = 8.1 Hz, 2 H, H^3), 7.54 (dd, $J_{6,4}$ = 2.2 Hz, 2 H, H^4), 8.33 (d, 2 H, H^6) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]acetone, 298 K): δ = 17.80 (CH_3), 125.90 (C^3), 138.40 (C^4), 151.05 (C^6) ppm.

[RuCl$_2$(*N*,*N*-4mdps)$_2$] (2): $RuCl_3 \cdot 3H_2O$ (1 g, 3.8 mmol), LiCl (1 g, 23.6 mmol) and 4mdps (1.65 g, 7.63 mmol) were refluxed in DMF (30 mL) under N_2 for 4 h. After cooling to room temperature and addition of acetone (30 mL), the mixture was allowed to stand at 4 °C overnight giving a dark-red solid which was filtered and washed with acetone. The compound was dried over P_4O_{10} in vacuo. Yield 0.92 g (40%). Selected IR data (KBr): $\tilde{\nu}$ = 1650 br, 1599 vs, 1282 s, 1140 s, 1082 s, 820 vs, 720 s cm^{-1}. ^1H NMR ($CDCl_3$, 298 K): δ = 2.23 (s, 6 H, CH_3), 2.34 (s, 6 H, CH_3), 6.62 (dd, $J_{6,5}$ = 6.0 Hz, $J_{5,3}$ = 1.9 Hz, 2 H, H^5), 7.13 (dd, $J_{6,5}$ = 6.0 Hz, $J_{5,3}$ = 1.9 Hz, H^5), 2 H, 7.14 (d, 2 H, H^3),7.31 (d, 2 H, H^3),8.30 (d, 2 H, H^6), 10.04 (d, 2 H, H^6) ppm. $C_{24}H_{24}Cl_2N_4RuS_2$ (604.58): calcd. C 47.68, H 4.00, N 9.27, S 10.61; found C 47.80, H 4.00, N 9.35, S 10.60.

[RuCl$_2$(*N*,*N*-5mdps)$_2$] (3): $RuCl_3 \cdot 3H_2O$ (1 g, 3.8 mmol), LiCl (1 g, 23.6 mmol) and 5mdps (1.65 g, 7.63 mmol) were refluxed in DMF (20 mL) under N_2 for 5 h. The solution was cooled to room temperature and 40 mL of acetone added. The mixture was allowed to stand at −24 °C overnight. An orange-red solid had formed which was filtered, washed with acetone/diethyl ether mixtures [2:1 (21 mL), 1:1 (30 mL) and 1:3 (40 mL)] and dried over P_4O_{10} in vacuo. Yield 1.03 g (45%). Selected IR data (KBr): $\tilde{\nu}$ = 1630 br, 1589 s, 1284 s, 1234 s, 1136 vs, 1101 vs, 822 vs, 722 s, 532 s cm^{-1}. ^1H NMR ([D$_6$]acetone, 298 K): δ = 2.01 (s, 6 H, CH_3), 2.41 (s, 6 H, CH_3), 7.33 (dd, $J_{4,3}$ = 7.9 Hz, $J_{6,3}$ = 0.8 Hz, 2 H, H^3), 7.38 (dd, $J_{4,3}$ = 7.9 Hz, $J_{6,4}$ = 2.5 Hz, 2 H, H^4), 7.53 (dd, $J_{4,3}$ = 7.9 Hz, $J_{6,3}$ = 0.8 Hz, 2 H, H^3), 7.62 (dd, $J_{4,3}$ = 7.9 Hz, $J_{6,4}$ = 2.5 Hz, 2 H, H^4), 8.30 (dd, 2 H, H^6), 10.04 (dd, 2 H, H^6) ppm. $C_{24}H_{24}Cl_2N_4RuS_2$ (604.58): calcd. C 47.68, H 4.00, N 9.27, S 10.61; found C 47.60, H 4.10, N 9.30, S 10.70.

[Ru(*N*,*N*-5edprs)$_2$Cl$_2$] (4): This red compound was obtained in the same way as above, starting from $RuCl_3 \cdot 3H_2O$ (1 g, 3.8 mmol), LiCl (1 g, 23.6 mmol) and 5etdprs (1.94 g, 7.63 mmol). Yield 0.88 g (35%). Selected IR data (KBr): $\tilde{\nu}$ = 1675 vs, 1540 vs, 1220 s, 1182 vs, 1136 vs, 1058 vs, 910 vs, 822 vs, 752vs, 740 vs 720 s, 662 s cm^{-1}. ^1H NMR ([D$_6$]acetone, 298 K): δ = 1.02 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 1.34 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, CH_3), 2.48 (q, 4 H, CH_2), 2.78 (q, 4 H, CH_2), 8.34 (dd, $J_{4,3}$ = 7.9 Hz, $J_{6,4}$ = 2.6 Hz, 2 H, H^4), 8.49 (dd, $J_{6,4}$ = 2.6 Hz, 2 H, H^6), 8.59 (d, $J_{6,4}$ = 2.8 Hz, 2 H, H^4), 10.01 (d, $J_{6,4}$ = 2.8 Hz, 2 H, H^6). $C_{24}H_{28}Cl_2N_8RuS_2$ (664.64): calcd. C 43.37, H 4.24, N 16.86, S 9.65; found C 43.50, H 4.30, N 17.00, S 9.70.

[Ru(*N*,*N*-dps)$_2$(*N*,*S*-a)][PF$_6$]$_2$ (1a): $[RuCl_2(dps)_2] \cdot 2H_2O$ (0.195 g, 0.33 mmol) and 2-pyridylmethyl *p*-tolyl sulfide (0.286 g, 1.33 mmol) were refluxed in 50 mL of ethanol/water (3:2) under N_2 for 4 h. After filtration of the solution into 80 mL of water containing NH_4PF_6 (0.49 g, 3 mmol), a yellow precipitate was obtained, filtered, washed with cold water (30 mL) and dried overnight. The solid was then dissolved in acetone (15 mL), precipitated with diethyl ether (100 mL), washed with diethyl ether (70 mL) and dried over P_4O_{10} under vacuum. Yield 0.165 g (50%). Selected IR data (KBr): $\tilde{\nu}$ = 1589 vs, 1561 ms, 1284 s, 1165 s, 878 vs, 843 br, 770 vs, 741 ms, 727 s, 558 vs cm^{-1}. $C_{33}H_{29}F_{12}N_5P_2RuS_3$ (982.81): calcd. C 40.33, H 2.97, N 7.12; found C 40.15, H 3.05, N 7.10. Conductivity: Λ_M (MeCN, 2 × 10^{-4} mol·dm^{-3}, 25 °C) = 316 S·cm^2·mol^{-1}.

[Ru(*N*,*N*-5mdps)$_2$(*N*,*S*-a)][PF$_6$]$_2$ (3a): The compound was obtained in the same way as **1a**, starting from $[RuCl_2(5mdps)_2]$ (0.201 g, 0.33 mmol) and 2-pyridylmethyl *p*-tolyl sulfide (0.286 g, 1.33 mmol). Yield 0.220 g (64%). Selected IR data (KBr): $\tilde{\nu}$ = 1667 s, 1597 s, 1565 ms, 1494 vs, 1283 vs, 1240 vs, 1120 vs, 1106 s, 877 vs, 840 br, 775 vs, 740 s, 725 ms, 557 vs, 530 vs cm^{-1}. $C_{37}H_{37}F_{12}N_5P_2RuS_3$ (1038.9): calcd. C 42.78, H 3.59, N 6.74; found C 42.90, H 3.60, N 6.80. Conductivity: Λ_M (MeCN, 2 × 10^{-4} mol·dm^{-3}, 25 °C) = 328 S·cm^2·mol^{-1}.

[Ru(*N*,*N*-dprs)$_2$(*N*,*S*-a)][PF$_6$]$_2$ (4a): $[RuCl_2(dprs)_2] \cdot 2H_2O$ (0.196 g, 0.33 mmol) and 2-pyridylmethyl *p*-tolyl sulfide (0.286 g, 1.33 mmol) were heated to reflux in 50 mL of ethanol/water (3:2). After 3 h, the solution was filtered and 50 mL of water containing NH_4PF_6 (0.65 g, 4 mmol) was added. The mixture was heated for 2 h. The solution obtained was allowed to stand until a brown precipitate was formed, which was filtered, washed with water, and dried overnight. The solid was then dissolved in acetone (10 mL) and added to the top of a chromatography column (diameter 2 cm) packed with aluminium oxide (50 g; Aldrich, neutral, 150 mesh, deactivated with water 0.15 g). Elution with CH_2Cl_2/acetone (3:2) gave a yellow-orange band which was collected, concentrated (10 mL) and precipitated with diethyl ether (50 mL). The solid obtained was washed with diethyl ether (50 mL) and dried over P_4O_{10} under vacuum. Yield 0.130 g (40%). Selected IR data (KBr): $\tilde{\nu}$ = 1604 ms, 1561 s, 1547 s, 1164 s, 1084 ms, 1014 ms, 876vs, 842 br, 762 vs, 751 ms, 722 ms, 649 ms, 597 ms, 558 vs cm^{-1}. $C_{29}H_{25}F_{12}N_9P_2RuS_3$ (986.76): calcd. C 35.30, H 2.55, N 12.78; found C 35.20, H 2.60, N 12.80. Conductivity: Λ_M (MeCN, 2 × 10^{-4} mol·dm^{-3}, 25 °C) = 305 S·cm^2·mol^{-1}.

[Ru(*N*,*N*-5edprs)$_2$(*N*,*S*-a)][PF$_6$]$_2$ (5a): This compound was prepared by refluxing a mixture of $[RuCl_2(5edprs)_2]$ (0.332 g, 0.50 mmol) and 2-pyridylmethyl *p*-tolyl sulfide (0.646 g, 3.0 mmol) in 50 mL of ethanol/water (3:2) under N_2 for 5 h. After filtration of the solution into 80 mL of water containing NH_4PF_6 (0.49 g, 3 mmol) an orange precipitate was obtained, which was filtered and dried overnight. The crude product was dissolved in acetone (10 mL) and

[Ru(*N*,*N*-dps)$_2$(*N*,*S*-c)][PF$_6$]$_2$ (1c): This yellow compound was obtained in the same way as **4a**, starting from [$RuCl_2$(dps)$_2$]·$2H_2O$ (0.195 g, 0.33 mmol) and 2′-pyridyl 2-pyridylmethyl sulfide (0.178 g, 0.882 mmol) Yield 0.226 g (70%). Selected IR data (KBr): $\tilde{\nu}$ = 1610 ms, 1588 s, 1571 s, 1561 ms, 1284 s, 1165 s, 1130 ms, 1089 ms, 878 s, 845 br, 769 vs, 741 s, 727 ms, 558 vs, 528 ms cm^{-1}. $^{13}C\{^1H\}$ NMR ([D_6]acetone, 298 K): δ = 45.9 (CH_2), 123.6 (C^5_c), 124.0, 125.4, 126.0, 126.7 (4 C^5_{dps}), 127.2 (C^5_c), 127.5 (C^3_c), 128.7, 128.8, 129.6, 130.2 (4 C^3_{dps}), 130.4 (C^3_c), 138.4 (C^4_c), 138.6, 139.3, 139.7, 140.0 (4 C^4_{dps}), 140.4 (C^4_c), 150.1 (C^6_c), 153.8 (C^2_c), 156.6 (C^2_{dps}), 157.1 (C^6_c), 157.1 (C^6_{dps}), 157.5 (C^2_{dps}), 157.9 (C^6_{dps}), 158.1 (C^2_{dps}), 158.4, 158.7 (2 C^6_{dps}), 159.2 (C^2_{dps}), 165.0 (C^2_c). $C_{31}H_{26}F_{12}N_6P_2RuS_3$ (969.77): calcd. C 38.40, H 2.70, N 8.67, S 9.92; found C 38.35, H 2.80, N 8.60, S 9.90. Conductivity: Λ_M (MeCN, 2×10^{-4} mol·dm^{-3}, 25 °C) = 327 S·cm^2·mol^{-1}.

Single-Crystal X-ray Diffraction Study of 1c: Suitable crystals of complex **1c** were obtained by slow evaporation of solvent from a diethyl ether/acetone (1:1) solution. Diffraction data were collected with a Siemens P4 automatic four-circle diffractometer. Lattice parameters were obtained from least-squares refinement of the setting angles of 42 reflections within the 2θ range 6−30°. A summary of the crystallographic data and the structure refinement is reported in Table 5. Monitoring of three standard reflection measurements evidenced no crystal deterioration. The reflection intensities were evaluated by a learnt-profile procedure[27] among 2θ shells and then corrected for Lorentz-polarization effects. Absorption correction was applied by fitting a pseudo-ellipsoid to the azimuthal scan data (0−360% range by a 10% step) of 15 high χ reflections.[28] Data collection and reduction were performed with the XSCANS[29] and SHELXTL[30] package. The structure was solved by a combination of standard Direct Methods[31] and Fourier synthesis, and refined by minimising the function $\Sigma w(F_o^2 - F_c^2)^2$ with the full-matrix least-squares technique based on all independent *F*, using SHELXL-97.[32] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in the model refinement with the "riding

Table 5. Crystallographic data for **1c**·C_3H_6O

Empirical formula	$[C_{31}H_{26}N_6S_3Ru][PF_6]_2$·$(CH_3)_2CO$
Formula mass	1027.85
Crystal dimensions	0.37 × 0.27 × 0.20 mm
Crystal colour and form	yellow, irregular
Crystal system	monoclinic
Space group	$P2_1/c$ (no. 14)
Unit cell dimensions	a = 11.760(1) Å
	b = 13.792(1) Å
	c = 25.883(2) Å
	β = 90.051(8)°
V	4197.8(6) Å^3
Z	4
F(000)	2064
$\rho_{calcd.}$	1.626 g/cm^3
μ	0.689 mm^{-1}
λ (graphite-monochromated)	0.71073 Å (Mo-K_α)
2θ range	4.3−50°
Data collected (2θ-ω)	8597
Data independent (refined)	7369 (R_{int} = 0.0240)
Data observed	5938 [$I \geq 2\sigma(I)$]
Variables	532
Completeness to 2θ = 50°	0.995
$R1$[a] (observed/refined data)	0.0462/0.0617
$wR2$[b] (observed/refined data)	0.1110/0.1210
GOF[c] (observed/refined data)	1.040/1.040
Max. diff. peak and hole	0.588/−0.547 e·Å^{-3}
Max. and mean shift/esd	0.002/0.001

[a] $R = (\Sigma||F_o| - |F_c||)/\Sigma|F_o|$. [b] $Rw = \{\Sigma[w(F_o^2 - F_c^2)^2]/[\Sigma w(F_o^2)^2]\}^{1/2}$. [c] GOF= $\{\Sigma[w(F_o^2 - F_c^2)^2/(N_{obs.} - N_{var.})]\}^{1/2}$.

model'' method with the X−H bond geometry and isotropic displacement parameter depending on the parent X atom. The co-crystallized acetone molecules and hexafluorophosphate anions show large atomic thermal ellipsoids due to the expected rotational disorder of their spherical moieties. Any attempt to represent the biggest ellipsoids as adjacent atomic partial occupancies was unsuccessful. The final geometrical calculations and drawings were carried out with the PARST program[33] and the XPW utility of the Siemens package, respectively. Selected bond lengths and bond angles are reported in Table 6 while Figure 7 represents the complex cation with its atomic labelling scheme. CCDC-226905 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Zwitterionic Phosphorus Ylide Adducts of Boron-Bridged *ansa*-Zirconocene Complexes as Precatalysts for Olefin Polymerization

Pamela J. Shapiro,*[a] Feilong Jiang,[a] Xiaoping Jin,[a] Brendan Twamley,[a] Jasson T. Patton,[b] and Arnold L. Rheingold[c]

Keywords: Zirconium / Metallocenes / Boron / Ylides / Catalysis

Methylenetriphenylphosphorane was coordinated to the boron of phenylborylidene-bridged bis(cyclopentadienyl)- and bis(2-Me,4-Ph-indenyl)zirconium dichloride to form zwitterionic *ansa*-zirconocene complexes. The cyclopentadienyl complex **2**, when activated with MAO, exhibits remarkable polymerization activity that is more than an order of magnitude greater than that of a related amidoborylidene-bridged complex as well as the commercially important pre-catalyst [Cp′–$SiMe_2$–*N*–*t*Bu]$TiCl_2$ (Cp′ = C_5Me_4). The zwitterionic bis(2-Me,4-Ph-indenyl)zirconium dichloride species is isolated as a mixture of *rac* and *meso* isomers **4**–**6**. The propylene polymerization efficiency of the isomer mixture activated by MAO is greater than that of a related silylene bridged system at 70 and 85 °C; however, the activity of the zwitterionic system decreased with further increase in temperature. The high level of isotactic triads (63.6%) and pentads (52.4%) in the polypropylene formed by **4**–**6** indicates that the *rac* isomer is the most active precatalyst of the mixture. The molecular structures of **2** and the *rac* bis-indenylzirconium isomer **4** and one of the *meso* isomers **5** are described.

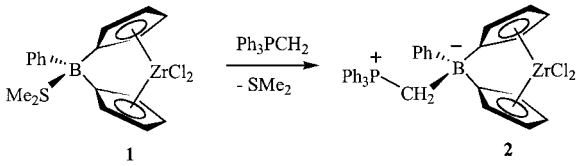
Introduction

Carbon and silicon are the most common constituents of the bridges connecting the two ancillary ligands in *ansa*-metallocene olefin polymerization catalysts. Bridges based on P,[1−4] As,[5] B,[6−12] and B−P[13] are also reported. Unique to these heteroatom bridges is the potential to vary their coordination environment and hybridization while the ligand is attached to the metal.

In developing boron-bridged metallocene complexes,[10−12] one of our objectives is to use the bridging atom as a noncoordinating counteranion for the cationic metal center. Work from our group[10] and from Bochmann's group[14] has demonstrated that, in some cases, the boron bridge coordinates anionic moieties such as Cl^-, CH_3^-, and $C_6F_5^-$ to form stable, isolable salts. The nature of the countercation and the alkyl anion appear to be crucial in these cases because reactions between complex **1** (Equation 1) and alkyllithium, Grignard, dialkylzinc, and alkylaluminum reagents generally lead to decomposition of the complex,[11] presumably as a result of alkyl anion attack at the boron. When we replaced the weakly bound dimethyl sulfide ligand in **1** with more strongly coordinating trimethylphosphane, we were able to alkylate the zirconium center using alkyllithium and Grignard reagents.[15] The trimethylphosphane adduct and the stable borate bridged complexes exhibit ethylene polymerization activity when activated with MAO, but complex **1** does not.[10]



(1)

Since phosphorus ylides have been shown to have a high affinity for Lewis acidic boron centers,[16−18] we introduced Ph_3PCH_2 onto the boron bridge of the *ansa*-zirconocene complex in order to protect the boron bridge from attack by organometallic alkylating reagents and activators such as MAO. The ylide conferred remarkable ethylene polymerization activity to the complex, prompting us to explore the effectiveness of this adduct in related boron-bridged bis(indenyl)zirconium systems in the context of propylene polymerization catalysis.

Results and Discussion

Synthesis and Structural Characterization of $[(Ph_3CH_2)PhB(\eta^5\text{-}C_5H_4)_2ZrCl_2]$

As shown in Equation 1, Ph_3PCH_2 readily displaces the Me_2S adduct on the boron in **1** to form complex **2**. Single crystals of **2** suitable for an X-ray structure determination were grown from dichloromethane solution. The molecular structure is shown in Figure 1, where pertinent bond lengths and angles are also listed. Crystallographic data is listed in Table 1. The most important geometrical parameters of the molecular structure are the angles about the boron bridge and the tilt of the cyclopentadienyl rings on zirconium. The centroid−Zr−centroid angle (120.2°) and dihedral angle between the cyclopentadienyl rings (66°) are within the range of the other boron-bridged dicyclopentadienylzirconium dichloride complexes.[10−12] Boron-bridged complexes exhibit greater distortion than silicon-bridged complexes and less distortion than carbon-bridged complexes relative to $(\eta^5\text{-}C_5H_5)_2ZrCl_2$.[12] The Cp−B−Cp angle of 97.1(4)° is close to that of $[Me(Ph)BCp_2ZrCl_2]^-$ [97.2(4)°],[10] and narrower than that of $[Cl(Ph)BCp_2ZrCl_2]^-$ [99.4(4)°][10] and the neutral complexes {(L)PhBCp$_2$ZrCl$_2$; L = SMe_2 [101.1(2)°], PMe_3 [100.1(3)°]}.[11] This indicates that the Lewis basicity of the ylide is similar to that of a methyl anion. The angle about the ylide carbon P(1)−C(17)−B(1) [121.7(3)°] is similar to that of $Ph_3CH_2B(C_6F_5)_3$ [123.38(10)°].[18] The P(1)−C(17) [1.788(5) Å] and C(17)−B(1) [1.666(7) Å] bond lengths are also similar to those of $Ph_3CH_2B(C_6F_5)_3$ [1.7919(14) Å and 1.675(2) Å, respectively], which has been characterized as a methylene-bridged phosphonium-borate betaine with bond lengths in the range of C(sp^3)−X bonds.[18]

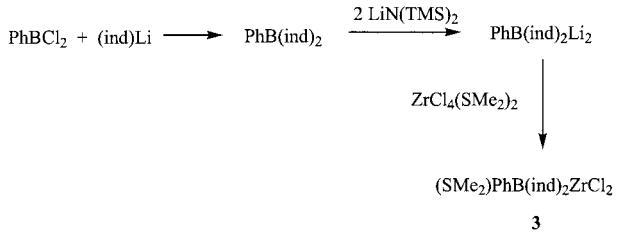
Olefin Polymerization Studies with 2

Complex **2** exhibits exceptionally high ethylene polymerization activity when activated with 1000 equiv. of MAO (Table 2). Although the experiment was run in the presence of 1-octene, the high density of the polymer product (>>0.92 g/mL) indicated that little, if any, octene was incorporated. The polymerization efficiency of precatalyst **2** is more than an order of magnitude greater than that of a related amidoborane-bridged system[6] and the commercially successful precatalyst [Cp′−$SiMe_2$−*N*−*t*Bu]$TiCl_2$[19] (Cp′ = C_5Me_4). Although less impressive, the propylene polymerization efficiency of **2** is comparable with other boron- and silicon-bridged precatalysts.

Bis(indenyl)Zr Analogs of 2

The favorable performance of **2** as a precatalyst for ethylene and propylene polymerization prompted us to examine boron-bridged bis(indenyl)zirconocene complexes for their propylene polymerization activity. A small number of boron-bridged bis(indenyl)zirconium complexes have been reported.[6−9] A couple of these exhibit propylene polymerization activities that are comparable with the most active silicon- and carbon-bridged systems.[6,7] Further, in one case, very high isospecificity from a *rac* isomer was observed.[7]

To prepare indenyl analogs of **2**, we made some minor modifications to the original synthetic approach to phenylborylidene-bridged bis(indenyl)zirconium dichloride reported by Reetz et al.[7] (Scheme 1). With the use of $ZrCl_4(SMe_2)_2$[20] as a starting material, we obtained SMe_2 adducts of the boron-bridged complexes instead of ethyl ether adducts. In general, the SMe_2 adducts reacted more cleanly with the phosphane ylides than the ether adducts and afforded higher yields of our target complexes. Initially, we pursued the synthesis of the simple, unsubstituted bis(indenyl) analog of **2**. The poor solubility of this species in toluene and its poor stability in $CHCl_3$ and CH_2Cl_2 made it difficult to purify. Coordinating solvents such as THF and DMSO were avoided because they competed with the ylide group for coordination to the boron. Furthermore, the ^1H, ^{13}C and 2-D NMR spectra of these complexes were of little use for structure identification because of difficulties with sorting indenyl ring resonances from the overlapping arene resonances of the phenyl rings on the ylide and the boron. We attempted to rectify these problems by replacing Ph_3PCH_2 with Me_3PCH_2. We hoped that Me_3PCH_2 would improve the solubility of the complex, simplify its NMR spectroscopic characterization, and form a more stable adduct with the boron bridge. Unfortunately, the PMe_3CH_2 adduct was even more sensitive to decomposition than the Ph_3PCH_2 adduct, and preliminary screenings of the polymerization activities of the *ansa*-zirconocene complexes indicated that the Ph_3PCH_2 adduct was by far the best candidate.



Scheme 1

The propylene polymerization activity of a sample of the ylide adduct of the boron-bridged bis(indenyl)zirconium complex and the molecular weight of the polymer were promising enough to convince us to modify the indenyl rings in order to form a more soluble system that would be easier to purify. Replacing the indenyl (ind) rings with 2-methyl,4-phenylindenyl[21] (2-Me,4-Ph-ind) rings gave us a ^1H NMR signal from the 2-Me group that was useful for evaluating the number and ratio of the three *ansa*-zirconocene diastereomers **4**−**6** (Figure 2) that constituted the product.

The ligand (2-Me,4-Ph-ind)$_2$BPh was prepared in a manner similar to Reetz's (ind)$_2$BPh.[7] In Reetz's synthesis, (ind)$_2$BPh was treated with the base P(*i*Pr)$_3$ in order to promote double bond isomerization within the indenyl rings and convert the bridgehead carbon atoms attached to boron from sp^3 to sp^2 so as to reduce the amount of boron−carbon bond cleavage during metallation of the ligand. Since this base-treatment step had no apparent effect on the isomer composition of (2-Me,4-Ph-ind)$_2$BPh, it was eliminated from our procedure. In addition, harsher conditions were necessary to doubly deprotonate (2-Me,4-Ph-

ind)$_2$BPh with Li[N(SiMe$_3$)$_2$] (48 h. at 75 °C) than were required for (ind)$_2$BPh. The increased solubility of the *ansa*-zirconocene complexes in hydrocarbon solvents such as benzene and toluene aided in their purification, crystallization, and NMR spectroscopic characterization.

