## Results and Discussion

### Preparation of the Platinum(II)–Bis(carbene) Complexes

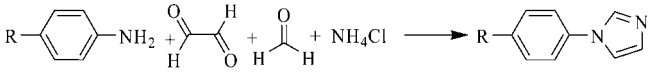
The previously reported syntheses of platinum–NHC complexes involve the preparation of either platinum precursors or free carbenes, which usually have to be handled under an inert gas atmosphere.[24–27] Since the acidic methylene protons in bis(imidazolium) salts might be attacked under common deprotonation conditions, a pathway via the free bis(carbenes) is only possible by using sterically demanding bases, but the yields are only moderate.[28,29] To circumvent the need for multi-step pathways we recently introduced a new synthetic route using the corresponding platinum(II) halide salts and sodium acetate as an external base for the synthesis of the metal complexes. However, the use of external bases like sodium acetate often leads to the formation of small amounts of platinum black, which produces lower yields in the reaction and is difficult to remove from the product.[22]

If platinum(II) acetylacetonate is used as metal precursor, no formation of platinum black is observed during the reaction. Like the platinum(II) halides used in our first protocol,[22] it is commercially available and can be handled in air. Furthermore, there are two major advantages for the use of platinum(II) acetylacetonate compared to platinum(II) halides. First, only platinum(II) halides with the same halides as the imidazolium salts can be used in the reaction to avoid anion scrambling in the complex, and platinum(II) halides are also much more expensive than platinum(II) acetylacetonate. Secondly, different from our

 InterScience © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

older procedure, no other external base has to be added since the basicity of the acetylacetonate anion is sufficient to deprotonate the imidazolium salt. When platinum(II) halides are used as metal precursors, sodium acetate has to be added to the reaction mixture, which leads to the formation of sodium halide salts during the reaction which have to be removed by washing the product with water several times.[22] In this case only pentan-2,4-dione emerges during the reaction, and this can be removed in vacuo along with the solvent. We were able to synthesize several new platinum–N-heterocyclic bis(carbene) complexes with different substituents at the aromatic ring following this method.

The synthesis of these new ligands can be accomplished in only two steps. First, the aromatic-substituted imidazoles were synthesized according to Scheme 1 from substituted anilines, which are commercially available in great diversity: 4-nitroaniline for **1a**, 4-chloroaniline for **1b**, 4-bromoaniline for **1c**, 4-methoxyaniline for **1d**, and ethyl 4-aminobenzoate for **1e**. The aromatic amine, glyoxal and formaldehyde are converted into an aromatic-substituted imidazole in a one-pot reaction. Additionally to the imidazoles prepared by Zhang et al.,[30] we extended this method to anilines substituted by different halogens. Both electron-donating and -withdrawing substituents are tolerated, although the yields of product are quite different (Table 1).



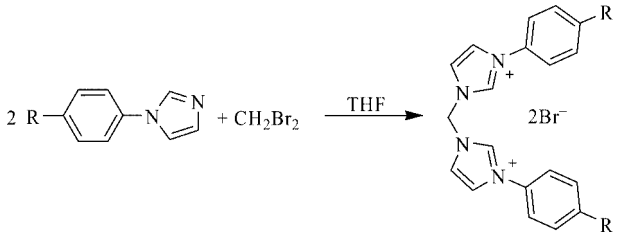
Scheme 1. Synthesis of imidazoles with different aromatic substituents [R = $NO_2$ (**1a**), R = Cl (**1b**), R = Br (**1c**), R = $OCH_3$ (**1d**), R = $COOCH_2CH_3$ (**1e**)].

Table 1. Isolated yields of **1a**–**1e**.

| | **1a** | **1b** | **1c** | **1d** | **1e** |
|---|---|---|---|---|---|
| Yield | 28.0% | 77.0% | 60.7% | 75.0% | 73.7% |

The low yield for **1a** can be explained by its lower solubility in organic solvents, so the extraction of the product is the limiting factor here. This reaction gives access to a wide range of N-substituted imidazoles with different functional groups at the aromatic ring, thereby allowing us to fine-tune the electronic situation in the N-heterocyclic carbene ligand.

These N-substituted imidazoles can be converted in good yields into the corresponding bis(imidazolium) salts by a nucleophilic substitution reaction with dibromomethane (Scheme 2). The reaction also works with diiodomethane,



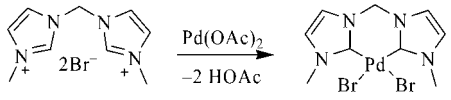
Scheme 2. Synthesis of the imidazolium salts [R = $NO_2$ (**2a**), R = Cl (**2b**), R = Br (**2c**), R = $OCH_3$ (**2d**), R = $COOCH_2CH_3$ (**2e**)].

as reported previously.[22] The preparation of the imidazoles and the following bridging step of two of these imidazoles with dibromomethane are compatible with a wide range of functional groups at the aromatic ring. Yields are given in Table 2.

Table 2. Isolated yields of **2a**–**2e**.

| | **2a** | **2b** | **2c** | **2d** | **2e** |
|---|---|---|---|---|---|
| Yield | 94.8% | 64.0% | 84.0% | 88.7% | 86.4% |

Finally, we succeeded in synthesizing the platinum–bis(carbene) complexes under very mild conditions, thus proving the application of our new compounds as suitable NHC ligands for late transition metals. In this case, the traditional metalation procedure involving deprotonation of the imidazolium precursor with strong bases produces unwanted side reactions because of the acidic protons in the bridging $CH_2$ group and in the functional groups at the aromatic ring.[31] Milder procedures were therefore needed that are compatible with more sensitive functionalities. Base-sensitive methylene-bridged bis(imidazolium) salts can be converted into the corresponding palladium–bis(carbene) complexes by treatment with $Pd(OAc)_2$ in wet dimethyl sulfoxide (DMSO) at elevated temperatures in high yields (Scheme 3).[14–16] This route is very useful in cases where the metal acetates are easily available. In the case of platinum, however, the corresponding acetate is not available and is difficult to synthesize.[32,33] So until now platinum(II) halides had to be used and sodium acetate had to be added to the reaction mixture as an external base, leading to the formation of sodium halides as by-products during the reaction.[22] Here we present a new synthetic approach that uses platinum(II) acetylacetonate as a commercially available metal precursor and base for the deprotonation of the imidazolium salt. The synthesis of the platinum complexes is illustrated in Scheme 4 and yields of the syntheses are given in Table 3.



Scheme 3. Synthesis of bridged palladium complexes from imidazolium salts and palladium(II) acetate.

To obtain these complexes in good yields it is necessary to follow the synthetic protocol described below. It is crucial that the halide salt of the bis(imidazolium) compound is completely converted into the platinum–monocarbene species by slowly heating the reaction mixture over several hours first to 60 °C, thereby deprotonating only one of the imidazolium rings, otherwise a substantial amount of platinum black formation is observed.[22] The reaction mixture should then be heated up to 130 °C to deprotonate the second imidazolium ring. This is consistent with the earlier findings of Herrmann et al. regarding palladium–bis(carbene) complexes,[34] but had not been observed for platinum carbenes before.

The molecular structures of complexes **3b**–**3e** are nearly identical with each other and with **4**; they contain a bowl-shaped NHC ligand. A DMSO solvent molecule, which covers the cavity, is found inside this bowl in all structures. The solid-state structure of complex **3d** is given in Figure 1 as an example, although the DMSO solvent molecule has been omitted for clarity. Pictures of the solid-state structures of the other complexes are given in the Supporting Information.

The Pt–carbene-C distances of the aromatic-substituted complexes **3b**–**3e** are equivalent within the margin of error. The biggest differences between these structures are found in the torsional angles of the plane of the aromatic rings towards the plane of the imidazole rings. Figure 2 shows a superposition of all four crystal structures; the DMSO and methanol solvent molecules found in the crystal structures have been omitted for clarity. The figure shows that the coordination environment of the metal center is highly preserved and so there are nearly no differences in the steric situation of the metal, even though the complexes crystallize in different space groups.

Although structurally quite similar these complexes have different electronic properties at the metal center, as can be seen from the $^{13}C$ NMR spectra. The effects of the different

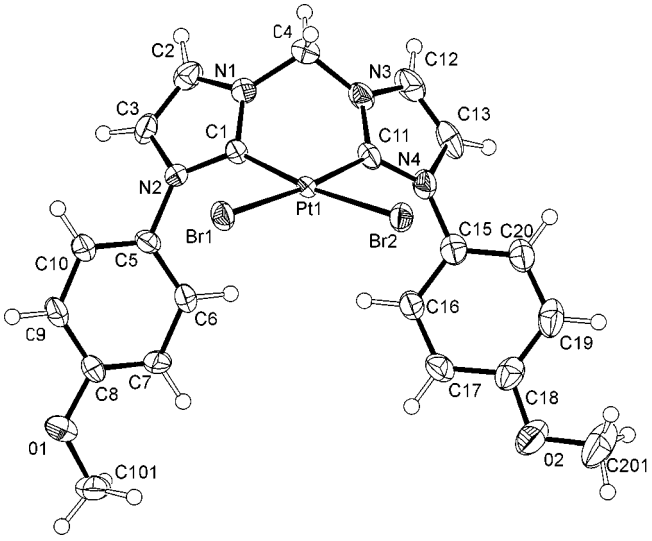

Figure 1. ORTEP-style plot of the solid-state structure of compound **3d**. Thermal ellipsoids are drawn at the 50% probability level. The disordered DMSO molecule in the crystal has been omitted for clarity.

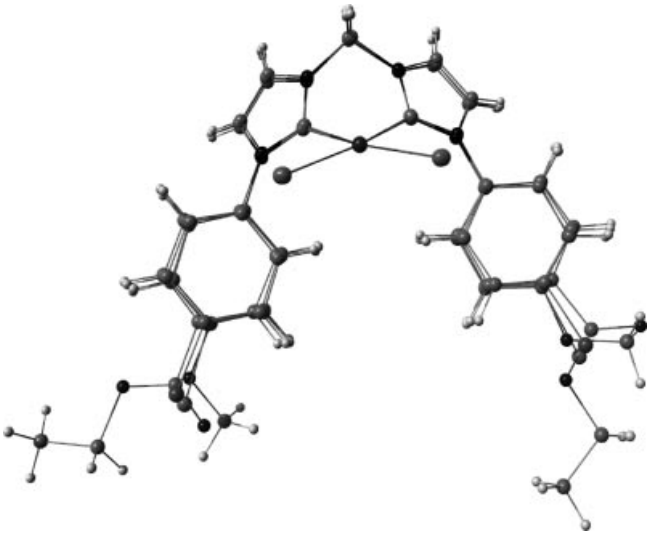

Figure 2. Superposition of the solid-state structures of **3b**–**3e**. Solvents omitted for clarity.

aromatic substituents $R_1$ on the $^{13}C$ chemical shifts for the carbene carbon atoms are shown in Figure 3. Therefore it is possible to fine-tune the electronic situation at the metal center by varying the functional groups at the aromatic ring. Electron-withdrawing groups like $NO_2$ or halogens at the aromatic ring lead to a shift of the $^{13}C$ signal of the

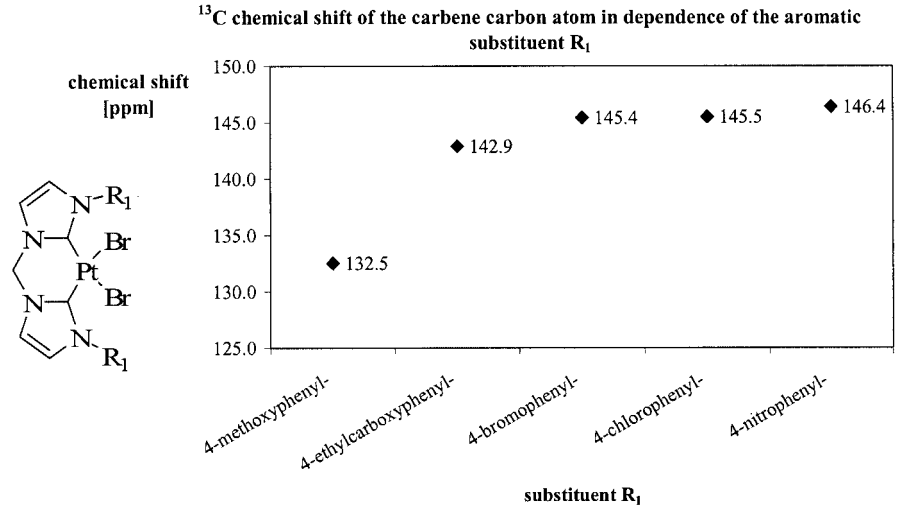

Figure 3. Dependence of the $^{13}C$ chemical shift of the carbene carbon atom on the aromatic substituents $R_1$.

carbene C to lower field, which is indicative of a higher partial negative charge at the carbene carbon atoms of the complex. As expected, the electron-withdrawing effects of a 4-chlorophenyl and a 4-bromophenyl group at the imidazole are nearly equivalent. On the other hand, electron-donating groups like the methoxy group at the aromatic ring lead to a high-field shift of the $^{13}C$ signal of the carbene carbon atom.

This type of complex also shows an unusually high thermal stability combined with a surprising resistance to acidic media. We have observed this stability previously for palladium(II)–NHC complexes like 1,1′-dimethyl-3,3′-methylene-4-diimidazoline-2,2′-diylidenepalladium(II) dibromide (**4**), which are catalysts for the activation of methane, while the analogous platinum(II)–NHC complex **5** decomposes quickly in trifluoroacetic acid (Figure 4).[9,10,22]

**4** **5**

Figure 4. Methyl-substituted bis-NHC complexes of palladium (**4**) and platinum (**5**).

With the introduction of aromatic ligands and the novel platinum(II) acetylacetonate synthesis presented here, we have been able to make several new platinum–bis(carbene) complexes with increased stability against strongly acidic conditions. While the analogous *N*-methyl-substituted complex **5** is stable towards air and moisture even at elevated temperatures, it decomposes within minutes to platinum black in trifluoroacetic acid.[9] However, the new complex **3b** does not decompose even after weeks in TFA or at elevated temperatures of up to 90 °C in the presence of strong oxidants like $K_2S_2O_8$. Complex **3e** can also be heated to 110 °C in 2 N HCl solution for 4 h with no change in the NMR spectrum. Neither reprotonation to the imidazolium salt nor hydrolysis of the ester functionality are observed under these conditions.

## Conclusion

We have shown that platinum(II)–bis(carbene) complexes with various aromatic substituents can be synthesized following our new protocol with platinum(II) acetylacetonate as metal precursor. Together with our new aromatic ligands with various substituents, acid-stable platinum(II)–bis(carbene) complexes are now synthetically available in great diversity. The electronic situation at the metal center can be fine-tuned by varying the functional groups at the aromatic ring without changing the steric situation of the metal center. This is important for future applications of these complexes in various catalytic reactions, since many known homogeneous catalytic processes depend on a particular electronic situation at the metal center.

## Experimental Section

**General Procedures:** Solvents of 99.5% purity were used throughout this study. Platinum(II) acetylacetonate (98%) was purchased from Acros. All other chemicals were obtained from common suppliers and used without further purification. Ligands **2a**–**2e** were prepared according to the procedures given in the Supporting Information. $^1H$ and $^{13}C$ NMR spectra were recorded with a Bruker AC 300 P, Jeol JNM GX-270, or Jeol JNM GX-400 spectrometer. As the $^1H$ and $^{13}C$ NMR spectra of one compound were not always measured on the same spectrometer, spectrometer frequencies of the measurements are given. The spectra were referenced internally to the resonances of the solvent ($^1H$, $^{13}C$). Elemental analyses were performed by the microanalytical laboratory at our institute using an EuroVektor Euro EA-300 Elemental Analyzer. Mass spectra were recorded with a Finnigan MAT 90 spectrometer.

**Synthesis of Platinum(II) Complex 3a:** 1,1′-Bis[1-(4-nitrophenyl)]-3,3′-methylenimidazolium dibromide (**2a**; 280.5 mg, 0.51 mmol) and platinum(II) acetylacetonate (200 mg, 0.51 mmol) were dissolved in 3 mL of dimethyl sulfoxide in a nitrogen-flushed Schlenk tube and heated for 2 h to 60 °C, 2 h to 80 °C, 2 h to 100 °C, and 1 h to 130 °C. At approximately 80 °C the reaction mixture became a clear, yellow solution. After removal of the solvent in vacuo the resulting residue was washed twice with 5 mL of diethyl ether and

5 mL of dichloromethane. The product was obtained as a yellow powder. Yield: 0.236 g (62.1%). $^1$H NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 6.31 (d, $J$ = 14.4 Hz, 1 H, NC$H_2$N), 6.38 (d, $J$ = 14.4 Hz, 1 H, NC$H_2$N), 7.79 (d, $J$ = 9.0 Hz, 2 H, NC$H_2$CH$_2$N), 7.97–8.03 (m, 4 H, arom. H), 8.36 (d, $J$ = 9.0 Hz, 2 H, NCH$_2$C$H_2$N), 8.51–8.55 (m, 4 H, arom. H) ppm. $^{13}$C NMR (75 MHz, [D$_6$]DMSO): $\delta$ = 62.4 (N$C$H$_2$N), 121.0 (N$C$HCHN), 122.6 (NCH$C$HN), 124.5 (C2, C6 of C$_6$H$_4$NO$_2$), 125.5 (C3, C5 of C$_6$H$_4$NO$_2$), 126.4 (C1 of C$_6$H$_4$NO$_2$), 146.4 ($C$–Pt), 146.8 ($C$–NO$_2$). $C_{19}H_{14}Br_2N_6O_4Pt$·0.5DMSO (745.24 + 39.07): calcd. C 30.63, H 2.18, N 10.72; found C 30.94, H 2.46, N 10.79. MS (FAB): $m/z$ = 584.2 [M – 2Br]$^+$, 462.2 [M – 2Br – C$_6$H$_4$NO$_2$]$^+$, 341.2 [M – 2Br – 2C$_6$H$_4$NO$_2$]$^+$, 147.3 [M – 2Br – Pt – 2C$_6$H$_4$NO$_2$]$^+$.

**Synthesis of Platinum(II) Complex 3b:** 1,1-Bis[1-(4-chlorophenyl)]-3,3′-methylenimidazolium dibromide (**2b**; 500 mg, 0.94 mmol) and platinum(II) acetylacetonate (370 mg, 0.94 mmol) were dissolved in 10 mL of dimethyl sulfoxide in a nitrogen-flushed Schlenk tube and heated for 2 h to 40 °C, 2 h to 60 °C, 2 h to 80 °C, 2 h to 100 °C and 1 h to 130 °C. At 60 °C the reaction mixture became a clear, yellow solution. After removal of the solvent in vacuo the resulting residue was washed twice with 5 mL of ethanol. The product was obtained as a white powder. Yield: 0.591 g (86.8%). $^1$H NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 6.10 (d, $J$ = 14.6 Hz, 1 H, NC$H_2$N), 6.31 (d, $J$ = 14.6 Hz, 1 H, NC$H_2$N), 7.64 (d, $J$ = 9.0 Hz, 4 H, arom. H), 7.73 (d, $J$ = 2.2 Hz, 2 H, NC$H$CHN), 7.77 (d, $J$ = 2.1 Hz, 2 H, NCHC$H$N), 7.81 (d, $J$ = 9.0 Hz, 4 H, arom. H) ppm. $^{13}$C NMR (75 MHz, [D$_6$]DMSO): $\delta$ = 67.0 (N$C$H$_2$N), 121.4 (N$C$HCHN), 122.2 (NCH$C$HN), 127.0 (C2, C6 of C$_6$H$_4$Cl), 128.6 (C3, C5 of C$_6$H$_4$Cl), 132.3 ($C$–Cl), 138.2 (C1 of C$_6$H$_4$Cl), 145.5 ($C$–Pt) ppm. $C_{19}H_{14}Br_2Cl_2N_4Pt$·DMSO (724.13 + 78.13): calcd. C 31.44, H 2.51, N 6.98, S 4.00; found C 31.16, H 2.51, N 6.65, S 4.00. MS (FAB): $m/z$ = 643.3 [M – Br]$^+$, 563.3 [M – 2Br]$^+$, 176.3 [C$_9$H$_6$N$_2$Cl$^+$].

**Synthesis of Platinum(II) Complex 3c:** 1,1-Bis[1-(4-bromophenyl)]-3,3′-methylenimidazolium dibromide (**2c**; 315.0 mg, 0.51 mmol) and platinum(II) acetylacetonate (200.0 mg, 0.51 mmol) were dissolved in 3 mL of dimethyl sulfoxide in a nitrogen-flushed Schlenk tube and stirred for 2 h at room temperature. The reaction mixture was then heated for 2 h to 60 °C, 1 h to 85 °C, and finally 1 h to 110 °C. The solvent was then removed in vacuo until only 0.5 mL of the solvent remained. After the addition of 3 mL of water a white solid precipitated. The aqueous solution was filtered off and the resulting residue was washed twice with 5 mL of dichloromethane. The product was obtained as a white powder. Yield: 0.278 g (67.0%). $^1$H NMR (270 MHz, [D$_6$]DMSO): $\delta$ = 6.10 (d, $J$ = 12.7 Hz, 1 H, NC$H_2$N), 6.31 (d, $J$ = 12.4 Hz, 1 H, NC$H_2$N), 7.53–7.95 (m, 12 H, remaining H) ppm. $^{13}$C NMR (67.9 MHz, [D$_6$] DMSO): $\delta$ = 62.5 (N$C$H$_2$N), 120.7 (N$C$HCHN), 121.5 ($C$–Br), 122.2 (NCH$C$HN), 127.3 (C2, C6 of C$_6$H$_4$Br), 131.6 (C3, C5 of C$_6$H$_4$Br), 138.8 (C1 of C$_6$H$_4$Br), 145.4 ($C$–Pt) ppm. MS (FAB): $m/z$ = 733.0 [M – Br]$^+$, 653.1 [M – 2Br]$^+$, 572.2 [M – 3Br]$^+$, 419.5 [M – 3Br – C$_6$H$_4$Br]$^+$.

**Synthesis of Platinum(II) Complex 3d:** 1,1-Bis[1-(4-methoxyphenyl)]-3,3′-methylenimidazolium dibromide (**2d**; 250.0 mg, 0.48 mmol) and platinum(II) acetylacetonate (188.3 mg, 0.48 mmol) were dissolved in 7 mL of dimethyl sulfoxide in a nitrogen-flushed Schlenk tube and stirred for 4 d at 60 °C. The solvent was then removed in vacuo and the product washed twice with 5 mL of water and twice with 5 mL of diethyl ether. The product was obtained as a white powder Yield: 0.240 g (69.9%). $^1$H NMR (300 MHz, [D$_6$] DMSO): $\delta$ = 3.86 (s, 6 H, OC$H_3$), 6.07 (d, $J$ = 14.6 Hz, 1 H, NC$H_2$N), 6.26 (d, $J$ = 14.6 Hz, 1 H, NC$H_2$N), 7.08 (m, 4 H, arom. H), 7.67 (s, 2 H, NC$H$CHN), 7.72 (s, 2 H, NCHC$H$N), 7.78 (m, 4 H, arom. H) ppm. $^{13}$C NMR (75 MHz, [D$_6$]DMSO): $\delta$ = 55.3 (O$C$H$_3$), 62.4 (N$C$H$_2$N), 113.7 (arom. $C$H), 122.5 (N$C$HCHN), 126.1 (arom. $C$H), 126.3 (NCH$C$HN), 126.7 (C1 of C$_6$H$_4$OMe), 132.5 (Pt–$C$), 158.8 ($C$–OMe) ppm. $C_{21}H_{20}Br_2N_4O_2Pt$ (715.30): calcd. C 37.25, H 3.25, N 6.68, S 1.91; found C 37.15, H 3.38, N 6.29, S 2.11.

**X-ray Crystal-Structure Determination for 3b–3e:** Crystals suitable for an X-ray investigation were obtained either by allowing methanol to condense into a saturated solution of the metal complex in DMSO (**3b**, **3c**) or by slowly cooling a hot, saturated solution of the complex in DMSO (**3d**, **3e**). The crystals were stored under perfluorinated ether, transferred to a Lindemann capillary, fixed, and sealed. Preliminary examination and data collection were carried out on an area-detection system (Kappa-CCD; Nonius) with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data collections were performed at 173 K (**3b**) or 198 K (**3c**–**3e**) in the $\Theta$ range 2.27° < $\Theta$ < 21.02° (**3b**) or 3.00° < $\Theta$ < 27.40° (**3c**–**3e**). The reflections were integrated, raw data were corrected for Lorentz, polarization, decay, and absorption effects. Due to the small size of the crystal the data set for **3d** was reduced to 25.00 and that of **3e** to 26.40. The absorption correction was applied using the PLATON DELABS algorithm for **3b** and SADABS for **3c**–**3e**. The independent reflections were used for all calculations after merging. The structures were solved by a combination of direct methods and difference Fourier syntheses. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were calculated in ideal positions as riding on the parent carbon atoms. During the final stage of the refinements it becomes evident that the crystal of **3b** contains unresolvable solvent molecules. This problem was cured by using the PLATON CALC SQUEEZE procedure. All other solvent molecules in **3c**–**3e** could be fully resolved. Full-matrix least-squares refinements were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ with SHELXL-97 weighting scheme and stopped at shift/err < 0.001. The final difference Fourier map showed high residual electron density peaks for **3b** (+1.610 and –2.096 e Å$^{-3}$) caused by the incomplete absorption correction and the incomplete removal of solvent molecules and **3c** (1.546 and –0.959 e Å$^{-3}$; distance to platinum 0.783 and 0.976 Å) caused by an incomplete absorption correction. Details of the structure determinations are given in Table 5. Neutral-atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International Tables for Crystallography. All calcu-

# Amine-Functionalised Hexagonal Mesoporous Silica as Support for Copper(II) Acetylacetonate Catalyst

**Ana Rosa Silva,[a] Karen Wilson,[b] Adrian C. Whitwood,[c] James H. Clark,[b] and Cristina Freire*[a]**

**Keywords:** Copper / Anchoring / Mesoporous silica / EPR spectroscopy / Aziridination

Copper(II) acetylacetonate was anchored onto a hexagonal mesoporous silica (HMS) material using a two-step procedure: (i) functionalisation of the surface hydroxy groups with (3-aminopropyl)triethoxysilane (AMPTSi) and then (ii) anchoring of the copper(II) complex through Schiff condensation with free amine groups, using two different metal complex loadings. Upon the first step, nitrogen elemental analysis, XPS and DRIFT showed the presence of amine groups on the surface of the HMS material, and porosimetry indicated that the structure of the mesoporous material remained unchanged, although a slight decrease in surface area was observed. Atomic absorption, XPS and DRIFT showed that copper(II) acetylacetonate was anchored onto the amine-functionalised HMS by Schiff condensation between the free amine groups and the carbonyl groups of the copper(II) complex; using EPR an $NO_3$ coordination sphere was proposed for the anchored copper(II) complex. The new [Cu(acac)$_2$]-AMPTSi/HMS materials were tested in the aziridination of styrene at room temperature, using PhI=NTs as nitrogen source and acetonitrile as solvent. The styrene conversion and total TON of the heterogeneous phase reaction are higher than those of the same reaction catalysed in homogeneous phase by [Cu(acac)$_2$]; nevertheless, the initial activity decreases and the reaction time increases due to substrate and product diffusion limitations. The heterogeneous catalyst showed a successive slight decrease in catalytic activity when reused for two more times.

## Introduction

Currently, transition-metal complexes with Schiff-base ligands of the salen type are the object of intense research due to their high activity, chemoselectivity and enantioselectivity in a large range of catalytic processes.[1–3] One of the best-known examples are (salen)manganese(III) complexes, that catalyse the epoxidation of alkenes,[1–3] and lead (by direct atom transfer to olefins) to epoxides, which are of great utility in organic synthesis.[1–3,4] The equivalent nitrogen-atom-transfer process catalysed by transition-metal complexes has been less exploited,[4,5] despite aziridines being valuable products as intermediates in organic synthesis,[4–7] efficient chiral auxiliaries and ligands in asymmetric catalysis.[6] Evans et al. reported that copper(II) acetylacetonate is a very efficient homogeneous catalyst for the aziridination of alkenes using 4-methyl-*N*-(phenyl-$\lambda^3$-iodanylidene)benzenesulfonamide (PhI=NTs) as nitrogen source;[4] (salen)copper(II) complexes have also been applied as homogeneous catalysts for the alkene aziridination using the same nitrogen source.[7]

However, homogeneous catalysts can not be separated from the reaction media and, subsequently, can not be reused. Thus, one way to improve the homogeneous chemical processes, preventing the requirement for laborious and inefficient extraction processes, is to immobilise the (sometimes) expensive homogeneous catalyst on solid supports.[8] In fact, the last decade has witnessed a growing interest in the heterogenisation of homogeneous metal complexes using several types of supports and several immobilisation strategies.[9–13] Initially, the complexes were just ion-exchanged or adsorbed on the porous supports and, consequently, could be susceptible to leaching.[14,15] More recently, several grafting and tethering procedures have been developed to covalently attach transition-metal complexes to organic polymers,[13] silica, zeolites and other micro- and mesoporous inorganic materials.[9–12]

Copper(II) acetylacetonate has already been immobilised in a polymer[6] and activated carbon,[16,17] and the new materials have acted as recoverable and reusable heterogeneous catalysts for the aziridination of olefins using PhI=NTs as nitrogen source.[6,17] In the first case, the copper(II) complex was microencapsulated in polystyrene, and in the latter it was anchored onto an amine-functionalised activated car-

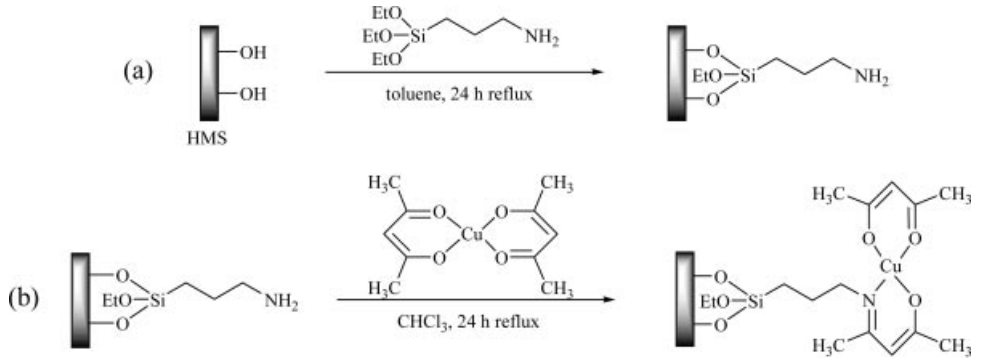
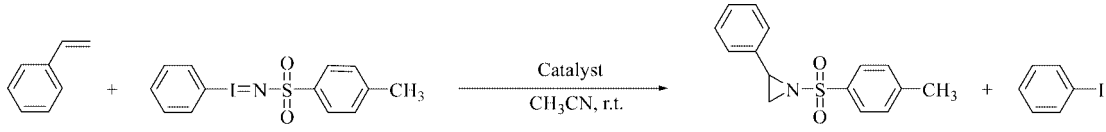


Scheme 1. Anchoring procedure: (a) functionalisation of the HMS with (3-aminopropyl)triethoxysilane and (b) anchoring copper(II) acetylacetonate onto AMPTSi-functionalised HMS.



Scheme 2. Aziridination of styrene using PhI=NTs as nitrogen source.

bon,[16] through Schiff-base condensation between the free amine group, covalently attached to the activated carbon surface with the carbonyl groups of the acetylacetonate ligand coordinated to copper(II). Both heterogeneous catalysts presented similar catalytic parameters as those obtained in homogeneous-phase reaction using [Cu(acac)$_2$], under similar experimental conditions, and no significant metal complex leaching was observed after the catalytic reactions.[6,17] However, in the case where activated carbon was used as support, inherent diffusion limitations were observed due to the porous structure of the support, and thus a decrease in the initial activity (TOF), and an increase in the reaction time was observed.[17] Furthermore, the spectroscopic characterisation by DRIFT and UV spectroscopy of the new carbon-based heterogeneous catalysts proved to be difficult and impossible, respectively, due to the highly absorbing carbon matrix, which limited the gathering of information about the copper(II) complex formed on the surface of the amine-functionalised activated carbon. Immobilisation on several porous supports of (Schiff base)copper(II) complexes previously synthesised[18] or prepared in situ on the porous structure,[19,20] have also been reported in the literature.

The silica-based inorganic mesoporous materials which offer pore sizes in the range 20–100 Å, are more suitable for liquid-phase reactions, because they allow easy diffusion of reactants to the active sites.[8,21] Their surface silanol groups can also be easily functionalised by using trialkyloxysilanes, with amine, thiol, carboxylic acid, phenyl, cyano, sulfonic acid and vinyl groups, hence allowing subsequent chemical attachment of the catalytic active species, namely inorganic coordination compounds.[8,21] Furthermore, they can be easily characterised by several spectroscopic techniques. Despite of the hexagonal mesoporous silicas (HMS) being less ordered than MCM-41 and SBA-15 materials, they are much easier and straightforward to synthesise due to the use of a cheap and neutral template, which does not require the need of strongly acidic conditions.[22]

In the present work, a new and simpler route to obtain immobilised (Schiff base)copper(II) complexes is presented. A hexagonal mesoporous silica (HMS), organically functionalised with (3-aminopropyl)triethoxysilane, was chosen to anchor copper(II) acetylacetonate. The anchoring process was done through Schiff condensation between the free amine group, covalently attached to the HMS surface (Scheme 1), with the carbonyl groups of the acetylacetonate ligand, coordinated to copper(II), as depicted in Scheme 1. All the materials were characterised by nitrogen elemental analysis, FTIR-DRIFT, nitrogen isotherms at 77 K and XPS, and those with immobilised copper(II) complex were also characterised by copper atomic absorption, UV diffuse reflectance spectroscopy and EPR. The catalytic activity of this new materials in the aziridination of styrene at room temperature using PhI=NTs as nitrogen source was studied (Scheme 2).

## Results and Discussion

### Characterisation of the HMS and Amine Functionalisation

The nitrogen adsorption isotherm at 77 K of the calcined HMS material is of type IV (Figure 1), and therefore is typical of mesoporous materials, although the presence of micropores can be detected in the lower relative pressure region. The material has a BET surface area of 1158 $m^2 g^{-1}$ (Table 1).

The infrared spectrum of the calcined HMS shows the typical Si–O lattice vibrations: two broad bands between 2100 and 1750 $cm^{-1}$, with medium intensity, a strong and broad band with two peaks in the region 1450–900 $cm^{-1}$, and two strong bands between 900 and 500 $cm^{-1}$. Furthermore, a very broad band centred at 3450 $cm^{-1}$, due to the

O–H stretching vibrations, and a very sharp band at 3745 cm$^{-1}$, with medium intensity, which is assigned to the stretching vibrations of isolated surface SiO–H groups, are observed. A band at 1622 cm$^{-1}$ is also observed in the spectrum and is attributed to the H–O–H bending vibrations of physisorbed water (Figure 2).

The HMS material was functionalised with (3-aminopropyl)triethoxysilane (AMPTSi) and both nitrogen elemental and XPS analyses show that nitrogen (Tables 1 and 2) was introduced on the surface of the material: 1.34 mmol g$^{-1}$ and 0.999 mmol g$^{-1}$, respectively. From the former value and taking into account the AMPTSi used in the functionalisation reaction (3.00 mmol g$^{-1}$), the anchoring efficiency of the amine derivative onto the support was 44.7%.

Upon amine functionalisation, a decrease in the intensity of the band at 3745 cm$^{-1}$ is observed (Figure 2A), indicating that the reaction between the isolated silanol groups of the surface of the HMS with the ethoxy groups of the silane derivative took place. The N–H and C–H stretching vibrations of AMPTSi are observed in the region 3400–3000 cm$^{-1}$ and 3000 cm$^{-1}$, respectively, and the corresponding H–N–H and H–C–H bending vibrations can also be observed in the regions 1700–1500 cm$^{-1}$ and 1500–1300 cm$^{-1}$, respectively, as weak intensity bands (Figure 1B).

No changes in the isotherm profile were observed upon surface functionalisation of HMS with AMPTSi, suggesting that the structure of the parent material was unaffected after this step (Figure 1); however, a decrease in the HMS surface area (Table 1), as well as some blockage of the micropores and a slight decrease in the mean mesopore size (Figure 1) are observed, as expected.

**Anchoring of Copper(II) Acetylacetonate onto the Amine-Functionalised HMS**

Two chloroform solutions containing different quantities of copper(II) acetylacetonate were refluxed for 24 h with the amine-functionalised HMS. Evidence for the effective anchorage of the copper(II) acetylacetonate complex onto the surface of AMPTSi/HMS was first provided by noting that (a) the blue colour of the complex solution disappears during the adsorption reaction, and (b) colourless solutions are obtained when the materials were purified by Soxhlet extraction.

Atomic absorption analysis (Table 1) of the materials revealed that the [Cu(acac)$_2$]AMPTSi/HMS_A material contains 362 μmol of copper/g of material and the [Cu(acac)$_2$]-AMPTSi/HMS_B material contains 68 μmol of copper/g. Relatively to the copper(II) complex quantity initially present in each solution, these values correspond to an anchoring efficiency of 73% and 82%, respectively, suggesting the presence of some diffusion control in the metal complex immobilisation reactions.

The N/Cu ratios obtained by elemental analysis and XPS have similar magnitudes (Table 1) suggesting that the anchored copper(II) species have the same chemical environment throughout the HMS matrix. Nevertheless, in both materials the spacer AMPTSi is always in excess relative to complex (larger excess in [Cu(acac)$_2$]AMPTSi/HMS_B).

No change in the isotherm profile was observed upon complex immobilisation (Figure 1), suggesting that the functionalised HMS structure was unaffected by complex anchoring; however, a further decrease in the material surface area (Table 1 and Figure 1), and a slight decrease in the mean mesopore size are observed, confirming indirectly the presence of the complex within the matrices. Surprisingly, the material with lower copper loading, [Cu(acac)$_2$]-AMPTSi/HMS_B, shows a larger decrease in the surface area, specially in the mesopore region, than the material with higher copper loading, [Cu(acac)$_2$]AMPTSi/HMS_A.

The IR spectra of [Cu(acac)$_2$AMPTSi]/HMS_A and [Cu-(acac)$_2$AMPTSi]/HMS_B show, with respect to the parent material, some changes in the regions where vibration from AMPTSi occur: 3500–3000 cm$^{-1}$ region, due to N–H stretching vibrations and 1700–1300 cm$^{-1}$, weak absorptions due to the H–N–H and H–C–H bending vibrations, suggesting that some molecular changes in the spacer took place. On the other hand, new broad bands are observed at about 1658 and 1555 cm$^{-1}$ (Figure 2), which may be attributed to a C=N stretching vibration and to the acetylacetonate ring vibrations of the metal complex, respectively. Furthermore, in the region between 1700 and 1300 cm$^{-1}$, where the fingerprint bands of [Cu(acac)$_2$] are usually detected, the DRIFT spectra of both [Cu(acac)$_2$AMPTSi]/HMS_A and [Cu(acac)$_2$AMPTSi]/HMS_B materials are different from that of free [Cu(acac)$_2$] (Figure 2), contrasting with a previous report for silica-supported [Cu(acac)$_2$], which shows a very similar DRIFT spectrum to that of the free complex.[23] These results clearly indicate that there was a Schiff condensation between the free amine groups on the surface of the HMS material and the oxygen atoms coordinated to copper(II), and that therefore the anchoring procedure occurred as depicted in Scheme 1.

The electronic spectrum of free [Cu(acac)$_2$] presents a large and asymmetric band with a maximum at $\lambda$ = 558 nm and a shoulder lying lower in energy at about $\lambda$ = 642 nm (Figure 3); this spectrum is typical of Cu$^{II}$ complexes with a square-planar geometry.[16] In this context the band at lower energy is assigned to the $d_{xy} \leftarrow d_{z^2}$ transition and the band at higher energies is attributed to the envelop of two other allowed d–d transitions: $d_{xy} \leftarrow d_{x^2-y^2}$ and $d_{xy} \leftarrow d_{xz} \approx d_{yz}$, which have very close energies.[24]

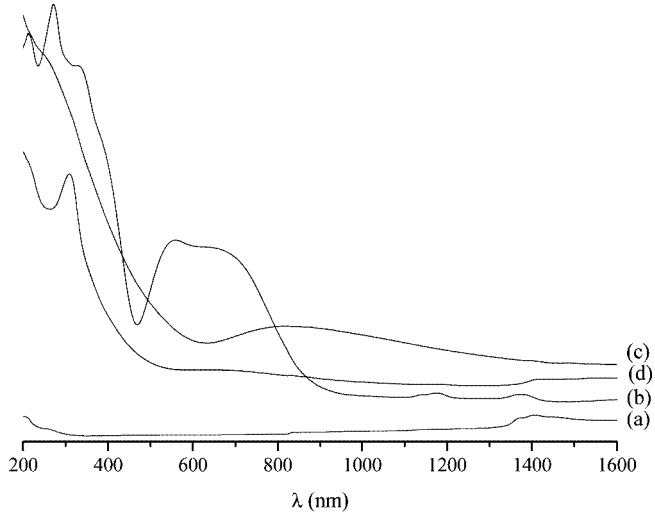

Figure 3. UV diffuse reflectance spectra of the HMS materials: (a) calcined HMS, (b) [Cu(acac)$_2$], (c) [Cu(acac)$_2$]AMPTSi/HMS_A and (d) [Cu(acac)$_2$]AMPTSi/HMS_B.

The electronic spectrum of the [Cu(acac)$_2$]AMPTSi/HMS_A material shows a broad asymmetric band at $\lambda$ = 823 nm tailoring to lower energies, which corresponds to the envelop of the three allowed d–d transitions ($d_{xy} \leftarrow d_{z^2}$, $d_{xy} \leftarrow d_{x^2-y^2}$ and $d_{xy} \leftarrow d_{xz} \approx d_{yz}$) with close energies. In comparison to the spectrum of free [Cu(acac)$_2$], the maximum of the band is shifted towards lower energy (Figure 3); this type of changes in the electronic spectrum of Cu$^{II}$ complexes can be interpreted as suggesting a tetrahedral distortion in the equatorial plane or axial coordination of a new ligand.[24] Although the first explanation could justify the proposed complex anchoring model, on the basis of electronic data alone, no choice between the two hypotheses can be made. The profile spectrum of [Cu(acac)$_2$]AMPTSi/HMS_B is similar to the previous one, but its low intensity, due to the lower copper content in this material, prevents any further interpretation (Figure 3).

Further insights into the copper(II) coordination sphere upon complex anchoring can be gathered from EPR spectroscopy. The EPR spectrum of [Cu(acac)$_2$]AMPTSi/HMS_B at 120 K, depicted in Figure 4 (b), is typical of copper(II) species: it is of the axial type and shows hyperfine couplings due to the interaction of the unpaired electron with the copper nucleus ($^{65}$Cu/$^{63}$Cu, $I$ = 3/2) in the low

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

magnetic field region (Figure 4b). The EPR spectrum of [Cu(acac)$_2$]AMPTSi/HMS_A (Figure 4a) shows band broadening due to the high local copper(II) concentration (2.30%, Table 1), which prevents any further analysis. In contrast, the EPR spectrum of the [Cu(acac)$_2$]AMPTSi/HMS_B shows smaller band-broadening effects, and thus could be analysed in detail.

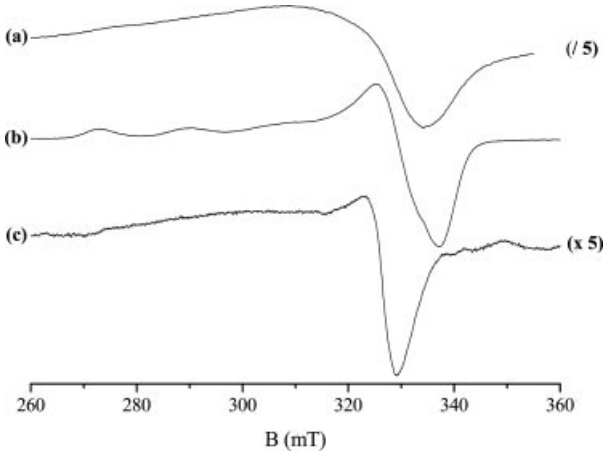

Figure 4. EPR spectra of the copper(II) acetylacetonate complexes, free and anchored onto HMS at 120 K: (a) [Cu(acac)$_2$]AMPTSi/HMS_A, (b) [Cu(acac)$_2$]AMPTSi/HMS_B and (c) [Cu(acac)$_2$]/HMS.

The EPR band profile of this material suggests that there is one major $Cu^{II}$ species within the HMS matrix[20] and its similarity with the EPR of analogous free $Cu^{II}$ complexes[18–20,25–28] allows the same orientation scheme for the tensor axes: $g_1 = g_2 = g_\perp$, $g_3 = g_\parallel$ (or $g_1 = g_x$, $g_2 = g_y$, $g_3 = g_z$), where $g_1$ and $g_3$ refer to the lowest and highest magnetic fields $g$ values (obviously, $A_1 = A_2 = A_\perp$, $A_3 = A_\parallel$ or $A_1 = A_x$, $A_2 = A_y$, and $A_3 = A_z$). In this context, as $g_x = g_y < g_z$ the ground state of $Cu^{II}$ in the immobilised complex has been kept and is $d_{xy}$; the values of the tensors $g$ and $A$ of the [Cu(acac)$_2$]AMPTSi/HMS_B were obtained by simulation and are compiled in Table 3, which also summarises the values for similar copper(II) acetylacetonate/salen-based complexes with $O_4$, $NO_3$ and $N_2O_2$ coordination spheres, as free complexes and immobilised onto other supports found in the literature.

Tetracoordinated copper(II) complexes with an equatorial $O_4$ coordination sphere generally possess higher $g_\parallel$ values (2.26–2.29)[26–28] relative to copper(II) complexes with an equatorial $N_2O_2$ coordination sphere (2.19–2.24),[18,29] because the introduction of nitrogen atoms into the equatorial plane increases the in-plane covalence. This can be confirmed by the data extracted from literature and compiled in Table 3. An $NO_3$ coordination sphere would give rise to intermediate $g$ values, with some overlap with the intervals given above, but confirmation with experimental data is quite difficult due not only to the failure of the preparation the free counterpart of the anchored complex (all synthetic attempts resulted in oils which we were unable to fully characterise), but also to the almost nonexistent EPR data for compounds with these coordinating atoms: only Murphy et al. reported a silica-anchored [Cu(salicylaldimine)] species with an $NO_3$ coordinating sphere, which showed a $g_\parallel$ = 2.29[20] and Talzi et al. reported $Cu^{II}$ complexes with an equatorial $NO_3$ coordination sphere with $g_\parallel$ = 2.27–2.28.[30] Nevertheless, some insights into the coordination sphere of the anchored complex can be gathered indirectly by comparison with $g$ and $A$ values of the parent copper complex and those with mixed $NO_3$ coordination spheres shown in Table 3.

Comparing the $g$ values of [Cu(acac)$_2$]AMPTSi/HMS_B with those of the free copper(II) acetylacetonate in a noncoordinating solvent ($CHCl_3$, Table 3) a decrease in $g_\parallel$ and $g_{\perp;}$ values, with consequent decrease in the $g_{av}$ value, is observed; these $g$ factors tendencies suggest that the anchored copper(II) complex has a different coordination sphere with higher equatorial covalence,[28] which is typical of the involvement of nitrogen atoms in the direct coordination with $Cu^{II}$.[20,28] As $g_\parallel$ = 2.275 is higher than the typical values observed for copper(II) complexes with an $N_2O_2$ coordinating sphere and similar to those observed by Talzi et al.,[30] we propose that the major Cu species immobilised in [Cu(acac)$_2$]AMPTSi/HMS_B have an $NO_3$ coordinating sphere as shown in Scheme 1 (other species, for example, with an $N_2O_2$ coordination sphere and present in low quantities, cannot be unambiguously excluded because of the solid-state broadening effects in the EPR spectra). Although

the spectrum was taken at low temperature, the bandwidths of the signals are still large to detect the nitrogen superhyperfine splittings (typically 14–25 G), due to the interaction between the copper unpaired spin and the nitrogen nuclear spin ($I$ = 1), hence hindering the direct confirmation of nitrogen atoms coordinated to the copper(II) centre in the equatorial plane. Further confirmation of the proposed $NO_3$ coordination sphere for Cu species in [Cu(acac)$_2$]-AMPTSi/HMS_B and the exclusion of complex immobilisation through axial coordination to the free amines of the support can be gathered from the $A_{\parallel}^{Cu}$ values. Axial coordination to a square-planar complex usually leads to a decrease of the metal hyperfine couplings:[26–29] in our case, upon immobilisation of the complex onto the support, no change in the $A_{\parallel}^{Cu}$ value was observed, suggesting that no effective axial coordination took place with the functionalised matrix.

Despite the band-broadening effects in the [Cu(acac)$_2$]-AMPTSi/HMS_A spectrum that prevented its simulation and detailed analysis, the same coordinating sphere is proposed, because the N/Cu ratio is much lower than in [Cu(acac)$_2$]AMPTSi/HMS_B (Table 1), and thus the in situ formation of an anchored copper(II) complex with an $N_2O_2$ coordinating sphere is less likely to occur.

It is noteworthy that in a control experiment, where a [Cu(acac)$_2$] solution in chloroform was refluxed with the unfunctionalised HMS for 24 h, a very low copper content (see Figure 4) was obtained after purification. This indicates that the functionalisation of the support with amine groups leads to higher metal loadings, as observed by us when activated carbon was used as the heterogeneous support.[16] The anchoring process of the copper(II) acetylacetonate onto the calcined HMS must occur through axial coordination of the $Cu^{II}$ centre to the isolated hydroxy groups of the HMS surface. The confirmation was achieved by the observation in the FTIR spectrum of a decrease in the intensity of the band at 3745 cm$^{-1}$, which is due to the isolated silanol groups. Taking into account that upon amine functionalisation of HMS there is a significant decrease in the intensity of this band (vide supra, Figure 2), it may be concluded that the axial coordination of the $Cu^{II}$ centre to the isolated hydroxy groups of the surface of the HMS is hindered in the amine-functionalised HMS material.

The EPR spectrum of this material, [Cu(acac)$_2$]/HMS, was also recorded and is shown in Figure 4c. Although the spectrum could not be simulated due to the low intensity of the signal, some qualitative information relating to the anchored complex can be gathered from the spectrum profile. With respect to the spectrum of [Cu(acac)$_2$]AMPTSi/HMS_B (Figure 4b), that of [Cu(acac)$_2$]/HMS shows the parallel region at higher magnetic field values as a broad band, which corresponds to the envelope of the unresolved four features due to the Cu hyperfine splittings. The main consequence of this is an increase in $g_{\parallel}$ and a decrease in $A_{\parallel}^{Cu}$. By using the data from analogous Cu complexes[26–29] and those referred to in Table 3, it can be clearly shown that in the unfunctionalised HMS, the Cu centre lies in an equatorial $O_4$ plane and possesses axial coordination to the matrix hydroxy groups. On the contrary, in the $NH_2$-functionalised HMS, the Cu centre has a coordination sphere which involves the nitrogen atoms of the modified matrix and no significant axial coordination takes place.

## Catalytic Experiments

The results obtained for the aziridination of styrene, catalysed by the [Cu(acac)$_2$] in homogeneous phase, and immobilised onto the amine-functionalised HMS are collected in Table 4, at room temperature, using PhI=NTs as nitrogen source.

Both [Cu(acac)$_2$]AMPTSi/HMS_A and [Cu(acac)$_2$]-AMPTSi/HMS_B materials acted as heterogeneous catalysts in the aziridination of styrene. As it was not possible to prepare the free counterparts of the anchored complexes, the catalytic activity of the heterogeneous copper complexes were compared with the parent free complex [Cu(acac)$_2$]. In this context, the former heterogeneous catalyst showed improved catalytic efficiency (styrene conversion and total TON, Figure 5) with respect to free [Cu(acac)$_2$] in the homogeneous phase, under similar experimental conditions. This is an important result, as the modification of the coordination sphere of the parent complex upon immobilisation

Table 4. Aziridination of styrene catalysed by the [Cu(acac)$_2$] in the homogeneous phase and heterogenised using PhI=NTs as nitrogen source.[a]

| Catalyst | Run | $t$ [h][b] | % C[c] | Total TON[d] | Initial TOF [h$^{-1}$][e] |

led to an increase in the catalytic activity, contrasting with usual decrease observed in the majority of the anchorage procedures, which involve the coordination sphere of the catalytic centres.

However, a decrease in the initial activity and increase in reaction time was observed, which may be due to the inherent diffusion limitations within the HMS porous structure, as the nitrogen source is a solid with limited solubility in acetonitrile, and its solubilisation is controlled by its rate of consumption.[4] Besides the formation of *p*-toluenesulfanamide, due to competitive homolytic cleavage of the PhI=NTs,[4] only very small amounts of benzaldehyde and epoxide were detected in the reaction media by gas chromatography.

The AMPTSi/HMS support also shows some catalytic activity in the conversion of styrene, but much smaller compared with the new heterogeneous catalysts. Nevertheless, the amount of the benzaldehyde by-product observed in the product mixture, can be related with residual catalytic activity of the support.

The materials could be reused at least in two other catalytic reactions with formation of aziridine. However, the catalyst $[Cu(acac)_2]$AMPTSi/HMS_A showed a loss of the catalytic activity with reuse, giving, nevertheless, better catalytic efficiency (total TON) than the reaction run in homogeneous phase with the $[Cu(acac)_2]$, under similar experimental conditions. The catalyst $[Cu(acac)_2]$AMPTSi/HMS_B showed improved catalytic efficiency in the 2nd reutilisation, and then a small drop in the 3rd cycle, which may be explained by a considerable decrease in the catalyst mass during the recycling procedure.

Nonetheless, the typical IR bands of the immobilised (Schiff base)copper(II) complex and silica backbone of both catalysts after the catalytic cycles remained unchanged, indicating the stability of the catalytic active species and support itself under the catalysis experimental conditions.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Hence, the loss of catalytic activity with reuse of the new heterogeneous catalyst may be due to slight leaching of active species, promoted by some degradation of the bond between the support and the spacer.

The [Cu(acac)$_2$]AMPTSi/HMS_A heterogeneous catalyst reported herein, which consists of copper(II) acetylacetonate anchored onto an amine-functionalised hexagonal mesoporous silica, presents higher catalytic activity in the aziridination of styrene, at room temperature, using PhI=NTs as nitrogen source, than [Cu(acac)$_2$] anchored onto a triamine-functionalised activated carbon.[17] However, it is not as stable and reusable as the latter heterogeneous catalyst, because this could be reused at least for 4 times with successive increase in styrene conversion, and thus in the total turnover number (TON) and initial activity (TOF).

## Conclusion

Copper(II) acetylacetonate was anchored onto an HMS material using a two-step procedure: (i) functionalisation of the surface hydroxy groups with (3-aminopropyl)triethoxysilane and then (ii) anchoring of the copper(II) complex through Schiff condensation with free amine groups, using two different metal loadings.

Nitrogen elemental analysis, XPS and DRIFT showed the presence of amine groups on the surface of the HMS material and porosimetry indicated that the structure of the mesoporous material remained unchanged after this step.

Atomic absorption and XPS data showed that the copper(II) acetylacetonate could be irreversibly immobilised onto the amine-functionalised HMS through Schiff condensation between the surface amine groups and the oxygen atoms of the copper(II) ligand, leading to an $NO_3$ coordination sphere for the anchored metal complex. This was confirmed by the combination of data extracted from FTIR and EPR spectra of the materials.

The new [Cu(acac)$_2$]AMPTSi/HMS materials were tested in the aziridination of styrene, using PhI=NTs as nitrogen source and acetonitrile as solvent, at room temperature. The styrene conversion and total TON of the heterogeneous phase reaction are higher than those of the same reaction catalysed in homogeneous phase by [Cu(acac)$_2$]; nevertheless, the initial activity decreases and reaction time increases due to substrate and product diffusion limitations. The heterogeneous catalyst showed a successive slight decrease in catalytic activity when reused for two more times.

## Experimental Section

**Materials and Reagents:** All reagents and solvents used in the preparation and modification of the hexagonal mesoporous silica (HMS) were used as received. Copper(II) acetylacetonate, 1-dodecylamine and (3-aminopropyl)triethoxysilane (AMPTSi) were from Aldrich; tetraethoxysilane was from Lancaster; toluene and other solvents used in the synthesis procedures were from Fischer Scientific (analytical reagent grade) and those used in the catalytic experiments and as eluents were from Romil or Fischer Scientific (HPLC grade). The nitrene donor 4-methyl-*N*-(phenyl-$\lambda^3$-iodanylidene)benzenesulfonamide (PhI=NTs) was synthesised using reported procedures.[31]

**Synthesis and Modification of Hexagonal Mesoporous Silica (HMS)**

**Synthesis of Hexagonal Mesoporous Silica (HMS):** The HMS was synthesised using a reported procedure;[22] tetraethoxysilane (37.0 mL, 0.166 mol) was added to a stirred solution of ethanol (88.1 mL, 1.51 mol), water (88.5 mL, 4.91 mol) and 1-dodecylamine (10.3 mL, 0.0448 mol). The mixture was stirred at room temperature for 24 h. The white precipitate obtained was vacuum-filtered, washed with deionised water (100 mL) and ethanol (100 mL). In order to remove the template (1-dodecylamine), the precipitate was calcined at 600 °C for 24 h.

**Functionalisation of the HMS with (3-Aminopropyl)triethoxysilane (AMPTSi/HMS):** A mixture of calcined HMS (3.00 g) in dry toluene (50.0 mL) and (3-aminopropyl)triethoxysilane (9.00 mmol, 2.10 mL) was refluxed for 24 h. The material was vacuum-filtered, washed with toluene (3 × 50 mL) and dried overnight in an oven at 85 °C.

**Anchoring of Copper(II) Acetylacetonate onto Amine-Functionalised HMS:** A solution of copper(II) acetylacetonate (0.1304 g, 498 μmol) in chloroform (100 mL, light blue solution) was refluxed with AMPTSi/HMS (1.02 g) for 24 h. At the end of the process, the colour of the solution was sligthtly blue. The solid was vacuum-filtered, washed with chloroform (3 × 20 mL), and then Soxhlet-extracted with chloroform for 6 h. Finally, the solid was dried overnight in an oven at 85 °C. This material will be referred to as [Cu(acac)$_2$]AMPTSi/HMS_A. Another material with lower complex loading was also prepared: [Cu(acac)$_2$]AMPTSi/HMS_B. In this case AMPTSi/HMS (0.35 g) was refluxed with copper(II) acetylacetonate (0.0077 g, 29 μmol) in chloroform (10 mL, light blue solution) for 24 h, after which an almost colourless solution was obtained after filtration of the material. The material was washed with chloroform (3 × 20 mL) and then Soxhlet-extracted with chloroform (150 mL) for 6 h. The blue solid was dried in an oven at 100 °C, after which it was light brown.

**Physico-Chemical Measurements:** Nitrogen elemental analysis and copper atomic absorption were performed by Microanalytical Services, University of Manchester, U. K. Surface area measurements were performed monitoring the $N_2$ adsorption isotherms at 77 K with a Micrometrics ASAP 2010 apparatus. Surface areas were calculated using the BET equation over the pressure range $p/p_0$ = 0.02–0.2. X-ray photoelectron spectroscopy was carried out with a Kratos AXIS His instrument equipped with a charge neutraliser and an Mg-$K_\alpha$ X-ray source. Spectra were recorded at normal emission with an analyser pass energy of 20 eV and an X-ray power of 225 W. The FTIR-DRIFT spectra of the powered materials were obtained with a Bruker Equinox 55 spectrophotometer in the region 400–4000 cm$^{-1}$. The UV diffuse reflectance spectra were obtained with a Shimadzu UV-3101 PC in the range 1600–200 nm, using barium sulfate as reference. EPR spectra were recorded with a Bruker ESP300 EPR spectrometer equipped with an X-band microwave bridge. Temperature control was achieved with a Bruker ER-4111 variable-temperature controller, the temperature at the centre of the EPR cavity was calibrated using a separate thermocouple. The spectra were taken at 120 K with the following typical experimental conditions: modulation frequency: 100 kHz; modulation amplitude: 5 G; microwave power: 1–5 mW. The EPR parameters were obtained by simulation using the program Win EPR Simfonia (Bruker) assuming axial or rhombic spin Hamiltonians. The reported values of $g_\perp$ (or $g_x$ and $g_y$) and $A_\perp$ (or $A_x$ and $A_y$) are less accurate because of their dependence on the used line

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

widths (50–60 G). GC-FID chromatograms were obtained with a Varian CP-3380 gas chromatograph using helium as carrier gas and a fused silica Varian Chrompack capillary column CP-Sil 8 CB Low Bleed/MS (30 m × 0.25 mm i.d.; 0.25 μm film thickness). Conditions: 60 °C (3 min), 5 °C $min^{-1}$, 170 °C (2 min), 20 °C $min^{-1}$, 200 °C (10 min); injector temperature: 200 °C; detector temperature: 300 °C. HPLC chromatograms were obtained with a Merck Hitachi Lachrom apparatus consisting of a pump L-7100, UV detector L-7400, interface D-7000, autosampler L-7200 and a column oven L-7300 equipped with a Phenomenex Luna 5u C18(2), 250 × 4.6 mm column. The eluent used was a mixture of 85% of acetonitrile and 15% of water with a flow rate of 1 mL $min^{-1}$.

**Catalysis Experiments:** The activity of the catalysts in the aziridination of styrene was studied at room temperature using a molar ratio of metal catalyst/alkene/chlorobenzene (internal standard)/PhI=NTs = 1:100:100:20 in acetonitrile (5.00 mL), whilst stirring. For the experiments with the catalyst $[Cu(acac)_2]$AMPTSi/HMS_A, styrene (1.22 mmol), chlorobenzene (1.22 mmol, internal standard), heterogeneous catalyst (0.0300 g) and PhI=NTs (0.244 mmol, nitrogen source) were used; for the experiments with catalyst $[Cu(acac)_2]$AMPTSi/HMS_B, styrene (0.20 mmol), chlorobenzene (0.20 mmol, internal standard), heterogeneous catalyst (0.0300 g) and PhI=NTs (0.041 mmol, nitrogen source) were used. During the experiment, 0.05-mL aliquots were taken from the solution with a hypodermic syringe, filtered through 0.2-μm PTFE syringe filters and directly analysed by GC-FID. When the entire PhI=NTs had disappeared from the solution and the ratio of the areas of iodobenzene and chlorobenzene in the chromatogram was constant, the solution was centrifuged at 3500 rpm for 15 min, and then to the decanted solution another portion of PhI=NTs (0.244 mmol) was added. This procedure checks the eventual existence of metal complex leaching to the reaction medium. The presence of the aziridine at the end of the reaction was confirmed by HPLC. The heterogeneous catalysts were then washed/centrifuged sequentially with acetonitrile (3 × 10 mL) and methanol (1 × 10 mL) and oven-dried at 90 °C overnight. These materials were reused for further two times using the same experimental procedure. To provide a framework for the results obtained using the heterogenised copper(II) complex, styrene aziridination was also carried out under experimental conditions comparable to those described above (a) in homogeneous media using the same amount of $[Cu(acac)_2]$ and (b) using the AMPTSi/HMS material, the precursor of both heterogeneous catalysts.

# Methyl-Hydroxypyridinecarboxylic Acids as Possible Bidentate Chelating Agents for Aluminium(III): Synthesis and Metal–Ligand Solution Chemistry

Valerio B. Di Marco,*[a] Annalisa Dean,[a] Maria Grazia Ferlin,[b] Robert A. Yokel,[c] Haitao Li,[c][‡] Alfonso Venzo,[d] and G. Giorgio Bombi[a]

**Keywords:** Aluminium / Carboxylate ligands / Potentiometry / Chelation therapy

In view of a possible application to aluminium chelation therapy, 1-methyl-3-hydroxy-4-pyridinecarboxylic acid (1M3H4P) and 1-methyl-4-hydroxy-3-pyridinecarboxylic acid (1M4H3P) were synthesized, and their chemical interactions with aluminium(III) were investigated in aqueous 0.6 m (Na)Cl at 25 °C by means of potentiometric titrations. The qualitative and quantitative results obtained were confirmed by UV spectrophotometry and $^1$H NMR spectroscopy. For both ligands, the species $AlL^{2+}$, $AlL_2^+$, $AlL_3$, and $AlL_2H_{-1}$ were identified, with $\log\beta_{1,1,0} = 7.66$, $\log\beta_{1,2,0} = 14.27$, $\log\beta_{1,3,0} = 19.099$, and $\log\beta_{1,2,-1} = 7.00$ for 1M3H4P, $\log\beta_{1,1,0} = 7.21$, $\log\beta_{1,2,0} = 13.41$, $\log\beta_{1,3,0} = 18.15$, and $\log\beta_{1,2,-1} = 6.4$ for 1M4H3P. The chelation strength of 1M3H4P and 1M4H3P is lower than that of other available aluminium(III) chelators, e.g. deferiprone (pAl difference at physiological pH: ca. 3 log units). The octanol/aqueous partitioning values of 1M3H4P and 1M4H3P were 0.0054 and 0.0015, respectively, showing high hydrophilicity. The efficiencies of the ligands to chelate aluminium(III) were evaluated at physiological pH and ion strength "in vitro". 1M3H4P and 1M4H3P were more effective than their non-methylated analogs 3H4P and 4H3P.

## Introduction

The therapy for metal-overload pathologies usually involves the administration of suitable chelating agents to selectively remove the metal from the body. Regarding aluminium(III) and iron(III), there is a need for new, safe, inexpensive, efficient, and orally effective chelators,[1–3] because the existing ones, i.e. desferrioxamine and deferiprone, have a number of drawbacks, including oral inefficacy and the high cost for the former,[4–6] and several toxic side effects and controversial efficiency for the latter.[5–8]

In a previous work[9] we proposed hydroxypyridinecarboxylic acids (HPs) as new possible chelating agents for aluminium(III) in view of several promising properties such as their lack of toxicity (references in ref.[9]), their low molecular weight (which is required for oral activity), and their very low affinity towards essential metal ions like $Zn^{2+}$.[10] Our results showed that the unsubstituted derivatives, i.e. 3H4P and 4H3P, cannot be regarded as possible alternatives to desferrioxamine and deferiprone, because they do not adequately complex aluminium(III) at physiological pH. As a strategy to improve the $Al^{III}$ complexation ability, without affecting the positive properties, alkylation of the pyridinic ring was proposed, because the electron-donor properties of the alkyl substituents can be expected to increase the basicity of chelating oxygen atoms and therefore to increase the affinity towards hard metal ions, such as aluminium(III) and iron(III).

In this work, the *N*-methyl derivatives of 3H4P and 4H3P, i.e. 1-methyl-3-hydroxy-4-pyridinecarboxylic acid (1M3H4P) and 1-methyl-4-hydroxy-3-pyridinecarboxylic acid (1M4H3P) (Figure 1), have been synthesized, and the formation of complexes between the ligands and aluminium(III) studied in aqueous solutions by means of potentiometric titrations. The speciation data obtained has been confirmed by UV/Vis and $^1$H NMR measurements. The partitioning of the ligands in an octanol/aqueous system was determined with UV/Vis spectroscopy. The efficiency of the ligands to chelate aluminium(III) has been determined at physiological conditions (pH and ion strength) in vitro.

## Results and Discussion

### Synthesis of the Ligands

To synthesize the new ligands, initially 3H4P and 4H3P (which are not commercially available) were prepared as de-

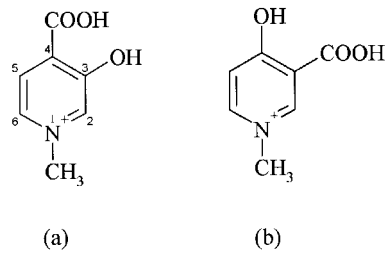

Figure 1. (**a**) 1-Methyl-3-hydroxy-4-pyridinecarboxylic acid (1M3H4P), (**b**) 1-methyl-4-hydroxy-3-pyridinecarboxylic acid (1M4H3P), both shown as the $H_2L^+$ forms.

scribed.[9] Next, the hydroxyacids were *N*-methylated by use of a conventional method ($CH_3I$ in dimethylformamide).[11]

## Solution Equilibria

### *Acidity Constants of the Ligands*

The potentiometric titration of the ligands alone allowed the computation of the p$K_a$ value for the HL form (for simplicity, charges will be generally omitted from the formulae, except in the Tables), corresponding to the deprotonation of the OH group (Table 1). Phenolic oxygen atoms in unsubstituted HPs, e.g. in 3H4P and 4H3P, generally have p$K_a$ values around 10–11:[9] the drastic ($10^4$–$10^5$-fold) increase of the acidity of this group in 1M3H4P and 1M4H3P can be explained by the strong inductive effect exerted by the positively charged nitrogen atom, and by the fact that the molecule is uncharged at the pH where OH deprotonates. In comparison, for 3H4P and 4H3P the nitrogen is neutral and the molecule is charged –1. For 1M4H3P the acidity is even higher because the positive charge of the nitrogen may exert also a resonance effect. To the best of our knowledge, a similar effect in a phenolic oxygen atom was observed only in a naphthyridine compound by Agafonova et al.:[12] for 8-hydroxy-1,6-naphthyridine the p$K_a$ was 8.33, whereas for 8-hydroxy-6-methyl-1,6-naphthyridinium it was 4.34.

Table 1. Acidic properties of 1M3H4P and 1M4H3P.[a]

| Species | **1M3H4P** | | **1M4H3P** | | Technique used to obtain the data |
|---|---|---|---|---|---|
| | $pK_a$ | $n$ | $pK_a$ | $n$ | |
| $H_2L^+$ | 0.28 ± 0.05 | 4 | 0.12 ± 0.02 | 2 | UV |
| HL | 6.6326 ± 0.0008 | 12 | 5.9578 ± 0.0006 | 8 | potentiometry |

[a] For potentiometric data, $n$ is the number of experiments from which the data were obtained. Values are shown as the mean and standard deviation of the mean. For UV data, $n$ is the number of wavelengths from which the data were obtained; a weighted mean and the corresponding weighted standard deviation were calculated from the data.

Accurate potentiometric measurements at pH values lower than ca. 1.5–2 cannot be executed, because in these conditions the pH modification is negligible because of the acid–base equilibria. Therefore, the more acidic pH region has been explored with UV measurements, which allowed the determination of the p$K_a$ value for the $H_2L$ form, corresponding to the deprotonation of the COOH group (Table 1). Its high acidity is in agreement with values previously observed for other HPs.[9]

### *Metal–Ligand Complexes – Potentiometric Results*

For both ligands, the potentiometric titrations of solutions containing the metal and the ligand allowed the identification of the complexes AlL, $AlL_2$, $AlL_3$, and $AlL_2H_{-1}$ (where HL represents either 1M3H4P or 1M4H3P in the neutral form). The values of their stability constants are reported in Table 2. The distribution diagrams for the two systems, as computed for a solution containing $10^{-3}$ m $Al^{III}$ and $4\cdot10^{-3}$ m ligand, are reported in Figure 2.

Table 2. Stability constants for Al–L complexes, at 25 °C in aqueous (Na)Cl 0.6 m (reactions: $m\,Al^{3+} + l\,L^- + h\,H^+ \rightleftharpoons Al_mL_lH_h^{3m-l+h}$; the p$K_a$ value refers to the equilibrium $AlL_2^+ \rightleftharpoons AlL_2H_{-1} + H^+$).

| Species | **1M3H4P** | | | **1M4H3P** | | |
|---|---|---|---|---|---|---|
| | log $\beta$ | p$K_a$ | $n$ | log $\beta$ | p$K_a$ | $n$ |
| $AlL^{2+}$ | 7.66 ± 0.03 | | 12 | 7.21 ± 0.06 | | 12 |
| $AlL_2^+$ | 14.27 ± 0.04 | 7.27 | 12 | 13.41 ± 0.03 | 7.0 | 12 |
| $AlL_2H_{-1}$ | 7.00 ± 0.07 | | 8 | 6.4 ± 0.1 | | 8 |
| $AlL_3$ | 19.099 ± 0.008 | | 8 | 18.15 ± 0.03 | | 8 |

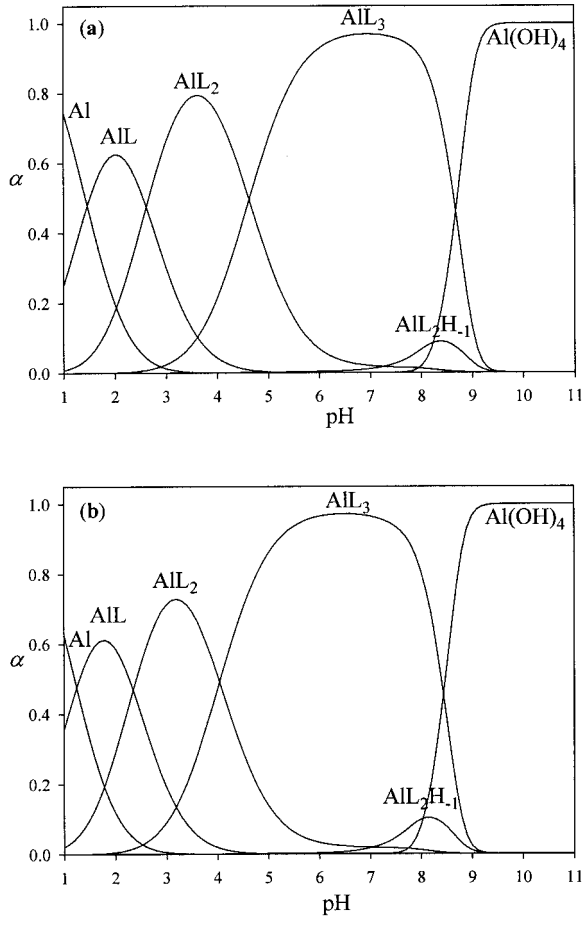

Figure 2. Distribution diagrams of the aluminium complexes in the presence of 1M3H4P (**a**) and 1M4H3P (**b**) in aqueous (Na)Cl 0.6 m, $T$ = 25 °C; $[Al]_0 = 10^{-3}$ m, $[ligand]_0 = 4\cdot10^{-3}$ m.

The free metal ion predominates only at very acidic pH values, i.e. below 1.5, wheras upon increasing the pH the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sequential formation of AlL, $AlL_2$ and $AlL_3$ is observed. A water molecule coordinated to the metal center in $AlL_2$ may deprotonate to form $AlL_2H_{-1}$. At basic pH values, all the complexes are destabilized owing to the formation of $Al(OH)_4$. In the investigated concentration range, the precipitation of aluminium hydroxide was not observed in either system in the presence of a threefold or higher excess ligand concentration, because of the high affinity of the ligands towards the metal ion.

The acidity of $AlL_2(H_2O)_2$ ($pK_a$ values around 7 for both ligands, see Table 2) is much lower than that of $Al(H_2O)_6$ ($pK_a = 5.52$[13]). This accounts for the negligible concentration of $AlL_2H_{-1}$ at acidic and neutral pH values. The lower acidity is due in part to statistical reasons [a smaller number of deprotonating water molecules in $AlL_2(H_2O)_2$ than in $Al(H_2O)_6$] and in part to a relatively high electronic density around the chelating oxygen atoms of the ligand, higher than that on the oxygen of water,[14] which destabilizes the deprotonation of the coordinated water molecules in $AlL_2(H_2O)_2$.

### *Metal–Ligand Complexes – UV Results*

Selected UV spectra for the Al/1M3H4P and the Al/1M4H3P solutions at acidic-to-neutral pH values are reported in Figure 3. All spectra show the typical absorption of substituted pyridinic rings. The increase of pH causes a bathochromic shift of the main peak and a general increase of the absorption coefficients. These effects are in agreement with the gradual formation of less positively charged, thus electron-richer, species ($AlL^{2+}$, $AlL_2^{+}$, $AlL_3$) at higher pH values.

In the elaboration of the UV data for both systems the formation constant of AlL was kept constant at the value determined from potentiometric titrations, as this species is already formed at the most acidic pH values investigated. The values for the stability constant of $AlL_2$ could be optimised: $\log \beta_{1,2,0} = 14.2 \pm 0.1$ for Al/1M3H4P, $\log \beta_{1,2,0} = 13.2 \pm 0.1$ for Al/1M4H3P. The $\log \beta$ values of $AlL_2$ compare reasonably well with the corresponding potentiometric ones ($\log \beta_{1,2,0} = 14.27 \pm 0.04$ and $13.41 \pm 0.03$, respectively). This agreement suggests the absence of systematic errors in the results.

### *Metal–Ligand Complexes – $^1$H NMR Results*

In the $^1$H NMR spectra of 1M3H4P in $D_2O$, the singlet of the $CH_3$ protons is at $\delta = 4.37$, and the signals due to the protons H(2), H(5), and H(6), are observed at $\delta = 8.52$ (s), $\delta = 8.28$ (d), and $\delta = 8.20$ (d), respectively. The signals do not show appreciable pD-dependent shift, at least in the investigated pD range (2–7). For 1M4H3P at acidic pD values (pD < 4), the singlet of the $CH_3$ protons appears at $\delta = 4.16$, and H(2), H(5), and H(6) are observed respectively at $\delta = 8.89$ (s), $\delta = 7.20$ (d), and $\delta = 8.31$ (d). At pD = 7.4, all signals appear at higher fields ($\delta = 3.94$, $\delta = 8.20$, $\delta = 6.70$, and $\delta = 7.89$, respectively), because of the deprotonation of the phenolic oxygen.

In the presence of aluminium(III), the peaks of the free ligands are observed only in acidic solutions, and new groups of peaks due to the complexes appear at all investigated pD values.

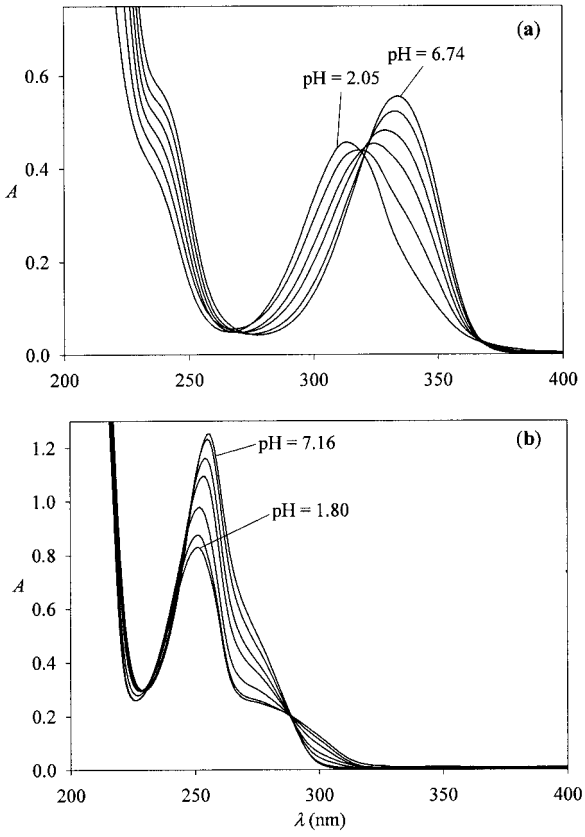

Figure 3. (a) UV spectra of Al/1M3H4P, (b) Al/1M4H3P at various pH values.

For Al/1M3H4P (Figure 4), at pD = 1.9 two additional peaks appear at $\delta = 4.30$ and $\delta = 4.28$, which represent the $CH_3$ protons of two complexes, i.e. AlL and $AlL_2$ according to the potentiometric data. The expected quantitative distribution suggests the attribution of the most intense signal ($\delta = 4.28$) to $AlL_2$. In the aromatic region AlL and $AlL_2$ give rise to two additional peaks, one more intense than the other, at $\delta = 8.05$ and $\delta = 8.00$, respectively, the other peaks of the complexes overlapping those of the free ligand. Upon increasing the pD to 4.0, the complexes give rise to four $CH_3$ signals at $\delta = 4.30$ (very low intensity, AlL), $\delta = 4.28$ ($AlL_2$), $\delta = 4.26$ and $\delta = 4.24$ ($AlL_3$, as discussed below). The peaks in the aromatic region show a complicated pattern in which only some peaks of the free ligand ($\delta = 8.52$ and 8.28 ppm) can be easily assigned. At pD = 6.5, even though only the species $AlL_3$ exists in solution in significant amount, four $CH_3$ signals are observed between 4.19 and 4.22 ppm, together with a fifth less intense peak at $\delta = 4.23$ ppm. This small signal is probably produced by $AlL_2$ and $AlL_2H_{-1}$, which at this pD value are about twenty times less concentrated than $AlL_3$. The other four signals can be explained considering that the ligand is not symmetrical and may chelate the metal, forming $AlL_3$, in two different spatial configurations (Figure 5). If the three ligands of $AlL_3$ chelate the metal ion in the same configurations, a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

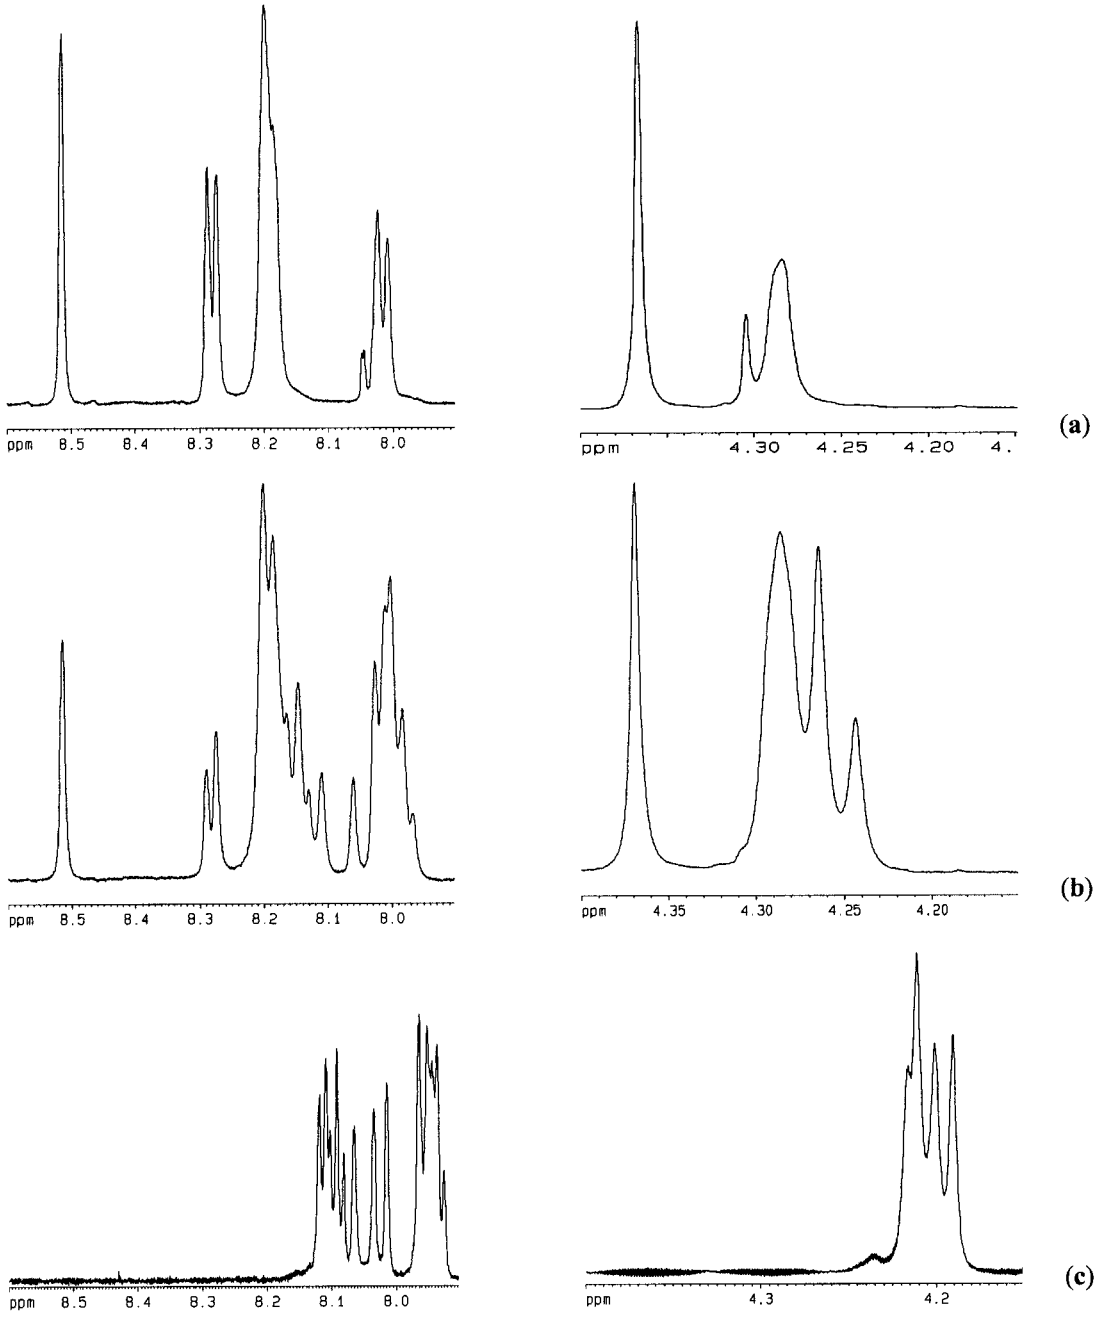

Figure 4. $^1H$ NMR spectra of $D_2O$ solutions containing $Al^{III}$ ($6.5 \cdot 10^{-3}$ m) and 1M3H4P ($1.9 \cdot 10^{-2}$ m), pD = 1.9 (a), 4.0 (b), 6.5 (c). For the spectrum at pD = 6.5, $v_0$ = 600 MHz. The sensitivity of spectra in the aromatic zone was enhanced by a factor 4.

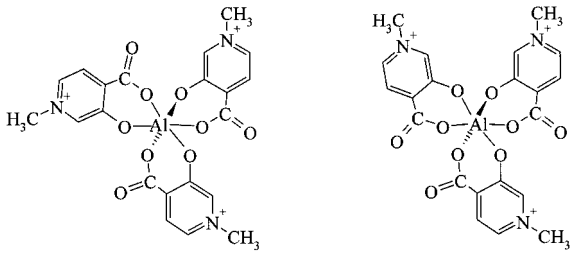

Figure 5. The two spatial diastereoisomers of $AlL_3$ (L = 1M3H4P).

symmetrical diastereoisomer ($AlL_{3-sym}$) forms, and the three $CH_3$ groups have the same NMR response. If one ligand chelates differently from the other two, an unsymmetrical diastereoisomer ($AlL_{3\text{-}unsym}$) forms, and the three $CH_3$ groups give rise to different signals in the NMR spectrum. In the aromatic region four signals are expected as well for each proton. The quite broad peaks at $\delta$ = 8.07, $\delta$ = 8.03, and $\delta$ = 8.01 do not show COSY couplings with other signals, and between them no reasonable coupling constant exists. Thus, they can be attributed to the H(2) protons of the two $AlL_3$ species. The fourth H(2) signal is

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

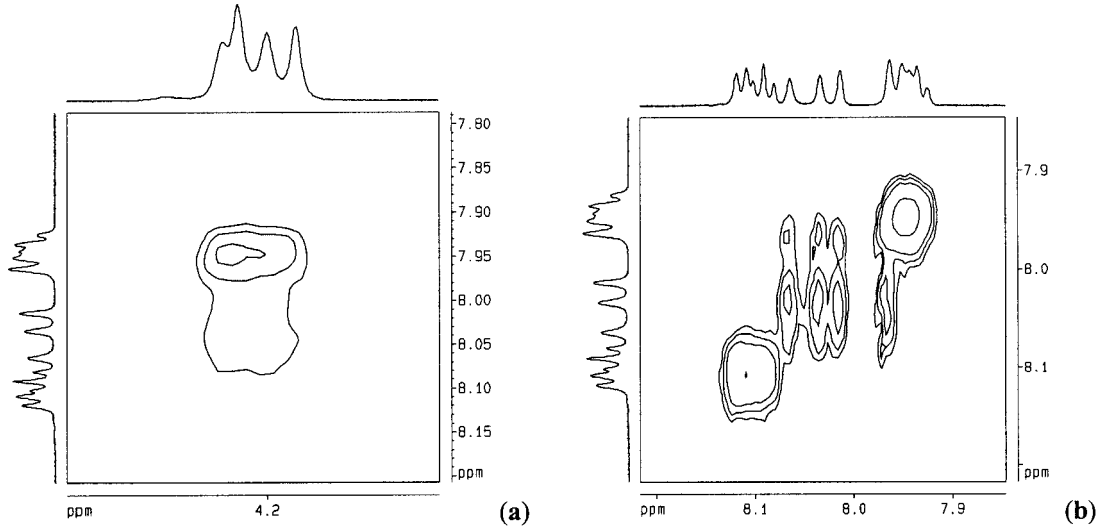

Figure 6. $^1H$ –$^1H$ phase sensitive NOESY spectra of a $D_2O$ solution containing $Al^{III}$ $6.5\cdot10^{-3}$ m and 1M3H4P $1.9\cdot10^{-2}$ m, pD = 6.46 ($\nu_o$, 600 MHz). (a) NOESY correlations between the aromatic (F1) and $CH_3$ (F2) protons. (b) *In phase* (exchange) correlations between the aromatic protons.

probably the singlet which appears at $\delta$ = 7.96 ppm. The four signals of H(5) and H(6) (centered at $\delta$ ca. 8.1 and $\delta$ ca. 7.95, respectively, COSY data) cannot be distinguished from each other due to strong overlap. The NOESY interactions between $CH_3$ and H(6) are significantly more intense than those between $CH_3$ and H(2) (Figure 6, a). This is in agreement with a distortion of the aromatic ring in the complex, which brings the $CH_3$ protons closer to H(6) than to H(2). In addition, NOESY spectra show strong correlation peaks between the aromatic protons which are in phase with the diagonal (Figure 6, b): this finding is in agreement with relatively fast chemical exchanges of the various ligand molecules in $AlL_3$.[15–17]

For Al/1M4H3P (Figure 7), at pD = 1.1 an additional $CH_3$ peak, and two H(5) and H(6) multiplets, are visible at higher fields. The pattern is in agreement with the formation of only one complex, which according to the potentiometric data is AlL [its H(2) signal overlaps with the corresponding signal of the free ligand at $\delta$ = 8.89 ppm]. In addition to the peaks of AlL and of the free ligand, at pD = 2.8 new broad signals of $CH_3$, H(2), H(5), and H(6) appear (e.g. at $\delta$ = 7.05 ppm) due to the formation of $AlL_2$. The broadness of these signals cannot be due to fast ligand exchanges, because the peaks of the free ligand are narrow. It may be explained as chemical-shift dispersion by the formation of four possible spatial isomers of $AlL_2$. At pD = 7.4, where only the species $AlL_3$ exists in solution in a significant amount, a complicated pattern is observed. The signal centered at $\delta$ = 6.95 ppm shows clearly four doublets having identical coupling constants ($^3J$ = 7.25 Hz), and as for Al/1M3H4P this pattern can be explained by assuming the formation of $AlL_{3\text{-sym}}$ and $AlL_{3\text{-unsym}}$. For this system it can be seen that the four doublets are equally intense, indicating that $[AlL_{3\text{-unsym}}] = 3\cdot[AlL_{3\text{-sym}}]$, as statistically expected. The independence of the relative intensities of these four doublets from pD was confirmed by another spectrum obtained at pD = 6.4 (not shown). The broad band at $\delta$ = 7.05 ppm, as well as the peak at 8.9 ppm, are produced by the minor species $AlL_2$ and $AlL_2H_{-1}$ (these two peaks do not couple with the peaks of $AlL_3$ centered at $\delta$ = 8.85, 8.20 and 6.95 ppm, as demonstrated by a COSY spectrum). The signals of the complexes, differently from those of the free ligand, do not show an appreciable pD-dependent shift, because they do not undergo any deprotonation (except $AlL_2$ to a small extent) in the entire pD range.

Generally, the use of $D_2O$ instead of $H_2O$ does not modify the qualitative results, i.e. the species existing in $H_2O$ should be present in $D_2O$ as well. However, heavy water introduces isotopic effects, which may modify the quantitative distribution of the species, especially of those bearing acidic protons.[18,19] In order to obtain NMR quantitative data directly comparable with the potentiometric results, the system Al/1M3H4P was investigated in $H_2O$. The spectra are identical to the corresponding ones in $D_2O$ (except that all peaks are broader). The integration values of the signals of the free ligand and of the complexes give the relative amount of free and complexed ligand. The results obtained are reported in Table 3, together with the corresponding values calculated from the stability constants reported in Table 1 and Table 2. The agreement between the two sets of data is very good at all pH values, suggesting the absence of systematic errors in the results.

### *Metal–Ligand Complexes – Comparison with Previous Results*

As previously mentioned, the methylation of the pyridinic ring is expected to increase the affinity of the ligand towards aluminium(III). To verify this, pAl plots[20] vs. pH for 1M3H4P, 1M4H3P, and their corresponding unmethylated compounds were computed (Figure 8): higher pAl values indicate stronger metal–ligand complexes. The plot for

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

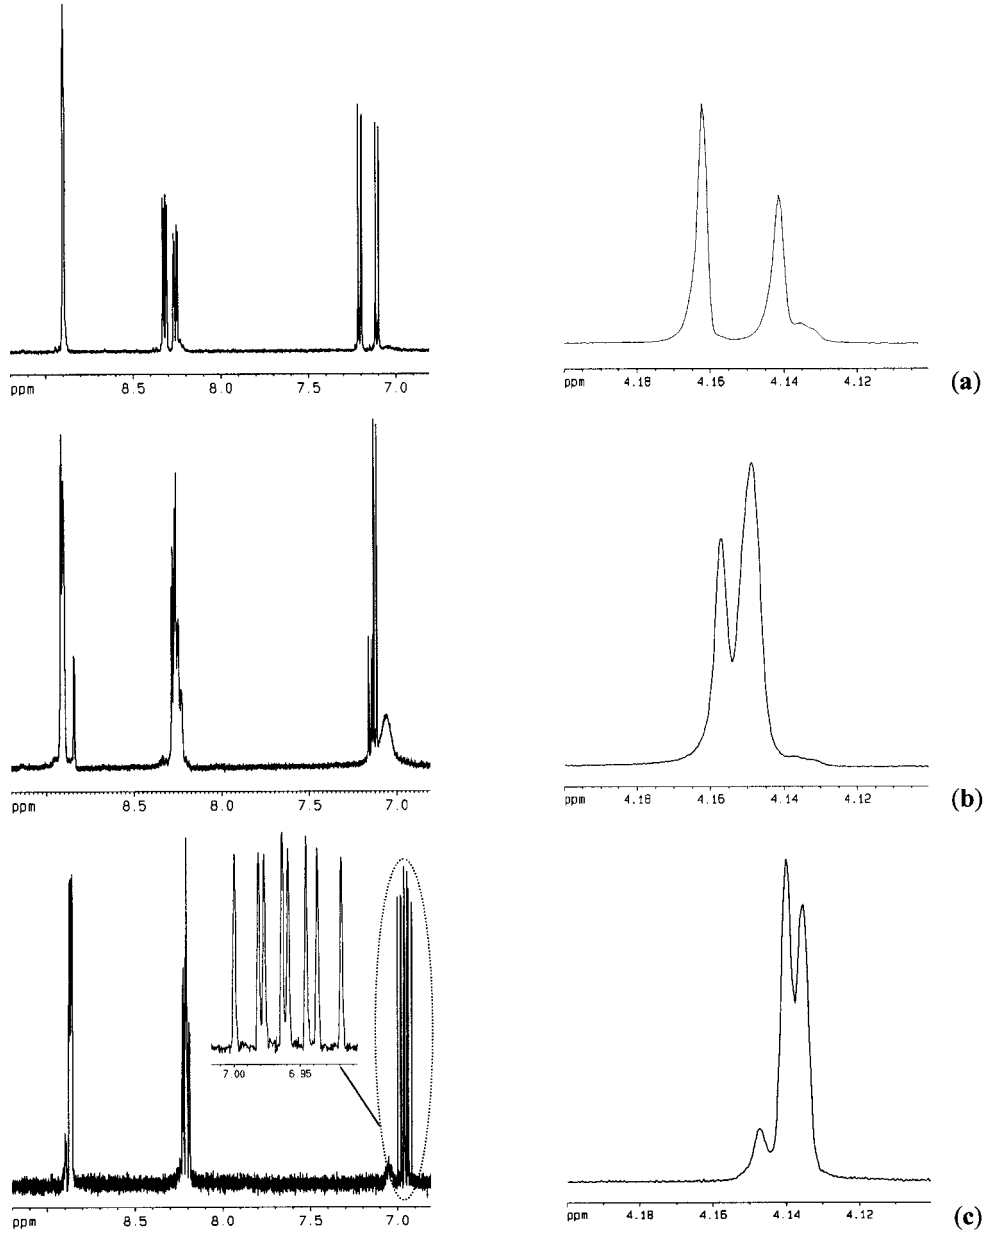

Figure 7. $^1H$ NMR spectra of $D_2O$ solutions containing $Al^{III}$ ($6.5 \cdot 10^{-3}$ m) and 1M4H3P ($1.1 \cdot 10^{-2}$ m), pD = 1.1 (a), 2.8 (b). Spectrum of $Al^{III}$ ($6.5 \cdot 10^{-3}$ m) + 1M3H4P ($2.0 \cdot 10^{-2}$ m), pD = 7.4 (c). The sensitivity of spectra in the aromatic zone was enhanced by a factor 4.

Table 3. Percentages of free and complexed ligand (Al/1M3H4P spectra in $H_2O$).

| pH | From NMR data | | From potentiometric results | |
|---|---|---|---|---|
| 2.08 | free ligand | 54.9 | $H_2L^+ + HL$ | 54.1 |
| | compl. ligand | 45.1 | $AlL^{2+} + 2\ AlL_2^+$ | 45.9 |
| 3.05 | free ligand | 40.1 | HL | 40.0 |
| | compl. ligand | 59.9 | $AlL^{2+} + 2\ AlL_2^+ + 3\ AlL_3$ | 60.0 |
| 4.04 | free ligand | 25.0 | HL | 26.2 |
| | compl. ligand | 75.0 | $AlL^{2+} + 2\ AlL_2^+ + 3\ AlL_3$ | 73.8 |
| 5.04 | free ligand | 12.0 | $HL + L^-$ | 14.7 |
| | compl. ligand | 88.0 | $2\ AlL_2^+ + 3\ AlL_3$ | 85.3 |
| 6.12 | free ligand | 8.6 | $HL + L^-$ | 8.5 |
| | compl. ligand | 91.4 | $2\ AlL_2^+ + 2\ AlL_2H_{-1} + 3\ AlL_3$ | 91.5 |

deferiprone (speciation data from ref.[21]) is reported for comparison. The HPs 3H4P, 4H3P, 1M3H4P, and 1M4H3P, are weaker aluminium(III) chelators than deferiprone at all pH values. However, it is important to note that 1M3H4P forms significantly more stable complexes with aluminium(III) than 3H4P does, especially at slightly acidic and neutral pH values: the pAl difference is up to two log units. On the other hand, the same methyl substitution in 4H3P did not produce any increase in chelation strength, as pAl values of 1M4H3P are almost identical to those of 4H3P. We do not yet have an explanation for the different effect of the *N*-methyl substitution in the two isomers. The

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

study of other alkylated HPs, now in progress, should better clarify this point.

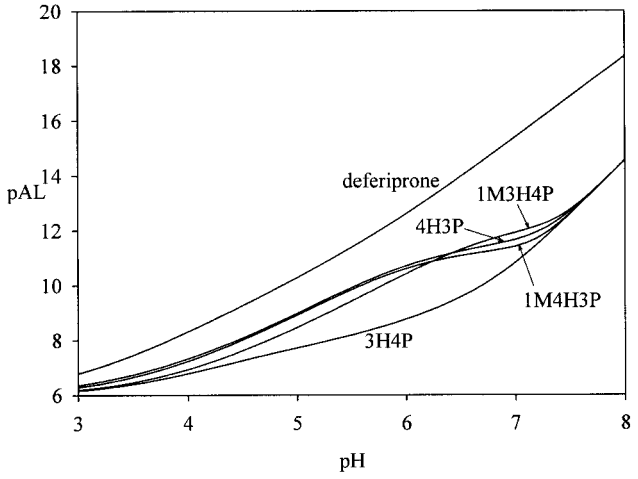

Figure 8. pAl for several ligands (see text); $[Al]_0 = 10^{-6}$ m, $[ligand]_0 = 5 \cdot 10^{-5}$ m.

### *n*-Octanol/Water Distribution and Chelation Efficacy

The octanol/water distribution coefficients of 1M3H4P, 1M4H3P and deferiprone were $0.0054 \pm 0.0042$, $0.0015 \pm 0.0013$, and $0.031 \pm 0.019$, respectively (mean ± standard deviation of 3 experiments, each conducted with duplicate observations), which shows the high hydrophilicity of these new ligands. In the presence of 1M3H4P and 1M4H3P, the concentration of Al in the octanol phase was very much lower than in the aqueous phase, which indicates very high hydrophilicity of the metal–ligand complexes. The results with deferiprone are reasonably similar to those previously published.[22]

The chelation-efficacy results obtained for deferiprone, 1M3H4P and 1M4H3P are summarized in Table 4. The efficiency of Al chelation of deferiprone (74%) is similar to that previously reported (65%).[22] As for 1M3H4P and 1M4H3P the results of the potentiometric studies show a 1:3 Al–ligand complex at pH 7.4 (Figure 2), the efficiency was calculated to show the percentage of ligand associated with aluminium in a 1:3 Al–ligand complex. Values for 3H4P and 4H3P are reported as well for comparison. An appreciable increase in efficiency can be observed for the 1-methyl derivatives. Statistical comparison of the efficiency of 3H4P, 4H3P, 1M3H4P and 1M4H3P by 1-way ANOVA followed by a Neuman–Keuls multiple comparison test shows a significant difference between 3H4P and 1M3H4P. Efficacy results are in agreement with thermodynamic data predictions at physiological pH, as the values at pH = 7.4 found in this study are in the same order as the pAl values are (Figure 8), i.e. 1M3H4P > 4H3P > 1M4H3P > 3H4P.

## Conclusions

Both 1M3H4P and 1M4H3P form strong complexes in solution with aluminium(III), so that in the investigated concentration range ($3 \cdot 10^{-4}$ m < $[Al]_0$ < $10^{-3}$ m, $10^{-3}$ m < $[L]_0$ < $4 \cdot 10^{-3}$ m) no metal hydroxide precipitates at neutral pH values in the presence of a threefold or higher ligand excess over aluminium(III). For both ligands the species AlL, $AlL_2$, $AlL_3$ and the minor species $AlL_2H_{-1}$ are formed in solution. UV spectra studies confirmed the stability constants for $AlL_2$ that were obtained in the potentiometric studies. $^1H$ NMR spectra in $D_2O$ at acidic pD values confirmed that several complexes coexist in solution. At neutral pD values the spectra allowed the detection of two different diastereoisomers of $AlL_3$, which could be quantified for 1M4H3P. For 1M3H4P the spectra indicated that in $AlL_3$ the aromatic ring of the ligand is distorted and that metal–ligand exchanges occur. For Al/1M3H4P, NMR spectra in $H_2O$ confirmed the quantitative ratio between free and complexed ligand at several pH values. The chelation efficiencies are quite high, and they are in agreement with thermodynamic data at physiological pH.

Table 4. $Al^{III}$ chelation efficiencies of some hydroxypyridinecarboxylic acids. The values for DFO and for deferiprone are reported for comparison. Values reported are mean ± standard deviation of three experiments with DFO, deferiprone, 3H4P and 4H3P, and six experiments with 1M3H4P and 1M4H3P, each conducted in duplicate.

| Ligand | Chelation efficiency (%) | Reference |
|---|---|---|
| DFO | 112 ± 29 | this work |
| deferiprone | 74 ± 6 | this work |
| 1M3H4P | 50 ± 16 | this work |
| 1M4H3P | 37 ± 15 | this work |
| 3H4P | 20 ± 2 | [9] |
| 4H3P | 43 ± 6 | [9] |

The metal–ligand complexes are very hydrophilic at physiological pH. This should be regarded as a positive property: although chelating agents having $D_{o/w}$ values around 0.2 were hypothesized to be best suitable,[23] in our evaluation of a series of 3,4-hydroxypyridinones we found that some very hydrophilic compounds were among the most orally bioavailable and effective chelators of Al.[24–26]

On the other hand, 1M3H4P and 1M4H3P form weaker complexes than deferiprone does at all pH values. Therefore, these derivatives are expected to not be as effective in vivo. The synthesis of HPs with stronger affinity towards aluminium(III) is advisable.

1M3H4P forms significantly stronger complexes with aluminium(III) than does 3H4P. This suggests that further alkylation of the pyridinic ring can be a good strategy towards the synthesis of stronger aluminium chelators. For 1M4H3P no increase of stability was observed with respect to 4H3P. It is therefore not clear whether the alkylation of the pyridinic ring can be effective for all HPs. Other derivatives should be investigated in order to clarify the effect of the alkyl substitution. In order not to affect significantly the high hydrophilicity of the complexes, the simple methyl derivatives seem to be more promising. Towards this goal, the syntheses of 2-methyl and 1,2-dimethyl derivatives of 3H4P and 4H3P, and the thermodynamic and in vitro studies of the complexation with aluminium(III), are now in progress.

## Experimental Section

### Synthesis of the Ligands

All chemicals and solvents were obtained from Aldrich Chimica, Lancaster or Acros. The identity and purity of the intermediates and of the final compounds were checked by melting point (m.p.) measurements (Gallenkamp MFB 595010 M/B capillary m.p. apparatus), $^1$H NMR spectra (Bruker 300 MHz), TLC (Merck silica gel 60F-254 glass plates), mass spectrometry (Mat, 112 Varian Mat Bremen mass spectrometer) and elemental analysis (Perkin–Elmer Elemental Analyzer Model 240B).

**1M3H4P:** 3H4P (0.5 g, 3.62 mmol) was dissolved in 30 mL DMF by adding NaOH 10% dropwise up to pH = 10, then $CH_3I$ (1.12 mL, $d$ = 2.280 g·cm$^{-3}$, 17.99 mmol) was added. The mixture was heated at 100 °C for 2 h and after cooling it was acidified with concd. HCl and the solvents evaporated to dryness. The residue was re-crystallized twice from ethanol and glacial $CH_3COOH$ giving 0.84 g (83% yield) of 1M3H4P·HI (*N*-methyl-3-hydroxy-4-carboxypyridinium iodide); m.p. 258 °C. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 4.24 (s, 3 H, $CH_3$), 7.97 [d, $^3J_{5,6}$ = 5.92 Hz, 1 H, H(5)], 8.05 [dd, $^3J_{5,6}$ = 5.92 and $^4J_{6,2}$ = 0.95 Hz, 1 H, H(6)], 8.42 [d, $^4J_{2,6}$ = 0.95 Hz, 1 H, H(2)] ppm.

The iodide salt was transformed into the 3-hydroxy-*N*-methylpyridinium-4-carboxylate zwitterion (betaine). To this aim, the iodide salt (0.984 g) was dissolved in water (10 mL), acidified at pH = 2 with concd. HCl, and added to IRA-400-Cl amberlite resin (2.21 g, previously conditioned with HCl 1 M). The mixture was stirred for 2 h and then the resin was filtered off, the filtrate evaporated and the residue re-crystallized from glacial $CH_3COOH$. The collected precipitate was washed with acetone and dried (0.44 g, yield 83%). M.p. 252 °C (dec.). IR (KBr): $\tilde{\nu}$ = 3387, 2857, 2510, 1722 cm$^{-1}$. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 4.19 (s, 3 H, $CH_3$), 8.02 [dd, $^3J_{5,6}$ = 5.8 Hz, 2 H, H(5) and H(6)], 8.44 [s, 1 H, H(2)] ppm. HR MS: $m/z$ = [MH]$^+$ 154.11. $C_7H_7NO_3$ (153.15): calcd. C 54.90, H 4.61, N 9.15; found C 54.85, H 4.62, N 9.10.

Finally, the betaine product was transformed into the corresponding chloride salt (1M3H4P·HCl), by dissolution in ethyl acetate and addition of concd. HCl. Then the resulting solution was evaporated to dryness (0.54 g, yield 100%). M.p. 220 °C. $^1$H NMR ($CD_3OD$): $\delta$ = 4.21 (s, 3 H, $CH_3$), 8.30 [d, $^3J_{5,6}$ = 6.3 Hz, 1 H, H(5)], 8.42 [d, $^3J_{5,6}$ = 6.4 Hz, 1 H, H(6)], 8.77 [s, 1 H, H(2)] ppm. HR MS : $m/z$ = [MH]$^+$ 155.23. $C_7H_8ClNO_3$ (189.60): calcd. C 44.34, H 4.25, N 7.39, Cl 18.70; found C 44.41, H 4.03, N 7.32, Cl 18.43. A 97.86% purity was obtained from potentiometric titrations.

**1M4H3P:** $CH_3I$ (4.25 mL, $d$ = 2.280 g·cm$^{-3}$, 68.26 mmol) was added to a 50-mL DMF solution containing 4H3P (1.89 g, 13.87 mmol). The mixture was heated to 100 °C for 2 h. The volatiles were then evaporated and the solid residue was re-crystallized from ethanol yielding a crystalline white product (2.10 g). Yield 99%; m.p. 248–249 °C. IR (KBr): $\tilde{\nu}$ = 3050, 1720, 1655 cm$^{-1}$. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 3.73 (s, 3 H, $CH_3$), 6.75 [d, $^3J_{5,6}$ = 7.43 Hz, 1 H, H(5)], 8.06 [dd, $^3J_{5,6}$ = 7.43 and $^4J_{2,6}$ = 2.2 Hz, 1 H, H(6)], 8.69 [d, $^4J_{2,6}$ = 2.2 Hz, 1 H, H(2)], 16.36 (br. s, 1 H, COOH) ppm. HR MS: $m/z$ = [MH]$^+$ 154.11. $C_7H_7NO_3$ (153.14): calcd. C 54.9, H 4.61, N 9.15; found C 54.24, H 4.71, N 8.89. A 99.33% purity was obtained from potentiometric titrations.

### Solution Equilibria

The experimental apparatus, reagents and measurement methods were almost the same as reported previously.[27] In the following, a summary will be given; details are reported only when different from those already described.

**Apparatus:** All potentiometric measurements were performed with a Radiometer ABU93 Triburette apparatus. UV spectra were recorded with a Perkin–Elmer Lambda 25 spectrophotometer, $^1$H NMR spectra with Bruker DRX-400 and DRX-600 spectrometers operating at 400.13 and 600.09 MHz, respectively.

**Reagents:** All analyte concentrations were expressed in the molality scale (mol/kg of water). For potentiometric and UV measurements, working solutions of HCl (0.2 m), NaOH (0.2 m) and $AlCl_3$ (0.1 m, containing 0.3 m HCl) were prepared and standardised. 1M3H4P and 1M4H3P were used as synthesized to prepare respectively 0.14 m and 0.15 m working solutions. The ionic strength of all the solutions was adjusted to 0.6 m (0.594 M) (Na)Cl. Solutions for $^1$H NMR measurements were prepared by dissolving in $D_2O$ (Aldrich, 99.9 atoms% D), or in $H_2O$, weighed amounts of ligand, $AlCl_3$ (Fluka, ≥ 99%) and NaCl.

**Potentiometric Titrations:** Potentiometric titrations carried out in this work are summarized in Table 5. Temperature was 25.0 ± 0.1 °C. Duplicate potentiometric measurements were executed by using two different glass electrodes (Radiometer pHG201 and BDH 309/1015/02) and a Ag/AgCl/0.6 m NaCl reference electrode[28,29] with a J-shaped junction. Its acidic liquid junction potential has been determined previously[30] and it can be represented by the equation[29] $E_j = -S\cdot\log(1 + J\cdot[H^+])$, with $J$ = 3.69 ± 0.08.

Table 5. Potentiometric titrations (titrant: NaOH).

| Solutions | | Conditions $[Al]_0/10^{-3}$ m | $[L]_0/10^{-3}$ m | $[L]_0/[Al]_0$ | pH |
|---|---|---|---|---|---|
| 1. | 1M3H4P | – | 0.47–3.78 | – | 2.5–11.0 |
| | 1M4H3P | | 1.29–4.14 | | 2.6–11.0 |
| 2. | Al + 1M3H4P | 0.36–1.03 | 1.16–3.76 | 1, 2, 3, 4, 8 | 2.2–9.0 |
| | Al + 1M4H3P | 0.32–1.10 | 1.27–4.12 | | |

As a check of the accuracy of the entire experimental system, the p$K_w$ value for water in (Na)Cl 0.6 m was computed from HCl + NaOH titrations. The values obtained from two different series of experiments (p$K_w$ = 13.719 ± 0.002 and p$K_w$ = 13.710 ± 0.002) compare well with the literature value[31] in NaCl 0.6 M at 25 °C (13.727 ± 0.001).

All stability constants were calculated with the computer program PITMAP.[32] The hydroxo metal species reported by Öhman[13] have been considered and the corresponding log $\beta$ values kept fixed during the elaboration of the data.

After the addition of the metal and one of the two ligands to an acidic solution (pH < 3), the measured electromotive force drifted and reached a constant value only after ca. 1 hour, suggesting a low complex formation rate. The kinetics of the aluminium–ligand reaction became "normal" (equilibration after ca. 1 min) at pH values above 3. These findings are in agreement with previous results with other HPs.[9,14,33] Experimental details regarding the handling of the slow kinetics during the titrations are reported.[14]

**UV Measurements:** UV measurements (Table 6) were carried out for solutions containing the ligand alone, and for solutions containing the ligand and the metal ion, at various pH values (cell path 0.1 cm). When the pH of the solution was below 2, it was computed from the stoichiometric concentration of HCl, because the $[H^+]$ modifications produced by the other species were negligible under these conditions. In other cases the pH was measured with the same electrodes and procedures as for potentiometric titrations. The p$K_{a1}$ for both ligands and the log $\beta$ values for some aluminium–ligand complexes were computed by the program PITMAP.

Table 6. UV measurements.

| Solutions | Conditions $[Al]_0/10^{-3}$ m | $[L]_0/10^{-3}$ m | pH | $\lambda$ (nm) for calcd. |
|---|---|---|---|---|
| 1M3H4P | – | 0.98 | 0.25–2.00 | 217; 249; 324; 346 |
| 1M4H3P | – | 1.01 | 0.23–2.55 | 252; 290 |
| Al + 1M3H4P | 0.29 | 0.92 | 2.05–6.74 | 229; 303; 338 |
| Al + 1M4H3P | 0.30 | 0.93 | 1.80–7.16 | 256; 266; 298 |

**NMR Measurements:** $^1$H NMR spectra were obtained at 298 K. The chemical shift values are given in $\delta$ units with reference to internal $Me_4Si$. Suitable integral values for the proton spectra were obtained by a pre-scan delay of 10 s. The assignments of the proton resonances were performed by standard chemical shift correlations, COSY, TOCSY and NOESY experiments. $^1$H spectra were collected for both 1M4H3P and 1M3H4P at various pD values in $D_2O$ solutions containing only the free ligand or the ligand and the metal. For Al+1M3H4P, additional spectra were obtained in $H_2O$ (Table 7). For $D_2O$ solutions, the pH was measured with a glass electrode BDH 309/1025/02 previously calibrated in buffered solutions at pH = 4 and pH = 7, and 0.41 pH units were added to the pH meter readings to correct for isotopic and solvent effects,[34] i.e. pD rather than pH values were measured. For the $H_2O$ solutions, the pH was measured as described above for potentiometric titrations. Heavy water, necessary for the instrumental lock, was in a capillary concentric with the NMR tube.

### *n*-Octanol/Water Distribution and Chelation Efficacy

**Materials:** NaCl, KCl, $NaHCO_3$, $H_3BO_3$ and *n*-octanol were obtained from EM, Fisher, or Sigma; Al borate from Pfaltz and Bauer (Waterbury, CT) and an Al atomic absorption standard from Sigma. Polypropylene test tubes (10 mL) with polyethylene caps were purchased from VWR.

**Methods:** The distribution coefficients ($D_{o/w}$) of the ligands were determined as their concentration in the octanol phase/their concentration in the aqueous phase at equilibrium with a Shimadzu UV-2501PC UV/Vis recording spectrophotometer. UV absorbance was measured at $\lambda_{max}$, determined from a wavelength scan of the ligand.

A method to assess the aluminium chelation efficiency in vitro was used.[35] An octanol/aqueous system containing 125 mM NaCl, 25 mM $NaHCO_3$, 4.5 mM KCl and 100 mM borate at pH 7.4 was established. Equal volumes (4 mL) of the aqueous phase and 1-octanol were placed in a screw-cap polypropylene tube. The octanol phase was saturated with the aqueous solution before use to avoid distribution of hydrophilic compounds into the aqueous component of the octanol phase which would produce a falsely elevated value for octanol distribution. The opposite (i.e., the saturation of the aqueous phase with octanol) was not needed for our hydrophilic compounds.

For each experiment, duplicate tubes were prepared to contain 1) only the octanol and the aqueous phase, 2) as 1) plus 7 to 8 mg of aluminum borate to provide an excess of undissolved Al, saturating the aqueous phase and octanol with Al, 3) as 1) plus the ligand introduced into the aqueous phase at $1 \cdot 10^{-3}$ M, and 4) as 3) plus 7 to 8 mg of aluminum borate. The tubes were agitated overnight at room temperature to establish equilibrium.

**Aluminum Analysis:** The tubes were centrifuged (3400 g, 10 min), the aqueous phase was filtered through a filter with a 0.22 μm nylon membrane and then each phase analyzed by electrothermal atomic absorption spectroscopy (Perkin–Elmer 4100ZL) to determine the Al concentration. Aluminum recovery from the filtered aqueous phase was found to be 101% ± 6% (mean ± standard deviation of 12 observations), showing no loss of Al due to the filter.

**Chelator Efficiency:** The amount of Al in each liquid phase of tubes with added Al but no ligand, minus the amount of Al in tubes without added Al or ligand represented Al solubility from aluminum borate. The increase in Al in each liquid phase of tubes with Al plus ligand, over that seen in the absence of the ligand, was taken as complexation of Al by the ligand. In addition to 1M3H4P and 1M4H3P, values for the hexadentate ligand desferrioxamine (DFO) and the bidentate ligand deferiprone were obtained as positive controls to confirm the ability of the method to predict Al complexation (values close to 100% were expected). For DFO, where at pH = 7.4 a 1:1 aluminium/ligand complex was anticipated, the chelator efficiency was calculated by

$$\frac{[\text{sum of the M Al concentration in each phase}]}{1 \times 10^{-3}\ \text{M}}$$

For deferiprone, 1M3H4P and 1M4H3P, where at pH = 7.4 a 1:3 aluminium/ligand complex was anticipated (see, for example Figure 2), the chelator efficiency was calculated by

$$\frac{3[\text{sum of the M Al concentration in each phase}]}{1 \times 10^{-3}\ \text{M}}$$

## Acknowledgments

We thank professor Gianfranco Chiarelotto for helpful suggestions for the syntheses, and Paolo Rossi and Rebecca Florence for careful experimental work.

# Complexes of Bidentate Phosphane Selenide Ligands with Mesitylenetellurenyl Iodide and with Tellurium Diiodide[‡]

Cristian G. Hrib,[a] Peter G. Jones,[a] Wolf-W. du Mont,*[a] Vito Lippolis,[b] and Francesco A. Devillanova[b]

**Keywords:** Phosphane selenides / Tellurium iodides / Heteronuclear NMR / Raman spectroscopy / Soft–soft interactions

Bis(diphenylphosphanyl)methane diselenide (dppm$Se_2$, **1**) and bis(diphenylphosphanyl)ethane diselenide (dppe$Se_2$, **2**) reacted with 2 equiv. $Br_2$ or $I_2$ to form the insoluble solid products, dppm$(SeX_2)_2$ (X = Br, **3**; X = I, **4**) and dppe$(SeX_2)_2$ (X = Br, **5**; X = I, **6**). However, using the iodine-like electrophile mesitylenetellurenyl iodide (MesTeI, **7**), fairly soluble complexes, dppm$Se_2$[Te(I)Mes]$_2$ (**8**) and dppe$Se_2$[Te(I)Mes]$_2$ (**9**), were obtained. Complexes **8** and **9** contain two T-shaped (10-Te-3) Se–Te(Mes)–I moieties bridged by dppm or dppe; solid **9** exhibits intermolecular *soft–soft* interactions between approximately linear Se–Te–I units. In a side reaction accompanying the crystallisation of complex **8**, or by the reaction of **1** with Te and $I_2$, a chelate complex dppm$Se_2TeI_2$ (**10**) was formed. Fortuitously, a crystal of the related compound dppe$Se_2TeI_2$ (**11**) was also obtained. In **10**, a square planar *cis*-$Se_2TeI_2$ group is part of a six-membered ring, and **11** is a coordination polymer with *trans*-$Se_2TeI_2$ moieties bridged by dppe. Averaged $^{31}$P- and $^{77}$Se NMR signals including $^{77}$Se–$^{31}$P couplings, together with broad $^{125}$Te NMR singlets indicate phosphane selenide ligand exchange in solution, that is, the kinetically labile behaviour of complexes **8** and **9**.

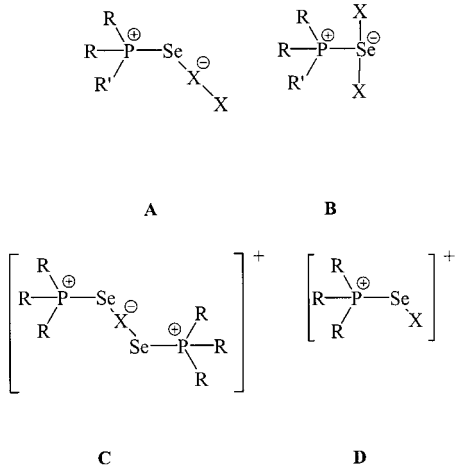
## Introduction

Phosphane chalcogenides $R_2R'P{=}Y$ (Y = S, Se) are known to act as donors towards dihalogen molecules.[2–5] Using phosphane selenides, which are stronger donors than the sulfides, a considerable number of 1:1 adducts $R_2R'PSeX_2$ have been isolated.[6–9] Iodine adducts exhibit type **A** (10-I-2) *molecular* structures $R_2R'PSeI_2$ (R, R′ = $C_6H_5$, $NMe_2$, $NEt_2$[7] and R = *t*Bu, R′ = I)[8] or type **C** (10-I-2) *ionic* structures $(R_3PSe)_2I^+I_3^-$,[6,10,11a] whereas bromination products exhibit type **B** (10-Se-3) T-shaped $PSeBr_2$ moieties in their structures (R, R′ = $NMe_2$, $C_6H_{11}$, *i*$C_3H_7$).[9,11a] With excess iodine, polyiodide salts featuring $R_3PSeI^+$ countercations (type **D**),[4,10,12] could be formed (Scheme 1). Many of these compounds are aggregated by further *soft–soft* contacts that lead to ion pairs, chains and extended networks.[3,4,6,8,9,11b,12] In particular, type **D**-like (iodoseleno)phosphonium cations behave as soft electrophiles by the iodine atom in the β position to the formally charged phosphorus atom (β-heteroatom Lewis acidity).[3,10,12]



Scheme 1. Various Lewis-type structures of halogen adducts of phosphane selenides. These structures must be intended purely as a formal illustration of the various compounds with no implication as to the real distribution of charges. The same considerations apply to Scheme 2 and Scheme 3.

To stimulate the formation of supramolecular networks using the earlier mentioned types of soft–soft interactions, we are introducing *bifunctional* donor-acceptor systems into our studies. In a previous paper we described the self-assembly of iodophosphane selenides RR′P(=Se)I as bifunctional donor-acceptor molecules (selenium donor, iodine acceptor).[8] The bifunctional selenocarbonyl ligand 1,2-bis(3-methyl-4-imidazolin-2-selone)ethane was recently

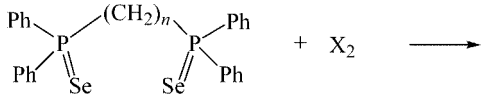
shown to undergo $Br_2$[13] and IBr[14] oxidative addition at the Se atom of the >C=Se group, exhibiting a subtle interplay of soft–soft and hydrogen-bonding interactions in the solid.

In our present work we evaluate the use of bifunctional phosphane selenides, bis(diphenylphosphanyl)methane diselenide (dppm$Se_2$, **1**) and bis(diphenylphosphanyl)ethane diselenide (dppe$Se_2$, **2**), towards halogens ($Br_2$, $I_2$) and towards the halogen-like electrophile mesitylenetellurenyl iodide [MesTeI, **7**; Mes = 2,4,6-$(CH_3)_3C_6H_2$][15] with the intention of creating supramolecular soft–soft networks. Arenetellurenyl chlorides and bromides are known to give stable 1:1 complexes with triphenylphosphane selenide,[16a] tri(morpholine)phosphane selenide[16a,16b] and tris(dimethylamino)phosphane selenide.[17]

## Results and Discussion

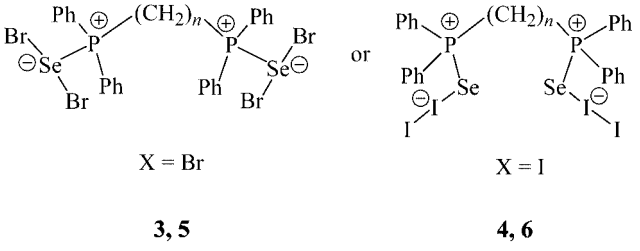
### Formation of 1:2 Adducts of dppm$Se_2$ (1) and dppe$Se_2$ (2) with $Br_2$ and $I_2$

Addition of 2 equiv. $Br_2$ or $I_2$ to solutions of bidentate phosphane selenides (dppm$Se_2$, **1**, and dppe$Se_2$, **2**) led to precipitation of solids of the composition dppm$(SeX_2)_2$ (X = Br, **3**; X = I, **4**) and dppe$(SeX_2)_2$ (X = Br, **5**; X = I, **6**) (Scheme 2).



*n* = 1, dppm$Se_2$, **1**

*n* = 2, dppe$Se_2$, **2**



X = Br X = I

**3, 5** **4, 6**

Scheme 2. 1:2 Reactions of dppm$Se_2$ and dppe$Se_2$ with $Br_2$ and $I_2$. For an alternative structure of **4**, see vibrational spectra.

Since these materials are insoluble in aprotic-dipolar solvents and thus cannot be recrystallised, compounds **3**–**6** were not obtained as single crystals. In the absence of crystal data, only Raman spectra could be of help in investigating the structural features of the expected $PSeX_2$ functions of the compounds (see later). Reaction of dppe-diselenide **2** with only 1 equiv. $I_2$ also led to precipitation of the 1:2 product **6**; however, from $CH_2Cl_2$ solutions containing 1:1 mixtures of dppm-diselenide **1** with iodine, precipitation did not occur. The $^{31}P$ NMR spectrum of this solution shows only one resonance with a $^{77}Se,^{31}P$ satellite coupling that is smaller than that of the starting material. The $^{31}P$ NMR singlet may be due to a symmetric bonding mode of **1** with iodine, or, alternatively, to a rapid equilibration of coordinated and noncoordinated PSe functions (that is, signal averaging). In the $^{77}Se$ NMR spectra, titration-like addition of $I_2$ led to stepwise deshielding [**1**: $\delta^{77}Se$ = –240 ppm, **1**/$I_2$ (1:1 complex): $\delta^{77}Se$ = –68 ppm] and line broadening. This observation implies signal averaging at all stages of the iodine addition. Crystals of the 1:1 product were not obtained; precipitation by addition of pentane led to the solid 1:2 product **4**. Similarly, attempts to prepare 1:1 adducts of **1** and **2** with bromine led to formation of insoluble **5** and **6**.

### Reactions of dppm$Se_2$ (1) and dppe$Se_2$ (2) with MesTeI (7)

With the intention of exerting control over solubility properties and of introducing the NMR-active $^{125}Te$ nucleus as an additional probe for solution studies, we decided to include tellurenyl iodides in our study. Arenetellurenyl halides are known to exhibit electrophilic properties towards soft ligands; typically bromide, iodide and S-donor ligands lead to T-shaped complexes. A few phosphane selenide–tellurenyl bromide and chloride complexes have been crystallographically studied,[16,17] but neither a systematic structural study nor any heteronuclear NMR spectroscopic data has yet appeared in the literature. To favour aryl packing in the solid, we chose the in situ generated mesitylenetellurenyl iodide [MesTeI, **7**; Mes = 2,4,6-$(CH_3)_3C_6H_2$][15] as the iodine-related electrophile for coordination with **1** and **2**.

Addition of **1** or **2** to 2 equiv. **7**, prepared from $Mes_2Te_2$ with $I_2$, led to compounds **8** and **9**, which were isolated in moderate yields by crystallisation (Scheme 3). Complexes **8** and **9** were characterised by multinuclear NMR spectroscopy in solution, and a single crystal of the dppe$Se_2$ complex **9** was studied by X-ray crystallography.

Attempts to grow single crystals from crude solutions of **8** led to a few single crystals of an unexpected tellurium diiodide chelate complex **10**. Compound **10** was also isolated in small yield from reaction mixtures that were intended to produce a 1:1 complex of **1** with **7**. The $^{31}P$ NMR spectra of the 1:1 complexes of **1** and **2** with MesTeI show $^1J_{^{77}Se,^{31}P}$ coupling constants between those of **1**,**2** and **8**,**9** (Table 1). Compound **10** was also accessible by addition of elemental tellurium and iodine to dissolved **1** (Scheme 3). Fortuitously, upon crystallisation of compound **9**, a single crystal of the related tellurium diiodide complex **11** of ligand **2** was also isolated and studied by X-ray crystallography.

Formation of the $TeI_2$ complexes **10** and **11** from **7** involves breaking the Te–C bond, but the fate of the "lost" mesityl group remains unclear. Te–C bond cleavage with mesityl group transfer has previously been observed after a bromination/bromide abstraction sequence started with $Mes_2Te$ and led to $Mes_3Te^+$ $SbF_6^-$ and $Mes_5Te_2^+$ $SbF_6^-$.[1]

Thermal decomposition of arenetellurenyl halides can also involve Te–C bond cleavage (loss of tellurium).[15]

## NMR Spectroscopic Investigation of Binuclear Complexes 8 and 9

The coordination of phosphane selenides with iodine or the oxidative addition of bromine to phosphane selenides is accompanied by a decrease in the NMR coupling constant $^1J_{^{31}P,^{77}Se}$.[7–10] The same observation is made when the bidentate phosphane selenide **1** reacts with 1 equiv. iodine, and when **1** or **2** coordinate with 2 equiv. mesitylenetellurenyl iodide **7**. Solutions containing **1** or **2** with fewer than 2 equiv. **7** do not give separate $^{31}P$ NMR signals for the different species in solution, instead averaged signals appear, which also show averaged $^{77}Se$ satellites. The averaged magnitudes of $^1J_{^{31}P,^{77}Se}$ decrease with increasing amounts of the electrophile **7**. The changes in the $^{77}Se$ NMR resonances of **1** and **2**[18,19] upon coordination with **7** (deshielding coordination shifts) are much larger than those of the $^{31}P$ NMR signals (Table 1). The $^{77}Se$ NMR resonances of **8** and **9** appear as (pseudo) doublets [X-parts of AA′X systems][18–20] due to $J_{^{77}Se,^{31}P}$, but they do not exhibit satellites from coupling with $^{125}Te$. Similarly, the broad $^{125}Te$ NMR signals do not allow the resolution of couplings with $^{31}P$: the kinetic lability (fast ligand exchange) of complexes **8** and **9** involves Se–Te bond breaking, whereas P–Se bonds stay intact. In relation to the signals of noncoordinated monomeric alkane- and arenetellurenyl halides [$(Me_3Si)_3CTeI$: $\delta^{125}Te$ = 1185 ppm,[21] 2,4,6-$iPr_3C_6H_2TeI$: $\delta^{125}Te$ = 842 ppm,[15] 2,4,6-$tBu_3C_6H_2TeI$: $\delta^{125}Te$ = 1162 ppm,[15] 2,4,6-$Me_3C_6H_2$-TeI: $\delta^{125}Te$ = 867 ppm], the $^{125}Te$ NMR signals of complexes **8** and **9** are deshielded by about 44–390 ppm. In the case of **8** and **9** and their mixtures with **1** and **2**, the exchange is apparently very fast on the NMR time scale.

## X-ray Crystallographic Studies

In solid $dppeSe_2[Te(I)Mes]_2$ (**9**), $dppeSe_2$ acts as a bridging bidentate ligand between two Te(I)Mes acceptor moieties (Figure 1a). The heavy-atom positions correspond to local inversion symmetry (rmsd = 6.6 pm; Figure 1b).

The molecules are packed in a way that allows side-on intermolecular soft–soft interactions between approximately linear Se–Te–I units, thus linking the molecules in chains parallel to the *x* axis (Figure 2).

The Te–I contacts are in the range of the sum of the relevant van der Waals radii. The "T"-type Se–Te(–C)–I

The Se–Te bonds in complex **9** are longer (Table 3) than those in chloro- and bromo-phenyl(trimorpholinophosphane selenide)tellurium(II)[16a,16b] and bromophenyl[tris(dimethylamino)phosphane selenide]tellurium(II),[17] and this correlates well with the weaker donor properties of alkyl-/arylphosphane selenides compared with aminophosphane selenides.[16a,16b,17,23] As expected, Se→Te donation is accompanied by P–Se bond expansion (ligand **2**: 209.4 pm,[18b] complex **9**: 215.1 pm).

[a] Symmetry transformations used to generate equivalent atoms: #1: $-x + 1, -y + 1, -z$; #2: $-x + , y - ½, -z + ½$.

A similar kind of distortion is documented in the chelate complexes $dppmS_2TeCl_4$,[24] $dppmSe_2HgI_2$,[25] $dppmSe_2HgBr_2$[25] and $dppmSe_2ZnBr_2$.[26] The distortion of the tellurium coordination spheres can be explained by the tendency of the ligands $dppmE_2$ (E = O, S, Se)[18a,27,28] to avoid intramolecular repulsion of the $P(=E)Ph_2$ groups (**1**: E = Se). In **10** the torsion angle Se(1)P(1)···P(2)Se(2) is 32°. The small bite angle Se(1)–Te–Se(2) (86.5°) is associated with a widening of the opposite angle I(1)–Te–I(2) (95.9°). Se–Te bond lengths in **10** are shorter than those of **9** because of the better acceptor properties of $TeI_2$ compared with MesTeI. Te–I distances [Te–I(1) 290.6 pm, Te–I(2) 291.4 pm] are slightly longer than those in **9** but shorter than those in the square planar $TeI_4^{2-}$ anion [298.5(2) pm].[29] In the case of bis[($\mu_2$-iodo)bis(ethyleneselenourea-Se)tellurium] diiodide[30] [Te–Se 261.8(1) pm] and *cis*-diiodobis(thiourea-S)tellurium,[31] Te–I distances

are very long [325.1(1) and 316.2(1) pm, respectively]. Complex **10** also exhibits intermolecular soft–soft interactions (Figure 4).

The Se(1)–Se(1′) interaction is shorter than the sum of the van der Waals radii and the Se(2)–I(1′) interaction is at the limit of the van der Waals radii. The selenium and iodine atoms exhibit borderline H···Se(I) intermolecular contacts (H···Se 316–334 pm, H···I 296–330 pm).

Complex **11** is a helical coordination polymer with centrosymmetric *trans*-$Se_2TeI_2$ moieties (12-Te-4) bridged by centrosymmetric dppe units (Figure 5, Table 5).

Table 5. Bond lengths [pm] and angles [°] of dppe$Se_2TeI_2$ (**11**).[a]

| | | | |
|---|---|---|---|

[a] Symmetry transformations used to generate equivalent atoms: #1: $-x + 1, -y, -z$; #2: $-x, -y, -z$.

The tellurium atom lies on the inversion centre ½, 0, 0 and the midpoint of the C1–C1′ bond lies on 0, 0, 0. Compared with the distorted chelate complex **10**, the coordination polymer **11** exhibits Se–Te bonds shorter by 3–4 pm and Te–I bonds longer by 3–4 pm. The coordination environment of Te in **11** deviates from square by expansion of the angle Se(1)–Te–I(1)#1 (93.2°) and compression of the angle Se(1)–Te–I(1) (86.8°). Among the three compounds **9**, **10** and **11**, the latter exhibits the shortest coordinative Se–Te bond (280.3 pm). The Te–I bond lengths are close to those in *trans*-diiodobis(tetramethylselenourea-Se)tellurium (*trans*-$Se_2TeI_2$ moieties) [295.4(1) pm][31] [Te–Se 282.1(1) pm], and are also similar to Te–I bonds in related *trans*-$S_2TeI_2$ moieties (293.3–298.2 pm).[32]

### Vibrational Spectra

FT-Raman spectroscopy is the main method of investigating the nature of the products obtained by the reactions of dihalogens/interhalogens with donor molecules containing 15- and 16-group elements in the absence of X-ray structural data.[33–38]

Among the compounds reported here, **3**–**6** are molecular adducts of dppm and dppe with $Br_2$ and $I_2$, while **8**–**11** are obtained by reacting the same ligands with MesTeI. No crystallographic data are available for **3**–**6**, but structural information can be obtained by comparing their FT-Raman spectra with those of several structurally characterised $I_2$ and $Br_2$ adducts with Se-donor molecules.[33–38] In contrast, no FT-Raman data are available from the literature for compounds similar to **8**–**11**, but the knowledge of the crystal structures of **9**–**11** allows a first tentative correlation between structural and FT-Raman data for these compounds.

Compounds **3** and **5** have similar FT-Raman spectra with two peaks at 144 and 195 $cm^{-1}$ for **3**, and at 157 and 191 $cm^{-1}$ for **5**, which agree with the presence of asymmetric Br–Se–Br groups in both compounds.[13,38,39]

The FT-Raman spectra of the corresponding adducts with $I_2$, **4** and **6**, differ from each other; compound **4** has a strong peak at 116 $cm^{-1}$ accompanied by a weaker peak at 145 $cm^{-1}$, whereas **6** has two well-defined peaks at 145 and 152 $cm^{-1}$ (see Figure 6).

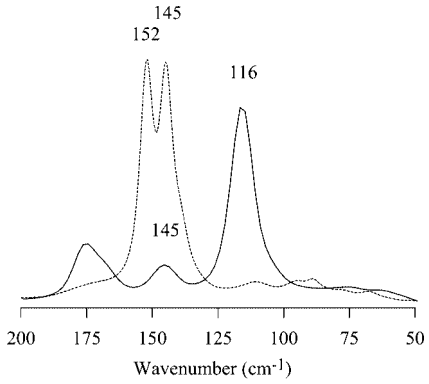

Figure 6. FT-Raman spectra of **4** (solid line) and **6** (dotted line).

The spectrum of **4** indicates the presence of asymmetric linear I–Se–I moieties,[35] whereas the spectrum of **6** is more consistent with a charge-transfer nature, characterised by the presence of linear Se–I–I groups. Strong $I_2$-charge-transfer adducts with selenium-donor molecules generally feature two bands in their FT-Raman spectra near 150 and 130 $cm^{-1}$ which are assigned to the antisymmetric and symmetric stretching modes, respectively, of the Se–I–I system.[34,35,37]

Complexes **8** and **9** have similar FT-Raman spectra with a strong peak at 126 $cm^{-1}$ accompanied by a weaker shoulder at 142 $cm^{-1}$ for **8**, and, correspondingly, at 129 and 146 $cm^{-1}$ for **9** (see Figure 7 for the FT-Raman spectrum of **8**).

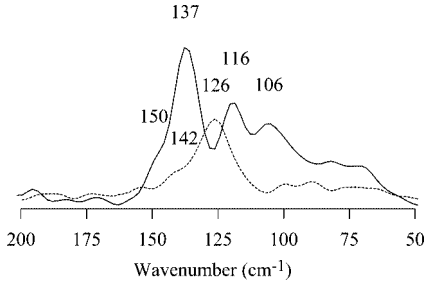

Figure 7. FT-Raman spectra of **8** (dotted line) and **10** (solid line).

On the basis of this similarity, it is possible to infer that the structural features of **8** are analogous to those of **9**; therefore, for both compounds the two FT-Raman peaks should be tentatively assigned to the symmetric and antisymmetric stretching vibrations of the Se–Te–I system. As already mentioned, these assignments cannot be supported by any data from the literature.[40] Significantly, the FT-Ra-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

man peaks observed for **8** and **9** occur at frequencies close to those normally observed for the peaks typical of strong charge-transfer adducts featuring linear Se–I–I groups. Therefore, the two systems Se–Te–I and Se–I–I appear to have a similar vibrational behaviour.

The spectrum of **10** shows four peaks at 150 (shoulder), 137, 116 and 106 $cm^{-1}$ in good agreement with its structural features (see Figure 7). In fact, by approximating the local symmetry around the Te atom to the $C_{2v}$ point group, four Raman-active stretching vibration modes are to be expected. Therefore, on the basis of the different atomic weight of Se and I, the peaks at 106 and 116 $cm^{-1}$ should have a predominant contribution from the symmetric and antisymmetric stretching modes of the $TeI_2$ group, respectively, while the peaks at 137 and 150 $cm^{-1}$ should have a predominant contribution from the analogous vibrations of the $TeSe_2$ group.

The local symmetry around the Te atom in **11** can be approximated instead to the $D_{2h}$ point group, and only the $A_g$ vibrations for the linear I–Te–I and Se–Te–Se groups should be Raman-active. Indeed, the FT-Raman spectrum of **11** shows a very strong peak at 110 $cm^{-1}$ and a much weaker peak at around 150 $cm^{-1}$. Also in this case, the peak at lower frequency should have a predominant contribution from the symmetric stretching vibration of the I–Te–I moiety, whereas that at higher frequency should have a predominant contribution from the symmetric stretching vibration of the Se–Te–Se moiety. This assignment can be considered as reasonable since the symmetric I–Te–I and Se–Te–Se groups are structurally comparable to the symmetric $I_3^-$ and $IBr_2^-$, respectively. Indeed, $I_3^-$ and $IBr_2^-$, when symmetric, are characterised by only one Raman peak at around 110 and 160 $cm^{-1}$, respectively.[37,38,41]

Unfortunately, the quality of the FTIR spectra for all the compounds considered prevents any further discussion.

## Experimental Section

NMR spectra were recorded using Bruker spectrometers AC 200, Avance 200, Avance 400 and AMX 300, with 85% $H_3PO_4$, $(CH_3)_2Se$, $(CH_3)_2Te$ and $SiMe_4$ as external or internal standards.

FT-Raman spectra, in the range 500–50 $cm^{-1}$, were recorded with a resolution of 2 $cm^{-1}$ with a Bruker RFS100 FT-Raman spectrometer, fitted with an In-Ga-As detector (room temp.) operating with a Nd-YAG laser (excitation wavelength 1064 nm; 50–100 mW), with a 180° scattering geometry. The values in parentheses next to the wavenumber values reported for each compound represent the intensities of the peaks relating to the strongest, taken to be 10.

**3:** Diselenide **1** (1.08 g, 2.0 mmol) was dissolved in dichloromethane (20 mL) and a solution of bromine (0.63 g, 4.0 mmol) in dichloromethane (20 mL) was added. The reaction mixture was stirred at room temp. for 2 h, after which the raw product **3** was isolated by vacuum evaporation of the solvent, and purified by washing with pentane and drying under vacuum evaporation. An orange dppm$(SeBr_2)_2$ complex was obtained. Yield: 1.53 g, 89%; m.p. 133–134 °C. $C_{25}H_{22}Br_4P_2Se_2$ (861.93): calcd. C 34.84, H 2.57; found C 34.19, H 2.34. FT-Raman: $\tilde{\nu}$ = 195 (10), 144 (10) $cm^{-1}$.

**4:** Diselenide **1** (1.08 g, 2.0 mmol) was dissolved in dichloromethane (20 mL) and a solution of iodine (1.01 g, 4.0 mmol) in dichloromethane (20 mL) was added. The reaction mixture was stirred at room temp. for 3 h, after which the raw product **4** was isolated by vacuum evaporation of the solvent, and purified by washing with pentane and drying under vacuum evaporation. A red dppm$(SeI_2)_2$ complex was obtained. Yield: 1.93 g, 92%; m.p. 138–139 °C. $C_{25}H_{22}I_4P_2Se_2$ (1049.23): calcd. C 28.60, H 2.11; found C 28.57, H 2.06. FT-Raman: $\tilde{\nu}$ = 145 (2), 116 (10) $cm^{-1}$.

**5:** Diselenide **2** (1.11 g, 2.0 mmol) was dissolved in dichloromethane (20 mL) and a solution of bromine (0.63 g, 4.0 mmol) in dichloromethane (20 mL) was added. The reaction mixture was stirred at room temp. for 2 h, after which the raw product **5** was isolated by vacuum evaporation of the solvent, and purified by washing with pentane and drying under vacuum evaporation. A yellow dppe$(SeBr_2)_2$ complex was obtained. Yield: 1.66 g, 95%; m.p. 148–149 °C. $C_{26}H_{24}Br_4P_2Se_2$ (875.95): calcd. C 35.05, H 2.76; found C 34.98, H 2.98. FT-Raman: $\tilde{\nu}$ = 191 (9.5), 157 (10) $cm^{-1}$.

**6:** Diselenide **2** (1.11 g, 2.0 mmol) was dissolved in dichloromethane (20 mL) and a solution of iodine (1.01 g, 4.0 mmol) in dichloromethane (20 mL) was added. The reaction mixture was stirred at room temp. for 2.5 h, after which the raw product **6** was isolated by vacuum evaporation of the solvent, and purified by washing with pentane and drying under vacuum evaporation. A red dppe$(SeI_2)_2$ complex was obtained. Yield: 1.96 g, 92%; m.p. 197–198 °C. $C_{26}H_{24}I_4P_2Se_2$ (1063.95): calcd. C 29.35, H 2.27; found C 29.29, H 2.23. FT-Raman: $\tilde{\nu}$ = 152 (10), 145 (10) $cm^{-1}$.

**8:** Dimesityl ditelluride (0.99 g, 2.0 mmol) was dissolved in dichloromethane (20 mL) and a solution of iodine (0.51 g, 2.0 mmol) in dichloromethane (10 mL) was added. The reaction mixture was added to a solution of diselenide **1** (1.08 g, 2 mmol) in dichloromethane and was stirred for 24 h at room temp., after which the raw product **8** was isolated by vacuum evaporation of the solvent, and purified by washing with pentane, drying under vacuum evaporation and recrystallised by gas diffusion from dichloromethane/pentane. Yield: 1.93 g, 75%; m.p. 77–78 °C. $C_{43}H_{44}I_2P_2Se_2Te_2$ (1289.69): calcd. C 40.05, H 3.44; found C 39.80, H 3.44. $^{31}P$ NMR ($CD_2Cl_2$): $\delta$ = 24.1 (s, $^1J_{P,Se}$ = 717.7 Hz, $^2J_{P,P}$ = 12.4 Hz, 2 P) ppm. $^{77}Se$ NMR ($CD_2Cl_2$): $\delta$ = –161 (br. d, $^1J_{Se,P}$ = 750 ± 50 Hz) ppm. $^{125}Te$ NMR ($CD_2Cl_2$): $\delta$ = 796 (br. s) ppm. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 2.2 (s, 6 H), 2.5 (s, 12 H), 4.3 (t, $J_{H,P}$ = 13.1 Hz, 2 H), 6.9 (s, 4 H), 7.3 (m, 8 H), 7.4 (m, 4 H), 7.6 (m, 8 H) ppm. $^{13}C$ NMR ($CD_2Cl_2$): $\delta$ = 21.3 (s, 2 C), 31.2 (s, 4 C), 34.2 (s, 1 C), 117.5 (s, 2 C), 127.5 (s, 4 C), 127.8 (s, 4 C), 129.2 (t, $J_{C,P}$ = 6.6 Hz, 8 C), 132.8 (t, $J_{C,P}$ = 5.9 Hz, 8 C), 141.4 (s, 2 C), 147.2 (s, 4 C) ppm. FT-Raman: $\tilde{\nu}$ = 142 (5), 126 (10) $cm^{-1}$.

