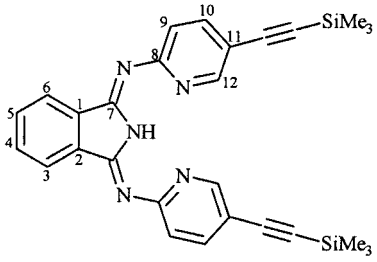
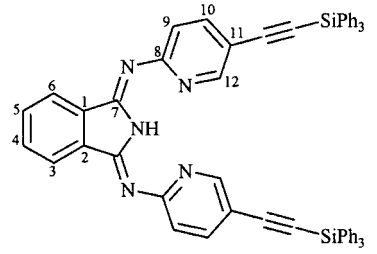
General Procedure for the Preparation of the Alkynyl-Substituted Ligands 4a−4c: The BPI derivative **1c** (0.7 mmol), six molar equivalents of the substituted acetylene, 0.2 molar equivalents of CuI and 0.2 molar equivalents of tetrakis(triphenylphosphane)palladium(0) were stirred in 10 mL of triethylamine at 60 °C. The reaction time was 6 d for **4a**, 4 d for **4b** and 24 h for **4c**. After cooling the reaction mixture to ambient temperature, the solvent was removed in vacuo. The residue was redissolved in 10 mL of CH_2Cl_2, the solution extracted with 10 mL of water and then dried over magnesium sulfate. The evaporation of the solvent in vacuo yielded the reaction products as pure yellow microcrystalline solids.

(11-TMS-ethynyl)-BPI (4a): Yield: 50%. M.p.: 168 °C. ^1H NMR (300.17 MHz, $CDCl_3$, 295 K): δ = 0.29 (s, 18 H, CH_3), 7.32 (d, $^3J_{H,H}$ = 7.4 Hz, 2 H, H-9), 7.58 (s, 2 H, H-5), 7.77 (dd, $^3J_{H,H}$ = 7.4, $^4J_{H,H}$ = 3.6 Hz, 2 H, H-10), 7.97 (s, 2 H, H-6), 8.66 (d, $^3J_{H,H}$ = 3.6 Hz, 2 H, H-12), 13.72 (s, 1 H, N−H) ppm. $^{13}C\{^1H\}$ NMR (75.48 MHz, $CDCl_3$, 295 K): δ = 0.9 (CH_3), 98.2 (C-Si), 102.2 (*C*-C$_{aryle}$), 116.3 (C-11), 122.6 (C-9), 128.3 (C-5), 131.7 (C-6), 135.5 (C-1,2), 140.8 (C-10), 150.9 (C-12), 153.8 (C-7), 159.2 (C-8) ppm. ^{29}Si NMR (79.5 MHz, $CDCl_3$, 295 K): δ = −17.4 ppm. IR (KBr): $\tilde{\nu}$ = 2959 (s), 2155 (s), 1624 (s), 1566 (s), 1465 (s), 1360 (w), 1307 (vw), 1251 (w), 1220 (s), 1096 (w), 1036 (w), 925 (vw), 872 (s), 843 (s), 758 (w), 695 (w) cm^{-1}. $C_{28}H_{29}N_5Si_2$ (491.74): calcd. C 68.39, H 5.94, N 14.24; found C 68.52, H 6.51, N 13.63.



(11-Ph$_3$Si-ethynyl)-BPI (4b): Yield: 69%. M.p.: 198 °C. ^1H NMR (300.17 MHz, $CDCl_3$, 295 K): δ = 7.37−7.72 (m, 34 H, Ph−H, H-5, H-9), 7.91 (d, $^3J_{H,H}$ = 7.0 Hz, 2 H, H-10), 8.07 (s, 2 H, H-6), 8.82 (s, 2 H, H-12), 13.77 (s, 1 H, N−H) ppm. $^{13}C\{^1H\}$ NMR (100.61 MHz, $CDCl_3$, 295 K): δ = 82.0 (C≡*C*Si), 91.7 (*C*≡CSi), 106.0 (C-Ph), 116.1 (C-11), 122.5 (C-5/9), 123.0 (C-5/9), 127.9 (C-Ph), 129.8 (C-Ph), 130.1 (C-Ph), 131.9 (C-6), 135.5 (C-1,2), 141.1 (C-10), 151.0 (C-12), 153.7 (C-7), 158.4 (C-8) ppm. ^{29}Si NMR (79.5 MHz, $CDCl_3$, 295 K): δ = −28.5 ppm. FAB-MS: *m*/*z* = 864 [M + H]$^+$. IR (KBr): $\tilde{\nu}$ = 3304 (br), 2935 (w), 2676 (s), 2070 (s), 1623 (vs), 1565 (vs), 1459 (s), 1428 (vs), 1185 (w), 1113 (vs), 1035 (w) cm^{-1}. $C_{58}H_{41}N_5Si_2$ (864.17): calcd. C 80.61, H 4.78, N 8.10; found C 80.36, H 4.33, N 7.72.



(11-Ph-ethynyl)-BPI (4c): Yield: 77%. M.p.: 246 °C. ^1H NMR (300.17 MHz, CD_2Cl_2, 295 K): δ = 7.39−7.45 (m, 10 H, Ph−H), 7.60 (d, $^3J_{H,H}$ = 7.9 Hz, 2 H, H-9), 7.68−7.70 (dd, $^3J_{H,H}$ = 5.5, $^4J_{H,H}$ = 3.0 Hz, 2 H, H-5), 7.89−7.93 (dd, $^3J_{H,H}$ = 7.9, $^4J_{H,H}$ = 2.2 Hz, 2 H, H-10), 8.05 (dd, $^3J_{H,H}$ = 5.5, $^4J_{H,H}$ = 2.9 Hz, 2 H, H-6), 8.84 (d, $^4J_{H,H}$ = 2.2 Hz, 2 H, H-12), 14.07 (s, 1 H, N−H) ppm. $^{13}C\{^1H\}$ NMR (75.48 MHz, $CDCl_3$, 295 K): δ = 86.5 (C≡C), 92.8 (C≡C), 107.2 (C-Ph), 116.6 (C-11), 122.6 (C-9), 127.6 (C-5), 128.4 (C-Ph), 128.6 (C-Ph), 129.5 (C-Ph), 131.6 (C-6), 135.3 (C-1,2), 140.4 (C-10), 150.5 (C-12), 153.8 (C-7), 158.9 (C-8) ppm. C 63.76, H 3.15, N 10.94; found C 63.32, H 2.99, N 10.63.

Catalyst Testing: The catalyst tests were carried out in THF at 1 bar H_2 pressure using 2 mol % of palladium catalyst (the catalyst concentration being ca. 1.5 μmol·mL^{-1}). The course of the catalytic hydrogenations was monitored by GC/MS performed with a Shimadzu GC-17A/GCMS-QP5050A. Column: SGE BPX5, 5% phenyl, polysilylphenylene-siloxane, nonpolar, 30 m, 0.22 mm, carrier gas He. The products were analyzed by comparison of the recorded mass spectra and retention times with those of authentic samples. The measured relative ratio of the products was calibrated by comparative measurements with known substance ratios using pure substances.

GC/MS Parameters for Styrene Hydrogenation: T (start) = 50 °C, T (injector) = 250 °C, T (interface) = 280 °C, 30.0 m (0.22 mm), 0.7 mL/min He (flow rate), 66.3 kPa (column pressure), temperature program: 5.0 min, 50 °C; 2 °C/min, 80 °C; 20 °C/min, 250 °C; retention times: t_R (ethylbenzene) = 7.84 min, t_R (styrene) = 9.12 min,

GC/MS Parameters for 1-Octene Hydrogenation: T (start) = 35 °C, T (injector) = 250 °C, T (interface) = 280 °C, 30.0 m (0.22 mm), 1.5 mL/min He (flow rate), 133.2 kPa (column pressure), temperature program: 8.0 min, 35 °C; 30 °C/min, 250 °C; t_R (1-octene) = 5.62 min, t_R (*n*-octane) = 5.93 min, t_R [(*cis*/*trans*)-2-octene] = 6.35 min.

GC/MS Parameters for Cyclohexene Hydrogenation: T (start) = 35 °C, T (injector) = 250 °C, T (interface) = 280 °C, 30.0 m (0.22 mm), 1.5 mL/min He (flow rate), 133.2 kPa (column press-

X-ray Crystallographic Study of 2c, 2e, 3, 5a and 5b: Suitable crystals of the complexes **2c**, **2e**, **3**, **5a** and **5b** were obtained by layering concentrated solutions of the compounds in dichloromethane or chloroform with hexanes and allowing slow diffusion at room temperature. The crystal data for **2c**, **3**, **5a** and **5b** were collected on a Nonius Kappa CCD diffractometer at −100 °C and transferred to a DEC Alpha workstation; for all subsequent calculations the Nonius OpenMoleN package was used.[21] The data for **2e** were collected on a CAD4 (Enraf−Nonius) four-circle diffractometer at −80 °C and the structure solution was carried out using the SHELX-97 structure-solution package.

All structures were solved by direct methods with absorption corrections being part of the scaling procedure of the data reductions. After refinement of the heavy atoms, difference Fourier maps revealed the maxima of residual electron density close to the positions expected for the hydrogen atoms; they were introduced as fixed contributors in the structure-factor calculations with fixed coordinates (C−H: 0.95 Å) and isotropic temerature factors [B(H) = 1.3 B_{eqv}(C) Å^2] but not refined. The hydrogen atoms of the solvents were not refined. Full least-square refinements on F^2. A final difference map revealed no significant maxima of electron density. The scattering factor coefficients and the anomalous dispersion coefficients were taken from the literature.[22] Crystal data and experimental details for the crystals of **2c**, **2e**, **3**, **5a** and **5b** are given in Table 3.

CCDC-232252 to -232256 (for **2c**, **2e**, **3**, **5a** and **5b**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank the Deutsche Forschungsgemeinschaft, the CNRS, and the Institut Universitaire de France for funding. We are grateful to Dr. André DeCian and Natalie Gruber for carrying out the X-ray diffraction studies.

Cationic and Neutral Rhodium(I) Oxazolinylcarbene Complexes

Vincent César,[a] Stéphane Bellemin-Laponnaz,*[a] and Lutz H. Gade*[a,b]

Keywords: Carbenes / N ligands / Oxazolines / Rhodium / X-ray diffraction

Reaction of $[Rh(\mu\text{-}O\textit{t}Bu)(diene)]_2$ [diene = 1,5-cyclooctadiene (COD) or bicyclo[2.2.1]hepta-2,5-diene (NBD)] with the oxazolinylcarbene ligand precursor 2-(4,4-dimethyl)oxazolinylimidazolium bromide ("$Me_2carboxH^+Br^-$", **2**) yielded the five-coordinate complexes [RhBr(Me_2carbox)(diene)] [diene = COD (**3**), NBD (**4**)]. Single-crystal X-ray structure analyses established a distorted trigonal bipyramidal configuration for **3**, whereas the molecular structure of **4** is distorted square pyramidal. The dynamic properties of these five-coordinate complexes have been investigated by variable temperature ^1H NMR spectroscopy, indicating polytopal rearrangements of the five-coordinate complexes. The two compounds were converted into the square-planar cationic complexes $[Rh(Me_2carbox)(diene)]^+$ (**5** and **6**, respectively), which have been isolated and fully characterised. The rhodium complex [RhBr(Me_2carbox)(CO)] (**7**) was obtained in high yield in a one-step reaction of the ligand precursor **2** and [Rh(acac)-$(CO)_2$] (acac = acetylacetonate).

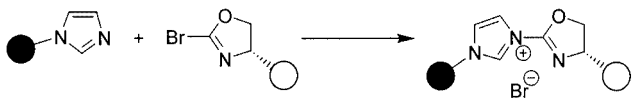
Introduction

The combination of ligand donor units with very different coordination properties in a di- or polydentate spectator ligand ("hetero-donor ligands") may permit a stereoelectronic control of the reactivity at the remaining coordination sites in a transition metal complex. This has been an underlying principle in the development of many phosphane-heteroatom-based polydentate ligands employed in molecular catalysts.[1]

In recent years, *N*-heterocyclic carbenes have emerged as a new class of spectator ligands in transition metal complexes with ever increasing potential in homogeneous catalysis.[2] They are strong σ-donors and in many respects resemble phosphorus-donor ligands rather than classical Fischer- or Schrock-type carbenes.[3] In this regard, they may replace phosphane units in heterodonor ligands in combination with more "classical" ligand functionalities.[4,5] Among these novel chelating ligand systems, *N*-functionalised carbene complexes have recently received much attention and have given rise to exciting results in homogeneous catalysis.[5,6]

We previously reported the direct coupling of oxazolines and *N*-heterocyclic carbenes, and this new class of C,N-donor ligands (**A**) has been successfully employed in various catalytic reactions.[6] The ligand synthesis is modular, assembling both units in a single coupling step, which was thought to be an efficient strategy in the development of novel catalysts.



(A)

The rigidity of the bidentate ligand **A** allows for the modeling of a well-defined active space in its molecular catalysts. In this paper we report a number of new complexes of rhodium(I) containing a type **A** ligand which is derived from a 2-(4,4-dimethyl)oxazolinylimidazolium salt. A detailed structural study was intended to provide insight into the nature of precursors and active rhodium catalysts based on these systems.[6b]

Results and Discussion

Synthesis and Structural Characterization of the Bromo{1-(4,4-dimethyl-4,5-dihydrooxazol-2-yl)-3-mesitylimidazol-2-ylidene}rhodium(I) Complexes 3 and 4

As described in a previous paper,[6a] the imidazolium salt **2** is readily obtained from 1-mesityl-1*H*-imidazole and commercially available 4,5-dihydro-4,4-dimethyloxazole. Following the procedure reported by Meyers and Novachek, the reaction of the lithiated oxazole (*t*BuLi, THF, −78 °C) with 1,2-dibromotetrafluoroethane gave the corresponding

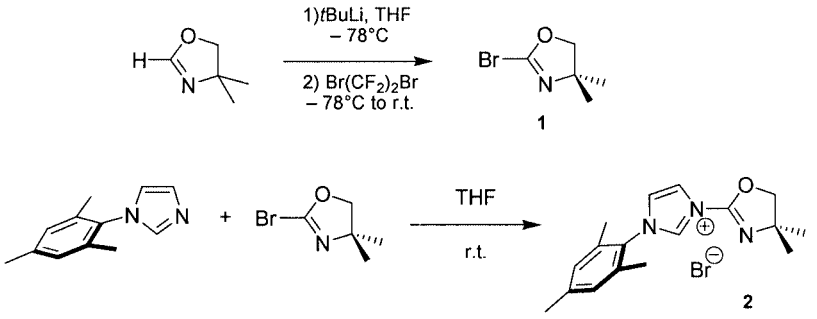

Scheme 1. Synthesis of the 2-bromooxazoline **1** and the oxazolinyl imidazolium salt **2** as ligand precursor

2-bromo-4,5-dihydro-4,4-dimethyloxazole **1** in 65−70% yield (Scheme 1).[7] Treatment of **1** with 1-mesityl-1*H*-imidazole in THF at 50 °C gave the ligand precursor, the 2-(4,4-dimethyloxazolinyl)imidazolium salt (Me_2oxcarb-H^+Br^-) **2**, in about 80% yield (Scheme 1).[6a]

All attempts to generate the free carbene Me_2oxcarb by reaction of **2** with an external base were unsuccessful and led to the nonspecific degradation of the compound. We therefore chose to generate the corresponding rhodium complexes by using precursors that already contain an anionic ligand with sufficient basicity and are capable of in situ deprotonation of the imidazolium salt. Following a general procedure first reported by Herrmann and co-workers,[8] we prepared the rhodium(I) alkoxide precursor [Rh(μ-O*t*Bu)(diene)]$_2$ in situ by reaction of [Rh(COD)Cl]$_2$ or [Rh(NBD)Cl]$_2$ with potassium *tert*-butoxide at room temperature in THF. The resulting solution was then slowly added to a suspension of the imidazolium salt **2** at −78 °C and the mixture was allowed to warm slowly to room temperature overnight. Using this procedure, we obtained the rhodium complexes [Rh(Me_2oxcarb)(COD)Br] (**3**) and [Rh(Me_2oxcarb)(NBD)Br] (**4**) as orange, air-stable solids in 86% and 84% yield, respectively (Scheme 2).

The formation of the carbene complexes was confirmed by ^{13}C NMR spectroscopy. Signals characteristic of N-heterocyclic carbene carbon nuclei[4,5] at δ = 177.2 ppm ($J_{Rh,C}$ = 53 Hz) and at δ = 183.6 ppm ($J_{Rh,C}$ = 55 Hz) were observed for complexes **3** and **4**, respectively Furthermore, a significant coordination shift of the *C*(=N)O ^{13}C NMR resonances in both cases (**3**: δ = 158.8 ppm; **4**: δ = 155.6 ppm) in comparison with the ligand precursor **2** (δ = 148.8 ppm) indicates the coordination of the oxazoline ring. The latter is also supported by the oxazoline ν(C=N) vibrational band which is shifted to lower wavenumbers (**3**: 1677 cm^{-1}; **4**: 1664 cm^{-1}) compared to the free oxazoline in **2** (1691 cm^{-1}). The details of the molecular structure of both complexes were determined by single-crystal X-ray

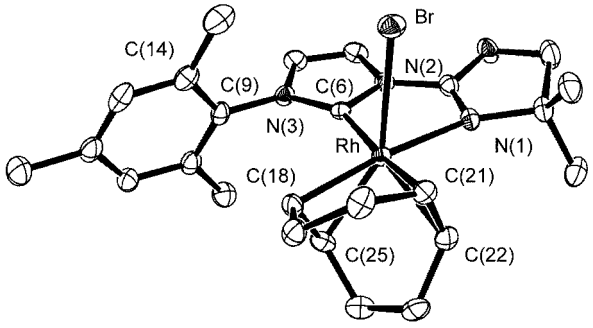

Figure 1. Molecular structure of **3**; selected bond lengths (Å) and angles (°): Rh−Br 2.7545(3), Rh−N(1) 2.255(2), Rh−C(6) 2.022(2), Rh−C(18) 2.090(3), Rh−C(25) 2.096(3), Rh−C(21) 2.223(2), Rh−C(22) 2.251(2), C(21)−C(22) 1.371(4), C(18)−C(25) 1.428(4); C(6)−Rh−N(1) 77.47(9), C(6)−Rh−Br 86.98(7), N(1)−Rh−Br 81.89(6)(4)

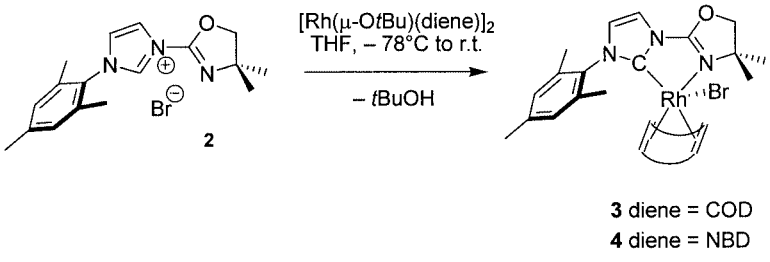
diffraction studies and are depicted in Figure 1 and 2, along with the principal bond lengths and interbond angles.

The X-ray structure analyses confirm the bidentate nature of the oxazolinylcarbene ligand in these rhodium complexes. The coordination geometry of **3** around the metal center is best approximated by a distorted trigonal bipyramidal arrangement with C(6), C(21) and C(22) occupying the apical positions whereas the coordination geometry of **4** is essentially square pyramidal. A steric interaction between the COD ligand and the mesityl ring seems to be the origin of the trigonal bipyramidal arrangement of **3**. The mesityl rings are oriented almost orthogonally to the imidazolyl rings [dihedral angle for **3**: C(14)−C(9)−N(3)−C(6) 80.0°; dihedral angle for **4**: C(10)−C(9)−N(2)−C(1) 78.6°].



Scheme 2. Synthesis of the five-coordinate complexes [RhBr(ligand)(diene)] **3** and **4**

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

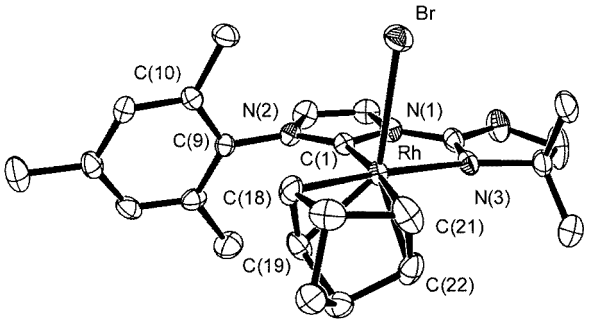


Figure 2. Molecular structure of **4**; selected bond lengths (Å) and angles (°): Rh−Br 2.7615(3), Rh−N(3) 2.178(2), Rh−C(1) 2.016(2), Rh−C(18) 2.070(2), Rh−C(19) 2.105(3), Rh−C(21) 2.192(2), Rh−C(22) 2.177(2), C(21)−C(22) 1.357(5), C(18)−C(19) 1.401(4); C(1)−Rh−Br 95.13(7), C(1)−Rh−N(3) 77.49(8), N(3)−Rh−Br 89.12(5)

As expected, the $Rh-C_{COD}$ distances in **3**, which are *trans* to the carbene carbon atom, are longer than the $Rh-C_{COD}$ bond lengths *trans* to the oxazoline [2.223(2)−2.251(2) Å versus 2.090(3)−2.096(3) Å]. This pronounced *trans* influence[5j,9] is also reflected in the difference in the C=C double bond distances of the coordinated COD ligand. For the double bond *trans* to the carbene a C=C bond length of 1.371(4) Å is found, in comparison with the value of 1.428(4) Å for the double bond *trans* to the oxazoline *N*-atom. In contrast, due to the more rigid conformation and smaller bite angle of the NBD ligand in complex **4**, compared to COD, the *trans* influence of the *N*-heterocyclic carbene in **4** on the Rh−C bond lengths of the diolefin is less pronounced [2.192(2)−2.178(2) Å versus 2.105(3)−2.070(2) Å *trans* to the oxazoline unit]. The distances between the rhodium and the carbene carbon atoms are 2.022(2) Å and 2.016(2) Å for **3** and **4**, respectively, and are similar to those found in related structures.[4b,10]

Signals attributable to the COD ligand are not observed in the ^{1}H NMR spectrum (recorded at 300 MHz) of **3** at 25 °C, indicating a coalescence phenomenon and thus a dynamic process. Upon lowering the temperature to −60 °C, four broad signals between δ = 1.5 and 2.5 ppm appear, which correspond to the -CH_2- groups, while two resonances for the olefin protons are observed at δ = 3.6 and 5.3 ppm. This exchange process has a free activation enthalpy $\Delta G^{\ddagger}$ of about 54 kJ/mol. The fact that only two signals of the four olefin protons are observed at low temperature, in spite of their chemical inequivalence, suggests that a second fast-exchange process takes place which has a low activation barrier (vide infra).

In the ^{1}H NMR spectrum of complex **4**, recorded at 25 °C, only one signal for the olefin protons is observed (δ = 3.59 ppm) indicating fast exchange at that temperature.[11] At −22 °C, this resonance coalesces, and two signals at δ = 4.67 ppm and at δ = 2.67 ppm are detected at −70 °C, as shown in Figure 3. The estimated $\Delta G^{\ddagger}$ of the exchange process associated with this coalescence is ca. 46 kJ/mol. The mechanism operating in the dynamic processes observed for **3** and **4** has to explain the rapid exchange of the two inequivalent C=C double-bond positions in the molecular structures of both complexes. In line with the ubiquitous dynamic processes observed for pentacoordinate molecules, we propose a sequence of Berry pseudorotations as displayed in Scheme 3.

One possible pathway interconverting the two square-pyramidal complexes **A** and **B** (each with a "marked" C=C double bond) involves the intermediates **I**−**III**, which are connected by Berry-type polytopal rearrangements. However, in the low-temperature-limit spectra of both **3** and **4** the (four inequivalent) olefin hydrogen atoms give rise to two signals and not four, as expected. This may be due to fast Br^- exchange even at these low temperatures. Dissociation and the subsequent reassociation of the anion to the ionic planar intermediate, combined with the Berry rearrangements of the pentacoordinate complexes, would indeed lead to the equilibration of the four olefin protons in both complexes. This rapid bromide dissociation and association mechanism is supported by the observed fast intermolecular bromide exchange between **3** and **4** and the respective square-planar complex cations, as discussed in the following section

Synthesis and Structural Characterization of the Cationic {1-(4,4-Dimethyl-4,5-dihydrooxazol-2-yl)-3-mesitylimidazol-2-ylidene}(diolefin)rhodium(I) Complexes 5 and 6

The bromo ligand in the pentacoordinate complex **3** can be removed by the addition of an excess of KPF_6 in dichloromethane (Scheme 4). The cationic complex [Rh(Me_2-carbox)(COD)](PF_6) (**5**) was isolated in nearly quantitative yield as a red solid. In the same fashion, the analogous cationic complex [Rh(Me_2carbox)(NBD)](BF_4) (**6**) derived from **4** was obtained by addition of an excess of $NaBF_4$ in a dichloromethane/water solvent system.

The formulation of compounds **5** and **6** was substantiated by their analytical data, and the molecular structures displayed in Scheme 4 are consistent with the resonance patterns in the NMR spectra. The ^{1}H NMR spectra of complexes **5** and **6**, recorded at room temperature, display two signals for the olefin protons since both square-planar complexes possess C_s symmetry. In the ^{13}C NMR spectra of **5** and **6** the carbene signals are observed at δ = 174.2 ppm ($J_{C,Rh}$ = 54 Hz) and δ = 175.3 ppm ($J_{C,Rh}$ = 59 Hz), respectively.

In order to establish the details of their molecular structures, both compounds were characterized by single-crystal X-ray diffraction which confirmed the expected square-planar arrangement of the ligands around the metal centre (Figure 4 and 5). As for complexes **3** and **4**, the mesityl ring is oriented almost orthogonally to the imidazolyl ring [dihedral angle for **5**: C(10)−C(9)−N(3)−C(8) 99.3°; dihedral angle for **6**: C(14)−C(9)−N(3)−C(8) 87.4°]. Both the Rh−C distances [Rh−C(8) = 2.037(7) Å for **5** and Rh−C(8) = 2.039(6) Å for **6**] and the nitrogen to rhodium distances [Rh−N(1) = 2.136(3) Å and Rh−N(1) = 2.120(5) Å] are within the expected range.[5a][5l][5m] A *trans* influence of the carbene ligand is also found, but appears to be less pronounced than for the pentacoordinate neutral complexes. This is also reflected in the C=C double-bond

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

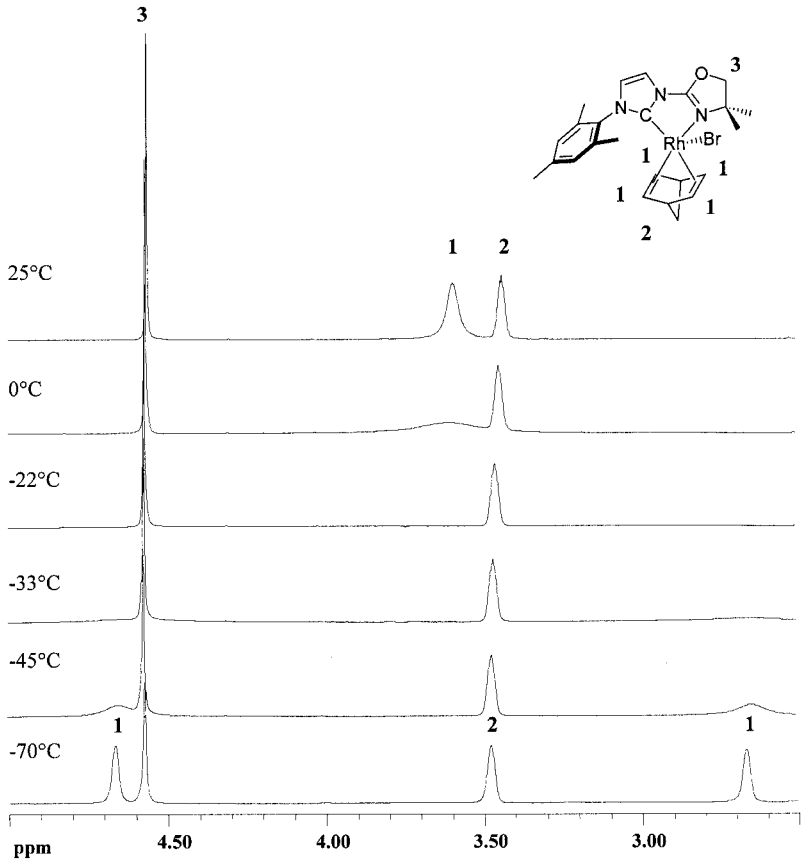

Figure 3. Variable temperature ^{1}H NMR spectra of **4** in the region δ = 2.5−5.0 ppm (recorded in CD_2Cl_2)

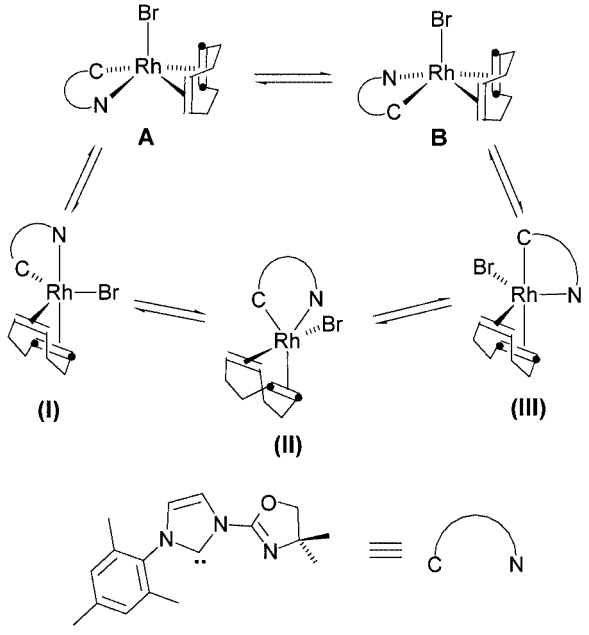

Scheme 3. A sequence of Berry pseudo-rotations leading to the exchange of the positions of the C=C double bonds in the chelating diolefin ligands relative to the C,N bidentate ligand. This process, together with the dissociation and re-association of Br^-, explains the exchange pattern observed in the variable temperature ^{1}H NMR spectra of **3** and **4**

lengths. In complex **5**, for instance, the bond length of the double bond *trans* to the carbene is 1.357(8) Å, compared with the value of 1.371(7) Å for the double bond *trans* to the oxazoline N-atom [1.371(4) Å and 1.428(4) Å in the neutral compound **3**].

The rapid dissociative Br^- exchange postulated for compounds **3** and **4** is supported by the observation of rapid intermolecular bromide exchange between these pentacoordinate complexes and their corresponding square-planar cations **5** and **6**. The ^{1}H NMR spectrum of a 1:1 mixture of the neutral complex **4** and the ionic complex **6**, dissolved in CD_2Cl_2, shows an average resonance pattern of those of **4** and **6**, instead of the spectra of separate species. The same average resonance is observed at −70 °C and is compared in Figure 6 with those of **4** and **6** recorded at the same temperature. This implies fast intermolecular exchange at low temperature (Scheme 5) and indicates that such a dissociative mechanism is probably at the origin of the low energy fluxional process in the neutral pentacoordinate complexes.

Synthesis and Structural Characterization of the Square-Planar Complex Bromo{1-(4,4-dimethyl-4,5-dihydrooxazol-2-yl)-3-mesitylimidazol-2-ylidene}(carbonyl)rhodium(I) (7)

Both the square-planar complexes **5** and **6** are cations. As a neutral analogue we synthesized a rhodium carbonyl derivative by direct reaction of the imidazolium precursor **2** with [Rh(acac)(CO)$_2$] (Scheme 6).[12] The complex

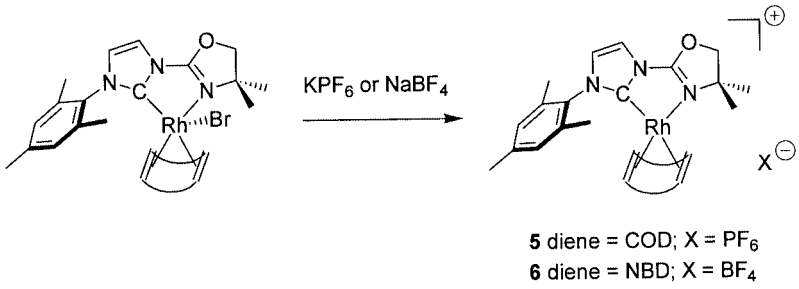

Scheme 4. Synthesis of the cationic four-coordinate complexes [Rh(ligand)(diene)]$^+$ **5** and **6**

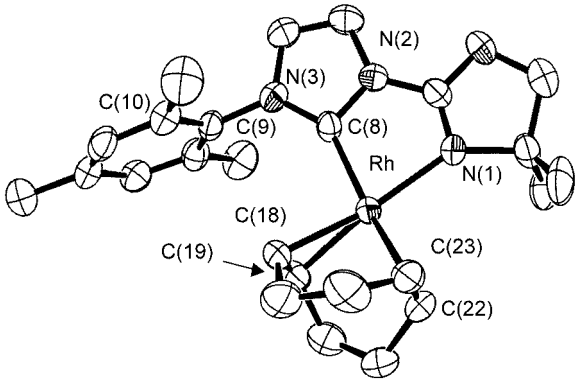

Figure 4. Molecular structure of **5**; selected bond lengths (Å) and angles (°): Rh−N(1) 2.136(3), Rh−C(8) 2.037(7), Rh−C(18) 2.122(4), Rh−C(19) 2.116(4), Rh−C(22) 2.226(5), Rh−C(23) 2.206(5), C(18)−C(19) 1.371(7), C(22)−C(23) 1.357(8); C(8)−Rh−N(1) 78.7(2), C(18)−Rh−C(23) 81.5(2)

[RhBr(Me$_2$carbox)(CO)] (**7**) was obtained in high yield by reacting the two components in THF at room temperature. The synthesis is based on the protonation of the acetylacetonate by the imidazolium precursor and trapping the resulting carbene by coordination to the rhodium(I) centre. The $\nu_{(C=O)}$ band of the carbonyl ligand is observed in the IR spectrum at 1974 cm^{-1} and the detection of a signal at δ = 184.0 ppm in the ^{13}C NMR spectrum, with a characteristic $J_{C,Rh}$ coupling constant of 60 Hz, established the formation of the carbene complex.

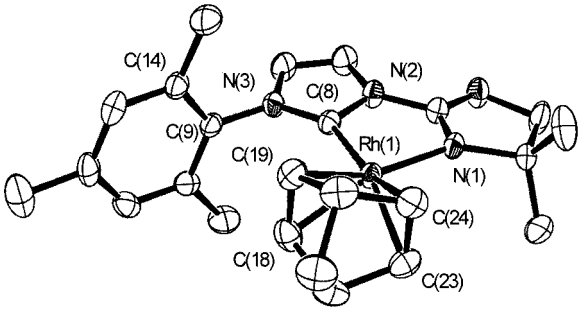

Figure 5. Molecular structure of **6**; selected bond lengths (Å) and angles (°): Rh(1)−C(8) 2.039(6), Rh(1)−N(1) 2.120(5), Rh(1)−C(18) 2.098(7), Rh(1)−C(19) 2.106(7), Rh(1)−C(23) 2.196(7), Rh(1)−C(24) 2.189(7), C(18)−C(19) 1.38(1), C(23)−C(24) 1.35(1); C(8)−Rh−N(1) 78.2(2), C(19)−Rh−C(24) 67.1(3)

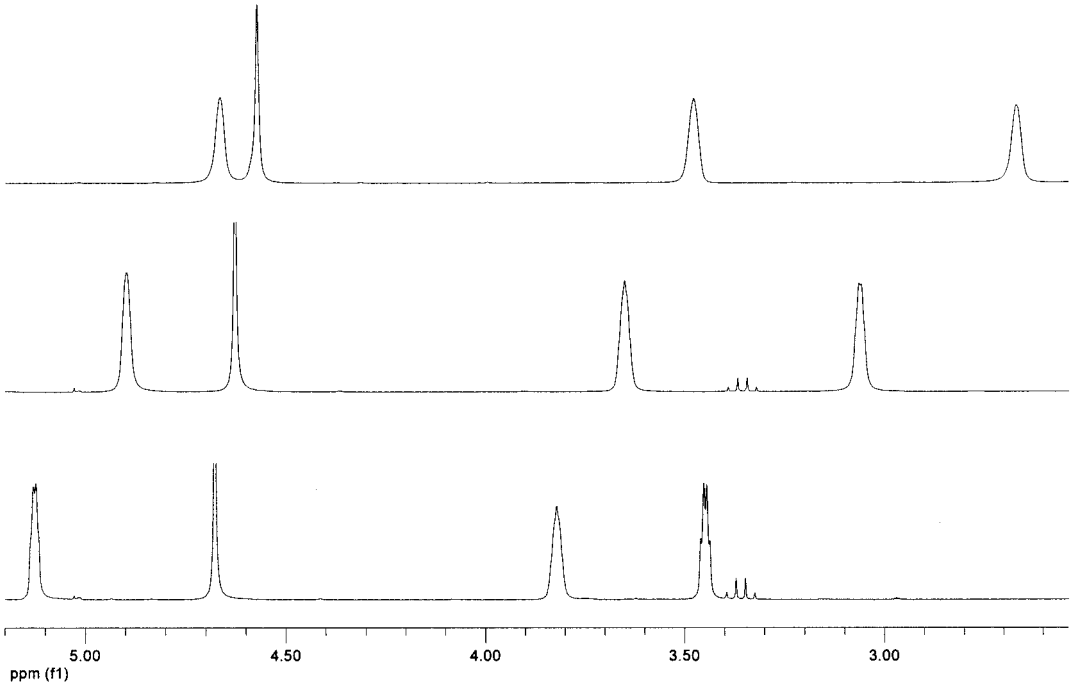

Figure 6. ^{1}H NMR spectra of complex **4** (top), a 1:1 mixture of **4** and **6** (middle) and **6** (bottom) recorded in CD_2Cl_2 at 203 K

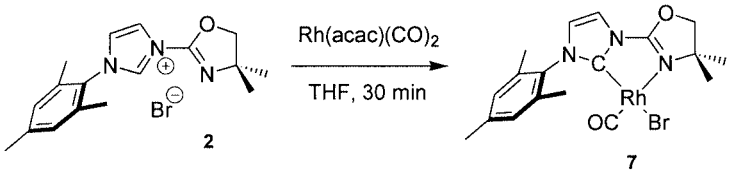
Scheme 5. Rapid intermolecular Br^- exchange between complexes **4** and **6**



Scheme 6. Synthesis of the neutral four-coordinate complexes [RhBr(ligand)(CO)] (**7**)

The single-crystal X-ray diffraction study of compound **7** confirmed the square-planar coordination geometry (Figure 7). The carbonyl ligand is disposed *trans* to the oxazoline unit whereas the bromide is coordinated *trans* to the carbene. The rhodium−carbene distance [Rh−C(2) = 1.950(4) Å] and the rhodium−nitrogen distance [Rh−N(3) = 2.143(3) Å]) are within the expected range.[13]

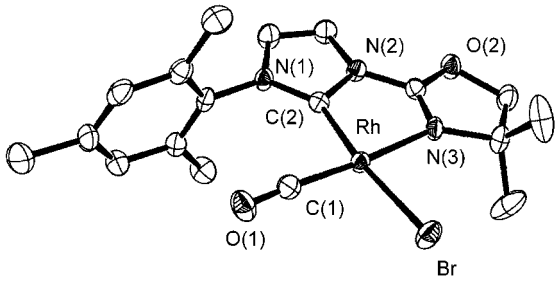


Figure 7. Molecular structure of **7**; selected bond lengths (Å) and angles (deg): Rh−Br 2.5072(5), Rh−C(1) 1.807(4), Rh−C(2) 1.950(4), Rh−N(3) 2.143(3), C(1)−O(1) 1.152(4); Br−Rh−C(1) 90.1(1), Br−Rh−C(2) 173.0(1), C(2)−Rh−N(3) 78.4(1).

It is interesting to compare the C−Rh−N bite angles of the chelating oxazolinylcarbene ligand in the molecular structures of compounds **3**−**7**. The values found for the five-coordinate complexes **3** and **4** are 77.47(9)° and 77.49(8)°, respectively, while the corresponding data of the square-planar cations **5** and **6** are 78.7(2)° and 78.2(2)°, respectively. In the neutral complex **7** this value is 78.4(1)°. The rigidity of the ligand upon coordination to a metal centre thus imposes very well defined metric data, with little variation, regardless of the coordination number or charge of the complex.

Conclusion

The direct condensation of a 2-bromooxazoline derivative with an imidazole provides a modular bidentate ligand precursor which readily coordinates to rhodium(I) complex fragments. The rigidity of the ligand allows for only small variations of the metal−ligand bond lengths and angles, regardless of the coordination number or charge of the complex. The structural details concerning the binding of this class of oxazolinylcarbene ligands have been established in this work. They provide the basis for a systematic use of these functionalised *N*-heterocyclic carbene ligands in catalysis. The first results in catalysis, which we obtained recently, indicate their considerable potential.[6]

Experimental Section

All manipulations were performed under an inert atmosphere of dry nitrogen using standard Schlenk techniques or by working in a glove box. THF and diethyl ether were distilled from sodium/benzophenone. Pentane was distilled from a sodium/potassium alloy, dichloromethane was dried over CaH_2 and subsequently distilled. ^1H and ^{13}C NMR spectra were recorded on a Bruker Avance 300 NMR spectrometer at 300 MHz and 75 MHz and were referenced to the residual proton solvent peak. Infrared spectra were obtained on a FT-IR Perkin−Elmer 1600 spectrometer and the mass spectra were recorded by the "service de spectrométrie de masse de l'Université Louis Pasteur" on an Autospec HF mass spectrometer. The elemental analyses were performed by the analytical services of the Strasbourg and Heidelberg Chemistry Departments. $[RhCl(COD)]_2$ and $[RhCl(nbd)]_2$ were prepared according to literature procedures.[14] $[Rh(acac)(CO)_2]$ was synthesized by reacting $[RhCl(CO)_2]_2$ with Na(acac) in THF. Potassium *tert*-butoxide was sublimed prior to use. $RhCl_3{\cdot}3H_2O$ was provided by BASF AG (Ludwigshafen). All other reagents were commercially available and used as received.

2-Bromo-4,5-dihydro-4,4-dimethyloxazole (1): *t*BuLi (17.7 mL, 1.7 M in pentane, 30.0 mmol) was added dropwise to a solution of 4,5-dihydro-4,4-dimethyloxazole (3.0 mL, 27.3 mmol) in anhydrous THF (80 mL) at −78 °C over a period of 5 min. The resulting yellow solution was stirred for an additional 15 min prior to the addition of 1,2-dibromo-1,1,2,2-tetrafluoroethane (4.84 mL, 36.8 mmol). The solution was allowed to warm to ambient temperature overnight and was subsequently concentrated to about 15 mL. The brown crude product was purified by a short bulb-to-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bulb distillation to yield a colorless solution of the expected bromo-oxazoline in THF (concentration of about 18% w/w) (2.58 g of pure compound, 53%). ^{1}H NMR ($CDCl_3$): δ = 4.12 (s, 2 H, oxa CH_2), 1.34 (s, 6 H, CH_3) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 141.4 (N*C*O), 76.3 (*C*H), 71.6 (*C*H_2), 25.5 (*C*H_3) ppm.

1-(4,5-Dihydro-4,4-dimethyloxazol-2-yl)-3-mesitylimidazolium Bromide (2): 1-Mesityl-1*H*-imidazole (1.11 g, 5.96 mmol) was added to a solution of **1** (1.11 g, 6.23 mmol) in THF (ca. 1.0 M) and the mixture was heated at 50 °C for 2 hours. A white solid precipitated during this period of time. After cooling, diethyl ether (10 mL) was added to complete the precipitation. The product was filtered, washed with diethyl ether (2 × 10 mL) and dried in vacuo to yield 1.80 g (82%) of **2** as a white powder. ^{1}H NMR ($CDCl_3$): δ = 10.57 (t, ^4J = 1.5 Hz, 1 H, NC*H*N), 8.14 (dd, ^3J = 2.1, ^4J = 1.5 Hz, 1 H, 4,5-imidazolium C*H*), 7.60 (dd, ^3J = 2.1, ^4J = 1.5 Hz, 1 H, 4,5-imidazolium C*H*), 7.00 (s, 2 H, mesityl C*H*), 4.53 (s, 2 H, CH_2), 2.32 (s, 3 H, *para* CH_3), 2.16 (s, 6 H, *ortho* CH_3), 1.45 (s, 6 H, oxazoline CH_3) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 148.8 (*C*NO), 142.2 (mesityl *C*), 138.3 (N$_2$*C*), 134.4, 130.5 (mesityl *C*), 130.4 (mesityl *C*H), 125.8, 121.3 (imidazolium *C*H), 83.2 (*C*H_2), 68.7 (oxazoline *C*^{4}), 28.4 (*ortho* *C*H_3), 21.5 (*para* *C*H_3), 18.4 (oxazoline *C*H_3) ppm. MS (FAB): *m*/*z* (%) = 284.0 [M]$^+$ (100), 187.0 [M − C_5H_8NO]$^+$ (22). FT-IR (KBr): $\tilde{\nu}$ = 1691 cm^{-1} (s, $\nu_{C=N}$). $C_{17}H_{22}BrN_3O$ (364.29): calcd. C 56.05, H 6.09, N 11.54; found C 55.66, H 6.08, N 11.49.

Bromo(η^4-1,5-cyclooctadiene){1-(4,5-dihydro-4,4-dimethyloxazol-2-yl)-3-mesitylimidazol-2-ylidene}rhodium(I) (3): [RhCl(1,5-COD)]$_2$ (48 mg, 0.098 mmol) and KO*t*Bu (24 mg, 2.2 equiv.) were stirred in THF (5 mL) for 30 min at room temperature. The resulting dark yellow solution was then slowly added to a suspension of the imidazolium salt **2** (72 mg, 2.0 equiv.) in THF (10 mL) at −78 °C. The mixture was allowed to warm to room temperature overnight. The bright yellow solution was centrifuged, the supernatant was separated and the solvents evaporated to give a yellow powder which was washed with pentane (2−3 mL) and dried in vacuo to yield compound **3** (97 mg, 86%). Suitable crystals for an X-ray diffraction studies were obtained by slow diffusion of Et_2O into a solution of **3** in CH_2Cl_2. ^{1}H NMR ($CDCl_3$, 298 K): δ = 7.69 (d, ^3J = 2.1 Hz, 1 H, 4/5-im C*H*), 6.96 (s, 2 H, mes C*H*), 6.82 (d, ^3J = 2.1 Hz, 1 H, 5/4-im C*H*), 4.66 (s, 2 H, oxa CH_3), 2.29 (s, 3 H, *para* CH_3), 2.12 (br, 4 H, COD CH_2), 2.08 (s, 6 H, *ortho* CH_3), 1.74 (br, 4 H, COD CH_2), 1.49 (s, 6 H, oxa CH_3) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 298 K): δ = 177.2 (d, $^1J^{103}_{Rh,}{}^{13}_{C}$ = 53 Hz, N$_2$*C*), 158.8 (N*C*O), 140.4 (*C*$_{mes}$), 134.5 (*C*$_{mes}$), 133.6 (*C*$_{mes}$), 129.5 (*C*H$_{mes}$), 125.2 (*C*H$_{im}$), 118.8 (*C*H$_{im}$), 84.3 (oxa *C*H$_2$), 67.8 (oxa *C*^{4}), 30.5 (br, COD *C*H$_2$), 27.8 (oxa *C*H$_3$), 21.2 (*para* *C*H$_3$), 18.1 (*ortho* *C*H$_3$) ppm. MS (ESI): *m*/*z* (%) = 486.09 (22) [M − Br − COD + 2CH$_3$CN + H$_2$O]$^+$, 527.12 (100) [M − Br − COD + 3CH$_3$CN + H$_2$O]$^+$. FT-IR (KBr): $\tilde{\nu}$ = 1677 cm^{-1} (s, $\nu_{C=N}$). $C_{25}H_{33}BrN_3ORh$ (574.36): calcd. C 52.28, H 5.79, N 7.32; found C 51.82, H 5.66, N 7.38.

Bromo{1-(4,5-dihydro-4,4-dimethyloxazol-2-yl)-3-mesitylimidazol-2-ylidene}(η^4-2,5-norbornadiene)rhodium(I) (4): Solid [RhCl(nbd)]$_2$ (86 mg, 0.186 mmol) and KO*t*Bu (46 mg, 0.41 mmol, 2.2 equiv.) were weighed and placed in a Schlenk tube. THF (6 mL) was then added and the reaction mixture was stirred for 30 minutes at ambient temperature. The solution thus obtained was slowly added to a suspension of the imidazolium salt **2** (136 mg, 0.373 mmol, 2.0 equiv.) in THF (12 mL) at −78 °C. The mixture was allowed to warm to ambient temperature overnight and was centrifuged. The resulting orange-red supernatant was separated and the solvents evaporated in vacuo. The crude solid was washed two or three times with pentane (5 mL). Complex **4** was obtained as an orange powder (175 mg, 84%). Crystallization from CH_2Cl_2/Et_2O gave small orange crystals suitable for an X-ray diffraction study. ^{1}H NMR ($CDCl_3$): δ = 7.30 (d, ^3J = 2.1 Hz, 1 H, 4/5-im C*H*), 6.95 (s, 2 H, C*H*$_{mes}$), 6.62 (d, ^3J = 2.1 Hz, 1 H, 4/5-im C*H*), 4.52 (s, 2 H, oxa CH_2), 3.58 (br. m, 4 H, 2/3/5/6-nbd C*H*), 3.45 (m, 2 H, 1/4-nbd C*H*), 2.30 (s, 3 H, *para* CH_3), 2.20 (s, 6 H, *ortho* CH_3), 1.45 (s, 6 H, oxa CH_3), 0.98 (s, 2 H, CH_{2nbd}) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 183.6 (d, $^1J^{103}_{Rh,}{}^{13}_{C}$ = 55 Hz, N$_2$*C*), 155.6 (N*C*O), 139.5 (*C*$_{mes}$), 135.6 (*C*$_{mes}$), 133.6 (*C*$_{mes}$), 128.8 (*C*H$_{mes}$), 123.5 (*C*H$_{im}$), 115.6 (*C*H$_{im}$), 84.6 (oxa *C*H$_2$), 67.3 (oxa *C*^{4}), 60.1 (nbd *C*H$_2$), 49.2 (1/4-*n*bd *C*H), 28.5 (oxa *C*H$_3$), 21.1 (*para* *C*H$_3$), 18.6 (*ortho* *C*H$_3$) ppm. MS (ESI): *m*/*z* (%) = 478.13 (100) [M − Br]$^+$. FT-IR (KBr): $\tilde{\nu}$ = 1664 cm^{-1} (s, $\nu_{C=N}$). $C_{24}H_{29}BrN_3ORh$ (558.32): calcd. C 51.63, H 5.23, N 7.53; found C 51.11, H 5.19, N 7.34.

(η^4-1,5-Cyclooctadiene){1-(4,5-dihydro-4,4-dimethyloxazol-2-yl)-3-mesitylimidazol-2-ylidene}rhodium(I) Hexafluorophosphate (5): Solid KPF_6 (34 mg, 0.185 mmol, 1.5 equiv.) was added to an orange solution of **3** (70 mg, 0.122 mmol) in CH_2Cl_2 (5 mL). Degassed water (5 mL) was subsequently added and the mixture was stirred vigorously for 30 minutes. The organic layer was decanted and the aqueous layer was washed with an additional 5 mL of CH_2Cl_2. The organic layers were combined, dried over Na_2SO_4 and the volatiles were removed in vacuo. After washing with Et_2O (5 mL) and drying, an orange powder was isolated (76 mg, 98%). Suitable crystals for an X-ray diffraction study were obtained by slow diffusion of Et_2O into a saturated solution of **5** in CH_2Cl_2/Et_2O. ^{1}H NMR ($CDCl_3$): δ = 7.50 (d, ^3J = 2.1 Hz, 1 H, 4/5-im CH), 6.96 (s, 2 H, C*H*$_{mes}$), 6.75 (d, ^3J = 2.1 Hz, 1 H, 4/5-im C*H*), 5.32−5.29 (m, 2 H, COD C*H*), 4.70 (s, 2 H, oxa CH_2), 3.66−3.64 (m, 2 H, COD C*H*), 2.33 (s, 3 H, *para* CH_3), 2.33−2.10 (m, 4 H, COD CH_2), 2.10 (s, 6 H, *ortho* CH_3), 1.98−1.92 (m, 2 H, COD CH_2), 1.82−1.76 (m, 2 H, COD CH_2), 1.49 (s, 6 H, oxa CH_3) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 298 K): δ = 174.2 (d, $^1J^{103}_{Rh,}{}^{13}_{C}$ = 54 Hz, N$_2$*C*), 160.2 (N*C*O), 140.8, 134.2, 133.0 (*C*$_{mes}$), 129.7 (*C*H$_{mes}$), 125.3 (*C*H$_{im}$), 118.2 (*C*H$_{im}$), 97.6 (d, $J^{103}_{Rh,}{}^{13}_{C}$ = 7.5 Hz, COD *C*H), 85.1 (oxa *C*H$_2$), 74.4 (d, $J^{103}_{Rh,}{}^{13}_{C}$ = 13 Hz, COD *C*H), 67.9 (oxa *C*^{4}), 31.8, 29.1 (COD *C*H$_2$), 27.4 (oxa *C*H$_3$), 21.2 (*para* *C*H$_3$), 17.6 (*ortho* *C*H$_3$) ppm. *C*H), 27.7 (oxa *C*H$_3$), 21.1 (*para* *C*H$_3$), 17.7 (*ortho* *C*H$_3$) ppm. MS (ESI): *m/z* (%) = 478.12 (24) [M − BF$_4$]$^+$, 510.11 (64) [M − BF$_4$ − nbd + 3CH$_3$CN]$^+$, 537.12 (100). FT-IR (KBr): $\tilde{\nu}$ = 1662 cm^{-1} (s, $\nu_{C=N}$).

Bromo(carbonyl){1-(4,5-dihydro-4,4-dimethyloxazol-2-yl)-3-mesityl-imidazol-2-ylidene}rhodium(I) (7): [Rh(acac)(CO)$_2$] (75 mg, 0.290 mmol) and the imidazolium salt **2** (106 mg, 1.0 equiv.) were placed in a Schlenk tube and dissolved in THF (8 mL). A rapid evolution of a gas (CO) was observed and the solution color immediately turned bright yellow. After stirring for 50 minutes at ambient temperature, the reaction mixture was centrifuged, the supernatant was separated and the solvents evaporated to dryness. The crude product was washed with pentane (2 × 4 mL) to yield the analytically pure compound **7** as a yellow microcrystalline solid (122 mg, 85%). Crystallization from CH_2Cl_2/pentane gave yellow crystals suitable for X-ray diffraction. ^{1}H NMR ($CDCl_3$): δ = 7.28 (d, ^3J = 2.3 Hz, 1 H, 4/5-im C*H*), 7.04 (s, 2 H, C*H*$_{mes}$), 6.70 (d, ^3J = 2.3 Hz, 1 H, 4/5-im C*H*), 4.62 (s, 2 H, oxa C*H*$_2$), 2.32 (s, 3 H, *para* C*H*$_3$), 2.10 (s, 6 H, *ortho* C*H*$_3$), 1.72 (s, 6 H, oxa C*H*$_3$) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 187.4 (d, $^1J^{103}_{Rh,}{}^{13}_{C}$ = 78 Hz, *C*O), 184.0 (d, $^1J^{103}_{Rh,}{}^{13}_{C}$ = 60 Hz, N$_2$*C*), 158.5 (N*C*O), 140.4 (*C*$_{mes}$), 135.0 (*C*$_{mes}$), 134.0 (*C*$_{mes}$), 129.4 (*C*H$_{mes}$), 123.5 (*C*H$_{im}$), 114.7 (*C*H$_{im}$), 86.4 (oxa *C*H$_2$), 67.4 (oxa *C*^{4}), 28.2 (oxa *C*H$_3$), 21.2 (*para* *C*H$_3$), 18.0 (*ortho* *C*H$_3$) ppm. FT-IR (KBr): $\tilde{\nu}$ = 1974 cm^{-1} (s, $\nu_{C=O}$), 1670 cm^{-1} (s, $\nu_{C=N}$). $C_{17}H_{21}BrN_3O_2Rh$ (494.19): calcd. C 43.75, H 4.28, N 8.50; found C 42.93, H 4.05, N 8.14.

Intermolecular Br$^-$ Exchange between Complexes 4 and 6: Equal amounts of compounds **4** and **6** (20 μmol) were weighed, placed into an NMR tube and dissolved in CD_2Cl_2 (0.5 mL). In an ^{1}H NMR spectrum, which was recorded at 203 K, the signals of complexes **4** and **6** were not observed separately but a set of resonances at the weighted mean chemical shift indicated a fast intermolecular exchange of bromide between **4** and **6**.

X-ray Crystallographic Study of Compounds 3−7: Suitable crystals of complexes **3**, **4**, **5**, **6** and **7** were obtained by layering concentrated solutions of the compounds in dichloromethane with pentane, hexane or diethyl ether (vide supra) and allowing slow diffusion at room temperature. The crystal data were collected at −100 °C on a Nonius KappaCCD diffractometer and transferred to a DEC Alpha workstation; for all subsequent calculations the Nonius OpenMoleN package was used.[15] The structures were solved by direct methods with absorption corrections being part of the scaling procedure of the data reductions. After refinement of the heavy atoms, difference Fourier maps revealed the maxima of residual electron density close to the positions expected for the hydrogen atoms; they were introduced as fixed contributors in the structure factor calculations with fixed coordinates (C−H: 0.95 Å) and isotropic temperature factors [B(H) = 1.3 B_{eqv}(C) Å^2] but not refined. Full least-square refinements on F^2. A final difference map revealed no significant maxima of electron density. The scattering factor coefficients and the anomalous dispersion coefficients were taken from the literature.[16] Crystal data and experimental details for the crystals of compounds **3**−**7** are given in Table 1.

CCDC-229779 ... -229783 (for **3**−**7**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterization of Platinum(II) Complexes of Diethyl [(Methylsulfinyl)methyl]phosphonate: Potential Drugs against Bone Tumors

Mariarita Laforgia,[a,b] Leonardo Cerasino,[a] Nicola Margiotta,[a] Maria A. M. Capozzi,[c] Cosimo Cardellicchio,[d] Francesco Naso,[d,e] and Giovanni Natile*[a,b]

Keywords: Antitumor agents / NMR spectroscopy / O ligands / Platinum / S ligands

Cisplatin is the most important metal-based drug used in tumor therapy; however, it suffers from severe side effects and a limited spectrum of activity. Since phosphonates are known to have a selective tropism for bones and calcified tissues, we have carried on the synthesis of different platinum complexes with a phosphonate ligand. The ligand used is diethyl [(methylsulfinyl)methyl]phosphonate (SMP), which can act as an O,S-donor towards Pt. Moreover, since the sulfur atom is a stable stereogenic center, the ligand is obtained in two enantiomeric forms. The synthesised complexes have the general formula $[PtL_2(SMP)]$, in which L_2 stands for a bidentate (dimethylmalonate, 1,2-diaminocyclohexane, ethylenediamine) or two monodentate (chloride) ligands. The formation of a five-membered chelate ring contributes to the chemical stability of complexes with SMP, and 2D NMR experiments have allowed determination of the ring puckering, which is dependent upon the chirality of the sulfur stereocenter. For the (*S*) configuration at the sulfur center (free ligand), the δ puckering of the chelate ring is favoured. Preliminary studies have shown that these compounds are stable under physiological conditions.

Introduction

Modern anticancer chemotherapy makes use of a variety of drugs having very different chemical structures and mechanisms of action. Among them, cisplatin is still one of the most frequently prescribed drugs for the treatment of several solid tumors, particularly testicular, ovarian, and bladder carcinomas.[1] In spite of its simple chemical structure, the mechanism of action of cisplatin is rather complex. The biological effect probably stems from covalent binding of platinum to two adjacent purine bases on the same strand of DNA.[2−6] This event causes remarkable changes in the natural DNA conformation and from there a cascade of biological alterations finally leading to cell death. The clinical use of cisplatin is limited by toxic side effects and by a narrow spectrum of activity.[7] In order to overcome these limitations, thousands of platinum compounds have been synthesised and tested with the aim of increasing either the activity or the selectivity against the great variety of tumors.

The replacement in the cisplatin molecule of either the two ammine or the two chlorine ligands by other ligands has represented a very general procedure for the synthesis of new potential drugs. Moreover, this methodology gives the possibility of targeting the drug to a particular organ or tissue by coordinating ligands that have a particular affinity for specific receptors (drug targeting approach).[8−10] To this end, Keppler has proposed a class of platinum compounds containing aminobis(phosphonate) ligands, which are expected to have a selective tropism for bones and other calcified tissues because of the affinity of the phosphonate group for Ca^{2+} ions (Scheme 1, A).[11,12] This expectation is justified by the clinical use of bis(phosphonates) (such as Etidronate, Clodronate, Pamidronate and Alendronate[13]) in the treatment of hypercalcaemia. Pharmacological studies performed on platinum complexes with aminobis(phosphonates) have confirmed the activity towards bone tumors and other forms of tumors involving an anomalous balance of Ca^{2+} ions and which are resistant to cisplatin.[14]

One limitation of the compounds with aminobis(phosphonates) is their chemical instability. The oxygen atom of

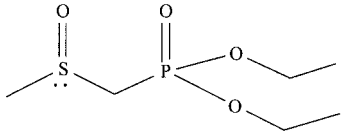
the phosphonate group and the nitrogen atom of a tertiary amine are weak donors for platinum and the aminobis(phosphonates) can be easily displaced by stronger nucleophiles, in spite of the stabilization stemming from the formation of a five-membered chelate ring.[15,16] However, the stability of this class of compounds can be increased by introducing in the molecule of the phosphonate a group with a higher coordination affinity for platinum, such as a sulfoxide. The use of sulfoxides as ligands in platinum drugs was already proposed by Farrell some years ago.[17] A series of compounds having the general formula [Pt(diamine)Cl(R^1R^2SO)]$^+$ showed interesting biological activity[18,19] in spite of their being positively charged (for years neutrality was considered a prerequisite for activity of cisplatin analogues).

Other O,S-donor ligands have been used in the past for the synthesis of cisplatin analogues. In particular, [2-(methylsulfanyl)phenyl]phosphonate has been used by Kozelka et al.[20] In that case, reaction with aquated cisplatin led to the loss of one ammine ligand and formation of a dimeric species with bridging phosphonate groups, which was practically insoluble in any solvent (Scheme 1, B). (Methylsulfinyl)-acetate and 2-(methylsulfinyl)benzoate have been used by Pasini and co-workers.[21] They used chelated diamines such as ethylenediamine (en) and 1,2-diaminocyclohexane (dach) in order to prevent dissociation of the amine group *trans* to the sulfur atom (Scheme 1, C). The obtained compounds were found to be moderately cytotoxic towards L1210 leukaemia cells; however, no selective tropism for particular tissues was investigated.

In the present study we report on the synthesis and spectroscopic characterization of platinum complexes with the new ligand diethyl [(methylsulfinyl)methyl]phosphonate (SMP; Scheme 2). Apart from the substitution of a sulfoxide for a tertiary amine, another major difference between Keppler's aminobis(phosphonates) and SMP is the presence in the latter ligand of phosphonic groups blocked as diethyl esters. This chemical change could be critical for modulating the hydrophobic/hydrophilic balance of the compounds.

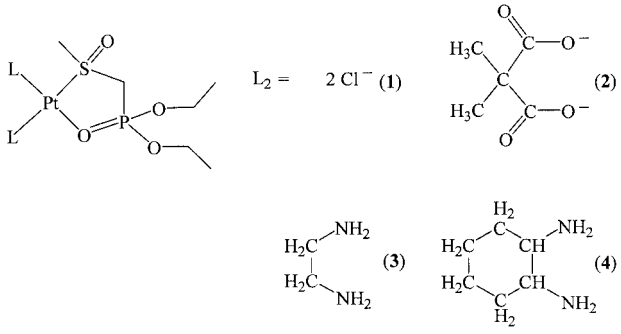


Scheme 2. Shorthand drawing of the diethyl [(methylsulfinyl)methyl]phosphonate ligand, SMP

Results and Discussion

Characterization of the Complexes

Two types of complexes have been synthesised and characterized in this work: neutral complexes (**1** and **2**; Scheme 3) containing, besides SMP, two chloride ions or a dimethylmalonate ligand (dmm), and cationic species (**3** and **4**; Scheme 3) in which a diamine (en or dach) and an SMP molecule saturate the four coordination positions of the platinum(II) center.



Scheme 3. Shorthand drawing of the synthesised complexes with the SMP ligand

The synthesis of the complexes is straightforward. The dichloro species **1** was prepared by direct reaction of potassium tetrachloroplatinate with SMP and is soluble both in aqueous and in organic solvents. Removal of the chloride ligands by reaction with silver sulfate and addition of potassium dimethylmalonate affords complex **2**, which is rather soluble both in water and in organic solvents such as methanol and ethanol. The cationic species **3** and **4** were prepared from **1** by addition of the selected diamine, which displaces the two chloride ions. Compounds **3** and **4** can also be prepared by reaction of SMP with a platinum complex already containing the diamine; however, in this case the two leaving ligands must be very labile (solvent molecules).

The stereochemical characterization of the complexes was performed essentially by NMR spectroscopy (Table 1).

[a] Precise chemical shifts and coupling constants of protons in multiplets have been calculated, when possible, through NMR decoupling experiments. [b] The signals of the central methylene protons in D_2O are detectable only soon after dissolution; exchange with deuterium then occurs and the signals disappear. [c] Only the chemical shift of the methylidene protons is reported for the (*R*,*R*)-dach ligand.

The SMP Ligand

Coordination of the SMP ligand through the sulfoxide functionality was clearly evident from the downfield shift (ca. 0.8 ppm) of the SMe protons. The coupling constant between the methyl protons and the platinum atom (18 Hz) is also in the normal range for sulfoxides *S*-coordinated to the platinum atom.[22] In D_2O, it is also possible to observe a long-range coupling between the methyl protons and the phosphorus atom ($^4J_{H,P} \approx 2$ Hz).

The protons of the methylene group bridging the sulfur and the phosphorus atoms are relatively acidic, and in D_2O or CD_3OD undergo rapid exchange with the deuterium of the solvent. Such a behavior resembles that of chelated amino acids.[23,24] The methylene proton signals, however, are nicely observable when [D_6]acetone solutions are measured (Figure 1) and in the following discussion we will refer to spectra taken in this solvent (apart from the free ligand, only compound **1** is soluble in acetone). The two methylene protons are magnetically non-equivalent, both in the free SMP ligand and in the complex, because of the diastereotopic splitting caused by the chiral sulfur center. Upon complexation, the signal of one proton of the methylene group undergoes a downfield shift similar to that observed for the SMe protons (δ = 4.05 ppm; $\Delta\delta$ = 0.73 ppm). In contrast, the second methylene proton signal undergoes a downfield shift which is almost twice as large (δ = 4.72 ppm; $\Delta\delta$ = 1.28 ppm). Each methylene proton shows couplings with the phosphorus atom ($^2J_{H,P}$ = 11.5 Hz), the geminal proton ($^2J_{H,H}$ = 15.2 Hz) and the platinum atom ($^3J_{H,Pt}$ = 15.6 and 13.3 Hz for the δ = 4.72 and 4.05 ppm resonances, respectively). The less-shielded proton has a higher coupling constant with platinum than the more shielded proton. The different values of the coupling constants with platinum are indicative of a different H−C−S−Pt torsion angle (higher coupling constant for torsion angles closer to 180° according to Karplus's rule).[25]

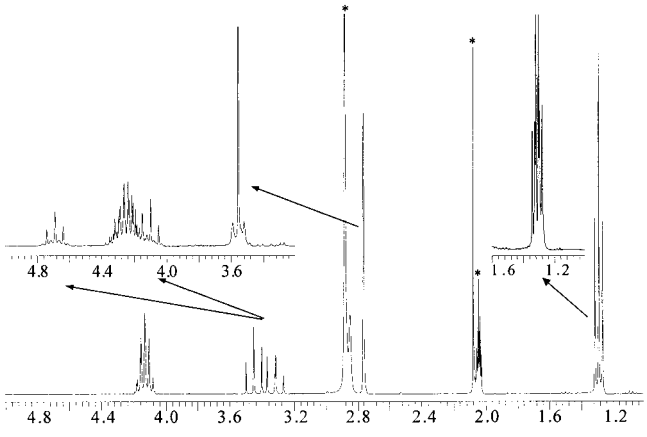

Figure 1. ^{1}H NMR spectra (300 MHz, [D_6]acetone) of the free ligand diethyl [(methylsulfinyl)methyl]phosphonate (SMP, bottom) in comparison with its platinum complex *cis*-[$PtCl_2$(SMP)] (top); asterisks indicate solvent peaks

A 2D NOE experiment has shown the presence of cross-peaks between both methylene protons and the SMe group (Figure 2). This is in agreement with a "quasi equatorial" disposition of the SMe group which, in a staggered confor-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mation, comes in between the two methylene protons. In contrast, a "quasi axial" disposition of the SMe group would be in agreement with the SMe group having NOE cross-peaks with only one methylene proton. A "quasi equatorial" SMe group implies that, starting with a free ligand having an (*S*) configuration at the sulfur center, in the complexed molecule the chelate ring assumes a δ puckering (Scheme 4). It should be noted that, upon coordination to the platinum atom, the priorities of the groups bound to the sulfur atom change; however, we have chosen to refer to the chirality of the free ligand also for the complexed sulfoxide. One NOE cross-peak is stronger than the other and involves the methylene proton less coupled with the platinum atom (and having more axial character); conversely, the NOE is weaker for the proton more coupled with the platinum atom (and having more equatorial character). This is the expected trend for a reduced puckering of the five-membered chelate ring and a conformation around the S−C(methylene) bond that is intermediate between staggered and eclipsed, with the consequence that the "quasi equatorial" SMe group is brought closer to the "quasi axial" methylene proton and farther from the "quasi equatorial" methylene proton.

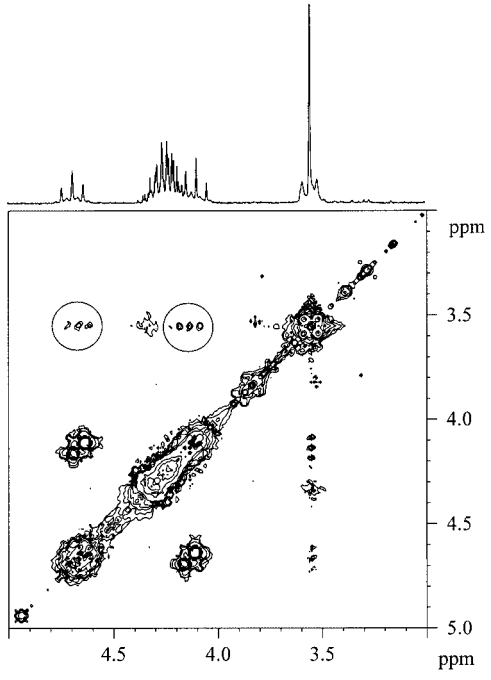

Figure 2. 2D-NOESY contour plot (300 MHz, [D_6]acetone) of complex **1**; cross-peaks between the SMe protons and the central methylene protons are in circles

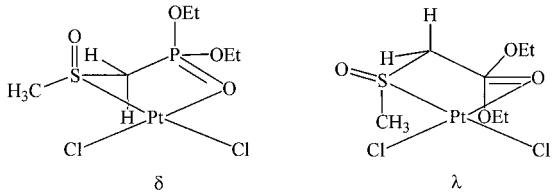
The deshielding effect of the S=O double bond of the sulfoxide is probably responsible for the greater shift to low field of the "quasi equatorial" methylene proton signal. The positioning of the SMe group in a "quasi equatorial" conformation is also in agreement with the smaller steric interaction between diaxial substituents in the 1,3-positions of the chelate ring [OEt and (S)O instead of OEt and (S)Me].



Scheme 4. δ and λ puckering of the five-membered chelate ring of coordinated SMP for an (*S*) configuration at the sulfur center of the free ligand; δ puckering is favoured

It is worth mentioning that for the analogous complex with (methylsulfinyl)acetate,[21] the correlation between the configuration of the sulfoxide and the puckering of the chelate ring is opposite to that observed in the present case [δ conformation of the chelate ring for an (*R*) configuration of the sulfoxide as deduced from crystallographic data]. Steric repulsions between "quasi axial" substituents in positions 1 and 3 of the ring are critical for the puckering of the chelate ring. Thus, diethyl [(methylsulfinyl)methyl]phosphonate prefers to place the methyl group in a "quasi equatorial" position and the oxygen in a "quasi axial" position because of a smaller repulsion between the axial substituents in positions 1 and 3 of the ring. This corresponds to a δ puckering of the chelate ring for an (*S*) configuration of the starting sulfoxide (Scheme 4). In contrast, in the case of (methylsulfinyl)acetate, there are no axial substituents in position 3 of the chelate ring with respect to the coordinated sulfur atom (the noncoordinated oxygen atom of the carbonyl group being nearly coplanar with the coordination plane). Therefore, it is most likely that the δ conformation of the ring for the (*R*) configuration of the sulfoxide, observed in the solid state of the latter complex, is not determined by intraligand steric constraints (practically absent), but by crystal lattice interactions.

Upon coordination to the platinum atom, the two ethoxy residues of the phosphonate group undergo a small downfield shift with respect to the free SMP ligand ($\Delta\delta \approx$ 0.1 ppm for the methylene protons and 0.04−0.02 ppm for the methyl protons). The phosphorus signal undergoes an upfield shift of ca. 5 ppm; moreover, it exhibits a coupling constant with Pt of ca. 90 Hz. Such a value for $^2J_{Pt,P}$ is perfectly compatible with tabulated values for classical Pt−O−P couplings (Figure 3, A).[26] It is worth noting that the $^2J_{Pt,P}$ coupling constant decreases from 90 to 46 Hz upon changing the solvent from [D_6]acetone to D_2O (Figure 3, B). We believe that such a dramatic change is correlated with the acidity of the methylene group bridging the sulfur and phosphorus atoms which, in water, are likely to undergo partial proton dissociation.

The acidity of the methylene group is revealed by the low pH (ca. 4.6) observed in solutions of compounds **1**, **2**, **3**, and **4** in water. This implies that the methylene group bridging the sulfur and the phosphorus atoms can dissociate one proton, becoming a carbanion. Because of the fast exchange with the solvent, it is only possible to detect the central methylene protons by performing the NMR experiments in H_2O/D_2O (90:10) (Figure 4).

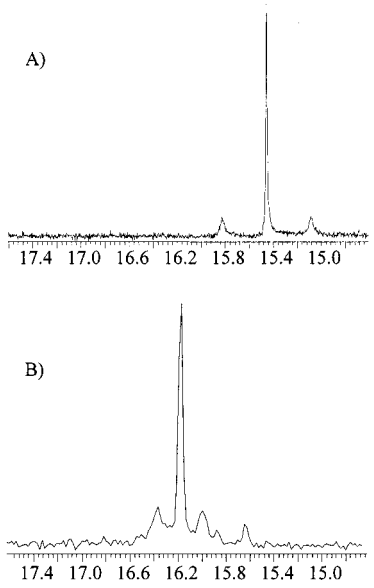

Figure 3. ^{31}P (121.5 MHz) NMR spectra of complex **1**: in [D_6]acetone (A) and in D_2O (B)

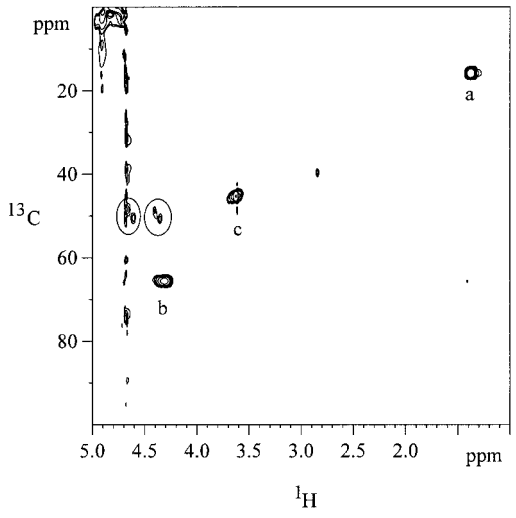

Figure 4. ^{13}C,^{1}H-2D-HETCOR contour plot of complex **1** in H_2O/D_2O (90:10, v/v) showing the cross-peaks (in circles) between ^{1}H and ^{13}C of the rather acidic methylene group bridging the sulfur and phosphorus atoms of the coordinated SMP ligand; cross-peaks a, b, and c are related to the ethoxy methyl and methylene groups and to the sulfoxide methyl group, respectively

The Malonato Ligand (Complex 2)

The ^{1}H NMR spectrum of compound **2**, besides the signals of the SMP ligand, which are very similar to those of the parent dichloro complex, exhibits two singlets at δ = 1.75 and 1.72 ppm assignable to the methyl groups of the dimethylmalonato ligand. The two methyl signals are shifted by 0.47 and 0.44 ppm with respect to those of free dimethylmalonato and are indicative of its bidentate coordination. The non-equivalence of the two methyl groups stems from the lack of symmetry of the coordination plane generated by the asymmetric sulfoxide.

The Diamine Ligands (Complexes 3 and 4)

The NMR signals of the SMP ligand of compounds **3** and **4** are also very similar to those of the parent dichloro complex. In compound **3**, the coordination of the ethylenediamine ligand is supported by the ^{1}H NMR signals of the two methylene groups bridging the two coordinated nitrogen atoms. In D_2O, the two methylene groups give a unique sharp singlet at $\delta \approx 2.84$ ppm (0.2 ppm downfield from the signal of free ethylenediamine) with a coupling with Pt of ca. 40 Hz (the usual value for $^{3}J_{Pt,H}$). The coordination of the 1,2-diaminocyclohexane ligand to Pt in compound **4** is supported by the downfield shifts of the proton signals of the cyclohexane ring. The shift is particularly relevant for the protons of the asymmetric carbon centers adjacent to the amine groups ($\Delta\delta \approx 0.7$ ppm).

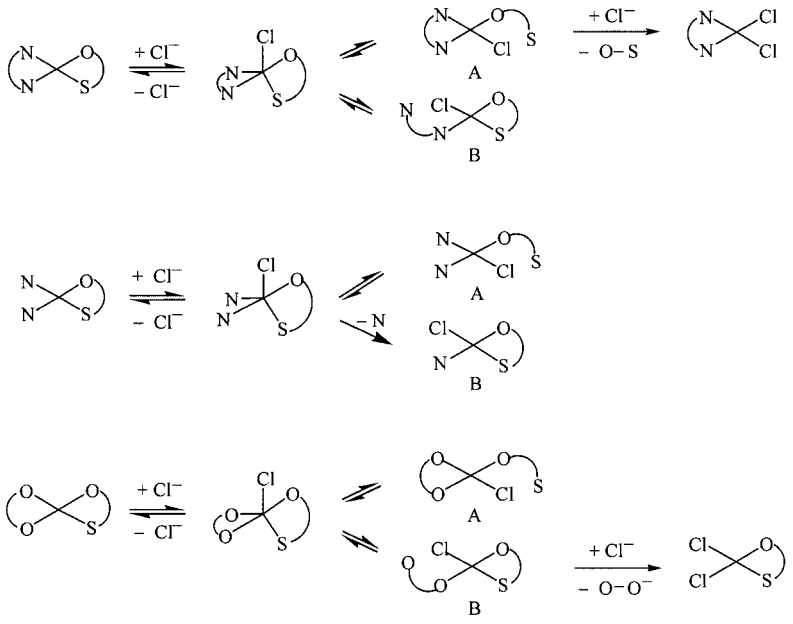
Stability of the Complexes

The dichloro complex **1** in aqueous solution undergoes a slow process of solvolysis, as revealed by the appearance of new signals. Particularly diagnostic are the two new signals belonging to the CH_3SO protons which, however, are very close to that of the starting complex and still show similar couplings with Pt. This implies that in the new species the sulfoxide group is still bound to the platinum atom. Moreover, the ^{31}P NMR spectra also show the appearance, with time, of two new signals which, again, are very close to that of the starting complex and still show similar couplings with Pt. Therefore, in the newly formed solvato species the phosphonate group is still bound to the platinum atom. All the new peaks disappear if LiCl (0.1 M concentration) is added to the solution. Therefore, it could be concluded that the new species are solvato species in which one or both chloride ligands of the starting substrate have been displaced by water molecules. It can be noted, however, that, due to the asymmetry of the SMP ligand, two monosolvato species can be formed, one with the solvent molecule *trans* to the sulfoxide and the other with the solvent molecule *trans* to the phosphonate group. Therefore, it is most likely that the observed new species are monosolvated.

The stability of the dimethylmalonato compound **2** was investigated in water solution containing a 0.1 M chloride concentration. Formation of a small amount of species containing a monodentate dmm ligand was observed soon after dissolution at room temperature. This was immediately followed by the appearance of the peak of free dmm. After 7 h at 25 °C, the intensities of bidentate and free dmm were ca. 1:1. After 3 d at 25 °C and pH = 6.3, the ratio of bidentate and free dmm was 1:3.8.

The stability of compounds **3** and **4** was also investigated. In water solution both compounds are stable in the absence of coordinating ligands. However, if chloride ions are present, ready replacement of the SMP ligand and precipitation of insoluble [$PtCl_2$(en)] or [$PtCl_2$(dach)] is observed. This behavior is in agreement with previous observations on the reactivity of platinum complexes containing chelated O,S ligands and bidentate amines.[20,21] In the case of bidentate amines the reaction with extra ligands (such as Cl^-)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 5. Different behavior of ancillary ligands in the displacement reaction with chloride ions

leads to displacement of the O,S ligand in preference to the bidentate diamine. In contrast, when the platinum complex contains, besides the O,S ligand, two monodentate amines, the reaction with extra ligands leads to displacement of the amine group *trans* to the sulfur atom.

The different behavior of compounds with monodentate and bidentate amines can be rationalized in the following way. In substitution reactions involving four-coordinate square-planar complexes, the trigonal-bipyramidal transition state is stabilized by electron-acceptor ligands lying in the trigonal plane (sulfur is a good acceptor having empty 3d orbitals, and in the case of sulfoxide there is also an unfilled π^* orbital). In the case of a bidentate amine (top row of Scheme 5), the entering of the first chloride ion can lead to two intermediate species, each of them having a monocoordinated bidentate ligand (species A and B); A will be more reactive than B because it contains a singly bonded O-donor ligand which is more labile than a singly bonded N-donor ligand. Therefore, A will react in preference to B with a second molecule of incoming nucleophile (the Cl^- anion) leading to the complete displacement of the O,S ligand. In contrast, in the case of monoamines (middle row of Scheme 5), the reaction path leading to B will be favoured with respect to that leading to A since in the case of B the back reaction is disfavoured (it requires the attack by a molecule of N which has already left).

By a similar reasoning we can explain the different reactivity with chloride of compound **2** (the malonato ligand displaced in preference to the SMP ligand) with respect to compounds **3** and **4** (the SMP ligand displaced in preference to the diamine). In the former case (bottom row of Scheme 5) the intermediate species A and B formed after the entering of the first chloride ion both contain an equally labile singly bonded O-donor ligand (oxygen is not a good donor for platinum). However, the equilibrium between A and B will be shifted in favour of B because the latter contains a better set of donor atoms (Cl, S, 2 O) than the former (Cl, 3 O). Therefore, the loss of the O,O ligand from the most abundant intermediate B will be the preferred reaction path.

Conclusions

In conclusion, diethyl [(methylsulfinyl)methyl]phosphonate (SMP) has proven to be a versatile ligand for platinum allowing the synthesis of different complexes in which SMP acts invariably as an O,S-donor ligand. Unlike the vast majority of metal phosphonate complexes reported in the literature, the present ligand is in the form of a dialkyl ester, coordinating the metal atom by the oxygen atom formally doubly bonded to the phosphorus atom.

It has been shown that the puckering of the O,S chelate ring depends upon the chirality at the sulfur center [δ puckering for an (*S*) configuration of the free ligand]. Moreover, for coordinated SMP, the protons of the methylene group bridging the sulfur and phosphorus atoms are rather acidic as revealed by the rather low pH of aqueous solutions of the complexes. Depending upon the nature of the ancillary ligands, the SMP can behave as a leaving ligand (ancillary diamines) or as a non-leaving ligand (ancillary monoamine, malonato or chloro ligands). The two possibilities are likely to influence in a different way the antitumor activities of these compounds.

We hope that some of these new platinum complexes might follow the promising route marked by Keppler's complexes with aminobis(phosphonates), which show selective

activity against bone tumors and those forms of tumors involving an anomalous balance of calcium ions.

Experimental Section

General Methods: NMR spectra were recorded with a Bruker AVANCE DPX-WB 300 MHz instrument. Standard Bruker automation programs were used for 2D NMR experiments. ^{1}H chemical shifts are referenced to TMS by using the residual protic peak of the solvent as internal reference (δ = 2.04 ppm for [D$_6$]acetone and δ = 4.80 ppm for deuterium oxide). ^{13}C NMR chemical shifts are also referenced to TMS. ^{31}P NMR chemical shifts are referenced to 85% H_3PO_4. IR spectra were obtained with a Perkin−Elmer Spectrum One Infrared Spectrophotometer using KBr as solid support for pellets. Elemental analyses were performed with a Carlo Erba Elemental Analyzer mod. 1106 instrument.

Starting Materials: The diethyl [(methylsulfinyl)methyl]phosphonate ligand (SMP) was prepared by a reported procedure.[27] The ligand contains a chiral sulfur atom and can be prepared either as the pure (*S*) or (*R*) enantiomer or as a racemic mixture. In our investigation we have used both the (*S*) enantiomer and the racemic mixture. The preparation of the (*R*) enantiomer is under way.

[PtCl$_2$(SMP)] (1): A solution of SMP (250 mg, 1.17 mmol) in water (10 mL) was added dropwise to a solution of potassium tetrachloroplatinate (510 mg, 1.23 mmol) in the same solvent (10 mL). Within a few minutes, the reaction mixture turned from red to yellow-orange. The solution was stirred at room temperature for 24 h, then the solvent was removed by lyophilization and the orange solid residue extracted with acetone in order to remove insoluble KCl and unchanged potassium tetrachloroplatinate. Concentration of the acetone solution to dryness under reduced pressure gave an oily residue which, after trituration with diethyl ether, afforded a yellow-orange solid which proved to be the pure complex [PtCl$_2$(SMP)]. Yield: 95% (533 mg). $C_6H_{15}Cl_2O_4PPtS$ (480.20): calcd. C 15.00, H 3.15; found C 15.04, H 3.15. IR: $\tilde{\nu}$ = 2913 (ν_{C-H}), 1253 ($\nu_{P=O}$), 1048 ($\nu_{S=O}$), 1013 (ν_{P-O-R}), 321 (ν_{Pt-Cl}) cm^{-1}. See Table 1 for NMR spectroscopic data.

[Pt(dmm)(SMP)] (2): A solution of potassium dimethylmalonate (dmm, 43 mg, 0.206 mmol) in water (2 mL) was added dropwise to a solution of [PtCl$_2$(SMP)] (99 mg, 0.206 mmol) in water (10 mL). After stirring at room temperature for 12 h, a stoichiometric amount of Ag_2SO_4 (64 mg, 0.206 mmol) was added to the solution and stirring was resumed for an additional 12 h. The suspension was filtered to remove AgCl and the solution concentrated to dryness by lyophilization. The yellow solid was extracted with methanol, to remove insoluble K_2SO_4, and the organic solution concentrated to dryness under reduced pressure. The resulting yellow solid proved to be the desired complex of composition [Pt(dmm)(SMP)]·H_2O. Yield: 69% (79 mg). $C_{11}H_{23}O_9PPtS$ (557.42): calcd. C 23.70, H 4.16; found C 23.48, H 4.54. IR: $\tilde{\nu}$ = 2935 (ν_{C-H}), 1633 ($\nu_{C=O}$), 1251 ($\nu_{P=O}$), 1050 ($\nu_{S=O}$), 1021 (ν_{P-O-R}) cm^{-1}. See Table 1 for NMR spectroscopic data.

[Pt(en)(SMP)]Cl$_2$ (3·2Cl) and [Pt{(*R*,*R*)-dach}(SMP)]Cl$_2$ (4·2Cl): A solution of ethylendiamine (en, 13.7 mg, 0.228 mmol) or (*R*,*R*)-1,2-diaminocyclohexane (*R*,*R*-dach, 26 mg, 0.228 mmol) in water (2 mL) was added dropwise to a solution of the chloro complex [PtCl$_2$(SMP)] (110 mg, 0.228 mmol) in the same solvent (10 mL). The reaction mixture turned immediately from yellow to colourless. Evaporation of the solvent under reduced pressure left a pale-yellow oily residue which, after trituration with diethyl ether, afforded a pale-yellow solid product, which proved to be the desired complex. Compounds **3**·2Cl and **4**·2Cl are highly hygroscopic materials and were characterized only by NMR spectroscopy (see Table 1).

[Pt(en)(SMP)](SO$_4$) (3·SO$_4$) and [Pt{(*R*,*R*)-dach}(SMP)](SO$_4$) (4·SO$_4$): The reaction was performed as described in the previous preparation. The resulting colourless solution was treated with a stoichiometric amount of Ag_2SO_4 (71 mg, 0.228 mmol) which caused precipitation of AgCl which was removed by filtration. Lyophilization of the solution left a white solid which proved to be the desired complex. Yield: 60%.

3·SO$_4$: $C_8H_{23}N_2O_8PPtS_2$ (565.46): calcd. C 17.00, H 4.10, N 4.95; found C 17.30, H 4.48, N 5.34. IR: $\tilde{\nu}$ = 3207 (ν_{N-H}), 2988 (ν_{C-H}), 1245 ($\nu_{P=O}$), 1127 (ν_{SO4}), 1052 ($\nu_{S=O}$), 1021 (ν_{P-O-R}) cm^{-1}. See Table 1 for NMR spectroscopic data.

4·SO$_4$: $C_{12}H_{29}N_2O_8PPtS_2$ (619.56): calcd. C 23.26, H 4.72, N 4.52; found C 23.16, H 5.10, N 4.88. IR: $\tilde{\nu}$ = 3205 (ν_{N-H}), 2988−2937 (ν_{C-H}), 1250 ($\nu_{P=O}$), 1117 (ν_{SO4}), 1049 ($\nu_{S=O}$), 1023 (ν_{P-O-R}) cm^{-1}. See Table 1 for NMR spectroscopic data.

Interaction of the $[GaH_4]^-$ Anion with Weak XH Acids − A Spectroscopic and Theoretical Study

Natalia V. Belkova,[a] Oleg A. Filippov,[a] Andrey M. Filin,[a] Liliya N. Teplitskaya,[a] Yulia V. Shmyrova,[a] Vyacheslav V. Gavrilenko,[a] Ludmila M. Golubinskaya,[a] Vladimir I. Bregadze,[a] Lina M. Epstein,*[a] and Elena S. Shubina*[a]

Keywords: Hydrides / Hydrogen bonding / IR spectroscopy / Theoretical methods / Boron / Gallium

The dihydrogen bonding (DHB) between the hydride atom of the $[Bu_4N][GaH_4]$ salt and different XH acids, namely CF_3CH_2OH, FCH_2CH_2OH, *i*PrOH, MeOH, indole and 4-$O_2NC_6H_4NH_2$, has been investigated for the first time by low-temperature IR spectroscopy. The DHB spectroscopic and thermodynamic parameters in solvents of low polarity and high basicity (E_j = 1.37) were obtained. The nature, structures, energies and electron distributions of the model DHB complexes of GaH_4^- with H_2O, MeOH, CF_3OH, H_2NCF_3 or $NO_2C_6H_4NH_2$ were studied by DFT calculations and compared with those of the analogous complexes of BH_4^- with H_2O, MeOH or CF_3OH. Two types of DHB structures with monodentate and symmetric chelate coordination were found. The lengthening of the X–H and Ga–H bonds, electron polarization and overlap population of the H···H bond are greater in the first type of structure. A comparative analysis of experimental data demonstrates that the spectroscopic and thermodynamic characteristics, e.g. ν(XH) and ν(GaH) band shifts, $\nu(XH)_{bonded}$ integral intensities, formation enthalpies and E_j of all the DHB complexes increase down the group (BH_4^-·HX < GaH_4^-·HX).

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The unconventional intermolecular hydrogen bond between XH proton donors and the hydride ligands of transition metal hydride complexes ($XH^{\delta+}\cdots{}^{-\delta}HM$) were discovered between 1995 and 1996 and have been actively investigated since this time with several reviews appearing on the topic.[1−6] The formation conditions, structural and energetic characteristics of these unusual hydrogen bonds were determined by low-temperature IR and NMR spectroscopy in solution and by X-ray and neutron diffraction in the solid state. A variety of theoretical methods were devoted to the nature and structure of this dihydrogen bond (DHB) formed by transition metal hydrides in the gas phase.[1,5,7,8] It has been shown that these H···H complexes are important intermediates in proton transfer reactions leading to transition metal dihydrogen complexes.[1,6,9−11] In very recent DFT work,[11] the solvent was introduced by a polarizable continuum model and its stabilising effect on the protonation process was studied.

The ability of main group element hydrides to form DHBs was studied for the first time using boron hydrides.[12−17] An analysis of the structures from the Cambridge Structural Database and theoretical calculations on the dimer $(BH_3NH_3)_2$ led to the conclusion that the DHB moiety is significantly bent.[12,13] Later, our IR investigations in solution combined with theoretical studies of the $(H_3NBH_3)_2$ dimer as well as the DHB of BH_4^- and BH_3NH_3 with proton donors (H_2O, MeOH and HCN) led to the conclusion that substantial deviations from linearity in the solid state are caused by the crystalline packing.[14,15] The linearity of the (B)H···HX moiety and reasonable electron density changes have been demonstrated by theoretical calculations of $(H_3NBH_3)_2$ using the RHF/6-31G[15] and A1M[16] methods, though the nonlinear bifurcated DHB (of C_{2v} symmetry) was reported in previous works (HF, DFT, MP2 methods).[17] Recently, neutron diffraction measurements corrected the "heavy" atom assignments for $(H_3NBH_3)_2$ leading to the structure with practically linear NH···H(B) DHBs and bent BH···H(N) moieties.[18] The similarity between BH···HX, MH···HX and classical H bonds in the structure was established.[1,6,15] Recently, some reports have been devoted to theoretical DHB calculations of the other main group hydride complexes EH···HX.[19−21] A theoretical study of DHB complexes between some simple hydrides (for example, BeH_2, MgH_2, SiH_4, GeH_4 and SnH_4) and HF showed a correlation between H···H distances and the energies of the DHB.[22] Cyclotriallumozane $(NH_2AlH_2)_3$ was found theoretically to have a favourable twist-boat conformation in the gas phase with two H···H interactions.[23] A comparison of the calculated structures and energies of NH···HE (E = B, Al, Ga) for $(NH_3EH_3)_2$ predicted C_2 symmetry for the dimers of the Al and Ga

hydrides and the DHB energy was shown to decrease down the group.[17]

It is noteworthy that experimental studies of Al and Ga hydrides have considered only the structures of the crystalline adducts.[20] An intramolecular NH···HAl hydrogen bond was determined from an X-ray diffraction study of the alane−piperidine complex[24] and six short H···H contacts were found in the structure of the $[(NH_2AlH_2)_3]_2$ dimer.[23] The neutron diffraction crystal structure of cyclotrigallozane $(NH_2GaH_2)_3$ indicated self-assembly from four NH···HGa dihydrogen bonds.[23] To date, there is no evidence for the existence of GaH···HX interactions in solution. However, DHB interactions are very important allowing control over reactivity and selectivity in solution. This has potential implications in catalysis and promises an important role in the creation of supramolecular assemblies and new covalent materials.[1,20]

In this work we present the results of a VT-IR investigation (190−290 K) including spectroscopic and thermodynamic characteristics of DHB formed in low-polarity solvents between GaH_4^- (**1**) and proton donors of different strength, i.e. CF_3CH_2OH, FCH_2CH_2OH, *i*PrOH, MeOH, indole and 4-$O_2NC_6H_4NH_2$. VT-IR spectroscopy, as has been previously shown, is a very convenient method for studying DHB complexes providing not only evidence of the formation of DHB, but also allowing the detection of the separate bands of the initial and H-bonded complexes. The technique also enables determination of the formation energy.[6,15]

The nature, structures, energies and electron distributions of the model DHB complexes formed between **1** and H_2O, MeOH, CF_3OH, H_2NCF_3 or 4-$O_2NC_6H_4NH_2$ are discussed on the basis of ab initio calculations and compared with those of analogous complexes of BH_4^- with H_2O, MeOH, or CF_3OH.

Results and Discussion

Spectroscopic Evidence for Hydrogen Bonding in Solution

The IR spectra of OH and NH acids (in the concentration range of 10^{-2} to 10^{-3} M in order to exclude self-association) were measured in dichloromethane with an excess of gallohydride **1**. The intensities of the ν(XH) stretching vibrations decrease in the presence of **1** and new, lower frequency broad bands (3392−3224 cm^{-1}) of H-bonded XH groups [$\nu(XH)_{bonded}$] appear (e.g. Figure 1). This pattern demonstrates formation of hydrogen bonds between proton donors and the gallium hydride. The intensities of the $\nu(XH)_{bonded}$ bands increase as the temperature decreases as illustrated in Figure 1 for MeOH. This indicates the right shift for the H-bonding equilibrium upon cooling.

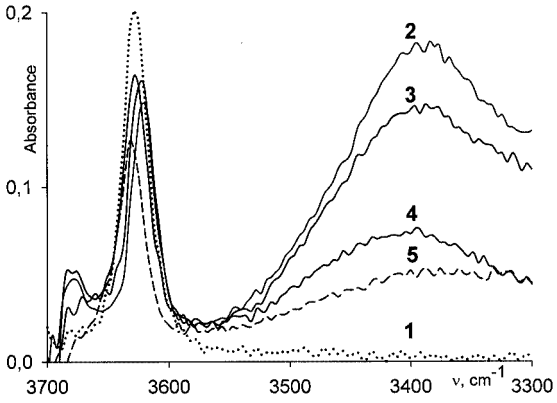

Figure 1. IR spectra in the ν(OH) range of MeOH (c = 0.015 M, CH_2Cl_2) at 260 K (1); in the presence of $[Bu_4N]GaH_4^-$ (0.09 M): at 200 K (2); 220 K (3); 260 K (4); 290 K (5)

All spectroscopic parameters, i.e. frequency shifts [$\Delta\nu(XH) = \nu(XH)_{free} - \nu(XH)_{bonded}$], half-widths of the $\nu(XH)_{bonded}$ bands ($\Delta\nu_{1/2}$) and integral intensities [$A(XH)_{bonded}$] increase with the increase of the proton-donating ability of XH in the following sequence: 4-$O_2NC_6H_4NH_2$ < *i*PrOH < MeOH < $FCH_2CH_2OH \approx C_8H_6NH$ < CF_3CH_2OH. The values of Δν(XH) increase along this series from 144 to 250 cm^{-1}, $A(XH)_{bonded}$ increases from 5.12×10^4 to 9.52×10^4 $L \cdot cm^{-2} \cdot mol^{-1}$ and $\Delta\nu_{1/2}$ increases from 97 to 287 cm^{-1} (Table 1).

Interesting results were obtained from the study of the GaH_4^-/4-$O_2NC_6H_4NH_2$ system in CH_2Cl_2 solution. Two bands of the NH_2 group of 4-$O_2NC_6H_4NH_2$ in the IR spectra can be assigned to asymmetrical (ν^{as} = 3509 cm^{-1}) and symmetrical (ν^{s} = 3411 cm^{-1}) stretching vibrations. In the presence of the anion **1**, two new bands (3481 and 3337

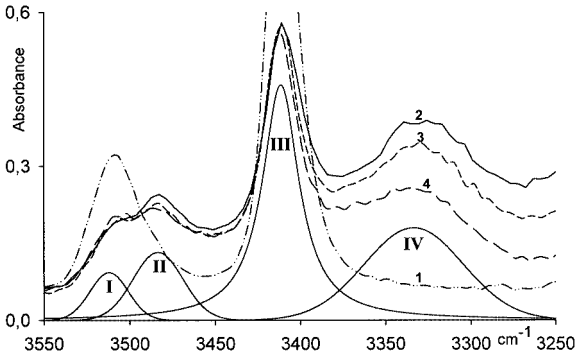

Figure 2. IR spectra in the ν(NH) range of 4-$O_2NC_6H_4NH_2$ (c = 0.02 M, CH_2Cl_2) at 200 K (1); in the presence of $[Bu_4N]GaH_4^-$ (0.09 M): at 200 K (2); 230 K (3); 250 K (4) and separation of the band (2) on the four components: $\nu(NH)^{as}$ (I), $\nu(NH)^{as}$ (III) and II, IV (see text for assignment)

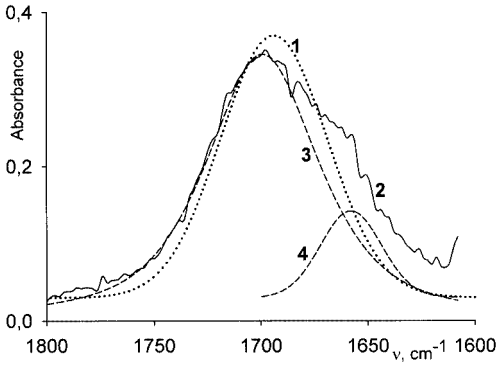

Figure 3. IR spectra in the ν(GaH) range of $[Bu_4N]GaH_4^-$ (c = 0.03 M, THF) at 200 K (1); in the presence of 4-$O_2NC_6H_4NH_2$ (0.08 M) at 200 K (2); separation of the band (2) on the two components: $\nu(GaH)_{free}$ (3) and $\nu(GaH)_{bonded}$ (4)

cm^{-1}) appear and grow upon cooling (Figure 2). There are two possibilities for the assignments of these two bands. In the case of monodentate coordination, these bands could be attributed to the free and bonded species, respectively. In the case of bidentate coordination, these bands would correspond to the ν^{as} and ν^{s} bands of the bonded species. Analysis of the IR spectra and band separation enables us to suggest the first type of assignment.[25] The new high-frequency band ν(NH) at 3481 cm^{-1} is narrow ($\Delta\nu_{1/2}$ = 34 cm^{-1}) and the second new band at 3337 cm^{-1} is much broader ($\Delta\nu_{1/2}$ = 68 cm^{-1}). Shifts of these bands corresponding to $[\nu(NH)^{as} + \nu(NH)^{s}]/2$ are −21 and 123 cm^{-1}, respectively. Taking into account both factors, we can assign these bands as $\nu(NH)_{free}$ = 3481 cm^{-1} and $\nu(NH)_{bond}$ = 3337 cm^{-1}. The results of theoretical calculations (see below) confirm both the monodentate coordination and this assignment.

Spectroscopic evidence for the hydride ligand being the site of DHB formation was obtained from a range of Ga−H stretching vibrations studied in THF at 180−290 K. It was shown earlier that DHB formation results in a low-frequency shift of the M−H or B−H stretches for the groups participating in H-bonding, whereas the bands corresponding to the groups that do not participate in H-bonding shift to the high-frequency region.[6,15] Thus, the formation of GaH···HX bonds, leads to some broadening of the ν(GaH) band accompanied by the appearance of low-frequency and high-frequency shoulders assignable to stretching vibrations of the one bonded and three free GaH bonds, respectively. Such changes were observed in the interaction with the weakest proton donor used, i.e. 4-$O_2NC_6H_4NH_2$ (Figure 3). The band intensity of **1**, ν(GaH) = 1700 cm^{-1}, decreases and the stretching vibrations of the free GaH groups in the DHB complex are displaced to the high-frequency range. Those of the GaH-bonded group appear as the low-frequency shoulder.

One could expect more pronounced changes for stronger XH acids, as in the case of the $BH_4^-/(CF_3)_2CHOH$ system.[15] However, less pronounced changes were observed in the IR spectra of **1** in the presence of FCH_2CH_2OH and indole at 200 K. Moreover, the ν(GaH) band intensity decreases as the temperature increases (> 240 K) probably due to proton transfer with subsequent H_2 gas evolution and formation of covalent Ga−O/Ga−N bonds. We have not yet studied this process in more detail, but there are many examples of boron hydride alcoholysis/hydrolysis studies in the literature, e.g. the BH_4^-/R^fOH[26] and GaH_4^-/ROH[27] systems. However, the H···H bonding was not considered as an intermediate along the reaction pathway. By analogy with transition metal hydrides,[6] we suggest Scheme 1 for the reaction with alcohols where the proton transfer from DHB complexes leads to nonclassical (η^2-H_2) complex formation followed by hydrogen elimination yielding alkoxy derivatives. Evidently, the (η^2-H_2) complexes of **1** should be very unstable as for other main group element hydrides, but the data concerning the theoretical and experimental evidence of the boron analogue[28] (IR spectra in cryogenic matrices at 13−27 K) support our hypothesis.

$$\underset{\mathbf{1}}{GaH_4^- + ROH} \rightleftharpoons \underset{\mathbf{2}}{[H_3Ga(H\cdots HOR)]^-} \rightleftharpoons \underset{\mathbf{3}}{[H_3Ga(\eta^2\text{-}H)\cdot OR]^-} \longrightarrow \underset{\mathbf{4}}{H_3GaOR^- + H_2}$$

Scheme 1

The participation of more alcohol molecules in the reaction generates alkoxy products of different compositions, $[H_{4-n}Ga(OR)_n]^-$.[27] The same is true of the aminolysis reactions. The reaction can stop at the first step of DHB intermediate formation, depending on temperature and the amount and strength of the proton donor. The interaction with weakest XH acid used (4-nitroaniline), as mentioned above, does not lead to proton transfer and H_2 evolution in the temperature range of 180−250 K. IR spectroscopic changes demonstrate only DHB formation (equilibrium **1** ⇆ **2**; Scheme 1). The temperature dependence is reversible. The interaction with the stronger FCH_2CH_2OH or indole leads to the reduction of the ν(GaH) intensity at 230 K and to practically full disappearance of this band at ambient temperature. At the same time, a very broad and high frequency absorbance (1800−1850 cm^{-1}) appears which probably corresponds to the Ga−H stretching of different al-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

coholysis or aminolysis products (**4** in Scheme 1). The same spectroscopic changes were observed in the interaction with the stronger OH acid F_3CCH_2OH (Figure 4, line 2). In this case, some decrease in the $\nu(GaH)_{free}$ band intensity (1700 cm^{-1}) of the DHB complex took place even at low temperature (200 K) with the simultaneous appearance of the broad high-frequency absorbance. Upon a temperature change from 200 to 290 K, broad overlapping bands (1763 cm^{-1} at 200 K and 1810 cm^{-1} at 290 K) increased irreversibly (Figure 4). Moreover, the intensity of these bands increased concomitantly with the decrease of the $\nu(GaH)_{free}$ band (Figure 4). These can be tentatively assigned to the ν(GaH) vibrations of $[GaH_{4-n}(OCH_2CF_3)_n]^-$.[27] However, a special study is necessary in order to obtain the data corresponding to the spectroscopic changes during the alcoholysis/aminolysis reactions and definite assignment of each band.

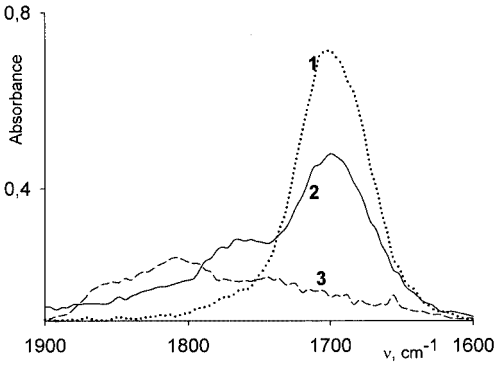

Figure 4. IR spectra in the ν(GaH) range of $[Bu_4N]GaH_4^-$ (c = 0.04 M, THF) at 200 K (1); in the presence of TFE (0.10 M): at 200 K (2); at 290 K (3)

It should be noted that the Δν(GaH) values of the DHB complexes of **1** with weak proton donors are 10−30 cm^{-1} larger than the Δν(BH) values for the analogous DHB complexes of BH_4^-.[15] The changes in the spectroscopic characteristics of the XH acids in the presence of **1**, such as ν(XH) band shifts, $\nu(XH)_{bonded}$ band half-widths ($\Delta\nu_{1/2}$) and integral intensities (A), are also higher than those in the presence of BH_4^-.

Strength of GaH···HX Bonds

The enthalpies ($-\Delta H$) of the GaH···HX bond formations were determined from the empirical correlation Equations (1) and (2). These were proposed by Iogansen for classical H-bonded systems[29−31] but have also proved to be valid for dihydrogen bonds to transition metal [6] and boron hydrides.[15]

$$-\Delta H^\circ = 18 \times \Delta\nu/720 + \Delta\nu \quad (1)$$

$$-\Delta H^\circ = 2.9(\Delta A)^{1/2} \quad (2)$$

The enthalpy values of dihydrogen-bonded complex formation obtained from frequency shifts [Equation (1)] and integral intensity changes [Equation (2)] have similar values as is apparent from Table 2. The GaH···HX bond energies correspond to medium-strength H bonds: $-\Delta H^0$ values of the DHB complexes change from 4.0 to 5.4 kcal·mol^{-1} with the exception of the weak DHB to 4-$O_2NC_6H_4NH_2$ (2.6 kcal·mol^{-1}).

Table 2. The enthalpy values of DHB complexes [kcal·mol^{-1}] of GaH_4^- (**1**) and P_i factors of proton donors[29]

HX	$-\Delta H^0$ [a]	$-\Delta H^0$[b]	P_i [29]
4-$O_2NC_6H_4NH_2$	2.6	–	0.41
Indole	4.4	4.5	0.75
*i*PrOH	4.0	–	0.58
CH_3OH	4.3	4.1	0.63
FCH_2CH_2OH	4.4	4.7	0.74
CF_3CH_2OH	5.4	5.2	0.89

[a] $-\Delta H^0$ calculated using Equation (1). [b] $-\Delta H^0$ calculated using Equation (2).

The proton accepting ability of the hydride hydrogen of **1** was determined using the "rule of factors" proposed by Iogansen [29] for organic systems [Equation (3)], where P_i is the proton-donating ability from Table 2,[29] i.e. $-\Delta H_{11}$ = 4.6 kcal·mol^{-1} for the phenol/ethyl ether pair in CH_2Cl_2, with $P_1 = E_1 = 1.0$.

$$-\Delta H_{ij} = -\Delta H_{11} P_i E_j \quad (3)$$

The basicity factor (E_j) is independent of the proton donor and solvent and for **1** is equal to 1.37±0.09. Thus, it is possible to compare the proton-accepting ability of **1** with those of boron complexes, some transition metal hydrides and even with organic bases (Table 3).

Table 3. Basicity factors of hydride ligands of GaH_4, boron and transition metal hydrides and some organic bases

Compound	E_j	Ref.	Compound	E_j	Ref.
GaH_4^-	1.37	this work	$[(CH_2CH_2PPh_2)_3FeH_2]$	1.0	[9]
BH_4^-	1.25	[15]	$[(CH_2CH_2PPh_2)_3RuH_2]$	1.33	[9]
$[B_{12}H_{12}]^{2-}$	0.61	[32]	$[MeC(CH_2PPh_2)_3(CO)RuH_2]$	1.39	[33]
$[B_{10}H_{10}]^{2-}$	0.78	[32]	$[(CH_2CH_2PPh_2)_3OsH_2]$	1.66	[9]
Et_3NBH_3	0.53	[15]	DMSO	1.27	[29]
$P(OEt)_3BH_3$	0.41	[15]	Py	1.67	[29]

The E_j value of **1**, as one can see from Table 3, is significantly larger than those of the neutral boron hydrides and even of BH_4^- (E_j = 1.25), i.e. the proton-accepting ability of hydride ligands increases down the group (B)−H < (Ga)−H. The proton-accepting ability of **1** is close to that of the strongest transition metal hydrides (and organic bases) known to date.[1,6,15] The transition metal hydrides with larger basicity factors ($E_j > 1.5$) undergo complete proton transfer from weak XH acids (fluorinated alcohols) to the hydride ligand.[1,6,9] Thus, the ease of proton transfer and alcoholysis during the interaction of **1** with

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

FCH_2CH_2OH and especially F_3CCH_2OH, in contrast to BH_4^-, could be due to the larger proton accepting ability of GaH_4^- compared with that of BH_4^-.

Computational Study

A theoretical investigation of the model complexes $GaH_4^-\cdot H_2O$ (**5**), $GaH_4^-\cdot 2H_2O$ (**5′**), $GaH_4^-\cdot CH_3OH$ (**6**), $GaH_4^-\cdot CF_3OH$(**7**), $GaH_4^-\cdot CF_3NH_2$(**8**) and $GaH_4^-\cdot O_2NC_6H_4NH_2$ (**9**) was performed using the B3LYP approximation with the standard basis set 6-311G(d,p) (see Exp. Sect.). In order to establish the role of the central atom, the model complexes $BH_4^-\cdot H_2O$ (**10**), $BH_4^-\cdot CH_3OH$ (**11**) and $BH_4^-\cdot CF_3OH$ (**12**) were calculated with the 6-311++G(d,p) basis set. This basis set was chosen because of better agreement between the calculated and experimental ν(BH) frequencies.

Structures of DHB Complexes

The results from the theoretical studies are in agreement with the experimental results, showing that the hydride ligand is a proton-accepting site in all cases. There are two types of XH acids. The first type involves the XH acids with only one proton available for donation (CH_3OH, CF_3OH). The XH acids of the second group possesses two H atoms (H_2O, CF_3NH_2, 4-$O_2NC_6H_4NH_2$). Therefore, the possibility of mono- or bidentate coordination for the last proton donor group was considered.

A linear arrangement of the triatomic HX···H(Ga) moiety for the first proton donor group was found (Table 4). The X−H···H angles are close to 180° (170.6°, 174.6° and 165.8° for **6**, **7** and **9**, respectively) and, as was shown earlier, this is typical for classical H-bonding and DHB complexes MH···HX and BH···HX.[1,6,15] The H···H distances are smaller than the sum of van der Waals radii (2.4 Å) and decrease for stronger alcohols (from 1.639 Å for **6** to 1.328 Å for **7**) (Table 4, Figure 5). Experimentally obtained H···H distances for MH···HX are in the range of 1.65−2.1 Å.[1,6] In the case of the neutral dimer ($NH_2HGaH\cdots HNHGaH_2$), this distance in the crystal is equal to 1.9 Å.[2] Therefore, the H···H distance obtained for **7** (1.328 Å) is probably too short.

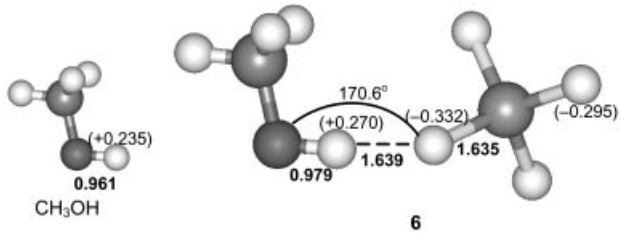

Figure 5. The geometries [Å and °] and Mulliken charges (in parentheses) of the model complex $GaH_4^-\cdot CH_3OH$ (**6**)

The formation of the H···H hydrogen bond leads to the elongation of the Ga−H and O−H bond lengths from their values in the isolated molecules. For example, r(Ga−H) = 1.622 Å in **1** and 1.635 Å in complex **6**, r(O−H) = 0.961 Å in CH_3OH and 0.979 Å in **6**. These changes are close to those previously reported for MH···HX and BH···HX complexes.[1,6,15] However, the H···H distance in **6** (1.639 Å) is shorter and the value of Δr(Ga−H) = 0.013 Å is larger than the corresponding values in complex **11** [r(H···H) = 1.654 Å and Δr(B−H) = 0.005 Å]. The increase in the elongations of the OH bonds is dependent of the OH acid strength (about three times when the CH_3 group (**6**, **11**) is substituted by CF_3 (**7**, **12**), Table 4).

Interesting results were obtained for the second group of XH acids. The minima on the potential energy surfaces for H_2O and CF_3NH_2 are achieved for bidentate coordination when the two hydride atoms of **1** interact with both hydrogen atoms of the XH_2 groups forming a symmetrical chelated structure (Figure 6). The interaction between these species leads to nonlinear OH···H and NH···H moieties and

Table 4. The characteristics of DHB complexes calculated by the DFT method

induces less bond elongation. The H···H distances are longer than in the complexes of the first group (Table 4).

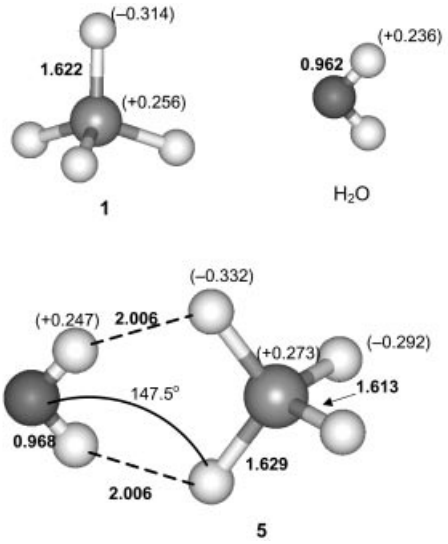

Figure 6. The geometries [Å and °] and Mulliken charges (in parentheses) of the model complex $GaH_4^-\cdot H_2O$ (**5**)

Thus, the DHB complexes **5** (Figure 6) and **8** exhibit longer H···H distances (2.005 and 2.047 Å) than for **6** and **7**, smaller elongations (0.007−0.011Å) and more acute O−H···H and N−H···H angles (147.5° and 140.8°, respectively). Interaction with the second water molecule leads to complex **5′** with a second symmetrical chelated ring and practically the same OH···H angle. Only the Ga−H elongations are less (in 0.004 Å) and the H···H distance is a little larger (in 0.027 Å) compared with that in **5**.

It was found that the differences in the structures of the $EH_4^-\cdot H_2O$ complexes depend on the central atom. The monodentate coordination of H_2O is characteristic for $BH_4^-\cdot H_2O$ (**10**) instead of the symmetrical chelate structure of **5** (Figure 6). The O−H···H angle of **10** (174.5°) is larger than in **5** and is close to 180°. The additional interaction between the free hydride atoms of BH_4^- and the free hydrogen atom in the water molecule[15] should not be regarded as the second H bond because the H···H distance is equal to 2.48 Å. This is larger than the sum of the van der Waals radii.

Reducing the proton donor strength by substitution of R in RNH_2 from CF_3 in **8** to 4-$O_2NC_6H_4$ in **9** also leads to monodentate coordination of the proton donor with an additional interaction of the second acidic hydrogen atom similar to the situation in **10**. This additional interaction can also not be regarded as a DHB bond (H···H distance = 2.449 Å; Figure 7).

The increase of the N−H···H angle (165.8°), the additional lengthening of the Ga−H and O−H bonds (0.021, 0.021 Å) and the shortening of the H···H distance (1.755 Å) are characteristic for **9** when compared with **8**.

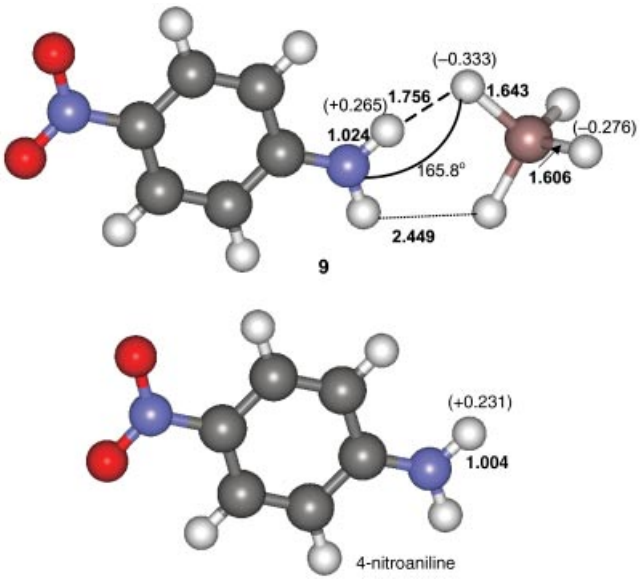

Figure 7. The geometries [Å and °] and Mulliken charges (in parentheses) of the model complex $GaH_4^-\cdot O_2NC_6H_4NH_2$ (**9**)

Energies of DHB Complexes and Electron Density Changes

The calculated energy values of the complexes (Table 4) are larger than those obtained experimentally. For example, the energy of $GaH_4^-\cdot CH_3OH$ (**6**) is about twice as high as the enthalpy value obtained from Equations (2) and (3) from IR spectroscopic data (Table 2). The probable cause of such overestimation may be the decrease of the DHB energy on going from the gas phase (calculations) to solution (experimental measurements).[6,15] As was indicated previously, the significant solvation effects are related to ion-molecular H bonds due to the significantly larger solvation energies for anions over hydrogen-bonded complexes.[34] Note, however, that the energy overestimation is more for $BH_4^-\cdot HOR$ complexes. This could be explained by the smaller dimension and greater solvation effect of BH_4^- in comparison with GaH_4^-.[34] It is remarkable that the calculated energy values for the linear monodentate complexes (9.1−19.6 kcal·mol^{-1}) are higher than for the bidentate nonlinear DHBs (5.35−6.3 kcal·mol^{-1} per bond). The energy increase is dependent on the XH acid strength, for example, **6** < **7** (Table 4).

The overlap populations (*o.p.*) of the H···H bonds and the electron redistribution upon DHB formation also depend on the type of coordination and the acid strength. The *o.p.* of the H···H bonds vary in the range of 0.016−0.095 and their values are larger in the case of linear monodentate coordination. Small but positive overlap populations indicative of the covalent component of DHB increase upon going from **6** to **7**. The electrostatic attraction between the partial negative charge of the hydrogen atom of GaH_4^- (−0.314) and partial positive charge of the proton donors (from 0.22 to 0.27 dependent on their strength) is the driving force for dihydrogen bonding $GaH^{\delta-}\cdots{}^{+\delta}HX$ as was previously determined for $MH^{\delta-}\cdots{}^{+\delta}HX$.[1,6] DHB formation leads to an increase of the charges which is a little

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

more substantial in the case of the monodentate complexes, especially for the hydrogen atom of the XH acids [for example, ΔqH(OH) = 0.035 for **6** and ΔqH(OH) = 0.010 for **5**] (Table 4).

The calculation of the interaction of **1** with a strong acid shows the proton transfer reaction leading to the dihydrogen complex formation [Equation (4)].

$$GaH_4^- + H_3O^+ \rightarrow GaH_3\text{-}(\eta^2\text{-}H_2) + H_2O \quad (4)$$

Upon proton transfer to a hydride ligand, the tetrahedron of **1** transforms in to the planar gallium trihydride with the side on (η^2-H_2) ligand (Figure 8). The H−H distance is equal to 0.756 Å which is a little longer than in the H_2 molecule (0.74 Å) and shorter than in transition metal dihydrogen complexes (0.8−1.1 Å).[1,4,6] The large energy calculated (167.16 kcal·mol^{-1}) is in agreement with Equation (4) which demands significant electron and structural reorganization. Such an unstable dihydrogen complex was predicted theoretically and observed experimentally by IR matrix isolation in the case of boron.[28]

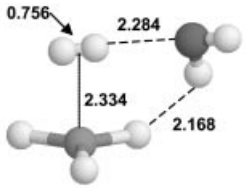

Figure 8. The geometries [Å] of the unstable products of the proton transfer reaction (4)

Spectroscopic Characteristics of DHB Complexes

The calculated spectroscopic characteristics of the complexes (stretching vibrations of X−H and Ga−H bonds) are presented in Table 5. The $\nu(XH)_{bonded}$ bands are shifted to the low-frequency range in agreement with the experimental observations. The values of the shifts depend on the strength of the XH acid and the linearity of the X−H···H moiety. Linear bonds result in larger ν values. The value of ν(OH) in complex **6** is about twice as large as in nonlinear **5**, although the acidity of methanol and water are similar ($pK_a \approx 15.5$). The ν(OH) value depends on the proton-donating ability in the sequence: $F_3COH > CH_3OH > NO_2C_6H_4NH_2 > H_2O \geq CF_3NH_2$.

The bands of the free Ga−H groups in the complexes increase in agreement with the experimental IR spectroscopic changes observed for DHB complexes with **1**, the boron analogue [15] and transition metal hydrides.[6]

Hence, the calculations reproduced the main structural features and the charge redistribution occurring as a result of hydrogen-bond formation as a function of the proton-donor strength and the type of coordination.

Conclusion

The present variable-temperature IR investigation of the interaction between GaH_4^- and different XH acids shows for the fist time the GaH···HX dihydrogen-bond formation in solution. The spectroscopic characteristics, DHB formation enthalpies with different XH acids and the E_j factors of GaH_4^- were determined and appear to be greater than those of the boron analogue DHB, demonstrating an increase in the proton-accepting ability down the group. Two types of DHB model complexes were determined from DFT calculations: the linear monodentate with XH acids or 4-nitroaniline and the nonlinear bidentate with XH_2 acids containing symmetrical chelate hydrogen bonds to two hydride atoms of **1**. This last type of DHB was not found for BH_4 and is specific to the GaH_4^- anion. It was shown that the elongation of the bonds of the GaH···HX moiety, polarisation of the partners and the energy depend on the type of coordination and the strength of the X−H acids.

A study of a number of group 13 hydride DHB complexes would be of great interest for determining the EH···HX energies and structures as a function of the position of the group 13 element, as well as the mechanisms of aminolysis and alcoholysis through DHB. We are currently investigating these issues.

Experimental Section

The $[Bu_4N][GaH_4]$ salt (**1**) was prepared as described in the literature.[36] Fluorinated alcohols were provided by P&M (Moscow, Russia). The solutions for IR studies were prepared under argon by standard Schlenk technique. Tetrahydrofuran (THF) was freshly distilled from $LiAlH_4$ and CH_2Cl_2 was purified by distillation from CaH_2 before use. The anhydrous solvents were thoroughly degassed prior to use.

[a] IR, Raman frequencies of $CsGaH_4$ in diglyme solution.[39] [b] IR frequency of ν(GaH) Bu_4NGaH_4 in THF solution: 1696 cm^{-1}.

The IR spectra of THF or CH_2Cl_2, solutions (cells CaF_2, $d = 0.012 - 0.120$ cm) were measured with a Specord M-82 (Carl Zeiss Jena) spectrometer with a 2−4 cm^{-1} resolution. The low-temperature IR studies were carried out in the OH and GaH stretching regions using a Carl Zeiss Jena cryostat in the temperature range of 200−300 K with the accuracy of the temperature setting being ±0.5 K. Concentrations of $[Bu_4N][GaH_4]$ were varied from 10^{-1} to 10^{-2} M in the range of ν(XH) to 10^{-2} to 10^{-3} M in the range of ν(GaH). The concentrations of the XH acids in the first range were between 10^{-2} and 10^{-3} M or between 10^{-1} to 10^{-2} M in the range of ν(GaH).

The theoretical calculations of the model complexes $GaH_4^- \cdot H_2O$, $GaH_4^- \cdot CH_3OH$, $GaH_4^- \cdot CF_3OH$, $GaH_4^- \cdot CF_3NH_2$, and $GaH_4^- \cdot NO_2C_6H_4NH_2$ were performed by the hybrid density functional method[37] with the Gaussian 98 series of programs.[38] Firstly, several basis sets were used to perform the GaH_4^- calculations (Table 6).

Finally, the choice of the basis set was made based on good agreement between the calculated and experimental ν(GaH) frequencies. For the first two basis sets [6-31G(d,p) and 6-31++G(d,p)] $\Delta\nu(GaH) = \nu(GaH)_{exp} - \nu(GaH)_{calcd.}$ values were too large (101.7 and 87.2 cm^{-1}, respectively), while for the 6-311G(d,p) basis set they were equal to 6.4[39] or 2.6 cm^{-1} (this work). The basis set chosen [6-311G(d,p)] is also better for the electron-density description, giving the positive charge on Ga (as for B in the boron analogue)[15,16] though the Ga atom has either negative, or near to zero charge with the first two poorer basis sets. The higher computational levels increased the time of computations but practically did not improve the results. Therefore, the basis set 6-311G(d,p) was chosen for further calculations of the above-mentioned complexes **1**·HX.

Electron Transfer Behavior of Multi-Iron Sandwich-Type Polyoxometalates and Electrocatalytic Reduction Reactions

Bineta Keita,[a] Israel Martyr Mbomekalle,[a] Yu Wei Lu,[a] Louis Nadjo,*[a] Patrick Berthet,[b] Travis M. Anderson,[c] and Craig L. Hill*[c]

Keywords: Polyoxometalates / Sandwich complexes / Iron / Cyclic voltammetry

The physicochemical and electrocatalytic behaviors of eight multi-iron Wells–Dawson sandwich-type polyoxometalates were studied with specific emphasis on the Fe^{III} centers. Magnetization measurements were used to identify and quantify the antiferromagnetic interactions between the edge-sharing Fe^{III} units. Electrochemical studies show the stepwise reduction of the Fe^{III} centers, in complete agreement with magnetization conclusions. The location of the potential of each wave depends on the pH of the solution, as well as the concentration and composition of the electrolyte. In addition, ion-pairing studies show there is a positive shift of the Fe^{III} centers with an increase in ion pairing (i.e. $K^+ > Na^+ > Li^+$). The electrocatalytic reduction of dioxygen and hydrogen peroxide is efficient for all the complexes. However, there is a pronounced increase in efficiency as the number of Fe^{III} centers in the complex increases (i.e. 4 $Fe^{III} > 3$ $Fe^{III} > 2$ Fe^{III}). The mixed-metal complexes [αββα-Na_{14}-$(Mn^{II}OH_2)_2(Fe^{III})_2(As_2W_{15}O_{56})_2$ and αββα-$Na_{14}(Mn^{II}OH_2)_2$-$(Fe^{III})_2(P_2W_{15}O_{56})_2$] are also efficient catalysts for the reduction of NO and HNO_2.

Introduction

Fundamental and applied studies on polyoxometalates (POMs for convenience) continue to grow unabated.[1−6] This is due, in part, to their proven value in catalysis and other areas, as well as their highly modifiable nature. Redox potentials, acidity, size, shape, polarity, and other properties can all readily be altered synthetically. Symmetries in the structures of the POMs result in the equivalence of several metal centers that are detectable, for example, by NMR spectroscopy on fully oxidized species, and by EPR and/or NMR spectroscopy on their reduced analogues.[7−13] This equivalence of the metal centers raises the following question about the molecular electrochemistry of these compounds: in the absence of other possible mechanistic complications, related usually to pH or ion pairing of the countercations, can it be expected that symmetry-equivalent metal centers will be reduced simultaneously, or will the interactions between adjacent metal centers induce a stepwise reduction?[14]

Despite the structural equivalence of the twelve metal centers in the α-$PW_{12}O_{40}^{3-}$ Keggin anion (Figure 1A), a stepwise reduction of the tungsten centers is observed.[8] EPR experiments on this species show that the added electron is delocalized (type II in the scheme proposed by Robin

and Day)[1,15] over all twelve tungsten centers suggesting that there is communication between the metal centers. In general, complete delocalization of the added electrons over all twelve metal centers appears to be the rule for all unsubstituted, highly symmetrical α-Keggin anions. Introduction of lower symmetry results in a variation in the degree of valence trapping.[10,11,13] Unlike the spherical α-Keggin anion, the Wells−Dawson structure (Figure 1B) is shaped like a prolate ellipsoid,[16] consisting of six "cap" tungsten centers and twelve "belt" tungsten centers. The non-equivalence of the "cap" and "belt" tungsten sites raises the issue of the initial site of the electron transfer. All the evidence supports the fact that the added electrons are first introduced into the "belt" tungsten sites.[9−13,17−23] Extended Hückel calculations provide a qualitative understanding of the initial electron transfer site in these compounds. In complete analogy with the Keggin model, a stepwise reduction of the equivalent metal centers is also seen in the Wells−Dawson POMs, with various degrees of valence trapping observed upon the introduction of other substituents such as d-electron-containing metal species.

Recently we reported the synthesis and electrochemical properties of the sandwich-type POM, αββα-$Na_{12}(Fe^{III}OH_2)_2(Fe^{III})_2(As_2W_{15}O_{56})_2$ (**Fe4As4**).[24] The accumulation of adjacent edge-sharing Fe^{III} centers in **Fe4As4** gives more favorable electrocatalytic properties to the complex than those observed in the monosubstituted complex, α_2-$As_2(FeOH_2)W_{17}O_{61}^{7-}$. Analogous complexes containing phosphorus heteroatoms (instead of arsenic) are known,[25−30] but the presence of arsenic facilitates the reduction of both Fe^{III} and W^{VI} centers. Preliminary studies of **Fe4As4** and its phosphorus analogue, αββα-$Na_{12}(Fe^{III}OH_2)_2(Fe^{III})_2(P_2W_{15}O_{56})_2$ (**Fe4P4**), indicate that both complexes show the stepwise reduction of the four antiferromagnetically coupled Fe^{III} centers in the central unit.[25] However, a comprehensive investigation of the equivalence of the heterometallic centers in the sandwich-type derivatives, highlighting their eventual interactions and rationalizing their electrochemistry, is lacking. We now report such a study. In the present work, magnetic measurements on several recently reported multi-iron Wells−Dawson sandwich-type POMs [including **Fe4As4**, **Fe4P4**, αααα-$Na_{16}(NaOH_2)_2(Fe^{III})_2(X_2W_{15}O_{56})_2$ [X = As^V (**Fe2As4**) or P^V (**Fe2P4**)], ααβα-$Na_{14}(NaOH_2)$-$(Fe^{III}OH_2)(Fe^{III})_2(X_2W_{15}O_{56})_2$ [X = As^V (**Fe3As4**) or P^V (**Fe3P4**)] and the mixed-metal complexes, αββα-Na_{14}-$(Mn^{II}OH_2)_2(Fe^{III})_2(X_2W_{15}O_{56})_2$ [X = As^V (**Fe2Mn2As4**) or As^V (**Fe2Mn2P4**)], see Figure 2 for structures] are used to identify and quantify the interactions between adjacent Fe^{III} (or Mn^{II}) centers, and electrochemical measurements illustrate how ion pairing, pH, and electrolyte compositions influence the redox properties of the complexes. In addition, these results show how the redox properties of the sandwich-type POMs are affected by the metal population of the central unit.[31] Specifically, the tetraferric complexes **Fe4As4** and **Fe4P4** are better than the diferric complexes **Fe2As4** and **Fe2P4** for the electrocatalytic reduction of dioxygen and hydrogen peroxide.

Results and Discussion

Magnetic Studies

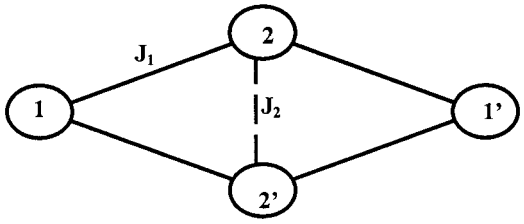
The crystallographic results of the present multi-iron sandwich-type complexes suggest that the arrangement of the Fe^{III} centers in edge-sharing octahedra will lead to electronic coupling between these metals.[24−27,29] Recently, we reported a detailed study of the magnetic properties of the arsenic complex, αββα-$Na_{12}(Fe^{III}OH_2)_2(Fe^{III})_2$-$(As_2W_{15}O_{56})_2$ (**Fe4As4**).[24] Here we report on the magnetic properties of the remaining complexes, which were all studied in a 0.1 T field. At 2 K, the magnetic moments per formula unit (for complexes **Fe4P4**, **Fe2As4**, **Fe2P4**, **Fe3As4**, **Fe3P4**, **Fe2Mn2As4**, and **Fe2Mn2P4**) are from three to seventy times lower than those expected for samples containing

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the same number of non-interacting Fe^{III} or Mn^{II} ions. This is the first indication that antiferromagnetic interactions are present between the magnetic ions that form the central cluster. The magnetic moments decrease regularly with temperature for the trinuclear clusters (**Fe3As4** and **Fe3P4**), while shoulders or bumps are observed for the dinuclear (**Fe2As4** and **Fe2P4**) and tetranuclear (**Fe4P4**, **Fe2Mn2As4**, and **Fe2Mn2P4**) clusters. Plots of χT versus T were calculated from the experimental data in order to carry out a quantitative analysis of the magnetic interactions (Figure 3). For that purpose, the experimental susceptibility was written as shown in Equation (1), where χ_0 represents the temperature independent contributions due mainly to the diamagnetism of the ligands, and $\chi_{cluster}$ represents the intrinsic susceptibility of the cluster. The latter is given by Equation (2), in which the mean value $<S_T(S_T + 1)>$ depends on the temperature, which in turn determines the population of the energy levels resulting from individual spin coupling. These energy levels are eigenvalues of the magnetic Hamiltonian of the cluster. For the POMs under study here, the more general Hamiltonian is that describing the tetranuclear clusters (**Fe4As4**, **Fe4P4**, **Fe2Mn2As4**, and **Fe2Mn2P4**), while the related trinuclear (**Fe3As4** and **Fe3P4**) and dinuclear (**Fe2As4** and **Fe2P4**) clusters may easily be deduced from the former by setting the spin value of one or two of the metal ions to zero. Since the magnetic ions of the central tetranuclear clusters are found at the corners of an almost regular rhomboid, the magnetic interactions may be represented by two exchange constants, J_1 and J_2, which describe the interactions along the sides of the rhomboid and along its shortest diagonal, respectively (Scheme 1).

$$\chi_{mol} = \chi_{cluster} + \chi_0 \quad (1)$$

$$\chi_{cluster} = g^2 N\beta^2 <S_T(S_T + 1)> /3k\ T \quad (2)$$



Scheme 1. Exchange pathways for the Fe_4 clusters

These interactions are of the superexchange type, and they are mediated by the two bridging oxygen atoms forming an edge shared by two neighboring FeO_6 or MnO_6 octahedra. Therefore, the magnetic energy of the cluster can be described by the following Heisenberg-type Hamiltonian [Equation (3)]. The eigenvalues of this Hamiltonian operator are obtained by the vector-coupling method of Kambe [Equation (4)],[32a] where S_{13}, S_{24}, and S_T are related with the spin operators $S_{13} = S_1 + S_3$, $S_{24} = S_2 + S_4$, and $S_T = S_{13} + S_{24}$. For a system of four ions with spin $S_i = 5/2$, there are 146 (S_T, S_{13}, S_{24}) combinations of energy E_i, whereas there are 27 and 6 combinations for systems with

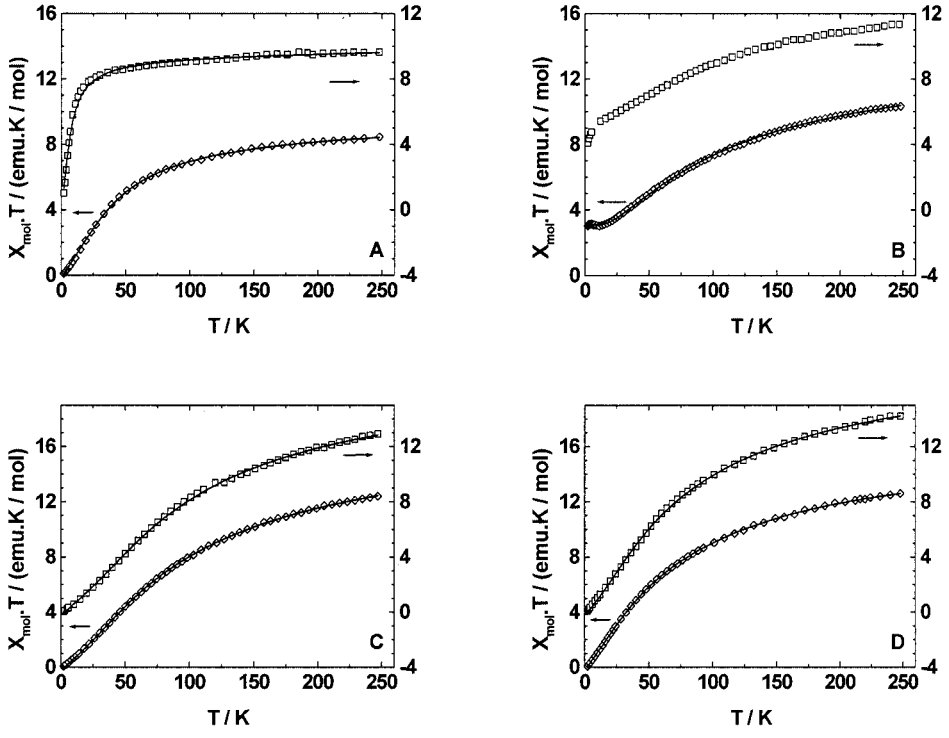


Figure 3. $\chi_{mol}T$ versus T plots for (A) **Fe2As4** and **Fe2P4**, (B) **Fe3As4** and **Fe3P4**, (C) **Fe4As4** and **Fe4P4**, and (D) **Fe2Mn2As4** and **Fe2Mn2P4**; the data corresponding to the phosphorus-based compounds are represented by squares, and the arsenic analogues are represented by diamonds; the continuous line represents the least-squares fit to the data using the parameters given in Table 1

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

three or two ions, respectively. After the calculation of these energies, the mean value of $<S_T(S_T + 1)>$ is obtained using Equation (5), with $b_i = 2S_T(E_i) + 1$ and $a_i = b_iS_T(Ei)$-$[S_T(E_i) + 1]$.

$$H = -2J_1(S_1S_2 + S_2S_3 + S_3S_4 + S_4S_1) - 2J_2S_1S_3 \quad (3)$$

$$E(S_T, S_{13}, S_{24}) = -J_1[S_T(S_T + 1) - S_{13}(S_{13} + 1) - S_{24}(S_{24} + 1)] - J_2[S_{13}(S_{13} + 1) - S_1(S_1 + 1) - S_3(S_3 + 1)] \quad (4)$$

$$<S_T(S_T + 1)> = \Sigma a_i \exp(-E_i/kT)/\Sigma b_i \exp(-E_i/kT) \quad (5)$$

The $\chi_M T$ versus T plots for all of the compounds are shown in Figure 3. It is possible to determine the magnetic parameters (g, J_1, J_2, $\chi_M T_{free}$, χ_0, E_0, and E_1) for each compound by fitting the calculated $\chi_{mol}T$ values to the experimental ones (Table 1). For **Fe4As4**, **Fe4P4**, **Fe2As4**, **Fe2P4**, **Fe2Mn2As4**, and **Fe2Mn2P4**, a small constant contribution $\chi_M T_{free}$ was subtracted from the experimental data before calculation. These contributions correspond to free Fe^{III} or Mn^{II} ions acting as countercations, or to fragments that occur as a result of some decomposition process taking place upon drying. Such a decomposition was reported by Coronado and co-workers for the closely related compound $\alpha\beta\beta\alpha$-$[(Mn^{II}OH_2)_2(Mn^{II})_2(P_2W_{15}O_{56})_2]^{16-}$.[32b] For most of the complexes under study here, the subtracted contributions represent less than 3% of the magnetic ions. However, for **Fe2P4**, this contribution represents nearly 17% of the magnetic ions, suggesting there is significantly more decomposition of this complex.

Examination of the values given in Table 1 confirms the antiferromagnetic nature of the interactions between the ions of spin $S_i = 5/2$. The ground states of complexes **Fe4As4**, **Fe4P4**, **Fe2As4**, **Fe2P4**, **Fe2Mn2As4**, and **Fe2Mn2P4** have a total spin of $S = 0$, whereas the ground state of **Fe3As4** is $S = 3/2$. For most complexes, the ground state is well separated (more than 5 cm^{-1}) from the first excited state. In complex **Fe3As4**, three antiferromagnetic interactions take place along the sides of a triangle; two of these interactions are described by J_1, and the third one by J_2. The orientations of the individual spins cannot simultaneously satisfy the constraints resulting from these interactions, and the system appears frustrated. Consequently, several configurations have close energies: the gap between $E_0(S_T = 3/2)$ and $E_1(S_T = 5/2)$ is 0.9 cm^{-1}, and that between E_0 and $E_2(S_T = 1/2)$ is 4.0 cm^{-1}. The values of the temperature-independent susceptibilities χ_0 are quite different from one complex to another and are sometimes positive. In addition, the Landé g-factors are close to 2 for all of the samples. A comparison of the interaction constants J_1 and J_2 shows that the interactions along an edge of the rhomboids are stronger than those interactions along the short diagonal. The structural data indicates first that the longest Fe−O distances are found along the diagonal bridges corresponding to J_2, and second, the lateral bridges corresponding to J_1 have longer Mn−O distances than Fe−O distances. Therefore, the differences between J_1(Mn−Fe), J_1(Fe−Fe), and J_2(Fe−Fe) may partially be explained by the M−O distances. However, the strength of these interactions also depends on the M−O−M bridging angles as well. The absolute value of J_2 determined for **Fe2P4** is lower than those obtained for the other complexes.[33] This low value accounts for the fast increase in $\chi_{mol}T$ at low temperature. This particular behavior was confirmed on a second sample from another batch, but it cannot be explained from the structural characteristics of the dinuclear unit, which are very close to those of **Fe2As4**. This suggests that some prominent modifications may have taken place when the product was dried, which is also consistent with the high value of χT_{free}. Attempts to fit the magnetic parameters of **Fe3P4** were unsuccessful. This is most likely due to the presence of a small amount of **Fe2P4** in the measured sample, which could explain the difference observed at low temperature between the $\chi_{mol}T$ product of **Fe3P4** and that of **Fe3As4**. However, this difference disap-

pears at higher temperature, suggesting that the magnetic interactions in both complexes are rather similar.

The susceptibilities of the tetranuclear clusters (**Fe4As4**, **Fe4P4**, **Fe2Mn2As4**, and **Fe2Mn2P4**) are very close to one another. With the use of the fitted parameters, the susceptibilities of **Fe4As4** and **Fe4P4** were extrapolated to 300 K, which gives 13.6 and 13.1 emu K mol^{-1}, respectively, for the $\chi_{mol}T$ products. These values are close to the calculated value of 13.3 emu K mol^{-1}, determined from the effective moment of **Fe4P4**, 10.3 μ_B, measured at 300 K by Zhang et al.[25]

pK_a Studies

To assess the stability of each of these complexes over a relatively large pH domain, we first determined their apparent pK_a values. In addition to the potential proton mobility of the water molecules fixed on the external $Fe^{III}-OH_2$ sites, protonatable sites might exist on the α-$X_2W_{15}O_{56}^{12-}$ (where X = As^V or P^V) unit itself. Measurements were performed with a 0.025 M solution of LiOH. The presence of Li^+ also helps to ensure the complete solubility of the samples. Experimental curves for all of the complexes are provided in the Supporting Information.[34]

Table 2 summarizes the results for complexes **Fe4As4**, **Fe4P4**, **Fe2As4**, **Fe2P4**, **Fe3As4**, and **Fe3P4**. The pK_a values are consistent with values reported for other similar sandwich-type complexes. Titration of the POMs without previous addition of acid gives similar results, and the results suggest that the number of mobile protons corresponds to the number of water molecules on the external Fe^{III} centers. Specifically, there are two, one, and zero mobile protons for complexes **Fe4As4** (and **Fe4P4**), **Fe3As4** (and **Fe3P4**), and **Fe2As4** (and **Fe2P4**), respectively. The pK_a values for the ionizable protons are comparable for similar complexes.[35−37] The number of protonatable sites on the POM framework itself seems to depend critically on the structure and, presumably, on the electronic interactions within the sandwich-type complexes. However, this behavior was not examined in more acidic solutions (less than pH = 2.5). It is also worth noting that the pK_a values do not smoothly increase as the pH of the solution is increased (and the POM deprotonated); in addition, the increase in the negative charge on the POM as a result of deprotonation causes an inversion in the observed pK_a values between the multi-iron sandwich complexes. This behavior has previously been observed in other POMs.[38−40] Finally, we note that the same acid−base properties are observed for both P and As heteroatoms.[41]

Electrochemical Studies

All of the compounds studied here are stable, at least in the timescale of the voltammetric studies, in the pH = 5 buffer medium (1 M CH_3COOLi and CH_3COOH) selected for these studies. The electrochemistry of the lacunary species (α-$P_2W_{15}O_{56}^{12-}$ and α-$As_2W_{15}O_{56}^{12-}$) were previously described.[24,42−44] There are positive potential shifts of the waves of α-$As_2W_{15}O_{56}^{12-}$ relative to those of α-$P_2W_{15}O_{56}^{12-}$ (20 mV and 54 mV for the first and second waves, respectively).[45] In contrast with the voltammograms of α-$As_2W_{15}O_{56}^{12-}$ and α-$P_2W_{15}O_{56}^{12-}$, those of **Fe4As4** and **Fe4P4** show four new waves in the potential domain +0.2 to −0.5 V. Figure 4A shows the CVs of α-$P_2W_{15}O_{56}^{12-}$ and **Fe4P4**. The four new waves are attributed to the reduction of the four Fe^{III} centers within the sandwich complex. At pH 3 (2 M NaCl + HCl), the formal potentials for the Fe^{III}/Fe^{II} redox couples are: 0.227, 0.124, −0.016 and − 0.093 V (vs. SCE), respectively. These potentials are distinctly more positive than the first W wave of α-$P_2W_{15}O_{56}^{12-}$ and **Fe4P4** (Figure 4A). This is consistent with the fact that Fe^{III} is known to reduce more easily than W^{VI} centers within substituted heteropolytungstates.[46] Corresponding data for the other complexes are included in the Supporting Information. The reduction of the W^{VI} centers is also influenced by the presence of the Fe^{III} centers in the sandwich molecule. The first wave of α-$P_2W_{15}O_{56}^{12-}$, which is slightly composite, splits into two waves in **Fe4P4**. This behavior is related to differences in the acid−base properties of the two POMs. Analogous to the CVs of α-$As_2W_{15}O_{56}^{12-}$ and α-$P_2W_{15}O_{56}^{12-}$, those of **Fe4As4** and **Fe4P4** are also very similar to each other. The presence of the arsenic heteroatom facilitates the reduction of both the Fe^{III} and W^{VI} centers (Figure 4B). The number of W^{VI} waves observed for **Fe4As4** or **Fe4P4**, and hence, the electron number for each wave, depends on the pH of the electrolyte. Rather classical electrochemical behaviors were observed for the W^{VI} centers in these complexes. Therefore, the focus of these studies will remain exclusively on the Fe^{III} centers. Figure 4C shows the stepwise reduction of the Fe^{III} centers in **Fe4P4**, with the potential domain restricted to that of the Fe^{III} redox processes. The X-ray crystal structures of **Fe4As4** and **Fe4P4** suggest that there are two types of symmetry-equivalent Fe^{III} centers.[24,25] There are two "external" Fe^{III} sites, which share two oxygen atoms with one α-$X_2W_{15}O_{56}^{12-}$ unit and three oxygen atoms with the other α-$X_2W_{15}O_{56}^{12-}$ unit. The sixth vertex of the octahedra is occupied by a water molecule. The sixth vertex of the two "internal" Fe^{III} sites is occupied by an additional

Table 2. Apparent pK_a values in 1 M LiCl at 25 °C for the multi-iron sandwich-type complexes

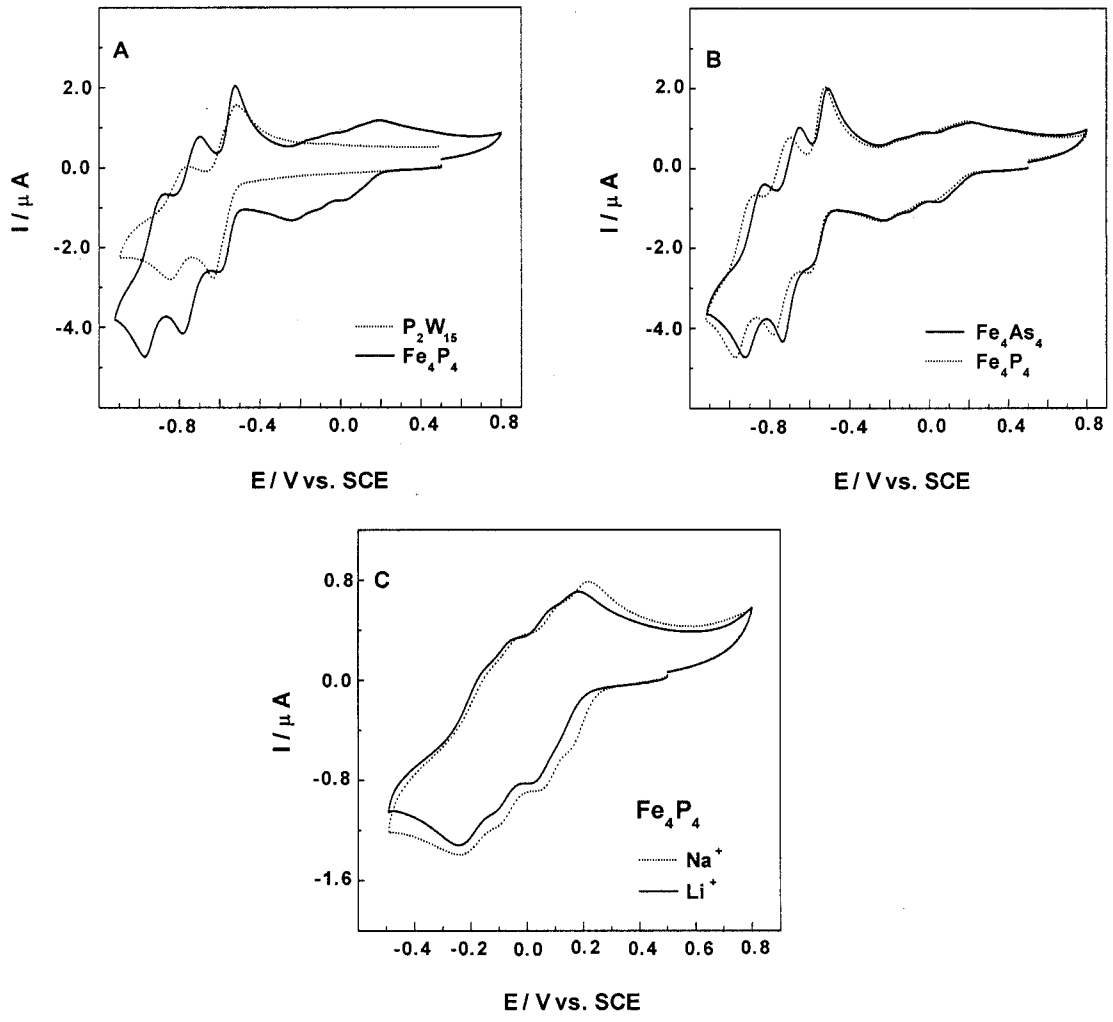

Figure 4. Cyclic voltammograms of **Fe4As4** and **Fe4P4** (2×10^{-4} M); the scan rate was 10 mV s^{-1}, the working electrode was glassy carbon, and the reference electrode was SCE; all measurements were performed in a 1 M CH_3COOLi + 1 M CH_3COOH (pH = 5) buffer solution except in (C), where the dotted line represents a measurement taken in a 0.5 M Na_2SO_4 + NaOH (pH = 5) buffer solution

oxygen atom from one of the two α-$X_2W_{15}O_{56}^{12-}$ units (rather than a water ligand). The structural data alone would suggest that there would be two groups of redox processes rather than four. The complete splitting into four distinct one-electron reduction processes suggests that there is some type of electronic communication involving the Fe^{III} centers.[47] This interaction must generate and/or reinforce inequivalence among the sites, especially in the reduced state; this is also consistent with the magnetic measurements. Finally, it is worth noting that all of the voltammetric patterns of **Fe4As4** and **Fe4P4** are perfectly well-defined and well-behaved at pH = 5. This observation is in contrast with the report that **Fe4P4** shows ill-defined waves with very small current intensities in media of pH > 4.[35] These differences may be due to differences in the media used to collect these measurements: this point was examined by running the CV in the same electrolyte (0.5 M Na_2SO_4 and NaOH, pH = 5) as that used in reference 35. The results in Figure 4C show that the waves remain perfectly well-defined (dotted line curve), and no decreased current is observed relative to the voltammogram recorded in acetate medium (solid line curve).

Ion Pairing

Although ion-pairing, pH, and ionic strength effects all exist simultaneously and act in competition, the data presented in Figure 4C allows the opportunity to discuss the first of these phenomena. In this system, an overall positive shift is observed for the Fe^{III} centers when a Na_2SO_4-based medium is used instead of CH_3COOLi. Since the two systems have the same ionic strength and pH (even though the buffer capacity is greater for CH_3COOLi), this positive shift must be due, in part, to the nature of the cation. It was previously shown that Na^+ engages in more intimate ion pairing with POMs than Li^+ since the hydrodynamic radius of Li^+ is greater than that of Na^+.[48,49] The positive shift of the potential for the Fe^{III} centers increases with increased ion pairing (i.e. $K^+ > Na^+ > Li^+$). For example, with both the pH and ionic strength kept constant, the formal potential measured for the Fe^{III}/Fe^{II} couple in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$Ge(FeOH_2)W_{11}O_{39}^{5-}$ is more positive with a Na^+ countercation than with Li^+. Complexes **Fe4As4** and **Fe4P4**, however, contain four Fe^{III} centers and could display more complex ion-pairing behavior. In addition, the two Fe^{III} sites with ionizable terminal water ligands further complicate the matter since ion-pairing and protonation can compete.[37] Figure 4C illustrates this complexity by showing that effects of the cation differ from one wave to the next. For example, the second and fourth redox couples (which are better behaved) experience a 35 mV shift and a negligibly small shift, respectively, with a change in medium from Na^+ to Li^+. The shift due to cation effects is larger for the first two redox couples. To further illustrate the competition between ion-pairing and protonation of the terminal water ligands, the pH of the system was lowered from five to three (prepared with 0.5 M Li_2SO_4 and H_2SO_4 or 0.5 M Na_2SO_4 and H_2SO_4). The results suggest that protonation supersedes ion-pairing with decreasing pH. These general trends are in good agreement with the apparent pK_a values measured previously. Complex **Fe4As4** gave results similar to **Fe4P4** under the same experimental conditions. The nature of the cation of the supporting electrolyte has a similar effect on the W^{VI} waves as described previously for monosubstituted Keggin derivatives.[37] For the remaining electrochemical studies, Na^+ is the countercation used since most of the POMs studied here were originally synthesized as the Na^+ salts.

pH Effects

The behavior of the W^{VI} waves of the POMs as a function of pH was the subject of several previous investigations.[1,4,37,43,46,50–52] Similar variations were observed within the present multi-iron sandwich-type derivatives, but they were not the focus of this particular study. We wished to determine how changes in pH affect the formal potentials of the Fe^{III} waves. Provisionally, it is worth noting that changes in pH might cause two or more of these waves to merge, although that phenomenon was not observed in these studies. For the present purpose, pH effects (from pH = 2 to pH = 7) were studied by adding an appropriate amount of concentrated mineral acid or base to a 2 M solution of NaCl. The high concentration of NaCl was used to minimize any effect induced by small ionic strength variations.

Figure 5 represents the variation in the formal potential between pH 2 and pH 7 for each of the Fe^{III} centers in **Fe4As4** and **Fe4P4**. The four Fe^{III} centers are numbered according to their formal potentials from the least negative (Fe1) to the most negative (Fe4). The formal potentials of the Fe^{III}/Fe^{II} redox couples do not vary smoothly with pH. Such an intricate pH dependence was described previously in the case of a single Fe^{III} center within monosubstituted Keggin derivatives.[37] Electronic communication between Fe^{III} centers in the sandwich-type derivatives might render the changes in their formal potentials pH interdependent, and possibly, might also render them more complex. Nevertheless, some new trends do appear in Figure 5. Focusing first on **Fe4As4**, the Fe1 and Fe2 centers show almost parallel formal potential changes; however, between pH 2–3 and pH 4–5 quasi-independent behavior is seen. The variation is almost linear above pH 5, with a slope of 55 mV/pH. In contrast, the formal potential for Fe3 is nearly independent for pH values up to 6, after which the potential begins to vary slightly. For Fe4, a linear dependence is observed from pH 3 to 5, with a slope of 26 mV/pH. At higher pH values, the potential is almost independent of pH. Although the present observations specifically concern the Fe^{III}/Fe^{II} redox couples and not only the Fe^{III} redox states, the variation in the formal potentials follow the trends expected based on the apparent pK_a values. In particular, the regions in which the formal potential is independent of pH are consistent with the possibility that ion pairing supersedes protonation. Furthermore, the formal potentials of the two internal Fe^{III} centers are not expected to depend directly on pH. The observed dependence must therefore be because of

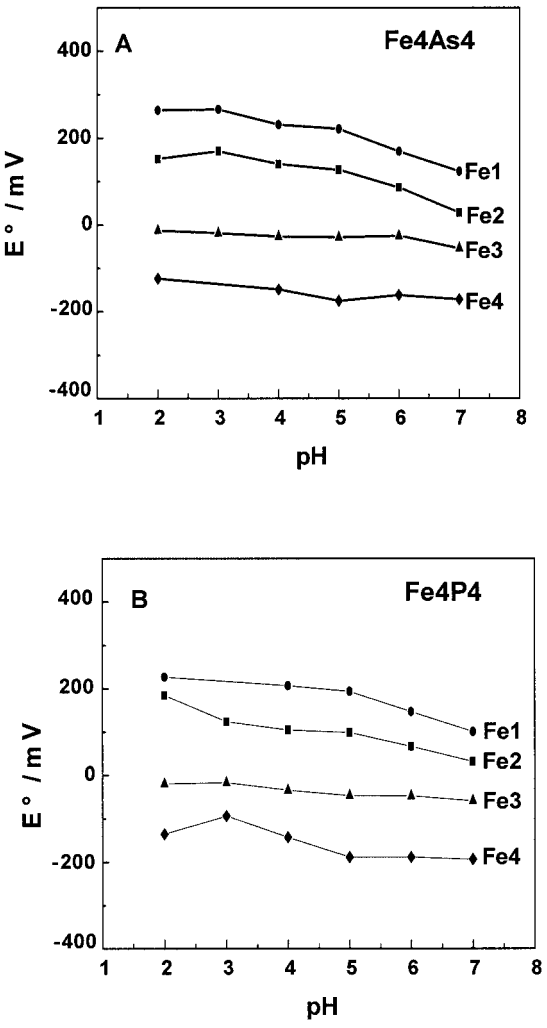

Figure 5. Plot of the formal potentials of **Fe4As4** (A) and **Fe4P4** (B) as function of pH for the four one-electron Fe^{III}-centered redox processes; the Fe^{III} centers are labeled FeX (with X = 1, 2, 3, or 4) from the most positive to the least positive reduction potential; the pH 2–3 solutions are comprised of 2 M NaCl + HCl, the pH 4–5 solutions are comprised of 2 M NaCl + 0.1 M CH_3COONa + 0.1 M CH_3COOH, and the pH 6–7 solutions are comprised of 2 M NaCl + 0.05 M NaH_2PO_4 + 0.05 M NaOH

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the electronic communication between all of the Fe^{III} centers. The same trends were observed for **Fe4P4** as well, albeit small differences, which are presumably linked to differences induced by the different heteroatoms (As versus P) within these complexes. Finally, ion-pairing and pH effects converge during the reduction processes to suggest that the external Fe^{III} centers are reduced first. This is consistent with Pope's report on $(MnOH_2)_2(Mn)_2(PW_9O_{34})_2^{10-}$, in which it was discovered that oxidation first occurs at the Mn centers with water ligands.[53] However, due to the low intensity of the observed effects and to the fact that oxidation and reduction might involve different molecular orbitals, support (or invalidation) for the present hypothesis will be sought from complementary theoretical calculations.

Diferric and Triferric Sandwich-Type Complexes

Figure 6 shows the voltammograms of **Fe4As4**, **Fe3As4**, and **Fe2As4**, restricted to the waves attributed to the reduction of the Fe^{III} centers only. Several conclusions emerge from these patterns. For each CV, the number of waves corresponds to the number of Fe^{III} atoms in each complex. These observations suggest there are sufficiently strong interactions between the Fe^{III} centers in each of the complexes to induce complete splitting of their redox processes into separate steps. Qualitatively, the overall current intensities are also consistent with the number of Fe^{III} atoms in each complex. The number of Fe^{III} centers was also investigated by controlled potential coulometry measurements, which give three electrons per molecule for **Fe3As4** and **Fe3P4** and two electrons per molecule for **Fe2As4** and **Fe2P4** for the exhaustive reduction of these centers. At pH 3, the following values were determined: 3.95 ± 0.05 electrons per molecule for **Fe4As4** and **Fe4P4** at − 0.250 V (vs. SCE); 2.95 ± 0.06 electrons per molecule for **Fe3As4** and **Fe3P4** with the potential set at − 0.300 V (vs. SCE); 1.95 ± 0.07 electrons per molecule for **Fe2As4** and **Fe2P4** at − 0.360 V (vs. SCE). The CV patterns shift in the negative potential direction with a decrease in the number of Fe^{III} atoms. This is most likely related to the overall increase in the negative charge of the POM due to the decrease in the number of Fe^{III} atoms, and it is probably also related to the differences in pK_a in the reduced forms. The formal potentials measured from the CVs of the Fe^{III}/Fe^{II} centers within the complexes are included in the Supporting Information.

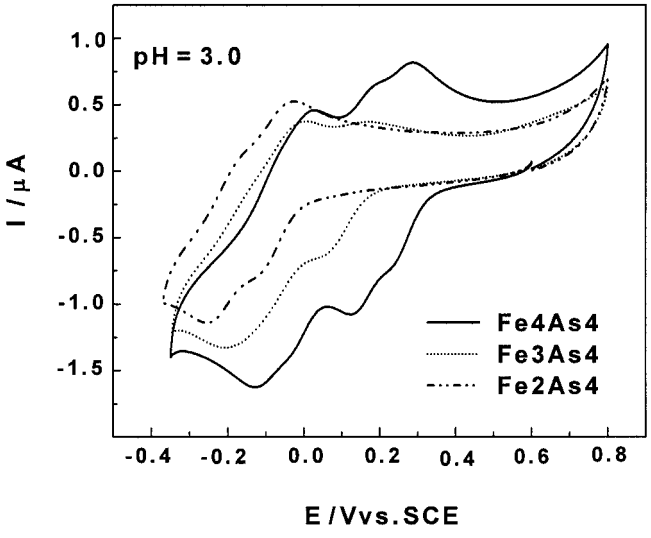

Figure 6. Cyclic voltammograms of **Fe4As4**, **Fe3As4**, and **Fe2As4** in 2×10^{-4} M, pH = 3 (2 M NaCl + HCl) buffer solution; the scan rate was 10 mV s^{-1}, the working electrode was glassy carbon, and the reference electrode was SCE

The relative potential shifts of the waves also seem to support the distinction between the external $Fe^{III}O_5(OH_2)$ centers and the internal $Fe^{III}O_6$ centers within the present complexes. Previously, we concluded that the external $Fe^{III}O_5(OH_2)$ centers are likely to be reduced before the internal $Fe^{III}O_6$ centers. Indeed, the CVs of **Fe3As4** and **Fe3P4** show the disappearance of a wave that can be attributed to an external $Fe^{III}O_5(OH_2)$ center in **Fe4As4** and **Fe4P4**. The CVs of **Fe2As4** and **Fe2P4**, which have no external $Fe^{III}O_5(OH_2)$ centers, also agree with this hypothesis since only two waves assigned to internal $Fe^{III}O_6$ centers are observed. These conclusions are also supported by the apparent pK_a values.

Mixed-Metal Sandwich-Type Complexes

Preliminary characterization of the mixed-metal multi-iron sandwich complexes indicated that they are stable from pH 0 to 7. In **Fe2Mn2P4**, the presence of Mn^{II} modifies the characteristics of the Fe^{III} and W^{VI} waves, which are observed at slightly more positive potentials than in **Fe2P4**. Figure 7 compares the Fe^{III}-based redox processes of complexes **Fe2P4** and **Fe2Mn2P4**. Controlled potential coulometry confirms that exhaustive reduction of these centers consumes 2.00 ± 0.05 electrons per molecule. Examination of Figure 7A shows that the first wave of **Fe2P4** is larger than that of **Fe2Mn2P4**, and that the first wave tends to merge with the second wave. Thus an ECE- or EEC-type process seems to be favored in the former complex. This observation leads to the conclusion that the reduced form of **Fe2Mn2P4** is less basic than the corresponding form of **Fe2P4**. The important influence of basicity is illustrated in Figure 7B. At pH 5, the two Fe^{III}-based waves merge in both complexes with coalescence being somewhat incomplete for **Fe2Mn2P4**, which shows a slightly composite wave.[54] The differences in the behavior of the arsenic analogues (complexes **Fe2As4** and **Fe2Mn2As4**) are less clear than those of the corresponding phosphorus analogues. The results indicate a clear influence of the central heteroatom, P or As, that consists (at pH 3) of an overall positive shift of the Fe^{III} waves without a current increase when P is replaced by As (see Supporting Information). A tentative explanation for this lack of change in the current is that the relevant pK_a values in the reduced forms of the As derivatives are very close from one complex to another.

A detailed study of the Mn^{II} wave in complex **Fe2Mn2P4** reveals, as expected, that the oxidation process becomes more difficult (i.e. moves towards more positive potentials) when the pH of the supporting electrolyte decreases. This point is illustrated for pH = 1 in Figure 7C where this process is kinetically sluggish. However, pre-treatment of the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

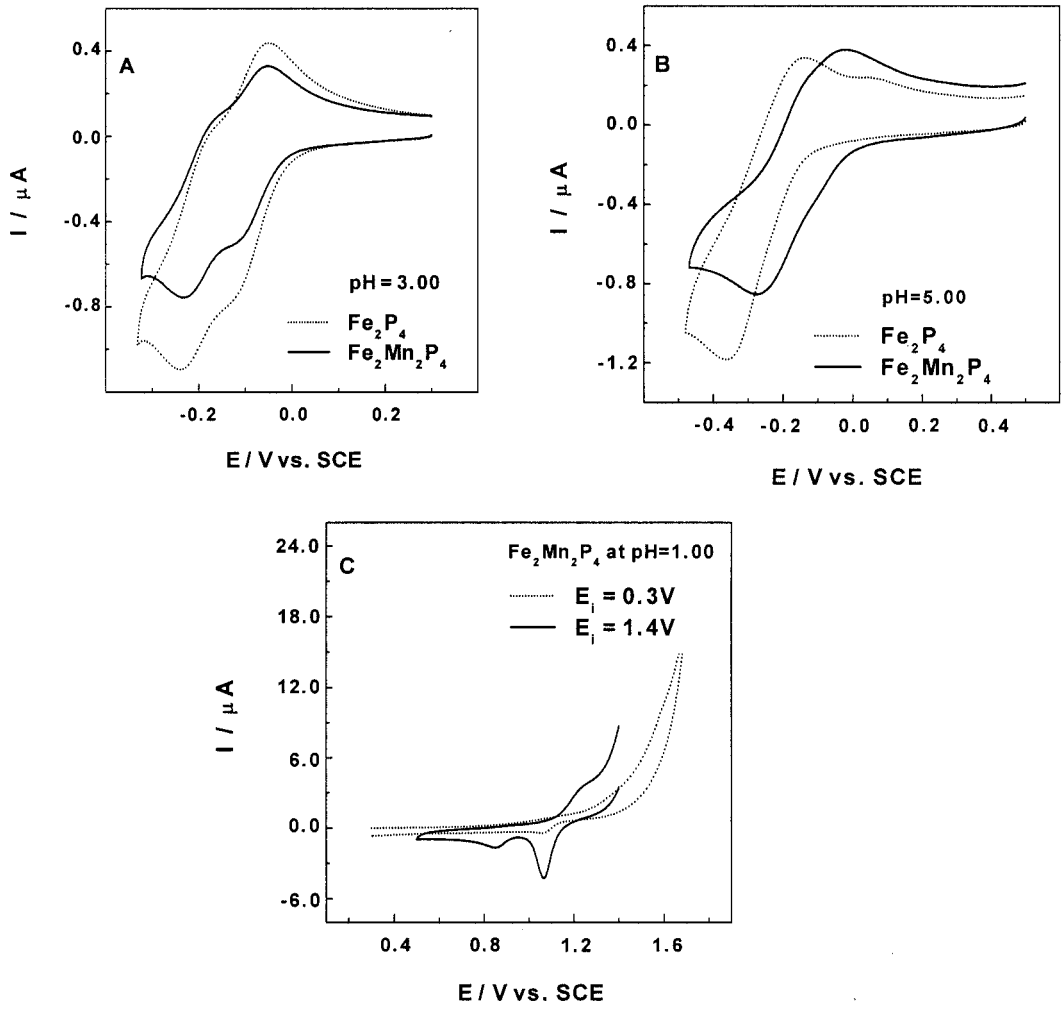

Figure 7. Cyclic voltammograms of **Fe2P4** and **Fe2Mn2P4** in different buffer solutions; the concentration of the POM was 2×10^{-4} M in all the solutions; the scan rate was 10 mV s^{-1}, the working electrode was glassy carbon, and the reference electrode was SCE; (A) comparison of **Fe2P4** and **Fe2Mn2P4** in a pH = 3 buffer (0.5 M Na_2SO_4 + H_2SO_4); (B) comparison of **Fe2P4** and **Fe2Mn2P4** in a pH = 5 medium (1 M CH_3COOLi +1 M CH_3COOH); (C) study of the Mn^{II} centers in **Fe2Mn2P4** in a pH = 1 medium (0.5 M Na_2SO_4 + H_2SO_4); E_i = initial potential; see the text for more details

electrode surface by pausing its potential at +1.4 V for a short time (120 s) prior to scanning the potential in the negative direction clearly reveals the presence of Mn^{II}. Under these conditions two reduction waves are observed, which are accompanied by a fairly well-behaved oxidation wave for the Mn^{II} centers on reversing the potential. This result is also shown in Figure 7C. Separation of the reduction into two steps is less pronounced in a pH 3 medium, where only a shoulder is observed. Examination of all these results together suggests that, for the two pH values we have explored (pH 3 and 5), the oxidation of Mn^{II} to Mn^{IV} is followed by the stepwise reduction of Mn^{IV} on reversing the potential. In addition, holding the potential at a selected positive value activates the electrode surface faster than continuous potential cycling. Continuous potential cycling of the electrode through the region in which the oxidation of interest is expected constitutes another technique in the activation of the glassy carbon surface electrode in the study of POM-based Mn^{II} centers. Steckhan and Sadakane found that this procedure gradually revealed the presence of the two waves of α-$Si(MnOH_2)W_{11}O_{39}^{6-}$ in a pH 6 phosphate buffer.[55] In contrast, we have previously shown that the merging of the two redox systems of Mn^{II} in α_2-$P_2(MnOH_2)Mo_2W_{15}O_{61}^{8-}$ results in a composite broad wave while cycling in a pH 6 phosphate medium (with concomitant deposition of an electroactive film on the electrode surface).[56]

Electrocatalysis

A pH 3 medium was selected for the studies on the electrocatalytic reductions of O_2 and H_2O_2. The efficiency of the catalytic process is evaluated by an excess parameter γ, which is defined as C° (O_2)/C° (POM) for dioxygen and C° (H_2O_2)/C° (POM) for hydrogen peroxide (C° = concen-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tration of the relevant species indicated in parentheses).[57] The catalytic efficiency (CAT) is defined as follows: CAT = [I (POM + O_2 or H_2O_2) − I^d (POM)]/I^d (POM), where I (POM + O_2 or H_2O_2) is the current for the reduction of the POM in the presence of O_2 or H_2O_2 and I^d is the corresponding diffusion current for the POM alone.

Figure 8A shows the CVs for **Fe4As4** in the absence and presence of dioxygen. The electrocatalytic reduction of O_2 starts after the second Fe^{III} reduction wave and precludes the possibility of observing other Fe^{III} reduction waves. This is consistent with the formation of an iron-dioxygen adduct upon reduction of the first two Fe^{III} centers. This adduct is subsequently reduced to give water with regeneration of the catalyst; an inner-sphere mechanism is likely to be operating. Water was confirmed to be the final product in the reduction of hydrogen peroxide by the same catalytic system. It is interesting that the final reduction process starts after the second Fe^{III} wave. Since the naked electrode does not reduce dioxygen in the potential region explored here, the reduced forms of the POM must drive the electrocatalytic process.[58] At the potential location of the second Fe^{III} wave, the number of electrons accumulated in the POM framework is not sufficient to carry out the overall process. Figure 8B compares the CVs of **Fe4As4**, **Fe3As4**, and **Fe2As4** in the presence of the same excess of dioxygen. The onset of the electrocatalytic process shifts in the negative potential direction when the number of Fe^{III} atoms decreases. Qualitatively, the catalytic efficiency follows the same trend. The reasons given before, which postulate an overall inner-sphere process remains valid here, even though an obvious binding site for dioxygen on **Fe2As4** is difficult to assign.

The electrocatalytic reduction of hydrogen peroxide by **Fe4As4** is shown in Figure 8C and compared with the reduction of dioxygen by the same system. The catalytic reduction of H_2O_2 is facile and occurs on the first Fe^{III} wave

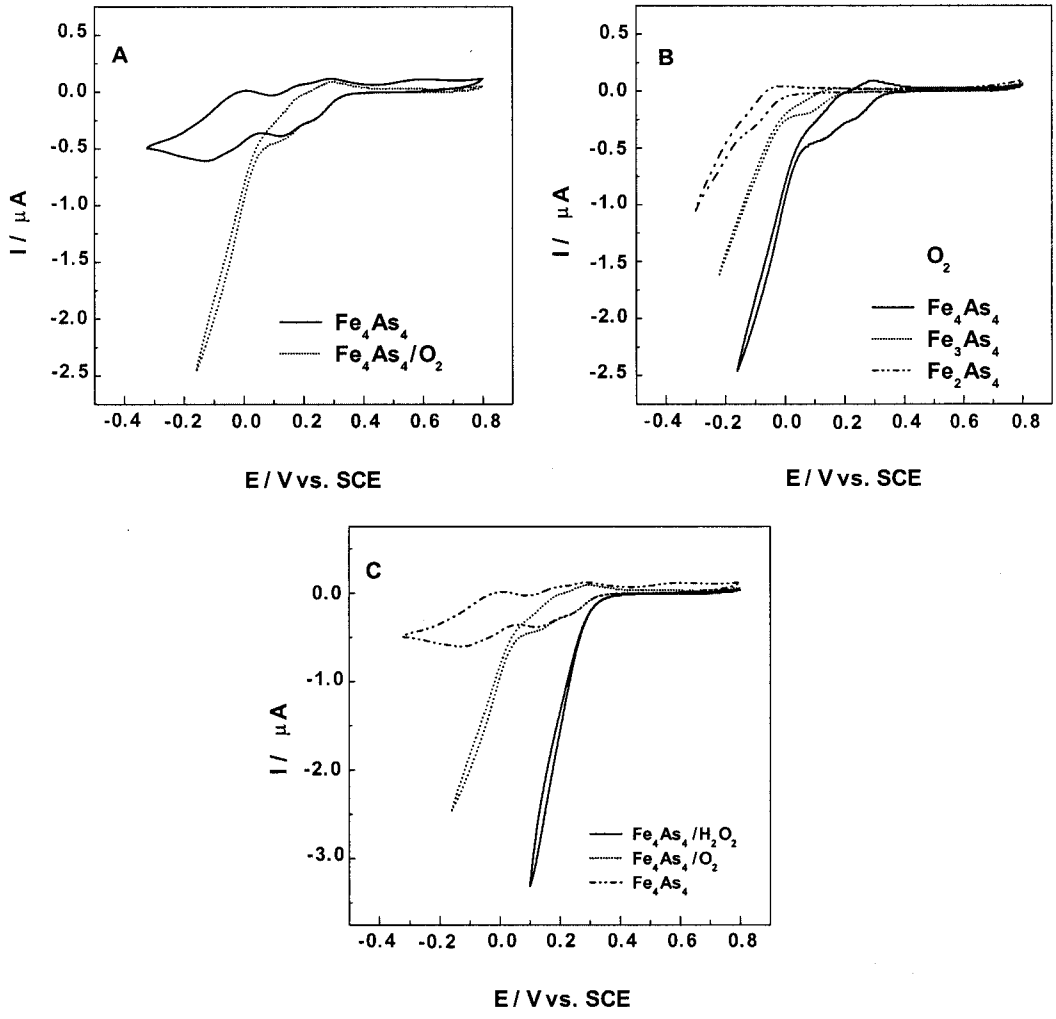

Figure 8. Cyclic voltammograms for the electrocatalytic reduction of dioxygen and hydrogen peroxide; the excess parameter for dioxygen or hydrogen peroxide was $\gamma = 5$, the scan rate was 2 mV s^{-1}, the working electrode was glassy carbon, the reference electrode was SCE, the concentration of the POM was 2×10^{-4} M, and the buffer had a pH of 3 (2 M NaCl + HCl); (A) electrocatalytic reduction with **Fe4As4**; (B) comparison of **Fe4As4**, **Fe3As4**, and **Fe2As4**; (C) comparison of the catalytic activity of **Fe4As4** towards dioxygen and hydrogen peroxide reduction

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of **Fe4As4** at a potential much more positive than that observed for the electrocatalytic reduction of O_2. This observation indicates that the final reduction product of dioxygen is water. Complexes **Fe2As4** and **Fe3As4** give similar results, and the onset of the electrocatalytic process is seen to strictly follow the order of reduction of the three complexes.

Selected values of catalytic efficiencies (CAT) for the reduction of dioxygen and hydrogen peroxide are included in the Supporting Information. The general trends from Figure 8 are confirmed and quantified. Focusing specifically on complexes **Fe4As4** and **Fe4P4**, it appears that under the same experimental conditions, the phosphorus-containing complex **Fe4P4** is slightly more efficient than the arsenic analogue **Fe4As4** for the reduction of dioxygen, while the opposite is true for the reduction of hydrogen peroxide. This observation underscores the impossibility of anticipating which electrocatalyst would be more efficient when an inner-sphere pathway is operative. Three points deserve special emphasis. First, the electrocatalytic processes observed here remain efficient in other media. For example, at pH = 5, a CAT value of 523% was measured for the electrocatalytic reduction of O_2 by **Fe4P4** at a potential of −240 mV. This observation, and others not specifically described here, are important in that they establish the utility of the Fe^{III} centers within these multi-iron sandwich complexes in media of low proton availability. Second, we found that there is still ample room for optimization of the selected media for efficient electrocatalytic processes within these compounds. Third, despite the apparent superiority of **Fe4As4** and **Fe4P4** in the present voltammetric study, **Fe3As4** and **Fe3P4** might ultimately be the most useful long term catalysts, in part, due to their better stability under a wide range of conditions.[27,29]

Examination of these two electrocatalytic processes sheds some light on the reaction pathways. Dioxygen does not coordinate to Fe^{III} but it does coordinate to Fe^{II}. In the presence of only one Fe center [as in α_2-$As_2(FeOH_2)W_{17}O_{61}^{7-}$], no electron source is available immediately after the reduction potential of Fe^{III} to drive the catalytic process to completion. This observation underscores the importance of the accumulation of Fe^{III} centers, which carry out immediate further reduction of the adduct. It is also important to note that the accumulation of these catalytic centers decreases the overall negative charge of the POM, rendering its reduction more facile, and ultimately, saving energy during the electrocatalytic process. If H_2O_2 complexes with the Fe^{III} centers, then this might result in a favorable process for the electrocatalytic reaction. In support of this, complexes **Fe3As4** and **Fe3P4**, which have only one such exchangeable center, have approximately the same efficiency as α_2-$As_2(FeOH_2)W_{17}O_{61}^{7-}$ for the electrocatalytic reduction of H_2O_2.

Cooperativity Effects In Electrocatalytic NO_x Reduction

It is well established that Fe^{III}-substituted POMs catalyze the reduction of NO and/or NO_2^-.[58−60] The first step in this process is the formation of a complex with the Fe^{II} form of the POM and nitrogen oxide.[31,58] The actual catalytic reduction of this complex takes place with remarkable enhancement of the current intensity at more negative potentials where a large number of supplementary electrons accumulate in the W framework. With the goal of saving energy by moving the electron reservoir closer to the Fe^{III}-reduction potential, we have previously synthesized several Wells−Dawson-type monosubstituted derivatives, including α_1-$P_2(FeOH_2)W_{17}O_{61}^{7-}$ and α_2-$P_2(FeOH_2)Mo_2W_{15}O_{61}^{7-}$ in which the Fe- and W-waves or Fe- and Mo-waves merge in an appropriate pH media.[31,56] This strategy is favorable, and the entire catalytic process occurs at the reduction potential of the Fe^{III} center, which is now observed concomitantly with the Mo^{VI} or W^{VI} reduction waves. The same phenomenon is observed here. These results are illustrated briefly with **Fe2Mn2P4** in Figure 9, with $NaNO_2$ as the starting substrate. An important current intensity increase is observed with increasing γ values [γ is the excess parameter defined as γ = C° (NO_x)/C° (POM)] at the reduction potential of the Fe^{III} centers in a pH 1 solution.[61] In this potential region, no reduction is observed for NO or HNO_2 present in the solution.[62][63] Figure 9 shows unambiguously that the catalytic process begins simultaneously with the reduction of the Fe^{III} centers. Furthermore, it is worth noting the high efficiency of the electrocatalytic process, even though modest γ values were used. Finally, in the timescale of cyclic voltammetry, **Fe2P4** shows the same phenomenon as **Fe2Mn2P4** with regard to the electrocatalytic reduction of NO and NO_2^-. However, the latter complex might be a better choice for this catalytic process due to the greater stability of its Fe^{II} forms.[29] Under the same experimental conditions, **Fe2Mn2As4** also shows good catalytic efficiency for the reduction of nitrite. In addition, its activity at 0 V is 25% higher than that of **Fe2Mn2P4** as seen by the positive potential shift of the Fe^{III} waves in the former complex relative to the latter due to the different heteroatoms (i.e. As vs. P).

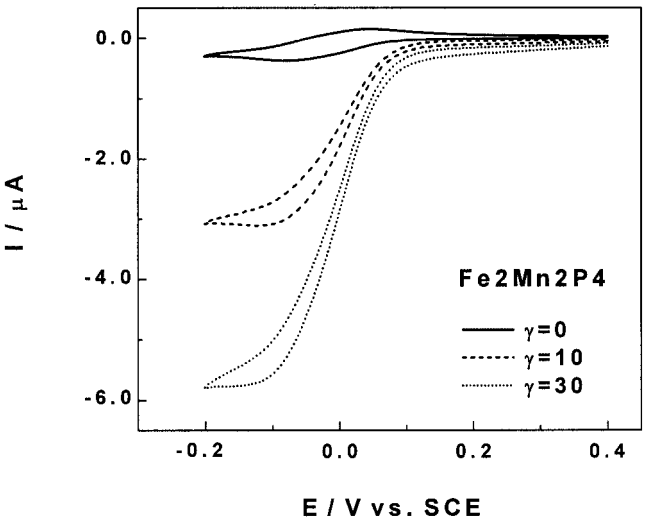

Figure 9. Cyclic voltammetric study of the electrocatalytic reduction of nitrite with a 2×10^{-4} M solution of **Fe2Mn2P4** in a pH = 1 medium (0.5 M Na_2SO_4 + H_2SO_4); the scan rate was 2 mV s^{-1}, the working electrode was glassy carbon, and the reference electrode was SCE

However, in a pH = 5 medium, the catalytic process (obtained with $NaNO_2$ as the starting substrate) is no longer observed in the iron reduction potential region, but rather it occurs in the reduction potential region of the first W wave. This observation is in full agreement with the expected absence of NO and HNO_2 in this medium. In contrast, experiments with pure NO[62,63] at pH = 5 show that the catalytic process starts directly in the potential region in which reduction of iron takes place . We have also examined the catalytic reduction of NO at pH = 1. All these results confirm that NO is the species that is electrocatalytically reduced by the present complexes throughout the evaluated pH region.

Conclusion

The X-ray crystallographic studies of **Fe4As4**, **Fe4P4**, **Fe2As4**, **Fe2P4**, **Fe3As4**, **Fe3P4**, and **Fe2Mn2P4** strongly suggest that electronic coupling exists between the Fe^{III} centers in this large class of multi-iron sandwich-type POMs. Magnetic studies corroborate this prediction and quantify these interactions in the oxidized states of the POMs. Electrochemical studies further indicate there is a stepwise reduction of the Fe^{III} centers. Ion-pairing studies show there is a positive shift of the Fe^{III} centers with increased ion pairing (i.e. $K^+ > Na^+ > Li^+$). Furthermore, ion-pairing and pH effects converge during the reduction processes to suggest that the external Fe^{III} centers of **Fe4As4** and **Fe4P4** are reduced before the internal Fe^{III} sites. Finally, electrocatalytic results show that the accumulation of Fe^{III} centers within a sandwich-type complex yield more favorable catalytic properties. This is attributable to the fact that there is a positive potential shift of the Fe^{III}-based redox processes associated with the accumulation of Fe^{III} centers, and in the case of the catalytic reductions of O_2, NO, or HNO_2, it also suggests that the presence of sites on the POM, which are likely to anchor the relevant molecule during its reduction, may also help to facilitate inner-sphere electron transfer.

Experimental Section

General Remarks: Samples of **Fe4As4**, **Fe4P4**, **Fe2As4**, **Fe2P4**, **Fe3As4**, **Fe3P4, Fe2Mn2As4**, and **Fe2Mn2P4** were obtained by published procedures,[25−27,29−30] and purity was confirmed by IR, elemental analysis, and cyclic voltammetry. Infrared spectra (1% by weight of POM in KBr) were recorded on a Perkin−Elmer Spectrum One FT-IR spectrometer. Measurements of pH and pK_a were performed with a Tacussel MVN 83 millivoltmeter-pH meter. Magnetic measurements were performed on a SQUID magnetometer, Quantum Design MPMS-5. The water content of the samples was measured by thermogravimetric analyses (TGA). All chemicals used were high purity grade and were used without further purification.

pK_a Studies: Measurements were carried out twice using LiOH (0.025 M) under the following conditions: after calibration of the experimental set-up, and standardization of the different reagent solutions, the initial 10 mL solution contained 5×10^{-4} M of the relevant POM dissolved in either pure 1.00 M LiCl or 1.00 M LiCl/3×10^{-3} M HCl. The measurement cell was thermostatted to 25 °C. The solutions were thoroughly deaerated with pure Ar, and the cell was kept under positive pressure at all times during the experiments.

Electrochemical Experiments: The pH values of the buffer solutions range from pH 2 to pH 7. Buffers between pH 2−3 are comprised of 2 M NaCl and HCl. Buffers between pH 4−5 are comprised of 2 M NaCl, 0.1 M CH_3COONa, and CH_3COOH, and buffers between pH 6−7 are made up of 2 M NaCl, 0.05 M NaH_2PO_4, and NaOH. Certain experiments required the use of more specialized buffer solutions. These buffer solutions are described in the text of the Results and Discussion. Solutions were deaerated with Ar for 30 min prior to measurements and kept under positive pressure at all times. Pure NO (N_2O grade) was purchased from Air Liquide (France). The concentration of POM in solution was 2×10^{-4} M, unless otherwise stated. The source, mounting, and polishing of the glassy carbon electrodes (GC, Tokai, Japan, 3 mm diameter) has been described in previous work.[31] The counter electrode was a platinum gauze of large surface area. The electrochemical apparatus was an EG and G 273A under computer control (M270 software). All experiments were performed at ambient temperature, and potentials are quoted against a saturated calomel electrode (SCE).

Acknowledgments

This work was supported in part by the University Paris XI and the CNRS (UMR, 8000 and 8648). We also thank the NSF (Grant CHE-0236686) for the research and Véronique Barra for running several experiments.

simple statistics in the absence of coupled chemical steps. For example, see F. Ammar, J. M. Savéant, *J. Electroanal. Chem.* **1973**, *47*, 115−125; F. Ammar, J. M. Savéant, *J. Electroanal. Chem.* **1973**, *47*, 215−221; J. B. Flanagan, S. Margel, A. J. Bard, F. C. Anson, *J. Am. Chem. Soc.* **1978**, *100*, 4248−4253. The second group includes molecules in which various phenomena (including conjugation, ion pairing, solvation changes, and structural variations) induce or reveal interactions between the sites, and correlatively, differences between their half reaction potentials. These constitute the majority of published examples. For example, see A. J. Bard, *Pure Appl. Chem.* **1971**, *25*, 379−393; A. J. Bard, J. Phelps, *J. Electroanal. Chem.* **1970**, *25*, A2−A5; J. [41] The present results differ substantially for at least one of the two pK_a values attributed by Ruhlmann and co-workers (ref.[35]) to the successive deprotonation of the two water molecules attached to the external metal atoms in αββα-$(MOH_2)_2(M)_2(P_2W_{15}O_{56})_2$ (M = Mn, Fe, Co, Cu, Zn, or Cd). In addition, the two pK_a values for **Fe2P4** are identical to those found for **Fe4P4**. However, the numbers for **Fe2P4** (even accounting for some experimental uncertainty) could only feature pK_a values for the protonable sites within the molecule.

[45] This observation is in agreement with the remark drawn from the study of α-$As_2W_{15}O_{56}^{12-}$ and α-$P_2W_{15}O_{56}^{12-}$ that the former species is easier to reduce than the latter, see B. Keita, I. M. Mbomekalle, L. Nadjo, R. Contant, *Eur. J. Inorg. Chem.* **2002**, 473−479.

[46] B. Keita, A. Belhouari, L. Nadjo, R. Contant, *J. Electroanal. Chem.* **1998**, *442*, 49−57.

[47] Although coupling between the Fe centers is invoked as an explanation for the separation (or lack thereof) of the various reduction waves, reduction of these centers (whether clearly sequential or not) may also depend simply on the effect of the extra negative charge taken on by the POM each time a Fe^{III} center is reduced to Fe^{II}. Literature has solved the case of the first reduction potentials of several Keggin species under conditions of no protonation. The correlation line has a slope of −0.18 V/unit charge (see ref.[1,18]). The same correlation was also suggested for select examples of second reduction potentials (see M. T. Pope, G. M. Varga Jr., *Inorg. Chem.* **1966**, *5*, 1249−1254). In the latter case, only highly symmetrical POMs with little or no ion pairing were addressed and the reduced centers were all W-based. In the multi-iron compounds we address here, electrons are localized essentially in the Fe_4 central unit where ion pairing is extensively operative and in competition with protonation. In addition, we have to consider the Wells-Dawson trivacant species as the precursors in the synthesis of the present sandwich complexes. Therefore only a semi-quantitative evaluation of this phenomenon can be made at best. However, the observation of a broad, single large cathodic current featuring the combined series of one-electron reduction processes of the four Fe centers made on $[Fe_4(OH_2)_{10}(β\text{-}XW_9O_{33})_2]^{n-}$ (n = 6, X = As^{III}, Sb^{III}; n = 4, X = Se^{IV}, Te^{IV}) in which Fe centers are not directly connected (ref.[51]) supports the idea of electronic communication between Fe centers. It can therefore be concluded that the stepwise addition of electrons required in molecular electrochemistry and the subsequent stepwise increase in the overall negative charge of the POM are not sufficient to split the waves measurably in a case where direct influence between structurally equivalent centers does not exist.

[48] Anson et al. (ref.[37]) have also shown that reduced forms of Fe^{III}-monosubstituted Keggin anions engage in ion-pairing with alkali metal cations.

Bonding, Metal-Atom Dynamics and Hyperfine Interactions of η-Phospholyl- and η-Pentaphospholyliron Complexes

Rolfe H. Herber,*[a] Israel Nowik,[a] Dmitry A. Loginov,[b] Zoya A. Starikova,[b] and Alexander R. Kudinov[b]

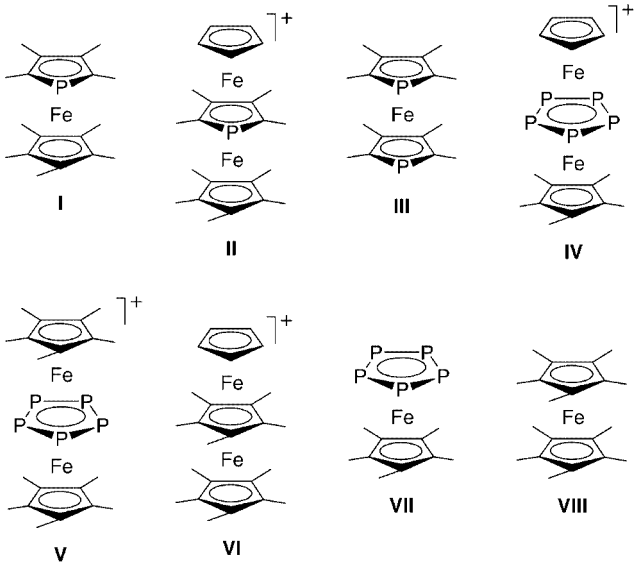
Keywords: Iron / Mössbauer spectroscopy / P ligands / Sandwich compounds / Spin−lattice relaxation

A number of structurally related sandwich compounds of iron, in which the central metal atom is ligated to rings containing one or five phosphorus atoms, have been investigated by temperature-dependent ^{57}Fe Mössbauer spectroscopy, differential scanning calorimetry and single-crystal X-ray diffraction. The quadrupole hyperfine interaction at 90 K evidences a linear dependence on the number of ring phosphorus atoms, decreasing by about 0.35 mm·s^{-1} for each ring carbon atom replaced by P. This effect is directly related to the change in the overlap between metal atom d-orbitals and ligand 3s,3p or 2s,2p orbitals due to an increase in the respective bond lengths. Several one-electron oxidation products of these compounds, which are paramagnetic, have also been examined and show spin–lattice relaxation rates which are fast compared to the characteristic Mössbauer timescale of 98 ns at all temperatures above 90 K.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

In a recent detailed study, Kudinov et al.[1] have discussed the synthesis, electrochemistry, and chemical reactivity of η-pentaphospholyl complexes of iron and ruthenium, including a number of double- and triple-decker sandwich compounds. In a continuation of previous research[2] in which temperature-dependent ^{57}Fe Mössbauer spectroscopy was used, in the present study the metal-atom lattice dynamics and hyperfine interactions of the central atom in the phosphorus-containing ferrocene-like complexes of Kudinov et al.[1] have been examined in detail over the temperature range 90 to 350 K (where appropriate). In addition, as needed, differential scanning calorimetry and magnetic susceptibility measurements have been carried out to extend these spectroscopic results. Such studies can shed light not only on the relationship between the dynamic properties of the iron atom and the details of the local molecular architecture, but also on the spin−lattice dynamics of such systems.

Among the complexes included in this study are [Cp*Fe(η-C_4Me_4P)] (**1**) (Cp* = η-C_5Me_5), [Cp*Fe(μ-η:η-C_4Me_4P)FeCp]PF_6 (**2**) (Cp = η-C_5H_5), [Fe(η-$C_4Me_4P)_2$] (**3**), [Cp*Fe(μ-η:η-P_5)FeCp]PF_6 (**4**), [Cp*Fe(μ-η:η-P_5)FeCp*]-BF_4 (**5**), [Cp*Fe(μ-η:η-Cp*)FeCp]PF_6 (**6**), [Cp*Fe(η-P_5)] (**7**), and [FeCp^*_2] (**8**) (the anions are omitted in the chart given below).



Single crystal X-ray diffraction data for **3** have also been acquired in the present study and are reported herein.

Results and Discussion

The Mössbauer spectra of all the compounds examined in this study consist of well-resolved doublets, and a typical spectrum (of **5**) is shown in Figure 1. The hyperfine parameters at 90 K — the isomer shift (IS), the quadrupole split-

ting, (QS) — as well as the temperature dependence of the logarithm of the recoil-free fraction (*f*) and of the IS, and the parameters derived therefrom, are summarized in Table 1. All IS's are referred to the center of a room temperature α-Fe absorber spectrum. In several cases, as will be noted below, the spectra also revealed the presence of a small quantity of an impurity which is the unavoidable consequence of the synthetic procedures. In these cases, appropriate corrections, especially to the spectral area calculations, were applied as needed.

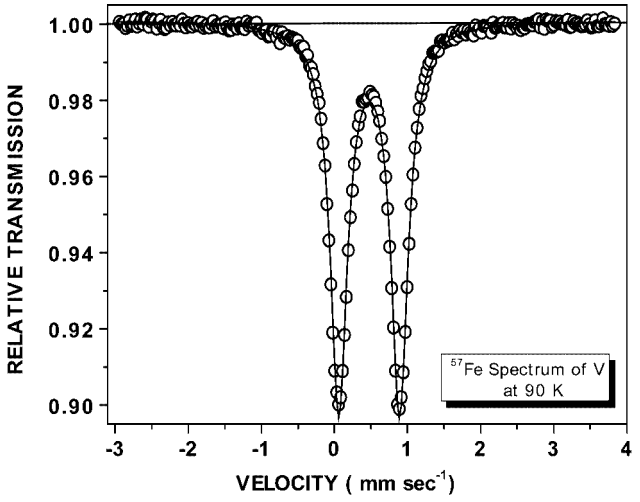

Figure 1. Mössbauer spectrum of **5** at 90 K; the velocity scale is with respect to the centroid of a room temperature α-Fe absorber spectrum

Compound 1

As will be noted from Table 1, the IS at 90 K is very similar to that of decamethylferrocene (**8**),[3] but somewhat smaller than that of the parent ferrocene itself ($0.537\ mm{\cdot}s^{-1}$), in agreement with the earlier conclusion[4] that ring substitution of H by CH_3 influences the s-electron density at the iron atom in only a very minor way. In contrast, the difference in the QS is smaller in **1** than in **8** by $0.277\ mm{\cdot}s^{-1}$, indicating a significant change in the details of the metal-ligand overlap when one of the ring CH groups is replaced by a phosphorus atom, an observation which will be further developed below. The temperature dependence of the IS in the high temperature limit (190−330 K) is well fitted by a linear regression, $[(4.70 \pm 0.06) \times 10^{-4}$ $mm{\cdot}s^{-1}{\cdot}K^{-1}]$ with a correlation coefficient (*R*) of 0.998 for 10 data points. The effective vibrating mass, M_{eff}, calculated from these data is 88 ± 2 daltons. The difference between this value and the "bare" iron atom value of 57 daltons is, of course, a reflection of the covalency of the metal−ring interaction, and is similar to the values reported for other ferrocene-related solids. Rayon and Frenking[5] have estimated the bonding interaction in ferrocene to be 45% coulombic and 55% covalent, and it is reasonable to assume that a comparable partitioning occurs in the present case.

The temperature dependence of the logarithm of the recoil-free fraction, $f = e^{-k^2x^2}$, which is given by the temperature dependence of the logarithm of the area, *A*, under the resonance curve for an optically "thin" absorber of **1**, is summarized graphically in Figure 2.

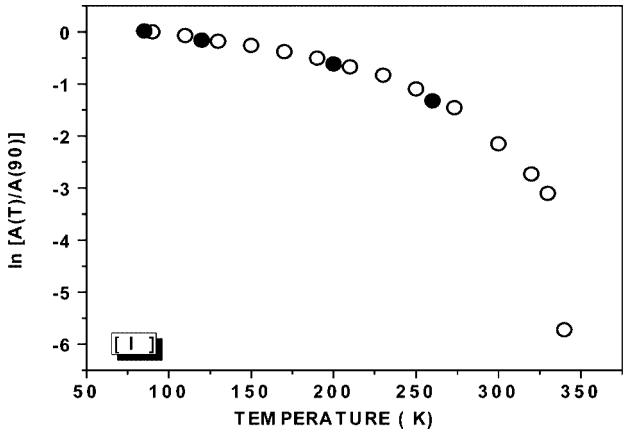

Figure 2. Temperature dependence of ln *A* for **1**; the open circles represent data acquired in a warming mode from 90 K, the full circles data acquired in a cooling mode following the measurement at 340 K

It is seen that although the data are completely reversible (filled versus open data points), the results are not at all well fitted by a linear regression, and, in fact, *f* becomes vanishingly small at temperatures above about 340 K. It should be noted that this temperature is significantly smaller than the melting point of the neat solid. These results have been associated[2,6] with the onset of ring rotation which, in the case of two five-membered rings, one of which has five methyl substituents and the other one (or more) ring substituents of very different steric requirements, such as an H or a ring P atom, leads to a librational motion of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the two rings relative to each other. This librational motion, in turn, results in the presence of low-frequency optical modes which can take up the recoil of the gamma absorption, and hence significantly reduce the *f* value of the iron atom, as has been observed in a number of octamethyl ferrocene complexes.

Finally, it is worth noting that the resonance spectra of **1** do not show any significant motional anisotropy of the iron atom of the kind noted[7] in other ferrocene-related solids, over the entire temperature range noted above.

Compound 2

As before, the hyperfine parameters at 90 K are included in Table 1. The IS is, as expected, very similar to that observed in **1** and in this context it is clear that the presence of an additional FeCp entity does not change this parameter (or the QS) significantly. However, it is worth noting that while the presence of two different Fe atoms in the structure cannot be resolved from the hyperfine parameters, the line widths in such compounds are invariably significantly larger than in compounds with only one kind of metal atom in the structure. In the case of **1** and **2** at the same temperature, this difference corresponds to a line width increase of about 0.050 mm·s^{-1}. A fit of the data for **2** with two equally intense doublets of natural line width yields a somewhat better χ^2 than that with one doublet of broad lines. The difference in QS between the two doublets is about 0.17 mm·s^{-1}. The QS is similar to that observed in **1** as a necessary consequence that both iron atoms "see" a single phospholyl ring in one direction, and a hydrocarbon ring in the opposite direction.

The temperature-dependence of ln *f* is linear above 170 K, and in this case does not show the sharp decrease observed in **1**, although this may be due to the fact that the maximum temperature used in this case was below the point where ring librational motion becomes significant. On the other hand, the temperature dependence of the area ratio in **2** evidences a significant motional anisotropy, as summarized graphically in Figure 3. It should also be noted that the temperature dependence of ln *f* is exceptionally large, leading to a rather "soft" covalent lattice as "seen" by the metal atom in this structure.

Compound 3

The Mössbauer parameters of this complex (Table 1) show, as expected, almost the same IS, but again a twofold decrease in the QS relative to compound **1**. The temperature dependence of the IS is linear over almost the entire range, except at the higher limit, for reasons that will be discussed below. The temperature dependence of the QS as well is nearly negligible over the entire range except at the highest temperatures. What is most remarkable about **3** is the temperature-dependence of ln *f*, which is summarized graphically in Figure 4. It will be immediately apparent that ln *f* is only moderately temperature dependent to about 338 K, and then drops sharply, becoming experimentally unobservable at temperatures above 340 K. It should be noted that

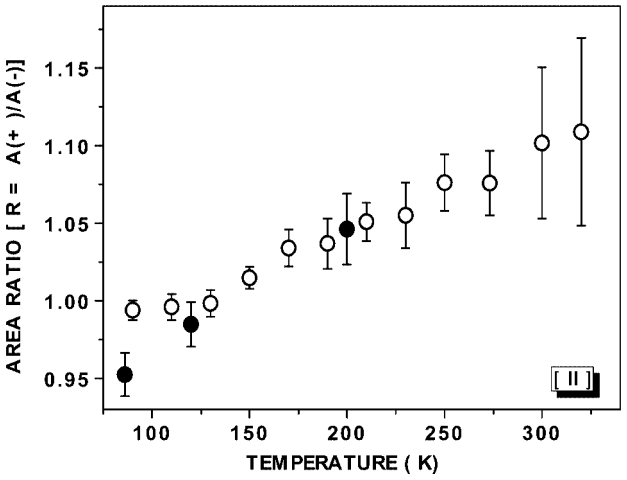

Figure 3. The temperature dependence of the area ratio for **2**; the non-unity value in the low temperature limit is presumed to arise from the temperature-independent texture effect of preferential crystallite orientation in the sample holder

the melting point of this compound is about 464 K, and has not been reported earlier in the literature.[8] Again, this *f* anomaly, *which occurs some 123 °C below the melting point*, is associated with the onset of librational motion of the two rings relative to each other. Strong supporting evidence for this interpretation is provided by the differential scanning calorimetry data summarized in Figure 5. The DSC data show a very sharp endothermic peak, starting at about 339 K and reaching a maximum at 341.8 K. On cooling, the exotherm is similarly sharp, with a maximum at 329 K. The 12.8 K hysteresis is also evident in the ln *f* data summarized in Figure 4, in which the cooling data, represented by the filled circles, do not evidence an experimentally observable resonance effect until a temperature of about 310 K is reached in this regime.

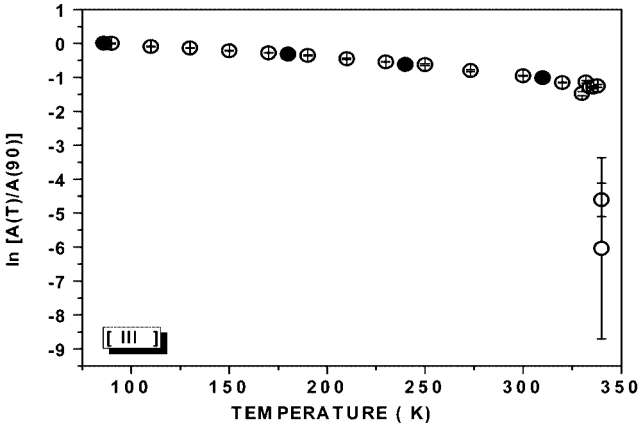

Figure 4. Temperature-dependence of ln *A* for **3**; the open circles pertain to data acquired in a warming mode, while the full circles represent data acquired in a cooling mode after the highest temperature point had been obtained

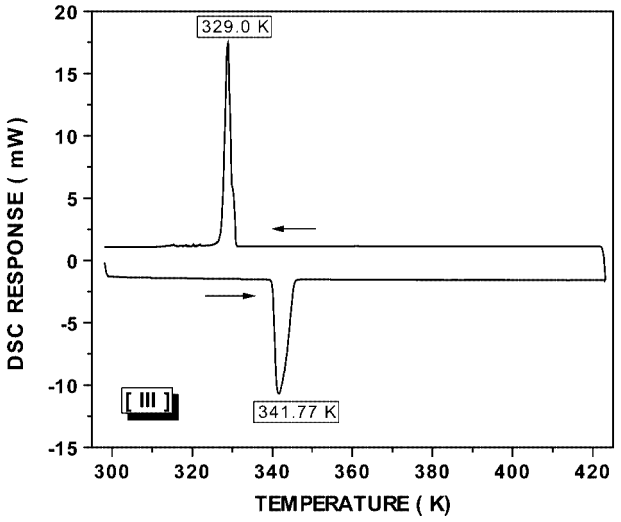

Figure 5. Differential scanning calorimetry data for **3** showing both the warming and cooling data; the approximate 12 degree hysteresis is also evident in the Mössbauer data, as discussed in the text

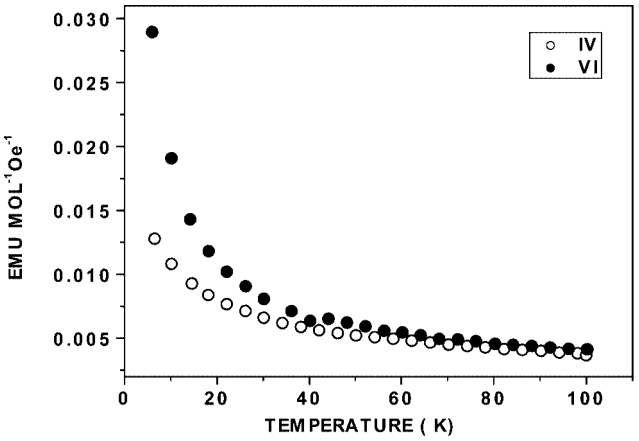

Figure 6. Magnetic susceptibility data for **4** and **6** consistent with paramagnetic behavior above 6 K

Compound 4

This compound is closely related to the pentaphospholyliron complex **7** described earlier,[9,10] with two significant differences: there is an additional FeCp group attached to the phosphorus ring, and the whole complex carries a positive charge, which is balanced by a PF_6^- counterion. The hyperfine interactions at 90 K and the derived parameters are included in Table 1. As noted above, despite the differences in the ligands attached to the two iron atoms, the Mössbauer parameters of the two metal atoms are sufficiently similar that they cannot be distinguished from each other. The IS (90 K) values of **4** and **7** are essentially identical, while the QS (90 K) values differ by about 0.24 mm·s^{-1}. It should be kept in mind, however, that the QS value for **4** reflects an average of the two different metal centers. Moreover, this parameter is nearly temperature independent in the range 90−300 K, and on further warming shows a pronounced negative slope to 350 K, while the temperature dependence of ln f is well fitted by a linear regression [$-(11.52 \pm 0.07) \times 10^{-3}$ K^{-1}; correlation coefficient: 0.993 for 21 data points] over the temperature range 90−350 K, and shows no discontinuity at about 300 K.

The spectra of **4** show two well-resolved maxima over the entire temperature range rather than the broadened collapsed spectrum characteristic of one-electron oxidized ferrocenoids, as reported earlier.[6,11] To substantiate the expected paramagnetic nature of **4**, the magnetic susceptibility of the compound (as well as of **6**) was determined over the temperature range 6−100 K under a field of 39 Oe; the results are summarized in Figure 6.

The experimental data were fitted by using the Curie−Weiss law $\chi = \chi_0 + C/(T - \Theta)$, where χ_0 is the temperature-independent susceptibility, C is the Curie constant and Θ is the Curie−Weiss temperature. For **4** the Curie constant is 0.167 emu·mol^{-1}·Oe^{-1} and the Curie−Weiss temperature is −0.09 K, showing clearly that **4** is paramagnetic over the entire temperature range. These results and those of the Mossbauer data provide clear evidence that the spin−lattice relaxation rate in this compound is fast with respect to the characteristic Mössbauer time scale (ca. 100 ns) at all temperatures above 90 K, while spin−spin relaxation can be ruled out in view of the local structure surrounding the iron atoms in next-neighbor molecules. There is no persuasive evidence for iron atom motional anisotropy over the range 90−350 K and the hyperfine parameters are completely reversible in cooling from the upper to the lower temperature of this range. It might be conjectured that the difference in the resonance spectra of compounds such as **4** (as compared to its neutral analogue) and that of ferrocenium ions and ferrocene might be related in some way to the presence of the five methyl groups in the Cp* ring. However, as will be discussed more fully below, resonance spectroscopic data for **8** and its one-electron oxidation product show clearly that the presence of the ring methyl substituents does not play a role in this difference of behavior.

Compound 5

The structure of **5** is very similar to that of **4** except that the second Cp ring is fully methyl substituted in the latter. The Mössbauer parameters, included in Table 1, are very similar to those of **4** and require no further elaboration except as noted below. Since the spectra of **5** again consist of two well-separated resonance maxima over the whole temperature range, the conclusions reached above for **4** relative to the spin−lattice relaxation rate are equally valid in this case.

The temperature dependence of ln f is shown graphically in Figure 7, from which it is seen that there is a significant change in slope on warming at about 170 K, and a second change in slope (of much smaller magnitude) between 190 and 200 K. To elucidate the origin of these changes a DSC scan was obtained over the temperature range 150−260 K. This scan shows two endotherms, one at about 170 K, the other at 193.5 K. The ΔH and ΔJ values for the latter transition are 1.19 kJ·mol^{-1} and 6.16 J·mol^{-1}·K^{-1}, respectively, in reasonable agreement with the barriers to internal rotation of the rings in polyene-metal complexes reported in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the literature.[12] Thus it is inferred that the discontinuity observed in the ln *f* data shown in Figure 7 can be associated with the onset of ring rotation/libration of the two Cp* rings relative to the central η^5-P_5 ring in the molecular center. As in the case of the structurally closely related **4** there is no significant motional anisotropy of the iron atom observable over the entire temperature range.

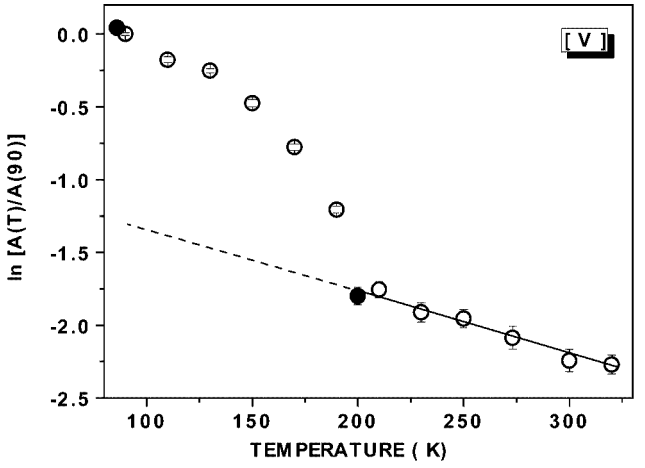

Figure 7. Temperature dependence of ln *A* for **5**; the two cooling regime data points (filled circles) were acquired after the 320 K data had been obtained

Compound 6

Finally, the Mössbauer spectra of **6** have been examined in considerable detail, although this molecule does not involve a phospholyl ring atom in its structure. The hyperfine parameters and associated constants are included in Table 1 and are not otherwise remarkable. As noted above, while the two different iron atoms are not resolvable on the basis of their hyperfine interactions, the linewidths (fwhm) in these spectra are again discernably broader than those observed in di-iron compounds in which the two metal atoms are located in identical environments.