NMR Characterization of Indenyl Complexes 3−6

The presence of two sets of methyl, phenyl, and indenyl resonances in the ^{1}H NMR spectrum of **3** reveals the presence of two isomers in a 2:1 ratio. Judging from the ratio of diastereomers obtained from the synthesis of **4**−**6** (vide infra), the predominant species corresponds to the *meso* isomers, and the less abundant isomer is the *rac* species. The appearance of only once set of signals for the *meso* isomers can probably be attributed to rapid exchange of SMe$_2$ between the diastereotopic sites on the borylidene bridge.[11]

A representative ^{1}H NMR spectrum of a mixture of **4**−**6**, isolated by crystallization from the bulk reaction product, is shown in Figure 3. With the exception of two olefinic resonances above δ = 6 ppm, the region between 6.5−8.1 ppm containing indenyl and arenyl resonances is quite complex. The methyl and methylene regions (2−4 ppm) of the ^{1}H spectrum are the most useful for evaluating the isomer composition of the material. A persistent unidentified impurity with ^{1}H NMR signals upfield of δ = 2 ppm was invariably present in recrystallized samples of the ylide adducts dissolved in CD_2Cl_2. Since the intensity of the peaks due to this impurity increased over time, and the solvent was predried over molecular sieves, we attribute the impurity to decomposition promoted by the solvent.

The ^{31}P spectrum of the mixture shows three distinct resonances, one for each isomer. The ^{31}P signals were correlated with methylene ^{1}H NMR resonances by selective phosphorus decoupling (Figure 4). The diastereotopic protons of the methylene group in the *rac* isomer **4** appear as two doublet of doublets (dd) at δ = 3.9 and 3.3 ppm. Saturation of the ^{31}P signal at δ = 32.2 ppm results in their collapse to two doublets. The other ^{31}P resonances at δ = 31.8 and 33.0 ppm must therefore be assigned to the *meso* isomers **5** and **6**. Notably, only one broad ^{11}B resonance at δ = −5 ppm is observed for the isomer mixture. Assignments of the 2-Me peaks of the indenyl rings were based on their intensities relative to the ylide methylene resonances. One of the two inequivalent methyl resonances of **4** is obscured by the methyl resonance of one of the *meso* isomers. We were not successful in purifying the *rac* isomers of either **3** or **4** from their *meso* isomers; however, we did isolate X-ray quality crystals of isomers **4** and **5**, allowing their molecular structures to be determined (vide infra).

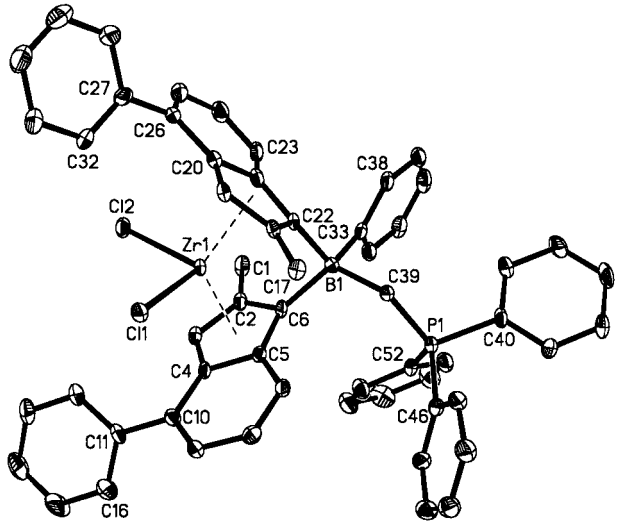

Figure 5. Molecular structure of complex **4**; hydrogen atoms are omitted for clarity

Crystallographic Characterization of Isomers 4 and 5

The molecular structures of **4** and **5** are shown in Figure 5 and Figure 6, respectively. Crystallographic data for both isomers are included with data for **2** in Table 1. Selected bond lengths and angles for **4** and **5** are listed in Table 3 and Table 4, respectively.

There are three other molecular structures of *rac* boron-bridged bis(indenyl)zirconium complexes in the literature: (L)PhB(ind)$_2$ZrCl$_2$ (L = THF, PMe$_3$) published by Reetz,[7] and the structure of *i*Pr$_2$NB(ind)ZrCl$_2$ published by Ashe.[6] Of the four structures, **4** has the smallest angle between the boron and the indenyl bridgehead carbon atoms; 97.6(3)° for **4** vs. 101.5 (L=THF) and 99.4 (L=PMe$_3$) for (L)PhB(Ind)$_2$ZrCl$_2$, and 104.9° for *i*Pr$_2$NB(ind)$_2$ZrCl$_2$. Nevertheless, the centroid−Zr−centroid angle for **4** (123.2°) is slightly larger than those of (L)PhB(Ind)$_2$ZrCl$_2$ (122.3, L=THF; 121.5, L=PMe$_3$), and the dihedral angle between the indenyl ring planes of **4** (65.7°) is slightly smaller than that of *i*Pr$_2$NB(Ind)$_2$ZrCl$_2$ (66.8°). Thus, small changes in the bite angle at boron has little effect on the geometry between the indenyl rings on the zirconium. On the other hand, changing the size of the bridging atom does influence the geometry of the metallocene, with silicon affording a more relaxed structure with a dihedral angle of 62° between the rings and carbon causing a more open structure with an angle of 71° between the ring planes.[12]

The geometric features of the boron-ylide adduct in **4** are very similar to those of **2**, even though chemically, the interaction appears to be weaker in **4**. The bond lengths B(1)−C(39) [1.662(7) Å] and P(1)−C(39) [1.807(5) Å] are very similar to the corresponding distances in **2**, as is the bond angle B(1)−C(39)−P(31) [123.2(4)°].

The molecular structure of **5** is the first structure of a *meso* isomer of a borylidene-bridged bis(indenyl)zirconium complex and is one of very few reported structures of *meso* *ansa*-bis(indenyl)zirconocene complexes of any kind reported in the literature.[22,23] The noticeable influence of the span of the bridge on the tilt of the indenyl rings is evident by comparing the cent−Zr-cent angle and of **5** (123.2°) and the dihedral angle between the ring planes (68.3°) with the corresponding angles of ethandiyl-bridged *meso*-C_2H_4[4,4′-(2,7-dimethylindenyl)$_2$]$ZrCl_2$ (131.8° and 52.9°, respectively).[22] The bond lengths and angles of the boron-ylide portion of the structure are, within statistical error, similar to the values for **2** and **4**.

Polymerization Activity of (Ph_3pch_2)PhB(2-Me,4-Ph-Ind)$_2ZrCl_2$ (4−6) as a Mixture of Isomers

The propylene polymerization activity of the mixture of *meso* and *rac* diastereomers **4**−**6** activated with MAO is compared with that of the silicon-bridged complex *rac*-$SiMe_2$(2-Me,4-Ph-Ind)$_2Zr$(1,4-Ph_2-butadiene)[24,25] (**7**) in Table 5. The activity of the mixture of boron-bridged species is more than twice that of the silicon-bridged complex at 70 °C and 85 °C; however, the activity of **4**−**5** drops substantially at ≥100 °C, while the activity of **7** increases at higher temperatures. The molecular weight of the polymer product starts out higher for **4**−**6** than for **7** and drops with increasing temperature for both systems. The polydispersity indexes are close to 2 for both systems, at least at the lower temperatures of 70 °C and 85 °C, signifying the homogeneity of the active catalyst centers. The narrow polydispersity and relatively high melting temperature of the polymer produced by **4**−**6** suggests that the *rac* isomer **4** is the most active species in the mixture of isomers. Indeed, ^{13}C NMR analysis of the microstructure of the polypropylene product formed by **4**−**6** reveals a 63.6:26.5:9.8 ratio of mm:mr:rr triads and a mmmm pentad composition of 52.4%.

Table 5. Propylene polymerization results for isomer mixture **4**−**6** and **7**

Complex	*T*p (°C)	Efficiency gP/gZr	MW (PDI)	T_m (°C)
4−**6**	70	1081024	373000 (1.96)	156.2
4−**6**	85	1020311	196000 (2.24)	155.3
4−**6**	100	713375	132000 (2.14)	154.5
4−**6**	115	333920	31900 (2.89)	152.7
7	70	450108	513000 (1.80)	158.8
7	85	502987	309000 (2.00)	156.8
7	100	834442	184400 (3.30)	153.7
7	115	900218	79800 (2.81)	153.7

Conclusion

The exceptionally high ethylene polymerization activity of MAO-activated **2** is a result that we do not yet understand. We are currently preparing alkyl derivatives of this system in order to examine their reactivity with various Lewis-acid activators to elucidate the nature of the active catalyst.[26]

Complex **2** is considerably more stable than its indenyl analogs **4**−**6**. Whereas **2** is stable indefinitely in chloroform or dichloromethane solution, the indenyl complexes decompose in these solvents. In addition, the indenyl compounds decompose over weeks in the solid state if they are not refrigerated (−30 °C).

Although at 70 °C and 85 °C the performance of **4**−**6** as precatalysts for propylene polymerization was significantly

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

better than that of a silicon-bridged species used as a benchmark in industry, the poor thermal stability of the boron-bridged system and our inability to isolate the *rac* isomer **4** from the mixture diminishes its utility.

The fairly high percentage of isotactic triads (63.6%) and pentads (52.4%) in the polypropylene formed with **4**−**6** is interesting because it indicates that *rac* isomer **4** is the most active species among the three diastereomers, since it constitutes only about 25% of the mixture. A more dramatic effect of the higher activity of a *rac* isomer on the isotacticity of polypropylene produced by a mixture of *rac* and *meso* *ansa*-zirconocene species has been reported by Collins et al.[22]

Alternative synthetic methods designed to increase selectivity for *rac* isomer **4** were explored, such as the reaction between (Ph)B(2-CH_3-4-Ph-ind)$_2$and $Zr(NMe_2)_4$[27,28] and the reaction of (Ph)B(2-CH_3-4-Ph-ind)$_2Li_2$ with either $Cl_2(PEt_3)_2Zr(\eta^2-1,4\text{-}Ph_2-C_4H_4)$[24,25] or Cl$_2$(THF)Zr[PhN-$(CH_2)_3$NPh];[29] these methods have been used successfully for the *rac*-selective synthesis of other bridged bis(indenyl)-zirconium complexes. Unfortunately, these approaches did not afford isolable *ansa*-zirconocene products.

The preparation of other ylide-like adducts of these boron-bridged *ansa*-zirconocene complexes is currently being explored in order to generate more stable species from which the pure *rac* isomer can be isolated.

Experimental Section

General Remarks: All manipulations were carried out under argon atmosphere using Schlenk and glovebox techniques. Argon and nitrogen were purified by passage over an oxy tower BASF catalyst (Aldrich) and molecular sieves (4 Å). ^{1}H, ^{13}C, ^{11}B, and ^{31}P NMR spectra were recorded on Varian Unit Plus 400 MHz NMR (100 MHz ^{13}C) IBM NR-300 (300 MHz ^{1}H; 75 MHz ^{13}C) and Bruker AVANCE 500 spectrometers (500 MHz ^{1}H; 125 MHz ^{13}C). ^{1}H and ^{13}C spectra were referenced to residual protons in the solvent. ^{11}B and ^{31}P were referenced to external standards (BF_3·OEt_2 and 80% H_3PO_4). Deuterated solvents were dried over molecular sieves (4 Å). $PhBCl_2$ (Aldrich) was used as received. Toluene, benzene, pentane, petroleum ether, and dichloromethane solvents were dried over alumina and stored in line pots over Na/benzophenone or CaH_2 in the case of dichloromethane. $Me_2S(Ph)B(\eta^5\text{-}C_5H_4)_2ZrCl_2$[11] and Ph_3PCH_2[30] were prepared according to literature procedures. 2-Methyl-4-phenylindene was prepared as described in the literature[21] and was also purchased from Boulder Scientific and used as received. Elemental analyses were performed by Desert Analytics (Tuscon, Az).

$Ph_3PCH_2(Ph)B(\eta^5\text{-}C_5H_4)_2ZrCl_2$ (2): Toluene (80 mL) was transferred to a mixture of Ph_3PCH_2 (1.71 g, 6.2 mmol) and **1** (3.30 g, 6.2 mmol) in a flask cooled to −78 °C. The reaction solution was warmed to room temperature and stirred for 18 h to give a grey suspension. The precipitate was isolated by filtration and washed with toluene (30 mL × 2), and dried under vacuum. The resulting yellow-grey solid was redissolved in dichloromethane (20 mL) and layered with pentane. Slow diffusion of the pentane into the dichloromethane caused the precipitation of crystalline product, which was washed with pentane (30 mL × 2) and dried under vacuum (yield: 3.05 g, 75%). ^{1}H NMR (300 K, $CDCl_3$): δ = 7.57 (m, 3 H, C_6H_5), 7.38 (m, 14 H, C_6H_5), 6.97 (m, 3 H, C_6H_5), 6.60 (m, 4 H, C_5H_4), 5.51 (m, 4 H, C_5H_4), 2.67 (d, $^2J_{PH}$ = 16.5 Hz, 2 H, PCH_2) ppm. ^{13}C{^{1}H} NMR (300 K, $CDCl_3$): δ = 135, 133.3 (BC_6H_5), 133.4, 133.3, 129.2, 129.1 (PC_6H_5), 127.112, 125.0, 124.8 (C_5H_4), 122.9 (d, $^1J_{P,C}$ = 84 Hz, PCH_2) ppm. ^{31}P{^{1}H} NMR (300 K, $CDCl_3$): δ = 37.1 ppm. ^{11}B NMR (300 K, $CDCl_3$): δ = −9.1 ppm. $C_{35}H_{30}BCl_2PZr$ (654.5): calcd. C 64.22, H 4.62; found C 64.03, H 4.71.

(Ph)(2-CH_3-4-Ph-ind)$_2$B: $PhBCl_2$ (1.3 mL, 1.58 g, 10 mmol) was added to a solution of (2-Me,4-Ph-ind)Li (4.2 g, 20 mmol) in Et_2O (70 mL) at −78 °C. The reaction mixture turned from red to yellow as it warmed to room temperature. After stirring for 15 h, the reaction was filtered, and the filtrate was dried under vacuum, to give a yellow solid that consisted of (Ph)(2-CH_3-4-Ph-ind)$_2$B as a mixture of double bond isomers complexed by 0.5 equiv. Et_2O (yield: 4.8 g, 91%). ^{1}H NMR (300 K, C_6D_6): δ = 7.60−7.50 (m, 6 H, C_6H_5), 7.30−7.01 (m, 30 H, C_6H_5 + PhC_6H_3), 6.50 (d, PhC_6H_3), 4.18, 4.11(s, 2 H, MeC_5H_2), 3.01 (m, 2 H, Et_2O), 1.84, 1.81, 1.73 (s, 6 H, CH_3), 0.90 (3 H, Et_2O) ppm.

(Ph)B(2-CH_3-4-Ph-Ind)$_2Li_2$: Lithium bis(trimethylsilyl)amide (2.88 g, 17.20 mmol) was added to a solution of (Ph)B(2-CH_3-4-Ph-ind)$_2$ (4.20 g, 7.93 mmol) in toluene (150 mL) cooled to −78 °C. The reaction mixture was allowed to warm to room temperature and then heated at 75 °C with stirring for 48 h to give a suspension. The precipitate was isolated by filtration and washed with toluene (30 mL × 2) and petroleum ether (50 mL), and dried under vacuum, to give a grey-orange solid (yield: 2.30 g, 54%). ^{1}H NMR (300 K, [D$_6$]DMSO): δ = 7.73 (d, $^3J_{H,H}$ = 7.4 Hz, 6 H, C_6H_5), 7.34 (t, $^3J_{H,H}$ = 7.5 Hz, 9 H, C_6H_5), 7.13 (t, $^3J_{H,H}$ = 7.0 Hz, 2 H, indenyl), 6.78 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, 6.29 (m, 2 H, indenyl), 6.06 (m, 2 H, indenyl), 1.89 (s, 6 H, CH_3) ppm.

$Me_2S(Ph)B(2\text{-}CH_3\text{-}4\text{-}Ph\text{-}ind)_2ZrCl_2$ (3): $Zr(SMe_2)_2Cl_4$ solid (0.98 g, 2.74 mmol) was added to a suspension of (Ph)B(2-CH_3,4-Ph-ind)$_2Li_2$ (1.40 g, 2.74 mmol) in toluene (120 mL) cooled to −78 °C. The mixture was allowed to warm to room temperature and stirred for 18 h. After filtration to remove LiCl, the volatiles were removed from the filtrate under vacuum. The filtrate residue was washed with petroleum ether (30 mL × 2) and dried under vacuum (yield: 1.70 g, 86%). Recrystallization of **3** from benzene/pentane gave a red-brown, crystalline product with the formula **3**·4C_6H_6. ^{1}H NMR (300 K, C_6D_6): minor isomer (*rac*): δ = 7.91 (d, $^3J_{H,H}$ = 7.2 Hz, 6 H, C_6H_5) 6.46, 6.77 (m, 6 H, C_6H_5), 2.11 (s, 6 H, CH_3) ppm; major isomer (*meso*): δ = 7.90 (d, $^3J_{H,H}$ = 7.2 Hz, 6 H, C_6H_5), 6.61 (m, 6 H, C_6H_5), 2.09 (s, 6 H, CH_3) ppm; both isomers: δ = 7.55−7.0 (m, 22 H, indenyl and C_6H_5), 2.24 (s, 12 H, SCH_3) ppm. ^{13}C{^{1}H} NMR (300 K, C_6D_6): δ 140.23, 139.97, 138.82, 137.54, 137.51, 134.30, 133.64, 131.19, 129.81, 128.84, 128.81, 128.76, 128.65, 128.62, 128.58, 128.55, 128.23, 125.49, 125.17, 123.41, 119.06, 117.86, 108.11, 106.89, 104.88, 19.30, 12.29, 19.14, 17.33, 16.45, 16.36. No ^{11}B signal was detected, possibly due to extreme broadening caused by rapid exchange of the Me_2S adduct. $C_{46}H_{41}ZrCl_2B$ (766.8): calcd. C 74.69, H 5.39; found C 74.67, H 5.13.

$Ph_3PCH_2(Ph)B(2\text{-}CH_3\text{-}4\text{-}Ph\text{-}Ind)_2ZrCl_2$ (4−6): Ph_3PCH_2 (511 mg, 1.85 mmol) was added to a solution of **3** (1.21 g, 1.85 mmol) in toluene (120 mL) at −78 °C, and the reaction was warmed to room temperature with stirring. The reaction solution was dark red in color after it was stirred at room temperature for 18 h. After filtration, the volatiles were removed from the filtrate under reduced pressure, and the residue was washed with pentane (50 mL × 2) and dried under vacuum to give a red solid. Recrystallization of the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

red solid from a benzene solution over which pentane was layered afforded red crystals that were suitable for X-ray diffraction studies. The crystals were washed with pentane and dried under vacuum (yield: 795 mg, 46%). ^{1}H NMR (300 K, C_6D_6): all isomers: δ 8.2−8.0 (m, C_6H_5), 7.88 (d, C_6H_5), 7.71 (m, C_6H_5), 7.59 (d, C_6H_5), 7.4−6.5 (large m) ppm; **4**: 3.96 (dd, $^2J_{PH}$ = 17.5, $^2J_{H,H}$ = 15 Hz, 1 H, PCH_2), 2.25 (s, 3 H, CH_3), 2.18 (s, 3 H, CH_3) ppm; **5** and **6**: 3.87 (d, $^2J_{PH}$ = 16.6 Hz, 1 H, PCH_2), 3.49 (d, $^2J_{PH}$ = 16.5 Hz,1 H, PCH_2), 3.30 (dd, $^2J_{PH}$ = 17.5, $^2J_{H,H}$ = 15 Hz, 1 H, PCH_2), 2.52 (s, 3 H, CH_3). 2.26 (s, 3 H, CH_3) ppm. ^{13}C NMR (300 K, C_6D_6): δ = 141.42, 136.48, 133.81, 130.65, 130.04, 129.19, 129.10, 129.19, 128.95, 128.72, 128.45, 128.34, 128.10, 126.98, 125.62, 124.48, 124.44, 123.78, 122.88, 122.06, 121.62, 118.87, 118.48, 108.37, 107.09, 104.89, 102.89, 42.75, 42.64, 21.51, 21.22, 21.04, 20.91 ppm. ^{31}P NMR (300 K, C_6D_6): **4**: δ = 32.21 ppm; **5** and **6**: δ = 31.8, 33.0 ppm. ^{11}B NMR (300 K, C_6D_6): δ = −5 ppm. $C_{57}H_{46}BCl_2PZr$ (934.9): calcd. C 73.23, H 4.96; found C 68.30, H 4.85. Carbon was repeatedly low when reanalyzed. We attribute this to impurities that we were unable to remove from the sample.

Ethylene/Octene Copolymerizations: All feeds were passed through columns of activated alumina and Q-5™ catalyst prior to introduction to the reactor. A stirred 2-L Parr reactor was charged with Isopar-E solvent (about 740 g) and 1-octene comonomer (118 g). Hydrogen was added as a molecular weight control agent by differential pressure expansion from a 75 mL addition tank at 25 psi (2070 kPa). The reactor contents were then heated to the polymerization temperature of 140 °C and saturated with ethylene at 500 psig (3.4 Mpa). The metal complex and activators were mixed as dilute toluene solutions, transferred to a catalyst addition tank and injected into the reactor through a stainless steel transfer line. The polymerization conditions were maintained for 15 minutes with ethylene added on demand to keep the pressure constant. Heat was continually removed from the reaction with an internal cooling coil. The resulting solution was removed from the reactor, quenched with isopropyl alcohol, and stabilized by the addition of a toluene solution (10 mL) containing a hindered phenol antioxidant (approximately 67 mg, Irganox™ 1010 from Ciba Geigy Corporation) and a phosphorus stabilizer (approximately 133 mg, Irgafos™ 168 from Ciba Geigy Corporation). Between polymerization runs, a wash cycle was conducted in which mixed alkanes were added (850 g) to the reactor that was then heated to 150 °C. The reactor was then emptied of the heated solvent immediately prior to a new polymerization run.

Propylene Polymerizations: All feeds were passed though columns of activated alumina and Q-5™ catalyst prior to introduction to the reactor. A stirred 2-L jacketed Autoclave Engineers Zipper-Clave™ reactor was charged with Isopar-E solvent (about 625 g) and propylene (about 150 g). Hydrogen was added as a molecular weight control agent by differential pressure expansion from a 75 mL addition tank (Δ350 kPa). The reactor was heated to 70 °C and allowed to equilibrate. The metal complex and activators were mixed as dilute toluene solutions, transferred to a catalyst addition tank and injected into the reactor through a stainless steel transfer line. Heat was continually removed from the reaction with a cooling coil in the jacket. The resulting mixture was removed from the reactor.

Polymers were recovered by drying for about 20 h in a vacuum oven set at 140 °C. High temperature gel permeation chromatography (GPC) analysis of polymer samples were carried out in 1,2,4-trichlorobenzene at 135 °C on a Waters 150C high temperature instrument. A polystyrene/polyethylene or polypropylene universal calibration was carried out on the isolated polyethylene or polypropylene polymer samples using narrow molecular weight distribution polystyrene standards from Polymer Laboratories.

^{13}C{^{1}H} NMR Analysis of Polypropylene: The solution ^{13}C analysis was performed on a Varian Unit Plus 400 MHz NMR spectrometer. The sample was prepared by heating the polymer (0.4 g) to 150 °C in a mixture of [D_2]tetrachloroethane/orthodichlorobenzene (3.0 g of 50:50 wt. mixture) containing 0.025 M chromium acetylacetonate until homogenized. The data were acquired at 120 °C using continuous ^{1}H decoupling, 4000 transients per data file, and a 0.7 s pulse repetition delay.

X-ray Crystallographic Study: Yellow crystals of **2** obtained by recrystallization from chloroform were sealed in capillaries under N_2. A suitable crystal was selected, and data were collected at 173 K on a Siemens P4/CCD instrument (Mo-*Kα* radiation, λ = 0.71073 Å). Crystals of **4** and **5** obtained by recrystallization from benzene/petroleum ether were covered with a layer of hydrocarbon oil. Suitable crystals of each were selected, attached to glass fibers, and placed in a low-temperature nitrogen stream. Data for both **4** and **5** were collected at 203(2) K on a Bruker/Siemens SMART APEX instrument (Mo-*Kα* radiation, λ = 0.71073 Å) equipped with a Siemens LT-2A low temperature device. Data were measured using omega scans of 0.3° per frame for 10 s, and a half sphere of data was collected. A total of 1471 frames were collected for each crystal with a final resolution of 0.84 Å. The first 50 frames were recollected at the end of data collection to monitor for decay. Cell parameters were retrieved with SMART software and refined with SAINTPlus on all observed reflections (SMART: v. 5.625 and SAINTPlus: v. 6.22, Bruker AXS, Madison, WI). Data reduction and correction for Lorentz polarization and decay were performed using the SAINTPlus software. Absorption corrections were applied to **2**, **4** and **5** with SADABS (SADABS: v. 2.01, Sheldrick, G.M., Bruker AXS Inc., Madison, WI).

All three structures were solved by direct methods and all refined by the least-squares method on F^2 with the SHELXTL program package (SHELXTL v. 5.10, Bruker AXS Inc., Madison, WI). All three structures were solved in the space group $P\bar{1}$ (# 2) by analysis of systematic absences. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were added geometrically and refined with a riding model with their parameters constrained to the parent atom site.

The structure of **2** contains two crystallographically independent molecules along with two molecules of chloroform in the asymmetric unit. The structure of **5** contains large voids in the asymmetric unit (ca. 446 Å^3). An irresolvable mixture of the solvent of crystallization, petroleum ether, occupied these voids. The solvent contribution to the scattering was removed using the SQUEEZE routine in PLATON,[31] and approximately 76 electrons were removed. No decomposition was observed during the collection for any of the crystals.