**9:** Dimesityl ditelluride (0.99 g, 2.0 mmol) was dissolved in dichloromethane (20 mL) and a solution of iodine (0.51 g, 2.0 mmol) in dichloromethane (10 mL) was added. The reaction mixture was added to a solution of diselenide **2** (1.11 g, 2 mmol) in dichloromethane and was stirred for 24 h at room temp., after which the raw product **9** was isolated by vacuum evaporation of the solvent, and purified by washing with pentane, drying under vacuum evaporation and recrystallised by gas diffusion from dichloromethane/pentane. Yield: 2.00 g, 77%; m.p. 158–159 °C. $C_{44}H_{46}I_2P_2Se_2Te_2$ (1303.67): calcd. C 40.54, H 3.56; found C 39.00, H 3.57. $^{31}P$ NMR ($CD_2Cl_2$): $\delta$ = 35.8 (s, $^1J_{P,Se}$ = 711.6 Hz, $^3J_{P,P}$ = 63.7 Hz, $^4J_{P,Se}$ = 12.2 Hz, 2 P) ppm. $^{77}Se$ NMR ($CD_2Cl_2$): $\delta$ = –281 (br. d, $^1J_{Se,P}$ = 690 ± 50 Hz) ppm. $^{125}Te$ NMR ($CD_2Cl_2$): $\delta$ = 798 (br. s) ppm. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 2.4 (s, 6 H), 2.7 (s, 12 H), 2.9 (d, $^2J_{H,P}$ = 2.3 Hz, 4 H), 7.03 (s, 4 H), 7.5 (m, 8 H), 7.6 (m, 4 H), 7.8 (m, 8 H) ppm. $^{13}C$ NMR ($CD_2Cl_2$): $\delta$ = 21.1 (s, 2 C), 25.3 (s, 2 C), 30.1 (s,

**10:** Diselenide **1** (0.99 g, 2.0 mmol) was dissolved in dichloromethane (20 mL). Tellurium (0.26 g, 2 mmol) and iodine (0.51 g, 2.0 mmol) were added. The reaction mixture was stirred for 4 d at room temp., after which the raw product **10** was isolated by vacuum evaporation of the solvent, and purified by washing with pentane, drying under vacuum evaporation and recrystallised by gas diffusion from dichloromethane/hexane. Yield: 1.61 g, 85%; m.p. 192–193 °C. $C_{25}H_{22}I_2P_2Se_2Te$ (923.69): calcd. C 32.51, H 2.40; found C 32.07, H 2.40. $^{31}$P NMR ($CD_2Cl_2$): $\delta$ = 21.8 (s, $^1J_{P,Se}$ = 682.3 Hz, $^2J_{P,P}$ = 8.9 Hz) ppm. $^{77}$Se NMR ($CDCl_3$): $\delta$ = –93 (br. d, $^1J_{Se,P}$ = 653 ± 50 Hz) ppm. FT-Raman: $\tilde{\nu}$ = 150 (3, shoulder), 137 (10), 116 (6) and 106 (5) cm$^{-1}$.

**Structure Determinations:** Numerical details are presented in Table 6. All X-ray data were collected with monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) on a Bruker SMART 1000 CCD area detector. Absorption corrections were based on multiple scans. The structures were solved by direct methods and refined anisotropically by full-matrix least-squares on $F^2$ (Program SHELXTL: Prof. G. M. Sheldrick, Univ. of Göttingen). Hydrogen atoms were included using a riding model (except methyl groups which were refined as rigid groups). Structure **9** was refined as a racemic twin. Structure **11** contains one ordered molecule of dichloromethane per asymmetric unit. CCDC-289068 (for **9**), -289069 (for **10**) and -289070 (for **11**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## COVER PICTURE

**The cover picture shows** the crystal structures of three related iron(II) complexes obtained with a triazine-based polypyridyl ligand, where minor structural changes result in very disparate magnetic properties, ranging from antiferromagnetic exchange through spin crossover to ferromagnetic coupling. These are clearly illustrated by the characteristic plots of the corresponding magnetic behaviours. The background map of Europe symbolizes the European collaboration responsible for the studies reported by P. Gamez, O. Roubeau, et al. on p. 1353 ff.

# Metalation Chemistry of *meso*-Aryl-Substituted Expanded Porphyrins

**Soji Shimizu[a] and Atsuhiro Osuka*[a]**

**Keywords:** Aromaticity / Conjugation / Macrocyclic ligands / Porphyrinoids

*meso*-Aryl-substituted expanded porphyrins are structural analogues of *meso*-aryl-substituted porphyrins. They exhibit rich and novel coordination behaviors, including multi-metal chelation due to the large cavities, spin–spin interaction arising from the proximity of metal centers, and large changes in their structural and electrochemical properties upon metalation. The recent discovery of a facile, one-pot synthesis of a series of *meso*-aryl-substituted expanded porphyrins enables us to investigate their metal-complexation chemistry. The aim of this Microreview is to highlight recent progress in the synthesis and characterization of metal complexes of *meso*-aryl-substituted expanded porphyrins.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Porphyrins, which play a key role in biological as well as artificial processes, are undoubtedly one of the most widely studied macrocycles and are characterized as 18π-electron aromatic ligands that can accommodate most metal ions to form 1:1 metal complexes.[1] In recent years, porphyrin analogues that include modified, confused, contracted, and expanded ones have attracted increasing attention owing to their intriguing properties, which are very difficult or impossible to achieve in porphyrins. Among these, expanded porphyrins bearing more than four pyrrole rings have been demonstrated to be quite promising due to their larger conjugation and diversity that allow remarkable absorption spectra ranging from the UV/visible to the near-IR region, variable oxidation states that are interconvertible among aromatic, antiaromatic, and nonaromatic systems, and multi-metal coordinating behaviors.[2–7] On account of these promising properties, they are in the spotlight in various fields, including receptors for anions,[8] ligands for several transition and lanthanoid metal ions, sensitizers for photodynamic therapy (PDT),[5,9] and magnetic resonance imaging (MRI) contrast agents.[10] In addition, they have re-

*Soji Shimizu was born in 1979 in Kyoto, Japan. He received his BSc and MSc degrees in 2002 and 2004, respectively, from Kyoto University. He is currently a PhD student with Professor Osuka at the same university, focusing on the synthesis and exploration of expanded porphyrins. During spring 2005, as a visiting fellow, he stayed at Professor Jonathan L. Sessler's laboratory in the Department of Chemistry and Biochemistry, the University of Texas at Austin. He was selected as a Research Fellow of the Japan Society for the Promotion of Science (JSPS) in 2004.*

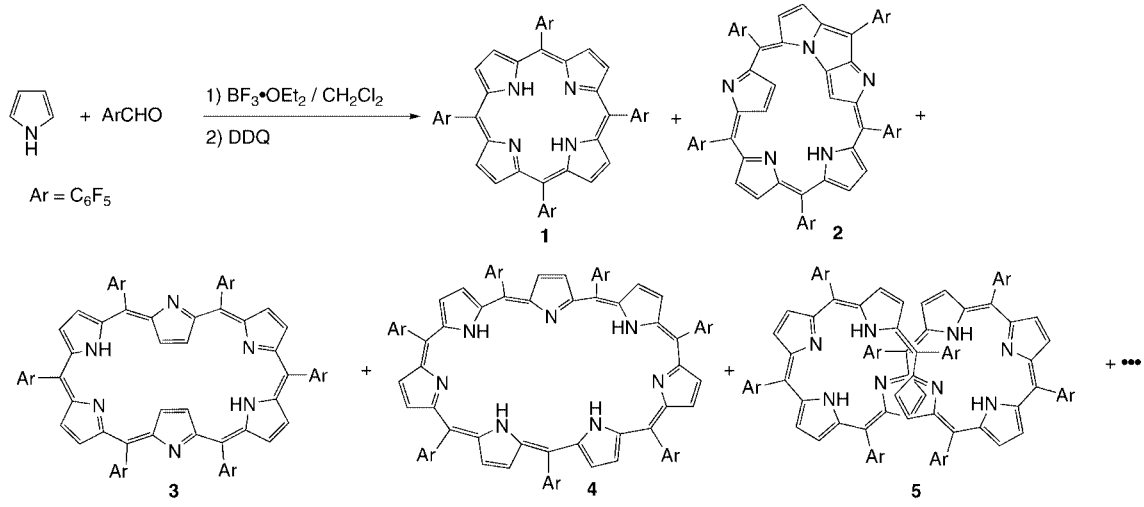
*Atsuhiro Osuka was born in Gamagori, Aichi, in 1954. He received his PhD degree from Kyoto University in 1982 on the photochemistry of epoxyquinones. In 1979, he started his academic career at the Department of Chemistry, Ehime University as an assistant professor. In 1984, he moved to the Department of Chemistry, Kyoto University, where he became a professor of chemistry in 1996. He was awarded the CSJS Award for Young Chemists in 1988 and the Japanese Photochemistry Association Award in 1999. His research interests cover many aspects of synthetic approaches toward the artificial photosynthesis and development of porphyrin-related compounds with novel structures and functions. He was selected as a project leader of Core Research for Evolutional Science and Technology (CREST) of JST.*

**MICROREVIEWS:** This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

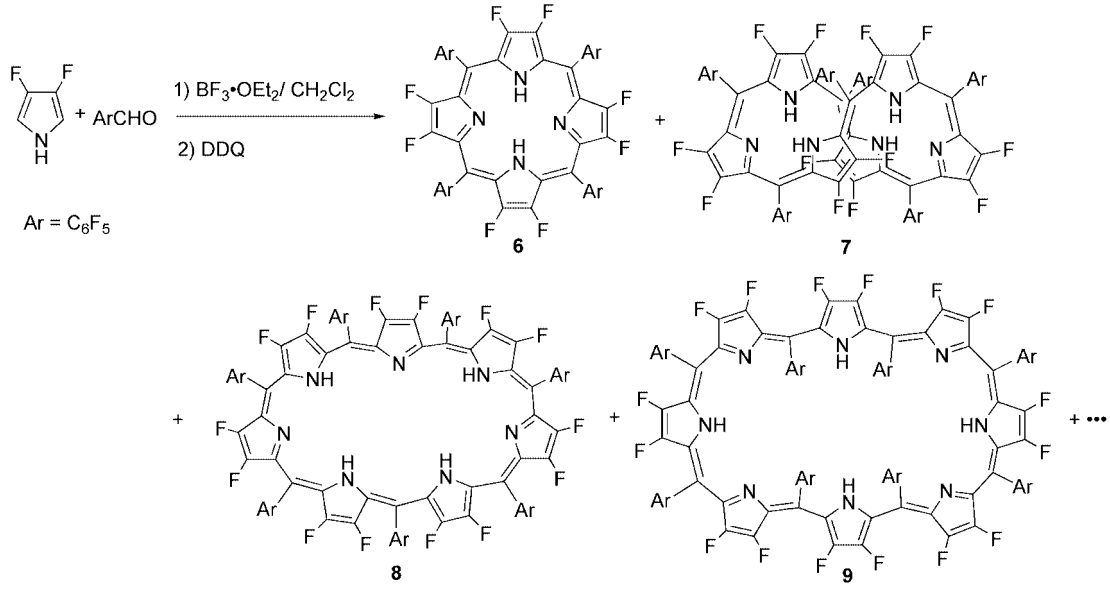
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cently been shown to have potential as nonlinear optical materials owing to their large two-photon absorption (TPA) cross-sections, which will lead to a broad range of applications such as three-dimensional microfabrication, optical data storage, and optical limiting.[11,12] These promising attributes have encouraged diverse synthetic efforts towards various expanded porphyrins that differ in ring size, ring connectivity, peripheral substituents, and core modification.[5,13–21] Recently, we found that a modified Rothemund–Lindsey porphyrin synthesis leads to the formation of a series of *meso*-aryl-substituted expanded porphyrins that are all real porphyrin homologues in terms of a regularly alternating pyrrole and methine carbon arrangement (Scheme 1).[22] This synthesis requires aryl aldehyde substrates bearing electron-deficient and bulky substituents both at the 2- and 6-positions and 10 times higher concentrations of substrates (ca. 67 mM) than those optimized for the porphyrin synthesis. A series of fully fluorinated expanded porphyrins was prepared in a similar manner from the reaction of 3,4-difluoropyrrole and pentafluorobenzaldehyde (Scheme 2).[23] The ring-size-selective synthesis of expanded porphyrins has been achieved by using dipyrromethane and tripyrromethane as starting substrates under milder reaction conditions (Scheme 3).[24] This ring-size-selective synthesis has also allowed the preparation of hexaphyrins and octaphyrins bearing electron-rich *meso*-aryl substituents.[25]

The metalation chemistry of expanded porphyrins can be traced back to the 1980s. Representative examples are summarized in Figure 1. In 1983, Gossauer et al. reported the preparation of β-dodecaalkyl-substituted [26]hexaphyrins, which were converted into their bis-$Zn^{II}$ and bis-$Pd^{II}$ complexes.[26] Vogel and co-workers have synthesized a series of β-alkyl-substituted octaphyrins bearing twisted fig-



Scheme 1. Synthesis of *meso*-aryl-substituted expanded porphyrins.



Scheme 2. Synthesis of perfluorinated expanded porphyrins.

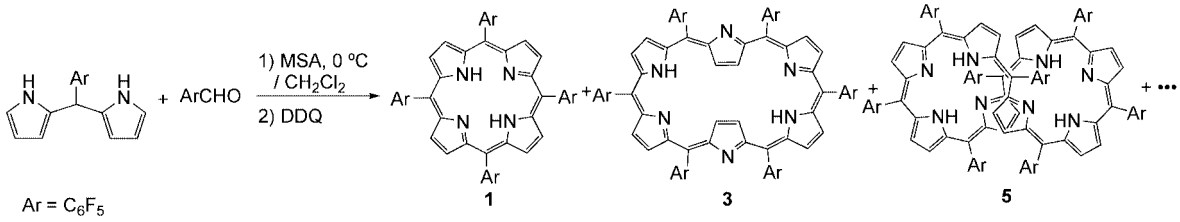

Scheme 3. Ring-size selective synthesis.

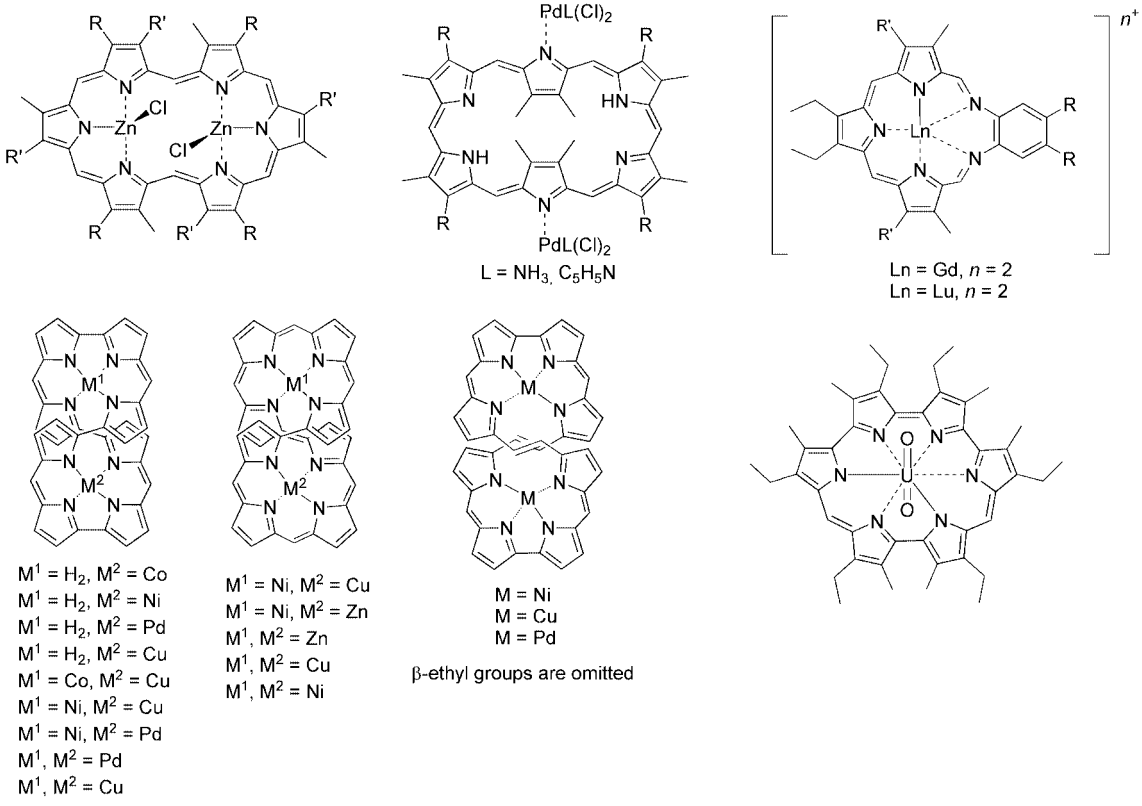

Figure 1. Representative examples of metal complexes of expanded porphyrins.

ure-eight conformations and revealed their facile complexation behaviors with several transition metal ions.[27] The figure-eight conformations were fixed upon complexation, which enabled optical separation of the metalated octaphyrins for the first time.[27a] Sessler et al. have investigated lanthanoid metal complexes of texaphyrins and medicinal applications of gadolinium texaphyrins as sensitizers for photodynamic therapy.[5,9] They synthesized the bis-$Cu^{II}$ complex of amethyrin and revealed the proximity of the metal centers and their antiferromagnetic behavior.[28] Recently, they have investigated the usage of expanded porphyrins as a colorimetric actinoid sensor.[29] Thus, expanded porphyrins are becoming increasingly important platforms for several metal ions and as promising materials in various fields. From this point of view, the *meso*-aryl-substituted expanded porphyrins can be regarded as another promising candidate to explore novel functional metal complexes since this facile, one-pot reaction affords a series of expanded porphyrins that differ in the number of the constituting pyrrolic subunits and thus in cavity size, conformational flexibility, and stable conformation.

In this Microreview we summarize our own contributions in the synthesis, characterization, and properties of metal complexes of *meso*-aryl-substituted expanded porphyrins, which are presented in order of their ring size. The compound names appearing in this review are partly based on a nomenclature put forward by Franck and Nonn for porphyrinic system.[30] The number in square brackets corresponds to the number of π-electrons in the shortest conjugation pathway and the core name represents the number of pyrroles.

## N-Fused Pentaphyrin ($NFP_5$)

### Structures and Properties of the Free Bases

*meso*-Pentafluorophenyl-substituted pentaphyrin was obtained as its N-fused form, whicht was found to exist as a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mixture of two oxidation states {[22]N-fused pentaphyrin ([22]$NFP_5$, **2a**) and [24]$NFP_5$ (**2b**); Figure 2} from the reaction shown in Scheme 1.[22,31] The yield of each compound varied depending on the oxidation time. Thus, **2a** was obtained after oxidation with an excess amount of DDQ for a long time (>15 h) in 18% yield as the sole pentapyrrolic product (Scheme 1).[31b] Alternatively, **2a** was prepared in 28% yield by an acid-catalyzed [3+2] condensation of tripyrrane and dipyrromethane (Scheme 4). Compound **2a** is easily reduced to **2b** with $NaBH_4$, which is quantitatively oxidized back to the original **2a** upon treatment with DDQ (Figure 2). An aromatic ring current effect arising from the 22π-electron conjugation is observed in the $^1H$ NMR spectrum of **2a**, while **2b** shows antiaromatic character due to its 24π-electron conjugation. According to X-ray diffraction analyses, both **2a** and **2b** possess a fused tripentacyclic ring (pyrroles A and B in Figure 3), an outward-pointing pyrrole ring (pyrrole C), and an inward-oriented dipyrromethene moiety (pyrroles D and E). The inverted pyrrole C is significantly tilted for each compound. Except for pyrrole C the entire structure of **2a** is planar, while that of **2b** is severely distorted.

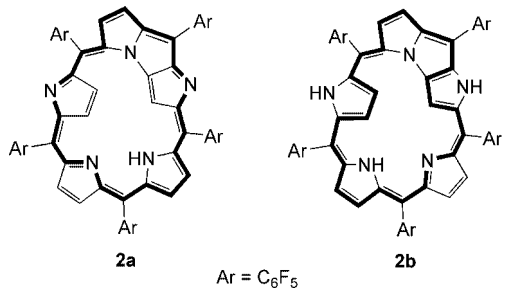

Figure 2. Redox behavior of $NFP_5$.

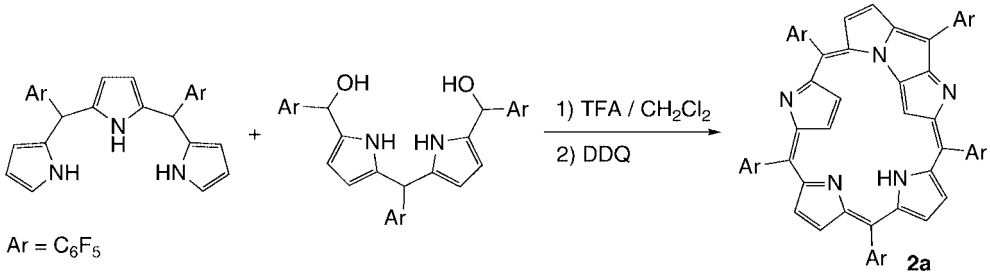
## Metal Complexes of $NFP_5$

Since both **2a** and **2b** possess a dipyrromethene moiety, we investigated complexation of $Rh^I$, which is known, in the coordination chemistry of porphyrinoids, to bind to one dipyrromethene ligand and two carbonyl ligands in a



Scheme 4. Synthesis of **2a** by a [3+2] condensation reaction.

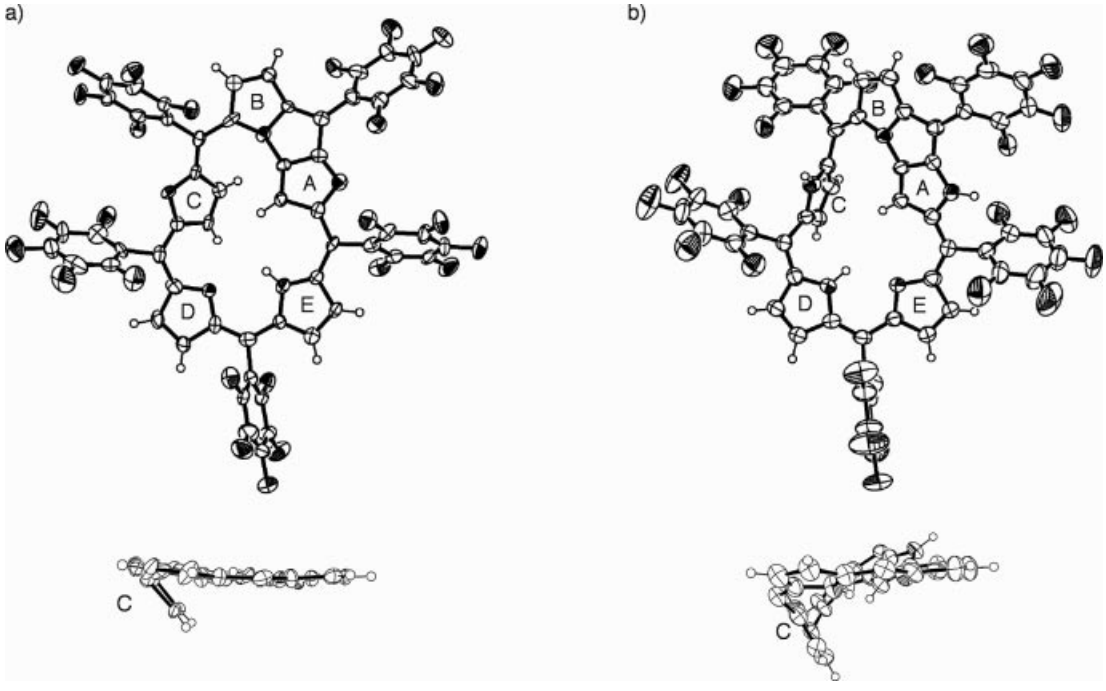


Figure 3. X-ray crystal structures of a) **2a** (preliminary) and b) **2b**; top views (top) and side views (bottom). *meso*-Aryl substituents have been omitted for clarity in the side views.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

square-planar fashion.[32–34] Two rhodium complexes **10** and **11** were isolated in 2.4% and 23% yields, respectively, from the metalation of **2a** with two equivalents of $[RhCl(CO)_2]_2$ in $CH_2Cl_2$ in the presence of sodium acetate at room temperature for 4 h (Figure 4).[31b] The product ratio of **11** to **10** decreased as the reaction time increased. Under refluxing conditions the yield of **10** (42%) was distinctly higher than that of **11** (18%). These results suggest that **10** is the thermodynamic product of this reaction. On the contrary, the complexation of **2b** with $[RhCl(CO)_2]_2$ gave complex **11** as the sole product in 60% yield at room temperature after 1 h.

In the crystal structures, both **10** and **11** preserve basic $NFP_5$ skeletons with a 22π- and 24π-electron conjugation, respectively, in which the $Rh^I$ ion is bound above the center of the cavity by the dipyrromethene unit (pyrroles D and E for **10** and pyrroles C and D for **11**), with N–Rh distances of around 2.1 Å, and two carbonyl ligands in a square-planar fashion (Figure 5). The entire structure of **10** is relatively planar except for the pyrrole C. On the other hand, **11** has a severely distorted bent conformation despite the fully conjugated system. In accordance with these results, the $^1H$ NMR spectrum of **10** displays peaks for the inner β-CH protons of pyrroles A and C as a singlet at $\delta$ = 0.05 ppm and as a pair of doublets at $\delta$ = 1.62 and 1.16 ppm, respectively, and the outer β-CH protons as three pairs of doublets at $\delta$ = 9.23, 9.21, 8.61, 8.29, 8.21, and 8.13 ppm that indicate a diatropic ring-current effect arising from the planar structure and 22π-electron conjugation. In the $^1H$ NMR spectrum of **11**, however, resonances due to the inner and outer NH protons of pyrroles E and A are observed at $\delta$ = 0.68 and 9.44 ppm, respectively, indicating, to our surprise, a substantial diatropic ring current for **11**, which is also supported by the up- and downfield shifts of the peaks due to the inner and outer β-CH protons, respectively.

Since complex **10** is the major product at high temperature, thermal conversion of **11** to **10** was examined in refluxing $CH_2Cl_2$; this reaction turned out to be unsuccessful. Considering that the number of conjugated π electrons is 22 for **10** and 24 for **11**, interconversion between these complexes by two-electron oxidation and reduction should be feasible. Thus, treatment of **11** with DDQ at room temperature quantitatively converted it into complex **10** by a novel pivot-like-walk rearrangement of Rh. The details of this process were monitored by $^1$H NMR spectroscopy, in which an intermediate **12** (Figure 4) was detected before the final formation of **10**. In contrast, reduction of **10** with $NaBH_4$ caused demetalation to give **2b** without producing **11**.

## Hexaphyrin

### Structures and Properties of the Free Bases

Hexaphyrin **3**, which was first synthesized by Cavaleiro and co-workers,[35] was one of the major products from the modified Rothemund–Lindsey reaction and was obtained in 16–20% yield as an oxidized form with 26π electrons in its conjugation (Scheme 1).[22] The yield was improved by using the ring-size selective synthesis.[24] Upon treatment with $NaBH_4$, [26]hexaphyrin (**3a**) was easily reduced to [28]-hexaphyrin (**3b**), which could be quantitatively oxidized back to the original [26]hexaphyrin (Figure 6). In the solid, **3a** exhibits a planar rectangular structure with two inverted pyrrole rings (Figure 7, a).[35] Although a structural analysis of **3b** unfortunately has not yet been successful, the structure of an analogue of **3b** bearing alkylamino substituents at the *p* position of the pentafluorophenyl groups and exhibiting almost identical UV/Vis and NMR spectra to **3b** was revealed crystallographically to possess a similar conformation to that of **3a**.[36] In solution, **3a** exhibits aromatic character due to the 26π-electron conjugation and planar conformation. On the other hand, the $^1$H NMR spectrum of **3b** indicates aromatic rather than antiaromatic character. The explanation for this is uncertain at this stage.

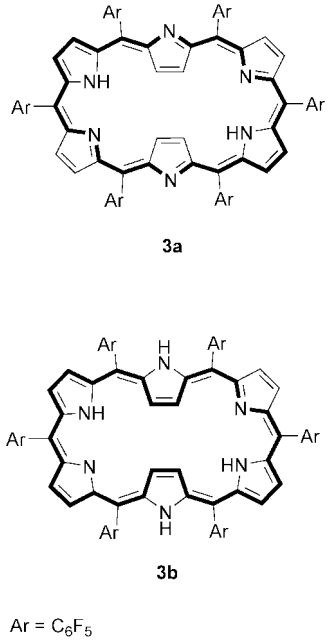

Figure 6. Redox behavior of hexaphyrin.

We have also investigated the synthesis of hexaphyrins bearing several substituents not only at the *meso* position but also at the β position. Perfluorinated [28]hexaphyrin (**7**) was isolated in 2–5% yield from a mixture of other perfluorinated expanded porphyrins obtained from the reaction of 3,4-difluoropyrrole with pentafluorobenzaldehyde.[23] In the solid state, **7** takes a figure-eight conformation and hence exhibits nonaromatic character (Figure 7, b). In addition to the coordination properties of these hexaphyrins, they are also drawing much attention as a near-IR absorbing dye.

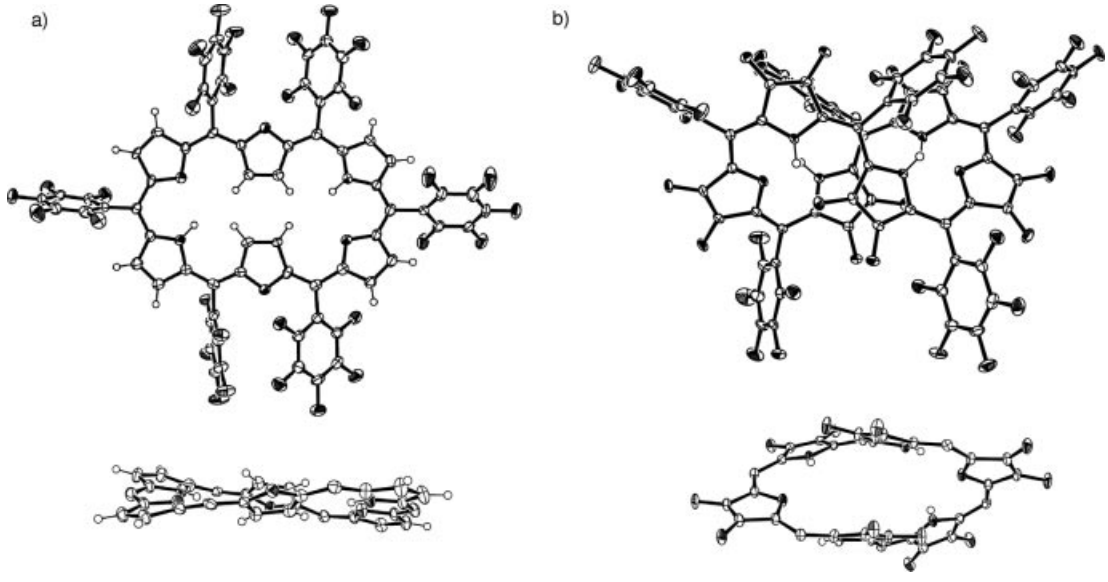

Figure 7. X-ray crystal structures of a) **3a** and b) **7**; top views (top) and side views (bottom). *meso*-Aryl substituents have been omitted for clarity in the side views.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The absorption spectrum of **3a** shows a Soret-like band at 568 nm and Q-like absorptions at 712, 898, and 1026 nm, and is formally similar to that of porphyrin although with substantial red-shifts owing to the extension of the π-conjugation.[11,35] Compound **3a** exhibits fluorescence emission at 1036 nm with a weak vibronic band at 1205 nm.[11] Recently, molecules having large two-photon absorption (TPA) cross-sections [$\sigma^{(2)}$] have been of great interest due to their potential applications in a variety of fields described in the previous section. Aromatic **3a** exhibits a large TPA cross-section value of about $10^4$ GM, which makes it quite attractive for further applications.[11]

### Copper Complexes of Hexaphyrins

The complexation reaction of **3a** with anhydrous $CuCl_2$ and NaOAc in $CH_2Cl_2$ gave the dicopper complex **13** in 84% yield.[37] Interestingly, metalation in the presence of anhydrous $Cu(OAc)_2$ and NaOAc led to isolation of a different dicopper complex **14** in 90% yield (Figure 8). Both structures were elucidated by X-ray single crystal analysis. The structure of **13** takes a gable structure with two semi-planar tripyrrolic planes in which each copper ion is bound to the bridging chloride atom, the oxygen atom attached at the *meso* position, and three nitrogen atoms of the tripyrrolic unit, in a square-pyramidal fashion (Figure 9, a). Compound **14** exhibits a similar gable structure with two copper ions, which are each bound to the *meso*-attached oxygen atom and three pyrrolic nitrogen atoms in a square-planar fashion (Figure 9, b). Contrary to complex **13**, there is no axial bridging in **14**.

Similar copper metalation was tested for perfluorinated [28]hexaphyrin (**7**). Complex **15** was obtained as the sole product (96% yield) from the reaction with $CuCl_2$, while metalation with $Cu(OAc)_2$ afforded a mixture of complex **15** and **16** in 26 and 56% yields, respectively (Figure 8). The structure of **15** is quite similar to that of **14**, while **16** takes a different structure in which the two copper ions are not directly bridged but are coordinated separately by the different tripyrrolic ligand and *meso*-attached oxygen atom (Figures 9, c and d). The oxygen ligands in **16** are from a tertiary alcohol and an alkoxide. Importantly, this structure leads to the assignment of **16** as a mixed-valence $Cu^I/Cu^{II}$ complex. The proximity of the two $Cu^{II}$ ions in **13**, **14**, and **15** allows antiferromagnetic couplings with exchange interaction values ($J$) of –8.27, –87.6, and –42.1 $cm^{-1}$, respectively. On the contrary, complex **16** has a temperature-independent $\chi_pT$ value (0.4229 emu K $mol^{-1}$) corresponding to an $S = 1/2$ state, in agreement with the $Cu^I/Cu^{II}$ mixed-valence state.

### Doubly N-confused [26]Hexaphyrin from [26]Hexaphyrin

In the course of their extensive investigations on N-confused porphyrinoids,[38] Furuta et al. have reported the synthesis of a doubly N-confused hexaphyrin (DNCH, **17**) bearing two oxygenated confused pyrrole rings, which offer efficient coordination sites for two transition metal ions such as $Cu^{II}$ **18** and $Ni^{II}$ **19** (Figure 10).[38c] Compound **17** and its bis-metal complexes are also attractive as near-IR-absorbing dyes due to their expanded π-electronic system but have been rather poorly explored, mainly due to the tedious, multi-step synthesis of the N-confused tripyrrane precursor.[38d] During our exploration of the metalation chemistry of hexaphyrin **3a**, we serendipitously found that treatment with $Cu^I$ under aerobic conditions in pyridine efficiently provided the bis-$Cu^{II}$ complex of DNCH (**18**; 24.4% yield), whose structure was confirmed by X-ray analysis (Figure 11, a).[39] Remarkably, both the inverted pyrrole rings of **3a** undergo simultaneous rearrangements to form N-confused pyrroles with concomitant oxygenation at the internal pyrrolic α positions. Although the reaction mechanism has not been elucidated yet, we anticipate the involvement of CuCl–pyridine–$O_2$ oxidation in this reaction on the basis of several experimental facts.

The bound copper ions are easily demetalated upon treatment with TFA in $CH_2Cl_2$ to give the free base **17**, which is a good ligand system for two divalent or trivalent metal ions ($Cu^{II}$ **18**, $Ni^{II}$ **19**, $Co^{II}$ **20**, $Zn^{II}$ **21**, $Mn^{III}$ **22**, and $Fe^{III}$ **23**; Figure 10). The $^1H$ NMR spectra of **17** and **21** display strong diatropic ring currents in line with their 26π aromatic conjugation. The absorption spectrum of **17** exhibits a Soret-like band at 566 nm with a shoulder at 586 nm and Q-like bands at 722, 793, 911, and 1047 nm. Interestingly, **17** shows fluorescence at 1058 nm, with a vibronic structure that has a very small Stokes shift. These observations suggest a rigid structure supported by multiple intramolecular hydrogen-bonding interactions.

### Group 10 Metal Complexes of Hexaphyrin

The copper complexes described above exhibit large structural changes upon metalation. Next, we investigated the complexation of hexaphyrin with group 10 metal ions such as $Ni^{II}$, $Pd^{II}$, and $Pt^{II}$.[40] When a toluene solution of **3a** and $Ni(acac)_2$ was refluxed for one hour in the presence of sodium acetate under anaerobic conditions the mono-$Ni^{II}$ complex **24** was obtained in 50% yield. Similarly, the mono-$Pt^{II}$ complex **27** was obtained in 56% yield from the reaction of **3a** with $PtCl_2$ and NaOAc in refluxing $CH_2Cl_2$ under argon. Curiously, however, metalation with $PdCl_2$ in refluxing $CH_2Cl_2$ in the presence of NaOAc provided a mixture of mono-$Pd^{II}$ (**25**) and bis-$Pd^{II}$ (**26**) complexes, which were isolated in 50 and 9% yields, respectively (Figure 12). Single crystal analyses revealed that complexes **24**, **25**, and **27** possess a metal–carbon bond and have distorted structures (Figures 13, a–c). The $^1H$ NMR spectra of **24**, **25**, and **27** show nonaromatic character due to the nonplanar structures. In the crystal structure of **26** the two $Pd^{II}$ ions are bridged by the chloride atom. One $Pd^{II}$ ion is bound to three pyrrolic nitrogen atoms and the other is bound to two pyrrolic nitrogen atoms and a pyrrolic α-carbon, and an N-fusion reaction of the pyrrole E and the adjacent pentafluorophenyl group has taken place to form a planar pentacyclic ring (Figure 13, d). Thus, the internal β-pyrrolic CH bond of **3a** is activated to form a metal–carbon bond in the metalation reactions with group 10 metal ions.

### Gold Complexes of Hexaphyrin

Metal complexes of hexaphyrin preserving the original planar and rectangular shape are of great interest from the viewpoint of regulation of aromaticity and antiaromaticity. Towards this goal, metal ions with a strong C–H activation ability would be promising. During the exploration of the complexation chemistry of hexaphyrins, we fortunately found that gold metalation of **3a** accomplished this goal to provide mono-$Au^{III}$ and bis-$Au^{III}$ complexes.[41] A solution of **3a** and $NaAuCl_4$ in a 4:1 mixture of $CH_2Cl_2$ and methanol was stirred in the presence of sodium acetate at room temperature for three days. Separation on a silica gel column provided the mono-$Au^{III}$ (**28**) and bis-$Au^{III}$ (**29**) complexes in 16 and 14% yield, respectively, along with 15% of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

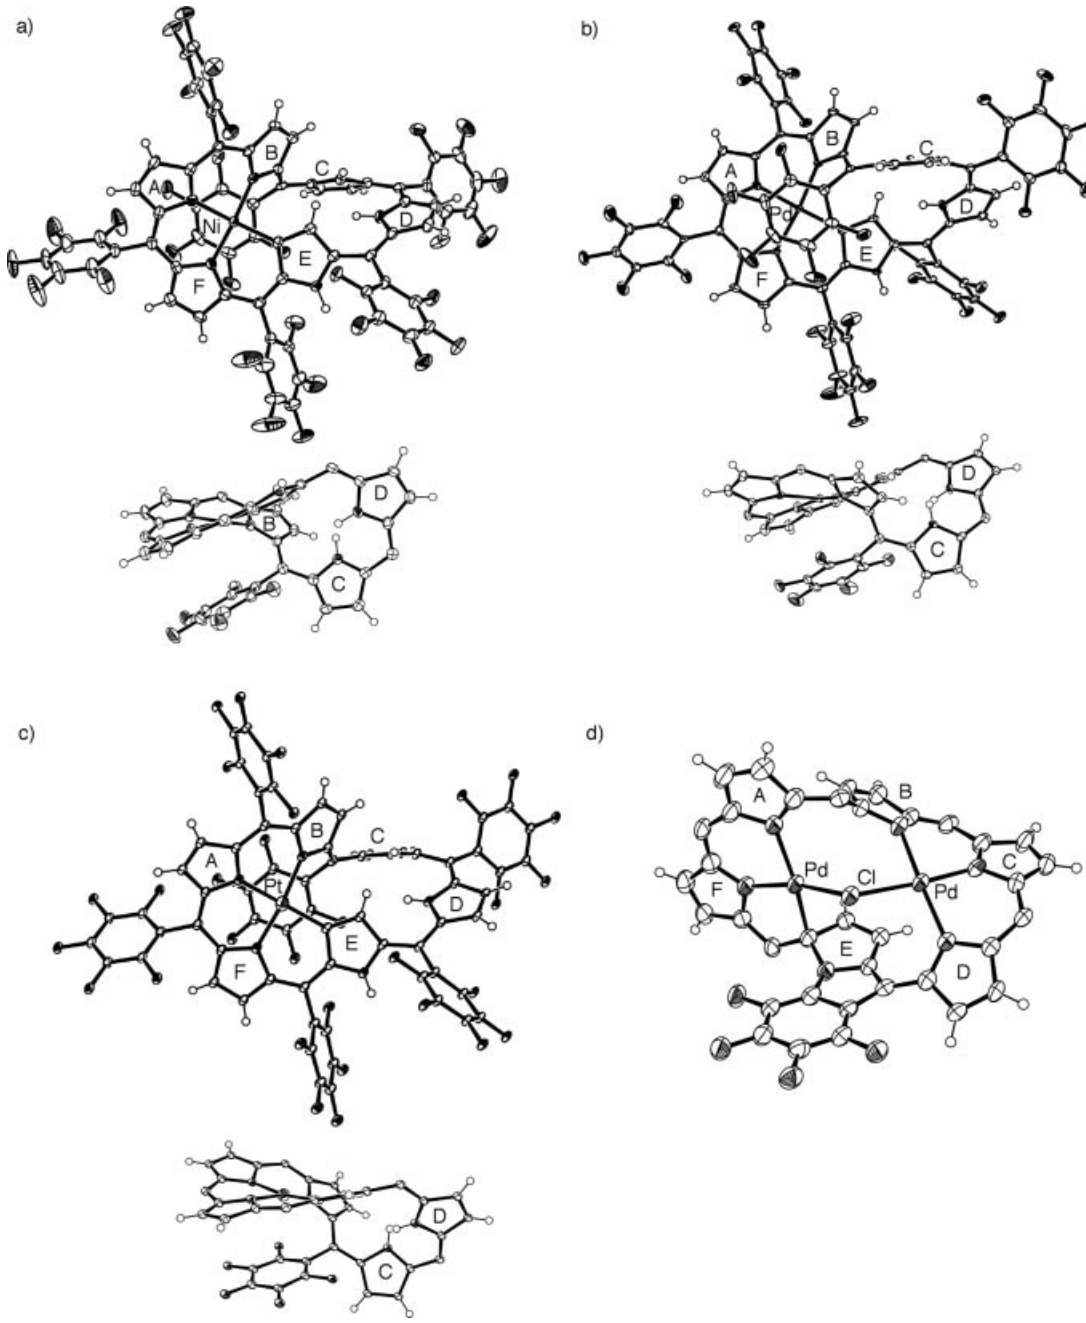

Figure 13. X-ray crystal structures of a) **24**, b) **25**, c) **27** (preliminary), and d) **26**; top views (top) and side views (bottom). *meso*-Aryl substituents have been partially omitted for clarity.

recovered **3a** (Figure 14). Curiously, in both crystal structures the inner β-CHs have been activated to form Au–C bonds and the $Au^{III}$ ions are coordinated to two pyrrolic nitrogen atoms and two pyrrolic β-carbon atoms within a flat [26]hexaphyrin core. The structure of **28** is planar in the coordinated moiety and rather distorted in the cavity, while **29** has a much more planar but overall bent structure (Figure 15). These structural differences can be explained by the steric congestion between the inner pyrrolic β-CHs. As anticipated from their crystal structures, aromaticity of these complexes was observed in their $^1$H NMR spectra. The outer β-CH protons of **28** appear downfield at $\delta$ = 9.51, 9.36, 9.35, and 9.03 ppm, and the inner β-CH and NH protons are seen at $\delta$ = –2.93 and –2.08 ppm, respectively, while for **29** the outer β-CH protons appear at $\delta$ = 9.66 and 9.51 ppm (Figures 16, a and b). Rigidification by Au coordination has been revealed to play a very important role in enhancing aromatic character, which, in turn, suggests a possible attainment of antiaromatic [28]hexaphyrin in the planar frame. Thus, complexes **28** and **29** were reduced with $NaBH_4$ to give complexes **30** and **31** without demetalation (Figure 14). The structures of **30** and **31** were both preliminarily revealed by X-ray analyses to keep the original rectangular structures but to have two NH hydrogen atoms at

the inverted pyrroles. Very curiously, and consistent with Hückel's rule, the $^1$H NMR spectra of **30** and **31** show a paratropic ring-current effect (Figures 16, c and d). In the $^1$H NMR spectrum of **30**, the inner β-CH and NH protons are observed at $\delta$ = 19.39 and 24.57 ppm, respectively, while the outer β-CH protons appear as four doublets at $\delta$ = 5.02, 4.92, 4.32, and 4.07 ppm and the outer NH protons appear at $\delta$ = 4.10 ppm. Similarly, the $^1$H NMR spectrum of **31** exhibits the outer β-CH protons as a pair of doublets at $\delta$ = 3.16 and 3.10 ppm and the outer NH protons as a broad singlet at $\delta$ = 1.81 ppm. Considering the nonaromaticity of the group 10 metal complexes **24**, **25**, and **27**, firm rigidification of the planar conformation causes the strong antiaromatic character in [28]hexaphyrin.

Complex **28** still has a vacant cavity that may allow coordination of another metal ion. This possibility was examined by treating **28** with $CF_3COOAg$ to give the $Au^{III}/Ag^{III}$ hetero complex **32** in 58% yield with concomitant oxidation of $Ag^I$ to $Ag^{III}$ in order to fit into the core.

## Octaphyrin

### Structures and Properties of the Free Bases

Due to its large conjugation, *meso*-aryl-substituted octaphyrin is supposed to possess three different redox states with 34π-, 36π-, and 38π-electrons (**5b**, **5a**, and **5c**, respectively, in Figure 17). From the reaction shown in Scheme 1, octaphyrin was obtained as [36]octaphyrin (**5a**) in 5–6% yield. The yield of **5a** was improved by using the ring-size selective synthesis.[24] In the crystal structure, **5a** takes a twisted figure-eight conformation in which there are two

porphyrin-like teterapyrrolic hemimacrocycles; it thus has the potential to coordinate one metal ion in each cavity (Figure 18, a).[22] Upon reduction with $NaBH_4$, **5a** is quantitatively converted into [38]octaphyrin (**5c**), while oxidation of **5a** with $MnO_2$ gives [34]octaphyrin **5b**. Unfortunately, however, the structures of [34]- and [38]octaphyrin have not been determined yet, mainly due to the their instability under ambient conditions. On the other hand, perfluorinated [36]octaphyrin (**9**) was obtained in 4–7% yield from the reaction of 3,4-difluoropyrrole and pentafluorobenzaldehyde.[23] Interestingly, **9** takes a different conformation: it is not twisted figure-eight but has a round ellipsoidal structure (Figure 18, b). Mainly due to their nonplanar structures, these octaphyrins do not exhibit any aromatic or antiaromatic character.

### Copper Metalation of [36]Octaphyrin and Perfluorinated [36]Octaphyrin

A solution of **5a** in toluene was stirred at 50 °C in the presence of ten equivalents of $Cu(OAc)_2$ and five equivalents of NaOAc and the metalation process was monitored by UV/Vis absorption spectroscopy. Compound **5a** exhibits absorption bands at 410 and 643 nm, which change to absorption bands at 412 and 668 nm after 2 h and then to absorption bands at 351 and 522 nm after 4 h (Figure 19). These spectral changes were ascribed to sequential formation of mono-$Cu^{II}$ (**33**) and bis-$Cu^{II}$ (**34**) complexes by comparison with the absorption spectra of authentic samples (Figure 20).[42] On further heating the small, shoulder-like absorption at 408 nm in the spectrum increased and finally

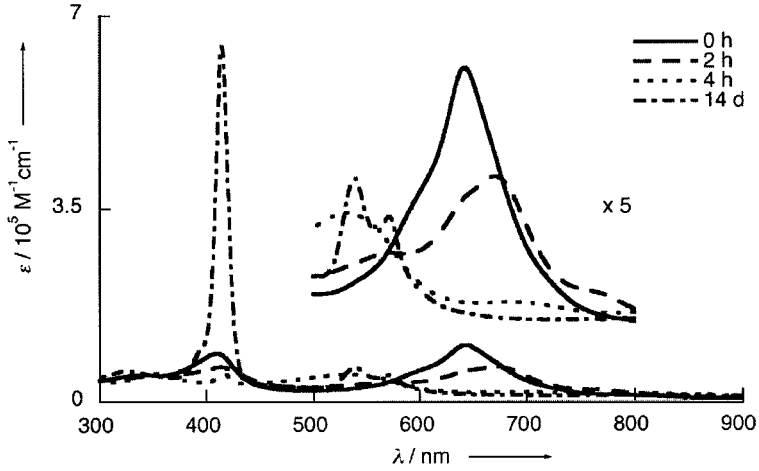

Figure 19. UV/Vis spectral changes recorded during metalation of **5a** with $Cu(OAc)_2$ at 50 °C in toluene.

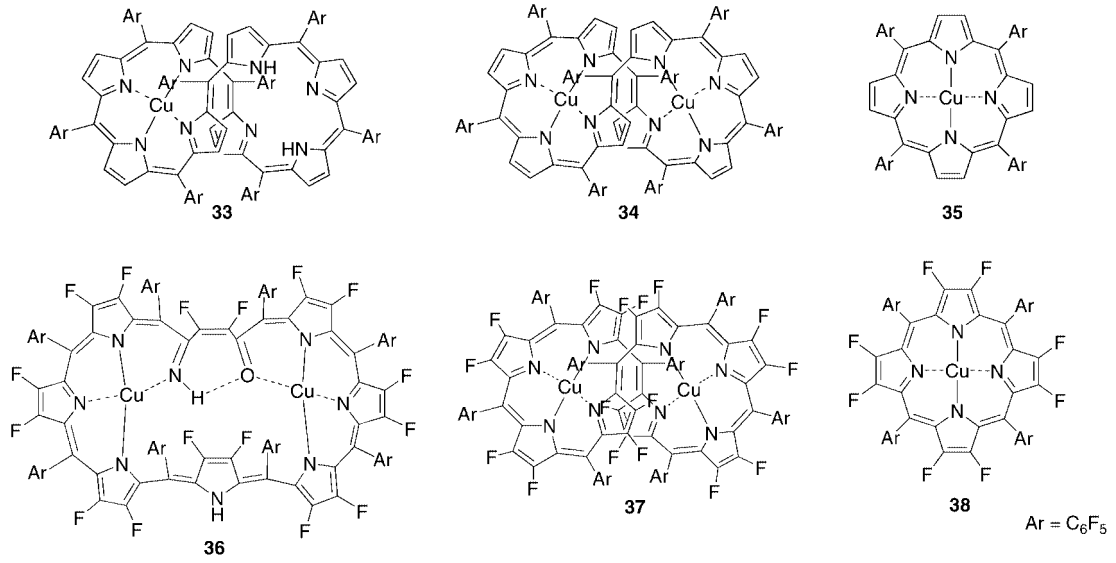

Figure 20. Copper complexes of octaphyrins and porphyrins.

the spectrum showed only the absorption at 408 nm with small bands at 535 and 570 nm after heating for two weeks (Figure 19). This final spectrum indicates the formation of the $Cu^{II}$ porphyrin **35** (Figure 20). The mono-$Cu^{II}$ complex **33** and the bis-$Cu^{II}$ complex **34** were prepared in 77 and 81% yields, respectively, under temperature-controlled conditions in a $CH_2Cl_2$ solution with a small amount of MeOH. In the solid state, **34** takes a similar twisted figure-eight conformation with two copper ions bound inside the porphyrin-like tetrapyrrolic cores. The coordination of the $Cu^{II}$ ions is severely distorted from square-planar coordination (Figure 21). Considering that neither free base **5a** nor **33** show splitting behavior, this structural feature suggests that the relief of strain in **34** may be the main driving force for this thermal splitting reaction.[42,43] We thus estimated the activation parameters of the splitting reaction by absorption spectroscopic analysis. The splitting reaction of **34** was found to be a unimolecular process with $\Delta H^{\ddagger}$ = 101 kJ mol$^{-1}$ and $\Delta S^{\ddagger}$ = –23.5 J K$^{-1}$ mol$^{-1}$. A possible mechanism of the splitting reaction may be a 2π + 2π cycloaddition process to give a spirocyclobutane intermediate, as shown in Scheme 5.

This thermal splitting reaction was also seen in the solid state. In the DSC experiment of **34**, a sharp exothermic re-

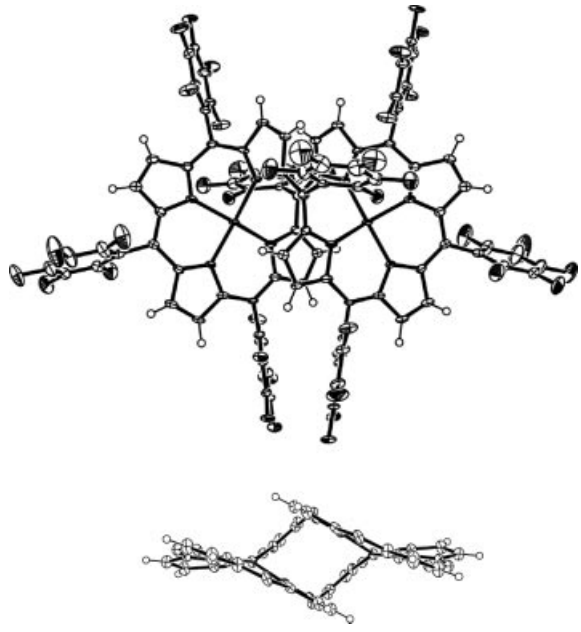

Figure 21. X-ray crystal structure of **34**; top view (top) and side-view (bottom). *meso*-Aryl substituents have been omitted for clarity in the side view.

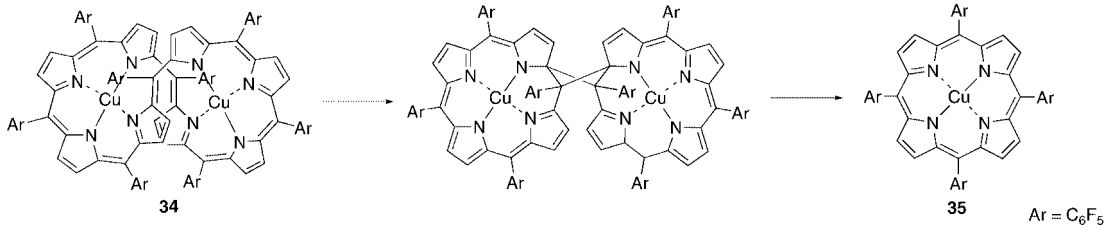

Scheme 5. A possible mechanism of the splitting reaction of **34**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sponse was observed between 240 and 280 °C, and **35** was obtained in high yield from this thermolysis experiment. The present thermal splitting reaction may be attractive for application as a recording device in light of the dramatic spectral changes and the perfect material balance. Fortunately, **34** was found to form a good transparent film when spin-coated onto quartz. A preliminary thermolysis experiment with this film indicated the more robust nature of **34** in the film up to 140 °C, but clean splitting into **35** at 200 °C.

A similar copper metalation reaction of perfluorinated [36]octaphyrin **9** revealed the formation of two bis-$Cu^{II}$ metal complexes **36** and **37** in 58 and 14% yields, respectively, when treated with $Cu(OAc)_2$ and NaOAc in $CH_2Cl_2$ solution (Figure 20).[44] The crystal structure of **36** was determined by single-crystal X-ray analysis (Figure 22). It takes a bent, U-shaped, ellipsoidal conformation in which one pyrrole ring is hydrolytically cleaved to give a keto-imine moiety. One of the two copper ions is bound to the keto-carbonyl oxygen atom and the nitrogen atoms of the nearby tripyrrolic subunit, while the other copper ion is bound to the imine nitrogen atom and the nearby second tripyrrolic subunit. The minor product **37** exhibits an absorption spectrum that is quite similar to that of **34**, and the high-resolution ESI-TOF mass spectrum indicated the formation of the bis-$Cu^{II}$ complex of perfluorinated [36]octaphyrin (**37**; Figure 20). Although efforts to obtain suitable crystals of **37** have been unsuccessful, these data suggest that **37** is a bis-$Cu^{II}$ complex with a figure-eight structure similar to that of **34**. Thus, we tested the thermolysis reaction of **37** both in $CH_2Cl_2$ solution and in the solid state. Upon heating in solution it goes hydrolysis to give **36** with concomitant decomposition, whereas, interestingly, thermolysis in the solid state led to splitting into **38**. During the copper metalation of **9**, one possible route to **36** may be initial formation of **37** followed by subsequent hydrolytic ring opening of one pyrrole ring facilitated by the strongly electron-deficient nature of the perfluorinated macrocycle.

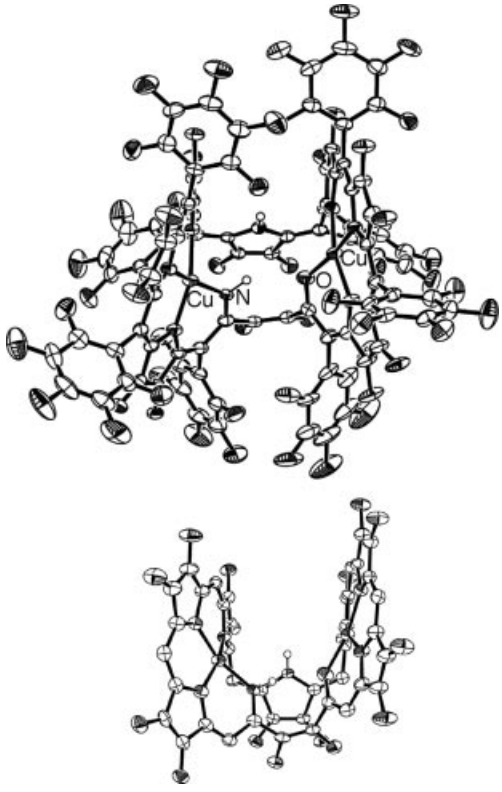

Figure 22. X-ray crystal structure of **36**; top view (top) and side view (bottom). *meso*-Aryl substituents have been omitted for clarity in the side view.

### Silver Metalation of [36]Octaphyrin and Perfluorinated [36]Octaphyrin

Among the transition metal ions tested, we found the complexation of **5a** and **9** with a salt of silver, a heavier congener of copper, proceeded smoothly without any skeletal rearrangement of the macrocyclic ring, in sharp contrast to the metalations with copper, to provide similar bis-silver complexes **39** and **40** almost quantitatively despite the different structures of the free base (Figure 23).[44] The bound silver ions are in the $Ag^{I}$ oxidation state judging from the coordination bond lengths and the diamagnetic nature of the complex observed in the $^1H$ NMR spectra, which indicates that [36]octaphyrin is oxidized to [34]octaphyrin by an excess amount of silver salt. The oxidized form acts as a divalent ligand to coordinate two $Ag^{I}$ ions. Both structures exhibit almost $C_2$-symmetric figure-eight conformations with two silver ions bound within porphyrin-like tetrapyrrolic cavities with Ag–N bond lengths in the range of 2.27–2.40 Å (Figure 24). Interestingly, pentafluorophenyl substituents at the crossing *meso* position lie just above the silver atoms in parallel with the tripyrrolic units, with interplanar distances of approximately 3.2 Å, while the β-substituents (hydrogen and fluorine atoms) of pyrroles D and H are placed below the silver ions with Ag–β-carbon distances of 2.89 and 2.87 Å for **39** and 3.14 and 3.16 Å for **40**. This proximity between the Ag ions and the substituents was supported by the additional through-space coupling with $Ag^{I}$ ($I$ = 1/2) observed in the $^1H$ and $^{19}F$ NMR spectra. Despite the figure-eight structures, which are similar to that of **34**, both **39** and **40** are thermally stable and do not exhibit the splitting reactivity observed for **34**. A major reason for this may be the 34π-electron system of **39** and **40**. Considering the instability of free base [34]octaphyrin

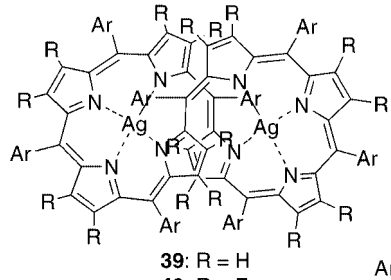

Figure 23. Bis-$Ag^{I}$ complexes of octaphyrins.

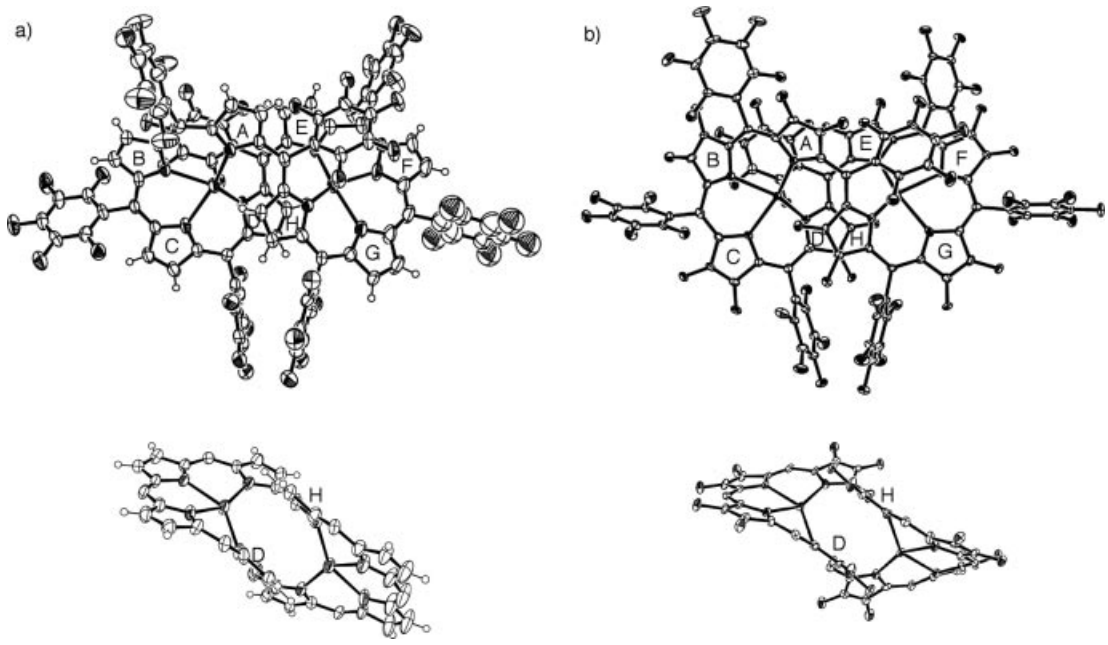

Figure 24. X-ray crystal structures of a) **39** and b) **40**; top views (top) and side views (bottom). *meso*-Aryl substituents have been omitted for clarity in the side views.

under ambient conditions, the oxidized octaphyrin ligands are stabilized by silver metalation. Despite the inertness of **39** and **40** upon heating, the Ag ions are easily removed upon reduction with $NaBH_4$ to provide the respective free base [38]octaphyrins.

## Summary and Outlook

The novel properties of the free bases and their metal complexes of expanded porphyrins have been revealed to be highly promising for various applications, including multimetal chelation, catalysis, receptors of anions and neutral molecules, PDT sensitizers, MRI contrast agents, and nonlinear optical materials. The serendipitous discovery of the facile, one-pot synthesis of *meso*-aryl-substituted expanded porphyrins has allowed the investigation of their fruitful coordination chemistry, which, however, still remains in its early stages. Investigation of their metal-complexation reactions and their fascinating properties for further applications is still in progress in our laboratory.

# A Novel 3D $Cu^{I}$ Metal–Organic Framework with Middle-Size Channels Despite the Sixfold $ThSi_2$ Interpenetrating Topological Structure

**Cheng-Zhi Xie,[a] Ze-Feng Zhang,[a] Bao-Feng Zhang,[a] Xiao-Qing Wang,*[a] Ru-Ji Wang,[a] Guang-Qiu Shen,[a] De-Zhong Shen,[a] and Bin Ding[b]**

**Keywords:** Metal–organic framework / Interpenetration / 1D channels / Topological structure / Copper / X-ray diffraction

A new univalent copper coordination polymer with an unusual asymmetric $ThSi_2$ topological structural network was synthesized and 1D middle-size channels were found despite the sixfold $ThSi_2$ interpenetrating topological structure.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

Recently, the assembly of metal–organic open frameworks (MOFs) has attracted great attention; MOFs with various network topologies have been prepared by using metal ions and organic building blocks. MOFs with flexible or rigid microporous channels have potential applications in selective molecular recognition and separation, physical gas storage, chemical absorption, ion-exchange and heterogeneous catalysis. Structural interpenetration has been widely used to design intriguing topologies in inorganic chemistry and may enhance the stability of porous materials.[1] Despite the simple and common formula, the rigid ligand 4,4′-bpy has been used extensively to ligate metal ions into an open framework of diamond-like networks[2] or networks with rectangular channels.[3]

In previous literature the hydrothermal method has been shown to be a promising technique for preparing highly stable, infinite metal–ligand frameworks.[4] It has been found that many interesting phenomena such as ligand oxidative coupling, hydrolysis, substitution and redox reaction, can occur under the in-situ hydrothermal conditions.[5] These reactions represent new routes for constructing novel coordination polymers. Encouraged by several recent reports showing that $Cu^{II}$ could be reduced to $Cu^{I}$ under basic hydrothermal conditions,[6] we synthesized a new 3D MOF copper(I) coordination polymer $[Cu_2(4,4'\text{-bpy})_2Cl](ClO_4)$ (**1**). A simple one-step synthesis procedure has been schematically illustrated in Figure 1.

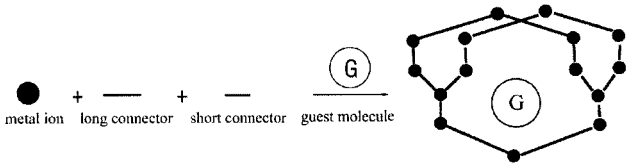

Figure 1. A schematic representation of the assembly of metal ions (dark spheres) and organic ligand connectors (dark rods: long connector; gray rods: short connector) to yield open frameworks with polygonal channels. The assembly is accompanied by the inclusion of a guest molecule G which occupies the void.

The hydrothermal reaction of $Cu(ClO_4)_2$ with 4,4′-bpy, pyrazine-2,3-dicarboxylic acid (or pyridine-2,6-dicarboxylic acid), and minor $CuCl_2$ led to the formation of a crystalline complex. The presence of the $Cu^{I}$ ion in the product indicates that the $Cu^{II}$ ion may act as an oxidant in a similar manner as shown in previous research in hydrothermal reactions.[6] Although the heterocycle carboxylic acids did not appear in the final complex **1**, they may change the pH value of the solution and therefore play a key role in the formation of the interpenetrating network. So it is quite different from the reported 2D structure of complex $[Cu_2Cl_2(bpy)]$.[5e] We synthesized the complex $[Cu_2Cl_2(bpy)]$ using a similar preparation procedure to complex **1** except that heterocycle multi-carboxylic acid is not involved in the starting material, and proved its structure by single-crystal X-ray diffraction.

X-ray single crystal analysis revealed that the actual crystal structure of complex **1** is a sixfold interpenetrating coordination network with a 3-connected $ThSi_2$ topological structure. This is in accordance with the fact that trigonal metal templates have a high tendency to form interpenetrated or self-inclusion compounds, if the cavities generated in this way are more than 50% of the crystal by volume.[7] In complex **1**, each $Cu^{I}$ ion in the 3D structure is

coordinated to two nitrogen atoms from two 4,4′-bpy ligands giving rise to a zigzag Cu–bpy chain. The chains are further connected to adjacent vertical chains via $\mu_2$-chlorine coordination bonds and extend into a 3D net as represented in Figure 2. The pyridyl rings and Cu atoms in the same chains are coplanar. The adjacent Cu–bpy–Cu chains are cross-linked in an almost perpendicular fashion (Cu1C···Cu1···Cu1A···Cu1D = 74.6°, as shown in Figure 3). The Cu–N and Cu–Cl distances [Cu1–N1 = 1.935(3) Å, Cu1–Cl1 = 2.3791(11) Å] are comparable with those found in [CuCl(bpy)],[8a] $[(CuCl)_2(C_{10}H_7N_3)]$,[8b] and $[Cu_2Cl_2(bpy)]$.[5e] The distances between the $Cu^I$ ions bridged by a Cl anion or by a 4,4′-bpy ligand are 4.758 and 10.968 Å, respectively. The shortest vector relating to adjacent nets equates to axis *a* (Cu···Cu inter-net distance of ca. 5.586 Å).

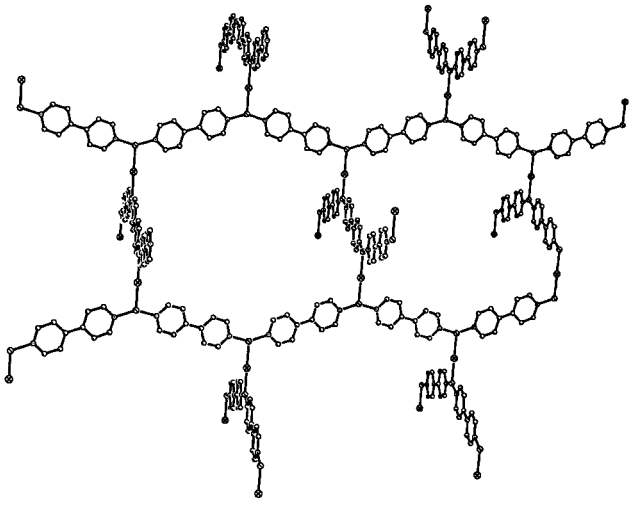

Figure 2. A view of a single framework of complex **1** with the perchlorate anion omitted.

Recent studies have shown the tendency of $Cu^I$ to form multi-dimensional structural units with halogen atoms and 4,4′-bpy under hydrothermal conditions. In these complexes the copper ions will always be four-coordinate and the structure will usually be 2D[5e,8–10] (except for complex [CuBr(bpy)][5e] that possesses a 3D structure formed by perpendicular interlocking 2D nets). To the best of our knowledge, no structurally characterized example of three-coordinate $Cu^I$ ions with bpy groups and hetero atoms has been documented to date. Compound **1** is a novel example of three-coordinate $Cu^I$ with bpy and $Cl^-$. It has a sixfold interpenetrating $ThSi_2$ topological structure of Class Ia with the interpenetration vector equating to axis *a*. This topological structure is rare, and the only known example is MOF $[Cu_2(4,4'\text{-bpy})_3](NO_3)_2(H_2O)_{1.25}$,[4a] but this has a different Class IIIa.

The most striking feature of complex **1** is that despite the sixfold interpenetrating 3D networks, complex **1** shows an unusual open framework containing middle-size hexagonal channels running along axis *a*, as shown in Figure 4 (the side lengths of the hexagonal channels are 4.16 and 6.66 Å, respectively). Guest perchlorate anions reside in the channels as counterions. The PLATON[11] programme reveals that the voids in complex **1** occupy 24.1% of the crystal volume (after the removal of the guest molecules). To compare the structural differences (especially in interpenetration) of complex **1** with $[Cu_2(4,4'\text{-bpy})_3](NO_3)_2(H_2O)_{1.25}$,[4a] we synthesized its isomorph $[Cu_2(4,4'\text{-bpy})_3](ClO_4)_2(H_2O)_2$ (**2**). From Figure 3, we can see that the interpenetration structures of the two polymers are different, while the latter possesses less channels as generally discussed in the literature.[4a] This is because of the two opposing rotations within the building unit of complex **2**: the pyridyl rings of two independent 4,4′-bpy rotate along the C–C single bond axis with dihedral angles of 33.3 and 40.1°; and the adjacent Cu–bpy–Cu chains are cross-linked with a lower angle (Cu1a···Cu1···Cu1c···Cu1e = 63.3°) compared to complex **1**.

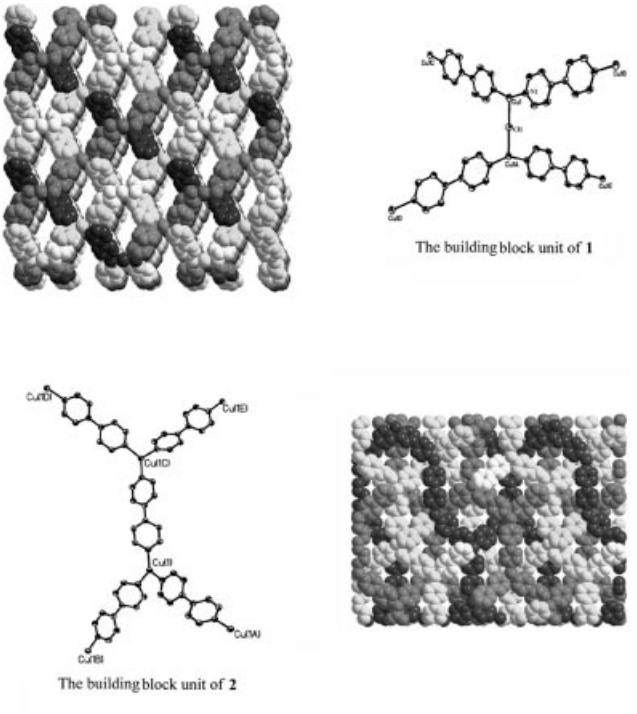

Figure 3. Schematic views of the 3D interpenetrating networks of complexes **1** (top) and **2** (bottom) along axis *a* showing the 1D channels.

Complex **1** is very stable in air at ambient temperature and is almost insoluble in common solvents such as water, alcohol, acetonitrile, chloroform, acetone, and toluene, being consistent with its polymeric nature. Thermal gravimetric analysis (TGA) from 80 to 500 °C indicates that complex **1** is thermally stable up to 240 °C (see Supporting Information, Figure S1). After heating a sample of complex **1** directly to 200 °C and keeping it for 1 h in an oven, the framework remains intact [monitored by X-ray powder diffraction (XRPD), see Supporting Information, Figure S2]. No signal was found in the ESR spectrum for complex **1**, which confirms that all the copper atoms in complex **1** are univalent.

In summary, a novel three-coordinate $Cu^I$ polymer possessing a sixfold interpenetrating 3D $ThSi_2$ topological

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

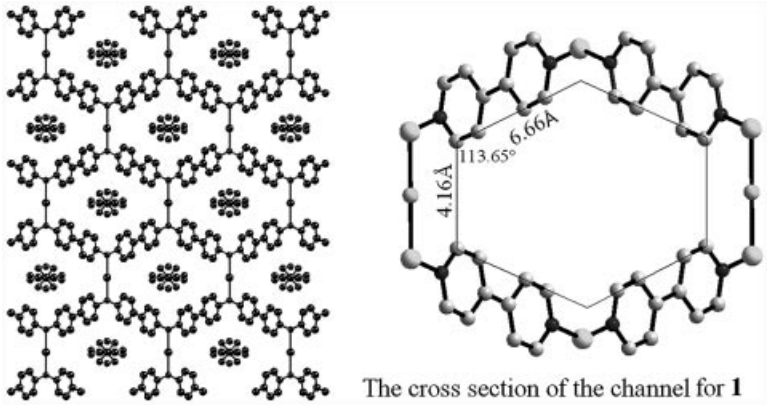

Figure 4. A ball and stick diagram of complex **1** showing the 1D channels formed by interpenetration.

structure was synthesized under hydrothermal conditions and characterized. Middle-size 1D channels were formed in the complex. To the best of our knowledge, there is no previous example of MOFs forming with mixed connectors containing the $ThSi_2$ topological structure.[12,13] The compound forms a 3-connected network with novel topology that has implications for understanding the relationship between related nets.

## Experimental Section

**General Remarks:** All chemicals were obtained from commercial sources and used as received. The C, H, N microanalyses were carried out with a Vario EL elemental analyzer. The IR spectra were recorded with a Magna-IR 750 spectrophotometer using the KBr pellet technique. Thermal gravimetric analysis (TGA) was carried out with a Perkin–Elmer TGA 7 thermogravimetric analyzer in $N_2$ condition with a heating rate of 10 °C min$^{-1}$. The electron paramagnetic resonance (EPR) powder spectrum was recorded at X-band with a Bruker ER 200B spectrometer. Powder XRD was performed with a Bruker D8 Advance X-ray diffractometer with monochromatized Cu-$K_\alpha$ radiation ($\lambda$ = 1.5418 Å).

### Preparations

**Synthesis of $[Cu_2(4,4'\text{-bpy})_2Cl](ClO_4)$ (1):** A mixture of $Cu(ClO_4)_2\cdot 6H_2O$ (0.186 g, 0.5 mmol), pyrazine-2,3-dicarboxylic acid (0.084 g, 0.5 mmol), 4,4′-bpy (0.096 g, 0.5 mmol), $CuCl_2$ (0.017 g, 0.1 mmol), and water (18.0 mL) in the molar ratio of 5:5:5:1:10000 was sealed in a 25-mL stainless steel reactor with Teflon liner, and heated directly to 180 °C. After being kept at 180 °C for 72 h, it was cooled slowly to 30 °C at a rate of 2 °C/h. From a large quantity of red deposit, the resulting orange block crystals of **1** were separated, washed, and dried in air (yield ca. 10% based on Cl). Replacing pyrazine-2,3-dicarboxylic acid by equivalent pyridine-2,6-dicarboxylic acid, the same crystals were obtained (yield ca. 5% based on Cl). $C_{10}H_8ClCuN_2O_2$ (287.17): calcd. C 41.83, H 2.81, N 9.76; found C 41.65, H 2.55, N 9.52. The pH value of the residuary solution is 4. IR (KBr): $\tilde{\nu}$ = 3441, 3070, 3042, 1635, 1601, 1526, 1482, 1408, 1326, 1215, 1109, 1084, 963, 817, 799, 724, 673, 625, 475.

**Synthesis of $[Cu_2(4,4'\text{-bpy})_3](ClO_4)_2(H_2O)_2$ (2):** A mixture of $Cu(ClO_4)_2\cdot 6H_2O$ (0.186 g, 0.5 mmol), 4,4′-bpy (0.096 g, 0.5 mmol), KI (0.083 g, 0.5 mmol), and water (18.0 mL) in the molar ratio of 1:1:1:1000 was sealed in a 25-mL stainless steel reactor with Teflon liner, and heated directly to 180 °C. After being kept at 180 °C for 72 h, it was cooled slowly to 30 °C at a rate of 2 °C/h. The resulting brown block crystals of complex **2** were washed and dried in air (yield ca. 15% based on Cu). $C_{15}H_{14}ClCuN_3O_5$ (830.56): calcd. C 43.34, H 3.37, N 10.11; found C 42.98, H 3.51, N 9.89. IR (KBr): $\tilde{\nu}$ = 3392, 3075, 3044, 1600, 1530, 1483, 1409, 1322, 1217, 1087, 818, 799, 673, 625, 473.

### X-ray Crystallography

**Crystal Data for Complex 1:** $C_{10}H_8ClCuN_2O_2$, $M$ = 287.17, orthorhombic, space group *Pnnn*, $a$ = 5.5864(18) Å, $b$ = 12.769(4) Å, $c$ = 15.621(5) Å, $V$ = 1114.3(6) Å$^3$, $Z$ = 4, $Dc$ = 1.712 g cm$^{-3}$, $\mu$ (Mo-$K_\alpha$) = 2.183 cm$^{-1}$, $F$(000) = 576, 1144 reflections measured, 829 [$I \geq 2\sigma(I)$] unique reflections were used in all calculations. The final $R_1$ = 0.0508, $wR_2$ = 0.1341, $S$ = 1.086.

**Crystal Data for Complex 2:** $C_{15}H_{14}ClCuN_3O_5$, $M$ = 415.28, orthorhombic, space group *Fddd*, $a$ = 18.747(2) Å, $b$ = 23.355(3) Å, $c$ = 30.404(4) Å, $V$ = 13312(3) Å$^3$, $Z$ = 16, $Dc$ = 1.658 g cm$^{-3}$, $\mu$ (Mo-$K_\alpha$) = 1.505 cm$^{-1}$, $F$(000) = 6752, 6258 reflections measured, 3839 [$I \geq 2\sigma(I)$] unique reflections were used in all calculations. The final $R_1$ = 0.0520, $wR_2$ = 0.1034, $S$ = 1.054. Data collections ($2.61 \leq \theta \leq 24.83°$ for complex **1**, $2.20 \leq \theta \leq 33.54°$ for complex **2**) were performed at 293 K with a Bruker SMART 1000 CCD diffractometer (Mo-$K_\alpha$, $\lambda$ = 0.71073 Å). The structures were solved with direct methods (SHELXS-97) and refined by full-matrix least-squares (SHELXL-97).

CCDC-227621 (for complex **1**) and -292359 (for complex **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (for details see the footnote on the first page of this article): TGA curve and X-ray powder diffration pattern of **1**.

# Decameric Water Clusters Shaped as Two Parallel Cyclic Pentamers with Staggered Conformation Stabilize Supramolecularly Bonded Infinite Chains of $H_2PO_4^-$ Ions

**Sujit K. Ghosh[a] and Parimal K. Bharadwaj*[a]**

**Keywords:** Dibasic phosphate chain / Cryptands / Supramolecular chemistry / X-ray diffraction / Water cluster

A laterally nonsymmetric aza-cryptand on acidification with $H_3PO_4$ affords an H-bonded infinite chain of $H_2PO_4^-$ ions. These chains are aligned parallel through H-bonding interactions with discreet decameric water clusters leaving large void spaces. Diprotonated cryptand molecules occupy these voids through supramolecular interactions. The crystal data for the compound are: triclinic space group $P\bar{1}$, $a$ = 12.765(5), $b$ = 13.254(2), $c$ = 13.817(4) Å, $V$ = 2137.3(14) Å$^3$, $Z$ = 2, $R1$ = 0.0582, $wR2$ = 0.1339, $S$ = 1.092.

## Introduction

The phosphate ion is an essential nutrient in biosystems and is transported by a phosphate-binding protein (PBP) that forms a strong H-bond with the mono- or dibasic form of phosphate.[1] Phosphate groups are frequently found with enzyme substrates or co-factors. It is not clear whether water plays any role in the translocation of inorganic phosphate across the cell membrane or in the formation of enzyme–substrate complexes. In DNA, water molecules are concentrated in six hydration sites per phosphate group and the positions as well as the occupancies of these sites are dependent on the conformation and nature of the nucleotide in addition to the type of DNA itself.[1] A water molecule exhibits uncertainty over the number of H-bonding interactions and their fluctuations with other water molecules−both of which are responsible for the anomalous behavior of bulk water. However, this diversity of H-bonding interactions is very important in the biological world as it can enforce a delicate balance among several possible conformations of an enzyme essential for its functional role(s). Recent years have witnessed both theoretical[2–5] and experimental[6–8] scrutiny of a number of small water clusters in different surroundings to investigate the development of properties of the condensed phase in a step-wise manner. We present here the structure of water decamers in the confinement of infinite H-bonded quasi-parallel chains of dibasic phosphates. Theoretical calculation[9] by Buck et al. had suggested that the minimum energy conformation for the decamer was as an octameric cube with two water molecules fused at one of the edges, while a more recent calculation showed two fused parallel pentamers to be energetically the most stable.[10] An ice-like diamondoid decamer[11] has been identified in a self-assembled metal-organic cage,[11d] while a water decamer in the form of two fused parallel cyclic pentamers with staggered conformation has been characterized[11c] in an organic host built from 5-hydroxyisophthalic acid and 18-crown-6. Supramolecular associations of water molecules forming a 3D structure with voids are potentially important for entrapment of molecules of interest if the water molecules can be removed without drastically altering the overall structure.

## Results and Discussion

Compound **1** is isolated as colorless crystals when an aza-cryptand (Scheme 1) is dissolved in water by dropwise addition of phosphoric acid. In the asymmetric unit (Figure 1), diprotonated cryptand, two $H_2PO_4^-$ anions, and seven water molecules are found. One of the water molecules (Ow7) is H-bonded inside the cryptand cavity, while another (Ow6) is H-bonded to the cryptand from outside. This molecule (Ow6) acts as an H-bond acceptor to one of the protonated amino nitrogen atoms of the cryptand arm with the N···O distance of 2.789 Å. This water molecule also forms an H-bond with $H_2PO_4^-$. The five remaining water molecules (Ow1–Ow5) describe a quasi-planar cyclic structure that eventually forms a decameric unit with five other centrosymmetrically related water molecules (Figure 2). The two pentameric cycles are oriented parallel to each other with a staggered conformation. Although this is a higher energy structure, it is stabilized by the environment. The $H_2PO_4^-$ anions form infinite H-bonded chains that run almost parallel to one another and the water deca-

mers connect these chains through strong H-bonding interactions (Table 1) forming almost rectangular voids (approximate dimension 13.2×7.5 Å) that are occupied by cryptand molecules (Figure 3). The water molecule Ow4 of the cyclic pentamer acts as an H-bond acceptor to the cryptand, while the remaining four are H-bonded to the $H_2PO_4^-$ chains. The cryptand shows only weak interactions with the phosphate chains and the water molecules act as a glue holding together both the phosphate chains and the cryptands leading to the supramolecular assembly (Figure 4). The two parallel pentamers are connected at two positions

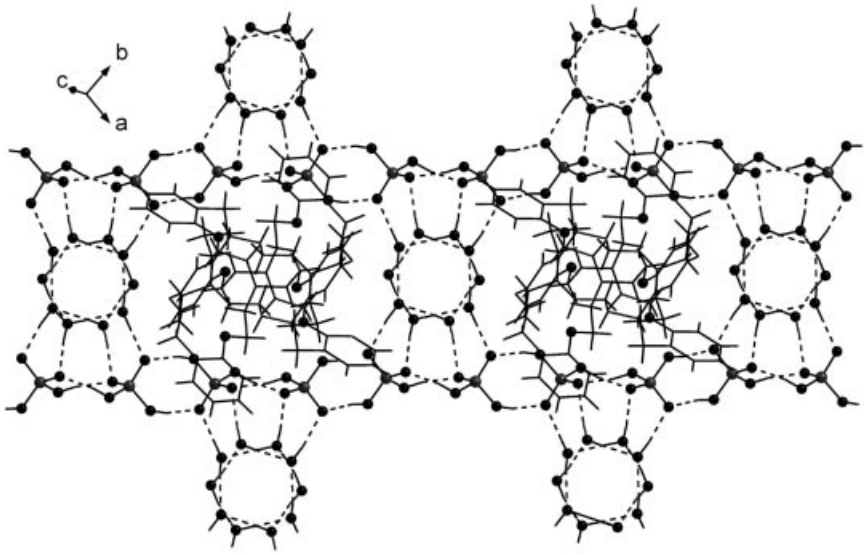

Figure 3. View showing chains of $H_2PO_4^-$ anions connected by water decamers with cryptand molecules occupying voids.

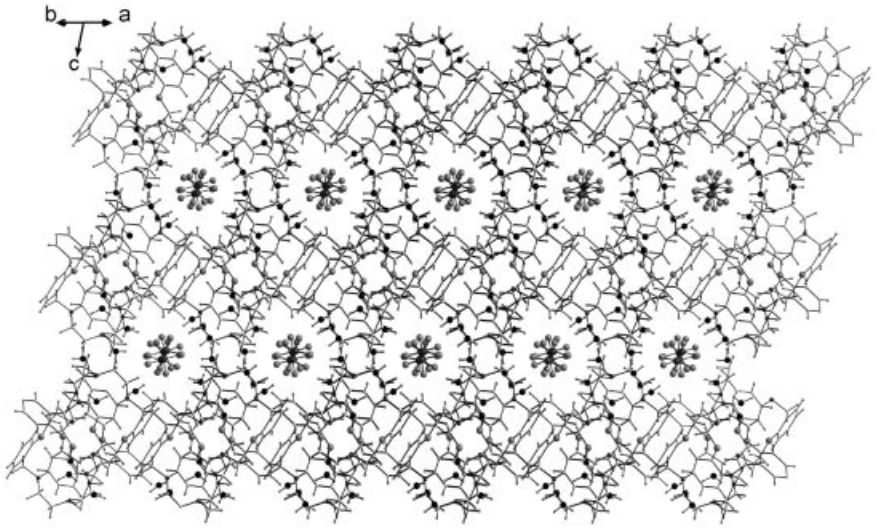

Figure 4. Self-assembled structure of compound **1** viewed along the phosphate chains.

through H-bonding and these four O atoms exhibit tetra-coordination while the rest are tri-coordinated. Such hydrogen-bond-deficient water molecules are, however, present[12,13] at the surface of liquid water or hexagonal ice. A wide range of O···O distances are observed (2.736–2.894 Å) in the present cluster as the water molecules adjust to the surroundings.

In the FTIR spectrum of compound **1**, a broad peak appears centering around 3420 $cm^{-1}$ attributable[14] to the water cluster. Thermal analysis of compound **1** shows that it begins to lose weight after ca. 50 °C without showing any plateau region.

## Conclusion

In conclusion, we have characterized a novel water decamer in the shape of two parallel five-membered staggered rings. These decamers glue quasi-parallel diphosphate chains resulting in large voids that are occupied by cryptand molecules.

## Experimental Section

**Materials:** All the reagent-grade chemicals were used without purification unless otherwise specified. Triethanolamine, salicylaldehyde, tris(2-aminoethyl)amine, and sodium borohydride were obtained from Aldrich. Sodium hydroxide, anhydrous sodium sulfate, phosphoric acid, and thionyl chloride were received from S. D. Fine Chemicals (India). Thionyl chloride and all the solvents were freshly distilled prior to use.

**Physical Measurements:** Spectroscopic data were collected as follows: IR (KBr disk, 400–4000 $cm^{-1}$): Perkin–Elmer Model 1320; thermogravimetric analysis (heating rate of 5 °C/min): Mettler Toledo Star System. Microanalysis data for the compound were obtained from CDRI, Lucknow.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Synthesis of $[LH^{+2}{\cdot}2H_2PO_4^{-2}{\cdot}7H_2O]$ (1):** The cryptand L was synthesized as reported previously.[15] The cryptand was dissolved in water by dropwise addtion of phosphoric acid, and the resulting solution, upon slow concentration at room temperature, afforded pale yellow rectangular parallelepiped crystals of $[LH^{+2}{\cdot}2H_2PO_4^{-2}{\cdot}7H_2O]$ (**1**) in 60% (0.530 g) yield. $C_{33}H_{65}N_5O_{18}P_2$ (881.84): calcd. C 44.94, H 7.43, N 7.94; found C 44.91, H 7.52, N 8.01.

**X-ray Structural Studies:** The X-ray data were collected with a Bruker SMART APEX CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation (0.71069 Å). Data collection and its reduction were achieved with SMART (version 5.628) and SAINT (version 6.45). The structure was solved by direct methods and refined on $F^2$ using the SHELX-97 package.[16] All the H atoms bonded to water O were located in the difference Fourier maps. The non-hydrogen atoms were refined anisotropically. The H atoms were not refined. Crystal data for **1**: pale yellow, rectangular parallelepiped, crystal dimensions $0.19 \times 0.15 \times 0.12$ mm, triclinic, $P\bar{1}$, $Z = 2$, $a = 12.765(5)$, $b = 13.254(2)$, $c = 13.817(4)$ Å, $V = 2137.3(14)$ Å$^3$, $\rho_{cald.} = 1.37$ g cm$^{-3}$, $T = 100$ K, $\mu = 0.18$ mm$^{-1}$, $\theta_{max} = 28.32°$. A total of 14357 reflections collected, of which 7784 were unique, $R1 = 0.0582$, $wR2 = 0.1339$, GOOF = 1.092 for $I > 2\sigma(I)$, residual electron density: 0.512 and –0.548 e Å$^{-3}$. CCDC-287356 contains the supplementary crystallographic data for this paper. These data can be obtained from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Figure showing the water clusters viewed along the phosphate chains.

# Photoinduced Phase Transition of the Coordinationally Unsaturated $d^9$ Metal Centers of Bis(*N*,*N*-diethylethylenediamine)copper(II) Perchlorate within the Thermal Hysteresis of the Spin-Exchange Interaction

**Panče Naumov,*[a,b,c] Kenji Sakurai,[d] Toru Asaka,[e] Alexei A. Belik,[a] Shin-ichi Adachi,[c,f] Junichi Takahashi,[c,f] and Shin-ya Koshihara[c,f,g]**

**Keywords:** Photoinduced phase transitions / Jahn–Teller effect / Photodiffraction / Photochromism / Thermochromism

Diffraction evidence is presented that the structure of one-dimensional arrays of strained, coordinationally unsaturated $d^9$ pseudo-Jahn–Teller centers of bis(*N*,*N*-diethylethylenediamine)copper(II) perchlorate is affected by excitation of the LMCT bands within the hysteresis region of a low-temperature ferromagnetic-to-antiferromagnetic phase transition.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

Novel materials with physical properties that can be efficiently controlled by light is one of the main goals of modern materials science.[1] Particularly interesting are the solid-to-solid phase transitions which can be induced by light, termed photoinduced phase transitions.

In some cases, such as the photoinduced metal–insulator phase transitions of organic one-dimensional molecular complexes,[2–4] the solid-state cooperativity enables very high efficiencies (more than one hundred molecules can be converted per absorbed photon through a domino-like mechanism), as well as ultra-fast photoresponses (picosecond scale). These two exotic properties are very prospective as a basis for the design of ultrafast devices that operate in the photon mode. Therefore, in addition to their importance for understanding fundamental solid-state phenomena, photoinduced phase transitions are very important for future applications in ultrafast photoelectronics. However, the number of known compounds undergoing photoinduced phase transitions is limited. The most studied are a group of iron complexes capable of light-induced spin-crossover[5,6] and organic molecular complexes similar to tetrathiafulvalene-chloranil which undergo light-induced intermolecular charge transfer followed by metal-to-insulator transition.[2–4] In this paper we report on a new strategy to build systems capable of photoinduced phase transition.

Nonlinear molecules with a partially filled set of degenerate orbitals are inherently Jahn–Teller (JT) unstable,[7] an effect which is considered to underpin important phenomena such as high-temperature superconductivity[8] and colossal magnetoresistance.[9] In this study, a pseudo-JT crystal composed of $d_{z^2}$ arrays of coordinationally unsaturated copper(II) ions was utilized as a potentially light-susceptible medium for which significant structural perturbations are expected upon excitation.

As a coordinationally unsaturated unit, the *trans*-square-planar bis(*N*,*N*-diethylethylenediamine)copper(II) cation in its perchlorate salt, $[Cu(dieten)_2](ClO_4)_2$, was selected (Figure 1A).[10] The bulky *gem*-dialkylamine ligands play multiple structural roles: first, they determine the square-planar geometry by shielding the apical metal valences from the approach of the anions beyond nonbonded distances; second, they effectively space out the metal ions, preventing dimerization; and third, they provide sufficient flexibility for distortions of the primary coordination sphere. The resulting instability can be compensated by pressure[11] or by heating above 317.6 K,[12] where the internal strain overweighs the energy gain from the electronic state ordering and the respective lattice distortions, resulting in spontaneous transition of the triclinic lattice ($P\bar{1}$, A) to a monoclinic one ($I2$, B) with doubled volume and tetrahedral distortion of the square-planar ligand plane (Figure 1).[13] Cooling of the crystal from ambient temperature results in a gradual change of the red color to orange, due to continuous change of the ligand field strength of the metal.[12]

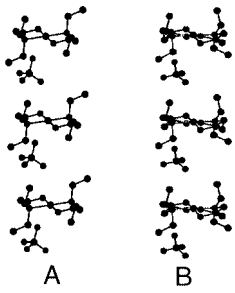

Figure 1. Structure of one-dimensional cationic chains in the low-temperature ordered (A) and high-temperature disordered (B) phases of $[Cu(dieten)_2](ClO_4)_2$ from single-crystal diffraction data.

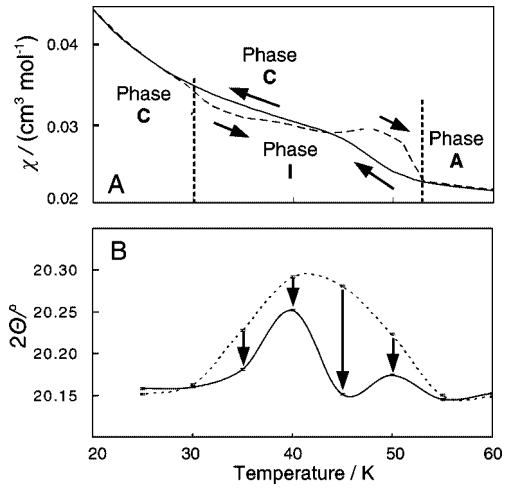

Figure 2. (A) Magnetic susceptibility recorded with the magnetic field vector $\perp\{100\}$ face of a $[Cu(dieten)_2](ClO_4)_2$ crystal cycled at low temperature (solid line: cooling, dashed line: heating). (B) Thermal profile of the position of the $(1\bar{1}0)$ reflection before (dotted line) and after (solid line) 1 s excitation with polychromatic UV light ($\lambda_{max}$ = 365 nm). The sample was annealed by heating to 300 K between each two temperatures. The abscissa is the same for both plots.

The magnetic susceptibility (see Experimental Section) of $[Cu(dieten)_2](ClO_4)_2$ single crystals cycled thermally in the dark below the phase transition A↔B (2–300 K) exhibits reproducible anomalies at low temperature (Figure 2A). On cooling ( ↓ ) from ambient temperature, a single-step transition occurs at 48 K ($T_\downarrow$), with onset at 60 K. During subsequent heating ( ↑ ) from 2 K to 300 K, the susceptibility is recovered in two steps between 25 and 57 K: at 30 ($T_{\uparrow,1}$) and 52 K ($T_{\uparrow,2}$). The hysteresis is reproducible by repeated thermal cycling with the magnetic field vector oriented perpendicular to each of the three crystal faces. The modified Curie–Weiss model[14] reveals a change of the weak-exchange interaction at $T_\downarrow$ from the high-temperature ferromagnetic regime I, phase A [80–290 K, $\Theta$ = 2.6(3) K, $\mu_{eff}$, $g$ = 1.743(3), 2.0126, $\chi_o$ = –3.36(3)·10$^{-4}$ cm$^3$/Cu-mol], to a low-temperature antiferromagnetic regime II, phase C [2–28 K, $\Theta$ = –0.467(15) K, $\mu_{eff}$, $g$ = 1.916(2), 2.2124, $\chi_o$ = –1.0(4)·10$^{-5}$ cm$^3$/Cu-mol], with hysteresis in the range 25–55 K. The two steps at $T_{\uparrow,1}$ and $T_{\uparrow,2}$ resolved on heating reveal that the one-step transition at $T_\downarrow$ on cooling from region I to region II involves two simultaneous processes. From the two steps on heating, the one at $T_{\uparrow,1}$ probably corresponds to switching of the exchange interaction of the antiferromagnetic phase C in region II to an intermediate phase in region III, which, by structural change of the lattice at $T_{\uparrow,2}$, is transformed back to the lattice A in region I.

From the combination of internal strain and the weak electronic coupling along the one-dimensional cationic chains, it is expected that local perturbations of this structure in the region of bistability are feasible and that they might influence the long-range structural order. In order to test this hypothesis, the effect of photoexcitation was examined with a specially designed system for temperature-controlled powder photodiffraction at laboratory scale (Figure 3).[15] Upon 365 nm flash-excitation of the ligand-to-metal-charge-transfer bands of $[Cu(dieten)_2](ClO_4)_2$ (200–400 nm), the strong reflections shift 0.04° on average, with various trends of change in the intensity and a remarkable change in color from bright orange to violet. The long time needed for data collection relative to the time of irradiation assured that the respective cell shrinkage was not due to heating effects but to the creation of a long-lived photoinduced ground state. From the peak shift, the overall effect of the excitation on the lattice is analogous to the cooling of the crystal. The temperature dependence of the photoinduced structural change, monitored by the position of the $(1\bar{1}0)$ reflection (Figure 3 and Figure 2B) showed that the photoexcitation strongly affects the lattice on cooling within the hysteresis region III, where phase C and the intermediate phase exist on cooling and heating, respectively. From the magnitude of the shift, it is concluded that the largest structural change occurs at 45 K, right after the transition of A to C has been completed (Figure 2B). This is an indication that the excitation induces transition from the low-temperature phase C, obtained in situ from cooled A, to the intermediate phase I between C and A, close to the transition point. Excitation below 30 K is less effective and results in qualitatively different structural changes, which was confirmed by comparison of the difference patterns in the $2\Theta$ region 5–60°. The photoinduced phase persists at 50 K, but it decays by thermal annealing at 300 K or by irradiation with visible light. Therefore, the diffraction experiments are conclusive that within and around the bistable region III, the photoexcitation significantly affects the crystal and electronic structure, particularly of the coupled cationic centers. Detailed structural studies are now underway.

In conclusion, the electronically coupled planar pseudo-JT cations in the one-dimensional cationic chains of $[Cu(dieten)_2](ClO_4)_2$ are subject to internal strain, balanced by a relatively strong, but moderately flexible ligand field. The lattice can withstand such strain only between 60 and 318 K; it can be collapsed by applying external pressure, or by altering the internal pressure by heating/cooling out of this temperature range. Above 318 K, the strain is released by tetrahedral distortion of the valence orbital orientation, enhanced ring puckering, disorder of the side ligand chains, and positional and rotational disorder of the counteranion.

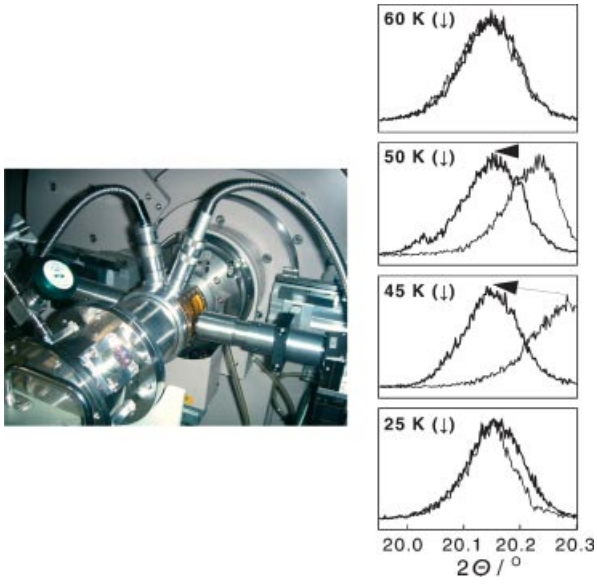

Figure 3. Left: Laboratory-built, low-temperature cryostat for powder X-ray photodiffraction. The double optical input on the top is connected to the UV output through a system of replaceable UV-transparent optics. The X-ray beam diffracts and is detected in horizontal $\Theta - 2\Theta$ geometry. Right: Temperature profile of the $(1\bar{1}0)$ reflection before (thin line) and after (thick line) flash excitation of cooled $[Cu(dieten)_2](ClO_4)_2$ powder. The ordinate represents intensity in arbitrary units. The sample was flash-excited at $\lambda_{max}$ = 365 nm, through biconvex fused-silica lenses and quartz windows, with polychromatic output from a high-pressure Hg lamp (SP-7, Ushio) and annealed at 300 K between the consecutive flashes.

Below 60 K, switching of the exchange interaction in virgin single crystals occurs from a ferromagnetic to an antiferromagnetic regime, with hysteresis between 25 and 55 K. In the region of low-temperature bistability, the phase transition can also be induced from the excited state by partial charge transfer, which results in overall shrinkage of the lattice. The possibility of employing the interplay between the JT instability and the ligand field strain, determined by a moderate flexibility of the primary coordination sphere, for triggering structural transitions by light, pressure, and temperature, paves the way to switching devices capable of multi-stimulus control.

## Experimental Section

Magnetic susceptibilities, $\chi = M/H$, were measured with a SQUID magnetometer (Quantum Design, MPMS) between 2 and 300 K in an applied field of 10 kOe [1 Oe = $(10^3/4\pi)$ A m$^{-1}$]. The temperature steps were 1 K between 2 and 100 K, and 5 K between 105 and 300 K. The heating/cooling rate was 10 K·min$^{-1}$ between the steps.

# Synthesis and Molecular Structure of [Cp*Ta(Ph)($P_6Ph_5$)]: A Terminal Phosphinidene Complex of the $(P_6Ph_5)^{3-}$ Ligand (Cp* = $C_5Me_5$)

**Robert Wolf[a] and Evamarie Hey-Hawkins*[a]**

**Keywords:** Tantalum / Phosphorus / P ligands / Oligophosphanes / Phosphinidene complexes

The terminal phosphanyl phosphinidene complex [Cp*Ta(Ph)($P_6Ph_5$)] (**2**) has been isolated in 16% yield from the reaction of [Cp*$TaCl_4$] with 2 equiv. $Na_2(P_4Ph_4)$ and displays an $\eta^4$-bound $(P_6Ph_5)^{3-}$ ligand according to X-ray crystallography and $^{31}P$ NMR spectroscopy.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

Terminal phosphinidene complexes [$L_nM(PR)$] are of much current interest due to their versatile reactivity and interesting bonding properties.[1,2] In this respect, phosphanyl phosphinidene complexes [$L_nM(PPR_2)$] are a particularly attractive subclass, as the phosphanyl group may or may not be involved in coordination.[3] The first representatives were described only recently.[4,5]

During our studies on the coordination chemistry of oligophosphanediide anions $(P_nR_n)^{2-}$ ($n$ = 2–4)[6–9] we could show that, in spite of its highly reducing nature,[9] the $(P_4Ph_4)^{2-}$ dianion remains intact in the transmetalation reaction of 2 equiv. of [$CuCl(PCyp_3)_2$] (Cyp = *cyclo*-$C_5H_9$) with $Na_2(P_4Ph_4)$ (**1**).[10] While this was an example of a successful transmetalation with a valence-electron-rich late-transition-metal halide,[11] we wished to extend the scope of this reaction to early transition-metal halides as well. Herein, we report the surprising result of the reaction of **1** with [Cp*$TaCl_4$] (Cp* = $C_5Me_5$). This led to the isolation of [Cp*Ta(Ph)($P_6Ph_5$)] (**2**), which not only contains an unprecedented oligophosphanide ligand $(P_6Ph_5)^{3-}$, but is also a rare example of a terminal phosphanyl phosphinidene complex of tantalum.

Complex **2** could be isolated in low, though reproducible, yield (16%) from the 2:1 reaction of **1** with [Cp*$TaCl_4$] (Scheme 1). An X-ray crystal structure analysis[12] of **2** revealed a mononuclear complex in which a trianionic $(P_6Ph_5)^{3-}$ ligand binds in an $\eta^4$ fashion to the metal center (Figure 1). The coordination sphere of tantalum is completed by an $\eta^5$-coordinated pentamethylcyclopentadienyl ligand and an $\eta^1$-bound phenyl ligand. Remarkably, the Ta–P bond of the "naked" phosphorus atom P1 is significantly shorter than the remaining Ta–P distances [$d$(Ta1–P1) = 2.416(2), $d$(Ta1–P2) = 2.528(2), $d$(Ta1–P5) = 2.561(2), $d$(Ta1–P6) = 2.659(2) Å], and this indicates multiple-bond character of the Ta–P1 bond. Nevertheless, it is longer than the Ta–P bonds in the phosphinidene-bridged Ta complexes [{Cp*TaCl(μ-PR)}$_2$] [R = Cy, *t*Bu, Ph, Mes, 2,4,6-*i*$Pr_3C_6H_2$; $d$(Ta–P) = 2.317(6)–2.358(3) Å][13,14] and the terminal phosphinidene complexes [N{$CH_2CH_2N(SiMe_3)$}$_3$Ta=PCy] [$d$(Ta–P) = 2.145(7) Å][2a] and [(*t*$Bu_3SiO)_3$Ta=PPh] [$d$(Ta–P) = 2.317(4) Å].[2b] The Ta–P distance of the other terminal phosphorus atom of the chain (P6) is much longer [$d$(Ta1–P6) = 2.659(2) Å]. It is in the upper range of the values found in other terminal phosphanido complexes of tantalum [$d$(Ta–P) = 2.390–2.595(3) Å].[14,15] The pyramidal coordination of P6 (sum of bond angles around P6: 301.3°) indicates that it acts as a one-electron donor to the metal center, which is also in accordance with the 18-electron rule (vide infra). The remaining Ta–P distances are in the known range for phosphane complexes of tantalum.[16,17] The Ta–C distance of the *ipso*-carbon atom of the $\eta^1$-coordinated phenyl ligand [$d$(Ta1–C1) = 2.230(7) Å] is similar to those found in other cyclopentadienyl-substituted phenyl complexes of tantalum.[18] While the P–P bond lengths of P2 to P6 are in the range of single bonds [$d$(P2–P3, P3–P4, P4–P5, P5–P6) = 2.133(3)–2.213(3) Å],[19] the P–P bond involving the naked phosphorus atom is distinctly shorter [$d$(P1–P2) = 2.096(3) Å]. Similarly short P–P bonds have been observed in other phosphanyl phosphinidene complexes[4] and also in diphosphene complexes.[20] In fact, the geometry of the (PPPh) unit in **2** closely resembles that in the recently described Nb phosphanyl phosphinidene complexes [Nb{N(R)$R^1$}$_3$($PPR^2_2$)] ($R^1$ = 3,5-$Me_2C_6H_3$, R = neopentyl, $R^2$ = Ph, *t*Bu).[4c]

Formally, compound **2** may be regarded as an 18-electron complex with a double bond between the metal center and the unsubstituted phosphorus atom (P1) and single bonds to the other coordinating P atoms (as depicted in Scheme 1). However, alternative descriptions of the bonding situation involving a multiply bonded PPPh fragment

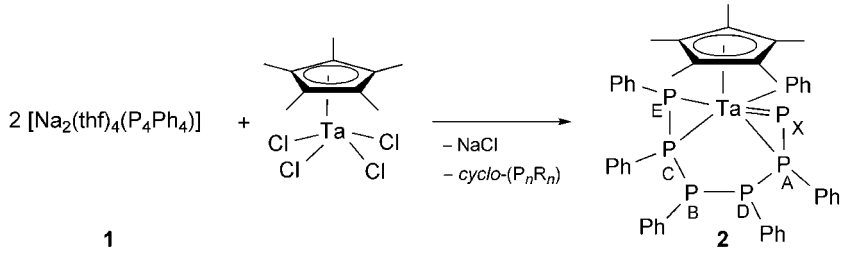

Scheme 1.

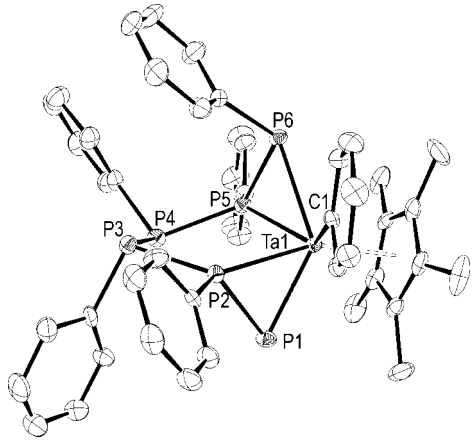

Figure 1. Solid-state molecular structure of **2**; H atoms omitted for clarity, ellipsoid probability: 30%. Selected bond lengths [Å] and angles [°]: Ta1–P1 2.416(2), Ta1–P2 2.528(2), Ta1–P5 2.561(2), Ta1–P6 2.659(2), Ta1–C1 2.230(7), av Ta–C in Cp* 2.451, P1–P2 2.096(3), P2–P3 2.213(3), P3–P4 2.185(3), P4–P5 2.211(3), P5–P6 2.133(3), C1–Ta1–P1 104.4(2), C1–Ta1–P2 78.6(2), C1–Ta1–P5 130.1(2), C1–Ta1–P6 89.6(2), P1–Ta1–P2 50.12(6), P1–Ta1–P5 93.61(7), P1–Ta1–P6 134.52(6), P2–Ta1–P5 78.55(6), P2–Ta1–P6 92.77(6), P5–Ta1–P6 48.20(6), P2–P1–Ta1 67.71(7), P5–P6–Ta1 63.50(7), P3–P2–Ta1 126.84(9), P4–P5–Ta1 118.84(9), P1–P2–P3 124.4(1), P2–P3–P4 95.7(1), P3–P4–P5 103.1(1), P4–P5–P6 129.4(1).

are equally plausible and may account for the relatively long Ta–P bond compared to other Ta phosphinidene complexes and the short bond between P1 and P2. Thus, the bonding situation is probably best described by a superposition of different mesomeric structures, as already suggested by Cummins and Pikies.[3,4,21]

The molecular composition of **2** was fully confirmed by IR spectroscopy, mass spectrometry, elemental analysis, and multinuclear NMR spectroscopy. Notably, no P–H stretch is observed in the IR spectrum. The $^1$H NMR spectrum shows multiplets in the region of 6.28 to 8.18 ppm for the phenyl groups and a singlet at $\delta$ = 1.81 ppm for the methyl resonances of the Cp* ligand. A characteristic low-field signal at +182.70 ppm is observed for the *ipso*-carbon atom of the Ta-bound phenyl group in the $^{13}C\{^1H,^{31}P\}$ NMR spectrum.[18,22] The $^{31}P\{^1H\}$ NMR spectrum displays a first-order ABCDEX spin system (Figure 2). No additional couplings are detected in the proton-coupled $^{31}$P NMR spectrum. Only the $^1J$(P–P) couplings could be assigned with certainty from the $^{31}P\{^1H\}$ NMR spectrum due to the line broadening caused by the interaction of four phosphorus nuclei ($P_X$, $P_A$, $P_C$, and $P_E$) with the $^{181}$Ta nucleus. Nevertheless, this observation permits the assignment of the individual resonances (cf. Scheme 1). The striking low-field shift of the two-coordinate, "naked" P atom $P_X$ ($\delta_X$ = +370.3, $^1J_{AX}$ = ±471 Hz) indicates multiple-bond character of the Ta–$P_X$ bond. Its chemical shift is comparable to those observed in the related Nb complexes [Nb{N(R)-$R^1$}$_3$($PPR^2_2$)] ($R^1$ = 3,5-$Me_2C_6H_3$, R = neopentyl; $R^2$ = Ph: $\delta$ = +401.3; $R^2$ = *t*Bu: $\delta$ = +405.5).[4c] The "phosphanyl moiety" ($P_E$ and $P_C$) displays a similarly large value for its $^1J$(P–P) coupling constant ($^1J_{CE}$ = ±444 Hz), but the resonance of its terminal P atom ($P_E$) is shifted to the typical high-field region observed for Ta phosphanides ($\delta_E$ = –127.7).[15] All in all, the $^{31}$P parameters confirm that the solid-state structure of **2** is retained in solution.

Besides the ABCDEX spin system of **2** a minor amount of *cyclo*-($P_4Ph_4$)[23] (ca. 4%) is observed in the $^{31}P\{^1H\}$

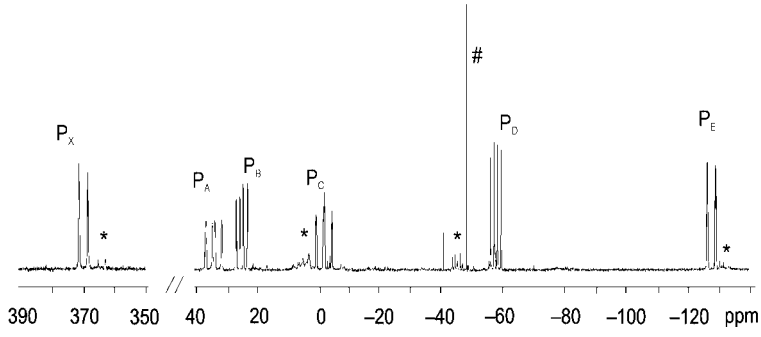

Figure 2. $^{31}P\{^1H\}$ NMR spectrum of **2** ($C_6D_6$, 161.97 MHz). The singlet of *cyclo*-($P_4Ph_4$)[23] is designated by #; * indicates signals of a further diastereomer of **2**. For the assignment of the individual multiplets, see Scheme 1.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

NMR spectrum. Furthermore, a number of less intense multiplets are reproducibly observed, with rather similar chemical shifts to **2** (Figure 2). For example, a broad low-field doublet is detected at +364.3 ppm ($^1J_{PP}$ = ca. ±387 Hz). The unequivocal assignment of all signals was impaired by their low intensity (partly owing to the low solubility of **2** once isolated). Most likely, they can be attributed to the presence of a second diastereomer of **2** in solution, which may be formed by inversion of either of the uncoordinated P atoms ($P_B$ or $P_D$). It is well-known that catenated oligophosphanes have significantly reduced inversion barriers, as was observed, for example, in the heterocycles *cyclo*-1,4-$(BH_3)_2(P_4Ph_4CH_2)$[24] and [M{*cyclo*-$(P_4Cy_4As)$}] (M = Li, Na).[25]

While rearrangement of oligophosphanide ligands during transmetalation reactions has been observed in a few instances,[11,26] the mechanism of formation of **2** is obviously rather complex. Presumably, it involves the initial formation of a low-valent Ta intermediate. Subsequently, the phenyl group may be transferred by oxidative addition of the P–C bond to the reduced metal center. $^{31}$P NMR spectra of the reaction mixture show the formation of the cyclooligophosphanes *cyclo*-$(P_nPh_n)$ ($n$ = 4–6)[23,27] and the phosphinidene-bridged complex [{Cp*TaCl(μ-PPh)}$_2$][13] (identified by its characteristic low-field singlet at +402.3 ppm) as major products. In addition, numerous low-intensity multiplets are observed but could not be assigned. This seems to indicate the presence of a number of P–P bonded byproducts in the reaction mixture. No further tantalum-containing products could be isolated from the reaction. Attempts to obtain further insights by variation of the stoichiometry, the reaction conditions, and the starting materials have remained futile. Thus, the yield of **2** could not be increased by warming the reaction mixture to +80 °C. Furthermore, **2** could not be obtained from the reaction of 2 equiv. $K_2(P_3Ph_3)$ with [Cp*TaCl$_4$], from the reaction of [{Cp*TaCl(μ-PPh)}$_2$][13] with *cyclo*-$(P_5Ph_5)$ (warming to +100 °C for 2 h), or from the reaction of **1** with [{Cp*TaCl$_2$}$_2$][28] (2:1). Only the cyclophosphanes *cyclo*-$(P_nMes_n)$ ($n$ = 3, 4)[29] were isolated from the reaction of [Cp*TaCl$_4$] with 2 equiv. $[Na_2(THF)_4(P_4Mes_4)]$.[8a] Clearly, a more detailed understanding of the reaction mechanism will only be gained from future studies.

In conclusion, we have shown that the unprecedented $(P_6Ph_5)^{3-}$ ligand containing six catenated phosphorus atoms is stabilized in the Ta phosphinidene complex [Cp*Ta(Ph)$(P_6Ph_5)$] (**2**). This adds to the growing evidence that, although not always straightforward,[9,11] the transmetalation reaction of alkali metal oligophosphanediides with transition metal halides represents a viable route to phosphorus-rich metal complexes with unusual structures and reactivities.

## Experimental Section

All experiments were performed under an inert atmosphere. The NMR spectra were recorded with a Bruker AVANCE-DRX-400 spectrometer. $^1$H NMR (400.13 MHz): internal standard solvent, external standard TMS. $^{31}$P NMR (161.9 MHz): external standard 85% $H_3PO_4$. $^{13}$C NMR (100.16 MHz): internal standard solvent, external standard TMS. For the assignment of the phosphorus signals, see Scheme 1. The mass spectrum was recorded with a MASPEC II spectrometer (FAB-MS, matrix: 3-nitrobenzyl alcohol). The IR spectra were recorded with an FTIR spectrometer Perkin–Elmer System 2000 (KBr) in the range 350–4000 cm$^{-1}$. All solvents were purified by distillation, dried, saturated with argon, and stored over a potassium mirror. $[Na_2(THF)_4(P_4Ph_4)]$ (**1**)[8a] and [Cp*TaCl$_4$][30] were synthesized according to the literature procedures.

**2:** A solution of **1** (6.18 g, 8.1 mmol) in toluene (40 mL) was added dropwise to a suspension of [Cp*TaCl$_4$] (1.85 g, 4.0 mmol) in toluene (30 mL) at –80 °C. The mixture turned dark-brown immediately on addition. The dark suspension was slowly warmed to room temperature and stirred overnight. The solvent was reduced to ca. 30 mL and the mixture was filtered. The dark-brown residue was washed three times with 20 mL of toluene. Then the combined filtrates were reduced to ca. 20 mL and the clear, dark brown solution was layered with *n*-hexane (35 mL). Dark red crystals of **2** formed on storage at room temperature for several weeks. Yield: 0.61 g (16% ref. to [Cp*TaCl$_4$]); m.p. 180–181 °C (red oil). $^1$H NMR ($C_6D_6$): $\delta$ = 1.81 (s, 15 H, Cp*), 6.28–8.18 (m, 30 H, Ph) ppm. $^{13}$C{$^1$H,$^{31}$P} NMR ($C_6D_6$): $\delta$ = 12.10 (s, $C_5Me_5$), 113.49–147.63 (s, Ph, $C_5Me_5$), 182.70 (s, *ipso*-C of Ta–Ph) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$): ABCDEX spin system, $\delta_X$ = +370.3 (br. d, 1 P), $\delta_A$ = +34.0 (br. ddd, 1 P), $\delta_B$ = +24.9 (m, 1 P), $\delta_C$ = –1.8 (br. m, 1 P), $\delta_D$ = –57.6 (ddd, 1 P), $\delta_E$ = –127.7 (br. d, 1 P), $^1J_{AX}$ = ±471 Hz, $^1J_{BD}$ = ±204 Hz, $^1J_{BC}$ = ±391 Hz, $^1J_{AD}$ = ±355 Hz, $^1J_{CE}$ = ±444 Hz. IR (KBr, cm$^{-1}$): $\tilde{\nu}$ = 3135 (w), 3050 (m), 2986 (m), 2957 (m), 2898 (m), 2723 (w), 1953 (w), 1882 (w), 1807 (w), 1753 (w), 1649 (w), 1579 (m), 1567 (m), 1551 (m), 1476 (m), 1433 (s), 1374 (m), 1333 (w), 1303 (m), 1262 (m), 1237 (w), 1184 (w), 1152 (w), 1082 (m), 1068 (m), 1054 (m), 1023 (s), 998 (m), 909 (m), 842 (m), 803 (m), 733 (s), 689 (s), 617 (vw), 563 (m), 520 (w), 479 (m), 467 (m), 405 (m). MS (FAB): $m/z$ = 964.94 [M + H]$^+$; $C_{46}H_{45}P_6Ta$ (964.59): calcd. C 57.27, H 4.70; found C 57.36, H 4.59.

On one occasion, the product still contained some *cyclo*-$(P_5Ph_5)$ and a green, insoluble material as byproducts. In this case, the compound was purified by dissolving in toluene, filtration, and layering the clear filtrate with *n*-hexane.

# Coordination Dependence of Magnetic Properties within a Family of Related [$Fe^{II}_2$] Complexes of a Triazine-Based Ligand

**Manuel Quesada,[a] Paul de Hoog,[a] Patrick Gamez,*[a] Olivier Roubeau,*[b] Guillem Aromí,[c] Bruno Donnadieu,[d] Chiara Massera,[e] Martin Lutz,[f] Anthony L. Spek,[f] and Jan Reedijk[a]**

**Keywords:** Iron(II) complexes / Magnetic properties / Spin crossover / 1,3,5-Triazine / Polydentate ligands

The coordination chemistry of the polydentate ligand 2,4,6-tris(dipyridin-2-ylamino)-1,3,5-triazine (dpyatriz) with $Fe^{II}$ has been explored, leading through variation of the counter-ion and the solvent system to the preparation of three different dinuclear complexes: $[Fe_2(dpyatriz)_2(H_2O)_2(CH_3CN)_2](ClO_4)_4$ (**1**), $[Fe_2(dpyatriz)_2(H_2O)_2(CH_3OH)_2](BF_4)_4$ (**2**) and $[Fe_2(dpyatriz)_2Cl_2](CF_3SO_3)_2$ (**3**). The X-ray structure of these compounds has revealed that besides the difference in the noncoordinated anion, complex **1** differs from complex **2** only in the nature of the terminal ligands. Bulk magnetisation studies and Mössbauer spectroscopy have shown that such a subtle difference produces a change to the crystal field on the metal atoms, originating an important disparity of the magnetic behaviour. Thus, complex **1** experiences a partial spin crossover centred at approximately 265 K, whereas complex **2** shows two uncoupled high-spin $Fe^{II}$ centres over most of the studied temperature range, experiencing the effect of very weak antiferromagnetic coupling and/or single-ion zero-field splitting at low temperature. By contrast, complex **3**, in which the triazine ring of dpyatriz is coordinated for the first time, displays (very uncommon) ferromagnetic coupling between both $Fe^{II}$ ions within the molecule, leading to an $S = 4$ spin ground state. A fit of the experimental data led to a value of the coupling constant of $J = +0.23\ cm^{-1}$ (using $H = -2JS_1S_2$ as the convention for the exchange Hamiltonian) and provided an estimation of $D = 0.63\ cm^{-1}$ for the ground-state axial zero-field splitting parameter.

## Introduction

The controlled design of molecule-based functional materials represents one of the research lines along which nanotechnological applications may develop. The area of coordination chemistry plays a primary role in this respect, as exemplified by the spectacular progress demonstrated in the context of molecular magnetism.[1] The search for molecular magnetic materials with specific functions is very often based on the use of ligands that will give rise to predictable chemical and physical properties. For instance, it is well known that azole-based ligands have the ability to generate the appropriate type of crystal field around $Fe^{II}$ ions, so as to prompt the appearance of the phenomenon of spin crossover (SC) within the metal atom.[2,3] Another example is the exploitation of the potential of certain ligand systems to propagate ferromagnetic interactions between paramagnetic metals with the aim of generating high-spin molecules or magnetically ordered materials. Among such ligand frameworks are (end-on) $N_3^-$ groups[4,5] and *m*-phenylene links (the latter usually facilitating ferromagnetism through a spin-polarisation mechanism).[6,7] Even more desirable in the preparation of versatile functional materials are systems capable of exhibiting different properties by introducing subtle changes of environment or of chemical nature.

With the aim of preparing novel coordination supramolecular architectures, some of us have recently synthesised and started to use the new multinucleating ligand 2,4,6-tris-(dipyridin-2-ylamino)-1,3,5-triazine (dpyatriz, Scheme 1)[8] in coordination chemistry reactions involving various metals. The versatility of this ligand has been demonstrated by the diversity of some of the coordination compounds obtained. Thus, the reaction with $Cu(NO_3)_2$ produces a magnetically exchanged 1D coordination polymer,[9] whereas a similar reaction involving $CuCl_2$ allows the characterisation

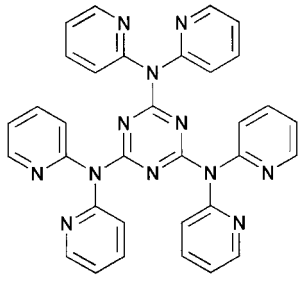
of the trinuclear discrete molecule $[(CuCl)_3(dpyatriz)_2][CuCl_4]Cl$.[10] The same process, using $Zn(NO_3)_2$, leads to the formation of the tetranuclear molecular species $[Zn_4(dpyatriz)_2(NO_3)_8]$.[11] In these products, the dpyatriz ligands have their three dipyridylamine (dpya) chelating units engaged in coordination. By contrast, the analogous reaction with $Co^{II}$ conduces to the dimeric complex $[Co_2(dpyatriz)_2(NO_3)_2(CH_3OH)_2](NO_3)_2$ in which each of the multidentate ligands maintains one of their dipyridyl chelating units uncoordinated. Very recently, we have discovered that using solvothermal conditions one can prepare compounds different than those formed from the corresponding reactions under normal conditions of temperature and pressure. In this manner, coordination polymers of $Cu^{II}$, $Zn^{II}$ and $Cd^{II}$ have been crystallographically characterised.[12] Despite the variety of coordination modes and structures observed, none of the complexes described so far shows the dpyatriz ligand using the N-donor of the triazine ring for coordination to a metal atom. It is conceivable that the versatility of dpyatriz can be exploited in the search of new supramolecular architectures exhibiting novel magnetic phenomena. With this aim, we engaged in exploring the reactivity of this ligand with various sources of $Fe^{II}$. We report herein on the ability of dpyatriz to form dinuclear complexes of magnetically exchanged $Fe^{II}$ ions in the form of the compounds $[Fe_2(dpyatriz)_2(H_2O)_2(CH_3CN)_2](ClO_4)_4$ (**1**), $[Fe_2(dpyatriz)_2(H_2O)_2(CH_3OH)_2](BF_4)_4$ (**2**) and $[Fe_2(dpyatriz)_2Cl_2](CF_3SO_3)_2$ (**3**), as revealed by single-crystal X-ray crystallography. The nature of the terminal ligands completing the coordination sites not occupied by dpyatriz affects either the ligand field around the metal ions or the coordination mode of the multinucleating ligand, leading thus to three related complexes with very disparate magnetic properties, ranging from spin crossover (**1**), antiferromagnetic exchange (**2**) or (very uncommon for Fe) ferromagnetic coupling (**3**). The synthesis of complexes **1**, **2** and **3** and their molecular structures are described, and the reasons for their very different magnetic behaviour discussed.



Scheme 1. Molecular structure of the ligand dpyatriz.

## Results

### Synthesis

In attempts to take advantage of the versatility of dpyatriz for the preparation of complexes with new and novel magnetic properties, reactions with different sources of $Fe^{II}$ in a variety of conditions have been conducted.

Mixing in acetonitrile $Fe(ClO_4)_2$ with dpyatriz close to the 1:2 molar ratio, and small amounts of ascorbic acid (in order to avoid aerial oxidation to $Fe^{III}$) led to a light pink solution from which crystals could be obtained by slow diffusion of $Et_2O$. The identity of this compound was established by X-ray crystallography (see below) as the dimeric discrete complex $[Fe_2(dpyatriz)_2(H_2O)_2(CH_3CN)_2](ClO_4)_4$ (**1**). Water in this compound originates from the hydrated iron salt, or from its adventitious presence in the solvent. Thus, the reaction leading to the formation of **1** can be described by a very simple chemical equation [Equation (1)].

$$2\ Fe(ClO_4)_2 + 2\ dpyatriz + 2\ H_2O + 2\ CH_3CN \rightarrow [Fe_2(dpyatriz)_2(H_2O)_2(CH_3CN)_2](ClO_4)_4\ (\mathbf{1}) \quad (1)$$

It was observed that crystals of **1**, crumbled upon exposure to air and turned into a yellowish crystalline material. Elemental analysis suggested the replacement of $CH_3CN$ molecules by $H_2O$, although no structural proof for the identity of the resulting material was obtained. Replacement of terminal $CH_3CN$ ligands by atmospheric water, while maintaining the core topology, is a very common process in coordination chemistry.[13] IR spectroscopy confirmed the absence of $CH_3CN$ in this new adduct, while the remaining spectral features were maintained.

The analogous reactivity was observed using $Fe(BF_4)_2$ and $CH_3OH$ as a solvent. Slow evaporation of the solvent from the reaction mixture resulted in the formation of light green crystals of a new complex, the formula of which was confirmed to be $[Fe_2(dpyatriz)_2(H_2O)_2(CH_3OH)_2](BF_4)_4$ (**2**) by single-crystal X-ray diffraction (see below) and elemental analysis. Thus, Equation (1) could serve to describe the formation of **2**, only replacing $CH_3CN$ and $ClO_4^-$ by $CH_3OH$ and $BF_4^-$, respectively. In contrast with **1**, however, this compound was found to be stable in air. The similarity of the synthesis and structure of **1** and **2** prompted us to test their interconversion. Indeed, when crystals of **1** are placed in $CH_3OH$, a slightly greenish powder is formed that does not turn purple when cooled to liquid $N_2$ temperature. Similarly, if crystals of **2** are immersed in $CH_3CN$, a slightly purple powder forms. Although this was not investigated further (mostly because the crystals crushed into powders), it seems that **1** and **2** can be converted into one another by simply changing their solvent environment.

Incorporation of $Cl^-$ into a system very similar to these described above gave comparable results, although with significant differences. Thus, dpyatriz and $Fe(CF_3SO_3)_2$ were mixed in benzyl cyanide in the presence of $Bu_4NCl$ and the solution brought to 100 °C inside a sealed pressure tube. Yellow crystals of the compound $[Fe_2(dpyatriz)_2Cl_2](CF_3SO_3)_2$ (**3**) formed under these conditions within a few days, according to the reaction described in Equation (2).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$2\ Fe(CF_3SO_3)_2 + 2\ dpyatriz + 2\ Bu_4NCl \rightarrow [Fe_2(dpyatriz)_2Cl_2](CF_3SO_3)_2\ (\mathbf{3}) + 2\ Bu_4NCF_3SO_3 \quad (2)$$

The identity of compound **3** was unveiled by X-ray crystallography (see below), which revealed that the $Cl^-$ ions are coordinated to Fe and that dpyatriz uses N-donors from the triazine moiety to bind the metal atom, a fact observed for the first time and bearing important consequences with regard to the magnetic behaviour of the complex. It was observed that when stoichiometric amounts of the chloride salt were used, the yields obtained were inferior compared with reactions involving limiting amounts of this reagent. A possible reason is that increased amounts of $Bu_4NCl$ favour the formation of the dinuclear anion $[Fe_2OCl_6]^{2-}$ at the expense of complex **3**. This anion is very stable and quite ubiquitous in aerobic reactions involving $Fe^{II}$ and chloride.[14]

## Description of Structures

Crystallographic data for complexes **1**–**3** are collected in Table 4 whereas selected metric parameters are listed in Tables 1, 2 and 3.

### *$[Fe_2(dpyatriz)_2(H_2O)_2(CH_3CN)_2](ClO_4)_4$ (1)*

Complex **1** is a centrosymmetric cationic dimer (Figure 1) comprising two octahedral $Fe^{II}$ ions bridged and chelated by two dpyatriz ligands through two of their dpya moieties, the third one remaining uncoordinated. The other two coordination sites on each metal atom are occupied in *cis* configuration by a molecule of $H_2O$ and one of $CH_3CN$, completing an $FeN_5O$ slightly distorted octahedral chromophore. The Fe–O and Fe–N($CH_3CN$) distances are 2.140(2) and 2.151(3) Å, respectively, whereas the Fe–N(dpyatriz) distances range from 2.159(2) to 2.177(2) Å. The Fe···Fe separation is 9.232(2) Å, while the shortest intermolecular Fe···Fe distance is 8.992 Å. Four perchlorate counteranions lie between the dinuclear units and exhibit disorder of their oxygen atoms. In addition, two lattice acetonitrile molecules are found in that space. No forces other than weak electrostatic and van der Waals interactions appear to operate within the crystal. The cation of **1** is structurally analogous to the equivalent complex with $Co^{II}$.[11]

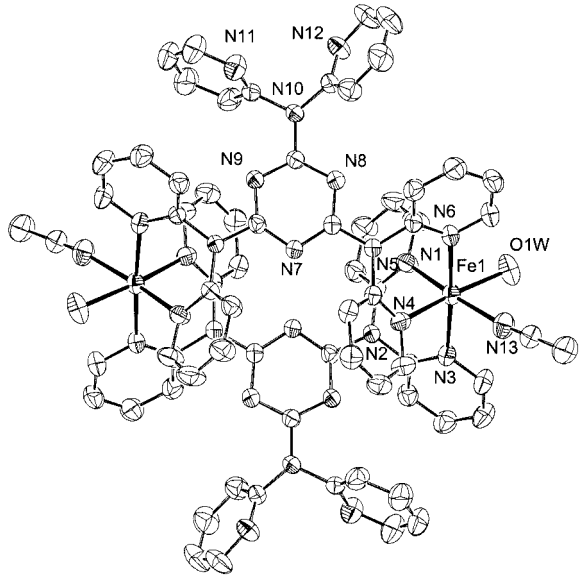

Figure 1. ORTEP representation at the 50% probability level of the cation of $[Fe_2(dpyatriz)_2(CH_3CN)_2(H_2O)_2](ClO_4)_4$ (**1**). Hydrogen atoms are not shown. Only unique non-carbon atoms are labelled.

### *$[Fe_2(dpyatriz)_2(H_2O)_2(CH_3OH)_2](BF_4)_4$ (2)*

The structure of **2** (Figure 2) is very similar to that of **1**. It also consists of centrosymmetric $Fe^{II}$ dinuclear entities held together by two dpyatriz ligands showing the same coordination mode. The only differences are the replacement of perchlorate by tetrafluoroborate and substitution of the $CH_3CN$ ligand by $CH_3OH$. The latter difference has important consequences for the magnetic properties of the system (see below). The geometric parameters also vary slightly;

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thus, the Fe–N bond lengths range from 2.152(2) to 2.190(2), whereas the Fe–O distances are 2.1708(18) Å ($CH_3OH$) and 2.0846(18) Å ($H_2O$). The intradimer Fe···Fe vector measures 9.2593(15) Å and the shortest interdimer Fe···Fe distance is 8.3577(14) Å. The $BF_4^-$ ions are again located between the complex cations, whereas each of the two free dipyridylamine moieties accept hydrogen bonds from one $CH_3OH$ molecule of crystallisation, thus forming a bifurcated hydrogen bond [N···O distances 3.112(3) and 2.816(3) Å].

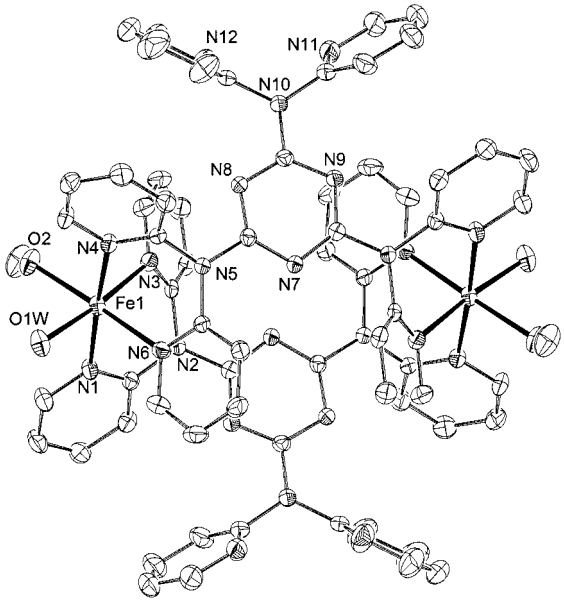

Figure 2. Labelled ORTEP representation at the 50% probability level of the cation of $[Fe_2(dpyatriz)_2(H_2O)_2(CH_3OH)_2](BF_4)_4$ (**2**). Hydrogen atoms are not shown. Only unique non-carbon atoms are labelled.

### *[Fe₂(dpyatriz)₂Cl₂](CF₃SO₃)₂ (3)*

Also the cationic complex **3** (Figure 3) consists of a centrosymmetric dimer in which two octahedral $Fe^{II}$ ions are connected by two dpyatriz ligands. In **3**, however, the binding mode of the multidentate ligand is very different from that observed in the two previous complexes. Here, each of the dpyatriz ligands chelates one iron cation through two nitrogen atoms from one dpya moiety and the other one with a N-donor from the triazine moiety and with two N atoms from dpya nonadjacent pyridyl rings. In this way two pyridyl rings in each dpyatriz ligand remain uncoordinated. Unlike in complexes **1** and **2**, the octahedral coordination around $Fe^{II}$ is not completed by solvent molecules, but by a terminal $Cl^-$ ion. The Fe1–Cl1 and Fe1–N7(triazine) distances are 2.336(2) and 2.220(4) Å respectively, while the other four Fe–N bonds involving the pyridyl groups vary from 2.205(4) to 2.234(4) Å (see Table 3). To the best of our knowledge complex **3** is the first crystallographically characterised compound where the central triazine moiety of dpyatriz is involved in coordination. The triazine rings of the two ligands lie mutually parallel although shifted with respect to each other, with a distance between the least-square planes passing through them of 3.584(1) Å. The intramolecular Fe···Fe [$-x$, $1-y$, $1-z$] separation is 8.324(1) Å, while the shortest intermolecular separation between two metal atoms is 9.041(2) Å. The two positive charges of the cationic complex $[Fe_2(dpyatriz)_2(Cl)_2]^{2+}$ are balanced by two disordered $CF_3SO_3^-$ anions located in the crystal lattice. Also two molecules of the solvent (benzyl cyanide) are present for each dimeric complex, orientated so that their CN groups point towards the triazine ring [the smallest distance of N1s to the least-squares plane passing through the ring being 3.038(9) Å].

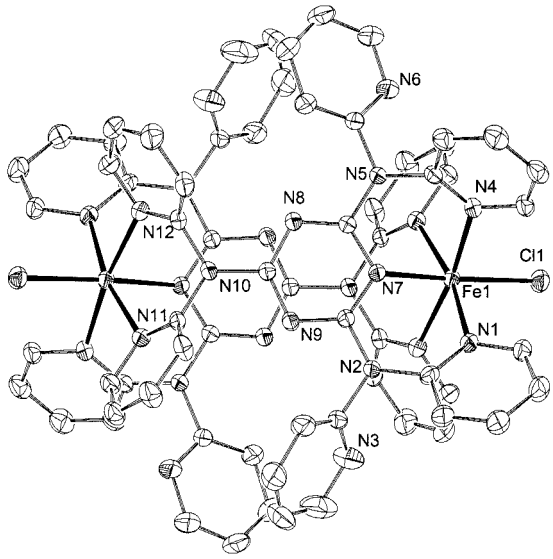

Figure 3. Labelled ORTEP representation at the 30% probability level of the cation of $[Fe_2(dpyatriz)_2Cl_2](CF_3SO_3)_2$ (**3**). Hydrogen atoms are not shown. Only unique non-carbon atoms are labelled.

### Magnetochemistry

The temperature dependence of the magnetisation of compounds **1**–**3** was studied on polycrystalline samples in the 2–350 K range. This is depicted in Figures 4, 7 and 8, for **1**, **2** and **3**, respectively, in the form of $\chi_m T$ versus $T$ plots, where $\chi_m$ is the molar paramagnetic susceptibility.

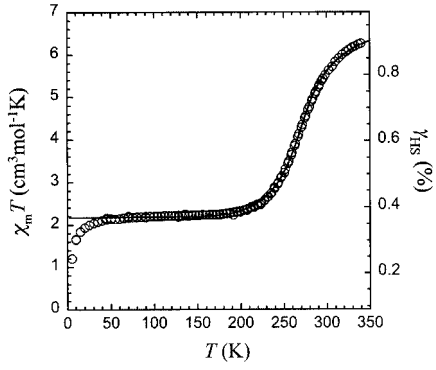

Figure 4. Plot of experimental $\chi_m T$ vs. $T$ for compound **1** (circles) collected with an applied field of 1000 Oe. The solid line is a fit to the regular solution theory model (see text for details), expressed as the HS fraction $\gamma_{HS}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

For compound **1** (Figure 4), the $\chi_m T$ product at 340 K is 6.27 $cm^3 \cdot mol^{-1} \cdot K$, in the range expected for two noninteracting high-spin (HS, $S = 2$) $Fe^{II}$ centres (6 $cm^3 \cdot mol^{-1} \cdot K$, for $g = 2$). As the temperature decreases, the $\chi_m T$ value starts immediately to drop gradually to 2.2 $cm^3 \cdot mol^{-1} \cdot K$ in the vicinity of 200 K, where it remains constant upon further cooling. This is consistent with a process of SC by a fraction of the $Fe^{II}$ centres (calculated to be 63%, see below), from HS to low spin (LS, $S = 0$). Only at very low temperatures, a decrease of $\chi_m T$ is observed anew, resulting either from zero-field splitting (ZFS) of the remaining $Fe^{II}$ HS centres and/or from antiferromagnetic coupling of the remaining HS–HS pairs. Thus, compound **1** exhibits a gradual and incomplete SC, centred at around 265 K, but does not exhibit a plateau at $\chi_m T \approx 3.0$ (50% of $Fe^{II}$ centres LS), which is often observed for $Fe^{II}$ dimers undergoing a spin transition.[15,16] This indicates a lack of strong intermolecular interactions, which would stabilise domains of HS–LS pairs. In order to present a quantitative description of the process of spin transition, the Mössbauer spectra of **1** (Figure 5) were collected at 293 K (near the transition temperature) and 77 K. Signals from both the HS and LS states were detected at both temperatures. From these experiments the fraction of $Fe^{II}$ centres in the HS state at 77 K was calculated to be 37%.[17] The temperature dependence of the HS fraction deduced from susceptibility and Mössbauer data was then fit to an equation resulting from a regular solution model [Equation (3)],[18,19] where $\gamma_{HS}$ is the variable HS fraction, $\Gamma$ is the interaction parameter[3] and the other terms have their usual meaning. Although it represents a crude approximation, the calculated values were normalised to the fraction of species undergoing spin crossover.

$$\ln\left(\frac{1-\gamma_{HS}}{\gamma_{HS}}\right) = \frac{\Delta H + \Gamma(1-2\gamma_{HS})}{RT} - \frac{\Delta S}{R} \quad (3)$$

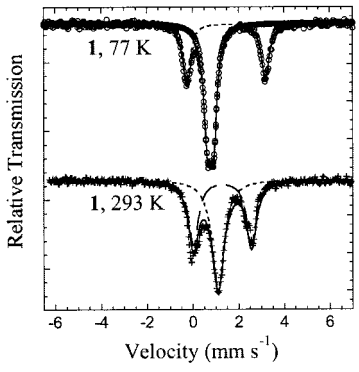

Figure 5. Mössbauer spectra of **1** at 77 and 293 K. Dashed lines represent subspectra used in the fitting procedure, while full lines are the overall fits to the experimental data.

The best fit provided (Figure 4, solid line) a value of $\Gamma$ = 2.9(2) $kJ \cdot mol^{-1}$ with $\Delta H$ = 11.0(1) $kJ \cdot mol^{-1}$ and $\Delta S$ = 40(1) $J \cdot mol^{-1} \cdot K^{-1}$. The cooperativity parameter $\Gamma$ is in agreement with the absence of strong interaction between the $Fe^{II}$ centres.[3] The entropy variation deduced is about three times that expected from the change in spin manifold ($R\ln 5$ = 13.4 $J \cdot mol^{-1} \cdot K^{-1}$), indicating, as usually observed, the presence of a vibrational contribution to the entropy variation. Both the transition entropy and enthalpy derived here are in agreement with the calorimetric characterisation of weakly cooperative SC systems.[20–23] The behaviour just described is retained only if the compound is kept sealed and/or in contact with acetonitrile. If complex **1** is left exposed to air, replacement of $CH_3CN$ by atmospheric water seems to take place (see above), the resulting material (**1a**) remaining HS throughout the whole range of temperatures.

The above results and spectroscopic evidence (see Figure 6 and below) show that the polydentate ligand dpyatriz constitutes a new member of the family of polypyridyl ligands capable of producing SC $Fe^{II}$ compounds in the presence of the right coligands.[24–26] The system shown here is peculiar in that it is dinuclear, unlike most previously reported examples. Also, it has the potential of acting as a building block in the formation of extended structures, a very attractive prospect, as high-dimensional SC systems are still rare.

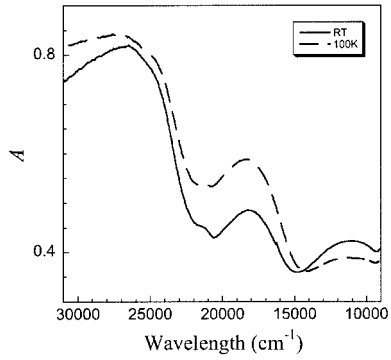

Figure 6. Absorption spectra of **1** at room temperature and about 100 K.