The temperature dependence of the IS shows a small amount of curvature at low temperatures, but is reasonably well fitted by a linear regression in the high temperature regime (210−350 K) with a correlation coefficient of 0.997 for 10 data points. The QS is essentially temperature independent, but the area-ratio parameter shows evidence for a significant metal atom motional anisotropy. The temperature dependence of ln *f* is linear over the entire temperature range with a correlation coefficient of 0.997 for 19 data points.

As was noted for **4** and **5**, the resonance spectra of **6** consist of well-resolved doublets over the entire range. Since the susceptibility data included in Figure 6 (Curie constant 0.176 emu·mol^{-1}·Oe^{-1} and Weiss constant −10.4 K) again show this compound to be paramagnetic over the entire temperature range, it is concluded that above 86 K, the spin−lattice relaxation rate is again fast compared to the characteristic Mössbauer timescale.

Compound 8 and its One-Electron Oxidation Product

The MS parameters of decamethylferrocene (**8**) are included in Table 1 and have been published previously.[3] They are included in the present discussion due to the obvious structural relationship of this compound to those of the "double decker" compounds discussed above. In addition, a detailed MS study of the relaxation spectra of its one-electron oxidation product (as both the BF_4^- and PF_6^- salts) has been carried out, and will be reported separately.[13] Suffice it to say in the context of the present discussion that the presence of the ring methyl groups plays little role in the rate of the spin−lattice relaxation and the conclusions reached above for this rate in **4**, **5**, and **6** are not related to this ring substitution, but to the presence of two iron atoms in the structure, separated by a η^5 ring moiety which gives rise to the fast relaxation rates observed in these solids.

Systematics of the QS Hyperfine Interaction

The present data set includes structurally very similar compounds with, however, a variable number of ring phosphorus atoms as part of the sandwich architecture. The parameter most influenced by this number is the QS, and the change in the QS as a function of the number of ring phosphorus atoms is summarized graphically in Figure 8 in which the correlation coefficient of the linear regression is 0.994 for eight data points. Clearly, in these structurally closely related compounds the concept of the "partial quadrupole splitting" parameter[14] appears well justified, with each ring phosphorus atom diminishing the QS by 0.35 mm·s^{-1}. The relationship summarized in Figure 8 can be accounted for in terms of the molecular orbital treatment of the metal−ligand interactions in ferrocene-like complexes. The fundamental treatment for ferrocene has been well dealt with in the 1965 paper by Collins,[15] who showed that the Dahl and Ballhausen[16] treatment (as well as the slightly different scheme of Shustorovich and Dyatkina[17]) accounts for both the magnitude of the quadrupole interaction in ferrocene, as well as the large reduction in this parameter observed in the one-electron oxidation product. A major contribution to the QS is from the overlap of the e_{2g} and $3d_2$ orbitals, and the decrease in the QS on one-electron oxidation arises from the removal of electron density from the $3d_0$ orbital in the HOMO of the combination. A detailed representation of the MO correlation diagram for the interactions between Fe^{2+} and five-membered cyclic ligands has been given by Frenking.[18] The corresponding MO-level scheme for P_5-containing systems has been published by von Schleyer et al.[19] as applied to a titanium complex. In particular, from the Cp-metal-P5 MO diagram[19] it is seen that the HOMO has contributions from metal e_2', a′, and e1′′ levels as well as the e_2' π-orbitals of the cyclic P_5 ligand. It is clear from a comparison of these two schemes that the nature of the HOMO in these complexes changes significantly when the 2s2p orbitals of carbon are replaced successively by the 3s3p orbitals of phosphorus, and it is this change which can account qualitatively for the experimental data summarized in Figure 8.

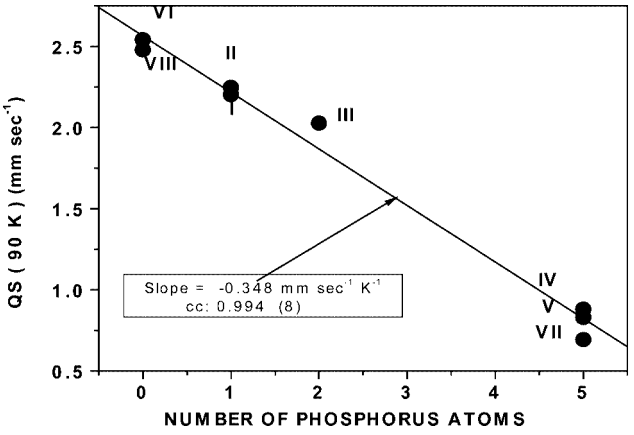

Figure 8. Dependence of the quadrupole hyperfine interaction at 90 K as a function of the number of ring phosphorus atoms in the compounds discussed in the text

Spin Relaxation in Triple-Decker Cations

As noted above, one-electron oxidation of ferrocene, decamethylferrocene (**8**) and related compounds, gives rise to relaxation spectra consisting of an asymmetric broadened resonance envelope, the temperature dependence of which is characteristic of a spin−lattice Raman relaxation process. In contrast, the triple-decker cations examined in the present study (**4**, **5**, and **6**) give rise to well-resolved doublet spectra, albeit with the quadrupole interactions given in Table 1. Since magnetic-susceptibility measurements have shown (in the case of **4** and **6**) that these compounds are paramagnetic at temperatures above 6 K, it is clear that the doublet spectra arise because the spin−lattice relaxation rate is rapid with respect to the characteristic Mössbauer time scale (ca. 10^{-9} s). Thus, at all temperatures of the present study, the resonant (scattering) nucleus sees an average zero hyperfine field, giving rise to narrow resonance lines in the spectra.

X-ray Diffraction Study

The structure of complex **3** was investigated by single-crystal X-ray diffraction. It has the expected sandwich structure (Figure 9). Selected bond lengths and angles are given in Table 2. These values are similar to those for other diphosphaferrocenes.[20−22] The conformation of the phospholyl rings corresponds to C_{2h} symmetry — the two P atoms are located in opposite directions (α = 180°). An analogous conformation was observed for one of two molecules in the unit cell of octaethyldiphosphaferrocene.[20] Other conformations reported for diphosphaferrocenes include C_{2v}, in which the two phosphorus atoms are eclipsed (α = 0°)[21] and C_1, in which the P atoms are superposed with the β-carbon of the other ring (α = 140−145°).[22]

Cowley et al.[23] have reported the X-ray structure of the complex $[Ag\{(\eta\text{-}C_4Me_4P)_2Fe\}_2]^+$ in which Ag^+ is coordinated to the lone pairs of phosphorus atoms of **3**. The metal-to-ring distances Δ(Fe···C_4Me_4P) (1.6851−1.7026 Å, average 1.694 Å) in the $[Ag\{(\eta\text{-}C_4Me_4P)_2Fe\}_2]^+$ cationare longer than the corresponding value in **3** (1.6578 Å). An analogous elongation of Δ in $[Pd\{(\eta\text{-}C_4Et_4P)_2Fe\}_2]$ as compared with $[Fe(\eta\text{-}C_4Et_4P)_2]$ was also observed.[20] This elongation is apparently connected with a weakening of direct donation due to a decrease of the donor ability of the ring ligand. Moreover, the phospholyl rings coordinated with the metal atom are in a staggered conformation leading to steric repulsion.

Summary and Conclusions

Eight organometallic compounds of iron, having a variable number of ring-phosphorus-containing ligands, have been examined by temperature-dependent ^{57}Fe Mössbauer spectroscopy, differental-scanning calorimetry, and single-crystal X-ray diffraction. The quadrupole splitting (QS) hyperfine interaction is sensitive to the number of ring P-atoms, and decreases as this number increases. The paramagnetic species produced by one-electron oxidation of the neutral precursors show slow spin−lattice relaxation which increases, as expected, with increasing temperature. Compound **3**, the bis-cyclopentadienylphospholyl complex, shows both from Mössbauer recoil-free fraction data and the DSC results that onset of ring rotation gives rise to librational motion affecting the dynamics of the metal atom.

Experimental Section

Complexes **1**,[24] **2**,[25] **3**,[8] **4**,[26] **5**,[1] **6**,[27] **7**[1] and **8**,[27] were prepared as described in the literature. All of the compounds examined in this study were rapidly transferred from sealed ampoules to

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

screw-cap perspex sample holders, sealed with Teflon tape and rapidly cooled to 78 K. Mössbauer spectra were recorded at increasing temperatures (in 20 K steps) to the maximum temperature, and then in a cooling mode to ascertain the reversibility of the data. The details of spectrometer calibration, temperature control and data reduction have been reported previously.[2] All isomer shifts are reported with respect to the centroid of a room temperature α-Fe absorber spectrum which was also used for spectrometer calibration.

Differential scanning calorimetry data (DSC) were acquired with a Mettler Toledo Star System at warming and cooling rates of 5 K per minute.

Magnetic susceptibility data were acquired in the temperature range 6 to 100 K using a commercial (Quantum Design MPMS-5S) super-conducting interference device (SQUID) magnetometer.

X-ray Crystal Structure Determination: The red plate-like crystals of **3** were grown by slow evaporation of the solvent from a pentane solution. Crystal data: $C_{16}H_{24}FeP_2$ (M = 334.14), monoclinic, space group $C2/c$ (no. 15), a = 14.298(2), b = 12.839(2), c = 8.849(1) Å, β = 104.369(3), V = 1573.6(4) Å^3, Z = 4, $d_{calcd.}$ = 1.410 g·cm^{-3}, μ = 1.146 mm^{-1}, $F(000)$ = 704, crystal size 0.20 × 0.40 × 0.60 mm.

Single-crystal X-ray diffraction experiments were carried out with a Bruker SMART 1000 CCD area detector, using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å, ω-scans with a 0.3° step in ω and 10 s per frame exposure, $2\theta < 60°$) at 120 K. Reflection intensities were integrated using SAINT software,[28] the absorption correction was applied by semi-empirical method SADABS,[29] T_{max}/T_{min} = 0.802/0.391. A total of 6332 reflections were measured, 2075 (R_{int} = 0.0179) independent reflections were used in further calculations and refinement. The structures were solved by direct methods and refined by the full-matrix least-squares method against F^2 in anisotropic (for non-hydrogen atoms) approximation. All hydrogen atoms were located from the difference Fourier syntheses and were included in the final refinement using a rigid motion model in isotropic approximation. The final refinements converged to R_1 = 0.0377 [from 1868 unique reflections with $I > 2\sigma(I)$] and wR_2 = 0.1055 (from all 2075 unique reflections); the number of refined parameters was 88, GOOF = 0.943, largest diff. peak and hole 1.891 and −0.641 eA^{-3}. All calculations were performed on an IBM PC/AT using the SHELXTL software.[30]

CCDC-232591 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Tin(II) and Lead(II) 4-Acyl-5-pyrazolonates: Synthesis, Spectroscopic and X-ray Structural Characterization

Claudio Pettinari,*[a] Fabio Marchetti,[a] Riccardo Pettinari,[a] Augusto Cingolani,[a] Eleonora Rivarola,[b] Christine Phillips,[c] Joseph Tanski,[c] Miriam Rossi,[c] and Francesco Caruso*[d]

Keywords: Lead / Mössbauer spectroscopy / N ligands / NMR spectroscopy / Tin

Novel tin(II) β-diketonate $Sn(Q)_2$ complexes [HQ = 1-R^1-3-R^3-4-R^4(C=O)-pyrazol-5-one; HQ^C: R^1 = Ph, R^3 = Me, R^4 = Cy; HQ^S: R^1 = Ph, R^3 = Me, R^4 = $CHPh_2$; HQ^L: R^1 = Ph, R^3 = Me, R^4 = CH_2Ph; HQ^T: R^1 = Ph, R^3 = Me, R^4 = CH_2tBu; HQ^E: R^1 = Ph, R^3 = Me, R^4 = Et; HQ^B: R^1 = Ph, R^3 = Me, R^4 = *t*Bu; HQ^W: R^1 = Ph, R^3 = Me, R^4 = *p*-(*t*Bu)Ph; HQ^R: R^1 = Ph, R^3 = Me, R^4 = *p*-[$(CH_2)_5CH_3$]Ph; HQ^N: R^1 = *p*-NO_2Ph, R^3 = Me, R^4 = Ph; HQ^M: R^1 = Me, R^3 = Me, R^4 = Ph; HQ^D: R^1 = Me, R^3 = Me, R^4 = Me; HQ^P: R^1 = Ph, R^3 = Ph, R^4 = Ph; HQ^G: R^1 = Ph, R^3 = Ph, R^4 = Me; HQ^F: R^1 = *p*-CF_3Ph, R^3 = Me, R^4 = Ph; HQ^H: R^1 = *p*-CF_3Ph, R^3 = Me, R^4 = Me] have been isolated and characterized by single-crystal X-ray diffraction analyses, IR, ^{1}H, ^{13}C, ^{119}Sn NMR and ^{119}Sn Mössbauer spectroscopy, ESI mass spectrometry, conductivity and molecular weight measurements. The tin complexes SnQ_2 are air-stable, contrary to equivalent compounds of classical β-diketones, and adopt mononuclear pseudo-trigonal-bipyramidal structures ($pSnO_4$, where p is a stereochemically active lone electron pair) in which both ligands chelate a single metal center, as confirmed in the X-ray crystal structure of $Sn(Q^L)_2$. This structure fits a trend for all "SnO_4" compounds: Sn–O(primary) and Sn–O(secondary) bonds are associated with small O(primary)–Sn–O(primary) and wide O(secondary)–Sn–O(secondary) bond angles. The reactivity of $Sn(Q^T)_2$ toward RI (R = Me or Et) and $CrCO_6$ has been investigated. The compounds PbQ_2 (HQ = HQ^T, HQ^B, HQ^W, HQ^D) have been also synthesized and the X-ray structures of $Pb(Q^B)_2$ and $Pb(Q^T)_2$ in the solid state determined. These are different from SnQ_2 and are composed of "PbO_4" moieties with additional interactions from neighboring units to produce polymeric forms. Compound $Pb(Q^T)_2$ is unusual in having the metal–O(pyrazolonato) bond longer than the metal–O(acyl) one, probably due to a Pb–arene interaction with a neighboring phenyl ring. The sterically less hindered $Pb(Q^D)_2$ reacts with phen (1,10-phenanthroline) yielding the mixed ligand complex [$Pb(Q^D)_2$(phen)]. In this work, in addition to the different coordination numbers expressed by Sn and Pb, associated with the larger covalent radius of the latter, the binding mode of 4-acyl-5-pyrazolonates to Pb is *syn* whereas for Sn it is *anti*.

Introduction

The discovery of several important new applications has led to renewed interest in tin(II) and lead(II) compounds containing chelating ligands. For example, SnF_2 has been incorporated into toothpaste for over two decades,[1] primarily as a convenient fluoride source, but more recently the inherent antimicrobial activity of the tin itself has also been claimed.[2–4] As a result, orally viable Sn^{II} derivatives are greatly desired and a number of researchers are involved in this field.[5] Moreover, new molecular precursors for MOCVD techniques are required to prepare suitable thin films of SnO_2, which is a semiconductor highly transparent in the visible region and highly reflective in the IR region,[6] adhesive to many substrates and with good chemical and mechanical stability. SnO_2 has a number of specific properties that make it useful as a transparent and conducting coating on glass,[7] in gas-sensing devices[8,9] and in transparent electrodes in photovoltaic devices.[10–12] β-Diketonates of tin(IV)[13–15] and tin(II)[16] seem to be good sources of SnO_2. Lead chelates are the basis for thin films of Pb-containing ferromagnetic ceramics such as [$PbTiO_3$], [$Pb(Zr,Ti)O_3$] and [$(Pb,La)(Zr,Ti)O_3$] that have important applications in nonvolatile ferroelectric memories, infrared detectors, electro-optic devices, sensors and micro-actuators.[17–26] Finally, the design and synthesis of new,

volatile and thermally stable lead(II) complexes has received increased attention.[27−29]

In the last decade we have reported on the interaction between 4-acyl-5-pyrazolones, an interesting family of asymmetric β-diketones (Figure 1), and several metal acceptors such as Sn,[30] Rh,[31] Ba,[32] Sr,[33] Cu,[34] Cd,[35] and Ag.[36] We have demonstrated that it is possible to tune the chemical properties by appropriate choice of the substituents in the R^1 and R^4 positions of the ligand. Sometimes the complexes obtained show unusual structural and physicochemical features such as good solubility in polar protic solvents.[37] More recently we have described antitumor titanium acylpyrazolonates,[38] and volatile copper acylpyrazolonates.[39]

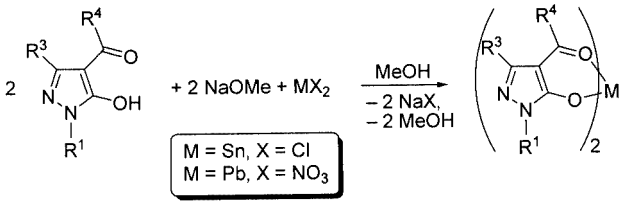
Figure 1. Q proligands used in this work

In 1994 we synthesized some tin(II) acylpyrazolonates[40] and found that these compounds are more stable than analogous tin(II) derivatives of classical β-diketonates.[16,41−43] Here we report a systematic investigation of the interaction of tin(II) with acylpyrazolonates to determine if variation of steric and electronic features of acylpyrazolones can affect the solid-state and solution structures of tin(II) compounds. The reactivity of the species obtained was also tested toward carbonylmetal compounds and alkyl halides. In addition, the structural properties and reactivities of new Pb^{II} acylpyrazolonates are compared.

Results and Discussion

Interaction of the acylpyrazolone proligands HQ with tin(II) dichloride in methanol, in the presence of sodium methoxide, yielded SnQ_2 derivatives **1**−**15** as precipitates (Scheme 1). In contrast to classical bis(β-diketonato)tin(II) complexes, Sn^{II} derivatives of the asymmetric Q^- ligands are quite stable to air and moisture. They are pale-yellow solids with sharp melting points. The solubility of **1**−**15** varies widely depending on the R^1, R^3 and R^4 substituents. When R^1 is a Ph or 4-$O_2NC_6H_4$ group and R^4 is an Me group (**1**−**9**), the compounds are soluble in DMSO, acetone and chlorohydrocarbon solvents, where they are not electrolytes. When R^1 = R^3 = Me (**10**, **11**), and when R^1 = *p*-$F_3CC_6H_4$ (**14**, **15**) higher solubility in acetonitrile, alcohols and aromatic solvents was found. Moreover, derivatives **12**−**15** are partially dissociated in DMSO, similar to diorganotin(IV) complexes of $(Q^P)^-$, $(Q^G)^-$, $(Q^F)^-$ and $(Q^H)^-$.[30,44,45] Compounds **1**−**15** do not undergo hydrolysis in chloroform or acetone solution. Molecular weight determinations carried out for all derivatives in chloroform suggest monomeric structures in solution.



Scheme 1

The infrared spectra of **1**−**15** show the disappearance of the broad band due to intramolecular O−H···O stretching vibration, which is observed in the free HQ proligands in the range 2300−2800 cm^{-1}. Only a small shift to lower frequencies (from about 1620 to about 1600 cm^{-1}) was found for the carbonyl band ν(C=O). In addition, new absorptions were identified in the region 300−500 cm^{-1}, likely due to ν(Sn−O).[30,37,44,45] These features are in accordance with deprotonation of acylpyrazolones and coordination to the tin atom through both oxygen atoms.[46,47]

In the case of derivatives **1**, **2**, **4** and **7**−**15** ^1H and ^{13}C NMR spectra carried out at room temperature show one set of resonances for each magnetically equivalent group of H or C, whereas the ^1H and ^{13}C NMR spectra of **3**, **5** and **6** show three sets of signals due to the three isomers depicted in Figure 2, assuming the tin atom exists in a trigonal-bipyramidal coordination environment. This different behavior is probably due to the steric bulk of Q in derivatives **3**, **5** and **6**, which increases the energetic barrier to interconversion among the three isomers. To confirm this hypothesis we recorded the ^1H NMR spectrum of compound **2** in dichloromethane at 183 K: two broad resonances for each equivalent group of protons emerged, in accordance with a lack of fluxionality at this temperature.

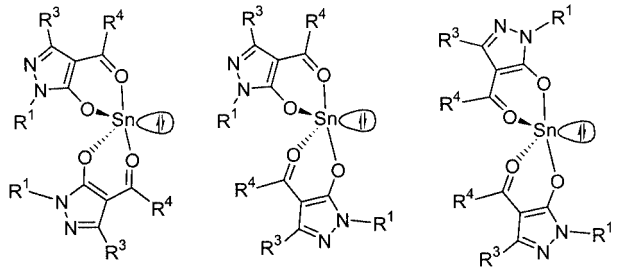


Figure 2. SnQ_2 stereoisomers found in chloroform solution of derivatives **3**, **5** and **6**

The ^{119}Sn NMR spectra of derivatives **1**−**15** show a single resonance in the range from δ = −700 to −775 ppm, typical of tin(II) derivatives with an SnO_4 core.[40,48−50] The presence of only one ^{119}Sn resonance in the case of deriva-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tives **3**, **5** and **6** seems to indicate that the tin center is not sensitive to changes in the configurational arrangement of the acylpyrazolonate donors. As previously observed, electron-withdrawing groups in the periphery of the acylpyrazolonato donors cause an upfield shift compared to those of electron-releasing ones, because of an increase in the ionic character of Sn−O bonds or, alternatively, to a greater contribution of the tin 5p atomic orbital to the Sn−O molecular orbital. An example is $Sn(Q^F)_2$ (δ = −775.2 ppm) with respect to $Sn(Q^D)_2$ (δ = −701.6 ppm). This allows the tin lone pair to became more concentrated in an orbital having increased 5s character.

We recorded ^{119m}Sn Mössbauer spectra of representative derivatives **1**−**6**, **8**−**12**, **14** and **15** and of six other similar complexes to verify this hypothesis in the solid state (Table 1). Systems containing divalent tin are readily recognized by their high δ values of 3−4 mm·s^{-1}. In fact, the lone pair of the Sn^{2+} ion retains a high 5s character; Sn^{II}−ligand covalent bonds induce a hybridization process having a partial p character leading to the decrease of isomer shift δ value and to moderate quadrupole splitting Δ values, typically 1−2 mm·s^{-1}.[51] The complexes examined by Mössbauer spectroscopy have 1:2 Sn^{II}/ligand stoichiometries and the tin atom, possessing a lone pair, is coordinated to four oxygen atoms from Q^- with formation of a six-membered chelate ring of the type Sn^{II}−O−C=C−C=O→Sn^{II}.[52]

Table 1. Mössbauer data of Sn^{II} complexes

Compound	δ [a][b] [mm·s^{-1}]	Δ [b] [mm·s^{-1}]	$\Gamma\pm$ [b] [mm·s^{-1}]

$Sn(Q^S)_2$ (**8**)	3.24	1.78	0.83
$Sn(Q^N)_2$ (**9**)	3.07	1.87	0.89
$Sn(Q^M)_2$ (**10**)	2.99	1.98	0.81
$Sn(Q^D)_2$ (**11**)	3.29	1.68	0.86
$Sn(Q^P)_2$ (**12**)	3.22	1.94	0.98
$Sn(Q^F)_2$ (**14**)	3.26	1.89	0.87
$Sn(Q^H)_2$ (**15**)	3.36	1.96	0.83
$Sn(Q^{Br})_2$ [c]	3.00	1.85	0.81
$Sn(Q^{R'})_2$ [d]	3.06	1.77	0.77
$Sn(Q^{Me})_2$ [e]	3.13	1.98	0.86
$Sn(Q^{CCl3})_2$ [f]	3.13	1.97	0.95
$Sn(Q^{Ph})_2$ [g]	3.15	1.83	0.89
$Sn(Q^{F'})_2$ [h]	3.26	1.69	0.92

[a] With respect to room-temperature spectrum of $CaSnO_3$. [b] ±0.01 mm·s^{-1}. [c] HQ^{Br} = 4-(*p*-bromophenyl)-3-methyl-1-phenylpyrazol-5-one. [d] $HQ^{R'}$ = 3-methyl-1-phenyl-4-(*p*-tolyl)pyrazol-5-one. [e] HQ^{Me} = 3,4-dimethyl-1-phenylpyrazol-5-one. [f] HQ^{CCl3} = 3-methyl-1-phenyl-4-(trichloroacetyl)pyrazol-5-one. [g] HQ^{Ph} = 3-methyl-1,4-diphenylpyrazol-5-one. [h] $HQ^{F'}$ = 3-methyl-1-phenyl-4-(trifluoroacetyl)pyrazol-5-one.

The variation of the Mössbauer parameter values of isomer shift, δ, and quadrupole splitting, Δ, (Tables 1 and 2) is around 0.37 mm·s^{-1} and 0.30 mm·s^{-1}, respectively, and the $\Gamma\pm$ values indicate that a unique Sn^{II} site is present in the complexes examined. The different R groups in the ligand may cause variations in the δ and Δ parameters: the electron-withdrawing nature of the R groups can influence the polarity of the Sn−O bond and the 5s electron density at the tin nucleus. Moreover, the R substituents can affect steric hindrance giving rise to a greater degree of distortion in the coordination sphere of the tin atom. In any case, the small variation observed may be indicative of the same type of coordination to the Sn^{II} atom. In any case, the small variation observed in the δ values may be indicative of a poor influence of electron-withdrawing groups of acylpyrazolonate donors.

Table 2. δ and Δ ranges in β-oxo enolates of Sn^{II}

Complex	δ	Δ	Ref.
Sn^{II}−Q ligand	2.99−3.36 (0.37)	1.68−1.98 (0.30)	this work
Sn^{II}−acac	2.92−3.60 (0.68)	1.66−2.21 (0.55)	[42]
Sn^{II}−β-oxo enolate	2.91−3.31 (0.40)	1.80−2.25 (0.45)	[43]

By comparing the Mössbauer parameter values with those of parent β-oxo enolates of Sn^{II} [42,43,53] and adopting the fingerprint method as a criterion of inferring structural arrangements (Table 2), a tin complex having four oxygen atoms from two molecules of the ligand in a trigonal-bipyramidal geometry can be assigned, with the lone pair occupying an equatorial site.

Selected positive electrospray MS data of complexes **2**, **5**, **6** and **9** are reported in Table 3. In our case, since only charged species are transferred from solution to the gas phase, quantitative ESI-MS results do not represent the real relative distribution of the species in solution. However, the data seem to indicate that, in solution, these derivatives can undergo loss of the anionic pyrazolonate ligands, which immediately interact with protons or sodium ions, yielding mono-charged species such as $[H_2Q]^+$ or $[Na(HQ)]^+$. The presence of Na adducts is typical of ESI mass spectra, due to the fact that the O-donor immediately interacts and aggregates with the small quantity of alkali metal ions present in the solvents. The possibility of interaction in solution is strongly dependent on the nature of the ligands. In some cases aggregation of Sn and Q in acetonitrile is significant even at 10^{-3} M, with smaller aggregates such as $[Sn(Q)]^+$, $[NaSn(Q)_2]^+$, $[Sn_2(Q)_3]^+$ being dominant over larger adducts. Some minor peaks present in the spectra of **2** and **5** are due to the interaction of the SnQ_2 species with K^+ or H^+. The isotopic distribution of these species is in agreement with the calculated composition.

The absence of ions containing MeCN indicates no binding between the solvent and Sn. In the ESI mass spectra of the same complexes, recorded in the negative detection mode, the predominant peak is always that due to the anionic ligand $[Q]^-$. In some cases, peaks due to association of two $(Q)^-$ ligands with one Na^+ cation were also identified. Interestingly, all spectra exhibit peaks due to $SnCl_3^-$, $Sn(Q)Cl_2^-$, $KSn(Q)Cl_3^-$, and $Sn(Q)_2Cl^-$: all species containing Cl from the solvent.

[a] Relative intensity in square brackets; FW = calculated molecular weight. [b] A peak at *m/z* = 605 is assigned to the species $[(Q)_2Na]^-$. [c] Other peaks: 691 [20] $[(HQ)_2Na]^+$, 1119 [10] $[(Q)_2Pb_2Cl]^+$, 1771 [100] $[(Q)_4Pb_2Na]^+$. [d] A peak at *m/z* = 360 [30] is assigned to the species $[(Q)Pb]^+$. [e] A peak at *m/z* = 542 [100] is assigned to the species $[(Q)Pb(Phen)]^+$.

The crystal structure of bis{3-methyl-1-phenyl-4-(phenylacetyl)pyrazolon-5-ato}tin(II) (**6**) consists of discrete molecules with no additional interactions besides those due to van der Waals forces. The tin atom lies on a crystallographic twofold axis. Table 4 shows selected bond lengths and angles for this molecule. Each tin atom is bound to four oxygen atoms from the two 4-acyl-5-pyrazolonato ligands (Figure 3). These four oxygen atoms are located on one side of the tin atom due to the presence of a stereochemically active lone pair on the opposite side. Generally, the 4-acyl-5-pyrazolonato ligands form a short metal−O(pyrazolonato) bond compared to the longer metal−O(acyl) bond. This is also the case here as the Sn1−O1 distance is 2.125(7) Å and the Sn1−O2 distance is 2.334(7) Å. The geometry at the tin atom is a distorted trigonal bipyramid with an axial O2−Sn−O52 bond angle of 146.2(3)°; such distortion from 180° is due to the presence of a lone pair and the chelating features of the ligand. The O1−Sn−O51 angle of 89.2(3)° also shows significant deviation from the ideal value of 120° due to the lone pair. This structure is similar to that of bis(4-acetyl-3-methyl-1-phenylpyrazolon-5-ato)tin(II), which has been determined crystallographically both as the pure complex[40] and as a methanol solvate,[54] although neither shows a twofold axis as for **6**. The structural parameters in the coordination sphere of all three structures are similar, as shown in Table 5.

The existence of two very different sets of Sn−O bond lengths in "SnO_4" compounds is also observed in other Sn^{II} β-diketonates and is not limited to compounds with asymmetric ligands. An analysis of compounds found in the Cambridge Database is shown in Figure 4. The lower left side of the graph shows the Sn−O(primary) bond and the upper right side shows the Sn−O(secondary) bond. For each "SnO_4" compound the Sn−O(primary) and Sn−O(secondary) bonds are associated with small O(primary)−Sn−O(primary) and wide O(secondary)−Sn−O(secondary) bond angles. The title compound is circled in Figure 4 and fits the trend as well. It is of interest to note the unique species located at the center of the graph — pentane-1,5-diaminium bis(oxalato)tin(II) — the only one showing four equal Sn−O bonds (2.21 Å) and four equal O−Sn−O bond angles (120°).[55]

$Sn(Q^T)_2$ (**2**) reacts with methyl iodide or ethyl iodide to afford $[SnMeI(Q^T)_2]$ (**16**) and $[SnEtI(Q^T)_2]$ (**17**), respectively (Scheme 2). Compounds **16** and **17** are air- and moisture-stable, and soluble in DMSO, acetone, aromatic and chlorohydrocarbon solvents, where they are non-electrolytes. Their IR spectra exhibit new bands in the range 500−600 cm^{-1} due to ν(Sn−C) and below 250 cm^{-1} caused by ν(Sn−I). Their ^1H NMR spectra show a multiplicity of broad resonances in accordance with the presence of several isomers in solution, as previously found for $SnRCl(Q)_2$-type derivatives.[52,56,57] Accordingly, the resonances in the ^{13}C NMR spectra are very broad and in the ^{119}Sn NMR spectra four (**17**) and five absorptions (**16**) are found in the range $\delta = -400$ to -700 ppm.[52,56,57]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

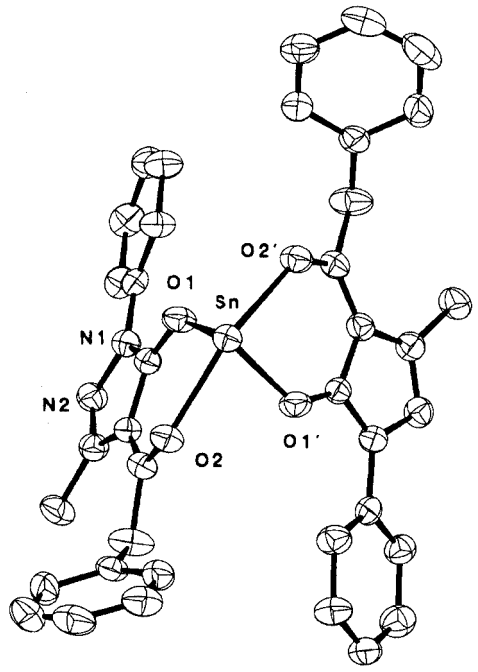

Figure 3. X-ray molecular structure of $Sn(Q^L)_2$ (**6**)

Compound **2** also reacts with $Cr(CO)_6$ in toluene to afford, upon irradiation, the novel derivative $[Cr(CO)_5Sn(Q^T)_2]$ (**18**; Scheme 2). Derivative **18** is the first example of a bis(acylpyrazolonato)tin(II) fragment acting as a Lewis base able to replace a CO ligand by donation of the lone pair to a $Cr(CO)_5$ fragment. This compound is stable in air and soluble in several organic solvents like DMSO, acetone, alcohols, aromatics and chlorohydrocarbons.

The IR spectrum of **18** shows several absorption bands in the metal−carbonyl stretching region at $\tilde{\nu}$ = 2059, 1947 and 1880 cm^{-1}. The second band is more intense than the others, in accordance with "local" C_{4v} symmetry for the $Cr(CO)_5$ fragment.[58] The ν(C=O) band of the acylpyrazolonato undergoes an upfield shift from $\tilde{\nu}$ = 1605 to 1610 cm^{-1} and in the far-IR region the ν(Sn−O) band shows a small downfield shift, indicating a lowering of the Sn−O bond strength.

The ^1H and ^{13}C NMR spectra of derivative **18** show one set of broad resonances, where the acyl fragment is shielded with respect to starting derivative **2**. The observed NMR and IR trends can be ascribed to the presence of back-donation Cr→Sn (*d*→*d*) π-bonding, as previously hypothesized for similar compounds.[59]

Scheme 2

By interaction of selected HQ proligands (HQ = HQ^B, HQ^T, HQ^W, HQ^D) with lead(II) nitrate in methanol, and in the presence of sodium methoxide, the air- and moisture-stable derivatives PbQ_2 **19**–**22** formed as precipitates (Scheme 1). They are pale-yellow solids with sharp melting points, soluble in DMSO, acetone and chlorohydrocarbon solvents, where they are non-electrolytes. Molecular weight determinations carried out in chloroform suggest aggregation in solution, as the experimental molecular weight is always higher than that expected for monomeric compounds. This observation is supported by the crystallographic results described below.

The IR and NMR spectra have features similar to those found in the tin(II) species. Interestingly, the number of signals and the chemical shift at room temperature do not seem to depend on the nature of the metal. However the low-temperature ^{1}H NMR spectrum of **20** suggests that there is no fluxionality at 183 K, as three sharp signals are seen for each equivalent group of protons.

The reactivity of derivative Pb(Q^D)$_2$ (**22**) was tested toward 1,10-phenanthroline, giving **23**. The ^{1}H NMR spectrum of **23** shows all the expected resonances for phen and for the pyrazolone protons in a 1:2 ratio. The ^{13}C NMR spectrum further confirms the existence and stability of compound **23** in chlorohydrocarbon solution, with no evidence of dissociation for either Q^D and phen ligands. However, the crystalline stability of **23** is lower than that of **19**–**22**. In fact, it has no sharp melting point and its decomposition starts at 156 °C, in accordance with a weak interaction of the {Pb(Q^D)$_2$} moiety with phen, probably due to the presence of the lead(II) lone pair.

Attempts to synthesize phen derivatives of lead(II) and tin(II) with other acylpyrazolonates failed, even under extreme reaction conditions, such as prolonged stirring and warming. Since these acylpyrazolonates contain bulky R^1 and R^4 groups (different from methyl in Q^D) we conclude that steric factors explain such a difference.

The ESI mass spectra of **21** and **22** exhibit peaks not only due to [H$_2$Q]$^+$ and [Na(HQ)]$^+$, but also due to [Pb(HQ)$_2$Cl]$^+$ and [NaPb$_2$(Q)$_4$]$^+$ species. The latter is particularly interesting since it suggests the possibility of aggregation between two different mononuclear lead species in solution. More surprisingly, the ESI mass spectrum of **23** exhibits a peak due to [Pb(Q)(phen)]$^+$, which is indicative of a strong interaction between Pb(Q)$_2$ and phen.

A crystallographic study of bis(3-methyl-1-phenyl-4-pivaloylpyrazolon-5-ato)lead(II), Pb(Q^B)$_2$ (**19**), shows no imposed symmetry (Figure 5). Table 6 shows selected structural data for this species. Similar to the tin compound **6**, each metal atom is bound to four oxygen atoms from the two Q^B ligands. The general pattern seen in metal 4-acyl-5-pyrazolonate compounds is also followed as the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Pb1−O1[O51](pyrazolonato) bond length is 2.274(6) Å [2.324(7) Å] and the Pb1−O2[O52](acyl) bond length is 2.56(1) Å [2.38(1) Å]; that is, the former is shorter. Both Q^B ligands are in a *syn* configuration — equivalent ligand substituents (for instance R^1 = Ph) are on the same side, whereas in the tin compound **6** they are opposite (*anti* configuration).

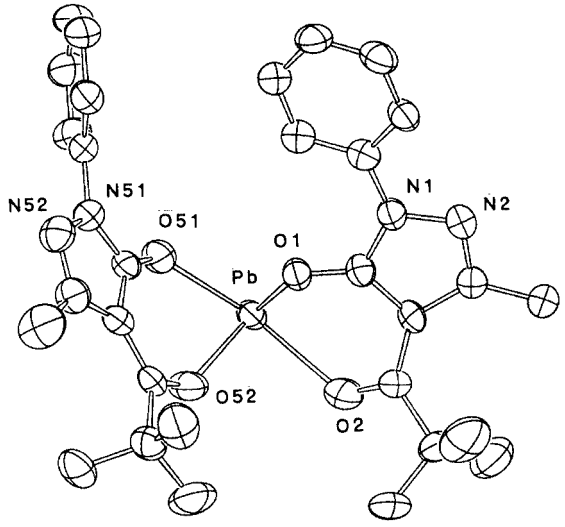

Figure 5. Atomic arrangement of the moiety $Pb(Q^B)_2$ (**19**)

The four oxygen atoms are located on one side of the lead atom, suggesting the presence of a stereochemically active lone pair as for **6**. However, unlike compound **6**, there are two additional atoms bound to the metal atom: N2′ [Pb1−N2′ = 2.961(8) Å], which belongs to the neighboring crystallographic unit (−*x*, −*y* + 2, −*z* + 1), and O51′′ [Pb1−O51′′ = 3.055(7) Å] of the unit (−*x* + 1, −*y* + 2, −*z* + 1; see Figure 6). These lead interactions suggest the metal coordination number to be six with a distorted octahedral geometry, because of departure from ideal *cis* angles of 90° [range from 72.1(3)° (O1−Pb1−O2) to 116.1(2)° (N2′−Pb1−O51′′)]. The latter wide *cis* bond angle and the corresponding long Pb−N2′ and Pb−O51′′ lengths indicate the presence of a stereochemically active lone pair in that area. Another factor contributing to octahedral distortion is the bent chelate ring (containing O1 and O2) that allows its attached pyrazole ring to stack with the pyrazole ring linked to another unit (of O1′ and O2′) at about 3.6 Å.

The linear polymeric structure propagates along the *a* axis in *anti*-parallel chains, and the hydrophobic region is located near the central area of the unit cell.

Bis(4-*tert*-butyl-3-methyl-1-phenylacetylpyrazolon-5-ato)lead(II), $Pb(Q^T)_2$ (**20**), was also studied using X-ray crystallographic methods (Figure 7) and shows no imposed symmetry on the molecular structure. Selected bond lengths and angles can be found in Table 7. As in compound **19**, a number of intermolecular interactions contribute to make the geometry of the lead atom distorted octahedral (Figure 8). They are different than in **19** and involve the nitrogen atom of one unit [Pb−N2′ = 3.121(6) Å] and a phenyl ring of another unit, with Pb−C bond lengths in the range 3.57−3.70 Å. The latter interaction is similar to that of bis(tetraphenyldithioimidodiphosphinato)lead(II), where the Pb−phenyl ring distances are in the range 3.07−3.31 Å.[60]

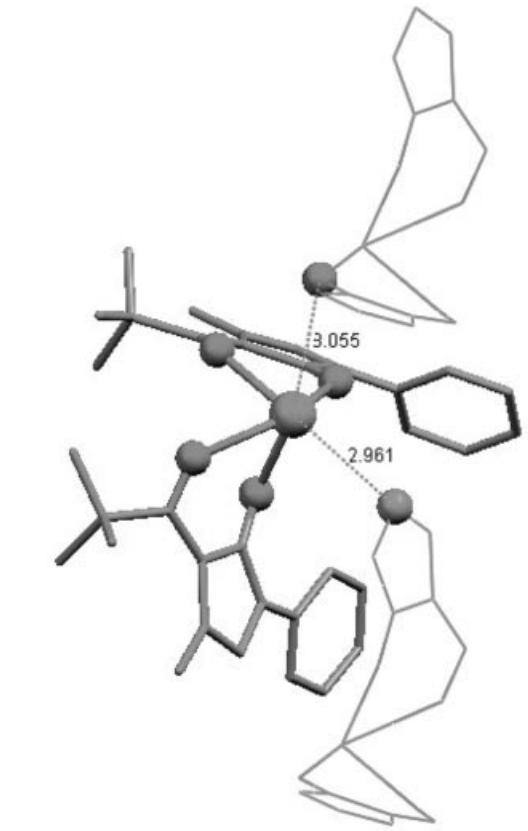

Figure 6. Whole coordination sphere for the polymeric chain of $Pb(Q^B)_2$ (**19**); Pb and its 6 bound atoms are depicted in ball-and-stick style, the 2 Q^B ligands bound at short distances as capped stick (shown also in Figure 5), and the 2 ligands bound at longer distances as wire frame [Pb−N2′ = 2.961(8) Å and Pb−O51′′ = 3.055(7) Å]

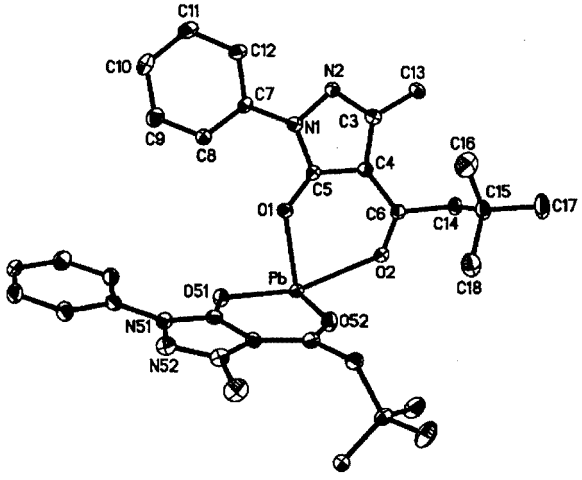

Figure 7. Atomic arrangement of the moiety $Pb(Q^T)_2$ (**20**)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

A similar interaction is present in $[Pb(1,2\text{-}C_6H_4Me_2)_2\text{-}(AlCl_4)_2]$ where the Pb−C(phenyl) distances are in the range 3.30−4.48 Å.[61] Therefore, compound **20** shows the best η^6-Pb−phenyl interaction.

As mentioned previously, 4-acyl-5-pyrazolonato ligands typically form a short metal−O(pyrazolonato) bond and a long metal−O(acyl) bond. In $Pb(Q^T)_2$ one ligand is consistent with this pattern as the Pb−O51(pyrazolonato) bond is 2.280(7) Å and the Pb−O52(acyl) bond is 2.458(7) Å. However, the other ligand is not since the Pb−O1(pyrazolonato) bond of 2.379(9) Å is longer than the Pb−O2(acyl) bond of 2.360(8) Å. This longer Pb−O(pyrazolonato) bond can be explained as this ligand contains the phenyl ring that interacts with the lead atom in a neighboring unit.

An investigation of "PbO_4" complexes in the CSD database shows that they have different packing arrangements with neighboring molecules in the solid. Only one "PbO_4" species, bis(dipivaloylmethanato)lead(II), has no interactions with the neighboring units, much like the "SnO_4" compounds described above, with both chelating ligands on the lead atom bent away from the stereochemically active lone pair.[62][63] The two bulky *t*Bu substituents on the symmetrical β-diketonato ligand probably prevent Pb from having a high coordination number. In general, the intermolecular interactions seen in other "PbO_4" compounds are not found in the similar "SnO_4" species. This is presumably due to the larger covalent radius of Pb allowing for a higher coordination number. Lead commonly interacts with nitrogen and oxygen ligands. For instance, the lead atom in bis(4-butanoyl-3-methyl-1-phenylpyrazolonato)lead(II), besides covalent bonds to the four oxygen atoms of the two chelating ligands, shows intermolecular interactions with lone pairs from two N atoms of neighboring units.[64] This interaction gives the lead atom a distorted octahedral geometry and allows for the molecules in the crystal to arrange in a polymeric chain. Another example is in *catena*-[bis(μ_2-1,1,1-trifluoro-5,5-dimethylhexane-2,4-dionato-*O*,*O*′)lead(II), where each Pb atom interacts with two oxygen atoms from neighboring units,[65] leading to a "PbO_6" system. The structure of bis(4-acetyl-3-methyl-1-phenylpyrazolon-5-ato)lead(II) is a trinuclear species that contains intermolecular interactions with two nitrogen atoms from a second ligand, and one oxygen atom from a third ligand.[64] Another variation is the formation of dinuclear compounds instead of polynuclear chains, as in bis(2,2-dimethyl-6,6,7,7,8,8-heptafluorooctane-3,5-dionato)lead(II) where the lead atoms stabilize a skewed geometry.[63]

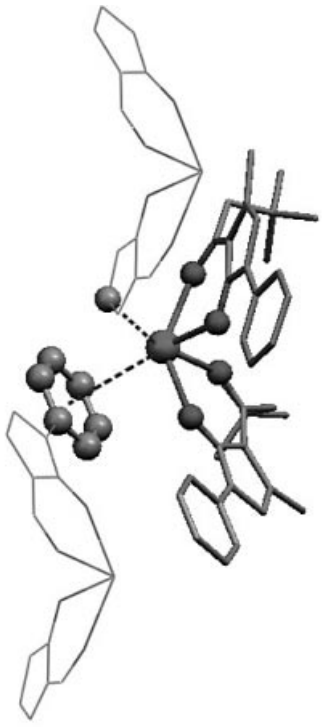

Figure 8. Whole coordination sphere for the polymeric chain of $Pb(Q^T)_2$ (**20**); Pb and its bound atoms are depicted in ball-and-stick style, the 2 Q^T ligands bound at short distances as capped stick (also shown in Figure 7), and the 2 ligands bound at longer distances as wire frame [Pb−N2′ = 3.121(6) Å and Pb−Ph′′ range = 3.55−3.70 Å]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In summary, Pb compounds **19** and **20** both contain a lead atom having coordination number 6 and interacting with atoms in neighboring units. Compound **19** is novel because this chain-like structure has a central PbQ_2 unit interacting on one side with a nitrogen atom from a second unit, and on the other side with an oxygen atom from a third unit; compound **20** shows an intermolecular interaction between the lead atom and all six C atoms of a phenyl ring.

Conclusion

4-Acyl-5-pyrazolones, HQ, form MQ_2 compounds for M = Sn^{II} and Pb^{II} that differ markedly in their structural features. Both Q ligands have an *anti* configuration on the tin atom and *syn* configuration on the lead atom. The tin compounds are mononuclear and have a trigonal-bipyramidal metal geometry, distorted by the metal lone pair located in the equatorial plane. The lead compounds show an increased coordination number, forming polynuclear compounds of varied structure. In this work a Pb−arene interaction has been found in $Pb(Q^T)_2$, whereas there is no such interaction in $Pb(Q^B)_2$. Such a dramatic structural change probably arises due to steric reasons, as the addition of a CH_2 moiety in the peripheral area of the Q^B acyl group makes this ligand equal to Q^T.

Ligand substitution is important if additional ligands are to be included in the coordination sphere of lead(II). Thus, the only PbQ_2 derivative able to react with phen is with Q = Q^D, a ligand containing R^1 = Me, in contrast with those that are not reactive and having R^1 = Ph.

The lone pair in SnQ_2 derivatives can be donated to, for instance, carbonylchromium derivatives stabilizing a Cr−Sn bond.

Experimental Section

General Remarks: 3-Methyl-1-phenylpyrazolon-5-one, *N*-methylhydrazine, *N*-(4-nitrophenyl)hydrazine, ethyl acetoacetate, ethyl benzoyl acetate, potassium hydroxide, sodium methoxide, tin(II) dichloride and the acyl chlorides employed (benzoyl chloride, acetyl chloride, cyclohexanecarbonyl chloride, pivaloyl chloride, *tert*-butylacetyl chloride, phenylacetyl chloride, diphenylacetyl chloride, propionyl chloride, ethanoyl chloride, 4-*tert*-butylbenzoyl chloride) were purchased from Aldrich (Milwaukee) and used as received. Solvent evaporations were always carried out under vacuum by using a rotary evaporator. The samples for microanalysis were dried in vacuo to constant weight (20 °C, ca. 0.1 Torr). All syntheses were carried out under nitrogen. Hydrocarbon solvents were dried by distillation from sodium/potassium; dichloromethane was distilled from calcium hydride. All solvents were degassed with dry nitrogen prior to use. Elemental analyses (C, H, N) were performed in-house with a Fisons Instruments 1108 CHNS-O Elemental Analyser. IR spectra were recorded from 4000 to 200 cm^{-1} with a Perkin−Elmer System 2000 FT-IR instrument. ^1H, $^{13}C\{^1H\}$, $^{19}F\{^1H\}$ and $^{119}Sn\{^1H\}$ NMR spectra were recorded with a VXR-300 Varian instrument (300 MHz for ^1H, 75 MHz for ^{13}C, 282.2 MHz for ^{19}F and 111.8 MHz for ^{119}Sn). The chemical shifts (δ) are reported in parts per million (ppm) from $SiMe_4$ (^1H and ^{13}C), $CFCl_3$ (^{19}F) or $SnMe_4$ (^{119}Sn); relative intensity (%) in square brackets. Melting points are uncorrected and were measured with an SMP3 Stuart scientific instrument and with a capillary apparatus. The electrical conductivity measurements (Λ_m, reported as $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$) of dichloromethane or DMSO solutions of complexes **1**−**23** were recorded with a Crison CDTM 522 conductimeter at room temperature. Molecular weight determinations (MW) were performed at 40 °C with a Knauer KNA0280 vapour pressure osmometer calibrated with benzil; the solvent was Baker Analysed Spectrophotometric grade chloroform. The results were reproducible to ±2%. ^{119m}Sn Mössbauer spectra were recorded on solid samples at liquid nitrogen temperature by using a conventional constant acceleration spectrometer, coupled with a multichannel analyser [a.e.n., Ponteranica (BG), Italy] equipped with a cryostat Cryo (RIAL, Parma, Italy). A $Ca^{119}SnO_3$ Mössbauer source, 10 mCi (from Ritverc, St. Petersburg, Russia) moving at room temperature with constant acceleration in a triangular waveform was used. The velocity calibration was made using a ^{57}Co Mössbauer source, 10 mCi, and an iron foil as absorber (from Ritverc, St. Petersburg, Russia). The 4-acyl-5-pyrazolones (here indicated as QH) were synthesized by the procedure reported by Jensen[66] or by our previous methods.[30−40]

$Sn(Q^C)_2$ (1): Potassium hydroxide (0.112 g, 2.0 mmol) and tin(II) dichloride (0.190 g, 1 mmol) were added to a methanol solution (30 mL) of Q^CH (0.566 g, 2 mmol). A colorless precipitate formed immediately. After 1 h, it was filtered off, washed with methanol (10 mL) and recrystallized from chloroform/methanol. Yield 0.603 g (88%). M.p. 166−169 °C. $C_{34}H_{38}N_4O_4Sn$ (685.4): calcd. C 59.58, H 5.59, N 8.17; found C 59.33, H 5.83, N 8.23. Λ_m (CH_2Cl_2, 1 × 10^{-3} M) = 0.1. MW ($CHCl_3$, c = 1.5 × 10^{-3} mol/L): 668. IR (nujol): $\tilde{\nu}$ = 1604 vs, 1593 vs ν(C=O), 451 s, 399 s ν(Sn−O) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.20−1.90 (m), 2.78 [t, 11 H, C(=O)-C_6H_{11}], 2.28 (s, 3 H, 3-CH_3), 7.15 (t), 7.38 (t), 7.72 (d, 5 H, NC_6H_5) ppm. ^{13}C NMR ($CDCl_3$): δ = 17.1 (s, 3-CH_3), 26.0, 26.1, 29.7, 46.6 [s, C(=O)C_6H_{11}], 103.9 (s, C-4), 121.5, 125.8, 128.7, 138.2 (s, C_{arom}), 148.1 (s, C-3), 161.6 (s, C-5), 199.9 (s, CO) ppm. ^{119}Sn NMR ($CDCl_3$): δ = −727.5 ppm.

$Sn(Q^T)_2$ (2): Compound **2** was synthesized as described for compound **1**. Yield 0.622 g (94%). M.p. 140−142 °C. $C_{32}H_{38}N_4O_4Sn$ (661.4): calcd. C 58.11, H 5.79, N 8.47; found C 58.25, H 5.65, N 8.49. Λ_m (CH_2Cl_2, 1 × 10^{-3} M) = 0.2. MW ($CHCl_3$, c = 1.6 × 10^{-3} mol/L): 659. Sn(Q^H)$_2$ (15): Compound **15** was synthesized as described for compound **1**. Yield 0.562 g (82%). M.p. 267−270 °C. $C_{26}H_{10}F_6N_4O_4Sn$ (685.1): calcd. C 45.58, H 2.94, N 8.18; found C 45.45, H 2.88, N 8.18. Λ_m (CH_2Cl_2, 1×10^{-3} M) = 0.1. Λ_m (DMSO, 1×10^{-3} M) = 11.1. MW ($CHCl_3$, $c = 1.8 \times 10^{-3}$ mol/L): 670. IR (nujol): $\tilde{\nu}$ = 1620 s, 1607 s ν(C=O), 444 s, 438 m, 404 m ν(Sn−O) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 2.15 (s, 3 H, 3-CH_3), 2.31 [s, 3 H, C(=O)CH_3] 7.58 (d), 7.95 (d, 4 H, $NC_6H_4CF_3$) ppm. ^{13}C NMR ($CDCl_3$): δ = 16.8 (s, 3-CH_3), 27.7 [s, C(=O)CH_3], 104.5 (s, C-4), 120.2, 125.7, 125.8, 138.2 (s, C_{arom}), 148.2 (s, C-3), 162.4 (s, C-5), 192.2 (s, CO) ppm; CF_3 signal not observed. ^{19}F NMR ($CDCl_3$): δ = −62.7 ppm. ^{119}Sn NMR ($CDCl_3$): δ = −741.9 ppm.

SnMeI(Q^T)$_2$ (16): Compound **2** (0.661 g, 1 mmol) was dissolved in an excess of methyl iodide (30 mL). The mixture was stirred under reflux for 4 d. Removal of the unconverted methyl iodide under reduced pressure left a solid residue, which was recrystallized from chloroform/*n*-hexane and shown to be compound **16**. Yield 0.755 g (94%). M.p. 123−125 °C. $C_{33}H_{41}IN_4O_4Sn$ (803.3): calcd. C 49.34, H 5.14, N 6.97; found C 49.68, H 5.25, N 7.06. Λ_m (CH_2Cl_2, 1×10^{-3} M) = 0.3. IR (nujol): $\tilde{\nu}$ = 1600 vs, 1581 vs ν(C=O), 552 sh, 542 m ν(Sn−C), 470 s, 392 m ν(Sn−O), 225 s br. ν(Sn−I) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 0.95 (s), 1.00 (s), 1.14 (s), 1.18 [s, 18 H, C(=O)$CH_2C(CH_3)_3$], 1.35 (s, $^2J_{Sn,H}$ = 116.8 Hz), 1.48 (s, $^2J_{Sn,H}$ = 118.0 Hz), (s, 3 H, $SnCH_3$), 2.45 (s), 2.49 (s), 2.55 (s, 6 H, -3CH_3), 2.64 (s), 2.67 (s), 2.68 [s, 4 H, C(=O)$CH_2C(CH_3)_3$], 7.09 (br. m), 7.30 (br. m), 7.49 (br. t), 7.57 (br. m), 7.86 (br. d), 8.04 (br. d, 10 H, NC_6H_5) ppm. ^{13}C NMR ($CDCl_3$): δ = 9.9 (br. s, $SnCH_3$), 17.9 (br. s, 3-CH_3), 30.3 [br. s, C(=O)$CH_2C(CH_3)_3$], 33.0 [br. s, C(=O)-$CH_2C(CH_3)_3$], 50.5 [br. s, C(=O)$CH_2C(CH_3)_3$], 106.9 (br. s, C-4), 120.5, 121.3, 121.8, 126.5, 129.0, 137.3 (br. s, C_{arom}), 149.2 (br. s, C-3), 162.2 (br. s, C-5), 196.3 (br. s, CO) ppm. ^{119}Sn NMR ($CDCl_3$): δ = −496.4, −652.2, −663.3, −668.5, −677.2 ppm.

SnEtI(Q^T)$_2$ (17): Compound **17** was synthesized as for compound **16**, but with ethyl iodide. Yield 0.719 g (88%). M.p. 134−137 °C. $C_{34}H_{43}IN_4O_4Sn$ (817.3): calcd. C 49.96, H 5.30, N 6.85; found C 50.03, H 5.45, N 6.90. Λ_m (CH_2Cl_2, 1×10^{-3} M) = 0.5. IR (nujol): $\tilde{\nu}$ = 1600 vs, 1583 vs ν(C=O), 555 m ν(Sn−C), 465 m, 396 w ν(Sn−O), 220 s br. ν(Sn−I) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 0.94 (s), 1.00 (s), 1.02 (s), 1.16 [s, 18 H, C(=O)$CH_2C(CH_3)_3$], 1.24 (t), 1.28 (t), 2.62 (m), 2.67 (m, 5 H, $SnCH_2CH_3$), 2.37 (br. s, 6 H, 3-CH_3), 2.49 (br. s, 4 H, C(=O)$CH_2C(CH_3)_3$], 7.12 (br. m), 7.30 (br. m), 7.45 (br. t), 7.60 (br. m), 7.88 (br. d), 8.04 (br. d, 10 H, NC_6H_5) ppm. ^{13}C NMR ($CDCl_3$): δ = 10.5, 32.9 (br. s, $SnCH_2CH_3$), 17.9 (br. s, 3-CH_3), 30.4 [br. s, C(=O)$CH_2C(CH_3)_3$], 32.1 [br. s, C(=O)-$CH_2C(CH_3)_3$], 50.6 [br. s, C(=O)$CH_2C(CH_3)_3$], 107.0 (br. s, C-4), 120.5, 121.2, 121.8, 126.4, 129.0, 137.4 (br. s, C_{arom}), 149.1 (br. s, C-3), 162.5 (br. s, C-5), 196.5 (br. s, CO) ppm. ^{119}Sn NMR ($CDCl_3$): δ = −614.1, −626.1, −631.0, −639.5 ppm.

Cr(CO)$_5$Sn(Q^T)$_2$ (18): Compound **2** (0.661 g, 1 mmol) was dissolved in a toluene solution (30 mL) of hexacarbonylchromium (0.220 g, 1 mmol). The mixture was irradiated and stirred under reflux for 4 d. Removal of the solvent under reduced pressure left a solid residue, which was recrystallized from chloroform/*n*-hexane and shown to be compound **18**. Yield 0.751 g (88%). M.p. 73−76 °C. $C_{37}H_{38}CrN_4O_9Sn$ (853.4): calcd. C 52.07, H 4.49, N 6.57; found C 52.45, H 4.61, N 6.88. Λ_m (CH_2Cl_2, 1×10^{-3} M) = 0.4. IR (nujol): $\tilde{\nu}$ = 2059 m, 1947 s, 1880 m ν(Cr−C≡O), 1610 vs, 1595 vs ν(C=O), 440 m, 433 m, 392 w ν(Sn−O) cm^{-1}. ^{1}H NMR ([D$_6$]benzene): δ = 1.05 [s, 9 H, C(=O)$CH_2C(CH_3)_3$], 2.20 (s, 3 H, 3-CH_3), 2.30 [s, 2 H, C(=O)$CH_2C(CH_3)_3$], 7.02 (t), 7.21 (t), 8.25 (d, 5 H, NC_6H_5) ppm. ^{13}C NMR ([D$_6$]benzene): δ = 16.1 (s, 3-CH_3), 30.0 [s, C(=O)$CH_2C(CH_3)_3$], 31.9 [s, C(=O)$CH_2C(CH_3)_3$], 49.6 [s, C(=O)$CH_2C(CH_3)_3$], 105.8 (s, C-4), 120.1, 126.1, 129.2, 138.3 (s, C_{arom}), 147.0 (s, C-3), 194.4 (s, CO) ppm; C-5 and Cr(*C*O) signals not observed. ^{119}Sn NMR ([D$_6$]benzene): δ = −377.2 ppm.

Pb(Q^B)$_2$ (19): Compound **19** was synthesized as described for compound **20** (see below). Yield 0.567 g (76%). M.p. 248−250 °C. $C_{30}H_{34}N_4O_4Pb$ (721.8): calcd. C 49.92, H 4.75, N 7.76; found C 49.62, H 4.90, N 7.77. Λ_m (CH_2Cl_2, 1×10^{-3} M) = 0.5. MW ($CHCl_3$, $c = 1.6 \times 10^{-3}$ mol/L): 950. IR (nujol): $\tilde{\nu}$ = 1600 vs, 1595 vs ν(C=O), 469 s, 434 m 412 vs, 386s ν(Pb−O) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 1.23 [s, 9 H, C(=O)$C(CH_3)_3$], 2.36 (3 H, 3-CH_3), 7.13 (t), 7.30 (t), 7.74 (d, 5 H, NC_6H_5) ppm. ^{13}C NMR ($CDCl_3$): δ = 20.4 (s, 3-CH_3), 28.3 [s, C(=O)$C(CH_3)_3$], 33.4 [s, C(=O)$C(CH_3)_3$], 104.8 (s, C-4), 121.9, 125.8, 128.9, 138.6 (s, C_{arom}), 145.5 (s, C-3), 163.6 (s, C-5), 204.6 (s, CO) ppm.

Pb(Q^T)$_2$ (20): Potassium hydroxide (0.112 g, 2.0 mmol) and $Pb(NO_3)_2$ (0.331 g, 1 mmol) were added to a methanol solution (30 mL) of Q^{T}H (0.566 g, 2 mmol). A colourless precipitate formed immediately. After 1 h, it was filtered off, washed with methanol (10 mL) and recrystallized from chloroform/methanol. Yield 0.562 g (75%). M.p. 224−227 °C. $C_{32}H_{38}N_4O_4Pb$ (749.9): calcd. C 51.26, H 5.18, N 7.47; found C 51.05, H 5.35, N 7.46. Λ_m (CH_2Cl_2, 1×10^{-3} M) = 0.4. MW ($CHCl_3$, $c = 1.8 \times 10^{-3}$ mol/L): 842. IR (nujol): $\tilde{\nu}$ = 1600 vs, 1592 vs ν(C=O), 441 vs, 411 w, 397 m ν(Pb−O) cm^{-1}. ^{1}H NMR ($CDCl_3$, 293 K): δ = 1.02 [s, 9 H, C(=O)$CH_2C(CH_3)_3$], 2.27 (s, 3 H, 3-CH_3), 2.53 [s, 2 H, C(=O)-$CH_2C(CH_3)_3$], 7.14 (t), 7.30 (t), 7.77 (d, 5 H, NC_6H_5) ppm. ^{1}H NMR (CD_2Cl_2, 293 K): δ = 1.05 [s, 9 H, C(=O)$CH_2C(CH_3)_3$], 2.32 (s, 3 H, 3-CH_3), 2.57 [s, 2 H, C(=O)$CH_2C(CH_3)_3$], 7.16 (t), 7.29 (t), 7.81 (d, 5 H, NC_6H_5) ppm. ^{1}H NMR (CD_2Cl_2, 193 K): δ = 0.93 (s). 1.05 [s, 9 H, C(=O)$CH_2C(CH_3)_3$], 1.62 (s), 1.75 (s), 1.87 (s, 3 H, 3-CH_3), 2.36 (s), 2.42 (s), 2.58 [s, 2 H, C(=O)$CH_2C(CH_3)_3$], 7.12 (t), 7.26 (t), 7.44 (t), 7.78 (d), 7.81 (d, 5 H, NC_6H_5) ppm. ^{13}C NMR ($CDCl_3$): δ = 18.4 (s, 3-CH_3), 30.4 [s, C(=O)$CH_2C(CH_3)_3$], 32.2 [s, C(=O)$CH_2C(CH_3)_3$], 51.0 [s, C(=O)$CH_2C(CH_3)_3$], 108.1 (s, C-4), 121.7, 125.7, 129.0, 138.5 (s, C_{arom}), 148.0 (s, C-3), 162.3 (s, C-5), 196.0 (s, CO) ppm.

Pb(Q^W)$_2$ (21): Compound **21** was synthesized as described for compound **20**. Yield 0.769 g (88%). M.p. 251−253 °C. $C_{42}H_{42}N_4O_4Pb$ (874.0): calcd. C 57.72, H 4.84, N 6.41; found C 57.43, H 5.01, N 6.47. Λ_m (CH_2Cl_2, 1×10^{-3} M) = 0.7. MW ($CHCl_3$, $c = 1.4 \times 10^{-3}$ mol/L): 1042. IR (nujol): $\tilde{\nu}$ = 1605 vs, 1595 vs ν(C=O), 473 m, 469 m, 412 m, 382 vs ν(Pb−O) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 1.35 [s, 9 H, C(=O)$C_6H_5C(CH_3)_3$], 1.64 (s, 3 H, 3-CH_3), 7.10 (t), 7.18 (t), 7.30 (d), 7.42 (d), 7.76 [d, 9 H, NC_6H_5 and C(=O)-

$C_6H_5C(CH_3)_3$] ppm. ^{13}C NMR ($CDCl_3$): δ = 16.6 (s, 3-CH_3), 31.4 [s, C(=O)$C_6H_5C(CH_3)_3$], 35.2 [s, C(=O)$C_6H_5C(CH_3)_3$], 106.2 (s, C-4),121.3, 125.3, 125.6, 128.4, 128.9, 138.5 (s, C_{arom}), 149.1 (s, C-3), 163.0 (s, C-5), 191.7 (s, CO) ppm.

$Pb(Q^D)_2$ (22): Compound **22** can be synthesized as described for compound **20**, but also as follows: $Pb(OOCCH_3)_2 \cdot 3H_2O$ (0.379 g, 1 mmol) was added to a water solution (30 mL) of Q^DH (0.308 g, 2 mmol). A colorless precipitate formed immediately and this was filtered, washed with methanol (10 mL), dried to constant weight under reduced pressure and recrystallized from chloroform/diethyl ether. Yield 0.345 g (65%). M.p. 214−216 °C. $C_{14}H_{18}N_4O_4Pb$ (531.7): calcd. C 32.75, H 3.52, N 10.91; found C 32.43, H 3.66, N 10.72. Λ_m (CH_2Cl_2, 1 × 10^{-3} M) = 0.4. MW ($CHCl_3$, c = 1.8 × 10^{-3} mol/L): 763. IR (nujol): $\tilde{\nu}$ = 1586 vs ν(C=O), 454 vs, 388 vs, 373 s ν(Pb−O) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.30 (s, 3 H, 3-CH_3), 2.40 [s, 3 H, C(=O)CH_3], 3.28 (s, 3 H, NCH_3) ppm. ^{13}C NMR ($CDCl_3$): δ = 17.4 (s, 3-CH_3), 28.1 (s, NCH_3), 31.5 [s, C(=O)CH_3], 105.9 (s, C-4), 147.1 (s, C-3), 161.8 (s, C-5), 192.8 (s, CO) ppm.

$Pb(Q^D)_2$(phen) (23): Compound **22** (0.532 g, 1 mmol) and phen (0.180 g, 1 mmol) were dissolved in benzene (30 mL) and the clear solution stirred at room temperature for 2 h. The solvent was then removed and the residue treated with diethyl ether (20 mL), affording a colorless precipitate, which was filtered off, dried to constant weight under reduced pressure and recrystallized from chloroform/*n*-hexane. Yield 0.541 g (78%). M.p. 156 °C (dec.). $C_{26}H_{26}N_4O_4Pb$ (693.7): calcd. C 45.02, H 3.78, N 12.11; found C 44.82, H 3.96, N 11.87. Λ_m (CH_2Cl_2, 1 × 10^{-3} M) = 0.3. MW ($CHCl_3$, c = 1.8 × 10^{-3} mol/L): 640. IR (nujol): $\tilde{\nu}$ = 1590 vs ν(C=O), 446 vs, 393 m, 374 s ν(Pb−O), 291 m ν(Pb−N) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.29 (s, 6 H, 3-CH_3), 2.32 [s, 6 H, C(=O)CH_3], 3.21 (s, 6 H, NCH_3), 7.73 (dd), 7.85 (s), 8.33 (dd), 9.38 (dd, 8 H, CH_{phen}) ppm. ^{13}C NMR ($CDCl_3$): δ = 17.3 (s, 3-CH_3), 28.2 (s, NCH_3), 31.0 [s, C(=O)CH_3], 105.5 (s, C-4), 123.7, 126.7, 129.3, 136.8, 146.5, 150.2 (s, C_{phen}), 145.8 (s, C-3), 162.6 (s, C-5), 191.8 (s, CO) ppm.

X-ray Crystallographic Study: Experimental data for compounds **6**, **19** and **20** can be found in Table 8. The crystal of bis(3-methyl-4-phenyl-1-phenylacetylpyrazolon-5-ato)tin(II) (**6**) decayed slightly but no decay correction was applied to the data. For crystals of bis(3-methyl-1-phenyl-4-pivaloylpyrazolon-5-ato)lead(II) (**19**) and bis(4-*tert*-butyl-3-methyl-1-phenylacetylpyrazolon-5-ato)lead(II) (**20**) no decay was seen. The data for compounds **6** and **19** were collected with a Syntex $P2_1$ diffractometer equipped with a graphite-monochromated beam at 298 K. The heavy-atom method in CAOS was used to solve both structures.[67] Once the heavy-atom peak had been located in the Patterson map, a Fourier synthesis was performed to locate the other non-hydrogen atoms until all atoms were found. All non-hydrogen atoms were refined anisotropically until convergence. The hydrogen atoms were then placed at a fixed C−H bond length of 0.96 Å using a subroutine of CAOS, further refinement was applied with the H atoms riding on their attached atoms until convergence. Data were refined by full-matrix least-squares

procedures on *F*. The data for compound **20** were collected with a Bruker P4 diffractometer equipped with a SMART CCD detector at 243 K. Absorption correction was applied with SADABS. The structure was solved by direct methods and standard difference-map techniques, and was refined by full-matrix least-squares procedures on F^2 with SHELXTL (Version 6.10).[68] Hydrogen atoms were included in calculated positions. Difference electron density measurements showed no important residual electron density for all three structures. CCDC-233990 to -233992 (for **6**, **19**, and **20**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Our thanks go to the University of Camerino, University of Palermo, CNR, Rome, Fondazione CARIMA, Vassar College URSI program, for financial support, and Dr. Ged Parkin for use of the diffractometer.

Solid- and Solution-Phase Synthesis of a Library of Mixed-Metal Complexes

Katja Heinze*[a] and Juan D. Bueno Toro[a]

Keywords: Bridging ligands / Heterometallic complexes / Isomers / Group 6 elements / Solid-phase synthesis

A solid-phase synthesis protocol has been developed for the stepwise assembly of mixed-metal dinuclear complexes built from chromium, molybdenum and tungsten and a directional bridging ligand. Complexes with all nine possible metal combinations have been prepared on polystyrene/divinylbenzene copolymer employing a metal-complex-compatible silyl ether linker. Release of the metal complexes from the polymeric support is accomplished by fluoridolysis under mild conditions. The metal sequence in these complexes is precisely determined by the reaction sequence and is retained under the applied reaction conditions as shown by IR, NMR and UV/Vis spectroscopic analysis of the cleaved soluble products. Additionally, the same complex library has been prepared by conventional solution-phase synthesis to allow evaluation of the advantages and disadvantages of the solid-phase synthesis method.

Introduction

Monodisperse oligomers are essential for understanding the chemistry and the physics of polymeric organic and inorganic materials.[1] Several synthetic strategies have been developed for their synthesis — self-organisation processes, random syntheses followed by separation processes or step-by-step syntheses — all of which have advantages and disadvantages. Full control over chain length, end groups and building-block sequence can be achieved using a stepwise assembly of building blocks.

Although the step-by-step synthesis is straightforward, it becomes increasingly difficult for higher oligomers due to the purification steps needed. An elegant solution to this problem is synthesis on a solid support (solid-phase synthesis[2]). This synthetic method, introduced by R. B. Merrifield for the synthesis of peptides,[3] allows the purification of all intermediates by simple filtration. The development of new synthetic sequences which enable the (preferably combinatorial) solid-phase synthesis of non-natural, functionalised oligomeric compounds might aid the identification of synthetic oligomers with the capability of performing functions similar to those of peptides and proteins, for example catalysis, molecular recognition, signal transduction or conversion of chemical into mechanical energy.[2]

Organometallic compounds, however, have only recently been synthesised by this method,[4−17] and the solid-phase synthesis of oligometallic complexes, in particular, remains a challenge.[5,17] This is probably due to the fact that the metal−ligand bonds of organometallic building blocks are much more labile than typical bonds of organic molecules, and thus the required orthogonal stability and reactivity of the polymer−molecule bond and the connections between the building blocks is much more difficult to achieve for organometallic complexes than for organic molecules.

A system satisfying the above criteria consists of a silyl ether linker between the molecule and the polymer support, which is cleavable by fluoride ions,[18] and inert metal−isocyanide bonds between the organometallic building blocks.[19]

The solution and solid-phase synthesis of homometallic di- and trinuclear complexes with carbonylmolybdenum complexes as building blocks has been reported recently.[5] The extension of this synthetic strategy to assembling mixed-metal dinuclear complexes is reported in this contribution.

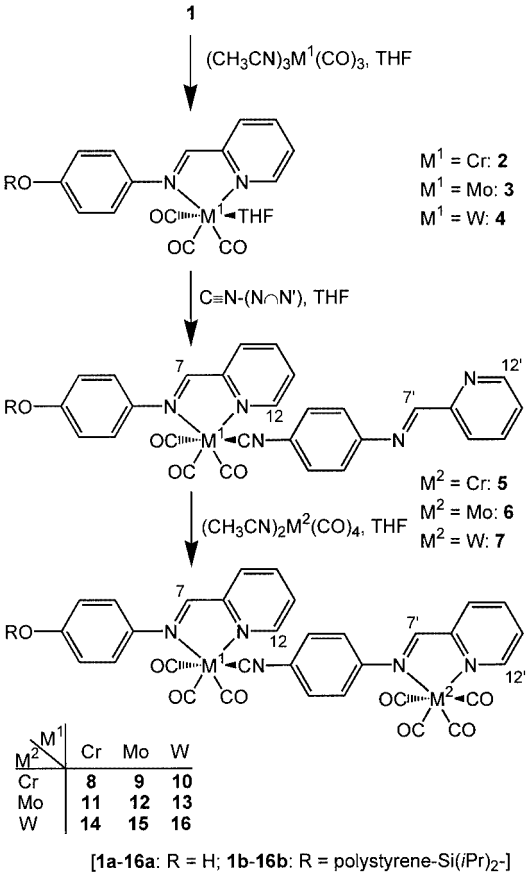
Results and Discussion

General Solution- and Solid-Phase Synthesis

The hydroxy-functionalised Schiff-base ligand **1a** was used as starting point for the stepwise assembly of mixed-metal complexes. For the solid-phase synthesis approach **1a** was attached to polystyrene/divinylbenzene copolymer by a silyl ether linker to give the immobilised ligand **1b** (Scheme 1).[4] The silyl ether allows the release of the final products of the solid-phase synthesis from the support by mild fluoridolysis.[4,5,18]

Addition of a suitable $\{M^1(CO)_3\}$ source (M^1 = Cr, Mo, W) to **1a** or **1b** furnished the reactive soluble or polymer-bound complexes **2a**−**4a** and **2b**−**4b**,[4], respectively (Scheme 2). These THF-containing complexes were subsequently treated with the bridging ligand (4-isocyanophenyl)(pyridin-2-ylmethylene)amine C≡N−(N∩N′)[19] to give the stable tricarbonyl isocyanide complexes **5a**−**7a** and **5b**−**7b**, respectively (Scheme 2). The potentially chelating diimine moiety of C≡N−(N∩N′) was finally coordinated to an $\{M^2(CO)_4\}$ fragment (M^2 = Cr, Mo, W) to give the dinuclear mixed-metal complexes **8a**−**16a** and **8b**−**16b**, respectively (Scheme 2). Each member of this "3 × 3 library" of mixed-metal complexes has been prepared by both solution- and solid-phase synthesis according to Scheme 2.



M^2 \ M^1	Cr	Mo	W
Cr	**8**	**9**	**10**
Mo	**11**	**12**	**13**
W	**14**	**15**	**16**

Scheme 2

All reactions in solution had to be performed under exact stoichiometric conditions to reduce the formation of side products such as X−(N∩N′)M(CO)$_4$ (X = CN, OH) or C≡N−(N∩N′)M(CO)$_3$C≡N−(N∩N′) which are difficult to remove after the synthesis of the dinuclear complexes (see Exp. Sect.).

Properties of the Soluble Complexes 5a−16a

The two Schiff-base ligands present in the mononuclear complexes **5a**−**7a** give rise to several overlapping signals in the aromatic region of the ^{1}H NMR spectra (see Exp. Sect.). Pronounced chemical-shift differences are observed for the two imine protons $H^7/H^{7'}$ and the two protons α to the pyridine nitrogen atom ($H^{12}/H^{12'}$) due to the presence (H^7: δ = 8.58−8.89 ppm; H^{12}: δ = 9.30−9.41 ppm) and absence ($H^{7'}$: δ = 8.73−8.74 ppm; $H^{12'}$: δ = 8.53−8.59 ppm) of a coordinated metal centre (see Scheme 2 and Exp. Sect. for atom numbering).

Complexes **5a**−**7a** display the typical ν_{CO} absorption pattern of a facially coordinated $\{M^1(CO)_3\}$ fragment with disturbed local C_{3v} symmetry[4,19−21] and an absorption band due to the coordinated isocyanide group of the C≡N−(N∩N′) ligand in their IR spectra (see Exp. Sect.). The absorption bands of **5a**−**7a** in the UV/Vis spectra between 613−655 nm can be assigned to a metal-to-ligand charge transfer transition of the $\{(diimine)M^1(CO)_3\}$ chromophore (see Exp. Sect.).[4,19−21] The MLCT bands show negative solvatochromism as expected (see Supporting Information).[22] A linear solvation-energy relationship analysis reveals that the most dominant term influencing the charge transfer is the polarity of the solvent, followed by the hydrogen-acceptor ability of the solvent (see Supporting Information).[23]

The IR spectra of the dinuclear complexes are superpositions of the spectra of the corresponding tricarbonyl and tetracarbonyl complexes [disturbed local C_{3v} and C_{2v} symmetry of the $M(CO)_n$ moieties, respectively];[4,19−21] one ν_{CN} absorption and five ν_{CO} absorptions (two absorptions are not resolved) are observed in each case (Table 1). This finding was corroborated by DFT calculations of complexes **8a**−**16a** (see Supporting Information): the ν_{CO} and ν_{CN} absorptions of the $M^1(CO)_3(CNR)$ moieties are independent of the metal in the $M^2(CO)_4$ fragment and vice versa (Figure 1; all standard deviations are below 2 cm^{-1}).

The ^{1}H NMR spectra of **8a**−**16a** consist of overlapping signals in the aromatic region. Particularly informative is the chemical shift of the two imine protons ($H^7/H^{7'}$: δ = 8.35−8.90 ppm) and the two protons α to the pyridine nitrogen atom ($H^{12}/H^{12'}$: δ = 9.14−9.40 ppm) which are influenced by metal coordination (cf. complexes **5a**−**7a**, Table 1, Exp. Sect.).

In the UV/Vis spectra of **8a**−**16a** two absorptions are observed in the visible region. These two absorptions arise from MLCT transitions of the $\{(diimine)M^1(CO)_3\}$ chromophore at lower energy and of the $\{(diimine)M^2(CO)_4\}$ chromophore at higher energy (Table 1).[4,19−21]

A thorough examination of the spectroscopic data reveals that all dinuclear complexes exhibit similar but distinguish-

[a] IR values given in cm^{-1}; λ_{max} in nm, ε in $M^{-1}\cdot cm^{-1}$; δ in ppm.

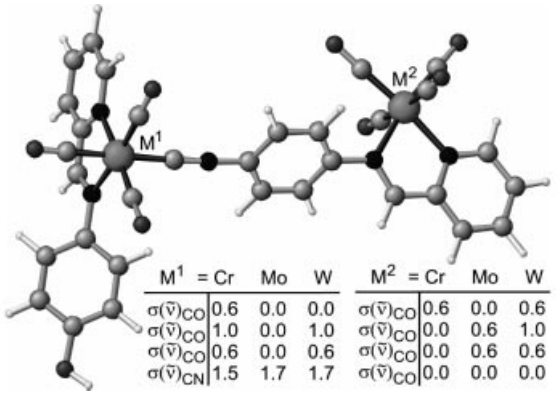

Figure 1. DFT (B3LYP, LANL2DZ) optimised geometry of complex **8a** ($M^1 = M^2 = Cr$) and standard deviations of the calculated average IR wavenumbers [cm^{-1}] of the $M(CO)_n$ fragments of complexes **8a**−**16a**

able features. This allows the determination of the metal sequence of the complexes simply by a combination of IR (Figure 2), ^{1}H NMR and UV/Vis spectroscopic data (Table 1, Supporting Information).[19]

There are five obvious criteria to distinguish complexes **8a**−**16a**:

(i):$\tilde{\nu}_{CN} \geq 2075$ cm^{-1}: M^1 = Mo (**9a**, **12a**, **15a**) (Figure 2);

(ii): $\tilde{\nu}^5_{CO} \geq 2012$ cm^{-1}: M^2 = Mo (**11a**, **12a**, **13a**) (Figure 2);

(iii): (i) and (ii): $M^1 = M^2$ = Mo (**12a**) (Figure 2);

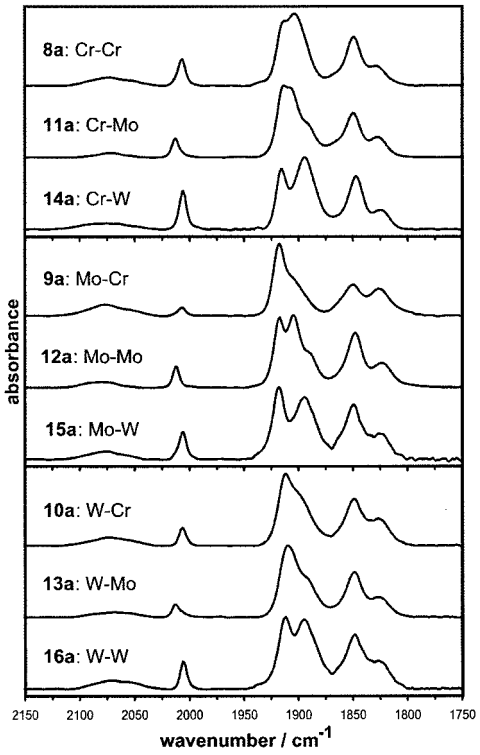

Figure 2. IR spectra of complexes **8a**−**16a** in THF

(iv): one $\delta_{H(imine)} \geq 8.87$ ppm: M^1 or M^2 = W (**10a**, **13a**, **14a**, **15a**);

(v): two $\delta_{H(imine)} \geq 8.87$ ppm: $M^1 = M^2$ = W (**16a**).

With these criteria the sequences of all complexes, except the Cr/W isomers **10a** and **14a**, can be unambiguously determined, for example (i) and (iv) describe complex **15a**. The two isomeric complexes **10a** and **14a** can be distinguished either by their IR spectroscopic pattern around 1900 cm^{-1}, as the difference between $\tilde{\nu}^3_{CO}$ and $\tilde{\nu}^4_{CO}$ amounts to 8 cm^{-1} for **10a** and 21 cm^{-1} for **14a** (Figure 2, Table 1), or by their MLCT absorptions in the UV/Vis spectra (Figure 3, Table 1). The energetic difference between the two MLCT absorptions is smaller for **10a** (2240 cm^{-1}) than for **14a** (3080 cm^{-1}) as expected from the MLCT absorptions of the corresponding mononuclear complexes (see Exp. Sect. and refs.[4,21]).

Thus, all complexes can be distinguished by their spectroscopic signatures. These findings also imply that the complexes retain their metal sequence under the applied reaction conditions — there is no rearrangement, polymerisation or carbonyl scrambling.

In the solid state the IR data of **8a**−**16a** show that hydrogen bonds from the hydroxy group of the ligand **1a** are present ($\tilde{\nu}_{OH}$ = 3340−3469 cm^{-1}, see Exp. Sect.). These energies are compatible with the formation of OH···O hydrogen bonds between OH groups of different complexes or between the OH group and carbonyl ligands of different complexes.[20,21]

For ligand **1a** and complexes **5a**−**7a** broad, structured absorption bands are observed in the region 3000−3455

cm^{-1}, which again suggests hydrogen-bonded structures. This has been confirmed by determination of the crystal structures of **1a** and **7a** (Figures 4 and 5). Intramolecular bond lengths and angles are unremarkable for both structures (Table 2), although the intermolecular connectivity is noticeable.

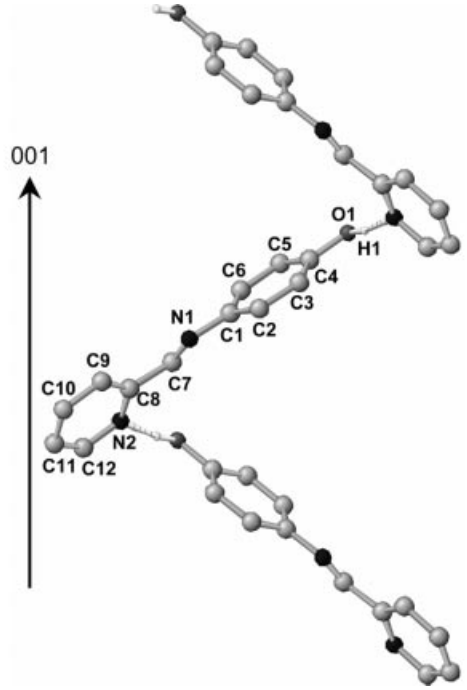

Figure 4. Structure of **1a** in the solid state

In both solid-state structures the OH group of the ligand forms hydrogen bonds to the nitrogen atom of a pyridine ring of a neighbouring molecule (**1a**: O1···N2; **7a**: O1···N5; Table 3, Figures 4 and 5). The molecules of **1a** form a zigzag chain along the 001 direction (a glide plane of the space group *Pbca*; repeat distance $c/2 = 6.8$ Å), while the molecules of **7a** form a linear chain along the 110 direction (repeat distance 13.9 Å). The repeat distance for **7a** is more than twice as large as for **1a**. Thus, **7a** can be viewed as a higher homologue of **1a** with a $W(CO)_3-C\equiv N-(N^{\cap}N')$ fragment inserted between the hydrogen donor and acceptor groups. In addition, this insertion introduces a directional change and thus straightens the zigzag chain of **1a** (angle between OH vectors of adjacent molecules ±61°) to a linear chain of **7a** (angle between OH vectors of adjacent molecules 0°).

Properties of 5b−16b

All polymer-bound complexes **5b**−**16b** were directly characterised on the solid support by IR and diffuse-reflectance UV/Vis spectroscopy, as well as thermogravimetric analyses (Table 4, Exp. Sect. and Supporting Information). The progress of the heterogeneous reactions can be monitored by IR spectroscopy due to the intense characteristic carbonyl and isocyanide absorption bands in this otherwise empty spectral region 1800−2100 cm^{-1}.[5,25,26] These characteristic patterns allow the detection of $\{M(CO)_3\}$ and

$\{M(CO)_4\}$ fragments on the polymer support. The intensity of these absorption bands can be compared to the intensity of the ν_{CH} absorption bands of the polymer backbone as internal standard, thus allowing a semi-quantitative reaction control.[5] The final immobilised dinuclear complexes display signals due to the $\{M(CO)_3\}$ and $\{M(CO)_4\}$ fragments and due to the isocyanide functional group (Table 4). The IR criteria (see above) for the different metal−metal sequences apply for the immobilised complexes as well, allowing the confirmation of the correct chain-growth even on a solid support:

The diffuse-reflectance spectra of the polymer-bound dinuclear complexes **8b**−**16b** show broad absorptions in the visible spectral region which can be assigned to the MLCT transitions of the two $\{(diimine)M(CO)_n\}$ chromophores ($n = 3$ at lower energy; $n = 4$ at higher energy; Table 4).[4,6]

These absorption bands are considerably shifted to lower energy relative to the MLCT bands of the soluble complexes as previously observed for similar immobilised complexes[4−6] (Tables 1 and 4). As the energy of the MLCT absorptions is dominated by the solvent polarity (see above and ref.[22]) the shift of the absorption bands of the immobilised complexes towards lower energy should be due to lower polarity of the polymer matrix. Even the degree of cross-linking influences the energy of the MLCT absorption bands. Resins with lower cross-linking (1% vs. 2% divinylbenzene) induce an even more pronounced bathochromic shift of the MLCT bands (Figure 6, Table 4 and ref.[5]). Obviously, the resin polarity decreases with decreasing cross-linking. This lower polarity of the 1% cross-linked resin might be induced by the lower internal pressure due to the pressure dependence of the polarity.[22] Thus, the MLCT absorption bands of the carbonyl complexes can be used to measure the resin polarity of different polymeric supports.

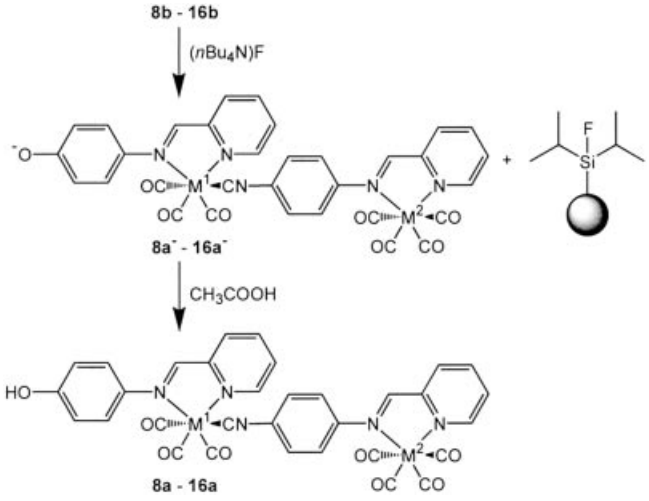

Scheme 3

Thermogravimetric analyses of resins **8b**−**16b** show that carbon monoxide is released up to 200 °C, as detected from the IR spectrum of the gas above heated samples.[5] The weight losses $\Delta m/m$ up to 200 °C of around 11% correspond well to the calculated weight losses (seven carbon monoxide molecules per immobilised complex) based on the initial ligand loading of the polymer (Figure 7, Table 4 and Supporting Information). This finding confirms the quantitative formation of the dinuclear complexes on the polymer, as the corresponding tricarbonyl complexes **5b**−**7b** show a weight loss, $\Delta m/m$, of around 6% (three carbon monoxide molecules per immobilised complex, Figure 7).

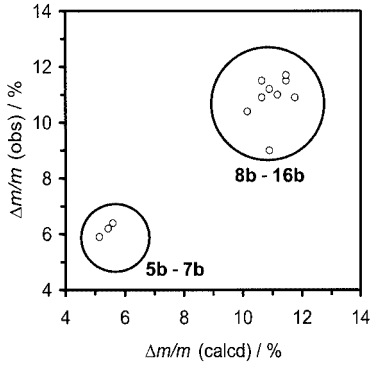

Figure 7. Correlation of experimental and calculated weight losses of resins **5b**−**16b**

In the final step of the solid-phase synthesis the dinuclear complexes were released from the support by cleavage of the Si−O bond with fluoride ions (Scheme 3).[4,5,18] The soluble anionic complexes **8a**$^-$−**16a**$^-$ can be detected in the IR and UV/Vis spectra of the cleavage solution (Table 5). All ν_{CO} absorption bands of **8a**$^-$−**16a**$^-$ are shifted to lower energy, while the MLCT absorption bands are hypsochromically shifted, due to the negatively charged ligand, relative to the neutral parent complexes **8a**−**16a**.

Protonation of **8a**$^-$−**16a**$^-$ with acetic acid yields the neutral complexes **8a**−**16a**, which were characterised as above. In all cases no spectroscopic evidence was observed for the formation of side products, thus confirming the identity and stability of the polymer-bound complexes.

Advantages/Disadvantages of the Synthetic Methods

The obvious drawback of the solution synthesis is the difficulty of obtaining pure samples. The solution synthesis requires exact stoichiometric reaction conditions to avoid formation of side products (mainly monomeric tetracarbonyl complexes) and tedious purification procedures of the products.

In the solid-phase synthesis approach, however, excess reagents can be used, driving the reactions to completion and thus avoiding the formation of polymer-bound side products. The reaction progress on the solid phase can be monitored by IR spectroscopy.[5,25,26] On the other hand the solid-phase synthesis requires adaptation of all reaction conditions and optimisation of the solid support. For the synthesis of the soluble complexes **8a**−**16a** identical reaction conditions can be applied irrespective of the metal centre to be incorporated (see Exp. Sect.). The synthesis of the polymer-bound complexes **8b**−**16b**, however, requires different reaction conditions depending on the metal fragment $\{M(CO)_3\}$ (M = Cr, Mo, W) to be attached. The highly reactive chromium derivatives must be handled at low temperatures (−30 °C) to avoid formation of tetracarbonyl complexes, which seems to be promoted by the polymer support, while the less reactive carbonyltungsten complexes must be activated at higher temperatures (60 °C); the solution reactions all proceed at room temperature (see Exp. Sect.). In addition, for reactions involving $\{M(CO)_n\}$ (M = Cr and W; n = 3, 4) the properties of the polymer support have to be optimised. The degree of cross-linking (2% divinylbenzene in the initial experiments with molybdenum[4,5]) has to be reduced to 1% divinylbenzene giving polymers

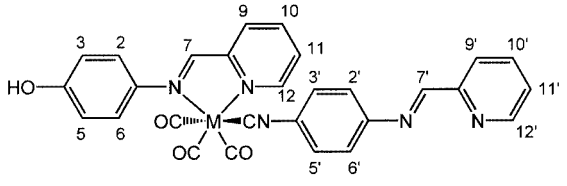
with better swelling properties and larger effective pore-sizes. The better swelling properties of the low cross-linked resins impart a lower internal pressure (as shown by the "solvent" dependence of the MLCT absorption bands) and thus render the heterogeneous reactions faster and more selective.

Conclusion

Dinuclear mixed-metal complexes with different metal centres at well-defined positions have been synthesised in solution and on a polymer support. The metal sequence of the soluble complexes can be determined by a combination of standard spectroscopic techniques and is retained under the applied reaction conditions. The solution synthesis is straightforward; however, the purification of the products is rather difficult, making this approach less suitable for longer-chain complexes. The solid-phase synthesis, although requiring more reaction steps (ligand immobilisation and product release) and differently optimised reaction conditions for each different reaction step, is much easier to accomplish. Furthermore, the solid-phase synthesis approach can easily be extended to longer-chain complexes by repeating the chain-growth reaction steps before the capping reaction without having to worry about solubility and purification of intermediates. This demonstrates the use of solid-phase synthesis methods in organometallic combinatorial chemistry.

Experimental Section

General: Unless noted otherwise, all manipulations were carried out under argon by means of standard Schlenk techniques. All solvents were dried by standard methods and distilled under argon prior to use. **1a**[4,5], **1b**[4,5] and C≡N−(N∩N′)[19] were prepared by literature methods. Polystyrene resins cross-linked with 1% divinylbenzene and with a ligand loading of 0.9 mmol·g^{-1} were used unless noted otherwise. The acetonitrile complexes were prepared from (cycloheptatriene)$M(CO)_3$ and (norbonadiene)$M(CO)_4$,[27,28] respectively, by reaction with CH_3CN (M = Cr, Mo, W). All other reagents were used as received from commercial sources. NMR spectra were recorded with a Bruker Avance DPX 200 at 200.15 MHz (^1H) at 303 K; chemical shifts are quoted in ppm with respect to residual solvent peaks as internal standards (CD_2Cl_2: δ = 5.32 ppm). IR spectra were recorded with a BioRad Excalibur FTS 3000 spectrometer using CaF_2 cells or CsI disks. UV/Vis/NIR spectra were recorded with a Perkin−Elmer Lambda 19, 0.2-cm cells (Hellma, Suprasil). DRS-UV/Vis spectra were measured with the same instrument using the Perkin−Elmer integrating sphere and poly(tetrafluoroethylene) as reference. Mass spectra were recorded with a Finnigan MAT 8400 spectrometer with a 4-nitrobenzyl alcohol matrix (FAB). Elemental analyses were performed by the microanalytical laboratory of the Organic Chemistry Department, University of Heidelberg. Thermogravimetric measurements were carried out with a Mettler TC 50, heating rate 10 K·min^{-1} under argon from 30−800 °C.



Solution Syntheses of 5a−7a: Freshly prepared $[M(CO)_3(CH_3CN)_3]$ (M = Cr, Mo, W) was added to a solution of **1a** (198 mg, 1 mmol) in THF (40 mL). The blue solution was stirred until IR control indicated complete formation of the THF complexes **2a**, **3a** or **4a**. C≡N−(N∩N′) (207 mg, 1 mmol) was added as a solid and the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

solution turned green immediately. The green solution was stirred until IR control indicated complete formation of the isocyanide complexes **5a**, **6a** or **7a**. The complexes were either isolated by addition of petroleum ether (boiling range 40−60 °C) and filtration of the precipitate or the solutions were used directly for the preparations of **8a−16a**.

Satisfactory elemental analyses could not be obtained due to the inclusion of variable amounts of solvent molecules.

7a: UV/Vis (THF): λ_{max} (ε) = 627 nm (3225 $M^{-1}\cdot cm^{-1}$). IR (THF): $\tilde{\nu}$ = 2071 (m, CN), 1913 (vs, CO), 1848 (s, CO), 1825 (s, CO) cm^{-1}. IR (CsI): $\tilde{\nu}$ = 3412 (br., OH), 2087 (m, CN), 1906 (vs, CO), 1831 (s, CO), 1807 (s, CO) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 7.01 (d, $^3J_{H,H}$ = 8.8 Hz, 2 H, $H^{3,5}$), 7.3−7.7 (m, 8 H, $H^{2,6}$, $H^{2',6'}$, $H^{3',5'}$, H^{11}, $H^{11'}$), 7.8−8.0 (m, 3 H, H^9, H^{10}, $H^{10'}$), 8.2−8.3 (m, 1 H, $H^{9'}$), 8.58 (br. s, 1 H, $H^{12'}$), 8.74 (br. s, 1 H, $H^{7'}$), 8.89 (br. s, 1 H, H^7), 9.40 (d, $^3J_{H,H}$ = 5.2 Hz, 1 H, H^{12}) ppm. Satisfactory elemental analyses could not be obtained due to the inclusion of variable amounts of solvent molecules.

Solution Syntheses of 8a−16a: Freshly prepared [$(CH_3CN)_2M(CO)_4$] (M = Cr, Mo, W) (1 mmol) was added to a solution of **5a**, **6a** or **7a** (1 mmol) in THF. The dark solution was stirred until IR control indicated complete formation of the dinuclear complex. Addition of petroleum ether (boiling range 40−60 °C) precipitated the product complexes, which were purified by repeated washings with diethyl ether (removal of mononuclear complexes) and recrystallisation from THF/diethyl ether.

8a: $C_{32}H_{19}Cr_2N_5O_8$ (705.5): calcd. C 54.48, H 2.71, N 9.93; found C 53.32, H 3.98, N 9.38. MS (FAB): *m/z* (%) = 705 (5) [M^+]. IR (CsI): $\tilde{\nu}$ = 3469 (br., OH), 2082 (m, CN), 2008 (m, CO), 1906 (vs, CO), 1833 (br., s, CO) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 7.1−7.7 (m, 10 H, $H^{2,6}$, $H^{2',6'}$, $H^{3,5}$, $H^{3',5'}$, H^{11}, $H^{11'}$), 7.7−8.0 (m, 4 H, H^9, $H^{9'}$, H^{10}, $H^{10'}$), 8.51 (br. s, 2 H, H^7, $H^{7'}$), 9.29 (d, $^3J_{H,H}$ = 3.6 Hz, 1 H, $H^{12/12'}$), 9.40 (d, $^3J_{H,H}$ = 3.8 Hz, 1 H, $H^{12/12'}$) ppm.

9a: $C_{32}H_{19}CrMoN_5O_8$ (749.5): calcd. C 51.28, H 2.56, N 9.34; found C 51.46, H 3.49, N 9.36. IR (CsI): $\tilde{\nu}$ = 3449 (br., OH), 2091 (m, CN), 2009 (m, CO), 1910 (vs, CO), 1831 (br., s, CO) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 6.88 (br. d, 2 H, $H^{3,5}$), 7.1−7.5 (m, 8 H, $H^{2,6}$, $H^{2',6'}$, $H^{3',5'}$, H^{11}, $H^{11'}$), 7.7−7.9 (m, 4 H, H^9, $H^{9'}$, H^{10}, $H^{10'}$), 8.35, 8.47 (s, 1 H, H^7, $H^{7'}$), 9.14 (m, 2 H, $H^{12,12'}$) ppm.

10a: $C_{32}H_{19}CrN_5O_8W$ (837.4): calcd. C 45.90, H 2.29, N 8.36; found C 45.49, H 3.43, N 7.90. IR (CsI): $\tilde{\nu}$ = 3399 (br., OH), 2088 (m, CN), 2009 (m, CO), 1904 (vs, CO), 1831 (br., s, CO) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 6.9−7.1 (m, 2 H, $H^{3,5}$), 7.3−7.7 (m, 8 H, $H^{2,6}$, $H^{2',6'}$, $H^{3',5'}$, H^{11}, $H^{11'}$), 7.9−8.1 (m, 4 H, H^9, $H^{9'}$, H^{10}, $H^{10'}$), 8.49 (s, 1 H, $H^{7'}$), 8.90 (s, 1 H, H^7), 9.29 (d, $^3J_{H,H}$ = 5.4 Hz, 1 H, $H^{12,12'}$), 9.40 (d, $^3J_{H,H}$ = 5.8 Hz, 1 H, $H^{12,12'}$) ppm.

11a: $C_{32}H_{19}CrMoN_5O_8$ (749.5): calcd. C 51.28, H 2.56, N 9.34; found C 51.43, H 3.53, N 9.62. MS (FAB): *m/z* (%) = 749 (5) [M^+], 665 (10) [$M^+ - 3$ CO]. IR (CsI): $\tilde{\nu}$ = 3449 (br., OH), 2091 (m, CN), 2014 (m, CO), 1909 (vs, CO), 1833 (br., s, CO) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 7.0−7.1 (m, 2 H, $H^{3,5}$), 7.2−7.7 (m, 8 H, $H^{2,6}$, $H^{2',6'}$, $H^{3',5'}$, H^{11}, $H^{11'}$), 7.8−8.1 (m, 4 H, H^9, $H^{9'}$, H^{10}, $H^{10'}$), 8.54, 8.57 (s, 1 H, H^7, $H^{7'}$), 9.20 (d, $^3J_{H,H}$ = 5.8 Hz, 1 H, $H^{12,12'}$), 9.40 (d, $^3J_{H,H}$ = 5.0 Hz, 1 H, $H^{12,12'}$) ppm.

12a: $C_{32}H_{19}Mo_2N_5O_8$ (793.4): calcd. C 48.44, H 2.41, N 8.83; found C 48.17, H 3.55, N 8.47. MS (FAB): *m/z* = 792 (5) [$M^+ - H$], 380 (100) [$M^+ - CN-(N\cap N') - Mo - 4$ CO]. IR (CsI): $\tilde{\nu}$ = 3340 (br., OH), 2088 (m, CN), 2013 (m, CO), 1913 (vs, CO), 1908 (vs, CO), 1833 (br., s, CO) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 6.99 (d, $^3J_{H,H}$ = 8.8 Hz, 2 H, $H^{3,5}$), 7.3−7.8 (m, 8 H, $H^{2,6}$, $H^{2',6'}$, $H^{3',5'}$, H^{11}, $H^{11'}$), 7.8−8.1 (m, 4 H, H^9, $H^{9'}$, H^{10}, $H^{10'}$), 8.57 (s, 1 H, $H^{7'}$), 8.61 (s, 1 H, H^7), 9.20 (d, $^3J_{H,H}$ = 4.8 Hz, 1 H, $H^{12,12'}$), 9.30 (d, $^3J_{H,H}$ = 4.8 Hz, 1 H, $H^{12,12'}$) ppm.

13a: $C_{32}H_{19}MoN_5O_8W$ (881.3): calcd. C 43.61, H 2.17, N 7.95; found C 42.45, H 2.93, N 7.92. MS (FAB): *m/z* = 881 (30) [M^+], 853 (38) [$M^+ - CO$], 741 (45) [$M^+ - 5$ CO]. IR (CsI): $\tilde{\nu}$ = 3396 (br., OH), 2085 (m, CN), 2013 (m, CO), 1904 (vs, CO), 1830 (br., s, CO) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 6.9−7.1 (m, 2 H, $H^{3,5}$), 7.3−7.7 (m, 8 H, $H^{2,6}$, $H^{2',6'}$, $H^{3',5'}$, H^{11}, $H^{11'}$), 7.9−8.1 (m, 4 H, H^9, $H^{9'}$, H^{10}, $H^{10'}$), 8.57 (s, 1 H, $H^{7'}$), 8.90 (s, 1 H, H^7), 9.20 (d, $^3J_{H,H}$ = 5.4 Hz, 1 H, $H^{12,12'}$), 9.40 (d, $^3J_{H,H}$ = 5.6 Hz, 1 H, $H^{12,12'}$) ppm.

14a: $C_{32}H_{19}CrN_5O_8W$ (837.4): calcd. C 45.90, H 2.29, N 8.36; found C 44.78, H 3.32, N 7.71. MS (FAB): *m/z* = 725 (15) [$M^+ - 4$ CO], 669 (8) [$M^+ - 6$ CO], 641 (10) [$M^+ - 7$ CO]. IR (CsI): $\tilde{\nu}$ = 3450 (br., OH), 2084 (m, CN), 2007 (m, CO), 1906 (vs, CO), 1831 (br., s, CO) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 6.9−7.1 (m, 2 H, $H^{3,5}$), 7.2−7.7 (m, 8 H, $H^{2,6}$, $H^{2',6'}$, $H^{3',5'}$, H^{11}, $H^{11'}$), 7.8−8.1 (m, 4 H, H^9, $H^{9'}$, H^{10}, $H^{10'}$), 8.53 (s, 1 H, H^7), 8.87 (s, 1 H, $H^{7'}$), 9.31 (br. s, 1 H, $H^{12,12'}$), 9.40 (br. s, 1 H, $H^{12,12'}$) ppm.

15a: $C_{32}H_{19}MoN_5O_8W$ (881.3): calcd. C 43.61, H 2.17, N 7.95; found C 44.38, H 3.32, N 8.02. MS (FAB): *m/z* = 853 (5) [$M^+ - CO$], 797 (4) [$M^+ - 3$ CO], 685 (5) [$M^+ - 7$ CO]. IR (CsI): $\tilde{\nu}$ = 3393 (br., OH), 2093 (m, CN), 2009 (m, CO), 1910 (vs, CO), 1829 (br., s, CO) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 7.02 (d, $^3J_{H,H}$ = 8.6 Hz, 2 H, $H^{3,5}$), 7.2−7.7 (m, 8 H, $H^{2,6}$, $H^{2',6'}$, $H^{3',5'}$, H^{11}, $H^{11'}$), 7.7−8.0 (m, 4 H, H^9, $H^{9'}$, H^{10}, $H^{10'}$), 8.57 (s, 1 H, H^7), 8.90 (s, 1 H, $H^{7'}$), 9.20 (d, $^3J_{H,H}$ = 5.2 Hz), 1 H, $H^{12,12'}$, 9.40 (d, $^3J_{H,H}$ = 5.2 Hz, 1 H, $H^{12,12'}$) ppm.

16a: $C_{32}H_{19}N_5O_8W_2$ (969.2): calcd. C 39.66, H 1.98, N 7.23; found C 40.77, H 2.69, N 7.98. MS (FAB): *m/z* = 969 (15) [M^+]. IR (CsI): $\tilde{\nu}$ = 3464 (br., OH), 2085 (m, CN), 2007 (m, CO), 1900 (vs, CO), 1831 (br., s, CO) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 7.02 (m, 2 H, $H^{3,5}$, $^3J_{H,H}$ = 7.2 Hz), 7.2−7.7 (m, 8 H, $H^{2,6}$, $H^{2',6'}$, $H^{3',5'}$, H^{11}, $H^{11'}$), 7.9−8.1 (m, 4 H, H^9, $H^{9'}$, H^{10}, $H^{10'}$), 8.87, 8.90 (s, 1 H, H^7, $H^{7'}$), 9.32 (d, $^3J_{H,H}$ = 5.2 Hz, 1 H, $H^{12,12'}$), 9.40 (d, $^3J_{H,H}$ = 5.8 Hz, 1 H, $H^{12,12'}$).

Solid-Phase Synthesis of 5b−7b: Freshly prepared [$M(CO)_3(CH_3CN)_3$] (M = Cr, Mo, W) (0.5 mmol), dissolved in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

CH_3CN (15 mL), was added to resin **1b** (ca. 0.25 mmol), swollen in toluene (15 mL). The suspension was stirred (M = Cr: 20 min, −30 °C; M = Mo: 20 min, 20 °C; M = W: 60 min, 60 °C) and the resin turned from yellow to blue. The solvents were removed by filtration and the polymer was quickly washed with toluene/CH_3CN (1:1) until IR spectroscopy of the solution indicated complete removal of the excess $[M(CO)_3(CH_3CN)_3]$. Due to the sensitivity of the immobilised complex, the resin swollen in toluene was immediately treated with the ligand C≡N−(N∩N′) (104 mg, 0.5 mmol), dissolved in THF (5 mL). The polymer turned green immediately, and after 30 min, the resin was washed with THF until IR spectroscopy indicated complete removal of the excess C≡N−(N∩N′). The resin was dried under reduced pressure giving a dark green powder or used directly for further reactions. No soluble (diimine)$Mo(CO)_x$ complexes were observed by IR spectroscopy at any stage of the reaction.

5b: IR (CsI): $\tilde{\nu}$ = 2074 (m, CN), 1919 (s, CO), 1863 (m, CO), 1833 (m, CO) cm^{-1}. UV/Vis: λ_{max} = 420 (sh), 880 (br.) nm. TG (200 °C): $\Delta m/m$ = 6.4% (calcd. 5.8%).

6b: IR (CsI): $\tilde{\nu}$ = 2084 (m, CN), 1922 (s, CO), 1857 (m, CO), 1826 (m, CO) cm^{-1}. UV/Vis: λ_{max} = 420 (sh), 810 (br.) nm. TG (200 °C): $\Delta m/m$ = 6.2% (calcd. 5.4%).

7b: IR (CsI): $\tilde{\nu}$ = 2072 (m, CN), 1913 (s, CO), 1850 (m, CO), 1822 (m, CO) cm^{-1}. UV/Vis: λ_{max} = 420 (sh), 830 (br.) nm. TG (200 °C): $\Delta m/m$ = 5.9% (calcd. 5.1%).

Solid-Phase Synthesis of 8b−16b: Freshly prepared $[M(CO)_4(CH_3CN)_2]$ (0.5 mmol) dissolved in THF (15 mL) was added to resin **5b**, **6b** or **7b** (ca. 0.25 mmol), swollen in THF (5 mL). After stirring at 20 °C for 2 h, the resin was washed with THF until IR spectroscopy indicated complete removal of the excess $[M(CO)_4(CH_3CN)_2]$. The resin was dried under reduced pressure giving a black powder. No soluble (diimine)$M(CO)_x$ complexes were observed by IR spectroscopy at any stage of the reaction.

Cleavage Procedure: A solution of tetra-*n*-butylammonium fluoride TBAF·$3H_2O$ (2 equiv.) in THF was added to a suspension of the appropriate resin in THF (10 mL). The suspension was stirred at ambient temperature for 6 h. IR spectroscopy indicated the formation of the anionic complexes **8a**$^-$−**16a**$^-$. The polymer was filtered and washed with THF until the wash solutions were colourless. The combined filtrates were acidified with acetic acid, concentrated under reduced pressure and the complexes were precipitated by addition of diethyl ether. Recrystallisation as above yielded the complexes **8a**−**16a**. After cleavage, mass spectrometry of the remaining silyl fluoride polymer indicated complete removal of the complexes.[18]

Crystallographic Structure Determinations: The measurements were carried out with an Enraf−Nonius Kappa CCD diffractometer using graphite monochromated Mo-K_α radiation. The data were processed using the standard Nonius software.[29] All calculations were performed using the SHELXT PLUS software package. Structures were solved using direct or Patterson methods with the SHELXS-97 program and refined with the SHELXL-97 program.[30] Graphical handling of the structural data during refinement was performed using XMPA[31] and WinRay.[32] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares calculations. Data relating to the structure determinations are collected in Table 6. CCDC-233938 (**1a**) and -233939 (**7a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Methods: Density functional calculations were carried out with the Gaussian03/DFT[33] program series. The B3LYP formulation of density functional theory was used employing the LanL2DZ basis set.[33] Harmonic vibrational frequencies and IR

Table 6. X-ray crystallographic data of **1a** and **7a**

	1a	**7a**
Empirical formula	$C_{12}H_{10}N_2O$	$C_{28}H_{19}WN_5O_4$·1.6THF

Phosphane-Catalyzed Reactions of $LAlH_2$ with Elemental Chalcogens; Preparation of [LAl(μ-E)$_2$AlL] [E = S, Se, Te, L = HC{C(Me)N(Ar)}$_2$, Ar = 2,6-*i*Pr$_2$C$_6$H$_3$]

Keywords: Aluminum / Catalysis / Chalcogens / Phosphanes / Reaction mechanisms

Addition of catalytic amounts of a phosphane to a reaction mixture containing $LAlH_2$ [**2**; L = HC{C(Me)N(Ar)}$_2$, Ar = 2,6-*i*Pr$_2$C$_6$H$_3$] and elemental Se or Te resulted in the formation of poorly soluble [LAl(μ-Se)$_2$AlL] (**3**) and [LAl(μ-Te)$_2$AlL] (**4**), respectively. The sulfur analogue [LAl(μ-S)$_2$AlL] (**5**) could not be obtained from the direct reaction of **2** with elemental sulfur; consequently, its synthesis was successfully achieved from the reaction of [$LAlH_2$] and [LAl(SH)$_2$]. A possible mechanism for the formation of [LAl(μ-Se)$_2$AlL] and [LAl(μ-Te)$_2$AlL] is discussed. The molecular structures of compounds **3**–**5** were determined by X-ray structure analyses.

Introduction

Aluminum compounds containing heavier Group 16 elements have been comparatively less-well studied than those containing Al−O bonds, mainly due to the thermodynamic stability of the latter species. Recently, we have reported the preparation of unusual species of composition [LAl(EH)$_2$] [L = HC{C(Me)N(Ar)}$_2$, Ar = 2,6-*i*Pr$_2$C$_6$H$_3$, E = O, S, Se],[1−3] as well as the catalytic role of P(NMe$_2$)$_3$ in the synthesis of [LAl(SH)$_2$] (**1**).[2] As an extension of our interest in this type of compounds, we explored the influence of phosphanes on the $LAlH_2$/Se(Te) system. So far, there are only a few examples of compounds containing Al−E moieties in which the chalcogen atom is not directly bonded to any alkyl, aryl or trialkylsilyl group.[4−25] Three different aggregation modes have been observed for species containing Al and chalcogen atoms in a 1:1 molar ratio, mainly depending on the hapticity of the chalcogen atom. In these systems, the chalcogens can act either as a μ- or μ$_3$-bridging ligand as a consequence of the steric hindrance of the substituents present on the aluminum. Thus, the [AlE]$_n$ core can be either square planar (n = 2),[4−13,17] cubic (n = 4)[13−17] or adopt a hexagonal drum structure (n = 6).[14] Other examples containing Al and E in a ratio that deviates from 1:1 have also been reported to exhibit a bent Al−E−Al moiety, adamantane-like Al_4E_6 or more complex structures.[3,20−24] We have recently shown that [$LAlH_2$] (**2**), prepared from LH and AlH_3·NMe$_3$, reacts with elemental selenium[3] and, in the presence of a phosphane as catalyst, also with elemental sulfur,[2] to give species of the general formula [LAl(EH)$_2$] (E = Se, S). The selenium derivative is thermodynamically unstable and decomposes to yield [{LAl(SeH)}$_2$Se] with elimination of H_2Se.[3] Nevertheless, no product formation was observed from the reaction of $LAlH_2$ with elemental Te, although extreme reaction conditions were used. Herein, we report on the significant influence of catalytic amounts of phosphane in the reaction of **2** and Se and Te leading to [LAl(μ-Se)$_2$AlL] (**3**) and [LAl(μ-Te)$_2$AlL] (**4**), respectively. [LAl(μ-S)$_2$AlL] (**5**) could not be obtained using this protocol, therefore **5** was synthesized by the direct reaction of [LAl(SH)$_2$] with [$LAlH_2$].

Results and Discussion

Addition of catalytic amounts of P(NMe$_2$)$_3$ or PMe_3 to a suspension of **2** and Se or Te resulted in the formation of [LAl(μ-E)$_2$AlL] (**3** E = Se; **4** E = Te) in high yields at ambi-

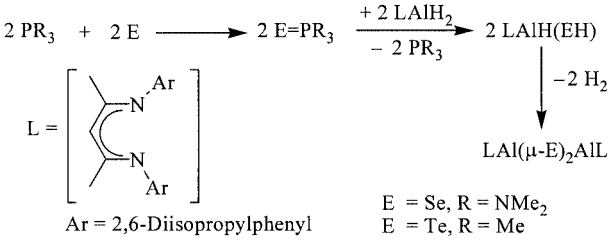
ent temperature. Compounds **3** and **4** are sparingly soluble in common organic solvents such as toluene, dichloromethane and tetrahydrofuran. In order to gain further insight regarding the role of the phosphane in this system, we investigated the reaction mechanism and possible by-products involved in this reaction. All attempts to follow the kinetics of these reactions by means of ^1H NMR spectroscopy failed due to the poor solubility of the elemental chalcogens and resulting products. However, previous experimental data revealed that the formation of **1** proceeds via the reactive intermediate [LAlH(SH)].[2] In order to obtain further insight into the reaction mechanism, we carried out several experiments varying the stoichiometry of the starting materials. The most striking finding was that, in the presence of phosphane, [LAl(μ-E)$_2$AlL]. analogous to the [LGa(μ-E)$_2$GaL] (E = O, S) derivatives prepared recently by Power et al.,[26] was the only product formed, regardless of the stoichiometry of the reagents employed; the direct reaction of **2** with elemental Se (in absence of the phosphane) led entirely to the formation of [LAl(SeH)$_2$].[3] In the latter case, another type of reaction mechanism involving a higher coordinated aluminum center formed by complexation of Se_2 to the aluminum has been suggested.[3,27–29] Finally, due to the fact that $TePR_3$ compounds are known to be good sources of soluble and reactive Te,[30–32] we carried out the direct reaction of **2** with $TePEt_3$ in an equimolar ratio. The reaction leads to pure **4** and free PEt_3 in almost quantitative yield, indicating that the gas evolved during the reaction is H_2 instead of H_2Te. All the experimental results outlined here are highly supportive of the proposed reaction mechanism. Therefore, we assume that Se and Te initially react with the corresponding phosphanes to yield $SeP(NMe_2)_3$ and $TePMe_3$, respectively. These compounds are unstable[30–32] and react in the following steps with **2** to yield [LAlH(EH)] (E = Se, Te), with elimination of phosphane. The last step corresponds to the formation of [LAl(μ-E)$_2$AlL] (E = Se, Te) by an elimination of two molecules of H_2. The splitting of the species into monomer units LAlE in the gas phase can indicate an intramolecular elimination followed by dimerisation, but we were not able to isolate such intermediates. Scheme 1 shows the steps involved in this reaction.



Scheme 1

As mentioned above, the reaction between [LAlH$_2$] (**2**) and elemental sulfur catalyzed by phosphane leads to [LAl(SH)$_2$] (**1**) and not to the desired [LAl(μ-S)$_2$AlL] (**5**).[2] Therefore we used the latent protic character of the hydrogen atoms from the SH groups of **1** and reacted the latter species in refluxing toluene with **2**. After 15 h we obtained **5** as a white insoluble microcrystalline solid in 92% yield. Scheme 2 summarizes the preparation of the three compounds.

Compounds **3**–**5** are insoluble in common organic solvents, and the powders obtained after the syntheses yielded nicely shaped monocrystals from a mixture of toluene/trichloromethane (10:1). The crystallization was achieved by solvation of [LAl(μ-E)$_2$AlL] with 2.32 equivalents of trichloromethane and 0.68 equivalents of toluene (**5**; E = S), two molecules of trichloromethane and one molecule of toluene (**3**; E = Se), or 2.73 molecules of trichloromethane and 0.27 molecules of toluene (**4**; E = Te) sharing the same spatial position in the crystal lattice, as shown by single-crystal X-ray structural analysis (Figures 1–3).[19]

The three isostructural compounds crystallize in the monoclinic space group *C*2/*m* and possess almost identical cell parameters (see Table 1). Taking into account the covalent radii (1.02 S, 1.17 Se and 1.35 Å Te),[33] the Al–S (2.237, 2.245 Å), Al–Se (2.359, 2.370 Å) and Al–Te bonds (2.575, 2.581 Å) are similar to one another. Furthermore, the E(1)–Al–E(1A) angles vary from 96.5° in **5** to 97.9° in

Te) angle is significantly more obtuse than those reported in the literature (99.9−103.6° for Se and 102.8−103.8° for Te)[4−12] due to the steric bulk of the β-diketiminato ligand. The latter values are similar to those of Al_4E_4 clusters (94.2−99.2° for Se and 94.1−96.3° for Te),[14,15] where the chalcogen atoms are always coordinated to three aluminum atoms. The S(1)−Al−S(1A) angle fits within the range of similar compounds (95.9−101.9°).[9−11] Selected bond lengths and angles for **3**−**5** are listed in Table 2.

All three compounds decompose without melting at temperatures above 200 °C, indicating their high thermal stability. The high stability of compounds **3**−**5** is further supported by the EI-mass spectra, which exhibit [M^+] ions for all three molecules: *m*/*z* = 952 (100%) for S, 1048 (48%) for Se and 1144 (25%) for Te. Unfortunately, due to the low solubility of **3**−**5** we were not able to record NMR spectra.

Conclusion

In summary, we have prepared and structurally characterized three new thermally stable aluminum chalcogenides [LAl(μ-E)AlL] (E = S, Se, Te). Furthermore, the significant influence of the phosphane on the product formation has been demonstrated and a possible mechanism for the conversion of aluminum hydrides to aluminum selenides and tellurides outlined.

glovebox. Toluene was dried (Na/benzophenone ketyl) and distilled prior to use. Tellurium (99.5%; Aldrich) and PMe_3 (1 M solution in toluene; Fluka) were used as received. $P(NMe_2)_3$ (97%; Aldrich) was freshly distilled prior to use. Elemental red selenium,[34] $[LAlH_2]$,[3] $[LAl(SH)_2]$[2] and $TePEt_3$ [35] were prepared by literature procedures.

Infrared spectra were recorded as KBr pellets on a Bio-Rad Digilab FTS-7 spectrometer in the range 4000−350 cm^{-1}. Mass spectra were obtained with a Finnigan MAT 8230 or a Varian MAT CH5 instrument (70 eV). Elemental analyses were performed by the Analytical Laboratory, Institute of Inorganic Chemistry, University of Goettingen. Melting points were measured in sealed glass tubes and are uncorrected.

[LAl(μ-Se)$_2$AlL] (3): Toluene (20 mL) was added to a mixture of **2** (1.000 g, 2.239 mmol) and red selenium (0.176 g, 2.239 mmol) and after dissolution of **2**, freshly distilled $P(NMe_2)_3$ (0.03 mL, 0.055 mmol) was added. The reaction mixture was stirred for an additional 16 h and the white insoluble product was filtered off, washed with toluene (5 mL) and dried in vacuo. Yield: 1.07 g (91%). Decomp. without melting above 260 °C. IR (KBr pellet): $\tilde{\nu}$ = 3061 vw, 2959 st, 2927 w, 2868 w, 1588 vw, 1544 vst, 1462 w, 1438 m, 1392 vst, 1317 m, 1291 vw, 1249 w, 1177 w, 1101 w, 1058 vw, 1024 w, 937 vw, 867 w, 801 m, 775 vw, 763 w, 539 vw, 463 vw, 435 w, 411 vw cm^{-1}. EI-MS: *m*/*z* (%) = 1048 (48) $[M]^+$, 523 (28) $[M/2]^+$. $C_{58}H_{82}Al_2N_4Se_2$ (1047.2): calcd. C 66.52, H 7.89, N 5.35; found C 67.10, H 8.03, N 5.33.

[LAl(μ-Te)$_2$AlL] (4). Method 1: Toluene (20 mL) was added to a mixture of **2** (1.000 g, 2.239 mmol) and tellurium (0.285 g, 2.230 mmol) and after complete dissolution of **2**, PMe_3 (0.03 mL, 1 M solution in toluene, 0.030 mmol) was added. The reaction mixture was stirred for an additional 15 h, the pale yellow insoluble product was filtered off, washed with toluene (5 mL) and dried in vacuo. Yield: 1.15 g (90% based on Te). Decomp. without melting above 260 °C. IR (KBr pellet): $\tilde{\nu}$ = 3061 w, 3024 vw, 2990 w, 2968 vs, 2956 vs, 2930 st, 2866 m, 1587 w, 1543 vs, 1462 vs, 1440 vs, 1394 vs, 1365 sh, 1300 m, 1251 s, 1176 m, 1100 m, 1057 m, 1024 m, 937 m, 942 w, 868 st, 798 vs, 780 m, 761 st, 708 vw, 648 w, 595 vw, 537 w, 447 vw, 417 vst cm^{-1}. EI-MS: *m*/*z* (%) = 1144 (25) $[M]^+$, 574 (60) $[M/2]^+$, 443 (100) $[M/2 - Te - H]^+$. $C_{58}H_{82}Al_2N_4Te_2$ (1144.5): calcd. C 60.87, H 7.22, N 4.90; found C 60.50, H 7.15, N 4.82.

Method 2: Toluene (20 mL) was added to a mixture of **2** (1.000 g, 2.239 mmol) and $TePEt_3$ (0.550 g, 2.239 mmol) and the reaction mixture was stirred for an additional 2 h. The pale-yellow insoluble product was filtered off, washed with toluene (5 mL) and dried in vacuo. Yield: 1.22 g (95%).

[LAl(μ-S)$_2$AlL] (5): Toluene (20 mL) was added to a mixture of **1** (1.144 g, 2.239 mmol) and **2** (1.000 g, 2.239 mmol) and the reaction mixture was refluxed over a period of 15 h. After this time, the mixture was cooled to ambient temperature and a white insoluble product was filtered off, washed with toluene (5 mL) and dried in vacuo. Yield: 1.96 g (92%). Decomp. without melting above 200 °C. IR (KBr pellet): $\tilde{\nu}$ = 3062 vw, 2959 st, 2924 m, 2866 w, 1589 vw, 1547 vst, 1529 sh, 1462 m, 1437 m, 1390 vst, 1317 st, 1291 vw, 1249 m, 1176 w, 1100 vw, 1058 vw, 1024 w, 937 vw, 868 w, 801 m, 775 w, 763 w, 652 vw, 541 w, 516 m, 472 w, 454 m cm^{-1}. EI-MS: *m*/*z* (%) = 952 (100) $[M]^+$, 937 (64) $[M - CH_3]^+$, 909 (21) $[M - C_3H_7]^+$, 477 (58) $[M/2]^+$. $C_{58}H_{82}Al_2N_4S_2$ (953.40): calcd. C 73.07, H 8.67, N 5.88; found C 72.63, H 8.53, N 5.88.

X-ray Crystallographic Study: Data for the X-ray structures of [LAl(μ-S)$_2$AlL] and [LAl(μ-Te)$_2$AlL] were collected on a Bruker three-circle diffractometer equipped with a SMART 6000 CCD area-detector, whereas data for the X-ray structural analysis of [LAl(μ-Se)$_2$AlL] were collected on a Stoe-AED 2 four-circle diffractometer. Structures were solved by direct methods (SHELXS-97)[36] and refined by full-matrix least-squares methods on F^2 with SHELXL-97.[37] The non-hydrogen atoms were refined anisotropically; hydrogen atoms were included at geometrically idealized positions and refined with the riding model.
CCDC-228825 (for **5**), -228826 (for **3**), -228827 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

The Thermal Decomposition of S_2O Forming SO_2, S_3, S_4 and S_5O − An ab initio MO Study

Ralf Steudel*[a] and Yana Steudel[a]

Keywords: Cycloaddition / Disproportionation / Sulfur / Sulfur heterocycles / Thermodynamics / Transition states

All chemically reasonable [2+2] and [2+3] dipolar addition reactions between two S_2O molecules forming heterocyclic intermediates of composition S_4O_2, as well as the decomposition of these species to generate the observed products S_3 and SO_2, have been studied by gas-phase ab initio MO calculations at the G3X(MP2) level of theory. The reaction enthalpies, Gibbs energies and, partly, activation enthalpies of 17 reactions have been calculated. The [2+2] cycloadditions of S_2O are all endothermic and are characterized by high barriers. The reaction of lowest activation enthalpy ($\Delta H^{\#}_{298}$ = 11 kJ·mol^{-1}) is the exothermic [2+3] cycloaddition of two S_2O molecules resulting in the five-membered heterocycle oxatetrathiolane 2-oxide S_4O_2 (**7**), which is predicted to decompose at 298 K exothermally and without any activation enthalpy to SO_2 plus S_3. The S_3 molecule is predicted to add exothermally to S_2O to give the five-membered homocycle S_5O which has, in fact, been prepared in this way before. The bimolecular decomposition of S_5O to SO_2, S_4 and S_5 is also exothermic and may explain the formation of the red S_4 molecule on condensation of S_2O at temperatures below –130 °C. The implications of these results for the understanding of the chemistry on Jupiter's moon Io are discussed.

Introduction

Disulfur monoxide is a combustion product of elemental sulfur under special reaction conditions, along with SO_2 and SO_3. S_2O is also formed in numerous redox reactions between reduced sulfur compounds and oxidizing agents as well as in thermal decomposition reactions of sulfur-rich sulfane oxides and sulfur oxides.[1] S_2O can be obtained in a practically pure form by the heterogeneous reaction of thionyl chloride vapor with solid silver sulfide at 160 °C and low pressures, see Equation (1).[2]

$$SOCl_2 + Ag_2S \rightarrow S_2O + 2AgCl \quad (1)$$

More recently, S_2O has seemingly been generated in solution by thermal decomposition of suitable organic precursors (e.g., sulfane oxides) or of S_8O, and the S_2O unit[3−5] and its decomposition product S_3 [5] have been trapped in situ by addition reactions with either unsaturated transition metal complexes[3] or with olefins, dienes or diazoalkanes.[4,5] These fascinating developments may result in a renaissance of S_2O chemistry in solution, although it must be stressed that this molecule has never been observed directly (e.g., spectroscopically) in liquid solutions.

The molecule S_2O is bent (C_s symmetry) in a similar fashion to its more symmetrical triatomic relatives O_3, SO_2 and S_3 (C_{2v} symmetry in each case). The most accurate experimental geometrical parameters of S_2O are d_{SO} = 145.6 pm, d_{SS} = 188.5 pm and a_{SSO} = 117.9°.[6]

The reactivity of S_2O has not been studied systematically, probably due to its thermal instability.[1] On condensation of gaseous S_2O at low temperatures, by dissolution in cold inert solvents or by increasing its partial pressure in the gas-phase at room temperature to values above 1 mbar, S_2O decomposes rapidly.[1] The final decomposition products of S_2O are elemental sulfur (S_8) and sulfur dioxide but the following intermediates have been observed under differing reaction conditions (in chronological order):

Deep-yellow amorphous polysulfur oxides of composition S_xO ($x > 3$) are formed on condensation of gaseous S_2O at −196 °C and subsequent warming of the condensate to 20 °C; at temperatures below −130 °C the initial condensates are cherry-red but after warming to near room temperature they turn yellow and on subsequent cooling they remain yellow.[2,7] The red color is as more intense with higher S_2O concentrations in the original gas.

Sulfur radicals have been detected by low-temperature ESR spectroscopy (−150 °C) in condensates formed from gaseous S_2O.[2]

The probably homocyclic oxide S_5O has been obtained in solution when a gaseous S_2O/SO_2 mixture was bubbled into inert solvents at low temperatures (e.g., $CHCl_3$ at −60 °C) followed by removal of the excess SO_2 under vacuum.[8] At temperatures above −20 °C the intensely yellow-colored dissolved S_5O decomposes with formation of SO_2 and elemental sulfur.

The yellow-green molecule S_3 has been detected by low-temperature Raman spectroscopy in matrix-isolation experiments with gaseous S_2O,[9] as well as by UV/Vis spectroscopy of condensates of from gaseous S_2O (absorption at 420 nm).[10]

The red molecule S_4 has been detected by UV/Vis spectroscopy (absorption at 530 nm) in the aforementioned low-temperature condensates of S_2O,[10] although the Raman spectra of matrix-isolated and then thermally decomposed S_2O (by controlled diffusion) did not show any evidence for S_4.[9]

The mechanisms by which these intermediates and products are formed are unknown. Therefore, we have calculated by ab initio MO methods the most likely initial products of the thermal S_2O decomposition as well as some of the relevant transition states using the high-level G3X(MP2) method which is known to produce reliable thermodynamic data for sulfur-rich molecules.[11,12] Bimolecular reactions have been assumed for the initial stages. Our results shed a new light on the interpretation of the colors observed on Jupiter's moon Io, the surface of which is partly covered by elemental sulfur and sulfur oxides.

Results and Discussion

According to the above discussion the primary decomposition reactions of S_2O are expected to be the following [Equations (2) and (3)].

$$2\,S_2O \rightarrow S_3 + SO_2;\quad \Delta H^\circ_{298} = -49\ \text{kJ·mol}^{-1},\ \Delta G^\circ_{298} = -50\ \text{kJ·mol}^{-1} \qquad (2)$$

$$S_2O + S_3 \rightarrow \textit{cyclo}\text{-}S_5O;\quad \Delta H^\circ_{298} = -87\ \text{kJ·mol}^{-1},\ \Delta G^\circ_{298} = -34\ \text{kJ·mol}^{-1} \qquad (3)$$

Our calculated energies, enthalpies as well as the Gibbs energies of the species mentioned in Equations (2)−(18) are listed in Table 1. These data show that the reactions according to Equations (2) and (3) are strongly exothermic as well as exergonic. This then also holds for the overall reaction [Equation (4)].

$$3\,S_2O \rightarrow S_5O + SO_2;\quad \Delta H^\circ_{298} = -136\ \text{kJ·mol}^{-1},\ \Delta G^\circ_{298} = -83\ \text{kJ·mol}^{-1} \qquad (4)$$

The homocyclic S_5O molecule (pentathiolane oxide) may be considered as the simplest representative of the so-called polysulfur oxides (mentioned in the Introduction), which probably consist of cyclic and chain-like sulfur-rich species of unknown molecular mass and with the oxygen atoms mainly present as sulfoxide groups.[1]

The calculated NBO atomic charges of the S_2O molecule are −0.78 for oxygen, +1.00 for the central and −0.23 for the terminal sulfur atom. Therefore, the molecule is expected to undergo dipolar addition reactions. In the following sections we investigate the most reasonable [2+2] and [2+3] cycloaddition reactions between two S_2O molecules. Any [3+3] cycloaddition, on the other hand, seems to be unlikely since atoms of equal charge would have to combine to form covalent bonds. The calculated geometrical parameters of S_2O are d_{SO} = 146.5 pm d_{SS} = 190.8 pm and α_{SSO} = 118.2°.

[2+2] Additions

The most likely first step of the reaction shown in Equation (2) is an intermolecular S···O attraction between the

positively charged central sulfur atom of molecule 1 and the negatively charged oxygen atom of molecule 2. Two such configurations — configurations A and B — are possible, as shown in Figure 1.

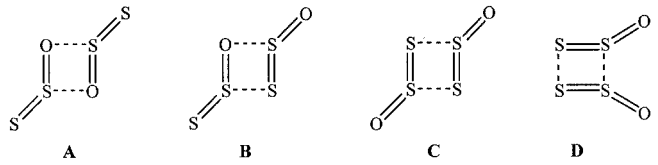

Figure 1. Four possible configurations for the [2+2] cycloaddition between two S_2O molecules

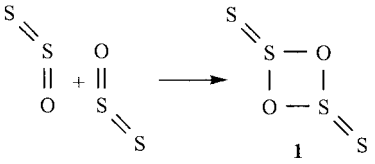
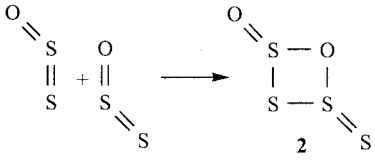
If the subsequent dipolar cycloaddition occurs according to the [2+2] type the four-membered heterocycles **1** or **2** of composition S_4O_2 shown in Figure 2 will result. However, the corresponding reactions given in Equations (5) and (6) are predicted to be strongly endothermic.



$\Delta H°_{298} = 101$ kJ mol^{-1}
$\Delta G°_{298} = 154$ kJ mol^{-1} (5)



$\Delta H°_{298} = 48$ kJ mol^{-1}
$\Delta G°_{298} = 100$ kJ mol^{-1} (6)

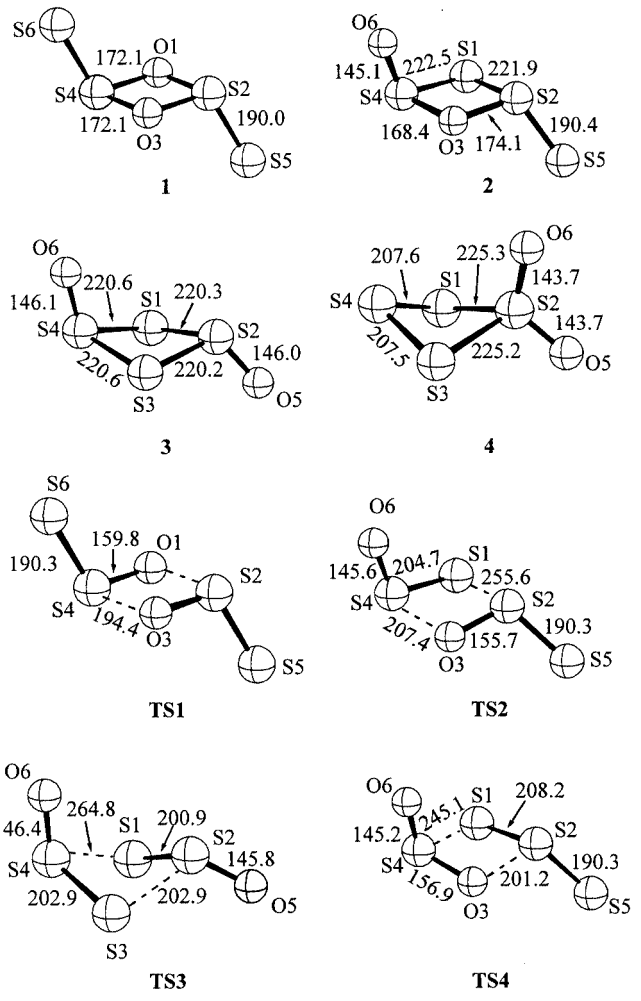


Figure 2. Geometries of four isomers of the four-membered heterocycles S_4O_2 (**1**−**4**) and of the transition states for their formation (**TS1**−**4**); the structures of **1** and **TS1** have C_{2h} symmetry, whereas all others have C_1 symmetry; bond lengths in pm (for more details see Tables 2 and 4)

The pseudo-heterocycle **1** (1,3,2,4-dioxadithiethane 2,4-disulfide) is of C_{2h} symmetry. The four-membered ring is planar and the two exocyclic sulfur atoms are located *trans* to each other (torsion angles S−S−O−S: ±108.3°). All bond lengths show normal values and the bond angles are in the expected range of 82−110° (Table 2). Compared to the S_2O molecule the charges on all atoms of **1** have increased ($S_{terminal}$: −0.25; $S_{central}$: +1.13; O: −0.88).

The transition state for the formation of **1** from S_2O (**TS1**) has been located on the potential-energy surface (PES) of S_4O_2; its structure is given in Figure 2. This structure is also of C_{2h} symmetry and rather similar to that of **1**, although the S−O bond lengths (159.8 and 194.4 pm) are different from those in **1** (172.1 pm; 146.5 pm in S_2O). Additional geometrical data are listed in Table 2. The formation of **TS1** from two molecules of S_2O requires an activation enthalpy of 111 kJ·mol^{-1} rendering this reaction rather unlikely.

The heterocycle **2** (oxatrithiethane 2-oxide 4-sulfide) has no symmetry at all. The maximum charge separation between the S and O atoms in **2** (2.3 electrostatic units) is even larger than in the case of **1** (see Table 3). Consequently, there is a relatively large dipole moment of 1.60 D. The four-membered ring of **2** is not planar (torsion angles in the ring: ±12−16°), and the two exocyclic atoms are in a *trans* position to each other as in the case of **1**.

The structure of the transition state for the formation of **2** from S_2O is also shown in Figure 2 (**TS2**, symmetry C_1). As expected, two of the bonds within the four-membered ring are extremely long (S1−S2: 255.6 pm; S4−O3: 207.4 pm). Bond angles and torsion angles are listed in Tables 2 and 4. The formation of **TS2** from two molecules of S_2O requires an activation enthalpy of 79 kJ·mol^{-1}.

If the dipolar addition of two S_2O molecules took place between the four sulfur atoms the homocyclic tetrathiethane 1,3-dioxide **3**, with two exocyclic oxygen atoms (Figure 1, configuration C), would result [Equation (7)].

$\Delta H°_{298}$ = 19 kJ mol^{-1}
$\Delta G°_{298}$ = 70 kJ mol^{-1}

Surprisingly, the structure of **3** is not of C_{2h} symmetry (in analogy to that of **1**) but approximately of C_s symmetry (see Figure 2; enforcing C_s symmetry results in one imaginary vibrational wavenumber). The S−S bond lengths within the homocycle are only pairwise equivalent but almost identical (220.2 and 220.6 pm). The absolute values of the four S−S−S−O torsion angles are also pairwise identical but the two pairs are quite different from each other (±90.7°

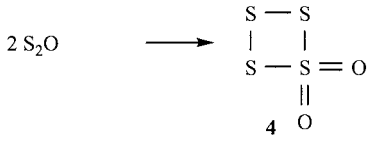
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and ±130.9°). The four S−S−S−S torsion angles are all ±20.5°. For further bond and torsion angles, see Tables 2 and 4.

The symmetrical structure of **3** (C_{2h} symmetry) is only 1 kJ·mol^{-1} less stable than the global minimum structure. However, this C_{2h} structure corresponds to a first-order transition state with one imaginary vibrational wavenumber and connects two equivalent structures of C_s symmetry that have dipole moments of 0.60 D.

The generation of **3** from S_2O requires an activation enthalpy of 53 kJ·mol^{-1}. The structure of the corresponding transition state **TS3** is shown in Figure 2. This structure is even less symmetrical than the structure of **3**, with S−S bond lengths in the range 200.9−264.8 pm and S−S−S−S torsion angles of ca. 28° and −38° (two each). For additional parameters, see Tables 2 and 4.

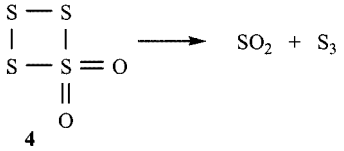
The formation of an isomeric tetrathiethane 1,2-dioxide from S_2O seems to be rather unlikely since atoms of equal charge would have to form bonds with each other (Figure 1, configuration D). Interestingly, the homocyclic S_4O_2 isomer **4** with a sulfone group (tetrathiethane 1,1-dioxide; see Figure 2) is also a stationary point on the PES of S_4O_2. This species is approximately of C_s symmetry (μ = 2.20 D) and exhibits the expected bond length pattern with two long S−S bonds (225.2 pm) and two S−S bonds of normal length (207.5 pm). The formation of **4** from S_2O is slightly exothermic. However, this transformation cannot be an elementary reaction but must be a multistep process [Equation (8)].



(8)

$\Delta H°_{298}$ = −8 kJ mol^{-1}
$\Delta G°_{298}$ = +46 kJ mol^{-1}

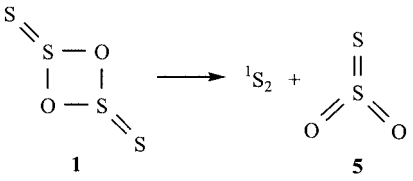
The hypothetical isomerization reactions of the heterocycles **1** or **2** to give **4** are exothermic by −109 and −56 kJ·mol^{-1}, respectively, but there is no simple mechanism either for these transformations. The decomposition of **4** to SO_2 and S_3 is exothermic, as expected [Equation (9)].



(9)

$\Delta H°_{298}$ = −42 kJ mol^{-1}
$\Delta G°_{298}$ = −96 kJ mol^{-1}

Other reactions of **1** and **2** may be possible besides isomerizations. In principle, isomer **1** could split into singlet S_2 ($^1\Delta_g$; $^1S_2$) and the hypothetical S_2O_2 isomer **5**, which is known to be the global minimum on the PES of singlet S_2O_2 [Equation (10)].[13]

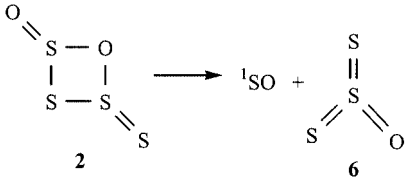


(10)

$\Delta H°_{298}$ = +29 kJ mol^{-1}
$\Delta G°_{298}$ = −15 kJ mol^{-1}

The planar molecule S_2O_2 is of C_{2v} symmetry with two equivalent S−O bonds of length 143.9 pm and an S−S bond of 189.7 pm (a_{OSO} = 119.5°; β_{OSS} = 120.3°; μ = 0.97 D). The S_2 molecule formed in Equation (10) would most probably return to is triplet ground state and either dimerize to give the spectroscopically observed S_4 molecule or trigger a radical-chain polymerization which would explain the sulfur radicals observed by ESR spectroscopy in condensates of S_2O at low temperatures.[2] The latter behavior of S_2 is well-known.

In a similar fashion, the S_4O_2 isomer **2** could theoretically split off singlet SO ($^1\Delta$) with formation of the hypothetical planar S_3O molecule **6** [Equation (11)] but this reaction is strongly endothermic.



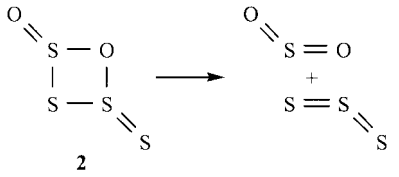
(11)

$\Delta H°_{298}$ = 201 kJ mol^{-1}
$\Delta G°_{298}$ = 155 kJ mol^{-1}

The planar star-like molecule S_3O is also of C_{2v} symmetry with the geometrical parameters d_{SS} = 190.7, d_{SO} = 145.2 pm and a_{SSS} = 121.4° (μ = 0.99 D). Sulfur monoxide (^{1}SO and ^{3}SO) is known to rapidly disproportionate to S_2O and SO_2.[1] The further fate of the species **5** and **6** cannot be predicted with certainty but disproportionation, with formation of elemental sulfur and either S_2O or SO_2, are most likely to occur.

The reactions shown in Equations (5) and (6) as well as Equations (10) and (11) are all highly unlikely at low temperatures due to their endothermic nature and, as far as is known, due to their high activation enthalpies. Nevertheless, it should be pointed out that isomer **2** could easily split into SO_2 and S_3 and thus explain these observed products by a cycloreversion reaction which was first proposed by Tang and Brown [Equation (12)].[9] This reaction is, in fact, strongly exothermic.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



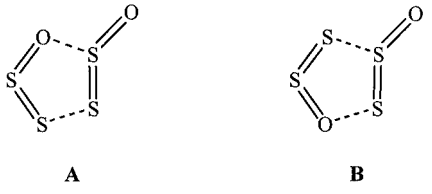
2 (12)

$\Delta H°_{298} = -98$ kJ mol^{-1}
$\Delta G°_{298} = -150$ kJ mol^{-1}

The structure of the transition state for the reaction shown in Equation (12) is also shown in Figure 2 (**TS4**); its formation from **2** requires only 10 kJ·mol^{-1}. The molecules S_3 and SO_2 are preformed in **TS4** and are connected by a very long S−O bond (201.2 pm) and a similarly long S−S bond (245.1 pm). For further data on **TS4**, see Tables 2−4.

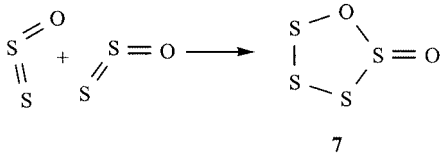
[2+3] Additions

Since the hypothetical [2+2] cycloadditions of two S_2O molecules cannot explain the thermal decomposition of this compound at low temperatures we have investigated the alternative [2+3] mechanism for which two approaches (A and B) are possible, as shown in Figure 3. In the case of A the two most highly charged atoms (O and $S_{central}$) of neighboring molecules would combine due to their opposite atomic charges. This interaction is more likely than configuration B, in which the highly negatively charged oxygen atom would combine with the slightly negatively charged terminal sulfur atom of the neighboring molecule resulting in 1-oxatetrathiolane 3-oxide. In addition, the latter molecule would not help to explain the formation of SO_2 and S_3. The product expected from configuration B (**7a**) was found to be much less stable than **7** and this also holds for the six-membered ring 1,4,2,3,5,6-dioxatetrathiane (**7b**) which would be the expected product of a [3+3] cycloaddition of two S_2O molecules.[14] For these reasons, we have only investigated in detail the formation of the 1-oxatetrathiolane 2-oxide **7** (configuration A in Figure 3).



A **B**

Figure 3. Two possible configurations for the [2+3] cycloaddition between two S_2O molecules



7 (13)

$\Delta H°_{298} = -11$ kJ mol^{-1}
$\Delta G°_{298} = +43$ kJ mol^{-1}

We predict that the reaction shown in Equation (13) is exothermic and therefore more likely than all alternative bimolecular reactions of S_2O discussed above.

The structure of **7** is shown in Figure 4. It is characterized by two normal S−S bonds and, neighboring the exocyclic oxygen atom, one rather long S−S bond (231.9 pm). The SO_2 structural unit is already close in geometry to the free SO_2 molecule, which is a well-known leaving group. This view is supported by the rather long S2−O3 single bond (176.5 pm) between the SO_2 and S_3 units. The second S−O single bond of **7** is of normal length (162.5 pm). The absolute values of the torsion angles within the ring are between 9° and 56° (Table 4). The exocyclic atom is in an axial position (μ = 2.26 D).

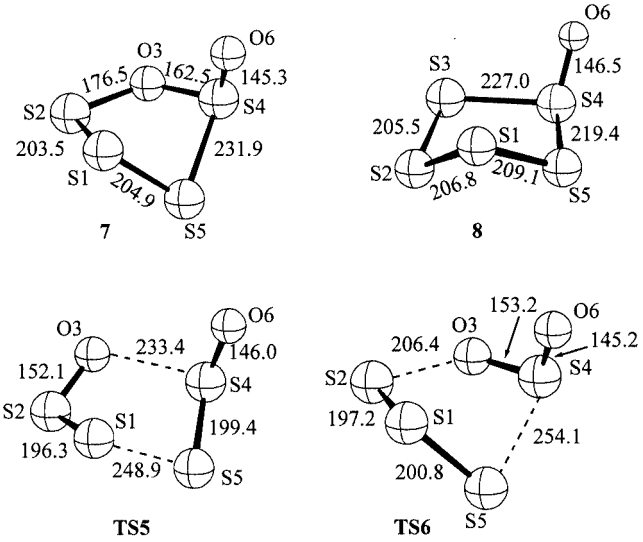


Figure 4. Geometries of the five-membered heterocycles S_4O_2 (**7**) and S_5O (**8**) and of the transition states for their formation (**TS5** and **6**); bond lengths in pm (for more details see Tables 2 and 4.)

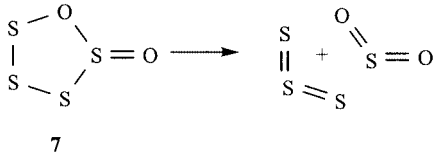
The formation of **7** from S_2O proceeds via the transition state TS5, the structure of which is also shown in Figure 4. This species is of C_1 symmetry and the two S_2O units are connected by an S−O bond of length 233.4 pm and an S−S bond of length 248.9 pm. The torsion angles within the five-membered ring range from 6° to 62° (absolute values). All bond angles have normal values (see Tables 2 and 4). The enthalpy of **TS5** is just 11 kJ·mol^{-1} above that of two S_2O molecules. Therefore, Equation (13) describes the reaction channel of lowest activation enthalpy of all reactions between two S_2O molecules studied in this work.

The thermal dissociation of **7** into S_3 and SO_2 [Equation (14)] is exothermic.



7 (14)

$\Delta H°_{298} = -38$ kJ mol^{-1}
$\Delta G°_{298} = -92$ kJ mol^{-1}

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The transition state for this reaction has been located on the PES (**TS6**). Its geometry is depicted in Figure 4, with more details in Tables 2 and 4. On the potential energy surface (E_o) **TS6** is 9 kJ·mol^{-1} less stable than oxatetrathiolane oxide **7** [B3LYP/6-31G(2df,p) data] but the G3X(MP2) enthalpies and Gibbs energies of **TS6** and **7** at 298 K are practically identical, with slightly lower values calculated for the **TS6** geometry (Table 1). Therefore, we assume that the dissociation of **7** proceeds spontaneously at 298 K and the reactions given in Equations (13) and (14) perfectly explain the initial stages of the thermal decomposition of S_2O at low and moderate temperatures.

The structure of S_3 calculated in this work (d_{SS} = 193.3 pm; α_{SSS} = 118.2°) agrees fairly well with the recently determined experimental gas-phase structure [d_{SS} = 191.7(1) pm, α_{SSS} = 117.36(6)°].[15] The calculated NBO atomic charges of the S_3 molecule are +0.32 for the central atom and −0.16 for the two terminal atoms. This molecule may therefore interact with S_2O with formation of the homocyclic S_5O molecule (**8**) by a [2+3] dipolar addition [Equation (3)]. The calculated structure of **8** is shown in Figure 4. The molecule contains the oxygen atom in an axial position with regard to the nonplanar S_5 ring. The S−S bond lengths vary between 205.5 and 227.0 pm (μ = 1.73 D). These structural data are in accordance with those of the related homocyclic oxides S_7O[16] and S_8O,[17] which have both been characterized by single-crystal X-ray diffraction analyses. The very long S3−S4 bond is probably the main reason for the thermal instability of S_5O, which decomposes on attempts to isolate it from solutions in which it has been prepared by dissolution of gaseous S_2O.[8] Since the torsion angle at this particular bond is only 11.6°, far from the optimum value of 90°, a large bond length is to be expected. We have previously shown that torsion angles and bond lengths in sulfur rings are related to each other.[18] All other torsion angles within the five-membered homocycle have absolute values of between 28° and 64°, mainly caused by the small ring size.

The IR spectrum of S_5O in CS_2 at −65 °C is characterized by a strong absorption at 1138 cm^{-1} in agreement with our calculated value for the S=O stretching vibration of 1131 cm^{-1} (scaled by 0.95). The remaining fundamentals of **8** are located at 490, 457, 398, 379, 305, 287, 260, 238, 212, 191 and 67 cm^{-1} [B3LYP/6-31G(2df,p) data, scaled by 0.95].

The formation of S_5O according to Equation (3) seems to proceed without any activation enthalpy. We have scanned the reaction coordinate of the reverse reaction — the dissociation of S_5O into S_2O and S_3 — by increasing the bond lengths S1−S5 and S3−S4 of **8** in steps of 0.5 pm up to 270 pm and optimizing all other parameters. The energy increased continuously to higher values but no maximum could be found.

The further fate of S_3 and S_5O in the decomposing S_2O/S_3 mixture can be discussed only in a somewhat speculative manner. If S_3 should attack S_5O the well-known S_8O[1] may be formed, although radicals may also originate from the head-to-tail polymerization of S_3. On the other hand, if two S_3 molecules undergo a cycloaddition reaction of the [2+3] type, the hypothetical S_5=S molecule will result, while a [3+3] addition would give the well-known *cyclo*-S_6. These cycloaddition reactions are both strongly exothermic.[19] However, so far no experimental evidence for the possible formation of either S_8O or S_6 from S_2O is available.

The reported formation of S_4 from S_2O has not been explained yet since no elementary reactions are known to generate this molecule directly from S_2O at low temperatures in an exothermic reaction. In principle, S_4 could originate from S_2 by dimerization but the direct formation of S_2 from S_2O is strongly endothermic even if the S_2 molecule is formed in its triplet ground state [Equation (15)].

$$2\,S_2O \rightarrow {}^3S_2 + S_2O_2\,(\mathbf{5});\quad \Delta H^\circ_{298} = +84\ \text{kJ·mol}^{-1},\ \Delta G^\circ_{298} = +90\ \text{kJ·mol}^{-1} \tag{15}$$

The red S_4 molecule is probably responsible for the cherry-red color of condensates made from pure or almost pure S_2O at liquid nitrogen temperature.[20] It seems that S_4 and the sulfur radicals detected by ESR spectroscopy are formed only if the concentration of S_2O is very high since no S_4 has been detected in matrix-isolation experiments with diffusion-controlled decomposition of S_2O.[9] Therefore, more complex reactions may be responsible for the formation of S_4. While the reaction in Equation (16) is spin-forbidden and endothermic[21] the bimolecular decomposition of S_5O is exothermic and might produce S_4 even at low temperatures [Equation (17)].

$$S_5O + S_2O \rightarrow SO_2 + S_4 + {}^3S_2;\quad \Delta H^\circ_{298} = +50\ \text{kJ·mol}^{-1},\ \Delta G^\circ_{298} = +1\ \text{kJ·mol}^{-1} \tag{16}$$

$$2\,S_5O \rightarrow SO_2 + S_4 + \textit{cyclo}\text{-}S_5;\quad \Delta H^\circ_{298} = -29\ \text{kJ·mol}^{-1},\ \Delta G^\circ_{298} = -84\ \text{kJ·mol}^{-1} \tag{17}$$

The observation that S_5O, dissolved in $CHCl_3$ or CS_2, decomposes at temperatures above −20 °C with formation of SO_2 and elemental sulfur[8] indicates that the reaction according to Equation (17) has a rather small activation enthalpy. In this context it is interesting to mention that S_2O, if condensed very slowly on a cold finger at −196 °C, produces a condensate that is transparent and just slightly pink colored but turns intensely red on warming to ca. −150 °C.[7]

Theoretically, S_4 could also be formed from S_3, as shown in Equation (18), but this reaction is slightly endothermic and spin-forbidden and therefore may require a substantial activation enthalpy.

$$2\,S_3 \rightarrow {}^3S_2 + S_4;\quad \Delta H^\circ_{298} = +13\ \text{kJ·mol}^{-1},\ \Delta G^\circ_{298} = +17\ \text{kJ·mol}^{-1} \tag{18}$$

Thus, the reactions shown in Equations (13), (14), (3) and (17) are most likely responsible for the formation of S_4 from

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

S_2O on condensation. However, S_4 will play a role only if the S_2O concentration and therefore the concentrations of S_3 and consequently of S_5O are not too low.

Implications for the Chemistry on Jupiter's Moon Io

Large parts of Jupiter's satellite Io are covered by elemental sulfur and solid sulfur dioxide ("SO_2 frost").[22] The surface temperature varies between 80 and 1400 K, not only due to day-and-night changes but also due to the presence of several "hot spots". There are a number of active volcanoes on Io, the most prominent of which is named Pele. The plume of Pele reaches a height of 350 km since both the gravitational force and the atmospheric pressure (ca. 10^{-7} bar) are much lower on Io than on Earth. Spectroscopic measurements have shown that Pele's plume contains SO_2, SO as well as S_2 and it is widely believed that this volcano is powered by hot silicate magma which heats underground deposits of SO_2 and elemental sulfur; if the pressure is high enough eruptions will occur.[23] Equilibrated hot mixtures of elemental sulfur and sulfur dioxide always contain a few percent of SO and S_2O, depending on temperature, total pressure and S:O ratio.[24] S_3 is also expected to be a prominent constituent of the hot sulfur/SO_2 mixture ejected from the magma chamber.[24] During the volcanic eruptions the unstable (highly reactive) species sprayed into the Ionian atmosphere experience both a sharp drop in total pressure and a steep temperature gradient but they are now also exposed to the UV radiation of the Sun. In addition, S_2O may also be formed within the plume from SO and S_3 by the following spin-allowed reaction [Equation (19), which we found to be exothermic and exergonic.[25]

$$^3SO + S_3 \rightarrow S_2O + {}^3S_2;\quad \Delta H^\circ_{298} = -70\ kJ{\cdot}mol^{-1},\ \Delta G^\circ_{298} = -68\ kJ{\cdot}mol^{-1} \qquad (19)$$

The question is then: What will be the lifetime and the sink for the S_2O molecules?

The present results indicate that S_2O will most probably react with S_3 to give S_5O as soon as the temperature within the volcanic plume drops below a certain limit and the chemical equilibrium is no longer established. Due to the low S_2O concentration a reaction between two S_2O molecules as in Equation (13) is less probable. The S_5O molecules may then be deposited on the surface of Io, but on exposure to UV radiation they will eventually decompose to elemental sulfur and SO_2. On the other hand, S_2O may also be decomposed photolytically into SO and sulfur atoms.

S_4 has been thought to be responsible for the orange or red deposits on the surface of Io which have been detected in particular in the vicinity of volcanoes, and S_2O has been suggested as the precursor of this S_4.[23] Our results and discussions show that S_2O is not likely to produce S_4 under the temperature and pressure conditions of the Ionian atmosphere since the concentrations of S_2O and its decomposition products S_3 and S_5O within the volcanic plumes will simply be too low to allow a series of bimolecular reactions like $S_2O \rightarrow S_3 \rightarrow S_5O \rightarrow S_4$. In addition, it should be mentioned that the published color pictures of Io's surface often use artificially enhanced colors ("false colors") to enhance the contrast of the color variations, in which case orange may look red, while the true colors of the sulfur deposits on Io's surface are more yellowish.[26]

Conclusion

The most likely initial step of the thermal decomposition of pure disulfur monoxide is a [2+3] cycloaddition between two S_2O molecules to give the five-membered ring oxatetrathiolane 2-oxide **7**. This reaction is exothermic and the activation enthalpy is small. The heterocycle **7** is predicted to spontaneously dissociate at 298 K into SO_2 and S_3, a reaction which is also exothermic and which has no barrier. Therefore, pure S_2O is not stable in the gas phase at partial pressures above 1 mbar, in solid condensates at temperatures above −130 °C, or in liquid solutions above −70 °C. The S_3 molecule can add exothermally to another S_2O molecule with formation of the homocyclic sulfoxide S_5O (pentathiolane oxide, **8**) which has previously been prepared in this way. However, at higher concentrations, as in condensates of pure or almost pure S_2O, the S_3 and S_2O molecules may also undergo radical-chain polymerization reactions since ESR spectra have shown the presence of sulfur radicals. The result of all of these reactions are polysulfur oxides of varying and partly unknown molecular size and, finally, especially at higher temperatures, elemental sulfur and sulfur dioxide. The most reasonable [2+2] cycloaddition reactions between two S_2O molecules resulting in various isomers of S_4O_2 are all strongly endothermic and therefore unlikely at low temperatures.

Computational Details

Standard ab initio calculations were carried out with the GAUSSIAN 98 series of programs[27] at the G3X(MP2) level of theory.[28] This theory corresponds effectively to QCISD(T)/G3XL//B3LYP/6-31G(2df,p) energy together with zero-point vibrational and isogyric corrections. The G3X(MP2) theory represents a modification of the G3(MP2) theory[29] with three important changes: (1) B3LYP/6-31G(2df,p) geometry, (2) B3LYP/6-31G(2df,p) zero-point energy, and (3) addition of a *g* polarization function to the G3Large basis set for the second-row atoms at the Hartree−Fock level. All three features are particularly important for the proper description of the sulfur-containing compounds examined in this work. For instance, the geometries of several cluster species are poorly predicted by the MP2 theory.

For all investigated molecules a charge-density analysis, at the B3LYP/6-31G(2df,p) level, was performed using the natural bond orbital (NBO) approach.[30] NBO atomic charges of small molecules have recently been demonstrated to agree well with experimental values obtained from X-ray diffraction data.[31] Unless otherwise noted, all relative enthalpies reported in this publication are given as ΔH°_{298} and correspond to the G3X(MP2) level.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The harmonic fundamental vibrations were calculated at the B3LYP/6-31G(2df,p) level. The corresponding eigenvalues were all positive for the minimum-energy structures reported below while transition states had one negative eigenvalue. Dipole moments (μ) are given in D (1 D = 3.336×10^{-30} Cm).

Molecular, One- and Two-Dimensional Systems Built from Manganese(II) and Phthalate/Diimine Ligands: Syntheses, Crystal Structures and Magnetic Properties

Chengbing Ma,[a] Wenguo Wang,[a] Xiaofeng Zhang,[a] Changneng Chen,[a] Qiutian Liu,*[a] Hongping Zhu,[a] Daizheng Liao,[b] and Licun Li[b]

Keywords: Manganese / N ligands / Magnetic properties / Structure elucidation

Several new Mn^{II} compounds, $[Mn_2(Hphth)_2(phen)_4](Hphth)_2{\cdot}2H_2O$ (**1**; H_2phth = phthalic acid, phen = 1,10-phenanthroline), $[Mn_2(Hphth)_2(phen)_4](ClO_4)_2{\cdot}2H_2O$ (**2**), $[Mn_4(phth)_4(phen)_4(H_2O)_4]{\cdot}2EtOH$ (**3**), $\{[Mn_4(phth)_2(phen)_8](PF_6)_4\}_2$ (**4**), $[Mn_4(phth)_2(bipy)_8](ClO_4)_4{\cdot}2EtOH$ (**5**; bipy = 2,2′-bipyridine), $[Mn(phth)(bipy)(H_2O)_2]_n$ (**6**), and $[Mn(phth)(pyz)(H_2O)_2]_n$ (**7**; pyz = pyrazine), have been synthesized by treatment of the appropriate Mn^{2+} salt and H_2phth with different diimine ligands. They were characterized by X-ray diffraction and show a variety of nuclearities, ranging from dinuclear (**1** and **2**) to tetranuclear (**3**–**5**), and dimensionalities, ranging from a 1D chain (**6**) to a 2D layer network (**7**), in which the phthalates act as primary bridging ligands coordinating to Mn atoms through their carboxylate groups in various bonding modes. Variable-temperature magnetic susceptibility measurements reveal weak anti-ferromagnetic coupling interactions in **1**, **3**, **4** and **6**.

Introduction

There has been increasing interest in the study and synthesis of discrete polynuclear or low-dimensional systems of paramagnetic metal ions, driven to a large extent by their specific structural features, their promising application in diverse areas of technology, such as magnetic recording and magnetic optics in the field of molecular magnetism,[1,2] and their unique properties,[3] as well as their potential as model compounds for the study of the active sites of the metalloenzymes with interacting paramagnetic centers.[4–6] A commonly used strategy to obtain such systems is to select appropriate extended bridging ligands which can transmit magnetic interactions and bind several metal centers through various bonding modes. In this sense, the terephthalate ligand has been used in many synthetic systems, and has generated a great variety of complexes whose magnetic behaviors have been extensively studied.[7–17] However, phthalate, an *o*-isomer of terephthalate, has been used only sparingly for this purpose,[18–20] in spite of the fact that it exhibits versatile bonding modes in metal complexes,[21] and that the neighboring carboxyls are noncoplanar with themselves and with the benzene ring. This could make the phthalate a promising candidate to produce new cluster topologies and to transmit various magnetic interactions.

Special attention has been paid to the structure and properties of manganese carboxylate cluster complexes due to their biological significance.[4,5,22] The Mn^{2+} ion usually plays a structural and/or hydrolytic role;[23] it is also found in some redox enzymes in the reduced form. Dinuclear manganese centers exist in manganese catalase, catalytically disproportionating H_2O_2,[24] and in ribonucleotide reductase, facilitating the reduction of RNA to DNA.[25] A tetranuclear manganese cluster in the oxygen-evolving center (OEC) of photosystem II successfully oxidizes H_2O to O_2,[26,27] though its structure is still a mystery. Recently, it has been shown that one pyrophosphatase needs three Mn^{2+} ions for catalytic activity.[28] To date, the chemistry of manganese cluster complexes with simple acetate and benzoate ligands has been fully developed,[29] but the use of dicarboxylate ligands for this purpose is relatively uncommon.[30–32] In the course of our ongoing work on manganese complexation by dicarboxylates, we have reported a trivalent dinuclear manganese complex with a (μ-oxo)bis(μ-Hphth) bridging core,[33] and have explored the structural transformation mediated by *o*-, *m*- and *p*-phthalate.[34] In this paper, keeping in mind that the number of the manganese complexes derived from phthalate is still low,[31,33–37] we have further explored the reaction of phthalic acid and a manganese(II) salt, with the introduc-

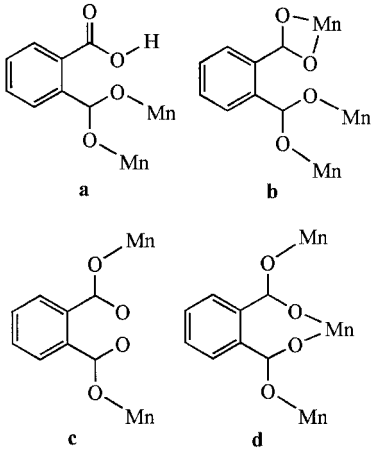
tion of the chelating 2,2′-bipyridine (bipy) and 1,10-phenanthroline (phen) ligands and the *exo*-bidentate μ-pyrazine (pyz) ligand as ancillary ligands, with the aim of inhibiting the expansion of the polymeric frameworks in order to obtain the desired polynuclear and low-dimensional complexes, or to induce the evolution of a novel structure, and obtained a new series of compounds (**1**−**7**). Various coordination modes of the phthalate to the Mn ion (Scheme 1) and a wide variety of structural topologies for these complexes are found. The magnetic properties of selected compounds are also discussed.



Scheme 1. Coordination modes of phthalate: (a) mono-bidentate; (b) bridging and chelating bis-bidentate; (c) bis-monodentate; (d) chelating/bridging bis-bidentate

Results and Discussion

Synthesis

Treatment of a mixture of H_2phth and an Mn^{2+} salt in the presence of various diimines gave compounds **1**−**7**, which were successfully isolated under different crystallization conditions. Partial deprotonation of H_2phth (H_2phth/KOH = 1:1) avoids the immediate precipitate derived from the direct reaction of $phth^{2-}$, Mn^{2+} and phen in EtOH/H_2O, leading to the formation of dinuclear compounds **1** and **2** with double μ-Hphth bridges; the use of H_2phth in the absence of KOH gave a known inclusion complex $[Mn(phen)_2(H_2O)Cl]Cl·0.5H_2phth$.[38] In general, increasing the KOH/H_2phth molar ratio is favorable to the complete deprotonation of H_2phth and leads to Mn complexes **3**, **4**, **6** and **7** containing completely deprotonated phthalate. Complex **5** contains a partially deprotonated Hphth ligand, probably due to the higher basicity of bipy. The use of neutral H_2phth and bipy resulted in the formation of a known Hphth compound with an $[Mn_2(\mu\text{-}O)(\mu\text{-}Hphth)_2]$ core.[33] The cyclic tetramanganese cluster **5** was isolated in the presence of bipy, while under similar conditions we only isolated the dinuclear complex **2** in the presence of phen. However, refluxing the reaction mixture containing $phth^{2-}$, Mn^{2+} and phen in EtOH/H_2O for several days caused the above-mentioned precipitate to dissolve, and led to the serendipitous formation of **3** and **4** from a one-pot reaction process. Here, PF_6^- as a specific counterion is crucial for the crystallization of both the compounds, even though there is no PF_6^- in compound **3**. When other counterions such as ClO_4^- was used instead of PF_6^-, we only isolated compound **2**. We also tried to omit the counterion from the reaction system, but either compound **1** or a known polymeric compound $[Mn(phth)(phen)(H_2O)_2]_n$ [35] was obtained depending on the degree of deprotonation of H_2phth. Attempts to prepare a bipy complex structurally analogous to **3** failed, even when varying counterion, solvent and starting Mn^{2+} salt. As expected, complex **7**, with a 2D layer framework, was isolated when the *exo*-bidentate μ-pyz ligand was used as the secondary linker instead of the chelating bipy ligand, as it is the end-capping bipy ligand that blocks the way towards higher dimensionality and maintains the 1D chain-like structure of **6**.

Structure Descriptions of Complexes 1−7

Both **1** and **2** contain the $[Mn_2(Hphth)_2(phen)_4]^{2+}$ cation, counterions and solvate water molecules in a molar ratio of 1:2:2 in the unit cell. The cations in **1** and **2** possess similar structural parameters, as listed in Table 1. Two equivalent Mn atoms related by a crystallographic inversion center are bridged by two carboxylate groups of Hphth ligands (Figure 1) in a *syn-anti* mode. The metal−metal distance of 4.786 Å for **1** (4.836 Å for **2**) is the largest amongst analogous dinuclear Mn^{2+} complexes with only two *syn-anti* bridging carboxylate groups: $[Mn_2(PhCOO)_2(bipy)_4]^{2+}$ (4.509 Å),[39] $[Mn_2(MeCOO)_2(bipy)_4]^{2+}$ (4.583 Å)[40] and $[Mn_2(ClCH_2COO)_2(phen)_4]^{2+}$ (4.613 Å).[41] The Mn atom

is in a distorted octahedral geometry, coordinated by four N atoms [Mn−N = 2.2557(19)−2.3088(18) Å for **1**, and 2.247(3)−2.286(3) Å for **2**] from two chelating phen ligands and two O atoms [Mn−O = 2.1176(16) Å and 2.1342(14) Å for **1**, and 2.117(2) Å and 2.127(2) Å for **2**] from bridging carboxylate groups. The Hphth, which acts as a mono-bidentate ligand (see a in Scheme 1), employs just one μ_2-carboxylate group to bridge two Mn atoms, with the other protonated one free. The characteristic IR absorptions for the stretching vibration of the protonated carboxylic group of Hphth appear at 1689 cm^{-1} for **1** (1701 cm^{-1} for **2**). The bond-valence sum (BVS) calculations based on the equation $s = \exp[(r_0 - r)/B]$[42] (r is the observed bond length and r_0 and B are empirically determined parameters[43]) give values of 1.97 and 1.99 for **1** and **2**, respectively, indicating that the Mn centers in both compounds are in the +2 oxidation state, and that the ligand is a partially deprotonated phthalate anion. The other complexes in this work gave similar values and are therefore not discussed further.

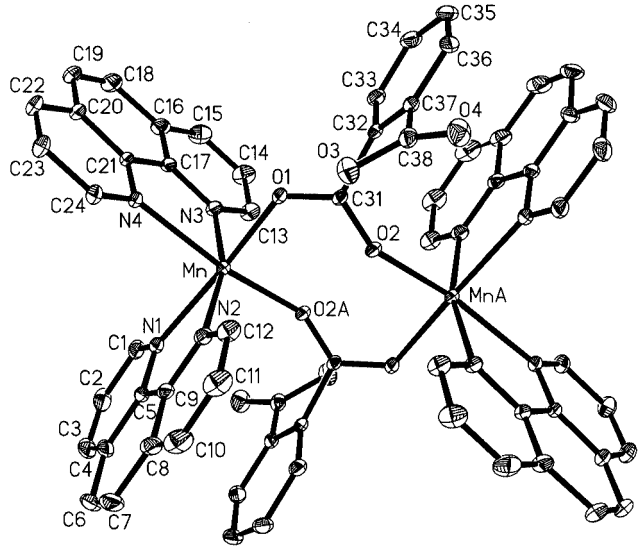

Figure 1. The structural view of the cation in **1** and **2** (ellipsoids at 20% probability)

Some differences were observed between the hydrogen-bonding networks of compounds **1** and **2**. Besides a short intramolecular hydrogen bond with an O6···O7 distance of 2.376 Å found in the uncoordinated Hphth ions, three intermolecular hydrogen bonds also exist in the structure of **1**. The water molecule (O9) bridges the coordinated Hphth ions of the adjacent cations through two hydrogen bonds to produce 1D chains [O9···O4$^{\#}$ 2.763 Å; O3···O9$^{\&}$ 2.544 Å; &: $-x - 1, -y + 1, -z + 1$; #: $x, y, z - 1$] (see a in Figure 2); the uncoordinated Hphth ions link to the hydrogen-bonded chain through a third intermolecular hydrogen bond with an O9···O8 distance of 2.725 Å. As for compound **2**, besides a hydrogen bond between the solvate water molecules, with an O9···O9 distance of 2.502 Å, a second intermolecular hydrogen bond between the protonated carboxylic groups of the adjacent cations links together the cations of **2** to form 1D hydrogen-bonded chains [O3···O4$^{\#}$ 2.634 Å; #: $-x + 3, -y + 2, -z$] (see b in Figure 2); no hydrogen-bonding interaction with the ClO_4^- counterion was observed.

The crystal structure of **3** contains one neutral discrete tetramanganese cluster and two solvate ethanol molecules in each independent crystallographic unit. The whole molecule lies on a crystallographic inversion center implying that only two Mn atoms (Mn1 and Mn2) are crystallographically independent. As shown in Figure 3, the four coplanar Mn^{2+} ions arrayed at the four corners of an approximate rhombus (sides 6.069−6.301Å and angles 140.65° and

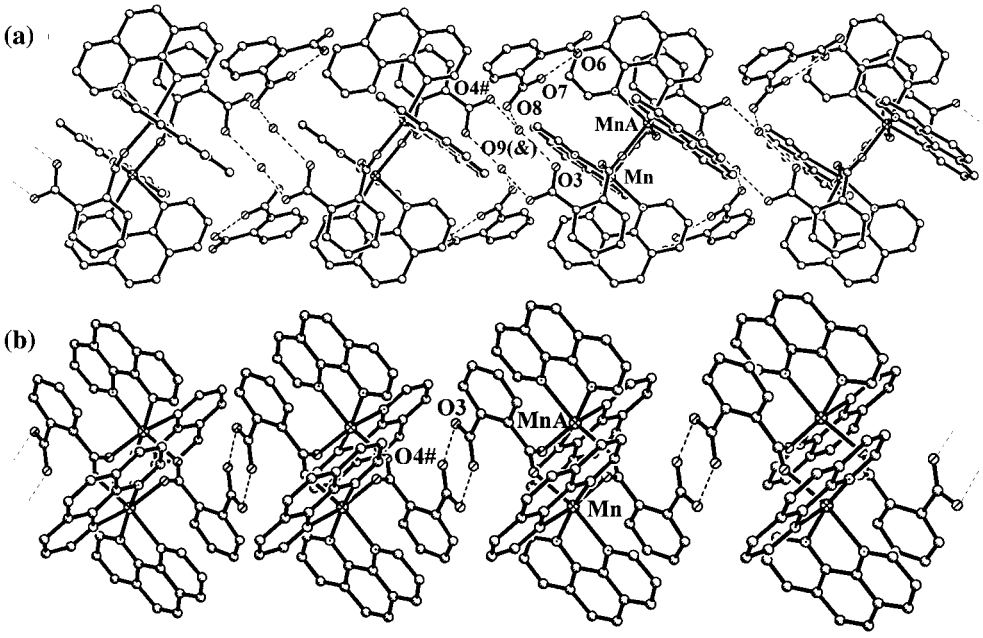

Figure 2. A view of the 1D hydrogen-bonded chains in **1** (a), and **2** (b)

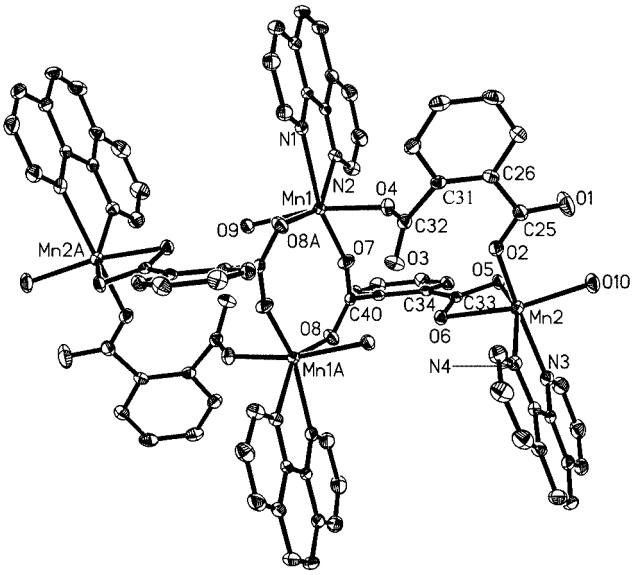

Figure 3. The structural view of the neutral tetranuclear cluster in **3** (ellipsoids at 30% probability)

39.35°), are bridged by two symmetry-related μ_3-phth ligands, one above and one below the Mn_4 rhombic plane. It is noteworthy that the phth ligand displays a unique bridging and chelating bis-bidentate mode, coordinating to three metal atoms through its one bridging carboxylate group and one chelating carboxylate group (see b in Scheme 1). To the best of our knowledge, this type of coordination mode for the phth ligand has not been found in other metal complexes.[21] In the Mn_4 rhombus, the two central Mn atoms (Mn1 and Mn1A, Mn1···Mn1A = 4.170 Å) are bridged by two bridging carboxylate groups of μ_3-phth ligands, and further linked to the two outer Mn atoms (Mn2 and Mn2A) through another chelating end of the same μ_3-phth ligands. Two bis-monodentate μ_2-phth ligands (see c in Scheme 1), four chelating phen ligands and four terminal water ligands complete the peripheral ligation, meaning that the Mn centers have distorted octahedral geometries (Table 2). All the phen-ring planes are nearly parallel with each other.

[a] Symmetry code: A: $-x + 1, -y + 1, -z + 1$.

It is worth noting that the rhombic Mn_4 cluster in **3**, with an unprecedented [$Mn_4(\mu_3$-phth$)_2$] core, provides an important addition to the available Mn_4 aggregate database, although several rhombic or "butterfly-like" Mn_4 carboxylate clusters with an [Mn_4{μ-carboxilic-O(H)}] core have been reported.[29,44−49]

Some interesting supramolecular contacts are observed in the solid-state structure of **3**. One hydrogen bond links the coordinated water molecule (O10) and the carboxyl O atom (O5) of the symmetry-related Mn-tetramer to generate 1D hydrogen-bonded ribbons [O10···O5& 2.723 Å; &:

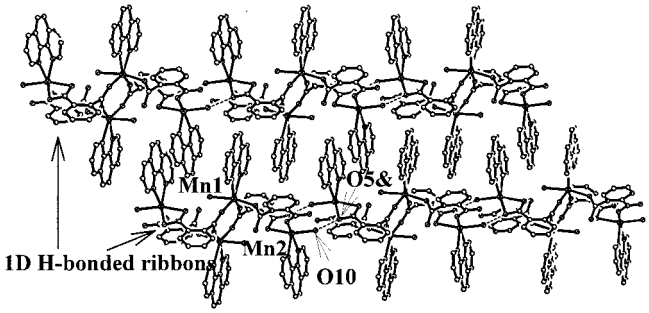

Figure 4. A view of the 2D supramolecular layer in **3**, showing the zipper-like intercalation of adjacent 1D hydrogen-bonded ribbons through face-to-face π-π interactions between the phen ligands; only two 1D hydrogen-bonded ribbons are displayed for clarity

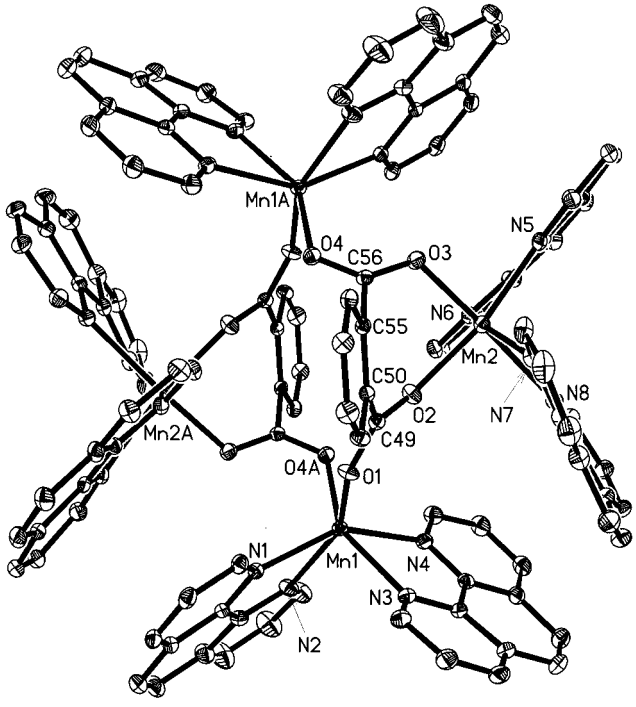

Figure 5. The structural view of one of the tetranuclear cluster cations in **4** (ellipsoids at 20% probability)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$-x, -y, -z$]; the adjacent ribbons are further intercalated in a zipper fashion into a 2D supramolecular layer through inter-ribbon π-π stacking interactions between the phen ligands, with face-to-face distances of 3.212−3.338 Å (Figure 4).

Each independent crystallographic unit of **4** contains two distinct, but very similar, discrete tetramanganese cluster cations, $[Mn_4(phth)_2(phen)_8]^{4+}$, and eight PF_6^- anions. The structure of one of these cations is shown in Figure 5. The cation possesses a crystallographically imposed center of symmetry implying that only two Mn atoms (Mn1 and Mn2) are crystallographically independent. The four coplanar Mn^{2+} ions are singly bridged by four *syn-anti* carboxylate groups from two phth ligands, each of which adopts a chelating/bridging bis-bidentate mode (Scheme 1d) to coordinate to three Mn atoms, forming a 16-membered nonplanar macrocyclic structure $(-Mn-O-C-O)_4$, with four Mn atoms located at the four corners of an approximate molecular rectangle of sides 4.941 Å and 5.456 Å. Each Mn center exhibits a strongly distorted octahedral geometry (Table 3), being coordinated by four N atoms [Mn−N = 2.288(5)−2.317(5) Å for Mn1; 2.222(5)−2.336(5) Å for Mn2] of two chelating phen ligands, and two O atoms [Mn−O = 2.100(4) Å for Mn1; 2.110(4) Å for Mn2] of carboxylate groups of phth ligand (s). The difference between the coordination environments around Mn1 and Mn2 is that the two O atoms coordinated to Mn1 belong to two phth ligands, whereas the two O atoms coordinated to Mn2 are from two ends of one phth ligand. There are no close intermolecular contacts in the structure, and the tetramanganese cluster units are well isolated, with a shortest intermolecular Mn···Mn distance of 8.573 Å.

[a] Symmetry code: A: $-x + 1, -y + 1, -z + 1$.

In each independent crystallographic unit of **5**, there is one discrete tetramanganese cluster cation, $[Mn_4(phth)_2(bipy)_8]^{4+}$, four ClO_4^- anions and two solvate ethanol molecules. The composition of the cation is similar to that in **4**, except that the chelating ligand is bipy in **5** rather than phen. In the structure of the cation (Figure 6), the phth ligand adopts the same coordination mode to that found in **4**, and the four Mn^{2+} ions also form a cyclic structure. Similarly to those found in **4**, the coordination environments around Mn1 and Mn2 are strongly distorted octahedral (Table 3), with four N atoms [Mn−N = 2.262(4)−2.393(3) Å for Mn1; 2.230(3)−2.276(4) Å for Mn2] of two chelating bipy ligands and two O atoms

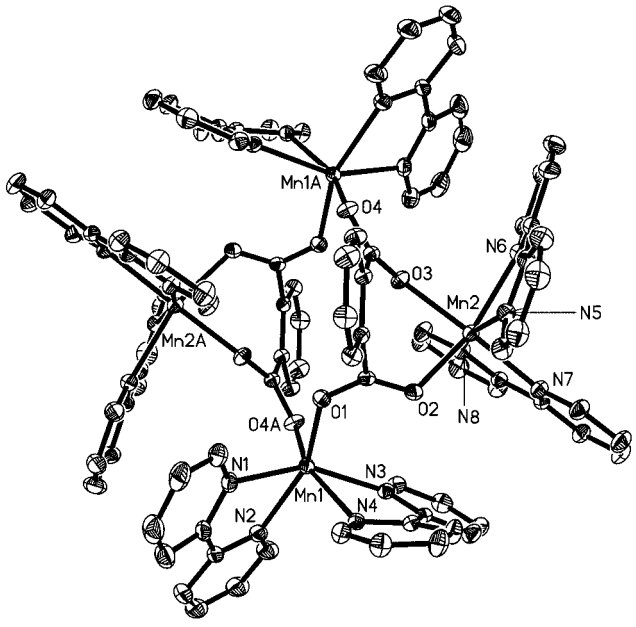

Figure 6. The structural view of the tetranuclear cluster cation in **5** (ellipsoids at 20% probability); Mn···Mn2A = 5.199 Å and Mn···Mn2 = 5.416 Å

[Mn−O = 2.101(3) and 2.113(3) Å for Mn1; 2.127(3) and 2.159(3) Å for Mn2] of carboxylate groups of the phth ligand (s) at the six apexes of the Mn octahedron. A similar complex with the same cationic core has been reported previously.[31]

Compound **6** consists of infinite 1D chains in which adjacent Mn atoms, with an interatomic distance of 7.131 Å, are bridged by one phth ligand (Figure 7a). The Mn atom is in a distorted octahedral geometry (Table 4), being coordinated by two N atoms [Mn−N1 = 2.312(2) Å, Mn−N2 = 2.289(2) Å] of one chelating bipy ligand, two O atoms [Mn−O5 = 2.193(2) Å, Mn−O6 = 2.285(2) Å] of water molecules and two O atoms [Mn−O1 = 2.128(2) Å, Mn−O4A = 2.135(2) Å] from bis-monodentate phth ligands (Scheme 1c). All bipy ligands parallel to each other are located on one side of the chain, with a dihedral angle of 105.4° between the bipy ligand plane and the benzene ring plane of the phth ligand, forming an unsymmetric chain structure. It should be noted that the coordination mode for the phth ligand exhibited in **6** differs greatly from

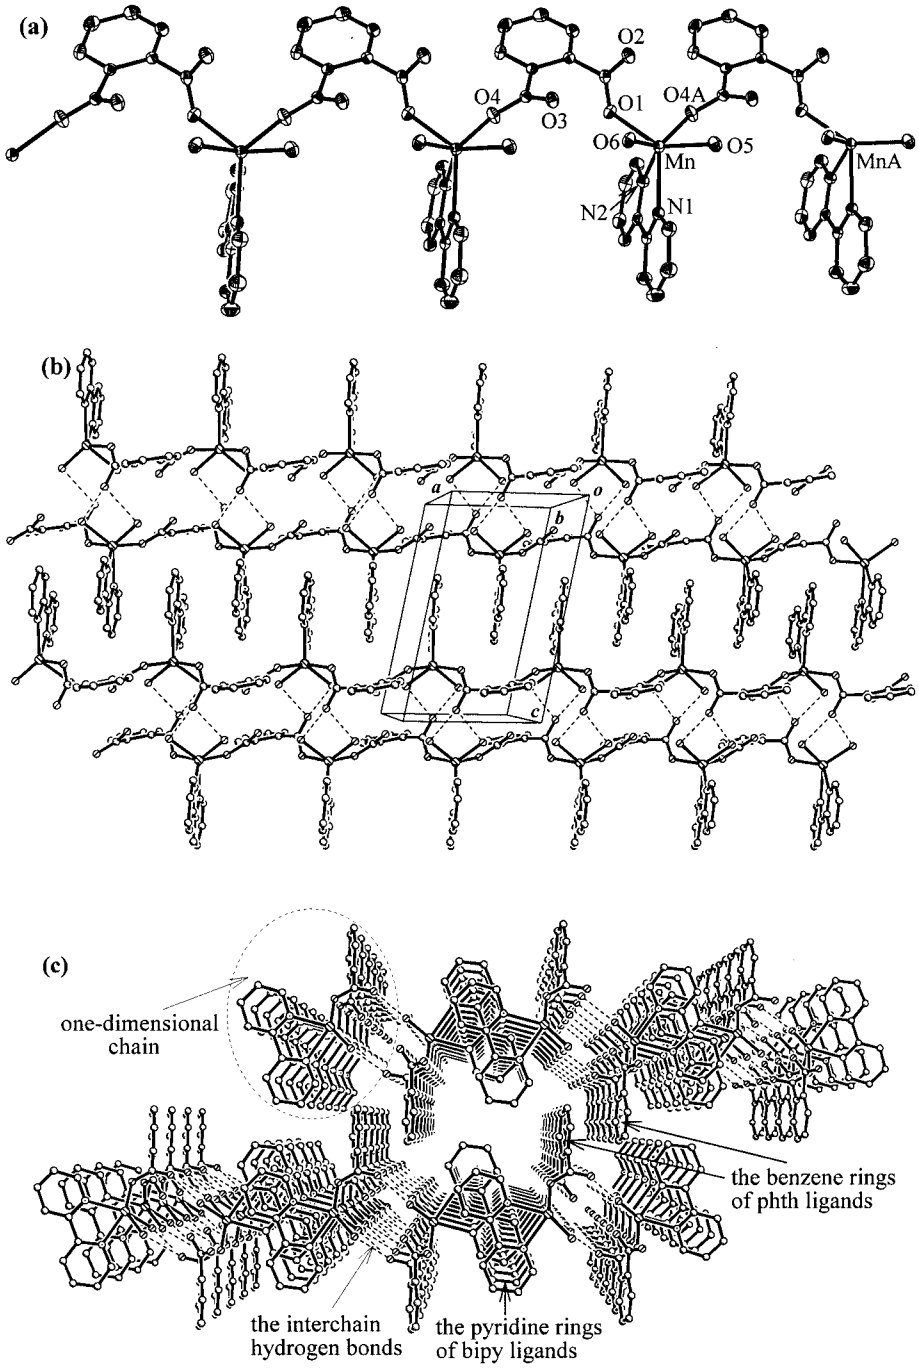

Figure 7. (a) The 1D chain structure of **6** (ellipsoids at 30% probability); (b) a view of the 2D supramolecular layer in **6**; (c) the packing diagram of **6**, showing the 3D supramolecular network sustained by complicated supramolecular contacts

that found in the known complex [Mn(phth)(phen)-$(H_2O)_2]_n$,[35] in which the phth dianion employs just one carboxylate group to bridge two Mn atoms, with the other free. Interestingly, in compound **6** two neighboring chains connect to each other by a hydrogen-bonding interactions [O5···O2# 2.884 Å; O6···O2# 2.712 Å; #: $-x + 1, -y, -z$] to form a set of 1D hydrogen-bonded double-chains with the bipy ligands growing outwards at both sides of the double-chain (Figure 7b). Meanwhile, the adjacent two sets of the double-chains are correlated through π-π stacking interactions between the bipy ligands, with face-to-face distances of about 3.512 Å and 3.535 Å (Figure 7b) to construct a 2D layer, which is further packed into a 3D supramolecular network (Figure 7c) through inter-layer π-π stacking interactions between the benzene rings of the phth ligands with a face-to-face distance of about 3.450 Å.

[a] Symmetry codes: (**6**) A: $x - 1, y, z$; (**7**) A: $-x + 1/2, -y + 3/2, z$; B: $x, -y + 3/2, z + 1/2$.

In the structure of **7**, as shown in Figure 8, the Mn atom is in a slightly distorted octahedral geometry (Table 4), being *trans*-coordinated by two N atoms [Mn−N1 = 2.377(5) Å, Mn−N2B = 2.330(5) Å] of μ-pyz ligands, two O atoms [Mn−O3 = 2.166(3) Å] of water molecules and two O atoms [Mn−O1 = 2.132(3) Å] from phth ligands. The phth ligand, in a coordination mode similar to that found in **6**, is coordinated to two Mn atoms through two O atoms from two carboxylate groups, resulting in a 1D $[Mn(phth)]_n$ chain in the *a* direction. The μ-pyz ligands link adjacent $[Mn(phth)]_n$ chains to generate an infinite 2D layer consisting of rectangular grids with dimensions of 7.511 × 7.630 Å measured through the μ-phth ligands and μ-pyz ligands, respectively. The adjacent layers parallel to each other are further inter-connected into a stacked multi-layer 3D supramolecular network through an inter-layer hydrogen bond between the water ligand and the carboxylate O atom [O3···O2# 2.762 Å; #: $-x, y + 1/2, -z + 1/2$] (Figure 9). Compound **7** is the first example of a Mn complex with both carboxylate and pyrazine ligands.

Magnetic Properties

The variable-temperature (5−300 K) magnetic behaviors of complexes **1** and **6**, and **3** and **4**, in the form of μ_{eff} vs. T plots are shown in Figure 10 and 11, respectively.

As shown in these figures, at room temperature the experimental effective magnetic moments (μ_{eff}) of 5.94 and 6.04 μ_B of **1** and **6**, respectively, are close to the value (5.92 μ_B) expected for one isolated Mn ion ($S = 5/2$); while the μ_{eff} value (11.75 μ_B or so) of **3** and **4** per Mn_4 unit is also close

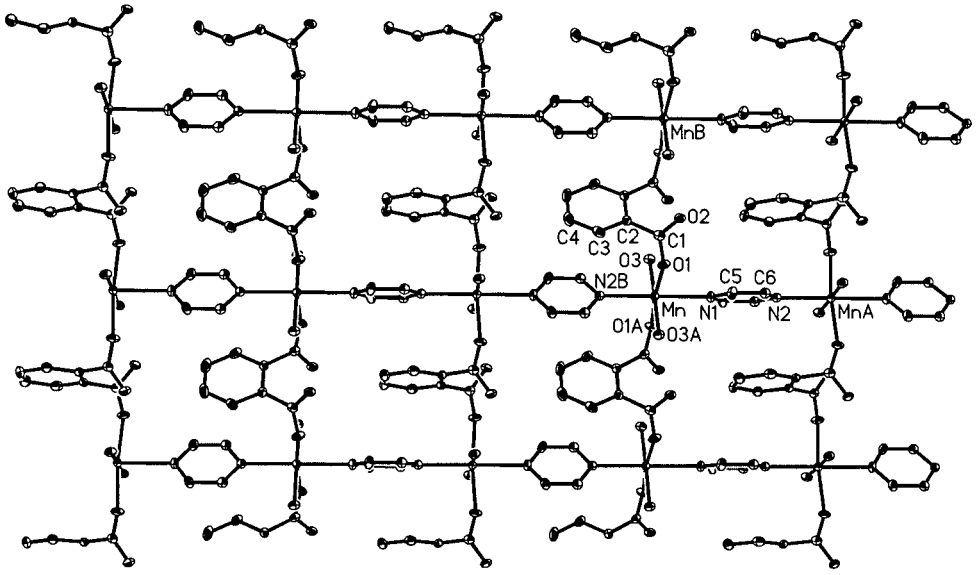

Figure 8. The 2D layer structure of **7** (ellipsoids at 30% probability)

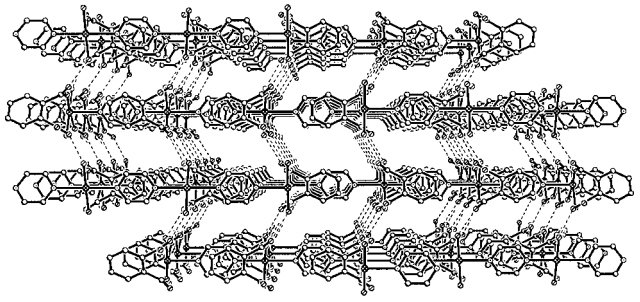

Figure 9. The packing diagram of **7**, showing the multi-layer-stacked 3D hydrogen-bonded network; the inter-layer hydrogen bonds are indicated by dotted lines

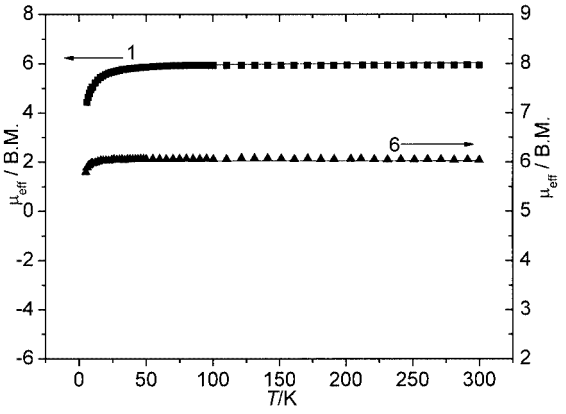

Figure 10. Effective magnetic moment (μ_{eff}) as function of temperature for **1** (■) and **6** (▲); the solid lines represent the calculated values

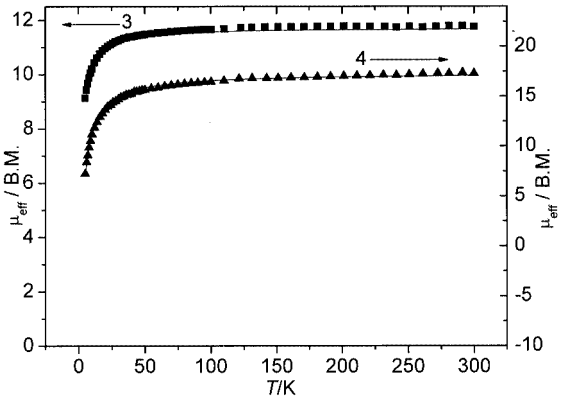

Figure 11. Effective magnetic moment (μ_{eff}) as function of temperature for **3** (■) and **4** (▲); the solid lines represent the calculated values

to the expected value of 11.83 μ_B. As the temperature is lowered to 75 K or lower, the μ_{eff} values remain essentially constant and then decrease gradually, indicative of an overall antiferromagnetic coupling between Mn^{2+} ions for these complexes. A dinuclear Heisenberg model ($H = -JS_1 \cdot S_2$) and a uniform chain model[50] ($\boldsymbol{H} = -2J \cdot \Sigma \boldsymbol{S}_i \cdot \boldsymbol{S}_{i+1}$) were used to fit the experimental data of **1** and **6**, respectively. The best-fit parameters over the full temperature range are as follows: $J = -0.34(4)$ cm^{-1}, $g = 2.04(9)$ and $R = 1.91 \times 10^{-4}$ for **1**; $J = -0.01(4)$ cm^{-1}, $g = 2.03$ and $R = 3.33 \times 10^{-4}$ for **6**, with the agreement factor, R, defined as $\Sigma[(\chi_M T)_{calcd.} - (\chi_M T)_{obsd.}]^2/[\Sigma(\chi_M T)_{obsd.}]^2$.

In either rhombic Mn_4 entity of **3** or rectangular Mn_4 entity of **4**, there are two possible exchange pathways: one through the μ-OCO bridge, and the other through both carboxylate moieties involving the benzene ring (Mn1−O4−C32−C31−C26−C25−O2−Mn2 in **3** and the similar path in **4**). The latter transmission of the coupling can be considered very small and negligible, therefore dinuclear and tetranuclear rectangular Heisenberg models were used for **3** [$H = -J(S_1 \cdot S_2)$] and **4** [$H = -2J(S_1 \cdot S_2 + S_2 \cdot S_3 + S_3 \cdot S_4 + S_4 \cdot S_1)$] to fit their experimental data, based on the consideration that all the coupling parameters (J) between adjacent pairs of Mn^{2+} ions are equal. The best-fit parameters over the full temperature range are as follows: $J = -1.09$ cm^{-1}, $g = 1.97$ and $R = 6.59 \times 10^{-4}$ for **3**; $J = -0.26$ cm^{-1}, $g = 2.00$ and $R = 2.25 \times 10^{-4}$ for **4**.

For complex **3**, the superexchange constant J (-1.09 cm^{-1}), corresponding to the coupling interaction between Mn1 and Mn1A doubly bridged by carboxylates of phth ligands (Figure 3), is similar to those previously reported between Mn^{2+} ions with a similar bridging network (J between -0.96 and -1.84 cm^{-1}),[9,12,51−54] and indicates the presence of a weak antiferromagnetic coupling through the short pathway of the carboxylate bridge of phth. A larger J value than that found in compound **1** [$-0.34(4)$ cm^{-1}] agrees well with the shorter metal−metal separation of 4.170 Å in **3** (4.786 Å in **1**).

For complex **4**, the small value of the superexchange constant ($J = -0.26$ cm^{-1}), corresponding to the coupling interaction transmitted by a single *syn-anti* carboxylate of a phth ligand (Figure 5), can be considered as normal, taking into account the nature of the bridging carboxylate. The exchange coupling through the carboxylato moiety is largely determined by the conformation of the bridge between two interacting metal centers.[55] Of three most common carboxylato bridging conformations (*syn-syn*, *anti-anti* and *syn-anti*), the *syn-anti* carboxylato bridge induces a much smaller J value than the other two types of conformations because of the expanded metallic core and the mismatch in the orientation of magnetic orbitals related to the high asymmetry of the *syn-anti* bridging network.[56] The non-planarity of the Mn−OCO−Mn bridging network accounts for the small value of the magnetic coupling interactions.

Conclusion

The phthalate-Mn^{2+}-diimine(bipy/phen/pyz) reaction system has been explored, and the ability of phthalate to act as a bridging ligand has been confirmed by synthesizing a new series of compounds (**1**−**7**), which show a variety of nuclearities and dimensionalities. Two singly deprotonated Hphth ligands bridging two Mn atoms in both dinuclear compounds **1** and **2** in a *syn-anti* conformation give the largest $Mn^{2+} \cdots Mn^{2+}$ distance among analogous dinuclear Mn^{2+} complexes. The coordination mode shown in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 1b is found for the first time in metal phthalate complexes, and compound **3** represents a novel structural type of Mn_4 clusters, with unique μ_3-phthalates supporting a rhombic Mn_4 unit. Two new tetranuclear compounds **4** and **5** crystallise as different salts, with the four Mn atoms located at the four corners of an approximate rectangle bridged by four *syn-anti* carboxylates of two phth ligands. The novel 2D layer network of compound **7** is reasonably formed from the novel 1D singly phth-bridged chain of compound **6** when the secondary bridging μ-pyz ligand is used in place of the end-capping bipy ligand. Although the Mn-acetate/benzoate-diimine(bipy/phen) system has given several compounds before, the new series of compounds reported in this work provides an important addition to the family of still poorly developed manganese dicarboxylate complexes, especially those in a discrete form.

Variable-temperature magnetic susceptibility measurements of compounds **1**, **3**, **4** and **6** reveal weak antiferromagnetic coupling interactions in all cases mediated through either the carboxylate group of the phth ligand or the whole extended phth ligand. The result indicates that, although magnetic interactions transmitted through the phth, as expected, are weak, the magnitude and nature of the coupling interactions can be influenced by various factors, such as the metal−metal separation, the carboxylate bridging modes and the degree of coplanarity of the bridging network.

Experimental Section

General Remarks: All chemicals were of reagent grade and used as received. Elemental analyses were performed with a Vario EL III CHNOS element analyzer. IR spectra of KBr pellets (4000−400 cm^{-1}) were recorded with a Magna-75 FT-IR spectrophotometer. The variable-temperature susceptibility (5−300 K) was measured with a model CF-1 superconducting extraction sample magnetometer in a 10 kG applied field with the crystalline sample kept in a capsule for weighing. Diamagnetic corrections were estimated with Pascal's table.[57]

$[Mn_2(Hphth)_2(phen)_4](Hphth)_2·2H_2O$ (1): A solution of 1,10-phenanthroline (phen) (0.40 g, 2 mmol) in EtOH (10 mL) was slowly addded with continuous stirring to an aqueous solution (20 mL) containing $Mn(OAC)_2·4H_2O$ (0.25 g, 1 mmol), phthalic acid (H_2phth; 0.17 g, 1 mmol) and KOH (0.056 g. 1 mmol). The mixture was stirred for five minutes at room temperature, then filtered. The filtrate was left to stand at room temperature for one week or so to deposit yellow crystals of **1** in 47% yield (0.72 g). $C_{80}H_{56}Mn_2N_8O_{18}$ (1527.2): calcd. C 62.91, H 3.70, N 7.34; found C 62.88, H 3.74, N 7.39. IR (KBr): $\tilde{\nu}$ = 3438 (m), 3068 (m), 1689 (s), 1591 (vs), 1558 (m), 1516 (s), 1497 (m), 1448 (m), 1425 (s), 1410 (vs), 1356 (m), 1342 (m), 1284 (m), 1254 (m), 1221 (m), 1159 (m), 1140 (m), 1101 (m), 1043 (m), 964 (m), 897 (w), 866 (m), 852 (s), 845 (s), 810 (m), 789 (m), 771 (m) 758 (m), 739 (m), 729 (vs), 681 (w), 638 (m), 627 (m), 584 (m), 555 (w), 434 (w), 420 (m) cm^{-1}.

$[Mn_2(Hphth)_2(phen)_4](ClO_4)_2·2H_2O$ (2): Compound **2** was prepared using a procedure similar to that used for preparing **1**, except that $Mn(ClO_4)_2·6H_2O$ was used as the starting Mn^{2+} source. Yellow crystals of **2** were obtained in 33% yield (0.46 g). $C_{64}H_{46}Cl_2Mn_2N_8O_{18}$ (1395.9): calcd. C 55.07, H 3.32, N 8.03; found C 55.02, H 3.34, N 8.07. IR (KBr): $\tilde{\nu}$ = 3427 (br. m), 3088 (m), 1701 (s), 1587 (vs), 1544 (m), 1493 (m), 1441 (m), 1411 (vs), 1367 (m),1348 (w), 1258 (w), 1142 (m), 1089 (s), 1043 (m), 1011 (m), 841 (m), 817 (m), 769 (m), 728 (s), 661 (m), 628 (m), 561 (m), 452 (w), 419 (m) cm^{-1}.

$[Mn_4(phth)_4(phen)_4(H_2O)_4]·2EtOH$ (3) and $\{[Mn_4(phth)_2(phen)_8](PF_6)_4\}_2$ (4): Compounds **3** and **4** were obtained from a one-pot synthetic procedure: A yellow suspension containing H_2phth (0.68 g, 4 mmol), KOH (0.46 g, 8 mmol), $Mn(OAc)_2·4H_2O$ (1.00 g, 4 mmol), phen (0.80 g, 4 mmol) and $(NMe_4)PF_6·6H_2O$ (1.31 g, 4 mmol) in H_2O/EtOH (1:1, 40 mL) was heated to reflux in a 50 mL round-bottomed flask for 10 days, during which time the yellow suspension turned tclear, and a large yellow cube-like crystal of **3** formed. Heating at lower temperature than before for an additional 2 d, during which time many soft and flimsy sheet crystals of **4** were deposited on the surface of the crystal of **3**. Crystals of **3** and **4** were mechanically collected in 27% yield (0.48 g) and 19% yield (0.49 g), respectively (based on Mn).

3: $C_{84}H_{68}Mn_4N_8O_{22}$ (1761.2): calcd. C 57.29, H 3.89, N 6.36; found C 57.33, H 3.81, N 6.43. IR (KBr): $\tilde{\nu}$ = 3450 (s), 3331 (br. s), 3062 (m), 1626 (s), 1547 (vs), 1516 (vs), 1495 (m), 1448 (m), 1423 (vs), 1402 (vs), 1342 (m), 1292 (w), 1219 (w), 1142 (w), 1101 (m), 1090 (m), 1043 (m), 995 (w), 941 (w), 864 (m), 850 (s), 812 (w), 781 (m), 758 (m), 729 (s), 702 (m), 648 (m), 636 (w), 592 (w), 557 (w), 451 (m), 420 (m) cm^{-1}.

4: $C_{224}H_{144}F_{48}Mn_8N_{32}O_{16}P_8$ (5139.0): calcd. C 52.35, H 2.82, N 8.72; found C 52.41, H 2.90, N 8.69. IR (KBr): $\tilde{\nu}$ = 3421 (w), 3079 (w), 1608 (s), 1591 (vs), 1566 (vs), 1497 (m), 1444 (m), 1425 (vs), 1407 (w), 1342 (m), 1317 (w), 1301 (w), 1223 (m), 1145 (m), 1103 (m), 1090 (w), 1049 (w), 953 (w), 841 (vs), 773 (w), 729 (s), 773 (m), 729 (s), 698 (w), 649 (w), 640 (w), 559 (s), 472 (w), 445 (w), 420 (m) cm^{-1}.

$[Mn_4(phth)_2(bipy)_8](ClO_4)_4·2EtOH$ (5): Compound **5** was obtained using a procedure similar to that used for preparing **2**, except that 2,2′-bipyridine (bipy) was used as the starting diimine species. Large yellow crystals of **5** were obtained in 56.5% yield (0.32 g). $C_{100}H_{84}Cl_4Mn_4N_{16}O_{26}$ (2287.4): calcd. C 52.51, H 3.70, N 9.80; found C 52.49, H 3.75, N 9.84. IR (KBr): $\tilde{\nu}$ = 3481 (br. m), 3070 (m), 1606 (m), 1593 (vs), 1564 (vs), 1489 (w), 1473 (m), 1439 (vs), 1417 (m), 1400 (m),1315 (w), 1248 (w), 1176 (w), 1142 (m), 1090 (vs), 1043 (w), 1014 (s), 862 (w), 833 (w), 814 (w), 764 (s), 739 (s), 727 (m), 696 (w), 652 (m), 623 (s), 558 (w), 567 (w), 449 (w), 415 (m) cm^{-1}.

$[Mn(phth)(bipy)(H_2O)_2]_n$ (6): A mixture containing $Mn(OAc)_2·4H_2O$ (0.50 g, 2 mmol), H_2phth (0.34 g, 2 mmol), KOH (0.22 g, 4 mmol) and bipy (0.31 g, 2 mmol) in EtOH/H_2O (1:5, 60 mL) was heated to reflux for 4 hours in a 100 mL round-bottomed flask, then filtered. The filtrate was left undisturbed at 4 °C for one month or so, resulting in the deposition of light-yellow crystals of **6** in 21.3% yield (0.18 g). $C_{18}H_{16}MnN_2O_6$ (411.27): calcd. C 52.56, H 3.92, N 6.81; found C 52.61, H 3.96, N 6.84. IR (KBr): $\tilde{\nu}$ = 3450 (br. m), 1603 (s), 1581 (vs), 1494 (m), 1414 (vs), 1389 (m), 1233 (m), 1250 (m), 1239 (m), 1111 (w), 884 (w), 826 (m), 756 (s), 690 (m), 645 (m), 589 (w), 525 (m), 411 (m) cm^{-1}.

$[Mn(phth)(pyz)(H_2O)_2]_n$ (7): A suspension containing $Mn(OAc)_2·4H_2O$ (0.50 g, 2 mmol), H_2phth (0.34 g, 2 mmol), KOH (0.22 g, 4 mmol) and pyrazine (pyz; 0.16 g, 2 mmol) in MeOH/H_2O (1:4, 20 mL) was heated at 140 °C for 4 days under autogenous pressure in a 25 mL sealed Teflon-lined stainless-steel vessel, then allowed to cool to room temperature, to give pale-yellow crystals

X-ray Crystallographic Study: Intensity data for complexes **1**−**7** were collected at 293 K with a Siemens SMART CCD diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). An empirical absorption correction was applied by using the SADABS program, and the structures were solved by direct methods and refined on F^2 by a full-matrix least-squares procedure with the SHELXTL-97 program package.[58] Non-hydrogen atoms were refined anisotropically, with the exceptions of F22, F23 and F24 in one of the PF_6^- ions in **4**, which were refined isotropically. Hydrogen atoms were introduced geometrically except for those on the water molecules and the solvate ethanol molecules, which were located from the difference Fourier syntheses and refined isotropically. Crystallographic data of **1**−**7** are outlined in Table 5 and 6.