CCDC-226719 to -226721 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44 1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[26] Note added in proof: Per the suggestion of a referee, we examined an NMR scale reaction between **2** and two molar equivalents of $AlMe_3$ in C_6D_6 in order to determine if MAO is possibly destructive to the complex. One major new species was observed, which we tentatively assign as the dimethylzirconium analog of **2**, along with two minor zirconocene species. Some decomposition was also apparent. There is no evidence of methane production, nor is there any evidence of ylide abstraction from the zirconocene by $AlMe_3$. We verified this by comparing the ^{31}P and ^{1}H NMR spectroscopic data for the reaction with that of a direct reaction between the ylide and $AlMe_3$.

COVER PICTURE

The cover picture shows a stereoselective mononuclear triple-stranded helicate complex. Three chiral binaphthol *N*-oxide derivative ligands are coordinated to a trivalent ytterbium metal atom. This very stable and symmetrical structure was obtained by spontaneous self-assembly. NMR spectroscopy and X-ray crystallography were used for unambiguous characterisation. In the picture, the greenish sphere indicates the ytterbium atom and the larger spheres indicate the oxygen atoms. All those ligands, depicted in different shades to highlight the helical effect, are identical. Details are discussed in the article by M. Capó et al. on p. 3405 ff.

Samarium(II) Iodide Mediated Reductions – Influence of Various Additives

Anders Dahlén[a] and Göran Hilmersson*[a]

Keywords: Samarium / Samarium iodide / Reduction / Additives / Co-solvent

Samarium(II) iodide is a one-electron transfer reagent that has become highly appreciated as a mild and selective reducing agent in recent years. It has been found experimentally that various additives and co-solvents largely control the reactivity of SmI_2. This microreview provides an overview of the current knowledge of the reagent SmI_2 as a reducing agent, in particular with additives that increase its reactivity. The use of various proton sources is covered, as well as the effect of co-solvents. Furthermore, the very powerful reagent mixture SmI_2/H_2O/amine is also described.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Reductions constitute a fundamental class of reactions in synthetic organic chemistry, the most common reducing agents are hydrogen gas in combination with Pd/C or active catalysts, alkali metals and hydrides. However, the chemoselectivity of these reagents is often low, which prevents effective synthesis of new more complex target molecules. It is in this respect that the mild reducing agent SmI_2, introduced by Kagan and co-workers in the late 1970s, is receiving much interest today. Kagan showed that SmI_2 promotes reduction of halides, aldehydes, ketones and carboxylic acids, and reductive eliminations and deoxygenations.[1] Since then, a number of SmI_2-based reductive couplings and sequenced reactions have been developed,[2] and new applications are steadily being discovered. SmI_2 is generally considered a selective single-electron transfer reagent that generates carbon-centred radicals from halides or related species. Therefore, it is particularly useful for ketone-olefin coupling reactions, pinacol coupling reactions and radical addition to alkenes and alkynes. SmI_2 has even begun to appear frequently in natural product and multi-step synthesis.[3] Due to the intense interest in this reagent, SmI_2 is now commercially available as a 0.1 M solution in THF.

Over the years, several reviews have been published on the use of SmI_2 in various reduction and coupling reactions.[4] However, recently there has been considerable progress in the use of SmI_2 as a simple reducing agent. SmI_2 represents an important reagent, but it is often necessary to enhance the reactivity by adding various salts and co-solvents. Due to limited knowledge of the active species in these mixtures, the emphasis in this review is not on the

Anders Dahlén was born in Trollhättan (Sweden) in 1977. He received his M. Sc. degree in 2001. The Diploma work was made at the Department of Chemistry, Göteborg University, with the title "Complexation of Lanthanide(II) iodide using Chiral Polyethers and Studies of the Rates of SmI_2-mediated Reductions". Since 2001, he is a PhD student at the Department of Chemistry at the Göteborg University under the supervision of Associate Professor Göran Hilmersson. His current research interests are mechanistic investigations and development of new synthetic methods mediated by lanthanide(II) reagents.

Göran Hilmersson was born in Alingsås (Sweden) in 1966. He studied chemistry at Göteborg University, and obtained his B. Sc. degree in 1991, followed by his PhD degree in 1996 under the supervision of Professor Per Ahlberg. He was a Research Associate for 14 months at The Scripps Research Institute, La Jolla, CA, USA with Professor Julius Rebek, Jr., a postdoc funded by the Knut and Alice Wallenberg Foundation. In 1997, he returned to Göteborg University as Assistant Professor and in 2000 he became Associate Professor of Organic Chemistry. His research is focused on structure and dynamics of chiral alkali metal complexes used in asymmetric addition reactions and development of lanthanide(II)-mediated reduction reactions.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

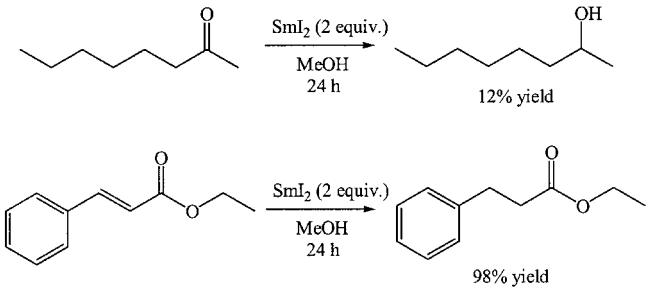
structures, but on the effect of various additives. The possibility to perform coupling reactions catalytically on SmI_2, with the aid of, for example, mischmetal has also been reported. However, this will not be discussed any further since a recent review is available,[5] in addition, the focus here will be on SmI_2-mediated reductions. Our intention is to deliver an updated summary of SmI_2-mediated reductions that may inspire further studies on structures and mechanisms of this highly interesting reducing agent.

Preparation of SmI_2

The compound SmI_2 has been known for more than seventy years,[6] but it did not receive much attention until Kagan and co-workers published their pioneering work.[1] They discovered the mild reducing properties of SmI_2 and a simple method for its preparation. A number of reports of SmI_2 prepared in THF from excess samarium metal and an iodine source, such as diiodoethane, diiodomethane, iodine or iodoform, have been published.[1,7] SmI_2 in THF is often obtained quantitatively as a deep blue solution with a concentration of 0.1 M. If excess iodine is used in the preparation, SmI_3 is formed, and the solution does not reach the intense dark blue, almost black, colour associated with SmI_2. Few reports describe the use of bulk solvents other than THF; however, SmI_2 can be readily produced in tetrahydropyran, acetonitrile, pivalonitrile and DME.[8] Kagan and co-workers concluded that addition of HMPA to SmI_2 in acetonitrile neither enhances the reactivity nor improves the amount of pinacol coupling, and that the maximum concentration of SmI_2 is generally lower in solvents other than THF.[8a] However, a thorough investigation into the reaction rates of various reductions and couplings with SmI_2 in different solvents is unfortunately not yet available.

Addition of Alcohols and Water

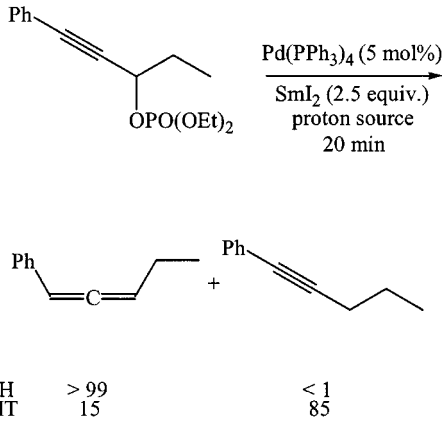
Ever since the introduction of SmI_2 in synthetic applications, it has been realised that various proton sources may be used to alter the product composition. By far the most commonly used alcohols in SmI_2-mediated reductions are methanol and *tert*-butyl alcohol (Scheme 1).[1b,9]



Scheme 1. Reduction of ketones and α,β-unsaturated esters with SmI_2 and methanol

The reductions of α,β-unsaturated esters proceed smoothly with either methanol or *tert*-butyl alcohol, but it appears that both of these alcohols are poor proton donors in the reduction of ketones, thus resulting in low yields.[1b]

The modification of the proton source has been investigated in the reduction of propargylic esters, in which a very high regioselectivity was obtained merely by changing the proton source from *t*BuOH to dimethyl L-tartrate (L-DMT). The allene isomer was obtained with *t*BuOH, while in the case of L-DMT an excess of the acetylene isomer was formed (Scheme 2).[10]



Scheme 2. Reduction of a propargylic ester with *t*BuOH and L-DMT

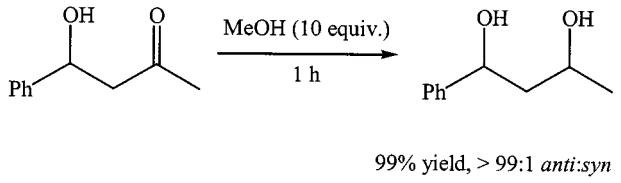
Keck and co-workers have shown that the presence of nearby chelating groups has a remarkable impact on the rates of reduction.[11] They concluded that methanol is the additive of choice to obtain high yields without loss of diastereoselectivity in the reduction of, for example, β-hydroxy ketones (Scheme 3).



Scheme 3. SmI_2/MeOH-mediated reduction of β-hydroxy ketones

Previous studies on solid-state structures of SmI_2, crystallised from ether solutions, have shown that ethers are excellent coordinating groups to SmI_2 (Figure 1).[8c,12]

As chelating ethers are known to coordinate to SmI_2, we wanted to explore the use of alcohols with coordinating groups as alternatives to other simple alcohols. The initial rate of reduction of a ketone (3-heptanone) with various alcohols was investigated, and chelating ether groups on the alcohol were used since they were expected to coordinate to Sm^{II}, thus placing the proton source close to the source of electrons (Figure 2).[13] This should, therefore, produce a strong reducing agent, resembling hydrogen radicals or hydride reagents.

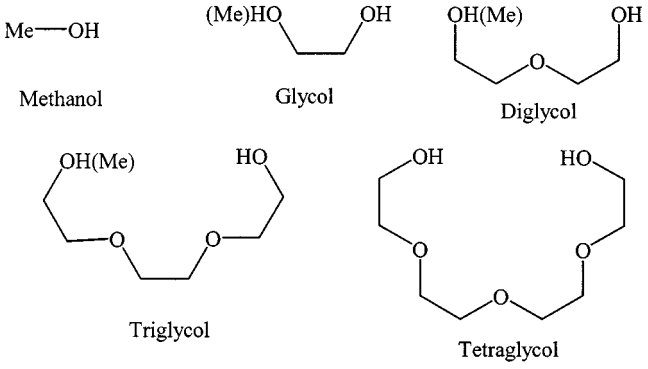


Figure 2. Chelating alcohols/glycols

The introduction of coordinating ether functions to the alcohol revealed a correlation between the rate and the number of coordinating groups. Monomethyl glycols gave higher rates of reduction for each extension of the ethereal group chain. SmI_2/tri(ethylene glycol) monomethyl ether resulted in a rate enhancement of approximately 5 times relative to that of SmI_2/MeOH. Further rate enhancements were noticed when glycols were used; the fastest rate for the glycols appeared to be with di(ethylene glycol) which was more than 70 faster than that with methanol, or 255 times faster than the rate with THF. The significant increase in rate with diglycol suggests that a dimeric transition state is present (Scheme 4). The presence of a primary kinetic isotope effect proved that the rate-limiting step in this reduction is the transfer of at least one proton. It was also shown that full occupancy of the coordination sphere, as with the tetradentate ligand tetra(ethylene glycol), resulted in a decrease in the rate. The coordination plays an important role in SmI_2-mediated reductions.

It has been found that steric hindrance around the substrate also affects the rate of reduction.[14] The less sterically crowded 4-phenyl-2-butanone was reduced approximately 130 times faster than 2-methyl-3-heptanone with the reagent mixture SmI_2/diglycol.

Recently, Flowers and co-workers investigated the role of the acidity constant (pK_a) of the alcohol in the reduction of acetophenone and found a linear correlation for the reaction rate vs. pK_a.[15] The more acidic alcohols resulted in higher reduction rates. However, water did not fit into this correlation, most likely due to unique, unexplained reactivity and complexation properties (Figure 3).[16]

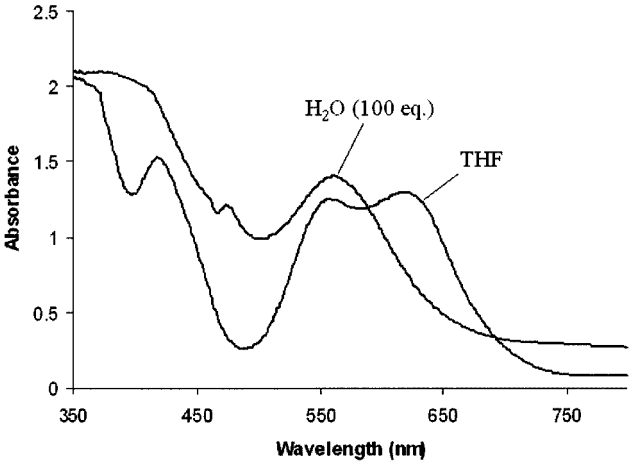

Figure 3. Comparison of SmI_2 in THF and SmI_2 in water

Nakamura and co-workers developed an enantioselective reduction of α-halo- and α-methoxy ketones with C_2-symmetric chiral diols, e.g. (*R*)-2,2′-bis[(*S*)-2-hydroxy-2-phenylethoxy]-1,1′-binaphthyl [(*R*,*S*)-DHPEB].[17] High yields were obtained with up to 94% *ee* within 2 h at −45 °C (Scheme 5). These diols contain four or five coordinating functional groups and, therefore, bind tightly to SmI_2, providing a transition state that facilitates the asymmetric protonation of the enolate.

Alcohols have been the dominating proton sources in SmI_2-mediated reductions, while water, even though it is also a good proton source, has not been employed to the same extent. Some of the previously mentioned studies confirm that the use of water leads to different product compositions and occasionally higher yields.[10,11a] Good to excellent yields were reported in the conversion of aromatic carboxylic acids to alcohols with a SmI_2/H_2O system (Scheme 6).[18]

Kamochi and Kudo have extensively studied the use of Brönsted acids and bases as additives in SmI_2-mediated reduction of carboxylic acids, amides, nitriles, pyridines and phenol derivatives. In particular aromatic compounds were reduced in high yields, and the use of acids and bases in

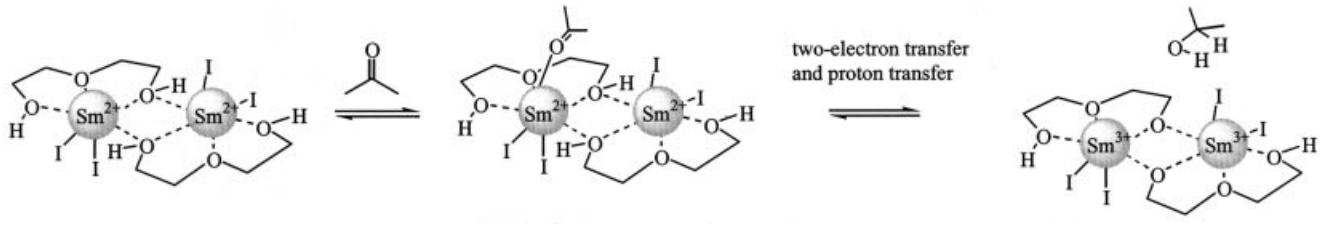
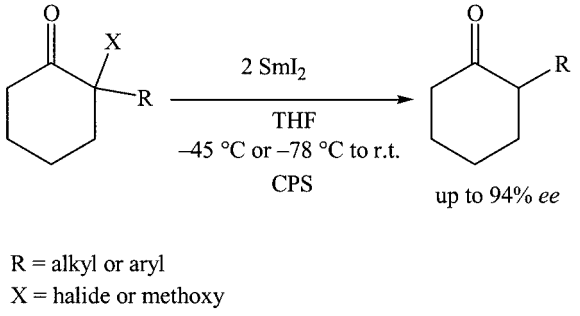
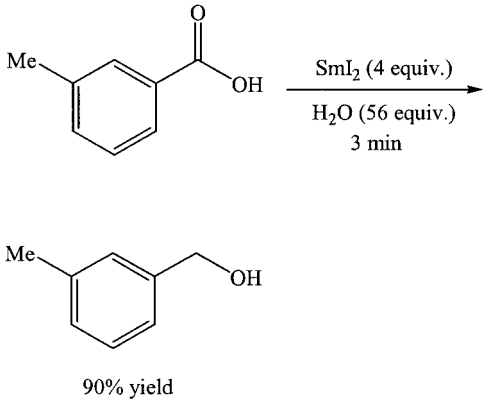


Scheme 4. SmI_2/diglycol-mediated reduction of a ketone



Scheme 5. Enantioselective reduction mediated by a chiral proton source (CPS)

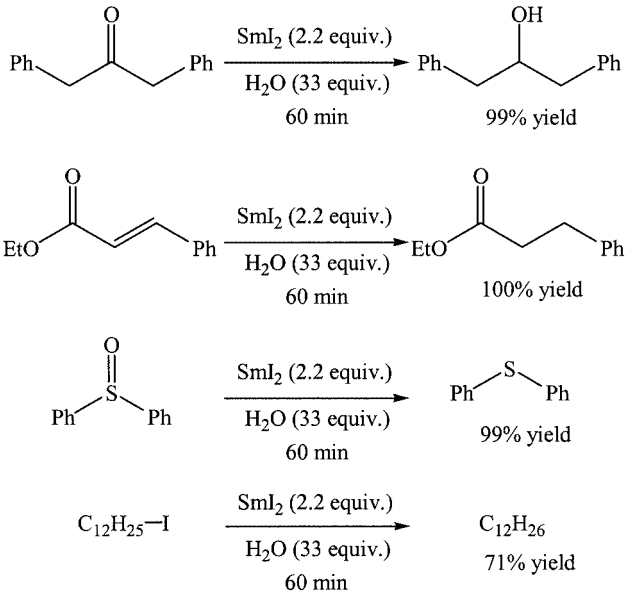


Scheme 6. Reduction of aromatic carboxylic acids with SmI_2/H_2O

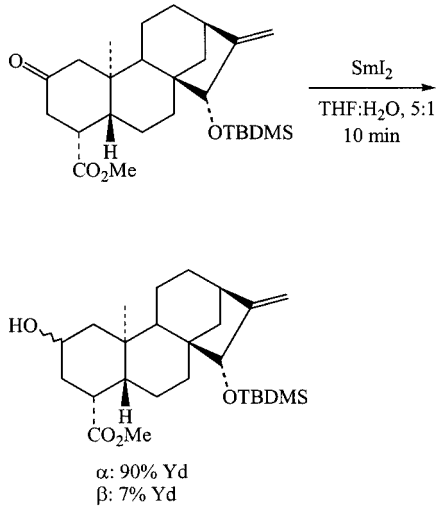
SmI_2-mediated reductions indicates that certain reactions are dependent on pH.[19]

Curran and co-workers reported on the SmI_2-mediated reduction of various functional groups in the presence of water (Scheme 7).[20] The reduction rate of ketones, α,β-unsaturated esters, sulfoxides and alkyl iodides was significantly accelerated by the addition of water. The results indicated that the accelerating role of water may be more intricate than simply acting as a proton donor, i.e. it may both accelerate the reduction by enhancing the reducing power as well as acting as a proton donor.

Only a few examples of high diastereoselectivity have been reported for SmI_2/H_2O-mediated reductions of ketones. One example of such a reduction is a step in the total synthesis of Atractyligenin (Scheme 8), which gave selectivity for the α-isomer.[21]



Scheme 7. Various SmI_2/H_2O-mediated reductions

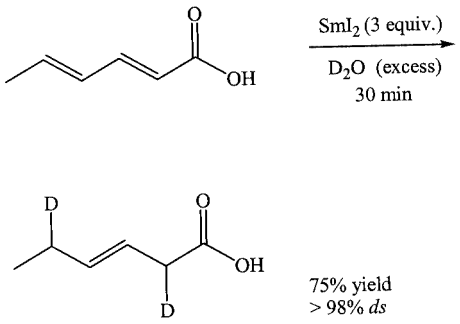


Scheme 8. Diastereoselective reduction of Atractyligenin with SmI_2/H_2O

Selective isotopic labelling with deuterium is an important feature, since it can be used to establish mechanistic pathways. This can be readily accomplished using deuterium oxide instead of water in SmI_2-mediated reductions. Deuterium oxide is one of the most inexpensive available sources of deuterium; in addition, it is a nonhazardous

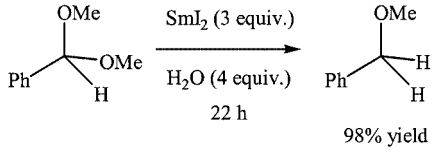
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compound. Dideuterated carboxylic acids have been successfully synthesised from unsaturated acids in high yields and diastereoselectivities (Scheme 9).[22]



Scheme 9. SmI_2/D_2O reduction of unsaturated carboxylic acid

Studer and Curran have reported on the reductive demethoxylation of aromatic dimethylacetals in the presence of SmI_2/H_2O with excellent yields. Comparison was also made with TFA and $BF_3{\cdot}Et_2O$ in this study, which gave pinacol as the major product, while addition of water gave mostly reduction (Scheme 10).[23]

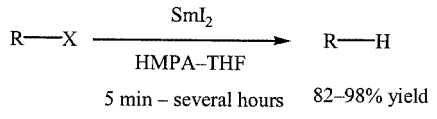


Scheme 10. Reductive demethoxylation with SmI_2/H_2O

SmI_2-HMPA-Mediated Reductions

The Effect of HMPA on Various Simple Reductions

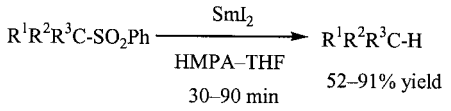
In 1987, Inanaga and co-workers reported that the addition of hexamethylphosphoramide (HMPA) to THF solutions of SmI_2 resulted in a substantial enhancement of the rate of reduction and reductive coupling.[24] Carbon–halogen bonds were effectively and quantitatively reduced to C–H bonds by a mixture of SmI_2-HMPA in THF (Scheme 11). Alkyl, vinyl and aryl halides were rapidly reduced, with approximately 5% HMPA as co-solvent in THF. Upon the addition of HMPA to the SmI_2 solution in THF, the colour changed from blue to purple.



Scheme 11. General SmI_2-HMPA-mediated reduction of alkyl halides

The mixture of SmI_2-HMPA was reported to promote reductive dimerisations of, for example, unsaturated carbonyl compounds.[25] Cabrera and Alper reported that SmI_2-HMPA was also efficient for selective reduction of α,β-unsaturated carbonyl compounds (the compounds investigated were esters, acids, amides and anhydrides).[26]

The reactive SmI_2-HMPA mixture was later proven to be useful for desulfonylation of various phenyl sulfones, as reported by Künzer and co-workers (Scheme 12).[27]



Scheme 12. SmI_2-HMPA-mediated reduction of phenyl sulfones

Fuh and co-workers have studied the kinetics of the SmI_2-mediated reduction of an aliphatic ketone to an alcohol. In the absence of HMPA, the reduction of 2-heptanone to 2-heptanol is very slow, only 28% of the ketone is reduced after 16 days. However, with only one equivalent of HMPA added, the reactions are reported to be complete in less than one hour.[28]

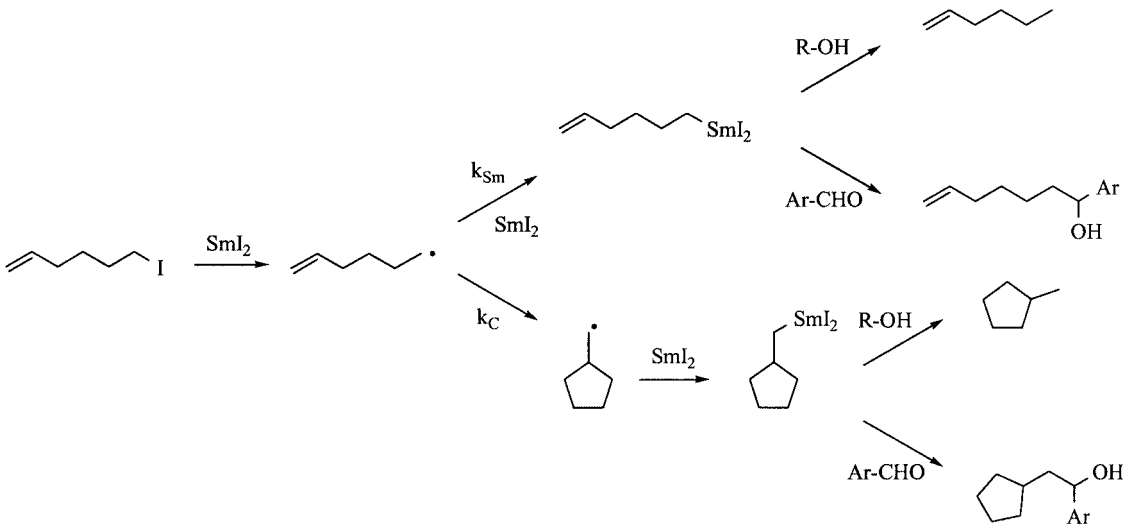
The Structure and Mechanism of the SmI_2-HMPA Reagent

The reduction of a simple functional group with a single electron transfer reagent must involve the formation of a radical intermediate. If there are several functional groups in the compound, there is a chance that this radical rearranges or undergoes an intramolecular reaction. Curran has utilised the radical clock technique to investigate the kinetics of reductions in the presence of HMPA.[29] The amount of directly reduced product was observed to increase upon addition of HMPA. They also predicted the presence of an alkylsamarium intermediate, which could either be coupled with an aldehyde or reduced in the presence of an alcohol, directly or through rearrangement, depending on the ratio of the rate constants k_{Sm}/k_C (Scheme 13).

It was not until Hou and Wakatsuki reported on the solid-state structure of $SmI_2(HMPA)_4$ that mechanistic details for the increased reactivity of the SmI_2-HMPA mixture could be rationalised (Figure 4).[30] The square-planar arrangement with four HMPA molecules coordinating to Sm^{II} could be the key for the selectivity of these reactions. The substrates can either approach the metal centre from above or below.