In contrast to complex **1**, the $\chi_m T$ product of **2** (Figure 7) remains practically constant at approximately 8.3 $cm^3 \cdot mol^{-1} \cdot K$ from room temperature to 50 K where it starts dropping to 2.65 $cm^3 \cdot mol^{-1} \cdot K$ at 2 K. This drop can

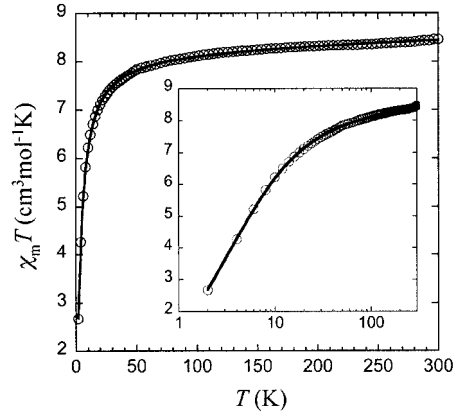

Figure 7. Plot of experimental $\chi_m T$ vs. $T$ for compound **2**. The inset is a semi-logarithmic form of that plot. The applied field was 1000 Oe. The full line corresponds to the best fit to a theoretical expression contemplating ZFS of $Fe^{II}$ ions (see text for details).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

be ascribed either to antiferromagnetic exchange coupling within the dimeric units in **2** and/or to single-ion ZFS of the $Fe^{II}$ centres ($S = 2$). The absence of a maximum in the $\chi_m$ versus $T$ plot indicates that the exchange coupling is very weak. In such situations both effects, if present, are approximately of the same order and cannot be discerned. We have therefore reproduced the experimental data considering either exchange coupling [Equations (4) and (5)][18] or axial ZFS of individual $Fe^{II}$ ions [Equations (6) and (7)],[18] including in both cases a temperature-independent paramagnetism (TIP).

$$\hat{H} = -2J(\hat{S}_1 \cdot \hat{S}_2) \quad (4)$$

$$\chi_m = \frac{N_A g^2 \beta^2}{k_B T} \cdot \frac{2e^{2x} + 10e^{6x} + 28e^{12x} + 60e^{20x}}{1 + 3e^{2x} + 5e^{6x} + 7e^{12x} + 9e^{20x}} \quad (5)$$

$$\hat{H} = 2 \times D[\hat{S}_z^2 - S(S+1)] \quad (6)$$

$$\chi_m = 2 \times \frac{N_A g^2 \beta^2}{k_B T} \cdot \left[\frac{\frac{1}{3}(2e^{-x} + 8e^{-4x}) + \frac{2}{3}\{6(1 - e^{-x})/x + 4(e^{-x} - e^{-4x})/3x\}}{1 + 2e^{-x} + 2e^{-4x}}\right] \quad (7)$$

In these expressions, $D$ represents the single-ion ZFS parameter, $J$ is the exchange coupling constant between $Fe^{II}$ ions within the dinuclear entities, while $x$ is either $J/k_BT$ [Equation (5)] or $D/k_BT$ [Equation (7)]. The experimental data are indeed reproduced correctly with both models, yielding on the one hand $g = 2.32(1)$, $J/k_B = -0.54(1)$ K ($J = -0.37$ $cm^{-1}$) and TIP = $1.6 \times 10^{-3}$ $cm^3 \cdot mol^{-1} \cdot K$, and on the other hand $g = 2.41(1)$ and $D/k_B = 5.71(6)$ K ($D = 3.97$ $cm^{-1}$), with TIP = $1.17 \times 10^{-3}$ $cm^3 \cdot K \cdot mol^{-1}$. The latter fit has a better quality ($\chi^2$ of 0.1 compared to 0.5),[27] indicating that, although both effects are likely to be present, ZFS is probably the dominant one. The fact that the $Fe^{II}$ centres in **2** are very weakly coupled, if at all, is consistent with the long distance mediating between them (see above) and the absence of any magnetic superexchange pathway connecting the two. On the other hand, positive values of $D$ are often found in $Fe^{II}$ HS species.[28]

The magnetic properties of complex **3** differ dramatically from the behaviour of the above complexes (Figure 8). The value of $\chi_m T$ at 300 K is 7.05 $cm^3 \cdot mol^{-1} \cdot K$, close to that expected for two uncoupled $Fe^{II}$ HS centres, and remains practically constant to approximately 50 K. From that temperature, $\chi_m T$ starts to increase upon cooling to reach a maximum of 7.85 $cm^3 \cdot mol^{-1} \cdot K$ at $T = 10$ K and then suddenly drops to $\chi_m T = 4.74$ $cm^3 \cdot mol^{-1} \cdot K$ at 2 K. This behaviour is consistent with the presence of ferromagnetic exchange between the Fe centres of the dinuclear complex to form a spin ground state of $S = 4$, while the decrease of $\chi_m T$ at lower temperatures is most likely because of ZFS and not interactions between complexes, as no intermolecular exchange pathways were observed in the crystal lattice. In order to describe this behaviour quantitatively, the experimental data were fit to a $\chi_m = f(T)$ expression [Equation (8)] derived from the Van Vleck equation for two exchange $Fe^{II}$ centres ($S = 2$), including a term $D$ for the ZFS of the spin ground state ($S = 4$) of the dimer.[29]

$$\chi_m = \frac{N_A g^2 \beta^2}{k_B T} \cdot \frac{6e^{17x} + 24e^{8x} + 54e^{-7x} + 96e^{-28x} + 84e^{-8y} + 30e^{-14y} + 6e^{-18y}}{e^{20x} + 2e^{17x} + 2e^{8x} + 2e^{-7x} + 2e^{-28x} + 7e^{-8y} + 5e^{-14y} + 3e^{-18y}} \quad (8)$$

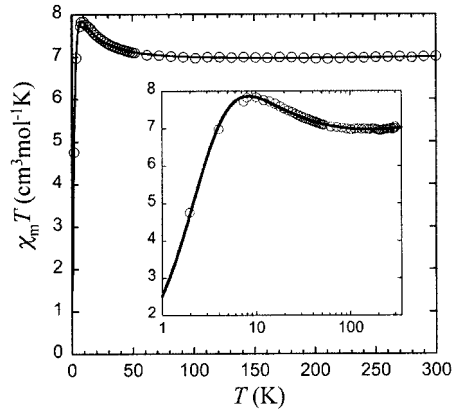

Figure 8. Plot of experimental $\chi_m T$ vs. $T$ for compound **3**. The inset is a semi-logarithmic form of that plot. The applied field was 1000 Oe. The full lines are best fits to the corresponding theoretical expression (see text for details).

In this equation, $x = D/3k_BT$ and $y = J/k_BT$. The best fit was obtained with $g = 2.12(1)$, $J/k_B = 0.33(1)$ K ($J = 0.23$ $cm^{-1}$) and $D/k_B = 0.91(2)$ K ($D = 0.63$ $cm^{-1}$). Ferromagnetic exchange coupling between $Fe^{II}$ centres is very uncommon.[30] A way of establishing this kind of interaction might be the mechanism of spin polarisation, by which the electronic cloud of species linking paramagnetic centres is polarised by the spin of the latter. For example, the alternation in the sign of the polarisation found within aromatic rings has allowed using them as linkers to induce predictably ferro- or antiferromagnetic interactions between spin carriers.[6] Complex **3** is the only one in the series of complexes reported here where the triazine rings are directly bound to $Fe^{II}$ and, thus, have chances of being polarised. It is possible that the weak ferromagnetic exchange occurs through the feeble π–π interaction between these two polarised rings, despite the fact that they are shifted with respect to each other. DFT calculations will be undertaken in order to establish the nature of the magnetic orbitals participating in this superexchange and rationalise the coupling.

### Solid-State Absorption Spectroscopy

Diffuse reflectance spectra of bulk **1** at 293 and about 100 K both display two very broad absorption bands centred around 11000 $cm^{-1}$ and 18200 $cm^{-1}$ (see Figure 6). These are typical for HS $^5T_2 \rightarrow {}^5E$ and LS $^1A_1 \rightarrow {}^1T_1$ transitions, respectively, in six-coordinate $Fe^{II}$ showing SC. The variation in relative intensities of these bands with temperature is in agreement with the spin crossover of **1** detected by magnetic susceptibility measurements. The corresponding ligand field parameter is derived as $10Dq^{HS}$ =

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

11000 $cm^{-1}$.[31] It is known that SC behaviour is to be expected for HS species having their $10Dq^{HS}$ in the range 10500–12000 $cm^{-1}$,[3] thus in agreement with the present observations. On the other hand, the $^5T_2 \rightarrow {}^5E$ transition in **2** is shifted towards higher energies, again in agreement with an HS ground state, and thus indicating that this compound does not show spin crossover behaviour.

## Conclusions

The reactivity of the polydentate ligand 2,4,6-tris(dipyridin-2-ylamino)-1,3,5-triazine with $Fe^{II}$ has been investigated for the first time. Small variations in reaction conditions have led to a new family of dinuclear complexes showing great diversity in magnetic behaviour. Changing solvents from $CH_3CN$ to $CH_3OH$ results in the change from SC behaviour in $[Fe_2(dpyatriz)_2(H_2O)_2(CH_3CN)_2](ClO_4)_4$ (**1**) to weak (or no) antiferromagnetic coupling within $[Fe_2(dpyatriz)_2(H_2O)_2(CH_3OH)_2](BF_4)_4$ (**2**). This effect is caused by the difference in crystal field produced by the solvent molecules, which in both cases act as terminal ligands. If a coordinating anion is included in the reaction, such as $Cl^-$, the complex $[Fe_2(dpyatriz)_2Cl_2](CF_3SO_3)_2$ (**3**) is obtained. In this case the structure of the complex differs significantly from before and $Fe^{II}$ is seen coordinated directly to N atoms from the triazine moiety. This results in a system exhibiting very rare ferromagnetic exchange between the metal atoms. These results suggest the possibility of fine-tuning important properties of the system by choosing the type of ligand occupying the peripheral positions of the dinuclear unit, or the prospect of preparing polymeric SC systems using the appropriate dimetallic moieties as a building block.

## Experimental Section

**Syntheses:** All reagents were used as received unless indicated otherwise. The ligand dpyatriz was prepared according to a previously published procedure.[8]

**$[Fe_2(dpyatriz)_2(CH_3CN)_2(H_2O)_2](ClO_4)_4$ (1):** dpyatriz (150 mg, 0.413 mmol) was added to a solution of $Fe(ClO_4)_2 \cdot 6H_2O$ (188 mg, 0.5 mmol) in acetonitrile (75 mL) and the mixture stirred. Slow diffusion of diethyl ether into this solution yielded pinkish parallelepiped crystals of $\mathbf{1} \cdot 2CH_3CN$ in 50% yield (185 mg). Complex **1** immediately lost $CH_3CN$ upon exposure to air, presumably to be replaced by water. The resulting species may be formulated as $[Fe_2(dpyatriz)_2(H_2O)_4](ClO_4)_4$ (**1a**) (see text). $\mathbf{1a} \cdot 4H_2O$ [$C_{66}H_{64}Cl_4Fe_2N_{24}O_{24}$ (1830.86)]: calcd. C 43.30, H 3.52, N 18.36; found C 42.94, H 3.05, N 17.95.

**$[Fe_2(dpyatriz)_2(H_2O)_2(CH_3OH)_2](BF_4)_4$ (2):** A solution of ligand dpyatriz (200 mg, 0.34 mmol) in methanol (20 mL) was mixed, whilst stirring, with a solution of $Fe(BF_4)_2 \cdot 6H_2O$ (344 mg, 1.01 mmol) and ascorbic acid (30 mg, 0.01 mmol) in methanol (10 mL) to give a green solution. After slow evaporation of the solvent in air at room temperature (3–4 d), green crystals of $\mathbf{2} \cdot 6H_2O$ were formed in 30% yield (90 mg), which were suitable for X-ray diffraction analysis. These crystals were collected by filtration, washed with methanol and dried in air. IR: $\tilde{\nu}$ = 1001.5, 1053.9, 1373.3, 3430, 3631.1 $cm^{-1}$. $\mathbf{2} \cdot 6CH_3OH$ [$C_{74}H_{84}B_4F_{16}Fe_2N_{24}O_{10}$ (1928.52)]: calcd. C 46.28, H 3.99, N 17.50; found C 45.75, H 4.06, N 17.99.

**$[Fe_2(dpyatriz)_2Cl_2](CF_3SO_3)_2$ (3):** A solution of ligand dpyatriz (230 g, 0.387 mmol) in benzyl cyanide (99%, 25 mL) was mixed, whilst stirring, with a solution of $Fe(CF_3SO_3)_2$ (230 mg, 0.581 mmol) in benzyl cyanide (99%, 10 mL) followed by addition of ascorbic acid (30 mg, 0.01 mmol). A solution of $Bu_4NCl$ (54 mg, 0.194 mmol) in benzyl cyanide (5 mL) was added to this mixture and the stirring maintained for several minutes. The resulting mixture was filtered and the filtrate placed into a pressure-sealed tube, which was then tightly closed and put in an oven at 100 °C. After 2 d at this temperature, yellow single crystals of $\mathbf{3} \cdot 2C_8H_7N$ suitable for X-ray diffraction were obtained. These crystals were collected and washed with methanol and diethyl ether. The yield was 15% (28 mg). IR: $\tilde{\nu}$ = 995.8, 1263.3, 1374.0 $cm^{-1}$. $\mathbf{3} \cdot 2C_8H_7N$ [$C_{84}H_{62}Cl_2F_6Fe_2N_{26}O_6S_2$ (1892.28)]: calcd. C 53.32, H 3.30, N 19.25; found C 53.03, H 3.54, N 19.55.

**Physical Measurements:** C,H,N analysis was performed with a Perkin–Elmer 2400 series. Infrared spectra (4000–300 $cm^{-1}$ range) were recorded with a Bruker 330V IR spectrophotometer equipped with a Golden Gate Diamond. The ligand field spectra of the solids (300–2000 $cm^{-1}$, diffuse reflectance) were taken with a Perkin–Elmer 330 spectrophotometer equipped with a home-made set-up to measure at low temperatures (down to about 100 K). Variable-temperature and field-magnetization measurements were carried out using Quantum Design MPMS-5S and MPMS-7XL SQUID magnetometers with fields up to 5 and 7 T, respectively, and in the temperature range 2–350 K. Corrections for diamagnetic contributions to the susceptibility of the sample, as deduced from Pascal's tables, and from the sample holder were applied. Mössbauer spectra were recorded in a constant acceleration mode using a $^{57}Co$ in Rh source. Isomer shifts are given relative to the sodium nitroprusside. Spectra were fitted with Lorentzian-shaped lines using a non-linear iterative minimisation routine. Accuracy for the isomer shift (I.S.) is 0.03 $mm \cdot s^{-1}$, for the electric quadrupole splitting (Q.S.) 0.05 $mm \cdot s^{-1}$ and for the spectral contribution (S.C.) 5%.

**X-ray Crystallographic Study:** The crystal structures were determined by single-crystal X-ray diffraction methods. Crystallographic and experimental details for the different structures are summarised in Table 4. **Compound 1:** Intensity data and cell parameters were recorded at 293(2) K with a Nonius Kappa CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). DENZO-SMN was used for data integration and SCALEPACK corrected data for Lorentz polarisation effects. Absorption corrections were applied for all data using the DIFABS program.[32] The SIR92 software package[33] and SHELXL 97, included in the WinGX package, were used for phase determination and structure refinement,respectively. Direct methods of phase determination followed by some subsequent difference Fourier maps led to an electron density map from which most of the non-hydrogen atoms were identified in the asymmetry unit of the unit cell. With subsequent isotropic refinement and Fourier difference synthesis, all of the non-hydrogen atoms were identified. Atomic coordinates, isotropic and anisotropic displacement parameters of all non-hydrogen atoms were refined by means of a full-matrix least-squares procedure on $F^2$. H atoms were included in the refinement in calculated positions, riding on the carbon atoms with an isotropic thermal parameter fixed 20% and 50% higher, respectively, than the $sp^2$- and $sp^3$-C atoms to which they are attached. **Compound 2:** Intensity data and cell parameters were recorded at 150 K. The structure was solved with direct methods[34] and refined with

SHELXL-97[35] against $F^2$ of all reflections. All hydrogen atoms were located in the difference Fourier map. The OH hydrogen atoms were kept fixed at their located position; the other hydrogen atoms were refined as rigid groups. Drawings, geometry calculations and checking for higher symmetry were performed with the program PLATON.[36] **Compound 3:** Intensity data and cell parameters were recorded at room temperature (293 K) with a Bruker AXS Smart 1000 single-crystal diffractometer (Mo-$K_\alpha$ radiation) equipped with a CCD area detector. The data reductions were performed using the SAINT[37] and SADABS[38] programs. The structure was solved by direct methods using the SIR97 program[34] and refined on $F_o^2$ by full-matrix least-squares procedures using the SHELXL-97 program.[35] The non-hydrogen atoms were refined with anisotropic atomic displacements with the exception of the disordered triflate ion. The hydrogen atoms were included in the refinement at idealised geometries (C–H 0.95 Å) and refined "riding" on the corresponding parent atoms. The weighting scheme used in the last cycle of refinement was $w = 1/[\sigma^2(F_o^2) + (0.1687P)^2]$ (**3**), where $P = (F_o^2 + 2F_c^2)/3$. Molecular geometry calculations were carried out using the PARST97 program.[39] Drawings were obtained by ORTEP3 in the WinGX suite.[40] Calculations for **3** were carried out with a DIGITAL Alpha Station 255 computer. CCDC-224510 (**1**), -277598 (**2**) and -276288 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[31] The ligand field strength $10Dq^{HS}$ can be determined directly from the ligand field spectrum, using the maximum of the $^5T_2 \rightarrow {}^5E$ transition. A good approximation to the ligand field strength of the low-spin state can be obtained from the corresponding spectrum using $10Dq^{LS} = E(^1T_1) - E(^1A_1) + [E(^1T_2) - E(^1T_1)]/4$. Unfortunately, the transition $^1A_1 \rightarrow {}^1T_2$ is not observed clearly in **1**, probably because of overlap with metal to ligand charge transfer.

# Magnetic Properties of the Ordered Double Perovskite $Sr_2MnTeO_6$

**Luis Ortega-San Martin,[a] Jon P. Chapman,[a] Luis Lezama,[a] Jorge Sánchez Marcos,[c] Jesús Rodríguez-Fernández,[c] María I. Arriortua,[b] and Teófilo Rojo*[a]**

**Keywords:** Perovskite phases / Magnetic structure / EPR spectroscopy / Neutron diffraction

The ordered double perovskite $Sr_2MnTeO_6$ was prepared by the freeze-drying method. The nuclear and magnetic structures were determined by both X-ray and neutron (D2B and D1B) powder diffraction. A distorted, double perovskite structure type described by the monoclinic $P12_1/n1$ space group is observed at room temperature and down to 4 K. The room temperature EPR spectrum shows an isotropic signal centered at a $g$ value of 1.998 indicating that manganese ions are in the +2 oxidation state. At low temperature the EPR signal broadens as the exchange and dipolar interactions between $Mn^{2+}$ cations increase. Below 25 K no signal is observed, indicating that the sample is magnetically ordered. The dc magnetic susceptibility shows the existence of antiferromagnetic interactions with an ordering temperature around 20 K. A sharp λ-type anomaly observed at 19 K in the specific heat curve and refinement of low-temperature neutron diffraction data confirm the presence of a three-dimensional, antiferromagnetic ordered structure with an ordering temperature of ca. 23 K. The propagation vector of the magnetic structure is $k = [0,0,0]$, yielding a type I antiferromagnetic ordering between $Mn^{2+}$ ($S = {}^5/_2$) cations. At 2 K, each manganese ion is antiferromagnetically aligned to 8 out of 12 nearest-neighbors at an approximate distance of 5.6 Å. This magnetic structure can be viewed as being composed of ferromagnetic arrangement of $Mn^{2+}$ moments in the $ab$ plane, coupled antiferromagnetically along the $c$ axis.

## Introduction

Ordered, double perovskites have been of technological interest since the early 1950s when the search for ferroelectric and piezoelectric materials, to be used mainly as capacitors, was extended from the common perovskite oxides, $ABO_3$ (A being Sr, Ba, Pb, or $Ln^{3+}$ cations and B transition metals), to more complex systems such as the ordered perovskites, $A_2BB'O_6$.[1] As a result, many double perovskites had been discovered and their dielectric properties determined by the mid 1970s.[2] The magnetic and other electrical properties of these ordered perovskites did not attract such interest until the discovery, by Kobayashi et al.[3] in 1998, of room temperature magnetoresistance in the half-metallic $Sr_2FeMoO_6$ oxide. The intense study in this class of materials carried out after this technologically important discovery has led to the observation of other potentially useful properties such as high temperature superconductivity in $Sr_2YRu_{0.85}Cu_{0.15}O_6$[4] and the coexistence of ferromagnetism and ferroelectricity in $Bi_2NiMnO_6$.[5]

The magnetic properties, and how the diverse magnetic behaviors depend on the constituent cations, continue to be one of the most important fields of study in these materials. $Sr_2FeB'O_6$ oxides ($B' = Mo^{5+}$ or $Re^{5+}$) are the best-known examples. These oxides show room temperature ferrimagnetic behavior which results from the incomplete cancellation of the localized Fe moments antiferromagnetically aligned with the delocalized Mo/Re moments, the latter being responsible for the half metallicity and magnetoresistance.[6] If Fe is substituted by Mn, magnetic and electrical behavior changes. $Sr(Mn_{0.5}Ru_{0.5})O_3$ is a partially disordered, ferrimagnetic perovskite with a $T_c$ of approximately 125 K, which also shows magnetoresistive effects. In this phase, however, magnetic exchange is complicated due to the mixed valences observed in the ionic pairs $Ru^{IV}/Ru^{V}$ and $Mn^{III}/Mn^{IV}$.[7] In other phases, manganese stabilizes as $Mn^{2+}$ leading to higher oxidation states of elements such as Re and Mo than in their Fe analogues, favoring an ordered arrangement of the B and B′ cations. $Sr_2MnReO_6$, for example, is also ferrimagnetic (arising from an antiferromagnetic coupling between ordered Re and Mn lattices) but has an ordering temperature of 100 K, a low electrical conductivity and shows a poor magnetoresistive effect.[8] $Sr_2MnMoO_6$ is, by contrast, an antiferromagnetic oxide with a low Néel temperature, of approximately 12 K.[9] In this case, $Mn^{2+}$ is the only paramagnetic cation present, producing a lengthening of the exchange pathways and a

weakening of the predominantly antiferromagnetic interactions. Below the Néel temperature this phase shows three-dimensional antiferromagnetic order, the observed magnetic structure being of 'type II'.

In the absence of mixed valences and/or vacancy formation, complete cancellation of the antiferromagnetically aligned planes should occur, yielding conventional antiferromagnetic systems with no overall magnetic moment. The magnetic properties reported by Azad et al. for the $A_2MnWO_6$ (A = Ca, Ba, or Sr) phases,[10] expected to behave in a similar way to the analogous $Sr_2MnMoO_6$, did not fit, however, with this simple behavior. Low temperature magnetic susceptibility measurements showed the presence of two distinct maxima, the first at ca. 40 K, and the second at temperatures ranging from 9 (A = Ba) to 16 K (A = Ca). The first maximum was attributed to a disordered, canted antiferromagnetic state composed of various domains that, on further lowering of the temperature, undergo a magnetic transition to a three-dimensionally ordered antiferromagnetic phase, also of type II.

Subsequent variable temperature neutron diffraction experiments performed by Muñoz et al.[9a] in samples of the same oxides showed that the Ca and Sr phases are only three-dimensionally ordered below ca. 17 and ca. 14 K respectively, with no intermediate magnetically ordered state between 40 and 20 K. More recently, Lin et al.[11] reported a typical antiferromagnetic behavior for $Sr_2MnWO_6$ with a unique maximum at ca. 16 K in the magnetic susceptibility curve and no additional features around 40 K. The substitution of Sr cations by La, however, seems to induce in some samples the presence of a small shoulder in the magnetic susceptibility curve and irreversibility in the zero-field cooled/field-cooled susceptibilities also around 40 K.

This diversity of magnetic properties observed in such similar systems highlights the need for detailed studies of the structural and physical properties in related $A_2MnB'O_6$ (B′ = diamagnetic cation) double perovskites, such as those having B′ = Te. We have previously published the room temperature structure and high temperature phase transitions of $Sr_2MnTeO_6$.[12] In this paper we present the low temperature structure and magnetic properties of this material and establish correlations between structural features and magnetic behavior.

## Results and Discussion

### Crystal Structure

As previously reported, the room temperature crystal structure of the $Sr_2MnTeO_6$ ordered double perovskite, refined simultaneously from X-ray and D2B neutron diffraction data, is described by a monoclinic distortion of the ideal cubic cell, in space group $P12_1/n1$.[12] At high temperature, $Sr_2MnTeO_6$ undergoes three structural phase transitions at approximately 250, 550, and 675 °C, the sequence being $P12_1/n1 \rightarrow I12/m1 \rightarrow I4/m \rightarrow Fm\bar{3}m$, in good agreement with the schemes proposed by Howard and Stokes.[13]

Rietveld refinement of the low temperature crystal structure from high resolution D2B neutron powder diffraction data recorded at 4, 30, and 60 K, showed that the room temperature $P12_1/n1$ symmetry is maintained down to 4 K. The structural model was as previously reported at 298 K (reproduced in Table 1 for comparison), with all atomic positions and isotropic thermal factors freely refined. No mis-site disorder or vacancy formation was observed at 298 K and so was not refined at low temperature. Refined structural parameters are shown in Table 1 and selected bond lengths and angles in Table 2. The Rietveld fits to the 60 and 4 K data are shown in Figure 1. The structure consists of a framework of corner sharing $TeO_6$ and $MnO_6$ octahedra, with in phase (+) rotations around the *c* axis and *anti*-phase (–) rotations normal to the *c* axis. The expected increase in the magnitudes of the octahedral rotations and reduction in the cell volume on lowering the temperature are the only significant structural variations.

Table 1. Refined parameters and reliability factors for $Sr_2MnTeO_6$ from D2B powder diffraction data at different temperatures.

occurs when the A cation, $Sr^{2+}$ in this case, is too small to fill the space in the three-dimensional network of $B/B'O_6$ octahedra, the result of this mismatch being the tilting of these octahedra around the three axes of the primitive cubic perovskite.

### Electron Paramagnetic Resonance Measurements

The room temperature EPR data (see Figure 2, a) show a single, sharp resonance of Lorentzian shape with $\Delta H_{pp}$ = 80(1) Oe and a resonance field of 3375.3(2) Oe, corresponding to a $g$ value of 1.998(1). This value of the gyromagnetic factor confirms the oxidation state of Mn as +2 and the sharpness of the resonance is further evidence for the chemical and structural homogeneity of the octahedral Mn environment observed from X-ray and neutron diffraction.

Thermal evolution of the EPR signal was also studied in order to extract information regarding the magnetic and dipolar interactions in the sample. The area of the signal ($A_{EPR}$) and the peak-to-peak linewidth as a function of temperature are shown in part b of Figure 2. The peak-to-peak linewidth ($\Delta H_{pp}$) can be related to the $Mn^{2+}$ spins' relaxation time, $\tau$, in a way that $\Delta H_{pp}$ is proportional to the inverse of $\tau$.[19] As $\tau$ usually increases with decreasing temperature we should expect reduction of the signal broadening with lowering temperature. The exchange and dipolar interaction between manganese ions, however, act in the opposite sense. Figure 2 (b) shows that $\Delta H_{pp}$ is almost constant down to ca. 30 K indicating that both effects counteract one another. Below 30 K an exponential increase of $\Delta H_{pp}$ is observed which indicates that the effect of the exchange interactions between manganese cations is strong and dominates the EPR resonance process. The area of the signal, $A_{EPR}$, is related to the number of paramagnetic spins and is generally considered as the "EPR susceptibility". In order to avoid errors in the determination of the intensity because of the broadening of the signal into magnetic field regions not covered by the measurements, $A_{EPR}$ was calculated as $Y{\cdot}\Gamma{\cdot}\pi$, which results from double integration of the derivative equation that defines the resonance process for Lorentzian line-shapes.[19] In this expression, $Y$ is the height of the signal and $\Gamma$ the half-width at half-height, both of which were directly obtained from fits to the experimental data. As shown in part b of Figure 2 the value for $A_{EPR}$ increases monotonically as the temperature is reduced. In order to obtain further information about the type of magnetic interactions, the inverse of the $A_{EPR}$ curve was fitted at high temperatures by a Curie–Weiss law, $\chi = C_m/(T - \theta)$ [see inset (b) in Figure 2] which gave a Weiss constant of ca. –160 K, indicating the presence of antiferromagnetic interactions. Below 25 K, the EPR signal is no longer observed due to significant broadening and reduction in intensity; see the inset (a) in Figure 2. These effects are consistent with the existence of strong magnetic correlations between $Mn^{2+}$ spins below this temperature and the presence of a three dimensionally ordered state (see "Magnetic structure" below).

### Magnetic Susceptibility Measurements

Figure 3a shows the temperature dependence of the molar magnetic susceptibility ($\chi_m$) and inverse susceptibility ($1/\chi_m$) curves measured at 1 kOe after cooling without an applied field (ZFC). At high temperature, $T > 150$ K, the

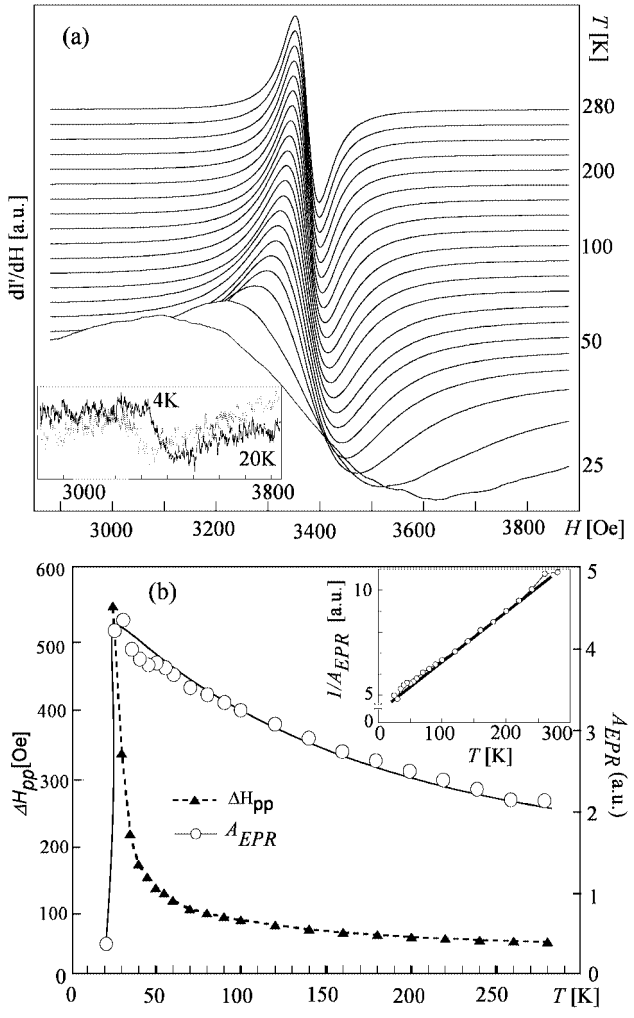

Figure 2. (a) Normalized EPR spectra between 280 and 25 K. The inset shows the weak EPR spectra observed at 4 and 20 K. (b) Thermal evolution of the signal area ($A_{EPR}$) and the peak-to-peak linewidth ($\Delta H_{pp}$).

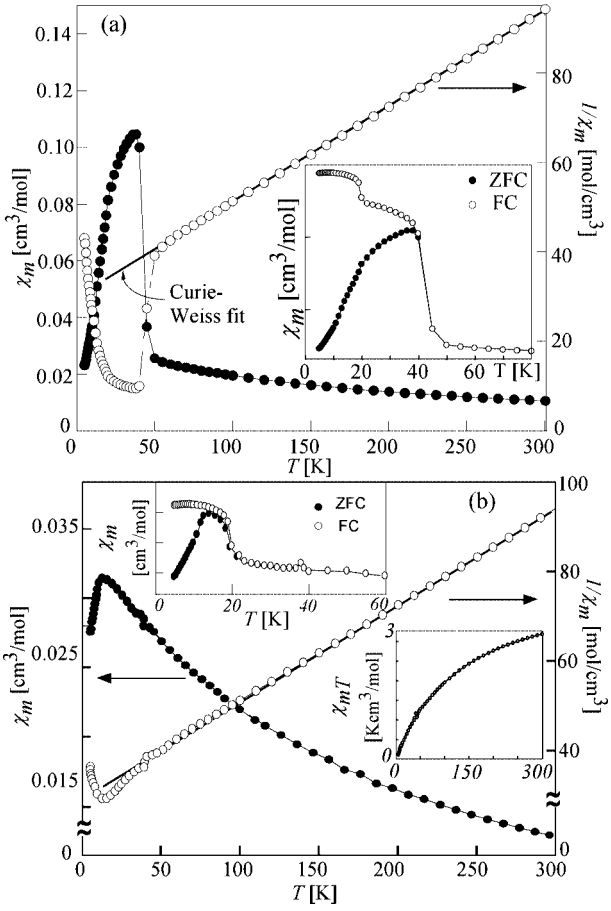

Figure 3. (a) Temperature dependence of the magnetic and reciprocal susceptibilities measured at 1 kOe. The inset shows low temperature details of the ZFC and FC modes of $\chi_m$. (b) Temperature dependence of the magnetic and reciprocal susceptibilities measured at 1 kOe after the subtraction of the component due to the presence of 1.5% by mass of $Mn_3O_4$. Inset are the corrected ZFC and FC modes and the corrected thermal evolution of the product $\chi_{mT}$.

thermal evolution of $\chi_m$ follows the classical Curie–Weiss law, with $C_m = 4.6$ cm$^3$·K/mol and $\theta = -136$ K indicating that the predominant interactions are of antiferromagnetic nature and in very good agreement with the values obtained from EPR. The effective magnetic moment ($\mu_{eff}$) calculated for the paramagnetic region well above the Néel temperature as $\mu_{eff} = 2.828\sqrt{C_m}$ gave the value of 6.05 $\mu_B$, very close to the theoretical value (5.91 $\mu_B$) obtained from $\mu_{eff} = g\sqrt{S(S+1)}$, considering high spin $S = {}^5/_2$ manganese cations with no orbital contribution.

The inset (a) in Figure 3 shows details of the low-temperature molar magnetic susceptibility ($\chi_m$) measured in ZFC and FC modes. Two distinct features, at approximately 40 and 20 K, can be observed in both modes. The most important characteristic of this low temperature behavior is that the maximum at ca. 40 K appears at the same tempera-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ture as that observed in all $A_2MnWO_6$ (A = Ca, Ba, Sr) phases studied by Azad et al.,[10] while the low temperature maximum appears at a different temperature in each sample. Similar characteristics have also been observed in phases of the $Sr_{2-x}La_xMnWO_6$ series.[11] It is worth noting that these features observed in some antiferromagnetic manganese-containing double perovskites are very similar to those reported for the ferrimagnetic $Mn_3O_4$, with a $T_c$ of 42 K.[20]

Field-dependent DC and AC susceptibility measurements, on both $Sr_2MnTeO_6$ and commercially available $Mn_3O_4$ (CAS number: 1317-35-7) showed very similar behavior, with the appearance of significant features around 40 K, the only difference being the appearance of a weak maximum in the DC susceptibility and in the real ($\chi'$) component of the AC susceptibility in the case of $Sr_2MnTeO_6$. These characteristics confirm that the maxima around 40 K correspond to $Mn_3O_4$ rather than originating from the magnetic behavior of $Sr_2MnTeO_6$. These observed DC susceptibility curves are similar to those reported for the similar double perovskite oxide $Ba_2MnWO_6$, in which the ferromagnetism observed below 40 K was attributed to a disordered canted antiferromagnetic state composed of various domains.[10c] Further details of the susceptibility study are available as supporting information to this article.

It is worth noting that the presence of undetected $Mn_3O_4$ has led to misinterpretation of the magnetic properties of many manganese-containing compounds. One of the first examples is the oxide MnO, which was considered to behave as a spin glass around 40 K, but the AC susceptibility revealed that the maximum observed in the DC susceptibility measurements at this temperature actually originated from an undetected fraction of $Mn_3O_4$.[21] Recently, Goff et al.[22] demonstrated that quantities as low as 1% of this oxide can completely mask the magnetic behavior of the majority phase. The magnetic behavior published for $A_2MnWO_6$ may be a further example of this type of undetected contamination with $Mn_3O_4$.[10] The DC susceptibility data for $Sr_2MnTeO_6$, corrected for an estimated 1.5% by mass of $Mn_3O_4$ are shown in Figure 3 (b). It is therefore clear that great care must be taken when analyzing the magnetic properties of manganese-containing compounds as manganese oxides exist with strong ferro/ferri-magnetic behavior that, well below the detection limit of other techniques, can completely dominate the magnetic properties of phases under investigation.

## Specific Heat Measurements

Figure 4 shows the observed total specific heat ($C_P$), the calculated contribution of lattice phonons to the specific heat, $C_{P(pho)}$, and the resulting magnetic specific heat, $C_{P(mag)}$. The total specific heat exhibits a three-dimensional ($\lambda$-type) magnetic ordering peak at 20 K, in agreement with the previous magnetic and neutron diffraction data. The contribution of the lattice vibrations to the specific heat capacity was calculated by fitting the experimental high temperature data (above the $\lambda$ anomaly) using a modified Debye model considering the existence of two phonon spectra. For a formula unit containing $N$ atoms, $n_1$ was assigned a Debye temperature $\theta_1$ and $n_2$, constrained such that $n_2 = N - n_1$, a Debye temperature $\theta_2$, yielding three independent variables to be refined, namely $\theta_1$, $\theta_2$, and $n_1$. Refined values indicate that, of the 10 atoms in the formula unit, 3.5 ($n_1$) have a Debye temperature of 217 K and 6.5 ($n_2 = N - n_1$) have a Debye temperature of 616.5 K. This result not only produces an excellent fit to the experimental data up to 300 K, but is also in good agreement with the chemical formula contents of 4 heavy atoms and 6 light atoms, the latter with a much higher Debye temperature. The magnetic specific heat, $C_{P(mag)}$, shown in Figure 4, being the result of subtracting the phonon component from the total specific heat ($C_P$).

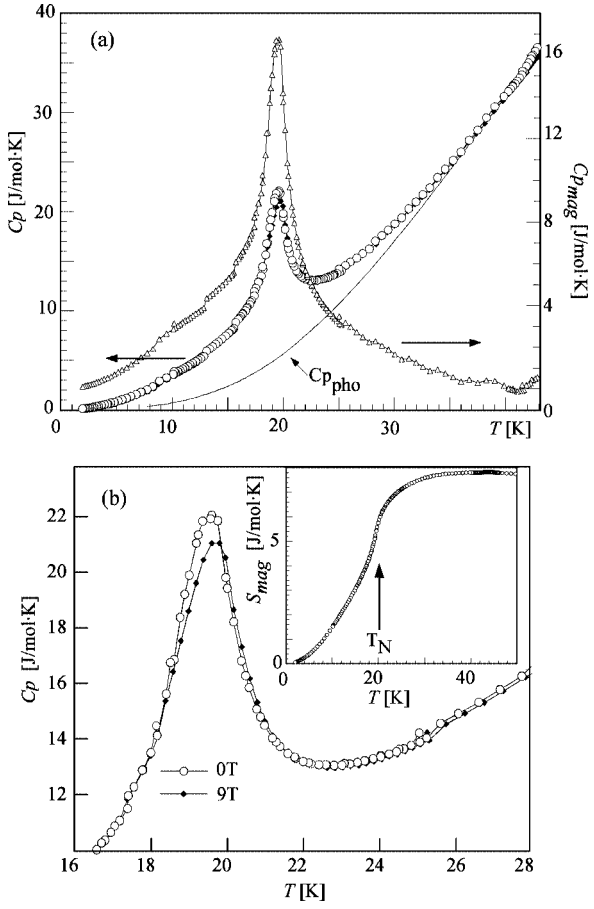

Figure 4. (a) Specific heat vs. temperature of $Sr_2MnTeO_6$ from 1.8 to 45 K showing total specific heat, $Cp$, the calculated phonon contribution, $Cp_{pho}$, and the resultant magnetic contribution, $Cp_{mag}$. (b) Comparison between the specific heat data measured at 0T and under an applied magnetic field of 9T. The inset shows the calculated magnetic entropy, $S_{mag}$.

The effect of a 9T magnetic field on the three-dimensional $\lambda$ peak in the heat capacity is shown in Figure 4 (b). In a pure antiferromagnetic sample, a small displacement of the peak to lower temperatures with increasing magnetic

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

field would be expected. It can be seen, however, that the peak is slightly displaced to higher temperature with the applied field, indicating a small ferromagnetic component. This ferromagnetic component may originate from a small canting in the antiferromagnetic structure as the small magnitude of the displacement is typical of highly anisotropic antiferromagnets. The thermal evolution of the magnetic entropy, $S_{mag}$, released in the ordering process for this phase is shown in the inset (b) of Figure 4. The total magnetic entropy, calculated from the $S_{mag}(T) = \int_0^T C_{mag}(T)/T \cdot dT$ expression, was found to be ≈8 J/mol·K above 20 K. This value is ≈60% of the theoretical value, $R \cdot \ln(2S + 1)$ = 14.9 J/mol·K, expected for the $S = {}^5/_2$ state of the $Mn^{2+}$ cation at low temperatures. This low value could be related to systematic errors in the subtraction of the lattice component around the observed maximum in the specific heat data or, as has been previously suggested, this deviation could indicate that some of the spins of the $Mn^{2+}$ ions are not correlated to the rest.[23] The latter explanation would, however, also imply a similar deviation of the low temperature magnetic moment of the $Mn^{2+}$ spins, an effect not observed in $Sr_2MnTeO_6$.

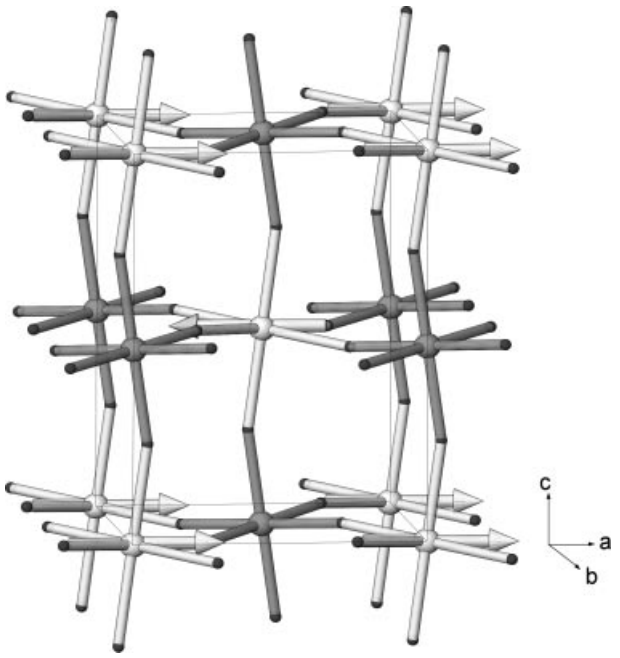

Figure 5. Type I antiferromagnetic structure of $Sr_2MnTeO_6$. Lighter spheres represent Mn and darker spheres Te. Sr atoms are omitted for clarity.

## Magnetic Structure

The 4 K neutron diffraction data show the presence of several additional peaks which arise from long-range magnetic order in the sample (see Figure 1, b). These reflections were not coincident with those of the nuclear structure indicating that this magnetic order is of antiferromagnetic nature. These peaks were indexed considering a magnetic cell with the same dimensions as that of the crystal cell (with parameters $\sqrt{2}a_p \times \sqrt{2}a_p \times 2a_p$, where $a_p$ is the primitive cubic perovskite parameter) in the $P1$ space group (refined neutron data are shown in Figure 1, b). The first two sharp magnetic peaks are, consequently, the unique (001) reflection and the unresolved doublet composed of the (010) and (100) reflections. The type I antiferromagnetic structure is the only collinear arrangement of magnetic ions compatible with these observed maxima. The strong (001) peak indicates that an important component of the magnetic moment is in the *ab* plane. The orientation of the magnetic moments in this plane could not be determined, because of the overlap of the (010) and (100) reflections. No significant component was observed in the *c*-direction. In the final model, magnetic moments of magnitude *M*, were fixed along *a* and –*a* in alternating planes in the *c*-direction. The refined structure at 4 K, showing the orientation of magnetic moments, is shown in Figure 5. In this magnetic structure each manganese cation is antiferromagnetically coupled by 90° superexchange interactions via diamagnetic –O–$Te^{6+}$–O– bridges to 8 out of 12 nearest-neighbors, NN, at an approximate distance of 5.6 Å. The six next nearest-neighbors, NNN, (at ca. 8.0 Å) are all ferromagnetically aligned via 180° –O–$Te^{6+}$–O– linkages.

Figure 6 shows the temperature-dependent D1B diffraction data. The thermal evolution of the refined magnetic moment ($M_x$) is represented in Figure 7. It can be observed that the three-dimensional magnetic order begins at 20 K. The $Mn^{2+}$ moment rapidly increases below 20 K, reaching saturation at approximately 10 K. The obtained value of $M_x$ = 4.55(5) $\mu_B$ is close to the theoretical value of 5 $\mu_B$ for high spin $S = {}^5/_2$ manganese at low temperature.

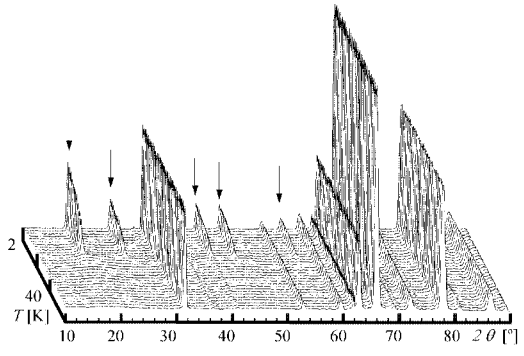

Figure 6. Temperature-dependent D1B neutron diffraction data from 2 to 60 K. Magnetic peaks are marked by arrows.

The temperature dependence of the refined lattice parameters and volume are shown in Figure 8. The thermal evolution of the lattice parameters is of particular interest. The *a* parameter exhibits almost no variation whereas the *b* and *c* parameters show different behaviors with temperature. Below 20 K, where three-dimensional magnetic order is observed, the parameters show no systematic change. At 20 K, a marked discontinuity is observed in both parameters with *c* increasing and *b* decreasing. Above 20 K, the *b* and *c* parameters are again virtually independent of tem-

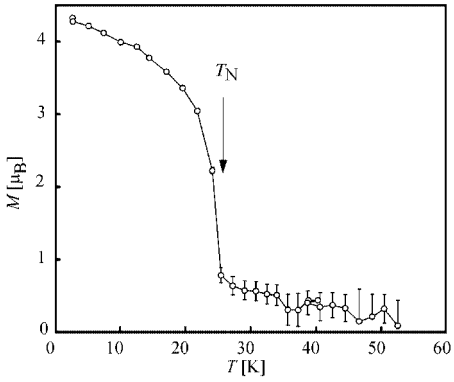

Figure 7. Temperature dependence of the magnitude of the magnetic moment refined from D1B neutron diffraction data from 2 to 60 K, with the Néel temperature, $T_N$ = 22 K, marked.

perature. The thermal evolution of the unit cell volume shows no change below 20 K and a small increase at higher temperatures.

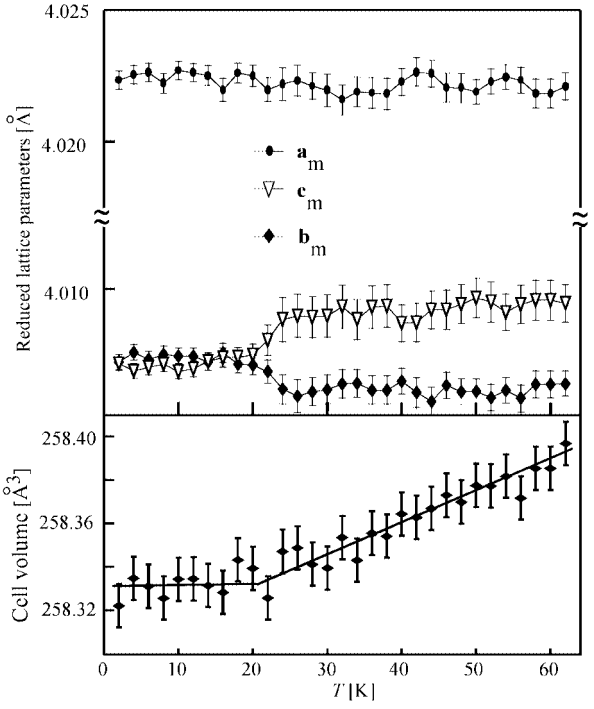

Figure 8. Temperature dependence of the reduced lattice parameters and cell volume refined from D1B neutron diffraction data from 2 to 60 K. Reduced lattice parameters were calculated as follows: $a_m = a/\sqrt{2}$, $b_m = b/\sqrt{2}$; cm = $c$/2.

The observed behavior could be associated to "spontaneous magnetostriction" resulting from a magnetically ordered state, in contrast to the "common magnetostriction" effect that results from the application of a magnetic field.[24] In $Sr_2MnTeO_6$, this effect can be viewed as the result of the nature of the magnetic order (see Figure 9), where moments perpendicular to the [001] direction attract one another, leading to a reduction of the $c$ parameter with the increase in $b$ parameter being the result of the repulsion between ferromagnetically aligned moments in the $ab$ plane. Similar, but more pronounced, spontaneous magnetostriction effects have also been recently observed in the ferromagnetic oxides $SrRu_{1-x}O_3$.[25a] Field-induced magnetostriction is common in other ferromagnetic perovskites, such as manganites and double perovskites,[25b–25c] but the observation of this spontaneous effect in this type of antiferromagnet is rare.

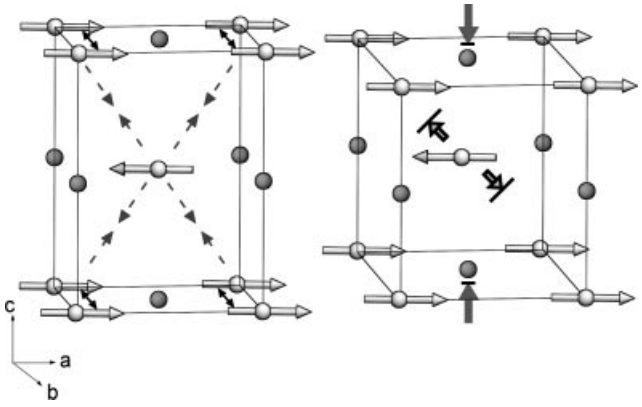

Figure 9. Origin of the spontaneous magnetostriction effect observed in $Sr_2MnTeO_6$. Dark spheres represent Te and light ones with arrows represent Mn with their magnetic moments. Also depicted are arrows indicating the compressions and elongations of the unit cell dimensions as a consequence of the magnetic ordering. Sr and O atoms are omitted for clarity.

## Conclusions

The ordered double perovskite $Sr_2MnTeO_6$ crystallizes at room temperature in space group $P12_1/n1$ and maintains its symmetry on cooling down to 4 K. Electron paramagnetic resonance spectroscopy shows the presence of a sharp resonance centred at a $g$ value of 1.998(2), indicating that manganese ions are in the +2 oxidation state. As the temperature is lowered and magnetic exchange interactions between $Mn^{2+}$ become stronger, the area of the resonance increases showing a maximum around 25 K. Below this temperature a large broadening of the signal occurs indicating that the sample is magnetically ordered.

Magnetic DC susceptibility follows the Curie–Weiss law at high temperatures, and a Weiss constant of –136 K indicates that the predominant interactions are of antiferromagnetic nature. The observed effective magnetic moment agrees well with a $S = {}^5/_2$ cation with no orbital contribution. The Néel temperature was estimated to be 20 K. At this same temperature the specific heat shows a $\lambda$-type anomaly typical of three-dimensionally ordered systems, which is slightly repressed on application of a field of 9T. Both effects are consistent with the observed anti-ferromagnetic ordering within the sample. Low temperature neutron diffraction indicates that the ordered antiferromagnetic state is of type I, in which planes perpendicular to the (001) direction contain $S = {}^5/_2$ $Mn^{2+}$ magnetic moments ferromagnetically coupled to one another within the plane via diamagnetic –O–$Te^{6+}$–O– bridges. These planes are coupled antiferromagnetically because of the stronger 90° Mn–

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

O···O–Mn linkages, producing the predominant antiferromagnetic inter-planar interactions. The observed magnetic moment per manganese ion of 4.5 $\mu_B$ indicates that virtually all the sample is magnetically ordered at this temperature. Discontinuities observed around the ordering temperature in the lattice parameters indicate that this phase also shows a small spontaneous magnetostriction effect.

## Experimental Section

Synthesis, room temperature structural refinement, and confirmation of nominal stoichiometry of the ordered double perovskite $Sr_2MnTeO_6$ have been reported previously.[12] Low temperature neutron powder diffraction data were collected at 4, 30, and 60 K on instrument D2B at the Institut Laue Langevin (I.L.L.), Grenoble, France. Neutrons of wavelength 1.595 Å were incident on 10 g of $Sr_2MnTeO_6$, contained in an 8-mm diameter vanadium can held in a liquid helium cryostat. Data were collected over the angular range $0 \leq 2\theta \leq 160°$, then normalized for subsequent refinement in GSAS.[26]

Temperature-dependent neutron powder diffraction data were collected on instrument D1B at the I.L.L. Neutrons of wavelength 2.52 Å were incident on 10 g of $Sr_2MnTeO_6$, contained in an 8-mm diameter vanadium can held in a liquid helium cryostat. Data were collected every 2 K from 2 to 60 K over the angular range $10 \leq 2\theta \leq 90°$. Evolution of lattice parameters and magnetic moment ($M_x$) with temperature were obtained by sequential refinement in FullProf[27] starting from the structural model refined with D2B data at 4 K.

X-band EPR spectra were recorded between 0 and 7 kOe from 300 to 5 K with a Bruker ESP 300 spectrometer. The temperature was controlled by an Oxford Instruments (ITC4) regulator. The magnetic field was measured with a Bruker BNM 200 gaussmeter and the frequency inside the cavity was determined using a Hewlett–Packard 5352B microwave frequency counter.

DC magnetic susceptibility measurements were performed using a Quantum Design MPMS-7 SQUID magnetometer whilst heating from 5 to 300 K in an applied field of 1 and 5 kOe. In both cases, data were collected after cooling either in the presence (field cooling –FC curve) or absence (zero-field cooling- ZFC curve) of the applied field. Magnetization as a function of applied field ($H$) was measured using the same MPMS-7 SQUID magnetometer after cooling the sample in zero field. Magnetization was also measured as a function of temperature between 5 and 80 K.

AC magnetic susceptibility measurements were made with a standard QD PPMS system with an alternate excitation field ($H_{ac}$) of 1 Oe at frequencies between $10^2$ and $10^4$ Hz. Data were recorded from 4 to 60 K as a function of both frequency and applied DC magnetic field.

Heat capacity measurements were carried out by a relaxation method using the same PPMS system. The sample was a plate of 0.3 mm thickness and 7 mg weight obtained by compressing the original powder. Data were collected with zero field (0T) and under an applied field of 9T from 1.8 to 300 K.

**Supporting Information** (for details see the footnote on the first page of this article): Further magnetic data are available as Supporting Information, due to the magnetic characterisation of $Sr_2MnTeO_6$ having been complicated by the presence of the ferromagnetic oxide, $Mn_3O_4$. Field-cooled and zero-field cooled DC susceptibilities at various applied fields and field- and frequency-dependent AC susceptibilities are presented for both the as-prepared $Sr_2MnTeO_6$ and commercially available $Mn_3O_4$. Also included is the field-dependence of the magnetization for $Sr_2MnTeO_6$.

# Synthesis and Reactivity of $[Ru(Cp^*)(L)(MeCN)_2][PF_6]$ (L = $Ph_2POMe$ or $Ph_2P$-*o*-tolyl) and $\{Ru(Cp^*)[Ph_2PCH_2C(tBu)=O](MeCN)\}[PF_6]$ Complexes, Their Involvement as Catalyst Precursors for Regioselective Allylic Substitution Reactions and Related $[Ru(Cp^*)Cl(Ph_2POMe)(RCHCHCH_2)][PF_6]$ $\eta^3$-Allyl Ruthenium(IV) Intermediates

**Bernard Demerseman,*[a] Jean-Luc Renaud,[a] Loïc Toupet,[a] Claudie Hubert,[a] and Christian Bruneau[a]**

**Keywords:** Allyl ligands / Allylation / Homogeneous catalysis / Regioselectivity / Ruthenium

The synthesis of the new complexes $[Ru(Cp^*)(L)(MeCN)_2][PF_6]$ (L = $Ph_2POMe$ or $Ph_2P$-*o*-tolyl) and $\{Ru(Cp^*)[Ph_2PCH_2C(tBu)=O](MeCN)\}[PF_6]$ (**2a–c**) is achieved starting from $[Ru(Cp^*)(MeCN)_3][PF_6]$. The acetonitrile ligands in complexes **2a–c** are labile, as emphasised by the easy formation of $\{Ru(Cp^*)(CO)_2[Ph_2PCH_2C(=O)tBu]\}[PF_6]$ (**3**). The keto-phosphane is used as a tool to convert **3** into $\{Ru(Cp^*)(CO)[Ph_2PCH_2C(tBu)=O]\}[PF_6]$ (**5**). Complex **5** reacts with 1,1-diphenyl-2-propyn-1-ol in methanol as solvent to afford the vinyl-carbene complex $\{Ru(Cp^*)(CO)[=C(OMe)CH=CPh_2][Ph_2PCH_2C(=O)tBu]\}[PF_6]$. The new $\eta^3$-allyl ruthenium(IV) derivatives $[Ru(Cp^*)Cl(Ph_2POMe)(CH_2CMeCH_2)][PF_6]$ and $[Ru(Cp^*)Cl(Ph_2POMe)(RCHCHCH_2)][PF_6]$ (R = Me; *n*Pr, **8d**; or Ph, **8e**) are obtained by reacting **2a** with the appropriate allylic halide. The X-ray crystal structure determination of the compounds **8d** and **8e** disclosed an *endo-trans*-$RCHCHCH_2$ $\eta^3$-allyl ligand. The formation of branched allyl aryl ethers is regioselectively favoured when complexes **2a–c** are involved as catalyst precursors for the etherification of cinnamyl chloride, chlorohexene and 3-chloro-4-phenylbut-1-ene with phenol, *p*-methoxyphenol, cresols and (*o* or *p*)-chlorophenols, in the presence of $K_2CO_3$.

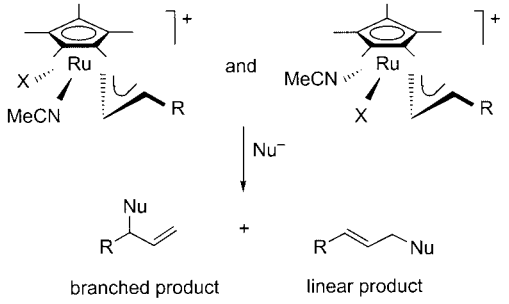
## Introduction

Recently, the labile ruthenium(II) complex $[Ru(Cp^*)(MeCN)_3][PF_6]$ (**1**) (Cp* = pentamethylcyclopentadienyl) was disclosed as an efficient catalyst precursor for the allylation of phenols with cinnamyl derivatives according to stereospecific and regioselective processes.[1,2] Furthermore, enantioselective synthesis was also achieved in the additional presence of a chiral bis-oxazoline ligand.[3] Enantioselective allylic amination and alkylation involving related catalysts based on tethered Cp′ rings resulting in planar chirality at the ruthenium centre have also been reported.[4] From a mechanistic point of view, these catalytic reactions occur through transient formation of electrophilic $\eta^3$-allyl ruthenium(IV) species.[5] Indeed, complexes $[Ru(Cp^*)X(MeCN)(\eta^3\text{-}RCHCHCH_2)][PF_6]$ resulted from the oxidative addition of allylic halides to **1**, but have been disclosed to be a mixture of stereoisomers in solution, as enantiomeric pairs (see Scheme 1).[2] The recently reported tethered complexes $[Ru(Cp'\text{-}PR_2)Cl(\eta^3\text{-}CH_2CRCH_2)][PF_6]$ involved a symmetrical $\eta^3$-allyl ligand precluding analogous stereoisomerism arising from the presence of four distinct coordinating centres besides the cyclopentadienyl ligand.[6]



Scheme 1. Stereoisomerism and isomerism from unsymmetrical $\eta^3$-$CH_2CHCHR$ allyl ligand.

Therefore, no information was available concerning the relationship between the regioselectivity of the catalytic nucleophilic substitution and the stereoselective formation of the putative $\eta^3$-allyl ruthenium(IV) intermediate. Moreover, using such ruthenium catalysts, the regioselective formation of branched products by nucleophilic attack at an unsymmetrical $\eta^3$-$RCHCHCH_2$ allyl ligand, as depicted in Scheme 1, largely remained a challenge when R was an alkyl group instead of an aryl one arising from cinnamyl substrates. On the other hand, while the reactivity of

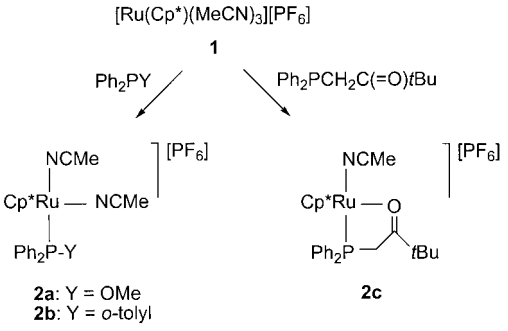
$[Ru(Cp)(PR_3)(MeCN)_2][PF_6]$ complexes towards alkynes continued to stimulate studies,[7] little was known concerning their reactivity towards allylic organic substrates, although $[Ru(Cp)Br(PR_3)(\eta^3\text{-}CH_2CHCH_2)][PF_6]$ complexes have been synthesised.[8]

We wish to report herein (i) the reaction between $[Ru(Cp^*)(MeCN)_3][PF_6]$ and methyl diphenylphosphinite, *o*-tolyldiphenylphosphane or a hemilabile β-keto-phosphane, which provides an efficient tool for the building of new organometallic derivatives, (ii) the synthesis of $[Ru(Cp^*)X(Ph_2POMe)(RCHCHCH_2)][PF_6]$ $\eta^3$-allyl ruthenium(IV) complexes bearing an unsymmetrical monosubstituted allyl ligand and (iii) the involvement of these complexes as catalyst precursors for regioselective allylic etherification.

## Results and Discussion

### Synthesis of Complexes

With a procedure very similar to the reported synthesis of $[Ru(Cp^*)(PEt_3)(MeCN)_2][PF_6]$,[9] the reaction of $[Ru(Cp^*)(MeCN)_3][PF_6]$ (**1**) with one equiv. of methyl diphenylphosphinite or of the bulkier *o*-tolyldiphenylphosphane selectively resulted in the substitution of one acetonitrile ligand to afford the expected complexes $[Ru(Cp^*)(L)(MeCN)_2][PF_6]$ (L = $Ph_2POMe$, **2a** and L = $Ph_2P$-*o*-tolyl, **2b**), in 78% and 99% yield, respectively (Scheme 2).



Scheme 2. Synthesis of the new complexes **2a**–**c**.

Distinctly, the reaction between **1** and the β-keto-phosphane $Ph_2PCH_2C(=O)tBu$ showed the substitution of two acetonitrile ligands to afford **2c** wherein the functional phosphane acted as a chelate, in 95% yield (Scheme 2). The new complexes **2a**–**c** were characterised by $^1H$, $^{13}C\{^1H\}$, $^{13}C$ DEPT and $^{31}P\{^1H\}$ NMR, IR spectroscopy and elemental analysis. The $^1H$ and $^{31}P\{^1H\}$ NMR spectra of **2a**–**c** unambiguously indicated the presence of coordinated acetonitrile and one phosphorus ligand besides the Cp* one. Additionally, IR spectroscopy provided evidence for the coordination of the keto function in **2c** ($\tilde{\nu}$ = 1611 $cm^{-1}$) as previously specified in the case of CpRu complexes.[10] Attempts of recrystallisation of **2b**,**c** invariably led to oils that transform to yellow solids under prolonged vacuum. By contrast, orange crystals of **2a** suitable for X-ray crystal structure determination easily formed according to diffusion of diethyl ether into a concentrated dichloromethane solution. An ORTEP drawing of **2a** is shown in Figure 1 and selected bond lengths and angles are given in the caption.

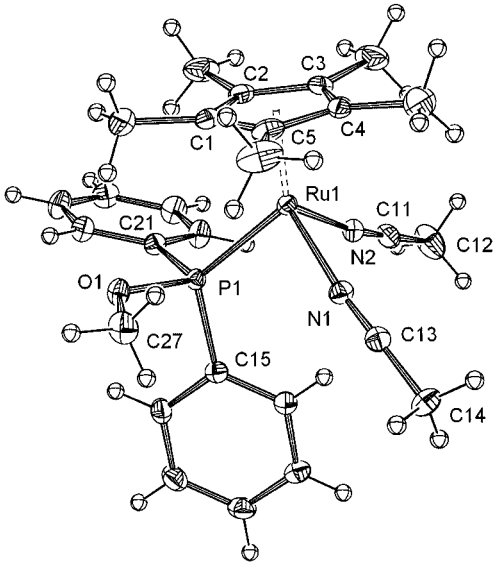


Figure 1. ORTEP drawing of **2a** showing 50% probability thermal ellipsoids. The $PF_6$ anion is omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–N1 2.076(2), Ru1–N2 2.067(2), Ru1–P1 2.2894(6); N1–Ru1–N2 87.74(8), N1–Ru1–P1 94.55(6), N2–Ru1–P1 90.77(6).

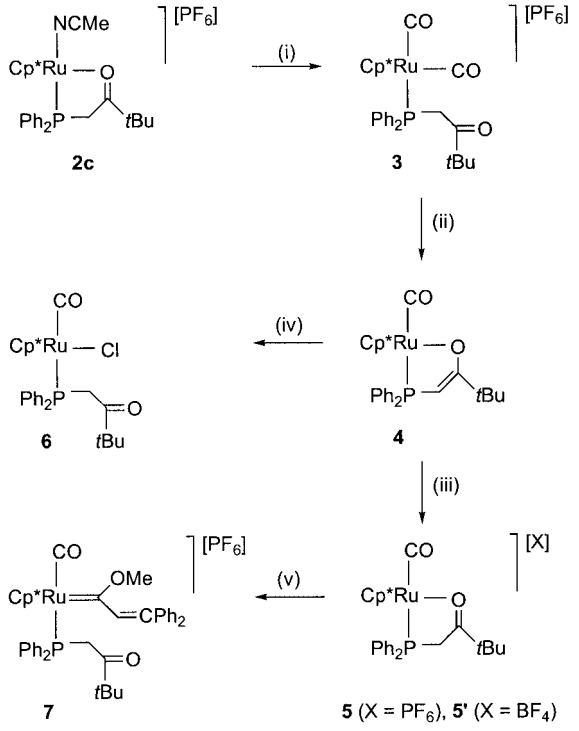
The cation of **2a** showed the expected piano-stool geometry. The N–Ru–N and N–Ru–P angles are close to 90° and the structure of **2a** thus consisted of a pseudo-octahedron with the Cp* ligand occupying three facial coordination sites.

Complex **2c** retained two labile coordinating atoms, as indicated by its reaction with carbon monoxide, which occurred under mild conditions (1 atm, ambient temperature) to straightforwardly afford the dicarbonyl complex **3** (Scheme 3).

The formal selective substitution of the acetonitrile ligand in **2c** by carbon monoxide was indirectly achieved by reacting **3** with $Me_3NO{\cdot}2H_2O$ to form the enolato-phosphane derivative **4** (Scheme 3). The reaction consisted of the oxidation of one carbon monoxide ligand into carbon dioxide, thus also generating $NMe_3$, which subsequently deprotonated the keto-phosphane. The neutral complex **4** was then easily reprotonated with $HPF_6$ as its aqueous solution or with $HBF_4$ as its $Me_2O$ adduct, to obtain **5** and **5′**, respectively, in yields up to 81%. The protonation of **4** was also achieved with hydrochloric acid, but the additional coordination of the chloride anion resulted in the neutral chloro complex **6** (Scheme 3). These reactions emphasised the usefulness of hemilabile keto-phosphanes as a tool for the building of coordination compounds. Furthermore, the coordinated keto-function in **5** is labile enough to allow the coordination of alkynols such as 1,1-diphenyl-2-propyn-1-ol. Using methanol as solvent, the reaction led at room temperature to a red precipitate of the vinyl-carbene derivative

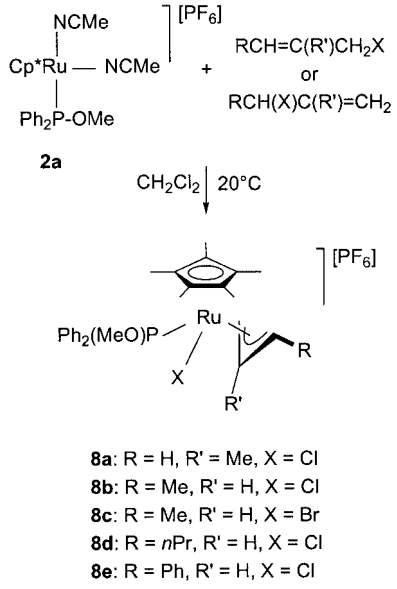
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. Reactivity of complex **2c**: (i) CO, 1 atm; (ii) $Me_3NO{\cdot}2H_2O$; (iii) $HPF_6$ or $HBF_4$; (iv) HCl; (v) $Ph_2C(OH)C{\equiv}CH$, MeOH.

**7** (Scheme 3). The reaction might be conceived as an addition of methanol to a transient allenylidene species as previously investigated for $[Ru(Cp)(CO)(acetone)(P\textit{i}Pr_3)][BF_4]$.[11] Complexes **3**–**7** were characterised from a combination of $^1H$, $^{13}C\{^1H\}$, $^{13}C$ DEPT and $^{31}P\{^1H\}$ NMR, IR spectroscopy and elemental analysis. Owing to the chiral ruthenium centre, the two $PCH_2$ protons of the keto-phosphane were found to be diastereotopic in complexes **2c**, **5**, **5′**, **6** and **7**. Characteristic of the vinyl-carbene ligand in **7** is the observation by $^{13}C\{^1H\}$ NMR spectroscopy of a very low field resonance at $\delta$ = 303.7 ppm (d, $^2J_{PC}$ = 2.5 Hz) corresponding to the Ru=C carbon nucleus.[11] Some steric congestion in **7** is likely responsible for the broadness of both the $^{31}P\{^1H\}$ NMR resonance at $\delta$ = 38.8 ppm and the $^1H$ NMR resonance assigned to the OMe protons at $\delta$ = 4.05 ppm. IR spectroscopic data accounted for the presence of carbon monoxide as a ligand and for the coordination mode of the functional phosphane ($\tilde{\nu} \approx 1700\ cm^{-1}$, uncoordinated C=O, in **3**, **6** and **7**; $\tilde{\nu} \approx 1600\ cm^{-1}$, coordinated C=O, in **5** and **5′**; $\tilde{\nu} = 1500\ cm^{-1}$, C=CO, in **4**).[10]

Complexes **2a**–**c** were observed to react with allylic halides but crystallisable products were obtained only starting from **2a**. Using dichloromethane as solvent, the $\eta^3$-allyl ruthenium(IV) derivatives **8a**–**e** resulted from the reaction at room temperature between **2a** and 3-chloro-2-methylpropene, crotyl chloride or bromide, chlorohexene as a mixture of isomeric $n$PrCH=CHCH$_2$Cl and $n$PrCH(Cl)CH=CH$_2$, and cinnamyl chloride (Scheme 4). Complexes **8a**–**e** were isolated in high yield (62–85%) as yellow to red crystals that were observed to be stable in air. Of interest, the formation of complexes **8** was observed to be sluggish in acetonitrile as solvent. Thus, the addition of cinnamyl chloride (an excess) to a solution of **2a** in acetonitrile showed only about 10% of **2a** to be converted into **8e** after standing for two days at room temperature, as monitored by $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopy. Indicating an irreversible formation, solutions of **8e** in acetonitrile were observed to be stable and unchanged after 8 days. Such an observation of a formation hindered by the presence of acetonitrile as coordinating solvent suggests a dissociative mechanism. The coordination of the olefinic bond of the allylic halide at a transient 16e-intermediate resulting from the loss of an acetonitrile ligand by **2a** would be a preliminary step allowing subsequent intramolecular oxidative addition.



Scheme 4. Synthesis of the new $\eta^3$-allyl ruthenium(IV) complexes, **8a**–**e**.

Complexes **8a**–**e** were characterised by NMR spectroscopic techniques including $^1H\{^{31}P\}$ for **8c**,**d**, and elemental analysis. Of main interest, $CD_2Cl_2$ solutions of **8a**–**e** disclosed single species by $^1H$, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectroscopy. The characterisation of complexes **8a**–**e** was finally completed by an X-ray crystal structure determination of **8d** and **8e**. ORTEP drawings of cations of **8d** and **8e** are shown on Figure 2 and Figure 3, respectively. Selected bond lengths and angles are given in the captions of the figures.

Cations of **8d** and **8e** displayed a square-pyramidal structure with a chlorine, a phosphorus and the terminal carbon atoms of an *endo*-$\eta^3$-allyl ligand, at basal positions. Likely resulting from an increased steric demand, the Ru–P bond length in **8d** or **8e** [Ru1–P1 = 2.368(1) and 2.360(1) Å, respectively] is longer than in **2a** [Ru1–P1 = 2.2894(6) Å]. Moreover, the phosphorus atom in **8d** and **8e** is located in a *trans* position relative to the substituted allylic carbon and such an arrangement would minimise steric constraints between the allyl and the phosphorus ligands. The Ru–Cl bond lengths [2.406(1) Å in **8d**, 2.396(1) Å in **8e**] revealed

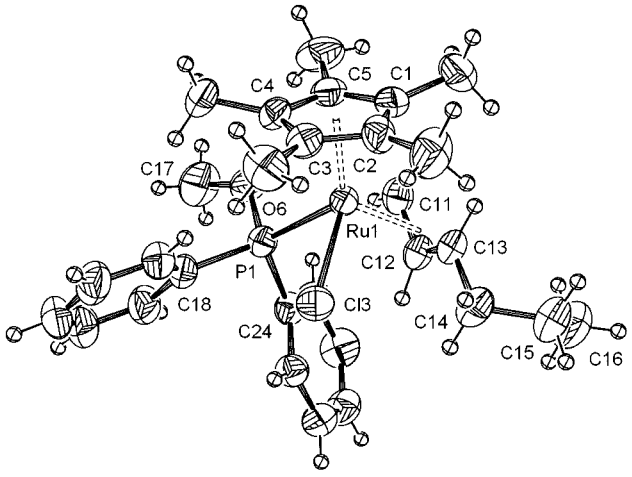

Figure 2. ORTEP drawing of **8d** showing 50% probability thermal ellipsoids. The $PF_6$ anion is omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–C11 2.191(4), Ru1–C12 2.198(4), Ru1–C13 2.339(4), Ru1–P1 2.368(1), C11–C12 1.406(6), C12–C13 1.395(6), C13–C14 1.497(6), Ru1–P1 2.368(1); C11–C12–C13 119.1(4), C12–C13–C14 123.7(4).

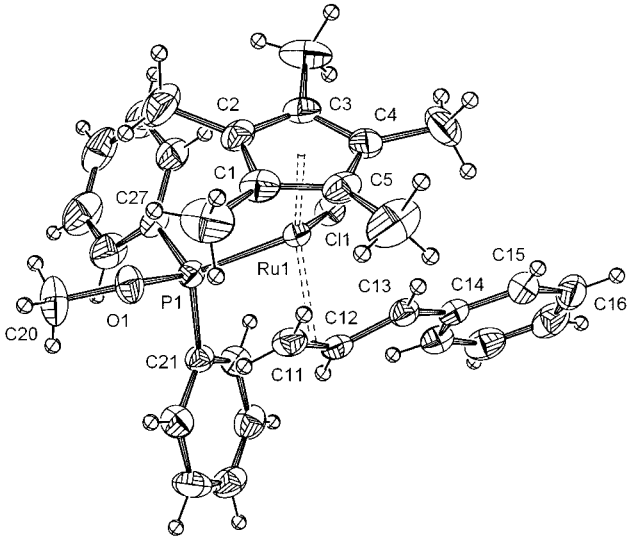

Figure 3. ORTEP drawing of **8e** showing 50% probability thermal ellipsoids. The $PF_6$ anion is omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–C11 2.182(5), Ru1–C12 2.210(4), Ru1–C13 2.452(4), C11–C12 1.398(6), C12–C13 1.396(6), C13–C14 1.457(6), Ru1–P1 2.360(1); C11–C12–C13 119.5(4), C12–C13–C14 125.7(4).

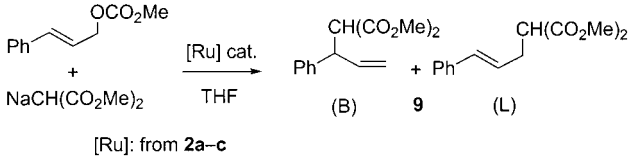
no special feature and are very close to the values previously reported in the case of the related complexes $[Ru(Cp^*)Cl(MeCN)(\eta^3\text{-}PhCHCHCH_2)][PF_6]$ and $[Ru(Cp^*)Cl_2(\eta^3\text{-}PhCHCHCH_2)]$ [2.3998(7) and 2.398(3) Å, respectively].[5,13]

The only difference between **8d** and **8e** was an alkyl *n*-propyl group instead of a phenyl group, respectively, as the substituent linked to one terminal carbon of the $\eta^3$-allyl ligand. The Ru–C bond lengths involving the unsubstituted terminal allylic C11 carbon atom [2.191(4) Å in **8d** and 2.182(5) Å in **8e**] and the medium C12 carbon atom [2.198(4) Å in **8d** and 2.210(4) Å in **8e**] were close. The Ru–C13 bond length involving the substituted terminal carbon of the $\eta^3$-allyl ligand was significantly longer, especially in the case of **8e** [2.452(4) vs. 2.339(4) Å in **8d**]. These observations are in agreement with those arising from the study of the complexes $[Ru(Cp^*)(phenanthroline)(\eta^3\text{-cinnamyl})][PF_6]_2$,[12] $[Ru(Cp^*)Br(MeCN)(\eta^3\text{-crotyl})][PF_6]$[2] and $[Ru(Cp^*)Cl(MeCN)(\eta^3\text{-cinnamyl})][PF_6]$.[13]

A minor contribution from a formal $\eta^2$-olefinic $CH_2{=}CH{-}C^{(+)}HR$ coordination of the allyl ligand might intuitively account for both observation of a longer Ru–CHR bond and enhanced electrophilic reactivity at the substituted allylic carbon.[2,12,13] The comparison between the Ru–CHR bond lengths in **8d** and **8e** [2.339(4) and 2.452(4) Å, respectively] obviously suggested a reduced contribution from the formal $\eta^2$-olefinic coordination of the allyl ligand in **8d**. Therefore, high regioselectivities in favour of branched products might be expected to be more difficult to reach when starting from unsymmetrical alkyl-allylic substrates compared to cinnamyl derivatives.[2] However, the location of a bulky phosphane ligand close to the unsubstituted terminal allylic carbon atom, as displayed in **8d** and **8e**, might distinctly contribute to favour nucleophilic addition at the substituted one. To test these assumptions, the study of the potential of complexes **2a**–**c** as catalyst precursors for ruthenium-catalysed allylic substitution reactions was undertaken.

### Allylation Reactions Catalysed by Complexes 2a–c

The characterisation of an $\eta^3$-allyl ruthenium(IV) complex arising from an oxidative addition reaction between $[Ru(Cp^*)(MeCN)_3][PF_6]$ and *tert*-butyl cinnamyl carbonate recently provided further evidence for the key role of $\eta^3$-allyl ruthenium(IV) catalytic intermediates in ruthenium-catalysed nucleophilic allylic substitution reactions.[14] The activity of complexes **2a**–**c** as catalyst precursors for the allylation of dimethyl sodiomalonate with methyl cinnamyl carbonate was investigated. Thus, the addition of dimethyl sodiomalonate (1.2 equiv.) to a solution of methyl cinnamyl carbonate (0.5 mmol) in THF (3.0 mL) in the presence of **2a**–**c** (1.5 mol-%) at ambient temperature led to the monosubstituted dimethyl malonate **9** as a mixture of branched (B) and linear (L) isomers [Equation (1)], and disclosed a favoured formation of the branched isomer (Table 1).



(1)

The results given in Table 1 clearly indicate that the three catalyst precursors **2a**–**c** provided complete conversion after 16 h of reaction. The regioselectivities in favour of the branched isomer of **9**, B/L ranging between 86:14 with **2c** and 92:8 with **2a**, were fairly good in comparison with those

observed using **1** as the catalyst precursor.[1] However, complexes **2a**–**c**, as well as **1**,[2] were unable to catalyse this allylic alkylation without prior deprotonation of dimethyl malonate as achieved with [RuCp*(bipy)($CH_3CN$)][$PF_6$] precursors.[12]

The reaction of phenol with cinnamyl chloride in the presence of **2a** and potassium carbonate in dichloromethane as solvent was investigated also [Equation (2)]. The results are given in Table 2. Under experimental conditions analogous to those used with **1** as catalyst,[2] the reaction led to the formation of the allyl phenyl ether **10a** in a 85:15 branched to linear ratio (entry 1).

[a] Conditions: 1.2 mmol of ArOH, 1.2 mmol of $K_2CO_3$, 1.0 mmol of cinnamyl chloride, 0.015 mmol of **2a** in 6 mL of $CH_2Cl_2$, room temperature, 16 h. [b] Relative to cinnamyl chloride (%). [c] As determined by $^1$H NMR spectroscopy. [d] THF as solvent. [e] Acetonitrile as solvent.

The regioselectivity was still fairly good although lower than that obtained with complex **1**.[2] Moreover, attempts to use THF or acetonitrile as solvent disclosed a lack of reactivity (entries 2, 3), whereas acetonitrile provided the best results in the case of catalyst **1**.[2] These observations suggested that the entrance of a phosphane ligand in complexes **2** would result in the strongest coordination of acetonitrile or THF, thus hindering the preliminary $\eta^2$-olefinic coordination of cinnamyl chloride as required for catalytic activity. The catalytic process proceeded smoothly for the allylation of various phenols in dichloromethane as solvent. Good regioselectivities were obtained starting from *p*-methoxyphenol (entry 4) and cresols (entries 5–7) as substituted phenols. Chlorophenols were also involved in the catalytic process (entries 8, 9) but only *o*-chlorophenol provided good regioselectivity.

Allyl aryl ethers arising from cinnamyl derivatives, valuable intermediates in organic chemistry, have drawn the main interest,[15] but another challenge is the development of efficient access to branched allyl aryl ethers starting from aliphatic allylic halides (vs. cinnamyl chloride-type substrates). The allylation of phenols with selected aliphatic or unconjugated allylic halides in the presence of **2a**–**c** as catalyst precursors was then investigated. Chlorohexene, synthesised as a 4:1 mixture of linear *n*PrCH=$CHCH_2$Cl and branched *n*PrCH(Cl)$CH=CH_2$ isomers starting from *trans*-2-hexen-1-ol and $PCl_3$,[16] reacted with various phenols to afford the allyl aryl ethers **11a**–**g**, as mixtures of branched *n*PrCH(OAr)$CH=CH_2$ and linear *n*PrCH=$CHCH_2$OAr isomers [Equation (3)]. The results are given in Table 3.

| 11 | **2a** | *p*-$ClC_6H_4$ | 99 | **11g** | 49:51 |

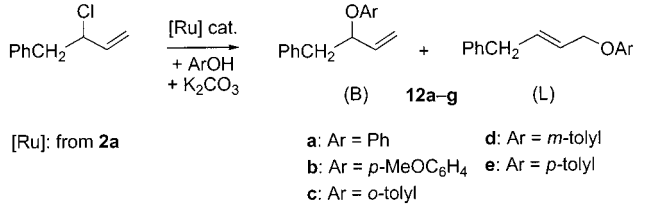
[a] Conditions: 1.2 mmol of ArOH, 1.5 mmol of $K_2CO_3$, 1.0 mmol of chlorohexene, 0.015 mmol of **2a**–**c** in 6 mL of THF, room temperature, 16 h. [b] Relative to chlorohexene (%). [c] As determined by $^1$H NMR spectroscopy. [d] Dichloromethane as solvent. [e] Acetonitrile as solvent.

In a typical run, the addition of phenol (1.2 equiv.) to chlorohexene (1.0 mmol) and $K_2CO_3$ (1.5 equiv.) in THF (6.0 mL) in the presence of **2a** (1.5 mol-%) for 16 h at ambient temperature resulted in the complete consumption of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chlorohexene and led to the formation of the allyl phenyl ether **11a** in a 75:25 B/L ratio (entry 1). Using complex **1** under similar catalytic conditions, chlorohexene was also converted into **11a**, but the regioselectivity was moderate, as emphasised by a B/L ratio of 60:40 in acetonitrile and 70:30 in acetone as solvent.[2] In the presence of complexes **2a**–**c**, the regioselectivity was slightly improved using THF or dichloromethane as solvent (entries 1, 2). As observed when starting from cinnamyl chloride, acetonitrile markedly disfavoured regioselectivity (entry 3). The involvement of **2b** and **2c** as catalysts (entries 4, 5) resulted in regioselectivities located in the same range as from **2a**. Complex **2a** was selected for the allylation of the substituted phenols. Using THF as solvent, satisfactory conversion and regioselectivity were reached with *p*-methoxyphenol and cresols (entries 6–9). The involvement of *p*-chlorophenol led to a 1:1 mixture of the branched and linear isomers of **11g** (entry 11), while *o*-chlorophenol was less reactive but provided a good B/L = 84:16 regioselectivity (entry 10). The low selectivity observed with *p*-chlorophenol might result from enhanced competition of the noncatalysed process, which contributed to the consumption of allylic halide but selectively led to the linear ether.

Readily available from benzyl bromide and allyl chloride,[17] 3-chloro-4-phenylbut-1-ene, $PhCH_2CH(Cl)CH=CH_2$, offered both the convenience of low volatility facilitating experimental work and an opportunity to test a pure branched allylic chloride under such catalytic conditions [Equation (4)]. The results are given in Table 4.



(4)

Table 4. Allylation of phenols ArOH with $PhCH_2CH(Cl)CH=CH_2$ catalysed by **2a**.[a]

| Entry | Ar | Conversion[b][c] | Products | B/L ratio |
|---|---|---|---|---|
| 1 | Ph | 87 | **12a** | 92:8 |
| 2[d] | Ph | 60 | **12a** | 73: 7 |
| 3[e] | Ph | 34 | **12a** | 50:50 |

| 8 | *o*-$ClC_6H_4$ | 0 | | |
| 9 | *p*-$ClC_6H_4$ | 0 | | |

[a] Conditions: 1.2 mmol of ArOH, 1.2 mmol of $K_2CO_3$, 1.0 mmol of allylic chloride, 0.015 mmol of **2a**–**c** in 6 mL of THF, room temperature, 16 h. [b] Relative to allylic chloride (%). [c] As determined by $^1H$ NMR spectroscopy. [d] Dichloromethane as solvent. [e] Acetonitrile as solvent.

Whereas the allylation of phenoxide anion in the presence of 3 mol-% of **1** afforded the ether **12a** with a rather poor B/L = 1.5:1 regioselectivity,[2] significantly increased regioselectivities up to B/L = 92:8 (entries 1, 2) were reached when catalyst **2a** was used. THF was an appropriate solvent but much lower conversion and regioselectivity were obtained in dichloromethane or acetonitrile (entries 1–3). It is worth noting the lack of reactivity when (*o*- or *p*-) chlorophenols were involved as the nucleophile (entries 8, 9), whereas good regioselectivities up to B/L = 96:4 were reached when *p*-methoxyphenol or (*o*-, *m*- or *p*-)cresols were involved as the nucleophile (entries 4–7).

## Conclusions

The reaction of one equiv. of phosphorus ligand with $[Ru(Cp^*)(MeCN)_3][PF_6]$ (**1**) allowed the selective substitution of one acetonitrile ligand, and the involvement of a hemilabile β-keto-phosphane provided a tool to selectively achieve the successive substitution of the three acetonitrile ligands by one phosphane, one carbon monoxide and one vinyl-carbene ligand. The products retaining acetonitrile as a ligand reacted with allylic halides to afford $\eta^3$-allyl ruthenium(IV) complexes and behave as catalyst precursors for allylic etherification of phenols with allylic chlorides in the presence of $K_2CO_3$, and alkylation of cinnamyl carbonate with dimethyl sodiomalonate under mild conditions. Although slightly less reactive than the unsubstituted parent complex **1**, the phosphane derivatives also favoured the formation of branched products when an unsymmetrical monosubstituted allylic substrate was involved, especially when starting from alkyl-substituted allylic substrates such as chlorohexene and 3-chloro-4-phenylbut-1-ene.

## Experimental Section

**General Comments:** The reactions were performed under inert argon according to Schlenk-type techniques. THF, diethyl ether and dichloromethane were distilled after drying according to conventional methods, whereas HPLC grade acetonitrile was straightforwardly used. NMR spectra were recorded at 297 K with AC 200 FT and AC 300 Bruker instruments and referenced internally to the solvent peak. IR spectra were recorded as Nujol mulls with Bruker IFS28. Elemental analyses were performed by the "Service de Microanalyse du CNRS" Vernaison, France. Complex **1** was synthesised according to the reported procedure.[2] Commercially available allylic halides were used without further purification whereas chlorohexene and 3-chloro-4-phenylbut-1-ene were prepared according to procedures described in the literature.[16,17]

**$[Ru(Cp^*)(Ph_2POMe)(MeCN)_2][PF_6]$ (2a):** Methyl diphenylphosphinite (2.0 mL, 9.98 mmol) was added to a cold solution (–80 °C) of **1** (5.04 g, 10.0 mmol) in a mixture of dichloromethane (70 mL) and acetonitrile (20 mL). After being stirred overnight at room temperature, the mixture was evaporated under vacuum. The crude product was dissolved in dichloromethane (80 mL) and the orange solution was covered with diethyl ether (200 mL). The natural diffusion of solvents resulted in the formation of orange crystals of **2a**. Yield: 5.30 g, 78%. $^1H$ NMR (200.13 MHz, $CD_2Cl_2$): $\delta$ = 1.57 (d, $^4J_{PH}$ = 2.0 Hz, 15 H, $C_5Me_5$), 2.27 (d, $^5J_{PH}$ = 1.3 Hz, 6 H, MeCN), 3.45 (d, $^3J_{PH}$ = 12.4 Hz, 3 H, OMe), 7.48–7.57 (m, 10 H, Ph) ppm. $^{13}C\{^1H\}$ NMR (50.32 MHz, $CD_2Cl_2$): $\delta$ = 4.2 (s, *Me*CN),

**{Ru(Cp*)[Ph$_2$PCH$_2$C(*t*Bu)=O](MeCN)}[PF$_6$] (2c):** A solution of $Ph_2PCH_2C(=O)tBu$ (2.58 g, 9.07 mmol) in dichloromethane (20 mL) was added to a cold solution (–80 °C) of **1** (4.58 g, 9.08 mmol) in a mixture of dichloromethane (60 mL) and acetonitrile (10 mL). After being stirred overnight at room temperature, the mixture was evaporated under vacuum. Methanol (30 mL) and diethyl ether (40 mL) were added to the residue and the mixture was stirred while an orange precipitate formed. The mixture was evaporated, then methanol (8 mL) and diethyl ether (60 mL) were added. The resulting orange crystalline precipitate was collected by filtration, then washed with diethyl ether and dried under vacuum. Yield: 6.06 g, 95%. IR: $\tilde{\nu}$ = 2269 cm$^{-1}$, C≡N; 1611 cm$^{-1}$, C=O. $^1H$ NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 1.26 (s, 9 H, *t*Bu), 1.47 (d, $^4J_{PH}$ = 1.8 Hz, 15 H, $C_5Me_5$), 2.09 (d, $^5J_{PH}$ = 1.5 Hz, 3 H, MeCN), 2.94 (dd, $^2J_{HH}$ = 18.6, $^2J_{PH}$ = 7.5 Hz, 1 H, $PCH_2$, $H_a$), 4.24 (dd, $^2J_{HH}$ = 18.6, $^2J_{PH}$ = 10.1 Hz, 1 H, $PCH_2$, $H_b$), 6.85–7.65 (m, 10 H, Ph) ppm. $^{13}C\{^1H\}$ NMR (50.32 MHz, $CD_2Cl_2$): $\delta$ = 4.1 (s, *Me*CN), 9.9 (s, $C_5Me_5$), 27.0 (s, C$Me_3$), 45.8 (d, $^3J$ = 1.8 Hz, *C*Me$_3$), 46.5 (d, $^1J$ = 21.5 Hz, $PCH_2$), 85.7 (d, $^2J$ = 2.2 Hz, $C_5Me_5$), 127.7 (s, Me*C*N), 129.2 (d, $^2J$ = 10.3 Hz, Ph, *ortho*), 129.4 (d, $^1J$ = 42.1 Hz, Ph, *ipso*), 129.6 (d, $^2J$ = 10.2 Hz, Ph, *ortho*), 130.7 (d, $^3J$ = 10.9 Hz, Ph, *meta*), 130.7 (d, $^4J$ = 2.5 Hz, Ph, *para*), 132.1 (d, $^4J$ = 1.3 Hz, Ph, *para*), 134.9 (d, $^3J$ = 14.0 Hz, Ph, *meta*), 137.0 (d, $^1J$ = 39.3 Hz, Ph, *ipso*), 228.9 (d, $^2J$ = 7.1 Hz, C=O) ppm. $^{31}P\{^1H\}$ NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = 62.1 (s) ppm. $C_{30}H_{39}F_6NOP_2Ru$ (706.65): calcd. C 50.99, H 5.56, N 1.98, P 8.77; found C 50.37, H 5.64, N 1.89, P 8.79.

**{Ru(Cp*)(CO)$_2$[Ph$_2$PCH$_2$C(=O)*t*Bu]}[PF$_6$]·CH$_2$Cl$_2$ (3):** A solution of **2c** (6.06 g, 8.58 mmol) in a mixture of methanol (40 mL) and dichloromethane (40 mL) was stirred for 24 h under carbon monoxide and was then evaporated under vacuum. The residue was dissolved in dichloromethane (25 mL) and the solution was covered with methanol (5 mL) then diethyl ether (250 mL), to afford pale brown crystals. Yield: 6.03 g, 87%. Note that several recrystallisations are needed to obtain almost colourless crystals. $^1H$ NMR spectroscopy and elemental analysis provided evidence for the retention of one molecule of dichloromethane. However, a minor crystalline form free of dichloromethane was also detected. IR: $\tilde{\nu}$ = 2046, 2005 cm$^{-1}$, C≡O; 1701 cm$^{-1}$, C=O. $^1H$ NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 0.97 (s, 9 H, *t*Bu), 1.72 (d, $^4J_{PH}$ = 2.0 Hz, 15 H, $C_5Me_5$), 3.83 (d, $^2J_{PH}$ = 9.6 Hz, 2 H, $PCH_2$), 7.33–7.56 (m, 10 H, Ph) ppm. $^{13}C\{^1H\}$ NMR (50.32 MHz, $CD_2Cl_2$): $\delta$ = 9.8 (s, $C_5Me_5$), 26.2 (s, C$Me_3$), 40.0 (d, $^1J$ = 36.8 Hz, $PCH_2$), 45.8 (d, $^3J$ = 2.2 Hz, *C*Me$_3$), 103.6 (s, $C_5Me_5$), 130.0 (d, $^1J$ = 50.2 Hz, Ph, *ipso*), 130.0 (d, $^2J$ = 11.1 Hz, Ph, *ortho*), 132.5 (d, $^3J$ = 11.6 Hz, Ph, *meta*), 132.6 (d, $^4J$ = 3.0 Hz, Ph, *para*), 198.8 (d, $^2J$ = 15.6 Hz, C≡O), 209.7 (d, $^2J$ = 4.0 Hz, C=O) ppm. $^{31}P\{^1H\}$ NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = 32.5 (s) ppm. $C_{30}H_{36}F_6O_3P_2Ru{\cdot}CH_2Cl_2$ (806.56): calcd. C 46.16, H 4.75, Cl 8.79, P 7.68; found C 46.47, H 4.68, Cl 7.35, P 7.67 (some presence of the minor form free of dichloromethane is likely responsible for the high carbon and low chlorine values).

**Ru(Cp*)(CO)[Ph$_2$PCH=C(*t*Bu)O] (4):** A mixture consisting of **3** (6.25 g, 7.75 mmol), $Me_3NO{\cdot}2H_2O$ (1.00 g, 9.00 mmol) and methanol (60 mL) was stirred overnight to afford a yellow slurry. Dissolution of the precipitate was subsequently obtained upon heating and completed by adding some dichloromethane (≈10 mL). The hot solution deposited yellow crystals of **4** upon cooling to –20 °C after partial removal of solvents (20 mL) under a stream of argon. Yield: 3.43 g, 81%. Note that further concentration of the solution led to a mixture of additional **4** and of ammonium salt. However, treatment of the mother liquor with an excess of $NH_4Cl$ allowed conversion of residual **4** into **6**, which may be subsequently separated according to selective dissolution in diethyl ether. IR: $\tilde{\nu}$ = 1933 cm$^{-1}$, C≡O; 1500 cm$^{-1}$, C=CO. $^1H$ NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 1.19 (s, 9 H, *t*Bu), 1.53 (d, $^4J_{PH}$ = 1.5 Hz, 15 H, $C_5Me_5$), 4.59 (d, $^2J_{PH}$ = 2.9 Hz, 1 H, PCH=), 7.13–7.66 (m, 10 H, Ph) ppm. $^{13}C\{^1H\}$ NMR (50.32 MHz, $CD_2Cl_2$): $\delta$ = 9.7 (s, $C_5Me_5$), 30.0 (s, C$Me_3$), 38.5 (d, $^3J$ = 12.2 Hz, *C*Me$_3$), 74.5 (d, $^1J$ = 59.8 Hz, PCH), 95.3 (s, $C_5Me_5$), 128.2 (d, $^2J$ = 10.3 Hz, Ph, *ortho*), 128.4 (d, $^2J$ = 11.0 Hz, Ph, *ortho*), 128.9 (d, $^4J$ = 2.4 Hz, Ph, *para*), 129.8 (s, *para*), 131.7 (d, $^3J$ = 9.8 Hz, Ph, *meta*), 133.3 (d, $^3J$ = 11.0 Hz, Ph, *meta*), 138.5 (d, $^1J$ = 59.8 Hz, Ph, *ipso*), 140.2 (d, $^1J$ = 40.3 Hz, Ph, *ipso*), 200.8 (d, $^2J$ = 17.1 Hz, =CO), 206.0 (d, $^2J$ = 19.5 Hz, C≡O) ppm. $^{13}C$ NMR (50.32 MHz, $CD_2Cl_2$, selected values): $\delta$ = 74.5 (dd, $J_{HC}$ = 162.4, $J_{PC}$ = 58.6 Hz, PCH=) ppm. $^{31}P\{^1H\}$ NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = 55.3 (s) ppm. $C_{29}H_{35}O_2PRu$ (547.64): calcd. data are given in Table 5. The cell parameters were obtained with Denzo and Scalepack[18] (**2a**, **8d**) and data collection with NONIUS KappaCCD Software[19] (**2a**, **8d**) and CrysAlis RED[20] (**8e**). Data reduction was carried out with Denzo and Scalepack[18] (**2a**, **8d**) and CrysAlis RED[20] (**8e**). The structures were solved with SIR−97, which revealed the non-hydrogen atoms.[21] After anisotropic refinement, many hydrogen atoms were found with Fourier difference calculations. The whole structures were refined with SHELXL97 by full-matrix least-squares methods on $F^2$ ($x$, $y$, $z$, $\beta_{ij}$ for Ru, P, N, Cl, F, C and O atoms; $x$, $y$, $z$ in riding mode for H atoms).[22] ORTEP views were prepared with PLATON98.[23]

CCDC-261933 (for **2a**), -272359 (for **8d**) and -258428 (for **8e**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Catalytic Experiments:** Organic compounds were identified from the comparison of $^1$H NMR spectra with available $^1$H NMR spectroscopic data.[24–26] In a typical experiment, a sample of phenol (1.2 mmol, 1.2 equiv.) was added to a stirred mixture consisting of allylic halide (1.0 mmol, 1.0 equiv.), catalyst precursor (0.015 mmol, 1.5 mol-%), $K_2CO_3$ (1.2–1.5 equiv.) and solvent (6.0 mL). The slurry was stirred at room temperature for 16 h and then was evaporated under vacuum. The residue was extracted with dichloromethane (20 mL) and the solution was filtered. The filtrate was evaporated to leave the crude product that was analysed by $^1$H NMR spectroscopy ($CDCl_3$) for conversion and regioselectivity determination.

# Tuning of the Spin States in Trinuclear Cobalt Compounds of Pyridazine by the Second Simple Bridging Ligand

Tao Yi*[a,b] Chang Ho-Chol,[b] Song Gao,[c] and Susumu Kitagawa*[b]

**Keywords:** Pyridazine/ Ligand tuning / Cobalt / Irregular spin states structure / Magnetic properties

Three novel trinuclear cobalt(II) compounds of pyridazine, $[Co_3(\mu\text{-}OH)_2(\mu\text{-}pdz)_4(pdz)_2(NO_3)_2(H_2O)_2]\cdot(NO_3)_2\cdot(THF)\cdot 2(MeOH)$ (**1**), $[Co_3(\mu\text{-}OH)_2(\mu\text{-}pdz)_4(pdz)_4(NO_3)_2]\cdot[Co_3(\mu\text{-}OH)_2(\mu\text{-}pdz)_4(MeOH)_4(NO_3)_2]\cdot(NO_3)_4$ (**2**), and $[Co_3(\mu\text{-}pdz)_4(\mu\text{-}NCS)_2(pdz)_2(NCS)_4]\cdot 2MeOH$ (**3**) (pdz = pyridazine), have been synthesized and characterized. The structures of all three compounds consist of centrosymmetric trimer building blocks bridged by the two nitrogen atoms of the pyridazine ligands and the second small bridging anions (hydroxide in **1** and **2**, and end-on thiocyanate in **3**). The two-atom bridging modes of the pyridazine ligand in **1** and **2** are unusual: each bridging pyridazine ligand affords two nitrogen donors to two metal ions with different bond lengths. This results in two kinds of spin states for the cobalt(II) atoms in **1**. Magnetic measurements show a typical antiferromagnetic interaction between the high-spin metals in **3**, but an unusual magnetic coupling through two high- and one low-spin cobalt atoms within the trimer in **1**. An irregular spin states structure is also observed in **1** at low temperature.

## Introduction

Since the discovery of high-$T_c$ magnetic molecular materials based on 3D metal-cyano compounds and the occurrence of the room-temperature, spin-crossover phase transition in 1,2,4-trizol compounds, strong magnetic interactions between two metal ions have played an important role in magnetic material chemistry.[1–4] Compounds with five-membered heterocyclic ligands such as 1,2,4-trizol attract much interest because of their special magnetic behavior, such as spin crossover,[4c] while the magnetic properties of diazine ligands are rarely considered to be important. Only a few examples of polynuclear copper(II) compounds of pyridazine (pdz)[5] and related ligands[6,7] have been structurally and magnetically characterized. Magnetic data and MO calculations indicate that the magnetic coupling of two metal ions in binuclear compounds of pdz always involves antiferromagnetic interactions through a short two-atom pdz exchange pathway.[8,9] However, in the trinuclear nickel(II) compound $[Ni_3(pdz)_6(\mu\text{-}SCN)_6]$,[10] for which the quasi Curie law magnetic behavior was published, the antiferromagnetic interaction through double pdz bridges was compensated for by the ferromagnetic interaction through a single end-on thiocyanato bridge. At that time, it was conjectured that the magnetic properties of such polynuclear systems could be tuned by the second bridging ligand. The cobalt ion would be a better magnetic center for this objective, because it has two spin states (high and low), depending only on its coordination environment.[11–12] Control of the cobalt(II) spin states by the choice of the axial ligand in pdz-bridged dicobalt(II) macrocyclic compounds has recently been reported by S. Brooker et al.,[13] whereas tuning of the spin states of metal ions through the different contributions of the two nitrogen donors of the pdz ligand by introducing a second bridging ligand has not been published yet. In this study, three novel trinuclear compounds bridged by the pdz ligand and a second bridging anion ($-OH^-$ or $-NCS^-$), $[Co_3(\mu\text{-}OH)_2(\mu\text{-}pdz)_4(pdz)_2(NO_3)_2(H_2O)_2]\cdot(NO_3)_2\cdot(THF)\cdot 2(MeOH)$ (**1**), $[Co_3(\mu\text{-}OH)_2(\mu\text{-}pdz)_4(pdz)_4(NO_3)_2]\cdot[Co_3(\mu\text{-}OH)_2(\mu\text{-}pdz)_4(MeOH)_4(NO_3)_2]\cdot(NO_3)_4$ (**2**), and $[Co_3(\mu\text{-}pdz)_4(\mu\text{-}NCS)_2(pdz)_2(NCS)_4]\cdot 2MeOH$ (**3**), have been isolated and characterized. In **1**, both triplet and singlet states of cobalt ions coexist within a trimer; an irregular spin states structure is observed at low temperature. The dominant magnetic interaction in **3** is antiferromagnetic.

## Results and Discussion

### Crystal and Molecular Structure of 1–3

Single crystals suitable for X-ray analysis were obtained, and the structure was characterized. Selected bond lengths and angles for the cobalt compounds **1**–**3**, as well as their crystallographic data are given in Table 1 and Table 2, respectively.

Compounds **1** and **2** (Figure 1 and Figure 2, respectively) have centrosymmetric linear structures. The central cobalt ion lies on a crystallographic inversion center of a generic octahedral coordination sphere. In **1**, there is only one kind of trimer, as observed in most trinuclear compounds, while in **2**, there are two different trimers (**2**A and **2**B). In every trimer of both compounds, the three cobalt atoms are linked together by four μ-pdz ligands and two μ-OH groups. The coordination environments of the central cobalt atoms are the same. The strong electronegativity of oxygen results in only 1.87 and 1.962 Å for the average lengths of the bonds between the central cobalt atom and its bridging OH and pdz ligands, respectively. Differing from the pdz compounds published previously,[5–9,13–15] the bridging pdz ligands in **1** and **2** afford two nitrogen donors to the two adjacent metal atoms with quite different bond lengths, an

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

average of 1.96 Å to the central and 2.17 Å to the terminal cobalt atoms. The bridging OH group also affords different bond lengths to the central (average 1.87 Å) and terminal cobalt atoms (average 1.98 Å). It is interesting that the average bond length of the central cobalt atom is 1.93 Å, which is shorter than that of the terminal cobalt atoms (2.09 Å), but similar to that of the low-spin-state cobalt(II) atoms in diazide derivatives.[13] A significant contribution to these differences comes from the two nitrogen donors of the bridging pdz ligands. All of the terminal cobalt atoms in **1** and **2** are coordinated with two bridging pdz ligands and one bridging OH group. The other three positions are occupied by one monodentate pdz ligand, one $NO_3^-$ ligand, and one water molecule in **1**, two terminal pdz ligands and one $NO_3^-$ ligand in **2**A, and one $NO_3^-$ ligand and two methanol molecules in **2**B. The angles subtended at the terminal cobalt(II) centers are 81.4(1)–95.9(1) in **1** and 81.5(2)–99.5(2) in **2**, whereas these angles are 88.95(9)–91.5(1) and 87.3(2)–92.7(2), very close to 90°, for the central cobalt(II) atoms of **1** and **2**, respectively, which indicates that the octahedral environment of the terminal cobalt centers is more distorted than that of the central one. The same situation was also observed when comparing the high-spin (HS) and low-spin (LS) cobalt compounds described in ref.[13]. By examining the structural information above, it can be postulated that the difference in the spin states of the central and terminal cobalt atoms is due to the varying strength of the ligand field around the two types of cobalt atoms. This is also proved by the magnetic data. The distance between the neighboring cobalt atoms in each trimer of both **1** and **2** is only 3.24 Å, much shorter than those in other pyridazine compounds.[13,14] The shortest intermolecular Co···Co distance is 7.04 Å. In **1**, there are two uncoordinated $NO_3^-$ groups per trimer in the structure. Each one affords two oxygen atoms to connect the terminally coordinated water molecules of two neighboring trimers by hydrogen bonds with the following distances and angles: 2.718(3) Å and 171(4)° (O2–H18···O6), and 2.782(4) Å and 170(4)° [O2–H19···O8# (#: $1 - x$, $-y$, $1 - z$)]. The trimers are connected together, forming a two-dimensional folded sheet structure through hydrogen bonds along the *bc* plane. Compound **2** contains three uncoordinated $NO_3^-$ counterions per trimer, but without intermolecular interactions. It should be noted that it is not common to have two different trimers in one crystal. The central cobalt atom in trimer **2**A occupies a central position of the cell, while that in trimer **2**B is at a corner position of the cell.

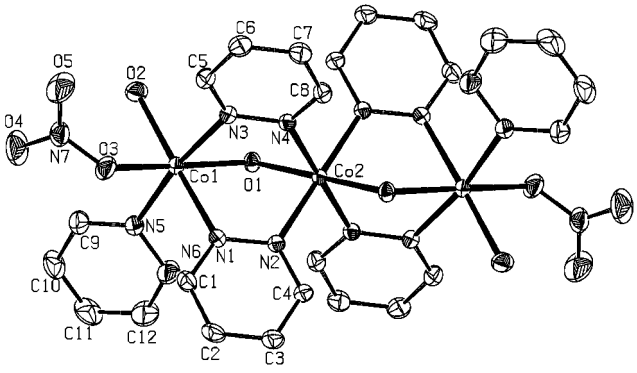

Figure 1. An ORTEP drawing of **1**, with the atom numbering scheme, showing 30% probability ellipsoids. Hydrogen atoms and solvent molecules are omitted for clarity.

In **3**, two monoatom bridged μ-SCN groups replace the OH groups in **1** and **2** to connect the three cobalt atoms (Figure 3). The lengths of the bonds of the central Co1 to the four centrosymmetric nitrogen atoms of pdz are 2.143(5) and 2.149(4) Å, and those to the two nitrogen atoms of μ-NCS are 2.125(4) Å. The terminal Co2 is coordinated to six nitrogen atoms: two from bridging pdz ligands, one from the μ-SCN group, one from the terminal pdz ligand, and another two from terminal NCS ligands. Differing from the close connections observed in **1** and **2**, the bond lengths of the cobalt atoms to the nitrogen atoms of the bridging NCS ligands are 2.125(4) (central Co) and 2.197(5) Å (terminal Co), which are longer than those to the terminal NCS ligands [2.056(7) and 2.041(5) Å, respectively]. The bridging pdz ligand in **3** affords two nitrogen donors with similar bond lengths [2.143(5) Å for Co1 and 2.192(4) Å for Co2] and angles [118.9(3) and 118.6(4)°] to

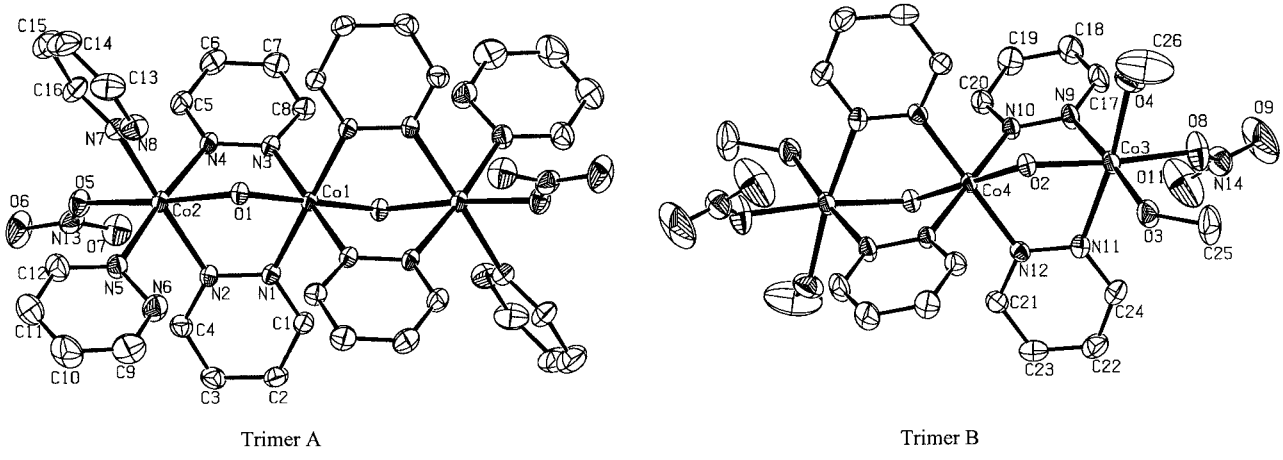

Figure 2. An ORTEP drawing of the two trimers in **2**, with the atom numbering scheme, showing 30% probability ellipsoids. Hydrogen atoms and uncoordinated anions are omitted for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the two adjacent metal atoms. The shortest intramolecular and intermolecular distances between the metal atoms are 3.43 and 8.55 Å, respectively, which are longer than those in **1** and **2**. Two uncoordinated methanol solvents are disordered in the molecular structure. A similar coordination sphere has been published for a nickel compound.[10]

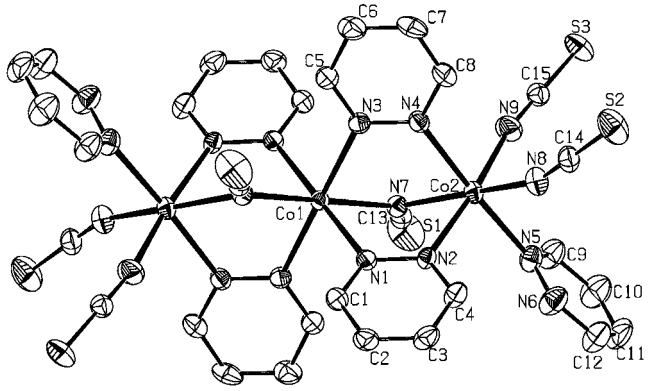

Figure 3. An ORTEP drawing of **3**, with the atom numbering scheme, showing 30% probability ellipsoids. Hydrogen atoms and solvent molecules are omitted for clarity.

As a bidentate bridging ligand, pdz can bond to different metal centers and display a variety of geometry and network motifs. The coordination modes of the pdz ligand could simply be summed up in three types according to the bridging methods. Type I is a typical monodentate mode as observed in the terminal ligands of multinuclear compounds, in which each pdz ligand only affords one nitrogen donor. The coordination type II is the typical bidentate bridging mode observed in **3** and other trinuclear or polymeric compounds,[5–9,13–15] in which the bridging pdz ligand affords two nitrogen donors symmetrically. Type III is the novel bridging mode first observed in **1** and **2**, in which the bond lengths between the two nitrogen atoms of the bridging pdz ligand and the two metal atoms are significantly different. It is obvious that the coordination mode of pdz is strongly affected by the second bridging ligand and the variety of bridging modes of pdz influences the magnetic properties of the compounds strongly.

## Magnetic Properties

All the samples used for magnetic measurements were pulverized crystals. The anisotropic magnetic measurement was not carried out, because the crystals lost their solvent molecules when they were powdered. The magnetic measurements of the thermal variation of the magnetic susceptibility for **1** and **3**, plotted as $\chi_M T$ vs. temperature in the temperature range 2–300 K (2–250 K for **3**) are shown in Figure 4 and Figure 5, respectively ($\chi_M$, the magnetic susceptibility per mole of trimer, was corrected for **1** by using the true molecular weight obtained from the elemental analysis). The $\chi_M T$ value for **1** at room temperature (5.19 $cm^3 \cdot K \cdot mol^{-1}$ at a magnetic field of 0.1 T) corresponds to that expected for two noninteracting high-spin cobalt atoms ($S$ = 3/2) and one low-spin cobalt atom ($S$ = 1/2), which is consistent with the results from the crystal structure data, in which the central Co atom is in a low-spin state with an average bond length of 1.93 Å, and the two terminal Co atoms are in a high-spin state with an average bond length of 2.09 Å. The $\chi_M T$ value remains practically unchanged down to 20 K, then decreases slightly, and finally increases quickly to 6.4 $cm^3 \cdot K \cdot mol^{-1}$ at 2 K under a magnetic field of 0.1 T, whereas at a magnetic field of 1 T, it goes through a maximum of 4.9 $cm^3 \cdot K \cdot mol^{-1}$ at 5.5 K and decreases again upon further cooling as a result of a field-saturation effect. The magnetic phenomenon in **1** can be explained by the irregular spin states structure, which has been reported in the $M^{II}Cu^{II}M^{II}$ (M = high-spin state of Mn, Co or Ni) system.[1,16] In the case of **1**, the interaction between Co(3/2) and Co(1/2) is weakly antiferromagnetic, the ground state is $E$(5/2, 3), above it there are $E$(7/2, 3), $E$(5/2, 2), $E$(3/2, 1), $E$(1/2, 0), $E$(1/2, 1), and $E$(3/2, 2). Such an irregular spin states structure exhibits quasi ferrimagnetic behavior in the $\chi_M T$ vs. $T$ plots as shown in Figure 4.

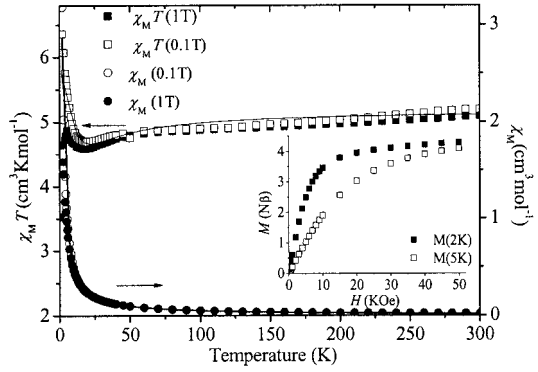

Figure 4. Thermal variation of $\chi_M T$ and $\chi_M$ for **1** at a magnetic field of 0.1 T (empty square and circle) and 1 T (filled square and circle), the solid line is the best fit for $\chi_M$ and $\chi_M T$ at 0.1 T using Equation (3). The inset is the magnetic field dependence of magnetization of **1** at temperatures of 2 and 5 K.

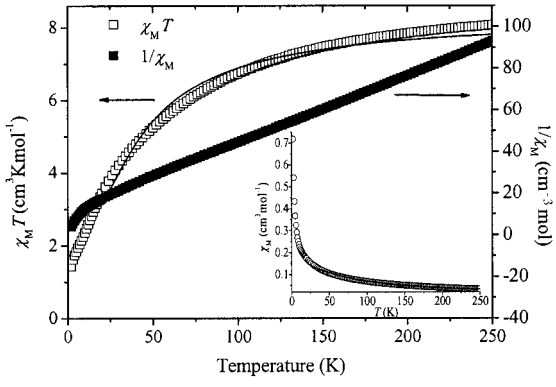

Figure 5. Thermal variations of $\chi_M T$ and $1/\chi_M$ for **3** at a magnetic field of 1 T. The inset is the curve of $\chi_M$ vs. $T$, and the solid line is the best fit for $\chi_M$and $\chi_M T$ using Equation (4).

To simulate the experimental magnetic behavior, the data of **1** and **3** are approximately fitted by the isotropic linear

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

trinuclear model.[1] The spin Hamiltonian and relative energies in the zero field are expressed as follows:

$$H = -J(S_{A1}.S_B + S_{A2}.S_B) \quad (1)$$

where $S_A = 3/2$, $S_B = 1/2$ for **1** and $S_A = S_B = 3/2$ for **3**.

$$E(S, S') = -(J/2)S(S+1) + (J/2)S'(S'+1);\ S' = S_{A1} + S_{A2},\ S = S' + S_B \quad (2)$$

The situation is always complicated for cobalt compounds. The exact expression of the Hamiltonian including spin-orbit coupling, axial and rhombic distortions, exchange, and Zeeman interactions[17] is not within the limits of our ability to calculate because of the very large size of the matrices. Therefore, the approximate fit for the average $\chi_M(T)$ [Equation (3)] was used for **1**, in which the orbital degeneracy on the distorted octahedral terminal $Co^{II}$ ($^4T_{1g}$) and the zero-field splitting effects were ignored.[1,13] Considering the phenomenon of an ascending $\chi_M T$ value at low temperature, both the antiferromagnetic exchange, $J$, between the neighboring HS and LS cobalt atoms and the weak ferromagnetic exchange, $J'$, between the two terminal cobalt atoms were included.

The best fit gives $g_A = 2.26$, $g_B = 2.04$, $J = -9.37\ cm^{-1}$, and $J' = 0.95\ cm^{-1}$ with $R = 3.9\cdot10^{-4}$ $\{R = \Sigma[(\chi_M T_{obs}) - (\chi_M T_{calc})]^2/\Sigma(\chi_M T_{obs}^2)\}$. The high values of $g_A$ for the terminal cobalt atoms reflect the spin-orbit coupling effects and the orbital degeneracy of octahedral HS $Co^{II}$.[13,18] The $J$ value is reasonably indicative of the exchange interactions across the pyridazine bridges.[13] The low-temperature limit of $\chi_M T$, $(\chi_M T)_{LT}$, is 5.736 $cm^3\cdot K\cdot mol^{-1}$, a little less than the value measured at 2 K (6.4 $cm^3\cdot K\cdot mol^{-1}$), which indicates an irregular spin states structure in **1** in the low-temperature range. If the temperature is low enough, the whole trimer is in the ground state with $S = 5/2$. The calculated saturation magnetization is 5.71 Nß at $g$ (5/2, 3) = 2.29. The measured magnetization of **1** as a function of field (0–5 T) gives a saturation magnetization value of 4.27 Nß at 2 K (Figure 4, inset), which is less than the value of $S = 5/2$, which also proves that the magnetic behavior at low temperature is a result of an irregular spin states structure.

The $\chi_M T$ value per trimer of **3** at 250 K is 8.07 $cm^3\cdot K\cdot mol^{-1}$ (Figure 5), which is larger than that for three noninteracting cobalt ions of $S = 3/2$ because of the orbital contribution. This value decreases gradually to 0.48 $cm^3\cdot K\cdot mol^{-1}$ from room temperature to 2 K. The $1/\chi_M$ value above 20 K fitted with the Curie–Weiss law gave $C$ = 3.016 $cm^3\cdot mol^{-1}$ and $\theta = -32.09$ K, which shows an intramolecular antiferromagnetic coupling of the adjacent cobalt atoms within the trimer. With the same approximations as in **1** and neglecting $J'$, the *Van Vleck* formula for **3** is expressed in Equation (4).

The best fit for temperatures greater than 20 K gives $g_A$ = 2.46, $g_B$ = 2.02, $J = -6.08\ cm^{-1}$ with $R = 9.5\cdot10^{-4}$. The larger value of $g_A$ indicates that the terminal cobalt atoms possess stronger anisotropy than the central one, which is consistent with the description of the molecular structure.

According to the theoretical calculations of magnetic interactions through bridged two-atom pdz and related compounds,[5,6,10,13] the magnetic coupling of the two cobalt atoms through pure bridging pdz ligands ($J \approx -10\ cm^{-1}$) are much weaker than that in the copper ($-J > 100\ cm^{-1}$) and nickel ($J \approx -30\ cm^{-1}$) compounds. It can be estimated that the contribution to the antiferromagnetic interaction between the adjacent cobalt atoms mainly comes from the bridging pdz ligands in **3**. End-on $NCS^-$ bridging may afford a weak ferromagnetic interaction, which compensates the antiferromagnetic interaction through the bridging pdz ligands to give a comparatively small value of $J$, as described for the corresponding nickel compound.[10] In the case of **1**, the entire magnetic interaction of the adjacent HS and LS cobalt atoms comes from the magnetic coupling through pdz and hydroxide, and the supra-exchange of the two metal ions. It can be deduced that the magnetic coupling through pdz must be an antiferromagnetic interaction

$$\chi_M = \frac{N\beta^2}{4kT} \times \frac{35g^2_{(5/2,3)} + 84g^2_{(7/2,3)}\exp(\frac{7J}{2kT}) + 35g^2_{(5/2,2)}\exp(\frac{3J-3J'}{kT}) + 10g^2_{(3/2,2)}\exp(\frac{J-6J'}{2kT}) + 10g^2_{(3/2,1)}\exp(\frac{5J-10J'}{2kT}) + g^2_{(1/2,1)}\exp(\frac{J-5J'}{kT}) + g^2_{(1/2,0)}\exp(\frac{2J-6J'}{kT})}{3 + 4\exp(\frac{7J}{2kT}) + 3\exp(\frac{3J-3J'}{kT}) + 2\exp(\frac{J-6J'}{2kT}) + 2\exp(\frac{5J-10J'}{2kT}) + \exp(\frac{J-5J'}{kT}) + \exp(\frac{2J-6J'}{kT})} \quad (3)$$

$$\chi_M = \frac{N\beta^2}{4kT} \times \frac{10g^2_{(3/2,3)} + 10g^2_{(3/2,0)}\exp(\frac{6J}{kT}) + g^2_{(1/2,1)}\exp(\frac{7J}{2kT}) + 35g^2_{(5/2,1)}\exp(\frac{15J}{2kT}) + g^2_{(1/2,2)}\exp(\frac{3J}{2kT}) + 84g^2_{(7/2,2)}\exp(\frac{9J}{kT}) + 165g^2_{(9/2,3)}\exp(\frac{21J}{2kT})}{2 + 2\exp(\frac{6J}{kT}) + \exp(\frac{7J}{2kT}) + 3\exp(\frac{15J}{2kT}) + \exp(\frac{3}{2}J/kT) + 4\exp(\frac{9J}{kT}) + 5\exp(\frac{21J}{2kT})} \quad (4)$$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

because of spin polarization in the bridging ligand. The antiferromagnetic coupling between two neighboring cobalt atoms through the $OH^-$ group is very weak because of poor overlap between the $d_{x^2-y^2}$ and $d_{z^2}$ magnetic orbitals of the central low-spin cobalt(II) atom and the p-type orbitals of the oxygen atom from the $OH^-$ group. The different magnetic orbital contributions for the high- and low-spin states of the cobalt atoms also cause the overlap of the electron clouds of the two neighboring metal atoms to tend to zero and the spins of the two high-spin magnetic centers to tend to be positioned in the same direction, compensating for the antiferromagnetic interaction between neighboring cobalt atoms. The magnetic exchange for the two kinds of spin states of cobalt atoms within one molecule is rarely reported. The tuning of the spin states through a simple bridging ligand may afford a new method for the modification of magnetic properties at the molecular level.

In conclusion, three novel cobalt(II) trinuclear compounds bridged by the pdz ligand and a second small anion (hydroxide and end-on thiocyanate) were structurally and magnetically characterized in this paper. The two-atom bridging modes of the pdz ligand in **1** and **2** are unusual: each bridging pdz ligand affords two nitrogen donors to the two metal ions with different bond lengths. This results in a significant difference in the ligand fields between the central and terminal cobalt(II) coordination spheres in **1** and **2**. Both the structural analysis and magnetic data show that two spin states (HS and LS) of cobalt(II) atoms coexist in **1**. An irregular spin states structure was also observed in this compound at low temperature. This work provides a unique example of the modification of magnetic properties through a simple bridging group.

## Experimental Section

**Materials:** $Co(NO_3)_2{\cdot}6H_2O$ (>98%, Wako), pyridazine (98%, Tokyo Chemical), $NH_4SCN$ (99.5%, Wako) were used as obtained from commercial sources without further purification.

**Physical Measurements:** The powder infrared spectra were recorded with a Perkin–Elmer System 2000 instrument using KBr pellets. Magnetic susceptibility measurements were carried out using a Quantum Design SQUID magnetometer in the 2–300-K temperature range. Corrections for diamagnetism were applied by using Pascal's constants.[1a]

**Synthesis of $[Co_3(\mu\text{-}OH)_2(\mu\text{-}pdz)_4(pdz)_2(NO_3)_2(H_2O)_2]{\cdot}(NO_3)_2{\cdot}(THF){\cdot}2(MeOH)$ (1) and $[Co_3(\mu\text{-}OH)_2(\mu\text{-}pdz)_4(pdz)_4(NO_3)_2]{\cdot}[Co_3(\mu\text{-}OH)_2(\mu\text{-}pdz)_4(MeOH)_4(NO_3)_2]{\cdot}(NO_3)_4$ (2):** After mixing a THF solution (5 mL) of pdz (1.1 mmol) and a THF solution (15 mL) of $Co(NO_3)_2{\cdot}6H_2O$ (0.5 mmol), a red sediment was produced, which was dissolved by adding methanol (5 mL). Red-brown, cube-shaped single crystals of **1** were obtained from the prepared red solution by slow vaporization at room temperature. The crystals lost their solvent molecules and powdered slowly in air. $C_{30}H_{46}Co_3N_{16}O_{19}$ (**1**): calcd. C 32.39, H 4.14, N 20.15; found C 27.55, H 3.38, N 21.47. The experimental data is consistent with that of the molecule in which three organic solvent molecules are replaced by four water molecules. $C_{24}H_{38}Co_3N_{16}O_{20}$ (**1** – THF – 2MeOH + $4H_2O$): found C 27.52, H 3.66, N 21.40. Pyramid-shaped red crystals of **2** were isolated after one year from the same mother liquor of **1**. $C_{52}H_{64}Co_6N_{34}O_{38}$ (**2**): calcd. C 29.37, H 3.03, N 22.39; found C 29.58, H 3.25, N 22.13.

**Synthesis of $[Co_3(\mu\text{-}pdz)_4(\mu\text{-}NCS)_2(pdz)_2(NCS)_4]{\cdot}2MeOH$ (3):** Pyridazine (2.2 mmol) was added dropwise to a solution of $CoCl_2{\cdot}6H_2O$ (1 mmol) and $NH_4SCN$ (2.2 mmol) in methanol (20 mL) under continuous stirring. The prepared blue solution was filtered and allowed to evaporate slowly at room temperature to give red cube-shaped single crystals of **3** after two months. IR

**X-ray Crystallography**

The single crystals of all the compounds were sealed into glass capillary tubes (0.7 mm, GLAS) containing a small amount of mother liquor and mounted on the crystal goniometer. The intensity data of all four samples were collected with the Rigaku Mercury CCD system using graphite monochromatic Mo-$K_\alpha$ radiation ($\lambda$ = 0.71069 Å) and the $\omega$ scan technique with a sample-to-detector distance of 35 mm at a temperature of 20 ± 1 °C (Table 2). The cell constants and orientation matrix were obtained from the reflections collected on the setting angles of six frames by changing $\omega$ by 0.5° for each frame.[19] Intensity data were collected in 480 frames with an $\omega$ scan width of 0.5° using two different $\psi$ settings (0 and 90°). The exposure time was 60, 90, and 150 s for **1**, **2**, and **3**, respectively. Empirical absorption corrections based on azimuthal scans were applied.[20] The data were also corrected for Lorentz and polarization effects.

All calculations were performed using the teXsan crystallographic software package[21] of the Molecular Structure Corporation. The structures were solved by direct methods and expanded using Fourier techniques.[22] The full-matrix least-squares refinement was performed by SHELXL-97[23] based on $F^2$. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. $R$ factor ($gt$) of the final full-matrix least-squares refinement was based on the observed data of $I > 2\sigma(I)$, while reflections of the weighted $R$ factor ($wR_2$) and GoF are based on all data. In **1** and **3**, the positions of the solvent molecules were disordered, while in **2**, the oxygen atoms of the terminally coordinated $NO_3^-$ were disordered. CCDC-276336 to 276338 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Novel Water-Soluble Carbosilane Dendrimers: Synthesis and Biocompatibility

Paula Ortega,[a][‡] Jesus F. Bermejo,[b][‡] Louis Chonco,[b] Ernesto de Jesus,[a] F. Javier de la Mata,*[a] Gerónimo Fernández,[b] Juan Carlos Flores,[a] Rafael Gómez,*[a] M. Jesús Serramía,[b] and M. Angeles Muñoz-Fernandez*[b]

**Keywords:** Bioinorganic chemistry / Dendrimers / Silicon / Drug delivery / Toxicity

A synthetic strategy has been developed for the preparation of new peripheral amine- or ammonium-terminated carbosilane dendrimers of type *n*G-[Si($OCH_2CH_2NMe_2$)$_y$]$_x$ or *n*G-[Si($OCH_2CH_2NMe_3^+I^-$)$_y$]$_x$, respectively. It consists of the alcoholysis of well-known chlorosilane-terminated dendrimers with *N*,*N*-dimethylethanolamine and the subsequent quaternization with MeI. All these systems are susceptible to hydrolysis, although the decomposition depends on concentration and dendrimer generation. Evaluation of dendrimer toxicities by phase-contrast light microscopy and MTT assay were carried out, and evidence of dendrimer/oligonucleotide complex formation was carried out by gel electrophoresis.

## Introduction

There is currently significant interest in dendrimers as a result of their potential applications, including light harvesting and energy transfer, nanoscale catalysis, chemical sensors, unimolecular micelles, enzyme mimics, encapsulation of guest molecules, molecular recognition, diagnostic agents, and gene and drug delivery.[1]

The two common drug delivery systems are liposomes and polymers, although both present some problems.[2] Liposome-based systems have poor stability, difficulty targeting specific tissues, side effects like lung-inflammatory reactions, and in transfection, processes may fail in the presence of serum. The main drawbacks of the use of conventional degradable polymers as delivery agents are their polydispersity and thermodynamic instability that result in a short in vivo lifetime of the active species. Dendrimers represent an alternative approach to liposomes and polymeric systems for drug delivery. Their major advantages are the uniform structure, multiple sites of attachment, and the versatility to modify their skeletons and surfaces, allowing a precise characterization of the dendrimer/drug interaction. There are two general methods for the use of dendrimers as drug carriers, that is (i) encapsulation of drugs inside the dendritic skeleton[3] or (ii) formation of dendrimer-drug conjugates in which the drug is attached preferentially to its surface. For the latter method, two methodologies have been developed. The first technique consists of a covalent link between peripheral units of the dendrimer and the drug. For instance, methotrexate or folic acid have been attached to the exterior of polyarylether[4] dendrimers or conjugated in poly(amidoimine) (PAMAM)[5] dendrimers. The second approach is based on electrostatic interactions and has been mainly focused on the delivery of DNA drugs into the cell nucleus for gene or antisense therapy. Numerous reports have been published on the use of amino-terminated PAMAM dendrimers,[6] phosphorus-based dendrimers,[7] polypropylenimine (PPI)[8] or poly(lysine)[9] dendrimers as nonviral gene-transfer agents.

However, to the best of our knowledge, no studies concerning the use of water-soluble carbosilane-based dendrimers as potential drug carriers have been published, although an in vitro biocompatibility report was recently published on poly(ethylene oxide)-grafted carbosilane dendrimers.[10] Besides, a scarce number of polyionic silane dendrimers have been reported so far.[11–13]

Here we describe the synthesis and characterization of novel water-soluble carbosilane dendrimers up to the third generation, and the analysis of their biocompatibility in primary cell cultures of peripheral blood mononuclear cells (PBMCs).

## Results and Discussion

### Amine-Terminated Carbosilane Dendrimers

We have studied the synthesis of dendrimers containing peripheral amine groups. For this purpose, first-, second-,

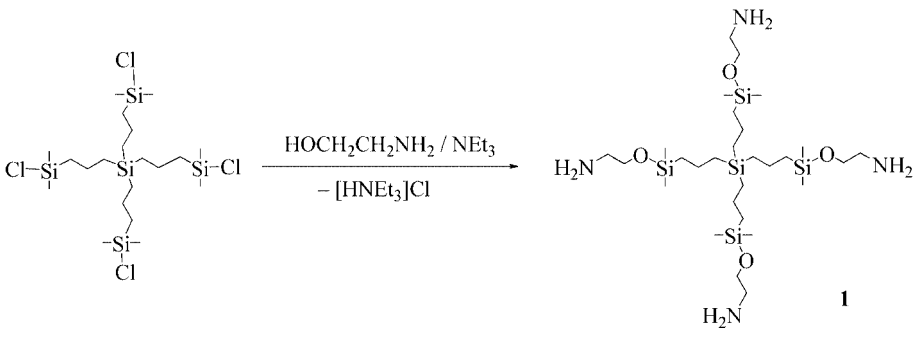
and third-generation chlorosilane-terminated dendrimers were synthesized as previously reported.[14] Typically, we used tetraallylsilane or other allylsilane-terminated dendrimers as the initiator core and chlorodimethylsilane or dichloromethylsilane for the hydrosilylation step in the presence of a platinum catalyst (Karstedt catalyst),[15] to afford the well-known Cl–Si-terminated dendrimers 1G-$(SiCl)_4$, 1G-$(SiCl_2)_4$, 2G-$(SiCl)_8$, 2G-$(SiCl_2)_8$, 3G-$(SiCl)_{16}$, and 3G-$(SiCl_2)_{16}$. These formed the starting materials for the preparation of new dendrimers by alcoholysis reactions.

Treatment of dendrimer 1G-$(SiCl)_4$ with 4 equiv. of ethanolamine at room temperature in diethyl ether and in the presence of $NEt_3$ led to the formation of the corresponding amine-terminated dendrimer 1G-[$Si(OCH_2CH_2NH_2)]_4$ (**1**), which was isolated as a brown oil after separation from the precipitated ammonium salt $[HNEt_3]Cl$ and evaporation of the solvent (Scheme 1). In the absence of $NEt_3$, the dendrimer precipitated as a white solid material that we initially assigned to the self-quaternization of the amine groups in **1** because addition of $NEt_3$ to this white material in DMSO dissolved it to afford **1** again as the sole spectroscopic compound. However, when we tried to dissolve this material in water, an insoluble residue of polysiloxanes and the soluble ammonium salt of ethanolamine were separated. The data of the $^1H$ NMR spectrum performed in $D_2O$ are consistent with the hydrolysis of the Si–O bonds under these slight acidic conditions. Derivative **1** exhibits a multiplet in the $^1H$ NMR spectrum located at $\delta$ = 1.32 ppm, attributed to the middle methylene group of the branch –$SiCH_2CH_2CH_2Si$–, and the two signals at $\delta$ = 0.63 and 0.53 ppm are assigned to the methylene groups directly bonded to silicon. The outer branch gives two triplets at $\delta$ = 3.55 and 2.74 ppm, corresponding to –$CH_2O$– and –$CH_2N$–. The $^{13}C$ NMR spectroscopic data are consistent with this assignment. Water-solubilization of dendrimer **1** was attempted by quaternization of the terminal amine groups. Reaction of **1** with a diethyl ether solution of HCl produced the hydrolytic breaking of the Si–O bonds, in accordance with the reactivity mentioned earlier. The attempt to quaternize derivative **1** using MeI also failed because of the hydrolysis of the Si–O bonds caused by the HI generated by Me/H exchanges with the amine protons.[16]

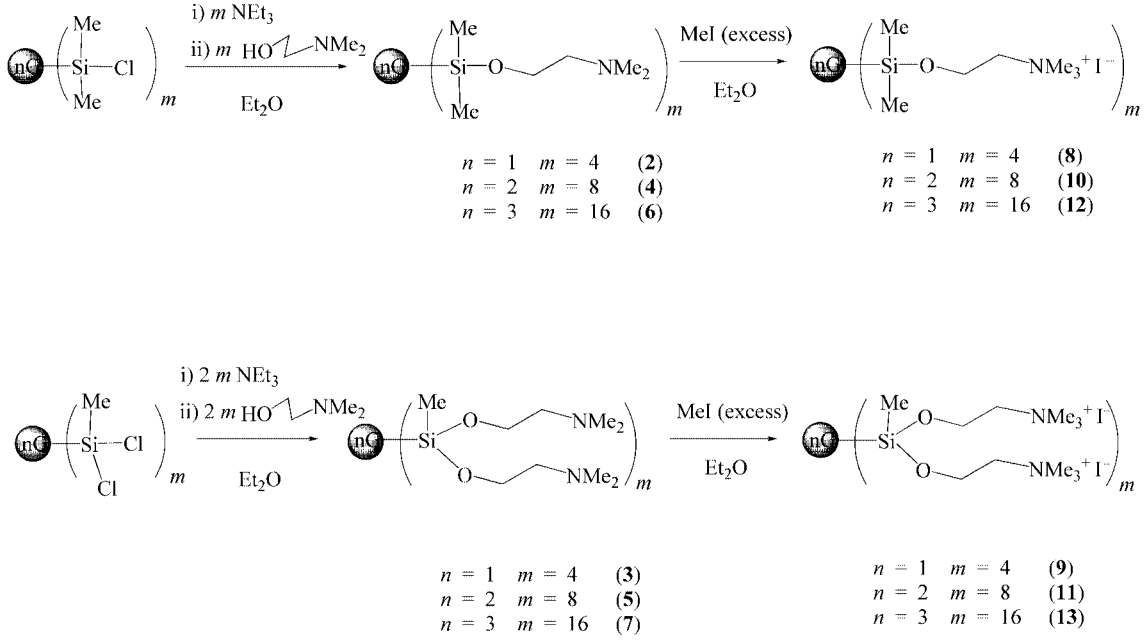
To overcome these problems, chlorosilane-terminated dendrimers were treated with stoichiometric amounts of *N*,*N*-dimethylethanolamine in diethyl ether and in the presence of stoichiometric $NEt_3$, to afford the corresponding amine-terminated dendrimers 1G-[$Si(OCH_2CH_2NMe_2)]_4$ (**2**), 1G-[$Si(OCH_2CH_2NMe_2)_2]_4$ (**3**), 2G-[$Si(OCH_2CH_2NMe_2)]_8$ (**4**), 2G-[$Si(OCH_2CH_2NMe_2)_2]_8$ (**5**), 3G-[$Si(OCH_2CH_2NMe_2)]_{16}$ (**6**), and 3G-[$Si(OCH_2CH_2NMe_2)_2]_{16}$ (**7**) as brown oils in high yields (Scheme 2). All these derivatives are soluble in common organic solvents, but are insoluble in water.

The NMR spectroscopic and analytical data for derivatives **2**–**7** are consistent with their proposed structures (Scheme 2). The $^1H$ NMR spectra of the carbosilane framework for dendrimers **2**–**7** have almost identical chemical shifts for analogous nuclei in different generations, although broader and less structured resonances are present with increasing generation. These features have been ascribed to both a polymer-like structure with slightly different chemical environments for the nuclei in different generations and restricted mobility of the respective protons in the outer shells.[17,18] Five sets of signals attributed to the methylene groups are observed with the expected integration ratio. For the $SiCH_2CH_2CH_2Si$ branches, the middle methylenes are located at $\delta$ = 1.30 ppm, whilst the methylene groups bonded directly to silicon atoms are centered at $\delta$ = 0.61 and 0.51 ppm. We ascribed the resonances at $\delta$ = 0.61 ppm to the –$CH_2SiO$– groups and those at $\delta$ = 0.51 ppm to the rest of the methylene groups, based on the enlargement of the latter signal intensity with increasing dendrimer generation, and also on 1D $^1H$ TOCSY and NOESY experiments. Two triplets are observed for the $SiOCH_2CH_2N$ fragment, located at $\delta$ = 3.64 (for dendrimers **2**, **4**, and **6**) or 3.74 ppm (for dendrimers **3**, **5**, and **7**) attributed to the –$CH_2O$– groups, and $\delta$ = 2.43 ppm for the –$CH_2N$– groups; this observation is supported by data from NOESY experiments. Interestingly, the downfield shifts shown by dendrimers **3**, **5**, and **7** are consistent with the presence of two oxygen atoms bonded to the silicon atom, although this effect is negligible for the –$CH_2N$– groups. The $^{13}C$ NMR spectra for the methylene groups show two resonances located at $\delta$ = 61.4 (–$CH_2N$–) and 60.7 ppm (–$CH_2O$–) for the outer



Scheme 1.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2.

$SiOCH_2CH_2N$ branches, and for the inner $SiCH_2CH_2CH_2Si$ branches, signals in the range of $\delta$ = 21.3 to 17.4 ppm are observed. HMQC experiments were required to locate their resonances. For the N–Me groups, the signals in the $^1$H- and $^{13}$C NMR spectra show unchanged resonances at $\delta$ = 2.23 and 46.1 ppm, respectively. Both the $–SiMe_2–$ and –SiMe– fragments can be easily distinguished in all derivatives and generations (see Exp. Sect.). It is worth noting that for the outer –SiMe– groups the resonance appears about $\delta$ = –1.7 ppm in dendrimers **2**, **4**, and **6**, whilst it is located around $\delta$ = –4.4 ppm for dendrimers **3**, **5**, and **7**, as a consequence, again, of the presence of one or two silicon-bonded oxygen atoms, respectively. This feature is clearly observed in the $^{29}$Si NMR spectra, although the innermost silicon atom is only detected for the first generations.

Dendrimers were also analyzed by mass spectroscopy (electrospray or MALDI-TOF MS) using 1,8,9-trihydroxyanthracene (dithranol) as a matrix. However, the molecular peaks were not observed for the second and third generations, as described for many high-molecular-weight dendrimers.[19]

### Ammonium-Terminated Carbosilane Dendrimers

Attempts to quaternize the amine-terminated carbosilane dendrimers **2**–**7** with stoichiometric amounts or an excess of HCl failed because of hydrolysis of the Si–O bonds. However, treatment of the dendrimers with an excess of MeI in diethyl ether led to quantitative quaternization of the amine groups within 24–48 h, causing the precipitation of the ammonium iodide salts 1G-$[Si(OCH_2CH_2NMe_3^+I^-)]_4$ (**8**), 1G-$[Si(OCH_2CH_2NMe_3^+I^-)_2]_4$ (**9**), 2G-$[Si(OCH_2CH_2NMe_3^+I^-)]_8$ (**10**), 2G-$[Si(OCH_2CH_2NMe_3^+I^-)_2]_8$ (**11**), 3G-$[Si(OCH_2CH_2NMe_3^+I^-)]_{16}$ (**12**), and 3G-$[Si(OCH_2CH_2NMe_3^+I^-)_2]_{16}$ (**13**) in high yields as white hygroscopic solids (Scheme 2). In the case of the amine-terminated dendrimer **7**, some dimethylamine groups remained unquaternized. The $^1$H NMR spectrum revealed that roughly 29 of the 32 amine groups were quaternized, even if we used a large excess of MeI and prolonged reaction times. All the dendritic ionic derivatives are insoluble in normal organic solvents, but are soluble in DMSO, MeOH, and $H_2O$, although slow decomposition occurs in protic solvents (see later for decomposition behavior).

The NMR spectroscopic and analytical data of derivatives **8**–**13** are consistent with their proposed structures (Scheme 2 and Figure 1). The $^1$H NMR spectra were recorded in DMSO at room temperature, although in this solvent the line widths of these spectra tended to be broader than those of derivatives soluble in common organic solvents. The $^1$H- and $^{13}$C NMR spectra of the quaternized dendrimers **8**–**13** exhibit identical resonance patterns to those observed in their counterparts **2**–**7** for the carbosilane framework, although broader signals are seen with increasing generation (see Exp. Sect. and Supporting Information). Two broad multiplets are observed for the outer $SiOCH_2CH_2N$ grouping, centered at $\delta$ = 3.94 (for dendrimers **8**, **10**, and **12**) or 4.12 ppm (for dendrimers **9**, **11**, and **13**) for the $–CH_2O–$ groups, and $\delta$ = 3.45 (for dendrimers **8**, **10**, and **12**) or 3.56 ppm (for dendrimers **9**, **11**, and **13**) for the $–CH_2N–$ fragment. The quaternization of the amine groups resulted in a deshielding of the chemical shifts of the $–CH_2O–$ groups by 0.3–0.4 ppm, whereas for the $–CH_2N–$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

methylene groups this shift was about 1 ppm, consistent with the presence of a positive charge on the nitrogen atom. Analogous shifts are observed for the carbon atoms in their $^{13}C$ NMR spectra. This behavior is also detected in the methyl groups, which appear in the $^{1}H$- and $^{13}C$ NMR spectra centered at $\delta$ = 3.18 and 52.6 ppm, respectively, downfield of those observed in the amine-terminated dendrimers **2**–**7**.

### Hydrolysis Behavior of Amine- and Ammonium-Terminated Dendrimers

As mentioned earlier, the amine-terminated dendrimers and the quaternized derivatives decompose in protic solvents. For instance, when dendrimers **3** or **9** are dissolved in methanol for several hours, after extraction with diethyl ether, a new dendrimer is formed, 1G-[Si(OMe)$_2$]$_4$, consistent with the alcoholysis of the Si–O bonds, the inclusion of methoxy groups,[20] and the respective formation of ethanolamine or its ammonium salt.