CCDC-231921 to -231927 (for **1**−**7**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of a Persistent $1\sigma^3,3\sigma^3$-Diphosphaallyl Cation Featuring a Localized Phosphorus−Carbon Double Bond

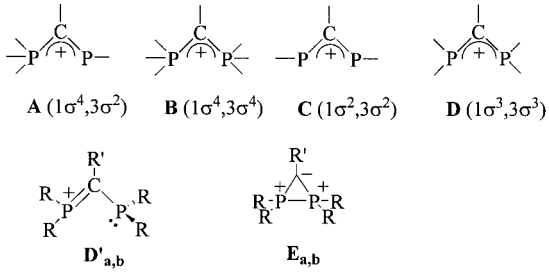
David Martin,[a,b] Antoine Baceiredo,*[a] and Guy Bertrand*[a,b]

Keywords: Allylic cations / Phosphorus / Phosphaalkenes / Phosphacumulenes / Phosphorus ylides

tert-Butyl thiol, 2,6-dimethylthiophenol, 2,6-dimethylphenol, and 2,6-bis(*tert*-butyl)-4-methylphenol cleanly add to the $1\sigma^4,3\sigma^2$-diphosphacumulene **1** to afford the corresponding *C*-phosphanyl phosphorus ylides **2a–d**. Treatment of **2a** with gallium trichloride quantitatively leads to the *C*-phosphonio phosphaalkene **3**, resulting from the1,3-migration of the sulfido group. Under the same experimental conditions, cleavage of the arylthio and aryloxy groups of **2b** and **2c** leading to the *C*-phosphonio phosphaalkene **4** is observed. In the case of the sterically most crowded derivative, **2d**, abstraction of the chloride ion affords the $1\sigma^3,3\sigma^3$-diphosphaallyl cation **5**, which is stable for several weeks in dichloromethane at –20 °C, but decomposes after a few minutes at above 0 °C. Compound **5** reacts at low temperatures with an excess of acetonitrile or benzaldehyde to afford quantitatively and regioselectively the corresponding five-membered heterocycles **6** and **7**. The NMR spectroscopy data and reactivity suggest that **5** features a localized double bond with a planar diamino-substituted phosphorus center, and a single bond with a pyramidalized (amino)(aryloxy)phosphanyl group.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The stability of the 1,3-diphosphaallylic cations **A**−**D** is strongly dependent on the coordination number of the phosphorus atoms. Compounds **A**[1] and **B**,[2] featuring one or two σ^4-P atoms, have been isolated, whereas cations of type **C**[1a,3] and **D**,[4] which feature two σ^2-P and two σ^3-P atoms, respectively, have only been postulated as transient intermediates. Interestingly, derivatives **D** are the phosphorus analogues of the well-known and highly stable amidinium salts.[5] This striking difference between nitrogen and phosphorus chemistry lies in the superior ability of nitrogen to achieve a planar configuration and therefore to act as a π-donor.[6] In the case of diaminocarbocations, both amino substituents are involved in the stabilization of the positive charge, while calculations[6b−6d] predict that for **D** only one phosphorus atom acts as a π-donor, while the second one remains pyramidal. Therefore **D** is best described as (phosphanylmethylene)phosphonium ion **D′** that bears simultaneously a nucleophilic and an electrophilic center. This ambivalence underlines the synthetic potential of this species, but it also explains their apparent instability, especially with respect to ring-closure reactions. Indeed, a theoretical study by Schoeller[4] demonstrated that, depending on the nature of the phosphorus and carbon substituents, the energy-minimum structure could either be the open form **D** or the cyclic three-membered heterocycle valence isomer **E**. We have already reported the isolation of the cyclic isomer $\mathbf{E_b}$,[4] and here we report the synthesis and characterization of the first persistent $1\sigma^3,3\sigma^3$-diphosphaallyl cation of type **D**, as well as its reactivity towards dipolarophiles.



a: R = NH_2, R′ = SiH_3: $\varepsilon_{(D)} - \varepsilon_{(E)} = 5.8$ kcal·mol^{-1}
b: R = N(*i*Pr)$_2$, R′ = $SiMe_3$: $\varepsilon_{(D)} - \varepsilon_{(E)} = -6.1$ kcal·mol^{-1}

Results and Discussion

According to the theoretical study, a decrease of the steric hindrance should favor the open cation **D** over its cyclic isomer **E**. However, our previous experimental work[4b] demonstrated that in order to observe **D**, it is not

[a] Laboratoire Hétérochimie Fondamentale et Appliquée (UMR, 5069), Université Paul Sabatier,

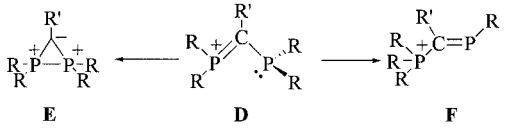
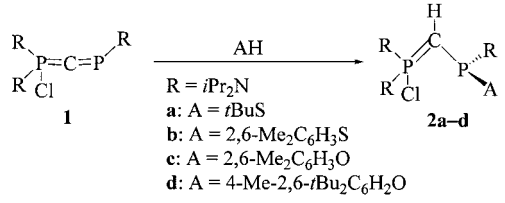
only necessary to avoid the ring closure to **E**, but also to prevent the 1,3-migration of a phosphorus substituent, which gives the far more stable phosphoniophosphaalkene isomer **F** (see Scheme 1). Since small substituents at phosphorus atoms favor the 1,3-migration process, we decided to keep bulky substituents on both phosphorus atoms and to decrease the size of the C substituent (R′); H was the best candidate.



E **D** **F**

Scheme 1

Abstraction of chloride from *P*-chloro phosphorus ylides is a known method to obtain the corresponding methylenephosphonium salts;[7] thus, *P*-chloro-*C*-phosphanyl phosphorus ylides **2** appeared to be potential precursors for the desired $1\sigma^3,3\sigma^3$-diphosphaallyl cation **D**. However, the classical routes to ylides are not applicable for the synthesis of **2a**−**d** and therefore we investigated several original approaches. We found that the recently discovered $1\sigma^4,3\sigma^2$-diphosphacumulene **1**[8] cleanly reacts with acidic compounds of type A−H to afford the desired ylides **2a**−**d** (see Scheme 2). Reactions take place at low temperatures except in the case of the very crowded 2,6-di-*tert*-butyl-4-methylphenol, which requires an additional hour at room temperature. All compounds were obtained as orange oils, and were unequivocally characterized by multinuclear NMR spectroscopy. In the ^{31}P NMR spectra, the addition of A−H resulted in the disappearance of the characteristic low-field signal for the σ^2-phosphorus atom of cumulene **1**, and ylides **2a**−**d** appeared as AX systems with a rather large phosphorus−phosphorus coupling constant ($^2J_{P,P} \approx$ 200 Hz). The PCP carbon atoms give doublet of doublets, with chemical shifts in the range δ = 30−50 ppm, as expected for ylides of this type.



1 **2a–d**

Scheme 2

Addition at −78 °C of 1 equiv. of gallium trichloride to the sterically least hindered ylide, **2a**, quantitatively afforded the (*E*)-*C*-phosphoniophosphaalkene **3**,[9] resulting from the 1,3-migration of the sulfido group. This compound displays an AX system at δ = 305 and 67 ppm ($^2J_{P,P}$ = 137 Hz), the low-field ^{31}P signal being characteristic of the phosphaalkene moiety. Therefore, it can be concluded that the steric demand of the *t*BuS group is not large enough and the σ^4,λ^4-phosphorus atom in **3** is able to accommodate two diisopropylamino and the alkylthio groups.

Taking this result into account, the *tert*-butylthio group was replaced by a larger 2,6-dimethylphenylthio substituent, and ylide **2b** was treated with 1 equiv. of $GaCl_3$ at low temperature. Here again, the expected diphosphaallyl cation was not observed. We obtained in near-quantitative yield the phosphonio phosphaalkene **4**,[9] resulting from the cleavage of the phenylthio group. The cation **4** (X = CF_3SO_3) can also be synthesized by simply adding at low temperature 1 equiv. of trifluoromethanesulfonic acid to a dichloromethane solution of **1** and therefore was unequivocally identified. In the same way, when ylide **2c**, featuring the 2,6-dimethylphenyloxy instead of the -phenylthio group, was treated with 1 equiv. of $GaCl_3$ at low temperature, the phosphonio phosphaalkene **4** was obtained in nearly quantitative yield.

These results might be rationalized by the complexation of the oxygen and sulfur atom by the Lewis acid that enhances their leaving-group ability. In an attempt to protect these heteroatom centers and favor the abstraction of chloride, the steric hindrance at the *ortho* positions of the phenyloxy substituent was increased by using *tert*-butyl instead of methyl groups; 1 equiv. of $GaCl_3$ was added at low temperature to a dichloromethane solution of ylide **2d**. The formation of a mixture of **4** and a new compound **5** was observed in a 20:80 ratio. The ^{31}P NMR spectrum of **5** displays an AX system at δ = 134 and 122 ppm ($^2J_{P,P}$ = 134 Hz). These signals are by far at too low a field for a cyclic structure of type **E**, and at too high a field for the phosphaalkene structure of type **F**. In the ^{13}C NMR spectrum, a CH signal appears as a doublet of doublets at δ = 91.4 ppm ($^1J_{P,C}$ = 146 and 84 Hz) and in the ^{1}H NMR spectrum, the signal for the corresponding proton is also a doublet of doublets at δ = 5.58 ppm ($^2J_{PH}$ = 11 and 4 Hz), demonstrating that the PCHP sequence is preserved. ^{1}H and ^{13}C NMR spectra, obtained while selectively irradiating one phosphorus center, demonstrated that two diisopropylamino groups are linked to the phosphorus atom with signal at δ = 134 ppm, and one amino and the phenoxide group are linked to the phosphorus center with signal at δ = 122 ppm. Clearly, derivative **5** is the desired cation, featuring two σ^3-phosphorus centers. The ^{31}P NMR chemical shifts are in the range for a bis(diisopropylamino)(methylene)phosphonium salt[10] and an (alkyl)(amino)(phenyloxy)phosphane; therefore, as predicted by the calculations, this "$1\sigma^3,3\sigma^3$-diphosphaallylic cation" features a localized double bond involving the diamino-substituted phosphorus atom and a single bond. In other words, the molecule is probably highly unsymmetrical, the phenyloxy-substituted phosphorus atom remains pyramidal. Although **5** is stable in dichloromethane at −20 °C for several weeks, it decomposes above 0 °C after a few minutes, preventing its isolation and an X-ray diffraction study.

As transient $1\sigma^3,3\sigma^3$-diphosphaallylic cations are known to undergo 1,3-dipolar cycloaddition,[4b] we tested the reactivity of **5** with two different dipolarophiles. Compound **5** reacts at low temperature with an excess of acetonitrile or

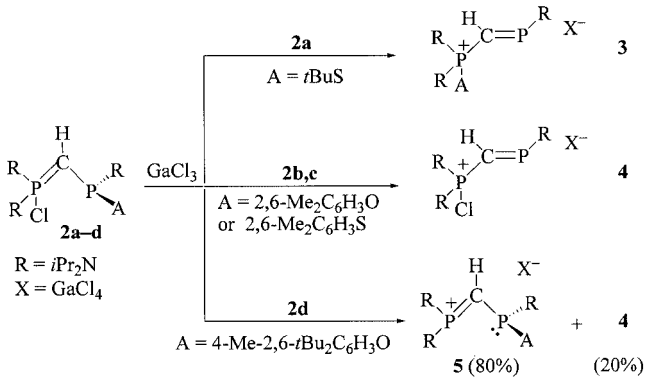
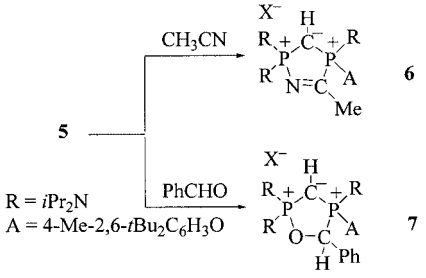


Scheme 3

benzaldehyde to afford quantitatively and regioselectively the five-membered heterocycles **6** and **7**, respectively.[11] The observed regioselectivity reinforced the hypothesis of the diamino-substituted P center acting as the electrophilic part of the molecule. Indeed, it is quite likely that the reaction proceeds stepwise: complexation of the heteroatom of the dipolarophile to the planar phosphorus atom, followed by nucleophilic attack of the phosphane center at the activated carbon atom of the nitrile and aldehyde groups.



Scheme 4

Conclusion

$1\sigma^3,3\sigma^3$-diphosphaallylic cations are thermodynamically stable species but they are highly reactive. The presence of bulky substituents at both phosphorus centers is required in order to prevent 1,3-shift, and the presence of a small substituent on the carbon atom is necessary to favor the open form and to therefore prevent the ring closure that leads to the three-membered heterocyclic isomer. At least for nonsymmetrically substituted compounds, there is no delocalization of the π system. We are currently investigating the possibility of preparing symmetrical, isolable $1\sigma^3,3\sigma^3$-diphosphaallylic cations, by including such species in a cyclic system.

Experimental Section

General Remarks: All manipulations were performed under argon using standard Schlenk techniques. Dry, oxygen-free solvents, freshly distilled thiol, thiophenol and freshly sublimed phenols were employed. ^{1}H, ^{13}C and ^{31}P NMR spectra were recorded with Bruker AC80, AC200, WM250 or AMX400 spectrometers. ^{1}H and ^{13}C chemical shifts are reported in ppm relative to Me_4Si as external standard. ^{31}P NMR downfield chemical shifts are expressed with a positive sign, in ppm, relative to external 85% H_3PO_4.

Preparation of *P*-Chloro-*C*-Phosphanyl Phosphorus Ylides 2a−d: In a typical experiment, a toluene solution (0.6 mL) of 1 equiv. of thiol, thiophenol or phenols was added to a toluene solution (1 mL) of cumulene **1** (0.11 mmol) at −78 °C. The reaction was monitored by ^{31}P NMR spectroscopy. Ylides **2a−c** were readily obtained after the solution mixture was warmed to room temperature. In the case of the more crowded ylide **2d**, the reaction was complete after 1 h at room temperature. After removal of the solvent under vacuum, derivatives **2a−d** were obtained as orange oils. They are formed in nearly quantitative yields and are used without further purification.

2a: $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 58.5 and 57.5 ($^2J_{P,P}$ = 200 Hz) ppm. ^{1}H NMR (C_6D_6): δ = 1.20 (d, $^3J_{H,H}$ = 7 Hz, 6 H, CHCH_3), 1.23 (d, $^3J_{H,H}$ = 7 Hz, 6 H, CHCH_3), 1.31 (d, $^3J_{H,H}$ = 6 Hz, 12 H, CHCH_3), 1.36 (d, $^3J_{H,H}$ = 7 Hz, 6 H, CHCH_3), 1.39 (d, $^3J_{H,H}$ = 7 Hz, 6 H, CHCH_3), 1.60 (s, 9 H, SCCH_3), 2.6 (pseudo t, $^2J_{PH}$ = 6 Hz, 1 H, PCHP), 3.68 (m, 2 H, NCH), 3.80 (m, 2 H, NCH), 4.07 (m, 2 H, NCH) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 23.0 (d, $J_{P,C}$ = 2 Hz, SCCH_3), 24.0 (d, $J_{P,C}$ = 3 Hz, CHCH_3), 24.2 (d, $J_{P,C}$ = 3 Hz, CHCH_3), 24.7 (d, $J_{P,C}$ = 3 Hz, CHCH_3), 33.9 (pseudo t, $J_{P,C}$ = 140 Hz, P*C*P), 44.4 (d, $J_{P,C}$ = 6 Hz, S*C*CH$_3$), 46.9 (br., NCH), 47.0 (br., NCH), 47.6 (br., NCH), 48.7 (br., NCH) ppm.

$^3J_{PH}$ = 12 Hz, 2 H, NCH), 7.11 (s, 2 H, $H_{arom.}$) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 21.3 (s, $C_{arom.}CH_3$), 23.9 (br., $CHCH_3$), 24.6 (d, $J_{P,C}$ = 6.3 Hz, $CHCH_3$), 25.1 (d, $J_{P,C}$ = 4.2 Hz, $CHCH_3$), 30.2 (s, CCH_3), 34.3 (s, CCH_3), 42.5 (dd, $J_{P,C}$ = 161 and 44 Hz, PCP), 47.3 (d, $J_{P,C}$ = 11.6 Hz, NCH), 48.0 (d, $J_{P,C}$ = 5.2 Hz, NCH), 48.3 (d, $J_{P,C}$ = 9.1 Hz, NCH), 48.4 (d, $J_{P,C}$ = 4 Hz, NCH), 125.8 (s, $C_{arom.}H$), 136 (s, $C_{arom.}$), 142 (d, $J_{P,C}$ = 2 Hz, $C_{arom.}$), 152 (d, $J_{P,C}$ = 40 Hz, $C_{arom.}$) ppm.

Abstraction of Chloride from Ylides 2a−d: In a typical experiment, a CH_2Cl_2 solution (0.8 mL) of ylide **2** (0.1 mmol) was added to a CH_2Cl_2 solution (0.3 mL) of 1 equiv. of $GaCl_3$ at −78 °C. The solution mixture was warmed to room temperature. The solvent was removed under vacuum and the residue was characterized without further purification. In the case of **5**, which is not stable above 0 °C, $CDCl_3$ was used as the solvent and the solution mixture was spectroscopically characterized at −40 °C.

3: $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 305 and 67 ($^2J_{P,P}$ = 137 Hz) ppm. ^1H NMR ($CDCl_3$): δ = 1.40 (d, $^3J_{H,H}$ = 7 Hz, 24 H, $CHCH_3$), 1.45 (d, $^3J_{H,H}$ = 6 Hz, 12 H, $CHCH_3$), 1.59 (d, $^3J_{H,H}$ = 1 Hz, 9 H, $SCCH_3$), 3.9 (septd, $^3J_{H,H}$ = 7, $^3J_{PH}$ = 14 Hz, 4 H, NCH), 4.2 (br., 2 H, NCH), 6.0 (dd, $^2J_{PH}$ = 12 and 7 Hz, 1 H, PCHP) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 23.4 (d, $J_{P,C}$ = 2 Hz, $CHCH_3$), 24.6 (d, $J_{P,C}$ = 2 Hz, $CHCH_3$), 33.7 (d, $J_{P,C}$ = 6 Hz, $SCCH_3$), 49.6 (d, $J_{P,C}$ = 6 Hz, NCH), 50.2 (d, $J_{P,C}$ = 4 Hz, NCH), 56.7 (d, $J_{P,C}$ = 6 Hz, $SCCH_3$), 100.0 (dd, $J_{P,C}$ = 118 and 55 Hz, PCP) ppm.

4: $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 309 and 60 ($^2J_{P,P}$ = 161 Hz) ppm. ^1H NMR ($CDCl_3$): δ = 1.37 (d, $^3J_{H,H}$ = 7 Hz, 12 H, $CHCH_3$), 1.38 (d, $^3J_{H,H}$ = 6 Hz, 12 H, $CHCH_3$), 1.42 (d, $^3J_{H,H}$ = 7 Hz, 12 H, $CHCH_3$), 3.9 (septd, $^3J_{H,H}$ = 7, $^3J_{PH}$ = 21 Hz, 4 H, NCH), 4.4 (m, 2 H, NCH), 6.4 (dd, $^2J_{PH}$ = 11 and 4 Hz, 1 H, PCHP) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 22.5 (d, $J_{P,C}$ = 12 Hz, $CHCH_3$), 26.6 (br., $CHCH_3$), 49.5 (d, $J_{P,C}$ = 4 Hz, NCH), 54 (d, $J_{P,C}$ = 13 Hz, NCH), 101 (dd, $J_{P,C}$ = 142 and 57 Hz, PCP) ppm.

5: $^{31}P\{^1H\}$ NMR ($CDCl_3$, 233 K): δ_A = 134 and δ_B = 122 ($^2J_{P,P}$ = 134 Hz) ppm. ^1H NMR ($CDCl_3$, 233 K): δ = 1.19 (d, $^3J_{H,H}$ = 6 Hz, $CHCH_3$), 6 H, 1.22 (d, $^3J_{H,H}$ = 7 Hz, 6 H, $CHCH_3$), 1.28 (d, $^3J_{H,H}$ = 6 Hz, 12 H, $CHCH_3$), 1.39 (d, $^3J_{H,H}$ = 6 Hz, 12 H, $CHCH_3$), 1.45 (s, 18 H, CCH_3), 2.31 (s, 3 H, $C_{arom.}CH_3$), 3.41 (septd, $^3J_{H,H}$ = 6, $^3J_{PAH}$ = 7 Hz, 2 H, NCH), 3.94 (br., coupled with P_A, 2 H, NCH), 4.0 (br., coupled with P_B, 2 H, NCH), 5.58 (dd, $^2J_{PAH}$ = 11 Hz and $^2J_{PBH}$ = 4 Hz, 1 H, PCHP), 7.06 (s, 2 H, $H_{arom.}$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 233 K): δ = 21.6 (s, $C_{arom.}CH_3$), 22.3 (br., coupled with P_A, $CHCH_3$), 23.3 (d, J_{PAC} = 4 Hz, $CHCH_3$), 24.5 (br., coupled with P_B, $CHCH_3$), 24.7 (br., coupled with P_A, $CHCH_3$), 30.6 (s, CCH_3), 31.8 (s, $C_{arom.}CCH_3$), 46 (br., NCH), 48 (br., NCH), 49 (br., NCH), 91.4 (dd, J_{PAC} = 146 Hz and J_{PBC} = 84 Hz, PCP), 125.9 (s, $C_{arom.}H$), 135.7 (s, $C_{arom.}$), 131.2 (d, J_{PBC} = 2 Hz, $C_{arom.}$), 148.4 (d, J_{PBC} = 10 Hz, $C_{arom.}$) ppm.

Five-Membered Heterocycles 6 and 7: A CH_2Cl_2 solution (0.8 mL) of ylide **2d** (0.1 mmol) was added to a CH_2Cl_2 solution (0.3 mL) of 1 equiv. of $GaCl_3$ at −78 °C. The formation of **5** was monitored by ^{31}P NMR spectroscopy at −40 °C. Then an excess of dried acetonitrile or benzaldehyde was added and the reaction mixture was warmed to room temperature. The solvent was removed under vacuum. The residue was washed with Et_2O and the resulting yellow powder was dried under vacuum.

6: $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 63 and 55 (AB system, $^2J_{P,P}$ = 229 Hz) ppm. ^1H NMR ($CDCl_3$): δ = 1.02 (dd, $^2J_{PH}$ = 9, 7 Hz, 1 H, PC*H*P), 1.22 (d, $^3J_{H,H}$ = 7 Hz, 6 H, $CHCH_3$), 1.29 (d, $^3J_{H,H}$ = 7 Hz, 12 H, $CHCH_3$), 1.39 (d, $^3J_{H,H}$ = 7 Hz, 6 H, $CHCH_3$), 1.43 (d, $^3J_{H,H}$ = 5 Hz, 6 H, $CHCH_3$), 1.43 (s, 18 H, CCH_3), 1.45 (d, $^3J_{H,H}$ = 5 Hz, 6 H, $CHCH_3$), 2.26 (s, 3 H, $C_{arom.}CH_3$), 2.82 (d, $^2J_{PH}$ = 6 Hz, 3 H, N=CCH_3), 3.37 (septd, $^3J_{H,H}$ = 5, $^3J_{P\tilde{H}}$ 1 Hz, 2 H, NCH), 3.70 (septd, $^3J_{H,H}$ = 7, $^3J_{P\tilde{H}}$ 1 Hz, 2 H, NCH), 3.90 (septd, $^3J_{H,H}$ = 7, $^3J_{PH}$ = 15 Hz, 2 H, NCH), 6.97 (s, 2 H, $H_{arom.}$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 16.8 (dd, $J_{P,C}$ = 163 and 167 Hz, PCP), 20.9 (s, $C_{arom.}CH_3$), 21.7 (d, $J_{P,C}$ = 5 Hz, $CHCH_3$), 22.8 (d, $J_{P,C}$ = 5 Hz, $CHCH_3$), 23.0 (d, $J_{P,C}$ = 5 Hz, $CHCH_3$), 23.3 (d, $J_{P,C}$ = 4 Hz, $CHCH_3$), 23.4 (d, $J_{P,C}$ = 6 Hz, $CHCH_3$), 29.7 (s, CCH_3), 30.3 (s, CCH_3), 48.1 (d, $J_{P,C}$ = 7 Hz, NCH), 48.6 (d, $J_{P,C}$ = 5 Hz, NCH), 49.6 (d, $J_{P,C}$ = 5 Hz, NCH), 125.5 (s, $C_{arom.}H$), 134.0 (s, $C_{arom.}$), 135.7 (s, $C_{arom.}$), 141.8 (d, $J_{P,C}$ = 9 Hz, $C_{arom.}$), 187 (d, $J_{P,C}$ = 64 Hz, C=N) ppm.

7: $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 72 and 66 (AB system, $^2J_{P,P}$ = 142 Hz) ppm. ^1H NMR ($CDCl_3$): δ = 0.76 (d, $^3J_{H,H}$ = 7 Hz, 6 H, $CHCH_3$), 1.10 (d, $^3J_{H,H}$ = 7 Hz, 6 H, $CHCH_3$), 1.23 (d, $^3J_{H,H}$ = 7 Hz, 6 H, $CHCH_3$), 1.40 (d, $^3J_{H,H}$ = 7 Hz, 12 H, $CHCH_3$), 1.43 (s, 18 H, CCH_3), 1.54 (d, $^3J_{H,H}$ = 7 Hz, 6 H, $CHCH_3$), 2.34 (s, 3 H, $C_{arom.}CH_3$), 3.26 (septd, $^3J_{H,H}$ = 7, $^3J_{PH}$ < 1 Hz, 2 H, NCH), 3.88 (septd, $^3J_{H,H}$ = 7, $^3J_{PH}$ < 1 Hz, 4 H, NCH), 5.9 (dd, $^2J_{H,P}$ = 7, 9 Hz, 1 H, PCHO), 7.2 (m, 3 H, $H_{arom.}$), 7.53 (s, 2 H, $H_{arom.}$), 7.7 (m, 2 H, $H_{arom.}$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 15.7 (dd, $J_{P,C}$ = 173 and 152 Hz, PCHP), 20.8 (s, $C_{arom.}CH_3$), 22.8 (br., $CHCH_3$), 23.2 (br., $CHCH_3$), 23.8 (d, $J_{P,C}$ = 5 Hz, $CHCH_3$), 25.6 (br., $CHCH_3$), 29.7 (s, CCH_3), 30.3 (s, CCH_3), 47.6 (d, $J_{P,C}$ = 7 Hz, N*C*H), 49.2 (d, $J_{P,C}$ = 5 Hz, N*C*H), 49.6 (d, $J_{P,C}$ = 5 Hz, NCH), 50.7 (d, $J_{P,C}$ = 5 Hz, NCH), 80.3 (dd, $J_{P,C}$ = 80 and 3 Hz, PCHO), 125.6 (s, $C_{arom.}H$), 128.6 (d, $J_{P,C}$ = 5 Hz, $C_{arom.}H$), 129.3 (d, $J_{P,C}$ = 1 Hz, $C_{arom.}H$), 133.0 (s, $C_{arom.}$), 134.0 (d, $J_{P,C}$ = 2 Hz, $C_{arom.}$), 135.2 (s, $C_{arom.}H$), 141.1 (d, $J_{P,C}$ = 5 Hz, $C_{arom.}$), 142.5 (s, $C_{arom.}$) ppm.

Gadolinium DTPA-Monoamide Complexes Incorporated into Mixed Micelles as Possible MRI Contrast Agents

Tatjana N. Parac-Vogt,[a] Kristof Kimpe,[a] Sophie Laurent,[b] Corinne Piérart,[b] Luce Vander Elst,[b] Robert N. Muller,[b] and Koen Binnemans*[a]

Keywords: MRI contrast agents / Lanthanides / DTPA-monoamide derivatives / Micelles

Four monoamide derivatives of Gd–DTPA with alkyl chains consisting of 12, 14, 16, or 18 carbon atoms were synthesized. The gadolinium(III) complexes with chain lengths of 14, 16 or 18 carbon atoms were efficiently incorporated into mixed micelles whereas the complex with a chain length of 12 carbon atoms was not incorporated into a micellar structure. The size distribution of the micelles was measured by photon correlation spectroscopy. The mean sizes of the micelles for all the complexes lay within a narrow range, typically between 11 and 20 nm. The NMRD curves of the gadolinium(III) DTPA-monoamide complexes incorporated into mixed micelles display higher relaxivity values than the commercially available Gd–DTPA contrast agent. Moreover, micelles with gadolinium DTPA-monoamide complexes showed higher relaxivities than micelles containing the corresponding gadolinium DTPA-bis(amide) complexes, most likely because of a more efficient exchange of the coordinated water molecule.

Introduction

MRI (magnetic resonance imaging) contrast agents are routinely used in medicine because they provide reliable results that assist in the rapid clinical interpretation of MRI images. Most of the commonly used contrast agents achieve their effect by enhancing the relaxation rate of water protons in tissues. In general, contrast agents consist of a paramagnetic metal centre, typically gadolinium(III), which must be complexed to a strong chelating ligand, since the free metal ions are toxic at the concentrations needed for diagnosis. Water-soluble, anionic $[Gd(DTPA)(H_2O)]^{2-}$ was the first contrast agent approved for use in humans and is currently in routine use as a clinical magnetic resonance imaging agent under the name Magnevist® (Schering, Berlin, Germany). This complex contains one inner-sphere water molecule[1–4] that exchanges rapidly with bulk water,[5] providing an efficient relaxation of the surrounding water protons. However, $[Gd(DTPA)(H_2O)]^{2-}$ is a nonspecific contrast agent since its hydrophilicity results in an efficient enhancement of contrast only through its preferential distribution in the bloodstream. In recent years, contrast agents with improved characteristics, such as increased efficacy and organ specificity, have been sought.

Several different approaches to slow the rotational motion of gadolinium-based contrast agents, and thus to improve their relaxation efficiency, have been reported in the literature. These include synthesis of covalently or noncovalently bound macromolecular gadolinium(III) chelates such as dendrimers,[6] linear polymers[7–9] or proteins.[10,11] Some of these strategies proved to be rather disappointing since the relaxivity gain obtained by increasing the molecular size was often far less than expected as a result of some internal flexibility or the nonrigid attachment of the chelate to the macromolecule.[6–11]

An increase in the relaxivity could also be achieved by the synthesis of molecules with an efficient targeting system that is able to provide interactions between the agent and specific macromolecular receptors. For these purposes various hydrophobic groups have been introduced into the DTPA molecule through amidation of monoacid tetraester DTPA derivatives. The paramagnetic complexes of these compounds were investigated for the detection of tumors and myocardial infections.[12–14] In addition, incorporation of certain amphipathic gadolinium(III) complexes into liposomal membranes yielded paramagnetically labeled liposomes which significantly enhanced proton relaxivity.[15–21] Liposomes bearing gadolinium(III) complexes with long alkyl chains are expected to be less toxic and more tissue-specific, and their potential to deliver various MRI contrast

enhancement agents to selective sites has also been investigated.[15−21]

Another interesting strategy for the development of new types of contrast reagents is the synthesis of amphiphilic gadolinium(III) complexes which can self-assemble to form micelles.[22,23] One example of this is the Gd−DOTA derivative (DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) with a long alkyl chain, which was reported by André et al.[24] This compound displayed high relaxation rates because of an increase in the rotational correlation time. Alternatively, the lipophilic gadolinium(III) complexes can be incorporated into mixed micelles in order to obtain supramolecular systems with a better control of the size.[25] We recently described the synthesis of amphiphilic bis(amide) derivatives of DTPA with alkyl chains consisting of 12, 14, 16, and 18 carbon atoms, whose gadolinium(III) complexes were incorporated into mixed micelles.[26] The resulting supramolecular structures showed an increase in relaxivity relative to Gd−DTPA, because of the lower mobility of the paramagnetic complex inside the micelle. In order to investigate the effects of the structure of the lipophilic gadolinium(III) complex on the overall relaxivity of the micelles, we have now synthesized amphiphilic monoamide derivatives of DTPA with alkyl chains of various lengths. The gadolinium complexes of these ligands were incorporated into mixed micelles and the NMRD profiles of these paramagnetic micelles are reported.

Results and Discussion

Ligands and Complexes

The ligands DTPA-monolaurylamide (DTPA−MC12), DTPA-monomyristylamide (DTPA−MC14), DTPA-monopalmitylamide (DTPA−MC16) and DTPA-monostearylamide (DTPA−MC18) were synthesized according to Scheme 1.

Infrared spectroscopic data of all the ligands showed strong absorptions in the regions around 3410 and 1745−1670 cm^{-1}, corresponding to NH and CO stretching modes, respectively.[27] Upon complexation with gadolinium(III), the CO stretching vibrations of the free acid groups disappear, while the CO stretching mode of the amide shifts ca. 40 cm^{-1}, indicating amide oxygen coordination to the lanthanide ion. Although the negative-mode electron-spray mass spectra were not very informative, the positive-mode electron-spray mass spectra of Gd−DTPA−MC12, Gd−DTPA−MC14, Gd−DTPA−MC16 and Gd−DTPA−MC18 in chloroform/methanol solutions showed cluster peaks at *m*/*z* values of 716, 744, 772, and 800, respectively, which indicate coordination of gadolinium(III) to the ligand. These results are consistent with the formation of complexes in which DTPA−MC12, DTPA−MC14, DTPA−MC16 and DTPA−MC18 act as octadentate ligands, and where the ninth coordination site of gadolinium(III) is occupied by a water molecule (Figure 1). Initially, it might seem unusual that these negatively charged complexes were detected in the positive-mode electron-spray mass spectra. However, we used the positive ESI-MS for the best sensibility of the technique. In the ESI spectra, we observed protonated molecular ions or adducts of sodium. This can be explained by the fact that the molecules contain basic groups (carboxylate and amine groups) that can be protonated readily. Moreover, these groups can exhibit Lewis basicity, forming adducts with sodium ions.

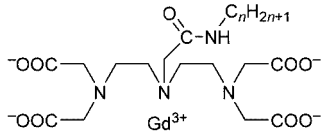

Figure 1. Schematic representation of the Gd−DTPA-monoamide complex; the ligand coordinates to the gadolinium(III) ion through four acetate oxygen atoms, three nitrogen atoms and one carbonyl oxygen atom of the amide group, while a water molecule occupies the ninth coordination site

^{1}H NMR Studies of the Complexes

The low solubility of the lanthanide(III) complexes of DTPA−MC14, DTPA−MC16 and DTPA−MC18 limited the scope of solution studies. A range of deuterated solvents including D_2O, $CDCl_3$, CD_2Cl_2, [D_6]DMSO, CD_3OH, CD_3CN, $(CD_3)_2CO$, and various combinations of these solvents, were used in attempts to obtain solutions of the complexes suitable for NMR measurements. Unfortunately, the concentration of most of the solutions was too low to obtain good-quality NMR spectra. However, in the case of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the La−DTPA−MC18 complex, it was possible to obtain a relatively well-resolved proton NMR spectrum in $[D_6]DMSO/CD_3OH$ solution. This spectrum showed that the DTPA resonances of the complex are significantly broadened compared to the free ligand. As previously described for the bis(amide)-DTPA complexes, the broadening of DTPA resonances indicates the presence of several interconverting isomers in solution.[26] Variable-temperature NMR studies on this complex did not provide more information about the exchange process since the strong solvent peaks at δ = 2.61 ppm ($[D_6]DMSO$) and 3.28 ppm (CD_3OH) obscured some of the DTPA resonances.

Mixed Micelle Formation and Size Distribution

A phospholipid (DPPC) and a surfactant (Tween 80), whose structures are given in the Supporting Information, together with the gadolinium(III) complexes of DTPA−MC12, DTPA−MC14, DTPA−MC16, and DTPA−MC18 ligands were used to prepare mixed micelles. The micelle size was determined at room temperature by photon correlation spectroscopy. All micelles were monodisperse. The mean diameters of the micelles were all within a narrow range (11−20 nm, see Supporting Information), indicating that their size is virtually independent of the length of the monoamide chain, and that the phospholipid DPPC determines micelle size. A schematic representation of a mixed micelle incorporating a gadolinium(III) complex is shown in Figure 2.

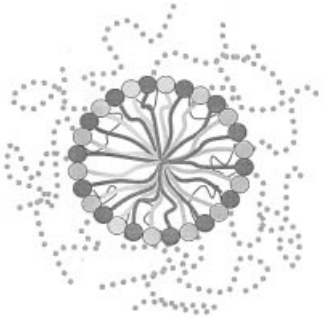

Figure 2. Schematic representation of the amphiphilic gadolinium(III) complex incorporated into a mixed micelle: gadolinium(III) complex (black circles and lines), DPPC phospholipid (gray circles and lines), Tween® 80 (gray dots)

Nuclear Magnetic Relaxation Dispersion (NMRD) Measurements

Figure 3 shows the proton NMRD profiles of the relaxivity of Gd−DTPA−MC12, Gd−DTPA−MC14, Gd−DTPA−MC16 and Gd−DTPA−MC18 in micellar solution at 37 °C. As expected, the inclusion of the gadolinium(III) complexes Gd−DTPA−MC14, Gd−DTPA−MC16 and Gd−DTPA−MC18 into micelles results in an increased relaxivity when compared with the parent complex Gd−DTPA. The hump at higher field strengths (20−60 MHz), which is typical for supramolecular structures, is also seen here. As explained previously, this is caused by a decrease in the rotational mobility of the paramagnetic complex.[26] On the other hand, the proton NMRD profile of Gd−DTPA−MC12 in micellar solution is much less intense and does not reach a maximum at high magnetic fields. This behaviour is typical of a hydrophilic gadolinium(III) complex of low molecular weight and suggests that this complex is very loosely bound or not incorporated at all into the micellar structure.

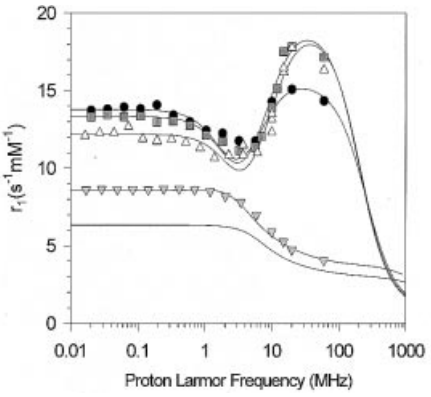

Figure 3. NMRD profiles of micellar solutions of Gd−DTPA−MC12 (triangles down), Gd−DTPA−MC14 (circles), Gd−DTPA−MC16 (squares) and Gd−DTPA−MC18 (triangles up), at 37 °C; the NMRD profile of Gd−DTPA (line underneath) has been added for comparison[32]

The data were analysed using the classical inner-sphere[28−29] and outer-sphere[30] theories. The distance of closest approach was set at 0.36 nm, the relative diffusion constant was fixed at 3.3×10^{-9} m^2s^{-1} and the distance for the inner-sphere interaction was set at 0.31 nm. The number of coordinated water molecules was assumed to be equal to one by analogy with other derivatives of Gd−DTPA.[31−33] The parameters describing the electronic relaxation of Gd (the electronic relaxation time at very low magnetic field, τ_{SO}, and the correlation time modulating the electronic relaxation, τ_V) as well as the "global" rotational correlation time, τ_R, and the residence time of the coordinated water molecule, τ_M, were simultaneously fitted. The results are shown in Table 1.

Table 1. Parameters obtained from the theoretical fitting of the proton NMRD data (T = 37 °C)

Compound	τ_R [ns]	τ_M [ns]	τ_{SO} [ps]	τ_V [ps]
Gd−DTPA−MC12	0.105	310	210	40
Gd−DTPA−MC14	0.91	680	194	41
Gd−DTPA−MC16	1.12	510	154	39
Gd−DTPA−MC18	1.07	500	127	38
Gd−DTPA[a]	0.059	143	82	23
Gd−DTPA−BMA[b]	0.064	967	76	23

[a] From ref.[32]: τ_R, τ_{SO} and τ_V obtained from the fitting of the proton NMRD data, τ_M obtained from the fitting of the ^{17}O transverse relaxation rates. [b] From ref.[33]

The parameters obtained for Gd−DTPA−MC14, Gd−DTPA−MC16 and Gd−DTPA−MC18 are quite similar, having a rotational correlation time of about 1 ns.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

This value is at least two orders of magnitude lower than the rotational correlation time calculated by the Stokes−Einstein theory for a rigid sphere (τ_R ranging between 112 and 673 ns depending on the micelle size). The observed difference can be related to the local motion of the gadolinium(III) complex within the micellar structure. The values of τ_M are in the same range for the three complexes, and are larger than for the parent compound Gd−DTPA but smaller than that of Gd−DTPA−BMA [a hydrophilic bis(amide) derivative of Gd−DTPA]. Indeed it is well known that Gd−DTPA derivatives with amide groups are characterized by a decreased exchange rate of the coordinated water molecule and that τ_M is related to the number of amide functions and their substituents.[34]

The values for τ_R are smaller than the ones reported for the corresponding bis(amide) derivatives incorporated into the same micellar structure. This is probably related to a more efficient immobilisation of the paramagnetic part of the bis(amide) derivatives caused by the incorporation of both hydrophobic chains into the micellar membrane. These smaller τ_R values are not reflected by a subsequent decrease but by an increase in relaxivity because of the smaller τ_M values, which induce an opposing effect. Moreover, the relaxivity of the micellar solution of the Gd−DTPA−MC18 complex bearing an amide chain of 18 carbon atoms, and thus longer than the DPPC chains, is similar to that of its analogue with 16 carbon atoms, at the magnetic field strengths used for imaging.

The τ_R value obtained for the complex Gd−DTPA−MC12 in the micellar solution is much lower than those of the other complexes, which indicates that this complex is either very loosely incorporated inside the micellar membrane or not incorporated at all. It seems that the aliphatic chain of this complex is too short and the hydrophobic character of the complex too low to allow efficient incorporation into the micellar structures.

Conclusion

While it appears that the gadolinium(III) complex of Gd−DTPA−MC12 does not form mixed micelles with DPPC and Tween 80, the gadolinium(III) complexes of DTPA−MC14, DTPA−MC16, and DTPA−MC18 ligands were successfully incorporated into mixed micelles to obtain supramolecular structures with a decreased mobility. The relaxivities of solutions containing these micelles are significantly higher than of solutions of Gd−DTPA as a result of the reduced mobility of the gadolinium(III) complexes. At imaging fields (20−60 MHz), all micellar solutions show similar relaxivities, which is in contrast to the bis(amide) complexes in which the lowest relaxivities were observed for the complex containing the longest side chains.[26] This observation suggests that the insertion of the monoamide compound Gd−DTPA−MC18 is similar to that of the homologues with shorter chain length despite being inserted into micelles composed of DPPC, whose alkyl chain is shorter. By a comparison of the relaxivity data of the monoamide compounds with those of the previously reported bis(amide) compounds, we can conclude that the relaxivity gain, relative to Gd−DTPA, is higher for mixed micelles in which monoamide complexes are inserted than for the micelles in which bis(amide) compounds of the same chain length are inserted.

Experimental Section

Chemicals: Reagents were obtained from Aldrich Chemical Co. Inc., Acros Organics, or Fluka, and used without further purification. 1,2-Dipalmitoyl-*sn*-glycero-3-phosphatidylcholine (DPPC) was obtained from Genzyme Pharmaceuticals (Switzerland). Gadolinium(III) chloride hexahydrate was purchased from GFS chemicals (USA).

Instruments: ^{1}H NMR spectra were obtained using a Bruker Avance 300 operating at 300 MHz. IR spectra (KBr pellets) were measured with a Bruker IFS66 FTIR spectrometer. Mass spectra were obtained using a Q-tof 2 (Micromass, Manchester UK). Samples (0.1 g) were dissolved in methanol/water (50:50) and infused at a rate of 5 μL/min.

Synthesis of the Ligands

***N*,*N*-Bis(2-{bis[2-(1,1-dimethylethoxy)-2-oxoethyl]amino}ethyl)-glycine (Product I in Scheme 1):** This compound was prepared according to a published procedure.[35] Yield 45%. IR: $\tilde{\nu}$ = 2977, 2935 (C−H alkyl stretch); 1733 (CO, ester); 1646 (COOH) cm^{-1}. ^{1}H NMR ([D$_6$]DMSO): δ = 1.45 (s, 36 H, 12 × CH_3), 2.98 (t, 4 H, 2 × CH_2), 3.10 (br., 4 H, 2 × CH_2), 3.36 (s, 8 H, 4 × CH_2), 3.58 (s, 2 H, CH_2) ppm. ES-MS$^+$: *m*/*z* = 618 [M + H]$^+$ ($C_{30}H_{55}N_3O_{10}$, $M_{calcd.}$ = 617).

DTPA-Monoamides: The alkylamine (4.72 mmol) was added to a solution of *N*,*N*-bis(2-{bis[2-(1,1-dimethylethoxy)-2-oxoethyl]-amino}ethyl)glycine (4.72 mmol) in DMF (80 mL). After the dropwise addition of DEPC [$(EtO)_2P(O)CN$] (0.8 mL, 5.28 mmol), the reaction mixture was kept at 3 °C by cooling in an ice bath. Triethylamine (5.92 mmol) was then added slowly to the solution. After 10 min, the amine had fully reacted and the solution was warmed to room temperature and allowed to stand for 30 min. DMF was then removed by evaporation under reduced pressure. The crude product dissolved in ethyl acetate (132 mL) and washed with saturated aqueous sodium hydrogen carbonate (2 × 100 mL) then saturated aqueous sodium chloride solution (2 × 80 mL) to obtain product **II** in Scheme 1. Product **II** (838 mg, 1.05 mmol) was dissolved in 6 N HCl (8 mL). The mixture was stirred at room temperature for 1 h and then washed with dichloromethane (2 × 10 mL). The aqueous phase was concentrated to give DTPA-monamide (product **III** in Scheme 1).

Analytical Data for the Ligands

DTPA−MC12: Yield 73% (1.93 g). IR: $\tilde{\nu}$ = 3422 (N−H stretch), 2938, 2851 (C−H alkyl stretch), 1745 (CO acid), 1674 (CO, amide I) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 0.80 (t, 3 H, CH_3), 1.1−1.3 (m, 20 H, 10 × CH_2), 2.7 (t, 4 H, 2 × CH_2), 2.8 (t, 4 H, 2 × CH_2), 3.35 (t, 2 H, CH_2), 3.4 (s, 2 H, CH_2), 3.9 (s, 8 H, 4 × CH_2), 4.4 (s, 4 H, 4 × OH) ppm. ES-MS$^+$: 561 [M + H]$^+$ ($C_{26}H_{48}N_4O_9$, $M_{calcd.}$ = 560).

DTPA−MC14: Yield 14% (390 mg). IR: $\tilde{\nu}$ = 3422 (N−H stretch), 2941, 2851 (C−H alkyl stretch), 1745 (CO acid), 1674 (CO, amide I) cm^{-1}. ^{1}H NMR (MeOD, $CDCl_3$): δ = 0.89 (t, 3 H, CH_3), 1.27

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(s, 22 H, 11 × CH_2), 1.55 (m, 2 H, CH_2), 2.89 and 3.02 (m, 8 H, 4 × CH_2), 3.45 (m, 4 H, 2 × CH_2), 3.92 (s, 8 H, 4 × CH_2) ppm. ES-MS$^+$: 589 $[M + H]^+$ ($C_{28}H_{52}N_4O_9$, $M_{calcd.}$ = 588).

DTPA−MC16: Yield (PA) 12% (349 mg). IR: $\tilde{\nu}$ = 3424 (N−H stretch), 2932, 2851 (C−H alkyl stretch), 1745 (CO acid), 1674 (CO, amide I) cm^{-1}. ^{1}H NMR (MeOD, $CDCl_3$): δ = 0.83 (t, 3 H, CH_3), 1.27 (s, 26 H, 13 × CH_2), 1.39 (m, 2 H, CH_2), 2.70 and 3.05 (m, 8 H, 4 × CH_2), 4.12 (s, 8 H, 4 × CH_2) ppm. ES-MS$^+$: 617 $[M + H]^+$ ($C_{30}H_{56}N_4O_9$, $M_{calcd.}$ = 616).

DTPA−MC18: Yield (SA) 22% (669 mg). IR: $\tilde{\nu}$ = 3432 (N−H stretch), 2921, 2843 (C−H alkyl stretch), 1745 (CO acid), 1671 (CO, amide I) cm^{-1}. ^{1}H NMR (MeOD/$CDCl_3$): δ = 0.89 (t, 3 H, CH_3), 1.27 (s, 30 H, 15 × CH_2), 1.55 (m, 2 H, CH_2), 2.89 and 3.02 (m, 8 H, 4 × CH_2), 3.45 (m, 4 H, 2 × CH_2), 3.92 (s, 8 H, 4 × CH_2) ppm. ES-MS$^+$: 667 $[M + Na]^+$, 645 $[M + H]^+$ ($C_{32}H_{60}N_4O_9$, $M_{calcd.}$ = 644).

Synthesis of the Gadolinium(III) Complexes (Product IV in Scheme 1): The complexes were synthesized according to the general procedure as follows: A solution of the hydrated $GdCl_3$ salt (1.1 mmol) in H_2O (1 mL) was added to the ligand (1 mmol) dissolved in pyridine (30 mL), and the mixture was heated at 70 °C for 3 h. The solvents were evaporated under reduced pressure and the crude product was then refluxed in ethanol for 1 h. After cooling to room temperature, the complex was filtered off and dried in vacuo. The absence of free gadolinium was confirmed using a xylenol orange indicator.[36]

Analytical Data for the Complexes

Gd−DTPA−MC12: Yield 74% (529 mg). IR: $\tilde{\nu}$ = 3408 (N−H stretch), 3092 (N−H amide), 2930, 2850 (C−H alkyl stretch), 1634 (CO, amide I/COO^- assym. stretch) cm^{-1}. ES-MS$^+$: 716 $[M + H]^+$ ($C_{26}H_{45}GdN_4O_9$, $M_{calcd.}$ = 715).

Gd−DTPA−MC14: Yield 85% (631 mg). IR: $\tilde{\nu}$ = 3410 (N−H stretch), 3090 (N−H amide), 2931, 2856 (C−H alkyl stretch), 1632 (CO, amide I/COO^- assym. stretch) cm^{-1}. ES-MS$^+$: 744 $[M + H]^+$($C_{28}H_{49}GdN_4O_9$, $M_{calcd.}$ = 743).

Gd−DTPA−MC16: Yield 61% (470 mg). IR: $\tilde{\nu}$ = 3410 (N−H stretch), 3094 (N−H amide), 2922, 2849 (C−H alkyl stretch); 1630 (CO, amide I/COO^- assym stretch) cm^{-1}. ES-MS$^+$: 772 $[M + H]^+$ ($C_{30}H_{53}GdN_4O_9$, $M_{calcd.}$ = 771).

Gd−DTPA−MC18: Yield 67% (535 mg). IR: $\tilde{\nu}$ = 3401 (N−H stretch), 3094 (N−H amide), 2926, 2848 (C−H alkyl stretch), 1630 (CO, amide I/COO^- assym. stretch) cm^{-1}. ES-MS$^+$: 800 $[M + H]^+$ ($C_{32}H_{57}GdN_4O_9$, $M_{calcd.}$ = 799).

Sodium/Potassium Content: Prior to incorporation into micelles, the potassium and sodium ion contents of the compounds were checked by flame photometry (IL, 943, Instrumentation Laboratories, Massachusetts, USA). The Na^+ and K^+ ion contents were measured using a sample that had been obtained by extracting a solution of complex (1.6 mg) in chloroform/methanol (10:1) with 2 mL of water. Na^+ content (mmol/mol of the complex): Gd−DTPA−MC12: 3.0; Gd−DTPA−MC18: 0.4; Gd−DTPA−MC16: 0.1; Gd−DTPA−MC14: 0.4. K^+ content: no K^+ was found in any of the complexes.

Preparation of Micelles: 1,2-Dipalmitoyl-*sn*-glycero-3 phosphatidylcholine (DPPC) (225 mg) and the complex (25 mg) were dissolved in chloroform/methanol (1:1) (50 mL). Concentration under reduced pressure yielded a thin film, which was then rehydrated with hot water (5 mL, 70 °C). This solution was sonicated for 15 min using a 70-W sonicator while maintaining the temperature at 65 °C with a thermostatic bath. After sonication, 75 mg of a surfactant was added (Tween 80®, polyoxyethylene sorbitan monooleate), followed by another 15 min of sonication.

Determination of Micelle Size: The mean micelle sizes were determined by photon correlation spectroscopy performed with a BIC multiangle laser light scattering system at room temperature and with a 90° scattering angle (Brookhaven Instruments Corporation, Holtsville, USA). The intensity-weighted micelle diameter was measured on diluted suspensions and calculated by a nonnegatively constrained least-squares (multiple pass) routine. The error is of the order of 20%. The diameters obtained are as follows: micellar solutions with Gd−DTPA−MC12: 20 nm, with Gd−DTPA−MC14: 13 nm, with Gd−DTPA−MC16: 18 nm, with Gd−DTPA−MC18: 11 nm.

***T_1* Measurements:** Proton Nuclear Magnetic Relaxation Dispersion (NMRD) profiles were recorded between 0.24 mT and 1.2 T with a Field Cycling instrument (Stelar Spinmaster FFC-2000, Stelar S.R.L., Mede, Italy) on 0.6 mL solutions in 10-mm (o.d.) tubes. Proton relaxation rates were also measured at 0.47 T, and 1.5 T with Minispec PC-120, and mq-60 (Bruker, Karlsruhe, Germany). All samples were diluted 10 times and the temperature was maintained at 37 °C. ^{1}H NMRD data were fitted according to the theoretical inner-sphere model described by Solomon[28] and Bloembergen[29] and to the outer-sphere contribution described by Freed.[30] Calculations were performed with a previously described software package.[37,38]

Mono- and Dinuclear High-Spin Half-Sandwich Manganese(II) Complexes Containing Acetylide and TMEDA Ligands

Sohrab Kheradmandan,[a] Thomas Fox,[a] Helmut W. Schmalle,[a] Koushik Venkatesan,[a] and Heinz Berke*[a]

Keywords: Alkyne ligands / Cyclopentadienyl ligands / Half-sandwich complexes / Molecular devices / N ligands

The d^5 high-spin Mn^{II} half-sandwich complexes [Mn(C≡CR)(MeC_5H_4)(tmeda)] (R = $SiMe_3$ **2**; Ph **3**; *t*Bu **4**; C≡C$SiMe_3$ **5**; C≡CPh **6**; tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) were prepared by the reaction of [Mn(MeC_5H_4)$_2$(tmeda)] (**1**) with 1 equiv. of the corresponding acetylene or the trimethyltin acetylide. The dinuclear complexes [Mn(C≡C–C≡C$SiMe_3$)$_2$(tmeda)]$_2$ (**7**) and [Mn_2($MeCp$)$_2$(μ_1-*t*BuC≡C)$_2$(μ_1-tmeda)] (**8**), which contain Mn–Mn bonds, were synthesized by treating **1** with an excess of HC≡C–C≡C$SiMe_3$ or HC≡C*t*Bu, respectively. Dinuclear complexes of the type [(MeC_5H_4)(tmeda)MnC≡C–X–C≡CMn(tmeda)(C_5H_4Me)] [X = 1,3-C_6H_4 **9**; 1,4-C_6H_4 **10**; 4,4′-(C_6H_4)$_2$ **11**] were obtained by treatment of **1** with 0.5 equiv. of the corresponding acetylides 1,3-C_6H_4-(C≡C$SnMe_3$)$_2$, 1,4-C_6H_4(C≡C$SnMe_3$)$_2$ and 4,4′-(C_6H_4)$_2$-(C≡C$SnMe_3$)$_2$ in benzene for 24 h to yield the corresponding dinuclear complexes in very good yields. All the mono- and dinuclear compounds have been characterized by NMR, IR, Raman spectroscopy and elemental analyses. X-ray diffraction studies have been performed on complexes **3** and **5**–**11**.

Introduction

Mono- and dinuclear transition metal acetylide complexes offer an interesting perspective for the construction of organometallic systems as molecular-level single-electron devices and the bottom-up construction of miniaturized components capable of performing specific electronic functions. This is an important challenge for many facets of modern chemistry.[1−15] During the last decade several organometallic research groups have focused on the development of facile synthetic routes to $L_mMC_xM'L'_{m'}$ rigid rod transition metal complexes.[2,16−91] Our ongoing interest in such building blocks is devoted to the synthesis and physical properties of molecular species that might function as wires. Specifically, they should consist of an all-carbon chain capped by two redox-active metal termini.[36,46,57,63,74,75] We have sought to explore reactions to prepare mono- and dinuclear precursors containing polyyne ligands. We have already reported some of the results involving manganese centers with strong-field ligands such as phosphanes.[36,46,57,63,74,75] We subsequently decided to synthesize and study the properties of molecules with weak-field ligands, such as tmeda, expecting high-spin configurations of the metal centers.[92−100] In addition to the above reasons, the $L_mMn-C_4-MnL_m$ systems were selected as target molecules because a build-up of di- and oligonuclear Mn complexes seemed not only to be synthetically feasible by acetylide substitution processes, but also by coupling of $Mn-C_2$ units, such as Mn−alkynyl and Mn−vinylidene moieties. These possibilities have been corroborated by recent studies in our group.[36,46,57,74,75,101] For instance, we have published the synthesis of redox-active dinuclear complexes of the type [{Mn(dmpe)$_2$(X)}$_2$(μ-C_4)]$^{n+}$ (X = C≡CH, C≡C−C≡C$SiMe_3$ and n = 0−2), which were obtained by an in situ C−C coupling of [Mn^{III}-(dmpe)$_2$(C≡CH)(C≡C)] units.[74,75,101] We have also previously reported the synthesis and characterization of [I(dmpe)$_2$MnC≡C−C≡CMn(dmpe)$_2$I]$^{n+}$ [57] in a preliminary communication and report herein the mononuclear half-sandwich complexes of the type [(MeC_5H_4)(tmeda)MnC≡CR] (R = $SiMe_3$, Ph, *t*Bu, C≡C$SiMe_3$, C≡CPh) and dinuclear half-sandwich complexes of the type [(MeC_5H_4)(tmeda)Mn−X−Mn(tmeda)(MeC_5H_4)] [X = 1,4-C_6H_4(C≡C)$_2$, 1,3-C_6H_4(C≡C)$_2$, 4,4′-$C_6H_4C_6H_4$-(C≡C)$_2$].

The first representatives of the manganocene family — [$MnCp_2$] and [Mn(MeC_5H_4)$_2$][102,103] — have been known for around 40 years and their electronic and structural properties have been studied extensively; however, their synthetic potential, in particular with regard to Cp or MeC_5H_4 replacement by other organometallic units, has not been exploited appropriately except for earlier work from our group.[63,104] The mononuclear complexes were obtained by the reaction of [(MeC_5H_4)$_2$Mn(tmeda)][105,106] with RC≡CR′ (R′ = H, $SnMe_3$, R = $SiMe_3$, Ph, *t*Bu,

C≡CSiMe$_3$, C≡CPh) and the corresponding dinuclear systems by treatment of 0.5 equiv. of the bifunctional acetylenes Me$_3$SnC≡C−R"−C≡CSnMe$_3$ [R′′ = 1,4-C$_6$H$_4$(C≡C)$_2$,[107−109] 1,3-C$_6$H$_4$(C≡C)$_2$,[107−109] or 4,4′-C$_6$H$_4$C$_6$H$_4$(C≡C)$_2$ [107−109] with [Mn(MeC$_5$H$_4$)$_2$(tmeda)].

Results and Discussion

On the basis of known, facile methylcyclopentadienyl replacements in [Mn(MeC$_5$H$_4$)$_2$(dmpe)],[63,103,105] where one of the methylcyclopentadienyl rings is bound to the manganese center in an η^5 fashion and the other in an η^2 fashion,[103,105] we thought that it should be even easier to replace one of the methylcyclopentadienyl rings in [Mn(MeC$_5$H$_4$)$_2$(tmeda)][106] (**1**), which comprises two η^1-methylcyclopentadienyl rings bound to the manganese center, by an acetylide ligand. Reaction of **1** with 1 equiv. of various acetylenes HC≡CSiMe$_3$ or Me$_3$SnC≡CSiMe$_3$, PhC≡CH or PhC≡CSnMe$_3$, *t*BuC≡CH or *t*BuC≡CSnMe$_3$, Me$_3$SiC≡C−C≡CH, Me$_3$SiC≡C−C≡CSnMe$_3$ or PhC≡C−C≡CSnMe$_3$ yielded, in THF at room temperature for 3 d, the corresponding high-spin d^5 Mn^{II} mononuclear complexes of the type [(MeC$_5$H$_4$)(tmeda)MnC≡CR] (R = SiMe$_3$ **2**; Ph **3**; *t*Bu **4**; C≡CSiMe$_3$ **5**; C≡CPh **6**) quantitatively (Scheme 1). The ^{1}H NMR spectra of complexes **3**, **4** and **6** at 20 °C contain proton resonances for the ring protons of the MeC$_5$H$_4$ group in the high-field region, while for **2** and **5** similar resonances are not present. The only proton resonances that are observed for complexes **2** and **5** are for the SiMe$_3$ protons at δ = 7.3 and 4.8 ppm, respectively. The signals of the methyl and the methylene protons of the tmeda ligand of these complexes are observed between δ = 60 and 110 ppm. The paramagnetic behavior of these complexes apparently influences the relaxation of the ^{15}N nucleus, so that ^{15}N resonances can be observed. The ^{15}N NMR spectra of **3**, **4** and **6** reveal resonances for the tmeda ligand at higher field, at $\delta \approx -75$ to −90 ppm. The proton resonances for the methyl and the methylene protons of the tmeda ligand are absent. The ^{1}H and ^{15}N NMR spectroscopic data for complexes **2**−**6** are summarized in Table 1.

Table 1. ^{1}H and ^{15}N NMR spectroscopic data (δ [ppm]) for complexes **2**−**6**

	^{15}N NMR	^{1}H NMR		
		$CH_3C_5H_4$	$CH_3C_5H_4$	CH_2 or CH_3
2	−75.6 (br.)	–[a]	–[a]	–[a]

6	−81.7 (br.)	−10.2	−9.0	–[a]

[a] Not observed.

Raman spectroscopy showed characteristic bands for the ν(C≡C) vibrations for these complexes between 2000 and 2100 cm^{-1}.

The structure of **3** was additionally confirmed by an X-ray diffraction study (Figure 1). A pseudo-tetrahedral coordination of the manganese center was found. The bond

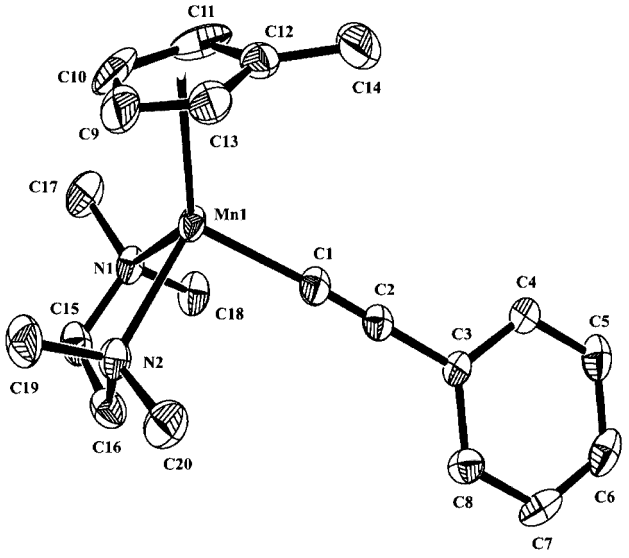

Figure 1. Molecular structure of **3** (30% probability displacement ellipsoids); hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Mn−C1 2.142(2), C1−C2 1.158(3), C2−C3 1.473(3), Mn−MeCp (centroid) 2.5144(2); Mn−C1−C2 176.76(19), C1−C2−C3 179.5(2)

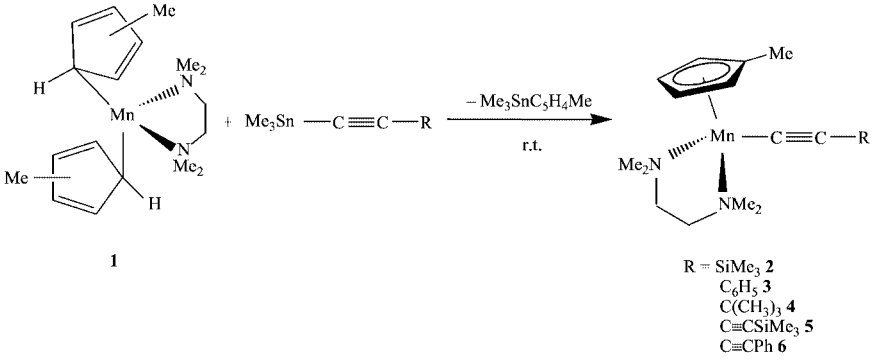

Scheme 1

lengths of 1.158(3) Å and 2.142(2) Å for C1−C2 and Mn−C1, respectively, fall into the range observed for similar kinds of complexes.[63]

The structure of **5** was also confirmed by a single-crystal X-ray diffraction study (Figure 2). The crystals were obtained by cooling the compound in a mixture of pentane and benzene to −30 °C. The solid-state structure reveals a pseudo-tetrahedral coordination of the manganese center. The bond lengths of 1.109(3) Å and 1.203(3) Å for C1−C2 and C3−C4, respectively, confirm the triple-bond nature of these bonds. An X-ray diffraction analysis also confirmed the spectroscopically derived structure of **6** which is related

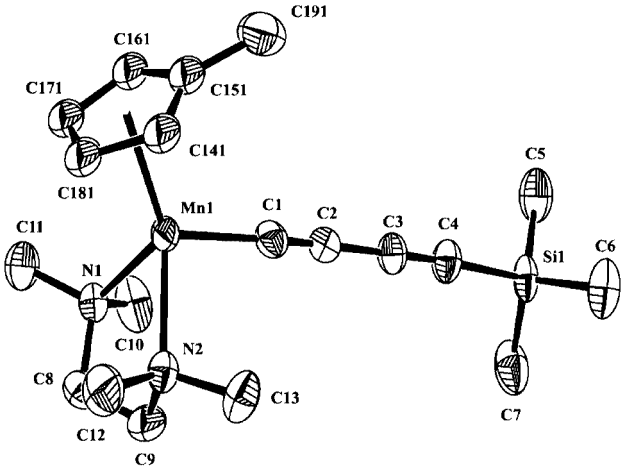

Figure 2. Molecular structure of **5** (30% probability displacement ellipsoids); hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Mn−C1 2.160(2), C1−C2 1.109(3), C2−C3 1.473(3), C3−C4 1.203(3), Mn−MeCp (centroid) 2.4805(5); Mn−C1−C2 176.5(2), C1−C2−C3 178.9(2), C2−C3−C4 179.3(2), C3−C4−Si 176.7(2)

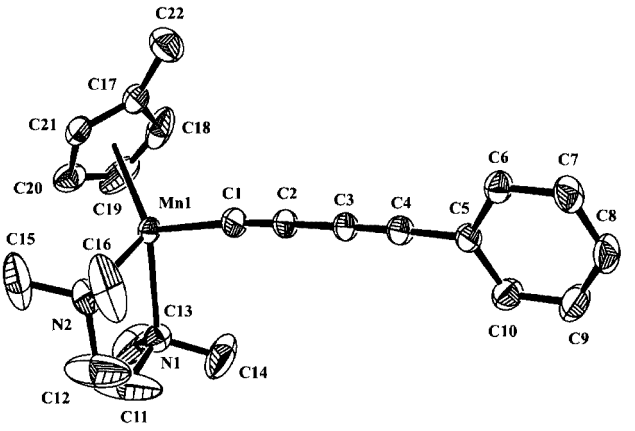

Figure 3. Molecular structure of **6** (30% probability displacement ellipsoids); hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Mn−C1 2.1222(19), C1−C2 1.220(3), C2−C3 1.397(3), C3−C4 1.206(3), Mn−MeCp (centroid) 2.4914(5); Mn−C1−C2 174.98(17), C1−C2−C3 178.3(2), C2−C3−C4 178.7(2), C3−C4−C5 176.0(2)

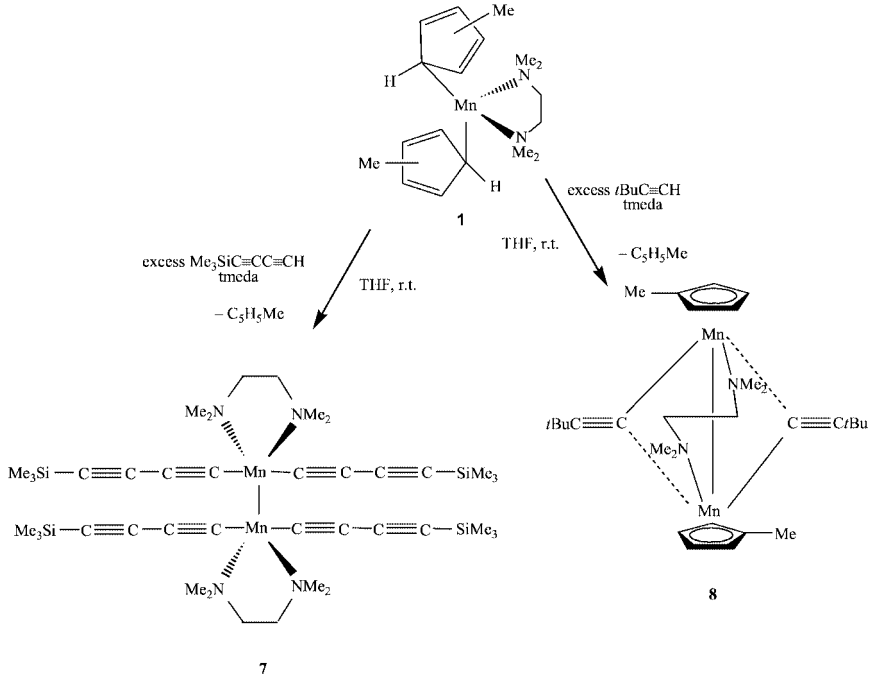
to **5** (Figure 3). The solid-state structure revealed the C1−C2 and C3−C4 bond lengths to be 1.220(3) Å and 1.206(3) Å, respectively.

Both methylcyclopentadienyl rings in **1** could be replaced by using an excess of the acetylene component. Stirring of **1** with $Me_3SiC{\equiv}C{-}C{\equiv}CH$ at room temperature for 5 d yielded the dinuclear complex **7** (Scheme 2). The ^1H NMR spectrum of **7** in [D_8]toluene at 25 °C shows only a signal for the $SiMe_3$ protons. In the ^{15}N NMR spectrum, the nitrogen atoms of the tmeda ligands are observed as a broad resonance at $\delta = -93.4$ ppm. Characteristic ν(C≡C) vibrations appear in the Raman spectrum at 2154, 2115 and 2001 cm^{-1}. The structure of **7** was confirmed by an X-ray



Scheme 2

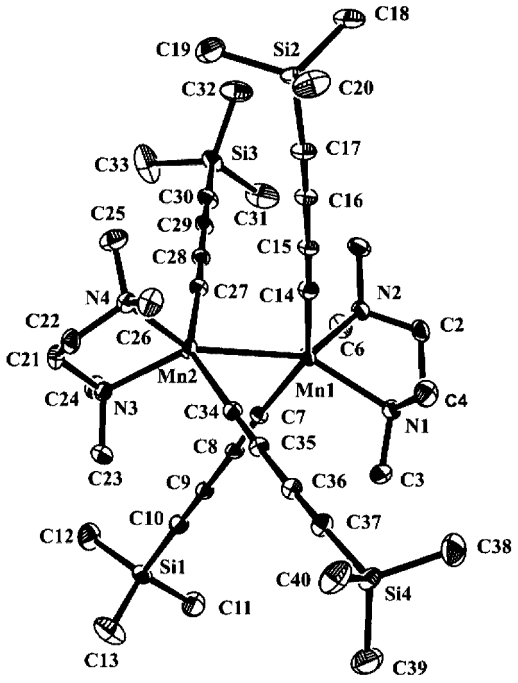

Figure 4. Molecular structure of **7** (30% probability displacement ellipsoids); hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Mn1−Mn2 2.8059(4), Mn1−C7 2.095(2), Mn1−C14 2.088(2), C7−C8 1.212(3), Mn2−C27 2.103(2), Mn2−C34 2.099(2), C27−C28 1.210(3), C8−C9 1.387(3), C9−C10 1.208(3), C14−C15 1.208(3), C15−C16 1.385(3), C16−C17 1.214(3), C28−C29 1.392(3), C29−C30 1.204(3), C34−C35 1.205(3), C35−C36 1.394(3), C36−C37 1.209(3); C7−Mn1−C14 147.43(8), Mn1−C7−C8 175.50(18), Mn1−C14−C15 176.57(19), C27−Mn2−C34 146.09(8), Mn2−C27−C28 173.18(19), Mn2−C34−C35 178.69(19), C7−C8−C9 177.5(2), C8−C9−C10 179.4(3), C27−C28−C29 178.3(2), C28−C29−C30 178.5(2), C9−C10−Si1 178.3(2), C14−C15−C16 177.7(2), C15−C16−C17 179.3(2), C16−C17−Si2 173.2(2), C29−C30−Si3 178.8(2), C34−C35−C36 178.2(2), C35−C36−C37 178.7(2), C36−C37−Si4 176.8(2), C27−Mn2−Mn1 76.11(6), C14−Mn1−Mn2 76.37(2), Mn1−Mn2−C34 70.11(6), Mn2−Mn1−C7 71.08(6)

diffraction analysis (Figure 4). In the solid-state structure a bond length of 2.8059(4) Å was found between the two manganese centers Mn1−Mn2, which is similar to compounds with Mn−Mn single bonds reported earlier, for instance $Mn_2(CO)_{10}$.[110−114] However, we should note that the electron counts for both complexes are different, so that the character of the unique single bond of **7** might also be different. The C7−C8 bond length was observed to be 1.212(3) Å, which is expected for a C≡C bond. The Mn1−C7−C8 unit possesses a bond angle of 175.50(18)°, which shows that this butadiynyl chain is slightly bent, as are the other three C_4 units. The coordination geometry of the Mn centers may thus be derived from a trigonal bipyramid with the tmeda ligand and the neighbouring manganese atom in the equatorial plane and the acetylide moieties in the axial positions [the angle between the planes (Mn2, N3, N4) (Mn2, Mn1, C4) is 84.48(7)°; other related angles between planes have similar values]. The rather acute C7−Mn1−C14 bond angle of 147.43(18)° stresses the fact that the two acetylide units at an Mn center are quite far away from the ideal *trans* position; the reason for this deviation could not be determined. It is supposed that there is an electronic driving force, and one possibility could be a secondary-type interaction between the manganese centers and the metal-adjacent triple bonds. For example, the Mn1−C34 distance of 2.877(2) Å is within the sum of the van der Waals radii and the Mn1−C35 distance of 3.531(2) Å is just about the sum of the van der Waals radii. When an excess of *t*BuC≡CH was used in the reaction with **1**, the unexpected dinuclear complex **8** was obtained (Scheme 2), with η^5-methylcyclopentadienyl rings at each Mn atom. The two manganese centers are bridged by one tmeda ligand and are connected by a presumably ligand-enforced Mn−Mn bond, which was confirmed by an X-ray diffraction study on **8** (Figure 5).

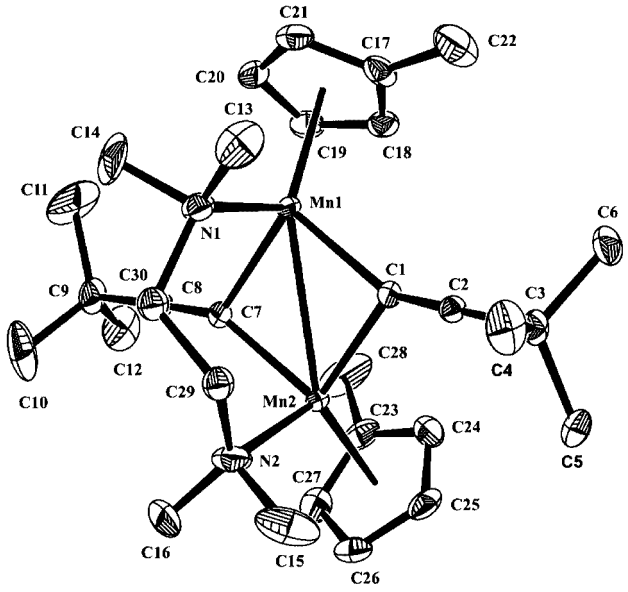

Figure 5. Molecular structure of **8** (30% probability displacement ellipsoids); hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Mn1−Mn2 2.8738(5), Mn1−C1 2.192(2), Mn1−C7 2.220(3), Mn2−C1 2.179(13), Mn2−C7 2.234(3), C1−C2 1.204(3), C2−C3 1.795(3), Mn1−MeCp1 (centroid) 2.491(3), Mn2−MeCp2 (centroid) 2.496(3); C1−Mn1−C7 98.58(9), C1−Mn2−C7 98.69(9), Mn1−C1−C2 152.8(2), Mn2−C7−C8 151.6(2), C1−C2−C3 179.5(3), C7−C8−C9 176.6(3), Mn1−C1−Mn2 80.98(7), C1−Mn1−Mn2 48.49(5), C1−Mn2−Mn1 48.89(5) Mn2−C7−Mn1 81.66(7), C7−Mn1−Mn2 50.14(7), C7−Mn2−Mn1 89.85(7)

The acetylide moiety also bridges the two manganese centers. The ^{1}H NMR spectrum of **8** in [D_8]toluene at 30 °C reveals a broad resonance for the methylcyclopentadienyl ring at $\delta = -11.4$ ppm and the corresponding resonances for the *tert*-butyl groups and the methyl and methylene groups of the tmeda ligand, which are observed at low field ($\delta = 14.2$, 34.6 and 65.5 ppm, respectively). The ^{15}N NMR spectrum shows a broad resonance at $\delta = -73.8$ ppm. In the Raman spectrum a band attributed to a ν(C≡C) vibration is observed at 2052 cm^{-1}.

The [Mn(MeC_5H_4)$_2$(tmeda)] complex **1** is a valuable starting material and allows access to dinuclear complexes

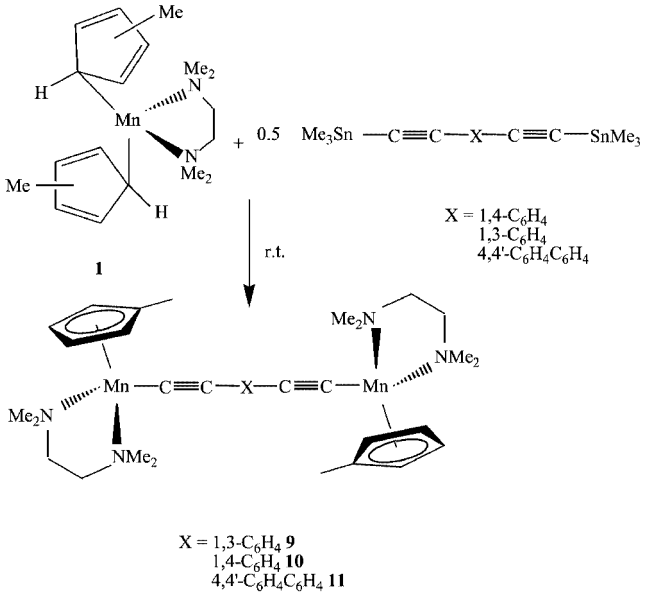
bridged by sp-carbon units. Complexes of this type have been widely studied in conjunction with potential molecular-wire applications.[32−35,43−45,50,52,55,56,66,69,70,72,87,115,127a] Complexes **9**, **10** and **11** were obtained by treatment of **1** with 0.5 equiv. of the corresponding acetylenes 1,3-$C_6H_4(C{\equiv}CSnMe_3)_2$, 1,4-$C_6H_4(C{\equiv}CSnMe_3)_2$ or 4,4′-$(C_6H_4)_2(C{\equiv}CSnMe_3)_2$ in benzene for 24 h to afford the corresponding dinuclear complexes in very good yields (Scheme 3). The ^{1}H NMR spectrum of **9** in [D$_8$]THF at 22 °C reveals two signals for the protons of the cyclopentadienyl rings, both paramagnetically shifted to high field at $\delta = -63.7$ and -45.9 ppm, and a broad resonance in the downfield region at $\delta = 163.3$ ppm. The proton resonance for the tmeda moieties appears at $\delta = 74.2$ ppm, while the aromatic protons are observed as two broad signals at $\delta =$ 38.6 and 41.6 ppm. The resonance of the tmeda ligands appears in the ^{15}N NMR spectrum (20 °C) as a broad signal at $\delta \approx -100.4$ ppm. The ^{1}H NMR spectra of complexes **10** and **11** show significant differences in comparison with that of complex **9**, since only the proton resonances corresponding to the methylcyclopentadienyl rings [$\delta = -8.1$ (**10**) and -24.9 ppm (**11**)] and the aromatic protons [$\delta = 27.2$ (**10**) and 20.7 ppm (**11**)] could be observed.



Scheme 3

The structures of complexes **9**, **10** and **11** were characterized by X-ray diffraction analyses. The solid-state structures of these complexes reveal different types of bonding of the methylcyclopentadienyl groups to the manganese centers. In complex **9** the methylcyclopentadienyl rings are η^3- and η^3-bound (see Supporting Information), whereas in **10** both possess η^2 hapticity (Figure 6); the maximum hapticity of the MeC_5H_4 rings (η^5,η^5) is observed in **11** (Figure 7). These different bonding situations might arise from the fact that the interaction between the methylcyclopentadienyl ring and the manganese center is quite ionic in nature and can therefore not be expressed by localized covalent interactions, but rather by partly localized ionic interactions of the ion-pair type.[100] Based on the ionic bonding, the energetic differences between the various binding modes are expected to be relatively small. Hence, simple packing forces on the order of 1 kcal·mol^{-1} might be just enough to induce different ring slippage modes in otherwise quite related structures. The C≡C bond lengths found in these complexes are similar to compounds already reported in the literature. CV experiments (ca. 0 to +1.5 V) failed to oxidize the complexes **9**, **10** and **11** possessing high-spin d^5-metal centers further.

Conclusions

Mono- and dinuclear complexes of polyynes capped by Mn^{II} half-sandwich units were synthesized. A series of these complexes has been structurally characterized showing a variety of different hapticities of the cyclopentadienyl rings. This observation witnesses quite ionic bonding of these rings as would indeed be expected for d^5 high-spin complexes. The manganese centers have a stable electron configuration additionally indicated by the inability to further oxidize them. Based on this we might conclude that the d electrons in the dinuclear complexes **9**−**11** are contracted, which also prevents strong electronic communication of the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

metal centers. It is therefore suggested that these complexes belong to class I or to the weaker interaction side of class II compounds according to the Robin/Day classification.[127b]

Experimental Section

General: Reagent-grade benzene, toluene, hexane, pentane, diethyl ether and tetrahydrofuran were dried and distilled from sodium benzophenone ketyl prior to use. Dichloromethane was distilled first from P_2O_5, and then prior to use from CaH_2. Literature procedures were used to prepare the following compounds: 1,2-bis(dimethylphosphanyl)ethane (dmpe),[128] $[Mn(MeC_5H_4)_2]$,[102,103] $[Mn(MeC_5H_4)_2(tmeda)]$,[105,106] $Me_3SnC{\equiv}CSiMe_3$,[129] $Me_3SiC{\equiv}C{-}C{\equiv}CH$,[130] $PhC{\equiv}CSnMe_3$, $tBuC{\equiv}CSnMe_3$,[128] $PhC{\equiv}C{-}C{\equiv}CSnMe_3$,[131] and $Me_3SnC{\equiv}C{-}R''{-}C{\equiv}CSnMe_3$ [R'' = 1,4-$C_6H_4(C{\equiv}C)_2$, 1,3-$C_6H_4(C{\equiv}C)_2$, 4,4′-$C_6H_4C_6H_4(C{\equiv}C)_2$].[107–109] *n*BuLi (1.6 M in hexane) and Me_3SnCl were used as received. All the manipulations were carried out under nitrogen using Schlenk techniques or in a drybox. IR spectra were obtained with a Bio-Rad FTS-45 instrument and the Raman spectra with a Renishaw Ramanscope spectrometer (514 nm). ^1H NMR spectra were measured with a Varian Gemini-2000 at 300 MHz and ^{15}N NMR spectra at 50.70 MHz with a Bruker DRX 500 spectrometer. All NMR spectra of paramagnetic compounds were obtained from concentrated solutions of analytically pure samples. The assignment of the ^1H NMR signals for paramagnetic signals is principally based on the investigations of Köhler et al.[132–134] Chemical shifts for ^1H are given in ppm with respect to the signals for residual solvent protons (^1H) of the deuterated solvents and for ^{15}N related to nitromethane.

Synthesis of $[Mn(\eta^1\text{-}MeC_5H_4)_2(tmeda)]$ (1): A diethyl ether solution (5 mL) of tmeda (116.2 mg, 1.0 mmol) was added to a diethyl ether solution (5 mL) of $[Mn(MeCp)_2]$ (213 mg, 1.0 mmol), and the mixture stirred at room temperature for 15 min. The solvent was then evaporated in vacuo and the solid residue was washed with pentane (3 × 5 mL). Colorless crystals of **1** were obtained by crystallizing from a mixture of THF (2 mL) and pentane (20 mL) at −40 °C. Yield 313 mg, 95%. $C_{18}H_{30}MnN_2$ (329.39): calcd. C 65.64, H 9.18, N 8.50; found C 65.36, H 9.41, N 8.45. ^1H NMR ([D$_8$]THF, 300 MHz, 30 °C): δ = −39.1 (br., 8 H, $CH_3C_5H_4$), −3.5 (br., 6 H, $CH_3C_5H_4$), 30.6 (br., 16 H, tmeda) ppm. $^{15}N\{^1H\}$ NMR ([D$_8$]THF, 50.70 MHz, 20 °C): δ = −75.7 (br., tmeda) ppm.

Synthesis of $[Mn(C{\equiv}CSiMe_3)(\eta^5\text{-}MeCp)(tmeda)]$ (2): A THF solution (5 mL) of $Me_3SiC{\equiv}CH$ (98.2 mg, 1.0 mmol) or $Me_3SiC{\equiv}CSnMe_3$ (261 mg, 1.0 mmol) was added to a THF solution (10 mL) of $[Mn(\eta^1\text{-}MeC_5H_4)_2(tmeda)]$, and the mixture stirred at room temperature for 3 d. The solvent was evaporated in vacuo and the solid residue was extracted with 10 mL of pentane. The pentane solution was concentrated to 5 mL, filtered through Celite and crystallized to give pure colorless crystals of **2** at −40 °C (330 mg, 95% yield). $C_{18}H_{30}MnN_2$ (347.48): calcd. C 65.64, H 9.18, N 8.50; found C 65.36, H 9.41, N 8.45. ^1H NMR ([D$_8$]THF, 300 MHz, 30 °C): δ = 7.3 (br., 9 H, $SiMe_3$) ppm. $^{15}N\{^1H\}$ NMR ([D$_8$]THF, 50.70 MHz, 7 °C): δ = −75.6 (br., tmeda) ppm. Raman: $\tilde{\nu}$ = 2021 [s, ν(C=C)] cm^{-1}.

Synthesis of $[Mn(C{\equiv}CPh)(\eta^5\text{-}MeCp)(tmeda)]$ (3): A THF solution (5 mL) of $PhC{\equiv}CH$ (102.1 mg, 1.0 mmol) or $PhC{\equiv}CSnMe_3$ (265 mg, 1.0 mmol) was added to a THF solution (10 mL) of $[Mn(\eta^1\text{-}MeC_5H_4)_2(tmeda)]$, and the mixture stirred at room temperature for 3 d. The solvent was evaporated in vacuo and the solid residue was extracted with 5 mL of benzene. The benzene solution was filtered through Celite and crystallized from a mixture of benzene (5 mL) and pentane (20 mL) to give pure yellow crystals of the title compound at −40 °C (341 mg, 97% yield). $C_{20}H_{28}MnN_2$ (351.40): calcd. C 68.36, H 8.03, N 7.97; found C 68.63, H 7.88, N 7.74. ^1H NMR ([D$_8$]THF, 300 MHz, 20 °C): δ = −27.7 (br., 4 H, $CH_3C_5H_4$), 24.9 (br., 5 H, C_6H_5), 62.1 (br., 16 H, tmeda), 106.5 (br., 3 H, $CH_3C_5H_4$) ppm. $^{15}N\{^1H\}$ NMR ([D$_8$]THF, 50.70 MHz, 10 °C): δ = −85.9 (br., tmeda) ppm. Raman: $\tilde{\nu}$ = 2074 [s, ν(C=C)] cm^{-1}.

Synthesis of $[Mn(C{\equiv}C\text{t}Bu)(\eta^5\text{-}MeCp)(tmeda)]$ (4): A THF solution (5 mL) of $tBuC{\equiv}CH$ (82.1 mg, 1.0 mmol) or $tBuC{\equiv}CSnMe_3$ (245 mg, 1.0 mmol) was added to a THF solution (10 mL) of $[Mn(\eta^1\text{-}MeC_5H_4)_2(tmeda)]$, and the mixture stirred at room temperature for 3 d. The solvent was evaporated in vacuo and the solid residue was extracted with 10 mL of pentane. The pentane solution was concentrated to 5 mL, filtered through Celite and crystallized to give pure light-blue crystals of **4** at −40 °C (265 mg, 80% yield). $C_{18}H_{32}MnN_2$ (331.41): calcd. C 65.24, H 9.73, N 8.45; found C 65.60, H 9.70, N 8.56. ^1H NMR ([D$_8$]toluene, 300 MHz, 20 °C): δ = −19.8 (br., 4 H, $CH_3C_5H_4$), 14.5 (br., 9 H, *t*Bu), 62.6, 102.1 (br., 16 H, tmeda), 151.0 (br., 3 H, $CH_3C_5H_4$) ppm. $^{15}N\{^1H\}$ NMR ([D$_8$]THF, 50.70 MHz, 10 °C): δ = −90.7 (br., tmeda) ppm. Raman: $\tilde{\nu}$ = 2075 [s, ν(C=C)] cm^{-1}.

Synthesis of $[Mn(C{\equiv}C{-}C{\equiv}CSiMe_3)(\eta^5\text{-}MeCp)(tmeda)]$ (5): A THF solution (5 mL) of $Me_3SiC{\equiv}C{-}C{\equiv}CH$ (122.2 mg, 1.0 mmol) or $Me_3SiC{\equiv}C{-}C{\equiv}CSnMe_3$ (285 mg, 1.0 mmol) was added to a THF solution (10 mL) of $[Mn(\eta^1\text{-}MeC_5H_4)_2(tmeda)]$ (329.4 mg, 1.0 mmol), and the mixture stirred at room temperature for 3 d. The solvent was evaporated in vacuo and the solid residue was washed with pentane (3 × 5 mL). Benzene (5 mL) was added to the pentane solution (5 mL) and the resulting mixture was filtered through Celite and crystallized to give pure light-yellow crystals of complex **5** at −40 °C (357 mg, 96% yield). $C_{19}H_{32}MnN_2Si$ (371.50): calcd. C 65.24, H 9.73, N 8.45; found C 65.60, H 9.70, N 8.56. ^1H NMR ([D$_8$]toluene, 300 MHz, 20 °C): δ = 4.8 (br., 9 H, $SiMe_3$) ppm. $^{15}N\{^1H\}$ NMR ([D$_8$]THF, 50.70 MHz, 10 °C): δ = −90.7 (br., tmeda) ppm. Raman: $\tilde{\nu}$ = 2075 [s, ν(C=C)] cm^{-1}.

Synthesis of $[Mn(C{\equiv}C{-}C{\equiv}C{-}Ph)(\eta^5\text{-}MeCp)(tmeda)]$ (6): A THF solution (5 mL) of $PhC{\equiv}C{-}C{\equiv}CSnMe_3$ (290 mg, 1.0 mmol) was added to a THF solution (10 mL) of $[Mn(\eta^1\text{-}MeC_5H_4)_2(tmeda)]$ (329.4 mg, 1.0 mmol), and the mixture stirred at room temperature for 3 d. The solvent was evaporated in vacuo and the solid residue was washed with pentane (3 × 5 mL). THF (5 mL) was added and the mixture filtered through Celite. Diethyl ether (30 mL) was added and light yellow brown crystals of complex **6** were obtained at −40 °C (353 mg, 92% yield). $C_{22}H_{28}MnN_2$ (375.42): calcd. C 70.39, H 7.52, N 7.46; found C 70.52, H 7.46, N 7.13. ^1H NMR ([D$_8$]toluene, 300 MHz, 20 °C): δ = −10.2, −9.0 (br., 4 H, $CH_3C_5H_4$), 15.5 (br., 5 H, C_6H_5) ppm. $^{15}N\{^1H\}$ NMR ([D$_8$]THF, 50.70 MHz, 10 °C): δ = −81.7 (br., tmeda) ppm. Raman: $\tilde{\nu}$ = 2174 (s), 2022 [s, ν(C=C)] cm^{-1}.

Synthesis of $[Mn(C{\equiv}C{-}C{\equiv}CSiMe_3)_2(tmeda)]_2$ (7): A THF solution (5 mL) containing an excess of $Me_3SiC{\equiv}C{-}C{\equiv}CH$ (1.22 g, 10 mmol) was added to a THF solution (10 mL) of $[Mn(\eta^1\text{-}MeC_5H_4)_2(tmeda)]$ (329.4 mg, 1.0 mmol), and the mixture stirred at room temperature for 5 d. The solvent was evaporated in vacuo and the solid residue was washed with pentane (3 × 5 mL). The olive-green solid was dissolved in toluene (5 mL) and pentane (30 mL) was added to obtain olive-green crystals of complex **7** at −40 °C (871 mg, 95% yield). $C_{40}H_{68}Mn_2N_2Si_2$ (827.23): calcd. C

58.08, H 8.29, N 6.77; found C 58.26, H 8.35, N 6.89. ^{1}H NMR ([D$_8$]toluene, 300 MHz, 25 °C): δ = 3.0 (s, 18 H, SiMe$_3$) ppm. ^{15}N{^{1}H} NMR ([D$_8$]toluene, 50.70 MHz, 10 °C): δ = −93.4 (br., tmeda) ppm. Raman: $\tilde{\nu}$ = 2154 (s), 2115 (s), 2001 [s, ν(C≡C)] cm^{-1}.

Synthesis of [Mn$_2$(MeCp)$_2$(μ$_1$-tmeda)(μ$_1$-*t*BuC≡C)$_2$] (8): A THF solution (5 mL) containing an excess of *t*BuC≡CH (821.5 mg, 10 mmol) was added to a THF solution (10 mL) of [Mn(η^1-MeC$_5$H$_4$)$_2$(tmeda)] (659 mg, 2.0 mmol), and the mixture stirred at room temperature for 5 d. The solvent was evaporated in vacuo and the solid residue was washed with pentane (3 × 5 mL). The olive-green solid was dissolved in benzene (5 mL) and pentane (30 mL) was added to obtain olive-green crystals of complex **8** at −40 °C (383 mg, 70% yield). C$_{30}$H$_{48}$Mn$_2$N$_2$ (546.60): calcd. C 65.92, H 8.85, N 5.13; found C 66.21, H 8.64, N 5.03. ^{1}H NMR ([D$_8$]toluene, 300 MHz, 30 °C): δ = −11.4 (br., 8 H, CH$_3$C$_5$*H*$_4$), 14.2 (s, 18 H, *t*Bu), 34.6, 65.5 (br., 16 H, tmeda) ppm. ^{15}N{^{1}H} NMR ([D$_8$]toluene, 50.70 MHz, 20 °C): δ = −73.8 (br., tmeda) ppm. Raman: $\tilde{\nu}$ = 2052 [s, ν(C≡C)] cm^{-1}.

Synthesis of [{(η^3-MeCp)(tmeda)Mn}$_2$(μ-1,3-C$_6$H$_4$(C≡C)$_2$] (9): A benzene solution (10 mL) of 1,3-C$_6$H$_4$(C≡CSnMe$_3$)$_2$ (452 mg, 1.0 mmol) was added to a benzene solution (20 mL) of [Mn(η^1-MeC$_5$H$_4$)$_2$(tmeda)] (659 mg, 2.0 mmol), and the mixture stirred at room temperature for 24 h. The solvent was evaporated in vacuo and the solid residue was washed with pentane (3 × 5 mL). The olive-green solid was dissolved in toluene (5 mL) and pentane (30 mL) was added to obtain light-orange crystals of complex **9** at −30 °C (469 mg, 75% yield). C$_{34}$H$_{50}$Mn$_2$N$_4$ (624.68): calcd. C 65.37, H 8.07, N 8.97; found C 65.08, H 8.44, N 8.68. ^{1}H NMR ([D$_8$]THF, 300 MHz, 30 °C): δ = −62.9 (br., 4 H, CH$_3$C$_5$*H*$_4$), −44.9 (br., 4 H, CH$_3$C$_5$*H*$_4$), 34.5 (br., 2 H, C$_6$H$_4$), 41.3 (br., 2 H, C$_6$H$_4$), 77.0 (br., 16 H, tmeda), 161.5 (br., 3 H, C*H*$_3$C$_5$H$_4$) ppm. ^{15}N{^{1}H} NMR ([D$_8$]THF, 50.70 MHz, 20 °C): δ = −100.4 (br., tmeda) ppm. Raman: $\tilde{\nu}$ = 2067 [s, ν(C≡C)] cm^{-1}.

Synthesis of [{(η^1-MeCp)(tmeda)Mn}$_2$(μ-1,4-C$_6$H$_4$(C≡C)$_2$] (10): A benzene solution (10 mL) of 1,4-C$_6$H$_4$(C≡CSnMe$_3$)$_2$ (452 mg, 1.0 mmol) was added to a benzene solution (20 mL) of [Mn(η^1-MeC$_5$H$_4$)$_2$(tmeda)] (659 mg, 2.0 mmol), and the mixture stirred at room temperature for 24 h. The solvent was evaporated in vacuo and the solid residue was washed with pentane (3 × 5 mL). The olive-green solid was redissolved in toluene (5 mL) and pentane (30 mL) was added to obtain light-orange crystals of the title compound at −30 °C (500 mg, 80% yield). C$_{34}$H$_{50}$Mn$_2$N$_4$ (624.68): calcd. C 65.37, H 8.07, N 8.97; found C 65.51, H 8.11, N 8.61. ^{1}H NMR ([D$_8$]THF, 300 MHz, 30 °C): δ = −8.8 (br., 8 H, CH$_3$C$_5$*H*$_4$), 27.2 (br., 4 H, C$_6$H$_4$) ppm. ^{15}N{^{1}H} NMR ([D$_8$]THF, 50.70, 20 °C): δ = −71.3 (br., tmeda) ppm. Raman: $\tilde{\nu}$ = 2071 [s, ν(C≡C)] cm^{-1}.

Synthesis of [{(η^5-MeCp)(tmeda)Mn}$_2${μ-4,4′-(C$_6$H$_4$)$_2$(C≡C)$_2$}] (11): A benzene solution (10 mL) of 4,4-(C$_6$H$_4$)$_2$(C≡CSnMe$_3$)$_2$ (528 mg, 1.0 mmol) was added to a benzene solution (20 mL) of [Mn(η^1-MeC$_5$H$_4$)$_2$(tmeda)] (659 mg, 2.0 mmol), and the mixture stirred at room temperature for 24 h. The solvent was evaporated in vacuo and the solid residue was washed with pentane (3 × 5 mL). The olive-green solid was redissolved in toluene (5 mL) and pentane (30 mL) was added to obtain light-orange crystals of complex **11** at −30 °C (500 mg, 80% yield). 20 °C): δ = −71.3 (br., tmeda) ppm. Raman: $\tilde{\nu}$ = 2071 [s, ν(C≡C)] cm^{-1}.

X-ray Diffraction Studies on 3 and 5−11: Crystals of **3** and **5**−**11**, protected in hydrocarbon oil, were selected for the X-ray experiments using a polarizing microscope. They were mounted on the tip of a glass fibre and immediately transferred to the goniometer of an imaging plate detector system (Stoe IPDS diffractometer), where they were cooled to 183(2) K [**10** and **11** 173(2) K] using an Oxford Cryogenic System. The crystal−image distances were set to 50 mm (**3**, **5**, **6**, and **8**), 60 mm (**7** and **10**), and 70 mm (**9** and **11**) (θ_{max} = 30.46, 30.34, 30.33, 30.35, 28.02, 27.89, 25.97 and 25.91° for **3** and **5**−**11**, respectively). The φ-rotation (**3**, **6**) or φ-oscillation (**5**, **7**−**11**) scan modes were applied according to the diffraction power of the measured crystals. For the cell-parameter refinements 7998 (**5**), 8000 (**3**, **6**−**10**) or 4287 (**11**) reflections were selected out of the whole limiting spheres. A total of 20820 (**3**), 25415 (**5**), 21358 (**6**), 39994 (**7**), 36111 (**8**), 36990 (**9**), 14209 (**10**), and 11833 (**11**) diffraction intensities were collected,[135] of which 5973, 6693, 6116, 11802, 8653, 7999, 4045, and 3604, respectively, were unique (R_{int} = 0.0618, 0.0504, 0.0524, 0.0424, 0.0762, 0.1014, 0.0932, and 0.1190 for **3** and **5**−**11**, respectively) after data reduction. Numerical absorption corrections[136] based on 16, 20, 12, 19, 15, 22, 6, and 6 crystal faces, respectively, were applied with FACEitVIDEO and XRED.[135] The structures were solved by direct methods (**5**) and by the Patterson method (for the other seven compounds) using the program SHELXS-97.[137] Interpretation of the difference Fourier maps, preliminary plot generations and checking for higher symmetry were performed with PLATON[138] and the implemented program LEPAGE.[139] All heavy atoms were refined (SHELXL-97)[140] using anisotropic displacement parameters, except for disordered atoms in the structures of **5**, **8**, and **9**, which were refined isotropically. The positions of the H atoms were calculated after each refinement cycle (riding model). Structural plots (Figures 1−7) were generated using ORTEP. Further crystallographic data and refinement results are presented in Tables 2 and 3, and Table S1 in the Supporting Information (see also the footnote on the first page of this article). It is noteworthy to mention the difficulties in performing a rapid preparation of the crystals in the protecting oil. Some crystals deteriorated relatively fast at room temperature, and in these cases a Peltier element was used at 253 K to save the crystals during the preparation under polarized light. For the intensity measurements of crystals of **5** and **6** a collimator with 0.80 mm diameter had to be used (see Table 2). For compound **7** two measurements were necessary (the last measurement with 37 h measuring time) to determine that the metrically tetragonal unit cell belongs to the Laue class $P2/m$ (space group $P2_1/c$). Furthermore, a twin refinement with ratio 1:3 was successfully performed using the twin matrix (001, 0−10, −100) for this structure. A detailed description of structure solution and refinement is given in the CIF file of **7**. Compound **9** most probably belongs to a modulated structure type: four very weak intensity peaks were observed between the strong reflection intensities in one reciprocal direction (modulo5). The weak reflections were not used for the unit-cell determination. Application of programmes DISPLA, XYZ, RECIPE, INDEX and CELL[135] resulted in space group $P21/c$. The structure was solved without difficulties; however, anisotropic refinement showed many non-hydrogen atoms to have non-positive definite displacement parameters or indicated many split atomic positions. Thus, most of the atoms were refined with

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

isotropic displacement parameters. It should be noted that only about 25% of the intensity data were observed [$I > 2\sigma(I)$]. Additionally, for a disordered toluene solvent molecule with very large isotropic displacement parameters the site occupation factors were fixed at estimated values of 1/4. For this reason compound **9** has a Z value of 1 and the enlarged chemical formula as given in Table 3. Finally, 45 distance restraints had to be used to stabilize the refinement. The structures of **10** and **11** possess centres of inversion that coincide with crystallographic inversion centres, thus only one half of each complex needed to be refined, resulting in Z values of 2 ($Z' = 1/2$). The crystals of compound **11** were very sensitive to mechanical touch. Due to the thin plate-like crystal (0.25 × 0.13 × 0.06 mm) and the necessity to seal the susceptible crystal of fair quality into a thin-walled glass capillary including protecting oil, the background intensities increased drastically. The centering procedure introduced systematic errors that were probably added to the measured intensity data. Only about 40% of these data were considered observed, which explains the relatively high R_{int} (11.9%) and $R\sigma(I)$ (21.65%) values. The reliability factors of the final refinement [$R1 = 5.59\%$ and $wR2 = 8.37\%$ (all data)] are acceptable, and the standard uncertainties for C−C bond lengths range between 0.005 Å and 0.009 Å, which can be considered as an acceptable result. CCDC-226222 to -226229 (**3**, **5**−**11**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

New Multifunctional Complexes $[Ru(\kappa^3\text{-}L)(EPh_3)_2Cl]^+$ [E = P, As; L = 2,4,6-Tris(2-pyridyl)-1,3,5-triazine] Containing both Group V and Polypyridyl Ligands

Sanjeev Sharma,[a] Manish Chandra,[a] and Daya Shankar Pandey*[a]

Keywords: Ruthenium / Tertiary phosphanes / 2,4,6-Tris(2-pyridyl)-1,3,5-triazine / DNA / Topoisomerase II

Synthesis, structure, reactivity and enzyme inhibitory activity of the new cationic ruthenium complexes $[Ru(\kappa^3\text{-}L)(EPh_3)_2Cl]BF_4$ [L = 2,4,6-tris(2-pyridyl)-1,3,5-triazine (tptz); E = P (**1**), As (**2**)] and their substitution products $[Ru(\kappa^3\text{-}tptz)(PPh_3)(dtc)]Cl$ (**3**), $[Ru(\kappa^3\text{-}tptz)(PPh_3)(CN)_2]$ (**4**), $[Ru(\kappa^3\text{-}tptz)(AsPh_3)(dtc)]BF_4$ (**5**), and $[Ru(\kappa^3\text{-}tptz)(AsPh_3)(CN)_2]$ (**6**) are reported. The complexes were characterized by analytical and spectroscopic methods and the structures of the complexes **1**, **2** and **3** determined by X-ray diffraction studies. C–H···X (X = Cl, F and S), C–H···π and π–π interactions were observed in these complexes. Further studies indicated that the complexes $[Ru(\kappa^3\text{-}L)(EPh_3)_2Cl]^+$ could find application as precursors in the synthesis of other ruthenium complexes or as metallo-ligands. The complexes also interact with DNA, which was illustrated by absorption titration studies with CT-DNA and inhibition of topoisomerase II of the filarial parasite *Setaria cervi*.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Recently, (polypyridyl)Ru^{II} complexes have received considerable attention owing to their possible application in conversion of solar energy to electrical energy,[1] in long-range electron and energy transfer,[2] molecular electronic devices,[3] self-assembly processes[4] and as photoprobes for DNA.[5] Polypyridyl bridging ligands containing a delocalized π-electron system have drawn special attention in this regard. Using such ligands, many luminescent and redox-active compounds have been synthesized and studied extensively.[6] During the past few years, we have been interested in the synthesis and characterization of metallo-ligands/synthons based on organometallic systems containing organonitriles and polypyridyl ligands.[7] During our studies on the reactivity of hydrated Ru^{III} chloride in the presence of excess EPh_3 or $[RuCl_2(PPh_3)_3]$ with 2,4,6-tris(2-pyridyl)-1,3,5-triazine (tptz), we have isolated a completely new series of cationic complexes $[Ru(\kappa^3\text{-}L)(EPh_3)_2Cl]^+$. These compounds are examples of ruthenium complexes containing both Group V and polypyridyl ligands, which are associated with classical coordination chemistry.

The new cationic complexes $[Ru(\kappa^3\text{-}L)(EPh_3)_2]Cl]^+$ all possess κ^3-bonded tptz, two tertiary phosphane or arsane ligands, a labile chloro group, and have the potential to exhibit rich chemistry. The ligand tptz primarily acts as a tridentate ligand similar to terpyridine (tpy), but is more versatile than tpy. The complexes under study offer a unique opportunity to behave as metallo-ligands because of the presence of vacant donor sites at the tptz ligand and, thus, could find applications in the synthesis of homo-, hetero di- or polynuclear systems. Furthermore, DNA binding studies have shown that ruthenium complexes containing polypyridyl ligands are of significant importance.[5] It was felt that the new complexes of the series $[Ru(\kappa^3\text{-}L)(EPh_3)_2Cl]^+$ could be used as DNA probes. Although, a number of reports dealing with DNA binding and inhibition activity of (polypyridyl)Ru^{II} complexes are available in the literature, activity of the complexes incorporating triphenylphosphane or triphenylarsane and a polypyridyl ligand have yet to be examined. We report herein, on the reactivity, absorption titration studies and inhibitory activity against DNA topo II of the filarial parasite *Setaria cervi* of the new, air-stable mononuclear complexes $[Ru(\kappa^3\text{-}tptz)(L_2)Cl]^+$.

Results and Discussion

The air-stable cationic complexes **1**, **2** and their representative substitution products $[Ru(\kappa^3\text{-}tptz)(PPh_3)(dtc)]Cl$ (**3**), $[Ru(\kappa^3\text{-}tptz)(PPh_3)(CN)_2]$ (**4**), $[Ru(\kappa^3\text{-}tptz)(AsPh_3)(dtc)]BF_4$ (**5**), and $[Ru(\kappa^3\text{-}tptz)(AsPh_3)(CN)_2]$ (**6**) were obtained in excellent yield as shown in Scheme 1. The compounds were characterized spectroscopically and gave satisfactory elemental analyses. The microanalyses, FAB-MS and NMR (^1H and ^{31}P) data of the complexes correspond to their respective formulas.

^1H NMR spectroscopic data of the complexes are given in the Exp. Sect. The positions and integrated intensities of

[a] Department of Chemistry, Awadhesh Pratap Singh University, Rewa 486003 (M.P.), India
E-mail: dsprewa@yahoo.com

the signals corresponding to tptz corroborated well with a system containing two magnetically equivalent coordinated pyridyl rings and one uncoordinated pyridyl ring. This observation indicated coordination of the tptz to Ru in a κ^3-manner. The aromatic protons of the PPh_3 and $AsPh_3$ ligands gave a broad multiplet in the usual region with δ = 7.26−7.07 ppm. Integrated intensities and positions of the signals were consistent with the respective formulas of the complexes. The main feature of the ^1H NMR spectra of the diethyl dithiocarbamate containing complexes **3** and **4** is the presence of multiplet signals at high field with chemical shifts characteristic of methyl and methylene protons. In the complexes **3** and **4**, these appeared at δ = 4.10 (q, J = 7.2 Hz, 2 H), 3.62 (q, J = 6.9 Hz, 2 H), 1.52 (t, J = 7.2 Hz, 3 H), 1.13 (t, J = 6 Hz, 3 H) and 4.03 (q, J = 7.2 Hz, 2 H), 3.55 (q, J = 7.2 Hz, 2 H), 1.50 (t, J = 7.2 Hz, 3 H), 1.10 (t, J = 6.1 Hz, 3 H) ppm, respectively. The presence of signals in this region strongly suggests coordination of the diethyl dithiocarbamate to the metal center. In the $^{31}P\{^1H\}$ NMR spectra of the complexes **1**, **3** and **5**, single sharp resonances were observable at δ = 16.24, 37.81 and 32.89 ppm, respectively. The presence of a single sharp peak in the $^{31}P\{^1H\}$ NMR spectrum of complex **1** suggests that both the ^{31}P nuclei are chemically equivalent and that the triphenylphosphane ligands are *trans*-disposed in this complex.

Electrochemical properties of the new complexes were observed by cyclic voltammetry. The cyclic voltammogram of complex $[Ru(\kappa^3\text{-tptz})(AsPh_3)_2Cl]BF_4$ (**2**) is shown in Figure 1. The ruthenium complexes with the tptz ligand $[Ru(\kappa^3\text{-tptz})(PPh_3)_2Cl]BF_4$ and $[Ru(\kappa^3\text{-tptz})(AsPh_3)_2Cl]BF_4$ exhibited reversible ($Ru^{II/III}$) metal-based oxidation couples at 1.05 (70) V and 1.02 (50) V, respectively.[8] In the cathodic potential window, three ligand-based reversible and quasi-reversible reduction couples were observed in the range 0.89−1.50 V for the tptz ligand.

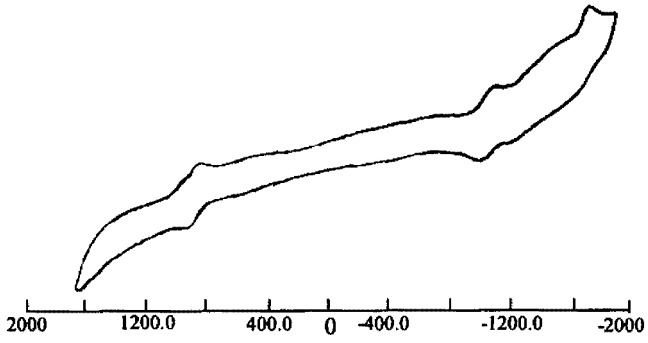

Figure 1. Cyclic voltammogram of the complex **2**

In the electronic absorption spectra of complexes **1** and **2**, the MLCT transitions appeared in the visible region at λ (ε) = 472 (24022) and 489 (6930) nm, respectively, while the ligand-centered transitions were observed at λ (ε) = 309 (63759), 273 (149195) (for **1**) and 342 (7250), 271.5 (21355) (for **2**) nm. Complexes **3**−**6** exhibited red-shifted absorptions when compared with complexes **1** and **2**. The complexes do not luminesce in air at room temperature.

Molecular structures of complexes **1**−**3** were established crystallographically.[9] Both complexes **1** and **2** crystallize in the $P2_1/c$ space group, while complex **3** crystallizes in a very rare $F2dd$ space group (Table 3). In all the complexes, Ru is

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bonded covalently within the major coordination sites of tptz in a κ^3-manner by two phosphorus or arsenic atoms from the triphenylphosphane or arsane ligand and a chloro group in complex **1** and **2** and one phosphorus atom from the triphenylphosphane ligand and a dithiolato group in complex **3**. There is a distorted octahedral coordination geometry about the ruthenium center. The N(1)−Ru(1)−N(2) and N(2)−Ru(1)−N(3) angles in complex **1** are essentially equal with 78.77(12) and 78.47(11)°, while in complexes **2** and **3** these angles are 78.91(13) and 78.44(12)° and 76.9(5) and 77.1(5)°, respectively. This suggests some inward bending of the coordinated pyridyl group and may be the reason for the observed distortion. The bond length of Ru(1) to the central triazine nitrogen atom Ru(1)−N(2) in complex **1** is 1.936(3) Å, which is shorter than the bond of Ru(1) to the coordinated pyridyl nitrogen atom Ru(1)−N(1) [2.110(3) Å] and Ru(1)−N(3) [2.103(3) Å]. Similarly, in complexes **2** and **3** Ru(1)−N(2) is 1.931(3) and 1.968(13) Å, and the Ru(1)−N(1) and Ru(1)−N(3) distances are 2.098(3), 2.099(3) Å and 2.099(17), 2.076(13) Å, respectively. The Ru−N bond lengths are consistent with a κ^3-coordination of tptz and similar to those reported for other $(tptz)Ru^{II}$ complexes.[10] The triphenylphosphane ligands in complex **1** and the triphenylarsane ligands in complex **2** are *trans*-disposed as indicated by the P(1)−Ru(1)−P(2) angle of 178.52(3)° and As(1)−Ru(1)−As(2) angle of 178.26(2)°. The Ru(1)−P(1) and Ru(1)−P(2) distances are 2.4130(11) and 2.4264(11) Å in complex **1**, while in complex **2** the Ru(1)−As(1) and Ru(1)−As(2) distances are 2.481(6) and 2.491(6) Å, respectively. In complex **3**, the Ru1−S1 and Ru1−S2 distances are 2.427(4) and 2.407(4) Å, respectively. These are essentially equivalent or similar to those in related complexes.[11] The Ru−Cl distances in both complexes **1** and **2** are normal and are similar to Ru−Cl distances in other complexes (Table 1).[12]

The triazine ring from tptz and the coordinated pyridyl rings are almost coplanar. In complexes **1** and **2**, the uncoordinated pyridyl ring is inclined from the coordinated part of the ligand tptz by 25.9 and 23.3°, respectively. In complex **3**, which is obtained by replacement of one PPh_3 ligand and the chloro group of complex **1** by a dithiocarbamate ligand, the tptz ligand has regained its planarity. This is suggested by the angle of inclination (2.4°).

Selection of ligands plays an important role amongst the factors that induce the self-assembly processes. The ligands EPh_3 and triazine are expected to show different propensities for molecular arrangement based on the stacking arrangement of phenyl or triazine rings. The X-ray structure for complexes **1**−**3** revealed intermolecular C−H···X (X =

F, N, S and Cl) and π−π interactions. (Table 2) Complex **1** shows C−H···Cl intramolecular interactions, which involve Cl and an adjacent hydrogen atom attached to the phenyl (PPh_3) rings. However, this type of interaction is not apparent in complex **2** which has an analogous structure. The absence of a C−H···Cl type interaction is probably due to the longer Ru−As bond in complex **2** when compared with the Ru−P distance in complex **1**. The importance of π−π stacking interactions between aromatic rings, which lie in the range 3.4−3.5 Å, has widely been recognized in the intercalation of drugs with DNA[13] in biological systems. In all the complexes **1**−**3**, intramolecular π−π interactions have been found with the interaction distances in the range 3.29−3.52 Å (see a, b and c in Figure 2). In complexes **1** and **2**, the intermolecular π−π stacking interaction [distance 3.42 Å (**1**) and 3.67 Å (**2**)] results in a single helical motif (see a in Figure 3), while C−H···π, C−H···S−C and π−π stacking (3.39 Å) interactions in complex **3** lead to a double helical network (b in Figure 3).[13]

Interaction of the complexes with DNA is supported by the results from absorption titration studies with calf thymus DNA and inhibition studies (gel electrophoresis) of topoisomerase II of the filarial parasite *S. cervi*. Chloride salts of the complexes were used for DNA binding and inhibition studies. It is well documented that nonplanar octahedral complexes can partially intercalate with the DNA helix or they can show groove binding interactions with the major or minor groove of the helix.[14] Fixed amounts of metal complexes [13.3 μM (**1**) and 40 μM (**2**)] were titrated with an increasing amount of CT-DNA over a range of DNA concentrations from 0 to 112 μM.[15] Absorption spectra were measured after equilibration and the binding constants of the complexes with CT-DNA were determined by monitoring the decay in absorbance with increasing DNA concentration. The model of Bard and Thorp for noncooperative and nonspecific binding was used.[16] Figure 4 depicts the UV/Vis spectra of complex **1** for a solution buffered at pH = 7.1 in the presence of increasing quantities of CT-DNA. Absorption spectra exhibited an average decrease in absorption (hypochromism) of 29% and 42% and bathochromic shifts of 7.5 and 6.5 nm for complexes **1** and **2**, respectively. These observations are consistent with the values reported for other polypyridyl transition metal complexes.[17,18] Binding constants for complexes **1** and **2** are 2.5×10^4 M^{-1} ($s = 0.25$) and 2.1×10^4 M^{-1} ($s = 0.21$), respectively. The value for $s < 1$ is similar to other re-

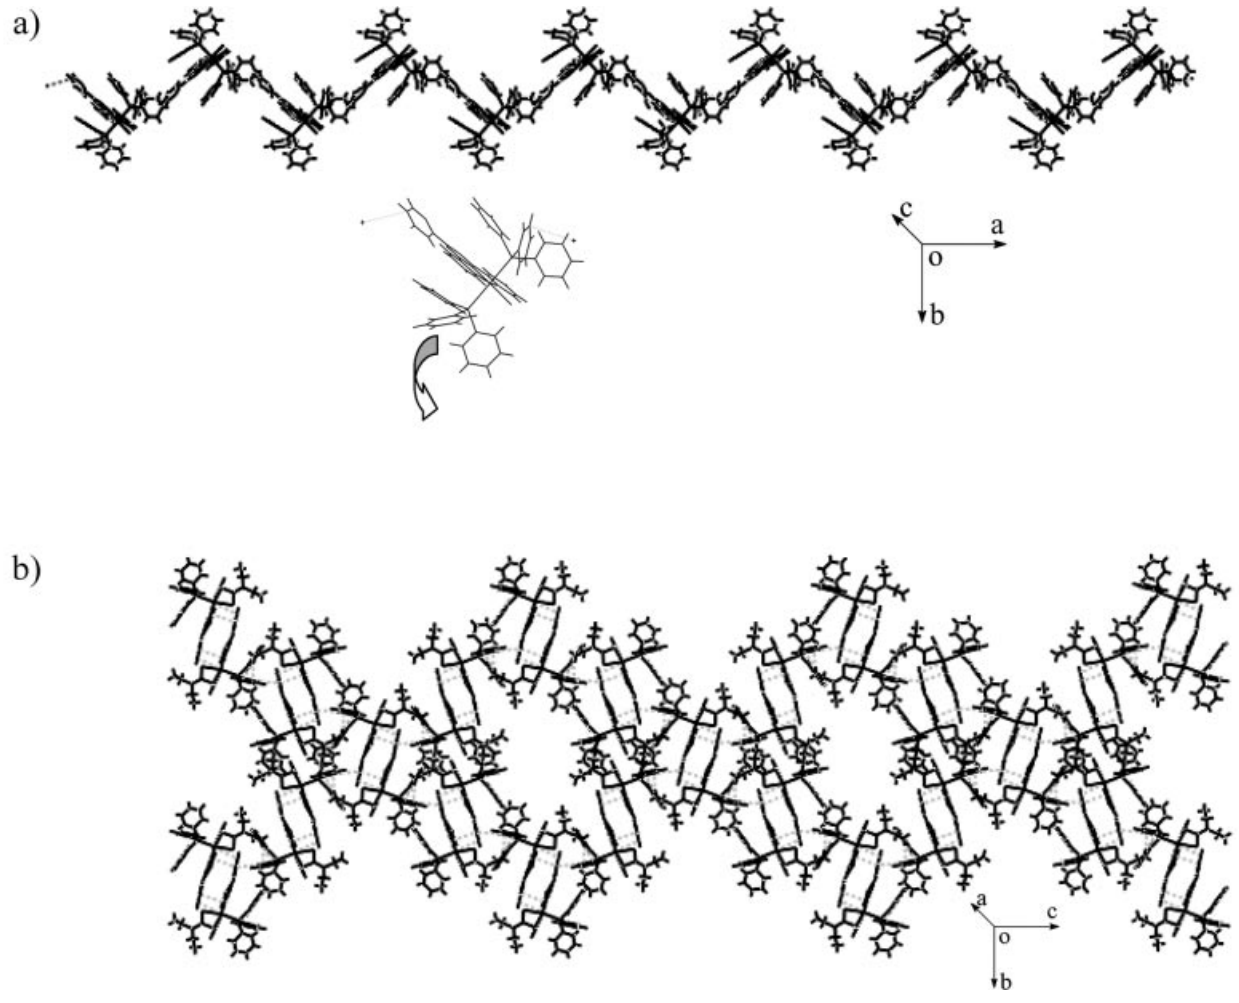

Figure 3. (a) An intermolecular π−π stacking interaction results in a single helical network for complex **1**; (b) intermolecular C−H···π, C−H···S−C and π−π stacking interactions result in a double helical network for complex **3**

ports.[17] The binding strength of the compounds **1** and **2** to nucleotides is relatively poor. This may be due to the presence of the bulky EPh_3 groups *trans* to each other, which causes steric hindrance. Also, the phenyl rings of EPh_3 restrict further the intercalating properties of the complexes. The six-coordinate ruthenium center does not intercalate with the nucleotide and the absorption titration data supports that tptz is stacking with other tptz ligands of nearby complexes bound on the surface of the DNA.[17] Further addition of a 12-fold excess of CT-DNA after saturation of a 13.3 μM solution of complex **1** or addition of a 16-fold excess of CT-DNA to a 40 μM solution of complex **2** caused no changes in the absorption spectra of the final equilibrium mixtures over a period of 48 h. This indicates a strong interactive binding mode of (κ^3- tptz)Ru^{II} complexes.

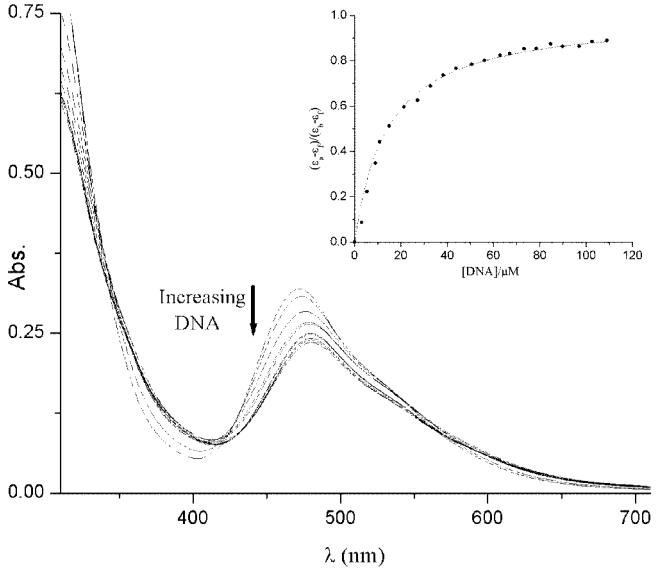

Figure 4. Absorption spectra of $[Ru(\kappa^3\text{-tptz})Cl(PPh_3)_2]^+$ (13.3 μM), in buffer A in the presence of an increasing amount of CT DNA (0−112 μM); inset represents a plot of $(\varepsilon_a - \varepsilon_f)/(\varepsilon_b - \varepsilon_f)$ vs. [DNA] in μM for $[Ru(\kappa^3\text{-tptz})Cl(PPh_3)_2]^+$; the best-fit line is superimposed on the data according to the model of Bard and Thorp[17] for the absorption titration [$K_b = 2.5 \times 10^4$ M^{-1} ($s = 0.25$)]

Efficacy of complexes **1** and **2** against DNA topoisomerase II (topo-II) of the filarial parasite *S. cervi* was examined. The interaction behavior is supported by the inhibitory effect of the metal complexes on DNA topoisomerase II of the filarial parasite. Potential antifilarial agents act either on membrane receptors or on metabolic enzymes. DNA topoisomerases are cellular enzymes that are intricately involved in the topographic structure of DNA transcription and mitosis.[18] In general, inhibition depends upon the availability of binding sites for the enzyme on DNA. Topoisomerase has been identified as an important biochemical target in chemotherapy and microbial infections. Complexes **1** and **2** are potential inhibitors of DNA topo-II of the filarial parasite *S. cervi* with 86% and 93% inhibition at a 10 μM concentration (Figure 5).

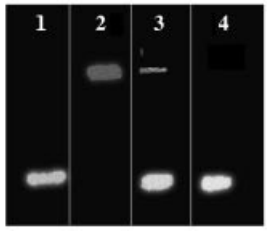

Figure 5. Inhibition of *S. cervi* topoisomerase II by complexes **1** and **2**; lane 1: pBR322 alone; lane 2: DNA + *S. cervi* topo II; lanes 3 and 4 correspond to complex $[Ru(\kappa^3\text{-tptz})Cl(PPh_3)_2]^+$ and $[Ru(\kappa^3\text{-tptz})Cl(AsPh_3)_2]^+$ (10 μM) and the inhibition percentage is 86% and 93%, respectively

Conclusions

In this work, we have presented the synthesis of the (polypyridyl)Ru^{II} complexes $[Ru(\kappa^3\text{-tptz})(PPh_3)_2Cl]^+$, which have many potential uses. We have shown that they can be employed as precursors of other Ru^{II} complexes, as metalloligands or as biocatalysts. Detailed studies of the structure, reactivity and assembling capability of the substituted complexes is in progress in our laboratory.

Experimental Section

General: All reactions were carried out under nitrogen and in deaerated solvents. The solvents were of AR grade and were purified rigorously by standard procedures[19] prior to use. Triply distilled and deionized water was used for the preparation of the various buffers. 2,4,6-Tris(2-pyridyl)-1,3,5-triazine (tptz), ammonium tetrafluoroborate, ruthenium(III) chloride hydrate (all Aldrich) and tetrabutylammonium perchlorate (Fluka) were used as received. Calf thymus (CT) DNA, supercoiled pBR322 DNA, bovine serum albumin (BSA), ATP, dithiothreitol (DTT), agarose, ethidium bromide, sodium dodecyl sulfate (SDS) and proteinase were procured from Sigma Chem. Topoisomersase II from filarial parasite *Setaria cervi* was partially purified according to the method by Pandeya et al.[20] The complex $RuCl_2(PPh_3)_3$ was prepared by a literature method.[21]

Physical Measurements

Spectroscopy and Electrochemistry: Microanalyses were performed by the microanalytical section of the Sophisticated Analytical Instrumentation Centre, Central Drug Research Institute, Lucknow. IR and electronic spectra were recorded with Shimadzu 8201PC and Shimadzu UV-1601 spectrophotometers, respectively. Electronic absorption spectra were measured in a quartz cuvette with a path length of 1 cm. ^1H, ^1H-^1H COSY, ^{13}C and ^{31}P NMR spectra were recorded with a Bruker DRX-300 NMR instrument. FAB mass spectra were recorded with a JEOL SX 102/DA 6000 mass spectrometer using Xenon (6 kV, 10 mA) as the FAB gas. The accelerating voltage was 10 kV and the spectra were recorded at room temperature with *m*-nitrobenzyl alcohol as the matrix. Thermal denaturation analyses were conducted with a DU-640 spectrophotometer. Electrochemical data were acquired with a PAR model 273A electrochemistry system at a scan rate of 50 mVs^{-1}. The sample solutions (10^{-3} M) were prepared in purified acetonitrile containing $Et_4N^+ClO_4^-$ (0.1 M) as the supporting electrolyte. Solutions were

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

deoxygenated by bubbling dinitrogen for about 20 min before each experiment. The platinum wire working and auxiliary electrodes, and an aqueous saturated calomel reference electrode were used in a three-electrode configuration.

X-ray Crystallography: Suitable crystals for X-ray crystallographic studies for the complexes **1**−**3** were obtained from CH_2Cl_2/petroleum ether (60−80°C) at room temperature over a period of 3 d. All the pertinent crystallographic data are recorded in Table 3. Intensity data were collected at 293(2) K with an Enraf−Nonius CAD 4 diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.70930) from plate-like crystals with dimensions 0.22 × 0.22 × 0.17 (**1**), 0.4 × 0.35 × 0.35 (**2**) and 0.25 × 0.35 × 0.41 mm (**3**) in the ω-2θ scan mode in the range from 1.51 to 24.92°. Intensities of these reflections were measured periodically to monitor crystal decay. The structures were solved by direct methods and refined by full-matrix least squares on F^2 (SHELX-97).[10] In the final cycles of refinement all the non-H atoms were treated anisotropically. The contribution due to H atoms attached to carbon atoms was included as a fixed contribution. Final residual values and goodness-of-fit were $R1$ = 0.0405, $wR2$ = 0.1132, GOF = 1.104 (**1**), $R1$ = 0.0343, $wR2$ = 0.0803, GOF = 1.063 (**2**) and $R1$ = 0.0673, $wR2$ = 0.1968, GOF = 1.066 (**3**). CCDC-229719 (**1**), -229720 (**2**) and -233890 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

DNA Binding and Cleavage Studies

DNA Topoisomerase II Estimation: For activity measurements, the reaction was carried out (10 μL) in a mixture containing buffer B, 10 mM $MgCl_2$, 1 mM ATP, 0.1 mM EDTA, 0.5 mM DTT, 30 μg/mL BSA and enzyme protein. The reaction was started by incubation at 37 °C for 30 min and stopped by addition of 5 μL of loading dye. The samples were electrophoresed on 1% agarose gel in tris-acetate buffer at 20 V for 18 h. Gels were stained with ethidium bromide (0.5 μg/mL) visualized and photographed on a UVP GDS 7500 UV trans-illuminator. The percentage relaxation was measured by micro densitometry of gel using the Gel base/Gel blot Pro Gel analysis software programme. ^{1}H-NMR and UV/Vis spectral analyses were used to check the stability of the complexes towards the solvent (water and DMSO) and no change was observed. Buffer A (5 mM Tris-HCl, pH = 7.1, 50 mM NaCl) was used for absorption titration and buffer B (50 mM tris-HCl, pH = 7.5, 50 mM KCl) was used for inhibition studies.

Preparation of $[Ru(\kappa^3\text{-tptz})(PPh_3)_2]Cl]BF_4\cdot H_2O$ (1): Complex **1** was prepared by either of the following two methods.

Method (a): Hydrated ruthenium trichloride $RuCl_3\cdot xH_2O$ (0.260 g, 1.0 mmol), dissolved in hot methanol (10 mL), was added to a refluxing solution of triphenylphosphane (PPh_3; 1.578 g, 6.0 mmol) in methanol (50 mL) and the solution was heated under reflux for 1 h. Ligand tptz (0.312 g, 1.0 mmol) was added to the resulting suspension and the contents of the flask were heated under reflux for 8−10 h. After the resulting purple solution was cooled to room temperature, any solid residue was filtered and the filtrate was concentrated under reduced pressure to one fourth of its volume. A saturated solution of ammonium tetrafluoroborate, dissolved in methanol, was added to the concentrated solution and the mixture left for slow crystallization in a refrigerator at 8 °C. The microcrystalline product, which slowly deposited, was separated by filtration and washed repeatedly with methanol and diethyl ether and then dried in vacuo. Yield 73% (0.786 g). $C_{54}H_{44}BClF_4N_6OP_2Ru$ (1078.3): calcd. C 60.11, H 4.08, N 7.79; found C 60.08, H 4.12, N 7.74. FAB-MS: *m/z* obsd. J = 7.5 Hz, 2 H), 8.00 (t, J = 7.8 Hz, 2 H), 7.58 (t, J = 5.1 Hz, 1 H), 7.38 (t, J = 6.3 Hz, 2 H) and 7.26−7.07 (br. m, aromatic protons of PPh_3) ppm. $^{31}P\{^1H\}$ NMR: δ = 16.24 (s) ppm. UV/Vis: λ_{max} (ε [dm^3 $mol^{-1}cm^{-1}$]) = 472 (24022), 309(63759), 273 (149195) nm.

Method (b): A suspension of $[RuCl_2(PPh_3)]$ (0.982 g, 1.0 mmol) in methanol (50 mL) was treated with tptz (0.312 g, 1.0 mmol) and the resulting solution was heated under reflux for 8.0 h resulting in a purple solution. After cooling to room temperature, the resulting solution was filtered through Celite to remove any solid impurities. A saturated solution of ammonium tetrafluoroborate, dissolved in methanol, was added to the filtrate and it was left in the refrigerator for slow crystallization. After several days, a purple-black crystalline product had separated. Analytical and spectroscopic data were identical to those of the previous method but the yield was higher.

Preparation of $[Ru(\kappa^3\text{-tptz})(AsPh_3)_2Cl]BF_4\cdot H_2O$ (2): This complex was prepared by a similar method (complex **1**) except that $AsPh_3$ (1.836 g, 6.0 mmol) was used in place of PPh_3. A violet-black complex was obtained. Yield 71% (0.827 g). $C_{54}H_{44}As_2BClF_4N_6ORu$ (1166.1): calcd. C 55.57, H 3.77, N 7.20; found C 55.62, H 3.68, N 7.12. FAB-MS: *m*/*z* obsd. (calcd.), rel. int., [assignm.]: 1061 (1061), 19, $[Ru(\kappa^3\text{-tptz})(AsPh_3)_2Cl]^+$; 755 (755), 54, $[Ru(\kappa^3\text{-tptz})(AsPh_3)Cl]^+$; 449 (449), 35, $Ru(\kappa^3\text{-tptz})Cl]^+$. ^1H NMR: δ = 9.26 (d, J = 5.1 Hz, 2 H), 8.93 (d, J = 3.6 Hz, 1 H), 8.69 (d,, J = 8.1 Hz 1 H), 8.65 (d, J = 7.8 Hz, 1 H), 8.11 (m, J = 7.5 Hz, 4 H), 7.59 (t, J = 5.1 Hz, 1 H), 7.51 (t, J = 6.3 Hz, 2 H) and 7.23−7.03 (br. m, aromatic protons of $AsPh_3$) ppm. UV/Vis: λ_{max} (ε [dm^3 $mol^{-1}cm^{-1}$]) = 489 (6930), 342 (7250), 271.5 (21355) nm.

Preparation of $[Ru(\kappa^3\text{-tptz})(PPh_3)(dtc)]Cl$ (3): Complex **3** was prepared by the reaction of $[Ru(\kappa^3\text{-tptz})(PPh_3)_2Cl]Cl$ (0.501 g, 0.5 mmol) with sodium diethyldithiocarbamate (0.112 g, 0.5 mmol) in methanol in the same way as Method (b) for complex **1**. Yield 75% (0.322 g). $C_{41}H_{37}ClN_7PRuS_2$ (859.4): calcd. C 57.24, H 4.30, N 11.40; found C 57.46, H 4.17, N 11.21. FAB-MS: *m*/*z* obsd. (calcd.), rel. int., [assignm.]: 824 (823), 100, $[Ru(\kappa^3\text{-tptz})(PPh_3)dtc]^+$; 561 (562), 94, $[Ru(\kappa^3\text{-tptz})(dtc)]^+$; 414 (413), 38, $[Ru(\kappa^3\text{-tptz})]^{+2}$. ^1H NMR: δ = 9.00 (d, J = 5.4 Hz, 2 H), 8.94 (d, J = 3.9 Hz, 1 H), 8.80 (d, J = 7.8 Hz, 1 H), 8.73 (t, J = 7.5 Hz, 2 H), 8.09 (m), 7.77 (t, J = 6 Hz, 2 H) 7.60 (t, J = 2.7 Hz, 1 H) 7.16 (m), 7.003 (t, J = 7.5 Hz, 6 H), 4.10 (q, J = 7.2 Hz, 2 H), 3.62 (q, J = 6.9 Hz, 2 H), 1.52 (t, J = 7.2 Hz, 3 H), 1.13 (t, J = 6 Hz, 3 H) ppm. $^{31}P\{^1H\}$ NMR: δ = 37.81 (s) ppm. Polynuclear Rhenium and Manganese Selenido-Carbonyl Complexes − Reversible Square to Butterfly Conversion of the Re_4Se_2 Core by CO Loss in $[Re_4(\mu_3\text{-}Se)_2(CO)_{16}(PPh_3)_2]$, and the Crystal Structure of $[Mn_2(\mu_2\text{-}Se_2)(CO)_5(PPh_3)_2]$

Daniele Belletti,[a] Claudia Graiff,[a] Roberto Pattacini,*[a] Giovanni Predieri,[a] and Antonio Tiripicchio[a]

Keywords: Cluster compounds / Manganese / Rhenium / Selenium

The reaction of Ph_3PSe with $[Mn_2(CO)_{10}]$ leads to the formation of $[Mn_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PPh_3)_2]$, which contains a butterfly "Mn_2Se_2 core", along with traces of $[Mn_2(\mu_2\text{-}Se_2)(CO)_5(PPh_3)_2]$ (**1**), which contains a tetrahedral Mn_2Se_2 core. The reaction of Ph_3PSe with $[Re_2(CO)_8(NCMe)_2]$ affords two new complexes, $[Re_4(\mu_3\text{-}Se)_2(CO)_{16}(PPh_3)_2]$ (**2**) and $[Re_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PPh_3)_2]$ (**3**). Their molecular structures, determined by X-ray diffraction methods, exhibit a nearly square-planar Re_2Se_2 and a butterfly Re_2Se_2 core, respectively. These air-stable tetrarhenium selenido-carbonyl species display a reversible loss/addition of a CO molecule, which is accompanied by the formation/cleavage of a Re–Re bond and the consequent rearrangement of the Re_2Se_2 core, from square to butterfly and vice versa.

Introduction

The chemistry of polynuclear transition-metal chalcogenide complexes is a continuously expanding research area, as pointed out in recent reviews.[1] Apart from their fundamental significance as a class of complexes with peculiar chemical and structural properties, the growing interest in these species stems from their potential applications as catalysts, electrocatalysts and precursors for semiconductors.[2] The presence of chalcogenide ligands often appears decisive in facilitating cluster-growth reactions,[3] and in this regard sulfur atoms have been shown to be highly effective,[4] as are selenium and tellurium atoms, although these have been much less studied.[2a,5,6]In this context, systematic investigations carried out by our group on the reactivity of tertiary phosphane and diphosphane selenides towards $[M_3(CO)_{12}]$ (M = Fe or Ru) have shown that these reactions provide simple, sometimes selective, synthetic routes to phosphane-substituted, selenido-carbonyl metal clusters.[6]

In recent years Adams and co-workers have described the reaction between thiirane and $[Mn_2(CO)_9(MeCN)]$, which gives the simplest sulfido-carbonyl manganese cluster $[Mn_2S_2(CO)_7]$ whose reactivity towards different metal fragments has been widely investigated.[7a,7c−7g] Moreover, the synthesis of the dimetallic selenido-carbonyl Mo−Mn complex $[CpMoMn(CO)_5(\mu\text{-}S_2)]$ has been achieved by treating $[CpMnMo(CO)_8]$ with elemental selenium.[7b,7h,7i]

Manganese clusters and complexes bearing selenide ligands have been scarcely investigated.[7a,7b] In particular, in the syntheses reported in the literature polyselenide anions,[8] diorganyl diselenides[9] and elemental selenium[10] have been used as starting materials.

Recently,[11] we have reacted different phosphane selenides with three manganese carbonyl complexes, namely $[Cp'Mn(CO)_2(THF)]$, $[CpMn(CO)_2(THF)]$ (Cp = η^5-C_5H_5, Cp′ = η^5-C_5H_4Me, THF = tetrahydrofuran) and $[Mn_2(CO)_8(NCMe)_2]$ in order to produce new phosphane-substituted selenido-carbonyl manganese derivatives. In particular, the reactions of tertiary phosphanes R_3PSe with $[Mn_2(CO)_8(NCMe)_2]$ in an equimolar ratio resulted in the formation of the bis-selenido tetramanganese clusters $[Mn_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PR_3)_2]$, the structures of two of which, $[Mn_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PPh_3)_2]$[7a] and $[Mn_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PMePh_2)_2]$,[11] having been determined by X-ray diffraction methods.

In this paper, the synthesis and crystal-structure characterization of the first tetrahedral Mn_2Se_2 carbonyl complex, $[Mn_2(\mu_2\text{-}Se_2)(CO)_5(PPh_3)_2]$, obtained by reacting two equivalents of phosphane selenide with $[Mn_2(CO)_{10}]$ in the presence of Me_3NO is described. Moreover, the reaction of Ph_3PSe with the analogous Re carbonyl derivative $[Re_2(CO)_8(NCMe)_2]$ yielded two new tetrarhenium selenido-carbonyl compounds, namely $[Re_4(\mu_3\text{-}Se)_2(CO)_{16}(PPh_3)_2]$ and $[Re_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PPh_3)_2]$, whose crystal structures were determined by X-ray diffraction methods. These com-

pounds show interesting reversible loss/addition of a CO molecule together with the formation/cleavage of a Re−Re bond and the consequent rearrangement of the Re_4Se_2 core.

Results and Discussion

Reaction of $Mn_2(CO)_{10}$ with Ph_3PSe; Crystal Structure of $[Mn_2(\mu_2\text{-}Se_2)(CO)_5(PPh_3)_2]$ (1)

The availability of sulfur-containing starting compounds such as thiirane allows for the efficient synthesis of the simplest tetrahedral Mn_2S_2 complex $[Mn_2(\mu_2\text{-}S_2)(CO)_7]$.[7c] However, the absence of analogous selenium compounds does not permit the easy synthesis of compounds containing an $Mn_2(\mu_2\text{-}Se_2)$ core. As has already been described,[11] the reaction of equimolar amounts of $[Mn_2(CO)_8(CH_3CN)_2]$ and Ph_2MePSe at 50 °C gives $[Mn_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PMePh_2)_2]$ as the unique product (80% yield). The same compound is also obtained when $Mn_2(CO)_{10}$ is treated with Ph_3PSe in a 1:2 molar ratio and in the presence of Me_3NO. In this case, however, the yield of the $[Mn_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PMePh_2)_2]$ cluster decreases to 70% while another complex, namely $[Mn_2(\mu_2\text{-}Se_2)(CO)_5(PPh_3)_2]$ (**1**), is also formed. Although only traces of compound **1** were isolated, suitable crystals for X-ray analysis were obtained.

The $^{31}P\{^1H\}$ NMR spectrum of **1** recorded at room temperature shows a broad peak at δ = 13.6 ppm, indicating the equivalence of the two phosphane ligands in solution. In addition, in the carbonyl region of the IR spectrum recorded in the solid state, a band at 1789 cm^{-1} is observed and attributed to a bridging carbonyl group. An ORTEP view of compound **1** is shown in Figure 1, together with the atom numbering scheme; selected bond lengths and angles are listed in Table 1.

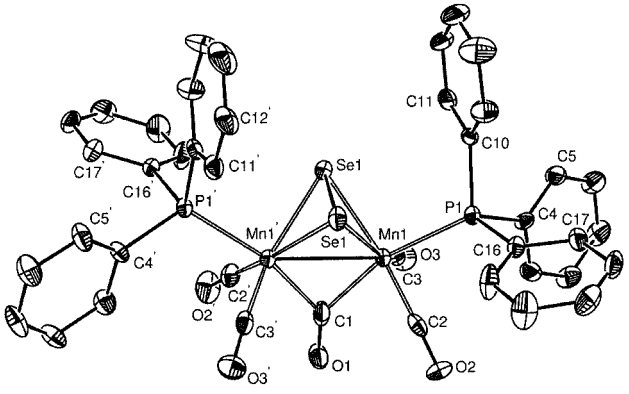

Figure 1. View (ORTEP, 30% probability level) of the molecular structure of **1** with the atom numbering scheme.

Complex **1** has a crystallographically imposed C_2 symmetry, with the twofold axis passing through the C1 and O1 atoms and the midpoints of the Mn1−Mn1′ and Se1−Se1′ bonds. The structure of this compound is very similar to that of the phosphane-unsubstituted and -monosubstituted sulfur derivatives $[Mn_2(\mu_2\text{-}S_2)(CO)_{7-n}(PPh_3)_n]$ (n = 0, 1)[7c,7d,7f] and the iron diselenide compounds $[Fe_2(\mu_2\text{-}Se_2)(CO)_{6-n}(PPh_3)_n]$ (n = 1, 2).[12] The complex possesses a tetrahedral Mn_2Se_2 core in which the Mn−Mn bond length is 2.702(2) Å, slightly longer than that observed in the sulfur derivatives [2.6745(5) and 2.6747(5) Å for n = 0 and n = 1, respectively]. The Se−Se bond length [2.311(2) Å] is in good agreement with those observed in $[Fe_2(\mu_2\text{-}Se_2)(CO)_{6-n}(PPh_3)_n]$ [2.297(2) and 2.296(1) Å for n = 1 and n = 2, respectively]. Moreover, each manganese atom is coordinated by two terminal carbonyls and by a posphane molecule [P1−Mn1 = 2.308(2) Å], while a CO group symmetrically bridges the Mn−Mn edge, with an Mn−C1 bond length of 2.01(1) Å.

Table 1. Selected bond lengths (Å) and angles (°) for **1**[a]

Mn(1)−Se(1′)[a]	2.4461(13)	Mn(1)−Se(1)	2.4478(13)
Mn(1)−Mn(1′)	2.702(2)	Se(1)−Se(1′)	2.3105(16)
Mn(1)−P(1)	2.308(2)		
P(1)−Mn(1)−Se(1′)	98.46(7)	P(1)−Mn(1)−Se(1)	92.99(7)

Se(1′)−Mn(1)−Mn(1)	56.52(3)	Se(1)−Mn(1)−Mn(1′)	56.46(3)
Se(1′)−Se(1)−Mn(1)	61.87(3)	Se(1′)−Se(1)−Mn(1)	61.79(4)
Mn(1′)−Se(1)−Mn(1)	67.02(5)		

[a] Symmetry transformations used to generate equivalent atoms: $-x, y, -z + 1/2$.

Reaction of $[Re_2(CO)_8(CH_3CN)_2]$ with Ph_3PSe; Crystal Structures of $[Re_4(\mu_3\text{-}Se)_2(CO)_{16}(PPh_3)_2]$ (2) and $[Re_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PPh_3)_2]$ (3)

The reaction of $[Re_2(CO)_8(CH_3CN)_2]$ with Ph_3PSe, carried out under the same experimental conditions used for the synthesis of $[Mn_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PMePh_2)_2]$,[11] led to the formation of two new tetrarhenium diselenide phosphane-substituted carbonyl compounds, namely $[Re_4(\mu_3\text{-}Se)_2(CO)_{16}(PPh_3)_2]$ (**2**) and $[Re_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PPh_3)_2]$ (**3**), whose structures were determined by X-ray diffraction methods.

ORTEP views of compounds **2** and **3** are shown in Figures 2 and 3, respectively, together with the atom numbering scheme; selected bond lengths and angles are listed in Tables 2 and 3.

Complex **2** displays a nearly planar Re_4Se_2 core [the dihedral angle between the Re1Re2Se1 and Re1Re2Se planes is 21.7° and the non-bonding Re1···Re2 and Se1···Se2 separ-

ations are 4.027(3) and 3.416(1) Å respectively]. Both Re1 and Re2 are bound to four terminal carbonyl groups and to two selenium atoms in a slightly distorted octahedral environment. Each of the two Se atoms is also bound to another Re atom from the $Re(CO)_4(PPh_3)$ group in which the P atom from the phosphane is coordinated to the Re atom [Re3−P1 and Re4−P2 = 2.511(2) and 2.503(2) Å respectively]. The two selenium atoms triply bridge three nonbonded rhenium atoms, with the six Se−Re bond lengths being almost equal [2.646(1)−2.668(1) Å].

The crystal structure of complex **3** compares well with that of the manganese derivative $[Mn_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PMePh_2)_2]$.[11] In contrast to compound **2**, in which the Re_4Se_2 group contains a nearly planar Re_2Se_2 array, in complex **3** a butterfly Re_2Se_2 core is observed. Thus, the two Re atoms occupy the hinge [Re1−Re2 bond length of 2.998(1) Å] and the two Se atoms the wing sites [the nonbonding Se1···Se2 separation is 3.164(1) Å and the dihedral angle between the Re1Re2Se1 and Re1Re2Se2 wings is 96.1°]. Both Re1 and Re2 atoms are bound to three terminal carbonyl ligands, while a fourth carbonyl group is involved in an incipient bridging interaction with Re1 [the Re(1)−C(7) and Re(2)−C(7) distances are 2.618(8) and 2.025(8) Å, respectively, and the O(7)−C(7)−Re(2) angle is 159.5(8)°]. The Re1−Re2 distance is in agreement with that expected for a metal−metal bond. Only one example of a carbonyl ligand bridging two Re atoms with a longer M−M distance [3.0391(6) Å] has been reported in the literature.[13] The butterfly Re_2Se_2 array is slightly asymmetrical, with the Re1−Se1 and Re1−Se2 bond lengths [2.5701(8) and 2.5759(10) Å, respectively] being shorter than the Re2−Se1 and Re2−Se2 ones [2.6364(9) and 2.6278(8) Å]. Analogously to compound **2**, each of the two Se atoms is also bound to another Re centre of a $Re(CO)_4(PPh_3)$ group in such a way that the Se atoms triply bridge three Re metal centres. In both complexes the atoms Re3, Se1, Se2, Re4 lie in a nearly planar array [maximum deviation for Se1 in **2** and Se2 in **3** of 0.078(2) and 0.0120(7) Å, respectively]. Regarding the position of the $Re(CO)_4PPh_3$ groups, a *trans* configuration is present in **3** with an Re3−Se1−Se2−Re4 torsion of 175.09° and a *cis* configuration in **2** with the corresponding torsion angle of 6.67°; in both cases the phosphane ligands point in the directions which minimize the steric hindrance. In particular, the disposition of the two phosphane molecules could be described as *cis* in compound **2** and *trans* in compound **3**.

Thermal Treatment of 2; Reversible Conversion to 3 by CO Loss

Stirring a solution of **2** in THF at room temperature leads slowly to the formation of **3**, in quantitative yield, by loss of a carbonyl molecule. This process is found to be faster in polar solvents and under moderate heating. This conversion can be monitored by IR spectroscopy. As shown in Figure 4, the IR absorption bands of the terminal CO group display distinct changes in the regions 1980−2040 (typical of a $Re(CO)_4L$ type of structure), and 2050−2100 cm^{-1}. Finally, the formation of an incipient bridging CO group is observed at 1896 cm^{-1}.

The loss of the carbonyl ligand induces a structural modification. A Re−Re bond is formed and the Re_2Se_2 conformation changes from nearly planar to butterfly. It is not possible to determine which carbonyl leaves the Re_2Se_2 core, although the longer C−Re distances involving the axial carbonyls [spanning from 1.98(1) to 2.01(1) Å] than the equatorial ones [spanning from 1.90(1) to 1.93(1) Å] suggest a higher lability. The subsequent rearrangement of the core carbonyls allows the rotation of the $Re(CO)_4P$ moiety around the Re−Se bond and the inversion of the selenium atom.

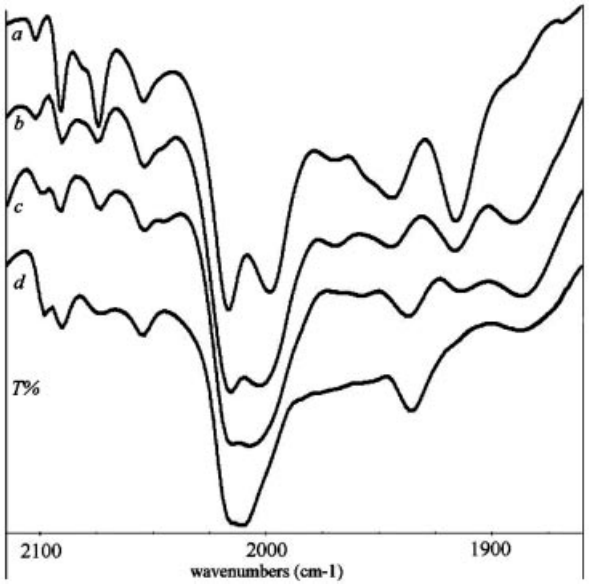

Figure 4. Conversion of **2** into **3** in THF/CH_2Cl_2 (1:1) at 50 °C monitored by FT-IR spectroscopy by sampling the mixture, drying *in vacuo* and redissolving the sample in CH_2Cl_2: (a) pure **2** (t = 0 min); (b) t = 15 min; (c) t = 30 min; (d) pure **3** (t = 45 min)

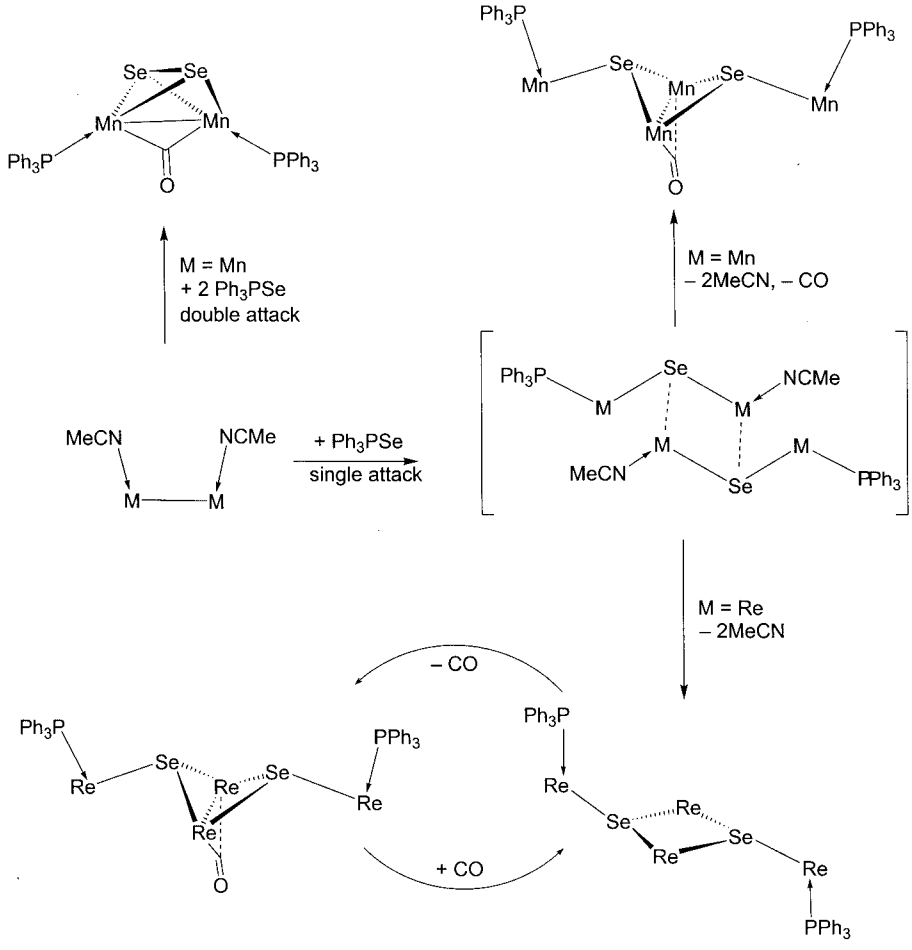
The process can be reversed by placing **3** under moderate CO pressure, obtaining complex **2** in quantitative yields. There are only a few known examples of reversible CO addition to transition metal compounds, mainly those supported on inorganic matrices or in high-nuclearity clusters.[14a,14b] Some examples of M−M bond cleavage due to reversible CO addition are knwon in the literature,[15] but very few involve two stable species.[16]

As pointed out for the synthesis of $[Mn_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PMePh_2)_2]$,[11] the reaction mechanism leading to the synthesis of M_4Se_2 core compounds (M = Mn, Re) is believed to proceed via the formation of intermediates of the type $[M_2(\mu\text{-}Se)(CO)_8(PR_3)]$ (PR_3 = tertiary phosphane ligand). This product results from the initial attack of the phosphane selenide on the dinuclear compound and can, in turn, undergo a dimerization, leading to the formation of $[M_4(\mu_3\text{-}Se)_2(CO)_{16}(PR_3)_2]$ complexes. Finally, the loss of a carbonyl ligand from the aforementioned structures can give rise to novel $[M_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PR_3)_2]$ complexes. In the case of rhenium, both final products were isolated, and seem to have similar thermodynamic stabilities. On the other hand, the manganese compound $[Mn_4(\mu_3\text{-}Se)_2(CO)_{16}(PR_3)_2]$ could not be isolated, probably because



Scheme 1. (terminal carbonyl groups omitted for clarity)

of the greater stability of the related decarbonylated compound (see Scheme 1).

Experimental Section

General Remarks: The starting reagents triphenylphosphane selenide, $[Re_2(CO)_{10}]$ and $[Mn_2(CO)_{10}]$ were pure commercial products (Aldrich and Fluka) and were used as received. The solvents (C. Erba) were dried and distilled by standard techniques before use. Preparative TLC was carried out on silica (Merck, 60 PF_{254}, 20 × 20 cm glass plates). After the chromatographic workup, the products were extracted with dichloromethane. Purity was checked by elemental analysis and ^{31}P NMR spectroscopy. Elemental (C, H) analyses were performed with a Carlo Erba EA 1108 automated analyzer. IR spectra (CH_2Cl_2 solutions) were recorded on a Nexus FT spectrometer. ^1H (300 MHz) and $^{31}P\{^1H\}$ (161.90 MHz, 85% H_3PO_4 as external reference) NMR spectra ($CDCl_3$ solutions) were recorded on a Bruker AC 300 and a Bruker AMX 400 instrument, respectively.

Synthesis of $[Mn_2(\mu_2\text{-}Se)_2(\mu\text{-}CO)(CO)_4(PPh_3)_2]$ (1): Ph_3PSe (350 mg, 1.03 mmol) and Me_3NO (23 mg, 1.03 mmol) were dissolved in toluene (60 mL) and the resulting solution brought to 45 °C. A 15 mL toluene solution of $[Mn_2(CO)_{10}]$ (200 mg, 0.52 mmol) was then added dropwise. A progressive colour change from yellow to deep brown was observed. The reaction was stopped after 30 min, the solvents removed in vacuo and the brown solid redissolved in a small amount of dichloromethane. Two products were isolated by preparative TLC (CH_2Cl_2/hexane, 2:1), namely brownish red $[Mn_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PPh_3)_2]$ (yield 70%), identified by comparison of the spectroscopic data with those observed previously,[11] and $[Mn_2(\mu_2\text{-}Se)_2(\mu\text{-}CO)(CO)_4(PPh_3)_2]$ (**1**) (yield 5%) as a brown crystalline solid.
1: FTIR (CH_2Cl_2): ν(CO) = 1979 vs, 1944 vs, 1890 vs, 1865 m, 1789 vs. $^{31}P\{^1H\}$ NMR: δ = 13.6 ppm. $C_{41}H_{30}Mn_2O_5P_2Se_2$: calcd. C 52.81, H 3.24; found C 52.84, H 3.25.

Reaction of $[Re_2(CO)_8(MeCN)_2]$ with Ph_3PSe: CH_3CN (41 mg, 1 mmol) and Me_3NO (68 mg, 0.61 mmol) were added to a dichloromethane solution of $[Re_2(CO)_{10}]$ (200 mg, 0.31 mmol in 40 mL) and the resulting reaction mixture stirred at room temperature for 2 h. Evaporation of the solvent gave $[Re_2(CO)_8(MeCN)_2]$ as a yellow solid, which was redissolved in 50 mL of toluene. Ph_3PSe (105 mg, 0.31 mmol) was added and the reaction mixture warmed to 70 °C for 2 h. A colour change from yellow to intense red was observed after 30 mins. Evaporation of the solvent yielded the crude product as an orange solid. Cromatography (preparative TLC; CH_2Cl_2/hexane, 1:1) gave red $[Re_4(\mu_3\text{-}Se)_2(CO)_{16}(PPh_3)_2]$ (**2**) and orange-yellow $[Re_4(\mu_3\text{-}Se)_2(\mu\text{-}CO)(CO)_{14}(PPh_3)_2]$ (**3**) bands together with some decomposition material and small amounts of unchanged reagents. Compound **2** is more soluble than **3** in all common laboratory solvents.
2: FT-IR (CH_2Cl_2): ν(CO) = 2090 w, 2074 w, 2016 vs, 1998 vs, 1954 sh, 1943 m, 1916 m. $^{31}P\{^1H\}$ NMR: δ = 1.0 (br) ppm. $C_{52}H_{30}O_{16}P_2Re_4Se_2$: calcd. C 33.30, H 1.64; found C 33.29, H 1.62.
3: FT-IR (CH_2Cl_2): ν(CO) = 2098 w, 2091 w, 2016 vs, 2011 vs (sh), 1936 m, 1895 m. $^{31}P\{^1H\}$ NMR: δ = 0.8 (br) ppm. $C_{51}H_{30}O_{15}P_2Re_4Se_2$: calcd. C 33.16, H 1.64; found C 33.14, H 1.61.

Thermal Treatment of 2; Conversion into 3: A solution of compound **2** (100 mg, 0.051 mmol) in 10 mL of THF was stirred for 40 minutes at 50 °C. The quantitative formation of **3** was monitored by FT-IR spectroscopy.

Reaction of 3 with CO; Conversion into 2: A suspension of **3** (100 mg, 0.054 mmol) in 5 mL of CH_2Cl_2 was stirred under 5 atm. of CO. After 5 h an orange solution was formed. Cluster **3** was quantitatively converted into **2**, as confirmed by FT-IR spectroscopy in CH_2Cl_2.

X-ray Data Collection, Structure Solution and Refinement for Complexes 1, 2·CH_2Cl_2 and 3: Crystals suitable for X-ray analysis were obtained by layering methanol on dichloromethane solutions (**1** and **2·CH_2Cl_2**) or by slow evaporation of solvent from a THF solution (**3**). The intensity data were collected at room temperature on a Philips PW 1100 (**1**) or on a Bruker area detector AXS Smart 1000 (**2·CH_2Cl_2** and **3**) diffractometer (both using graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å). Crystallographic and experimental details for the structures are summarized in

Table 4. An empirical absorption correction was made for **1** (maximum and minimum value for the transmission coefficient 1.000 and 0.625).[17a,17b] For complexes **2·CH_2Cl_2** and **3** (maximum and minimum effective transmission value 1.000 and 0.405, 1.000 and 0.534. respectively) the raw frame data were processed using SAINT and SADABS to yield the reflection data file and the Bruker software was used for the absorption correction.[17c−17e] The structures were solved by Patterson and Fourier methods and refined by full-matrix least-squares procedures (based on F_o^2) (SHELX-97),[18] first with isotropic thermal parameters and then with anisotropic thermal parameters in the last cycles of refinement for all the non-hydrogen atoms**.** In the crystals of **2·CH_2Cl_2** dichloromethane molecules of solvation were found. The hydrogen atoms in **1**, **2·CH_2Cl_2** and **3** were introduced into their geometrically calculated positions and refined as riding on the corresponding parent atoms, except the hydrogen atoms of the solvent molecule.

CCDC-230259 (for **1**), -230260 (for **2·CH_2Cl_2**) and -230261 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows a butterfly mimicking the main features of compounds $[L_2Pt(\mu\text{-}S)_2PtL_2]$ (L_2 = phosphane). Its flight simulates the flexibility of the $\{Pt(\mu\text{-}S)_2Pt\}$ core about the S–S axis; its body represents the strongly nucleophilic sulfide ligands and the wings the $\{PtL_2\}$ fragments. Exploration of the reactivity of the butterfly compounds has revealed an exceptionally rich and diverse chemistry. Details are discussed in the Microreview by P. González-Duarte et al. on p. 3585ff., who acknowledge Victor Sarto i Monteys for the butterfly picture (V. S. i M. holds the copyright).

Extending The Reaction Landscape of the {Pt(μ-S)$_2$Pt} Core: From Metal Centers to Non-Metallic Electrophiles

Pilar González-Duarte,*[a] Agustí Lledós,[a] and Rubén Mas-Ballesté[a]

Keywords: Platinum / Sulfur / Metalloligand / Nucleophile / Building block

The outstanding nucleophilicity of the {Pt(μ-S)$_2$Pt} core in compounds [L$_2$Pt(μ-S)$_2$PtL$_2$] (L$_2$ = phosphane) accounts for their ability to act as metalloligands towards main group and transition metals, and thus for the high number of [{L$_2$Pt(μ$_3$-S)$_2$PtL$_2$}$_x$ML′$_y$]^z aggregates already described. However, the electronic and molecular features underpinning this behavior anticipate a landscape of comparable richness for the reactions of [L$_2$Pt(μ-S)$_2$PtL$_2$] with non-metal electrophiles. Exploration of the chemistry of [L$_2$Pt(μ-S)$_2$PtL$_2$] (L$_2$ = chelating diphosphane) towards various electron-acceptor species has been the aim of our research for the past years. In this microreview we survey the synthetic strategies of [L$_2$Pt(μ-S)$_2$PtL$_2$] compounds, their distinguishing electronic and molecular features, the dynamic processes and electron-donor properties of the {Pt(μ-S)$_2$Pt} core, and its binding ability towards metal centers. Moreover, particular attention is given to the reaction chemistry of [L$_2$Pt(μ-S)$_2$PtL$_2$] with organic electrophiles and protic acids, as well as to the influence of the {Pt(μ-S)$_2$Pt} core on the reactivity of inorganic or organic L′ ligands in [{L$_2$Pt(μ$_3$-S)$_2$PtL$_2$}$_x$ML′$_y$]^z aggregates.

Introduction

The outstanding ability of sulfur to bind heavy metals is not only evidenced by the enormous variety of metal sulfide minerals found in nature, but also by the occurrence of platinum group metals in mineral ores different from native deposits. One of these examples is cooperite, a platinum-bearing sulfide with the general formula $Pt_{0.6}Pd_{0.3}Ni_{0.1}S$, in which platinum(II) ions are coordinated by sulfide anions in a square-planar arrangement and these are tetrahedrally coordinated by four platinum ions.[1] In parallel to their

Pilar González-Duarte (center) was born in Barcelona (Spain). She studied Chemistry at the Universitat de Barcelona and obtained a Master Degree in Chemistry at the University of Michigan (Ann Arbor, US). She received her Ph.D. at the Universitat Autònoma of Barcelona in 1975 with Prof. E. Casassas, in the area of analytical chemistry. After holding several positions at the Universitat Autònoma de Barcelona she became full professor of Inorganic Chemistry in 1990. Following her initial studies on metal thiolates in the solid phase and in solution she has, since 1990, been studying the coordination ability of recombinant metallothioneins and the reactivity of metal complexes with sulfur containing ligands.
Rubén Mas-Ballesté (right) was born in Barcelona (Catalonia, Spain) in October of 1975. He studied Chemistry at the Universitat Autònoma de Barcelona where he obtained his BSc. degree in Chemistry in June of 1998, and his Ph.D. in February of 2004 under the supervision of Prof. Pilar González-Duarte and Prof. Agustí Lledós. From June 2004 he is doing a postdoctoral stay in the Lawrence Que's group at the University of Minnesota (USA). His research interests are the reactivity of metal chalcogenides and the synthesis and reactivity of structural and functional models of non-heme iron proteins.
Agustí Lledós (left) was born in 1955 in Barcelona. He received his BSc degree in Chemistry from the Universitat Autònoma de Barcelona in 1979, and his Ph.D. in 1984 at the same university, under the supervision of Juan Bertrán. After a postdoctoral stay at the Université de Paris-Sud (Orsay) with Yves Jean, he returned to the Universitat Autònoma in 1987 and created a research group devoted to the computational study of transition metal complexes. He was appointed Professor of Physical Chemistry in 1994. His research interests concern the computational modeling of transition metal systems, with focus on hydride complexes, σ-bond activation, bimetallic compounds and homogeneous catalysis.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

abundance, the chemistry of metal sulfides has also been the object of extensive studies and still attracts great attention, mainly because of their structural diversity,[2] essential role in catalysis,[3] and rich solid-state and bioinorganic chemistry.[4] In contrast, platinum sulfide chemistry has received much less attention for many decades of the past century despite the fact that the first platinum-sulfur complex, $(NH_4)_2[Pt(\eta^2\text{-}S_5)_3]$, was isolated in 1903.[5]

A main hallmark in the field of platinum(II)−sulfur chemistry was established by Chatt and Mingos in 1970, who obtained several complexes of various nuclearities and structures.[6] Among them, $[(PMe_2Ph)_2Pt(\mu\text{-}S)_2Pt(PMe_2Ph)_2]$, followed by $[(PPh_3)_2Pt(\mu\text{-}S)_2Pt(PPh_3)_2]$[7] reported by Ugo et al. one year later, constitute the first examples of platinum(II) sulfide complexes containing the $\{Pt(\mu\text{-}S)_2Pt\}$ core. As a result of these studies, they also described the corresponding monoalkylated species $[L_2Pt(\mu\text{-}S)(\mu\text{-}SR)PtL_2]^+$ (L = PMe_2Ph, R = $PhCH_2$ [6] and L = PPh_3, R = CH_3 [7]) and the trinuclear $[Pt_3(PMe_2Ph)_6(\mu_3\text{-}S)_2]Cl_2$ complex,[6] whose formation provided the first evidence for the nucleophilicity of the bridging sulfido ligands in the $\{Pt(\mu\text{-}S)_2Pt\}$ core.

The evolution of the chemistry of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ (L = phosphane) has proceeded very rapidly over the past two decades. Thus, the significant number of known homo- and heterometallic derivatives of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ shows that this species is one of the most effective metalloligands identified to date. A summary of the historical milestones in platinum-sulfur chemistry leading to sulfide-bridged aggregates with the $\{Pt(\mu\text{-}S)_2Pt\}$ core, as well as the main developments in their synthesis, structure, and reactivity were excellently reviewed by Fong and Hor, who have made important contributions to this field.[8] Overall, the ability of the sulfido ligands in the $\{Pt(\mu\text{-}S)_2Pt\}$ core to extend their coordination mode from μ-S to μ_3-S accounts for the behavior of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ as building blocks for higher nuclearity complexes, and the flexible hinge angle between the two $Pt^{II}S_2$ planes for the varied coordination geometries at the heterometal M in the corresponding $[\{L_2Pt(\mu_3\text{-}S)_2PtL_2\}_xML'_y]^z$ aggregates.

Remarkably, the reaction chemistry of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds towards nonmetallic electrophiles was not the object of systematic studies until much more recently. Combination of experimental results and theoretical calculations has allowed for a detailed knowledge of the cascade of reactions of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ in the presence of either organic electrophiles, such as CH_2Cl_2,[9] or the simplest electron-acceptor species, the proton.[10] In addition, the influence of $\{Pt(\mu\text{-}S)_2Pt\}$ core on the reactivity of L′ in $[\{L_2Pt(\mu_3\text{-}S)_2PtL_2\}_xML'_y]^z$ aggregates has been explored.[11] All these results promise to inspire new approaches that contribute towards the unveiling of the potential of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds as nucleophilic agents.

Understanding the rich and diverse chemistry of the $\{Pt(\mu\text{-}S)_2Pt\}$ core has been the aim of our research for the past several years. Our approach has focused on the use of chelating diphosphanes as terminal L ligands,[12] with an emphasis on the chemistry of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ with nonmetal electrophiles[9,10] and ML'_y fragments.[11] This report surveys the present knowledge on the nucleophilicity of the $\{Pt(\mu\text{-}S)_2Pt\}$ core in $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds; the previous review by Fong and Hor is our starting point.[8] Thus, the peculiarities concerning the synthesis of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds, their distinguishing electronic and molecular features, the dynamic processes and electron-donor properties of the $\{Pt(\mu\text{-}S)_2Pt\}$ core, and the reactivity of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ towards metallic and nonmetallic electrophiles will be summarized.

Synthesis, and Molecular and Electronic Structures of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ Complexes

Synthetic Procedures

Despite their apparent simplicity, the synthetic routes reported for complexes with the formula $[L_2Pt(\mu\text{-}S)_2PtL_2]$ (Scheme 1) are not straightforward, often leading to mixture of products.[8] The most common procedure is based on the metathesis reaction between $[PtCl_2L_2]$ and $Na_2S{\cdot}9H_2O$,[6] for which only monometallic precursors with L = phosphane ligands have been used. These have generally been obtained by replacing 1,5-cyclooctadiene (cod) in $[PtCl_2(cod)]$ by the corresponding phosphane.[13] Other less direct routes entail the oxidation of $[PtL_4]$ with S_8, which affords phosphane sulfide as secondary product,[7] or, the reaction between $[PtCl_2L_2]$ and NaSH.[14] The latter involves the formation of $[Pt(SH)_2L_2]$ first and then its subsequent reaction with a second equivalent of $[PtCl_2L_2]$, thus yielding $[L_2Pt(\mu\text{-}S)_2PtL_2]$ plus two equivalents of HCl. However, as commented below, the presence of HCl is inconvenient as it can cause disintegration of the $\{Pt(\mu\text{-}S)_2Pt\}$ core.[10] Overall, the first pathway offers more advantages and becomes particularly adequate when the solubility of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ in the organic solvent used is high, and thus its separation from unreacted $Na_2S{\cdot}9H_2O$ and formed NaCl is feasible. This requirement is best accomplished by the chelating diphosphanes 1,2-bis(diphenylphosphanyl)ethane (dppe) or 1,3-bis(diphenylphosphanyl)propane (dppp) than by PPh_3.[9,15]

Our studies on the reactivity of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ (L_2 = dppe or dppp) towards nonmetal electrophiles[9,10] have provided information about the appropriate reaction conditions to obtain $[L_2Pt(\mu\text{-}S)_2PtL_2]$ from $[PtCl_2L_2]$ and $Na_2S{\cdot}9H_2O$ with maximum yield and purity (Scheme 2). To this end, the use of nonchlorinated solvents, the absence of protic acids in the reaction medium, and the purity of the reagent $Na_2S{\cdot}9H_2O$ are the main requirements. The choice of solvent is relevant so as to circumvent its reaction with $[L_2Pt(\mu\text{-}S)_2PtL_2]$, which occurs for L = PMe_2Ph, PPh_2py, PPh_3 and L_2 = dppf, dppe, dppp in the presence of CH_2Cl_2, as explained below. For the same reason, traces of CH_2Cl_2 that may be present in the $[PtCl_2L_2]$ starting complex should be eliminated. Similarly, the presence of protic acids should be avoided as they may cause protonation and subsequent disintegration of the $\{Pt(\mu\text{-}S)_2Pt\}$ core in the final $[L_2Pt(\mu\text{-}S)_2PtL_2]$ product.[10] Concern for the quality of the

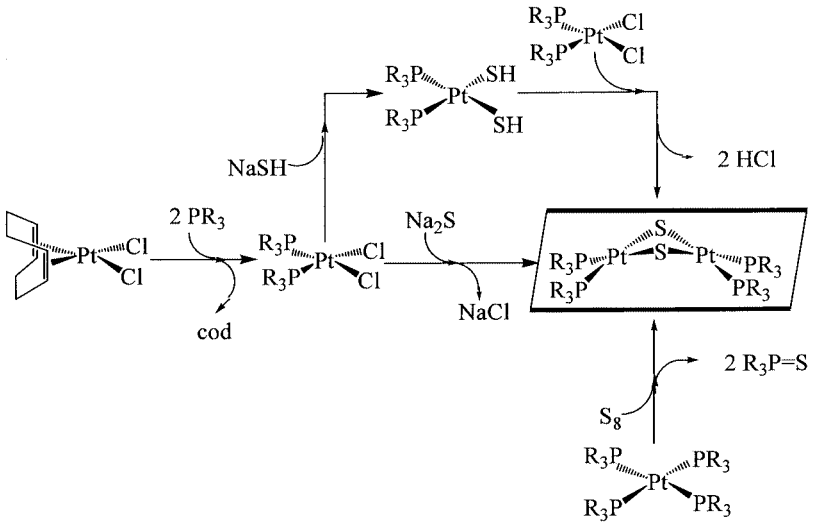
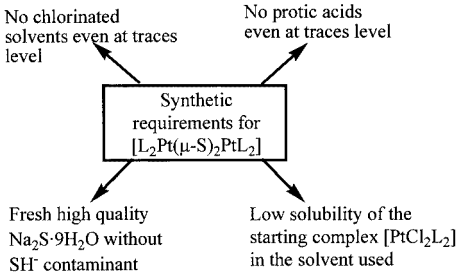


Scheme 1. Common synthetic procedures for [$L_2Pt(\mu\text{-}S)_2PtL_2$] complexes with unidentate or bidentate terminal phosphane ligands



Scheme 2. Optimum reaction conditions for obtaining [$L_2Pt(\mu\text{-}S)_2PtL_2$] complexes from [$PtCl_2L_2$] and $Na_2S{\cdot}9H_2O$

reagent $Na_2S{\cdot}9H_2O$ arises from the observation that [$Pt(SH)_2L_2$], whose formation requires the presence of hydrogen sulfide anions, is not an uncommon by-product in the synthesis of [$L_2Pt(\mu\text{-}S)_2PtL_2$]. Finally, an additional factor that may hamper the synthesis of pure [$L_2Pt(\mu\text{-}S)_2PtL_2$] is the formation of the trimetallic complex [{$L_2Pt(\mu_3\text{-}S)_2PtL_2$}$PtL_2$]$Cl_2$ as a consequence of the coexistence in solution of the final product, [$L_2Pt(\mu\text{-}S)_2PtL_2$], with one of the reagents, [$PtCl_2L_2$]. This undesirable process is minimized with the use of solvents in which [$PtCl_2L_2$] is very slightly soluble and, consequently, the [$PtCl_2L_2$]/[$L_2Pt(\mu\text{-}S)_2PtL_2$] concentration ratio in solution during the reaction is very low.

All previous conclusions regarding the synthesis of [$L_2Pt(\mu\text{-}S)_2PtL_2$] from [$PtCl_2L_2$] and $Na_2S{\cdot}9H_2O$ have been obtained by monitoring the reactions with L_2 = dppe or dppp over time by ^{31}P-NMR spectroscopy.[12] This technique is revealed to be very useful for the monitoring of the evolution of the products from the reagents, as well as for the determination of the reaction time that corresponds to the maximum yield.

Molecular and Electronic Structures

The core of [$L_2Pt(\mu\text{-}S)_2PtL_2$] compounds consists of a four-membered {$Pt(\mu\text{-}S)_2Pt$} ring, with the platinum(II) atoms in a square-planar arrangement. The main geometric parameters for complexes structurally characterized by X-ray diffraction are shown in Table 1.[9,14–17] A distinguishing structural feature within this family of compounds is the degree of hinging of the {Pt_2S_2} core, which is measured by the dihedral angle θ between the two PtS_2 planes. According to reported data, this angle is highly dependent on the nature of the terminal L ligands. Similar features have been found for complexes containing {M_2S_2}

Table 1. Main geometric parameters of the {$Pt(\mu\text{-}S)_2Pt$} core in structurally characterized complexes; distances in angstroms and angles in degrees

Complex	Pt–S	Pt–P	Pt···Pt	S···S	Pt–S–Pt	S–Pt–S	P–Pt–P	θ[a]	Ref.

cores, in which M = Ni[18] or Pd.[19] According to a theoretical and structural analysis on $[L_2M(\mu\text{-}X)_2ML_2]$ complexes, in which M has a d^8 electronic configuration, the driving force for the hinging of the $\{M_2S_2\}$ core arises from attractive metal···metal interactions between an occupied d_{z^2} orbital and an empty p_z orbital (Figure 1).[20] This interaction is modulated by the nature of the metal center, the terminal ligands, and the bridging atoms. Thus, the tendency to form bent structures increases with the diffuseness of the metal orbitals (i.e. going down the group of the periodic table), with the σ-donor ability of the terminal L ligands, and with decreasing electronegativity of the bridging X atoms. On the basis of these general rules it is clear that complexes with the formula [(phosphane)Pt(μ-S)$_2$Pt(phosphane)] are very well suited to adopt bent structures. However, steric interactions between terminal ligands can prevent the folding of the $\{M_2S_2\}$ core, as observed for M = Pt and L = PPh_2py[14] or PPh_3,[16] where the resulting core is planar or almost planar, respectively. Moreover, the increase in the Pt−X distances from X = S to Te could account for the planar structures observed for the $\{Pt(\mu\text{-}X)_2Pt\}$ core with Se^{2-} or Te^{2-} bridging ligands (Table 2).[21−24] This increase involves elongation of the Pt···Pt distance, which thus becomes too long to allow for the attractive interactions that underlie the folding of the $\{Pt(\mu\text{-}X)_2Pt\}$ core.

The electronic structure of complexes containing the $\{Pt(\mu\text{-}X)_2Pt\}$ (X = S, Se or Te) core has been analyzed from a theoretical point of view in recent works.[25,26] Thus, DFT calculations for model complexes using simplified terminal phosphane ligands have revealed that in all cases the highest energy occupied molecular orbital (HOMO) consists of an antibonding combination of the chalcogen p_π orbitals (p_z). A 3-D plot of this molecular orbital calculated for the model compound $[(PH_3)_2Pt(\mu\text{-}S)_2Pt(PH_3)_2]$ is shown in Figure 2. In addition, the orbital HOMO-1 consists essentially of a bonding combination of the same atomic orbitals. From this orbital analysis it can be inferred that a high electron density is located on the bridging chalcogenide ligand, which will thus be responsible for the nucleophilic character of $[L_2Pt(\mu\text{-}X)_2PtL_2]$ compounds. The energy of the HOMO is a good criterion for the comparison of the relative Lewis basicity of complexes containing the $\{Pt(\mu\text{-}X)_2Pt\}$ core. The energy of the HOMO in $[Pt_2(\mu\text{-}Te)_2(PMe_3)_4]$ (−3.46 eV) is considerably higher than that calculated for $[Pt_2(\mu\text{-}S)_2(H_2P(CH_2)_nPPH_2)_2]$ (n = 2, 3) (−3.89 eV), indicating that the lone electron pairs in the $\{Pt_2Te_2\}$ core are more accessible than those in the sulfur analogue.[25] These energy values are consistent with the lower oxidation potentials found for $\{Pt_2Te_2\}$ than for $\{Pt_2S_2\}$ containing complexes.

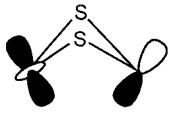

Figure 1. The driving force underlying the hinging of the $\{Pt(\mu\text{-}S)_2Pt\}$ core: $d_{z^2}-p_z$ metal to metal interactions

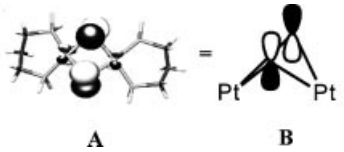

Figure 2. (A) 3D plot of the HOMO orbital in the model complex $[\{PH_2(CH_2)_3PH_2\}Pt(\mu\text{-}S)_2Pt\{PH_2(CH_2)_3PH_2\}]$; (B) corresponding schematic drawing

The structural and electronic features of complexes $[L_2Pt(\mu\text{-}S)_2PtL_2]$ reveal new perspectives for further studies. On the one hand, the different values found for the dihedral angle between the two PtS_2 planes in related $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds show the flexibility of the $\{Pt_2S_2\}$ core and anticipate its involvement in dynamic processes. On the other hand, the high electron-density on the sulfide ligands in the above-mentioned core accounts for the electron-donor behavior of this family of complexes, which should be explored by means of electrochemical measurements. Both issues are considered in the following sections.

Dynamic Processes: The Flight of the Butterfly

Structural data on $[L_2Pt(\mu\text{-}S)_2PtL_2]$ complexes show a wide range for the folding degree of the $\{Pt_2S_2\}$ core, from strongly bent (θ = 121°, L = PMe_2Ph)[17] to planar (θ = 180°, L = PPh_2py)[14] rings (Table 1). In addition, theoretical calculations indicate that the energy cost for the hinging movement is low; the energy difference between bent and planar geometries is about 4−8 kcal/mol.[20,27] Interestingly, in theoretically studied model systems the planar geometry is not a minimum in the potential energy surface but, instead, it constitutes the transition state from a folded geometry to the corresponding reverse folding, as depicted

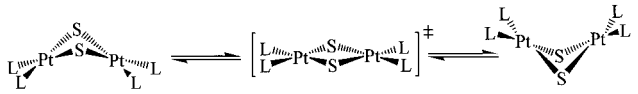
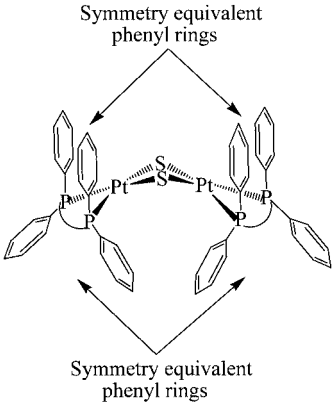


Scheme 3. Dynamic process arising from the flexibility of the {Pt(μ-S)$_2$Pt} core; the sign ‡ denotes a transition state

in Scheme 3. The low energy of the transition state is consistent with the hinging process that occurs at room temperature. Experimental evidence was obtained from ^{13}C NMR spectroscopic data on [L$_2$Pt(μ-S)$_2$PtL$_2$] complexes with the chelating phosphanes dppe or dppp as terminal ligands that showed the equivalence of all phenyl groups at room temperature in solution (Scheme 4). However, the hinged geometry of the {Pt$_2$S$_2$} core in the corresponding X-ray structures[9,15] was inconsistent with NMR data unless a dynamic process enabled the phenyl rings to become symmetry-equivalent in solution. The fact that this equivalence is maintained even at low temperature is indicative of the low energy barrier of the bending process. In addition, it is worth noting that [L$_2$Pt(μ-S)$_2$PtL$_2$] complexes containing unidentate phosphane PR$_3$ do not allow for the distinguishing of the hinging process and the fast rotation along the Pt−P bond, which could account for the observed equivalence of all R groups in ^{13}C NMR measurements. Overall, the well-established term butterfly to designate [L$_2$Pt(μ-S)$_2$PtL$_2$] complexes appears particularly adequate on the basis of the dynamic properties of the {Pt$_2$S$_2$} core.



Scheme 4. Asymmetry of the phenyl rings in a chelating phosphane considering a hinged geometry for the {Pt(μ-S)$_2$Pt} core

Other fast reversible intramolecular dynamic processes involving the {Pt$_2$S$_2$} core have also been observed. One of them, consisting of the intramolecular S−H···S proton exchange in the complexes [L$_2$Pt(μ-S)(μ-SH)PtL$_2$]$^+$ (L$_2$ = dppe or dppp),[28] provided the first example of a fast S−H···S proton exchange in a metal complex. Experimental evidence came from VT-^{31}P{^{1}H} NMR spectroscopic data (Figure 3), which showed the equivalence of the four phosphorus nuclei at 300 K in solution. However, the proton transfer between both sulfur atoms is frozen at 200 K and, consequently, the phosphorus nuclei in the *trans* and *cis* dispositions with respect to the bridging SH group show different chemical shift values. From the NMR data, $\Delta G^{\ddagger}$ of about 11 kcal/mol was estimated for the S−H···S proton-transfer process. Theoretical studies corroborated the feasibility of the S−H···S proton transfer process as well as its corresponding experimental energy. They also showed that the transition state involves a trigonal S−H−S arrangement, in which the partial rupture of the S−H bond is compensated by the partial formation of the new S−H bond (Scheme 5).

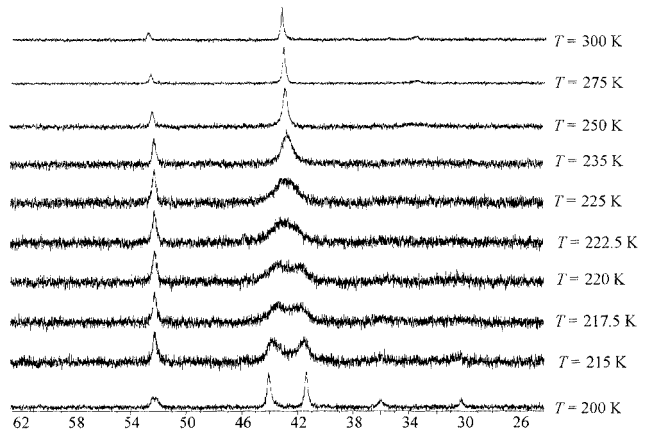


Figure 3. VT-^{31}P{^{1}H} NMR spectra of complex [Pt$_2$(dppe)$_2$(μ-S)(μ-SH)]ClO$_4$

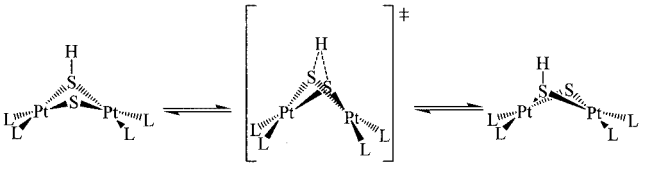

Scheme 5. Fast intramolecular S−H···S proton transfer in [L$_2$Pt(μ-S)(μ-SH)PtL$_2$]$^+$

It is worth mentioning the role played by the flexibility of the {Pt$_2$S$_2$} ring in the process. Thus, the S···S distance is notably shorter in the transition sate (2.98 Å) than in the reactants (3.24 Å), the shortening of this distance is attained by increasing the degree of folding of the {Pt$_2$S$_2$} ring ($\theta > 130°$ in the reactants and about 109° in the transition sate).

Remarkably, no proton transfer processes have been observed for [L$_2$Pt(μ-S)(μ-SH)PtL$_2$]$^+$ complexes in which PPh$_3$ replaces dppe or dppp.[29,30] One possible factor to account for these differences is the bulkiness of PPh$_3$ that could prevent the hinging of the {Pt(μ-S)$_2$Pt} fragment, thus disfavoring the folded transition state required for the intramolecular S−H···S proton transfer. Another explanation is the possible interaction of the S−H proton with a phenyl ring of PPh$_3$, thus stabilizing the [L$_2$Pt(μ-S)(μ-SH)PtL$_2$]$^+$ cation in relation to the transition state.

A similar transfer process has been observed in [(PPh$_3$)$_2$Pt(μ-S){μ-S-Au(PPh$_3$)}Pt(PPh$_3$)$_2$]$^+$, closely related to [L$_2$Pt(μ-S)(μ-SH)PtL$_2$]$^+$, on the basis of the isolobal analogy of [H]$^+$ and [AuPPh$_3$]$^+$ fragments (Scheme 6).[31] It is noteworthy that in the former cation, the intramolecular exchange is observed even if the terminal ligand is PPh$_3$. Probably, the larger size of the gold atom, which in the transition state interacts with the two sulfur atoms of the {Pt(μ-S)$_2$Pt} core, provokes less important geometric constraints

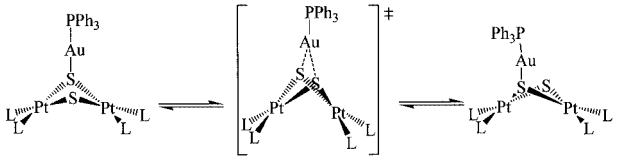

Scheme 6. Fast intramolecular exchange of the $[AuPPh_3]^+$ group in the $[L_2Pt(\mu\text{-}S)\{\mu\text{-}S\text{-}(AuPPh_3)\}PtL_2]^+$ cation

in this core than the proton. In all, the lower flexibility of the $\{Pt_2S_2\}$ ring in $[(PPh_3)_2Pt(\mu\text{-}S)\{\mu\text{-}S\text{-}Au(PPh_3)\}\text{-}Pt(PPh_3)_2]^+$ is not an impediment for the observation of intramolecular exchange of the $[AuPPh_3]^+$ fragment.

The $\{Pt(\mu\text{-}S)_2Pt\}$ Core as Electron-Donor in Redox Processes

An immediate consequence arising from the electronic structure of the $\{Pt(\mu\text{-}S)_2Pt\}$ core is its ability to act as an electron-donor. The more direct way to observe this property is the study of the possible oxidation processes of the $[L_2Pt(\mu\text{-}S)_2PtL_2]$ complexes. Despite the potential interest of the redox properties of $[L_2M(\mu\text{-}X)_2ML_2]$ systems in the field of bioinorganic chemistry,[32−34] this feature had not been considered in the study of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ complexes until very recently. On the other hand, theoretical analysis has allowed to establish that bonding between antipodal atoms in binuclear complexes depends on the total number of electrons in the framework. Thus, qualitative rules anticipate that electrochemical oxidation of the $\{M_2X_2\}$ (M = d^8-metal) core induces formation of X−X or M−M bonds as a result of changing the number of electrons in the framework molecular orbitals.[20,27,32,35] However, experimental evidence showing variations in the connectivity of the atoms in the $\{M(\mu\text{-}X)_2M\}$ rings as a consequence of the redox processes are very scarce.

Recently, the energetic and structural consequences of the successive removal of two electrons from the $\{Pt(\mu\text{-}S)_2Pt\}$ core in $[L_2Pt(\mu\text{-}S)_2PtL_2]$ (L_2 = dppe or dppp) complexes have been studied by combining electrochemical measurements and DFT calculations. Assignment of the structure corresponding to the species involved in the cyclic voltammogram peaks relied on the theoretical calculations.[25] The cyclic voltammetric measurements were indicative of two consecutive monoelectronic oxidations. In addition, cyclic voltammetric data showed that the radical cation $[L_2Pt(\mu\text{-}S)_2PtL_2]^+$ is unstable and gives rise to the disintegration of the $\{Pt(\mu\text{-}S)_2Pt\}$ core. The stability of the oxidized $[L_2Pt(\mu\text{-}S)_2PtL_2]^+$ form is highly dependent on the nature of the terminal ligand, and is greater for dppp than for dppe.

Structural data obtained from theoretical calculations on the species $[L_2Pt(\mu\text{-}S)_2PtL_2]^{n+}$ (n = 0, 1, 2; L_2 = $H_2P(CH_2)_2PH_2$ or $H_2P(CH_2)_3PH_2$) show differences between neutral and monocationic species, the latter having slightly shorter S···S distances and smaller S−Pt−S angles, as well as longer Pt···Pt distances. These changes involve the formation of an incipient S−S bond. The abstraction of a second electron from the $\{Pt(\mu\text{-}S)_2Pt\}$ core enhances the structural tendencies found in the monoxidized complexes. These variations eventually lead to the formation of a S−S bond (S−S = 2.11 Å), with the concomitant lengthening of the Pt···Pt distance (Pt···Pt approximately 3.50 Å) and the larger folding along the S−S axis to give a highly bent geometry (θ = 104 °). In all, the oxidation of the $\{Pt(\mu\text{-}S)_2Pt\}$ core consists of two subsequent one-electron removals, thus giving rise to the bridging of the two metal centers by a disulfide S_2^{2-} ligand. The redox behavior of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ (L_2 = dppe or dppp) together with the main calculated structural features for neutral and oxidized forms in the model compound $[\{H_2P(CH_2)_2PH_2\}Pt(\mu\text{-}S)_2Pt\{H_2P(CH_2)_2PH_2\}]$ are depicted in Scheme 7. The evolution of the NPA (Natural Population Analysis) charges throughout the oxidation process agrees with the oxidation of the sulfur ligands.

With the aim of verifying that theoretical and experimental data were fully consistent, the redox potentials of the oxidation processes were calculated. The accurate calculation of redox potentials is still a very demanding problem, and only very recently the reduction potentials for some small organic molecules have been reported.[36] In large systems, with transition metal atoms, only semi-quantitative results can be expected. The methodology used for the theoretical estimation of the redox potentials involving the oxidation of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds requires calculation of the Gibbs energy of the oxidation reaction in solution, $(\Delta G_{ox})_{sol}$, following the approach based on continuum solvent models.[37] The absolute redox potential can be calculated according to the following expression: $E_{ox} = (\Delta G_{ox})_{sol}/nF$.

To obtain the electrode potential value referenced with respect to a reference electrode it is necessary to calculate the difference between the calculated absolute potential and the absolute potential of the reference electrode. For this purpose, we used the value of +4.43 V assigned to the absolute reduction potential of the hydrogen electrode.[38] The closeness between the electrochemical data and DFT calculations confirmed that the experimentally observed abstraction of two electrons from $[L_2Pt(\mu\text{-}S)_2PtL_2]$ results in the formation of a S−S bond to give the disulfide containing complexes $[L_2Pt(\mu\text{-}S_2)PtL_2]^{2+}$.

Studies devoted to the redox behavior of complexes $[L_2Pt(\mu\text{-}X)_2PtL_2]$ (X = S, Se, Te) are very scarce in the literature. From a theoretical perspective, an early work demonstrated the ability of the $\{Pt(\mu\text{-}Se)_2Pt\}$ core to present a redox behavior similar to that observed for the $\{Pt(\mu\text{-}S)_2Pt\}$ core. Thus, Hartree−Fock calculations on $[(PH_3)_2Pt(\mu\text{-}Se)_2Pt(PH_3)_2]^{n+}$ (n = 0, 2) provided evidence for the formation of a Se−Se bond as a result of the oxidation of the $\{Pt(\mu\text{-}Se)_2Pt\}$ core.[21] The closest work to the study of the redox properties of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ complexes consists of the isolation and characterization of $[(PEt_3)_2Pt(\mu\text{-}Te)_2Pt(PEt_3)_2]$ and $[(PEt_3)_2Pt(\mu\text{-}Te_2)Pt(PEt_3)_2]^{2+}$.[23] Analogously to the $\{Pt(\mu\text{-}S)_2Pt\}$ core, chemical oxidation of $[(PEt_3)_2Pt(\mu\text{-}Te)_2Pt(PEt_3)_2]$ causes a decrease in the Te−Te distance from a nonbonding (3.263 Å) to a bonding dis-

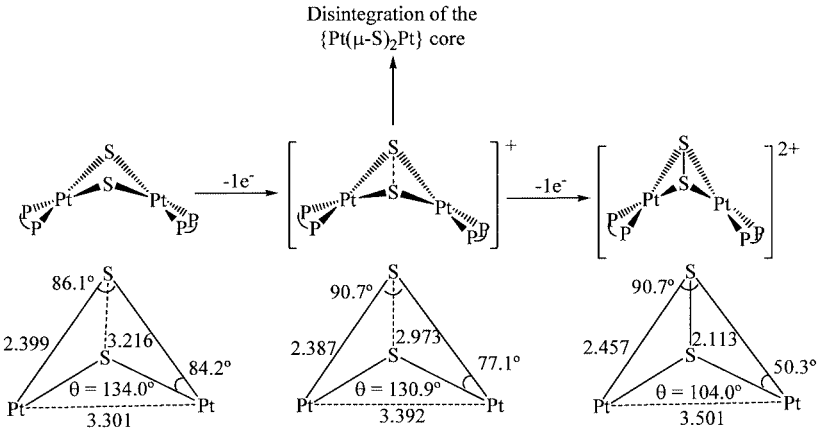

Scheme 7. Redox behavior of [L_2Pt(μ-S)$_2$PtL_2] (L_2 = dppe or dppp); calculated main structural parameters for [Pt_2{$H_2P(CH_2)_2PH_2$}$_2$(μ-S)$_2$]$^{n+}$ (n = 0, 1 or 2) are included

tance (2.695 Å), indicating the formation of a Te−Te bond in the dication.

According to the experimental CV data, the difficulties found in determining all the species involved in the oxidation of the {Pt_2S_2} core arise from the disintegration of the monocationic species, which leads to the well-known trimetallic [{L_2Pt(μ$_3$-S)$_2$PtL_2}PtL_2]$^{2+}$ complex as the main product. Calculations of the thermodynamics of possible processes following disintegration of [L_2Pt(μ-S)$_2$PtL_2]$^+$ show that the most favorable process involves the recombination of two [L_2Pt(μ-S)$_2$PtL_2]$^+$ species to give the cited trimetallic complex and the neutral mononuclear [L_2Pt(S_2)] complex.

Complexes with functionalized {Pt(μ-S)$_2$Pt} cores are also able to show redox properties. In [(PPh_3)$_2$Pt(μ-S)(μ-SHgR))Pt(PPh_3)$_2$]$^+$, the observed process consists of the monoelectronic oxidation of the sulfide ligand that is not coordinated to the mercury atom.[39] However, the poor solubility of [(PPh_3)$_2$Pt(μ-S)$_2$Pt(PPh_3)$_2$] hampered comparison between the redox properties of the {Pt(μ-S)$_2$Pt} and {Pt(μ-S)(μ-SHg)Pt}$^+$ cores. Notwithstanding this, results obtained with the highly soluble [L_2Pt(μ-S)$_2$PtL_2] (L_2 = dppe or dppp) are consistent with the hypothesis presented by Hor et al., indicating that the sulfide ligands in the {Pt(μ-S)$_2$Pt} fragment are electroactive.

When the two sulfur atoms of the {Pt(μ-S)$_2$Pt} core act as electron-donors towards a metal center, a different redox activity is observed. Thus, electrochemical studies on the trimetallic clusters [{L_2Pt(μ$_3$-S)$_2$PtL_2}PtL_2]$^{2+}$ (L_2 = dppm, dppe, dppp, dppb) have shown that the cationic core {Pt_3(μ$_3$-S)$_2$}$^{2+}$ is able to accept one electron, as observed by means of cyclic voltammetric measurements.[40] These data indicate that the electron-donor properties of the {Pt(μ-S)$_2$Pt} core can be reversed, thus becoming an electron-acceptor, after coordination to a metal center. The electrochemical features of this family of trimetallic complexes are also highly dependent on the chelate ring size of the phosphane ligands.

Compounds [L_2Pt(μ-S)$_2$PtL_2] as Metalloligands to Metal Centers

Homo- and Heterometallic Derivatives of [L_2Pt(μ-S)$_2$PtL_2]

The behavior of [L_2Pt(μ-S)$_2$PtL_2] (L = phosphane) as a metalloligand to metal centers has prompted most of the research undertaken in this field of chemistry. The electronic and dynamic properties of the {Pt(μ-S)$_2$Pt} core, already explained, account for the outstanding ability of [L_2Pt(μ-S)$_2$PtL_2] compounds to act as building blocks for higher nuclearity aggregates with the general formula [{L_2Pt(μ$_3$-S)$_2$$L_2$}$_xML'_y$]^z. At the same time, the wide coordination environments offered by main group or transition metals together with the nature of their accompanying L′ species, either ligands or counter ions, enhance the structural diversity of this family of derivatives. As depicted in Scheme 8, aggregates of known structure include those with varied coordination geometries about the heterometal: linear,[41,42] angular,[43] T-shaped,[42,44] Y-shaped,[45] tetrahedral,[12,15,46] square planar,[12,47] square pyramidal,[48] distorted trigonal prismatic,[49] trigonal bipyramidal,[50] hexagonal bipyramidal,[51] "piano stool"[52] and others.[53,54] These aggregates also display the ability of the [L_2Pt(μ-S)$_2$PtL_2] metalloligand to function as a unidentate,[41] bridging,[53] or chelating ligand.[52] Concerning the nature of the heterometal M, a wide range of p- and d-block elements have been studied. Those included in [{L_2Pt(μ$_3$-S)$_2$$L_2$}$_xML'_y$]^z aggregates described subsequently to the earlier report by Fong and Hor,[8] are the following: V^V,[51] Mo^{VI},[51] Re^I,[50] Os^{II},[52] Rh^{III},[52] Ir^{III},[52] Zn^{II},[12,48] Cd^{II},[12,48] U^{VI},[51] and Sn^{IV}.[29] Moreover, it is remarkable that [L_2Pt(μ-S)$_2$PtL_2] metalloligands allow stabilization of oxidation states that are unstable in sulfur-thiolate environments as it occurs in tetrahedral {M^{II}(SR)$_4$}$^{2-}$, M = Co[55] or Cu,[15] complexes. Overall, on the basis of this formidable body of information, it seems that current knowledge on the wide family of the homo- and heterometallic deriva-

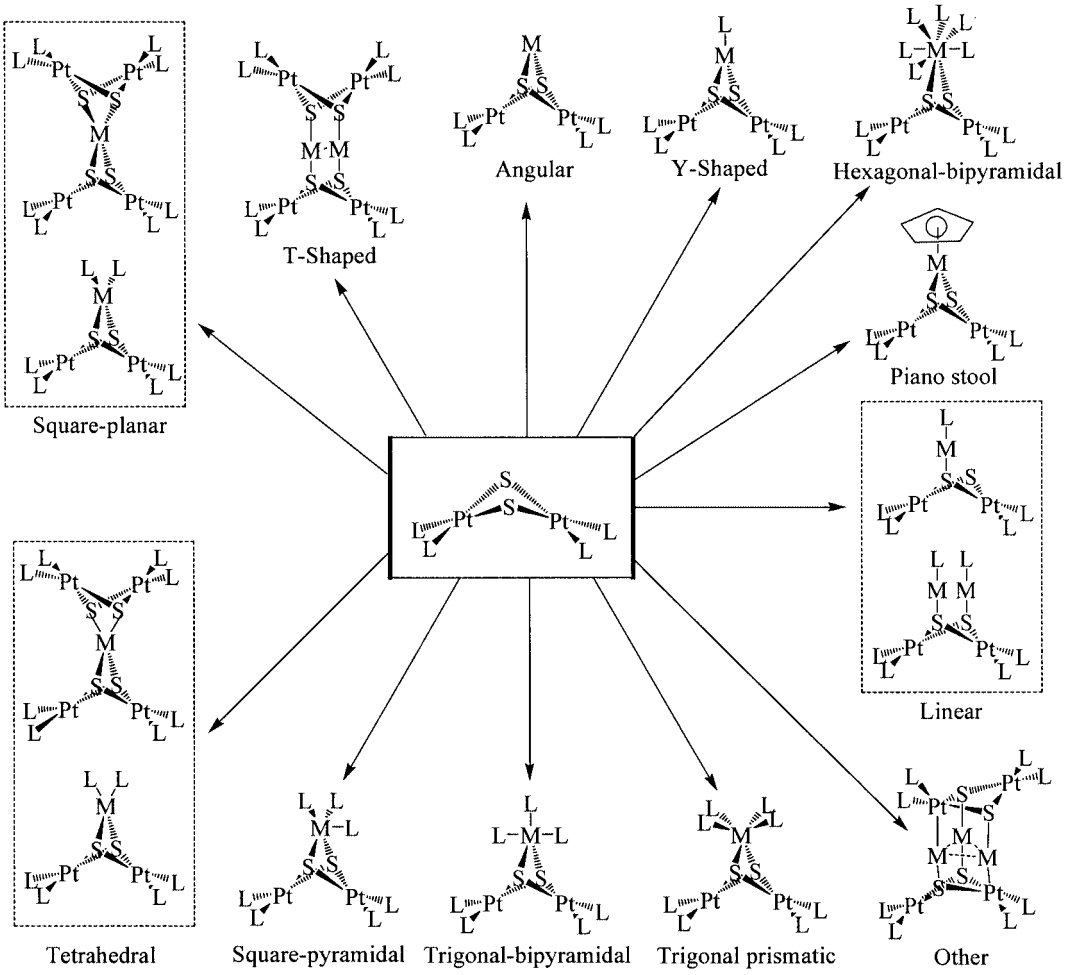


Scheme 8. Coordination environments at M in $[\{L_2Pt(\mu\text{-}S)_2PtL_2\}_xML'_y]^z$ aggregates

tives of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds has achieved a considerable degree of maturity.

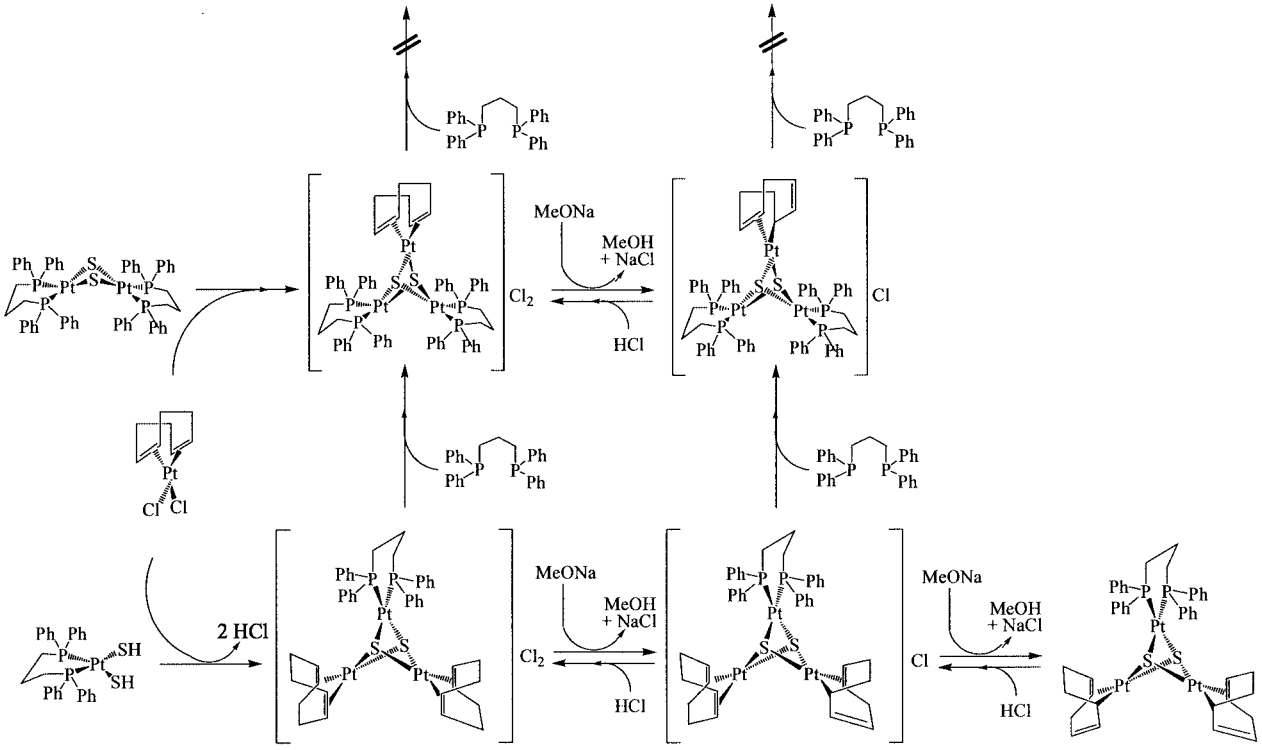
The suitability of electrospray mass spectrometry (ESI MS) to characterize charged inorganic species in solution has allowed its use for probing the reactivity of the $\{Pt(\mu\text{-}S)_2Pt\}$ core towards metal ions. This technique has proved very effective in providing a preliminary detection and characterization of the heterometallic aggregates predominant in solution as a result of a particular reaction. On the basis of the good correlation found between the ESI mass spectra and synthesis-scale reactions, the synthetic strategies can thus be focused on the synthesis of those aggregates that are supported by ESI MS evidence.[29,30]

Influence of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ on the Reactivity of ML′ Fragments

Significantly, despite the widespread attention devoted to the synthesis and characterization of $[\{L_2Pt(\mu_3\text{-}S)_2L_2\}_xML'_y]^z$ aggregates, studies on the influence of the $[L_2Pt(\mu\text{-}S)_2PtL_2]$ metalloligand on the reactivity of L′ remained unreported. In order to fill this gap, we recently described the synthesis and structural characterization of complexes $[\{(dppp)Pt(\mu\text{-}S)_2Pt(dppp)\}PtL']^z$ (L′ = cod,[11] $z = 2+$ or L′ = 2Cl, $z = 0$[56]), and studied the substitution reactions of cod and chloride ligands. Experimental results showed that cod was substitutionally inert towards dppp while chloride was easily replaced by dmso or phosphane ligands. These features were inconsistent with the common procedure used to obtain $[PtCl_2(dppp)]$ from $[PtCl_2(cod)]$ and dppp, and with the usual stability of $[PtCl_2(dppp)]$ in dmso solvent. Within this context, the influence of $[(dppp)Pt(\mu\text{-}S)_2Pt(dppp)]$ on the reactivity of the $\{Pt(cod)\}^{II}$ or $\{PtCl_2\}$ fragments deserved further consideration. Results obtained on the unusual reactivity observed for $[\{(dppp)Pt(\mu\text{-}S)_2Pt(dppp)\}Pt(cod)]^{2+}$ in the presence of $NaCH_3O$ are described below. Those concerning the substitution of chloride ligands in $[\{(dppp)Pt(\mu\text{-}S)_2Pt(dppp)\}PtCl_2]$ are given in the next section.

With the aim of exploring the influence of the $\{Pt(\mu\text{-}S)_2Pt\}$ core on the reactivity of the $\{Pt(cod)\}^{II}$ fragment, we obtained complexes $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}Pt(cod)]Cl_2$ and $[\{Pt_2(\mu_3\text{-}S)_2(cod)_2\}Pt(dppp)]Cl_2$ by reacting $[Pt_2(\mu\text{-}S)_2(dppp)_2]$ and $[PtCl_2(cod)]$ (1:1), and $[Pt(SH)_2(dppp)]$ and $[PtCl_2(cod)]$ (1:2), respectively.[11] In contrast with the general behavior of cationic olefin complexes of platinum,[57,58] the synthesized complexes did not undergo spontaneous loss of the unsaturated ligand and thus allowed exploration of their reactivity towards a strong nucleophile such as so-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 9. Reactivity of cod containing derivatives of $[L_2Pt(\mu\text{-}S)_2PtL_2]$

dium methoxide (Scheme 9). Remarkably, unlike previous reports on the attack of $NaCH_3O$ on the $\{Pt(cod)\}^{II}$ fragment,[59][60] the above reactions did not promote the nucleophilic attack of the methoxide anion, but only deprotonation of cod, thus leading to $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}Pt(C_8H_{11})]Cl$, $[\{Pt_2(\mu_3\text{-}S)_2(cod)(C_8H_{11})\}Pt(dppp)]Cl$ and $[\{Pt_2(\mu_3\text{-}S)_2(C_8H_{11})_2\}Pt(dppp)]$. Concerning the substitution of cod, in neutral or anionic form, by dppp, the five complexes obtained behaved differently. Those containing the $\{Pt_2(\mu_2\text{-}S)_2(dppp)_2\}$ moiety were substitutionally inert. By contrast, those based on the $\{Pt_2(\mu_2\text{-}S)_2(dppp)L\}$ moiety with $L = C_8H_{12}$ or $C_8H_{11}^-$ underwent the substitution reaction readily. However, DFT calculations indicated that thermodynamic factors were not responsible for the observed differences. Consequently, kinetic effects should account for the reluctance of the ligand cod to be replaced by dppp in $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}Pt(cod)]^{2+}$ and $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}Pt(C_8H_{11})]^+$, where the steric hindrance imposed by $\{Pt_2(\mu_2\text{-}S)_2(dppp)_2\}$ disfavors an associative pathway for the corresponding exchange reactions.