Interestingly, when 10 equivalents of HMPA were added to the SmI_2 solution, purple crystals of $Sm(HMPA)_6I_2$ were formed.[31] It was suggested that the six bulky HMPA molecules, coordinated to the samarium centre, block the approaching substrate, thereby giving rise to a lowering of selectivity through an outer-sphere mechanism. Flowers and co-workers reported, based on linear sweep voltammetric studies,[32] that the oxidation potential of SmI_2 in THF increases from −1.33 V to −2.05 V (vs. $Ag/AgNO_3$ in THF) when four equivalents of HMPA was added. Further addition of HMPA did not affect the oxidation potential. They also determined the standard potentials $E°(SmI_2^+/SmI_2)$ and $E°(SmI_2^+$-HMPA/SmI_2-HMPA) in THF to be -0.98 ± 0.04 and -1.75 ± 0.06 V vs. SCE, respectively.[33] Accordingly, the change in reducing power for SmI_2 upon

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 13. Suggested pathways of the alkylsamarium intermediate

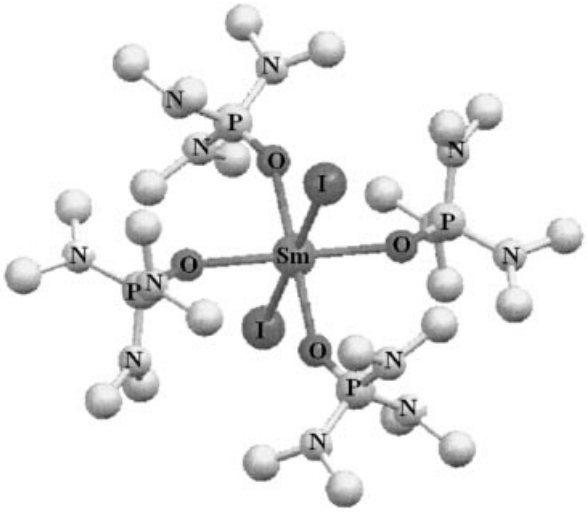


Figure 4. Ball-and-stick representation of the solid-state structure of $SmI_2(HMPA)_4$; hydrogen atoms have been omitted

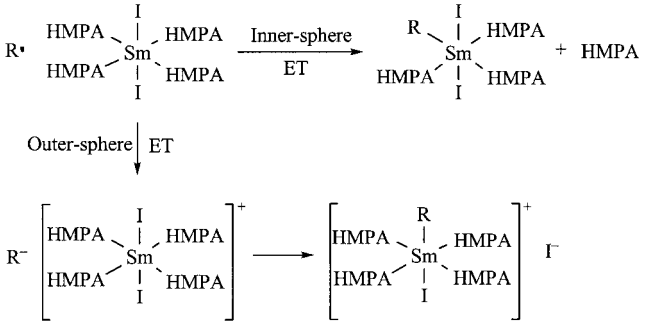
addition of HMPA was 0.8 V (corresponding to a decrease in free energy of 18 kcal mol^{-1}). Skrydstrup and co-workers also determined the standard potential $E°$ of SmI_2^+/SmI_2 by cyclic voltammetry, which was -1.41 ± 0.08 V vs. Fe^+/Fe.[34]

Further work on the SmI_2-HMPA reagent proved, by vapour pressure osmometry (VPO), that SmI_2 is a monomer in HMPA-THF.[35] Based on UV/Vis studies it was also concluded that there are four HMPA molecules coordinated to SmI_2 in solution. Moreover, the strength of the bonds between Sm and O in SmI_2-HMPA was investigated by detailed VPO analysis. It was concluded that the fourth HMPA molecule is not very tightly bonded, indicating that some reduction may occur through an inner-sphere electron transfer after dissociation of one HMPA molecule (Scheme 14).



Scheme 14. Inner- and outer-sphere mechanistic pathways

Addition of HMPA to SmI_2 in THF was reported by Daasbjerg and co-workers to result in a strong increase in conductivity, which strongly indicates that HMPA induces ionic cluster formation.[36] In addition, cyclic voltammetry, conductivity measurements, UV spectroscopy and kinetic measurements were performed. The equilibria shown in Equation (1) and Equation (2) are suggested.

$$Sm(THF)_5I_2 + 4\ HMPA \rightleftharpoons [Sm(HMPA)_4(THF)_2]^{2+}\ 2I^- + 3\ THF \quad (1)$$

$$[Sm(HMPA)_4(THF)_2]^{2+}\ 2I^- + 2\ HMPA \rightleftharpoons [Sm(HMPA)_6]^{2+}\ 2I^- + 2\ THF \quad (2)$$

With four equivalents of HMPA, almost all Sm^{2+} exists in the complex $[Sm(HMPA)_4(THF)_2]^{2+}2I^-$, while approximately 10 equivalents of HMPA are necessary to drive the equilibrium towards $[Sm(HMPA)_6]^{2+}2I^-$. The redox couple

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[Sm(HMPA)_4(THF)_2]^{3+}2I^-/[Sm(HMPA)_4(THF)_2]^{2+}2I^-$ was determined to be -1.79 ± 0.08 V vs. SCE (or 0.9 V larger than that of Sm^{3+}/Sm^{2+} in THF). The degree of outer-sphere character of the reduction of alkyl halides is smallest for chlorides and increases with increasing atomic number (Cl < Br < I). Altogether, the rate of reduction was observed to increase by a factor of up to 15 000 with four equivalents of HMPA per SmI_2 in THF.

The knowledge of Sm^{II}-HMPA complexes was expanded with additional kinetic and mechanistic studies by Flowers and co-workers.[37] The reduction of a series of halides and ketones were investigated again, and it was suggested that the halides are reduced by $[Sm(HMPA)_4(THF)_2]I_2$ through an outer-sphere electron transfer, while the ketones are reduced by $[Sm(HMPA)_4(THF)_2]I_2$ through an inner-sphere electron transfer. The activation parameters for ketone reductions were almost identical using either $[Sm(HMPA)_4(THF)_2]I_2$ or $[Sm(HMPA)_6]I_2$, indicating that the reduction proceeds via the same or a similar transition state regardless of the amount of HMPA.

Other Co-Solvents

The addition of HMPA to SmI_2 has been found to give a very reactive, yet selective, reducing agent. However, its toxicity has encouraged several research groups to search for viable nontoxic co-solvents or additives as replacements for HMPA. Hasegawa and Curran reported that DMPU (1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone) could be used as an alternative to HMPA (Figure 5).[20] However, in order to obtain similar results they had to use acetonitrile as solvent instead of THF, as the effect of DMPU was too small. Later, Flowers and co-workers studied the reducing power of SmI_2 in THF in the presence of various additives, for example, trimethyl phosphate (TMP), pentamethylphosphoramidate (PMP) and DMPU.[38] It was necessary to use a large excess (30 equiv.) of DMPU to attain the maximum increase of 0.9 V in the oxidation potential. It was also found that the reduction potential for SmI_2-DMPU in acetonitrile was between that of SmI_2 in THF and that of SmI_2-HMPA in THF.[39] Cabri and co-workers reported promising results using nitrogen additives [Et_3N, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) or 1,1,3,3-tetramethylguanidine (TMG)] in a SmI_2-mediated cyclisation reaction.[40]

Addition of Metal Salts and Other Counterions

Beside the extensive use of co-solvents and various proton donors, a few reports also describe the addition of metal salts and the use of different counterions. However, these methods often provide coupling in the absence of a proton source.

Flowers and co-workers reported on the addition of LiBr and LiCl to SmI_2. A large rate enhancement was observed in the pinacol coupling of cyclohexanone when adding LiBr or LiCl. Undried salts resulted in reduction of the ketone

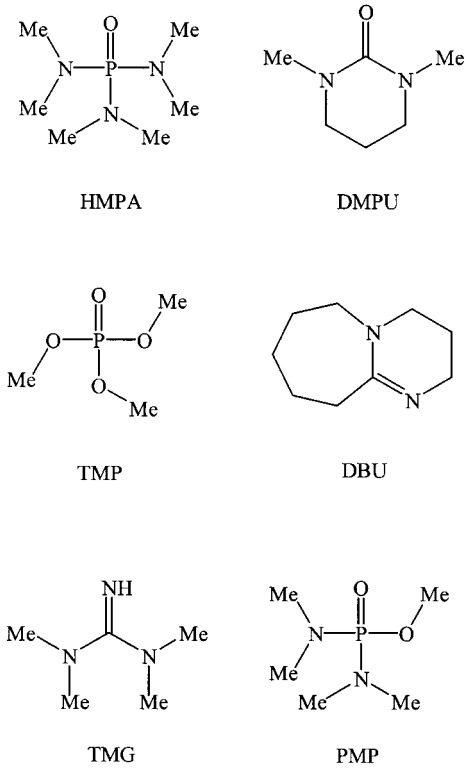


Figure 5. Various co-solvents

to the corresponding alcohol.[41] An extended study of the SmI_2/LiBr mixture showed that the redox potential had increased to -2.07 V vs. $Ag/AgNO_3$ (relative to SmI_2 with a redox potential of -1.58 V).[42] This suggests that $SmBr_2$ and LiI are formed, since $SmBr_2$ is known to be a stronger reductant than SmI_2. Addition of HMPA to the mixture of SmI_2 and LiBr made led to a more powerful mixture with a redox potential of -2.63 V vs. $Ag/AgNO_3$ and, as expected, a significant rate enhancement was observed in the reduction of various functional groups. Samarium(II) bromide is also readily prepared from Sm metal and tetrabromoethane, as recently reported by Namy and co-workers.[43] They used the black suspension of $SmBr_2$ in THF in combination with mischmetal in various pinacol couplings of ketones.

Another fascinating counterion for Sm^{II} is the silylamide. Samarium(II) disilylamide [$Sm(HMDS)_2$] has been prepared from sodium hexamethyldisilazane (Na-HMDS) and SmI_2 (Scheme 15).[44]

The samarium disilylamide has a redox potential of -2.1 V vs. $Ag/AgNO_3$, and is thus a stronger alternative to SmI_2. In addition, the $Sm(HMDS)_2$ provides a somewhat higher rate of reaction than $[Sm(HMPA)_6]I_2$, is less carcinogenic and has better solubility properties than SmI_2, especially in solvents other than THF.[45] However, this reagent has so far not seen any widespread use. The solid-state structure of $Sm(HMDS)_2$ has the shape of a distorted tetrahedron (Figure 6).[44]

Addition of catalytic amounts (1%) of, for example, $ZrCl_4$, VCl_3 and NiI_2 to SmI_2 have been reported to improve the reaction rates to the extent that HMPA can be

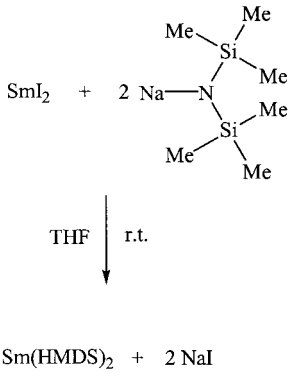

Scheme 15. Preparation of $Sm(HMDS)_2$ from SmI_2 and Na-HMDS in THF

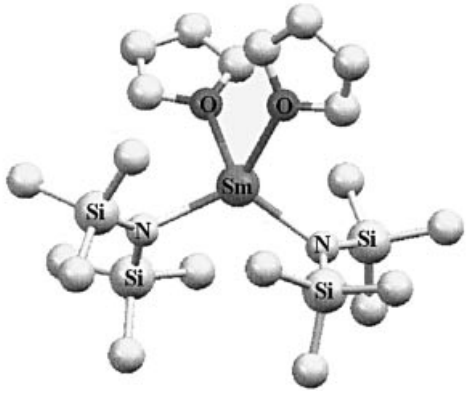

Figure 6. Ball-and-stick representation of the solid-state structure of $Sm(HMDS)_2$; hydrogen atoms have been omitted

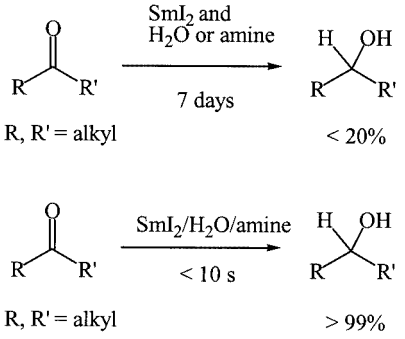
avoided in several reactions.[46] Especially, reduction of epoxides to alkenes is considerably accelerated with NiI_2 (the reaction time is 20 minutes, while the uncatalysed reaction requires 12 h). Furthermore, reduction of dodecyl phenyl sulfone to dodecane occurs in good yield after 2 h at reflux. Several couplings and reductions are completed in less than 30 minutes. In addition, hetero couplings between ketones and imines are obtained in high yields by the SmI_2/NiI_2 mixture within five minutes.[47] However, the details regarding the high reactivity of this catalytic system is not yet available preventing full utilisation of this interesting additive.

SmI_2/H_2O/Amine-Mediated Reductions

With the aim of finding a nontoxic replacement for HMPA in SmI_2-mediated reductions, a number of ligands were screened in a simple reduction of a ketone, in combination with methanol or water as proton source. The rate of reduction was not affected by mono or polyethers. However, addition of triethylamine and water had a dramatic effect on the reduction rate.[48] Other amines (e.g. TMEDA and PMDTA) were employed in the reduction and showed similar results. With one or two equivalents of amine, there is a very fast initial reduction, but the reaction stops with a low chemical yield. This reaction requires water as a proton source, while methanol can be used, it is considerably less powerful. Incremental addition of amine and water proved that the reduction of ketones requires two equivalents of SmI_2, four equivalents of amine and six equivalents of water in order to obtain a quantitative yield of the alcohol. The product in the reaction is often very simple to purify since all water, amine, samarium and iodide precipitates as $Sm(OH)_3$ and $R_3N{\cdot}HI$. The by-products can be removed by filtration, which leaves the THF solution of the reduced alcohol. The balanced reduction reaction is given in Equation (3).

$$R_2C{=}O + 2\,SmI_2 + 6\,H_2O + 4\,R_3N \rightleftharpoons R_2CHOH + 2\,Sm(OH)_3 + 4\,R_3N{\cdot}HI \quad (3)$$

The combination of SmI_2, amine and water gives significantly increased rates of reduction relative to the commonly used SmI_2-HMPA mixtures. The rates of reduction of ketones using the combination of water and amine is more than 100 000 times higher than those without proton sources (Scheme 16).[48] Recently, we showed that this instantaneous and quantitative reduction of ketones also constitutes a simple and accurate quantitative determination of [SmI_2], [$SmBr_2$] and [YbI_2].[7f]



Scheme 16. The rate of reduction of ketones mediated by SmI_2/H_2O/amine is more than 100 000 times faster than with SmI_2 and H_2O or amine

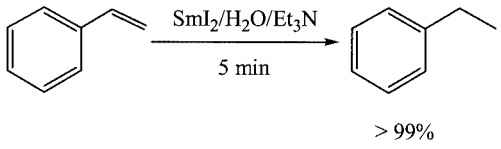
During our continuing study on the reactivity of the SmI_2/H_2O/amine mixtures, we observed that not only ketones but also imines and α,β-unsaturated esters were reduced instantaneously, i.e. reactions were complete in less than 10 seconds.[14] The SmI_2/H_2O/amine mixture is particularly useful for the reductive imino-pinacol coupling of hindered imines and iminium perchlorates, since these are difficult to couple by other methods.[49]

UV/Vis studies have revealed that water is a very good ligand for samarium(II), i.e. it readily replaces THF. The amine Et_3N, however, does not compete with the bulk THF for coordination to samarium. Unfortunately, the reduction

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

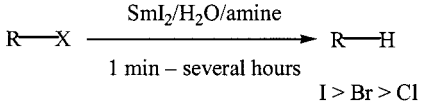
of ketones with SmI_2/H_2O/amine is too fast for kinetic investigations. Phosphor ligands, on the other hand, also form hydrohalide salts. We found that the reductions of ketones indeed are accelerated using a phosphorus ligand, i.e. $Me_2PCH_2CH_2PMe_2$. Since the rate of reduction using this ligand was much lower, we could determine that there is a kinetic isotope effect, $k^{H2O}/k^{D2O} = 4.5$, indicating a rate determining hydrogen-transfer in the reduction of ketones. The driving force for the reaction has been suggested to be the precipitation of the by-products.[14]

When conjugated double and triple bonds were found to be rapidly reduced to simple alkenes or alkanes, it was concluded that the SmI_2/H_2O/amine mixture is a very powerful reductant (Scheme 17).[50]



Scheme 17. Reduction of conjugated olefins

The reagent mixture SmI_2/H_2O/amine is also superior for the reduction of halides relative to various other additives (Scheme 18). The reduction of bromides, which takes hours with SmI_2-HMPA, proceeds in minutes with SmI_2/H_2O/amine. Alkyl and aryl iodides are reduced in less than one minute with SmI_2/H_2O/amine.[51]

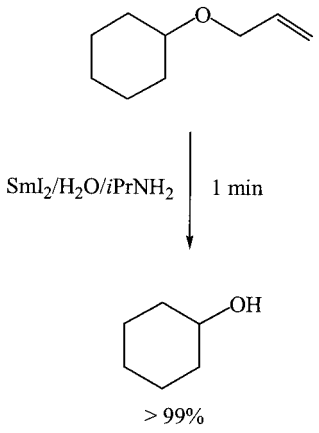


Scheme 18. Reduction of alkyl and aryl halides mediated by SmI_2/H_2O/amine

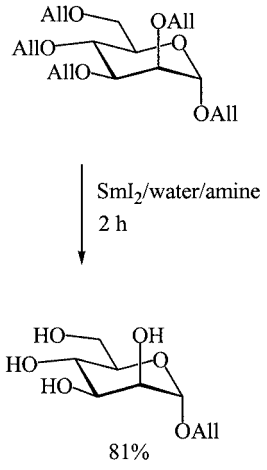
Kinetic studies have proven that there is a first-order dependence on amine, indicating that the amine is part of the rate-limiting step of the reduction. There is no observed kinetic isotope effect on addition of water. Electrochemical investigations were also carried out on the SmI_2/H_2O/amine mixture. The addition of only amine had no effect on the oxidation potential. Addition of both water and amine to a THF solution of SmI_2 resulted in an irreversible oxidation, and the redox potential could not be determined. The oxidized Sm^{3+} precipitates rapidly from the solution, preventing the measurement of the redox potential of the Sm^{2+}/Sm^{3+} couple.[51]

Recently, we discovered that SmI_2/H_2O/amine mixtures also mediate deallylation reactions (Scheme 19).[52]

This novel deprotection reaction was employed in the cleavage of various allyl ether-protected carbohydrates. The high yields observed with this method makes it particularly useful for the simultaneous deprotection of several allyl groups. There is an unusual chemoselectivity for deprotection. The allyl group on the anomeric carbon does not undergo any deprotection when SmI_2/H_2O/amine is used (Scheme 20), while the other allyl groups are rapidly deprotected.



Scheme 19. Allyl ether cleavage



Scheme 20. Selective deallylation of allylmannoside with SmI_2/water/amine

The use of SmI_2/H_2O/amine is particularly advantageous for reductions, since it does not react violently with moisture or oxygen, in strong contrast to most other strong reducing agents, for example alkali metals, hydrogen gas or different hydrides.

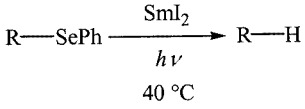
Photoinduced Reduction System

The very reactive $SmI_2/h\nu$ system developed by Ogawa and co-workers deserves to be mentioned in this review even though it is not strictly an additive. Ogawa and coworkers discovered in 1997 that alkyl halides, and in particular chlorides that are generally difficult to reduce with SmI_2 (even with SmI_2-HMPA), are efficiently reduced by SmI_2 in THF upon irradiation with visible light ($700 > h\nu > 300$ nm).[53] Irradiation with light of higher or lower wavelengths has no effect on the reactions. Interestingly, the optimum wavelength is similar to the absorption maxima for SmI_2 in THF at 565 and 617 nm, respectively, indicating that SmI_2 is activated by light irradiation.

Additionally, it was found that $SmI_2/h\nu$ also gives excellent results for the cleavage of C−Se, C−Te and C−OTs

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bonds (Scheme 21).[54] Organic selenides cannot be reduced by SmI_2-HMPA.



Scheme 21. Photoinduced reduction of selenides by SmI_2 in the presence of visible light

Conclusion

Herein we have summarised that the reactivity of SmI_2 can be significantly adjusted using various additives and or co-solvents. The addition of various additives to SmI_2 clearly gives the working chemist tools to modify and control the reducing properties, which is important for selective reduction of one particular group of several similar groups within the same substrate. SmI_2 is beginning to be appreciated as a mild and selective reducing agent in synthetic organic chemistry, but the reaction mechanisms through which the addition of various additives and co-solvents act are far from understood. The current mechanistic knowledge is mainly based on the initial suggestion made by Kagan some 25 years ago, and since then only small achievements have been reported. New applications for SmI_2 and for other lanthanide(II) reagents will most likely emerge from detailed structural and mechanistic studies of SmI_2 and other lanthanide(II) reagents. SmI_2 is attractive as a general reducing agent, since it is considered nontoxic and its handling procedures are nonhazardous, in contrast to most other reducing agents.

Self-Assembly of Stereoselective, Mononuclear, Triple-Stranded Helicate Complexes ML_3 with Trivalent Scandium and Lanthanide Metal Ions – Quantitative Transmetallation of the Lanthanide(III) Ion by Sodium(I) Ions

Magdalena Capó,*[a] José Gonzalez,[a] and Harry Adams[b]

Keywords: Helical structures / Lanthanides / Self-assembly / Stereoselective / Transmetallation

Mononuclear triple-stranded helicate complexes ML_3 (M = Sc^{3+}, La^{3+}, Sm^{3+}, Yb^{3+}) were self-assembled and structurally characterized by NMR spectroscopy and high-resolution mass spectrometry. The solid-state structure of the ytterbium complex was determined by X-ray crystallography. The core lanthanide metal ion was replaced quantitatively by three sodium ions. Homo- and heterotrinuclear complexes containing the alkali metal ions Li^+ and Na^+ were obtained from the mononuclear lanthanide complexes.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

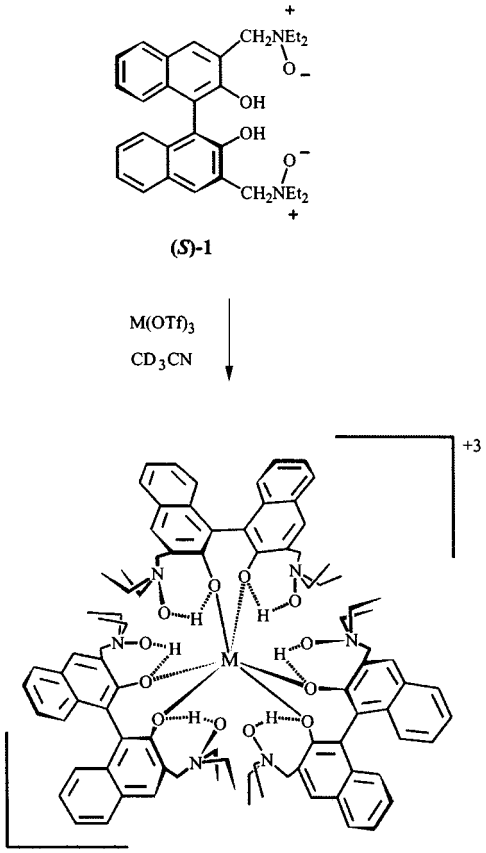
Helicate derivatives by self-assembly of multidentate organic ligands and metal ions have been a subject of current interest during the last two decades.[1] A tetradentate chiral ligand unit **1**[2] has been designed that self-assembles with lanthanide ions of different sizes to yield mononuclear triple-stranded helicates. The chiral ligand **1** in solution is able to form trinuclear helicates by self-assembly in the presence of sodium or lithium triflates[3] and mononuclear helicates in the presence of trivalent scandium or lanthanide triflates.

Here we report the formation of four stereoselective triple helices obtained quantitatively from the enantiomerically pure ligand (*S*)-**1**[4] and $M(OTf)_3$ (Scheme 1). The stoichiometry of the complexes has been determined by NMR titration experiments and mass spectrometry.

Results and Discussion

Treatment of $Sc(OTf)_3$ in acetonitrile with racemic or enantiopure (*S*)-**1** in the ratio 1:3 led to the formation of a single highly symmetrical metal complex, as demonstrated by the ^1H NMR spectrum, which contains a single set of resonances[5] (Figure 1).

A ^{45}Sc NMR spectrum was recorded to study the interaction between the ligand and the scandium ion. After



2 M = Sc^{+3}
3 M = La^{+3}
4 M = Sm^{+3}
5 M = Yb^{+3}

addition of 3 equiv. of the ligand (*S*)-**1** to a solution of $Sc(OTf)_3$ in acetonitrile, the ^{45}Sc NMR resonance of the bound cation undergoes a downfield shift to δ = 106 ppm. The presence of a sharp singlet evidences a magnetically equivalent arrangement around the scandium cation (Figure 1c). The ^{45}Sc NMR spectrum of free $Sc(OTf)_3$ shows a broad singlet at δ = −30 ppm. The diastereotopic benzilic protons were used as probe for the ^{1}H NMR analysis of the complexes **2**−**5**. The signals of the benzilic protons are largely split into two AB patterns, except for the ytterbium complex **5**, where they appear as a broad doublet at δ = 1.2−1.11 ppm (Figure 2). A characteristic NMR property of a paramagnetic lanthanide ion, such as Yb^{III}, is the large chemical-shift range usually shown by the ligand resonances.[6] These paramagnetically shifted resonances are highly sensitive to slight structural and electronic variations.

The appearance of ^{1}H NMR resonances with a large downfield shift [δ(OH) = 31.53 ppm], and aromatic and benzilic protons with large upfield shifts (δ = 4.53 and 1.2−1.01 ppm, respectively) is consistent with complexation of the ligand (*S*)-**1** by the paramagnetic ytterbium ion (Figure 2).