The hydrolysis of the second- and third-generation ammonium-terminated dendrimers **10** and **12** was studied in more detail. Both dendrimers degrade in deuterated water to form [DOCH$_2$CH$_2$NMe$_3^+$I$^-$] and an insoluble polymeric carbosiloxane material. The changes in dendrimer concentration were measured by $^{1}H$ NMR spectroscopy on the basis of the integration of both –OCH$_2$CH$_2$N– methylene proton resonances, which were always at pD = 7.2. A plot of ln[dendrimer] versus time showed an apparently first-order decomposition (see Figure 2). However, when the plot was performed using different initial dendrimer concentrations (see Supporting Information) the results showed that the rate constant decreases with increasing dendrimer concentration. The same decrease is observed on going from the second to the third generation when the hydrolytic processes were carried out at the same pD and initial concentrations in [Si–O] bonds, suggesting the existence of a dendritic effect (Figure 2). A plausible explanation for all these features may be the presence of interactions between branches in a cooperative effect that may decrease the rate of the process, making the decomposition a result of complex behavior.

### Evaluation of Dendrimer Toxicity

Quaternized second-generation carbosilane dendrimers **10** and **11** were tested on a primary cell culture of PBMCs (from healthy donors) as an initial screen for biocompatibility. Dendrimers of first generation were too water-sensitive for toxicity evaluation, while those of third generation were not tested because of solubility problems. As a primary cell culture, PBMCs are more sensitive to external challenge than immortalized cell lines; thus, they are good models in which to perform toxicity studies. Furthermore, there are a number of diseases that affect these cells (for example leukemia, viral infections such as HIV or HTLV, genetic disorders such as Severe Combined Immunodeficiency (SCID), and so on), and they are also a major target for immunomodulation. Additionally, PBMCs placed in the bloodstream are easily accessible to systemic drugs. In order to evaluate the range of biocompatibility of dendrimers **10** and **11**, PBMCs were incubated for 48 h with increased concentrations of free dendrimer (1, 5, 10, 20, and 100 μM). Untreated cells were used as a control for viability. After this period of incubation, cells were observed under a phase-contrast light microscope. In parallel, mitocondrial activity (MA) of cells challenged with dendrimers was evaluated by MTT test and compared with that shown by the control cells. MTT results demonstrated a similar MA in cells treated with both second-generation dendrimers **10** and **11** at the different concentrations tested (Figure 3). At the concentration of 1 μM, MA was around 80% of that shown by the control, while at 5 μM, MA decreased to 30%. Observation of cells under phase-contrast light microscopy showed that cells treated with concentrations from 1 to 5 μM of the dendrimers were alive, with no visible differences from control cells. Cells treated with concentrations of 10 μM or higher exhibited reduced membrane birefringence and a concentration-dependent increase in mortality, and even more, at these concentrations, formation of cell aggregates was observed with dendrimer **11**, probably caused by the presence of a higher cationic charge on its surface (not only dendrimers, but cationic macromolecules in general cause destabilization of the cell membrane).[1j–21] Overall, the results from the MTT test and the microscopic observa-

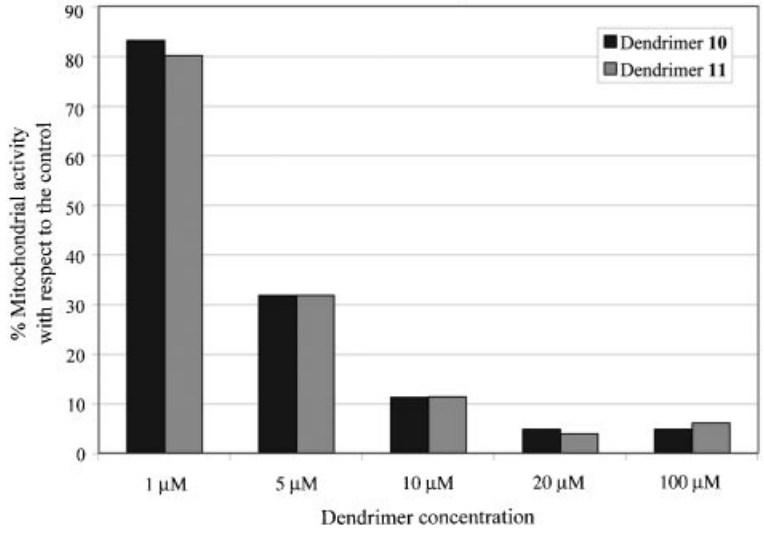

Figure 3. Quantification of mitochondrial activity of cells by MTT test after 48 h of incubation with different concentrations of the carbosilane dendrimers **10** and **11**.

tions lead to the conclusion that the biocompatible concentrations for both dendrimers are between 1 and 5 μM.

A preliminary study of the capacity of these dendrimers in the complexation with the nucleic material to give the so-called dendriplexes was performed by electrophoretic analysis. The technique was carried out in agarose gel using dendrimer **10** and a fluoresceinated phosphorothioate oligodeoxynucleotide (ODN) at different electrostatic charge ratios (+)/(–) (see Figure 4). The retardation of the ODN migration observed in the gel electrophoresis indicates that the ODN is associated with the dendrimer demonstrating a successful complex formation, even at 2:1 charge ratio in which the dendrimer concentration is in the range of biocompatibility mentioned earlier. Because of the hydrolytic problems shown by the carbosilane dendrimers with Si–O bonds, an experiment was performed to ensure that the quaternized dendrimers are responsible for the ODN retardation, rather than charged terminal functional groups detached from the dendritic structure. To this end, mixtures of ODN with the terminal groups [$HOCH_2CH_2NMe_3^+I^-$] alone were subjected to electrophoresis and retardation of the ODN assessed (see also Figure 4). The results clearly show that the terminal branches alone were not able to retard ODN migration, indicating that the whole functionalized dendrimer was necessary to form complexes with ODN. The dendriplexes released the ODN progressively between 6–24 h, which is adequate time for some biomedical applications.

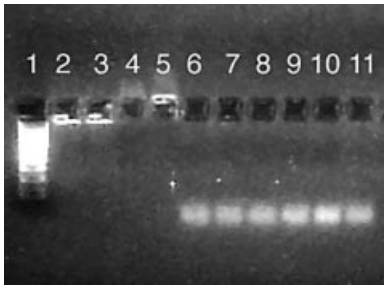

Figure 4. Electrophoresis of dendrimer **10** or [$HOCH_2CH_2NMe_3^+I^-$] and ODN on a 3% agarose gel: (1) a 100 bp DNA ladder as reference; (2) **10**/ODN ratio (+)/(–), 2:1; (3) **10**/ODN ratio (+)/(–), 4:1; (4) **10**/ODN ratio (+)/(–), 20:1; (5) **10**/ODN ratio (+)/(–), 40:1; (6) ODN only; (7) [$HOCH_2CH_2NMe_3^+I^-$]/ODN ratio (+)/(–), 2:1; (8) [$HOCH_2CH_2NMe_3^+I^-$]/ODN ratio (+)/(–), 4:1; (9) [$HOCH_2CH_2NMe_3^+I^-$]/ODN ratio (+)/(–), 20:1; (10) [$HOCH_2CH_2NMe_3^+I^-$]/ODN ratio (+)/(–), 40:1; (11) ODN only.

## Conclusion

A synthetic strategy has been developed for the preparation of new peripheral amine- or ammonium-terminated carbosilane dendrimers. It consists of the alcoholysis of well-known chlorosilane-terminated dendrimers with *N*,*N*-dimethylethanolamine and the subsequent quaternization reaction with MeI. This procedure was shown to be suitable for the growth of high generations, although partial quaternization was observed in the more crowded third-generation dendrimer **7**. Evaluation of dendrimer toxicity by phase-contrast light microscopy and MTT assay revealed that the second-generation dendrimers **10** and **11** show good toxicity profiles in primary cell culture models over extended periods for concentrations between 1 and 5 μM, making them attractive for potential use as biocompatible drug carriers. All these systems are sensitive towards hydrolysis by breaking of the Si–O bonds with the subsequent liberation of their peripheral units. This feature may have a detrimental effect on the dendrimer properties, however, such a process could be useful in the design of carriers for controlled release of drugs. In addition, the capacity of dendrimer/oligonucleotide complex formation was confirmed by electrophoresis. These experiments open the way to use these dendritic macromolecules as drug delivery systems by an electrostatic approach and their posterior release by means of the hydrolytic process. Further studies are in progress to modify the external ammonium motif of the carbosilane dendrimers in order to control their stability towards hydrolysis.

## Experimental Section

**General:** All manipulations of oxygen- or water-sensitive compounds were carried out under argon using standard Schlenk techniques or an argon-filled glovebox. Solvents were dried and freshly distilled under argon prior to use: hexane from sodium-potassium, toluene from sodium, tetrahydrofuran and diethyl ether from sodium benzophenone ketyl, and dichloromethane from $P_4O_{10}$. Unless otherwise stated, reagents were obtained from commercial sources and used as received. *n*G-$(SiCl_y)_x$ dendrimers were prepared according to reported methods.[14]

$^1$H-, $^{13}$C-, and $^{29}$Si NMR spectra were recorded with Varian Unity VXR-300 and Varian 500 Plus Instruments. Chemical shifts ($\delta$, ppm) were measured relative to residual $^1$H and $^{13}$C resonances for [$D_1$]chloroform and [$D_6$]dimethyl sulfoxide which were used as solvents, and $^{29}$Si chemical shifts were referenced to external $SiMe_4$ ($\delta$ = 0.00 ppm). The integral values of the signals in the $^1$H NMR spectra of dendrimer complexes represent only 25% of the total amount of hydrogen atoms. C, H, and N analyses were carried out with a Perkin–Elmer 240 C microanalyzer. MALDI-TOF MS samples were prepared in a 1,8,9-trihydroxyanthracene (dithranol) matrix, and spectra were recorded with a Bruker Reflex II spectrometer equipped with a nitrogen laser emitting at 337 nm and operated in the reflector mode at an accelerating voltage in the range 23000–25000 V.

**Synthesis of 1G-[Si(OCH$_2$CH$_2$NH$_2$)]$_4$ (1):** To a diethyl ether solution (50 mL) of the first-generation chloro-terminated dendrimer 1G-$(SiCl)_4$ (0.35 g, 0.61 mmol) were added a slight excess of $NEt_3$ (0.40 mL, 2.86 mmol) and ethanolamine (0.16 mL, 2.44 mmol). The reaction mixture was stirred for 12 h at room temp. and then evaporated to dryness to remove residual $NEt_3$. The residue was extracted with $Et_2O$ (50 mL) and filtered through Celite to remove the ammonium salt $NEt_3$·HCl. The resulting solution was evaporated under reduced pressure to give **1** as a brown oil (0.21 g, 51%). $^1$H NMR ($CDCl_3$): $\delta$ = 3.55 (t, 2 H, C$H_2$O), 2.74 (t, 2 H, C$H_2$N), 1.46 (s, 2 H, N$H_2$), 1.32 (m, 2 H, SiCH$_2$C$H_2$CH$_2$SiO), 0.63 (m, 2 H, C$H_2$SiO), 0.53 (m, 2 H, C$H_2$Si), 0.07 (s, 6 H, OSi$Me_2$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 64.8 (*C*H$_2$N), 44.3 (*C*H$_2$O), 21.3 (*C*H$_2$SiO), 17.9, 17.2 (Si*C*H$_2$*C*H$_2$CH$_2$SiO), –1.9 (OSi$Me_2$) ppm. $C_{28}H_{72}N_4O_4Si_5$ (668.4): calcd. C 50.27, H 10.77, N 8.38; found C 51.01, H 11.03, N 8.06.

**Synthesis of 1G-[Si(OCH$_2$CH$_2$NMe$_2$)]$_4$ (2):** To a diethyl ether (40 mL) solution of the first-generation chloro-terminated dendrimer 1G-$(SiCl)_4$ (0.85 g, 1.49 mmol) were added a slight excess of $NEt_3$ (0.86 mL, 6.2 mmol) and *N*,*N*-dimethylethanolamine (0.6 mL, 5.97 mmol). The reaction mixture was stirred for 1 h at room temp. and then evaporated to dryness to remove residual $NEt_3$. The residue was extracted with $Et_2O$ (30 mL) and filtered through Celite to remove the ammonium salt $NEt_3$·HCl. The resulting solution was evaporated under reduced pressure to give **2** as a pale yellow oil (0.98 g, 84%). $^1$H NMR ($CDCl_3$): $\delta$ = 3.64 (t, 2 H, C$H_2$O), 2.40 (t, 2 H, C$H_2$N), 2.22 (s, 6 H, N$Me_2$), 1.31 (m, 2 H, SiCH$_2$C$H_2$CH$_2$SiO), 0.60 (m, 2 H, C$H_2$SiO), 0.53 (m, 2 H, C$H_2$Si), 0.07 (s, 6 H, OSi$Me_2$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 61.5 (*C*H$_2$N), 60.8 (*C*H$_2$O), 46.1 (N*Me*$_2$), 21.3 (*C*H$_2$SiO), 18.1, 17.4 (Si*C*H$_2$*C*H$_2$CH$_2$SiO), –1.7 (OSi$Me_2$) ppm. $^{29}$Si{$^1$H} NMR ($CDCl_3$): $\delta$ = 0.49 ($G_0$-Si), 17.62 ($G_1$-Si) ppm. $C_{36}H_{88}N_4O_4Si_5$ (780.4): calcd. C 55.36, H 11.28, N 7.17; found C 55.16, H 11.22, N 7.06.

**Synthesis of 1G-[Si(OCH$_2$CH$_2$NMe$_2$)$_2$]$_4$ (3):** This dendrimer was prepared using a similar method to that described for **2**, starting from 1G-$(SiCl_2)_4$ (0.54 g, 0.87 mmol), *N*,*N*-dimethylethanolamine (0.7 mL, 6.94 mmol), and $NEt_3$ (1.0 mL, 7.2 mmol) to obtain compound **3** as a colorless oil (0.75 g, 80%). $^1$H NMR ($CDCl_3$): $\delta$ = 3.74 (t, 4 H, C$H_2$O), 2.43 (t, 4 H, C$H_2$N), 2.23 (s, 12 H, N$Me_2$), 1.31 (m, 2 H, SiCH$_2$C$H_2$CH$_2$SiO), 0.63 (m, 2 H, C$H_2$SiO), 0.52 (m, 2 H, C$H_2$Si), 0.09 (s, 3 H, OSi*Me*) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 61.4 (*C*H$_2$N), 60.7 (*C*H$_2$O), 46.2 (N*Me*$_2$), 18.7 (*C*H$_2$SiO), 17.7, 17.2 (Si*C*H$_2$*C*H$_2$CH$_2$SiO), –4.4 (OSi*Me*) ppm. $^{29}$Si{$^1$H} NMR ($CDCl_3$): $\delta$ = 0.47 ($G_0$-Si), –3.65 ($G_1$-Si) ppm. $C_{48}H_{116}N_8O_8Si_5$ (1072.4): calcd. C 53.71, H 10.82, N 10.44; found C 53.54, H 11.33, N 10.06. MALDI-TOF MS: *m*/*z* 1095.8 [M + H]$^+$ (calcd. 1095.8).

**Synthesis of 2G-[Si(OCH$_2$CH$_2$NMe$_2$)]$_8$ (4):** This dendrimer was prepared using a similar method to that described for **2**, starting from 2G-$(SiCl)_8$ (0.27 g, 0.18 mmol), *N*,*N*-dimethylethanolamine (0.15 mL, 1.47 mmol), and $NEt_3$ (0.25 mL, 1.79 mmol) to obtain compound **4** as a pale yellow oil (0.31 g, 90%). $^1$H NMR ($CDCl_3$): $\delta$ = 3.64 (t, 4 H, C$H_2$O), 2.41 (t, 4 H, C$H_2$N), 2.23 (s, 12 H, N$Me_2$), 1.30 (m, 6 H, SiCH$_2$C$H_2$CH$_2$SiO and SiCH$_2$C$H_2$CH$_2$Si overlapping), 0.65 (m, 4 H, C$H_2$SiO), 0.53 (m, 8 H, rest of C$H_2$Si), 0.07 (s, 12 H, OSi$Me_2$), –0.09 (s, 3 H, Si*Me*) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 61.5 (*C*H$_2$N), 60.8 (*C*H$_2$O), 46.1 (N*Me*$_2$), 21.1 (*C*H$_2$SiO), 18.6, 17.9 and overlapped signals (Si*C*H$_2$C*H*$_2$CH$_2$SiO and Si*C*H$_2$*C*H$_2$*C*H$_2$Si overlapping), –1.9 (OSi$Me_2$), –4.9 (Si*Me*) ppm. $^{29}$Si{$^1$H} NMR ($CDCl_3$): $\delta$ = 0.93 ($G_1$-Si), 17.60 ($G_2$-Si) ppm, $G_0$-Si was not observed. $C_{88}H_{212}N_8O_8Si_{13}$ (1873.0): calcd. C 56.38, H 11.32, N 5.98; found C 55.98, H 11.20, N 5.78.

**Synthesis of 2G-[Si(OCH$_2$CH$_2$NMe$_2$)$_2$]$_8$ (5):** This dendrimer was prepared using a similar method to that described for **2**, starting from 2G-$(SiCl_2)_8$ (0.48 g, 0.30 mmol), *N*,*N*-dimethylethanolamine (0.48 mL, 4.77 mmol), and $NEt_3$ (0.7 mL, 5.02 mmol) to obtain compound **5** as a colorless oil (0.66 g; 90%). $^1$H NMR ($CDCl_3$): $\delta$ = 3.75 (t, 8 H, C$H_2$O), 2.44 (t, 8 H, C$H_2$N), 2.24 (s, 24 H, N$Me_2$), 1.34 (m, 6 H, SiCH$_2$C$H_2$CH$_2$SiO and SiCH$_2$C$H_2$CH$_2$Si overlapping), 0.64 (m, 4 H, C$H_2$SiO), 0.51 (m, 8 H, rest of C$H_2$Si), 0.09 (s, 6 H, OSi*Me*), –0.10 (s, 3 H, Si*Me*) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 61.4 (*C*H$_2$N), 60.7 (*C*H$_2$O), 46.2 (N*Me*$_2$), 18.6 (*C*H$_2$SiO), 17.7, 17.0 and overlapped signals (Si*C*H$_2$C*H*$_2$CH$_2$SiO and Si*C*H$_2$*C*H$_2$*C*H$_2$Si overlapping), –4.4 (OSi*Me*), –4.8 (Si*Me*) ppm. $^{29}$Si{$^1$H} NMR ($CDCl_3$): $\delta$ = 0.92 ($G_1$-Si), –3.54 ($G_2$-Si) ppm, $G_0$-Si was not observed. $C_{112}H_{268}N_{16}O_{16}Si_{13}$ (2457.0): calcd. C 54.70, H 10.91, N 9.12; found C 54.20, H 10.37, N 9.59.

**Synthesis of 3G-[Si(OCH$_2$CH$_2$NMe$_2$)]$_{16}$ (6):** This dendrimer was prepared using a similar method to that described for **2**, starting from 3G-$(SiCl)_{16}$ (0.20 g, 0.06 mmol), *N*,*N*-dimethylethanolamine (0.10 mL, 0.99 mmol), and $NEt_3$ (0.16 mL, 1.14 mmol) to obtain compound **6** as a pale yellow oil (0.18 g, 74%). $^1$H NMR ($CDCl_3$): $\delta$ = 3.65 (t, 8 H, C$H_2$O), 2.42 (t, 8 H, C$H_2$N), 2.24 (s, 24 H, N$Me_2$), 1.23 (m, 14 H, SiCH$_2$C$H_2$CH$_2$SiO and SiCH$_2$C$H_2$CH$_2$Si overlapping), 0.64 (m, 8 H, C$H_2$SiO), 0.53 (m, 20 H, rest of C$H_2$Si), 0.07 (s, 24 H, OSi$Me_2$), –0.10 (s, 9 H, Si*Me*) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 61.5 (*C*H$_2$N), 60.8 (*C*H$_2$O), 46.1 (N*Me*$_2$), 21.1 (*C*H$_2$SiO), 18.6, 17.9 and overlapped signals (Si*C*H$_2$*C*H$_2$CH$_2$SiO and Si*C*H$_2$*C*H$_2$*C*H$_2$Si overlapping), –1.8 (OSi$Me_2$), –4.8 (Si*Me*) ppm. $^{29}$Si{$^1$H} NMR ($CDCl_3$): $\delta$ = 0.95 ($G_2$-Si), 17.95 ($G_3$-Si) ppm, $G_0$-Si and $G_1$-Si were not observed. $C_{192}H_{460}N_{16}O_{16}Si_{29}$ (4058.3): calcd. C 56.77, H 11.33, N 5.52; found C 56.17, H 11.28, N 5.34.

**Synthesis of 3G-[Si(OCH$_2$CH$_2$NMe$_2$)$_2$]$_{16}$ (7):** This dendrimer was prepared using a similar method to that described for **2**, starting from 3G-$(SiCl_2)_{16}$ (0.19 g, 0.05 mmol), *N*,*N*-dimethylethanolamine (0.17 mL, 1.68 mmol), and $NEt_3$ (0.24 mL, 1.79 mmol) to obtain compound **7** as a pale yellow oil (0.20 g, 72%). $^1$H NMR ($CDCl_3$): $\delta$ = 3.75 (t, 16 H, C$H_2$O), 2.44 (t, 16 H, C$H_2$N), 2.24 (s, 48 H, N$Me_2$), 1.32 (m, 14 H, SiCH$_2$C$H_2$CH$_2$SiO), 0.66 (m, 8 H,

$SiCH_2CH_2CH_2SiO$), 0.53 (m, 20 H, rest of $SiCH_2$), 0.07 (s, 12 H, $OSiMe$), –0.10 (s, 9 H, $SiMe$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 61.4 ($CH_2N$), 60.7 ($CH_2O$), 46.1 ($NMe_2$), a range 18.4–17.4 and overlapped signals ($SiCH_2CH_2CH_2SiO$ and $SiCH_2CH_2CH_2Si$ overlapping), –4.7 ($OSiMe_2$), –5.2 ($SiMe$) ppm. $C_{240}H_{572}N_{32}O_{32}Si_{29}$ (5226.3): calcd. C 55.11, H 10.95, N 8.57; found C 56.11, H 11.89, N 8.13.

**Synthesis of 1G-[Si(OCH$_2$CH$_2$NMe$_3^+$I$^-$)]$_4$ (8):** To a diethyl ether (10 mL) solution of **2** (0.12 g, 0.15 mmol) was added a MeI solution (0.4 mL, 0.8 mmol, 2 M in $Et_2O$). The resulting solution was stirred for 48 h at room temp. and then evaporated under reduced pressure to remove residual MeI. The residue was washed with $Et_2O$ (2 × 5 mL) and dried under vacuum to give **8** as a white solid (0.20 g, 96%). $^1H$ NMR (DMSO): $\delta$ = 3.94 (m, 2 H, $CH_2O$), 3.43 (m, 2 H, $CH_2N$), 3.09 (s, 9 H, $NMe_3^+$), 1.29 (m, 2 H, $SiCH_2CH_2CH_2SiO$), 0.66 (m, 2 H, $CH_2SiO$), 0.56 (m, 2 H, $CH_2Si$), 0.11 (s, 6 H, $OSiMe_2$) ppm. $^{13}C\{^1H\}$ NMR (DMSO): $\delta$ = 65.8 ($CH_2N$), 55.8 ($CH_2O$), 52.6 ($NMe_3^+$), 19.7 ($CH_2SiO$), 16.9, 16.1 ($SiCH_2CH_2CH_2SiO$), –2.6 ($OSiMe_2$) ppm. $C_{40}H_{100}I_4N_4O_4Si_5$ (1348.0): calcd. C 35.61, H 7.42, N 4.15; found C 36.67, H 7.65, N 4.42.

**Synthesis of 1G-[Si(OCH$_2$CH$_2$NMe$_3^+$I$^-$)$_2$]$_4$ (9):** This first-generation dendrimer was prepared using a similar method to that described for **8**, starting from **3** (0.17 g, 0.16 mmol) and a MeI solution (0.80 mL, 1.6 mmol, 2 M in $Et_2O$). Compound **9** was isolated as a white solid (0.29 g, 86%). $^1H$ NMR (DMSO): $\delta$ = 4.12 (m, 4 H, $CH_2O$), 3.54 (m, 4 H, $CH_2N$), 3.17 (s, 18 H, $NMe_3^+$), 1.29 (m, 2 H, $SiCH_2CH_2CH_2SiO$), 0.75 (m, 2 H, $CH_2SiO$), 0.54 (m, 2 H, $CH_2Si$), 0.20 (s, 3 H, $OSiMe$) ppm. $^{13}C\{^1H\}$ NMR (DMSO): $\delta$ = 65.8 ($CH_2N$), 56.0 ($CH_2O$), 52.7 ($NMe_3^+$), 17.3 ($CH_2SiO$), 16.5, 15.9 ($SiCH_2CH_2CH_2SiO$), –5.3 ($OSiMe$) ppm. $C_{56}H_{140}I_8N_8O_8Si_5$ (2207.6): calcd. C 30.44, H 6.34, N, 5.07; found C 31.47, H 6.47, N, 5.19.

**Synthesis of 2G-[Si(OCH$_2$CH$_2$NMe$_3^+$I$^-$)]$_8$ (10):** This dendrimer was prepared using a similar method to that described for **8**, starting from **4** (0.25 g, 0.13 mmol) and a MeI solution (0.6 mL, 1.2 mmol, 2 M in $Et_2O$). Compound **10** was isolated as a white solid (0.35 g, 87%). $^1H$ NMR (DMSO): $\delta$ = 3.96 (m, 4 H, $CH_2O$), 3.45 (m, 4 H, $CH_2N$), 3.11 (s, 18 H, $NMe_3^+$), 1.29 (m, 6 H, $SiCH_2CH_2CH_2SiO$ and $SiCH_2CH_2CH_2Si$), 0.65 (m, 4 H, $SiCH_2CH_2CH_2SiO$), 0.52 (m, 8 H, rest of $SiCH_2$), 0.11 (s, 12 H, $OSiMe_2$), –0.10 (s, 3 H, $SiMe$) ppm. $^{13}C\{^1H\}$ NMR (DMSO): $\delta$ = 65.7 ($CH_2N$), 55.9 ($CH_2O$), 52.6 ($NMe_3^+$), 19.7, 17.5, 16.9 and overlapped signals ($SiCH_2CH_2CH_2SiO$ and $SiCH_2CH_2CH_2Si$), –2.5 ($OSiMe_2$), –5.3 ($SiMe$) ppm. $C_{96}H_{236}I_8N_8O_8Si_{13}$ (3008.2): calcd. C 38.29, H 7.85, N 3.72; found C 38.87, H 8.32, N, 3.79.

**Synthesis of 2G-[Si(OCH$_2$CH$_2$NMe$_3^+$I$^-$)$_2$]$_8$ (11):** This dendrimer was prepared using a similar method to that described for **8**, starting from **5** (0.10 g, 0.04 mmol) and a MeI solution (0.5 mL, 1.0 mmol, 2 M in $Et_2O$). Compound **11** was isolated as a white solid (0.17 g, 87%). $^1H$ NMR (DMSO): $\delta$ = 4.13 (m, 8 H, $CH_2O$), 3.56 (m, 8 H, $CH_2N$), 3.19 (s, 36 H, $NMe_3^+$), 1.28 (m, 6 H, $SiCH_2CH_2CH_2SiO$ and $SiCH_2CH_2CH_2Si$), 0.72 (m, 4 H, $SiCH_2CH_2CH_2SiO$), 0.55 (m, 8 H, rest of $SiCH_2$), 0.21 (s, 6 H, $OSiMe$), –0.08 (s, 3 H, $SiMe$) ppm. $^{13}C\{^1H\}$ NMR (DMSO): $\delta$ = 65.7 ($CH_2N$), 56.0 ($CH_2O$), 52.7 ($NMe_3^+$); 19.2, 17.2, 16.4 and overlapped signals ($SiCH_2CH_2CH_2SiO$ and $SiCH_2CH_2CH_2Si$), –5.2 ($OSiMe$), –5.6 ($SiMe$) ppm. $C_{128}H_{316}I_{16}N_{16}O_{16}Si_{13}$ (4727.4): calcd. C 32.49, H 6.68, N 4.74; found C 33.32, H 7.03, N, 4.72.

**Synthesis of 3G-[Si(OCH$_2$CH$_2$NMe$_3^+$I$^-$)]$_{16}$ (12):** This dendrimer was prepared using a similar method to that described for **8**, starting from **6** (0.12 g, 0.03 mmol) and a MeI solution (0.4 mL, 0.8 mmol, 2 M in $Et_2O$). Compound **12** was isolated as a white solid (0.16 g, 83%). $^1H$ NMR (DMSO): $\delta$ = 3.96 (m, 8 H, $CH_2O$), 3.47 (m, 8 H, $CH_2N$), 3.13 (s, 36 H, $NMe_3^+$), 1.28 (m, 14 H, $SiCH_2CH_2CH_2SiO$ and $SiCH_2CH_2CH_2Si$), 0.65 (m, 8 H, $SiCH_2CH_2CH_2SiO$), 0.52 (m, 20 H, rest of $SiCH_2$), 0.10 (s, 24 H, $OSiMe_2$), –0.08 (s, 9 H, $SiMe$) ppm. $^{13}C\{^1H\}$ NMR (DMSO): $\delta$ = 65.8 ($CH_2N$), 55.9 ($CH_2O$), 52.6 ($NMe_3^+$), 19.7, 17.2, 16.0 and overlapped signals ($SiCH_2CH_2CH_2SiO$ and $SiCH_2CH_2CH_2Si$), –2.7 ($OSiMe_2$), –5.5 ($SiMe$) ppm. $C_{208}H_{508}I_{16}N_{16}O_{16}Si_{29}$ (6328.7): calcd. C 39.43, H 8.03, N 3.54; found C 39.19, H 8.19, N, 3.68.

**Reaction of 3G-[Si(OCH$_2$CH$_2$NMe$_2$)$_2$]$_{16}$ (7) with MeI:** The reaction of **7** with MeI using a similar method to that described for **8** afforded the dendrimer 3G-[Si($OCH_2CH_2NMe_3^+I^-)_2$]$_{16}$ (**13**). However, the NMR analysis revealed that not all the amine groups were quaternized: roughly 29 groups were methylated, based on integration of the corresponding chemical shift of the outer –$OCH_2CH_2N$– branch for the amine or ammonium groups.

### Biocompatibility Studies

**Cells:** PBMC cells were derived from healthy voluntary donors, and obtained from leukophoresed blood by Ficoll™ gradient and elutriation centrifugation. Prior to challenge with dendrimers, PBMCs were stimulated for 48 h with phytohemagglutinin (2 μg/mL) and Interleukin 2 (IL-2, 100 IU/mL). On the day of the challenge, PBMCs were recovered and washed with Phosphate Buffered Saline (PBS), and then seeded in RPMI medium supplemented with 10% of fetal calf serum, 1% L-glutamine, antibiotics, and IL-2 (50 IU/mL), in a 5% $CO_2$ environment (100 000 cells per well in 96-well plates for the toxicity curve of dendrimer concentrations). The final volume in each well was 200 μL for the 96-well plates and 500 μL for the 24-well plates. For the toxicity curve of dendrimer concentrations, wells were coated with 20 μL of fibronectin/well at a concentration of 5 μg/mL. The intention was not to lose cells through pipetting during the MTT assay. In the case of the 24-well plates, stimulated cells were seeded in 340 μL of complete medium.

**Phase-Contrast Light Microscopy:** After incubation with dendrimers, changes in morphology and characteristics of PBMCs, such as cell membrane birefringence, were observed using a phase-contrast inverted microscope (Nikon TMS, Nikon, Japan) equipped with a 100X objective (Plan 10/0,30DL/Ph1, Nikon, Japan). Live PBMCs are bright, have a defined spherical shape, and float in the culture medium. Dead cells have a darker appearance, and are mostly present in the bottom of the well. In addition, we assessed the presence or absence of cell aggregation.

**MTT [3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium Bromide] Assay:** This method was selected to analyze detrimental intracellular effects on mitochondria and metabolic activity. The colorimetric MTT test, based on the selective ability of viable cells to reduce 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide to purple formazan, relies on intact metabolic activity, and is frequently used for cytotoxicity screening. After 48 h of incubation of PBMCs with different concentrations of dendrimers in a 96-well plate, culture medium containing the dendrimers was replaced with serum-free Optimem (200 μL). Sterile filtered MTT (Sigma) stock solution (20 μL) in PBS pH = 7.4 (5 mg/mL) was added to each well to achieve a final concentration of 0.5 mg MTT/mL. After 4 h, unreacted dye was removed by aspiration, and the formazan crystals were dissolved in dimethyl sulfoxide (200 μL per well) (Merck, Darmstadt, Germany). The concentration of formazan was then determined spectrophotometrically in a plate reader at a wavelength of 570 nm (test) and 690 nm (reference). The spectrophotometer was calibrated to zero absorbance using Optimem medium without cells. The relative cell viability (%) related to control wells

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(cells with no dendrimer) was calculated by [A] test/[A] control × 100. Each dendrimer concentration was tested in triplicate, according to ATCC directives.

**Formation of Dendrimer/Oligonucleotide Complexes:** The fluoresceinated phosphorothioate oligodeoxynucleotide (ODN) sequence was 25 bases long and corresponded to an antisense (complementary) sequence of the HIV Anti-Gag. Complex formation between dendrimer **10** or [$HOCH_2CH_2NMe_3^+I^-$] and ODN was performed using an electrostatic approach. Ratios of ODN to dendrimer were based on the calculation of the electrostatic charge present on each component, for example the number of phosphate groups in the ODN versus the number of terminal ammonium groups on the dendrimer. The dendrimer or [$HOCH_2CH_2NMe_3^+I^-$] was diluted in sterile distilled water at 2 mg/mL, and the ODN concentration for complexation with the carbosilane dendrimer was 0.88 μM (2.57 μg). All complexes or mixtures at different charge ratios were formed in serum-free RPMI medium (60 μL), with an incubation time of 20 min at room temp. Complex formation was assessed by evaluation of migration retardation of fluoresceinated ODN during electrophoresis on 3% agarose gel. A 100 bp DNA ladder was used as reference (Gibco BRL™).

**Supporting Information** (for details see the footnote on the first page of this article): Selected data as $^1$H-, $^{13}$C-, and $^{29}$Si NMR spectra of **1**, **3**–**6**, **9**–**11** (Figure S1–S3 and S6–S10), 2D HMQC and HMBC spectra of **4** (Figure S4–S5), and plots of the hydrolysis processes of **10** and **12** at different concentrations (Figure S11).

# Interactions of Cationic Palladium(II)- and Platinum(II)-$\eta^3$-Allyl Complexes with Fluoride: Is Asymmetric Allylic Fluorination a Viable Reaction?

**Lukas Hintermann,*[a,b] Florian Läng,[a] Pascal Maire,[a] and Antonio Togni[a]**

**Keywords:** Palladium / Platinum / Allyl ligands / Fluorination / Naked fluoride

The complex cations $[M(\eta^3\text{-}R_2All)(PPFPz\{3\text{-}t\text{Bu}\})]^+$ (M = $Pd^{II}$, $R_2$All = 1,3-diphenylallyl, 1,3-dicyclohexylallyl, indenyl; M = $Pt^{II}$, $R_2$All = 1,3-diphenylallyl; PPFPz-{3-*t*Bu} = 3-*tert*-butyl-1-{1-[2-diphenylphosphanyl-ferrocenyl]ethyl}-1*H*-pyrazole) have been prepared as salts with $PF_6^-$ or $SbF_6^-$. They have been characterized by NMR spectroscopy in solution and by X-ray crystallography in the solid state. Their reactions with sources of nucleophilic and "naked" fluoride have been investigated by multinuclear NMR spectroscopy. The $Pd^{II}$ complexes did not undergo any nucleophilic substitution with concomitant release of allyl fluorides. The dicyclohexylallyl fragment was released as a 1,3-diene by elimination, but with other allyl complexes nonspecific decomposition reactions predominated. The complex $[Pt(\eta^3\text{-}1,3\text{-}Ph_2C_3H_3)(PPFPz\{3\text{-}t\text{Bu}\})]PF_6$ underwent an anion exchange with $Me_4NF$ to give $[Pt(1,3\text{-}Ph_2C_3H_3)(PPFPz\{3\text{-}t\text{Bu}\})]F$ which existed as a mixture of interconverting allyl isomers in solution at ambient temperature. For the bromide salt, $[Pt(\eta^3\text{-}1,3\text{-}Ph_2C_3H_3)(PPFPz\{3\text{-}t\text{Bu}\})]Br$, allyl isomerization was slow at ambient temperature. Precursors of $Pt^0$ reacted with bromo-1,3-diphenylprop-2-ene to give $[Pt_2(\mu\text{-}Br)_2(\eta^3\text{-}1,3\text{-}Ph_2All)_2]$ and precursors of $Pd^0$ underwent oxidative additions with bromo- and fluoro-1,3-diphenyl-2-propene to give 1,3-diphenylallyl complexes of $Pd^{II}$. Therefore, the nucleophilic attack of fluoride on the allyl fragment of $Pd^{II}$ complexes is endergonic, and the high energy barrier of this step is difficult to overcome in a catalytic allylic fluorination reaction.

## Introduction

The organometallic and coordination chemistry of fluoride and the C–F bond have recently received much attention. Initial work centered around transition-metal fluoro complexes,[1–3] the coordination ability of the notoriously inert C–F bond[4] and its cleavage by means of electron-rich transition-metal centers using either stoichiometric[5] or catalytic methods.[6] Furthermore, "fluoride effects" have been discovered in homogeneous catalysis, which points to an important role of fluoride as a steering ligand in transition-metal-catalyzed reactions.[7,8] By contrast, the metal-catalyzed generation of C–F bonds (i.e. catalytic fluorination of organic compounds) has long been limited to industrial applications of the Swarts reaction[9] and some examples of the Pd-catalyzed fluorocarbonylations.[10,11] Research on the generation of fluoroarenes by reductive eliminations from aryl-fluoropalladium(II) complexes is actively pursued but not yet realized.[12] The neglect of transition-metal mediated fluorination methodologies comes as a surprise when the importance of fluorinated organic compounds in the chemical, agricultural, and pharmaceutical industry is considered. Here, selectively fluorinated organic compounds are in high demand for diverse applications.[13] In response to this situation, we have initiated a research program directed towards transition-metal catalyzed selective fluorination reactions at $sp^3$ centers. This has already resulted in a fluoro-$Ru^{II}$-complex-mediated halogen exchange reaction[14] and a titanium-catalyzed asymmetric catalytic α fluorination of β-keto esters.[15] Similar asymmetric fluorinations have been discovered by us and others using $Pd^{II}$,[16] $Cu^{II}$,[17–19] $Ni^{II}$,[18,20] and $Ru^{II}$[21] complexes as catalysts, all of them relying on electrophilic fluorination reagents. The present work involves a promising alternative strategy for asymmetric catalytic fluorination using fluoride nucleophiles. We were inspired by the observation that catalytic allylic substitution reactions enable the attachment of a variety of nucleophiles at allylic fragments with high enantioselectivity.[22] Consequently, we hoped to realize a palladium catalyzed allylic fluorination reaction starting from suitable allylic substrates and fluoride nucleophiles using chiral $Pd^{II}$ complexes as catalysts.[23] Since cationic $\eta^3$-allyl complexes of palladium(II) are well-established intermediates in asymmetric allylic substitution reactions,[24] we also wanted to investigate the interaction of such species with fluoride anions in order to clarify: (a) if nucleophilic attack of fluoride takes place; or (b) what other interactions (coordination, ion-pairing etc.) play a role. Analogous experiments with platinum(II) complexes were also planned

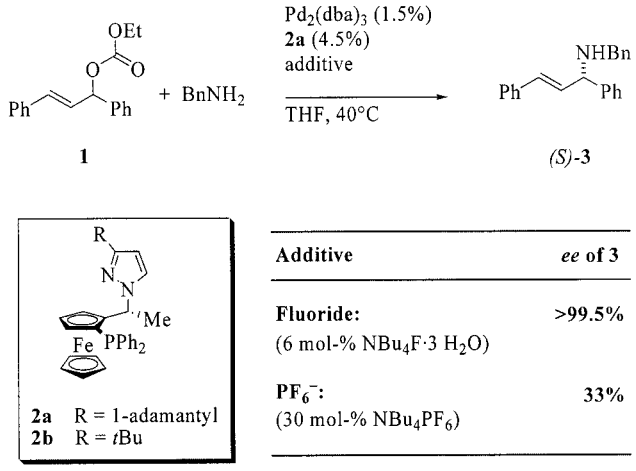
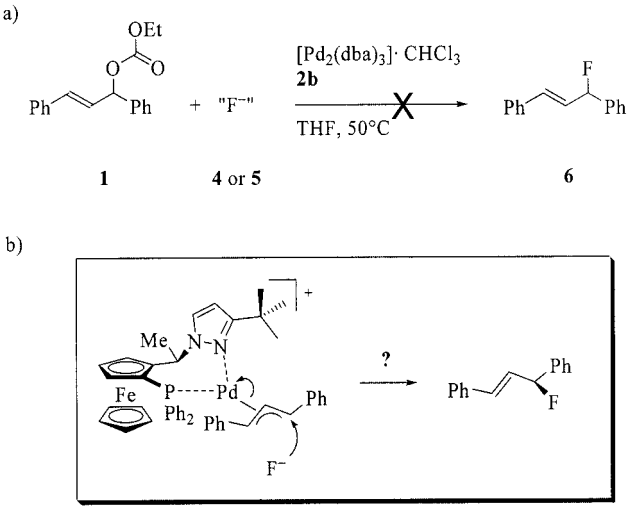
because the slower kinetics of $Pt^{II}$ relative to $Pd^{II}$ compounds should allow for the observation of short-lived intermediates with the added advantage of having $^{195}Pt$ NMR spectroscopy as a selective analytical tool.[25] Finally, we also hoped to clarify the issue of a "fluoride-effect" that we had observed earlier in the asymmetric amination of ethyl 1,3-diphenylallyl carbonate (**1**) catalyzed by $Pd^{II}$ with ligand **2a** (Scheme 1). The reaction gives the amination product **3** in either very high or low enantioselectivity, depending on the counterion ($F^-$ or $PF_6^-$) of the ammonium salt additive.[8]



Scheme 1. The palladium-catalyzed asymmetric allylic amination is subject to astonishing anion effects on enantioselectivity.[8] dba = dibenzylidene acetone, Bn = benzyl.

## Results

The new phosphanyl-ferrocenyl pyrazole **2b**, (PPFPz-{3-*t*Bu}, 3-*tert*-butyl-1-{(*R*)-1-[2-($S_P$)-diphenylphosphanyl-ferrocenyl]ethyl}-1*H*-pyrazole), (Scheme 1) was prepared from 3(5)-*tert*-butylpyrazole[26] and (*R*,*S*)-PPFA[27] (PPFA = *N*,*N*-dimethyl-1-[2-diphenylphosphanyl-ferrocenyl]ethylamine) in high yield as a single regioisomer according to our standard method.[28] A test run with **2b** as the ligand in the palladium-catalyzed allylic amination reaction,[29] shown in Scheme 1, using cocatalytic $NBu_4F{\cdot}3H_2O$ (3 equiv. relative to [Pd]),[8] gave the amination product (*S*)-**3** with an *ee* > 99.5%. Thus, **2a** and **2b** behaved identically in this reaction, but **2b** was the preferred ligand for mechanistic studies because of the simplicity of the $^1H$ NMR-signal of the *tert*-butyl group over the adamantyl group. Using similar reaction conditions, we next attempted to perform catalytic allylic fluorination reactions with carbonate **1** (Scheme 2, a). The catalyst was generated in situ from $Pd(dba)_2$ and **2b**. The sources of nucleophilic fluoride that were tested are TBAT {$NBu_4[SiF_2Ph_3]$ (**4**)},[30] a nucleophilic non-basic fluoride transfer reagent, and $Me_4NF$ (**5**),[31] a "naked" fluoride[32] of high basicity. Anhydrous versions of these reagents are available and they also show considerable solubility in nonprotic organic solvents, which is an important characteristic because the nucleophilicity of fluoride is reduced by solvation in protic media or in the presence of trace water.[33] It should be noted that more traditional fluoride sources (such as KF, CsF, or $NBu_4F$) are either insoluble in nonprotic solvents or cannot be dried without decomposition.[34]



Scheme 2. Nucleophilic allylic fluorination of palladium complexes. (a) Attempted, but unsuccessful allylic fluorination with a $Pd^0$ catalyst. (b) The nucleophilic attack of fluoride on cationic allylpalladium(II) complexes is the key step in a postulated allylic fluorination reaction, as investigated in this work.

Analysis of reaction solutions from catalysis experiments using $^{19}F$ NMR spectroscopy did not show signals corresponding to 1,3-diphenylallyl fluoride (**6**),[14a,35] or any other organofluorine compound. Straightforward allylic fluorination in a catalytic manner is thus not feasible. We therefore proceeded to study the stoichiometric variant of this reaction, namely the attack of fluoride on isolated, fully-characterized cationic $\eta^3$-palladium(II) and -platinum(II) complexes (Scheme 2, b).

### Synthesis and Structure of Allylpalladium(II) and -platinum(II) Complexes

Several cationic palladium(II) allyl complexes incorporating the ligand **2b**, (PPFPz-{3-*t*Bu}), were synthesized in the usual manner[36] by reaction with the dinuclear allylpalladium(II) chlorides (**7**) followed by halide abstraction with either $TlPF_6$, $AgSbF_6$, or $(Et_3O)BF_4$ (Scheme 3 and Scheme 5). In some cases, we applied a new halide abstraction technique that relies on the combination of epichlorohydrine (or any other reactive epoxide) with an acid and a nonnucleophilic counterion, such as $HPF_6$. This method relies on the ability of epoxides to scavenge halide anions by nucleophilic-ring opening.

The diphenylallyl complex **8a** occurs predominantly as the *exo-syn-syn* isomer[37] (>98% by $^{31}P$ NMR spectroscopy) in $CDCl_3$ solution, in agreement with observations on complexes with similar ligands.[29] The same isomer is also present in the solid state, as shown by X-ray crystallography (vide infra, Figure 7). $\eta^3$-1,3-Dicyclohex-

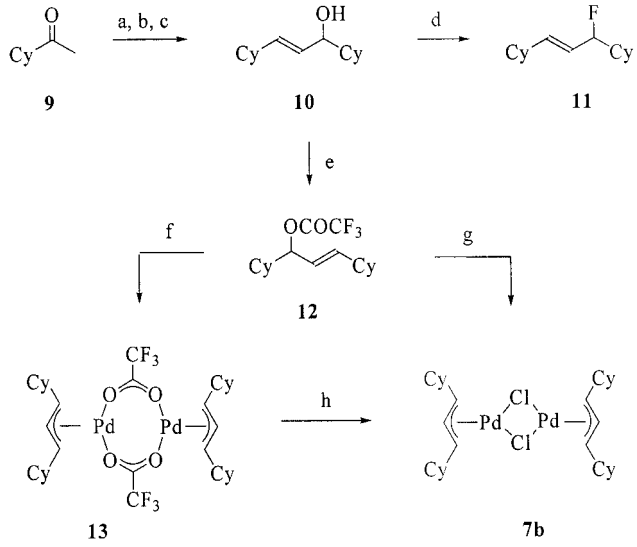
**7a** R = Ph
**7b** R = Cy
**7c** $R_2$ = 1,2-$C_6H_4$

**8a** R = Ph, Z = $PF_6$
**8b** R = Cy, Z = $PF_6$
**8c** $R_2$ = 1,2-$C_6H_4$, Z = $SbF_6$

Scheme 3. Synthesis of cationic allylpalladium(II) complexes. (a) **2b**, halide abstracting reagent (see Exp. Section). **8a**: 87%; **8b**: 96%; **8c**: 82%. Cy = cyclohexyl.

ylallyl complexes of palladium(II) are new. Our synthetic route (Scheme 4) started with an aldol addition of cyclohexyl methyl ketone (**9**) followed by elimination to the α,β-unsatuarated ketone and Luche reduction[38] to give dicyclohexylallyl alcohol (**10**). Fluorination with DAST [(diethylamino)sulfur(II) trifluoride][39] produced a reference sample of allyl fluoride **11**. According to a general procedure by Vitagliano et al.,[40] allyl trifluoroacetate (**12**) was treated with $Pd(dba)_2$ by oxidative addition to give the trifluoroacetate-bridged dimer **13**, and this complex underwent ligand exchange with LiCl to give the chloro-bridged dimer **7b**. Alternatively, and more conveniently, the last two steps could be performed in a single synthetic operation (**12**→**7b**).



Scheme 4. Synthesis of (1,3-dicyclohexylallyl)palladium(II) complexes. (a) 1. LDA, THF, –78 °C; 2. CyCHO; 3. MsCl. (b) DBU, $Me_2CO$; 70% (from **9**). (c) $NaBH_4$, $CeCl_3 \cdot 7H_2O$, MeOH, room temp.; 77%. (d) DAST, $CH_2Cl_2$, –78 °C; quant. (e) TFAA, Py, 0 °C; 93%. (f) $Pd(dba)_2$, THF/MeCN (3:1), 40 °C; 93%.·(g) $Pd(dba)_2$, LiCl, THF/MeCN (3:1); 97%. (h) LiCl. LDA = lithium diisopropylamide, DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene, TFAA = trifluoroacetic acid anhydride.

The bridged trifluoroacetate **13** showed interesting conformational isomerism in solution, similar to that reported for $[Pd_2(\mu\text{-}OAc)_2(\eta^3\text{-}R_2All)_2]$ complexes.[41] The VT $^1H$ NMR spectroscopic shifts (Table 1) were assigned to the $C_S$ symmetric isomer **A**, which has two sets of allylic protons, and the $C_{2v}$ symmetric isomer **B** (Figure 1). Interchange of **A** and **A′** was relatively slow up to a temperature of 273 K. Interchange of **A** with **B** was slow over the whole temperature range studied (253–298 K), but notable line broadening occurred at 298 K. The allyl units had the *syn-syn* configuration in both **A** and **B**, as deduced from the coupling [$^3J_{H,H}$ = 11 Hz] between the central and terminal allyl protons.

Table 1. $^1H$ NMR spectroscopic data for allyl hydrogen atoms within the conformational isomers of **13** at 253 K.

| Conformer | Central H | *anti* H |
|---|---|---|
| **A** | 5.39 ppm, t, $J$ = 11.1 | 3.48 ppm, dd, $J$ = 10.9, 5.1 |
| | 5.06 ppm, t, $J$ = 11.1 | 3.71 ppm, dd, $J$ = 10.9, 7.5 |
| **B** | 5.42 ppm, t, $J$ = 11.1 | 3.43 ppm, dd, $J$ = 11.0, 5.7 |

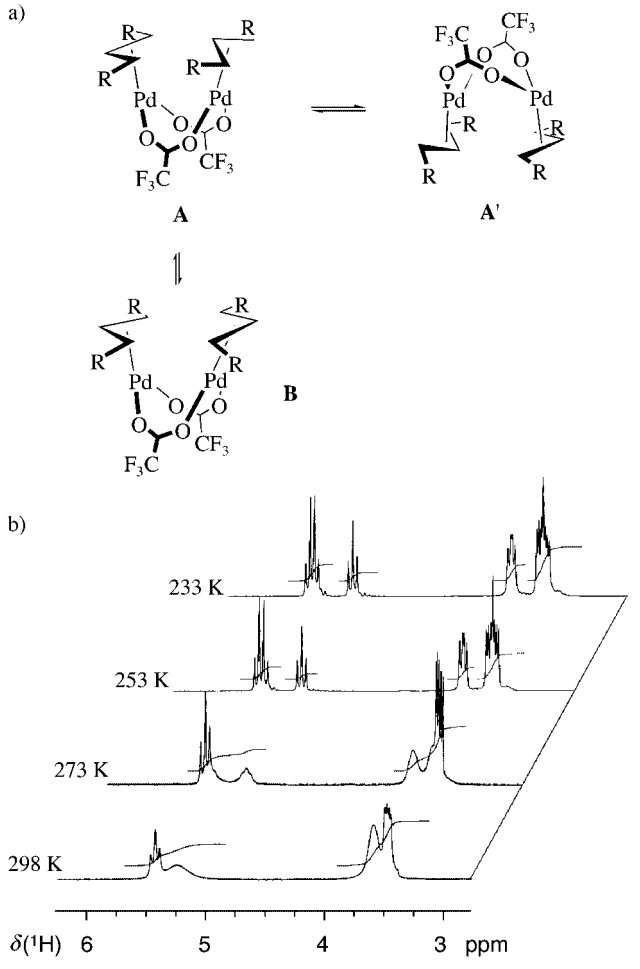


Figure 1. Conformational isomerism and VT $^1H$ NMR spectra of **13** ($CDCl_3$, 300 MHz). (a) Conformational isomerism and dynamic behavior of **13**. (b) VT-NMR: Signals of **A**/**A′** and **B** (compare in Table 1) are partially overlapping at all temperatures; the virtual quartet at 233 and 253 K is a superimposition of two triplets. At 298 K, the interconversion of **A** and **A′** approaches coalescence. Other processes such as conformational changes of the Cy substituents presumably add to the dynamics.

Incorporation of the (1,3-dicyclohexylallyl)palladium(II) fragment into a cationic complex with ligand **2b** (Scheme 3) yielded **8b**, initially as an 82:18 mixture of two allyl isomers. This ratio changed to about 1:1 (52:48) after recrystallization from hot methanol. On the basis of the $^1$H NMR coupling data, the *syn-syn* configuration was assigned to the main isomer, and the *syn-anti* (*anti* Cy group *trans* to N) configuration to the minor isomer, but the one-dimensional analysis did not give conclusive information about the *endo* or *exo* orientation. An X-ray crystal structure of **8b** supported the NMR spectroscopic assignment in a surprising way: the complex had crystallized as a statistical 1:1 mixture of allyl isomers possessing the *exo-syn-syn* and *endo-anti-syn* (*anti trans* to N) configurations, respectively (Figure 2). Apparently, both isomeric dicyclohexylallyl fragments had flexibly adapted to the coordination environment of the metal-ligand framework (Figure 2, **A** and **B**), which was kept as a common unit during the refinement of the structure. The bonding data for the dicyclohexylallyl fragments are not very accurate because of the disorder and will not be discussed.

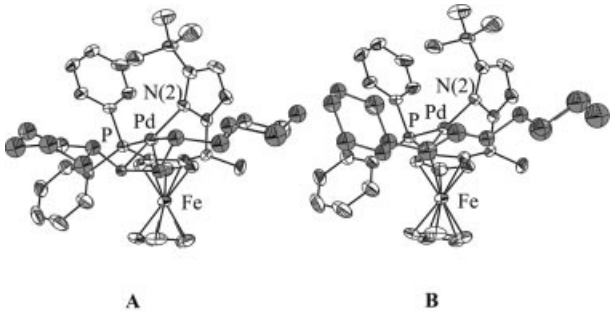

Figure 2. ORTEP representations (30% probability ellipsoids) of cationic fragments displaying configurational allyl isomerism in the solid-state structure of **8b**. $PF_6$ anions and hydrogen atoms are omitted for clarity, carbon atoms within the dicyclohexylallyl fragments are filled in as grey. **A**: *endo-syn-anti* isomer; **B**: *exo-syn-syn* isomer. Selected bond lengths [Å] and angles [°]: Pd–N(2) = 2.143(6), Pd–P 2.325(2); N(2)–Pd–P = 89.16(18). As a result of the disorder, values for the allyl fragments are not accurate.

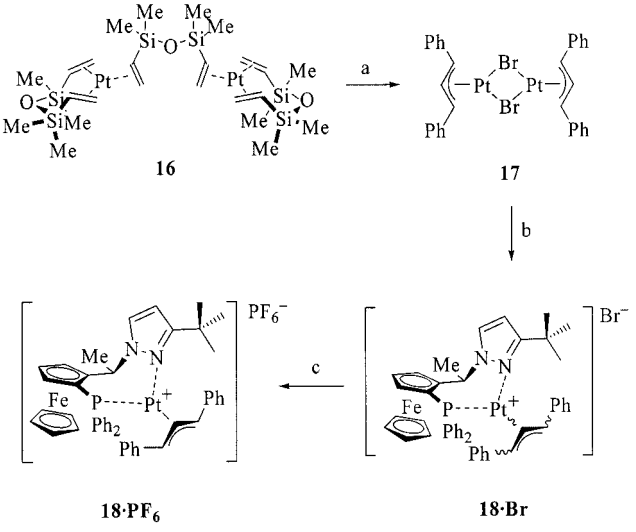
The dark-red indenyl complex **8c** was prepared from $\{PdCl(Ind)\}_n$ (**7c**)[42] in the usual way (Scheme 3). Unlike most other cationic complexes described here, the indenyl compound was somewhat air-sensitive, with solutions of it slowly decomposing in air. A mixture of *exo* and *endo* isomers was present in solution, with *exo*-**8c** as the major species, as shown by H,H NOESY cross peaks of the central allyl hydrogen and the *tert*-butyl group. In the solid state only the *exo* isomer is present (Figure 3). The X-ray crystal structure also shows that the indenyl fragment is $\eta^3$-bonded, rather than $\eta^5$.

Unlike the much studied (1,3-diphenylallyl)palladium(II) complexes,[29,43,44] the corresponding platinum compounds are unknown, even though platinum-catalyzed allylic alkylation (including that of 1,3-diphenylallyl substrates) has been studied and the intermediacy of cationic $\eta^3$-allyl complexes have been invoked in analogy to Pd chemistry.[45,46] We have found that the addition of 1,3-diphenylallyl bromide (**15**)[47] to a Karstedt complex solution (**16**)[48,49] readily produces a yellow precipitate of the allylplatinum(II) bromide (**17**) (Scheme 5). $Pt_2(dba)_3$[50] also underwent this oxidative addition, but the resulting product was less pure due to metallic platinum residues in the precursor complex. Reaction of **17** with **2b** gave the complex **18·Br**, which was converted to **18·PF$_6$** using the new $HPF_6$/epichlorohydrine reagent (Scheme 5).



Scheme 5. Synthesis of (1,3-diphenylallyl)platinum(II) complexes. (a) PhCH=CHCH(Br)Ph (**15**), *t*BuOMe, 0 °C; 77%. (b) **2b**, THF; 97%. (c) 1. epichlorohydrine, $HPF_6$, $Me_2CO$; 2. crystallization from $CH_2Cl_2$/MeOH; 73% (from **17**).

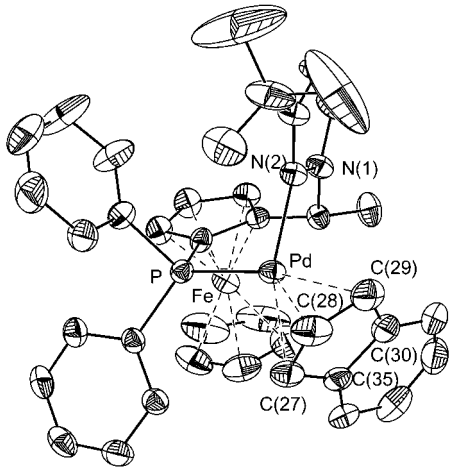


Figure 3. ORTEP plot (30% probability ellipsoids) of **8c·$CH_2Cl_2$**. Hydrogen atoms, $CH_2Cl_2$, and $SbF_6$ anion are omitted for clarity. Selected bond lengths [Å] and angles [°]: Pd–P = 2.303(2), Pd–N(2) = 2.122(6), Pd–C(27) = 2.191(8), Pd–C(28) = 2.225(9), Pd–C(29) = 2.260(10), Pd–C(30) = 2.570(9), Pd–C(35) = 2.576(8), C(27)–C(28) = 1.397(14), C(27)–C(35) = 1.460(13), C(28)–C(29) = 1.424(17), C(29)–C(30) = 1.421(17), C(30)–C(35) = 1.431(12); N(2)–Pd–P(1) = 92.32(18), C(27)–C(28)–C(29) = 106.4(10).

Comparative spectroscopic data for the platinum compounds was collected from a range of reference complexes

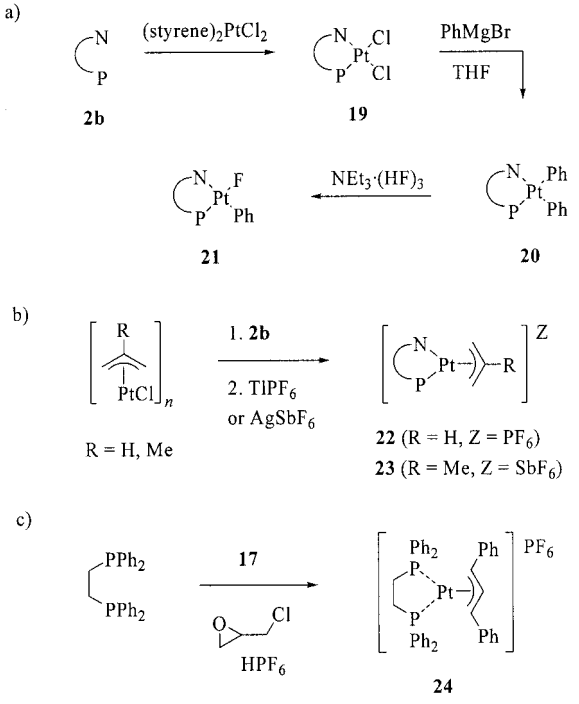
whose synthesis is displayed in Scheme 6. Pregosin's bis(styrene)platinum(II) chloride[51] served as the most suitable precursor for dichloro complex **19** under mild conditions. The diphenyl complex **20** resulted from reaction of **19** with excess Grignard reagent. Interestingly, the substance crystallized with one equivalent of phenol, which originated from a partially oxidized PhMgBr solution. The X-ray crystal structure of **20·PhOH** is shown in Figure 4. The phenolic OH group is presumably involved in a weak hydrogen bond with the electron-rich $Pt^{II}$ center.[52] The phenol is arranged with the OH group pointing towards the Pt center and the O–Pt distance is 4.21 Å. By comparison, O–Pd distances of 3.2–3.7 Å have been observed for related interactions between $Pd^0$ and aliphatic alcohols.[53]



Scheme 6. Syntheses of platinum(II) complexes incorporating ligand **2b** and/or an allyl ligand.

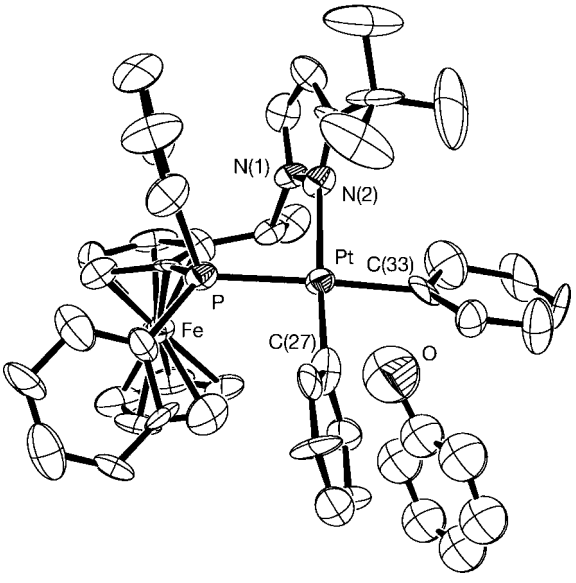


Figure 4. ORTEP plot (50% probability ellipsoids) of **20·PhOH**. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Pt–P = 2.33(2), Pt–N(2) = 2.18(5), Pt–C(27) = 1.97(5), Pt–C(33) = 2.08(3); P–Pt–N(2) = 88.7(16), C(27)–Pt–C(33) = 86.8(19), P–Pt–C(27) = 93.1(12), P–Pt–C(33) = 175.4(5), N(2)–Pt–C(33) = 91.8(13), N(2)–Pt–C(27) = 174.6(9).

The fluoro complex **21** was obtained in situ in an NMR tube by protonolysis of the diphenylplatinum complex **20** with $NEt_3$·$(HF)_3$. Only one bond was cleaved even though an excess of reagent was added. The presence of a Pt–F bond in this complex is evident from the coupling patterns in the $^{19}F$ NMR spectrum (doublet with platinum satellites) and the $^{31}P$ NMR spectrum (doublet with platinum satellites) (Figure 5). Any complex containing a covalent Pt–F bond in our study would have similar NMR characteristics, whereas ionic $Pt^+/F^-$ interactions would not be expected to result in such $^{19}F$ NMR signals or coupling characteristics.

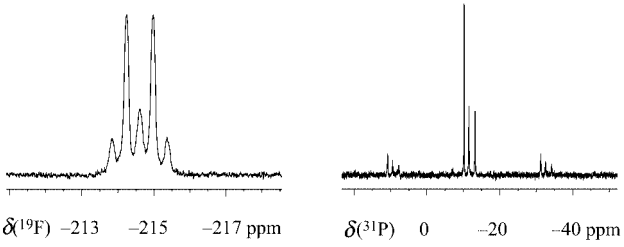

Figure 5. NMR spectra of fluoro complex **21**. (a) $^{19}F$ NMR (282.4 MHz, $CDCl_3$), the signal at $\delta$ = –214.6 ppm ($^2J_{P,F}$ = 207, $^1J_{Pt,F}$ = 210 Hz) is due to the platinum bound fluoro ligand. (b) $^{31}P$ NMR (121.5 MHz, $CDCl_3$), the signal at $\delta$ = –11.8 ppm (d, $J_{P,F}$ = 207, $J_{Pt,P}$ = 5104 Hz) is due to the fluoro complex, while the signal at $\delta$ = –9.6 ppm (s, $J_{Pt,P}$ = 5107 Hz) belongs to an unidentified side product.

The allyl complex **22** and the methallyl derivative **23** were obtained by the usual method (Scheme 6, b). They formed equilibrium mixtures of *exo* and *endo* isomers in solution, with the larger methallyl group inducing a slightly higher amount of the *exo* isomer (Table 2).

### Solution Structure of (1,3-Diphenylallyl)platinum(II) Complexes

The $\eta^3$-allyl complex **18·PF$_6$** occurs predominantly as the *exo-syn-syn* isomer in either [$D_8$]THF or $CDCl_3$ solution in the same manner as its Pd-counterpart **8a** (Figure 6).

In contrast, the bromide **18·Br** exists as a mixture of four main isomers in $CDCl_3$ solution (Table 2) and the isomeric ratio remained unchanged on refluxing a solution of the complex in toluene. The allyl isomers of **18·Br** could be of the cationic $\eta^3$-type (eight possible diastereomers) or the neutral $\eta^1$-type with coordinated bromide (four possible diastereomers), or mixtures thereof. The $J_{Pt,P}$ coupling constants of the **18·Br** isomers were in the range of 4700 to 5100 Hz (Table 2), which is close to the value for the $\eta^3$-allyl complex **18·PF$_6$**, but rather high compared to the value of [$PtBr_2$(**2a**)].[55] The low frequency $^{195}Pt$ NMR chemical shifts of **18·Br** also point towards a cationic $\eta^3$-configuration. However, the most important notion is that the nature

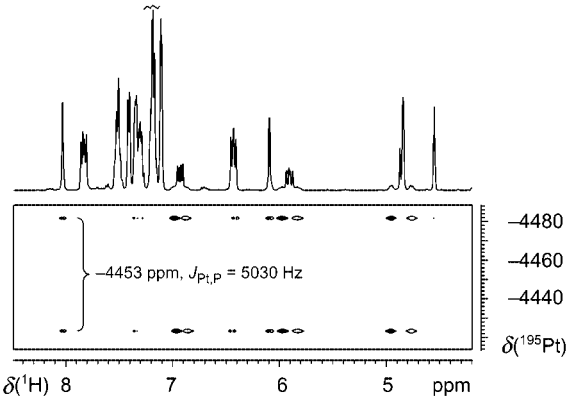

Figure 6. $^{195}$Pt,$^1$H HMQC of **18·PF$_6$** in [D$_8$]THF. The crosspeaks lie below the positions of the $^{195}$Pt satellites in the $^1$H NMR spectrum and are split vertically into a doublet ($J_{Pt,P}$ = 5030 Hz). Intense crosspeaks are observed for allylic protons ($\delta$ = 4.9, 5.9, and 6.9 ppm), whereas weaker coupling is observed with two sets of *ortho*-hydrogen atoms of phenyl groups ($\delta$ = 6.4, 7.4 ppm) and with the pyrazole hydrogen 4-H at 8.0 ppm.

of the anion directly and strongly influences the equilibrium composition of the allyl isomer mixture.

### Solid-State Structures of (1,3-Diphenylallyl)platinum(II) Complexes

Crystals of **18·PF$_6$** were easily obtained and the result of the X-ray structural analysis is shown in Figure 7 (a) along with a structure comparison generated by overlaying the structure of the palladium analog **8a** (Figure 7, b). These complexes are almost perfectly isostructural within differences in bond lengths of less than 2%. The interplane angle between the allyl plane and the coordination plane (defined by P, Pt, N) in these structures is 64.8°, and the rotation of the allyl vector normal plane [approximated by the plane C(27)–Pt/Pd–C(29)] out of the coordination plane is 14°. This numerical value serves as a measure of the asymmetry induced on the allyl fragment by the chiral ligand.[29] The $^{31}$P NMR chemical shifts of **8a** and **18·PF$_6$** also match closely (Table 2). These results justify, once more, the approach of using kinetically more inert platinum complexes as analogs for the corresponding palladium species in mechanistic research. In fact, **18·PF$_6$** is also a catalyst for the allylic alkylation of ethyl 1,3-diphenylallyl carbonate (**1**) with dimethyl malonate, giving the product of allylic alkylation in 74% *ee* in a slow reaction,[56,65] whereas analogous Pd complexes (with ligand **2a**) react much faster to give the alkylation product in 91% *ee*.[55] Asymmetric allylic alkylation of 1,3-diphenylallyl substrates using Pt complexes has been studied in detail by Williams and coworkers.[46]

Another example of a cationic (1,3-diphenylallyl)platinum(II) complex is the DIPHOS derivative **24**, which was also structurally characterized as the *syn-syn* isomer in both the $CD_2Cl_2$ solution and in the solid state (Figure 7, c). The bite angle P–Pt–P in this complex is 86.4° instead of the 94.5° for **18·PF$_6$**. The interplane angle defined by C(1)–C(2)–C(3)/P(1)–Pt–P(2) is 67° in this complex and the rotation of the allyl fragment vector normal plane (approximated by C(1)–Pt–C(3)), out of the idealized perpendicularity to the coordination plane [defined by P(1)–Pt–P(2)], is only 1°, a very low value despite the local chiral $C_2$ symmetry that the DIPHOS ligand adopts in its solid-state conformation.

### Reactions of Cationic Allyl Complexes with Fluoride

In the first series of experiments, one of the complexes **8a**, **8b**, or **8c** and one of the fluoride sources TBAT (**4**), Me$_4$NF (**5**), or Schwesinger's phosphazenium fluoride P$_2$F (**25**)[57] were mixed in deuterated solvents ($CDCl_3$ or [D$_3$]-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

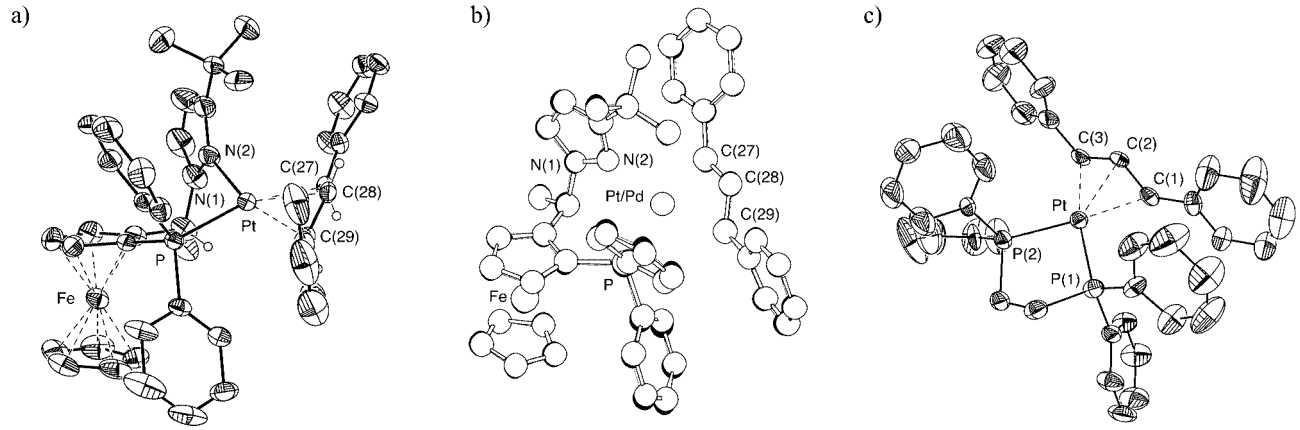

Figure 7. X-ray crystal structures of the cationic 1,3-diphenylallyl complexes **18·PF$_6$**, **8a**, and **24**. (a) ORTEP plot (30% probability ellipsoids) of platinum complex **18·PF$_6$**. The anion and most hydrogens are omitted for clarity. Selected data (bond lengths [Å]; bond angles [°]): Pt–P = 2.265(2), Pt–N(2) = 2.121(5), Pt–C(27) = 2.283(6) =, Pt–C(28) = 2.195(6), Pt–C(29) = 2.113(6); N(2)–Pt–P = 94.5(2). (b) Alignment of ball and stick representations of the complex cations of **8a** (grey filled atoms, below) and **18·PF$_6$** (white filled atoms, on top). The structures of the complexes match closely. Selected data for **8a**: Pd–P = 2.3123(8), Pd–N(2) = 2.159(3), Pd–C(27) = 2.283(3), Pd–C(28) = 2.193(3), Pd–C(29) = 2.137(3); N(2)–Pd–P = 94.49(8). The atom numbering has been adapted here to match that from the structure of **18·PF$_6$**, but is different in the CSD CIF file. (c) ORTEP plot (30% probability ellipsoids) of platinum complex **24**, anion and hydrogen atoms are omitted for clarity. Selected data: Pt–C(1) = 2.233(8), Pt–C(2) = 2.168(7), Pt–C(3) = 2.233(8), Pt–P(1) = 2.258(2), Pt–P(2) = 2.270(2); P(1)–Pt–P(2) = 86.37(8).

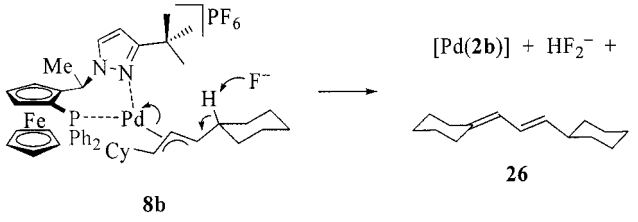
MeCN for **4**, [D$_3$]MeCN for **5**, $C_6D_6$ for **25**) and the samples were then monitored using $^1$H, $^{19}$F, and $^{31}$P NMR spectroscopy over a suitable range of time. If no change was observed at room temperature the samples were warmed to 50 °C. The appearance of peaks arising from allyl fluorides was carefully checked by $^{19}$F NMR spectroscopy (**6**: $\delta\{^{19}F\}$ = –165.4 ppm;[14a] **11**: –175.2 ppm; indenyl fluoride: –201.24 ppm[58]), but these signals were not detected. In experiments with $Me_4NF$ (**5**) and 1,3-diphenylallyl complex **8a**, the main fluorinated species observed was $DF_2^-$, resulting from deprotonation of [D$_3$]MeCN by naked fluoride.[31] A specific reaction pattern was only observed with complex **8b** and the naked fluorides $Me_4NF$ (**5**, in [D$_3$]-MeCN) and $P_2F$ (**25**, in $C_6D_6$), where diene **26**[59] was released in an elimination reaction (Scheme 7). Other reactant combinations resulted in no reaction at all or unspecific decomposition with precipitation of palladium metal on heating.[60]



Scheme 7. Fluoride-mediated elimination of diene **26** from dicyclohexylallyl complex **8b**.

We then turned our attention to the reaction of cationic allylplatinum complex **18·PF$_6$** with naked fluoride $Me_4NF$ (**5**). A suspension of the reactants in toluene was stirred at ambient temperature, which resulted in a slow but clean anion exchange reaction to give a yellow solution of **18·F** and a colorless precipitate of $Me_4NPF_6$. Evaporation of the filtered solution gave **18·F** as an amorphous yellow powder, which was soluble in most organic solvents. The $^{19}$F NMR spectrum of **18·F** in $CDCl_3$ consisted of a broad signal at $\delta$ = –139.8 ppm ($\Delta_{1/2}$ = 15 Hz), a value which is close to that given by Grushin[61] ($\delta$ = –141 ppm, $\Delta_{1/2}$ = 9 Hz) for an in situ generated naked fluoride in $CDCl_3$. In [D$_8$]toluene solution the $^{19}$F NMR peak for fluoride disappeared in background noise that was generated from fluorinated polymers within the NMR probe head. The $^{31}$P NMR spectrum

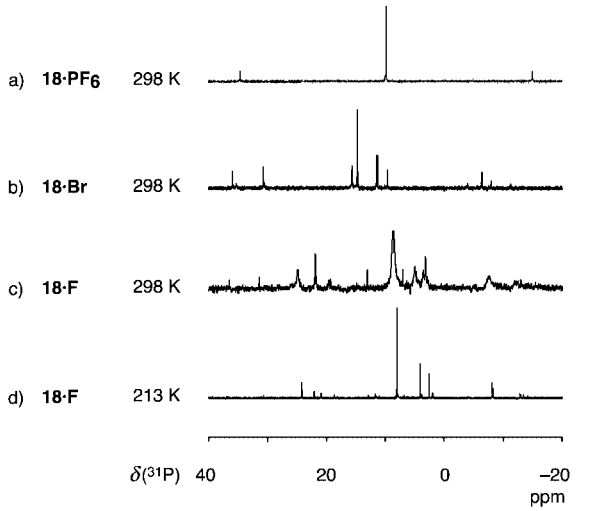


Figure 8. $^{31}$P NMR spectra of **18·PF$_6$**, **18·Br**, and **18·F**. (a) 101.3 MHz, [D$_8$]THF. **18·PF$_6$** is exclusively present as the *exo-syn-syn* isomer. Note the $^{195}$Pt satellites ($J_{Pt,P}$ = 5029 Hz). (b) 121.5 MHz, $CDCl_3$. **18·Br** forms a mixture of four allyl isomers. (c) 121.5 MHz, [D$_8$]toluene. **18·F** forms a mixture of allyl isomers whose lines are broadened due to exchange. (d) As in (c), but at 213 K (–60 °C). The interconversion of allyl isomers of **18·F** is "frozen" at low temperature, resulting in a spectrum similar to that of **18·Br** at room temperature. Splitting due to $J_{P,F}$ is absent.

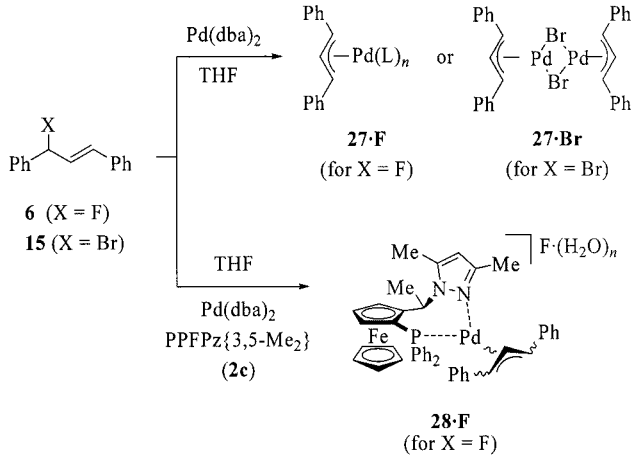
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

consists of one main broad peak and smaller additional signals (Figure 8, c). On cooling to 213 K, the spectrum becomes clearer and a set of at least five lines (each with platinum satellites), corresponding to allyl isomers, appear (see d in Figure 8 and Table 2). Again, no peak was detected by $^{19}F$ NMR spectroscopy, but this should be seen in connection with experimental difficulties (mentioned above) and the low concentration of the sample. The absence of $^{31}P/^{19}F$ couplings (which are so clearly visible for **21**) shows that no inert covalent Pt–F bond is present in **18·F**. When combined these pieces of evidence suggest that **18·F** consists of a mixture of isomeric allyl cations $[Pt(\mathbf{2b})(\eta^3\text{-}Ph_2All)]^+$ in solution, which form lipophilic contact ion pairs with fluoride. The fluoride anions themselves are involved in a fast exchange between the ion pairs. At room temperature there is notable interconversion of configurationally isomeric allyl cations within **18·F** (broad lines in the $^{31}P$ NMR spectrum, Figure 8, c), but slow interconversion among the allyl isomers of **18·Br** (separate, sharp lines in the $^{31}P$ NMR spectrum, Figure 8, b). This important finding directly relates the nature of the counterion of a cationic allyl complex to the kinetics of its allyl isomerization.

### Oxidative Addition of $Pd^0$ with $Ph_2AllF$ (6) and $Ph_2AllBr$ (15)

The failure to observe any allylic substitution products resulting from attack of fluoride on cationic allyl complexes indicates that this reaction is thermodynamically unfavorable.[62] To test this assumption, we investigated whether the reverse reaction, namely the oxidative addition of allyl fluorides to $Pd^0$, would proceed instead. The addition of a solution of **6**[14a] to either $Pd(dba)_2$ or mixtures of $Pd(dba)_2$ and phosphanyl pyrazole (**2c**) (Scheme 8) did, in fact, result in oxidative addition and the formation of $\eta^3$-allylpalladium(II) compounds **27·F** or **28·F**, respectively. Identification of these compounds was based on the characteristic $^1H$ NMR and $^{31}P$ NMR spectra of the cationic units since a well-defined complex did not crystallize from solutions of **27·F**. The properties and spectroscopic data of **28·F** match closely those of the hydrated fluoride salts of cationic palladium complexes investigated earlier in our laboratory.[8] The analogous oxidative addition of 1,3-diphenylallyl bromide (**15**) with $Pd(dba)_2$ gave the $\eta^3$-allyl bromide **27·Br** (Scheme 8).



Scheme 8. The oxidative addition of 1,3-diphenylallyl fluoride and bromide to $Pd^0$ complexes is a spontaneous reaction that leads to products containing the cationic allylpalladium(II) fragment. L = F or solvent molecules.

The $^1H$ NMR spectroscopic data of **27·F** and **27·Br** in DMSO are very similar to those of the known chloro analog **27·Cl**.[44b]

## Discussion

### Fluoride Effects in Asymmetric Allylation Reactions

We have identified two modes in the reaction of "naked" or nucleophilic fluorides with cationic allyl complexes of palladium(II) and platinum(II): Allyl complexes bearing hydrogens α to the allyl group can either undergo base-mediated elimination (see Scheme 7) or a simple anion exchange can take place, which gives cationic allyl complexes as contact ion pairs with fluoride as the counterion. NMR spectroscopic studies of the platinum complexes **18·PF$_6$**, **18·Br**, and **18·F** revealed that the counterion in these ion pairs dramatically influences: (a) the allyl isomer composition at equilibrium; and (b) the kinetics of exchange between these isomers. In the presence of fluoride, allyl isomers interconvert at room temperature (cf. Figure 8, c) whereas this process is slow for the bromide salt (Figure 8, b) and probably even slower for the hexafluorophosphate (Figure 8, a). This evidence, obtained from a platinum model system, supports our earlier proposal of an anion effect in the catalytic asymmetric amination reaction (cf. Scheme 1):[8] Addition of fluoride accelerates the isomerization of allyl isomers and therefore effectively deletes the "memory of chirality"[63] stored within the configuration of the allyl isomers. However, addition of $PF_6^-$ has an inverse effect by slowing down isomerization. This assumption has now been justified by experimental results.

### The Viability of an (Asymmetric) Catalytic Allylic Fluorination

The reaction of cationic allyl complexes of palladium(II) and platinum(II) with naked or nucleophilic fluorides does not produce allyl fluorides. On the contrary, the oxidative addition of allyl fluoride **6** to $Pd^0$ proceeds with ease. This finding is in agreement with calculations by Hagelin et al. who have found that the attack of fluoride on the allylpalladium(II) cation is energetically favorable in the gas phase, but becomes unfavorable in the polar condensed phase because of the solvation of the fluoride anion.[64] Despite this thermodynamically unfavorable step, an overall catalytic allylic fluorination reaction should still be exergonic, as long as energetically high lying (reactive) sources of fluoride are used. Nevertheless, the presence of an energetically low-lying, nonreactive intermediate (such as **18·F**) in the reaction

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pathway presents a severe obstacle for catalysis for kinetic reasons. If possible, alternative pathways will be followed (cf. release of **26** from **8b**, Scheme 7) and $Pd^0$ will eventually precipitate. These factors appear to cause the failure of the desired palladium-catalyzed asymmetric allylic fluorination reaction when it is carried out in analogy to known asymmetric allylic substitutions.

## Conclusion

We have reported the synthesis of new cationic allyl complexes of palladium(II) and platinum(II), among them the previously unknown (1,3-diphenylallyl)platinum(II) complexes. The reactivity of these complexes towards naked and nucleophilic sources of fluoride has been investigated. Stoichiometric allylic fluorination was shown to be thermodynamically unfeasible, and catalytic reactions are probably also unfeasible due to a kinetic barrier in the reaction pathway. It was shown that the counterions of cationic allylplatinum(II) complexes determine both the exchange kinetics between allyl isomers and the isomer composition at equilibrium. This finding has been used to rationalize a "fluoride anion effect" observed earlier in palladium-catalyzed asymmetric allylic amination reactions.

## Experimental Section

**General Remarks:** Syntheses of, and with, sensitive products were performed using Schlenk and glovebox techniques. Naked fluorides were handled exclusively in a glovebox. NMR spectroscopy: $^1$H NMR shifts relative to internal TMS, $^{13}$C NMR shifts relative to TMS, but referenced by solvent signals, notably $\delta(CDCl_3)$ = 77.0 ppm. $^{19}$F NMR shifts relative to external $CFCl_3$, $^{31}$P NMR shifts relative to external $H_3PO_4$ (85%), $^{195}$Pt NMR shifts relative to external $Na_2[PtCl_6]$ (aq). General techniques for NMR structure elucidation were the same as in ref.[29] For additional $^{13}$C NMR and IR data, see ref.[65]

**Abbreviations and Substances:** All = allyl ($C_3H_5$), $Ph_2All$ = 1,3-diphenylallyl etc., CC = column chromatography on $SiO_2$, HV = high vacuum (<0.01 mbar), Ms = methylsulfonyl, Pz = pyrazole, *t*BuOMe = *tert*-butyl methyl ether. The following substances were prepared according to literature procedures: (*R*,$S_P$)-PPFA[27] (recrystallized twice from EtOH to ensure high enantiomeric purity), anhydrous $Me_4NF$ (**4**),[31] TBAT [tetrabutylammonium difluorotriphenylsilicate(II)] (**5**),[30] 3-*tert*-butylpyrazole,[26] $[Pt_2(dba)_3]$,[50] $[Pd_2(dba)_3]\cdot CHCl_3$ or $Pd(dba)_2$,[66] $[\{PdCl(Ph_2All)\}_2]$ (**7a**),[44b] $[\{PdCl(Ind)\}_n]$ (**7c**),[42] 1,3-diphenylallyl bromide (**15**),[47] Karstedt catalyst (**16**).[49b] Schwesinger's phosphazenium fluoride $P_2F$ (**25**)[57] was obtained from Fluka.

**3-*tert*-Butyl-1-{(*R*)-1-[($S_P$)-2-(diphenylphosphanyl)ferrocenyl]ethyl}-1*H*-pyrazole (PPFPz{3-*t*Bu}, 2b):** Degassed HOAc (5 mL), (*R*,*S*)-PPFA (2.047 g, 4.628 mmol) and 3-*tert*-butylpyrazole (862 mg, 6.94 mmol) were stirred for 1 d at 70 °C. After workup with water and extraction with $CH_2Cl_2$, CC (*t*BuOMe/pentane, 1:20, and 3% $NEt_3$) gave 2.022 g (84%) as orange crystals. $[\alpha]_D$ = –281.7 (*c* = 0.88, MeOH). M.p. 130 °C. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 1.06 (s, 9 H, *t*Bu), 1.83 (d, *J* = 6.9 Hz, 3 H, *Me*CH), 3.87 (m, 1 H-Cp), 3.99 (s, 5 H, Cp′), 4.34 (t, *J* = 2.5 Hz, 1 H-Cp), 4.64 (br. s, 1 H-Cp), 5.52 (d, *J* = 2.3 Hz, 4-H, Pz), 5.77 (qd, *J* = 6.9 Hz, 3.2 Hz, 1 H, *H*CMe), 6.67–6.75 (m, 2 H, aryl), 6.82 (d, *J* = 2.3 Hz, 5-H, Pz), 6.92–7.02 (m, 3 H, aryl), 7.28–7.33 (m, 3 H, aryl), 7.49–7.56 (m, 2 H, aryl) ppm. $^{31}$P NMR (101.3 MHz, $CDCl_3$): $\delta$ = –24.5 (s) ppm. MS (EI): *m*/*z* (%) = 520 (100) [$M^+$], 455 (25), 396 (20), 331 (59). $C_{31}H_{33}FeN_2P$ (520.44): calcd. C 71.54, H 6.39, N 5.38; found C 71.60, H 6.47, N 5.33.

**Bis(μ-chloro)-bis(η³-1,3-dicyclohexylallyl)dipalladium(II) (7b):** A suspension of $Pd(dba)_2$ (658.7 mg, 1.146 mmol), **12** (403 mg, 1.266 mmol), and LiCl (1.203 mmol 1.05 equiv.) in THF (15 mL) and MeCN (5 mL) was stirred for 15 min at 30 °C. The greenish reaction mixture was evaporated to dryness, taken up in $CH_2Cl_2$ and filtered through $SiO_2$. Evaporation yielded 385.5 mg (97%) of a light yellow powder. M.p. 174 °C. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 1.02–1.36 (m, 20 H-Cy), 1.53–1.87 (m, 20 H-Cy), 2.02–2.07 (m, 4 H-Cy), 3.62 (dd, *J* = 11.2 Hz, 5.2 Hz, 4 H, 1-H/1′-H, 3-H/3′-H), 5.14 (t, *J* = 11.2 Hz, 2 H, 2-H/2′-H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 26.1 ($CH_2$), 26.2 ($CH_2$), 31.7 ($CH_2$), 32.8 ($CH_2$), 39.5 (CH), 88.2 (CH), 103.43 (CH) ppm. MS (FAB): *m*/*z* (%) = 659 (100) [M – Cl]$^+$. $C_{30}H_{50}Cl_2Pd_2$ (694.47): calcd. C 51.89, H 7.26; found C 51.77, H 7.09.

**Indenylpalladium(II) Chloride (7c):** In our hands, only the method reported by Lin and Boudjouk gave a pure product.[42] Others have made similar observations.[42b] We note that the use of 94% EtOH in the synthesis is important because residual water favors the reaction.

**[Pd(η³-$Ph_2$All)(2b)]$PF_6$ (8a):** $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-}Ph_2All)_2]$ (226.8 mg, 0.338 mmol) was added to **2b** (352.2 mg, 0.677 mmol) in acetone (40 mL) and the mixture was stirred until dissolution occurred (3 min). $TlPF_6$ (236.4 mg, 0.677 mmol) was added and the resulting suspension stirred for 1 h. Filtration through Celite, evaporation to dryness, and precipitation from $CH_2Cl_2$/pentane gave 570.4 mg (87%) of an orange powder. $[\alpha]_D$ = –278 (*c* = 0.50, $CHCl_3$). M.p. dec. from 190 °C. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 0.48 (s, 9 H, *t*Bu), 2.35 (d, *J* = 6.9 Hz, 3 H, *Me*CH), 3.90 (s, 5 H, Cp′), 3.97–4.01 (m, 1 H-Cp), 4.41 (t, *J* = 2.6 Hz, 1 H-Cp), 4.54–4.58 (m, 1 H-Cp), 5.25 (d, *J* = 10.0 Hz, allyl H, *anti*, *trans* N), 5.91 (d, *J* = 2.7 Hz, 4-H, Pz), 6.21 (dd, *J* = 14.1 Hz, 9.9 Hz, allyl H, *central*), 6.08–6.16 (m, 2 H, aryl), 7.01–7.32 (m, 15 H, 13 H, aryl + allyl H, *anti*, *trans* P + C*H*Me), 7.45–7.55 (m, 3 H, aryl), 7.58 (d, *J* = 2.7 Hz, 5-H, Pz), 7.70–7.89 (m, 2 H, aryl) ppm. $^{13}$C NMR (62.9 MHz, $CDCl_3$): $\delta$ = 18.4 ($CH_3$), 29.6 ($CH_3$), 31.8 (C), 58.4 (d, $J_{P,C}$ = 5 Hz, CH, *C*HMe), 66.0 (d, $J_{P,C}$ = 3 Hz, CH, Cp), 66.1 (d, $J_{P,C}$ = 1 Hz, allyl CH, *trans* N), 70.6 (d, $J_{P,C}$ = 6 Hz, Cp-CH), 71.3 (CH, Cp′), 73.0 (CH, Cp), 74.9 [d, $J_{P,C}$ = 42 Hz, C(1)-Cp], 93.8 [d, $J_{P,C}$ = 20, C(2)-Cp], 107.1 [CH, C(4) Pz], 107.1 (d, $J_{P,C}$ = 19 Hz, allyl CH, *trans* P), 112.4 (d, $J_{P,C}$ = 4 Hz, allyl CH, *central*), 127.3 (d, $J_{P,C}$ = 2 Hz, CH), 127.9 (d, $J_{P,C}$ = 3, CH), 128.1 (d, $J_{P,C}$ = 9 Hz, CH), 128.3–129.4 (several CH), 130.7 (d, $J_{P,C}$ = 48 Hz, C), 130.9 (d, $J_{P,C}$ = 2 Hz, CH), 131.4 (d, $J_{P,C}$ = 11 Hz, CH), 133.1 (d, $J_{P,C}$ = 44 Hz, C), 134.3 (d, $J_{P,C}$ = 14 Hz, CH), 135.4 (d, $J_{P,C}$ = 5 Hz, C), 138.9 (d, $J_{P,C}$ = 3 Hz, C), 162.7 [C, C(3) Pz] ppm. $^{31}$P NMR (101.3 MHz, $CDCl_3$): $\delta$ = –142 (sept, $J_{PF}$ = 695 Hz, $PF_6^-$), 10.5 (s) ppm. IR (KBr): $\tilde{\nu}$ = 842 (s), 696 (m), 558 (m) cm$^{-1}$. MS (FAB): *m*/*z* (%) = 1783 (3) [2 M – $PF_6$]$^+$, 819 (100) [M – $PF_6$]$^+$, 625 (12) [M – $PF_6$ – $Ph_2All$]$^+$. $C_{46}H_{46}F_6FeN_2P_2Pd$ (965.07): calcd. C 57.25, H 4.80, N 2.90; found C 57.08, H 4.95, N 2.94.

**[Pd(η³-$Cy_2$All)(2b)]$PF_6$ (8b): 7b** (179.5 mg, 0.258 mmol) was added to a solution of **2b** (269.1 mg, 0.517 mmol) in acetone (35 mL) and the mixture was stirred until dissolution was complete (15 min). After addition of $TlPF_6$ (180.6 mg, 0.517 mmol) and stirring for 1.5 h, the suspension was filtered through Celite and the filtrate evaporated to dryness. Precipitation from $CH_2Cl_2$/pentane gave

MS (FAB): *m*/*z* (%) = 741.3 (100) $[M - SbF_6]^+$, 626.2 (33) $[M - Ind - SbF_6]^+$. $C_{40}H_{40}F_6N_2PFePdSb$ (977.74): calcd. C 49.14, H 4.12, N 2.87; found C 48.84, H 4.17, N 2.80.

**(*E*)-1,3-Dicyclohexylprop-2-en-1-ol (10): (a) (*E*)-1,3-Dicyclohexylpropenone:** Acetylcyclohexane (**9**) (6.9 mL, 50 mmol) was slowly dropped into a stirred solution of LDA (31 mL, 2 M in hexanes, 62 mmol) in THF (80 mL) at –78 °C. After 1 h, CyCHO (6.9 mL, 57.1 mmol) was slowly added and the reaction mixture stirred for 4 h at –78 °C. MsCl (9.7 mL, 125 mmol) was added dropwise. After 1 h the reaction mixture was warmed to room temp., quenched with sat. $NaHCO_3$ solution (50 mL) and extracted with *t*BuOMe. The organic phases were dried ($Na_2SO_4$) and the solvents evaporated. DBU (12.4 mL, 83.3 mmol) was added dropwise at 0 °C to the residue in acetone (100 mL). After 1 h stirring, workup ($NH_4Cl$ sat/*t*BuOMe) gave an oil which was purified by CC (*t*BuOMe/hexanes, 1:20) to give 7.707 g (70%) of a colorless liquid. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 1.08–1.82 (m, 20 H-Cy), 2.08–2.19 (m, 1 H-Cy), 2.50–2.60 (m, 1 H-Cy), 6.10 (dd, $J$ = 15.9 Hz, 1.4 Hz, 2-H), 6.80 (dd, $J$ = 15.9 Hz, 6.8 Hz, 3-H) ppm. $^{13}$C NMR (62.9 MHz, $CDCl_3$): $\delta$ = 25.7 ($CH_2$), 25.7 ($CH_2$), 25.9 ($CH_2$), 25.9 ($CH_2$), 28.7 ($CH_2$), 31.8 ($CH_2$), 40.6 (CH), 48.6 (CH), 126.0 [CH, C(3)], 151.9 [CH, C(2)], 203.9 [C(1)] ppm. MS (CI): *m*/*z* (%) = 221 (100) $[M + H]^+$, 165 (3), 137 (61) $[C_9H_{13}O]^+$, 83 (11), $[C_6H_{11}]^+$, 55 (15). IR ($CHCl_3$): $\tilde{\nu}$ = 1684 (m, C=O), 1655 (m), 1620 (m, C=C) cm$^{-1}$. $C_{15}H_{24}O$ (220.35): calcd. C 81.76, H 10.98; found C 82.02, H 11.03.

**(b) (*E*)-1,3-Dicyclohexyl-2-propen-1-ol (10):** $NaBH_4$ (167 mg, 4.41 mmol) was added to a solution of 1,3-dicyclohexylpropenone (973 mg, 4.41 mmol) and $CeCl_3 \cdot 7H_2O$ (1646 mg, 4.41 mmol) in MeOH (12 mL) at room temp. The mixture was stirred for 10 min and worked up with aq. HCl (2.5 M, 3 mL), $H_2O$ and *t*BuOMe. Purification by CC (*t*BuOMe/hexanes, 1:10) gave 758 mg (77%) of a colorless liquid. $^1$H NMR ($CDCl_3$): $\delta$ = 0.85–1.42 (m, 11 H-Cy), 1.45 (d, $J$ = 3.0 Hz, OH), 1.63–1.74 (m, 9 H-Cy), 2.01–1.81 (m, 2 H-Cy), 3.75 (ddd, $J$ = 6.9 Hz, 6.9 Hz, 3.1 Hz, 3-H), 5.39 (ddd, $J$ = 15.5 Hz, 7.2 Hz, 0.9 Hz, 2-H), 5.56 (dd, $J$ = 15.5 Hz, 6.5 Hz, 1-H) ppm. Known compound, CAS number 79605-63-3.

**(*E*)-1,3-Dicyclohexylallyl Fluoride (11):** DAST (101.8 mg, 0.63 mmol) was added at –78 °C to a solution of **10** (126.6 mg, 0.569 mmol) in $CH_2Cl_2$ (11 mL) while stirring. The temperature was raised to 0 °C and the mixture stirred for another 10 min. Quenching with aq. $NaHCO_3$ (10 mL), followed by extraction with three portions of *t*BuOMe (20 mL) gave, after drying ($MgSO_4$) and evaporation, 130 mg (quant.) of a yellowish oil. Kugelrohr distillation (90 °C/0.01 mbar) gave a colorless oil. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 0.9–2.1 (m, 22 H-Cy), 4.49 (dt, $J$ = 48.6 Hz, 7.2 Hz, 1-H), 5.44 (dddd, $J$ = 15.6 Hz, 9.8 Hz, 7.6 Hz, 1.3 Hz, 2-H), 5.67 (ddd, $J$ = 15.6 Hz, 6.4 Hz, 4.6 Hz, 3-H) ppm. $^{13}$C NMR (62.9 MHz, $CDCl_3$): $\delta$ = 25.7 ($CH_2$), 25.9 ($CH_2$), 25.9 ($CH_2$), 26.1 ($CH_2$), 26.4 ($CH_2$), 28.1 (d, $J_{F,C}$ = 5, $CH_2$), 28.2 (d, $J_{F,C}$ = 5 Hz, $CH_2$), 32.5 (d, $J_{F,C}$ = 2 Hz, $CH_2$), 32.7 (d, $J_{F,C}$ = 2 Hz, $CH_2$), 40.3 (CH), 42.5 (d, $J_{F,C}$ = 22 Hz, CH), 98.5 [d, $J_{F,C}$ = 164 Hz, CH, C(1)], 124.5 [d, $J_{F,C}$ = 20 Hz, CH, C(2)], 141.8 [d, $J_{F,C}$ = 12 Hz, CH, C(3)] ppm. $^{19}$F NMR (282.4 MHz, $CDCl_3$): $\delta$ = –175.2 (dddt, $J_{F,H} \approx$ 48.5 Hz, 13.9 Hz, 9.8 Hz, 5 Hz) ppm.

**(*E*)-1,3-Dicyclohexylallyl Trifluoroacetate (12):** TFAA (0.634 mL, 4.56 mmol) was slowly added to **10** (506.8 mg, 2.28 mmol) in pyridine (8.6 mL) at 0 °C and the reaction mixture stirred for 1 h. Workup with *t*BuOMe and washing of the organic phase (aq. HCl, aq. sat. $NaHCO_3$, $H_2O$) gave, after drying ($Na_2SO_4$) and evaporation, 680 mg (93%) of a colorless liquid. An analytical sample was

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

purified by Kugelrohr distillation (90 °C/0.005 mbar). The substance decomposed within a few days at room temp. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 0.92–1.31 (m, 10 H-Cy). 1.60–1.77 (m, 10 H-Cy), 1.92–2.04 (m, 2 H-Cy), 5.10 (dd, $J$ = 8.1 Hz, 7.2 Hz, 1-H), 5.34 (ddd, $J$ = 15.5 Hz, 8.4 Hz, 1.3 Hz, 2-H), 7.75 (dd, $J$ = 15.5 Hz, 6.6 Hz, 3-H) ppm. $^{13}$C NMR (62.9 MHz, $CDCl_3$): $\delta$ = 25.6 ($CH_2$), 25.7 ($CH_2$), 25.8 ($CH_2$), 26.0 ($CH_2$), 26.2 ($CH_2$), 28.4 ($CH_2$), 32.4 ($CH_2$), 40.3 (CH), 41.3 (CH), 84.7 (CH), 122.1 (CH), 143.8 (CH) ppm. IR ($CHCl_3$): $\tilde{\nu}$ = 1777 (s), 1450 (s), 1272 (s) cm$^{-1}$. $C_{17}H_{25}F_3O_2$ (318.38): calcd. C 64.13, H 7.91; found C 63.94, H 8.07.

**Bis(μ-trifluoroacetato)-bis(η³-1,3-dicyclohexylallyl)dipalladium(II) (13):** A suspension of $Pd(dba)_2$ (756 mg, 1.32 mmol) and **12** (461 mg, 1.45 mmol) in THF (12 mL) and MeCN (3 mL) was stirred for 1 h at room temp. , followed by 10 min at 40 °C. The resulting solution was evaporated to dryness and repeatedly extracted with MeCN/$H_2O$ (70:30). The extract was evaporated to a yellow powder, which was purified by precipitation from $Et_2O$/pentane to give 520 mg (93%) of yellow crystals. M.p. 82 °C (dec.). $^1$H NMR (250 MHz, $C_6D_6$ + 10% [$D_3$]MeCN): $\delta$ = 1.00–1.98 (m, 44 H-Cy), 3.43 (dd, $J$ = 11.6 Hz, 4.9 Hz, 4 H, 1-H, 1′-H, 3-H, 3′-H), 5.10 (t, $J$ = 11.6 Hz, 2 H, 2-H, 2′-H) ppm. VT NMR: see Scheme 5 and Table 1. $^{13}$C NMR (75.5 MHz, $CDCl_3$/[$D_3$]MeCN 3:1): $\delta$ = 25.5 ($CH_2$), 25.6 ($CH_2$), 25.6 ($CH_2$), 31.6 ($CH_2$), 32.0 ($CH_2$), 39.1 (CH), 88.2 (br., CH), 106.5 (br., CH) ppm. MS (FAB): *m/z* (%) = 1084 (9), 737 (47) [M – $OCOCF_3$]$^+$, 311 (100) [Pd($Cy_2$All)]$^+$. $C_{34}H_{50}F_6O_4Pd$ (849.60): calcd. C 48.99, H 6.05; found C 48.09, H 5.92.

**Di-μ-bromo-bis(η³-1,3-diphenylallyl)diplatinum(II) (17):** (a) A Karstedt complex solution (corresponding to 4 mmol of Pt) was added dropwise to a solution of **15** (1.37 g, 5.0 mmol) in *t*BuOMe (30 mL) at 0 °C while stirring. A vanilla-yellow powder precipitated. After stirring for 2 h at 0 °C, filtration and washing with MeOH, a fine, bright yellow powder (1.440 g, 77%) was obtained that was hardly soluble in any solvents, except for DMSO and pyridine. (b) A suspension of $Pt_2(dba)_3$ (109 mg, 0.1 mmol) and **15** (58 mg, 0.21 mmol) in acetone (2 mL) and THF (2 mL) was stirred for 1 d at room temp. The reaction mixture was evaporated to dryness and the solid was suspended in MeOH (2 mL) and filtered. Washing with MeOH and acetone gave 66 mg (70%) of a greyish yellow powder. The discoloration was caused by finely divided $Pt^0$ already present in $Pt_2(dba)_3$. M.p. 159 °C (dec.). $^1$H NMR (250 MHz, [$D_6$]-DMSO): $\delta$ = 4.46 (d, $J$ = 11.0 Hz, $J_{Pt,H} \approx$ 56 Hz, 4 H, 1-H, 3-H), 6.05 (t, $J$ = 11.0 Hz, $J_{Pt,H} \approx$ 76 Hz, 2 H, 2-H), 7.10–7.70 (m, 20 H, aryl) ppm. $^{13}$C NMR (62.9 MHz, [$D_6$]DMSO): $\delta$ = 74.6 (br.), 104.7, 130.7, 131.3, 131.8, 141.4 ppm. IR (KBr): $\tilde{\nu}$ = 755 (s), 698 (s) cm$^{-1}$. $C_{30}H_{26}Br_2Pt_2$ (936.50): calcd. C 38.48, H 2.80; found C 38.54, H 2.89.

**[Pt(η³-$Ph_2$All)(2b)]$PF_6$ (18·$PF_6$):** Ligand **2b** (515 mg, 0.99 mmol) and **17** (463 mg, 0.494 mmol) were stirred in acetone (10 mL) until they had completely dissolved. Epichlorohydrine (1.0 mL, 12.8 mmol) and $HPF_6$ (1 M, 1.1 mL, 1.1 mmol, freshly prepared from 75% aq. $HPF_6$ and EtOH) were added, and the mixture stirred for 20 min and then evaporated to dryness. The residue was thoroughly dried under HV, washed with *t*BuOMe and then dissolved in $CH_2Cl_2$ (5 mL) and the solution filtered through a cotton plug into MeOH (10 mL). On standing in the fridge (4 °C), dark orange crystals formed (763 mg, 73%). $^1$H NMR (400 MHz, [$D_8$]-THF): $\delta$ = 0.51 (s, 9 H, *t*Bu), 2.37 (d, $J$ = 6.9 Hz, 3 H, *Me*CH), 3.94 (s, 5 H, Cp′), 4.05–4.08 (m, 1 H-Cp), 4.51 (t, $J$ = 2.3 Hz, 1 H-Cp), 4.79–4.80 (m, 1 Cp-H), 4.81 (d, $J$ = 9.2 Hz, $J_{Pt,H}$ = 77 Hz, allyl H, *anti*, *trans* N), 5.86 (ddd, $J$ = 13.9 Hz, 9.1 Hz, 2.1 Hz, $J_{Pt,H}$ = 56, allyl H, *central*), 6.05 (d, $J$ = 2.9 Hz, $J_{Pt,H} \approx$ 11 Hz, 4-H, Pz), 6.35–6.43 (m, 2 H, aryl), 6.89 (dd, $J$ = 13.8 Hz, 7.0 Hz, $J_{Pt,H}$ = 49 Hz, allyl H, *anti*, *trans* P), 7.04–7.08 (m, 3 H, aryl), 7.10–7.18 (5 H, aryl), 7.22–7.32 (m, 3 H, aryl), 7.25 (q, $J$ = 6.9 Hz, C*H*Me), 7.34–7.39 (m, 2 H, aryl), 7.42–7.50 (m, 3 H, aryl), 7.75–7.82 (m, 2 H, aryl), 7.98 (d, $J$ = 2.9 Hz, 5-H, Pz) ppm. $^{13}$C NMR (62.9 MHz, [$D_8$]THF): $\delta$ = 18.2 ($CH_3$), 30.8 (s, $J_{Pt,C}$ = 7 Hz, $CH_3$), 33.1 (C), 51.4 (s, $J_{Pt,C}$ = 318 Hz, allyl CH, *trans* N), 59.5 (d, $J_{P,C}$ = 3 Hz, *C*HMe), 67.9 [d, $J_{P,C}$ = 7 Hz, CH, C(3) Cp], 71.9 [d, $J_{P,C}$ = 7 Hz, CH, C(4) Cp], 72.3 (CH, Cp′), 74.4 [d, $J_{P,C}$ = 3 Hz, $J_{Pt,C}$ = 40 Hz, CH, C(5′) Cp], 75.4 (d, $J_{P,C}$ = 58 Hz, C), 94.8 (d, $J_{P,C}$ = 17 Hz, C), 100.7 (d, $J_{P,C}$ = 19 Hz, CH, All *trans* P), 108.9 [s, $J_{Pt,C}$ = 34 Hz, CH, C(4) Pz], 109.8 (s, $J_{Pt,C}$ = 33 Hz, allyl CH, *central*), 127.2 (CH), 128.8 (CH), 129.1 (d, $J_{P,C}$ = 10 Hz, CH) 129.1 (d, $J_{P,C}$ = 2 Hz, CH), 129.3 (CH), 129.4 (d, $J_{P,C}$ = 1 Hz, CH), 129.5 (d, $J_{P,C}$ = 1 Hz, CH), 129.6 (d, $J_{P,C}$ = 1 Hz, CH), 130.9 (CH), 130.9 [CH, C(5) Pz], 131.1 (d, $J_{P,C}$ = 65 Hz, C), 131.8 (d, $J_{P,C}$ = 3 Hz, CH), 132.9 (d, $J_{P,C}$ = 10 Hz, CH, *ortho*-PPh axial), 134.2 (d, $J_{P,C}$ = 57 Hz, C), 135.4 (d, $J_{P,C}$ = 13 Hz, CH, *ortho*-PPh equatorial), 136.8 (d, $J_{P,C}$ = 4 Hz, C), 142.0 (d, $J_{P,C}$ = 1 Hz, C), 163.2 [C, C(3) Pz] ppm. $^{31}$P NMR (161.9 MHz, [$D_8$]THF): $\delta$ = –142.7 (sept, $J_{PF}$ = 714 Hz, $PF_6^-$), 10.4 (s, $J_{Pt,P}$ = 5029 Hz), 9.2 (s, minor isomer, <2%). $^{195}$Pt NMR (86.0 MHz, HMQC, [$D_8$]THF): $\delta$ = –4453 (d, $J_{Pt,P}$ = 5030 Hz) ppm. $C_{46}H_{46}F_6FeN_2P_2Pt$ (1053.75): calcd. C 52.43, H 4.40, N 2.66; found C 52.38, H 4.44, N 2.63.

**[Pt(η³-$Ph_2$All)(2b)]Br (18·Br):** A combination of **2b** (30 mg, 58 mmol) and **17** (27 mg, 29 mmol) in THF (2 mL), followed by filtration and evaporation gave a yellow residue. Crystallization from $CH_2Cl_2$/pentane at 5 °C (over layering) produced fine yellow needles (43.5 mg, 76%). Additional material was crystallized from the mother liquors (12 mg, total 97%). M.p. 141–147 °C. $^{31}$P NMR (101.3 MHz, $CDCl_3$) and $^{195}$Pt NMR (HMQC, 64.3 MHz, $CDCl_3$): see Table 2. MS (FAB): *m/z* (%) = 908.4 (73) [M – Br]$^+$, 715.3 (100) [M – Br – $Ph_2$All]$^+$. $C_{46}H_{46}BrFeN_2PPt$ (988.69): calcd. C 55.88, H 4.69, N 2.83; found C 55.99, H 4.74, N 2.75.

**[Pt(η³-$Ph_2$All)(2b)]F (18·F):** (a) $Me_4NF$ (17 mg, 0.18 mmol) was added to a solution of **18·$PF_6$** (128 mg, 0.12 mmol) in THF (1 mL) and the resulting suspension stirred at room temp. Samples of the supernatant solution were taken and $C_6D_6$ was added for locking purposes, and the NMR spectra recorded. After 1 d, some $PF_6^-$ remained in the solution ($^{19}$F NMR, $^{31}$P NMR), but after 2 d such signals had disappeared. The reaction mixture was filtered and the filtrate evaporated under HV. A yellow solid remained which was soluble in benzene. $^{19}$F NMR (282.4 MHz, $CDCl_3$): $\delta$ = –139.8 (br. s, $\Delta_{1/2}$ = 15 Hz, $F^-$) ppm. $^{31}$P NMR (121.5 MHz, $CDCl_3$): $\delta$ = 2.2 (s, $J_{Pt,P}$ = 3903 Hz), 3.5 (s, $J_{Pt,P}$ = 4094 Hz), 7.0 (br. s, $J_{Pt,P}$ = 3947 Hz) ppm.

(b) Reaction in toluene: **18·$PF_6$** (115 mg) and $Me_4NF$ (15 mg) were stirred for 2 d in [$D_8$]toluene (3 mL). The sample was filtered into a J. Young NMR tube. $^{19}$F NMR (282 MHz, [$D_8$]toluene, 298 K): $\delta$ = –116 (br. s) ppm. Note that the signal is within a region of heavy artifacts (due to fluoropolymers within the NMR probe head). $^{31}$P NMR (121.5 MHz, [$D_8$]toluene, 298 K): $\delta$ = 2.4 (s, $J_{Pt,P}$ = 3908 Hz), 4.1 (br. s, $J_{Pt,P}$ = 4070 Hz), 7.8 (br. s, $J_{Pt,P}$ = 3938 Hz) ppm. VT $^{31}$P NMR (121.5 MHz, [$D_8$]toluene, 213 K): see Table 2.

**[$PtCl_2$(2b)] (19):** Bis(styrene)platinum(II) chloride (0.475 g, 1.00 mmol) and **2b** (0.5377 g, 1.03 mmol) were stirred in $CH_2Cl_2$ (10 mL) for 1 d at 40 °C. Filtration through Celite, evaporation to 2 mL and addition of pentane gave an orange precipitate. This was dissolved in a little $CH_2Cl_2$ and over layered with EtOAc. Slow evaporation in the fume hood gave orange-red crystals containing

the solvent of crystallization. Yield as $[PtCl_2(\mathbf{2b})]\cdot 0.35\ CH_2Cl_2\cdot 0.25$ AcOEt: 0.716 g (87%). An analytical sample was dried to remove solvents of crystallization. M.p. 215 °C (dec.). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 1.18 (s, 9 H, *t*Bu), 2.12 (d, $J$ = 7.2 Hz, 3 H, CH*Me*), 3.75–3.79 (m, 1 H-Cp), 4.16 (s, 5 H, Cp′), 4.41 (t, $J$ = 2.5 Hz, 1 H-Cp), 4.74–4.79 (m, 1 H-Cp), 6.05 (d, $J$ = 2.9 Hz, 4-H, Pz), 6.68–6.78 (m, 2 H, aryl), 7.14–7.23 (dt, $J$ = 8 Hz, 3 Hz, 2 H, aryl), 7.29–7.36 (m, 1 H, aryl), 7.42–7.58 (m, 3 H, aryl), 7.52 (d, $J$ = 2.9 Hz, 5-H, Pz), 8.08 (q, $J$ = 7.2 Hz, C*H*Me), 8.11–8.20 (m, 2 H, aryl) ppm. $^{13}$C NMR (62.9 MHz, $CDCl_3$): $\delta$ = 17.3 ($CH_3$, CH*Me*), 31.3 ($CH_3$, *t*Bu), 33.3 (C, *t*Bu), 57.5 (CH, *C*HMe), 68.0 (d, $J_{P,C}$ = 8 Hz, CH, Cp), 70.7 (d, $J_{P,C}$ = 7 Hz, CH, Cp), 71.1 [d, $J_{P,C}$ = 67 Hz, C, C(1)-Cp], 71.3 (CH, Cp′), 73.8 (d, $J_{P,C}$ = 4 Hz, CH, Cp), 92.4 [d, $J_{P,C}$ = 15 Hz, C, C(2)-Cp], 107.8 [CH, C(4)-Pz], 127.4 (d, $J_{P,C}$ = 11 Hz, CH), 127.5 (d, $J_{P,C}$ = 68 Hz, C), 127.6 [CH, C(5)-Pz], 128.3 (d, $J_{P,C}$ = 10 Hz, CH), 130.1 (d, $J_{P,C}$ = 3 Hz, CH), 131.3 (d, $J_{P,C}$ = 3 Hz, CH), 131.6 (d, $J_{P,C}$ = 10 Hz, CH), 132.7 (d, $J_{P,C}$ = 61 Hz, C), 135.7 (d, $J_{P,C}$ = 10 Hz, CH), 162.7 [C, C(3)-Pz] ppm. $^{31}$P NMR (125.5 MHz, $CDCl_3$): $\delta$ = –16.1 (s, $J_{Pt,P}$ = 3783 Hz) ppm. $^{195}$Pt NMR (HMQC, 64.525 MHz, $CDCl_3$): $\delta$ = –3700 (d, $J_{Pt,P}$ = 3790 Hz) ppm. MS (FAB): *m*/*z* (%) = 1537 (50) [2 M – Cl]$^+$, 786 (27) M$^+$, 750 (92) [M – Cl]$^+$, 714 (100) [M – 2 Cl]$^+$, 630 (74). $C_{31}H_{33}Cl_2FeN_2PPt$ (786.42): calcd. C 47.35, H 4.23, N 3.56; found C 47.43, H 4.45, N 3.61.

**[PtPh$_2$(2b)] (20):** (a) Complex **19** (100 mg, 0.127 mmol) was added to a 10–20 fold excess of PhMgBr in THF (ca. 2 mL) and stirred for 1 d at 50 °C. Quenching with aq. $NH_4Cl$ and extraction with *t*BuOMe, followed by drying of the organic phase ($MgSO_4$) and evaporation gave a yellow semisolid. This was crystallized from heptane/$CH_2Cl_2$ by slow evaporation at 4 °C to give orange-yellow crystals (81 mg, 73%).

(b) An aged solution of PhMgBr (2 mL, 2 M, 4 mmol) was added dropwise to **19** (0.21 mmol) in THF (7 mL). After stirring for 1 d at 50 °C the reaction was quenched with water and extracted with *t*BuOMe. Drying over $MgSO_4$ and evaporation gave an orange oil that was filtered through $SiO_2$ using *t*BuOMe/hexane (1:10). The yellow fractions were collected and the solvents evaporated. Heptane (3 mL) was added to the residue and enough $CH_2Cl_2$ to dissolve all solids. Diffusion against heptane at –20 °C gave 160 mg (79%) of orange crystals of the phenol adduct (**20·PhOH**, $M_r$ = 963.82). The PhOH was apparently an impurity arising from the Grignard reagent used. Analytical data for the solvate-free compound: M.p. 185–189 °C (dec.). $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 0.66 (s, 9 H, *t*Bu), 2.21 (d, $J$ = 7.3 Hz, 3 H, *Me*CH), 3.66–3.71 (m, 1 H-Cp), 3.97 (s, 5 H, Cp′), 4.30 (t, $J$ = 2.6 Hz, 1 H-Cp), 4.66–4.71 (m, 1 H-Cp), 5.95 (d, $J$ = 2.7 Hz, 4-H,Pz), 6.49–6.59 (m, 2 H, aryl), 6.69–7.38 (m, 16 H, aryl), 7.49 (d, $J$ = 2.7 Hz, 5-H, Pz), 7.52–7.91 (br. m, 2 H, aryl), 8.82 (q, $J$ = 7.2 Hz, C*H*Me) ppm. $^{13}$C NMR (62.9 MHz, $CDCl_3$): $\delta$ = 18.4 ($CH_3$), 30.2 ($CH_3$), 31.9 (C), 56.8 (d, $J_{P,C}$ = 1 Hz, $CH_3$), 67.3 (d, $J_{P,C}$ = 6 Hz, CH), 70.3 (d, $J_{P,C}$ = 4 Hz, CH), 70.4 (CH, Cp′), 73.6 (CH), 74.9 (d, $J_{P,C}$ = 42 Hz, C, Cp), 93.5 (d, $J_{P,C}$ = 18 Hz, C, Cp), 106.0 (CH), 120.9 (d, $J_{P,C}$ = 1.5 Hz), 122.0 (d, $J_{P,C}$ = 1.0 Hz), 125.8 (CH), 126.2 (d, $J_{P,C}$ = 7 Hz, CH), 127.0 (d, $J_{P,C}$ = 9 Hz, CH), 127.5 (d, $J_{P,C}$ = 9 Hz, CH), 128.0 (d, $J_{P,C}$ = 2 Hz, CH), 128.5 (CH), 129.2 (d, $J_{P,C}$ = 56 Hz, C), 129.5 (d, $J_{P,C}$ = 2 Hz, CH), 131.3 (d, $J_{P,C}$ = 10 Hz, CH), 131.6 (d, $J_{P,C}$ = 44 Hz, C), 135.9 (d, $J_{P,C}$ = 10 Hz, CH), 137.7 ($J_{Pt,C}$ = 38 Hz), 138.7 (C), 138.9 (br.), 139.3 (C), 139.5 (br.), 143.0, 143.2, 144.6, 158.9, 160.8 ppm. Some of the signals were not detected due to line broadening, which arose from hindered rotation of the phenyl groups. $^{31}$P NMR (101.3 MHz, $CDCl_3$): $\delta$ = 5.3 (s, $J_{Pt,P}$ = 1688 Hz) ppm. MS (FAB): *m*/*z* (%) = 1584.8 (14) [2 M – 2 Ph]$^+$, 868.4 (5) [M]$^+$, 791.3 (12) [M – Ph]$^+$, 715.3 (100) [M – 2 Ph]$^+$. $C_{43}H_{43}FeN_2PPt$ (869.73): calcd. C 59.38, H 4.98, N 3.22; found C 59.38, H 5.05, N 3.21.

**[Pt(Ph)F(2b)] (21):** In an NMR tube, **20** (10 mg) in $CDCl_3$ (0.5 mL) was mixed with 2 drops of $NEt_3\cdot(HF)_3$. NMR analysis revealed two species (ratio 1.4:1) with similar $^1$H NMR spectra. The major species was the fluoro complex and the minor species remains unknown. No attempt was made to isolate the compounds. $^1$H NMR (300 MHz, $CDCl_3$), selected signal: $\delta$ = 7.36 (s, 6 H, benzene) ppm. $^{19}$F NMR (282.4 MHz, $CDCl_3$): $\delta$ = –214.6 (d, $J_{P,F}$ = 207 Hz, $J_{Pt,F}$ = 210 Hz), –129.7 (br. s, $Et_3NH^+/F^-$, excess reagent), –165.0 (br. s, $HF/HF_2^-$) ppm. $^{31}$P NMR (121.5 MHz, $CDCl_3$): $\delta$ = –9.6 (s, $J_{Pt,P}$ = 5107 Hz), –11.8 (d, $J_{PF}$ = 207, $J_{Pt,P}$ = 5104 Hz) ppm.

**[Pt($\eta^3$-All)(2b)]SbF$_6$ (22):** $[\{PtCl(C_3H_5)\}_4]$[67] (103 mg, 0.095 mmol) and **2b** (203 mg, 0.39 mmol) were stirred in acetone (3 mL) and $CH_2Cl_2$ (3 mL) until a homogeneous solution was obtained. $AgSbF_6$ (135 mg, 0.39 mmol) was added and the resulting suspension stirred for 30 min. After filtration through Celite and evaporation, the residue was purified by precipitation from acetone/hexane to give 284 mg (71%) of orange crystals containing 0.5 equiv. acetone. $^{31}$P NMR (81.0 MHz, $CDCl_3$): $\delta$ = 12.5 (s, $J_{Pt,P}$ = 4413 Hz, *exo* isomer), 12.6 (s, *endo* isomer) ppm. MS (FAB): *m*/*z* (%) = 1276.8 (16) [2 M – $PF_6$]$^+$, 756.4 (100) [M – $PF_6$]$^+$, 715.4 (25), [M – $PF_6$ – $C_3H_5$]$^+$. $C_{34}H_{38}F_6FeN_2PPtSb\cdot 0.5\,C_3H_6O$ (1021.36): calcd. C 41.75, H 4.05, N 2.74; found C 41.83, H 4.00, N 2.83.

**[Pt($\eta^3$-2-MeAll)(2b)]PF$_6$ (23):** Ligand **2b** (193 mg, 0.37 mmol) and $[Pt_2(\mu\text{-}Cl)_2(2\text{-}MeAll)_2]$[68] (98.6 mg, 0.17 mmol) were stirred at room temp. for 2 h in $CH_2Cl_2$ (3 mL). $AgPF_6$ (94 mg, 0.37 mmol) in MeOH (3 mL) was added and the resulting suspension was stirred for 30 min, then filtered through Celite. The solution was evaporated to dryness and the residue crystallized from $CH_2Cl_2$/*t*BuOMe (slow diffusion) to give 254 mg (81%) of orange crystals. $^{31}$P NMR (81.0 MHz, $CDCl_3$): $\delta$ = –143.5 (sept, $J_{PF}$ = 713 Hz, $PF_6^-$), 11.5 (s, $J_{Pt,P}$ = 4291 Hz, major isomer); 11.9 (s, $J_{Pt,P}$ = 4010 Hz, minor isomer) ppm. MS (FAB): *m*/*z* (%) = 770.4 (100) [M – $PF_6$]$^+$. $C_{35}H_{40}F_6FeN_2P_2Pt$ (915.57): calcd. C 45.91, H 4.40, N 3.06; found C 45.97, H 4.61, N 3.03.

**[Pt($\eta^3$-Ph$_2$All)(dppe)]PF$_6$ (24):** A mixture of **17** (51.5 mg, 0.055 mmol) and 1,2-bis(diphenylphosphanyl)ethane (43.8 mg, 0.11 mmol) in acetone (1 mL) and $CH_2Cl_2$ (1 mL) was stirred until completely dissolved. Epichlorohydrine (0.1 mL, 1.28 mmol) and $HPF_6$ solution [0.1 mL, 0.114 mmol; freshly prepared from 0.6 mL $HPF_6$ (75%) and EtOH up to 5.0 mL total volume] were then added dropwise. After 30 min stirring, the reaction mixture was evaporated to dryness and the residue dried under HV. The yellow solid was dissolved in $CH_2Cl_2$ (2 mL), the solution filtered through Celite, and the filtrate reduced to a volume of 1 mL. Addition of butanone (1 mL) followed by slow evaporation in the fume hood gave yellow, rhombic crystals (67 mg, 65%), suitable for X-ray analysis. $^1$H NMR (250 MHz, $CD_2Cl_2$): $\delta$ = 2.28–2.62 (m, $J_{Pt,H}$ = 34 Hz, 4 H, $CH_2CH_2$), 4.80 (m, AA′ of AA′BXX′, $J_{AB}$ = $J_{A'B}$ = 12.8 Hz, $J_{AX}$ + $J_{AX'}$ = 22.1 Hz, $J_{Pt,H}$ = 45.3 Hz, 2 allyl H, *anti*), 6.14 (t, B of AA′BXX′, $J$ = 12.8 Hz, $J_{Pt,H}$ = 45 Hz, 1 allyl H, *central*), 7.80–6.80 (m, 30 H, aryl) ppm. $^{13}$C NMR (62.9 MHz, $CD_2Cl_2$): $\delta$ = 31.0 (AMM′, ψ-dd, $J$ = 41 Hz, 9 Hz, $J_{Pt,C}$ = 56 Hz, $CH_2$), 83.5 [AMM′, ψ-d, $J$ = 27 Hz, $J_{Pt,C}$ = 55 Hz, CH, All-C(1,3)], 110.9 [A of $AM_2$, t, $J_{P,C}$ = 4 Hz, $J_{Pt,C} \approx$ 17 Hz, CH, All–C(2)], 126.8 (AMM′, ψ-dd, $J$ = 57 Hz, 0.8 Hz, $J_{Pt,C}$ = 49 Hz, C, PPh-*ipso*-C), 128.4 (AMM′, ψ-quint, $J$ = 2 Hz, CH), 128.7 (AMM′, ψ-dd, $J$ = 56 Hz, 0.6 Hz, $J_{Pt,C}$ = 38 Hz, C, PPh-*ipso*-C), 129.3 (AMM′, ψ-t, $J$ = 1.5 Hz, CH), 130.3 (AMM′, ψ-t, $J$ = 1.3 Hz, CH), 131.1–131.6 (m, 2 CH), 133.7 (AMM′, CH), 133.8 (AMM′, $J_{Pt,C}$ = 24 Hz, CH), 134.5 (AMM′, CH), 134.9 (AMM′, $J_{Pt,C}$ =

25 Hz, CH), 137.7 (AMM′, C) ppm. Spin system nomenclature: A corresponds to the carbon atom in question, M and M′ correspond to the $^{31}$P nuclei. $^{31}$P NMR (101.3 MHz, $CD_2Cl_2$): $\delta$ = –143.7 (sept, $J_{P,F}$ = 711 Hz, $PF_6^-$), 44.7 (s, $J_{Pt,Pt}$ = 3847 Hz) ppm. $^{195}$Pt NMR (HMQC, 64.2 MHz, $CD_2Cl_2$): $\delta$ = –5521 (t, $J_{Pt,P} \approx$ 3830 Hz) ppm. MS (FAB): *m*/*z* (%) = 1717 (9) $[2\ M - PF_6]^+$, 786 (100) $[M - PF_6]^+$, 592 (10) $[M - PF_6 - Ph_2All]^+$. $C_{41}H_{37}F_6P_3Pt$ (931.72): calcd. C 52.85, H 4.00; found C 52.83, H 4.14.

**(*E*)-1-Cyclohexyl-3-cyclohexylidenepropene (26):** (a) The substance was formed, in NMR experiments, from **8b** and an excess of either $Me_4NF$ (in $[D_3]$MeCN) or Schwesinger's $P_2F$[57] (in $C_6D_6$). (b) A reference sample was obtained as follows: MsCl (56.0 mg, 0.488 mmol) was added dropwise at –78 °C to a solution of **10** (98.8 mg, 0.444 mmol) and *i*$Pr_2$NEt (0.091 mL, 0.533 mmol) in THF (5 mL). After stirring for 45 min and another addition of *i*$Pr_2$NEt (0.18 mL, 1.06 mmol) and MsCl (120 mg, 1 mmol) the reaction mixture was warmed to room temp. and stirred for 2 h. Workup with $H_2O$/*t*BuOMe gave, after drying ($MgSO_4$) and evaporation to dryness, a residue that was filtered through $SiO_2$ (*t*BuOMe) to yield 38.7 mg (42%) of a colorless oil. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 0.75–2.30 (m, 21 H-Cy), 5.54 (dd, *J* = 15.2 Hz, 7.0 Hz, 1-H), 5.73 (dd, *J* = 10.9 Hz, 0.7 Hz, 3-H), 6.25 (ddd, *J* = 15.2 Hz, 10.8 Hz, 1.2 Hz, 2-H) ppm. $^{13}$C NMR (62.9 MHz, $CDCl_3$): $\delta$ = 26.1 ($CH_2$), 26.2 ($CH_2$), 26.8 ($CH_2$), 27.6 ($CH_2$), 28.4 ($CH_2$), 29.2 ($CH_2$), 33.1 ($CH_2$), 37.2 ($CH_2$), 41.0 (CH), 122.1 (CH), 123.2 (CH), 138.3 (CH), 141.2 (C) ppm. IR ($CHCl_3$): $\tilde{\nu}$ = 2930 (s), 2853 (m), 1616 (w), 1448 (m), 1344 (w), 968 (m) cm$^{-1}$. MS (EI): *m*/*z* = 204 $[M]^+$.

**Oxidative Addition of $Ph_2$AllF (6) to Pd(dba)$_2$ (→27·F):** Pd(dba)$_2$ (170 mg, 0.29 mmol) and $Ph_2$AllF (**6**)[14a] (76 mg, 0.36 mmol, solution in 7 mL hexane) were stirred in THF (10 mL). Within 15 min, the color changed from violet to yellow, and a yellow solid precipitated. After filtration, the solid was dried under HV. The product could not be further purified and was only analyzed spectroscopically for the presence of the (1,3-diphenylallyl)palladium(II) fragment. $^1$H NMR ($[D_6]$DMSO): $\delta$ = 5.29 [d, *J* = 12.0 Hz, 4 H, C(2),C(3)], 6.98 [t, *J* = 11.8 Hz, 2 H, C(2)], 7.39 (br. m, 12 H, aryl), 7.78 (br. m, 8 H, aryl) ppm. $^{19}$F NMR: no signal detected.

**Di-μ-bromobis($\eta^3$-1,3-diphenylallyl)dipalladium(II) (27·Br):** Pd(dba)$_2$ (40 mg, 0.070 mmol) and **15** (22.8 mg, 0.083 mmol) were stirred in THF (20 mL) at room temp. The color of the violet suspension became brighter within 20 min and a yellow precipitate was deposited. The solid was isolated by filtration and dried under HV. No further purification was attempted due to the small scale of the reaction. $^1$H NMR ($[D_6]$DMSO): $\delta$ = 5.19 (d, *J* = 11.7 Hz, 4 H, allyl H, *anti*), 6.80 (t, *J* = 11.7 Hz, 2 H, allyl H, *central*), 7.30–7.27 (m, 12 H, aryl), 7.66–7.69 (m, 8 H, aryl) ppm. $C_{30}H_{26}Br_2Pd_2$ (759.18): calcd. C 47.46, H 3.45; found C 46.87, H 3.48.

**Oxidative Addition of $Ph_2$AllF (6) to Pd(dba)$_2$ in the Presence of PPFPz{3,5-Me$_2$} {→[Pd($\eta^3$-$Ph_2$All)(PPFPz{3,5-Me$_2$})]F·($H_2O$)$_n$ (28·F)}:** PPFPz{3,5-$Me_2$} (**2c**)[28] (54.2 mg, 0.11 mmol) and Pd(dba)$_2$ (57.5 mg, 0.10 mmol) were stirred in THF (10 mL) at 40 °C for 30 min to give an orange-brown solution. $Ph_2$AllF (**6**)[14a] (2 mL, 75 mM in *N*,*N*-dimethylformamide, 0.15 mmol), was added and the reaction mixture, which quickly turned yellow, was stirred for 1 h at room temp. Solvents were removed under HV and the residue purified by precipitation (in air) from $CH_2Cl_2$/pentane. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 0.71 (s, 3 H, Me-Pz), 1.67 (s, ca. 4 H, $H_2O$), 2.29 (d, *J* = 7.4 Hz, 3 H, CH*Me*), 2.31 (s, 3 H, Me–Pz), 3.75 (s, 1 H-Cp), 4.18 (s, 5 H, Cp′); 4.35–4.37 (m, 1 H-Cp), 4.65 (s, 1 H-Cp), 5.30 (s, 1 H-Pz), 6.12–6.19 (m, 3 H, 1 allyl H,, 2 H, aryl), 6.43–6.52 (m, 1 allyl H,), 6.98–8.03 (m, 19 H, 1 allyl H,, 18 H, aryl) ppm,

peaks broadened. $^{19}$F NMR (282.4 MHz, $CDCl_3$): no signal detected. $^{31}$P NMR ($CDCl_3$): $\delta$ = 12.1 (br. s) ppm. $C_{44}H_{42}FFeN_2PPd + 3H_2O$ (865.10): calcd. C 61.09, H 5.59, N 3.24; found C 61.02, H 5.09, N 2.77.

**X-ray Crystallography:** Data were collected at 293 K with a Siemens SMART CCD diffractometer (graphite-monochromated Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, ω-scan technique), except for **20·PhOH** and **24**, for which the data was collected with a Syntex P21 4-circle diffractometer. The structures were solved by direct methods using SHELXS-97.[69] A full matrix least-squares refinement on $F^2$ was performed with SHELXL-97.[70] Allyl fragments in **8b** and the phenol solvate in **20·PhOH** were refined isotropically, all other non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in calculated positions and assigned using an isotropic displacement parameter of 0.08 Å$^2$. SADABS[71] was used to perform area-detector scaling and absorption corrections. No absorption correction was applied for **20·PhOH** and **24**.

CCDC-279484 to -279489 (cf. Table 3 and Table 4) contain the supplementary crystallographic data for this paper. This data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

L. H. thanks Solvias AG, Basel, for a Ph.D. grant, the Deutsche Forschungsgemeinschaft for current support with an Emmy Noether Programm, and Prof. C. Bolm for continued support. Credit for crystallographic measurements, preliminary structure solutions, data shuffling, and final solutions goes to Diego Broggini, Ulli Englert, Céline Gambs, Volker Gramlich, Arianna Martelletti, Gerhard Raabe, Michael Wörle, and Stefan Zürcher. Daniel Whelligan is thanked for eliminating English glitches.

# A Single-Source-Precursor Approach to Late Transition Metal Molybdate Materials: The Structural Role of Chelating Ligands in the Formation of Heterometallic Heteroleptic Alkoxide Complexes

**Pia Werndrup,[a] Gulaim A. Seisenbaeva,[a] Gunnar Westin,[b] Ingmar Persson,[a] and Vadim G. Kessler*[a]**

**Keywords:** Cobalt molybdate / EXAFS / Heterogeneous catalysis / Materials / Nickel molybdate / Sol–gel processes

The synthesis and structural determination of three new heterometallic molybdenum complexes, one with cobalt and two with nickel and two of these with β-diketonate ligands and one with amino alcohol ligands, are presented. The reaction of cobalt acetylacetonate with $[MoO(OMe)_4]$ provides $[Co_2Mo_2O_2(acac)_2(OMe)_{10}]$ (**1**) and $[MoO(acac)(OMe)_3]$ (**4**), and the reaction of nickel acetylacetonate with $[MoO(OMe)_4]$ provides $[Ni_2Mo_2O_2(acac)_2(OMe)_{10}]$ (**2**) and **4**. The reaction of $[Ni(OR^N)_2]$ ($R^N$ = $CHMeCH_2NMe_2$) with $[MoO(OMe)_4]$ yields $[Ni_2Mo_2O_2(OR^N)_2(OMe)_{10}]$ (**3**). The two new oxomolybdenum complexes undergo ether elimination upon storage to give the corresponding dioxo complexes $[MoO_2(acac)(OMe)]_2$ (**5**) and $[MoO_2(OR^N)(OMe)]_2$ (**6**). Compounds **3** and **4** could also be obtained from the reaction of stoichiometric amounts of Hacac with $[MoO(OMe)_4]$ and $[MoO_2(OMe)_2]$, respectively. The local structure around the nickel atom in compound **2** in solution and compound **3** in the solid state and in toluene/hexane solution has been determined by means of EXAFS spectroscopy. The complexes are intended to be used as single-source precursors, which are attractive in coatings and for the preparation of mesoporous materials; its application for the synthesis of nickel molybdate by sol–gel processing is therefore reported. The oxide material obtained from **3** displays a uniform grain size and a large surface area. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

The development of low-temperature routes to late transition metal molybdates with small grain size and a high active surface is today one of the most intensively explored fields in materials science related to heterogeneous catalysis. Cobalt and nickel molybdates have been reported to be efficient catalysts in such reactions as oxidative dehydrogenation of alkanes[1] and disproportionation of carbon monoxide with formation of single-walled carbon nanotubes.[2] Nitridation and sulfidation of the initially prepared oxide materials has provided efficient catalysts for higher productivity ammonia synthesis[3] and hydrodesulfurisation reactions,[4] respectively. A great deal of attention has been paid to the properties of the final catalyst in relation to the preparation conditions, especially the pH during the synthesis in aqueous media,[5] and also to the effects of different chemical impurities, both in the original material and introduced by reactants, on the activity and stability of the catalysts.[6] Cobalt and nickel molybdates are usually applied as coatings on different supports, most commonly alumina ($\gamma$-$Al_2O_3$)[6] or activated carbon.[7] Application of these catalysts deposited on niobia for hydrodesulfurisation applications and comparison of the influence of different oxide substrates has been reported.[8] A common approach to late transition metal molybdates is a high-temperature decomposition of a salt mixture, such as $Co(NO_3)_2{\cdot}6H_2O$ and $(NH_4)_6Mo_7O_{24}$, leading to the formation of a molybdate powder.[7,9] Great efforts have been made to enhance homogenisation of the components in the course of preparation of these materials by using approaches such as freeze-drying,[10] impregnation of porous supports by water solutions of salts stabilized by chelating ligands, such as, for example, nitrilotriacetates[11] or ethylenediamine in combination with hydrothermal treatment,[12] and electrodeposition in sulfate-citrate medium.[13] Very recently, a special focus in this research field has been the development of sol–gel approaches to this class of materials, applying silica[14] or non-ionic[15] or block-copolymer zwitterionic surfactants[16,17] to ensure the chemical homogeneity and development of desired morphological features. It would be advantageous to be able to deposit a $M^{II}MoO_4$ phase selectively on substrates from solutions. Single-source precursors have been very successfully used in coatings and the preparation of mesoporous materials. It is very simple, once the precursor has beens prepared, to use sol–gel techniques for spin- or dip-coating of surfaces or to hydrolyse and condense the precursors in

the solution in order to make a gel, which will become a mesoporous powder after calcination, often at a lower temperature than that used in solid-state reactions.[18] This mesoporous coating will be formed on a chosen substrate, which represents an additional advantage for this procedure.

Heterometallic alkoxide complexes of late and heavy transition metals are of interest as single-source precursors for catalytically active materials. The synthetic approaches to heterometallic compounds are restricted, however, because alkoxides of late transition metals are insoluble and unreactive. A promising pathway to heterometallic complexes is provided by the reaction between a metal alkoxide and a β-diketonate complex of another metal atom. This approach has been pioneered by Mosset et al., who observed formation of cobalt-zirconium[19] and iron-zirconium[20] alkoxide complexes in minor yields in alcoholic media. We have previously[21,22] investigated in detail the interaction of divalent metal β-diketonate complexes and tantalum or niobium alkoxides. The main products of this reaction − a new class of heterometallic heteroleptic alkoxide complexes $[M^{II}_2M^{V}_2(acac)_2(OR)_{12}]$ ($M^{II}$ = Co, Ni, Zn, Mg, R = Me, Et, and $M^{V}$ = Ta, Nb) − are formed quantitatively in hydrocarbon solvents according to Equation (1).

$$[M^{II}(acac)_2] + 2[M^{V}(OR)_5] \rightarrow \tfrac{1}{2}[M^{II}_2M^{V}_2(acac)_2(OR)_{12}] + [M^{V}(acac)(OR)_4 \quad (1)$$

If the late transition metal complex contains a different chelating ligand, the reaction with an alkoxide can provide heterometallic heteroleptic alkoxide complexes with different solubility and reactivity than the homoleptic alkoxide. This will alter the hydrolytic properties and provide a tool to control the sol–gel preparation of materials for catalysis. We present here the synthesis, structure determination and sol–gel processing of three new heterometallic molybdenum complexes, one with cobalt and two with nickel, and two of these with β-diketonate ligands and one with amino alcohol ligands.

## Results and Discussion

### Synthesis of Precursor Compounds

In order to develop the concept of molecular structure design for a synthetic approach to single-source precursors suitable for production of inorganic materials[23] we wanted to use the synthetic strategy formulated with the syntheses of the heterometallic heteroleptic complexes $[M^{II}_2M^{V}_2(acac)_2(OMe)_{12}]$ ($M^{II}$ = Co, Ni, Zn, Mg, and $M^{V}$ = Ta, Nb).[21] These reactions use the β-diketonate metal complexes to provide stability in the solution (due to the chelating effects of the β-diketonate ligands) and the methoxide complexes as Lewis bases. The complexes are formed when the initial $M^{II}/M^{V}$ ratio is lower than 1:2; we tested ratios between 1:2.1 and 1:3.5 and the syntheses were successful. Extending the synthetic strategy to molybdenum and late transition metal complexes, we used cobalt acetylacetonate in the reaction with molybdenum oxomethoxide $[MoO(OMe)_4]$. The reaction was successful and provided $[Co_2Mo_2O_2(acac)_2(OMe)_{10}]$ (**1**) [Figure 1 and Equation (2)] in high yields at Co/Mo ratios less than or equal to 1:2.

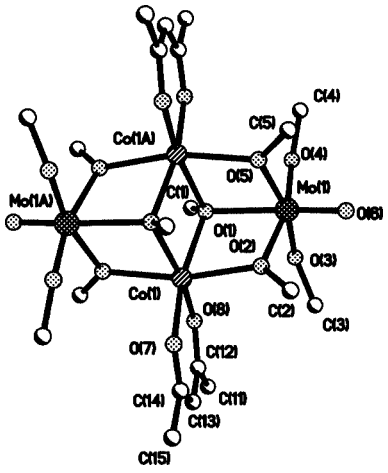

Figure 1. Molecular structure of $[Co_2Mo_2O_2(acac)_2(OMe)_{10}]$ (**1**).

$$[Co(acac)_2] + 2[MoO(OMe)_4] \rightarrow \tfrac{1}{2}[Co_2Mo_2O_2(acac)_2(OMe)_{10}]\ (\mathbf{1}) + [MoO(acac)(OMe)_3]\ (\mathbf{4}) \quad (2)$$

The use of nickel acetylacetonate in hexane instead of cobalt acetylacetonate in the reaction with $[MoO(OMe)_4]$ provided $[Ni_2Mo_2O_2(acac)_2(OMe)_{10}]$ (**2**). The compositions of the reaction products indicate the same reaction pathway [Equation (2)] for both nickel and cobalt acac derivatives, analogous to the one observed earlier for the formation of bimetallic complexes of niobium and tantalum[21,22] [Equation (1)]. Both new cobalt-molybdenum and nickel-molybdenum complexes have much lower solubility in toluene than the corresponding tantalum or niobium ones. In order to improve this low solubility we altered the reaction pathway [Equation (3)] by using an amino alcohol complex, in hexane, instead of the acetylacetonate one.