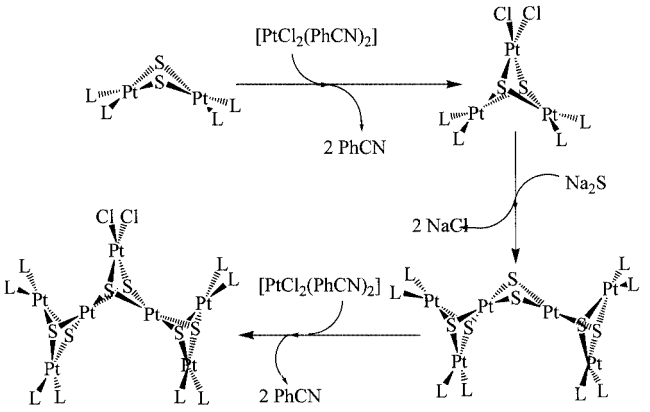
An interesting example to test the influence of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ on the properties of a $\{ML'_y\}$ fragment has recently been provided by Brunner et al.,[61] who synthesized the heterometallic trinuclear complex $[\{Pt_2(\mu\text{-}S)_2[\{(-)\text{-diop}\}]Rh(cod)]Cl$ by reacting the chiral $[Pt_2(\mu\text{-}S)_2\{(-)\text{-diop}\}]$ metalloligand with $[Rh(cod)Cl]_2$. However, its further use as a catalyst in enantioselective transformations afforded moderate results, which are mainly attributed to the reluctance of cod to be displaced from the trinuclear complex. This observation is consistent with the low tendency of cod in $[\{(PPh_3)_2Pt(\mu\text{-}S)_2Pt(PPh_3)_2\}Rh(cod)]^+$ to be substituted by H_2, CO, SO_2, and dppe, as reported by Briant et al. in 1985.[62] Overall, reported results fully confirm that the binding of the $[L_2Pt(\mu\text{-}S)_2PtL_2]$ metalloligand to $\{Pt(cod)\}^{2+}$ or $\{Rh(cod)\}^+$ causes profound alterations in the chemistry of such fragments. Extension of these findings to other fragments and studies on the influence of terminal L ligands on their properties may provide new perspectives within the area of organometallic chemistry.

$[L_2Pt(\mu\text{-}S)_2PtL_2]$ Compounds as Building Blocks

Further evidence of the influence of the $\{Pt(\mu\text{-}S)_2Pt\}$ core on the reactivity of bonded ML'_y fragments was recently provided by the lability of chloride ligands in $[\{(dppp)Pt(\mu\text{-}S)_2Pt(dppp)\}PtCl_2]$.[56] This became apparent through independent experimental data: (i) the partial or total loss of chloride ligands in some of the species identified in the characterization of this compound by ESI MS; (ii) the isolation of $[\{(dppp)Pt(\mu\text{-}S)_2Pt(dppp)\}PtCl(dmso)]Cl$ when the former complex is dissolved in dmso; and (iii) the displacement of chloride ligands by formation of $[\{(dppp)Pt(\mu\text{-}S)_2Pt(dppp)\}Pt(dppp)]Cl_2$ after addition of an stoichiometric amount of dppp. All these findings were in good agreement with previous reports on the lability of chloride ligand in the $[\{(PPh_3)_2Pt(\mu\text{-}S)_2Pt(PPh_3)_2\}PtCl(PPh_3)]^+$ complex.[63]

On the basis of the ability of the $\{Pt(\mu\text{-}S)_2Pt\}$ core to facilitate substitution of chloride ligands in $[\{Pt_2S_2\}PtCl_2]$ fragments, we designed a novel route to obtain multimetallic aggregates containing a $\{Pt_2S_2\}_n$ core (Scheme 10). The synthetic strategy involves first the expansion of the $\{Pt_2S_2\}$ ring to a $[\{Pt_2S_2\}PtCl_2]$ moiety. Replacement of chloride ligands by sulfide then causes the $\{PtCl_2\}$ fragment to form a $\{Pt_2S_2\}$ linking unit between two $\{Pt_2S_2\}$ rings, thus af-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 10. Synthetic strategy to obtain multimetallic complexes containing the $\{Pt(\mu\text{-}S)_2Pt\}_n$ core

fording a new $[\{Pt_2S_2\}_2\{Pt_2S_2\}]$ core. Its subsequent evolution into $[\{Pt_2S_2\}_3PtCl_2]$ lays the foundation for a new cycle.

According to the first step in Scheme 10, the reaction between $[(dppp)Pt(\mu\text{-}S)_2Pt(dppp)]$ and $[PtCl_2(PhCN)_2]$ afforded the unprecedented trinuclear $[\{(dppp)Pt(\mu\text{-}S)_2Pt(dppp)\}PtCl_2]$ complex, in spite of the fact that other nuclearities had been proposed for related complexes obtained under similar reaction conditions.[47,64] Another interesting feature as a result of the reactions depicted in Scheme 10 is that the characterization of the high nuclearity complexes $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}_2\{Pt_2(\mu\text{-}S)_2\}]$ and $[\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}Pt_2(\mu_3\text{-}S)_2PtCl_2\{Pt_2(\mu_3\text{-}S)_2(dppp)_2\}]$ was mainly achieved by means of MALDI-TOF mass spectrometry, which thus revealed its potential use in further studies.

In all, while high nuclearity heterometallic derivatives of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ had been reported,[42,53] the systematic approach described above to obtain multimetallic derivatives is unprecedented. In fact, it demonstrates that the nucleophilicity of the $\{Pt(\mu\text{-}S)_2Pt\}$ core can be driven to build nuclearity-controlled multinuclear aggregates containing a $\{Pt_2S_2\}_n$ core. Extension of the same strategy to other metals with square-planar coordination may allow control of the size of metal chalcogenide compounds and thus of their properties and potential applications.

Reactivity towards Non-Metallic Electrophiles

Organic Electrophiles

The nucleophilicity of the sulfide bridges in the $\{Pt(\mu\text{-}S)_2Pt\}$ core towards organic electrophiles was established as a result of the reaction of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ (L = PMe_2Ph, PPh_3) compounds with $PhCH_2Br$[6] or CH_3I.[7] These reactions led to the corresponding monoalkylated cation $[L_2Pt(\mu\text{-}S)(\mu\text{-}SR)PtL_2]^+$ (R = Me or CH_2Ph), even if stoichiometric excess of the alkyl halide was present. Very recently, extension of the previous reaction to organic dihal-

ides has allowed isolation of the dialkylated derivative $[(PPh_3)_2Pt(\mu\text{-}(SC_2H_4S)\text{-}S,S')Pt(PPh_3)_2]$ by reacting $[(PPh_3)_2Pt(\mu\text{-}S)_2Pt(PPh_3)_2]$ with 100-fold excess of 1,2-dichloroethane.[65] Similar double alkylations have been achieved in complexes containing the $\{Pt(\mu\text{-}Se)_2Pt\}$[66,67] or $\{Ni(\mu\text{-}S)_2Ni\}$[18] core.

A particular case of the previous reaction involving organic halides is the surprising progression of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds when they are dissolved in chlorinated solvents, mainly CH_2Cl_2. Thus, in recent years, several different species have been characterized as a result of often unexpected reactions in this solvent (Table 3).[9,14,46,68−71] The first attempt to account for the apparent dispersion of the compounds obtained is due to Fong and Hor, who proposed a possible mechanism for the formation of various thiolato complexes from the disintegration of the $\{Pt(\mu\text{-}S)_2Pt\}$ core in CH_2Cl_2.[8] However, the lack of a systematic study prompted us to monitor the reaction of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ (L_2 = dppe, dppp) with CH_2Cl_2 by means of ^{31}P, ^1H, and ^{13}C NMR spectroscopy, electrospray mass spectrometry, and X-ray data.[9] DFT calculations were also performed to obtain an energetic picture of the process. It is worth noting that the main information on both reactions was obtained by a series of $^{31}P\{^1H\}$ NMR spectra recorded as a function of time, as shown in Figure 4. These results allowed us not only to formulate all the steps involved from the initial to the final products (Scheme 11), but also to account for the nature and diversity of the compounds reported in closely related systems (Table 3).

The evolution of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds with various phosphanes as terminal ligands (L = PMe_2Ph, PPh_2py, PPh_3; L_2 = dppf, dppe, dppp) upon exposure to the weak alkylating agent CH_2Cl_2 is depicted in Scheme 11. Thus, the first step of the reaction involves monoalkylation of the corresponding $\{Pt(\mu\text{-}S)_2Pt\}$ core to yield spectroscopically identifiable intermediates with the formula $[L_2\{Pt(\mu\text{-}S)(\mu\text{-}SCH_2Cl)Pt\}L_2]^+$,[9,68,69] whose energy is only slightly higher than that of the reactants. The monoalkylated intermediates subsequently undergo an internal self-alkylation process to afford $[L_2\{Pt(\mu\text{-}S_2CH_2)Pt\}L_2]^{2+}$ species, of elusive nature, but fully consistent with the double alkylation reported as a result of the reaction between $[(PPh_3)_2Pt(\mu\text{-}S)_2Pt(PPh_3)_2]$ and 1,2-dichloroethane. Calculations indicate that $[L_2\{Pt(\mu\text{-}S_2CH_2)Pt\}L_2]^{2+}$ are highly unstable species, that should decompose to give the monometallic complexes $[L_2PtCl_2]$ and $[L_2Pt(S_2CH_2)]$. Consistently, further pro-

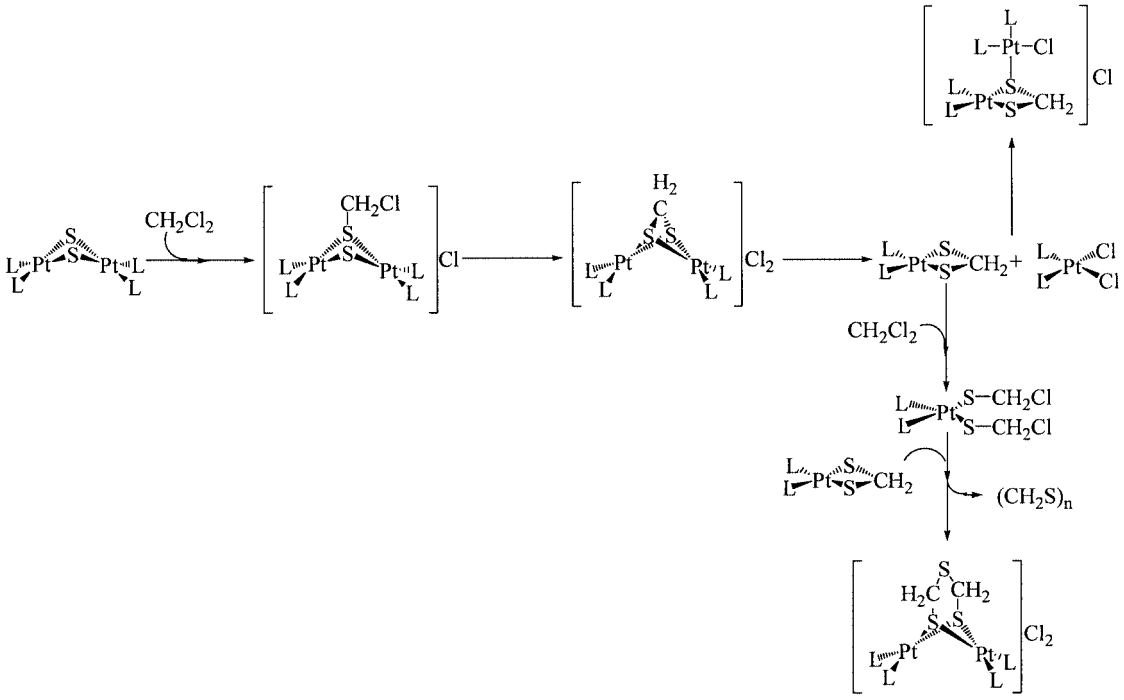
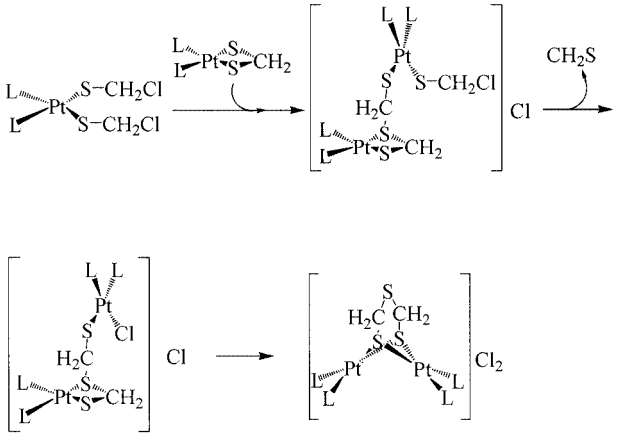


Scheme 11. Reaction pathway corresponding to the evolution of compounds $[L_2Pt(\mu\text{-}S)_2PtL_2]$ in CH_2Cl_2; the nature of phosphane L ligands is given in the text

gression of $[L_2\{Pt(\mu\text{-}S_2CH_2)Pt\}L_2]^{2+}$ leads to a mixture of the above monometallic products. Compound $[L_2PtCl_2]$ is well-established in the literature for a wide range of terminal ligands, and $[L_2Pt(S_2CH_2)]$ has been fully characterized for L = PMe_2Ph,[70] dppy,[14] dppe,[9] and dppp[9] (Table 3). Remarkably, up to this stage, the reaction pathway is common for all $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds (L = PMe_2Ph, PPh_2py, PPh_3; L_2 = dppf, dppe, dppp); further evolution is dependent on the nature of the terminal ligands. Thus, for PMe_2Ph, PPh_2py and dppe, the reaction of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ with CH_2Cl_2 does not progress any further after formation of the corresponding $[L_2PtCl_2]$ and $[L_2Pt(S_2CH_2)]$ compounds. Significantly, the latter species form faster for dppe- than for dppp-containing complexes.

Further evolution of the reaction mixture of $[L_2PtCl_2]$ and $[L_2Pt(S_2CH_2)]$ in CH_2Cl_2 depends on the nucleophilicity of the sulfur atoms in the latter compound. Hence, activation of a second molecule of CH_2Cl_2 yields complex $[L_2Pt(SCH_2Cl)_2]$, as observed for L_2 = dppf.[69] Subsequent activation of the C−Cl bonds in the latter compound by reaction with an additional molecule of $[L_2Pt(S_2CH_2)]$ leads to the bimetallic complex $[L_2Pt\{\mu\text{-}(SCH_2SCH_2S)\text{-}S,S'\}PtL_2]Cl_2$, by means of the mechanism depicted in Scheme 12, as observed for L_2 = dppp.[9] Surprisingly, the evolution of $[L_2PtCl_2]$ and $[L_2Pt(S_2CH_2)]$ for L = PPh_3 has shown two different alternatives. On the one hand, analogously to that observed for L_2 = dppf, complex $[(PPh_3)_2Pt(SCH_2Cl)_2]$ was isolated.[71] However, in addition, the condensation reaction between $[(PPh_3)_2PtCl_2]$ and $[(PPh_3)_2Pt(S_2CH_2)]$ to afford $[(PPh_3)_2Pt(S_2CH_2)Pt(PPh_3)_2Cl]Cl$ has recently been described.[46]



Scheme 12. Mechanism of the evolution from $[L_2Pt(SCH_2Cl)_2]$ to $[L_2Pt\{\mu\text{-}[S_3(CH_2)_2]\}PtL_2]Cl_2$ as observed for L_2 = dppp

Overall, the reactivity of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ towards CH_2Cl_2 provides evidence for the complex sequence of reactions triggered by the nucleophilicity of the sulfur atoms in the $\{Pt_2S_2\}$ core and shows the ability of the terminal phosphane ligands to tune such reactions. On the basis of the high number and different natures of the isolated species, it seems that the reaction of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ with organic electrophilic agents deserves further attention.

Protic Acids

A nice demonstration of the nucleophilicity of the sulfur atoms in the $\{Pt(\mu\text{-}S)_2Pt\}$ ring should be provided by the reaction of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds with the simplest

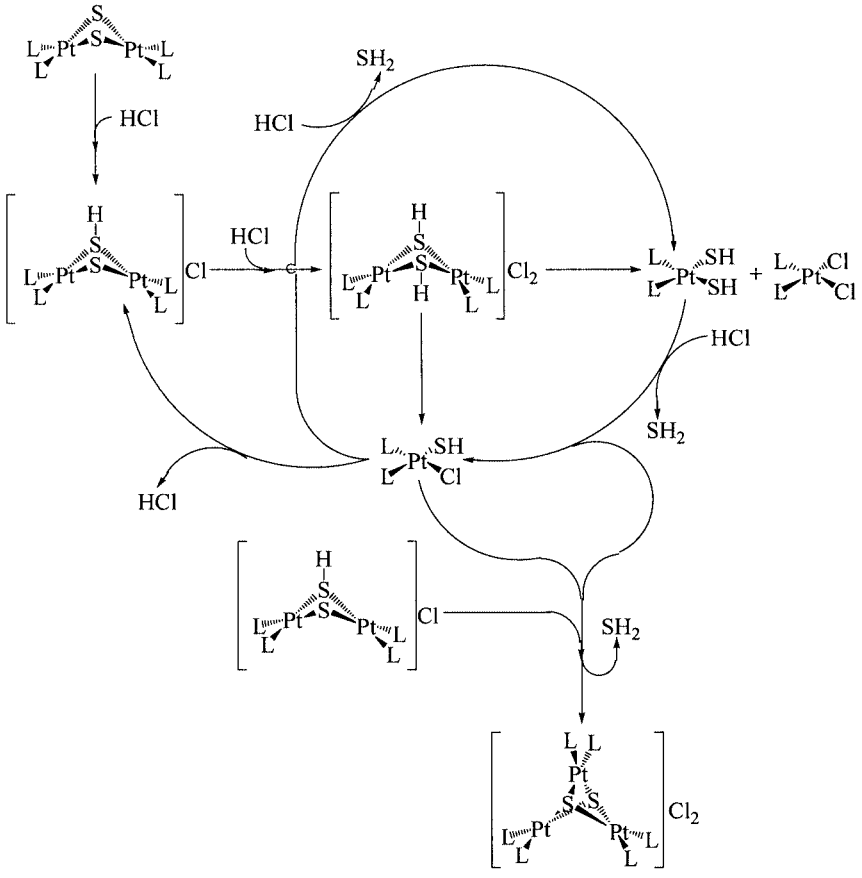
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

electron-acceptor species, i.e. the proton. In other words, the well-established reactivity of [L_2Pt(μ-S)$_2$PtL_2] towards metal centers and organic electrophiles assures the basic character of such compounds in the presence of protic acids. Notwithstanding this, the systematic study of these properties had not been undertaken until very recently. As a result, the whole set of reactions ensuing the protonation of the {Pt(μ-S)$_2$Pt} core has been established for L_2 = dppe and dppp.[10]

The first evidence of the protonation of [L_2Pt(μ-S)$_2$PtL_2] compounds were provided by Hor et al. who fully characterized the [(PPh$_3$)$_2$Pt(μ-S)(μ-SH)Pt(PPh$_3$)$_2$]$^+$ cation following its previous identification by ESI MS measurements.[29,30] However, consistently with the results obtained for L_2 = dppe and dppp,[10] the corresponding diprotonated [(PPh$_3$)$_2$Pt(μ-SH)$_2$Pt(PPh$_3$)$_2$]$^{2+}$ complex was not isolated. Remarkably, the only example of a {Pt(μ-SH)$_2$Pt} core was found for L = $C_6F_5^-$, although in this case neither the monoprotonated nor the totally deprotonated precursors were described.[72] As opposed to the reluctance of the {Pt(μ-S)$_2$Pt} core to afford complexes [L_2Pt(μ-SH)$_2$PtL_2]$^{2+}$ (L = phosphane), its [(PPh$_3$)$_2$Pt(μ-SeH)$_2$Pt(PPh$_3$)$_2$]$^{2+}$ analog is the only species reported as a result of the protonation of the {Pt(μ-Se)$_2$Pt} core.[73]

The reaction pathways by which compounds [L_2Pt(μ-S)$_2$PtL_2] (L_2 = dppe, dppp) react with protic acids were obtained by monitoring their titration with HCl (Scheme 13) or $HClO_4$ by ^{31}P{H} NMR spectroscopy and mass spectrometric techniques.[10] Characterization of all the species involved required previous isolation and structural characterization of [Pt(SH)$_2$$L_2$] and [{$L_2$Pt(μ-S)$_2PtL_2$}Pt$L_2$]$^{2+}$, for both dppe and dppp ligands. DFT calculations corroborated the thermodynamic feasibility of the reactions proposed on the basis of the experimental data. The first protonation step leads to the structurally characterized [L_2Pt(μ-S)(μ-SH)PtL_2]$^+$ cations, but the second step implies disintegration of the platinum-sulfur ring, thus giving rise to various mononuclear species. The subsequent evolution of some of these species allows regeneration of [L_2Pt(μ-S)(μ-SH)PtL_2]$^+$, while formation of complexes [Pt$Cl_2$$L_2$] and [{$L_2$Pt(μ-S)$_2PtL_2$}Pt$L_2$]$^{2+}$ is responsible for the cycles' dead end. Whereas the reaction pathway is essentially common for both phosphane ligands, dppe and dppp, the different coordinating ability of Cl^- or ClO_4^- determines the nature of the final products, a mixture of [Pt$Cl_2$$L_2$] and [{$L_2$Pt(μ-S)$_2PtL_2$}Pt$L_2$]$Cl_2$ or only [{L_2Pt(μ-S)$_2$PtL_2}PtL_2](ClO_4)$_2$.

The previous results show that the evolution of complexes [L_2Pt(μ-S)$_2$PtL_2] (L_2 = dppe or dppp) in the presence of protic acids depends on several factors: (i) the concentration and nature of the protic acid, i.e. the coordinative features of the conjugate anion; (ii) the nature of the ter-



Scheme 13. Reaction pathway corresponding to the evolution of [L_2Pt(μ-S)$_2$PtL_2] upon exposure to HCl as observed for L_2 = dppe or dppp

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

minal phosphane ligand, dppe containing species are more reactive than those with dppp; and (iii) the reaction medium used, the amount of $[Pt_3(\mu_3\text{-}S)_2(L_2)_3]^{2+}$ formed is directly related to the polarity of the solvent.

In summary, the reaction of compounds $[L_2Pt(\mu\text{-}S)_2PtL_2]$ (L_2 = dppe or dppp) with protic acids provides a new insight into the exceptionally rich chemistry arising from the nucleophilicity of the $\{Pt_2S_2\}$ core. On the one hand, protonation of the stable monoprotonated $[L_2Pt(\mu\text{-}S)(\mu\text{-}SH)PtL_2]^+$ complexes triggers a cascade of sequential reactions by which compounds $[Pt(SH)_2L_2]$ are formed. These are the keystone species for regenerating $[L_2Pt(\mu\text{-}S)(\mu\text{-}SH)PtL_2]^+$ complexes, and thus for the cyclical nature of the overall process. Remarkably, complex species containing the Pt−SH fragment, which is present in the above complexes, have been proposed as intermediates in the removal of sulfur as SH_2 from petroleum feedstock, known as hydrodesulfurization (HDS).[74−76] Both the cyclical nature of the processes described and the relevance of complexes containing the Pt−SH fragment in HDS provide additional interest to the results obtained with respect to their potential catalytic applications.

Concluding Remarks and Perspectives

The chemistry of compounds $[L_2Pt(\mu\text{-}S)_2PtL_2]$ (L = phosphane) is becoming increasingly important because of the exceptional ability of the $\{Pt_2S_2\}$ core to act as a powerful nucleophile towards virtually any electron-acceptor species. While its behavior as a metalloligand to metal centers has attracted unceasing attention, exploration of the chemistry involved in the reaction with nonmetal electrophiles has emerged in the recent years. The outstanding richness of this chemistry is witnessed by the cascade of reactions that the $\{Pt_2S_2\}$ core undergoes upon exposure to organic electrophiles and protic acids. The cyclical nature of some of these reactions as well as some of the intermediate species involved are promising for possible catalytic applications. In addition, the unusual reactivity of $\{ML'_y\}$ fragments in $[\{L_2Pt(\mu\text{-}S)_2PtL_2\}ML'_y]^z$ compounds has allowed taking advantage of the influence of the $\{Pt(\mu\text{-}S)_2Pt\}$ core to substantially modify the chemistry of either organic or inorganic L′ ligands. Because of this influence, an atypical C−H allylic activation for cod and an enhanced lability for chloride ligands have been established. The former allows envisaging further developments in organometallic chemistry. The latter has led to a novel route for the building of nuclearity-controlled multimetallic aggregates containing a $\{Pt_2S_2\}_n$ core that may be of use to obtain metal chalcogenide compounds of definite size and thus specific properties.

Our interest in exploring the chemistry of $[L_2Pt(\mu\text{-}S)_2PtL_2]$ compounds has been widely rewarded by its exceptional richness and diversity. Further developments will contribute to establish the still undefined limits of the nucleophilicity of the $\{Pt_2S_2\}$ core, as well as to find applications of this reactivity in main areas of chemistry. The potential of the $\{Pt_2S_2\}$ core to activate slightly polarized bonds involving carbon atom is the aim of our research for future studies.

Acknowledgments

We wish to thank our coworkers, who are cited in the literature section, for their numerous contributions and Prof. William Clegg for his extremely valuable crystallographic studies. We are also grateful to the Ministerio de Educación y Ciencia of Spain (projects CTQ2004-01463/BQ4 and BQU2002-04110-CO2-02) for financial support.

Monocarbaborane Chemistry: Cage Opening of *nido*-1-CB_8H_{12} by Tertiary Bases − an Example of a Straightforward *nido* → *arachno* Transformation; Isolation of a New Series of 4-L-*arachno*-5-CB_8H_{12} Compounds (L = NMe_3, NEt_3, and Quinoline)

Bohumil Štíbr,*[a,b] Josef Holub,[a] Mario Bakardjiev,[a] Wolfgang Milius,[b] and Bernd Wrackmeyer[b]

Keywords: Boranes / Carboranes / Monocarbaboranes / NMR spectroscopy / X-ray diffraction

Room-temperature reactions between the carborane *nido*-1-CB_8H_{12} (**1**) and selected tertiary Lewis bases [L = NMe_3, NEt_3, and quinoline (quin)] in CH_2Cl_2 at room temperature for 24 h resulted in the isolation of a series of 4-L-*arachno*-5-CB_8H_{12} compounds (**2**; L = NMe_3, **2a**, L = NEt_3, **2b** and L = quin, **2c**). This main reaction mode can be classified as a straightforward *nido* → *arachno* transformation and was characterized by a cage opening of the original pentagonal face in **1** by L at the bridging site adjacent to the carbon apex with the formation of a hexagonal open face. The formation of **2a** was clean, whereas that of **2c** was accompanied by formation of the *closo*-[4-CB_8H_9]$^-$ (**3**) anion as a side-product. The first representative of the zwitterionic 1-L-*closo*-4-CB_8H_8 (**4**) series, 1-quin-*closo*-4-CB_8H_8 (**4c**), was isolated as another side product from the quinoline reaction. The structure of compound **2b** was determined by an X-ray diffraction analysis and the constitution of all compounds is consistent with the results of mass spectrometry. Multinuclear (^1H, ^{11}B, and ^{13}C), two-dimensional [^{11}B-^{11}B]-COSY, and $^1H\{^{11}B$(selective)$\}$ magnetic resonance measurements lead to complete assignments of all resonances and are in excellent agreement with the structures proposed.

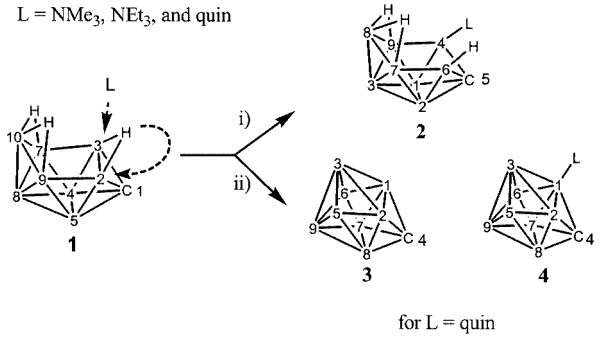
Introduction

Although the *nido*-1-CB_8H_{12} (**1**) carborane has been known since 1977,[1] not much chemistry of this interesting compound has so far been reported. Carborane **1** was employed as a starting material for the preparation of the smaller monocarbaborane anions [2-CB_6H_7]$^-$, [1-CB_7H_8]$^-$, and [4-CB_8H_9]$^-$ (**3**), completing a series of the parent seven,[2] eight,[2,3] and nine-vertex[4] *closo* monocarbaboranes. The sole example of metallacarborane chemistry based on carborane **1** so far, has been the synthesis of the platinacarborane [6,6-$(PPh_3)_2$-*arachno*-6,4-$PtCB_7H_{11}$].[5] In the present work, we have extended the rather undeveloped chemistry of carborane **1** by its room-temperature reactions with selected tertiary amines (L = NMe_3, NEt_3, and quin). We would like to demonstrate that these reactions lead to a simple opening of the *nido* cage in **1** and the formation of a series of corresponding 4-L-*arachno*-5-CB_8H_{12} compounds. Numbering systems for the nine-vertex *closo*, *nido*, and *arachno* skeletons used in this work are given in Scheme 1. Structures are presented in a simplified manner; unmarked vertices in Scheme 1 stand for cluster BH units, while C denotes the CH vertex.



Scheme 1. Simplified scheme for the cluster opening in *nido*-1-CB_8H_{12} (**1**) by selected tertiary Lewis bases (L = NMe_3, NEt_3, and quinoline) and the formation of side products; i) L, ambient temperature, main reaction mode; ii) side reaction mode

Results and Discussion

As shown in path i) of Scheme 1, room-temperature reactions of the *nido*-1-CB_8H_{12} (**1**) monocarbaborane with

selected tertiary amines (L = Me_3N, Et_3N, and quin) in dichloromethane afforded a series of Lewis-base adducts of general formula 4-L-*arachno*-5-CB_8H_{12} (**2**) (**2a** for L = Me_3N, **2b** for L = Et_3N, and **2c** for L = quin) as the main reaction products in yields of 96, 36, and 35 %, respectively.

The formation of compounds of type **2** in this reaction can be classified as a clean *nido* → *arachno* transformation, in which the base L adds two more cluster electrons to the original 22-electron *nido* system of **1** to form 24-electron *arachno* ligand derivatives of structure **2**. As also outlined in Scheme 1, the most likely mechanism of this reaction involves an attack by L at the B4 site in **1**, followed by transfer of the 4,6-μ-H bridging hydrogen onto the B6 vertex with the formation of the cage BH_2 group. The reaction with Me_3N is very clean, while in the case of quinoline the formation of the *closo*-[4-CB_8H_9]$^-$ (**3**) anion in small yields was also observed. As shown in path ii) of Scheme 1, the quinoline reaction also produced small amounts of anion **3** (yield 12%) and 1-quin-*closo*-4-CB_8H_8 (**4c**) (yield 15%), compound **4c** being the first representative of the zwitterionic L-*closo*-CB_8H_8 series. The anion **3** and compound **4c** are most probably formed by air oxidation of compound **2c** during chromatography on silica gel.

The structure of **2b** was determined by an X-ray diffraction analysis and is depicted in Figure 1.

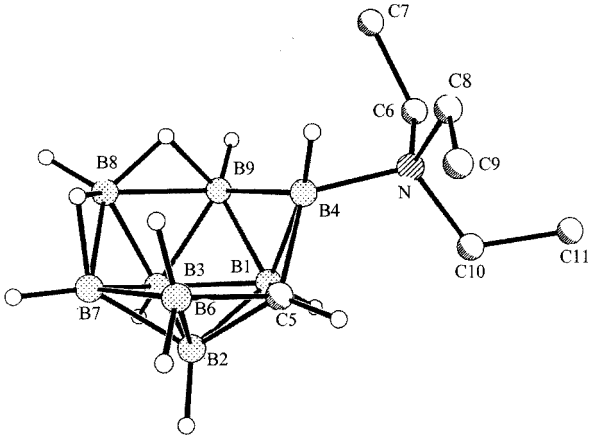

Figure 1. ORTEP representation of the molecular structure of 4-Et_3N-*arachno*-5-CB_8H_{12} (**2b**); selected bond lengths (Å) and angles (°): B1−B2 1.768(6), B1−B3 1.795(7), B1−B4 1.795(6), B1−C5 1.660(6), B1−B9 1.715(7), B2−B3 1.794(7), B2−C5 1.644(6), B2−B6 1.762(8), B2−B7 1.716(8), B3−B7 1.781(8), B3−B8 1.699(8), B3−B9 1.767(7), B4−C5 1.632(6), B4−B9 2.074(7), B4−N 1.639(5), C5−B6 1.673(7), B6−B7 1.991(8), B7−B8 1.805(8), B8−B9 1.789(8), C5−B4−B9 99.6(3), B4−C5−B6 111.8(4), B7−B6−C5 99.8(3), B7−B8−B9 104.6(4), and B8−B9−B4 112.0(4)

The molecule contains one BH_2 and one LBH group, one CH vertex and two non-equivalent BHB bridges within an open hexagonal face. A significant feature is that the cage CH group does not occupy the position of lowest connectivity 4, but the vertex of connectivity 5. The Et_3N substituent is attached at the B4 site in an asymmetric manner. The compounds are thus isomeric with the 6-L-*arachno*-4-CB_8H_{12} species reported previously by one of our groups.[6,7] The longest B−B separations (in Å) can be found in the open face for B4−B9 [2.074(7)] and B6−B7 [1.991(8)], followed by the "bridging" B7−B8 [1.805(8)] and B8−B9 [1.789(8)] distances. The shortest B−B distance can be seen for B3−B8 [1.699(8)], and all other B−B distances fall within the usual limits. In the open-face, the C5−B4 bond [1.632(6)] is shorter than C5−B6 [1.673(7)], and the other two C−B cage distances are in the usual range.

The constitutions of the *arachno* compounds of type **2** and that of the *closo* compound **4c** are in agreement with the results of NMR spectroscopy. All ^{11}B resonances were interrelated by [^{11}B-^{11}B]-COSY spectroscopy,[8] which, in combination with $^1H\{^{11}B(selective)\}$ measurements,[9] led to complete assignments of the resonances to individual cluster BH vertices for all compounds. Simplified stick diagrams interrelating the ^{11}B chemical shifts are given in Figure 2.

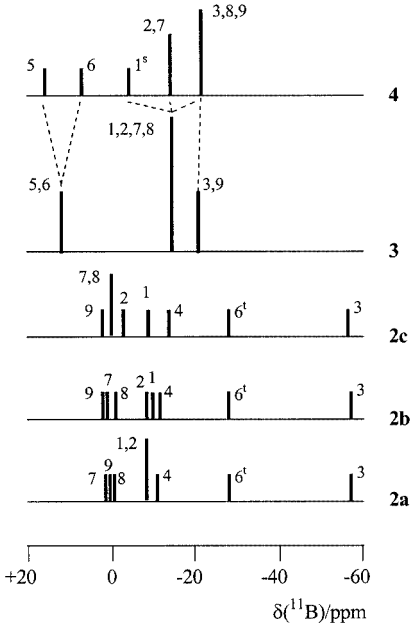

Figure 2. Simplified stick diagrams showing comparison of the ^{11}B NMR shifts and relative intensities for the 4-L-*arachno*-5-CB_8H_{12} compounds (**2**) (**2a** for L = NMe_3, **2b** for L = NEt_3, and **2c** for L = quin) (bottom traces), *closo*-[4-CB_8H_9]$^-$ (**3**) anion (data from reference[4]), and 1-quin-*closo*-4-CB_8H_8 (**4c**) (upper diagrams)

In accord with the crystallographic structure of **2b**, the ^{11}B NMR spectra of all compounds of type **2** (see bottom traces in Figure 2) consist of seven different doublets for BH vertices and one triplet due to the $B(6)H_2$ unit. Apart from resonances of the ligand L, the $^1H\{^{11}B\}$ NMR spectra of these compounds consist of thirteen singlets attributable to eight different *exo*-BH units, one *endo*-BH group, two signals of the *exo* and *endo* components of the cage CH_2 vertex, and to two different B−H−B bridges. The $^{13}C\{^1H\}$ NMR spectra of compounds of type **2** contain a broad singlet assigned to the cluster CH_2 group, the shifts for **2a** and **2b** being essentially the same. The mass spectrum of **2c** shows the expected molecular cut-off, whereas the spectra of **2a** and **2b** indicate fragmentation to [CB_8H_{10}] and L un-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

der the conditions of the MS experiment as the main fragmentation mode.

Although crystals of 1-quin-*closo*-4-CB_8H_8 (**4c**) were not suitable for an X-ray diffraction analysis, its structure in solution can be elucidated on the basis of NMR spectroscopy. As demonstrated in Figure 2 (upper traces), the ^{11}B NMR spectrum of **4c** shows straightforward similarities to that of the parent *closo*-[4-CB_8H_9]$^-$ anion (**3**).[4] It consists of seven different doublets, of which those assigned to B2,7 and B3,8,9 overlap, and one singlet assigned to the ligand-substituted boron B1. The $^1H\{^{11}B\}$ NMR spectrum of **4c** shows a set of low-field quinoline resonances of integral intensity 7 and seven resonances (integral intensity 9) due to the cage BH units, of which those attributed to 3-H, 8-H, and 9-H overlap. Moreover, the mass spectrum of **4c** shows the expected molecular cut-off, and the 1-quin-*closo*-4-CB_8H_8 constitution is the only asymmetric possibility among the 1-, 3- and 5-substituted isomers of the L-*closo*-4-CB_8H_8 series.

Conclusion

The room-temperature reactions between tertiary amines and compound **1** discussed in this work, especially that with trimethylamine, represent a straightforward *nido* → *arachno* transformation in the nine-vertex series of monocarbaboranes. Of similar character is the previously reported[10] conversion of the *nido*-[B_9H_{12}]$^-$ anion into 4-C_5H_5N-*arachno*-4-B_9H_{13} by treatment with C_5H_5N·HCl in the nine-vertex borane series. It is highly probable that compound **2b** acts as an intermediate in the formation of the *closo* anions [1-CB_7H_8]$^-$ and [1-CB_8H_9]$^-$,[4] and we are currently investigating this assumption in more detail together with the possibility of heteroatom insertion into the open face of compounds of type **2**. The 1-quin-*closo*-4-CB_8H_8 (**4c**) is the first representative of the zwitterionic 1-L-*closo*-4-CB_8H_8 (**4**) series and work aimed at a more effective preparation of these or similar compounds is in progress.

Experimental Section

General Remarks: All reactions were carried out with use of standard vacuum or inert-atmosphere techniques as described by Shriver[11] although some operations, such as column LC, were carried out in air. The starting carborane **1** was prepared according to the literature.[1] Dichloromethane and hexane (Fluka) were dried with CaH_2 and freshly distilled before use. Other chemicals were reagent or analytical grade and were used as purchased. The analytical TLC and column chromatography, melting points, mass spectrometry, and NMR spectroscopy were essentially carried out as described in other work from our laboratories.[12]

4-(Me_3N)-*arachno*-5-CB_8H_{12} (2a): A stream of anhydrous Me_3N was bubbled through a solution of compound **1** (111 mg, 1 mmol) in CH_2Cl_2 (20 mL) for 10 min at 0 °C and the mixture was then left stirring for 24 h at ambient temperature. Volatiles were then evaporated and the residue was subjected to chromatography on a silica gel column (30 × 2.5 cm) yielding a pure fraction of R_f (CH_2Cl_2) 0.64 which was identified by NMR spectroscopy as **2a** (162 mg, 96%). An analytical sample of **2a** was obtained by crystallization from a saturated CH_2Cl_2 solution, which was carefully covered by the same volume of hexane. **For 2a:** R_f (CH_2Cl_2) 0.64; m.p. >350 °C (dec.). ^{11}B NMR ($CDCl_3$): δ = 2.4 (d, $^1J_{B,H}$ ≈145 Hz, 1 B, B7), 1.6 (d, $^1J_{B,H}$ = 147 Hz, 1 B, B9), 0.15 (d, $^1J_{B,H}$ ≈150 Hz, 1 B, B8), −8.5 (d, $^1J_{B,H}$ ≈160 Hz, 2 B, B1,2), −10.6 (d, $^1J_{B,H}$ = 149 Hz, 1 B, B4), −27.6 (t, $^1J_{B,H}$ = 122/119 Hz,1 B, B6), −58.4 (d, $^1J_{B,H}$ = 150 Hz, 1 B, B3) ppm, all theoretical [^{11}B-^{11}B]-COSY cross-peaks observed, except for B6-B7, B7-B8, and B8-B9. $^1H\{^{11}B\}$ NMR ($CDCl_3$): δ = 3.35 (s, 1 H, 8-H), 3.22 (s, 1 H, 9-H), 3.12 (s, 1 H, 7-H), 2.86 (s, 9 H, Me_3N), 2.43 (s, 1 H, 1-H or 2-H), 2.38 (s, 1 H, 1-H or 2-H), 1.32 (s, 1 H, *endo*-4-H), 1.23 (s, 1 H, *exo*-6-H), 0.80 (s, 1 H, 5-H), 0.60 (s, 1 H, *endo*-6-H), −0.72 (s, 1 H, 3-H), −1.96 (s, 1 H, 7,8-μ-H), −2.06 (s, 1 H, 8,9-μ-H,) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 10.6 (br. s, 1 C, C5) ppm. MS (70 eV, EI): *m*/*z* (%) = 110 (9) [M − Me_3N − 2H]$^+$, 107 (100) [M − Me_3N − 5H]$^+$, 59 (48) [M − CB_8H_{12}]$^+$. $C_4H_{21}B_8N$ (169.76): calcd. C 28.29, H 12.47; found C 30.15, H 11.80.

4-(Et_3N)-*arachno*-5-CB_8H_{12} (2b): A solution of compound **1** (111 mg, 1 mmol) in CH_2Cl_2 (20 mL) was treated with triethylamine (303 mg, 3 mmol) and the mixture was then left stirring for 24 h at ambient temperature. Volatiles were then evaporated and the residue was subjected to chromatography on a silica gel column (30 × 2.5 cm) yielding a pure fraction of R_f (CH_2Cl_2) 0.5 which was identified by NMR spectroscopy as **2b** (76 mg, 36%). An analytical sample of **2b** was obtained by crystallization from a saturated CH_2Cl_2 solution that was covered by the same volume of hexane. **For 2b:** R_f (CH_2Cl_2) 0.5; m.p. >350 °C (dec.). ^{11}B NMR ($CDCl_3$): δ = 3.1 (d, $^1J_{B,H}$ ≈ 140 Hz, 1 B, B9), 2.2 (d, $^1J_{B,H}$ ≈ 145 Hz, 1 B, B7), −0.1 (d, $^1J_{B,H}$ = 155 Hz, 1 B, B8), −7.9 (d, $^1J_{B,H}$ = 155 Hz, 1 B, B2), −9.7 (d, $^1J_{B,H}$ = 158 Hz, 1 B, B1), −11.4 (d, $^1J_{B,H}$ = 156 Hz, 1 B, B4), −27.3 (t, $^1J_{B,H}$ = 116/119 Hz,1 B, B6), −58.2 (d, $^1J_{B,H}$ = 149 Hz, 1 B, B3) ppm, all theoretical [^{11}B-^{11}B]-COSY cross-peaks observed, except for B6-B7, B7-B8, and B8-B9. $^1H\{^{11}B\}$ NMR ($CDCl_3$): δ = 3.31 (s, 2 H, 8,9-H), 3.06 (s, 1 H, 7-H), 3.06 (s, 6 H, CH_3CH_2N), 2.39 (s, 1 H, 2-H), 2.30 (s, 1 H, 1-H), 1.34 (s, 9 H, CH_3CH_2N), 1.15 (s, 1 H, *exo*-6-H), 1.04 (s, 1 H, *endo*-4-H), 0.80 (s, 1 H, 5-H), 0.63 (s, 1 H, *endo*-6-H), −0.72 (s, 1 H, 3-H), −1.94 (s, 1 H, 7,8-μ-H), −2.04 (s, 1 H, 8,9-μ-H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 10.6 (br. s, 1 C, C5) ppm. MS (70 eV, EI): *m*/*z* (%) = 213 (0.1) [M]$^+$, 110 (5) [M − Et_3N − 2H]$^+$, 101 (10) [M − CB_8H_{12}]$^+$. $C_7H_{27}B_8N$ (211.85): calcd. C 39.68, H 12.85; found C 40.25, H 11.92.

4-quin-*arachno*-5-CB_8H_{12} (2c), (quinH)$^+$*closo*-[4-CB_8H_9]$^-$ (3), and 1-quin-*closo*-4-CB_8H_8 (4c): A solution of compound **1** (111 mg, 1 mmol) in CH_2Cl_2 (20 mL) was treated with quinoline (303 mg, 3 mmol) and the mixture was then left stirring for 24 h at ambient temperature. Volatiles were then evaporated and the residue was subjected to chromatography on a silica gel column (30 × 2.5 cm) using CH_2Cl_2 as the mobile phase yielding pure fractions of R_f (CH_2Cl_2) 0.71 and 0.20 which were identified by NMR spectroscopy as **2c** (83 mg, 35%) and **4c** (35 mg, 15%). Further elution with MeCN/CH_2Cl_2 (1:2, v/v) gave a fraction of R_f = 0.23, which was identified by NMR spectroscopy[4] as **3** (28 mg, 12%). **For 2c:** R_f (CH_2Cl_2) 0.71; m.p. 245 °C. ^{11}B NMR ($CDCl_3$): δ = 3.5 (d, $^1J_{B,H}$ = 157 Hz, 1 B, B9), 0.5 (d, $^1J_{B,H}$ ≈ 150 Hz, 2 B, B7,8), −3.4 (d, $^1J_{B,H}$ = 147 Hz, 1 B, B2), −7.9 (d, $^1J_{B,H}$ = 151 Hz, 1 B, B1), −14.6 (d, $^1J_{B,H}$ = 150 Hz, 1 B, B4), −27.4 (t, $^1J_{B,H}$ = ≈115 Hz, 1 B, B6), −57.3 (d, $^1J_{B,H}$ = 151 Hz, 1 B, B3) ppm, all theoretical [^{11}B-^{11}B]-COSY cross-peaks observed, except for B3-B9, B6-B7, B4-B9, B7-B8, and B8-B9. $^1H\{^{11}B\}$ NMR ($CDCl_3$): δ = 3.45 (s, 2 H, 7-

H,8), 3.30 (s, 1 H, 9-H), 2.76 (s, 1 H, 2-H), 2.45 (s, 2 H, 1-H, *endo*-4-H), 1.41 (s, 1 H, *exo*-6-H), 1.18 (s, 1 H, 5-H), 0.50 (s, 1 H, 3-H), 0.80 (s, 1 H, C*H*5), 0.63 (s, 1 H, *endo*-6-H), −0.72 (s, 1 H, 3-H), −1.69 (s, 1 H, 7,8-μ-H), −1.73 (s, 1 H, 8,9-μ-H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 30.0 (br. s, 1 C, C5) ppm. MS (70 eV, EI): *m*/*z* (%) = 241 (32) $[M]^+$, 239 (100) $[M - 2H]^+$. $C_{10}H_{19}B_8N$ (239.82): calcd. C 50.08, H 7.99; found C 52.10, H 8.32. **For 4c:** R_f (CH_2Cl_2) 0.20; m.p. > 350 °C. ^{11}B NMR ($CDCl_3$): δ = 16.5 (d, $^1J_{B,H}$ = 141 Hz, 1 B, B5), 7.2 (d, $^1J_{B,H}$ = 140 Hz, 1 B, B6), −6.5 (s, 1 B, B1), −15.7 (d, $^1J_{B,H} \approx$ 135 Hz, 2 B, B2,7), −21.0 (d, *J* = 150 Hz, 3 B, B3,8,9) ppm, all theoretical [^{11}B-^{11}B]-COSY cross-peaks observed, except for B1-B2, B1-B7, B3-B5, B5-B8, and B5-B9. $^1H\{^{11}B\}$ NMR ($CDCl_3$): δ = 9.65−7.06 (m, 7 H, quin-H), 5.90 (s, 1 H, 4-H), 4.83 (s, 1 H, 5-H), 4.32 (s, 1 H, 6-H), 1.99 (s, 1 H, 2-H or 7-H), 1.47 (s, 1 H, 2-H or 7-H), 0.87 (s, 3 H, 3,8,9-H,) ppm. MS (70 eV, EI): *m*/*z* (%) = 237 (40) $[M]^+$, 236 (48) $[M - H]^+$.

X-ray Crystallographic Study: Crystals of **2b** were grown by slow diffusion of hexane vapors into a CH_2Cl_2 solution. The reflection intensities for compound **2b** were collected on a Siemens P4 diffractometer (graphite-monochromated Mo-K_α radiation, λ = 71.073 pm). The structure solution and refinement was carried out with the program package SHELXTL-PLUS V.5.1. The collection temperature for the structure determination was 296 K. All non-hydrogen atoms were refined with anisotropic temperature factors. The hydrogen atoms in **2b** were located by difference Fourier maps and the remaining hydrogen atoms were placed in calculated positions. All hydrogen atoms were refined applying the riding model with fixed isotropic temperature factors. Crystal data: $C_7H_{27}B_8N$, a colorless irregular block with dimensions 0.22 × 0.18 × 0.16 mm crystallizes in the monoclinic space group $P2_1/c$ with the lattice parameters *a* = 1119.06(19), *b* = 765.84(8), *c* = 1723.10(18) pm, β = 97.576(9)°, *V* = 1463.8(3) 10^6 pm^3, *Z* = 4, μ = 0.046 mm^{-1}; 3447 reflections collected in the range 2° ≤ 2ϑ ≤ 50°, 2554 reflections independent, 1238 assigned to be observed [$I > 2\sigma(I)$], full-matrix least-squares refinement against F^2 with 161 parameters converged at *R*1/*wR*2-values of 0.084/0.225; the max./min. residual electron density was 0.38/−0.39 10^{-6} e·pm^{-3}. CCDC-223376 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Boranes / Carboranes / Geometry optimization / GIAO calculations / Monocarbaboranes

The conditions for a reaction between *nido*-$B_{10}H_{14}$ (**1**) and aqueous formaldehyde in an alkaline solution have been optimized, which resulted in the isolation of the [*arachno*-6-CB_9H_{14}]$^-$ anion (**2**) in 52% yield. Anion **2** was used as a convenient source for the synthesis of a series of basic monocarbaborane compounds. Thus, oxidation of **2** (Et_4N^+ salt) with I_2 in CH_2Cl_2 in the presence of Et_3N at room temperature afforded the [*nido*-6-CB_9H_{12}]$^-$ anion (**3**). Acidification of anion **2** (generated in situ from borane **1**) with hydrochloric acid, in the presence of both $FeCl_3 \cdot 6H_2O$ and CH_2O, led to the formation of *arachno*-4-CB_8H_{14} (**4**), from which *nido*-1-CB_8H_{12} (**5**) was obtained by dehydrogenation at 200 °C in quantitative yield. Compound **4** can easily be converted into the [*closo*-1-CB_7H_8]$^-$ anion (**6**) in 71% yield via reaction with Et_3N and I_2 in THF at –78 °C. Anion **6** is also formed in 75% yield by treatment of carborane **5** with Et_3N in refluxing toluene. The [*closo*-1-CB_8H_9]$^-$ anion (**7**) was isolated by iodination of carborane **5** in the presence of Et_3N (yield 81%) or by the heating of the PPh_4^+ salt of anion **2** at 220 °C (yield 95%). The structure of anion **2** was determined by an X-ray diffraction study and the structures of compounds **2**, **4**, **5**, and **7** were geometry optimized at the RMP2(fc)/6-31G* level. The NMR spectroscopic measurements are in some cases complemented by unpublished ^{13}C NMR spectroscopic data. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Until recently, the syntheses of the eight-, nine- and ten-vertex monocarbaboranes have been a rather difficult task[1] as the procedures for the preparation of the parent (unsubstituted) representatives of these families were based on multistep reaction sequences starting from *nido*-decaborane(14), $B_{10}H_{14}$. A new, simple synthesis of the previously reported[2] [*arachno*-6-CB_9H_{14}]$^-$ anion and some of its C-substituted derivatives is a straightforward breakthrough into the area of monocarbaborane chemistry. The work also includes facile routes to the isomeric *closo* anions [2-CB_9H_{10}]$^-$ and [1-CB_9H_{10}]$^-$ developed by one of the authors.[3] Based on these results, experimental details of the synthesis of [*arachno*-6-CB_9H_{14}]$^-$ and *arachno*-4-CB_8H_{14} have been communicated in a preliminary fashion[4] and a few of the authors immediately started investigating further consequences of this chemistry, especially those relating to the C-phenyl and other substituted monocarbaborane derivatives of designed cluster shapes.[5] We report here on the optimization of the new synthesis of the [*arachno*-6-CB_9H_{14}]$^-$ anion[2] together with new routes to the basic parent monocarbaboranes [*nido*-6-CB_9H_{12}]$^-$,[6] *arachno*-4-CB_8H_{14},[6,7] *nido*-1-CB_8H_{12},[6b,8] [*closo*-1-CB_7H_8]$^-$,[9] and [*closo*-4-CB_8H_9]$^-$.[4] Even though most of these compounds have been previously reported, the methods outlined in this paper dramatically improve access to most of these monocarbaborane species and make them generally available. The numbering systems used for compounds discussed in this work are in Scheme 1.

Results and Discussion

Syntheses

It has previously been communicated[3,4] that the reaction of *nido*-decaborane(14), $B_{10}H_{14}$ (**1**), with an aqueous NaOH solution, followed by the addition of aqueous formal-

C=CH and unmarked vertices of individual polyhedra stand for BH cluster units)

dehyde, generates the [*arachno*-6-CB_9H_{14}]$^-$ anion (**2**) (see path i) of Scheme 1]. The reaction may reasonably be predicted to proceed via the long-known[10] [*arachno*-6-$B_{10}H_{13}OH$]$^{2-}$ anion as in Equation (1) and Equation (2) and the overall reaction is then represented by Equation (3).

$$B_{10}H_{14} + 2\,OH^- \rightarrow [6\text{-}B_{10}H_{13}OH]^{2-} + H_2O \quad (1)$$

$$[6\text{-}B_{10}H_{13}OH]^{2-} + CH_2O + 2\,H_2O \rightarrow [6\text{-}CB_9H_{14}]^- + B(OH)_4^- + H_2 \quad (2)$$

$$B_{10}H_{14} + 2\,OH^- + CH_2O + H_2O \rightarrow [6\text{-}CB_9H_{14}]^- + B(OH)_4^- + H_2 \quad (3)$$

It was found, however, that the reaction of Equation (3) did not give the best yields of anion **2** using a 1:1 molar ratio of **1**/CH_2O. The reaction was in fact accompanied by a side formation of the previously reported[6] [*nido*-6-CB_9H_{12}]$^-$ anion (**3**) as in Equation (4).

$$[6\text{-}CB_9H_{14}]^- + CH_2O \rightarrow [6\text{-}CB_9H_{12}]^- + CH_3OH \quad (4)$$

Reaction 3 was therefore examined at variable **1**/CH_2O ratios, using 10% NaOH as the reaction medium at room temperature. The reaction was quenched after 5 h by precipitation with NEt_4Cl and the reaction products were analyzed by ^{11}B NMR spectroscopy. The results are shown in Table 1, from which it can be inferred that excess CH_2O promotes the side formation of anion **3**. Optimum reaction conditions for the formation of anion **2**, given in the Exp. Sect., are at molar ratios of 1:3.05. Anion **2** is then removed from the reaction mixture by extraction with Et_2O, followed by precipitation with a suitable countercation in water. The yield of **2,** prepared in this manner in several experiments, is approximately 50%; this one-pot procedure surpasses the previously reported method[2] in all aspects. Mechanistically, the formation of anion **2** is consistent with a unique subrogation of the B6H(OH) vertex in [*arachno*-6-$B_{10}H_{13}OH]^{2-}$ with the formaldehyde CH_2 unit.

Table 1. Products and yields of reactions 3 and 4

Molar ratio **1**/CH_2O[a]	Overall yield (%)[b]	**2**[c]	**3**[c]
1:1.05	43	90	10
1:2.05	45	90	10
1:3.05	58	95	–
1:4.5	76	67	33
1:6.5	68	72	20

[a] In 10% NaOH, room temp., 5 h, then precipitated with NEt_4Cl. [b] Sum of yields of NEt_4^+**2** and NEt_4^+**3**. [c] Content of anions **2** and **3** (in molar%) in the anionic mixture isolated (estimated from ^{11}B NMR spectra).

Anion **2** has become a multipurpose reagent for the preparation of the whole series of monocarbaborane compounds (see Scheme 1). As outlined in path ii) of Scheme 1, a room temperature reaction between Et_4N^+[*arachno*-6-$CB_9H_{14}]^-$ (Et_4N^+**2**) and elemental I_2 in CH_2Cl_2 in the presence of NEt_3 (proton scavenger) resulted in the oxidation of **2** and quantitative formation of the [*nido*-6-$CB_9H_{12}]^-$ anion,[6] which was isolated as its Et_4N^+ salt, Et_4N^+[*nido*-6-$CB_9H_{12}]^-$ (Et_4N^+**3**). The reaction is consistent with the stoichiometry as in Equation (5).

$$[6\text{-}CB_9H_{14}]^- + 2\,Et_3N + I_2 \rightarrow [6\text{-}CB_9H_{12}]^- + 2\,Et_3N{\cdot}HI \quad (5)$$

Anion **2** has also been found to be a very convenient source of the nine-vertex carborane *arachno*-4-CB_8H_{14} (**4**). A room temperature reaction of Na^+**2** with hydrochloric acid and $FeCl_3{\cdot}6H_2O$ in an aqueous medium in the presence of hexane (extraction medium) results in almost

$$6\text{-}CB_9H_{14}^- + Fe^{3+} + 3\,H_2O \rightarrow 4\text{-}CB_8H_{14} + Fe^{2+} + B(OH)_3 + 3/2\,H_2 \quad (6)$$

$$6\text{-}CB_9H_{14}^- + CH_2O + H_3O^+ + 2\,H_2O \rightarrow 4\text{-}CB_8H_{14} + CH_3OH + B(OH)_3 + H_2 \quad (7)$$

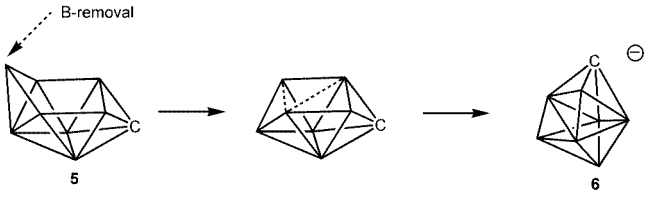
quantitative isolation of carborane **4** [see path iii) of Scheme 1 and Equation (6)]. Another, equally effective alternative, is the use of CH_2O in place of the iron trichloride as in Equation (7). Both reactions are carried out more conveniently in one pot from decaborane via in situ generation of anion **2** with typical yields in the range of 45−50% (based on the use of **1**). The formation of carborane **4** is obviously associated with a hydrolytic removal of the B9 vertex in **2**.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Carborane **4** was converted quantitatively into *nido*-1-CB_8H_{12} (**5**) by heating in vacuo for 6 h at 200 °C (path iv) of Scheme 1) via lower-temperature modification of the previously reported method (sublimation through a hot tube at 350 °C).[6b] Compound **5** was then conveniently used for generating other important compounds of the eight- and nine-vertex monocarbaborane family. As shown in path v) of Scheme 1, treatment of carborane **5** with Et_3N in refluxing toluene led to the isolation of the [*closo*-1-$CB_7H_8]^-$ anion (**6**),[9] the reaction being consistent with the stoichiometry of Equation (8).

$$1\text{-}CB_8H_{12} + 2\,Et_3N \rightarrow Et_3NH^+[1\text{-}CB_7H_8]^- + Et_3N{\cdot}BH_3 \quad (8)$$

The anion **6** was then isolated in 75% yield as its PBu_4^+ salt, PBu_4^+**6**, upon treatment with aqueous NaOH and precipitation with PBu_4Cl. Salts of anion **6,** with any arbitrary countercation, may be similarly prepared. The reaction is consistent with the elimination of the B9 vertex in **5**, followed by closure of the rest of the carborane cage (see Scheme 2). As shown in path vi) of Scheme 1 [see also Equation (9)], anion **6** can also be generated in 71% yield via reaction between the *arachno* carborane **4** and I_2 in the presence of Et_3N in THF at −78 °C.



Scheme 2. Proposed formation of the [*closo*-1-$CB_7H_8]^-$ (**6**) anion via removal of the B9 vertex from *nido*-1-CB_8H_{12} (**7**); extra hydrogen atoms omitted for clarity

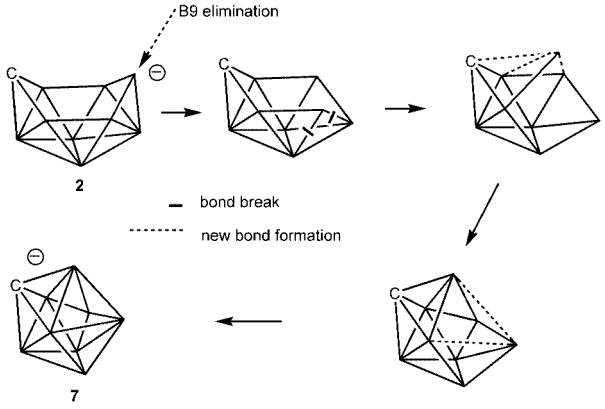
$$4\text{-}CB_8H_{14} + 4\,Et_3N + I_2 \rightarrow Et_3NH^+[1\text{-}CB_7H_8]^- + Et_3N{\cdot}BH_3 + 2\,Et_3N{\cdot}HI \quad (9)$$

The reaction may be explained by removing the B6 vertex in **4**, followed by oxidative closure of the remaining CB7 skeleton. A similar mechanism was proposed earlier for the formation of anion **6** from 6-Me_3N-*arachno*-4-CB_8H_{12}.[9] The Et_3NH^+ salt was again converted into PBu_4^+**6** as in the preceding case. Both procedures of Equations (8) and (9) are very simple and anion **6** now becomes one of the best available compounds of monocarbaborane chemistry. The same applies to the nine-vertex anion [*closo*-4-$CB_8H_9]^-$ (**7**) which was reported in a preliminary communication.[4] One method for the preparation of **7** is based on treatment of compound **5** with I_2 in the presence of Et_3N in THF at −78 °C [Equation (10) and path vii) of Scheme 1].

$$1\text{-}CB_8H_{12} + 3\,Et_3N + I_2 \rightarrow Et_3NH^+[4\text{-}CB_8H_9]^- + 2\,Et_3N{\cdot}HI \quad (10)$$

$$[6\text{-}CB_9H_{14}]^- \rightarrow [4\text{-}CB_8H_9]^- + [BH_3] + H_2 \quad (11)$$

The Et_3NH^+ salt was again converted in situ into PBu_4^+**7** (yield 81%) in an alkaline solution by precipitation with PBu_4Br. Other salts with suitable countercations can be isolated in a similar manner. The formation of **7** can be classified as a clean *nido* → *closo* conversion in which the original B2, B5 and B9 vertices in **5** are interconnected via oxidation to **7**. A very simple access to anion **7** is also the heating of PPh_4^+**2** at 220 °C [see Equation (11) and path viii) of Scheme 1]. The reaction provides PPh_4^+**7** in 95% yield as a single product and is associated with a clean elimination of the B9 vertex from anion **2** followed by cage closure. The process is probably associated with the rearrangement of one of the boron vertices as suggested in Scheme 3. This method is much more convenient than a similar heating of Cs^+**2**[4] (maximum yield of **7** 60%), which is associated with the side formation of other anions.



Scheme 3. Proposed formation of the [*closo*-1-$CB_8H_9]^-$ (**7**) anion via removal of the B9 vertex from the [*arachno*-6-$CB_9H_{14}]^-$ (**2**) cage; extra hydrogen atoms omitted for clarity

Structural Studies

The structures of anions **6** (I_2 and 1-Ph derivatives)[5b][5e,9] and **7**[4] have already been determined crystallographically and those of anions **6**,[11] and **7**[4,11] have been geometry-optimized. In this work these studies are complemented by an X-ray diffraction study of anion **2** (see Figure 1) and the geometries of compounds **2**, **3**, **4**, and **5** optimized at the RMP2(fc)/6-31G* level (see Figure 2).

The crystallographic structure of PPh_3Me^+**2**, depicted in Figure 1, is in agreement with the earlier proposed structure.[2] The anionic part contains one CH_2 and one BH_2 unit in the apical positions and two hydrogen bonds in the open hexagonal face. The longest bond lengths in the open face are those attached to B9, followed by the "bridging" B−B distances and C−B separations. The B8−B9−B10 angle is significantly (10.7°) smaller than B5−C6−B7. Other intracluster C−B and B−B distances are within usual limits. Comparisons between experimental and calculated bond lengths for anion **2** show good agreement, which reflects the accuracy of the calculations.

In the *nido* anion **3**, the calculated B5−B10 distance is 0.068 Å longer than the corresponding "bridged" B5−B10 separation in its *arachno* counterpart **2**. The B5−B10 dis-

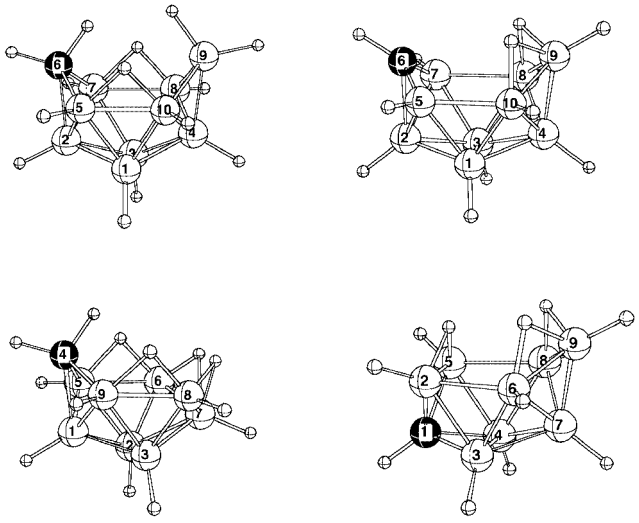

Figure 2. Geometry-optimized structures of $[arachno\text{-}6\text{-}CB_9H_{14}]^-$ (**2**), $[nido\text{-}6\text{-}CB_9H_{12}]^-$ (**3**), $arachno\text{-}4\text{-}CB_8H_{14}$ (**4**), and $nido\text{-}1\text{-}CB_8H_{12}$ (**5**) at the RMP2(fc)/6-31G* level; selected bond lengths (Å) and angles (°): **2** B1−B2 1.734, B1−B3 1.810, B1−B4 1.788, B1−B5 1.772, B1−B10 1.770, B2−B5 1.774, B2−C6 1.671, B4−B9 1.735, B4−B10 1.737, B5−C6 1.7233, B5−B10 1.849, B8−B9 1.913, B−H (mean) 1.199, B5-μH5,10 1.358, B10-μH5,10 1.284, C6−H (mean) 1.088, B5−C6−B7 112.2, B8−B9−B10 101.5; **3** B1−B2 1.749, B1−B3 1.809, B1−B4 1.804, B1−B5 1.765, B1−B10 1.765, B2−B5 1.793, B2−C6 1.696, B4−B9 1.710, B4−B10 1.777, B5−C6 1.539, B5−B10 1.917, B8−B9 1.762, B−H (mean) 1.198, B8-μH8,9 1.315, B9-μH8,9 1.338, C6−H 1.093, B5−C6−B7 118.1, B8−B9−B10 104.1; **4** B1−B2 1.798, B1−B3 1.733, B1−B5 1.799, B1−B6 1.720, B1−B7 1.816, B3−B4 1.669, B3−B5 1.762, B4−B9 1.720, B5−B6 1.827, B9−B7 1.837, B8−B9 1.827, B−H (mean) 1.189, B5-μH5,6 1.368, B6-μH5,6 1.290, C4−H (mean) 1.087, B6-μH6,7 1.246, B7-μH6,7 1.526, B5−C4−B9 114.6, B6−B7−B8 127.3; **5** C1−B2 1.592, C1−B3 1.608, B2−B5 1.891, B2−B6 1.937, B3−B4 1.817, B6−B7 1.799, B7−B9 1.696, B8−B9 1.775, B−H (mean) 1.189, B2-μH2,5 1.331, B6-μH6,9 1.315, B9-μH6,9 1.337, C1−H 1.087, B8−B9−B6 100.5

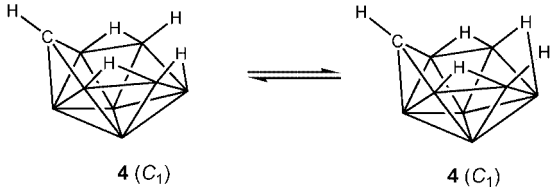
tance in **3** is also 0.155 Å longer than the "bridged" B8−B9 bond length. Further comparisons suggest that the B5−C6−B7 and B8−B9−B10 angles in **3** are 5.9 and 2.6° larger, respectively, than those in **2** and the B5−C6−B7 angle in **3** is also 14° larger than B8−B9−B10. This means than the open hexagonal faces in both anions **2** and **3** are rather irregular and more open in the area around the carbon vertices.

Calculations on the neutral carborane **4** at both the MP2/6-31G* and B3LYP/6-31G* levels characterized the C_s structure shown in Figure 2 as a minimum. Comparison of computed chemical shifts for this structure to experimental data leaves no doubt that the solution spectra are due to a static structure (C_s symmetric) and not time averaging of rapidly rearranging C_1 structures shown in Scheme 4. The *C*s structure contains two pairs of asymmetrical hydrogen bonds; the B5-μH5,6 distance is 0.078 Å longer than B6-μH5,6 and the B6-μH6,7 separation is 0.28 Å shorter than B7-μH6,7, which at 1.526 Å is extremely long. Comparison of the calculated open-face C−B (1.720/1.733 Å) and the bridging B−B (1.827/1.849 Å) distances and the B−C−B angles (114.6/112.2°) in anions **4** and **2**, respectively, suggests that the C4−B5−B6−B8−B9 section in **4** is very similar to the corresponding B5−C6−B7−B8−B10 part of the molecule of **2**. This corresponds to the fact that the two molecules are related by removing one boron vertex. Comparison of the bridging B−B distances in **4** shows that the B6−B7 separation is only slightly (0.01 Å) longer than the B5−B6 distance. In the *nido* compound **5**, the B2−B6 separation is significantly (0.162 Å) longer than the bridging B6−B9 distance and the other bridging B2−B5 separation is 0.116 Å longer than B6−B9. The B6−B9−B8 angle is at 100.5°, which is similar to the B8−B9−B10 angle in the *nido* anion **3** (cf. 104°) (Scheme 4).



Scheme 4. Time averaging between two C_1 structures for compound **4**; averaged ^{11}B NMR shifts computed for this process at the IGLO-HF/DZ level are: 4.3 (B1), −39.8 (B2,3), 9.2 (C4), −9.6 (B5,9), −25.8 (B6,8), 26.8 (B7)

The ^{11}B and ^{1}H NMR spectroscopic data for all compounds encountered in this work have mostly been reported previously, in some cases we have added the data for anions with different countercations. The work is supplemented by the unpublished ^{13}C NMR shifts of the cage CH or CH_2 units for selected compounds. The optimized geometries have been used as a basis for the calculation of theoretical ^{11}B and ^{13}C NMR chemical shifts. A comparison between calculated and experimental shifts (see Exp. Sect.) is generally in good agreement.

Conclusions

The efficient route from $B_{10}H_{14}$ to the starting monocarbaborane anion **2** has improved the yield of this anion by about five times, in comparison with the original procedure.[2] This means that the eight-, nine- and ten-vertex species prepared in this work are now one of the most readily accessible monocarbaboranes. Their chemistry should now contribute substantially to the development of carborane science. For example, the *closo* anions **6** and **7**, together with the recently reported [*closo*-$CB_6H_7]^-$ anion,[12] could act as "weakly coordinating anions" to complement $[CB_9H_{10}]^-$ and $[CB_{11}H_{12}]^-$, and their derivatives.[13] The compounds are also likely to be amenable to extensive substitution and metallacarborane chemistries. We are currently developing these areas with the aim of extending the knowledge of the chemistry of monocarbaboranes with less than ten cluster atoms.

Experimental Section

General Procedures: All reactions were carried out with the use of standard vacuum or inert-atmosphere techniques as described by Shriver,[14] although some operations, such as column LC, were carried out in air. The starting compound **1** was sublimed in vacuo at 80 °C using an apparatus equipped with a water-cooled sublimation finger. THF was distilled from sodium diphenyl ketyl, dichloromethane and hexane were dried over CaH_2 and freshly distilled before use. Other chemicals were reagent or analytical grade and were used as purchased. The purity of the individual compounds was checked by analytical TLC on Silufol (silica gel on aluminum foil; detection by iodine vapors, followed by 2% aqueous $AgNO_3$ spray). Melting points were measured in sealed capillaries under argon and are uncorrected. Multinuclear (^1H, ^{11}B, and ^{13}C) NMR spectroscopy was performed essentially with the instrumentation described in other related papers from our laboratories.[15] The ^{11}B and ^{13}C chemical shifts are given in the following manner: δ(exp.)/δ(calcd., IGLO-HF/DZ), δ(calcd., GIAO-HFII), δ(calcd., GIAO-B3LYP/II).

Salts of [*arachno*-6-$CB_9H_{14}]^-$ (2) (Optimized Procedure): A solution of compound **1** (1.24 g, 10 mmol) in 20 mL of hexane was treated with 10% aqueous NaOH (70 mL) whilst stirring and cooling at 0 °C. The cooling was continued and 2.5 g of an aqueous CH_2O solution (37%, w/w, stabilized with methanol) (ca. 31 mmol of CH_2O) diluted with 10 mL of water was added over a period of 1 h. The stirring was continued at ambient temperature for 12 h. The hexane layer was separated and the aqueous solution was extracted by three 10-ml portions of Et_2O and the combined extracts were evaporated with water (30 mL) to remove the diethyl ether. The remaining aqueous solution (solution A) was precipitated alternatively with solid $Et_4N^+Cl^-$ (1.7 g, 10 mmol), $PPh_4^+Cl^-$ (3.75 g, 10 mmol), and $Ph_3PMe^+Cl^-$ (3.15 g, 10 mmol). The white precipitates were isolated by filtration, the solids were washed with cold water (2 × 10 mL) and vacuum dried for 12 h to give pure Et_4N^+ (1.3 g, 51%), PPh_4^+ (2.6 g, 56%), and Ph_3PMe^+ (2.1 g, 52%) salts of anion **2**, respectively. The salts were recrystallized by diffusion of hexane vapors into solutions of CH_2Cl_2. M.p. 348 °C (decomp.). ^{11}B NMR (128.3 MHz, CD_3CN, 295 K): δ = −1.4/ 3.2, 5.4, −2.7 [d, ^1J(B,H) = 129 Hz, 1 B, B4], −10.3/−8.3, −5.6, −13.2 (d, ^1J(B,H) ≈160 Hz, 1 B, B2), −12.9/−14.2, −11.2, −17.3 [d, ^1J(B,H) = 154 Hz, 2 B, B5,7], −23.3/−21.1, −21.4, −25.5 [t, ^1J(B,H) = 106 Hz, 1 B, B9], −28.8/−28.6, −26.9, −32.1 [d, ^1J(B,H) = 128 Hz, 2 B, B8,10], −39.8/−41.4, −38.9, −44.4 [d, ^1J(B,H) = 138 Hz, 2 B, B1,3]. $^{13}C\{^1H\}$ NMR [100.6 MHz, $(CD_3)_2SO$, 295 K]: δ = −4.8/−1.4, −12.5, −2.0 (s br., 1 C, C6). $C_9H_{42}B_9N$ (253.75): calcd. C 42.60, H 16.68; found C 43.20, H 15.62.

Et_4N^+[*nido*-6-$CB_9H_{12}]^-$ (Et_4N^+3): Triethylamine (0.5 mL) was added to a solution of Et_4N^+**2** (381 mg, 1.5 mmol) in CH_2Cl_2 (20 mL) and the mixture was treated with solid I_2 (381 mg, 1.5 mmol) in several portions over a period of 2 h whilst stirring at room temperature. The mixture was then shaken with 5% aqueous $Na_2S_2O_3$ (20 mL) and water (20 mL). The bottom layer was separated, evaporated and the residual solid was vacuum dried at ambient temperature for 12 h to give pure Et_4N^+**3**. M.p. 298 °C (decomp.). ^{11}B NMR (128.3 MHz, CD_2Cl_2, 295 K): δ = 1.7/2.5.4.7, −1.1 [d, ^1J(B,H) = 135 Hz, 2 B, B5,7], −1.8/−3.0, −0.9, −10.0 [d, ^1J(B,H) ≈ 150 Hz, 1 B, B9], −4.6/−3.1, 1.7, −5.7 [d, ^1J(B,H) = 134 Hz, 2 B, B1,3], −12.5/−13.5, −9.6, −15.0 [d, ^1J(B,H) = 140 Hz, 2 B, B8,10], −30.7/−34.5, −31.2, −33.8 [d, ^1J(B,H) = 147 Hz, 1 B, B2], −37.9/−41.4, −38.4, −43.4 [d, ^1J(B,H) = 142 Hz, 1 B, B4]. ^{13}C NMR [100.6 MHz, $(CD_3)_2SO$, 295 K]: δ = 126.4/129.9, 124.7, 140 (d, $^1J_{C,H}$ = 144 Hz, 1 C, C6). $C_9H_{40}B_9N$ (251.73): calcd. C 42.94, H 16.02; found C 41.15, H 15.38.

***arachno*-4-CB_8H_{14} (4):** a) Solution A from the preparation of anion **2** (containing ca. 5.2 mmol of Na^+**2**) was added dropwise to a stirred mixture of aqueous HCl (ca. 4.5 M, 35 mL), $FeCl_3{\cdot}6H_2O$ (6.5 g) and hexane (30 mL) and the stirring was continued for 6 h (hydrogen evolution). The hexane layer was separated, evaporated and the residue sublimed at 50 °C (bath temperature) to obtain compound **4** (540 mg, 48%, based on **1** used), which was identified by NMR spectroscopy. ^{11}B NMR: δ = 17.0/16.3, 18.8, 12.6 (B7), −3.7/−2.9, 1.3, −6.5 (B1), −6.3/−7.8, −4.7, −9.7 (B5,9), −34.9/−36.4, −34.5, −42.8 (B6,8), −41.1/−47.1, −44.4/−49.6 (B2,3), experimental data from ref.[6a] ^{13}C NMR (125.8 MHz, $CDCl_3$, 295 K): δ = −10.8/−13.1, −16.4, −10.0 (t, $^1J_{C,H}$ = 134 and 162 Hz, 1 C, C4). b) Hexane (40 mL) and an aqueous solution of CH_2O (37%, w/v, stabilized with methanol) (1.6 g, ca. 20 mmol of CH_2O) were added to solution A from the preparation of anion **2** whilst stirring and cooling to 0 °C (bath temperature). The mixture was then treated dropwise with aqueous HCl (ca. 4.5 M, 35 mL) at 0 °C for 1 h, and the stirring was then continued for 6 h at room temperature (hydrogen evolution). The hexane layer was separated and pure compound **4** (563 mg, 50% based on **1**) was isolated as in the preceding experiment.

***nido*-1-CB_8H_{12} (5):** Freshly sublimed compound **4** (500 mg, 4.44 mmol) was placed in a 250-mL Pyrex tube equipped by a break seal and sealed in vacuo under cooling liquid nitrogen. The tube was then heated at 200 °C for 6 h and opened into a vacuum manifold under cooling with liquid nitrogen. The solid residue was then sublimed into a −78 °C trap to obtain pure compound **7** (495 mg, 99%), which was identified by spectroscopy. ^{11}B NMR: δ = 7.6/6.4, 8.9, 2.0 (B9), −3.3/−0.3, 0.2, −5.4 (B3,4), −11.5/−12.6, −9.3, −14.2 (B6,8), −26.5/−26.0, −24.7, −31.2 (B2,5), −53.3/−54.4, −52.6, −58.8 (B7), experimental data from ref.[16] ^{13}C NMR (125.8 MHz, $CDCl_3$, 295 K): δ = 31.1/29.5, 19.6, 35.7 (d, $^1J_{C,H}$ = 199 Hz, 1 C, C1).

[*closo*-1-$CB_7H_8]^-$ Anion (6): a) NEt_3 (1.6 mL) was added to a solution of compound **4** (260 mg, 2.31 mmol) in THF (20 mL) and the mixture was treated with a solution of I_2 (1175 mg, 4.62 mmol) in THF (30 mL) under vigorous stirring and cooled to −78 °C over

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a period of 1 h. The volatiles were then evaporated, the residual materials dried in vacuo for 1 h and then treated with a mixture of 5% KOH (20 mL) and CH_2Cl_2 (20 mL) under shaking. The CH_2Cl_2 layer, containing $NEt_3{\cdot}BH_3$ (identified via ^{11}B NMR), was discarded and the aqueous layer treated with solid PBu_4Cl (681 mg, 2.31 mmol). The precipitate was isolated by filtration and dried under vacuum for 2 h at room temperature. Crystallization by diffusion of hexane vapors into a CH_2Cl_2 solution gave white crystals (586 mg, 71%) which were identified by ^{11}B NMR spectroscopy[9] as PBu_4^+**6**. $^{13}C\{^{11}B\}$ NMR [100.6 MHz, $(CD_3)_2CO$, 295 K]: δ = 60.1 (s, 1 C, C1). b) Under strictly anaerobic conditions (deoxygenated Ar), a solution of compound **5** (300 mg, 2.71 mmol) in toluene (30 mL) was treated with NEt_3 (1 mL) and then heated at reflux for 6 h. The mixture was then cooled to ambient temperature and extracted with two 10-ml portions of 5% KOH. The aqueous layer was treated with solid PBu_4Cl (800 mg, 2.71 mmol) and then extracted with CH_2Cl_2 (20 mL). The organic layer was placed onto a silica gel column (2.5 × 20 cm) and elution with 5% MeCN in CH_2Cl_2 gave the main fraction of R_f = 0.23. This was evaporated to dryness and the residue crystallized by diffusion of hexane vapors into a CH_2Cl_2 solution to isolate white crystals of PBu_4^+**6** (681 mg, 75%).

[*closo*-4-CB_8H_9]$^-$ Anion (7): a) A solution of freshly sublimed compound **5** (150 mg, 1.36 mmol) in THF (10 mL) was treated with Et_3N (0.5 mL) whilst stirring and cooling to −78 °C and solid I_2 (346 mg, 1.36 mmol) was then added in several portions over a period of 1 h. The THF was evaporated and the residual solid treated with 5% aqueous KOH while shaking and cooling. The Et_3N thus evolved was evaporated and the residual solution filtered. The filtrate was treated with PBu_4Br (462 mg, 1.36 mmol) and extracted with CH_2Cl_2 (20 mL). The CH_2Cl_2 extract was mounted onto a silica gel column (2.5 × 20 cm) and elution with 5% MeCN in CH_2Cl_2 gave a pure fraction of R_f = 0.2. This was evaporated and the residual solid crystallized by diffusion of hexane vapors into a CH_2Cl_2 solution to isolate the white crystals of PBu_4^+**7** (405 mg, 81%). Other salts of anion **7** can be obtained by precipitation of the aqueous filtrate with a suitable countercation. ^{11}B NMR (160.4 MHz, $CDCl_3$, 25 °C): δ = 12.8 [d, ^1J(B,H) = 145 Hz, 2 B, B5,6], −14.3 [d, ^1J(B,H) = 148 Hz, 4 B, B1,2,7,8], −20.3 [d, ^1J(B,H) = 136 Hz, 1 B, B3,9], all theoretical [^{11}B-^{11}B]-COSY cross-peaks observed. $^1H\{^{11}B\}$ NMR (500 MHz, $CDCl_3$, 25 °C): δ = 4.37 (s, 2 H, H5,6), 4.13 (s, 1 H, H4), 1.47 (s, 4 H, H1,2,7,8), 0.64 (s, 2 H, H3,9). ^{13}C NMR (125.8 MHz, $CDCl_3$, 25 °C): δ = 44.5 (br.d, $^1J_{C,H}$ = 182 Hz, 1 C, C4). b) Solid PPh_4^+**2** (926 mg, 2 mmol) was heated for 2 h at 220 °C. The residual solid was dissolved in CH_2Cl_2 (10 mL) and the solution was carefully covered by hexane (20 mL). The white crystals that separated on standing for 3 days were identified by NMR spectroscopy as pure PPh_4^+**9** (849 mg, 95%).

Computational Details: The GAUSSIAN94 program package[17] was used for calculations, which were performed on the Power Challenge XL computer of the Supercomputing Center of the Charles University in Prague. The structures proposed on the basis of experimental ^{11}B and ^1H NMR spectroscopy were optimized first at RHF/6-31G* within the given symmetry restriction. Frequency calculations, carried out at the same level, determined the nature of the stationary points. Minima are characterized by zero imaginary frequency (NIMAG = 0). Further optimizations at RMP2(fc)/6-31G* included the effect of electron correlation. Selected geometry parameters are given in Figure 2. For MP2/6-31G* optimized geometries the chemical shieldings were calculated at a SCF level using both the IGLO (invariant gauge for localized orbitals) and GIAO (gauge-invariant atomic orbital) method. In addition the B3LYP density functional theory level was applied using GIAO, the latter being incorporated in the GAUSSIAN94. NMR shift calculations employed Huzinaga basis sets:[18] DZ (double zeta) and II well-designed for magnetic properties calculations.[19]

X-ray Crystallographic Study: Crystals of PPh_3Me^+**2** were grown by slow diffusion of hexane vapors into a CH_2Cl_2 solution. The crystal was mounted on a glass fiber with epoxy cement and measured on a four-circle diffractometer Nonius KappaCCD equipped with a CCD area detector at 150(2)K with Mo-K_α radiation (λ = 0.71073 Å, graphite-monochromated). The structure was solved by the direct method (SIR97)[20] and refined by a full-matrix least-squares procedure based on F^2 (SHELXL-97).[21] All non-hydrogen atoms were refined with anisotropic temperature factors. The hydrogen atoms of the carborane cage were located on difference Fourier maps and refined isotropically; remaining hydrogen atoms of PPh_3Me^+ were on calculated positions and refined applying the riding model with assigned temperature factors either $H_{iso}(H)$ = 1.2 U_{eq}(pivot atom) or $H_{iso}(H)$ = 1.5 U_{eq}(pivot atom) for the methyl moiety.

Crystal data: $C_{20}H_{32}B_9P$, a colorless block of dimensions 0.70 × 0.45 × 0.4 mm crystallizes in the monoclinic space group $P2_1/c$ with the lattice parameters a = 11.7370(2), b = 15.0650(2), c = 14.0740(2) Å, β = 107.8960(8)°, V = 2368.13(6) Å^3, Z = 4, μ = 0.122 mm^{-1}; 39627 reflections collected in the range 2° ≤ 2θ ≤ 55°, 5417 reflections independent (R_{int} = 0.029), 4824 assigned to be observed [$I > 2\sigma(I)$], full-matrix least-squares refinement against F^2 with 328 parameters converged at $wR(F^2)$ = 0.0990 ($R[F^2 > 2\sigma(F^2)]$ = 0.0356, $w = 1/[\sigma^2(F_o^2) + (0.0519P)^2 + 0.6888P]$ where $P = F_o^2 + 2F_c^2)/3$) and the max./min. residual electron density was 0.309/−0.303 e·Å^{-3}. CCDC-230897 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: BN triple bonds / Insertion reactions / (*N*-Metal-*tert*-butylamino)(2,2,6,6-tetramethylpiperidino)boranes / Multinuclear NMR / X-ray structures

(*tert*-Butylimino)(2,2,6,6-tetramethylpiperidino)borane (**1**) is a highly reactive species. Its B≡N triple bond inserts into the B–H bond of boranes, R_2BH, generating diborylamines of the type tmp–BH–N*t*Bu–BR_2 (tmp = 2,2,6,6-tetramethylpiperidino; R = H, Cl, Br, or organyl). Thexylborane reacts analogously, but only one of its two B–H bonds is used for the hydroboration of **1**. However, dihaloboranes $HB(Hal)_2$–SMe_2 (Hal = Cl, Br) give *B*-haloboration products tmp–B(Hal)–N*t*Bu–BH(Hal), while reactions with $H_2B(Hal)$–SMe_2 produce a mixture of two isomers by competing hydroboration and haloboration reactions. Tmp–BH–N*t*Bu–AlH_2 was obtained from **1** and AlH_3–NMe_3. It is a dimer in the solid state with pentacoordinate Al atoms and AlH_2Al bridges. Hydrosilylation of **1** was achieved with Me_2SiHCl, $SiHCl_3$ or Ph_2SiH_2 to give the *N*-silyl-substituted diaminoboranes tmp-BH-N*t*Bu–$SiX_{3-n}R_n$. Me_3SnH and Bu_3SnH behave similarly, giving the corresponding *N*-stannylated diaminoboranes. However, when Ph_3SnH was treated with **1**, the stannylborane tmp–B($SnPh_3$)–NH*t*Bu was formed showing an umpolung of the hydrostannylation. Organyllithium compounds provide access to *N*-lithiodiaminoboranes of the type tmp–BR–N*t*Bu–Li. The stability of these compounds depends on the substituent R. The least stable compound was the B–*t*Bu derivative followed by the *B*-methyl compound. However, in the presence of TMEDA tmp–BMe–N*t*Bu–Li is sufficiently stable to allow reactions, e.g. with *B*-chlorocatecholborane, to produce tmp–BMe–N*t*Bu–$BO_2C_6H_4$. The most stable lithium compound so far is tmp–BPh–N*t*Bu–Li–OEt_2, whose structure has been determined by X-ray crystallography. $MgBu_2$ behaves like LiR and both of its Mg–C bonds can be used for the insertion reaction. The same is also true of $ZnMe_2$. In contrast, at ambient temperature, only one of the E–C bonds of triorganylalanes, triorganylgallanes and $InPh_3$ is used for the insertion reaction. In the solid state, most of the new compounds show a weak to strong coordinate bond between the electrophilic centre (Li, Mg, Zn, Cd, B, Al, Ga and In) and the nitrogen atom of the tmp group which generates a four-membered ring.

Introduction

Iminoboranes, RN=BR′, featuring a B≡N triple bond are highly reactive chemical species due to their unsaturated character. Their reactivity exceeds that of the corresponding isolobal alkynes, a consequence of the higher polarity of the B≡N bond compared with the less polar C≡C bond of alkynes. The chemistry of iminoboranes has been reviewed in two comprehensive articles.[1,2] Iminoboranes have a high tendency to dimerize to 1,3-diaza-2,3-diboretidines or trimerize to borazine derivatives.[3,4] In the case of the (*tert*-butylimino)(2,2,6,6-tetramethylpiperidino)borane (tmp−B=N−*t*Bu, **1**) the rate of dimerization is retarded for steric and electronic reasons.[4] Besides this and related cycloaddition reactions, the (amino)(imino)boranes add to carbonylmetal fragments at the imino nitrogen atom of **1**. They also add protic acids HX or an E−X bond of sufficiently strong Lewis acids EX_n across the B≡N triple bond.[1,2] Here we

report a systematic study of the behaviour of **1** towards hydrides of group 13 and 14 as well as organyl derivatives of the group 1, 2, 13 and 14 elements. Several hydroboration reactions of iminoboranes are already known,[1,2,5] but these and (amino)(imino)boranes offer even more interesting scopes.[6,7]

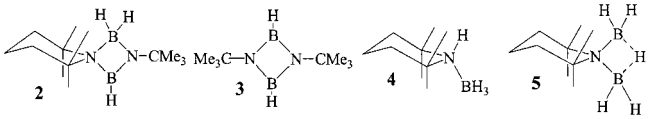
Usually, acidic polar hydrogen compounds HX [X = halogen, OR, SR, NHR, NR_2, $Co(CO)_4$] react with **1** by protonation of the *tert*-butylimino nitrogen atom according to Equation (1). In the case of bulky X groups, for instance $Co(CO)_4$,[8] diaminoborinium salts are formed as shown in Equation (2). This indicates that the first step in reaction (1) is the protonation of the imino nitrogen atom. On the other hand, when hydrides of electropositive elements, $ER_{rn-n}H_n$, are allowed to react with **1**, then the hydrogen atom of an E−H bond attacks at the boron atom.[2] This finally results in the formation of *N*-substituted diaminoboranes tmp−BH−N*t*Bu−$ER_{m-n}H_{n-1}$ as shown in Equation (3). Reaction (3) starts with an electrophilic attack at the N atom of the $NCMe_3$ group by the Lewis acidic centre of the element hydride $ER_{m-n}H_n$, followed by a hydride transfer to the boron atom. This kind of reaction will not occur if the central E atom is too weak a Lewis acid.

In this work we report on the behaviour of various hydrides of boron, aluminium, silicon and tin as well as of organyl compounds of lithium, magnesium, zinc, cadmium, boron, aluminium, gallium and indium.

Results

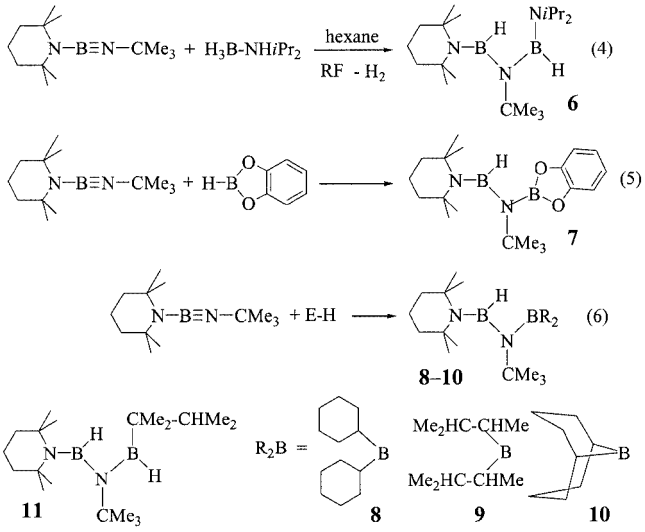
Reactions with Hydrides of Boron and Aluminium

We have already recently reported on the reaction of BH_3−THF with **1**.[5] When diborane is used as the source of BH_3 in the presence of hexane as a solvent, four compounds, **2**−**5**, besides the dimer of **1**, can be detected. After warming the reaction mixture from −196 °C to ambient temperature, ^{11}B NMR signals were found at δ = 28.7 and −4.4 (for **2**), 37.2 (for **3**), −20.8 (for **4**), and −26.2 ppm (for **5**). However, when BH_3−THF was used, the product distribution depended both on the concentration and the temperature of the solutions. At −60 °C, dilute solutions favoured the formation of **2**. Yields up to 82% can be achieved.



An almost quantitative conversion of **1** to **2** can be achieved, however, by employing H_3B−SMe_2 as the hydroborating reagent. In this case, it is important to add a hexane solution of **1** slowly at ambient temperature to a solution of H_3B−SMe_2 in hexane. Under these conditions the dimerization of **1** is prevented due to the presence of a local excess of the borane reagent.

On the other hand, no hydroboration of **1** was observed when employing the aminoboranes H_3B−NEt_3 or H_3B−$NHiPr_2$ at ambient temperature. However, when a solution of **1** and H_3B−$NHiPr_2$ was kept at reflux in hexane, hydrogen gas was formed besides the diborylamine **6** as shown in Equation (4). Hydroboration of **1** can also be achieved with catecholborane, dicyclohexylborane, diisoamylborane or 9-borabicyclo[3.3.1]nonane (9-BBN) as shown in Equations (5) and (6).



Because the B≡N triple bond of **1** also inserts into the B−C bond of triorganylboranes (vide infra), there might be competition between the insertion of the B−C bond and the B−H bond if both are present in the molecule. The results with the diorganylboranes indicate convincingly that the B−H bond is more reactive than the B−C bond, although thermodynamically there should be no strong difference between the two since the number of B−C and B−H bonds does not change. Kinetic investigations into the hydroboration of alkynes have shown that the rate of hydroboration depends on the equilibrium between the dimeric borane and the monomeric borane.[9,10] In spite of the high steric requirements of the diorganylboranes used in this study, all three compounds reacted chemoselectively. However, the rates of the reactions were quite different. 9-BBN reacted fastest and the reaction was complete within 2 h. Disiamylborane required 24 h and dicyclohexylborane needed 96 h. Amongst these, the dicylohexylborane is certainly the least bulky. Nevertheless, it showed the lowest rate. This is because the concentration of its monomeric unit is very low compared with those of the other species.[9] One factor that governs the monomer/dimer equilibrium is the strength of the BHB bridge bond as demonstrated by the corresponding BHB bridge frequencies in the IR spectra. These frequencies are 1590 cm^{-1} for dicyclohexylborane,[11] 1551 cm^{-1} for disiamylborane[12] and 1560 cm^{-1} for 9-BBN.[13] In contrast to these diorganylboranes, the symmetric dithexyldiborane shows a BHB band at 1565 cm^{-1} which is very close to that of the dimeric disiamylborane.[14] However, 8 d are required for a quantitative conversion of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1 into **11**. In contrast to the hydroboration of organic substrates with thexylborane,[14–16] only one of its two B–H hydrogen atoms is used for the hydroboration of **1**.

In contrast, the haloboranes $H_{3-n}B(Hal)_n$ in the form of their Me_2S adducts react with **1** by hydroboration and/or haloboration. The dihaloboranes $HBCl_2$ and $HBBr_2$ show high positive charges at the boron atoms, e.g. +0.976 in $HBCl_2$ (see Table 1) which is almost the same as for BCl_3 but less than in BH_2Cl. Bond dissociation energies may also play a role and should favour the hydroboration route.[17] Both $HBCl_2$–SMe_2 and $HBBr_2$–SMe_2 exclusively give, however, the haloboration products **12** and **13** [Equation (7)]**.** This can be readily demonstrated by the absence of a doublet in the ^{11}B NMR spectrum for the tricoordinate B atom but the presence of a doublet for the tetracoordinate boron atom. This also confirms that compounds **12** and **13** have cyclic structures.

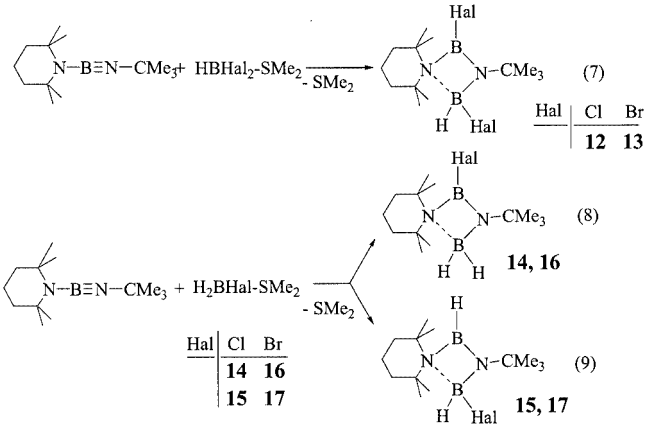


Table 1. Calculated charge densities for the series of chloroboranes $BH_{3-n}Cl_n$

	BH_3	H_2BCl	$HBCl_2$	BCl_3
q_B	0.495	0.724	0.976	0.9995
q_H	−0.165	−0.209	−0.149	
q_{Cl}	–	−0.307	−0.414	−0.3332

On the other hand, reactions of H_2BCl–SMe_2 and H_2BBr–SMe_2 with **1** lead to a mixture of the hydroboration products **15** and **17** with the haloboration products **14** and **16**. The product ratio of **14/15** was 33:66 while it was 50:50 for **16/17**. Therefore, there is a statistical preference for the hydroboration product **15** but not for **17**.

In order to obtain an insight into the formation of compounds **14** and **15**, we performed calculations at the B3LYP/6-311g and B3LYP/8-311+g(2d,f) levels for the model system $ClBH_2/H_2N–B=N–Me$. The results are summarised in Table 2 and shown in Figure 1. The two B–N bonds of the (amino)(imino)borane are in agreement with a higher bond order for the imino nitrogen atom, but also the B–N bond of the amino group NH_2 reveals π-bonding. Thus, the electronic structure of $H_2N–B=N–Me$ is best described by the two formulae **A** and **B**.

$$\underset{\mathbf{A}}{H_2N–B{\equiv}N–Me} \leftrightarrow \underset{\mathbf{B}}{H_2N{=}B{=}N–Me}$$

The adduct **C**, which is considered to be the first step in the hydro/haloboration of $H_2N–B=N–Me$, is more stable by 110.68 kJ/mol compared with the reagents. The adduct shows an allene-type configuration with a torsion angle H–N–N–C of −95.7°. The B–N bond lengths for the $H_2N–B$ and $B–NMe(BH_2Cl)$ groups were calculated as 1.357 and 1.309 Å while the B–N bond to the monochloroborane unit is 1.606 Å. This type of structure has been deduced from NMR spectroscopic data for **1**–ECl_3 (E = Al, Ga)[18] or **1**–$M(CO)_5$ (M = Cr, W)[19] and determined by X-ray crystallography for tmp=B=N*t*Bu(ECl_3) [E = Ga, and In with 1.345(2) and 1.316(2) Å, respectively].[20] These data are in agreement with B=N double bonding between the dicoordinate B atom and the tricoordinate N atoms (see Figure 1).

The adduct **C** is, however, less stable than the chloroboration/hydroboration compounds **D** and **E**. The hydroboration product **E** is more stable by 154.46 kJ/mol than **C**, while the chloroboration product **D** is more stable by178.76 kJ/mol. As expected, the energy difference between **D** and **E** of 24.21 kJ/mol is not large. In each case, the "open chain" structures are energetically favoured over the ring structures **F** and **G**. The energy difference between **D** and **F** is 65.47 kJ/mol in favour of **D**, while **E** is 65.62 kJ/mol more stable than the ring compound **G**. Thus, chloroboration to **D** is the thermodynamically more favourable reaction. This is in contrast to the observed preferred hydroboration of **1** with BH_2Cl. Thus, the model system does not mirror the experimental system.

The calculated B–N bond lengths in **E** are in agreement with B=N double bonding. The shortest B–N bond (1.395 Å) was calculated for an $H_2N–B$ bond while those to the BH_2 group are longest at 1.417 Å. However, the "central" B–N bond is also short at 1.449 Å. This indicates a bonding situation also found in 1,3-butadienes. In the case of **D** and **E**, the *cis* conformations were found to be energy minima. As can be seen from the B–N bond lengths of the ring structure **F** (see Table 2), there is only one N bond with double bond character. The $H_2N\cdots BH_2$ bond is rather long at 1.701 Å and the N and B atoms now exhibit tetracoordination. Although compound **F** shows three B–N single bonds and one B–N π-bond, one B–N bond in particular is quite weak and this is certainly the reason why the chain compound **D** with three B–N π-bonds is more stable. On the other hand, although the chloroboration chain compound **D** is favoured over the hydroboration product **E**, the ring isomer **G** is definitely more stable than the ring **F**. One of the reasons for this is that the B–N bond of the group $H_2N–BHCl$ is much shorter than in **F** which leads to its stabilisation. However, as shown experimentally for compound **14** and **15**, only the ring structures were experimentally observed and not the open-chain compounds as the

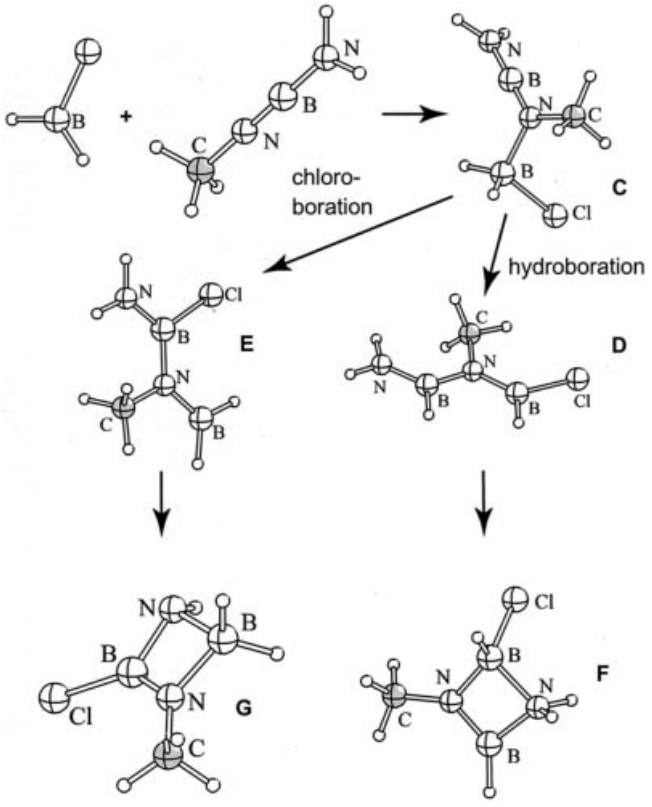

Figure 1. Optimised structures in the $BH_2Cl/H_2N-B=N-Me$ system

calculations suggest and this may be due to the fact that the amino nitrogen atom of the tmp unit is more basic than the NH_2 group of the model system.

For this reason we also performed calculations on tmp−BPh−N*t*Bu−BH_2 whose ring structure was determined by X-ray crystallography.[21] Indeed, optimization of the open-chain structure leads to the ring as the most stable species (Figure 2). The calculated B−N bond lengths compare favourably with the experimental values [experimental: PhB−N 1.594(3), PhB−N*t*Bu 1.367(3), *t*BuN−BH_2 1.555(3), H_2B−N(tmp) 1.665(3) Å, calcd. 1.618, 1.377, 1.561, 1.691 Å]. Clearly, a sufficiently basic N atom of the amino group is needed to favour the ring structure over the open-chain isomer.

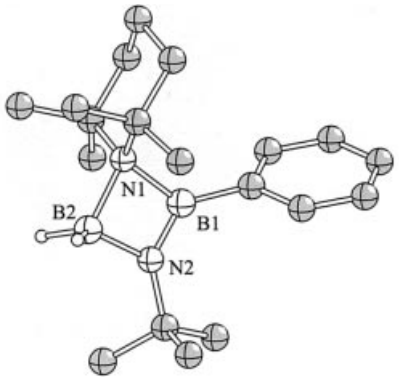

Figure 2. Optimised structure for tmp−BPh−N*t*Bu−BH_2 at the B3LYP/6-311G level of theory

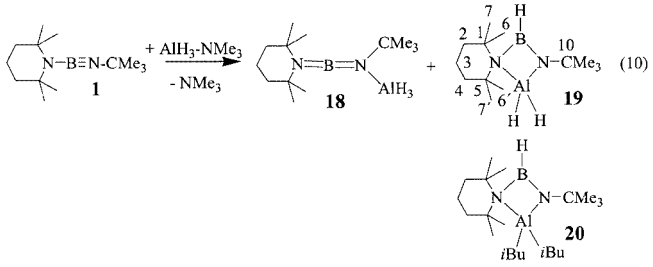
Compound **1** forms adducts of type **C** with $AlCl_3$, $AlBr_3$, $GaCl_3$ and $InCl_3$[18,20] and no insertion reactions have so far been observed for these trihalide adducts in contrast with halosilanes.[22] It was, therefore, of interest to study the

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

behaviour of AlH_3. This hydride was employed as AlH_3-NMe_3 [see Equation (10)].



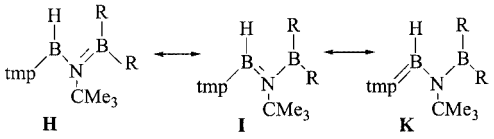
The reaction was followed in hexane solution by ^{11}B NMR spectroscopy which showed that two products were formed. Two new ^{11}B NMR signals appeared at $\delta = 33$ and 27 ppm in a ratio of 1:4. In the proton coupled ^{11}B NMR spectrum, the signal at $\delta = 27$ ppm was a doublet showing that this boron atom carries one hydrogen atom as expected for a hydroalumination product. Two ^{27}Al NMR signals at $\delta = 115$ and 80 ppm in an intensity ratio of 1:4 support the formation of two products. While the low-field signal points to the presence of a tetracoordinate Al atom, the other represents a pentacoordinate Al centre. The intensities of the ^{11}B and ^{27}Al signals change with time. The two high-field signals gain intensity and the low-field signals decrease correspondingly. Moreover, the IR spectrum contains a strong band at 1806 cm^{-1} which is typical for an antisymmetric NBN vibration. These latter data are in agreement with the formation of compound **18**.

Attempts to separate the two compounds by fractional crystallisation from toluene were unsuccessful. The solid obtained showed the same NMR signals as the original reaction mixture. However, well-formed single crystals of dimeric **19** (vide infra) could be selected from the solid material which separated from a hexane solution.

Diisobutylalane reacted chemoselectively with **1** by hydroalumination to the cyclic compound **20**. No transfer of the organyl group was observed. Thus, this reaction corresponds to the hydroalumination of C−C multiple bonds.[23] Nevertheless, compound **20** could not be obtained in a pure form. The reaction of $[(t\text{BuO})_2\text{AlH}]_2$ [24] produced a mixture of three compounds according to the ^{11}B NMR spectrum. We were unable to separate these compounds.

NMR and IR Spectra

Table 3 summarises the NMR spectroscopic data of the hydroboration/haloboration products of the (amino)-(imino)borane **1**. For the diborylamines of the type tmp−BH−N*t*Bu−BX_2, one would expect two ^{11}B NMR signals. This is, however, not the case for **8**, **9**, **10** and **11**. Only one broad signal was observed which showed a barely resolved doublet structure, indicating the presence of a BH group. In the proton-decoupled spectra the doublet vanished but the signal was still broad. Chemical shifts which can be compared with those of **8** to **11** occur in (amino)(organyl)boranes $R_2N-B(H)-R$ ($\delta^{11}B = 41-43$ ppm), monomeric aminoboranes R_2N-BH_2 ($\delta^{11}B = 37-39$ ppm) as well as diborylamines of the type $(R_2N)_2B-NMe-BMe_2$ ($\delta^{11}B = 44-46$ ppm) for the Me_2B group.[25] Thus, the observed chemical shifts for **8**−**10**, which show a better shielding than for any of these aminoboranes, indicate not only that B−N π-bonding is present for the BH group but also that there is a weak interaction of the R_2B group with the tmp nitrogen atom. This is in agreement with a bonding description provided by the formulae **H**−**K**.



The contribution of **K** cannot be significant because there are only single ^1H and ^{13}C resonance signals for the methyl groups at positions 6/7 of the tmp unit in compounds **9** and **10** which indicates free rotation about the B−N bond of the tmp group. However, for the disiamylborane **8**, there are two signals for these hydrogen atoms and four ^{13}C resonances. This can be rationalised by the presence of a nonplanar NBNB skeleton or by a slow interconversion between a cyclic and a noncyclic species. In contrast to these diborylamines, those bearing hydrogen and halogen atoms at the boron atoms are of a cyclic nature as evidenced by two ^{11}B NMR signals as well as two ^1H and ^{13}C resonances for the tmp methyl groups. Those of the tricoordinate boron atoms can be found between $\delta = 20.0$ and 28.8 ppm, whereas those of the tetracoordinate boron atoms are in the range of $\delta = 2.8$ to -5.9 ppm. There are six ^1H NMR signals for the NMe_2 groups of tmp in the mixture of the monohalogen derivatives **14**−**17**. One may expect that compounds **14** and **16** should give rise to two signals for the methyl groups of the tmp ligand and four for compounds **15** and **17**. For the cyclic diborylamines one can expect four signals for these methyl groups provided that the ring is not planar. This is the case for the cyclic diborylamine $Cl_2B-Nt\text{Bu}-\text{BCl}-\text{tmp}$.[26] The C-1/5 carbon atoms of the tmp unit in the dichloro derivative **12** are more deshielded than in the monochloro isomers **14** and **15**, an effect of the stronger Lewis acidic character of the Cl_2B group compared with BHCl. Unfortunately, the corresponding ^{13}C NMR spectroscopic data for the bromo compounds are not available. Conversely, the parent cyclic diborylamine **2** shows only two signals for the methyl groups at positions 6 and 7 both in the ^1H and ^{13}C NMR spectra.[5]

Compounds **19** and **20** give two ^1H and ^{13}C NMR signals for the methyl groups of the tmp substituent in agreement with its cyclic structure. However, the proton resonance for **19** is not well resolved and appears as a broad signal. While the ^{11}B NMR signal for **19** at $\delta = 26.8$ ppm is a doublet in the proton-coupled spectrum [$^1J(^{11}B^1H) = 130$ Hz] no Al−H coupling was observed for the broad ^{27}Al signal at $\delta = 80$ ppm ($h_{1/2} = 9670$ Hz) or for that in **18** [$\delta^{27}Al = 32.6$ ($h_{1/2} = 5170$ Hz]. A strong band at 2468 cm^{-1} in the IR spectrum is typical for a terminal ^{11}BH group of a tricoordinate boron atom. Only a broad and unresolved band centred at 1830 cm^{-1} was observed for the AlH_n vibrations.

Crystal Structure of 19

The cyclic (tmp)borylaminoalane **19** crystallises in the triclinic space group $P\bar{1}$ with $Z = 4$. Therefore, there are two independent monomeric molecules in the unit cell. As shown in Figure 3, the monomers are connected to dimeric molecules via Al−H−Al bridges. The dimeric molecules possess crystallographic inversion centres making each Al atom pentacoordinate. The Al1−N1 bond is 0.242 Å longer than the Al1−N2 bond to the tricoordinate nitrogen atom N2. Also the B1−N1 bond is considerably longer [1.546(5) Å] than the B1−N2 bond [1.369(5) Å] which is typical for B−N π-bonding in monoaminoboranes. The hydrogen bonds between the two Al atoms are asymmetric as shown by the Al(1)−H1 and Al(1A)−H1 bond lengths of 1.65 and 1.46 Å, respectively, while the terminal Al−H bond has a length of 1.48 Å. The four-membered N1−B1−N2−Al1 ring is almost planar, the largest deviation from the mean plane is 0.012(3) Å. The geometry around Al1 is strongly distorted tetragonal-pyramidal. This is of course due to the sharp bond angles N1−Al1−N2 of 72.6(1)° and B1−N1−Al1 of 82.2(1)°. The bond angle N1−Al1−H1 to the apical atoms is 156.7°. As expected, the tmp ring adopts a chair conformation.

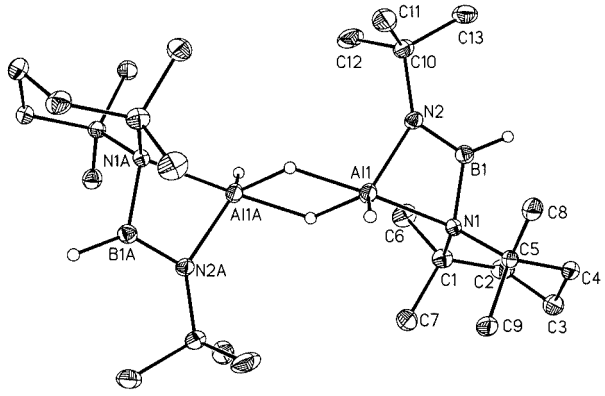

Figure 3. ORTEP representation of the molecular structure of **19**; selected bond lengths [Å]: Al1−N1 2.115(3), Al1−N2 1.873(1), Al1···B1 2.445(4), Al···Al1A 2.813(1), B1−N1 1.546(5), B1−N1 1.369(5), N1−C1 1.534(5), N1−C5 1.582(4), N2−C10 1.483(5), Al1−H1 1.65, Al1−H1A 1.46, Al1−H2 1.48, B1−H1B 1.18; selected bond angles [°]: N1−Al1−N2 72.6(1), N1−B1−N2 108.5(3), Al1−N1−B1 82.2(2), B1−N2−Al1 96.7(2), Al1−N1−C5 116.2(2), Al1−N1−C1 117.2(1), Al1−N2−C10 135.6(2), H1−Al1−H1A 121(1), H1−Al1−H1C 111, Al1−H1−Al1A 130, N1−Al1−H1A 103, N1−Al1−H1 157, H1B−B1−N2 130, H1B−B1−N1 121

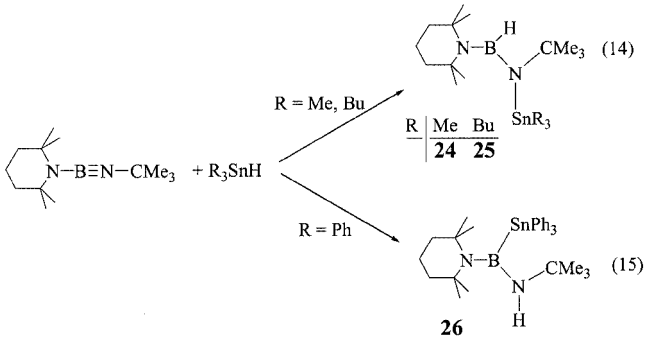
Reactions with Hydrides of Silicon, Germanium and Tin

Within the series of hydrides of the heavier group 14 elements, the bond polarity of the E−H bond changes considerably. Moreover, the hydrides are only weak Lewis acids. Therefore, one may surmise that these hydrides will either not react with **1** or do so only very sluggishly and the hydrogen atom will either move to the boron atom or the nitrogen atom depending on the polarity of the E−H bond. The latter can, of course, be influenced by substituents.

No reaction was observed between Me_3SiH or Ph_3SiH and **1**. However, Ph_2SiH_2 did hydrosilylate **1** according to Equation (11) to yield tmp−BH−N*t*Bu−$SiPh_2H$ (**21**). Moreover, when **1** was treated with Me_2SiHCl or $SiHCl_3$ the corresponding hydrosilylation products **22** and **23** were formed and isolated as viscous oils in good yields.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Me_3GeH and Ph_3GeH did not react with **1** at ambient temperature. At elevated temperature only the dimerization of **1** to its corresponding 1,3,2,4-diazadiboretidine occurred.[4] However, Me_3SnH and Bu_3SnH hydrostannylated **1** as shown in Equation (14) while Ph_3SnH reacted according to Equation (15).



NMR Spectra

In the ^{11}B NMR spectrum of **26** [$\delta^{11}B$ = 44.6 ppm (br., $h_{1/2}$ = 700 Hz)], no $^{11}B^{119}Sn$ coupling could be observed. This is not unusual because of the rapid relaxation due to the quadrupole moment of the ^{11}B nucleus. Also, no ^{119}Sn resonance was found for the same reason. However, a broad ^1H NMR signal at δ = 5.13 ppm indicates the presence of an NH group. Moreover, the IR spectrum of **26** contains a strong band at 3383 cm^{-1} due to the NH vibration.[27] In addition, the ^1H and ^{13}C NMR spectra show three sets of signals for the phenyl groups. Clearly, the vicinity of the bulky tmp substituent induces hindered rotation about the Sn−C bonds. Furthermore, there is only one broad ^1H NMR signal for the methyl group at the tmp substituent and there was no sharpening of the signal at −60 °C. There are, however, two ^{13}C resonances for the methyl groups showing that rotation about the B−N bond is hindered. Most likely, the tmp group stands perpendicular to the N1−B1−Sn1−N2 plane. The final proof of the structure of **26** came from an X-ray diffraction study.

Table 4 shows that the boron nuclei of the two stannylation products of **1** are better shielded than they are in the hydrosilylation products. Moreover, the ^1H and ^{13}C resonances for the tmp methyl groups are at higher field than those of the silyl compounds **21** and **22**. Compounds **21** to **24** all show two ^1H and ^{13}C resonances for these methyl groups indicating hindered rotation. Therefore, one can assume that all these compounds most likely have cyclic structures.

X-ray Structure Analysis of 26

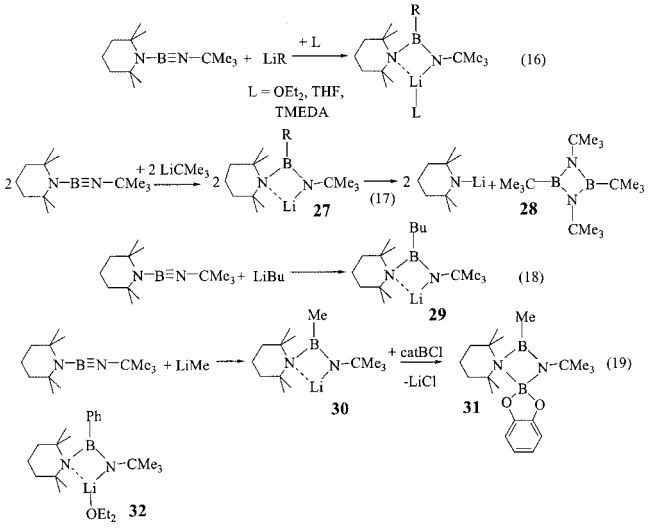
Crystals of **26** are orthorhombic. The space group is $P2_12_12_1$ with Z = 4. Figure 4 depicts the molecular structure of this molecule. It supports the conclusions deduced from the spectroscopic data.

The B−Sn bond length in **26** of 2.295(2) Å corresponds to a single bond as found, for example, in $Me_3Sn(Me_2N)B-B(NMe_2)SnMe_3$ [2.276(2) Å].[28] The two B1−N bonds differ by 0.087(3) Å, the longer bond involves the B−N bond to the tmp group which shows a crown configuration and whose C1−N1−C5 plane includes a twist angle with the N1−B1−N2 plane of 85.2°. The sum of the bond angles at N1 is 354.2° which shows that the N1 atom is almost sp^2-hybridised. There is a strong steric interaction between one of the phenyl groups with the *tert*-butyl group as seen by a B1−N2−C10 bond angle of 137.2(2)°. The torsion angle for the atoms Sn1−B1−N2−C10 is 13.5°, and the tmp substituent (C1−N1−C5) stands almost vertical (91.7°) to the N1−B1−Sn1 plane.

Reactions of Main Group Elements with Organyl Compounds MR_n (n = 1−3)

Reactions with Organyllithium Compounds

Some reactions of organylmetal compounds MR_n with **1** have so far only been described for M = Li and Mg in a review article.[3] In principle, organyllithium compounds should add to **1** according to Equation (16) but the stability of the resultant *N*-lithiodiaminoboranes depends on the nature of R.



For instance, *tert*-butyllithium reacts according to Equation (16) but the product **27** is unstable and decomposes into Li(tmp) and the 1,3,2,4-diazadiboretidine **28** [Equation (17)]**.** In contrast, *n*-butyllithium leads to the stable *N*-lithiodiaminoborane **29**. Methyllithium yields compound **30** which, like **27**, decomposes. However, when the reaction (19) is performed in the presence of tetramethylethylenediamine then **30** can be treated with *B*-chlorocatecholborane to produce the cyclic diborylamine **31**. No reaction occurred between fluorenyllithium and **1**, but phenyllithium reacted smoothly in diethyl ether to give compound **32** which could be isolated as single crystals from a hexane/diethyl ether solution.

X-ray Structural Analyses of 32 and 31

Figure 5 shows the molecular structure of **32**. It features a four-membered LiN_2B ring with a tricoordinate Li atom. The Li1−N2 bond is 0.21 Å shorter than the coordinate Li1−N1 bond. Atom N2 has a planar geometry which al-

lows good B−N π-bonding. The phenyl group stands almost perpendicular to the N1−B1−N2 plane (τ = 89.5°). This prevents B−C π-bonding. The four-membered ring has a flat butterfly structure as shown by an interplanar angle τ = 9.1° for the planes B1−N2−Li1 and B1−N1−Li1. As usual, the tmp ring has a chair conformation. Its N1 atom adopts a distorted tetrahedral geometry with bond angles ranging from 78.9(2) to 118.0(2)°. Although the ring structure of **32** is certain in the solid state, it is very likely that this structure is not retained in solution since only a single signal was observed for the methyl groups at the tmp substituent, both in the ^{1}H and ^{13}C NMR spectra.

An ORTEP plot of the molecular structure of the cyclic diborylamine **31** is shown in Figure 6. It features a planar four-membered B_2N_2 ring. The B1−N1 bond is 0.262 Å longer than the B1−N2 bond [1.378(3) Å]. The B−N bonds to B2 are 1.753(3) Å (N1) and 1.495(3) Å (N2), respectively. The latter is typical for a single bond between an sp^3-hybridised boron atom and an sp^2-hybridised N atom. The long B2−N1 distance corresponds to a weak bond which is in agreement with the NMR spectra which show only one signal for the tmp methyl groups indicating rotation about its B−N bond in solution. Although one might have expected the two B−O bonds to be equal in length, this is not the case and they differ by 0.04 Å. Their lengths are similar to those found for the bis(catecholato)borate anion.[29] The planes N1−C1−C5 and B2−O1−O2 stand almost perpendicular to the B1−N1−B2−N2 ring plane by 92.5 and 89.8°, respectively.

Reactions with Diorganylmagnesium, -zinc, -cadmium and -mercury Compounds

In order to test the possibility of a double insertion of **1** into metal−carbon bonds of dialkylmetal compounds ER_2 (E = Mg, Zn, Cd, Hg), we studied the reaction of **1** with

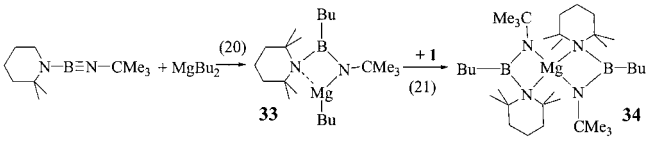
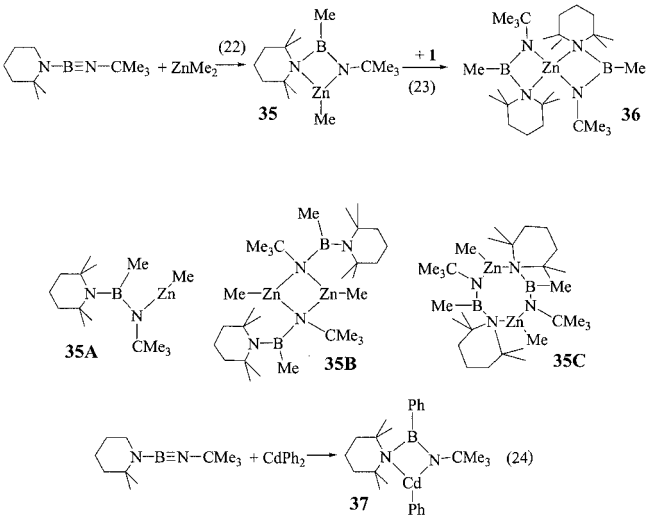
dibutylmagnesium. Reactions (20) and (21) proceeded rapidly at −78 °C. Only a single ^{11}B NMR signal was found at $\delta^{11}B = 37.6$ ppm. This value is typical for metallated diaminoboranes. Compound **33** was obtained as a viscous oil and attempts at crystallisation were unsuccessful. Because the NMR spectroscopic data for **33** and **34** are rather similar to those of the lithium compound **30**, we assume that the magnesium atom is coordinated to the tmp nitrogen atom. Dibutylmagnesium reacts with **1** not only in a 1:1 stoichiometry but also in a 1:2 ratio to produce **34**. This product is also a viscous oil with $\delta^{11}B = 39.0$ ppm.



Dialkylzinc compounds are less reactive than dialkylmagnesium compounds. Nevertheless, **1** reacted with dimethylzinc in toluene to produce a solid 1:1 insertion product **35**, $\delta^{11}B = 39.4$ ppm, as shown in Equation (22). The compound was obtained as single crystals. A reaction in a 1:2 ratio to give **36** was also successful.

As a representative of organylcadmium compounds we studied the reaction of diphenylcadmium with **1** in toluene. Reaction (24) proceeded smoothly to give compound **37**. In contrast, diphenylmercury did not react with **1** either at ambient temperature or in refluxing toluene.

From the solutions of **37**, a few well-shaped crystals separated within several days. These, however, proved not to be compound **37** but rather $CdPh_2$. As far as we know, the structure of this compound has not yet been determined. Therefore, some data for this linear compound are listed in the references.[30] **37** is isostructural with $HgPh_2$.[31]



NMR Spectra

An overview of relevant NMR spectroscopic data of the lithium, magnesium, zinc and cadmium compounds is given in Table 5. The magnesium compound **33** exhibits only single ^1H and ^{13}C NMR signals for the methyl groups at the piperidino ring. This suggests a weak interaction of the Mg atom with the tmp nitrogen atom allowing rotation of the tmp group in solution. A similar situation is, therefore, expected for **34** which shows a broad low-field proton NMR signal for the C-6/7 group but two ^{13}C NMR signals. This can be explained by a hindered rotation about the B−N bond of the $BNCMe_3$ group where the *t*Bu group attached to the boron atom can be oriented either *cis* or *trans* to the *tert*-butyl group. This suggestion is supported by the strong deshielding of the protons of the CMe_3 group in **34**. The ^{11}B NMR signals of the two Mg compounds are rather similar, and the shielding of the boron nuclei are similar to those of the Li and Zn compounds.

The ^1H NMR spectrum of **35** reveals two sharp singlets for the BMe and ZnMe groups in a 1:1 ratio. Also, two ^{13}C NMR signals were observed for these groups. These are sharp for ZnMe ($\delta^{13}C = 11.3$ ppm) and broad for BMe ($\delta^{13}C = 1.0$ ppm). A single resonance represents the methyl groups at tmp and two signals in a 2:1 ratio were found for the CH_2 groups of the piperidino ring. Thus, in solution, the structure of compound **35** may either be monomeric or dimeric. However, in the case of the dimer (**35B**) one would expect a low-field shift of the protons of the CMe_3 group, due to the tetracoordination of the respective nitrogen atom. Because monomeric organylzinc amides are scarce, the alternative **35A** is not very likely. Another possibility might be the dimeric structure **35C** which we regard as unlikely because two sets of NMe_2 group are to be expected. However, the molecular structure of **35** has been shown to be a cyclic *N*-(methylzinc)diaminoborane in the solid state. For this reason we suggest that the structure of **36** is also spirocyclic in solution as found for **35** in the solid state.

37	35.4	1.32 (t)	1.54 (m)	1.06, 1.38	1.08	53.2	43.5	17.8	50.6	35.6	25.3, 38.6

The chemical shift $\delta^{11}B = 35.4$ ppm for **37** is compatible with the suggested $PhBN_2$ unit as found in $PhB(NMe_2)_2$ ($\delta = 32.4$ ppm) or $PhB(NEt_2)_2$ ($\delta = 34.1$ ppm).[25] As for **34**, only one ^{1}H NMR signal but two ^{13}C resonances were observed for the methyl groups at tmp in the ^{1}H and ^{13}C NMR spectra. The presence of the Cd atom follows from the satellites observed on the methyl carbon resonance which indicates a $^3J(^{111/113}Cd^{13}C)$ coupling.

Molecular Structure of 35

The zinc compound **35** crystallises in the monoclinic space group $P2_1/c$. Figure 7 shows the ORTEP plot. In the solid state, the methyl[*N*-(methylzinc)-*tert*-butylamino](tetramethylpiperidino)borane is present as a four-membered almost planar ring. Its shape, however, is a strongly distorted trapezoid due to four different endocyclic bond lengths. Endocyclic bond angles range from 70.43(8)° (N1−Zn1−N2) to 98.7(2)° (B1−N2−Zn1). The interplanar angle, τ, between the planes N1−Zn1−N2 and N1−B1−N2 is 2.9°. Notable is the tricoordinate zinc atom (sum of the bond angles = 360°). The B1−N2 bond is quite short at 1.350(4) Å, implying the presence of a B−N π-bond. As in many of the other structures presented here, the B1−N1 bond is long [1.555(3) Å], typical for a single bond. Analogously, the Zn1−N1 bond [2.222(2) Å] is much longer than the Zn1−N2 bond (1.908 Å). The tmp group adopts a chair conformation.

As far as we are aware, the structure of compound **35** is unique since alkylzinc amides $RZnNR_2$ are usually dimeric, containing a four-membered Zn_2N_2 ring.[31,32] The X-ray structure of $(MeZnNPh_2)_2$[33] shows Zn−N bond lengths of 2.080 and 2.066 Å to the tetracoordinate nitrogen atoms. These are much shorter than in compound **35** but longer than the Zn1−N2 bond to the tricoordinate N atom. Dimers of the type $(RZnNR_2)_2$ can be broken up with donors such as pyridine, but no adducts of the type $RZnNR_2(py)$ have yet been characterised in contrast to $RZnNR_2(py)_2$, in which the zinc atom is tetracoordinate.[33]

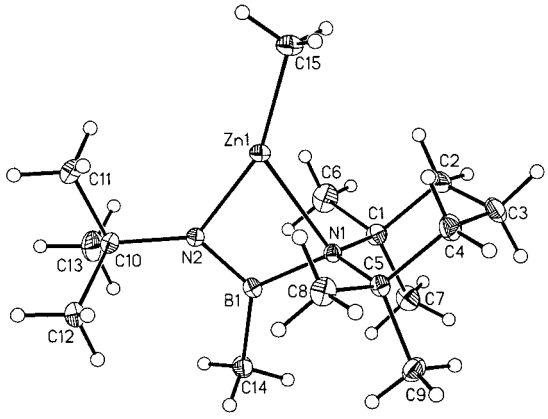

Figure 7. Molecular structure of **35** in the solid state; selected bond lengths [Å]: Zn1−N1 2.222(2), Zn1−N2 1.908(2), Zn1−C15 1.944(3), N1−C1 1.514(3), N1−C5 1.514(3), B1−N1 1.555(3), B1−N2 1.380(4), B1−C14 1.597(4), N2- C10 1.481(3); selected bond angles [°]: Zn1−N1−B1 81.59(2), Zn1−N1−C1 110.9(2), Zn1−N1−C5 110.2(2), N1−B1−N2 109.2(2), N1−B1−C14 122.8(2), N2−Zn1−N1 70.43(8); angles between planes [°]: Zn1N1nB1/Zn1N2B1 2.9, C1N1C5/Zn1N2B1N2 90.0

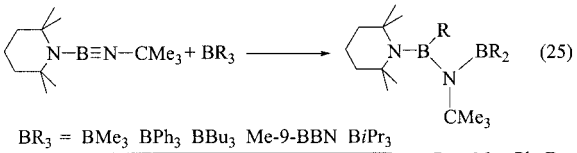
Reactions with Triorganylboranes, -alanes, -gallanes, and -indanes

The triorganyl compounds of the group 13 elements are medium to strong Lewis acids, the acidity being determined principally by the steric requirements of the organyl group. It was, therefore, expected that no 1:1 adducts would be observed in reactions with **1** because the (amino)(imino)-borane is only a moderate base. Indeed, no evidence for a stable 1:1 coordination compound with triorganylboranes was observed by NMR spectroscopy. However, organoboration of **1** occurs easily, but the rate depends strongly on the steric requirements of the organyl group. This is shown by the data for reaction (25).



BR_3 =	BMe_3	BPh_3	BBu_3	Me-9-BBN	$BiPr_3$
rate (h)	1[a]	16	24	96	336

R = Me, Ph Bu [b] *i*Pr
38 **39** **40** **41** **42**

[a] at -78°C

[b] R = Me, BR_2 = 9-BBN

To rationalise these results we assume that there is a pre-equilibrium **1** + BR_3 ⇄ **1**·BR_3. The position of this equilibrium lies more on the side of the individual components the more bulky the R group becomes. Thus, the lower the concentration of the adduct, the slower the reaction rate. In the case of *B*-methyl-9-borabicyclo[3.3.1]nonane, it is the methyl group which moves to the boron atom. Most of

these new asymmetrically substituted diborylamines (**38**−**42**) are liquids.

Although the triorganyl compounds of the heavier group 13 element are all dimeric, they react rapidly with **1** according to Equation (26). Most of the resultant compounds are viscous liquids. Some are solids, however, but single crystals of these could not be obtained.

NMR Spectra

The NMR spectroscopic data of compounds **38**−**41** and **43**−**48** are summarised in Table 6 (ignoring the data for the substituents at element E which are found in the Exp. Sect.). The dialkyl[*N*-(tetramethylpiperidinoboryl)-*tert*-butylamino]boranes **38**−**41** exhibit two ^{11}B NMR signals. In case of **39**, only a single signal was observed. This is not totally surprising since resonances of CBN_2 and C_2BN groups can be close together [Ph_2BNR_2: δ = 40−43 ppm; $PhB(NR)_2$: δ = 33−36 ppm; $(Ph_2B)_2NH$: δ = 41 ppm].[25] In general, for the two groups, those of the C_2BN type are less well shielded than those for CBN_2. In general, boron atoms of diborylamines are less well shielded than boron atoms of aminoboranes. In all cases, two resonances were observed for the C-6/7 atoms revealing hindered rotation about the tmp group. No systematic influence on the $\delta^{11}B$ shifts by the group 13 element atoms in compounds **39**−**48** could be observed. Because all show two ^1H and ^{13}C signals for the C-6/7 methyl groups, it follows that these compounds most likely have ring structures with E−N1 bonds. This is supported by a ^{27}Al NMR signal at δ = 105 ppm for **43** which is consistent with a tetracoordinate Al atom. On the other hand, the rather broad ^{27}Al NMR signal at δ = 150 ppm for **44** points to a noncyclic structure with hindered rotation about the B−N bond of the tmp group. This conclusion for **43** as well as for **46** is supported by the X-ray structures of tmp−BPh−N*t*Bu−EMe_2 (E = Al, Ga) which will be discussed shortly.[21]

Discussion

The B≡N triple bond of iminoboranes is highly reactive and this has been further demonstrated by results described here for the (amino)(imino)borane **1**. The reaction with diborane is not selective because four different compounds were observed in addition to the hydroboration product **2**. The by-products result from B−N bond cleavages. However, **2** can be formed in high yield by employing $H_3B{-}SMe_2$ as the borane source. On the other hand, only hydroboration of **1** occurs with diorganylboranes and thexylborane (employed as its dimer). Hence, this reaction is faster than the organoboration of **1** which can be achieved by using triorganoboranes. This can be rationalised by the higher negative charge at the hydrogen atom compared with the organyl group, as well as of the ability of the hydridic hydrogen atom to form hydrogen bonds between two electropositive atoms. The competition between hydroboration and haloboration is chemoselective for the former in the case of the dihaloboranes $HB(Hal)_2{-}SMe_2$, while in case of monohaloboranes both reactions compete with each other. In this case, the hydroboration should be statistically more favourable. This is indeed observed for $H_2BCl{-}SMe_2$ but not for $H_2BBr{-}SMe_2$. In the latter case the observed 1:1 product ratio of the two isomers shows that bromoboration is favoured. If the determining factor were the partial negative charges at the hydrogen and halogen atoms, then the haloboration should win the competition as observed for $HB(Hal)_2$. From this point of view it was most surprising to find that $HSiCl_3$ reacts with **1** exclusively by hydrosilylation, although statistically the chlorosilylation of **1** should be favoured and this is indeed observed when em-

Table 6. Selected NMR spectroscopic data of compounds **38**−**48**; chemical shifts δ in ppm; additional data can be found in the Exp. Sect.

ploying diorganyldichorosilanes, trichloro(organyl)silanes or silicon tetrahalides.[8,22] The silanes must be sufficiently Lewis acidic. Thus, Me_3SiH and Ph_3SiH do not react with **1** in contrast to Me_2SiHCl and Ph_2SiH_2, although both are not strong Lewis acids but obviously of sufficient strength to induce the hydrosilylation of **1**. On the other hand, the hydrides Ph_3EH (E = Si, Ge) did not react with **1** in contrast to Me_3SnH, Bu_3SnH and Ph_3SnH. This indicates that steric factors also influence the hydrometallation of **1**. However, it was most surprising that with Ph_3SnH an umpolung of the insertion occurs. The imino nitrogen atom of **1** is protonated with formation of a B−Sn bond.

The organylmetal compounds LiR, MgR_2, ZnR_2, CdR_2, BR_3, AlR_3, GaR_3 and $InPh_3$ all react with **1** by organometallation. This is a new route to compounds of the type tmp−BR−N*t*Bu−ER_{n-1}. Paetzold et al. have studied the reactions of LiR compounds with the iminoboranes X−B=N−CMe_3 (X = Me, Et, Bu). These react in a 1:2 ratio and provided *N*-lithioazaborazoniaborate compounds.[34] However, with iminoboranes X−B≡N−CMe_3 [X = CMe_3, $N(SiMe_3)CMe_3$] *N*-lithioaminoboranes $LiN(CMe_3)$−BXR were obtained of which (TMEDA)$LiN(CMe_3)$−$B(CMe_3)_2$ was crystallographically characterised.[34] Usually, *N*-lithioaminoboranes are prepared by deprotonation of aminoboranes R_2B−NHR′, $RB(NHR')_2$ or $B(NHR)_3$.[35−40] Deprotonation of the diborylamine mes_2B−NH−$Bmes_2$ with LiR in diethyl ether leads to ionic $[(Et_2O)_3Li][N(Bmes_2)_2]$ with a linear BNB unit of an allenic type and short B−N bonds [1.343(5), 1.348(5) Å] due to the dicoordinate N atom,[36] while deprotonation of mes_2B−NH_2 gives dimeric $[(Et_2O)LiNHBmes_2]_2$.[37] In both cases the Li atoms are tricoordinate. In the latter case, the nitrogen atoms are tetracoordinate. Consequently, the B−N bond of the dimeric molecule is longer [1.386(4) Å] than in mes_2BNH_2. Association of *N*-lithioaminoboranes can be prevented by using multidentate bases as ligands as has been demonstrated for 9-*N*-lithio(trimethylstannylamino)borabicyclo-[3.3.1]nonane−pentamethylethylenetriamine.[39] The monomeric *N*-lithiodiaminoborane **32** is unique because in the solid state the intramolecular coordinative Li−N bond stabilises the tricoordination of the Li atom and the bulkiness of the groups at the two nitrogen atoms hinders association. The B2−N2 bond of **32** is at the shorter end for B−N bonds [1.361(4) Å] between tricoordinate B and N atoms indicating a high degree of π-bonding. However, the Li1−N1 bond is weak and is 0.2 Å longer than the Li1−N2 bond. This is a general observation for all the *N*-metallated diaminoboranes reported here (**19**, **32** and **35**) and many others of a similar type.[21] In solution, however, the coordinate Li1−N1 bond (also Mg−N, B−N, Al−N, Ga−N and In−N bonds) is opened as shown by only one ^1H or ^{13}C NMR signal for the methyl groups attached to the piperidino ring. For those where two or more signals were observed, one can assume that the ring structure with a coordinate N1−E bond is retained in solution as shown, for instance, for compounds **12**−**17**. In particular, the lithium compound **32** proved to be a versatile reagent and we will report on its chemistry in a forthcoming paper.[21]

Experimental Section

General: All experiments were performed under anhydrous conditions using Schlenk or vacuum-line techniques. Solvents were dried by conventional methods. Commercial chemicals were purified either by distillation, crystallisation or were used as supplied (solutions of LiR compounds). Several compounds were already available in our laboratory. The following compounds were prepared by literature methods: **1**,[4] $AlMe_3$−OEt_2,[40] Ph_3In−1,4-dioxane,[41] Ph_3Al,[42] thexylborane,[12] disiamylborane,[43,44] $HBCl_2$−SMe_2 and H_2BCl−SMe_2,[45] $HBBr_2$−SMe_2 and H_2BBr−SMe_2,[46] 9-BBN.[47] NMR: Bruker AC 200 (^7Li, ^{11}B, ^{119}Sn), Jeol GS270 (^1H, ^7Li, ^{11}B, ^{13}C, ^{14}N, ^{119}Sn), Jeol EX400 (^1H, ^{13}C) instruments. If not otherwise stated all NMR spectra were recorded in C_6D_6. References: $SiMe_4$ (int.), BF_3−OEt_2 (ext.), 1 M aqueous LiCl (ext.), C_6D_6 (int.), aqueous 1 M $NaNO_3$ (^{14}N), $SnMe_4$ (ext.). IR: Nicolet FT-IR spectrometer (liquids as capillary films, solids as nujol mulls). MS: Atlas CH7 instrument, 70 eV; reported data: mass, relative intensity, assignment. X-ray: Siemens P4 diffractometer equipped either with a scintillation counter or a CCD detector. Low-temperature device LT2, Mo-K_α radiation, graphite monochromator.

[(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]-borane (2): A solution of H_3B−SMe_2 (0.39 mL, 7.0 M solution in hexane, 2.8 mmol) was added to a solution of **1** (2.9 mL of a 0.96 M solution, 2.8 mmol) in hexane. The reaction was slightly exothermic. After 24 h of stirring, all volatile components were removed at ambient temperature in vacuo. **2** remained as a colourless oil. ^1H (^{11}B-decoupled) NMR: δ = 3.91 (br., 2 H, BH_2), 4.77 (br., 1 H, BH) ppm. $C_{13}H_{30}B_2N_2$ (236.0): calcd. C 66.16, H 17.94, N 11.87; found C 64.76, H 17.25, N 11.67.

[(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]diisopropylaminoborane (6): To a solution of freshly distilled diisopropylamine (0.42 mL, 3.0 mmol) in hexane (20 mL) was added at 0 °C a solution of BH_3−THF in hexane (1.0 M, 3.0 mL). After warming to ambient temperature, all volatile components were removed in vacuo leaving behind 0.44 g of H_3B−NH(*i*Pr)$_2$ {$\delta^{11}B$ = −20.58 [quat., $^1J(^1H^{11}B)$ = 96 Hz] ppm}. A solution of **1** in hexane (0.96 M, 3.10 mL, 3.0 mmol) was then added at −78 °C. No reaction occurred at room temperature. On heating to reflux overnight, the formation of **6** was noted by its ^{11}B NMR signal at δ = 50.6 ppm. The compound was isolated as a solid after removal of all volatile components in vacuo. Yield 0.82 g of **6** (98%). The ^1H NMR spectrum was not very informative as the signals were strongly overlapping.

[(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]dicyclohexylborane (8): A solution of **1** (7.9 mL, 0.462 M, 3.6 mmol) in hexane was added with stirring to tetracyclohexyldiborane (0.65 g, 1.8 mmol). The diborane derivative dissolved slowly. About 2 h later, a precipitate formed. According to ^{11}B NMR spectroscopy the reaction was complete after 4 d. After removal of the solvent in vacuo, a colourless powder remained which proved to be pure **8**. Yield 1.4 g of **8** (98%), m.p. 122−124 °C. ^1H NMR: δ = 1.78 (br., 22 H, C_6H_{11}), 2.15 (br., 1 H, BH) ppm. ^{13}C NMR: δ = 24.1 (br., BC), 27.7 (*p*-C of C_6H_{11}), 28.7 (*m*-C), 28.9 (*o*-C) ppm. MS (70 eV): *m*/*z* (%) = 400 (75) [M^+], 385 (15) [M^+ − Me], 317 (100) [M^+ − C_6H_{11}] and others. $C_{25}H_{50}B_2N_2$ (400.31): calcd. C 75.01, H 12.59, N 7.00; found C 74.54, H 11.25, N 6.77.

[(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]diisoamylborane (9): A solution of **1** (8.65 mL, 0.462 M, 4.0 mmol) in hexane was added with stirring to a hexane solution of freshly prepared

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dimeric disiamylborane (4.0 mmol). ^{11}B NMR spectroscopic analysis showed that the hydroboration of **1** was complete after 24 h. Removal of volatile material in vacuo left an oily residue which turned out to be pure **9**. Yield 1.47 g (97%). ^{1}H NMR: δ = 3.78 (br., 1 H, BH), 1.36, 1.35 [each 3 H, B(CH*Me*)], 1.01, 1.08 (each 6 H, CH*Me*$_2$) ppm. ^{13}C NMR: δ = 16.6 (br., BC), 23.0 (CH*Me*$_2$), 22.7 (BCH*Me*), 55.7 (CH*Me*$_2$) ppm. MS (70 eV): *m*/*z* (%) = 376 (28) [M$^+$], 361 (14) [M$^+$ − Me], 319 (40) [M$^+$ − C$_4$H$_9$], 305 (100) [M$^+$ − C$_5$H$_{11}$], 235 (100) [305 − C$_5$H$_{10}$]$^+$, 222 (24) [235 − CH$_2$]$^+$ and fragments of lower mass. $C_{23}H_{50}B_2N_2$ (376.29): calcd. C 73.42, H 13.39, N 7.44; found C 74.25, H 13.66, N 7.80.

9-[(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]-9-borabicyclo[3.3.1]nonane (10): A solution of dimeric 9-borabicyclo[3.3.1]nonane (0.30 g, 1.4 mmol) in pentane (30 mL) was cooled to −78 °C. A solution of **1** (12.3 mL, 0.277 M, 2.8 mmol) in pentane was then slowly added. After stirring for 2 h at ambient temperature, the reaction was complete. A light yellow oil remained after removal of the pentane in vacuo (50 Torr). After addition of hexane (1 mL) and cooling of the solution to −50 °C, a colourless powder of **10** precipitated. Yield 0.91 g (95%), m.p. 65−67 °C. ^{1}H NMR: δ = 1.05 (2 H, CH), 1.90 (br., 12 H, 6 CH$_2$) ppm. ^{13}C NMR: δ = 12.1 (br., BMe), 23.5 (C$_a$), 26.5 (C$_d$), 33.0 (C$_c$) 33.2 (C$_b$) ppm. ^{14}N NMR: δ = −231 ppm. MS (70 eV): *m*/*z* (%) = 344 (95) [M$^+$], 329 (90) [M$^+$ − Me], 288 (15) [M$^+$ − C$_4$H$_8$], 261 (93) [M$^+$ − C$_6$H$_9$], and fragments of lower mass. $C_{21}H_{42}B_2N_2$ (344.20): calcd. C 73.28, H 12.30, N 8.14; found C 75.43, H 12.75, N 7.83.

[(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino](1,1,2-trimethylpropyl)borane (11): To freshly prepared *sym*-dithexyldiborane(6) (2.5 mmol) was added, with stirring, a solution of **1** (10.8 mL, 0.462 M, 5.0 mmol) in hexane. After stirring for 8 d. the reaction was complete as shown by ^{11}B NMR spectroscopy. After removal of the hexane in vacuo, a colourless, mobile liquid was left. Yield 1.19 g of **11** (98%). The compound decomposed on attempted distillation at 130 °C/10^{-2} Torr with formation of 2,3-dimethyl-2-butene (trapped at −196 °C and identified by NMR spectroscopy). ^{1}H NMR: δ = 0.91 [d, ^3J(^{1}H^{1}H) = 6.6 Hz, 6 H, CHMe$_2$], 0.94 (6 H, C*Me*$_2$) ppm. ^{13}C NMR: δ = 18.6 (CH$_2$), 22.5 (C*Me*$_2$), 29.0, (br., CB), 37.3 (*C*HMe$_2$) ppm. MS (70 eV): *m*/*z* (%) = 236 (32) [M$^+$ − C$_6$H$_{12}$], 180 (9) [236 − C$_4$H$_8$]$^+$, no M$^{\cdot+}$. $C_{19}H_{42}B_2N_2$ (320.18): calcd. C 71.28, H 13.23, N 8.75; found C 72.14, H 13.11, N 9.21.

{(*tert*-Butyl)[chloro(2,2,6,6-tetramethylpiperidino)boryl]amino}borane (14) and [(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]chloroborane (15): To an emulsion of BH$_2$Cl−SMe$_2$ in hexane (2.7 mmol in 1.60 mL) was added dropwise a hexane solution of **1** (10.3 mL, 0.267 M, 2.7 mmol). After stirring for 5 h, a clear solution resulted. All volatile materials were removed in vacuo leaving behind a colourless viscous oil. In C$_6$D$_6$, this solution showed the presence of two isomers. **14:** ^{11}B NMR: δ = −5.9 [t, ^1J(^{11}B^{1}H) = 125 Hz], 25.1 ppm (ratio 1:1). **15:** ^{11}B NMR: δ = 3.8 [d, ^1J(^{11}B^{1}H) = 125 Hz], 30.6 [d, ^1J(^{11}B^{1}H) = 142 Hz] ppm (ratio 1:1). In addition a signal for (tmpB−NCMe$_3$)$_2$ (δ^{11}B = 34.6 ppm) was observed. The mixture could not be separated by fractional distillation.

{[Bromo(2,2,6,6-tetramethylpiperidino)boryl](*tert*-butyl)amino}borane (16) and Bromo[(*tert*-butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]borane (17): In analogy to **15** the components H$_2$BBr−SMe$_2$ (1.50 mL, 1.5 M, 2.2 mmol) and **1** (4.87 mL, 0.462 M, 2.2 mmol) were allowed to react in hexane. After 24 h, neither of the two starting materials could be detected by ^{11}B NMR spectroscopy. Four new signals were present, both as pairs in a 1:1 ratio. **16:** ^{11}B NMR: δ = 2.4 [t, ^1J(^{11}B^{1}H) = 75 Hz], 30.8 (s) ppm. **17:** ^{11}B NMR: δ = 1.0 [d, ^1J(^{11}B^{1}H) = 50 Hz], 32.3 [d, ^1J(^{11}B^{1}H) = 105 Hz] ppm. The mixture of isomers was not characterised by elemental analysis.

{(*tert*-Butyl)[chloro(2,2,6,6-tetramethylpiperidino)boryl]amino}chloroborane (12): To a stirred solution of HBCl$_2$−SMe$_2$ (1.50 mL, 1.30 M, 1.9 mmol) was added dropwise a hexane solution of **1** (7.28 mL, 0.267 M, 1.9 mmol). After 48 h, the reaction was quantitative. Removal of the volatile material left behind a colourless oil. Yield 0.55 g of **12** (93%). IR: ṽ = 2480 (νBH), 1480, 1450 (νBN$_2$), 660 (νBCl) cm^{-1}. $C_{13}H_{28}B_2Cl_2N_2$ (304.9): calcd. C 51.21, H 9.26, N 9.89; found C 51.11, H 9.39, N 9.34.

Bromo{[bromo(2,2,6,6-tetramethylpiperidino)boryl](*tert*-butyl)amino}borane (13): In analogy to **12** a hexane solution of HBBr$_2$−SMe$_2$ (19 mL, 0.23 M, 4.4 mmol) was allowed to react with **1** (7.33 mL, 0.23 M, 4.4 mmol). The reaction was slightly exothermic. After heating for several minutes to reflux, all volatile materials were removed in vacuo. **13** was obtained as a colourless viscous oil. Yield 1.69 g of **13** (97%). $C_{13}H_{28}B_2Br_2N_2$ (313.89): calcd. C 49.70, H 8.92, N 8.92; found C 48.98, H 8.97, N 8.76.

Dimeric [(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]alane (19): A solution of **1** in hexane (18.7 mL, 0.186 M, 3.5 mmol) was diluted further with hexane (15 mL), cooled to −78 °C, and a solution of AlH$_3$−NMe$_3$ (0.31 g, 3.5 mmol in 25 mL of diethyl ether) was added dropwise with stirring. After warming the mixture to ambient temperature, the ^{11}B NMR spectrum showed a broad signal at δ = 34.7 ppm and doublet at δ = 27.1 ppm. The volume of the solution was then reduced by about 50%. After 1 d at −20 °C, crystals had separated. The majority of the crystals were well-developed prisms which proved to be **19**. The compound is very moisture-sensitive. Selected IR bands: ṽ = 2515, 2468 (ν$^{10/11}$BH), 1831 (νAlH), 1460 (νBN$_2$) cm^{-1}. $C_{25}H_{60}Al_2B_2N_4$ (504.37): calcd. C 61.92, H 11.99, N 11.11; found C 57.05, H 11.78, N 9.45.

[(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]diisobutylalane (20): To a stirred solution of **1** (3.0 mL, 0.96 M, 2.9 mmol) in hexane was added a hexane solution of *i*Bu$_2$AlH (2.9 mL, 1.0 M diluted with 10 mL of hexane). After 24 h, the hexane was removed in vacuo leaving behind **20** as a colourless air- and moisture-sensitive liquid (1.05 g, 99%). ^{1}H NMR: δ = 0.46 [d, ^3J(^{1}H^{1}H) = 6.3 Hz, 4 H, AlC*H*$_2$], 1.22 [d, ^3J(^{1}H^{1}H) = 6.3 Hz, 12 H, CH(C*H*$_3$)$_2$], 2.20 [m, 2 H, C*H*(CH$_3$)$_2$] ppm. ^{13}C NMR: δ = 28.8, 29.2 [CH(*C*H$_3$)$_2$], 32.7 ppm; *C*H(CH$_3$)$_2$, Al*C* not observed. ^{27}Al NMR: δ = 109.5 ($h_{1/2}$ = 1960 Hz) ppm. IR: ṽ = 2460 cm^{-1} (νBH). $C_{21}H_{46}AlBN_2$ (364.41): calcd. C 69.22, H 12.72, N 7.69; found C 68.21, H 12.08, N 8.12.

[(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]diphenylsilane (21): To a solution of Ph$_2$SiH$_2$ (0.415 g, 2.25 mmol) in toluene (10 mL) was added a solution of **1** (4.6 mL, 0.5 M) in hexane diluted with toluene (10 mL). The mixture was stirred for 2 weeks. After this time, the ^{11}B NMR signal of **1** could no longer be detected. Removal of the solvents left behind a colourless oil. Attempts at crystallisation were unsuccessful. Because the NMR spectroscopic data showed no impurities, no further purification attempts were deemed necessary. ^{1}H NMR: δ = 0.57 (SiMe$_2$), 7.10−9.0 (m, Ph) ppm. ^{13}C NMR: δ = 129.01, 129.53, 130.17, 136.17, 17.71 (Ph) ppm. ^{29}Si NMR: δ = −21.87 [^1J(^{1}H^{29}Si) = 21 Hz] ppm. Selected IR bands: ṽ = 2490, 2395 (νBH), 2120 (νSiH) cm^{-1}. $C_{25}H_{39}BN_2Si$ (406.2): calcd. C 73.96, H 9.68, N 6.89; found C 72.63, H 9.77, N 7.08.

[(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinobory)amino]trichlorosilane (22): To a toluene solution of **1** (0.67 g, 3.0 mmol in 4.6 mL) was

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

added at 0 °C a solution of $SiHCl_3$ (0.4 mL, 0.54 g, 4.0 mmol) in toluene (6 mL). After stirring for 30 min, all volatile material was removed in vacuo. Distillation afforded 0.66 g of **22** (62%), b.p. 110−115 °C/0.005 Torr, m.p. 40 °C. ^{14}N NMR: δ = −235, −298 ppm. IR: $\tilde{\nu}$ = 2492, 2460 st (νBH) cm^{-1}. $C_{13}H_{28}BCl_3N_2Si$ (357.64): calcd. C 43.66, H 7.89, N 7.83; found C 43.06, H 8.04, N 7.93.

[(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]chlorodimethylsilane (23): Me_2SiHCl (300 mg, 3.2 mmol) was cooled to −78 °C. A solution of **1** (0.71 g, 3.2 mmol) in toluene (4.9 mL) was then added. The solution was then allowed to warm to room temperature with stirring. All volatile materials were removed in vacuo and the remaining liquid distilled at 70 °C/10^{-3} Torr. Yield 0.96 g of **23** (95%), m.p. 25−26 °C. ^1H NMR: δ = 0.57 ($SiMe_2$), 5.3 (BH, at −54 °C) ppm. ^{13}C NMR: δ = 8.75 (SiC) ppm. ^{14}N NMR: δ = −248, −307 ppm. IR: $\tilde{\nu}$ = 2460 (sh), 2420 m (νBH) cm^{-1}. $C_{15}H_{34}BClN_2Si$ (316.80): calcd. C 56.87, H 10.82, N 8.84; found C 54.07, H 10.79, N 9.28. The same result was achieved in the presence of a small amount of hydroquinone as a catalyst.

[(*tert*-Butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]trimethylstannane (24): To a solution of **1** (0.44 g, 2.0 mmol) in hexane (14 mL) was added Me_3SnH (1 mL). After heating the mixture to 50 °C, the reaction was complete (^{11}B NMR). All volatile materials were removed in vacuo. The residue, a colourless oil, proved to be sufficiently pure. However, on distillation only **1** could be isolated, b.p. 100−130 °C/0.1 Torr. Yield (before distillation) 0.40 g of **24** (93%). ^1H NMR: δ = 0.4 [$^2J(^1H^{119}Sn)$ = 55.1 Hz), $SnMe_3$] ppm. ^{13}C NMR: δ = 2.11 [$^1J(^{13}C^{119}Sn)$ = 388 Hz, $SnMe_3$] ppm. IR: $\tilde{\nu}$ = 2413, 2385 m (νBH) cm^{-1}. $C_{16}H_{37}BN_2Sn$ (386.99): calcd. C 49.66, H 9.64, N 7.24; found C 49.43, H 9.31, N 7.21.

Tributyl[(*tert*-butyl)(2,2,6,6-tetramethylpiperidinoboryl)amino]stannane (25): A solution containing **1** (0.89 g, 4.0 mmol) and Bu_3SnH (1.32 mL, 5.0 mmol) in toluene (10 mL) was heated to 60 °C for 2 h. The ^{11}B NMR spectrum showed the absence of **1** and a new signal at δ = 39.6 ppm. Volatile materials were removed from the solution in vacuo (0.001 Torr). The remaining colourless oil was distilled. The fraction of b.p. 120−135 °C/0.001 Torr consisted of 90% **25** and 10% Bu_3SnH according to NMR spectroscopic data. ^1H NMR (only main component): δ = 0.8−1.5 (m, Bu) ppm. ^{13}C NMR: δ = 18.75 [$^1J(^{13}C^{119}Sn)$ = 360 Hz, C_α], 29.09 [$^2J(^{13}C^{119}Sn)$ = 16 Hz, C_β], 27.79 [$^3J(^{13}C^{119}Sn)$ = 76 Hz, C_γ], 13.79 (C_δ) ppm. IR: $\tilde{\nu}$ = 2415 sh, 2388 m (νBH) cm^{-1}.

(*tert*-Butyl)[(2,2,6,6-tetramethylpiperidino)(triphenylstannyl)boryl]amine (26): Ph_3SnH (0.53 g, 1.5 mmol) was dissolved in toluene (50 mL). A solution of **1** in hexane (5.6 mL, 0.27 M, 1.5 mmol) was then added with stirring. After stirring for 1 d, a single ^{11}B NMR resonance at δ = 44.6 ppm was observed. A solid residue was left after removing all volatile components in vacuo. The solid was crystallised from hexane (40 mL) at −80 °C. Yield 0.44 g of **26** (75%), m.p. 106 °C. ^1H NMR: δ = 7.19 (m, 9 H, *o*-Ph and *p*-Ph), 7.81(m, 6 H, *m*-Ph) ppm. ^{13}C NMR: δ = 128.1, 128., 138.2, 144.6 ppm. ^{119}Sn NMR signal not detectable. $C_{31}H_{43}BN_2Sn$ (573.17): calcd. C 64.90, H 7.50, N 4.98; found C 64.74, H 7.41, N 4.62.

Lithium (*tert*-Butyl)(2,2,6,6-tetramethylpiperidinophenylboryl)amide−Diethyl Ether (32): A hexane solution of **1** (0.89 M, 5.59 mL, 5.0 mmol) was cooled to −78 °C. A solution of PhLi in cyclohexane/diethyl ether (2.0 M, 2.8 mL, 5.0 mmol) was then added dropwise with stirring. After the clear solution had reached room temperature, a light yellow precipitate appeared which redissolved on continued stirring. The solution showed a ^{11}B NMR signal at δ = 33.3 ppm. The brownish solid that remained after evaporation of the solvents in vacuo was crystallised from toluene at −78 °C. Yield 1.55 g of **32** (61%), m.p. 162 °C. ^{13}C NMR: δ = 125.14, 126.44, 134.13 (Ph) ppm; BC not found. ^7Li NMR (hexane): δ = 2.3 ($h_{1/2}$ = 9.7 Hz) ppm. $C_{23}H_{42}BLiN_2O$ (380.34): calcd. C 72.63, H 11.13, N 7.37; found C 64.75, H 10.04, N 7.41.

Lithium (*tert*-Butyl)[methyl(2,2,6,6-tetramethylpiperidino)boryl]amide−Tetramethylethylenediamine (30-TMEDA): To a solution of **1** (13.6 mL, 0.22 M, 3.0 mmol) in hexane at −78 °C was added tetramethylethylenediamine (0.45 mL, 3.0 mmol). A solution of LiMe in diethyl ether was then added (1.88 mL, 1.6 M, diluted with 25 mL of diethyl ether). After the addition, the solution became a bluish colour but at room temperature the solution was colourless. Some solid had formed which was removed by filtration. Dissolved in C_6D_6, this solid proved to be tmp−BMe−$NCMe_3$Li. Two ^{11}B NMR signals were observed for the filtrate at δ = 35.3 (90%) and 39.6 ppm (10%). The signal at δ = 39.6 ppm increased in intensity with time.

(*tert*-Butyl)[methyl(2,2,6,6-tetramethylpiperidinoboryl)amino]catecholborane (31): A solution of **30−TMEDA** (3.0 mmol, 16 mL) was allowed to quickly reach room temperature. A solution of *B*-chlorocatecholborane (0.6 g, 3.0 mmol) in diethyl ether (15 mL) was then added with stirring. A white precipitated rapidly formed. The suspension was stirred for 3 h and the solid was then removed by filtration and the filtrate reduced in volume to about 20 mL in vacuo and kept at −20 °C. Crystals of **31** separated within 2 d. Yield 0.75 g (73%), m.p. 158 °C. ^1H NMR: δ = 0.78 (s, BMe), 6.69−1.76 (m, 5 H) ppm. ^{13}C NMR: δ = 110.0, 119.27, 150.55 (C_{arom}) ppm. $C_{20}H_{34}BN_2O_2$ (356.11): calcd. C 67.45, H 9.62, N 7.87; found C 67.42, H 9.51, N 7.83.

Reaction of 1 with Butyllithium: BuLi (7.46 mL of a 0.670 M hexane solution, 5 mmol) was stirred and cooled to −78 °C followed by addition of a hexane solution of **1** (3.2 mL, 1.57 M). After warming to room temperature, a yellow solution formed. Evaporation of the solvent in vacuo gave a yellow solid, m.p. 74−75 °C. It showed a ^{11}B NMR signal at δ = 33.6 ppm (about 70%) and two other signals in toluene solution. The ^1H and ^{13}C NMR spectra indicated that the product was not pure. Attempts at purification by sublimation or crystallisation were unsuccessful.

Reaction of 1 with *tert*-Butyllithium. Formation of 1,2,3,4-*tert*-Butyl-1,3,2,4-diazadiboretidine (28): To a stirred solution of **1** (7.46 mL, 0.670 M) in hexane at −78 °C was added a hexane solution of $LiCMe_3$ (3.13 mL, 1.60 M, 5 mmol). The mixture was then allowed to warm to room temperature with stirring to give a yellow solution. After removal of all volatile components in vacuo, a yellow solid remained which on sublimation at 40 °C/0.001 Torr yielded colourless crystals of the diazadiboretidine **28**, m.p. 58−60 °C. ^1H NMR: δ = 1.23 (s, $BCMe_3$), 1.32 ($NCMe_3$) ppm (ratio 1:1). ^{13}C NMR: δ = 30.5 ($BCMe_3$), 33.8 ($NCMe_3$), 49.5 ($NCMe_3$) ppm; BC not detected. ^{11}B NMR: δ = 41.1 ppm.

Butylmagnesium (*tert*-Butyl)[butyl(2,2,6,6-tetramethylpiperidino)boryl]amide (33): A hexane solution of **1** (17.5 mL, 0.114 M, 2.0 mmol) was further diluted with hexane (20 mL). To the stirred solution at −78 °C was added a hexane solution of $MgBu_2$ (2.0 mL, 1 M). At room temperature the solution showed only one ^{11}B NMR signal at δ = 37.5 ppm indicating a quantitative reaction. Removal of the volatile materials gave an oily, non-volatile, moisture-sensitive residue. Attempted crystallisation from pentane at low temperature afforded no crystals. Attempted distillation in vacuo led to decomposition. ^1H NMR: δ = 0.95, 1.04, 1.11, 1.91, 1.27, 1.38, 1.51, 1.59 (Bu groups) ppm. ^{13}C NMR: δ = 14.3, 19.2, 27.0,

27.8, 32.7, 38.6 (Bu) ppm. $C_{21}H_{45}BMgN_2$ (360.72): calcd. C 69.98, H 12.50, 7.76; found C 63.65, H 11.90, N 7.30.

Magnesium Bis{(*tert*-butyl)[butyl(2,2,6,6-tetramethylpiperidino)-boryl]amide} (34): Prepared in analogy to **33** from **1** (0.114 M solution, 22.0 mL, 2.4 mmol) and $MgBu_2$ (1.25 mL, 1 M, 1.25 mmol). Colourless oil, yield 0.7 g (95%). ^{11}B NMR: δ = 39.0 ppm. ^1H NMR: δ = 0.72−1.59 ppm (br. m, 2/4-H, 3-H, Bu). ^{13}C NMR: δ = 14.0, 27.5, 29.5, 31.8, 38.1 ppm (main signals). $C_{24}H_{72}B_2MgN_4$ (582.90): calcd. C 70.06, H 12.45, N 9.61; found C 67.61, H 12.02, N 8.74.

Methylzinc (*tert*-Butyl)[methyl(2,2,6,6-tetramethylpiperidino)boryl]-amide (35): To a stirred solution of **1** (0.27 M, 7.4 mL, 2.0 mmol), diluted with hexane (20 mL) at −78 °C, was added a solution of $ZnMe_2$ (0.09 M, 2.9 mL, 2.0 mmol), dissolved in toluene (10 mL). After the solution had attained ambient temperature, the volume of the solution was reduced to about 20 mL. At −78 °C, crystals appeared within a week. These were highly sensitive towards moisture. Recrystallisation at −40 °C from hexane yielded single crystals. The yield was not determined. ^1H NMR: δ = −0.09 (ZnMe), 0.62 (BMe) ppm. ^{13}C NMR: δ = −11.3 (ZnMe), 1.0 (br., BMe) ppm. $C_{15}H_{33}BN_2Zn$ (317.61): calcd. C 56.67, H 10.39, N 8.52; found C 52.44, H 9.75, N 8.49.

Zinc Bis{(*tert*-butyl)[methyl(2,2,6,6-tetramethylpiperidino)boryl]-amide} (36): Prepared in analogy to **35** from **1** (2.5 mmol) in hexane (40 mL) and $ZnMe_2$ (1.8 mL, 0.69 M, 1.25 mmol), dissolved in toluene (10 mL).**36** is a sticky oil from which no crystals could be obtained. Yield 0.64 g (96%). ^{11}B NMR: δ= 39.1 ppm. ^1H NMR: δ = 0.62 (BMe) ppm. ^{13}C NMR: δ = 1.32 (br., BMe) ppm. $C_{28}H_{60}B_2N_4Zn$ (539.81): calcd. C 62.40, H 11.13, N 10.04; found C 62.95, H 11.41, N 10.12.

Phenylcadmium (*tert*-Butyl)[phenyl(2,2,6,6-tetramethylpiperidino)-boryl]amide (37): A solution of **1** (3.2 mmol) in hexane (49 mL) was cooled to −78 °C. A solution of $CdPh_2$ (0.16 g, 3.2 mmol) in $CHCl_3$ (30 mL) was then added with stirring. At room temperature, all volatile materials were removed in vacuo and the oily residue treated with small quantities of toluene. From the resultant solution appeared some well-shaped crystals which proved to be $CdPh_2$. Concentration of the solution yielded **37** as a microcrystalline powder. Yield 1.19 g of **37** (76%), m.p. 160 °C (dec.). ^1H NMR: δ = 7.13, 7.21, 7.27, 7.53, 7.50, 7.71 (m, Ph) ppm. ^{13}C NMR: δ = 126.0, 126.8, 128.3, 132.9, 139.5 (Ph) ppm. $C_{25}H_{37}BCdN_2$ (488.36): calcd. C 61.43, H 7.63, N 5.73; found C 59.00, H 7.60, N 5.52.

{(*tert*-Butyl)[methyl(2,2,6,6-tetramethylpiperidino)boryl]amino}-dimethylborane (38): A solution of **1** in hexane (11.0 mL, 0.362 M,) was frozen at −196 °C and BMe_3 (4.1 mmol) condensed onto it. The mixture was allowed to slowly thaw. After 4 h of stirring, all volatile material was evaporated in vacuo at 50 Torr. A colourless oil remained. Yield 1.07 g of **38** (97%), m.p. 18−20 °C. ^1H NMR: δ = 0.58 (6 H, BMe_2), 0.82 (3 H, BMe) ppm. ^{13}C NMR: δ = 12.1 (br., BMe, BMe_2) ppm. ^{14}N NMR: δ = −230.6 ($h_{1/2}$ = 500 Hz) ppm. MS (70 eV): *m*/*z* (%) = 263 (1) [M^+ − Me], 222 (100) [$tmpBNCMe_3^+$]. $C_{16}H_{36}B_2N_2$ (278.10): calcd. C 69.10, H 13.05, N 10.07; found C 69.02, H 12.85, N 10.32.

{(*tert*-Butyl)[phenyl(2,2,6,6-tetramethylpiperidino)boryl]amino}-diphenylborane (39): To a suspension of BPh_3 (1.00 g, 4.1 mmol) in hexane (20 mL) was added a solution of **1** in hexane (14.7 mL, 0.283 M, 4.1 mmol). After stirring for 16 h, the ^{11}B NMR spectrum showed the absence of **1**. When the solvent was removed in vacuo a precipitate appeared which was isolated by filtration. A second crop was obtained from the filtrate. Yield 1.65 g of **39** (86%), m.p. 107−110 °C. ^1H NMR: δ = 7.25−8.04 ppm (m, 15 H, Ph). ^{13}C NMR: δ = 149.6 (br., BC), 125.9, 126.8, 127.4 130.8, 135.9, 138.8 (Ph), 149.6 (BC) ppm. MS (70 eV): *m*/*z* (%) = 464 (5) [M^+], 449 (15) [M^+ − Me], 387 (35) [M^+ − Ph], 299 (25) [M^+ − BPh_2], 222 (47) [**1**$^+$]. $C_{31}H_{42}B_2N_2$ (464.2): calcd. C 80.19, H 9.12, N 6.03; found C 78.02, H 9.05, N 5.80.

Dibutyl{(*tert*-butyl)[butyl(2,2,6,6-tetramethylpiperidino)boryl]-amino}borane (40): To a hexane solution of **1** (8.80 mL, 0.283 M, 2.5 mmol) at room temperature was added BBu_3 (0.40 g, 2.5 mmol) with a syringe. After stirring for 2 d, the reaction was complete. Volatile materials were then removed in vacuo. The remaining colourless oil of **40** solidified at −78 °C. Yield 0.95 g (94%). ^1H NMR: δ = 0.87−1.24 (several m, Bu) ppm. ^{13}C NMR: δ = 14.4 (Me of Bu), 20.1 (br., BC), 24.0 (br., N_2BC), 26.6, 27.0, 27., 30.2, 34.2 ($BCH_2CH_2CH_2Me$) ppm. $C_{25}H_{54}B_2N_2$ (404.34): calcd. C 74.26, H 13.46, N 6.93; found C 72.97, H 13.03, N 6.77.

9-{(*tert*-Butyl)[methyl(2,2,6,6-tetramethylpiperidino)boryl]-amino}-9-borabicyclo[3.3.1]nonane (41): A solution of **1** (2.5 mmol in 8.9 mL of hexane) at −78 °C was added to 9-methyl-9-borabicyclo[3.3.1]nonane (0.34 g, 2.5 mmol). Within 4 d, a clear solution had formed. Most of the solvent was then removed in vacuo and the solid material isolated by filtration. Yield 0.8 g of **41** (93%), m.p. 82 °C. The product was pure as shown by the NMR spectroscopic data. ^1H NMR: δ = 1.95 (br., 12 H) ppm. ^{13}C NMR: δ = 22.9 (C-α), 23.1 (C-β), 32.5 (C-γ) ppm.

{(*tert*-Butyl)[methyl(2,2,6,6-tetramethylpiperidino)boryl]amino}-dimethylalane (43): A hexane solution of $(AlMe_3)_2$ (0.95 mL, 2.19 M, 1.05 mmol) at −78 °C was added to a stirred solution of **1** in hexane (3.5 mL, 0.586 M, 2.1 mmol). At room temperature, the mixture was stirred for 24 h. The hexane was then removed. The remaining oil could not be distilled without decomposition. Yield 0.58 g of **43** (96%). Due to the high sensitivity of the oil towards moisture and air only an approximate elemental analysis was obtained, while the ^1H NMR spectrum showed the correct intensities for the CMe_3, $AlMe_2$ and BMe groups. The same compound was obtained by using $AlMe_3{\cdot}OEt_2$ instead of Al_2Me_6. Elemental analysis was performed without sufficient protection against the atmosphere. ^1H NMR: δ = −0.11 ($AlMe_2$), 0.78 (BMe) ppm. ^{13}C NMR: δ = 7.0 ($AlMe_2$), 18.9 (br., BMe) ppm. ^{27}Al NMR: δ = 105.9 ($h_{1/2}$ = 780 Hz) ppm. $C_{16}H_{30}AlBN_2$ (294.27): calcd. C 63.11, H 15.53, N 9.53; found C 51.82, H 9.04, N 7.93 (ratio C/H/N = 15:31:2).

{(*tert*-Butyl)[ethyl(2,2,6,6-tetramethylpiperidino)boryl]amino}-diethylalane (44): Prepared in analogy to **43**. $AlEt_3$ (0.38 g, 0.33 mmol) in hexane (3.3 mL), 10.9 mL of a hexane solution of **1** (0.306 mmol). Mobile, air- and moisture-sensitive liquid. Yield 1.11 g of **44** (98%). ^1H NMR: δ = 0.40 [q, $^3J(^1H^1H)$ = 7.3 Hz, 4 H, $AlCH_2$], 0.81−1.19 (m, 5 H, BEt), 1.42 [t, $^3J(^1H^1H)$ = 7.3 Hz, 6 H, $AlCH_2CH_3$] ppm. ^{13}C NMR: δ = 7.9 (br., $AlCH_2$), 10.7 ($AlCH_2CH_3$), 11.5 (BCH_2CH_3), 14.2 (br., BCH_2) ppm. MS (70 eV): *m*/*z* (%) = 336 (2) [M^+] and others. $C_{19}H_{42}AlBN_2$ (336.35): calcd. C 67.85, H 12.59, N 8.33; found C 62.97, H 11.84, N 7.69.

{(*tert*-Butyl)[phenyl(2,2,6,6-tetramethylpiperidino)boryl]amino}-diphenylalane (45): Obtained in analogy to **43**. To $AlPh_3$ (0.26 g, 1.0 mmol, 5 mL hexane) was added a solution of **1** in hexane (4.0 mL, 0.252 M, 1.0 mmol). The mixture was stirred for 4 d and the solid isolated by filtration (0.38 g). From the solution another crop of 0.08 g was obtained by partially removing the hexane. Yield: 0.46 g of **45** (95%), m.p. 168−170 °C (dec.). ^1H NMR ($CDCl_3$):δ = 7.22−8.11 (m, 15 H, Ph) ppm. ^{13}C NMR ($CDCl_3$): δ = 126.8, 126.9, 127.1, 128.7, 134.1, 17.6, 139.2 (Ph) ppm.

{(*tert*-Butyl)[methyl(2,2,6,6-tetramethylpiperidino)boryl]amino}-dimethylgallane (46): At −78 °C a solution of **1** (10.9 mL, 0.306 M, 3.3 mmol) was slowly added to $GaMe_3$ (0.38 g, 3.3 mmol) with stirring. The mixture was stirred at ambient temperature for 5 d. Removal of the hexane left a colourless, highly air-sensitive mobile oil which proved to be pure **46** by NMR spectroscopy. ^{1}H NMR ($CDCl_3$): δ = −0.12 (6 H, $GaMe_2$), 0.58 (3 H, BMe) ppm. ^{13}C NMR ($CDCl_3$): δ= 3.3 (br., $GaMe_2$), 14.2 (br., BMe) ppm. IR: $\tilde{\nu}$ = 1370 ($\delta_{as}GaMe_2$), 1210 ($\delta_{sym}GaMe_2$) cm^{-1}. MS (70 eV): *m*/*z* (%) = 336 (1) [M$^+$], 321 (100) [M$^+$ − Me]. $C_{16}H_{36}BGaN_2$ (337.01): calcd. C 57.02, H 10.74, N 8.31; found C 61.52, H 10.96, N 7.87.

{(*tert*-Butyl)[ethyl(2,2,6,6-tetramethylpiperidino)boryl]amino}-diethylgallane (47): Obtained from $GaEt_3$ (0.34 g, 2.2 mmol) and **1** (7.2 mL, 0.306 M, 2.2 mmol); 24 h of stirring at ambient temperature. Colourless, mobile liquid, very moisture-sensitive. Due to the high sensitivity of the compound only an unsatisfactory C,H analysis was obtained. ^{13}C NMR ($CDCl_3$): δ = 10.8 (BCH_2CH_3), 11.4, 11.5 (GaEt), 14.0 (br., BCH_2CH_3) ppm. MS (70 eV, ^{11}B, ^{69}Ga): *m*/*z* (%) = 349 (7) [M$^+$ − Et], 239 (5) [tmpGaEt$^+$], 126 (100) [tmp$^+$ − Me]. $C_{19}H_{42}BGaN_2$ (379.09): calcd. C 60.20, H 11.17, N 7.39; found C 59.07, H 7.45, N 7.03.

{(*tert*-Butyl)[phenyl(2,2,6,6-tetramethylpiperidino)boryl]amino}-diphenylindane (48): Triphenylindium−1,4-dioxane (0.95 g, 2.2 mmol) in hexane (15 mL) was treated for 15 min with a hexane solution of **1** (7.2 mL, 0.306 M, 2.2 mmol). After 24 h of stirring, all volatile components were removed in vacuo and the solid **48** crystallised from a minimum amount of hexane. Yield 1.12 g (89%), m.p. 133−135 °C. ^{1}H NMR ($CDCl_3$): δ = 7.37−8.07 (m, Ph) ppm. ^{13}C NMR ($CDCl_3$): δ = 126.5 (*p*-C), 126.9, 127.3 (*p*-, *m*-, *o*-C of BPh); 127.9, 134.0, 138.6 (*p*-, *m*-, *o*-Ph of $InPh_2$), 144.0 (br., *i*-C of BPh), 156.5 (br., *i*-C of $InPh_2$) ppm. MS (70 eV): *m*/*z* (%) = 568 (2) [M$^{\cdot+}$], 491 (5) [M$^+$ − Ph], and many others. $C_{31}H_{42}BInN_2$ (568.32): calcd. C 65.52, H 7.45, N 4.93; found C 53.37, H 7.30, N 4.93.

X-ray Structural Determinations: Single crystals were placed in perfluoro ether oil under a blanket of nitrogen in the case of very sensitive crystals at −40 °C and a suitable crystal was selected. It was mounted on the tip of a glass fibre which was placed on the goniometer head while cooling with a stream of nitrogen, generally held at −80 °C. After alignment, data were collected on five sets of 15 frames each, which were used to determine the unit cell (Program SMART).[48] Data collection was then started (in case of data collection with a CCD device, data on 1200 frames were collected). After data reduction (Program SAINT),[48] the cell parameters were determined with a larger set of data. No absorption correction was applied except in the case of compound **24**. All structures were solved by direct methods (SHELX97).[49] Non-hydrogen atoms were refined anisotropically. In most cases, the hydrogen atoms were placed in calculated positions using the riding-model approach. However, NH, BH and AlH hydrogen positions were taken from the difference Fourier maps and refined isotropically. Relevant data can be found in Table 7. CCDC-221516 to -221520 contain the supplementary crystallographic data for this paper. These data

Lithium *tert*-Butyl[phenyl(2,2,6,6-tetramethylpiperidino)boryl]amide: A Versatile Reagent[‡]

Ulrike Braun,[a] Tassilo Habereder,[a] and Heinrich Nöth*[a]

Dedicated to Professor Nils Wiberg on the occasion of his 70th birthday

Keywords: Lithium *tert*-butyl[phenyl(2,2,6,6-tetramethylpiperidino)boryl]amide / *N*−Metal borylamides

A new synthesis of tmp(PhB)N(*t*BuNLi) (**1**, tmp = 2,2,6,6-tetramethylpiperidino) is presented. Compound **1** reacts with many group 13–15 halides, as well as with BH_3·THF, to afford, in most cases, compounds of the type tmp(PhB)N*t*Bu–ER_{n-1} (E = B, Al, Ga, In, Ge, Sn, P, As, Sb, and R = H, Me, Hal). The borane, alane, gallane and indane derivatives have cyclic structures, as shown by X-ray structure determinations, whereas ER_{n-1} = $GeCl_3$, $SnMe_3$, $SnMe_2Cl$, SnCl, catecholatophosphanyl, $AsCl_2$ and $SbCl_2$ are noncyclic, although the arsane and stibane derivatives show weak intramolecular E–N coordination to the tmp–N atom.

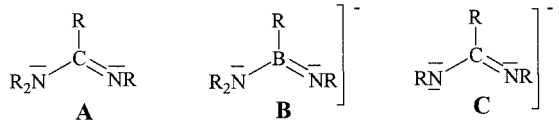
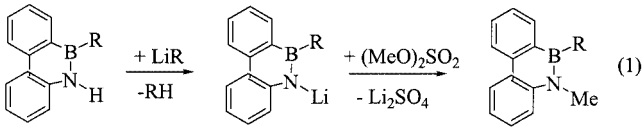
Introduction

Although *N*-lithioaminoboranes are well known and have been used in the synthesis of various types of aminoboranes, those of type **B** can be compared with amidines (**A**) and amidates (**C**); solid-state structures of their alkali metal salts of the latter are available.[2−5] The first structurally characterized amidine was the trimethylsilyl derivative $PhC(=NSiMe_3)N(SiMe_3)_2$.[6] Since then, the chemistry of amidines and amidinates has been extended into transition metals chemistry.[7,8] It is, therefore, of interest to compare the chemistry of alkali metal compounds containing type **B** anions with that of the carbon analogs. The former can also be seen as a special type of N−metal borylamides.



The structures of *N*-lithioborylamides[9−13] have been determined relatively recently, although some were used as reagents much earlier. The first reaction of an *N*-lithioaminoborane was reported by Dewar at al.[14] [Equation (1)]. Borazinylborazines have been obtained from N-lithioborazines and chloroborazines by Wagner and Bradford,[15] while both symmetrically and asymmetrically substituted diborylamines resulted from reactions of $R_2B-NR'Li$ and R''_2BCl.[16] Moreover, by using $PhB(NRLi)_2$ [17] a series of four-membered rings containing metal atoms, $M(NR)_2BPh$, as well as spirocyclic compounds, $M[(NR)_2BPh]_n$, have been obtained.[18] As reported in the preceding paper, many asymmetrically substituted diborylamines and metallated diaminoboranes of the type tmp−BX−$NCMe_3$−EX_{n-1} (tmp = 2,2,6,6-tetramethylpiperidino, E = B, Al, Ga, In, Si, Sn, Li, Mg, Zn, Cd; X = H, Me, Bu, Ph, Cl, Br) are accessible.[1] Among these is the stable lithium borylamide tmp−BPh−$NCMe_3Li$·OEt_2 (**1**), which offered itself as a reagent for further synthesis. The anion **B** of this compound is isoelectronic and isolobal with **A**.



Results

Reactions of tmp−BPh−N(CMe$_3$)Li with Group 13 Compounds

Although the lithium compound **1** can be readily prepared by the addition of LiPh to the aminoiminoborane tmp−B=N−CMe_3 [1] we were looking for a more convenient synthesis, circumventing the isolation of the amino-

[‡] Contribution to the Chemistry of Boron, 254. Part 253: Ref.[1]

iminoborane. Consequently, we developed a one-pot synthesis of **1** according to Equation (2). Yields are almost quantitative, and the resulting suspension of LiCl in the solution of **1** can be used directly for further synthesis.

The reaction of **1** with BH_3·THF in THF requires 2 equivalents of the borane reagent as the LiH formed as an intermediate reacts with the borane component to produce $LiBH_4$ [Equation (3)].[19] A 1:2 stoichiometry is also necessary for the quantitative conversion of **1** into the difluoroborane derivative **3**. The cyclic nature of **2** and **3** is proven by two ^{11}B NMR signals for a tricoordinate and a tetracoordinate boron atom as well as by X-ray structure determinations (see below).

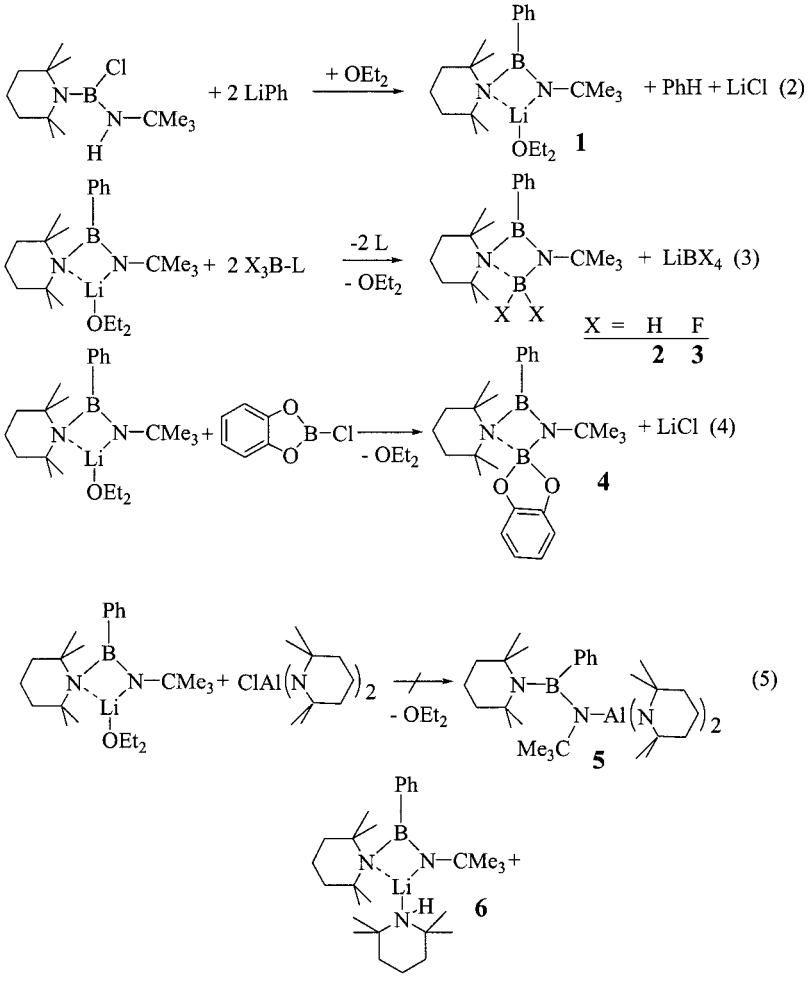
Although boron halides cleave the CO bonds of ethers, no ether cleavage was observed in the reaction of **1** with *B*-(chloro)catecholborane, see Equation (4). The resulting borylated diaminoborane **4** is cyclic, as evidenced by ^{11}B NMR spectroscopy and the determination of its molecular structure. However, **1** did not react at ambient temperature with $tmpBCl_2$, tBuNHBCl_2, 2,4,6-trichloroborazine, and tB$uBCl_2$ in non-polar solvents.

Dimethylchloroalane, -gallane and -indane are dimeric in nonpolar solvents and may, therefore, be less likely to be attacked by **1** as a nucleophile. However, in the presence of diethyl ether, mononuclear species $Me_2ECl\ OEt_2$ form that may react with **1**. Indeed, reactions according to Equation (**7**) proceed readily to yield compounds **7**–**9**, all of which were shown to be cyclic by NMR spectroscopic data and X-ray structure determinations.

To synthesize noncyclic tmp–BPh–$NCMe_3$–AlX_2 compounds we treated the bulky monomeric bis(amino)chloroalane tmp_2AlCl [20] with **1**. The reaction was expected to proceed according to Equation (5). However, the only product we could isolate, in very low yield, was compound **8**, the tmpH solvate of tmp–BPh–$NCMe_3Li$. No LiCl precipitated.

After refluxing the mixture, the ^{11}B NMR spectrum exhibits a new signal at $\delta = 35.7$ ppm in addition to that of **1** in a 1:1 ratio, and a new broad ^{27}Al signal at $\delta = 82$ ppm. The isolated compound **6** shows practically the same NMR spectroscopic data as **1**, with additional signals for tmpH in the ^1H NMR spectrum.

Because the reaction was performed under strictly anhydrous conditions, we exclude the formation of tmpH by hydrolysis of tmp_2AlCl. Therefore, we assume that tmpH is formed by ether cleavage, as suggested in Equation (6). To test this hypothesis we kept an ether solution of tmp_2AlCl under reflux. While tmp_2AlCl shows a ^{27}Al NMR signal in

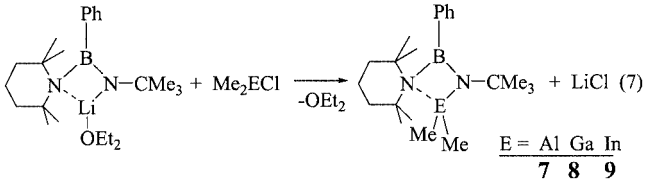


$$(tmp)_2AlCl + OEt_2 \longrightarrow tmpAl(Cl)OEt + tmpH + C_2H_4 \quad (6)$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hexane at δ = 134 ppm, ($h_{1/2}$ = 13 700 Hz), the ether solution, after heating for some time, exhibits two additional signals at δ = 112.8 and 82 ppm. The first of these results from $tmp_2AlCl{\cdot}OEt_2$,[21] while the second corresponds with dimeric tmpAl(OEt)Cl.[22] Although pure compounds could not be isolated, the data indicate that the assumption of ether cleavage by tmp_2AlCl is not unjustified.

We have not yet studied the interaction of **1** with $AlBr_3$, $GaCl_3$ and $InCl_3$ to see whether more than one halogen atom can be replaced by the anion of **1** in the formation of chelates where the coordination number of the metal atom could increase up to six.



Spectra

Table 1 summarizes the ^1H, ^{11}B and ^{13}C NMR spectroscopic data of compounds **2**–**4** and **6**–**9**. Compound **6**, which is akin to **1**, shows a sharper ^{11}B signal than **1**, and a somewhat deshielded boron nucleus. Protons of the CMe_2 groups of the tmp substituent are better shielded than those of the coordinated tmpH molecule, although both nitrogen atoms are tetracoordinate. Proton signals of the CH_2 groups overlap (H2,3,4), while in **1** the protons at C2/4 and C3 are nicely separated triplets and multiplets.[1] Moreover, there is only one set of ^{13}C resonance each for the two tmp units in **6**. Thus, in solution the molecule is fluxional.

^{11}B resonances of the tricoordinate boron atom of **2**–**4** are shifted to lower field compared with **1**. This mirrors the influence of the charge withdrawal from the BN bonds as the substituents at the tetracoordinate B atom become more electronegative. The coupling constants $^1J(^{11}B^1H)$ and $^1J(^{19}F^{11}B)$ are similar to those in the corresponding 1,3,2,4-diazadiboretines.[23] Moreover, the difference in chemical shifts for the two ^1H and ^{13}C resonance of atoms H6,7 and C6,7 increases from **2** via **3** to **4**. The data confirm that the cyclic nature of these compounds is retained in solution.

Conversely, the ^{11}B shielding for the PhB boron atom is almost uninfluenced by the heteroatoms Al, Ga, and In in **7**–**9**. For the indium compound **9**, only a single resonance appears in the ^1H and ^{13}C NMR spectrum for H6,7 and C6,7, respectively. This indicates that, in solution, the In1–N1 bond is opened, while it is present in the solid state. That its structure in solution differs from that of **7** and **8** becomes apparent from the low field ^{13}C resonance of atoms C1,5. This deshielding is still noticeable for C2/4 and C3.

The fragmentation of compounds **2** and **3** in the mass spectrum starts from the molecular ion, which has a 100% relative intensity for the boron hydrogen compound **2**, but only 4.5% for the fluoroborane derivative **3**. In both cases, a methyl group is lost in a first step, which most likely comes from breaking the respective bond at the tmp unit (62 and 100% relative intensity, respectively). Strong peaks appear for ions ($M^+ - CMe_3$) (28 and 82%). Moreover, ions derived from the imino borane are also readily detected, as shown by fragments $tmp{-}B{=}NCMe_3^{+\cdot}$, $tmpB{-}Ph^+$, and $PhB{=}NCMe_3^+$. Loss of a tmp radical from $M^{\cdot+}$ can also be noted.

Fragmentation of the Al and Ga compounds **7** and **8** is characterized by strong peaks for the [M^+ − Me] ions (100 and 43%, respectively) where the E–C bonds of Al and Ga are broken. In addition, a [$M^+ - CMe_3$] peak appears for **7** (21.5%) but not for **8**. Also, fragments [$tmp{-}EMe^+$] are observed (100%, 42%), showing the preferred formation of $Me_3C{-}N{=}B{-}Ph$ in the fragmentation process, which is a stable leaving group. In contrast, fragmentation to give [$tmp{-}B{-}Ph^{\cdot+}$] is less favored because this would generate molecules $MeE{=}NCMe_3$, which are, most likely, not as stable as an imino borane unit.

Molecular Structures

The molecular structures of **2**–**4** and **6**–**9** were determined by X-ray structure analysis. Table 2 contains selected and relevant structural parameters. The molecular structures of **2**–**4** and **6**–**8** are depicted in Figure 1–6, respectively; data for compound **1** are added for comparison with **1·tmpH** (= **6**). In all cases, these compounds feature a four-membered ring.

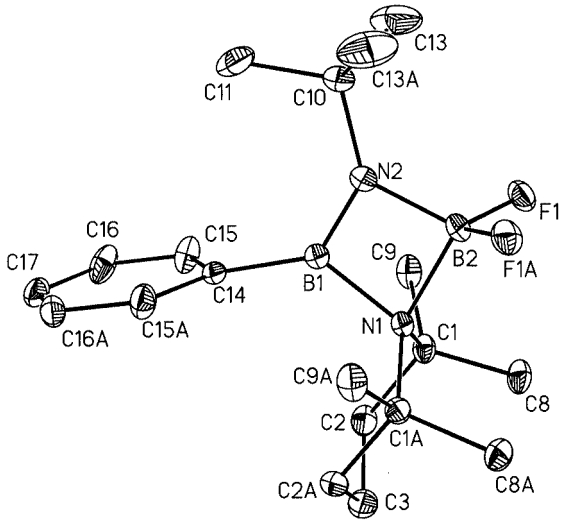

Figure 1. Molecular structure of compound **2**

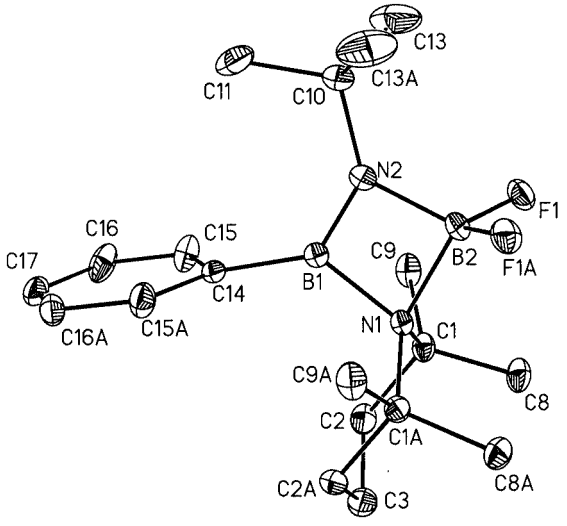

Figure 2. Molecular structure of compound **3**

B1, B2, N1, N2, C14, C17, C10 and C13 of compounds **2** and **3** sit on a mirror plane in the orthorhombic unit cell. The four-membered ring is planar and the phenyl group as well as the C1−N1−C1A unit of the chair-shaped tmp ring stand orthogonal to the ring plane. The B2−N1 bond length of the tetracoordinate atoms increase in the order $BH_2 < BF_2 <$ Bcat. This can be attributed to inductive effects, which are also mirrored in the B2−N2 bond length (H > F > OR). As expected, the B1−N2 bond is shorter, by about 0.2 Å, than the B1−N1 bond because the bond to N1 is a single bond to a tricoordinate boron atom. Moreover, the B2−N1 bond is even longer in both compounds [1.665(3) and 1.689(3) Å, respectively]. Compound **3** is isostructural with **2**; its B1−N1 bond is shorter than in **2** by

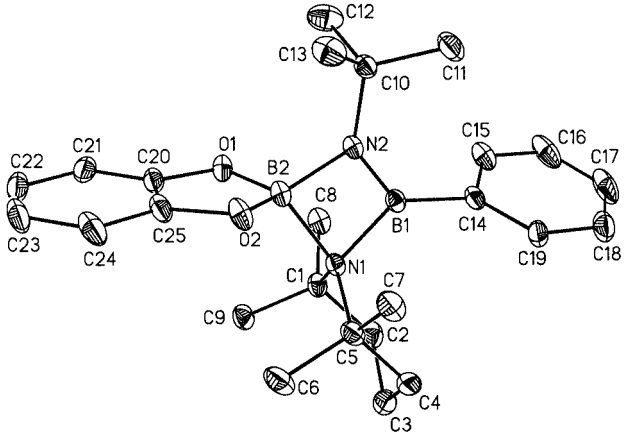

Figure 3. Molecular structure of compound **4**

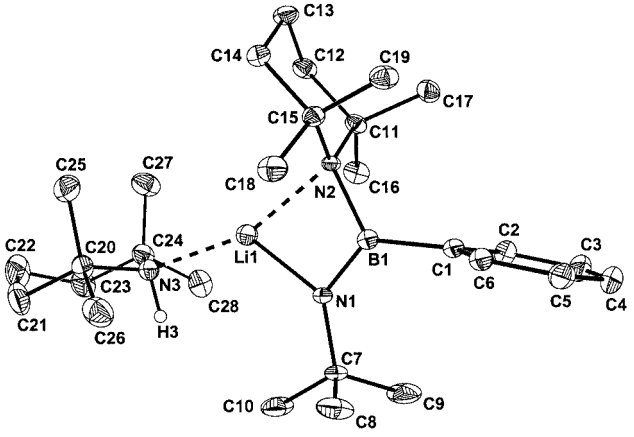

Figure 4. Molecular structure of compound **6**

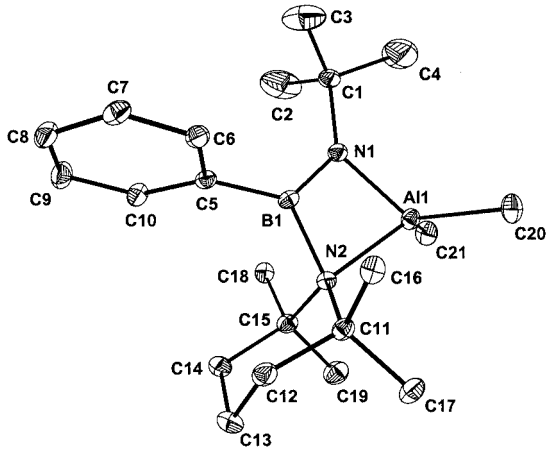

Figure 5. Molecular structure of compound **7**

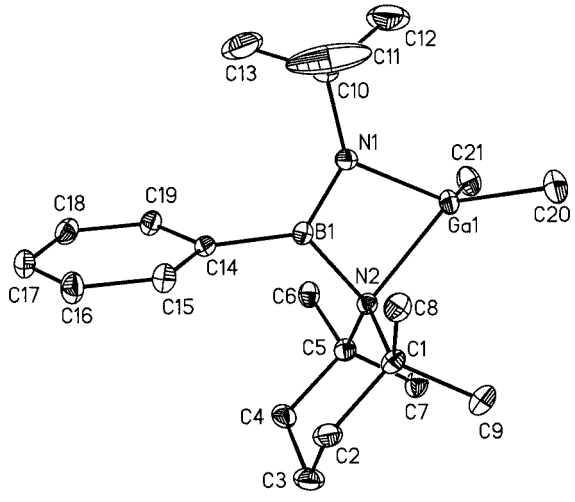

Figure 6. Molecular structure of compound **8**

0.006 Å but the B1−N2 bond is 0.009 Å longer. The B2−N2 bond is significantly shorter [1.523(4) Å] in **3** than in **2** [1.555(3) Å]. Bond angles at the boron atoms in these two compounds are more open than at the nitrogen atoms, and the N−B−N bond angle at the tetracoordinate boron atom is almost 10° smaller than at the tricoordinate boron atoms B1.

While the B1−N1 bond lengths decrease by 0.019 Å when moving from the aluminium compound **7** to the indium compound **9**, the B1−N2 bond lengths remain unaffected by the heavy group 13 atoms. However, the effect of these atoms leads to a shrinking of the N1−C1/5 bonds on moving from Al to In. There is a wider N1−B1−N2 bond angle for the indium compound [109.3(2)°] than in the aluminum derivative [105.9(3)°]; this can be attributed to the lengthening of the E−N1 bond from 2.079(3) Å in **7** to 2.376(2) Å in **9**.

As expected, the E−N2 bond lengths for the pair **7**/**9** also increase, but the difference is larger (0.298 Å) than for E−N1 (0.268 Å).

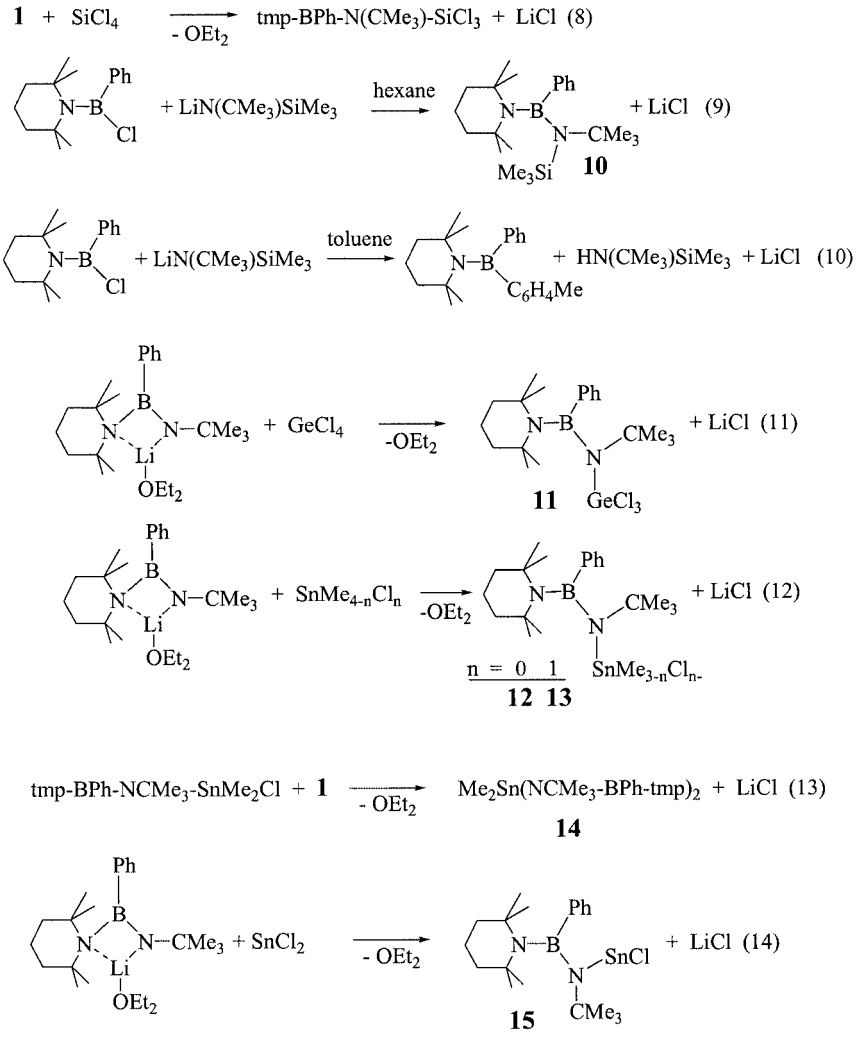
The four-membered ring of **7** is not planar. The molecule shows an interplanar N1−B1−N2/N1−Al1−N2 angle of 6.3°. In contrast, the ring of **8** is planar; nevertheless, its phenyl group is not perpendicular to the N1B1N2 plane but is twisted about the B1−C14 bond by 74.3°. The same twisting is found for the indium compound **9**. While the C_2E (E = Al, Ga, In) units stand orthogonal or almost perpendicular to the N1−E−N2 plane the C1−N1−C5 planes deviate from orthogonality with respect to the B1−N1−E plane by 4° for **7** and by 3.4° for **9**.

Reactions of tmp−BPh−N(CMe$_3$)Li with Group 14 Compounds

Particularly for steric reasons, the reactions of **1** with halides of group 14 should be less favored than with group 13 halides. Indeed, neither Me_3SiCl nor Ph_3SiCl reacted with **1**. However, $SiCl_4$, a stronger Lewis acid than the R_3SiCl compounds, reacts according to Equation (8) with the formation of tmp−BPh−N*t*Bu−$SiCl_3$. Such compounds can also be obtained from tmp−BPh(Cl) and LiN(CMe$_3$)(SiMe$_3$) in the presence of toluene [Equation (9)]. However, in addition to **10**, tmpBPh(Tol) is formed [Equation (10)]. The two compounds could not be separated by crystallization. Obviously, Li(tol) results from the solvent toluene that is metallated by the lithium amide, a not uncommon reaction.[24]

Like Me_3SiCl, the methylhalogermanes Me_3GeCl and Me_3GeBr are unreactive towards **1**, but $GeCl_4$, like $SiCl_4$, afforded the trichlorogermyl derivative **11** [Equation (11)], but reflux conditions in hexane are required. In contrast, **1** and Me_3SnCl interact easily to produce the trimethylstannyl derivative **12**, and reaction with Me_2SnCl_2 afforded compound **13**. However, an attempt to use Me_2SnCl_2 to attach two diaminoborane units to the Me_2Sn fragment [Equation (13)] was not successful − only monosubstitution was observed. In addition, on heating, decomposition occurred to give the diazadiboretidine (tmpB−N*t*Bu)$_2$, which was detected by ^{11}B NMR spectroscopy.[23] All these metallated diaminoboranes of type tmp−BPh−N*t*Bu−EX_n (E = Ge, Sn), **11**−**13**, are noncyclic (see below). No reactions were noted between **1** and Ph_3GeCl, Ph_3SnCl, and Ph_3PbCl in the presence of hexane, most likely due to steric reasons.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Similarly, only a single Cl atom of $SnCl_2$ could be replaced by the tmpBPh−N*t*Bu group [Equation (14)]. No ^{119}Sn resonance signal was detected for **15**, but $\delta^{11}B = 38.0$ ppm agrees with a metallated diaminoborane. In the gas phase, no mass higher than M^+ was found for **15**, suggesting that the compound is most likely monomeric in solution. No single crystals could be obtained, and, therefore, it was not possible to determine its solid-state structure.

NMR Spectra

In the NMR data of **11**−**13** and **15** (Table 3) the shielding of the ^{11}B nuclei is practically identical and at lower field than with the cyclic species **2**−**9**. In contrast to the latter, the N1 atoms reside in a planar environment and, therefore, can be considered to be sp^2 (see below). Since there are two NMR signals for the CMe_2 groups in the ^1H and ^{13}C NMR spectra there must be a hindered rotation about the B1−N1 bond. Indeed, the interplanar angle CN1C5/N1B1N2 is only 30° for the $GeCl_3$ compound; these angles are 118.3° and 117.7° for the tin compounds **12** and **13**. Therefore, B1−N1 π-bonding should not be pronounced in **12** and **13**. For **11** there may be hindered rotation about the B1−N1 bond due to steric hindrance. Cl substitution at Ge and Sn leads to a deshielding of the protons of the *t*Bu groups but this is not reflected in the ^{13}C resonances of either C10 or C11 to C13. In particular, the ^{13}C resonances for C1 and C5 fall in the same range as those for the cyclic species; however, those of C6/7 seem to be less well shielded. Thus, these data do not allow us to decide whether these compounds are cyclic or noncyclic. However, $\delta^{119}Sn$ for **12** and **13** are $\delta = 17.9$ and 93.1 ppm, indicating the presence of a tetracoordinate tin atom.[25] In particular, the tin resonance of **13** falls well within the range found for similar compounds [13,25] while the ^{119}Sn resonance of **12** corresponds well with that of $Me_3Sn(tBu)N-BH-tmp$ ($\delta^{119}Sn$ = 27.4),[21] 2-[trimethylsilyl(trimethylstannyl)amino]pyridine ($\delta^{119}Sn$ = 10.2 ppm),[26] and 8-[bis(trimethylstannyl)amino]-quinoline ($\delta^{119}Sn$ = 26.4).[27] Unfortunately, we were unable to record a ^{119}Sn spectrum for the tin(II) compound **15**. Since its ^1H, ^{11}B and ^{13}C NMR spectroscopic data are rather similar to those of the other two tin compounds we assume that this molecule is not associated (e.g. dimeric or trimeric). In accord with this, its mass spectrum shows the parent peak as the highest mass.

Molecular Structures

Selected structural parameters for **11**−**13** are summarized in Table 4, and the structures of these compounds are depicted in Figures 7−9, respectively. In all these compounds the sum of bond angles at N1 is close to 360°, demonstrating that the atoms N1 are of sp^2 type. Therefore, this atom may form BN π-bonds with atom B1 in addition to atom N2.

Surprisingly, the B1−N1 bond of the trichlorogermyl compound **11** is significantly shorter than the B1−N2 bond [1.422(4) vs. 1.510(4) Å]. Inspection of the respective interplanar angles gives a value of 30.3° for C1N1C5/N1B1N2 and 60.5° for GeN2C10/N2B1N1. Therefore, the tmp group is better suited for BN π-bonding. The N1−B1−N2 bond angle of 123.3(3)° accords with the noncyclic structure. Another feature of interest is that one of the three Ge−Cl bond lengths is about 1% shorter than the other two. However, there is no apparent significant H···Cl interaction (all distances are longer than 3.35 Å) that would explain this deviation. The arrangement of the Ge1−N2−B2−N1 chain is *cisoid* in the solid state.

In contrast, the methylstannyl compounds **12** and **13** show a *transoid* arrangement for the Sn1−N2−B1−N1 chain. In **12** the B1−N1 bond is longer [1.475(5) Å] than the B1−N2 bond [1.430(4) Å], in agreement with interplanar angles of C1N1C5/N1B1N2 (116.4°) and C10N2Sn1/N2B1N1 (32.2°). The phenyl group is twisted against the N1B1N2 plane by 44.1°. B1 and N2 reside in a planar environment, as is also found for the chlorodimethylstannyl compound **13**. The B1−N1 bond in **13** is 0.01 Å shorter than in **12**, while the B1−N2 bond in **13** is 0.008 Å longer than in **12**. Such differences arise from the differ-

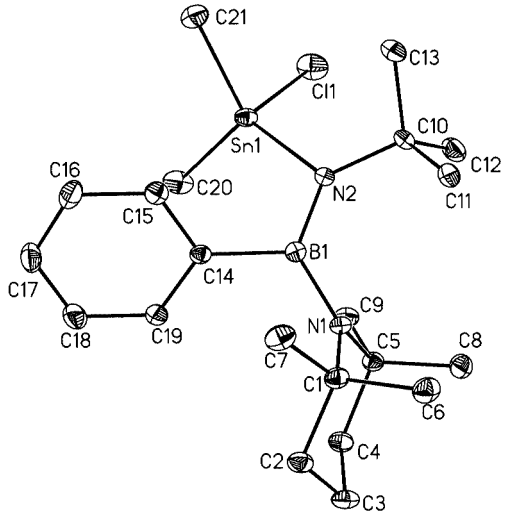

Figure 9. Molecular structure of **13**

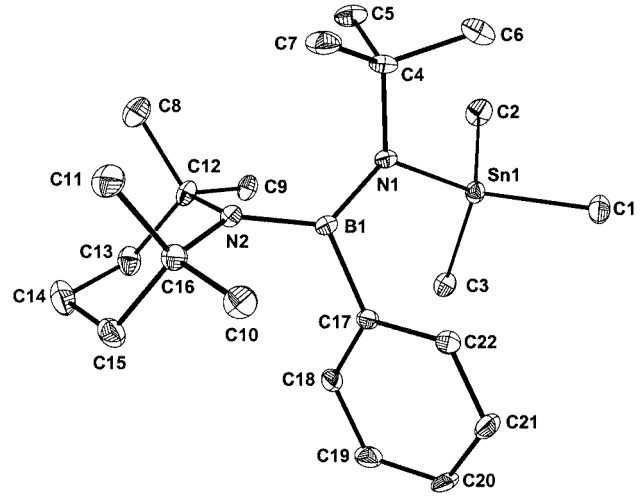

Figure 8. Molecular structure of **12**

ent interplanar angles of 30.9° for N1B1N2/B1N2Sn1 and 117.7° for N1B1N2/C1N1C5. The phenyl group is twisted against the N1B1N2 plane by 43.7°. Thus, the shortening is not a π-bonding effect but is rather due to the stronger electron-withdrawing $SnClMe_2$ substituent. This is also visible in the shorter SnC and SnN bonds in **13** although the differences are small. Notably, the C−Sn−C bond angles in **12** vary from 103.1(2) to 112.8(1)° and for **13** the Cl−Sn−C bond angles are 96.0 and 101.2(1)°, with a wide bond angle of 116.7(1)° for C20−Sn−C21.