Due to the fact that the chemical shift in paramagnetic complexes is strongly temperature-dependent, significant changes in the proton resonances can be observed with small temperature variations for complex **5** (Figure 2). A 2D ^{1}H-^{1}H DQF-COSY (ESI) NMR experiment allowed the assignment of all peaks of complex **5**.

Single crystals of the ytterbium complex **5** suitable for an X-ray diffraction study could be obtained.[7] The crystal structure shows **5** to be mononuclear in the solid state[8] (Figure 3a). Each (*S*)-**1** ligand wraps around the metal ion. All the oxygen atoms are distributed in a tubular maner. In the center of the cavity the ytterbium ion is surrounded by six oxygen atoms, with Yb−O distances ranging from 2.208 to 2.248 Å (Figure 3b).

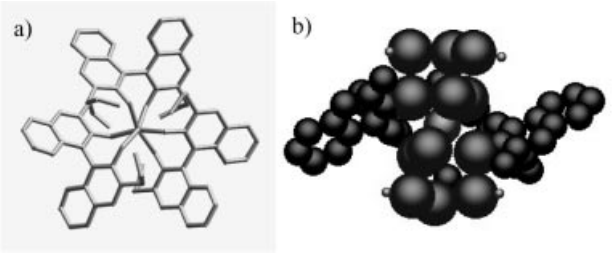

Figure 3. a) Molecular structure of Δ-[Yb{(*S*)-**1**}$_3$] (OTf)$_3$ (**5**) (top view); ethyl chains and triflates are omitted for clarity; b) space-filling representation; selected bond lengths [Å]: Yb(1)−O(1) 2.208, Yb(1)−O(2) 2.212, Yb(1)−O(3) 2.237, Yb(1)−O(4) 2.244, Yb(1)−O(5) 2.250, Yb(1)−O(6) 2.248, Yb(1)−O(7) 4.103, Yb(1)−O(8) 4.180, Yb(1)−O(9) 4.215, Yb(1)−O(10) 4.136, Yb(1)−O(11) 4.240, Yb(1)−O(12) 4.251

The selectivity of the ligand (*S*)-**1** with Ln^{III} ions in acetonitrile was monitored by ^{1}H NMR spectroscopy by adding a solution containing La/Sm/Yb in a 1:1:1 ratio to 3 equiv. of the ligand. The ^{1}H NMR spectrum shows the presence of a single metal complex corresponding to the ytterbium complex **5**.

The characterization of heteronuclear complexes bearing lanthanides is interesting because magnetic superexchange interactions between the bridged metal atoms may exist.[9] Further studies to obtain trinuclear dimetallic complexes $Ln^{III}/2Na^{I}$ or $Ln^{III}/2Li^{I}$ (Scheme 2) were therefore performed. Unfortunately, the addition of 2 equiv. of sodium or lithium triflate to the lanthanide complexes **3**−**5** to synthesize heterotrinuclear complexes failed, probably due to the repulsion between the lanthanide and the alkali ions. However, treatment of complexes LnL_3 with sodium acetate

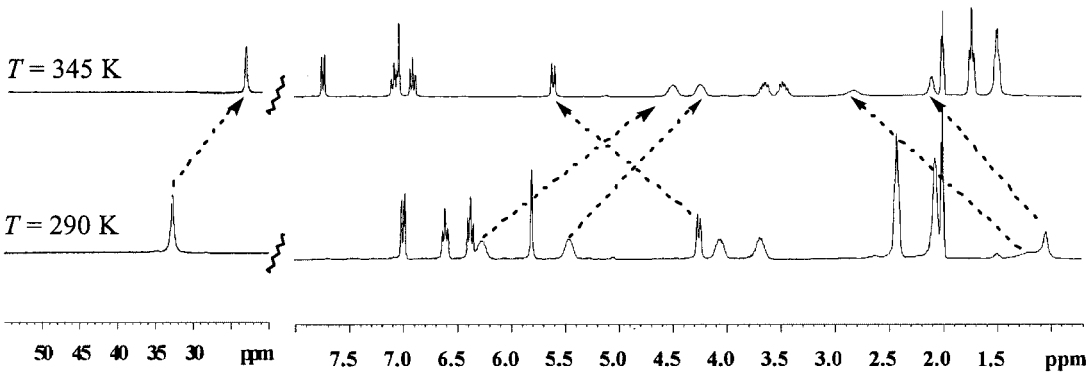

Figure 2. ^{1}H NMR spectra of complex **5**

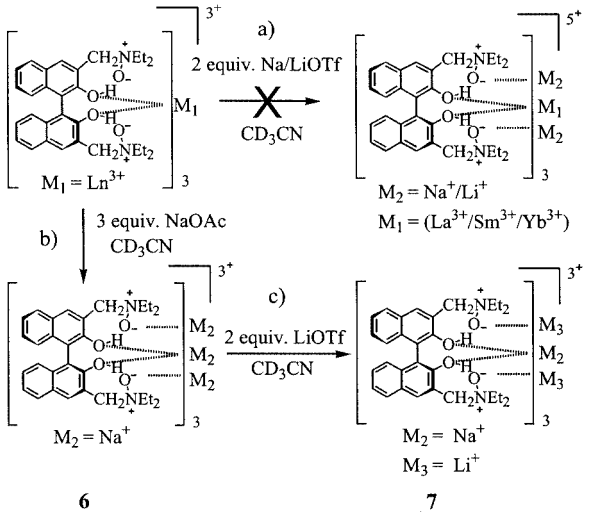
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

resulted in spectral changes, completed by the addition of 3 equiv. of sodium acetate. As a result, the central Ln^{III} ion of the homonuclear complexes **3**−**5** was replaced quantitatively by the alkali metal ion, and ytterbium acetate was isolated by filtration as a white microcrystalline powder. Interestingly, the addition of sodium acetate to complexes **3**−**5** gave identical spectra to the trinuclear helicate **6** obtained from the ligand (*S*)-**1** and 3 equiv. of sodium triflate.[3] Finally, a heterotrinuclear complex **7** was obtained by substitution of the two external sodium ions by addition of 2 equiv. of lithium triflate to complex **6**.



Scheme 2

The exchange process was observed by ^{7}Li NMR spectroscopic studies in CD_3CN (Figure 4) where, if we compare the lithium spectrum of complex **7** with that of complex **8**, we can observe a signal at δ = 1.35 ppm corresponding to the lithium ions placed at the external positions. The selective exchange of the two sodium ions at the apical positions by two lithium ions can be attributed to the fact that the size and shape of the sites are more suitable for the ionic radius and the coordination geometry of this ion. Evidence for this substitution was also observed in a ^{7}Li-^{1}H 2D HOESY NMR spectrum.

The formation of the homo- and heterotrinuclear complexes Δ-[Na_3{(*S*)-**1**}$_3$](OTf)$_3$ (**6**) and Δ-[$LiNa_2${(*S*)-**1**}$_3$](OTf)$_3$ (**7**) was further confirmed by ESI mass spectrometry {ESI-MS: *m*/*z* = 1832.6791 (calcd. for $C_{92}H_{108}F_6N_6Na_3O_{18}S_2$ [M − OTf]$^+$), found 1832.6344; MS (FAB$^+$): *m*/*z* = 1972 [MNa^+], 1956 [MLi^+], 1950 [MH^+], 1800 [M − OTf]}.

In summary, we have presented our efforts to prepare and characterize different stereoselective triple helical lanthanide complexes in solution and the solid state by the choice of a large La^{III}, a medium-sized Sm^{III} and a small Yb^{III} lanthanide ion. The recognition of one specific lanthanide ion (ytterbium) in the presence of others (lanthanum and samarium) is of great interest due to the minimal size differences of these ions and their similar chemical properties.

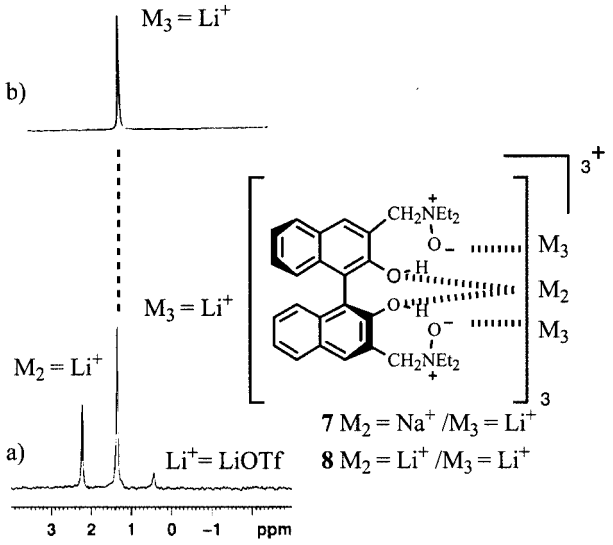


Figure 4. a) ^{7}Li NMR soectrum of complex **8** in CD_3CN solution; b) ^{7}Li NMR of complex **7** where there is only one signal corresponding to the lithium ions at the symmetrical external positions M_3

The homo- and heterotrinuclear complexes containing alkali atoms were obtained from the mononuclear lanthanide complexes. To the best of our knowledge this is the first case where a lanthanide(III) ion is replaced quantitatively by an alkali metal ion.

Experimental Section

General: The 1:3 complexes were prepared by mixing the ligand (*S*)-**1** with stoichiometric amounts of M(OTf)$_3$ in acetonitrile. The complexes were directly isolated in 70−80% yield by removing the solvent.

(*S*)-1: $[\alpha]_{589}^{25}$ = −186 (*c* = 0.010, CH_3CN). ^{1}H NMR (CD_3CN, 300 MHz): δ = 16.40 (br. s, 2 H, OH), 7.90−788 (m, 2 H), 7.28−7.26 (m, 4 H), 7.14−7.12 (m, 2 H), 4.73 (m, 4 H), 3.39 (m, 8 H), 1.4 (t, *J* = 7.2 Hz, 12 H) ppm. ^{13}C NMR (CD_2Cl_2, 75 MHz) 156.5, 136.4, 132.8, 128.7, 127.8, 127.3, 125.3, 122.9, 122.0, 119.6, 69.5, 60.7, 60.3, 9.5, 9.2 ppm. MS (FAB$^+$): *m*/*z* = 489 [MH^+]. HRMS (FAB+): *m*/*z* = 489.2753 (calcd. for $C_{30}H_{37}N_2O_4$), found 489.2741.

Δ-[Sc{(*S*)-1}$_3$](OTf)$_3$ (2): M.p. 256−257 °C. $[\alpha]_{589}^{25}$ = +190.8 (*c* = 0.24, CH_2Cl_2). ^{1}H NMR (CD_3CN): δ = 14.16 (s, 6 H), 8.10 (d, *J* = 8.0 Hz, 6 H), 7.74 (s, 6 H), 7.50 (t, *J* = 7.5 Hz, 6 H), 7.31 (t, *J* = 7.7 Hz, 6 H), 7.03 (d, *J* = 8.4 Hz, 6 H), 4.03 (d, *J* = 13.5 Hz, 6 H), 3.13−2.76 (m, 24 H), 2.81 (d, *J* = 13.5 Hz, 6 H), 1.03 (t, *J* = 7.1 Hz, 18 H), 0.61 (t, *J* = 7.2 Hz, 18 H) ppm. ^{13}C NMR (CD_3CN, 75 MHz): δ = 156.6, 135.9, 134.7, 128.8, 128.3, 127.5, 125.9, 123.7, 121.9, 119.8, 63.5, 60.8, 57.5, 7.4, 7.2 ppm. ^{45}Sc NMR (CD_3CN, 72 MHz): δ = 106 ppm. MS (FAB$^+$): *m*/*z* = 1980 [MNa^+], 1958 [MH^+], 1808 [M − OTf].

Δ-[La{(*S*)-1}$_3$](OTf)$_3$ (3): M.p. 243−244 °C. $[\alpha]_{589}^{25}$ = +79.2 (*c* = 0.24, CH_2Cl_2). ^{1}H NMR (CD_3CN): δ = 14.64 (s, 6 H), 8.17 (d, *J* = 8.0 Hz, 6 H), 7.85 (s, 6 H), 7.52 (t, *J* = 7.4 Hz, 6 H), 7.34 (t, *J* = 7.6 Hz, 6 H), 6.93 (d, *J* = 8.4 Hz, 6 H), 3.92 (d, *J* = 13.7 Hz, 6 H),

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3.14−2.88 (m, 24 H), 2.98 (d, J = 13.7 Hz, 6 H), 1.07 (t, J = 7.1 Hz, 18 H), 0.59 (t, J = 7.2 Hz, 18 H) ppm. ^{13}C NMR (CD_3CN, 75 MHz): δ = 153.8, 135.8, 135.0, 128.7, 127.9, 124.8, 123.7, 121.5, 119.9, 64.0, 60.3, 58.8, 7.0, 6.8 ppm. MS (FAB$^+$): m/z = 2073 [MNa^+], 2051 [MH^+], 1902 [M − OTf].

Δ-[Sm{(*S*)-1}$_3$](OTf)$_3$ (4): M.p. 238−239 °C. $[\alpha]_{589}^{25}$ = +159 (c = 0.024, CD_3CN). ^{1}H NMR (CD_3CN): δ = 18.03 (s, 6 H), 7.86 (d, J = 6.9 Hz, 6 H), 7.38 (t, J = 7.3 Hz, 6 H),7.31(s, 6 H), 7.16 (t, J = 7.2 Hz, 6 H), 6.59 (d, J = 8.4 Hz, 6 H), 3.57 (d, J = 13.7 Hz, 6 H), 3.38−3.16 (m, 24 H), 2.65 (d, J = 13.7 Hz, 6 H), 1.27 (t, J = 6.9 Hz, 18 H), 0.86 (t, J = 6.9 Hz, 18 H) ppm. ^{13}C NMR (CD_3CN, 75 MHz): δ = 155.5, 135.38, 134.36, 128.75, 127.81, 127.04, 124.65, 123.33, 119.75, 117.85, 64.02, 61.00, 58.94, 7.40, 7.28 ppm. ESI-MS: m/z = 1916.4758 [M − OTf].

Δ-[Yb{(*S*)-1}$_3$](OTf)$_3$ (5): M.p. 254−255 °C. $[\alpha]_{589}^{25}$ = +200.8 (c = 0.12, CH_2Cl_2). ^{1}H NMR (CD_3CN): δ = 31.53 (br. s, 6 H), 7.05 (d, J = 8.1 Hz, 6 H), 6.65 (t, J = 7.5 Hz, 6 H), 6.42 (t, J = 7.4 Hz, 6 H), 6.12 (br. s, 6 H), 5.89 (s, 6 H), 5.39 (br. s, 6 H), 4.35 (d, J = 8.4 Hz, 6 H), 4.07−4.01 (m, 6 H), 3.69−3.62 (m, 6 H), 2.36 (s, 18 H), 2.03 (s, 18 H), 1.38 (br. s, 6 H), 1.11 (s, 6 H) ppm. ^{13}C NMR (CD_3CN, 75 MHz): δ = 132.5, 129.8, 127.9, 127.3, 125.9, 125.7, 125.0, 124.0, 123.5, 119.9, 63.3, 61.4, 59.4, 8.8, 8.3 ppm. MS (FAB$^+$): m/z = 2109 [MNa^+], 2087 [MH^+], 1936 [M − OTf]. HRMS (FAB$^+$): m/z = 1936.64543 (calcd. for $C_{92}H_{108}F_6N_6O_{18}S_2Yb$ [M − HOTf + H^+]), found 1936.65769. Pale-yellow single crystals of **5** were obtained by the slow evaporation of the solvent from a CH_3CN solution.

Δ-[Na$_3${(*S*)-1}$_3$](OTf)$_3$ (6): $[\alpha]_{589}^{25}$ = +299 (c = 0.014, CH_3CN). ^{1}H NMR (CD_3CN, 300 MHz): δ = 16.01 (s, 6 H, OH), 8.14 (d, J = 5 Hz, 6 H), 7.68 (s, 6 H), 7.49 (t, J = 7 Hz, 6 H), 7.33 (t, J = 7 Hz, 6 H), 7.03 (d, J = 8.4 Hz, 6 H), 3.86 (d, J = 13.2 Hz, 6 H), 2.94 (m, 24 H), 2.72 (d, J = 13.2 Hz, 6 H), 1.02 (t, J = 6.9 Hz, 18 H), 0.5 (t, J = 6.9 Hz, 18 H) ppm. ^{13}C NMR (CD_3CN, 75 MHz): δ = 154.05, 135.07, 133.64, 128.39, 128.06, 127.20, 124.93, 123.27, 122.25, 118.97, 65.62, 60.91, 58.00, 7.98, 7.21 ppm. ^{23}Na NMR (CD_3CN, 79 MHz): δ = 5.69, −1.06 ppm. ESI-MS: m/z = 1832.6791 (calcd. for $C_{92}H_{108}F_6N_6Na_3O_{18}S_2$ [M − OTf]$^+$); found 1832.6344.

Δ-[Li$_2$Na{(*S*)-1]$_3$}(OTf)$_3$ (7): ^{1}H NMR (CD_3CN, 300 MHz): δ = 15.66 (s, 6 H, OH), 8.08 (d, J = 5 Hz, 6 H), 7.53 (s, 6 H), 7.48 (t, J = 7 Hz, 6 H), 7.36(t, J = 7 Hz, 6 H), 7.08 (d, J = 8.4 Hz, 6 H), 4.11 (d, J = 13 Hz, 6 H), 3.03−2.83 (m, 24 H), 2.82 (d, J = 13 Hz, 6 H), 1.02 (t, J = 6.9 Hz, 18 H), 0.57 (t, J = 6.9 Hz, 18 H) ppm. ^{13}C NMR (CD_3CN, 75 MHz): δ = 153.89, 135.91, 134.55, 129.41, 129.06, 128.39, 125.45, 124.39, 122.47, 119.70, 66.95, 61.72, 58.75, 9.46, 7.85 ppm. ^{7}Li NMR (CD_3CN, 116 MHz): δ = 1.32 ppm. MS (FAB$^+$): m/z = 1972 [MNa^+], 1956 (MLi^+), 1950 [MH^+], 1800 [M − OTf] ESI-MS: m/z = 1799.7284 (calcd. for $C_{92}H_{108}F_6Li_2N_6NaO_{18}S_2$ [M − OTf]$^+$); found 1799.7358.

Δ-[Li$_3${(*S*)-1}$_3$](OTf)$_3$ (8): $[\alpha]_{589}^{25}$ = +329 (c = 0.012, CH_3CN). ^{1}H NMR (CD_3CN, 300 MHz): δ = 15.36 (s, 6 H, OH), 8.08 (d, J = 5 Hz, 6 H), 7.50 (s, 6 H), 7.48 (t, J = 7 Hz, 6 H), 7.35(t, J = 7 Hz, 6 H), 7.08 (d, J = 8.4 Hz, 6 H), 3.89 (d, J = 13 Hz, 6 H), 3.05−2.87 (m, 24 H), 2.72 (d, J = 13 Hz, 6 H), 1.01 (t, J = 6.9 Hz, 18 H), 0.52 (t, J = 6.9 Hz, 18 H) ppm. ^{13}C NMR (CD_3CN, 75 MHz): δ = 153.25, 134.85, 133.88, 128.50, 128.37, 127.33, 125.18, 123.57, 122.18, 119.16, 65.35, 60.87, 57.26, 8.58, 6.88 ppm. ^{7}Li NMR (CD_3CN, 116 MHz): δ = 2.23, 1.35 ppm. HRMS (ES): m/z = 1783.7546 (calcd. for $C_{92}H_{108}F_6Li_3N_6O_{18}S_2$ [M − OTf]$^+$), found 1783.7593.

Electron-Rich Organoantimony(III) Dithiolate Complexes

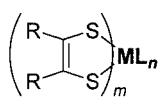
Narcis Avarvari,[a] Marc Fourmigué,*[a] and Enric Canadell[b]

Keywords: Antimony / Noncovalent interactions / S ligands / X-ray diffraction

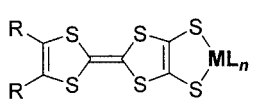
Electron-rich dithiolene complexes of the antimony(III) PhSb moiety, formulated as [SbPh(dddt)] (**1**) (dddt: 5,6-dihydro-1,4-ditthine-2,3-dithiolate) and [SbPh(EDT-TTFS$_2$)] (**2**) (EDT-TTFS$_2$: 4,5-ethylenedithio-tetrathiafulvalene-4′,5′-dithiolate), have been prepared by deprotection of the corresponding precursors and trapping of the intermediate dithiolates with $PhSbCl_2$. Both complexes have been structurally characterized. The analysis of their single-crystal X-ray structures shows original supramolecular organizations governed by secondary Sb···S contacts, with distorted octahedral coordination geometries around the Sb center. Band-structure calculations for complex **2** reveal only weak dispersion of the valence and conduction bands, with an energy gap of 1.68 eV.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Following their discovery in the 1960s,[1] homoleptic dithiolene complexes,[2] and particularly the square-planar complexes of d^8 metal cations (Ni, Pt, Pd), became the subject of extensive investigations,[3] mainly oriented toward the preparation and understanding of their magnetic[4] and conducting (eventually superconducting) salts.[5] In that respect, heteroleptic complexes, which involve one or more dithiolate ligands together with other ligands (bipy, dppe, Cp, CN,....) in the metal coordination sphere, have been much less investigated,[6,7] despite a wide variety of possible applications, for example as luminescent[8] or magnetic systems.[9] More recently, the dithiolate ligand built directly on a tetrathiafulvalene core ($TTFS_2^{2-}$) ($TTFS_2^{2-}$: tetrathiafulvalene-4,5-dithiolate) became available[10,11] and prompted the preparation of a wealth of novel dithiolene complexes, such as the homoleptic ones — the square-planar metallic Ni, Pt or Pd complexes described by Kobayashi and co-workers[12,13] or the tris(dithiolene) vanadium complexes[14] — or heteroleptic ones of general formula [$ML_n(TTFS_2)$] [ML_n = $TiCp_2$,[15] $Ni(CN)_2$,[16] Pt(bipy),[17,18] CoCp,[19] Pt(dppe),[20] Au(py-Ph),[21] M(dppf),[22]...]. These tetrathiafulvalene-4,5-dithiolate complexes are particularly attractive since they combine the properties of the TTF core with those of the dithiolene complex moiety.



$(dt)_mML_n$ complexes



$(TTFS_2)ML_n$ complexes

We recently became interested in main-group derivatives of such heteroleptic dithiolene complexes and concentrated on the antimony moiety SbPh as the ML_n group in order to take advantage of both the diffuse lone pair of the Sb^{III} and its capacity to exhibit secondary coordination.[23] Indeed, in [SbPh(dmit)]·(THF) (dmit: 1,3-dithiole-2-thione-4,5-dithiolate),[24] the oxygen atom of the THF molecule and the outer sulfur atom of the C=S fragment enter the antimony coordination sphere of neighboring molecules, affording dimerized infinite chains stabilized by these Sb···O and Sb···S interactions. The flexibility of the coordination around antimony is further demonstrated by the observation of two successive single-crystal structural phase-transitions. On the other hand, in [SbPh(dmid)],[25] secondary Sb···S contacts lead to the formation of a centrosymmetric cyclic octagonal "Sb_4S_4" motif as a result of a formal tetramerization of the [SbPh(dmid)] molecule. Such motifs are also encountered in open-framework antimony sulfides.[26]

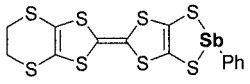
PhSb(dddt)



(EDT-TTFS$_2$)SbPh

Although [SbPh(dmit)] and [SbPh(dmid)] differ only in the terminal chalcogen C=X (X = O, S) atom, they have rather distinct structures, demonstrating a very high structural flexibility in the solid state thanks to secondary Sb···S and Sb···O contacts in which the terminal chalcogen is always involved. This prompted us to investigate Sb^{III}-based dithiolene complexes with a completely different backbone

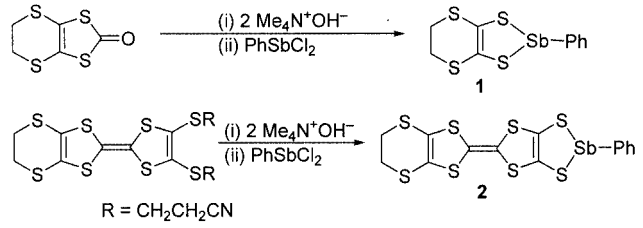
in order to study the structural adaptability of the system, and we focused on more electron-rich dithiolate ligands, thus keeping an eye on the possibility of accessing open-shell species upon oxidation. Therefore, complexes derived from $dddt^{2-}$ and EDT-$TTFS_2^{2-}$ have been prepared. Their solid-state crystalline structures along with the band-structure calculation for the TTF-based compound are reported here.

Results and Discussion

Syntheses

Deprotection of 5,6-dihydro-[1,3]dithiolo[4,5-*b*][1,4]dithiin-2-one[27] with two equivalents of (Me_4N·OH) in THF leads to the formation of the corresponding dithiolate $dddt^{2-}$. Subsequent fast addition of $PhSbCl_2$,[28] followed by purification workup, afforded **1** as an orange solid (Scheme 1). The elemental analysis and ^1H NMR spectroscopic data are in agreement with the proposed formulation. Suitable single crystals for an X-ray analysis (vide infra) were grown by slow evaporation of the solvent from a CH_2Cl_2 solution of the complex. Similarly, deprotection of 4,5-bis[(2-cyanoethyl)thio]-4′,5′-ethylenedithiotetrathiafulvalene[29,30] with two equivalents of (Me_4N·OH) in THF afforded the highly air sensitive TTF dithiolate. This was quenched with $PhSbCl_2$ to give complex **2**, which was analyzed by ^1H and ^{13}C NMR spectroscopy, mass spectrometry and elemental analysis. Red crystals of **2**, suitable for an X-ray analysis, were obtained by recrystallization from toluene. The complex is readily soluble in THF and only sparingly soluble in other organic solvents. As described in our previous study,[25] the addition rate of $PhSbCl_2$ is a crucial parameter in order to reach an optimum yield of the dithiolene complex. This is related to the reactivity of **1** or **2**, once formed, towards a second equivalent of dithiolate to give a highly reactive dianionic species. A fast addition of $PhSbCl_2$ to the dithiolate suspension ensures a good yield of the desired product.