The use of $Ni(OR^N)_2$ ($R^N$ = $CHMeCH_2NMe_2$) in the reaction with $[MoO(OMe)_4]$ provided the nickel-molybdenum complex $[Ni_2Mo_2O_2(OR^N)_2(OMe)_{10}]$ (**3**). A ligand-exchange reaction occurs when $Ni(L)_2$ (L = acac or $OR^N$) and $[MoO(OMe)_4]$ react in hexane, which gives two new heterometallic heteroleptic alkoxide complexes (**2**, **3**) along with new molybdenum complexes containing the chelating ligand [Equation (3)]. The structure of the by-product com-

$$\begin{array}{l} Ni(L)_2 + 2\ MoO(OMe)_4 \rightarrow \tfrac{1}{2}\ Ni_2Mo_2O_2(L)_2(OMe)_{10}\ (L = acac\ \mathbf{2},\ OR^N\ \mathbf{3}) + MoO(L)(OMe)_3\ (L = acac\ \mathbf{4}) \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \downarrow - Me_2O \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \tfrac{1}{2}\ [MoO_2(L)(OMe)]_2\ (L = acac\ \mathbf{5},\ OR^N\ \mathbf{6}) \end{array} \quad (3)$$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plex containing the acac ligand [MoO(acac)$(OMe)_3$] (**4**) (Figure 2, A) was determined by a single-crystal X-ray study. The two new $M^{II}$-molybdenum complexes undergo ether elimination upon storage [Equation (3)] to give the corresponding dioxo complexes [$MoO_2$(acac)$(OMe)]_2$ (**5**) and [$MoO_2(OR^N)(OMe)]_2$ (**6**). The structures of **5** and **6** were also determined by single-crystal X-ray diffraction studies [Figures 2, B and C, respectively]. The presence of dimethyl ether was detected in both mother liquors by the GC-MS technique. Compound **4** was also successfully prepared by the reaction between [$MoO(OMe)_4$] and Hacac. Compound **5** is formed from **4** very slowly at room temperature. An attempt to accelerate this process by refluxing the solutions of **4** led to quick development of a reddish-brown colour associated with reduction of $Mo^{VI}$ to $Mo^{V}$. The mother liquor in this case contained the dimethyl acetal of formaldehyde [$CH_2(OMe)_2$], which is the organic by-product of this reduction reaction.[24] The same kind of reduction associated with ligand redistribution turned out to be major obstacle in the synthesis of **5**, and especially **6**, by the reaction of insoluble [$MoO_2(OMe)_2$] with acetylacetone or (dimethylamino)propanol. The white [$MoO_2(OMe)_2$] turns blue on refluxing with these reagents in toluene, while the solution becomes reddish brown. GC-MS indicated that the solution contained $CH_2(OMe)_2$ in both cases. Compound **5** was isolated in minor yield from the mother liquor by crystallisation, but the solution derived from molybdenum dioxomethoxide and (dimethylamino)propanol did not provide any isolable product.

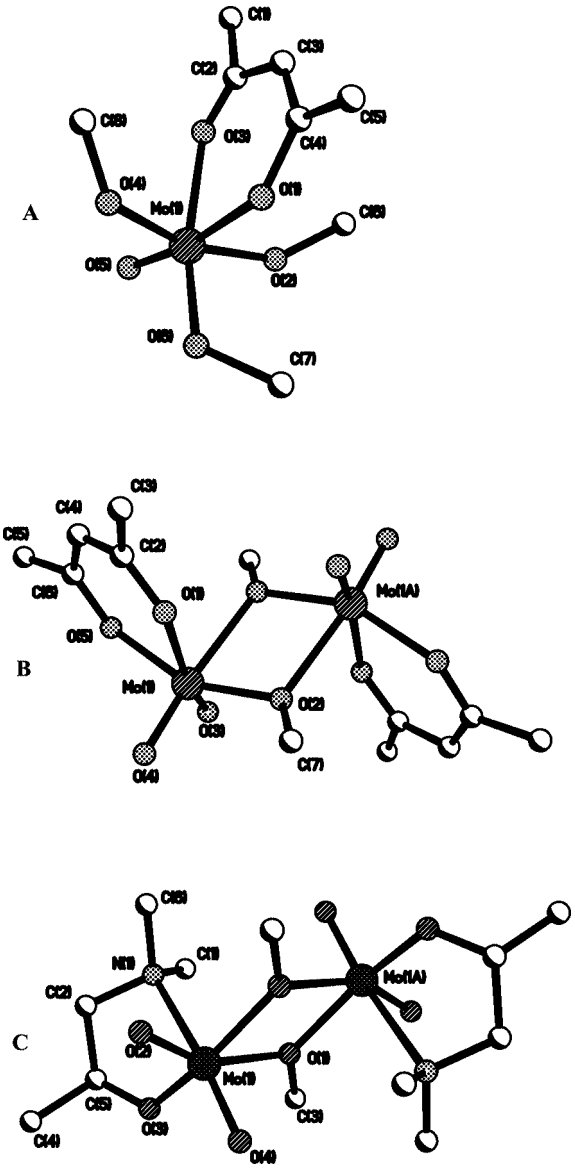

Figure 2. Molecular structure of [MoO(acac)$(OMe)_3$] (**4**; A), [$MoO_2$(acac)$(OMe)]_2$ (**5**; B) and [$MoO_2(OR^N)(OMe)]_2$ (**6**; C).

## Structure Determinations

The molecular structure of the cobalt-molybdenum complex **1** follows the well-known [$Ti_4(OMe)_{16}$] structural type.[25] The structure of **1** was determined by a single-crystal X-ray study (Figure 1 and Table 1). The octahedron surrounding the Co atoms is distorted because of the two types of oxygen atoms from the μ- and $\mu_3$-OR groups in the complex; the *trans* O–Co–O angles are 165.74(14)–166.81(14)°. The acac ring does not distort the octahedron − the O–Co–O angle in the ring is 90.61(16)°. The Co–O distances in **1** are 2.019(4)–2.135(3) Å, depending on the bonding mode of the oxygen atoms. The ionic radii of the cobalt(II) (high spin) and nickel ions in octahedral configuration are 0.745 and 0.690 Å, respectively,[26] and, along with the radius of the water-oxygen-bound di- and trivalent metal ion (1.34 Å),[27] this gives expected Co–O and Ni–O bond lengths of 2.09 Å and 2.03 Å, respectively. The shortest Co–O distances in **1** are to the oxygen atoms in the acac ring (both terminal and chelating) and the longest ones are for the $\mu_3$-oxygens in the complex. In **1**, the Co···C distances in the acac ring are calculated to be 2.995(5) and 2.996(5) Å for the two carbon atoms connected to an oxygen atom in the acac ring, and 3.281(5) Å for the one in the centre of the ring. The molybdenum atom has a distorted octahedral coordination environment with six oxygen atoms. None of the *trans* O–Mo–O angles have ideal 180° angles; they vary between 162.00(17) ° and 165.67(16)°. It is the angle between the two Mo-μ-O bonds that distorts the octahedron the most; it is only 85.59(15)°. The Mo–O bonds for the two terminal methoxide groups [1.857(4) and 1.834(4) Å] are in agreement with the corresponding bonds in complexes such as [$Mo(OMe)_6$][28] and [$Mo_2O_2(OMe)_8$],[29] and very close to those in [$Mg_2Mo_2O_2(OMe)_{10}(MeOH)_4$],[30] a close structural analogue of **1**, where they vary between 1.862(4) and 1.909(4) Å. The two Mo–μ-O bonds are longer [1.998(3) and 1.998(4) Å, respectively] and the Mo–$\mu_3$-O bond is even longer [2.187(3) Å] as this kind of bonding, with an atom shared with one or two other atoms, normally results in a significant increase of bond lengths. The Mo=O bond also causes a deviation from a perfect octahedron. The length of the double bond [1.683(4) Å] is in agreement with the length of the same kind of bond in [$MoO(OMe)_4$] [1.672(5) Å].[29] It is interesting to note that **1** is only the

second cobalt-molybdenum alkoxide complex reported in the literature after [{$Mo_2$(DAniF)$_3$}$_2$Co(OMe)$_4$] (DAniF = *N*,*N*′-di-*p*-anisylformamidinate).[31,32]

[a] Symmetry transformations used to generate equivalent atoms: #1 –*x*, – *y* + 1, –*z* + 2.

The acac ring in compound **4** (part A in Figure 2 and Table 2) distorts the octahedral surrounding of the Mo atom along with the other four oxygens surrounding the Mo atom. The O–Mo–O angle in the acac ring is 80.5(2)° and influences the other O–Mo–O angles such that all four of the O=Mo–O angles are larger than 90° [they vary between 92.0(6)° and 100.6(3)°]. The *trans* O–Mo–O angles are in the range 162.29(19)–171.1(6)°. The Mo–O bond length for the three terminal methoxide groups is 1.846(15)–1.861(4) Å, in agreement with the lengths of the same kind of bonds in [Mo(OMe)$_6$]. The Mo=O bond is also the shortest one in **4** [1.683(14) Å], and the Mo–O bonds to the oxygen in the acac ring are 2.080(10)–2.182(10) Å.

After ether elimination from the two new $M^{II}$-molybdenum complexes [Equation (3)] two new dioxo complexes

were isolated. The structures of these complexes – [$MoO_2$(acac)(OMe)]$_2$ (**5**) and [$MoO_2$($OR^N$)(OMe)]$_2$ (**6**) – were determined by single-crystal X-ray diffraction studies (Figures 2, B and C, respectively). The molybdenum atoms all have distorted octahedral surroundings in these two complexes. In **5**, the octahedron contains only oxygen atoms, with *trans* O–Mo–O angles in the range 155.02(12)–163.83(15)° (Table 3). The acac ring distorts the octahedron to give an O–Mo–O angle of 80.02(12)°. The Mo–O bonds in the ring are 2.004(3) and 2.166(3) Å, respectively, in good agreement with the same kind of bond in **4**. As with all Mo=O bonds discussed previously, they are the shortest Mo–O bonds in this complex [1.696(3) and 1.697(3) Å, respectively]. In **6**, the octahedron surrounding the Mo atom is composed of five oxygen atoms and one nitrogen atom. The ring distorts the octahedron such that the *trans* N–Mo–O(4) angle is 167.4(3)° and the two *trans* O–Mo–O angles are 153.2(2)° and 155.1(3)° (Table 4). The N–Mo–O(3) angle in the ring is 72.4(2)° and the (μ-O)–Mo–(μ-O) angle is 67.4(2)°. The Mo=O bonds are also the shortest Mo–O ones in **6**, at 1.688(6) and 1.690(6) Å, respectively, and the longest are the Mo–(μ-O) bonds [2.053(6) and 2.175(5) Å]; the Mo–N bond is 2.485(7) Å. The bonding within the aminoalkoxide ring is considerably different from that in the known complexes of $Mo^{VI}$ with triethanolamine, where the presence of several fused chelating cycles results in considerably shortened Mo–N distance, such as 2.342(6) Å in, for example, [$HMoO_2(OC_2H_4)_3N$].[33]

Single crystals of the heterometallic complexes [$Ni_2Mo_2O_2(L)_2(OMe)_{10}$] (**2** and **3**), large enough for single-crystal X-ray studies, have not yet been isolated. The cobalt and nickel atoms are of similar size, and therefore occupy approximately the same volume in a molecule, with nickel being the smaller one (see above). Cobalt atoms have a higher preference to ideal octahedral angles in the inner sphere than nickel. On the other hand, the distortion of the inner sphere of a nickel atom can be severe, and the O–Ni–

[a] Symmetry transformations used to generate equivalent atoms: #1 $-x, -y, -z + 1$.

O angles are shifted instead of differentiating the Ni–O bond lengths in the octahedron. Despite this difference in inner-sphere flexibility, we propose the structure of **1** as a model for the description of the nickel-molybdenum complexes **2** and **3**.

A powder of the acac complex **2** was studied by Ni-EXAFS (part A in Figure 3 and Table 5), which gave a mean Ni–O distance of 2.024(2) Å (Figure 4, A). This distance is significantly shorter than the same kind of distances in the model, obtained from the X-ray single-crystal experiment, of the cobalt analogue **1** with a range of 2.123(4)–2.135(3) Å for the Co–(μ-O) and Co–($\mu_3$-O) distances. No Ni···C distances could be determined from the EXAFS experiment. The Ni···Ni distance in **2** is 3.150(11) Å and the Ni···Mo distance is 3.311(2) Å, both in agreement with the observed distances in **1** (3.208 Å for Co···Co and 3.348 Å for Co···Mo) taking into account the smaller ionic radius of nickel.

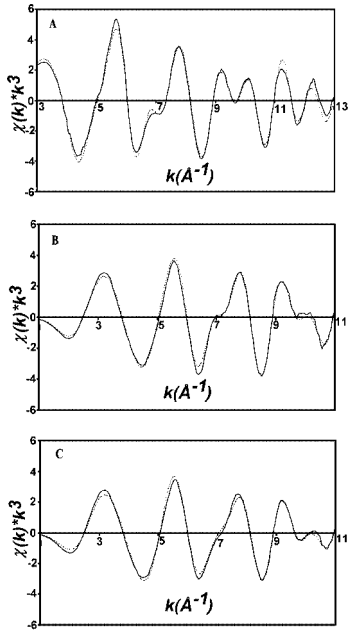

Figure 3. EXAFS spectra of $[Ni_2Mo_2O_2(acac)_2(OMe)_{10}]$ (**2** as a powder; **A**) and $[Ni_2Mo_2O_2(OR^N)_2(OMe)_{10}]$ [**3** as a powder (**B**) and in solution (C)]. Solid lines represent experimental data and dotted lines calculated data.

Table 5. EXAFS model parameters[a] for **2** (in solution) and **3** (powder and in solution).

| Interaction | *N* | *d* [Å] | $\sigma^2$ [Å$^2$] | $E_o$ [eV] | $S_o^2$ |
|---|---|---|---|---|---|
| **2** solution | | | | | |
| Ni–O | 6 | 2.024(2) | 0.0076(2) | 8330.0(3) | 0.83(2) |
| Ni···Ni | 1 | 3.150(11) | 0.015(2) | | |
| Ni···Mo | | 2 | 3.311(2) | 0.0060(1) | |
| **3** powder | | | | | |
| Ni–O | 5 | 2.058(2) | 0.0065(3) | 8329.9(3) | 0.86(3) |
| Ni–N | 1 | 2.336(13) | 0.0088(15) | | |
| Ni···Ni | 1 | 3.144(2) | 0.0040(2) | | |
| Ni···Mo | 2 | 3.297(2) | 0.027(4) | | |
| **3** solution | | | | | |
| Ni–O | 5 | 2.033(3) | 0.0073(6) | 8327.7(4) | 0.69(2) |
| Ni–N | 1 | 2.133(9) | 0.0010(6) | | |
| Ni···Ni | 1 | 3.127(2) | 0.0036(2) | | |
| Ni···Mo | 2 | 3.120(21) | 0.029(4) | | |

[a] The parameters are the number of interactions (*N*), bond length (*d*), Debye–Waller factor ($\sigma^2$), threshold energy ($E_0$) and amplitude reduction factor ($S_0^2$).

A powder and a toluene/hexane solution of **3** were also studied by Ni-EXAFS (B and C in Figures 3 and Table 5). The heterometallic complex is preserved in solution, as can be seen by the similarity of the EXAFS curves. Fourier transforms of the EXAFS curves (Figures 4, B and C) provide similar Ni–O distances in the powder and in solution [2.058(2) Å and 2.033(3) Å, respectively]. The Ni–N bond

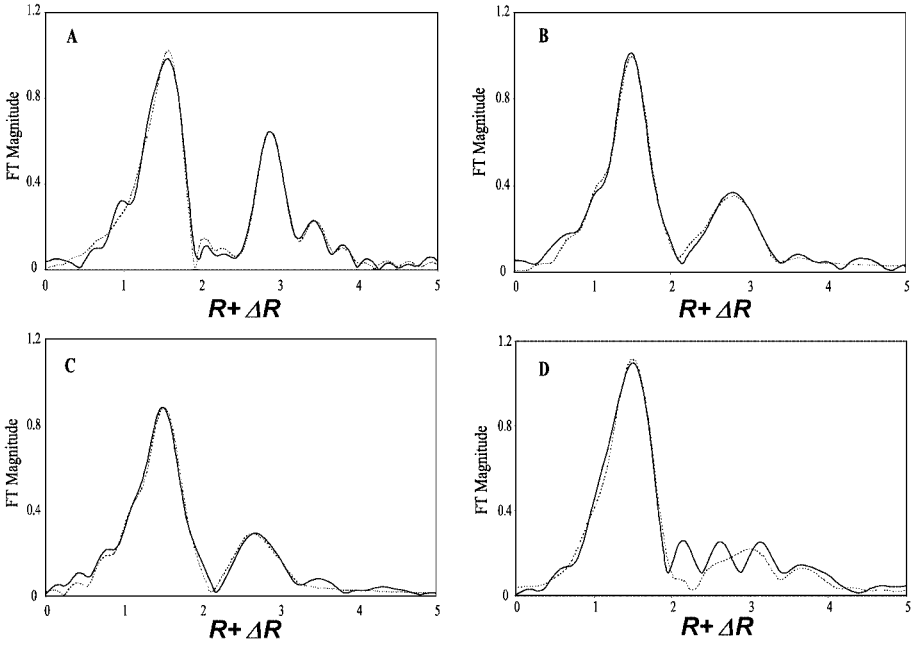

Figure 4. Fourier transforms of $[Ni_2Mo_2O_2(acac)_2(OMe)_{10}]$ (**2** as a powder; **A**), $[Ni_2Mo_2O_2(OR^N)_2(OMe)_{10}]$ [**3** as a powder (**B**) and in solution (**C**)] and $[Co_2Nb_2(acac)_2(OMe)_{12}]$ (powder; D). Solid lines represent experimental data and dotted lines calculated data.

in **3** was determined to be 2.336(13) Å for the powder and 2.133(9) Å for the solution, which is close to the Mo–N bond in **6**. Also for **3** the Ni···Ni distances were refined to 3.144(2) Å for the powder and 3.127(2) Å for the solution. The Ni···Mo distances were refined to 3.297(2) Å for the powder and 3.120(21) Å for the solution, which is in good agreement with the observed distances in **2** and the molecular structure of **1**.

Similarities in the results from the EXAFS experiment of complexes **2** and **3** indicate similarities in the molecular structures of these compounds, the nature of the chelating ligands being the only difference between them. The molecular structures of these heterometallic complexes are therefore analogous and follow the model found in the X-ray single-crystal study well. The Fourier transform of the EXAFS curve for the powder of $[Co_2Nb_2(acac)_2(OMe)_{12}]$ is included for comparison in Figure 4 (see part D).[21] This Co–Nb complex is also a tetranuclear molecule belonging to the $[Ti_4(OMe)_{16}]$ structural type, with Co–O distances of 2.096(11) Å for the four longest bonds and 1.963(14) Å for the two shortest ones, and with Co···Co and Co···Nb distances close to 3.30 Å.

## Sol–Gel Preparation

The sol–gel technique is a useful and attractive means of obtaining nanocomposite materials due to its easy handling

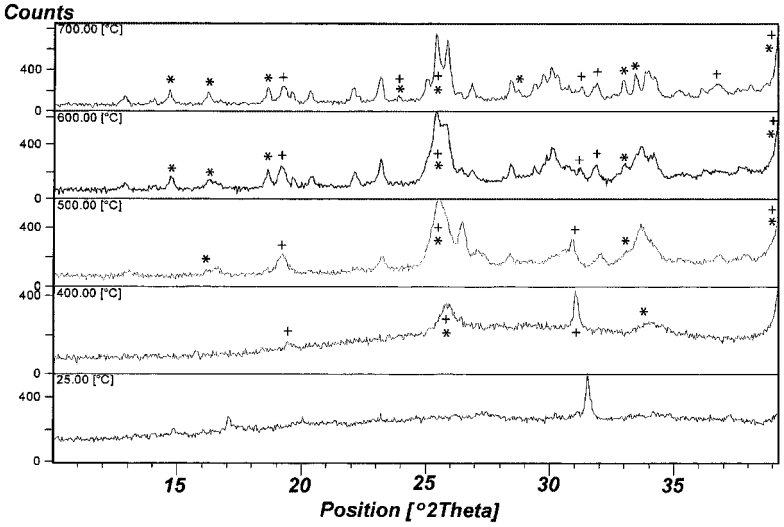

Figure 5. Powder X-ray diffraction of **3** at different temperatures. +: monoclinic (*P*2/*c*) $NiMoO_4$ [16-0291];[34] *: monoclinic (*I*2/*m*) $NiMoO_4$ [33-0948].[34]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

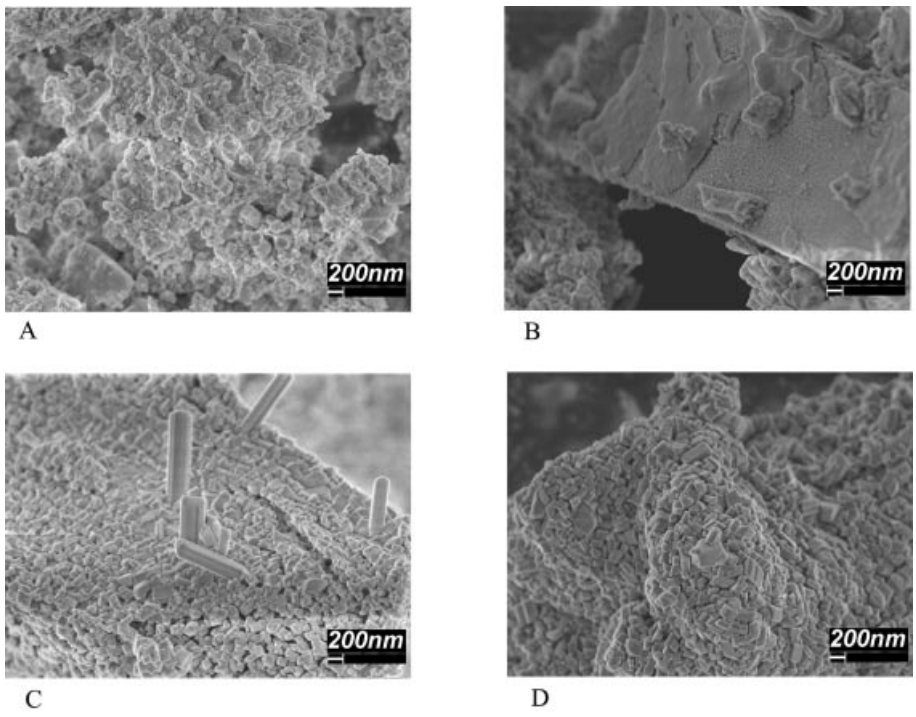

Figure 6. SEM images of the xerogel from **3** annealed at 300 °C (A), 400 °C (B), 500 °C (C) and 700 °C (D).

and low annealing temperatures. Complex **3** was used to obtain xerogel powders. The hydrolysed complex was checked by TGA to confirm the annealing temperatures used. At 315 °C the curve shows a sharp decrease in weight until 420 °C, and at 535 °C the decomposition ends, with only minor weight loss at higher temperatures. Powder X-ray diffraction of the xerogel shows the incipient crystallisation of $NiMoO_4$ [16-0291][34] at 400 °C (Figure 5). At 700 °C, the crystallisation of the monoclinic (*P*2/*c*) oxide $NiMoO_4$ is more pronounced and a monoclinic (*I*2/*m*) $NiMoO_4$ phase [33-0948][34] is seen as well. Scanning electron microscopy of the annealed xerogels confirmed the results from the powder X-ray diffraction analysis. At 300 °C, the gel is porous with a low degree of crystallinity; no sharp edges on the grains can be seen (Figure 6, A). Annealing at 400 °C started the crystallisation and the grains become larger but are still porous (Figure 6, B). The crystallisation process is well underway at 500 °C. The grains are uniform in size (75–100 nm) and well packed with a large surface area (Figure 6, C). Small rods of crystallised oxide can be seen. At 700 °C, the grains are even larger (175–250 nm; Figure 6, D), and rods of crystallised oxide with a diameter of 1 μm are uniformly spread over the sample. The grains have lost the porosity visible at 300 °C, and they are well packed with a large surface area, leaving the material well suited for catalysis experiments.

## Conclusions

The two chelating ligands used appear to play analogous structural roles leading, in both cases studied, to the formation of complexes belonging to the $[Ti_4(OMe)_{16}]$ structural type. The structure of the Co–Mo complex determined by X-ray single-crystal study has been used successfully as a prototype for different Ni–Mo structures studied by EXAFS spectroscopy. The preparation of oxide material from the new nickel-molybdenum amino alcohol complex was successful, with the materials annealed at 500 °C showing uniform grain size and a large surface area.

## Experimental Section

**Reagents and General Procedures:** All experimental procedures were carried out under a dry nitrogen atmosphere using Schlenk techniques or a dry box. $[Ni(OR^N)_2]$ ($R^N$ = $CHMeCH_2NMe_2$), $[MoO(OMe)_4]$ and $[MoO_2(OMe)_2]$ were prepared as described elsewhere.[29,35,36] $[Ni(acac)_2]$ and $[Co(acac)_2]$ (acac = acetylacetonate) (Aldrich, p.a.) were dried by vacuum sublimation.[21] Toluene (Merck, p.a.) and hexane (Merck, p.a.) were dried by distillation over $LiAlH_4$. The IR spectra of nujol mulls were recorded with a Perkin–Elmer FT-IR spectrometer 1720 X. $^1H$ NMR spectra were obtained for solutions in anhydrous $CDCl_3$ with a Bruker 400 MHz spectrometer. SEM was performed with a LEO 1550 high-resolution scanning electron microscope at an accelerating voltage of 20 kV. X-ray powder diffraction was performed with a Phillips SR5056 temperature-programmed diffractometer. Thermogravimetric analysis (TGA) was performed with a Setaram Setsystem 16/18 coupled to a TGA/DSC instrument. The GC-MS analysis was carried out with a JEOL JMS-SX/SX-102A mass spectrometer for fractions of mother liquors distilled in vacuo. The metal ratio in the samples was determined by the Arrhenius Laboratory, Stockholm University, Sweden, with a JEOL-820 scanning electron microscope (SEM) fitted with a Link AN-10000 energy dispersive spectrometer (EDS). The microanalysis data for C, H, N content were obtained at the Laboratory of Organic Analysis at the Moscow State University, Russia, and at MikroKemi AB, Sweden.

**Preparation of $[Co_2Mo_2O_2(acac)_2(OMe)_{10}]$ (1):** $[MoO(OMe)_4]$ (1.2477 g, 5.285 mmol) was dissolved in dry toluene (5 mL). $[Co(acac)_2]$ (0.6594 g, 2.567 mmol) was then added (molar ratio Co/Mo = 1:2.1) and the solution was refluxed for 30 min. The solution was cooled and purple crystals of $[Co_2Mo_2O_2(acac)_2(OMe)_{10}]$ (**1**) precipitated at 4 °C overnight. Yield: 1.53 g (1.80 mmol, 70%). $C_{20}H_{44}Co_2Mo_2O_{16}$ (850.29): calcd. C 28.3, H 5.2; found C 27.7, H 4.9. Co/Mo ≈ 1:1 by EDS. IR: $\tilde{\nu}$ = 2932 s cm$^{-1}$, 2857 s, 2726 s, 2672 sh, 2362 w, 2343 w, 2027 br, 1571 s, 1461 s, 1377 s, 1304 s, 1090 s, 970 w, 941 w, 891 w, 847 w, 768 sh, 627 s, 565 br.

**Preparation of $[Ni_2Mo_2O_2(acac)_2(OMe)_{10}]$ (2):** $[MoO(OMe)_4]$ (0.2276 g, 0.964 mmol) was dissolved in dry hexane (6 mL). $[Ni(acac)_2]$ (0.1238 g, 0.482 mmol) was then added (molar ratio Ni/Mo = 1:2) and the solution was refluxed for 30 min. After cooling, dry toluene (1 mL) was added and the solution was refluxed again for 15 min. Small greenish crystals of $[Ni_2Mo_2O_2(acac)_2(OMe)_{10}]$ (**2**) precipitated at 4 °C overnight. Yield: 0.246 g (0.289 mmol, 60%). $C_{20}H_{44}Mo_2Ni_2O_{16}$ (849.80): calcd. C 28.2, H 5.2; found C 27.8, H 5. In 100% metal content Ni = 52.7% and Mo = 47.3% by EDS. IR: $\tilde{\nu}$ = 2921 s cm$^{-1}$, 2726 s, 2672 w, 2363 w, 1576 s, 1518 s, 1456 s, 1376 s, 1307 sh, 1260 sh, 1196 sh, 1151 w, 1088 s, 1044 w, 1016 sh, 987 w, 934 w, 920 w, 897 w, 767 s, 627 s, 553 br. After several weeks at –30 °C crystals of $[MoO(acac)(OMe)_3]$ (**4**) and $[MoO_2(acac)(OMe)]_2$ (**5**) (identified by their single-crystal X-ray unit-cell parameters) were obtained in minor yields from the decanted solution.

**Isolation and Direct Synthesis of $[MoO(acac)(OMe)_3]$ (4) and $[MoO_2(acac)(OMe)]_2$ (5):** $[MoO(acac)(OMe)_3]$ (**4**) was obtained in a practically quantitative yield by addition of a stoichiometric amount of Hacac to $[MoO(OMe)_4]$. Thus, $[MoO(OMe)_4]$ (0.2168 g, 0.918 mmol) was dissolved in hexane (4 mL) at room temperature and Hacac (0.09 mL) was added with a syringe. The slightly brownish-yellow solution was evaporated in vacuo and the brownish-yellow powder obtained was identified as **4** by microanalysis and spectroscopic data (quantitative yields). $C_8H_{16}MoO_6$ (304.15): calcd. C 31.6, H 5.3; found C 30.7, H 5.5. IR: $\tilde{\nu}$ = 1595 br cm$^{-1}$, 1521 s, 1461 s, 1377 s, 1307 w, 1271 s, 1090 s, 941 s, 817 w, 771 w, 656 w, 627 s, 567 br. $^1$H NMR ($CDCl_3$): $\delta$ = 5.75 (1 H, acac-C*H*), 4.71 {3 H, C$H_3$-[O(6)Me]}, 4.41 {6 H, C$H_3$-[O(2 and 4)Me]}, 2.11 [6 H, C$H_3$-(acac-Me)] ppm. $[MoO_2(acac)(OMe)]_2$ (**5**) was obtained in moderate yields (25–30%), although always contaminated with minor amounts of $[MoO_2(acac)_2]$, by treatment of $[MoO_2(OMe)_2]$ with sub-stoichiometric amounts of Hacac in hexane at reflux. In a typical procedure, $[MoO_2(OMe)_2]$ (0.8162 g, 4.3 mmol) was mixed with 5 mL of hexane and Hacac (0.21 mL, 2.1 mmol) and refluxed for 30 min. The light yellow mother liquor was separated by decantation and the solvents evaporated to dryness. The resulting yellowish residue was recrystallised from 1 mL of hexane. Yield: 0.1409 g (26% in relation to Hacac). $C_{12}H_{20}Mo_2O_{10}$ (516.16): calcd. C 27.9, H 3.9; found C 27.6, H 3.8. IR: $\tilde{\nu}$ = 1591 s cm$^{-1}$, 1527 s, 1461 s, 1377 s, 1305 w, 1275 s, 1091 s, 1031 m, 982 s, 931 s, 819 w, 769 sh, 628 s, 565 br. $^1$H NMR ($CDCl_3$): $\delta$ = 5.84 (1 H, acac-C*H*), 3.50 {3 H, C$H_3$-[O(6)Me]}, 2.14 [3 H, C$H_3$-(acac-Me)], 216 [3 H, C$H_3$-(acac-Me)] ppm.

Preparation of both **4** and **5** can also be carried out with toluene as solvent but provides only a few single crystals of these compounds, probably due to their much higher solubility in this solvent. The yields could be increased by subsequent recrystallisation from hexane, but application of the latter for the whole synthetic procedure appears more attractive.

**Preparation of $[Ni_2Mo_2O_2(OR^N)_2(OMe)_{10}]$ (3):** $[MoO(OMe)_4]$ (0.3815 g, 1.616 mmol) was dissolved in dry hexane (4 mL). $[Ni(OR^N)_2]$ (0.2828 g, 0.7963 mmol) was then added (molar ratio Ni/Mo = 1:2) and the solution was refluxed for 30 min. After cooling, dry toluene (1 mL) was added and the solution was refluxed again for 15 min. Small greenish crystals of $[Ni_2Mo_2O_2(OR^N)_2(OMe)_{10}]$ (**3**) precipitated at 4 °C overnight. Yield: 0.375 g (0.438 mmol, 55%). $C_{20}H_{54}Mo_2N_2Ni_2O_{14}$ (855.91): calcd. C 28.0, H 6.3, N 3.3; found C 29.1, H 6.4, N 3.5. In 100% metal content Ni = 55.2% and Mo = 44.8% by EDS. IR: $\tilde{\nu}$ = 3354 br cm$^{-1}$, 3191 sh, 2921 s, 2852 s, 2726 s, 1603 s, 1461 s, 1377 s, 1309 w, 1279 w, 1136 s, 1088 s, 1032 s, 942 s, 902 s, 860 s, 835 s, 722 s, 627 s, 595 s, 532 s, 509 w, 476 w. The decanted solution was stored at –30 °C for several weeks and $[MoO_2(OR^N)(OMe)]_2$ (**6**) precipitated (minor yield).

**X-ray Structure Determinations:** Data collection was performed using a Bruker SMART CCD 1 K diffractometer, at 295(2) K, with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å; see Table 6 for details). The SAINT PLUS and the SHELXTL-NT program packages were used for data reduction and computations.[37] Empirical absorption correction was applied using the Bruker SADABS program package. The structures were solved by direct methods. The coordinates of the heavy atoms were taken from the initial solution and the non-hydrogen atoms were located in subsequent Fourier syntheses.

The structures were refined by full-matrix least-squares techniques in an isotropic and then finally in an anisotropic approximation.

CCDC-283731 to -283734 (for **1**, **4**, **5** and **6**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**EXAFS Data Collection and Data Treatment:** Nickel and cobalt K-edge X-ray absorption spectra were recorded at the wiggler beam line 4-1 at the Stanford Synchrotron Radiation Laboratory (SSRL), Stanford, USA. SSRL operates at 3.0 GeV and at a maximum current of 100 mA. The EXAFS station was equipped with a Si[220] double crystal monochromator. Data collection was performed in transmission and fluorescence mode simultaneously at ambient temperature. Higher-order harmonics were reduced by detuning the second monochromator to 50% of the maximum intensity at the end of the scans. The solid compounds were diluted with boron nitride to give an edge step of about one unit in the logarithmic intensity ratio, and the sample cells were made of 1-mm brass frames and Mylar tape windows. The toluene/hexane solution was measured in a sample cell with a 2-mm Vitone spacer and Kapton tape windows. The energy scales of the X-ray absorption spectra were calibrated by assigning the first inflection points of the K edges of a nickel foil to 8331.6 eV and a cobalt foil to 7709.5 eV.[38] For each sample 2–3 scans were averaged, giving satisfactory data ($k^3$-weighted) up to $k = 14$ Å$^{-1}$. The EXAFSPAK program package was used for all data treatment and refinement.[39] The EXAFS oscillations were obtained after performing standard procedures for pre-edge subtraction, normalisation and spline removal. The $k^3$-weighted model functions were calculated using ab initio calculated phase and amplitude parameters obtained by the FEFF7 program package (version 7.01).[40] The given errors of the calculated bond lengths in Table 5 originate from the EXAFSPAK algorithms. The errors given are the statistical ones and the true errors of the bond lengths are usually a few times larger.

**Hydrolysis and Heat-Treatment:** Hydrolysis of **3** was performed in toluene by adding an equimolar amount of water with respect to the number of alkoxy groups in **3** and stirring. The sol was poured into a dish and the solvent evaporated to leave a fine powder. The thermal evolution of the powder was investigated by TGA in air at a rate of 10 °C min$^{-1}$ between 23 and 800 °C. Oxide formation of the hydrolysed **3** was performed by heating the powder in air at a rate of 10 °C min$^{-1}$ to the annealing temperature (300–700 °C) for 60 min in a Comecta SA 3L furnace. Scanning electron microscopy (SEM) was performed on the samples in order to study their morphology. X-ray powder diffraction was used to establish the nature of the obtained phases.

**Supporting Information** (see footnote on the first page of this article): $^1$H NMR spectra of [MoO(acac)(OMe)$_3$] (**4**) and [MoO$_2$(acac)(OMe)]$_2$ (**5**) in Figure S1.

## Acknowledgments

Financial support from the Swedish Research Council (VR) is gratefully acknowledged. Mr. Anders Johansson at the Department of Materials Chemistry Ångström Laboratory, Uppsala University, Sweden, is acknowledged for running the SEM analysis. Mr. Gerald Spijksma, Inorganic Materials Science Group, University of Twente, The Netherlands, is acknowledged for help with TGA and XRD analyses. Mr. Rolf Andersson, SLU, is acknowledged for help with the NMR studies. Portions of this research were carried out at the Stanford Synchrotron Radiation Laboratory, a national user facility operated by Stanford University on behalf of the U.S. Department of Energy, Office of Basic Energy Sciences. The SSRL Structural Molecular Biology Program is supported by the Department of Energy, Office of Biological and Environmental Research, and by the National Institutes of Health, National Centre for Research Resources, Biomedical Technology Program.

# A 3D Manganese Coordination Polymer $[Mn_3(IMDC)_2(H_2O)_4]$ Constructed from $[Mn_2(IMDC)_2(H_2O)_2]$ Layers and $[Mn(H_2O)_2]$ Pillars (IMDC = 4,5-imidazoledicarboxylate)

**Man-Bo Zhang,[a] Yong-Mei Chen,[b] Shou-Tian Zheng,[a] and Guo-Yu Yang*[a]**

**Keywords:** Carboxylate ligands / Coordination polymers / Hydrothermal synthesis / Manganese

A novel three-dimensional coordination polymer $[Mn_3(IMDC)_2(H_2O)_4]$ (**1**) (IMDC = 4,5-imidazoledicarboxylate), consisting of $[Mn_2(IMDC)_2(H_2O)_2]$ layers and $[Mn(H_2O)_2]$ pillars, was synthesized hydrothermally and characterized by IR spectroscopy, elemental analysis, TGA, and magnetic measurements. It is the first example of a 3D framework containing 4,5-imidazoledicarboxylate in the family of manganese complexes. Variable-temperature magnetic susceptibility measurements show a weak antiferromagnetic coupling interaction between the $Mn^{II}$ ions of the dimeric units.

## Introduction

Extended solids containing manganese and bridging ligands have been investigated widely in the past decades, mainly for use as molecule-based magnets in both fundamental and potential applications, especially those that exhibit spontaneous magnetization,[1,2] and in the synthesis of manganese metalloenzyme mimics in some biological redox-active systems,[3] as well as the intriguing varieties of architectures and topologies displayed by these compounds.[4,5] In the research area of metalloenzyme mimics, carboxylate-bridged systems are the focus of investigation. To date, many manganese complexes of carboxylic acids with six-membered heterocycles, such as 2,3-pyrazinedicarboxylic acid,[6] 2-pyrazinecarboxylic acid,[7] pyridine-2,6-dicarboxylic acid,[4,5] and pyridine-3,4-dicarboxylic acid[8] have been reported. However, the coordination chemistry of manganese and carboxylic acids with five-membered heterocycle is less developed. 4,5-Imidazoledicarboxylic acid ($H_3IMDC$) exhibits several interesting characteristics: a) it can be partially or completely deprotonated to generate $H_2IMDC^-$, $HIMDC^{2-}$, and $IMDC^{3-}$ by controlling the pH carefully, which allows 4,5-imidazoledicarboxylate anions to display various coordination modes;[9] b) the departure of carboxyl groups from the plane of the imidazole ring may allow 4,5-imidazoledicarboxylate to be used for the construction of helical structures; c) its six potential coordination donors allow the formation of interesting higher-dimensional structure. To the best of our knowledge, transition metal complexes of 4,5-imidazoledicarboxylate are usually either mononuclear,[10,11] dinuclear,[12] a 1D chain,[13,14] or a 2D layered network;[15] no 3D open framework is known. The typical coordination modes of 4,5-imidazoledicarboxylate anions are summarized in Scheme 1 (a–i). Herein, we report the synthesis, crystal structure, and magnetic properties of the first 3D coordination polymer of manganese with multidentate IMDC as ligand and linker, namely $[Mn_3(IMDC)_2(H_2O)_4]$ (**1**).

## Results and Discussion

### Synthesis and Structure

As a few high dimensional coordination polymers of 4,5-imidazoledicarboxylic acid ($H_3IMDC$) have already been documented, we aimed to assemble the IMDC ligands and manganese ions into polymers with an open framework. In general, $H_3IMDC$ is insoluble in water under neutral or acidic conditions at room temperature and is difficult to deprotonate under acidic conditions, which makes the construction of high-dimensional complexes difficult. In addition, although the sodium salt of 4,5-imidazoledicarboxylate is soluble in water, it easily forms precipitates, rather than crystals, in the presence of manganese ions. Taking into account the above two aspects, we chose the insoluble manganese salt $MnCO_3$ as starting material, with an $H_3IMDC/MnCO_3$ molar ratio of 2:1, and heated the mixture hydrothermally at 175 °C for 15 days, expecting that the insoluble $MnCO_3$ should slow the reaction down and allow the $H_3IMDC$ time to deprotonate. We also carried

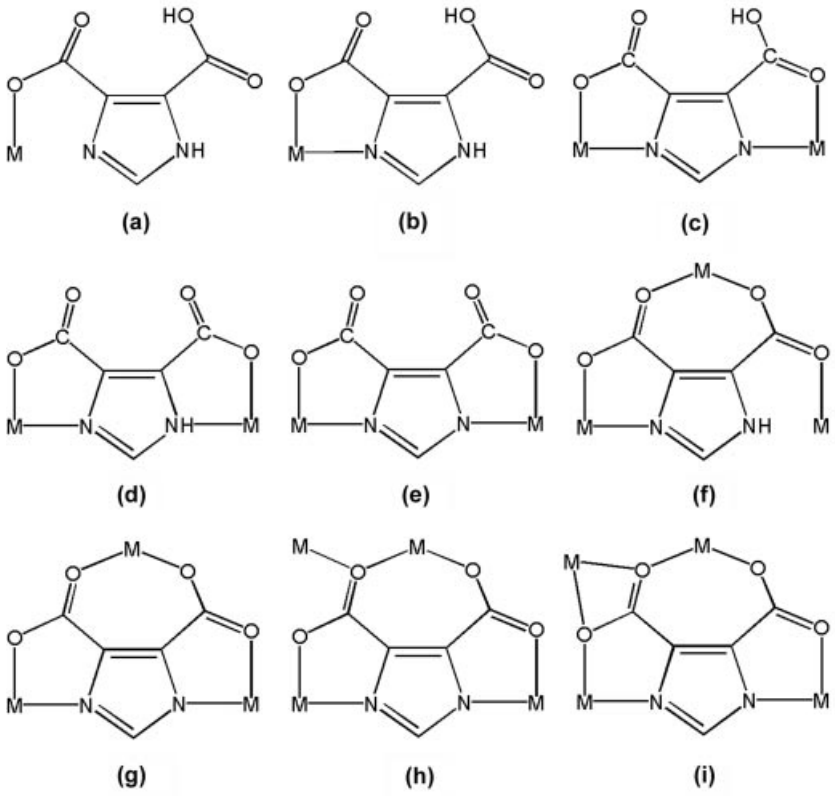

Scheme 1. Typical coordination modes of the IMDC ligand.

out the same reaction in a period shorter than 10 days, but no crystals were obtained. Thus, the slower rate and longer time may be crucial factors for the crystallization of **1**.

X-ray analysis revealed that the asymmetric unit consists of two crystallographically independent $Mn^{2+}$ centers, one IMDC ligand, and two coordinated water molecules (Figure S1, see Supporting Information). The coordination mode of the IMDC in **1** is illustrated in Scheme 1 (h) and Figure S2 in the Supporting Information. The coordination environments of the Mn(1) and Mn(2) atoms and the IMDC ligand in the symmetric unit are presented in Figure 1. Both Mn(1) and Mn(2) are six coordinated to form two octahedra, $Mn(1)NO_4(H_2O)$ and $Mn(2)N_2O_2(H_2O)_2$. In the $Mn(1)NO_4(H_2O)$ moiety the six donors are one N atom of an imidazole ring, one water molecule, and four O atoms of four carboxylate groups, with one in mode A, two in mode B, and one in mode C (Scheme 1), while in $Mn(2)N_2O_2(H_2O)_2$ the donors are two N atoms from two IMDC ligands, two water molecules, and two O atoms of two carboxylate groups (mode A). As for the IMDC ligand, the carboxyl groups bonds to four Mn atoms in four different coordination modes:[16] a $\mu_2$-carboxylato-*syn-anti* mode for Mn(1)–O(1)–C(1)–O(2)–Mn(1d), a $\mu_2$-carboxylato-*anti-anti* mode for Mn(1)–O(1)–C(1)–O(2)–Mn(1e), a $\mu_2$-carboxylato-*anti-anti* mode for Mn(2)–O(4)–C(4)–O(3)–Mn(1e), and a bis($\mu_2$,$\eta^1$-carboxylato) mode for Mn(1d)–O(2)–Mn(1e) (see Figure S2).

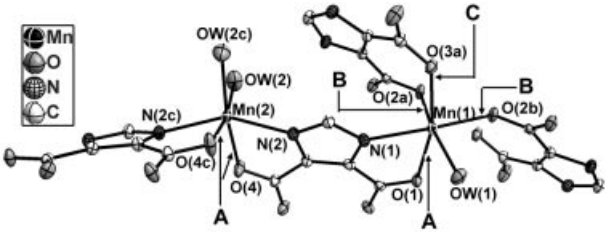

Figure 1. ORTEP drawing (ellipsoids at 50% probability) with the atom-labeling scheme for the symmetric unit of complex **1**. The labels "a" or "b" refer to symmetry-generated atoms and the labels "A", "B", and "C" refer to the different binding modes of the carboxylate groups of then IMDC ligand.

Although both Mn(1) and Mn(2) are six-coordinate, the different coordination environments around them result in an Mn(1) dimer and Mn(2) monomer (Figure S3). In the dimer, the O(2) atom from a mode-B carboxylate group bonds two Mn(1) centers to form the dimeric unit $Mn_2(IMDC)_2(H_2O)_2$ [Mn(1)–O(2) = 2.169 Å] whose Mn···Mn distance is 3.477 Å; the O–Mn–O angle in the $Mn_2O_2$ ring is 75.46°, while the Mn–O–Mn angle is 104.54°. These values fall in the range of similar dinuclear manganese complexes.[17–19] In the structure, each $Mn_2(IMDC)_2(H_2O)_2$ dimer further connects to adjacent dimeric units through O(1) from a mode-A carboxylate group and N(1) atoms to form a 2D layer in the *ab* plane (Figures 2 and 3).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

It is worth noting the presence of left- and right-handed helical chains consisting of repeating –Mn(1)–O(2)–C(1)–O(1)– linkages in the layer along the [100] direction (Figures 3 and S4). O(4) from a mode-A carboxylate group and the N(2) atoms coordinate to the Mn(2) center to give rise to the 3D open framework (Figures 4 and S5). In other words, the Mn(1) centers mainly contribute to constructing the layers together with IMDC ligand, while the Mn(2) centers act as pillars between the layers.

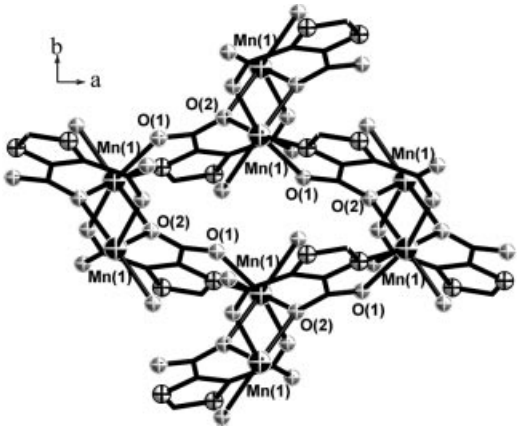

Figure 2. Layer containing $Mn_2(IMDC)_2(H_2O)_2$ dimers.

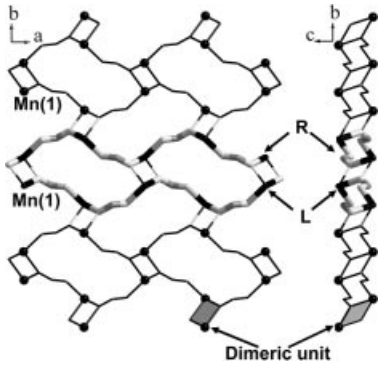

Figure 3. View of the layer constructed by $Mn_2(IMDC)_2(H_2O)_2$ dimers along the *c* and *a* axis; the imidazole rings of IMDC ligands have been omitted for clarity; L and R indicate the left- and right-handed helical chains. The thick, two-colored line represents the helical chains in the *ab* plane.

The $H_3IMDC$ is completely deprotonated in compound **1**, and all six potential donor atoms coordinate to four Mn centers through coordination mode h of Scheme 1, which plays a key role in constructing the 3D framework of **1** (Figure S1). The previously reported coordination modes of the IMDC ligand, i.e. modes a and b of Scheme 1, can only coordinate to one metal center, thus monomers are the favorable entity to accommodate them.[10,11] As for coordination modes c, d, and e, they can link two metal centers through two chelating five-membered rings on the opposite side of the imidazole group to form a linear bridge. For example, if the IMDC ligands connect the metal centers along one direction, chain-like structures are formed as in [Mn(phen)(HIMDC)][13] and $[Cd(HIMDC)(H_2O)_2]$[14] (Figure S6a), whereas if the ligands connect the metal

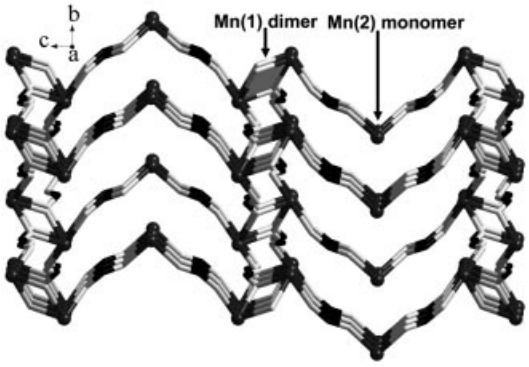

Figure 4. View of the 3D framework constructed by 2D layers containing Mn(1) atoms and pillars consisting of Mn(2) atoms.

centers perpendicularly, a square tetramer, as in $[Na_2\{Co^{II}_2Co^{III}_2(IMDC)_4(bipy)_4\}]\cdot 12H_2O$[20] (Figure S6b) or a cubane-like $[Ni_8(HIMDC)_{12}]^{8-}$ cluster unit, as in $[Ni_8(HIMDC)_{12}(H_2TMDP)_4(DMF)_4(EtOH)_4(H_2O)_6]$[21] (Figure S6c) are formed. Mode f in Scheme 1 tends to yield a 2D layered network.[15] In the structures of a series of lanthanide complexes $[Ln_2(IMDC)_2(H_2O)_3]\cdot nH_2O$,[9] the IMDC ligands displays modes g and i: in the g mode they connect three lanthanide atoms to form a 1D helical channel, while in the i mode they contribute to connecting the helical channels to form a 3D framework. From the above discussion, we can conclude that multidentate modes of the IMDC ligand, such as g, h, and i, benefit the formation of higher-dimensional frameworks.

### IR Spectrum and Thermal Stability Analysis

The absence of any strong bands around 1700 $cm^{-1}$ in the IR spectrum of **1** indicates that 4,5-imidazoledicarboxylic acid has been completely deprotonated to generate $IMDC^{3-}$ anions. The sharp bands in the region 1581–1541 $cm^{-1}$ may be attributed to the $COO^-$ asymmetric stretching modes, and the bands at 1384 $cm^{-1}$ are characteristic of the symmetric stretching modes of $COO^-$ (Figure S7). The value of the difference $\Delta(\nu_{as} - \nu_s)$ between the two stretching modes is about 197 $cm^{-1}$, which indicates strong coordination of the carboxylate oxygen to the manganese center. In contrast to **1**, the presence of a medium intensity band in the region 1730–1710 $cm^{-1}$ in the IR spectrum of *cis*-$[Ru(PPh_3)_2(L^3H_2)_2]$ ($L^3H_2 = H_2IMDC$) suggests that the 4,5-imidazoledicarboxylic acid is only partially deprotonated.[22]

The TG curve shows that the structure is stable up to 210 °C, and the weight loss of complex **1** can be divided into three steps in the range 210–1000 °C (Figure S8). The weight loss of 13.5 % during the first step from 210 to 350 °C corresponds to the loss of four coordinated water molecules (calcd. 13.3 %). On further heating, the material loses weight continuously during the second and the third steps, with the combined weight loss of 47.3% (calcd. 47.5%) corresponding to decomposition of the IMDC ligand. Assuming the residue is MnO, the observed weight

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(38.8%) is in good agreement with the calculated value (39.2%).

### Magnetic Properties

Temperature-dependent magnetic susceptibility measurements for complex **1** were performed over a temperature range from 5 to 300 K at 5 kOe. The magnetic susceptibility above 6 K obeys the Curie–Weiss law and gives a Curie constant, $C$, of 13.6 $cm^3 K mol^{-1}$ and a Weiss constant, $\theta$, of –14.1 K. The value of $C$ is in agreement with that expected for three magnetically isolated $Mn^{2+}$ ions with $S = 5/2$ (13.1 $cm^3 K mol^{-1}$; $g = 2$). Upon cooling, the value of $\chi_M T$ decreases monotonically, attaining a value of 3.0 $cm^3 K mol^{-1}$ at 5 K. Such behavior is characteristic of the presence of weak antiferromagnetic interactions between the neighboring $Mn^{2+}$ ions (Figure 5).

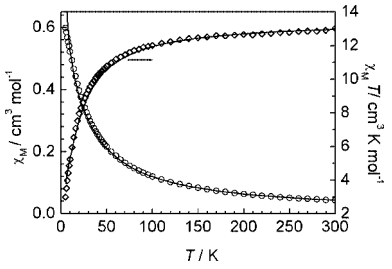

Figure 5. Plot of the $\chi_M T$ product and $\chi_M$ versus $T$ for complex **1**. The solid lines represent the best fit to the model with inclusion of the ZFS term.

From the known structural data, there are four types of Mn···Mn exchange pathways via the carboxylate groups in the structure (Figure S2). As the Mn···Mn distance of 3.477 Å within the bis($\mu_2$,$\eta^1$-carboxylato)-bridged bimetallic $Mn_2O_2$ core is much shorter than the Mn···Mn separations of 5.60–6.52 Å through $\mu_2$-1,3-carboxylato modes (in *anti-anti*/*syn-anti*) or an IMDC bridge, and the latter is generally less capable of transmitting magnetic interactions,[13,23–26] we can simplify the coupling interaction system as a doubly $\mu_2$,$\eta^1$-carboxylato-bridged dimeric manganese combining an isolated $Mn(2)^{2+}$ ion. The magnetic behavior of the compound is therefore approximated by the sum of the contributions of one $Mn^{2+}$ dimer (Bleaney–Bowers-like equation based on the isotropic Heisenberg model $H = -2JS_1 \cdot S_2$)[27] and one isolated $Mn^{2+}$ ion, in which a Weiss constant, $\theta'$, is included to describe the interdimer interactions and the exchange coupling between Mn1 and Mn2 is neglected. The corresponding analytical expression for the $\chi_M T$ product is given as follows [Equations (1), (2), and (3)].

$$\chi_M T = \chi_{dimer} T + \chi_{mono} T \quad (1)$$

where

$$\chi_{dimer} = \frac{2Ng^2\beta^2}{k(T-\theta)} \times \left[ \frac{e^x + 5e^{3x} + 14e^{6x} + 30e^{10x} + 55e^{15x}}{1 + 3e^x + 5e^{3x} + 7e^{6x} + 9e^{10x} + 11e^{15x}} \right]$$

$$x = 2J/kT \quad (2)$$

and

$$\chi_{mono} = \frac{Ng^2\beta^2 S(S+1)}{3kT} \quad (3)$$

in which $N$, $g$, $k$, and $\beta$ have their usual meanings, and $J$ is the exchange coupling constant between the doubly $\mu_2$,$\eta^1$-carboxylato-bridged manganese ions. The fitting using Equation (1) gave a satisfactory result above 10 K with the superexchange parameters $J = -1.34\ cm^{-1}$, $\theta' = -7.40$ K, and $g = 2.03$. The agreement factor $R$, defined as $\Sigma[(\chi_M T)_{obs} - (\chi_M T)_{calc}]^2/\Sigma(\chi_M T^2_{obs})$ is equal to $1.85 \times 10^{-3}$. These values confirm the antiferromagnetic character of the magnetic interaction between the $Mn^{2+}$ ions via double $\mu_2$,$\eta^1$-carboxylato bridges. The deviation below 10 K may arise from the neglect of the coupling interactions involving the Mn(2) ion or its zero-field splitting (ZFS).

When the zero-field splitting ($D$) of the Mn(2) ions is considered by using the theoretical expression[28] for an $S = 5/2$ spin instead of Equation (3), a better agreement between the observed and calculated $\chi_M T$ value at low temperature is found with the four-parameter fits than with the three-parameter fit. However, the parameters $D$ and $\theta'$ are strongly dependent on each other, therefore it is difficult to calculate these values with reasonable accuracy. If the values of $J$, $g$, and $\theta'$ are constrained to the value obtained by the simplified expression based on Equations (2) and (3), the best fitting based on the model with inclusion of ZFS term yields $D = 7.89\ cm^{-1}$ with $R = 5.4 \times 10^{-4}$. The $D$ value is obviously larger than those observed in similar systems,[29,30] suggesting that there are still some disparities between the present magnetic model and the actual magnetic interaction system. The small $J$ value ($-1.34\ cm^{-1}$) indicates weak antiferromagnetic coupling in the dimeric units of complex **1**, which is comparable to the values found in the doubly $\mu_2$,$\eta^1$-carboxylato-bridged manganese complexes ($-0.631$ to $-0.942\ cm^{-1}$).[19,25] Due to a shorter Mn···Mn distance (3.477 Å), the $J$ value of **1** is slightly larger than those of the above mentioned manganese complexes (3.67–3.73 Å).

## Conclusion

In summary, we have synthesized a novel 3D Mn-IMDC coordination polymer under hydrothermal conditions. The structure is constructed from $[Mn(H_2O)_2]$ pillars and $[Mn_2(IMDC)_2(H_2O)_2]$ layers containing left- and right-handed helical chains. The 4,5-imidazoledicarboxylic acids are completely deprotonated and adopt coordination mode h of Scheme 1. Compared with the coordination modes shown in this scheme, mode h allows the 4,5-imidazoledicarboxylate ligand to form a high dimensional framework. The TG curve shows **1** is very stable below 210 °C and the magnetic measurement of **1** indicates the presence of weak antiferromagnetic exchange interactions.

## Experimental Section

**General Remarks:** 4,5-Imidazoledicarboxylic acid ($H_3IMDC$) and $MnCO_3$ were purchased from commercial sources and used as received. Elemental analysis (C,H,N) was carried out with a Vario EL III elemental analyzer. IR spectra (400–4000 $cm^{-1}$) were recorded from KBr pellets on an ABB Bomem IR MB102 series spectrophotometer. The thermogravimetric analysis was performed with a Mettler Toledo TGA/SDTA 851e analyzer in $N_2$ with a heating rate of 10 °C $min^{-1}$ from 30 to 1000 °C. The variable-temperature magnetic susceptibility measurement of a crystalline sample was performed in a field of 5 kOe with a Quantum Design MPMS-7 magnetometer; the susceptibility of the sample holder and diamagnetic contribution were subtracted from the raw data for the complexes.

**Synthesis and Initial Characterization:** A mixture of $H_3IMDC$ (0.2341 g, 1.5 mmol), $MnCO_3$ (0.0862 g, 0.75 mmol), and $H_2O$ (5 mL; $MnCO_3/H_3IMDC/H_2O$ molar ratio of 1:2:370) was stirred under ambient conditions. The resulting mixture with a pH of 4 was sealed in a 25-mL Teflon-lined steel autoclave and heated at 175 °C for 15 d under autogenous pressure. After cooling to room temperature, the colorless prismatic crystals of **1** were filtered off, washed with distilled water, and dried at ambient temperature (39 mg, yield 28.7% based on $MnCO_3$). $C_{10}H_{10}Mn_3N_4O_{12}$ (543.04): calcd. C 22.12, H 1.86, N 10.33; found C 22.20, H 2.01, N 10.35. IR (KBr pellet): $\tilde{\nu}$ = 3542 (s) $cm^{-1}$, 3280 (s), 1662 (m), 1581 (s), 1515 (vs), 1409 (vs), 1384 (vs), 1276 (m), 1241 (s), 1107 (m), 1099 (m), 803 (m), 671 (m).

**X-ray Crystallographic Study:** A crystal of dimensions $0.35 \times 0.18 \times 0.15$ $mm^3$ was used for data collection on a Siemens Smart CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Of the 8895 reflections ($2\theta_{max}$ = 50.04°), 1422 were independent ($R_{int}$ = 0.0199) and 1396 reflections with $I > 2\sigma(I)$. The structure of **1** was solved by direct methods and all calculations were performe with the SHELXL program and refined by full-matrix, least-squares minimizations of $(F_o - F_c)^2$ with anisotropic thermal parameters for all non-hydrogen atoms. The position of the hydrogen atoms were found in the difference Fourier maps and refined isotropically. The last successful full-matrix least-squares refinement with anisotropic thermal parameters for all non-hydrogen atoms converged to $R_1$ = 0.0226, $wR_2$ = 0.0640. Experimental details for X-ray data collection of **1** are presented in Table 1, while selected bond lengths and angles are listed in Table 2.

# The Role of Anions in Addressing the Outcome of the Reaction of Tetramethylthiourea with *cis*-$Pt^{II}(phos)_2$ Moieties (phos = $PPh_3$ or ½dppe), Cyclometallation vs. Hydrolysis to Monothiocarbamato, and the Crystal Structure of *trans*-Bis(*N*-dimethylmonothiocarbamato)bis(triphenylphosphane)-platinum(II)

**Maria Alesi,[a] Serena Fantasia,[a] Mario Manassero,*[b] and Alessandro Pasini*[a]**

**Keywords:** Carboxylate ligands / Phosphane ligands / Ligands reactivity

The product of the reaction between tetramethylthiourea (tmtu) and *cis*-$Pt^{II}(phos)_2$ moieties (phos = $PPh_3$, or ½ dppe) depends on the anionic species present. With $NO_3^-$, $CF_3CO_2^-$, $CF_3SO_3^-$ and $BF_4^-$, the cyclometallate cationic complex $[Pt(phos)_2(tmtu^*\text{-}C,S)]^+$ is obtained (tmtu* is tmtu deprotonated at one methyl group). The acetato and malonato complexes are inactive towards such deprotonation, but, in the presence of water, promote tmtu hydrolysis with formation of *N*-dimethylmonothiocarbamato (mtc) complexes in which mtc is *S*-coordinated. *cis*-$[Pt(PPh_3)_2(mtc)_2]$ isomerises slowly to the *trans* isomer, whose crystal structure is reported.

## Introduction

A knowledge of the factors that influence the reactivity of coordinated ligands is of great importance in coordination and organometallic chemistry. Here we wish to report that the proper choice of anionic ligands may affect the outcome of the reaction between tetramethylthiourea (tmtu) and *cis*-$Pt^{II}(phos)_2$ moieties (phos = $PPh_3$ or ½ dppe).

We have recently found that the reaction of *cis*-$[Pt(PPh_3)_2(NO_3)_2]$ (**1**) with tmtu does not give the disubstituted product *cis*-$[Pt(PPh_3)_2(tmtu)_2]^{2+}$, but that the initially formed *cis*-$[Pt(PPh_3)_2(NO_3)(tmtu)](NO_3)$ (**2**) transforms into the cyclometallated complex $[Pt(PPh_3)_2(tmtu^*\text{-}C,S)](NO_3)$ (**3**) [tmtu*, tetramethylthiourea deprotonated at one methyl group], with formation of nitric acid (Scheme 1).[1] This reaction, performed at room temperature in either chloroform or $CH_2Cl_2$, was found to be unaffected by both air and water, which, in some experiments, was purposely added to extract the nitric acid formed during the reaction.[1]

Such facile cyclometallation is clearly favoured by the lability of the nitrate ion *cis* to tmtu in **2**; detachment of this ionic ligand produces a vacant coordination site which can interact with a C–H bond of a methyl group of tmtu, activating the bond towards deprotonation.[2,3] The proton is then captured by a "free" (i.e. uncomplexed) $NO_3^-$ ion to give nitric acid.[1] In order to better understand the role of the anion either as a ligand, or as a base, we decided to investigate the reaction of tmtu with a series of other *cis*-$Pt^{II}(PPh_3)_2$ complexes with various anionic ligands and we found that the product of the reaction depends on the nature of the anions present. Thus, while cyclometallation also occurs with *cis*-$[Pt(PPh_3)_2(CF_3CO_2)_2]$ (**4**) and *cis*-$[Pt(PPh_3)_2(CH_3CN)_2]X_2$ (**5a**, X = $BF_4^-$; **5b**, X = $CF_3SO_3^-$, TfO), the reaction of tmtu with *cis*-$[Pt(PPh_3)_2(AcO)_2]$ (**6**) and $[Pt(PPh_3)_2(malonato)]$ (**7**) follows a completely different route: these anionic ligands promote tmtu hydrolysis, giving rise to the dimethylmonothiocarbamato (mtc) complexes

*cis*-[Pt(PPh$_3$)$_2$(mtc)$_2$] (**8**) and *trans*-[Pt(PPh$_3$)$_2$(mtc)$_2$] (**9**). The Pt$^{II}$(dppe) complexes behave similarly. We report here these studies, as well as the X-ray structure of *trans*-[Pt(PPh$_3$)$_2$(mtc)$_2$] (**9**). Although the structure of a phosphane-Pd$^{II}$ complex of mtc has been reported,[4] to the best of our knowledge this is the first X-ray structure of a Pt-mtc derivative. Dialkyldithiocarbamato-Pt complexes are well known,[5] but there are very few reports on Pt-mtc complexes,[4,6] and indeed mtc complexes have been little studied,[7] a possible reason being the unpleasant synthesis of the mtc$^-$ ligand, which requires the use of carbonyl sulfide.[6] The hydrolysis reaction reported here may therefore represent an easy route to Pt-mtc complexes.

## Results and Discussion

### Cyclometallation versus Hydrolysis: the Role of the Anions

While *cis*-[Pt(PPh$_3$)$_2$(CF$_3$CO$_2$)$_2$] (**4**) is a known compound,[8] $BF_4^-$ and $TfO^-$ have a rather poor complexing ability, therefore we have synthesised the salts of these anions with *cis*-[Pt(PPh$_3$)$_2$(CH$_3$CN)$_2$]$^{2+}$, **5a** and **5b**, respectively. Reactions of tmtu with these three complexes, in $CH_2Cl_2$ solutions, give the corresponding salts of the cationic cyclometallated complex **3**, which were characterised by elemental analyses and by comparison of their NMR spectra with those of the already described nitrate derivative.[1] When the reactions between tmtu and compounds **5** were followed by $^{31}$P NMR spectroscopy, we observed, in both cases, the fast formation of a species **10**, which shows two doublets (Table 1), consistent with one phosphane *trans* to an S ligand ($\delta$ = 13.7 ppm; $J_{Pt-P}$ = 2890 Hz, compared with, for instance, ref.[9]) and one *trans* to $CH_3CN$ ($\delta$ = 7.6 ppm; $J_{Pt-P}$ = 3839 Hz, compared with the data for **5**). The $^1$H NMR spectrum displays a peak at $\delta$ = 3.30 ppm, which integrates for 12 protons, and a singlet at $\delta$ = 2.00 ppm (three protons). We therefore conclude that **10** is *cis*-[Pt(PPh$_3$)$_2$(CH$_3$CN)(tmtu)]$^{2+}$. The TfO salt of this intermediate evolves to **3**(TfO) in a few hours, whereas such a conversion is much slower for the $BF_4$ derivative (>24 h). A fast conversion of **10**($BF_4$) to **3**($BF_4$) can be achieved by heating the solution at 40 °C or, rather interestingly, also at room temperature by addition of $(Et_4N)NO_3$ to the solution, which shows the high activity of nitrate anions in the cyclometallation reaction (Scheme 2).

When we investigated *cis*-[Pt(PPh$_3$)$_2$(AcO)$_2$] (**6**) in the initial runs, we did not use anhydrous conditions, since, as explained in the Introduction, cyclometallation of tmtu is not affected by the presence of water.[1] However, to our surprise, the reaction of **6** with tmtu did not afford **3**, but a mixture, which, according to $^{31}$P NMR spectroscopy (Table 1), contains essentially two products **8** and **9** (minor component), with no detectable signal from **3**. Slow diffusion of hexane into a $CH_2Cl_2$ solution of this mixture gave crystals, which were found to be *trans*-[Pt(PPh$_3$)$_2$(mtc)$_2$] through X-ray analysis, see below. A $CDCl_3$ solution of these crystals produced a $^{31}$P NMR spectrum consistent with that of **9**.

Compounds **8** and **9** were also obtained by reaction of tmtu with the malonato complex **7**.

Table 1. $^{31}$P and relevant $^1$H NMR spectroscopic data.[a]

### Structure and Characterization of *trans*-[$Pt(PPh_3)_2(mtc)_2$] (9)

The structure consists of the packing of [$Pt(PPh_3)_2(mtc)_2$] molecules with normal van der Waals contacts. An ORTEP[10] view of the complex is shown in Figure 1, while selected bond lengths and angles are reported in Table 2. The metal ion is four-coordinate square planar, with two mutually *trans* phosphane groups and two *trans* mtc anions that are monodentate and coordinated through their sulfur atoms. The planarity around Pt is rigorous, since this atom lies on a crystallographic inversion centre. The mtc ligand is essentially planar, with maximum deviations from the least-squares plane of +0.033(1) Å for S and –0.037(3) Å for C(3). The Pt–P bond length [2.316(1) Å] is comparable with values found in other *trans*-$Pt(PPh_3)_2$ complexes.[11,12] To the best of our knowledge, no Pt-mtc complex has ever been structurally characterised, however, we note that the Pt–S bond length in **9** is in the range of those found in the few instances of monodentate dialkyldithiocarbamate complexes of $Pt^{II}$.[13] In particular, a compound analogous to **8**, *trans*-[$Pt(PMe_2Ph)_2$(dttc-*S*)$_2$], displays a very similar Pt–S distance [2.335(2) Å].[14] The dihedral angle between the mtc best plane and the metal coordination plane is 68.0(5)° and can be compared with that of the analogous *trans*-[$Pd(PPh_3)_2$(*N*-dipropylmonothiocarbamato)$_2$].[4] Bond lengths within the thiocarbamato ligand are also similar.[4]

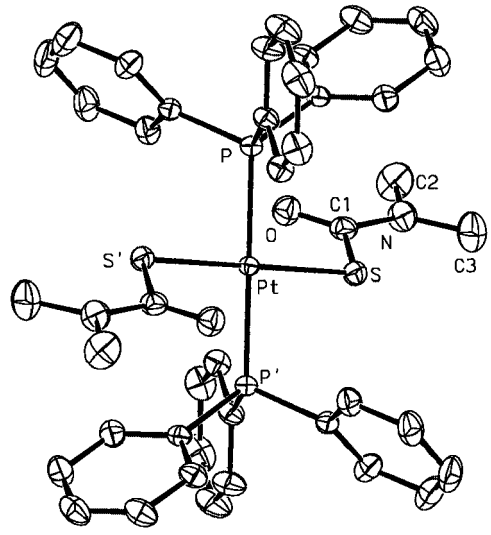

Figure 1. ORTEP view of complex**9**. Ellipsoids are drawn at the 30% probability level.

The NMR spectroscopic data of **9** are reported in Table 1. Note the rather high Pt–P coupling constant, which in *trans*-$Pt^{II}(PPh_3)_2$ complexes is usually in the 2500–3000 Hz range; higher values have, however, also been reported.[12,15] The $FAB^+$ mass spectrum of **9** (see Experimental section) shows only a weak peak (ca. 5%) corresponding to $[M]^+$; the most abundant peaks are due to $[Pt(PPh_3)_2(SCO)_2]^+$ and $[Pt(PPh_3)_2(mtc)]^+$. This behaviour seems characteristic of these phosphane mtc complexes.

Table 2. Selected bond lengths [Å] and angles [°] for **9**, with estimated standard deviations in parentheses.

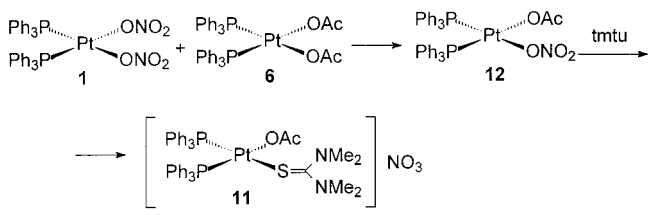
### Mechanistic Studies

When the reaction between tmtu and **6** was followed by $^{31}P$ NMR spectroscopy, we observed the fast formation of two main species, **8** and **11**. The resonances due to **11** diminish with time, and after 4 hours at room-temperature, the spectrum shows only peaks from **8** and **9**. The concentration of **9** increases on standing, although at a very slow rate (weeks); it is therefore likely that isomerisation occurs after hydrolysis. Isolation of the *trans* isomer **9** as a pure sample is due to its lower solubility in the crystallisation procedure.

As for the intermediate **11**, NMR spectroscopic data (see Table 1) suggest the formula *cis*-[$Pt(PPh_3)_2$(AcO)(tmtu)](AcO). In fact, tmtu is still present as such (i.e. not yet hydrolysed), as shown by the presence in the $^1H$ NMR spectrum of a peak at $\delta$ = 2.71 ppm, which integrates for 12 protons. As for the $^{31}P$ NMR spectrum, the Pt–P coupling constant of the doublet at $\delta$ = 17.2 ppm (3246 Hz) is in accordance with a P atom *trans* to an S ligand,[1,9] while the doublet at $\delta$ = 6.82 ppm ($J_{Pt-P}$ = 3979 Hz) is assigned to P *trans* to the acetato moiety (compared with $\delta$ = 5.72 ppm, $J_{Pt-P}$ = 3826 Hz in **6**). In order to prove the assignment of **11**, we performed the following experiment. We mixed, in $CH_2Cl_2$, equimolar quantities of **1** and **6**, obtaining the fast equilibration of these two materials with a new species **12** in the ratio 1:1:3. The two doublets shown in the $^{31}P$ NMR spectrum of this new species are in agreement with two phosphane groups *trans* to the $NO_3$ and AcO ligands (Table 1, $\delta$ and $J_{Pt-P}$ values of **12** compared with those of **1** and **6**). Since no other ligand is present, **12** must be *cis*-[$Pt(PPh_3)_2$(AcO)($NO_3$)]. Upon addition of one mole of tmtu per mole of Pt, we obtained a compound with the same NMR parameters as **11**, as the only species in solution (Scheme 3).



Scheme 3.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

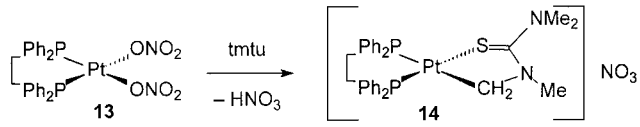
The latter solution is stable (>1 day), i.e. no hydrolysis was observed, even in wet $CH_2Cl_2$. Because no "free" (i.e. uncomplexed) acetate is present, it is concluded that it is this ion that triggers the hydrolysis reaction. It must be noted that in this experiment, **11** was obtained as the nitrate salt, but no cyclometallation was observed, despite the presence of free $NO_3^-$, which, according to the results described in a previous section, should promote such a reaction. However, the C–H activation step of the cyclometallation process requires a labile ligand that is *cis* to tmtu.[1–3] In **11**, this position is occupied by an acetato group that is *trans* to a phosphane group, a situation that, because of the antisymbiosis effect,[16] renders a carboxylato ligand rather inert to substitution,[17] as we have recently observed.[18]

Characterisation of **8** presents the problem that it could not be isolated in a pure form, as a result of contamination with **9**. Only after repeated crystallisations could a few milligrams of a pure sample of **8** be obtained, which is just enough for mass and NMR spectroscopy. The $^{31}P$ NMR parameters of **8** [a singlet with Pt–P coupling constant in the 3200 Hz range (Table 1)] are indicative of a *cis*-$PtP_2S_2$ coordination set, i.e. two equivalent phosphane groups *trans* to sulfur ligands.[9] Moreover, the peak at $\delta$ = 3.21 ppm in the proton spectrum integrates for 12 protons. These facts suggest the formula *cis*-[$Pt(PPh_3)_2(mtc)_2$] for **8**. A final confirmation of its stoichiometry was obtained by a high resolution $ESI^+$ spectrum, which showed a peak that corresponds to $[M + Na]^+$ (100%) and whose position differs by only 1 ppm from that computed. Fragmentation is similar to that of **9** (see Experimental Section).

In conclusion, the course of the hydrolysis reaction is summarised in Scheme 4.

Because **8** was always contaminated with the *trans* isomer, and to avoid the problem of *cis–trans* isomerisation, we decided to investigate the dppe derivatives.

First of all we wanted to check whether reaction of [$Pt(dppe)(NO_3)_2$] (**13**) with tmtu gives, in analogy with **1**, the cyclometallated product [Pt(dppe)(tmtu*)]($NO_3$) (**14**). This was indeed obtained, although at a much slower rate than in the case of **1**. Compound **14** was isolated and characterised by elemental analysis, $^1H$ and $^{31}P$ NMR spectroscopy (see Table 1). Not only are the Pt–P coupling constants in agreement with a P atom *trans* to a carbon atom and a P atom *trans* to an S ligand, but, more importantly, in the $^1H$ NMR spectrum, the resonances resulting from tmtu* are also very similar to those of **3**. In particular, the signal centred at 4 ppm, which integrates for 2 protons and displays Pt–H coupling (54.4 Hz), is assigned to Pt–$CH_2$ (Scheme 5).



Scheme 5.

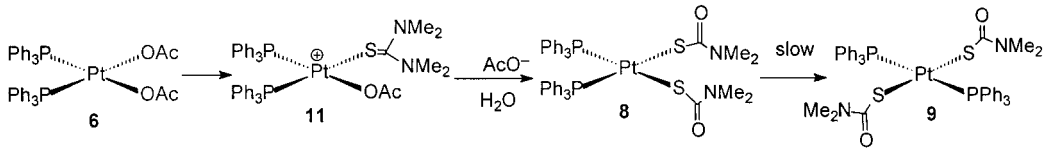
We then moved on to [$Pt(dppe)(AcO)_2$] (**15**). Reaction of this compound with tmtu led to the isolation of [$Pt(dppe)(mtc)_2$] (**16**) as a pure product. Besides elemental analysis and mass spectroscopy (see Experimental Section), its identification is confirmed by NMR spectroscopy (Table 1): a $^1H$ singlet which integrates for 12 protons and one $^{31}P$ singlet with $J_{Pt-P}$ in accordance with a P atom *trans* to an S atom. On the basis of comparing the Pt–P coupling constants, and by remembering that in the case of the dppe derivatives such constants are usually about 100 Hz lower than those of the analogous $PPh_3$ complexes,[19] we can confirm the assignment of the structure *cis*-[$Pt(PPh_3)_2(mtu)_2$] to **8**.

The above results show that the course of the reaction between these Pt–phosphane complexes and tmtu depends on the nature of the anion and the lability of the ligand in the position *cis* to tmtu. Thus, even in the presence of water, no hydrolysis of tmtu was observed with the nitrato and trifluoroacetato complexes as well as with compounds **5a** and **5b**; the only product is the cyclometallated species. On the contrary, with the acetato and malonato derivatives, cyclometallation seems to be inhibited, and, in the presence of water, tmtu is hydrolysed and the mtc complexes **8**, **9** and **16** are formed. To better clarify these points we performed the following experiments.

First, under strictly anhydrous conditions, no reaction was observed between tmtu and **6**, which was recovered unchanged after 4 hours. Addition of water, or allowing humidity to enter the reaction vessel by opening it, produced the monothiocarbamato complexes **8** and **9**, showing that water not only hydrolyses tmtu, but also, rather interestingly, that it has an active role in labilising the Pt–acetato bonds.

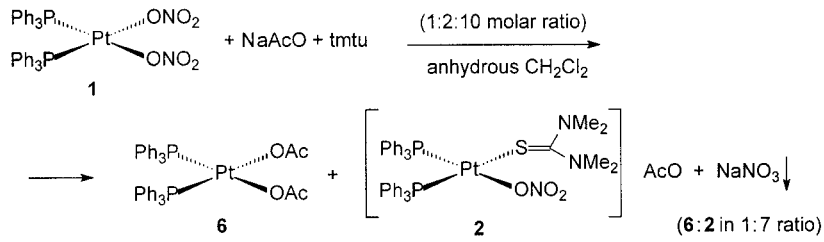
Second, again under anhydrous conditions, we mixed, in $CH_2Cl_2$, **1**, tmtu and NaAcO in the molar ratio 1:2:10. This led to the precipitation of $NaNO_3$ and to the formation of a 1:7 mixture of **6** and the acetato salt of **2** (Scheme 6).

The formation of **2** was easily recognised by NMR spectroscopy, since its nitrate salt is already known, as it was the intermediate species that was detected during the cyclometallation reaction of tmtu with **1**.[1] While this mixture is stable for more than one day, it slowly transforms into **11**.



Scheme 4.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 6.

However, before such a transformation takes place, not only does no hydrolysis occur (no water is present), but also no cyclometallation is observed. This experiment confirms that the latter reaction is promoted by the presence of "free" nitrate and not by acetate; the promotion by free nitrate must be ruled out under these conditions as $NaNO_3$ is insoluble in $CH_2Cl_2$. When this experiment was repeated using wet $CH_2Cl_2$, tmtu was hydrolysed, as expected.

## Conclusions

We have shown that the interaction of tmtu with the *cis*-$Pt^{II}(phos)_2$ moieties can follow two different reaction paths according to the nature of the anions present. Thus $NO_3^-$, $CF_3CO_2^-$, $BF_4^-$ and $TfO^-$ lead to the cyclometallated products **3** or **14**, whereas $AcO^-$ and malonate are inactive and, in the presence of water, promote tmtu hydrolysis to give the mtc complexes **8**, **9** and **16**. The two reaction routes are not competitive: no hydrolysis occurs with the former anions and no cyclometallation is observed with the acetato and malonato complexes. As to the origin of the different behaviour, we note the following points.

Cyclometallation requires intermediate cationic complexes, such as **2** or **10**, in which *S*-coordinated tmtu is *cis* to a labile ligand (here $NO_3$, $CF_3CO_2$, $CH_3CN$). Dissociation of these ligands gives rise to a vacant coordination site in the position *cis* to tmtu, which through a σ C–H interaction with the metal centre is a key step in the C–H activation process.[2,3] On the contrary, an acetato group *cis* to tmtu and *trans* to a phosphane group, as in **11**, is less prone to substitution because of the antisymbiosis effect.[16–18] In the latter cationic complex, a methyl group of *S*-coordinated tmtu cannot interact with Pt and tmtu is activated towards nucleophilic attack. However, the function of the "free" anion is less clear; in particular, it is not obvious why deprotonation of a tmtu methyl group (whatever its intimate mechanism) is easily accomplished by $NO_3^-$ and not by $AcO^-$ (see the stability of the acetate salt of **2** in Scheme 6). We propose two possible explanations. First, the relative strengths of protic acids in $CHCl_3$ or $CH_2Cl_2$ cannot be compared with those in aqueous solutions. For instance, spectroscopic evidence suggests that $HNO_3$ is a weak acid (and hence $NO_3^-$ a strong base) in chlorinated solvents, even in the presence of water.[20] Thus $NO_3^-$ can easily capture a proton, favouring deprotonation of a $CH_3$ group. However, the reason why "free" $NO_3^-$ does not induce hydrolysis in the presence of water remains unclear. A second point is that in non-ionising solvents, such as $CHCl_3$ and $CH_2Cl_2$, the anions are not "free", but presumably strongly associated with the cationic complexes that are the intermediate species in both C–H activation (**2**) and hydrolysis (**11**). The different reaction routes reported here may also depend on the degree and the nature of these ion pairs, which, at the present stage, are difficult to rationalise.

Formation of the *trans* isomer **9** deserves a final comment. In all the hydrolysis runs of tmtu with either **6** or **7**, the *cis* isomer **8** was found to be more abundant, but a small amount of **9** was always present. Formation of such *trans* isomers is not surprising. Not only has the analogous Pd complex this geometry,[4] but also it has been reported that complexes with a somewhat similar coordination set, i.e. $[Pt(phos)_2(ER)_2]$ (E = S, Se, Te), crystallise with a *trans* geometry[21] or the initially obtained *cis* complex slowly rearranges to the *trans* isomer, which has been calculated to be more stable.[22] It is tempting to think that the formation of **9** may be associated with the rather large $J_{Pt-P}$ value, an indication of a large σ contribution to the Pt–P interaction, which probably originates from the poor σ-donor ability of S-coordinated mtc groups. Thus, formation of this isomer may arise from a subtle balance between the *trans* and *cis* influence.

## Experimental Section

Elemental analyses were performed at the Microanalytical Laboratory, the University of Milano. $^1H$ and $^{31}P\{^1H\}$ NMR spectra (Table 1) were recorded on a Bruker Advance DRX 300 at 300 and 121 MHz respectively; $\delta$ values (ppm) are vs. external $Me_4Si$ and $H_3PO_4$. Mass spectra were recorded with a VCA Analytical 7070 EQ ($FAB^+$, from nitrobenzyl alcohol, with xenon as the FAB source) and with an ICR-FTMS APEX II with a 4.7-T magnet, Bruker Daltonics ($ESI^+$, $CH_2Cl_2$/methanol, 1:1). Isotope cluster abundance was checked by computer simulation.

All chemicals were reagent grade. Except where otherwise stated, solvents were used as received.

The syntheses of $[Pt(phos)_2(NO_3)_2]$ have been described previously.[5] *cis*-$[Pt(PPh_3)_2(CH_3CN)_2](BF_4)_2$, *cis*-$[Pt(PPh_3)_2(CH_3CN)_2](CF_3SO_3)_2$ and *cis*-$[Pt(PPh_3)_2(CF_3CO_2)_2]$ have been prepared according to literature procedures.[9,23] cis-$Pt[(PPh_3)_2(AcO)_2]$ (**6**), $[Pt(PPh_3)_2(malonato)]$ (**7**) and $[Pt(dppe)(AcO)_2]$ (**15**) were obtained in 75% yields, by a modification of literature methods,[8] using excess sodium acetate or malonate instead of the corresponding silver salts.

**Cyclometallation of tmtu with the Acetonitrile Complexes**

**3($BF_4$):** A $CH_2Cl_2$ solution (20 mL) of **5a** (0.120 g, 0.123 mmol) and tmtu (0.016 g, 0.123 mmol) was refluxed for 4 h. The solution was concentrated to 2 mL under reduced pressure, and addition of ethyl acetate gave 0.087 g of the product (75%). $C_{41}H_{41}BF_4N_2P_2PtS$ (937.68): calcd. C 52.5, H 4.4, N 3.0%; found C 52.8, H 4.7, N 3.2%.

**3(TfO):** This was obtained in a manner similar to that described above from **5a** (0.155 g) and tmtu (0.019 g), but the reaction was performed at room temperature. Yield: 69.4% (0.110 g). $C_{42}H_{41}F_3N_2O_3P_2PtS_2$ (999.94): calcd. C 50.5, H 4.1, N 2.8%; found C 50.2, H 4.3, N 3.0%.

***cis*-[Pt($PPh_3$)$_2$(AcO)(tmtu)]$^+$ (11):** An equimolar amount of tmtu (0.006 g) was added to a solution of [Pt($PPh_3$)$_2$($NO_3$)$_2$] (0.035 g, 0.041 mmol) and [Pt($PPh_3$)$_2$(AcO)$_2$] (0.035 g, 0.041 mmol) in $CH_2Cl_2$ (20 mL). After 6 h at room temperature, the solution was concentrated under reduced pressure. Addition of diisopropyl ether gave a white product. Yield: 0.053 g (65.3%). $C_{43}H_{45}N_3O_5P_2PtS$ (972.93): calcd. C 53.1, H 4.7, N 4.3%; found C 52.8, H 4.6, N 4.3%. The presence of coordinated acetate and ionic nitrate was confirmed by IR spectroscopy (KBr pellets): $\tilde{\nu}$ = 1595 ($\nu_{asym}$ coordinated carboxylate), 1384 (sharp, ionic $NO_3^-$) $cm^{-1}$.

***trans*-[Pt($PPh_3$)$_2$(mtc)$_2$] (9):** A $CH_2Cl_2$ solution (20 mL) of [Pt($PPh_3$)$_2$(AcO)$_2$] (0.060 g, 0.0717 mmol) and tmtu (0.019 g, 0.144 mmol) was left at room temperature for 6 h. After two weeks diffusion of *n*-hexane gave crystals (10 mg) suitable for X-ray investigation. FAB-MS: *m*/*z* (%) = 927 (5) $[M]^+$, 839 (50) $[M - 2\ NMe_2]^+$, 823 (100) $[M - mtc]^+$, 719 (100) $[M - 2\ mtc]^+$.

***cis*-[Pt($PPh_3$)$_2$(mtc)$_2$] (8):** The $CH_2Cl_2$/hexane solution obtained above, after filtration of **9**, was evaporated to 2 mL and filtered. Addition of diisopropyl ether to the filtrate gave a white precipitate, which was found by $^{31}P$ NMR spectroscopy to consist of **9** with an impurity of **8**. Repeated crystallizations gave a few milligrams of pure **8** ($^{31}P$ NMR evidence). FAB-MS: *m*/*z* (%) = 927 (5) $[M]^+$, 839 (80) $[M - 2\ NMe_2]^+$, 823 (80) $[M - mtc]^+$, 719 (100) $[M - 2\ mtc]^+$. ESI-MS: *m*/*z* (%) = 950 (100) $[M + Na]^+$, 928 (5) $[M + 1]^+$, 839 (5) $[M - 2\ NMe_2]^+$, 823 (5) $[M - mtc]^+$. High resolution ESI-MS: calcd. 950.1706 $[M + Na]^+$; found 950.1712.

**[Pt(dppe)(tmtu*)]$NO_3$ (14):** This compound was obtained by refluxing a solution of [Pt(dppe)($NO_3$)$_2$] (0.050 g, 0.07 mmol) and tmtu (0.009 g, 0.07 mmol) for two days. The white product was obtained by addition of diisopropyl ether. Yield: 0.033 g (60%). $C_{31}H_{35}N_3O_3P_2PtS$ (786.72): calcd. C 47.3, H 4.5, N 5.3%; found C 47.0, H 4.9, N 5.6%. FAB-MS: *m*/*z* = 724 $[M - NO_3]^+$.

**[Pt(dppe)(mtc)$_2$] (16):** A solution of [Pt(dppe)(AcO)$_2$] (0.055 g, 0.077 mmol) in $CH_2Cl_2$ (20 mL) and tmtu (0.021 g, 0.155 mmol) was left at room temperature for 4 h and concentrated under reduced pressure. The product was obtained by addition of diisopropyl ether. Yield: 0.054 g (86.8%). $C_{32}H_{36}N_2O_2P_2PtS_2$ (801.80): calcd. C 47.9, H 4.5, N 3.5%; found C 47.5, H 4.3, N 3.8%. FAB-MS: *m*/*z* (%) = 713 (100) $[M - 2\ NMe_2]^+$, 697 (20) $[M - mtc]^+$, 591 (5) $[M - 2\ mtc]^+$. ESI-MS: *m*/*z* (%) = 824 (5) $[M + Na]^+$, 713 (100) $[M - 2\ NMe_2]^+$, 697 (50) $[M - mtc]^+$.

**Reaction of 1 with tmtu and Sodium Acetate:** Sodium acetate (0.039 g 0.476 mmol) was added to a solution of [Pt($PPh_3$)$_2$($NO_3$)$_2$] (0.040 g, 0.048 mmol) and tmtu (0.013 g, 0.055 mmol) in $CH_2Cl_2$ (20 mL). The resulting slurry was vigorously stirred for 4 h at room temperature, and the solvent was evaporated completely under reduced pressure. The $^{31}P$ NMR spectrum of a $CDCl_3$ solution of the residue showed the presence of the monothiocarbamato complexes.

**Reactions under Anhydrous Conditions:** The following reactions were performed under an atmosphere of dry nitrogen, using reagents which had been dried under vacuum for 24 h. $CH_2Cl_2$ was distilled over $CaH_2$ immediately before use.

**Reaction of *cis*-[Pt($PPh_3$)$_2$(AcO)$_2$] (6) with tmtu:** tmtu (0.013 g, 0.10 mmol) was added to a solution of **6** (0.042 g, 0.05 mmol) in anhydrous $CH_2Cl_2$ (20 mL). The solution was left for 6 h at room temperature under a nitrogen atmosphere. The solvent was evaporated to dryness under vacuum and redissolved in $CDCl_3$. $^{31}P$ NMR spectroscopy showed the presence of only the starting material.

**Reactivity of 1 with tmtu and Sodium Acetate:** Dry sodium acetate (0.042 g, 0.512 mmol) was added to a $CH_2Cl_2$ solution (20 mL) of [Pt($PPh_3$)$_2$($NO_3$)$_2$] (0.043 g, 0.051 mmol) and tmtu (0.0134 g, 0.103 mmol). The slurry was stirred vigorously for 4 h at room temperature under a nitrogen atmosphere, and the solvent was then evaporated completely under vacuum. $^{31}P$ NMR spectroscopy of a $CDCl_3$ solution of the residue showed the presence of a mixture of [Pt($PPh_3$)$_2$(AcO)$_2$] (**6**) and [Pt($PPh_3$)$_2$($NO_3$)(tmtu)]$^+$ (**2**).

**X-ray Data Collection and Structure Determination:** Crystal data are summarised in Table 3. The diffraction experiment was carried out with a Bruker SMART CCD area-detector diffractometer at 296 K, using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073) with a graphite crystal monochromator in the incident beam. No crystal decay was ob-

served, therefore no time-decay correction was needed. The collected frames were processed with the software SAINT,[24] and an empirical absorption correction was applied (SADABS)[25] to the collected reflections. Calculations were performed using the Personal Structure Determination Package,[26] and the physical constants tabulated therein.[27] The structure was solved by direct methods (SHELXS)[28] and refined by full-matrix least-squares using all reflections and minimising the function $\Sigma w(F_o^2 - kF_c^2)^2$ (refinement on $F^2$). All the non-hydrogen atoms were refined with anisotropic thermal factors. The hydrogen atoms were placed in their ideal positions (C–H = 0.97 Å), with the thermal parameter *B* 1.10 times that of the carbon atom to which they are attached, and were not refined. In the final Fourier map, the maximum residual was 0.76(6) e Å$^{-3}$ at 0.82 Å from Pt. CCDC-272407 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# An Electron Microscopy Study of New Chemically Twinned Phases in the $MgS$-$Yb_2S_3$ System

**Esteban Urones-Garrote,*[a] Adrián Gómez-Herrero,[b] Ángel R. Landa-Cánovas,[c] and L. Carlos Otero-Díaz[a,b]**

**Keywords:** Chemical twinning / Electron microscopy / Rare earths / Sulfides / Solid-state structures

Four new phases in the $MgS$-$Yb_2S_3$ system have been identified and characterised by means of transmission electron microscopy and associated techniques, such as microdiffraction and X-ray energy dispersive spectroscopy analysis. The observed stoichiometries are: $MgYb_2S_4$ [$a$ = 0.3752(2), $b$ = 1.259(1), $c$ = 1.268(2) nm] and $Mg_2Yb_6S_{11}$ [$a$ = 0.37297(4), $b$ = 1.2592(2), $c$ = 3.4853(3) nm] with orthorhombic symmetry (space group $Cmcm$) and $Mg_3Yb_8S_{15}$ [$a$ = 1.2637(1), $b$ = 0.37176(5), $c$ = 2.4132(2) nm; $\beta$ = 100.40(1)°] and $MgYb_4S_7$ [$a$ = 1.2578(2), $b$ = 0.3735(3), $c$ = 1.1417(7) nm; $\beta$ = 104.88(6)°] with monoclinic symmetry (space group $C2/m$). Their structures can be described and derived from the NaCl-type by the crystallographic operation of chemical twinning at the unit-cell level along the $\{113\}_{NaCl}$ planes. The $a$ and $b$ lattice parameters are common in all the structures while the $c$ parameter depends on the total extension of the twin slabs' sequence, $n$, such that $c \approx n \times d(113)_{MgS}$ (for orthorhombic phases) or $d(001) \approx n \times d(113)_{MgS}$ (for monoclinic phases). All the unit-cell parameters were refined from the X-ray powder diffraction data after the unit-cell symmetries had been deduced from electron microscopy data.

## Introduction

The crystallographic operation termed "chemical twinning at the unit-cell level" by Hyde and Andersson[1,2] is very useful for understanding, describing and clarifying many crystal structures as this concept allows the building of apparently complex structures from simple units. The regular and repeated reflection twinning on the {113} planes of the NaCl-type parent structure produces a series of homologous ordered phases in an important number of systems, including sulfides, sulfo salts and oxides.[1,2] Ferraris et al.[3] denote it as a "lillianite homologous series", after the structure of $Pb_3Bi_2S_6$.[4] The twinning operation generates trigonal prisms in the composition planes perpendicular to $[113]_{NaCl}$ that share their triangular faces. The frequency of these composition (or twin) planes is responsible for the stoichiometry. They are separated by blocks of NaCl-type structure whose thickness and ordering reflect the $c$ unit-cell parameter. The block thickness can be denoted by the number of atom layers parallel to the twin planes.[1] The members of the homologous series present equal $a$ and $b$ crystal parameters while the $c$ parameter varies with the total twin slabs' sequence and is proportional to $d(113)_{NaCl}$.

Several phases derived from the NaCl-type by chemical twinning have been reported in the Pb-Bi-S system, such as natural sulfo salts[3] and synthetic samples,[5,6] including $PbBi_4S_7$, with a $Y_5S_7$-type structure,[7] which presents a ...(4,3)... twin sequence. Other phases with more complex twin slab sequences have also been found, such as $Pb_2Bi_6S_{11}$ [...(4,4,3,4,4,3)...] and $Pb_3Bi_{10}S_{18}$ [...(4,4,3,4,3,4,4,3,4,3)...]. Bakker and Hyde were the first to study these structures by means of transmission electron microscopy (TEM), especially several phases in the Mn-Y-S system,[8] including the phase $MnY_2S_4$, which has a $CaTi_2O_4$-type structure[9] with a ...(4,4)... twin sequence. Some other phases were observed and predicted between $MnY_2S_4$ and $MnY_4S_7$ stoichiometries, such as $Mn_3Y_8S_{15}$ and $Mn_2Y_6S_{11}$, whose structure can be considered as an ordered intergrowth between the former phases.

The Cr-Er-S system has been extensively studied, mainly by X-ray powder diffraction (XRPD) data, by Tomas et al.,[10–12] who reported several different phases, such as $CrEr_2S_4$, $Cr_2Er_6S_{11}$ and $CrEr_4S_7$. The structure of $CrEr_2S_4$ is reported to be a twofold superstructure of $MnY_2S_4$ along the short axis due to the Jahn–Teller effect on $Cr^{2+}$-centred octahedra. The $Cr_2Er_6S_{11}$ phase presents the orthorhombic space group $Cmc2_1$, whereas some other phases with the same stoichiometry present the $Cmcm$ space group, including $Fe_2Yb_6S_{11}$[13] and the binary sulfide $Tm_8S_{11}$.[14] Phases derived from an NaCl-type structure by the operation of

chemical twinning have also been found in the Mn-Er-S series. For example, Tomas et al. have studied the $Mn_{0.4}Er_{4.6}S_7$ phase[15] from single-crystal X-ray diffraction data, and a more detailed characterisation of the system was carried out by TEM.[16,17] Disordered intergrowths of $Mn_2Er_6S_{11}$ and $Mn_3Er_8S_{15}$ along the *c* axis of the structures were also found, along with well-ordered crystals. The transformation of the $MnEr_2S_4$ sulfospinel into different chemically twinned (CT) phases and into NaCl-type structure was observed in this system[18] due to irradiation damage effects under the electron microscope beam (intermediate acceleration voltage of 400 kV). The Ca-Tl-O system presents several CT phases belonging to the homologous series $Ca_nTl_2O_{n+3}$.[19,20] The structure of each phase was further studied by means of neutron diffraction by Berastegui et al.[21]

Some other CT phases have the same stoichiometry as $CaTi_2O_4$ but with a twin sequence that is different to ...(4,4)..., as is the case of $HgBi_2S_4$[22] and $CdBi_2S_4$,[23] which are monoclinic phases with a ...(5,3)... twin slabs' sequence, denoted as a pavonite homologous series by Ferraris et al.[3]

The formation of NaCl-type MS-$RE_2S_3$ solid solutions (M = divalent metal; RE = rare-earth element) is well documented,[24] mainly by characterisation with XRPD data. When M = Mg, Mn and Ca extensive solid solutions with NaCl-type structure are generated for the heavy rare-earth elements and for Y. Some orthorhombic and monoclinic phases have also been reported in these systems from XRPD data,[25,26] although none was isolated with M = Mg and RE = Yb. TEM studies carried out in the Mg-Yb-S system[27] indicate that a transition from an NaCl-type to a spinel-type structure occurs through short-range order phenomena and segregation of extended defects. In this work, we present the preparation and characterisation of four new CT phases derived from the NaCl-type structure in this ternary system, as determined by TEM and associated techniques [microdiffraction and X-ray energy dispersive spectroscopy (XEDS) analysis]. XRPD information is employed to refine the crystal parameters of each phase once their unit-cell symmetries have been determined from the electron diffraction data.

## Results and Discussion

The XRPD patterns of each sample are complex, with a large number of maxima (about 40) in the range $5° \leq 2\theta \leq 70°$ due to the presence of different phases with large unit cells. The diffraction maxima are also broad, which indicates the existence of defects. All these observations were confirmed by the study of the samples by TEM and associated techniques. The phases present in each of the samples were first identified from their selected-area electron diffraction (SAED) patterns, from which the approximate unit-cell dimensions can be obtained and then refined from XRPD data. Four CT ordered phases were observed, with the average stoichiometries indicated in Table 1 and discussed below.

### $MgYb_2S_4$

The XRPD pattern indicates the presence of the cubic spinel-type phase $MgYb_2S_4$ [$a$ = 1.0951(2) nm], which has been described previously,[27] as well as other phases. An ordered major phase was identified by means of TEM observations. An orthorhombic unit cell could be assigned to these crystals from SAED patterns taken along different orientations (see Figure 1). The approximate crystal parameters are: $a \approx 0.37$, $b \approx 1.25$, $c \approx 1.26$ nm.

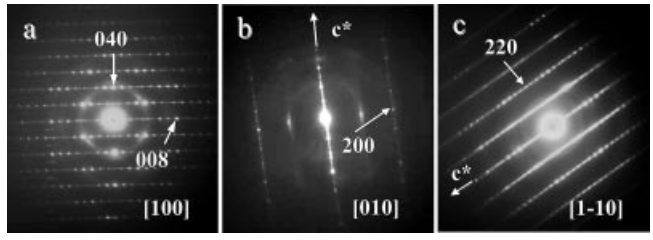

Figure 1. SAED patterns along different orientations, belonging to three different crystals of the sample with a nominal Mg:Yb ratio of 1:2. Note the streaking of the reflections along *c**, which is indicative of the presence of plane defects and/or disorder perpendicular to *c*.

The one-dimensional (1D) intensity streaking of the diffraction maxima along *c** in some of the diffraction patterns indicates the presence of disordered planar defects perpendicular to *c*. The cation ratio was semi-quantitatively measured by XEDS (ten crystals were analysed) with an average result of Mg/Yb = 0.46 [$Mg_{0.93(4)}Yb_{2.03(4)}S_4$], which is very close to a 1:2 stoichiometry. There are several possible orthorhombic structure-types with a similar $AB_2S_4$ ideal stoichiometry, such as the $CaFe_2O_4$ type[7] ($a$ = 0.9230, $b$ = 0.3024, $c$ = 1.0705 nm; space group *Pnma*), the $CaTi_2O_4$ type[9] ($a$ = 0.3136, $b$ = 0.9727, $c$ = 0.9976 nm; space group *Cmcm*) and the $Yb_3S_4$ type[28] ($a$ = 1.2777, $b$ = 0.3837,

Table 1. Crystal parameters of the different CT phases previously described, refined from XRPD data. The space group and the twin slabs' sequences inside the unit cell are included in each case.

| Phase | XEDS analysis | S/(Mg+Yb) ratio | Space group | Lattice parameters [nm] | $Z$ | Twin sequence |
|---|---|---|---|---|---|---|

$c$ = 1.2926 nm; space group *Pnma*). The measured unit-cell parameters do not allow us to differentiate between them. The actual space group can be identified by means of the microdiffraction technique[29,30] by studying the "ideal symmetry" of the microdiffraction patterns, which is determined by the position and relative intensity of the reflections, either on the zero-order Laue zone (ZOLZ) or in the whole pattern (WP), which includes high-order Laue zones (HOLZ). The difference of periodicity and the shifts between the Laue zones give information about the presence of glide planes and screw axes and about the centring of the lattice, respectively. A microdiffraction pattern along the [010] zone axis, where a shift of the FOLZ and the ZOLZ along $c^*$ can be observed, is shown in Figure 2 (a). The $h0l$ reflections with $h = 2n + 1$ are absent in the ZOLZ but the $h1l$ ones with $h = 2n + 1$ are present in the FOLZ (first-order Laue zone). Furthermore, $00l$ ($l = 2n + 1$) reflections are observed in the ZOLZ but the $01l$ reflections are absent in the FOLZ. This shift of the Laue zones along $c^*$ due to the indicated extinctions is indicative of the C-centring of the lattice, according to the extinction condition $hkl$: $h + k = 2n + 1$. Two possible orthorhombic space groups have the same extinction conditions for compounds with the stoichiometry $AB_2S_4$: *Cmcm* and $Cmc2_1$. The tilted pattern of Figure 2 (b) shows the presence of an *m*-plane perpendicular to *c*, and the [110] ZOLZ microdiffraction pattern of Figure 2 (c) shows (2*mm*) "ideal" symmetry, which confirms, together with the information obtained from the other patterns, that this phase presents the *Cmcm* space group.[29,30] The $Cmc2_1$ space group would have shown (*m*) "ideal" symmetry along the [110] zone axis. Therefore, the major well-ordered phase found in this sample [XEDS: $Mg_{0.93(4)}Yb_{2.03(4)}S_4$] can be considered to be isostructural with a $CaTi_2O_4$-type structure, in other words it can be described as a ...(4,4)... CT structure according to the nomenclature proposed by Hyde and Andersson.[1] An idealised model of this CT-$MgYb_2S_4$ structure, viewed along the [100] direction, is included in Figure 3. $Mg^{2+}$ cations are located in octahedral coordination sites and the $Yb^{3+}$ cations lie in the remaining octahedral sites (50%) and in the bicapped trigonal prisms present in the twin planes. Both cations occur randomly in the octahedral sites.

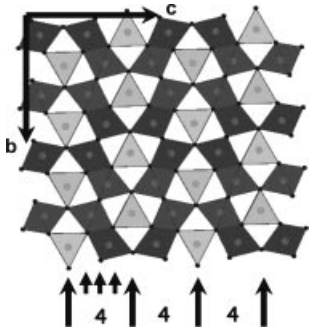

Figure 3. Idealized model of the ...(4,4)... CT structure of the $MgYb_2S_4$ phase ($Z$ = 4). The $\{(Mg,Yb)S_6\}$ octahedra are represented in dark grey and the $\{YbS_{6+2}\}$ bicapped trigonal prisms are represented in light grey. The caps have been excluded from the model for clarity. The twin slabs' sequence in the unit cell is clearly visible.

In order to confirm the proposed structure model, HRTEM (high-resolution TEM) images were taken along the short axis (in this case the *a* axis), which best reflects the CT structure. Figure 4 shows an HRTEM Fourier-filtered image of the CT-$MgYb_2S_4$ phase along [100], and the corresponding fast Fourier transform (FFT) is included as an inset. Simulated images were obtained at several microscope defocus and crystal thickness values, using the ideal $CaTi_2O_4$-type atomic positions and the experimentally refined crystal parameters from XRPD patterns. The best fit with

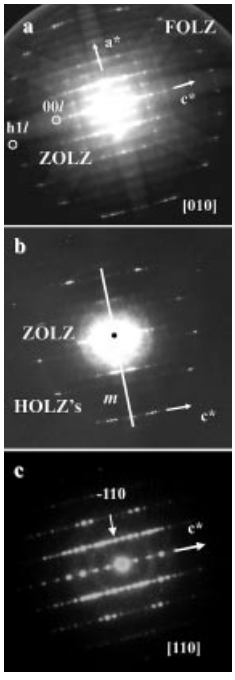

Figure 2. Microdiffraction patterns corresponding to a crystal with a Mg:Yb ratio of 1:2. Information about the centring of the lattice (C) and the actual space group (*Cmcm*) are deduced from them (see the text for details). The pattern in (b) is tilted off-axis in order to observe the HOLZ reflections.

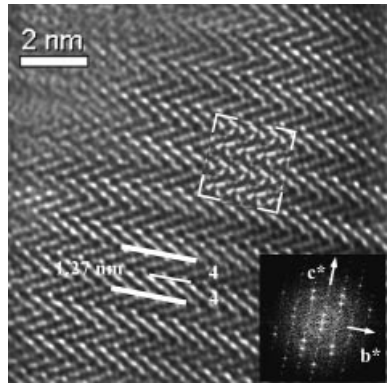

Figure 4. Fourier-filtered HRTEM image of an $MgYb_2S_4$ crystal taken along the short-axis of the CT structure. The corresponding FFT is included in the lower right part as an inset. The simulated image (defocus, $\Delta f$ = –40 nm; thickness, $t$ = 8 nm) agrees well with the experimental one.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the experimental image is superimposed in Figure 4 and shows a good correspondence with the experimental image, which indicates that the observed phase presents the Ca-$Ti_2O_4$-type structure.[9]

### $MgYb_4S_7$

Detailed TEM observations of the sample with a nominal Mg/Yb ratio of 1:4 showed the existence of a major, well-ordered phase as well as a minor $MgYb_2S_4$ spinel phase (which was not observed in the XRPD pattern) and crystals with disordered lattice planes. The SAED patterns of the major phase (see Figure 5) can be assigned to a monoclinic phase with the approximate unit cell parameters $a \approx 1.26$, $b \approx 0.37$ and $c \approx 1.15$ nm, and $\beta \approx 105°$.

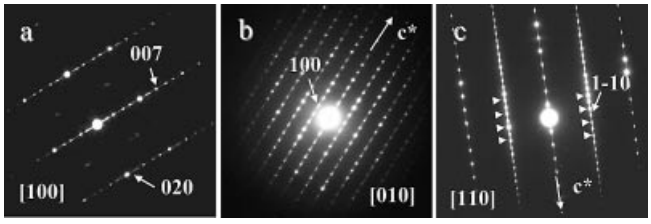

Figure 5. SAED patterns along different orientations, belonging to different crystals of the sample with a nominal Mg:Yb ratio of 1:4. Note the intensity streaking of the reflections along $c^*$, which is indicative of the presence of defects and/or disorder.

XEDS analyses of 10 crystals provided the average cation ratio Mg/Yb $\approx$ 0.26 [$Mg_{1.03(6)}Yb_{3.98(4)}S_7$], which is very close to 1:4 ratio. A possible structure type with $AB_4S_7$ stoichiometry is $Y_5S_7$,[7] whose structure can be described as a ...(4,3)... CT phase.

The actual space group can be identified by means of microdiffraction patterns. Thus, the [100] microdiffraction pattern of Figure 6 (a) shows that the ZOLZ reflections are shifted by $1/2\,b^*$ with respect to the FOLZ ones. The $0kl$ reflections turn into $1kl$ reflections in the FOLZ, and are absent when $1 + k = 2n + 1$. The shift provoked by these extinctions is indicative of the C-centring of the lattice. The [110] ZOLZ microdiffraction pattern in Figure 6 (b) presents (*2*) "ideal" symmetry, which agrees with the *C*2/*m* space group,[29,30] whereas *C*2 and *Cm* space groups, which present the same extinction conditions, would display (*1*) "ideal" symmetry along the same zone axis. Therefore, microdiffraction results support the *C*2/*m* space group rather than *C*2 or *Cm*, and the observed phase can be described as a ..(4,3)... CT phase, with an ideal $MgYb_4S_7$ stoichiometry [XEDS: $Mg_{1.03(6)}Yb_{3.98(4)}S_7$] and a $Y_5S_7$-type structure.

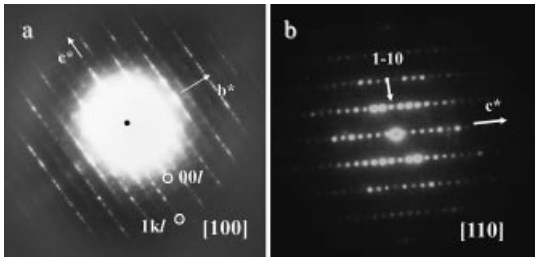

Figure 6. Microdiffraction patterns corresponding to the major ordered phase in the sample with a nominal Mg:Yb ratio of 1:4. The C-centring of the lattice is deduced from (a) and the "ideal" symmetry of the ZOLZ pattern in (b) − (*2*) − indicates that the phase presents the *C*2/*m* space group. See text for details.

Note that some intensity streaking is observed in the diffraction maxima along $c^*$ in the SAED patterns of Figure 5, which is indicative of plane defects perpendicular to *c*. Furthermore, in the [110] SAED pattern of Figure 5 (c), extra maxima are present (marked with arrows) due to the presence of macroscopic twin planes in the crystal, parallel to (001), which can be attributed to unit-cell twin sequences of the type ...4,3,4,3,4/4,3,4,3,4...

An idealised model of the CT-$MgYb_4S_7$ structure, along [010], is shown in Figure 7, where $Mg^{2+}$ and half of the $Yb^{3+}$ cations lie in octahedral sites at random and the other half of the $Yb^{3+}$ cations lie in the trigonal prisms at the composition planes.

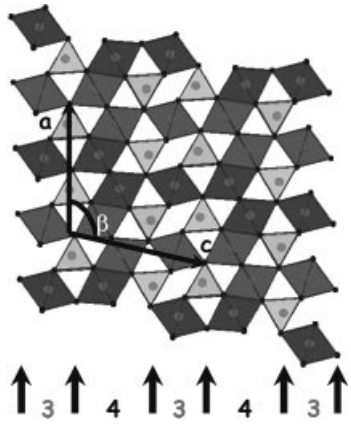

Figure 7. Idealized model of the ...(4,3)... CT structure of the $MgYb_4S_7$ phase (isostructural with $Y_5S_7$). The {(Mg,Yb)$S_6$} octahedra are represented in dark grey, and the {$YbS_6$} trigonal prisms are represented in light grey.

HRTEM images were obtained along the short axis of the structure to confirm the proposed model. Image simulations were calculated from the ideal atomic positions of the $Y_5S_7$-type structure and the refined crystal parameters from the XRPD pattern. The correspondence of the experimental images and the simulated ones is quite good, as shown in Figure 8, thus confirming the proposed structure model.

### $Mg_3Yb_8S_{15}$ and $Mg_2Yb_6S_{11}$ Phases

TEM observations from the crystals previously described as $MgYb_2S_4$ and $MgYb_4S_7$ showed the existence of disorder along $c^*$ due to the presence of both phases intergrown in a disordered manner. The ordered crystals found in this system had 3:8 and 1:3 Mg/Yb ratios, so two new samples were prepared with these nominal chemical compositions.

In the first case the XEDS analyses of ten crystals indicated a Mg/Yb ratio of about 0.38, close to an ideal $A_3B_8S_{15}$ stoichiometry [$Mg_{3.04(9)}Yb_{7.97(6)}S_{15}$], as reported before in the Mn-Er-S system[16,17] mentioned above. This phase is monoclinic, with the following approximate lattice

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

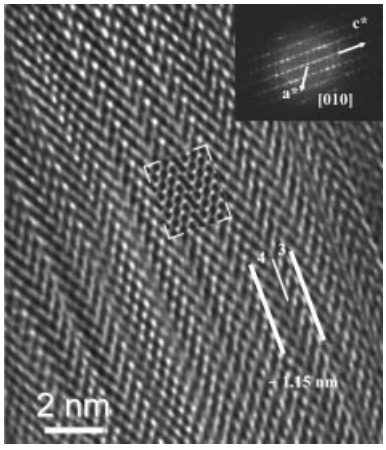

Figure 8. Fourier-filtered HRTEM image along the short axis of a CT-$MgYb_4S_7$ crystal ([010] direction). The corresponding FFT is included as an inset. The simulated image ($\Delta f$ = –50 nm; $t$ = 2 nm) agrees well with the experimental one.

parameters measured from SAED patterns (see Figure 9): $a \approx 1.26$, $b \approx 0.37$, $c \approx 2.40$ nm; $\beta \approx 100°$.

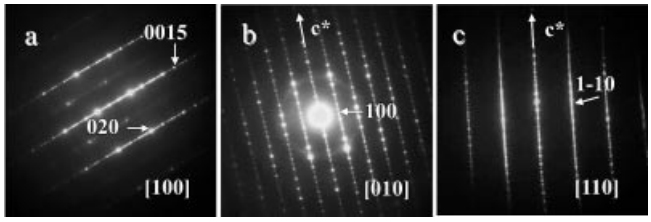

Figure 9. SAED patterns along different orientations, belonging to different crystals of the sample with a nominal Mg:Yb ratio of 3:8.

Most of the observed CT-$Mg_3Yb_8S_{15}$ crystals present streaking along $c$*, so the identification of its actual space group by means of microdiffraction patterns was problematic. However, the C-centring of the lattice was observed in the [100] microdiffraction pattern due to the shift of the ZOLZ and FOLZ reflections.

HRTEM images along the short axis of the structure (see Figure 10) indicated a ...(4,4,4,3)... twin slabs' sequence. The simulated image that showed the best fit among different defocus and thickness values is shown as the inset in Figure 10. The calculations were performed with the ideal atomic positions directly obtained from the ...(4,4,4,3)... model and the HRTEM image (*C*2/*m* space group), and with the crystal parameters refined from XRPD data. Therefore, according to this model, the CT-$Mg_3Yb_8S_{15}$ structure presents a ...(4,4,4,3)... twin sequence, with $Mg^{2+}$ and half of the $Yb^{3+}$ cations in octahedra (at random) and the other half in trigonal prisms at the composition planes (see Figure 11).

In the case of the sample with a 1:3 cation ratio, the previously described CT phases were observed, together with the sulfospinel $MgYb_2S_4$. An orthorhombic ordered phase was also found, with the following approximate crystal parameters obtained from SAED patterns: $a \approx 0.37$, $b \approx 1.26$, $c \approx 3.50$ nm.

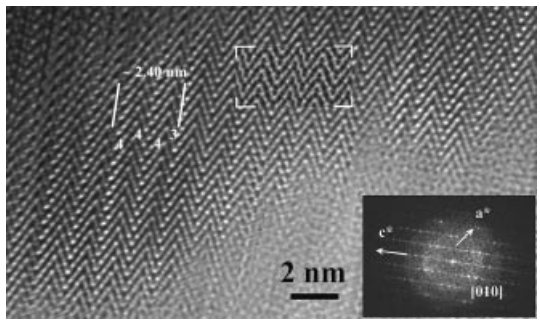

Figure 10. Fourier-filtered HRTEM image along the short axis of a CT-$Mg_3Yb_8S_{15}$ crystal ([010] direction). The corresponding FFT is included as an inset. The simulated image ($\Delta f$ = –50 nm; $t$ = 2 nm) agrees well with the experimental one. It was calculated by employing the preliminary crystal parameters measured from SAED patterns (*C*2/*m* space group) and the atomic parameters directly obtained from the ideal model and from the image.

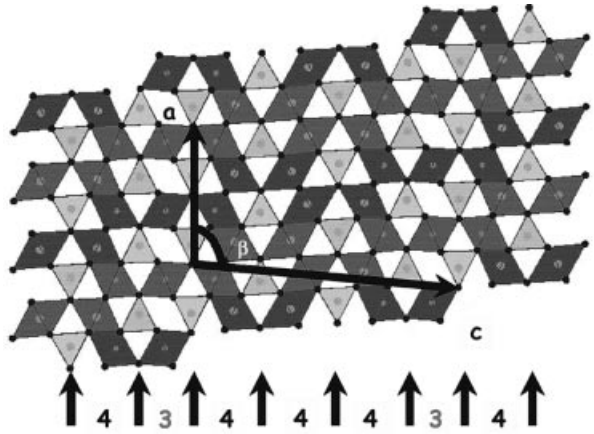

Figure 11. Idealized model of the CT-$Mg_3Yb_8S_{15}$ phase ($Z$ = 2). The twin slabs' sequence is ...(4,4,4,3)... in this case. The {(Mg,Yb)-$S_6$} octahedra are represented in dark grey, and the {$YbS_6$} trigonal prisms are represented in light grey.

The measured XEDS (six crystals) Mg/Yb ratio was about 0.32, which corresponds to a 1:3 cation stoichiometry. The chemical composition and lattice parameters are similar to the previously described $Tm_8S_{11}$ and $Mn_2Er_6S_{11}$ structures,[14,17] so that the average XEDS analysis can be formulated as $Mg_{1.96(7)}Yb_{6.03(5)}S_{11}$. The crystals belonging to this CT phase are usually disordered along $c$* (1D intensity streaking of the diffraction spots along that direction, as observed in the SAED patterns; see Figure 12). The model was confirmed by HRTEM images, such as the one shown in Figure 13 along the [110] orientation. The experimental image agrees quite well with the simulated one (inset) calculated with the ideal $Fe_2Yb_6S_{11}$ atomic positions (*Cmcm* space group) and with the crystal parameters refined from the XRPD data. Therefore, the observed $Mg_2Yb_6S_{11}$ structure is a new phase and can be described as a ...(4,4,3,4,4,3)... CT one. As in the previously described phases, $Mg^{2+}$ and half of the $Yb^{3+}$ cations occupy octahedral positions at random, whereas the other half of the $Yb^{3+}$ cations lie in the trigonal prisms at the composition planes, as shown in the structural model in Figure 14.

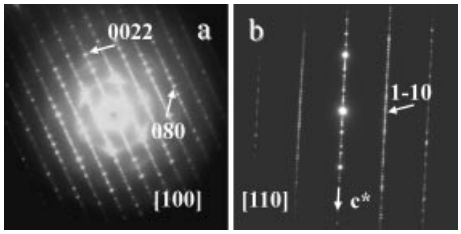

Figure 12. SAED patterns along different crystal orientations, belonging to the sample with a nominal Mg:Yb ratio of 1:3. Intensity streaking along the $c^*$ reflections can be observed due to the presence of plane defects perpendicular to $c$.

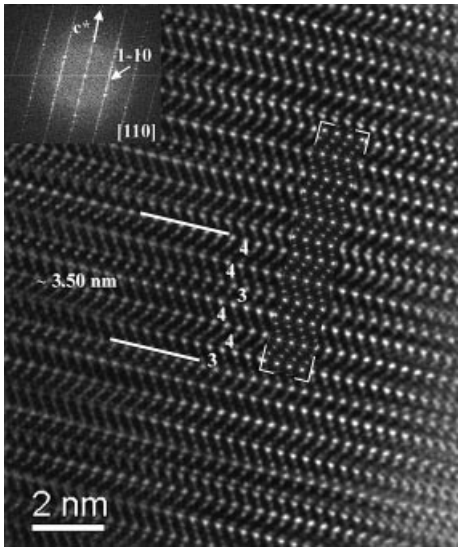

Figure 13. Fourier-filtered HRTEM image of the CT-$Mg_2Yb_6S_{11}$ phase along the [110] direction. The corresponding FFT is included as an inset. The simulated image ($\Delta f$ = –50 nm; $t$ = 6 nm) agrees well with the experimental one and reflects the twin slabs' sequence in the unit cell.

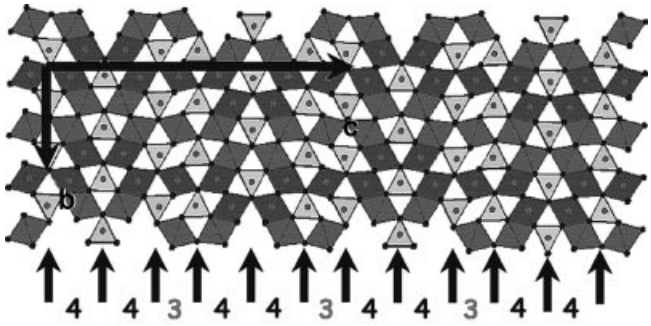

Figure 14. Idealized model of the ...(4,4,3,4,4,3)... structure of the CT-$Mg_2Yb_6S_{11}$ phase. It presents the $Fe_2Yb_6S_{11}$-type structure (*Cmcm* space group and $Z$ = 4). The {(Mg,Yb)$S_6$} octahedra are represented in dark grey, and the {$YbS_{6+1}$} mono-capped trigonal prisms are represented in light grey (the caps have been excluded for clarity).

Disorder perpendicular to $c$ is common in these phases, as was previously observed in the SAED patterns (1D streaking). Intergrowths were also found in many crystals, as can be seen in the HRTEM image included in Figure 15, where slabs of $Mg_2Yb_6S_{11}$ and $Mg_3Yb_8S_{15}$ alternate along $c$, apparently at random.

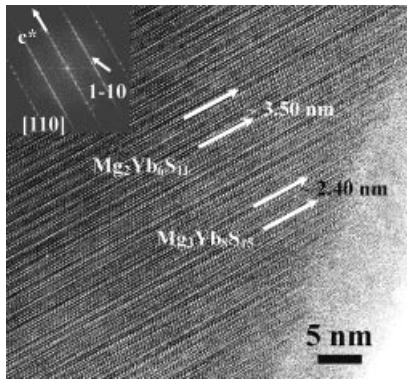

Figure 15. HRTEM image of a crystal from the sample with nominal composition $Mg_2Yb_6S_{11}$, showing a disordered intergrowth of the CT-$Mg_3Yb_8S_{15}$ and CT-$Mg_2Yb_6S_{11}$ structures along $c$. The corresponding FFT is included as an inset.

In the phases derived from the NaCl-type structure by chemical twinning the $c$ parameter accounts for the twin blocks periodicity [$c \approx n \times d(113)_{MgS}$ for orthorhombic phases and $d(001) \approx n \times d(113)_{MgS}$ for monoclinic ones], i.e., it indicates the stoichiometry of the phase. The value of $n$, which stands for the total extension of the NaCl-type slabs between the twin planes included in the unit cell, can be derived from the superstructure periodicity along $[113]^*_{NaCl}$ (or $c^*$). Figure 16 includes an enlargement of the $c^*$ rows belonging to the four CT phases described in this work, with $n$ = 8 for CT-$MgYb_2S_4$, $n$ = 15 for CT-$Mg_3Yb_8S_{15}$, $n$ = 22 for CT-$Mg_2Yb_6S_{11}$ and $n$ = 7 for CT-$MgYb_4S_7$ (see Table 1).

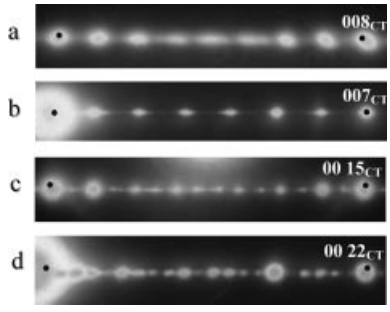

Figure 16. Detail of the 00l reflections row ($c^*$) of the four CT phases described in this work. The superstructure periodicity inside $113_{NaCl}$ is directly related to the twinning sequence ($n$). a) $MgYb_2S_4$, with $n$ = 8 and twin sequence ...(4,4)...; b) $MgYb_4S_7$, $n$ = 7 and ...(4,3)...; c) $Mg_3Yb_8S_{15}$, $n$ = 15 and ...(4,4,4,3)...; d) $Mg_2Yb_6S_{11}$, $n$ = 22 and ...(4,4,3,4,4,3)...

## XRPD Studies

Once the four observed phases had been identified and characterised by means of TEM and associated techniques, the lattice parameters were refined from XRPD data. The results are summarised in Table 1, including the twin slabs' sequences.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Since the origin of these CT structures is the regular and repeated twinning on $\{113\}_{NaCl}$ planes, the variation of $d(113)_{NaCl}$ vs. composition has been studied in the MgS-$Yb_2S_3$ system, including samples with NaCl and spinel structures reported previously,[27] with lower $Yb^{3+}$ content than the CT phases described in this work. The change in $d(113)_{NaCl}$ with the Yb/Mg ratio is represented in Figure 17. This parameter increases in the NaCl-type structure samples as the $Yb^{3+}$ concentration is increased, since the ionic radius of $Yb^{3+}$ in sixfold coordination (0.1008 nm) is bigger than in the case of $Mg^{2+}$ (0.0710 nm).[31] The introduction of $Yb^{3+}$ into the matrix of MgS generates cation vacancies.[27] When a spinel-type phase is formed with higher $Yb^{3+}$ content, there is a sudden variation in $d(113)_{NaCl}$ [$\approx 1/2 \times d(113)_{spinel}$], which is related to the structure change, with ordering of vacancies. It remains constant with slight composition variations since the unit-cell enlargement due to the increase of vacancies and $Mg^{2+}$ substitution by $Yb^{3+}$ must be compensated by the occupancy of tetrahedral positions.[27] When considering the CT phases described in this work, the $d(113)_{NaCl}$ value, which is directly related to the $d(001)_{CT}$, as mentioned before, decreases significantly and abruptly with respect to the spinel phase values due to the elimination of all the cation vacancies by the chemical twinning operation. The $d(113)_{NaCl}$ value decreases slightly (see Figure 17) as the relative number of composition planes in the unit cell of each CT phase increases, i.e., from $MgYb_2S_4$ [two composition planes every eight $(113)_{NaCl}$ planes] to $MgYb_4S_7$ [two composition planes every seven $(113)_{NaCl}$ planes].

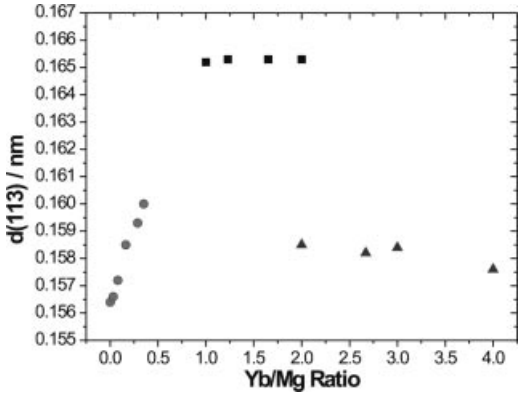

Figure 17. Variation of $d(113)_{NaCl}$ with the Yb/Mg ratio. The grey circles correspond to phases with an NaCl structure,[27] the black squares correspond to phases with a spinel-type structure with cationic excess[27] and the grey triangles correspond to the CTP phases described in this work.

## Conclusions

As can be observed in Table 1, the phases described in this work present common *a* and *b* crystal parameters while the *c* axis changes according to the composition. It was mentioned previously that the composition variations in the phases derived from the NaCl-type structure by the chemical twinning operation are accommodated through the twin slabs' sequence and periodicity, i.e., the generation of twin (composition) planes. These CT structures can be considered as members of a homologous series, with the two different symmetries (orthorhombic and monoclinic) depending on the twin slabs' sequence within the unit cell and with variation of the *c* axis with the stoichiometry.

As the twin sequence gets more complicated, i.e. the *c* axis gets larger, the difficulty of long-range ordering increases, as was observed in the $Mg_3Yb_8S_{15}$ and $Mg_2Yb_6S_{11}$ phases, which very often present intergrowths between CT structures. These two phases, whose Mg/Yb ratio lies between $MgYb_2S_4$ and $MgYb_4S_7$, are regular intergrowths of the ...(4,4)... and the ...(4,3)... sequences. Therefore, within this composition range, some other ordered phases could be expected, as predicted by Bakker et al.[8] in the Mn-Y-S system or as observed in other related systems,[5,11,13,14] which are actually built up from the $MgYb_2S_4$ and $MgYb_4S_7$ "units". In the system studied in this work, no more ordered CT phases were observed.

The co-existence of the CT-$MgYb_2S_4$ and the normal spinel with the same nominal stoichiometry is an interesting case of polymorphism, which extends to the high-pressure polymorph with $Th_3P_4$-type structure.[32] We have not been able to relate this polymorphism with temperature (annealing at 1373 K does not give any change in the relative abundance of the phases). However, slight but significant composition differences have been found between them, as measured by XEDS analysis. The CT-$MgYb_2S_4$ phase presents an excess of $Yb^{3+}$ with respect to the Mg/Yb ratio of 0.50, while the spinel phase has an excess of $Mg^{2+}$ [XEDS: $Mg_{1.1(1)}Yb_{1.92(7)}S_4$]. Therefore, although the $AB_2S_4$ composition is the ideal one for both phases, it seems to be the separating line between them.

## Experimental Section

**Preparation of the Samples:** Several mixtures of nitrates $Mg(NO_3)_2 \cdot 6H_2O$ and $Yb(NO_3)_3 \cdot 5H_2O$ were placed in graphite boats inside a tubular furnace and heated under a flow of $H_2S$ (10%)/Ar (50 mL/min) and Ar (20 mL/min) (bubbling in $CS_2$). The samples with nominal cation ratio (Mg/Yb) 1:2 and 1:4 were prepared at 1273 K for 10 h, whereas the other ones (3:8 and 1:3) were treated first at 798 K for 4 h and then at 1273 K for four more hours. The gas flow was maintained while raising the temperature. Each sample was cooled down to room temperature by switching off the furnace and maintaining a flow of Ar to avoid oxidation. The gases at the exit of the furnace were neutralised in a concentrated NaOH solution.

**Characterisation of the Samples:** Specimens for TEM observations were obtained from suspensions ultrasonically dispersed in butanol. A drop of each corresponding suspension was placed on a copper grid covered with a holey carbon film. A JEM 2000FX electron microscope, equipped with a LINK ISIS 300 XEDS analysis system, was employed to explore the reciprocal lattice of the samples (double-tilt specimen holder: ±45°) and to analyse the chemical composition. A Philips CM200 FEG (field emission gun) electron microscope, equipped with an EDAX DX4 XEDS analysis system was employed for the microdiffraction studies. HRTEM images were taken with a JEM 3000F (point resolution: 0.17 nm)

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

electron microscope. Due to the preferential cleavage of the crystals, the short axis of the structures under study could not be observed because they were beyond the tilt capacities of the JEM 3000F microscope (double-tilt specimen holder: ±20°). Therefore, the samples were embedded in epoxy resin and thin slices were obtained with an ultramicrotome for TEM observations. Crystals close to the short-axis orientation could be found in this way.

The as-prepared sulfides were studied by XRPD, using a Philips X'pert Diffractometer (Cu-$K_{\alpha 1}$ radiation) to refine the lattice parameters.

# Zinc Thiolate Complexes $[ZnL_n(SR)]^+$ with Azamacrocyclic Ligands: Synthesis and Structural Properties

Johannes Notni,[a] Helmar Görls,[b] and Ernst Anders*[a]

**Keywords:** Enzyme models / Macrocyclic ligands / S ligands / Solid-state structures / Zinc

A series of 24 novel zinc thiolate complexes containing saturated macrocyclic polyamine ligands with the general formula $[Zn(L_n)(SR)]ClO_4$ ($L_n$: *n*-dentate azamacrocyclic ligand) has been synthesized. Two different thiolate ligands (R = phenyl, benzyl) and 12 macrocyclic ligands with ring sizes varying from 11 to 16 atoms and containing three, four, and five nitrogen donors (including a new macrocyclic triamine ligand, 8-methyl-[11]ane$N_3$) have been used. The solid-state structures of 20 of the 24 complexes have been characterized by X-ray diffraction. The crystal lattice of all compounds is comprised exclusively of monomers. The tetracoordinate $N_3S$ compounds exhibit Zn–S bond lengths ranging from 2.2259(5) to 2.2492(9) Å and the pentacoordinate $N_4S$ systems from 2.266(2) to 2.3200(7) Å. In addition, two complexes with the very rare $N_5S$ coordination environment for zinc have been found. They exhibit Zn–S bond lengths of 2.3782(7) and 2.42 Å (mean value of two independent molecules). The thiolate complexes are suitable model systems for the precursor proteins of matrix metalloproteases (proMMPs) as well as for thiolate alkylating enzymes such as cobalamine-dependent/independent methionine synthases, farnesyl transferase, and the Ada repair protein.

## Introduction

Zinc thiolate complexes have received considerable attention in the past decade. This interest derives from the fact that many enzymes feature the alkylation (methylation) of a zinc–thiolate bond.[1,2] The most prominent among them are the Ada repair protein,[3] cobalamine-dependent/independent methionine synthases,[4,5] and farnesyl transferase.[6] The studies focusing on zinc thiolate complexes have thus paid special attention to the mechanism of the alkylation of thiols. Two different possible reaction modes are discussed. On the one hand, the alkylation may occur intramolecularly and the thiol is alkylated in the zinc-bound state, whereas the reaction could also start with an initial heterolytic dissociation, followed by a reaction of free thiolate. Wilker and Lippard have employed the anionic tetrathiolate $[Zn(SPh)_4]^{2-}$ as a functional model for Ada.[7] They found a methylation of the complex by $(MeO)_3PO$ to yield PhSMe and postulated a dissociative reaction mechanism. Vahrenkamp et al. have studied the methylation of [tris(pyrazolyl)borato]zinc thiolates ($Tp^{R,R}ZnSR$) and have provided strong evidence (gained from kinetic measurements) that these reactions occur intramolecularly and feature a four-center transition structure.[8–10] A similar interpretation has been provided by Carrano et al., who have investigated the methylation of a series of (scorpionato)zinc thiolates.[11–13] Darensbourg et al. have investigated the alkylation of a zinc complex with a bis(thiolate) $[N_2S_2]^{2-}$ chelate ligand.[14] They also obtained the thioether derivatives, but did not discuss the mechanism.

The above (incomplete and arbitrary) list of examples provides insight into some established applications of zinc thiolate complexes as enzyme models. They also resemble, however, the catalytic domain of another important class of enzymes, the matrix metalloproteases (MMPs or matrixins). These play an important role in the degradation of extracellular matrix components, such as collagen.[15,16] The enzymes are secreted into the extracellular space in a latent (inactive) form, the so-called proMMPs, therefore an additional activation step is required to induce protease activity. This is a sensitive process, since the active form can digest its own framework and thus the timing of activation is critical. Furthermore, an imbalance of the active enzyme and its inhibited form is implicated in the pathology of diseases such as arthritis, cancer, multiple sclerosis, and cardiovascular diseases.[17] Thus, it is vitally important to gain a detailed understanding of the activation mechanism.[18]

The catalytic zinc(II) ion in the latent enzymes − the MMP precursor proteins (proMMPs) − is bound to the deprotonated sulfhydryl group of a cysteine and to three histidine residues.[19,20] In vitro experiments have shown that an activation can be achieved with a variety of reagents, but the initial step is always a hydrolytic cleavage of the zinc–sulfur linkage.[21] The coordination sphere of the zinc ion is then completed by a water molecule to form the catalytically active $His_3ZnOH$ motif.[22] A model reaction for this

 InterScience © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

process has been reported by Parkin et al., who performed the hydrolytic cleavage of a tripodal $S_3Zn$–SR complex and obtained free thiolate.[23] To the best of our knowledge, no model complex that resembles the $His_3Zn$–Cys coordination motif of the inactive enzyme has been used for these investigations so far. Our complexes might thus prove to be useful in this field of research.

Furthermore, recent investigations have suggested that carbonic anhydrase[24,25] plays a pivotal role in the fixation of carbonyl sulfide according to the equation $L_nZnOH + COS \rightarrow L_nZnSH + CO_2$.[26] Quantum mechanical calculations have revealed that a zinc hydrosulfide moiety $His_3Zn$–SH is formed in the course of this interconversion.[27] A suitable structural model − the neutral hydrosulfide complex $Tp^{Ph,Me}ZnSH$ − has been found by Vahrenkamp et al.[28,29] Our efforts to obtain an equivalent zinc hydrosulfide complex with an azamacrocyclic ligand were not successful because these compounds are not stable. Nevertheless, due to their positive overall charge, our thiolate complexes also could be regarded as suitable model systems for this species.

In this article we focus on the solid-state structures of cationic zinc monothiolates bearing a polyazamacrocyclic ligand. Azamacrocyclic ligands are available with many ring sizes and different numbers of donor atoms, therefore they allow a wide range of complexes to be synthesized with different electronic properties and steric demands. Thus, one can study the influence of the "protein-imitating" ligand on the binding mode and reactivity of a zinc-bound thiolate in great detail. With regard to future investigations or possible synthetic applications, it is convenient to choose the most suitable thiolate complex out of a large pool of substances with different reactivities and solubilities. We cover complexes formed with a wide range of azamacrocycles and reveal insights into both zinc thiolate coordination chemistry and coordination geometries of polyazamacrocyclic ligands on zinc centers. In subsequent articles, we will report on the reactions that these thiolates are capable of undergoing.

## Results and Discussion

### Starting Materials

Figure 1 illustrates the macrocyclic ligands that we used for complexation experiments. They feature ring sizes varying from 9 to 16 atoms and contain three, four, or five nitrogen donors. In addition, we report the synthesis of a new azamacrocycle, 8-methyl-[11]aneN$_3$ (**4**). All azamacrocycles were prepared using a slightly modified Richman–Atkins procedure.[30]

### Complexation Experiments

Zinc monothiolates with macrocyclic amine ligands are a novel class of compounds, and only two such examples are documented in the literature. Koike, Kimura et al.[31] postulated the formation of a complex of $[Zn(cyclen)]^{2+}$ with captopril, a hypertensive drug containing a thiolate function, but they did not characterize this substance. Their work illustrates, however, the biological significance of this type of compounds. In addition, Addison and Sinn have reported the complex *trans*-$[Zn(cyclam)(SC_6F_5)_2]$, which bears two pentafluorothiophenolate ligands.[32] Initially, we prepared our complexes in a similar way by treating equimolar amounts of the macrocyclic ligand with zinc perchlorate in methanol. This was followed by addition of an equimolar amount of sodium thiolate in methanol. The desired compounds $[Zn(L_n)(SR)]ClO_4$ precipitated with good yields. The reaction mode is outlined in Equation (1).

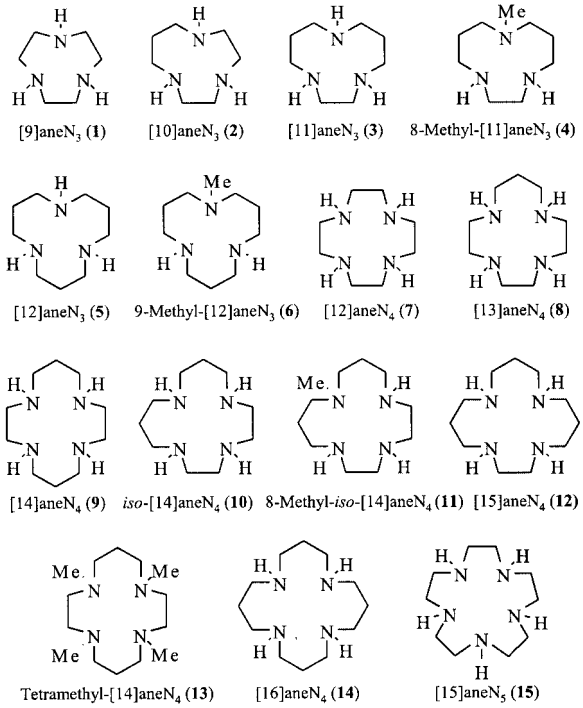

Figure 1. Macrocyclic polyamine ligands used for complexation experiments.

$$L_n + Zn(ClO_4)_2 + NaSR \rightarrow [Zn(L_n)(SR)]ClO_4 + NaClO_4 \quad (1)$$

A higher purity and better yields were achieved with potassium thiolates since the precipitation of potassium perchlorate forces the equilibrium towards the desired products.

However, this synthesis has its limits. The nature of the thiolate has a marked influence on this reaction: only arene- and phenylmethanethiolates yield the desired thiolate complexes. This is in contrast to the [tris(pyrazolyl)borato]zinc thiolates, for which aryl- *and* alkyl derivatives are available.[9] Alkyl thiolates (e.g. MeSH, EtSH, *t*BuSH) only afford the zinc bis(thiolates) $Zn(SR)_2$ and the bis(perchlorate) complexes $[Zn(L_n)](ClO_4)_2$.

Restrictions are also encountered when the ligand does not possess the proper ring size and the right type and number of nitrogen donor sites. If the macrocycle is smaller than 11 atoms (ligands **1** and **2**), the synthesis again yields only the bis(thiolate) salts $Zn(SR)_2$ and complexes of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

composition $[Zn(L_3)_2](ClO_4)_2$. The reason is that small ring systems form extremely stable metal complexes[33] that are much more stable than complexes with larger rings.[34] In addition, 9- and 10-membered cyclic triamines do not react according to a 1:1 stoichiometry with zinc ions, which prevents the coordination of an additional monodentate ligand. Instead, a 1:2 complex precipitates from solutions, thus leaving behind noncomplexed zinc(II), which then forms a bis(thiolate) salt. A similar observation was made in the case of $L_4$ (tetramethylcyclam, **13**). This ligand always exhibits an unfavorable steric arrangement in its complexes with zinc as well as with other metal ions [it normally adopts the (+ + + +) configuration;[35] see below for details]. These complexes are generally less stable than complexes of its unsubstituted analogue, cyclam (**8**).[36] In the present case, the zinc(II) ion is removed from the macrocycle by formation of the more stable bis(thiolate) of zinc, releasing the free ligand.

## Structures

As already mentioned, of all the mercaptans tested only phenylmethane- and arenethiols form the desired complexes. Therefore we synthesized two series of isomeric complexes $[Zn(L_n)(SR)]ClO_4$ employing phenylmethanethiol (**a**; R = $CH_2C_6H_5$) and 4-methylbenzenethiol (**b**; R = $C_6H_4CH_3$). Twenty four novel thiolate complexes were obtained, of which 20 were characterized by single-crystal X-ray diffraction. (In the structure representations, the hydrogen atoms on carbon atoms and the perchlorate ions have been omitted for clarity.)

### *[Zn(3)(SR)]ClO$_4$ (17) and [Zn(4)(SR)]ClO$_4$ (18)*

The complexes derived from the 11-membered ring ligands **3** and **4** are remarkably similar regarding their individual structural parameters. The $N_3ZnS$ unit exhibits a slightly distorted tetrahedral coordination geometry (Figure 2), and all four Zn–S bond lengths are in the very narrow range of 2.2295(5)–2.2394(6) Å. The Zn–N bonds have distances between 2.037(2) and 2.076(2) Å. There is no significant correlation with the nature of the N donor, i.e. secondary or tertiary. The IR spectra show a single N–H band

Selected bond lengths [Å]: **17a**: Zn–S 2.2353(9), Zn–N1 2.044(3), Zn–N2 2.047(3), Zn–N3 2.073(7); **17b**: Zn–S 2.2394(6), Zn–N1 2.056(2), Zn–N2 2.066(4), Zn–N3 2.048(2); **18a**: Zn–S 2.2295(5), Zn–N1 2.076(2), Zn–N2 2.060(2), Zn–N3 2.066(2); **18b**: Zn–S 2.2358(5), Zn–N1 2.068(2), Zn–N2 2.065(2), Zn–N3 2.037(2).

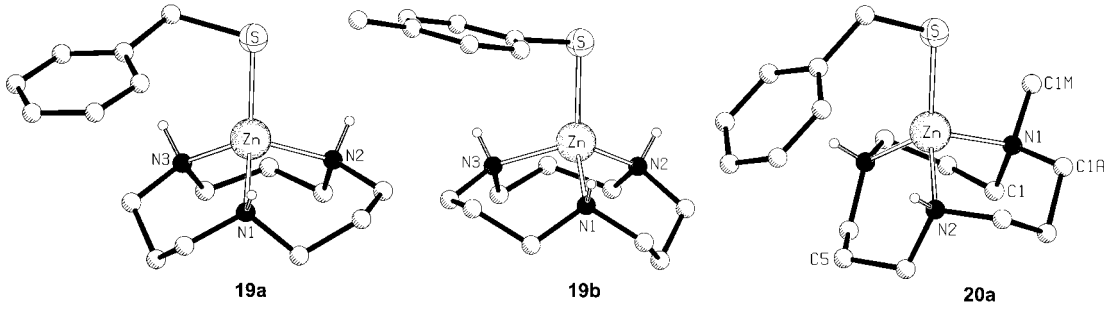

Figure 3. Molecular structures of **19a**, **19b**, and **20a**. Selected bond lengths [Å]: **19a**: Zn–S 2.245(2), Zn–N1 2.046(3), Zn–N2 2.056(3), Zn–N3 2.052(3); **19b**: Zn–S 2.2492(9), Zn–N1 2.036(3), Zn–N2 2.032(3), Zn–N3 2.052(3); **20a**: Zn–S 2.2367(7), Zn–N1 2.075(2), Zn–N2 2.050(2).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in the range of 3261–3271 $cm^{-1}$, which is broadened to a varying extent. This indicates the high degree of chemical analogy of these hydrogen atoms. Interestingly, the ligand's methyl substitution in **18a** has a marked effect on its solubility; it is readily soluble in dichloromethane, while the unsubstituted analogue, **17a**, is not.