Reactions with Halides of Group 15

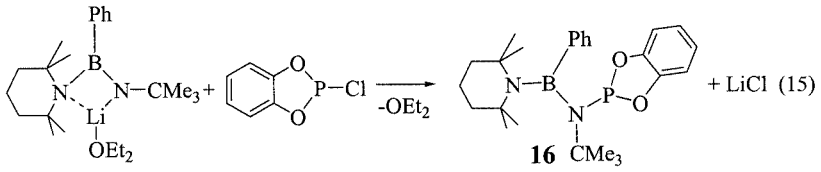
While **1** reacted with PCl_3 in a 1:1 molar ratio to give an inseparable mixture of products, Ph_2PCl proved unreactive towards **1**. Ph_2PCl is not a strong electrophile, and its behavior corresponds with that of Ph_3GeCl and Ph_3SnCl. In contrast, 1,3,2-benzodioxaphosphorus chloride reacted smoothly with **1** according to Equation (15) to produce the borylated aminophosphane **16**. Its ^{31}P resonance at δ = 163.5 ppm for the tricoordinate P atom lies on the deshielded side for compounds with a PO_2N core.[28] The coupling constant $^2P(^{31}P^{13}C)$ is 23.3 Hz. Its sign, which has not been determined, would allow the determination of the configuration at the P atom. However, the compound is quite clearly noncyclic.

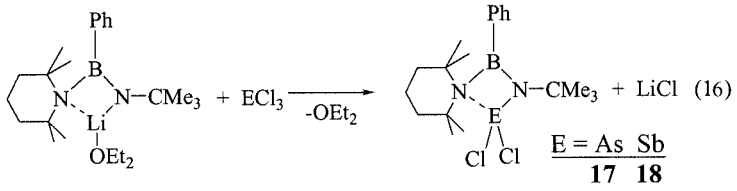
In contrast to PCl_3, both $AsCl_3$ and $SbCl_3$ reacted smoothly in the presence of diethyl ether to give the borylamino-dichloroarsane **17** and the borylamino-dichlorostibane **18**, respectively [Equation (16)]. However, $BiCl_3$ did not react in the nonpolar solvent hexane.

NMR Spectra

NMR spectroscopic data of **16**−**18** are summarized in Table 3. The ^{11}B NMR signals are typical for tricoordinate boron atoms and are slightly deshielded in comparison with the trichlorogermyl and methylstannyl derivatives tmp−BPh−N*t*Bu−EX_2. The protons of the *t*Bu groups are significantly deshielded compared with the compounds listed in Table 1. This seems to be due to the inductive effect of the chlorine atoms that, however, do not affect the protons of the CMe_2 groups, although a particularly large difference is noted for the arsenic compound **17**. In line with this is the deshielding of the ^{13}C nucleus of C10 in **16**, which is also noticeable for **17** and **18**.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim





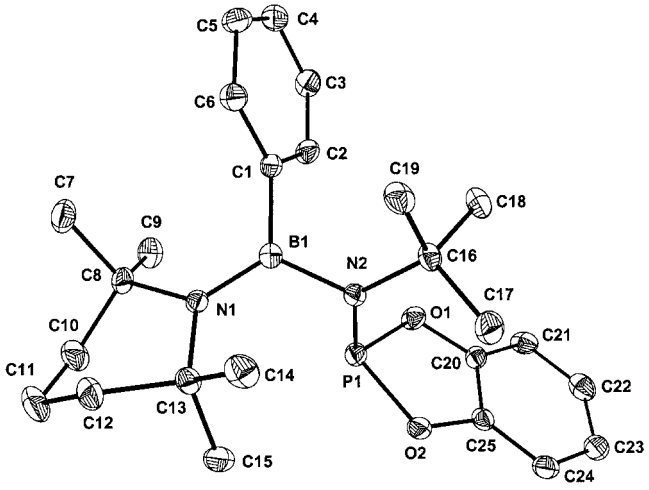


Figure 10. Molecular structure of **16**

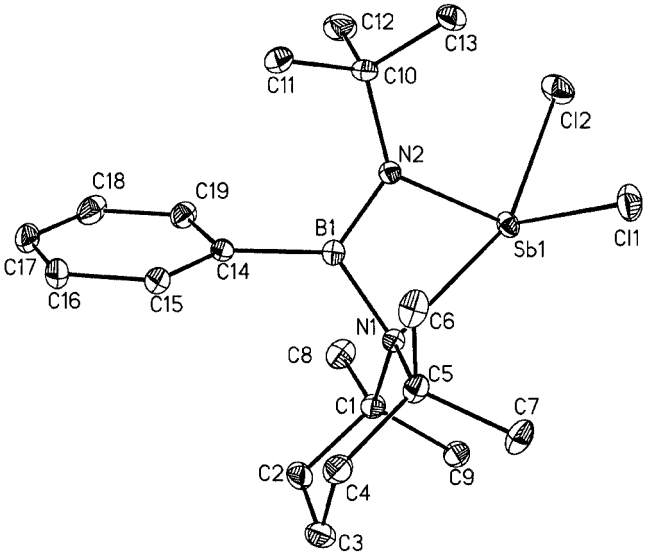

Figure 12. Molecular structure of **18**

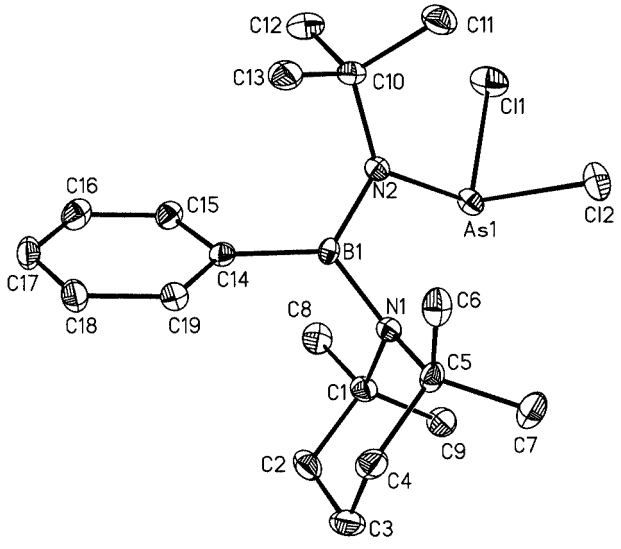

Figure 11. Molecular structure of **17**

Since there are two resonances each for these three compounds for the CMe_2 groups, hindered rotation about the B1–N1 bond is indicated. However, the NMR spectroscopic data are not conclusive as to whether **17** and **18** are cyclic or noncyclic in solution, while the ^{31}P resonance for **16** proves its noncyclic nature in solution. It was, therefore of interest to determine the solid-state structures of these compounds.

Molecular Structures

In analogy to the trichlorogermyl compound **11** there is also a shorter B–N bond in **16** to N1 [1.431(4) Å] than to N2 [1.528(3) Å]. This is due to a more planar arrangement of plane C1–N1–C5 with respect to the plane N1–B–N2 compared with the P1–N2–B1 plane (28.9° and 67.6°, respectively). Thus, there is stronger BN π-bonding to the N1 atom of the tmp unit, which possess not the usual chair conformation but rather the unusual skew conformation. The molecular conformation is, moreover, determined by a sterically most favored conformation; in this the C1N1C5 and C10N2P10 units are practically perpendicular (87.7°). This also allows a sterically favorable arrangement of the *t*Bu and the catecholatophosphorus units by opening the P1–N2–C10 bond angle to 128.5°. Notably, P1 points in the direction of N1 although there is no bonding interaction between these two atoms as the P1···N1 distance is as large as 3.174 Å.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Conversely, the P1−N2 bond is short [1.670(3) Å]. Usually, P−N distances between tricoordinate P atoms and N atom are of the order of 1.80 Å [29]

The arsenic compound **17** shows a *cisoidal* arrangement of the N1B1N2As1 skeleton (Figure 11). B1−N1 π-bonding is excluded as the N1−B1 bond is longer than the B1−N2 bond and, in addition, N1 is not sp^2 as the sum of its bond angles is 349.0°. While the Cl1−As1−Cl2 angle is sharp [93.00(5)°] the N2−As1−Cl bond angle is 104.8(2)° and As1−N2−C10 is as wide as 128.6(2)°. However, the B1−N2−As1 bond angle is only 103.0°, pointing to preformation of a four-membered N1B1N2As1 ring. This, however, seems to be a steric effect exerted by the bulky *t*Bu group, as almost the same situation holds for the antimony compound **18**. Here, the Sb1−N2 bond is 2.072(2) Å and the Sb1−N1 atom distance is 2.539(1) Å. The N1−E and N2−E bond lengths differ by 0.644 Å in **17** and by 0.467 Å in **18**. All bond angles about E1 deviate strongly even for an approximate ψ-trigonal bipyramidal arrangement of atoms about the As and Sb centers, as the N1−As1−Cl1 and N1−Sb1−Cl2 bond angles of 158.4° and 157.6°, respectively, show. No doubt there is a weak E−N1 interaction, which is probably not retained in solution.

Discussion

The results described above demonstrate that **1** is a versatile reagent, leading to noncyclic and cyclic metallated diaminoboranes. The new compounds show structural features that are also present in metallo amidines.[2−8] However, the high steric requirement of the anion of **1** makes it less reactive than several lithium diorganylborylamides $R_2B-NR'Li$.[17,18,31]

Cyclic compounds **2**−**4** are readily accessible, while the cyclic compounds tmp−BX−N*t*Bu−BX_2 (X = Cl, Br) are better obtained by insertion of the BN triple bond of the amino iminoborane tmpB≡N*t*Bu into a boron halogen bond of BX_3.[32] These, like **2**−**4**, exhibit four different B−N bond lengths that depend on the combination of sp^2- and sp^3-type boron and nitrogen atoms; the shortest bonds involve tricoordinate B and N atoms, the longest tetracoordinate B and N atoms. These examples add to the arguments given by Power et al. on the influence of hybridization and multiple bonding in BN systems.[33]

While the catecholatoborane **4** as well as the analogous methyl derivative [1] are cyclic the liquid parent compound tmp−BH−N*t*Bu−Bcat[34] is considered to be noncyclic. This conclusion was based on NMR spectroscopic data. Thus, in contrast to **4**, only one set of ^1H and ^{13}C resonances occurs for the two CMe_2 groups, implying free rotation about the B1−N1 bond, while there are two for **4**. Moreover, even for **4** the B2−N1 bond may break at higher temperatures as it is rather long at 1.741(3) Å, which is close to the longest B−N bond of 1.756 Å found for $B_2Cl_4{\cdot}2NMe_3$.[35]

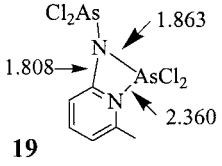
Halides of Al, Ga, and In react with alkali metal amidinates to give various analogs of the amindinato complexes of these element, all of which have chelate structures with either tetra-, penta- or hexacoordinate metal atoms.[36−39] In this study only one type has been characterized: compounds **6**−**8** are all four-membered chelates with tetracoordinate metal atoms. As expected, the coordinate E1−N1 bond is much longer than the single bond between atoms E1 and N2 (Table 2). Actually, this bond [2.078(2) Å] is longer than in most other amine adducts of $AlR_{3-n}X_n$, for which a range of 1.96−2.04 Å has been reported.[40,41] The Al1−N2 bond in **6** [1.869(2) Å] is longer than the terminal Al−N bonds in $[Al(N{=}CPh_2)_3]_2$ (av. 1.78 Å)[42] and several others,[43] but a better value for comparison is the Al−N bond in $[tmp_2AlF]_2$ [1.832(2) Å] where the fluorine atoms bridge the Al atoms.[20] Its Al−N bonds comprise tetracoordinate Al atoms and a tricoordinate N atom, as observed for **6**. Lesser differences in the two bond lengths are found for cyclic $Me_2Al(N\mathit{t}Bu)_2SMe(N\mathit{t}Bu)$ [1.908(2) and 1.918(2) Å][44] and cyclic $Me_2Al(NC_6H_2\mathit{t}Bu_3)_2P$ [1.974(3) and 1.981(4) Å] although the shorter bonds are longer than in **6**.[45] The same features are observed for **7** and **8**. With **7** the two Ga−N bonds can be compared with those of $[Ga(NMe_2)_3]_2$.[46] In this compound the bridging N atoms show Ga−N bond lengths of 1.964 and 1.974 Å while the Ga−N bonds to the terminal NMe_2 groups are, on average, 2.01 Å. Thus, the Ga1−N1 distance of 2.175(2) Å exceeds those of the bridging NMe_2 groups significantly while the Ga1−N2 bond length of 1.935(2) Å is considerably longer than the Ga−N bond to the terminal NMe_2 groups. The opening of the C−E−C bond angle from **6** to **8** suggests that the weakening of the E1−N1 bond is responsible for this change in structure, and that the In1−N1 bond is the easiest to break. Indeed, in solution this bond opens, as shown by the free rotation of the tmp unit about the B1−N1 bond. Most In−N bond lengths to tetracoordinate In lie in the range 2.196−2.246 Å.[47−50] Consequently, the In1−N1 bond [2.376(2) Å] is weak.

In contrast to the rich chemistry of silylamidines and silylamidinato complexes,[5,51,52] which allows even the synthesis of hexacoordinate Si chelates, no reactions of **1** with either trimethylhalosilanes or triphenylhalosilanes were observed, and even the reaction with $SiCl_4$ was not straightforward − the expected product tmp−BPh−N*t*Bu−$SiCl_3$ could not be isolated. In fact, in the synthesis of silylamidines the products formed are not only dependent on the stoichiometry of the reagents as *trans*-silylation reactions were also observed.[51] From the results obtained, the electrophilic character of element halides clearly plays a decisive role as well as steric factors. While Me_3SiCl and Me_3GeCl do not react with **1**, the more Lewis acidic Me_3SnCl readily did so. However, double substitution of halogen atoms in Me_2SnCl_2 and $SnCl_2$ were unsuccessful. This, we assume, is due to the bulkiness of **13** and **15**.

In line with these observations concerning reactivity, Ph_2PCl does not react with **1** while PCl_3 leads to an inseparable mixture of products. Conversely, the reactions with $AsCl_3$ and $SbCl_3$ produced the well-characterized compounds **17** and **18**. In **17**, the As1−N1 bond is 0.744 Å longer than the As1−N2 bond, indicating only a very

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

weak interaction. In the analogous compound tmp−BCl−N*t*Bu−$AsCl_2$, As1−N1 is 2.619(4) Å and As1−N2 is 1.869(4) Å.[53] The latter is not significantly shorter than in **17** [1.872(3) Å]. As−N bonds to tricoordinate As and tricoordinate N atoms span the range 1.79−1.95 Å.[53−55] The compound closest in structure to **17** is the cyclic $ClAs(NPPh_3)_2SbCl_4$,[53] with As−N bond lengths of 1.843 and 1.946 Å; compound **19** is even more closely related.[54] The difference in Sb−N bonds lengths in **18** is 0.467 Å, and in tmp−BCl−N*t*Bu−$SbCl_2$ 0.471 Å.[55] Comparable Sb−N bond lengths in $Cl_2Sb(NSiMe_3)_2CPh$ are 3.262 and 2.122 Å [56] or 4.144 and 2.097 Å for $Cl_2Sb(NSMe_2NSiMe_3)SbCl_2$.[57] Therefore, these latter two compounds exhibit much weaker Sb−N interactions than Sb1−N1 in **18**.



19

In conclusion, there are many analogies between the aminoborylamides and amidates, although **1** seems to be not as efficient a reagent as $R_2NCR-NR$ anions. This, however, is due to the large steric requirements of the anion of **1**. Thus, alkali metal salts with an anion $R_2N-BR'-NR''^-$ with R, R′, R″ = Me or R, R′ = Me and R″ = *i*Pr will be closer in reactivity to smaller amidates. However, *N*-metallated amino-, diamino- and triaminoboranes undoubtedly offer a wide new field for research and application.

Experimental Section

General Remarks: All experiments were conducted under anhydrous conditions using the Schlenk technique. Element halides or methyl element halides were commercial products of high quality. Compound **1** was prepared as described previously[1] or by the alternative procedure described below.

Elemental analyses were performed at the department's microanalytical laboratory. NMR: Bruker ACP-200 (^{7}Li, ^{11}B, ^{31}P, ^{119}Sn) or Jeol EX 400 (^{1}H, ^{13}C, ^{19}F); internal standards: C_6D_6, $CDCl_3$; external standards (1 M aqueous LiCl, H_3PO_4, $SnMe_4$) for all other nuclei. Mass spectra: VARIAN Atlas CH7; the mass numbers given refer to the most abundant isotope, and mass, relative intensity and assignment are reported. X-ray diffraction: Siemens P4 four circle diffractometer with a CCD area detector and LT2 device, Mo-K_α radiation, graphite monochromator. Data collection was performed with the programs implemented in SMART.[59]

(*tert*-Butylamino)[phenyl(2,2,6,6-tetramethylpiperidino)boryl]-lithium−Diethyl Ether (1): A solution of $tmpBCl_2$ (3.8 mL, 18 mmol) in hexane (20 mL) was added to a suspension of $LiHNCMe_3$ (1.44 g, 18.0 mmol) in hexane (30 mL). After stirring for 1 h the resultant precipitate was filtered off. All volatile material from the filtrate was then removed by distillation and the resultant oily residue of tmp−BCl−$NHCMe_3$ subjected to vacuum distillation (b.p. of 63 °C/0.001 Torr). Some $tmpB(NHCMe_3)_2$ was also obtained (higher boiling fraction). A 2 M solution of LiPh in cyclohexane/diethyl ether (8:2, 10.0 mL) was added dropwise while stirring to this bis(amino)chloroborane dissolved in hexane (100 mL). The resulting precipitate (LiCl) was filtered off, and the solvents were removed from the filtrate in vacuo. The so-obtained residue was then dissolved in hexane (30 mL) and the solution cooled to −20 °C. Within a few days colorless crystals separated. Yield: 3.4 g of **1** (95%). For further reactions, the suspension containing LiCl can be used directly.

General Procedure: A solution of the element halide compound was added to a freshly prepared and stirred solution of **1** in hexane at −78 °C. The insoluble material that formed in most of the reactions was removed by filtration (glass frit), and the solvents from the filtrate in vacuo. The residue was then crystallized from a suitable solvent.

2-*tert*-Butyl-5,5,9,9-tetramethyl-1-phenyl-2-aza-4-azonia-1-bora-3-borataspiro[3.5]nonane (2): A solution of BH_3·THF (1.77 mL, 3.4 M, 6.0 mmol) diluted with THF (100 mL) was added to **1** (3.0 mmol) in hexane (25 mL) at −78 °C. After warming to ambient temperature the ^{11}B NMR spectrum (^{1}H coupled) of the turbid solution shows a quintuplet at δ = −40.7 ppm ($LiBH_4$), a singlet at δ = 32.7 ppm (BPh), and a triplet at δ = −4.4 ppm (BH_2). All solvents were then removed and the residue extracted with hexane (about 25 mL) to leave behind white $LiBH_4$. The filtrate was subsequently reduced to about 15 mL. At −20 °C colorless crystals of **2** separated within a few days. Yield: 0.73 g (79%); m.p. 113 °C. $C_{19}H_{34}B_2N_2$ (312.09): calcd. C 73.29, H 10.61, N 9.00; found C 72.04, H 11.21, N 8.66. MS: (70 eV): *m*/*z* (%) = 312 (100) [M^+], 297 (62) [M^+ − Me], 255 (18) [M^+ − Bu], 240 (13) [M^+ − Me − Bu], 227 (43) [M^+ − H_2B − NBu], 187 (46) [M^+ − 125], 171 (35) [M^+ − tmpH], 144 (47) [M^+ − $tmpBH_2$ − Me], 126 (78) [tmp − Me^+].

2-*tert*-Butyl-3,3-difluoro-5,5,9,9-tetramethyl-1-phenyl-2-aza-4-azonia-3-borataspiro[3.5]nonane (3): A solution of BF_3·OEt_2 (0.75 mL, 6.0 mmol) in diethyl ether (10 mL) was slowly added, with stirring, to a solution of **1** (3.0 mmol) in hexane (30 mL). The solution showed at ambient temperature two ^{11}B singlet signals of almost equal intensity at 35.7 (BPh) and δ = 1.6 ppm ($LiBF_4$) (broad) and a triplet at δ = 4.8 ppm (BF_2). All volatile components were then removed in vacuo and the residue extracted with several portions of hexane. Subsequently, the insoluble $LiBF_4$ was removed from the last portion of the extracting hexane solution. The combined filtrates were then reduced to about 15 mL and kept at −20 °C. Within a few days, clear crystals of **3** separated. Yield: 0.7 g (72%), m.p. 121 °C. $C_{19}H_{32}B_2F_2N_2$ (348.08): calcd. C 65.50, H 9.19, N 8.04; found C 67.41, H 9.14, N 7.78. MS (70 eV): *m*/*z* (%) = 348 (4.5) [M^+], 333 (100) [M^+ − Me], 277 (82) [M^+ − Bu], 228 (15) [$tmpBPh^+$], 222 (16) [$tmpBNtBu^+$], 126 (23) [tmp − Me^+].

3-(Benzodioxo)-2-*tert*-butyl-5,5,9,9-tetramethyl-1-phenyl-2-aza-4-azonia-1-bora-3-borataspiro[3.5]nonane (4): A solution of *B*-chlorocatecholborane (0.46 g, 3.0 mmol) in diethyl ether (10 mL) was added at room temperature to a hexane solution of **1** (3.0 mmol). A white precipitate formed immediately. After stirring overnight the precipitate was separated by filtration and the filtrate reduced to 15 mL in vacuo. At −78 °C colorless crystals of **4** formed. Yield: 0.92 g (76%), m.p. 185 °C. $C_{25}H_{36}B_2N_2O_2$ (417.6): calcd. C 71.80, H 8.68, N 6.70; found C 71.83, H 8.97, N 6.69. MS (40 °C, 70 eV): *m*/*z* = 417 [M^+], 403 [M^+ − Me], 347 [M^+ − Me − Bu], 318 [$PhBNBu^+$], 277 [M^+ − tmp], 222 [$tmpBNBu^+$], m* = 298.8.

(2,2,6,6-Tetramethylpiperidine)lithium *tert*-Butyl[phenyl(2,2,6,6-tetramethylpiperidino)boryl]amide (6): A solution of **1** (3.0 mmol) in hexane (25 mL) was allowed to react at ambient temperature with

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a solution of tmp_2AlCl (3.0 mmol, 12.6 mL of a 0.238 M solution in hexane). The turbid mixture was then maintained at reflux for 1 d; 50% of **1** had reacted to a new compounds with $\delta^{11}B = 35.7$ ppm. Additional heating afforded no change in the ^{11}B NMR spectrum. The precipitate that had formed was filtered off. The yellow filtrate was then kept at −20 °C, providing a small amount of crystals of **6** that showed an ^{11}B NMR signal at δ = 35.5 ppm but no ^{27}Al NMR signal; m.p. 210 °C (dec.). $C_{28}H_{51}BLiN_3$ (447.47): calcd. C 75.16, H 11.49, N 9.39; found C 72.93, H 10.65, N 8.98. MS (70 eV): *m*/*z* (%) = 299 (100) [M^+ − tmpH − Li], 284 (100) [299 − Me^+], 243 (12) [299 − Bu^+], 126 (100) [tmp − Me^+].

2-*tert*-Butyl-3,3,5,5,9,9-hexamethyl-1-phenyl-2-aza-4-azonia-1-bora-3-aluminataspiro[3.5]nonane (7): A 1 M solution of Me_2AlCl in hexane (3 mL) was added to a suspension of **1** with LiCl (3.0 mmol **1** in 30 mL of hexane/diethyl ether) at room temperature. After stirring for 1 h the insoluble material was filtered off and the so-obtained colorless solution reduced to 15 mL. At −20 °C, colorless, moisture and air-sensitive crystals separated. Yield: 0.92 g of **7** (86%), m.p. 160 °C. $C_{21}H_{38}AlBN_2$ (356.32): calcd. C 70.72, H 10.66, N 7.88; found C 63.81, H 9.17, N 6.70. ^1H NMR (C_6D_6): δ = −0.06 (s, 6 H, $AlMe_2$) ppm. ^{13}C NMR ((C_6D_6): δ = 0.24 (br., $AlMe_2$) ppm. ^{27}Al NMR (C_6D_6): δ = 164, ($h_{1/2}$ = 1800 Hz) ppm. MS (70 eV): *m*/*z* (%) = 356 (8.5) [M^+], 341 (100) [M^+ − Me], 300 (21.5) [M^+ − Bu], 284 (100) [M^+ − Me − Bu], 269 (64) [284 − Me^+], 256 (32) [Me_2NBu^+], 228 (36.5) [tmpBPh$^+$], 216 (100) [M^+ − tmp], 183 (100) [tmpAlMe$^+$], 159 (100) [PhBNBu$^+$].

2-*tert*-Butyl-3,3,5,5,9,9-hexamethyl-1-phenyl-2-aza-4-azonia-1-bora-3-gallataspiro[3.5]nonane (8): Prepared in analogy to **7** by using Me_2GaCl (0.45 g, 3.0 mmol) dissolved in hexane (30 mL) to furnish very moisture- and air-sensitive crystals of **8**. Yield: 1.05 g (88%). $C_{21}H_{38}BGaN_2$ (399.06): calcd. C 63.1, H 9.52, N 7.02; found C 58.18, H 8.43, N 6.29. ^1H NMR (C_6D_6): δ = 0.32 (s, GaMe ppm.^{13}C NMR (C_6D_6): δ = 1.13 ($GaMe_2$) ppm. MS (70 eV): *m*/*z* (%) = 399 (0.5) [M^+], 384 (43) [M^+ − Me], 297 (9.5) [$GaMe_2^+$?], 224 (42) [tmpGaMe$^+$], 126 (11.5) [tmp − Me^+].

2-*tert*-Butyl-3,3,5,5,9,9-hexamethyl-1-phenyl-2-aza-4-azonia-1-bora-3-indataspiro[3.5]nonane (9): Prepared in analogy to **7** by using Me_2InCl (0.54 g, 3.0 mmol) dissolved in hexane (20 mL), with workup after stirring for 5 h. The filtrate was then reduced to ca. 20 mL. Crystals of **9** separated from the solution at −78 °C. Yield: 0.90 g (68%), m.p. > 200 °C. $C_{21}H_{38}BInN_2$ (444.16): calcd. C 56.74, H 8.56, N 6.30; found C 51.04, H 7.96, N 5.78. ^1H NMR (C_6D_6): δ = 0.06 (s, $InMe_2$) ppm. ^{13}C NMR ($CDCl_3$): δ = 1.0 ($InMe_2$) ppm.

Insufficient protection against air for **7**−**9** is responsible for the large deviation between calculated and found values in the elemental analysis.

[(*tert*-Butyl)(trimethylsilyl)amino](phenyl)(2,2,6,6-tetramethylpiperidino)borane (10): Li(tmp) (0.87 g, 5.9 mmol) was suspended in hexane (30 mL). After cooling the suspension to −78 °C, a solution of $PhBCl_2$ (0.78 mL, 5.9 mmol) in hexane (5 mL) was added with stirring. At room temperature only a single signal at $\delta^{11}B$ = 41.8 ppm was present, showing the complete conversion of $PhBCl_2$. The solid was filtered off and the filtrate treated with a freshly prepared solution of Li*N*t*Bu*($SiMe_3$) (5.9 mmol) in hexane (20 mL). The mixture was then kept under reflux for 5 d. Three ^{11}B NMR signals, at δ = 34.2 (60%), 23.4 (15%) and at 28.0 (25%) ppm, were detected, the first of which corresponds to **10**. In addition, three ^{27}Si NMR signals were found at δ = 9.1 (main signal), 17.6 and δ = 8.0 ppm. After removal of the hexane in vacuo the residue was treated with hexane (10 mL), the solid was removed by filtration and the so-obtained yellow solution kept at −20 °C. No crystals separated. Also, distillation did not allow **10** to be separated from the by-products.

[(*tert*-Butyl)(trichlorogermyl)amino](phenyl)(2,2,6,6-tetramethylpiperidino)borane (11): The solvent from a freshly prepared solution of **1** (1.77 mmol) in hexane (30 mL) was removed and the residue dissolved in diethyl ether (40 mL). $GeCl_4$ (0.3 mL) was then added to this solution, and the resultant suspension kept at reflux for 2 h. Since no complete conversion was noted the mixture was maintained at reflux for 5 days, after which only a single ^{11}B NMR signal was seen. The ether was then removed and the resultant oily residue treated with hexane (40 mL). On reducing the filtrate's volume to about 50%, crystals of **11** separated at −20 °C. Yield: 0.63 g (75%), m.p. 205 °C. $C_{19}H_{32}BCl_3GeN_2$ (478.22): calcd. C 47.68, H 6.69, N 5.85, Cl 22.24; found C 47.45, H 6.73, N 5.75, Cl 20.91.

[(*tert*-Butyl)(trimethylstannyl)amino](phenyl)(2,2,6,6-tetramethylpiperidino)borane (12): Prepared in analogy to **11** from **1** in hexane (3.0 mmol, 20 mL) and Me_3SnCl (0.76 g, 2.8 mmol) in hexane (15 mL). The suspension was then stirred for 2 days. Although only the ^{11}B NMR signal of **12** (δ = 39.8 ppm) was noted, the first crystals that separated from the filtrate at −20 °C proved to be Me_3SnCl. These were removed and the filtrate kept at −78 °C to afford crystals of **12**. Yield: 0.97 g (70%), m.p. 98 °C. $C_{22}H_{41}BN_2Sn$ (464.24): calcd. C 57.01, H 8.85, N 6.05; found C 54.80, H 8.68, N 5.68. ^1H NMR (C_6D_6): δ = 0.08 [t, $^2J(^{119}Sn^1H)$ = 56.3 Hz, 9 H] ppm. ^{13}C NMR (C_6D_6): δ = 1.4 [$^1J(^{119}Sn^{13}C)$ = 395.1 Hz] ppm. ^{119}Sn NMR (C_6D_6): δ = 17.9 ppm. MS (70 eV): *m*/*z* (%) = 464 (22) [M^+], 449 (100) [M^+ − Me], 324 (100) [M^+ − tmp], 165 (100) [$SnMe_3^+$].

[(*tert*-Butyl)(chlorodimethylstannyl)amino](phenyl)(2,2,6,6-tetramethylpiperidino)borane (13): A solution of Me_2SnCl_2 (0.44 g, 2.0 mmol) dissolved in boiling hexane (50 mL) was added to freshly prepared **1** (2.0 mmol) in hexane (30 mL) kept at −78 °C. The resulting suspension showed, at ambient temperature, only a single ^{11}B NMR signal at δ = 39.4 ppm. The filtrate was then reduced to 20 mL, and on cooling to −20 °C crystals of **13** separated. Yield: 0.71 g (73%), m.p. 145 °C (dec.). $C_{21}H_{38}BClN_2Sn$ (483.48): calcd. C 52.12, H 7.86, N 5.79; found C 45.67, H 7.51, N 5.74. ^1H NMR (C_6D_6): δ = 0.02 [d, $^2J(^{119}Sn^1H)$ = 52 Hz, 6 H, $SnMe_2$] ppm. ^{13}C NMR (C_6D_6): δ = −2.6 [$^1J(^{119}Sn^{13}C)$ = 390 Hz] ppm. ^{119}Sn NMR (C_6D_6): δ = 93.1 ppm.

Reaction of Me_2SnCl_2 with 1 in a 1:2: Ratio: In analogy to **13**, Me_2SnCl_2 (2.0 mmol) in hexane (50 mL) was reacted with **1** [4.0 mmol in hexane (40 mL)] at −78 °C. The ^{11}B NMR spectrum of the suspension showed, at ambient temperature, a signal at δ = 39.2 ppm in addition to that of the starting material. After 3 days, additional signals appeared at δ = 48.3 and δ = 5.4 ppm. A ^{119}Sn NMR spectrum revealed a signal at δ = 98.3 ppm, corresponding to $tmpMe_2SnCl$, while the ^{11}B NMR signal at δ = 39.2 ppm is typical for (tBuNBPh)$_2$.[23]

{(*tert*-Butyl)[chlorostannyl(II)]amino}(phenyl)(2,2,6,6-tetramethylpiperidino)borane (15): $SnCl_2$ (0.38 g, 2.0 mmol) was dissolved in THF (30 mL) and treated at 0 °C with a freshly prepared solution of **1** (4.0 mmol) in hexane (40 mL). A suspension formed, and the ^{11}B NMR spectrum shows a 50% conversion of **1**. On further stirring, no change was observed. After filtration and removal of solvent in vacuo a yellow oil remained that was dissolved in hexane (20 mL). At −20 °C compound **15** separated as a slightly yellow solid that is soluble in benzene, tetrahydrofuran or chloroform. No single crystals separated from these solutions. $C_{19}H_{32}BClN_2Sn$ (454.14): calcd. C 50.33, H 7.11, N 6.18; found C 48.75, H 7.05, N 5.51. MS (70 eV): *m*/*z* (%) = 454 (9) [M^+], 439 (25) [M^+ − Me],

419 (9) [M^+ − Cl], 301 (60) [M^+ − MeSnCl], 278 (100) [M^+ − Cl − tmp], 126 (77)) [tmp − Me^+].

{(*tert*-Butyl)[(phenyl)(2,2,6,6-tetramethylpiperidino)boryl]amino}-1,3,2-benzodioxaphosphane (16): A solution of benzodioxaphosphorus chloride (0.35 g, 2.0 mmol) in toluene (20 mL) was added to a solution of **1** (2.0 mmol) in hexane (40 mL) with stirring to afford a white precipitate that dissolved on prolonged stirring. After 3 days, the reaction was complete (^{11}B NMR signal at δ = 41.1 ppm). Following removal of the solvents the resultant oily, semi-solid residue was treated with toluene (30 mL) and the insoluble material filtered off. From the filtrate, crystals of **16** separated at −20 °C. Yield: 0.59 g (67%), m.p. 177 °C. $C_{26}H_{36}BN_2O_2P$ (438.36): calcd. C 68.53, H 8.23, N 6.39; found C 64.88, H 8.32, N 6.30. ^{1}H NMR (C_6D_6): δ = 6.69 [dd, $^3J(^1H^1H)$ = 5.76, $^4J(^1H^1H)$ = 3.4 Hz], 6.95 [dd, $^3J(^1H^1H)$ = 5.76, $^4J(^1H^1H)$ = 3.2 Hz, cat H], 7.17, 7.18, 7.71

[1] $w^{-1} = \sigma^2F_o^2 + (xP^2 + yP)$; $P = (F_o^2 + 2F_c^2)/3$.

(Ph) ppm. ^{13}C NMR (C_6D_6): δ = 112.3, 122.0 (cat C), 126.8, 128.9, 136.0 (Ph) ppm. ^{31}P NMR (C_6D_6): δ = 163.5 ppm.

{*tert*-Butyl[phenyl(2,2,6,6-tetramethylpiperidino)boryl]-amino}dichloroarsane (17): A solution of $AsCl_3$ (0.17 mL, 2.0 mmol) in hexane (10 mL) was added to a hexane solution of **1** (2.0 mmol in 30 mL). The mixture turned black and on continued stirring became a brownish suspension. After 3 h a ^{11}B NMR signal at δ = 41.3 ppm was detected. The solid was then removed and the yellow solution reduced to about 20 mL. At −20 °C an amorphous solid separated that was crystallized from hexane at ambient temperature. Yield: 0.58 g of **17** (65%), m.p. > 200 °C. $C_{19}H_{32}AsBCl_2N_2$ (445.10): calcd. C 51.22, H 7.19, N 6.29, Cl 15.93; found C 51.15, H 7.46, N 6.29, Cl 15.62.

{*tert*-Butyl[phenyl(2,2,6,6-tetramethylpiperidino)boryl]amino}-dichlorostibane (18): This was prepared from $SbCl_3$ (0.46 g, 2.0 mmol) and **1** (2.0 mmol) in hexane (30 mL). After 3 h the insoluble material was removed by filtration, and on cooling the filtrate (−20 °C) crystals of **18** separated. These crystals are highly sensitive to moisture. Yield: 0.65 g (66%), m.p. 144 °C. $C_{19}H_{32}N_2BCl_2Sb$ (491.93): calcd. C 46.35, H 6.50, N 5.69; found C 45.32, H 6.42, N 5.38. MS (79 eV): *m*/*z* (%) = 473 (25) [M^+ − Me], 456 (7) [M^+ − Cl], 332 (15) [tmpSbCl$_2^+$], 318 (33) [332 − Me^+].

X-ray Structure Determinations: Single crystals were covered with a polyfluoro ether oil and a specimen selected and mounted on the tip of a glass fiber. After cooling the crystal on the goniometer head to −80 °C with an LT2 device, the unit cell was determined from reflection collected on a total of 60 frames at five different settings of the ω and χ circles. Data collection was performed in the hemisphere mode (1264 frames). The program SAINT[59] was used for data reduction, and an absorption correction was applied using SADABS.[60] The structures were solved by direct methods (heavy atom methods for the Sb compound) using SHELX97.[61] This program was also applied for structure refinement. Non-hydrogen atoms were refined with anisotropic description. Most hydrogen atoms were visible after anisotropic refinement, but were placed in calculated positions and included in the refinement by applying a riding model. Data related to crystallography, data reduction and refinement are summarized in Table 5. CCDC-226743 to -226753 and -231319 (**9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Metalation of 2-Propenylphenol

Cristina Wippert Rodrigues,[a] Christian Limberg,*[b] and Hans Pritzkow[a]

Keywords: Molybdenum / Oxo complexes / Alkoxides / Lithium / Metalation

In order to generate 2-propenylphenolate, **PO**$^-$, as a potential ligand for oxomolybdenum compounds, the lithiation of the parent phenol derivative, **POH**, was investigated. Treatment of **POH** with BuLi in THF yielded a tetramer of the corresponding alkoxide "**POLi**" with a heterocubane structure in which the coordination spheres of the Li centres are completed by THF molecules, i.e. $\{Li(THF)[\mu_3\text{-}OC_6H_4(CH{=}CH{-}CH_3)\text{-}2]\}_4$ (**1**). Compound **1** proved to be rather unreactive and unsuitable as a starting material for the introduction of the corresponding aryloxide ligands into the coordination sphere of molybdenum by salt metathesis. The latter did occur, however, when "**POLi**" was synthesised in the presence of 12-crown-4 and subsequently treated with molybdenyl chloride. This led to an unidentified aryloxide compound as well as to a hitherto unknown chlorooxomolybdate anion in the complexes [Li(12-crown-4)][MoO_2Cl_3(THF)] (**2**) and [{Li(12-crown-4)}$_2$Cl][MoO_2Cl_3(THF)] (**2′**) with an octahedral coordination sphere at the molybdenum centre in each case. An Mo(**PO**) complex was finally isolated for the first time when $MoO_2(OtBu)_2$ was employed as a starting material and treated with "**POLi**" prepared in situ in the presence of the crown ether. This led to the isolation of [Li(12-crown-4)$_2$][MoO_2(**PO**)$_3$] (**3**), which represents a rare example of a five-coordinate dioxomolybdenum(VI) complex as well as being the first example among these complexes with a square-pyramidal ligand arrangement. Comparison of **2** with **3** suggests that the low coordination number of the 14-electron compound **3** originates from the bulkiness of the **PO**$^-$ ligands. The crystal structures of all three compounds **1**–**3** are discussed.

Introduction

In order to establish a potential model of the surface intermediates during the SOHIO process, in which propene is oxidised with O_2 on bismuth molybdate catalysts to give acrolein,[1] we have been interested in the synthesis of high-valent (π-allyl)Mo complexes. Since the tendency of (π-allyl)Mo units to release allyl radicals increases with increasing oxidation state of the molybdenum centre, we decided to tether the allyl ligand through a donor function to the molybdenum atom thereby increasing the stability of the Mo−allyl bonding. By using phosphane donor functions, we succeeded in isolating a stable (allyl)Mo^{IV} compound (Scheme 1) which was prepared from an (olefin/phosphane)Mo chelate complex.[2] In order to obtain (allyl)molybdenum compounds in even higher oxidation states, ideally containing oxo ligands at the same time, it would be advantageous to replace the phosphane donor function by a "harder" oxo donor function. We thus decided to exploit the behaviour of the potential **PO**$^-$ ligand in contact with high valent molybdenum compounds.

Results and Discussion

We envisioned that in-situ preparation of "**POLi**" as a source of **PO**$^-$ could be achieved simply by treatment of the parent phenol, **POH**, with BuLi in THF. Surprisingly, numerous attempted reactions between the corresponding reaction mixtures and high- or low-valent starting materials containing Mo−Cl units did not lead to LiCl salt metathesis. Since it has been shown in the past, that the structures and degree of aggregation of group 1 metal alkoxides can have a strong influence on their reactivity,[3] compound **1**, resulting from the lithiation reaction, was crystallised by cooling a concentrated solution in THF. A subsequent single-crystal X-ray diffraction study of **1** revealed the reason for its low reactivity; 4 equiv. of "**POLi**" assemble themselves in **1** to form an aggregate with an Li_4O_4 heterocubane core in the centre (see Figure 1 and Scheme 2). Each oxygen atom is thus connected to three Li cations as well as the aryl residue, while each Li ion is linked to three alkoxide oxygen atoms as well as to the O atom of a THF solvent molecule (selected bond lengths and angles are listed in Tables 1 and 2). While [Li(THF)(OPh)] forms a hexamer,[4] a heterocubane structure as shown in Scheme 2 was previously found for [Li(*N*-methylcaprolactam)(μ_3-OPh)]$_4$ [5] and, furthermore, it is reminiscent of the structure displayed by $[Li(THF)O_3SCF_3]_4$.[6] In this latter compound, the Li−O bonds are somewhat shorter than those observed for **1**

O(4)−Li(2)	1.942(5)	Li(3)−Li(4)	2.652(6)

(1.928−1.996 Å) which in turn compare well with those found in [Li(*N*-methylcaprolactam)(μ_3-OPh)]$_4$ (1.88−2.00 Å). The Li−Li distances are all very similar (2.604−2.652 Å) and only somewhat longer than those in organolithium compounds with a heterocubane structure such as [Li(THF)*t*BuCH$_2$CH$_2$]$_4$ (2.479 Å in average).[7] The bond angles within the cubes amount to 90±8°, i.e. the cubic geometry is only slightly distorted. Even though a (*Z*)/(*E*) ligand mixture (1:5) was employed for the synthesis of **1**, only (*E*)- configured olefinic moieties were found in the molecular structure of **1** as shown by X-ray crystallography and there is no evidence for (*Z*)-configured groups in the crystalline bulk material on the basis of NMR spectroscopic investigations (signal assignments are supported by ^{1}H-^{1}H-COSY and ^{1}H-^{13}C-HSQC spectroscopic data and are thus unambiguous). Apparently, crystallisation proceeds only for the (all-*E*) arrangement and hence the yield of crystalline material is only 17%.

Table 2. Selected bond angles [°] for **1**

Li(1)−O(1)−Li(4)	85.3(3)	O(1)−Li(1)−O(2)	94.5(2)

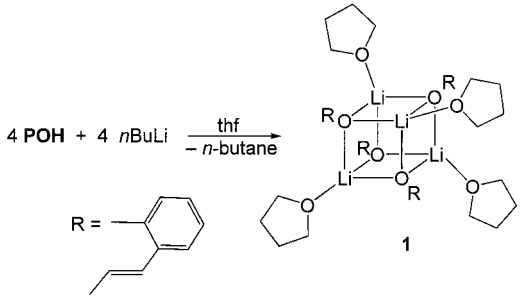


Scheme 2

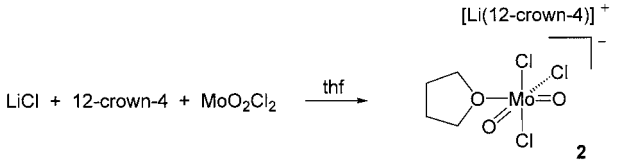
It is also clear from Figure 1 that the Li_4O_4 core is effectively shielded by the large organic residues as well as the THF residues which altogether form a lipophilic-like layer around the alkoxide O atoms. Hence, a reaction with Mo−Cl units or even with water is indeed problematic. Accordingly, **1** proved to be stable to air whereas [Li(*N*-methylcaprolactam)(μ_3-OPh)]$_4$ was reported[5] to be air-sensitive.

To avoid formation of the stable tetrameric form of "**PO-Li**" in solution, i.e. **1**, and to thus obtain it in a more reac-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tive state, 12-crown-4 was employed in subsequent experiments to separate the Li^+ ions. These potential ligands must be added to **POH** previous to the addition of BuLi and the resultant mixture has to be employed in situ since subsequent treatment of **1** with 12-crown-4 in THF does not enhance the reactivity.

Among other starting materials, MoO_2Cl_2 was chosen for treatment with 1 equiv. of "**POLi**" prepared by the above-mentioned route in the presence of 12-crown-4. Some of the MoO_2Cl_2 reacts to give a molybdenum aryloxide compound which, however, could neither be isolated in a pure state nor identified while the remainder apparently reacts with the Li(12-crown-4)Cl thus formed to give **2** with the hitherto unknown simple chlorooxo anion $[MoO_2Cl_3(THF)]^-$ (Scheme 3).



Scheme 3

Accordingly, for the formation of **2**, addition of **POH** is not necessary as shown by an analogous experiment performed without **POH** (1 equiv. of MoO_2Cl_2 then reacts to give LiCl and "MoO_2Bu_2" which decomposes while the other equiv. reacts with LiCl to give **2**). The chemistry of chlorooxomolybdenum compounds has been well explored and a large variety of such complexes (charged and uncharged) has been synthesised in the past.[8] The anion of **2** was unknown until now and while comparable anions of the type $[MoO_2Cl_3L]^-$ (with L = any donor) have been synthesised, for instance with L = H_2O,[9] their structures have so far eluded determination. Hence, attempts were made to crystallise **2** directly from the reaction mixture produced as described above. This led to crystals of **2′** where the $[Li(12\text{-crown-4})]^+$ cation is replaced by the novel cation $[\{Li(12\text{-crown-4})\}_2Cl]^+$. The molecular structure is shown in Figure 2 (selected bond lengths and angles are listed in Table 3). The cation is composed of two $[Li(12\text{-crown-4})]^+$ moieties which both coordinate to a chloride anion at almost identical distances [Li(1)−Cl(3) 2.305(9) Å; Li(2)−Cl(3) 2.310(8) Å]. One of the 12-crown-4 ligands is disordered with respect to both C and O atoms. The crystal structure of the neutral complex [Li(12-crown-4)Cl] has been determined previously.[10] A comparison with the corresponding $[\{Li(12\text{-crown-4})\}_2Cl]^+$ cation in **2′** revealed that, as expected in the absence of the second $[Li(12\text{-crown-4})]^+$ cation, the remaining Li−Cl bond is somewhat shorter [2.290(4) Å]. The difference is, however, not as large as might have been expected. In contrast to [Li(12-crown-4)Cl], in which all Li−O distances are equal, the Li−O bonds within each of the [Li(12-crown-4)] moieties in **2′** are all different, spanning a range of 1.976−2.210 Å. The Mo centre of the anion is surrounded by its ligands in a distorted octahedral geometry. The bond lengths of the two

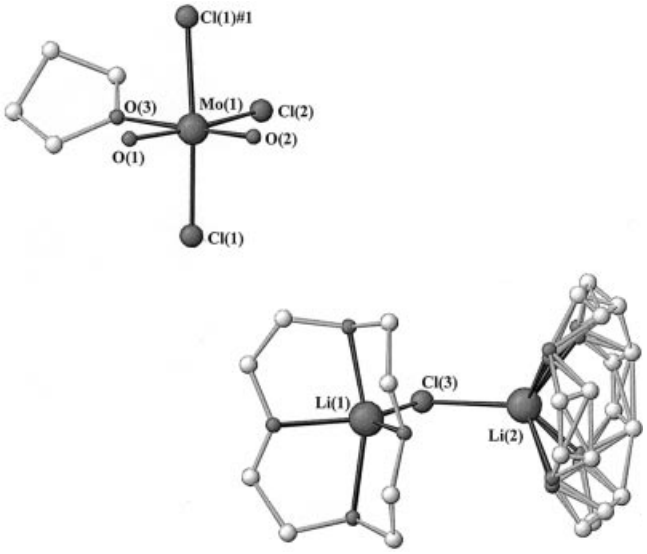


Figure 2. Molecular structure of **2′** with partial atom labelling scheme; hydrogen atoms have been omitted for clarity

Mo=O groups are significantly different since the comparatively weak THF donor is found in a *trans* position to O2 [→ strong bond to Mo; 1.670(5) Å] while a chloro ligand is bonded in a *trans* position to O1 [→ weaker bond to Mo; 1.704 Å]. The bond angle O2−Mo−O1 amounts to 102.9° and thus compares well with the angles found in other octahedral complexes containing the MoO_2^{2+} unit.

Table 3. Selected bond lengths [Å] and bond angles [°] for **2′**

Mo(1)−O(2)	1.670(5)	Mo(1)−Cl(1)	2.380(2)
Mo(1)−O(1)	1.704(4)	Mo(1)−Cl(2)	2.510(2)
Mo(1)−O(3)	2.293(3)	Li(1)−Cl(3)	2.305(9)
		Li(2)−Cl(3)	2.310(8)
O(2)−Mo(1)−O(1)	102.9(2)	O(3)−Mo(1)−Cl(1)	82.92(5)
O(2)−Mo(1)−O(3)	174.0(3)	O(2)−Mo(1)−Cl(2)	93.8(2)
O(1)−Mo(1)−O(3)	83.1(3)	O(1)−Mo(1)−Cl(2)	163.3(2)
O(2)−Mo(1)−Cl(1)	96.58(5)	O(3)−Mo(1)−Cl(2)	80.24(9)
O(1)−Mo(1)−Cl(1)	93.58(4)	Cl(1)−Mo(1)−Cl(2)	84.39(3)

Since the tendency of MoO_2^{2+} units to bind chloride is clearly very strong, $MoO_2(OtBu)_2$ was subsequently chosen as the starting material in order to finally obtain and isolate a $\mathbf{PO^-}$ complex by the synthetic route discussed above (direct treatment with **POH** leads to an air-sensitive brown oil which could not be purified sufficiently to allow its identification). After workup, a yellow, microcrystalline, very air-sensitive solid was obtained. IR spectroscopic measurements indicated the presence of an MoO_2 moiety whereas the ^1H NMR spectrum showed signals for (*E*)-configured **PO** residues [again there was no evidence for (*Z*) moieties] and 12-crown-4. Recrystallisation from 1,4-dioxane/hexane provided crystals suitable for a single-crystal X-ray diffraction study which indicated the composition [Li(12-crown-

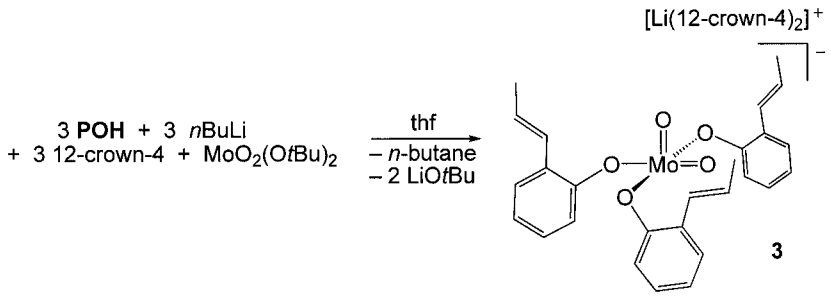

Scheme 4

4)$_2$][MoO_2(**PO**)$_3$] (**3**) (Scheme 4, Figure 3, selected bonds lengths and angles are listed in Table 4). The arrangement of the five oxygen atoms around the molybdenum centre represents a distorted square pyramid ($\tau^{[11]} = 0.1$) with O5 at the apical position. Five-coordinated dioxomolybdenum(VI) complexes such as the anion of **3** are rare. When formed, these 14-electron complexes are usually stabilised by additional donor molecules (e.g. solvent molecules such as here THF/dioxane) or aggregation. Accordingly, only five monomeric complexes displaying five-coordination in the solid state are known today[12–17] which uniformly exhibit trigonal-bipyramidal coordination geometries. The square-pyramidal arrangement of the ligands in **3** is thus unique. The successful isolation of the known compounds has been ascribed to the employment of bulky ligands and this hypothesis has very recently been confirmed in a systematic study.[16]

Table 4. Selected bond lengths [Å] and bond angles [°] for **3**

Mo(1)–O(5)	1.676(6)	Mo(1)–O(2)	1.977(4)
Mo(1)–O(4)	1.704(4)	O(1)–C(1)	1.357(6)

O(5)–Mo(1)–O(2)	110.2(2)		

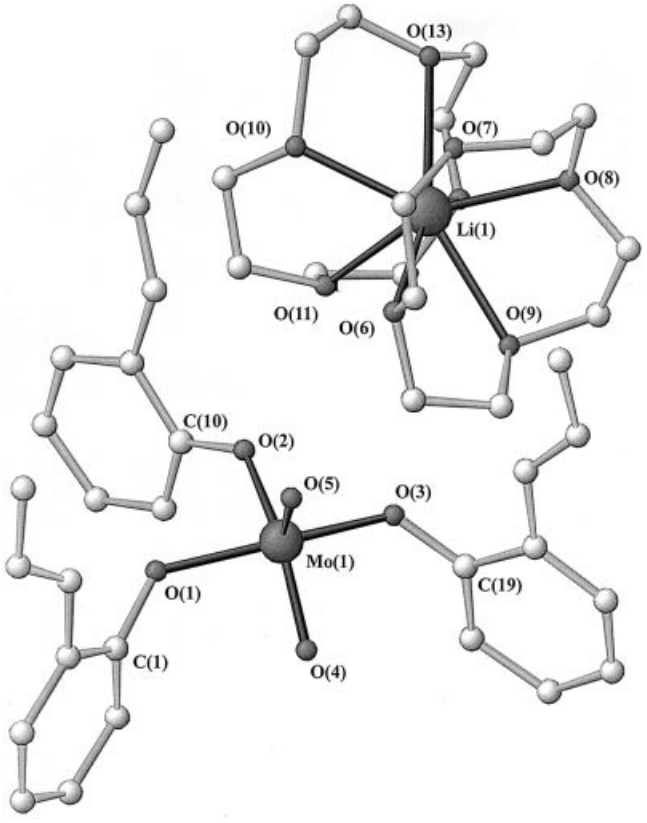

Figure 3. Molecular structure of **3** with partial atom labelling scheme; hydrogen atoms have been omitted for clarity

Along these lines, an explanation for the five-coordination of the molybdenum centre in **3** could also be based on the bulkiness of its aryl residues and the structural data support this assumption (see below).

Due to the square-pyramidal arrangement, the two terminal O atoms show quite different distances to Mo, i.e. the length of the bond between Mo and O5, lacking a *trans* ligand, amounts to 1.676(6) Å while the Mo–O4 bond is significantly longer [1.704(4) Å]. Atoms O1–O4 lie roughly in a plane (the deviations from the mean ideal plane amount to ±5.4 pm) and, as expected, the angles O5–Mo–O(1–4) are all somewhat larger than 90° (103.8–110.2°), the largest one occurring for O2 which is "clamped" by two bulky aryl residues so that C10 has to bend out of the basal plane. Furthermore, the small terminal oxo ligand O4 allows C1 and C19 to position themselves approximately within this plane. Accordingly, the O–Mo–O angles within the square base amount to 92.3–80.1°. In Figure 3 it can be seen that all aryl rings are arranged almost perpendicular to the basal plane to minimise steric crowding. All propenyl residues point in the same direction and an additional sixth ligand would have to approach from the other side where it would surely come into conflict with the aryl residues thus explaining the 5-coordination in the case of **3**. Due to the fact that three of these bulky aryloxide ligands were unexpectedly introduced at Mo in the course of the reaction shown in Scheme 4, an interaction between their olefinic functions and the Mo centre is clearly not possible either.

The complex anions of **3** and **2/2′** both contain an MoO_2^{2+} moiety and three anionic ligands. In the case of **2/2′** these are chloride ligands whereas in **3** they are bulky aryloxide ligands. The latter prevent binding of an additional neutral donor leading to five-coordination in **3** while the "compact" chloride ligands in **2/2′** permit coordination of an additional THF molecule.

Conclusion

In summary, we have clarified the unusual behaviour of lithiated **POH** by elucidating the molecular structure of the corresponding lithium aryloxide. It displays a heterocubane arrangement in which the organic ligands and residues insulate the inorganic core and, with this in mind, precautions could be taken to avoid formation of this structure. These enabled the synthesis and characterisation of the first Mo/**PO** complex **3**. Compound **3** is a rare example of a five-coordinate MoO_2^{2+} complex which, at the same time, represents the first example of an MoO_2^{2+} compound with a square-pyramidal arrangement of its ligands. Moreover, the first structural characterisation of a compound with an anion of the type $[MoO_2Cl_3L]^-$ has been achieved. Compound **2** contains such an anion where L is THF. Exchange of bulky $\mathbf{PO}^-$ by Cl^- in the $[MoO_2X_3]^-$ moiety thus allows the additional coordination of a solvent molecule in **2** supporting the hypothesis that steric factors do indeed determine the coordination numbers observed in MoO_2^{2+} compounds.

Experimental Section

General Remarks: All manipulations were carried out with a vacuum line (at a background pressure $< 10^{-3}$ mbar), in a glovebox or by means of Schlenk-type techniques involving the use of dry argon. The $MoO_2(OtBu)_2$ complex was prepared as described in the literature.[18] All other starting materials were obtained commercially. Microanalyses were performed by the Analytische Laboratorien des Organisch-Chemischen Institutes der Universität Heidelberg using a Heraeus CHN-Analyser. All NMR spectra were recorded using a Bruker Avance-DPX 200 MHz spectrometer. Infrared (IR) spectra were recorded using samples prepared as KBr pellets with a Digilab Excalibur™ FTS 3000 FTIR spectrometer. Low-resolution mass spectra were recorded with a Finnigan MAT 8400 instrument. High-resolution mass spectra were performed at the Zentrum für Massenspektrometrie des Organisch-Chemischen Instituts der Universität Heidelberg using a JEOL JMS-700 spectrometer. The ions were generated by EI (70 eV).

[Li(THF){μ$_3$-OC$_6$H$_4$(CH=CH−CH$_3$)-2}]$_4$ (1): A solution of 2-propenylphenol (1.00 g, 7.45 mmol) in THF (10 mL) was cooled to −20 °C and a BuLi solution (1.6 M in hexane, 4.66 mL) was added slowly. After warming to room temp., all volatiles were removed yielding analytically pure **1** (1.30 g 1.53 mmol, 82%). Crystals were obtained by cooling a THF solution to −30 °C for 12 h. $C_{52}H_{68}Li_4O_8$ (848.9): calcd. C 73.58, H 8.07; found C 73.40, H 8.14. MS (EI/LR): *m/z* (%) = 707 (25) [(5 **POLi**)$^+$ + Li], 560 (8) [(4 **POLi**)$^+$], 427 (100) [(3 **POLi**)$^+$ + Li], 287 (19) [(2 **POLi**) + Li], 280 (12) [(2 **POLi**)$^+$], 147 (100) [**POLi**$^+$ + Li], 134 (100) [**POH**$^+$]. MS (EI/HR): *m/z* found (calcd.) = 707.4242 (707.4227, Δ*m* = 1.5 mmu) [$C_{45}H_{45}O_5{}^7Li_6$], 706.4225 (706.4219, Δ*m* = 0.6 mmu) [$C_{45}H_{45}O_5{}^6Li^7Li_5$], 560.3282 (560.3254, Δ*m* = 2.8 mmu) [$C_{36}H_{36}O_4{}^7Li_4$], 427.2577 (427.2600, Δ*m* = 2.3 mmu) [$C_{27}H_{27}O_3{}^7Li_4$], 426.2599 (426.2591, Δ*m* = 0.8 mmu) [$C_{27}H_{27}O_3{}^6Li^7Li_3$], 287.1790 (287.1787, Δ*m* = 0.3 mmu) [$C_{18}H_{18}O_2{}^7Li_3$], 280.1633 (280.1627, Δ*m* = 0.6 mmu) [$C_{18}H_{18}O_2{}^7Li_4$]. IR (KBr): $\tilde{\nu}$ = 3528 (w), 3054 (w), 3019 (w), 2976 (m), 2909 (w), 2876 (w), 2731 (w), 1589 (s), 1533 (m), 1476 (s),1447 (m), 1375 (w), 1304 (m), 1271 (m), 1184 (w), 1151 (m), 1105 (w), 1045 (m), 980 (m), 895 (w), 857 (m), 798 (m), 754 (s), 727 (m), 579 (m) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 7.02 (m, 16 H, H_{Ar}), 6.87 (d, $^3J_{H,H}$ = 16.39 Hz, 4 H, $CH_3CH{=}CHC_6H_4$), 6.12 (m, 4 H, $CH_3CH{=}CHC_6H_4$), 3.53 (m, 16 H, THF), 1.70 (d, $^3J_{H,H}$ = 6.49 Hz, 12 H, $CH_3CH{=}CHC_6H_4$), 1.61 (m, 16 H, THF) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 164.15 (s, 4 C, C_{Ar}−O), 130−114 (m, 20 C, C_{Ar}), 128.57 (s, 4 C, $CH_3CH{=}CHC_6H_4$), 123.41 (s, 4 C, $CH_3CH{=}CHC_6H_4$), 68.46 (s, 8 C, THF), 25.64 (s, 8 C, THF), 18.84 (s, 4 C, $CH_3CH{=}CHC_6H_4$) ppm.

[Li(12-crown-4)][MoCl$_3$O$_2$(THF)] (2): A solution of MoO_2Cl_2 (0.55 g, 2.79 mmol) in THF (40 mL) was cooled to −20 °C and 12-crown-4 was added (0.49 g, 2.79 mmol). To the resultant solution, butyllithium was slowly added (1.11 mL of a 2.5 M toluene solution) resulting in a change of the original yellow colour to a dark brown. After warming to room temp., the solution was stirred for 0.5 h and a fine black solid precipitated which was filtered. All volatiles were removed from the filtrate and the residue extracted with acetone (40 mL). Removal of the solvent yielded the pure product **2** (0.55 g, 1.13 mmol, 40.5%). $C_{12}H_{24}Cl_3LiMoO_7$ (489.6): calcd. C 29.44, H 4.94; found C 29.54, H 4.97. IR (KBr): $\tilde{\nu}$ = 2935 (m), 2877 (w), 1705 (m), 1452 (m), 1362 (m), 1286 (m), 1243 (m), 1136 (m), 1086 (s), 1021 (m), 985 (s), 927 (s), 860 (s), 741 (s), 529 (w), 423 (w) cm^{-1}. ^{1}H NMR ([D$_8$]THF): δ = 3.84 (s, 16 H, 12-crown-4), 3.63 (m, THF), 2.10 (s, acetone), 1.78 (m, THF) ppm. ^{13}C{^{1}H} NMR ([D$_6$]acetone): δ = 68.93 (s, 16 C, 12-crown-4), 68.49 (s, 2 C, THF). Crystals of **2′** could be obtained by extraction of the residue mentioned above with THF rather than acetone and cooling the resultant solution for several weeks to −28 °C.

[Li(12-crown-4)$_2$][MoO$_2${OC$_6$H$_4$(CH=CHCH$_3$)-2}$_3$] (3): A solution of 2-propenylphenol (1.04 g, 7.45 mmol) and 12-crown-4 (1.33 g, 7.56 mmol) in THF (10 mL) was cooled to −20 °C and BuLi was slowly added (3.1 mL 2.5 M solution in toluene). After stirring for 5 min, the resultant mixture was added slowly to $MoO_2(OtBu)_2$ (0.70 g, 2.57 mmol), dissolved in THF (10 mL) held at −20 °C. After stirring for 2 h, the resultant yellow-brown solution was reduced to a volume of 5 mL. After 24 h at −28 °C, microcrystalline **3** had precipitated and, due to the high sensitivity of **3** in the solid state (almost any manipulation caused the formation of a white solid at the surface) and the varying amounts of crown ether complexed to the lithium cations (NMR spectroscopy shows that the Li/crown ether ratios varies between 1:1 and 1:2), we failed to obtain a correct elemental analysis. Yield 0.993 g, 1.120 mmol, 43.6%. IR (KBr): $\tilde{\nu}$ = 2974 (w), 2913 (w), 2879 (w), 1590 (s), 1555 (w), 1477 (s), 1447 (s), 1371 (w), 1304 (m), 1246 (w), 1184 (w), 1146 (w), 1090 (m), 1045 (s), 980 (s), 926 (w), 856 (s), 799 (m), 755 (s), 727 (m), 579 (m), 418 (m) cm^{-1}. ^{1}H NMR ([D$_8$]THF, *T* = 30 °C): δ = 7.33 (br, 3 H, H_{Ar}), 7.03 (d, $^3J_{H,H}$ = 16.04 Hz, 3 H, $CH_3CH{=}CHC_6H_4$), 6.9−6.7 (br, 6 H, H_{Ar}), 6.42 (br, 3 H, H_{Ar}), 6.00 (m, 3 H, $CH_3CH{=}CHC_6H_4$), 3.65 (s, 12-crown-4), 1.67 (br, 9 H, $CH_3CH{=}CHC_6H_4$). ^{1}H NMR ([D$_8$]THF, *T* = −30 °C): δ = 7.33 (d, $^3J_{H,H}$ = 7.51 Hz, 3 H, H_{Ar}), 7.03 (d, $^3J_{H,H}$ = 16.04 Hz, 3 H, $CH_3CH{=}CHC_6H_4$), 6.9−6.7 (m, 6 H, H_{Ar}), 6.42 (t, 3 H, H_{Ar}), 6.00 (m, 3 H, $CH_3CH{=}CHC_6H_4$), 3.65 (s, 12-crown-4), 1.67 (d, $^3J_{H,H}$ = 6.49 Hz,

9 H, $CH_3CH{=}CHC_6H_4$) ppm. $^{13}C\{^1H\}$ NMR ([D$_8$]THF, T = 30 °C): δ = 164.77 (s, 3 C, C_{Ar}−O), 130−114 (m, 15 C, C_{Ar}), 128.77 (s, 3 C, $CH_3CH{=}CHC_6H_4$), 120.40 (s, 3 C, $CH_3CH{=}CHC_6H_4$), 71.25 (s, 12-crown-4), 18.23 (s, $CH_3CH{=}CHC_6H_4$) ppm. Recrystallisation of microcrystalline **3** from 1,4-dioxane/hexane at room temperature yielded crystals suitable for a single-crystal X-ray diffraction study.

X-ray Crystallographic Studies:[19] Crystals were obtained as described above. Diffraction data were recorded with a Bruker AXS Smart CCD diffractometer. Empirical absorption corrections were applied. The structures were solved using direct methods and refined anisotropically with the SHELXL-97[20] and SHELXS-97[21] programs. Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5 times those of the atoms to which they are attached. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma||F_o| - |F_o|/\Sigma|F_o|$, $R_w = [\Sigma(F_o^2 - F_c^2)^2/\Sigma w(F_o)^2]^{0.5}$. Table 5 lists the crystallographic data.

Synthesis of a Dinuclear Ruthenabicyclic Complex and Its Ligand-Substitution Reactions

Yoshihiko Yamamoto,*[a] Yumiko Miyabe,[b] and Kenji Itoh[b]

Keywords: Alkyne ligands / Carbonyl ligands / Metallacycles / Phosphane ligands / Ruthenium

A trinuclear carbonylruthenium complex, $[Ru_3(CO)_{12}]$, was treated with diynes bearing ester, phenyl, or trimethylsilyl groups on the alkyne termini to give rise to various complexes. A diyne diester afforded a dinuclear ruthenacycle complex similar to known iron ferrole complexes and a mononuclear ruthenacyclopentadiene complex. The selectivity for the formation of these products varied depending on the ratio of the diyne diester toward $[Ru_3(CO)_{12}]$. When a phenyl-substituted diyne was employed, a cyclopentadienone complex was formed together with the expected dinuclear ruthenacycle complex. In contrast, a bis(trimethylsilyl)diyne gave the corresponding cyclopentadienone complex as the only product. Treatment of the obtained ruthenabicycle complex with trimethylamine oxide (Me_3NO) gave a mono(trimethylamine) complex, which was further converted into various phosphane complexes upon reaction with phosphanes in refluxing THF. The corresponding monophosphane complexes were obtained for all monodentate or bidentate phosphanes except for bis(diphenylphosphanyl)methane, which afforded a bridging bis(phosphane) complex. In contrast, when an isolated monodentate phosphane complex of 1,2-bis(diphenylphosphanyl)ethane and diphenyl(2-pyridyl)phosphane was treated with Me_3NO, P-P or P-N chelate complexes were formed, respectively. The dinuclear mono(amine)ruthenacycle complex also reacted with dimethyl butynedioate (dimethyl acetylenedicarboxylate, DMAD) in refluxing THF to afford a novel μ-η^2-alkyne complex together with the [2+2+2] cycloadduct between the diyne and DMAD. The highly electron-deficient character of DMAD is imperative for the formation of the μ-alkyne complex. Methyl propiolate and diphenylacetylene gave no corresponding μ-alkyne complexes.

Introduction

Metallacyclopentadienes have received considerable attention because of their close relevance to alkyne cyclooligomerization reactions.[1] The oxidative cyclization of two alkyne molecules with a low-valent transition-metal fragment gives rise to a metallacyclopentadiene. The diene moiety of a metallacyclopentadiene can be coordinated by another metal fragment to form a dinuclear complex.[2] Among such dinuclear metallacycle complexes, iron ferrole complexes, $[Fe_2(CO)_6(RC_2R')_2]$,[3,4] and their cobalt analogues[5] have been extensively explored as intermediates for the formation of a variety of organic molecules from alkynes and carbonyl transition-metal complexes. With respect to the ruthenium analogues, most examples have been obtained from the reaction of a trinuclear carbonyl cluster, $[Ru_3(CO)_{12}]$ (**1**), with monoalkynes and conjugated polyalkynes.[6,7] However, the reported yields of the dinuclear complexes were not high and generally below 50%. Therefore, further exploration of the dinuclear ruthenacycle complexes awaits an improved synthetic method.

We have recently developed ruthenium-catalyzed [2+2+2] cycloadditions of 1,6-diynes with unsaturated molecules, resulting in the formation of benzenes, cyclohexadienes, pyridines, pyridones, etc.[8] These cycloadditions essentially did not take place with monoalkynes, except for electron-deficient ones, indicating that the 1,6-diyne substrates play a critical role in the formation of the ruthenacycle key intermediate: the oxidative cyclization of the 1,6-diynes is entropically more favorable than that of monoalkynes. With these facts in mind, we further investigated the reaction of **1** with diynes to establish a highly efficient route to bicyclic analogues of the dinuclear ruthenacycle complexes.[9] Herein we report on the efficient synthesis of a dinuclear ruthenabicycle complex, using a diyne diester as an alkyne substrate, and its ligand-substitution reactions.

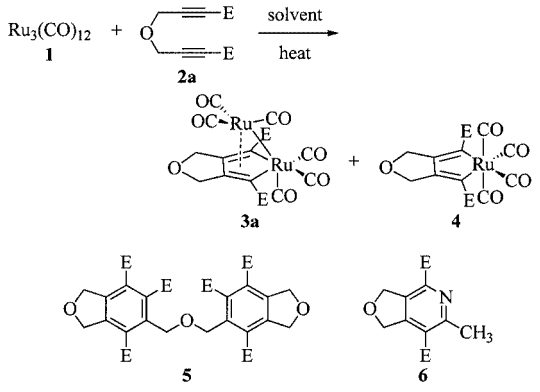
Results and Discussion

Reaction of $[Ru_3(CO)_{12}]$ with Diynes

At the outset, the diyne diester **2a** bearing methoxycarbonyl terminal substituents was examined as a diyne sub-

strate (Scheme 1) because the electron-deficient alkyne termini favor oxidative cyclization with a low-valent transition-metal fragment.[10] The trinuclear cluster $[Ru_3(CO)_{12}]$ (**1**) and **2a** were allowed to react under various reaction conditions (Table 1). In toluene, **1** and 2 equiv. of **2a** were heated at 110 °C under Ar for 0.5 h (run 1). The TLC analysis of the crude reaction mixture showed the complete consumption of **2a**. Separation by silica-gel chromatography gave pure **3a**. In the ^{1}H NMR spectrum of **3a**, the absorptions of the methylene protons adjacent to the ether oxygen atom appear at δ = 4.80 (dd, $J_{H,H}$ = 15.3, 2.4 Hz, 2 H) and 5.08 (dd, $J_{H,H}$ = 15.3, 2.4 Hz, 2 H) ppm, indicative of the diyne having undergone oxidative cyclization. This was also confirmed by the IR spectrum, which shows no alkyne absorption. Instead, strong absorptions corresponding to the CO ligands were observed around 2000 cm^{-1}. The ^{13}C NMR spectrum shows the resonance of the CO ligands at δ = 192.21, 193.60, and 194.37 ppm as well as three sp^2- and two sp^3-carbon signals. Finally, single-crystal X-ray crystallography unambiguously revealed that **3a** is a dinuclear ruthenacycle complex, as shown in Figure 1. The unit cell contains two crystallographically unique molecules **3a(A)** and **3a(B)**. Similar to known ferrole-type complexes,[6] the $[Ru_2(CO)_6]$ fragments of **3a** have a "non-sawhorse" geometry typified by a semi-bridging CO ligand and an Ru−Ru single bond of about 2.72 Å, which is within the range of Ru−Ru single bond lengths found previously.[6] In **3a(A)**, the Ru2−C2 and Ru2−C7 bond lengths are 2.071(9) and 2.105(8) Å, respectively, and the C2−C3 and C6−C7 bonds [1.467(11) and 1.478(10) Å] are longer than the C3−C6 bond [1.351(12) Å]. In contrast, the Ru2−C2 and Ru2−C7 bonds [2.096(7) and 2.114(8) Å] in **3a(B)** are longer than those in **3a(A)**, and the C3−C6 bond of 1.456(11) Å is longer than the C2−C3 and C6−C7 bonds [1.369(12) and 1.375(12) Å] in **3a(B)**. These data indicate that **3a(A)** and **3a(B)** are represented as structures **I** and **II**, respectively, in Scheme 2. These structural features are quite similar to the previously reported tetrakis(methoxycarbonyl) analogue.[6d]



Scheme 1. Reaction of $[Ru_3(CO)_{12}]$ (**1**) with diyne diester **3a**

Together with **3a**, the diyne trimer **5** was also obtained in 13% yield as a result of the [2+2+2] cycloaddition of **2a**.[10c,10d] In addition, 51% of **1** was recovered intact. To improve the yield of **3a**, the reaction conditions were further optimized. Using acetonitrile instead of toluene as a solvent successfully suppressed the formation of **5**, although a trace amount of pyridine **6** was formed by [2+2+2] cycloaddition of **2a** with CH_3CN (Table 1, run 2). As a consequence, the yield of **3a** was raised to 56%. Although **1** was almost completely consumed, total recovery of ruthenium (**3a** and recovered **1**) was not more than 60%. This was probably because **1** decomposed under argon with concomitant extrusion of CO. Thus, the reaction was then conducted under 1 atm of CO in refluxing CH_3CN (run 3). The starting **2a** was totally consumed within 1 h. However, the yield of **3a** was not improved, and an additional product, **4**, was obtained as well as recovered **1**. The IR spectrum of **4** is very similar to that of **3a**. The absorptions of a conjugated carbonyl group and the CO ligands are observed at 1676 cm^{-1} and around 2000 cm^{-1}, respectively. In contrast to **3a**, only two singlet signals assigned to $-OCH_2-$ and $-OCH_3$ with a 2:3 integral ratio appear at δ = 4.65 and 3.75 ppm, respectively, in the ^{1}H NMR spectrum. Furthermore, in the ^{13}C NMR spectrum, five sp^2-carbon peaks are observed at δ = 171−190 and 133.66 ppm along with sp^3-carbon peaks assigned to $-OCH_2-$ and $-OCH_3$ at δ = 70.62 and 51.98 ppm, respectively. These data suggest that **4** is a highly symmetrical carbonylruthenium complex derived from **2a**. The detailed structural assignment was accomplished by X-ray crystallographic analysis. As shown in Figure 1, **4** is a mononuclear ruthenabicycle complex bearing four CO ligands. The unit cell contains two crystallographically unique molecules. The geometry of the ruthenium center is distorted octahedral with the basal plane consisting of the two CO ligands and the metallacycle carbon atoms C2 and C7; there are two apical CO ligands. The C13−Ru1−C14 angles are 164.5(3)° and 165.0(3)°. The ruthenacycle moieties present normal metallacyclopentadiene geometries with $C_\alpha-C_\beta$ bond lengths ranging from 1.307(13) to 1.388(12) Å, which are shorter than the $C_\beta-C_\beta$ bonds [1.471(12) and 1.432(12) Å]. The $Ru-C_\alpha$ distances, ranging from 2.110(10) to 2.172(8) Å, are similar to those of typical Ru−sp^2-C single bonds.[11]

Further optimization of the reaction conditions was carried out by performing the reaction under higher CO pressure in an autoclave. Under 5 atm of CO, **1** and 2 equiv. of **2a** were heated in CH_3CN at 120 °C for 12 h to afford **3a** in an improved isolated yield of 74% together with **4** in 20% yield (Table 1, run 4). Trace amounts of **6** and recovered **1** were also detected. Similar results were obtained from the reaction under 10 atm of CO (run 5). The reduced amounts of the diyne **2a** increased the product selectivity in favor of the dinuclear complex **3a**. The use of 1.5 equiv. of **2a** (**2a**/Ru = 1:2) gave predominantly **3a** in 87% yield (run 6). The reaction terminated after 1 h resulted in lower conversion of **1** (70%), and, interestingly, both **3a** and **4** were obtained in 43 and 21% yields, respectively (run 7). This result suggests that the initially formed mononuclear complex **4** might be converted into the dinuclear complex **3a**. In fact, the isolated **4** was treated with **1** (1 equiv. Ru) in CH_3CN at 120 °C under 5 atm of CO for 12 h to afford **3a** in 78% yield together with recovered **4** and **1** (18% and 23%, respec-

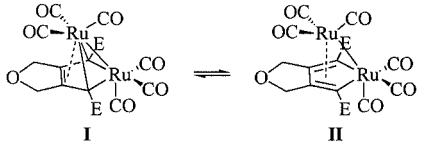
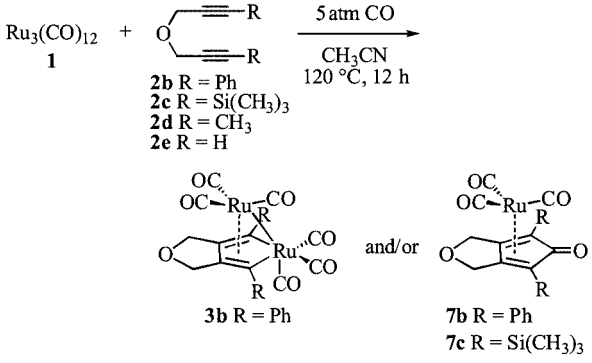


Scheme 2. Two unique structures of dinuclear ruthenabicycle complex **3a** (E = CO_2CH_3)

tively). In contrast, the reaction of **3a** with 1 equiv. of **2a** under the same conditions did not produce the mononuclear complex **4**. In this case, **3a** and **2a** were recovered in 98 and 96% yields, respectively. These facts clearly show that the use of exactly 1 equiv. of **2a** per 2 Ru atoms is essential for the selective formation of the desired dinuclear complex.

Next, diynes **2b**−**e** bearing other substituents were treated with **1** (Scheme 3). The phenyl-substituted diyne **2b** was found to be a less-efficient substrate under the reaction conditions optimized with respect to **2a**, resulting in a low conversion of **1** (Table 1, run 8). The expected dinuclear complex **3b** was obtained in 20% yield. In addition to **3b**, a small amount of new product **7b** was also obtained. In its IR spectrum, a weak absorption is observed at 1635 cm^{-1} as well as sharp and strong absorptions corresponding to the carbonyl ligands at 2086 and 2031 cm^{-1}. The former can be assigned to a conjugated ketone carbonyl group. In accordance with this assignment, a peak of the conjugated ketone carbon atom is observed at δ = 173.42 ppm in the ^{13}C NMR spectrum. The absorption of the CO ligands also appears as a single peak at δ = 193.53 ppm. On the basis of these spectroscopic data, **7b** was assigned to the cyclopentadienone complex depicted in Scheme 3.[12] This assignment was further confirmed by X-ray crystallography (Figure 2). The use of 3 equiv. of **2b** improved the conversion of **1**, while the yields of both products were only slightly increased (run 9).



Scheme 3. Reactions of [$Ru_3(CO)_{12}$] (**1**) with diynes **2b**−**e**

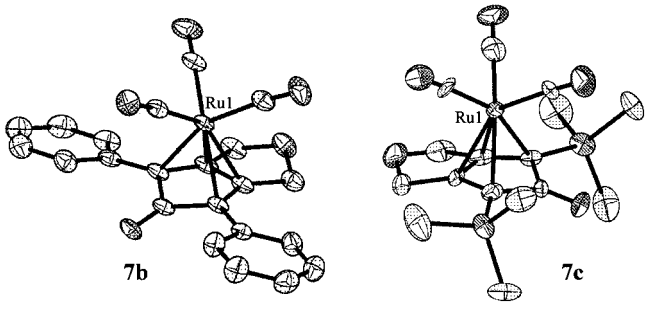


Figure 2. ORTEP diagrams of **7b** (left) and **7c** (right); all hydrogen atoms have been omitted for clarity

The reaction of the trimethylsilyl-substituted diyne **2c** with **1** gave rise to a sole product (Scheme 3). Its IR spectrum shows the presence of a conjugated carbonyl group (1623 cm^{-1}) and CO ligands (2136−2009 cm^{-1}), and the ^{13}C NMR spectral pattern is quite similar to that of **7b**, except for the upfield signal of the TMS-substituted sp^2-

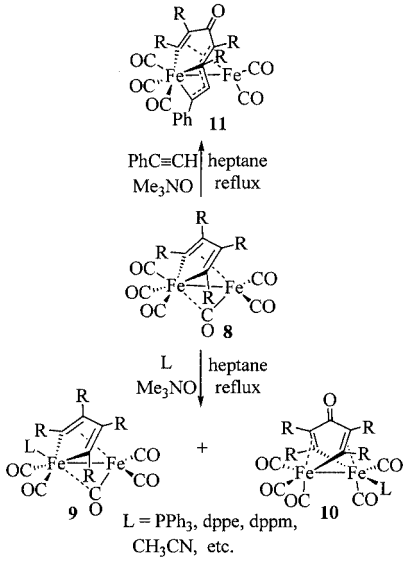
 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

carbon atoms (δ = 65.78 ppm). These spectroscopic data allowed us to assign this product as the cyclopentadienone complex **7c**. This assignment was confirmed by X-ray crystallographic analysis (Figure 2). When 1.5 equiv. of **2c** (**2c**/Ru = 1:2) was employed, **7c** was isolated in 41% yield along with 43% recovered **1** (Table 1, run 10). The increased amount of **2c** (3 equiv., **2c**/Ru atom = 1:1) raised the yield of **7c** up to 76% yield (run 11).

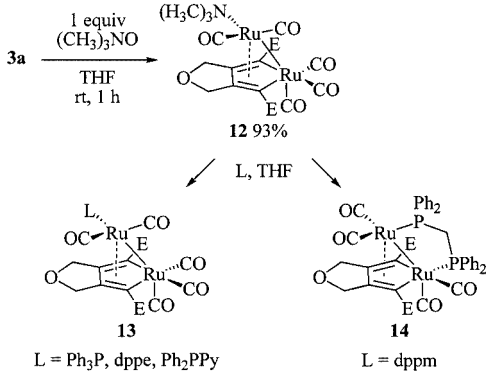
In contrast to the diynes **2a**−**c**, the diynes bearing terminal methyl substituents (**2d**) or a propargyl ether (**2e**) gave intractable product mixtures. Therefore, the electron-withdrawing methoxycarbonyl group is the optimal terminal substituent for the formation of the dinuclear ruthenacycle framework.

Ligand-Substitution Reactions of Dinuclear Ruthenabicyclic Complex 3a

Having established the high-yield synthesis of the dinuclear ruthenacycle complex **3a**, we then explored its ligand-substitution reactions. Previously, Sappa, Tiripicchio, and co-workers have reported that a ferrole complex **8** reacts with various mono- and diphosphanes or nitriles in the presence of trimethylamine *N*-oxide (Me_3NO) to afford diferracycloheptadienones **10** together with simple ligand-substitution products **9** (Scheme 4).[3o] Such "flyover-bridged" complexes can be further converted into cyclopentadienone and *p*-benzoquinone derivatives. On the other hand, the reaction with phenylacetylene under the same reaction conditions resulted in the formation of a bicyclic complex **11**, probably via a "flyover" complex similar to **10**. In these cases, the ferracyclopentadiene moiety was singly cleaved at its $C_\beta-C_\beta$ bond, and subsequent CO insertion formed the "flyover-bridged" complexes. In contrast, we anticipated that such a metallacyclic ring cleavage cannot be viable for our bicyclic ruthenium complex **3a** because the ruthenacyclopentadiene moiety is stabilized by the fused dihydrofuran ring. In fact, the treatment of **3a** with 1 equiv. of Me_3NO in THF at room temperature for 1 h afforded a trimethylamine complex **12** in 93% isolated yield (Scheme 5). Its ^1H and ^{13}C NMR spectra are very similar to those of the parent **3a** except for the additional peaks of the trimethylamine ligand. The X-ray crystallographic analysis of **12** clearly showed that the amine ligand is located on the upper ruthenium(0) center (Ru1, Figure 3). This ligand substitution regioselectivity is in contrast to that observed for the iron ferrole complex **9**, in which the newly introduced ligands are uniformly found on the metallacycle iron(II) center. The Ru−Ru and Ru−N bond lengths are 2.70775(19) and 2.2468(13) Å, respectively. One of the two CO ligands on the Ru1 center occupies the semi-bridge position. The $C_\alpha-C_\beta$ bonds are only slightly longer than the $C_\beta-C_\beta$ bond, indicative of the ruthenacycle moiety behaving as a typical η^4-butadienyl ligand.



Scheme 4. Ligand-substitution reactions of iron ferrole complex **8** (R = C_2H_5)



Scheme 5. Ligand-substitution reactions of dinuclear ruthenabicycle complex **3a** (E = CO_2CH_3)

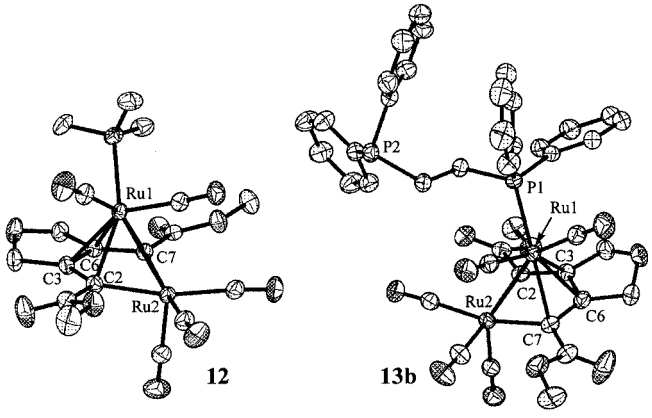


Figure 3. ORTEP diagrams of **12** (left) and **13b** (right); all hydrogen atoms have been omitted for clarity

Next, we carried out the substitutions of the amine ligand with various phosphanes, as outlined in Scheme 5 and Table 2. Upon treatment with 5 equiv. of triphenylphosphane in THF, **12** was completely consumed at room temperature after 96 h to give the expected phosphane complex **13a** (L = PPh_3) in 91% yield (run 1). Its ^1H NMR spectrum shows one singlet [δ = 3.41 (OCH_3) ppm] and a pair of doublets [δ = 3.94 and 4.65 ($-CH_2OCH_2-$) ppm] as well as the resonance of the aromatic protons (δ = 7.33−7.49

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ppm). The phosphorus resonance of **13a** is observed at lower field (δ = 41.87 ppm) than that of free PPh_3 (δ = −4.94 ppm) in the ^{31}P NMR spectrum. These facts clearly show the presence of the coordinated PPh_3 ligand in **13a**. Similarly, 1,2-bis(diphenylphosphanyl)ethane (dppe) was allowed to react with **12** at room temperature for 97 h (run 2). In the ^{31}P NMR spectrum of the obtained product both coordinated and free phosphorus peaks appear at δ = 40.77 and −11.57 ppm as doublets ($J_{P,P}$ = 42.3 Hz), indicative of dppe behaving as a two-electron donor ligand rather than a chelating one. This coordination mode was unambiguously confirmed by X-ray crystallography (Figure 3). The dppe ligand is located on the upper ruthenium center, and one of the remaining CO ligands occupies the semi-bridge position. The Ru1−P1 bond length is 2.3381(5) Å. At room temperature, the ligand exchange is slow and the yield of **13b** is moderate. In refluxing THF, however, the reaction is complete within 2 h, and the yield increases from 66% to 93% (run 3). Therefore, the amine complex **12** was subjected to the reaction with other phosphanes in refluxing THF.

Table 2. Reaction of trimethylamine complex **12** with phosphanes

Run	Phosphane (equiv.)	Conditions[a]	Product (yield [%])
1	Ph_3P (5)	room temp., 96 h	**13a** (91)
2	$Ph_2P(CH_2)_2PPh_2$ (5)	room temp., 97 h	**13b** (66)
3	$Ph_2P(CH_2)_2PPh_2$ (5)	reflux, 5 h	**13b** (88)
4	$Ph_2PCH_2PPh_2$ (5)	reflux, 2.5 h	**14** (91)
5	Ph_2PPy (5)	reflux, 2 h	**13c** (97)

[a] All reactions were carried out in THF under Ar.

Upon treatment with bis(diphenylphosphanyl)methane (dppm) under the same reaction conditions, **12** was consumed within 2.5 h (run 4). In contrast to the above complexes, the obtained product **14** turned out to have an unsymmetrical structure. In its ^1H NMR spectrum, the methoxy groups appear as two singlet peaks at δ = 3.00 and 3.82 ppm. Similarly, the dihydrofuran ring methylene groups in an unsymmetrical environment are observed as four doublets of doublets, and the methylene protons of the dppm ligand appear as a pair of doublets of doublets [δ = 4.95 ($J_{H,H}$ = 14, $J_{P,H}$ = 22.1 Hz) and 5.69 ($J_{H,H}$ = 14, $J_{P,H}$ = 26.9 Hz) ppm]. In the ^{31}P NMR spectrum, the two phosphorus atoms resonate at δ = 13.31 and 15.01 ppm ($J_{P,P}$ = 47.9 Hz). These data suggest that the dppm ligand forms an unsymmetrical ring. The structure of **14** was established by X-ray crystallography. As depicted in Figure 4, the dppm ligand bridges the two ruthenium centers to form a five-membered ring. The Ru2−P2 bond [2.3525(9) Å] is slightly longer than the Ru1−P1 bond [2.3276(8) Å]. The Ru−Ru bond of 2.7478(4) Å is slightly longer than those of **3a** [2.7156(7) Å] or **13b** [2.7208(2) Å].

As described above, the slight difference between dppe and dppm resulted in contrasting results. The former gave the monophosphane complex, whereas the latter directly formed the dppm-bridged complex with concomitant extrusion of 1 CO ligand. In this context, we further examined whether a similar dppe-bridged complex can be formed

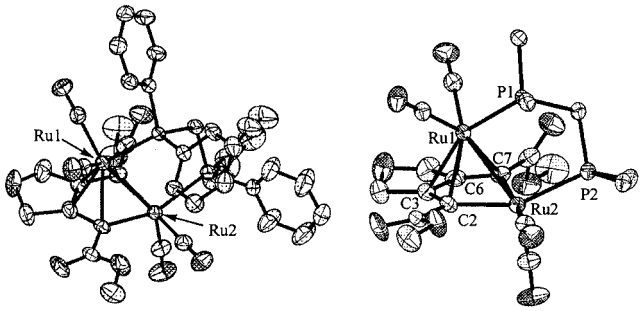

Figure 4. ORTEP diagrams of **14**; all hydrogen atoms and phenyl rings (right) have been omitted for clarity

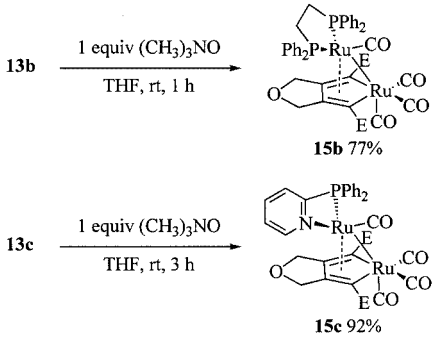
when **13b** is treated with Me_3NO. The isolated **13b** was allowed to react with 1 equiv. of Me_3NO in THF at ambient temperature for 1 h to afford a new complex **15b** (Scheme 6). Its ^{31}P NMR spectrum, however, shows only one singlet signal at δ = 68.60 ppm, indicative of the dppe ligand forming a symmetrical chelate ring. The ^1H NMR spectrum also revealed its symmetrical structure: only one methoxy signal and a pair of doublets corresponding to the methylene protons on the dihydrofuran ring are observed together with the absorptions of the benzene rings and the ethylene tether of dppe. The detailed structure of **15b** was confirmed by an X-ray crystallographic analysis (Figure 5). In contrast to **14**, both phosphorus atoms of dppe are located on the Ru1 center, and the remaining CO ligand on Ru1 occupies the semi-bridge position. The Ru−P bonds of 2.3099(16) and 2.3125(7) Å are slightly shorter than that of the parent **13b**. Consequently, the difference in the P−P distances of these two bis(phosphane) ligands alters the coordination mode from the bridge-type for dppm to the chelating one for dppe.



Scheme 6. Reactions of dinuclear ruthenabicycle phosphane complexes **13b** and **13c** with $(CH_3)_3NO$ (E = CO_2CH_3)

In addition to the above bis(phosphanes), a P-N ligand, Ph_2PPy (Py = 2-pyridyl), was also subjected to the ligand-substitution reaction with **12** (Table 3, run 5). As a result, Ph_2PPy behaved as a monophosphane ligand to give **13c** in 97% yield. In a similar manner to **15b**, a P-N chelate complex **15c** was obtained from **13c** in 92% yield (Scheme 6). The detailed structural data for these complexes were obtained by X-ray crystallography (Figure 6). The Ru−P bond is shortened from 2.3603(9) Å for **13c** to 2.3065(15)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

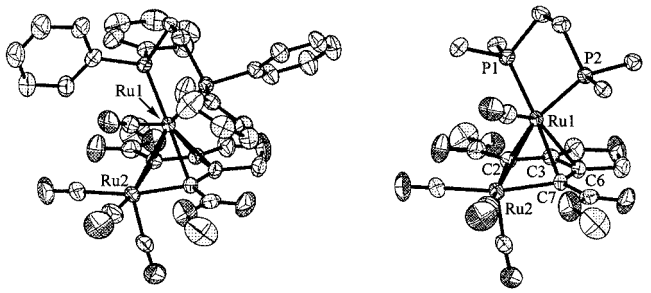


Figure 5. ORTEP diagrams of **15b**; all hydrogen atoms and phenyl rings (right) have been omitted for clarity

Å for **15c**. The Ru−Ru distance also decreases, from 2.7060(4) Å to 2.6774(6) Å, upon formation of the P-N chelate ring. The Ru1−N bond length is 2.152(5) Å.

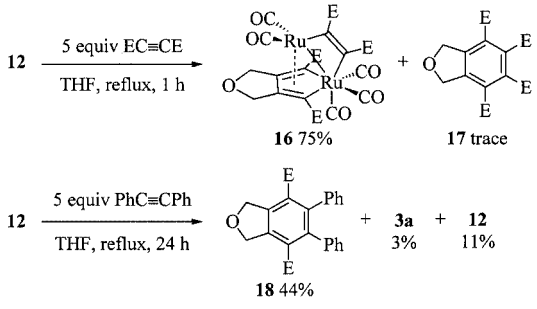
Reaction of Dinuclear (Amine)ruthenabicycle Complex 12 with Alkynes

As mentioned above, metallacyclopentadiene complexes have been investigated as intermediates in alkyne cyclotrimerizations.[1] Ferrole-type cobalt complexes have also been considered to be intermediates for $[Co_2(CO)_6]$-mediated alkyne cyclotrimerizations.[5f] In this respect, dicobalt complexes bearing a "flyover" hexatrienyl ligand have been obtained from the reaction of (cobaltacyclopentadiene)cobalt complexes with alkynes.[13] In addition, the reaction of a dinuclear cobaltacyclopentadiene complex derived from an amine-tethered diyne with phenylacetylene has been reported to give a fused benzene in high yield.[9a] With these facts in mind, we finally explored the reactivity of the amine complex **12** toward monoalkynes. At the outset, **12** was treated with 5 equiv. of dimethyl acetylenedicarboxylate (DMAD) in refluxing THF for 1 h (Scheme 7). As a result, a new ruthenacycle complex **16** was obtained together with trace amounts of the [2+2+2] cycloadduct **17** between the diyne **2a** and DMAD.[10c][10d] The ^{1}H NMR analysis of **16** disclosed that the complex consists of the symmetrical ruthenacycle moiety and the unsymmetrically coordinated DMAD fragment. The methoxy and methylene protons of the ruthenacycle appear as one singlet (δ = 3.68 ppm) and two doublet peaks [δ = 4.84 and 5.06 ($J_{H,H}$ = 14.7 Hz) ppm], respectively, whereas the methoxy protons of DMAD resonate at δ = 3.84 and 3.89 ppm. Similarly, the ^{13}C NMR spectrum shows 3 and 4 sp^2-carbon signals for the ruthenacycle (δ = 169.81, 155.07, and 147.95 ppm) and the DMAD ligand (δ = 171.58, 165.96, 127.31, and 88.77 ppm), respectively. The structure of **16** was finally determined by X-ray crystallography (Figure 7). The unit cell contains two crystallographically unique molecules **16(A)** and **16(B)**. DMAD bridges two ruthenium centers in a "parallel" μ-η^2 fashion. The μ-alkyne bond lengths are 1.337(12) and 1.294(12) Å, and the Ru−C_{alkyne} bond lengths range from 2.028(8) to 2.224(9) Å. These bond lengths are similar to those of previously reported (μ-alkyne)diruthenium complexes.[14] The Ru−Ru distances of 2.7289(7) Å and 2.7293(7) Å, similar to those of the above dinuclear ruthenacycle complexes [2.7039(7)−2.7478(4) Å], show the existence of a metal−metal bond. The lengths of the Ru−C_{alkyne} bonds as well as the Ru2−C2 or the Ru2−C7 bonds [2.082(8)−2.191(8) Å] are very similar to those of typical Ru−sp^2-C single bonds.[11] Thus, the formal oxidation state of the Ru1 and Ru2 centers can be regarded as +1 and +3, respectively. According to this analysis, we can conclude that the dinuclear (μ-alkyne)ruthenabicycle complex **16** is formed by a dinuclear oxidative addition of DMAD onto the ferrole-type dinuclear framework of **12**.



Scheme 7. Reactions of dinuclear (trimethylamine)ruthenacycle complex **12** with DMAD and diphenylacetylene (E = CO_2CH_3)

The novel (μ-alkyne)ruthenacycle complex **16** seemed to be an intermediate for the formation of **17**. Indeed, upon heating **16** in refluxing THF for 24 h, compound **17** was obtained in 11% yield, although 50% of starting **16** was recovered intact. A small amount of the hexacarbonyl complex **3a** was also detected (5%). The highly electron-de-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

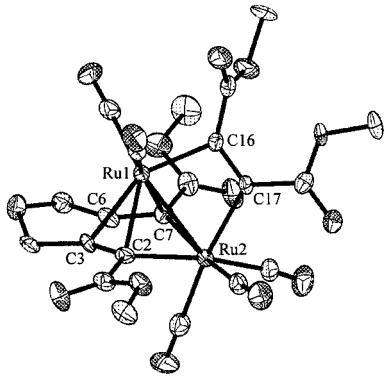


Figure 7. ORTEP diagrams of **16**, showing one of two crystallographically unique molecules in the unit cell; all hydrogen atoms have been omitted for clarity

ficient DMAD is essential for the formation of a μ-alkyne complex such as **16**. The reaction with electronically neutral diphenylacetylene afforded a coupling adduct **18** in 44% yield as well as the recovered **12** and trace amounts of **3a** (Scheme 7). Methyl propiolate never gave the corresponding complex because of its self-cyclotrimerization leading to 1,2,4- and 1,3,5-tris(methoxycarbonyl)benzenes. In contrast to our previous catalytic systems involving mononuclear ruthenacyclic intermediates,[8] the present dinuclear complex is less effective for the [2+2+2] cycloaddition due to the stabilization of the ruthenacycle moiety by coordination to the additional ruthenium center.

Conclusion

In conclusion, the diyne diester **2a** proved to be a suitable precursor for the synthesis of the dinuclear ruthenacyclic complex **3a**. The ratio of **2a**/Ru turned out to be critical as an excess of **2a** decreased the yield of **3a** because of the concomitant formation of the mononuclear ruthenacycle complex **4**, which is the precursor of **3a**. On the other hand, the diphenyldiyne **2b** gave the cyclopentadienone complex **7b** together with the desired ruthenacycle complex **3b**, and the disilyldiyne **2c** exclusively afforded the cyclopentadienone complex **7c** in good yield.

The treatment of the ruthenacycle complex **3a** with Me_3NO gave the mono(trimethylamine) complex **12**, which was further converted into various phosphane complexes upon reaction with phosphanes in refluxing THF. Among the bidentate phosphane ligands used, only dppm afforded the bridging diphosphane complex **14** directly. In contrast, the initially formed monodentate phosphane complexes of dppe and $PyPPh_2$ were treated with Me_3NO to give the P-P and P-N chelate complexes **15b** and **15c**, respectively.

The reaction of **12** with DMAD gave the novel μ-η^2-alkyne complex **16** together with the [2+2+2] cycloadduct **17**. The highly electron-deficient character of DMAD is imperative for the formation of the μ-alkyne complex; methyl propiolate and diphenylacetylene gave no corresponding μ-alkyne complexes.

Experimental Section

General Remarks: Flash chromatography was performed with a silica gel column (Merck Silica gel 60) eluting with a mixture of solvents (hexane/EtOAc). ^1H and ^{13}C NMR spectra were obtained for samples in $CDCl_3$ solution at 25 °C with a Varian Mercury 300 spectrometer. ^1H NMR chemical shifts are reported in δ units, in ppm relative to the singlet at $\delta = 7.26$ ppm for chloroform. ^{13}C and ^{31}P NMR spectra were fully decoupled and are reported in terms of chemical shift (δ, ppm) relative to the triplet at δ = 77.0 ppm for $CDCl_3$ or H_4PO_4 (85% in H_2O) as external standard, respectively. Coupling constants are reported in Hz. Infrared spectra were recorded for $CHCl_3$ sample solutions in 0.2-mm path-length sodium chloride cavity cells with a JASCO FT/IR-230 spectrometer. Elemental analyses were performed by the Microanalytical Center of Kyoto University. Melting points were obtained in capillary tubes and are uncorrected. Toluene and acetonitrile were dried with CaH_2 and distilled. THF was dried with benzophenone ketyl, and distilled.

Typical Procedure for the Reaction of $[Ru_3(CO)_{12}]$ with Diynes. Synthesis of Dinuclear Ruthenacycle Complex 3a from $[Ru_3(CO)_{12}]$ and Diyne 2a: A glass tube (28 mm o.d.) fitted with a stirring bar was charged with $[Ru_3(CO)_{12}]$ (128.0 mg, 0.20 mmol) and acetonitrile (2 mL) and saturated with CO. The tube was placed in a 100-mL stainless steel autoclave. The reactor was pressurized by CO to 5 atm. The contents were stirred at ambient temperature for 10 min, and then the pressurized CO was purged under a hood. A solution of diyne **2a** (63.4 mg, 0.30 mmol) in acetonitrile (3 mL) was added to this tube with a syringe, at ambient temperature. The reactor was pressurized again with CO to 5 atm. The contents were stirred at 120 °C for 12 h, and cooled to ambient temperature. After purging the excess CO under a fume hood, the reaction mixture was concentrated in vacuo. The residue was chromatographed on silica gel using hexane/EtOAc (10:1) as an eluent to give **3a** (151.1 mg, 87%) as a yellow solid: M.p. 110.0−111.0 °C. IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2096, 2068, 2062, 2029, 2011, 1689 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 3.68$ (s, 6 H), 4.80 (dd, $J_{H,H} = 15.3$, 2.4 Hz, 2 H), 5.08 (dd, $J_{H,H} = 15.3$, 2.4 Hz, 2 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): $\delta = 52.28$, 70.31, 127.62, 137.23, 172.38, 192.21, 193.60, 194.37 ppm. $C_{16}H_{10}O_{11}Ru_2$ (580.38): calcd. C 33.11, H 1.74; found C 33.11, H 1.91. Other reactions of $Ru_3(CO)_{12}$ with diynes **2a**−**c** were carried out in a similar way under the conditions summarized in Tables 1 and 2.

Mononuclear Ruthenacycle Complex 4: M.p. 128.5−130.0 °C. IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2145, 2073, 1676 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 3.75$ (s, 6 H), 4.65 (s, 4 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): $\delta = 51.98$, 70.62, 133.66, 171.08, 177.11, 186.32, 189.82 ppm. $C_{14}H_{10}O_9Ru$ (423.29): calcd. C 39.72, H 2.38; found C 39.69, H 2.48.

Dinuclear Ruthenacycle Complex 3b: M.p. 158.0−158.5 °C. IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2081, 2052, 2010 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 4.43$ (dd, $J_{H,H} = 13.8$, 1.8 Hz, 2 H), 5.15 (dd, $J_{H,H} = 13.8$, 1.8 Hz, 2 H), 7.00−7.04 (m, 4 H), 7.11−7.17 (m, 2 H), 7.21−7.27 (m, 4 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): $\delta = 69.50$, 126.57, 127.03, 128.13, 135.91, 147.15, 154.41, 193.49, 195.99, 198.52 ppm. $C_{24}H_{14}O_7Ru_2$ (616.50): calcd. C 46.76, H 2.29; found C 46.80, H 2.48.

Cyclopentadienone Complex 7b: M.p. 200 °C (decomp). IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2086, 2031, 1635 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 5.11$ (dd, $J_{H,H} = 13.5$, 2.4 Hz, 2 H), 5.27 (dd, $J_{H,H} = 13.5$, 2.4 Hz, 2 H), 7.26−7.32 (m, 2 H), 7.35−7.41 (m, 4 H),

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

7.80−7.85 (m, 4 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 68.77, 75.26, 103.37, 126.96, 127.63, 128.76, 132.17, 173.42, 193.53 ppm. $C_{22}H_{14}O_5Ru$ (459.41): calcd. C 57.52, H 3.07; found C 57.37, H 3.35.

Cyclopentadienone Complex 7c: M.p. 143.5−144.5 °C. IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2136, 2084, 2064, 2028, 2009, 1623 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.25 (s, 18 H), 4.77 (s, 4 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = −0.29, 65.78, 68.14, 114.07, 185.48, 193.67 ppm. $C_{16}H_{22}O_5RuSi_2$ (451.58): calcd. C 42.55, H 4.91; found C 42.39, H 4.83.

Synthesis of Trimethylamine Complex 12: $Me_3NO/2H_2O$ (24.6 mg, 0.22 mmol) was added to a degassed solution of **3a** (120.6 mg, 0.21 mmol) in THF (10 mL), and the reaction mixture was stirred for 1 h at ambient temperature under Ar. The solvent was removed in vacuo, and the residue was chromatographed on silica gel using hexane/EtOAc (2:1) as eluent to give **12** (117.8 mg, 93%) as a dark-red solid. M.p. 120 °C (decomp). IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2077, 2006, 1952, 1682 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 2.69 (s, 9 H), 3.60 (s, 6 H), 4.76 (dd, $J_{H,H}$ = 15.9, 2.7 Hz, 2 H), 5.09 (dd, $J_{H,H}$ = 15.9, 2.7 Hz, 2 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 51.62, 59.78, 70.43, 120.84, 137.03, 174.69, 194.33, 195.62, 201.48 ppm. $C_{18}H_{19}NO_{10}Ru_2$ (611.48): calcd. C 35.36, H 3.13, N 2.29; found C 35.28, H 3.10, N 2.24.

Typical Procedure for the Reaction of 12 with Phosphanes: Synthesis of dppe Complex 13b from 12: A degassed solution of **12** (122.4 mg, 0.20 mmol) and dppe (398.6 mg, 1.0 mmol) in THF (10 mL) was refluxed under N_2 for 5 h. The reaction mixture was concentrated in vacuo, and the residue was chromatographed on silica gel using hexane/EtOAc (8:1−4:1) as eluent to give **13b** (166.9 mg, 93%) as a yellow solid. M.p. 143.5−144.0 °C. IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2077, 2008, 1683 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.92−2.04 (br. m, 2 H), 2.32−2.46 (br. m, 2 H), 3.47 (s, 6 H), 3.98 (d, $J_{H,H}$ = 13.2 Hz, 2 H), 4.67 (d, $J_{H,H}$ = 13.2 Hz, 2 H), 7.18−7.48 (m, 20 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 22.13 (d, $J_{P,C}$ = 15.9 Hz), 28.03 (d, $J_{P,C}$ = 19.4 Hz), 51.73, 69.19, 128.39−128.74 (m), 130.68 (d, $J_{P,C}$ = 2.3 Hz), 131.54, 132.10 (d, $J_{P,C}$ = 10.2 Hz), 132.35 (d, $J_{P,C}$ = 18.2 Hz), 134.71, 136.99 (d, $J_{P,C}$ = 12 Hz), 173.14, 194.67, 195.36, 201.40 (d, $J_{P,C}$ = 13.1 Hz) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 25 °C): δ = −11.57 (d, $J_{P,P}$ = 42.3 Hz), 40.77 (d, $J_{P,P}$ = 42.3 Hz) ppm. $C_{41}H_{34}O_{10}P_2Ru_2$ (950.79): calcd. C 51.79, H 3.60; found C 51.91, H 3.50. The reactions of **12** with other phosphanes were carried out in a similar way under the conditions summarized in Table 3.

Complex 13a: M.p. 171.0−172.0 °C. IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2077, 2013, 1989, 1961, 1683 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.41 (s, 6 H), 3.94 (d, $J_{H,H}$ = 13.4 Hz, 2 H), 4.65 (d, $J_{H,H}$ = 13.4 Hz, 2 H), 7.33−7.49 (m, 15 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 51.62, 69.18, 127.85 (d, $J_{P,C}$ = 6.8 Hz), 128.39 (d, $J_{P,C}$ = 10.3 Hz), 130.64 (d, $J_{P,C}$ = 2.3 Hz), 132.26, 132.91, 133.07 (d, $J_{P,C}$ = 11.4 Hz), 135.56, 173.21, 194.70, 195.45, 200.95 (d, $J_{P,C}$ = 13.7 Hz) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 25 °C): δ = 41.87 ppm. $C_{33}H_{25}O_{10}PRu_2$ (814.66): calcd. C 48.65, H 3.09; found C 48.61, H 3.16.

Complex 13c: M.p. 153.5−154.0 °C. IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2075, 2014, 1987, 1682 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.41 (s, 6 H), 4.06 (d, $J_{H,H}$ = 12.9 Hz, 2 H), 4.71 (dd, $J_{H,H}$ = 12.9, 1.5 Hz, 2 H), 7.20−7.30 (m, 2 H), 7.40−7.52 (m, 10 H), 7.63 (ddt, $J_{H,H}$ = 7.8, 3.6, 2.1 Hz, 1 H), 8.77−8.81 (m, 1 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 51.55, 69.34, 123.91 (d, $J_{P,C}$ = 2.3 Hz), 126.85 (d, $J_{P,C}$ = 18.8 Hz), 128.38 (d, $J_{P,C}$ = 10.3 Hz), 130.71, 130.81 (d, $J_{P,C}$ = 2.9 Hz), 131.32, 133.62 (d, $J_{P,C}$ = 11.4 Hz), 134.57, 135.56 (d, $J_{P,C}$ = 6.8 Hz), 150.24 (d, $J_{P,C}$ = 18.2 Hz), 158.41, 159.42, 173.36, 195.07, 195.80, 200.18 (d, $J_{P,C}$ = 13.7 Hz) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 25 °C): δ = 46.12 ppm. $C_{32}H_{24}NO_{10}PRu_2$ (815.65): calcd. C 47.12, H 2.97, N 1.72; found C 46.99, H 3.13, N 1.69.

Complex 14: M.p. 235 °C (decomp). IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2032, 2010, 1977, 1941, 1682 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.00 (s, 3 H), 3.82 (s, 3 H), 4.39 (d, $J_{H,H}$ = 13.2 Hz, 1 H), 4.69 (d, $J_{H,H}$ = 12.6 Hz, 1 H), 4.95 (dd, $J_{P,H}$ = 22.1, $J_{H,H}$ = 14 Hz, 1 H), 4.95 (d, $J_{H,H}$ = 13.2 Hz, 1 H), 5.18 (dd, $J_{H,H}$ = 12.6, 3.9 Hz, 1 H), 5.69 (dd, $J_{P,H}$ = 26.9, $J_{H,H}$ = 14 Hz, 1 H), 6.72−6.78 (m, 2 H), 6.95−7.11 (m, 3 H), 7.32−7.67 (m, 13 H), 7.94−8.02 (m, 2 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 48.41 (dd, $J_{P,C}$ = 29, 18.2 Hz), 51.18, 51.66, 69.11, 71.07, 114.52 (dd, $J_{P,C}$ = 14.3, 5.2 Hz), 119.73 (d, $J_{P,C}$ = 5.7 Hz), 127.70−129.83 (m), 131.47 (d, $J_{P,C}$ = 2.3 Hz), 132.06 (d, $J_{P,C}$ = 13.1 Hz), 135.47−136.16 (m), 136.88, 137.22−137.45 (m), 140.89, 141.63, 143.39 (d, $J_{P,C}$ = 14.8 Hz), 143.99 (d, $J_{P,C}$ = 14.8 Hz), 174.80, 176.47, 176.52, 195.77 (d, $J_{P,C}$ = 9.7 Hz), 199.10 (d, $J_{P,C}$ = 12.5 Hz), 200.32 (d, $J_{P,C}$ = 9.1 Hz), 201.75 (dd, $J_{P,C}$ = 10.8, 9.1 Hz) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 25 °C): δ = 13.31 (d, $J_{P,P}$ = 47.9 Hz), 15.01 (d, $J_{P,P}$ = 47.9 Hz) ppm. $C_{39}H_{32}O_9P_2Ru_2$ (908.75): calcd. C 51.55, H 3.55; found C 51.27, H 3.62.

Typical Procedure for Reaction of Phosphane Complexes 13b,c with Me_3NO. Synthesis of dppe Chelate Complex 15b: $Me_3NO/2H_2O$ (12.4 mg, 0.11 mmol) was added to a degassed solution of **13b** (95.0 mg, 0.10 mmol) in THF (25 mL) and the reaction mixture was stirred at ambient temperature under Ar for 1 h. The solvent was removed in vacuo, and the residue was chromatographed on silica gel using hexane/EtOAc (2.5:1−1:1) as eluent to give **15b** (71.0 mg, 77%) as a yellow solid. M.p. 190 °C (decomp). IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2063, 1996, 1975, 1929, 1673 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 2.40−2.65 (m, 4 H), 3.18 (s, 6 H), 3.47 (d, $J_{H,H}$ = 12.6 Hz, 2 H), 4.43 (dd, $J_{H,H}$ = 12.6, 2.4 Hz, 2 H), 7.19−7.26 (m, 4 H), 7.38−7.48 (m, 12 H), 7.64−7.72 (m, 4 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 30.68 (dd, $J_{P,C}$ = 23.3, 22.2 Hz), 50.83, 68.75, 124.38 (t, $J_{P,C}$ = 8.5 Hz), 128.15 (t, $J_{P,C}$ = 6.8 Hz), 128.21 (t, $J_{P,C}$ = 6.8 Hz), 130.20, 130.52, 131.81 (t, $J_{P,C}$ = 5.7 Hz), 132.77 (d, $J_{P,C}$ = 3.5 Hz), 133.40 (t, $J_{P,C}$ = 5.1 Hz), 133.65, 133.95, 174.70, 196.34, 197.30, 203.98 (t, $J_{P,C}$ = 13.7 Hz) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 25 °C): δ = 68.60 ppm. $C_{40}H_{34}O_9P_2Ru_2$ (922.78): calcd. C 52.06, H 3.71; found C 51.96, H 3.71.

Complex 15c: M.p. 175.0−176.0 °C. IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2063, 1994, 1971, 1923, 1670 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.21 (dt, $J_{H,H}$ = 12.5, 1.8 Hz, 1 H), 3.32 (s, 3 H), 3.69 (s, 3 H), 4.33 (dd, $J_{H,H}$ = 13.5, 2.1 Hz, 1 H), 4.51 (ddt, $J_{H,H}$ = 12.5, 3.6, 1.8 Hz, 1 H), 4.84 (dt, $J_{H,H}$ = 13.5, 1.8 Hz, 1 H), 6.94−7.02 (m, 2 H), 7.32−7.47 (m, 5 H), 7.55−7.61 (m, 3 H), 7.82−7.93 (m, 3 H), 8.04 (dd, $J_{H,H}$ = 5.4, 0.8 Hz, 1 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 50.72, 51.56, 68.18, 70.13, 113.83 (d, $J_{P,C}$ = 19.9 Hz), 118.81 (d, $J_{P,C}$ = 3.4 Hz), 126.51 (d, $J_{P,C}$ = 2.3 Hz), 127.14, 127.99 (d, $J_{P,C}$ = 2.9 Hz), 128.34, 128.75 (d, $J_{P,C}$ = 10.8 Hz), 128.91, 129.07 (d, $J_{P,C}$ = 10.8 Hz), 129.21, 130.71 (d, $J_{P,C}$ = 2.3 Hz), 131.21 (d, $J_{P,C}$ = 11.3 Hz), 132.03 (d, $J_{P,C}$ = 2.3 Hz), 134.40 (d, $J_{P,C}$ = 13.1 Hz), 134.66, 137.26 (d, $J_{P,C}$ = 3.5 Hz), 152.19 (d, $J_{P,C}$ = 15.4 Hz), 172.40, 173.10, 177.13 (d, $J_{P,C}$ = 2.3 Hz), 177.39, 195.91, 197.08, 197.52, 205.02 (d, $J_{P,C}$ = 12.5 Hz) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 25 °C): δ = −2.60 ppm. $C_{31}H_{24}NO_9PRu_2$ (787.64): calcd. C 47.27, H 3.07, N 1.78; found C 47.19, H 3.23, N 1.70.

Typical Procedure for the Reaction of 12 with Alkynes. Synthesis of DMAD Complex 16: A degassed solution of **12** (122.8 mg, 0.20 mmol) and DMAD (145.1 mg, 1.0 mmol) in THF (10 mL) was refluxed under N_2 for 1 h. The reaction mixture was concentrated in vacuo, and the residue was chromatographed on silica gel using hexane/EtOAc (8:1) as eluent to give **16** (104.7 mg, 75%) as a yellow solid. M.p. 119.0−120.0 °C. IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 2113, 2056, 2009, 1704 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.68 (s, 6 H), 3.84 (s, 3 H), 3.89 (s, 3 H), 4.84 (d, $J_{H,H}$ = 14.7 Hz, 2 H), 5.06 (d, $J_{H,H}$ = 14.7 Hz, 2 H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 52.73, 53.19, 71.64, 88.77, 127.31, 147.95, 155.07, 165.96, 169.81, 171.58, 187.87, 188.83, 194.10 ppm. $C_{21}H_{16}O_{14}Ru_2$ (694.48): calcd. C 36.32, H 2.32; found C 36.17, H 2.32. The reactions of **12** with other alkyes were carried out in a similar way.

Cycloadduct 18: M.p. 150.0−151.0 °C. IR ($CHCl_3$, 25 °C): $\tilde{\nu}$ = 1723 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.49 (s, 6 H), 5.31 (s, 4 H), 6.90−6.96 (m, 4 H), 7.09−7.13 (m, 6 H). ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 52.01, 73.80, 126.65, 127.16, 128.28, 129.61, 138.39, 139.29, 141.07, 167.33 ppm. MS (EI): *m/z* (%) =

388 (100) [M^+], 373 (28) [$M^+ - CH_3$], 356 (82) [$M^+ - HOCH_3$]. $C_{24}H_{20}O_5$ (388.41): calcd. C 74.21, H 5.19; found C 73.97, H 5.43.

X-ray Crystallographic Determination: Single crystals suitable for X-ray analysis were obtained by recrystallization from hexane at −15 °C (**3a**), CH_2Cl_2/hexane at room temp. (**4**), EtOAc/hexane at room temp. (**7b**), EtOAc/hexane at −15 °C (**7c**), CH_2Cl_2/diethyl ether at −15 °C (**12**), diethyl ether/hexane at room temp. (**13b**), diethyl ether/hexane at room temp. (**13c**), $CHCl_3$/hexane at room temp. (**14**), CH_2Cl_2/hexane at room temp. (**15b**), CH_2Cl_2/diethyl ether at room temp. (**15c**), or CH_2Cl_2/hexane at 0 °C (**16**). Each crystal was mounted on a quartz fiber, and diffraction data were collected in θ ranges specified in Tables 4 and 5 at 173 K with a Bruker SMART APEX CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). An absorption correction was applied using SADABS. The structure was solved by direct methods and refined by full-matrix least squares on F^2 with SHELXTL.[15] All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were placed in calculated positions. Final refinement details are compiled in Tables 4 and 5. CCDC-227166 (**3a**), -227167 (**4**), -227168 (**7b**), -227169 (**7c**), -227170 (**12**), -227171 (**13b**), -227172 (**13c**), -227173 (**14**), -227174 (**15b**), -227175 (**15c**), and -227176 (**16**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Rational Design of Metal-Organic Frameworks Based on 5-(4-Pyridyl)tetrazolate: From 2D Grids to 3D Porous Networks

Chao Jiang,[a] Zhaopeng Yu,[a] Sujing Wang,[a] Chao Jiao,[a] Jiaming Li,[a] Zhiyong Wang,*[a] and Yong Cui*[a]

Keywords: Coordination polymers / Fluorescence / Hydrothermal synthesis / N ligands / Self-assembly

The hydrothermal reactions of $Zn(ClO_4)_2·6H_2O$/$Cu(NO_3)_2·6H_2O$ with 5-(4-pyridyl)tetrazole in an ethanol/water or ethanol/water/pyridine medium yield one 2D and one 3D metal-organic coordination framework $[Zn_2(OH)(4\text{-ptz})_3]$ (**1**) and [Cu(4-ptz)·0.5(py)] (**3**) [4-ptz = 5-(4-pyridyl)-tetrazolate, py = pyridine], respectively. Complex **1** possesses two identical and independent rectangular grid sheets with twofold parallel interpenetration, in which the four-connected nodes of the net are provided by $Zn_2(OH)$ units connected to one another through 4-ptz and $(4\text{-ptz})_2$ bridges. These composite sheets are stacked one on top of another by hydrogen-bonding interactions to afford a 3D structure. There are many structural similarities between complex **1** and the recently reported 2D layered network [Zn(OH)(4-ptz)(H_2O)] (**2**), in particular the components of the network, the coordination mode of the 4-ptz ligand and the in situ formation of hydroxy groups. Complex **2** can be synthesized by the hydrothermal reaction of $Zn(ClO_4)_2·6H_2O$ and 5-(4-pyridyl)tetrazole in an ethanol/water/pyridine medium. The structural characterization of complex **3** shows a porous structure that contains the guest pyridine molecules. Additionally, compounds **1** and **2** exhibit strong fluorescence at room temperature in the solid state.

Introduction

The study of coordination frameworks has received increasing attention over recent years with a growing range of structural motifs being discovered. As far as is known, the functions of materials come from their structural features.[1] Many functional materials can be prepared by supramolecular self-assembly because the required structural variety and thermal stability can be obtained. For instance, the combination of organic spacers and transition-metal centers in coordination frameworks can affect the assembly of supramolecules, giving new types of electroluminescent materials, which have potential applications as light-emitting diodes (LEDs).[2] Also, a variety of NLO materials have been obtained by noncentrosymmetric organization of molecular building blocks,[3] while magnetic compounds have been synthesized by supramolecular chemistry dealing with open-shell units.[4] Therefore, the discovery of methods to control the assembly and solid-state structures in three dimensions has become one of the main challenges in crystal engineering. Many of these studies have heightened the awareness of the influence of the metal ion and ligand,[5] as well as the anion[6] and the solvent[7] on self-assembly. Recently, many chemists have focused on the control exerted by organic ligands on the supramolecular structure. Among them, N-donor bridging ligands,[1] in particular those with pyridyl[8] and nitrile[9] donor groups, have been used to construct coordination frameworks showing novel structural features. Due to the aromaticity and multiple N-donor atoms, tetrazolate is also an excellent donor group with potential applications in the construction of coordination frameworks.[10] Recently, three coordination frameworks, $[Zn_2(OH)(4\text{-ptz})_3]$ (**1**), [Zn(OH)(4-ptz)(H_2O)] (**2**), and [Cu(4-ptz)0.5(py)] (**3**), were prepared in our laboratory with 5-(4-pyridyl)tetrazolate (4-ptz) ligands. The present report is concerned with the syntheses, crystal structures and luminescent properties of these compounds.

Results and Discussion

Complex **1** was prepared by treating $Zn(ClO_4)_2·6H_2O$ with 5-(4-pyridyl)tetrazole in ethanol and water under hydrothermal conditions (Scheme 1). Addition of pyridine to the reaction solutions gave complex **2** under the same conditions as for complex **1**. The proportion of hydroxy groups in complex **2** is higher than that in complex **1**; they are presumably formed from water in situ. Complex **3** was prepared by the same method as complex **2** (Scheme 1), except that $Cu(NO_3)_2·6H_2O$ was used instead of $Zn(ClO_4)_2·6H_2O$; the Cu^+ ions are likely formed by the re-

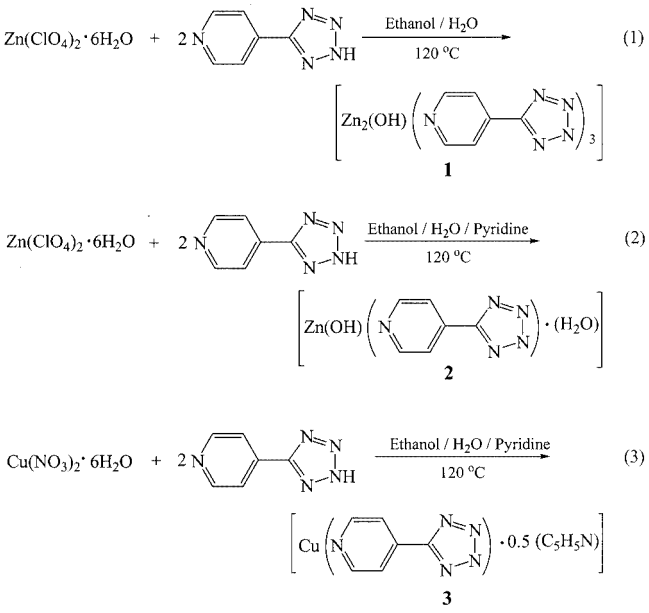
duction of Cu^{2+} by ethanol in situ.[11] The observed tetrazolate stretching frequencies (1624 and 1435 cm^{-1} in **1** and 1627 and 1439 cm^{-1} in **2** and 1616 and 1442 cm^{-1} in **3**) in the IR spectra of these compounds are consistent with those of other tetrazolate-based assemblies reported previously.[10]



Scheme 1

Structural Description

$[Zn_2(OH)(4\text{-ptz})_3]$ (1) and $[Zn(OH)(4\text{-ptz})(H_2O)]$ (2)

The asymmetric unit of complex **1** comprises two Zn atoms, three 4-ptz ligands and a hydroxy group (Figure 1). Two crystallographically distinct zinc centers, Zn1 and Zn2, are linked by one hydroxy group with a Zn−O−Zn angle of 120.4(2)° [123.18(14)° in complex **2**]. Each doubly bridging 4-ptz ligand coordinates through the two nitrogen atoms of the tetrazolate and the pyridine moiety. Each zinc center is in a tetrahedral environment surrounded by one hydroxy group and three different 4-ptz ligands (in complex **2**, the zinc center is surrounded by two hydroxy groups and two different 4-ptz ligands) with the difference being that the Zn1 center is coordinated to two tetrazolate nitrogen atoms and one pyridine nitrogen atom, while the Zn2 center is coordinated to two pyridine nitrogen atoms and one tetrazolate nitrogen atom. The N−Zn−N(O) angles vary from 101.9(2) to 109.2(2)° [104.09(12) to 110.46(12)° in complex **2**], while O1−Zn1−N7 [127.0(2)°] and O1−Zn2−N10 [120.7(2)°] are much larger [O−Zn−O of 120.47(13)° in complex **2**]. All donor atoms form reasonably strong bonds with the zinc atom: the Zn−N bond lengths range from 1.991(5) to 2.048(6) Å [2.021(3) and 2.079(4) Å in complex **2**], and the Zn−O bond lengths of Zn1 and Zn2 are 1.902(4) and 1.908(5) Å, respectively [1.922(3) and 1.936(3) Å in complex **2**].

The structure of complex **1** consists of two identical and independent rectangular grid sheets, interpenetrating parallelly in the manner shown in Figures 2 and 3. This mode of interpenetration is topologically equivalent to that in [Cu(tcm)(bipy)], as can be appreciated from its topological essence.[12] The four-connected nodes of the net are provided by $Zn_2(OH)$ units, which are connected to one another through 4-ptz and $(4\text{-ptz})_2$ bridges, with grid lengths of 13.1 and 11.5 Å, respectively, and a grid angle of 91°. Individual sheets are corrugated so as to allow this interweaving. There are π−π interactions between the pyridyl or tetrazolate groups from two independent interpenetrat-

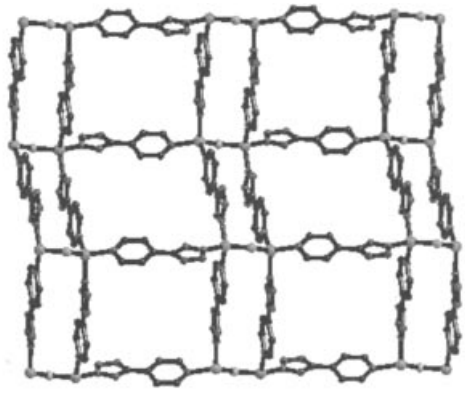

Figure 2. 2D rectangular grid net in **1**

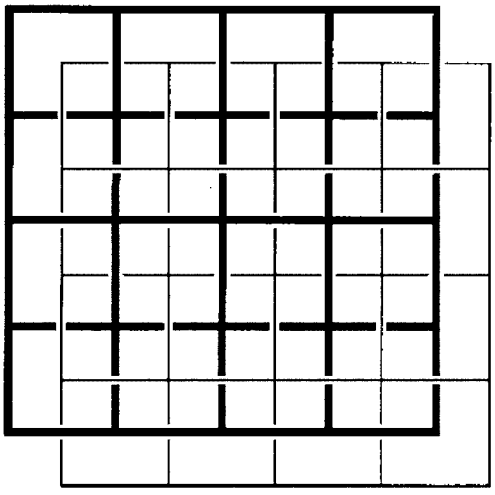

Figure 3. Schematic representation of the mode of interpenetration of two parallel rectangular grid nets; the four-connected nodes shown represent the centers of the $Zn_2(OH)$ aggregates

ing nets, which can be regarded as a stabilizing factor for the interpenetration. The composite structure resulting from this form of interpenetration is itself two-dimensional, and these composite sheets are stacked one on top of another by hydrogen-bonding interactions [O1···N3 (at $-x$, $-y$, $-z + 1$), 2.843 Å] forming a 3D structure (Figure 4).

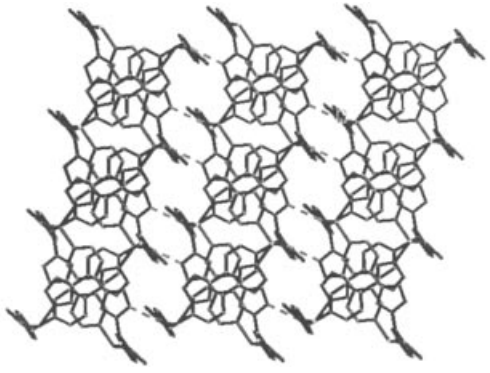

Figure 4. Three layers of the internally interwoven double sheets viewed approximately "edge-on"; the dashed lines represent the hydrogen bonding between layers in **1**

Comparing the structure of complex **1** with the recently reported 2D layered network [Zn(OH)(4-ptz)(H_2O)] (**2**),[10c] we can find many structural similarities involving the components of the network, the coordination mode of the 4-ptz ligand and in situ formation of the hydroxy groups. Complexes **1** and **2** differ mainly in their metal/ligand proportion, the presence of intercalated water molecules, and the topology and connectivity of their 2D coordination networks.[13] Comparing the 2D networks in complexes **1** and **2**, half of the hydroxy groups in complex **2** are replaced by 4-ptz ligands for complex **1**, which makes the grid sheets in complex **1** have bigger grid windows than in complex **2**. Thus, in complex **1** the grid sheets can undergo a twofold parallel interpenetration (see Supporting Information). The structural features exhibited by complexes **1** and **2** imply that the different pH values of the reaction solutions leads to different coordination environments of the metal ion and thus affects the self-assembly progress, resulting in a variety of coordination frameworks.

[Cu(4-ptz)·0.5(py)] (3)

The asymmetric unit of complex **3** comprises one Cu atom, one 4-ptz ligand and half a pyridine molecule (Figure 5). Each Cu atom coordinates to three tetrazolate nitrogen atoms and to one pyridyl nitrogen atom of four different 4-ptz ligands. Each Cu center adopts a highly distorted tetrahedral geometry. The bond angles vary from 90.41(14) to 123.57(14)°; this large range of bond angles is due to the large bulk of the tetrazolate and pyridyl groups compared with the radius of Cu^+. As such, each 4-ptz ligand is coordinated to four Cu atoms through the 1-, 2-, and 4-nitrogen atoms of tetrazolate, and the pyridyl nitrogen atom. The nitrogen donor atoms form strong bonds with the copper atom [from 1.985(3) to 2.130(3) Å]. The tetrazolate groups link the Cu atoms into a one-dimensional chain along the *a* axis (Figure 6). These chains are then interconnected by pyridyl groups from the 4-ptz ligands to give the resulting three-dimensional structure. Because of the bulkiness of the pyridyl groups of the 4-ptz ligands, channels form along the

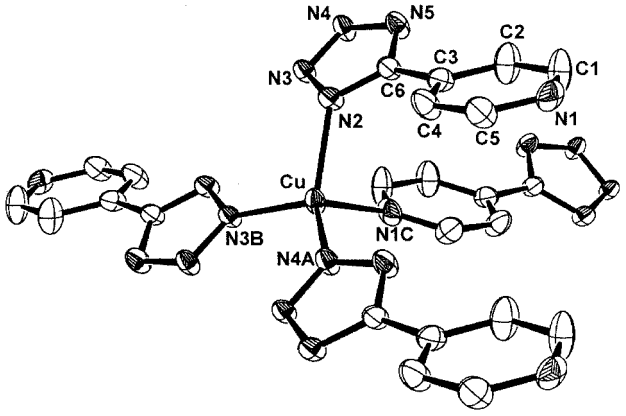

Figure 5. ORTEP drawing of **2** showing the local coordination environment of the Cu^I center (thermal ellipsoids at 50% probability)

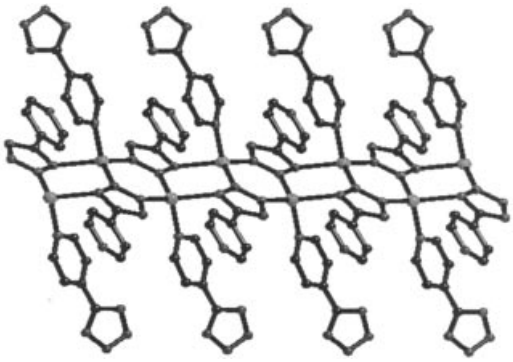

Figure 6. View of the one-dimensional copper chain linked by tetrazolate groups

a axis with an approximate cross-section of 4.4 × 4.4 Å (Figure 7). The solvent pyridine molecules reside in these channels (see Supporting Information). Thermogravimetric analysis showed that **3** loses 15.2% of its total weight in the 103−205 °C temperature range, which corresponds to the expected weight loss of half a pyridine molecule per formula unit (15.9%). Further details of the desolvation processes of complex **3** will form part of a future study.

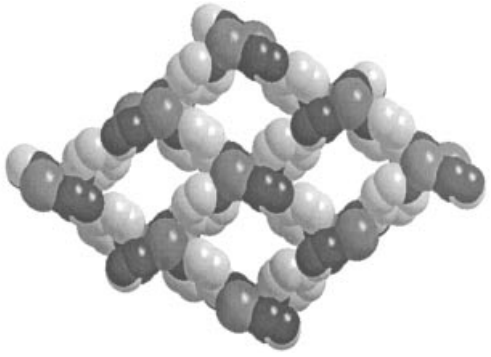

Figure 7. Space-filling view of the three-dimensional structure of **2** along the *a* axis

Structural Analysis

From the structures of complexes **1**, **2** and **3**, it can be seen that the metal ions in the three complexes all adopt a tetrahedral coordination environment, the difference being that Cu^{+} in complex **3** possesses a more distorted coordination geometry than Zn^{2+} in complexes **1** and **2**. Complex **1** has a bridging μ_2-OH group between two zinc ions and complex **2** possesses a Zn−OH−Zn−OH chain. As far as we know, the radius of Zn^{2+} (0.74 Å) is smaller than that of Cu^{+} (0.96 Å) so that there is a restriction of the coordination space around Zn^{2+} in comparison with Cu^{+}. As a result, Cu^{+} can tolerate a more congested tetrahedral coordination environment while Zn^{2+} has to employ bridging μ_2-OH ligands to extend its coordination space and thereby relax the crowded coordination sphere. On the other hand, the Pauling electronegativity of Cu is 1.90 while that of Zn is 1.65. As a result of this difference, copper has a stronger coordination capability than zinc. Due to this strong coordination capability and the larger coordination space of copper, three nitrogen atoms from the tetrazolate group of 4-ptz take part in the coordination in complex **3**, resulting in the three-dimensional framework. These observations confirm that different metals can affect or control the self-assembly process of a supramolecular coordination framework even when the ligands in the supramolecule are the same and the reaction conditions are similar.

Fluorescent Properties

The luminescent properties of complexes **1**, **2** and **3** were investigated in the solid state (Figure 8). Upon excitation at 296 nm, complex **1** shows a strong emission peak at 356 nm. The emission of complex **1** is neither MLCT (metal-to-ligand charge transfer) nor LMCT (ligand-to-metal charge transfer) in nature, and can probably be assigned to intraligand fluorescent emission since a similar emission (λ_{max} = 352 nm) is also observed for free 5-(4-pyridyl)tetrazole.

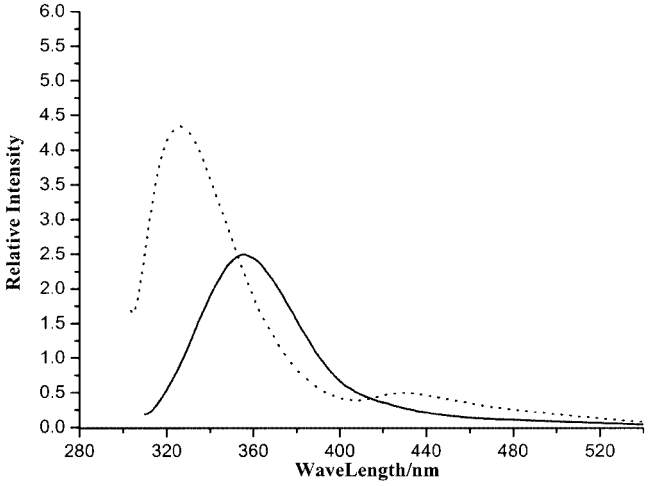

Figure 8. Excitation spectra and emission spectra of complex **1** (solid line) and complex **3** (dotted line) in the solid state at room temperature

Upon excitation at 294 nm, complex **2** displays a strong emission peak at 326 nm that can also be assigned to an intraligand fluorescent emission. Complex **2** shows an enhancement of the fluorescent intensity, which is almost twice that of free 5-(4-pyridyl)tetrazole. A relatively weak peak at 428 nm is also observed for **2**, and this peak may be tentatively assigned to phosphorescence.[10b] The Zn−OH−Zn−OH chain of complex **2** may be responsible for this phosphorescent emission since complex **1** only displays a strong emission peak at 352 nm. The exact phosphorescent-emission mechanism for complex **2** is unclear.

Complex **3** only displays a weak emission peak at 532 nm. The thermal stability of complexes **1** and **2** up to about 300 °C (TGA measurement) and their insolubility in common solvents make them good candidates for potential fluorescent materials.

Conclusions

In summary, we have prepared two new coordination frameworks containing the 5-(4-pyridyl)tetrazolate ligand. The structural features exhibited by complexes **1**, **2** and **3** show the coordination flexibility of the tetrazolate group. The radius of the coordination metal ion also has a great influence on the self-assembly in a crystal, which provides a crucial clue for possible modification and tuning of the supramolecular framework. The luminescent results indicate that metal coordination and formation of coordination framework can affect the emission wavelength and intensity of the organic material. A more detailed study in this area is in progress in our laboratory.

Experimental Section

General Remarks: The ligand 5-(4-pyridyl)tetrazole was prepared from NaN_3 and 4-cyanopyridine according to a reported procedure.[14] Zinc perchlorate hexahydrate was prepared by the reaction of zinc hydroxide with perchloric acid.[15] ***Caution:*** *$Zn(ClO_4)_2{\cdot}6H_2O$ is potentially explosive and should be used with care!* All other chemicals were of AR grade. Elemental analyses (C, H, N) were performed using an Elementar Vario ELIII elemental analyser. IR spectra as KBr discs were recorded with a Bruker VECTOR-22 FT-IR spectrophotometer. Thermal gravimetric analysis was performed with a Shimadzu TGA-50H Thermal Gravimetric Analyzer at a heating rate of 5 °C·min^{-1}. Excitation and emission spectra were recorded with a Perkin−Elmer LS55 instruments luminescence spectrometer.

Preparation of 1: Hydrothermal treatment of $Zn(ClO_4)_2{\cdot}6H_2O$ (0.1 mmol, 0.037 g), 5-(4-pyridyl)tetrazole (0.2 mmol, 0.015 g), ethanol (0.6 mL), and water (0.2 mL) at 120 °C for 12 h yielded colorless plate crystals (0.015 g, only one pure phase) in 51% yield based on $Zn(ClO_4)_2{\cdot}6H_2O$. $C_{18}H_{13}N_{15}OZn_2$ (586.17): calcd. C 36.88, H 2.24, N 35.84; found C 37.02, H 2.19, N 35.97. IR (KBr): $\tilde{\nu}$ = 3444 (w), 1624 (s), 1556 (m), 1435 (s), 1374 (m), 1228 (m), 1176 (m), 1031 (s), 1011 (m), 976 (m), 850 (m), 756 (m), 719 (m), 556 (m), 532 (s), 496 (m) cm^{-1}.

Preparation of 2: Hydrothermal treatment of $Zn(ClO_4)_2{\cdot}6H_2O$ (0.1 mmol, 0.037 g), 5-(4-pyridyl)tetrazole (0.2 mmol, 0.015 g), ethanol (0.6 mL), water (0.2 mL) and pyridine (0.2 mL) at 120 °C for 12 h yielded colorless plate crystals (0.014 g, only one pure phase) in 57% yield based on $Zn(ClO_4)_2{\cdot}6H_2O$. $C_6H_7N_5O_2Zn$ (246.54): calcd. C 29.20, H 2.84, N 28.39; found C 29.33, H 2.94, N 28.54. IR (KBr): $\tilde{\nu}$ = 3250 (m), 3043 (w), 1626 (s), 1557 (w), 1453 (w), 1439 (s), 1382 (w), 1230 (m), 1172 (w), 1087 (w), 1049 (w), 1018 (m), 854 (m), 754 (w), 719 (m), 538 (w), 512 (m), 472 (w) cm^{-1}.

Preparation of 3: Hydrothermal treatment of $Cu(NO_3)_2{\cdot}6H_2O$ (0.1 mmol, 0.030 g), 5-(4-pyridyl)tetrazole (0.2 mmol, 0.015 g), ethanol (0.6 mL), water (0.2 mL), and pyridine (0.2 mL) at 120 °C for 48 h yielded yellow block crystals (0.011 g, only one pure phase) in 43% yield based on $Cu(NO_3)_2{\cdot}6H_2O$. $C_{17}H_{13}Cu_2N_{11}$ (498.46): calcd. C 40.96, H 2.63, N 30.91; found C 41.09, H 2.54, N 31.12. IR (KBr): $\tilde{\nu}$ = 3443 (w), 2919 (m), 1616 (s), 1442 (s), 1212 (m), 1059 (m), 1045 (m), 1007 (m), 840 (m), 754 (m), 708 (m), 530 (m), 470 (m) cm^{-1}.

X-ray Crystallographic Study: Crystal data and details of the structure refinements are presented in Table 1. Intensity data were collected with an R-AXIS-IV four-circle diffractometer using Mo-K_α radiation (λ = 0.71073 Å) at 291 K for compound **1**, and with a CCD area detector diffractometer at 293 K for compound **3**. The structure solutions and refinements were carried out using SHELXS-96[16] and SHELXL-97, respectively.[17] All hydrogen atoms were identified from difference maps and were included in the successive refinement cycles. All non-hydrogen atoms (including those of solvent water molecules) were refined anisotropically. CCDC-212430 (**1**) and -228746 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Catalytic Activity of (η^6-*p*-Cymene)(phosphane)ruthenium(II) Complexes Supported on Poly(biphenoxyphosphazene) or Chiral Poly(binaphthoxyphosphazene) Copolymers

Gabino A. Carriedo,*[a] Pascale Crochet,[a] Francisco J. García Alonso,[a] José Gimeno,*[a] and Alejandro Presa-Soto[a]

Keywords: Phosphazenes / Polymers / Immobilization / Arene ligands / Hydrogen transfer / Ruthenium

The polyphosphazene random copolymer containing diphenylphosphane ligands $\{[NP(OC_6H_4PPh_2)_2]_{0.4}[NP(O_2C_{12}H_8)]_{0.6}\}_n$ (**1a**) ($O_2C_{12}H_8$ = 2,2′-dioxy-1,1′-biphenyl), and the chiral binaphthoxy analogues $\{[NP(OC_6H_4PPh_2)_2]_{0.1}[NP(O_2C_{20}H_{12})]_{0.9}\}_n$ [$O_2C_{20}H_{12}$ = (*R*)-2,2′-dioxy-1,1′-binaphthyl] (**1b**) and $\{[NP(OC_6H_4PPh_2)_2]_{0.2}[NP(O_2C_{20}H_{10}Br_2)]_{0.8}\}_n$ [$O_2C_{20}H_{10}Br_2$ = (*R*)-2,2′-dioxy-6,6′-dibromo-1,1′-binaphthyl] (**1c**), reacted in dichloromethane at room temperature with appropriate amounts of the dimeric complex $[Ru(\eta^6\text{-}p\text{-cymene})Cl(\mu\text{-}Cl)]_2$ to give the corresponding polymeric (phosphane)Ru^{II} complexes $\{[NP(OC_6H_4PPh_2[RuCl_2(\eta^6\text{-}p\text{-cymene})]_x)_2]_{0.4}[NP(O_2C_{12}H_8)]_{0.6}\}_n$ [*x* = 0.5 (**2a**), 1 (**2b**)], $\{[NP(OC_6H_4PPh_2[RuCl_2(\eta^6\text{-}p\text{-cymene})])_2]_{0.1}[NP(O_2C_{20}H_{12})]_{0.9}\}_n$ (**3**) and $\{[NP(OC_6H_4PPh_2[RuCl_2(\eta^6\text{-}p\text{-cymene})])_2]_{0.2}[NP(O_2C_{20}H_{10}Br_2)]_{0.8}\}_n$ (**4**). The isolated products are soluble reddish solids, and are thermally very stable with very high glass transition temperatures. The reaction of **1b** or **1c** with the cationic precursor $[RuCl(PPh_3)_2(\eta^6\text{-}p\text{-cymene})][PF_6]$ in refluxing THF gave the crosslinked insoluble cationic polymeric complexes $\{[NP(OC_6H_4PPh_2)_2]_{0.1}[NP(O_2C_{20}H_{12})]_{0.9}[RuCl(\eta^6\text{-}p\text{-cymene})(PF_6)]_{0.05}\}_n$ (**5**) and $\{[NP(OC_6H_4PPh_2)_2]_{0.2}[NP(O_2C_{20}H_{10}Br_2)]_{0.8}[RuCl(\eta^6\text{-}p\text{-cymene})(PF_6)]_{0.08}\}_n$ (**6**). All the complexes were active catalysts in transfer hydrogenation of acetophenone by propan-2-ol, but the C_2-pockets containing the catalytic centers gave no enantioselectivity because of the conformational behavior of the chiral derivatives.

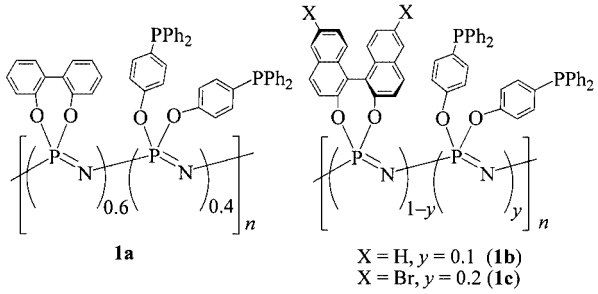
Introduction

Although many linear polyphosphazenes[1−5] $(N{=}PR_2)_n$, carrying ligands as lateral groups, can be used to form transition metal complexes,[6−12] the resulting materials have not been extensively characterized as polymer-supported catalysts.[13] Recently, according to the synthesis of the homopolymers $[NP(O_2C_{12}H_8)]_n$ ($O_2C_{12}H_8$ = 2,2′-dioxy-1,1′-biphenyl)[14] and the chiral analogue $[NP(O_2C_{20}H_{12})]_n$ [$O_2C_{20}H_{12}$ = (*R*)-2,2′-dioxy-1,1′-binaphthyl],[15] we reported the preparation of phosphazene random copolymers bearing diphenylphosphane groups (Scheme 1) $\{[NP(OC_6H_4PPh_2)_2]_x[NP(O_2C_{12}H_8)]_{1-x}\}_n$ (*x* = 0.4; **1a**),[16] $\{[NP(OC_6H_4\text{-}PPh_2)_2]_{0.1}[NP(O_2C_{20}H_{12})]_{0.9}\}_n$ [$O_2C_{20}H_{12}$ = (*R*)-2,2′-dioxy-1,1′-binaphthyl] (**1b**),[17] and $\{[NP(OC_6H_4\text{-}PPh_2)_2]_{0.2}[NP(O_2C_{20}H_{10}Br_2)]_{0.8}\}_n$ (**1c**) [$O_2C_{20}H_{10}Br_2$ = (*R*)-2,2′-dioxy-6,6′-dibromo-1,1′-binaphthyl].[17] The latter chiral polymers **1b**, **1c** were considered of potential interest in catalysis because they have the phosphane ligands located in the space (chiral pocket) defined by two consecutive



Scheme 1. Polyphosphazenes **1a**, **1b**, **1c**

$[NP(O_2C_{20}H_{10}X_2)]_n$ (X = H, Br) units,[18] and the very high glass transition temperatures of the polymers indicate their stereochemical rigidity.

(Arene)ruthenium(II) complexes have been widely used in homogeneous catalysis and have proven to be efficient precatalysts in a wide number of organic transformations of academic and industrial interest.[19] In particular, they have shown outstanding performance in catalytic transfer hydrogenations.[20] In order to explore the actual potential of the polyphosphazenes as supporting polymers, we considered the synthesis of well-defined complexes containing (arene)-ruthenium(II) fragments. It is well known that the development of cleaner and low-cost catalytic processes requires

the immobilization of catalysts through coordination to functionalized polymers, and this immobilization has been revealed as one of the most reliable methodologies.[21]

Herein, we describe the synthesis and characterization of novel neutral or cationic polymeric (η^6-*p*-cymene)ruthenium(II) complexes supported by diphenylphosphane ligands in the achiral polyphosphazene **1a** and in the chiral polyphosphazenes **1b** and **1c**. They have proven to be active and recyclable catalysts in transfer hydrogenation of acetophenone by propan-2-ol although no enantiomeric excesses were observed when using the chiral derivatives. The stereochemical factors, which may determine this lack of selectivity by the chiral binaphthoxy derivatives, are also discussed.

Results and Discussion

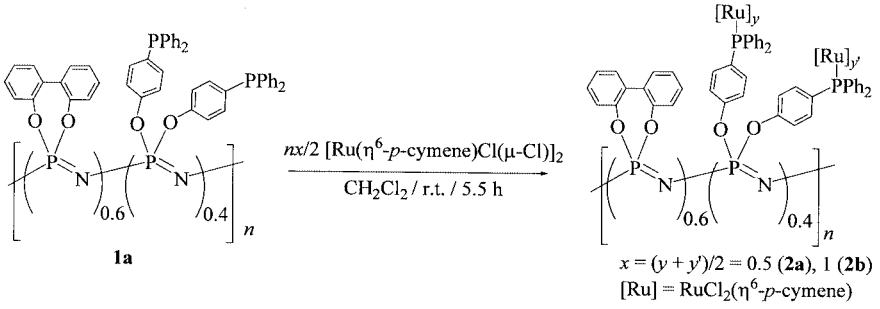
Synthesis and Characterization of (Arene)(Linear and crosslinked polymeric phosphazene−phosphane)Ru^{II} Complexes

The reaction of the polyphosphazene−phosphane $\{[NP(OC_6H_4PPh_2)_2]_{0.4}[NP(O_2C_{12}H_8)]_{0.6}\}_n$ (**1a**) with $0.4x$ equiv. (x = 0.5, 1) of [Ru(η^6-*p*-cymene)Cl(μ-Cl)]$_2$ per polymeric unit in dichloromethane at room temperature gave the well-defined polymeric (phosphane)ruthenium(II) complexes $\{[NP(OC_6H_4PPh_2[RuCl_2(\eta^6\text{-}p\text{-cymene})]_x)_2]_{0.4}[NP(O_2C_{12}H_8)]_{0.6}\}_n$ [x = 0.5 (**2a**), 1 (**2b**)] (83 and 92% yield, respectively) (Scheme 2). The reaction was monitored by the decrease in intensity of the $^{31}P\{^1H\}$ singlet resonance due to the PPh_2 groups in **1a** ($\delta \approx -6$ ppm) and the appearance of a new singlet at δ = 23.7 ppm, arising from the coordinated PPh_2 groups in **2a**, **2b**. The final relative intensities of the phosphorus resonances were in agreement with the expected value for each polymer. Thus, all the diphenylphosphanyl groups available in complex **2b** were coordinated to ruthenium centers, while in **2a** 50% of the ligands remained free.

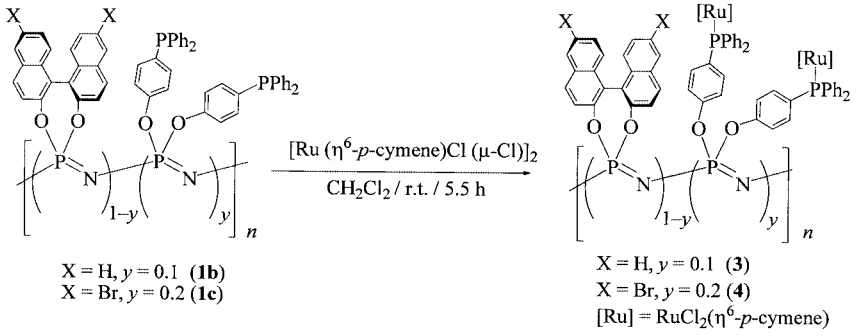
According to a similar procedure (Scheme 3), the ruthenium(II) polymeric complexes $\{[NP(OC_6H_4PPh_2[RuCl_2(\eta^6\text{-}p\text{-cymene})])_2]_{0.1}[NP(O_2C_{20}H_{12})]_{0.9}\}_n$ (**3**) and $\{[NP(OC_6H_4PPh_2[RuCl_2(\eta^6\text{-}p\text{-cymene})])_2]_{0.2}[NP(O_2C_{20}H_{10}Br_2)]_{0.8}\}_n$ (**4**) were obtained (90 and 88% yield) by treating the chiral polyphosphazenes **1b** and **1c** with 0.1 and 0.2 equiv., respectively, of [Ru(η^6-*p*-cymene)Cl(μ-Cl)]$_2$ per polymeric unit. The high ratio of binaphthoxy/diphenylphosphanyl groups of the polymers **1b**, **1c** ensured the location of the ruthenium fragments within the potentially chiral pocket formed by two consecutive binaphthoxy units.

Complexes **2a**, **2b, 3** and **4** were isolated as red, air-stable solids, which are soluble in dichloromethane but insoluble in hexane or propan-2-ol. Analytical and spectroscopic data (IR and ^1H, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR) supported the proposed formulations (see Exp. Sect. for details). As expected, the NMR signals of the polymers were broad to very broad and several of the weaker peaks could not be observed clearly.

The presence of the organometallic moiety [Ru(η^6-*p*-cymene)] was shown in the ^1H and $^{13}C\{^1H\}$ NMR spectra by the expected resonances for the nuclei of the aromatic ring, as well as for the methyl and isopropyl substituents. $^{31}P\{^1H\}$ NMR spectra contain resonances at $\delta \approx 23$ ppm corresponding to the coordinated diphenylphosphanyl groups, which compare well with those of the analogous



Scheme 2



Scheme 3

complex $[RuCl_2(PPh_3)(\eta^6\text{-}p\text{-cymene})]$ (δ = 23.1 ppm). In the case of **2a**, a signal corresponding to the uncoordinated PPh_2 groups (δ = −6.2 ppm) was also observed. The spectra also showed two broad signals corresponding to the distribution of chemical shifts of the two different phosphazene repeating units present in the polymeric chains, one at $\delta \approx -5$ ppm $[NP(O_2C_{12}H_8)]$ or $\delta = -3$ ppm $\{[NP(O_2C_{20}H_{12})]$ or $[NP(O_2C_{20}H_{10}Br_2)]\}$, and another at $\delta \approx -23$ ppm $[NP(OC_6H_4PPh_2)_2]$. In all cases, the relative intensities were in agreement with the chemical formulae proposed.

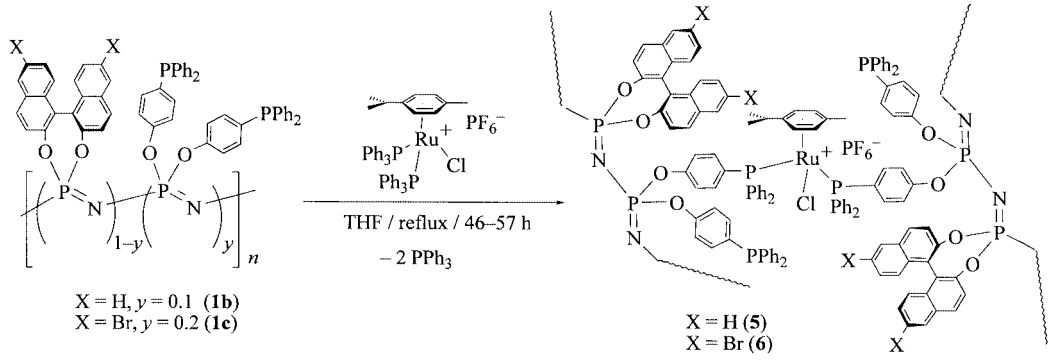
The DSC curves of the polymeric complexes **2a** and **2b** showed a well-defined glass transition. The measured T_g values (149 and 189 °C) were, as expected,[22] higher than that of the starting polymer **1a** (95 °C) and increased with increasing metal content. The glass transition could not be detected for the chiral binaphthoxy derivatives **4** and **5**, but they should be higher than those of the corresponding polymers **1b** (268 °C) and **1c** (256 °C). These values, and the very broad NMR spectra observed at room temperature, are clear indicators of the high stereochemical rigidity of the polymeric chains, a factor that should favor the stereochemical selectivity of the chiral sites in asymmetric processes.[23]

In order to investigate whether the inclusion of the Ru^{II} active centers inside a solid chiral matrix would result in the expected[24] enhanced enantiomeric induction, the crosslinked polymeric complexes $\{[NP(OC_6H_4PPh_2)_2]_{0.1}[NP(O_2C_{20}H_{12})]_{0.9}[RuCl(\eta^6\text{-}p\text{-cymene})(PF_6)]_{0.05}\}_n$ (**5**) and $\{[NP(OC_6H_4PPh_2)_2]_{0.2}[NP(O_2C_{20}H_{10}Br_2)]_{0.8}[RuCl(\eta^6\text{-}p\text{-cymene})(PF_6)]_{0.08}\}_n$ (**6**) were synthesized (Scheme 4) by treating the ligands $\{[NP(OC_6H_4PPh_2)_2]_{0.1}[NP(O_2C_{20}H_{12})]_{0.9}\}_n$ (**1b**) and $\{[NP(OC_6H_4PPh_2)_2]_{0.2}[NP(O_2C_{20}H_{10}Br_2)]_{0.8}\}_n$ (**1c**) with the appropriate amount of the cationic precursor $[RuCl(PPh_3)_2(\eta^6\text{-}p\text{-cymene})][PF_6]$ in refluxing THF. The displacement of the PPh_3 ligands in the cationic complex by the PPh_2 groups attached to the polymer was favored by the insolubility of the final products. Therefore, this substitution method is very convenient for the preparation of crosslinked polymeric complexes with controlled composition, as has been already observed in other cases with phosphazenes carrying pyridine ligands.[25]

Materials **5** and **6**, isolated (95 and 94 yield%) as air-stable, slightly red and green solids, respectively, were insoluble in common organic solvents. Microanalysis (including Ru and P) and spectroscopic data (IR and ^{31}P NMR) support the proposed formulation. Their ^{31}P NMR spectra in the solid state show broad signals at δ = 24.4, 23.2 (**5**) and 24 (**6**) ppm corresponding to the coordinated diphenylphosphanyl groups, and a very broad resonance at δ = −8.5 (**5**) and −9.3 (**6**) ppm for the phosphorus atoms of the polymeric chain. The composition and structure were also confirmed by the IR spectra that showed the absorptions (i) at $\tilde{\nu}$ = 2965 (m) and 2855 (w) cm^{-1} due to the *p*-cymene fragment, (ii) at $\tilde{\nu}$ = 838 cm^{-1} from the PF_6^- anion, and (iii) in the $\tilde{\nu}$ = 1200−1300 cm^{-1} region for the stretching ν(PN) modes of the phosphazene chain.

Catalytic Activity in the Transfer Hydrogenation of Ketones

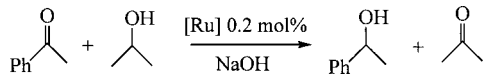
In order to test the catalytic activity and enantioselectivity of the Ru^{II} complexes supported on the chiral phosphazenes, the transfer hydrogenation of acetophenone by propan-2-ol was investigated, in the presence of catalytic amounts of **2a**, **2b**, **3**, **4**, **5** and **6** (Scheme 5). For comparative purposes, the efficiencies of the analogous homogeneous ruthenium(II) catalysts, $[RuCl_2(\eta^6\text{-}p\text{-cymene})(PPh_3)]$ and $[RuCl(\eta^6\text{-}p\text{-cymene})(PPh_3)_2][PF_6]$, were also observed under the same reaction conditions. In a typical experiment, NaOH was added to either a suspension of the supported ruthenium catalyst precursor (**2a**, **2b**, **3**−**6**) or a solution of the respective mononuclear complex and acetophenone (0.25 M) in propan-2-ol (ketone/Ru/base = 500:1:24) at reflux. The reactions were monitored by gas chromatography. Table 1 shows the catalytic performances. Supported ruthenium(II) complexes **2a**, **2b, 3** and **4** afforded high conversions after ca. 24 h (TON = 450−475; Table 1, Entries 3−6). It is interesting to note that a fast initial rate is observed in the reduction of acetophenone by complex **4**, giving a yield of 53% after 1 h (TOF = 265 h^{-1}). As expected, complexes $[RuCl_2(\eta^6\text{-}p\text{-cymene})(PPh_3)]$ and $[RuCl(\eta^6\text{-}p\text{-cymene})(PPh_3)_2][PF_6]$ were active under homogeneous conditions, showing comparable efficiencies (TON = 475 and 480, respectively) to those of the supported catalysts, but with higher rates (4.5 h) (Table 1, En-



Scheme 4

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tries 1 and 2). The crosslinked supported complexes **5**−**6** were also active catalysts although they were less efficient than their linear analogues **3** and **4** (Table 1, Entries 7 and 8).



Scheme 5

Table 1. Transfer hydrogenation of acetophenone

Entry[a]	Catalyst	Yield [%][b]	Time [h]	TON[c]
1	$[RuCl_2(PPh_3)(p\text{-cymene})]$	95	4.5	475
2	$[RuCl(PPh_3)_2(p\text{-cymene})][PF_6]$	96	4.5	480
3	**2a**	90	24	450
4	**2b**	92	24	460
5	**3**	92	24	460
6	**4**	95	24	475
7	**5**	70	24	350
8	**6**	65	24	325

[a] Conditions: reactions were carried out at 82 °C using 5 mmol of acetophenone (0.25 M in propan-2-ol); ketone/Ru/NaOH = 500:1:24. [b] Yield in 1-phenylethanol, determined by GC. [c] Turnover number, TON = mol of 1-phenylethanol/mol of Ru.

In order to take advantage of the insolubility of the immobilized catalysts in propan-2-ol, the catalytic activity of the supported ruthenium(II) complexes was examined by successive runs after recycling by simple decantation (see Exp. Sect. for details). Catalysts **2b**, **3**−**6** were active in the second run (40−60% yields) but with a notable reduction in efficiency (Table 2). In contrast, catalyst **2a** showed only a slight loss of activity after six successive runs (Figure 1) with a cumulative turnover number of 2430.

Table 2. Transfer hydrogenation of acetophenone; second run for complexes **2b**, **3**−**6**

Entry[a]	Catalyst	Yield [%][b]	Time [h]	Cumulative TON[c]
1	**2b**	57	24	745
2	**3**	60	24	760
3	**4**	47	24	710
4	**5**	54	24	620
5	**6**	40	24	525

[a] Conditions: reactions were carried out at 82 °C using 5 mmol of acetophenone (0.25 M in propan-2-ol); ketone/Ru/NaOH = 500:1:24. [b] Yield in 1-phenylethanol, determined by GC. [c] Turnover number calculated over the two runs.

Although we made no attempt to characterize the recycled catalysts, it is apparent that the active catalytic species show a moderate to good stability after the first run has been completed. As is well established from a variety of mechanistic studies, transient ruthenium(II) hydride derivatives are the active species in this type of transfer hydrogenation.[26] These species are formed during the first catalytic

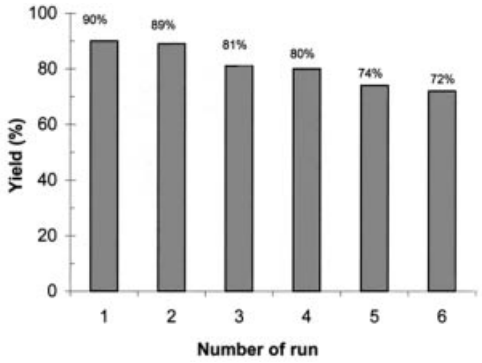


Figure 1. Transfer hydrogenation of acetophenone by **2a**; conditions: reaction carried out at 82 °C using 5 mmol of acetophenone (0.25 M in propan-2-ol); ketone/Ru/NaOH = 500:1:24; yield of 1-phenylethanol after 24 h determined by GC; global TON for six uses = 2430

cycle in which the supported pre-catalyst undergoes a chloride/isopropoxide ligand exchange followed by β-elimination. Although in the first run the required excess of NaOH (24 mol per mol of Ru) for the formation of the active species is used, we observed that better conversions are achieved by addition of NaOH in each run.[27]

In all cases, the leaching of ruthenium from the support during the catalytic experiments was determined by atomic absorption spectroscopy of the metal in solution, after removal of the polymer. When complex **2a** was used, the leaching never exceeded 5% of the initial quantity of ruthenium, in agreement with its recyclability. In contrast, the polymers **2b**, **3** and **4** suffered a greater loss of ruthenium during the first use (ca. 35−50%), which probably accounts for the large decrease in their catalytic activity. As expected in the case of the crosslinked polymers **5** and **6**, the ruthenium leaching is very low and their poor catalytic performances most likely reflect the low accessibility of the active center.

Unfortunately, enantiomeric excesses were observed with neither linear nor crosslinked chiral polymers. As the presence of the active centers within the chiral pockets is unquestionable, these results seem to indicate that in the overall average arrangement of the solid matrix, the local conformations of the polymer chains bearing the chiral sites are too open to induce enantioselectivity. However, another more subtle factor could be the helical secondary structure found for analogous phosphazene chains with binaphthoxy groups.[28] It is well known that the helical polymers form good enantioselective catalysts,[29] but the combination of the secondary helical structure and the centrochiralities present in the main chain may be counterproductive.[30] In this case, it might be better to use a catalyst with either one or another of these features.

Conclusions

This work shows that neutral $[Ru(\eta^6\text{-}p\text{-cymene})Cl_2]$ and cationic $[Ru(\eta^6\text{-}p\text{-cymene})Cl]^+$ fragments can be supported by chiral and achiral polyphosphazenes, giving rise to linear

or crosslinked polymeric complexes (**2a**, **2b**, **3**−**6** in Schemes 2−4) in which the metal fragments are linked to the polymeric backbone through phosphane lateral groups.

These materials are active polymer-supported catalysts for the transfer hydrogenation of acetophenone with high conversions. Complex **2a** was also recyclable and, in contrast with its homogeneous counterparts which were active only in one run, it could be recovered without significant ruthenium leaching after various catalytic transformations (cumulative TON = 2430 after 6 runs). The activity of **2a** is similar to that of the previously described ruthenium(II) catalyst supported on commercially available R_2P-Merrifield-type polymers.[21f]

Although the active centers supported in polymers **3**−**6** are situated in the chiral pockets generated by two consecutive chiral binaphthoxyphosphazene units, no enantiomeric excess of the resulting secondary alcohol was observed. This may be due to the conformational characteristics of the polymeric chains with pockets that are too wide to induce enantioselectivity. Our observations may represent another experimental example of the combination of chiral polymeric units within a secondary helical structure being counterproductive in asymmetric induction.[30]

Experimental Section

General Comments: All reactions were carried out under nitrogen. The polymeric ligand $\{[NP(OC_6H_4PPh_2)_2]_{0.4}[NP(O_2C_{12}H_8)]_{0.6}\}_n$ (**1a**) was prepared by a method described elsewhere,[16] using $[NPCl_2]_n$ obtained by the procedure described by Magill et al.[31] The product had less than 0.14% of unchanged chlorine, a negligible fraction of oxidized phosphane sites (ca. 3.5%), and contained 0.7 units of polytetrahydrofuran (PTHF). Therefore, its actual degree of functionalization with PPh_2 groups was 1.87 mmol per gram of polymer $(FD)_P = 1.87$. As observed with the previously published analogue,[16] the GPC chromatogram was poorly defined indicating a very broad distribution with an estimated average M_w of 300000 ($M_w/M_n = 12.5$). The T_g (DSC) occurred at 95 °C ($\Delta C_p = 0.19\ Jg^{-1}K^{-1}$). In the polymers $\{[NP(OC_6H_4PPh_2)_2]_{0.1}[NP(O_2C_{20}H_{12})]_{0.9}\}_n$ [17] (**1b**) and $\{[NP(OC_6H_4PPh_2)_2]_{0.2}[NP(O_2C_{20}H_{10}Br_2)]_{0.8}\}_n$,[17] (**1c**) a fraction of the $-PPh_2$ sites had been oxidized to $-P(=O)Ph_2$ (20% and 12%, respectively) and their actual degrees of functionalization with active PPh_2 ligands (the values used to calculate the stoichiometric amounts of Ru complex below) were $(FD)_P = 0.45$ mmol/g and $(FD)_P = 0.69$ mmol/gram, respectively. The precursor complexes $[RuCl_2(PPh_3)(\eta^6\text{-}p\text{-cymene})]$[32] and $[Ru(\eta^6\text{-}p\text{-cymene})Cl(\mu\text{-}Cl)]_2$ [33] were prepared as described previously. $[RuCl(PPh_3)_2(\eta^6\text{-}p\text{-cymene})][PF_6]$ was prepared similarly to the analogous complexes described in the literature.[34] THF was treated with KOH and distilled twice from Na in the presence of benzophenone. The IR spectra were recorded with a Perkin−Elmer FT Paragon 1000 spectrometer. NMR spectra were recorded with Bruker AC-200, AC-300, DPX-300 and Avance 300 instruments, using $CDCl_3$ as solvent unless otherwise stated. ^{31}P NMR spectra of the insoluble polymers were obtained from $[D_6]$DMSO or $CDCl_3$ suspensions using a Varian Unity plus (300 MHz) instrument at the Universitat de Barcelona (Serveis Cientifico-Tècnics). ^1H and $^{13}C\{^1H\}$ NMR chemical shifts are given in δ relative to TMS. $^{31}P\{^1H\}$ NMR chemical shifts are given in δ relative to external 85% aqueous H_3PO_4. Coupling constants are in Hz. C, H, N analyses were performed with a Perkin−Elmer 240 microanalyzer. Ru analyses were performed by Galbraith Laboratories. T_g values were measured with a Mettler DSC 300 differential scanning calorimeter in the second heating cycle unless otherwise stated. Thermal gravimetric analyses were performed with a Mettler TA 4000 instrument. The polymer samples were heated at a rate of 10 °C/min from ambient temperature to 800 °C under a constant flow of nitrogen. Gas chromatographic measurements were carried out with a Hewlett Packard HP6890 instrument. HP-INNOWAX cross-linked polyethylene glycol (30 m, 250 μm) or Supelco Beta-Dex™ 120 (30 m, 250 μm) columns were used.

General Procedure for Catalytic Transfer Hydrogenation of Acetophenone: Under an inert gas, acetophenone (5 mmol), the ruthenium catalyst precursor (0.01 mmol of Ru, 0.2 mol %) and propan-2-ol (17.5 mL) were introduced into a Schlenk tube fitted with a condenser, and heated at 82 °C for 15 min. Then NaOH (2.5 mL of a 0.096 M solution in propan-2-ol, 4.8 mol %) was added and the reaction monitored by gas chromatography. Acetone and 1-phenylethanol were the only products detected in all cases. The recycling process was carried out as follows: After cooling the reaction mixture to room temperature, the insoluble polymer was decanted and washed twice with 10 mL of propan-2-ol. Then, propan-2-ol (17.5 mL), acetophenone (5 mmol) and NaOH (2.5 mL of a 0.096 M solution in propan-2-ol, 4.8 mol %) were added and the mixture heated at 82 °C.

$\{[NP(OC_6H_4PPh_2[RuCl_2(\eta^6\text{-}p\text{-cymene})]_x)_2]_{0.4}[NP(O_2C_{12}H_8)]_{0.6}\}_n$ [x = 0.5 (2a); 1 (2b)]: The dimer $[Ru(\eta^6\text{-}p\text{-cymene})Cl(\mu\text{-}Cl)]_2$ (0.043 g, 0.14 mmol of Ru) was added to a solution of $\{[NP(OC_6H_4PPh_2)_2]_{0.4}[NP(O_2C_{12}H_8)]_{0.6}\}_n$ (**1a**) (0.15 g, 0.28 mmol of PPh_2 groups) in CH_2Cl_2 (15 mL), and the mixture stirred at room temperature for 5.5 h. The resulting solution was concentrated to ca. 1 mL and poured dropwise into hexane (500 mL) to give **2a** as a slightly reddish solid that was dried in vacuo. Yield 0.16 g, (83%). The reddish complex **2b** was prepared similarly using $\{[NP(OC_6H_4\text{-}PPh_2)_2]_{0.4}[NP(O_2C_{12}H_8)]_{0.6}\}_n$ (**1**) (0.20 g, 0.37 mmol of PPh_2 groups) and the dimer $[Ru(\eta^6\text{-}p\text{-cymene})Cl(\mu\text{-}Cl)]_2$ (0.114 g, 0.37 mmol of Ru) and stirring for 5.5 h. The yield was 0.29 g (92%).

2a: $^{31}P\{^1H\}$ NMR (25 °C): δ = 23.7 (m, $C_6H_4PPh_2Ru$), −5.6 [m, $N{=}P(O_2C_{12}H_8)$], −6.2 ($C_6H_4PPh_2$), −22.5 [m, $N{=}P(OC_6H_4PPh_2)_2$] ppm. ^1H NMR (25 °C): δ = 7.5, 7.3, 7.1, 6.7 (aromatic rings); 4.9, 4.7 [$CH_3C_6H_4CH(CH_3)_2$]; 3.4, 1.6 (PTHF), 2.7 [$CH_3C_6H_4CH(CH_3)_2$], 1.5 [$CH_3C_6H_4CH(CH_3)_2$], 0.9 [$CH_3C_6H_4CH(CH_3)_2$] ppm. $^{13}C\{^1H\}$ NMR (25 °C): δ = 152.5, 135, 121.5 (PC_6H_4O), 138, 134, 129 [$P(C_6H_5)_2$], 149, 130.5, 129, 126, 123 ($PO_2C_{12}H_8$); 96, 89.5, 87, 30.5, 22 (*p*-cymene), 71, 27 (PTHF) ppm. Mechanism of Reduction of the Nitrite Ion by Cu^{I} Complexes

Ariela Burg,[a] Evgenia Lozinsky,[a] Haim Cohen,[a,b] and Dan Meyerstein*[a,c]

Keywords: Nitrite / Copper(I) / Reduction / NO

The reaction of Cu^{+}_{aq} with NO_2^- was studied. The results are consistent with the mechanism: $Cu^{+}_{aq} + NO_2^- \leftrightarrows (Cu^{+}NO_2^-)$, $K = 140 \pm 30$ M^{-1}; $(Cu^{+}NO_2^-) + H^+ \rightarrow Cu^{2+} + NO + OH^-$, $k = 4.6 \times 10^5$ M^{-1}s^{-1}. It is proposed that the copper is bound to the nitrogen in the transient complex $(Cu^{+}NO_2^-)$. In addition, the reaction was studied with $(Cu^{I}L^{i})^{+}$ complexes. The results show that the ligands reduce the value of K and that their effect on k depends on the redox potential of the $(Cu^{II/I}L^{i})$ couple. This reaction is the simplest model for the CuNIR (NIR = Nitric reductase) enzymes.

Introduction

The one-electron reduction of nitrite to NO is of major importance in a variety of biological processes[1−3] and in waste water treatment.[4−6] The reducing agent, or the electro-catalytic active agent,[7−9] is usually a low valent transition metal complex, e.g. Fe^{II},[9−13] Co^{I},[14,15] Ru^{II},[8,16] Cu^{I}.[17−20] For example, one of the steps in the important nitrogen cycle is the reduction of nitrite to nitric oxide.[21] Dinitrogen is released into the atmosphere by the activity of denitrifying bacteria found in soils and sediments.[22−25] The enzyme nitrite reductase (NIR) is essential for these bacteria.[1,2] Several mechanistic studies on the reduction of NO_2^- by Cu^{I} complexes in organic solvents were performed in order to elucidate the reduction mechanism, and as plausible models for the enzymatic process.[26−35] In the present work, we decided to study the mechanism and kinetics of the reaction between $Cu^{+}_{aq}/(Cu^{I}L)^{+}$ complexes and NO_2^-. The results indicate that a transient complex, $(Cu^{+}NO_2^-)$, is formed initially, and that this complex reacts with H_3O^+ to yield the final products.

It is of interest to note that the oxidation of NO by $Fe^{III}L$ complexes proceeds via the reverse mechanism[35] [see reaction (1)].

$$[Fe^{III}L] + NO \rightleftarrows [Fe^{III}L{\cdot}NO] \xrightarrow{OH^-} [Fe^{II}L] + HNO_2 \quad (1)$$

Results and Discussion

When Cu^{+}_{aq} is introduced into a solution containing excess $NaNO_2$ $(2.5-100) \times 10^{-3}$ M in the pH range 4.15−5.45 (buffered by 0.10 M acetate, the results are independent of the acetate concentration in the range 0.10−0.50 M), a decrease in the absorption at 355 nm due to nitrite is observed. The kinetics of this process, followed using the stopped-flow technique, obey a first order rate law on Cu^{I}. The observed rate increases with increasing $[NO_2^-]$. However, the results indicate that a limiting rate is observed at high $[NO_2^-]$ (see Figure 1).

Analysis of the results assuming a mechanism involving the fast formation of an intermediate complex fits well with the experimental data [Figure 2, reaction (2)]. The value of k_2 (Table 1) derived from the intercepts of plots analogous to Figure 2 is pH-dependent. A plot of k_2 vs. $[H_3O^+]$ (Figure 3) yields a straight line ($k_2 = k_{*2}[H_3O^+]$). From the slope of the line in this figure one obtains $k_{*2} = (4.6 \pm 0.5) \times 10^5$ M^{-1} s^{-1}.

$$Cu^{+}_{aq} + NO_2^- \xrightleftharpoons{K_{2app}} [Cu^{+}NO_2^-] \xrightarrow[H^+]{k_2} Cu^{2+}_{aq} + NO + OH^- \quad (2)$$

$$-d[NO_2^-]/dt = (k_2K_{2app}[NO_2^-][Cu^{+}_{aq}])/(1 + K_{2app}[NO_2^-])$$

$$1/k_{obsd.} = 1/(k_2K_{2app}[NO_2^-]) + 1/k_2$$

The results indicate that a mechanism in which an unreactive $Cu^{I}-NO_2^-$ complex is formed [reactions (3) and (4)] could yield the same rate law. However, this would require that the reaction according to reaction (4) is a third order process. Thus, this mechanism seems unlikely.

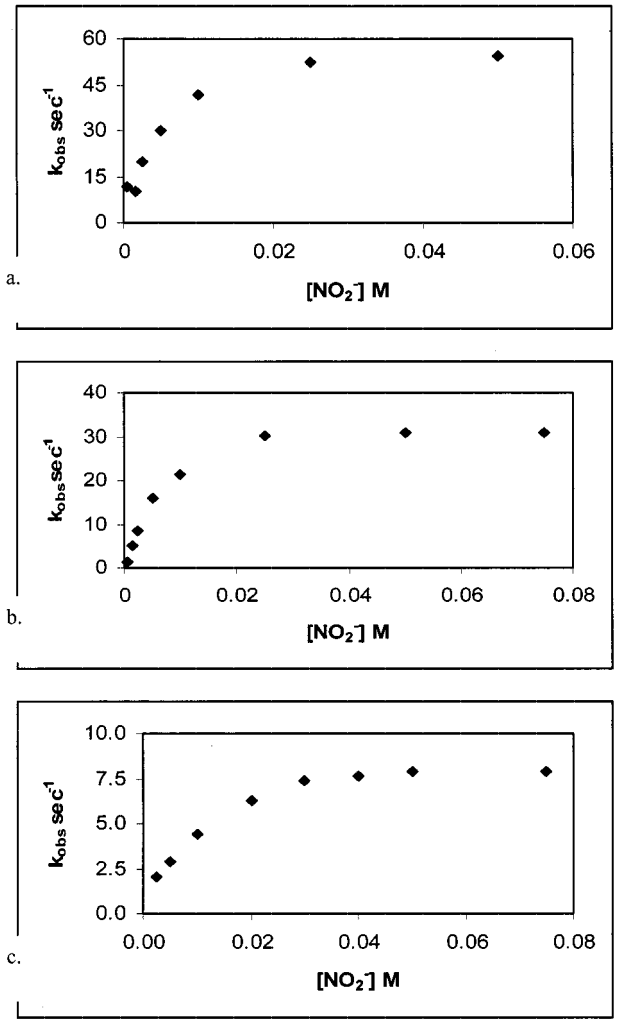

Figure 1. Dependence of $k_{obsd.}$ on the $[NO_2^-]$. The experiments were performed in solutions containing 5.0×10^{-4} M Cu^+_{aq}, 0.10 M $NaClO_4$, 0.10 M acetic acid, 0.023 M NH_4^+, helium saturated at a final pH of: a. 4.3, b. 4.65, c. 5.25.

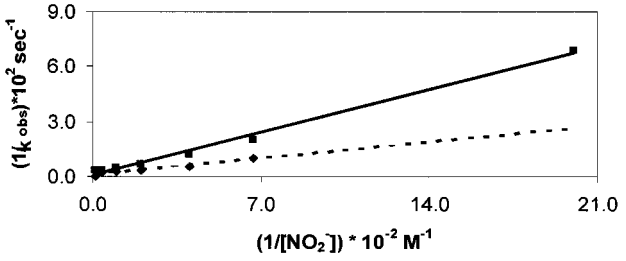

Figure 2. Dependence of $1/k_{obsd.}$ on $1/[NO_2^-]$. The experiments were performed in solutions containing 5.0×10^{-4} M Cu^+_{aq}, 0.10 M $NaClO_4$, 0.10 M acetic acid, 0.023 M NH_4^+, helium saturated, the final pH: 4.3 (-----), 4.65 (—)

$$Cu^+_{aq} + NO_2^- \rightarrow (Cu^+NO_2^-) \quad (3)$$

$$Cu^+_{aq} + NO_2^- \rightarrow P \quad (4)$$

$$Cu^+_{aq} + NO_2^- + H_3O^+ \rightarrow Cu^{2+}_{aq} + NO + OH^- \quad (5)$$

Table 1. The effect of $[H_3O^+]$ on k_2 and on the observed stability constant of the $(Cu^+NO_2^-)$ complex (the experiments were performed on helium-saturated solutions containing 5.0×10^{-4} M Cu^+_{aq}, 0.10 M $NaClO_4$, 0.10 M acetic acid, 0.023 M NH_4^+)

K_{2app} (M^{-1})	k_2 (M^{-1}s^{-1})	$[H_3O^+]$ (M)	pH
77	2.9	3.5×10^{-6}	5.45
62	3.4	4.0×10^{-6}	5.40
62	5.0	1.3×10^{-5}	4.90
152	8.2	2.0×10^{-5}	4.70
120	12	2.2×10^{-5}	4.60
132	12.7	4.0×10^{-5}	4.40
110	23	5.0×10^{-5}	4.30
154	33	7.1×10^{-5}	4.15

The value of k_2 (Table 1), derived from the intercepts of plots analogous to Figure 2, is pH dependent.

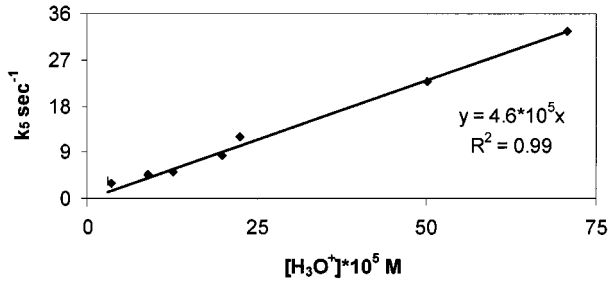

Figure 3. Dependence of k_5 on $[H_3O^+]$. The experiments were performed in solutions containing 5.0×10^{-4} M Cu^+_{aq}, 0.10 M $NaClO_4$, 0.10 M acetic acid, 0.023 M NH_4^+, helium saturated.

The apparent values of K_{2app}, derived from the slopes of the straight lines, e.g. from Figure 2 (at several pH's in this pH range) are presented in Table 1. The average of K_{2app} in the pH range 4.15−4.70 is 130 ±25 M^{-1} (Table 1). When the pH is increased, pH ≥ 4.7, the formation of CuOH [K_{sp}(CuOH) = 1×10^{-14} M^{-2} [36]] causes an apparent decrease in K_{2app}, (Table 1). The contribution of reaction (6)[37] to K_{2app} was examined, $K_2 = K_{2app}(1 + K_a[H^+])$.

$$HNO_2 \leftrightarrows NO_2^- + H^+; pK_a = 3.25 \quad (6)$$

This analysis indicates that reaction (6) has a minor effect on K_2, $K_2 = 140 \pm 30$ M^{-1}. From K_2, it can be calculated that when $[NO_2^-] = 7$ mM, the observed rate of reaction is ca. 50% of the maximum rate. Therefore, the binding of NO_2^- to Cu^+_{aq} is ca. 100 times weaker than that to CuNIR, in which $K_M = 0.074$ mM.[38]

Solutions of $NaNO_2$ were mixed with Cu^+_{aq} at a final pH of 2.20 (at this pH the nitrite is present mostly as HNO_2). Figure 4 describes $k_{obsd.}$ as a function of $[NaNO_2]$ at this acidic pH. It is apparent that there is no limiting rate (at higher pH's and the same NO_2^- concentrations a deviation from linearity is observed, as shown in Figure 1). Though

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

HNO_2 is a stronger oxidant than NO_2^-,[37] there is no reason to suggest that reaction (7) occurs.

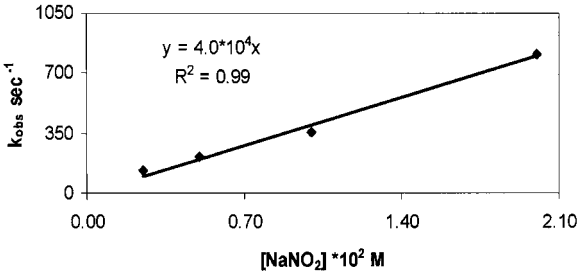

Figure 4. Dependence of $k_{obsd.}$ on $[NaNO_2]$. The experiments were performed in solutions containing 5.0×10^{-4} M Cu^+_{aq}, 0.10 M $NaClO_4$, 0.023 M NH_4^+, the final pH was 2.20, helium saturated

$$Cu^+_{aq} + HNO_2 \leftrightarrows (Cu^+HNO_2)^+ \quad (7)$$

Moreover, if $(Cu^+HNO_2)^+$ were formed its pK_a is expected to be lower than the pK_a of HNO_2. Therefore, when the pH $\geq$ 4.15, $(Cu^INO_2^-)$ is clearly the complex formed. At pH values lower than the pK_a of HNO_2, the NO_2^- concentration is low so that the apparent value for $k_{*5}K_5$ is expected to be lower at pH 2.20 than that observed at pH 4.15−5.45. The slope of the line in Figure 4 equals the apparent value of $k_{*2}K_2[H_3O^+] = 4.0 \times 10^4$, i.e. $k_{*2}K_2$ (at pH 2.20) $= 5.5 \times 10^6$ $M^{-2}sec^{-1}$ as compared to $k_{*2}K_2 = 4.6 \times 10^5 \times 140 = 6.4 \times 10^7$ $M^{-2}sec^{-1}$ at pH = 4.15−4.70. Thus, at pH 2.20 the apparent value of $k_{*2}K_2$ equals ca. 10% of that observed at pH 4.15−4.80. The nitrite concentration at pH 2.20 is ca. 10% of its concentration at pH $\geq$ 4.15. This result is in agreement with the suggested mechanism: It should be pointed out that if HNO_2 were the oxidant, a lower apparent rate is expected also at pH 2.20, as the concentration of HNO_2 is not proportional to $[H_3O^+]$ below the pK_a of HNO_2. However, the nonlinear dependence of the observed rate at pH $\geq$ 4.1 and the linear dependence at pH 2.20 on $[NO_2^-] + [HNO_2]$, proves that the active oxidant is NO_2^-.

The yield of NO from the reaction was measured by two techniques: 1. EPR, by measuring the effect of the addition of NO to 4,4,5,5-tetramethyl-2-(1-pyryl)-2-imidazoline-1-oxyl 3-oxide (PN) on the EPR spectrum. 2. Mass spectrometry. Both techniques revealed that [NO] $\geq$ 75% $[Cu^+_{aq}]$. This result demonstrates that the yield of NO is quantitative as some dioxygen always enters the samples during the handling of the solutions.

The mechanism observed here is in agreement with that observed for several other Cu^I complexes in methanol/acetonitrile.[26,28,29] However, the rate constant is considerably higher for Cu^+_{aq} than for those complexes. This observation is attributed to the stabilization of Cu^I by the ligands used in those studies, caused by an anodic shift of the redox potential of the $Cu^{II/I}$ couple. Therefore, it seemed of interest to study the mechanism and kinetics of reduction of NO_2^- by $(Cu^IL)^+$ complexes in aqueous solutions. Two complexes were studied:

1. A copper(I) complex which is a stronger reducing agent than Cu^+_{aq}. For this purpose, $(Cu^IL^1)^+$ (L^1 = 2,5,8,11-tetramethyl-2,5,8,11-tetraazadodecane, Figure 5) was chosen, $E^0(Cu^{II}L/Cu^IL^1) = 0.116$ V (vs. NHE),[39] at pH 5.0. At this pH $k[NO_2^- + (Cu^IL^1)^+] = 35 \pm 10$ $M^{-1}s^{-1}$ is obtained. The observed rate is nearly independent of $[H_3O^+]$ in the pH range 5.0−6.0. This rate is considerably higher than that obtained for Cu^+_{aq} over this pH range. The lack of dependence on $[H_3O^+]$ suggests that, in this case, H_2O acts as the proton donor, i.e. the general mechanism for the decomposition of the complex $[(Cu^IL^i)^+NO_2^-]$ is according to reaction (8).

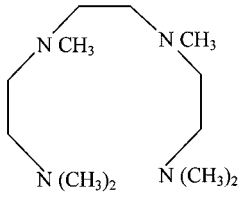

Figure 5. L^1 = 2,5,8,11-tetramethyl-2,5,8,11-tetraazadodecane

$$[(Cu^IL^i)^+NO_2^-] + H_3O^+/H_2O \rightarrow (Cu^{II}L^i)^{2+} + NO + (OH^- + H_2O)/2OH^- \quad (8)$$

From the results, which indicate that the observed rate increases linearly with $[NO_2^-]$, it can be estimated that $K = [(Cu^IL^1)^+NO_2^-)]/([(Cu^IL^1)^+][NO_2^-]) \leq 7$ M^{-1}, i.e. the ligation of NO_2^- to the complex is considerably weaker than to Cu^+_{aq}. This is probably due to steric hindrance caused by the ligand L^1, which is a very bulky ligand, or to the competition for a ligation site between a terminal tertiary amine group of L^1 and NO_2^-.

2. Copper(I) complexes which are weaker reducing agents[40,41] than Cu^+_{aq}. For this purpose, the complexes $[Cu^I(CH_3CN)_n]^+$ were chosen. These solutions contain a mixture of several species: $[Cu^+_{aq}$, $Cu^I(CH_3CN)]^+$, $[Cu^I(CH_3CN)_2]^+$, $[Cu^I(CH_3CN)_3]^+$, and the detailed composition of each solution can be calculated from the known stability constants of these complexes.[40,41] Solutions of $[Cu^I(CH_3CN)_n]^+$ 5.0×10^{-4} M were mixed with NO_2^- $[(2.5-100) \times 10^{-3}$ M) at different pH's (4.0−4.8) and different CH_3CN concentrations (0.048−0.96) M. The results demonstrate that:

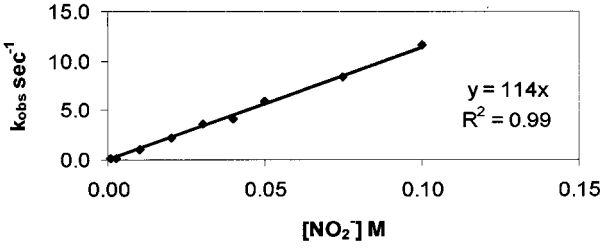

Figure 6. Dependence of $k_{obsd.}$ on $[NO_2^-]$. The experiments were performed in solutions containing 5.0×10^{-4} M Cu^+_{aq}, 0.10 M $NaClO_4$, 0.10 M acetic acid, 0.048 M CH_3CN, the final pH was 4.40, helium saturated.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a) The observed rate depends linearly on $[NO_2^-]$ at all the CH_3CN concentrations studied (for example, see Figure 6). From these results, it can be calculated that $K_{10} = [(Cu^I(CH_3CN)_nNO_2^-)]/([Cu^I(CH_3CN)_n]^+[NO_2^-]) \leq 30$ M^{-1} [reaction (9)].

$$[Cu^I(CH_3CN)_n]^+ + NO_2^- \underset{}{\overset{K_9}{\rightleftharpoons}} [Cu^I(CH_3CN)_nNO_2^-] \quad (9)$$

$$\xrightarrow{k_9} \text{products}$$

The observation that $K_9 < K_2$ is probably due to one or more of the following facts:

I. Competition between one of the CH_3CN ligands and NO_2^- for the same ligation site. II. A change of hybridization from sp to sp^3 is required for the binding of NO_2^- to $[Cu^I(CH_3CN)_2]^+$, which is the major complex present in the solution.

b) The observed rate increases linearly with $[H_3O^+]$ at all the CH_3CN concentrations studied, e.g. Figure 7. The slope of the graph equals $k_9K_9 = 4.0 \times 10^5$ $M^{-2}sec^{-1}$. $k^*_2K_2$ for the Cu^+_{aq} system equals $140 \times 4.6 \times 10^5 = 6.4 \times 10^7$ $M^{-2}sec^{-1}$, i.e. at this CH_3CN concentration, acetonitrile reduces the rate of reaction by a factor of 150.

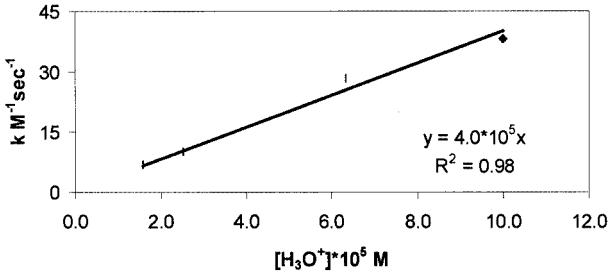

Figure 7. Dependence of k on $[H_3O^+]$. The experiments were performed in solutions containing 5.0×10^{-4} M $[Cu^I(CH_3CN)_n]^+$, 0.10 M $NaClO_4$, 0.10 M acetic acid, 0.96 M CH_3CN, helium saturated.

c) The observed rate at constant pH and $[NO_2^-]$ decreases with $[CH_3CN]$, (e.g. Figure 8).

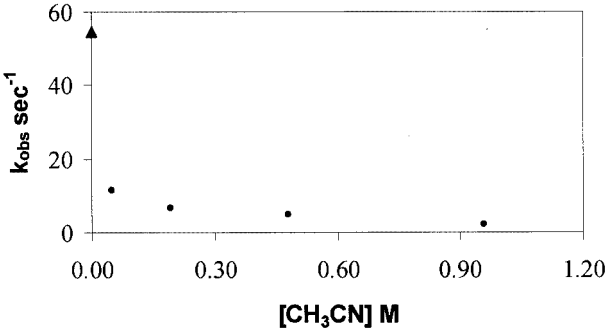

Figure 8. Dependence of k on $[CH_3CN]$. The experiments were performed in solutions containing 5.0×10^{-4} M $[Cu^I(CH_3CN)_n]^+$, 0.10 M $NaClO_4$, 0.10 M acetic acid, 0.10 M NO_2^-, helium saturated. solid triangle: result in the absence of CH_3CN, solid circles: results in presence of CH_3CN.

If Cu^+_{aq} were the only reacting species in solutions containing CH_3CN, i.e. if the rate of reaction of $[Cu^I(CH_3CN)_n]^+$ were negligible, then the expected observed rate in solutions containing 0.96 mol·dm^{-3} CH_3CN at pH 4.4 would be $k_{*2}K_2 \times [H_3O^+] \times ([Cu^+_{aq}]/[Cu^I]_T) = 140 \times 4.6 \times 10^5 \times 4 \times 10^{-5} \times (2.1 \times 10^{-9}/5.0 \times 10^{-4}) = 0.011$ $M^{-1}s^{-1}$. (Cu^+_{aq} concentration in this equation was calculated using the stability constants[40,41] of the $[Cu^I(CH_3CN)_n]^+$ complexes). However, $k_{obsd.} = 24$ $M^{-1}s^{-1}$ is obtained under these conditions. These results clearly demonstrate that the $[Cu^I(CH_3CN)_n]^+$ complexes react with NO_2^- and contribute to the observed rates of reaction. The results are not accurate enough to evaluate the rate constant of the reaction of each of the $[Cu^I(CH_3CN)_n]^+$ species accurately. However, the results (Figure 8) clearly demonstrate that the rate constants decrease with an increase in n.

Conclusions

The value of $K_2 = [(Cu^+NO_2)]/([Cu^+_{aq}][NO_2^-]) = 140 \pm 25$ M^{-1} is similar to values reported in the literature for Cu^I complexes with other ligands in organic solvents,[28,29] but higher than the values measured in this work for $[(Cu^IL^1)^+NO_2^-]$ $K \leq 7$ M^{-1} and for $[(Cu^I(CH_3CN)_n)^+NO_2^-]$, $K \leq 30$ M^{-1}. The stability constant of the $(Cu^+NO_2^-)$ complex suggests that nitrite binds to the copper via the nitrogen atom, as the stability constants of Cu^I complexes with oxo-anions are expected to be considerably lower.[42,43]

Experimental Section

Materials and Methods: $NaNO_2$, $CuSO_4$, Cu^0, NH_3, L^1 (L^1 = 2,5,8,11-tetramethyl-2,5,8,11-tetraazadodecane), acetonitrile, acetic acid, $NaClO_4$, and $HClO_4$ were purchased from Aldrich. PN [4,4,5,5-tetramethyl-2-(1-pyryl)-2-imidazoline-1-oxyl 3-oxide] was prepared according to modified procedures, along with small amounts of 4,4,5,5-tetramethyl-2-(1-pyryl)-2-imidazoline.[44] All solutions were prepared using A.R. grade chemicals and from distilled water further purified by passing through a Milli Q Millipore setup, final resistivity >10 mΩ/cm. The experiments were carried out at $[NaClO_4] = 0.1$ mol·dm^{-3}, at room temperature, 22±2 °C.

Solutions of $[Cu^I(NH_3)_2]^+$ and $(Cu^IL^i)^+$ were prepared via the conproportionation process, reaction (10). Solid copper metal was added to deaerated solutions containing $CuSO_4$ and an excess of NH_3, or L^i at the appropriate pH values.

$$Cu^0_s + (Cu^{II}L_n)^{2+}_{aq} + (2m - n)L \leftrightharpoons 2(Cu^IL_m)^+_{aq} \quad (10)$$

Cu^+_{aq} was obtained by injecting $[Cu^I(NH_3)_2]^+$ into an acetate buffer solution (acidic solution), or into an $HClO_4$ solution containing the nitrite. Under these conditions the following reactions (11) and (12) occur.

$$[Cu^I(NH_3)_2]^+ \underset{}{\overset{\text{fast}}{\rightleftharpoons}} Cu^+_{aq} + 2NH_3 \quad (11)$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$NH_3 + H^+ \underset{}{\overset{\text{fast}}{\rightleftharpoons}} NH_4^+ \quad (12)$$

Thus, at pHs considerably lower than the pK_a of NH_4^+/NH_3 all the $[Cu^{I}(NH_3)_2]^+$ is transformed into Cu^{+}_{aq} (The ligand exchange of Cu^{I} is fast[45]).

Kinetic Measurements: Stopped-flow experiments were carried out using an SX.18 Applied PhotoPhysics stopped-flow instrument that enables kinetic measurements of reactions with lifetimes ≥ 2 msec. A 05−109 Spectra Kinetics Monochromator, which enables measurements in the range of 200−700 nm, was used. The optical path was 10 mm. All the kinetic runs are the average of at least a triplicate. The error limit for the rate constants and for the equilibria constants is ±10%.

The time-dependence of the absorbances at 355 nm was observed . This wavelength is the maximum of the absorption band of NO_2^- for the reactions of Cu^{+}_{aq} and $Cu^{I}(CH_3CN)_n^+$. Alternatively, the absorbance of the band at 635 nm, the maximum of the absorption band of $(Cu^{II}L^1)^{2+}$ for the reaction of $(Cu^{I}L^1)^+$, was observed.

Electron Paramagnetic Resonance (EPR) spectra were recorded using a Bruker EMX-220 digital X-band (ν = 9.4 GHz) spectrometer equipped with a Bruker EP 4241VT temperature control system. All spectra were recorded at room temperature (T = 297 K) with the following parameters: 20.12 mW nonsaturating microwave power, 100 kHz field modulation of 0.1 mT amplitude. EPR spectra were processed using the Bruker WIN-EPR and Microcalc™ Origin™ software.

Solutions of $(Cu^{I}L)^+$, nitrite and PN were mixed producing 4,4,5,5-tetramethyl-2-(1-pyryl)-2-imidazoline (PPN), which has a completely different EPR spectrum (Figure 9) from PN (PN reacts only with NO to produce PPN).
Mass Spectra: The mass spectrometer used in this study was a Balzers Quadrupole model QMG-421 instrument, with an SEM (secondary electron multiplier) detector.

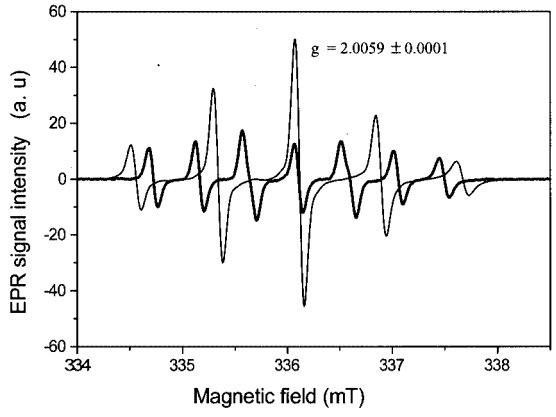

Figure 9. The EPR spectrum of PPN (bold line), formed by mixing 1:1 1.0 × 10^{-3} M $[Cu^{I}(NH_3)_2]^+$ with 5.0 × 10^{-2} M $NaNO_2$; this solution was mixed 4:1 with 1.55 × 10^{-3} M PN. The experiment was carried out in solutions containing also 0.08 M $NaClO_4$ and 0.08 M acetic acid. The EPR spectrum of PN (thin line) which does not change after mixing 1:1 2.0 × 10^{-4} M PN with 0.03 M $NaNO_2$, 0.10 M $NaClO_4$, 0.20 M acetic acid. The final pH was 4.7, the solutions were helium-saturated, ν = 9.424 GHz.

Acknowledgments

This study was supported in part by a grant from the Budgeting and Planning Committee of The Council of Higher Education. D. M. wishes to express his thanks to Mrs. Irene Evens for her ongoing interest and support.

Heterobimetallic Complexes Based on $[(Tp)Fe(CN)_3]^-$: Syntheses, Crystal Structures and Magnetic Properties

Shi Wang,[a] Jing-Lin Zuo,*[a] Hong-Cai Zhou,[b] You Song,[a] Song Gao,[c] and Xiao-Zeng You*[a]

Keywords: Chain structures / Cyanide ligands / Iron / Magnetic properties / Polynuclear complexes

With the anionic precursor $[(Tp)Fe^{III}(CN)_3]^-$ [**1**; Tp: hydrotris(pyrazolyl)borate] as a building block, two trinuclear complexes, $[(Tp)_2Fe^{III}{}_2(CN)_6Mn(CH_3OH)_4]\cdot 2CH_3OH$ (**2**), $[(Tp)_2Fe^{III}{}_2(CN)_6Ni(cyclam)]\cdot 2H_2O$ (**3**; cyclam: 1,4,8,11-tetraazacyclotetradecane) and a one-dimensional polymer, $[(Tp)Fe^{III}(CN)_3Cu(dien)]ClO_4\cdot H_2O$ (**4**; dien: diethylenetriamine), have been synthesized and structurally characterized. In complex **2**, each of the two $[(Tp)Fe(CN)_3]^-$ units binds through one of its three cyanide groups to a central $[Mn(CH_3OH)_4]^{2+}$ core. In complex **4**, a zigzag chain is formed by combining $[TpFe(CN)_3]^-$ and $[Cu(dien)]^{2+}$ fragments alternately through cyano bridges. The magnetic properties of complexes **2**–**4** have been investigated in the temperature range 2–300 K. A weak antiferromagnetic interaction between the Mn^{II} and Fe^{III} ions has been found in complex **2**. The magnetic data of **2** can be fitted with the isotropic Hamiltonian $\hat{H} = -2J(\hat{S}_1\cdot\hat{S}_2 + \hat{S}_2\cdot\hat{S}_3) - 2J'\hat{S}_1\cdot\hat{S}_3$, where J and J' are the intramolecular exchange coupling parameters between adjacent and peripheral spin carriers, respectively. This leads to values of $J = -2.19$ cm^{-1} and $g = 2.13$. The same fitting method was applied to complex **3** to give values of $J = 17.2$ cm^{-1} and $g = 2.37$, showing that there is a ferromagnetic interaction between the Fe^{III} and Ni^{II} ions. The 1-D chain of **4** is treated as alternating uniform Fe–Cu dimers with different intradimeric (J_d) and interdimeric (J_c) exchange constants, leading to $J_d = 10.9$ cm^{-1}, $J_c = 1.29$ cm^{-1} and $g = 2.54$.

Introduction

Tremendous effort has been devoted to the study of cyanide-containing metal complexes because of their unique magnetic properties, such as high-*Tc* magnetism and light- or pressure-tuning of magnetization.[1−4] Among those, low-dimensional as well as polynuclear clusters have attracted much attention since such systems can be used to investigate the intermetallic magnetic coupling quantitatively; there is no appropriate model for quantitative magnetic analysis to high-dimenisonal systems. Recently, synthetic strategies to prepare cyanide-bridged bimetallic systems by using modified cyanometalates as multidentate ligands and linkers have been developed. The following are representative examples: $[(tacn)M(CN)_3]$ ($M = Co^{3+}$, Cr^{3+}; tacn = 1,4,7-triazacyclononane),[5] $[(Me_3tacn)M(CN)_3]$ ($M = Cr^{3+}$, Mo^{3+}; Me_3tacn = *N*,*N*′,*N*′′-trimethyl-1,4,7-triazacyclononane),[6] $[(tach)M(CN)_3]$ ($M = Cr^{3+}$, Fe^{3+}, Co^{3+}; tach = 1,3,5-triaminocyclohexane),[7] $[Fe(bipy)(CN)_4]^-$, $[Fe(bipy)(CN)_4]^{2-}$ and $[Fe(phen)(CN)_4]^-$ (bipy = 2,2′-bipyridine; phen = 1,10-phenanthroline).[8,9] In an effort to extend this interesting chemistry, we chose the tailored cyanometalate precursor $(Bu_4N)[(Tp)Fe(CN)_3]$ [**1**; Tp = hydrotris(pyrazolyl)borate; Bu_4N^+ = tetrabutylammonium cation], which consists of three CN^- groups and a hydrotris(pyrazolyl)borate (Tp) ligand. The anion has recently been reported by Julve's group as its tetraphenylphosphonium salt.[10] Tp is a classical scorpionate ligand containing a C_3 axis. It has been used as a protecting group to prepare topological analogues of the P clusters of nitrogenase.[11] Compared to tacn-type ligands, Tp is sterically similar but bears a negative charge. Thus, it may direct the formation of new complexes with interesting structures and magnetic properties. Herein, we report the preparation, crystal structures and magnetic properties of two trinuclear complexes $[(Tp)_2Fe^{III}{}_2(CN)_6Mn(CH_3OH)_4]\cdot 2CH_3OH$ (**2**) and $[(Tp)_2Fe^{III}{}_2(CN)_6Ni(cyclam)]\cdot 2H_2O$ (**3**; cyclam: 1,4,8,11-tetraazacyclotetradecane), and a one-dimensional polymer $[(Tp)Fe^{III}(CN)_3Cu(dien)]ClO_4\cdot H_2O$ (**4**; dien: diethylenetriamine).

Results and Discussion

Synthesis and Spectral Features

In this paper the anionic precursor $[(Tp)Fe(CN)_3]^-$ (**1**) is used as a building block to prepare cyanide-bridged multinuclear clusters and coordination polymers. The tetrabutylammonium salt of **1** was isolated as an orange crystalline solid in 78% yield. Only one C≡N stretching vibration (2117 cm^{-1}) is observed in its IR spectrum. It is soluble in most organic solvents such as acetonitrile, acetone, methanol and DMF.

Reaction of $Mn(ClO_4)_2$ with $(Bu_4N)[(Tp)Fe^{III}(CN)_3]$ (**1**) in methanol yields the trinuclear complex $[(Tp)_2Fe^{III}{}_2(CN)_6Mn(CH_3OH)_4]\cdot 2CH_3OH$ (**2**). The occurrence of two peaks of medium intensity in the C≡N stretching region of the IR spectrum is consistent with the presence of bridging (2151 cm^{-1}) and terminal (2129 cm^{-1}) cyanide ligands. Another trinuclear complex, $[(Tp)_2Fe^{III}{}_2(CN)_6Ni(cyclam)]\cdot 2H_2O$ (**3**), was formed from the reaction of $Ni(cyclam)(ClO_4)_2$ and $(Bu_4N)[(Tp)Fe(CN)_3]$ in ethanol and water. The C≡N stretching frequencies are located at 2119 and 2157 cm^{-1}. Both complexes are soluble in some organic solvents. The solvates in both **2** and **3** can easily lose solvent upon exposure to air.

The reaction of $Cu(ClO_4)_2\cdot 6H_2O$, dien and $(Bu_4N)[(Tp)Fe(CN)_3]$ in aqueous solution leads to the formation of brown, crystalline $[(Tp)Fe^{III}(CN)_3Cu(dien)]ClO_4\cdot H_2O$ (**4**). The C≡N stretching region of the IR spectrum of **4** is consistent with the presence of bridging (a peak of medium intensity at 2157 cm^{-1}) and terminal (a weak absorption at 2131 cm^{-1}) cyanide ligands.

Crystal Structures

Selected bond lengths and angles for complexes **2**−**4** are compiled in Table 1−3.

Table 1. Selected bond lengths and angles in complex **2**

Bond lengths (Å)			
Fe(1)−N(2)	1.975(2)	Fe(1)−N(4)	1.966(2)
Fe(1)−N(6)	1.977(3)	Fe(1)−C(10)	1.931(3)

The ORTEP drawing for complex **2** is depicted in Figure 1. Complex **2** consists of a trinuclear $[\{(Tp)Fe(CN)_3\}_2Mn(CH_3OH)_4]$ cluster and two methanol solvate molecules. In this trinuclear cluster, the $[(Tp)Fe(CN)_3]^-$ unit acts as a monodentate ligand through one of its three cyanide groups toward a central $[Mn(CH_3OH)_4]^{2+}$ core. Each iron(III) ion is coordinated by three Tp nitrogen atoms and three cyanide carbon atoms, with a C_{3v} symmetry. The Fe(1)−C(cyano) bond lengths [1.915(3)−1.931(3) Å] are in good agreement with those observed in other low-spin iron(III) complexes.[8,9] The Fe−C≡N angles for both terminal [175.9(3)° and 177.9(3)°] and bridging [176.1(3)°] cyanide groups depart slightly from strict linearity. The manganese atom is six-coordinate in a

squashed octahedral geometry. Four oxygen atoms from the methanol molecules form the equatorial plane. The Mn(1)−O distances [2.198(2) and 2.1906(19) Å] are almost equivalent. Two cyanide nitrogen atoms occupy the axial positions. The Mn(1)−N(9) distance is 2.174(2) Å. The Mn(1)−N(9)≡C(12) bond angle [167.2(2)°] deviates significantly from 180°. The O(1)−Mn(1)−N(9) and O(2)−Mn(1)−N(9) bond angles are 89.72(9)° and 90.63(8)°, respectively. Non-coordinated CH_3OH molecules are inserted into the crystal spaces.

The intramolecular Fe···Mn and Fe···Fe separations are 5.193(2) and 10.386(3) Å, respectively, and the shortest intermolecular Fe···Fe, Mn···Fe, and Mn···Mn distances are 10.056(3), 8.819(5) and 10.950(3) Å, respectively.

The structure of complex **3** is very similar to that of complex **2** (Figure 2) except for the central $[Ni(cyclam)]^{2+}$ core. The Fe(1)−C(12)≡N(9) and Ni(1)−N(9)≡C(12) bond angles are 177.8(4)° and 171.5(3)°, respectively, which depart somewhat from strict linearity. The nickel atom is in an elongated octahedral environment. Four nitrogen atoms from the cyclam ligand form the equatorial plane. Two cyanide nitrogen atoms occupy the axial positions. The Ni(1)−N(9) distance is 2.096(3) Å, which is slightly longer than the average Ni−N(cyclam) bond length [2.061(3) Å].

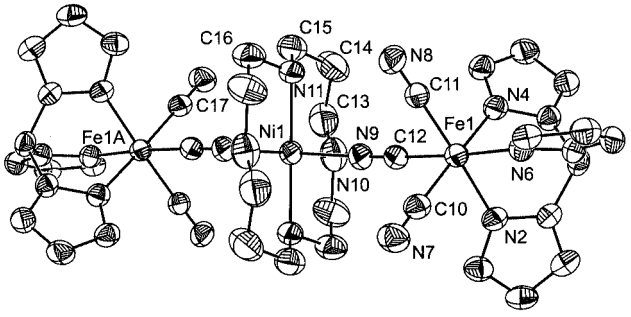

Figure 2. Molecular structure of $[(Tp)_2Fe^{III}{}_2(CN)_6Ni(cyclam)]\cdot 2H_2O$ (**3**); the solvate water molecules and hydrogen atoms have been omitted for clarity (ORTEP, 50% ellipsoids)

The intramolecular Fe···Ni and Fe···Fe separations through bridging cyanides are 5.132(2) and 10.265(5) Å, respectively. The shortest intermolecular Fe···Fe, Ni···Fe, and Ni···Ni distances are 7.622(4), 6.996(2) and 11.046(1) Å, respectively.