Scheme 1

Structure of [SbPh(dddt)]

The complex crystallizes in the triclinic system, space group $P\bar{1}$, with three crystallographically independent molecules (noted A, B and C in the following) in the unit cell, together with one CH_2Cl_2 molecule (Figure 1). Selected intramolecular bond lengths and bond angles for each of the molecules are listed in Table 1 and 2, respectively. They are similar to those observed in [SbPh(dmit)] and [SbPh(dmid)], with a primary coordination pattern around the antimony atom consisting, as expected, of two S (dithiolate) atoms and one C(*ipso*) atom, with the phenyl group almost perpendicular to the S−Sb−S plane. The folding angle of the SbS_2C_2 metallacycle along the S···S hinge, a characteristic of coordinated dithiolene complexes, amounts to 31.89(23)°, 24.23(27)° and 26.98(18)° in molecules A−C, respectively. The differences between the three molecules are not so important if one takes into account that the rotation barrier of such metallacycles is rather low.[9] Every molecule completes its coordination sphere by a complex set of secondary Sb···S interactions (Figure 2). Both Sb1A and Sb1B exhibit two short Sb···S contacts with sulfur atoms of neighboring molecules located in the least-square equatorial plane along with the two dithiolene sulfur atoms (see Table 1). The intermolecular Sb···S distances lie between 3.31 and 3.61 Å, well below the sum of the van der Waals radii (3.80 Å).[31] Altogether, the coordination around Sb1A and Sb1B is of distorted octahedral type if one takes into account the $5s^2$ lone pair, probably lying *trans* to the phenyl group. On the other hand, Sb1C engages in only one such Sb···S secondary interaction and appears, from that point of view, coordinatively unsaturated. These secondary interactions around Sb1A and Sb1B give rise to the formation of an eight-membered ring with alternating Sb and S atoms. The resulting tetramolecular Sb_4S_4 units

are connected together by two molecules C, affording infinite chains running along the *a*-axis. These chains are well separated from each other by: (i) the phenyl and ethylene groups of the constituting molecules, which point toward the outside of the columns, and (ii) by disordered CH_2Cl_2 molecules included into the channels formed between the columns. These Sb_4S_4 cyclic patterns have also been identified in the structure of [SbPh(dmid)], while Sb_2S_2 motifs are found in [SbPh(dmit)]. They are also frequently observed in the open-framework antimony sulfides based on the primary Sb−S bonds.

Structure of [SbPh(EDT-TTFS$_2$)]

The complex crystallizes in the orthorhombic system, space group $Pca2_1$ with one molecule in a general position in the unit cell (Figure 3). Intramolecular bond lengths and angles are in the usual range (Table 3). The EDT-TTF moieties stack on top of each other along the *b*-axis. As often observed with neutral tetrathiafulvalene derivatives, the dithiole rings are folded along the S···S hinge, by 19.97(69)° on the ethylenedithio side and by 13.30(63)° on the metallacycle side. On the other hand, the metallacycle itself is also distorted, with a folding along the S···S hinge of 19.09(32)°, weaker than that observed in [SbPh(dddt)]. The antimony coordination sphere (Figure 4) is completed by four Sb···S secondary interactions, two of them with sulfur atoms (S7, S8) located in the least-square equatorial plane along with the two dithiolene sulfur atoms (Sb···S7: 3.85 Å; Sb···S8: 3.47 Å) and two with sulfur atoms (S3, S4) of a neighboring molecule in the stack along the *b*-axis (Sb···S3: 3.83 Å, Sb···S4: 3.89 Å). Note that these distances, excluding the shortest Sb···S8 one, are close to or above the van der Waals Sb···S (3.80 Å) distance, indicating weaker interactions than in [SbPh(dddt)].

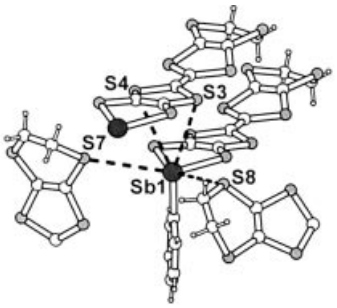

Figure 4. Detail of the coordination sphere of antimony in (EDT-$TTFS_2$)SbPh

iour and hence its potential utilization as a donor in electrocrystallization experiments. Although the two characteristic oxidation peaks, corresponding to the formation of the $[\mathbf{2}]^{+\cdot}$ radical cation at $E = 0.69$ V (SCE) and the $[\mathbf{2}]^{2+}$ dication at $E = 0.89$ V (SCE), are observed as expected, the overall process is only partially reversible, showing that the oxidized species of **2** is not stable in solution. This kinetic instability can be related to the flexibility of the antimony coordination sphere, leading to a multitude of ligand-scrambling reactions in solution.[25] Solutions of the neutral complex **2** in THF are also unstable, since a deposit of unidentified compounds precipitated out of the solution within one day. These observations show that the complex **2** is probably not a suitable donor for electrocrystallization experiments.

However, the complex set of intermolecular contacts identified within the crystalline structure of **2** prompted us to undertake a band-structure calculation in order to evaluate the energy gap between the valence and the conduction band of **2** along with the dispersion of these bands, thus envisaging the eventuality of an intrinsic semiconducting behavior for this compound. Indeed, previous studies dealing with the tetrakis(telluromethyl)tetrathiafulvalene (MeTe)$_4$TTF reported interesting results concerning the semiconducting properties of the compound in neutral state, very likely due to zigzag chains formed by Te···Te contacts.[32] The calculated band structure for complex **2**, represented in Figure 5, shows a valence-band built up from the HOMO of the EDT fragment, with a dispersion of about 0.2 eV.

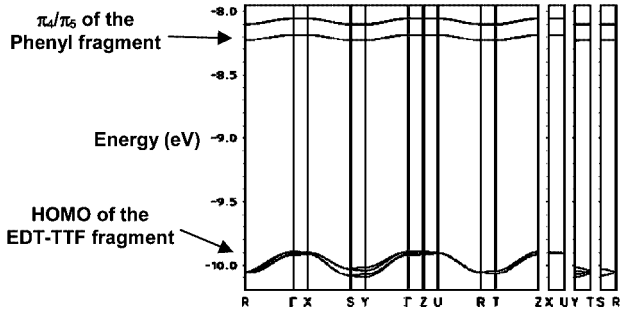

Figure 5. Calculated band structure for **2**; Γ = (0, 0, 0), R = (0.5, 0.5, 0.5), X = (0.5, 0, 0), S = (0.5, 0.5, 0), Y = (0, 0.5, 0), Z = (0, 0, 0.5), U = (0.5, 0, 0.5), T = (0, 0.5, 0.5) in units of the reciprocal lattice vectors

This rather weak value for the valence-band dispersion is very likely due to the absence of an antimony contribution to the HOMO of the molecule. An Sb-based HOMO would probably have led to a larger dispersion band when taking into account the numerous Sb···S intermolecular contacts. The conduction band, the dispersion of which is even weaker, also has no Sb contribution, but is exclusively formed from the empty π_4 and π_5 orbitals of the phenyl rings. Although these dispersions are somewhat slightly underestimated because of the single-ζ basis-set employed in the calculation, the bands still remain rather flat. This result, along with the gap-energy value of 1.68 eV, allows us to assess that complex **2** should be a modest semiconductor. Preliminary conductivity measurements on compressed pellets gave a σ value of about 10^{-5} S·cm^{-1}.

Experimental Section

General: The syntheses of the complexes were carried out under nitrogen, using standard Schlenk techniques. Dry toluene and hexane were obtained by distillation over Na and dry CH_2Cl_2 and CH_3CN by distillation over P_2O_5; THF was distilled from sodium/benzophenone. NMR spectra were recorded on a Bruker ARX 500 spectrometer operating at 500.04 MHz for ^{1}H and 125.75 MHz for ^{13}C. Mass spectrometry was performed on an HP 5989A spectrometer in the EI mode, with an ionization energy of 70 eV. Elemental analyses were performed by the "Service d′Analyse du CNRS" at Gif/Yvette, France. 5,6-Dihydro-[1,3]dithiolo[4,5-*b*][1,4]dithiin-2-one,[27] EDT-TTF(SCH_2-CH_2CN)$_2$,[29,30] and phenyldichlorostibane[28] were prepared according to literature methods.

[SbPh(dddt)] (2): A solution of Me_4NOH (3.5 g 25 wt % in MeOH, 9.6 mmol) in 5 mL of THF was added to a Schlenk tube containing 5,6-dihydro-[1,3]dithiolo[4,5-*b*][1,4]dithiin-2-one (1 g, 4.8 mmol) in 30 mL of THF under magnetic stirring. A yellow precipitate appeared immediately corresponding to the formation of dddt^{2-}. After 10 min of stirring at room temperature, dichlorophenylstibane (1.3 g, 4.8 mmol) in 10 mL of THF was rapidly added. The solution became orange and a cream precipitate of tetramethylammonium chloride was formed. The suspension was stirred for 2 h and then filtered through Celite. After evaporation of the solvent, the resulting oil was dissolved in a minimum amount of toluene and then rapidly chromatographed with toluene through a short silica-gel column. After removal of solvent under vacuum, addition of a small volume of THF, precipitation with pentane, filtration and drying on a vacuum line, complex **2** was recovered as a yellow solid. Yield 0.6 g (33%). Single crystals for X-ray analysis were grown by slow evaporation of the solvent from a solution of **2** in CH_2Cl_2. ^{1}H NMR ($CDCl_3$): δ = 2.97−3.02 (m, 2 H, CH_2), 3.18−3.21 (m, 2 H, CH_2), 7.36−7.43 (m, 3 H, H *para* and *meta*), 7.60 (dd, $^3J_{H,H}$ = 8.1, $^4J_{H,H}$ = 1.4 Hz, 2 H, H *ortho*) ppm. $C_{10}H_9S_4Sb$·THF: calcd. C 37.26, H 3.80; found C 37.11, H 3.71.

[SbPh(EDT-$TTFS_2$)] (2): A solution of EDT-TTF(SCH_2-CH_2CN)$_2$ (1 g, 2.15 mmol) in 40 mL of THF was treated with a solution of Me_4NOH (1.57 g, 25 wt % in MeOH, 4.3 mmol) in 10 mL of THF. An orange precipitate of EDT-TTF-S_2^{2-} was formed within a few minutes and after 30 min of stirring dichlorophenylstibane (0.58 g, 2.15 mmol) in 10 mL of THF was added rapidly. The reaction mixture was stirred for 2 h, then the solvent was evaporated, the residue washed with methanol, dissolved in THF and filtered through Celite. After evaporation of THF to a small volume, MeCN was ad-

ded, and then the resulting precipitate was filtered through a glass frit and dried under vacuum to yield complex **2** as a red-brown powder. Yield 0.58 g (49%). ^{1}H NMR ([D$_8$]THF): δ = 3.31 (s, 4 H, CH$_2$), 7.33 (tt, $^3J_{H,H}$ = 7.2, $^4J_{H,H}$ = 1.3 Hz, 1 H, H *para*), 7.40 (t, $^3J_{H,H}$ = 7.2 Hz, 2 H, H *meta*), 7.84 (dd, $^3J_{H,H}$ = 7.2, $^4J_{H,H}$ = 1.4 Hz, 2 H, H *ortho*) ppm. ^{13}C NMR ([D$_8$]THF): δ = 30.2 (CH$_2$), 107.7 (C=C), 113.8 (C=C), 121.4 (C=C), 128.9 (CH-*meta*), 129.8 (CH-*para*), 133.8 (CH-*ortho*), 149.0 (C-*ipso*) ppm. MS (EI): *m*/*z* (%) = 553, 555 (60) [M$^+$]. $C_{14}H_9S_8Sb$: calcd. C 30.27, H 1.63; found C 30.07, H 1.61.

Electrochemistry: Cyclic voltammetry experiments were performed on a VPM potentiostat in dry-THF solutions of 0.05 M nBu$_4$NPF$_6$ as electrolyte at room temperature, at a scan rate of 100 mV·s^{-1}. A Pt working electrode (diameter 1 mm), a Pt counter electrode and an SCE reference electrode were used.

Band-Structure Calculations: The tight-binding band-structure calculations were based upon the effective one-electron Hamiltonian of the extended Hückel method.[33] The off-diagonal matrix elements of the Hamiltonian were calculated according to the modified Wolfsberg−Helmholz formula.[34] All valence electrons were explicitly taken into account in the calculations, and the basis set consisted of single-ζ Slater-type orbitals, because of the higher reliability in the case of atoms with very diffuse orbitals such as antimony when compared with the double-ζ basis set.[35]

X-ray Crystallography: Crystals of [SbPh(dddt)] or [SbPh(EDT-TTFS$_2$)] were mounted on top of a thin glass fiber. Data were collected on a Stoe Imaging Plate Diffraction System (IPDS) with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). The crystal data are summarized in Table 4. Structures were solved by direct methods (SHELXS-97) and refined (SHELXL-97) by full-matrix least-squares methods. Absorption corrections were applied for both structures. Hydrogen atoms were introduced at calculated positions (riding model), included in structure factor calculations, and not refined.

Keywords: Electrochemistry / Electrophosphorescence / Iridium / Luminescence / N ligands

A series of dimethyl-substituted tris(pyridylphenyl)iridium(III) derivatives [(*n*-MePy–*n*′-MePh)$_3$Ir] [*n* = 3, *n*′ = 4 (**1**); *n* = 4, *n*′ = 4 (**2**); *n* = 4, *n*′ = 5 (**3**); *n* = 5, *n*′ = 4 (**4**); *n* = 5, *n*′ = 5 (**5**)] have been synthesized and characterized to investigate the effect of the substitution of methyl groups on the solid-state structure and photo- and electroluminescence. The absorption, emission, cyclic voltammetry and electroluminescent performance of **1**–**5** have also been systematically evaluated. The structures of **2** and **4** have been determined by a single-crystal X-ray diffraction analysis. Under reflux (> 200 °C) in glycerol solution, *fac*-type complexes with a distorted octahedral geometry are predominantly formed as the major components in all cases. Electrochemical studies showed much smaller oxidation potentials relative to Ir(ppy)$_3$ (Hppy = 2-phenylpyridine). All complexes exhibit intense green photoluminescence (PL), which has been attributed to metal-to-ligand charge transfer (MLCT) triplet emission. The maximum emission wavelengths of thin films of **1**, **3**, **4** and **5** at room temperature are in the range 529–536 nm, while **2** displays a blue-shifted emission band (λ_{max} = 512 nm) with a higher PL quantum efficiency (Φ_{PL} = 0.52) than those of complexes **1** and **3**–**5**; this is attributed to a decrease of the intermolecular interactions. Multilayered organic light-emitting diodes (OLEDs) were fabricated by using three (**2**, **3** and **4**) of these Ir^{III} derivatives as dopant materials. The electroluminescence (EL) spectra of the devices, which have the maximum peaks at 509–522 nm, with shoulder peaks near 552 nm, are consistent with the PL spectra in solution at 298 K. The devices show operating voltages at 1 mA/cm^2 of 4.9, 5.6, 5.1, and 4.6 V for Ir(ppy)$_3$, **2**, **3**, and **4**, respectively. In particular, the device with **2** shows a higher external quantum efficiency (η_{ext} = 11% at 1 mA/cm^2) and brightness (4543 cd/m^2 at 20 mA/cm^2) than Ir(ppy)$_3$ (η_{ext} = 6.0% at 1 mA/cm^2; 3156 cd/m^2 at 20 mA/cm^2) and other Ir(dmppy)$_3$ derivatives, (dmppy = dimethyl-substituted ppy), under the same conditions. The methyl groups at the *meta* (Ph) and *para* (Py) positions to the Ir metal atom have a great influence on absorption, emission, redox potentials and electroluminescence.

Introduction

Luminescent transition metal complexes, such as those of groups 9 or 10, are currently of great interest due to their various applications in photochemistry, organic light-emitting diodes (OLEDs), and chemical sensors for small molecules.[1] Among these transition metal complexes, Ir^{III} complexes have been regarded as excellent phosphorescent materials because of their ability to achieve maximum internal quantum efficiency, nearly 100%, as well as high external quantum efficiency in OLEDs.[2] Based on previous reports, a promising phosphorescent metal complex in OLEDs should have a short lifetime in the excited state and high phosphorescent efficiency. Based on these considerations, a number of researchers have focused recently on the development of cyclometallated (C^N)Ir^{III} complexes.[2] In particlar, luminescent Ir(ppy)$_3$ (Hppy = 2-phenylpyridine) derivatives have been described where adjustment of the band gap between the HOMO and LUMO energy levels could be achieved by modification of the substituents on the ppy rings.[3] Accordingly, to control the energy of the Ir(ppy)$_3$ system from blue light emission to red, a judicious incorporation of electron donors/acceptors as substituents on the ppy frameworks is an essential prerequisite.[4,5] For example, introduction of electron-donating groups to the pyridine ring and electron-withdrawing groups to the phenyl ring can cause a decrease of the HOMO level and an increase of the LUMO level, respectively, inducing a larger

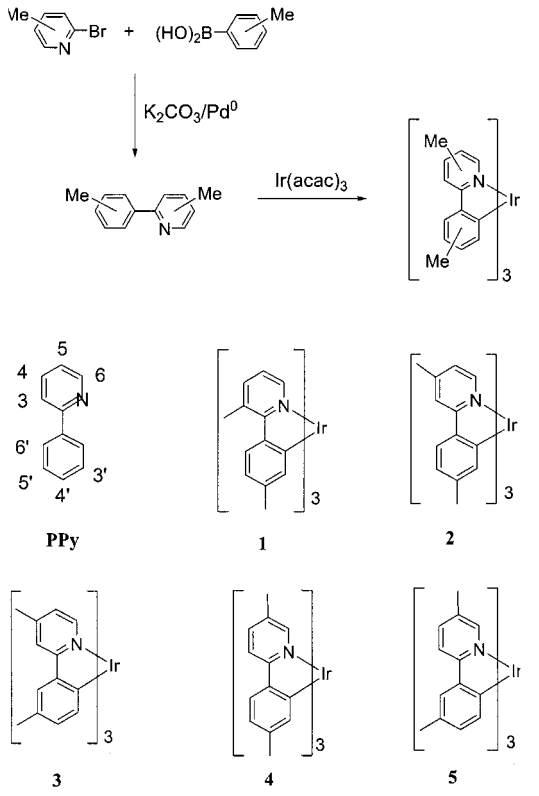
band gap than that of $Ir(ppy)_3$. Although extensive research on the investigation of luminescent properties of Ir^{III} derivatives containing two *ortho*-chelating (C^N) ligands and a bidentate ancillary LX (e.g. monoanionic chelating ligands, acac = acetylacetonate, pic = picolinate, sal = salicyliminate), and their use and performance as triplet emitters in EL devices has been well documented over several years, the illustration of the effect of substituents, such as simple functional groups, and the dependence on their positions on the phenyl or pyridine rings in the ppy backbone, still remains virtually unexplored.[1e,5] During our ongoing investigation of phosphorescent $Ir(ppy)_3$ derivatives, we have observed that attached methyl groups as substituents on the ppy ligand have a remarkable influence on the electrochemical and photophysical properties.[6] Our interest in the development of highly efficient phosphors for application in OLEDs has prompted us to synthesize $Ir(ppy)_3$ derivatives and investigate their photophysical and electroluminescent characteristics. The methyl moiety was chosen for the following reasons: (i) The emissions of $Ir(ppy)_3$ derivatives come from phosphorescence with triplet character of both ligand-centered ($\pi-\pi^*$) and MLCT (metal-to-ligand charge transfer) transitions. This phosphorescence is strongly affected by the triplet energy of the *ortho*-chelating C∧N ligands. Therefore substituents, even methyl groups, on the ppy rings could play a key role in the alteration of the triplet energy. (ii) Although a methyl group is a weaker electron-donating group than other functional groups (e.g. OMe, NR_2 etc.), incorporating the methyl group as a substituent on the ppy rings has an influence on the HOMO and/or the LUMO level, as well as the ^{3}MLCT state of the complex. Herein we describe the results of our systematic investigation on the preparation, structural characterization, electrochemical behavior, photophysical properties and the fabrication of multiplayer phosphorescent light-emitting devices of a series of *fac*-[Ir^{III}(dmppy)$_3$] complexes [Hdmppy = *n*-methyl-2-(*n′*-methylphenyl)pyridine].

Results and Discussion

Syntheses and Structures

The methyl-substituted ppy ligands were synthesized by the Suzuki coupling[7] reaction of 2-bromo-*n*-methylpyridine with the corresponding *n′*-methylphenylboronic acid in the presence of K_2CO_3 and [$Pd(PPh_3)_4$] catalyst (Scheme 1).

These ligands were obtained in good yields (70−90%). Complexes **1**−**5** were synthesized by a slight modification of the previous synthetic methodology reported by Watt et al.[8b] The reaction of [$Ir(acac)_3$] with the corresponding methyl-substituted ppy ligands at high temperature (> 200 °C), gave **1**−**5** in moderate yields. Even though the ligands methylated at the 6- or 3′-position were synthesized successfully in moderate yields, the complexation of these ligands with the Ir^{III} starting material hardly occurs under the same reaction conditions. We attribute this mainly to steric factors.



Scheme 1

There is a possibility of the formation of two isomers (*fac* and *mer*) during the reaction of $Ir(acac)_3$ and the Hdmppy ligands.[8a] However, we found that the *fac* isomer was formed as the major component, although some *mer* isomer was also formed. The formed *mer* isomers were not isolated because of their extremely low yields. All complexes are very stable up to 300 °C without degradation in air. In the ^{1}H NMR spectra, complexes **1**−**5** exhibit six well-resolved peaks due to the ppy rings, indicating that all complexes

have a facial geometry around the Ir atom. Complexes **1**−**5** were fully characterized by mass spectrometry and elemental analyses, and crystal structures of **2** and **4** were obtained. Selected bond lengths and angles are presented in Table 1; refinement and structure-solution data can be found in the Exp. Sect. Complexes **2** and **4** exhibit only the *fac* configuration, with a distorted octahedral geometry around the Ir atom, as shown in Figures 1 and 2, respectively. The dihedral angle between the phenyl and pyridine rings in **2** (8.81°) is approximately three times larger than that of **4** (3.4°), indicating a decreased conjugation of the 4,4′-ppy ligands. The Ir−C bond lengths, ranging from 2.002(5) to 2.034 Å, are within the range reported for other mononuclear complexes with the $Ir(ppy)_2$ moiety [1.97(2)−2.13(6) Å],[9] and are also close to values reported for $[(tpy)_2Ir(\mu\text{-}Cl)_2Ir(tpy)_2]$ [Htpy = 2-(*p*-tolyl)pyridine] and other substituted *fac*-$[Ir(ppy)_3]$ derivatives.[8a,10] The σ-donor C atoms in the dmppy ligand arrange in a *trans* disposition to the dative N atoms of adjacent ppy ligands. The Ir−N bonds [2.111(5)−2.131 (6) Å] observed in **2** and **4** are slightly longer than those of $[Ir(acac)(tpy)_2]$ [2.040(5) Å] and $[Ir(acac)(ppy)_2]$ [2.010(9) Å].[5b] These observed elongations imply a stronger *trans* influence of the phenyl ring in comparison to the pyridyl groups having a *trans*-*N*,*N*′ configuration. In the crystal packing, **4** displays an effective overlap of the pyridine rings between two adjacent molecules (Figure 2). The shortest separation distance is about 3.22 Å, which is sufficiently short to suggest π−π stacking interactions. Complex **2** does not exhibit an effective overlap in the crystal packing, as shown in Figure 1. Recently, many reports have described that intermolecular π−π interactions have a direct influence on luminescent properties.[2c,5] The influence of this intermolecular interaction on the luminescence of the Ir^{III} complexes in this work is discussed below.

Photoluminescent and Electrochemical Properties

Table 2 summarizes the photophysical data of **1**−**5**. The UV/Vis spectra of all compounds exhibit intense absorption bands between 250 and 310 nm ($\varepsilon > 10^4$ $mol^{-1}{\cdot}dm^3{\cdot}cm^{-1}$), indicating that the electronic transitions are mostly ligand-centered (LC) π−π * transitions (Figure 3). The absorption patterns of **1**−**5** and [Ir(ppy)$_3$] are similar in the 250−550 nm region.[11] However, the ^{1}MLCT and ^{3}MLCT peaks in **1**, **3**, **4** and **5** appear at lower energies than in [Ir(ppy)$_3$], while those of **2** occur at much higher energy with larger extinction coefficients. These observed blue- or red-shifted MLCT bands show that the methyl groups on the dmppy rings have a significant effect on the electronic

transition energies. The emission spectra of all complexes in solution and as thin films at room temperature are dominated by phosphorescence in the region 509−534 nm. Interestingly, both the absorption and emission spectra of **2** are blue-shifted relative to the other complexes and [Ir(ppy)$_3$]. This result can be explained by correlating the electronic and steric effects due to the methyl substituents. As reported previously,[5] the emission energy of [Ir(ppy)$_3$] can be controlled readily by adding substituents to the rings. To investigate the electronic effects caused by the addition of methyl groups, cyclic voltammetry experiments were carried out for all complexes, including [Ir(ppy)$_3$]. Due to the limited range available in CH_2Cl_2 and the inability of our instrument to measure the reduction potentials in the range −2.7 to −3.5 V, we obtained only the oxidation potentials for complexes **1**−**5** (Table 2). For the electrochemical behavior of Ir(ppy)$_3$ analogues it has been proposed that the oxidative and reductive processes involve the Ir−phenyl and −pyridine moiety of the C^N ligand, respectively. DFT calculations on a similar methyl-substituted Ir(ppy)$_3$ derivative, tris[2-(3-methylpyrid-2-yl)phenyl]iridium(III), provide evidence that the HOMO levels are mostly due to the Ir d_{z^2} orbital with some π-orbital contributions from the phenyl rings, while the LUMO levels in this complex are mostly due to the pyridine π* orbital.[8c] The same description complex has also been reported theoretically for the parent [Ir(ppy)$_3$] complex by Hay.[12] Reversible oxidation waves are observed for all complexes between 0.47 and 0.54 V. It is noteworthy that all of the complexes show lower oxidative potentials than [Ir(ppy)$_3$], indicating the relative ease of oxidation (see Figure 4). This can be ascribed to the great electron-donating ability of the methyl group. Complexes **3** and **5**, in particular, exhibit lower oxidation potentials than those of the other methyl-substituted complexes **1**, **2**, and **4**. Based on our DFT calculations, there are nodes at the 4′- and 6′-positions in the HOMO. In the HOMO, the electron density is mostly dispersed at the 3′- and 5′-positions, and also involves the 1′- and 2′-positions in the phenyl ring. Therefore, the donating effect from the methyl groups at either the 4′- or the 6′-position does not have a significant influence on the HOMO energy levels, while methyl groups at the 3′- or 5′-positions effectively donate electron density to the dmppy moiety, leading to a decrease in the oxidation potentials. The reduction process of the Ir(ppy)$_3$ derivatives was also shown to be due to the C^N ligand and is also affected by the various substituents.[8a] However, one of the key factors that affect the reduction potential in these systems is the degree of conjugation between the phenyl and pyridine rings. More effective conjugation stabilizes the LUMO, leading to a decreased reduction potential. Although we could not observe the reductive process, the reduction potential of **2** should be higher than that of complex **4**, as supported by the structural data.