### *[Zn(5)(SR)]$ClO_4$ (19) and [Zn(6)(SR)]$ClO_4$ (20)*

The three structurally characterized compounds **19a**, **19b**, and **20a** (Figure 3), synthesized with ligands **5** and **6**, show the same geometrical equivalence as observed for the complexes **17** and **18**. Slightly longer Zn–S bonds than in the case of the 11-membered cycles are encountered. However, the values for the Zn–N bonds are found in the same range. The IR spectra again show single bands in the region between 3252 and 3259 $cm^{-1}$. If the complex is asymmetric, they are broadened as mentioned above. Compound **20a** is symmetric along the C5–Zn–S plane (apart from a disorder of the atoms C1, C1A, N1, and C1M); therefore, the two hydrogen atoms attached to N2 and N2A are identical and give rise to a single, very narrow IR absorption. This shows the usefulness of IR absorption bands of N–H groups in determining the symmetry properties of macrocyclic amine complexes, a concept which will be referred to again later. Complex **20b** also exhibits a single band at almost the same value as **20a**, but it is noticeably broadened. This indicates the absence of a strict symmetry here. However, the structure is likely to follow the same motif. Similar to **18a**, the additional methyl group induces a solubility of **20a** in dichloromethane.

## Coordination Geometries in $N_4$ Complexes

Whether a five-coordinate complex belongs to the trigonal-bipyramidal or the tetragonal-pyramidal type is a question which is tricky to answer in the present case. Justifying an answer solely by the values of the bond angles, and thus seeking a more or less distorted trigonal bipyramidal axis, does not suffice. Upon first inspection, all the structures would appear to be a form of distorted square pyramid (see Figures 4–7 below). One thus needs to pay closer attention to the Zn–N bond lengths. In some cases (**23a**, **23b**, and to a lesser extent **27a**), the Zn–N bonds have almost the same lengths and the coordination polyhedra should therefore be regarded as being tetragonal-pyramidal with the sulfur atom in the apical position. The other complexes exhibit strongly differing values for pairs of opposing Zn–N bonds. They can therefore be classified as trigonal-bipyramidal. In these cases the thiolate ligand assumes an equatorial position. This effect is most strongly pronounced in complex **26a** (Figure 7): the mean deviation between adjacent Zn–N bond lengths is nearly twice as large (0.14 Å) as the difference between the *average* Zn–N and Zn–S bond length (0.08 Å). The species **21a** and **21b** must be classified as being "in between", since they exhibit neither a peculiar "axis" nor sufficiently small deviations in the Zn–N bond lengths.

The nitrogen atoms in these complexes are chiral in nature and we describe their actual configuration using established conventions.[37,38] The positions of hydrogen atoms or methyl groups are denoted relative to a plane (or near-plane) defined by the nitrogen atoms. If the N-bound residues are found on the side of the complex that bears the thiolate, their position is indicated with a (+). N-bound residues opposite the thiolate side are denoted with a (–). It is obvious that the configuration of the $N_3$ complexes is always (+ + +), as is expected for ligands whose cavities are too small for the respective metal ion.[37]

### *[Zn(7)(SR)]$ClO_4$ (21) and [Zn(8)(SR)]$ClO_4$ (22)*

The ring size of ligands **7** and **8** is rather small and all four structures accordingly exhibit the (+ + + +) configuration (Figure 4). Although compounds **21** both have a pair of opposing "long" and "short" bonds, the difference of both "axes" is too small to consider the geometries as being

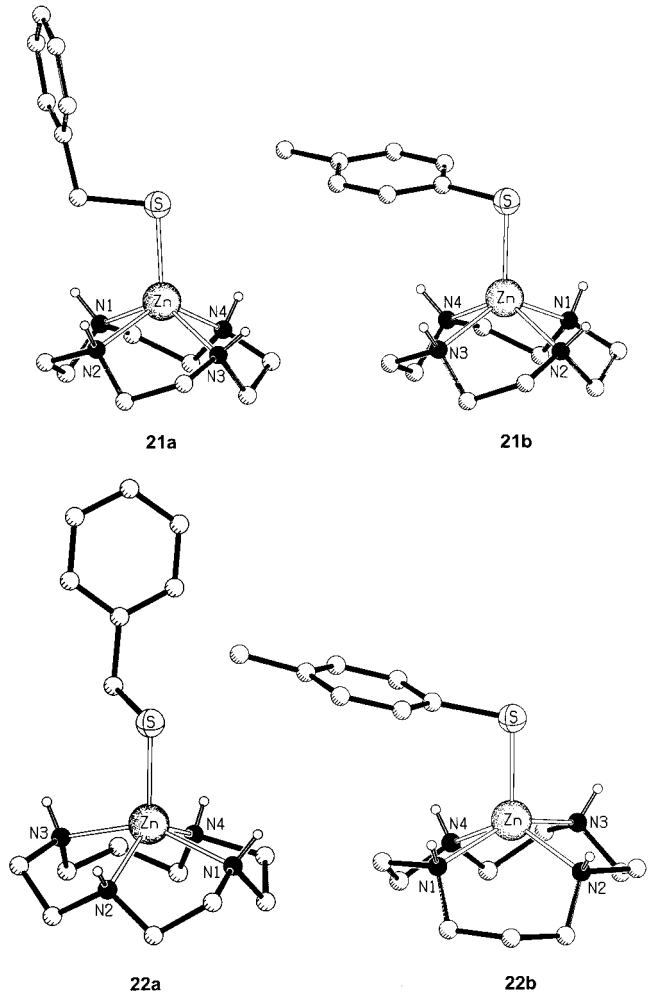

Figure 4. Molecular structures of **21a**, **21b**, **22a**, and **22b**. Selected bond lengths [Å]: **21a**: Zn–S 2.266(2), Zn–N1 2.159(4), Zn–N2 2.205(5), Zn–N3 2.151(4), Zn–N4 2.176(4); **21b**: Zn–S 2.2796(7), Zn–N1 2.175(2), Zn–N2 2.143(3), Zn–N3 2.201(3), Zn–N4 2.162(2); **22a**: Zn–S 2.2853(9), Zn–N1 2.218(3), Zn–N2 2.127(3), Zn–N3 2.187(3), Zn–N4 2.114(4); **22b**: Zn–S 2.2957(5), Zn–N1 2.200(2), Zn–N2 2.109(2), Zn–N3 2.208(2), Zn–N4 2.138(2).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

trigonal-bipyramidal. The reason for this distortion is the small ring size of the ligand **7**, which enforces a marked rigidity in the coordination polyhedron. Although the system obviously strives for bipyramidality, steric constraints imposed by the ring force a tetragonal-pyramidal structure. In the case of complexes **22**, the ring is considerably larger and allows the formation of a (severely distorted) trigonal bipyramid. In agreement with this assignment, the IR spectra show a single N–H stretching band for complexes **21a** (3292 $cm^{-1}$) and **21b** (3301 $cm^{-1}$), emphasizing the degree of equivalence of the nitrogen atoms. In contrast to this, the N–H protons of compounds **22** are chemically inequivalent and three stretching bands are observed for both **22a** (3276, 3288, and 3306 $cm^{-1}$) and **22b** (3272, 3289, and 3322 $cm^{-1}$).

### *[Zn(9)(SR)]ClO$_4$ (23)*

With regard to the other [$N_4$] ligands, cyclam (**9**) yields an unusual result as complexes of **9** are the only ones which exhibit an almost perfect square-pyramidal geometry (Figure 5). This is particularly surprising since the ligand is clearly large enough to allow the formation of a trigonal bipyramid. The influence of the thiolate ligand on the conformation is minimal. All the Zn–N bond lengths are almost identical, with their maximum deviation being less than 0.02 Å for **23a** and 0.01 Å for **23b**. The two Zn–S bond lengths are identical within experimental error. Both complexes exhibit a (+ + – –) configuration which has been reported as being generally the most stable geometry.[39] Of the investigated complexes, **23b** is the only one which possesses a rigorous molecular symmetry ($C_s$) in the solid state, with the plane of symmetry being defined by C1, Zn, and S. The IR spectrum of **23b** thus exhibits two extraordinarily sharp N–H stretching bands at 3270 and 3259 $cm^{-1}$ with exactly the same intensity. In contrast, the absorptions of **23a** at 3272 and 3259 $cm^{-1}$ are not as sharp and their intensities show a marked difference.

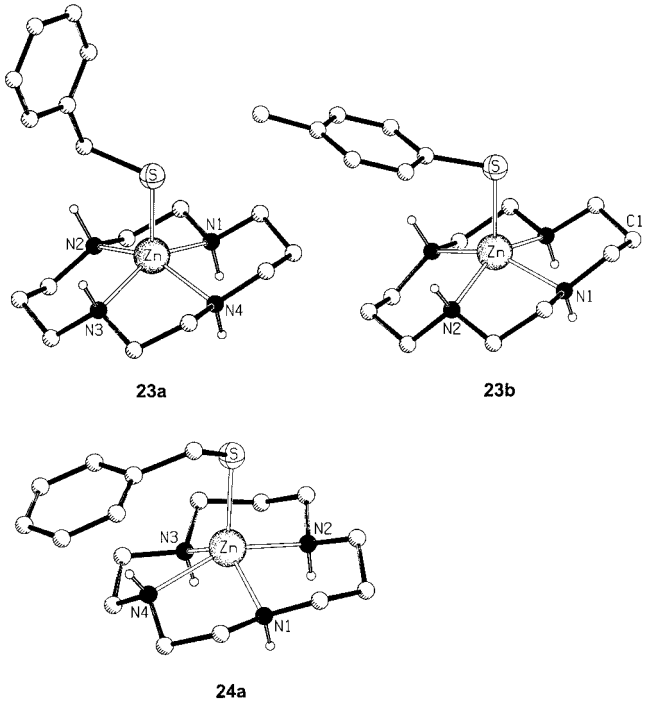

Figure 5. Molecular structures of **23a**, **23b**, and **24a**. Selected bond lengths [Å]: **23a**: Zn–S 2.3161(7), Zn–N1 2.155(2), Zn–N2 2.151(2), Zn–N3 2.149(2), Zn–N4 2.139(2); **23b**: Zn–S 2.3174(8), Zn–N1 2.139(2), Zn–N2 2.147(2); **24a**: Zn–S 2.2902(6), Zn–N1 2.112(2), Zn–N2 2.187(2), Zn–N3 2.123(2), Zn–N4 2.218(2).

### *[Zn(10)(SR)]ClO$_4$ (24)*

Complex **24a** possesses a (+ – – –) configuration which complies with the structural symmetry of the ligand (Figure 5). The symmetry of **24a** results in essentially two amine bands in its IR spectrum. One is located at 3268 $cm^{-1}$ (br., N1–H, N2–H, N3–H) and apparently consists of two closely overlapping bands, and the second band at 3309 $cm^{-1}$ is quite sharp (N4–H). The IR spectrum of **24b** is very similar. It also exhibits two bands at 3248 and 3305 $cm^{-1}$. We therefore assume that **24b** is very likely to have the same configuration.

### *[Zn(11)(SR)]ClO$_4$ (25)*

The most significant difference between the two compounds derived from ligand **11** is the configuration of the tertiary nitrogen atom, which is found to be (+) in complex **25a** and (–) in **25b**. This results in differing symmetries for the complexes (Figure 6). A related observation has been reported by Alcock et al.,[40] who have determined from $^1$H NMR spectroscopic data that a $D_2O$ solution of [Zn(**11**)]$(NO_3)_2$ contains two isomers, one of which is symmetric and the other asymmetric. In the present case, this effect can be observed in the $^1$H NMR spectrum of **25a** but not for **25b** due to the lack of an isolated signal. The benzylic methylene protons of **25a** yield two peaks at $\delta$ = 3.80 and 3.76 ppm with a relative intensity of 5:1. Its $^{13}$C NMR spectrum shows a predominant set of signals with five ring methylene peaks. For **25b**, two different $^{13}$C NMR spectroscopic data sets could be detected for the methylene carbon atoms of the macrocycle, a major set with five peaks and a

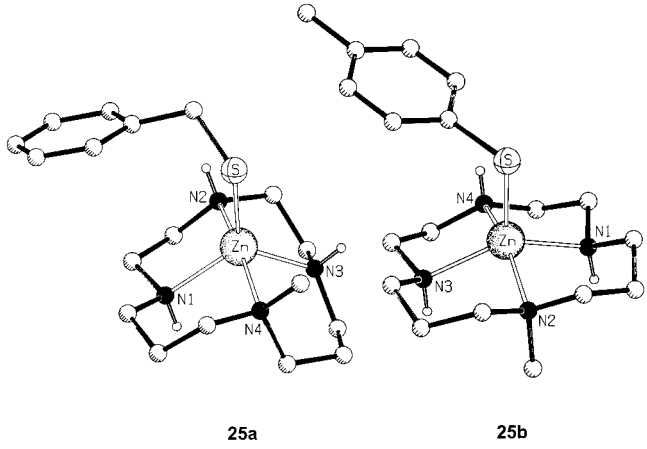

Figure 6. Molecular structures of **25a** and **25b**. Selected bond lengths [Å] and angles [°]: **25a**: Zn–S 2.3200(7), Zn–N1 2.118(2), Zn–N2 2.235(2), Zn–N3 2.133(2), Zn–N4 2.202(2); N2–Zn–N4 165.81(9); **25b**: Zn–S 2.3182(9), Zn–N1 2.106(3), Zn–N2 2.171(3), Zn–N3 2.105(3), Zn–N4 2.191(3); N2–Zn–N4 154.3(2).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

minor set consisting of ten peaks. We thus assume that in both cases the predominant species is of the same symmetric configuration as found in the solid-state structure of **25b**. The minor component is of an asymmetric configuration, analogous to the solid-state structure of **25a**.

The fact that the crystal lattices of **25a** and **25b** contain different configurational isomers is also reflected in their IR spectra. Three N–H bands at 3239, 3308 and 3346 $cm^{-1}$ are present in the case of the unsymmetrically configured **25a** and only two at 3246 (br.) and 3293 $cm^{-1}$ for the symmetric ligand configuration found in **25b**.

### *[Zn(12)(SR)]$ClO_4$ (26)*

As mentioned above, **26a** (synthesized from ligand **12**) has the largest deviations in its Zn–N bond lengths. It clearly adopts a trigonal-bipyramidal geometry and a (+ – – –) configuration of the nitrogen atoms (denoted in the order N1–N2–N3–N4; see Figure 7). Similar to **25a**, the NMR spectra reveal that a chloroform solution of complex **26a** contains two isomers. The $^{13}C$ NMR spectrum exhibits 11 methylene carbon peaks for the main component and seven for the minor component. The major component possesses an asymmetric configuration of the chiral nitrogen atoms, which is very likely identical to the solid-state structure of this compound. The symmetric configuration of the minor component might be (+ – – +) or all-(–), but this question could not be answered from the routine NMR spectroscopic data. The $^1H$ NMR spectrum shows a multiplet for the benzylic methylene protons. Upon closer inspection, this multiplet consists of a singlet at $\delta$ = 3.85 ppm (minor component, 15% of total integral value of benzyl protons) overlapping with an AB spin system at $\delta$ = 3.81 ppm (main component, $J$ = 14.3 Hz, $\Delta\delta$ = 9.7 Hz). This observation fits perfectly, since the asymmetric configuration of the nitrogen atoms ensures a chiral zinc atom. The benzyl protons are thus in a diastereotopic environment, which causes the multiplicity of their NMR signal. (Why this is only observed for **25a** and not for the other complexes of asymmetric configuration remains a mystery. A possible explanation could be found in different velocities of configurational change, which might cause enhanced line-widths for the other complexes and render the detection of signal multiplicities impossible. However, we are not sure about this.) The IR spectrum shows only three bands at 3251, 3266, and 3286 $cm^{-1}$, which is not surprising since the structural environments of N2 and N4 are very similar. For compound **26b**, only one structural motif could be obtained by X-ray crystallography. It reveals, however, that the configuration of the ligand is the same as found in **26a**.

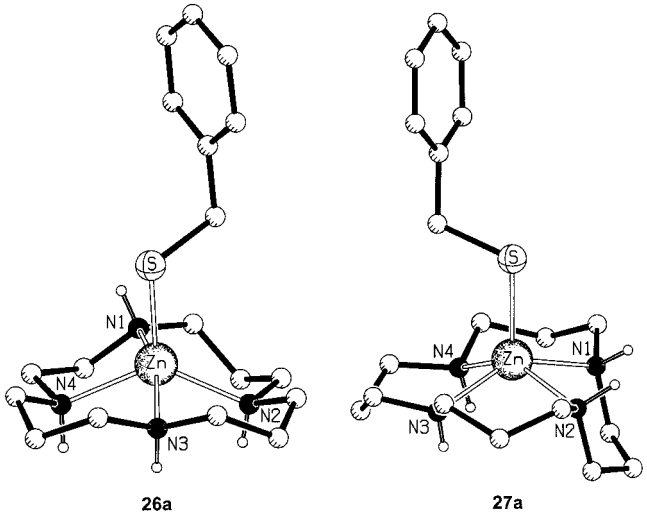

Figure 7. Molecular structures of **26a** and **27a**. Selected bond lengths [Å]: **26a**: Zn–S 2.28(2), Zn–N1 2.271(3), Zn–N2 2.115(3), Zn–N3 2.256(3), Zn–N4 2.123(3); **27a**: Zn–S 2.299(2), Zn–N1 2.208(3), Zn–N2 2.182(3), Zn–N3 2.194(3), Zn–N4 2.189(3).

### *[Zn(14)(SR)]$ClO_4$ (27)*

Ligand **14** is known to form complexes that are less stable than complexes formed from smaller macrocycles. A detailed study has shown that the steric strain in the six-membered chelate rings is responsible for this.[37] Zinc(II) tends to form the complex [Zn(**14**)]$(ClO_4)_2$ with a (+ – + –) configuration. Its stability stems from the fact that the metal ion's size and the Zn–N bond length ensure a chair conformation in each of the four chelate rings. A mixture of this compound with **27a** was obtained when sodium thiolate was used for synthesis; only the potassium salt afforded the pure thiolate complex. In the case of **27a**, the central $Zn^{2+}$ ion is pentacoordinate (Figure 7), which obviously does not allow the nitrogen atoms to arrange in a tetrahedral manner. However, the ligand folds in such a way that only chelate rings with a chair conformation are formed. The N–Zn–N angles of the adjacent nitrogen atoms vary between 78 and 89°. Obviously, ring strain is low enough to render the complex more stable than [Zn(**14**)]$(ClO_4)_2$. In accordance with the observed molecular symmetry, the IR spectrum of **27a** shows only one N–H absorption at 3249 $cm^{-1}$. Two IR bands were observed for compound **27b**, which comply with two pairs of chemically nonequivalent hydrogen atoms. This does not, however, necessarily indicate the presence of another configuration.

### *[Zn(15)(SR)]$ClO_4$ (28)*

When sodium thiolate was used to synthesize complex **28a**, the sulfur-free complex [Zn(**15**)]$(ClO_4)_2$ (**16**) was obtained instead (Figure 8). Only the use of the potassium salt afforded complex **28a**, while **28b** was also obtained with sodium *p*-methylbenzenethiolate. These compounds and complex **16** are the first reported zinc complexes of the ligand [15]ane$N_5$ (**15**). They all show a high degree of structural equivalence regarding the configuration of the macrocycle. The unit cell of **28b** contains two independent molecules with almost superimposable coordination polyhedra, although noticeable deviations in the bond lengths are encountered. Since the two molecules have nearly the same appearance, only one of them is depicted in Figure 8.

These hexacoordinate zinc complexes with the rare $N_5S$ coordination environment (only one structurally charac-

Selected bond lengths [Å]: **16**: Zn–N1 2.100(2), Zn–N2 2.067(2), Zn–N3 2.170(2), Zn–N4 2.179(2), Zn–N5 2.168(2); **28a**: Zn–S 2.3782(7), Zn–N1 2.199(3), Zn–N2 2.366(3), Zn–N3 2.192(3), Zn–N4 2.368(3), Zn–N5 2.221(3); **28b** (molecule A): Zn–S 2.405(2), Zn–N1 2.206(7), Zn–N2 2.331(6), Zn–N3 2.152(5), Zn–N4 2.385(6), Zn–N5 2.194(5); (molecule B, not depicted): Zn–S 2.435(2), Zn–N1 2.265(5), Zn–N2 2.309(6), Zn–N3 2.199(5), Zn–N4 2.307(6), Zn–N5 2.205(5).

terized example has been reported until now[41]) do not have much in common with the other complexes discussed in this work. Their coordination polyhedra cannot be assigned to a specific structure type. Of the complexes discussed in this study, **28a** reveals the largest mean Zn–N bond length (2.267 Å), and **28b** shows the largest deviation within a single molecule (0.23 Å). However, the most significant characteristics are probably the zinc–sulfur bond lengths, which are 2.3782(7) Å for **28a** and 2.405(2) and 2.435(2) Å for **28b**, respectively. These are extraordinarily long Zn–S bonds compared to the average bond length of 2.29 Å for terminal zinc thiolates listed in the Cambridge Structural Database.[1] This makes complexes **28** somewhat equivalent to the zinc tetrathiolate *anion* $[Zn(SPh)_4]^{2-}$, which has a Zn–SPh bond length of 2.36 Å,[42,43] and accentuates their exceptional structural properties.

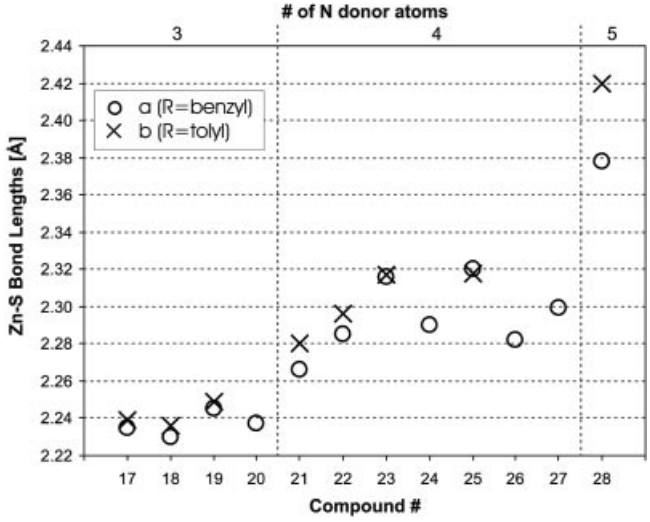

Figure 9. Zn–S bond lengths [Å] (mean value for **28b**).

## Comparative Considerations

Figure 9 shows that the Zn–S bond lengths depend on the number or the nature of the nitrogen donor sites in only a loose way. It is much more obvious that there is a certain correlation with the ring size: as it increases from 11 to 13 atoms, the Zn–S bond lengths increase from approx. 2.23 to 2.29 Å. The Zn–S bonds in complexes with 14-membered or larger rings (compounds **23** to **27**) seem to scatter around a "standard" length of approx. 2.3 Å, which is close to the average zinc thiolate linkage of 2.29 Å as mentioned above. The fact that compounds **28** are much less stable than the other complexes is reflected in their extremely long Zn–S bonds.

In contrast to the previous case, it is not the ring size of the macrocyclic ligand but rather the number of nitrogen donors that seems to have the pivotal influence on the average Zn–N bond lengths. The plot depicted in Figure 10 reveals three distinct groups of compounds, corresponding to the number of nitrogen atoms involved. Their secondary or tertiary nature does not contribute to a Zn–N bond length alteration in a noticeable way. As far as can be

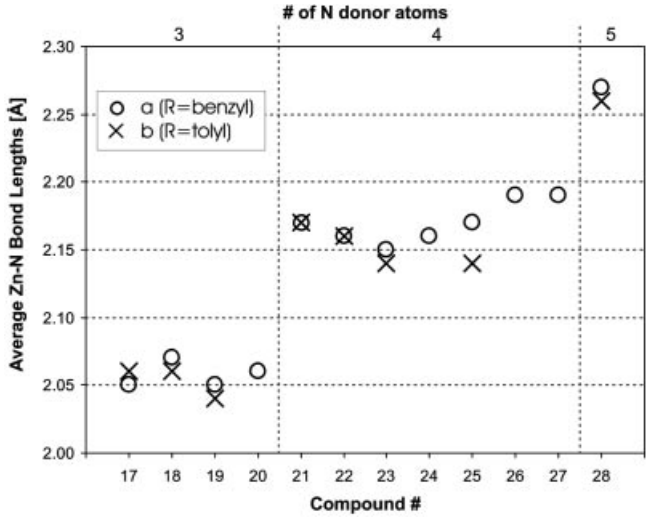

Figure 10. Average Zn–N bond lengths [Å].

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

judged from this incomplete data (four structures are missing), the type of thiolate has no significant influence either.

### NMR Spectra

The $^1$H NMR spectra generally show only nonspecific multiplets and broadened peaks for the hydrogen atoms attached to the macrocycle. This is very likely caused by dynamic effects. Measurements of gradually diluted solutions with concentrations ranging from 0.1 to 4 mM yield unaltered spectra. This allows the conclusion that there is no distinct contribution of intermolecular interactions. Only the benzyl methylene, the tolyl methyl groups, and the aromatic hydrogen atoms exhibit the usual line shape. However, their shifts show only very little dependence on macrocycle substitution. Nevertheless, these signals are suitable for reaction monitoring.

The $^{13}$C NMR spectra are resolved much better, even though they sometimes exhibit considerably increased linewidths for the methylene carbon atoms of the macrocyclic ligands. For all complexes but **26**, the number of detected methylene peaks is smaller than the number of methylene carbon atoms of the macrocycle and correlates directly with the valence symmetry of the macrocyclic ligand. This allows the conclusion that either the complexes adopt a symmetrical structure in solution or the dynamic conformational changes proceed quickly enough to override the asymmetry of the macrocycle that originates in the conformation enforced by the metal coordination. Nevertheless, compounds **19**, **20b**, **22**, **23a**, **25b**, and **26** exhibit additional signals of small intensities for the carbon atoms of the macrocycle. This indicates the presence of at least one additional isomer. In case of the more rigid systems **19**, **20b**, and **22** it is possible that conformational changes in the bridging ethylene and propylene units require comparably high energy barriers and hence are slow on the NMR timescale, thus allowing the detection of the conformers as separate signal sets. Another possible interconversion between species in solution is the configuration inversion of a chiral nitrogen atom. This seems to hold for **23a**, **26**, and particularly for **25b** (see discussion of structures above).

### Mass Spectra

Mass spectra, recorded in ESI mode with a mixture of MeOH and MeCN as solvents, provide valuable information on the stability of the Zn–S bond. The weaker the thiolate is bound, the more species are detected with the monodentate thiolate ligand being replaced by $HO^-$, $MeO^-$, or MeCN, or simply without the ligand. Thus, the intensity of these signals as compared to the molecular peak $[Zn(L_n)(SR)]^+$ may be considered as an indicator of complex stability.

According to this approach, the mass spectra reveal the complexes containing small macrocyclic ligands to be the most stable. All complexes with rings of up to 12 atoms (**17**–**21**) show none or only small amounts (up to 10% intensity) of the mentioned degradation products. For the compounds with 13- to 16-membered rings (**28** not considered), the peak intensities of the solvent complexes increase with the ring size, reaching a maximum for compounds **27**. In addition, the aromatic thiolate yields complexes of considerably higher stability than phenylmethanethiolate. This agrees with the observations made during the preparation of **27a** and **28a**. The "overcrowded" complexes **28** are the least stable ones. In the case of the phenylmethanethiolate complex **28a**, the molecular peak could not even be detected. In no case was any evidence for a dissociation of the macrocycle from the zinc center found.

## Conclusions

Azamacrocycles have been found to be suitable ligands to obtain stable, soluble thiolate complexes of $Zn^{II}$. In retrospect, this cannot be taken as a matter of course. The fact that only certain ring sizes and thiolates yield the desired complexes illustrates how sensitive these systems are to steric and electronic influences. (It is worth mentioning that substituted arene- and phenylmethanethiolates are generally suitable for these syntheses, as some additional experiments have shown. However, a more detailed investigation of the issue has not been performed because we did not expect it to provide any fundamentally enhanced insight into the matter.) It is surprising that the crystal lattices of all complexes comprise only monomeric structures. We assume that the steric demand of the benzyl and aryl residues of the thiolate ligands is a substantial factor behind this behavior. Less sterically hindered thiolates such as $MeS^-$ would presumably promote the formation of dimers or oligomers. However, this will probably remain speculation because these compounds are elusive and our efforts to develop alternative synthetic routes were not successful.

The main advantage of this class of complexes is its structural diversity. A large number of thiolate–zinc linkages that differ in length, stability, and bond order can be studied. With the exception of **28**, their solubility in non- and semipolar organic solvents allows the investigation of reactions under conditions that resemble the hydrophobic cavities of enzyme proteins. In addition, there are two characteristics that make them ideally suited for studies combining experimental work and computational methods. First, their molecular structure data are, except for a few examples, available with high accuracy. Second, they contain a comparably small number of non-hydrogen atoms. Thus, quantum mechanical calculations of these compounds can actually be performed at sufficiently high levels of theory to gain insight into reaction mechanisms. Finally, their easy accessibility, long-term stability, and the variety of characterized compounds renders this class of complexes useful for biomimetic studies wherever zinc thiolates are involved.

## Experimental Section

**Materials and Methods:** All reagents used were of analytical purity. Solvents were not dried prior to use, except where indicated. NMR

spectra were recorded using a Bruker AC 250 spectrometer at a temperature of 30 °C. IR spectra were recorded from the neat substances using a Nicolet Avatar 320 FT-IR spectrometer. Elemental analyses were performed using a Heraeus Vario EL III system. Melting points were determined with a Büchi Melting Point B 545 apparatus and are uncorrected. Mass spectra were recorded using a Finnigan MAT SSQ 710 or a Finnigan MAT 900XL TRAP.

**Preparation of the Azamacrocycles:** The preparation essentially followed a published procedure.[30] Small alterations were made to the reaction conditions of the cyclization (2–3 h at 125 °C) and the workup procedure of the deprotected amine. The preparation of 8-methyl-[11]ane$N_3$ (**4**) serves as an example.

**Preparation of 8-Methyl-1,4,8-triazacycloundecane (8-Methyl-[11]ane$N_3$) (4):** A solution of the disodium salt[30] of *N*,*N*-bis[3-(*p*-tolylsulfonyl)aminopropyl]methylamine[44] (88 mmol) and 1,2-bis(*p*-tolylsulfonyloxy)ethane (88 mmol) in dry DMF (1.5 L) was stirred at 140 °C for 3 h. Three-quarters of the solvent was then distilled off in vacuo and the mixture was poured into 1 L of an ice/water mixture. The product was filtered off, washed with plenty of water, and recrystallized from ethanol to yield 56% of 8-methyl-1,4-bis(*p*-toluenesulfonyl)-1,4,8-triazacycloundecane as a colorless solid. M.p. 161 °C. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 1.78 (q, $J$ = 5.65 Hz, 4 H, C$H_2$), 2.19 (s, 3 H, N–C$H_3$), 2.45 (s, 6 H, Ph–C$H_3$), 2.58 (t, $J$ = 6.25 Hz, 4 H, C$H_2$), 3.16 (t, $J$ = 5.73 Hz, 4 H, C$H_2$), 3.37 (s, 4 H, C$H_2$), 7.30 and 7.69 (d, $J$ = 6.56 Hz, 4 H each, Ph–*H*) ppm. $^{13}$C NMR (62.9 MHz, $CDCl_3$): $\delta$ = 21.5, 24.4, 42.4, 48.5, 50.8, 52.5, 127.5, 129.7, 134.9, 143.4 ppm. $C_{23}H_{33}N_3S_2O_4$ (479.67): calcd. C 57.59, H 6.39, N 8.76, S 13.37; found C 57.32, H 7.17, N 8.60, S 13.24. For detosylation, the solid was heated in concd.

N–*H*) ppm. $^{13}$C NMR (62.9 MHz, DMSO): $\delta$ = 44.6, 44.8, 45.3, 46.0 ppm. IR: $\tilde{\nu}$ = 3298 m, 2944 m, 2887 m, 1467 m, 1342 w, 1071 vs, 973 s, 945 s, 798 s, 621 vs cm$^{-1}$.

**Preparation of the Thiolate Complexes:** The ligand (4 mmol) was added with stirring to 40 mL of a hot 0.1 M solution of $Zn(ClO_4)_2 \cdot 6H_2O$ in methanol. Stirring and heating were continued for an additional 15 min. Depending on the ligand, some precipitation occurred. A solution of 4 mmol of the thiol in 8 mL of 0.5 M KOH was then added dropwise, whereupon potassium perchlorate precipitated. The solution was filtered and, after a varying amount of time, colorless crystals separated spontaneously. The precipitates were filtered off and, if necessary, recrystallized from methanol. All complexes revealed a 1:1:1:1 composition of zinc/macrocyclic amine/thiolate/perchlorate, consistent with the general formula $[Zn(L)(SR)]ClO_4$.

**Note:** It is important that the precipitation starts as quickly as possible. Prolonged standing of concentrated solutions lowers the yields and the purity of the products considerably, most likely due to oxidation processes. Thus, it is best to induce the formation of crystals by adding a seed crystal or by ultrasound treatment. If the precipitation of the complex occurs instantly upon addition of the potassium thiolate, which is not normally the case, separation from the solid potassium perchlorate is difficult. In such cases, the synthesis should be carried out using a sodium thiolate solution. The desired complex will then be obtained in a good yield, although without the removal of the alkali metal perchlorate.

**General Properties and Solubility:** All thiolate complexes **17**–**28** form colorless crystalline solids. Substances featuring macrocycles with ring sizes from 14 to 16 atoms and four nitrogen atoms (i.e. **23**–**27**) are readily soluble in chloroform. All complexes, with the exception of **28**, are soluble in acetonitrile and nitromethane, but only partially in methanol. Compounds **28** show only low solubility in all solvents mentioned, but are soluble in DMSO. Other data [elemental analytical data, melting points, and yields (Table 1), IR and mass spectroscopic data (Table 2), and $^1$H (Table 3) and $^{13}$C NMR (Table 4) data] are given in the respective tables.

**Crystal Structure Determination:**[45] The intensity data for compound **23b** were collected with a Nonius CAD4 diffractometer and for the other compounds with a Nonius KappaCCD diffractometer, using graphite-monochromated Mo-$K_\alpha$ radiation. Data were corrected for Lorentz and polarization effects, but not for absorption.[46–48] The structures were solved by direct methods (SHELXS[49]) and refined by full-matrix least-squares techniques against $F_o^2$ (SHELXL-97[50]). For all compounds except for **17b**, **19a**, **20a**, and **21b**, the hydrogen atoms of the amine groups were located by difference Fourier synthesis and refined isotropically. All other hydrogen atoms were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[50] The absolute structures of compounds **16**, **19a**, **21a**, and **28b** could not be determined because they show racemic twinning. XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations. The drawings in this paper were generated using PLATON.[51]

# Synthesis of $\eta^2$-Allene Complexes by the Reaction of a $\eta^1$-Vinylidene Tungsten Complex with Diazoalkanes

**Junes Ipaktschi,*[a] Parham Rooshenas,[a] and Ansgar Dülmer[a]**

**Keywords:** Tungsten / Vinylidene ligands / Allene ligands / Diazoalkanes

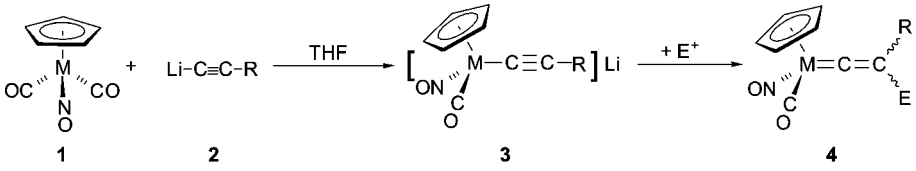
The reaction of the $\eta^1$-vinylidene complex Cp(CO)(NO)-W=C=$CH_2$ (**5**) with diazomethane, to give complex **8**, as well as with ethyl diazoacetate, to give complexes **10** and **11**, is described. The crystal structures of these complexes are reported.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

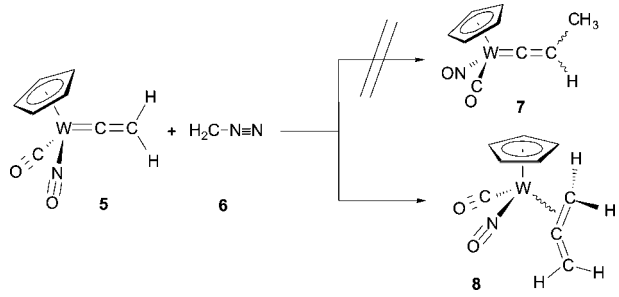
In recent years we have investigated the chemistry of tungsten and molybdenum $\eta^1$-acetylide complexes **3** and the corresponding $\eta^1$-vinylidene complexes **4**.[1] A broad range of differently substituted derivatives of **3** and **4** are prepared by the reaction of the corresponding lithium acetylide **2** with the carbonyl complex **1** in THF at –30 °C, which gives rise to the $\eta^1$-acetylide **3**, and by subsequent addition of electrophiles such as dilute acids, alkylating reagents like alkyltriflates, or iminium salts, which leads to the $\eta^1$-vinylidene complexes **4** (Scheme 1).

Because of the limited accessibility of propyne and also the low solubility of Li–C≡C–$CH_3$, the corresponding complexes **3** and **4** with R = methyl that are prepared by this procedure have low yields. In order to avoid using propyne we have also reported the preparation of **3** and **4** by the reaction of in situ prepared propynyllithium, generated by dehydrobromination of 2-bromopropene, with **1** and concomitant protonation.[2]



Scheme 1.

Owing to the high C–H acidity on the β-carbon atom of the $\eta^1$-vinylidene complexes[3] and in order to obtain complex **7** in good yield, we tested the reaction of $\eta^1$-vinylidene complex **5** with diazomethane. Contrary to the results obtained for the methylation of ruthenium $\eta^1$-vinylidene complexes with diazomethane,[4] we obtained the $\eta^2$-allene derivative **8** instead of complex **7**.[5] In this paper we describe the results of the reaction of diazomethane and ethyl diazoacetate with the $\eta^1$-vinylidene complex **5** (Scheme 2).



Scheme 2.

## Results and Discussion

The reaction of diazomethane with the $\eta^1$-vinylidene complex **5** was carried out in THF/ether at –30 °C (Scheme 2). The progress of the reaction was followed by IR spectroscopy, and after the starting material had disappeared, the solvent was evaporated and the product was

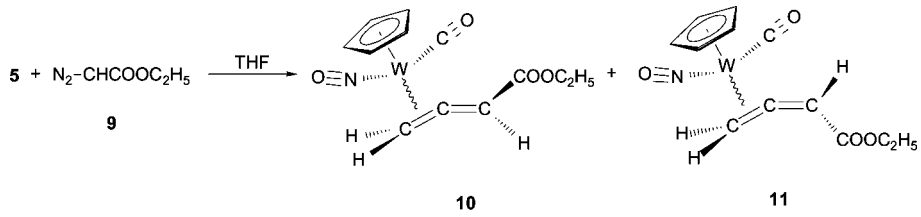

Scheme 3.

purified by chromatography on a short silica column. Complex **8** was isolated in high yields as bright yellow air-stable crystals, which are soluble in most organic solvents. On the basis of the NMR spectroscopic data, it was found that the compound consists of two rotamers in a ratio of 2:1. The structure of **8** was fully characterized by spectroscopic methods (see Exp. Sect.)[6] and by single-crystal X-ray analysis of one of the rotamers. The variable-temperature measurement NMR spectroscopic studies ([$D_6$]DMSO) show that both rotamers of **8** interconvert to one another. The singlet for the Cp protons at $\delta$ = 6.0 and 5.9 ppm broadens at higher temperatures and finally collapses because of the fast equilibration of both rotamers. The free activation energy for this process, calculated from the coalescence temperature (77 kJ·mol$^{-1}$), is higher than the reported energies for allene complexes such as dicarbonyl $\eta^5$-cyclopentadienyl($\eta^2$-tetramethylallene)iron.[7]

Similarly, treatment of the $\eta^1$-vinylidene complex **5** at 40 °C in THF with excess ethyl diazoacetate (**9**) resulted in the formation of the stereoisomers **10** and **11** in 87% yield (Scheme 3). According to the $^1$H NMR spectrum, the crude product consists of a mixture of **10** and **11** in a ratio of 1:5. Complex **10** consists of two rotamers in a ratio of 3:5 depending on the relative orientation of the NO and CO ligands. Complexes **10** (mixture of rotamers) and **11** were isolated by HPLC and characterized by means of elemental analysis, spectroscopic methods (see Experimental Section), and single-crystal X-ray analysis. The significant difference between the structures of **10** and **11** is the relative orientation of the ester group toward the tungsten center (*E* or *Z*). While in the minor component **10** the orientation of the ester group and the tungsten atom is *Z* relative to each other, the orientation of these groups in complex **11** is *E*.

### Molecular Structure of Complexes 8, 10, and 11

Suitable crystals for a single-crystal X-ray diffraction analysis of complexes **8** and **10** were grown from pentane and crystals of **11** from an ether solution at 4 °C. The molecular structures are shown in Figure 1, Figure 2, and Figure 3, respectively, and relevant crystal data are included in Table 1. The crystal structures of these complexes consist of a well-spaced array of molecular units, and the intermolecular contacts correspond to normal van der Waals distances and the angles are as expected. Complexes **8**, **10**, and **11** all display a piano-stool coordination geometry about the metal atom. The allene ligand is bent in a manner that is generally found in $\eta^2$-allene complexes: the C1–C2–C3

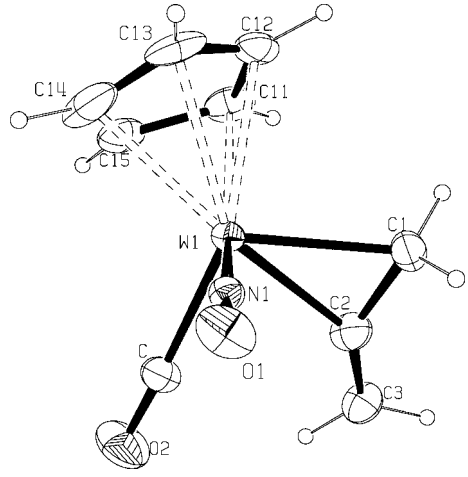

Figure 1. Molecular structure and atom-numbering scheme for complex **8**. Thermal ellipsoids are shown at the 20% probability level. Selected bond lengths [Å] and angles [°] (with standard deviations): W1–N1 1.767(10), W1–C 2.027(14), W1–C2 2.185(14), W1–C1 2.188(14), C1–C2 1.46(2), C2–C3 1.31(2), O1–N1 1.234(13), C–O2 1.096(18), N1–W1–C 91.3(5), N1–W1–C2 103.8(5), C–W1–C2 70.6(6), N1–W1–C1 93.1(5), C–W1–C1 108.1(6), C2–W1–C1 38.9(6), C2–C1–W1 70.4(8), C3–C2–C1 144.9(15), C3–C2–W1 144.3(14), C1–C2–W1 70.7(8), O1–N1–W1 176.1(9), O2–C–W1 177.5(16).

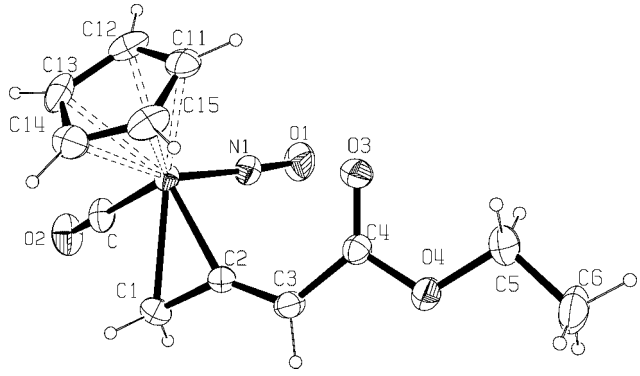

Figure 2. Molecular structure and atom-numbering scheme for complex **10**. Thermal ellipsoids are shown at the 20% probability level. Selected bond lengths [Å] and angles [°] (with standard deviations): W1–N1 1.795(5), W1–C 2.009(5), W1–C2 2.112(5), W1–C1 2.250(6), N1–O1 1.188(6), C–O2 1.121(6), C1–C2 1.402(7), C2–C3 1.330(7), C3–C4 1.454(7), C4–O3 1.203(6), N1–W1–C 90.7(2), N1–W1–C2 90.0(2), C–W1–C2 108.9(2), N1–W1–C1 102.2(2), C–W1–C1 73.6(2), C2–W1–C1 37.3(2), O1–N1–W1 176.7(5), O2–C–W1 179.4(5), C2–C1–W1 66.0(3), C3–C2–C1 139.7(5), C3–C2–W1 143.0(4), C1–C2–W1 76.7(3), C2–C3–C4 124.2(5).

angle is 144.9(15)° in complex **8**, 139.7(5)° in complex **10**, and 142.1(6)° in complex **11**.[8] The length of the coordinated double bond in **8** [C1=C2, 1.46(2) Å] is significantly longer than that of the uncoordinated bond [C2=C3, 1.330(7) Å]. However, relative to the C1–C2 bond in **8**, the coordinated double bonds in complexes **10** and **11** are slightly shorter: 1.402(7) Å in **10** and 1.393(8) Å in **11**. The length of the C4–O3 bond of the acyl function falls into the expected average value range for an α-β unsaturated ketone: 1.203(6) Å in **10** and 1.215(0) Å in **11**.[9] The distance from the metal to the central carbon atom of the allene ligand (W–C2) is slightly shorter than the distance from the metal to the terminal carbon atom (W–C1). This difference is 0.138 Å in complex **11** and 0.45 Å in **10**.[10] The overlap between a filled d orbital on the metal and both of the unoccupied orthogonal π* orbitals of the central carbon atom contribute to this difference.[11] However, this interaction seems to be unpronounced in complex **8**.

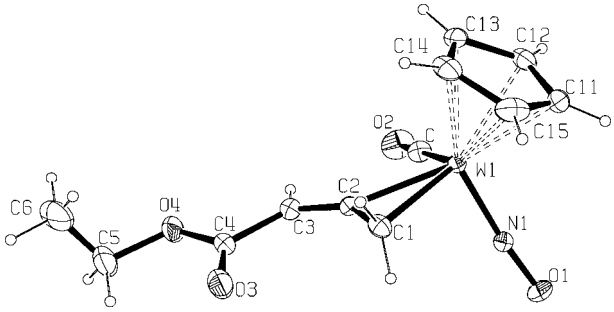

Figure 3. Molecular structure and atom-numbering scheme for complex **11**. Thermal ellipsoids are shown at the 20% probability level. Selected bond lengths [Å] and angles [°] (with standard deviations): W1–N1 1.783(5), W1–C 1.964(7), W1–C2 2.175(5), W1–C1 2.220(6), C1–C2 1.393(8), C2–C3 1.314(8), C3–C4 1.478(9), N1–O1 1.212(6), N1–W1–C 92.6(3), N1–W1–C2 99.5(2), C–W1–C2 74.9(3), N1–W1–C1 92.0(2), C–W1–C1 111.4(3), C2–W1–C1 37.0(2), C2–C1–W1 69.8(3), C3–C2–C1 142.1(6), C3–C2–W1 144.5(5), C1–C2–W1 73.3(3), C2–C3–C4 122.4(7), O1–N1–W1 173.8(4), O2–C–W1 178.1(7).

## Experimental Section

**General Considerations:** All reactions were carried out under an argon atmosphere (99.99%, by Messer-Griesheim). Solvents were purified by standard methods and distilled under argon prior to use. Literature methods were used to prepare [($\eta^5C_5H_5$)(CO)(NO)W=C=$CH_2$] (**5**),[12] $CH_2N_2$,[13] and $N_2CHCO_2CH_3$[14]. All other compounds were commercially available. NMR spectra were obtained with Bruker AM 400 and AC 200 spectrometers. Proton and

carbon chemical shifts were referenced to tetramethylsilane. MS measurements (70 eV) were performed with a Varian MAT 311-A. IR spectra were recorded with a Bruker FT-IR IFS 85. Microanalyses were done on a Carlo–Erba 1104 elemental analyzer.

**Preparation of [($\eta^5$-$C_5H_5$)(CO)(NO)W($\eta^2$-$H_2C{=}C{=}CH_2$)] (8):** A solution of $CH_2N_2$ (0.14 M, 230 mL) in diethyl ether (33.3 mmol) was slowly added to a solution of **5** (990 mg, 3.3 mmol) in THF (10 mL) at –30 °C, and the progress of the reaction was monitored by IR Spectroscopy. After 6 h, the solvent was removed under vacuum, and the crude product was purified by chromatography on silica gel with a pentane/ether mixture (1:1). The yellow compound was recrystallized from an ether/pentane solution to give 700 mg of complex **8** (61% yield), which consists of two isomers with a diasteriomeric ratio of 2:1, determined from $^1$H NMR spectroscopic data. $C_9H_9O_2NW$ (347.01): calcd. C 31.15, H 2.61, N 4.04; found: C 31.52, H 2.28, N 3.89. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 6.91 and 6.86 (t, $^4J_{H,H}$ = 3.5 Hz for both rotamers, 1 H, C3) and 6.09 and 5.81 (t, $^4J_{H,H}$ = 3.5 Hz for both rotamers, 1 H, C3), 5.71 and 5.66 (Cp), 1.86 and 2.19 and 1.77 (the major component: t, $^4J_{H,H}$ = 3.5 Hz; the minor component: two dt, $^2J_{H,H}$ = 11 Hz, $^4J_{H,H}$ = 3.5 Hz, 2 H, C1) ppm.$^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 213.7 and 215.0 (CO), 161.3 and 160.2 (C2), 110.3 and 107.1 (C3), 95.9 and 95.5 (Cp), 7.2 and –4.1 (C1) ppm. IR (KBr): $\tilde{\nu}$ = 1988 (C≡O), 1599 (N≡O) cm$^{-1}$.

**Preparation of (*E*/*Z*)-{($\eta^5$-$C_5H_5$)(CO)(NO)W[$\eta^2$(2,3)-$H_2C{=}C{=}CH$-$C(O)OCH_2CH_3$]} (10 and 11):** A solution of ethyl diazoacetate (464 mg, 4 mmol) in THF (10 mL) was added to a solution of the vinylidene complex **5** (1 mmol, 333 mg) in THF (10 mL) at a rate of 1 ml per hour at 45 °C. The reaction mixture was monitored by IR Spectroscopy, and the reaction reached completion after 12 h. The solvent was removed under vacuum. The crude product was redissolved in pentane and purified by chromatography on a silica column. The yellow band was eluted with $CH_2Cl_2$/pentane (1:2), which resulted in 182 mg of a mixture of two stereoisomers **11** and **10** (87% yield), in a ratio of 5:1. The isomers were separated by HPLC, with TBME/hexane as the eluent mixture on a Diol-Phase. $C_{12}H_{13}O_4NW$ (405.07): calcd. C 34.39, H 3.13, N 3.34; found C 34.34, H 3.15, N 3.31.

**(*Z*)-{($\eta^5$-$C_5H_5$)(CO)(NO)W[$\eta^2$(2,3)-$H_2C{=}C{=}CHC(O)OCH_2CH_3$]} (10):** $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 7.43 (t, X part of an ABX spin system, 1 H, C3), 5.80 (s, 5 H, Cp), 4.24 (m, 2 H, C5); 2.07 (dd, $^2J_{H,H}$ = 12.1, $^4J_{H,H}$ = 2.7 Hz, B part of the ABX system, 1 H, C1), 1.77 (dd, $^2J_{H,H}$ = 12.1 Hz, $^4J_{H,H}$ = 3.2 Hz, A part of the ABX system, 1 H, C1), 1.33 (t, 3 H, C6) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 212.9 (*C*O), 180.0 (C4), 167.8 (C2), 117.0 (C3), 96.7 (Cp), 59.6 (C5), 14.5 (C6), 3.9 (C1) ppm. IR (KBr): $\tilde{\nu}$ = 2030 (W–*C*≡*O*), 1703 (C=O ester), 1625 and 1671 (N≡O) cm$^{-1}$.

**(*E*)-{($\eta^5$-$C_5H_5$)(CO)(NO)W[$\eta^2$(2,3)-$H_2C{=}C{=}CHC(O)OCH_2CH_3$]} (11):** The major component was recrystallized from an ether/pentane solution and consisted of two rotamers in a ratio of 3:5. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 6.67 and 6.47 (t, $^4J_{H,H}$ = 3.0 Hz, $^4J_{H,H}$ = 3.6 Hz, C3, X part of ABX spin-system, 1 H), 5.72 and 5.70 (s, 5 H, Cp), 4.24 (m, 2 H, C4); 2.58 and 2.29, (dd, AB part, $^2J_{H,H}$ = 12.8 Hz, $^4J_{H,H}$ = 3.0 Hz, 1 H, C1 with the first order approximation), 2.24 and 2.17 (dd, $^2J_{H,H}$ = 12.8 Hz, $^4J_{H,H}$ = 3.0 Hz, 1 H, C1 with the first order approximation), 1.31 (t, $^3J_{H,H}$ = 6.9 Hz, 3 H, C6) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 213.0 and 210.8 (C*O*), 179.1 and 176.4 (C4), 165.9 and 164.9 (C2), 118.9 and 115.7 (C3), 96.0 and 95.6 (Cp), 60.2 and 60.6 (C5), 14.4 and 14.3 (C6), 10.4 and –0.2 (C1) ppm. IR (KBr): $\tilde{\nu}$ = 2006 (W–*C*≡O), 1717 (C=O ester), 1681 and 1598 (N≡O) cm$^{-1}$.

CCDC-288085 to -288087 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Phase Relations Between β-Tricalcium Phosphate and Hydroxyapatite with Manganese(II): Structural and Spectroscopic Properties

Isaac Mayer,*[a] Frederic J. G. Cuisinier,[b] Ina Popov,[c] Yechezkel Schleich,[a] Sarit Gdalya,[a] Olaf Burghaus,[d] and Dirk Reinen[d]

**Keywords:** Manganese / β-Tricalcium phosphate / EPR spectroscopy

The preparation of Mn-containing β-tricalcium phosphate (β-TCP) samples was achieved in two ways: a) transformation of precipitated Mn-containing calcium hydroxyapatite (HA) to β-TCP by heating at 1100 °C, and b) preparation by solid-state reaction of a mixture of $CaCO_3$, $(NH_4)_2HPO_4$, and $Mn(NO_3)_2$ at 1100 °C. Powder X-ray diffraction (XRD) analyses of the samples, obtained by both methods, show well-defined patterns with structural data of the rhombohedral R3c, β-TCP phase. The calculated lattice constants are smaller than those known for β-$Ca_3(PO_4)_2$ because of substitution of $Ca^{2+}$ by $Mn^{2+}$. EPR spectroscopy indeed reveals that manganese is divalent in the samples. Apparently, the Ca(5) site in the β-TCP structure is occupied by $Mn^{2+}$. The distribution of $Mn^{2+}$ between the β-TCP and the HA phase in the case of preparation (b) was studied by EPR spectroscopy, and a pronounced preference for the former lattice was found. Micron- and submicron-sized crystals with visible faces were observed by TEM in the case of β-TCP prepared by solid-state reaction, and large micron-sized, droplike-shaped crystals, sensitive to beam radiation, were found in the case of samples prepared by heating HA at elevated temperatures.

## Introduction

Calcium hydroxyapatite (HA), the main constituent of bones and teeth, is biocompatible and widely used in dentistry and orthopedics to repair bone defects and substitution, and as coating material for metallic implants. β-Tricalcium phosphate is also known as a biocompatible material and is found in many cases to be advantageous as compared with HA.[1–3] It is also used as a host when doped with Mg, Zn, and Cd ions.[4,5]

In previous work,[6] HA samples containing $Mn^{2+}$ were prepared by a precipitation method. The motivation for the addition of $Mn^{2+}$ ions to HA was due to the fact that divalent $Mn^{2+}$ has been linked to the activation of integrins,[7] a family of receptors that mediate cellular interactions with extracellular matrix and cell surface ligands. In the presence of $Mn^{2+}$ ions the ligand affinity of integrin increases and cell adhesion is promoted. High-temperature treatment of the precipitated samples showed that samples with low carbonate content transform partially or completely to β-TCP. EPR spectroscopy proved that manganese is divalent also in the heated samples and is found to partly occupy $Ca^{2+}$ sites in the β-TCP structure.[6] In further work,[8] human osteoblasts were cultured on the surfaces of Mn-doped HA thin films deposited on etched Ti substrates. Biological tests demonstrated that the Mn-doped HA coatings favor osteoblasts proliferation, activation of their metabolism, and differentiation.

The aim of the present work was to prepare Mn-doped β-TCP samples and to determine the $Mn^{2+}/Ca^{2+}$ miscibility limit. Two preparation methods were applied: a) transformation of Mn-containing HA to β-TCP, and b) preparation of β-TCP by high-temperature solid-state reaction of stoichiometric mixtures of $CaCO_3$, $(NH_4)_2HPO_4$, and $Mn(NO_3)_2$.

## Results

### β-TCP Prepared by Heating Precipitated HAMn

HAMn samples were prepared with a broad range of Mn content (0.1–4.0%). In Table 1, Mn content and Ca/P molar ratios of the samples are listed. The Ca/P values of the original HAMn samples were always lower than 1.67, indicating nonstoichiometric HA, and these values decreased with increased Mn content. The powder XRD patterns of the precipitated HAMn samples had reflections solely of the hexagonal apatite structure. The XRD patterns of the samples after heating to 400 °C showed no change in their crystal structure. At 600 °C the XRD patterns already contained

Table 1. β-Tricalcium phosphate phases obtained by heating HAMn samples to 800–1000 °C. Lattice constants and unit cell volumes, Mn content, Ca/P molar ratios (in the initial HA phase), and estimated rates of transformation to β-TCP.

| Sample | Mn (1)[a] molar content | Lattice constants [Å] *a* | *c* | Lattice volume [Å$^3$] | Ca/P molar ratios | Transformation to β-TCP [%] |
|---|---|---|---|---|---|---|
| $Ca_3(PO_4)_2$ | – | 10.43 | 37.38 | 3522 | 1.50 | – |
| HAMn28 | 0.030 | 10.42 | 37.37 | 3510 | 1.54 | 65 |
| HAMn5b | 0.035 | 10.42 | 37.35 | 3510 | 1.49 | 85 |
| HAMn147 | 0.070 | 10.41 | 37.33 | 3505 | 1.48 | 65 |
| HAMn142 | 0.105 | 10.40 | 37.29 | 3494 | 1.48 | 70 |
| HAMn145 | 0.117 | 10.39 | 37.25 | 3482 | 1.51 | 75 |
| HAMn146 | 0.130 | 10.39 | 37.20 | 3478 | 1.45 | 75 |
| HAMn149 | 0.150 | 10.39 | 37.24 | 3483 | 1.41 | 75 |
| HAMn158 | 0.165 | 10.30 | 37.29 | 3473 | 1.41 | 75 |

[a] (1) in β-TCP, if complete transformation would occur.

reflections of two crystal phases: reflections of the original hexagonal HA phase[9] and reflections of the rhombohedric β-TCP.[10] In the 800–1000 °C region, most of the HA (around 75%) transformed to β-TCP. The degree of transformation of HA to β-TCP was roughly estimated by the relative peak heights of the strongest HA (211) and β-TCP (0.2.10) reflections. These findings suggest that the hexagonal apatite structure of the nonstoichiometric HA samples is stable even at very low Ca/P ratios and transforms to the rhombohedral structure only on heating. The structural data of the rhombohedral phases are listed in Table 1.

### β-TCP Prepared by Solid-State Reaction

Samples with a general composition of $Ca_{3-x}Mn_x(PO_4)_2$ were prepared with different $x$ values in the range of 0.1–1.0 in intervals of 0.1 and appear in Table 2. The XRD patterns of the obtained samples revealed that these samples crystallize in the R3c rhombohedral structure characteristic of β-TCP. No reflections of a different impurity phase were present up to the composition $Ca_{2.4}Mn_{0.6}(PO_4)_2$. Above this composition the XRD pattern contained peaks of a second unknown crystal phase. Apparently, about 20 mol-% of $Mn^{2+}$ can be substituted for $Ca^{2+}$ in β-TCP.

Table 2. Structural data of β-$Ca_{3-x}Mn_x(PO_4)_2$ solid solutions obtained by solid-state reaction.

| Lattice constants [Å] *c* | *a* | Lattice volume [Å$^3$] | Composition | Samples |
|---|---|---|---|---|
| 37.38 | 10.431 | 3522 | $Ca_3(PO_4)_2$ | TCP |
| 37.37 | 10.424 | 3517 | $Ca_{2.9}Mn_{0.1}(PO_4)_2$ | TCPMn1 |
| 37.32 | 10.404 | 3498 | $Ca_{2.8}Mn_{0.2}(PO_4)_2$ | TCPMn2 |
| 37.32 | 10.376 | 3480 | $Ca_{2.7}Mn_{0.3}(PO_4)_2$ | TCPMn3 |
| 37.31 | 10.395 | 3491 | $Ca_{2.6}Mn_{0.4}(PO_4)_2$ | TCPMn4 |
| 37.26 | 10.366 | 3465 | $Ca_{2.5}Mn_{0.5}(PO_4)_2$ | TCPMn5 |
| 37.22 | 10.351 | 3453 | $Ca_{2.4}Mn_{0.6}(PO_4)_2$ | TCPMn6 |

All samples listed in Table 1 and Table 2 were pink at high Mn concentrations and were white at low Mn concentrations. This is in agreement with a +2 oxidation state and hence with the presence of only very weak Laporte- and spin-forbidden transitions in the d-d spectrum of the visible region.

### EPR Analysis

Our previously published EPR spectroscopic data showed that precipitated HAMn[6] contains $Mn^{II}$ in the cubic or nearly cubic environment of an impurity phase, presumably $MnCO_3$ or $Mn(OH)_2$. The EPR spectra in Figure 1 show the characteristic six-line hyperfine structure with $A \approx 90$ G ($\approx 0.0085$ cm$^{-1}$) at Q-band frequency, without any indication of a zero-field splitting also in the X-band, thus excluding the presence of $Mn^{2+}$ in $Ca^{2+}$ positions. On heating to 600 and 800 °C the samples behaved differently, depending on their carbonate content: carbonate-rich (CR) samples retained the apatite structure, while carbonate-poor (CP) samples transformed partly or fully to the β-TCP type.

The Q-band spectrum of $Mn^{2+}$-doped β-TCP prepared by high-temperature solid-state reaction is shown, together with a simulated spectrum with a zero-field splitting of $D$ = 0.047 cm$^{-1}$ (500 G), in Figure 2 (bottom). Besides the partly resolved central signal, whose hyperfine splitting is not accounted for in the simulation ($A$ = 0), the agreement is fairly good, suggesting that the chosen $D$-parameter is near to the one of the experimental spectrum. Inspecting the crystal structure of β-TCP[11] with its five different Ca positions, it is most likely that $Mn^{2+}$ is substituted into the Ca(5) site. The coordination number (CN) is six, the polyhedron geometry is a slightly hexagonally distorted octahedron with $C_3$ point symmetry, and Ca–O bond lengths of 2.263(25) Å are much shorter than the average distances in the other polyhedra with CNs between seven and nine (>2.4 Å). The reported Ca(5)–O bond lengths are surprisingly even smaller than those in CaO (2.40 Å) and rather close to those in MnO (2.22 Å),[13] which both crystallize in the NaCl type. Because the symmetry of the $Ca(5)O_6$ polyhedron is axial, a vanishing (orthorhombic) $E$-parameter is indeed expected in the case of isomorphous substitution of $Ca^{2+}$ by $Mn^{2+}$. Figure 2 (top) shows, in small size, the spectrum of a CP sample with β-TCP structure as well, but obtained from solution by subsequent heating to 800 °C. It is identical with the bottom spectrum, though less resolved because of a poorer sample crystallinity. It can be concluded, therefore, that Mn is present as $Mn^{II}$ in a $Ca^{2+}$ position of the β-TCP host. The X-band measurement on the same two samples confirms this result (Figure 3). The spec-

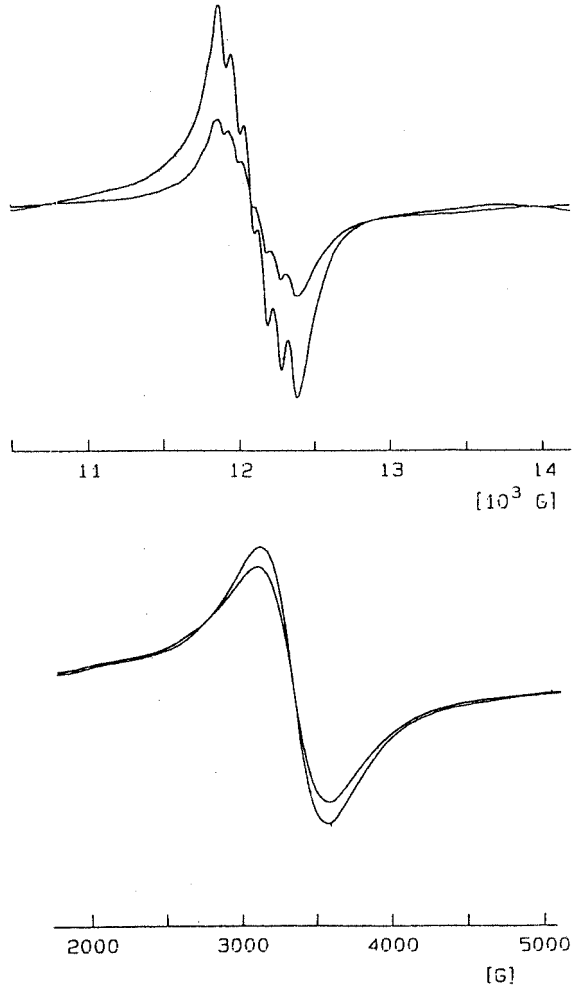

Figure 1. Typical Q- (33.93 GHz) and X-band (9.26 GHz) spectra of precipitated calcium hydroxyapatites in the presence of Mn (298 K).

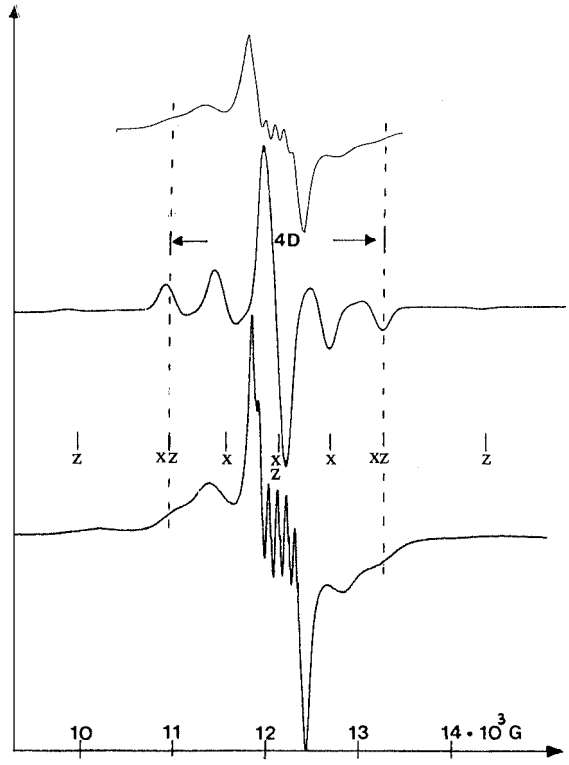

Figure 2. EPR Q-band spectra (34.0 GHz) of $Mn^{2+}$-doped β-TCP obtained by solid-state reaction (TCPMn1; 126 K, bottom) and from solution after subsequent heating to 800 °C with nearly complete transformation to β-TCP (298 K, top), as compared with a simulated spectrum with $D = 0.047\ cm^{-1}$, $A = 0$ (adopted from ref.[12]). The transition parallel ($z$) and perpendicular ($x = y$) to the preferred axial direction are indicated.

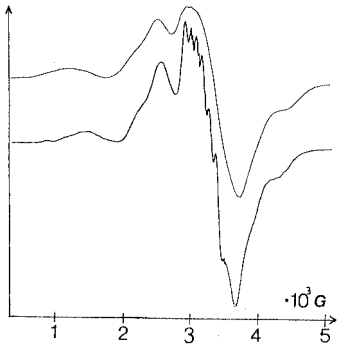

Figure 3. X-band spectra (9.22 GHz; 298 K) of $Mn^{2+}$-doped β-TCP by solid-state reaction (TCPMn1; bottom) and of a CP sample from solution after subsequent heating to 800 °C (top).

tra are identical, but again with a partly resolved hyperfine structure in the case of the sample obtained by solid-state reaction.

The Q-band EPR spectra (Figure 4) of heated Mn-doped CR samples have a completely different appearance from the one in Figure 2 (top). Each hyperfine line in the central part of these spectra undergoes an increasingly pronounced splitting when raising the temperature; this is obviously mainly caused by better resolution due to an improved sample crystallinity at higher heating temperatures. It corresponds to a tiny zero-field $D$-parameter of about 0.002 $cm^{-1}$ (≈ 20 G). It is distinctly smaller than $A$ and by far too small to indicate substitution into a $Ca^{2+}$ site in the lattice. The solids turned blue after heating above 400 °C. Very weak features between 8000 and 17000 G (not shown here) and the well-resolved half-field signal (Figure 4, inset) are indicative of this color effect, caused by the formation of $Mn^{V}$ in the tetrahedral $P^{V}$ position of the apatite host, as was substantiated by optical spectroscopy.[6] A rough assignment of the latter resonances is possible with the parameters $D \approx 0.40\ cm^{-1}$, $E \approx 0.05\ cm^{-1}$, and a $g$-factor of ca. 1.96, values which are near to those of $Mn^{V}$-doped $Sr_5(PO_4)_3$-Cl.[14] The obvious reason that $Mn^{2+}$ is not substituted into the $Ca^{2+}$ site of the apatite lattice, even after heating to 800 °C, is the weak tendency to occupy $Ca^{2+}$ positions of CNs seven and nine in this structure, at least at moderate heating temperatures. Apparently, the preference of $Mn^{2+}$ to enter a $Ca^{2+}$ position in the two alternative host lattices is much stronger in the case of β-TCP and is supported by ionic size considerations.

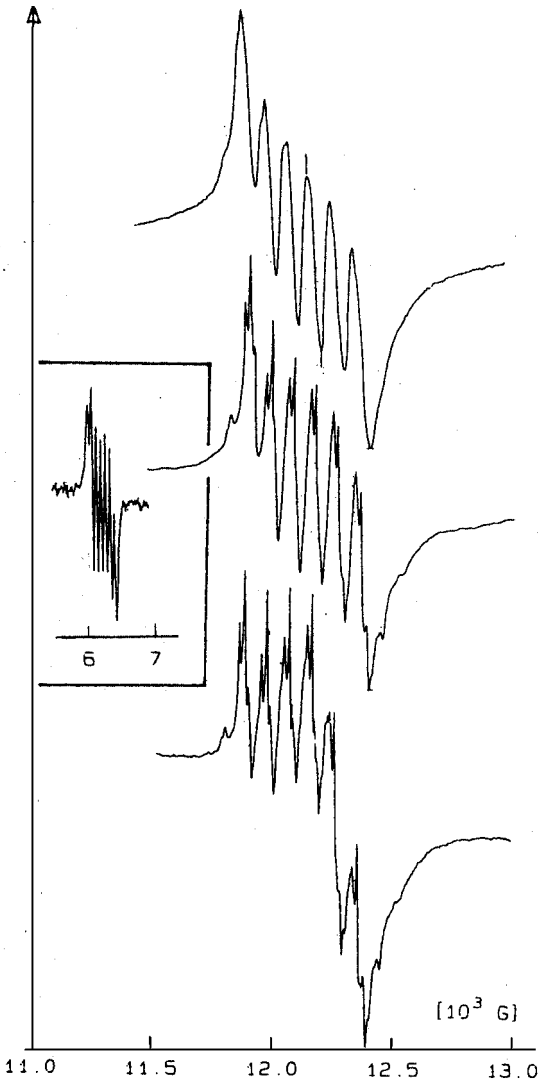

Figure 4. Q-band spectra (34.0 GHz; 298 K) of a CR sample from solution in the presence of Mn, when subsequently heated to 400 °C (top), 600 °C, and 800 °C (bottom). The (enlarged) half-field signal (inset), is due to $Mn^{V}$.

Considering TCP samples with increased Mn content, the X-band spectrum of TCPMn3 (Table 2, Figure 5) or the very similar spectrum of sample HAMn146 after the heat treatment at 800 °C (Table 1), still show the essential features of TCPMn1 (Figure 3), though the increase in the $Mn^{2+}$ concentration has partly narrowed the signal, as a result of exchange interactions between the $d^5$ cations in the lattice. However, a striking feature is that a further increase in the Mn concentration far beyond the one which corresponds to the full occupation of the Ca(5) site ($Mn_{0.286}$), completely removes the features characterizing the zero-field splitting (TCPMn6 in Figure 5). This result might be the consequence of the substitution of further $Ca^{2+}$ sites in such a way that neighbored polyhedra to $Mn(5)O_6$ (which lie isolated in the lattice) with common oxygen ligand atoms are involved, inducing intense exchange narrowing in the EPR spectra.

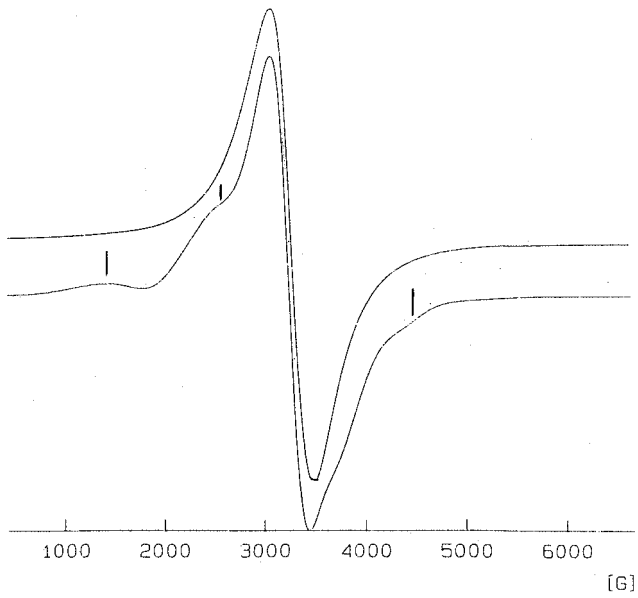

Figure 5. X-band spectra (9.11 GHz; 298 K) of solids TCPMn3 (bottom; the zero-field splitting is marked, see Figure 3) and TCPMn6 (top), with high Mn concentrations (Table 2).

## TEM

Two β-TCP samples were analyzed by TEM methods: a sample prepared after heating sample HAMn147, and $Ca_{2.7}Mn_{0.3}(PO_4)_2$ prepared by solid-state synthesis.

The HAMn147 crystals were 3D, rounded, and droplike-shaped (Figure 6). The smallest crystals were 100 nm in size, but in general they were larger, up to tens of microns. The small crystals had a polyhedral shape in most cases, while small round crystals were also observed. The crystals were not transparent enough to see their lattice, but several good

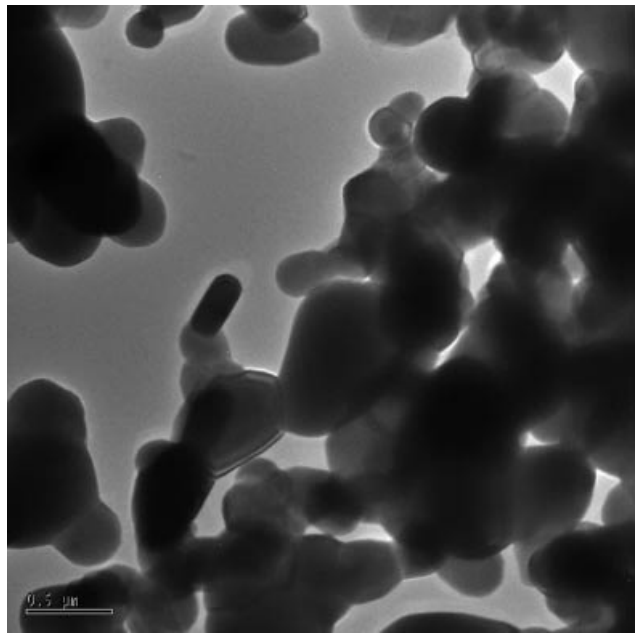

Figure 6. Droplike-shaped crystal of sample HAMn147 after heating to 800 °C.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

images of their lattice were still observed. The crystals were extremely sensitive to radiation damage; holes were formed in the crystallites. This most probably indicated that the material was composed of nanometer-sized crystalline flakes, which lost their mutual order under the radiation but did not disappear. Comparison of these results with the TEM results of parent HA[6] shows that after heat treatment the morphology changed from thin platelike polygons to 3D crystals.

In the case of $Ca_{2.7}Mn_{0.3}(PO_4)_2$ two groups of crystallites were observed: 2D polygonal flakes of crystallites of nanometer size (nonstable under radiation) (Figure 7) and large, hundreds of nanometers in size, 3D crystallites which were more stable under radiation. Good lattice images and at least one good electron-diffraction pattern from the big crystallites were obtained.

## Discussion

The aim of the present work was to prepare Mn-doped β-TCP samples which can be considered as improved biocompatible coating materials for metallic implants. The results of this study reveal that these materials can be prepared either by heating precipitated Mn-containing HA samples above 600 °C, or by solid-state reaction. The low observed Ca/P ratios for the samples with relatively high Mn concentration (Table 1) indicate an enhanced substitution of $HPO_4^{2-}$ anions into the HA lattice, thus generating $Ca^{2+}$ vacancies. This might be caused by the release of $H^+$ as the consequence of precipitation of some amorphous $MnCO_3$ or $Mn(OH)_2$. Ca/P ratios even below 1.5 favor the transformation to β-TCP in the presence of larger percentages of Mn with the ability to occupy $Ca^{2+}$ positions (see Table 2).

XRD analyses prove that the samples obtained by both methods crystallize in the rhombohedric β-TCP structure; the lattice constants and volumes (hexagonal setting) listed in Table 1 and Table 2 show a slight but continuous decrease with the increase in Mn content. This indicates the formation of solid solutions by partial replacement of $Ca^{2+}$ by the smaller $Mn^{2+}$ ions in the β-TCP lattice. In the case of the precipitated samples, transformation of HA to β-TCP is partial, and a mixture of HA and β-TCP is always obtained; the maximum transformation, about 75%, is reached at 800 °C. Such mixtures are actually often recommended for coating purposes. In the solid-state reaction, the product is of the rhombohedric β-TCP crystal phase only, with maximum Mn content of the composition $Ca_{2.4}Mn_{0.6}(PO_4)_2$.

The unit cell parameters of the $Ca_{3-x}Mn_x(PO_4)_2$ series indicate a discontinuity around $x = 0.3$, which is in well agreement with EPR spectroscopic findings. The full occupation of the Ca(5) site in the β-TCP structure would correspond to $x = 0.286$. The rather high preparation temperature of 1000 °C apparently allows the substitution into further sites with larger CN and bond lengths: preferably Ca(1) with CN = 7 (≈ 2.4 Å) + 1 (≈ 3.0 Å) and/or Ca(2) with CN = 6 (≈ 2.4 Å) + 2 (≈ 2.7 Å). These sites have oxygen atoms with Ca(5) in common, which may well explain the mentioned discontinuity through geometric rearrangements between the interconnected polyhedra. EPR spectroscopy is indicative of such interconnections as well, where exchange narrowing along O–Mn–O bridgings occurs.

Finally, one might speculate about the improvement of biocompatibility of HA by Mn in light of these results. Possibly, the local formation of intermediary β-TCP phases plays a certain role in the respective mechanisms. As shown in this contribution, the phase effect becomes very distinct at higher concentrations of the manganese dopant.

## Experimental Section

### Synthesis of β-TCP from Mn-Containing HA Samples

Samples of HA with Mn (0.1–4.0%) and with carbonate (1.0–3.0%) and without carbonate were prepared by a precipitation method described in more detail elsewhere.[15] A phosphate solution [$(NH_4)_2HPO_4$ (3.7 g) in triple distilled water (TDW) (200 mL)] was added dropwise to a calcium solution [$Ca(NO_3)_2{\cdot}4H_2O$ (9.47 g) in TDW (200 mL)]. Carbonate (5.0 and 10.0 mL) was added from a $NaHCO_3$ stock solution (1 M). These additions were designed to give 2.5–3.5% carbonate in the final sample. The amount of Mn added was 0, 2.5, 5.0, 10, 15.0, 20.0, and 25.0 mL per sample from a $MnCl_2$ solution (0.025 M).

HA samples with $Mn^{2+}$ were prepared at pH = 5.8–6.0. The pH was maintained constant during precipitation by addition of NaOH solution using a Mettler pH-stat automatic titrator. The precipitation was carried out over 2 h, and following this, the temp. was raised to the boiling point and the system was refluxed for 2 h. The sample was then washed with TDW and dried overnight in air at 120 °C.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The Ca, P, and Mn contents of the samples were determined by ICP-atomic emission spectroscopy with a precision of ±0.1, ±0.5, and ±0.3% for Ca, P, and Mn, respectively.

The subsequent heating, over 5 h, was carried out in porcelain crucibles in an electric furnace, from 600 °C to 1000 °C in 200 °C intervals.

**Synthesis of β-TCP by High-Temperature Solid-State Reaction**

Stoichiometric amounts of $CaCO_3$, $(NH_4)_2HPO_4$, and $Mn(NO_3)_2$ were thoroughly crushed and mixed in an agate mortar and heated in an alumina crucible at 300 °C for 3 h, recrushed, mixed and then heated at 1000 °C overnight. The samples with higher Mn content had a reddish-purple color.

**Characterization Methods**

XRD was used for crystal phase and lattice constant determination. The X-ray diffraction analyses were made by a Philips Automatic Diffractometer using Cu-$K_\alpha$ radiation. The samples were scanned in the $2\theta$ range of 20–55°. The lattice parameters were calculated by a least-square computer program. Maximum deviation of the lattice constants was ±0.003 Å.

The characterization of the samples by infrared (IR) spectroscopy was performed by a Nicolet FTIR spectrometer. Samples (approx. 1 mg) were pressed into pellets with KBr (approx. 150 mg). The carbonate content of the samples was estimated by IR analysis using the extinction ratio of the carbonate (1420 $cm^{-1}$) and phosphate (575 $cm^{-1}$) bands. Carbonate is determined by this method with an accuracy of ±5%.[16]

EPR measurements were performed at X- and Q-band frequencies between 300 and 80 K with a Bruker ESP-300 spectrometer. UV/Vis spectra were recorded using the powder diffuse reflection technique with a Zeiss PMQII.

Samples were also examined by TEM. For this purpose they were ground and sonicated in ethanol. The obtained suspension was deposited onto a honeycomb carbon-coated grid. All of the study was done using the transmission electron microscope Tecnai F20 $G^2$ (FEI Company) operated at 200 kV and equipped with STEM HAADF detector and EDAX EDS detector.

# Mandelohydroxamic Acid as Ligand for Copper(II) 15-Metallacrown-5 Lanthanide(III) and Copper(II) 15-Metallacrown-5 Uranyl Complexes

**Tatjana N. Parac-Vogt,*[a] Antoine Pacco,[a] Peter Nockemann,[a] Yao-Feng Yuan,[a] Christiane Görller-Walrand,[a] and Koen Binnemans[a]**

**Keywords:** Lanthanides / Hydroxamic acid / Metallacrowns / Rare earths / Uranium

The formation of pentanuclear copper(II) complexes with the mandelohydroxamic ligand was studied in solution by electrospray ionization mass spectrometry (ESI-MS), absorption spectrophotometry, circular dichroism and $^1$H NMR spectroscopy. The presence of lanthanide(III) or uranyl ions is essential for the self-assembly of the 15-metallacrown-5 compounds. The negative mode ESI-MS spectra of solutions containing copper(II), mandelohydroxamic acid and lanthanide(III) ions (Ln = La, Ce, Nd, Eu, Gd, Dy, Er, Tm, Lu, Y) or uranyl in the ratio 5:5:1 showed only the peaks that could be unambiguously assigned to the following intact molecular ions: $\{Ln(NO_3)_2[15\text{-}MC_{Cu^{II}N(MHA)}\text{-}5]^{2-}\}^-$ and $\{Ln(NO_3)[15\text{-}MC_{Cu^{II}N(MHA)}\text{-}5]^{3-}\}^-$, where MHA represents doubly deprotonated mandelohydroxamic acid. The NMR spectra of the pentanuclear species revealed only one set of peaks indicating a fivefold symmetry of the complex. The pentanuclear complexes synthesized with the enantiomerically pure *R*- or *S*-forms of mandelohydroxamic acid ligand, showed circular dichroism spectra which were mirror images of each other. The pentanuclear complex made from the racemic form of the ligand showed no signals in the CD spectrum. The UV/Vis titration experiments revealed that the order in which the metal salts are added to the solution of the mandelohydroxamic acid ligand is crucial for the formation of metallacrown complexes. The addition of copper(II) to the solutions containing mandelohydroxamic acid and neodymium(III) in a 5:1 ratio lead to the formation of a pentanuclear complex in solution. In contrary, titration of lanthanide(III) salt to the solution containing copper(II) and mandelohydroxamic acid did not show any evidence for the formation of pentanuclear species. ## Introduction

Hydroxamic acids, whether naturally occurring or synthetic, are an important family of organic bioligands.[1] One of the first biomedical applications of hydroxamic acids was associated with the uptake or removal of iron from the body.[2] In recent years it has become evident that these weak acids possess other types of biological activities.[3–7] Their role as potent and selective inhibitors of a range of metalloenzymes has been of special interest to inorganic chemists, because the biological activities of hydroxamic acids have been mainly attributed to their complexing properties toward transition-metal ions.[8] As a result, the transition-metal complexes of hydroxamic acids are frequently used as bioinorganic model compounds to investigate the enzymatic interactions and binding properties of these bioligands.

Hydroxamic acid ligands can exhibit different possible chelation modes, and this results in a rich variety of metal complex structures.[9,10] By far the most common mode of metal binding is the bidentate coordination mode through the deprotonated hydroxamate and carbonyl oxygen atoms, resulting in the formation of simple mononuclear complexes. The introduction of secondary coordinating groups can significantly modify the coordination behavior of hydroxamate ligands. For instance, aminohydroxamic acids can coordinate to metals through (*O*,*O*) as a singly deprotonated hydroxamate, through (*N*,*N*) of the amino and the deprotonated hydroxamic nitrogen, or as a (*N*,*N*)-(*O*,*O*) bridging bis-chelating ligand. Very often, the complexation to metal ions leads to formation of oligomeric or polymeric complexes.[9] However, under certain conditions, the formation of metallacrowns, types of compounds which are analogous to crown ethers in both structure and function, has been observed.[11–13] For example, a pentanuclear [12-metallacrown-4]copper(II) complex is self-assembled from solutions of copper(II) and β-alaninehydroxamic acid (Scheme 1, a). Besides the β-aminohydroxamic acids several other ligands like salicylhydroxamic acid (Scheme 1, b), 2-aminophenylhydroxamic acid, 2-pyridylacetohydroxamic acid and 3-naphthohydroxamic acid have also been used in the 12-metallacrown-4 synthesis.[14] In addition to the [12-metallacrown-4]copper(II) complexes, 12-metallacrown-4 complexes containing other ring metals such as manganese(II), manganese(III), iron(III), oxovanadium(IV) and gallium(III) have been synthesized.[15–21]

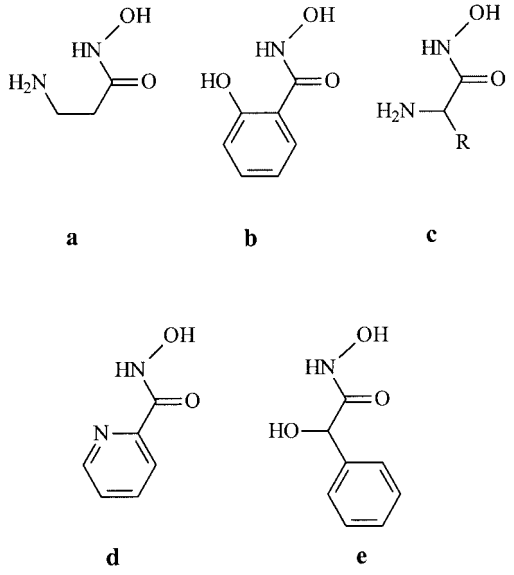


Scheme 1. Precursor ligands used for the synthesis of metallacrown complexes. (a) β-Alaninehydroxamic acid; (b) salicylhydroxamic acid; (c) α-aminohydroxamic acid; (d) picolinehydroxamic acid; (e) mandelohydroxamic acid.

In contrast to the numerous 12-metallacrown-4 structures reported so far, there are only very few examples of ligands capable of forming planar rings of the larger 15-metallacrown-5 structure type. Up to now, only α-aminohydroxamic acids and picolinehydroxamic acid (Scheme 1, c–d) have been found to form planar 15-metallacrown-5 complexes. The key property of these two ligand scaffolds is that they are able to form two fused five-membered chelate rings, which allows five metals and five ligands to form a planar 15-metallacrown-5 structure.[22,23] The planar 15-metallacrown-5 complexes formed in this way are capable to incorporate in their central cavity cations with a larger ionic radius and with a higher coordination number than 12-metallacrown-4 complexes. As a result, lanthanide(III)[24–28] and uranyl ($UO_2^{2+}$)[23,28,29] ions have been incorporated in the center of a 15-metallacrown-5 ring.

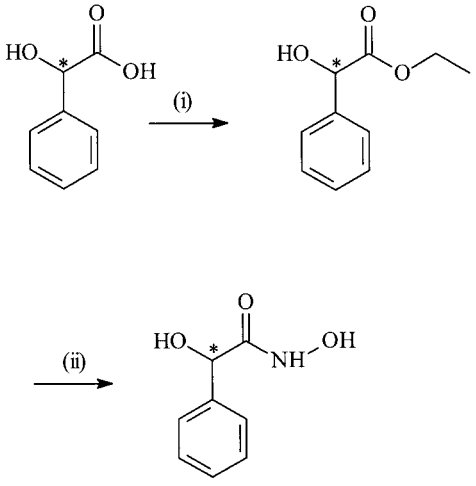
The limited number of ligands that are reported to form planar 15-metallacrown-5 complexes creates a challenge for the predesigned synthesis of these structural motifs. The geometry of a particular ligand and its known interaction with a metal ion should contain all the information required for the successful self-assembly of the metallacrown compounds. Therefore, when planning the synthesis of metallacrowns, the general choice of ligand type, ligand geometry, metal type and reaction conditions have to be considered. Although many metal complexes of hydroxamic acids and their derivatives have been studied in detail, the coordination chemistry of mandelohydroxamic acid (Scheme 1, e) is virtually unexplored. A few complexes of divalent cations have been prepared through precipitation in aqueous solution,[30,31] and the metal-ligand stability constants for some mononuclear complexes have been reported.[32] However, no structural data are available for this type of metal complexes.

In this paper, we show that in the presence of copper(II) and lanthanide(III) ions, mandelohydroxamic acid forms stable 15-metallacrown-5 complexes in solution by self-assembly. The copper(II) ion was chosen as the ring metal, as it can form complexes of square-planar geometry, and because its relatively labile metal–ligand bonds should allow the rearrangement of initially formed kinetic products into the thermodynamically stable product. The role of lanthanide(III) and uranyl ions as central templating ions for the self-assembly was examined, as well as conditions which are necessary for the formation of 15-metallacrown-5 complexes.

## Results and Discussion

### Complexation of Mandelohydroxamic Acid to Copper(II)

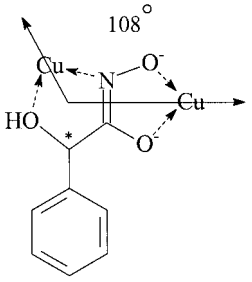
Mandelohydroxamic acid (MHA) was synthesized from mandelic acid according to Scheme 2. The racemic DL and the enantiomerically pure (*S*)-(+) and (*R*)-(–) forms of the MHA ligand were obtained depending on the stereochemistry of the starting material. Our intention to use mandelohydroxamic acid (MHA) as the ligand for the formation of 15-metallacrown-5 complexes was based on the fact that this ligand possesses a secondary coordinating hydroxy group, and that bidentate coordination through this hydroxy group and the hydroxamate nitrogen would form five-membered chelate rings. The additional coordination by two oxygen atoms can lead to the formation of two five-membered chelate rings (Scheme 3), with an angle of 108° between the two metal atoms. This is, according to the rational design, a geometrical prerequisite for the formation of the 15-metallacrown-5 structure.[21]



Scheme 2. Synthesis of mandelohydroxamic acid. Conditions: (i) ethanol, $H_2SO_4$, (ii) $NH_2OH{\cdot}HCl$, KOH, methanol.

Previous studies of the mandelohydroxamic acid (MHA) ligand have shown that in the presence of divalent metal ions 1:1 and 2:1 complexes are formed, in which the coordination of the MHA occurs by the formation of five-membered chelates through the deprotonated hydroxamate and carbonyl oxygen atoms.[30–32] The coordination of the hy-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. Rationale for the formation of planar 15-metallacrown-5 complexes.

droximato nitrogen and hydroxy oxygen to the metal ions has not been observed.

Mixing of copper(II) and the enantiomerically pure *R*- or *S*-form of MHA in aqueous solutions resulted in the formation of a green solid after few hours of stirring. Similar reactions occurred when methanol or ethanol were used as solvents. The elemental analyses carried out for the precipitate isolated from methanolic or ethanolic solutions indicated the formation of a complex with the stoichiometry [CuL]. However, the insolubility of this solid in all conventional solvents suggests a polymeric nature of the complex. Polymeric complexes of hydroxamic acids which possess a secondary coordinating group have been previously reported.[33]

When racemic DL-mandelohydroxamic acid was used instead of the enantiomerically pure *S*- or *R*-form, the equimolar mixture of $Cu(OAc)_2$ and MHA in methanol or ethanol remained clear during the course of several weeks. The UV/Vis spectrum of the green solution exhibits an absorption maximum at 650 nm, which is equal to the values observed in [Cu(acetohydroxamate)$_2$] ($\lambda_{max}$ = 653 nm)[34] and other copper(II) complexes with deprotonated hydroxamate and carbonyl oxygen donors.[35] The ESI-MS spectra did not show any evidence for the presence of metallacrown species, so it is likely that the complex formed in solution is the mononuclear $Cu(MHA)_2$ complex in which the coordination to copper(II) occurs by the deprotonated hydroxamate and carbonyl oxygen donors. This finding is in sharp contrast to the analogous reaction between α-aminohydroxamic acids and copper(II), in which exclusively the $[Cu_5(\alpha\text{-aha})_4]^{2+}$ (aha = aminohydroxamic acid) 12-metallacrown-4 complex is formed in solution.[12] In that metallacrown complex the coordination of aminohydroxamic acid occurs also by the deprotonated hydroxamate and carbonyl oxygen atoms; however, the second five-membered ring is also formed through the coordination of hydroximato nitrogen and amino nitrogen to copper(II). This leads to the formation of a puckered structure with four copper(II) ions in the backbone of the metallacrown and a cavity which accommodates the fifth copper(II) ion.

Although the coordination geometries of α-aminohydroxamic acids and mandelohydroxamic acid are almost identical, the main difference between these two ligands is that mandelohydroxamic acid possesses a hydroxy group instead of the amino group of α-aminohydroxamic acids. The presence of the hydroxy group, which is a weaker ligating group for copper(II) ions, probably prevents the formation of the second chelating ring, and thus the formation of a 12-metallacrown-4 metallacrown structure.

### Formation of 15-Metallacrown-5 Complex Monitored by ESI-MS

Our previous studies have shown that lanthanide(III) and uranyl ions have a large influence on the structure of the metallacrown complexes based on α-aminohydroxamic acid and copper(II) ion.[29,36,37] The addition of lanthanide(III) and uranyl ions to $[Cu_5(\alpha\text{-aha})_4]^{2+}$ induces a complete reassembly of the 12-metallacrown-4 structure to the 15-metallacrown-5 structure, in which lanthanide(III) or uranyl ions occupy the central cavity of the planar ring. Although lanthanide(III) ions seem to be essential for the synthesis of 15-metallacrown-5 complexes, their exact role has never been examined.[24] Previously, it has been suggested that lanthanide(III) ions are being merely recognized end-encapsulated by the 15-metallacrown-5 ring, and that this inclusion may contribute to the stability of the whole metallacrown structure. These findings prompted us to exploit lanthanide(III) and uranyl ion as possible templates for the formation of metallacrown complexes based on mandelohydroxamic acid and copper(II). When 0.25 equiv. of neodymium(III) were present in an equimolar solution of copper(II) and (*S*)-mandelohydroxamic acid, the color of the solution gradually changed from blue to green. The addition of sodium formate or sodium acetate salts resulted in the formation of a microcrystalline solid (see Exp. Section). Unfortunately, all attempts to isolate crystals of quality good enough for X-ray single crystal analysis were unsuccessful, but the elemental analysis results were consistent with the stoichiometry $Nd[Cu_5(MHA)_5]\cdot 3(HCOO)\cdot 3(H_2O)$ and $Nd[Cu_5(MHA)_5]\cdot 3(CH_3COO)\cdot (H_2O)$, where MHA represents the doubly deprotonated mandelohydroxamic acid. Crystallization techniques, such as evaporation of the solvent, diffusion techniques (vapor and liquid), and various co-crystallants were used on all three types of metallacrown complexes containing racemic DL and the enantimerically pure *S*-(+)and *R*-(–) forms of the mandelohydroxamate ligand. The only few crystals that were obtained were of insufficient quality for X-ray diffraction studies. The only reflections that could be observed were weak reflections in the small-angle region and were not suitable for the determination of the crystallographic unit cell. The solutions containing equimolar amounts of (*S*)-mandelohydroxamic acid and copper(II) acetate, in which 0.2 mol equivalents of different trivalent rare-earth ions (Ln = La, Ce, Nd, Eu, Gd, Dy, Er, Tm, Lu, Y) or uranyl ions ($UO_2^{2+}$) were present, have been further analyzed by electrospray ionization mass spectrometry (ESI-MS). In recent years, ESI-MS has been proven very useful for the analysis of self-assembled clusters. The results obtained by ESI-MS have been often regarded as indicative for the solution behavior of a species rather than for its gas-phase behavior.[38] The method has

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

also been proven as very useful for confirming the integrity of metallacrown complexes in solution.[14] Several studies indicate that the results obtained by ESI-MS correlate very well with those obtained by other techniques, such as NMR and X-ray diffractometry.[38,39] Nonetheless, ESI-MS studies of large self-assembled metal complexes remain nontrivial and often require thorough optimization of the experimental parameters. All peaks detected in the mass spectra of $Cu^{II}$/MHA/$Ln^{III}$ and $Cu^{II}$/MHA/$UO_2^{2+}$ solutions appear as cluster peaks, because of the different copper(II) and lanthanide(III) isotopes in the detected complexes. Species with different degrees of protonation were detected in the ESI-MS spectra. This may be due to the deprotonation or protonation during the ionization process, or may be due to the different degree of protonation of mandeloxydroxamate ligand. It is possible that the deprotonation of the mandelohydroxamate ligand occurs not only on the hydroxamate nitrogen and oxygen atoms, like it was reported for other hydroxamate ligands that form 15-metalacrown-5,[24–29] but that the hydroxyl group may also be deprotonated. Both protonated and deprotonated forms of the hydroxyl group can bind to copper(II), and moreover, the Lewis acidity of the copper(II) may cause the deprotonation of the hydroxyl group upon binding. The peaks that were observed in the ESI-MS spectra are summarized in Table 1 and Table 2. The reported *m*/*z* values are the maxima of the cluster peaks. All the peaks detected in the negative mode (Table 1) could be unambiguously assigned to the following two intact molecular ions: $\{Ln(NO_3)_2[15\text{-}MC_{Cu^{II}N(MHA)}\text{-}5]^{2-}\}^-$ and $\{Ln(NO_3)[15\text{-}MC_{Cu^{II}N(MHA)}\text{-}5]^{3-}\}^-$, where MHA represents doubly deprotonated mandelohydroxamic acid (mandelohydroximate) (Figure 1). If the neodymium(III) perchlorate was used instead of neodynium(III) nitrate, peaks corresponding to $\{Nd(ClO_4)_2[15\text{-}MC_{Cu^{II}N(MHA)}\text{-}5]^{2-}\}^-$ and $\{Nd(ClO_4)_3[15\text{-}MC_{Cu^{II}N(MHA)}\text{-}5]^{2-}\}^{2-}$ species with two and three perchlorate counterions were observed. Thus, the positive charge of the central lanthanide(III) ions is always compensated by the negative charge of the ring and by nitrate or perchlorate anions present in the solution.

[a] Value calculated for $\{M[15\text{-}MC\text{-}5]^{3-}\}^-$.

When lutetium(III) or thulium(III) were used as central cavity ions, additional peaks, that could not be attributed to a 15-metallacrown-5 species with a lanthanide(III) ion in the central cavity, were observed in the ESI-MS spectra. In both cases, a peak at *m*/*z* = 1222 was detected which corresponds to a 15-metallacrown-5 species with copper(II) ion in the central cavity: $\{Cu(OH)[15\text{-}MC_{Cu^{II}N(MHA)}\text{-}5]^{2-}\}^-$. Another peak at *m*/*z* = 993 could be assigned to $\{Cu(OH)[12\text{-}MC\text{-}4]^{2-}\}^-$. As thulium(III) and lutetium(III) are lanthanide ions with a small ionic radius (87 and 85 pm, respectively), this probably leads to less effective encapsulation into the central cavity and thus to a reduced stability of the 15-metallacrown-5 complexes.

[a] Values calculated for $\{M[15\text{-}MC\text{-}5]\}^{2+}$ and $\{M[15\text{-}MC\text{-}5]^-\}^+$.

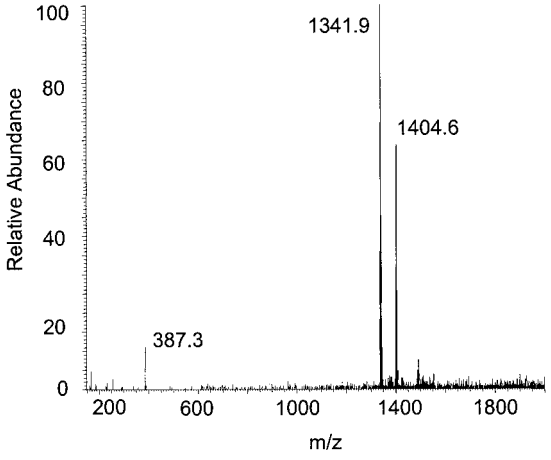

Figure 1. Negative-ion mode ESI-MS spectra of the methanolic solutions containing $Cu^{II}$/MHA/$La^{III}$ in 5:5:1 ratio.

The ESI-MS spectra in the positive mode also gave strong evidence for the existence of 15-metallacrown-5 complexes (Table 2). The peak with the highest intensity corresponds to the doubly charged $\{Ln(NO_3)[15\text{-}MC_{Cu^{II}N(MHA)}\text{-}5]\}^{2+}$ species. Another peak with approx. 10% of the intensity of the former was detected in all the spectra and could be assigned to the $\{Ln(NO_3)[15\text{-}MC_{Cu^{II}N(MHA)}\text{-}5]^-\}^+$ molecular ion.

Only one peak at *m*/*z* = 1410 was observed in the ESI-MS spectra taken in the negative mode for the solution containing the uranyl ion. The mass of this peak could be un-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ambiguously assigned to the intact $\{UO_2[15\text{-}MC_{Cu^{II}N(MHA)}\text{-}5]^{3-}\}^{-}$ molecular ion. The axial coordination of two oxygen atoms in the uranyl ion does not allow for additional binding of counterions, and the first coordination sphere of the uranyl ion is completed by five equatorial oxygen atoms from the metallacrown ring. In the positive mode ESI-MS spectra of the solution containing the uranyl ion, two peaks at $m/z$ = 706 and 1412 were detected (Figure 2). They correspond to the $\{UO_2[15\text{-}MC_{Cu^{II}N(MHA)}\text{-}5]\}^{2+}$ and $\{UO_2[15\text{-}MC_{Cu^{II}N(MHA-)}\text{-}5]^{-}\}^{+}$ pentanuclear species, respectively. The peak at $m/z$ = 1412.7 corresponds to a 15-metallacrown-5 species in which the hydroxyl group in one of the ligands is deprotonated, and the peak at $m/z$ = 706.4 corresponds to a metallacrown species in which all five hydroxyl groups are protonated.

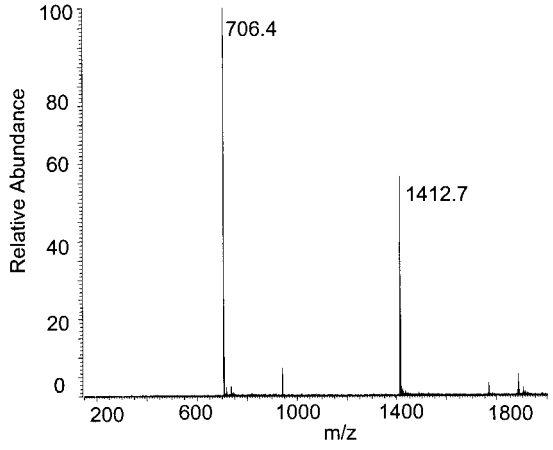

Figure 2. Positive-ion mode ESI-MS spectra of the methanolic solutions containing $Cu^{II}$/MHA/$UO_2^{2+}$ in 5:5:1 ratio.

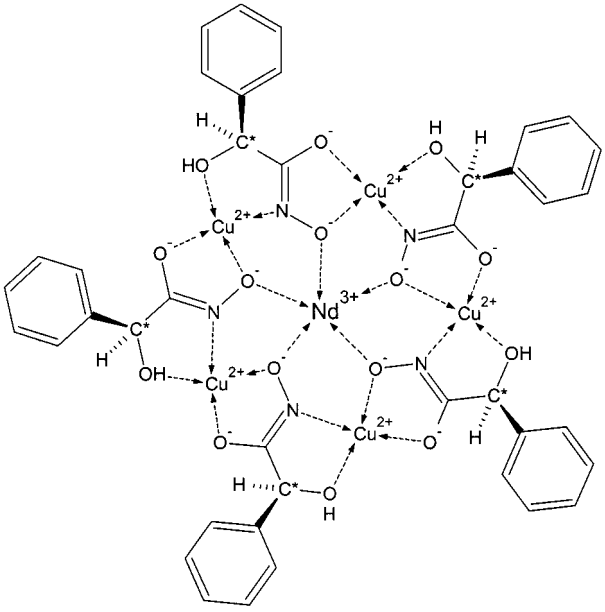

Figure 3. Proposed structure of the pentanuclear Nd[15-$MC_{Cu^{II}N[(S)\text{-}MHA]}$-5] metallacrown complex in solution. The coordination sphere of neodymium(III) ion is completed by nitrate or water ligands.

The spectra of solutions containing racemic DL-mandelohydroxamic acid, copper(II) and neodymium(III) or uranyl were also recorded, and the $m/z$ values observed in those spectra were identical to the $m/z$ values observed when (*S*)-mandelohydroxamic acid was used as coordinating ligand.

The presented ESI-MS data indicate that solutions containing copper(II) salt, mandelohydroxamic acid [DL- or (*S*)-] and a central templating ion in methanolic and ethanolic solutions are forming pentanuclear species. The only species detected for the solutions prepared with M = Y, La, Ce, Nd, Eu, Gd, Dy, Er, and $UO_2$ correspond to the intact M[15-$MC_{Cu^{II}N(MHA)}$-5] pentanuclear species. On the basis of the previously mentioned geometric considerations, it is very likely that the structure of the pentanuclear species corresponds to the structure of the planar 15-metallacrown-5 ring, in which lanthanide(III) ions or uranyl ions are encapsulated in the central cavity (Figure 3).

### Complexation of Mandelohydroxamic Acid Monitored by UV/Vis Spectroscopy

Titration experiments were performed in order to gain insight into the formation of the metallacrown complexes. Surprisingly, these experiments revealed that the order in which the metal salts are added to the MHA solution is crucial for the formation of metallacrown complexes. Titration of $Cu^{II}$/DL-MHA solution with neodymium(III) and uranyl in steps of 0.04 equivalents caused a slight decrease in the intensity of the broad shoulder between 300 nm and 450 nm and also the decrease of the d–d transition band at 687 nm. Even after the reaction mixture was let to react for 24 hours, no appearance of new peaks and shifting of the ligand field or d–d bands was observed. The ESI-MS spectra of these solutions were recorded and they did not show any evidence for the existence of pentanuclear species.

On the contrary, the titration of copper(II) to the solutions containing DL-MHA and neodymium(III) in a 5:1 ratio caused significant changes in the UV/Vis spectra. New bands at 330 nm and 638 nm (Figure 4) appeared, and their intensity increased until 5 equivalents of copper(II) were added, and it leveled off upon addition of 6 equivalents of copper(II). The molar absorptivity of the copper(II) ligand field band observed at a Cu/Ln ratio of 5:1 was consistent with the isolated 15-metallacrown-5 sample, dissolved in MeOH. The plot of the ratio of concentrations of neodymium(III) to copper(II) vs. the molar absorptivity at 330 nm and 638 nm is shown in Figure 5. The composition of the sample in which the ratio of Nd/MHA/Cu was 1:5:5 is consistent with the formula Nd[15-$MC_{Cu^{II}N(MHA)}$-5]. With the further increase of lanthanide concentration, no changes in the copper(II) ligand field band were observed, indicating that the presence of excess of lanthanide or uranyl ions does not disturb the metallacrown structures. Indeed, the ESI-MS spectra of the final solution showed exclusively cluster peaks which could be unambiguously assigned to the 15-metallacrown-5 species. The UV/Vis spectrum of Nd[15-$MC_{Cu^{II}N(MHA)}$-5] resembles the UV/Vis spectra of other

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pentanuclear complexes with lanthanide(III) ions. The band at 330 nm is in agreement with the band at 336 nm observed in the 15-metallacrown-5 complexes with tryptophanhydroxamic acid.[40] This band contains most likely contributions of $N^-–O^-_{(nitrogen)}$ and $N^-–O^-_{(oxygen)}$ to copper(II) charge-transfer transitions.

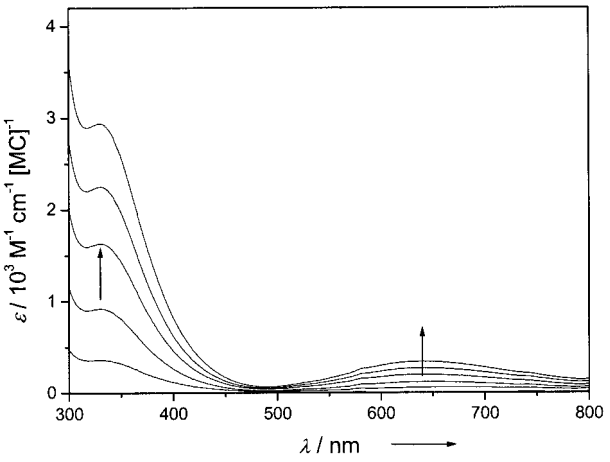

Figure 4. Changes in the UV/Vis absorption spectra of $Nd^{III}$/MHA solutions in methanol, upon addition of copper(II) ions. Copper(II) ions were added in 0.2 equiv. increments, until the final ratio of $Nd^{III}$/MHA/$Cu^{II}$ reached 1:5:5 ratio.

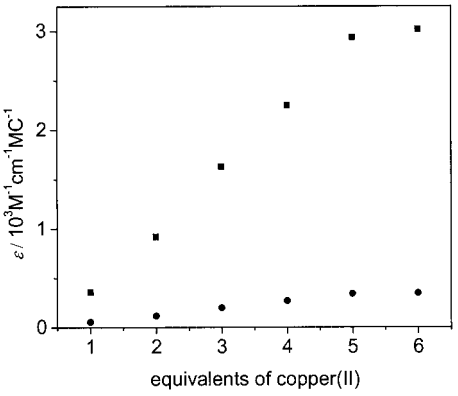

Figure 5. Change of molar absorptivity at 330 nm (squares) and 638 nm (circles) of the $Nd^{III}$/MHA/$Cu^{II}$ solution as a function of number of copper(II) equivalents.

The complex formation of lanthanide(III) with mandelohydroxamic acid has not been reported before, and no information about the stability of such complexes is available. The X-ray single-crystal structure of the complex formed between europium(III) and analogous α-alaninehydroxamic acid has shown that the hydroxamate group of α-alaninehydroxamate ligands forms a bridge between two europium(III) ions, so that a binuclear complex is formed.[41] However, it has been shown that the addition of copper(II) to solutions of lanthanide(III) and α-aminohydroxamic acid leads to the formation of the 15-metallacrown-5 structure.[37] Obviously, the high lability of the lanthanide(III) ligand bonds may allow for the initially formed products to rearrange into the 15-metallacrown-5 structure upon addition of copper(II) ion.

However, it must be mentioned that factors, such as the acidity of the solution and the different protonation states of the ligand, may be responsible for the fact that the order in which the metal salts are added to the MHA solution is crucial for the formation of the metallacrown complex. The determination of the degree of protonation of the ligand in the presence of copper(II) and lanthanide(III) ions would require thorough potentiometric titrations and evaluation of many possible equilibria involved in the ternary $H^+$/MHA/$Cu^{2+}$/$Ln^{3+}$ system.

### CD Spectroscopy of 15-Metallacrown-5 Complexes

Because the *R*- and *S*-enantiomeric forms of the MHA are chiral, their copper(II) complexes are expected to be optically active as well. The chirality of the 15-metallacrown-5 complexes formed with *R*- and *S*-enantiomeric forms of the MHA has been studied by circular dichroism (CD) spectroscopy. The ESI-MS spectra of all the solutions used for the spectrophotometric measurements were recorded, and the species observed were consistent with the Ln[15-$MC_{Cu^{II}N(MHA)}$-5] structure as described earlier in the mass spectrometric results. The CD spectrum of methanolic solutions of (*S*)-MHA/$Cu^{II}$/$Nd^{III}$ (ratio: 1:1:0.2), shows a positive Cotton effect at 342 nm ($\Delta\varepsilon$ = 2.86 mol·$L^{-1}$ $cm^{-1}$) and two negative Cotton effects at 603 ($\Delta\varepsilon$ = –1.2 mol·$L^{-1}$ $cm^{-1}$) and 733 nm ($\Delta\varepsilon$ = –1.08 mol·$L^{-1}$ $cm^{-1}$). If (*R*)-MHA was used as the ligand, the CD spectrum of the resulting complex was the mirror image of the spectrum of the complex of (*S*)-MHA. As expected, the 15-metallacrown-5 complex made from the racemic MHA showed no signal in the CD spectrum (Figure 6).

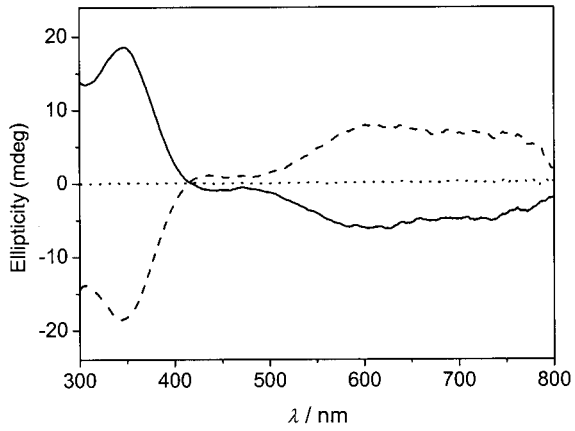

Figure 6. CD absorption spectra of Nd[15-$MC_{Cu^{II}N[(S)\text{-MHA}]}$-5] (full line), Nd[15-$MC_{Cu^{II}N[(R)\text{-MHA}]}$-5] (dotted line) and Nd[15-$MC_{Cu^{II}N(DL\text{-MHA})}$-5] (dashed line) in methanol.

The chirality of the 15-metallacrown-5 complex implies that all five phenyl groups of the MHA ligand have to be positioned upon the same face of the metallacrown. This side-chain orientation is enforced by the directionality of the metal–nitrogen–oxygen bonds, as it was previously reported in other chiral 15-metallacrown-5 complexes.[22,24]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### Proton NMR of of 15-Metallacrown-5 Complexes

Proton NMR signals of nuclei close to paramagnetic metal ions are usually very broad and the extent of paramagnetically induced line broadening depends on the electronic relaxation time of the metal centers.[42] Complexes with paramagnetic copper(II) ions usually exhibit broad NMR signals because of the relatively long electronic relaxation times of copper(II) ($\tau_s$ = $1 \cdot 10^{-9}$ s to $5 \cdot 10^{-9}$ s). However, a shortening of the electronic relaxation times can occur because of the magnetic coupling between the metal ions.[42] Previous studies have shown that the copper(II) ions in the 15-metallacrown-5 are antiferromagnetically coupled,[22,24] so that the $\tau_s$ value of those metallacrowns is shorter than it would be in the absence of magnetic coupling. This could allow the detection of relatively narrow peaks in high-resolution NMR experiments.

The $^1$H NMR spectrum of the Nd[15-MC$_{Cu^{II}N[(R)\text{-MHA}}$-5] complex in [D$_4$]MeOH showed three peaks at $\delta$ = 5.85, 6.58, and 7.75 ppm (Figure 7). The α-proton of the ligand could not be observed, most likely because it was too broad. It has been shown that the protons to the closest proximity to the paramagnetic center are showing the greatest line broadening.[43] The assignment of the peaks was done with the help of two-dimensional proton correlation spectroscopy (COSY). The comparison with the proton NMR spectrum of the previously reported Nd[15-MC$_{Cu^{II}N(L\text{-tyrha})}$-5] complex revealed that the aromatic protons of the mandelohydroxamate ligand appear in the same region as the signals of the aromatic protons of the tyrosinehydroxamate ligand. The simplicity of the spectra, i.e. the presence of only one set of resonances indicates the fivefold pseudosymmetry of the molecule. The NMR results are consistent with those of the previously studied lanthanide(III) containing 15-metallacrown-5 copper(II) complexes, which also showed only one set of ligand resonances.[24]

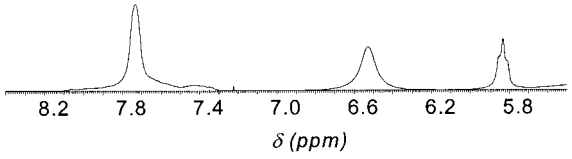

Figure 7. Proton NMR spectrum of Nd[15-MC$_{Cu^{II}N[(R)\text{-MHA}]}$-5] complex in [D$_4$]MeOH solution.

It is noteworthy to emphasize the fact that whereas the NMR signals were observable for the 15-metallacrown-5 complex in which several highly paramagnetic ions are present, no NMR spectrum could be obtained for the complexes formed in the absence of lanthanide(III) ions. Obviously, there are significant differences in the relaxation times of copper(II) ions in these two types of complexes. The absence of any protons in the NMR spectrum recorded in the absence of lanthanide(III) is consistent with the presence of mononuclear copper(II) complexes.

## Conclusions

In this paper we explore the strategy that leads to the formation of pentanuclear copper(II) complexes with the mandelohydroxamic ligand. The results of ESI-MS, UV/Vis, CD, and NMR studies are consistent with the formation of 15-metallacrown-5 complexes. The mandelohydroxamic ligand as novel scaffold for the 15-metallacrown-5 complex fulfils the geometric requirements which bring five metal ions into a plane, enforcing an angle of 108° between adjacent metal ions, and thus enforcing the formation of a planar, pentagonal ring. Our study shows that for the self-assembly of the 15-metallacrown-5, the presence of lanthanide(III) or uranyl ions is essential, as it has been demonstrated before. As it has been suggested before that lanthanide(III) ions are being recognized and encapsulated by 15-metallacrown-5 complexes, this study shows that lanthanide(III) ions may have a templating effect and could play a crucial role in the early stages of 15-metallacrown-5 formation.

## Experimental Section

**Synthesis of the Ligands:** The ligands, (*R*)-(–)-mandelohydroxamic acid, (*S*)-(+)-mandelohydroxamic acid and DL-mandelohydroxamic acid were synthesized from the corresponding ethyl ester. The preparation method for (*S*)-(+)-mandelohydroxamic acid and DL-mandelohydroxamic acid is identical to that of the synthesis of (*R*)-(–)-mandelohydroxamic acid that is described below.

**Synthesis of Ethyl (*R*)-(–)-Mandelate:** To a solution of (*R*)-(–)-mandelic acid (100 mmol, 15.2 g) in ethanol (170 mL) was added $H_2SO_4$ (5 mL) as the catalyst. The reaction mixture was heated at reflux temperature for 4 h. After the reaction mixture was cooled to room temperature, the solvent was evaporated under reduced pressure. Then, after addition of dichloromethane, the organic layer was neutralized by a saturated $NaHCO_3$ solution and dried with $MgSO_4$. Dichloromethane was removed under reduced pressure. Yield: 91% (16.41 g). $^1$H NMR ([D$_6$]DMSO, 300 MHz, ppm): $\delta$ = 1.13 (t, 3 H, $CH_3$), 4.07 (t, 2 H, $OCH_2$), 5.11 (d, 1 H, CH), 6.04 (d, 1 H, OH), 7.40 (m, 5 H, H-aromatic).

**Synthesis of (*R*)-(–)-Mandelohydroxamic Acid:** To a solution of $NH_2OH \cdot HCl$ (2 equiv., 182 mmol, 12.65 g) in methanol (110 mL), potassium hydroxide (3 equiv., 273 mmol, 15.29 g) dissolved in methanol (42 mL) was added under nitrogen. The hydroxylamine solution was cooled to 0 °C and KCl was removed by filtration. The solution was added to (*R*)-(–)-mandelic ethyl ester (1 equiv., 91 mmol, 16.41 g) and stirred at room temperature during 12 h. The white precipitate of the potassium salt was filtered off and dried (10.53 g, 51 mmol, 56% yield). To a suspension of the potassium salt in methanol was added 12 M HCl (51 mmol, 4.25 mL). Potassium chloride precipitated and was filtered off. The solvent of the filtrate was partially removed under reduced pressure and water was added to the solution. The solution was left to stand at 4 °C to allow the final product to crystallize. Yield: 51% (4.35 g). $^1$H NMR ([D$_6$]DMSO, 300 MHz, ppm): $\delta$ = 4.89 (d, 1 H, CH), 5.95 (d, 1 H, OH), 7.40 (m, 5 H, H-aromatic), 8.77 (s, 1 H, NH), 10.72 (s, 1 H, $OH_{hydr.}$). $C_8H_9NO_3$ (167 g/mol): calcd. C 57.48, H 5.43, N 8.38; found C 57.16, H 5.49, N 8.32.

**Synthesis of the Metallacrowns**

**(1) Nd[15-MC-5]·3(HCOO)·3($H_2O$):** $Nd(NO_3)_3 \cdot 6H_2O$ (109 mg, 0.25 mmol) was dissolved into methanol (50 mL) and (*R*)-MHA (167 mg, 1 mmol) was added. The solution was stirred for 10 min, then sodium methoxide (108 mg, 2 mmol) was added to the reaction mixture. After another 10 min, anhydrous copper(II) chloride

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(170 mg, 1 mmol) was added. The mixture was stirred for 2 h until the solution became green. Finally sodium formate (68 mg, 1 mmol) was added, and the blue-green precipitate was filtered, washed with water to remove sodium chloride and dried under vacuum. $C_{43}H_{44}Cu_5N_5NdO_{24}$ (1476.8 g/mol): calcd. C 34.97, H 3.00, N 4.74; found C 35.15, H 3.57, N 4.81.

**(2) Nd[15-MC-5]·3($CH_3COO$)·($H_2O$):** $Nd(NO_3)_3·6H_2O$ (109 mg, 0.25 mmol) was dissolved into methanol (50 mL) and (*R*)-MHA (167 mg, 1 mmol) was added. The solution was stirred for 10 min, then sodium methoxide (108 mg, 2 mmol) was added to the reaction mixture. After another 10 min, anhydrous copper(II) chloride (170 mg, 1 mmol) was added. The mixture was stirred for 2 h until the solution became green. Finally the sodium acetate (82 mg, 1 mmol) was added, and the blue-green precipitate was filtered, washed with water to remove sodium chloride and dried under vacuum. $C_{46}H_{46}Cu_5N_5NdO_{22}$ (1518.9 g/mol): calcd. C 37.26, H 3.13, N 4.72; found C 37.41, H 3.13, N 4.69.

**UV/Vis and CD Spectrophotometry:** UV/Vis absorption spectra were recorded with a Shimadzu UV-1601PC spectrophotometer using quartz cells of 1-cm path length. Circular dichroism spectra were recorded with a JASCO J-810 spectropolarimeter using quartz cells of 2-cm path length. The spectra were measured between 200 nm and 900 nm. The concentration of the copper(II) and mandelohydroxamic acid in methanol was always 0.5 mM. A neodymium(III) nitrate stock solution (0.25 mM). was prepared in methanol for the UV/Vis titration experiment. Different amounts of this solution were added to the copper(II)/mandelohydroxamic solution in order to obtain different ratios of $Nd^{III}/Cu^{II}$. The solutions were left to stir overnight before measurement. The $Nd^{III}/Cu^{II}$ ratio was varied in steps of 0.04 from 0 to 0.28.

**ESI-MS Method:** Electrospray ionization mass spectra were recorded with a Q-TOF 2 mass spectrometer (Micromass, Manchester, UK). Some of a ethanolic metallacrown solution, prepared with 1 mmol of the copper(II) and mandelohydroxamic acid and 0.2 mmol of the central metal ion, was injected in the apparatus at a flow rate of 5 μL/min.

**Proton NMR:** Proton nuclear magnetic resonance spectra were recorded in deuterated methanol solutions with a Bruker Avance 300 spectrometer operating at 300 MHz. A 500 μL solution of [$D_4$]MeOH containing equimolar amounts of $Cu(OAc)_2$ and (*R*)-(–)-mandelohydroxamic acid (0.1 M) was added 1.0 equiv. of $Nd(NO_3)_3$. This was achieved by adding 60 μL of a neodymium(III) nitrate [$D_4$]MeOH solution (0.166 M).

## Acknowledgments

T. N. P.-V. and K. B. thank the K. U. Leuven (VIS/01/006.01/20002-06/2004 and GOA 03/03) and the F. W. O. Flanders (Belgium) (project G.01117.03) for financial support. T. N. P.-V. acknowledges the F. W. O. Flanders for a Postdoctoral Fellowship. Financial support by the IWT-Vlaanderen to A. P. is gratefully acknowledged. The authors thank Prof. Thierry Verbiest (K. U. Leuven) for access to his CD spectrometer. ESI-MS spectra were recorded by Ms. Leen Van Nerum. CHN analyses were performed by Ms. Petra Bloemen.

# Hypercoordinated Organotin(IV) Halides Containing 2-($Me_2NCH_2$)$C_6H_4$ Groups: {2-($Me_2NCH_2$)$C_6H_4$}$_2SnX_2$ (X = F, Cl, Br, I) and {2-($Me_2NCH_2$)-$C_6H_4$}$R_2SnX$ (R = Me, Ph; X = F, Cl, Br, I) and Their Solution Behaviour and Solid-State, Hydrogen-Bonding-Based Supramolecular Architecture

**Richard A. Varga,[a] Adina Rotar,[a] Markus Schürmann,[b] Klaus Jurkschat,[b] and Cristian Silvestru*[a]**

**Keywords:** Halides / Hydrogen bonding / Hypercoordination / Supramolecular chemistry / Tin

The hypercoordinated di- and triorganotin(IV) chlorides [{2-($Me_2NCH_2$)$C_6H_4$}$_2SnCl_2$] (**1a**) and [{2-($Me_2NCH_2$)$C_6H_4$}-$R_2SnCl$] [R = Me (**2a**), Ph (**3a**)] were prepared by treating $SnCl_4$ or $R_2SnCl_2$ with [Li{2-($Me_2NCH_2$)$C_6H_4$}]. Halide-exchange reactions between the organotin(IV) chlorides and the appropriate potassium halides gave [{2-($Me_2NCH_2$)-$C_6H_4$}$_2SnX_2$] [X = F (**1b**), I (**1d**)], [{2-($Me_2NCH_2$)$C_6H_4$}-$Me_2SnX$] [X = F (**2b**), Br (**2c**), I (**2d**)] and [{2-($Me_2NCH_2$)-$C_6H_4$}$Ph_2SnX$] [X = F (**3b**), I (**3d**)]. Their solution behaviour was investigated by multinuclear ($^1H$, $^{13}C$, $^{19}F$ and $^{119}Sn$) NMR spectroscopy, including variable-temperature studies. Single-crystal X-ray diffraction analyses revealed that the strong intramolecular coordination of the nitrogen atom from the pendant $CH_2NMe_2$ group to tin induces chirality. The influence of the identity and the number of the halogen atoms and the organic substituents at tin is discussed in relation with the hydrogen-bonding network, which results in different supramolecular architectures in the crystal.

## Introduction

Several organotin(IV) halides containing the [2-($Me_2NCH_2$)$C_6H_4$] group or related organic ligands have been investigated so far both in solution and the solid state. Single crystal X-ray diffraction studies have revealed, in all cases, hypercoordinated structures obtained as a result of strong intramolecular N→Sn interactions.[1–27] On the basis of NMR spectroscopic data, octahedrally and trigonal bipyramidally configured tin atoms were suggested in solution for the intramolecularly coordinated diorganotin dihalides [{2-($Me_2NCH_2$)$C_6H_4$}$_2SnX_2$] and triorganotin halides [{2-($Me_2NCH_2$)$C_6H_4$}$R_2SnX$] (X = halogen), respectively. Single-crystal X-ray diffraction studies have confirmed the hypercoordinated nature of [{2-($Me_2NCH_2$)$C_6H_4$}-$Me_2SnCl$] (**2a**)[17] and [{2-($Me_2NCH_2$)$C_6H_4$}$Ph_2SnX$] [X = Cl (**3a′**),[20] Br (**3c**)[3]), but no crystallographic data are available for the diorganotin(IV) derivatives [{2-($Me_2$-$NCH_2$)$C_6H_4$}$_2SnX_2$], and no studies on the influence of the identity and number of halogen atoms and organic substituents on the association through hydrogen bonds in the solid state have been reported. On the other hand, it has been shown previously that intramolecular coordination of the nitrogen atom to a metal atom in compounds containing a [2-($Me_2NCH_2$)$C_6H_4$]M moiety induces chirality at the metal centre,[27–31] and therefore the crystals usually contain 1:1 mixtures of (*R*) and (*S*) isomers [with the C(1)–C(6) aromatic ring and the N(1) atom as chiral plane and pilot atom, respectively].[32] While this work was in progress the molecular structures of the fluorides [{2-($Me_2NCH_2$)-$C_6H_4$}$R_2SnF$] [R = Me (**2b′**), Ph (**3b′**)], which crystallise in different space groups,[26] were reported, but no details concerning the planar chirality induced by the intramolecular N→Sn interaction and the hydrogen-bond network in the crystal were mentioned.

Here we report the synthesis and spectroscopic characterisation of some organotin(IV) halides, as well as the crystal and molecular structures of [{2-($Me_2NCH_2$)-$C_6H_4$}$_2SnX_2$] [X = Cl (**1a**), F (**1b**), I (**1d**)], [{2-($Me_2NCH_2$)-$C_6H_4$}$Me_2SnX$] [X = Cl (**2a**), F (**2b**), Br (**2c**), I (**2d**)] and [{2-($Me_2NCH_2$)$C_6H_4$}$Ph_2SnX$] [X = F (**3b**), I (**3d**)]. The discussion of the solid-state structure is focused on the hydrogen-bonding-based network between the isomers, which results in different supramolecular architectures in the crystal.

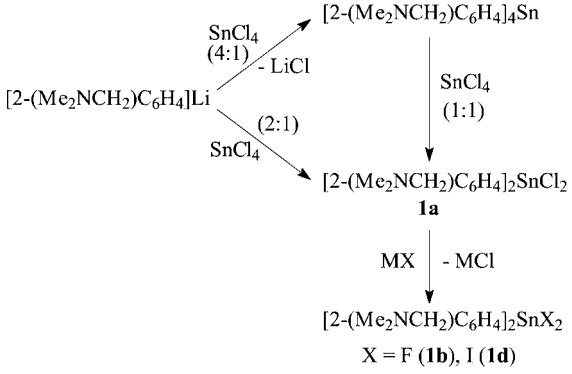
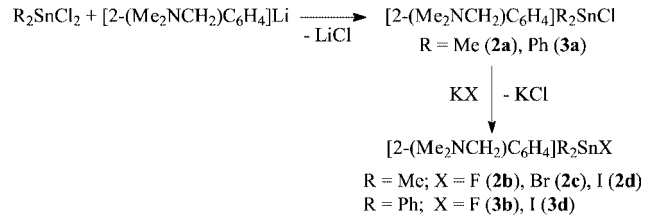
## Results and Discussion

The diorganotin(IV) dihalides were prepared according to Scheme 1. The ligand-redistribution reaction between [{2-($Me_2NCH_2$)$C_6H_4$}$_4$Sn] and $SnCl_4$ in the absence of a solvent has proved to be an excellent alternative to the direct synthesis from [Li{2-($Me_2NCH_2$)$C_6H_4$}] and $SnCl_4$ for the preparation of **1a** as it allows a better control of the stoichiometry of the reagents. The halide-exchange reactions between the organotin(IV) chlorides and the appropriate potassium halides (Schemes 1 and 2) were performed according to a modified literature procedure[33] in a two-layer solvent system ($H_2O$/MeOH/$CH_2Cl_2$).



Scheme 1. Synthesis of compounds **1a**–**1d**.

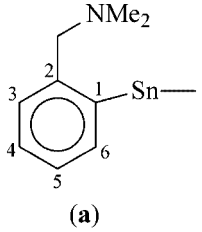


Scheme 2. Synthesis of compounds **2a**–**2d**, **3a**, **3b** and **3d**.

All compounds were isolated as air-stable, colourless, crystalline products. They are soluble in common organic solvents, such as chloroform, methylene dichloride or benzene.

### Solution Behaviour

All compounds were investigated by multinuclear ($^1$H, $^{13}$C, $^{119}$Sn) NMR spectroscopy in solution at room temperature. For the organotin fluorides, the $^{19}$F NMR spectra were also recorded.



**(a)**

The assignments of the $^1$H and $^{13}$C resonances according to the numbering scheme above were based on 2D experiments and tin–carbon coupling constants, and were confirmed for several compounds by simulation of the aromatic region of the $^1$H NMR spectra using the gNMR program (see Supporting Information).

The low-temperature $^1$H NMR spectra of the diorganotin derivatives [{2-($Me_2NCH_2$)$C_6H_4$}$_2$$SnX_2$] [X = Cl (**1a**), F (**1b**) and I (**1d**)] are very similar (see Supporting Information) to that reported for the dibromide analogue **1c**,[6] i.e. an AB system and two singlet resonances in the aliphatic region for the diastereotopic $CH_2$ protons and the $CH_3$ groups at nitrogen, respectively. This is consistent with a *trans* arrangement of the organic ligands and a *cis* arrangement of the two coordinated nitrogen atoms and halogen atoms in solution,[6] as subsequently proved by single-crystal X-ray diffraction for compounds **1a**, **1b** and **1d** (see below). When the temperature is raised, the diorganotin dichloride **1a** and the diorganotin diiodide **1d** exhibit a similar behaviour to the diorganotin dibromide **1c**.[6,22] The two singlets for the methyl protons of the $NMe_2$ group coalesce at 20 °C for **1a** ($\Delta G^{\ddagger}$ = 13.8 kcal mol$^{-1}$) and 0 °C for **1d** ($\Delta G^{\ddagger}$ = 12.6 kcal mol$^{-1}$) in $CDCl_3$. This coalescence indicates that the process involving N→Sn dissociation/recoordination, with inversion at a three-coordinate nitrogen atom and rotation of the $C_{methylene}$–N bond, becomes fast on the NMR timescale. The AB pattern for the methylene protons is retained even at 60 °C, thus indicating configurational stability of the tin atom in the [{2-($Me_2NCH_2$)$C_6H_4$}$_2$$SnX_2$] derivatives containing heavier halogens. In contrast, coalescence of both the two resonances of the $NMe_2$ group ($\Delta G^{\ddagger}$ = 14.2 kcal mol$^{-1}$) and the AB pattern of the $CH_2$ group ($\Delta G^{\ddagger}$ = 14.3 kcal mol$^{-1}$) is observed at 10 °C for the diorganotin difluoride **1b** in $CDCl_3$. This suggests that exchange of the chloride by fluoride results in a considerable decrease of the configurational stability of the tin atom in **1b** compared to **1a**. There is no indication for a *cis–trans* equilibrium in solution such as that observed for [{$Me_2N(CH_2)_3$}$_2$$SnF_2$]·2$H_2O$.[34]

The magnitudes of the $^{119}$Sn chemical shifts for the diorganotin halides **1a** (s, $\delta$ = –260.7 ppm), **1b** (t, $\delta$ = –386.7 ppm) and **1d** ($\delta$ = –346.9 ppm) at room temperature are typical for six-coordinate diorganotin(IV) species in solution [cf. [{$Me_2N(CH_2)_3$}$_2$$SnF_2$]·2$H_2O$[34] ($\delta$ = –292.0 ppm in $CD_2Cl_2$) and [(8-$Me_2NC_{10}H_6$)$_2$$SnI_2$][11] ($\delta$ = –361.9 ppm in $C_6D_5CD_3$)]. The equivalence of the fluoride atoms in **1b** is reflected in a singlet $^{19}$F resonance surrounded by tin satellites ($\delta$ = –181.5 ppm, $^1J_{F,Sn}$ = 2567/2683 Hz) and a triplet $^{119}$Sn resonance ($\delta$ = –386.7 ppm, $^1J_{F,Sn}$ = 2663 Hz).

The $^1$H and $^{13}$C NMR spectra for the triorganotin halides [{2-($Me_2NCH_2$)$C_6H_4$}$Me_2$SnX] [X = Cl (**2a**), F (**2b**), Br (**2c**), I (**2d**)] and [{2-($Me_2NCH_2$)$C_6H_4$}$Ph_2$SnX] [X = F (**3b**), I (**3d**)] are very similar to those of benzyldimethylamine, regardless of the nature of the halogen and the other organic groups attached to tin. Two singlet resonances are observed in the aliphatic region for the methylene and the methyl protons, respectively, which is compatible either with a tetrahedral or with a pentacoordinate structure (assuming a fast conformational change of the five-membered $SnC_3N$ nonplanar chelate ring in solution, which gives averaged $^1$H NMR signals). The $^{13}$C NMR spectrum contains two sing-

[a] Spectra recorded in $CDCl_3$ at room temperature. [b] In $CH_2Cl_2$/[D$_6$]acetone. [c] Ref.[26]: $\delta_{^{119}Sn}$ = –53.8 ppm ($^1J_{F,Sn}$ = 2023 Hz), $\delta_{^{19}F}$ = –178.8 ppm. [d] In $C_6D_5CD_3$. [e] $^{119}$Sn MAS NMR spectroscopic data. [f] Ref.[26]: $\delta_{^{119}Sn}$ = –198.6 ppm ($^1J_{F,Sn}$ = 2141 Hz), $\delta_{^{19}F}$ = –182.3 ppm.

let signals for the methylene and the methyl carbon atoms, respectively, but the tin satellites are well resolved only for the former; the magnitude of the $^2J_{C,Sn}$ (ca. 28–30 Hz) couplings is consistent with the presence of an intramolecular N→Sn coordination, i.e. a trigonal bipyramidal (*C*,*N*)-$C_2SnX$ core. The major difference noted in the $^1$H NMR spectra of the two series of compounds is the downfield shift of the resonance for the aromatic H-6 proton, which is a result of the intramolecular interaction of this proton with the halogen atom.

The increase in the H-6 chemical shift follows the order F < Cl < Br < I ($\delta$ = 7.97, 8.17, 8.26 and 8.31 ppm for the triaryltin halides **2b**, **2a**, **2c** and **2d**, respectively). In addition to the resonances assigned to the 2-($Me_2NCH_2$)$C_6H_4$ ligand, the $^1$H and $^{13}$C NMR spectra for the [{2-($Me_2NCH_2$)-$C_6H_4$}$R_2SnX$] derivatives also contain signals corresponding to equivalent methyl and phenyl groups, respectively.

A comparison of the $^{19}$F and $^{119}$Sn NMR parameters for the diorganotin dihalides [{2-($Me_2NCH_2$)$C_6H_4$}$_2$$SnX_2$] and the triorganotin halides [{2-($Me_2NCH_2$)$C_6H_4$}$R_2SnX$] described in this work and the related [$Ph_2SnX_2$], [$Me_2PhSnX$] and [$Ph_3SnX$] derivatives is given in Table 1. The increase of the coordination number at the metal atom in solution to six and five, respectively, is supported by the upfield shift of the $^{119}$Sn chemical shift in the 2-($Me_2NCH_2$)$C_6H_4$-containing derivatives (X = Cl, Br, I) with respect to the corresponding monomeric, tetrahedral [$Ph_2SnX_2$], [$Me_2PhSnX$] and [$Ph_3SnX$] compounds.

In conclusion, the NMR spectroscopic data indicate that both [{2-($Me_2NCH_2$)$C_6H_4$}$_2$$SnX_2$] and [{2-($Me_2NCH_2$)-$C_6H_4$}$R_2SnX$] compounds exhibit intramolecular N→Sn coordination in solution, which results in similar coordination geometries to those found in the solid state (see below).

## Solid-State Structures

The crystal and molecular structures of **1a**, **1b**, **1b**·$CH_2Cl_2$, **1d**, **2a**, **2a′**, **2b**–**2d**, **3a**, **3b** and **3d** were determined by single-crystal X-ray diffraction. Crystals suitable for X-ray diffraction analysis were generally grown by solvent diffusion from dichloromethane and *n*-hexane. Crystals of the dichloromethane solvate of the diorganotin difluoride [{2-($Me_2NCH_2$)$C_6H_4$}$_2$$SnF_2$], namely **1b**·$CH_2Cl_2$, were obtained from a $CH_2Cl_2$/*n*-hexane (approximately 1:3) mixture, and were measured immediately after removal from solution. The crystal was stable enough for a sufficiently good measurement, but they turned opaque within two days in the air due to loss of the crystallisation solvent, as proved by $^1$H NMR spectroscopy. Crystals of [{2-($Me_2NCH_2$)$C_6H_4$}$_2$$SnF_2$] (**1b**), free of crystallisation solvent, were also obtained by slow crystallisation from a $CH_2Cl_2$/*n*-hexane (approximately 1:5) mixture. The triorganotin chloride [{2-($Me_2NCH_2$)$C_6H_4$}$Me_2SnCl$] crystallises in different forms from ethanol (**2a**; orthorhombic, space group *Pbca*) and *n*-hexane (**2a′**; orthorhombic, space group $Pna2_1$. This form has also been reported by Rippstein et al.[17] for crystals grown from $CHCl_3$). Monoclinic crystals (space group $P2_1/n$) with different unit-cell parameters were obtained for [{2-($Me_2NCH_2$)$C_6H_4$}-$Ph_2SnCl$] when the compound was crystallised from tolu-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ene[20] or $CH_2Cl_2$/*n*-hexane (**3a**); the first form contains one molecule in the unit cell[20] while the second one contains two independent molecules. The crystals of [{2-($Me_2NCH_2$)-$C_6H_4$}$Ph_2SnF$] (**3b**; monoclinic, space group $P2_1/n$, which is different from the reported space group $P2_1/c$[26]) also contain two independent molecules in the unit cell.

Selected molecular parameters are given in Tables 2, 3 and 4, and the molecular structures of representative compounds **1b** and **3d**, with the atom numbering schemes, are shown in Figures 1 and 2, respectively. The molecules of all compounds investigated in this work feature a metal atom strongly coordinated by two or one nitrogen atoms of the pendant arms *trans* to an Sn–halogen bond in diorganotin(IV) and triorganotin(IV) halides, respectively [the Sn–N distance exceeds the sum of the covalent radii for the corresponding atoms, $\Sigma_{cov}$(Sn,N) = 2.1 Å[40]]. This results in different coordination environments of the metal atom, i.e. octahedral $(C,N)_2SnX_2$ for **1a**, **1b** and **1d**, and trigonal bipyramidal $(C,N)C_2SnX$ configurations for **2a**–**2d**, **3b** and **3d**.

The $(C,N)_2SnX_2$ core in the [{2-($Me_2NCH_2$)-$C_6H_4$}$_2SnX_2$] derivatives shows a *trans*-$SnC_2$ fragment, while the N and X atoms are *cis* (Figure 1). This contrasts with the molecular structure reported for the related [{$Me_2N(CH_2)_3$}$_2SnF_2$]·$2H_2O$,[34] which exhibits an all-*trans* octahedral $(C,N)_2SnX_2$ configuration. The difference in the configuration of the octahedral environment of tin is reflected in the lengthening and shortening of the Sn–F and Sn–N bond lengths, respectively, in **2b** [Sn(1)–F(1) = 1.9726(14), Sn(1)–F(2) = 1.9774(13), Sn(1)–N(1) = 2.5083(19) and Sn(1)–N(2) = 2.6064(18) Å] in comparison

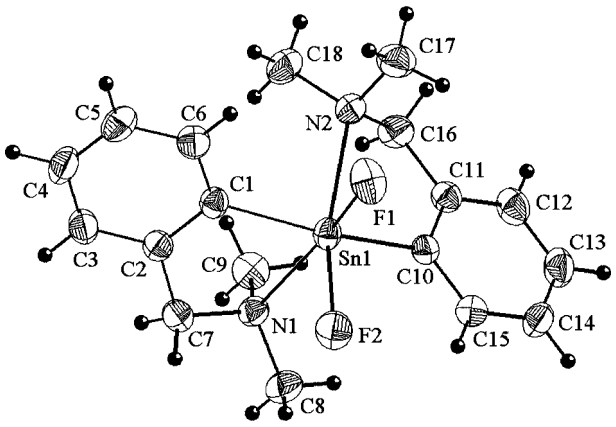

Figure 1. ORTEP representation at 50% probability and atom-numbering scheme for the isomer ($R_{N1}$,$S_{N2}$)-**1b**.

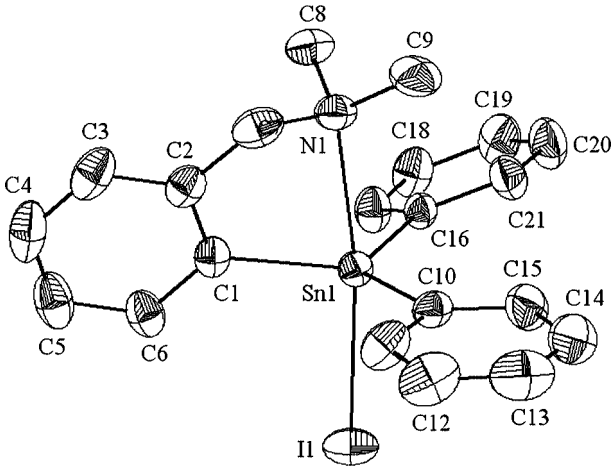

Figure 2. ORTEP representation at 30% probability and atom-numbering scheme for the isomer (*S*)-**3d**. Hydrogens have been omitted for clarity.

with [{$Me_2N(CH_2)_3$}$_2$$SnF_2$]·$2H_2O$ [Sn(1)–F(1) = 2.084(6) and Sn(1)–N(1) = 2.366(8) Å].[34]

The molecular structures of the triorganotin halides [{2-($Me_2NCH_2$)$C_6H_4$}$R_2$SnX] (**2a**–**2d**, **3b** and **3d**) are very similar. One representative is shown in Figure 2. The tin–nitrogen distances are not dramatically affected by the identity of the halogen atom *trans* to the nitrogen atom. The Sn(1) atom is displaced from the equatorial plane defined by C(1), C(10) and C(16) (Figure 2) in the direction of the X(1) atom, which means that the X–Sn–C angles are larger than the N–Sn–C angles.