X-ray crystallography of **4** reveals that the structure consists of a one-dimensional cationic polymer $[\{TpFe(CN)_3\}\{Cu(dien)\}]_n^{n+}$, with free perchlorate counteranions (Figure 3 and 4). The zigzag chain is made up of a cyano-bridged alternating $[TpFe(CN)_3]^-$−$[Cu(dien)]^{2+}$ fragment. Within the chain, $[TpFe(CN)_3]^-$ uses two *cis*-CN groups to connect with two $[Cu(dien)]^{2+}$ units, while each $[Cu(dien)]^{2+}$ unit is linked to two $[TpFe(CN)_3]^-$ ions at *cis* positions. The central iron atom is six-coordinate with three Tp nitrogen atoms and three cyanide carbon atoms. The Fe(1)−N(Tp) bond lengths [1.970(2)−1.978(2) Å] are considerably shorter than those found in the high-spin iron(III) complex $[Fe(Tp)Cl_3]^-$ [2.152(4)−2.175(5) Å].[12] The Fe−C≡N angles of the bridging cyanide ligands [170.7(3)° and 178.9(3)°] and of the terminal cyanide groups [176.0(3)°] depart somewhat from strict linearity. The Cu^{II} center adopts a distorted square-pyramidal geometry, where one $[TpFe(CN)_3]^-$ unit is bound to the basal site [Cu(1)−N(4), 1.978(3) Å] and the other is bound to the elongated apical site [Cu(1)#2−N(11), 2.443(3) Å] [#2: x, $-y + 1/2$, $z - 1/2$]. The remaining three basal sites are occupied by the dien ligand, with an average Cu−N bond length of 2.000(3) Å. The value of the Cu(1)−N(4)≡C(10) bond angle is 170.4(3)°. However, the Cu(1)#2−N(11)≡C(15) bond angle is 138.1(3)°. The Fe···Cu separations within the chain are 5.040(2) Å for Fe(1)···Cu(1) and 5.062(2) Å for Fe(1)···Cu(1)#2. The shortest interchain Fe···Fe, Cu···Cu and Fe···Cu distances are 8.169(2), 13.345(2) and 11.062(4) Å, respectively.

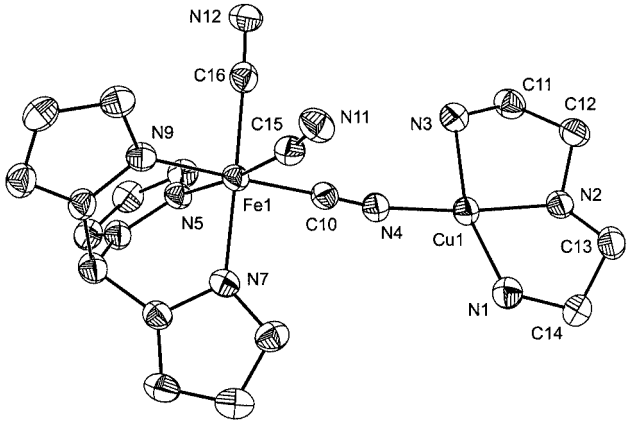

Figure 3. Molecular structure of $[(Tp)Fe^{III}(CN)_3Cu(dien)]ClO_4\cdot H_2O$ (**4**); the solvate water molecule, perchlorate and hydrogen atoms have been omitted for clarity (ORTEP, 50% ellipsoids)

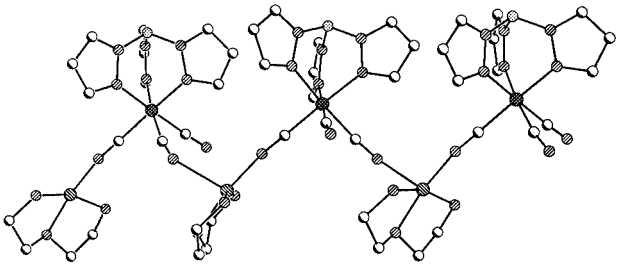

Figure 4. Structure of the one-dimensional chain of **4** running parallel to the *c* axis

Magnetic Properties

The temperature dependence of $\chi_M T$ for complex **2** (χ_M being the magnetic susceptibility per Fe_2Mn unit) is shown in Figure 5. The value of $\chi_M T$ at room temperature is 5.74 emu·K·mol^{-1} (6.78 μ_B). This value is consistent with the presence of a high-spin Mn^{II} atom and two low-spin Fe^{III} atoms magnetically isolated. As the temperature is lowered, $\chi_M T$ decreases steadily until it reaches a value of 1.03 emu·K·mol^{-1} at 2.0 K, indicating a weak antiferromagnetic interaction between the Mn^{II} and Fe^{III} ions.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

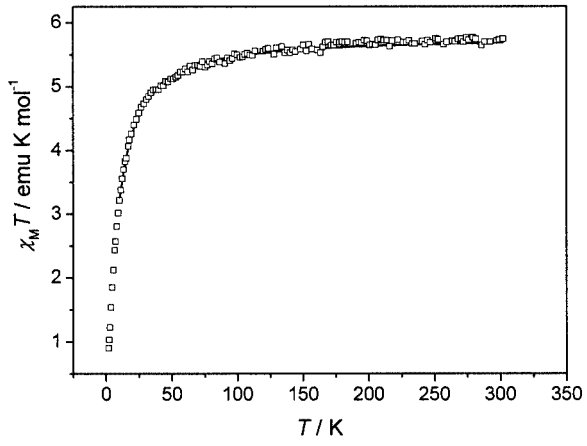

Figure 5. Plot of temperature dependence of $\chi_M T$ measured at 30 kOe field for **2**; the solid line represents the best-fit curve from 10 K to 300 K

The magnetic data has been fitted into the isotropic Hamiltonian:

$$\hat{H} = -2J\cdot(\hat{S}_1\cdot\hat{S}_2 + \hat{S}_2\cdot\hat{S}_3) - 2J'\cdot\hat{S}_1\cdot\hat{S}_3 \quad (1)$$

where $\hat{S}_1$, $\hat{S}_2$ and $\hat{S}_3$ are the spin operators of iron(III), manganese(II) and iron(III), respectively; J and J' are the intramolecular exchange coupling parameters between adjacent and peripheral spin carriers, respectively. Because the two iron(III) ions in the iron(III)-manganese(II)-iron(III) cluster are far apart, the quality of the fit does not depend on J', and hence the fit with $J' = 0$ has been used. The theoretical expression of the magnetic susceptibility of the Fe^{III}-Mn^{II}-Fe^{III} unit ($S_1 = S_3 = 1/2$, $S_2 = 5/2$) is:

$$\chi_M = Ng^2\beta^2/4kT(A/B) \quad (2)$$

where $A = 35 + 10\exp(-7J/kT) + 35\exp(-2J/kT) + 84\exp(5J/kT)$ and $B = 3 + 2\exp(-7J/kT) + 3\exp(-2J/kT) + 4\exp(5J/kT)$. The best fit to the experimental data above 10 K gives $J = -2.19$ cm^{-1} and $g = 2.13$. The agreement factor $R = \Sigma[(\chi_M T)_{obsd} - (\chi_M T)_{cald}]^2/\Sigma[(\chi_M T)_{obsd}]^2$ is 7.7×10^{-5}, which indicates a good agreement, as shown in Figure 5. The J value can be compared with the value of -0.9 cm^{-1} observed in another centrosymmetric Fe^{III}-Mn^{II}-Fe^{III} trinuclear complex.[9b]

The magnetic centers in complex **3** have similar linkages to complex **2**, but they show very different magnetic behaviors due to the replacement of the Mn^{II} ion in **2** by the Ni^{II} ion in **3** (Figure 6). For complex **3**, the value of $\chi_M T$ at room temperature is 2.70 emu·K·mol^{-1} (4.65 μ_B), which is higher than the expected spin-only value of 1.75 emu·K·mol^{-1} per Fe_2Ni unit ($g_{Fe} = g_{Ni} = 2$, $S_{Fe} = 1/2$ and $S_{Ni} = 1$), indicating a possible ferromagnetic coupling between the Fe^{III} and Ni^{II} centers. When the temperature is lowered, the $\chi_M T$ product increases up to a maximum value of 5.03 emu·K·mol^{-1} at 6.0 K and then decreases abruptly below this temperature. This indicates that the ferromagnetic interaction between the metal ions dominates the magnetic properties in this system, which is in agreement with the field dependence of the magnetization (the saturation magnetization $Ms = 4.65\ N\beta$, see Figure 7).

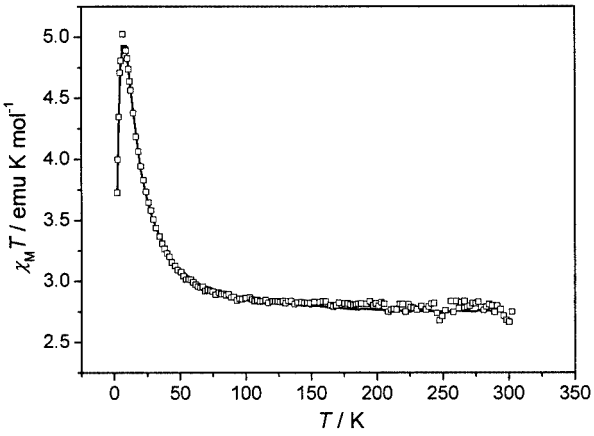

Figure 6. Plot of temperature dependence of $\chi_M T$ measured at 10 kOe field for **3**; the solid line represents the best-fit curve

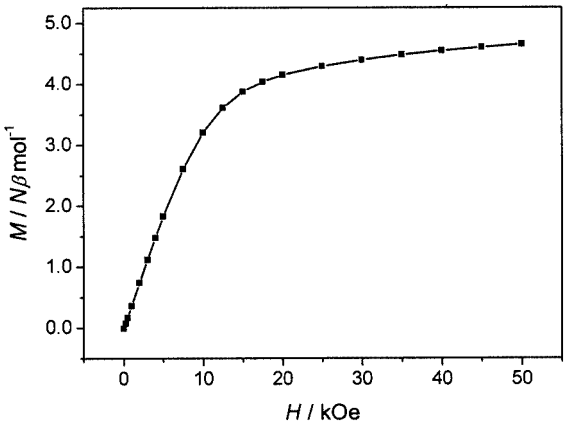

Figure 7. Field dependence of magnetization of complex **3** at 1.85 K

The same fitting method as complex **2** is suitable for the magnetic properties of complex **3**, except that $S_2 = 1$ (for Ni^{II} ion); the theoretical expression of the magnetic susceptibility is:

$$\chi_M = 2Ng^2\beta^2/kT(A/B) \quad (3)$$

where $A = 1 + 5\exp(2J/kT) + \exp(-2J/kT)$ and $B = 3 + 5\exp(2J/kT) + 3\exp(-2J/kT) + \exp(-4J/kT)$. The best fit to the experimental data in the whole temperature range gives $J = 17.2$ cm^{-1} and $g = 2.37$. The agreement factor $R = \Sigma[(\chi_M T)_{obsd} - (\chi_M T)_{cald}]^2/\Sigma[(\chi_M T)_{obsd}]^2$ is 9.2×10^{-4} (Figure 6).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The magnetic behavior of complex **4** (χ_M being the magnetic susceptibility per FeCu unit) is shown in Figure 8. $\chi_M T$ at room temperature is 1.21 emu·K·mol^{-1} (3.11 μ_B), a value expected for a low-spin iron(III) atom and a copper(II) atom magnetically isolated. It increases continuously on cooling, reaching a maximum value of 2.62 emu·K·mol^{-1} at 3 K, and then decreases to 2.33 emu·K·mol^{-1} at 2 K. This curve is in agreement with a ferromagnetic coupling between the Fe^{III} (S = 1/2) and Cu^{II} (S = 1/2) ions. The susceptibility data per FeCu (unit) can be fitted by a Curie−Weiss law $\chi_M = C/(T - \theta)$ in the temperature range 50−300 K, giving a Curie constant C of 1.20 emu·K·mol^{-1}, and a Weiss constant θ, of +6.16 K. The C value corresponds to one Fe^{III} (S = 1/2) ion and one Cu^{II} (S = 1/2) ion magnetically isolated. The positive value of θ indicates a ferromagnetic interaction between the Fe^{III} and Cu^{II} ions. On the basis of the crystal data, complex **4** has a 1-D zigzag chain structure and, furthermore, the Fe−CN−Cu linkages are unequal. Therefore, when the Heisenberg−Dirac−Van Vleck dimer model ($H = -2JS_1S_2$) or the 1-D uniform chain model[13] was used in this magnetic system, no rational result was obtained. To get a set of useful fitting results to interpret the magnetic exchange between the magnetic centers, the theoretical approach and treatment reported by Rojo and Kou[14] are suitable here. Thus, the 1-D chain can be considered as alternating uniform Fe−Cu dimers with different intradimeric and interdimeric exchange constants. Therefore,

$$\chi_d = \frac{2Ng^2\beta^2}{kT}\frac{1}{3+\exp(-2J_d/kT)} \quad (4)$$

$$\chi_d = \frac{Ng^2\beta^2}{3kT}S_d(S_d+1) \quad (5)$$

$$\chi_M = \chi_{chain} = \frac{Ng^2\beta^2}{3kT}\frac{1+u}{1-u}S_d(S_d+1) \quad (6)$$

where $u = \coth[J_cS_d(S_d + 1)/kT] - kT/[J_cS_d(S_d + 1)]$ and J_d and J_c are intradimeric and interdimeric exchange constants, respectively.

The best fit to the experimental data above 5 K gives J_d = 10.9 cm^{-1}, J_c = 1.29 cm^{-1} and g = 2.54. The agreement factor $R = \Sigma[(\chi_M T)_{obsd} - (\chi_M T)_{cald}]^2/\Sigma[(\chi_M T)_{obsd}]^2$ is 6.3 × 10^{-4} (Figure 8). The Fe^{III}-Cu^{II} exchange coupling parameter is comparable to that of the cyano-bridged cyclic tetranuclear complex $[Fe^{III}_2Cu^{II}_2(\mu\text{-}CN)_4(bipy)_6](PF_6)_6\cdot 4CH_3CN\cdot 2CHCl_3$ (J = 6.3 cm^{-1}).[9a] The small J_c value might be attributed to the more bent Cu(1)#2−N(11)≡C(15) bond angle [138.1(3)°], which has an unfavorable effect on the magnetic coupling.

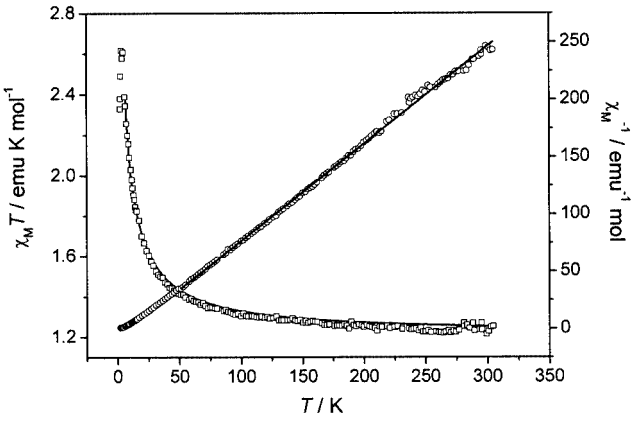

Figure 8. Plots of temperature dependence of $\chi_M T$ (open squares) and χ_M^{-1} (open circles) measured at 10 kOe field for **4**; the solid lines represent the best-fit curve from 5 K to 300 K for $\chi_M T$ and the best fit to the Curie−Weiss law from 50 K to 300 K for χ_M^{-1}

Experimental Section

Materials and Physical Measurements: $Ni(cyclam)(ClO_4)_2$ was synthesized as described previously.[15] The amine ligands diethylenetriamine (dien), 1,4,8,11-tetraazacyclotetradecane (cyclam) and all other reagents were purchased from standard sources and used as received. The IR spectra were recorded on a Nicolet-170SX FT-IR spectrophotometer with KBr pellets in the range 4000−400 cm^{-1}. Elemental analyses for C, H and N were performed on a Perkin-Elmer 240C analyzer. Variable-temperature magnetic susceptibility date were collected using a Quantum Design MPMS SQUID magnetometer. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal's Tables).[16]

Safety Note: Although we have experienced no problem with the compounds reported in this work, perchlorate salts with organic ligands are often explosive and should be handled with great caution.

$[(Tp)_2Fe^{III}_2(CN)_6Mn(CH_3OH)_4]\cdot 2CH_3OH$ (2): Solid $Mn(ClO_4)_2\cdot 6H_2O$ (36 mg, 0.1 mmol) was added to a methanol solution (5 mL) of $(Bu_4N)[(Tp)Fe(CN)_3]$ (59 mg, 0.1 mmol). After slow evaporation of the resulting solution, red plate-like crystals **2** were formed and collected by filtration. Yield: 75%. $C_{28}H_{36}B_2Fe_2MnN_{18}O_4$: calcd. C 38.35, H 4.14, N 28.75; found C 38.61, H 4.45, N 28.64. IR (KBr): $\tilde{\nu}$ = 2129 (ν_{CN}) and 2151 cm^{-1} (ν_{CN}).

$[(Tp)_2Fe^{III}_2(CN)_6Ni(cyclam)]\cdot 2H_2O$ (3): A mixture of ethanol and water (1:1, 10 mL) was gently layered on top of a solution of $Ni(cyclam)(ClO_4)_2$ (91 mg, 0.2 mmol) in water (3 mL). A solution of $(Bu_4N)[(Tp)Fe(CN)_3]$ (118 mg, 0.2 mmol) in ethanol (2 mL) was added carefully as a third layer. Orange crystals of **3** were obtained after one week, washed with ethanol and diethyl ether, and dried in air. Yield: 60%. $C_{34}H_{46}B_2Fe_2N_{22}NiO$: calcd. C 42.06, H 4.78, N 31.74; found C 41.67, H 5.07, N 31.14. IR (KBr): $\tilde{\nu}$ = 2119 (ν_{CN}) and 2157 cm^{-1} (ν_{CN}).

$[(Tp)Fe^{III}(CN)_3Cu(dien)]ClO_4\cdot H_2O$ (4): A stock solution (0.075 M, 2 mL) of dien was added to an aqueous solution of

$Cu(ClO_4)_2 \cdot 6H_2O$ (4 mL, 56 mg, 0.15 mmol). A methanol solution of $(Bu_4N)[(Tp)Fe(CN)_3]$ (5 mL, 89 mg, 0.15 mmol) was added to this dark blue solution. Slow evaporation of the resulting solution in air afforded brown crystals. Yield: 80%. $C_{16}H_{25}BClCuFeN_{12}O_5$: calcd. C 30.45, H 3.99, N 26.63; found C 30.74, H 4.06, N 26.35. IR: (KBr): $\tilde{\nu}$ = 2131 (ν_{CN}) and 2157 cm^{-1} (ν_{CN}).

X-ray Crystallography: The structures of complexes **2**−**4** were determined. Suitable crystals were obtained by slow evaporation of the preparative reaction solution. Crystals were mounted in Paratone oil and placed in the dinitrogen cold stream of a Bruker Apex D8 diffractometer equipped with a 4 K CCD area detector for complex **2** or a Bruker-AXS P3 diffractometer equipped with a 1 K CCD area detector for complex **4**. Cell parameters were retrieved using SMART software and refined using SAINT on all observed reflections. Data were collected using the following strategy: 606 frames of 0.3° in ω with φ = 0°, 435 frames of 0.3° in ω with φ = 90°, and 235 frames of 0.3° in ω with φ = 180°. An additional 50 frames of 0.3° in ω with φ = 0° were collected to allow for decay correction. The highly redundant data sets were reduced using SAINT and corrected for Lorentz and polarization effects. Absorption corrections were applied using SADABS supplied by Bruker. Structures were solved by direct methods using the program SHELXL-97. The positions of metal atoms and their first coordination spheres were located from direct-methods *E*-maps; other non-hydrogen atoms were found in alternating difference Fourier syntheses and least-squares refinement cycles and, during the final cycles, refined anisotropically. Hydrogen atoms were placed in calculated positions and refined as riding atoms with a uniform value of U_{iso}. Crystallographic parameters and agreement factors are contained in Table 4.

CCDC-231294 (for **2**), -231295 (for **3**) and -231296 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: +44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterisation of Coordination Polymers of Cu^{II} and Zn^{II} with 1,3-Bis(1,2,3,4-tetrazol-2-yl)propane − Rotational Freedom of the Donor Group Favours Structural Diversification

Robert Bronisz[a]

Keywords: Coordination polymers / Copper / Flexibility / N ligands / Zinc

The novel bidentate ligand 1,3-bis(1,2,3,4-tetrazol-2-yl)propane (pbtz), which possesses a flexible spacer, was synthesised in order to investigate the influence of the flexibility of ligand molecules on the architecture of coordination polymers. For that purpose the reactions between pbtz and $M(ClO_4)_2 \cdot 6H_2O$ salts (M = Cu^{II} and Zn^{II}) were performed. The complexes $[\{Cu(pbtz)_3\}(ClO_4)_2]_\infty$ and $[\{Zn(pbtz)_3\}(ClO_4)_2 \cdot 2EtOH]_\infty$ were characterised by IR and UV/Vis spectroscopy and their crystal structures were determined by single-crystal X-ray diffraction measurements. In both compounds the pbtz ligand molecules act as N4,N4′ connectors bridging the central atoms, and the 2-substituted tetrazole rings coordinate in a monodentate fashion to the central atoms forming M(tetrazole)$_6$ cores. $[\{Cu(pbtz)_3\}(ClO_4)_2]_\infty$ was isolated as a 1D coordination polymer. The copper(II) ions are triply bridged by ligand molecules, leading to the formation of infinite 1D chains. A highly unusual manner of bridging, with the tethering of two neighbouring central atoms by the same kind of ligand molecules, although possessing different conformations, is observed. In $[\{Zn(pbtz)_3\}(ClO_4)_2 \cdot 2EtOH]_\infty$ the six-coordinate zinc(II) ions, which are bridged by single ligand molecules, serve as topological nodes, leading to the formation of a 3D α-polonium-type network. The crystal structure of the Zn^{II} complex contains only one such net solvated by ethanol molecules. A conformational analysis of the ligand molecules in both compounds demonstrates that the flexibility of the pbtz and the ability of the tetrazole rings in particular to adopt various, relative orientations is responsible for the diversity of the architectures of the obtained complexes.

Introduction

The schematic method created by Wells[1] and developed further by Robson[2] for the description of coordination polymers characterises such materials as a self-repeating system of nodes (central atoms) and rods (ligand molecules). This approach assumes the presence of a coordination bond, which is much stronger than other contacts such as hydrogen bonds or π−π interactions, and points to the importance of the coordination geometry of the central atom. In effect, the presence of coordination bonds means that the coordination geometry of the central atom can be propagated throughout the network. This indicates the possibility of a more reasoned approach to the synthesis of new materials with a desired topology and dimensionality, especially in the case of the application of rigid rod-like molecules as ligands.[3,4] In reality, however, this simple way of forecasting the architecture of the coordination networks is strongly perturbed both by the ability of the metal ions to form complexes with heteroleptic surrounded central atoms and by the influence of the angularity of the rigid ligand molecules,[5−10] *cis*/*trans* isomerism,[11] and the conformational freedom of ligands possessing a flexible spacer.[12−16] The flexibility of the ligand molecules usually leads to great structural diversification of the products, including the formation of supramolecular isomers.[17]

The length of the ligand molecule affects the distance between the bridged central atoms. This separation implies either the formation of voids, which can be filled by solvent molecules, or interpenetrated structures.[18−20] In bis(4-pyridyl)alkanes the position of the nitrogen donor atom means that although various configurations can be adopted by the pyridyl rings in relation to the alkyl spacer, the intraligand N···N′ distance depends only on the conformation of the alkyl spacer.[14] A more complicated situation arises in the case of five-membered polyazole rings as the donor groups. Conjugated bis(polyazoles) can act as linear or angular connectors, and in such a situation the distance between the central atoms bridged by common ligand molecules depends on the relative orientation of the polyazole rings.[21−29] The incorporation of an alkyl spacer tethering imidazole,[30−34] pyrazole,[35] benzimidazole,[36,37] triazole,[38−45] benzotriazole,[37,46,47] or tetrazole[48−57] moieties causes a significant increase of the flexibility of the ligand molecule, thus allowing the formation of a wide range of coordination polymer architectures.

Among the five-membered polyazoles, the coordination chemistry of 2-substituted tetrazoles is very much under-

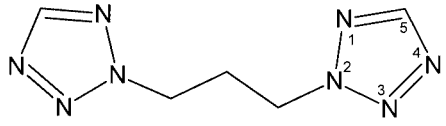
developed, especially in relation to their 1-substituted isomers.[47−54,58−63] In the majority of 2-substituted tetrazole complexes the polyazole ring coordinates to the metal ion in a monodentate fashion through the N4 nitrogen atom.[55,56,64,65] This ability to form a coordination bond through the *exo*-nitrogen atom of the tetrazole ring enables the use of this donor group for the preparation of nonchelating bi- and polypodal ligands appropriate for the construction of coordination polymers. Indeed, the results of recently started investigations of a new family of ligands, namely 1,ω-bis(1,2,3,4-tetrazol-2-yl)alkanes, point to their usefulness in the preparation of coordination networks with various dimensionalities and topologies. Thus, 1,2-bis(1,2,3,4-tetrazol-2-yl)ethane (ebtz) reacts with Zn^{II} to form a triple-stranded 1D linear chain,[55] whereas the complexes obtained from the reaction of Cu^{II} with 1,4-bis(1,2,3,4-tetrazol-2-yl)butane (bbtz) were isolated, depending on the reaction conditions, as either 2D or 3D networks.[56] Naturally, in such a situation an intriguing question arises concerning the architecture of the coordination polymers in the case of the application of an intermediate-length spacer tethering the tetrazole rings, namely 1,3-propylene; therefore a new flexible ligand 1,3-bis(1,2,3,4-tetrazol-2-yl)propane (pbtz; Scheme 1) was synthesised.



Scheme 1

Taking into account the tendency to structural diversification of the products in the case of the application of flexible ligand molecules, the investigation of the coordination abilities of pbtz was focused first of all on octahedrally coordinating metal ions, aiming especially at complexes with a homoleptic ligand environment. In this paper the synthesis of the pbtz ligand and the coordination polymers obtained from the reaction of pbtz with perchlorate salts of Cu^{II} and Zn^{II} is reported in detail. The results of spectroscopic investigations and single-crystal X-ray diffraction studies of 1D and 3D polynuclear complexes are also presented.

Results and Discussion

Synthesis, Properties and Spectroscopic Characterisation

The new flexible ligand 1,3-bis(1,2,3,4-tetrazol-2-yl)propane (**1**) was synthesised by alkylation of sodium tetrazolate with 1,3-dibromopropane, according to the method described previously for other members of this family of ligands.[55,56] Because of the competitive process of formation of 1-substituted tetrazoles in this synthetic route[66−68] a low yield of pbtz was also obtained in this case due to the formation of other bis(tetrazole) ligands, namely 1,3-bis(1,2,3,4-tetrazol-1-yl)propane and 1-(1,2,3,4-tetrazol-1-yl)-3-(1,2,3,4-tetrazol-2-yl)propane.[54] The pbtz ligand was isolated as a colourless liquid. It is completely miscible in polar solvents such as methanol, acetonitrile, and dichloromethane, although it is significantly less soluble in CCl_4 and is completely insoluble in aliphatic hydrocarbons; it is stable during storage at room temperature.

The results of elemental analysis indicated that the reactions between pbtz and $M(ClO_4)_2{\cdot}6H_2O$ salts (M = Cu^{II}, Zn^{II}), performed in a 3:1 ligand/metal stoichiometry, afforded complexes with formula $[\{Cu(pbtz)_3\}(ClO_4)_2]_\infty$ (**2**) and $[\{Zn(pbtz)_3\}(ClO_4)_2{\cdot}2EtOH]_\infty$ (**3**).

The synthesis of **2** leads first of all to the formation of small amounts of a light-blue polycrystalline solid. After about 10 d, crystals of **2** started to grow accompanied by the partial disappearance of the products precipitated during the first stage of the synthesis. Because only very small amounts of these polycrystalline products were formed, and due to their lack of homogeneity, it was not possible to characterise them. Therefore, only the light-blue crystals of complex **2** were isolated and characterised. The synthesis of the Cu^{II} complex depends strongly on the ethanol volume, the presence of water in the solvent, and the growing time of the crystals, and therefore this influences both the yield of product **2** and amount of the polycrystalline mixture formed.

The preparation of the zinc(II) complex was successful only in absolute ethanol; the addition of water prevents formation of the product. Under these reaction conditions only the formation of complex **3** was observed. In contrast to **2**, the zinc(II) complex is unstable during storage in air, and a few days after removal from the mother liquor crystals of **3** become cloudy.

The IR spectrum of pbtz is characteristic of 2-alkyltetrazoles.[69] The formation of a coordination bond through the N4 nitrogen atom of the tetrazole ring involves changes in the bands that are composed from combinations of the vibrations of the tetrazole ring components. The characteristic narrow band located at 3141 cm^{-1} and assigned to $\nu(C_{ring}-H)$ stretching vibrations in **1** is shifted to higher frequencies by 10 cm^{-1} and 6 cm^{-1} for complexes **2** and **3**, respectively. The bands attributed to the stretching vibrations of the N=N (1450 cm^{-1}), C=N (1360 cm^{-1}) and N−N (1290 cm^{-1}) bonds in the IR spectrum of the free pbtz ligand are also shifted to higher wavenumbers after complexation. These changes are in agreement with those observed for $[Cu(2\text{-alkyltetrazole})_2X_2]$ (X = Cl^-, SCN^-)[70] and complexes of Zn^{II} and Cu^{II} with ebtz[55] and bbtz[56] ligands. In contrast to **2**, the broad, intense band located at 3393 cm^{-1} observed for compound **3** confirms the presence of alcohol molecules in the crystal lattice of the Zn^{II} complex. The presence of nonsplit, strong absorption bands at 1094 and 624 cm^{-1} for **2** and 1090 and 626 cm^{-1} for **3** points to a lack of strong deviation of the perchlorate anions from tetrahedral symmetry.[71]

The electronic spectrum of complex **2** shows a d-d transition at 15400 cm^{-1} with a shoulder at 9800 cm^{-1}. These values are characteristic of square-planar CuN_4 or distorted octahedral CuN_4X_2 (X = N, O) chromophores[72] and are

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

similar to those found for mononuclear complexes of 1-alkyltetrazoles, such as $[Cu(1\text{-alkyltetrazole})_6](BF_4)_2$.[73]

Structural Studies

Description of the Crystal Structure of 2

The structure of **2** is depicted in Figure 1 together with the labelling scheme of the atoms. The Cu^{II} ion environment is formed by six 2-substituted tetrazole rings coordinating monodentately through their N4 nitrogen atoms. The four nitrogen atoms forming an equatorial plane are placed at distances of 1.993(2) and 2.061(2) Å. The distance to both axially located nitrogen atoms is equal to 2.414(2) Å. The N−Cu−N angles are close to 90°, ranging from 88.36(6) to 91.64(6)°. This coordination geometry of the elongated octahedron is typical for CuN_6 chromophores distorted by the Jahn−Teller effect and is similar to those found for other complexes of both 2-substituted[56] and 1-substituted tetrazoles.[47,60]

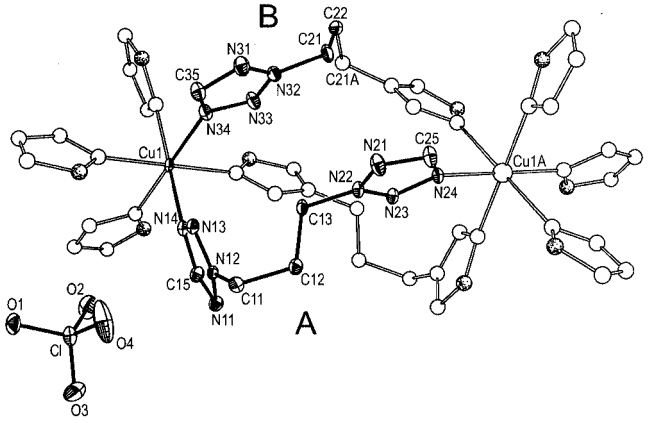


Figure 1. Coordination geometry around Cu^{II} in **2** and labelling scheme of atoms (50% probability displacement ellipsoids); hydrogen atoms are omitted for clarity; selected torsion angles [°] for ligand molecule **A**: N11−N12−C11−C12 86.0(2), N12−C11−C12−C13 54.2(2), C11−C12−C13−N22 172.6(2), N21−N22−C13−C12 −91.2(2) (*TG* conformation); for ligand molecule **B**: N31−N32−C21−C22 −132.6(2), N32−C21−C22−C21a −75.9(2) (*GG′* conformation); atom C21A generated by symmetry operation $-x, y, -z + 3/2$

Each molecule of pbtz acts as an N4,N4′ bridging ligand and three molecules of pbtz simultaneously link two neighbouring copper(II) ions. This bridging propagates along the *c* axis and leads to the formation of an infinite chain (Figure 2a). In the case of 1,3-bis(polyazolyl)propane ligands a similar motif of a triple-stranded infinite chain has been found for complexes of Fe^{II} and Cu^{II} with 1,3-bis(1,2,3,4-tetrazol-1-yl)propane.[54] Among polynuclear complexes based on 1,ω-bis(polyazolyl) ligands possessing an alkyl spacer other than 1,3-propylene, this type of bridging of the metal atoms has been observed for complexes of 1,1-bis(1,2,3,4-tetrazol-2-yl)methane,[74] 1,2-bis(1,2,3,4-tetrazol-2-yl)ethane,[55] 1,2-bis(1,2,3,4-tetrazol-1-yl)ethane[47,49] and 1,2-bis(1,2,3,4-tetrazol-1-yl)propane.[50] In **2** the copper atoms linked by common ligand molecules are separated by a distance of 9.001(1) Å while the shortest distance between the copper atoms from neighbouring chains is 8.950(1) Å. These data clearly show that in relation to 1D coordination polymers based on bis(tetrazolyl)ethane ligands[47,49,50,55] an elongation of the spacer in pbtz results in an increase of the metal−metal separation within the polymeric unit of **2** by 1.6−2.3 Å.

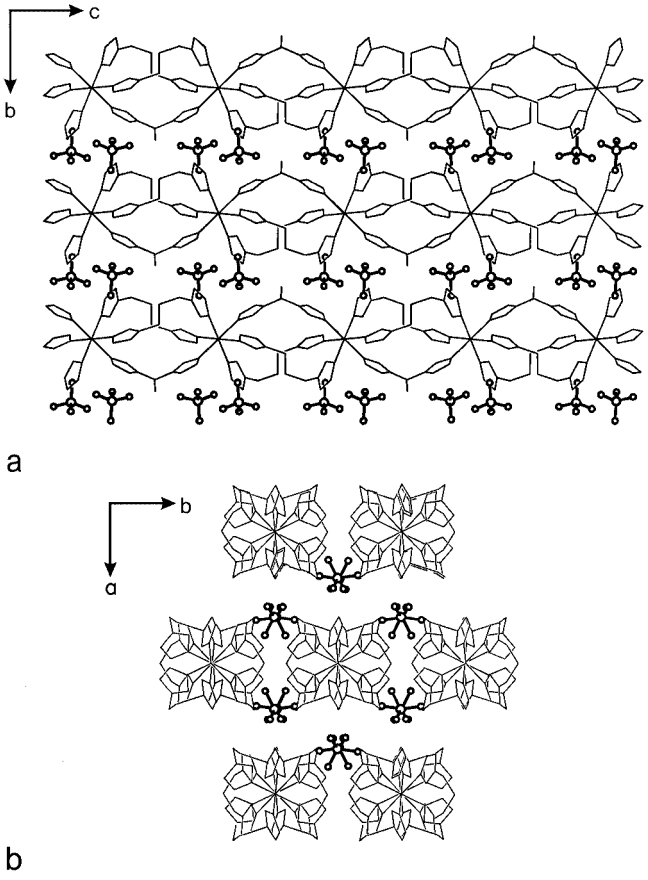

Figure 2. Projection of the structure of **2** (a) along the *a* axis and (b) along the *c* axis; hydrogen atoms are omitted for clarity

An unusual feature of the triple-stranded bridge in **2** is the presence of ligand molecules with two different conformations that simultaneously tether the same two central atoms. In this compound two crystallographically related ligand molecules adopt *TG* conformations whereas the third molecule of pbtz adopts a *GG′* conformation. A comparison of the torsion angles for both types of pbtz ligands shows that a change of the spacer conformation in ligand **A** is accompanied by rotation of the tetrazole ring, which leads to an adjustment of the intramolecular N4···N4′ distance relative to that in ligand **B**. Hence, despite differences between the conformations of the pbtz molecules the N4···N4′ distances are similar and are equal to 7.015(2) Å and 6.827(3) Å for molecules adopting the *TG* and *GG′* conformations, respectively. This behaviour, observed here for the first time for complexes based on alkylbis(polyazole) ligands, demonstrates a fundamental difference of the properties of the pbtz ligand in relation to those of 1,3-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bis(pyridyl-4-yl)propane — the distance between the metal centers depends only on the alkyl spacer conformation.[14]

The architecture of **2** enforces a localisation of the perchlorate ions in the channels between the polymeric chains (Figure 2b). The perchlorate ions do not form any coordination bonds with the copper(II) ions. However, they are engaged in the formation of C15−H15···O2(Cl) ($-x$, $-y + 1$, $-z + 2$) and C25−H25···O4(Cl) ($-x + 1/2$, $y + 1/2$, $-z + 3/2$) contacts. Direct C25−H25···N13 (x, $-y + 2$, $z - 1/2$) contacts are also observed between the polymeric chains. As a result no voids are accessible for the incorporation of solvent molecules.

Description of the Crystal Structure of 3

In **3** there are two crystallographically independent zinc(II) ions. The coordination environments of both central atoms are similar and consist of six nitrogen atoms from monodentate 2-substituted tetrazole moieties (Figure 3). There are two sets of metal−ligand bond lengths for Zn1−N [2.150(3) and 2.172(3) Å], whereas for the second crystallographically independent zinc atom the Zn2−N distances are practically the same, ranging from 2.163(3) to 2.166(3) Å. The values of the N−Zn−N angles vary from 87.0(1) to 92.2(1)° for Zn1 and from 88.8(1) to 90.9(1)° for Zn2, indicating a significantly larger rhombic distortion of the coordination environment in the case of the Zn1 atom, consisting in this case of a compression of the coordination octahedron along the threefold axis in the c direction. The coordination geometry, especially in the case of the Zn1 atom, is similar to that found for Zn^{II} in the 1D coordination polymer $[\{Zn(ebtz)_3\}(ClO_4)_2]_\infty$.[55]

The pbtz molecule acts as an N4,N4′ bridging ligand. In this case, contrary to **2**, six pbtz molecules are coordinated to one central atom and two central atoms are bridged only by a single ligand molecule. This bridging fashion of the adjacent zinc atoms spreads in the three noncoplanar directions, leading to the formation of a 3D coordination polymer. In this way an octahedral network composed of distorted rhombohedral "boxes" is formed (Figure 4). The topology of the network in **3** originates from the coordination symmetry of the zinc atoms. However, differences in the relative orientations of the neighbouring octahedra mean that the coordination bond directions do not determine the direction of the propagation of the network. In spite of this the flexibility of the pbtz molecules enables a bridging of the central atoms, which are separated by distances of 10.666(1) and 10.706(1) Å. In comparison with octahedral networks based on butylbis(polyazole) ligands, this fitting of the geometry of the pbtz molecules to the localisation of the coordination sites of the neighbouring central atoms involves a significant shortening of the appropriate M···M distances by about 2.4−3.6 Å.[33,34,52,54] As a consequence, such a large decrease of the distances between the central atoms causes a lack of free space accessible for the interpenetration, leading, in the case of the 1,3-propylene spacer, to the formation of a coordination polymer composed from only one octahedral network. Known α-

polonium-type 3D systems based on alkylbis(polyazole) ligands contain four or more methylene groups in the alkyl spacer and they are composed from two[33,34,51] or three[52,54] 3D interpenetrated nets. Compound **3** therefore represents the first example of a non-interpenetrated 3D α-polonium-type system based on a flexible bis(polyazole) ligand.

The transition from compound **2** (1D net) to compound **3** (3D net) involves an increase of the number of pbtz molecules possessing the opposite localisation of the nitrogen donor atoms. This is expressed by an increase of the angles between the nitrogen−metal bonds (for central atoms bridged by common ligand molecule) from about 60 to 110°. This corresponds to the change of character of the pbtz molecules from angular (in **2**) to more linear (in **3**) connectors. In consequence, the distances between the zinc atoms separated by common ligand molecules in **3** are about 1.7 Å greater than the analogous Cu···Cu distance in **2**. Naturally, this large separation of the metal atoms in **3** explains the lack of bridging ligand molecules possessing a *GG′* conformation. The differences between ligand molecules possessing a *TG* conformation of the spacers suggests that the increase of the intramolecular N4···N4′ distances in **3** relative to **2** is achieved in two ways. A comparison of ligands **A** (inverted structure) in **2** and **C** in **3** indicates that a combined effect both of the change of the spacer conformation and the relative orientation of the rings is responsible for the increase of the N4···N4′ distance. Surprisingly, the torsion angles for ligand **A** (compound **2**) and ligand **D** (compound **3**) suggest that the increase of the metal···metal separations in this case results from the change of the relative orientation of the tetrazole rings; the conformation of the alkyl spacers remains unchanged (see Figure 5). In contrast to ligands possessing axially symmetrical donor groups, (e.g. 4-pyridyl), a noncolinear orientation of the metal−nitrogen bond and the ring−alkyl bond (here N−C) enables the bridging of metal atoms separated by different distances despite the retention of the same conformation of the alkyl spacer. The conformational flexibility of the spacer observed in complexes **2** and **3**, and especially the rotational freedom of the tetrazole ring, is responsible for the adoption of various relative orientations by the donor groups and therefore by the N4 donor atoms, which leads to the difference in the metal−metal distances and the topology of the networks as well.

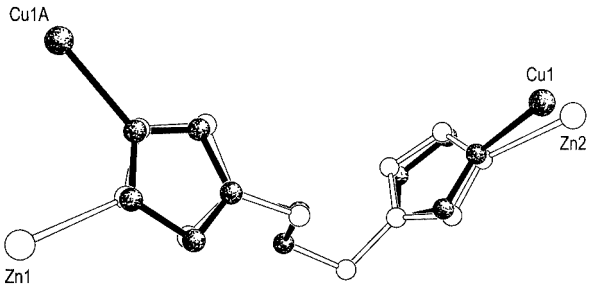

Figure 5. A superposition of the ligand molecules **A** (compound **2**) and **D** (compound **3**); hydrogen atoms are omitted for clarity; atom Cu1A generated by symmetry operation: $-x$, y, $-z + 3/2$

The perchlorates are noncoordinated and are gathered around the Zn(tetrazole)$_6$ cores. The remaining free space (943 Å^3; 17.1% of the unit cell volume) is composed of two kinds of voids with approximate volumes of 82 and 68 Å^3. The ethanol molecules that occupy the larger voids are arranged in pillars positioned parallel to the *c* axis (Figure 6). The space situated in the void of the rhombohedral boxes is occupied by ethanol molecules disordered about the threefold axis. The perchlorates are engaged in the formation of hydrogen bonds O2−H2···O21(Cl) ($-y + 2/3$, $x - y + 1/3$, $z + 1/3$) and O2−H2···O11(Cl) ($x + 1/3$, $y + 2/3$, $z + 2/3$) with both types of ethanol molecules.

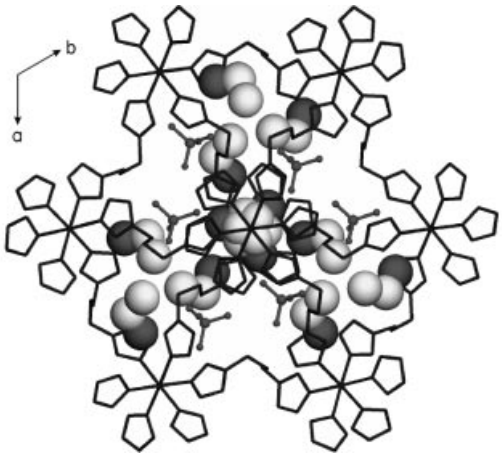

Figure 6. A view along the *c* axis showing channels filled by ethanol molecules in **3**; hydrogen atoms are omitted for clarity

Concluding Remarks

The new flexible ligand 1,3-bis(1,2,3,4-tetrazol-2-yl)propane and two coordination polymers of Cu^{II} and Zn^{II} have been synthesised. They were characterised spectroscopically and the crystal structures of both complexes were determined. The bidentate and nonchelating nature of the pbtz ligand is reflected in the polymeric structure of the complexes: $[\{Cu(pbtz)_3\}(ClO_4)_2]_\infty$ crystallises as a 1D triple-stranded infinite chain, whereas $[\{Zn(pbtz)_3\}(ClO_4)_2 \cdot 2EtOH]_\infty$ was isolated as a 3D network.

A strong influence of the spacer length on the architecture of the coordination polymers in this series of complexes based on 1,ω-bis(1,2,3,4-tetrazol-2-yl)alkanes is observed. Thus, use of pbtz rather than 1,2-bis(1,2,3,4-tetrazol-2-yl)ethane,[55] resulted not only in a 1D system but also in a coordination polymer of higher dimensionality (3D). In comparison with 1,4-bis(1,2,3,4-tetrazol-2-yl)butane,[56] a shortening of the alkyl spacer to 1,3-propylene resulted in the lowering of the degree of interpenetration and the formation of coordination polymers built up from only one octahedral network.

The coordination polymers described in this paper are based exclusively on octahedrally coordinated central atoms. Differences between the coordination properties of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the Cu^{II} and Zn^{II} ions are reflected both in the course of the syntheses and in the diversification of the architectures of the isolated complexes. The flexibility of the ligand molecules, and especially the rotational freedom of the tetrazole rings, enable this structural diversification. The conformational analysis has shown that a rotation of the tetrazole rings around the ring−spacer bond ($C_{alkyl}-N2_{ring}$) can compensate a change of conformation of the alkyl spacer, leading to adjustment of the distances between the N4 and N4′ donor atoms. This peculiarity enables a bridging of the same two central atoms by the ligand molecules even though they possess different conformations. On the other hand the possibility of changing the relative orientation of the donor groups (tetrazole rings) by the simultaneous retention of the spacer conformation significantly influences the intrapolymer metal−metal distances. This leads, in consequence, to the formation of a coordination network with a different architecture. In summary, the rotational freedom of donor groups, especially their relative orientations, plays a similar role to the orientation effect of the donor group in the case of rigid ligands,[75,76] enabling here the formation of 1D and 3D networks.

Experimental Section

General Remarks: The infrared spectra of pbtz and its complexes were recorded with a Bruker IFS66 IR FTIR spectrometer in the range 50−4000 cm^{-1} as nujol mulls. ^1H and ^{13}C NMR spectra were obtained with an AMX Bruker NMR 300 MHz spectrometer at room temperature in CD_3CN solutions. The ligand-field spectra were measured on powdered, pure samples with the diffuse-reflectance technique using a Cary 500 SCAN UV/Vis/NIR spectrometer. Elemental analyses for C, H, N were performed with a Perkin−Elmer 240C elemental analyser. Ethanol was dried by distilling from magnesium ethanolate. 1*H*-tetrazole was prepared by a previously described procedure.[55,77] The degree of hydration of the $Cu(ClO_4)_2{\cdot}6H_2O$ and $Zn(ClO_4)_2{\cdot}6H_2O$ salts was determined with an ICP spectrometer. The other commercially available reagents were used without further purification. ***Caution:*** Even though no problems were encountered it is worth mentioning that complexes containing perchlorates are potentially explosive and should be synthesised on a milligram scale and handled with care!

Synthesis of 1,3-Bis(1,2,3,4-tetrazol-2-yl)propane (1): A solution of NaOH (0.15 mol, 6.0 g) in water (20 mL) was added in a few portions to 1*H*-tetrazole (0.15 mol, 10.5 g) dissolved in water (20 mL). After cooling, the resulting clear solution was concentrated to dryness in a rotary evaporator. The remaining solid matter was finally dehydrated by an azeotropic distillation with three portions (100 mL each) of absolute ethanol. 1,3-Dibrompropane (0.07 mol, 7.15 mL) was then added to the obtained sodium tetrazolate suspended in MeCN (300 mL). The reaction mixture was stirred and refluxed for 4 d. The NaBr formed was filtered off and solvents were evaporated under reduced pressure. The resulting yellow oil was dissolved in water (150 mL). The aqueous solution was extracted with pentane (3 × 100 mL) and then with CCl_4 (10 × 100 mL). The crude product was isolated by removal of the solvent from the CCl_4 phase and purified by column chromatography on silica gel (230 mesh) using dichloromethane/acetone (100:5, v/v) as eluent (R_f = 0.38). Yield: 1.81 g (12.8%). $C_5H_8N_8$ (180.17): calcd. C 33.3, H 4.48, N 62.2; found C 33.8, H 4.60, N 61.9. ESI-MS: *m*/*z* calcd. for $C_5H_9N_8$ [LH^+] 181.2; found 181.1. IR: $\tilde{\nu}$ = 3141 (m), 3012 (w), 2965 (w), 1773 (w), 1629 (w), 1450 (s), 1361 (s), 1284 (s), 1186 (m), 1167 (w, sh), 1135 (s), 1051 (w, sh), 1028 (s), 1009 (m), 986 (w), 887 (m), 803 (w), 757 (w), 727 (w), 709 (s), 689 (m), 661 (w), 640 (w), 475 (m), 370 (m) cm^{-1}. ^1H NMR (300 MHz, CD_3CN, 298 K): δ = 2.69 (q, $^3J_{H,H}$ = 6.7 Hz, 2 H, 2-H), 4.74 (t, $^3J_{H,H}$ = 6.7 Hz, 4 H, 1-H, 3-H), 8.58 (s, 2 H, 5-H) ppm. ^{13}C NMR (300 MHz, CD_3CN, 298 K): δ = 29.09, 50.83, 153.98 ppm.

Synthesis of $[\{Cu(pbtz)_3\}(ClO_4)_2]_\infty$ (2): A solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (0.020 mmol, 7.4 mg) in EtOH (2.0 mL) was added to a solution of pbtz (0.060 mmol, 10.8 mg) in EtOH (2.0 mL). The reaction mixture was heated to 50 °C to give a clear solution. A few minutes after cooling, the solution became turbid and a small amount of precipitate appeared. The precipitate was left in the solution. The reaction mixture was kept in a closed tube at room temperature. Light-blue crystals were formed after 3 weeks. The crystals of **2** were separated manually under the microscope from the rest of the polycrystalline solids and then dried in air. Yield: 3.8 mg (24%). $C_{15}H_{24}Cl_2CuN_{24}O_8$ (802.95): calcd. C 22.4, H 3.01, N 41.9; found C 22.7, H 3.11, N 41.5. IR: $\tilde{\nu}$ = 3549 (w), 3151 (m), 3036 (w), 2980 (m, sh), 2923 (s), 2854 (s, sh), 1626 (w), 1468 (s, sh), 1460 (s), 1447 (sh), 1378 (m), 1367 (m), 1312 (m), 1292 (m), 1273 (w), 1211 (w), 1205 (w), 1185 (m), 1151 (s), 1139 (s), 1092 (vs), 1044 (w), 1044 (w), 1037 (w), 1029 (w), 1023 (w), 974 (w), 900 (w), 885 (m), 844 (m), 810 (w), 756 (w), 719 (w), 710 (w), 700 (m), 693 (m), 673 (w), 644 (w), 624 (s), 473 (w), 455 (w), 404 (m), 391 (w), 361 (w), 295 (w), 276 (w), 251 (w), 210 (w), 183 (w) cm^{-1}. UV/Vis: λ_{max} = 15400, 9800 cm^{-1}.

Synthesis of $[\{Zn(pbtz)_3\}(ClO_4)_2{\cdot}2EtOH]_\infty$ (3): A solution of pbtz (0.06 mmol, 11.6 mg) in absolute ethanol (0.4 mL) was added to a solution of $Zn(ClO_4)_2{\cdot}6H_2O$ (0.02 mmol, 7.4 mg) in ethanol (0.4 mL). The resulting clear solution was allowed to stand in a closed tube at room temperature for 1 week. After this time, colorless crystals were collected and dried in a stream of nitrogen. Yield: 10.3 mg (57.4%). $C_{15}H_{24}Cl_2N_{24}O_8Zn{\cdot}2EtOH$ (896.92): calcd. C 25.4, H 4.04, N 37.5; found C 25.0, H 3.89, N 37.6. IR: $\tilde{\nu}$ = 3396 (br. s), 3169 (w), 3146 (m), 2953 (s, sh), 2925 (s), 2854 (m), 1650 (w, br), 1466 (m), 1455 (m), 1374 (m), 1364 (w, sh), 1304 (w), 1285 (m), 1204 (w), 1181 (w), 1151 (s, sh), 1140 (s, sh), 1109 (vs), 1090 (s, sh), 1029 (m, sh), 991 (w), 940 (w), 929 (w), 877 (w), 818 (w), 708 (w), 689 (m), 637 (m, sh), 626 (s), 475 (w), 388 (w), 191 (w) cm^{-1}.

X-ray Crystallographic Study: Single crystals of complexes **2** and **3** were obtained directly from the synthesis. The crystals were coated with a layer of inert oil, mounted on a glass fiber and transferred to the cold nitrogen stream of the diffractometer. Measurements of crystals of both compounds were performed with a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo-K_α radiation, equipped with an Oxford Cryosystem device. Crystal data and refinement details for **2** and **3** are listed in Table 1. The data were corrected for Lorentz and polarisation effects. No absorption correction was applied. Data reduction and analysis were carried out with the Oxford Diffraction (Poland) Sp. z o.o (formerly Kuma Diffraction Wroclaw, Poland) programs. The structures were solved by direct methods (program SHELXS-97[78]) and refined by the full-matrix least-squares method on all F^2 data using the SHELXL-97[79] programs. An analysis of the holes was performed using the Platon program.[80] The visualisation of the extended structure depicted in Figure 6 was prepared using the OLEX[81] program. For **2** all non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were located from the Fourier difference map and were refined with isotropic displacement parameters. For **3** the zinc atoms, the atoms of the

Largest diff. peak/hole [e·Å^{-3}]	0.405/−0.999	0.798/−0.605

ligands, the perchlorate anions and one of the two ethanol molecules were refined with anisotropic displacement parameters. Hydrogen atoms were included from the geometry of the molecules and were then refined isotropically. The three residual density peaks positioned about a threefold axis were modelled as the second ethanol molecule. For refinement of the respective position of this EtOH molecule three distance restraints — C−C = 1.44(1), C−O = 1.42(1) and C···O = 2.38(1) Å — were applied.[82] The oxygen and carbon atoms were refined isotropically. A refinement with a freely established occupancy factor showed the partial occupation of this position. A consideration of the presence of these additional small amounts of ethanol molecules (ca. 0.4 ethanol molecules per formula unit) solvating the crystal lattice of **3** leads to agreement with the results of the elemental analysis. CCDC-232496 (**2**) and -232497 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

I would like to thank Prof. Zbigniew Ciunik and Dr. Andrzej Kochel for the single-crystal X-ray data collection and Dr. Krzysztof Drabent for his valuable comments. The author thanks the MENiS for financial support.

Keywords: Amides / Manganese / Schiff bases / 1-D chains

Three novel neutral manganese(III) complexes of stoichiometry Mn(R-amsal-3,5-di-*t*Bu)$(H_2O)_n$ [H_3-R-amsal-3,5-di-*t*Bu = 3-aza-4-(2-hydroxyphenyl)-*N*-(2-hydroxyphenyl)but-3-enamide; (R = H, 4-Me, 5-*t*Bu)] have been synthesised using potentially trianionic and pentadentate Schiff-base ligands containing an amide group. Complexes were thoroughly characterised by elemental analysis, FAB mass spectrometry, infrared spectroscopy, magnetic susceptibility measurements and molar conductivities. Recrystallisation of these complexes from methanol yielded single crystals of [Mn_2(amsal-3,5-di-*t*Bu)$_2$(MeOH)$_2$]$_n$ **1**, [Mn_2(4-Me-amsal-3,5-di-*t*Bu)$_2$-(MeOH)$_2$]$_n$ **2** and [Mn_2(5-*t*Bu-amsal-3,5-di-*t*Bu)$_2$(MeOH)$_2$]$_n$ **3** with methanol as solvate. Their X-ray characterisation shows that these complexes consist of infinite one-dimensional chains with a repeating cyclic dimeric unit, where the amide oxygen atom is bridging two neighbouring manganese(III) ions. Paramagnetic ^{1}H NMR spectroscopy confirmed the presence of Mn^{III} in these complexes, while the cyclic voltammetry studies suggest the possibility of obtaining polynuclear Mn^{IV} complexes with this kind of ligand.

Introduction

In recent years, considerable efforts have been focused on the synthesis and characterisation of polynuclear manganese complexes.[1] This is mainly because di- or multi-nuclear manganese sites involving oxygen or nitrogen donor ligands are important in the function of enzymes such as alkaline phosphatase,[2] pseudocatalases,[3] manganese-based superoxide dismutase (MnSOD)[4] and the oxygen evolving complex (OEC) of photosystem II.[5] Moreover, the synthetic complexes have been shown to exhibit a variety of interesting structural and physical properties.[6]

Recently, we have directed our attention to the coordination chemistry of manganese with Schiff bases containing amide groups. Our interest in this kind of ligands derives from the known ability of ligands containing amide groups to stabilise high oxidation states of metal ions when coordinated with the deprotonated nitrogen atom.[7–9]

Previously, we succeeded in stabilising the neutral Mn^{III} complexes[10] with ligands derived from H_3-amsal [H_3-amsal = 3-aza-4-(2-hydroxyphenyl)-*N*-(2-hydroxyphenyl)but-3-enamide] by two methods (an electrochemical synthesis and the Boucher procedure[11]). Nevertheless, the low solubilities of these complexes in most common solvents have prevented, until now, their structural characterisation by X-ray diffraction. The knowledge of such structures should improve understanding of ligand design and the synthesis of high oxidation state polymeric manganese complexes.

In order to establish the structural make-up of these complexes, we decided to investigate whether the introduction of *tert*-butyl groups on the aromatic rings of the Schiff base ligands would improve the solubility of the resulting complexes and allow structural characterisation. We have designed some new amide-derived Schiff base ligands in order to prepare novel manganese(III) complexes, and in this paper we report the results.

Results and Discussion

Synthesis and Characterisation of the Ligands

The new unsymmetrical Schiff base ligands reported in this study were prepared in a manner analogous (Scheme 1) with the three-step method to similar ligands described by us previously.[10]

The first step involves a carbodiimide amide coupling[12] of *N*-benzyloxycarbonylglycine with 2-hydroxyaniline, 2-hydroxy-4-methylaniline or 2-hydroxy-5-*tert*-butylaniline in THF. This reaction proceeds in excellent yield (see Exp. Sect.) and large quantities of amides **1a**, **1b** or **1c** can be

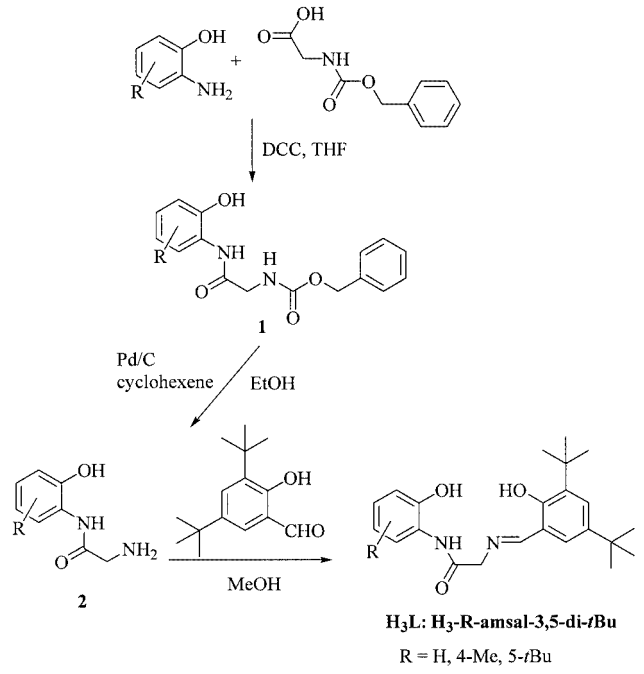

Scheme 1. Reaction diagram for the preparation of the Schiff−base ligands

prepared. The second step involves the removal of the *Z* protecting group from the amine functionality by sacrificial hydrogenation using cyclohexene and palladium on charcoal as the catalyst.[13] This methodology yielded the desired amines **2a**, **2b** or **2c** in high yield and with high purity. Amines **2a**, **2b** and **2c** were then employed as the precursors of the new ligands via conventional condensation reactions with a commercially available substituted salicylaldehyde. The obtained Schiff bases were satisfactorily characterised by elemental analysis, mass spectrometry (Table 1), ^{1}H NMR (Table 2), ^{13}C NMR and IR (Table 3) spectroscopy.

Mass Spectrometry, NMR and IR Spectroscopy

The mass spectra of the ligands each show the peak for H_3L^+ at 100% intensity (see Table 1), in accord with the proposed formulae.

The ^{1}H NMR spectroscopic data for the ligands are shown in Table 2. The spectra of H_3-R-amsal-3,5-di-*t*Bu, recorded using [D$_6$]DMSO as solvent, exhibit a singlet at $\delta \approx 8.6$ ppm assigned to the imine hydrogen atom, corroborating the formation of C=N bonds. The aromatic protons lie in the range $\delta = 6.50-8.03$, while the presence of a singlet at $\delta \approx 4.5$ indicates the presence of the methylene group. Furthermore, all spectra show three singlets in the region of 9.21−13.79 that disappear on deuteration. The peak at higher field was assigned to the NH proton while the two signals at lower field correspond to the OH protons. The spectra of these Schiff bases also show two singlets (for H_3-amsal-3,5-di-*t*Bu and H_3-4-Me-amsal-3,5-di-*t*Bu) or three singlets (for H_3-5-*t*Bu-amsal-3,5-di-*t*Bu) in the range $\delta = 1.2-1.4$, indicating the presence of two or three non-equivalent *tert*-butyl groups, respectively.

The ^{13}C NMR spectra of the ligands in [D_6]DMSO show signals corresponding to the aromatic carbon atoms (between δ = 115 and 160 ppm), a signal due to the imine carbon atom (around 165 ppm) and a resonance assigned to the carbonyl carbon atom (around 168 ppm). Additionally, the methylene carbon and the methyl and *tert*-butyl groups, where appropriate, give signals below δ = 70 ppm.

The most significant IR bands for the ligands are recorded in Table 3. They have been assigned by comparison with the IR spectra of the amine precursors and on the basis of our knowledge in this field.[10a]

Synthesis and Characterisation of Manganese Complexes

The manganese complexes were prepared following a variation of the Boucher method reported by us.[10c,14]

The brown powdery solid compounds were obtained in high yield via this synthetic route, and appear to be stable in the solid state and in solution. They are moderately soluble in common organic solvents and soluble in polar aprotic coordinating solvents such as DMF and DMSO.

Elemental analyses indicate that these manganese complexes have the general stoichiometry Mn(R-amsal-3,5-di-*t*Bu)(H_2O)$_4$, suggesting that they are neutral manganese(III) species in which the ligands are tri-deprotonated. Molar conductivity measurements in 10^{-3} M DMF solutions, in the range 3−9 μS cm^{-1}, show the non-electrolytic behaviour of these complexes.[15]

Mass Spectrometry and IR Spectroscopy

Fast atom bombardment (FAB) mass spectra contain peaks relating to fragments of the form $[MnL]^+$, indicating ligand coordination to the metal centre. Furthermore, these

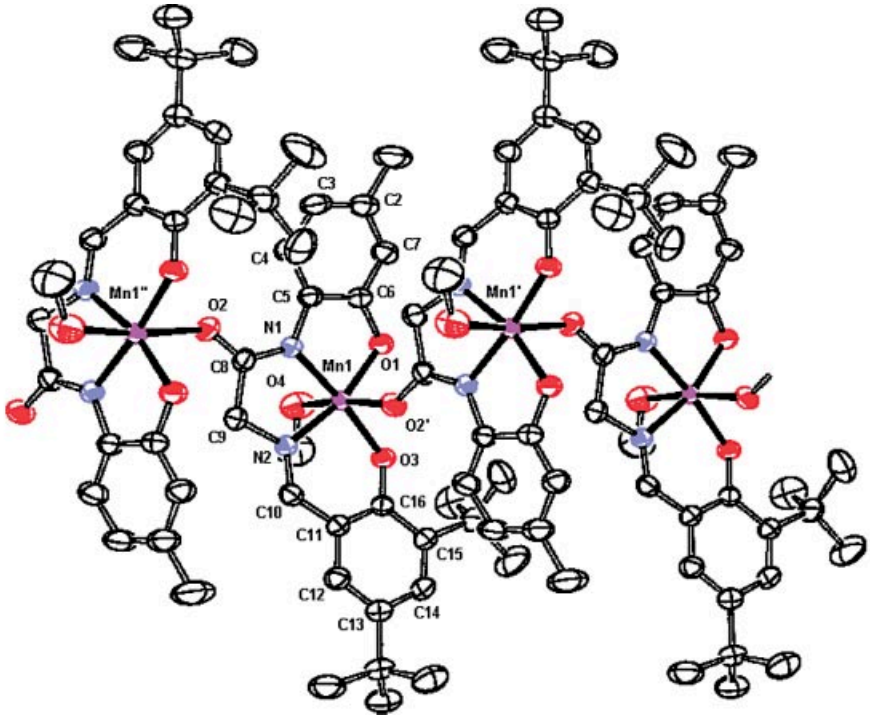

Figure 2. An ORTEP view of the crystal structure of [Mn_2(4-Me-amsal-3,5-di-*t*Bu)$_2$(MeOH)$_2$]$_n$ (**2**); ellipsoids are drawn at 50% probability; symmetry operations: ′: $-x + 1$, $y + 1/2$, $-z + 1/2$; ′′: $-x + 1$, $y - 1/2$, $-z + 1/2$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

spectra exhibit peaks due to the fragment $[Mn_2L_2]^+$, which can be attributed tentatively to the presence of dimeric/polymeric species in the solid state.

The ligand coordination to the metal centre is also supported by the IR spectra, which are very similar for all the complexes. Thus, a band at about 1620 cm^{-1}, attributable to ν(CN), shifted to lower energy compared with the free ligands values, indicating the coordination of the ligand to the metal through the imine nitrogen atom. This ν(CN) band is strong and broad and it obscures the amide I and amide II bands. Additionally, bands centred at ca. 3400 cm^{-1} can be observed in these spectra, in accordance with the presence of coordinated and/or lattice water or methanol.

Finally, the absence of a strong band at ca. 1100 cm^{-1} confirms the absence of perchlorate anions in these manganese complexes.

X-Ray Diffraction Studies

Crystal Structures of Complexes 1, 2 and 3

Single crystals of $[Mn_2(amsal\text{-}3,5\text{-di-}t\text{Bu})_2(MeOH)_2]_n$ (**1**), $[Mn_2(4\text{-Me-amsal-}3,5\text{-di-}t\text{Bu})_2(MeOH)_2]_n$ (**2**) and $[Mn_2(5\text{-}t\text{Bu-amsal-}3,5\text{-di-}t\text{Bu})_2(MeOH)_2]_n$ (**3**) suitable for X-ray diffraction studies were grown as detailed in the Exp. Sect. These analyses show that **1**, **2** and **3** have similar structures that consist of a polymeric chain of repeating dimeric units. These dimeric units contain two ligand units, two manganese centres and two molecules of methanol. Furthermore, complexes **1**, **2** and **3** contain methanol as solvate. Complexes **1** and **2** crystallise in the orthorhombic space group *Pbca*, while complex **3** crystallises in the monoclinic space group *C*2/*c*. The ORTEP diagrams for **1** and **2** are shown in Figure 1 and Figure 2, respectively. The ORTEP view of the environment of the manganese atom for complex **3** is shown in Figure 3. Experimental details are given in Table 4 and selected bond lengths and angles in Table 5.

The geometry around each Mn atom can be described as distorted octahedral, where the trianionic and pentadentate ligand coordinates the Mn^{III} centre with the two phenol O-atoms [O(1), O(3)], the imine N-atom [N(2)] and the amide N-atom [N(1)] occupying the equatorial positions (see Figure 3). The coordination sphere around each manganese centre is then completed by a capping methanol molecule [O(4)] and an amide O-atom [O(2′)] from the neighbouring complex molecule. Thus, the amide oxygen atom [O(2)] of one ligand is coordinated to the manganese ion of the neighbouring molecule, acting as a bridge, which generates an infinite one-dimensional chain $Mn-O_{amide}(L)-Mn-O'_{amide}(L)$ resulting in a Mn···Mn distance of 6.064 Å for **1**, 6.120 Å for **2**, and 6.035 Å for **3**.

It is well known that Mn^{III} complexes are able to form dimeric or polymeric species through different coordinative bridges:[14,16] μ-Oxo, μ-phenoxo, μ-aquo, μ-carboxylate, μ-cyanide, μ-thiocyanate, etc. μ-oxo and μ-phenoxo bridges generate dimeric structures; μ-carboxylate, μ-cyanide and μ-thiocyanate usually yield polymeric species, while the μ-aquo ligand can generate both dimeric or polymeric structures. The distance Mn···Mn for the complexes reported herein are longer than the corresponding distances in μ-oxo, μ-phenoxo or μ-aquo Mn^{III} complexes, and shorter than the distances found for μ-carboxylate Mn^{III} complexes. On the other hand, ionic metal(II) complexes with amide ligands where oxygen amide atoms behave as bridges have been reported.[17] However, to the best of our knowledge, the type of compound reported in the present case, with Mn^{III}, has not been described previously in the literature.

The bond distances in the equatorial plane Mn−N [ranging from 1.933 to 1.964 Å] and Mn−O [in the range 1.875−1.930 Å] are typical of manganese(III) complexes[16,18] and corroborate complete deprotonation of the ligands. The distances $Mn-O4_{methanol}$ [2.270−2.281 Å] are in agreement with other previous results,[18] and are longer than the axial distances $Mn-O2'_{amide}$, except for complex **3**. The distances $O2=C_{amide}$ (ca. 1.247) are longer than those found for the related free ligands (ca. 1.235),[10a] as expected. The axial Mn−O distances are considerably longer than the equatorial Mn−O bond lengths quoted above, indicating that the Jahn−Teller elongation expected for a high-spin d^4 manganese(III) ion is present along the chain of these polymers.

The deviation from an ideal octahedral geometry is also revealed by the range of angles observed around the metal centre [from 80.84 to 104.35°], as well as by the interaxial angle O4−Mn1−O2′ of ca. 173°. The slight deviation of the equatorial plane from planarity further reinforces this distortion (maximum deviation from the calculated least-squares plane formed by O1, N1, N2 and O3 is ca. 0.004 Å for **1**, 0.009 Å for **2** and 0.025 Å for **3**, with the manganese atoms lying out of this plane by ca. 0.011 Å for **1**, 0.006 Å for **2** and 0.025 Å for **3**). These planes also present a gauche conformation.

These ligands are expected to show a high degree of planarity owing to the conjugation and presence of only one sp^3 atom in the chelate rings (named as C8 for **1**, C9 for **2** and C12 for **3** in Figures 1, 2 and 3, respectively). In fact, the angles between calculated chelate planes present values of 0.81° and 4.43° for **1**, 2.90° and 7.68° for **2**, and the highest values for **3** (10.87° and 14.91°).

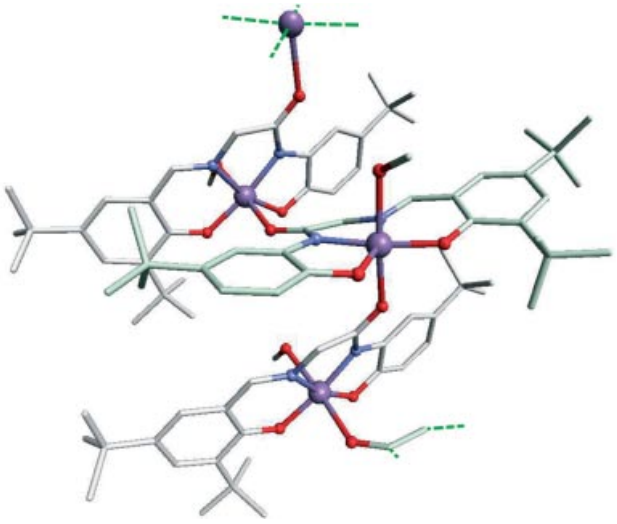

Figure 4. Part of the polymeric 1−D chain of **3**, showing the zigzag disposition of the manganese centres (in violet)

It is interesting to note that these infinite chains are not linear (see Figure 4), as the manganese atoms are situated in a zigzag arrangement. The angles between neighbouring manganese atoms (Mn1′−Mn1−Mn1′′) are 93.85° for **1**, 92.03° for **2** and 74.17° for **3**. The head-to-tail arrangement of the ligands allows coordination of the amide oxygen atom of each unit to the metal ion of the next unit in the chain.

Magnetic Studies

The study of room temperature magnetic properties for the complexes shows that their magnetic moments (see Exp. Sect.) are all close to the spin-only value of 4.9 BM, expected for a magnetically dilute octahedral high-spin d^4 manganese(III) ion.

Variable temperature magnetic susceptibility of the complexes were measured in the temperature range 5−300 K using a small applied field of 5000 G. Plots of the reciprocals of the magnetic susceptibilities against absolute temperature are linear, so that all the complexes obey the Curie−Weiss law. An example is shown in Figure 5 for complex **2**.

The magnetic behaviours of complexes **1**, **2** and **3** are identical and can be illustrated by the thermal variation of the $\chi_M T$ versus T plot for complex **2** as in Figure 6. The $\chi_M T$ product is practically constant in the 300−100 K range with an observed value (3.34 ± 0.3 $cm^3\ mol^{-1}\ K$) corresponding to the value expected for an isolated high-spin Mn^{III} cation. On further reduction of the temperature, this value decreases smoothly down to 2.99 $cm^3\ mol^{-1}\ K$ at 30 K, and then more steeply to reach a value of 1.17 $cm^3\ mol^{-1}\ K$ at 5 K.

We attempted theoretical calculations to reproduce, and for comparison with, the experimental results. For an infinite chain of 4/2 local spins the simpler analytical expression that may be used to fit the experimental data derives from Fisher's expression:[19]

$\chi T = [Ng^2\beta^2 S(S + 1)/3k][(1 + u)/(1 - u)]$ where
$u = \coth[-2JS(S + 1)/kT] - [kT/-2JS(S + 1)]$

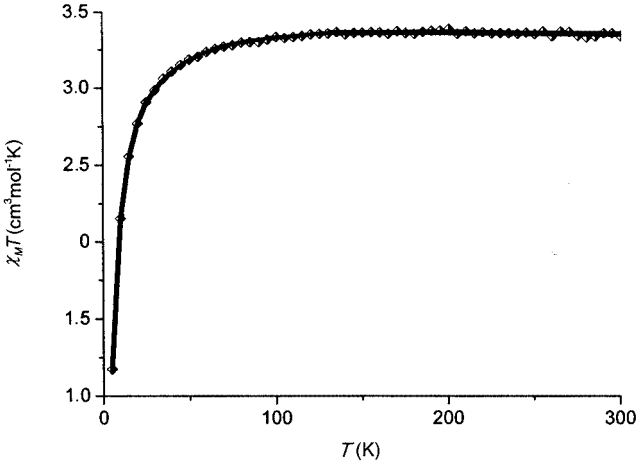

Figure 6. Thermal dependence of $\chi_M T$ for **2**; the full line (−) corresponds to the best data fit

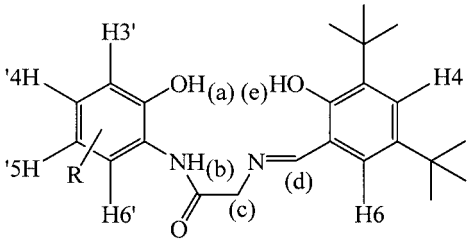
The best agreement between experimental and calculated data from 300 to 5 K corresponds to $J = -0.3\ cm^{-1}$ and $g = 2.05$ with an agreement factor R ($= \Sigma[(\chi_M T)_{obsd.} - (\chi_M T)_{calcd.}]^2/\Sigma[(\chi_M T)_{obsd.}]^2$) of $3.4.10^{-4}$.

This study indicates little or no antiferromagnetic interaction between neighbouring metal centres in the solid state. Therefore, we can interpret the magnetic properties of these Mn^{III} polymer complexes as ordinary paramagnetic[19] and this is in agreement with the intermolecular Mn···Mn distances of about 6 Å.

^{1}H NMR Spectroscopy

Paramagnetic ^{1}H NMR spectra for the complexes were recorded in [D_6]DMSO at room temperature. The data are presented in Table 6.

The spectra obtained for these complexes contain three or four proton resonances that lie outside the diamagnetic region (δ = 0−14). The interpretation of these data is based on the findings of Pecoraro and co-workers[21] and also on our own results[10a,10b,22] for other Mn^{III} complexes with related Schiff base ligands. The protons *ortho* to the ring position occupied by a Mn-coordinated atom H3′, H6 and H6′ (see Scheme 2), were not observed.



Scheme 2. Hydrogen atom labelling of the ligands for the ^{1}H NMR studies

Two or three relatively sharp peaks are observed upfield between δ = −14 and −32 ppm, which we have assigned to the H4 protons of the aldehyde and to H4′ and H5′ protons of the amine.[10a,10b,21,22] The comparison between the spec-

tra of these three complexes, with substitution of the H4′ and H5′ positions of the amine ring, provides an indication of the appropriate assignments. Clearly the upfield peaks at $\delta \approx -32$ correspond to the H4 protons. The features at $\delta = -14.80$ and -18.42 arise from H4′ protons, while the downfield resonances at $\delta = -25.90$ and -27.08 arise from H5′ protons.

Additionally, one broad peak observed downfield ($\delta = 30-36$) can be assigned to the aliphatic protons in the methylene bridge between the imine and amide nitrogen atoms.

It is well known that high-spin Mn^{III} complexes in an octahedral field show isotropically shifted ^1H NMR spectra arising from ligand protons.[23] Therefore, the data obtained from these NMR studies serve to corroborate the formation of these novel manganese(III) complexes.

Electrochemical Behaviour of the Complexes

Cyclic voltammograms of all the complexes were obtained from dimethylformamide solutions at slow scan rates of 0.02 V s^{-1} over a potential range from +1 to −1 V. The numerical data are given in Table 6 and a typical voltammogram is shown in Figure 7.

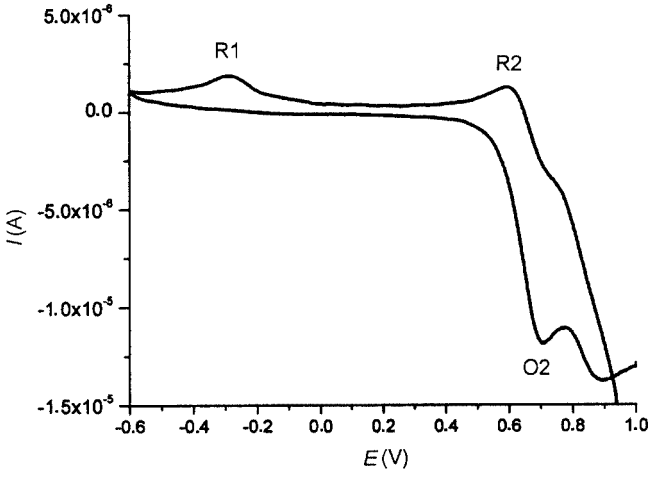

Figure 7. Cyclic voltammetry for **3**

All the complexes behave similarly. All voltammograms display an irreversible process at negative potentials (quoted as R1 in Table 6), which we assign to the reduction of manganese(III) to manganese(II).[14,24]

On the other hand, a second redox process assigned to the oxidation of manganese(III) to manganese(IV) is present at positive potentials for all the complexes (quoted as O2 in Table 6). This redox wave is irreversible for **1** and **2**, but for **3** presents an important rate of reversibility (R2, see Figure 7).

It is interesting to note that the presence of the methyl or *tert*-butyl groups on the aromatic ring of the amine precursor decreases this oxidation potential as it does with related ligands.[25] Hence, it seems obvious that manganese(IV) could be stabilised by this kind of ligand, containing hard donor atoms, especially if an electron-donating substituent were to be introduced.[7a,7b,8a,8b]

We found that the complexes exhibit low current intensities in their redox waves. This behaviour is attributed to the polymeric nature of these complexes, which results in a lower diffusion coefficient.[26]

Conclusion

Self-assembly of manganese ions with the novel unsymmetrical and potentially trianionic pentadentate amide group-containing Schiff base ligands, leads to neutral, polymeric manganese(III) complexes. The X-ray crystal structures of these complexes show that the oxygen amide atom of these ligands can act as a bridge between neighbouring manganese atoms and afford zigzag one-dimensional chains, previously unreported for manganese(III) ions. In addition, the observations reported here could be helpful for the study of biological systems, in which relatively weak but cooperative interactions between sets of metal ions and linked amide groups are present.

Finally, it seems that this kind of ligand is suitable for stabilization of Mn^{III} complexes, and could have potential in the synthesis of polynuclear Mn^{IV} complexes.

Experimental Section

General: Starting materials were purchased from Aldrich except manganese(II) perchlorate hexahydrate (Fluka) and cyclohexene (Panreac) and were used without further purification.
Elemental analyses were performed on a Carlo Erba EA 1108 analyser. NMR spectra were recorded on a Bruker WM-250 spectrometer using [D_6]DMSO as solvent; δ = chemical shift in ppm; s = singlet, d = doublet, t = triplet, m = multiplet, br = broad. Infrared spectra were recorded as KBr pellets on a Bruker UFS-66V spectrophotometer in the range 4000−600 cm^{-1}. The bands are reported as: vs = very strong, s = strong, m = medium, w = weak, sh = shoulder, and br = broad. Mass spectrometry (Electronic Impact) was performed on a Hewlett−Packard 5988A mass spectrometer, whilst fast atom bombardment (FAB) was done on a Micromass AutoSpec mass spectrometer, employing *m*-nitrobenzyl alcohol as the matrix. Magnetic susceptibility measurements in the 5−300 K temperature range were performed using a SQUID magnetometer operating at 5000 G. Room temperature magnetic susceptibilities were measured using a Digital Measurement system MSB-MKI, calibrated using tetrakis(isothiocyanato)cobaltate(II). Conductivities were obtained at 25 °C from 10^{-3} M solutions in DMF on a Philips PW9526 instrument. Cyclic voltammetry was performed by using an EG&G PAR model 273 potentiostat, controlled by the EG&G PAR model 270 software, in conjunction with a three-electrode cell, fitted with a purge gas inlet and outlet, consisting of a graphite disc working-electrode, a saturated calomel reference electrode and a platinum auxiliary electrode. Voltammograms were obtained from ca. 10^{-3} M dimethylformamide solutions of the metal complexes containing 0.1 M tetraethylammonium perchlorate as supporting electrolyte.

Syntheses

Preparation of Schiff Base Ligands: Ligands were prepared according to a three-step method previously reported by us[10] and which is shown in Scheme 1.

First Step. Synthesis of Precursors 1a, 1b and 1c

***N*-(2-Hydroxyphenyl)-2-[(phenylmethoxy)carbonylamino]ethanamide (1a):** 2-Hydroxyaniline (2.61 g, 23.9 mmol) and a slight excess of *N*,*N*′-dicyclohexylcarbodiimide (5.3 g, 25.7 mmol) was added to a solution of *N*-benzyloxycarbonylglycine (5 g, 23.9 mmol) in THF (100 mL). This mixture was stirred at room temperature for four hours.[12] The insoluble *N*,*N*′-dicyclohexylurea was removed by filtration and the solvent replaced by ethyl acetate (100 mL). Addition of petroleum ether (b.p. 40−60 °C) afforded 6.46 g (90%) of the amine **1a**. M.p. 172 °C. ^{1}H NMR (250 MHz, [D$_6$]DMSO): δ = 4.06 (d, 2 H), 5.30 (s, 2 H), 6.96 (m, 1 H), 7.56 (m, 5 H), 7.91 (t, 1 H), 8.09 (d, 1 H), 9.31 (s, 1 H), 10.09 (s, 1 H) ppm. IR (KBr): $\tilde{\nu}$ = 3392 (s, OH), 3270 and 3075 (both s, NH), 1677 (vs, amide I), 1618 (s, amide II) cm^{-1}. EI-MS: *m*/*z* = 300.1. $C_{16}H_{16}N_2O_4$ (300.0): calcd. C 64.0, H 5.4, N 9.3; found C 64.1, H 5.5, N 9.4.

***N*-(2-Hydroxy-4-methylphenyl)-2-[(phenylmethoxy)carbonylamino]-ethanamide (1b):** Preparation as described above, using 2-hydroxy-4-methylaniline (2.95 g, 23.9 mmol). Yield 6.78 g (90%). M.p. 185 °C. ^{1}H NMR (250 MHz, [D$_6$]DMSO): δ = 2.43 (s, 3 H), 4.07 (d, 2 H), 5.30 (s, 2 H), 6.82 (d, 1 H), 6.92 (s, 1 H), 7.60 (m, 5 H), 7.94 (t, 1 H), 7.97 (s, 1 H), 9.30 (s, 1 H), 9.99 (s, 1 H) ppm. IR (KBr): $\tilde{\nu}$ = 3392 (s, OH), 3269 and 3076 (both s, NH), 1677 (vs, amide I), 1618 (s, amide II) cm^{-1}. EI-MS: *m*/*z* = 314.1. $C_{17}H_{18}N_2O_4$ (314.0): calcd. C 65.0, H 5.8, N 8.9; found C 65.1, H 6.0, N 9.1.

***N*-(2-Hydroxy-5-*tert*-butylphenyl)-2-[(phenylmethoxy)carbonylamino]ethanamide (1c):** Preparation as described above, using 2-hydroxy-5-*tert*-butylaniline (3.95 g, 23.9 mmol). Yield 6.4 g (75%). M.p. 185 °C. ^{1}H NMR (250 MHz, [D$_6$]DMSO): δ = 1.30 (s, 9 H), 3.88 (d, 2 H), 5.09 (s, 2 H), 6.80 (d,1 H), 6.96 (d, 1 H), 7.37 (m, 5 H), 7.71 (t, 1 H), 7.92 (s, 1 H), 9.15 (s, 1 H), 9.66 (s, 1 H) ppm. IR (KBr): $\tilde{\nu}$ = 3390 (s, OH), 3268 (s, NH), 3077 (m, NH), 1678 (vs, amide I), 1617 (s, amide II) cm^{-1}. EI-MS: *m*/*z* = 356.1. $C_{20}H_{24}N_2O_4$ (356.0): calcd. C 67.4, H 6.8, N 7.9; found C 67.5, H 6.9, N 7.8.

Second Step. Synthesis of precursors 2a, 2b and 2c

2-Amino-*N*-(2-hydroxyphenyl)ethanamide (2a): A solution of **1a** (2 g, 6.7 mmol) in ethanol (100 mL) was mixed with cyclohexene (5 mL, in excess to the molar proportion required) and commercial 10% Pd−C catalyst (0.50 g; catalyst:substrate ratio 1:4 by weight).[13] The mixture was refluxed for 15 min. The catalyst was removed by filtration and washed with ethanol, and the combined filtrates were evaporated under reduced pressure to give the deprotected amine **2a**. Yield 1.05 g (95%). M.p. 148 °C. ^{1}H NMR (250 MHz, [D$_6$]DMSO): δ = 3.26 (s, 2 H), 6.77 (m, 1 H), 6.88 (s, 1 H), 6.89 (s, 1 H), 8.18 (d, 1 H) ppm. IR (KBr): $\tilde{\nu}$ = 3431 (s, OH), 3420 and 3252 (both s, NH$_2$), 3083 (s, br, NH), 1649 (vs, amide I), 1614 (s, amide II) cm^{-1}. EI-MS: *m*/*z* = 166.0. $C_8H_{10}N_2O_2$ (166.0): calcd. C 57.8, H 6.1, N 16.9; found C 57.5, H 6.2, N 16.6.

2-Amino-*N*-(2-hydroxy-4-methylphenyl)ethanamide (2b): Preparation as described above, using **1b** (2 g, 6.36 mmol). Yield 1.09 g (95%). M.p. 175 °C. ^{1}H NMR (250 MHz, [D$_6$]DMSO): δ = 2.12 (s, 3 H), 3.17 (s, 2 H), 6.49 (d, 1 H), 6.61 (d, 1 H), 7.49 (d, 1 H) ppm. IR (KBr): $\tilde{\nu}$ = 3356 (s, OH), 3278 (s, NH$_2$), 3046 (s, br, NH), 1655 (vs, amide I), 1606 (s, amide II) cm^{-1}. EI-MS: *m*/*z* = 180.1. $C_9H_{12}N_2O_2$ (180.0): calcd. C 60.0, H 6.7, N 15.6; found C 60.3, H 6.9, N 15.5.

2-Amino-*N*-(2-hydroxy-5-*tert*-butylphenyl)ethanamide (2c): Preparation as described above, using **1c** (2 g, 5.61 mmol) Yield 1 g (80%). M.p. 210 °C. ^{1}H NMR (250 MHz, [D$_6$]DMSO): δ = 0.91 (s, 9 H), 3.12 (s, 2 H), 6.55 (d, 1 H), 6.69 (d, 1 H), 8.03 (s, 1 H) ppm. IR (KBr): $\tilde{\nu}$ = 3380 (vs, OH), 3270 (vs, NH$_2$), 3065 (m, NH), 1650 (vs, amide I), 1610 (s, amide II) cm^{-1}. EI-MS: *m*/*z* = 222.1. $C_{12}H_{18}N_2O_2$ (222.0): calcd. C 64.9, H 8.1, N 12.6; found C 64.6, H 8.1, N 12.7.

Third Step. Preparation of Schiff Base Ligands: The Schiff-base ligands were prepared in a standard manner by the reaction of equimolecular quantities of 3,5-di-*tert*-butyl-2-hydroxybenzaldehyde and the appropriate amines **2a**, **2b** or **2c**, which is typified by the preparation of H$_3$-5-*t*Bu-amsal-3,5-di-*t*Bu. The amine **2c** (0.5 g, 2.25 mmol) and the salicylaldehyde (0.53 g, 2.25 mmol) were dissolved in methanol (100 mL) and the solution was brought to reflux. The volume of the solution was reduced over a three hour period to ca. 50 mL, using a Dean−Stark trap and was then allowed to cool. The solid, which precipitated, was collected by filtration, washed with diethyl ether (3 mL) and dried in vacuo. The purity of the ligands was checked by elemental analysis, mass spectrometry (Table 1), ^{1}H NMR (Table 2), ^{13}C NMR and IR (Table 3) spectroscopy.

Synthesis of the Complexes

All of the manganese complexes were obtained using the same procedure. A typical preparation is outlined below.

Mn(amsal-3,5-di-*t*Bu)(H$_2$O)$_4$: A solution of NaOH (0.03 g, 0.78 mmol) in water (3 mL) was added to a solution of the ligand H$_3$-amsal-di-*t*Bu (0.1 g, 0.26 mmol) in methanol (15 mL). Manganese(II) perchlorate hexahydrate (0.15 g, 0.41 mmol) in 5 mL of methanol was then added and a rapid change of solution colour was observed, from yellow to brown. (***CAUTION:*** All perchlorates are potentially explosive. Although no problems have been encountered during this study, care should be taken in the handling and treatment of these materials). After stirring at room temperature in the presence of air for 12 h, the solid formed was collected by filtration, washed with hexane and dried in vacuo. Yield 80%. $C_{23}H_{35}MnN_2O_7$ (505.9): calcd. C 54.6, H 6.9, N 5.5; found C 54.8, H 6.7, N 5.3. MS(FAB): *m*/*z* (%) = 434 (100, MnL), 869 (12, Mn_2L_2). Magnetic moment μ_{eff} = 5.0 B. M. Conductivity (in DMF) Λ_M = 3 μS cm^{-1}.
Recrystallisation of the dark brown powder from methanol by slow evaporation afforded brown crystals of [Mn$_2$(amsal-3,5-di-*t*Bu)$_2$(MeOH)$_2$]$_n$ **1**, suitable for X-ray diffraction studies.

Mn(4-Me-amsal-3,5-di-*t*Bu)(H$_2$O)$_2$: Yield 65%. $C_{24}H_{33}MnN_2O_5$ (483.9): calcd. C 59.5, H 6.8, N 5.8; found C 60.1, H 6.6, N 5.5. MS(FAB): *m*/*z* (%) = 449 (100, MnL), 898.1 (16, Mn_2L_2). Magnetic moment μ_{eff} = 5.1 B. M. Conductivity (in DMF) Λ_M = 3 μS cm^{-1}. Recrystallisation of the brown powder in methanol yielded crystals of [Mn$_2$(4-Me-amsal-3,5-di-*t*Bu)$_2$(MeOH)$_2$]$_n$ **2**, suitable for X-ray analyses.

Mn(5-*t*Bu-amsal-3,5-di-*t*Bu)(H$_2$O)$_4$: Yield 70%. $C_{27}H_{43}MnN_2O_7$ (561.9): calcd. C 57.7, H 7.7, N 5.0; found C 58.1, H 7.5, N 5.0. MS(FAB): *m*/*z* (%) = 490.3 (100, MnL), 981.6 (18, Mn_2L_2). Magnetic moment μ_{eff} = 4.9 B. M. Conductivity (in DMF) Λ_M = 9 μS cm^{-1}.
Recrystallisation of the brown powder in methanol yielded crystals of [Mn$_2$(5-*t*Bu-amsal-3,5-di-*t*Bu)$_2$(MeOH)$_2$]$_n$ **3**, suitable for X-ray studies.

Crystallographic Measurements

Crystals of **1, 2** and **3** suitable for single-crystal X-ray studies were obtained as described above. Data were collected at 293 K for **1** and **2**, and at 120 K for **3** on a Bruker SMART 1000 diffractometer, employing graphite-monochromated MoK_α (λ = 0.71073 Å) radiation. The structures were solved by direct methods[26] and finally refined by full-matrix least-squares based on F^2. An empirical absorption correction was applied using SADABS.[27] Non-hydrogen atoms were anisotropically refined. Hydrogen atoms were included in the structure factor calculation in idealised positions.

CCDC-228228 (for **1**), -228227 (for **2**) and -228226 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Syntheses and Crystal Structures of Two Cobalt Carboxylate−Phosphonates with 4,4′-Bipyridine as a Secondary Metal Linker

Jun-Ling Song,[a] Andrey V. Prosvirin,[b] Han-Hua Zhao,[b] and Jiang-Gao Mao*[a]

Keywords: Hydrothermal synthesis / Crystal structure / Cobalt phosphonates / Inorganic-organic hybrids / Open frameworks

The hydrothermal syntheses and crystal structures of two novel cobalt carboxylate–phosphonates with 4,4′-bipyridine (4,4′-bipy) as the secondary metal linker are reported. Compound **1**, $[Co_3(H_2L)_2(H_2O)_4(4,4'\text{-bipy})]$, where H_5L = 4-$HO_2CC_6H_4CH_2N(CH_2PO_3H_2)_2$, crystallizes in the monoclinic space group $C2/c$ with a = 25.9281(5), b = 9.76310(10), c = 17.3671(5) Å, β = 103.290(2)°, V = 4278.6(2) Å^3, and Z = 4. Its structure contains a pillar-layered architecture in which Co^{II} octahedra are linked by carboxylate–phosphonate ligands to form a 2D layer and these layers are crosslinked further by 4,4′-bipy ligands to form a porous 3D network. Compound **2**, $[Co_2(PMIDA)(H_2O)_5(4,4'\text{-bipy})]\cdot 4H_2O$, where H_4PMIDA = $H_2O_3PCH_2N(CH_2CO_2H)_2$, crystallizes in the triclinic space group $P\bar{1}$ with a = 7.8009(7), b = 13.4560(12), c = 13.5453(12) Å, α = 65.207(2), β = 88.035(2), γ = 77.135(2)°, V = 1255.57(19) Å^3, and Z = 2. The crystal structure of compound **2** contains 1D zigzag chains in which two cobalt(II) ions are bridged by PMIDA ligand to form dimeric units, and these dimeric units are connected further by bridging 4,4′-bipy ligands.

Introduction

Recently, many research studies have been devoted to the synthesis of metal phosphonates with open-framework or microporous structures because of their potential applications in ion-exchange, catalysis and sensors.[1−6] Furthermore, interesting magnetic properties have been observed in some of these systems. For example, weak ferromagnetic or canted antiferromagnetic behavior has been observed in some Mn^{II}, Fe^{II}, Cu^{II} and Co^{II} compounds.[3,7−14] The strategy of attaching functional groups such as carboxylic acids, crown ethers and amines to the phosphonic acid molecule has been found to be an effective method for the preparation of metal phosphonates with open-framework and microporous structures. For example, a series of novel microporous materials has been synthesized by hydrothermal reactions of different metal salts with carboxylate-functionalised phosphonic acids $H_2O_3PCH_2CH_2CO_2H$ and $H_2O_3PCH_2CO_2H$.[15−17] The use of additional bidentate metal linkers, such as 1,10-phenanthroline, 2,2′-bipyridine, piperazine and 4,4′-bipyridine, results in various mixed-metal hybrids of V and Mo.[13,18] Reports regarding the corresponding divalent transition metal compounds are rare.[12,13] We selected two carboxylate−phosphonic acids, H_5L [H_5L = 4-$HOOCC_6H_5CH_2N(CH_2PO_3H_2)_2$] and H_4PMIDA [H_4PMIDA = $H_2O_3PCH_2N(CH_2COOH)_2$] (Scheme 1), in combination with 4,4′-bipyridine (4,4′-bipy) as the secondary metal linker. Zinc(II) and cobalt(II) compounds prepared from H_4PMIDA have been reported previously.[19] Hydrothermal reactions of the metal salts with the above phosphonic acids and 4,4′-bipy led to two new cobalt carboxylate−phosphonates, namely $[Co_3(H_2L)_2(H_2O)_4(4,4'\text{-bipy})]$ (**1**) and $[Co_2(PMIDA)(H_2O)_5(4,4'\text{-bipy})]\cdot 4H_2O$ (**2**). Herein we report their syntheses and crystal structures.

Results and Discussion

Crystal Structure Descriptions for Compounds 1 and 2

As shown in Figure 1, the asymmetric unit of compound **1** contains two unique Co^{II} atoms. The Co(1) atom is octahedrally coordinated by the tridentate phosphonate ligand (1 N and 2 O), two phosphonate oxygen atoms from two other phosphonate ligands, and one nitrogen atom from a 4,4′-bipy ligand. The Co(1)−O bond lengths are in the range from 2.036(7) to 2.087(6) Å, and the Co(1)−N bond lengths are in the range from 2.154(8) to 2.348(8) Å. The O−Co−O and O−Co−N bond angles deviate from the values for an ideal octahedron (Table 1). The atom Co(2) lies on a twofold symmetry axis and is octahedrally coordinated to two phosphonate oxygen atoms from two Co(1)(H_2L) units, and four water ligands. The Co−O bond lengths fall between 2.049(6) and 2.152(7) Å, and the O−Co−O bond angles are in the range from 84.5(3) to 95.6(3)°. These bond lengths and angles are similar to those in $Co_2[PMIDA]_2(H_2O)_5{\cdot}H_2O$,[19] as well as for other cobalt(II) phosphonates.[13,14,20] The carboxylate−phosphonate ligand is hexadentate and occupies three coordination sites on one Co^{II} ion and also bridges three Co^{II} ions. The phosphonate group containing P(2) is tridentate, whereas the one containing the atom P(1) is bidentate. It should be noted that the benzoic acid moiety does not coordinate to metal ions and remains protonated (O2). The atom O(11) in the P(1)O_3 group is also noncoordinating. This PO_3 group is singly protonated based on P−O distances and charge balance. The noncoordinating carboxylate (O2) and phosphonate (O11) oxygen atoms are hydrogen-bonded to an aquo ligand (O1W) (Table 1). The [CoN_2O_4] and [CoO_6] octahedra are interconnected by bridging carboxylate−phosphonate ligands in the plane {400} (Figure 2). The interlayer distance is 12.9 Å (1/2*a*). The 2D layers are further crosslinked by 4,4′-bipy ligands

to form a pillar-layered structure (Figure 3), which contains channels with a size of about 9 × 11 Å based on the crystal structure. The benzoic acid moieties are located in these channels.

Compound **2** features a 1D zigzag chain structure. There are two independent Co^{II} ions in the asymmetric unit of compound **2** (Figure 4). Co(1) is octahedrally coordinated to a tetradentate PMIDA ligand, an aquo ligand and a nitrogen atom from a 4,4′-bipy ligand, whereas Co(2) is octahedrally coordinated by one 4,4′-bipy N atom, one phosphonate oxygen atom from a neighboring Co(1)(PMIDA) chelating unit as well as four aquo ligands. The Co−O distances are in the range from 2.082(4) to 2.181(4) Å, and the Co−N distances fall in the range 2.115(3) to 2.156(4) Å. These bond lengths are similar to those in other Co^{II} complexes with O- and N-containing ligands.[13,14,19,20] The PMIDA ligand is pentadentate, occupying four sites on a Co^{II} ion (1 N, 3 O) and bridging to another Co^{II} ion. O(1) and O(3) atoms of the carboxylate groups remain noncoordinating. The phosphonate group adopts a bidentate and bridging coordination mode, with one oxygen atom (O11) not involved in metal coordination. This type of coordination mode is different from that for $Co_2[PMIDA]_2(H_2O)_5{\cdot}H_2O$,[19] in which the phosphonate group is tridentate and one carboxylate group is bidentate. The PMIDA ligand in compound **1** has been fully deprotonated based on charge balancing.

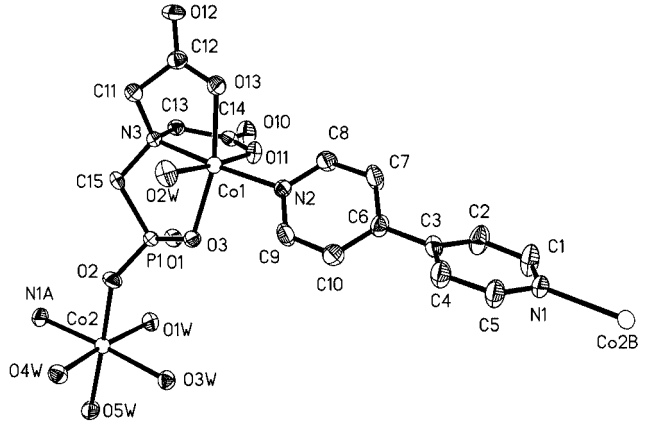

Figure 4. An ORTEP representation of the asymmetric unit of **2**; thermal ellipsoids are drawn at the 30% probability level

The two types of cobalt(II) octahedra are bridged by a PMIDA ligand to form a dimeric unit, and such dimeric units are further interconnected by bridging 4,4′-bipy ligands to form a 1D chain (Figure 5). These chains are held together by hydrogen bonds among noncoordinating carboxylate (O12 and O10) and phosphonate(O1) oxygen atoms as well as aquo ligands, resulting in a porous 3D network (Figure 6, Table 2). The lattice water molecules are located in the pores and are also involved in hydrogen bonding (Table 2, Figure 6).

TGA Studies

The TGA diagram of compound **1** shows three main stages of weight loss. The first stage begins at 138 °C and is complete at 342 °C, and corresponds to the loss of four water molecules. The observed weight loss of 6.4% is in good agreement with the calculated value of 6.7%. The second stage, occurring between 347 and 820 °C, corresponds to the combustion of 4,4′-bipy and diphosphonate ligands. The third stage, which overlaps with the second, continues up to 1000 °C and corresponds to further decomposition of the compound. Assuming the final product is a mixture

Symmetry transformations used to generate equivalent atoms: #1: $x, y + 1, z - 1$; #2: $-x + 1, -y + 1, -z + 2$; #3: $-x, -y + 1, -z + 2$; #4: $x, y + 1, z$; #5: $x + 1, y, z$; #6: $-x, -y + 1, -z + 1$; #7: $x - 1, y, z$.

of $Co(PO_3)_2$ and $Co_2P_2O_7$ in a molar ratio of 1:1, the total weight loss should be 52.8%. On the other hand, if compound **1** completely decomposes to CoO, the total weight loss is calculated to be 79.2%. The observed weight loss (70.2%) is between these two theoretical values, and indicates the partial decomposition of $Co(PO_3)_2$ and $Co_2P_2O_7$ to CoO. The TGA weight loss curves of compound **2** also exhibit three stages. The first stage (24−269 °C) corresponds to loss of the four water molecules of crystallisation and five aquo ligands. The observed weight loss of 24.8% is in good agreement with the calculated value of 24.9% based on the loss of a total of nine H_2O molecules. The second loss occurs at 330−570 °C, and corresponds to the decomposition of the 4,4′-bipy and carboxylate−phosphonate ligand. The third stage, occurring between 620 and 1000 °C, corresponds to further decomposition of the organic groups. If the residue is assumed to be a mixture of CoO and $Co_2P_2O_7$ in a molar ratio of 2:1, the total weight loss is calculated to be 66.5%. On the other hand, if the final residue is CoO alone, the total weight loss is calculated to be 88.6%. The observed weight loss (74.8%) is between these two theoretical values, indicating that some $Co_2P_2O_7$ has decomposed to CoO.

Conclusion

In summary, the hydrothermal syntheses and crystal structures of two novel cobalt carboxylate−phosphonates containing 4,4′-bipy as the secondary metal linker have been described. The interconnection of the metal carboxylate−phosphonate layer in compound **1** by 4,4′-bipy leads to a pillar-layered architecture. In compound **2**, the dinuclear metal carboxylate−phosphonate units are crosslinked by 4,4′-bipy ligands resulting in a 1D chain. We believe that a wide range of new open-frameworks and microporous materials can be developed by self-assembly or by structure-directed synthesis of other metal phosphonate building blocks with secondary metal linkers such as 4,4′-bipy or acidic carboxylic acid. In the latter case, the carboxylate ligand may remain protonated and noncoordinated, in other words, it can act as an intercalated species between two metal phosphonate layers. Such compounds may have good ion-exchange properties and could exhibit proton conductivity.

Experimental Section

Materials and Instrumentation: All chemicals were obtained from commercial sources and used without further purification. Elemental analyses were performed with a Vario EL III elemental analyzer. Thermogravimetric analyses were carried out with a NETZSCH STA 449C unit at a heating rate of 15 °C/min under nitrogen. IR spectra were recorded with a Magna 750 FT-IR spectrophotometer on KBr pellets in the range 4000−400 cm^{-1}. ^1H and ^{31}P NMR spectra were recorded with a Varian Unity 500 NMR spectrometer using D_2O as solvent. H_3PO_4 (85%) was used as ^{31}P standard reference.

Preparation of H_5L and H_4PMIDA: H_5L was prepared by a Mannich-type reaction using 4-(aminomethyl)benzoic acid (15.1 g, 0.1 mol), hydrochloric acid (16 mL), deionized water (20 mL), phosphoric acid (32.8 g, 0.4 mol) and paraformaldehyde (9.0 g, 0.3 mol), according to known procedures.[16,21] The ^{31}P NMR spectrum shows a single peak at $\delta = 7.69$ ppm. ^1H NMR (D_2O) : $\delta = 3.50$ (d, $J_{H,P} = 12.5$ Hz, 4 H, NCH_2PO_3), 4.74 (s, 2 H, 3-H), 7.73 (d, $J_{H,H} = 5.5$ Hz, 2 H, 2-H), 8.13 (d, $J_{H,H} = 5.5$ Hz, 2 H, 1-H) ppm (see Scheme 1 for atomic labeling). IR (KBr): $\tilde{\nu} = 3423$ (w), 2995 (m), 2771 (m), 2657 (m), 1720 (s), 1618 (w), 1583 (w), 1458 (m), 1435 (w), 1417 (w), 1327 (m), 1232 (m), 1138 (s), 1107 (s), 1022 (s), 939 (s), 862 (w), 810 (w), 746 (m), 710 (m), 580 (s), 519 (w), 494 (m), 451 (m) cm^{-1}. H_5L: $C_{10}H_{15}NO_8P_2$ (339.18): calcd. C 35.53, H 4.34, N 4.22; found C 35.41, H 4.46, N 4.13. H_4PMIDA

was also synthesized by a Mannich-type reaction according to procedures described previously.[22]

Preparation of [$Co_3(H_2L)_2(H_2O)_4$(4,4′-bipy)] (1): A mixture of $CoCl_2·6H_2O$ (0.24 g, 1.0 mmol), H_5L (0.17 g, 0.5 mmol) and 4,4′-bipy (0.09 g, 0.5 mmol) in distilled water (10 mL) was placed in a sealed hydrothermal reaction vessel equipped with a Teflon liner (25 mL), and then heated to 170 °C for 5 d. Pink crystals of **1** were collected. Yield: 0.09 g (ca. 26% based on cobalt). The initial and final pH values of this solution were 4.0 and 3.5, respectively. $C_{30}H_{40}Co_3N_4O_{20}P_4$ (1077.33): calcd. C 33.45, H 3.74, N 5.20; found C 33.65, H 3.56, N 5.26.

Preparation of [Co_2(PMIDA)$(H_2O)_5$(4,4′-bipy)]·$4H_2O$ (2): A mixture of $Co(CH_3COO)_2·2H_2O$ (0.24 g, 1.0 mmol), H_4PMIDA (0.11 g 0.5 mmol) and 4,4′-bipyridine (0.09 g 0.5 mmol) in distilled water (10 mL) was placed in a sealed hydrothermal reaction vessel equipped with a Teflon liner (25 mL), and then heated to 80 °C for 5 d. The resulting orange-red solution was filtered and ethanol was allowed to diffuse slowly into the solution at room temperature. Orange-red crystals of **2** appeared after several days and were collected. Yield: 0.16 g (ca. 48% based on cobalt). The initial and final pH values of the solutions were 4.0 and 4.5, respectively. IR (KBr): $\tilde{\nu}$ = 3290 (s), 1668 (m), 1612 (s), 1578 (m), 1537 (m), 1433 (w), 1371 (m), 1335 (w), 1259 (w), 1119 (m), 1086 (s), 1070 (s), 960 (s), 814 (m), 769 (m), 735 (w), 636 (m), 575 (w), 515 (w), 488 (w). $C_{15}H_{32}Co_2N_3O_{16}P$ (659.27): calcd. C 27.33, H 4.89, N 6.37; found C 27.41, H 4.76, N 6.42.

X-ray Crystallographic Study: Single crystals of compounds **1** and **2** were mounted on a Siemens Smart CCD diffractometer equipped with a graphite-monochromated Mo-K_α radiation source (λ = 0.71073 Å). Intensity data were collected by the narrow-frame method at 293 K. A hemisphere of data (1271 frames at 5 cm detector distances) was collected with scan widths of 0.30° in ω and exposure time of 20 s per frame. The first 50 frames were collected again at the end of data collection to assess the stability of the crystal, and it was found that the decay in intensity was less than 1%. Both data sets were corrected for Lorentz and polarization factors as well as for absorption using the SADABS program.[23] Both structures were solved by direct methods and refined by full-matrix least-squares fitting on F^2 using SHELX-97.[23] All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were located at geometrically calculated positions and refined with isotropic thermal parameters. Crystallographic data and structural refinements for compounds **1** and **2** are summarized in Table 3. Selected bond lengths and angles are listed in Tables 1 and 2, respectively. CCDC-233617 (**1**) and -233618 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Three New Organically Templated Polyoxomolybdates with Capping Selenite Anions

Mei-Ling Feng[a] and Jiang-Gao Mao*[a]

Keywords: Hydrothermal synthesis / Inorganic-organic hybrid composites / Molybdenum / Polyoxometalates / Selenium

Three new organically templated polyoxomolybdates with selenite anions as capping groups have been synthesized by hydrothermal reactions and structurally characterized. The structure of $\{Hbipy\}_3\{KMo_4O_{13}(SeO_3)\}$ (**1**; bipy = 4,4′-bipyridine) features a 1D anionic double chain of $\{KMo_4O_{13}(SeO_3)\}^{3-}$ units. Four $Mo^{VI}O_6$ octahedra in compound **1** form a planar Mo_4O_{13} cluster unit through corner-, edge- and face-sharing. The Mo_4O_{13} cluster unit is further capped by an $Se^{IV}O_3$ group in a bidentate fashion. These monocapped cluster units are further interconnected by bridging K^+ cations into a 1D double chain. Both $\{H_2bipy\}_2\{Mo_5O_{15}(SeO_3)_2\}\cdot H_2O$ (**2**) and $\{H_2pip\}_2\{Mo_5O_{15}(SeO_3)_2\}\cdot 3H_2O$ (**3**; pip = piperazine) contain a bicapped Mo_5O_{15} cluster unit in which five $Mo^{VI}O_6$ octahedra form a planar Mo_5O_{15} cluster unit through edge- and corner-sharing, with the two $Se^{IV}O_3$ anions as tridentate capping groups on the two open sides of the cluster unit to form an $\{Mo_5O_{15}(SeO_3)_2\}^{4-}$ anion. The $\{Mo_5O_{15}(SeO_3)_2\}^{4-}$ cluster anions in compounds **2** and **3** are further inter-linked by the organic templates through hydrogen bonds to form a 2D layer.

Introduction

Polyoxometalates (POMs) are one of the most widely used inorganic components due to the extreme variability of their compositions, molecular characteristics, properties and applications.[1] Recently, a lot of research efforts have been focused on the functionalization of POMs with transition metal complex or lanthanide complex moieties — the coordinated transition metal or lanthanide metal complex cation serves to provide charge-compensation, space-filling, and structure-directing roles. In most cases, the transitional-metal and the rare-earth ions are found to be either sandwiched between two polymolybdate anions or as a capping atom on the cluster unit.[2−5] For polyoxomolybdates with a small cluster unit, such as Mo_4O_{13}, Mo_5O_{15} and Mo_6O_{18}, the cluster unit can be further capped by one or two tetrahedral groups such as PO_4, RPO_3, SO_4, AsO_4, $RAsO_3$, etc.[6−8] However, studies on polymolybdates with capping XO_3 groups (X = Se^{IV}, Te^{IV}, As^{III}, Sb^{III}, Bi^{III}) are rare.[9]

We are particularly interested in metal selenites. A few examples of open frameworks of metal selenites have been reported.[10−13] An organically templated 2D zinc selenite was first reported by Harrison et al.[10] Organically templated 3D iron(II), cobalt(II), nickel(II) and zinc(II) selenites have also been reported by Rao and co-workers.[11] Both organically templated and organically linked vanadium selenites have also been reported.[12,13] So far only polyoxomolybdates with an Mo_6O_{18} cluster unit capped by a selenite group have been reported.[9] We therefore decided to study systematically the syntheses and crystal structures of organically templated polyoxomolybdates containing capping selenite groups. Our research efforts led to three new organically templated polyoxomolybates with selenite anions as capping groups, namely $\{Hbipy\}_3\{KMo_4O_{13}(SeO_3)\}$ (**1**), with an $\{Mo_4O_{13}\}^{2-}$ cluster unit, and $\{H_2bipy\}_2\{Mo_5O_{15}(SeO_3)_2\}\cdot H_2O$ (**2**) and $\{H_2pip\}_2\{Mo_5O_{15}(SeO_3)_2\}\cdot 3H_2O$ (**3**) containing an Mo_5O_{15} cluster unit capped by two $Se^{IV}O_3$ anions. We report here their syntheses, characterizations and crystal structures.

Results and Discussion

The synthetic procedures for the formation of compounds **1**−**3** are interesting. Both compounds **1** and **2** were obtained from the same starting materials but in a different molar ratio: a higher Mo/Se ratio leads to compound **2** with an MO_5O_{15} cluster unit but without K^+ as an inter-cluster linker. For the synthesis of compound **3**, it is necessary to use $(NH_4)_6Mo_7O_{24}$ as the source of the Mo^{VI} ions as the use of K_2MoO_4 led to $\{H_2bipy\}_3\{Mo_8O_{27}\}$ with a known $\{Mo_8O_{27}\}^{6-}$ cluster unit.[14] Thus, the source of molybdenum, the Mo/Se ratio, the cation used and the pH value of the reaction have a strong effect on the compound formed.

The structure of compound **1** (Figure 1) features a 1D anionic double chain composed of $\{KMo_4O_{13}(SeO_3)\}^{3-}$ units in which the monocapped $Mo_4O_{13}(SeO_3)$ cluster units are interconnected by bridging K^+ cations. As shown in

Figure 1, there are four Mo and one Se atoms in an asymmetric unit. All four Mo atoms are octahedrally coordinated. The Mo−O bonds are in the range 1.689(4)−2.416(4) Å. The MoO_6 octahedra are severely distorted, two Mo−O bonds are significantly elongated and two Mo−O(terminal) bonds are much shorter than the remaining ones. The Se atom is three-coordinate, with Se−O distances ranging from 1.644(5) to 1.738(4) Å. These Mo−O and Se−O distances are similar to those reported in the literature.[6,9] Based on the results of bond-valence calculations, all Mo atoms are in the +6 oxidation state, and the Se atom has a +4 oxidation state: the calculated total bond valences for the Mo atoms are in the range of 5.945 to 6.062, and that for the Se atom is 4.03.[15] Thus, the polyhedron of Se^{IV} can be described as a ψ-SeO_3 tetrahedron with one corner of the tetrahedron occupied by the lone pair of electrons.

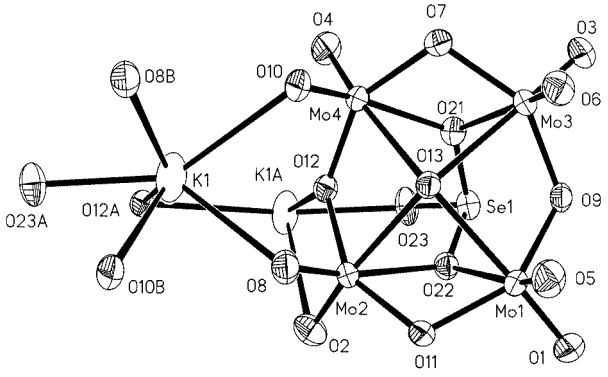

Figure 1. ORTEP representation of the asymmetric unit of compound **1**; thermal ellipsoids are drawn at 50% probability; the organic templates have been omitted for clarity; symmetry codes for the generated atoms: a: $-x + 1/2, -y + 1/2, -z + 1/2$; b: $-x + 1/2, -y + 1/2, -z + 2$

The four $Mo^{VI}O_6$ octahedra are interconnected by edge- and face-sharing to form a planar $Mo_4O_{13}(SeO_3)$ cluster unit. The mean deviation from the plane defined by Mo(1), Mo(2), Mo(3), and Mo(4) is 0.0104 Å. O(13) is a μ_4 metal linker, bridging all four Mo^{VI} centers and lies 0.734 Å out of the Mo_4 plane. The selenite group is capping on the opposite site of O(13) in a bidentate fashion. O(21) and O(22) each bridge two Mo^{VI} centers, whereas O(23) is not bonded to the Mo^{VI} center. Two $Mo^{VI}O_6$ octahedra [Mo(1) and Mo(2) or Mo(3) and Mo(4)] form a dimer by face-sharing, resulting in two relatively short Mo···Mo separations [3.1428(8) and 3.1543(8) Å]. These dimers are further interconnected by edge-sharing, although with larger Mo···Mo separations [3.304(1) and 3.329(1) Å]. The Mo−O(SeO_3) bond lengths are in the range 2.258(4)−2.289(4) Å (Table 1), and are similar to those reported in heteropolymolybdates of Se^{IV} functionalized by amino acids containing an $Mo_6O_{18}(SeO_3)$ cluster core.[9] To some extent, such a $Mo_4O_{13}(SeO_3)$ cluster unit resembles those reported in tetramolybdo complexes of dialkyl and diaryl arsinates.[6] However, this type of cluster unit differs significantly from the Mo_4O_{12} cluster in copper−Mo−$O_3PCH_2CH_2PO_3$ com-

pounds,[16] in that one Mo^{VI} ion in the latter cluster compounds is in a square-pyramidal geometry and the cluster units are noncyclic.

The $\{Mo_4O_{13}(SeO_3)\}^{4-}$ cluster units in compound **1** are bridged by K^+ ions through K−O(23) bonds to form a novel 1D double chain along the *c* axis (Figure 2). The K^+ ion is six-coordinate, with four terminal oxygen atoms from four cluster units, one bridging oxygen atom [O(12a)] from a cluster unit and one oxygen atom from a selenite group. The K−O distances are in the range 2.564(5)−3.069(5) Å (Table 1). The templates — the bipy ligands — are singly protonated. Packing of these templates forms cavities, which are occupied by $\{KMo_4O_{13}(SeO_3)\}^{3-}$ anionic chains (Figure 3).

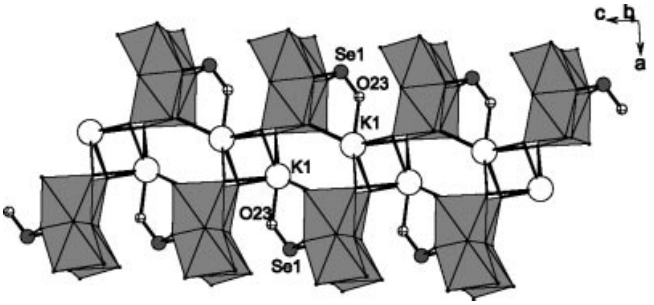

Figure 2. The 1D anionic chain of $\{KMo_4O_{13}(SeO_3)\}^{3-}$ moieties along the *c* axis in **1**; the MoO_6 octahedra are shaded in gray; the K, Se and O atoms are drawn as open, hatched and crossed circles, respectively

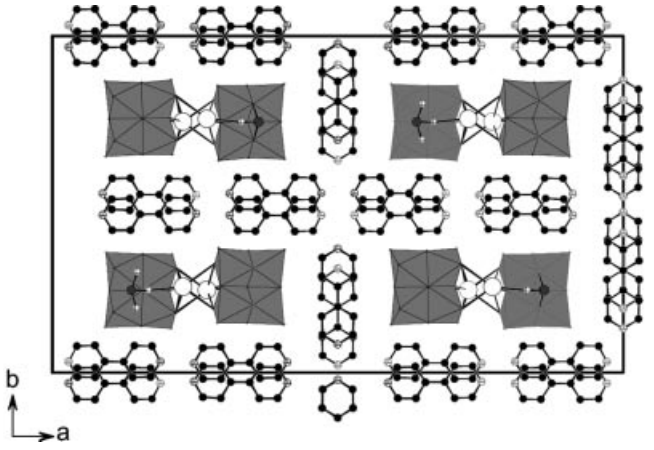

Figure 3. A view of the crystal structure of **1** along the *c* axis; the MoO_6 octahedra are shaded in gray; the K, Se, C, N and O atoms are drawn as open, hatched, black, octanded and crossed circles, respectively

Compounds **2** and **3** both contain a bicapped $\{Mo_5O_{15}(SeO_3)_2\}^{4-}$ anionic cluster unit (Figure 4). Five MoO_6 octahedra form a planar Mo_5O_{15} unit by sharing four edges and one corner. The corner-sharing occurs between two $Mo(2)O_6$ octahedra in compound **2**, and between $Mo(3)O_6$ and $Mo(4)O_6$ octahedra in compound **3.** The two opposite sides of the cluster unit are capped by two selenite groups (Figure 4). This type of bicapped Mo_5O_{15} cluster unit is similar to those reported previously in polymolybdophosphonates or -phosphates.[7] The Mo_5O_{15} cluster unit in compound **2** is less coplanar than the Mo_4O_{13} cluster unit in compound **1**. The mean deviation from the plane defined by Mo(1), Mo(2), Mo(3), and Mo(2a) and Mo(3a) is 0.1847 Å. The two Se^{IV} centers are 2.133 Å away from the Mo_5 plane. The Mo−O and Se−O distances are similar to those in compound **1** (Table 1). All Mo atoms are in the +6 oxidation state and the Se atoms are in the +4 oxidation state based on the results of bond-valence calculations.[15]

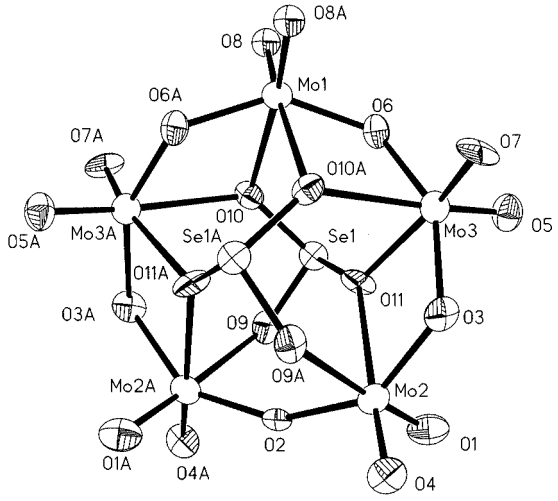

Figure 4. ORTEP representation of the $Mo_5O_{15}(SeO_3)_2^{4-}$ unit in **2**; the thermal ellipsoids are drawn at 50% probability; symmetry code for the generated atoms: a: $1 - x, y, 1 - z$

The bicapped $\{Mo_5O_{15}(SeO_3)_2\}^{4-}$ anionic cluster units in compounds **2** are hydrogen-bonded with the templates, which in this case are doubly protonated bipy ligands, $\{H_2bipy\}^{2+}$, resulting in a hydrogen-bonded <201> 2D layer (Figure 5). The hydrogen bonds are formed between the amine groups of bipy and the terminal oxygen atoms of the cluster unit (Figure 5, Table 1). The lattice water mol-

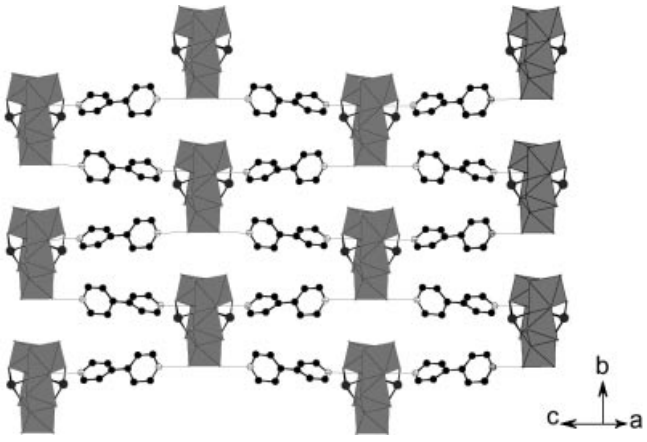

Figure 5. A <201> layer built from $Mo_5O_{15}(SeO_3)_2^{4-}$ units interconnected by $[H_2bipy]^{2+}$ cations through hydrogen bonding in **2**; the MoO_6 octahedra are shaded in gray; the Se, C, N and O atoms are drawn as open, black, octanded and crossed circles, respectively; hydrogen bonds are drawn as dotted lines

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ecules are located between the layers and are involved in hydrogen bonding with the oxygen atom [O(9)] of the selenite group (Table 1).

Similar to compound **2**, the bicapped $\{Mo_5O_{15}(SeO_3)_2\}^{4-}$ anionic cluster units of compounds **3** are also interlinked by hydrogen bonds, although in this case to doubly protonated piperazines, containing atoms N1 and N2, resulting in a <040> corrugated layer (Figure 6, Table 1). The other doubly protonated piperazine molecules, containing N3 and N4, are located in the cavities formed by packing of the 2D layers, as are the lattice water molecules. These lattice water molecules are also involved in hydrogen bonding (Table 1).

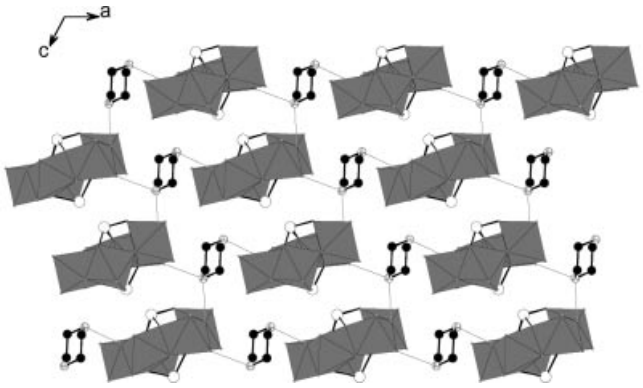

Figure 6. A <040> corrugated layer built from $Mo_5O_{15}(SeO_3)_2^{4-}$ units interconnected by $[H_2pip]^{2+}$ cations through hydrogen bonding in **3**; the MoO_6 octahedra are shaded in gray; the Se, C, N and O atoms are drawn as open, black, octanded and crossed circles, respectively; hydrogen bonds are drawn as dotted lines

The results of XRD powder-diffraction studies for compounds **1**−**3** indicate that all three compounds were isolated as single phases.

The IR spectra of compounds **1**−**3** all exhibit a strong band around 930−933 cm^{-1}, characteristic of ν(Mo=O). The bands around 720−730 and 438−457 cm^{-1} can be assigned to the vibrations of the selenite groups. The bands around 1614−1622 and 1403−1421 cm^{-1} originate from the templates — bipy in compounds **1** and **2**, and piperazine in compound **3**.

The TGA diagram of compound **1** indicates that it is stable up to 234 °C (Figure 7). The subsequent weight loss corresponds to the release of the template molecules and the decomposition of the cluster chain. The process is complete at 490 °C. Compound **2** starts to release its lattice water at 160 °C; the second weight loss corresponds to the release of the template bipy molecules and the decomposition of the cluster unit, which is complete at 487 °C. The TGA curves of compound **3** show two main weight losses (Figure 7). The first one starts at 143 °C and is complete at 202 °C, corresponding to the release of its three lattice water molecules. The unusually high temperature needed for the release of lattice water molecules may be due to the strong hydrogen bonds formed. The observed weight loss of 4.3% is in good agreement with the calculated value (4.5%). The

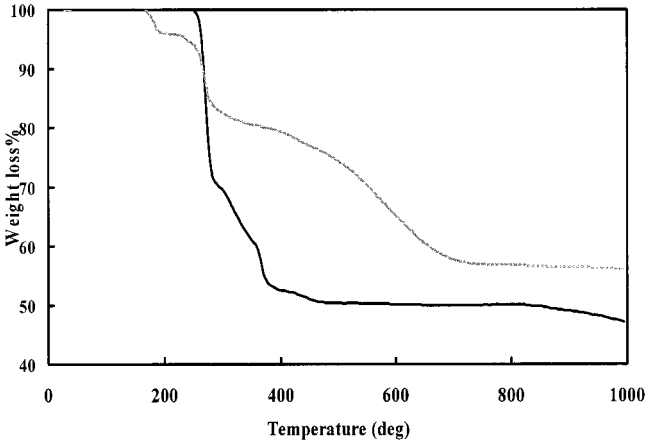

Figure 7. TGA curves for compounds **1** (black line) and **3** (grey line)

second weight loss, covering a temperature range from 235 to 843 °C, corresponds to the loss of the piperazine molecules and decomposition of the compound. The residual solids were not identified due to insufficient samples collected.

Conclusion

Three novel organically templated polymolybdates containing selenite groups as capping groups have been synthesized by hydrothermal reactions. These three examples demonstrate that the selenite group can be capped on many other polymolybdate cluster units in addition to the Mo_6O_{18} cluster reported previously.[9] Our future work will explore more organically templated selenite- or tellurite-containing polymolybdates.

Experimental Section

Materials and Methods: All chemicals were obtained from commercial sources and used without further purification. Mo, K and Se analyses were carried out with an ICPQ-100 spectrometer. IR spectra were recorded with a Magna 750 FT-IR spectrometer as KBr pellets in the range 4000−400 cm^{-1}. Thermogravimetric analyses were carried out with a NETZSCH STA 449C unit at a heating rate of 15 °C/min under nitrogen. The XRD powder patterns were collected with a Philips X'Pert-MPD diffractometer using graphite-monochromated Cu-K_α radiation in the angular range $2\theta = 5-70°$ with a step size of 0.02° and a counting time of 3 s per step.

Preparation of $\{Hbipy\}_3\{KMo_4O_{13}(SeO_3)\}$ (1): A mixture of K_2MoO_4 (0.270 g, 1.0 mmol), SeO_2 (0.221 g, 2.0 mmol) and 4,4′-bipyridine (0.0792 g, 0.5 mmol) in 10 mL of distilled water was sealed in an autoclave equipped with a Teflon liner (25 mL), and then heated at 160 °C for 6 d. The pH values before and after the reaction were 5.0 and 5.5, respectively. Colorless, needle-shaped crystals of **1** were collected in about 33% yield (0.101 g) (based on Mo). $C_{30}H_{27}KMo_4N_6O_{16}Se$ (1229.4): calcd. C 29.28, H 2.21, K 3.18, Mo 31.22, N 6.83, Se 6.42; found C 29.13, H 1.85, K 2.8, Mo 30.6, N 6.76, Se 6.7. IR (KBr): $\tilde{\nu}$ = 3435 br, 2047 m, 1614 s, 1595 s, 1567 m, 1526 m, 1489 s, 1407 m, 1326 m, 1213 s, 1065 m, 1009

m, 995 m, 930 s, 907 s, 894 s, 870 s, 807 s, 723 s, 685 s, 568 s, 539 m, 457 m cm^{-1}.

Preparation of $\{H_2bipy\}_2\{Mo_5O_{15}(SeO_3)_2\}\cdot H_2O$ (2): A mixture of K_2MoO_4 (0.551 g, 2.0 mmol), SeO_2 (0.229 g, 2.0 mmol) and 4,4′-bipyridine (0.0792 g, 0.5 mmol) in 10 mL of distilled water was sealed in an autoclave equipped with a Teflon liner (25 mL), and then heated at 160 °C for 6 d. The initial and final pH values for the reaction solution were 5.0 and 6.0, respectively. Colorless, plate-shaped crystals of **2** were collected in about 48% yield (0.251 g) (based on Mo). $C_{20}H_{22}Mo_5N_4O_{22}Se_2$ (1308.4): calcd. C 18.34, H 1.69, Mo 36.55, N 4.28, Se 12.07; found C 18.09, H 1.8, Mo 36.1, N 4.56, Se 11.8. IR (KBr): $\tilde{\nu}$ = 3089 br, 2080 m, 1622 s, 1557 m, 1514 m, 1489 s, 1404 m, 1371 m, 1204 s, 1001 m, 932 s, 904 s, 847 m, 803 s, 723 s, 684 s, 584 s, 553 s, 442 m cm^{-1}.

Preparation of $\{H_2pip\}_2\{Mo_5O_{15}(SeO_3)_2\}\cdot 3H_2O$ (3): A mixture of $(NH_4)_6Mo_7O_{24}$ (0.355 g, 0.29 mmol), SeO_2 (0.339 g, 3.0 mmol) and piperazine (0.0896 g, 1.0 mmol) in 10 mL of distilled water was sealed in an autoclave equipped with a Teflon liner (25 mL), and then heated at 110 °C for 5 d. The pH values before and after the reaction were 5.0 and 5.5, respectively. Colorless, brick-shaped crystals of **3** were collected in about 53% yield (0.132 g) (based on Mo). $C_8H_{30}Mo_5N_4O_{24}Se_2$ (1204.0): calcd. C 7.97, H 2.51, Mo 39.84, N 4.65, Se 13.12; found C 7.819, H 2.38, Mo 39.2, N 4.39, Se 12.7. IR (KBr): $\tilde{\nu}$ = 3017 br, 1615 s, 1579 s, 1454 s, 1421 s, 1382 s, 1329 w, 1307 m, 1205 s, 1086 m, 1075 m, 1059 m, 1004 s, 932 s, 902 s, 780 w, 730 s, 651 s, 578 s, 480 m, 438 m cm^{-1}.

X-ray Single-Crystal Structure Determination: Single crystals of compounds **1**−**3** were mounted on a Siemens Smart CCD diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Intensity data were collected by the narrow-frame method at 293 K. All three data sets were corrected for Lorentz and polarization factors, as well as for absorption, with the SADABS program.[17a] The space groups of compounds **1** and **3** were determined uniquely to be *C*2/*c* and $P2_1/n$, respectively. For compound **2** the space group could be one *C*2, *C*2/*m*, or *Cm*. However, based on the E-value statistics, it is noncentrosymmetric, and furthermore, no reasonable solution was found for *C*2/*m* and *Cm*; thus, *C*2 was used for the subsequent refinements of compound **2**. All structures were solved by direct methods and refined by full-matrix least-squares fitting on F^2 with SHELX-97.[17b] All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms attached to carbon atoms and of amine groups were located at geometrically calculated positions and refined with isotropic thermal parameters. The hydrogen positions for the singly protonated bipy ligands in compound **2** were difficult to determine accurately and were not refined; neither were the hydrogen atoms of the lattice water molecules. Crystallographic data and structural refinements for compounds **1**−**3** are summarized in Table 2. Selected bond lengths are listed in Table 1. CCDC-234093 (**1**), -234094 (**2**) and -234095 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

A New 3-D Open-Framework Zinc Phosphate $[C_6H_{16}N_2]\cdot[Zn_2(HPO_4)_3]$ Synthesized by a Solvothermal Combinatorial Approach

Yu Song,[a] Jihong Yu,*[a] Yi Li,[a] Min Zhang,[a] and Ruren Xu*[a]

Keywords: Solvothermal synthesis / Structure / Combinatorial approach / Host-guest systems / Zinc phosphate

By application of a combinatorial approach, a new open-framework zinc phosphate $[C_6H_{16}N_2]\cdot[Zn_2(HPO_4)_3]$ (denoted as phase **D**) has been obtained in the $Zn(OAc)_2\cdot2H_2O/H_3PO_4/N,N'$-dimethylpiperazine/ethylene glycol solvothermal reaction system at 180 °C. The factors influencing formation of the reaction products, such as crystallization temperature, solvent, as well as gel compositions, have been systematically studied. Phase **D** was characterized by X-ray powder diffraction, ICP, and TG analyses, and its structure was determined by single-crystal X-ray diffraction analysis. It crystallizes in the monoclinic space group $P2_1/n$ (no.14), with a = 8.6931(3) Å, b = 14.4394(5) Å, c = 12.6492(3) Å, β = 96.418(2)°, and Z = 4. It is composed of ZnO_4, $PO_3(OH)$ and $PO_2(OH)(=O)$ tetrahedral units linked by Zn–O–P bonds, forming an open-framework with intersecting eight-membered ring channels along the [100], [010], and [101] directions.

Introduction

Since pioneering work on the preparation of aluminophosphate molecular sieves by Wilson et al. in 1982,[1] open-framework metal phosphates have received much attention because of their great importance in many current fields of applied chemistry. This results from their catalytic and adsorptive properties, as well as optical, electronic and magnetic properties.[2–5] These materials are generally prepared under hydrothermal or solvothermal conditions in the presence of an organic amine as a structure-directing agent. A large number of metal phosphates (MePOs) with interesting open-framework structures have been obtained (Me = Al, Ga, In, Mn, Fe, Co, Ni, Zn, Sn, Ti, Zr, V, and Mo, etc.), amongst which open-framework zinc phosphates exhibit a vast structural diversity. To date, a large number of zinc phosphates have been prepared with 0-D cluster, 1-D chain, 2-D layer and 3-D open-framework structures.[6–16] Notable examples are the extra-large microporous compounds, such as ND-1 with 24-membered ring channels,[13] and $[H_3N(CH_2)_6NH_3][Zn_4(PO_4)_2(HPO_4)_2]\cdot3H_2O$ with 20-membered ring channels,[15] and the helical channel compounds, such as $[NH_3(CH_2)_2NH_2(CH_2)_2NH_3][Zn(PO_4)_3(HPO_4)]$[14a] which contains intersecting helical channels, and $[Zn_2(HPO_4)_4][Co(dien)_2]H_3O$ (dien = diethylenetriamine) with multidirectional helical channels.[16] The structures of these compounds are typically built up from tetrahedral ZnO_4 and PO_4 units, although in some cases ZnO_5 and ZnO_6 polyhedra exist. The structural variety is greatly enriched by the employment of various templating agents or structure-directing agents, such as organic amines, alkali metal cations and metal complexes.

Compared to the traditional synthesis methods for materials, the combinatorial approach has been proven as a high-throughput technique for the discovery of new materials. Following their application in the discovery of new drugs, combinatorial methods have been employed in many research areas, such as organic and inorganic chemistry, and biochemistry.[17–20] In recent years, a hydrothermal combinatorial method has been applied successfully in the syntheses of zeolites and related open-framework materials.[21–25] Akporiaye and co-workers first reported the application of a combinatorial strategy to the hydrothermal synthesis of zeolites using a multiple autoclave to perform at least 100 crystallizations under hydrothermal conditions.[21] Maier and co-workers modified the multi-autoclave so that the microgram-scale hydrothermal synthesis of TS-1 could be conducted in an array format on an Si wafer.[22] Bein and co-workers developed this methodology by introducing automatic identification of the products within the autoclave blocks.[23] By applying a hydrothermal combinatorial approach we have obtained three open-framework zinc phosphates including phases **A** $\{[C_6H_{16}N_2]_{0.5}\cdot[C_5H_{14}N_2]\cdot[Zn_6(PO_4)_5(H_2O)]\cdot3H_2O\}$ with sixteen-, ten- and eight-membered ring channels, phase **B** $[Zn_3(PO_4)_2(H_2O)]$ with eight-membered ring channels, and phase **C** $\{[C_4H_{14}N_2]\cdot[Zn_5(PO_4)_4(H_2O)]\}$.[24] Zhang et al. reported application of the combinatorial method to the synthesis of SAPO-34 by a vapor-phase transport technique.[25]

Recently, we reported a new 2-D layered aluminophosphate $[C_2H_8N]_2{\cdot}[Al_2(HPO_4)(PO_4)_2]$ with a distinctive H-bonded helix formed by the organic amine templates and the inorganic network, prepared using a solvothermal combinatorial method.[26]

In this work, a new open-framework zinc phosphate $[C_6H_{16}N_2]{\cdot}[Zn_2(HPO_4)_3]$ from the $Zn(OAc)_2{\cdot}2H_2O/H_3PO_4$/*N*,*N*′-dimethylpiperazine/ethylene glycol reaction system has been obtained using the solvothermal combinatorial approach at 180 °C. The influence of various synthetic factors on the nature of the crystalline products, such as crystallization temperature, solvent type, as well as the gel compositions, has been systematically examined.

Results and Discussion

Using *N*,*N*′-dimethylpiperazine as the template and ethylene glycol as the solvent, a new phase **D** $\{[C_6H_{16}N_2]{\cdot}[Zn_2(HPO_4)_3]\}$ was crystallized from the $Zn(OAc)_2{\cdot}2H_2O/H_3PO_4$/*N*,*N*′-dimethylpiperazine/ethylene glycol system at 180 °C. Figure 1 shows its crystallization field. Pure phase **D** can be formed over a wide range at this temperature. Interestingly, if a certain amount of H_2O is added to the ethylene glycol, i.e., H_2O/ethylene glycol (1:4), phase **A** $\{[C_6H_{16}N_2]_{0.5}{\cdot}[C_5H_{14}N_2]{\cdot}[Zn_6(PO_4)_5(H_2O)]{\cdot}3H_2O\}$, with 16-membered ring main channels,[24] and phase **B** $[Zn_3(PO_4)_2(H_2O)]$, with eight-membered ring channels,[24] are formed. In addition, the range of formation for phase **D** becomes narrow. Furthermore, if 80% H_2O is added to the solvent mixture then no phase **D** is formed. Under this condition, the crystallization diagram is similar to that of the H_2O system at 180 °C, as reported previously.[24]

The powder X-ray diffraction pattern for phase **D** $\{[C_6H_{16}N_2]{\cdot}[Zn_2(HPO_4)_3]\}$ is shown in Figure 2, and is in agreement with the simulated XRD pattern generated from the single-crystal structural data of **D**, proving the phase purity.

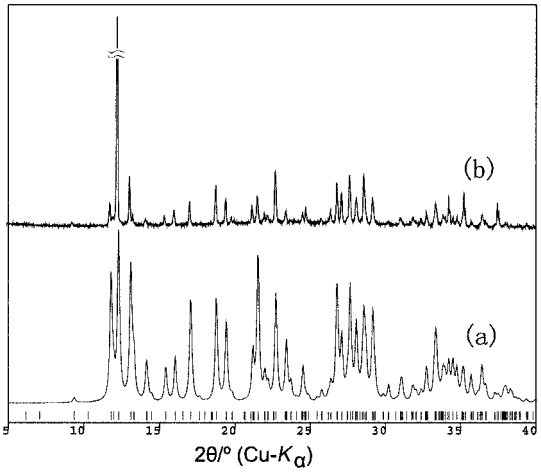

Figure 2. (a) Simulated and (b) experimental X-ray powder diffraction patterns of phase **D**

The influence of crystallization temperature was studied further. Upon reduction of the crystallization temperature to 140°C, phase **B** and an amine−phosphate cluster $([C_6H_{16}N_2]{\cdot}[H_2PO_4]_{0.5})$[28] (denoted as phase **E**), crystallize from the above system, and no phase **D** was obtained. As shown in Figure 3, phase **B** forms in the areas where $3 \leq P/Zn \leq 5$ and $3 \leq R/Zn \leq 7$ (R = *N*,*N*′-dimethylpiperazine), $4 \leq P/Zn \leq 5$ and $2 \leq R/Zn < 3$, with pH values of 7−9, while upon increase or decrease of the H_3PO_4 content, phase **E** begins to appear. Phases **B** and **E** coexist in the areas where $1 \leq P/Zn \leq 2$ and $1 \leq R/Zn \leq 7$, $6 \leq P/Zn \leq 7$ and $3 \leq R/Zn \leq 7$, and P/Zn = 3 and R/Zn = 3. Phase **E** forms in the areas where $3 \leq P/Zn \leq 5$ and $1 \leq R/Zn \leq 1.5$, and $6 \leq P/Zn \leq 7$ and $1 \leq R/Zn \leq 2$. On the other

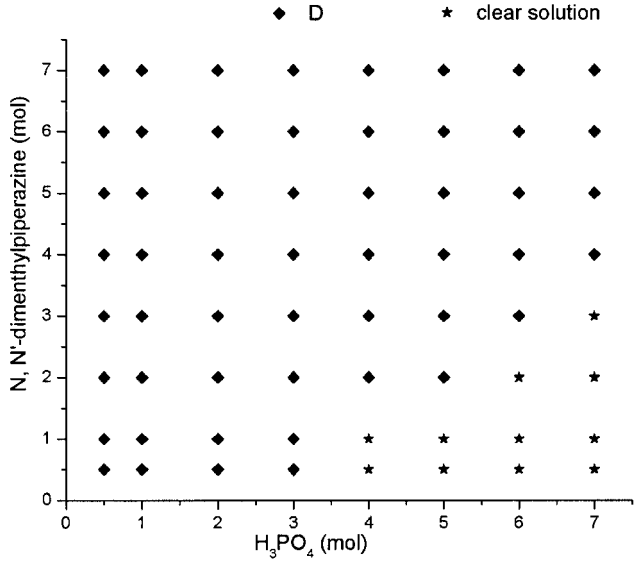

Figure 1. Crystallization field of phase **D** in the ethylene glycol system at 180 °C

hand, when the the temperature was increased to 200°C, no crystalline product was obtained in the ethylene glycol system. However, phases **B** and **C** $\{[C_4H_{14}N_2]\cdot[Zn_5(PO_4)_4(H_2O)]\}$[26] are formed in the H_2O system at this temperature. Figure 4 shows its formation diagram. Phase **C** was obtained previously at 180 °C in the presence of trace amounts of transition metal cations, in the H_2O system.[24]

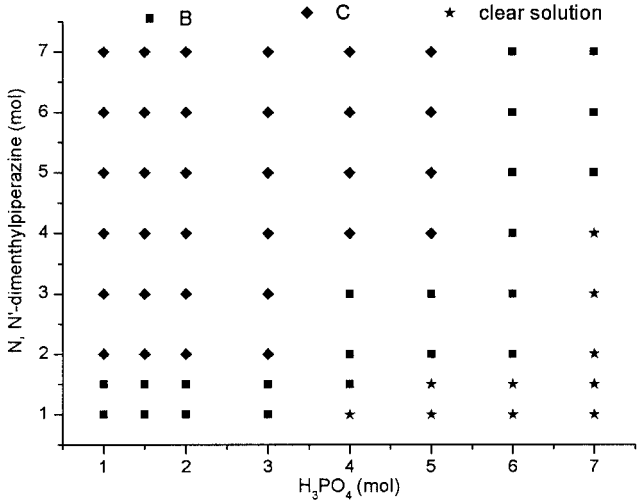

Figure 4. Crystallization field of phases **B** and **C** in the H_2O system at 200°C

Phase **D** $\{[C_6H_{16}N_2]\cdot[Zn_2(HPO_4)_3]\}$ crystallizes in the monoclinic space group $P2_1/n$ (no.14) with a = 8.6931(3) Å, b = 14.4394(5) Å, c = 12.6492(3) Å, β = 96.418(2)°, and Z = 4. As shown in Figure 5, each asymmetric unit contains 25 non-hydrogen atoms, of which 17 belong to the framework and eight to the guest molecules. There are two crystallographically independent zinc and three crystallographically independent phosphorus atoms. The Zn atoms are all tetrahedrally coordinated to oxygen atoms, and each makes four Zn−O−P bonds. The Zn−O bond lengths are in the range 1.922(2)−1.979(2) Å and the O−Zn−O bond angles are in the range 102.02(11)−114.99(11)°, which are typical for zinc phosphates.[6−16] The P atoms are tetrahedrally coordinated. P(1) and P(2) each share three oxygen atoms with adjacent Zn atoms. The $P-O_{bridging}$ bond lengths are in the range 1.509(3)−1.538(2) Å. The fourth P−O bond belongs to a P−OH group, with bond lengths of 1.574 (3) Å for P(1)−O(9)H and 1.572(3) Å for P(2)−O(10)H Å. The P(3) atom shares two oxygen atoms with adjacent Zn atoms. The P−O bond lengths are 1.504(3) Å for P(3)−O(3) and 1.499(3) Å for P(3)−O(8). The terminal O(11) and O(12) atoms are both disordered over two sites. P(3)−O(11) is a terminal P=O bond, while P(3)−O(12) is a terminal P−OH bond.

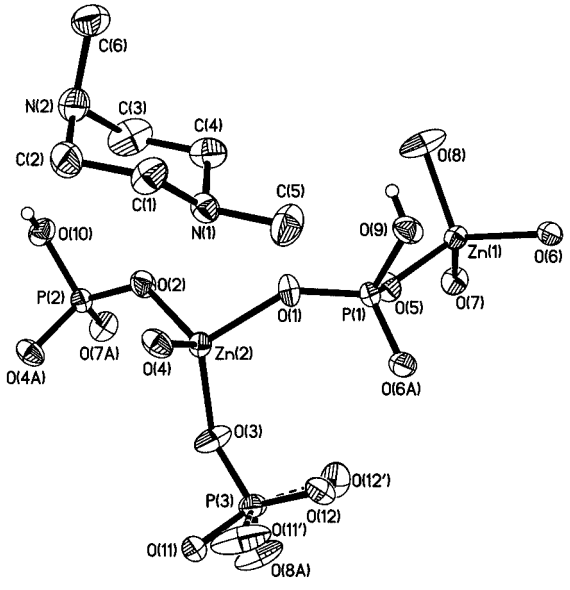

Figure 5. Thermal ellipsoid plot (50%) for **D** showing the atom labeling scheme

The alternation of ZnO_4, $PO_3(OH)$ and $PO_2(OH)(=O)$ tetrahedral units through Zn−O−P linkages forms an open-framework with eight-membered ring channels along the [100] direction (Figure 6), which are intersected with eight-membered ring channels along both the [010] and [101] directions. The 3-D open-framework can be viewed as a network of 4.8.12-net sheets parallel to the *ac* plane through O(7) atoms. This 4.8.12-net sheet is illustrated in Figure 7.

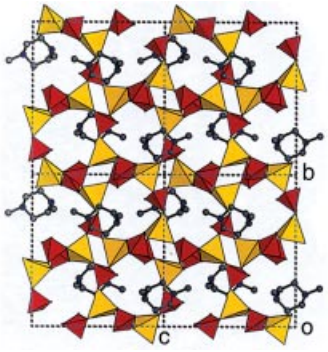

Figure 6. Polyhedral view of the framework structure of **D** viewed along the [100] direction showing the eight-membered ring channels (color code: Zn: yellow; P: red; C: grey; N: blue)

The balance of charge in the complex is achieved by diprotonation of *N*,*N*′-dimethylpiperazine. Each N atom of *N*,*N*′-dimethylpiperazine forms one H-bond to a framework oxygen atom. The N···O distances are in the range of 2.715(4)−3.015(5) Å.

Analysis of the structures of these phases gives some insight into the relative influence of various synthetic factors on the nature of the resulting crystalline products. In this work, the organic templating agent added to the initial reaction system for all the above compounds is *N*,*N*′-dimethylpiperazine. However, it was partially decomposed to *N*-methylpiperazine in phase **A**, which crystallized at 180°C in the H_2O system, and to *N*,*N*′-dimethylethylenediamine in phase **C**, which crystallized at 200°C in the H_2O system. It remained intact in phase **D** crystallized at 180°C in the ethylene glycol system and in phase **E** crystallized at 140

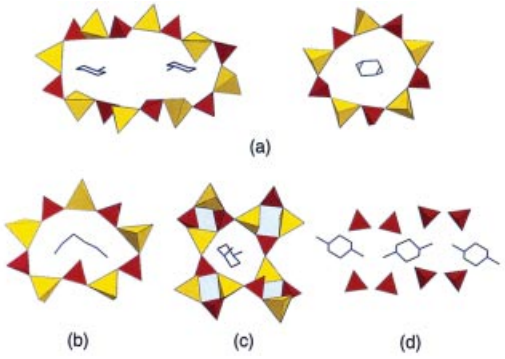

Figure 8. (a) The two diprotonated *N*-methylpiperazine molecules residing in the 16-membered ring channel viewed along the [100] direction and one diprotonated *N*,*N*′-dimethylpiperazine molecule residing in the 10-membered ring channel along [010] direction of **A**; (b) one diprotonated *N*,*N*′-dimethylethylenediamine molecule in the 10-membered ring channel of **C**; (c) one diprotonated *N*,*N*′-dimethylpiperazine molecule in the eight-membered ring channel of **D**; (d) structure of **E** containing a discrete zinc phosphate cluster and *N*,*N*′-dimethylpiperazine molecules (color code: Zn: yellow; P: red; C: grey; N: blue)

°C in the ethylene glycol system. Figure 8 (a−d) shows the templating molecules in the structures of phases **A**, **C**, **D** and **E**. It appears that *N*,*N*′-dimethylpiperazine is easily decomposed in the H_2O system at 180−200°C, but remains intact in the ethylene glycol system at 140−180°C. The above results indicate that the identities of crystallization products are strongly dependent on the organic amine species that are in turn affected by the crystallization temperature, as well as the solvent under solvothermal conditions.

Conclusions

A new open-framework zinc phosphate $[C_6H_{16}N_2]\cdot[Zn_2(HPO_4)_3]$ (phase **D**) with intersecting eight-membered ring channels has been obtained by applying a solvothermal combinatorial approach to the $Zn(OAc)_2\cdot 2H_2O/H_3PO_4/N,N'$-dimethylpiperazine/ethylene glycol system at 180°C. Factors such as gel composition, crystallization temperature and solvent, have significant influence on the resulting crystalline products. Four open-framework zinc phosphate phases **A** $\{[C_6H_{16}N_2]_{0.5}\cdot[C_5H_{14}N_2]\cdot[Zn_6(PO_4)_5(H_2O)]\cdot 3H_2O\}$, **B** $[Zn_3(PO_4)_2(H_2O)]$, **C** $\{[C_4H_{14}N_2]\cdot[Zn_5(PO_4)_4(H_2O)]\}$, **D** $\{[C_6H_{16}N_2]\cdot[Zn_2(HPO_4)_3]\}$, and an amine−phosphate cluster **E** $\{[C_6H_{16}N_2]\cdot[H_2PO_4]_{0.5}\}$, were obtained in the presence of the structure-directing agent *N*,*N*′-dimethylpiperazine in the H_2O or ethylene glycol systems. Our studies show that the state of the organic species, which is affected by the crystallization temperature and the solvent used, play an important role in the formation of the final crystalline products. This work further demonstrates that the combinatorial approach will assist greatly in the discovery of new open-framework materials and can improve our understanding of the factors that influence the crystallization of such materials.

Experimental Section

Synthesis and Characterization: The reactions were performed on the $Zn(OAc)_2\cdot 2H_2O/H_3PO_4/N,N'$-dimethylpiperazine/ethylene glycol or H_2O system in a multiautoclave with dimensions of 14 cm × 14 cm × 5.5 cm. The multiautoclave consists of a stainless steel block (3 cm in height) with 64 individual Teflon chambers (0.7 cm in diameter, 3.0 cm in depth, 800 μL in volume per chamber). Firstly, an aqueous or glycol solution of $Zn(OAc)_2$ was added to each Teflon chamber while they were mounted in a frame, using a Tecan CH Miniprep 75 pipette robot, followed by addition of *N*,*N*′-dimethylpiperazine (98.5%, ACROS) and H_3PO_4 (85 wt%). The reaction mixtures were shaken for homogenization using a vibration apparatus for 1 h. The 64 Teflon chambers were placed in the stainless steel block, then sealed by two stainless steel covers on top and bottom. Sixty-four individual Teflon covers (0.5 cm in thickness) were mounted on the top cover. The multiautoclave was heated in an oven at 140−200 °C for 60 h. After cooling, the arrays of Teflon chambers were put into a Hermle 2300 centrifuge apparatus for sample separation. The products were washed with deionized water followed by centrifugation several times. The products were dried at room temperature. The dried samples were transferred to a sample holder with 64 holes for automated X-ray analysis. Automated X-ray diffraction analysis was carried out with a computer-controlled *xyz* stage with a Bruker D8 Discover microdiffractometer with GADDS equipped with a CCD detector and using Cu-K_α radiation. Traditional X-ray diffraction analyses were performed with the X-ray diffraction (XRD) patterns collected with a Siemens D5005 diffractometer with Cu-K_α radiation (λ = 1.541 Å). Inductively coupled plasma (ICP) analyses were performed with a Perkin-Elmer Optima 3300DV spectrometer. Elemental analyses were conducted using a Perkin-Elmer 2400 elemental analyzer. Inductively coupled plasma (ICP) analysis showed that phase **D** contains 23.2 and 16.8 wt% of Zn and P, respectively (calcd. 24.3 and 17.4 wt%, respectively). The elemental analysis gave C, H and N contents of 13.8, 3.9 and 5.6 wt%, respectively (calcd. 13.5, 3.6 and 5.2 wt%, respectively). A NETZSCH STA 449C unit was used to carry out the thermogravimetric analysis (TGA) in air with a heating rate of 20°C/min. The occluded *N*,*N*′-dimethylpiperazine molecules decomposed at 200−450°C with a weight loss of 22.0 wt% (calcd. 22.2%).

Structure Determination: A suitable single crystal of phase **D** with dimensions 0.15 × 0.10 × 0.10 mm, was carefully selected under a polarizing microscope and glued to a thin glass fiber with cyanoacrylate (superglue) adhesive. The intensity data were collected with a Siemens diffractometer fitted with a Bruker SMART CCD detector, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Data processing was done using the SAINT processing program. The structure was solved by direct methods and refined on F^2 by full-matrix least squares using SHELXTL97.[27] The Zn and P atoms were located first, and then the oxygen, carbon, and nitrogen atoms were located in the Fourier difference maps. O(11) and O(12) are disordered over two sites. The diprotonation of *N*,*N*′-dimethylpiperazine is suggested for the balance of charge. The hydrogen atoms on the amine molecules and in the P−OH bond were located geometrically. All non-hydrogen atoms were refined with anisotropic thermal parameters. The details of data collection and refinement are given in Table 1. Selected bond lengths and bond angles are listed in Table 2. CCDC-228303 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Group 4 Complexes of Chelating Dianionic [OSO] Binaphtholate Ligands; Synthesis and Alkene Polymerisation Catalysis

Louise S. Natrajan,[a] Claire Wilson,[a] Jun Okuda,[b] and Polly L. Arnold*[a]

Keywords: Binaphthol ligands / Polymerisation catalysis / Organometallic / Group 4 elements / Zirconium / Titanium

Mono- and bis(ligand)titanium and -zirconium complexes of a sulfur-bridged binaphtholate [1,1′-S(2-$HOC_{10}H_4$-*t*Bu_2-3,6)$_2$] ($H_2\mathbf{L^{SN}}$) have been synthesised and characterised. Complexes of the general form [M($\mathbf{L^{SN}}$)X_2] (X = Cl, CH_2Ph) are prepared by protonolysis or metathesis. X-ray crystallographic structural characterisation of the dibenzyl complex [Zr($\mathbf{L^{SN}}$)(CH_2Ph)$_2$] is reported, as well as the structure of its partially oxidised derivative [Zr($\mathbf{L^{SN}}$)(CH_2Ph)(OCH_2Ph)]$_2$. Complexes of the form [M($\mathbf{L^{SN}}$)$_2$] are readily formed; these can be converted by comproportionation reactions into the mono-$\mathbf{L^{SN}}$ derivatives above. The X-ray crystal structure of a bis(sulfur-bridged biphenolate) is presented. The representative complexes have been tested as alkene polymerisation catalysts, in conjunction with a methylalumoxane cocatalyst, and for the first time a zirconium complex of a sulfur-bridged biphenolate-type ligand has been found to be active in the polymerisation of ethene.

1 Introduction

The continuing search for alternatives to cyclopentadienyl-based ancillary ligand sets for Group 4 olefin polymerisation catalysts has produced a huge range of new polydentate ligand systems, of which biphenolates have been identified as good ligands.[1,2] However, aryloxides are not generally considered to contribute sufficient electron density to be isolobal with the cyclopentadienyl ligand.[3] Biphenol ligands in which the two phenol rings are joined in the *ortho* position by a potential donor group, such as sulfur, can provide an increased stabilisation of reactive, electron-deficient metal centres.[4] A diverse range of complexes that contain these atom-bridged biphenolates, where the coordinating ligand set is denoted [OXO] (X = S^5, $S_2{}^6$, SO^7, P^8 for example), have now been reported.

Group 4 complexes incorporating [OXO] ligands have been identified as promising alkene polymerisation systems in the form {M[OXO]$_2$$Cl_2$}/MAO (MAO = methylalumoxane).[9] The bridging heteroatom, if coordinated, helps provide the stereochemically rigid framework essential for stereoregular polymer formation.[4] Density functional calculations show that a bridging sulfur atom increases the polymerisation rate by destabilising the π-bound intermediate [Ti(tbmp)Me-(H_2C=CH_2)]$^+$ {tbmp = 2,2′-thiobis(6-*tert*-butyl-4-methylphenol), an [OSO] ligand} with respect to the reactants.[10] Additionally, the calculations suggest that the unsaturated backbone provided by the phenolate plays an important role in stabilising the transition states. The titanium complexes [Ti(tbmp)X_2] (X = Cl, O*i*Pr) exhibit high catalytic activities for the polymerisation of ethene,[9] styrene[11] and dienes[12] when activated with MAO, and can also co-polymerise ethene and styrene.[13]

There are very few reports of the analogous zirconium(IV) complexes. The zirconium derivatives are reportedly far more air- and moisture-sensitive than their titanium counterparts and react less cleanly.[2] In contrast with zirconocene α-olefin polymerisation catalysts,[14] the Zr[OSO] complexes reported so far exhibit no catalytic activity.[2] We have recently introduced the use of the larger naphtholate analogues of [OSO] biphenolates, [1,1′-S(2-$HOC_{10}H_4$-*t*Bu_2-3,6)$_2$] ($H_2\mathbf{L^{SN}}$), in order to stabilise the first sulfur-bridged bis(aryloxide) complexes of lanthanides;[15] the thionaphthol [$\mathbf{L^{SN}}$] thus seemed better suited as a supporting ancillary ligand for zirconium(IV).

Herein, we report the first structurally characterised zirconium(IV) complexes supported by an [OSO] ligand set. Comparative investigations between $H_2\mathbf{L^{SN}}$ and tbmp have led us to synthesise and characterise a new family of Group 4 complexes of the general formula [M($\mathbf{L^{SN}}$)X_2] (X = chloride, amide, alkyl; M = Ti, Zr). In addition, their stability and activity towards olefin polymerisation has been studied and compared with that of relevant tbmp analogues.

2 Results and Discussion

2.1 Halide Complexes Supported by L^{SN}

2.1.1 Reaction of K_2L^{SN} with $TiCl_4$·2THF

Treatment of the solvent-free dipotassium salt [$K_2\mathbf{L}^{SN}$] with [$TiCl_4$·2THF] in toluene results in the formation of the monomeric complex [Ti($\mathbf{L}^{SN}$)Cl_2·THF] (**1**), albeit in poor yield (18%). It is found that the bis(ligand) complex [Ti($\mathbf{L}^{SN}$)$_2$] (**2**) is consistently formed by over-reaction,[16] and is always initially present as one third of the product mixture irrespective of the reaction stoichiometry employed (Scheme 1).

The formation of the bis(ligand) complexes analogous to **2** in the reactions of chelating biphenols only becomes significant when the addition of ligand to metal is accelerated or conducted in the absence of a donating solvent.[16,17] Although single crystals of **2** were obtained from a diethyl ether solution at −30 °C, they were unsuitable for single-crystal X-ray diffraction analysis due to rapid loss of lattice solvent.

The ^{1}H NMR spectrum of **2** reveals the presence of two sets of aromatic signals for the ligand, indicating the presence of a single geometrical isomer out of the three possible ones. The *cis*-facial conformation of ligands in **2** (C_2), rather than a *trans*-facial (C_i) or *mer-trans* (D_{2d}) arrangement, affords two sets of ligand resonances. This has been observed previously in the bis[OOO]zirconium complex [Zr{(OC_6H_3*t*Bu-2-Me-4-CH_2-6)$_2$)O}$_2$] {[OOO] = 2-oxapropanediyl-1,3-bis(2-*tert*-butyl-4-methylphenol)},[17] and in the biphenolato bis[OCO]Zr complex {[OCO] = [2,2′-methylenebis(6-*tert*-butyl-4-methylphenol)}.[18] In **2**, this apparent C_2 symmetry is consistent with the coordination of both sulfur atoms. In contrast, the structurally characterised bis[ONO]titanium(IV) complex [Ti{($OC_6H_2Me_2$-2,4)$_2$NPr}$_2$] adopts the more familiar *trans-mer* conformation.[19]

High-temperature ^{1}H NMR spectroscopy of [D_8]toluene solutions of **2** do not show any processes that render the two aromatic rings of the ligands equivalent. Thus, besides the structural rigidity of **2** over an accessible temperature range, the thermal barrier to *fac-cis*/*fac-trans* isomerism is high.

2.1.2 Reaction of H_2L^{SN} with $TiCl_4$

The reaction of [$H_2\mathbf{L}^{SN}$] with neat $TiCl_4$ in hexane or toluene yields the THF-free complex **1a**, which is anticipated to be dimeric in solution[20] (Scheme 1). If triethylamine is added to precipitate the HCl by-product, only the bis(ligand) complex is isolated.[2] However, if THF is added, further conversion of **1** into **2** is slowed down but not eliminated completely, so that neither product is formed in good yield. Analytically pure **2** is most readily obtained in a synthetically useful yield of 70% by the protonolysis reaction of [$H_2\mathbf{L}^{SN}$] with [Ti($OEt)_4$] (vide infra).

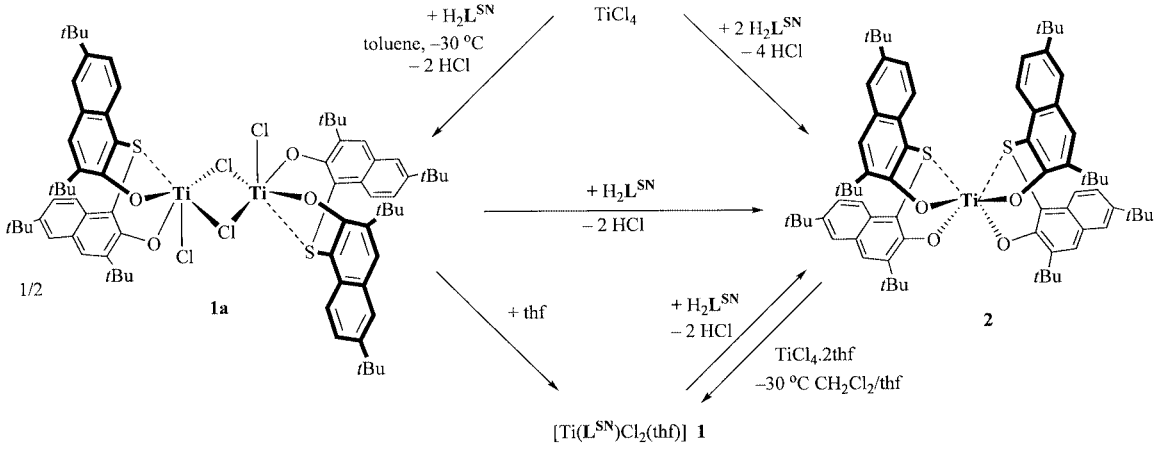
As an alternative route to **1**, a stoichiometric reaction of $H_2\mathbf{L}^{SN}$ with [Ti($NMe_2)_2Cl_2$] was undertaken. Again, monitoring the reaction by ^{1}H NMR spectroscopy reveals the existence of a relatively short-lived species assigned as [Ti($\mathbf{L}^{SN}$)(Cl)NMe_2] (**3**) by comparison with related complexes, but its decomposition into **2** precludes further characterisation.

2.1.3 Preparation of 1 by Comproportionation

The synthesis of **1** is best achieved by comproportionation: Treatment of **2** with 1 equiv. of [$TiCl_4$·2THF] in a 4:1 mixture of dichloromethane/tetrahydrofuran at −60 °C (Scheme 1) affords, after warming to ambient temperature, a dark brown solution from which **1** may be isolated in 96% yield.

2.1.4 Reactions of [L^{SN}] with $ZrCl_4$·2THF

Treatment of stoichiometric solvent-free [$K_2\mathbf{L}^{SN}$] with [$ZrCl_4$·2THF] in toluene results in the formation of the colourless bis(ligand) complex [Zr($\mathbf{L}^{SN}$)$_2$·THF] (**5**) in an



Scheme 1. Reactions of $H_2\mathbf{L}^{SN}$ with $TiCl_4$

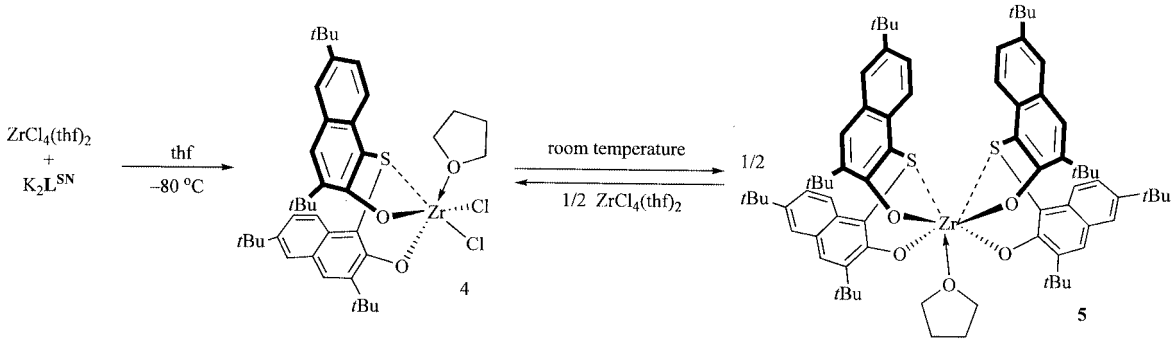

Scheme 2. Synthesis of $Zr^{IV}-\mathbf{L}^{SN}$ adducts

isolated yield of 34% (Scheme 2). Single crystals of **5** suitable for X-ray diffraction were grown by slow cooling of a saturated diethyl ether solution of **5** to −30 °C. The comproportionation of **5** and [$ZrCl_4$·2THF] in THF affords the desired complex [$Zr(\mathbf{L}^{SN})Cl_2$·THF] (**4**) in 53% yield.

$$Zr(NMe_2)_2Cl_2 + H_2\mathbf{L}^{SN} \xrightarrow[-80\ ^\circ C]{thf} Zr(\mathbf{L}^{SN})(NMe_2)Cl\ \mathbf{6} \xrightarrow{\text{room temp}} Zr(\mathbf{L}^{SN})_2(HNMe_2)\ \mathbf{7} \quad (1)$$

The protonolysis reaction of $H_2\mathbf{L}^{SN}$ with [$Zr(NMe_2)_2Cl_2$·2THF] yields the amido chloride **6** as an intermediate. Irrespective of the reaction solvent polarity, this rapidly undergoes a ligand redistribution reaction to form the amine-stabilised analogue of **5**, [$Zr(\mathbf{L}^{SN})_2(HNMe_2)$] (**7**), as the major product [Equation (1)]. The coordinated molecule of $HNMe_2$ is retained in the product even when the reaction solvent is THF.

2.2 Single-Crystal X-ray Analysis of [$Zr(\mathbf{L}^{SN})_2$·THF] (5)

Cooling of a concentrated diethyl ether solution of **5** to −30 °C affords single colourless blocks suitable for a X-ray diffraction study. The solid-state molecular structure (Figure 1) confirms the expected connectivity. Selected interatomic distances and angles are collected in Table 1.

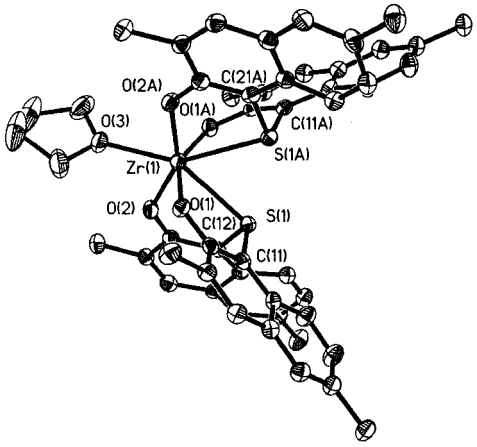

Figure 1. Thermal ellipsoid drawing of **5**·Et_2O (50% probability); methyl groups and solvent of crystallisation removed for clarity

The first significant feature of the molecular structure of **5** is the co-facial arrangement of the two binaphthol ligands, which imparts a distorted capped octahedral ge-

ometry on the seven-coordinate zirconium centre. The four naphtholate oxygen atoms describe the equatorial plane, while S(1) and S(1A) occupy approximate axial positions. The bound THF molecule resides in the apical site, opposite and in between the two sulfur atoms. However, the O(1)−Zr(1)−O(1A) and O(2)−Zr(1)−O(2A) angles are not linear, and are 150° and 94°, respectively. Naphtholate−zirconium bond lengths are in the range expected for zirconium−oxygen single bonds (observed range: 1.89−2.06 Å).[21] The C(11)−S(1)−C(21) bond angle of each thionaphthol ligand [109.6(1)°] is relatively large, and the naphthol wings are opened out slightly, enabling the sulfur atom to come into close proximity to the metal ion. As a result, a sulfur−zirconium interaction with a distance of 2.7657(8) Å is established.[22]

The C−S−C dihedral angle between the two naphthol planes of each ligand is 57°, and notably, the intramolecular S−S distance is 3.015 Å which is considerably shorter than the sum of the van der Waals radii of two S atoms (3.6 Å), and shorter than 3.33 Å (a single S−S bond plus 1.50 Å) − it was suggested that this value indicates a nonbonding interaction between two atoms (Figure 2).[23] This implies a significant intramolecular sulfur interaction in the solid state. The nonlinearity of the O(1)−Zr(1)−O(1A) and O(2)−Zr(1)−O(2A) moieties also suggests an S−S interaction that bends both *fac* ligands towards each other.

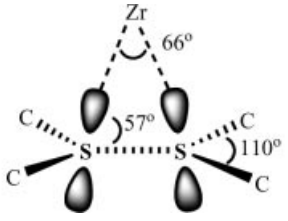

Figure 2. Suggested S−S (σ−π)-(π−π) interaction in **5** (for clarity, only the filled p orbital on each S atom is indicated); the dashed lines represent the Zr−S vector on the C_{2v} plane of each binaphthol ligand and the S−S interaction

Nonbonded intramolecular sulfur−sulfur interactions are relatively rare but can be energetically favourable. For example, the S_4 moiety in bis[8-(phenylthio)naphthyl] 1,1′-disulfide, which exhibits short nonbonded sulfur distances of 2.988(2) Å, is aligned in a linear fashion displaying two $n_p(S)$-σ*(S−S) 3-c-4-e bonds.[24] Nonbonding S interactions in this system are noted to have a greater influence on the solid-state geometry in the naphthalene complexes than in the corresponding phenyl disulfide. In the same way, the p-type lone pair orbital of Se in the R−Se−R′ fragments (R ≠ R′ = alkyl/aryl) has also been shown to play an important role in intramolecular nonbonding interactions.[25]

Ab initio calculations and statistical studies indicate that S···S close contacts in R−S−R fragments (R = H, alkyl, aryl) are attractive for a range of orientations (i.e. for a range of dihedral angles between the C_{2v} axis of each fragment), and there is a maximum probability for a colinear S···S arrangement.[26] Although calculations show that at short distances (3 Å) the interactions are mainly repulsive,[27,28] the dispersion contribution, which is substantial for the large, polarisable sulfur atom, provides an important attractive force that is able to compensate the repulsive electrostatic force. In **5**, the hard metal ion binds a molecule of THF, and the sulfur−sulfur dipole interaction is preferred over the formation of closer dative bonds between the metal and the soft sulfur atoms.

2.3 Alkyl Derivatives of L^{SN}

2.3.1 Dialkyltitanium Complexes

Attempts to prepare the dibenzyl complex [Ti(L^{SN})($CH_2Ph)_2$] by protonolysis of [Ti($CH_2Ph)_4$] with [H_2L^{SN}] resulted only in the recovery of starting materials. This contrasts with the facile preparation of the biphenolate complex [(tbmp)Ti($CH_2Ph)_2$].[2] ^{1}H NMR spectroscopy suggests the formation of [Ti(L^{SN})($CH_2Ph)_2$] (**8**) by metathesis between **1** and the Grignard reagent $PhCH_2MgCl$, but no tractable product could be isolated.

In an attempt to synthesise a dimethyl complex [Ti(L^{SN})Me_2], a hexane solution of **1** was treated with 2 equiv. of LiMe.[29] However, even at temperatures below −10 °C, the reaction mixture quickly became dark to yield an intractable mixture of products. A one-pot reaction at −80 °C of H_2L^{SN} with 4 equiv. of LiMe, followed by addition of $TiCl_4$, also yielded no tractable product.

2.3.2 Dibenzylzirconium Complexes

In contrast to the tetrabenzyltitanium reaction, treatment of 1 equiv. of [H_2L^{SN}] with tetrabenzylzirconium in THF results in the rapid formation of the bis(ligand) THF adduct **5**. No intermediates were detectable (by solution NMR spectroscopy) during the course of this reaction. This route to **5** gives higher yields than metathesis reactions with zirconium tetrachloride.

$$ZrBz_4 + H_2L^{SN} \xrightarrow[-80\ ^\circ C]{thf} \underset{\mathbf{9}}{Zr(L^{SN})(CH_2Ph)_2(thf)} \quad (2)$$

A synthetic scale-up of the reaction (about 2.0 g) sufficiently reduces the extent of ligand redistribution to permit the isolation of the dibenzyl complex **9** as a pale yellow solid in moderate yield (47%) [Equation (2)]. This complex is significantly less sensitive to light than the parent alkyl compound, and if the reaction is carried out in the absence of donating solvents, an intractable product mixture results. The ^{1}H NMR spectroscopic resonances ([D_6]benzene) for the methylene benzyl moieties appear as a singlet at δ = 2.67 ppm, rather than an AB quadruplet.[30] Low-temperature ^{1}H NMR studies in [D_8]toluene and CD_2Cl_2 reveal no fluxional process slower than the NMR timescale that would render the two methylene protons inequivalent.[31]

2.3.3 Single-Crystal X-ray Analysis of [Zr(L^{SN})($CH_2Ph)_2$·THF] (9)

The molecular structure of **9** is shown in Figure 3. It is evident that the metal atom maintains a mononuclear en-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

vironment, and the bound THF molecule occupies an apical coordination site of a distorted octahedron. The ligand facially caps the zirconium atom, with relatively short naphtholate oxygen−zirconium distances of 1.981(2) and 2.004(2) Å for O(1) and O(2), respectively. The sulfur atom is geometrically placed in a *trans* arrangement to C(40) of the η^1-benzyl group, with a correspondingly long sulfur−zirconium distance of 2.9248(7) Å. As a result, the mean planes of the two naphthalene rings of the ligands form a dihedral angle of 78.0°, with an associated C(11)−S(1)−C(21) bond angle of 106.3(1)°.

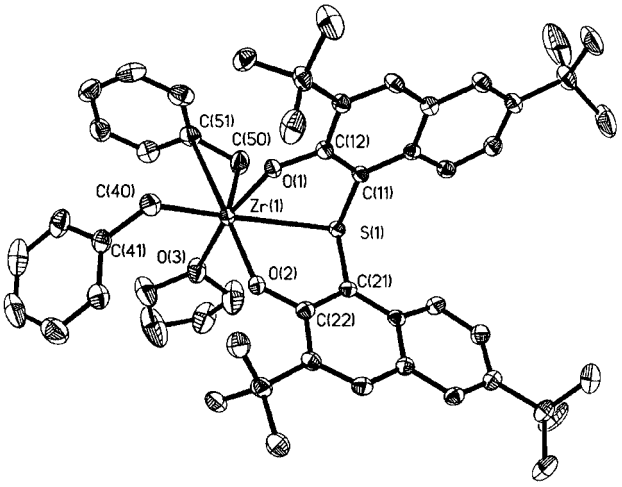

Figure 3. Molecular structure of **9**; view along the 100 plane; ellipsoids set at the 50% probability level; H atoms removed for clarity

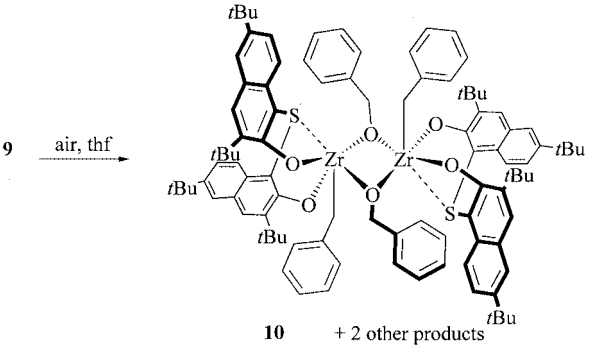
The two coordinated benzyl groups are clearly distinguishable in the solid state, and display η^1- and η^2-bonding modes.[30] The η^2-bound benzyl ring [C(50), (C51)] has an acute Zr(1)−C(50)−C(51) angle of 95.3(2)°, in contrast to that of the η^1-benzyl group [Zr(1)−C(40)−C(41) 118.8(2)°]. The acuteness of this angle results in the close proximity of the phenyl ring to the zirconium atom, and in particular gives rise to a short Zr−C_{ipso} interaction of 2.850(3) Å.[30]

2.3.4 Reactivity of 9 with Air

Exposure of dibenzyl compound **9** to air affords three compounds, which can be identified by ^{1}H NMR spectroscopy [Equation (3)]. To date, we have been unable to isolate the analytically pure major product by recrystallisation, but were able to obtain single crystals suitable for structure analysis to confirm the identity. The complex is formally the product of the insertion of one oxygen atom per metal atom into the Zr−C bond of a benzyl group. The controlled O atom insertion into a bound alkyl group at an early transition metal is unusual,[32] and to the best of our knowledge, this is the first time a benzyl group has been selectively oxygenated. Usually, reaction with an oxygen atom source such as pyridine *N*-oxide or trimethylamine *N*-oxide, or air or water, forms oxo adducts containing the Zr−O−Zr unit.[33] Treatment of the dibenzyl complex **9** with trimethylamine *N*-oxide shows that the same product is formed, confirming that **10** derives from the reaction with air; but while the yield is greatly improved for this reaction, we were unable to obtain correct elemental analysis data for this complex. Work is in progress to identify whether the oxidisable sulfur bridge is involved in this oxygen atom insertion into the Zr−C bond.



(3)

The molecular structure of **10** (Figure 4) is dinuclear and unsolvated. The geometry at Zr is essentially octahedral with a *fac*-$\mathbf{L^{SN}}$ ligand, a small cone angle of the [OSO] group and a relatively long Zr(1)−S(1) contact of 2.8881(13) Å. The remaining benzyl group shows no additional agostic interaction with the metal atom. The oxygenated benzyl group bridges the zirconium centre and its symmetry-related equivalent in a nearly symmetrical fashion with an average Zr−O distance of 2.15 Å, relative to an average Zr−$O_{naphtholate}$ distance of 1.99 Å, and a Zr−Zr′ distance of 3.490(1) Å.

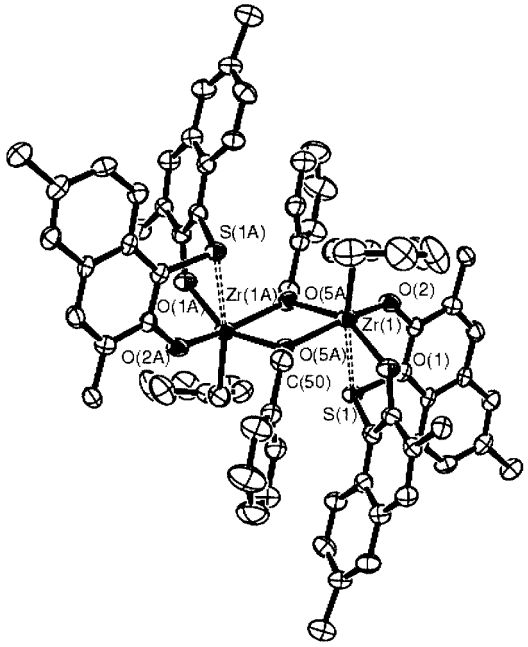


Figure 4. Molecular structure of **10**; ellipsoids set at the 50% probability level; solvent and Me groups removed for clarity

Interestingly, the Zr−S distances in both [Zr($\mathbf{L^{SN}}$)$_1$X$_2$] complexes are longer than those in the sterically more congested [Zr($\mathbf{L^{SN}}$)$_2$] complex, giving further weight to the at-

tractive S−S interaction's dominance of the local geometry of the ligands in the bis(ligand) complex **5**.

2.4 Polymerisation of Ethene and Propene

Three suitable complexes were chosen for the polymerisation studies, [Ti($\mathbf{L^{SN}}$)Cl_2·THF] (**1**), [Zr($\mathbf{L^{SN}}$)Cl_2·THF] (**4**) and [Zr($\mathbf{L^{SN}}$)$(CH_2Ph)_2$·THF] (**9**). The results are collated in Table 2; for comparison, the analogous tbmp complexes have been included. A significant exotherm was observed during the first 10 min of each polymerisation run (except **4**/MAO), attaining a maximum temperature of 50 °C. For the remainder of each polymerisation run, the autoclave temperatures remained almost constant (within 5 °C).

The titanium dichloride system **1**/MAO and the bis(benzyl)zirconium complex **9**/MAO exhibit moderate activities for the polymerisation of ethene and produce polyethene with high molecular weights, whereas the corresponding zirconium chloride system **4**/MAO shows a much lower propensity to polymerise ethene. Under identical conditions, **1**/MAO also shows moderate activity for the polymerisation of propene. Theory suggests that the Ti-based catalysts are more active than their zirconium counterparts due to a slightly lower activation energy barrier;[10] the complete inactivity of the (tmbp)Zr species is therefore surprising.

The ethene polymerisation activity of **1**/MAO (28.94 kg PE mol^{-1}[Ti] bar^{-1} h^{-1}) compares well with the dimeric complex [(tbmp)$TiCl_2]_2$, which was tested at a lower catalyst concentration (220 kg PE mol[Ti]$^{-1}$ bar^{-1} h^{-1}).[20] However, the binaphthol-based catalyst remains an order of magnitude less active than the corresponding biphenol system. Theoretical studies also suggested that the catalyst activity is influenced by the extent of conjugation in the ligand backbone and that a C=C bridged system should be more active than a C−C system.[2,10] The naphthol bridge in these systems, which has a lower aromaticity than a phenol, supports this argument.

However, the Zr naphtholate systems are better catalysts than their phenolate counterparts. In view of the inactivity of the reported Zr-based biphenolates towards ethene polymerisation, these results are encouraging. Narrow molecular weight distributions and polydispersities for the sample isolated from the **1**/MAO/ethene run suggest that this a well-defined single-site catalyst. This is in contrast to the higher PDI reported for the [(tbmp)$TiCl_2$]/MAO system run for a brief period of time.[2] The polyolefin from the **1**/MAO/propene run was isolated as a viscous oil, with a low average molecular weight for the polymer. The molecular weight distribution appears bimodal, suggesting an ill-defined active catalyst species and/or the presence of more than one active site. Again, a bimodal distribution is apparent in the **4**/MAO/ethene system.

2.5 Conclusions

Titanium(IV) and zirconium(IV) complexes supported by the binaphtholate $\mathbf{L^{SN}}$ dianion have been synthesised and structurally characterised. The formation of bis($\mathbf{L^{SN}}$) complexes renders the direct syntheses of titanium(IV) and zirconium(IV) dichloride complexes difficult, with possible further stabilisation of the zbis($\mathbf{L^{SN}}$)irconium complex by an S−S interaction. However, unlike aminebis(phenolate) [ONO] derivatives of Group 4 metals, the bis[OSO] complexes undergo disproportionation reactions to form heteroleptic adducts.

The first crystallographically characterised Zr[OSO] complexes have been isolated. The bis(OSO)zirconium THF adduct exhibits a co-facial arrangement of the naphthol ligands, a distorted capped octahedral geometry at Zr and close S−S distances, which suggest an unusual noncovalent S···S interaction in the solid state. The zirconium [OSO] complexes are kinetically more labile than related aminebis(phenolate) [ONO] adducts, but less labile than their titanium counterparts, and heteroleptic complexes are easier to isolate. The dibenzylzirconium complex reacts with air to insert an O atom rather than decompose to a μ-oxodizirconium complex. Preliminary reactions with the oxygen atom source trimethylamine *N*-oxide show that the same product is formed. Structural studies of the complexes have shown that the smaller Group 4 metal cations accommodate the symmetrical *fac* conformation of the $\mathbf{L^{SN}}$ ligand much more readily than the twisted conformation observed in the corresponding lanthanide chemistry.[15,34]

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The complexes **1** and **9** are effective ethene polymerisation pre-catalysts, whereas the dichloride **4** displays a surprisingly low activity towards ethene polymerisation. The catalyst system **1**/MAO is also moderately active for the polymerisation of propene.

3. Experimental Section

General Procedures: All experimental procedures were performed under dry, oxygen-free argon or dinitrogen, with standard Schlenk techniques (mechanical pump for vacuum 10^{-4} mbar). Subsequent manipulations of isolated compounds were carried out in a glove box (MBraun Unilab) under dry dinitrogen. All ^{1}H and ^{13}C NMR spectra were recorded with a Bruker DPX 300 spectrometer, operating frequency variable temperature unit at 300 K, unless otherwise stated. Chemical shifts are reported in parts per million and referenced to residual proton resonances in [D_6]benzene calibrated against external TMS. Mass spectra (EI and FAB) were run by Dr. Ali Abdul-Sada with a Kratos MS80RF instrument. Elemental analyses were determined by Dr. Stephen Boyer at London Metropolitan University and by Mr. Trevor Spencer at the University of Nottingham. Polymerisation runs were conducted in a purpose-built rig in the laboratory of Professor F. G. N. Cloke, at the University of Sussex, and GPC analysis was performed by Rapra Technology Ltd. A glass autoclave with a magnetically coupled stirrer was charged with a toluene solution of each complex, 1000 equiv. of MAO, and the vessel pressurised at 20 °C with 10 bar of ethene or 10 bar of propene for 1 h. Samples from the **1**/MAO/ethene and **4**/MAO/ethene were found to contain a significant amount of insoluble (in 1,2,3-trichlorobenzene) material and were difficult to filter. The chromatogram peak area for **4**/MAO/ethene is less than 20% that of the **1**/MAO/ethene and **9**/MAO/ethene samples, suggesting that the bulk of this sample remained insoluble. The insolubility of the polymer could be due to an exceptionally high molecular weight or a high degree of cross-linking. All solvents used (toluene, THF, diethyl ether, hexane, dichloromethane) were either degassed and purified by passage through activated alumina towers prior to use, or were freshly distilled from the appropriate alkali metal under dinitrogen, and thoroughly degassed prior to use. NMR spectroscopic grade [D_6]benzene and [D_8]toluene were refluxed over potassium metal, and CD_2Cl_2 refluxed over CaH_2 and vacuum-distilled before use. All chemicals were either obtained from Aldrich Chemicals, except *n*BuLi and sulfur dichloride (Acros), or were synthesised according to standard literature procedures.[35] Literature procedures for the preparation of [1,1′-S(2-HO$C_{10}H_4t$Bu$_2$-3,6)$_2$] ($H_2\mathbf{L}^{SN}$)[15] and [1,1′-S(2-KO$C_{10}H_4t$Bu$_2$-3,6)$_2$(THF)$_2$] ($K_2\mathbf{L}^{SN}$)[36] have previously been described.

[($\mathbf{L}^{SN}$)TiCl$_2$·THF] (1): A solution of $TiCl_4$·2THF in THF (30 mg, 0.09 mmol, 10 mL) was added dropwise to a solution of **2** in a 1:1 mixture of THF/dichloromethane (0.1 g, 0.09 mmol, 30 mL) cooled to −78 °C. The reaction mixture was left to warm slowly to ambient temperature, upon which it changed colour from orange to dark brown. After 12 h, all volatiles were removed under reduced pressure. The crude product was extracted into hexane and cooled to −30 °C. Analytically pure **1** was isolated as a microcrystalline brown solid in 96% yield (62 mg). ^{1}H NMR (C_6D_6): δ = 8.66 (d, $^3J_{H,H}$ = 8.85 Hz, 1 H, 8-H), 7.51 (s, 3H 4-H, 5-H, 7-H), 3.81 (br., 2 H, CH_2 THF), 1.62 (s, 9 H, 3-*t*Bu), 1.32 (br., 2 H, CH_2 THF), 1.19 (s, 9 H, 6-*t*Bu) ppm. $C_{36}H_{44}Cl_2O_2STi$·THF (731.71): calcd. C 65.66, H 7.16; found C 65.67, H 7.39.

[($\mathbf{L}^{SN}$)Ti(μ-Cl)Cl]$_2$ (1a): ^{1}H NMR/C_6D_6: δ = 8.61 (br., 1 H, 8-H), 7.38 (m, 3H 4-H, 5-H, 7-H), 1.48 (s, 9 H, 3-*t*Bu), 1.18 (s, 9 H, 6-*t*Bu) ppm.

[($\mathbf{L}^{SN}$)$_2$Ti] (2): A solution of $\mathbf{H_2L^{SN}}$ in THF (0.2 g, 0.37 mmol, 15 mL) was added dropwise to a cooled solution of Ti(OEt)$_4$ in THF (19.0 μL, 0.185 mmol, 10 mL) at −30 °C over a period of 20 min, and the mixture was warmed to room temperature over 12 h, by which time **2** had precipitated from the reaction mixture. The supernatant was decanted from the precipitate, and the crude powder washed with 3 × 10 mL cold hexane to yield analytically pure **2** in 70% yield (0.146 g). ^{1}H NMR (C_6D_6): δ = 8.93 (br., 1 H, 8-H), 8.87 (br., 1 H, 8-H), 7.59 (m, 6 H, 4-H, 5-H, 7-H), 1.67 (s, 9 H, 3-*t*Bu), 1.59 (s, 9 H, 3-*t*Bu), 1.23 (s, 9 H, 6-*t*Bu) ppm. EI-MS: *m*/*z* (%)= 1128 (24) [M^+]. $C_{72}H_{88}O_4S_2Ti$ (1128): calcd. C 76.56, H 7.85; found C 76.48, H 7.80.

[($\mathbf{L}^{SN}$)Ti(μ-NMe$_2$)Cl]$_2$ (3a): ^{1}H NMR (C_6D_6): δ = 8.48 (d, $^3J_{H,H}$ = 8.82 Hz, 1 H, 8-H), 7.58 (m, 3H 4-H, 5-H, 7-H), 1.78 (s, 3 H, NMe_2), 1.16 (s, 9 H, 3-*t*Bu), 1.31 (s, 9 H, 6-*t*Bu) ppm.

[($\mathbf{L}^{SN}$)Ti(μ-Cl)NMe$_2$]$_2$ (3b): ^{1}H NMR: δ = 8.79 (d, $^3J_{H,H}$ = 8.70 Hz, 1 H, 8-H), 7.58 (m, 3H 4-H, 5-H, 7-H), 1.78 (s, 3 H, NMe_2), 1.26 (s, 9 H, 3-*t*Bu), 1.71 (s, 9 H, 6-*t*Bu) ppm.

[($\mathbf{L}^{SN}$)ZrCl$_2$·THF] (4): A slurry of $ZrCl_4$·2THF in toluene (21 mg, 0.056 mmol, 7 mL) was added dropwise over a period of 20 min to a solution of **5** in toluene (70 mg, 0.056 mmol, 7 mL),which was cooled to −60 °C. The resultant solution was allowed to slowly attain room temperature over 4 h and stirred at room temperature for a further 10 h. All volatiles were removed under reduced pressure, and the crude product extracted into hexane (15 mL). Cooling to −30 °C afforded a colourless precipitate that was isolated and washed with cold hexane (3 × 5 mL) to give analytically pure **4** in 53% yield (0.021 g). ^{1}H NMR (C_6D_6): δ = 8.83 (br., 1 H, 8-H), 7.58 (m, 3 H, 4-H, 5-H, 7-H), 3.70 (br., 4 H,CH_2 THF), 1.58 (br., 9 H,3-*t*Bu), 1.35 (br., 4 H, CH_2 THF), 1.23 (s, 9 H, 6-*t*Bu) ppm. $C_{36}H_{44}Cl_2O_2SZr$·THF (775.1): calcd. C 61.98, H 6.76; found C 61.47, H 7.03.

[($\mathbf{L}^{SN}$)$_2$Zr·THF] (5): In the absence of light, a solution of $H_2\mathbf{L}^{SN}$ in THF (500 mg, 0.92 mmol, 20 mL) was added dropwise to a solution of Zr(CH_2Ph)$_4$ in THF (210 mg, 0.46 mmol, 15 mL), which was cooled to −60 °C over 30 min. Upon completion of the addition of the ligand, the reaction mixture was slowly warmed to room temperature and stirred at ambient temperature for a further 10 h. All volatiles were removed under reduced pressure, and the crude solid extracted into 5 mL of diethyl ether. Subsequent cooling to −30 °C afforded single crystals suitable for X-ray diffraction analysis in 45% yield (258 mg). ^{1}H NMR (C_6D_6): δ = 8.80 (d, $^3J_{H,H}$ = 8.97 Hz, 1 H, 8-H), 7.64 (s, 1 H, 4-H), 7.57 (s, 1 H, 5-H), 7.11 (d, $^3J_{H,H}$ = 8.97 Hz, 1 H, 7-H), 4.10 (br., 2 H, CH_2 THF), 1.57 (s, 9 H, 3-*t*Bu), 1.36 (br., 2 H, CH_2 THF) 1.23 (s, 9 H, 6-*t*Bu) ppm. $C_{72}H_{88}O_4S_2Zr$·THF (1245.0): calcd. C 73.37, H 7.77; found C 73.19, H 7.54.

[($\mathbf{L}^{SN}$)Zr(μ-NMe$_2$)Cl]$_2$ (6a): ^{1}H NMR (C_6D_6): δ = 8.81 (br., 2 H, 8-H), 7.56 (m, 6 H, 4-H, 5-H, 7-H), 3.85 (s, 3 H, μ-NMe_2), 1.66 (s, 18 H, 3-*t*Bu), 1.23 (s, 18 H, 6-*t*Bu) ppm.

[($\mathbf{L}^{SN}$)Zr(μ-Cl)NMe$_2$]$_2$ (6b): ^{1}H NMR (C_6D_6): δ = 8.76 (d, $^3J_{H,H}$ = 8.76 Hz, 2 H, 8-H), 7.56 (m, 6 H, 4-H, 5-H, 7-H), 1.61 (s, 3 H, NMe_2), 1.58 (s, 18 H, 3-*t*Bu), 1.19 (s, 18 H, 6-*t*Bu) ppm.

[($\mathbf{L}^{SN}$)$_2$Zr·HNMe$_2$] (7): ^{1}H NMR (C_6D_6): δ = 8.67 (br., 2 H, 8-H,), 7.59 (s, 2 H, 4-H), 7.55 (br., 2 H, 7 H), 7.44 (d, $^3J_{H,H}$ = 8.74 Hz,

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2 H, 7-H), 2.66 (br., 3 H, $HNMe_2$) 1.53 (s, 18 H, 3-*t*Bu), 1.23 (s, 18 H, 6-*t*Bu) ppm.

[(L^{SN})Ti(CH_2Ph)$_2$] (8): ^{1}H NMR (C_6D_6): δ_H = 8.69 (d, $^3J_{H,H}$ = 9.03 Hz, 1 H, 8-H), 7.51 (m, 3H 4-H, 5-H, 7-H), 7.05 (m, 5 H, CH_2Ph) 2.10 (s, 2 H, CH_2Ph), 1.62 (s, 9 H, 3-*t*Bu), 1.17 (s, 9 H, 6-*t*Bu) ppm.

[(L^{SN})Zr(CH_2Ph)$_2$·thf] (9): A solution of H_2L^{SN} in THF (2.0 g, 3.69 mmol, 25 mL) was added dropwise to a solution of $Zr(CH_2Ph)_4$ in THF (1.68 g, 3.69 mmol, 15 mL), which was cooled to −60 °C over 45 min. Upon completion of addition of the ligand, the reaction mixture was slowly warmed to room temperature and stirred for a further 15 h. All volatiles were removed under reduced pressure, and the crude solid extracted into 25 mL of diethyl ether. Cooling of the solution to −30 °C resulted in the precipitation of analytically pure **10** as a yellow powder, which was washed with 3 × 5 mL cold diethyl ether, and isolated in 47% yield (1.54 g). Single crystals suitable for X-ray diffraction studies were grown from slow concentration of the supernatant at −30 °C. ^{1}H NMR (C_6D_6): δ = 8.94 (d, $^3J_{H,H}$ = 8.76 Hz, 1 H, 8-H), 7.62 (s, 1 H, 4-H), 7.60 (s, 1 H, 7-H), 7.57 (s, 1 H, 5-H), 7.55 (m, 2 H, CH_2Ph), 6.87 (m, 3 H, CH_2Ph), 3.53 (br., 2 H, CH_2 THF), 2.67 (s, 2 H, CH_2Ph), 1.56 (s, 9 H, 3-*t*Bu), 1.24 (s, 9 H, 6-*t*Bu), 1.01 (br., 2 H, CH_2 THF) ppm. ^{13}C NMR (C_6D_6): δ = 166.68, 130.00, 129.67, 129.28 (quaternary C), 145.49, 140.10, 137.85, 133.39, 127.68, 126.17, 125.65 (CH), 65.48 (CH_2Ph) 31.34, 30.08 (*t*Bu), 73.18, 25.05 (THF) ppm. $C_{50}H_{54}O_2SZr$·thf (882.4): calcd. C 73.22, H 7.46; found C 73.49, H 7.69.

[(L^{SN})Zr(OCH_2Ph)(CH_2Ph)$_2$] (10). a) A Schlenk tube containing powdered **9** was exposed to air for 2 min. The resulting colourless powder was recrystallised from diethyl ether, from which crystals of **10** suitable for single-crystal X-ray diffraction were isolated. **b)** Under N_2, a glass vial was charged with a [D_6]benzene solution of **9** (20 mg, 22.6 μmol), and a [D_6]benzene solution of Me_3NO (1.6 mg, 22.6 μmol). The resultant mixture was filtered through glass wool into a Young's PTFE tap equipped NMR tube, and a ^{1}H NMR spectrum recorded immediately. The reaction was further monitored by ^{1}H NMR spectroscopy. t = 0 h: The ^{1}H NMR spectroscopic resonances of **9** have completely given way to a new transient species (not identified) and **10** in a 1:1 ratio. ^{1}H NMR (C_6D_6) of **10**: δ = 8.98 (d, $^3J_{H,H}$ = 8.46 Hz, 1 H, 8-H), 7.61 (m, 9 H, Ar), 3.59 (br., 1 H, OCH_2), 3.25 (br., 1 H, CH_2), 1.73 (s, 9 H, 3-*t*Bu), 1.26 (s, 9 H, 6-*t*Bu) ppm. $C_{50}H_{58}O_3SZr$ (830.3): calcd. C 72.32, H 7.04; found C 67.01, H 7.96. Yield, isolated from a mixture with **9** (42 mg, 1.4%). ^{1}H NMR (C_6D_6) of transient: δ = 9.16 (d, $^3J_{H,H}$ = 8.94 Hz, 1 H, 8-H), 7.41 (m, 9 H, Ar), 2.94 (br., 1 H, CH_2), 1.68 (s, 9 H, 3-*t*Bu), 1.45 (s, 9 H, 6-*t*Bu) ppm. t = 1 h: The ^{1}H NMR spectroscopic resonances due to **10** have grown considerably, while those for the transient species have decreased to a ratio of 5:2. t = 24 h: ^{1}H NMR spectrum contains a few more resonances of insignificant integral value but is essentially unchanged. t = 168 h: No change in ^{1}H NMR spectrum.

Crystallographic Data: X-ray data (Table 3) were collected using Mo-K_α radiation (λ = 0.71073 Å) with a Bruker SMART1000 CCD area detector diffractometer using ω scans. Structure solution and refinement was carried out with the SHELX suite of programs.[37] CCDC-217721 (**5**), -217722 (**9**) and -217723 (**10**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Characterisation, Properties and X-ray Structures of Cu^{II} Coordination Compounds with 5,5′-Dimethylbipyridine and Various Anions: Control of Stoichiometry and Structure by the Counterions

Gerard A. van Albada,[a] Aminou Mohamadou,[a][‡] Ilpo Mutikainen,[b] Urho Turpeinen,[b] and Jan Reedijk*[a]

Keywords: Copper / EPR spectroscopy / Infrared spectroscopy / Magnetic properties / N ligands

The synthesis, crystal structures, and electronic and magnetic properties of eight new Cu^{II} compounds containing the ligand 5,5-dimethyl-2,2′-bipyridine (dmbpy) with the general formula $[Cu^{II}(dmbpy)_x(L)_2]$ (where L = BF_4^-, $CF_3SO_3^-$, NO_3^-, Br^-, NCS^-, N_3^-, $HCOO^-$, and x = 1–3) are reported. The geometries of the Cu^{II} ions include a four-coordinate square-planar polymeric compound $[Cu(dmbpy)(N_3)_2]_n$ (**7**), the five-coordinate compounds, $[Cu(dmbpy)_2(C_2H_6O)](CF_3SO_3)_2$ (**2**), $[Cu(dmbpy)_2(NO_3)](NO_3)$ (**3**), $[Cu(dmbpy)_2(Br)]Br$ (**5**), $[Cu(dmbpy)(NCS)_2]_n$ (**6**) and $[Cu(dmbpy)_2(HCOO)](CF_3SO_3)$ (**8**), which have geometries ranging from square pyramidal to trigonal bipyramidal, and the six-coordinate compounds $[Cu(dmbpy)_3](BF_4)_2(C_2H_6O)$ (**1**) and $[Cu(dmbpy)(NO_3)_2]$ (**4**), which adopt an octahedrally based geometry. Except for compounds **3** and **4**, with nitrate as the anion, a variation of the copper/ligand ratios in the synthesis has no influence on the stoichiometry. The compounds have been characterised in detail by infrared, ligand field and EPR spectroscopy; the data are consistent with the single-crystal X-ray structures.

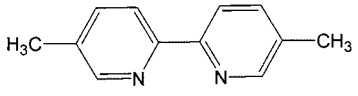
Introduction

The flexible coordination sphere around the copper(II) ion, in combination with steric and packing forces, is one of the effects that give rise to an enormous structural diversity in Cu^{II} coordination chemistry.[1] Copper(II) is one of the most important transition metals, especially due to its relevance as the active-site structure of metalloproteins,[2] but also with respect to its magnetochemistry.[3]

In structural chemistry, hydrogen bonding and π-π stacking forces are known to be important in stabilising the lattice structure. The ligand 2,2′-bipyridine (bpy) is one which has been studied extensively due to its structural aspects[4] and magneto-chemical properties.[3a][3b] Ssubstituted bpy ligands are also known, but their complexes are far less common.

Only a few X-ray crystal structures with Cu^{II} and the ligand 4,4′-dimethyl-2,2′-bipyridine have been reported — two mononuclear structures[5a][5b] and three polynuclear structures with copper(II) halides.[5c–5e] Recently the first X-ray structures of di- tri- and tetranuclear Cu^{II} compounds with this ligand were reported.[5f–5h]

In the present study the ligand 5,5′-dimethyl-2,2′-bipyridine (dmbpy; Scheme 1) has been selected. Quite surprisingly this ligand has hardly been studied and, to the best of our knowledge, only one 3D structure of a Cu^{II} compound has been published.[6] We have now extended this study towards Cu^{II} coordination compounds of general formula $[Cu^{II}(dmbpy)_x(L)_2]$ (where L = BF_4^-, $CF_3SO_3^-$, NO_3^-, Br^-, NCS^-, N_3^-, $HCOO^-$, and x = 1–3). A variety of new structures of different stoichiometry and dimensionality are reported together with their spectroscopic and magnetic properties.



5,5′-dimethyl-2,2′-bipyridine (5,5′-dimethyl-2,2′-dipyridyl)

Scheme 1

Results and Discussion

Eight new Cu^{II} compounds containing the ligand 5,5-dimethyl-2,2′-bipyridine (dmbpy) with the general formula

[a] Abbreviations: (v)br = (very)broad, sh = shoulder, s = strong. [b] Coordination number is given in brackets. Abbreviations: oc = octahedral; sq.pyr. = square pyramidal; sq.pl. = square planar; tbp = trigonal bipyramidal.

$[Cu^{II}(dmbpy)_x(L)_2]$ (where L = BF_4^-, $CF_3SO_3^-$, NO_3^-, Br^-, NCS^-, N_3^-, $HCOO^-$, and $x = 1-3$) have been synthesised (see Table 1). Except for compounds **3** and **4**, with nitrate as the anion, variation of the copper/ligand ratios in the synthesis has no influence on the stoichiometry. The crystal and molecular structures vary greatly, depending on the counterion, from case to case, as will be described below.

Description of the Crystal Structures

[Cu(dmbpy)$_3$](BF$_4$)$_2$(C$_2$H$_5$OH) (1)

The structure of **1** consists of a $[Cu(dmbpy)_3]^{2+}$ cation, two non-coordinating BF_4^- anions and an ethanol lattice molecule. The structure is depicted in Figure 1 together with the numbering scheme. Selected bond lengths and angles are listed in Table 2.

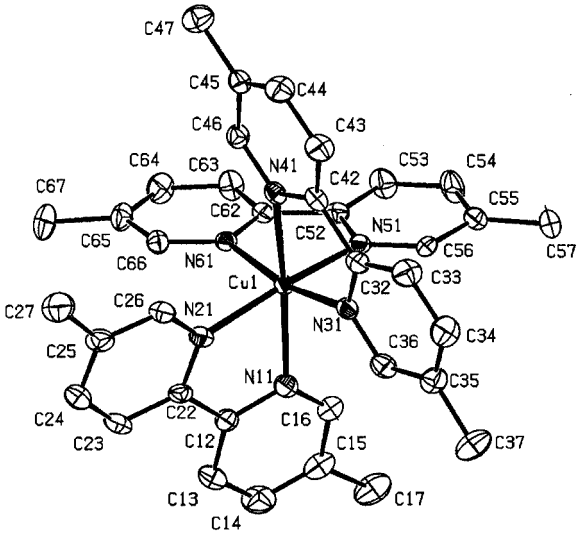

Figure 1. Thermal ellipsoid plot (50% probability) of $[Cu(dmbpy)_3](BF_4)_2(C_2H_5OH)$ (**1**) with atom-labelling scheme; non-coordinating tetrafluoroborate anions, ethanol molecule and H-atoms are omitted for clarity

Table 2. Selected bond lengths (Å) and angles (°) for $[Cu(dmbpy)_3](BF_4)_2(C_2H_6O)$ (**1**)

Cu1−N31	2.040(4)	Cu1−N21	2.050(4)
Cu1−N51	2.054(4)	Cu1−N61	2.056(4)
Cu1−N41	2.274(4)	Cu1−N11	2.281(4)
N31−Cu1−N21	95.03(15)	N31−Cu1−N51	94.13(14)
N21−Cu1−N51	166.73(15)	N31−Cu1−N61	168.52(15)
N21−Cu1−N61	92.54(14)	N51−Cu1−N61	79.97(14)
N31−Cu1−N41	76.56(15)	N21−Cu1−N41	96.67(14)
N51−Cu1−N41	94.78(14)	N61−Cu1−N41	94.02(14)
N31−Cu1−N11	99.42(15)	N21−Cu1−N11	76.37(14)
N51−Cu1−N11	92.67(14)	N61−Cu1−N11	90.74(14)
N41−Cu1−N11	171.76(13)		

The Cu atom has a distorted, elongated octahedral coordination with the basal plane comprised of four nitrogens from three chelating dmbpy ligands. The Cu−N distances vary from 2.040(4) to 2.056(4) Å with basal angles of 166.73(15)° and 168.52(15)°. The apical positions are occupied by nitrogen atoms of the two different bis-chelating dmbpy ligands [Cu−N distances of 2.274(4), 2.281(4) Å with an angle of 171.76(13)°].

The lattice structure is stabilised by weak stacking between the pyridine groups (shortest ring-ring distances of 4.29 Å) and by strong hydrogen bonding between the hydroxo group of the ethanol molecule and a fluorine atom of the tetrafluoroborate anion (O1···F12: 2.765 Å).

[Cu(dmbpy)$_2$(C$_2$H$_5$OH)](CF$_3$SO$_3$)$_2$ (2)

The structure of **2** consists of a $[Cu(dmbpy)_2(C_2H_6O)]^{2+}$ cation and two non-coordinating $CF_3SO_3^-$ anions. The structure is depicted in Figure 2 together with the number-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing scheme. Selected bond lengths and angles are listed in Table 3. The geometry around the copper(II) ion is distorted trigonal bipyramidal with the trigonal plane formed by the two nitrogens of two dmbpy ligands and an oxygen atom of a coordinating ethanol molecule, with a distance of 2.211(2) Å, which is in agreement with the few other structures with a $CuN_4O_{ethanol}$ chromophore.[4a,7]

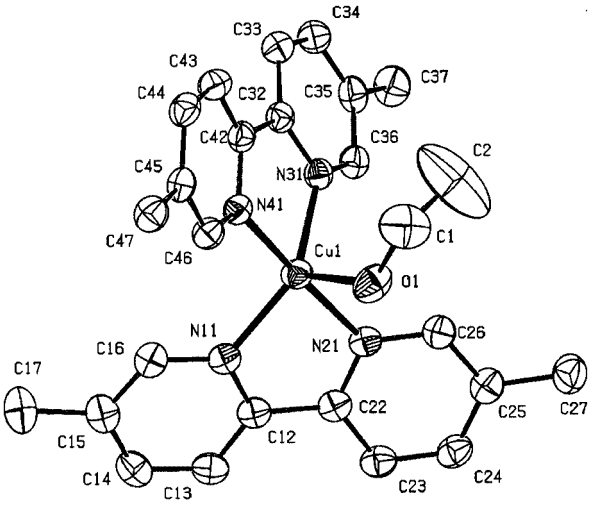

Figure 2. Thermal ellipsoid plot (50% probability) of $[Cu(dmbpy)_2(C_2H_5OH)](CF_3SO_3)_2$ (**2**) with atom-labelling scheme; non-coordinating triflate anions and H-atoms are omitted for clarity

Table 3. Bond lengths (Å) and angles (°) for $[Cu(dmbpy)_2(C_2H_6O)](CF_3SO_3)_2$ (**2**)

Cu1−N21	1.974(3)	Cu1−N41	1.976(3)
Cu1−N11	2.029(3)	Cu1−N31	2.036(3)
Cu1−O1	2.211(2)		
N21−Cu1−N41	171.08(10)	N21−Cu1−N11	81.53(10)
N41−Cu1−N11	101.63(10)	N21−Cu1−N31	102.34(10)
N41−Cu1−N31	81.37(10)	N11−Cu1−N31	135.43(10)
N21−Cu1−O1	87.21(10)	N41−Cu1−O1	83.94(9)
N11−Cu1−O1	117.99(10)	N31−Cu1−O1	106.57(10)

The Cu−N distances vary from 1.974(3) to 2.036(3) Å. The apical positions are occupied by two nitrogen atoms of the two dmbpy ligands with a *trans* angle of 135.43(10)°. The distortion from square pyramidal can be best described by the structural parameter τ (τ describes the relative amount of trigonality; $\tau = 0$ for square pyramid and $\tau = 1$ for trigonal bipyramidal), which in this case is 0.61. The structure can therefore be best described as distorted trigonal bipyramidal.[8] The lattice is stabilised by stacking of the pyridine rings, with a short ring-ring distance of 3.83 Å and a strong hydrogen bond between the ethanol oxygen hydrogen and the oxygen atom of one of the triflate anions (O1···O21: 2.6967 Å).