Another fact affecting the nature of the luminescence in [Ir(ppy)$_3$] is the degree of steric hindrance. Lee et al. have demonstrated that higher photoluminescence quantum efficiencies (Φ_{PL}) and shorter lifetimes in [Ir(ppy)$_3$] derivatives can be achieved by the introduction of sterically hindered spacers, such as pinene.[2c] Although the effect on luminescence, such as excimer formation and from intermolecular π−π interactions, is less demonstrated in octahedral complexes than in square-planar Pt^{II} complexes,[13] these blue-shifted absorption and emission maxima for **2** could be attributed to a reduction of π-orbital conjugation between the phenyl and pyridine rings as well as the lack of intermolecular interactions in the solid state.[16] Therefore, we believe that the observed blue-shifted absorption and emission spectra of complex **2** are probably due to steric factors with a contribution from the strong electron-donating effect of the methyl group.

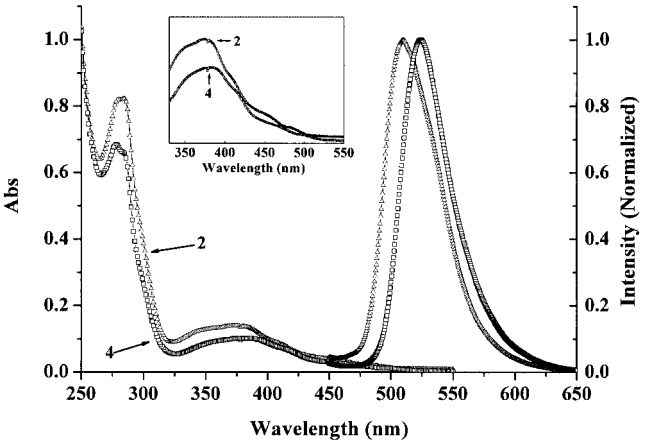

Figure 3. Absorption and emission spectra of **2** (triangles) and **4** (squares) in CH_2Cl_2 at room temperature; inset: MLCT bands of **2** and **4** in the UV/Vis region

The PL quantum yields were obtained relative to [Ir(ppy)$_3$] (Φ_{PL} = 0.4) and increase in the order [Ir(4,4′dmppy)$_3$] (**2**) > [Ir(3,4′dmppy)$_3$] (**1**) > [Ir(5,4′dmppy)$_3$] (**4**) > [Ir(4,5′dmppy)$_3$] (**3**) > [Ir(5,5′dmppy)$_3$] (**5**). The observed high Φ_{PL} value for **2** can

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

be attributed partially to the reduction of intermolecular interactions. The lifetimes of the excited state in all complexes at room temperature are longer (> 1 μs) than that of [Ir(ppy)$_3$], indicating that the substituents generate a number of vibronic modes in the excited state of [Ir(dmppy)$_3$] (see Supporting Information).[15]

Based on our observation with respect to **2**, the blue-shifted emission energy, high PL efficiency and absence of intermolecular interactions are due to the incorporation of methyl groups at the *para* position of the pyridine and the *meta* position of the phenyl rings relative to the Ir atom. This phenomenon shows that the position of the substitution on the pyridine or phenyl rings as well as the electronic effect of the substituent have an influence on the phosphorescence of [Ir(ppy)$_3$] and related systems. When compared to the other positions, the 4- and 4′-positions are quite sensitive to both the photophysical and structural aspects.

Electroluminescent Properties

The electroluminescent properties of compounds **2**, **3** and **4** were investigated. Devices with the Ir phosphor doped into the emissive layer were fabricated. EL-device performance was conducted using complexes **2**, **3** or **4** as dopant and 4,4′-bis(9-carbazolyl)-1,1′-biphenyl (CBP) as host in all cases. In addition, to compare with previous works, EL devices with a similar structure were also fabricated with [Ir(ppy)$_3$], except for the cathode, as reported by Thompson et al.,[1b] by vacuum-deposition techniques. The device structure used in this work is a typical multi-layer, employing indium tin oxide (ITO) as the anode, copper-phthalocyanine (CuPc: 10 nm) as the hole injection material, 4,4′-bis[(1-naphthyl)(phenyl)amino]-1,1′-biphenyl (NPD: 40 nm) as the hole-transport material, **2**, **3**, or **4** as the dopant material, CBP as the host material (20 nm), 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP: 10 nm) as the hole-blocking material, aluminium tris(8-quinolinolate) (Alq$_3$: 40 nm) as the electron-transport material, LiF as the electron-injection layer, (1 nm) and Al (100 nm) as the cathode, as shown in Figure 5. All complexes display green emission in the range of 508−520 nm in the EL spectra, which are well matched to those of the PL spectra in solution. There are no characteristic emission peaks from CBP or Alq$_3$, indicating that the emission originates mostly from the dopant (Figure 6). Furthermore, these results support the proposal that effective energy transfer from the host (CBP) to the dopant (Ir complex) occurs in the emissive layer. More detailed EL characteristics are shown in Table 3. The turn-on voltages (defined as 1 mA/cm^2) of [Ir(ppy)$_3$], **2**, **3** and **4** are 3.4, 5.6, 5.1 and 4.6 V, respectively (Figure 7). The intermolecular interactions (e.g. π−π stacks in molecular crystals) in the solid state and the ability to trap charges in the emissive layer are considered the most important factors in determining the operating voltage. The strong electronic coupling and intermolecular interactions in the molecular crystals contribute to effective injection and transport of charges, leading to lower operating voltages.[16] On the other hand, effective charge-trapping by the dopants gives rise to increasing driving voltages in OLEDs.[17] If the dopant material functions as a hole trap, the HOMO level of the dopant could be above that of the host material. In other words, materials having a lower oxidation potential can function as effective hole traps in OLEDs. Therefore, the observed higher operating voltages for **2** and **4**, relative to [Ir(ppy)$_3$], are predominantly caused by effective hole trapping.[18] These results are consistent with the electrochemical behaviors of **1**−**5** and [Ir(ppy)$_3$]. The brightness of the devices at 20 mA/cm^2 are 4543 cd/m^2, 4470 cd/m^2, 3551 cd/m^2 and 3235 cd/m^2, for **2**, **3**, **4** and [Ir(ppy)$_3$], respectively. With increasing current density, the external quantum efficiency of devices containing **2**, **3**, **4** and [Ir(ppy)$_3$] gradually decreased. Similar results have been reported previously, and are attributed to the increase of triplet-triplet annihilation of the exciton at high voltage levels. As expected, the device fabricated using complex **2** exhibits higher brightness and external quantum efficiency, as well as stronger EL intensity, than those of the other complexes or [Ir(ppy)$_3$] (see Figures 8 and 9). In contrast, the device efficiencies of **1** and **4** are lower than that of [Ir(ppy)$_3$] under the same conditions. The positions of the substituents as well as the nature of the substituents on the ppy rings could be important factors in achieving high electroluminescent efficiency in substituted Ir(ppy)$_3$ systems.

Conclusion

A series of dimethyl-substituted $[Ir(dmppy)_3]$ derivatives have been synthesized and characterized, including their photo-electroluminescent and electrochemical properties. The nature of their solid-state structures depends on the position of the methyl groups on the phenyl and pyridine rings. These methyl groups give rise to several distinct triplet states, affecting the electrochemical behavior and electroluminescence of the Ir^{III} complexes. As expected, they also considerably perturb the absorption, redox potentials, and photo- and electroluminescent efficiency. Lower oxidation potentials than that of $[Ir(ppy)_3]$ were observed in all cases, indicating that the methyl group induces a relatively easy oxidation and leads to effective hole trapping. Complex **2**, which has methyl groups at the 4′- and 4-positions exhibits a brighter green emission and higher Φ_{PL} than $[Ir(ppy)_3]$. In addition, a significant improvement of the external quantum efficiency (η_{ext} = 11%), which is nearly 200% higher than that of $[Ir(ppy)_3]$, is also observed in OLEDs. Further investigation on the effects on luminescent properties depending on other bulky functional groups into various positions of the ppy ligand is currently in progress.

Experimental Section

General Considerations. All experiments were performed under dry N_2 using standard Schlenk techniques. All solvents were freshly distilled from appropriate drying reagents prior to use. All starting materials were purchased from either Aldrich or Strem and used without further purification. Methyl-substituted phenyl or pyridine compounds were synthesized by slight modification of previous reports.[8]

Measurements: ^1H NMR and mass spectra were recorded with a Bruker DRX 500 MHz spectrometer and JEOL-JMS 700 instrument, respectively. UV/Vis and photoluminescent spectra for all samples with concentrations in the range of 10−50 μM were obtained with a Lambda 900 UV/Vis spectrometer and a Perkin−Elmer Luminescence spectrometer LS 50B. All solutions for photophysical experiments were degassed with more than three repeated freeze-pump-thaw cycles in a vacuum line. Melting points were determined with an Electrothermal 9100 apparatus. Emission lifetimes were measured with the fourth harmonic of a Q-switched Nd-YAG laser using the upper excited state energy transfer with a pulse duration of 6 ns and a repetition rate of 10 Hz. The laser beam had a diameter of 5 mm and an optical power of about 50 mJ. The emission from the film was recorded by a gated intensified diode array detector through a monochromator. The system allows for an integration time (gate width) of detection from 100 ns to 10

ms and a variable delay after excitation. Cyclic voltammetry was performed with an Autolab potentiostat from Echochemie under nitrogen in a one-compartment electrolysis cell consisting of a platinum wire working electrode, a platinum wire counter electrode, and a quasi Ag/AgCl reference electrode. Cyclic voltammograms were monitored at scan rates of either 100 $mV \cdot s^{-1}$ or 50 $mV \cdot s^{-1}$ and recorded in distilled dichloromethane. The concentration of the complex was maintained at 0.5 mM or less and each solution contained 0.1 M of tetrabutylammonium hexafluorophosphate (TBAP) as the electrolyte. The ferrocenium/ferrocene couple (0.40V) was used as the internal standard.

X-ray Crystallographic Analysis: Suitable crystals of **2** and **4** were obtained from slow vapor diffusion of toluene/benzene/hexane (2:1:1) into a solution of **2** or **4** in CH_2Cl_2. The crystal of **2** or **4** was attached to a glass fiber and mounted on a Bruker SMART diffractometer equipped with a graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation, operating at 50 kV and 30 mA and a CCD detector; 45 frames of two-dimensional diffraction images were collected and processed to obtain the cell parameters and orientation matrix. All data collections were performed at 173 K. The data collection 2θ ranges were 3.1−56.62° for **2** and 4.26−56.56° for **4**. No significant decay was observed during the data collection. The raw data were processed to give structure factors using the SAINT program. Each structure was solved by direction methods and refined by full-matrix least squares against F^2 for all data using the SHELXTL software (version 5.10).[19] All non-hydrogen atoms in compounds **2** and **4** were anisotropically refined. All other hydrogen atoms were included in the calculated positions and their contributions in structural factor calculations were included. Compound **2** cocrystallizes with benzene in the monoclinic crystal system with space group $P2_1/n$. The disordered benzene molecule was not modeled successfully. However, hydrogen atoms in benzene were included in the calculated positions and their contributions included in the structure factor. Compound **4** belongs to the cubic crystal system ($I\bar{4}3d$ space group). Crystal data for **2** and **4** are summarized in Table 4. Selected bond lengths and angles for **2** and **4** are given in Table 1. In the case of **2**, since the large positive (3.236 $e/Å^{-3}$) and negative (−3.306 $e/Å^{-3}$) difference Fourier peaks are located at short distances from Ir (0.84 Å and 0.90 Å, respectively), these peaks can be attributed to ghosts of the heavy Ir atom.[20] CCDC-220262 (**2**) and -220263 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336 033; E-mail: deposit@ccdc.cam.ac.uk].

Fabrication of Electroluminescent Devices: A glass substrate precoated with indium tin oxide (ITO) was cleaned in an ultrasonic bath of acetone, followed by 2-propanol. Surface treatment was carried out by exposing ITO to a UV ozone plasma. OLEDs withg CBP as host material were fabricated as follows. The hole-injecting layer, a 10 nm thick film of CuPc was deposited on the ITO surface by high-vacuum thermal evaporation and a 40 nm thickness α-NPD as hole-transporting layer was deposited onto the CuPc. An [Ir(dmppy)$_3$]-doped (dmppy = dimethyl-substituted ppy) host CBP layer was thermally co-evaporated onto the α-NPD layer. The [Ir(dmppy)$_3$] doping concentration was 8% in CBP. A 10 nm thick BCP (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline) layer was then deposited as the exciton-blocking layer, followed by a 40 nm thick Alq_3 layer as an electron-transporting layer. Finally, LiF (1 nm) and Al (100 nm) were deposited on top of the organic layers by thermal evaporation. The fabricated multilayer organic light-emitting devices have the structure of ITO/CuPc (10 nm)/α-NPD (40 nm)/CBP-Ir(dmppy)$_3$ (20 nm)/BCP (10 nm)/Alq_3 (40 nm)/LiF (1 nm)/Al (100 nm).

General Preparation of [Ir(n,n'-dmppy)$_3$]: The corresponding complexes were synthesized by a slight modification of Watt's procedures.[8b] A solution of the corresponding methyl-substituted phenylpyridine ligand (6 equiv., 2.64 mmol) in glycerol was added at ambient temperature under N_2 to a stirred anhydrous degassed glycerol solution (20 mL) of [Ir(acac)$_3$] (0.217 g, 0.44 mmol). The reaction mixture was refluxed for 24−48 h. The reaction mixture was then cooled to room temperature, 1 N HCl was added, and the mixture filtered to give a crude product. The pure complexes were obtained by chromatographic workup on silica gel using ethyl acetate/hexane as eluent.

[Ir(3,4′dmppy)$_3$] (1): ^{1}H NMR (CD_2Cl_2, 25 °C): δ = 7.86 (d, J = 8.4 Hz, 3 H), 7.46 (dd, J = 7.5, 0.9 Hz, 3 H), 7.36 (dd, J = 5.4, 1.5 Hz, 3 H), 6.67−6.78 (m, overlap, 9 H), 2.82 (s, 9 H, CH_3), 2.12 (s, 9 H, CH_3) ppm. MS (EI): m/z = 739 [M^+]. $C_{39}H_{36}IrN_3$ (739.25): calcd. C 63.39, H 4.91, N 5.69; found C 63.31, H 4.89, N 5.67.

[Ir(4,4′dmppy)$_3$] (2): ^{1}H NMR (CD_2Cl_2, 25 °C): δ = 7.71 (s, 3 H), 7.56 (d, J = 8.1 Hz,, 3 H), 7.36 (d, J = 5.47 Hz, 3 H), 6.71−6.74 (m, overlap, 6 H), 6.61 (dd, J = 1.2, 0.3 Hz, 3 H), 2.44 (s, 9 H, CH_3), 2.12 (s, 9 H, CH_3) ppm. MS (EI): m/z = 739 [M^+]. $C_{39}H_{36}IrN_3$ (739.25): calcd. C 63.39, H 4.91, N 5.69; found C 63.38, H 4.95, N 5.71.

[Ir(4,5′dmppy)$_3$] (3): ^{1}H NMR (CD_2Cl_2, 25 °C): δ = 7.74 (s, 3 H), 7.50 (s, 3 H), 7.42 (d, J = 5.7 Hz, 3 H), 6.75 (dd, J = 1.5, 0.9 Hz, 3 H), 6.64 (d, J = 0.6 Hz, 6 H), 2.44 (s, 9 H, CH_3), 2.27 (s, 9 H, CH_3) ppm. MS (EI): m/z = 739 [M^+]. $C_{39}H_{36}IrN_3$ (739.25): calcd. C 63.39, H 4.91, N 5.69; found C 63.40, H 4.86, N 5.61.

[Ir(5,4′dmppy)$_3$] (4): ^{1}H NMR (CD_2Cl_2, 25 °C): δ = 7.80 (d, J = 8.4 Hz, 3 H), 7.55 (d, J = 7.8 Hz, 3 H), 7.47 (ddd, J = 7.8, 2.1, 0.6 Hz, 3 H), 7.31 (dd, J = 1.2, 0.9 Hz, 3 H), 6.72 (dd, J = 7.8, 1.2 Hz, 6 H), 6.58 (d, J = 0.9 Hz, 3 H), 2.15 (s, 9 H, CH_3), 2.12 (s, 9 H, CH_3) ppm. MS (EI): m/z = 739 [M^+]. $C_{39}H_{36}IrN_3$ (739.25): calcd. C 63.39, H 4.91, N 5.69; found C 63.30, H 4.84, N 5.62.

Synthesis, Structures and Catalytic Properties of Bis(2-pyridylimino)-isoindolatopalladium Complexes

Bettina Siggelkow,[a] Markus B. Meder,[a] Christian H. Galka,[a] and Lutz H. Gade*[a]

Keywords: Hydrogenation / N ligands / Palladium

Reaction of the bis(2-pyridylimino)isoindole derivatives (10-Me)-BPI (**1a**), (11-Me)-BPI (**1b**), (11-Br)-BPI (**1c**), (4-Me)-BPI (**1d**) and 4-Me-10-*t*BuBPI (**1e**) with $[PdCl_2(PhCN)_2]$ and triethylamine in benzene gave the square-planar palladium(II) complexes [PdCl{(10-Me)-BPI}] (**2a**), [PdCl{(11-Me)-BPI}] (**2b**), [PdCl{(11-Br)-BPI}] (**2c**), [PdCl(4-MeBPI)] (**2d**) and [PdCl(4-Me-10-*t*BuBPI)] (**2e**), respectively. Extraction of the crude product **2b** with aqueous sodium carbonate solution led to the formation of the dinuclear carbonato-bridged complex $[\{(11\text{-Me-BPI})Pd\}_2(\mu\text{-}CO_3)]$ (**3**) which was characterized by an X-ray structure analysis. Reaction of 11-Br-BPI (**1c**) with a large excess (6 equiv.) of the acetylenes Me_3SiCCH, Ph_3SiCCH and PhCCH under Sonogashira conditions gave the alkynylated derivatives 11-(Me_3SiCC)-BPI (**4a**), 11-(Ph_3SiCC)-BPI (**4b**) and 11-(PhCC)-BPI (**4c**), which were metallated with bis(benzonitrile)dichloropalladium(II) to yield the Pd^{II} complexes [PdCl{11-(Me_3SiCC)-BPI}] (**5a**), [PdCl{11-(Ph_3SiCC)-BPI}] (**5b**) and [PdCl{11-(PhCC)-BPI}] (**5c**), respectively. The activity of **2b** in the catalytic hydrogenation of C=C double bonds was tested for the reaction with styrene, 1-octene and cyclohexene. The stability of the palladium complex, the reproducibility of the reaction kinetics, the different behaviour towards the three olefins chosen as substrates, as well as the possibility of isolating the non-decomposed catalyst after several catalytic runs, provides circumstantial evidence for molecular catalysis with the BPI-palladium complexes.

Introduction

Polydentate ligands have been widely used in the development of homogeneous hydrogenation catalysts.[1] In most cases phosphane or phosphane-heterodonor ligands have been chosen due to the well-established capacity of the soft phosphane ligators to stabilize the low-valent intermediates in the catalytic cycle.[2] A practical disadvantage in the use of phosphorus-based ligands is their propensity to be oxidized if exposed to air over extended periods of time. This has encouraged research into non-phosphorus-containing hydrogenation catalysts which combine molecular stability with sufficient activity to allow the catalytic hydrogenation of alkenes at atmospheric dihydrogen pressure.[3]

Costa, Pelagatti et al. have recently studied the hydrogenation activity of palladium(II) complexes stabilized by polydentate P∩N∩O,[4,5] N∩N∩S,[6] and N∩N∩N ligands.[7] In particular, the use of tridentate nitrogen donor ligands gave rise to relatively efficient Pd^{II} hydrogenation catalysts. The activation of dihydrogen is thought to involve the protonation of a basic site in the polydentate N-ligand and this formally protonated site is subsequently involved in the elimination of the saturated reaction product.

In view of this work on palladium-catalyzed homogeneous hydrogenations we have studied the catalytic activity of Pd complexes containing derivatives of the well-established bis(2-pyridylimino)isoindolate (BPI) ligands (**A**).[8–10] These ligands have been extensively studied in oxidation catalysis;[11] however, there is as yet no report of their application to other catalytic reactions. This class of formally anionic ligands appeared to be promising for the development of new palladium-based hydrogenation catalysts due to their tendency to tautomerise and act as neutral ligands **A′**, as has been recently established for the free ligand in solution and for the Cd complex **B** by X-ray diffraction.[12] Given the work by Costa, Pelagatti and coworkers,[4–7] this capacity of the BPI ligands was thought to favour homogeneous hydrogenation activity of their palladium(II) complexes.

There are only two previous reports in the literature of the coordination of BPI ligands to divalent palladium,[13,14] although with no further investigation of their reactivity. In this work we report the synthesis and structural characterization of several new BPI-Pd complexes, the first results of the integration of the BPI-ligand unit into more elaborate molecular architectures and, finally, a first study of the hydrogenation activity of a BPI-Pd derivative towards several alkenes.

Results and Discussion

Synthesis and Structural Characterization of the BPI-Palladium Complexes

The bis(2-pyridylimino)isoindole derivatives **1a**−**1e** were prepared according to the synthetic route first described by Siegl et al. by reaction of a 2-aminopyridine derivative with an *ortho*-phthalodinitrile (Scheme 1).[9] A slight modification of the reaction conditions — the replacement of *n*-butanol by *n*-hexanol as the solvent — gave significantly better yields of the ligand precursors than those reported in the literature.

The preparation of the corresponding square-planar palladium(II) complexes **2a**−**2e** was carried out in benzene using $[PdCl_2(PhCN)_2]$ as the Pd^{II} precursor and triethylamine as auxiliary base (Scheme 1). The coordination of the BPI ligands to palladium(II) can be conveniently monitored by ^1H NMR spectroscopy. The most characteristic change in the NMR spectra is the coordination shift of the 6-pyridyl protons from ca. $\delta = 8.4$ ppm in the free ligand to ca. $\delta = 9.5$ ppm in the palladium complexes, and the disappearance of the NH resonance of the isoindole unit.

Since there is no previous example of an X-ray structure analysis of a BPI-Pd complex, and in order to establish the structural details of these compounds, single-crystal X-ray diffraction studies of compounds [PdCl(11-Br-BPI)] (**2c**) and [PdCl(4-Me-10-*t*Bu-BPI)] (**2e**) were carried out. Their molecular structures are displayed in Figure 1 and 2, respectively, and their principal bond lengths and angles are compared in Table 1.

Both complexes are mononuclear and possess the expected square-planar coordination geometry. The central palladium atom is coordinated to the three ligating nitrogen atoms of the BPI ligand (N1, N3 and N5) as well as to the chloro ligand. The chloropalladium units are slightly displaced from the molecular plane defined by the three N atoms, as is evident from the N1−Pd−N5 angles of 172.0(1)° and 171.0(2)° for **2c** and **2e**, respectively. This distortion is reflected in an even more pronounced way by the N3−Pd−Cl angles [**2c**: 167.75(9)°; **2e**: 166.3(2)°] and may be due to the repulsive interaction of the chloro ligand with the *ortho*-hydrogen atoms of the pyridyl groups. The Pd−N bond lengths to the pyridyl units are in the range of 2.053−2.071 Å, whereas the amide-type central Pd−N3 bond length is contracted to 1.962(3) Å for **2c** and 1.957 Å for **2e**. This pattern is consistent with the previously reported structural data of BPI-transition metal complexes.[9,10] The Pd−Cl bond lengths of 2.333(1) Å (**2c**) and 2.332(3) Å (**2e**) are similar to those found for other chloropalladium complexes bearing tridentate ligands.[15]

crude product was extracted with an aqueous sodium carbonate solution on one occasion, which led to a partial exchange of the chloro ligand by the carbonate dianion. From this mixture the dinuclear carbonato-bridged complex [{(11-Me-BPI)Pd}$_2$(μ-CO_3)] crystallized and its structure was established by a single-crystal X-ray structure analysis. Its molecular structure is displayed in Figure 3 along with the principal bond lengths and angles.