As a result of the intramolecular coordination of the nitrogen to the tin atom a five-membered $SnC_3N$ ring is formed. This ring is not planar but is folded along the Sn(1)···$C_{methylene}$ axis, with the nitrogen atom lying above the best plane defined by Sn(1), C(1), C(2) and C(methylene). This induces planar chirality at the metal atom,[27–31] and all compounds reported here crystallise as racemates. The crystals of the triorganotin(IV) derivatives (**2a**, **2a′**, **2b**–**2d**, **3a**, **3a′**, **3b**, **3b′** and **3d**) contain 1:1 mixtures of (*R*) and (*S*) isomers, with the C(1)–C(6) aromatic ring and the N(1) atom as chiral plane and pilot atom, respectively.[32] The crystals of the diorganotin(IV) derivatives contain either ($S_{N1}$,$R_{N2}$) and ($R_{N1}$,$S_{N2}$) isomers (for **1b**) or ($S_{N1}$,$S_{N2}$) and ($R_{N1}$,$R_{N2}$) isomers (for **1a** and **1d**) with respect to the two chelate rings in a molecular unit. The discrete monomeric molecular units are separated by normal van der Waals distances between heavy atoms.

However, a closer check of the crystal structures revealed several intermolecular hydrogen-bonding interactions shorter than the sum of the corresponding van der Waals radii [i.e. $\Sigma_{vdW}$(F,H) ≈ 2.55, $\Sigma_{vdW}$(Cl,H) ≈ 3.0, $\Sigma_{vdW}$(Br,H) ≈ 3.15 and $\Sigma_{vdW}$(I,H) ≈ 3.35 Å].[40] This results in different supramolecular architectures that are presented in the subsequent discussion taking into account the increasing degree of association, with the common patterns summarised in Table 5 (further details are available in the Supporting Information). Thus, in the crystal of the fluoride **3b** (space group $P2_1/n$) pairs of isomers (*S*,*S* or *R*,*R*) of the two independent molecules are associated through F(1)···H(34)$_{aryl}$ contacts (2.50 Å). The short interatomic distance (2.56 Å) between the F(2) atom and a methyl hydrogen of a neighbouring dinuclear unit of the same type is at the limit of a van der Waals contact. The crystal of **3b′** (space group $P2_1/c$[26]) contains polymeric chains of (*S*) and (*R*) isomers, respectively, built through F(1)···H(17Ba)$_{methylene}$ interactions (2.37 Å). Similar polymeric chains of (*S*) and (*R*) isomers, respectively, were also found in the crystals of the triorganotin chlorides **3a**, **3a′**[20] and the triorganotin iodide **3d**. In contrast to the phenyl derivatives, the crystals of the methyl analogues **2a** (space group *Pbca*) and **2b** contains chains of alternating (*S*) and (*R*) isomers. There are no further halogen–hydrogen contacts between the parallel polymeric chains.

For compound **1b**·$CH_2Cl_2$, alternating ($R_{N1}$,$S_{N2}$)- and ($S_{N1}$,$R_{N2}$)-**1b** isomers are connected through F(2)···H-(7Ab)$_{methylene}$ interactions (2.52 Å) and further bridged by $CH_2Cl_2$ molecules [F(1)···H(19A)$_{solvent}$ = 2.37, Cl(2a)···H-(8A)$_{methyl}$ = 2.94 Å], resulting in ribbon-like chains (Figure 3), with no further inter-chain halogen–hydrogen contacts.

Polymeric chains of (*S*) and (*R*) isomers, respectively, built through I(1)···H(7Ba)$_{methylene}$ interactions (3.16 Å), are also found in the crystal of the triorganotin iodide **2d**, but in this case additional I(1)···H(10Ac)$_{Sn–methyl}$ contacts (3.29 Å) between chains of the same isomers result in a 2D supramolecular architecture. The crystal consists of layers alternating in the sequence -*R*-*R*-*S*-*S*-*R*-*R*-*S*-*S*-, with no further inter-layer contacts. The triorganotin chloride **2a′** (space group $Pna2_1$) and the triorganotin bromide **2c** also form polymeric chains, but in this case they are built from alternating (*S*) and (*R*) isomers [Cl(1)···H(8Bb)$_{N–methyl}$ = 2.81 Å for **2a′**; Br(1)···H(9Bb)$_{N–methyl}$ = 3.02 Å for **2c**]. For **2a′**, weak inter-chain contacts [Cl(1)···H(8Cc)$_{N–methyl}$ = 2.98 Å] result in a 2D network with a honeycomb motif (Figure 4, a) in which each molecule is linked to four neighbouring molecules (two isomers of a different type for the polymeric chain and two isomers of the same type for the parallel chains). For **2c**, the weak inter-chain contacts between the halogen and an aromatic hydrogen atom [Br(1)···

H(4d)$_{aryl}$ = 3.15 Å, at the limit of a van der Waals contact] lead to a different two-dimensional motif, with rings built from two molecules [(*R*)- and (*S*)-**2c** isomers] and four molecules [(*R*)-(*R*)-(*S*)-(*S*)-**2c** isomers], respectively (Figure 4, b). In both cases there are no further contacts between the parallel layers.

In contrast to **1b**·$CH_2Cl_2$, the crystal structure of the diorganotin difluoride **1b** consists of layers in which alternating polymeric chains of ($R_{N1}$,$S_{N2}$)- and ($S_{N1}$,$R_{N2}$)-**1b** isomers [F(2)–H(12a)$_{aryl}$ = 2.38 Å] are connected through F(1)–H(7Ad)$_{methylene}$ (2.47 Å) interactions. The overall layer network resembles that observed in the crystal of the triorganotin iodide **2d**, with both fluorine atoms being involved in weak hydrogen-bonding interactions.

Three-dimensional supramolecular architectures (Table 5) were found for the diorganotin dihalides **1a** and **1d**. Thus, in the crystal of the diorganotin diiodide **1d** there are parallel chains built from alternating ($S_{N1}$,$S_{N2}$) and

($R_{N1}$,$R_{N2}$) isomers through I···$H_{methyl}$ contacts [I(2)–H-(9Ca)$_{methyl}$ = 3.15 Å]. Inter-chain contacts [I(2)···H-(8Ac)$_{methyl}$ = 3.26 Å] result in a similar layer network to that observed for **2a′** (Figure 5, a). Additional weak, inter-layer contacts between I(1) and an aromatic proton [I(1)···H(14f)$_{aryl}$ = 3.32 Å] lead to a 3D network. By contrast, in the crystal of the diorganotin dichloride **1a** only aromatic protons are involved in hydrogen bonding. The molecules are associated into layers built of the same type of isomer [Cl(1)···H(4a′)$_{aryl}$ = 2.81 Å] (Figure 5, b) and alternating parallel layers of ($S_{N1}$,$S_{N2}$) or ($R_{N1}$,$R_{N2}$) isomers are bridged through weak Cl(1)···H(6f′)$_{aryl}$ (2.94 Å) interactions (Figure 5, c).

## Conclusion

The hypercoordinated di- and triorganotin(IV) halides [{2-($Me_2NCH_2$)$C_6H_4$}$_2$$SnX_2$], [{2-($Me_2NCH_2$)$C_6H_4$}-$Me_2$SnX] and [{2-($Me_2NCH_2$)$C_6H_4$}$Ph_2$SnX] (X = F, Cl, Br, I) have been prepared and their solutions investigated by multinuclear NMR spectroscopy, including variable-temperature studies. Single-crystal X-ray structure analyses have revealed that the strong intramolecular coordination of the nitrogen atom from the pendant $CH_2NMe_2$ group to tin induces planar chirality and the compounds crystallise as racemates. The influence of the identity and number of halogen atoms and organic substituents attached to the tin atoms is reflected in different supramolecular architectures based on hydrogen-bonding networks.

## Experimental Section

**General Remarks:** All manipulations were carried out under argon using dried solvents freshly distilled prior to use. The $^1$H and $^{13}$C NMR spectra were recorded with Bruker Avance DRX 400 (including 2D experiments), Bruker Avance 300 and Bruker DPX 200 instruments. The $^{19}$F NMR were recorded with Bruker Avance DRX 400 and Bruker DPX 300, and $^{119}$Sn NMR were obtained using Bruker DPX 400 and Varian Unity 300 instruments. Variable-temperature $^1$H NMR studies were performed with a Varian Unity 300 (compound **1a**) and a Varian Gemini 300S (compound **1b**). The chemical shifts are reported in ppm relative to the residual peak of solvent ($CHCl_3$; $\delta_{^1H}$ = 7.26, $\delta_{^{13}C}$ = 77.0 ppm for $^1$H and $^{13}$C, $CFCl_3$ for $^{19}$F and neat $SnMe_4$ for $^{119}$Sn). Starting materials such as $SnCl_4$, $BuSnCl_3$, $Ph_2SnCl_2$, $Me_2SnCl_2$ KX (X = F, Br, I), *N*,*N*-dimethylbenzylamine and *n*-butyllithium were commercially available. The compounds [Li{2-($Me_2NCH_2$)$C_6H_4$}],[41] [{2-($Me_2NCH_2$)$C_6H_4$}$_4$Sn][17] and [{2-($Me_2NCH_2$)$C_6H_4$}$Ph_2$SnCl] (**3a**)[20] were prepared according to the literature methods.

**Synthesis of [{2-($Me_2NCH_2$)$C_6H_4$}$_2$$SnCl_2$] (1a). Procedure 1:** A suspension of [Li{2-($Me_2NCH_2$)$C_6H_4$}] [prepared as above from *n*BuLi in *n*-hexane (24.6 mL, 1.6 M, 20% excess) and $Me_2NCH_2C_6H_5$ (4.43 g, 32.8 mmol) in 200 mL of anhydrous *n*-hexane] in anhydrous toluene (150 mL) was added dropwise, whilst stirring, to a cooled (–78 °C) solution of $SnCl_4$ (4.27 g, 16.4 mmol) in 300 mL of toluene (300 mL). After all the suspension had been added, the reaction mixture was stirred for 1 h at –78 °C, and then allowed to reach room temperature overnight. The reaction mixture was filtered under inert atmosphere and the solvent of the filtrate was removed in vacuo. The solid residue was recrystallised from $CH_2Cl_2$/*n*-hexane to give 6.1 g (81%) of the title compound as colourless crystals.

**Procedure 2:** $SnCl_4$ (0.437 g, 1.68 mmol) was added to [{2-($Me_2NCH_2$)$C_6H_4$}$_4$Sn] (1.1 g, 1.68 mmol) under inert atmosphere and the mixture was slowly heated whilst stirring until a homogeneous melt was obtained. The heating was maintained for 15 min and then the reaction mixture was cooled to room temperature. Recrystallisation from a $CH_2Cl_2$/*n*-hexane mixture (approximately 1:4) provided 1.2 g (78%) of **1a** as colourless crystals (m.p. 257–259 °C). $^1$H NMR ($CDCl_3$, 300 MHz, 20 °C): $\delta$ = 2.22 (br. s, 12 H, $NCH_3$), AB spin system with $\delta_A$ = 3.37 and $\delta_B$ = 4.07 ($^2J_{H,H}$ = 14.1 Hz, 4 H, $CH_2N$), 7.18 (m, 2 H, 3-H), 7.41 (m, 4 H, 4,5-H), 8.22 (m, $^3J_{H,Sn}$ = 108 Hz, 2 H, 6-H) ppm. $^1$H NMR ($CDCl_3$, 300 MHz, 60 °C): $\delta$ = 2.21 (br. s, 12 H, $NCH_3$), AB spin system with $\delta_A$ = 3.38 and $\delta_B$ = 4.04 (br. s, 4 H, $CH_2N$), 7.17 (d, $^3J_{H,H}$ = 6.9 Hz, 2 H, 3-H), 7.52 (m, 4 H, 4,5-H), 8.25 (d, $^3J_{H,H}$ = 6.3, $^3J_{H,Sn}$ = 108 Hz, 2 H, 6-H) ppm. $^1$H NMR (300 MHz, $CDCl_3$, –60 °C): $\delta$ = 2.05 (s, $^3J_{H,Sn}$ = 39 Hz, 6 H, $NCH_3$), 2.55 (s, $^3J_{H,Sn}$ = 39 Hz, 6 H, $NCH_3$), AB spin system with $\delta_A$ = 3.39 and $\delta_B$ = 4.14 ($^2J_{H,H}$ = 14.2, $^3J_{H,Sn}$ = 39 Hz, 4 H, $CH_2N$), 7.19 (d, $^3J_{H,H}$ = 6.6 Hz, 2 H, 3-H), 7.41 (m, 4 H, 4,5-H), 8.19 (d, $^3J_{H,H}$ = 6.8, $^3J_{H,Sn}$ = 110 Hz, 2 H, 6-H) ppm. $^{13}$C NMR ($CDCl_3$, 100.6 MHz, 20 °C): $\delta$ = 46.78 (br. s, $NCH_3$), 63.80 (s, $^2J_{C,Sn}$ = 42.8 Hz, $CH_2N$), 127.85 (s, $^3J_{C,Sn}$ = 97.1/99.3 Hz, C-3), 128.18 (s, $^3J_{C,Sn}$ = 104.8/107.6 Hz, C-5), 130.16 (s, $^4J_{C,Sn}$ = 19.1 Hz, C-4), 135.47 (s, $^2J_{C,Sn}$ = 61.3 Hz, C-6), 140.79 (s, $^2J_{C,Sn}$ = 62.8 Hz, C-2; $^1J_{C,Sn}$ = 1167.1/1221.3 Hz, C-1) ppm. $^{119}$Sn NMR ($CH_2Cl_2$/[D$_6$]acetone, 149.2 MHz, 20 °C): $\delta$ = –260.7 ppm (s). $C_{18}H_{24}Cl_2N_2Sn$ (458.00): calcd. C 47.21, H 5.28, N 6.12; found C 47.34, H 5.43, N 5.84.

**Synthesis of [{2-($Me_2NCH_2$)$C_6H_4$}$_2$$SnF_2$] (1b):** Dichloromethane was added to a suspension of **1a** (0.3 g, 0.65 mmol) in MeOH (20 mL) until the solid compound dissolved. An aqueous solution of KF (0.2 g, 3.44 mmol) was then added and the mixture was stirred for 3 h at room temperature. The organic layer was separated and the water solution was washed twice with 5 mL of $CH_2Cl_2$. The combined organic layers were dried with anhydrous $Na_2SO_4$. The latter was filtered, the solvent was removed in vacuo and the obtained white solid residue was recrystallised from a $CH_2Cl_2$/*n*-hexane mixture to give **1b** (0.25 g, 90%; m.p. 213–215 °C). Colourless crystals suitable for single-crystal X-ray diffraction were obtained by slow crystallisation from a $CH_2Cl_2$/*n*-hexane (approximately 1:5) mixture. $^1$H NMR ($CDCl_3$, 400 MHz, 20 °C): $\delta$ = 2.24 (br. s, 12 H, $NCH_3$), 3.66 (br. s, 4 H, $CH_2N$), 7.16 (m, 2 H, 3-H), 7.38 (m, 4 H, 4,5-H), 8.08 (m, $^3J_{H,Sn}$ = 92.2 Hz, 2 H, 6-H) ppm. $^1$H NMR ($CDCl_3$, 300 MHz, 55 °C): $\delta$ = 2.24 (s, 12 H, $NCH_3$), 3.66 (s, 4 H, $CH_2N$), 7.17 (m, 2 H, 3-H), 7.39 (m, 4 H, 4,5-H), 8.09 (m, $^3J_{H,Sn}$ = 91.5 Hz, 2 H, 6-H) ppm. $^1$H NMR ($CDCl_3$, 300 MHz, –55 °C): $\delta$ = 2.10 (s, 6 H, $NCH_3$), 2.42 (s, 6 H, $NCH_3$), AB spin system with $\delta_A$ = 3.53 and $\delta_B$ = 3.82 ($^2J_{H,H}$ = 14.3 Hz, 4 H, $CH_2N$), 7.17 (m, 2 H, 3-H), 7.38 (m, 4 H, 4,5-H), 8.05 (m, $^3J_{H,Sn}$ = 93.3 Hz, 2 H, 6-H) ppm. $^{13}$C NMR ($CDCl_3$, 100.6 MHz, 20 °C): $\delta$ = 46.09 (br. s, $NCH_3$), 64.10 (s, $^2J_{C,Sn}$ = 48.4 Hz, $CH_2N$), 127.31 (s, $^3J_{C,Sn}$ = 96.7 Hz, C-3), 127.93 (s, $^3J_{C,Sn}$ = 99.3 Hz, C-5), 129.97 (s, $^4J_{C,Sn}$ = 17.6 Hz, C-4), 136.30 (s, $^2J_{C,Sn}$ = 49.5 Hz, C-6), 139.23 (t, $^3J_{C,F}$ = 22.5 Hz, C-1), 141.04 (s, $^2J_{C,Sn}$ = 66.7 Hz, C-2) ppm. $^{19}$F NMR ($CDCl_3$, 282.38 MHz, 20 °C): $\delta$ = –181.5 ppm (s, $^1J_{F,Sn}$ = 2567/2683 Hz). $^{119}$Sn NMR ($CH_2Cl_2$/[D$_6$]acetone, 149.2 MHz, 20 °C): $\delta$ = –386.7 ppm (t, $^1J_{F,Sn}$ = 2663 Hz). $C_{18}H_{24}F_2N_2Sn$ (425.09): calcd. C 50.86, H 5.69, N 6.59; found C 50.58, H 5.33, N 6.37.

**Synthesis of [{2-($Me_2NCH_2$)$C_6H_4$}$_2$$SnI_2$] (1d):** A saturated aqueous solution of $NH_4I$ (20 mL) was added to a solution of **1a** (0.79 g,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1.73 mmol) in $CH_2Cl_2$ (20 mL)/EtOH (4 mL) and the reaction mixture was stirred for 10 h at room temperature. The organic layer was separated and the water solution was washed twice with 5 mL of $CH_2Cl_2$. The organic solution was separated and dried with anhydrous $Na_2SO_4$. The latter was filtered, the solvent was removed in vacuo and the solid residue was recrystallised from a $CH_2Cl_2$/*n*-hexane mixture to give **1d** as colourless crystals (0.66 g, 60%; m.p. 238 °C). $^1$H NMR ($CDCl_3$, 300 MHz, 20 °C): $\delta$ = 2.23 (br. s, 12 H, $NCH_3$), AB spin system with $\delta_A$ = 3.19 and $\delta_B$ = 4.22 ($^2J_{H,H}$ = 12.7 Hz, 4 H, $CH_2N$), 7.13 (d, $^3J_{H,H}$ = 6.9 Hz, 2 H, 3-H), 7.37 (dd, $^3J_{H,H}$ = 7.4 Hz, 2 H, 4-H), 7.47 (dd, $^3J_{H,H}$ = 7.5 Hz, 2 H, 5-H), 8.19 (d, $^3J_{H,H}$ = 7.2, $^3J_{H,Sn}$ = 111.9 Hz, 2 H, 6-H) ppm. $^1$H NMR ($CDCl_3$, 300 MHz, 50 °C): $\delta$ = 2.21 (s, $^3J_{H,Sn}$ = 39.1 Hz, 12 H, $NCH_3$), AB spin system with $\delta_A$ = 3.24 and $\delta_B$ = 4.16 (br. s, 4 H, $CH_2N$), 7.12 (d, $^3J_{H,H}$ = 7.3 Hz, 2 H, 3-H), 7.37 (dd, $^3J_{H,H}$ = 7.4 Hz, 2 H, 4-H), 7.47 (dd, $^3J_{H,H}$ = 7.5 Hz, 2 H, 5-H), 8.21 (d, $^3J_{H,H}$ = 7.3, $^3J_{H,Sn}$ = 111.9 Hz, 2 H, 6-H) ppm. $^1$H NMR (300 MHz, $CDCl_3$, –50 °C): $\delta$ = 1.96 (s, $^3J_{H,Sn}$ = 39.2 Hz, 6 H, $NCH_3$), 2.63 (s, $^3J_{H,Sn}$ = 38.8 Hz, 6 H, $NCH_3$), AB spin system with $\delta_A$ = 3.17 and $\delta_B$ = 4.30 ($^2J_{H,H}$ = 14.2 Hz, 4 H, $CH_2N$), 7.13 (d, $^3J_{H,H}$ = 7.2 Hz, 2 H, 3-H), 7.37 (dd, $^3J_{H,H}$ = 7.4 Hz, 2 H, 4-H), 7.46 (dd, $^3J_{H,H}$ = 7.4 Hz, 2 H, 5-H), 8.15 (d, $^3J_{H,H}$ = 7.4, $^3J_{H,Sn}$ = 115.3 Hz, 2 H, 6-H) ppm. $^{13}$C NMR ($CDCl_3$, 100.6 MHz, 20 °C): $\delta$ = 46.90 (br. s, $NCH_3$), 62.80 (s, $^2J_{C,Sn}$ = 35.6 Hz, $CH_2N$), 128.02 (s, $^3J_{C,Sn}$ = 104.1 Hz, C-5), 128.22 (s, $^3J_{C,Sn}$ = 90.8 Hz, C-3), 130.29 (s, $^4J_{C,Sn}$ = 18.2 Hz, C-4), 135.73 (s, $^2J_{C,Sn}$ = 67.1 Hz, C-6), 138.17 (s, C-1), 140.51 (s, C-2) ppm. $^{119}$Sn NMR ($CDCl_3$, 111.9 MHz, 20 °C): $\delta$ = –346.9 ppm (s). $C_{18}H_{24}I_2N_2Sn$ (640.90): calcd. C 33.73, H 3.77, N 4.37; found C 33.42, H 3.53, N 4.12.

**Synthesis of [{2-($Me_2NCH_2$)$C_6H_4$}$Me_2SnCl$] (2a):** A suspension of [Li{2-($Me_2NCH_2$)$C_6H_4$}] [prepared as above from *n*BuLi in *n*-hexane (17.6 mL, 1.6 M, 20% excess) and $Me_2NCH_2C_6H_5$ (3.18 g, 23.5 mmol) in 50 mL of anhydrous *n*-hexane] in anhydrous toluene (50 mL) was added dropwise, whilst stirring, to a cooled (–78 °C) solution of $Me_2SnCl_2$ (5.17 g, 23.5 mmol) in 150 mL of toluene (300 mL). After all the suspension had been added the reaction mixture was stirred for 1 h at –78 °C, and then allowed to reach room temperature overnight. The reaction mixture was filtered under inert atmosphere and the solvent was removed in vacuo. The white solid residue was recrystallised from $CH_2Cl_2$/*n*-hexane to give **2a** (5.2 g, 69%) as colourless crystals (m.p. 119–121 °C; ref.[12] 120–123 °C). $^1$H NMR ($CDCl_3$, 200 MHz, 20 °C): $\delta$ = 0.73 (s, $^2J_{H,Sn}$ = 64.1/67.0 Hz, 6 H, $SnCH_3$), 2.29 (s, 6 H, $NCH_3$), 3.62 (s, 2 H, $CH_2N$), 7.12 (m, 1 H, 3-H), 7.32 (m, 2 H, 4,5-H), 8.17 (m, $^3J_{H,Sn}$ = 67.2 Hz, 1 H, 6-H) ppm. $^{13}$C NMR ($CDCl_3$, 50.3 MHz, 20 °C): $\delta$ = –0.28 (s, $^1J_{C,Sn}$ = 492.4/515.4 Hz, $SnCH_3$), 45.15 (s, $NCH_3$), 64.78 (s, $^2J_{C,Sn}$ = 28.8 Hz, $CH_2N$), 126.46 (s, $^3J_{C,Sn}$ = 59.1 Hz, C-3), 127.88 (s, $^3J_{C,Sn}$ = 67.2 Hz, C-5), 129.32 (s, $^4J_{C,Sn}$ = 13.2 Hz, C-4), 137.60 (s, $^2J_{C,Sn}$ = 42.9 Hz, C-6), 140.28 (s, C-1), 141.78 (s, $^2J_{C,Sn}$ = 38.6 Hz, C-2) ppm. $^{119}$Sn NMR ($CH_2Cl_2$/[$D_6$]acetone, 149.2 MHz, 20 °C): $\delta$ = –48.7 ppm (s). $C_{11}H_{18}ClNSn$ (318.41): calcd. C 41.49, H 5.70, N 4.40; found C 41.23, H 5.61, N 4.53.

**Synthesis of [{2-($Me_2NCH_2$)$C_6H_4$}$Me_2SnF$] (2b):** Same procedure as for **1b**, using **2a** (0.25 g, 0.78 mmol) and KF (0.228 g, 3.92 mmol). Recrystallisation from $CH_2Cl_2$/*n*-hexane (approximately 1:3) mixture gave **2b** (0.21 g, 89%) as colourless crystals (m.p. 92–94 °C). $^1$H NMR ($CDCl_3$, 400 MHz, 20 °C): $\delta$ = 0.56 (d, $^3J_{H,F}$ = 3.7, $^2J_{H,Sn}$ = 64.8/67.2 Hz, 6 H, $SnCH_3$), 2.28 (s, 6 H, $NCH_3$), 3.59 (s, 2 H, $CH_2N$), 7.12 (m, 1 H, 3-H), 7.32 (m, 2 H, 4,5-H), 7.97 (m, $^3J_{H,Sn}$ = 60.4 Hz, 1 H, 6-H) ppm. $^{13}$C NMR ($CDCl_3$, 100.6 MHz, 20 °C): $\delta$ = –3.67 (d, $^2J_{C,F}$ = 16.7, $^1J_{C,Sn}$ = 507.7/531.3 Hz, $SnCH_3$), 45.16 (s, $NCH_3$), 64.91 (s, $^2J_{C,Sn}$ = 30.3 Hz, $CH_2N$), 126.47 (s, $^3J_{C,Sn}$ = 58.3 Hz, C-3), 127.83 (s, $^3J_{C,Sn}$ = 64.6 Hz, C-5), 129.24 (s, $^4J_{C,Sn}$ = 12.8 Hz, C-4), 137.19 (s, $^2J_{C,Sn}$ = 38.2 Hz, C-6), 141.32 (d, $^3J_{C,F}$ = 21.7 Hz, C-1), 142.04 (s, $^2J_{C,Sn}$ = 39.4 Hz, C-2) ppm. $^{19}$F NMR ($CDCl_3$, 376.5 MHz, 20 °C): $\delta$ = –178.4 ppm (s, $^1J_{F,Sn}$ = 1944.2/2034.6 Hz). $^{119}$Sn NMR ($CDCl_3$, 111.9 MHz, 20 °C): $\delta$ = –52.7 ppm (d, $^1J_{F,Sn}$ = 2039.3 Hz). $C_{11}H_{18}FNSn$ (301.96): calcd. C 43.75, H 6.01, N 4.64; found C 43.41, H 5.79, N 4.41.

**Synthesis of [{2-($Me_2NCH_2$)$C_6H_4$}$Me_2SnBr$] (2c):** An aqueous solution of KBr (0.93 g, 7.85 mmol) was added to a solution of **2a** (0.5 g, 1.57 mmol) in $CH_2Cl_2$ (30 mL) and the reaction mixture was stirred for 3 h at room temperature. The organic layer was separated and the water solution was washed twice with 10 mL of $CH_2Cl_2$. The organic solution was dried with anhydrous $Na_2SO_4$. The solvent was removed in vacuo and the obtained pale brown-red residue was recrystallised from a $CH_2Cl_2$/*n*-hexane mixture to give **2c** (0.52 g, 91%) [m.p. 136–138 °C (dec); ref.[2] white solid, 136–137 °C]. Colourless crystals suitable for single-crystal X-ray diffraction were obtained from a $CH_2Cl_2$/*n*-hexane (approximately 1:4) solution. $^1$H NMR ($CDCl_3$, 200 MHz, 20 °C): $\delta$ = 0.87 (s, $^2J_{H,Sn}$ = 63.5/66.4 Hz, 6 H, $SnCH_3$), 2.32 (s, 6 H, $NCH_3$), 3.64 (s, 2 H, $CH_2N$), 7.12 (m, 1 H, 3-H), 7.35 (m, 2 H, 4,5-H), 8.26 (m, $^3J_{H,Sn}$ = 68.5 Hz, 1 H, 6-H) ppm. $^{13}$C NMR ($CDCl_3$, 50.3 MHz, 20 °C): $\delta$ = 1.02 (s, $^1J_{C,Sn}$ = 483.1/505.1 Hz, $SnCH_3$), 45.22 (s, $NCH_3$), 64.74 (s, $^2J_{C,Sn}$ = 28.1 Hz, $CH_2N$), 126.46 (s, $^3J_{C,Sn}$ = 58.9 Hz, C-3), 127.89 (s, $^3J_{C,Sn}$ = 67.6 Hz, C-5), 129.39 (s, C-4), 138.22 (s, $^2J_{C,Sn}$ = 44.7 Hz, C-6), 139.54 (s, C-1), 141.58 (s, $^2J_{C,Sn}$ = 37 Hz, C-2). $^{119}$Sn NMR ($CDCl_3$, 149.2 MHz, 20 °C): $\delta$ = –55.5 ppm (s). $C_{11}H_{18}BrNSn$ (362.86): calcd. C 36.41, H 5.00, N 3.86; found C 36.11, H 5.21, N 3.67.

**Synthesis of [{2-($Me_2NCH_2$)$C_6H_4$}$Me_2SnI$] (2d):** Same procedure as for **1b**, using **2a** (0.2 g, 0.63 mmol) and KI (0.52 g, 3.14 mmol). Recrystallisation from a $CH_2Cl_2$/*n*-hexane (approximately 1:3) mixture gave **2d** (0.21 g, 82%) as pale-yellow crystals (m.p. 105–107 °C). $^1$H NMR ($CDCl_3$, 300 MHz, 20 °C): $\delta$ = 1.05 (s, $^2J_{H,Sn}$ = 63.2/65.0 Hz, 6 H, $SnCH_3$), 2.34 (s, 6 H, $NCH_3$), 3.65 (s, 2 H, $CH_2N$), 7.11 (d, $^3J_{H,H}$ = 7.0 Hz, 1 H, 3-H), 7.35 (m, 2 H, 4,5-H), 8.30 (d, $^3J_{H,H}$ = 6.6, $^3J_{H,Sn}$ = 71.2 Hz, 1 H, 6-H) ppm. $^{13}$C NMR ($CDCl_3$, 75.5 MHz, 20 °C): $\delta$ = 3.18 (s, $^1J_{C,Sn}$ = 470.1/492.0 Hz, $SnCH_3$), 45.42 (s, $NCH_3$), 64.84 (s, $^2J_{C,Sn}$ = 26.9 Hz, $CH_2N$), 126.54 (s, $^3J_{C,Sn}$ = 58.9 Hz, C-3), 128.03 (s, $^3J_{C,Sn}$ = 69.4 Hz, C-5), 129.58 (s, $^3J_{C,Sn}$ = 13.7 Hz, C-4), 138.26 (s, $^1J_{C,Sn}$ = 664.0/694.8 Hz, C-1), 139.62 (s, $^2J_{C,Sn}$ = 46.2 Hz, C-6), 141.40 (s, $^2J_{C,Sn}$ = 35.8 Hz, C-2) ppm. $^{119}$Sn NMR ($CDCl_3$, 111.9 MHz, 20 °C): $\delta$ = –72.8 ppm (s). $C_{11}H_{18}INSn$ (409.87): calcd. C 32.24, H 4.43, N 3.42; found C 32.11, H 4.25, N 3.33.

**Synthesis of [{2-($Me_2NCH_2$)$C_6H_4$}$Ph_2SnF$] (3b):** Same procedure as for **1b**, using **3a** (0.25 g, 0.56 mmol) and KF (0.164 g, 2.82 mmol). Recrystallisation from a $CH_2Cl_2$/*n*-hexane (approximately 1:3) mixture gave **3b** (0.21 g, 87%) as colourless crystals (m.p. 161–163 °C). $^1$H NMR ($CDCl_3$, 400 MHz, 20 °C): $\delta$ = 1.97 (s, 6 H, $NCH_3$), 3.56 (s, 2 H, $CH_2N$), 7.20 (d, $^3J_{H,H}$ = 7.2 Hz, 1 H, 3-H), 7.44 (m, 8 H, 4,5-H + $C_6H_5$-*meta*,*para*), 7.72 (m, $^3J_{H,Sn}$ = 61.1 Hz, 4 H, $C_6H_5$-*ortho*), 8.31 (d, $^3J_{H,H}$ = 7.0, $^3J_{H,Sn}$ = 64.4 Hz, 1 H, 6-H) ppm. $^{13}$C NMR ($CDCl_3$, 100.6 MHz, 20 °C): $\delta$ = 45.76 (s, $NCH_3$), 64.82 (s, $^2J_{C,Sn}$ = 31.2 Hz, $CH_2N$), 127.03 (s, $^3J_{C,Sn}$ = 64.6 Hz, C-3), 128.05 (s, $^3J_{C,Sn}$ = 68.7 Hz, C-5), 128.75 (s, $^3J_{C,Sn}$ = 67.5 Hz, $C_6H_5$-*meta*), 129.53 (s, $^4J_{C,Sn}$ = 13.5 Hz, $C_6H_5$-*para*), 129.93 (s, $^4J_{C,Sn}$ = 13.1 Hz, C-4), 136.03 (s, $^2J_{C,Sn}$ = 44.8 Hz, $C_6H_5$-*ortho*), 138.34 (s, $^2J_{C,Sn}$ = 39.1 Hz, C-6), 140.29 (d, $^3J_{C,F}$ = 15.5 Hz, $C_6H_5$-*ipso*), 142.88 (s, $^2J_{C,Sn}$ = 44.3 Hz, C-2) ppm; the resonance for C-1 is overlapped by the resonance of C-6. $^{19}$F NMR ($CDCl_3$, 376.5 MHz, 20 °C): $\delta$ = –182.4 ppm (s, $^1J_{F,Sn}$ = 2058.3/2154.0 Hz). $^{119}$Sn NMR ($CDCl_3$,

**X-ray Crystallographic Study:** The crystal structure measurement and refinement data for **1a**, **1b**, **1b**·$CH_2Cl_2$, **1d**, **2a**, **2a′**, **2b**–**2d**, **3a**, **3b** and **3d** are given in Tables 6, 7 and 8. Data for **1a** were collected with a Nonius KappaCCD diffractometer (University of Dortmund) at 291 K. For all the other compounds the data were collected using a SMART APEX diffractometer ("Babes-Boyai" University) at 297 K. In both cases a graphite monochromator was used to produce a wavelength (Mo-$K_\alpha$) of 0.71073 Å. The structures were solved by direct methods (full-matrix least-squares on $F^2$). All non-hydrogen atoms were refined with anisotropic thermal parameters. For structure solving and refinement the SHELX-97 software package was used.[42] The drawings were created with the Diamond program by Crystal Impact GbR.[43]

CCDC-231308 (for **1a**), -230620 (for **1b**), -230621 (for **1b**·$CH_2Cl_2$), -285103 (for **1d**), -215229 (for **2a**), -215230 (for **2a′**), -215224 (for **2b**), -230622 (for **2c**), -215380 (for **2d**), -215228 (for **3a**), -215226 (for **3b**) and -215227 (for **3d**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information Available** (for details see the footnote on the first page of this article): Figure S1 (variable-temperature $^1$H NMR spectra for **1a** and **1b**, in $CDCl_3$ solution), Figures S2–S8 (simulation of the aromatic region of the $^1$H NMR spectra for **1a**, **1b**, **2a**–**2d** and **4b**, respectively) and Figures S9–S43 (details of the different supramolecular architectures based on hydrogen-bonding networks in the crystals of investigated compounds).

## Acknowledgments

This work was supported by the National University Research Council of Romania [a CNCSIS grant ($A_T$-23/552/2004) and a CERES Project (contract no. 32/12.11.2004). We thank the National Center for X-ray Diffraction ("Babes-Bolyai" University, Cluj-Napoca) for performing the single-crystal X-ray diffraction studies.

# Proton-Coupled Redox Chemistry, Oxidative Reactivity, and Electronic Characterization of Aqua-, Hydroxo-, and Oxo-Triruthenium Clusters

**Genebaldo S. Nunes,[a] Anamaria D. P. Alexiou,[a] Koiti Araki,[a] André L. B. Formiga,[a] Reginaldo C. Rocha,*[b] and Henrique E. Toma*[a]**

**Keywords:** Ruthenium–acetate clusters / Mixed-valence complexes / Oxygen-transfer catalysis / Proton-coupled electron transfer / Pourbaix diagram / Electrocatalysis / Spectroelectrochemistry

The pH-dependent electronic and electrochemical properties of a series of triangular $\mu_3$-oxo-centered trinuclear clusters of the type $[Ru_3O(Ac)_6(py)_2(OH_x)]^n$ (Ac = acetate; py = pyridine; $x$ = 0, 1, or 2; where the formal oxidation states on the metal ions range from +II to +IV) have been investigated with emphasis on the elucidation of the successive proton-coupled redox processes spanning the interconvertible aqua- ($x$ = 2), hydroxo- ($x$ = 1), and oxo- ($x$ = 0) forms, from which the complete Pourbaix diagram has been proposed. From the spontaneous slow coupling reaction of the monomeric cluster in its deprotonated (oxo) form at high pH, the μ-oxo-bridged cluster dimer (i.e. $\{(py)_2(Ac)_6ORu_3\}$-O-$\{Ru_3O(Ac)_6(py)_2\}$) has been isolated and fully characterized by spectroelectrochemistry as well. A further understanding of the underlying electronic interactions across the various oxidation and protonation states, and the role of such phenomena in the activation of the Ru–O bonding system in oxygen-transfer catalysis, have also been explored.

## Introduction

The chemistry of water as a ligand in coordination compounds can be rather puzzling when the metal ions display many successive oxidation states.[1] That is mostly because, in such systems, the ligand acid–base behavior and metal-centered redox properties are coupled and, therefore, proton and electron transfer can simultaneously occur in connection with chemical and electronic transformations in the complex. The consequences of this type of dynamic synergism called proton-coupled electron transfer (PCET) are, in many different aspects, widespread in synthetic and natural systems (e.g. from sol-gel processes in materials chemistry to photosynthetic oxygen evolution in green plants).[2,3]

In the particular context of model systems towards (electro)catalytic oxidation of organics, a remarkable series of (polypyridyl)ruthenium complexes involving oxidation-state/pH-dependent equilibrium PCET reactions of the type $H_2O$–$Ru^{II} \rightleftharpoons$ HO–$Ru^{III} \rightleftharpoons$ O=$Ru^{IV}$ (i.e. aqua, hydroxo, and oxo forms, respectively), has been largely investigated by Meyer and co-workers.[4] In the light of those studies, an extraordinary chemistry has been revealed from the apparently simple Ru–O structure. In addition to the complexity introduced by the multiple ligand-based protonation states coexisting with the metal-based oxidation states, a detailed understanding of the underlying metal–ligand interactions can be especially challenging when metal–metal electronic coupling is also involved, as in the case of the triangular μ-oxo-centered triruthenium clusters $[Ru_3O(Ac)_6(py)_2(OH_x)]^n$ (Ac = acetate ion, py = pyridine), focused herein (Scheme 1, a).

The trinuclear ruthenium complexes of the type $[Ru_3O(Ac)_6(L)_3]^n$ and $[Ru_3O(Ac)_6(L)_2(L')]^n$ (where L is usually a pyridyl ligand) have been extensively investigated[5] since the seminal work by Wilkinson[6,7] and Meyer[8,9] and co-workers, on the mixed-valence properties of the $Ru_3O$ cluster core. In addition to the metal–metal bonding, the triangular center is strongly held by six acetate bridges and a central oxygen atom (oxo) that is capable of interacting with up to three empty Ru $d_\pi$ orbitals. When L′ is $H_2O$, its acid–base properties are expected to be sensitive to the redox states of the Ru ions and, to some extent, the electronic coupling within the trinuclear cluster core. There is also the possibility of forming oxo-bridged dimers (Scheme 1, b), expanding the influence of the mixed-valence interactions over the entire polymetallic system. All these aspects have been investigated in this work, with especial emphasis on the elucidation of the proton-coupled redox processes by electrochemical and spectroelectrochemical methods. Further, the role of intermetallic electronic interactions in the activation of the Ru–O bonding structure in oxygen-transfer catalysis has also been explored.

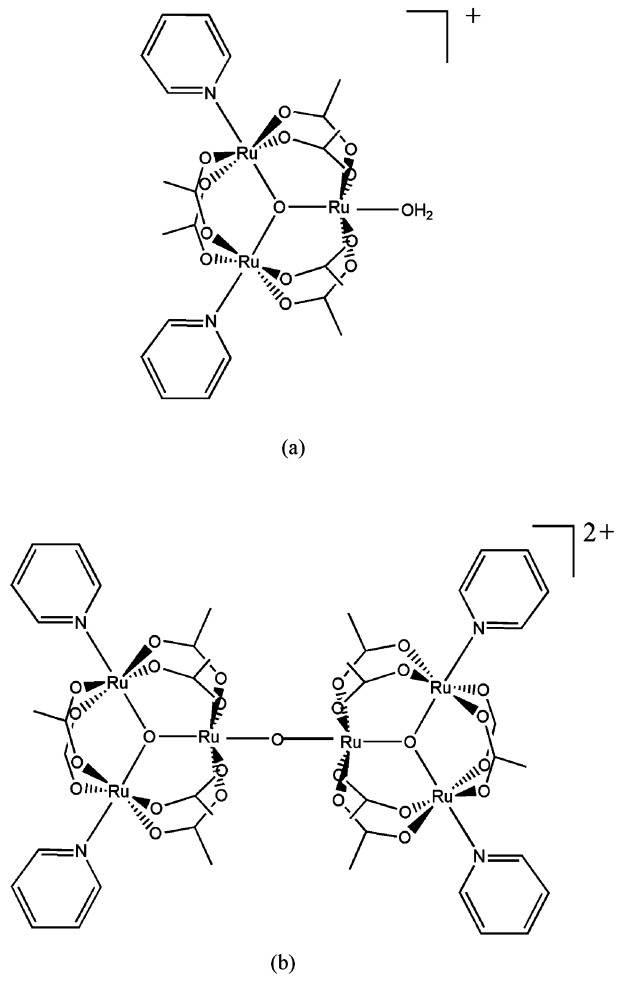

Scheme 1. Structural formulas of (a) the cluster $[Ru_3O(Ac)_6(py)_2(H_2O)]^+$ and (b) the oxo-bridged cluster dimer $[\{Ru_3O(Ac)_6(py)_2\}_2(\mu\text{-}O)]^{2+}$.

## Results and Discussion

### Electronic Absorption Spectra

The electronic spectra of the $[Ru_3^{III,III,III}O(Ac)_6(py)_2(H_2O)]^+$ complex in aqueous solution, at various pH values, are shown in Figure 1. In general, a characteristic set of absorption bands is observed at 498 ($\varepsilon$ = 1630), 607 ($\varepsilon$ = 3390), and 683 nm ($\varepsilon$ = 4300), in addition to a shoulder near 390 nm. The main visible absorption envelope and the higher-energy shoulder have been associated to intracluster (IC) metal–metal electronic transitions and $Ru_3O(d_\pi)\rightarrow py(\pi^*)$ charge-transfer (CT) transitions, respectively, on the basis of previous detailed assignments.[5,9–11]

As shown in Figure 1, no spectral change is observed in the pH range of 1.9–6.5. Above pH 6.5, a systematic spectral shift of the IC bands to 592, 702, and ≈808 nm occurs, accompanied by two isosbestic points at 577 and 712 nm. In the pH range of 6.5–11.5, the process is essentially reversible, corresponding to the acid–base equilibrium of Equation (1).

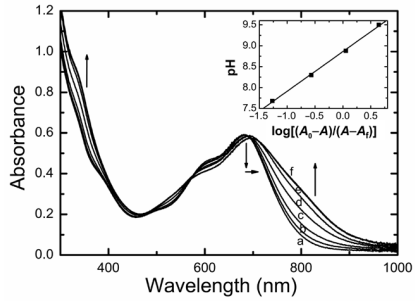

Figure 1. Eletronic spectra of $[Ru_3O(Ac)_6(py)_2(H_2O)]^+$ ($1.4\cdot10^{-4}$ M) in BR buffer at various pH values: (a) 1.9–6.5; (b) 7.7; (c) 8.3; (d) 8.9; (e) 9.5; and (f) 11.1 and 12.0. Inset: pH vs. $\log[(A_0 - A)/(A - A_f)]$, where A is the measured absorbance at any given pH, $A_0$ is the starting absorbance at the lowest pH, and $A_f$ is the final absorbance at the highest pH.

$$[Ru_3^{III,III,III}O(Ac)_6(py)_2(H_2O)]^+ \rightleftharpoons [Ru_3^{III,III,III}O(Ac)_6(py)_2(OH)] + H^+ \quad (1)$$

From the linear plot of pH vs. $\log[(A_0 - A)/(A - A_f)]$ (Figure 1; inset), the $pK_a$ for the process given in Equation (1) was calculated to be 8.86 (±0.02). It is interesting to notice that the $K_a$ of the aqua ligand in the $[Ru_3^{III,III,III}O(Ac)_6(py)_2(H_2O)]^+$ species herein is about four orders of magnitude smaller than that previously reported for the $[Ru_3^{III,III,III}O(Ac)_6(OH)_2(H_2O)]^-$ species ($pK_a$ > 12).[5,6] This observation reflects the influence of the π-backbonding ability of the pyridine ligands, in contrast with the hydroxo ligands. Also, considering that the $pK_a$ of the $[Ru(bpy)_2(py)(H_2O)]^{3+}$ complex is 0.85,[12] the dominant role of the metal–metal interactions in the trinuclear $Ru^{III}$ cluster becomes quite evident. Actually, the presence of the strong bonding and delocalization within the $Ru_3O$ core provides an electronic environment that closely resembles that of mononuclear $Ru^{II}$ complexes such as $[Ru(bpy)_2(py)(H_2O)]^{2+}$ and *trans*-$[Ru(bpydip)(H_2O)_2]^{2+}$ [where bpy is 2,2′-bipyridine, and bpydip is a tetradentate Schiff base ligand, *N*,*N*′-bis(7-methyl-2-pyridylmethylene)-1,3-diiminopropane], as deduced from their $pK_a$ of 10.6 and 8.9, respectively.[4,13]

By monitoring the electronic spectra of the hydroxo, neutral $[Ru_3^{III,III,III}O(Ac)_6(py)_2(OH)]$ species as a function of time (Figure 2), it was observed that the systematic decrease of the absorption band around 700 nm occurs simultaneously with the rise of a broad band around 900 nm, which is characteristic of the aqua cluster $[Ru_3^{III,III,II}O(Ac)_6(py)_2(H_2O)]$ (as demonstrated below by spectroelectrochemistry). Therefore, as shown in Equation (2), the hydroxo-[III,III,III] species slowly disproportionates, at high pH, generating the corresponding protonated/reduced (aqua-[III,III,II]) and deprotonated/oxidized (oxo-[IV,III,III]) forms.

Figure 2 (b) shows the corresponding kinetics for the disproportionation reaction of Equation (2). The initial rates measured at 700 nm $(1.04\pm0.02)\cdot10^{-5}$ $s^{-1}$ and 900 nm $(1.98\pm0.03)\cdot10^{-5}$ $s^{-1}$, were in excellent agreement with the theoretical relationship of Equation (3).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

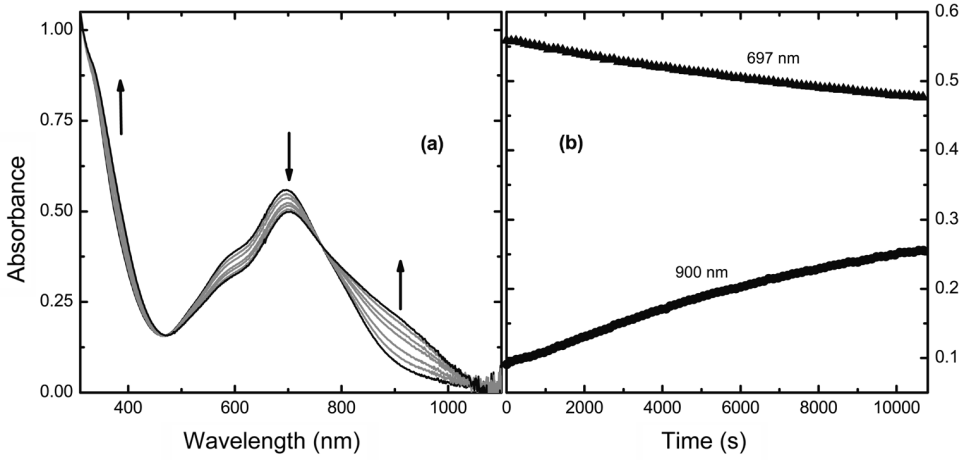

Figure 2. (a) Spectral changes of $[Ru_3O(Ac)_6(py)_2(H_2O)]^+$ ($1.4 \cdot 10^{-4}$ M) in BR buffer at pH 11.4, as a function of time; (b) absorbance changes at 697 and 900 nm as a function of time.

$$2\ [Ru_3^{III,III,III}O(Ac)_6(py)_2(OH)] \rightleftharpoons [Ru_3^{III,III,II}O(Ac)_6(py)_2(OH_2)] + [Ru_3^{IV,III,III}O(Ac)_6(py)_2(O)] \quad (2)$$

$$-(1/2)\ d[Ru_3^{III,III,III}(OH)]/dt = d[Ru_3^{III,III,II}(OH_2)]/dt \quad (3)$$

In order to evaluate the end point of the reaction, the sample undergoing disproportionation was kept in the dark for 24 h and, then, the spectra were measured again at several pH values (Figure 3). The major differences (relative to the spectra of Figure 2, a) were observed above pH 11; i.e., the main absorption band was shifted from 683 nm to 702 nm, and there was an enhancement of the absorption at 343 nm. In addition, the lack of isosbestic points indicates the occurrence of further reactions following the disproportionation process.

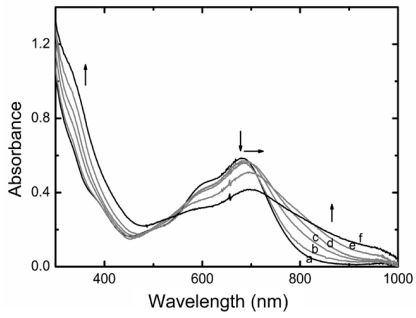

Figure 3. Eletronic spectra of $[Ru_3O(Ac)_6(py)_2(H_2O)]^+$ ($1.4 \cdot 10^{-4}$ M) in BR buffer at various pH values: (a) 1.9; (b) 8.3; (c) 8.9; (d) 9.5; (e) 11.1; (f) 12.0. The sample solution was prepared 24 h prior to the measurements.

By treating the solution (aged for 24 h at pH 12) with diethyl ether, only the neutral aqua cluster, i.e. $[Ru_3^{III,III,II}O(Ac)_6(py)_2(OH_2)]$, could be detected in the organic fraction, as shown in Figure 4, a (see below for detailed assignments).

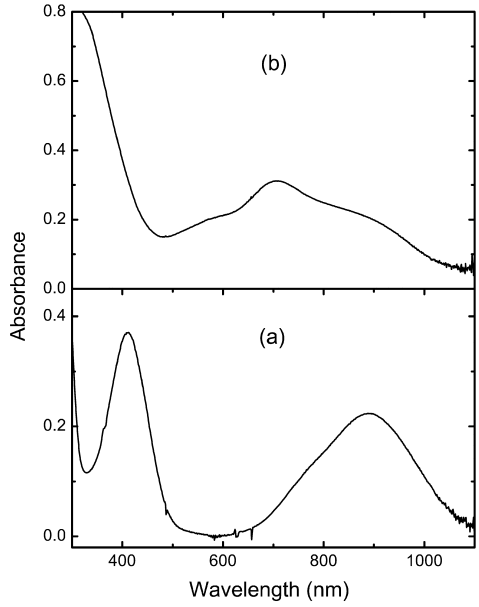

Figure 4. Electronic spectra of (a) the diethyl ether fraction containing the reduced aqua species, $[Ru_3^{III,III,II}O(Ac)_6(py)_2(OH_2)]$, and (b) the remaining, previously ether-treated aqueous solution at pH 12.0 (BR buffer, 0.1 M).

The spectrum of the ether-treated aqueous solution (Figure 4, b) exhibits absorption bands at 893, 712, 566 and 343 nm. In principle, according to the disproportionation reaction of Equation (2), before the extraction with ether the reaction mixture should also contain the oxo species, $[Ru_3^{IV,III,III}O(Ac)_6(py)_2(O)]$, and perhaps some remainder of the starting hydroxo species, $[Ru_3^{III,III,III}O(Ac)_6(py)_2(OH)]$. However, although these are both electrically neutral species, none of these forms could be detected in the extracted organic phase containing the aqua counterpart. A plausible explanation for this observation is that, after aging for 24 h at pH > 11, the $[Ru_3^{IV,III,III}O(Ac)_6(py)_2(O)]$ species would dimerize into $[\{Ru_3^{IV,III,III}O(Ac)_6(py)_2\}_2(O)]^{2+}$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[Equation (4)], analogously to the previously reported for the $[Ru(bpy)_2(py)(O)]^{2+}$ complex.[14]

$$2\ [Ru_3^{IV,III,III}O(Ac)_6(py)_2(O)] + H_2O \rightleftharpoons [\{Ru_3^{IV,III,III}O(Ac)_6(py)_2\}_2(O)]^{2+} + 2\ OH^- \quad (4)$$

Alternatively, the oxo-[IV,III,III] species could react with any remaining amount of the cluster in the hydroxo-[III,III,III] form to yield the mixed-valent dimer, as shown in Equation (5).

$$[Ru_3^{IV,III,III}O(Ac)_6(py)_2(O)] + [Ru_3^{III,III,III}O(Ac)_6(py)_2(OH)] \rightleftharpoons [(py)_2(Ac)_6ORu_3^{IV,III,III}(O)Ru_3^{III,III,III}O(Ac)_6(py)_2]^+ + OH^- \quad (5)$$

In order to obtain additional evidence on the formation of such dimeric species, the final product was further isolated and characterized as follows. The starting $[Ru_3^{III,III,III}O(Ac)_6(py)_2(H_2O)]Cl$ compound was dissolved in a minimum volume of water and treated with an equimolar amount of NaOH. After 24 h, the one-electron reduced, neutral species ($H_2O$-[III,III,II]) was extracted from the mixture with diethyl ether (as above), and the treated aqueous solution was evaporated to dryness. Mass spectra (ESI-MS; see Exp. Sect. for details) of the product, in methanol, exhibited a main peak at $m/z = 1751$, consistent with the $[\{Ru_3O(Ac)_6(py)_2\}_2(O)]Cl_2^+$ formulation ($m/z = 1751$) which, therefore, corresponds to the μ-oxo-bridged mixed-valent [IV,IV,III–IV,III,III] cluster dimer after ionization in gas phase. It is worth noting that the chloride ions were present as counterions because the cluster dimer was generated from the starting $[Ru_3O(Ac)_6(py)_2(H_2O)]Cl$ complex. Isolation of the dimeric species in pure form (using conventional liquid chromatography) has not yet been accomplished because such species seems to undergo facile interconversion between the mixed-valence states, as confirmed by the ESI-MS experiments.

## Electrochemical Behavior

Typical cyclic voltammograms of the $[Ru_3O(Ac)_6(py)_2(H_2O)]^+$ cluster in aqueous solution, at three representative pH values, are shown in Figure 5. A characteristic reversible wave, assigned to the Ru-centered III,III,III/III,III,II redox couple, was observed with $E_{1/2} = 0.20$ V (vs. SHE); Equation (6). Above pH 8, the process exhibits a pH-dependent, Nernstian behavior with $E^o$ (V vs. SHE) = 0.20 – 0.059·pH. The $pK_a$ associated with the equilibrium of Equation (7) was evaluated from the Pourbaix ($E_{1/2}$ vs. pH) plot shown in Figure 6, with the determined value of 8.7 in agreement with that obtained by spectrophotometry (8.86) as above.

$$[Ru_3^{III,III,III}(H_2O)]^+ + e \rightleftharpoons [Ru_3^{III,III,II}(H_2O)] \quad E_{1/2} = 0.20\ V \quad (6)$$

$$[Ru_3^{III,III,III}(H_2O)]^+ \rightleftharpoons [Ru_3^{III,III,III}(OH)] + H^+ \quad pK_a = 8.8 \quad (7)$$

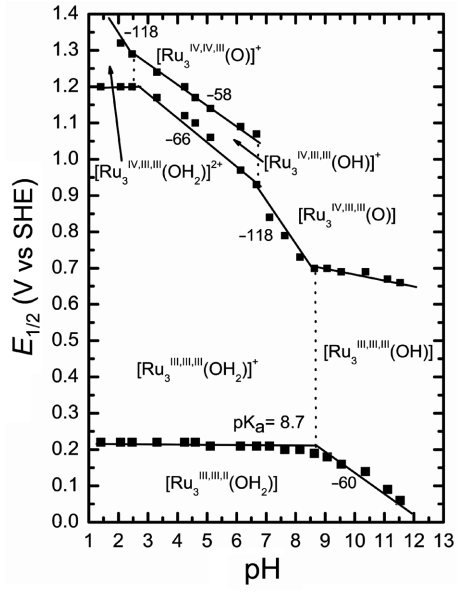

Figure 6. Pourbaix diagrams for $[Ru_3O(Ac)_6(py)_2(OH_x)]^n$ in aqueous solution; $pK_a$ values and slopes (given in mV) are also noted in the Figure. At pH > 9 and $E^o > 1.0$ V, the dimeric species (not shown) predominate; see text for details.

The corresponding spectral changes accompanying the above redox transformations are shown in Figure 7. The electrochemical III,III,III/III,III,II reduction of the aqua cluster at pH 6.7 proceeds reversibly, generating the characteristic cluster-core IC bands with $\lambda_{max}$ around 890 nm and the $Ru_3O(d_\pi) \rightarrow py(p_\pi^*)$ CT band at 364 nm.

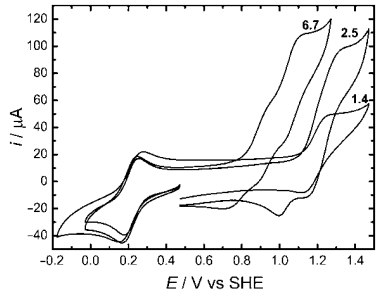

Figure 5. Cyclic voltammograms (at 50 mV $s^{-1}$) of $[Ru_3O(Ac)_6(py)_2(H_2O)]^+$ ($1.3 \cdot 10^{-3}$ M) in BR buffer/NaTFA (0.1 M) at pH 1.4, 2.5, and 6.7.

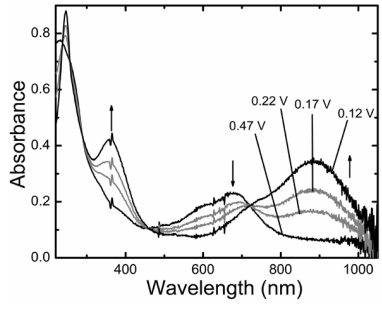

Figure 7. Spectroelectrochemical changes in a solution of $[Ru_3O(Ac)_6(py)_2(H_2O)]^n$ ($1.9 \cdot 10^{-3}$ M), at pH 6.7 [BR buffer/NaTFA (0.1 M)], in the potential range of 0.47 V ($Ru_3^{III,III,III}$; $n = 1+$) to 0.12 V ($Ru_3^{III,III,II}$; $n = 0$).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

At pH 1.4, the cyclic voltammograms display another reversible wave at 1.2 V (Figure 5), corresponding to the IV,III,III/III,III,III redox couple [Equation (8)], which is dramatically sensitive to pH changes. The Pourbaix plots (Figure 6) exhibit two breaking points at pH 2.5 and 6.7, which correspond to the p$K_a$'s of the equilibria in Equation (9) and Equation (10), respectively.

$$[Ru_3^{IV,III,III}(H_2O)]^{2+} + e \rightleftharpoons [Ru_3^{III,III,III}(H_2O)]^{+} \quad E_{1/2} = 1.20\ V \quad (8)$$

$$[Ru_3^{IV,III,III}(H_2O)]^{2+} \rightleftharpoons [Ru_3^{IV,III,III}(OH)]^{+} + H^{+} \quad pK_a = 2.5 \quad (9)$$

$$[Ru_3^{IV,III,III}(OH)]^{+} \rightleftharpoons [Ru_3^{IV,III,III}(O)] + H^{+} \quad pK_a = 6.7 \quad (10)$$

Because the required potentials for the oxidation of the $[Ru_3^{III,III,III}O(Ac)_6(py)_2(H_2O)]^+$ species were near the working limits of water, the formation of the IV,III,III redox state could not be monitored spectroelectrochemically. Instead, a spectrophotometric redox titration was carried out in $HClO_4$ (0.1 M) using $Ce^{IV}$ as a chemical oxidant. As shown in Figure 8 (b), the redox titration was consistent with a 1:1 stoichiometry. The oxidized $[Ru_3^{IV,III,III}O(Ac)_6(py)_2(H_2O)]^{2+}$ species exhibits two characteristic IC bands at 565 and 776 nm, as shown in Figure 8 (a).

At pH 2.5, an additional oxidation wave was discernible at 1.3 V, overlapping the existing reversible wave with $E_{1/2}$ = 1.2 V. The intensity of the resulting convoluted wave was two times that of a monoelectronic process. The new cathodic wave is pH-dependent and was assigned to the 1-$H^+$ or 2-$H^+$ proton-coupled IV,IV,III/IV,III,III redox process of Equation (11) or Equation (12), respectively, depending on the pH region (Figure 6).

$$[Ru_3^{IV,IV,III}(O)]^{+} + 2\,H^{+} + e^{-} \rightleftharpoons [Ru_3^{IV,III,III}(OH_2)]^{2+} \quad pH < 2.5 \quad (11)$$

$$[Ru_3^{IV,IV,III}(O)]^{+} + H^{+} + e^{-} \rightleftharpoons [Ru_3^{IV,III,III}(OH)]^{+} \quad pH > 2.5 \quad (12)$$

The overall redox processes discussed above have been collected in the Pourbaix diagrams of Figure 6.

It should be noted that at pH 6.7 the spectroelectrochemical oxidation (Figure 9) of $[Ru_3^{III,III,III}O(Ac)_6(py)_2(H_2O)]^+$, starting from 0.47 V, actually involves two overlapping successive redox processes. At 0.97 V, the hydroxo species $[Ru_3^{IV,III,III}O(Ac)_6(py)_2(OH)]^+$ should be predominantly formed; at 1.12 V, the product of oxidation (coupled to deprotonation) is expected to be $[Ru_3^{IV,IV,III}O(Ac)_6(py)_2(O)]^+$. A new band at 418 nm was observed for the latter, in addition to a broad band around 850 nm. On the other hand, the vestiges of the initial band around 700 nm may be an indication of some partial regeneration of the starting complex, perhaps by a parallel catalytic process involving the decomposition of water by the highly oxidized, oxo-[IV,IV,III] species (a point that will be discussed below).

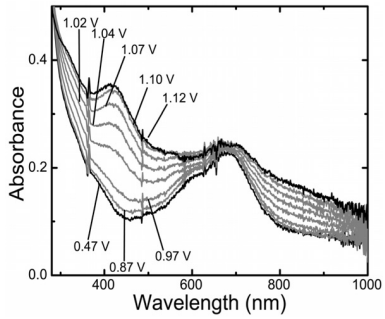

Figure 9. Spectroelectrochemical changes in a solution of $[Ru_3O(Ac)_6(py)_2(OH_x)]^+$ ($1.9\cdot10^{-3}$ M), at pH 6.7 [BR buffer/NaTFA (0.1 M)], in the potential range of 0.47 V (aqua-$Ru_3^{III,III,III}$) to 0.97 V (hydroxo-$Ru_3^{IV,III,III}$), and then to 1.12 V (oxo-$Ru_3^{IV,IV,III}$).

At pH 9.5 a different electrochemical pattern is observed (Figure 10), with three oxidation waves in the 0.7–1.2 V range. The anodic process at 0.73 V seems to follow a regular pattern when it is inserted into the Pourbaix diagram (Figure 6), and is consistent with the proton-coupled redox process of Equation (13).

$$[Ru_3^{III,III,III}(OH)] + OH^{-} \rightarrow [Ru_3^{IV,III,III}(O)] + H_2O + e^{-} \quad (13)$$

The remaining anodic peaks around 1.0 V exhibit relative intensities strongly dependent on the potential scan rates, indicating the occurrence of chemical reactions coupled with the oxidation of the $[Ru_3^{IV,III,III}O(Ac)_6(py)_2(O)]$ species (into $[Ru_3^{IV,IV,III}O(Ac)_6(py)_2(O)]^+$). A possibility is the decomposition of water by the oxo-[IV,IV,III] species [Equation (14)], which accounts for the catalytic peak mani-

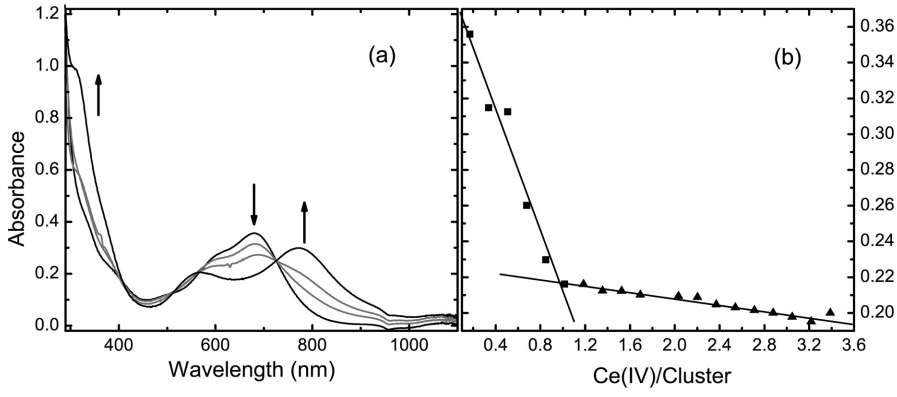

Figure 8. (a) Spectrophotometric redox titration of $[Ru_3O(Ac)_6(py)_2(H_2O)]^+$ ($1.0\cdot10^{-4}$ M) in $HClO_4$ (0.1 M) with Ce(IV) in $H_2SO_4$ (1.0 M). (b) Plot of absorbance (at 683 nm) vs. Ce(IV)/cluster molar ratio.

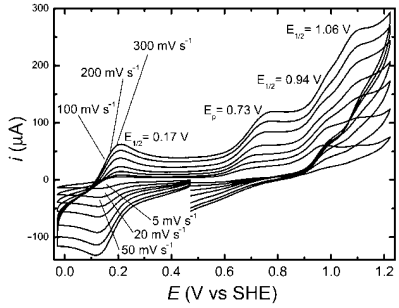

Figure 10. Cyclic voltammograms, at several scan rates, of $[Ru_3O(Ac)_6(py)_2(H_2O)]^+$ ($1.3\cdot10^{-3}$ M) in BR buffer/NaTFA (0.1 M) at pH 9.5.

fested near 1.0 V at low scan rates (Figure 10). This reaction regenerates the starting aqua-[III,III,III] species, thus explaining the lack of cathodic waves in the reverse scan.

$$2\ [Ru_3^{IV,IV,III}(O)]^+ + 2\ H_2O \rightarrow 2\ [Ru_3^{III,III,III}(H_2O)]^+ + O_2 \qquad (14)$$

By increasing the scan rates, two inflections can be noted around 0.95 and 1.15 V, in addition to the catalytic wave. As shown below, these signals can be assigned to the presence of small amounts of dimeric species. In fact, cyclic voltammograms of the product isolated from the disproportionation reaction discussed above, in acetonitrile (Figure 11), are consistent with the existence of dimeric species.

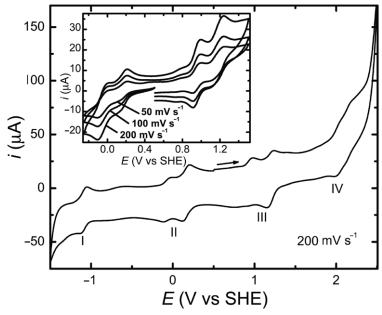

Figure 11. Cyclic voltammograms of the cluster dimer $[\{Ru_3O(Ac)_6(py)_2\}_2(O)]^{2+}$ ($1.9\cdot10^{-3}$ M) in acetonitrile/TEAP (0.1 M).

The voltammograms of the cluster dimer in acetonitrile exhibit essentially the characteristic waves for the cluster monomer "in duplicate". Table 1 summarizes the corresponding processes in four distinct regions: (I) –1.09 V; (II) –0.07 and 0.16 V; (III) 0.95 and 1.17 V; (IV) 2.01 and 2.14 V (see also Figure 11).

Table 1. Redox potentials for the oxo-bridged cluster dimer, $[\{Ru_3O(Ac)_6(py)_2\}_2(O)]^n$, in acetonitrile/TEAP (0.1 M).

| Redox couple ($Ru_3$–$Ru_3$) | $E_{1/2}$ (V vs. SHE) |
|---|---|
| [III,III,II]–[III,III,II]/2[III,II,II] | –1.09 |
| [III,III,III]–[III,III,II]/[III,III,II]–[III,III,II] | –0.07 |
| [III,III,III]–[III,III,III]/[III,III,III]–[III,III,II] | 0.16 |
| [IV,III,III]–[III,III,III]/[III,III,III]–[III,III,III] | 0.95 |
| [IV,III,III]–[IV,III,III]/[IV,III,III]–[III,III,III] | 1.17 |
| [IV,IV,III]–[IV,III,III]/[IV,III,III]–[IV,III,III] | 2.01 |
| [IV,IV,III]–[IV,IV,III]/[IV,IV,III]–[IV,III,III] | 2.14 |

The reversible waves observed at 0.95 and 1.17 V are consistent with those obtained in aqueous solution at pH 9. From the splitting of the redox couples involving mixed-valent states, the comproportionation constant for the $[Ru_3–Ru_3]^n + [Ru_3–Ru_3]^{n+2} \rightleftharpoons 2\times[Ru_3–Ru_3]^{n+1}$ equilibrium can be calculated as $K_c = \exp[(\Delta E\cdot F)/RT]$,[15] where $\Delta E$ is the potential separation between the $[Ru_3–Ru_3]^{n+2}/[Ru_3–Ru_3]^{n+1}$ and $[Ru_3–Ru_3]^{n+1}/[Ru_3–Ru_3]^n$ redox couples (i.e., $\Delta E_{1/2}$). In this way, the obtained values for regions II–IV are: $7.7\cdot10^3$ ($\Delta E$ = 230 mV; region II), $5.2\cdot10^3$ ($\Delta E$ = 220 mV; region III) and $1.6\cdot10^2$ ($\Delta E$ = 130 mV; region IV). As comproportionation constants can be related to the stabilization promoted by the electronic delocalization in the mixed-valence states,[15] according to this evaluation of $K_c$ based on the closely-spaced redox potentials, the electronic coupling between the two cluster units does not appear to be particularly strong within the oxidation-state range studied and reported herein. Consistent with these findings are also preliminary results of ongoing theoretical calculations of molecular and electronic structures, which provide additional evidence for the moderate extent of cluster-to-cluster electronic communication (despite the obvious metal–ligand mixing and delocalization within each cluster).

Attempts to detect the existence of cluster-to-cluster intervalence charge-transfer (IVCT) bands in the mixed-valence states of the cluster dimer were conducted by means of Vis/near-IR spectroelectrochemistry in acetonitrile, in the potential range of –1.0 to 1.2 V. Unfortunately, the results were not conclusive, resembling those of the monomeric species. No evidence of such IVCT transitions was found, most likely due to weak absorptivity or convolution with the broad IC bands.

## Electrocatalytic Activity in the Oxidation of Benzyl Alcohol

Oxo–metal complexes are of great interest in the catalytic oxidation of organic substrates[16–31] because of their ability to promote selective oxygen-transfer reactions, without the participation of less specific oxygen-free radical agents.[24,29,30] For this reason, we extended the study on the redox properties of the oxo–ruthenium clusters to include their electrocatalytic behavior in the oxidation of benzyl alcohol in aqueous solution.

Figure 12 shows typical cyclic voltammograms of the $[Ru_3^{III,III,III}O(Ac)_6(py)_2(H_2O)]^+$ complex in aqueous solution, at pH 3.0, in the presence of increasing amounts of benzyl alcohol. A linear increase of the amperometric current is observed at 1.2 V, which coincides with the convoluted waves assigned above to the proton-coupled oxidation of $[Ru_3^{III,III,III}O(Ac)_6(py)_2(H_2O)]^+$ into $[Ru_3^{IV,III,III}{}_3O(Ac)_6(py)_2(OH)]^+$ and $[Ru_3^{IV,IV,III}O(Ac)_6(py)_2(O)]^+$. The lack of redox response from the benzyl alcohol up to 1.4 V, and the absence of the cathodic waves from the oxidized clusters in the reverse scan, are consistent with the electrocatalytic oxidation of benzyl alcohol.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

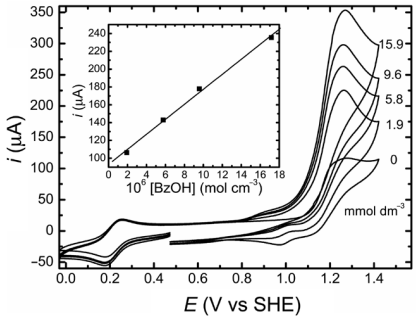

Figure 12. Cyclic voltammograms (at 50 mV $s^{-1}$) of $[Ru_3O(Ac)_6(py)_2(H_2O)]^+$ ($1.3\cdot10^{-3}$ M) in BR buffer/NaTFA (0.1 M), at pH 3.0, in the presence of various amounts of benzyl alcohol. The inset shows the linear dependence of the anodic peak current above 1.2 V vs. the concentration of benzyl alcohol.

Additional insight into the electrocatalytic oxidation of benzyl alcohol was obtained from the cyclic voltammograms of similar sample solutions at pH 6.7 (Figure 13). In this case, the pH-dependent reduction potential of the hydroxo-[IV,III,III]/aqua-[III,III,III] redox/protonation couple was shifted to 0.9 V. From the current increase at 1.1 V,

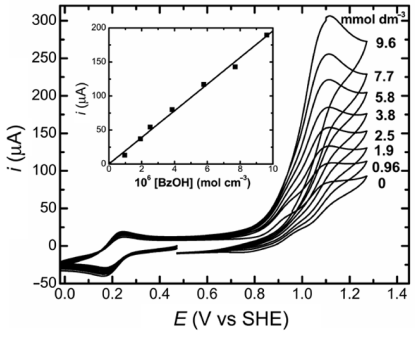

Figure 13. Cyclic voltammograms (at 50 mV $s^{-1}$) of $[Ru_3O(Ac)_6(py)_2(H_2O)]^+$ ($1.3\cdot10^{-3}$ M) in BR buffer/NaTFA (0.1 M), at pH 6.7, in the presence of various amounts of benzyl alcohol. The inset shows the linear dependence of the anodic peak current around 1.1 V vs. the concentration of benzyl alcohol.

the catalytic wave can be readily associated with participation of the oxo-[IV,IV,III]/hydroxo-[IV,III,III] couple.

The electrocatalytic scheme in this case corresponds to that categorized by Nicholson and Shain[32] as type VII, which involves a reversible electron transfer followed by a reaction regenerating the starting complex [Equation(15)].

$$R \rightleftharpoons O + ne^- \quad (15a)$$

$$O + Z \rightarrow R\ (k'_f) \quad (15b)$$

For this scheme, assuming a diffusional process for the catalytic reaction, Sawyer[33] has shown that, when the scan rates increase by an order of magnitude, the peak potential ($E_p$) is shifted by approximately 0.030 V, as expressed by Equation (16) (where α is the electron-transfer coefficient, $n_\alpha$ is the number of electrons involved in the process, and $v$ is the potential scan rate). From the slope of the linear plot in Figure 14 (a), $\alpha\cdot n_\alpha = 0.91$. Similarly, by combining this value into Equation (17)[32,33] (where $i_p$ is the oxidation peak current, $A$ is the electrode area, $C_0$ is the substrate concentration, and the diffusion coefficient, $D_0 = 7.1\cdot10^{-6}$ $cm^2 s^{-1}$, was estimated from the Stokes-Einstein[25] equation: $D = k_B T/6\pi r\eta$, $k_B$ = Boltzmann's constant, $T$ = temperature, $r$ = solvodynamic radius, and $\eta$ = viscosity), the number of electrons $n$ was calculated to be 2.04 from the slope of the corresponding linear plot shown in Figure 14 (b). Therefore, the oxidation of benzyl alcohol proceeds by a two-electron-transfer process to generate benzaldehyde, as also confirmed by standard tests with (2,4-dinitrophenyl)hydrazine.

$$E_p = K + (0.03/\alpha\cdot n_\alpha)\log(v) \quad (16)$$

$$i_p = 2.99\cdot10^5\, n\, (\alpha\cdot n_\alpha)^{1/2}\, A\cdot C_0\cdot D_0^{1/2}\cdot v^{1/2} \quad (17)$$

The catalytic kinetic constant ($k_f$) can be determined from the working plot of $i_k/i_d$ vs. $\psi^{1/2}$ (where $i_k$ is the catalytic current, $i_d$ is the diffusion current, $\psi = k_f/a$ and $a = nFv/RT$), as described by Nicholson and Shain[32] (Figure 15, a). The catalytic current, in this case, was measured in the presence of benzyl alcohol under pseudo-first-order conditions ($C = 9.6\cdot10^{-3}$ M). The diffusion current was given

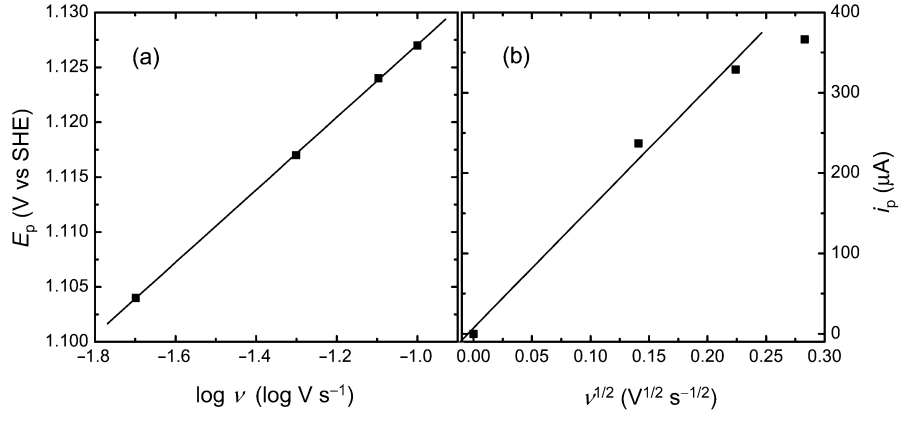

Figure 14. Plots of the catalytic potential peak vs. log$v$ (a) or catalytic current peak vs. $v^{1/2}$ (b), for the oxidation of benzyl alcohol ($3.85\cdot10^{-3}$ M) by the cluster ($1.3\cdot10^{-3}$ M) at pH 6.7 [BR buffer/NaTFA (0.1 M)].

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

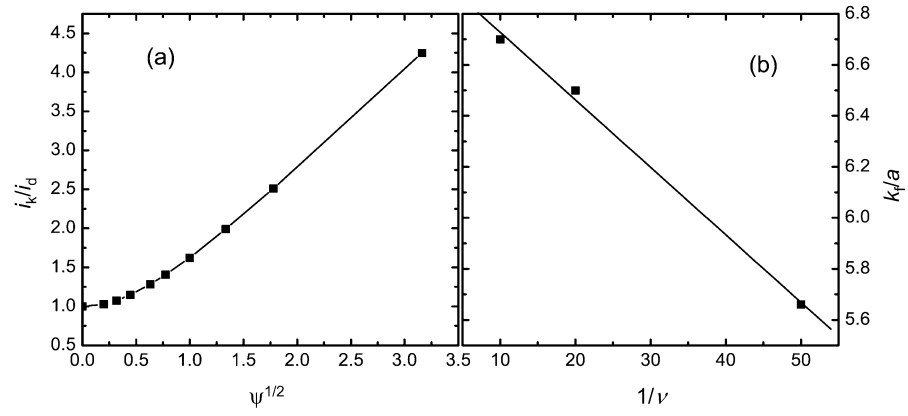

Figure 15. Plots of (a) $i_k/i_d$ vs. $\psi^{1/2}$, and (b) $k_f/a$ vs. $1/\nu$ (see text for details).

by the same measurement in the absence of the substrate. The calculated $k_f/_a$ values are then plotted against $1/\nu$ and, from the slope, $k_f/(nF/RT)$ is obtained. In this way, $k_f$ was determined to be 2.1 $s^{-1}$ and, the corresponding second-order rate constant, $k'_f = k_f/[\text{substrate}]$, is $2.2 \cdot 10^2$ $M^{-1}$ $s^{-1}$.

It is interesting to notice that the kinetic constant for the oxidation of benzyl alcohol by the cluster is significantly higher than those reported[34] for the complexes $[Ru^{IV}(tpy)(bpy)(O)]^{2+}$, at pH 13, ($k'_f$ = 36.1 $M^{-1}$ $s^{-1}$) or $[Ru^{IV}(tpy)(bpz)(O)]^{2+}$ ($k'_f$ = 23.0 $M^{-1}$ $s^{-1}$), at pH 11 (tpy = 2,2′′:6,2′′-terpyridine; bpz = 2,2′-bipyrazine). Considering the redox potentials for these complexes (0.86 V and 0.90 V, respectively),[34,35] the comparatively enhanced catalytic activity of the $[Ru_3^{IV,IV,III}O(Ac)_6(py)_2(O)]^+$ cluster may arise from its stronger oxidizing character ($E^o$ = 1.1 V at pH 6.7).

## Conclusion

In summary, the trinuclear ruthenium clusters of the type $[Ru_3O(Ac)_6(py)_2(OH_x)]^n$ exhibit a very rich proton-coupled redox chemistry in aqueous solution. On the basis of cyclic voltammetry and spectroelectrochemical measurements as a function of pH, the various protonation/oxidation states have been characterized and the complete Pourbaix diagram has been proposed for the system, which comprises all reversible one-proton/one-electron transformations involving the aqua- ($x$ = 2), hydroxo- ($x$ = 1), and oxo- ($x$ = 0) forms with the increasing oxidation states of the triangular redox center. An enhanced catalytic activity for the $[Ru_3^{IV,IV,III}O(Ac)_6(py)_2(O)]^+$ oxo species has been demonstrated in the oxidation of benzyl alcohol, evidencing the activation of the $Ru^{IV}$–O bonding in oxygen-transfer reactions. Moreover, the new μ-oxo-bridged cluster dimer $[\{(py)_2(Ac)_6ORu_3\}\text{-}O\text{-}\{Ru_3O(Ac)_6(py)_2\}]^n$ has been isolated and characterized, and the combined electrochemical and spectroscopic results indicate only moderate electronic coupling between the two triangular cluster units through the oxo bridge. Next, additional understanding of the molecular and electronic structures of these systems will also be pursued by means of theoretical quantum chemical calculations, which should be of invaluable assistance in providing a comprehensive view of the electronic interactions across the various oxidation/protonation states as well as the wealth of useful properties arising from the proton-coupled redox chemistry of these *apparently* simple triruthenium clusters.

## Experimental Section

**Chemical Preparations:** The precursor complex $[Ru_3O(Ac)_6(py)_2(CH_3OH)]PF_6$ was prepared according to reported procedures.[5] All other reagents and solvents were of analytical grade and used as supplied. Britton–Robinson (BR) buffer solution (0.1 M) was employed in the pH-controlled experiments (pH 4–12). Sodium trifluoroacetate (NaTFA) or tetraethylammonium perchlorate (TEAP) was used as supporting electrolyte ($I$ = 0.1 M) in sample solutions for (spectro)electrochemical measurements in water or acetonitrile, respectively.

$[Ru_3O(Ac)_6(py)_2(H_2O)]Cl$ was obtained by treating $[Ru_3O(Ac)_6(py)_2(CH_3OH)]PF_6$ (400 mg; 0.40 mmol) with $[AsPh_4]Cl$ (170 mg; 0.40 mmol) dissolved in water (30 mL), whilst stirring, for at least 2 h. The resulting white precipitate of $[AsPh_4]PF_6$ was collected on a fine filter containing microcrystalline cellulose, and the filtrate was roto-evaporated to dryness. The solid product was stored under vacuum. Yield: 230 mg (65%). $C_{22}H_{30}ClN_2O_{14}Ru_3$ (885.1): calcd. C 29.85, H 3.42, N 3.16; found C 28.77, H 3.35, N 3.29. IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 1556 m ($\upsilon_{as,}$ $CO_2$) , 1418 s ($\upsilon_s$, $CO_2$) , 1607 m ($\upsilon_{ring}$, py), 1485 m, and 1448 sh.

**Physical Methods:** Electronic spectra were recorded with either a HP 8453 diode-array spectrophotometer (UV/Vis) or a Guided Wave 260 fiber-optic instrument (near-IR). Cyclic voltammetry measurements were carried out with an Autolab PGSTAT 30 potentiostat/galvanostat and a conventional three-electrode cell containing a glassy-carbon working electrode ($A$ = 0.196 $cm^2$), a platinum-wire auxiliary electrode, and an Ag/AgCl (1.0 M KCl, $E^0$ = 0.222 V vs. SHE) or $Ag/AgNO_3$ (0.010 M, $E^0$ = 0.503 V vs. SHE) reference minielectrodes in aqueous or acetonitrile solutions, respectively. A three-electrode system, arranged in a rectangular quartz cell ($l$ = 0.25 mm), was used for the spectroelectrochemical measurements. In this case, a gold minigrid as a transparent working electrode was used with the above mentioned auxiliary and reference minielectrodes. All measurements were performed at room temperature (25 °C). Electrospray mass spectra were recorded with

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a Micromass Q-Tof mass spectrometer with a quadrupole (Qq) and high-resolution orthogonal time of flight (o-TOF) configuration. Samples dissolved in pure methanol were injected using a syringe pump (Harvard Apparatus, Pump 11, 10 μL/min) through an uncoated fused-silica capillary. The ESI-MS mass spectra were acquired using an ESI capillary voltage of 3 kV and a cone voltage of 10 V.

# The First End-On Bonded Superoxo Complexes of Ga and In: The Oxygen-Rich Compounds $GaO_4$ and $InO_4$

**Benjamin Gaertner,[a] Andreas Köhn,[b] and Hans-Jörg Himmel*[a]**

*Dedicated to Prof. Hansgeorg Schnöckel on the occasion of his 65th birthday*

**Keywords:** Oxidation / Ga metal / Superoxo complex / Reaction mechanism / Matrix isolation / Vibrational spectrosopy

We report the first sighting and characterization of the oxygen-rich molecules $GaO_4$ and $InO_4$, being the products of a three-step process taking place in an Ar matrix. This process includes (i) reaction of Ga or In atoms (M) with one dioxygen molecule to give the cyclic superoxo complex $MO_2$, (ii) photoisomerization into linear OMO by the action of UV light, and (iii) reaction of linear OMO with an additional $O_2$ molcule. The molecules can be described as end-on bonded superoxo complexes $OMO(O_2)$. On the basis of the observed isotopic data the O–Ga–O angle can be estimated to be ca. 165°. In addition to the experimental studies, quantum chemical calculations were performed to achieve a more complete characterization of these interesting new and unusual molecules, representing the first ever found examples of end-on bonded superoxo complexes of Ga and In.

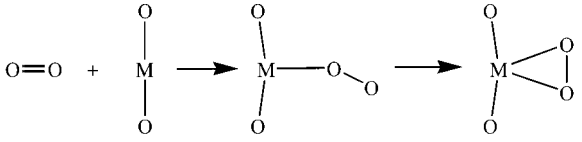
## Introduction

Oxidation of a metal is an important but very complex process. To shed more light on this process, the interaction of $O_2$ with a number of metals was studied intensively in the past decades.[1] The matrix isolation technique offers the possibility to study in detail the reactivity of metal atoms and small clusters towards dioxygen. E.g. Co atoms react upon photolysis with $O_2$ to give firstly the linear OCoO molecule with a $^2\Sigma_g^-$ electronic ground state.[2,3] Reaction of this species with a second $O_2$ molcule leads to an end-on bonded OCoO(OO) complex,[4] which in the matrix slowly undergoes conversion into a side-on bonded complex. According to quantum chemical calculations, the electronic ground state, $^2A_2$, of this complex is indeed the side-on bonded form. The calculations predict a decrease of the OCoO angle from 180° to 116° in the course of complexation. However, a $^4A'$ electronic state with an end-on bonded $O_2$ unit is only about 35 kJ·mol$^{-1}$ higher in energy. The experimental results show that the excited $^4A'$ state is firstly formed and that the product then relaxes in a spin-forbidden process [Equation (1)] from the end-on bonded complex to the side-on bonded complex. The excited state lifetime amounts to ca. 23 min in Ar and 15 min in Ne. In an Ar matrix, the $\nu$(O–O) mode of the ligated $O_2$ unit shows at 1286.2 cm$^{-1}$ in the case of the end-on bonded complex and at 950.6 cm$^{-1}$ for the side-on bonded form.



(1)

Very recently it has been shown that Al atoms can bind up to three $O_2$ units, leading to the oxygen-rich tris-superoxo complex $Al(O_2)_3$.[5] The species $Al(O_2)_2$ was also sighted, being a radical (one unpaired electron) featuring $D_{2d}$ symmetry. It was also shown that photolytically activated AlX (X = F, Cl, Br) molecules react with $O_2$ to give the peroxo complex $XAlO_2$,[6] or, with an excess of $O_2$, the bis-superoxo complex $XAl(O_2)_2$.[7] These examples show that group 13 elements and subvalent compounds undergo interesting and complex reactions with $O_2$.

The reaction of Ga atoms with one $O_2$ molcule leading to $GaO_2$ has now been studied in some detail both in inert gas matrices[8–10] and in the gas phase.[11] First the cyclic superoxo complex $GaO_2$ is formed in the course of a spontaneous reaction in the absence of any significant reaction barrier. The quantum chemical results indicate that the electron is transferred from the Ga atom to the $O_2$ unit at a distance of ca. 270 pm between Ga and the $O_2$ centroid. Cyclic $GaO_2$ in its $^2A_2$ electronic ground state is characterised by an O–Ga–O bond angle of 39° and an O–O bond length of 136 pm. This molecule can be photoconverted

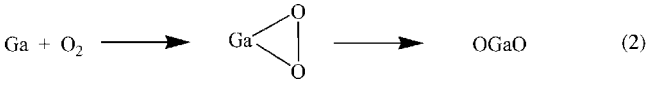
into the linear isomer OGaO [see Equation (2)], which is formally valence isoelectronic to the $[OCO]^+$ cation, by the action of UV light ($\lambda_{max}$ = 254 nm).[10] Isomerization only by thermal means is opposed to a massive barrier in the order of ca. 300 kJ·mol$^{-1}$. Quantum chemical calculations on linear OGaO proved to be extremely difficult. Only if highly correlated methods are applied, it can be shown that linear OGaO in its $^2\Pi_g$ electronic ground state is ca. 18 kJ·mol$^{-1}$ more stable than cyclic $GaO_2$ ($^2A_2$ electronic ground state). As discussed in detail in a previous publication, calculations on the vibrational properties are hampered due to singlet instabilities of the ROHF wavefunction.[10] The analogous reaction between In atoms and $O_2$ has also been studied.



(2)

Here we will show that the linear OGaO and OInO molecules are capable of binding to an $O_2$ molcule leading to a species with the overall formula $GaO_4$ and $InO_4$, respectively. The vibrational (IR as well as Raman) spectra were used to characterize these interesting species. The results of quantum chemical calculations are also discussed. In the light of the problems with the calculations in the case of OGaO it does not come as surprise that the $O_2$ complex of this species turned also out to be difficult to calculate.

## Results and Discussion

In the following, the results for the reactions of Ga and In atoms with $O_2$ using IR and Raman spectroscopy will be reported in turn.

### Ga + $O_2$

**IR.** In experiments in which Ga atoms were codeposited together with 1% of $^{16}O_2$ in Ar, bands were observed in the IR spectrum at 1089.3, 380.5/378.9, and 283.2 cm$^{-1}$ which were already sighted previously and shown to belong to the cyclic superoxo complex $GaO_2$, **1a**. An increase of the $O_2$ concentration brought about an increase of the band intensities in a way characteristic for a species containing two O atoms. However, even in a pure $O_2$ matrix the spectra showed no sign of any product of a spontaneous reaction of Ga with more than one $O_2$ molcule. Thus, under the conditions of our experiments, Ga spontaneously takes up not more than one dioxygen molecule. Subsequently the matrix was subjected to a 15 min period of photolysis with UV light ($\lambda_{max}$ = 254 nm). The IR spectrum taken after this photolysis treatment (see Figure 1) displayed two families of bands, which both were absent in the spectra taken before photolysis. At the same time, the bands due to the cyclic superoxo complex $GaO_2$, **1a**, decreased significantly in intensity. The first family showed at 912.6/908.5 and 204.9/204.0 cm$^{-1}$. The absorber responsible for these bands was already identified to be the linear molecule OGaO, **2a**, formed via photoisomerization of cyclic $GaO_2$, **1a**.[10] The second group of bands belongs to a different species **3a**, which has not yet been identified. A very intense absorption of **3a** was observed with its maximum of intensity at 568.7 cm$^{-1}$. Figure 2 shows that this band can be fitted satisfactorily with two pairs of Lorenzian-type curves having their maxima at 568.7/566.2 and 565.9/563.6 cm$^{-1}$. The relative intensities within each of the pairs amount to 60.1:39.9, reflecting the natural abundances of $^{69}$Ga and $^{71}$Ga in a species containing only one Ga atom. Thus it is likely that **3a** contains one Ga atom. Convincing support comes from the inspection of the two weaker bands at lower wavenumbers (174.8/174.1 and 165.6/164.9 cm$^{-1}$), which both clearly show the isotopic pattern ($^{69}$Ga/$^{71}$Ga) characteristic for a species containing one Ga atom. The bands of **3a** at 1264.2/1261.8 cm$^{-1}$ come in a region in which ν(O–O) modes of end-on coordinated $O_2$ groups are expected to show [cf. Fe(OO) 1204.5,[12] OCoO(OO) 1286.2 cm$^{-1}$ [4]]. Bands at 1824.7/1820.0, 1816.7/1811.7 cm$^{-1}$ are most likely due to a combination mode between the modes showing near 568 and near 1264 cm$^{-1}$ (the presence of four maxima of absorption is then caused by matrix splitting of the fundamentals).

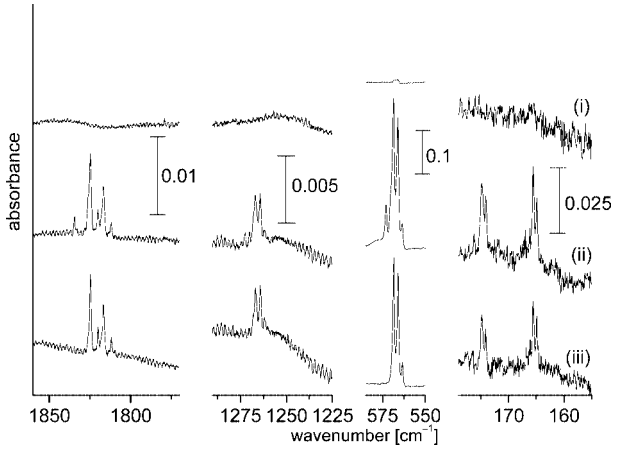


Figure 1. Some regions of the IR spectra recorded for a matrix containing Ga atoms and 0.3% $O_2$. (i) following deposition, (ii) upon UV photolysis ($\lambda_{max}$ = 254 nm), and (iii) annealing of the matrix to 30 K.

The experiments were repeated with different concentrations of Ga and $O_2$ in the matrix. Figure 3 compares two regions of the IR spectra taken for a matrix containing Ga and a) 0.3% and b) 1.0% $O_2$ in Ar. These two regions show bands characteristic for cyclic $GaO_2$, **1a**, which appear directly upon deposition and are virtually extinguished upon UV photolysis, and for linear OGaO, **2a**, and species **3a**, which both grow in upon UV photolysis and decrease in intensity upon annealing. For the low concentration of 0.3% of $O_2$ in the matrix the bands due to linear OGaO are much more intense than the ones due to **3a**. For higher concentrations of $O_2$ in the matrix (1%), the bands due to **3a** gain in relative intensity. This variation in the relative intensities indicates that two $O_2$ molcules are involved in the formation of **3a**, arguing for a species with the overall formula $GaO_4$. Using similar arguments experiments with

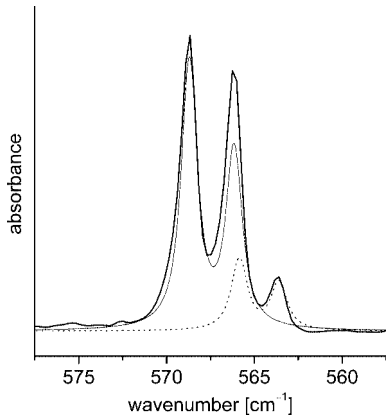

Figure 2. High-resolution IR spectrum showing the structure of the band near 570 cm$^{-1}$. The band structure can be fitted with two pairs of Lorenzian curves with intensities within each pair in agreement to the natural abundance of the $^{69}$Ga and $^{71}$Ga isotopomers.

different Ga concentrations are in agreement with the presence of only one Ga atom in **3a**, in line with the observed isotopic pattern.

Subsequently, experiments were carried out in a solid $O_2$ matrix (see Figure 4). In these experiments, the bands due to cyclic $GaO_2$, **1a**, were observed in the spectrum recorded immediately after deposition, in analogy to the situation in an $O_2$-doped Ar matrix. The bands decreased in intensity upon UV photolysis. However, there was no sign of the bands attributable to linear OGaO, **2a**, after photolysis. Instead, the spectra showed massive bands in close energetic proximity to those measured for **3a** in an Ar matrix (at 1853.5/1845.4, 1842.5/1834.3, 1286.0/1283.8, 1279.3/1276.3, 580.5/577.8, 575.9/573.3, 178.2, and 163.3 cm$^{-1}$). No bands belonging to another product of the reaction between Ga and $O_2$ were observed. Thus we conclude that $GaO_4$ can not take up another $O_2$ molcule. This is in clear difference to Al, which has been shown to form the tris-superoxo complex $Al(O_2)_3$, but in line with the general finding that Ga prefers lower coordination numbers than Al.

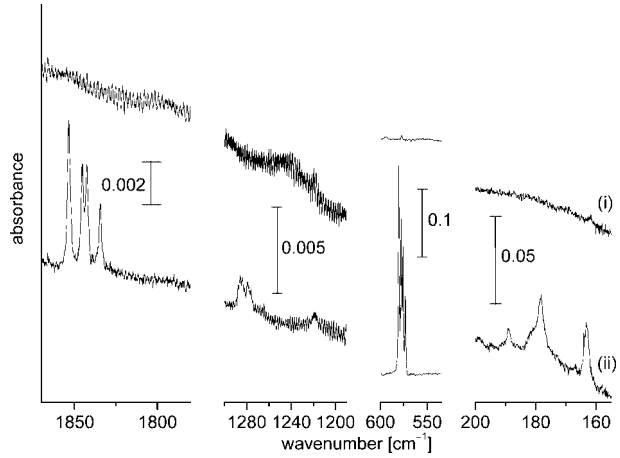

Figure 4. IR spectrum taken for an $O_2$ matrix containing Ga atoms. (i) upon deposition. (ii) upon UV radiation ($\lambda_{max}$ = 254 nm).

Finally, the experiments were repeated with different $O_2$ isotopomers. Figure 5 shows the regions of the IR spectra which contain bands due to **3a** for $^{16}O_2$, $^{18}O_2$, equimolar mixtures of $^{16}O_2$ and $^{18}O_2$ and 1:2:1 mixtures of $^{16}O_2$, $^{16}O^{18}O$, and $^{18}O_2$. Note that the spectra in the low (600–30 cm$^{-1}$) and high (2000–600 cm$^{-1}$) wavenumber region had to be recorded for different matrices using a Bolometer for the low and an MCT detector for the high wavenumber region (since we had to change the material of the windows of our high-vacuum apparatus from CsI for measurements with the MCT detector to polyethylene for measurements with the bolometer). It can be seen that all bands due to **3a** are red-shifted if $^{16}O_2$ is replaced by $^{18}O_2$. The IR spectra taken in the case of equimolar mixtures of $^{16}O_2$ and $^{18}O_2$ in the matrix virtually are the superposition of the IR spectra taken for $^{16}O_2$ and $^{18}O_2$ alone. The only difference is a

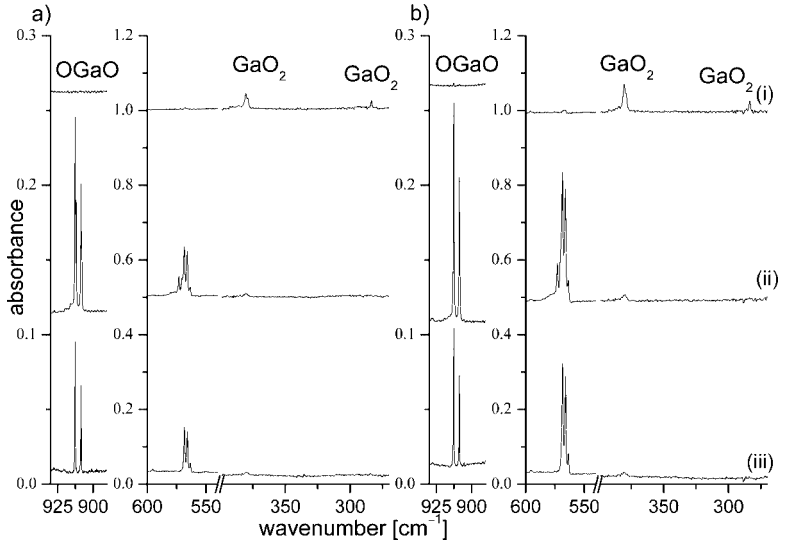

Figure 3. IR spectra taken for an Ar matrix containing Ga atoms (emitted from an oven kept at 1000 °C) and a) 0.3% and b) 1% $O_2$. (i) after deposition at 10 K, (ii) after UV photolysis ($\lambda_{max}$ = 254 nm), and (iii) after annealing to 30 K.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

slight but nevertheless significant (see Discussion) broadening of the bands, especially those around 1266 and 1824 $cm^{-1}$ and the corresponding bands observed for the $^{18}O$ counterpart. This broadening is significant and will be shown to be consistent with the formulation of **3a** as an end-on bonded OGaO(OO) complex. The spectra taken with 1:2:1 mixtures of $^{16}O_2/^{16}O^{18}O/^{18}O_2$ give evidence for extra bands with wavenumbers between those measured for $^{16}O_2$ and $^{18}O_2$. The wavenumbers of all bands are included in Table 1.

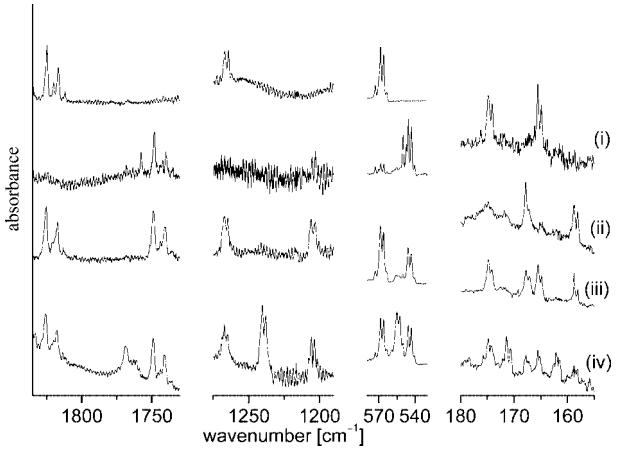

Figure 5. IR spectra taken after UV photolysis ($\lambda_{max}$ = 254 nm) of Ar matrices containing Ga atoms and (i) $^{16}O_2$, (ii) $^{18}O_2$, (iii) an equimolar mixture of $^{16}O_2$ and $^{18}O_2$, and (iv) a 1:2:1 mixture of $^{16}O_2/^{16}O^{18}O/^{18}O_2$.

Table 1. Wavenumbers observed for the reaction between Ga atoms and $O_2$ in Ar and pure solid $O_2$ matrices following photolysis at $\lambda_{max}$ = 254 nm.

[a] Observed in the Raman experiments.

**Raman.** The Raman spectrum of a matrix containing Ga and $^{16}O_2$ showed an intense signal at 716.2 $cm^{-1}$ (Figure 6, i). This signal is already present directly after deposition, and shows no significant alterations in intensity upon radiation with UV light. On the basis of experiments in which the concentration of $O_2$ and Ga in the matrix was varied, it is likely that species **3a** is the author of this signal. Since the experiments have shown that photolysis is necessary to generate **3a**, the only reasonable explanation for the appearance of the band directly upon deposition is that **3a** is generated by the laser light used to excite the Raman spectra. In Figure 6, the Raman spectra taken for $^{16}O_2$, $^{18}O_2$, 1:1 mixtures of $^{16}O_2$ and $^{18}O_2$, and 1:2:1 mixtures of $^{16}O_2$, $^{16}O^{18}O$, and $^{18}O_2$ are compared. Again, the spectrum measured for a 1:1 mixture of $^{16}O_2$ and $^{18}O_2$ is not significantly different to the superposition of the spectra taken for $^{16}O_2$ and $^{18}O_2$ alone, thus showing two signals at 716.2 and 676.0 $cm^{-1}$. An extra signal at 697.6 $cm^{-1}$ appeared in the spectra taken for a 1:2:1 mixture of $^{16}O_2$, $^{16}O^{18}O$, and $^{18}O_2$. The wavenumbers are included in Table 1. Experiments were also carried out with Ga isolated in a solid $O_2$ matrix. These experiments give evidence for a signal at 723.0 $cm^{-1}$, slightly blue shifted with respect to the signal detected in an Ar matrix.

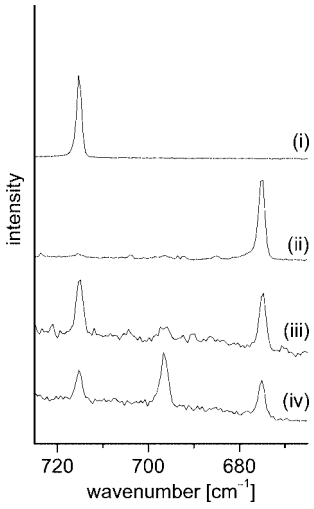

Figure 6. Raman spectra upon deposition for an Ar matrix containing Ga atoms and (i) $^{16}O_2$, (ii) $^{18}O_2$, (iii) an equimolar mixture of $^{16}O_2$ and $^{18}O_2$, and (iv) a 1:2:1 mixture of $^{16}O_2/^{16}O^{18}O/^{18}O_2$.

## In + $O_2$

**IR.** The IR spectra taken for an Ar matrix containing In atoms and $^{16}O_2$ are displayed in Figure 7. The spectrum taken immediately upon deposition contains sharp absorptions at 1084.2, 331.7 and 276.5 $cm^{-1}$ which were already previously assigned to cyclic $InO_2$, **1b**.[9,10] The effect of photolysis of the matrix with UV radiation ($\lambda_{max}$ = 254 nm) is the decrease of the bands due to **1b**. At the same time, two families of absorptions grow in. One family shows at 754.6 and 159.7 $cm^{-1}$ and belongs to linear OInO, **2b**.[10] The other family shows at 1498.8/1493.4, 1067.6/1063.8, 462.1/459.2, 151.3, and 146.5 $cm^{-1}$ and can be assigned to a new species **3b**. The conditions of its appearance indicate that **3b** is the In analogue to **3a**. In analogy to the experiments with Ga, the response of the bands due to **3b** to different concentrations of In and $O_2$ in the matrix are in agreement with the presence of one In atom and four O

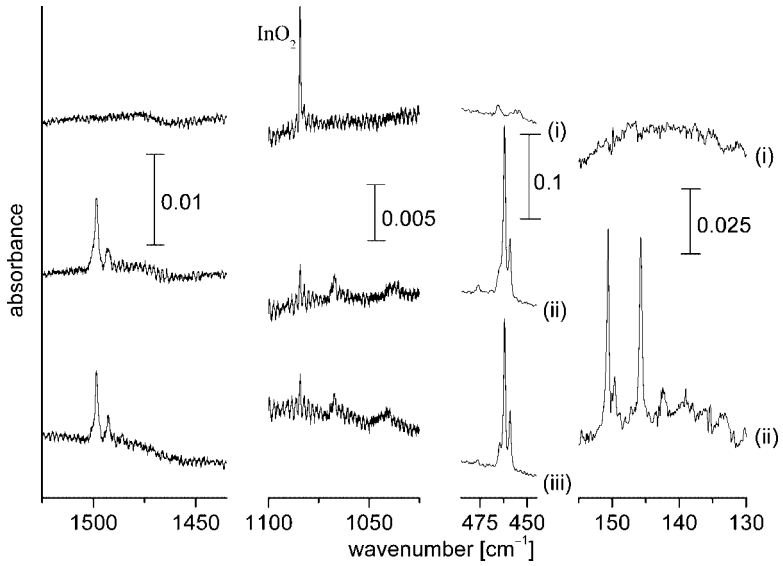

Figure 7. IR spectra of an Ar matrix containing Ga atoms and $^{16}O_2$. (i) upon deposition, (ii) upon UV photolysis ($\lambda_{max}$ = 254 nm), (iii) upon annealing to 30 K.

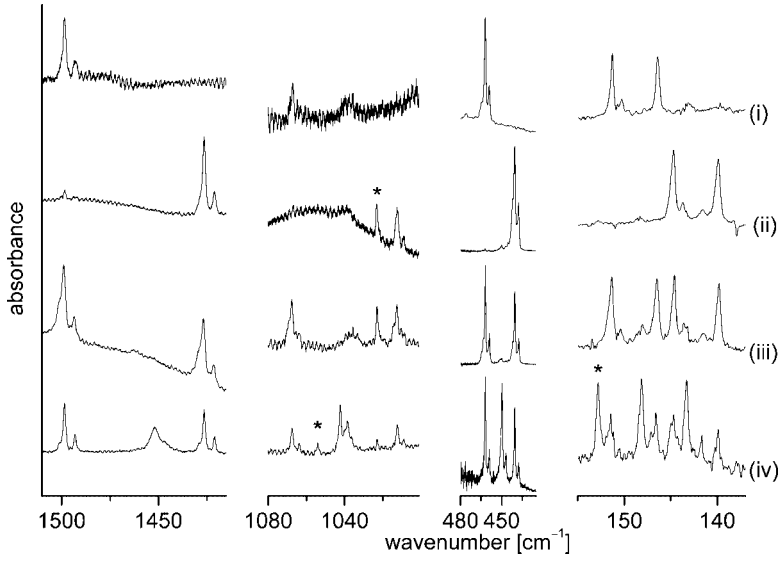

Figure 8. IR spectra taken after UV photolysis ($\lambda_{max}$ = 254 nm) of an Ar matrices containing Ga atoms and (i) $^{16}O_2$, (ii) $^{18}O_2$, (iii) an equimolar mixture of $^{16}O_2$ and $^{18}O_2$, and (iv) a 1:2:1 mixture of $^{16}O_2/^{16}O^{18}O/^{18}O_2$. Bands marked by an asteriks are due to $InO_2$.

atoms in the molecule. Figure 8 compares the spectra measured in experiments using different $O_2$ isotopomers ($^{16}O_2$, $^{18}O_2$, equimolar mixtures of $^{16}O_2$ and $^{18}O_2$, and 1:2:1 mixtures of $^{16}O_2/^{16}O^{18}O/^{18}O_2$). The band at 1498.8/1493.4 cm$^{-1}$ in the experiments with $^{16}O_2$ shifts to 1426.8/1421.5 cm$^{-1}$ with $^{18}O_2$. The band at 1067.6/1063.8 cm$^{-1}$ experienced a red-shift to 1012.6/1009.1 cm$^{-1}$ [$\nu(^{16}O):\nu(^{18}O)$ = 1.054]. The intense absorption at 462.1/459.2 cm$^{-1}$ shifts to 440.5/437.7 cm$^{-1}$ [$\nu(^{16}O):\nu(^{18}O)$ = 1.049]. The two bands which occur at 151.3 and 146.5 cm$^{-1}$ in the experiments with $^{16}O_2$ show at 144.6 and 139.8 cm$^{-1}$ with $^{18}O_2$. All bands are included in Table 2.

**Raman.** In difference to the reaction with Ga, the Raman spectra taken immediately upon deposition of In with $O_2$ shows the signals characteristic of cyclic $InO_2$, **1b** (see Figure 9). These signals decrease in intensity if the matrix is subjected to UV photolysis ($\lambda_{max}$ = 254 nm). At the same time a new intense signal appears at 621.0 cm$^{-1}$. Its response to photolysis and annealing and to variations in the concentrations of In and $O_2$ in the matrix indicates that this signal belongs to species **3b**. In experiments in which $^{16}O_2$ was replaced by $^{18}O_2$, the signal shifts to 586.6 cm$^{-1}$.

## Identification and Characterization

The identification of **3a** and **3b** can be made on the basis of (i) the $^{69}Ga/^{71}Ga$ isotopic shifts and the effects observed in experiments in which $^{16}O^{18}O$ and $^{18}O_2$ were used in place for $^{16}O_2$, (ii) the effects of varying the concentration of Ga or In and $O_2$ in the matrix and of annealing on the IR

[a] Observed in the Raman experiments.

and Raman intensities, (iv) the conditions of formation and consumption of the bands due to **3a** and **3b**, and (v) the IR and Raman intensities. It will be shown that **3a** and **3b** can be described as dioxygen complexes to OGaO and OInO, respectively. The discussion in this work will predominantly concentrate on the Ga reaction, because that of In atoms follows a similar pattern.

The experiments indicate that product **3a** contains one Ga atom and four O atoms. They also suggest that it is formed by reaction of linear OGaO and $O_2$. As already mentioned, the band at 1266.9/1264.2 $cm^{-1}$ can be assigned to the ν(O–O) mode of an $O_2$ unit, which is weakened by coordination. The wavenumber of the ν(O–O) mode can be compared e.g. with that observed for the end-on bonded complexes FeOO (1204.5 $cm^{-1}$)[13] or $O_2Co(O_2)$ (1286.2 $cm^{-1}$).[4] Of course, the electronic situation in these transition metal dioxygen complexes is different, but the coupling between the O–O coordinate and the other coordinates in the molecule is in all cases fairly weak. This gets also evident when the isotopic data are considered. The ν(O–O) mode of the coordinated $O_2$ unit of $^{18}O_2Co(^{16}O_2)$ occurs virtually at the same wavenumber as that of $^{16}O_2Co(^{16}O_2)$. Similarly, the O–O coordinate of the ligated $O_2$ unit in **3a** (and **3b**) is not significantly coupled to the other Ga–O coordinates. The only sign of weak coupling is a slight increase of the halfwidth of some of the bands in the experiments with $^{16}O_2/^{18}O_2$ mixtures with respect to those with $^{16}O_2$ or $^{18}O_2$ alone (see the bands around 1266 and 1824 $cm^{-1}$). In the case of the end-on bonded complex FeOO, the wavenumber measured for the ν(O–O) band is almost identical for the two versions $Fe^{16}O^{18}O$ and $Fe^{18}O^{16}O$ (1173.0 and 1170.4 $cm^{-1}$). The same is the case for $O_2Co(O_2)$ and also for **3a** and **3b**. The mode at 568.7/565.9/563.6 $cm^{-1}$ exhibits a smaller isotopic shift than the one at 1266.9/1264.2 $cm^{-1}$ when $^{16}O_2$ is replaced by $^{18}O_2$ (about –23 $cm^{-1}$). The obvious inference is that it belongs to a ν(Ga–O) mode, this time involving motion of the other O atoms in **3a**. The observed Ga isotopic splitting is in agreement with this assignment. From these considerations we conclude that **3a** is a complex between OGaO and $O_2$. The mode at 568.7/565.9/563.6 $cm^{-1}$ is then the antisymmetric Ga–O stretch, $\nu_{as}$(Ga–O), of the OGaO unit. This mode is IR-active, but virtually Raman silent. The corresponding symmetric Ga–O stretch, $\nu_s$(Ga–O), on the other hand, is visible at 716.2 $cm^{-1}$ in the Raman spectra, but more or less IR silent. Because the Ga atom is not involved in the motion, this signal exhibits no observable Ga isotopic splitting. The fact that no detectable band appears at 716.2 $cm^{-1}$ in the IR spectra indicates that the O–Ga–O bond angle of the OGaO unit is still close to 180° after coordination of $O_2$. The isotopic pattern observed for the antisymmetric stretch is in good agreement to this assumption. Thus the

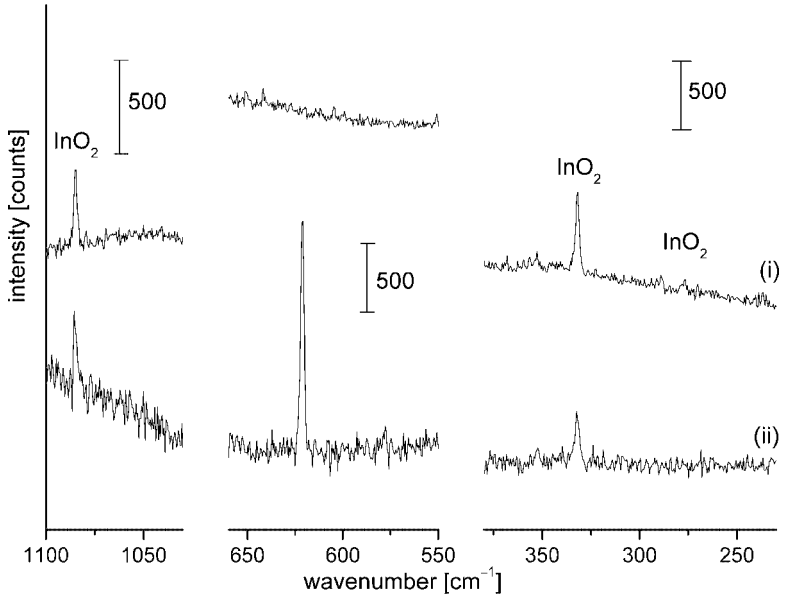

Figure 9. Raman spectra of an Ar matrix containing In atoms and $^{16}O_2$. (i) upon deposition. (ii) upon UV photolysis ($\lambda_{max}$ = 254 nm).

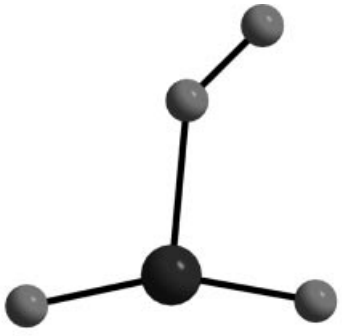
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mode occurs at 568.7 $cm^{-1}$ for the $O^{69}GaO$ unit and at 566.2 $cm^{-1}$ for the $O^{71}GaO$ unit. From this isotopic shift the O–Ga–O angle can be estimated to be 165°. Strong support for this assignment comes also from the wavenumbers as measured for the $\nu_{as}$(Ga–O) and $\nu_s$(Ga–O) modes of the $^{16}OGa^{18}O(O_2)$ version of **3a**. The band due to the $\nu_{as}$(Ga–O) mode is slightly red shifted with respect to the center of the bands measured for the $^{16}O_2$ and $^{18}O_2$ isotopomers. On the other hand, the band due to the $\nu_s$(Ga–O) mode is slightly blue shifted with respect to the corresponding center. This shift is a consequence of the coupling of the symmetric and antisymmetric stretch in the $^{16}OGa^{18}O(O_2)$ isotopomer. The bands at 1824.7, 1820.0, 1816.7, and 1811.7 $cm^{-1}$ can be assigned to the combination $\nu$(O–O) + $\nu_{as}$(Ga–O). The sum of the wavenumbers measured for the two modes is between 1835.6 and 1827.8 $cm^{-1}$. The bands at 174.8/174.1 and 165.6/164.9 $cm^{-1}$ most likely belong to deformation modes involving some degree of motion of the Ga atoms as evidenced by the isotopic pattern. Thus our experiments hit on five fundamentals and one combinational mode of $GaO_4$.

In a previous publication, the band at 568.7 $cm^{-1}$ has been assigned to the $[OGaO]^-$ anion.[9] However, on the basis of our new experiments it can be immediately concluded that this identification cannot be correct, since it is impossible to produce a charged species in our experimental setup. Of course, **3a** cannot be this species also because the number of fundamentals detected for **3a** in our experiments exeeds the number of fundamentals a threeatomic molecule exhibits. Nevertheless, we have performed quantum chemical calculations on this species. The linear $[OGaO]^-$ molecule exhibits a $^1\Sigma_g^+$ electronic state. Applying CASSCF/TZVPPext, the following vibrational modes were calculated (in $cm^{-1}$, with IR intensities in km $mol^{-1}$ given in parenthesis): 752.5 (0, $\sigma_g$), 224.0 (114, $\pi_u$), 909.4 (145, $\sigma_u$). Thus no mode should be visible in the region around 570 $cm^{-1}$. A cyclic form $[OGaO]^-$, exhibiting a $^1A_1$ electronic state, is 131 kJ·$mol^{-1}$ higher in energy (including vibrational zero-point energy corrections). It is characterized by Ga–O and O–O bond lengths of 189.9 and 160.9 pm, respectively, and an O–Ga–O bond angle of 50.1°. The vibrational properties (in $cm^{-1}$, with IR intensities in km $mol^{-1}$ given in parenthesis) were calculated to be: 743.8(33), 513.0(74), and 461.9(22). We also performed calculations on the cationic species $GaO_2^+$. If the $OGaO(O_2)$ complex can be regarded as a superoxo complex, the OGaO unit should carry a formal charge of +1. As anticipated and in difference to the situation with $GaO_2^-$, a bent structure ($^3A_2$) is more stable in the case of the cation. Cyclic $[GaO_2]^+$ is by ca. 73 kJ·$mol^{-1}$ (according to CASSCF/TZVPPext) more stable than linear $[OGaO]^+$. Its vibrational fundamentals are calculated to show at the following wavenumbers (in $cm^{-1}$, with IR intensities in km·$mol^{-1}$ given in parenthesis): 998.6(2), 573.4(47), and 420.2(0). Thus there is indeed a strong fundamental in the region around 570 $cm^{-1}$. The calculated isotopic shifts –22.4 $cm^{-1}$ for $Ga(^{18}O)_2$ and –10.5 $cm^{-1}$ for $Ga(^{16}O^{18}O)$ are also close to those observed in the experiments. According to the calculations, the Ga–O and O–O bond lengths are 190.4 and 141.3 pm and the O–Ga–O bond angle is 43.5°.

Because of the fact that the electronic situation in linear OGaO is already very complicated and extremely difficult to calculate,[10] it might not come as surprise that $GaO(O_2)$ turned out to be difficult to calculate. Nevertheless, using the BP86 method and an SVP basis set, we succeeded in finding an energy minimum which should be close to the correct structure.[14] According to these calculations, the coordination of the $O_2$ molcule to the OGaO unit results in a decrease of the O–Ga–O angle to a value of 157.8°. This value is not too far away from the 168° estimated from the experimental results. The coordinating $O_2$ molcule features an O–O distance of 125.6 pm and is thus significantly elongated with respect to the distance in free $O_2$ (121.6 pm as calculated using the same method and basis set). In line with this elongation the $\nu$(O–O) mode (a′ symmetry) is calculated to occur at 1304.7 $cm^{-1}$. This wavenumber compares with an experimental one of 1264.2/1261.8 $cm^{-1}$. Two vibrations at very low wavenumbers and with sufficient IR intensity are calculated to show at 189.9 (a′) and 151.0 (a″) $cm^{-1}$. In the experiments, two bands show at 174.8/174.1 and 165.6/164.9 $cm^{-1}$. As already experienced in the case of linear OGaO, calculations on the symmetric and antisymmetric $GaO_2$ stretches of the OGaO unit are not very reliable. While the calculated 662.7 $cm^{-1}$ for the symmetric $GaO_2$ stretch (a′) is in fair agreement with the observed 716.2 $cm^{-1}$, the calculated 732.3 $cm^{-1}$ for the antisymmetric stretch (also a′) is not in good agreement with the observed 568.7 $cm^{-1}$. Other calculated wavenumbers are 705.5 (a″), 258.7 (a′), 108.6 (a′), and 81.7 (a′); however, all these bands are predicted to have only very small IR intensities. In summary the calculations, although there are inconsistencies, are in line with the description of $GaO_4$ as an end-on bonded $O_2$ complex to OGaO. Using the observed wavenumbers the valence force constant *f*(Ga–O) of the OGaO unit in $GaO_4$ can be estimated to be 350 N·$m^{-1}$. Thus the force constant is significantly smaller than that of OGaO prior to $O_2$ complexation (586 N·$m^{-1}$). This decrease is not surprising since the donation of electron density from the OGaO unit into the ligated $O_2$ leads to a partial depopulation of one of the bonding $\pi_g$ orbitals.



Model of the $GaO_4$ molecule, **3a**

Thus the geometry of $GaO_4$ is very different to that reported for the $AlO_4$ molcule.[5] $AlO_4$ in its energy minimum

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

form exhibits $D_{2d}$ symmetry and is characterized by O–O and Al–O distances of 148 and 175 pm, respectively. The distances of the $O_2$ groups are both equal and the unpaired electron is located in parts on both groups. This means that the $O_2$ groups can be described as being in between superoxo- and peroxo groups. In the case of $GaO_4$, the $D_{2d}$ symmetric structure defines not an energy minimum on the potential energy hypersurface. For the doublet electronic state we calculated O–O and Ga–O bond lengths of 148 and 184 pm, respectively. According to B3LYP/TZVPP calculations, its energy is 89 kJ·mol$^{-1}$ higher than that of separated OGaO and $O_2$.

There are all indications that $InO_4$, **3b**, has a structure similar to that of $GaO_4$. The ν(O–O) mode of the ligated $O_2$ unit shows now at 1067.6/1063.8 cm$^{-1}$. This wavenumber is close to that adopted e.g. in the end-on bonded superoxo complex CuOO (1089.6 cm$^{-1}$).[15] In line with this assignment, the ν($^{16}$O)/ν($^{18}$O) ratio is relatively large (1.054). The $\nu_{as}$(In–O) mode and the $\nu_s$(In–O) mode of the OInO unit in $InO_4$ show at 462.1/459.2 and 621.0 cm$^{-1}$.[16] The fact that one is IR active and the other Raman active indicates that the O–In–O angle is, in similarity with the Ga homologue, close to 180°. DFT (BP86) calculations yielded a structure for this complex with In–O and O–O bond lengths of 192.3 and 127.7 pm, respectively, and O–In–O and In–O–O bond angles of 147.8° and 137.8°, respectively. The ν(O–O) mode of the ligated $O_2$ unit was calculated to show at 1220.8 cm$^{-1}$. Thus, the calculations predict the wavenumber to be lower than the corresponding one of the Ga homologue. This trend is in agreement with the experimental results (1264.2/1261.8 cm$^{-1}$ for $GaO_4$ and 1067.6/1063.8 cm$^{-1}$ for $InO_4$), although the deviation between experiment and calculation is quite high. The $\nu_{as}$(In–O) mode of the OInO unit is calculated to show at 578.0 cm$^{-1}$. This value compares with an observed one of 462.1/459.2 cm$^{-1}$. Like in the case of $GaO_4$, the calculations predict a too low wavenumber for the $\nu_s$(In–O) mode of the O–In–O unit (calculated: 551.9 cm$^{-1}$, measured: 621.0 cm$^{-1}$). Two modes calculated at 204.9 cm$^{-1}$ (a″) and 175.3 cm$^{-1}$ (a′) can be assigned to observed ones at 151.3 and 146.5 cm$^{-1}$. Other weak modes, which were not detected in our experiments, were calculated to show at 303.5 (a′), 113.9 (a″), 91.9 (a′), and 77.5 (a′) cm$^{-1}$.

## Conclusions

The reactions of Ga and In atoms in Ar matrices with $O_2$ lead spontaneously to the cyclic $GaO_2$ and $InO_2$ molcules, respectively. These species can be photoconverted into linear OGaO and OInO. Reaction of linear OGaO and OInO with a second $O_2$ molcule leads to the new end-on bonded superoxo complexes $OGaO(O_2)$ [see Equation (3)] and $OInO(O_2)$. These molecules represent the first ever experimentally verified end-on bonded superoxo complexes of Ga and In. Our experimental findings show that the group 13 elements Ga and In are capable to bind up to four O atoms. The experimental results indicate that the O–Ga–O angle in this complex is ca. 165°. Quantum chemical calculations provide further details of the structure of the new molecules, which differs remarkably from that of the $D_{2d}$ symmetric $Al(O_2)_2$ complex. The characterization of these oxidation processes is of relevance to the mechanism of metal oxidation in general and thus contributes to a more detailed understanding of this very important but complex class of reactions.

## Experimental Section and Calculational Details

In a vacuum apparatus, thermally evaporated gallium or gallium metal was deposited together with dioxygen in an excess of Ar onto a freshly polished Cu block kept at 12 K with the aid of a closed-cycle refrigerator (Leybold LB115). The experiment was repeated with different dioxygen isotopomers. $^{16}O_2$ was used as delivered from Messer (purity 99.9998%). $^{18}O_2$ was purchased from Linde (isotopic purity 99.0%). For experiments with a 1:2:1 mixture of $^{16}O_2$/$^{16}O^{18}O$/$^{18}O_2$, an equimolar mixture of $^{16}O_2$ and $^{18}O_2$ in a glass bulb was subjected for several hours to an electric discharge. The resulting $O_3$ molcules were trapped in a cold finger at 77 K. Subsequently the cold finger was warmed up again to room temperature and decomposition of the $O_3$ molcules results in the statistical 1:2:1 mixture of $^{16}O_2$/$^{1}O^{18}O$/$^{18}O_2$. Experiments in solid $O_2$ matrices were also carried out. Further details of the matrix isolation technique can be found elsewhere.[17]

IR spectra were recorded on a Bruker 113v FT-IR spectrometer equipped with a DTGS and an MCT detector for measurements in the spectral regions 4000–200 cm$^{-1}$, respectively, and a bolometer for measurements between 700 and 30 cm$^{-1}$.

Raman spectra were measured on a XY800 spectrometer from Jobin Yvon Horiba, equipped with a CCD camera (Wright Instruments). The spectra were excited with an $Ar^+$ ion laser. Both the 488.0 nm and 514.5 nm lines were used.

Quantum chemical (DFT) calculations using the B3LYP[18] and the BP86[19] functionals were performed with the aid of the TURBOMOLE[20] programme and using either an SVP[21] or a TZVPPext[22] basis set. The Dalton programme code[23] was used for CASSCF calculations. All valence orbitals were included into the active space.

# N–H···S Hydrogen Bonds in a New Family of Ion-Pair Complexes Between Cationic Nickel Tetraazabicyclononane and Anionic Metal Dithiolates: Synthesis, Characterization and Properties of $[Ni(C_9H_{22}N_6)][M(mnt)_2]$ ($M^{II}$ = Cu, Ni, Pd)

**Vedichi Madhu[a] and Samar K. Das*[a]**

**Keywords:** Hydrogen bonds / Ion pairs / N ligands / Nickel / S ligands

The ion-pair complexes $[Ni(C_9H_{22}N_6)][Cu(mnt)_2]$ (**1**), $[Ni(C_9H_{22}N_6)][Ni(mnt)_2]$ (**2**), and $[Ni(C_9H_{22}N_6)][Pd(mnt)_2]$ (**3**; $mnt^{2-}$ = 1,2-dicyanoethylenedithiolate, $C_9H_{22}N_6$ = 3,7-bis(2-aminoethyl)-1,3,5,7-tetraazabicyclo[3.3.1]nonane) have been synthesized and characterized by elemental analysis, IR, UV/Vis, and $^1H$ NMR spectroscopy, X-ray powder diffraction, and electrochemical studies, and unambiguously by single-crystal X-ray crystallography. All three complexes are isostructural and crystallize in the monoclinic space group $P2_1/n$. The N–H···S-type hydrogen-bonding capabilities of the classical sulfur-containing complex anions $[M^{II}(mnt)_2]^{2-}$ (A; M = Cu, Ni and Pd) have been explored using amine groups containing the nickel complex cation $[Ni(C_9H_{22}N_6)]^{2+}$ (C) in the ion-pair compounds **1**, **2**, and **3**. In the crystal, the cation interacts with two different anions through three N–H···S hydrogen bonds and, likewise, the anion is hydrogen-bonded to two different cations through three hydrogen bonds, resulting in the formation of a chain-like arrangement. The average N–H···S hydrogen-bond lengths are 3.498(3), 3.505(3), and 3.490(5) Å for compounds **1**, **2**, and **3**, respectively. Another crystallographic feature is the presence of CC–AA–CC–AA-type packing with short S···Ni contacts in the crystal structures. Besides crystallography, the existence of these N–H···S hydrogen bonds between cation $[Ni(C_9H_{22}N_6)]^{2+}$ (C) and anion $[M^{II}(mnt)_2]^{2-}$ (A) is strongly supported by the IR and $^1H$ NMR studies. The stability of the $[Ni(C_9H_{22}N_6)]^{2+}$ (C) moiety in compounds **1**, **2**, and **3** is discussed in light of electrochemical studies performed on these compounds and $[Ni(C_9H_{22}N_6)](ClO_4)_2$. Complex **1** exhibits a well-resolved ESR signal corresponding to a $Cu^{2+}$ ($d^9$) system at liquid-nitrogen temperature.

## Introduction

The assembly of cationic and anionic components into ion-pair-containing supramolecular systems in which the positive and negative partners interact through noncovalent hydrogen bonding and/or π–π interactions is a challenging task in modern chemistry.[1] Bis(1,2-dithiolene)–transition metal complexes have been extensively studied as one of the ion-pair components because of their importance as functional materials, for example as near-infrared (NIR) laser dyes,[2] conducting[3] and magnetic materials,[4] and in nonlinear optics.[5] The molecular-conductor-type ion-pair charge-transfer (IPCT) complexes $[A^{2+}\{ML_2\}^{2-}]$ [$A^{2+}$ = bipyridinium dication derivative, $[ML]^{2-}$ = metal bis(dithiolate), $M^{2+}$ = Ni, Pd, Pt, and Cu] exhibit an IPCT transition in the solid state due to a supramolecular electronic interaction between the cation and anion.[6] A class of ion-pair complexes has been obtained with a combination of uncharged organic components and, in this case, the ion pairing is achieved by a radical mechanism.[7] Although charge-transfer (CT) complexes of metal dithiolenes with organic cations as acceptors have been investigated quite well, including their structural characterization, ion-pair complexes of metal dithiolenes with transition metal inorganic complexes as cations are rare.[8] We have been working on ion-pair supramolecular systems in order to explore the noncovalent, hydrogen-bonding interactions between cationic and anionic components by choosing appropriate H-bond donor and acceptor sites. We have recently reported the NIR absorption due to a supramolecular electronic interaction between an anion and cation in a three-dimensional hydrogen-bonded networking material, namely [4,4′-$H_2$bpy][$Cu(mnt)_2$], emphasizing the N–H···N-type hydrogen bonding between cation and anion.[9] Now we extend this study to an inorganic transition metal complex, $NiL^{2+}$ {L = $C_9H_{22}N_6$ = 3,7-bis(2-aminoethyl)-1,3,5,7-tetraazabiclo[3.3.1]nonane} as a cation and $[M^{II}(mnt)_2]^{2-}$ (M = Cu, Ni and Pd; $mnt^{2-}$ = 1,2-dicyanoethylenedithiolate) as anions in ion-pair complexes (Scheme 1).

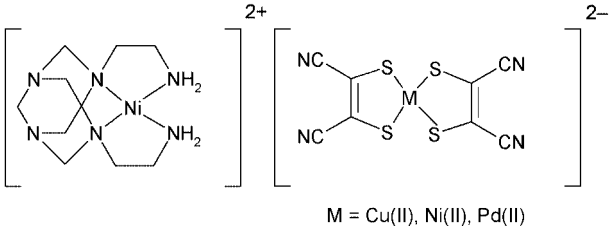

Scheme 1.

In this group of ion-pair complexes the nickel complex cation has coordinated $NH_2$ groups. The aim of this work was to examine whether these amine hydrogens form N–H···S-type hydrogen bonds with the thiolate sulfur of the mnt ligands of the anions. Living systems contain several important sulfur-containing molecules, such as cysteine and methionine, and hydrogen bonding between amide groups and the cysteine sulfur is a common feature of all iron-sulfur proteins.[10] For example, the formation of N–H···S hydrogen bonds plays a crucial role in the function of many proteins, including *Pasteurella aerogenes* ferredoxin and *Clostridium pasteurianum* rubredoxin.[11] Much of the importance of the N–H···S hydrogen-bonding interaction derives from the fact that it may modulate the redox potentials of several of these proteins.[10,12] Therefore, the study of N–H···S hydrogen bonds using simple inorganic compounds may have fundamental importance in understanding the chemical functions of those metal-associated proteins in which the negative metal–sulfur cluster is hydrogen-bonded to the surrounding amide groups of peptides/proteins. Various metal thiolate complexes have been synthesized and structurally characterized as model compounds of these natural proteins.[13] In many of these model studies, intramolecular N–H···S hydrogen-bonding interactions are observed because the ligand coordinated to the metal center has amide-type functional groups. Intermolecular amide–thiolate hydrogen-bonding interactions have been described[14] for the complex $[(CH_3)_3NCH_2CONH_2]_2[Co(SC_6H_5)_4]$ and the metal-free compound $[(CH_3)_3NCH_2CONH_2][SC_6H_5]$. Herein we describe the synthesis, crystal structures, and properties of a new family of ion-pair complexes, namely $[Ni(C_9H_{22}N_6)][Cu(mnt)_2]$ (**1**), $[Ni(C_9H_{22}N_6)][Ni(mnt)_2]$ (**2**), and $[Ni(C_9H_{22}N_6)][Pd(mnt)_2]$ (**3**), all of which contain N–H···S hydrogen bonds between the cation and anion in their ion pairs. Our results show a systematic decrease in $M–S_H$ bond lengths with respect to the $M–S_N$ bond length ($M = Cu^{2+}$, $Ni^{2+}$ and $Pd^{2+}$; $S_H$ is the sulfur atom involved in hydrogen bonding and $S_N$ that which is not involved in hydrogen bonding). We explain this trend in terms of N–H···S hydrogen-bonding interactions. We also describe detailed IR and $^1H$ NMR studies that support the existence of N–H···S hydrogen bonds between the cation (C) and anion (A).

## Results and Discussion

### Synthesis

The reaction of $[Ni^{II}(C_9H_{22}N_6)](ClO_4)_2$ with $[Bu_4N]_2[M^{II}(mnt)_2]$ (M = Cu, Ni, and Pd) in MeCN solution leads to the isolation of the ion-pair complexes $[Ni(C_9H_{22}N_6)][M(mnt)_2]$. The relevant reactions can be described according to Equation (1).

$$[Ni^{II}(C_9H_{22}N_6)](ClO_4)_2 + [Bu_4N]_2[M^{II}(mnt)_2] \rightarrow [Ni^{II}(C_9H_{22}N_6)][M^{II}(mnt)_2] + 2\,Bu_4NClO_4 \quad (1)$$

Crystals of compounds **1** (M = Cu), **2** (M = Ni), and **3** (M = Pd) gave satisfactory elemental analyses. The numbers of Cu and Ni sites in compound **1** and of Pd and Ni sites in compound **3**, as revealed by single-crystal X-ray structure analyses, are consistent with the results of EDAX analyses, which gave an average Ni/Cu value of around 1:1 for compound **1** and a Ni/Pd value of about 1:1 for compound **3**. All three compounds were obtained in high yield. However, these high-yield procedures produced microcrystalline products instead of the single crystals required for crystal-structure determination. Single crystals were obtained by a slow-diffusion technique, as described in the Experimental Section.

### X-ray Powder-Diffraction Studies

X-ray powder-diffraction patterns of microcrystalline compounds **1**–**3** were recorded. The simulated patterns were generated from the single-crystal X-ray data of the appropriate compounds obtained by the slow-diffusion technique. The simulated patterns match the respective experimentally observed powder-diffraction patterns very well, as shown in SI-Figure 38 (see Supporting Information). This confirms the homogeneity and the purity of the bulk samples **1**–**3**.

### Description of the Structures

Complexes **1**–**3** crystallize in the monoclinic space group $P2_1/n$. A thermal ellipsoidal plot of the non-hydrogen atoms is presented in Figure 1. This shows the presence of $[Ni(C_9H_{22}N_6)]^{2+}$ as a cation and $[M(mnt)_2]^{2-}$ as an anion. The four nitrogen donor atoms in the $[Ni(C_9H_{22}N_6)]^{2+}$ cation form a plane with a maximum deviation of 0.0022 Å. The nickel ion is displaced by 0.040(1) Å from the least-squares plane. The average Ni–N bond length is $1.913 \pm 0.002$ Å, which is about 0.01 Å longer than those in the crystal structure of the previously reported[15] compound $[Ni(C_9H_{22}N_6)](ClO_4)_2$, which contains the same cation. However, the quality of the crystal of this complex was too poor to be refined aniosotropically (disorder problem of the whole cation in addition to disordered perchlorate anions).[15] This is reflected in some of the C–N bond lengths, which are either unreasonably short or unreasonably long. In the present study, we were able to overcome this disorder problem of the $[Ni(C_9H_{22}N_6)]^{2+}$ cations in complexes **1**–**3**. There are 14 N–C single bonds in the ligand $C_9H_{22}N_6$ (Figure 1). Depending on the environments of the nitrogen atoms in the $[Ni(C_9H_{22}N_6)]^{2+}$ cation, the N–C bond lengths show systematic variations ranging from 1.433 to 1.522 Å for compound **1**. There are four tertiary nitrogen atoms, namely N(7), N(8), N(9), and N(10). The six bonds

from N(7) and N(8) to their immediate carbon atoms are the longest, with an average distance of 1.507 ± 0.003 Å. This is considerably longer than the average N–C bond lengths (1.445 ± 0.004 Å) observed for the other six bonds from N(9) and N(10) to their immediate carbon atoms. The lengthening of these N–C bonds is consistent with the fact that N(7) and N(8) are coordinated to the nickel ion and N(9) and N(10) are not.

The N(5)–Ni(1)–N(7) bite angle in one of the five-membered chelate rings [Ni(1)–N(5)–C(17)–C(16)–N(7)] in the cation of **1** is 87.45(10)° and the N(6)–Ni(1)–N(8) bite angle of the other five-membered ring [Ni(1)–N(8)–C(10)–C(9)–N(6)] is 87.35(10)°. The respective bite distances are 2.647 and 2.642 Å (Figure 1). These values are consistent with those in the five-membered rings of other $Ni^{II}$ macrocyclic complexes,[16–19] including the tetraazabicyclononane–$Ni^{II}$ complex $[Ni(C_{12}H_{27}N_7)](ClO_4)_2$.[15] The N(5)–Ni(1)–N(6) angle, which is not constrained by any ring closure (Figure 1), is 94.99(11)° and the length between the N(5) and N(6) atoms is 2.817 Å. Interestingly, the N(7)–Ni(1)–N(8) bite angle of 90.11(10)° and the N(7)–N(8) bite distance of 2.713 Å involving two six-membered rings in bicyclononane are considerably smaller than those for the open side of the cation. This N(7)–N(8) separation, in principle, should be determined by the intracyclic valence angles at the C(11), C(15), C(13), C(14), N(9), and N(10) centers of the bicyclononane ring (Figure 1). These angles, which range from 111.7° to 114.6°, are already larger than the normal values of 107° for N($sp^3$) and 109.5° for C($sp^3$). Therefore, there is no chance for a lengthening of the bite distance between atoms N(7) and N(8).

There are four six-membered and two five-membered rings in the cation. The two six-membered rings [C(12)–N(9)–C(14)–N(7)–C(13)–N(10) and C(12)–N(9)–C(11)–N(8)–C(15)–N(10)] in the bicyclononane ring assume a stable chair conformation with average intracyclic torsion angles of 58° and 57.44° in the cation of compound **1** (see Figure 1). The two six-membered chelate rings formed between the bicyclononane ring and the nickel ion also assume a chair conformation. These rings are Ni(1)–N(7)–C(14)–N(9)–C(11)–N(8) and N(10)–C(13)–N(7)–Ni(1)–N(8)–C(15) in the cation of compounds **1**–**3**, as shown in Figure 2.

The anion $[Cu(mnt)_2]^{2-}$ has a planar structure, in good agreement with other relevant literature data.[20] The anion (A) and the cation (C) are arranged face to face, forming a mixed-stacked CC–AA-CC–AA-type arrangement along the crystallographic *a* axis (Figure 3). The angle between the planes of the cation and anion, defined by Ni(1)–N(5)–N(7)–N(8)–N(6) and Cu(1)–S(1)–S(3)–S(2)–S(4), is 38.28(6)° (Figure 1) for compound **1**, which comes under the category of noncoplanar structures among ion-pair compounds. The closest intra-stack distance of 3.947 Å is found between Ni(1) and S(1) in the case of compound **1** (Figure 3).

The single-crystal X-ray diffraction analyses revealed that compounds **2** and **3** are isostructural with **1** and therefore the unit-cell dimensions, volumes, and other related data for the structure determinations of all three compounds vary only slightly (see table in Experimental Section). Selected bond lengths and angles for compounds **1**–**3** are presented in Table 1.

Table 1. Selected bond lengths [Å] and angles [°] for compounds **1**–**3** (see Figure 1).[a]

[a] Atoms marked with an asterisk * are involved in N–H···S hydrogen-bonding interactions.

### N–H···S Hydrogen Bonds Between the Cation and Anion

The inorganic transition metal complex $NiL^{2+}$ (L = $C_9H_{22}N_6$ = 3,7-bis(2-aminoethyl)-1,3,5,7-tetraazabiclo-[3.3.1]nonane) was chosen as a cation since the nickel-coordinated $NH_2$ groups can provide potential points of organization for the formation of N–H···S hydrogen bonds with the thiolate sulfur atoms of the anions $[M(mnt)_2]^{2-}$ (M = $Cu^{2+}$, $Ni^{2+}$, $Pd^{2+}$). Even though the electronegativity difference between H and S ($\delta$ = 0.38, Pauling scale) is very small compared to those between H and X (X = Cl, N, O), and therefore the hydrogen bonds involving H and S will necessarily be weak due to the poorer match between the hard proton and soft sulfur, N–H···S hydrogen bonds have been observed in crystals of sulfur-containing organic molecules,[21] inorganic coordination complexes,[13,22] and metalloproteins.[10–12] In many cases, N–H···S hydrogen bonds play important roles, for example, the arrangement of proteins having amide and amine functional groups

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

around Fe–S clusters in *Pasteurella aerogenes* ferredoxin and *Clostridium pasteurianum* rubredoxin has been suggested to contribute to the stabilization of the negatively charged cluster by providing possible hydrogen-bond donors in forming N–H···S hydrogen bonds.[11]

The N–H···S bonds involving the amine nitrogen atoms of the cation $[Ni(C_9H_{22}N_6)]^{2+}$ and the dithiolate sulfur atoms of $[M(mnt)_2]^{2-}$ (M = $Cu^{2+}$, $Ni^{2+}$, $Pd^{2+}$) are illustrated in Figure 4; the geometrical parameters of these hydrogen bonds are presented in Table 2. As shown in Figure 4, the cation interacts with two different anions through three N–H···S hydrogen bonds (two H-bonds with one anion and one H-bond with another anion). Similarly, the anion is hydrogen bonded to two different cations through three hydrogen bonds. This results in the formation of a chain-like arrangement consisting of alternating cations and anions, as shown in Figure 5. The N···S and H···S distances are 3.485–3.512 and 2.65–2.73 Å, respectively, for compound **1**. The same distances in **2** are 3.468–3.527 and 2.63–2.76 Å and in **3** are 3.471–3.500 and 2.64–2.74 Å (see Table 2). The N–H···S bond angles in these compounds range from 142.3° to 159.6° and show a direct correlation whereby a decreasing bond angle results in a lengthening, and therefore weakening, of the hydrogen bond (Table 2). These N–H···S hydrogen-bond parameters are similar to those observed in the crystal structure of *Clostridium pasteurianum* rubredoxin protein.[11]

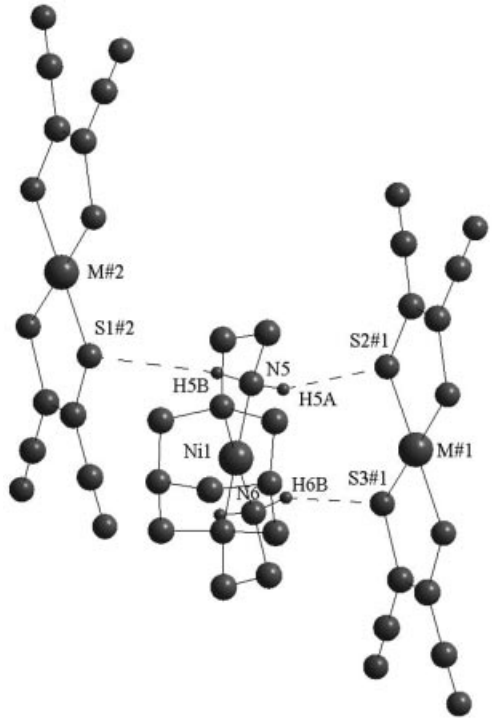

Figure 4. Crystal structure of compounds $[Ni(C_9H_{22}N_6)][M(mnt)_2]$ (M = $Cu^{2+}$, $Ni^{2+}$, and $Pd^{2+}$) showing intermolecular N–H···S hydrogen bonding between the cation and anion. Dotted lines indicate the N–H···S hydrogen bonds. Methylene hydrogen atoms have been omitted for clarity. Atoms with additional labels #1 and #2 are related to each other by the following symmetry operations: #1 1 – *x*, –*y*, 1 – *z*; #2 –*x*, –*y*, 1 – *z*.