[Cu(dmbpy)$_2$(NO$_3$)](NO$_3$) (3)

The mononuclear structure **3** consists of a copper(II) ion, two dmbpy ligands, one monodentate coordinated nitrate anion and one uncoordinated nitrate anion. The structure is depicted in Figure 3 together with the numbering scheme. Selected bond lengths and angles are listed in Table 4.

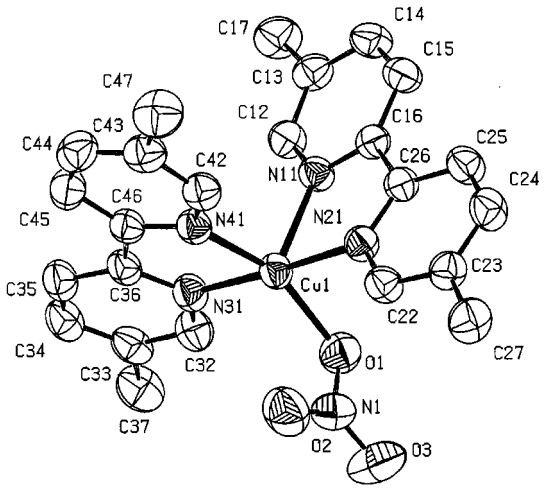

Figure 3. Thermal ellipsoid plot (50% probability) of $[Cu(dmbpy)_2(NO_3)](NO_3)$ (**3**) with atom-labelling scheme; the non-coordinating nitrate anion and H-atoms are omitted for clarity

Table 4. Bond lengths (Å) and angles (°) for $[Cu(dmbpy)_2(NO_3)](NO_3)$ (**3**)

Cu1−N31	1.974(2)	Cu1−N21	2.002(2)
Cu1−N41	2.034(2)	Cu1−O1	2.044(2)
Cu1−N11	2.156(2)	Cu1−O2	2.669(2)
N31−Cu1−N21	177.16(9)	N31−Cu1−N41	81.30(9)
N21−Cu1−N41	97.68(9)	N31−Cu1−O1	93.99(9)
N21−Cu1−O1	87.99(9)	N41−Cu1−O1	156.59(9)
N31−Cu1−N11	98.56(9)	N21−Cu1−N11	79.01(8)
N41−Cu1−N11	101.10(9)	O1−Cu1−N11	102.27(9)
O2−Cu1−N11	153.20(9)		

The geometry around the Cu^{II} atom is distorted square pyramidal with the basal plane formed by three nitrogen atoms of two ligands [distances vary from 1.974(2) to 2.034(2) Å] and one oxygen atom of the coordinated nitrate anion [Cu1−O1: 2.044(2) Å]. The apical position is occupied by a nitrogen atom of one ligand (Cu1−N11: 2.156 Å). A second oxygen atom of the coordinated nitrate anion is at a semi-coordination distance [Cu1−O2: 2.669(2) Å]. The angles of the basal plane are 177.16(9)° and 156.59(9)° and the distortion parameter τ in this case is 0.34. The lattice is stabilised by stacking of the pyridine rings, with a ring-ring distance of 3.74 Å.

[Cu(dmbpy)(NO$_3$)$_2$] (4)

The mononuclear structure **4** consists of a copper(II) ion, one dmbpy ligand, and two didentate-coordinated nitrate anions. The structure is depicted in Figure 4 together with the numbering scheme. Selected bond lengths and angles are listed in Table 5.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

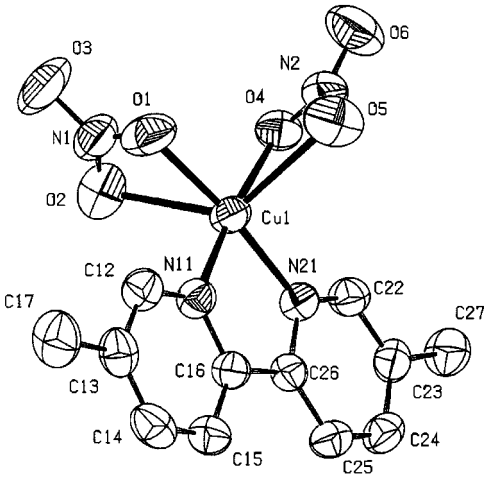

Figure 4. Thermal ellipsoid plot (50% probability) of $[Cu(dmbpy)(NO_3)_2]$ (**4**) with atom-labelling scheme; H-atoms are omitted for clarity

Table 5. Bond lengths (Å) and angles (°) for $[Cu(dmbpy)(NO_3)_2]$ (**4**)

Cu1−N11	1.966(3)	Cu1−N21	1.969(3)
Cu1−O4	1.979(3)	Cu1−O1	1.994(3)
Cu1−O2	2.484(4)	Cu1−O5	2.465(4)
N11−Cu1−N21	82.30(13)	N11−Cu1−O4	172.06(12)
N21−Cu1−O4	95.19(13)	N11−Cu1−O1	95.49(13)
N21−Cu1−O1	172.34(15)	O4−Cu1−O1	87.95(13)
O2- Cu1- O5	131.38(13)		

The geometry around the Cu^{II} atom is elongated octahedral with the basal plane formed by two nitrogen atoms of the dmbpy ligand [Cu−N distances 1.966(3), 1.969(3) Å] and two oxygen atoms of two different coordinated nitrate anions [Cu−O distances 1.979(3), 1.994(3) Å]. The apical positions are occupied by the other two oxygen atoms of two nitrate anions [Cu−O distances 2.484(4), 2.465(4) Å]. The angles of the basal plane deviate by only about 8° from linear [172.06(12)° and 172.34(15)°].

The lattice is stabilised by stacking of the pyridine rings, with a ring-ring distance of 3.70 Å. The nitrate anion is known to be a versatile anion, which in many cases gives rise to different coordinations. Also with the ligand bpy, a number of Cu^{II} compounds exists with different variations in the coordination of the nitrate anion.[6b,9]

[Cu(dmbpy)$_2$(Br)]Br (5)

The structure of **5** consists of a Cu^{II} ion, two dmbpy ligands, one coordinated bromide atom and one uncoordinated bromide atom. The structure is depicted in Figure 5 together with the numbering scheme. Selected bond lengths and angles are listed in Table 6. The geometry around the copper(II) ion is distorted trigonal bipyramidal with the trigonal plane formed by three nitrogens of the two dmbpy ligands. The apical positions are occupied by an N-atom and a bromide atom, with a *trans* angle of 135.32(8)°. The Cu−N distances vary from 1.979(3) to 2.113(3) Å, while the Cu−Br distance is 2.4256(6) Å.

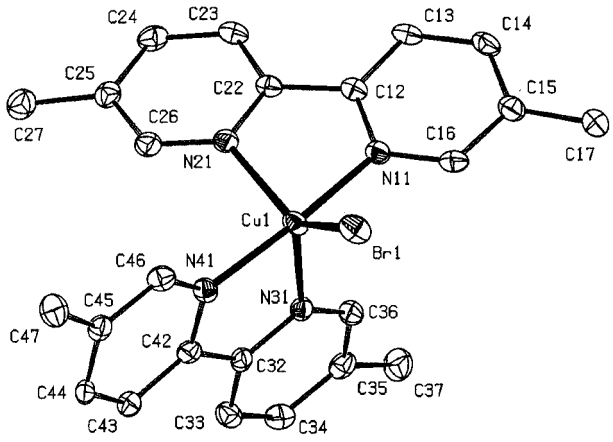

Figure 5. Thermal ellipsoid plot (50% probability) of $[Cu(dmbpy)_2(Br)]Br$ (**5**) with atom-labelling scheme; the non-coordinating bromide anion and H-atoms are omitted for clarity

Table 6. Bond lengths (Å) and angles (°) for $[Cu(dmbpy)_2(Br)]Br$ (**5**)

Cu1−N41	1.979(3)	Cu1−N11	1.985(3)
Cu1−N21	2.106(3)	Cu1−N31	2.113(3)
Cu1−Br1	2.4256(6)		
N41−Cu1−N11	173.31(11)	N41−Cu1−N21	94.79(11)
N11−Cu1−N21	79.40(11)	N41−Cu1−N31	80.29(11)
N11−Cu1−N31	97.07(11)	N21−Cu1−N31	97.65(10)
N41−Cu1−Br1	93.32(8)	N11−Cu1−Br1	93.17(8)
N21−Cu1−Br1	135.32(8)	N31−Cu1−Br1	127.03(8)

The distortion parameter τ in this case is 0.63. The lattice is stabilised by stacking of the pyridine rings, with a ring-ring distance of 3.60 Å. The parameters are in agreement with related structures with a $[Cu(N_4)Br]Br$ chromophore;[10] the parameters of $[Cu(bpy)_2(Br)]Br$[10c] are closest to those of compound **5**, with only a slight difference in the N11−Cu1−N31 bite angle of the bpy rings [106.7°; 97.07(11)° in **5**].

[Cu(dmbpy)(NCS)$_2$]$_n$ (6)

The structure of **6** is polymeric and consists of a Cu^{II} ion, one dmbpy ligand, one bridging and one monodentate coordinating thiocyanate anion. The structure is depicted in Figure 6 together with the numbering scheme. Selected bond lengths and angles are listed in Table 7. The geometry around the copper(II) ion is distorted square pyramidal with the basal plane formed by the two nitrogen atoms of the dmbpy ligand and two nitrogen atoms of two thiocyanate anions. The Cu−N distances vary from 1.950(3) to 2.014(3) Å. The apical position is occupied by a sulfur atom of the bridging thiocyanate anion with a Cu−S distance of 2.6335(12) Å, forming in this way a polynuclear compound in which the NCS^- anion forms a zigzag chain with the Cu

[a] a = $-x + 1$, $y + 1/2$, $-z + 1/2$.

ions. The angles of the square plane are 166.03(14)° and 154.57(15)°. The distortion parameter τ in this case is 0.19, and the two thiocyanate anions are almost linear (178.43° and 179.01°). The lattice is stabilised by stacking of the pyridine rings, with a ring-ring distance of 3.70 Å. The distances and angles are similar to the related compound $[Cu(bpy)(NCS)_2]_n$.[11a]

[Cu(dmbpy)(N$_3$)$_2$]$_n$ (7)

The structure of **7** is also polymeric and consists of a Cu^{II} ion coordinated by one dmbpy ligand and two bridging azide anions. The structure is depicted in Figure 7 together with the numbering scheme. Selected bond lengths and angles are listed in Table 8.

The geometry around the copper(II) ion is square-planar based with the basal plane formed by the two nitrogen atoms of the dmbpy ligand and two nitrogen atoms of two azide anions [Cu−N distances vary from 1.980(5) to 2.047(5) Å]. The basal planes are 171.1(2)° and 170.2(2)°. The two azide anions are almost linear [176.4° and 174.9(7)°]. The apical positions are occupied by nitrogen atoms of neighbouring azide anions at semi-coordination distances of 2.652(6) Å (Cu1−N31a, 1,1-azide bond) and 2.708(7) Å (Cu1−N43b, 1,3-azide bond), forming in this way a polymeric array (Figure 8). This array (--Cu--[(1,1-$N_3)_2$]--Cu--[(1,3-$N_3)_2$]--Cu--) is rather rare. So far, to the best of our knowledge, only one Cu^{II} compound, [Cu(3-picoline)$(N_3)_2]_n$,[12a] has been published with this alternating azide array. The lattice of the compound is further stabilised by stacking of the pyridine rings, with a ring−ring distance of 3.72 Å.

O1B−Cu1−N31	102.9(2)	O1B−Cu1−N11	160.3(2)

[a] O1A, O1B are the major and minor disordered components of the formato anion which were refined in two positions with ratio 0.8:0.2.

The geometry around the copper(II) ion is distorted trigonal bipyramidal with the trigonal plane formed by three nitrogens of the two dmbpy ligands [Cu-N distances vary from 1.9955(19) to 2.1585(19) Å]. The apical positions are occupied by an N-atom and an oxygen atom of the formato anion with a *trans* angle of 145.59(8)° (the *trans* angle of the major component of the disordered formato anion is chosen here). The second oxygen of the formato anion (O2A) is at a very long distance [2.912(2) Å]. All distances are in agreement with the few other known structures with the formato anion.[13] The distortion parameter τ for this compound is 0.49 (angle taken from the major component), and is therefore intermediate between trigonal pyramidal and square pyramidal. The lattice is stabilised by stacking of the pyridine rings, with a ring-ring distance of 3.672 Å.

Infrared Spectroscopy

In the infrared spectra the most important bands for characterisation of the compounds are those of the anions. In compound **1** the vibration of the tetrafluoroborate anion is observed at 1030 cm^{-1} as a single strong band. The most sensitive characteristic vibrations of the triflate anion is the $\nu_{as}S-O$, which is observed in compound **2** at 1245 cm^{-1} as a broad band with a weak, but sharp, peak at 1273 cm^{-1} and in compound **8** at 1263 cm^{-1}, in agreement with the literature for mononuclear or H-bonded triflate anions.[14]

The two related compounds **3** and **4** differ in composition (1:1 and 1:2, respectively). In compound **3** one nitrate anion is coordinating and one is non-coordinating, while in compound **4** both nitrate anions are coordinated. Most of the regions that are characteristic of nitrate vibrations[11b,15] are overlapped by strong ligand vibrations. However, in the region 1200−1300 cm^{-1} a clear difference in the infrared spectra is observed. In both compounds a broad strong band is observed at about 1270 cm^{-1}, which originates from the chelating nitrate anion.[11b,16] In addition, in compound **3**, which has two different types of nitrate coordination, a strong vibration is observed at about 1333 cm^{-1}. Although this value is slightly higher than expected for a free nitrate bond,[11b,15] this vibration must originate from the non-coordinated nitrate anion.

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In compound **6** the vibrations of the thiocyanate anion are observed as a strong split band at 2084 and 2047 cm^{-1} in agreement with the two types of thiocyanate (bridging and monodentate) present in the structure,[11] while in compound **7** the vibration of the azide anion is found as a split strong band at 2027 and 2070 cm^{-1}, in agreement with the two different types of bonding of the azide anions.[12]

The C=O stretching vibration of the formato anion in compound **8** is observed at 1597 cm^{-1} as a clear, strong, sharp band, in accordance with the literature[11b] and also with the fact that this band is absent in compounds **1**−**7**.

Electronic Spectroscopy

The diffuse-reflectance spectra of all compounds measured as solids are tabulated in Table 1. Compounds **1**, **4** and **7**, which have a square-planar based geometry exhibit bands at around 14.3−15.5 × 10^3 cm^{-1}, which is normal for planar-based (octahedral) geometries.[17] Compound **1** also displays a very broad shoulder at 7.6 × $10^3 cm^{-1}$, which is rather rare for distorted octahedral geometries and must originate from a small Jahn−Teller distortion.[17a]

The five-coordinate compounds **2**, **3**, **5**, **6** and **8**, which have trigonal bipyramidal or square-pyramidal geometries, all show bands at around 13.5−15.1 × $10^3 cm^{-1}$ and 10.1−10.8 × $10^3 cm^{-1}$, which are considered normal transitions for these geometries.[17]

All compounds have charge-transfer bands at around 26−28 × $10^3 cm^{-1}$, except the thiocyanate compound **6**, which has a band at 21.5 × 10^3 cm^{-1} of medium intensity that originates from a Cu^{II}−NCS charge transfer.[11] The azide compound **7** displays a very strong band at 23.4 × $10^3 cm^{-1}$, which originates from the strong Cu^{II}-azide charge transfer.[18]

Magnetic Properties

EPR Spectroscopy

The powder EPR spectrum of compound **1** at room temperature reveals an axial signal with $g_\perp$ = 2.10 and $g_\parallel$ = 2.26. A weak hyperfine splitting is observed with $A_\parallel$ = 11.5 mT. At 77 K the hyperfine splitting $A_\parallel$ becomes 13.3 mT, an indication that the geometry is changing at low temperature. The EPR values are in agreement with the distorted octahedral structure of this compound.

The spectrum of compound **2** at room temperature and at 77 K displays a rhombic signal with g_1 = 2.03, g_2 = 2.12 and g_3 = 2.28. This last value (g_3) is observed as a weak band. This spectrum agrees with the square-pyramidal geometry of the Cu^{II} atom.[17]

The EPR spectra of the nitrate compounds show a different pattern according to their different Cu^{II} geometry. Compound **3** at room temperature and at 77 K reveals an isotropic signal with g = 2.14, while compound **4** at room temperature and at 77 K shows the same axial signal with a $g_\perp$ of 2.07 and an unresolved $g_\parallel$ of 2.27.

The powder EPR spectra of compounds **5** and **6** (Figures 10 and 11) each display a rhombic pattern with three distinct g values. Compound **5** shows an inverted EPR signal with g_x = 2.20, g_y = 2.15 and g_z = 2.01. This pattern (with the lowest g value < 2.03) agrees with the fact that this compound has a compressed rhombic site and a predominant d_{z^2} ground state.[3b,17,19a] This value agrees with a trigonal bipyramidal geometry with an unpaired electron situated along the N11−N41 axis. For compound **6** the lowest g value is greater than 2.03, with g_x = 2.05, g_y = 2.11 and g_z = 2.23, which indicates a $d_{x^2-y^2}$ ground state.[3b,17,19b,19c]

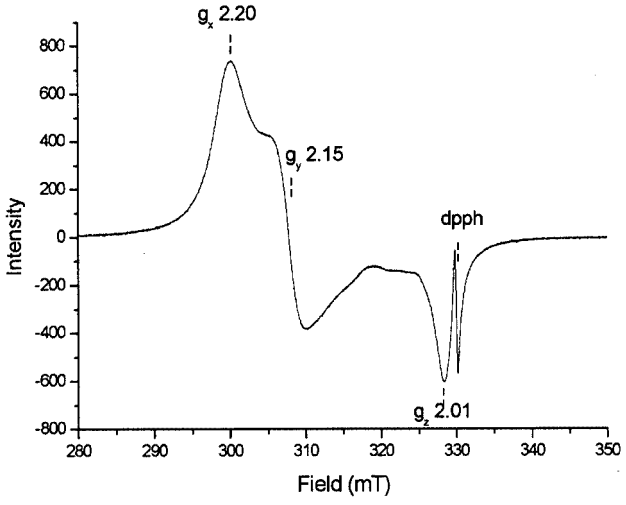

Figure 10. EPR spectrum (solid) of compound (**5**), see text

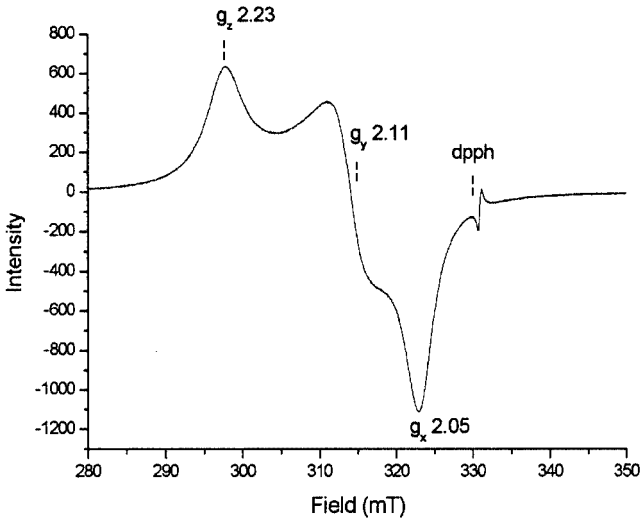

Figure 11. EPR spectrum (solid) of compound (**6**), see text

The EPR spectrum of compound **7** at room temperature and at 77 K reveals the same axial signal with a $g_\perp$ of 2.06 and an unresolved $g_\parallel$ of 2.23, which confirms the square-planar based structure of the compound.

The EPR spectrum of compound **8** at 77 K shows, like compound **5**, an inverted EPR signal with $g_x \approx 2.22$, g_y =

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2.12 and $g_z = 2.02$. The g_x appears as a broad band. This pattern (with lowest g value < 2.03) indicates a predominantly d_{z^2} ground state,[3b,17,19a] which is in agreement with the five-coordinate geometry.

For assigning the ground state in rhombic spectra the parameter $R = (g_2 - g_1)/(g_3 - g_2)$, with $g_3 > g_2 > g_1$, has been introduced.[3b,17c] This parameter is greater or smaller than 1 if the ground state is d_{z^2} or $d_{x^2-y^2}$, respectively. For the rhombic compounds **2**, **5**, **6** and **8** the R values are 0.56, 2.80, 0.50 and about 1.0, respectively, which confirms our conclusions.

Magnetic Susceptibility

For a few of the new compounds with potential magnetic exchange as a result of their structure and bridging anions, detailed variable-temperature magnetic susceptibility studies were performed. In the literature a number of Cu^{II} thiocyanate compounds exist which display a weak magnetic interaction even though the Cu−Cu distance is large (about 6 Å) and the magnetic orbitals are not co-planar. Examples are the compounds $[Cu(bpy)(NCS)_2]_n$ and $[Cu(pyrazine)(NCS)_2]_n$, with a weak antiferromagnetic interaction,[11a,11f] and two mixed-metal (Cu^{II}-Co^{II}) thiocyanide compounds,[11e] which give rise to a weak ferromagnetic interaction. In light of these results the magnetic susceptibility of a powdered sample of **6** was measured from 5 to 300 K. The spectrum of μ_{eff} versus T does not change significantly and stays within a range of 1.65−1.75 BM, which is close to the spin-only value of Cu (1.77 BM), so no significant interaction could be observed between neighbouring Cu atoms.

Similar results were obtained for compound **7**, which also gives no significant change between 5 and 300 K (μ_{eff} between 1.76−1.82 BM), so no magnetic interaction could be detected between neighbouring Cu atoms. This behaviour can be understood on the basis of the magnetic orbital orientation.[3a]

Conclusions

In this study eight new mononuclear Cu^{II} compounds with the ligand dmbpy have been synthesized and characterised. Depending on the selected anions, a great variety of geometries have been observed with Cu^{II}. In all cases the dmbpy ligand appears to be rather rigid, irrespective of whether one, two or three ligands bind to Cu^{II}. Five-coordinate structures, varying from square pyramidal to trigonal bipyramidal, are observed with triflate, nitrate, bromide, thiocyanate and formate as the anion. With tetrafluoroborate, nitrate and azide square-planar based (square planar to octahedron) complexes are obtained.

Comparing our results to Cu^{II} compounds with bpy as a ligand, we observe quite important differences: with bpy a very large number of mononuclear and anion-bridged dinuclear compounds has been reported with a similar set of anions,[4b] while the method of synthesis is similar to ours. Apparently the steric hindrance of the methyl groups of dmbpy prevents crystallisation of such dinuclear compounds.

In summary: the effect of the two methyl groups has resulted in a great variety of new compounds, which have no counterparts in bipyridine-containing complexes. Such dramatic differences resulting from apparently small ligand changes are as yet not fully understood.

Experimental Section

All chemicals were purchased from commercial sources and used as received.

General Synthesis of the Compounds: An equimolar amount of dmbpy and the copper(II) salt were dissolved separately in ethanol and were then slowly mixed together (Cu solution added to the ligand solution) and heated to about 40 °C. The solution was filtered to remove any solid particles and left to evaporate at room temperature. Crystals were obtained in a few days to a few weeks. Yields 43 to 72%. A difference in the ligand:copper ratio had no influence on the compounds, except for the nitrate compounds **3** and **4**, which are very sensitive to the exact ratio (1:1 and 1:2, respectively). The products were characterised by IR spectroscopy and elemental analysis (see Table 1).
Compounds **6** and **7** were prepared in the same way as above (using Cu^{II} triflate as the copper salt), but an equimolar amount of sodium thiocyanate or sodium azide, respectively, dissolved in a very small amount of water, was added slowly to the total solution. The solution was then filtered and left standing in the open air.
Compound **8** was initially obtained by using Cu^{II} triflate and the ligand dmbpy in methanol and adding a few drops of sodium hydroxide dissolved in water to the total solution. Within a few weeks dark-blue blocks of crystals appeared, which turned out to contain the formato anion. Apparently, the formato anion was formed in situ, a phenomenon observed earlier by using triethyl orthoformate.[13a,20] Subsequently, this compound was also synthesized in higher yield by adding sodium formate (dissolved in water) to the Cu/ligand solution in methanol.

Physical Techniques: C,H,N determinations were performed on a Perkin−Elmer 2400 Series II analyser. Ligand-field spectra were obtained on a Perkin−Elmer Lambda900 spectrophotometer using the diffuse-reflectance technique, with MgO as a reference. FT-IR spectra were obtained on a Perkin−Elmer Paragon 1000 FT-IR spectrophotometer equipped with a Golden Gate ATR device, using the reflectance technique (4000−300 cm^{-1}, resolution 4 cm^{-1}). X-band EPR spectra were recorded on polycrystalline samples at room temp. and at 77 K with a Jeol RE2X electron spin resonance spectrometer using DPPH ($g = 2.0036$) as a standard. Magnetic susceptibility measurements (5−300 K) were carried out using a Quantum Design MPMS-5 5T SQUID magnetometer (measurements carried out at 1000 Gauss). Data were corrected for magnetisation of the sample holder and for diamagnetic contributions, which were estimated from Pascal constants.

X-ray Crystallography. Compounds 1−4: A crystal was selected and mounted onto a glass fiber using the oil-drop method. Data were collected on a Rigaku AFC-7S diffractometer (graphite-monochromated Mo-K_α radiation, ω-2θ scans). The intensity data were corrected for Lorentz and polarisation effects, for absorption (psi-scan absorption correction) and extinction. The structures were solved by direct methods. The programs teXsan,[21a] SHELXS-97,[21b] and SHELXL-97[21c] were used for data reduction, structure solution

and structure refinement, respectively. All non-hydrogen atoms were refined anisotropically. All H atoms, except the hydroxo atom of the ethanol molecule in compound **2**, were introduced in calculated positions and refined with fixed geometry with respect to their carrier atoms.

Compounds 5–8: Crystals suitable for structure determination were mounted in Lindemann-glass capillaries and transferred into the cold nitrogen stream of a Nonius KappaCCD diffractometer on a rotating anode (Mo-K_α radiation, graphite monochromator, λ = 0.71073). The intensity data were corrected for Lorentz and polarisation effects, and for absorption and extinction. The structures were solved by direct methods. The programs COLLECT,[21d] SHELXS-97,[21b] and SHELXL-97[21c] were used for data reduction, structure solution and structure refinement, respectively. All non-hydrogen atoms were refined anisotropically. All H atoms were introduced in calculated positions and refined with fixed geometry with respect to their carrier atoms. For compound **8** the formato anion was found to be disordered and was refined in two positions with ratio 0.8/0.2. Plots were obtained using the PLATON package.[21e] Crystallographic data of all compounds are listed in Table 10.

CCDC-228793–228800 (for compounds **1**–**8**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Towards Cationic Gallium Derivatives: Metallacycles from the Reactions of Organogallium Compounds with Tetraorganodichalcogenoimidodiphosphinates and a New *N*-(Diphenylthiophosphinyl)thioureato Ligand

Virginia Montiel-Palma,[a] Estefanía Huitrón-Rattinger,[a] Sara Cortés-Llamas,[a] Miguel-Ángel Muñoz-Hernández,*[a] Verónica García-Montalvo,[b] Eddie López-Honorato,[b] and Cristian Silvestru[c]

Keywords: Cationic catalysts / Chelating ligands / Gallium / Metallacycles / Phosphorus

The organometallic complexes of general formulae $[Me_2Ga\{\eta^2\text{-}E,E'\text{-}[R_2P(E)NP(E')R'_2]\}]$ [R = R′ = Ph, E = E′ = O (**1**); R = R′ = Ph, E = E′ = S (**2**); R = R′ = Ph, E = E′ = Se (**3**); R = R′ = Ph, E = O, E′ = S (**4**); R = Me, R′ = Ph, E = S, E′ = O (**5**)] and $[Me_2Ga\{\eta^2\text{-}S,S'\text{-}[Ph_2P(S)NC(S)(C_9H_{10}N)]\}]$ (**6**) were obtained by facile methane elimination reactions from $GaMe_3$ and the acidic ligands L^1H $[(XPPh_2)_2NH$ (X = O, S, Se), $(OPPh_2)(SPPh_2)NH$, and $(OPMe_2)(SPPh_2)NH]$ and L^2H $[Ph_2P(S)NHC(S)(C_9H_{10}N)]$ in toluene. Replacement of one phosphorus atom by a carbon atom in the ligand skeleton of L^1H gave the new ligand L^2H, which, upon reaction with $GaMe_3$, gave compound **6**, which shows no significant structural differences with respect to **1**–**5**. Therefore, L^2H does not induce partial planarity in the six-membered ring, indicating the necessity for replacing both phosphorus atoms of the ligand by carbon atoms, as in the β-diketonate-type derivatives, in order to impose ring planarity. Thus, despite originating from a variety of ligands with differing donor atoms and substituents at the phosphorus atoms, all complexes show little structural differences.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Comparisons between the bonding in organic and inorganic (carbon-free) analogs are widely sought throughout chemistry and have led to a higher understanding of electronically related systems. In particular, the consequences of π-electron delocalization in planar chelate rings have been traditionally assessed by comparison of their properties with those of their nonplanar counterparts arising from atom substitution.[1,2]

In this light, tetraorganodichalcogenoimidodiphosphinato $\{[R_2P(E)NP(E')R'_2]^-$ (E = E′ = chalcogen) $(L^1)\}$ and *N*-(diorganothiophosphinyl)thioureato $\{[R_2P(S)NC(S)R''_2]^-$ $(L^2)\}$ ligands can be regarded as inorganic analogs of the much used β-diketonate ligands. It is the flexibility of the six-membered $M\{\eta^2\text{-}E,E'\text{-}(EPNPE')\}$ (M = main group or transition metal) ring derived from L^1 that has been credited for the variety of structural and coordination modes encountered, a number of which have even given rise to supramolecular structures or proved to be potential building blocks for the design of new materials; others have found prospective industrial use in catalytic systems or biological applications.[3,4] Accordingly, the last decade has seen a considerable growth in the investigations of complexes bearing this kind of ligands, yet surprisingly only a discrete number of organometallic gallium derivatives have been isolated.

From the first organogallium derivative of L^1, $[Et_2Ga\{\eta^2\text{-}Se,Se'\text{-}[Ph_2P(Se)NP(Se)Ph_2]\}]$[5] (**3**-Et), to Uhl's organodigallium(II) compounds, $[\{(Me_3Si)_2HC\}_2Ga\{\eta^2\text{-}O,O'\text{-}[Ph_2P(O)NP(O)Ph_2]\}]$, $[\{(Me_3Si)_2HC\}Ga\{\mu\text{-}\eta^2\text{-}O,O'\text{-}[Ph_2P(O)NP(O)Ph_2]\}]_2$, and $[\{(Me_3Si)_2HC\}Ga\{\eta^2\text{-}S,S'\text{-}[Ph_2P(S)NP(S)Ph_2]\}]_2$,[6] this class of compounds has given insights into the feasibility of preparation and stability towards ligand-redistribution reactions.

Perhaps more importantly, however, cationic gallium species with chelating ligands are desirable for applications in homogeneous catalytic reactions such as alkene polymerization to prevent undesirable ligand exchange/redistribution reactions. Amongst some of the most representative examples are those gallium cations supported by sal-

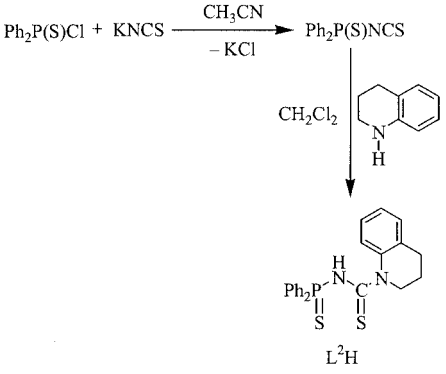
omphen,[7] amidinate,[8,9] β-diketonate[10] and more recently terphenyl[11] ligands. In these systems, ligand bite angles and steric protection play a crucial role in the prevention of nucleophilic attack, besides allowing electronic and steric control. Indeed, Jordan has demonstrated that along the cationic amidinate series $[\{MeC(NiPr)_2\}_2Ga_2Me_3]^+$, $[\{tBuC(NiPr)_2\}GaMe_2\{tBuC(NiPr)_2\}GaMe]^+$ and $[\{tBuC(NtBu)_2\}GaMe]^+$, susceptibility to dimerization decreases, as does nucleophilic addition.[8,9]

In our search for new organogallium cations we recently started a program to systematically explore the incorporation of bulky wide-bite-angle tetraorganodichalcogenoimidodiphosphinato (L^1) and *N*-(diorganothiophosphinyl)thioureato (L^2) ligands at organogallium centers. The ligands in these complexes are closely related to the bis(iminophosphorano)methanide ligand system, which has been used to prepare the monomeric aluminum complexes [κ*N*,κ*N*′-$\{[Ph_2P(Me_3SiN)]_2CH\}AlR_2$] (R = Me, Bu) and [κ*N*,κ*N*′-$\{[Ph_2P(Me_3SiN)]_2CH\}Al(Cl)Et$], and the dimetallic complex [κ*C*,κ*C*′,κ*N*,κ*N*′-$\{[Ph_2P(Me_3SiN)]_2C\}(Me_2Al)_2$]. These complexes show catalytic activity towards ethylene polymerization when activated by trityl tetrafluoroborate, presumably due to formation of a cationic species.[12] Herein we report the facile synthesis and characterization of complexes of general formulae [$Me_2Ga\{\eta^2$-*E*,*E*′-$[R_2P(E)NP(E')R'_2]\}$] and [$Me_2Ga\{\eta^2$-*S*,*S*′-$[Ph_2P(S)NC(S)R'')]\}$] which were envisioned to be good precursors of organometallic cationic species.

Results and Discussion

The synthesis of the new proligand L^2H was carried out in two steps. First, diphenyl isothiocyanide was synthesized according to reported general procedures for the synthesis of similar types of ligands from $Ph_2P(S)Cl$ and KNCS.[13−15] The purified product was then treated with tetrahydroquinoline in CH_2Cl_2, yielding L^2H after treatment with hexane (Scheme 1). Crystals suitable for X-ray diffraction analysis were deposited from hexane at −20 °C. The molecular structure is shown in Figure 1 and the collection and crystal data are given in the Exp. Sect.



Scheme 1. The synthesis of the new ligand L^2H

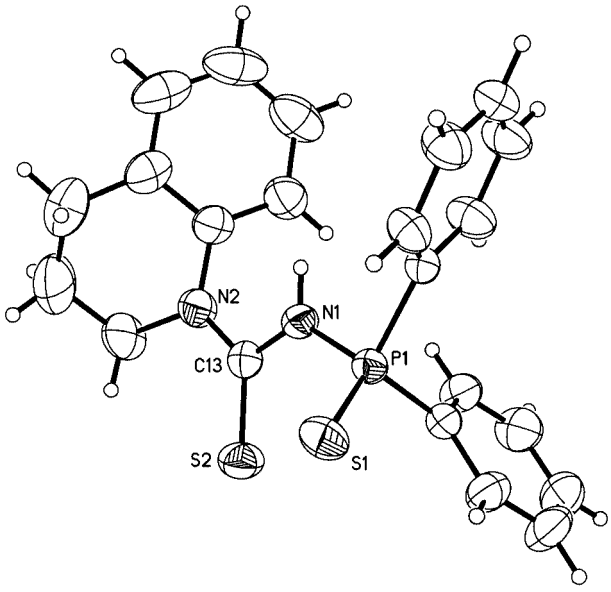


Figure 1. Molecular structure of L^2H with thermal ellipsoids at 50% probability level

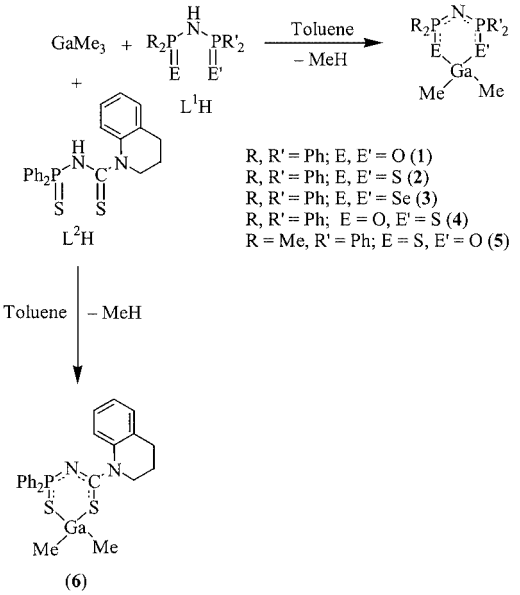
The organogallium compounds of general formulae [$Me_2Ga\{\eta^2$-*E*,*E*′-$[R_2P(E)NP(E')R'_2]\}$] [R = R′ = Ph, E = E′ = O (**1**); R = R′ = Ph, E = E′ = S (**2**); R = R′ = Ph, E = E′ = Se (**3**); R =R′ = Ph, E = O, E′ = S (**4**); R = Me, R′ = Ph, E = S, E′ = O (**5**)] and [$Me_2Ga\{\eta^2$-*S*,*S*′-$[Ph_2P(S)NHC(S)(C_9H_{10}N)]\}$] (**6**) were obtained in good yields by room temperature methane elimination reactions between $GaMe_3$ and the ligands L^1H or L^2H in toluene, as depicted in Scheme 2.



Scheme 2. General synthesis of complexes **1**−**6**

Apart from the organogallium complexes mentioned in the introduction, only one other Ga derivative bearing this

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

type of ligand has been structurally characterized. The inorganic tris(chelate) [Ga{η²-*O*,*O*′-[$Ph_2P(O)NP(O)PPh_2$]$_3$}] exhibits a slightly distorted octahedral GaO_6 core as well as three six-membered Ga(OPNPO) rings.[16] On the other hand, the coordination chemistry with thiophosphorylthioureato (L^2) type ligands is much less developed. Only a few complexes of this kind have been reported and, to the best of our knowledge, no group-13 derivatives have been isolated. Interestingly, the formation of a cavity that would host an alkaline metal ion led to the X-ray diffraction study of cadmium and palladium dinuclear *N*-thiophosphorylated thiourea complexes from α,ω-diamines that allow the connection of two units of tetracoordinate transition metal centers.[15]

Complexes **1**−**6** were characterized by physical (m.p.), chemical (C, H and N analysis), and spectroscopic techniques (multinuclear NMR and IR spectroscopy). In addition, solid-state structures of **1**, **2**, **4**, **5** and **6** were obtained by single-crystal X-ray diffraction.

The first indications of the complexation of L^1 and L^2 were given by the absence of ν(NH) bands in the IR spectra and of the N*H* resonances in the ^{1}H NMR solution spectra of the products, particularly in complexes **2**−**6**.[3] Moreover, as expected for metal coordination, the $^{31}P\{^1H\}$ NMR spectra show a high-field shift of the resonance signals for the homoleptic complexes **2** and **3**, and for the P−O resonance of the mixed-chalcogen species. Furthermore, in the case of the selenium derivative **3** there is a considerable decrease in the $^1J_{P,Se}$ coupling constant with respect to the free ligand (Table 1). On the contrary, there is a small down-field change in the chemical shift of the $^{31}P\{^1H\}$ NMR resonance of **1**, although it should be noted that in the tetraphenylimidodiphosphinic acid (L^1H) used as precursor, the acidic hydrogen atom is probably located in an intermolecular O−H···O bridge[17] which does not permit straightforward deductions.

Table 1. Selected spectroscopic parameters of complexes **1**−**6** compared to acidic ligands L^1H and L^2H

Crystals of complexes **1**−**6** (Figures 2−6, respectively) suitable for X-ray analysis were grown from saturated hexane solutions at −20 °C. The molecular structures of the five complexes show a six-membered metallacycle with the geometry around the gallium center being that of a distorted tetrahedron (see below). The dimethylgallium fragment is found to coordinate in a bidentate fashion to the L^1 or L^2 ligands (Tables 2 and 3). Although the crystals of **3** diffracted, we were unable to obtain an acceptable refinement of the data, which, however, show good similarities with those of the already reported diethyl analogue [Et_2Ga{η²-*Se*,*Se*′-[$Ph_2P(Se)NP(Se)Ph_2$]}] (**3-Et**).[5]

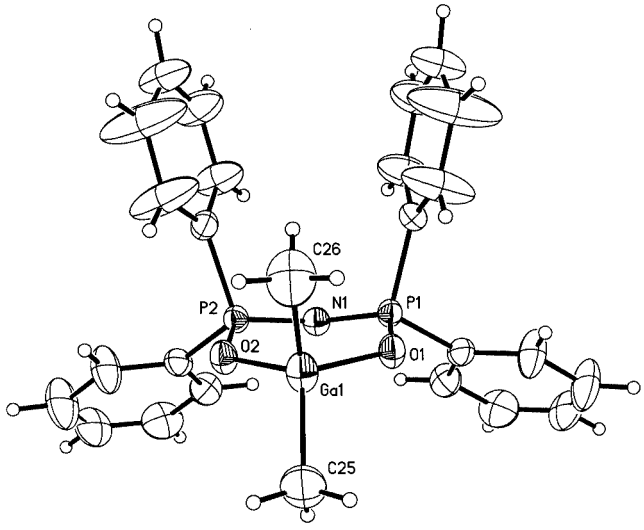

Figure 2. Molecular structure of **1** with thermal ellipsoids at 30% probability level

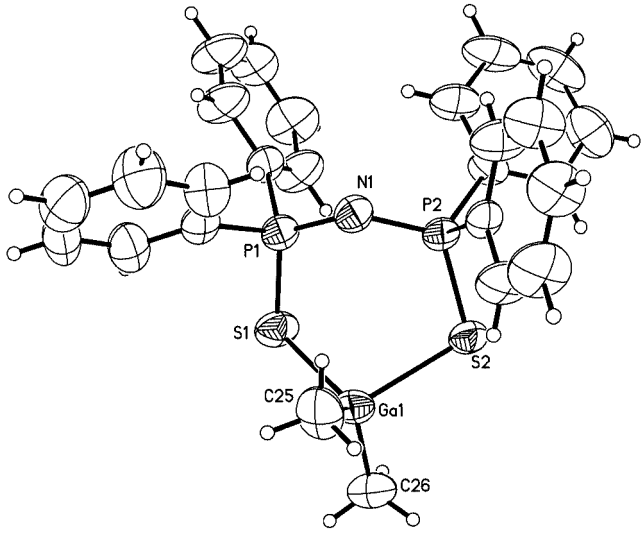

Figure 3. Molecular structure of **2** with thermal ellipsoids at 30% probability level

Compared to the free acidic ligands, the structural features of the complexes are as expected, with the P−E and P−E′ distances enlarged and the P−N distances shortened evidencing changes in bond orders. The P−O distances in the complexes — 1.526(3) and 1.527(3) Å (**1**), 1.530(3) (**4**) and 1.527(1) Å (**5**) — are longer than typical P=O distances [cf. $Ph_2P(O)OH$:[22] P−O 1.526(6), P=O 1.486(6) Å]. Accordingly, the P−S distances — 2.037(2) and 2.040(1) Å (**2**), 2.030(2) Å (**4**), and 2.011(1) Å (**6**) — are also longer than the distances of typical P=S bonds (1.89−1.96 Å). The

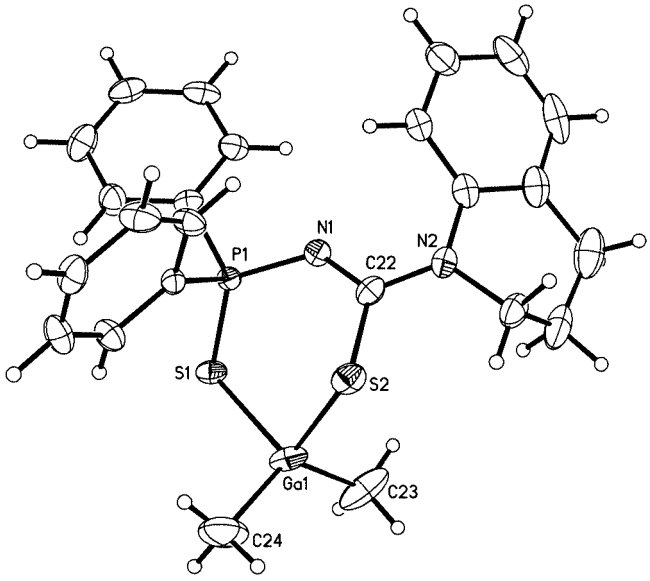

Figure 6. Molecular structure of **6** with thermal ellipsoids at 50% probability level

P−N bond lengths range from 1.59 to 1.61 Å and are somewhat shorter than typical P−N bond lengths {cf. [2-(Me_2NCH_2)C_6H_4]TeSPPh_2=NPPh_2=S:[23] P−S 2.057(1), P=S 1.945(1), P−N 1.612(3), P=N 1.557(3) Å} as expected due to a higher bond order.

In contrast, along the series, the C−Ga−C angles of the dimethylgallium fragments are practically the same, ranging from 125.3(2)° in **6** to 127.6(3)° in **4**. Additionally, apart from the dioxo derivative, comparisons of the P−N−P (or P−N−C) angles of the complexes with respect to those of the free ligands show little tendency to variation, with the largest difference being 6.4° in complex **2**. Amongst all the complexes, these angles differ very little as they range only from 123.4(1) Å in **1** to 138.1(2) Å in **2** (Table 3).

As demonstrated by the X-ray analysis, the conformations of the six-membered metallacycles are diverse: **1** is a chair with the Ga and N(1) atoms at the apices, **2** adopts an envelope conformation with Ga out of the plane, **4** has a twist-boat conformation also with Ga and N(1) at the apices, and **5** and **6** are both boats with Ga and N(1), and P(1) and S(2), respectively, at the apices. The closely related selenium derivative [Et_2Ga{η^2-*Se*,*Se*-[Ph_2P(Se)NP(Se)-Ph_2]}] (**3-Et**)[5] shows a distorted boat conformation with Se and P atoms at the apices. A nonplanar ring is a common feature of complexes derived from tetraorganodichalcogenoimidodiphosphinato ligands, as demonstrated by the variety of examples encountered in main-group and transition-metal chemistry. On the contrary, replacing phos-

phorus with carbon in the ligand skeleton, as in the tetrahedral imidoylamidinato complex [$Me_2Ga\{\eta^2$-*N*,*N*′-$[HNC(CF_3)NC(CF_3)NH]\}$][27] leads to all atoms of the ring being coplanar. In addition, a small number of planar gallacycle rings have been structurally characterized as derivatives of β-diketonate ligands. For example, four-coordinate $[GaCl_2(bdk)]$[10] [bdk = (2,4-pentanedionato), acac and (2,2,6,6-tetramethylheptanedionato)], [GaMeCl(acac)][28] and $[GaCl\{N(SiMe_3)_2\}(acac)]$[28] all show planar six-membered GaO_2C_3 rings with O−Ga−O bite angles ranging from 96.1 to 99.3°. It is thus significant that in complex **6** replacement of one phosphorus atom by a carbon atom does not induce partial planarity in the ring.

Perhaps the most striking feature is the fact that along a series of chemically differing ligands, the structural variation is not as large as expected, despite the well-documented versatility of the PNP ligand.

The fact that the bite angles of the ligands in the complexes studied are in the range 96.3−108.4° (see Table 3) is indicative of their prospective good potential as cationic precursors. Steric protection for catalytically active metal centers can be provided by bulky multidentate ligands, and various examples have been reported with late transition metals[29] as well as aluminum.[30] Indeed, large bite angles in cationic, three-coordinate aluminum complexes have proved to be an effective approach to stabilize these highly reactive species. Bulky aluminum amidinate complexes $[\{RC(NR')_2\}AlMe]^+$ with small bite angles (N−Al−N angle of about 70° in neutral derivatives) are thermally unstable but the *N*,*N*′-diaryldiketiminate complex $[\{HC(CMeNAr)_2\}AlMe_2]$ (Ar = 2,6-*i*$Pr_2C_6H_3$) with a larger bite angle (N−Al−N angle of about 96°) and bulky *N*-aryl substituents yield a stable, three-coordinate cation upon abstraction of the alkyl group.[31] Moreover, in contrast to most precursors documented in the literature, the family of complexes reported herein is easily accessible and requires little purification. Current work in our laboratory is focused in this direction, treating complexes **1**−**6** and others with strong Lewis acids. The results of this work will be reported shortly.

Conclusion

Gallium metallacycles derived from dichalcogenoimidodiphosphinato ligands were obtained by facile methane elimination reactions. In the new complexes, the Ga center is in a distorted tetrahedral environment forming part of a six-membered metallacycle. The conformations of these rings do not correlate with the nature of the chalcogen nor with the substituents at the phosphorus or carbon atoms, but in all cases a nonplanar ring was observed. Exchanging a phosphorus atom by a carbon atom in the metallacycle ring does not result, even partially, in a planar structure of complex **6**.

Experimental Section

General Remarks: All glassware was rigorously dried in an oven at 130 °C for 24 h, assembled hot, and then allowed to cool under argon. All the manipulations of the air-sensitive compounds were conducted using standard inert-gas bench-top and glove-box techniques. Solvents were dried with sodium or potassium/benzophenone and freshly distilled prior to use. The L^1H ligands were synthesized according to literature methods: $(XPPh_2)_2NH$ (X = O,[32] S,[33] Se[33]), $(OPPh_2)(SPPh_2)NH$,[34] and $(OPMe_2)(SPPh_2)NH$.[35] NMR spectroscopic data (^1H, ^{13}C and ^{31}P) were obtained with Varian-Inova 400 MHz and Varian-Gemini-200 MHz instruments at 19 °C. Chemical shifts are reported relative to $SiMe_4$ for ^1H and ^{13}C, 85% H_3PO_4 for ^{31}P and are in ppm. Microanalyses were obtained with an Elementar Vario EL III instrument in the CHNS operation mode. Infrared spectra were recorded as KBr pellets with a Bruker Equinox 55 Spectrometer and are reported in cm^{-1}.

Synthesis of $Ph_2P(S)NHC(S)(C_9H_{10}N)$ (L^2H): Tetrahydroquinoline (0.65 mL, 5.1 mmol) was added to a stirred solution of $Ph_2P(S)NCS$ (1.42 g, 5.1 mmol) in CH_2Cl_2 (20 mL). After 4 h, the solvent was removed under vacuum, hexane (30 mL) was added and the mixture stirred for a further 2 h. The white solid deposited was filtered and dried under vacuum. Yield: 1.89 g (90%), m.p. 71−73 °C. Selected ^1H NMR data ($CDCl_3$, 300 MHz): δ = 3.97 (s, 1 H, NH) ppm. ^{13}C NMR ($CDCl_3$, 75.4 MHz): δ = 150.50 (C=S) ppm. ^{31}P NMR ($CDCl_3$, 121.4 MHz): δ = 56.89 (s) ppm. IR: $\tilde{\nu}$ = 3309 (νNH), 1445 (νCN), 1103 (νCS), 957, 882 (νPN), 647 (νPS) cm^{-1}. Crystals suitable for X-ray diffraction analysis were grown from hexane solution.

Synthesis of $[Me_2Ga\{\eta^2\text{-}O,O'\text{-}[Ph_2P(O)NP(O)Ph_2]\}]$ (1): A solution of trimethylgallium (0.08 g, 0.70 mmol) in toluene (10 mL) was added to a stirred suspension of $(OPPh_2)_2NH$ (0.3 g, 0.72 mmol) in toluene (20 mL), causing vigorous gas evolution and the formation of a clear colorless solution which was stirred for 4 h. Removal of the volatiles under reduced pressure produced a viscous substance, which was treated with hexane (5 mL) and stirred until the deposition of a white solid. The solid was separated from the solution by cannula filtration and dried under high vacuum. The remaining hexane solution at −20 °C deposited suitable crystals for X-ray analysis. Yield 0.27 g (87%), m.p. 77−78 °C. ^1H NMR ($CDCl_3$, 400 MHz): δ = −0.31 (s, 6 H, $GaCH_3$), 7.34−7.40 (m, 12 H, C_6H_5), 7.75 (m, 8 H, C_6H_5) ppm. ^{13}C NMR ($CDCl_3$, 100.6 MHz): δ = −4.52 (s, CH_3Ga), 128.30−131.26 (C_6H_5), 136.04 (d, $^1J_{C,P}$ = 140 Hz, *ipso*-C_6H_5) ppm. $^{31}P\{^1H\}$ NMR (C_6D_6, 161.8 MHz): δ = 26.43 (s) ppm. IR: $\tilde{\nu}$ = 3072 (m), 2960 (m), 2718 (w), 2365 (w), 2336 (w), 200.22 (w), 1959 (w), 1893 (w), 1814 (w), 1674 (w), 1590 (w), 1482 (m), 1436 (s), 1126 (s), 691 (s) 590 (s) cm^{-1}. $C_{26}H_{26}GaNO_2P_2$ (516.14): calcd. C 60.50, H 5.08, N 2.71; found C 60.43, H 5.03, N 2.72.

Compounds **2**−**6** were prepared in a similar manner to **1**.

$[Me_2Ga\{\eta^2\text{-}S,S\text{-}[Ph_2P(S)NP(S)Ph_2]\}]$ (2): $(SPPh_2)_2NH$ (0.30 g, 0.67 mmol) and trimethylgallium (0.08 g, 0.70 mmol) afforded **2** as a white solid. Yield 0.30 g (82%), m.p. 103−105 °C. ^1H NMR ($CDCl_3$, 400 MHz): δ = −0.25 (s, 6 H, CH_3Ga), 7.35 (m, 12 H, C_6H_5), 7.83 (m, 8 H, C_6H_5P) ppm. ^{13}C NMR ($CDCl_3$, 100.6 MHz): δ = −0.79 (s, $GaCH_3$), 128.41−131.36 (C_6H_5), 137.31 (d, $^1J_{C,P}$ = 140 Hz, *ipso*-C_6H_5) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 161.8 MHz): δ = 36.71 (s) ppm. IR: $\tilde{\nu}$ = 3069.3 (w), 2962.3 (m), 2901.4 (w), 1999.5 (w), 1892.5 (w), 1809.7 (w), 1674 (w), 1582.8 (w), 1476.7 (m), 1433 (m),1258.9 (m), 1196.4 (s), 1104.7 (s), 1022.8 (s), 807.5 (s), 743.7 (s), 694.8 (s), 577.5 (s), 530.3 (s) cm^{-1}. $C_{26}H_{26}GaNP_2S_2$ (548.26): calcd. C 56.96, H 4.78, N 2.55, S 11.70; found C 57.01, H 4.79, N 2.60, S 11.87.

$[Me_2Ga\{\eta^2\text{-}Se,Se\text{-}[Ph_2P(Se)NP(Se)Ph_2]\}]$ (3): $(SePPh_2)_2NH$ (0.3 g, 0.55 mmol) and trimethylgallium (0.063 g, 0.55 mmol) generated **3** as a white solid. Yield 0.31 g (88%), m.p. 143 °C. ^1H NMR ($CDCl_3$, 400 MHz): δ = −0.11 (s, $^1J_{C,H}$ = 162, $^3J_{Se,H}$ = 4 Hz, 6 H, $GaCH_3$), 7.34−7.44 (m, 12 H, C_6H_5), 7.81 (m, 8 H, C_6H_5) ppm. $^{13}C\{^1H\}$ ($CDCl_3$, 100.6 MHz): δ = 0.20 ($GaCH_3$), 128.2−131.4 (C_6H_5), 136.8 (dd, $^1J_{P,C}$ = 98.49, $^2J_{C,Se}$ 4.19 Hz, *ipso*-C_6H_5) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 81 MHz): δ = 29.3 (s, $^1J_{P,Se}$= 525 Hz) ppm. IR: $\tilde{\nu}$ = 3060 (w), 1583 (w), 1477 (w), 1433 (m), 1210 (s), 1108 (s), 1025 (w), 925 (w), 803 (m), 691 (s), 562 (s), 516 (m), 486 (m) cm^{-1}. $C_{26}H_{26}GaNP_2Se_2$ (642.08): calcd. C 48.64, H 4.08, N 2.18; found C 48.85, H 4.11, N 2.14.

$[Me_2Ga\{\eta^2\text{-}S,O\text{-}[Ph_2P(S)NP(O)Ph_2]\}]$ (4): Compound **4** was obtained as a white solid from $(SPPh_2)NH(OPPh_2)$ (0.3 g, 0.69 mmol) and trimethylgallium (0.08 g, 0.70 mmol). Yield 0.27 g, 73%, m.p. 83−85 °C. ^1H NMR (200 MHz, C_6D_6): δ = 0.22 (s, 6 H, $GaCH_3$), 6.98 (m, 12 H, C_6H_5), 7.96 (m, 8 H, C_6H_5) ppm. ^{13}C NMR (50.3 MHz, C_6D_6): δ = −1.50 (s, $GaCH_3$), 128.59 (m, and C_6H_5), 131.58 (m, C_6H_5), 136.23 (d, $^1J_{C,P}$ = 105 Hz, *ipso*-C_6H_5), 139.32 (d, $^1J_{C,P}$ = 83 Hz, *ipso*-C_6H_5) ppm. $^{31}P\{^1H\}$ NMR (161.8 Hz, C_6D_6): δ = 27.07 (d, $^2J_{P,P}$ = 3.56 Hz, $GaOPPh_2$), 34.78 (d, $^2J_{P,P}$ = 3.56 Hz, $GaSPPh_2$) ppm. X-ray Crystallographic Study: Crystals suitable for X-ray diffraction for compounds L^2H, **1**, **2**, **4**, **5** and **6** were obtained from saturated hexane solutions as described above. X-ray data were collected with a Bruker APEX CCD diffractometer with Mo-K_α radiation. The structures were refined using the software package SHELXTL vers. 6.1.[36] All of the non-hydrogen atoms were refined anisotropically. The hydrogen atoms were put into calculated positions. Absorption correction in all cases was applied using SADABS.[37] Further details of the structure analyses are given in Table 4.[38]

Syntheses and Characterizations of Metal-Organic Frameworks with Unusual Topologies Derived from Flexible Dipyridyl Ligands

Ruihu Wang,[a] Lei Han,[a] Lijin Xu,[b] Yaqiong Gong,[a] Youfu Zhou,[a] Maochun Hong,*[a] and Albert S. C. Chan[b]

Keywords: Bridging ligands / Cadmium / Coordination polymers / X-ray diffraction / Zinc

Two flexible *exo*-bidentate ligands, 2,2′-bis(3-pyridylmethyleneoxy)-1,1′-biphenylene (3,3′-bpp) and 2,2′-bis(4-pyridylmethyleneoxy)-1,1′-biphenylene (4,4′-bpp), were synthesized and employed for the preparation of coordination polymers. Seven metal-organic complexes, $[Zn_2(3,3'\text{-bpp})_2Cl_4]$ (**1**), $[Zn_2(3,3'\text{-bpp})_2Br_4]$ (**2**), $[Zn(4,4'\text{-bpp})Cl_2]_n$ (**3**), $[Zn(4,4'\text{-bpp})Br_2]_n$ (**4**), $[Co(4,4'\text{-bpp})_2(SCN)_2]_n$ (**5**), $\{[Cd(4,4'\text{-bpp})_2(SCN)_2]\cdot 2H_2O\}_n$ (**6**) and $[Cd(4,4'\text{-bpp})(dca)_2]_n$ (**7**) (dca^- = dicyanamide), have been obtained through self-assembly reactions of 3,3′-bpp or 4,4′-bpp with the divalent metal ions Zn^{II}, Co^{II} and Cd^{II}. Crystal structure analyses reveal that **1** and **2** are dinuclear metallomacrocycles, are isomorphous and possess a layer network built from metallomacrocycles through π–π interactions. In drastic contrast, **3** and **4** exhibit a three-dimensional structure consisting of one-dimensional polymeric chains held together through π–π interactions between adjacent pyridyl rings. The metal-organic frameworks of **5**, **6**, and **7** possess unusual topologies: Complex **5** is a two-dimensional polymer based on folded rectangular boxes and zigzag chains, whereas **6** is a polycatenated species consisting of inclined interpenetrating two-dimensional layers, and each layer is constructed by the alternating assembly of left-hand (*M*) and right-hand (*P*) cylindrical 2_1 helices. In **7**, dca^- connects Cd^{II} centers forming a two-dimensional $\{Cd(dca)_2\}_n$ layer, which is fused with (*M*)- and (*P*)-Cd-(4,4′-bpp) helical chains into a three-dimensional structure. The results suggest that the nature of organic ligands and the coordination preferences of transitional metal ions have a great influence on the structures of metal-organic complexes.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Metal-directed self-assembly of organic ligands and metal ions, or organometallic moieties, to form well-defined structures has been a very attractive field in recent years.[1−6] The increasing interest in this field is justified not only by the intellectual challenge in controlling and manipulating the self-assembly process,[3,4] but also by their fascinating structural diversities and potential application in functional materials, nanotechnology and biological recognition.[5,6] In this context, novel supramolecular topologies with various sizes and shapes of channels or cavities can be controlled and tuned through judiciously selecting assembly-influencing factors, such as structural characteristics of polydentate organic ligands,[7,8] the coordination nature of the metal ions,[9] counter anions,[10] the metal/ligand ratio,[11] and solvent system.[12] So far, of diverse elegant efforts to find the key factors in the course of the construction of metal-based supramolecules, the dominant and most efficient synthetic strategy is the employment of various organic ligands as molecular building blocks or tectons. Among these organic ligands, one of the most fruitful choices has been the use of neutral pyridyl-containing bidentate or multidentate organic building blocks, owing to their simple bridging mode and strong coordination ability to transition-metal ions. Rigid, rod-like, *exo*-bidentate ligands, such as 4,4′-bipyridine (4,4′-bipy),[13,14] are suitable examples of tectons that have been used often for the rational design of solid-state architectures of coordination polymers. Moreover, structures containing larger holes can potentially be built by using longer rigid connectors between the pyridyl rings. For example, Fujita et al. have reported a series of two-dimensional square frameworks with different sizes upon increasing the number of phenyl rings between the pyridyl rings.[15] Compared to rigid bridging ligands, flexible bridging tectons can produce some unique frameworks with beautiful aesthetics and useful properties because of their flexibility and conformational freedom.[16] However, owing to the difficulty in predicting the structures of the products, the rational design of coordination poly-

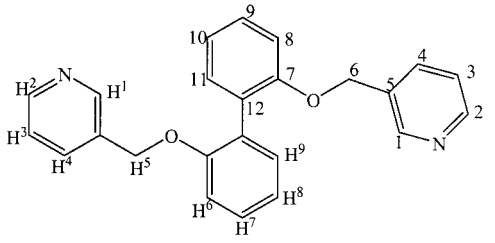
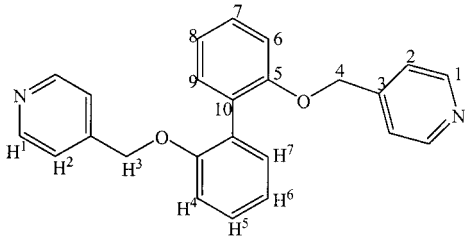
mers from flexible ligands is still a formidable challenge.[17]

In our previous studies we prepared a series of flexible organosulfur ligands by connecting (methylsulfanyl)pyridyl or -pyrimidyl groups to aromatic ring spacers.[18−21] Assembly of such flexible tectons and metal ions resulted in several unique structural motifs, such as a metallosupramolecular cube,[18] a one-dimensional nanotube,[19] square rings with guest molecules,[20] and two-dimensional crown-like structures.[20,21] Considering the geometric requirement of symmetry and stereochemistry, and with the aim of investigating the effects of distortion of the connector in the dipyridyl ligands on the assembly process and products, we have introduced a biphenyl connector into the reaction system and prepared two more flexible ligands, 2,2′-bis(3-pyridylmethyleneoxy)-1,1′-biphenylene (3,3′-bpp) and 2,2′-bis(4-pyridylmethyleneoxy)-1,1′-biphenylene (4,4′-bpp), in which the distortion of the biphenyl connector can endow the metal-organic frameworks with unique structural and functional properties.[22] Moreover, metal-organic complexes with a biphenyl connector can be used as simple probes for the investigation of chiral complexes derived from 1,1′-bi-2-naphthol.[23,24] Herein, we wish to report the syntheses and characterizations of two metallomacrocyclic complexes based on 3,3′-bpp — $[Zn_2(3,3'\text{-bpp})_2Cl_4]$ (**1**) and $[Zn_2(3,3'\text{-bpp})_2Br_4]$ (**2**) — and five novel coordination polymers based on 4,4′-bpp — $[Zn(4,4'\text{-bpp})Cl_2]_n$ (**3**), $[Zn(4,4'\text{-bpp})Br_2]_n$ (**4**), $[Co(4,4'\text{-bpp})_2(SCN)_2]_n$ (**5**), $[\{Cd(4,4'\text{-bpp})_2(SCN)_2\}\cdot 2H_2O]_n$ (**6**), and $[Cd(4,4'\text{-bpp})(dca)_2]_n$ (**7**) (dca^- = dicyanamide).



3,3'-bpp



4,4'-bpp

Result and Discussion

Synthesis and Characterization

The ligands 3,3′-bpp and 4,4′-bpp are readily prepared from commercially available 2,2′-biphenol and 3-picolyl chloride hydrochloride or 4-picolyl chloride hydrochloride in the presence of NaOH by a convenient method. The ligands are soluble in most solvents, except for water. Treatment of 3,3′-bpp with $ZnCl_2$ or $ZnBr_2$ in a 1:1 molar ratio in $MeOH/H_2O$ for several hours produced large amounts of white precipitates of **1** and **2**, respectively, in quantitative yield. The elementary analysis results are consistent with dinuclear metallomacrocycles of formula $Zn_2(3,3'\text{-bpp})_2Cl_4$ and $Zn_2(3,3'\text{-bpp})_2Br_4$, respectively. Compounds **1** and **2** are poorly soluble in common solvents except for DMF and DMSO. Hence, ^1H NMR spectra were recorded in $[D_6]$DMSO; the results confirmed the proposed formula, displaying a symmetric pattern.

It is well known that the relative orientation of coordination sites in organic ligands is also one of the most important factors for controlling the construction of supramolecular architectures. Hence, it is expected that the relative different orientation of the nitrogen donors in the pyridyl rings might lead to unusual building blocks, whose assembly with metal ions can produce unique structural frameworks. Indeed, assembly of 4,4′-bpp with $ZnCl_2$ or $ZnBr_2$ in a 1:1 molar ratio generated the one-dimensional polymeric chain complexes **3** and **4**. The directed reaction of 4,4′-bpp and $ZnCl_2$ or $ZnBr_2$ in $MeOH/H_2O$ afforded precipitates that are not soluble in any solvents. The MeOH solution of 4,4′-bpp was layered on the top of an aqueous solution of $ZnCl_2$ or $ZnBr_2$, affording crystals suitable for X-ray single-crystal diffraction. Compounds **3** and **4** are insoluble in most common solvents. It is noteworthy that the Zn^{II} centers in **1**−**4** adopt a distorted tetrahedral coordination geometry, with two halide counteranions coordinating to a metal center as terminal ligands, preventing the formation of extended frameworks. This prompted us to choose either a metal ion with a high coordination number or bridging counteranions. Co^{II} and Cd^{II} are known to be usually six-coordinate with an octahedral geometry in their pyridyl-containing $Co(SCN)_2$ [25] and $Cd(SCN)_2$ [26] complexes. Reactions of 3,3′-bpp with Co^{II} and Cd^{II} with different counteranions failed to generate desirable single crystals, but we succeeded in the isolation of **5** and **6** by assembly of 4,4′-bpp with $Co(SCN)_2$ and $Cd(SCN)_2$ under the same reaction conditions. Interestingly, the metal centers demonstrate a similar coordination environment and the ligands possess the same coordination mode, although **5** and **6** represent two distinctly different structural motifs. Upon introducing the bridging dca^- ligand[27,28] into the reaction system, the three-dimensional complex **7**, consisting of dca−Cd layers and Cd-(4,4′-bpp) helical chains, was successfully isolated.

In the IR spectra of complexes **1**−**7**, the absorption bands of the skeletal vibrations of the aromatic rings appear in the 1420−1630 cm^{-1} region. The C≡N stretching vibration of the thiocyanate group in **5** and **6** appears as a single and very strong peak at 2075 and 2030 cm^{-1}, respectively, similar to those found in thiocyanate-*N* coordination.[24,25] The IR spectrum in complex **7** displays strong absorption bands in the 2170−1305 cm^{-1} region, indicating the presence of C≡N of dca^-.[27,28]

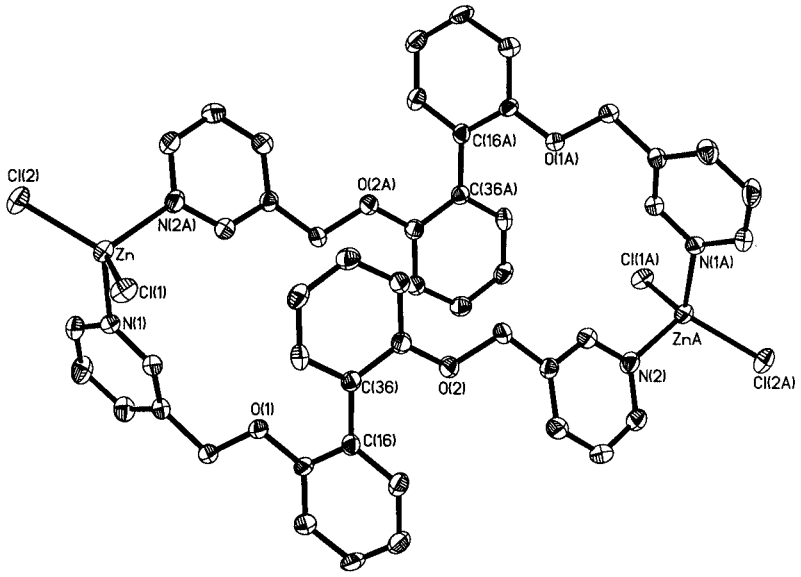

Figure 1. Molecular structure of complex **1** with the thermal ellipsoids at 30% probability level

Structural Description

$[Zn_2(3,3'\text{-bpp})_2Cl_4]$ (1)

The single-crystal X-ray diffraction analysis of **1** shows a neutral, dinuclear, metallacyclic structural motif with the Zn^{II} having a distorted tetrahedral geometry. As shown in Figure 1, each Zn^{II} is coordinated by two nitrogen atoms from different 3,3′-bpp and two terminal Cl^- ions. The Zn−N bond lengths are in the range 2.061(4)−2.070(5) Å, which are typical values for $Zn^{II}-N_{py}$ coordination distances.[29] The Cl(1)−Zn−Cl(2) bond angle [123.52(7)°] is larger than the N(1)−Zn−N(2A) bond angle [99.53(18)°], probably in order to minimize Cl···Cl interactions. The dihedral angle between the two pyridyl rings attached to Zn^{II} is 83.2°, which means that they are approximately perpendicular; 3,3′-bpp acts as an *exo*-bidentate ligand, where the pyridyl rings are slightly twisted with respect to the corresponding linking phenyl rings, with the dihedral angles between them being 24.7° and 26.5°, respectively. The two phenyl rings about the central bond have a drastic twisting, with the dihedral angle between them being 130.5°. The combination of these twistings allows 3,3′-bpp to link $ZnCl_2$ units into a dinuclear metallacycle. The Zn···Zn separation in the cycle is 14.015 Å, which is longer than in known zinc macrocycles.[29] Owing to the high distortion and flexibility of 3,3′-bpp, no enclathration of guest molecules is observed in **1**. There are no other noteworthy weak interactions between the adjacent macrocycles. Interestingly, every macrocycle has significant π−π interactions with its four closet neighbors. As shown in Figure 2, one phenyl ring of 3,3′-bpp and one pyridyl ring from the adjacent macrocycle are approximately parallel, with the dihedral angle between them being 24.7° and the distance between their centroids being 4.155 Å,[31] resulting in the formation of one-dimensional stacked macrocycles; the other phenyl ring of 3,3′-bpp and one phenyl ring from another adjacent macrocycle are completely parallel, with the distance between their centroids being 3.922 Å, further producing a layered network formed by stacked macrocycles.[32]

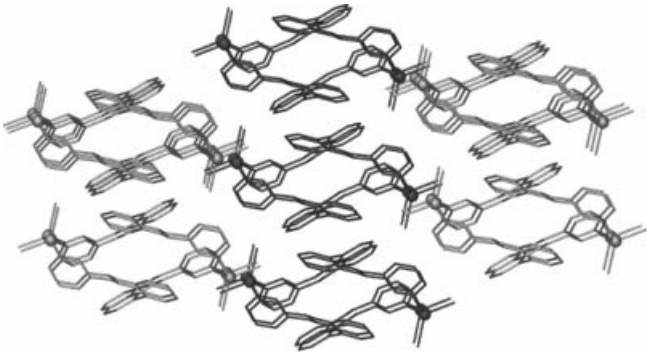

Figure 2. View of packing structure along *a* axis in **1** showing that there are no other interactions between adjacent macrocycles

$[Zn_2(3,3'\text{-bpp})_2Br_4]$ (2)

Compounds **1** and **2** are isomorphous, which suggests that the Br^- and Cl^- counteranions have no effect on the formation of the metallomacrocycle. As shown in Figure 3, Zn^{II} is coordinated by two nitrogen atoms from different 3,3′-bpp ligands and two terminal Br^- ligands in a distorted tetrahedral geometry. The Zn−N bond lengths and the N−Zn−N bond angle are 2.068(8)−2.085(9) Å and 98.6(3)°, respectively, similar to those in **1**. The dihedral angle of the two pyridyl rings coordinated to Zn^{II} is 81.0°. In the *exo*-bidentate 3,3′-bpp ligand, the dihedral angles between the two phenyl rings as well as between the phenyl rings and their corresponding linking pyridyl rings are 130.2, 28.5 and 26.1°, respectively. Thus, 3,3′-bpp connects $ZnBr_2$ units forming a dinuclear metallomacrocycle with a Zn···Zn separation of 14.113 Å. Similar to **1**, π−π interactions between every macrocycle and its four adjacent

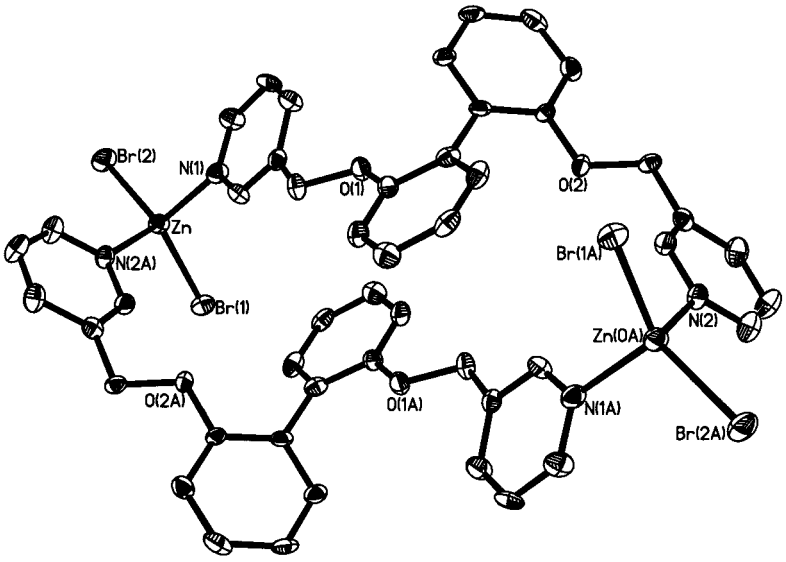

Figure 3. Molecular structure of complex **2** with the thermal ellipsoids at 30% probability level

macrocycles further stack it into a layered network structure.

$[Zn(4,4'\text{-bpp})Cl_2]_n$ (3)

The single-crystal X-ray structural analysis reveals that **3** is a one-dimensional zigzag chain formed through interconnection of $ZnCl_2$ units and 4,4′-bpp ligands. As shown in Figure 4, each Zn^{II} is coordinated by two nitrogen atoms from different 4,4′-bpp and two terminal Cl^- ligands in a distorted tetrahedral coordination environment. The Zn−N bond lengths are 2.041(5) and 2.057(4) Å, slightly shorter than those in **1**. However, the N(1)−Zn−N(2A) bond angle of 102.93(19)° is larger than that in **1**. All the 4,4′-bpp ligands behave in an *exo*-bidentate mode and lie on the same side of the polymer chain. The pyridyl rings are twisted with respcet to their corresponding linking phenyl rings, with the dihedral angles between them being 20.8 and 44.6°, respectively. The twisting angle of 76.2° between two phenyl rings about the central bond is smaller than those in **1** and **2**, which means that 4,4′-bpp connects the $ZnCl_2$ units into a one-dimensional polymeric chain instead of a macrocycle. The adjacent Zn···Zn separation bridged by 4,4′-bpp is 11.580 Å. It should be emphasized that there are significant π−π interactions between a pyridyl ring and the adjacent equivalent pyridyl rings from another chain (Figure 5); they are approximately parallel, with the dihedral angle between them being 12.9° and the distance between their centroids being 3.817 Å (Figure 6).[30] There are no other noteworthy weak interactions between the adjacent chains.

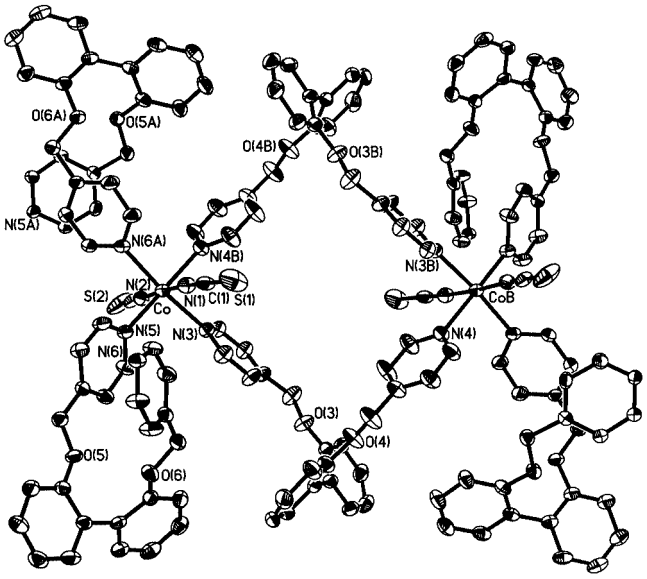

Figure 8. View of the folded rectangular box in **5** with the thermal ellipsoids at 30% probability level

$[Zn(4,4'\text{-bpp})Br_2]_n$ (4)

Compounds **3** and **4** are isomorphous. Zn^{II} is coordinated by two nitrogen atoms from different 4,4′-bpp and two terminal Br^- ligands in a distorted tetrahedral geometry. The Zn−N bond lengths and the N−Zn−N bond angles are 2.052(7)−2.069(7) Å and 101.5(1)°, respectively, similar to those in **3**. The Zn−Br bond lengths of 2.3512(15)−2.3560(13) Å and the Br(1)−Zn−Br(2) bond angle of 119.90(6)° are slightly smaller than their counterparts in **2**. An *exo*-bidentate 4,4′-bpp ligand bridges a pair of adjacent Zn^{II} centers on the same side forming a one-dimensional zigzag chain. The Zn···Zn separation bridged by 4,4′-bpp is 11.688 Å; π−π interaction between the pyridyl ring and an adjacent pyridyl ring from another chain stacks the polymeric chains into a network architecture (Figure 7).

$[Co(4,4'\text{-bpp})_2(SCN)_2]_n$ (5)

The single-crystal X-ray diffraction analysis reveals that **5** is a two-dimensional polymer consisting of folded rectangular boxes (Figure 8) and zigzag chains (Figure 9) bridged by Co^{II}. As shown in Figure 8, each Co^{II} has a compressed octahedral coordination environment with four pyridyl nitrogen atoms from different 4,4′-bpp situated in the equatorial plane and two *trans*-thiocyanato nitrogen atoms at the axial positions. The four pyridyl units associated with Co^{II} are arranged in a propeller fashion. The Co^{II} is approximately coplanar with the mean plane of four equatorial pyridyl nitrogen atoms, with a deviation of 0.0116 Å towards the axial donor atoms. The $Co-N_{py}$ bond lengths range from 2.162(5) to 2.239(5) Å [av. 2.201(5) Å], which are longer than the $Co-N_{NCS}$ bond lengths of 2.062(5) and 2.080(6) Å [av. 2.071(6) Å]. The SCN^- groups are almost linear, with N(1)−C(1)−S(1) and N(2)−C(2)−S(2) bond angles of 179.7(6) and 178.6(7)°, respectively. The connections between Co^{II} and SCN^- groups are slightly bent, with C(1)−N(1)−Co and C(2)−N(2)−Co bond angles of 170.1(6) and 174.7(5)°, respectively, suggesting that the two SCN^- ligands are not perpendicular to the equatorial plane. Interestingly, there are two independent 4,4′-bpp ligands in this complex, one bridges two Co^{II} centers forming a folded rectangular box of two planes.[24] The Co···Co separation within the box is 11.446 Å. This type of box is similar to that constructed by dipyridyl ligands with a 1,1′-bi-2-naphthol connector and $[Pt(dppp)(OSO_2CF_3)_2]$[24] [dppp = 1,3-bis(diphenylphosphanyl)propane] and very different from the common rectangular boxes derived from other *exo*-bidentate pyridyl-

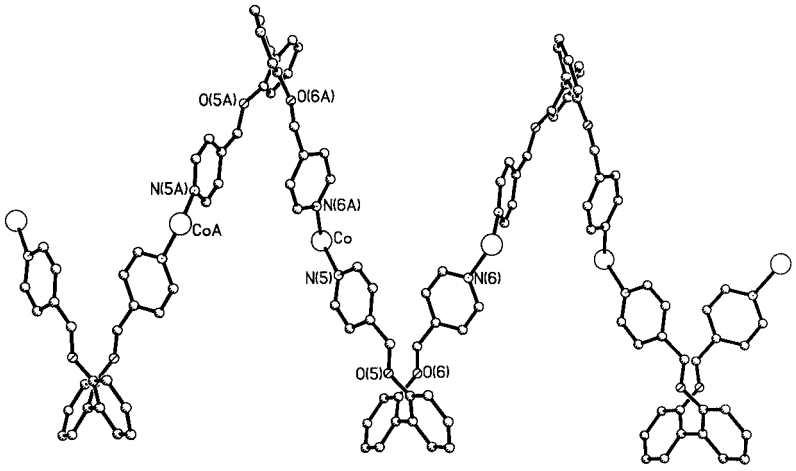

Figure 9. View of the zigzag chains in **5**

containing ligands.[31] In the 4,4′-bpp ligand the dihedral angle between the two phenyl rings is 65.6°. The dihedral angle of 50.8° between the two phenyl rings in the other independent 4,4′-bpp unit is smaller than that in the former and those in complexes **3** and **4**, which results in 4,4′-bpp linking two adjacent Co^{II} into a one-dimensional zigzag chain. Different from **3** and **4**, the 4,4′-bpp ligands lie on different sides of the zigzag chain. The closest Co···Co separation in the zigzag chain is 8.032 Å, which is much shorter than those in the zigzag chains of **3** and **4**. The most intriguing feature in **5** is that rectangular boxes and zigzag chains are fused into a two-dimensional polymer through $Co(NCS)_2$ units (Figure 10). To the best of our knowledge, this type of complex containing folded rectangular boxes and zigzag chains is unprecedented, which suggests that the distortion of the biphenyl connector has a great effect on the construction of novel structural motifs (Figure 11).

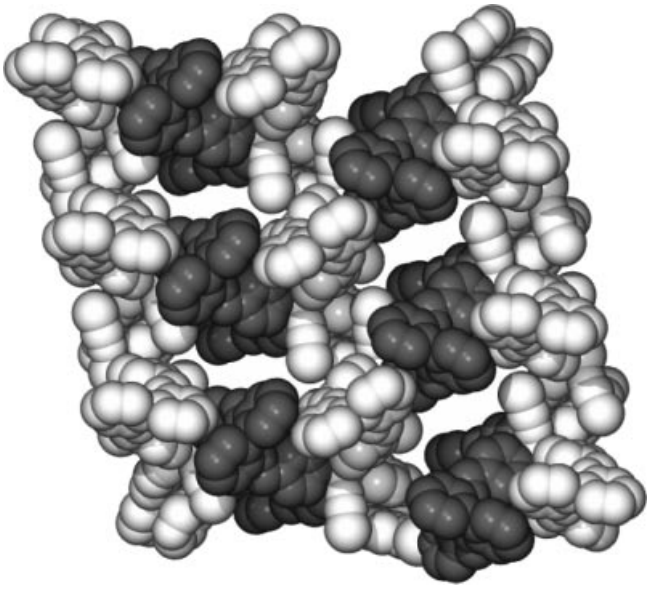

Figure 10. The two-dimensional structure formed by the folded rectangular boxes and zigzag chains in **5**

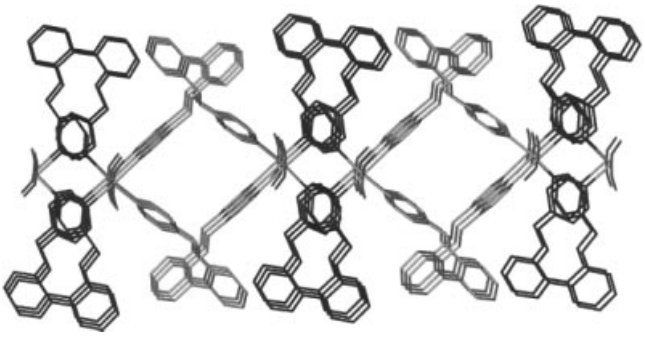

Figure 11. The packing structure along the *b* axis in **5** showing the linkage of the folded rectangular boxes and zigzag chains

$[\{Cd(4,4'\text{-bpp})_2(SCN)_2\}\cdot 2H_2O]_n$ (6)

Complex **6** is a polycatenated species[6] whose structure is made up of inclined interpenetrated two-dimensional layers. Each layer is composed of an alternating assembly of left-hand (*M*) and right-hand (*P*) cylindrical 2_1 helices along the *b* axis.[32] As shown in Figure 12, the coordination sphere of Cd^{II} is defined by four pyridyl nitrogen atoms from different 4,4′-bpp ligands situated in the equatorial plane and two *trans*-thiocyanato nitrogen atoms at the axial positions, resulting in a compressed octahedral coordination environment. The Cd^{II} is displaced 0.0240 Å out of the equatorial plane. The $Cd-N_{py}$ and $Cd-N_{SCN}$ bond lengths are in the range 2.379(5)−2.405(5) Å [av. 2.390(5) Å] and 2.308(7)−2.329(6) Å [av. 2.319(7) Å], respectively. The SCN^- groups are almost linear, with N(1)−C(1)−S(1) and N(2)−C(2)−S(2) bond angles of 177.9(9) and 174.0(8)°, respectively. The two SCN^- groups are not perpendicular to the equatorial plane and the C(1)−N(1)−Cd and C(2)−N(2)−Cd bond angles are 135.3(6) and 139.6(6)°,

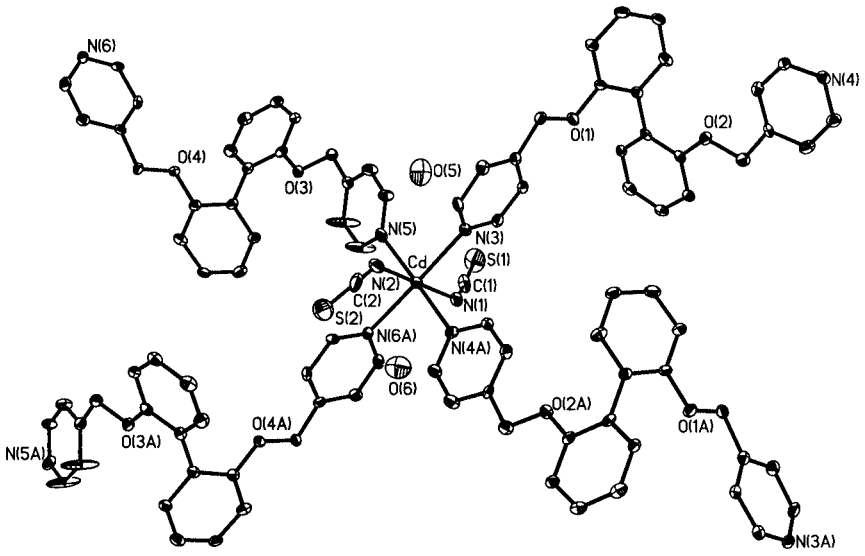

Figure 12. View of the coordination environment of Cd^{II} in **6** with the thermal ellipsoids at 30% probability level

respectively. These values are similar to those in complex **5**. It should be emphasized that there are two independent 4,4′-bpp ligands in this complex, one of which bridges six-coordinate Cd^{II} forming an (*M*) helical column (Figure 13). The repeating period in the helical column is 17.050 Å, which is slightly longer than the Cd···Cd distance bridged by 4,4′-bpp (16.590 Å). In the 4,4′-bpp ligand the dihedral angles between phenyl rings and their corresponding linking pyridyl rings are 23.3 and 6.0°, respectively. A drastic twisting is observed between two phenyl rings, with a dihedral angle of 116.9°, which is much larger than those in **3**−**5** and leads to the formation of the helical column. Interestingly, the other *cis* ligand coordinates to Cd^{II} and forms a (*P*) helical column (Figure 13). The distance of the helical pitch and Cd···Cd separation bridged by 4,4′-bpp are 17.050 and 16.668 Å, respectively. In the 4,4′-bpp ligand the dihedral angles between the two phenyl rings as well as between the phenyl rings and their corresponding linking pyridyl rings are 118.1, 32.9 and 10.9°, respectively, which are slightly different from the other 4,4′-bpp ligand These two types of cylindrical columns are alternatively connected, with the $Cd(SCN)_2$ units functioning as hinges, forming a unique two-dimensional layer structure (Figures 14 and 15). It should be emphasized that the longer helical pitch and the 4,4′-bpp ligands result in the formation of larger void cavities in the two-dimensional network, which greatly exceeds that required to accommodate the guest molecules in the reaction system. Thus, instead of forming an open, microporous structure, the potential voids are filled by mutually inclined interpenetration of identical two-dimensional frameworks (Figure 16). Uncoordinated water molecules act as guest molecules and further fill in its space.

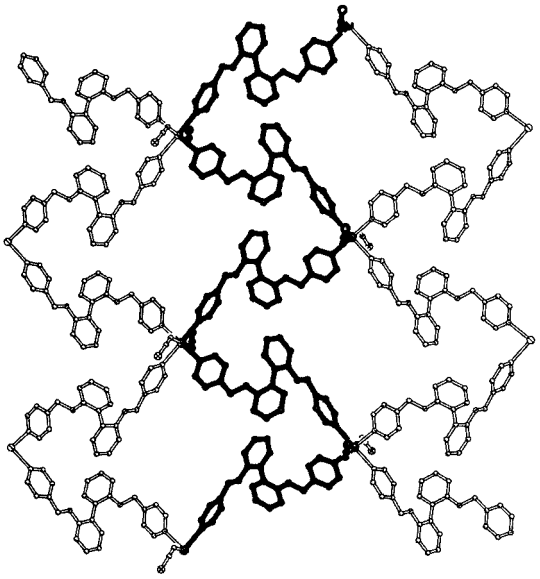

Figure 15. Packing structure along the *c* axis in **6** with uncoordinated water molecules omitted for clarity

Although there have been many helical coordination polymers reported, to the best our knowledge this type of helix-assembled polycatenated motif is unprecedented.

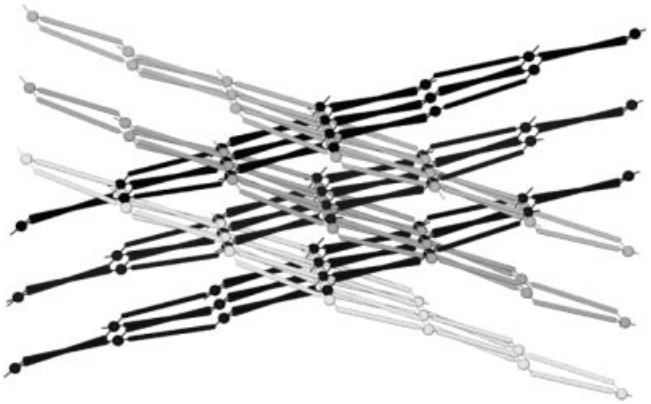

Figure 16. Packing structure of the inclined interpenetrating two-dimensional layers in **6** with partial atoms omitted for clarity

$[Cd(4,4'\text{-bpp})(dca)_2]_n$ (7)

Complex **7** consists of two-dimensional $Cd(dca)_2$ layers bridged by 4,4′-bpp ligands. As shown in Figure 17, Cd^{II} is coordinated by six nitrogen atoms in a distorted octahedral geometry, in which four nitrogen atoms from different dca^- ligands form the equatorial plane, and two pyridyl nitrogen atoms from different 4,4′-bpp occupy the apical positions. The $Cd-N_{dca}$ and $Cd-N_{py}$ bond lengths are in the range 2.317(6)−2.475(7) Å [av. 2.367(7) Å] and 2.321(6)−2.352(7) Å [av. 2.337(7) Å], respectively; dca^- has two distinctly different bridging modes: one adopts a usual end-to-end μ-1,5 bridging mode,[27] and the other acts as a rare μ-1,3 bridge through a terminal nitrile nitrogen atom and the middle nitrogen atom.[28] These two types of dca^- bridge Cd^{II} to form a neutral two-dimensional layer structure (Figure 18). The Cd···Cd separations bridged by μ-1,5- and μ-1,3-dca^- are 7.725 and 6.050 Å, respectively. The 4,4′-bpp ligand acts as an *exo*-bidentate ligand; the dihedral angle between two phenyl rings is 131.6°. However, the dihedral angles between the phenyl rings and their corresponding linking pyridyl rings are 10.1 and 19.1°, respectively. As a result, the 4,4′-bpp ligands are situated at two sides of the layers to saturate the six-coordinate Cd^{II} center and connect the Cd−dca layers into a three-dimensional network. It is note-

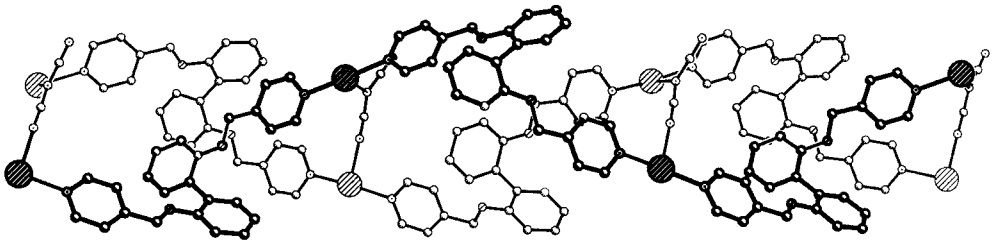

Figure 19. (*M*)- (light) and (*P*)-Cd-(4,4′-bpp) (dark) helical chains bridged by μ-1,3-dca in **7**

worthy that the 4,4′-bpp ligands bridge Cd^{II} to form (*M*) and (*P*) helical chains (Figure 19). Different from **6**, the adjacent (*M*) and (*P*) helical chains are connected by μ-1,3-dca ligands instead of metal centers. The distance of the helical pitch and Cd···Cd distance bridged by 4,4′-bpp are 29.629 and 15.697 Å, respectively. Hence, complex **7** can be regarded as the fusion of two-dimensional $Cd(dca)_2$ layers with (*M*)- and (*P*)-Cd-(4,4′-bpp) helical chains through Cd^{II} centers (Figure 20).

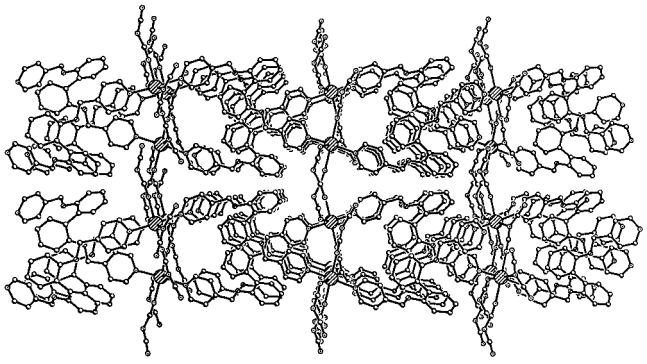

Figure 20. Packing structure along the *a* axis in **7** showing the linkage of the helical chains and the two-dimensional layer

It should be interesting and essential to compare the related structural data of 3,3′-bpp and 4,4′-bpp in complexes **1**−**7**. As suggested in Table 1, the twisting angles of the biphenyl connector about the central bond in 3,3′-bpp and 4,4′-bpp are responsible for the formation of the structural motifs. Owing to the steric hindrance from the relative orientation of the coordination sites in the pyridyl rings, 3,3′-bpp and 4,4′-bpp bridge $ZnCl_2$ or $ZnBr_2$ units generating metallomacrocycles and one-dimensional zigzag chains with 4,4′-bpp at the same sides, respectively. The distortion angles of the biphenyl connector in 3,3′-bpp (130.5° for **1** and 130.2° for **2**) are much larger than those in 4,4′-bpp (76.2° for **3** and 79.6° for **4**); however, the distortion angles of the biphenyl connector of 50.8 and 65.6° in 4,4′-bpp in **5**, which are smaller than those in the polymeric chains of **3** and **4**, lead to the formation of a one-dimensional zigzag chain with 4,4′-bpp at two sides and a folded rectangular box, respectively. When the distortion angles of the biphenyl connector in 4,4′-bpp increase to 116.9 and 118.1°, cylindrical 2_1 helical structures are generated. The largest distortion angle of the biphenyl connector in 4,4′-bpp (131.6°) results in a one-dimensional helical chain in complex **7**. Correspondingly, the dihedral angles between the phenyl rings and linking pyridyl rings are different in each type of structural motif. In the zigzag chain with 4,4′-bpp at two sides, the smallest twisting angle of the biphenyl connector in 4,4′-bpp (50.8°) results in the shortest distance between the metal centers bridged by 4,4′-bpp (8.032 Å) in **5**; the longest distance is found in the right-handed cylindrical 2_1 helix (16.668 Å) of complex **6**. It should be emphasized that the two phenyl rings in free 4,4′-bpp can rotate freely about the central bond, but the rotation is restricted in metal-organic complexes because of pyridyl-*N* coordination; consequently, this restricted rotation gives rise to two confor-

Table 1. Comparison of the structural data from 3,3′-bpp or 4,4′-bpp in **1**−**7**

Compound	Ligand	Dihedral angles [°]			Distance between metal centers bridged by ligand [Å]	Structure
		[a]	[b]	[c]		
1	3,3′-bpp	130.5	24.7 and 26.5	83.2	14.015	dimetallomacrocycle
2	3,3′-bpp	130.2	26.1 and 28.5	81.0	14.113	dimetallomacrocycle
3	4,4′-bpp	76.2	20.8 and 44.6	76.0	11.580	1D polymeric chain
4	4,4′-bpp	79.6	15.1 and 42.8	77.7	11.688	1D polymeric chain
5	4,4′-bpp	65.6	21.6 and 45.3	74.9	11.446	folded rectangular box
	4,4′-bpp	50.8	24.1 and 49.5	77.4	8.032	1D zigzag chain
6	4,4′-bpp	116.9	23.3 and 6.0	80.8	16.590	(*M*) cylindrical 2_1 helix
	4,4′-bpp	118.1	32.9 and 10.9	89.3	16.668	(*P*) cylindrical 2_1 helix

mations [(*M*) and (*P*)] in complexes **6** and **7**.[22] Therefore, the flexibility of ligands, the coordination propensity of metal ions and the secondary ligands play important roles in the formation of the final networks, meaning that the structural topologies of complexes **5**, **6**, and **7** are unusual.

Conclusions

Seven novel metal-organic complexes containing the flexible dipyridyl ligands 2,2′-bis(3-pyridylmethyleneoxy)-1,1′-biphenylene (3,3′-bpp) and 2,2′-bis(4-pyridylmethyleneoxy)-1,1′-biphenylene (4,4′-bpp) have been prepared and structurally characterized. In complexes **1**−**4**, *exo*-bidentate 3,3′-bpp and 4,4′-bpp ligands link ZnX_2 (X = Cl^- and Br^-) units into dinuclear metallomacrocycles and one-dimensional zigzag chains, respectively, in which the metal centers adopt a distorted tetrahedral geometry. This reveals that the relative orientation of the nitrogen donors in the pyridyl rings has a great influence on the construction of the supramolecular architectures. The metal centers in both **5** and **6** all have a compressed octahedral geometry, although $Co(SCN)_2$ and $Cd(SCN)_2$ hinges fuse one-dimensional zigzag chains and folded rectangular boxes as well as left-handed and right-handed cylindrical 2_1 helices into two distinctly different two-dimensional networks. The topological differences in complexes **3**−**6** are attributed to the different geometric requirement of the metal ions. The results of structural analyses of **3**−**6** containing 4,4′-bpp reveal that their structures mainly depend on the geometric requirement of the metal ions and are not influenced greatly by the counteranions, which only act as terminal ligands. The introduction of bridging dca^- counteranions into the reaction system produces a three-dimensional complex **7**, in which 4,4′-bpp functions as a bridge between the adjacent Cd−dca layers. Such differences in **1**−**7** are realized through the distortion of the biphenyl connector in 3,3′-bpp and 4,4′-bpp. In summary, this research shows that assembly of dipyridyl ligands with a biphenyl connector and metal ions can generate unique structural motifs, which cannot be obtained using normal rigid or flexible *exo*-bidentate organic ligands, such as 4,4′-bipy and related organic ligands. In this regard, we are currently using these results as probes for axial chiral ligands derived from 1,1′-bi-2-naphthol and extending our research to prepare chiral supramolecular species.

Experimental Section

General: 2,2′-Biphenol, 3-picolyl chloride hydrochloride and 4-picolyl chloride hydrochloride were purchased from Acros. All other chemicals are commercially available and were used as purchased without further purification. The NMR spectra were recorded with a Varian Inova-500 spectrophotometer at room temperature and the chemical shifts are quoted in δ (ppm) relative to the deuterated solvent used. The mass spectra were recorded in the Mass Spectrometry Laboratory of the Department of Applied Biology and Chemical Technology, The Hong Kong Polytechnic University with a Fisons VG platform. The IR spectra as KBr disks were recorded with a Magna 750 FT-IR spectrophotometer. C, H and N elemental analyses were determined with an Elementary Vario ELIII elemental analyzer.

Synthesis of 3,3′-bpp: A mixture of 2,2′-biphenol (1.86 g, 10 mmol), 3-picolyl chloride hydrochloride (3.61 g, 22 mmol) and NaOH (1.76 g, 44 mmol) in acetone (50 mL) was stirred at reflux under nitrogen for 3 d. After cooling to room temperature, the inorganic salt was removed by filtration and washed with acetone several times. The combined solutions were concentrated under reduced pressure and the red residue was dissolved in ethyl acetate and then washed twice with water and once with brine. The organic layer was dried with anhydrous Na_2SO_4 and filtered. After removal of the solvent under reduced pressure, the residue was purified by chromatography on silica gel to afford a colorless solid. Yield: 3.24 g (88% based on 2,2′-biphenol). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 8.44 (d, J = 3.0 Hz, 2 H, H^2), 8.38 (s, 2 H, H^1), 7.40 (d, J = 7.5 Hz, 2 H, H^4), 7.30−7.34 (m, 2 H, H^3), 7.29 (d, J = 1.5 Hz, 2 H, H^9), 7.04−7.11 (m, 4 H, H^7, H^8), 7.00 (d, J = 8.5 Hz, 2 H, H^6), 4.96 (s, 4 H, H^5) ppm. ^{13}C NMR ($CDCl_3$, 125 MHz): δ = 155.6 (C^7), 148.7 (C^1), 148.0 (C^2), 134.4 (C^4), 132.7 (C^5), 131.4(C^{12}), 128.7(C^9, C^{11}), 123.1 (C^3), 121.2 (C^{10}), 112.9 (C^8), 67.9 (C^6) ppm. ES-MS: m/z = 368 [M^+ + 1]. HRMS: calcd for $C_{24}H_{20}N_2O_2$ [M^+ + 1]: m/z = 368.4342; found 368.4345.

Synthesis of 4,4′-bpp: The procedure was similar to the synthesis of 3,3′-bpp except that 4-picolyl chloride hydrochloride was used instead of 3-picolyl chloride hydrochloride. Yield: 2.75 g (75% based on 2,2′-biphenol). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 8.37 (d, J = 6.0 Hz, 4 H, H^1), 7.27 (d, J = 7.5 Hz, 4 H, H^2), 7.04 (d, J = 7.0 Hz, 2 H, H^9), 6.97 (d, J = 5.5 Hz, 4 H, H^6 and H^8), 6.88 (d, J = 7.5 Hz, 2 H, H^7), 4.92 (s, 4 H, H^5) ppm. ^{13}C NMR ($CDCl_3$, 125 MHz): δ = 155.7 (C^5), 149.8 (C^1), 146.6 (C^3), 131.7 (C^7), 129.0 (C^{10}), 128.5 (C^9), 121.5 (C^8), 121.0 (C^2), 112.6 (C^6), 68.5 (C^4) ppm. ES-MS: m/z = 368 [M^+ + 1]. HRMS: calcd for $C_{24}H_{20}N_2O_2$ [M^+ + 1]: m/z = 368.4342; found 368.4349.

Synthesis of [Zn_2(3,3′-bpp)$_2Cl_4$] (1): A solution of $ZnCl_2$ (0.034 g, 0.25 mmol) in H_2O (10 mL) was slowly added to a stirring solution of 4,4′-bpp (0.092 g, 0.25 mmol) in MeOH (10 mL) to give a white precipitate. The reaction mixture was heated to 60 °C and DMF was added dropwise (about 1 mL) until the precipitate dissolved. The resulting solution was filtered and kept in air at room temperature for two weeks. Colorless crystals of **1** suitable for X-ray diffraction were obtained. Yield: 0.08 g (63%). $C_{24}H_{20}Cl_2N_2O_2Zn$ (504.69): calcd. C 57.11, H 3.96, N 5.55; found C 57.09, H 4.98, N 5.57. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 8.44 (s, 4 H), 8.42 (s, 4 H), 7.58 (d, J = 7.5 Hz, 4 H), 7.33 (t, J = 7.5 Hz, 15 Hz, 4 H), 7.27−7.29 (m, 4 H), 7.23 (dd, J = 2.0, 7.5 Hz, 4 H), 7.16 (d, J = 8.0 Hz, 4 H), 7.02 (t, J = 7.0 Hz, 14 Hz, 4 H), 5.10 (s, 8 H) ppm. IR (KBr pellet): $\tilde{\nu}$ = 3121 cm^{-1} (vw), 3047 (w), 2913 (vw), 2858 (w), 1614 (m), 1593 (m), 1564 (w), 1504 (w), 1482 (s), 1456 (m), 1436 (s), 1431 (s), 1387 (m), 1335 (w), 1265 (s), 1234 (s), 1194 (m), 1163 (w), 1125 (s), 1057 (m), 1032 (s), 1002 (m), 933 (vw), 867 (w), 814 (w), 796 (m), 766 (s), 697 (m), 658 (m), 642 (w), 613 (vw), 540 (vw), 486 (vw), 453 (vw).

Synthesis of [Zn_2(3,3′-bpp)$_2Br_4$] (2): The procedure was similar to the synthesis of complex **1** except that $ZnBr_2$ (0.056 g, 0.25 mmol) was used instead of $ZnCl_2$. Yield: 0.10 g (67%). $C_{24}H_{20}Br_2N_2O_2Zn$ (593.61): calcd. C 48.56, H 3.37, N 4.72; found C 48.52, H 3.40, N 4.70. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 8.44 (s, 4 H), 8.43 (s, 4 H), 7.58 (d, J = 7.0 Hz, 4 H), 7.33 (t, J = 8.5 Hz, 17 Hz, 4 H), 7.28−7.31 (m, 4 H), 7.23 (d, J = 6.0 Hz, 4 H), 7.16 (d, J = 7.0 Hz,

4 H), 7.02 (t, J = 7.0 Hz, 14 Hz, 4 H), 5.10 (s, 8 H) ppm. IR (KBr pellet): $\tilde{\nu}$ = 3121 cm^{-1} (vw), 3045 (w), 2910 (w), 2858 (w), 1614 (m), 1595 (m), 1563 (vw), 1504 (w), 1483 (s), 1458 (m), 1437 (s), 1385 (m), 1335 (w), 1284 (w), 1263 (s), 1232 (s), 1194 (m), 1165 (w), 1124 (s), 1057 (m), 1034 (s), 1020 (m), 1001 (m), 933 (vw), 912 (vw), 866 (w), 793 (m), 764 (s), 698 (s), 658 (m), 615 (vw), 544 (vw), 486 (vw), 454 (vw).

Synthesis of $[Zn(4,4'\text{-bpp})Cl_2]_n$ (3): A solution of 4,4′-bpp (0.037 g, 0.1 mmol) in MeOH (5 mL) was carefully layered on top of a solution of $ZnCl_2$ (0.014 g, 0.1 mmol) in H_2O (5 mL). Diffusion between the two phases over a period of two weeks produced colorless crystals. Yield: 0.04 g (79%). $C_{24}H_{20}Cl_2N_2O_2Zn$ (504.69): calcd. C 57.11, H 3.96, N 5.55; found C 57.07, H 4.02, N 5.53. IR (KBr pellet): $\tilde{\nu}$ = 3121 cm^{-1} (vw), 3052 (w), 2916 (w), 2852 (w), 1624 (s), 1593(m), 1563 (w), 1504 (m), 1481 (m), 1450 (s), 1436 (s), 1390 (m), 1329 (vw), 1306 (m), 1265 (s), 1234 (s), 1163 (vw), 1121 (m), 1057 (m), 1032 (s), 1005 (w), 933 (vw), 866 (w), 814 (s), 786 (m), 752 (s), 642 (w), 613 (vw), 486 (w), 453 (vw).

Synthesis of $[Zn(4,4'\text{-bpp})Br_2]_n$ (4): The procedure was similar to the synthesis of complex **3** except that $ZnBr_2$ (0.023 g, 0.1 mmol) was used instead of $ZnCl_2$. Yield: 0.05 g (84%). $C_{24}H_{20}Br_2N_2O_2Zn$ (593.61): calcd. C 48.56, H 3.37, N 4.72; found C 48.51, H 3.39, N 4.68. IR (KBr pellet): $\tilde{\nu}$ = 3121 cm^{-1} (vw), 3062 (w), 2910 (w), 2856 (w), 1624 (s), 1593 (m), 1563 (w), 1504 (s), 1481 (s), 1440 (s), 1431 (s), 1387 (s), 1328 (w), 1284 (s), 1267 (s), 1234 (s), 1158 (w), 1121 (s), 1056 (s), 1030 (s), 1005 (m), 933 (vw), 912 (vw), 864 (w), 829 (w), 810 (s), 770 (s), 750 (s), 717 (w), 641 (m), 613 (vw), 544 (vw), 513 (vw), 486 (w), 454 (w).

Synthesis of $[Co(4,4'\text{-bpp})_2(SCN)_2]_n$ (5): The procedure was similar to the synthesis of complex **3** except that $Co(NO_3)_2{\cdot}6H_2O$ (0.029 g, 0.1 mmol) and NH_4SCN (0.015 g, 0.2 mmol) were used instead of $ZnCl_2$. Yield: 0.04 g (88% based on 4,4′-bpp). $C_{50}H_{40}CoN_6O_4S_2$ (911.93): calcd. C 65.85, H 4.39, N 9.21; found C 65.82, H 4.42, N 9.18. IR (KBr pellet): $\tilde{\nu}$ = 3423 cm^{-1} (w), 3064 (w), 2914 (w), 2854 (w), 2075 (vs), 1618 (s), 1595 (m), 1564 (w), 1504 (m), 1483 (m), 1441 (s), 1421 (s), 1385 (m), 1325 (w), 1271 (s), 1225 (s), 1163 (vw), 1113 (m), 1057 (m), 1016 (m), 939 (vw), 810 (m), 762 (s), 634 (w), 618 (vw), 494 (w).

Synthesis of $[\{Cd(4,4'\text{-bpp})_2(SCN)_2\}{\cdot}2H_2O]_n$ (6): The procedure was similar to the synthesis of complex **3** except that $Cd(NO_3)_2{\cdot}6H_2O$ (0.031 g, 0.1 mmol) and NH_4SCN (0.015 g, 0.2 mmol) were used instead of $ZnCl_2$. Yield: 0.04 g (80% based on 4,4′-bpp). $C_{50}H_{44}CdN_6O_6S_2$ (1001.4): calcd. C 59.96, H 4.39, N 8.39; found C 59.91, H 4.37, N 8.32%. IR (KBr pellet): $\tilde{\nu}$ = 3435 cm^{-1} (w), 3120 (w), 2914 (w), 2852 (w), 2033 (vs), 1615 (s), 1596 (m), 1562 (w), 1504 (w), 1479 (m), 1436 (s), 1423 (s), 1399 (m), 1324 (vw), 1269 (m), 1231 (s), 1161 (vw), 1126 (m), 1062 (m), 1013 (m), 939 (vw), 814 (m), 751 (m), 635 (w), 619 (vw), 486 (w).

Synthesis of $[Cd(4,4'\text{-bpp})(dca)_2]_n$ (7): The procedure was similar to the synthesis of complex **3** except that $Cd(NO_3)_2{\cdot}4H_2O$ (0.031 g, 0.1 mmol) and $Na(dca)_2$ (0.018 g, 0.2 mmol) were used instead of $ZnCl_2$. Yield: 0.05 g (82%). $C_{28}H_{20}CdN_8O_2$ (612.92): calcd. C 54.87, H 3.26, N 18.27; found C 54.85, H 3.29, N 18.25. IR (KBr pellet): $\tilde{\nu}$ = 3529 cm^{-1} (w), 3061 (w), 2916 (w), 2891 (w), 2845 (w), 2305 (s), 2258 (s), 2229 (vs), 2170 (vs), 1618 (m), 1597 (w), 1562 (w), 1504 (w), 1479 (m), 1425 (s), 1369 (m), 1327 (w), 1306 (m), 1263 (s), 1252 (s), 1227 (s), 1161 (vw), 1124 (m), 1061 (m), 1018 (m), 933 (w), 816 (s), 802 (m), 756 (s), 638 (w), 613 (vw), 510 (w), 490 (m), 467 (vw).

X-ray Crystallographic Study: Intensity data for complexes **1**−**7** were measured with a Siemens Smart CCD diffractometer with

graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at room temperature. All empirical absorption corrections were applied with the SADABS program.[33] The structures were solved by direct methods[34] and refined on F^2 by full-matrix least squares using the SHELXL-97 program package.[35] The positions of H atoms were generated geometrically (C−H bond fixed at 0.96 Å), assigned isotropic thermal parameters, and allowed to ride on their parent carbon atoms before the final cycle of refinement. The selected bond lengths and angles for **1**−**7** are listed in Table 2. Crystal data and structure determination data for **1**−**7** are listed in Table 4. CCDC-232662 to -232668 (**1**−**7**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

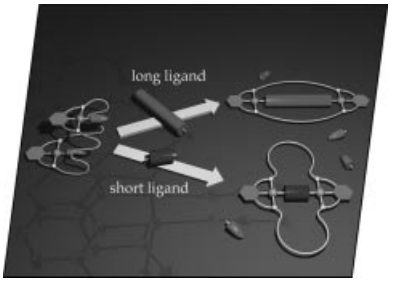
COVER PICTURE

The cover picture shows a flexible Pd metallocrown ether that has two SCS-pincer ligand moieties. A long bidentate ligand binds to the host in a bridging fashion to close the crown cavity, whereas a short one divides the cavity to give two small polyether rings. Details are discussed in the Short Communication by T. Nabeshima et al. on p. 3779 ff.



SHORT COMMUNICATION

Contents

3779 **T. Nabeshima,* D. Nishida, S. Akine, T. Saiki**

Synthesis, Structure and Complexation Ability of Novel Metalloreceptors Containing Two Pincer Complexes of Palladium(II)

Synthesis, Structure and Complexation Ability of Novel Metalloreceptors Containing Two Pincer Complexes of Palladium(II)

Tatsuya Nabeshima,*[a] Daisuke Nishida,[a] Shigehisa Akine,[a] and Toshiyuki Saiki[a]

Keywords: Host-guest systems / Pincer ligands / Palladium / Metalloreceptors / Crown ethers

Metalloreceptors **1a** and **1b** were synthesized by palladation of 42- and 54-membered crown ethers that have two SCS-pincer ligand moieties. The X-ray crystallographic analysis reveals that the metalloreceptor **1b** has a folded structure in which the two pincer-Pd moieties are stacked in a parallel manner. The metalloreceptor **1b** recognizes the aromatic bidentate guests 4,4′-bipyridine, pyrazine, and pyrimidine and binds to them in a bridging fashion to form the corresponding bimacrocyclic 1:1 complex.

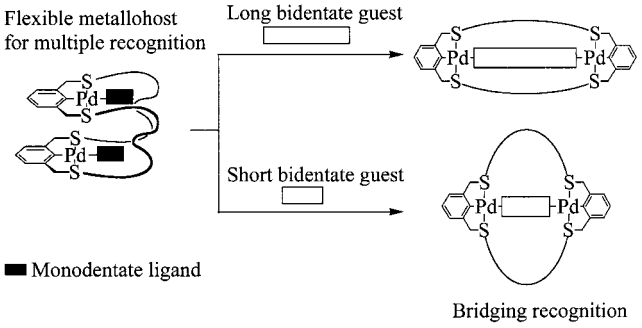
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Metalloreceptors have recently attracted much attention in supramolecular chemistry because the physical and chemical properties of the metal center can be applied in guest binding, sensing, and regulation of molecular functions.[1] In particular, the coordination of various ligands to metals is very useful for the formation of a stable supramolecular system.[2−6] Combination of the coordinate bonding and other intermolecular interactions provides a strong and selective recognition.

Complexes between Pd and pincer ligands are useful as they provide a nice coordination site for host-guest interaction.[7] For example, crown ethers containing a Pd center inside the ring and molecular recognition have been reported.[8−10] Cooperative binding of the Pd unit and the crown ether moiety to nucleobases such as cytosine and adenine was observed in this system.[11,12] However, a host molecule containing several pincer complexes as a binding site has not been synthesized although this type of host is very interesting as a multi-point receptor.

Here we report the synthesis, structure and molecular recognition ability of large macrocyclic hosts **1**, which contain two pincer complexes of Pd^{II}. The metallohosts are expected to bind bidentate guests of different sizes in the cavity because the framework of these hosts is flexible so as to cause induced-fit recognition (Scheme 1).

Metallohosts **1** containing the two Pd centers were prepared according to Scheme 2. Diols **2a**[13] and **2b**[14] were treated with *p*-toluenesulfonyl chloride to afford **3a** and **3b** in 80% and 63% yield, respectively. Reaction of dithiol **4**[15] with **3a, 3b** in the presence of K_2CO_3 afforded diols **5a, 5b**,



Scheme 1. Recognition of bidentate guests in a bridging fashion

and the following tosylation gave **6a, 6b**. The ditosylates **6a** and **6b** were then treated with **4** under high dilution conditions to give crown ethers **7a** and **7b** in 42% and 45% yield, respectively. Metallation of **7** with $[Pd(CH_3CN)_4](BF_4)_2$[16] yielded metallohosts **1a, 1b**.

All spectroscopic data are consistent with the formula of **1** (see Exp. Sect.). Palladation of **7** caused broadening of the ^1H NMR signals, probably due to the enhanced rigidity of the structure, which restricts the free rotation of the methylene group. On metallation, downfield shifts of the signals for the SCH_2CH_2 protons (e.g. $\delta = 2.60$ for **7b**, $\delta = 3.32$ for **1b**, Figure 1) and the benzyl protons is observed. This is elucidated by the decreased electron-density of these protons. ESI-MS for **1b** gave signals at $m/z = 614.1$ ($C_{52}H_{70}O_{12}S_4Pd_2$, $[\mathbf{1b}-2BF_4-2CH_3CN]^{2+}$) and $m/z = 1247.2$ ($C_{52}H_{70}FO_{12}S_4Pd_2$, $[\mathbf{1b}-2BF_4-2CH_3CN+F]^+$), (the F^- anion was obtained from decomposition of the BF_4^- anion during the ESI-MS measurements). In addition, the X-ray crystallographic analysis clarified the structure of **1b** (Figure 2). The two complex moieties exhibit square-planar geometry at Pd, with three donor atoms provided by the rigid SCS chelate. The Pd−S distances are in

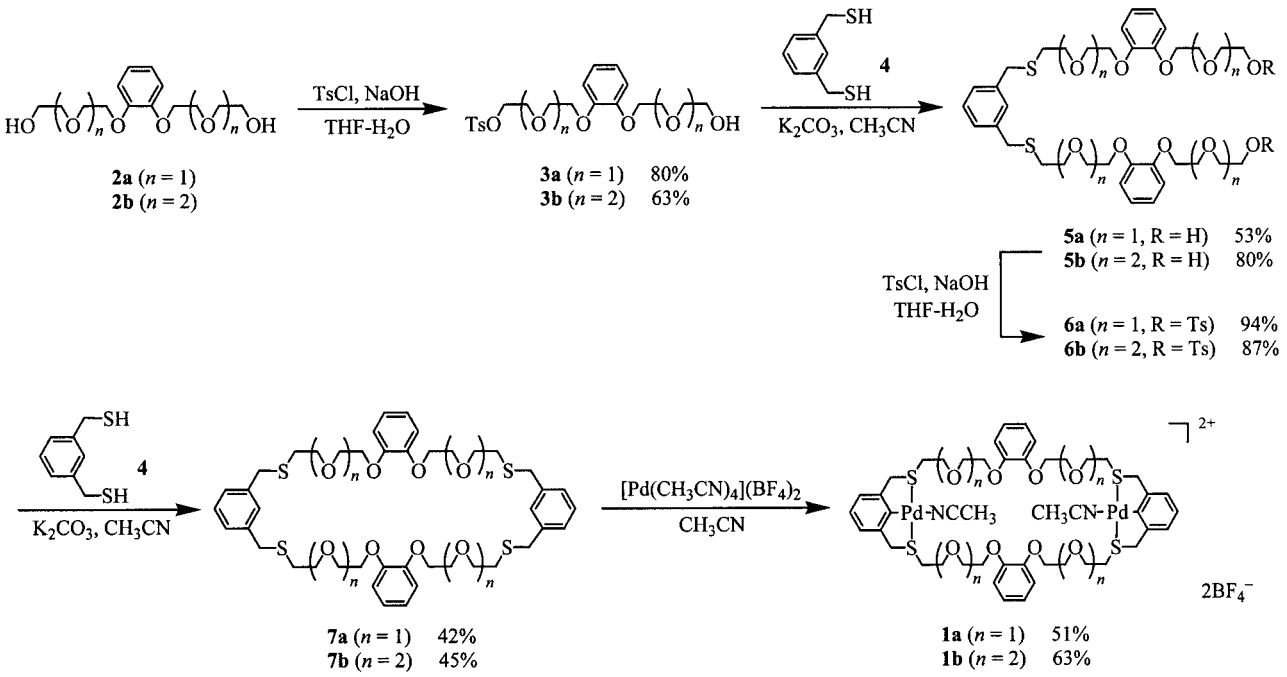

Scheme 2. Synthesis of metallohosts **1**

the range between 2.334 Å and 2.286 Å. The two aromatic rings, which bind the palladium atoms, are stacked. The distance between the mean planes of the benzene rings (3.4 Å) suggests the existence of π-π interactions. Furthermore, the palladium atoms are located in closely proximity of the sulfur atoms. The distance between Pd2−S2 (3.371 Å) is shorter than the sum of van der Waals radii for sulfur and palladium (3.43 Å). Two CH_3CN molecules coordinate to Pd, and the Pd1−N1 and Pd2−N2 distances are 2.105 Å and 2.092 Å, respectively.

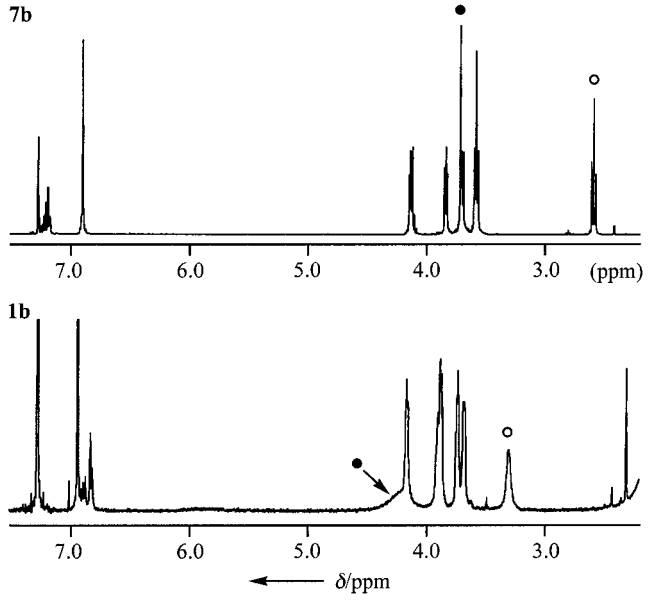

Figure 1. ^1H NMR spectral changes of **7b** upon palladation (400 MHz, $CDCl_3$); SCH_2CH_2O and benzyl protons are indicated with open and filled circles, respectively

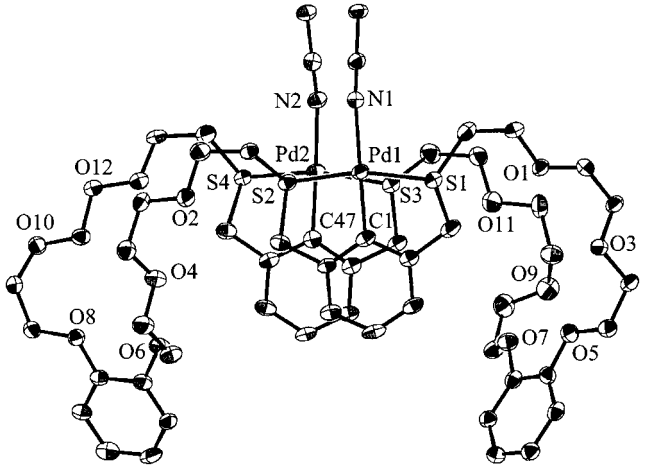

Figure 2. Crystal structure of **1b**; thermal ellipsoids are drawn at 30% probability level; the minor component of the disordered atoms, counter anions, and hydrogen atoms are omitted for clarity

The interaction between **1b** and 4,4′-bipyridine was evaluated by ^1H NMR spectroscopy (Figure 3). Signals of free **1b** disappear when 1.0 equiv. of 4,4′-bipyridine is added, and no change is observed in the presence of excess ligand. This result supports the 1:1 complexation between **1b** and 4,4′-bipyridine in a bridging fashion as illustrated in Scheme 1. ESI-MS also supports the 1:1 complexation. A mixture of **1b** and 4,4′-bipyridine gives a signal at m/z = 692.1 (calcd. for $C_{62}H_{78}N_2O_{12}S_4Pd_2$, $[\mathbf{1b}-2BF_4-2CH_3CN+4,4'\text{-bipyridine}]^{2+}$). In addition, the absorbance of **1b** at 304 nm increases until 1.0 equivalent of 4,4′-bipyridine is added (Figure 4). All the experiments described above indicate the 1:1 complexation between **1b** and 4,4′-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bipyridine. Pyrazine and pyrimidine as bidentate ligands also give rise to 1:1 complexation, as seen by ^{1}H NMR spectroscopic experiments, although the distances involving the ligating nitrogen atoms of pyrazine and pyrimidine are much shorter than that of 4,4′-bipyridine.

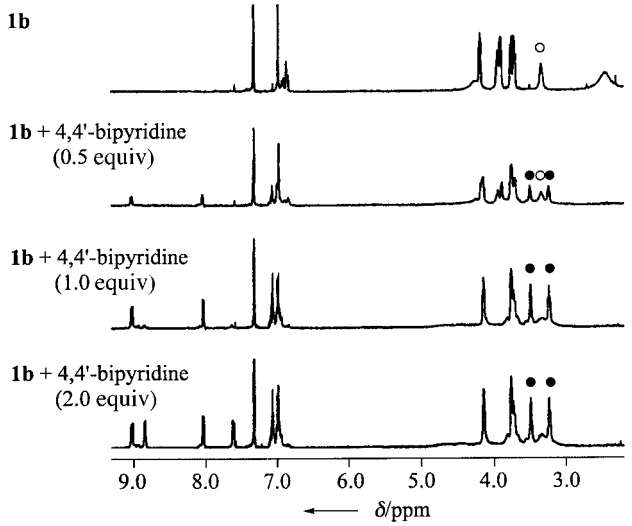

Figure 3. ^{1}H NMR spectral changes of **1b** upon addition of 4,4′-bipyridine (400 MHz, $CDCl_3$, [**1b**] = 2.0 mM); signals for free and complexed **1b** are indicated with open and filled circles, respectively

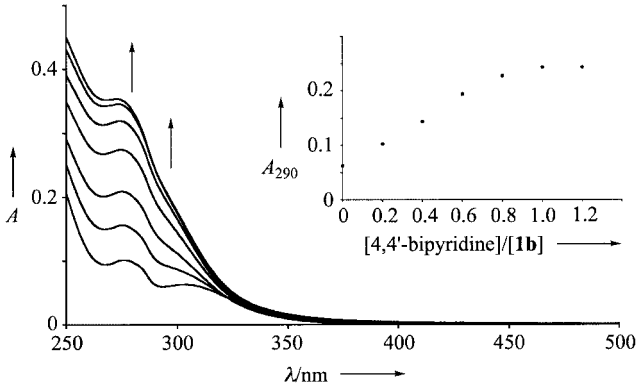

Figure 4. UV/Vis spectral changes of **1b** upon addition of 4,4′-bipyridine ($CHCl_3$, [**1b**] = 1.0×10^{-5} M)

Complexation of **1b** with these bidentate ligands should give two small cavities which are almost half as large as that of **1b** (Scheme 1). The change in cavity size is very interesting, because this strategy may be most useful to regulate recognition ability of artificial receptors.[17−19]

In conclusion, we have prepared metallohosts **1** bearing two Pd centers inside the cavity, and studied the structure and guest-binding ability of **1b** in detail by ^{1}H, ^{13}C NMR spectroscopy or X-ray crystallographic analysis. We are currently investigating this bridging strategy to control molecular recognition.

Experimental Section

Synthesis of 1a: A solution of $[Pd(CH_3CN)_4](BF_4)_2$ (302 mg, 0.680 mmol) in acetonitrile (10 mL) was added to a solution of crown ether **7a** (271 mg, 0.322 mmol) in acetonitrile (20 mL), and the mixture was stirred for 2 h at room temperature. The mixture was refluxed for 13 h, and then the solvent was evaporated. The residue was dissolved in dichloromethane (20 mL) and filtered. The filtrate was concentrated and dried in vacuo to afford **1a** (215 mg, 51%) as a yellow solid, which was further purified by recrystallization from acetonitrile to give pale yellow crystals. ^{1}H NMR (400 MHz, CD_3CN): δ = 3.30 (br. s, 8 H), 3.80 (t, J = 4.2 Hz, 8 H), 3.90 (br. t, 8 H), 4.12 (t, J = 4.2 Hz, 8 H), 4.29 (br. t, 8 H), 6.77 (d, J = 7.6 Hz, 4 H), 6.90−6.99 (m, 10 H) ppm. ^{13}C NMR (100 MHz, CD_3CN): δ = 40.00, 46.78 (br.), 69.20, 70.54 (×2, CH_2), 114.78, 122.39, 123.96, 126.65 (CH), 149.49, 151.65 (br.), 156 (br., C) ppm. ESI-MS: *m/z* found 1071.1 [**1a**−2BF_4−2CH_3CN+F]$^+$. $C_{48}H_{60}B_2F_8N_2O_8Pd_2S_4$: calcd. C 44.09, H 4.62, N 2.14; found C 43.78, H 4.57, N 2.28.

Synthesis of 1b: 1b was prepared from **7b** (319 mg, 0.315 mmol) and $[Pd(CH_3CN)_4](BF_4)_2$ (302 mg, 0.680 mmol) in 63% yield by a procedure similar to that for **1a**. **1b**: yellow oil. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.32 (br. s, 8 H), 3.67−3.69 (m, 8 H), 3.73−3.75 (m, 8 H), 3.86−3.89 (m, 8 H), 3.90−3.92 (m, 8 H), 4.16 (t, J = 4.0 Hz, 8 H), 4.18 (br., 8 H), 6.79 (d, J = 7.0 Hz, 4 H), 6.85 (t, J = 7.0 Hz, 2 H), 6.92 (s, 8 H) ppm. ^{13}C NMR (100 MHz, CD_3CN): δ = 39.68, 46.35, 69.40, 70.50 (× 2), 71.29, 71.38 (CH_2), 115.09, 122.40, 124.01, 126.65 (CH), 149.62, 151.72, 156.59 (C) ppm. ESI-MS: *m/z* found 1247.2 [**1b**−2BF_4−2CH_3CN+F]$^+$. $C_{56}H_{76}B_2F_8N_2O_{12}Pd_2S_4$·$CHCl_3$: calcd. C 42.70, H 4.84, N 1.75; found C 42.30, H 5.06, N 2.08.

X-ray Crystallographic Analysis of 1b:[20] Pale yellow crystals (0.3 × 0.15 × 0.1 mm) were obtained after oily **1b** was allowed to stand at room temperature. $C_{56}H_{76}B_2F_8N_2O_{12}Pd_2S_4$, M = 1483.85. Intensity data were collected at 130 K on a Rigaku R-AXIS Rapid diffractometer with Mo-K_α radiation (λ = 0.71069 Å). Reflection data were corrected for Lorentz and polarization factors, and for absorption using the multi-scan method. Crystal system, triclinic, a = 13.2731(12) Å, b = 14.4368(16) Å, c = 18.1120(19) Å, α = 71.267(4)°, β = 71.424(3)°, γ = 86.580(3)°, V = 3112.0(6) Å^3, space group $P\bar{1}$, Z = 2, μ(Mo-K_α) = 0.797 mm^{-1}, $D_{calcd.}$ = 1.584 g/cm^3, $2\theta_{max}$ = 52°, collected reflections 25108, unique reflections 12053 (R_{int} = 0.0719). The structure was solved by Patterson methods (DIRDIF-99)[21] and refined by full-matrix least-squares on F^2 using SHELXL 97.[22] The non-hydrogen atoms were refined anisotropically except for the minor component of disordered sulfur atoms (S4 and S6). Hydrogen atoms were idealized by using the riding models. Occupancy factor involving the disordered sulfur atoms was refined to be 0.888(3) for S3 and S5, and 0.112(3) for S4 and S6. $R1$ = 0.0618 [$I > 2\sigma(I)$], $wR2$ = 0.1537 (all data), GOF (F^2) = 1.036 for 786 parameters.

Keywords: Bridging ligands / Coordination polymers / Magnetic properties / N ligands / Transition metals

One-pot reactions in aqueous solutions of the polynitrile anion dcne$^-$ {2,2-dicyano-1-ethoxyethenolate = $[(CN)_2CC(O)OEt)]^-$} with the M^{II} ions (M = Mn, Fe, Co, Cu) in the presence of bpym (2,2′-bipyrimidine) afford the first mixed dcne/bpym compounds $[M_2(bpym)(dcne)_4(H_2O)_2]$ (**1**: M = Mn; **2**: M = Co) and $[M_2(bpym)(dcne)_4(H_2O)_4]\cdot 2H_2O$ (**3**: M = Fe; **4**: M = Cu). The new compounds have been characterized by IR spectroscopy and X-ray crystallography. Compounds **1** and **2** are isostructural, with each metal ion being located in an MN_5O pseudo-octahedral environment with three N atoms coming from three dcne$^-$ ligands, two nitrogen atoms from bpym and one oxygen atom from a water molecule. The extended structures of **1** and **2** are best described as dcne-bridged zigzag chains of M^{II} ions running along the [100] direction; connections of these chains in the [010] direction, by the bis(chelating) bpym ligand, afford 2D structures. Compounds **3** and **4** are isostructural, and consist of discrete dinuclear units involving MN_4O_2 octahedrally coordinated M^{II} ions bridged by bis(bidentate) 2,2′-bipyrimidine and terminal dcne ligands. Magnetic measurements for the 2D compounds **1** and **2** exhibit maxima in the χ_m vs. *T* plots (at about 4.5 K for **1** and about 20 K for **2**) which are characteristic of weak antiferromagnetic exchange interactions between the high-spin metal centres. While the dinuclear iron complex **3** presents a similar behaviour (maximum in χ_m vs. *T* plot at 12 K), the antiferromagnetic exchange interactions are stronger in the copper complex **4**. Fits of magnetic data for compounds **1**, **3** and **4** with appropriate models led to *J* values of –0.6, –1.5 and –99.0 cm^{-1} respectively.

Introduction

Polynitrile molecules are interesting ligands for the preparation of a large variety of discrete and extended molecular structures due to the fact that their cyano groups are disposed in such a way that they cannot coordinate to the same metal cation and that association of the π electronic system of the CN groups with the π system of the central fragment induces electronic delocalization that facilitates transmission of electronic effects between the metal centers (Scheme 1).[1,2]

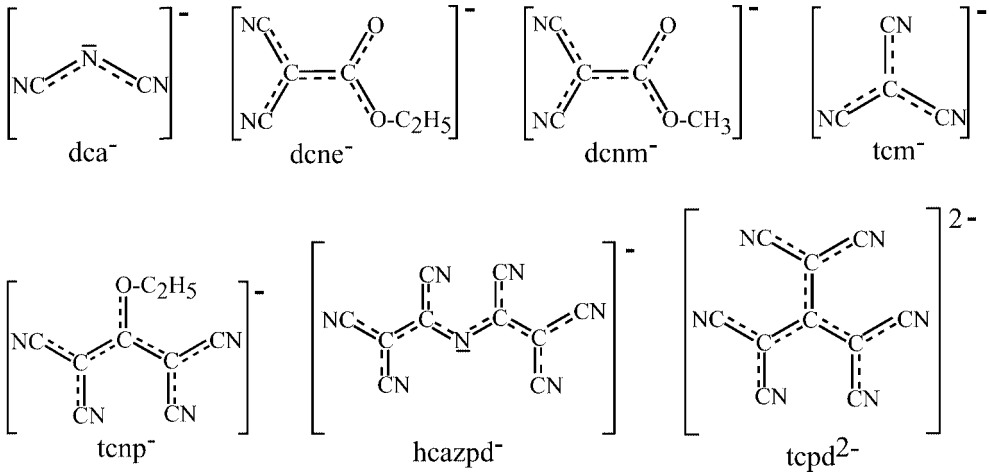
Reactions of dca$^-$,[3,4] tcm$^-$,[3,5] dcnm$^-$,[6] dcne$^-$,[7] tcnp$^-$,[8] tcpd^{2-} [9] and hcazpd$^-$ [10] with transition metal ions by us and others have led to the isolation of a variety of new compounds, many of which exhibit extended structures and interesting magnetic properties.

Taking into account the crucial role of the bridging ligands in the magnetic properties of such polynuclear or polymeric derivatives, we are interested in using polynitrile ligands in combination with other bridging ligands with the aim of generating new molecular architectures associated with new properties.[11] In this context, the 2,2′-bipyrimidine (bpym) ligand, which is known to transmit antiferromagnetic coupling between paramagnetic centers separated by more than 5.5 Å,[12] is a particularly interesting choice.[13–16] Recently reported results obtained for dca/bpym mixed-ligand complexes reveal that this combination affords a rich variation in molecular architectures. For example, $[M(dca)_2(bpym)(H_2O)]$ (M = Mn, Fe, Co) and $[Mn(dca)_2(bpym)]$ have 1D structures,[17,18]



Scheme 1. Examples of polynitrile units with two to six CN groups

$[M_2(dca)_4(bpym)]\cdot H_2O$ (M = Fe, Co) and $[Fe_2(dca)_4(bpym)(H_2O)_2]$ 2D structures,[17,19] and $[M_2(dca)_4(bpym)]$ (M = Mn, Cu) 3D structures.[18,20]

Recently we described M^{II}–dcne binary derivatives of general formula $[M(dcne)_2(H_2O)_2]$ (M = Mn, Fe, Co, Ni, Zn) and $[Cu(dcne)_2(H_2O)]$ with the 2,2-dicyano-1-ethoxyethenolate ligand ($[(CN)_2CC(O)OEt]^-$ = $dcne^-$; Scheme 1). These compounds crystallize as one-dimensional structures with bridging polynitrile ligands.[7] Magnetic measurements indicated that very weak antiferromagnetic coupling occurs in these systems. In order to increase the dimensionality of the materials and therefore favour stronger magnetic coupling, we decided to introduce an auxiliary neutral bridging ligand in these binary systems. These efforts have resulted in the first examples of mixed M^{II}–dcne/bpym ternary compounds whose structures and properties are described herein.

Results and Discussion

Syntheses and IR Characterisation

One-pot reactions in aqueous solutions of the polynitrile anion $dcne^-$ {$[(CN)_2CC(O)OEt]^-$} with M^{II} ions (M = Mn, Fe, Co, Cu) in the presence of bpym (2,2′-bipyrimidine) afforded new mixed dcne/bpym compounds of formula $[M_2(bpym)(dcne)_4(H_2O)_2]$ (**1**: M = Mn; **2**: M = Co) and $[M_2(bpym)(dcne)_4(H_2O)_4]\cdot 2H_2O$ (**3**: M = Fe; **4**: M = Cu).

It is well known that IR spectroscopy can be used as a diagnostic tool for identifying the coordination modes of the 2,2′-bipyrimidine (bpym) ligand, which can act as a single chelate or as a bis(chelate) ligand.[13,16] The former is typically characterised by two intense, absorption features of nearly equal intensities at about 1580 and 1560 cm^{-1}, while the latter is indicated either by an asymmetric doublet or by a single, strong broad feature near 1580 cm^{-1}.[13,16] The single strong band observed near 1580 cm^{-1} in the spectra of **1**–**4** points to a bis(chelate) coordination mode of the bpym ligand.

For the dcne ligand, two absorption bands assigned to ν(CN) are observed in the range 2180–2240 cm^{-1}. The first mode is very similar to that observed for the uncoordinated $dcne^-$ moiety in K(dcne) (intense doublet centered at 2195 cm^{-1}), while the second feature is slightly shifted to higher wavenumbers.[7] These data are in good agreement with the presence of both coordinated and uncoordinated CN groups in compounds **1**–**4**, as confirmed by the X-ray structures.

For each compound, a broad feature indicative of the presence of water molecules [ν_s(OH) and ν_{as}(OH)] is observed (from 3279 cm^{-1} in **2** to 3472 cm^{-1} in **4**); this observation does not allow for the assignment of free versus coordinated H_2O.

Single-Crystal X-ray Studies of Compounds 1–4

The four compounds were characterised by X-ray crystallography. Selected bond lengths and bond angles are provided in Tables 1–3 and the molecular structures are displayed in Figures 1–4.

Structures of $[M_2(bpym)(dcne)_4(H_2O)_2]$ [M = Mn^{II} (1), Co^{II} (2)]

Compounds **1** and **2** are isostructural (see Exp. Sect). Their asymmetric unit consists of one M^{II} ion, two dcne anions and a water molecule, all on general positions, and one bpym molecule centered on the special position (0,0,0). Each metal ion resides in an MN_5O pseudo-octahedral environment with three nitrogen atoms (N3, N4 and N5) coming from three $dcne^-$ ligands, two nitrogen atoms (N1 and N2) from bpym and one oxygen atom (O5) from a water molecule (Figure 1). The metal-ion environment, which involves three $dcne^-$ ligands in a *fac* arrangement, is highly distorted due to the small bite angle of the bpym ligand [71.71(6)° for **1**, 76.44(6)° for **2**] (Table 1). It is noteworthy that the two M–N(bpym) bonds (average: 2.309 Å for **1**

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and 2.169 Å for **2**) are longer than the other four M−L bonds (average: 2.178 Å for **1** and 2.085 Å for **2**), the difference being more pronounced in **1** (ca. 0.13 Å) than in **2** (ca. 0.08 Å).

N3−M−N5	94.02(9)	92.44(8)
N3−M−O5	172.79(7)	175.86(7)
N4−M−N5	101.44(8)	95.39(8)
N4−M−O5	91.88(8)	91.83(7)
N5−M−O5	93.19(8)	91.52(7)

The two crystallographically equivalent dcne ligands exhibit μ_2-coordination modes while the other one is monodentate; the bpym ligand acts as a bis(bidentate) ligand. The extended structure resulting from these coordination modes is best described as dcne-bridged zigzag chains of M^{II} ions running along the [100] direction; connections of these chains, in the [010] direction, by the bis(chelating) bpym ligand afford the 2D structure shown in Figure 2. The metal−metal distances across the bpym bridges [6.1152(5) in **1** and 5.7853(4) Å in **2**] are close to those observed in other Mn^{II}−bpym (6.1−6.3 Å)[13] and Co^{II}−bpym (5.76−5.95 Å)[15] derivatives. The M···M distances across

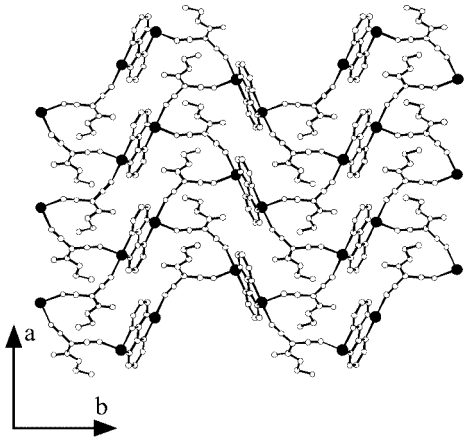

Figure 2. ORTEP view of compound **1** showing the two-dimensional structure (similar to compound **2**); the terminal dcne ligands have been omitted for the sake of clarity

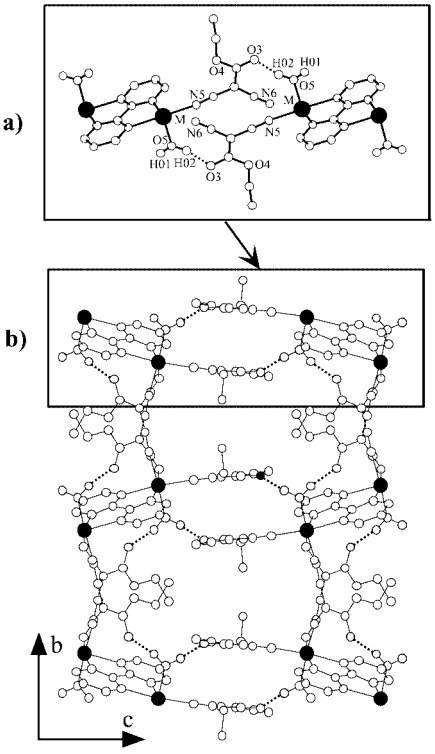

Figure 3. ORTEP view of compound **1** showing the hydrogen bonds between two adjacent sheets (similar to compound **2**)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the span of the dcne bridges [8.1420(5) in **1** and 8.0867(4) Å in **2**] are longer than the analogous distances observed in the 1D binary compounds $[Co(dcne)_2(H_2O)_2]$ [7.4270(2) Å][7] and $[Mn(dcne)_2(H_2O)_2]$ [7.5906(3) Å].[21]

Careful examination of the inter-layer distances revealed the presence of hydrogen bonds between the terminal oxygen atom of the $dcne^-$ ligands (O3) and the oxygen atom of the water molecule (O5). These hydrogen bonds occur between adjacent sheets [O3···H02 1.731(2) Å and O3···H02−O5 157.6(1)° for **1**; 1.731(2) Å and 164.9(1)° for **2**] as shown in Figure 3, giving rise to overall 3D structures.

Structures of $[M_2(bpym)(dcne)_4(H_2O)_4]\cdot 2H_2O$ (M = Fe^{II}(3), Cu^{II} (4)]

Compounds **3** and **4** are isostructural (see Exp. Sect.). Their asymmetric unit consists of one M^{II} ion, two dcne anions and three water molecules, all on general positions, as well as one bpym molecule centered on the special position (0,1/2,1/2). Each metal ion resides in a *trans*-MN_4O_2 pseudo-octahedral geometry (Figure 4). The four nitrogen atoms are from bpym (N1 and N2) and from two independent *cis*-$dcne^-$ ligands (N3 and N5); the two oxygen atoms arise from water molecules (O5 and O6) in a *trans* arrangement.

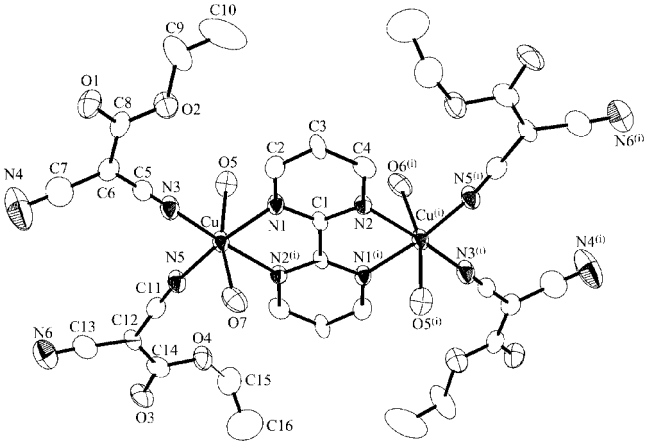

Figure 4. ORTEP view showing the metal environment and the atom labelling scheme in compound **3** (similar to compound **4**); code of equivalent position: (i): $-x$, $1-y$, $1-z$

As in the cases of **1** and **2**, the metal-ion environments are highly distorted due to the small bite angle of the bpym ligand [75.4(1)° for **3** and 80.8(2)° for **4**], but this distortion is more pronounced in compound **4** since the axial Cu−O bonds [2.338(3) and 2.494(3) Å] are much more longer than the four equatorial Cu−N ones (averaged $Cu-N_{bpym}$: 2.06 Å and averaged $Cu-N_{dcne}$: 1.96 Å; Table 2).

O5−M−O6	172.2(2)	166.5(1)

While the bpym ligand acts as a bis(bidentate) bridge as in **1** and **2**, all of the dcne ligands in this structure are monodentate, which results in the formation of discrete dinuclear units (Figure 4). The intradinuclear M···M distances through the bpym bridges [5.881(1) in **3** and 5.506(1) Å in **4**] are in the same range observed for other Fe^{II}−bpym (5.5−6.0 Å)[14] and Cu^{II}−bpym (5.3−5.7 Å)[16] derivatives. Careful examination of the inter-dinuclear distances clearly reveals an absence of hydrogen bonding.

Structure of the dcne Ligand

An examination of bond lengths and angles of the dcne ligand in **1**−**4** reveals that the metrical parameters of the dcne ligands are not significantly different in the series (Table 3). Apart from the terminal ethyl group, each dcne ligand is essentially planar within a maximum deviation of 0.1 Å (0.08, 0.10, 0.08 and 0.06 Å for **1**−**4**, respectively) from the corresponding mean plane. The two central carbon atoms of each dcne unit (C6−C8 and C12−C14) exhibit an sp^2 hybridization whereas the carbon atoms of the cyano groups are sp-hybridized, which permits a strong electronic delocalization as indicated by the C−C bonds with bond lengths from 1.390 to 1.436 Å in **1**−**4**. This delocalization is also evident from the rather short terminal C−O bond (range 1.223−1.248 Å), which deviates from a typical C−O single bond (1.50 Å), and by a C−OEt bond (range 1.334−1.350 Å) that also indicates some degree of multiple bonding. As previously reported for the binary system M^{II}−dcne,[7] the structural data in this work are in agreement with the electronic structure depicted in Scheme 2.

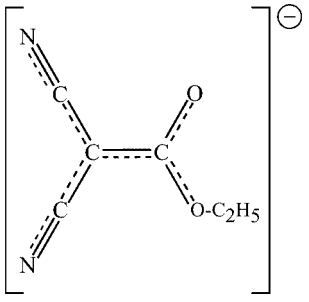

Scheme 2. Mean electronic structure of the dcne ligand

It is particularly noteworthy that the negative charge is not located on the terminal oxygen atom for the dcne ligand and therefore it is not surprising that this atom does not enter in the coordination sphere of the metal atom.

Magnetic Properties

The magnetic properties for compounds **1** (Figure 5), **2** (Figure 6), and **3** (Figure 7) are displayed as the thermal dependence of χ_m and the $\chi_m T$ product, where χ_m is the magnetic susceptibility per formula unit (2 mol of metal ions). These compounds exhibit similar behaviour in the temperature range 2−300 K. The room-temperature $\chi_m T$ values (8.4, 5.4 and 6.0 emu·K·mol^{-1} for **1**, **2** and **3**, respectively) are in good agreement with the expected values for two magnetically isolated high-spin ions [two Mn^{II} (S = 5/2), two Co^{II} (S = 3/2), and two Fe^{II} (S = 2) for **1**, **2** and **3**, respectively].[7,8,13−15] Upon cooling, the $\chi_m T$ products for **1** and **3** remain constant down to approximately 100 K, at which temperature the value decreases sharply and

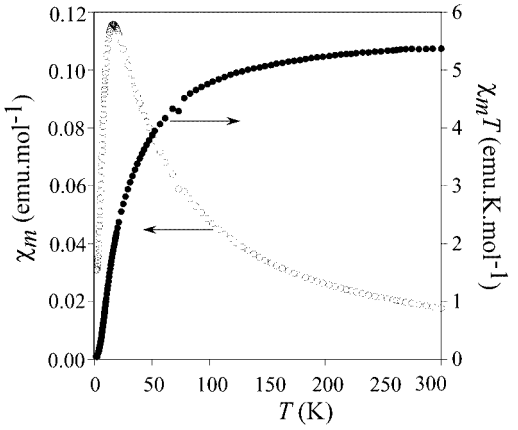

Figure 6. Thermal variations of the magnetic susceptibility in the form $\chi_m T$ (•••) and χ_m (ooo) for compound **2**

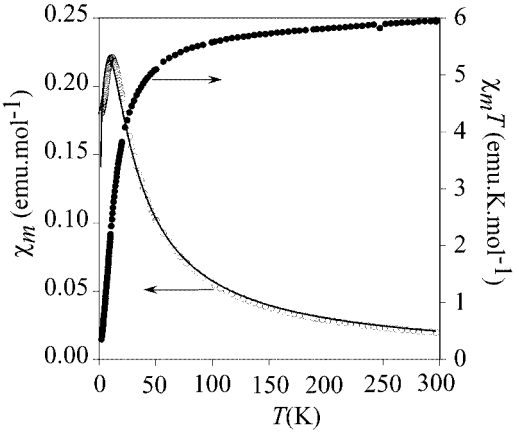

Figure 7. Thermal variations of the magnetic susceptibility in the form $\chi_m T$ (•••) and χ_m (ooo) for compound **3** (solid lines represent the best fit)

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reaches values of 0.92 and 0.36 emu·K·mol^{-1} at 2 K for **1** and **3**, respectively. For the Co derivative **2**, the decrease in the $\chi_m T$ product begins at higher temperatures due to the well-known orbital contribution for this ion,[22] and tends to a value close to zero at 2 K (Figure 6). These data are characteristic of antiferromagnetic exchange interactions between the metal ions and is corroborated by the presence of susceptibility maxima at 4.5, 20 and 12 K for **1**, **2** and **3**, respectively.

A perusal of magnetic data for various related compounds indicates that magnetic interactions through the dcne bridge are weaker ($-J_{dcne} \approx 0.04-0.40$ cm^{-1})[7,13−15] than those observed through a bis(bidentate) bpym ligand ($-J_{bpym} \approx 0.6-10$ cm^{-1} for M = Mn, Fe, Co).[7,13−15] This conclusion led us to fit the magnetic data with a model that only takes into account interactions through the bpym ligand. Thus, to treat the magnetic data we used the susceptibility expressions derived from the spin pairs (5/2-5/2, 3/2-3/2 and 2-2 for **1**−**3**, respectively) coupled through an isotropic exchange interaction J (the Hamiltonian is written as $H = -2JS_aS_b$).[22] This isotropic model cannot be used for the Co derivative **2**, however, due to the important zero-field splitting for this ion, as previously reported for $[Co_2(dca)_4(bpym)]\cdot H_2O$.[17] The analytical expressions are given in Equations (1) and (2) with $C = Ng^2\mu_B{}^2/(k_B)$, $x = J/(k_BT)$, and the parameters N, g, μ_B and k_B having their usual meanings.

$$\text{for } \mathbf{1}: \chi_m = 2(C/T)\{[e^{2x} + 5e^{6x} + 14e^{12x} + 30e^{20x} + 55e^{30x}]/[1 + 3e^{2x} + 5e^{6x} + 7e^{12x} + 9e^{20x} + 11e^{30x}]\} \quad (1)$$

$$\text{for } \mathbf{3}: \chi_m = 2(C/T)\{[e^{2x} + 5e^{6x} + 14e^{12x} + 30e^{20x}]/[1 + 3e^{2x} + 5e^{6x} + 7e^{12x} + 9e^{20x}]\} \quad (2)$$

For both compounds, a satisfactory agreement with the experimental data were observed over the entire temperature range (solid lines in Figures 5 and 7) with the sets of parameters displayed in Table 4. The J values are very similar to those reported for other dinuclear Mn^{II} (−0.4 to −0.6 cm^{-1})[13] and Fe^{II} (−1.5 to −2.1 cm^{-1})[14] derivatives with a bis(bidentate) bpym bridge.

For the Cu derivative **4**, the thermal variation of the magnetic susceptibility presents a broad susceptibility maximum at approximately 150 K (Figure 8) which is higher than the values observed for **1**−**3**, an indication of the presence of strong antiferromagnetic coupling between the two metal ions. The increase observed below 50 K is attributed to the presence of paramagnetic impurities. As for compounds **1** and **3**, the magnetic data were modelled using the susceptibility expression derived from the spin pair 1/2-1/2, by adding in this case a term to take into account a paramagnetic contribution. The analytical expression is given in Equation (3) where $\chi_D = 2(C/T)[1/(3 + e^{-2x})]$ and ρ represents the fraction of uncoupled impurities for which the molecular weight is the same as that of the investigated compound. The best fit, obtained with the values given in Table 4, is plotted as solid lines in Figure 8a.

$$\chi_m = (1 - \rho)\chi_D + (C/2T)\rho \quad (3)$$

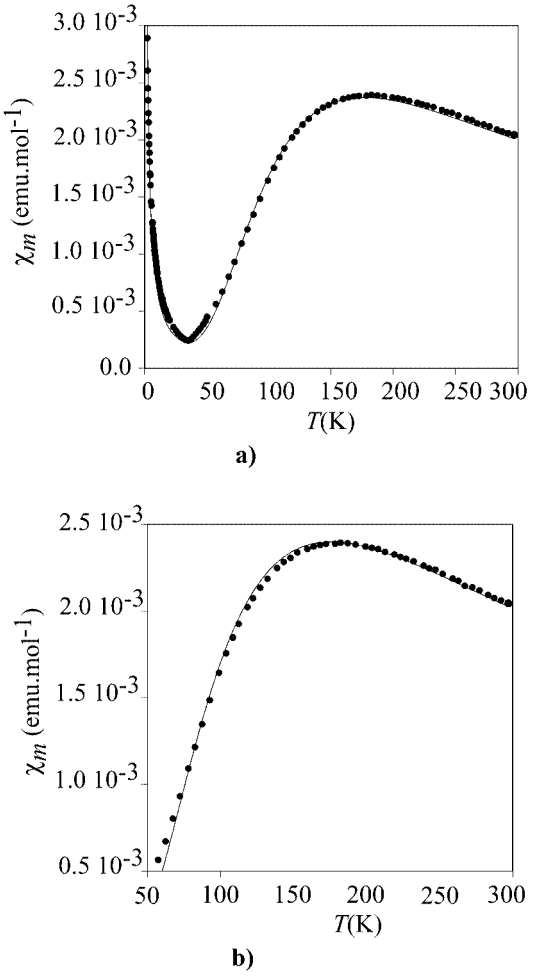

Figure 8. Thermal variations of the magnetic susceptibility for compound **4**, showing two fits of the magnetic data (solid lines): (a) using a model taking into account the paramagnetic impurities, and (b) using a simple model without paramagnetic impurities (see text)

Table 4. Magnetic parameters for compounds **1**, **3** and **4**.

Compound	S	J [cm^{-1}]	g	ρ
$[Mn_2(bpym)(dcne)_4(H_2O)_2]$ (**1**)	5/2	−0.6	2.00	
$[Fe_2(bpym)(dcne)_4(H_2O)_4]\cdot 2H_2O$ (**3**)	2	−1.5	2.05	
$[Cu_2(bpym)(dcne)_4(H_2O)_4]\cdot 2H_2O$ (**4**)	1/2	−99.0	2.12	0.008

In order to confirm the presence of the paramagnetic impurities, a second fit was carried out in the range 50−300 K using the same model but with no paramagnetic impurities ($\rho = 0$; $\chi_m = \chi_D$). The best agreement was obtained with $g = 2.12$ and $J = -98$ cm^{-1} (Figure 8b); these values are very similar to those obtained for the first fit (Table 4),

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

which corroborates the hypothesis that the increase in χ_m below 50 K is due to paramagnetic impurities. Finally, it is worth pointing out that the magnetic coupling is much more stronger in the Cu derivative than in other compounds; such a difference has been reported previously in several other compounds with bpym bridges.[16]

Conclusion

This study, which reports a new series of transition-metal derivatives with two types of bridging ligands, confirms the ability of such mixed systems to generate a variety of molecular architectures. The combination of dcne with bpym as ligands afforded both 2D derivatives $[M_2(bpym)(dcne)_4(H_2O)_2]$ (**1**: M = Mn; **2**: M = Co) and discrete dinuclear compounds $[M_2(bpym)(dcne)_4(H_2O)_4]\cdot 2H_2O$ (**3**: M = Fe; **4**: M = Cu). Since compounds without the bpym ligand, such as $[M(dcne)_2(H_2O)_2]$ (M = Mn, Fe, Co, Ni, Zn) and $[Cu(dcne)_2(H_2O)]$, are known to exhibit 1D structures, it is obvious that the introduction of an additional bridging ligand induces significant structural modifications. In an effort to increase the dimensionality of these mixed polynitrile/co-ligand compounds, further work is in progress that involves a similar synthetic strategy with polynitrile anions that possess more than two nitrile substituents.

Experimental Section

Materials and Physical Measurements: All reagents were purchased from commercial sources and used as received (2,2′-bipyrimidine from Lancaster). The potassium 2,2-dicyano-1-ethoxyethenolate {K(dcne) = K[$(CN)_2CC(O)OEt$)]} was prepared according to a recently reported procedure.[7] Elemental analyses were obtained from the Service Central d'Analyses (Vernaison) and Service de Microanalyses de ICSN-CNRS (Gif-sur-Yvette). Infrared spectra were recorded in the range 4000−200 cm^{-1} as KBr pellets on a FT-IR NEXUS NICOLET Spectrometer. Magnetic studies were carried out on powder samples at 0.1 T after zero-field cooling, in the temperature range 2−300 K with an MPMS-XL SQUID magnetometer from Quantum Design housed in the Chemistry Department at Texas A&M University. The susceptibilities were corrected for the sample holder and the diamagnetic contributions of all atoms.

Syntheses: All syntheses were performed under aerobic conditions using the following procedure: 2,2′-Bipyrimidine (20 mg, 0.126 mmol) and K(dcne) (89 mg, 0.504 mmol) were successively added with continuous stirring to a hot aqueous solution of the hydrated metal(II) chloride (0.252 mmol). The resulting solution was filtered and then slowly concentrated to yield crystals which were removed by filtration and air-dried.

Compound 1: Yield 74% (79 mg). $C_{32}H_{30}Mn_2N_{12}O_{10}$ (852.54): calcd. C 45.08, H 3.55, N 19.72; found C 44.92, H 3.61, N 19.59. Colorless crystals. X-ray Structural Determinations: Data were collected at 288 K with a Nonius KappaCCD Diffractometer, equipped with an Oxford Cryosystem Cryostream cooler device and graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The crystal structures were solved by direct methods and successive Fourier difference syntheses, and were refined on F^2 by weighted anisotropic full-matrix least-squares methods (Table 5).[23] The positions of all hydrogen atoms of the dcne ligands were calculated [d(C−H) = 0.95Å]; the thermal parameters were taken as $U_{iso} = 1.3U_{equ}$(C) and therefore included as isotropic fixed contributors to F_c in the four structures. The hydrogen atoms of the water molecules were not observed, except those of the coordinated water molecule O5 of compounds **1** and **2**, which were located by difference Fourier maps and refined isotropically. Scattering factors and corrections for anomalous dispersion were taken from the International Tables for X-ray Crystallography.[24] All calculations were performed with an Alphastation 255 4/233 computer. Selected bond lengths and angles are listed in Tables 1−3, pertinent crystal data in Table 5. CCDC-232956 to -232959 (**1**−**4**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat. + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Magnetic Properties of Lone-Pair-Containing, Sandwich-Type Polyoxoanions: A Detailed Study of the Heteroatomic Effect

Ashley C. Stowe,[a] Saritha Nellutla,[a] Naresh S. Dalal,*[a] and Ulrich Kortz*[b]

Keywords: Copper / EPR spectroscopy / Magnetic properties / Polyoxometalates / Self assembly / Tungsten

Magnetic susceptibility and high-frequency EPR spectroscopy investigations were carried out on the isostructural family of tricopper(II)-substituted, sandwich-type polyoxotungstates $[Cu_3(H_2O)_3(\alpha\text{-}AsW_9O_{33})_2]^{12-}$ (**1**), $[Cu_3(H_2O)_3(\alpha\text{-}SbW_9O_{33})_2]^{12-}$ (**2**), $[Cu_3(H_2O)_3(\alpha\text{-}SeW_9O_{33})_2]^{10-}$ (**3**), and $[Cu_3(H_2O)_3(\alpha\text{-}TeW_9O_{33})_2]^{10-}$ (**4**) with the intention of examining the possible influence of the diamagnetic heteroatoms X (X = As^{III}, Sb^{III}, Se^{IV}, Te^{IV}) on the magnetic exchange properties of the three Cu^{2+} ions in the central belt. Magnetic susceptibility data indicate a single antiferromagnetic spin exchange constant J for the triangular Cu_3 belts in **1**–**4**. Variable-temperature, W-band (ca. 94 GHz) EPR spectra reveal that the Cu_3 units have $S_T = 1/2$ as the spin ground state with the excited state $S_T = 3/2$ located within a few cm^{-1}. We also determined the g matrix components for both the $S_T = 1/2$ and 3/2 states. The zero-field parameter D has been measured for the $S_T = 3/2$ state, and its sign is shown to be positive for **1**–**4**. From the analysis of the g matrix components for the molecular and the local Cu^{2+} site symmetry, the unpaired electrons are shown to occupy the $3d_{x^2-y^2}$ orbitals. The J values change from –1.36 to –1.04 cm^{-1} for **1** and **2**, and from –1.52 to –1.48 cm^{-1} for **3** and **4**, respectively. The g values follow a similar trend, but the D value for **4** implies a role of through-space as well as through-bond sources for the magnetic interactions in the Cu_3 belt. Our results suggest that the heteroatoms, containing lone pairs, allow the fine tuning of the magnetic parameters of **1**–**4**.

Introduction

Polyoxoanions constitute a rapidly growing class of molecular metal−oxygen clusters with an enormous diversity of structures.[1,2] These molecules also display a unique multitude of properties based on their highly alterable sizes, shapes, charge densities, and reversible redox potentials. As a consequence, possible applications span a wide range of domains including catalysis, electrocatalysis, medicine, materials science, photochemistry, analytical chemistry and magnetochemistry.[3−6]

The synthesis of new classes of compounds with ground states with high electronic spin, S, is a topic of high current interest in synthetic chemistry, fundamental theoretical understanding of quantum phenomenon and future nanotechnology.[7] Incorporation of multiple transition metal ions in lacunary polyoxoanion fragments can lead to species with various stoichiometries and structural features combined with interesting magnetic properties.[8] Thus, studies of well-characterized polyoxoanions containing exchange-coupled paramagnetic metal centers should add useful data to the literature on polyoxometalates. Polyoxoanions can be considered as intermediate in complexity between monomeric metal coordination complexes and high-spin multinuclear clusters that have received considerable attention.[9−12] Since in polyoxoanions the magnetic fragment is usually encapsulated by a diamagnetic tungsten−oxo cluster, they provide ideal structural supports for the study of the magnetic exchange interactions in clusters.[13,14]

Although an enormous number of polyoxoanions with different structures is known, there are relatively few isostructural polyoxoanion families that contain several, well-characterized members. Probably the best known examples are the tetrametal-substituted, sandwich-type polyoxotungstates of the Keggin type $\{[M_4(H_2O)_2(B\text{-}\alpha\text{-}XW_9O_{34})_2]$ (M = Mn^{2+}, Fe^{3+}, Co^{2+} etc.; X = P, As, Si, Ge)$\}$ and the Wells−Dawson analogues $\{[M_4(H_2O)_2(B\text{-}\alpha\text{-}X_2W_{15}O_{34})_2]$ (M = Mn^{2+}, Fe^{3+}, Co^{2+} etc.; X = P, As)$\}$.[8b,15] Over the last decade or so the magnetic properties of transition-metal-substituted polyanions have been investigated predominantly by Coronado et al.[16] In these studies the properties of derivatives containing different transition metals (e.g. Cu^{2+} vs. Mn^{2+}) were investigated. There is essentially no report on a systematic, comparative magnetic study of isostructural polyoxoanions involving the heteroatoms.

The $(Cu^{2+})_3$ fragment represents the simplest example of a spin-frustrated system, provided (i) the exchange interaction is antiferromagnetic and (ii) the copper centers are symmetry-related through a C_3 axis. The compounds studied here belong to this class. Although many compounds containing a $(Cu^{2+})_3$ fragment have been reported, there is no system that allows one to fine-tune the magnetic interactions of the $(Cu^{2+})_3$ moiety.[17−25] Polyoxometalates appear to be an excellent candidate for such a study.

Recently Kortz et al. reported on the synthesis and structural characterization of the four copper(II)-substituted, lone-pair-containing polyoxotungstates $[Cu_3(H_2O)_3(\alpha\text{-}AsW_9O_{33})_2]^{12-}$ (**1**), $[Cu_3(H_2O)_3(\alpha\text{-}SbW_9O_{33})_2]^{12-}$ (**2**), $[Cu_3(H_2O)_3(\alpha\text{-}SeW_9O_{33})_2]^{10-}$ (**3**), and $[Cu_3(H_2O)_3(\alpha\text{-}TeW_9O_{33})_2]^{10-}$ (**4**).[26] The isostructural nature of polyanions **1**−**4** allows one to correlate the magnetic properties of these compounds with structural details.

We used high-frequency EPR spectroscopy and SQUID magnetometry to study the effects of heteroatomic substitution on the magnetic properties of **1**−**4** and we discovered an interesting trend.

Results and Discussion

For the study reported here we used $Na_{12}[Cu_3(H_2O)_3(\alpha\text{-}AsW_9O_{33})_2]\cdot 32H_2O$ (**Na-1**), $Na_{12}[Cu_3(H_2O)_3(\alpha\text{-}SbW_9O_{33})_2]\cdot 46H_2O$ (**Na-2**), $K_9Na[Cu_3(H_2O)_3(\alpha\text{-}SeW_9O_{33})_2]\cdot 16H_2O$ (**K-3**) and $K_9Na[Cu_3(H_2O)_3(\alpha\text{-}TeW_9O_{33})_2]\cdot 16H_2O$ (**K-4**) which were synthesized according to the published procedure.[26]

The copper(II)-substituted, lone-pair-containing polyoxotungstates $[Cu_3(H_2O)_3(\alpha\text{-}AsW_9O_{33})_2]^{12-}$ (**1**), $[Cu_3(H_2O)_3(\alpha\text{-}SbW_9O_{33})_2]^{12-}$ (**2**), $[Cu_3(H_2O)_3(\alpha\text{-}SeW_9O_{33})_2]^{10-}$ (**3**), and $[Cu_3(H_2O)_3(\alpha\text{-}TeW_9O_{33})_2]^{10-}$ (**4**) consist of two $(\alpha\text{-}XW_9O_{33})$ units joined by three equivalent Cu^{2+} ions (see Figure 1). All copper ions have one terminal water molecule resulting in a square-pyramidal coordination geometry. Therefore, these polyanions have idealized D_{3h} symmetry. The space in between the three transition metal ions is occupied by three sodium ions (X = As^{III}, Sb^{III}) or potassium ions (X = Se^{IV}, Te^{IV}) leading to a central belt of six metal atoms alternating in position.

The separations of the three copper ions and the two heteroatoms in polyanions **1**−**4** are summarized in Table 1.

Magnetic Susceptibility

Figure 2 shows a plot of $\chi_m T$ vs. T for compound **K-4**. This type of behavior indicates the presence of antiferromagnetic exchange interactions between the Cu^{2+} ions. The behavior of compounds **Na-1**, **Na-2** and **K-3** is very similar. The solid-state structures of polyanions **1**−**4** indicated that two of the three copper centers are crystallographically inequivalent, but nevertheless all three are oriented in a very regular triangular fashion.[26] Therefore, we used the equilateral triangle model in order to explain the observed magnetic properties of **Na-1**, **Na-2**, **K-3** and **K-4**. The Heisenberg spin exchange Hamiltonian corresponding to this model is given in Equation (1).[24,25,27] Here J is the spin exchange coupling constant, and $\hat{S}_i$ (i = 1, 2, 3) is the spin operator of the ith ion. The eigenvalues associated with the Hamiltonian in Equation (1) can be given as in

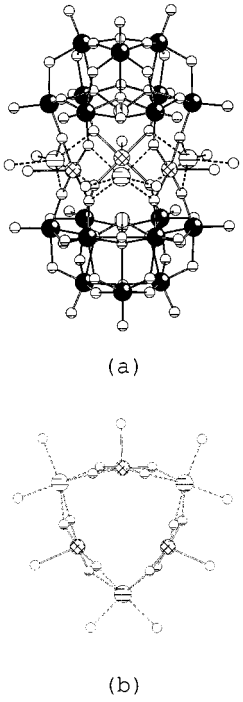

Figure 1. (a) Ball-and-stick diagram of $[Cu_3(H_2O)_3(\alpha\text{-}AsW_9O_{33})_2]^{12-}$ (**1**); this figure is also representative of $[Cu_3(H_2O)_3(\alpha\text{-}SbW_9O_{33})_2]^{12-}$ (**2**), $[Cu_3(H_2O)_3(\alpha\text{-}SeW_9O_{33})_2]^{10-}$ (**3**), and $[Cu_3(H_2O)_3(\alpha\text{-}TeW_9O_{33})_2]^{10-}$ (**4**); (b) representation of the central belt in **1**; Cu (cross-hatched), Na (horizontally hatched), As (vertically hatched), O (shaded), H_2O (unshaded)

Table 1. Cu···Cu and heteroatom (X···X) separations in polyanions **1**−**4**[26]

Polyanion	Cu···Cu [Å]	X···X [Å]
$[Cu_3(H_2O)_3(\alpha\text{-}AsW_9O_{33})_2]^{12-}$ (**1**)	4.69	5.34
$[Cu_3(H_2O)_3(\alpha\text{-}SbW_9O_{33})_2]^{12-}$ (**2**)	4.84	4.85
$[Cu_3(H_2O)_3(\alpha\text{-}SeW_9O_{33})_2]^{10-}$ (**3**)	4.84	5.38
$[Cu_3(H_2O)_3(\alpha\text{-}TeW_9O_{33})_2]^{10-}$ (**4**)	4.87	4.95

Equation (2),[24,25,27] where S_T is the total spin and S_i (i = 1, 2, 3) is the spin of each ion.

$$\hat{H} = -2J[\hat{S}_1\cdot\hat{S}_2 + \hat{S}_2\cdot\hat{S}_3 + \hat{S}_3\cdot\hat{S}_1] \quad (1)$$

$$E(S_T,S_1,S_2,S_3) = -J[S_T(S_T+1) - S_1(S_1+1) - S_2(S_2+1) - S_3(S_3+1)] \quad (2)$$

Since for each Cu^{2+} ion $S_1 = S_2 = S_3 = 1/2$, S_T can take values 1/2 ($\uparrow\uparrow\downarrow$), 1/2 ($\uparrow\downarrow\uparrow$) or 3/2 ($\uparrow\uparrow\uparrow$). The S_T = 1/2 state is thus doubly degenerate, with an energy of $-3J/2$, while the S_T = 3/2 state has an energy of $3J/2$. Substitution of these values into the standard Van Vleck equation[28] yields the expression for the molar magnetic susceptibility [Equation (3)]. Here N is the Avogadro number, g the Landé g factor, β the electronic Bohr magneton, k the Boltzmann constant and T the temperature in Kelvin.

$$\chi_m = \frac{Ng^2\beta^2}{4kT}\left[\frac{1+5\exp(3J/kT)}{1+\exp(3J/kT)}\right] \quad (3)$$

The experimental $\chi_m T$ data for **Na-1**, **Na-2**, **K-3** and **K-4** have been fitted to Equation (3) by treating g and J as adjustable parameters. The agreement between the theoretical curve and the measured data is quite satisfactory. The best least-squares fit parameters are given in Table 2. The negative sign of J indicates the presence of antiferromagnetic intra-trimer interactions and hence, the doubly degenerate S_T = 1/2 state is the ground spin state in all four compounds. The g values are consistent with the g_{iso} values obtained directly from the EPR measurements (vide infra).

As indicated above, two of the three copper centers in **1**−**4** are crystallographically inequivalent, which inevitably results in two different Cu···Cu separations. Although these differences are very small (< 0.04 Å), we also attempted to fit the experimental data to an isosceles triangle model [cf. Equation (4)],[28] where J_1 and J_2 represent the two kinds of exchange interactions. Due to the similar magnetic environment, however, we could not improve the fits by using the two spin exchange constants J_1 and J_2.

$$\chi_m = \frac{Ng^2\beta^2}{4kT}\left[\frac{1+10\exp(3J_1/kT)+\exp(2(J_1-J_2)/kT)}{1+2\exp(3J_1/kT)+\exp(2(J_1-J_2)/kT)}\right] \quad (4)$$

In all four polyanions **1**−**4**, the Cu $3d_{x^2-y^2}$ orbitals, which contain the unpaired electrons, are directed along the $Cu-O_{eq}$ vectors. Therefore, spin exchange coupling takes place by an indirect pathway involving two tungsten and three oxygen atoms of each XW_9O_{33} (X = As^{III}, Sb^{III}, Se^{IV}, Te^{IV}) fragment. Hence, we expected weak spin exchange interactions between the Cu^{2+} ions. The small magnitude of the observed J values (ca. 1 cm^{-1}) supports this model (see Table 2).

The coupling constants J for **Na-1**, **Na-2**, **K-3** and **K-4** are plotted as a function of the Cu···Cu separations in Figure 3. It can be seen that for **Na-1**/**Na-2** and **K-3**/**K-4** there is a decrease of J with increasing Cu···Cu separation. The average equatorial $Cu-O_{eq}$ distances in polyanions **1**−**4** are very similar [**1**, 1.921(6) Å; **2**, 1.937(6) Å; **3**, 1.918(9) Å; **4**, 1.927(9) Å], so that the differences in the Cu···Cu separations between **1**−**4** must be due to the different heteroatoms. The heteroatoms of **1** (As^{III}) and **2** (Sb^{III}) are from main group V, whereas the hetero groups of **3** (Se^{IV}) and **4** (Te^{IV}) are from main group VI.

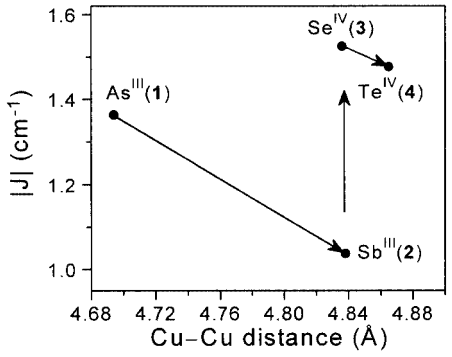

Figure 3. Dependence of the magnetic coupling constant J on the average Cu···Cu separations in $Na_{12}[Cu_3(H_2O)_3(\alpha\text{-}AsW_9O_{33})_2]\cdot 32H_2O$ (**Na-1**), $Na_{12}[Cu_3(H_2O)_3(\alpha\text{-}SbW_9O_{33})_2]\cdot 46H_2O$ (**Na-2**), $K_9Na[Cu_3(H_2O)_3(\alpha\text{-}SeW_9O_{33})_2]\cdot 16H_2O$ (**K-3**) and $K_9Na[Cu_3(H_2O)_3(\alpha\text{-}TeW_9O_{33})_2]\cdot 16H_2O$ (**K-4**)

When comparing **1** and **2**, it can be noted that both have the same charge, but the latter has the larger heteroatom. With the above in mind, the increase in the Cu···Cu separation in **2** compared to **1** must be due to an "equatorial expansion motion" of the former polyanion in the belt region. We believe that this is caused by lone pair···lone pair

Table 2. Magnetic parameters for polyanions **1**−**4** obtained from EPR and magnetic susceptibility measurements; the error in the g values is ± 0.005 and the error in J is ± 0.01

Polyanion	EPR							Susceptibility	
	S_T = 1/2			S_T = 3/2					
	$g_\parallel$	$g_\perp$	g_{iso}	$g_\parallel$	$g_\perp$	g_{iso}	D [cm^{-1}]	J [cm^{-1}]	g_{iso}
1 (X = As)[a]	2.117	2.254	2.208	2.060	2.243	2.182	0.0230	−1.36	2.209
2 (X = Sb)	2.128	2.257	2.219	2.061	2.231	2.175	0.0225	−1.04	2.223
3 (X = Se)	2.120	2.263	2.216	2.064	2.243	2.183	0.0219	−1.52	2.212
4 (X = Te)	2.127	2.288	2.234	2.065	2.239	2.181	0.0240	−1.48	2.226

[a] Ref.[8a]

interaction of the two heteroatoms, which is more pronounced in **2** than in **1** due to the larger size of Sb^{III} compared to As^{III} (see Table 1). The same trend is observed for **3** and **4** and we suggest an analogous explanation.

When comparing the magnetic exchange coupling constants *J* of **1** and **3** it must be remembered that the charge of the polyanions differs by 2 units. This is due to the fact that the heteroatoms are As^{III} and Se^{IV}, respectively. In **1** and **3** the heteroatom separation is essentially equivalent (see Table 1), so that the differences in the average Cu···Cu separation must be due to charge effects. The Cu···Cu separation is larger in **3** than in **1** which indicates an "equatorial expansion motion" similar to above, but this time it must be caused by excess negative charge on the polyanion. However, the exchange coupling constant *J* is larger for **3** than for **1**, indicating that an increase of the negative charge on the polyanion leads to an increase of the magnetic coupling constant. The same trend is observed for **2** and **4** and we suggest an analogous explanation. Nevertheless it remains to be seen if this observation can be generalized.

The two straight lines in Figure 3 perfectly reflect the size differences of the 4p (As^{III}, Se^{IV}) vs. 5p (Sb^{III}, Te^{IV}) heteroatoms. The fact that the slope of both lines is very similar indicates that the same trend is valid for group V and group VI heteroatoms. We have also shown that magnetic exchange coupling constants can reflect structural details of heteropolyanions. We believe that the graph in Figure 3 can also be used to predict coupling constants of related polyanions that have not yet been synthesized, e.g. the Bi derivative of **1** and **2**. We expect that the hypothetical polyanion $[Cu_3(H_2O)_3(\alpha\text{-}BiW_9O_{33})_2]^{12-}$ has a coupling constant *J* which is smaller than 1 cm^{-1}.

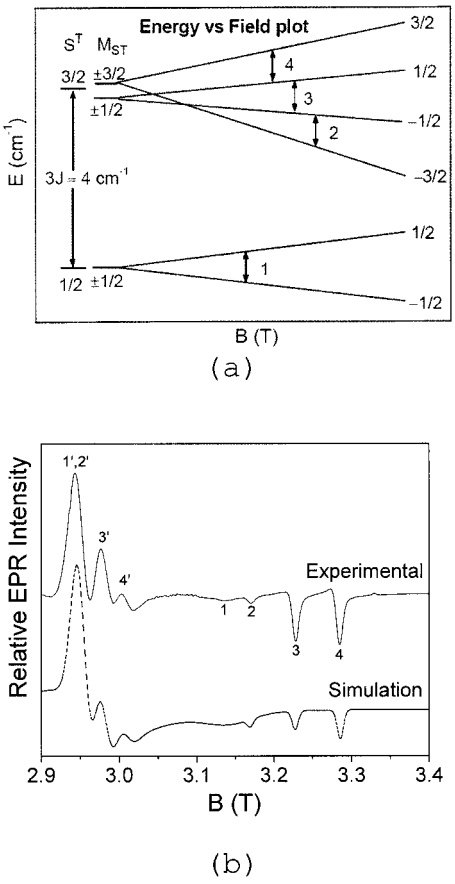

Figure 4. (a) Energy level diagram and the expected EPR transitions; (b) experimental and simulated W-band (ν = 93.494 GHz) powder EPR spectra of $K_9Na[Cu_3(H_2O)_3(\alpha\text{-}TeW_9O_{33})_2]\cdot 16H_2O$ (**K-4**) at 4 K

EPR Spectroscopy

Polycrystalline powder samples of **Na-1**, **Na-2**, **K-3** and **K-4** show similar EPR spectra with a quadruplet excited spin state at slightly higher energy than the S_T = 1/2 spin ground state (see Figure 4). The observed EPR spectra were analyzed using the spin Hamiltonian in Equation (5), where S_T is the total spin operator, *D* is the zero-field splitting parameter, and *g*, β, *B* have their usual meaning.

$$\hat{H} = \hat{S}_T \cdot D \cdot \hat{S}_T + \beta \cdot B \cdot g \cdot \hat{S}_T \quad (5)$$

The possible spin states correspond to a total spin of S_T = 3/2 or 1/2, which is expected for a frustrated triangle containing an unpaired electron et each vertex. Here we neglect the hyperfine structure due to the $^{63,65}Cu$ nuclei, since it is exchange-averaged. Also, we do not consider *J* here because its effect is not detected by standard EPR measurements, except through the detection of separate spectra from the ground and thermally accessible excited states. The small magnitude of exchange determined by magnetic susceptibility is not large enough to see intensity changes between different spin states.[25] Assuming axial symmetry, and the high-field limit ($g\beta B >> |D|$, as is the case here), the solution of Equation (5) is straightforward.[29] The line centers will be given by the *g* factor, and each line will be split into $2S_T$ components. For a system with axial symmetry, such as the $(Cu^{2+})_3$ moiety here, the fine structure splitting varies essentially as $D(3\cos^2\Theta - 1)$, where Θ is the angle between the applied field direction and the axis of symmetry. Thus, for an S_T = 3/2 spin state, the powder pattern in the limit $g\beta B >> |D|$ should consist of a triplet around the principal *g* components. The triplet separation around the *g* peak is 2*D* while the separation of perpendicular transitions around the $g_{\|}$ peak is 2|*D*|.

Figure 4 (a) shows the energy level diagram and the expected magnetic dipole ($\Delta M_{ST} = \pm 1$) transitions, labeled 1−4. Figure 4 (b) shows the 4 K experimental W-band EPR spectrum of the tellurium analog **K-4** with the best-fit simulation. The experimental spin Hamiltonian parameters used in this simulation and those obtained for compounds **Na-1**, **Na-2** and **K-3** are summarized in Table 2. Figure 5 shows the measured room-temperature and 4 K W-band EPR spectra for **K-4**. In the room-temperature spectrum, only the quadruplet fine structure transitions are observed for the quadruplet excited spin state. At 4 K, a fourth parallel peak centered at *g* = 2.117 was observed. The higher intensity of the lowest field line suggests that the perpendicular component of the S_T = 1/2 state is superimposed. This ob-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

servation lends credence to a lower energy spin state being present. The ground spin state for the $(Cu^{2+})_3$ triangle is therefore the doublet $S_T = 1/2$ state. Further analysis of the signal intensity with respect to temperature reveals the sign of the zero field splitting. At lowest temperature, only the lowest energy states are thermally populated. Hence, at 4 K, the fine structure line intensity shifts into the outermost parallel and perpendicular lines, indicating a positive sign for the D value. The $M_{ST} = \pm 1/2$ states are therefore of lower energy. Compounds **Na-1**, **Na-2**, **K-3** have analogous EPR spectra and show an $S_T = 1/2$ ground spin state; however, the magnetic parameters vary slightly. It should be noted that in all cases the quadruplet state transitions are still observed at 4 K because the spin exchange between states is small (ca. 4 cm^{-1}).

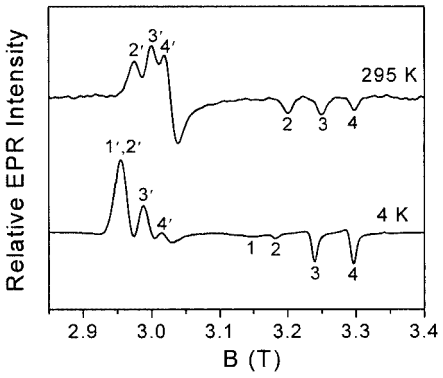

Figure 5. W-band (ν = 93.494 GHz) powder EPR spectra of $K_9Na[Cu_3(H_2O)_3(\alpha\text{-}TeW_9O_{33})_2]\cdot 16H_2O$ (**K-4**) at 295 K and 4 K as indicated; numbering corresponds to Figure 4 (a)

The geometrical arrangement of the CuO_5 groups in polyanions **1**−**4** is such that their perpendicular directions correspond to the C_3 axis of the heteropolyanion, while the parallel direction of each CuO_5 unit is perpendicular to the molecular C_3 axis. The square-pyramidal geometry of each CuO_5 unit has C_{4v} site symmetry. Since, the axial Cu−Ow distance in each unit is longer than the four equatorial Cu−O distances,[26] the $3d_{z^2}$ orbital is stabilized with respect to $3d_{x^2-y^2}$ such that the unpaired electron resides in the $3d_{x^2-y^2}$ orbital. Siedle et al. have shown that the observed EPR g matrix parameters can be transformed with respect to the g matrix of the individual copper centers.[30] If g(m) represents the g matrix of an individual CuO_5 unit, the relation between g(m) and the observed g values can be written as $g_{\|} = g_{\perp}(m)$ and $g_{\perp} = (1/2)[g_{\|}(m) + g_{\perp}(m)]$. Applying these relations to the polyanion **4**, for example, yields $g_{\|}(m)$ and $g_{\perp}(m)$ values as 2.449 and 2.127, respectively. With this geometrical framework $g_{\|}(m) > g_{\perp}(m) > g_e$, g_e being the free electron g value of 2.0023, proving that the $d_{x^2-y^2}$ orbital contains the unpaired electron.

Finally, an interesting observation from Table 2 is that for **4**, the D value magnitude does not fit the trend of the Cu···Cu distances. Normally, one would expect that the D value should fall off sensitively with the Cu···Cu separations. For **4**, however, while the Cu···Cu distance is the largest, the D value is also the largest. This breakdown in the D value vs. Cu···Cu distance relationship suggests a significant role for the through-bond interactions in **4**.

Conclusions

W-band EPR and SQUID measurements have enabled us to measure the influence of the charge and size properties of the lone pair containing heteroatoms on the central Cu^{2+} triangle embedded in a series of four isostructural polyoxometalates. The g_{iso} value calculated from EPR measurements for the ground spin state for compounds **Na-1**, **Na-2**, **K-3** and **K-4** varies from the best fit parameters determined by $\chi_m T$ vs. T plots. For **Na-1** and **K-3**, which have larger J values, the agreement between magnetic susceptibility and EPR spectroscopic results is within experimental error. For **Na-2** and **K-4**, a 3% difference was observed in the g values determined from the two techniques. We tentatively ascribe this difference to the fact that the susceptibility measurements extend over a wide temperature range.

In summary, we have performed the first systematic study of the magnetic properties of an isostructural family of polyoxoanions. Not surprisingly, magnetic susceptibility and EPR measurements have revealed that the magnetic exchange coupling constant J is a sensitive parameter that can reflect very small structural differences in the magnetic core (e.g. Cu···Cu separations) of polyanions. More importantly, we have also shown that these structural differences can be rationalized by size and charge effects of the heteroatoms. This means that magnetic measurements can be used as an indirect analytical tool, in order to investigate phenomena that originate in nonmagnetic regions of magnetic molecules.

Experimental Section

Synthesis: The polyoxoanions $Na_{12}[Cu_3(H_2O)_3(\alpha\text{-}AsW_9O_{33})_2]\cdot 32H_2O$ (**Na-1**), $Na_{12}[Cu_3(H_2O)_3(\alpha\text{-}SbW_9O_{33})_2]\cdot 46H_2O$ (**Na-2**), $K_9Na[Cu_3(H_2O)_3(\alpha\text{-}SeW_9O_{33})_2]\cdot 16H_2O$ (**K-3**) and $K_9Na[Cu_3(H_2O)_3(\alpha\text{-}TeW_9O_{33})_2]\cdot 16H_2O$ (**K-4**) were synthesized according to the published procedure.[26]

Magnetic Susceptibility Measurements: Magnetic susceptibility measurements on **Na-1**, **Na-2**, **K-3** and **K-4** were carried out using a Quantum Design MPMS-XL SQUID magnetometer. Data for polycrystalline samples were collected over 1.8−200 K at 1000 G, using approximately 70 mg of sample. The data were corrected for the sample holder, diamagnetism using Klemm constants,[31] and temperature-independent paramagnetism (TIP) contributions.

EPR Spectroscopy: Polycrystalline powder EPR spectra of **Na-1**, **Na-2**, **K-3** and **K-4** were recorded at W-band frequencies (ca. 94 GHz) at the high-field electron magnetic resonance facility at the National High Magnetic Field Laboratory in Tallahassee, as described elsewhere.[32,33] Temperature variation was measured from room temperature to 4 K. An Oxford Instruments Teslatron superconducting magnet, able to sweep between 0 and 17 T, was used to apply the Zeeman field. In all experiments the modulation

amplitudes and microwave power were adjusted for optimal signal intensity and resolution. The Bruker XSophe EPR simulation program was used with the appropriate spin Hamiltonian to generate simulated EPR spectra. This program includes a Boltzmann term that considers thermal population of particular spin levels.

Roesky's Ketone: Structure, Aromaticity and Reactivity

Joris Van Droogenbroeck,[a] Karla Tersago,[a] Christian Van Alsenoy,[a] Stephen M. Aucott,[b] Heather L. Milton,[b] J. Derek Woollins,[b] and Frank Blockhuys*[a]

Keywords: Aromaticity / Density functional theory / Dithiadiazole / Reactivity / X-ray diffraction

The molecular and crystal structure of the title compound, 5-oxo-1,3,2,4-dithiadiazole or Roesky's ketone (**1**), is studied experimentally by re-determining the crystal structure and theoretically by calculations at the density functional level of theory using an extended basis set. A comprehensive set of properties, consisting of orbital topologies, atomic charges, atomic and molecular dipoles, aromaticity parameters and Fukui functions of the title compound and a number of its constitutional isomers was calculated in order to formulate a description of its structure, its aromaticity and reactivity.

Introduction

The discovery of the metallic properties of polymeric $(SN)_x$ in 1973,[1] and the finding that it becomes a superconductor at low temperatures two years later,[2] opened a new era in the research on conducting polymers. In $(SN)_x$ compounds the alternating sulfur and nitrogen atoms donate two π-electrons and one π-electron, respectively, which makes these compounds electron-rich and leads to a partial occupancy of the π*-orbital.[3,4] Such electron-rich compounds are known to be very reactive. One of the approaches to stabilize these interesting systems, and the one we adopted in this work, is to enclose chains of a limited length, for example an $(SN)_2$ unit, in a five- or six-membered ring, thus extending the π-delocalisation and stabilizing the heteroatomic fragment. The resulting new compounds have very different properties when compared with their hydrocarbon analogues. When, for example, naphthalene is compared with 1,3λ^{4}δ^2,2,4-benzodithiazine, its analogue containing an $(SN)_2$ unit, we see that upon changing the −C=C−C=C− fragment into an −N=S=N−S− one the number of double bonds is retained but, in addition, one lone pair from the singly bound sulfur atom is introduced into the π-system. This causes 1,3λ^{4}δ^2,2,4-benzodithiazine to become antiaromatic, while naphthalene itself is aromatic. These effects of electronic (de)localization, combined with the promising magnetic and electronic properties that result from the peculiar electronic structure, make these new compounds very interesting systems for further theoretical and experimental investigations.

Here we present an in-depth study of the structure, aromaticity and reactivity of one of these ring systems, in particular 5-oxo-1,3,2,4-dithiadiazole or Roesky's ketone, by combining the results from theoretical calculations and experimental techniques. A previous study on 1,3λ^{4}δ^2,2,4-benzodithiazine and its fluorinated derivatives[5,6] provided a unique way to gain a deeper understanding of the properties of the molecule and to find out the best suited theoretical level to describe these properties, by comparing calculated geometries with the results of a gas-phase electron diffraction (GED) experiment. To complement the work presented here the influence of the theoretical level and basis set on the structure of Roesky's ketone was recently performed.[7] The small number of atoms makes this molecule especially interesting in such a study as we were able to use very high-level theories and very extended basis sets. Roesky's ketone can thus act as a model system for more complicated $(SN)_2$ systems. We are currently performing a similar study on an organometallic $(SN)_2$ compound containing a cobalt atom.

Roesky's ketone was first synthesised by Roesky and Wehner[8] in 1975 and later by Neidlein and Leinberger.[9,10] In 1978, the crystal structure of the ketone was determined by Roesky et al.[11] by means of X-ray diffraction (XRD). In 1993 deLaat et al.[12] studied Roesky's ketone in the gas phase by infrared (IR) and photoelectron spectroscopy (PES), and by a limited theoretical study using semi-empirical and low-level ab initio methods. In this work Roesky's ketone is subjected to a low-temperature X-ray diffraction study, yielding data with a higher resolution than the existing set. This experimental structural study is complemented by the calculation of a theoretical gas-phase geometry which is compared with the XRD results. A further descrip-

tion of the molecular properties of Roesky's ketone is given based on calculated atomic charges, molecular and atomic dipoles, deformation densities, bond orders, Nucleus-Independent Chemical Shift (NICS) values, Fukui functions and softnesses, to gain a complete insight into the structure, reactivity and aromaticity of the title compound. To tackle the issue of aromaticity three constitutional isomers of Roesky's ketone, given in Figure 1, were included in the study.

Results and Discussion

Experimental and Theoretical Geometry

The geometry of Roesky's ketone (**1**), which was synthesised as shown in Figure 2, was optimized at the DFT/B3LYP level of theory and the geometrical results are given in Table 1 together with the experimental solid-state geometry. The data show that the geometries of the two independent molecules in the unit cell are identical within the experimental errors; the torsion angles (not given in Table 1) are limited to 1.69(12)° and confirm the near-planar conformation of the compound in the solid state. This is in agreement with the planar conformation found in the calculations and suggests that the slight deformation in the crystal is due to packing effects. Keeping in mind that r_{XRD} are r_α-type distances which are compared to calculated (or r_e) distances, the agreement for the three N−S bonds is excellent for the longer one but less impressive for the two shorter ones, even though the relative bond lengths in the NSNS fragment are quite well reproduced. The difference between the calculated and the experimental bond length for the C−N and C−O bonds amounts to 0.02 Å; the calculation underestimates both. The only bond which is grossly overestimated by the DFT calculation is the C−S bond, with a difference of up to 0.11 Å compared to the experimental value. From a more systematic study of the influence of the level of theory, the functional used in DFT and the basis set on the calculated structure of Roesky's ketone, the results of which can be found elsewhere,[7] it is clear that B3LYP/6-311+G* leads to a high-quality structure in a relatively short computational time.

5-Oxo-1,3,2,4-dithiadiazole (**1**) is a five-membered-ring structure which is characterised by one longer (1.641 Å) and two shorter (av. 1.579 Å) S−N bonds, a regular-length C−N bond (1.385 Å), a longer C−S bond (1.830 Å) and a localised C=O double bond (1.211 Å). The internal angles of the ring are all centred around 110°, which is close to the ideal value of 108° for a regular pentagon, apart from the C5−S1−N2 angle, which severely distorts the structure, as can be seen in Figure 1. Figure 3 shows the crystal structure and packing of the title compound: the orthorhombic unit consists of 16 molecules (two in the asymmetric unit) packed in a parallel configuration, which are slightly distorted from the planar conformation.

Frontier Orbitals and Geometries of the Anion and Cation

In Figure 4 the frontier orbitals are visualized using the program gOpenMol[13,14] for values of the contour surfaces of −0.035 and 0.035. Based on these pictures, the geometries of the anionic and cationic forms of Roesky's ketone can be rationalized. The geometries of the anion and the cation and the differences with the neutral molecule are given in Table 2. Based on the nodes of the HOMO, it is to be expected that the C5−S1, N4−C5 and N2−S3 bonds are longer in the cation than in the neutral molecule, as the HOMO has bonding character on these bonds: upon removing an electron from that orbital, the bonding will decrease, resulting in the lengthening of the bonds. This is indeed observed, as can be seen from Table 2: an increase in interatomic distance of up to 0.077 Å is found for the N2−S3 bond. The same reasoning can be applied for the three remaining bonds, which all become shorter. The removal of an electron from an orbital with anti-bonding character (the nodes in Figure 4a) will increase the bonding and shorten the bonds. Similar conclusions can be drawn for the anion, taking into account that here an extra electron is introduced into the LUMO. The bond lengths of the bonds where this orbital has anti-bonding character — all of them except N4−C5 — will increase, since the anti-bonding character is further increased. The bond length corresponding to the one bond in which there is bonding character (N4−C5) will decrease. All these trends can be found in the calculated geometry differences, given in Table 2.

Charges and Dipoles

As the Hirshfeld partitioning of the electron density is an excellent way to attribute charges to atomic centers, stockholder charges, which are calculated according to this scheme, are known to be chemically very acceptable.[15−18] Stockholder charges were therefore calculated for the neutral 5-oxo-1,3,2,4-dithiadiazole (**1**) and for both its cation and anion; the obtained values are given in Table 3. Several features which are based on chemical knowledge, such as the dipole in the carbonyl group, the positive charges on the sulfur atoms and the negative charges on the nitrogen atoms, are reproduced well. The charges of the ionic forms of **1** will be used later in the reactivity discussion.

The molecular dipole moment, μ, was calculated to be 3.104 D and its components are μ_x = −0.259 D and μ_y = −3.093 D, in the axis system given in Figure 5. The nth component of the molecular dipole, μ_n, with $n = x, y, z$, can be written as

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

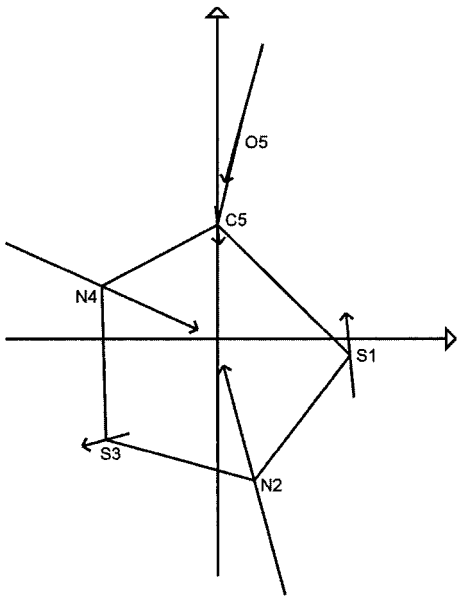

Figure 5. Atomic dipole moments in the Cartesian frame of the calculation; the size of the atomic dipole moment vector arrows has been increased by a factor of 100

$$\mu_n = \sum_A q_A R_{A,n} + \sum_A \mu_{A,n}$$

which is the sum of the contributions of charge transfer (first term, with q_A the stockholder charge and $R_{A,n}$ the coordinate of atom A) and of the intra-atomic charge polarization, calculated by the atomic dipole moment components $\mu_{A,n}$ (second term). Table 4 compiles these components for all six atoms in Roesky's ketone. It is clear that the contributions of the atomic dipoles, represented by the arrows in Figure 5, can be summed over the whole molecule to a net dipole with components of about 0.1 D in both the x and y directions. On the other hand, the charge-transfer contributions of the five ring atoms can be summed to a net zero charge transfer, indicating that the total charge transfer is determined solely by the value of the oxygen atom. Since the absolute values of the components of the total charge transfer outweigh those of the total atomic dipole, it can be said that the charge transfer of the oxygen atom indirectly determines the total molecular dipole moment. This is indeed found when the components of the charge transfer contribution of the oxygen atom (−0.336 and −2.819 in the x and y directions, respectively) are compared to the components of the total molecular dipole moment (−0.259 and −3.093 D in the x and y directions, respectively).

Aromaticity

Aromaticity remains a very complicated and debated issue in the whole of chemistry. Particularly in the field of computational chemistry, many researchers have tried to formulate unambiguous criteria for this elusive property during the past few decades; for a comprehensive work on aromaticity we refer to the book by Minkin, Glukhovstev and Simkin.[19] It is known that aromaticity involves the cyclic electron delocalisation coupled with an energetic stabilization, but the underlying physical nature of this aromatic stabilization is not known. An extensive set of criteria, which can be grouped into structural, energetic and magnetic criteria, can be found in literature, but it is believed that none of them alone can lead to an unambiguous definition of aromaticity. For this reason, an attempt is made in this work to combine a structural, an energetic and a magnetic criterion in order to ascertain whether the title compound is aromatic, anti-aromatic or nonaromatic.

In the first instance an attempt was made to qualitatively describe the influence on the aromaticity of the fragment closing the heterocyclic NSNS ring using structural and magnetic criteria. For a benzene ring as the closing fragment it was found in the gas-phase electron diffraction (GED) study[5] of 1,3λ²δ⁴,2,4-benzodithiadiazine that the heterocycle features one localized single S−N bond [1.697(5) Å] and two localized S=N double bonds [1.548(3) and 1.543(3) Å]; this trend was confirmed by a B3LYP/6-311+G* calculation yielding 1.717, 1.570 and 1.566 Å as the bond lengths, respectively. This geometrical data, together with a calculated NICS value of 14.99 ppm at the B3LYP/6-31+G* level,[6] indicates that the heterocyclic ring is anti-aromatic; a positive value indicates anti-aromaticity, a value approximating zero nonaromaticity and a negative value aromaticity. For 5-oxo-1,3,2,4-dithiadiazole (**1**), where the ring is closed by a carbonyl group, we find more intermediate bond lengths of 1.641, 1.608 and 1.595 Å, which suggest a higher degree of electron delocalisation and thus a higher degree of aromaticity. The NICS value of −11.13 ppm confirms the suggestion that the molecule is aromatic. Other structural criteria also express this electron delocalisation. Table 5 presents the calculated bond orders of Roesky's ketone (**1**), which can be conveniently combined with a graphical representation of the electron delocalisation in the form of a deformation electron density. For Roesky's ketone (**1**) the latter is plotted in Figure 6 through the molecular plane. It is clear from Figure 6 that the bond-order values can be correlated with the peak heights on the bonds in the deformation map: the three N−S bonds have similar bond orders (0.94, 1.23 and 0.98) and produce peaks of similar height in the density map, indicative of electron delocalisation. The C−N bond is somewhat stronger (1.33)

and the C=O bond can be interpreted as a true double bond (1.94). The C−S bond (0.74), which is longer than expected, has indeed the lowest electron density between the two nuclei involved in the bond.

As the second part of this qualitative description, an energetic criterion was used as a measure of the (anti/non)aromatic character. For 1,3λ^{2}δ^4,2,4-benzodithiadiazine the UV/Vis absorption spectrum shows a maximum at 617 nm which is due to the heterocycle.[20] Our own measurements performed on Roesky's ketone produce a maximum absorption wavelength of 369 nm. The calculated value of the HOMO−LUMO gap, which is 342 nm at the B3LYP/6-311+G* level, is relatively close to the experimental one. It is known that the HOMO−LUMO separation may serve as an indicator of structural stability and reactivity; in the case of aromaticity, a larger HOMO−LUMO gap indicates a larger aromatic stabilisation (see ref.[19] and references cited therein). Based on this, the difference between the two λ_{max} values of the two compounds can serve to distinguish 5-oxo-1,3,2,4-dithiadiazine (aromatic) from 1,3λ^{2}δ^4,2,4-benzodithiadiazine (antiaromatic). The three criteria form a consistent set. As already mentioned in the introduction, the properties of compounds containing an NSNS fragment differ considerably from those of their hydrocarbon analogues. This can be illustrated here again by comparing Roesky's ketone (6 π-electrons), which is clearly aromatic, with its hydrocarbon analogue, the antiaromatic cyclopentadienone (4 π-electrons). These findings are in agreement with Hückel's $4n + 2$ π-electron rule.[21] In 1972 Banister[22] proposed that planar sulfur−nitrogen heterocycles are electron-rich compounds that show aromaticity, in agreement with Hückel's rule. He supported this contention with S_2N_2, S_4N_3 and S_5N_5 as examples. In our study we see that the aromaticity of our ring system, containing a carbonyl group besides the nitrogen and sulfur atoms, complies with Hückel's rule as well.

After this successful qualitative description of the aromaticity of the title compound, an attempt was made to obtain a quantitative insight into the combination of calculated bond orders, bond lengths and NICS values so that a description of the degree of aromaticity could be constructed. To do this, three constitutional isomers of 5-oxo-1,3,2,4-dithiadiazole (**1**), in which the sulfur and nitrogen atoms are permutated, were included in the calculations. The structures of the isomers 5-oxo-1,2,3,4-dithiadiazole (**2**), 5-oxo-1,4,2,3-dithiadiazole (**3**) and 5-oxo-2,3,1,4-dithiadiazole (**4**) are given in Figure 1. The molecular geometries, bond orders, total energies and NICS values of these three compounds are given in Table 5; the data for Roesky's ketone (**1**) is added for comparison. The NICS(0) values, calculated in the molecular plane, are negative for all isomers. It has been pointed out by Schleyer et al.[23] that there are some artifacts in NICS(0) values calculated in the plane of the molecule, due to the σ-framework of the molecule. In order to circumvent this, they proposed to calculate NICS(1) values at 1 Å above the ring center, since aromaticity rather involves the delocalization of the π-electrons. Based on the NICS(0) values, all molecules are aromatic. For **3** the NICS(0) and NICS(1) values are almost equal and considerably smaller than for the other isomers, suggesting that this isomer is nonaromatic. The bond orders and bond lengths of **3** indicate that all bonds are single, except the N=N and C=O bonds, which are localized double bonds. The localized nature of the latter bond is found in all isomers and we conclude that these π-electrons do not play any role in stabilizing the ring. The fact that all other bonds in **3** are single or localized double bonds is in

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

accordance with the magnetic criterion NICS, and together they confirm that 5-oxo-1,4,2,3-dithiadiazole (**3**) is nonaromatic.

The other three isomers — **1**, **2** and **4** — all have larger negative values for NICS(0) and considerably negative values of NICS(1). These compounds must, therefore, all be aromatic, and the most aromatic of the series, according to this magnetic criterion, is 5-oxo-2,3,1,4-dithiadiazole (**4**). For this compound all bond orders have a value of about 1.00, which suggests there is maximum electron delocalization, i.e. a very narrow range of bond-order values of the bonds in the five-membered ring. This is in agreement with the two NICS values. The two remaining compounds, 5-oxo-1,3,2,4-dithiadiazole (**1**) and 5-oxo-1,2,3,4-dithiadiazole (**2**), could be classified as being of intermediate aromaticity, even though the structural and magnetic criteria put them in a different order.

We notice here that the overestimation of the C−S bond length at the B3LYP/6-311+G* level of theory has apparently no influence on the description of the electron delocalisation, whereas the excellent description of the relative bond lengths in the NSNS fragment by this method is obviously very important.

As a more general conclusion it can be stated that it is possible to qualitatively determine the (anti/non)aromatic nature of a system by combining structural, energetic and magnetic criteria. Some general quantitative trends can be found as well, even though a real numerical determination of the degree of aromaticity for Roesky's ketone (**1**) and its three studied isomers does not lead to an unambiguous order of aromaticity. Since these isomers cannot be interrelated by isodesmic reactions, no conclusion pertaining to their aromaticity can be drawn from the total energy values, which are also given in Table 5. The energy differences contain both different contributions due to the different kinds of bonds in the isomers and contributions due to the aromatic stabilization. Because these contributions cannot be separated, the total energies cannot be used as an aromaticity criterion.

Reactivity and Reactive Sites

We finally turn our attention to the local reactivity description by means of the condensed Fukui functions and local softnesses calculated for Roesky's ketone (**1**); these are given in Table 6. The stockholder charges, discussed above, will be used in this reactivity description as well. For all details on Fukui functions and local softnesses, and on the related global and local softness and hardness concept, we refer the reader to a recent review.[24] We mention here that a maximum value of the Fukui function, f^+, and local softness, s^+ (or f^- and s^-), indicates the most suitable place for nucleophilic (or electrophilic) attack by a soft species. As can be seen from Table 6, S3 has the largest s^+ value, and it also has the largest positive charge (Table 3). From these findings we know that S3 is the preferred site for a nucleophilic attack both by soft and hard reagents. The most likely site for an electrophilic attack is S1, but in view of its positive charge one does not expect a charge-controlled electrophilic attack to take place at this atom; rather, S1 is the favoured site for an orbital-controlled (based on the Fukui functions) electrophilic attack. The question of which site in Roesky's ketone (**1**) *is* favoured for a charge-controlled electrophilic attack can be answered in the following way.

The next highest value of f^- in Table 6 is found for S3 but, again, this site is disfavoured for a charge-controlled electrophilic attack due to its high positive atomic charge. Just below the value of S3 we find O5 and, even though it has a lower local softness value for electrophilic attack than both sulfur atoms, it has a pronounced negative charge and therefore is the most likely site for the charge-controlled attack by a hard electrophile. This has indeed been observed experimentally:[11] reactions between Roesky's ketone and electron-deficient hard Lewis acids like BF_3, $SbCl_5$ and $SnCl_4$ always yield adducts in which the metal atom is coordinated to the oxygen atom, the site predicted by assuming a charge-controlled regioselectivity.

Finally, we note that the local softness can also be seen as a measure of the ability of an atom to adapt its charge when electrons are added to or removed from a molecule. Upon inspection of the calculated stockholder charges of the cationic and anionic forms of Roesky's ketone (Table 3), we indeed find that the sulfur atoms — the softest atoms — are most suited as electron donor and as electron acceptor: upon oxidation or reduction of **1** the change of the atomic charge of both sulfur atoms is the largest in the molecule. More qualitatively, the softness of an atom can also be expressed by the diffuseness of the electron cloud surrounding it, and in this context we refer to the figure containing the deformation electron-density map (Figure 6): the lone pairs on the sulfur atoms — the softest atoms — are more diffuse than the ones on the harder nitrogen atoms.

Table 6. Fukui functions, f^+ and f^-, and local softnesses, s^+ and s^-, of the different atoms in Roesky's ketone (**1**)

Conclusions

5-Oxo-1,3,2,4-dithiadiazole was synthesized and its structure re-determined experimentally by single-crystal X-ray diffraction. The experimental molecular geometry was compared to the B3LYP/6-311+G* geometry and a good agreement was found, except for the C−S bond, which is overestimated by the calculation. Further molecular and atomic properties were calculated at this level to obtain insight into the structure, aromaticity and reactivity of the title com-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pound. A Hirshfeld partitioning of the electron density was used to calculate the atomic charges and dipoles, which led directly to the understanding of the origin of the molecular dipole. Based on frontier-orbital topologies, the geometries of the ionic forms of Roesky's ketone were explained. A consistent combination of structural, magnetic and energetic criteria confirmed that the compound is aromatic. An attempt to quantify the aromaticity, based on NICS values, bond lengths, bond orders and deformation densities, was made, and even though some general trends can be found, a real quantification was not possible for these compounds. Finally, a number of reactivity descriptors from conceptual DFT were calculated and the reactive sites within the molecule could be identified.