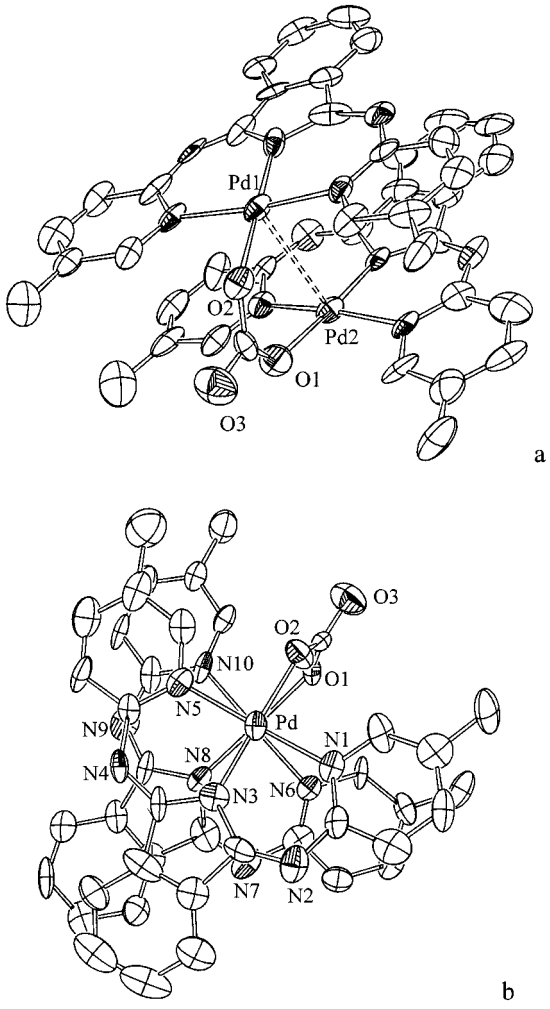

Figure 3. a) Molecular structure of complex **3**; selected bond lengths (Å) and angles (°): Pd1−N1 2.05(1), Pd2−N6 2.07(1), C41−O1 1.23(2), Pd1−N3 1.93(2), Pd2−N8 1.94(1), C41−O2 1.34(2), Pd1−N5 2.05(1), Pd2−N10 2.06(2), C41−O3 1.22(2), Pd1−O2 2.04(1), Pd2−O1 2.03(1); N1−Pd1−N5 172.5(5), N1−Pd1−O2 89.7(6), N6−Pd2−O1 90.4(7), N6−Pd2−N10 73.4(5), N3−Pd1−O2 178.3(5), N8−Pd2−O1 175.7(6); b) view along the Pd−Pd axis

As is evident from the structure represented in Figure 3, the exchange of the chloro ligands in two of the Pd complexes by a bridging carbonato ligand gives a dinuclear complex with a stacked arrangement of the two complex fragments. The relative disposition of the two molecular halves and their parallel orientation may be due to the combination of a weakly attractive Pd−Pd contact and π-stacking interactions between the aromatic rings in the ligands. The Pd−Pd distance of 3.031 Å is in the range of previously established d^8-metal-metal contacts.[16] The view along the Pd−Pd axis in Figure 3b reveals the slight twist in the orientation of the two planar metal-ligand units (N5−Pd1−Pd2−N10 = 16.5°).

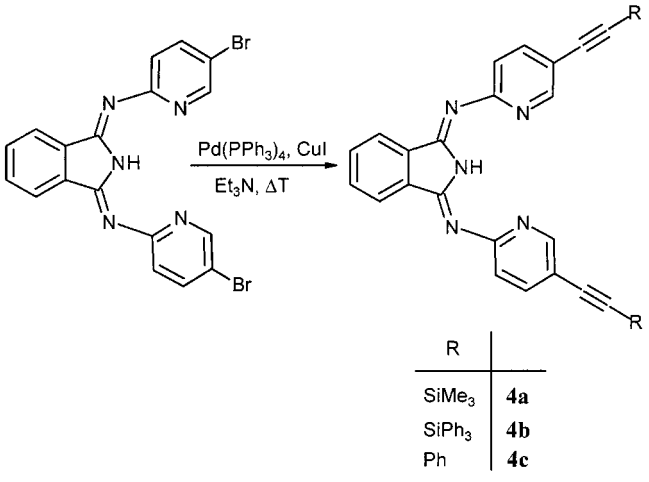
We note that Gagné et al. have reported the crystal structure of a dinuclear BPI-copper complex containing a bridging carbonato ligand.[9c] In contrast to the Pd complex presented in this work, the CO_3^{2-} ligand in their Cu complex

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

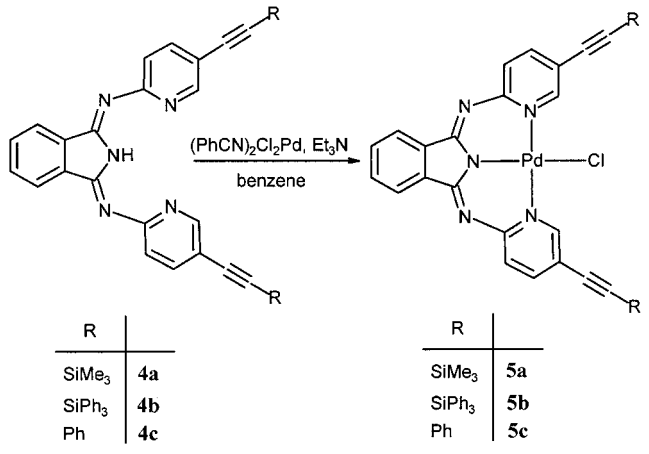
connects two orthogonally oriented BPI-metal units. Both Pd atoms in compound **3** possess an almost ideal square-planar coordination geometry and the two halves of the molecule are structurally almost identical and very similar to **2c** and **2e**. The carbonato ligand is almost planar, with similar metric parameters to the copper complex mentioned above. It is interesting to note the difference in the C−O bond lengths [C41−O1 1.23(2), C41−O3 1.22(2) Å, C41−O2 1.34(2) Å] in the bridging ligand.

Synthesis of Alkynyl-Substituted BPI Ligands

The bis(2-pyridylimino)isoindole ligands give well-defined complex structures and may thus be used as building blocks in more complex molecular architectures. In order to test whether the ligand periphery of the BPI ligands may be modified a posteriori, we studied the alkynylation of the ligand **1c** by the Sonogashira method.[17] The reaction of 11-Br-BPI (**1c**) with a large excess (6 equiv.) of the acetylenes Me_3SiCCH, Ph_3SiCCH and PhCCH in Et_3N using 10 mol % of $[Pd(PPh_3)_4]$/CuI gave the alkynylated derivatives 11-(Me_3SiCC)-BPI (**4a**), 11-(Ph_3SiCC)-BPI (**4b**) and 11-(PhCC)-BPI (**4c**) as yellow solids in good yields (Scheme 2).



Scheme 2. Synthesis of the alkynyl-substituted BPI ligands **4a**−**4c**



Scheme 3. Synthesis of the alkynyl-substituted BPI-palladium(II) complexes **5a**−**5c**

Synthesis and Structural Characterization of the Alkynyl-Substituted BPI-Palladium Complexes

The synthesis of the corresponding palladium(II) complexes was carried out as described above for complexes **2a**−**2e**, by reaction of the ligands **4a**−**4c** with bis(benzonitrile)dichloropalladium(II) and triethylamine in benzene. After workup, the orange complexes [PdCl{11-(Me_3SiCC)-BPI}] (**5a**) and [PdCl{11-(Ph_3SiCC)-BPI}] (**5b**) as well as the dark-red compound [{11-(PhCC)-BPI}PdCl] (**5c**), respectively, were isolated in good yields (Scheme 3).

The metallation of the BPI ligands **4a** and **4b** may be conveniently monitored by ^{29}Si NMR spectroscopy. The resonances of the Me_3Si-substituted ligand are shifted from $\delta = -17.4$ ppm in **4a** to $\delta = -22.0$ ppm in [PdCl{11-(Me_3SiCC)-BPI}] (**5a**) and from $\delta = -28.5$ ppm in **4b** to $\delta = -22.1$ ppm in [PdCl{11-(Ph_3SiCC)-BPI}] (**5b**). The formation of the alkynyl-substituted complexes **5a**−**5c** was confirmed by their FAB mass spectra, in which the $[M - Cl]^+$ cation was found as the principal fragment.

Single crystals of **5a** and **5b** which were suitable for X-ray diffraction were obtained from solutions of the compounds in CH_2Cl_2 (**5a**) and CH_2Cl_2/pentane (**5b**) at ambient temperature. In order to establish the details of the influence that the alkynyl substitution exerts upon the molecular structures of the BPI-palladium complexes, X-ray structure analyses of both complexes **5a** and **5b** were carried out. Their molecular structures are displayed in Figure 4 and 5, respectively, and their principal bond lengths and angles are compared in Table 2.

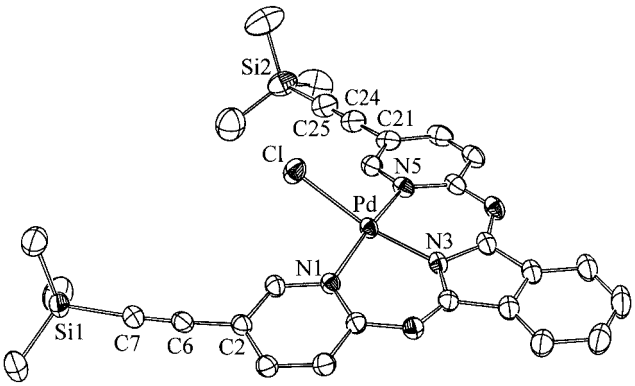


Figure 4. Molecular structure of complex **5a**; selected bond lengths and angles are listed in Table 2

The general features of the metal complex structures of **5a** and **5b** are similar to those of **2c** and **2e**. As in the case of the latter, the palladium atom is slightly displaced from the plane defined by the N-donors, as can be inferred from the N5−Pd−N1 angles [**5a**: 168.41(6)°; **5b**: 167.4(1)°]. The "bending" of the chloro ligands out of the plane of the BPI-Pd unit is even more pronounced than in **2c** and **2e** [N3−Pd−Cl = 165.30(5)° (**5a**) and 163.75(8)°(**5b**)]. This decrease of the N3−Pd−Cl angle may be attributed to increased steric crowding at the 11-position in the series Br < Me_3Si < Ph_3Si, along with the *ortho*-H···Cl repulsion, thus

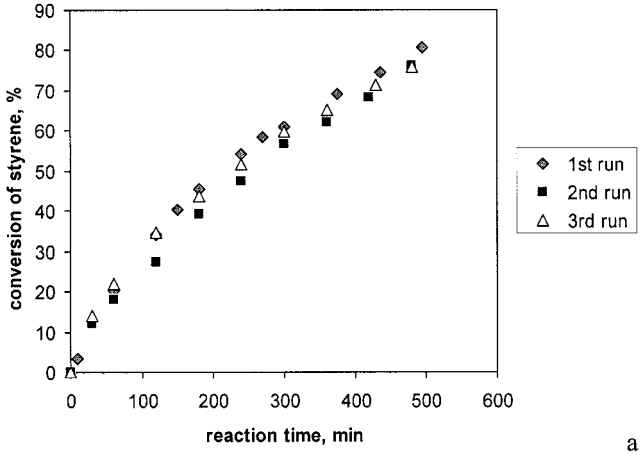
pushing the Cl ligands out of the plane. The Pd−N bond-length pattern is again similar to that observed in **2c** and **2e**, with greater Pd−N distances for the pyridyl groups [Pd−N5 = 2.046(2) Å (**5a**), 2.027(2) Å (**5b**) and Pd−N1 = 2.052(2) Å (**5a**), 2.034(3) Å (**5b**)] and contracted bond lengths for the central formally anionic donor [Pd−N3 = 1.958(2) Å (**5a**) 1.952(2) Å (**5b**)].

Catalytic Hydrogenation of Olefins with [PdCl(4-Me-BPI)] (2b)

As indicated in the introduction, there is a substantial interest in the development of molecular non-phosphane-containing palladium catalysts for homogeneous hydrogenations. A limiting factor is the propensity of many palladium complexes of that type to undergo degradation under the conditions of the catalytic reaction. Given the stability of the BPI-Pd complexes and the capacity of the imino units in the ligand framework to act as sites of intermediate protonation, we hoped that they might hydrogenate alkenes without decomposition. As a first test system we chose the complex [PdCl(4-Me-BPI)] (**2b**) which is significantly more soluble in polar organic solvents than the unsubstituted parent complex. In order to test its activity towards hydrogenation of C=C double bonds in different chemical environments, the hydrogenation of three substrates — styrene, 1-octene and cyclohexene — was investigated.



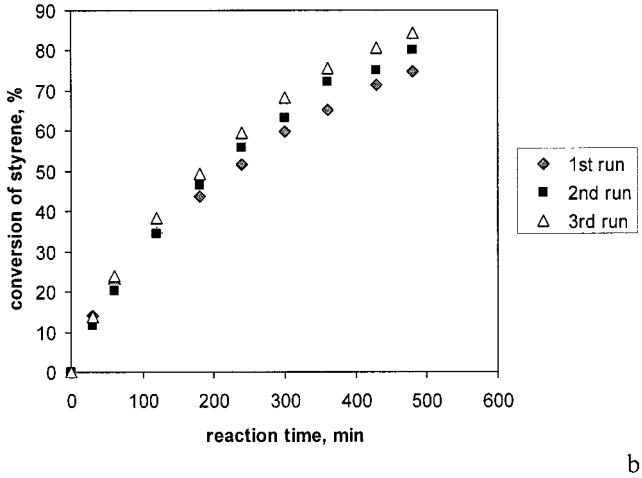


Figure 6. Hydrogenation of styrene at 25 ± 1 °C in THF at a hydrogen pressure of 1 bar using 2 mol % of the catalyst **2b**: a) the conversion curves for three independent catalytic runs; b) isolation of the catalyst that had been used in the third run and re-used in two further catalytic runs

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

All reactions were carried out at 25 ± 1 °C in THF at a hydrogen pressure of 1 bar using 2 mol % of the catalyst **2b**. We first studied the hydrogenation of styrene to ethylbenzene. The conversion curves for three independent catalytic runs are displayed in part a of Figure 6 which were carried out under the specified standard conditions and the same substrate and catalyst concentrations; in all three cases the catalyst **2b** was isolated without detectible decomposition after the conversion. In view of this apparent stability of the catalyst, the sample which had been used in the third run and had subsequently been isolated, was employed in two further catalytic runs, again under identical conditions. As can be seen in part b of Figure 6, this procedure also did not lead to a significant change in the catalytic activity of **2b**. After each of the three catalytic runs, the solvent and reaction product were removed in vacuo, the solid residue characterized by ^{1}H NMR spectroscopy and then used in the subsequent catalytic conversion. It is evident from the absence of a signal at δ = 8.5 ppm, which would be due to the demetallated BPI ligand, that there was no decomposition even after three cycles. The stability of the system is shown by comparison of the ^{1}H NMR spectra of **2b** before the catalysis (Figure 7, top) with that recorded after the three cycles of catalysis, isolation of the catalyst and re-use of the catalyst (Figure 7, bottom). We were not able to detect hydridopalladium intermediates by ^{1}H NMR spectroscopy during the course of the catalytic reaction.

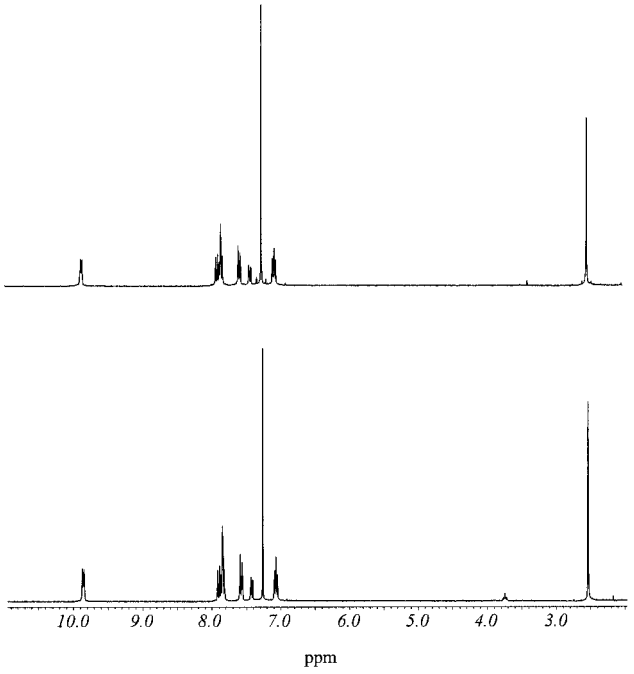

Figure 7. Top: ^{1}H NMR spectrum of **2b** before the catalysis; bottom: ^{1}H NMR spectrum of the catalyst recorded after three cycles of catalysis, isolation of the catalyst, and re-use of the catalyst

We found that if the hydrogenation is carried out in methanol instead of THF as solvent, the palladium complex decomposes during the course of the reaction leading to the precipitation of palladium black, which is inactive under the reaction conditions. This catalyst degradation is evidenced by ^{1}H NMR spectroscopy and the observation of the proton signal of the free ligand at δ = 8.5 ppm.

As a second substrate, and as an example of a long-chain terminal alkene, the hydrogenation of 1-octene catalyzed by **2b** was investigated. Of particular interest was the competing reaction in this transformation, the isomerization of the alkene to a mixture of *E*- and *Z*-2-octene. The course of this reaction, as followed by GC-MS, is represented in Figure 8.

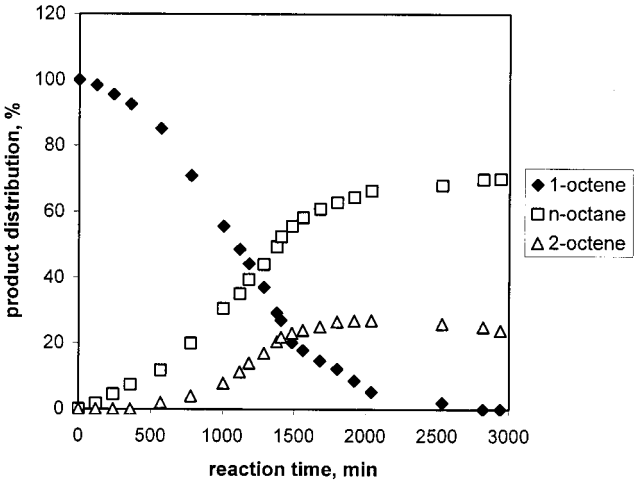

Figure 8. Hydrogenation of 1-octene catalyzed by **2b** and the concomitant isomerization of the alkene to a mixture of *E*- and *Z*-2-octene, as followed by GC-MS

After a short induction period, during which the catalytically active species is generated, the conversion of 1-octene sets in, giving n-octane and a mixture of *Z*-2-octene and *E*-2-octene. After the complete consumption of 1-octene, the conversion into n-octane was around 70%, while 27% of the starting material were converted into the mixture of 2-octenes. The hydrogenation of the latter is extremely slow and practically insignificant within the timeframe represented in Figure 8.

The lack of activity in the hydrogenation of internal C=C double bonds was also apparent from the reaction with cyclohexene. Whereas this substrate is readily hydrogenated by colloidal or heterogeneous Pd catalysts, it is known to be converted only very slowly by molecular Pd catalysts.[18] After 1500 minutes only 5% of the alkene had been converted and even after 9000 minutes the conversion was only at about 12%. A comparison of the conversion curves for the hydrogenation of the three alkenes investigated in this study is given in Figure 9.

As previously noted by Elsevier et al. for N-ligand Pd catalysts, the "mercury test"[19] for potential colloidal metal catalysis is not applicable to palladium compounds such as **2b**.[3d,18] However, the stability of complex **2b** that we observed in the catalytic hydrogenations, the reproducibility of the reaction kinetics, the different behaviour towards the three olefins chosen as substrates and, finally, the possibility of isolating the non-decomposed catalyst after several cata-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

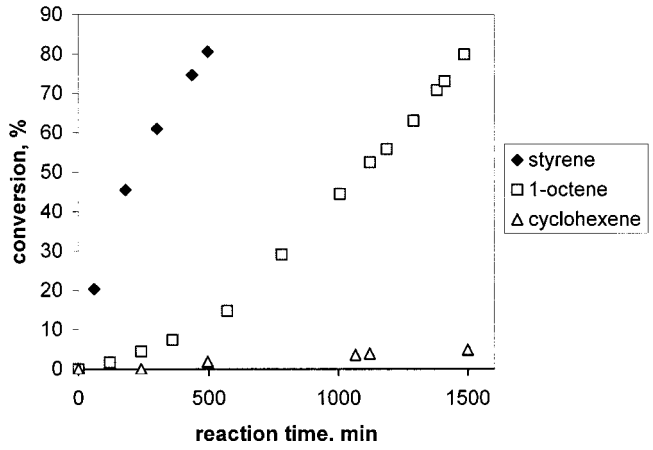

Figure 9. A comparison of the conversion curves for the hydrogenation of styrene, 1-octene and cyclohexene

lytic runs, provides strong circumstantial evidence for molecular catalysis with the BPI-palladium complex.

Although the mechanistic details of the catalytic cycle remain to be established, and no reaction intermediates could be detected to date, a reaction sequence based on the mechanistic proposal by Costa, Pelagatti and co-workers,[4−7] is put forward in Scheme 4. It takes the previously observed possibility of imino-N protonation in the ligand framework into account.[12] Preliminary studies with the other BPI derivatives reported in this work indicate an essentially similar behaviour.

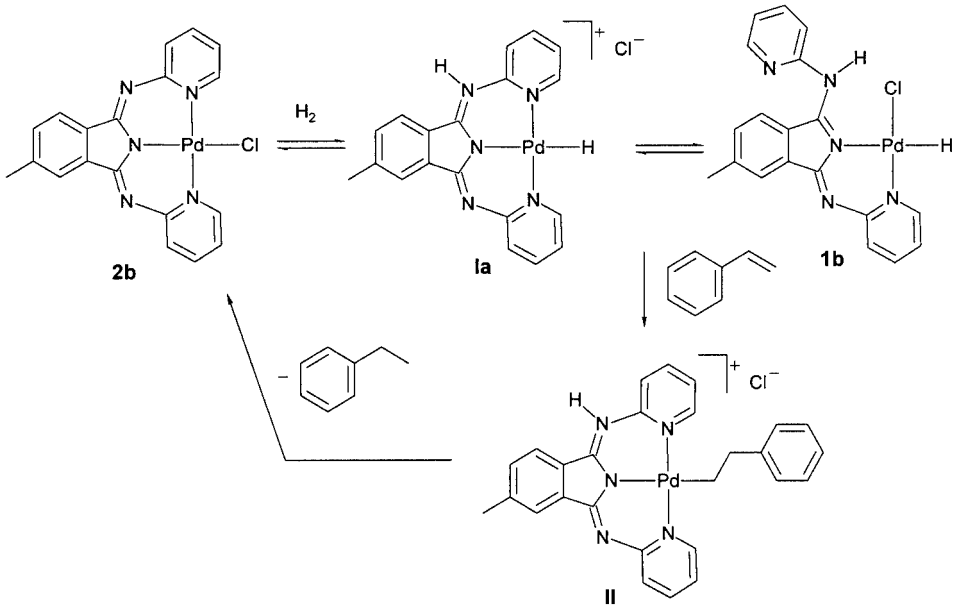
Conclusion

In this paper we have reported the first detailed synthetic and structural study of bis(2-pyridylimino)isoindolatopalladium(II) complexes. The possibility of modifying the peripheral ligand structure after the assembly of the BPI unit has been demonstrated by the Sonogashira alkynylation of a bromopyridyl derivative. This provides the first example of a possible modular variation of these ligands which is of particular interest in catalyst design based on these systems. A detailed study into the hydrogenation activity of one of the Pd complexes has established a novel active molecular catalyst for alkene hydrogenation. Current and future work is aimed towards the elucidation of the mechanism of this catalytic reaction.

Experimental Section

All manipulations were performed under nitrogen. Solvents were dried according to standard methods and saturated with nitrogen. The deuterated solvents used for the NMR spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and stored over 4 Å molecular sieves. Solids were separated from suspensions by filtration through dried Celite or by centrifugation. The ^{1}H, ^{13}C and ^{29}Si NMR spectra were recorded on Bruker AC 200, Bruker Avance 250 and Bruker AMX 400 FT NMR spectrometers, respectively [reference: tetramethylsilane, using the residual protonated solvent peak (^{1}H) or the carbon resonance (^{13}C)]. Infrared spectra were recorded on a Nicolet Magna IRTM 750 spectrometer. Elemental analyses were carried out by the microanalytical service at the Chemistry Department of the University of Strasbourg. (10-Me)-BPI (**1a**), (11-Me)-BPI (**1b**), (11-Br)-BPI (**1c**), (4-Me)-BPI (**1d**)[9] and $[PdCl_2(PhCN)_2]$[20] were prepared according to published procedures. All other chemicals used as starting materials were obtained commercially and used without further purification.

Preparation of 4-Me-10-*t*BuBPI (1e): 4-Methylphthalodinitrile (1.50 g, 10.6 mmol) and 2-amino-4-(*tert*-butyl)pyridine (3.96 *g* = 26.1 mmol) were heated unter reflux in hexanol in the presence of a catalytic amount of $CaCl_2$ (0.16 g, 1.36 mmol) for 18 h. After



Scheme 4. Proposed mechanism of the Pd-catalyzed hydrogenation

General Procedure for the Preparation of the Palladium(II) Complexes 2a−2e: The bis(2-pyridyl)isoindole (BPI) derivative (in general 0.3 mmol) together with 1.1 molar equivalents of $[PdCl_2(PhCN)_2]$ and 1.1 molar equivalents of NEt_3 were dissolved in benzene and stirred at room temperature for two days. Depending on the substitution pattern of the ligand, the palladium complex either precipitated directly from the reaction mixture or remained in solution. For compounds **2a−2d** direct precipitation of the reaction product was observed and the resulting solid was separated by filtration. The co-product NEt_3HCl was extracted from the solid by extraction three times with 50 mL of water and the crude product thus obtained was recrystallized from CH_2Cl_2/*n*-hexane. In the case of complex **2e** the reaction product remained in solution. After removal of the solvent and the volatiles in vacuo, the solid residue was extracted with 10 mL of benzene and the solvent of the extract evaporated in vacuo. After washing three times with 50 mL of water and 10 mL of hexane, the crude product thus obtained was recrystallized from CH_2Cl_2/*n*-hexane. Compounds **2a−2e** are deep yellow-ochre crystalline solids.