We note that, based on the finding that the π-system in the heterocycle of Roesky's ketone is delocalised over the entire ring, it would be incorrect to use the λ,δ-nomenclature, as this suggests localisation. The contrast between 1,3$\lambda^2\delta^4$,2,4-benzodithiadiazine (localised π-system and antiaromatic compound) and 5-oxo-1,3,2,4-dithiadiazole (**1**; delocalised π-system and aromatic compound) can now be conveniently made by omitting the λ,δ descriptors.

Experimental Section

Synthesis: 5-Oxo-1,3,2,4-dithiadiazole (**1**) was synthesised by a modification of a procedure reported by Neidlein and Gieren;[9] the reaction sequence is given in Figure 2. Unless otherwise stated, manipulations were performed under oxygen-free argon using standard Schlenk techniques and flame-dried Schlenk glassware. Hexane and chloroform were dried, purified and stored according to common procedures.[25] Chlorocarbonylsulfenyl chloride was purchased from Lancaster and used as received; bis(trimethylsilyl)-sulfur diimide was prepared according to a literature method.[26] The UV/Vis absorption spectrum was obtained from a solution in dry CH_2Cl_2 with a Hitachi U-2001 double-beam spectrometer. A solution of bis(trimethylsilyl)sulfur diimide (5.23 g, 5.97 mL, 25.33 mmol) in chloroform (30 mL) was added dropwise over a 40 min period to a stirred and cooled (0 °C) solution of chlorocarbonylsulfenyl chloride (3.32 g, 2.10 mL, 25.35 mmol) in chloroform (30 mL). Once the addition was complete, the stirred reaction mixture was slowly warmed to room temperature, then heated to 40 °C for 20 min and then allowed to cool to room temperature. Hexane (60 mL) was added and the mixture was filtered through a stainless steel cannula to remove any insoluble material. The volume of the filtrate was reduced in vacuo to approximately 50 mL and then stored at −14 °C overnight. The resulting yellow crystalline material was collected by suction filtration, washed with cooled (0 °C) hexane (10 mL) and then dried briefly in vacuo. The yield was 1.63 g (53%). UV/Vis (CH_2Cl_2): λ_{max} = 369 nm.

X-ray Structure Determination: Single crystals of 5-oxo-1,3,2,4-dithiadiazole (**1**) suitable for X-ray diffraction studies were obtained by slow sublimation of the bulk material at room temperature and pressure under argon over a two month period. Crystal structure data for the compound were collected at 125 K with a Bruker SMART CCD diffractometer equipped with an Oxford Instruments low-temperature attachment, using Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2. Refinements were performed using SHELXTL (Version 5.10, Bruker AXS, 1999). Crystal data for 5-oxo-1,3,2,4-dithiadiazole (**1**): CN_2OS_2, M = 120.15, orthorhombic, a = 13.029(3), b = 12.762(3), c = 9.145(2) Å, V = 1520.6(6) Å^3, T = 125(2) K, space group *Pbca*, Z = 16 with two nonequivalent molecules in the asymmetric unit, D_c = 2.099 g·cm^{-3}, μ(Mo-K_α) = 1.207 mm^{-1}, 1359 unique reflections (R_{int} = 0.0206) measured. Final R_1 [1097, $F \geq 2\sigma(F)$] = 0.0225, wR (all F^2) = 0.0580. CCDC-238171 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Calculations: All calculations were performed on isolated molecules using the BRABO[27] and Gaussian 98[28] suites of programs applying the Density Functional level of theory (DFT), using the Becke-type three-parameter hybrid functional,[29] B3LYP[30] and the 6-311+G*[31,32] basis set. Initially, the geometry of Roesky's ketone was calculated in C_1 symmetry, but the structure converted into a planar conformation. Consequently, the symmetry was raised to C_s, the geometry was re-calculated and a frequency calculation was performed to ascertain that the resulting structure was indeed an energy minimum. All subsequent calculations of molecular properties were performed at the B3LYP/6-311+G* geometry. Deformation densities were calculated by subtracting the pro-molecular density from the total molecular density. Stockholder charges were calculated as previously reported,[15] based on the Hirshfeld partitioning of the space.[33] Atomic dipole moments, μ_A, were calculated according to

$$\mu_{A,n} = -\int r_n \Delta\varrho_A(\vec{r}) \mathrm{d}\vec{r}$$

with $n = x, y, z$, $\vec{r}$ = the position vector of the atom and $\Delta\rho$ = the deformation density, as usually defined.[16] Nucleus-Independent Chemical Shifts (NICS)[34] were calculated at the B3LYP/6-311+G* level of theory, in the geometrical centre of the ring [NICS(0)] and at a distance of 1 Å perpendicularly above the ring centre [NICS(1)], using the Gauge Independent Atomic Orbitals (GIAO) method as implemented in Gaussian 98. Bond orders were calculated according to Mayer's definition.[35] The Fukui function[36] was calculated by the finite difference approach.[24] Geometries and molecular properties of the three constitutional isomers **2**−**4** and the anionic and cationic forms of Roesky's ketone (**1**) were calculated at the B3LYP/6-311+G* level. A procedure analogous to the one applied to the parent compound indicated that the constitutional isomers and the ionic forms also have C_s symmetry. Cartesian coordinates and energies of all compounds are given in the Supporting Information.

Synthesis and Characterization of Mixed Phthalocyaninato and *meso*-Tetrakis(4-chlorophenyl)porphyrinato Triple-Decker Complexes – Revealing the Origin of Their Electronic Absorptions

Xuan Sun,[a] Renjie Li,[a] Daqi Wang,[b] Jianmin Dou,[b] Peihua Zhu,[a] Fanli Lu,[a] Changqin Ma,[a] Chi-Fung Choi,[c] Diana Y. Y. Cheng,[c] Dennis K. P. Ng,[c] Nagao Kobayashi,[d] and Jianzhuang Jiang*[a]

Keywords: Phthalocyanines / Porphyrins / Rare earth metals / Sandwich complexes / Triple-decker complexes

Two series of mixed phthalocyaninato and porphyrinato rare earth(III) triple-decker complexes $[M_2(Pc)(TClPP)_2]$ (**1a–10a**) and $[M_2(Pc)_2(TClPP)]$ (**1b–11b**) [M = Y, La–Er except Ce and Pm; Pc = phthalocyaninate; TClPP = tetrakis(4-chlorophenyl)-porphyrinate] have been prepared by treating the half-sandwich complexes [M(TClPP)(acac)] (acac = acetylacetonate), generated in situ from $[M(acac)_3]\cdot nH_2O$ and $H_2(TClPP)$, with $Li_2(Pc)$. All the triple-decker complexes have been characterized by a wide range of spectroscopic and electrochemical methods. The molecular structures of $[M_2(Pc)(TClPP)_2]$ (M = Y, Ho) have also been determined, and show a symmetrical disposition of ligands, with two outer domed TClPP and one inner Pc rings. A systematic investigation of the optical and electrochemical data of these complexes has revealed the nature of the HOMO and LUMO, as well as the origin of the electronic absorptions of these triple-decker complexes.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Triple-decker rare-earth complexes with mixed phthalocyaninato and porphyrinato ligands have received considerable attention.[1] With two different classes of macrocyclic ligands, which can be arranged in different order in the complexes, this exotic class of compounds exhibits intriguing spectroscopic and electrochemical properties that cannot be found in non-sandwich counterparts. Owing to the high stability, the presence of multiple redox states, and the ability to store charge for a significant period of time, these triple-decker complexes are promising molecular-based materials for information-storage devices such as multistate counters and molecular capacitors.[2] Despite these important applications and other intrinsic interest in the structural and spectroscopic aspects, heteroleptic triple-deckers with these tetrapyrrole ligands remain rare and are confined to a number of lanthanides.[2–4] As part of our continuing interest in heteroleptic rare-earth complexes with tetrapyrrole ligands,[1,4] we describe herein a systematic study of two series of phthalocyaninato and porphyrinato triple-decker complexes, namely $[M_2(Pc)(TClPP)_2]$ (M = Y, La–Ho except Ce and Pm) and $[M_2(Pc)_2(TClPP)]$ (M = Y, La–Er except Ce and Pm), including their synthesis, spectroscopic and structural characterization, and electrochemical properties. A detailed examination of these properties has led to a better understanding of their electronic structure as well as the origin of the electronic transitions of these complexes.

Results and Discussion

Synthesis and Characterization

According to our previously described procedure,[4a,4b] treatment of [M(TClPP)(acac)] (M = Y, La–Er except Ce and Pm), generated in situ from $[M(acac)_3]\cdot nH_2O$ and $H_2(TClPP)$, with $Li_2(Pc)$ gave a mixture of the triple-deckers $[M_2(Pc)(TClPP)_2]$ and $[M_2(Pc)_2(TClPP)]$, which could be separated readily by column chromatography (Figure 1). The yields for both series of complexes {5–48% for $[M_2(Pc)(TClPP)_2]$ and 4–40% for $[M_2(Pc)_2(TClPP)]$} were higher for lanthanides with a moderate size, while both

early and late lanthanide analogues gave a lower yield (Tables S1 and S2, and Figure S1 in the Supporting Information). Attempts to isolate the late lanthanide complexes $[M_2(Pc)(TClPP)_2]$ (M = Er−Lu) and $[M_2(Pc)_2(TClPP)]$ (M = Tm−Lu) were not successful. Apparently, mid-lanthanides have an appropriate size to optimize the separation of the three ligands so that they are close enough to maximize the stabilization due to π-π interactions yet the axial compression of the π-systems remains tolerable. This balance leads to a higher stability and therefore a higher yield of the complexes.

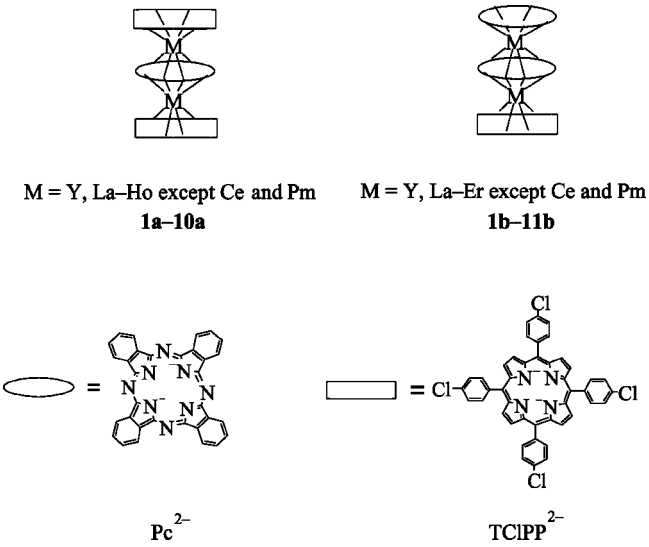

Figure 1. Schematic structures of the mixed-ring rare-earth triple-decker complexes with phthalocyaninato and *meso*-tetrakis(4-chlorophenyl)porphyrinato ligands

Except for a few early lanthanide triple-deckers, which are not very stable even in the solid state, all the triple-deckers gave satisfactory elemental analysis results (Tables S1 and S2). Intense molecular ion (or protonated molecular ion) peaks with expected isotopic patterns were also observed in the MALDI-TOF mass spectra for all these complexes. The mass spectroscopic data are also summarized in Tables S1 and S2, and a partial MALDI-TOF spectrum of $[Tb_2(Pc)(TClPP)_2]$ (**7a**) showing the isotopic distribution of the protonated molecular ion and the corresponding simulated spectrum is given in the Supporting Information (Figure S2) as an example.

Table 1 collects the ^1H NMR spectroscopic data of the triple-deckers $[M_2(Pc)(TClPP)_2]$ [M = Sm (**4a**), Y (**9a**)] and $[M_2(Pc)_2(TClPP)]$ [M = Sm (**4b**), Y (**9b**)] in $CDCl_3$. The spectral assignment could easily be made on the basis of the integration and multiplicity of the signals, and with reference to the previous results for the Eu analogues **5a** and **5b**,[4b] and the triple-deckers $[M_2(Pc)(TPyP)_2]$ [M = La, Eu; TPyP = *meso*-tetrakis(4-pyridyl)porphyrinate].[4f] Satisfactory NMR spectroscopic data, however, could not be obtained for the other triple-deckers due to the highly paramagnetic character of the metal centers.

Electronic Absorption Spectra

The electronic absorption spectra for both series of triple-decker complexes **1a**−**10a** and **1b**−**11b**, were measured in $CHCl_3$ and the data are compiled in Tables 2 and 3. Figures 2 and 3 display the spectra for $[M_2(Pc)(TClPP)_2]$ and $[M_2(Pc)_2(TClPP)]$ (M = Nd, Gd, Dy), respectively, as examples. For the first series of complexes, the Pc Soret band at 354−360 nm shifts slightly to the blue, while the Q-band absorptions at 485−494, 548−573, and 876−997 nm are all red-shifted due to the lanthanide contraction (Table 2). The TClPP Soret band at 418−420 nm and the remaining Q band at 606−608 nm remain relatively unshifted for the whole series of complexes.

Some of the absorption bands of **1b**−**11b** are also dependent on the size of the metal centers. As shown in Table 3, the TClPP Soret band at 411−418 nm and the longest-

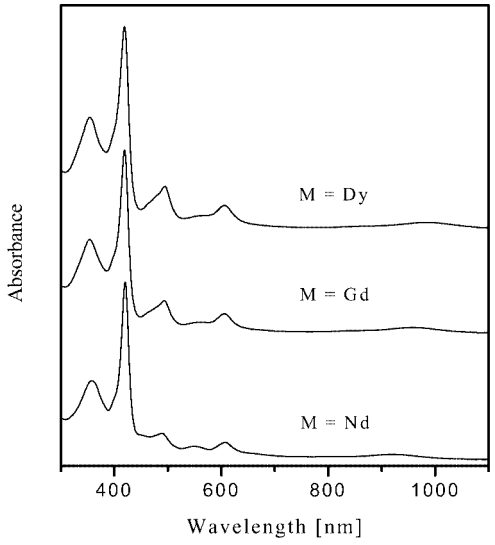

Figure 2. Electronic absorption spectra of $[M_2(Pc)(TClPP)_2]$ (M = Nd, Gd, Dy) in $CHCl_3$

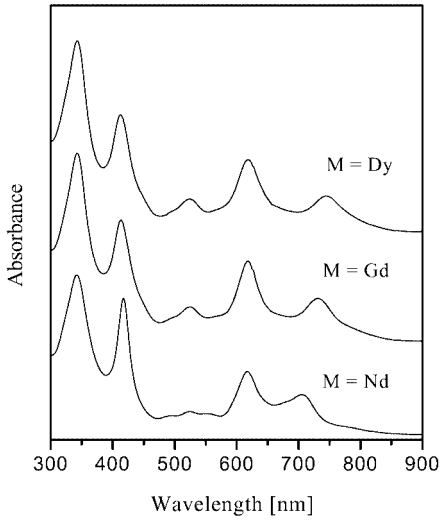

Figure 3. Electronic absorption spectra of $[M_2(Pc)_2(TClPP)]$ (M = Nd, Gd, Dy) in $CHCl_3$

wavelength Q-band at 689−757 nm are shifted to the blue and red, respectively, across the lanthanide series. For this series of complexes, the positions of the Pc Soret band (342−343 nm) and the other Q-bands in the visible region are not very sensitive to the metal centers.

In the mixed-ring triple-deckers $[M_2(Pc)(TClPP)_2]$ (**1a**−**10a**) and $[M_2(Pc)_2(TClPP)]$ (**1b**−**11b**), the close proximity of the three conjugated π-systems in a face-to-face configuration induces a splitting of the monomer (Pc and TClPP) molecular orbitals. As shown in Figure 4, the interactions of the doubly degenerate e_g LUMO of both ligands, the a_{1u} HOMO of Pc, and the a_{1u} second HOMO of TClPP result in the formation of three doubly degenerate lowest-unoccupied molecular orbitals (the bonding LUMO, second non-bonding LUMO, and third anti-bonding LUMO) and three non-degenerate highest-occupied molecular orbitals (the third bonding HOMO, second non-bonding

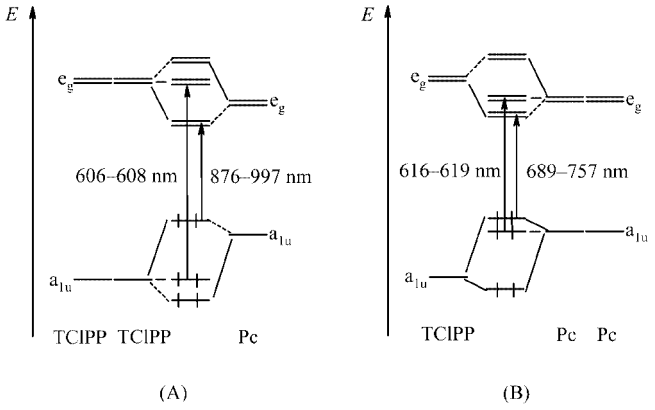

Figure 4. Partial molecular-orbital diagrams for $[M_2(Pc)(TClPP)_2]$ (A) and $[M_2(Pc)_2(TClPP)]$ (B)

HOMO, and first anti-bonding HOMO).[5] Due to the intrinsic difference in the electronic structure, the a_{1u} orbital of Pc is higher in energy than that of TClPP, while the e_g orbitals of Pc are lower than those of TClPP. Therefore, for both series of triple-deckers, the first anti-bonding HOMO and the first bonding LUMO are mainly from the phthalocyaninato ligand(s), whereas the third bonding HOMO and third anti-bonding LUMO have higher porphyrin character. The second non-bonding HOMO and non-bonding LUMO are pure TClPP and Pc orbitals, respectively, for $[M_2(Pc)(TClPP)_2]$ (**1a**−**10a**) and $[M_2(Pc)_2(TClPP)]$ (**1b**−**11b**). Along with the lanthanide contraction, the ring-to-ring interactions increase, resulting in an increase in the splitting between the first and second HOMOs as well as the second and third HOMOs of the triple-deckers. This simplified bonding picture can be used to interpret the electronic absorption data of these triple-decker complexes. For both series of complexes, the lowest-energy absorption band can be attributed to the electronic transition from the anti-bonding HOMO to the bonding LUMO, which is red-shifted across the lanthanide series (Tables 2 and 3). The second-lowest-energy absorption band can be ascribed to the transition from the second non-bonding HOMO to the second non-bonding LUMO, which remains essentially unchanged for the whole lanthanide series. Similarly, the Soret bands at 418−420 nm for $[M_2(Pc)(TClPP)_2]$ (**1a**−**10a**) and 342−345 nm for $[M_2(Pc)_2(TClPP)]$ (**1b**−**11b**) should also involve non-bonding orbitals with a pure TClPP or Pc character, respectively. It is worth noting that the dependence of the other Soret bands at 354−360 nm for $[M_2(Pc)(TClPP)_2]$ (**1a**−**10a**) and 412−418 nm for $[M_2(Pc)(TClPP)_2]$ (**1b**−**11b**) on the rare-earth ionic size clearly indicates the mixed phthalocyanine and porphyrin character of these transitions, suggesting the contributions from both porphyrin and phthalocyanine ligands to the molecular orbitals involved in these transitions.

IR Spectra

IR spectroscopy is a useful tool to reveal the nature of phthalocyaninato ligands in their rare-earth sandwich complexes. The IR characteristics of several series of double- and triple-decker phthalocyaninato and/or porphyrinato rare-earth compounds, namely $[M(Pc')_2]$, $[M(Pc')(Por)]$, $[M_2(Pc')(Por)_2]$, and $[M_2(Pc')_2(Por)]$ (Pc′ = general phthalocyaninate; Por = general porphyrinate) have been systematically studied.[6] An intense band at 1312−1323 cm^{-1} has been observed for neutral bis(phthalocyaninato) and mixed (phthalocyaninato)(porphyrinato) rare earth(III) double-decker complexes. This can be attributed to the $Pc^{\cdot-}$ IR marker band. On the other hand, a moderately strong band at ca. 1329 cm^{-1} has been observed for $[Ce^{IV}(Pc)_2]$ and $[M_2(Pc)_2\{Pc(OC_8H_{17})_8\}]$ $[Pc(OC_8H_{17})_8$ = 2,3,9,10,16,17,23,24-octaoctyloxyphthalocyaninate], which contain dianionic phthalocyanine rings. This band is therefore regarded as the characteristic IR band for Pc^{2-}.[6] For the present two series of complexes, the dianionic nature of the phthalocyaninato ligand(s) was unambiguously verified by the observation of the characteristic Pc^{2-} IR band at ca. 1330 cm^{-1}. As expected, the relative intensity of this band is higher for **1b**−**11b** than for **1a**−**10a** due to the higher Pc/TClPP ratio.

Structural Studies of $[M_2(Pc)(TClPP)_2]$ (M = Y, Ho)

The molecular structures of $[M_2(Pc)(TClPP)_2]$ [M = Y (**9a**), Ho (**10a**)] were determined by X-ray diffraction analysis. Both compounds are isostructural and crystallize in the same tetragonal system with a *P*4/*n* space group together with a disordered CH_2Cl_2 molecule. It is worth noting that structurally characterized mixed-ring triple-deckers remain rare so far, and to the best of our knowledge they are limited to [(TPP)Ce(Pc)Gd(OEP)] (TPP = *meso*-tetraphenylporphyrinate; OEP = octaethylporphyrinate),[7] $[Ce_2(Pc)_2(TOMePP)]$ [TOMePP = *meso*-tetrakis(4-methoxyphenyl)porphyrinate],[8] $[Ce_2\{Pc(OMe)_8\}(TPP)_2]$ [Pc-$(OMe)_8$ = 2,3,9,10,16,17,23,24-octamethoxyphthalocyaninate],[8] $[Nd_2(Pc)_2(TOMePP)]$,[9] and $[Nd_2(Nc)(OEP)_2]$ (Nc = naphthalocyaninate).[4d]

Figure 5 shows the molecular structure of $[Ho_2(Pc)(TClPP)_2]$ (**10a**) in two different perspective views. Each holmium center is octa-coordinated by the pyrrole and isoindole nitrogen atoms of an outer TClPP and the central Pc rings, respectively, confirming the arrangement of ligands as [(TClPP)Ho(Pc)Ho(TClPP)]. The two holmium centers, however, are not identical in terms of their coordination geometry and separation from the ligands. The Ho1 atom adopts a slightly distorted square-antiprismatic structure while the Ho2 atom exhibits a slightly distorted cubic geometry. The Pc ring is slightly domed toward the Ho2 atom. Both holmium centers lie closer to the TClPP ring due to its larger central cavity compared with the Pc ligand (1.131 vs. 2.004 Å for Ho1; 1.218 vs. 1.687 Å for Ho2), and are not equidistant from the TClPP and Pc ligands. These structural features are clearly different from those revealed in the triple-deckers $[Ce_2\{Pc(OMe)_8\}(TPP)_2]$[8] and $[Nd_2(Nc)(OEP)_2]$,[4d] which are centrosymmetric and have two identical metal environments. This could be attributed to the different crystal packing forces for these complexes.

Electrochemistry

The redox behavior of the mixed-ring triple-deckers **1a**−**10a** and **2b**−**11b** was studied by cyclic voltammetry (CV) and differential pulse voltammetry (DPV) in CH_2Cl_2. Within the electrochemical window of CH_2Cl_2, five quasi-reversible one-electron oxidations and up to four quasi-reversible one-electron reductions were revealed for **1a**−**10a**. An additional reduction couple was observed for most of the triple-deckers in the series $[M_2(Pc)_2(TClPP)]$ (**3b**−**9b** and **11b**). The half-wave potentials for these two series of complexes are summarized in Tables 4 and 5. All these redox processes can be attributed to the successive removal of electrons from, or addition of electrons to, the ligand-based orbitals, as the oxidation state of the central trivalent rare-earth metals does not change. Figure 6 displays the cyclic and differential pulse voltammograms of **3a** and Figure 7 shows the variation of the redox potentials of **1a**−**10a** with the rare-earth ionic radii. It can be seen that the half-wave potentials of the first (O^1) and second (O^2) oxidation processes for **1a**−**10a**, which involve the removal of electrons from the HOMO, decrease linearly as the size of the metal center decreases. In contrast, the potentials of the other oxidation processes, including O^3 and O^4, which involve the second HOMO, remain virtually unchanged at 1.37−1.43 and 1.60−1.65 V (except **1a**). These results indicate that along with the lanthanide contraction, the HOMO increases in energy while the energy level of the second-highest occupied orbital remains relatively unchanged. This directly reveals the anti- and non-bonding nature for the HOMO and second HOMO and indirectly suggests the bonding nature for the third HOMO. All the reduction processes (R^1, R^2, R^3, and R^4) also appear to be insensitive to the size of the rare earth metal centers, suggesting that the energy level of the first (as well as the second and the third) lowest unoccupied orbital remains relatively constant for the whole series. Therefore, the energy separation between the HOMO and the LUMO diminishes across the series, while that between the second-highest non-bonding occupied orbital and the second-lowest non-bonding unoccupied orbitals remains constant. The decrease in energy gap between the HOMO and LUMO is in agreement with the red-shift of the longest-wavelength near IR band at

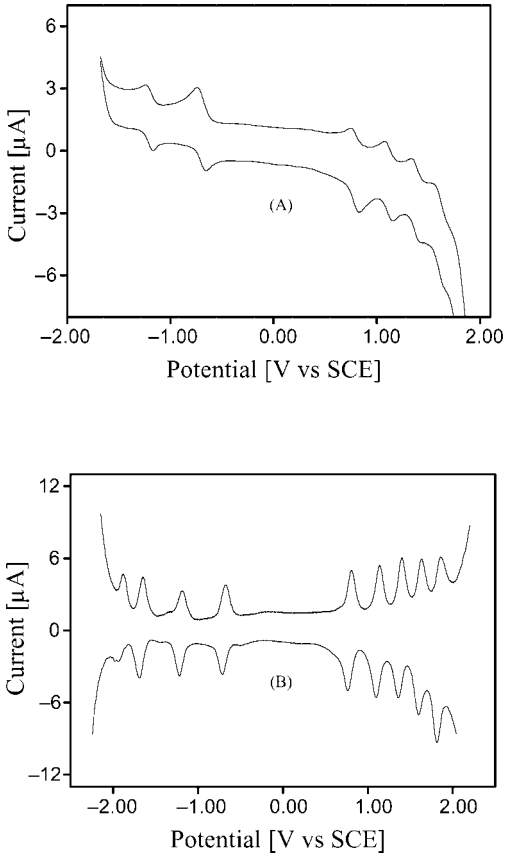

Figure 6. (A) Cyclic voltammogram and (B) differential pulse voltammogram of $[Nd_2(Pc)(TClPP)_2]$ (**3a**) in CH_2Cl_2 containing 0.1 M $[NBu_4][ClO_4]$ at a scan rate of 20 and 10 mV s^{-1}, respectively

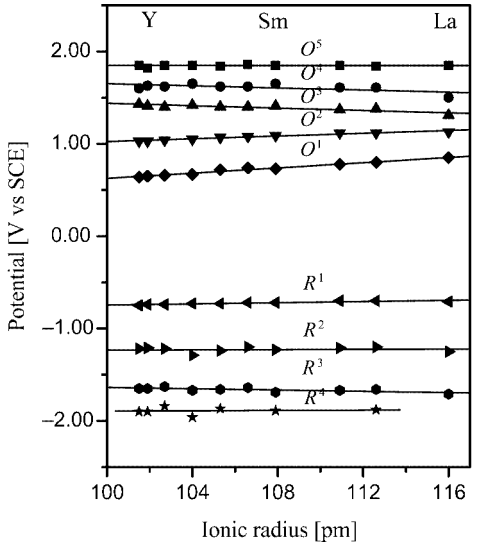

Figure 7. Plot of the half-wave potentials of the oxidation and reduction processes of $[M_2(Pc)(TClPP)_2]$ (**1a**−**10a**) as a function of the ionic radius of M^{III}

876−997 nm (Table 2). The main Q-band at 605−608 nm, which remains relatively unchanged for the whole series of complexes, can then be assigned to the electronic transition from the second-highest non-bonding occupied orbital to the second-lowest non-bonding unoccupied orbitals. The remaining weak Q-band at 551−573 nm is red-shifted as the size of the metal centers decreases (Table 2). This suggests that this absorption may arise from the electronic transition from the HOMO to the third-lowest unoccupied orbitals as the energy gap between these two sets of orbitals decreases across the series from La to Ho. Figure S3 (Supporting Information) compares the energy levels for the La (**1a**) and Ho (**10a**) triple-deckers.

The electrochemical behavior of $[M_2(Pc)_2(TClPP)]$ (**2b**−**11b**) is similar to that of $[M_2(Pc)(TClPP)_2]$ (**1a**−**10a**). Similar trends were observed for their redox potentials (Table 5) as a function of the ionic radius of the metal center. Thus, similar conclusions could be drawn about the frontier molecular orbitals and the corresponding electronic transitions for this series of complexes, except that the second-highest occupied orbitals and the second-lowest unoccupied orbitals are of pure Pc character instead of pure TClPP character in $[M_2(Pc)(TClPP)_2]$. By comparing the data in Tables 4 and 5, it can be seen that the $[M_2(Pc)_2(TClPP)]$ complexes undergo oxidation (O^1 and O^2) and reduction (R^1 and R^2) more readily than the corresponding $[M_2(Pc)(TClPP)_2]$ complexes.

As the first oxidation and the first reduction processes involve a one-electron transfer from the HOMO and to the LUMO of the molecule, respectively, the energy difference between these two redox processes, $\Delta E^\circ_{1/2}(O^1 - R^1)$, should reflect the energy required for the electronic transition from

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the HOMO to the LUMO. This should therefore correlate with the lowest-energy electronic transition. As shown in Tables 4 and 5, the HOMO−LUMO gap for $[M_2(Pc)(TClPP)_2]$ (**1a**−**10a**) (1.39−1.56 V) is larger than that for $[M_2(Pc)_2(TClPP)]$ (**2b**−**11b**) (1.04−1.20 V). However, the lowest-energy electronic absorption band of **1a**−**10a** appears at longer wavelength than that of **2b**−**11b** due to the different ligand composition and ring-ring interaction in the two series. According to the electrochemical and absorption data for both series of triple-deckers tabulated in Tables 2−5, the equations $\Delta E^{\circ}_{1/2}(O^1 - R^1) - h\nu = -0.14$ (±0.02) and $\Delta E^{\circ}_{1/2}(O^1 - R^1) - h\nu = -0.58$ (±0.02) eV could be established for the series **a** and **b**, respectively, instead of the equation $\Delta E^{\circ}_{1/2}(O^1 - R^1) - h\nu = 0.01$ eV established for monomeric metalloporphyrins containing a pure porphyrin ligand.[10]

Conclusions

Two series of mixed (phthalocyaninato)(porphyrinato) rare earth triple-decker complexes $[M_2(Pc)(TClPP)_2]$ and $[M_2(Pc)_2(TClPP)]$ have been prepared. All these compounds have been fully characterized with a wide range of spectroscopic and electrochemical techniques. The molecular structures of two triple-deckers $[M_2(Pc)(TClPP)_2]$ (M = Y, Ho) have also been determined. Systematic studies of the spectroscopic and electrochemical properties of both series of compounds reveal the nature of some frontier molecular orbitals and the electronic absorption bands of these complexes.

Experimental Section

General Remarks: Anhydrous TCB (Aldrich) was used as received. Details regarding the treatment of the other solvents, preparation of the starting materials, and the instrumentation have been described previously.[11]

General Procedure for the Preparation of $[M_2(Pc)(TClPP)_2]$ (1a−10a) and $[M_2(Pc)_2(TClPP)]$ (1b−11b): A mixture of $H_2(TClPP)$ (75 mg, 0.10 mmol) and $[M(acac)_3]\cdot nH_2O$ (ca. 150 mg, 0.30 mmol) in TCB (20 mL) was refluxed under a slow stream of nitrogen for 4 h. The resulting dark cherry-red solution was cooled to room temperature, then $Li_2(Pc)$ (80 mg, 0.15 mmol) was added. The mixture was refluxed for a further 6 h, then the solvent was removed under reduced pressure. The violet-blue residue was chromatographed on a silica gel column using $CHCl_3$/hexanes (1:1) as eluent to give an olive-green band, which contained mainly the triple-decker $[M_2(Pc)(TClPP)_2]$, and a small amount of the double-decker $[M(Pc)(TClPP)]$ and unchanged $H_2(TClPP)$. After collecting this band, the column was further eluted with $CHCl_3$ to give a mixture of the triple-decker $[M_2(Pc)_2(TClPP)]$ and the double-decker $[M(Pc)_2]$. The triple-decker products were further purified by chromatography, followed by recrystallization from $CHCl_3$ and MeOH to give dark green or dark blue microcrystals of $[M_2(Pc)(TClPP)_2]$ and $[M_2(Pc)_2(TClPP)]$, respectively.

X-ray Crystallographic Analysis of 9a and 10a: Crystals suitable for X-ray diffraction analysis were grown by layering MeOH onto a CH_2Cl_2 solution of the compounds. Crystal data and details of data collection and structure refinement are given in Table 6. Data were collected with a Bruker SMART CCD diffractometer with an Mo-K_α sealed tube (λ = 0.71073 Å) at 293 K, using the ω-scan mode with an increment of 0.3°. Preliminary unit-cell parameters were obtained from 45 frames. Final unit-cell parameters were obtained by global refinements of reflections obtained from integration of all the frame data. The collected frames were integrated using the preliminary cell-orientation matrix. SMART software was used for collecting frames of data, indexing reflections, and determination of lattice constants; SAINT-PLUS for integration of intensity of reflections and scaling;[12] SADABS for absorption correction;[13] and SHELXL for space group and structure determination, refinements, graphics, and structure reporting.[14] CCDC-208839 (**9a**) and -208840 (**10a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336033; E-mail: deposit@ccdc.cam.ac.uk].

Diastereoselective Insertion of Isocyanide into the Alkyl−Metal Bond of Methylbenz[*e*]indenyl *ansa*-Zirconocene Complexes

Alfredo Sebastián,[a] Pascual Royo,*[a] Pilar Gómez-Sal,[a] and Carmen Ramírez de Arellano[b]

Keywords: Metallocenes / Zirconium / Insertion / Isocyanides / Polymerization

Alkylation of *ansa*-zirconocene [Zr{(η^5-C_5H_5)$SiMe_2$-(MBI)}Cl_2] (MBI = η^5-2-Me–$C_{13}H_7$) with MgRCl gave the dimethyl complex [Zr{(η^5-C_5H_5)$SiMe_2$(MBI)}Me_2], but unresolvable mixtures containing mono-alkylated compounds were obtained when bulkier alkyls were used. However pure dialkyl complexes [Zr{(η^5-C_5H_5)$SiMe_2$(MBI)}R_2] (R = CH_2Ph, CH_2SiMe_3) were easily obtained using K(CH_2Ph) and Li(CH_2SiMe_3) as alkylating agents. Diastereoselective insertion into the MBI-unprotected Zr–R bond was observed when all of these dialkyl complexes were treated with 2,6-xylyl isocyanide to give the iminoacyl compounds [Zr{(η^5-C_5H_5)$SiMe_2$(MBI)}R{CR[η^2-*N*-(2,6-xylyl)]}] (R = Me, CH_2Ph, CH_2SiMe_3). All of the new complexes were characterized by NMR spectroscopy and the X-ray molecular structures of the dibenzyl and the imino-benzyl compounds were determined. The catalytic activity for ethene polymerization and ethene/1-hexene copolymerization of the dichloro zirconocenes [Zr{(η^5-C_5H_5)EMe_2(MBI)}Cl_2] (E = C, Si), activated with methylalumoxane (MAO), was measured.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

The rational design of different types of group 4 metallocenes to be used as olefin polymerization catalysts, after activation with methylalumoxane (MAO), has been the objective of a great number of scientific contributions.[1−5] Extensive studies have demonstrated the high degree of electronic and steric control provided by sterically demanding cyclopentadienyl ligands, making them powerful tools for producing convenient single-site catalysts for the known broad range of precisely functionalized, tacticity-controlled, branched and block polymers and copolymers.[6−8] The main targets of many of the studies have been the optimization of catalytic activity, stereospecificity and the modulation of the molecular weight of the resulting polymers.[9,10] It is well-known that the presence of condensed benzene rings in the indenyl ligands of metallocene-type complexes induces a remarkable increase in their catalytic activity, and the addition of a 2-methyl substituent in their Cp rings reduces the incidence of β-elimination processes, providing a significant increase in the molecular weight of the polymer. In this regard the 2-methylbenz[*e*]indenyl ligand (MBI) is an excellent choice for this purpose. The isolation of the first group 4 metallocenes containing this ligand has demonstrated high performance in ethylene and propylene polymerization[11,12] as well as in copolymerization processes using ethylene and octene[13] or ethylene/polar monomers such as 10-undecene-1-ol and allyl alcohol.[14,15]

Metal alkyl compounds are convenient models not only for olefin polymerization but also for other insertion and transmetallation reactions and as carbon−carbon bond formation precursors.[16−18] Insertion of unsaturated substrates into metal−alkyl bonds are basic reactions for which many synthetic, mechanistic and theoretical studies have been developed.[19] The migratory insertion of isocyanide has provided numerous iminoacyl complexes[20−24] and a solid knowledge of the steric and electronic effects of the ligands on the reactivity[25] and catalytic activity[9] of different systems.

We report herein the effect of the bulky MBI ligand on the stereoselectivity of the migratory insertion of 2,6-dimethylphenyl isocyanide into the metal−alkyl bonds of new dialkyl metallocenes prepared from the dichloro derivatives reported recently.[26] We also report the results found from our studies of catalytic activity of these dichloro-metallocenes in the homopolymerization of ethylene and copolymerization of ethylene/1-hexene.

Results and Discussion

The dichloro *ansa*-zirconocenes [Zr{(η^5-C_5H_5)EMe_2(η^5-2-Me−$C_{13}H_7$)}Me_2] (E = C: **1a**, E = Si: **1b**) containing the

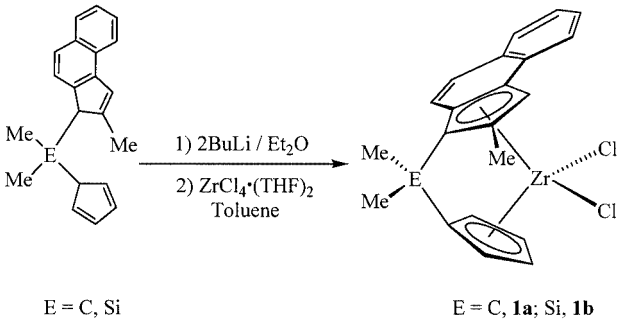
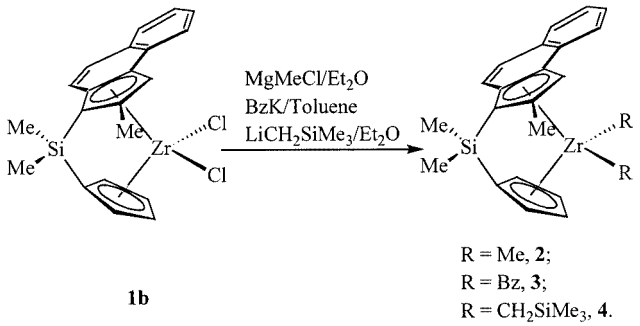
MBI ligand were isolated previously[26] by reaction in toluene of $ZrCl_4(THF)_2$ with the dilithium salts of the corresponding $-CMe_2-$ and $-SiMe_2$-bridged indenyl-cyclopentadienyl derivatives, as shown in Scheme 1.



Scheme 1

The reaction of complex **1b** with 2 equiv. of MgClMe gave dimethyl zirconocene [Zr{(η^5-C_5H_5)$SiMe_2$(η^5-2-Me$-C_{13}H_7$)}Me_2] (**2**) in high yield. However this type of dialkyl compound is not so easily accessible when bulky substituents are located at the cyclopentadienyl β-carbon of rigid *ansa*-metallocenes. The steric demands of the benzene rings attached to the α and β positions of the η^5-cyclopentadienyl unit in the MBI ligand of complex **1b**, make dialkylation difficult when bulky alkyl groups are used. In fact alkylation of **1b** with two equiv. of $MgCl(CH_2Ph)$ gave low yields of the dibenzyl complex [Zr{(η^5-C_5H_5)$SiMe_2$(η^5-2-Me$-C_{13}H_7$)}$(CH_2Ph)_2$] (**3**) which was always contaminated by significant amounts of the monobenzyl compounds. However complex **3** could be isolated in high yield as the unique component when $K(CH_2Ph)$ was used as the alkylating agent. Similarly, $MgCl(CH_2SiMe_3)$ has been extensively used[27,28] to produce dialkyl derivatives of many metallocenes with free cyclopentadienyl ligands, whereas related *ansa*-metallocenes usually yield the corresponding monoalkyl compounds.[29] Consistently the dialkyl complex [Zr{(η^5-C_5H_5)$SiMe_2$(η^5-2-Me$-C_{13}H_7$)}$(CH_2SiMe_3)_2$] (**4**) could not be isolated using the Grignard reagent but was easily obtained in high yield with the lithium derivative $Li(CH_2SiMe_3)$. It is therefore evident that the steric hindrance due to the bulky MBI ligand may be overcome using more appropriate nucleophilic alkylating agents, as shown in Scheme 2. The air sensitive dialkyl compounds **2**–**4** are



Scheme 2

stable in $CDCl_3$ under an inert atmosphere although they are transformed into the dichloro complex **1b** when heated at 110 °C in Teflon-valved NMR tubes.

The enantiotopic face of the MBI ligand makes these dialkyl compounds, **2**–**4,** asymmetric molecules with two nonequivalent alkyl groups. The ^{1}H NMR spectrum of **2** shows two singlets for the Zr-methyl groups, one shifted significantly highfield ($\delta = -1.29$) compared with the typical value ($\delta = 0.09$ ppm) observed for the other, which was in the range found for related methyl zirconocenes.[30] NOE experiments demonstrated that the highfield singlet is due to the methyl group located under the benzene ring attached to the indenyl moiety. Similar behavior was observed for the four doublets due to the two diastereotopic methylene protons of the benzyl (**3**) and methylsilyl (**4**) ligands. Two of the signals, corresponding to the alkyl group located under the ring-fused benzene, are shifted highfield ($\delta = 0.18$ ppm and 0.28 ppm for **3**; $\delta = -2.20$ ppm and -0.94 ppm for **4**) due to the anisotropic effect of the aromatic ring. However this anisotropic contribution was not observed in the ^{13}C and gHMQC NMR spectra (see Exp. Sect.). In addition, the ^{1}H NMR spectra of complexes **2**–**4** show the expected singlet for the MBI-methyl group, two singlets for Si–Me, four multiplets for the C_5H_4 ring and one singlet for the C_5H(MBI) ring proton. All of the remaining MBI nonequivalent protons give the set of signals corresponding to two AB and ABCD spin systems.

Slow cooling at −30 °C of a toluene solution of the dibenzyl complex **3** rendered appropriate crystals for X-ray diffraction studies. The X-ray structure of **3** is shown in Figure 1 with the atomic labeling scheme and selected bond lengths and angles are listed in Table 1.

The coordination geometry of the zirconium atom is the typical distorted tetrahedron formed by the two ring centro-

ids and the carbon atoms of the benzyl ligands. The Cp(centroid)−Zr−Cp_{MBI}(centroid) [125.8°] and the C(2)−Zr(1)−C(1) [97.4(2)°] angles are similar to those observed for related *ansa*-MBI compounds and the Cp(centroid)−Zr distances [Cp 2.212Å and Cp_{MBI} 2.262Å] are in the range found in related indenyl zirconocenes.[12,26,31,32]

The most remarkable difference is the orientation of the two nonequivalent benzyl ligands. One is located above the plane (torsion angle Cp_{MBI}−Zr(1)−C(1)−C(11) 62.6°) while the other is located below (torsion angle Cp_{MBI}−Zr(1)−C(2)−C(21) 158.1°), with respect to the C(1)−Zr(1)−C(2) plane. The benzyl ligand eclipsed by the MBI system positions the methylene C(2) under the benzene ring condensed to the indenyl moiety with the phenyl ring oriented towards the other Cp system, whereas the benzyl ring located on the open side, far away from the MBI system, has its phenyl ring directed towards the moiety with the MBI system using the wide space. In spite of these different orientations both benzyl ligands show Zr−C distances [Zr−C(1) 2.315(6) Å and Zr−C(2) 2.308(4) Å] and Zr−C−C(Ph) angles [Zr−C(1)−C(11) 121.8(4)° and Zr−C(2)−C(21) 125.5(3)°] typical of σ-bonded benzyl groups without benzallylic interactions [Zr−C(11) 3.338 and Zr−C(21) 3.389 Å], and are similar to values found[31,33] for other benzyl zirconium compounds with bulky Cp systems.

Reaction of diethyl ether solutions of the dialkyl complexes **2**−**4** with 1 equiv. of 2,6-xylyl isocyanide at room temperature gave the corresponding iminoacyl compounds [Zr{(η^5-C_5H_5)$SiMe_2$(η^5-2-Me−$C_{13}H_7$)}R{CR[η^2-*N*-(2,6-xylyl)]}] (R = Me: **5**, CH_2Ph: **6**, CH_2SiMe_3: **7**) as shown in Scheme 3, which were isolated as solids and characterized by elemental analysis and NMR spectroscopy. When monitoring the reactions by ^1H NMR spectroscopy it was observed that insertion was easier for less bulky alkyl ligands following the order **5** < **6** < **7**. The η^2-coordination of the isocyanide ligand is consistent with the IR [(Nujol): $\tilde{\nu}_{C=N}$ = 1600, 1585 and 1590 cm^{-1}] and ^{13}C NMR spectroscopic data [δ = 245.4 (**4**), 244.5 (**5**), 245.4 (**6**)]. Further reactions with an additional 1 equiv. or an excess of isocyanide were not observed under any conditions, as was expected for these types of coordinately saturated 18e species.

These insertion reactions may lead to two diastereomers depending on which of the two nonequivalent alkyl groups migrate to the isocyanide ligand. The ^1H NMR spectra confirm that one unique diastereoisomer is obtained in all of these reactions, for which the signals due to the alkyl group located under the MBI system remain almost unmodified [δ = −1.20(s) (**5**), 0.27(d) and 0.56(d) (**6**), −1.86(d) and −2.97(d) (**7**)]. In contrast, signals due to the alkyl group located far from the MBI system are significantly shifted lowfield [δ = 2.36(s) (**5**), δ 3.60(d) and 3.68(d) (**6**), 2.45(d) and 2.63(d) (**7**)] as expected for the migrated C-bonded alkyl ligand. NOE experiments on the methyl derivative (**5**) demonstrate that the highfield shifted singlet corresponds to the methyl group located under the MBI system, which is affected by the anisotropic effect of the aromatic ring.

Similar behavior is also observed in the ^{13}C NMR spectra which show significant lowfield shifts for all the signals due to the migrated alkyl group bound to the iminoacylic carbon atom, appearing at δ = 22.2, 44.6 and 22.7 for **5**, **6** and **7**, respectively. All of the remaining ^1H and ^{13}C NMR signals show no significant changes.

The ^1H NMR spectrum of complex **7** represented in Figure 2 shows the typical pattern of signals observed for both dialkyl and iminoacyl complexes.

Therefore it is possible to conclude that the steric demands of the bulky MBI system have a significant effect on the high diastereoselectivity of all of these insertion reactions, although the electronic contribution demonstrated for related [MBI]-silyl-η^1-amido zirconium complexes (work still in progress),[34] for which electronic effects are significantly important, cannot be discarded. However the spectroscopic data do not distinguish between the *exo*-*N*-coordinated iminoacyl formed under kinetic control and the usually more favorable *endo*-*N*-coordinated iminoacyl isomer formed under thermodynamic control. The *endo*-configuration was confirmed for complex **6** by X-ray diffraction studies of its molecular structure.

Appropriate crystals of **6** were isolated by slow evaporation of a C_6D_6 solution. Figure 3 shows the X-ray molecular structure of **6** with the atomic labeling scheme. Selected bond lengths and angles are collected in Table 2.

The pseudotetrahedral coordination of the zirconium atom is defined by the Cp, the Cp_{MBI}, the benzyl methylene

C(10)−Zr−N	32.92(6)	C(10)−N−Zr	71.12(12)
C(10)−Zr−C(2)	116.43(7)	C(61)−N−Zr	161.83(13)
N−Zr−C(2)	84.18(6)	N−C(10)−C(1)	124.31(19)
C(1)−C(10)−Zr	159.54(15)	N−C(10)−Zr	75.96(12)

carbon and the midpoint of the iminoacyl C−N bond. Both, the Cp−Zr and Cp_{MBI}−Zr lines are almost perpendicular to the corresponding C(31)−C(35) and C(41)−C(53) cyclopentadienyl main planes (87.3 and 85.0°, respectively). The Cp−Zr−Cp_{MBI} bond angle [124.3°] is closer than that observed for complex **3** indicating the larger bite of the cyclopentadienyl rings. The structure shows η^2-coordination of the iminoacyl ligand with the C−N bond almost perpendicular to the line going from the Zr atom to the C−N bond midpoint (87.4°). The iminoacylic-N adopts an *endo*-configuration, with a C(2)−Zr−C(10)−N torsion angle of 12.6(1)°, giving rise to a very open C(2)−Zr−C(10) angle [116.44(7)°]. The benzyl ligand is eclipsed by the MBI system, locating the methylene C(2) under the benzene ring condensed to the cyclopentadienyl moiety [C(2)−Zr−C(44)−C(45) torsion angle 16.4(2)°]. The phenyl group of the benzyl ligand [C(21)−C(26)] is *anti* to the MBI system with respect to the Zr−C(2) bond [C(21)−C(2)−Zr−Cp_{MBI} torsion angle 178.0°]. Thus, the benzyl group adopts a geometry similar to that observed for the eclipsed benzyl group in compound **3**.

The zirconium-carbon bond length [Zr−C(2) 2.372(2) Å] to the sp^3 methylene benzyl ligand is 0.06Å longer than that observed in complex **3** and longer than the distance to the sp^2 iminoacyl carbon atom[35] [Zr−C(10) 2.231(2) Å], which is in the range [2.164−2.363Å] observed for related iminoacyl zirconium compounds.[21,36] However the zirconium-nitrogen bond length [Zr−N 2.2872(16) Å] is

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

slightly longer than those found in related zirconium iminoacyl compounds in the range 2.148−2.250Å.[37,38] The double bond character of the iminoacyl C(10)−N bond is confirmed by the 1.281(3) Å distance, which is longer than usual for related zirconium iminoacyl compounds and close to that known for organic C=N bonds [1.28Å].[35] All of these elongated bonds are consistent with the steric hindrance due to the bulky MBI ring and the benzyl and 2,6-xylyl substituents.

Both the iminoacyl N and the C(10) sp^2 atoms show a profoundly distorted trigonal planar disposition, although the sum of their angles is 360°. The distortion is mainly seen in the close C(10)−N−Zr [71.13(12)°] and N−C(10)−Zr [75.95(12)°] angles and together with the small angle at the zirconium center [C(10)−Zr−N 32.92(6)°] are a consequence of the η^2-coordination of the iminoacyl ligand.

The Zr−Cp distance [2.246Å] is shorter than the $Zr-Cp_{MBI}$ distance [2.311Å]. Consistently the distances from zirconium to the Cp ring carbon atoms [2.492(2)−2.605(2) Å] are slightly shorter than the corresponding distances to the MBI carbon atoms [2.530(2)−2.708(2) Å], the Zr−C(44) and Zr−C(53) bond lengths being unusually long [2.708(2) and 2.649(2) Å, respectively].

Olefin Polymerization Results

The dichlorozirconocenes **1a** and **1b**, activated with a large excess methylalumoxane (MAO), were used as catalyst precursors for the polymerization of ethylene and copolymerization of ethylene/1-hexene. All experiments were carried out at 70 °C in heptane for 15 min, under 4.0 bar of ethylene in a Büchi autoclave, with variable amounts of catalyst and a 10% toluene solution of MAO.

The reaction conditions, measured activities and properties of the resulting polymers are summarized in Table 3 and compared with data for $[ZrCp_2Cl_2]$ and $[Zr(SiMe_2Cp_2)Cl_2]$ used as references.

Both catalysts **1a** and **1b** polymerize ethylene to give linear polyethylene with high activities. Complex **1b** shows a catalytic activity four times higher than that observed for complex **1a** (entries 1, 6) leading to a polymer of much higher molecular weight, similar to that observed for $[ZrCp_2Cl_2]$, although their polydispersities are similar. Under similar conditions (entries 3, 9) complex **1b** is significantly more active than $[ZrCp_2Cl_2]$ and almost 10 times more active than $[Zr(SiMe_2Cp_2)Cl_2]$. Increasing Al/Zr ratios (entries 3, 4 and 5, 6) produce higher activities which were only slightly dependent on the catalyst concentration.

Both metallocenes show higher catalytic activities (entries 1, 2 and 4, 7, 8) in the presence of the comonomer 1-hexene as a consequence of the known "comonomer effect".[39] In all cases incorporation of 1-hexene to the polymer chain is rather high for both catalysts, and is significantly higher (6.69%) for the methylene-bridged complex **1a** with its more open bite compared to the silyl-bridged complex **1b**. The process was always accompanied by a very significant decrease in molecular weight due to the favored β elimination produced by the presence of terminal 1-hexene inserted units.

In most cases the polydispersity is close to the typical value expected for "single site" catalysts, although occasional values higher than 3.0 are observed.

Experimental Section

General Considerations: All manipulations were performed under argon using Schlenk and high-vacuum line techniques or a glove box model HE-63. The solvents were pre-dried over sodium wire prior to purification by distillation under argon using the appropriate drying/deoxygenated agent: toluene, hexane and pentane (sodium-potassium alloy) and diethyl ether, THF (sodium-benzophenone). After being collected, the dried solvent was stored under argon in an ampoule over potassium mirrors or 4 Å molecular sieves (THF). Deuterated solvents from Scharlau were dried, degassed and stored over molecular sieves. C, H and N microanalyses were performed on a Perkin−Elmer 240B and/or Heraeus CHN−O-Rapid microanalyzer. IR spectra were performed in nujol mulls on a Perkin−Elmer 883 spectrophotometer. NMR spectra, measured at 25 °C, were recorded on a Varian Unity FT-300 (^{1}H NMR at 300 MHz, ^{13}C NMR at 75 MHz) or FT-500 (^{1}H NMR at 500 MHz, ^{13}C NMR at 125 MHz) spectrometer and chemical shifts were referenced to the residual protons or carbons of the deuterated solvents. MgMeCl and (2,6-xylyl)isocyanide were purchased

from Aldrich and used without further purification. [Zr{(η^5-2-$MeC_{13}H_8$)(η^5-C_5H_4)EMe_2}Cl_2] (E = C, Si)[26], Li(CH_2SiMe_3)[40] and K($CH_2C_6H_5$)[41] were prepared following the literature methods.

Preparation of [Zr{(η^5-2-$MeC_{13}H_7$)(η^5-C_5H_4)$SiMe_2$}Me_2] (2): A THF solution of ClMgMe (3.0 M, 0.5 mL, 1.52 mmol) was added to a stirred suspension of [Zr{(η^5-2-$MeC_{13}H_7$)(η^5-C_5H_4)$SiMe_2$}Cl_2] (**1b**) (0.35 g, 0.75 mmol) in diethyl ether (50 mL) at −78 °C. The mixture was allowed to warm to room temperature and stirred for a further 12 h. The solvent was removed under reduced pressure and the mixture was extracted into hexane. The supernatant solution was then filtered through celite from the $MgCl_2$ residue, concentrated (10 mL) and cooled to -35 °C to give **2** as a pale yellow powder. Yield 0.27 g, 84%. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = −1.29 (s, 3 H, ZrMe), 0.09 (s, 3 H, ZrMe), 0.41 (s, 3 H, SiMe), 0.53 (s, 3 H, SiMe), 1.95 (s, 3 H, CMe), 5.43 (m, 1 H, C_5H_4), 5.52 (m, 1 H, C_5H_4), 6.50 (m, 1 H, C_5H_4), 6.59 (m, 1 H, C_5H_4), 7.1−7.2 (m, 3 H, $C_{13}H_7$), 7.27 (m, 1 H, $C_{13}H_7$), 7.39 (m, 1 H, $C_{13}H_7$), 7.67 (m, 1 H, $C_{13}H_7$), 8.05 (m, 1 H, $C_{13}H_7$) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = −1.2 (SiMe), −0.8 (SiMe), 18.0 (CMe), 31.0 (ZrMe), 35.5 (ZrMe), 86.2 (C_{ipso}, Si*C*), 100.2 (C_{ipso}, Si*C*), 110.2, 113.0, 113.6, 120.3, 120.6, 122.1, 123.7, 125.4, 125.9, 127.3, 128.9; (CH, C_5H_4, $C_{13}H_7$), 128.5, 129.2, 131.2, 131.5, 131.7; (C_{ipso}, C_5H_4, $C_{13}H_7$) ppm. $C_{23}H_{26}SiZr$ (421.76): calcd. C 65.60, H 6.21; found C 65.81, H 6.28.

Preparation of [Zr{(η^5-2-$MeC_{13}H_7$)(η^5-C_5H_4)$SiMe_2$}($CH_2C_6H_5$)$_2$] (3): Diethyl ether (50 mL) at −78 °C was added to a mixture of [Zr{(η^5-2-$MeC_{13}H_7$)(η^5-C_5H_4)$SiMe_2$}Cl_2] (**1b**) (0.4 g, 0.86 mmol) and K($CH_2C_6H_5$) (0.22 g, 1.72 mmol) and the resulting suspension was allowed to warm to room temperature and stirred for a further 12 h. The supernatant solution was then filtered through celite from the KCl residue, concentrated under reduced pressure (10 mL) and cooled to -35 °C to give **3** as an orange solid. Recrystallization from toluene/hexane gave **3** as a microcrystalline solid. Yield 0.38 g, 78%. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = −0.18 (d, 1 H, $ZrCH_2$, 11 Hz), 0.28 (d, 1 H, $ZrCH_2$, 11 Hz), 0.34 (s,3 H, SiMe), 0.46 (s, 3 H, SiMe), 1.75 (s, 3 H, CMe), 1.95 (d, 1 H, $ZrCH_2$, 11 Hz), 2.13 (d, 1 H, $ZrCH_2$, 11 Hz), 5.20 (m, 1 H, C_5H_4), 5.29 (m, 1 H, C_5H_4), 5.80 (m, 1 H, C_5H_4), 6.31 (m, 1 H, C_5H_4), 6.52 (m, 2 H, C_6H_5), 7.17−7.13 (m, 6 H, C_6H_5), 6.93 (s, 1 H, $C_{13}H_7$), 6.78 (m, 1 H, $C_{13}H_7$), 7.21(m, 1 H, $C_{13}H_7$), 7.22(m, 1 H, $C_{13}H_7$), 7.33(m, 2 H, C_6H_5), 7.41(m, 1 H, $C_{13}H_7$), 7.53(m, 1 H, $C_{13}H_7$), 7.89(m, 1 H, $C_{13}H_7$) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = −0.7 (SiMe), −1.3 (SiMe), 17.2 (CMe), 61.4 (CH_2), 68.4 (CH_2), 85.7 (C_{ipso}, Si*C*), 100.7 (C_{ipso}, Si*C*), 111.6, 113.6, 116.1, 121.1, 121.3, 122.5, 124.0, 124.0, 124.3, 125.3, 125.3, 126.3, 126.4, 126.4, 126.6, 127.6, 128.5, 128.7, 128.7, 128.9, 129.3; (CH.), 125.0, 128.8, 130.3, 131.0, 132.3, 153.4, 154.6 (C_{ipso}) ppm. $C_{35}H_{34}SiZr$ (573.95): calcd. C 73.24, H 5.97; found C 73.02, H 5.76.

Preparation of [Zr{(η^5-2-$MeC_{13}H_7$)(η^5-C_5H_4)$SiMe_2$}(CH_2SiMe_3)$_2$] (4): In a procedure analogous to that described above for **3** a mixture of [Zr{(η^5-2-$MeC_{13}H_7$)(η^5-C_5H_4)$SiMe_2$}Cl_2] (**1b**) (0.35 g, 0.75 mmol) and Li(CH_2SiMe_3) (0.14 g, 1.52 mmol) were reacted in diethyl ether (50 mL) to yield a pale yellow powder characterized as **4**. Yield 0.29 g, 68%. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = −2.20 (d, 1 H, $ZrCH_2$, 11 Hz), −0.94 (d, 1 H, $ZrCH_2$, 11 Hz), −0.07 (d, 1 H, $ZrCH_2$, 11 Hz), −0.21 (s, 9 H, $SiMe_3$), 0.24 (s, 9 H, $SiMe_3$), 0.25 (d, 1 H, $ZrCH_2$, 11 Hz), 0.42 (s, 3 H, SiMe), 0.49 (s, 3 H, SiMe), 2.07 (s, 3 H, CMe), 5.58 (m, 1 H, C_5H_4), 5.66 (m, 1 H, C_5H_4), 6.68 (m, 1 H, C_5H_4), 6.79 (m, 1 H, C_5H_4), 7.15 (s, 1 H, $C_{13}H_7$), 7.17−7.4 (m, 5 H, $C_{13}H_7$), 7.60 (m, 1 H, $C_{13}H_7$), 8.07 (m, 1 H, $C_{13}H_7$) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = −1.5 (SiMe), −0.5 (SiMe), 2.6 ($SiMe_3$), 3.5 ($SiMe_3$), 18.3 (CMe), 47.7 (CH_2), 49.4 (CH_2), 88.4 (C_{ipso}, Si*C*), 103.8 (C_{ipso}, Si*C*), 111.8, 112.6, 112.9, 116.6, 119.7, 123.1, 123.8, 125.9, 126.2, 127.5, 128.9; (CH.), 125.3, 126.7, 130.4, 130.8, 132.2 (C_{ipso}) ppm. $C_{29}H_{42}Si_3Zr$ (566.12): calcd. X-ray Structure Determination for Complex 3: Orange crystals of compound **3** were obtained by cooling a concentrated toluene solution and a suitable sized crystal was mounted in a Lindemann tube and mounted on an Enraf−Nonius CAD 4 automatic four-circle diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71073Å). Crystallographic and experimental details are summarized in Table 4. Data were collected at room temperature. Intensities were corrected for Lorentz and polarization effects in the usual manner. No absorption or extinction corrections were made. The structure was solved by direct methods and refined by least-squares against F^2 (SHELXL 97).[42] All non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were introduced from geometrical calculations and refined using a riding model with the exception of the hydrogens of the CH_2 groups which were found in the difference Fourier map. The hydrogen atoms of the disorder toluene molecule were not included.

X-ray Structure Determination for Complex 6: Data were recorded using Mo-K_α radiation (λ = 0.71073 Å), graphite monochromator and ω scans on a Nonius Kappa CCD diffractometer (see Table 4). The structure was refined anisotropically using the program SHELXL-97.[42] Hydrogen atoms were included using rigid methyl groups or a riding model.

CCDC-236220 (for **3**) and -236644 (for **6**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Polymerization Procedures

Ethylene Polymerizations: Polymerizations were carried out in a Büchi autoclave equipped with a heating bath, mechanical stirrer and connection to argon-vacuum lines. The reactor was evacuated, flushed several times with argon and then charged at 25 °C with 600 mL of freshly distilled heptane and variable amounts of a 10% toluene solution of MAO. The solution was saturated and pressurized with ethylene at 4.0 bar and the thermostat set at 70 °C. Polymerization was started by injection of variable volumes of a previously prepared toluene solution of the zirconocene catalyst. The reaction was stopped by addition of 5 mL of acidified methanol (HCl/methanol, 1:1). Polymers were recovered by filtration, washed with methanol and dried under vacuum at 80 °C for 1 day. The molecular weight of the resulting polyethylene was evaluated by GPC.

Ethylene/1-Hexene Polymerizations: The same procedure described above was followed for copolymerization experiments, the appropriate volume of 1-hexene being initially charged into the reactor together with the solvent. The resulting copolymer was characterized by ^{13}C NMR spectroscopy in $C_6D_3Cl_3$ to evaluate the ethylene/1-hexene ratio by reported methods.[43]

A Cationic Tetranuclear $[Ni^{II}_4(MeOH)_2(pko)_6]^{2+}$ Cluster Showing Antiferro- and Ferromagnetic Features

Maria Alexiou,[a] Catherine Dendrinou-Samara,[a] Catherine P. Raptopoulou,[b] Aris Terzis,[b] Vassilis Tangoulis,*[c] and Dimitris P. Kessissoglou*[a]

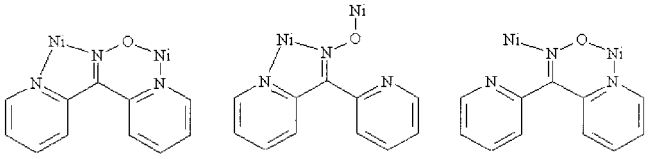
Keywords: Cluster compounds / Magnetic properties / Oximato ligands / Nickel

The majority of reported nickel tetranuclear clusters have a dicubane-like structural core. The compound presented here is the second example possessing an Ni_4O_2 core based on a chair or butterfly "out-of-face" topology. This compound also belongs to the family of compounds characterized as metallacrowns with an $[Ni–N–O–]_n$ linkage and is the only example with three Ni–O–N–Ni strands bridging the nickel atoms. The values obtained from the fitting procedure are $J_1 = 55.8$ cm^{-1}, $J_2 = -67.2$ cm^{-1}, $g = 2.2$, $\rho = 1.1\%$. These values suggest the presence of both ferromagnetic and antiferromagnetic interactions, while a small paramagnetic impurity is also present. This magnetic behaviour with antiferromagnetic internal coupling and ferromagnetic spin-alignment is the second example in the literature and the first in the metallacrown family.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

Our interest in polynuclear nickel[1–4] or manganese[5–10] complexes showing interesting structural and magnetic features has focused especially on metallacrowns, a molecular class that exhibits selective recognition of cations and anions. An attractive feature of metallacrowns is that they concentrate a large number of metal ions into a small area. These large concentrations of metal ions may lead to interesting magnetic behaviour.[1,10–12] The structural features of each metallacrown can lead to high magnetic moments per compound through ferromagnetic exchange or coupling to low-lying paramagnetic states. Previously reported metallacrowns[1–27] have been prepared using hydroxamic acids and/or ketone oximic acids as constructing ligands. Hpko is a bifunctional ligand that can bind metal atoms in either five- or six-membered chelate rings. The deprotonated di-2-pyridyl ketone oxime can act in two binding modes: (i) bichelate and (ii) monochelate. In (i) the ketone oxime oxygen atom (O_k) and one pyridine nitrogen atom (N) bind to one metal atom and the other pyridine nitrogen atom (N) plus the ketone oxime nitrogen atom (N_k) chelate an adjacent metal atom in a *syn-anti* arrangement (form A). In (ii) the ketone oxime nitrogen atom (N_k) and one pyridine nitrogen atom (N) are coordinated to one metal atom in a five-membered chelate ring in a *syn-syn* arrangement (form B_1) or the ketone oxime oxygen atom (O_k) and one pyridine nitrogen atom (N) are bound to one metal atom in a six-membered chelate ring in a *syn-anti* arrangement (form B_2). These juxtaposed five- and six-membered chelate rings form the basis of the metallacrown ring through the $[M-N-O-]_n$ linkage.



For tetranuclear nickel clusters the majority of the compounds reported have a dicubane-like structural core[28–41] with only one example possessing an Ni_4O_2 core based on a chair or butterfly "out-of-face" topology.[42] The compound presented here is the second example that may be characterized as having a chair topology and the only example showing a metallacrown $[M-N-O-]_n$ linkage with three Ni–O–N–Ni strands bridging the nickel atoms. This compound is also the first metallacrown showing antiferromagnetic internal coupling and ferromagnetic spin alignment.

Results and Discussion

The reaction of $Ni(ClO_4)_2$ with dipyridyl ketone oxime, $(2\text{-py})_2C{=}NOH$ (Hpko) in a 1:1 ratio in methanol in the

[a] Department of General and Inorganic Chemistry, Faculty of Chemistry, Aristotle University of Thessaloniki, 54124 Thessaloniki, Greece

[c] Department of Materials Science, University of Patras, 26500 Patras, Greece

presence of NaOH gives red-brown crystals of the cluster $[Ni^{II}_4(CH_3OH)_2(pko)_6](OH)(ClO_4)\cdot 2CH_3OH\cdot 4H_2O$ (**1**) after slow evaporation of the solvent. The synthesis of cluster **1** was achieved by the reaction

$$4\ Ni(ClO_4)_2 + 6\ Hpko + 7\ NaOH \xrightarrow{Methanol} [Ni(II)_4(CH_3OH)_2(pko)_6](OH)(ClO_4) + 7\ NaClO_4 + 6\ H_2O$$

The compound crystallizes in the tetragonal space group *P4/n*. The asymmetric unit contains half of the tetranuclear cation, half a perchlorate and hydroxide counterion, two lattice water molecules and one methanol solvent molecule of crystallization. The tetranuclear $[Ni^{II}_4(pko)_6(CH_3OH)_2]^{2+}$ cation is centrosymmetric; the inversion center lies in the center of the Ni(2)−O(1)−Ni(2)−O(1) moiety. The whole structure can be characterized as having a "metallacrown chair" topology (Figure 1). Two nickel atoms with a distorted octahedral NO_5 coordination environment are bridged by two oxygen atoms from pko ligands to form the Ni_2O_2 core, in which the Ni(2)−O(1) or Ni(2)−O(1)# distances are found to be 2.086(8) Å and 2.101(8) Å, respectively, the Ni(2)···Ni(2)# and O(1)···O(1)# separations to be 3.059 Å and 2.861 Å, respectively, and the Ni(2)−O(1)−Ni(2)# and O(1)−Ni(2)−O(1)# angles to be 93.70° and 86.16°, respectively (Table 1). Each nickel atom of the Ni_2O_2 core is bound to two oximato oxygen atoms with Ni(2)−O(11) and Ni(2)−O(21) distances of 1.974(9) and 2.047(8) Å, respectively; the octahedron is completed by a methanol oxygen atom at a distance of 2.113(8) Å.

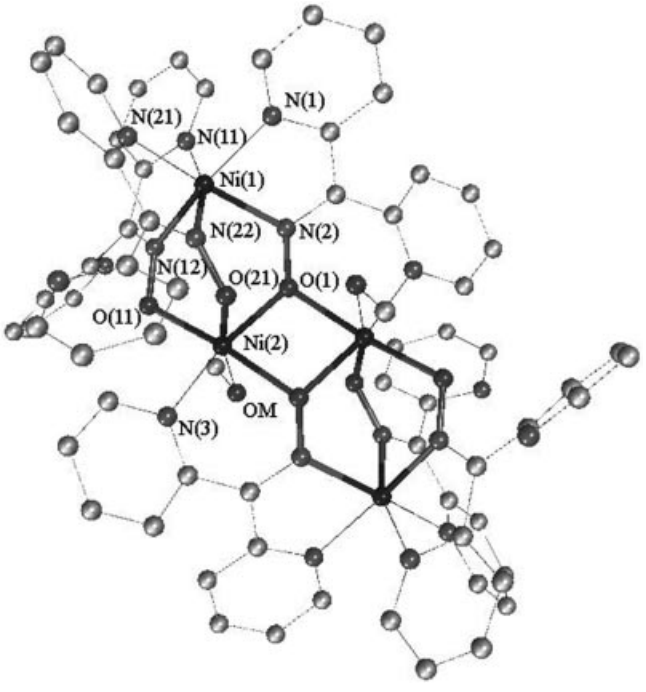

Figure 1. Crystal structure of the the $[Ni^{II}_4(pko)_6(CH_3OH)_2]^{2+}$ ion; the core and ring connectivity have been highlighted; perchlorate and hydroxy ions are not shown

Two pko oximato moieties bridge the core nickel atom with the "wing" nickel atom in a monochelate mode and a *syn-syn* arrangement(form B_1), while the third pko ligand bridges the "wing" nickel atom Ni(1) and the symmetrically equivalent Ni(2)# nickel atom through the oximato moity in bichelate mode and a *syn-anti* arrangement (form A). The two "wing" nickel atoms have a pure N_6 coordination environment with three nitrogen atoms coming from three oximato moieties [Ni(1)−$N_{oximato}$ (av.) = 2.036 Å] and three nitrogen atoms from three pko-pyridine groups [Ni(1)−$N_{pyridine}$ (av.) = 2.105 Å]. Four of the six pko ligands have the second pyridine nitrogen atom uncoordinated. The "wing" nickel atoms Ni(1) and Ni(1)# lie on opposite sides of the Ni_2O_2 parallelogram at 3.469 Å and 4.744 Å from the core nickel atoms Ni(2). The formation of the 12-membered metallacrown follows the pattern (Ni−N−O−Ni−O−N−Ni−N−O−Ni−O−N) and, in cooperation with the *syn-anti* mode of one pko-oximato ligand, allows the construction of the chair-like metallacrown shape.

Magnetic Study

The temperature dependence of the susceptibility data in the form of χ_M and $\chi_M T$ vs. T plots is shown in Figure 2.

The room-temperature value of $\chi_M T$ is 3.5 emu·mol^{-1}·K lower than the value expected for four uncorrelated $S = 1$ spins (4.0 emu·mol^{-1}·K for $g = 2.0$) showing that an overall antiferromagnetic behavior characterizes the magnetic interaction between the magnetic centers. As the temperature decreases the value of $\chi_M T$ also decreases until about 17 K, where its value is close to zero. After that temperature a plateau forms until 2 K, revealing that a paramagnetic impurity is present. This is shown better in the χ_M data, where a Curie tail appears below 7 K. Another important aspect of the χ_M data is the peak at about 67 K, which is evidence of different types of interaction in the cluster.

Magnetization measurements were carried out in the field range 0−12 T at 2 K in order to verify the ground state and possibly to observe a jump to an excited state (Figure 3). The reduced magnetization at 12 T is 0.0135 μ_B and this is

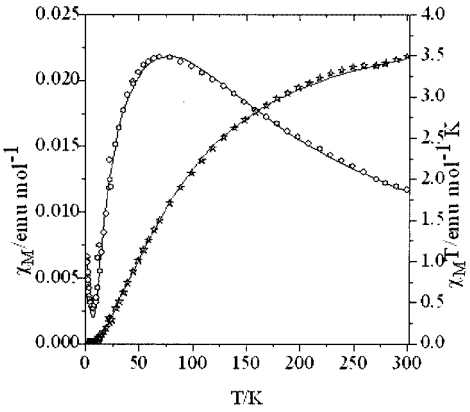

Figure 2. Temperature dependence of the susceptibility data in the form of χ_M (open circles) and $\chi_M T$ (open stars) vs. T plots in an applied field of 0.1 T; the solid lines represent the best fit according to Equation (1) (see text for details)

due to the paramagnetic impurity of the system; there is no population of the excited state with $S_{tot} > 0$ until 12 T.

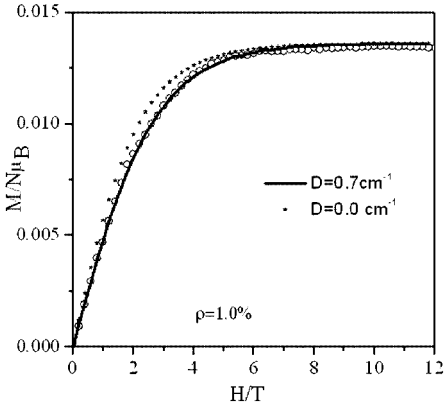

Figure 3. Magnetization data at 2 K and in the field range 0−12 T; the lines represent 1.0% of an $S = 1$ system with $D = 0$ cm^{-1} (dotted) and $D = 0.7$ cm^{-1} (solid)

The safe conclusions from the study of the magnetic experiments are: (a) there are both ferro- and antiferromagnetic interactions in the cluster, which lead to an overall antiferromagnetic behavior; (b) the ground state of the system is $S = 0$ with a small percentage of paramagnetic impurity of an $S = 1$ system.

In order to calculate the interactions between the magnetic ions the zero-field Hamiltonian according to Equation (1) was used, where the numbering of the spins and the exchange couplings are based on the magnetic model in Figure 4, according to crystallographic criteria.

$$H = J_1(S_1S_2 + S_3S_4) + J_2(S_2S_3) + J_3(S_1S_3 + S_2S_4) \quad (1)$$

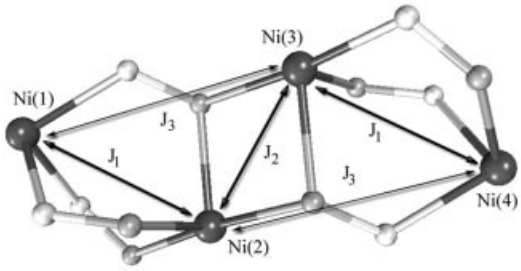

Figure 4. The magnetic model showing the interaction vectors; Ni(3) and Ni(4) are symmetry equivalents of Ni(2) and Ni(1), respectively

The fitting results are shown in Figure 2 in the form of solid lines and the values obtained are: $J_1 = 48.1$ cm^{-1}, $J_2 = -12.1$ cm^{-1}, $J_3 = 14.5$ cm^{-1}, $g = 2.2$, $\rho = 1.1\%$.

The interaction between the two central ions Ni(2) and Ni(3) is ferromagnetic, which is in accordance with the Ni−O−Ni angle (93.7°) and the small distance between the two ions (3.059 Å), while the interaction between Ni(1) and Ni(2) and Ni(3) and Ni(4) is antiferromagnetic due to the superexchange pathway [Ni(1)−N−O−Ni(2)] and the long distance between the magnetic ions (3.470 Å).

It is interesting to note that a third antiferromagnetic interaction exists between Ni(1) and Ni(3) and Ni(2) and Ni(4) despite the long distance between the Ni ions (4.743 Å). A ferromagnetic Ni−Ni interaction is observed when the Ni−O−Ni angle is close to orthogonal. Antiferromagnetic interactions have also been observed for Ni−O−Ni bridging angles larger than 99°. Following the lead of Christou et al.,[43] for comparison purposes the magnetic interactions (J) are represented in Figure 5 as a function of average Ni−O−Ni angles.

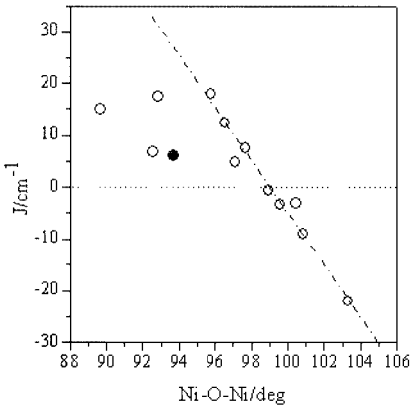

Figure 5. Exchange interaction (J) as a function of the Ni−O−Ni angle for different cores of the type Ni_4O_4 described in the literature (open circles)[36] and that reported in this contribution (solid circle)[44]

The energy scheme according to the previous parameters reveal that the ground state is $S = 0$, and that this is well separated from the first excited state ($S = 1$, $\Delta E = 36$ cm^{-1}; Figure 6).

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

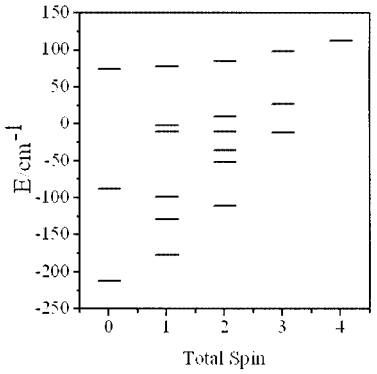

Figure 6. Energy scheme of the magnetic model according to fitting results (see text for details)

Concerning the magnetization data, a simulation procedure was carried out in order to obtain information about the paramagnetic impurity. Assuming that the ground state $S = 0$ is well isolated (which is true according to the susceptibility data) at 2 K the magnetization curve belongs to the paramagnetic impurity of an $S = 1$ system. The simple Brillouin function of a 0.008% $S = 1$ state is not completely superimposed on the data, which implies that the zero-field term may play an important role. By adding the zero-field term the best simulation was obtained for a D value of 0.7 cm^{-1}.

Conclusions

While tetranuclear nickel clusters have been reported, the compound presented here shows some very interesting features. It is the second example possessing an Ni_4O_2 core based on a "chair or butterfly out-of-face" topology. This compound also belongs to the family of compounds characterized as metallacrowns with an $[Ni-N-O-]_n$ linkage and is the only example with three strands Ni−O−N−Ni bridging the nickel atoms. The magnetic study shows the presence of both ferromagnetic and antiferromagnetic interactions. The magnetic behaviour with antiferromagnetic internal coupling and ferromagnetic spin alignment is the second example in the literature and the first in the metallacrown family.

Experimental Section

CAUTION: *Perchlorate compounds of metal ions are potentially explosive; only a small amount of material should be prepared and handled with caution!*

Materials: The chemicals for the synthesis of the compounds were used as purchased. DMF was distilled from calcium hydride (CaH_2) and CH_3OH from magnesium (Mg); they were both stored over molecular sieves (3 Å). Hpko and $Ni(ClO_4)_2·6H_2O$ were purchased from Aldrich Co. All chemicals and solvents were reagent grade.

Physical Measurements: Infrared spectra (200−4000 cm^{-1}) were recorded with a Perkin−Elmer FT-IR 1650 spectrometer with samples prepared as KBr pellets. UV/Vis spectra were recorded with a Shimadzu-160A dual-beam spectrophotometer. C, H and N elemental analysis was performed with a Perkin−Elmer 240B elemental analyser; Ni was determined by atomic absorption spectroscopy with a Perkin−Elmer 1100B spectrophotometer. Electrical-conductance measurements were carried out with a WTW model LF 530 conductivity outfit and a type-C cell, which had a cell constant of 0.996. This represents a mean value calibrated at 25 °C with potassium chloride. The temperature dependence of the magnetic susceptibility was measured on polycrystalline powder samples using a Cryogenics S600 SQUID Magnetometer with an applied field of 0.1−1.0 T in the temperature range 2−300 K. Data were corrected for sample-holder contribution and diamagnetism of the sample using standard procedures.

Synthesis of $[Ni^{II}_4(CH_3OH)_2(pko)_6](OH)(ClO_4)·2CH_3OH·4H_2O$ (1): Dipyridyl ketone oxime (1.19 g, 6 mmol) was added to a solution of sodium hydroxide (0.24 g, 6 mmol) in CH_3OH (20 mL). The resulting mixture was stirred for 1 h, generating a pale-yellow solution. $NiClO_4·6H_2O$ (1.46 g, 4 mmol) dissolved in CH_3OH (20 mL) was then added with stirring. The resulting red-brown solution was stirred for 1 h. Brown crystals suitable for X-ray diffraction studies were obtained by slow concentration. Yield 50%. $C_{70}H_{73}ClN_{18}Ni_4O_{19}$ (1740.8): calcd. C 48.3, H 4.2, N 14.5, Ni 13.4; found C 47.9, H 4.4, N 14.2, Ni 13.0. IR: $\tilde{\nu}$ = 1597 [vs, ν(C=N)], = 1462 [vs, ν(N=O)] cm^{-1}. UV/Vis (DMF): λ_{max} (ε [$dm^3·mol^{-1}·cm^{-1}$]) = 524 (722, sh) nm.

X-ray Crystal-Structure Determination: Slow crystallization of **1** from methanol yielded red prismatic crystals. A crystal with approximate dimensions 0.08 × 0.25 × 0.40 mm was mounted in a capillary. Diffraction measurements were made with a $P2_1$ Nicolet diffractometer upgraded by Crystal Logic using graphite-monochromated Cu radiation. Unit-cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the range $22° < 2\theta < 54°$. These data are given in Table 2. Intensity data were recorded using a θ-2θ scan to $2\theta(max) = 100°$ with a scan speed of 1.5°/min and scan range 2.4 plus a_1a_2 separation. Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarization and ψ-scan absorption corrections were applied using the Crystal Logic software. Symmetry-equivalent data were averaged with $R = 0.0703$ to give 4442 independent reflections from a total of 4725 collected. The structure was solved by direct methods using SHELXS-86 and refined by full-matrix least-squares techniques on F^2 with SHELXL-93 using 4442 reflections and refining 518 parameters.[45−47] The final values for $R1$, $wR2$ and GOF for observed data are given in Table 2, and for all data are 0.1724, 0.3409 and 1.057 respectively. The maximum and minimum residual peaks in the final difference map were 1.123 and −0.599 e/Å. The largest shift/esd in the final cycle was 0.017. CCDC-223110 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk]. Structural remarks: The crystals were small and of poor quality (the peak scans showed small shoulders). For this reason we did not collect data above $2\theta = 100°$, and even for the data we did collect about 40% was unobserved. This problem is due especially to disordered perchlorate and hydroxy anions and solvent molecules. The quality of the $[Ni^{II}_4(pko)_6(CH_3OH)_2]^{2+}$ ion is very satis-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

factory, particularly for interpreting the magnetic data. All hydrogen atoms of the pko ligands were introduced at calculated positions as riding on bonded atoms. All non-hydrogen atoms were refined anisotropically. The perchlorate counterion was refined as follows: two independent chlorine atoms were found in the difference Fourier map, one located on a fourfold axis of symmetry, Cl(1), and the second on a fourfold inverse axis of symmetry, Cl(2). One of the oxygen atoms on Cl(1), O(31), is also located on the fourfold axis of symmetry, while the other three oxygen atoms, O(32), O(33), O(34), are on general positions and were refined with occupation factor 0.25 as disordered over the C_4 axis. Only one oxygen atom, O(41), was found near Cl(2), generating the perchlorate anion due to the fourfold inverse axis of symmetry. Atoms Cl1 and Cl2 were refined anisotropically, while all oxygen atoms were refined isotropically. The hydroxide counterion was refined as follows: two independent oxygen atoms were found in the difference Fourier map, both located on a fourfold axis of symmetry and were refined isotropically with occupation factors 0.25. The water and methanol solvent molecules were refined isotropically as follows: one of the water molecules, OW(1), was found disordered and it was refined over three positions with occupation factors of a total sum one. The second water molecule, OW(2), was also found disordered and it was refined over two positions with occupation factors of a total sum one. The methyl group of the methanol solvate was found disordered and it was refined over three positions with occupation factors of a total sum of one.

Table 2. Summary of crystal, intensity collection and refinement data of **1**

Empirical formula	$C_{70}H_{73}ClN_{18}Ni_4O_{19}$
Formula mass	1740.75
Temperature [K]	293
Radiation (Cu-K_a) [Å]	1.54180

Synthesis, X-ray Structural Analysis and Spectroscopic Investigations (IR and ^{31}P MAS NMR) of Mixed Barium/Strontium Fluoroapatites

Abdallah Aissa,[a] Béchir Badraoui,[a] René Thouvenot,*[b] and Mongi Debbabi*[a]

Keywords: Barium / IR spectroscopy / NMR spectroscopy / Strontium / X-ray diffraction

Continuous solid solutions of barium/strontium fluoroapatites $Ba_{(10-x)}Sr_x(PO_4)_6F_2$ ($Ba_{(10-x)}Sr_xFAp$; $0 \leq x \leq 10$) were obtained in an aqueous medium. They were investigated by Rietveld structure-refinement methods using powder X-ray diffraction patterns and by chemical analysis, IR spectroscopy and ^{31}P MAS NMR spectroscopy. Replacement of barium by strontium induces a regular decrease of the lattice constants *a* and *c* according to Vegard's law. The results of the powder-fitting structure refinements indicate a clear preference of strontium for the S(1) site of the apatitic structure. A high-wavenumber shift of the IR absorption bands characteristic of PO_4 internal modes is also observed, in agreement with the diminution of the ionic character of the M–O bonds. For increasing strontium content, a regular δ_{iso} increase is shown in the ^{31}P MAS NMR spectra, from $\delta = 0.91$ ppm for $Ba_{10}FAp$ to $\delta = 3.06$ ppm for $Sr_{10}FAp$. For all mixed Ba/Sr fluoroapatites, the low intensities of the spinning bands reflect the weak ^{31}P chemical-shift anisotropy, in agreement with the low distortion of the PO_4 tetrahedron, as shown by Rietveld refinement.

Introduction

Apatite is a general name for a large family of isomorphous compounds, with the structure belonging basically to the hexagonal space group $P6_3/m$.[1] The general chemical formula is $M_{10}(XO_4)_6Y_2$, where M corresponds to a divalent cation such as Ca^{2+}, Sr^{2+}, Ba^{2+}, Cd^{2+}, or Pb^{2+}, XO_4 is a trivalent anion, essentially PO_4^{3-}, VO_4^{3-} or AsO_4^{3-}, and Y a monovalent anion, like OH^-, F^-, Cl^-, Br^-.[2,3] Furthermore, M^{2+} may be partially replaced by mono- or trivalent cations (Na^+, K^+, Al^{3+}, ...) and XO_4^{3-} may be replaced by tetravalent anions like SiO_4^{4-} and divalent anions like CO_3^{2-} and SO_4^{2-}.

The natural fluoroapatite, $Ca_{10}(PO_4)_6F_2$, is considered as a good structural model for apatitic compounds.[1] The Ca^{2+} cations are located in two nonequivalent crystallographic sites (Figure 1). In each unit cell four Ca(1) atoms, located on the threefold axis, are coordinated by six oxygen atoms as nearest neighbors belonging to the PO_4 group. The site S(1), occupied by Ca(1) atoms, is 4f (symmetry C_3). The other six Ca(2) atoms in the unit cell are coordinated by six oxygen atoms from the PO_4 tetrahedra and by one F^- ion located on the sixfold axis. The site S(2), occupied by Ca(2), is 6h (symmetry C_s). This structure can accommodate a variety of substitutions which affect the physicochemical properties of the materials. In particular, ionic substitutions are involved in dental and bone pathologies, bioceramics for bone implants, pollution by phosphate fertilizers, ion-exchange ability for water treatment and radioactive-waste confinement, as well as in catalytic and luminescent properties.[4,5]

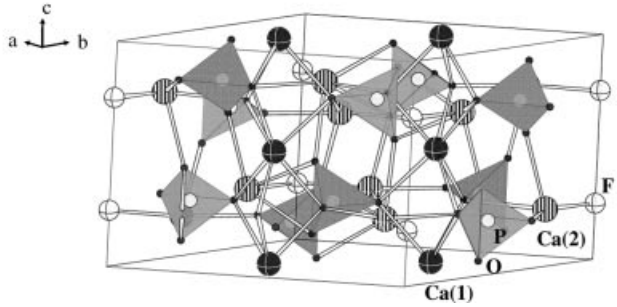

Figure 1. Perspective view of $Ca_{10}(PO_4)_6F_2$ structure

Fluoroapatites are known for the divalent metals Ca, Sr, Ba and Pb,[6–8] and dicationic systems of Sr-, Cd-, and Pb-substituted Ca fluoroapatites have been widely investigated.[9–11] For these systems the limit of miscibility may be correlated to the relative properties of the metals (polarisability, electronegativity and essentially cationic

size).[12,13] The lattice parameters of these mixed apatites decrease with increasing content of the smaller metal cation, and in the case of the Ca/Sr and Ca/Pb systems the results of powder pattern fitting refinement indicate a clear preference of Ca^{2+} for the site S(1) of the apatitic structure. On the contrary, for Ca/Cd fluoroapatites, the smaller Cd^{2+} cations prefer the S(2) site; this can be explained by a good affinity of cadmium to fluorine. To the best of our knowledge, no other mixed divalent-metal fluoroapatites have been reported.

In this paper we report the synthesis in aqueous medium and the chemical analysis of a continuous series of mixed strontium/barium fluoroapatites; the results of powder fitting structure refinement are discussed in relation with the spectroscopic data (IR and ^{31}P MAS NMR).

Results

X-ray Analysis

The results of X-ray diffraction pattern identification for all products $Ba_{(10-x)}Sr_x(PO_4)_6F_2$ (hereafter $Ba_{(10-x)}Sr_xFAp$; $0 \leq x \leq 10$) indicate that the samples are constituted of a single apatitic phase.

The structural analysis by Rietveld methods for seven samples gave the following formulae: $Ba_{10}FAp$, $Ba_{9.01}Sr_{0.99}FAp$, $Ba_{6.92}Sr_{3.08}FAp$, $Ba_{5.05}Sr_{4.95}FAp$, $Ba_{2.92}Sr_{7.08}FAp$, $Ba_{1.03}Sr_{8.97}FAap$ and $Sr_{10}FAp$. The results of the refined structural parameters for these samples are reported in Table 1. The stoichiometry of these samples is close to that of the synthesis and agrees very well with the chemical analysis (Table 2). Therefore, to simplify, from now onwards the samples will be named as $Ba_{(10-x)}Sr_xFAp$ where x corresponds to the stoichiometry of the synthesis.

The progressive replacement of barium by strontium leads to a slight decrease in the crystallographic parameters a and c; the variations are linear and obey Vegard's law[14] according to the following Equations.

$a = (10.173 - 0.045x)$ Å; $\sigma(a) = 4.5 \times 10^{-2}$ Å
$c = (7.726 - 0.045x)$ Å; $\sigma(c) = 2.3 \times 10^{-2}$ Å
$V = (691.4 - 9.6x)$ Å^3; $\sigma(V) = 0.7$ Å^3

As a typical comparison between the observed and calculated profiles the final plot for Ba_5Sr_5FAp is displayed in Figure 2.

The structural refinement shows that strontium occupies both the S(1) and S(2) sites of the apatitic structure. However, the occupancy in S(1) is always higher than expected from the statistical distribution, as shown in Figure 3 and in Table 3.

The bond lengths and angles for the two metal environments, obtained by DIAMOND,[15] and the distortion indexes of the phosphate tetrahedron calculated by Baur relations,[16] are reported in Table 4. The M−M, M−O, and M(2)−F distances decrease with increasing strontium content and the distortion indexes of the mixed phases are slightly larger than those of the limiting phases.

Infrared Absorption Spectroscopy

The infrared spectra of the mixed fluoroapatites present the characteristic absorption bands (stretching and bending) of the PO_4^{3-} group and a band at about 300 cm^{-1} assigned to an M_3-F "ν_3-type stretching "of the 2[M_3-F] sublattice.[17] All IR data are displayed in Table 5 and two typical spectra are presented in the Supporting Information. The progressive replacement of the barium ions by strontium induces a regular shift of all the absorption bands towards greater wavenumbers (Figure 4). Furthermore there is a splitting of the ν_3-[M_3-F] band into two or three components; this effect is markedly pronounced for the intermediate phases, from Ba_6Sr_4FAp to Ba_1Sr_9FAp.

^{31}P Solid-State NMR Analysis

The ^{31}P MAS NMR spectra of the whole series of mixed Ba-SrFAp's are depicted in Figure 5 and the data are given in Table 6. For increasing Sr content, the isotropic signal (δ_{iso}) shows a regular shift towards high frequency between the two limiting phases $Ba_{10}FAp$ (δ_{iso} = 0.91 ppm) and $Sr_{10}FAp$ (δ_{iso} = 3.06 ppm; Figure 6). The low intensity of the spinning side bands (SSB) even at low spinning rate (2 kHz) indicates low chemical-shift anisotropy (CSA) of the phosphorus nucleus; this prevents the determination of the chemical shift tensor components by the classical analysis of the SSB intensity.[18]

As for the Sr/Pb hydroxyapatite system, only one isotropic signal is observed whatever the strontium content. However, for the mixed phases this signal appears complex and contains many components. Despite the weak amplitude of variation of δ_{iso}, numeric simulation allows the decomposition of the isotropic resonance into separate signals, corresponding to different phosphate environments (Figure 7). For the phases with low content of either Sr or Ba (x = 1, 8, 9), the decomposition allows the evaluation of

Table 3. Refinement occupancy compared with the statistic distribution for strontium in the two metal sites S(1) and S(2) of Ba/Sr fluoroapatites

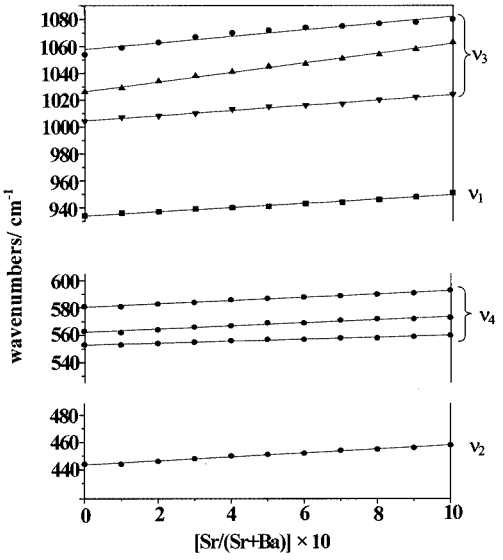

Figure 4. Evolution of the wavenumbers of the PO_4 IR absorption modes as a function of the strontium content

the respective populations of the phosphate sites (Table 7).

For all compositions, the static ^{31}P NMR spectra are quite symmetric, as can be seen in a typical plot (Figure 8); they exhibit a pseudo-Gaussian shape with full width at half maximum (fwhm) of about 14 ppm. The shape of the static spectrum is likely essentially determined by dipolar ^{31}P-^{19}F interactions.

Discussion

The results of this study indicate that the small difference between the cationic radius of Ba^{2+} (1.48 Å) and Sr^{2+} (1.32 Å)[19] allows the formation of a continuous solid solution of barium and strontium fluoroapatites. The replacement of barium in the apatitic structure by the smaller strontium cation induces, as expected, a linear decrease of the lattice

$Sr_{10}FAp$	3.06	0.92	12.87

parameters. Despite the variation in the cell dimensions there are no dramatic distortions of the PO_4 tetrahedron (Table 4). The geometry of the phosphate anions remains regular (quasi T_d symmetry) with only small variations over the whole series.

Structural refinements by the Rietveld method show that the Sr^{2+} ions are distributed between the two crystallographic sites S(1) and S(2), with a strong preference for the smaller site S(1). This is particularly marked for low Sr concentrations (Figure 3). Moreover, as the metal−metal distances, determined for $Ba_{10}FAp$, differ markedly for the two types of metallic sites [Ba(1)−Ba(1) = 3.87 Å and Ba(2)−Ba(2) = 4.39 Å] the S(1) sites appear more suitable to accommodate small cations. Furthermore, in $Ba_{10}FAp$ the fluorine atom is shifted to the z position close to 0.3, whereas it is about 0.25 for all solid solutions. This displacement can be related to the sole presence of larger cations (Ba^{2+}) at the S(2) site and the weak affinity of the soft acid Ba^{2+} for the hard base F^-.

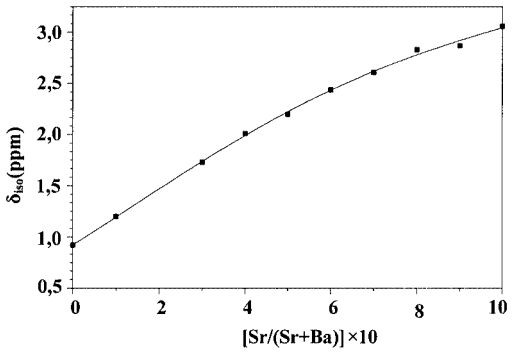

Figure 6. Variation of δ_{iso} as a function of Sr content

The infrared spectra of all mixed fluoroapatites are very similar, especially with respect to the phosphate bands. In particular, the splitting of the triply degenerate ν_3 and ν_4 bands and the intensity of the infrared-inactive bands (for T_d symmetry) ν_1 and ν_2 remain nearly constant over the whole series, in agreement with the minor geometrical perturbations of the PO_4 group (see above). Increasing the strontium content leads, however, to an increase of the frequencies of the PO_4 vibrational modes, and there is a quasi-linear variation of all wavenumbers with the strontium atomic ratio x (Figure 4). As noted by Fowler, who studied pure Ca and Sr hydroxyapatites, this might be due to increased anion−anion repulsions concomitant with decreased lattice dimensions,[17] and also by the higher covalency of the P−O bonds resulting from increased ionicity of the M−O bonds.[13]

According to Fowler,[17] the low-wavenumber bands around 300 cm^{-1} may be assigned to a "ν_3-type stretching" of the M_3−F unit. The multiplicity of these ν_3-[M_3−F] bands observed in the mixed phases can be explained by the various F^- environments — FBa_3, FBa_2Sr, $FBaSr_2$ and FSr_3 — and also by loss of the degeneracy of this E mode by symmetry lowering (D_{3h} to C_{2v}) through metal substitution. This splitting is observed only for the compositions between Ba_6Sr_4FAp and Ba_1Sr_9FAp, when the sites S(2) are significantly occupied by both cations according to the Rietveld refinements (15% Sr/85% Ba for Ba_6Sr_4FAp and 84% Sr/16% Ba in Ba_1Sr_9FAp). Outside this composition range, there is almost exclusively one symmetrical fluorine environment, either FBa_3 or FSr_3, which explains the single ν_3-[M_3−F] absorption band. Two relevant spectra, for

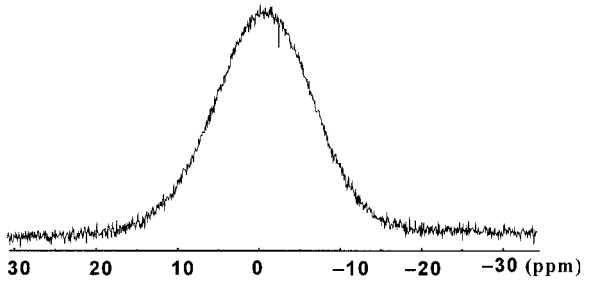

Figure 8. 162 MHz ^{31}P solid-state NMR static spectrum of Ba_5Sr_5FAp

Ba_4Sr_6FAp (38% Sr/Ba 62%) and Ba_5Sr_5FAp (28% Sr/Ba 72%), are given as Supporting Information.

Let us now consider the ^{31}P solid-state MAS NMR results. Solid-state MAS ^{31}P NMR spectra of phosphate compounds generally present a central resonance at δ_{iso} associated with a spinning side-band pattern, characteristic of the chemical shift anisotropy (CSA) of the phosphorus nucleus. In the present case the spectra of all fluoroapatites exhibit low-intensity spinning side-bands, even at moderate spinning rates (Figure 5). This corresponds to a very small CSA interaction, in agreement with the structural analysis, which shows a regular geometry of the phosphate anion for all species (see above).

The limiting phases Ba_{10}FAp and Sr_{10}FAp exhibit a single isotropic resonance, at δ = 0.91 and 3.06 ppm, respectively, in agreement with the equivalence of all phosphate groups in the apatitic structure. For the mixed Ba/Sr fluoroapatites there is a monotonic shift of the position of the isotropic resonance as a function of the strontium content (Figure 6). This regular deshielding of the P nucleus may be correlated to the regular contraction of the lattice parameters.[20]

The variation of δ_{iso} between Ba_{10}FAp and Sr_{10}FAp ($\Delta\delta$ = 2.15 ppm, ca. 350 Hz) is very weak compared to the linewidth of the isotropic signal of these phases (100 and 150 Hz, respectively). Therefore, contrary to what was observed in the Cd/Pb hydroxyapatites system,[21] the isotropic signals associated to different environments of phosphate ions are not resolved in the experimental spectra of the mixed phases. Actually, the ^{31}P resonances of the Ba/Sr fluoroapatites appear as relatively broad signals due to the distribution of the ^{31}P chemical shifts (Figure 5, Table 6). For the phases with low content of either metal — i.e. for x = 1, 8 and 9 — the isotropic resonance has an asymmetrical shape and may be easily decomposed into individual components by using the DOMFIT program.[18] For this analysis we considered that the ^{31}P chemical shift is primarily determined by the cationic environments of the phosphate groups.[22] In the apatitic structure, the phosphorus atoms display nine O−M contacts (Scheme 1). For the nine oxygen−metal contacts around each P atom, neglecting the incidence of the relative positions of Ba and Sr, one expects therefore 10 different P environments, noted $PBa_{(9-y)}Sr_y$ (y = 0, 1, ..., 9). Their relative proportions, which depend on the composition of the apatitic phase, are calculated according to

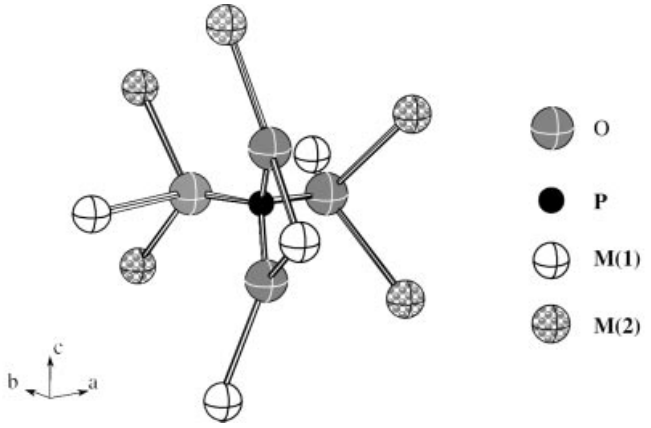
$$p[PBa_{(9-y)}Sr_y] = C_9^y (p_{Ba})^{(9-y)} (p_{Sr})^y$$

where

$$C_9^y = \frac{9!}{y!(9-y)!}$$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is the binomial coefficient, and p_{Ba} and p_{Sr} are the atomic fractions of Ba and Sr, respectively (Supporting Information). Considering that P environments with less than about 5% abundance would not contribute to the ^{31}P isotropic signal, we can nicely simulate the spectra of Ba_9Sr_1FAp and Ba_1Sr_9FAp with four components (Figure 7). The decomposition of the isotropic signals for these phases give populations of the PO_4 environments close to the statistic weight obtained from their chemical composition (Table 7). From Figure 7, it appears that the linewidth of the individual $PBa_{(9-y)}Sr_y$ resonances increases as y increases (or decreases) towards 0.5. Moreover for "reverse" compositions, strontium-rich environments give broader resonances than their barium-rich analogues (compare Figure 7, right and left). Actually, according to Scheme 1, each $PBa_{(9-y)}Sr_y$ motif corresponds to various slightly different P environments, depending on the relative positions of Ba and Sr in the metallic sites. This may result in subtle variations in ^{31}P chemical shifts and finally in a broader signal than for the single environments PBa_9 and PSr_9. Of course, maximal broadening is expected for the PBa_5Sr_4 and PBa_4Sr_5 motifs. For small y values, corresponding to barium-rich samples, preferential location of strontium at S(1) leads to less-numerous $PBa_{(9-y)}Sr_y$ environments than for the reverse composition $PBa_ySr_{(9-y)}$.



Scheme 1. The cationic environment of the phosphate group in apatitic structure

A more puzzling observation is that the individual lines of the various $PBa_{(9-y)}Sr_y$ motifs shifts more strongly through Ba/Sr substitution (up to 1 ppm, Table 7) than the experimentally observed isotropic signal (mean value of the shift about 0.2 ppm, Table 6 and Figure 6).

Moreover, whereas $\delta_{iso}(PSr_9)$ remains nearly constant (within the accuracy) in Ba_2Sr_8FAp (+2.98 ppm), Ba_1Sr_9FAp (+3.04 ppm) and $Sr_{10}FAp$ (+3.06 ppm), PBa_9 in Ba_9Sr_1FAp (+0.21 ppm, Table 7) is significantly shielded with respect to the same motif in the "pure" phase $Ba_{10}FAp$ (+0.91 ppm, Table 6). Even more surprisingly, PBa_3Sr_6 (in Ba_1Sr_9FAp) and PBa_4Sr_5 (in Ba_2Sr_8FAp) are shielded with respect to PBa_9 in $Ba_{10}FAp$. From all these observations it appears that the ^{31}P isotropic chemical shifts (and linewidths) of the $PBa_{(9-y)}Sr_y$ environments depend significantly on the composition of the apatitic phase; therefore the δ_{iso} values reported in Table 7 cannot be transferred for further simulations.

At variance with the hydroxyapatites,[23] the full width at half maximum ($\Delta\nu_{1/2}$) for the static signal does not change significantly throughout the whole series (14 ± 1 ppm, Table 6). As the P−F dipolar interaction is likely the dominant interaction, the quasi-invariance of $\Delta\nu_{1/2}$ for fluoroapatites shows that the P−F dipolar interaction does not vary when substituting Sr for Ba, in agreement with the P−F distances remaining always of the order of 3.7 Å. By contrast, for hydroxyapatites of space group $P6_3/m$ the statistical orientation of the OH^- ions gives different P−H distances and therefore different dipolar P−H interactions.

Conclusions

Barium strontium fluoroapatites form a continuous series of solid solutions. Structure refinements indicate a clear preference of strontium for the S(1) site of the apatitic structure. Despite the weak amplitude of variation of δ_{iso}, decomposition of the isotropic ^{31}P MAS-NMR resonance into separate signals, corresponding to different phosphate environments, was done for the phases with low content of either Sr or Ba.

Experimental Section

Synthesis: All chemicals, $Ba(CH_3CO_2)_2$, $Sr(NO_3)_2$, NH_4F, and $(NH_4)_2HPO_4$ were of reagent grade (Prolabo, 99% purity) and used without further purification. The mixed barium and strontium fluoroapatites $Ba_{(10-x)}Sr_xFAp$, with x ranging from 0 to 10, were obtained by a double decomposition method.[24,25] This method consists of the preparation in aqueous medium from a solution containing the two metallic cations (A) and a solution of phosphate and ammonium fluoride (B). Concentrations of the solutions in barium, strontium and phosphate ions correspond to the stoichiometry of the desired apatite. A mixture of barium acetate and strontium nitrate, with a total concentration of metal cations of 0.2 M (solution A, 250 mL) and 0.2 M ammonium dihydrogen phosphate solution (solution B, 150 mL) were prepared. Solution A was added dropwise to solution B, maintained at boiling temperature, under nitrogen. The pH of the slurry was maintained at approximately 11 by regular addition of small amounts of ammonia (d = 0.89; 28% aqueous solution). The resulting solid phase was kept in contact with the mother solution at boiling temperature for 1 h. The precipitate was then filtered, washed with hot distilled water, dried at 100 °C for 12 h and calcined at 500 °C for 4 h to improve its crystallinity. The compounds thus obtained were submitted to XRD, chemical analysis, IR spectroscopy and ^{31}P MAS NMR analyses.

Chemical Analyses and Instrumental Methods: Barium and strontium contents were determined with a Perkin−Elmer 3110 atomic absorption spectrophotometer. Phosphorus was determined colorimetrically as phosphovanadomolybdate, by measurement of its absorbance at 430 nm.[26] Fluorine content was determined by potent-

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

iometry, using an ionometer equipped with a fluoride-specific electrode, at ambient temperature and a pH of about 6. The support electrolyte was a 1 M aqueous solution of sodium citrate. The crystallographic data were collected with a Philips PW1710 diffractometer equipped with a copper anode and a graphite monochromator. The investigated range was from 15 to 100° (2θ), with a step of 0.03° and a counting time of 15 s for each step. IR spectra were obtained from KBr pellets (1 mg sample and 300 mg KBr) with a Bio-Rad FTS 6000 IRFT spectrophotometer in the range 4000−200 cm^{-1}, with a spectral resolution of 4 cm^{-1}. The NMR experiments were performed on powdered samples at room temperature with a Bruker MSL400 spectrometer (9.4 T) operating at 162 MHz. A Doty probehead equipped with 4-mm (diameter) rotors was used for MAS spinning rates up to 6.5 kHz. The spinning rate was monitored by a Bruker pneumatic unit, allowing the control of bearing and drive-inlet air pressure. The spectral width was 45 kHz (280 ppm). The spectra were acquired using a simple one-pulse sequence with phase cycling (CYCLOPS sequence). Pulse duration was 1 μs, (15° flip angle) and the preacquisition and interpulse delays were 22 μs and 5 s, respectively. The 4 K free-induction decay was zero-filled to the size of 8 K and convoluted with an exponential function (exponential multiplication) using a 10-Hz line-broadening factor. The final digital resolution of the spectrum was 10 Hz (0.07 ppm). A better digital resolution, for more accurate determination of the isotropic chemical shifts (±0.05 ppm), was obtained after 16 K zero-filling and no window function. Chemical shifts are reported with respect to external 85% H_3PO_4 in the IUPAC convention, i.e. positive δ corresponds to a resonance at higher frequency (deshielding) than the reference.

Structural Analysis: Rietveld-method crystal-structure refinements from the powder diffraction data were carried out with the DBWS-9411 program.[27,28] The space group ($P6_3/m$) and the atomic positions of the $Ba_{10}(PO_4)_6F_2$ structure were used as starting data in the refinement. First of all, the scale factor and the background coefficients were refined. The peaks were fitted with a "pseudo-Voigt" function. The half-width of the diffraction peaks as a function of 2θ was evaluated by the Caglioti equation.[29] Successively, the pattern parameters (true 2θ zero, peak widths and their dependence on 2θ, asymmetry parameter, preferred orientation parameter) and the lattice parameters were allowed to vary. Finally, the structural parameters (occupancy factor, atomic coordinates) were refined. No constraint was imposed on the overall strontium content. The two sites S(1) and S(2) were imposed to be fully and complementarily occupied by barium and strontium. The occupancy factors of O and P were assumed as constant, in agreement with the apatite stoichiometry. The fractional atomic coordinates were refined starting from the atomic positions of the two metals. No attempt was made to differentiate the barium positions from strontium ones. Rietveld refinement was performed in several stages, the parameters obtained in each stage being deferred in the following. In the last refinement cycles, all 29 parameters were released. Then, the refined parameters were used as initial model for apatite with barium content immediately lower, and so on. The results of the refinement structural parameters (atomic positions, anisotropic thermal parameters, lattice parameters, reliability pattern factors R_p and weighted factors R_{Wp}) are reported in Table 1, while a comparison between the calculated and observed profiles of Ba_5Sr_5FAp is reported in Figure 2. Table 4 gives interatomic distances and distortion indices of phosphate tetrahedron. The strontium-ion distribution between the two sites and chemical analysis results are gathered in Table 2.

Equivalent thermal parameters

$$B_{eq} = \sum_i \sum_j \beta_{ij} (\vec{a}.\vec{b})$$

are calculated by the relation[30]

$$B_{eq} = 4(a^2\beta_{11} + b^2\beta_{22} + c^2\beta_{33} + ab\beta_{12}\cos(\gamma)/3$$

Two Copper(II) Complexes Built from a Novel Redox-Active Bipyridinium Dimer Ligand and Oxalate Anions: Synthesis, Crystal Structure and Magnetic Properties

Yan-Qiong Sun,[a] Jie Zhang,*[a] Jing-Lin Chen,[a] and Guo-Yu Yang[a]

Keywords: Copper(II) / Bipyridium dimer / Oxalate / X-ray diffraction

The synthesis of a novel V-shaped redox-active bipyridinium dimer ligand, 2,6-bis(4′-pyridyl-1′-pyridiniumyl)pyrazine (**Bpypr**) dichloride and its copper complexes, (H_2**Bpypr**)[$Cu_2(C_2O_4)_4$] (**1**) and {[(**Bpypr**)$Cu_2(C_2O_4)_3$-$(H_2O)_2$]·$5H_2O$}$_n$ (**2**), are described. Single-crystal X-ray diffraction studies confirm that complex **1** contains one V-shaped H_2**Bpypr** cation and two essentially planar [$Cu(C_2O_4)_2$]$^{2-}$ anions, which participate in two hydrogen bonds through the two N–H moieties. Complex **2** has a 1D zigzag chain structure composed of [$Cu_2(C_2O_4)_3$]$^{2-}$ units bridged by V-shaped **Bpypr** cations. The magnetic study revealed the occurrence of a weak ferromagnetic interaction within the dinuclear copper unit of complex **2**.

Introduction

In recent years, the design and synthesis of metal-organic coordination polymers has attracted considerable attention in supramolecular chemistry and crystal engineering,[1−5] because these supramolecular assemblies have interesting structures as well as potentially useful properties such as magnetic, catalytic, and nonlinear optical activities or electrical conductivity, amongst others.[6−9] A developing strategy in this field is to build supramolecular arrays by use of polynuclear coordination complexes as the secondary architectural units, which introduces the appealing possibility of constructing porous materials[10,11] and molecular-scale wires.[12,13] In order to produce defined architectures and interesting functions in a controlled fashion, careful selection of the metal ions, peripheral ligands and modular bridging ligands is required.[14] At present, most of the systems studied are composed of molecular subunits, containing metal ions coordinated to appropriate ligands, and which are linked by extended bridging spacers such as alkanes, alkynes, or polycyclic aromatic groups. The geometry and photoelectrochemical properties of the assemblies are generally controlled by the presence of a polynuclear coordination complex.[15−17] Currently, not many bridging ligands with electrochemical and photochemical properties are available. Bipyridinium dimers, as derivatives of the viologens, exhibit photoelectrochemical activity and a change of spin multiplicity upon external stimulus.[18−20] Their terminal N-donor atoms and π-conjugated system can provide various coordination modes and structural motifs, which enable construction of versatile molecular assemblies and incorporation of optical, electronic and magnetic properties. In this paper, we report the design and synthesis of a novel V-shaped bipyridinium dimer bridging ligand (Scheme 1), 2,6-bis(4′-pyridyl-1′-pyridiniumyl)-pyrazine dichloride (**Bpypr**Cl_2), which exhibits two-step electrochemical reduction processes and photochemical activity. Two new copper complexes (H_2**Bpypr**)[$Cu_2(C_2O_4)_4$] (**1**) and {[(**Bpypr**)$Cu_2(C_2O_4)_3(H_2O)_2$]·$5H_2O$}$_n$ (**2**), possessing quite different architectures despite use of the same starting materials, were obtained by molecular self-assembly.

Results and Discussion

Redox and Photochemical Properties of the $BpyprCl_2$ Ligand

The electrochemical behavior of the **Bpypr**Cl_2 ligand was investigated by cyclic voltammetry in a 0.1 M acetonitrile solution of $(Bu_4N)PF_6$. The two-step quasi-reversible electron-transfer processes occurring at $E_{1/2} = -0.271$ V and -0.419 V vs. Ag^+/Ag, respectively, correspond to the first and second reduction of the **Bpypr**Cl_2 ligand. The photochemical activity of **Bpypr**Cl_2 was investigated spectrochemically in methanol solution. Under illumination with a 350-W xenon lamp, the absorption band of the ligand at 310 nm decreases in intensity and undergoes a slight blue-shift, while a new broad band appears between 400 to 600 nm, characteristic for the generation of photoinduced radicals.[21]

Structural Description

X-ray diffraction analysis reveals that complex **1** contains one V-shaped H_2**Bpypr** cation and two essentially planar $[Cu(C_2O_4)_2]^{2-}$ anions (Figure 1). Each cupric cation is coordinated by four oxygen atoms from two oxalate anions to give a square-planar geometry. The bond lengths of Cu−O range from 1.913(5) Å to 1.950(5) Å and the bond angles of O−Cu−O range from 85.3(2)° to 95.7(2)°. The H_2**Bpypr** ligand, with a two-fold axis passing through N(4) and N(3) atoms, is slightly twisted between the pyrazine ring and adjacent pyridyl rings, while the bipyridyl unit is close to planarity with a small dihedral angle of 7.82(25)°. Two $[Cu(C_2O_4)_2]^{2-}$ anions and one H_2**Bpypr** cation are involved in hydrogen-bonding interactions, having appropriate distances and orientation for N(1)−H(1)···O(7) [2.763(9) Å] and N(1)−H(1)···O(8) [3.012(9) Å], leading to the formation of a V-shaped dimer. These V-shaped dimers are cross-packed to yield an extended rhombic motif along the *a* axis, with $[Cu(C_2O_4)_2]^{2-}$ anions sitting in the center of the rhombus (Figure 2). No specific π−π stacking interactions are identifiable between N-heterocyclic rings.

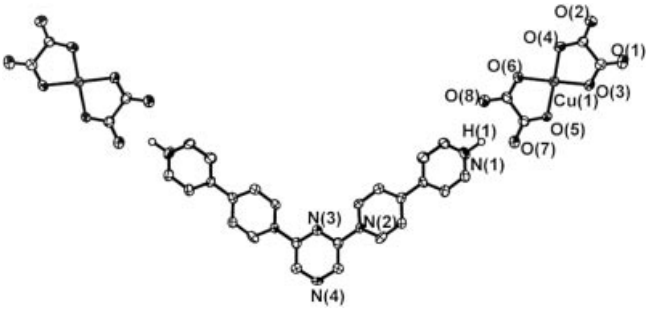

Figure 1. ORTEP drawing (50% probability level) with atom-numbering scheme of complex **1**, $(H_2Bpypr)[Cu_2(C_2O_4)_4]$, showing the local coordination environment of Cu^{II}; all hydrogen atoms are omitted for clarity with the exception of H(1) on the nitrogen atom

Complex **2** possesses a one-dimensional zigzag chain structure composed of $[Cu_2(C_2O_4)_3]^{2-}$ units bridged alternately by V-shaped **Bpypr** cations. As shown in Figure 3,

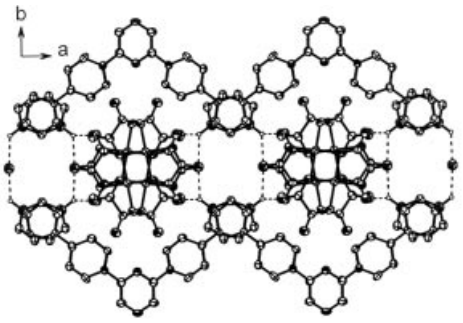

Figure 2. Packing structure for complex **1**, $(H_2$**Bpypr**$)[Cu_2(C_2O_4)_4]$, viewed along the *c* axis; all hydrogen atoms are omitted for clarity with the exception of H(1) on the nitrogen atom

the crystallographically independent copper ion has an elongated octahedral geometry with the equatorial plane defined by one nitrogen atom of the **Bpypr** ligand [Cu−N: 2.026 (5) Å] and three oxalate oxygen atoms [average Cu−O: 1.961(5) Å], with the axial sites occupied by one water molecule [Cu−O 2.618(7) Å] and one oxygen atom from a centrosymmetric bridging oxalate [Cu−O 2.334(6) Å]. The bridging oxalato ligand is almost planar, with an inversion center lying in the middle of the C−C bond. The C−O bond lengths are not equivalent [1.241(8) Å, 1.283(9) Å], and those involving axial coordination are shorter. The **Bpypr** ligand, with a two-fold axis passing through N(4) and N(3) atoms, shows a nonplanar configuration. The two adjacent pyridyl rings are twisted by 16.35(52)° with respect to each other, while the dihedral angle between the pyrazine ring and the neighboring pyridyl ring is 18.61(57)°.

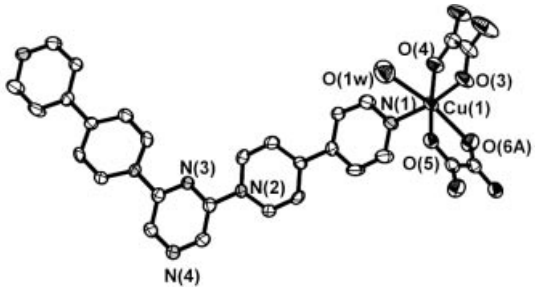

Figure 3. ORTEP drawing (50% probability level) with atom numbering scheme of complex **2**, $\{[($**Bpypr**$)Cu_2(C_2O_4)_3(H_2O)_2]\cdot 5H_2O\}_n$, showing the local coordination environment of Cu^{II}; the H atoms are omitted for clarity; atom labels having "A" refer to symmetry-generated atoms

The bridging oxalate ligand coordinates to a central-symmetry-related Cu^{II} ion in bis(bidentate) fashion to give the dinuclear $[Cu_2(C_2O_4)_3]^{2-}$ ions as a secondary building unit. The Cu−Cu′ distance across the oxalate ion is 5.581(2) Å, within the range observed in dinuclear Cu^{II} complexes containing oxalate bridges in an asymmetrical bis(bidentate) coordination between the two metal centers.[22,23] V-shaped **Bpypr** cations link the $[Cu_2(C_2O_4)_3]^{2-}$ dinuclear units to form polymeric chains running along the *c* axis of the unit cell (Figure 4). These chains are stacked on top of each other along [101] to yield a subunit motif consisting of

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

alternate rhombic sheets with a plum-blossom-like configuration. The rhombic sheets are held together further by hydrogen bonds between the terminal oxygen atoms of the uncoordinated oxalate and water molecules [O···O = 2.627(24)−3.098(27) Å], resulting in a three-dimensional supramolecular network.

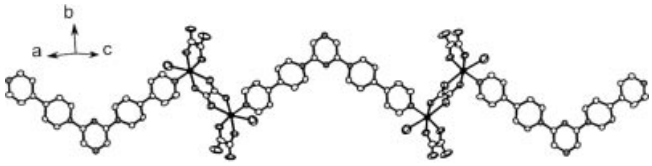

Figure 4. Zigzag chain of complex **2**, $\{[(\mathbf{Bpypr})Cu_2(C_2O_4)_3(H_2O)_2]\cdot 5H_2O\}_n$

Thermogravimetric Analysis

The thermal stabilities of the two complexes were determined by thermogravimetric analysis (TGA) under a flow of N_2. The TGA curve for **1** shows an initial weight loss of 65.23% from 40 °C to 455 °C which corresponds well to the loss of one H_2**Bpypr** cation and two oxalate anions per formula unit (calcd. 65.22%). Above 455 °C, the residual oxalate ion of complex **1** decomposes completely and the sample converts to cupric oxide above 800 °C. The TGA curve for **2** displays a three-step weight loss process. The initial weight loss of 10.31% between 50 and 120 °C corresponds to the loss of five uncoordinated water molecules per formula unit (calculated: 9.92%). The second weight loss of 50.14% is observed from 120 to 385 °C, and is attributed to the removal of two coordinated water molecules, one $\mathbf{Bpypr}^{2+}$ cation and one CO molecule (from incomplete decomposition of an oxalate anion) per formula unit (calculated: 50.07%). Above 385 °C, the residual oxalate ion of complex **2** starts to decompose and the sample converts to cupric oxide at 720 °C (residual CuO, calculated: 17.53%; found 17.38%).

Electron Spin Resonance Spectroscopy

X-band powder ESR spectra of complex **1** and **2** at room temperature show broad axial signals at $g_{\|} = 2.1527$, $g_{\perp} = 2.0792$ ($g_{av} = 2.1163$) for **1**, and $g_{\|} = 2.2816$, $g_{\perp} = 2.0747$ ($g_{av} = 2.1806$) for **2**, corresponding basically to a $d_{x^2-y^2}$ ground state for the Cu^{II} ion (inverted type with $g_{\|} > g_{\perp} > 2.0$). The g values are similar to those expected for the CuO_4 chromophores of **1** with a square-planar-type geometry around the copper ion, and for those $CuNO_3O_2'$ chromophores of **2** where the copper atom is in a very elongated octahedral environment.

Magnetic Behavior

The temperature dependence of the magnetic susceptibilities was measured in the temperature range 300 to 5 K in an applied field of 10 kOe. Figure 5 shows the magnetic behavior of complex **2** in the form of the $\chi_M T$ product (χ_M is the molar magnetic susceptibility per two Cu^{II} ions) versus temperature. At room temperature, $\chi_M T$ is 0.87 $cm^3\cdot K\cdot mol^{-1}$, in agreement with the expected spin-only value for two magnetically dilute Cu^{II} centers with $S = 1/2$ ($g = 2.15$). With decreasing temperature, the $\chi_M T$ value steadily increases attaining a value of 0.99 $cm^3\cdot K\cdot mol^{-1}$ at 5 K. This behavior suggests a weak ferromagnetic interaction between the Cu^{II} ions, which is further confirmed by a positive Weiss constant ($\theta = +1.16$ K). In order to evaluate the exchange interaction between neighbouring Cu^{II} atoms, the variable-temperature susceptibility data were analyzed using Equation (1) derived[24] from the Heisenberg isotropic spin Hamiltonian ($H = -JS_1\cdot S_2$), for two coupled $S = 1/2$ ions, given by the Bleaney−Bowers expression for a dinuclear Cu^{II} compound. The interaction between adjacent dinuclear units in the 1D chain was considered in molecular-field approximation; J is the intradimer coupling constant between Cu^{II} ions, zJ' is the interdimer magnetic exchange, treated in the molecular field approximation. A best fit, which affords the solid line in Figure 5, was obtained with values of $g = 2.15$, $J = 3.86\ cm^{-1}$, $zJ' = -0.28\ cm^{-1}$. The agreement factor R, defined as $\Sigma[(\chi_M)_{obsd.} - (\chi_M)_{calcd.}]^2/\Sigma(\chi_M)^2_{obsd.}$, is equal to 5.73×10^{-6}. The positive J value demonstrates a ferromagnetic coupling between the two Cu^{II} ions.

$$\chi_M = 2Ng^2\beta^2[kT - 2zJ'/(3 + \exp(-J/kT))]^{-1}[3 + \exp(-J/kT)]^{-1} \quad (1)$$

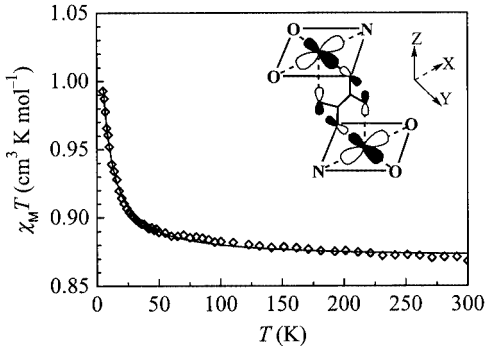

Figure 5. The temperature dependences of the product $\chi_M T$ (diamonds) for complex **2**, $\{[(\mathbf{Bpypr})Cu_2(C_2O_4)_3(H_2O)_2]\cdot 5H_2O\}_n$; the solid line corresponds to the best theoretical fit; the inset shows a model depicting the magnetic interaction in the oxalate-bridged Cu^{II} complex **2**

The complex **2** exhibits an elongated octahedral geometry, with the unpaired electron around each metal center described by a magnetic orbital of the $d_{x^2-y^2}$ type pointing toward the three oxalato oxygen atoms and one pyridyl nitrogen atom of the equatorial plane, which is perpendicular to the oxalate bridge. This situation corresponds to the coordination mode shown in the inset of Figure 5. Due to a poor overlap between the axial oxalato oxygen orbital and the metal $d_{x^2-y^2}$ orbital, a ferromagnetic coupling dominates the magnetic properties of the Cu dinuclear unit of complex **2**. The magnitude of the coupling observed is in the same range as several reported examples.[25,26]

Conclusion

A novel V-shaped redox-active bipyridinium dimer ligand, 2,6-bis(4′-pyridyl-1′-pyridiniumyl)pyrazine (**Bpypr**) dichloride has been designed and synthesized. Two new copper complexes, $(H_2$**Bpypr**$)[Cu_2(C_2O_4)_4]$ (**1**) and $\{[($**Bpypr**$)Cu_2(C_2O_4)_3(H_2O)_2]\cdot 5H_2O\}_n$ (**2**), were obtained by assembling the **Bpypr**Cl_2 ligand with $(NH_4)_2Cu(C_2O_4)_2$. The 1-D zigzag chain of **2** is composed of $[Cu_2(C_2O_4)_3]^{2-}$ units bridged by V-shaped **Bpypr** cations in an alternating fashion. The variant assembly modes of **Bpypr** ligand with $(NH_4)_2Cu(C_2O_4)_2$ provide a great potential for construction of multifunctional organic-inorganic hybrid materials and for the observation of important structure-property relationships. More physical properties and further assemblies of the **Bpypr** ligand with other anionic donors is in progress.

Experimental Section

General Remarks: All chemicals were used as purchased without purification except those used for electrochemical measurements. The ^{1}H NMR spectrum was recorded with a Varian Unity 500 MHz spectrometer. IR spectra were measured as KBr pellets with a Bomem BM102 FT-IR in the range 400−4000 cm^{-1}. The elemental analyses were determined using a Vario EL III CHNOS elemental analyzer. Thermogravimetric data were collected with a Mettler Toledo TGA/SDTA 851^e analyzer under a stream of nitrogen at a heating rate of 5 °C/min. ESR spectra were recorded with a Bruker ER-420 spectrometer at the X-band frequency. Variable-temperature magnetic susceptibilities were measured from 300 K to 5 K with an applied field strength of 10 KOe using a Quantum Design MPMS-7 magnetometer. Diamagnetic corrections were estimated from Pascal's constants. Photochemistry of the samples in KBr pellets was investigated using a 350-W Xenon lamp. The cyclic voltammogram was obtained by use of a Perkin-Elmer potentiostat/galvanostat model 263A in 1 mM acetonitrile solution containing 0.1 M $(Bu_4N)PF_6$ as supporting electrolyte at a scan rate of 100 $mV\cdot s^{-1}$. Platinum and glassy graphite were used as working and counter electrodes, respectively. Potentials were referenced to Ag/AgCl.

Preparation of the BpyprCl$_2$ Ligand: A mixture of 4,4′-bipy(3.12 g, 20 mmol) and 2,6-dichloropyrazine (1.47 g, 10 mmol) was dissolved in 8 mL of DMF. After stirring at 120 °C under nitrogen for 4 h, the solution was concentrated to a small volume under reduced pressure. Then an excess of hot benzene was added and the precipitate was collected by filtration, washed with hot benzene and dried in vacuo to afford a pale yellow powder (1.62 g, 35.3%). ^{1}H NMR ($CDCl_3$, 500MHz): δ = 8.12 (d, 4 H), 8.85 (d, 4 H), 8.89 (d, 4 H), 9.88 (d, 4 H), 9.92 (s, 2 H) ppm. IR (KBr): $\tilde{\nu}$ = 3478 (s), 3413 (s), 3118 (w), 3033 (w), 1634 (vs), 1597 (m), 1557 (m), 1463 (w), 1438 (s), 1412 (s), 1347 (w), 1281 (m), 1263 (m), 1212 (m), 1161 (w), 1019 (m), 866 (m), 821 (s), 754 (m), 718 (m), 637 (w), 619 (w), 538 (w), 501 (m) cm^{-1}.

Synthesis of $(H_2$Bpypr$)[Cu_2(C_2O_4)_4]$ (1): A mixture of **Bpypr**Cl_2 (102.2 mg, 0.2 mmol) and $CuCl_2$ (34 mg, 0.2 mmol) was dissolved in water. The resulting solution was layered with an H_2O/DMSO (5:1, v/v) solution (20 mL) of $(NH_4)_2Cu(C_2O_4)_2$ (55.1 mg, 0.2 mmol) in a 1:1 ratio in a straight glass tube. Black-green prism crystals were obtained by slow interface diffusion after a few days. Yield 11%. IR (KBr): $\tilde{\nu}$ = 3556 (m), 3454 (m), 3114 (w), 3037 (w), 1707 (w), 1652 (vs), 1431 (s), 1415 (m), 1378 (s), 1278 (m), 1241 (m), 1201 (m), 1007 (m), 818 (m), 792 (m), 551 (w), 497 (m) cm^{-1}. $C_{32}H_{20}Cu_2N_6O_{16}$ (871.62): calcd. C 44.10, H 2.31, N 9.64; found C 43.76, H 1.86, N 9.54.

Synthesis of $\{[($Bpypr$)Cu_2(C_2O_4)_3(H_2O)_2]\cdot 5H_2O\}_n$ (2): A mixture of **Bpypr**Cl_2 (102.2 mg, 0.2 mmol) and $CuCl_2$ (34 mg, 0.2 mmol) was dissolved in water. The resulting solution was layered with an H_2O/DMSO (5:1, v/v) solution (20 mL) of $(NH_4)_2Cu(C_2O_4)_2$ (55.1 mg, 0.2 mmol) in a 1:1 ratio in a straight glass tube. Green needle crystals were obtained by slow interface diffusion after a few days. Yield 32%. IR (KBr): $\tilde{\nu}$ = 3416 (s), 3121 (w), 3038 (w), 1691 (vs),

X-ray Crystallography: Data sets for **1** and **2** were collected at room temperature using a Siemens SMART CCD diffractometer with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation in the ω- and φ-scanning mode. An empirical absorption correction was applied using the SADABS program. The structures were solved by direct methods and refined by full-matrix least-squares on F^2 using the SHELXTL-97 program package.[27] All hydrogen atoms were generated geometrically (C−H = 0.93 Å) with the exception of the hydrogen atoms of all free water molecules and H(1) of **1**. H(1) of **1** was located in the difference Fourier map and its position and isotropic displacement parameters were refined. The crystallographic data for complexes **1** and **2** are listed in Table 1. Selected bond lengths and angles are shown in Table 2. CCDC-220468 (**1**) and -220467 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

2,4-*N*,*N*′-Bis(dialkylamido)-2,4-dithioxo-1,3,2λ^5,4λ^5-dithiadiphosphetanes

Anton Dimitrov,*[a] Irmgard Hartwich,[a] Petra Neubauer,[a] and Manfred Meisel[a]

Keywords: Donor-acceptor systems / N-ligands / Fluorinated ligands / Sulfur / Phosphorus

Dialkylamide derivatives of the monometadithioxaphosphoric acid stabilised by pyridine as a donor, i.e. $[(C_5H_5N)PS_2NR_2]$, readily react with $AlCl_3$. The elimination of the donor and formation of the adduct $C_5H_5N{\cdot}AlCl_3$ liberates the unstable $\sigma^3\lambda^5$-phosphoranes (PS_2NR_2). The latter are stabilised by [2+2] "cycloaddition-dimerization" leading to the title compounds $[PS_2NR_2]_2$ in nearly quantitative yields. The synthesis and characterisation of two compounds possessing NR_2 substituents of very different basicities clearly demonstrate the generalisation of such a procedure as an easy way of accessing further derivatives in this class.

Introduction

Whereas studies of dithiadiphosphetane disulfides $(PS_2X)_2$ (X = alkyl, aryl, alkylthio, arylthio, and some "exotic substituents" such as ferrocenyl[1] or $[W(CO)_5]$[2]) have been well documented, with more than 20 published crystal structures[3], literature reports of the same class of substances with X = NR_2 remain rare, speculative or have been shown to be incorrect. During the reaction between P_4S_3 and $S[N(CH_3)_2]_2$, Fluck et al. observed the formation of the title compound $[PS_2NMe_2]_2$ (**1a**).[4] From numerous signals appearing in the ^{31}P NMR spectra of the reaction products, the authors assigned a singlet at δ = 23.9 ppm to compound **1a**. The decrease of its intensity in the mixture was concomitant with the formation of crystals. The remaining components of the reaction mixture were not characterised. After successful completion of the process, the isolated crystals showed practically no solubility in common organic solvents. By means of mass spectrometric, IR and Raman data the composition of the crystals was postulated as a mixture of the dimer **1a** and the trimer $[PS_2NMe_2]_3$. An X-ray investigation of a crystal from the heterogeneous solid mixture revealed the structure of **1a**, the only known crystal structure, up to now, of a bis(dialkylamido)dithiadiphosphetane. By attempting to reproduce the synthesis of Fluck et al.[4], we succeeded in the preparation of **1a** with a yield of about 7%. The ^{31}P NMR spectra taken from the product mixture revealed the inaccessibility of this synthesis: the main peaks were unknown and did not correspond to **1a**. Furthermore we were unable to confirm the reported[4] insolubility of **1a** in common organic solvents. Thus, **1a** prepared in nearly quantitative yield by our method [see Equation (2)] allows at least the convenient measuring of ^{31}P NMR spectra in toluene.

In 1994 Nizamov et al.[5] reported the reaction between P_4S_{10} and R_2NSR' as a high yield synthesis for the title compounds **1a** or $[PS_2NEt_2]_2$ **1b**, respectively.

$$P_4S_{10} + 4\ R_2NSR' \longrightarrow 2\ \text{(1a/1b)} + 2\ R'SSR' + 1/4\ S_8 \qquad (1)$$

1a R = Me, R' = Et, *i*Pr
1b R = Et, R' = Et, *i*Pr, *i*Bu

The authors' interpretation of the data obtained from Equation (1) is, however, clearly incorrect. All of the ^{31}P NMR spectra taken from the reaction products showed no signals in the chemical shift region which is typical for compounds having a dithiadiphosphetane ring (δ = 20−26 ppm, see below), but signals at much lower field (between δ = 90 and 120 ppm). Because the elemental analysis[5] of the reaction products supports the presence of compounds with a composition equal to **1a** and **1b**, the reported δ(^{31}P) values of the NMR spectra could only be explained if the reaction products are isomers of **1** with a P_2N_2 four membered ring such as 1,3-dialkyl-2,4-bis(alkylthio)-2,4-dithioxo-1,3-diaza-2λ^5,4λ^5-diphosphetidines[6] and/or some cyclic oligomers, $[R_2NPS_2]_n$ (n = 3,4). However, the various signals listed in reference 5 which result from the main products of the reaction between P_4S_{10} and alkylsulfendialkylamides (R_2NSR'), show that Equation (1) clearly results in a mixture of undefined (not identified) products with no measurable formation of **1**. Altogether, the data from the

literature reveal that at the present time, a suitable approach to the synthesis of **1** does not exist.

Results

During our investigations into the differences in the structures and reactivities of amides of the donor stabilised monometadithioxaphosphoric acid with various alkyl substituents, $(C_5H_5N)PS_2NR_2$ (**2**), we developed an easy synthesis for **1** by treating **2** with the Lewis acid $AlCl_3$.

R	**2** (^{31}P NMR Signal)
CH_3	**2a** (122.0 ppm)[7]
CH_2CH_3	**2b** (122.9 ppm)[8]
CH_2CF_3	**2c** (120.9 ppm)

$$2\,(C_5H_5N)PS_2NR_2 \;(\mathbf{2a–c}) + 2AlCl_3 \rightarrow 2\,C_5H_5N{\cdot}AlCl_3 + [PS_2NR_2]_2 \;(\mathbf{1a–c}) \quad (2)$$

1 (^{31}P NMR Signal)
1a (23.9 ppm)[4]
1b (21.8 ppm)[8]
1c (25.7 ppm)

The starting compounds **2** can be obtained very pure and in high yields by treating the pyridine stabilized σ^{4}λ^5-dithiochlorophosphorane, Py→PS_2Cl, with the corresponding *sec*-amines.[9] The single-crystal X-ray diffraction investigations of **2b**[10] and **2c**[11] (Figure 1) show the distorted tetrahedral surroundings of the P atoms in both compounds. By comparing the two structures, one can recognize that the lengthening of the P−N_{amide} bond in **2c**, caused as expected by the influence of the CF_3 groups, does not affect the P−N_{donor} and P=S distances at all.

Our high temperature ^{31}P NMR investigations confirm the formation of small amounts of **1b** by heating **2b**, an observation already noted by Meisel and Donath.[8] This observation has been explained by the liberation of σ^{3}λ^5-PS_2NEt_2 intermediates from **2b** at high temperatures as reactive species which undergo [2+2] cycloaddition reactions. This hypothesis[8] has been strongly supported by our results which make it seem very plausible. The reaction of **2** with the strong Lewis acid $AlCl_3$ which forms the adduct Py → $AlCl_3$ with the donor base pyridine, results exclusively in the formation of **1**, Equation (2).[13]

The molecular structures of **1b**[14] (Figure 2) and **1c**[15] show a completely planar P_2S_2 four member ring in each case, with a *trans* arrangement of the exocyclic ligands. The P centres are in distorted tetrahedral environments. The tetrahedra are joined along a common edge (built by the endocyclic S atoms) to the dimeric molecules **1**. The significant difference in the bond lengths between the two endocyclic S atoms and phosphorus within the dithiadiphosphetane ring reveals the tendency for a monomer formation in **1b** and **1c** but, surprisingly, not in **1a**. In Table 1 some selected bond angles and distances are given.

Equation (2) which we have dealt with in this work leads, in its first step and under mild conditions, to the formation of reactive $\sigma^3\lambda^5$ phosphoranes. The subsequent [2+2] cycloaddition reaction immediately forms the stable dimeric title compounds **1**. At present we are investigating the viability of the analogous reactions of Py→$POSNR_2$ and Py→PO_2NR_2 with $AlCl_3$. By successfully applying these reactions it may be possible to access the corresponding dimeric compounds with P_2O_2 or P_2OS four membered rings.

Experimental Section

General Remarks: All experiments were performed under purified dry argon in a glove box and/or on a glass high-vacuum line. Py→PS_2Cl was prepared according to the literature procedure from P_4S_{10}, pyridine and $PSCl_3$ [16]. Toluene was heated to reflux over Na and freshly distilled prior to use. The NMR spectra were recorded with a 400 MHz Bruker spectrometer at the appropriate ^{31}P, ^{1}H, ^{13}C and ^{19}F frequencies using H_3PO_4, TMS and F11 as external standards, respectively.

Single-crystals suitable for X-ray analyses were isolated and prepared in a cold stream of nitrogen. Data collection was carried out with an IPDS diffractometer (Stoe & Cie) at 180 K using graphite-monochromated Mo-K_α radiation (71.073 pm) and a cryostream cooler (Oxford Cryosystems). The data set was collected in the φ-oscillation scan mode. The structures were solved[17] and refined[18] with SHELX 97 (see refs.[10−15]). CCDC-232449 (for **1b**), -232450 (for **1c**), -232451 (for **2b**) and -232448 (for **2c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of 1: Compound **2** (5 mmol) was partially dissolved in toluene (15 mL) in a 50-mL Schlenk tube. To this suspension was added an equivalent amount of $AlCl_3$ (668 mg) dissolved in toluene (15 mL) and the reaction mixture became a clear solution. Within 1−2 hours the reaction was complete and the adduct $C_5H_5N{\cdot}AlCl_3$ separated as an oil and/or solid participate. The clear toluene phase was separated, its volume reduced to about 1/3 by evaporation of the solvent and stored overnight at −20 °C for crystallisation. The resultant crystals were separated, washed with toluene and dried in vacuo.

1b: Yield 80.5%, $C_8H_{20}N_2P_2S_2$ (334.45): calcd. C 28.73, H 6.03, N 8.38, P 18.52, S 38.34; found C 27.87, H 6.43, N 8.13, P. 18.92, S 38.29. NMR spectroscopic data ([D$_8$]toluene): ^{31}P NMR: δ = 21.8 ppm. ^{1}H NMR: δ = 0.92 (t, $^{3}J_{H,H}$ = 6.9 Hz, 6 H, CH_3), 3.42 (d/q, $^{3}J_{H,P}$ = 17.7, $^{3}J_{H,H}$ = 6.9 Hz, 4 H, CH_2) ppm. ^{13}C NMR: δ = 13.7 (s, CH_3), δ = 41.6 (s, CH_2) ppm.

1c: Yield 73.1%, $C_8H_8F_{12}N_2P_2S_4$ (550.33): calcd. N 5.09, P 11.26, S 22.3; found N 4.93, P 11.82, S 23.77. NMR spectroscopic data [D$_8$]toluene: ^{31}P NMR: δ = 25.7 ppm. ^{1}H NMR: δ = 3.93 (d/q, $^{3}J_{H,P}$ = 16.2, $^{3}J_{H,F}$ = 8.3 Hz, 4 H, CH_2) ppm. ^{13}C NMR: δ = 47.3 (q, $^{2}J_{C,F}$ = 33.5 Hz, CH_2), δ = 124.6 (q, $^{1}J_{C,F}$ = 282.1 Hz, CF_3) ppm. ^{19}F NMR: δ = −68.04 (t, $^{3}J_{F,H}$ = 8.3 Hz, CF_3) ppm.

Synthesis of 2: Py → PS_2Cl (10 mmol) was partially dissolved in toluene (25 mL) in a 75 mL Schlenk tube. To this suspension was added the corresponding *sec*-amine dissolved in toluene (10 mL). Two equivalents were used for **2b** and a single equivalent together with one equivalent of pyridine for **2c**. The reaction mixtures became clear solutions and after heating for 2 hours at 60 °C under an Argon atmosphere the reactions were complete. The precipitated amine hydrochlorides were filtered after cooling to room temperature and the clear filtrates stored overnight at −20 °C for crystallisation. The crystals were separated, washed with toluene and dried in vacuo.

2b: Yield 73.5%, $C_9H_{15}N_2PS_2$ (246.32): calcd. C 43.88, H 6.14, N 11.37, P 12.57, S 26.03; found C 43.20, H 6.14, N 10.93, P 12.85, S 26.07. NMR spectroscopic data (CD_3CN): ^{31}P NMR: δ = 123.3 ppm. ^{1}H NMR: δ = 0.95 (t, $^{3}J_{H,H}$ = 7.1 Hz, 6 H, CH_3), 3.50 (d/q, $^{3}J_{H,P}$ = 15.2, $^{3}J_{H,H}$ = 7.1 Hz, 4 H, CH_2), 7.81 (m, 2 H, β-CH), 8.25 (m, 1 H, γ-CH), 9.45 (m, 2 H, α-CH) ppm. ^{13}C NMR: δ = 14.2 (d, $^{3}J_{C,P}$ = 2.2 Hz, CH_3), 42.2 (d, $^{2}J_{C,P}$ = 3.6 Hz, CH_2), 126.9 (s, β-CH), 142.9(s, α-CH), 144.4 (s, γ-CH) ppm.

2c: Yield 69.1%, $C_9H_9F_6N_2PS_2$ (354.27): calcd. N 7.91, P 8.74, S 18.1; found N 7.51, P 9.26, S 18.46. NMR spectroscopic data (CD_3CN): ^{31}P NMR: δ = 120.9 ppm. ^{1}H NMR: δ = 4.47 (d/q, $^{3}J_{H,P}$ = 13.2, $^{3}J_{H,F}$ = 8.9 Hz, 4 H, CH_2), 7.9 (m, 2 H, β-CH), 8.4(m, 1 H, γ-CH), 8.7 (m, 2 H, α-CH) ppm. ^{13}C NMR: δ = 49.0 (q/d, $^{2}J_{C,F}$ = 32.7, $^{2}J_{C,P}$ = 5.0 Hz, CH_2), 125.8 (q/d, $^{1}J_{C,F}$ = 282, $^{3}J_{C,P}$ = 2.2 Hz, CF_3), 127.9 (s, β-CH), 143.1 (s, α-CH), 146.2 (s, γ-CH) ppm. ^{19}F-NMR: δ = −68.19 (t, $^{3}J_{F,H}$ = 8.9 Hz, CF_3) ppm.

Hydrothermal Synthesis, Structure and Magnetic Properties of a One-Dimensional Iron Arsenate, $^1_\infty[NH_3(CH_2)_2NH(CH_2)_2NH_3][Fe_2F_4(HAsO_4)_2]$

Sandip Chakrabarti,[a] Swapan K. Pati,[b] Mark A. Green,[c] and Srinivasan Natarajan*[a]

Keywords: Iron arsenate / Antiferromagnetism / Hydrothermal reactions / Iron / Magnetic properties

A novel one-dimensional iron arsenate, $^1_\infty[NH_3(CH_2)_2NH(CH_2)_2NH_3][Fe_2F_4(HAsO_4)_2]$, built up exclusively from SBU-4 units (two octahedral units sharing an edge and connected through two tetrahedra) with Fe^{3+} ions in the high-spin state has been synthesized by hydrothermal methods. Structure elucidation reveals that the compound is a two-leg ladder with very weak antiferromagnetic exchanges along the chains. The magnetic susceptibility data show activated behaviour at T = 14 K, suggesting a finite spin gap between the nonmagnetic ground state and the excited triplet state. We have estimated the exchange parameters theoretically based on the S = 5/2 Majumdar–Ghosh model with frustrations and dimerisations. Although the magnetic gap is quite small, this is the first example, to the best of our knowledge, where the rungs with two S = 5/2 spins form strong singlet dimers.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2004)

Introduction

In recent years, one-dimensional and quasi-one-dimensional systems have received considerable attention. Due to large quantum fluctuations, low-dimensional systems often show unusual properties such as a gap between a singlet ground state and a magnetic excited state; this leads to exponentially vanishing magnetic susceptibility at low temperature. Many low-dimensional systems have been realised experimentally, of which the Haldane gap spin-1 system is a good example.[1−3] Other examples include the spin-ladder systems in which a small number of chains interact with each other.[4,5] It has been observed that if each rung of the ladder contains an odd number of spin-1/2 sites, then the system effectively behaves like a spin-1/2 chain with a gapless low-energy spectrum. Such behaviour has been observed in $Sr_2Cu_3O_5$.[6] Conversely, ladders with an even number of spin-1/2 sites in the rung behave like an integer spin chain with a finite spin gap to the lowest excited spin state [for example, $SrCu_2O_3$,[7] $(VO)_2P_2O_7$,[8] $Cu_2(C_5H_{12}N_2)_2Cl_4$ [9]]. Another interesting observation in a quasi-one-dimensional spin system, $CuGeO_3$, is that it spontaneously dimerises below the spin-Peierls transition temperature leading to opening up of a spin gap.[10]

We have been interested in the intricate relationship between structure, dimensionality and magnetism. As part of a research program aiming to produce new compounds based on iron, a new iron arsenate, $^1_\infty[NH_3(CH_2)_2NH(CH_2)_2NH_3][Fe_2F_4(HAsO_4)_2]$ (**I**), possessing a one-dimensional structure was synthesized. Although the syntheses and structures of a large number of metal phosphates with open-framework structures have been reported in the literature,[11] research on metal arsenates is just beginning to emerge.[12−16] In many of the metal phosphates, the use of fluorine in the synthesis mixture appears to give rise to a variety of novel structures, especially in iron phosphates.[17] The concept of secondary building units has evolved to describe complex crystal structures based on tetrahedral connectivity.[18] During the last few years, this has been expanded to include nontetrahedral connectivity as well.[19] In the case of octahedral-tetrahedral structures, such as those present in iron phosphates and arsenates, the common structural features prompted Ferey to propose a set of secondary building units (SBUs) to describe and understand such structures.[20−22] The simplest of the SBUs is the one containing two octahedral and tetrahedral units (SBU-4), wherein the octahedral units share edges/corners and are connected through the tetrahedra. Compound **I**, described here, is the first one-dimensional structure built up exclusively from SBU-4 building units.

The two-leg ladder $^1_\infty[NH_3(CH_2)_2NH(CH_2)_2NH_3][Fe_2F_4(HAsO_4)_2]$ (**I**) consists of high-spin Fe^{3+} (S = 5/2) ions. Due to strong exchange interactions between the rung

spins, each rung can be considered as a singlet spin dimer. The magnetic susceptibility measurements show that the system has a spin gap of about 10 K. The theoretical fit to the experimental data suggests that the system is a weakly linked rung dimer. We have also measured magnetisation as a function of magnetic field at two different temperatures. At low field strength, both of the magnetisation curves follow unit-cell-polarised Brillouin functions (each unit cell contains two $S = 5/2$).

Results and Discussion

The asymmetric unit of **I** contains two crystallographically unique Fe and As atoms. Of these, Fe(1) and As(1), and Fe(2) and As(2) are connected together, giving rise to two independent one-dimensional ladders. Both the Fe atoms, Fe(1) and Fe(2), are octahedrally coordinated by three O and three F atoms with Fe−O/F bond lengths in the range 1.874(3)−2.064(3) Å (average 1.9852 Å). Each iron atom is linked to three arsenic atoms through three Fe−O−As bonds (average angle 127.5°), has two Fe−F−Fe bonds (average angle 101.43°) and possesses a terminal Fe−F bond. Each As atom also has three As−O−Fe bonds and one terminal As−O bond. The As atom is tetrahedrally coordinated by oxygen atoms with an average As−O distance of 1. 6832 Å and an O−As−O bond angle of 109.4°. The terminal As−O bonds, for both As(1) and As(2), are As−OH bonds; this agrees well with the proton position found next to the oxygen atoms in the difference Fourier map. The Brown−Altermatt formalism[23] for the bond length/bond valence relationship for Fe−O, Fe−F and As−O was used to calculate bond-order sums for the cations and anions (Table 3). The calculated bond-order sums for both cations and anions are in agreement with the formal oxidation states of +3, +5 and −2 for Fe, As and O atoms, respectively (Table 3).

The structure of **I** consists of FeO_3F_3 octahedral and $HAsO_4$ tetrahedral building units connected through their vertices. Thus, the connectivity between $Fe(1)O_3F_3$ and $As(1)O_3(OH)$, and $Fe(2)O_3F_3$ and $As(2)O_3(OH)$ gives rise to two distinctand independent one-dimensional structure units (Figure 1). The FeF_3O_3 octahedra are connected together through two Fe−F−Fe bridges forming edge-shared dimers. The $Fe_2F_4O_6$ dimers are linked through $AsO_3(OH)$ tetrahedra completing the basic building unit, which resembles the secondary building unit, SBU-4, enumerated by Ferey.[20−22] The SBU-4 units are joined together to give rise to the one-dimensional ladder structure (Figure 1). The charge-compensating doubly protonated diethylenetriamine (DETA) molecules are located between the ladders and interact through N−H···O and N−H···F hydrogen bonds. The view of the ladders and the arrangement of the SBU-4 units along the *c* axis are shown in Figure 2. The presence of terminal fluoride, along with OH groups, gives rise to a number of hydrogen-bond interactions involving the amine. Important hydrogen-bond interactions are listed in Table 1.

The presence of Fe_2F_2 dimers in **I**, and strong intrachain and weak interchain interactions between the SBU-4 units

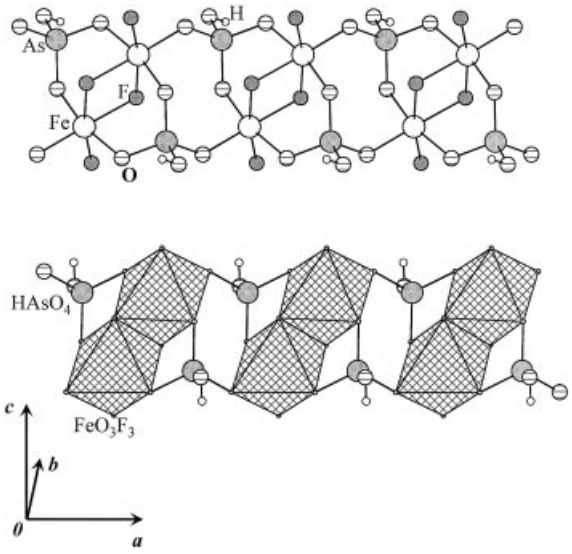

Figure 1. Structure of **I** showing the arrangement of the ladders; note that the SBU-4 units are connected through a four-membered ring; amine molecules are not shown for clarity

prompted us to evaluate the magnetic properties of **I**. The magnetic characterization of **I** was carried out using a SQUID magnetometer in the temperature range 5−300 K. The temperature dependence of the magnetic susceptibility (χ) of **I** is shown in Figure 3. The special feature to be noticed is the activated behaviour at $T \approx 14$ K, below which the susceptibility (χ) drops exponentially to zero. This activated behaviour corresponds to a finite spin gap in the material. For low-dimensional spin-gap systems, considering the magnon excitations approximately, Troyer et al. have derived a general expression for χ: $\chi = (1/K_BT)z(K_BT)/[1 + 3z(K_BT)]$, with $z(K_BT) = 1/\pi \int \exp(-E_K/K_BT)dK$, where E_K is the nondegenerate triplet magnon dispersion.[24] For low temperature, the above expression can be approximated as

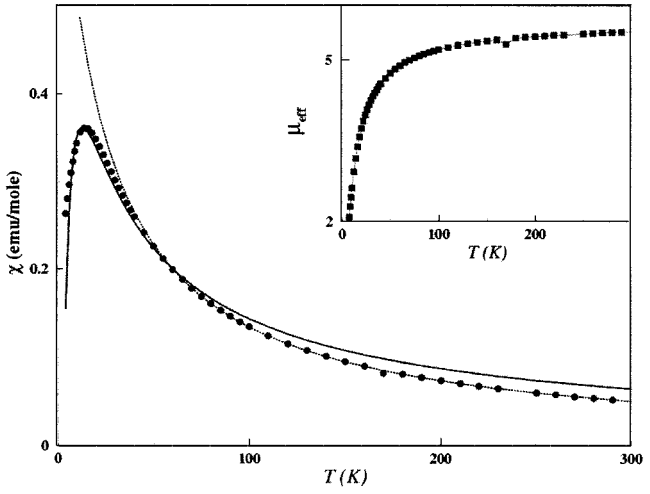

Figure 3. χ [emu/mol] vs. T plot at 100 Gauss; the solid line is the exponential fit at low temperature mentioned in the text; the dotted line is the Curie−Weiss law fit for χ at high temperature; the inset shows the effective magnetic moment μ_{eff} as a function of T

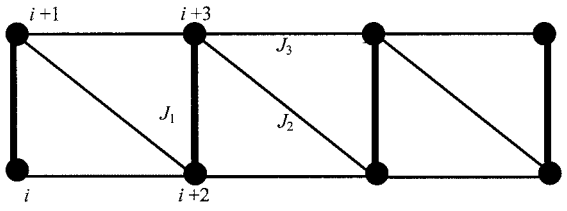
$\chi_{low\text{-}T} = A\cdot\exp(-\Delta/K_BT)/(K_BT)^{\zeta}$. This formulation can be applied for any half-integer spin with parabolic triplet magnon dispersion at low temperature.[25] Note that, at the dimer limit, $\Delta = 1$ and the exponent ζ becomes 1. However, for a gapped spin-1/2 extended lattice, it is shown that $\zeta = 1/2$. Clearly, this exponent relates the transition from a dimer limit to the extended system. By fitting the above form of $\chi_{low\text{-}T}$ with the experimental data, we find that the best fit is obtained with $A = 6$, $\Delta = 10.3$ K and $\zeta = 0.78$. The fit is shown as a solid line in Figure 3. At high temperature, the value of χ saturates to the paramagnetic value for two $S = 5/2$ spins. The high-temperature susceptibility, $\chi_{high\text{-}T}$, fits very well down to $T = 60$ K with a Curie−Weiss form $\chi_{cw} = C/(T-\Theta)$, with $C = 16.39$ and $\Theta = -22$ K (dotted line in Figure 3). The inset shows the effective magnetic moment μ_{eff} as a function of temperature. The room-temperature μ_{eff} per Fe is approximately equal to 5.5 μ_B, which steadily decreases to 1.45 μ_B at 5 K, indicating strong antiferromagnetic behaviour (see inset, Figure 3). This room-temperature value of μ_{eff} compares fairly well with the spin-only moment for high-spin Fe^{3+}.

The maximum and the subsequent decrease of χ with an increase in T correspond to short-range antiferromagnetic exchange interactions in the system. A careful investigation of the structure reveals that there are three different superexchange pathways as shown below in Scheme 1. All the superexchange angles between the corresponding pair of localised Fe^{3+} ions through the intervening atoms suggest that all three exchanges are antiferromagnetic, making the system highly frustrated. In addition, J_1 exchanges in the rung (Fe dimers) are through two fluorine atoms, while J_2 and J_3 are through $HAsO_4$ tetrahedral links. This clearly shows that the intradimer exchange interactions are much stronger than the interdimer exchanges. Although we specify two different exchanges between the rungs, they are similar in magnitude and are quite small relative to J_1.



Scheme 1

If we neglect J_3, the system is a $S = 5/2$ J-alternating one-dimensional chain with exchange values J_1 and J_2 respectively. If $J_1 = J_2$, the system is an isotropic half-integer spin chain, which is gapless. Defining $\alpha = J_1/J_2$, for small J_2, the spin gap increases as $\alpha^{2/3}$ with increase in J_2. For a gap of $\Delta = 10.3$ K, J_2 would be more than 30 times smaller than J_1, which is quite small. For a proper estimation of the magnitudes of the three exchange constants (J_1, J_2 and J_3), we have chosen temperatures corresponding to two values of χ; one at the maximum and the other where χ saturates to its paramagnetic value. The Hamiltonian corresponding to this system can be written as $H = \Sigma_i\{[J + (-1)^{i-1}\delta]S_i\cdot S_{i+1} + J_3S_i\cdot S_{i+2}\}$, where $(J \pm \delta)$ corresponds to J_1 and J_2.[26] We solve this Majumdar−Ghosh Hamiltonian for a range of system sizes (two and three unit cells) with $S = 5/2$ spins and with exchange parameters J_1, J_2 and J_3. We find that the best fit to the experimental data is obtained with $J_2 = J_3 = 0.35J_1$. All three exchange interactions are antiferromagnetic and their magnitudes are also reasonable considering the distance between the corresponding spin centres.[27]

The dependence of magnetisation (M) as a function of magnetic field (B) at 5 and 15 K are shown in Figure 4. For both temperatures $M(B)$ increases rapidly with increasing B, indicating that the excited spin states are significantly populated. It is clear from the figure that at these temperatures there is no alignment of spins. For a comparison, we have computed Brillouin functions for two independent $S = 5/2$ spins in the unit cell and for a large unit cell with $S =$

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

5. The $M = f(B)$ curve at $T = 15$ K is between the two Brillouin functions mentioned above. This proves that even at $T = 15$ K, the magnetic polarisation of the unit cell with two high-spin Fe^{3+} ions is not complete. Since the lowest excited spin state is a triplet with a gap of 10 K, the sharp initial rise in $M(B)$ for small B values corresponds to the Zeeman-coupling-assisted increase in population of the triplet state. With the fitted values of the exchange parameters ($J_2 = J_3 = 0.35J_1$), we have computed the magnetisation for the temperature values, $T = 5$, 15 and 30 K. For $T = 15$ and 30 K, they are plotted with the corresponding experimental $M = f(B)$ curves for comparison. In the inset of Figure 3, we have plotted all three theoretical $M = f(B)$ curves up to high magnetic field strengths. The $M = f(B)$ curve at $T = 5$ K closely follows Brillouin functions with one independent $S = 5$ unit-cell spin. Thus, at small T, the magnetisation corresponds to the magnetic polarisation of one unit cell (1 unit cell = 2 Fe^{3+} ions). We estimate theoretically that for the complete alignment of the spins on all the unit cells (complete polarisation) for this one-dimensional ladder would require magnetic field strengths of the order of 8 Tesla even at low temperatures (i.e. about 5 K).

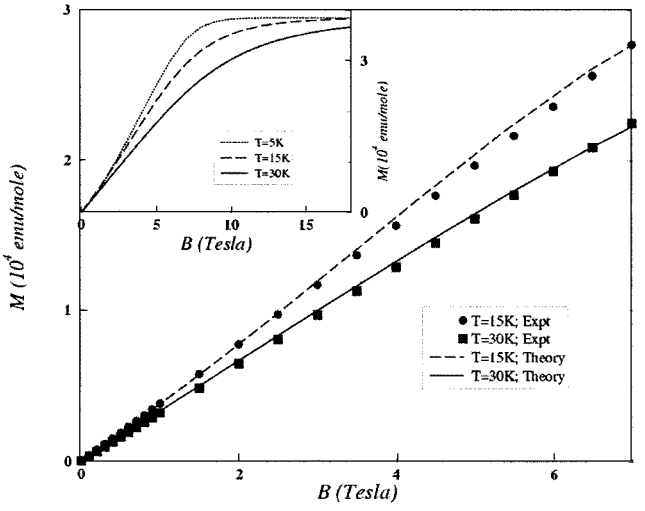


Figure 4. Magnetisation (M) as a function of magnetic field (B) at two different temperatures, $T = 5$ K (filled circles) and $T = 15$ K (filled squares); the dashed line and the solid line are the theoretical magnetisation plots for the corresponding T values; the inset shows the theoretical M vs. B curve for three different temperatures, $T = 5$ K (dotted line), $T = 15$ K (dashed line) and $T = 30$ K (solid line)

Conclusions

The synthesis, structure and magnetic characterization of a one-dimensional iron arsenate, $^1_\infty[NH_3(CH_2)_2NH(CH_2)_2NH_3][Fe_2F_4(HAsO_4)_2]$ (**I**), has been accomplished. The theoretical estimate of the exchange parameters based on the Majumdar−Ghosh model shows the presence of a frustrated solid with one strong and two weak short-range antiferromagnetic couplings. A two-dimensional layer structure built up exclusively from SBU-4 units has been reported recently by us,[28] and we have now stabilized SBU-4 in a one-dimensional structure. More importantly, the low-dimensional structures of the type investigated here provide an opportunity for the theoretical evaluations of the interplay between the coupling strength, the geometrical frustrations and the low-temperature phase transitions, as such materials are rarely isolated. We are vigorously pursuing further work in this direction.

Experimental Section

Compound **I** was synthesized hydrothermally in the presence of diethylenetriamine (DETA). In a typical synthesis iron acetylacetonate [Fe(acac)$_3$] (0.196 g) was dispersed in water (2 mL). To this, As_2O_5 (0.378 g) and HF (48%, 0.08 mL) were added while stirring continuously. Finally, DETA (0.25 mL) was added, and the mixture was homogenised at room temperature for 30 min. The reaction mixture with the composition Fe(acac)$_3$/As_2O_5/HF/DETA/H_2O (1:3:4:4:200) was transferred into a PTFE-lined stainless-steel pressure vessel (23 mL) and heated at 180 °C under autogenous pressure for 72 h. The initial pH of the reaction mixture was approximately equal to 5 and the pH after the reaction was approximately 4. The resulting product, a crop of fine pale-yellow rod-shaped crystals, was filtered, washed with water and dried at room temperature (yield 70% based on Fe). An EDAX analysis indicated that the ratio Fe/As was 1:1, and that fluorine was present. $C_4H_{17}As_2F_4Fe_2N_3O_8$ (572.75): calcd. C 8.4, H 3.0, N 6.3; found C.8.1, H 2.8, N 6.3. A potentiometric titration also confirmed the presence of fluorine (calcd. 13.27%; found 12.9%).[29]

A suitable single crystal was carefully selected under a polarising microscope and glued to a thin glass fibre. Crystal structure determination by X-ray diffraction was performed with a Siemens Smart-CCD diffractometer equipped with a normal focus, 2.4 kW sealed-tube X-ray source (Mo-K_α radiation, $\lambda = 0.71073$Å) op-

erating at 40 kV and 40 mA. An empirical absorption correction based on symmetry-equivalent reflections was applied with the SADABS program.[30] The structure was solved and refined using the SHELXTL-PLUS suite of programs.[31] All hydrogen atoms were located in the difference Fourier maps. For the final refinement the hydrogen atoms were placed geometrically and held in the riding mode. The final refinement included atomic positions for all atoms, anisotropic thermal parameters for all non-hydrogen atoms and isotropic thermal parameters for all hydrogen atoms. Full-matrix least-squares refinement against $|F^2|$ was carried out using the SHELXTL-PLUS[31] suite of programs. Details of the structure solution and final refinement for $^1_\infty[NH_3(CH_2)_2NH(CH_2)_2NH_3][Fe_2F_4(HAsO_4)_2]$ (**I**) are given in Table 2. CCDC-205336 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Structure Comparison of Early and Late Lanthanide(III) Homodinuclear Macrocyclic Complexes with the Polyamine Polycarboxylic Ligand H_8OHEC

Ulrike A. Böttger,[a] Brendon O'Sullivan,[b] Burkhard Ziemer,[a] Herbert Schumann,[b] Clemens Mügge,[a] and Hardy Weißhoff*[a]

Keywords: Solid-state structures / Lanthanides / Macrocyclic ligands / Polyamine polycarboxylic acid / Solution thermodynamics

The solid-state structures of two new homodinuclear chelate complexes with the late lanthanide(III) ions Yb and Lu, $[Na_2(Yb_2OHEC)]\cdot 14.5H_2O$ (**1**), and $[Na_2(Lu_2OHEC)]\cdot 14.5H_2O$ (**2**) (H_8OHEC = 1,4,7,10,14,17,20,23-octaazacyclohexacosane- 1,4,7,10,14,17,20,23-octaacetic acid), have been determined by X-ray crystal structure analysis. Each lanthanide(III) ion is coordinated by eight donor atoms of the ligand and the geometry of the coordination polyhedron approaches a bicapped trigonal prism. These structures are compared with those of the homodinuclear chelate complexes with the same ligand and the mid to early lanthanide(III) ions Gd, Eu, La and also Y. A distinctive structural change occurs across the lanthanide series. The centrosymmetric mid to early lanthanide(III) complexes are all ninefold-coordinated in a capped square antiprismatic arrangement with a water molecule coordinated in a prismatic position. This structure is maintained in aqueous solution, together with an asymmetric minor isomer. The late lanthanide(III) OHEC complexes not only lack the inner-sphere water, but the change of coordination sphere also results in a loss of symmetry of the whole complex molecule. The observed change of coordination mode and number of the lanthanide ion may offer a geometric model for the isomerization process in eight- and ninefold-coordinated complex species that are isomers in a possible coordination equilibrium observed by NMR in aqueous solution. This model may also explain the intramolecular rearrangements necessary during water exchange in the inner coordination sphere of the complex $[(Gd_2OHEC)(H_2O)_2]^{2-}$ through a slow dissociative mechanism. Protonation constants of the H_8OHEC ligand and complex formation constants of this ligand with Gd^{III}, Ca^{II}, Cu^{II} and Zn^{II} have been determined by solution thermodynamic studies.

Introduction

H_8OHEC (1,4,7,10,14,17,20,23-octaazacyclohexacosane-1,4,7,10,14,17,20,23-octaacetic acid) is a macrocyclic polyaminocarboxylate with a 26-atom-membered ring formed from the eight amine and bridging ethylene or propylene groups. It was developed as a potential MRI contrast agent ligand, combining two aims: (i) to increase the rotational correlation time compared with conventional DOTA and DTPA, thereby enhancing the relaxivity, the measure of drug efficiency; (ii) to obtain previously unknown binuclear contrast agents with two closely sited gadolinium ions, and to study the intramolecular interaction of the two paramagnetic centres as well as their influence on the electronic relaxation. Previous studies focussed on the preparation[1] of this ligand and its properties as a chelator for lanthanides and small transition metals.[2] The crystal structures of the homodinuclear complexes of yttrium(III), gadolinium(III), europium(III), and lanthanum(III) with H_8OHEC have been discussed, as well as the solution structure and dynamics of its diamagnetic Y^{III} complex.[2,3] These complexes are almost isostructural in that they all crystallise in the monoclinic space group $P2_1/n$, and the conformation of the OHEC macrocycle as well as the coordination geometry around the metal ions is nearly the same. NMR studies on the yttrium complex revealed that the same centrosymmetric structure is maintained in aqueous solution as is found in the solid state. In addition, in aqueous solution the complexes are present in two isomeric forms.[3,4] The doubled NMR signal number of the second isomer obviously reveals an asymmetrical molecule, the geometry of which could not be deduced from the NMR spectroscopic data because of strongly overlapping signals with those of the main isomer.

Coordination polyhedra of the ninefold-coordinated complexes investigated by X-ray crystal structure analysis were interpreted with special regard to their metal-bound water molecule in the inner coordination sphere. A second inspection showed that these structures must be reconsidered. In this report they will be discussed anew together with the structures of two new homodinuclear OHEC com-

plexes with the late lanthanides ytterbium(III) and lutetium(III).

The acidity constants of H_8OHEC and the thermodynamic stabilities of its complexes formed with Gd^{3+}, Ca^{2+}, Cu^{2+} and Zn^{2+} are reported here. These metals were chosen to examine the in vivo stability and selectivity of OHEC complexed gadolinium with respect to its possible application as a contrast agent for magnetic resonance imaging.

Results and Discussion

X-Ray Crystal Structures

Molecular Structures of 1 and 2

The crystals contain $[C_{34}H_{52}Ln_2N_8O_{16}]^{2-}$ anions, sodium cations, hydroxide ions, ethanol molecules and water of crystallization. Their compositions correspond to $[Na_2(Yb_2OHEC)]\cdot 14.5H_2O$, C_2H_5OH, 0.5NaOH (**1**) and $[Na_2(Lu_2OHEC)]\cdot 14.5\cdot H_2O$, C_2H_5OH, 0.5NaOH (**2**). The complexes are isostructural and crystallise in the triclinic space group $P\bar{1}$ (no. 2), which is centrosymmetric. There are the two molecules of the complex per unit cell, which are connected via sodium cations and are centrosymmetric with respect to each other. Crystals are built up from infinite one-dimensional chains of $[Ln_2(OHEC)]^{2-}$ units, arranged parallel to the *a* axis and linked by a network of $Na^+\cdots O$ contacts, involving the sodium cation, the carboxylate oxygen atoms and the water molecules associated with the cation. Thus, although **1** and **2** lack the inner-sphere water molecules, the complexes are wrapped in a water matrix. The shortest distances between bulk water molecules and metal ion centres are 430(14) ($O_{aqua(18)}-Yb_1$) / 453(8) pm ($O_{aqua(32)}-Yb_2$) for **1** and 432(5) ($O_{aqua(18)}-Lu_1$) / 451(10) pm ($O_{aqua(32)}-Lu_2$) for **2**. As the centre of symmetry lies outside the complex molecule, the two chemically identical halves of the complex molecules **1** and **2**, containing the Yb^{III} and Lu^{III} ions, respectively, can only be interconverted by a pseudo-C_2 symmetry operation. The complex molecule itself possesses no kind of symmetry.

Conformation of the Macrocycle in Lanthanide OHEC Complexes

The two lanthanide ions in **1** and **2** are completely encapsulated by the macrocyclic ligand (Figure 1). Each lanthanide ion is coordinated by the four nitrogen and four carboxylic oxygen atoms belonging to one-half of the overall hexadecadentate ligand.

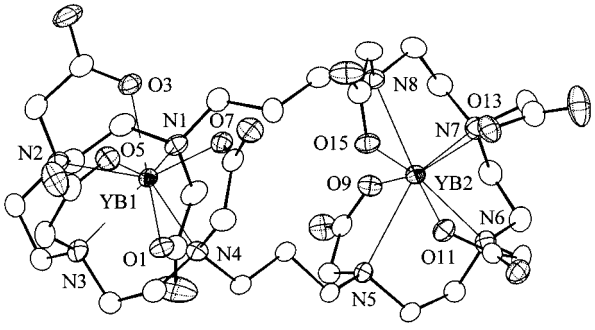

Figure 1. Solid-state conformation of $Na_2(Yb_2OHEC)$ (**1**)

Figure 2 shows the overall conformation of the OHEC macrocycle in the di-ytterbium complex **1**, together with the qualitative torsion angles. Measured torsion angles are listed in Table 1. In contrast to the light lanthanide(III) OHEC complexes, the rings of which adopt a centrosymmetric biangular conformation, {1313}, according to the terminology of Dale[5], the complexes with the smaller and heavier lanthanides ytterbium(III) and lutetium(III) form quadrangular ring conformations with four genuine corners, {7272}. This leads to essentially tighter folding of the ring around the central atoms, leaving no room for an inner-sphere water molecule. The fivefold repetition of *anti* torsion angles in the propylene chains allows for a maximal

separation of the two lanthanides, thereby minimizing electrostatic repulsion.

While the centrosymmetric conformation of the macrocyclic ring of the lighter lanthanide(III) OHEC complexes[3] as well as for the corresponding OHEC-amine ligand and its binuclear copper(II) complex $[Cu_2(OHEC\text{-}amine)](SO_4)_2$ [1] corresponds to the chair shape, for **1** and **2** the ring adopts the boat conformation with a typical pseudo-C_2 symmetry axis. In the OHEC complexes with the chair shape the central atoms as well as the inner-sphere water molecules lie alternately below and above a mean ring plane of the macrocycle, formed by the four propylene bridged nitrogen atoms.[1,3] No such mean plane is found for **1** and **2**. Here, the metal ions both sit on the same side, within the boat conformation of the macrocyclic ring. They are, in each case, sandwiched between nitrogen atoms and three carboxylate arms coordinating the metal from the upper side of the boat, while the forth carboxylate side arms fixed on N1 and N5 coordinate the metals from the lower side of the boat. The layout of the acetate arms depends on the inherent symmetries of these two types of rings. Whereas in the centrosymmetric conformations the pendent arms with up-up-up-down orientations are inverted for both molecule halves at the centre of symmetry, in the boat conformation the up-up-up-down orientations of the four pendant arms of each molecule half can be only interconverted by rotation around a pseudo-C_2 symmetry axis.

Coordination Geometry of the Late Lanthanide Ions

The two lanthanide ions in **1** and **2** are chelated by the hexadecadentate ligand H_8OHEC and adopt eight-coordinate geometry. The coordination sphere for each lanthanide ion consists of four amine nitrogens of the macrocycle and four carboxylic oxygens of the acetate side arms. The large OHEC-ring system is quite flexible but the accommodation of two lanthanide ions is a considerable steric demand. As all eight nitrogen donor atoms belong to one large macrocyclic system they experience a steric constraint. Moreover, as all faces of the polyhedra are built up by mixed donor atoms, by nitrogen atoms and carboxylate oxygens, significant deviations from the ideal geometry can be expected.

Using the criterion established by Haigh for distinguishing the types of structures in eightfold-coordinated complexes, based on a pattern of bond angles,[6] the 28 LML′ angles at the central atom the 16th, 17th and 18th lowest angles were compared. For Yb1 in **1** these are 91.99°, 97.22° and 118.60°, for Lu1 in **2** the corresponding values are 92.93°, 95.71° and 117.42°. The structure should be square antiprism (SAP) if the gap between the 16th and 17th lowest angles is more than 20°. This is not the case. As the gap between the 17th and 18th lowest LML′ angles is substantial the structure should be close to a bicapped trigonal prism (BCTP) (Figure 3). Compared with reclassified structures,[6] on the basis of Haigh's criterion the gap in **1** and **2** is large enough to assign the structure as distorted BCTP. The third possibility, a triangular dodecahedron, must be ruled out as the 16th, 17th and 18th LML′ angles are not close together.

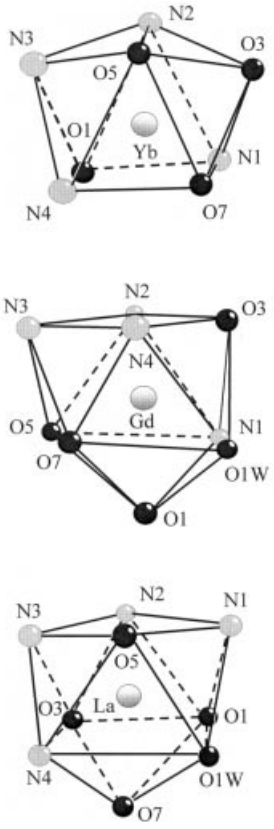

Figure 3. Coordination polyhedron about the ytterbium ion in **1** (top), gadolinium ion in **4** (middle) and lanthanum ion in **6** (bottom)

Comparison of the dihedral angles δ in the primary coordination sphere of the central atoms of **1** and **2**, which are sensitive to symmetry and shape, with those of an ideal D_{4d} (SAP) and C_{2v} (BCTP) geometry gives a more objective assessment of shape (Table 2).[7] The observed deviations from the ideal indicate the ligand's difficulty in satisfying the steric demands of the two central atoms. Of the two alternative polyhedra the polytopal shape of **1** and **2** is best described with the distorted BCTP geometry. For a SAP geometry the two square planes that should be nearly parallel to each other could not be found. Deviations from planarity of the second face are too large (Table 2).

The three different lengths of the prismatic heights of the coordination cage is also a measure of distortion from the ideal BCTP (Table 2). Therefore, the triangular faces of the polyhedra are far from being parallel.

For Yb1 in **1**, atoms N4, O7, O5 and O1, N1, N2 form the triangular faces and the capping positions are occupied by N3 and O3 (Figure 3). For Yb2 in **1** and the two Lu atoms in the isostructural complex **2** the same coordination geometry is found. The metal ions are close to the centre of the trigonal prism, slightly shifted toward the face capped with an acetate oxygen atom and shifted down toward the triangular face of the trigonal prism containing two oxygen donor atoms. The mean $Lu-O_{carboxylate}$ bond

	O11−O15−O13−N8	43.32(14)	48.2 (BCTP); 52.4 (SAP)
2 (Lu1)	N3−O5−N2−O3	−152.39(16)	0 (SAP)
	N4−O1−O7−N1	−179.77(15)	0 (SAP)
2 (Lu2)	N5−O15−O9−N8	179.76(16)	0 (SAP)
	O11−N6−O13−N7	−143.99(16)	0 (SAP)
Edge lengths of the prismatic heights in the BCTP polyhedron [pm]			
	N4−O1	O5−N2	O7−N1
1	299(17)	341(14)	367(13)
2	296(19)	341(16)	361(19)
	O15−N5	O13−N6	N8−O9
1	367(17)	322(18)	293(18)
2	366(18)	324(17)	295(19)

length in **2** is 224.3 pm, slightly shorter than in the ninefold-coordinated Na[LuDOTA(H_2O)] complex (227.9 pm).[8] Also, the mean Lu−N distance in **2** (254.9 pm) is shorter than in Na[LuDOTA(H_2O)] (261.4 pm). Consistent with the lanthanide contraction the mean distances in **1** are slightly longer than in **2** (mean Yb−$O_{carboxylate}$ 225.4 pm and mean Yb−N 256.3 pm). For the eight-coordinate K[Tm(DOTA)],[9] a complex with the lanthanide ion next to Yb^{3+} in the periodic table, the mean Tm−$O_{carboxylate}$ distance of 228 pm is, as expected, longer than in **1**, whereas the mean Tm−N distance of 252.9 pm is slightly shorter than in **1** and also than in **2**.

Table 3 lists the Ln−O and Ln−N distances of LnOHEC complexes, which reflect well the shrinkage of the ionic radii of the chelated lanthanide ions.

The differences between the maximum and minimum interatomic distances in **1** and **2** (Table 4) are too small to indicate distortions within the molecule caused by steric constraints.

Coordination Geometry of the Early to Mid Lanthanide Ions: Implications for the Inner-sphere Water Exchange and an Isomeric Coordination Equilibrium

Since Ln^{3+} aqua ions and other polyaminocarboxylate complexes have varying hydration numbers throughout the series, a varying coordination number may be expected in OHEC lanthanide complexes, depending upon the size of the Ln^{3+} cation.[10]

In the early to mid di-lanthanide complexes of the H_8OHEC ligand the central atoms are all ninefold-coordi-

nated.[2,3] Besides the eight donor atoms per metal ion provided by the ligand the ninth site in the metal coordination sphere is occupied by a water molecule. In most such polyamine polycarboxylate ligand complexes the oxygen atom of the inner-sphere water molecules occupies a special site in the coordination polyhedron: it takes a capping position both in the square antiprismatic structures in DOTA-like complexes[11,12] and in the trigonal prismatic structures of acyclic ligand complexes, e.g. as in $[Gd(BOPTA)(H_2O)]^{2-}$.[13]

Initial discussion regarding the structure of homodinuclear OHEC complexes $[Na_2(Y_2OHEC)(H_2O)_2]$ (**3**), $[Na_2(Gd_2OHEC)(H_2O)_2]$ (**4**), $[Na_2(Eu_2OHEC)(H_2O)_2]$ (**5**) and $[Cs_2(La_2OHEC)(H_2O)_2]$ (**6**) was led by the thought that the water molecule should occupy a capping position, as in the DOTA complexes, resulting in an irregular coordination polyhedron. After reinspecting the lanthanide environment in these complexes we found, in all cases, a distorted capped

square antiprism (CSAP) as coordination polyhedron, as in DOTA-like complexes but, importantly, the inner-sphere water molecule occupies a prismatic position instead of a capping one (Figure 3). The positions of both square faces are occupied by mixed donor atoms of the ligand. For **3**, **4** and **5** the uncapped square is formed by three ring nitrogens (N2, N3 and N4) and O3, whereas the capped square face is formed by N1, two carboxylate oxygens, O5 and O7, and one inner-sphere water oxygen O1W. Considering the coordination geometry in **6** as a strongly distorted CSAP structure, the uncapped square is formed by N1, N2, N3 and O5. The capped square face is formed by N4, two carboxylate oxygens, O1 and O3, and one inner-sphere water oxygen O1W. For the gadolinium(III) complex **4** the polyhedron comes closest to the ideal CSAP structure. The uncapped square face deviates from planarity by less than 1°. Lanthanum(III) structure **6** shows the highest deviation (Figure 3). Table 5 summarises the most important angles characterising the coordination cage of the lanthanide ions in the four OHEC complexes.

The change of coordination number from nine for the early to mid lanthanides to eight for the late lanthanides in the same type of chelate complex as a result of the lanthanide contraction has been well investigated by NMR for lanthanide(III) DOTA complexes,[9,14] and has also been observed for other polyamine polycarboxylate ligands.[15,16] For lanthanide OHEC complexes, the change of complex geometry is accompanied by a loss of symmetry. This is clearly observable upon considering the CO−CH_2 connectivities in the HMBC spectra of the centrosymmetric Y_2OHEC (**3**, four cross peak pairs) and Lu_2OHEC without a centre of symmetry (**2**, eight cross peak pairs) (Figure 4).

For DOTA complexes, besides the two enantiomeric pairs of ninefold-coordinated stereoisomers, differing in the ligand conformation, a coordination change is superimposed.[14] The loss of the metal-bound water molecule leads to two further structures in which the metal ion is only eight-coordinate but where the coordination geometries are fundamentally maintained since the departing inner-sphere water occupies the capping position in a squared antiprism. This peculiar capping site provides a readily accessible intermediate to water exchange via a more dissociatively activated mechanism for the gadolinium(III) complexes,[17] which yields relatively rapid exchange rates, with $k_{ex}(298)$ in the range of 4.1×10^6 s^{-1} for DOTA[18] and 1.6×10^6 s^{-1} for DO3A−bz−NO_2 [19] for such compounds. As the square antiprism for DOTA-like complexes is unchanged during the exchange process for all investigated lanthanide(III) complexes, there is little difference in the energies between the nine- versus eight-coordinate complexes. Thus, despite the high rigidity of the inner-sphere structure in DOTA complexes the activation energy for the water exchange reaction is very small.[14]

NMR investigations of the di-yttrium complex **3** show that its geometry in aqueous solution is very similar to that in the solid state.[3,11] For each complex, two isomers undergoing conformational changes were proven. Interchange from the major to the minor isomer is accompanied by a loss of centrosymmetry. Figure 5 shows this by means of the Eu_2OHEC ^{1}H NMR spectrum. The same observations have been made for the lanthanide OHEC complexes with Ln^{III} = Eu, Gd, and Tb by means of NMR, UV/Vis, EPR and luminescence spectroscopy.[4] For the europium complex **5** and the gadolinium complex **4** the metal centres change their coordination number from 9 to 8 during isomerisation equilibrium, such as $[Ln_2(OHEC)_2(H_2O)_2]^{2-} \rightarrow [Ln_2(OHEC)]^{2-} + 2H_2O$. As the structures of these two isomers correspond to the two structure types of lanthanide OHEC complexes found in the solid state, the major isomer must have a centrosymmetric, nine-coordinate CSAP structure while the minor isomer has the distorted eight-coordinate BCTP structure without molecular symmetry. Therefore, the isomeric equilibrium not only involves changes of conformation but also of coordination. Figure 6 depicts the rearrangement of the complex molecule in an exchange equilibrium between the two isomers. In contrast to DOTA-like complexes, a water molecule that enters or leaves the metal coordination sphere in lanthanide OHEC complexes gives rise to a considerable reorganisation of the donor atoms and the ring conformation about the metal atom, as the inner-sphere water is less accessible at a prismatic position of the coordination polyhedron. Notably, this rearrangement does not require the release of ligand donor coordination bonds, while removal of the metal-bound water molecules, which are also stabilised by hydrogen bonds, can be considered as the first step in the isomerisation process.

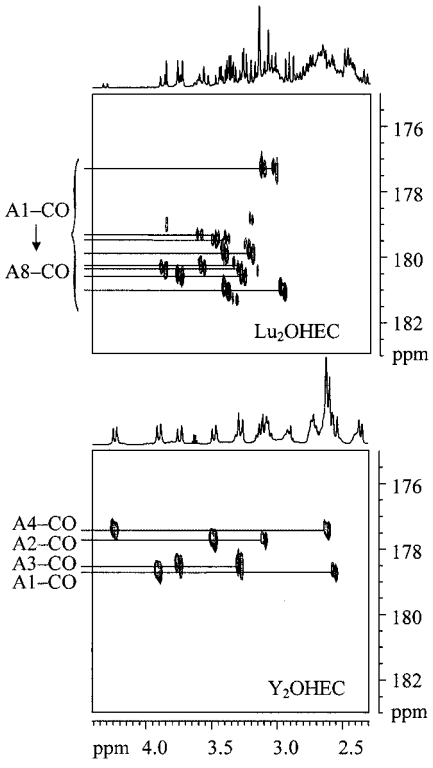

Figure 4. CO−CH_2 region of the HMBC spectra of Lu_2OHEC (**2**, top) and Y_2OHEC (**3**, bottom); there are twice as many NMR cross peaks for Lu_2OHEC than for the main isomer of Y_2OHEC, which can be correlated directly with the loss of symmetry

During the structural change, only four of the eight donor atoms nearly keep their positions. The N1 atom, which carries the O1 atom, is probably moved by a conformational change of the macrocycle. Simple rotation of the acetate arms can accomplish all other changes of positions.

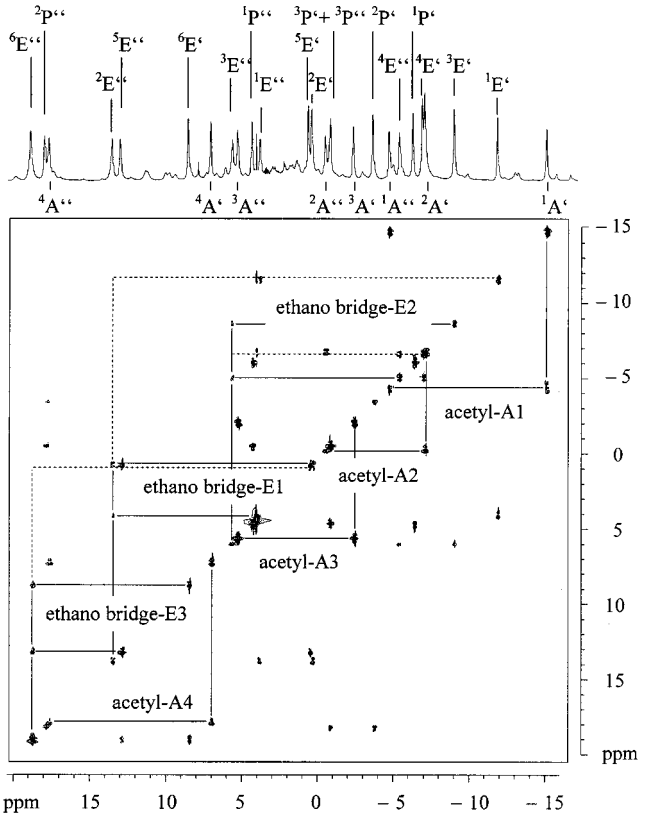

Figure 5. $^1H-^1H$ COSY spectrum of the binuclear Eu^{III} complex of OHEC at 600 MHz; assignment of the centrosymmetric, major isomer $Eu_2OHEC(H_2O)_2$ is shown; the protons can be classified into three ethylene groups (ethano bridge E1−E3, consisting of protons $^1E/^2E$, $^3E/^4E$ and $^5E/^6E$), four acetate arms A1−A4 and one propylene group; the symbols ′ and ″ refer to two geminal protons; assignment of the protons of the minor isomer, preformed using exchange spectroscopy (EXSY), is not shown for clarity

These ligand rearrangements, which take place simultaneously in both halves of the molecule, may account for the extremely slow isomerisation rate [$k_{is}(298) = 73.0\ s^{-1}$] and the very slow water exchange rate [$k_{ex}(298) = 0.40 \times 10^6\ s^{-1}$] in the $[Gd_2OHEC(H_2O)_2]^{2-}$ complex.[4] The rate constant is similar to that of DTPA-bis(amides).[18,20]

Interaction of this inner-sphere water with the gadolinium(III) ion and its exchange with bulk water is the basis for the action of MRI contrast agents of such compounds. However, the distances between the gadolinium atom and the water oxygen atom, and between the gadolinium atom and the acetate oxygen atom in most known polyamine polycarboxylate structures, show that the water ligand does not bind at an exceptionally different distance. Thus, the preferred capping position in DOTA-like complexes for the water molecule, as discussed above, results not from constraints imposed by the donor atoms but rather results from the favourable preorganisation of the ligand. The exchange process is fast on the proton NMR time scale, so that two isomers differing only in the water coordination number while retaining the same ligand conformation are indistinguishable.

Solution Thermodynamics

Potentiometry

Potentiometric titration data for the ligand OHEC may be represented conveniently by calculation of the average number of ligand-bound protons ($\tilde{n}_H$) for each point in the titrations, as in Figure 7. Equation (1) defines $\tilde{n}_H$ in terms of K_w, the ionisation constant of water, H_T and L_T, the total (analytical) concentrations of protons and the ligand, respectively, and $[H^+]$ the concentration of free protons. Notably, $\tilde{n}_H$ is calculated entirely from observable param-

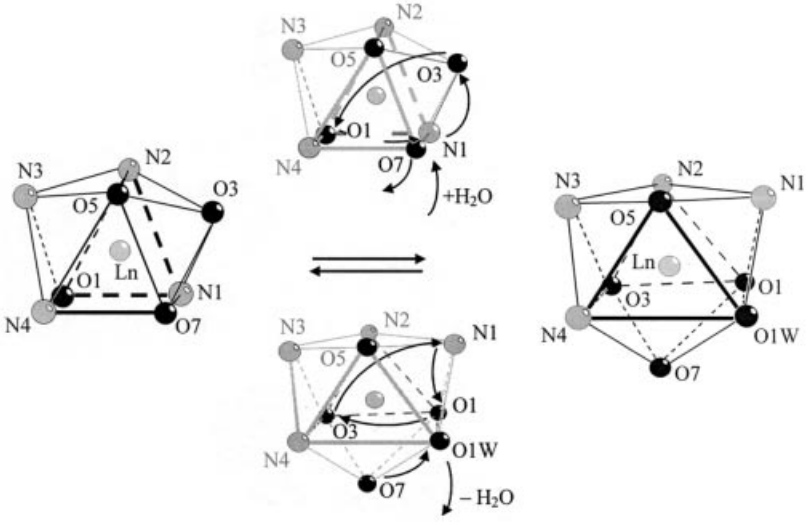

Figure 6. Coordination equilibrium for isomers of lanthanide(III) OHEC complexes

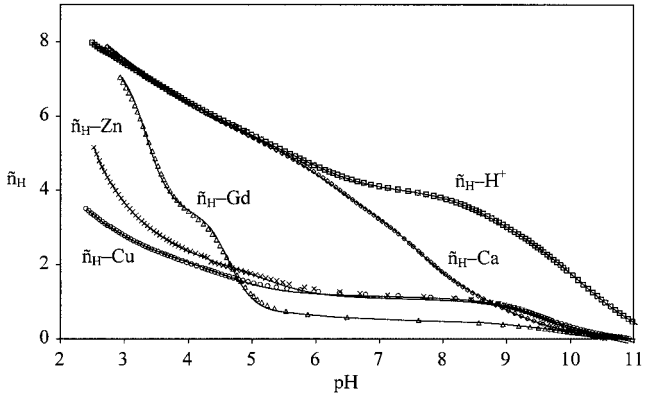

Figure 7. Average number of protons bound ($\tilde{n}_H$) to the ligand OHEC in the presence of the indicated metals, where H^+ indicates the absence of any coordinating metal ion; symbols give observed titration curves and lines the calculated fits to those curves; data were obtained using metal-to-ligand ratios for Cu of 1.9:1, Zn 1.95:1, Ca 1.86:1 and Gd 1.75:1

eters (observed pH and the analytical concentrations) and is, therefore, independent of the chemical model used to extract stability constants from the data. Thus, careful inspection of $\tilde{n}_H$ curves will reveal insights into the chemical equilibria present, and act as a guide in model selection. The solid lines in Figure 7 also give the $\tilde{n}_H$s as derived from the calculated pH. In this manner, the quality of fit between the observations and the refinements is presented.

$$\tilde{n}_H = \frac{H_T - [H^+] + K_W \cdot [H^+]^{-1}}{L_T} \quad (1)$$

All $\tilde{n}_H$ curves in Figure 7 approach zero above pH 11. In this highly basic region, OHEC forms only fully deprotonated species, either as the free ligand or as the various metal complexes. At lower, more acidic pHs, the $\tilde{n}_H-H^+$ curve climbs rapidly, indicating protonation of the ligand with up to eight protons by pH 2.5. In fact the $\tilde{n}_H-H^+$ curve shows no sign of reaching a plateau at this level and more than eight protonation constants might be calculated (OHEC contains up to 16 acid/base donor groups). This was indeed possible, giving protonation constants up to β_{019} (Table 6). The remaining protonation constants up to the 16th value are too acidic to allow measurement by conventional potentiometry.

The $\tilde{n}_H$ curve for Ca^{2+} coincides with that of $\tilde{n}_H-H^+$ below pH 6. Thus, for the conditions of the titration, no coordination with calcium is expected below pH 6, with relatively weak complexation at higher pHs. Indeed, the constants for calcium are the smallest of all metals in Table 6 and the distribution diagram of Figure 8 confirms the absence of calcium-binding below pH 6.

In contrast, OHEC is bound very strongly by Cu^{2+} and Zn^{2+}, affording $\tilde{n}_H$ curves well displaced from that for $\tilde{n}_H-H^+$, even at the strongly acidic pH of 2.5. In fact, the 3.5 protons that remain bound to OHEC at pH 2.5 in the presence of Cu^{2+} are barely enough to allow measurement of the stability constants by potentiometry. Interestingly, both Cu^{2+} and Zn^{2+} generate $\tilde{n}_H$ curves with wide plateaus between pH 6 and 9 at one bound proton, revealing a highly stable M_2LH species, while complete deprotonation of the two metal-centre complex is observed only above pH 9. These observations are reflected in the complexation constants of Table 6 and the lowermost species distribution diagram of Figure 8, which is calculated from those constants.

Finally, Gd^{3+} displays a coordination strength with OHEC that is between those of Ca^{2+} and Cu^{2+}. Below pH 3 the curve $\tilde{n}_H-Gd^{3+}$ rapidly approaches that for $\tilde{n}_H$-H^+, indicating acidic liberation of Gd^{3+} from the ligand. At higher pH, coordination proceeds rapidly and is complete by pH 5.5. The species distribution diagram of Figure 8 with the end species reflects this behaviour, Gd_2L dominating from pH 6 and higher.

Table 6. Protonation and metal complexation constants determined for the ligand OHEC, defined as in Equation (2); figures in parentheses give the standard deviation (σ) expressed in units of the least significant figure of each constant, calculated from the variation between repeat determinations; *n* is the number of determinations for each constant. Note that for the protonation constants the index m is always zero. Logarithms calculated with the decimal basis ($\log_{10}$)

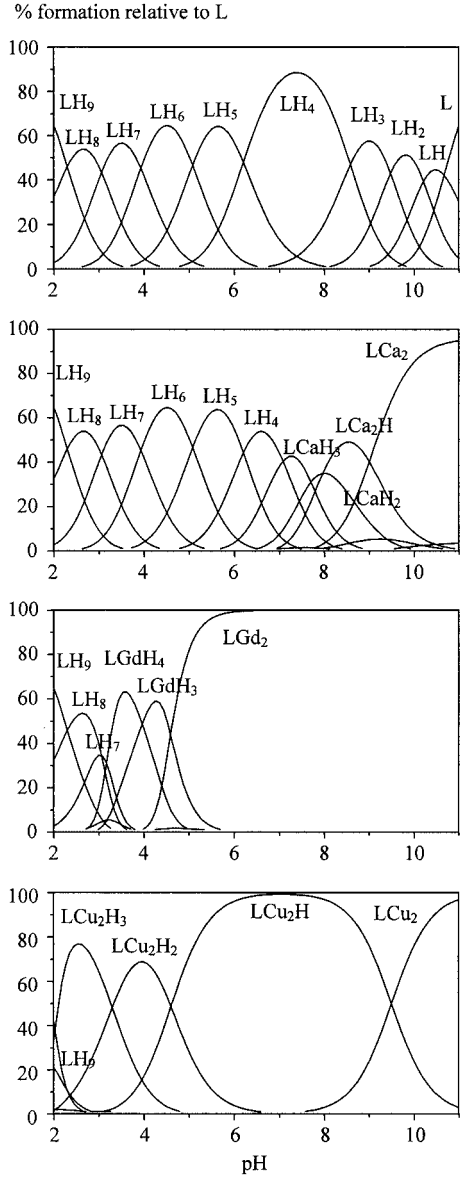

Figure 8. Species distribution diagrams for OHEC and indicated metals (top: calculated for the absence of a coordinating metal). All figures calculated for total concentrations of 5×10^{-4} M ligand and 1×10^{-3} M metal. "L" denotes the deprotonated ligand species OHEC

Comparison of OHEC with Similar Chelators

Macrocyclic OHECs are most easily compared with similar open-chain polyamine polycarboxylic acids by use of the parameter pM, the negative logarithm of the concentration of the free metal species formed at equilibrium for given total concentrations of metal, ligand and pH. Higher pMs indicate stronger complexation since the free metal concentration is depressed to a lower level. This parameter has the advantage that ligands of differing basicity, denticity and nucleacity may be compared directly, which is not the case when the absolute magnitude of stability constants is simply compared. pMs for OHEC and all the studied metals along with the values for the ligands DTPA, DOTA and EDTA are given in Table 7.[21−32] The relatively weak binding properties of OHEC are immediately apparent. Reading across the rows for each metal, OHEC gives rise to the smallest pM amongst all ligands. This is probably due to the binuclear nature of OHEC, such that the second metal centre is always more weakly bound than the first. Nonetheless, the binding strength of OHEC for Gd^{3+} remains very high and similar to that of the commercially applied contrast agents.

Table 7. pM for the ligands OHEC, DTPA, DOTA, and EDTA, calculated for a total metal concentration of 1×10^{-6} M and a total ligand concentration 1×10^{-5} M at pH 7.4; for OHEC the equilibrium constants determined in this work were used, for other ligands literature values were used[22−33]

pM	OHEC	DTPA	DOTA	EDTA
Gd	14.6	18.7	18.9	16.4
Ca	6.0	7.5	11.3	8.4
Cu	15.5	18.1	17.6	17.3
Zn	14.2	15.3	16.0	14.3

Also apparent from Table 7 is the improved selectivity of OHEC for Gd^{3+} over Ca^{2+} with respect to the selectivity of the commercially applied contrast agents DTPA and DOTA. Indeed, the pM for OHEC and Ca^{2+} is 6.0, indicating no complexation of the metal, i.e. all the Ca^{2+} exists as the free cation under the conditions of the calculation. In contrast, OHEC displays a poorer selectivity for Gd^{3+} over the transition metals Cu^{2+} and Zn^{2+}. The pM for OHEC and Zn^{2+} (14.2) approaches that for Gd^{3+} (14.6) while that for Cu^{2+} (15.5) even exceeds that of Gd^{3+}. Thus, the selectivity of OHEC for Gd^{3+} over these latter two transition metals most closely resembles that of EDTA, a ligand whose gadolinium complex gives rise to toxic impacts.[33] However, the in vivo concentration of Ca^{2+} within human blood serum (2.5−4 millimolar)[34] is much higher than the concentrations of Cu^{2+} and Zn^{2+} (1−10 micromolar and 10−50 micromolar, respectively).[34] The high selectivity of OHEC for Gd^{3+} over Ca^{2+} is therefore a positive result for the potential application of this ligand as a contrast agent for MRI.

The relatively weak binding of Ca^{2+} and Gd^{3+} by OHEC is consistent with the presence of propylene bridging groups in this ligand. These give rise to six-membered chelate rings and a significantly reduced "bite-size"[36] (2.5 Å in the idealised conformation) between the chelating nitrogen atoms of the amine. In the corresponding five-membered rings formed by ethylene-bridged amines this bite-size is 2.8 Å for the idealised conformation. The ligands of Table 7 to which OHEC is compared, all contain exclusively ethylene-bridged amines. As has been reviewed,[35] this decrease in bite-size for six-membered chelate rings has virtually no effect on the stability of complexes formed with Cu^{2+} and Zn^{2+} since these metals have relatively small ionic radii, 0.73 and 0.74 Å, respectively.[36] However, for the larger cations Ca^{2+} and Gd^{3+} (ionic radii of 1.12 and 1.053 Å, respectively)[36] the decrease in bite-size reduces complex

 © 2004 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

stability since the six-membered chelate rings can no longer fully span the metal centres. With Gd^{3+}, however, the complex remains significantly stable since this trivalent cation has a higher charge density than Ca^{2+}. The identical trend in thermodynamic stabilities has been observed for complexes formed between the metals Cu^{2+}, Zn^{2+}, Ca^{2+}, and Gd^{3+} with DOTA and a pair of propylene-bridged derivative ligands.[22,37]

Conclusion

The polyaminocarboxylate macrocycle OHEC ligand developed here can bind two lanthanide ions in close proximity. Homodinuclear lanthanide complexes of OHEC show an interesting coordination equilibrium, depending on the ionic radii of the bound lanthanide ions. Whereas ninefold-coordinated CSAP solid-state structures are found for the mid to early lanthanide(III) ions (Gd, Eu, La) with larger radii, the late lanthanides (Lu, Yb) show eightfold coordination in BCTP structures. These two solid-state structures are the basis for the recently published extensive characterization of the isomerization equilibrium of Ln-OHEC complexes in solution and were used as starting structures for MD calculations.[4]

Ninefold-coordinated Ln-OHEC isomers have one water molecule per lanthanide ion in the inner coordination sphere; this is essential for the efficiency of Gd_2OHEC as a MRI contrast agent. The simultaneous presence of eightfold-coordinated metal centres in solution without water in the first coordination sphere results in a decrease of relaxivity according to the share in the isomerization equilibrium of about 25%.

Nevertheless, OHEC is a useful model ligand in investigating intramolecular electron-spin interactions caused by a short metal−metal distance between paramagnetic lanthanide ions, as shown for the Gd_2OHEC complex. EPR spectra of Gd^{III}- and mixed Gd^{III}/Y^{III} binuclear complexes clearly show that the two Gd^{III} centres interact intramolecularly, resulting in an enhancement of the electronic relaxation of the Gd^{III} electron spins.[38] Other candidates for the investigation of intramolecular electron-spin interactions include bimetallic azacryptates with $Ln^{III}-Ln^{III}$ distances of around 3.5 pm.[39]

The complex solution equilibria of the ligand OHEC have been studied successfully by potentiometry. Using just a single dependent variable, i.e. pH as a function of solution composition, the complete range of solution species and their thermodynamic stabilities could be determined. So much information was extracted from such a simple technique by taking considerable care in the analysis and interpretation of the data. The parameter $\tilde{n}_H$ provided an initial guide in developing a realistic speciation model. Chemical species were included in each metal/ligand/proton system on the basis of their effect upon Σ, the scaled sum of squares. Multiple titrations with suitable variations in concentration and in the metal to ligand ratio were performed for each system. Species that gave rise to highly variable stability constants between independent investigations were viewed as spurious and removed from the model. As a further precaution, titrations were collected for all systems from both forward (vs. KOH) and backward (vs. HCl) titrations. Thus, the equilibrium state was approached from both directions.

The thermodynamic studies revealed that the ligand OHEC is a relatively good chelator for Cu^{2+} and Zn^{2+} while the chelation of Gd^{3+}, and more dramatically Ca^{2+}, is weakened. These trends in complex stability are consistent with the introduction of propylene-bridged amines within the molecular structure of OHEC. The effective deselection of Ca^{2+} by OHEC is a positive result for the potential application of this ligand in a Gd^{3+}-based MRI contrast agent.

Experimental Section

Materials: All reagents used for the preparation of compounds were purchased from either Merck or Aldrich and used as received.

Synthesis: H_8OHEC was prepared by the published method.[1] The sodium salt of the complexes **1** and **2** was prepared by mixing Ln_2O_3, the ligand and NaOH in deionised water (50 mL). The resultant white suspension was heated at 80 °C for several days, until a clear solution was obtained. After cooling to room temperature, the reaction mixture was then filtered and centrifuged to remove undissolved solid material. The final solution was then evaporated to dryness to give a white solid.
Elemental analysis and FAB mass spectra confirmed the composition of the compounds. Elemental analysis: Perkin-Elmer 2400 Series CHNS/O Analyzer. MC: Double-focusing ZAB instrument, VG company (FAB).

X-ray Crystallographic Study: The molecular structures of the complexes **1** and **2** were determined by single-crystal X-ray diffraction. X-ray quality crystals were obtained from saturated aqueous solutions of the pure complexes by slow diffusion of ethanol into the solution of **1** and **2** or by dissolving the solid in a water−ethanol mixture that was kept at 4 °C for several weeks.
Single crystals of compounds **1** and **2** were measured on a STOE Stadi-4 four circle diffractometer at 180 K in a nitrogen atmosphere. Intensity data were corrected for Lorentz, polarisation and absorption (psi-scan technique).[40] Structures were solved by direct methods and refined by full-matrix least-squares against F^2 supported by STOE Xstep software.
Crystal data, data collection and refinement parameters of the structures **1** and **2** are listed in Table 8.
The thermal motion of all non-hydrogen atoms was treated anisotropically, that of hydrogen atoms isotropically and tied 1.2 times higher than the corresponding attached atom.
CCDC-230877 (for **1**) and -230876 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.)+44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

NMR Spectroscopy: NMR spectra were recorded on a Bruker AMX 600 and an AVANCE 400 spectrometer equipped with a Silicon Graphics O2 workstation and a HP workstation x1100, respectively. All samples examined were dissolved in deuterated water,

[a] $R1 = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$. [b] $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. [c] $GoF = \{[w(F_o^2 - F_c^2)^2]/(n - p)\}^{1/2}$.

which was also used as fixed internal reference. The signal due to residual HDO was suppressed by continuous low-power irradiation. To assign the spectra, 2D and 1D NOE difference experiments were carried out. 2D ^{1}H NMR experiments (H,H-COSY, TOCSY and EXSY) were recorded at 278 K with a sweep-width of δ = 12 ppm for non-paramagnetic compounds and δ = 60 ppm for Eu_2OHEC. Data matrices typically consisted of 4096 complex points in F2 for each of the 1024 F1 increments, the data being zero-filled to a 8192 × 2048 complex matrix before transformation. The EXSY spectrum was recorded using the conventional NOESY phase-sensitive pulse sequence ($90° - t_1 - 90° - \tau_m - 90° -$ acq) with a mixing time of 60 ms.

Solution Thermodynamics: Equilibrium constants were measured at 25 °C in aqueous solution with a supporting electrolyte of 0.1 M KCl. They are defined, Equation (2), as cumulative formation constants (β_{mlh}, where M, L and H refer to the free metal, ligand and proton species, respectively).

$$\beta_{mlh} = \frac{[M_m L_l H_h]}{[M]^m [L]^l [H]^h} \quad (2)$$

Determination of the solution equilibria formed by the ligand OHEC is a challenging problem. The ligand contains 16 donor atoms that simultaneously interact with solution protons and any coordinating metals present. The macrocyclic ring may incorporate up to two metal centres. Ultra-violet/visible spectroscopic measurements were not possible as the ligand is an aliphatic amino-carboxylate. Thus, classical potentiometry was applied.

Apparatus: Titrations were performed in a custom-built 100-mL cell and were held under a positive pressure of N_2 to eliminate ingress of CO_2. The cell was constructed of Pyrex glass with a water jacket for temperature control and a PVC lid with various openings for gas control and insertion of the electrode and burette tips. The glass-bulb pH electrode was obtained from Corning (General Purpose High Performance, catalogue no. 476146). An autoburette from Metrohm (model 716) was employed for titrant delivery and measurement of the electrode potential. The burette was controlled by a personal computer using the LABVIEW[41] programming environment, which allowed automated titration execution. An analytical grade balance (±0.05 mg) was used.

Electrode Calibration: The electrode was calibrated, using a published protocol, over the pH range 2.5 to 11.5 before each titration.[42] Data were analysed using the program GLEE.[43] The parameters E^0 (standard potential), *s* (slope of the electrode) and γ (correction factor of the base concentration) were refined while pK_w was fixed at 13.78.[44,45]

Reagents: All solutions were prepared from deionised (resistivity ≥ 18 MΩ) water. Dissolved CO_2 was removed by boiling and subsequent cooling under N_2. Acid and base solutions (≈0.1 M HCl and KOH) were prepared using Merck Titrisol ampoules and standardized to ±0.2% against potassium hydrogen phthalate (99.95% Aldrich) with phenolphthalein as a visual end-point indi-

cator. Stock solutions of the various metals were prepared in 0.01 M HCl from high purity chloride salts ($GdCl_3$ 99.9% ChemPur, $CaCl_2$ 99% ChemPur, $CuCl_2$ 99.999% Alfa Aesar, $ZnCl_2$ 99.999% Alfa Aesar). These stock solutions were standardised by chelometric titration against a solution of EDTA ($Na_2EDTA{\cdot}2H_2O$ 99% Aldrich) which was in turn standardised by potentiometric titration against an HCl solution. For each metal ion, an appropriate buffer system and indicator dye was used in the chelometric standardisations: for Gd^{3+} Arsenazo III[46] in 0.05 M ammonium acetate, for Ca^{2+} and for Zn^{2+} Xylenol Orange[47] in 6×10^{-4} cetylpyridinium chloride and 0.05 M ammonium acetate adjusted to pH 9, and for Cu^{2+} Xylenol Orange[45] in 0.05 M ammonium acetate adjusted to pH 7. The particular batch of H_8OHEC used for the titrations was isolated as an hydrochloride salt and gave an analytical analysis: $C_{34}H_{60}N_8O_{16}{\cdot}3.5HCl{\cdot}4.5H_2O$ (1044.6): calcd. C 39.1, H 7.0, N 10.7, Cl 11.9; found C 38.7, H 6.5, N 10.4, Cl 12.3.