Table 2. Hydrogen bonds for compounds **1**–**3** (see Figure 4).[a]

| D–H···A | *d*(D···H) | *d*(H···A) | *d*(D···A) | <(DHA) |
|---|---|---|---|---|
| Compound **1** | | | | |
| N5–H5A···S2 #1 | 0.90 | 2.65 | 3.499(3) | 158.3 |
| N5–H5B···S1 #2 | 0.90 | 2.73 | 3.485(3) | 142.3 |
| N6–H6B···S3 #1 | 0.90 | 2.68 | 3.512(3) | 155.0 |
| Compound **2** | | | | |

| N5–H5B···S1 #2 | 0.90 | 2.76 | 3.527(3) | 144.1 |
| N6–H6B···S3 #1 | 0.90 | 2.63 | 3.468(3) | 156.0 |
| Compound **3** | | | | |
| N5–H5A···S2 #1 | 0.90 | 2.65 | 3.499(5) | 157.5 |
| N5–H5B···S1#2 | 0.90 | 2.74 | 3.500(5) | 142.8 |
| N6–H6B···S3 #1 | 0.90 | 2.64 | 3.471(5) | 154.3 |

[a] Atoms with additional labels #1 and #2 are related to each other by symmetry operations: #1 1 –*x*, –*y*, 1 – *z*; #2 –*x*, –*y*, 1 – *z*.

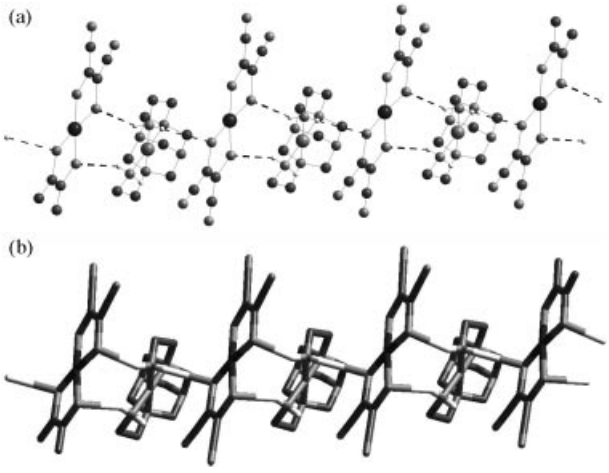

Figure 5. Chain-like arrangement consisting of alternating $[Ni(C_9H_{22}N_6)]^{2+}$ (cation) and $[M(mnt)_2]^{2-}$ (anion) formed by N–H···S hydrogen bonds in the crystal structure of $[Ni(C_9H_{22}N_6)][M(mnt)_2]$ (M = $Cu^{2+}$, $Ni^{2+}$, and $Pd^{2+}$): (a) ball-and-stick representation and (b) wire-frame representation. Methylene hydrogen atoms have been omitted for clarity.

The average Cu–$S_H$ bond length in **1** involving hydrogen-bonded sulfur ($S_H$) is 2.265(1) Å, which is 0.014 Å shorter than the Cu–$S_N$ bond length [2.279(1) Å], in which $S_N$ is not involved in hydrogen-bonding interactions. In the case of compound **2**, the average Ni–$S_H$ bond length [2.170(1) Å] is 0.012 Å shorter than the Ni–$S_N$ bond length [2.182(1) Å]. Compound **3** also follows the same trend but with a smaller difference [average Pd–$S_H$ = 2.287(1) and Pd–$S_N$ = 2.295(1) Å]. The shortening of the M–$S_H$ (M = $Cu^{2+}$, $Ni^{2+}$, $Pd^{2+}$) bonds compared to the M–$S_N$ bond can be explained by a molecular orbitals approach. Thiolate sulfurs are σ- and π-electron donors and the π orbitals that are occupied by a lone pair of electrons interact with the occupied p and d orbitals on the metal ion $M^{2+}$. The occupation of these metal orbitals, which have antibonding character, results in the weakening of the M–S interaction.[23] However, in the present case, it can be expected that the N–H···S hydrogen bonding stabilizes the sulfur π-donor orbitals and thereby diminishes the M–S antibonding interaction. This results in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a slight shortening of the M–$S_H$ (M = $Cu^{2+}$, $Ni^{2+}$, $Pd^{2+}$) bonds compared to the M–$S_N$ bonds.

In concert with the metal–sulfur bond length changes in the anion $[M(mnt)_2]^{2-}$, it is expected that the N–H bonds would be lengthened by the N–H···S hydrogen-bonding interaction, while the C–$N_H$ and Ni–$N_H$ bonds ($N_H$ = hydrogen-bonded nitrogen) in the cation $[Ni(C_9H_{22}N_6)]^{2+}$ would be shortened.[24,25] In the present study, the N–H bond lengths cannot be considered because the amine hydrogens were assigned positions on the basis of geometrical considerations in the crystal-structure determination. On the other hand, and in contrast to our expectations, a trend of increasing C–$N_H$ and Ni–$N_H$ bond lengths in the $[Ni(C_9H_{22}N_6)]^{2+}$ cations of **1**, **2**, and **3** is evident when comparing them with those in the crystal structure of $[Ni(C_9H_{22}N_6)](ClO_4)_2$. The average C–N and Ni–N bond lengths (adjacent to amine groups) in $[Ni(C_9H_{22}N_6)](ClO_4)_2$ are 1.37(5) and 1.90(3) Å, respectively.[15] The corresponding average C–$N_H$ and Ni–$N_H$ distances in the cations of **1**–**3** are 1.476(4) and 1.910(2) Å for **1**, 1.479(2) and 1.903(2) Å for **2**, and 1.474(6) and 1.905(2) Å for **3**. The shortening of the Ni–$N_H$ bond lengths compared to the Ni–$N_N$ ($N_N$ = non-hydrogen-bonded nitrogen) bond lengths in the cations of **1**–**3** [average Ni–$N_N$ bond lengths are 1.917(2), 1.914(2), and 1.909(4) Å for **1**–**3**, respectively] is consistent with the fact that the $N_H$ atoms are involved in N–H···S hydrogen-bonding interactions.

## IR Spectra

The N–H···S hydrogen-bonding interactions described above are also reflected in the IR spectra of compounds **1**–**3**. The perchlorate salt of the cation, $[Ni(C_9H_{22}N_6)](ClO_4)_2$ exhibits two NH bands at 3342 and 3296 $cm^{-1}$ in its IR spectrum (Figure 6, a). In the IR spectra of compounds **1**–**3** these bands shift to about 3260 and 3200 $cm^{-1}$, respectively (Figure 6, b–d). This large shift of the NH bands suggests that compounds **1**–**3** have intermolecular N–H···S hydrogen bonds involving cation and anion. The CN bands of the anions $[M(mnt)_2]^{2-}$ (M = $Cu^{2+}$, $Ni^{2+}$, $Pd^{2+}$) in compounds **1**–**3** appear at around 2195 $cm^{-1}$ and the corresponding C=C bands are observed at 1465, 1485, and 1485 $cm^{-1}$, respectively, for **1**–**3** (for IR spectra, see Supporting Information).

## $^1$H NMR Spectra

The $^1$H NMR spectra of $[Ni(C_9H_{22}N_6)](ClO_4)_2$ and compound **2** were recorded in [$D_6$]DMSO (see SI-Figure 6 in the Supporting Information). The protons of the two $NH_2$ groups are observed at $\delta$ = 5.75 and 6.97 ppm, respectively, in the spectrum of $[Ni(C_9H_{22}N_6)](ClO_4)_2$. These two peaks are shifted downfield, appearing at $\delta$ = 7.18 and 8.42 ppm, respectively, in the spectrum of **2**, which also shows the $CH_2$ protons in the range $\delta$ = 2 to 6 ppm. The downfield shift of the $NH_2$ protons from $[Ni(C_9H_{22}N_6)](ClO_4)_2$ to **2** can be ascribed to the existence of the N–H···S hydrogen-bonding

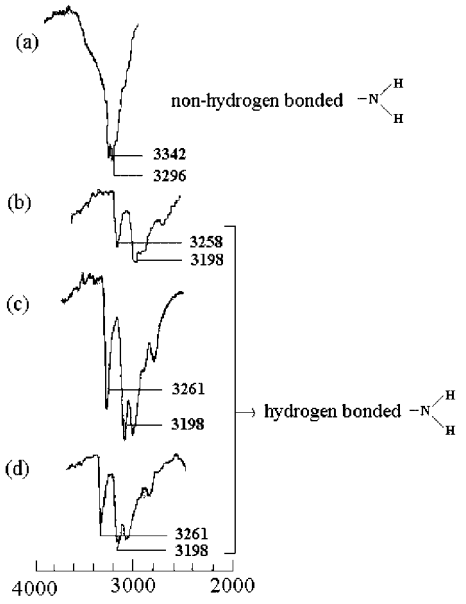

Figure 6. Selected IR bands in the $NH_2$ region of (a) $[Ni(C_9H_{22}N_6)](ClO_4)_2$, (b) $[Ni(C_9H_{22}N_6)][Cu(mnt)_2]$ (**1**), (c) $[Ni(C_9H_{22}N_6)][Ni(mnt)_2]$ (**2**), and (d) $[Ni(C_9H_{22}N_6)][Pd(mnt)_2]$ (**3**) in the solid state (KBr pellets).

interactions between cation and anion (hydrogen bonding decreases the electron density around proton). A similar downfield shift of the amide NH signal was observed in the $^1$H NMR spectrum of the compound $(NEt_4)_2[Hg(S\text{-}2\text{-}CH_3NHCOC_6H_4)_4]$ compared with the bis(carbamoylthiophenoate) complex in [$D_6$]DMSO due to the formation of intramolecular N–H···S hydrogen bonds in the mercury complex.[26]

When the initial concentration of **2** is increased a steady chemical-shift change is observed for the $NH_2$ protons involved in N–H···S hydrogen-bonding interactions. This demonstrates that the percentage of hydrogen-bonded species increases with increasing initial concentrations of **2**. At a concentration of $1 \times 10^{-3}$ M no shift of the $NH_2$ protons with respect to that of $[Ni(C_9H_{22}N_6)](ClO_4)_2$ was observed. However, at higher concentrations (in the range of 0.013 to 0.034 M) a downfield shift of the $NH_2$ protons from $[Ni(C_9H_{22}N_6)](ClO_4)_2$ to **2** was observed (see Figure 7 in the Supporting Information for concentration-dependent NMR spectra). The $^1$H NMR spectra of $[Ni(C_9H_{22}N_6)](ClO_4)_2$ were recorded in the same concentration range used for compound **2**; the peak positions for the $NH_2$ group remained essentially same.

## Electrochemistry

The cationic complex $[Ni(C_9H_{22}N_6)](ClO_4)_2$ shows a quasi-reversible oxidation at +1.24 V vs. SCE and a quasi-reversible reduction at –1.34 V vs. SCE in MeCN solution.[15] However, its ion-pair compounds **1**–**3** are not soluble in MeCN, therefore we performed the electrochemical studies in DMF. In DMF, the reversible oxidation and reduction are observed at +1.00 V vs. SCE and at –1.30 V vs.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

SCE, respectively, for $[Ni(C_9H_{22}N_6)](ClO_4)_2$ (see Supporting Information). Cyclic voltammograms of **1**–**3** are shown in Figure 7. Compounds **2** and **3** show similar features in their cyclic voltammograms. The reversible reductions at around –1.30 V (vs. SCE) for $[Ni(C_9H_{22}N_6)](ClO_4)_2$ become quasi-reversible in its ion-pair compounds and the oxidative response at around +1.00 V (vs. SCE) for $[Ni(C_9H_{22}N_6)](ClO_4)_2$ is not clearly observed in the ion-pair compounds. Instead, all three cyclic voltammograms (Figure 7) exhibit a strong irreversible oxidation at around +1.16 V (vs. SCE) whose shape is rather complicated. This can be assigned to the oxidation of the dithiolate sulfurs of the mnt ligands (by comparing the cyclic voltammograms of $[Bu_4N]_2[M(mnt)_2]$). This complicated feature might also include the oxidative response of $[Ni(C_9H_{22}N_6)]^{2+}$ at a shifted (higher) potential, which is in agreement with the small bump observed around +1.25 V for all complexes. These data indicate that the oxidation of $[Ni(C_9H_{22}N_6)]^{2+}$ becomes somewhat more difficult in the ion-pair compounds **1**–**3** than in the perchlorate complex $[Ni(C_9H_{22}N_6)](ClO_4)_2$ and the reduced complex $[Ni(C_9H_{22}N_6)]^{+}$ becomes more unstable in the ion-pair compounds than in the perchlorate complex (on the cyclic voltammetric timescale). This implies that the stability of $[Ni(C_9H_{22}N_6)]^{2+}$ in its ion-pair compounds would make the transition from $Ni^{II}$ to $Ni^{III}$ or $Ni^{I}$ more unfavorable than in its perchlorate salt. Compound **1** shows an additional irreversible reduction at around –0.75 V vs. SCE (Figure 7, a) that is not observed in the case of compounds **2** and **3** (Figures 7, parts b and c, respectively). We assign this reductive response to the $[Cu(mnt)_2]^{2-}/[Cu(mnt)_2]^{3-}$ couple based on relevant literature data.[27] Compounds **1**–**3** exhibit a reversible oxidation that corresponds to the couple $[M(mnt)_2]^{-}/[M(mnt)_2]^{2-}$ (M = $Cu^{2+}$, $Ni^{2+}$ and $Pd^{2+}$; 0.33 V vs. SCE for **1**, 0.33 V vs. SCE for **2** and 0.54 V vs. SCE for **3** in DMF).

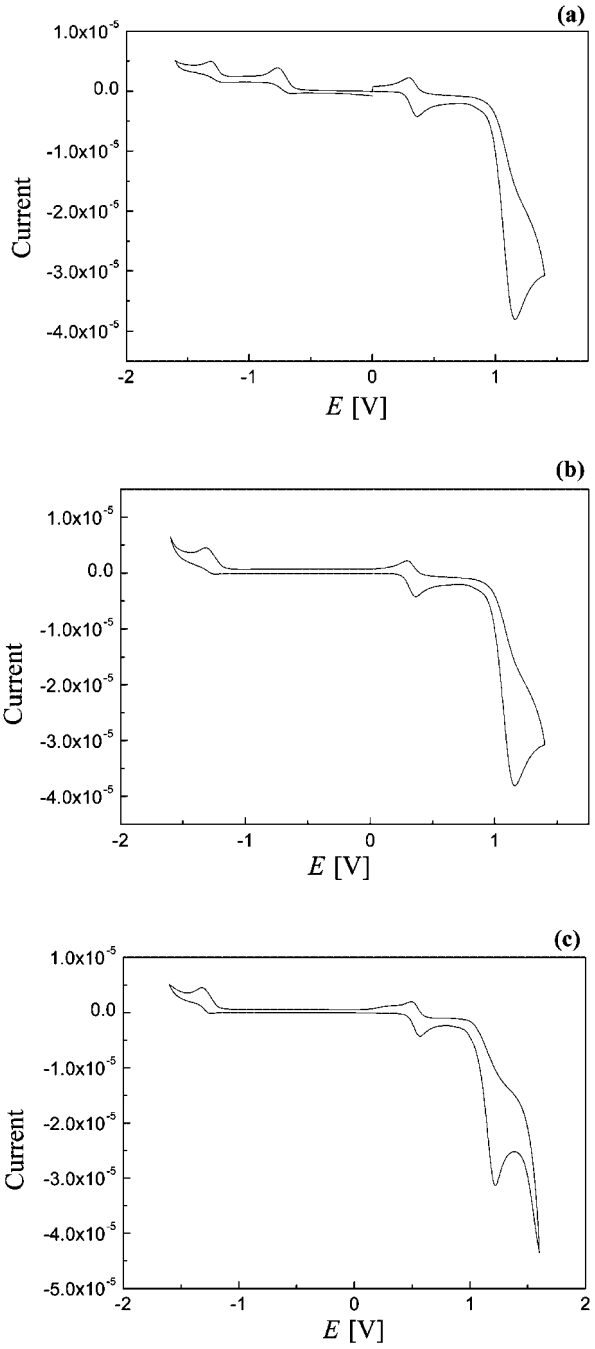

Figure 7. Cyclic voltammograms of a 1.0 mM solution of (a) $[Ni(C_9H_{22}N_6)][Cu(mnt)_2]$ (**1**), (b) $[Ni(C_9H_{22}N_6)][Ni(mnt)_2]$ (**2**), and (c) $[Ni(C_9H_{22}N_6)][Pd(mnt)_2]$ (**3**) in DMF at room temperature. Scan rate: 100 mV $s^{-1}$. Current given in A.

## UV/Vis-NIR Spectra

The UV/Vis spectra of compounds **1**–**3** were measured both in solution and the solid state at room temperature. The perchlorate salt of the cation $[Ni(C_9H_{22}N_6)](ClO_4)_2$ exhibits a d-d band at around 450 nm in the solid state and at 440 nm in solution ($\varepsilon$ = 80 $M^{-1}cm^{-1}$ in MeCN), which is the characteristic absorption for a square-planar $Ni^{II}$-$N_4$ chromophore (Figures 18 and 19 in the Supporting Information). The d-d band of $[Ni(C_9H_{22}N_6)]^{2+}$ at 440 nm is obscured by the intense MLCT charge-transfer bands for the metal–dithiolene moieties in the ion-pair complexes (at around 430 nm for **1**, 470 nm for **2**, and 430 nm for **3**). The d-d bands at around 1100 (for **1**), 860 (for **2**), and 630 nm (for **3**) are characteristic features of $[Cu(mnt)_2]^{2-}$, $[Ni(mnt)_2]^{2-}$, and $[Pd(mnt)_2]^{2-}$ respectively (see SI-Figure 20 in the Supporting Information).

## ESR Spectroscopy

The ESR spectrum of compound **1** in DMF at liquid-nitrogen temperature was also measured. It exhibits hyperfine structure due to $^{63,65}Cu$ nuclei. Interestingly, both $g_{\|}$ and $g_{\perp}$ features are resolved due to $^{63,65}Cu$ hyperfine coupling, which is very rarely observed in metal–dithiolene complexes. The average value of the hyperfine coupling parameters (determined from $|A_{\|}|$ = 15.3 mT and $|A_{\perp}|$ = 4.8 mT) is 8.3 mT, which is not identical to that (7.4 mT) of the solution ESR spectrum at room temperature (see SI-Figures

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

21–23 in the Supporting Information). This is consistent with the NMR studies.

## Conclusion

Numerous model compounds of sulfur-containing metallo-proteins have been reported that emphasize the importance of N–H···S hydrogen bonds in stabilizing the negatively charged metal–sulfur cluster (the active site) of the relevant protein. Intramolecular N–H···S hydrogen bonding was observed in many of these model studies and, in a few cases, intermolecular hydrogen bonding was also identified. We have introduced, for the first time, this N–H···S hydrogen-bonding interaction between a novel cationic inorganic complex $[Ni(C_9H_{22}N_6)]^{2+}$ (that has H-bond donor sites) and the classical inorganic anionic complexes $[M(mnt)_2]^{2-}$ ($M = Cu^{2+}$, $Ni^{2+}$ and $Pd^{2+}$) with dithiolato sulfur anions as H-bond acceptor sites. The existence of such supramolecular intermolecular N–H···S interactions in this new family of ion-pair compounds is additionally supported by IR, $^1H$ NMR, and ESR spectral studies. The complex cation $[Ni(C_9H_{22}N_6)]^{2+}$ was reported earlier as its perchlorate salt, although its crystal structure was not discussed in detail because of disorder problems. We have succeeded in resolving this disorder problem in the crystal structures of the ion-pair compounds **1**–**3**.

## Experimental Section

**General:** Microanalytical (C, H, N, S) data were obtained with a FLASH EA 1112 Series CHNS Analyzer. IR spectra were recorded for KBr pellets with a JASCO FT/IR-5300 spectrometer in the region 400–4000 $cm^{-1}$. Electronic spectra were recorded with a UV-3101PC/UV/Vis-NIR spectrophotometer (Shimadzu) equipped with a diffuse reflectance accessory (reflectance spectra were recorded for KBr pellets). The diffuse reflectance spectra obtained were then Kubelka–Munk corrected. The ESR spectra were recorded with a (JEOL) JES-FA200 ESR spectrometer. A Cypress model CS-1090/CS-1087 electroanalytical system was used for cyclic voltammetric experiments. The electrochemical experiments were measured in DMF containing $Bu_4NClO_4$ as a supporting electrolyte, using a conventional cell consisting of two platinum wires as working and counter electrodes, and a saturated calomel electrode (SCE) as reference. The potentials reported here are uncorrected for junction contributions. Some electrochemical measurements were performed on a BAS i Epsilon-EC Bioanalytical System Inc. using Ag/AgCl reference electrode and glassy carbon as a working electrode. Powder X-ray diffraction data were collected on Phillips PW 3710 diffractometer. EDAX analyses were performed using Philips XL 30 SEM equipment.

**Materials:** All commercially available chemicals were of reagent grade and were used as received without further purification. The solvents were dried and distilled according to standard procedures for the electrochemical and spectroscopy experiments. The acyclic $Ni^{II}$ complex of 3,7-bis(2-aminoethyl)-1,3,5,7-tetraazabiclo[3.3.1]-nonane was synthesized as its perchlorate salt according to a reported method.[15] The salts $[Bu_4N]_2[M(mnt)_2]$ ($M = Ni^{2+}$, $Pd^{2+}$, and $Cu^{2+}$) were prepared according to a literature procedure.[28] Disodium maleonitriledithiolate [the disodium salt of 1,2-dicyanoethylenedithiolate ($Na_2mnt$)] was prepared following a synthetic procedure described in the same paper.[28]

**Synthesis of $[Ni(C_9H_{22}N_6)][Cu(mnt)_2]$ (1):** $[Ni(C_9H_{22}N_6)](ClO_4)_2$ (0.047 g, 0.10 mmol) was dissolved in 10 mL of MeCN by mild heating in a water bath. The resulting clear, yellow solution was treated with $[Bu_4N]_2[Cu(mnt)_2]$ (0.082 g, 0.1 mmol) dissolved in 15 mL of MeCN. The final reaction mixture was then heated to about 50 °C in an oil bath for 10 min with stirring, whereby the dark microcrystalline compound **1** precipitated out within a day. The crystals of **1** were filtered, washed with diethyl ether, and dried at room temperature. Yield: 0.045 g (74% based on Cu). $C_{17}H_{22}CuN_{10}NiS_4$ (616.94): calcd. C 33.09, H 3.59, N 22.70, S 20.79; found C 33.29, H 3.48, N 22.59, S 21.01. IR (KBr): $\tilde{\nu}$ = 3258 (w), 3192 (m), 2191 (s), 1570 (w), 1464 (s), 1281 (w), 1150 (m), 1086 (s), 992 (w), 941 (m), 908 (w), 856 (s), 814 (s), 716 (w), 607 (m), 586 (w), 511 (s) $cm^{-1}$. UV/Vis/NIR (DMF): $\lambda_{max}$ ($\varepsilon$) = 321 nm (36360 $M^{-1}cm^{-1}$), 372 (23230), 426 (12120), 485 (10100), 1200 (74).

Single crystals suitable for an X-ray structure determination were grown in a $\lambda$-shaped glass tube with two terminals. $[Ni(C_9H_{22}N_6)](ClO_4)_2$ was dissolved in 10 mL of MeCN in a 20-mL round-bottomed flask and this was fixed to one terminal of the tube; the other terminal of the tube was connected to a 20-mL round-bottomed flask containing 10 mL of an MeCN solution of $[Bu_4N]_2[Cu(mnt)_2]$. Finally, the empty part of the tube was slowly filled with MeCN (from the top) and sealed. The crystals collected after 25 days from the top of the tube were identified as **1**.

**Synthesis of $[Ni(C_9H_{22}N_6)][Ni(mnt)_2]$ (2):** This compound was synthesized by stirring an MeCN solution (10 mL) of $[Ni(C_9H_{22}N_6)](ClO_4)_2$ (0.047 g, 0.10 mmol) with an MeCN solution (15 mL) of $[Bu_4N]_2[Ni(mnt)_2]$ (0.082 g, 0.1 mmol) at room temperature for half an hour. The red microcrystals of **2** were separated by filtration, washed with diethyl ether, and dried at room temperature. Yield: 0.05 g (82% based on Ni). $C_{17}H_{22}N_{10}Ni_2S_4$ (612.11): calcd. C 33.36, H 3.62, N 22.88, S 20.95; found C 33.58, H 3.53, N 22.78, S 21.06. IR (KBr): $\tilde{\nu}$ = 3264 (w), 3196 (m), 2195 (s), 1570 (w), 1485 (s), 1280 (w), 1233 (m), 1149 (s), 1086 (s), 1055 (m), 990 (m), 943 (w), 909 (w), 856 (s), 814 (s), 713 (w), 605 (s), 546 (w), 509 (s) $cm^{-1}$. UV/Vis/NIR (DMF): $\lambda_{max}$ ($\varepsilon$) = 317 nm (41410 $M^{-1}cm^{-1}$), 387 (10100), 482 (6060), 510 (3131), 770 (53).

Single crystals suitable for an X-ray crystal structure determination were grown as described for compound **1**.

**Synthesis of $[Ni(C_9H_{22}N_6)][Pd(mnt)_2]$ (3):** This compound was synthesized by the same procedure as described for compound **2**, starting from MeCN solutions of $[Ni(C_9H_{22}N_6)](ClO_4)_2$ (0.047 g, 0.1 mmol) and $[Bu_4N]_2[Pd(mnt)_2]$ (0.087 g, 0.1 mmol). Yield: 0.041 g (63% based on Pd). $C_{17}H_{22}N_{10}NiPdS_4$ (659.80): calcd. C 30.94, H 3.36, N 21.23, S 19.44; found C 31.06, H 3.31, N 21.34, S 19.66. IR (KBr): $\tilde{\nu}$ = 3262 (w), 3198 (m), 2195 (s), 1568 (w), 1485 (s), 1338 (m), 1279 (w), 1232 (w), 1202 (w), 1178 (w), 1146 (s), 1086 (s), 1043 (w), 990 (w), 943 (w), 909 (w), 854 (s), 815 (s), 713 (w), 605 (m), 507 (s) $cm^{-1}$. UV/Vis (DMF): $\lambda_{max}$ ($\varepsilon$) = 367 nm (2121 $M^{-1}cm^{-1}$), 429 (5050), 450 (5454), 637 (110).

***Caution!*** *Perchlorate salts are potentially explosive and should be handled in small quantities with caution.*

**X-ray Crystallography:** Crystal data were collected with an Enraf–Nonius CAD4 diffractometer at 25 °C equipped with a graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation source. An empirical absorption correction based on a series of $\psi$ scans was applied. The structures were solved by direct methods (SHELXS-97)[29] and refined by full-matrix least-squares on $F^2$ (SHELXL-97).[30] All non-hydrogen atoms were refined anisotropi-

cally. Hydrogen atoms were introduced at calculated positions and included in the refinement as riding on their respective parent atoms. The crystallographic data and the parameters of structure refinement for compounds **1**–**3** are summarized in Table 3.
CCDC-273272 (for **1**), -273273 (for **2**), and -273274 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** available (for details see the footnote on the first page of this article): Figures related to crystal structures for compounds **1**, **2** and **3**; $^1$H NMR spectrum for compound **2** and $^1$H NMR spectra for concentration-dependent NMR studies; IR spectra for compounds **1**, **2** and **3**; cyclic voltammograms for compounds **1**, **2** and **3**; solution and solid-state electronic spectra for compounds **1**, **2** and **3**; ESR spectra for compound **1**; X-ray powder diffraction patterns (simulated and observed).

## Acknowledgments

We thank CSIR, Government of India, for financial support [Project No.: 01(1737)/02/EMR-II]. The National X-ray Diffractometer facility at University of Hyderabad by the Department of Science and Technology, Government of India, is gratefully acknowledged. We are grateful to UGC, New Delhi, for providing infrastructure facility at University of Hyderabad under UPE grant. The authors thank Professor S. Pal for providing electrochemical data for this work. We also thank Professor Sabyasachi Sarkar and Mr. Kuntal Pal (Department of Chemistry, IIT Kanpur, India) for helping us by providing some electrochemical data at the revision stage of this work. V. M. thanks CSIR, New Delhi, for a fellowship.

# Ring Closure of Alkoxycarbonyl(tetracarbonyl)pyruvoyliron Complexes into Metallalactones Induced by Nucleophilic Attack of Carbanions

**Patrice Cabon,[a] René Rumin,[a] Jean-Yves Salaün,*[a] Hervé des Abbayes,[a] and Smail Triki[a]**

**Keywords:** Carbanions / Carbonyl ligands / Iron / Metallacycles / Nucleophilic addition

The reaction of carbanions with the pyruvoyl-substituted iron complex $[(CO)_4Fe(CO_2CH_3)\{C(O)C(O)CH_3\}]$ (**1**) affords the anionic trifunctionalized metallalactones $[(CO)_3Fe\{C(O)C(CH_3)(CRR'R'')OC^4(O)(Fe–C^4)\}(CO_2CH_3)]^-$ (**3**), whose formation results from the addition of the nucleophile to the β carbonyl of the pyruvoyl moiety, followed by attack of the oxygen of this β carbonyl on a terminal carbonyl ligand. These anionic lactones react, at low temperature, with HCl to give rise to the neutral lactones $[(CO)_4Fe\{C(O)C(CH_3)(CRR'R'')OC^4(O)(Fe–C^4)\}]$ (**2**), which were previously obtained by addition of NuH nucleophiles to **1**. Complex **3(3)**, whose lactonic ring formation has been performed using the diethyl malonate anion (R = R′ = $CO_2C_2H_5$; R′′ = H), and the dimethyl-substituted neutral lactone **2(1)** (R = R′ = R′′ = H) have been characterized by X-ray diffraction studies.

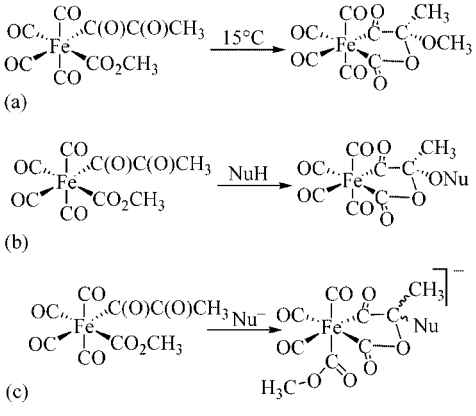
## Introduction

Nucleophilic attacks upon organic ligands coordinated to transition metals are important processes in the formation of new reactive organometallic intermediates that are useful in organic synthesis. Although it is possible to assess the reactivity of various ligands toward nucleophiles, it is more difficult to predict the site of nucleophilic attack on polyfunctional complexes. Thus, while nucleophiles react very easily with terminal carbonyls of metal–carbonyl compounds to afford acyl, aroyl, alkoxycarbonyl, or carbamoyl ligands, the same reaction occurs regiospecifically at the α-carbon of a carbene ligand,[1] at the α- and γ-carbons of an allenylidene,[2,3] and at the β-carbon of an allenyl ligand[4] of analogous complexes. It has also been shown that acyl ligands are less electrophilic than terminal carbonyl ligands.[5] In the course of a study of complexes considered as possible models for double or polycarbonylation reactions, we investigated the reactivity of compounds displaying a ligand with a C(O)C(O)R chain toward nucleophilic reagents. Indeed, addition of nucleophiles at $C_\alpha$ of this type of ligand has been proposed to account for the formation of phenylpyruvic esters by dicarbonylation of organic halides catalyzed by $[Co(CO)_4]^-$.[6] The very few nucleophilic additions performed on cationic (Fe[7] Pt[8]) or neutral complexes (Fe[9]) displaying an M–C(O)–C(O)–R chain have been shown to occur at a terminal carbonyl ligand of the molecule. We recently observed the original behavior of the complex *cis*-$[(CO)_4Fe\{C(O)C(O)CH_3\}(CO_2CH_3)]$ (**1**), which afforded its cyclic isomer **2** quantitatively, at 15 °C, in a reaction involving the formation of a metallalactone ring by addition of the oxygen of the β carbonyl of the pyruvoyl to the alkoxycarbonyl ligand and a migration of the methoxy group of this latter ligand to the β carbon of the pyruvoyl (Scheme 1, a).[10]



Scheme 1.

This reaction appeared very similar to the ring-chain isomerism observed for organic γ-keto esters.[11] Indeed, as the alkoxycarbonylpyruvoyliron complex **1** can be considered as a γ-keto ester with a metal inserted into the chain linking its two organic functions, a parallel between the organic reaction and the organometallic process can be drawn. When performed in the presence of an excess of pronucleophilic reagents (Nu–H), the reaction affords Nu-sub-

stituted metallalactones (Scheme 1, b) which are formed, under these conditions, by an addition of the nucleophile to the β carbonyl of the pyruvoyl followed by metallalactone ring formation due to attack of the oxygen of this β carbonyl on the alkoxycarbonyl ligand and elimination of the methoxy group of this latter ligand.[7] To the best of our knowledge, prior to our study, only one example of nucleophilic addition at a carbonyl carbon of a ligand displaying a double C(O) chain had been described in the literature. In this paper, hydride was reported to attack the β carbonyl of a ligand of $[(CO)_5Mn\{C(O)C(O)C_6H_5)\}]$ to afford an anionic metallalactone by cyclization of the phenylglyoxyl with a terminal carbonyl.[12] These results prompted us to perform the cyclization of **1** with anionic nucleophiles ($RO^-$, $RS^-$, or $R_2P^-$).[13] These reactions, as they only afford two isomers of the anionic trifunctionalized metallalactone **3** (Scheme 1, c), also suggested that the formation of the metallalactonic ring could indeed proceed by addition to a terminal carbonyl rather than to the alkoxycarbonyl ligand. However, as the structure of these trifunctionalized anions **3** was not firmly established, we tried to perform analogous reactions using C–H nucleophiles and carbanions of various nucleophilicity and of different steric effects. The results of this study will be the topic of this paper.

## Results and Discussion

### Reaction of 1 with Activated C–H Bonds or Carbanions as Nucleophiles

Although often used as nucleophiles,[14] pronucleophiles displaying activated methylenes, such as diethyl malonate (1 equiv.) or malononitrile (20 equiv.), were found to be unreactive towards **1** at –10 °C. This lack of reactivity is not too surprising as **1** only reacts slowly with $CH_3OH$, $C_2H_5SH$, $HP(C_6H_5)_2$, or $HP(C_6H_{11})_2$.[7] On the other hand, as shown by IR monitoring, **1** reacts very rapidly with carbanionic reagents such as MeLi, *n*BuLi, $NaCH(CO_2C_2H_5)_2$, $NaCH(C{\equiv}N)_2$, $NaCH[C(O)CH_3]_2$, $NaCH[C(O)CH_3](CO_2CH_3)$, $NaCH(CO_2C_2H_5)(C{\equiv}N)$, $NaC(CH_3)(CO_2C_2H_5)_2$, or $NaC(CH_2CH{=}CH_2)(CO_2C_2H_5)_2$ to afford instantaneously, even at –70 °C, new complexes displaying a set of three ν(C≡O) bands between 2084 and 1970 $cm^{-1}$. These frequencies are similar to those observed for the product of the reaction between **1** and $RO^-$, $RS^-$, or $R_2P^-$ anions,[13] and are intermediate between the ν(C≡O) of the monofunctionalized anion $[Fe(CO)_4(CO_2R)]^-$ (three bands around 1910 $cm^{-1}$)[15] and those of their homologues of the neutral complex *cis*-$[Fe(CO)_4(CO_2R)_2]$ (four bands between 2130 and 2050 $cm^{-1}$).[16] They fall within the range of those of trifunctionalized mono anions such as *fac*-$[(CO)_3Fe(CO_2R)_3]^-$ (two bands at 2080 and 2015 $cm^{-1}$), which are themselves obtained by addition of $RO^-$ to a terminal carbonyl of $[(CO)_4Fe(CO_2R)_2]$.[9] These values measured for ν(C≡O) are therefore consistent with a moderate increase of the electron density on the metal. The observation of three ν(C≡O) bands instead of the two required by $C_{3v}$ symmetry could result from the presence of a metallacycle in the complex. These results suggest the *fac* trifunctionalized metallalactone structure **3** for the products of these reactions (see Scheme 2).

**3g**: R = $CO_2CH_3$, R' = CN, R'' = H
**2h** or **3h**: R = R' = $CO_2C_2H_5$, R'' = $CH_3$
**2i** or **3i**: R = R' = $CO_2C_2H_5$, R'' = $CH_2CH{=}CH_2$

Scheme 2.

This assumption was confirmed by the $^{13}C$ NMR spectroscopic data of these compounds. Although most of these complexes were found to be sparingly soluble in organic solvents, the $^{13}C$ NMR spectra of these compounds could be obtained in $[D_8]$THF (see Exp. Sect.). The anionic structure of complexes **3** was indicated by a shift of the signals of the carbonyls linked to the metal toward lower fields relative to their homologues **1** ($\Delta\delta$ = 10 ppm for the terminal carbonyls and 15 ppm for the carbon of the alkoxycarbonyl).[13] However, the negative charge is very probably delocalized over the three carbonylated substituents of the complex as the chemical shifts of the terminal carbonyls of **3** (from $\delta$ = 205 to 212 ppm) fall between those observed for **1** ($\delta$ = 200 ppm)[13] and those of $[(CO)_4Fe(CO_2R)]^-$ ($\delta$ = 220 ppm).[15] The electron density of the metal center of **3** is therefore intermediate between that observed for neutral complexes and for the monofunctionalized anion. The formation of a metallacycle in complexes **3** is shown by the signal of their disubstituted cyclic quaternary carbon atom between $\delta$ = 86.5 and 96.9 ppm. This value is not very different from those observed for similar carbons substituted by OR ($\delta$ = 111 ppm), SR ($\delta$ = 95.5 ppm), or $PR_2$ ($\delta$ = 90 ppm) groups.[13] As **3(1)** displays two methyl substituents on this cyclic quaternary carbon, it only exists as one isomer. The formation of this single isomer is shown in the $^{13}C$ NMR spectrum by the observation of one signal for each carbon of this complex. The nonequivalency of these two methyls, shown by two signals at $\delta$ = 15.8 and 8.4 ppm, results from the *fac* position of the alkoxycarbonyl ligand. Reaction of **1** with *n*BuLi afforded

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a similar complex. This compound, which has both *n*-butyl and methyl substituents on the quaternary carbon of its metallalactone [R = R′ = H; R′′ = $C_3H_7$; **3(2)**], was formed as a 50:50 mixture of two isomers. The presence of these two isomers is shown by the observation of two signals of equal intensities at $\delta$ = 274.1 and 271.5 ppm for the C=O acyl, at $\delta$ = 96.9 and 96.7 ppm for the cyclic $sp^3$ carbon, and at $\delta$ = 60.5 and 59.9 ppm for the $OCH_3$ group of the alkoxycarbonyl ligand. Surprisingly, the same reaction performed with $NaCH(CO_2C_2H_5)_2$ afforded only one isomer of the anion **3(3)** (R = R′ = $CO_2C_2H_5$; R′′ = H). Indeed, the $^{13}C$ NMR spectrum of this compound only displays one signal at $\delta$ = 269.3 ppm for the acyl C=O, at $\delta$ = 94.3 ppm for the cyclic $sp^3$ carbon, at $\delta$ = 50.9 ppm for the methoxy of the methoxycarbonyl ligand, and at $\delta$ = 21.7 ppm for the methyl located on the cyclic $sp^3$ carbon. On the other hand, due to the asymmetry of the metallalactone ring, the two ethoxycarbonyls of the malonyl group are not equivalent and appear as two signals at $\delta$ = 168.7 and 167.3 ppm, 62.65 and 62.55 ppm, and 13.6 and 13.7 ppm for the carbonyl, the $CH_2$, and the $CH_3$ carbon atoms, respectively, while the central carbon of this malonyl group only displays a single resonance at $\delta$ = 55.25 ppm. The solubility of **3(3)** is significantly better than **3(1)** and **3(2)**.

When **1** was treated with the anions obtained from 2,4-pentanedione or malononitrile, **3(4)** [R = R′ = $C(O)CH_3$, R′′ = H] and **3(5)** (R = R′ = CN, R′′ = H) were formed, respectively. As shown by their $^{13}C$ NMR spectra (see Exp. Sect.), they are obtained as mixtures of two isomers (70:30 and 60:40, respectively). As observed for **3(3)**, the $CH_3C(O)$ and CN groups of each isomer of these complexes are not equivalent. Thus, **3(4)** displays four $CH_3$ resonances at $\delta$ = 32.9, 32.7, 32.3, and 32.1 ppm (the signals for the C=O groups of the terminal carbonyls are not detectable) and **3(5)** four CN resonances at $\delta$ = 113.7, 113.45, 112.6, and 112.5 ppm while two peaks are observed for the central carbon of the malononitrile group of **3(5)** at $\delta$ = 31.1 and 30.8 ppm [the resonance of the homologue carbon atom of **3(4)** is probably hidden by the signal of the THF]. Asymmetric nucleophiles such as $NaCH[C(O)CH_3](CO_2CH_3)$ or $NaCH(CO_2C_2H_5)(CN)$ also afforded anions of type **3**. The formed complexes **3(6)** (R = $CO_2CH_3$, R′ = $C(O)CH_3$, R′′ = H) or **3(7)** (R = $CO_2CH_3$, R′ = CN, R′′ = H) were again obtained as two *cis*/*trans* isomers (50:50) but, due to the asymmetry of their metallacycle and of the central carbon of their nucleophile group, each of these isomers is observed as two diastereoisomers. For this reason, the $^{13}C$ NMR spectra of **3(6)** and **3(7)** exhibit four signals for each of their carbon atoms. For example, **3(6)** displays four acyl CO signals at $\delta$ = 268.5, 267.4, 267.0, and 266.8 ppm, four peaks for the cyclic quaternary carbon at $\delta$ = 94.2, 93.1, 92.6, and 92.1 ppm, and four signals for the resonance of the central carbon atom of the nucleophilic group at $\delta$ = 62.5, 62.2, 61.9, and 61.2 ppm. In the same way, the $^{13}C$ NMR spectrum of **3(7)** shows four CO signals at $\delta$ = 267.5, 266.8, 266.5, and 266.2 ppm, four CN signals at $\delta$ = 118.0, 117.5, 117.3, and 116.8 ppm, four resonances for the cyclic quaternary carbon at $\delta$ = 93.0, 92.5, 91.5, and 91.0 ppm, and four signals for the central carbon of the nucleophile at $\delta$ = 44.5, 43.5, 42.5, and 42.0 ppm.

As shown by IR monitoring, the reaction of **1** with the bulky nucleophiles $NaC(CH_3)(CO_2C_2H_5)_2$ or $NaC(CH_2CH{=}CH_2)(CO_2C_2H_5)_2$ also affords trifunctionalized anionic metallalactones. However, the $^{13}C$ NMR spectra of the thus formed compounds **3(8)** (R = R′ = $CO_2C_2H_5$, R′′ = $CH_3$) and **3(9)** (R = R′ = $CO_2C_2H_5$, R′′ = $CH_2CH{=}CH_2$) are found to display broad signals whose chemical shifts are in good agreement with those expected for anionic metallalactones (see Exp. Sect.). The detection of at least three signals for the resonances of the acyl CO or for their cyclic quaternary carbon suggests the presence of at least three isomers for these two complexes. The broadness of the observed signals probably results from slow interconversion between the observed species. However, no change was observed in the spectra of these compounds when they were recorded at different temperatures (from 20 °C to –50 °C). The only isomer of **3(3)** was obtained as single crystals suitable for an X-ray diffraction study.

### Structural Study of Complex 3(3)

Single crystals of **3(3)**, with $K^+$ as counterion, were grown from a hexanes/dichloromethane mixture (90:10) at –30 °C. An ORTEP diagram of the anion is displayed in Figure 1, crystallographic data are given in the Exp. Sect., and selected bond lengths and angles are gathered in Table 1 and Table 2, respectively.

The crystal structure confirms the proposed anionic, metallacyclic, trifunctionalized geometry for **3(3)**. The structure can be described as being composed of four crystallographically different (Figure 1, a) trifunctionalized entities linked to four potassium ions (Figure 1, b). As these anions exhibit slight differences in their bond lengths and angles, the values measured for each of these entities (a, b, c, and d) will be mentioned in the following discussion. The crystal structure study establishes that the only formed complex is the isomer with the alkoxycarbonyl ligand and the malonyl group *trans* to each other on the metallacycle (Figure 1, a). This complex, which is sterically less hindered than the corresponding *cis* isomer, is probably the species observed in solution. The coordination polyhedron at the metal center is a distorted octahedron built of three terminal carbonyl ligands, an alkoxycarbonyl, and the chelating carbonylated ligand. As observed for neutral metallalactones[7,10,12,13] and for five-membered iron metallacycles,[17] the bite angle of the chelate C(7)–Fe–C(6) [82.3(5)–83.4(5)°] is smaller than the angle measured between the two organic carbonylated ligands of the noncyclic *cis*-bis(alkoxycarbonyl)iron complex $[(CO)_4Fe(CO_2tBu)_2]$ [88.5(2)°].[18] Therefore, its opposite angle on the metal [C(1)–Fe–C(2)] displays a larger value than that expected for an octahedral geometry [96.0(6)–100.2(5)°]. The axial alkoxycarbonyl ligand is bent toward the metallacycle [C(4)–Fe–C(6) from 81.3(5)° to 84.6 (5)° and C(4)–Fe–C(7) from 84.8(5)° to 89.0(5)°]. The other angles around the metal are normal,

with values close to 90°. The Fe–terminal carbonyl distances [1.79(1)–1.90(1) Å] are similar to those in the homologous trifunctionalized iron monoanion[9] or to the neutral complex $[(CO)_4Fe(CO_2tBu)_2]$[18] but are longer than the Fe–C≡O distance observed in a monofunctionalized iron anion.[19] These data confirm a reduced electron density on the metal due to the delocalization of the negative charge of the complex on the carbonylated organic ligands. The short Fe–cyclic(C=O)O distances [Fe–C(6) from 1.93(1) to 1.97(1) Å] associated with long C(6)–O(6) bonds [from 1.21(1) to 1.23(1) Å] show the enolate character of this group whose C=O oxygen is bound to three potassium ions (see below). Such a lengthening of the C=O double bond is not observed for C(4)=O(4), C(11)=O(9), or C(14)=O(11), whose oxygens are only bound to one potassium, or for C(7)=O(7), which does not interact with this metal. The other bond lengths or angles of the complex are analogous

to those measured for neutral metallalactones.[7,10,13] As shown by the deviations of O(8) (+0.13 and +0.18 Å) and C(8) (+0.11 and +0.20 Å) from the plane defined by C(6)–Fe–C(7), the metallalactone ring of **3(3)** is not rigorously planar. It is worth noting that C(8) and O(8) are located on the same side of this plane. The steric effect of the malonyl group induces a pseudo axial position of the methyl substituent of the metallacycle, as shown by deviations of C(9) from the C(6)–Fe–C(7) plane of between 1.42 and 1.53 Å; deviations of between 0.91 and 1.09 Å are observed for C(10), which is the central atom of the malonyl group. As mentioned above, **3(3)** is composed of four slightly different entities in the solid state that display their four potassium ions and four cyclic ester carbonyl oxygens [O(6)] alternately at the corners of a distorted cube (see Figure 1, b). This cube displays small O–K–O angles (71.5–83.5°) and larger K–O–K angles (92.0–108.3°). Each potassium is linked to seven oxygen atoms; for example, K(4) interacts with O(6d) and O(8d), which are the two oxygen atoms of the cyclic ester group of d, with the oxygen atoms [O(9d) and O(11d)] of the two carbonyl oxygens of the malonyl group of d, with the oxygen atoms of the carbonyl of the cyclic esters of molecules b and c [O(6b) and O(6c)], and with the carbonyl oxygen of the alkoxycarbonyl ligand of complex c [O(4c)]. Short K–O(4) distances (2.61–2.68 Å) are observed between the potassium and the oxygen of this latter ligand. Recall that O(6) − the carbonyl oxygen of the cyclic ester group of each anion − interacts with three potassium ions, which induces a lengthening of the C(6)–O(6) bond (1.23 vs. 1.19 Å observed for neutral lactones[7,10,13]) and a shortening of the Fe–C(6) distance (1.93 vs. 1.99 Å). The complexation of O(6) with a potassium ion [K(4)] that is itself bound to O(8), O(9), and O(11) of the same molecule brings about a reduction of the O(6)–C(6)–O(8) $sp^2$ angle from 112(1)° to 113.8 (9)°. The absence of complexation of the cyclic acyl oxygen O(7) must also be noted.

This crystallographic work confirms without any doubt the structure attributed to this series of anionic trifunctionalized metallalactones **3**. However, a clear relation between the nature of the nucleophile and the *trans*/*cis* ratio observed for the different complexes **3** (from 100% to 50% of the *trans* isomer) has not been established. For example, the steric hindrance of $KCH(CO_2C_2H_5)_2$ cannot justify the specific formation of the *trans* isomer of **3(3)** except if the possible formation of aggregates of the anionic nucleophile is considered. Such a hypothesis has already been taken into account to explain the stereospecific nucleophilic additions on organic ketones. The formation of anionic compounds **3** when the transformation of **1** is induced by anionic nucleophiles raises the question of the specific formation of neutral lactones **2** by reaction of **1** with pronucleophiles Nu–H. An answer to this question is given by the reaction of complexes **3** with anhydrous HCl.

### Reaction of Anionic Lactones 3 with HCl

As shown by IR monitoring of the process, the reaction of complexes **3(1)**, **3(2)**, **3(3)**, **3(4)**, **3(6)**, **3(8)**, and **3(9)** with one equivalent of anhydrous HCl at –80 °C instantaneously affords new compounds displaying four ν(C≡O) bands between 2131 and 2041 $cm^{-1}$. The presence of these four IR bands and their frequencies suggested the formation of neutral *cis* disubstituted complexes. Under the same reaction conditions an analogous process was observed for **3(5)** and **3(7)**, although the formed complexes rapidly evolved into $Fe(CO)_5$ and organic compounds. Complexes **2(1)**, **2(2)**, **2(3)**, **2(4)**, **2(6)**, **2(8)**, and **2(9)**, formed by reaction of **3(1)**, **3(2)**, **3(3)**, **3(4)**, **3(6)**, **3(8)**, and **3(9)** with HCl, respectively, were obtained as pale-yellow crystals from a hexanes/$CH_2Cl_2$ (95:5) mixture at –30 °C. Their $^{13}C$ NMR spectra confirm their neutral character as they display terminal C≡O resonances between $\delta$ = 202.75 and 196.2 ppm (vs. $\delta$ = 212.5–201.0 ppm for the starting complexes). Their other resonances are very close to those exhibited by neutral metallalactones: a C=O cyclic acyl between $\delta$ = 249.9 and 254.1 ppm (vs. $\delta$ = 274.1 and 262.3 ppm for the anionic lactones) and a cyclic C=O ester indiscernible from the terminal C≡O. The presence of a metallacycle in these complexes is shown by the observation of signals corresponding to cyclic quaternary carbons between $\delta$ = 92.3 and 98.4 ppm. All these characteristics are in good agreement with the formation of neutral metallalactones of type **2** (Scheme 2). Complex **2(1)**, whose quaternary cyclic carbon is substituted by two methyl groups, displays a single signal for its two axial terminal carbonyl ligands at $\delta$ = 200.2 ppm. This equivalence may result either from the quasi planarity of the metallacycle or from rapid interconversion between different conformations of the metallacycle. Other complexes **2** whose cyclic quaternary carbons are substituted by two different groups exhibit two signals for their axial carbonyl ligands. For example, five peaks are observed for the four terminal C≡O groups and the C=O of the cyclic ester of **2(2)** between $\delta$ = 200.5 and 196.5 ppm. Due to the asymmetry of the lactone ring, the two ethoxycarbonyl groups of the malonyl substituent of **2(3)** are not equivalent (two peaks are observed for the C=O at $\delta$ = 168.74 and 168.70 ppm, for the $CH_2$ at $\delta$ = 62.2 and 62.15 ppm, and for the $CH_3$ at $\delta$ = 13.9 and 13.75 ppm, whereas a single signal at $\delta$ = 58.6 ppm corresponds to the CH). A similar spectrum should be obtained for **2(4)**. However, as its acetyl C=O signals are hidden by those of the terminal C≡O, the presence of two different acetyl groups is only shown by the two peaks of their methyl groups at $\delta$ = 31.05 and 30.2 ppm. Complex **3(6)**, which displays an acetomethyl acetate and a methyl group on its cyclic quaternary carbon, affords, upon reaction with HCl, the neutral complex **2(6)**. Owing to the presence of the asymmetric central carbon of the acetoacetate group and to the asymmetry of the metallacycle itself, **2(6)** is obtained as an equimolecular mixture of two diastereoisomers. The presence of these two isomers is shown in the $^{13}C$ NMR spectrum by two C=O acyl resonances at $\delta$ = 251.32 and 251.22 ppm, by numerous signals between $\delta$ = 202.06 and 196.29 ppm [terminal carbonyls, cyclic ester group and organic C(O) acetyl], and by the splitting in two of the other signals: the organic C=O ester at $\delta$ = 169.9 and 169.4, the cyclic quaternary carbon at $\delta$ = 92.78 and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

92.32 ppm, the CH at $\delta$ = 65.86 and 65.35 ppm, the $OCH_3$ at $\delta$ = 53.30 and 53.08 ppm, the acetyl $CH_3$ at $\delta$ = 30.11 and 29.42 ppm, and the other $CH_3$ at $\delta$ = 22.19 and 22.15 ppm. Recall that anions **3(8)** and **3(9)**, whose metallacycle is substituted by the crowded diethyl methyl- or allylmalonate groups, exhibit broad signals in their $^{13}C$ NMR spectra. Their reaction with HCl also affords complexes of type **2**, whose formation confirms the structure attributed to these anions. Contrary to their precursors, **2(8)** and **2(9)** give very well resolved $^{13}C$ NMR spectra. The characteristics of these spectra are very close to those of **2(3)**, which bears an unsubstituted malonyl, as they display two nonequivalent ethoxycarbonyls on their substituted malonyl group. This is shown by a splitting in two of the signals of the carbons of these ethoxycarbonyl groups, whereas the resonances of the third substituent and of the central quaternary carbon of the malonyl are found as singlets (see Exp. Sect.). Among this series of neutral complexes **2**, crystals suitable for a structural study were obtained for **2(1)**.

### Crystallographic Study of Complex 2(1)

Single crystals of **2(1)** suitable for an X-ray diffraction study were obtained from a hexanes/dichloromethane mixture (95:5) at –30 °C. Figure 2 displays an ORTEP drawing of the molecule; selected bond lengths and angles are listed in Table 3, and further crystallographic data can be found in the Exp. Sect.

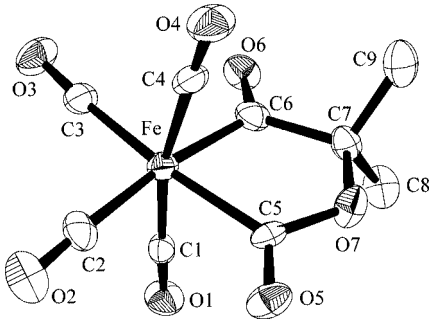

Figure 2. ORTEP view of **2(1)** (50% probability ellipsoids).

As observed for **3(3)**, the coordination around the iron atom in this complex can be described as a distorted octahedron with a reduced metallacyclic angle [C(6)–Fe–C(5) = 82.6(3)°, vs. an average of 82.8° for **3c**] and a larger value for its opposite angle C(3)–Fe–C(2) of 96.8(2)° due to the presence of the metallacycle. As already described by us for other neutral metallalactones,[7,10,13] the two axial terminal carbonyls of **2(1)** are bent toward the metallacycle [C(1)–Fe–C(4) = 167.7(2)°; C(4)–Fe–C(6) = 88.1(2)°; C(4)–Fe–C(5) = 83.8(2)°; C(1)–Fe–C(6) = 84.2(2)°; C(1)–Fe–C(5) = 85.7(2)]°. The Fe–cyclic ester bond [Fe–C(5)] of 1.991(5) Å and the C=O bond of this organic function [C(5)–O(5) = 1.199 (6) Å] are respectively longer and shorter than their homologues in **3(3)** (average of 1.95 Å for the first and 1.22 Å for the second). These bond lengths, which are similar to those measured for neutral metallalactones,[7,10,13] are indicative of an absence of enolate character of this function, whose oxygens are linked to the counterion in **3(3)**. The metallacycle is quasi planar, as shown by the torsion angles C(5)–Fe–C(6)–C(7) [–4.6(4)°] and C(6)–Fe–C(5)–O(7) [+6.2(4)°]. However, contrary to **3(3)**, O(7) and C(7) are no longer located on the same side of the C(6)–Fe–C(5) plane. The rapid evolution of complexes **3** into neutral metallalactones **2** when treated with HCl sheds new light on the direct formation of **2** by reaction of **1** with Nu–H nucleophiles. These observations suggest that the formation of **2** could result from a cyclization of the pyruvoyl and a terminal carbonyl ligand (and not, as considered earlier, the alkoxycarbonyl ligand) that affords an anionic, trifunctionalized metallalactone **3**. This intermediate, which would have $H^+$ as counterion, would then instantaneously evolve into **2**. The formation of complexes **2** by cyclization of the pyruvoyl and the alkoxycarbonyl ligand is therefore not necessarily involved in the process of anionic lactone formation. The reaction of **2** with NaOMe will confirm that this compound is not an intermediate of the reaction of formation of **3** by cyclization of **1** by anionic reagents.

### Reactions of Neutral Lactones 2 with NaOMe

The formation of anionic trifunctionalized metallalactones **3** by nucleophilic addition of $CH_3O^-$ to a terminal carbonyl of complexes **2** was performed with **2(1)** (R = R′ = $CH_3$; R′′ = H), **2(3)** (R = R′ = $CO_2C_2H_5$; R′′ = H), and **2(8)** (R = R′ = $CO_2C_2H_5$; R′′ = $CH_3$). As shown by the IR, $^1H$, and $^{13}C$ NMR spectra of the formed complexes, **2(1)** affords **3(1)** while **2(3)** gives rise to **3(3)**, again as a single isomer. The product formed by reaction of **2(8)** with NaOMe also displays the IR spectrum of a trifunctionalized anionic lactone. Its $^{13}C$ NMR spectrum is similar to that of **3(8)** obtained by cyclization of **1** performed with

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$CH(CH_3)(CO_2C_2H_5)_2$ and exhibits broad signals that again reveal the formation of at least three isomers of this compound. Upon reaction with HCl at low temperature this latter compound, which is very probably **3(8)**, was again found to evolve into **2(8)**. The yield of complexes **3(1)**, **3(3)** and **3(8)**, upon addition of NaOMe to a terminal carbonyl of neutral lactones, remains low (from 30 to 35%), and careful IR monitoring of the process showed that their formation is always concomitant with the detection of another product displaying the IR spectrum of a monofunctionalized anion (three bands around 1900 $cm^{-1}$). Unfortunately, the low stability of this complex did not allow its characterization.

## Conclusion

This work has allowed us to show that in complex **1**, which displays an alkoxycarbonyl, a pyruvoyl, and terminal carbonyl ligands, the β carbonyl of the pyruvoyl is the most electrophilic site of the molecule. Addition of various nucleophiles to this site affords anionic trifunctionalized metallalactones **3** whose metallalactone ring is formed by addition of the oxygen of this β carbonyl to a terminal carbonyl. When treated with HCl, the rapid evolution of these complexes **3** into neutral metallalactones **2** explains the direct formation of **2** when the cyclization of **1** is performed with pronucleophiles (Nu–H). Recall that, starting from complex **1**, the formation of **3** could also be performed by the intermediate formation of **2** obtained by cyclization of the pyruvoyl ligand of **1** with the alkoxycarbonyl moiety of the same complex and release of $CH_3O^-$. The rapid addition of this $CH_3O^-$ to a terminal carbonyl of **2** was then supposed to afford **3**. This work allowed us to dismiss this hypothesis as the reaction of complex **2** with $CH_3O^-$ was only found to afford **3** in very low yield. However, two aspects of this work remain unclear: i) the formation of a single isomer of **3(3)** from the cyclization of **1** with the anion of diethyl malonate, and ii) the broadness of the NMR signals of **3(8)** and **3(9)** associated with the high number of isomers observed for the complexes bearing a diethyl methylmalonate or a diethyl allylmalonate as substituent. Further experiments are under progress to find an answer these questions.

## Experimental Section

**General Remarks:** All reactions were carried out with Schlenk techniques under dry, oxygen-free argon. All solvents were purified by preliminary distillation from an appropriate drying agent.[20] $CD_2Cl_2$ and [$D_8$]THF were stored over molecular sieves under inert atmosphere until needed. Infrared spectra were recorded in the range 2300–1600 $cm^{-1}$ in solution in hexanes, $CH_2Cl_2$, or THF with a FT-IR NEXUS NICOLET spectrometer. $^1H$ and $^{13}C$ NMR spectra were recorded at 0 °C in $CD_2Cl_2$ or [$D_8$]THF with a Bruker AMX-3 300 or Bruker DRX 400 spectrometer. NMR HMQC, HMBC, and COSY spectra were recorded with a Bruker DRX 500. Chemical shifts are reported in $\delta$ units (ppm) downfield from tetramethylsilane. Elemental analyses were performed by the Service Central d'Analyses du CNRS. $Fe(CO)_5$, NaOMe, $CH_3Li$ (1.6 M in diethyl ether), *n*BuLi (1.6 M in hexanes), $CH_2(CO_2C_2H_5)_2$, $CH_2[C(O)CH_3]_2$, $CH_2(CN)_2$, $CH(CH_3)(CO_2C_2H_5)_2$, $CH_2(CO_2C_2H_5)$-$[C(O)CH_3]$, and $CH_2(CO_2C_2H_5)(CN)$ were purchased from commercial sources and used as received. $CH(CH_2CH{=}CH_2)$-$(CO_2C_2H_5)_2$ was prepared as described in the literature[21] by reaction of $ClCH_2CH{=}CH_2$ with $NaCH(CO_2C_2H_5)_2$[21–23] and purified by distillation (b.p. 105 °C, 15 Torr). Complex **1** was obtained as described elsewhere[13] by reaction of $ClC(O)C(O)CH_3$[24] with $[(CO)_4Fe(CO_2CH_3)]^-$.[15]

**General Procedure for the Preparation of Stabilized Carbanions:** These anions were prepared as described in the literature.[21,23] The substrate (1.5 mmol) in solution in THF (5 mL) was added dropwise, over a period of 10 min, to a suspension of NaH (36 mg, 1.5 mmol obtained from a 40% dispersion in mineral oil washed with 5 × 5 mL of hexanes before use) in THF (10 mL) at room temperature. $H_2$ gas evolution was observed. The solution obtained was stirred for 10 min and used without further purification.

**Reaction of $[(CO)_4Fe\{C(O)C(O)CH_3\}(CO_2CH_3)]$ (1) with Carbanions. General Procedure for the Preparation of the Trifunctionalized Anionic Complexes 3:** The carbanion (1.5 mmol; 0.94 mL of a 1.6 M solution of $CH_3Li$ in diethyl ether, 0.6 mL of a 2.5 M solution of *n*BuLi in hexanes, or the solution of the stabilized carbanion prepared as described above) was added, with stirring, to a solution of **1** (450 mg, 1.5 mmol) in THF (30 mL) at –70 °C. As shown by IR monitoring, the reaction was very fast as three new bands were rapidly observed in the ν(CO) region. The temperature was then raised to –10 °C and the solvent evaporated to dryness. The residue was washed with hexanes at –20 °C (3 × 5 mL) to afford a white powder, which was generally found to be insoluble in most organic solvents, with the exception of the complexes obtained with $(CO_2C_2H_5)_2C(R)^-$ (R = H, $CH_3$ or allyl) and $(CO_2C_2H_5)[C(O)$-$CH_3]C(H)^-$, which could be extracted with a hexanes/$CH_2Cl_2$ mixture (75:25) at 0 °C (3 × 30 mL) and recrystallized from this mixture at –40 °C. We were unable to obtain correct analysis of these rather unstable anionic complexes **3**.

**Reaction of 1 with $CH_3Li$:** According to the general procedure for this reaction, **1** (450 mg, 1.5 mmol) was treated with $CH_3Li$ (950 μL of a 1.6 M solution in diethyl ether) to give **3(1)** (385 mg, 80% yield). IR (THF): ν(C≡O) = 2070 (w), 1995 (s), 1970 $cm^{-1}$ (s); ν(C=O) = 1680 (br), 1635 (br), 1605 (br). $^1H$ NMR (400 MHz, [$D_8$]THF, 273 K): $\delta$ = 3.3 (br. s, 3 H, $OCH_3$), 1.1 (br. s, 6 H, $CH_3$) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, THF, 273 K): $\delta$ = 262.3 (C=O), 225.4 [cyclic C(O)O-], 209.7, 208.3, 207.2 and 206.3 [CO and C(O)-O-], 94.3 (cyclic quaternary carbon), 50.3 ($OCH_3$), 15.8 ($CH_3$), 8.4 ppm ($CH_3$).

**Reaction of 1 with *n*BuLi:** The reaction of **1** (1.5 mmol, 450 mg) with *n*BuLi (600 μL of a 2.5 M solution in hexanes) was found to afford white crystals of **3(2)** (270 mg, 50% yield). IR (THF): ν(C≡O) = 2068 (m), 2002 (s), 1982 $cm^{-1}$ (s); ν(C=O) = 1660 (sh), 1636 (m), 1610 (m). $^1H$ NMR (400 MHz, [$D_8$]THF, 273 K): $\delta$ = 3.4 (br. s, 1.5 H, $OCH_3$), 3.2 (br. s, 1.5 H, $OCH_3$), 1.7–0.8 (br. m, 12 H, *n*Bu and $CH_3$) ppm. $^{13}C\{^1H\}$ NMR [400 MHz, THF, 273 K; two isomers (50:50)]: $\delta$ = 274.1, 271.5 (C=O), 229.5, 228.8 [cyclic C(O)O-], 212.5–208.0 [numerous signals for CO and C(O)O], 96.9, 96.7 (cyclic quaternary carbon), 60.5, 59.9 ($OCH_3$), 50.3, 50.1, 38.2, 37.7, 23.1, 22.2 ($CH_2$), 22.5, 22.1, 14.7, 14.5 ppm ($CH_3$).

**Reaction of 1 with $NaC(H)(CO_2C_2H_5)_2$:** Complex **1** (450 mg, 1.5 mmol) was treated at –70 °C with a solution of $NaC(H)$-$(CO_2C_2H_5)_2$ (1.5 mmol, prepared as described above) in THF (10 mL). The product of the reaction, obtained as a white powder, was extracted at –10 °C with a hexanes/$CH_2Cl_2$ (60:40) mixture

(3 × 30 mL) and recrystallized at –40 °C from this solution to give white crystals of **3(3)** (650 mg, 90% yield). IR ($CH_2Cl_2$): ν(C≡O) = 2082 (s), 2022 (s), 2000 $cm^{-1}$ (s); ν(C=O) = 1747 (s), 1624 (s). $^1H$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 4.26 (dq, $J$ = 7, $J'$ = 3 Hz, 1 H, $OCH_2$), 4.09 (dq, $J$ = 7, $J'$ = 3 Hz, 1 H, $OCH_2$), 3.88 (dq, $J$ = 7, $J'$ = 3 Hz, 1 H, $OCH_2$), 3.74 (dq, $J$ = 7, $J'$ = 3 Hz, 1 H, $OCH_2$), 3.74 (s, 1 H, CH), 3.24 (s, 3 H, $OCH_3$), 1.21 (t, $J$ = 7 Hz, 3 H, C$H_3$$CH_2$), 1.09 (t, $J$ = 7 Hz, 3 H, C$H_3$$CH_2$), 1.06 (s, 3 H, C$H_3$C) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 269.3 (C=O), 229.5 [cyclic C(O)O-], 207.1, 206.9, 206.4 and 204.4 [CO and C(O)O], 168.7 (C=O ester),; 167.3 (C=O ester), 92.0 (cyclic quaternary carbon), 62.65 ($OCH_2$), 62.55 ($OCH_2$), 55.25 (CH), 50.9 ($OCH_3$), 21.7 (C$CH_3$), 13.7 ($CH_2CH_3$), 13.6 ($CH_2CH_3$) ppm. The different signals were allocated to each carbon by HMBC and HMQC sequences.

**Reaction of 1 with NaC(H)[C(O)CH$_3$]$_2$:** As described in the general procedure, **1** (450 mg 1.5 mmol) was added at –70 °C to a suspension of NaC(H)[C(O)$CH_3$]$_2$ (1.5 mmol) in THF (10 mL) to give **3(4)** as a white powder (475 mg, 75% yield) that was found to be insoluble in most organic solvents. IR (THF): ν(C≡O) = 2071 (s), 2011 (s), 1985 $cm^{-1}$ (s); ν(C=O) = 1726 (w), 1697 (w), 1651 (s), 1598 (w). $^1H$ NMR (400 MHz, [$D_8$]THF, 273 K): $\delta$ = 3.54 (s, 1 H, CH), 3.39 (s, 3 H, $OCH_3$), 2.20 (s, 3 H, $CCH_3$), 2.06 [s, 6 H, C(O)$CH_3$] ppm. $^{13}C\{^1H\}$ NMR [400 MHz, [$D_8$]THF, 273 K; 2 isomers (70:30)]: $\delta$ = 268.8 (C=O), 267.5 (C=O), 220.9 [cyclic C(O)O], 207.7, 207.1, 206.3, 205.1, 204.6, 203.5, 203.15, 202.6, and 201.6 [CO, C(O)O, and $C$(O)$CH_3$], 94.0 (cyclic quaternary carbon), 69.2 [$C${C(O)$CH_3$}$_2$], 51.85, 50.45 ($OCH_3$), 34.05, 33.88, 33.05,32.05 [C(O)$CH_3$], 21.95, 20.3 ($CH_3$) ppm.

**Reaction of 1 with NaC(H)(C≡N)$_2$:** As described in the general procedure, **1** (450 mg, 1.5 mmol) was added at –70 °C to a solution of NaC(H)(C≡N)$_2$ (1.5 mmol) in THF (10 mL). The yellow powder of **3(5)** which was obtained (375 mg, 65% yield) was insoluble in most organic solvents. IR (THF): ν(C≡N) = 2253 $cm^{-1}$ (w); ν(C≡O) = 2075 (s), 2015 (s), 1987 (s); ν(C=O) = 1658 (s), 1622 (sh), 1601 (sh). $^1H$ NMR [400 MHz, [$D_8$]THF, 273 K; 2 isomers (60:40)]: $\delta$ = 4.98 (s, 0.6 H, CH), 4.61 (s, 0.4 H, CH), 3.34 (s, 1.8 H, $OCH_3$), 3.30 (s, 1.2 H, $OCH_3$), 1.39 (s, 1.8 H, $CH_3$), 1.15 (s, 1.2 H, $CH_3$) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, [$D_8$]THF, 273 K): $\delta$ = 267.6 (C=O), 264.5 (C=O), 220.4, 219.25 [cyclic C(O)O], 208.7, 207.8, 207.35, 207.2, 206.9, 206.65 (CO), 206.2, 205.25 [s, C(O)$OCH_3$], 113.7, 113.45, 112.6, 112.5 (C≡N), 90.5, 88.5 (cyclic quaternary carbon), 51.5, 50.65 ($OCH_3$), 31.1, 30.8 [$C$(C≡N)$_2$], 22.15, 21.0 (C$CH_3$) ppm.

**Reaction of 1 with NaC(H)(CO$_2$CH$_3$)[C(O)CH$_3$]:** Following the general procedure, **1** (450 mg, 1.5 mmol) was allowed to react with a solution of NaC(H)($CO_2CH_3$)[C(O)$CH_3$] (1.5 mmol) in THF (10 mL) at –70 °C to give **3(6)** as a yellow powder (490 mg, 75% yield) after extraction with a 60:40 hexanes/$CH_2Cl_2$ mixture (3 × 15 mL) at 0 °C and crystallization from this mixture at –40 °C. IR ($CH_2Cl_2$): ν(C≡O) = 2071 (s), 2011 (s), 1984 $cm^{-1}$ (s); ν(C=O) = 1744 (s), 1655 (sh), 1621 (s). $^1H$ NMR (400 MHz, $CD_2Cl_2$, 273 K; 4 isomers): $\delta$ = 4.2 (s, 1 H, CH), 3.65 (s, 3 H, $OCH_3$), 3.4 (s, 1.5 H, $OCH_3$), 3.25 (s, 1.5 H, $OCH_3$), 2.3 [s, 1.5 H, C(O)$CH_3$], 2.1 (s, 1.5 H, C(O)$CH_3$], 1.2 (s, 1.5 H, $CCH_3$), 1.1 (s, 1.5 H, $CCH_3$) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, [$D_8$]THF, 273 K): $\delta$ = 268.5, 267.4, 267.1, 267.0 (C=O), 221.9, 221.3, 220.6, 220.4 [cyclic C(O)O], 211.7, 209.6, 208.5, 208.4, 208.3, 208.1, 207.7, 207.2, 207.1, 203.5, 203.3, 202.7, 201.0 [CO, $C$(O)$OCH_3$, and $C$(O)$CH_3$], 169.6, 169.2 (2), 168.7 [organic C(O)$OCH_3$], 93.9, 93.1, 92.6, 92.3 (cyclic quaternary carbon), 62.5, 62.2, 61.9, 61.2 (CH), 52.7, 52.5, 52.2, 50.8 (2), 50.5, 50.3, 49.9 ($OCH_3$), 32.9, 32.7, 32.3, 32.1 [$CH_3$ C(O), 24.1, 23.7, 23.2, 22.9 (C$CH_3$) ppm.

**Reaction of 1 with NaC(H)(CO$_2$C$_2$H$_5$)(C≡N):** Complex **1** (450 mg, 1.5 mmol) was treated with a solution of NaC(H)-($CO_2C_2H_5$)(C≡N) (1.5 mmol) in THF (10 mL) at –70 °C. After evaporation of the solvent, the yellow oily residue was washed with hexanes (3 × 15 mL) at 0 °C to afford **3(7)** as a brown powder (350 mg; 59% yield). IR (THF): ν(C≡N) = 2246 $cm^{-1}$ (w); ν(C≡O) = 2073 (s), 2012 (s), 1987 (s), ν(C=O) = 1749 (m), 1652 (s). $^1H$ NMR (400 MHz, [$D_8$]THF, 273 K): $\delta$ = 4.45 (s, 1 H, CH), 4.10 (m, 2 H, $OCH_2$), 3.30 (s, 3 H, $OCH_3$), 1.10 (m, 3 H, $CH_2CH_3$), 1.05 (s, 3 H, C$CH_3$) ppm.$^{13}C\{^1H\}$ NMR (400 MHz, [$D_8$]THF, 273 K; four isomers): $\delta$ = 267.5, 266.8, 266.5, 266.2 (C=O), 222.5–202.0 [numerous peaks for CO, $C$(O)$OCH_3$, and cyclic $C$(O)O], 167.0, 166.2, 165.5, 164.0 [organic $C$(O)$OC_2H_5$], 118.0, 117.5, 117.3, 116.8 (C≡N), 93.0, 92.5, 91.5, 91.0 (cyclic quaternary carbon), 60–52 (numerous peaks for $OCH_3$ and $OCH_2$), 14–10 (numerous resonances for C$CH_3$ and $CH_2CH_3$) ppm.

**Reaction of 1 with Substituted Malonate Anions NaC(R)(CO$_2$C$_2$H$_5$)$_2$ (R = CH$_3$ or allyl):** Compound **1** (450 mg 1.5 mmol) was treated at –70 °C with NaC(R)($CO_2C_2H_5$)$_2$ [1.5 mmol in solution in THF (10 mL) prepared as described above: 300 mg for R = $CH_3$ or 330 mg for R = allyl]. The product of the reaction, obtained as a white powder, was extracted at 0 °C with a hexanes/$CH_2Cl_2$ (60:30) mixture (3 × 30 mL) but, despite several attempts, we were unable to get crystals from these solutions. The solvent was removed to give 550 mg (R = $CH_3$; 75% yield) or 505 mg (R = allyl; 65% yield) of a white powder which was probably composed of several isomers of **3(8)** (R = $CH_3$) or **3(9)** (R = allyl).

**3(8):** IR ($CH_2Cl_2$): ν(C≡O) = 2084 (s), 2023 (s), 2000 $cm^{-1}$ (s); ν(C=O) = 1721 (s), 1606 (s); (THF): ν(C≡O) = 2069 (s), 2006 (s), 1995 $cm^{-1}$ (s); ν(C=O) = 1735 (s), 1637 (s). $^1H$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 4.20 (br. m, 4 H, $OCH_2$), 3.41 (br. s, 3 H, $OCH_3$), 1.46 (br. s, 3 H, $CH_3$), 1.40 (br. s, 3 H, $CH_3$), 1.23 (br. m, 6 H, $CH_3$) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 262.3, 266.2, 265.8 (C=O), 237.8, 236.3 [cyclic C(O)O], 210.9, 210.6, 209.4, 208.9, 206.3, 205.6, 205.2 [CO and C(O)O], 173.7, 168.2 (C=O ester), 96.3, 96.2, 95.4, 95.0 (cyclic quaternary carbon), 62.9, 62.3, 62.2, 62.1, 59.6, 59.2 ($OCH_2$), 52.0, 51.8, 51.5 [O$CH_3$, $C$($CH_3$)], 22.4, 21.6, 20.2, 19.3, 18.4, 13.9, 13.8 ($CH_3$) ppm.

**3(9):** IR ($CH_2Cl_2$): ν(C≡O) = 2070 (s), 2010 (s), 1983 $cm^{-1}$ (s); ν(C=O) = 1749 (s), 1610 (s). $^1H$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 5.74 (br. m, 1 H, CH allyl), 5.30 (br. m, 2 H, $CH_2$ allyl), 4.16, 4.05 (br. m, 4 H, $OCH_2$), 3.36 (br. s, 3 H, $OCH_3$), 2.61, 2.19 (br. m, 2 H, $CH_2$ allyl), 1.36 (br. s, 3 H, $CH_3$), 1.15 (br. s, 6 H, $CH_3$) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 272 (br., C=O), 237.5 [br., cyclic C(O)O], 210.0, 206.7, 206.3 [br., CO and C(O)O], 171.3, 167.6 (C=O ester), 134.4, 133.8, 132.4 (allylic CH), 119.3, 118.2, 117.3 (allylic $CH_2$), 95.6, 93.9, 92.2 (cyclic quaternary carbon), 64.5 (malonyl quaternary carbon), 62.1, 61.7 ($OCH_2$), 51.6, 51.3 ($OCH_3$), 36.5, 35.3, 34.5 (allylic $CH_2$), 25.5, 22.8 (C$CH_3$), 13.6 ($CH_3$) ppm.

**Reaction of the Anionic Trifunctionalized Metallalactones 3 with HCl. General Procedure for Preparation of Neutral Alkyl-Substituted Lactones 2:** A 1 M solution of HCl in diethyl ether (1 mL) was added to a slurry of anionic lactones **3** (1 mmol) in THF (40 mL) at –70 °C. As shown by IR monitoring of the reaction, the reaction was very fast. After 15 min at this temperature the ν(CO) bands of neutral complexes **2** at 2120, 2070, 2060, and 2040 $cm^{-1}$ were found to have totally replaced those of the starting complexes **3** at 2080, 2020, and 2000 $cm^{-1}$. The temperature was then raised to –10 °C and the solvent removed to dryness. The residue was extracted at –10 °C with a hexanes/$CH_2Cl_2$ (95:5) mixture (5 × 25 mL). This

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

solution was reduced to 10 mL at –40 °C to afford pure crystals of complexes **2**.

**Reaction of 3(1) with HCl: Preparation of 2(1):** Following the general procedure, **3(1)** (385 mg, 1.20 mmol) was treated with HCl (1.2 mL of a 1 M solution in diethyl ether) to afford **2(1)** (219 mg 65% yield). IR (hexanes): ν(C≡O) = 2125 (m), 2073 (sh), 2064 (m), 2042 $cm^{-1}$ (s); ν(C=O) = 1780 (m), 1685 (sh). $^1H$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 1.3 (s, 6 H, $CH_3$) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 254.1 (C=O), 200.2 (2 C, axial C≡O), 198.4, 196.6, 196.3 [CO and cyclic C(O)O], 96.2 (cyclic quaternary carbon), 24.1 ($CH_3$) ppm. $C_9H_6FeO_7$ (281.95): calcd. C 38.33, H 2.14, Fe 19.80; found C 38.21, H 2.12, Fe 19.73.

**Reaction of 3(2) with HCl. Preparation of 2(2):** The reaction of **3(2)** (270 mg, 0.75 mmol) with HCl (750 μL of a 1 M solution in diethyl ether) gave rise to **2(2)** (134 mg, 55% yield). IR (hexanes): ν(C≡O) = 2124 (s), 2072 (sh), 2063 (s), 2041 $cm^{-1}$ (s); ν(C=O) = 1738 (w), 1704 (s). $^1H$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 1.5–1.2 (br. m, 9 H, *n*Bu), 0.85 (br. s, 3 H, $CH_3$) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 254.1 (C=O), 200.5, 200.3, 198.4, 196.6, 196.5 [CO and cyclic C(O)O], 98.4 (cyclic quaternary carbon), 36.9, 26.9, 25.6, 23.0, 21.9 ($CH_2$ and $CH_3$) ppm. $C_{12}H_{12}FeO_7$ (324.03): calcd. C 44.48, H 3.73, Fe 17.23; found C 44.62, H 3.92, Fe 17.15.

**Reaction of 3(3) with HCl. Preparation of 2(3):** Complex **3(3)** (480 mg, 1 mmol) and HCl (1 mL of a 1 M solution in diethyl ether) were reacted to afford **2(3)** (255 mg, 60% yield). IR (hexanes): ν(C≡O) = 2131 (s), 2083 (m), 2064 (s), 2047 $cm^{-1}$ (s); ν(C=O) = 1734 (m), 1689 (s). $^1H$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 4.13 (m, 4 H, $OCH_2$), 3.70 [s, 1 H, C(*H*)$(CO_2C_2H_5)_2$], 1.34 (s, 3 H, CC*H*$_3$), 1.22 (m, 6 H, $CH_2CH_3$) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 251.8 (C=O), 202.0, 199.4, 199.05 (2 C), 196.3 [CO and cyclic C(O)O], 166.3, 166.1 ($CO_2C_2H_5$), 92.6 (cyclic quaternary carbon), 62.2, 62.15 ($OCH_2$), 58.6 (CH), 22.2 (C*C*H$_3$), 13.9, 13.75 ppm ($CH_2CH_3$). $C_{15}H_{14}FeO_{11}$ (426.12): calcd. C 42.28, H 3.31, Fe 13.11; found C 42.46, H 3.35, Fe 13.05.

**Reaction of 3(4) with HCl. Preparation of 2(4):** Complex **3(4)** (1 mmol 420 mg) was reacted at –50 °C with HCl (1 mL of a 1 M solution in diethyl ether) to afford **2(4)** (200 mg, 55% yield). IR (hexanes): ν(C≡O) = 2131 (s), 2085 (m), 2064 (s), 2047 $cm^{-1}$ (s); ν(C=O) = 1720 (sh), 1705 (s), 1690 (sh). $^1H$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 2.15 (s, 3 H, C*C*H$_3$), 2.02 [s, 6 H, C(O)C*H*$_3$] ppm. $^{13}C\{^1H\}$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 251.65 (C=O), 202.1, 201.8, 201.3, 199.3 (2 C), 197.85, 196.2 [CO, cyclic C(O)O and *C*(O)$CH_3$], 92.65 (cyclic quaternary carbon), 74.0 (CH), 31.05, 30.2 [*C*H$_3$C(O)], 22.2 (C*C*H$_3$) ppm. $C_{13}H_{10}FeO_9$ (366.064): calcd. C 42.65, H 2.75, Fe 15.26; found C 42.78, H 2.85, Fe 15.22.

**Reaction of 3(6) with HCl. Preparation of 2(6):** The reaction of **3(6)** (500 mg, 1.15 mmol) with HCl (1.15 mL of a 1 M solution in diethyl ether) at –50 °C was found to afford **2(6)** (285 mg 65% yield). IR (hexanes): ν(C≡O) = 2131 (m), 2085 (m), 2064 (s), 2047 $cm^{-1}$ (s); ν(C=O) = 1755 (w), 1721 (sh), 1703 (m). $^1H$ NMR (400 MHz, $CD_2Cl_2$, 273 K; two isomers: $\delta$ = 3.98 (s, 0.6 H, CH), 3.92 (s, 0.4 H, CH), 3.78 (s, 1.8 H, $OCH_3$), 3.66 (s, 1.2 H, $OCH_3$), 2.25 [s, 1.2 H, C(O)C*H*$_3$], 2.12 [s, 1.8 H, C(O)C*H*$_3$], 1.28 (s, 1.8 H, CC*H*$_3$), 1.25 (s, 1.2 H, CC*H*$_3$) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 251.32, 251.22 (C=O), 202.06, 201.94, 200.72, 200.01, 198.41, 198.31, 198.15, 198.08, 198.02, 196.29 [CO, cyclic C(O)O and *C*(O)$CH_3$], 167.70, 167.18 ($CO_2CH_3$), 92.78, 92.32 (cyclic quaternary carbon), 65.86, 65.35 (CH), 53.30, 53.08 ($OCH_3$), 30.11, 29.42 [C(O)C*H*$_3$], 22.19, 22.15 (C*C*H$_3$) ppm. $C_{13}H_{10}FeO_{10}$ (382.063): calcd. C 40.87, H 2.64, Fe 14.62; found C 41.05, H 2.63, Fe 14.52.

**Reaction of Complexes 3(5) or 3(7) with HCl:** The reactions of these complexes, which contain one or two C≡N groups, with 1 equiv. of HCl was found, even at low temperature (–80 °C), to lead to their decomposition into $Fe(CO)_5$ and organic compounds.

**Reaction of the Mixture of Isomers of 3(8) or 3(9) Bearing Bulky Substituents with HCl. Preparation of 2(8) and 2(9):** The reaction of **3(8)** or **3(9)** [1 mmol, 500 mg for **3(8)** (R = $CH_3$) or 520 mg for **3(9)** (R = allyl)] with HCl (1 mL of a 1 M solution in diethyl ether) at –50 °C afforded **2(8)** (310 mg, 70% yield) or **2(9)** (233 mg, 50% yield), respectively, as white powders after crystallization from hexanes at –40 °C.

**2(8):** IR (hexanes): ν(C≡O) = 2131 (s), 2084 (m), 2052 (m), 2050 $cm^{-1}$ (s); ν(C=O) = 1727 (m), 1695 (s). $^1H$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 4.11 (q, *J* = 7 Hz, 4 H, $OCH_2$), 1.58 (s, 3 H, $CH_3$), 1.44 (s, 3 H, $CH_3$), 1.20 (t, *J* = 7 Hz, 6 H, $CH_2CH_3$) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 249.9 (C=O), 202.6, 199.55 (3 C), 196.35 [CO and cyclic C(O)O], 169.9, 169.4 ($CO_2C_2H_5$), 95.25 (cyclic quaternary carbon), 62.1, 61.8 [quaternary malonic carbon and $OCH_2$ (2 C)]; 20.1 ($CH_3$), 18.95 ($CH_3$), 13.8 [$CH_2CH_3$ (2 C)] ppm. $C_{16}H_{16}FeO_{11}$ (440.143): calcd. C 43.66, H 3.66, Fe 12.67; found C 43.85, H 3.63, Fe 12.62.

**2(9):** IR (hexanes): ν(C≡O) = 2128 (s), 2083 (m), 2059 (m), 2041 $cm^{-1}$ (s); ν(C=O) = 1750 (m). 1737 (m), $^1H$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 5.8 (m, 1 H, =CH), 5.1 (m, 2 H, $=CH_2$), 4.15 (m, 4 H, $OCH_2$), 2.8 (d, *J* = 5 Hz, 2 H, allylic $CH_2$), 1.49 (s, 3 H, $CH_3$), 1.22 (t, *J* = 7 Hz, 6 H, $CH_2CH_3$) ppm. $^{13}C\{^1H\}$ NMR (400 MHz, $CD_2Cl_2$, 273 K): $\delta$ = 249.84 (C=O), 202.75, 198.48, 198.34, 197.98, 196.41 [CO and cyclic C(O)O-], 168.74, 168.70 ($CO_2C_2H_5$), 133.94 (=CH), 118.16 ($=CH_2$), 95.60 (cyclic quaternary carbon), 65.71 (quaternary malonic carbon), 62.19, 62.07 ($OCH_2$), 37.59 (allylic $CH_2$), 19.90 ($CH_3$), 13.94, 13.80 ($CH_2CH_3$) ppm. $C_{18}H_{18}FeO_{11}$ (466.181): calcd. C 46.38, H 3.89, Fe 11.98; found C 46.52, H 3.93, Fe 11.97.

**Reaction of 2(1) (R = R′ = R′′ = H), 2(3) (R = R′ = $CO_2C_2H_5$; R′′ = H), and 2(8) (R = R′ = $CO_2C_2H_5$; R′′ = $CH_3$) with NaOMe. Formation of 3(1), 3(3), and 3(8):** Complex **2** [0.5 mmol; 140 mg of **2(1)**, 210 mg of **2(3)**, or 220 mg of **2(8)**] in solution in THF (30 mL) at 0 °C was added to a suspension of 28 mg of NaOMe in THF. The reaction was monitored by IR spectroscopy. After 90 min the solvent was removed to dryness. The residue of the reaction performed with **2(1)** was washed with $CH_2Cl_2$ (3 × 5 mL) at 0 °C. The residues obtained from **2(3)** and **2(8)** were washed with hexanes (3 × 5 mL) and extracted with a hexanes/$CH_2Cl_2$ (60:40, 3 × 10 mL) mixture and crystallized from this solution at –40 °C. The $^{13}C$ NMR spectra of the obtained products were found to be similar to those of **3(1)**, **3(3)**, and **3(8)**, respectively. These reactions were found to afford 60 mg of **3(1)** (35% yield), 70 mg of **3(3)** (30% yield), or 75 mg of **3(8)** (30% yield).

**X-ray Crystallographic Studies:** Data for compounds **2(1)** and **3(3)** were collected on a Xcalibur 1 diffractometer (Oxford Diffraction) at 150 and 100 K, respectively. The very low stability of compound **3(3)** made a correct X-ray data collection difficult. In this case we had only a few seconds to select a correct single crystal which was very quickly mounted on the goniometer head of the diffractometer at 100 K. After several attempts we succeeded in finding a correct single crystal of **3(3)** suitable for the data collection. Both structures were solved by direct methods and successive Fourier difference syntheses, and were refined by weighted anisotropic full-matrix least-squares methods.[25] The hydrogen atoms of compound **2(1)** were located by difference Fourier techniques and were refined isotropically; while those of compound **3(3)** were calculated [*d*(C–H) = 0.95 Å]; their thermal parameters were taken as $U_{iso}$ = 1.3·$U_{equ}$(C) and therefore included as isotropic fixed contributors to $F_c$. Scattering factors and corrections for anomalous dispersion

## COVER PICTURE

**The cover picture shows** the honeycomb structure formed by π-π stacking of homoleptic octahedral $Ni^{II}$ complexes of the "large-surface" ligand 1,12-diazaperylene (dap), $[Ni(dap)_3](BF_4)_2$ (Ni red, N green, C dark yellow, B blue, F light yellow). The $[Ni(dap)_3]^{2+}$ cation and one of the $BF_4^-$ counterions form parallel nanosized channels (ca. 9.60 Å in diameter), which run along the crystallographic *c* axis and are filled with the other disordered $BF_4^-$ counterion (omitted for clarity). The $C_3$ symmetry of $[Ni(dap)_3]^{2+}$ is a prerequisite for forming the highly symmetrical supramolecular assembly. Details are discussed in the article by H.-J. Holdt et al. on p. 1547 ff.

# Two Novel 5f–3d Bimetallic Cyano-Bridged Complexes

**Lin-Ping Zhang,[a,b] Peter A. Tanner,*[c] and Thomas C. W. Mak[a]**

**Keywords:** Cyano bridge / Transition metal / Uranium / Electronic structure

Bimetallic cyano-bridged uranyl Co and uranyl Fe compounds crystallize in the same space group but are not isomorphous and each comprises two different types of uranyl ion. The spectroscopic consequences with regard to band intensities and positions for the transitions at these different uranyl ion sites are novel and are rationalized.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

There has been considerable interest in 3d–4f bimetallic cyano-bridged complexes due to their catalytic, semiconductive and magnetic properties.[1] Du et al.[2] have listed another 15 applications. Although there have been several reports of 3d–5f complexes,[3] attention has not been directed towards cyano-bridged 3d–5f complexes, so that we decided to synthesize such complexes comprising the uranyl ion, because the electronic structure and spectroscopy of this actinide ion are well-documented.[4] Two novel complexes involving also the coordination of dimethylformamide (dmf) and aqua ligands to $U^{VI}$ are reported herein: $[UO_2(H_2O)_4(dmf)_2]_{0.5}\cdot\{UO_2[M(CN)_6](dmf)_2\}$, M = Co (**1**), Fe (**2**) and their spectroscopic properties have been investigated.

## Results and Discussion

### Crystal Structures

Compound **1** comprises two ionic components (Figure 1, a). The anionic component is a cyano-bridged infinite layer in which the $U^{VI}$ cation is seven-coordinate in a pentagonal-bipyramidal geometry, bonding to two oxygen atoms [U1–O1, 1.727(7) Å, U1–O2, 1.761(7) Å], two dmf molecules [U1–O3, 2.325(6) Å, U1–O4, 2.359(5) Å], and three cyanide groups from different $[Co(CN)_6]^{3-}$ ions [U1–N1, 2.494(6) Å, U1–N2a, 2.499(6) Å, U1–N5b, 2.492(6) Å]. The $Co^{III}$ cation is octahedrally coordinated by six cyanide groups (Co–C, 1.884–1.904 Å), with three of them connecting three different $U^{VI}$ cations. The $U^{VI}$ ions bridge other $[Co(CN)_6]^{3-}$ ions through cyanide groups, forming an infinite two-dimensional anionic layer parallel to the *bc* plane (Figure 2, a). The cationic component comprises discrete centrosymmetric $[UO_2(H_2O)_4(dmf)_2]^{2+}$ cations, situated above and below the anionic layer, each forming O–H···N interactions with it. This $U^{VI}$ cation is eight-coordinate in a hexagonal bipyramidal geometry, being coordinated by

two oxo groups [U2–O5 = U2–O5c, 1.750(7) Å], two dmf molecules [U2–O6 = U2–O6c, 2.27(2) Å], and four aqua ligands [U2–O1W = U2–O1Wc, 2.58(2) Å;U2–O2W = U2–O2Wc, 2.39(2) Å]. The latter form O–H···N hydrogen bonds with the non-bridging cyanide group of the anionic layers, linking them into a three-dimensional network.

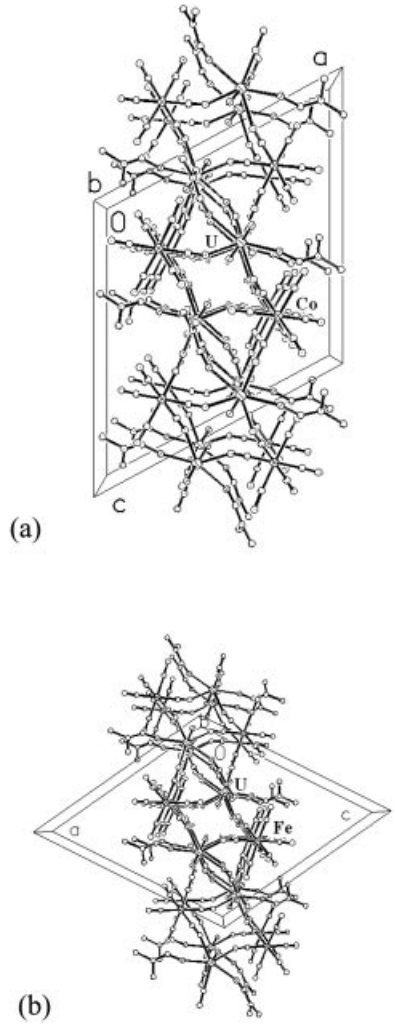

Figure 2. (a) Anionic layer viewed along the [010] direction in **1**; (b) **2**.

Although **1** and **2** both crystallize in the same space group $P2_1/c$ with very similar unit-cell dimensions, they are not isomorphous as the atoms take different positions in the unit cell (see parts a and b in Figure 1). However, compound **2** is isostructural to compound **1** in all respects, and the only difference is that the anionic layer in **2** runs parallel to the plane (1,–1,0), rather than parallel to the *bc* plane as in the case of **1** (see Figure 2, a and b).

### Spectroscopic Properties of 1 and 2

The IR and Raman spectra of **1** and **2** exhibit at least four bands between 2120 and 2180 $cm^{-1}$, corresponding to terminal and bridging CN vibrations, with the energies for **1** being slightly higher than those for **2**, just as in $Cs_2LiM(CN)_6$ (M = Co, Fe).[5] The spectroscopic properties of **1** and **2** are interesting because they each contain uranium atoms in two types of coordination geometry: seven-coordinate U1 situated at a $C_1$ site and eight-coordinate U2 at a $C_i$ site. Besides this, there are two U1 atoms for every U2 atom in the unit cell. Sixfold equatorial coordination of the uranyl ion exhibits rather different spectral characteristics as compared to fivefold, and drastic differences also occur for noncentrosymmetric vs. centrosymmetric uranyl ions.[4] Thus, as well as vibrations due to dmf and aqua ligands in the IR spectrum of **2**, two strong bands due to antisymmetric stretch of the uranyl ion are observed, at 933 and 949 $cm^{-1}$. The higher energy band is associated with sixfold equatorial coordination [c.f. $MUO_2(NO_3)_3$ M = Rb 962 $cm^{-1}$, M = Cs 956 $cm^{-1}$], whereas that at lower energy is due to fivefold coordinated $UO_2^{2+}$ [c.f. $UO_2(H_2PO_2)_2{\cdot}H_2O$ 909 $cm^{-1}$].[4] Also, the relative intensities of the 933, 949 $cm^{-1}$ bands are in the ratio 2:1, being consistent with the atom ratio U1:U2.

The 10-K absorption spectrum of **1** is shown in Figure 3. The lowest energy absorption bands of the uranyl ion correspond to the $\Sigma_g^+ \rightarrow \Pi_g$ ($D_{\infty h}$) electronic transition, and because this involves a large increase in bond length, a strong progression in the totally symmetric uranyl stretching mode, $\nu_s$(OUO) is based upon the electronic origin. Now, for lower than fourfold symmetry of the uranyl ion the final state is not degenerate, and whereas the transition is magnetic dipole-allowed for centrosymmetric uranyl ions, additional electric dipole intensity is present when this is not the case. Finally, it has been found that a blue-shift occurs when the equatorial coordination number increases from 5 to 6.[4] With these facts in mind, the intense bands at lowest energy are marked and assigned to the electronic origins of uranyl ions U1 and U2, with that of the noncentrosymmetric U1 being more intense and at lower energy. The $\nu_s$(OUO) progression frequency based upon the U1 origin (724 $cm^{-1}$) is about 10 $cm^{-1}$ lower than the corresponding one for U2. The resolution of the absorption spectrum does not permit a clear, detailed interpretation but the intense

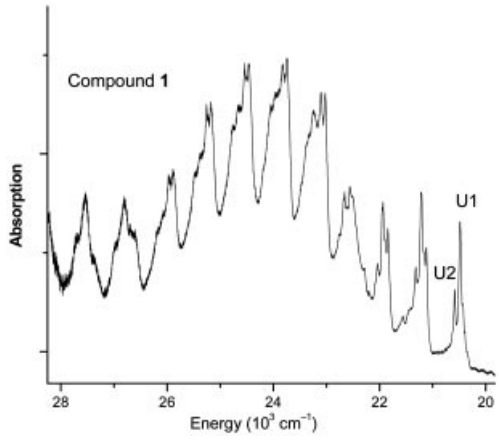

Figure 3. 10-K absorption spectrum of a crystal of **1** between 20000–28000 $cm^{-1}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bands commencing at 23021, 23102 $cm^{-1}$ mark the beginning of a new progression, presumably of U1.

The 10 K luminescence spectrum of **1** is also dominated by the transitions from the lowest energy site U1. The symmetric and antisymmetric OUO stretching frquencies are $857 \pm 5\ cm^{-1}$ and $943\ cm^{-1}$, respectively, and the progressions are observed up to 5 members.

## Conclusions

In summary, two cyano-bridged 3d–5f complexes **1** and **2** have been synthesized with three-dimensional structures comprising uranyl groups arranged in cationic and anionic layers. Although both compounds crystallize in space group $P2_1/c$ with very similar unit-cell dimensions, they are not isomorphous. The electronic absorption and emission spectra of the uranyl ions in **1** are dominated by the uranyl ions of site symmetry $C_1$, which are subjected to less restrictive optical selection rules and more numerous than those of site symmetry $C_i$.

## Experimental Section

**Physical Methods:** Electronic absorption spectra were obtained between 300 and 10 K at the resolution 2 $cm^{-1}$ by a Biorad FTS-60A spectrometer equipped with a photomultiplier tube detector. The sample was placed in an Oxford Instruments closed-cycle cryostat. Emission spectra were recorded at temperatures down to 10 K using a tunable pulsed laser (Panther OPO system pumped by the third harmonic of a Surelite Nd:YAG). The signal was collected at 90° by an 0.5 m Acton monochromator, with gratings blazed at 250 nm (1800 grooves/mm), 500 nm (1200 groove/mm), and 750 nm (600 groove/mm), respectively, and a back-illuminated SpectruMM CCD detector. Infrared and Raman spectra were recorded with a Perkin–Elmer 2000 FTIR spectrometer equipped with a Raman unit.

**Materials and Synthesis of Compounds 1 and 2:** For compound **1**, $UO_2(NO_3)_2{\cdot}6H_2O$ (0.151 g; 0.3 mmol; Strem 99.99%) was dissolved in 10 $cm^3$ water (solution A). Yellow $K_3Co(CN)_6$ (0.067 g; 0.2 mmol; Acros 95%) was dissolved in 10 $cm^3$ dmf, to which solution A was added dropwise with continuous stirring, and the resulting solution was stirred for another 30 min in the dark and filtered. The filtrate was allowed to stand for several weeks in the dark at room temperature for crystallization. Compound **2** was prepared analogously using a molar ratio $UO_2(NO_3)_2{\cdot}6H_2O$: $K_3Fe(CN)_6$ of 3:2. **1:** $C_{15}H_{25}CoN_9O_8U_{1.5}$ (875.41): calcd. C 20.58, H 2.88, N 14.40; found C 20.36, H 1.93, N 14.17. **2:** $C_{15}H_{25}FeN_9O_8U_{1.5}$ (872.34): calcd. C 20.65, H 2.87, N 14.45; found C 20.24, H 1.61, N 14.38. IR of **2** ($cm^{-1}$): $\tilde{\nu}$ = 3339 w ($H_2O$), 2131 sh, 2137 s, 2147 sh, 2157 m CN, 1651 ms (C=O), 949 m, 933 s ($UO_2$ asymm.), 872 vw, 856 vw ($UO_2$ symm.). Raman of **1** ($cm^{-1}$): 2178 s, 2161 m, 2151 m, 2146 sh CN, 862 vs. ($UO_2$ symm.), 2951 m, 1657 vw, 1440 m, 1427 vs, 687 m dmf.

**X-ray Crystallography:** Intensity data of compounds **1** and **2** were collected with a Bruker SMART 1000 CCD diffractometer with graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 293 K. The structures were solved by direct methods and refined by full-matrix least-squares based on $F^2$ using the SHELXTL program package. All the non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were generated geometrically except for those of the water molecules, which were located from the $\Delta F$ maps. The crystallographic data of the complexes **1** and **2** are summarized in Table S1, and selected bond lengths and angles are given in Table S2 (see Supporting Information; for details see the footnote on the first page of this article). Complex **1**, $C_{15}H_{25}CoN_9O_8U_{1.5}$: $P2_1/c$, $a$ = 16.066(2) Å, $b$ = 11.365(1) Å, $c$ = 16.884(2) Å, $\alpha$ = 90°, $\beta$ = 118.323(2)°, $\gamma$ = 90°, $Z$ = 4, $R_1$ = 0.0456. Complex **2**, $C_{15}H_{25}FeN_9O_8U_{1.5}$: $a$ = 16.154(2) Å, $b$ = 11.373(1) Å, $c$ = 16.975(2) Å, $\alpha$ = 90°, $\beta$ = 118.651(2)°, $\gamma$ = 90°, $Z$ = 4, $R_1$ = 0.0441.

CCDC-281906 and -281907 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Crystal data and structure refinement parameters, bond lengths and angles, hydrogen bonds, descriptions of structure; Raman, infrared and emission spectra are available from the authors.

# Supramolecular Assemblies with Honeycomb Structures by π-π Stacking of Octahedral Metal Complexes of 1,12-Diazaperylene

**Stefan Kammer,[a] Holger Müller,[a] Nicolas Grunwald,[a] Anja Bellin,[a] Alexandra Kelling,[a] Uwe Schilde,[a] Wulfhard Mickler,[a] Carsten Dosche,[b] and Hans-Jürgen Holdt*[a]**

**Keywords:** Nickel / Iron / N ligands / π Interactions / Self-assembly

Homoleptic $Ni^{II}$ and $Fe^{II}$ complexes of the "large-surface" phenanthroline-type ligand 1,12-diazaperylene (dap), $[Ni(dap)_3](BF_4)_2$ (**1**) and $[Fe(dap)_3](PF_6)_2$ (**2**), respectively, were synthesized. In the crystal structure the complex cation $[M(dap)_3]^{2+}$ (M = Ni, Fe) exhibits $C_3$ symmetry and interacts with three other cations by π-π stacking. It forms a new metalla-supramolecular assembly with a honeycomb structure containing nanochannels running parallel to the crystallographic *c* axis. Aggregation by π-π stacking between metal complexes of "large-surface" ligands should give new perspectives for inorganic supramolecular chemistry.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

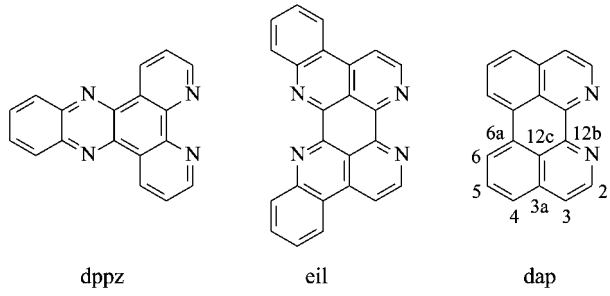
## Introduction

The design and construction of nanoporous supramolecular systems has recently become one of the most active research subjects in modern coordination chemistry.[1] It is well known that weak intermolecular noncovalent interactions such as hydrogen bonds[2] and aromatic π-π stacking interactions[3] play important roles in supramolecular systems. The understanding and utilization of all noncovalent interactions, including π-π stacking, is of fundamental importance for the further development of inorganic supramolecular chemistry and the tuning and prediction of crystal structures.[3c]

In particular, π-π stacking interactions have been reported to exist between metal complexes with aromatic nitrogen-containing ligands, such as bipyridine- and 1,10-phenanthroline-based ligands.

Aggregation by π-π stacking becomes increasingly favorable with an increasing number of arene rings connected to the aromatic nitrogen-containing ligands. Dipyrido[3,2-*a*:2′,3′-*c*]phenazine[4] (dppz), eilatin[5] (eil), and 1,12-diazaperylene[6] (dap) (Scheme 1) are such ligands with increased π-surfaces (called "large-surface" ligands[7]).

In the planar dichloro(dipyridophenazine)platinum(II) complex $[PtCl_2(dppz)]$, both ligand-ligand and platinum-platinum π-π interactions lead to aggregation of this complex in the crystal, forming two infinite stacks with an interplanar distance of about 3.45 Å between the dipyridophenazine moieties.[8] The octahedral mono(eilatin) $Ru^{II}$ and $Os^{II}$ complexes $[M(L–L)_2(eil)]^{2+}$ (M = Ru, Os; L–L = bipyridyl-type ligands) dimerize by π-π stacking between the eilatin moieties in the solid state and in solution.[9] In all solid-state structures a well-defined discrete dimer is observed, in which the eilatin surfaces are about 3.4 Å apart, a typical distance for systems held by π-π stacking interactions.[3c,10]



Scheme 1. "Large-surface" phenanthroline-type ligands.

Homoleptic octahedral complexes with three "large-surface" phenanthroline-type ligands are rare[11] because the steric requirements for coordination at the metal center are greater than those of the parent 1,10-phenanthroline. However, such complexes provide the opportunity for optimal π-π interactions by three "large surface" ligands. They are potential rigid building blocks for the self-assembly into well-defined supramolecular architectures mediated by effective π-π interactions.

Recently Chouai et al. synthesized the $Ru^{II}$ complex of 1,12-diazaperylene, $[Ru(dap)_3](PF_6)_2$.[11a] In the crystal structure the asymmetric unit of $[Ru(dap)_3](PF_6)_2$ contains two $[Ru(dap)_3]^{2+}$ cations which exhibit large distortions

from the expected $D_3$ symmetry. π-π Interactions are observed between two dap ligands between both complex cations of the asymmetric unit. The distance between the two approximately parallel planes that separate the two dap ligands is 3.42 Å. No other π-π interactions are observed. To utilize the π-π interaction opportunities of all three "large surface" ligands of an octahedral metal complex in order to form a supramolecular assembly, a symmetrically octahedral complex is probably necessary.

It is well known that complexes of first row transition metals can show more regular geometries than those of second row transition metals. To investigate the π-π interaction opportunities of first row transition octahedral metal complexes with "large surface" ligands, we synthesized the dap complexes of $Ni^{II}$ and $Fe^{II}$, $[Ni(dap)_3](BF_4)_2$ (**1**) and $[Fe(dap)_3](PF_6)_2$ (**2**), respectively. In the solid state, **1** and **2** form honeycomb structures built by π-π stacking.

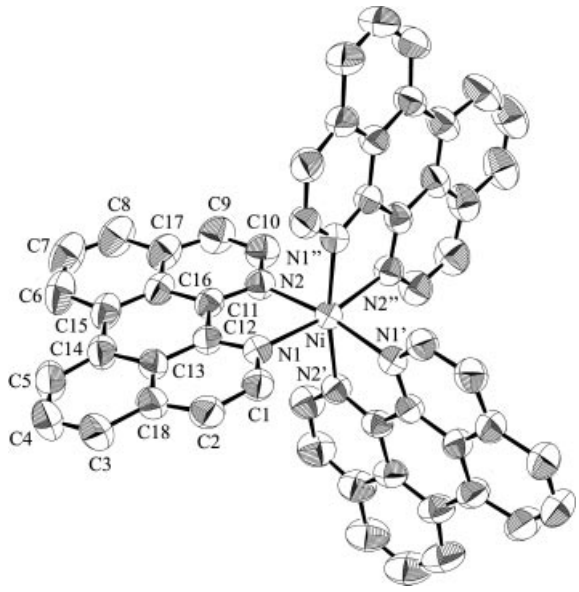

Figure 1. Structure of $[Ni(dap)_3]^{2+}$ in **1** with 50% ellipsoids. Hydrogen atoms have been omitted for clarity.

## Results and Discussion

Homoleptic 1,12-diazaperylene complexes of $Ni^{II}$ and $Fe^{II}$ are best prepared under microwave heating. **1** was synthesized by the reaction of $Ni(BF_4)_2{\cdot}6H_2O$ with dap in ethanol and **2** by the reaction of $Fe(NH_4)_2(SO_4)_2{\cdot}6H_2O$ with dap in water and subsequent addition of $NH_4PF_6$.

Crystals suitable for the X-ray structure determinations were obtained by slow evaporation of a solution of **1** in acetone and by diffusion of ethanol into a solution of **2** in a solvent mixture of acetone, acetonitrile, and chloroform.

In the crystal structure, the complex cation $[Ni(dap)_3]^{2+}$ of **1** exhibits $C_3$ symmetry. Figure 1 shows the structure of the cation along the threefold axis which coincides with the crystallographic *c* axis. The asymmetric unit of $[Ni(dap)_3](BF_4)_2$ (**1**) contains one third of $[Ni(dap)_3]^{2+}$ and also one third of one $B(1)F_4^-$ anion. One of the fluorine atoms of $B(1)F_4^-$ is partially disordered. $[Ni(dap)_3]^{2+}$ and $B(1)F_4^-$ are located alternately along the crystallographic *c* axis.

The bond lengths of Ni–N1 [2.105(2) Å], Ni–N2 [2.109(2) Å] and the bite angle of N1–Ni–N2 [78.54(8)°] are similar to the corresponding values of $[Ni(phen)_3]^{2+}$.[12] The diazaperylene ligand is coplanar to within 0.1617(36) Å. The dap ligands are almost perpendicular to each other, with a dihedral angle of 87.36 °.

Each complex cation $[Ni(dap)_3]^{2+}$ interacts with three other cations by π-π stacking, using all three dap ligands (see Figure 2, a). It forms a honeycomb structure containing channels running parallel to the crystallographic *c* axis (see Figure 2, b). If the van der Waals radii of the atoms are taken into account the resulting channels are approximately 9.60 Å in diameter. The channels contain the second anion, $B(2)F_4^-$, which shows a strong degree of disorder.

The $[Fe(dap)_3](PF_6)_2$ (**2**) compound is isostructural with **1**. The resulting channels in the honeycomb structure of **1** are 0.15 Å greater in diameter (ca. 9.75 Å). The Fe–N bond lengths amount to 1.9826(19) Å and 1.9779(18) Å. The N1–Fe–N2 bite angle is 81.71(7)°. These data are similar to the corresponding values of $[Fe(phen)_3]^{2+}$.[13]

The π-π stacking between two dap ligands of two $[Ni(dap)_3]^{2+}$ moieties in **1** are shown in Figure 3. The distance between the two approximately parallel planes that separate the 1,12-diazaperylene ligands is 3.341 Å (**2**: 3.456 Å). Only one arene ring of each dap is involved in π-π stacking. They interact in an offset or parallel-displaced mode.[3c] The centroid-centroid distance is 3.663 Å (**2**: 3.633 Å) and the displacement angle is 24.2° (**2**: 17.96°).

To the best of our knowledge, supramolecular assemblies with honeycomb structures were not, until now, built by π-π stacking of a metal complex.

In addition to the single-crystal X-ray structure analysis, high resolution transmission electron microscopy (HRTEM) was performed on samples of **2** to further characterize the structure of the compound. Unfortunately, the crystals of **2** were very sensitive to electron-beam-induced damage, even at low temperature (–180 °C).

The nickel(II) complex was found to be paramagnetic, with a value of 2.77 ± 0.02 B.M., as expected for a typical $d^8$ system. The $^1H$ NMR spectrum of complex **2** in $[D_6]$-acetone exhibits five signals, consistent with the expected $D_3$ symmetry of $[Fe(dap)_3]^{2+}$ in solution.

The absorption spectra for complexes **1**, **2**, and dap are illustrated in Figure 4. The free dap resembles perylene, showing a strong well-resolved π-π* transition at 442 nm. This same transition is evident in the $Ni^{II}$ and $Fe^{II}$ complexes, but is shifted to a longer wavelength by 36 and 41 nm, respectively. Moreover, the spectrum of the $Fe^{II}$ complex **2** shows the expected MLCT transition at 684 nm. This value is the lowest-energy absorption for a tris(diimin)-iron(II) complex that has been observed. As already observed for the phenanthroline $Fe^{II}$ complex[14] **2** shows no phosphorescence or CT emission even if cooled to 10 K.

Cyclic voltammetry experiments in $CH_3CN$ revealed that the $Fe^{II}$ complex **2** and the reference complex $[Fe(phen)_3]$-

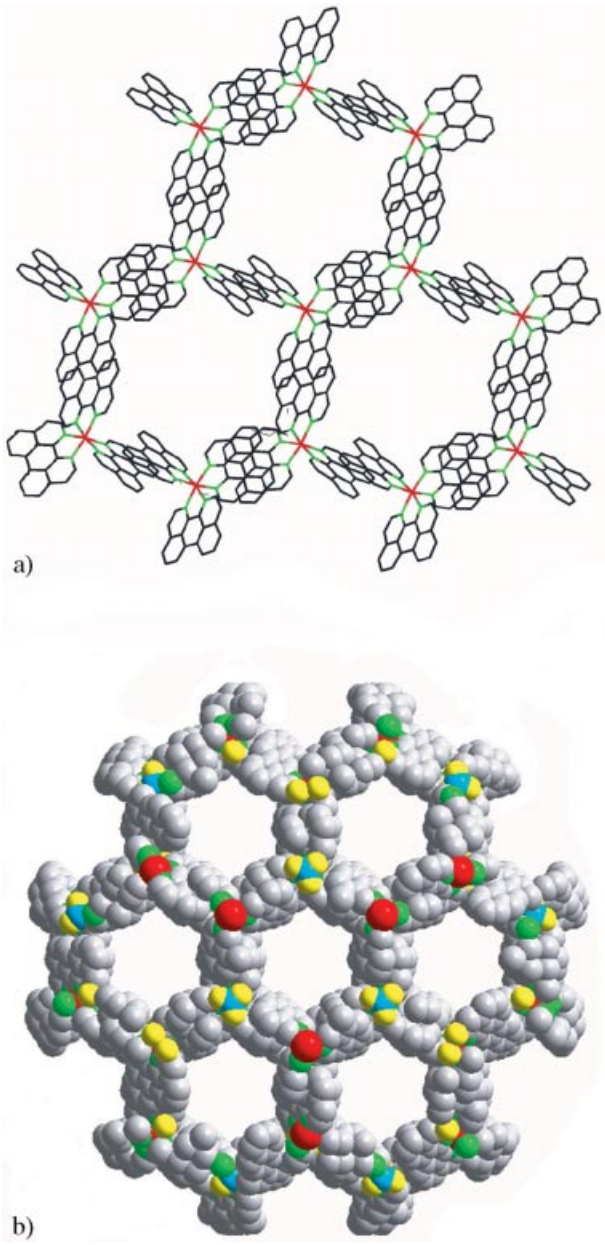

Figure 2. (a) Aggregation by π-π stacking between $[Ni(dap)_3]^{2+}$ moieties in $[Ni(dap)_3](BF_4)_2$ (**1**), viewed along the crystallographic *c* axis. Hydrogen atoms have been omitted for clarity. (b) Honeycomb structural motif in **1** (view down c) as a space-filling representation. $[Ni(dap)_3]^{2+}$ and one $B(1)F_4^-$ ion form parallel nanosized channels, which run along the crystallographic *c* axis and are filled with the second disordered $B(2)F_4^-$ counterion (omitted for clarity). Red: Ni, pink: B, yellow: F, green: N, grey: C.

$(PF_6)_2$ are oxidized at +0,69 V (rev., vs. $Fc/Fc^+$). These metal-centered oxidations indicate that the iron d orbitals are not influenced by complexation with dap as compared with that of phen. The reduction processes for the $Fe^{II}$ complex **2**, as well as the $Ni^{II}$ complex **1**, occur at the same potential (–1.08 V, irr.), probably because reduction is ligand-centered. The $Ni^{II}$ complex **1** is oxidized at 1.34 V (irr.) and $[Ni(phen)_3](BF_4)_2$ at 1.58 V (irr.).

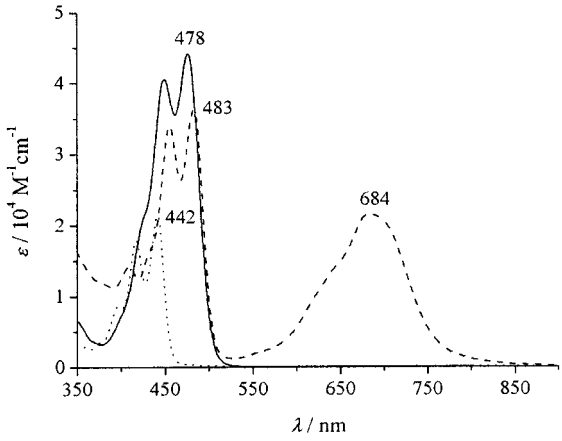

Figure 4. Absorption spectra of the complexes **1** (——) and **2** (– – – –), and of dap (·····), recorded in acetonitrile ($c = 10^{-5}$ mol/L).

## Conclusions

In conclusion, we have shown that homoleptic octahedral metal complexes of 1,12-diazaperylene are able to form supramolecular assemblies with honeycomb structures by π-π stacking when the complex cation, $[M(dap)_3]^{2+}$ (M = Ni, Fe), adopts a $C_3$ symmetry and the anions are $BF_4^-$ or $PF_6^-$. Further studies with other metal complexes of 1,12-diazaperylene and derivatives of dap using π-π stacking for self-assembly are in progress. Aggregation by π-π stacking between metal complexes of "large surface ligands" should give new perspectives for the development of inorganic supramolecular chemistry.

## Experimental Section

**General:** All reactions were carried out in dry solvents under an argon atmosphere. 1,12-Diazaperylene was prepared according to a known procedure.[6] Reference complexes $[Ni(phen)_3](BF_4)_2$ and $[Fe(phen)_3](PF_6)_2$ were synthesized following the methods described for complexes **1** and **2**, respectively. NMR spectra were recorded using an Avance 300 spectrometer. IR spectra were recorded with a Thermo Nicolet NEXUS FTIR instrument. UV/Vis measurements were carried out with an Analytik Jena Specord S 100 spectrophotometer using sealed quartz cuvettes. The ESI spectra were recorded using a Micromass Q-$TOF_{micro}$ mass spectrometer in positive electrospray mode. Elemental analyses (C, H, N) were performed with an Elementar Vario EL elemental analyzer. For phosphorescence emission measurements, the samples were pro-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vided as solids on quartz substrates. The samples were cooled to 10 K with a helium cryostat (Optistat CF, Oxford Instruments, Wiesbaden, Germany). For excitation, 2 mJ pulses from an optical parametric oscillator (VisIR 2/120, GWU, Erfstadt, Germany), which was pumped at 355 nm with a Q-switched Nd-YAG laser (SL 400, GWU), were used. The samples were excited in the ligand π-π* band at 440 nm. Electrochemical measurements were performed with a BAS 100B system using a platinum working and auxiliary electrode, and a $Ag/AgNO_3$ reference electrode. The experiments were conducted using degassed MeCN solutions using 0.1 M [$n$Bu$_4$N$^+$][$PF_6^-$] as the supporting electrolyte, and the Ferrocene/Ferrocinium ($Fc/Fc^+$) couple as a reference. Magnetic studies were performed at room temp. on a vibration sample magnetometer V.S.M. 3001.

**[Ni(dap)$_3$](BF$_4$)$_2$ (1):** A suspension of 1,12-diazaperylene (228.9 mg, 0.9 mmol) in ethanol (3 mL) was added to a solution of $Ni(BF_4)_2 \cdot H_2O$ (102.1 mg, 0.3 mmol) in ethanol (4 mL). The mixture was heated in a CEM-Discover microwave oven for 15 min (temp.: 85 °C, pressure: 17 bar). After cooling the mixture the precipitate was filtered. Dichloromethane (10 mL) and diethyl ether (100 mL) were added to the crude product, the solid was filtered and dried under vacuum to yield an orange powder (245 mg, 0.25 mmol, 82%). M.p. > 360 °C. IR (KBr): $\tilde{\nu}$ = 1051 (s, B–F) $cm^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$) = 478 (42700), 451 (39400), 426 (20300) sh, 352 (6400) sh nm. ESI(HR)-MS: $m/z$ calcd. for $[M - 2BF_4]^{2+}$ ($[C_{54}H_{30}NiN_6]^{2+}$) 410.0942, found 410.0915. $C_{54}H_{30}B_2F_8N_6Ni$ (995.17): C 65.17, H 3.04, N 8.44; found C 64,92, H 3.10, N 8.37.

**[Fe(dap)$_3$](PF$_6$)$_2$ (2):** A suspension of 1,12-diazaperylene (255 mg, 1 mmol) and $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$ (98.04 mg, 0.25 mmol) in water (8 mL) was heated in a CEM-Discover microwave oven for 10 min (temp.: 120 °C, pressure: 15 bar). After cooling the solution, $NH_4PF_6$ (122.3 mg, 0.75 mmol) was added to precipitate **2**. The raw product was filtered and dissolved in acetone (25 mL). The desired product was precipitated by addition of diethyl ether (100 mL), filtered, and dried under vacuum to yield a dark green powder (270 mg, 0.24 mmol, 97%). M.p. > 360 °C. $^1$H NMR (300 MHz, [D$_6$]acetone): $\delta$ = 8.83 (dd, $^3J_{H,H}$ = 7.4, $^4J_{H,H}$ = 0.6 Hz, 2 H, 6-H), 8.09 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, 4-H), 8.01 (t, $^3J_{H,H}$ = 7.4 Hz, 2 H, 5-H] 7.87 (d, $^3J_{H,H}$ = 6.4 Hz, 2 H, 3-H), 7.60 (d, $^3J_{H,H}$ = 6.4 Hz, 2 H, 2-H) ppm. $^{13}$C NMR (300 MHz, [D$_6$]acetone): $\delta$ = 159.2 (C12b), 148.1 (C2), 138.2 (C3a), 135.3 (C5), 131.4 (C6a), 129.9 (C4), 127.6 (C3), 127.3 (C12c), 127.1 (C6) ppm. IR (KBr): $\tilde{\nu}$ = 838 (s, P–F), 558 (m, P–F) $cm^{-1}$. UV/Vis($CH_3CN$): $\lambda_{max}$ ($\varepsilon$) = 684 (21900), 483 (36700), 456 (34400), 433 (16500) sh, 410 (14500), 346 (16900) nm. ESI(HR)-MS: $m/z$ calcd. for $[M - 2PF_6]^{2+}$ ($[C_{54}H_{30}FeN_6]^{2+}$) 409.0940, found 409.0908. $C_{54}H_{30}F_{12}FeN_6P_2$ (1108.65): C 58.50, H 2.73, N 7.58; found C 58.27, H 2.80, N 7.50.

**Crystallographic Data:** Data were collected with a STOE IPDS-2 diffractometer at 210(2) K using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Spherical absorption corrections were applied. Structure solution by direct methods (SHELXS-97)[15] and full-matrix refinement against $F^2$ (SHELXL-97).[16] Non-hydrogen atoms were refined with anisotropic temperature factors.

CCDC-290982 (for **1**) and -290981 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**1:** $C_{54}H_{30}B_2F_8NiN_6$, 995.16 g·mol$^{-1}$, orange prism 0.62 × 0.31 × 0.14 mm, trigonal, $P\bar{3}$, $a = b$ = 18.126(3), $c$ = 11.1481(13) Å, $V$ = 3171.9(7) Å$^3$, $Z$ = 2, $F$(000) = 930, $\rho_{calc}$ = 0.961 g·cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 0.35 mm$^{-1}$, 26875 reflections measured ($2\Theta_{max}$ = 50.0°), of which 3728 were unique ($R_{int}$ = 0.0482). 253 parameters, $wR_2$ = 0.1355, $S$ = 0.974 (all data), $R_1$ [2806 data with $I > 2\sigma(I)$] = 0.0463, max./min. residual electron density: 0.259/–0.185 e·A$^{-3}$. Either of the tetrafluorborate anions, B(1)$F_4^-$, are located on the threefold axis, of which the F atoms are disordered over a mixture of full and partial occupancy sites. The second $BF_4^-$ counterion, B(2)$F_4^-$, is accommodated inside the channel. Because of its strong disordered positions, a suitable refinement model could not be found. Therefore this ion was disregarded by the SQUEEZE instruction of the program PLATON[17] and not accounted for in the final refinement cycles.

**2:** $C_{54}H_{30}F_{12}FeN_6P_2$, 1108.63 g·mol$^{-1}$, green prism 0.6 × 0.35 × 0.32 mm, trigonal, $P\bar{3}$, $a = b$ = 18.3658(14), $c$ = 11.5512(8) Å, $V$ = 3374.2(4) Å$^3$, $Z$ = 2, $F$(000) = 1120, $\rho_{calc}$ = 1.091 g·cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 0.34 mm$^{-1}$, 21742 reflections measured ($2\Theta_{max}$ = 50.0°), of which 3956 were unique ($R_{int}$ = 0.0555). 206 parameters, $wR_2$ = 0.1258, $S$ = 0.898 (all data), $R_1$ [2801 data with $I > 2\sigma(I)$] = 0.0448, max./min. residual electron density: 0.255/–0.214 e·A$^{-3}$. The first $PF_6^-$ counterion, P(1)$F_6^-$, could be found with certainty from the Fourier map, located on the threefold axis. The second counterion, P(2)$F_6^-$, as well as solvent molecules, fill the channels. The extremely diffuse electron density indicates severely disordered occupancies. Because it was not possible to assign atoms, the observed structure factors were corrected by subtracting the electron density in this region using the SQUEEZE instruction of PLATON.

# Peculiarities of the Synthesis of Lithium Ion Conducting Lanthanum Tantalate by Solid-State Reaction and Precipitation from Solutions

**Anatolii Belous,*[a] Oksana Gavrilenko,[a] Olena Pashkova,[a] Cyrille Galven,[b] and Odile Bohnké[b]**

**Keywords:** Tantalates / Solid-state reactions / Precipitation from solution / Microstructure / Ionic conductivity

Synthesis of lithium ion conducting tantalates has been carried out by conventional solid-state reaction (SSR) techniques and by precipitation from solutions (PS). It is shown that the latter chemical route leads to the formation of a pure perovskite phase, made up of nanosized particles, and uses milder conditions when compared with the solid-state reaction technique. Thermal analyses, X-ray powder diffraction (XRD) and infrared (IR) spectroscopy are used to investigate the phase transformations that occur during the preparation of these tantalates from powder precursors. After sintering, the nanosized particles of the powder obtained by the (PS) route are preserved and pellets with good compactness (89 %) are obtained. The electrical properties of the sintered ceramics have been investigated by ac impedance spectroscopy. These experiments showed that the total ionic conductivity (bulk and grain boundaries) of the (PS) pellet is slightly lower than that of the (SSR) pellet. This decrease of conductivity is attributed to an enhancement of the blocking effect of the grain boundaries resulting from the microstructure of the fine-grain ceramics. The bulk conductivity is not affected by the synthetic route.

## Introduction

Much attention is given to the investigation of solid-state lithium ion conductors because of their potential use in electrochemical devices as solid electrolytes, electrodes or ion-selective membranes. The lithium containing lanthanum titanates, which have a defect perovskite structure $(Li_{3x}La_{4/3-x}v_{2/3-2x})Ti_2O_6$ (v = vacancy), have deserved much attention these last years because of their high ionic conductivity of $10^{-3}$ S·cm$^{-1}$ at 300 K.[1–3] Apart from the titanate perovskites, the lithium-containing lanthanum tantalates, which also display a defect perovskite structure $(Li_{3x}La_{2/3-x}v_{4/3-2x})Ta_2O_6$ with a large number of vacancies, show an ionic conductivity of $10^{-4}$ S·cm$^{-1}$ at 300 K, only one order of magnitude smaller than the ionic conductivity of the titanates. The crystallographic structure and transport properties of these tantalates prepared by solid-state reactions have already been studied.[4–8] However, the details and peculiarities of the different chemical reactions and phase transformation occurring during the synthesis of the lanthanum tantalate $(La_{2/3}v_{4/3})Ta_2O_6$ and the lithium-containing lanthanum tantalates $(Li_{3x}La_{2/3-x}v_{4/3-2x})Ta_2O_6$ have never been considered. This is the main purpose of this work. Furthermore, since it is clearly established that the method of synthesis affects the microstructure and consequently the properties of the oxides, we investigated two different methods of synthesis: the precipitation from solution (PS) and the more conventional solid-state reaction (SSR) methods. An advantage of the (PS) method is the possibility to greatly reduce the synthesis temperature and also to produce nanosized particles.[9]

The aim of the present work is then to investigate the phase transformations occurring during the synthesis of lithium-containing lanthanum tantalate $(Li_{3x}La_{2/3-x}v_{4/3-2x})Ta_2O_6$ either by the solid-state reaction (SSR) technique or by precipitation from solution (PS), and to study the effect of the synthetic method on the microstructure and the electrophysical properties of these tantalates.

## Results And Discussion

### Synthesis

#### *Solid-State Reaction (SSR) Method*

According to the results of the XRD analysis, the mixture of the original reagents after a mild homogenisation consists of monoclinic $Li_2CO_3$ (for lithium-containing samples), hexagonal $La(OH)_3$ and orthorhombic $Ta_2O_5$. Figure 1 (a) shows DTA, DTG and TG curves for four mixtures of the original reagents with different lithium contents: $3x = 0$ (curve 1), 0.50 (curve 2), 1.10 (curve 3) and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1.85 (curve 4). The DTG curves display four loss peaks, which are accompanied by endothermic reactions, as shown in the DTA. The first peak at 620–650 K (A), which decreases with $x$ content and disappears in curve 4 when La is almost absent, can be attributed to $La(OH)_3$ dehydration. The second one at 910–990 K (B), which does not appear in curve 1 when Li is absent and that increases with $x$ content, is attributed to $Li_2CO_3$ thermolysis. As the $Li_2CO_3$ content increases (curves 2 to 4), the initial $Li_2CO_3$ decomposition temperature range increases and the decomposition rate increases. For instance, for $(Li_{3x}La_{2/3-x}v_{4/3-2x})Ta_2O_6$ samples at $3x = 0.50$, 1.10 and 1.85, the $Li_2CO_3$ decomposition temperature range becomes wider: from 820–990 K to 770–990 K and finally to 720–990 K, respectively. Finally, the two other peaks, marked as (∗) and (o) on the curves, can be attributed to the partial (700–800 K) and complete (1050–1075 K) $La_2O_2CO_3$ decarbonation. The appearance of lanthanum dioxomonocarbonate has been proved by XRD analysis on samples calcined at 770 K. The complete decomposition temperature of lanthanum dioxomonocarbonate decarbonation in lithium-containing samples shifts towards higher temperatures as compared with the basic $La_{2/3}Ta_2O_6$ sample. This is accounted for by the fact that the thermal decomposition of dioxomonocarbonate slows down in an atmosphere rich in $CO_2$.[10]

Figure 1 (b) shows IR spectra, recorded at room temperature, of raw materials $Ta_2O_5$ (curve 1), $La_2O_3$ (curve 2), $Li_2CO_3$ (curve 3) and of their homogenised mixtures (curves 4–7). The IR spectra of the mixtures (curves 4–7) are characterised by a superposition of absorption bands, which are typical of the spectra of original reagents. However, small shifts can be observed. The stretching vibration band of the CO groups, observed at 1480 $cm^{-1}$ in pure $Li_2CO_3$, shifts slightly towards higher frequencies.[11] Furthermore, the deformation vibration $\delta$ band and stretching vibration $v$ band of Ta–O observed at 355 $cm^{-1}$ and 555 $cm^{-1}$, respectively, in pure $Ta_2O_5$, shift to higher and lower frequencies, respectively. The shifts depend on the Li content ($3x$). For instance, the Ta–O vibration frequencies of samples at $3x = 0$, 0.50, 1.10, 1.85 are observed at 355 and 555 $cm^{-1}$, 368 and 545 $cm^{-1}$, 375 and 525 $cm^{-1}$, 380 and 510 $cm^{-1}$, respectively. From these results, it can be inferred that the system obtained after homogenising milling differs from a simple mixing of the original reagents.

Powder XRD spectra have been recorded at room temperature on powders as a function of composition and firing temperature, in the temperature range from 370 K to 1770 K. The results are summarised in Table 1. From these results, it is evident that during the formation of the lanthanum metatantalate with a defect perovskite structure of the composition $La_{2/3}Ta_2O_6$ ($3x = 0$) the reaction between lanthanum oxide and tantalum oxide begins at 1320 K, and carries on actively at temperatures above 1470 K. According to the XRD spectra analysis, the synthesis proceeds via the formation of intermediate phases: monoclinic lanthanum orthotantalate ($LaTaO_4$), orthorhombic lanthanum heptatantalate ($LaTa_7O_{19}$) and pentatantalate ($LaTa_5O_{14}$).[12] Lanthanum metatantalate as the main phase

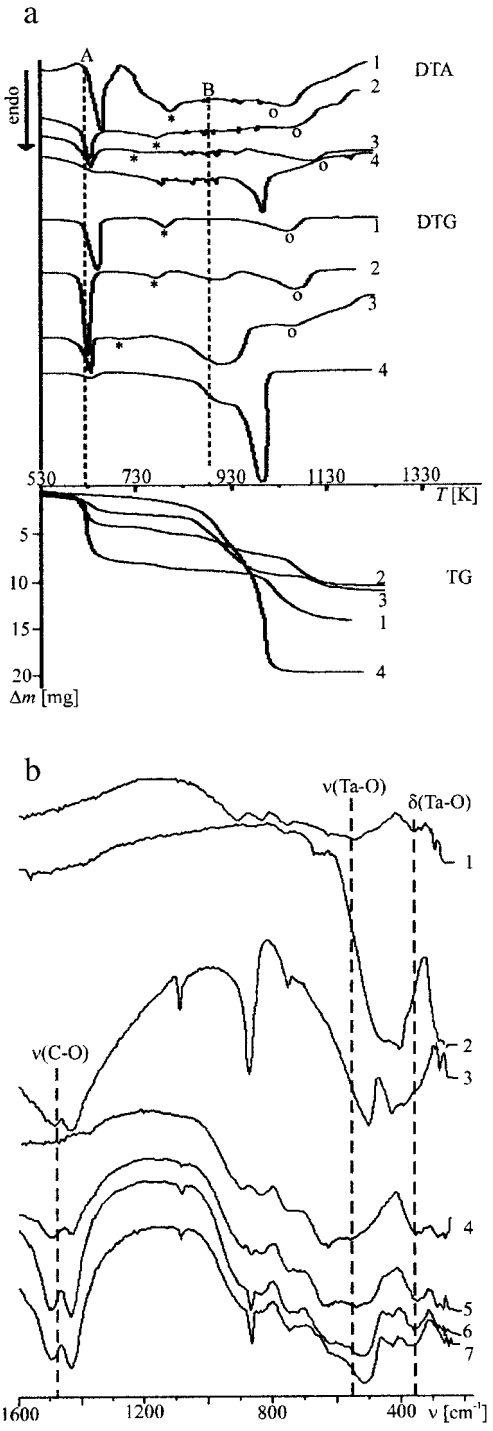

Figure 1. (a) Thermal analyses of the mixture of original reagents, with different lithium contents, for the synthesis by the (SSR) route of $(Li_{3x}La_{2/3-x}v_{4/3-2x})Ta_2O_6$: (1) $3x = 0$, (2) $3x = 0.50$, (3) $3x = 1.10$, (4) $3x = 1.85$. (b) IR spectra, recorded at room temperature, of the original reagents (1) $Ta_2O_5$, (2) $La_2O_3$, (3) $Li_2CO_3$ and of their homogenised mixtures, with different lithium contents, for the synthesis by the (SSR) route of $(Li_{3x}La_{2/3-x}v_{4/3-2x})Ta_2O_6$: (4) $3x = 0$, (5) $3x = 0.50$, (6) $3x = 1.10$, (7) $3x = 1.85$.

was found in the samples calcined at 1570 K. At 1770 K, the yield of the phase with the perovskite structure is 95% (Table 1). It is obvious that a higher temperature is required for the complete reaction of formation of $La_{2/3}Ta_2O_6$ by the

SSR method. According to Portnoi et al. this temperature is 1870 K.[13] On the basis of the analysis of the phase composition and phase ratio as a function of firing temperature (Table 1) and taking into account the literature data,[14,15] the process of formation of lanthanum metatantalate, $La_{2/3}Ta_2O_6$ ($LaTa_3O_9$), with a defect perovskite structure of the tetragonal system, may be represented by Equations (1), (2), (3), (4) and (5).

$$La_2O_3 + Ta_2O_5 \xrightarrow{1320-1570\ K} 2\ LaTaO_4 \quad (1)$$

$$LaTaO_4 + Ta_2O_5 \xrightarrow{1320-1570\ K} LaTa_3O_9 \quad (2)$$

$$LaTa_3O_9 + Ta_2O_5 \xrightarrow{1320-1420\ K} LaTa_5O_{14} \quad (3)$$

For lithium-containing samples $(Li_{3x}La_{2/3-x}v_{4/3-2x})Ta_2O_6$, the primary phase that appears in the process of

$$LaTa_5O_{14} + Ta_2O_5 \underset{1470-1570\ K}{\overset{1320-1420\ K}{\rightleftharpoons}} LaTa_7O_{19} \quad (4)$$

$$LaTa_5O_{14} + LaTaO_4 \xrightarrow{1320-1770\ K} 2\ LaTa_3O_9 \quad (5)$$

heat treatment of a homogenised mixture of original reagents is lithium metatantalate ($LiTaO_3$) of the rhombohedral system, which appears in diffractograms of samples fired at 770 K [Equation (6)].

$$Li_2O + Ta_2O_5 \xrightarrow{770-1320\ K} 2\ LiTaO_3 \quad (6)$$

When the temperature is raised to 1170 K, the amount of $LiTaO_3$ increases and an orthorhombic lanthanum paratantalate ($La_3TaO_7$) phase appears [Equation (7)].

$$3\ La_2O_3 + Ta_2O_5 \xrightarrow{770-1170\ K} 2\ La_3TaO_7 \quad (7)$$

The $La_3TaO_7$ phase transforms into the lanthanum orthotantalate ($LaTaO_4$) for the temperature range 1170–1220 K. During the synthesis of $La_{2/3}Ta_2O_6$ ($3x = 0$), $LaTaO_4$ is formed at 1320 K (Table 1). Therefore, its appearance at a lower temperature (1220 K) in lithium-containing samples is probably due to the decomposition of $La_3TaO_7$ as expressed by Equation (8).[14]

$$La_3TaO_7 \xrightarrow{1170-1220\ K} La_2O_3 + LaTaO_4 \quad (8)$$

At 1220 K, $LiTaO_3$ from Equation (6) as well as $La_2O_3$ and $LaTaO_4$ from Equation (8) can react partially with the remaining $Ta_2O_5$ to form the monoclinic phase of lithium polytantalate $LiTa_3O_8$, $LaTaO_4$ and $LaTa_3O_9$, respectively, according to the following reactions, Equations (9), (10) and (11).

$$LiTaO_3 + Ta_2O_5 \underset{1450-1600\ K}{\overset{1220-1420\ K}{\rightleftharpoons}} LiTa_3O_8 \quad (9)$$

$$La_2O_3 + Ta_2O_5 \xrightarrow{1220-1320\ K} 2\ LaTaO_4 \quad (10)$$

$$LaTaO_4 + Ta_2O_5 \xrightarrow{1220-1570\ K} LaTa_3O_9 \quad (11)$$

At the same time, $LiTaO_3$ and $LaTa_3O_9$ react to form the lithium-containing metatantalates (P) with the perovskite structure.

When the temperature is raised to 1320 K, the $LaTa_5O_{14}$ phase begins to form in addition to the above-mentioned phases [Equation (12)].

$$LaTa_3O_9 + Ta_2O_5 \xrightarrow{1320-1770\ K} LaTa_5O_{14} \quad (12)$$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

This phase can react with $LaTaO_4$ to form $LaTa_3O_9$ [Equation (13)].

$$LaTa_5O_{14} + LaTaO_4 \xrightarrow{1320–1770\ K} 2\ LaTa_3O_9 \quad (13)$$

It should be noted that in the diffractograms of all the samples fired at 1320 K and higher, the diffraction lines typical of the high-temperature modification (F1) of tantalum(v) oxide appear in addition to the lines resulting from the low-temperature modification (F) of $Ta_2O_5$[12] (Figure 2, a). The appearance of a defect-perovskite structure in lithium-containing samples is observed at 1220 K, which is 100 K lower than the initial formation temperature in the synthesis of $La_{2/3}Ta_2O_6$ ($3x = 0$). As generally observed in Ca tantalates[16] or La titanates,[17] the addition of lithium greatly decreases the required synthesis temperature of the perovskite compounds.

Figure 2 (a) shows diffractograms recorded at room temperature in the $2\theta$ range from 20° to 40° of $Li_{0.5}La_{0.5}Ta_2O_6$ ($3x = 0.5$) samples fired at and above 1320 K. As discussed previously, at 1320 K the formation of the perovskite phase (P) can be observed by the appearance of the diffraction line at $2\theta = 32.5°$. All the other phases are present: $Ta_2O_5$ (F and F1), $LiTaO_3$ (B), $LaTaO_4$ (C), the monoclinic form of $LiTa_3O_8$ (G1) and $LaTa_5O_{14}$ (D) in a small amount. As temperature increases, the amount of perovskite (P) increases. The formation of lithium-containing metatantalates (P) is accompanied by a consumption of the phases $Ta_2O_5$ (F1), $LiTaO_3$ (B), $LaTaO_4$ (C) and $LiTa_3O_8$ (G1 and G2). At 1770 K, a $Li_{0.5}La_{0.5}Ta_2O_6$ sample containing 92.3% of the perovskite phase is obtained with 7.7% of the $LaTa_5O_{14}$ phase. It is obvious that the temperature of 1770 K is not sufficient for the completion of the reaction, as in the case of the synthesis of lithium-free lanthanum metatantalate. A higher yield of 96–97% of the perovskite phase (P) can be achieved for higher lithium content ($0.5 < 3x < 1$). As $3x$ increases, the impurity phase observed at 1770 K changes from $LaTa_5O_{14}$ to $LiTaO_3$. This is clearly shown in Figure 2 (b), which shows fragments of diffractograms of $La_{0.3}Li_{1.1}Ta_2O_6$ ($3x = 1.1$) samples fired at 1320, 1570 and 1770 K. The presence of $LaTa_5O_{14}$ as the impurity can be explained by the existence of a partial reaction [Equation (13)] when $3x$ is small. At 1320 K, the formation of the perovskite phase (P) is observed with the presence of all the above-mentioned phases (F), (B) in a greater amount, (C), (G1) and (D). A two-phase sample (perovskite and $LiTaO_3$) is obtained at 1570 K. An increase in the amount of the perovskite phase (P) accompanied by a decrease in the amount of $LiTaO_3$ (B) in the two-phase sample, over the temperature range 1570–1770 K, demonstrates unambiguously that lithium metatantalate ($LiTaO_3$) is involved in the reaction.

The end reaction of lanthanum-lithium metatantalate formation may proceed according to Equation (14).

$$(2/3\text{-}x)\ LaTa_3O_9 + 3x\ LiTaO_3 \xrightarrow{1220–1770\ K} Li_{3x}La_{2/3\text{-}x}Ta_2O_6 \quad (14)$$

Thus, it has been found that the processes of formation of lanthanum metatantalate and lithium-containing lanthanum metatantalate proceed via the formation of the intermediate phases $LaTaO_4$, $LaTa_5O_{14}$, $LaTa_7O_{19}$ and $LiTaO_3$, $LiTa_3O_8$, $LaTaO_4$, $LaTa_3O_9$, $LaTa_5O_{14}$, respectively. This complex multistep mechanism of the formation of $(Li_{3x}La_{2/3-x}v_{4/3-2x})Ta_2O_6$ by the SSR method predetermines the micro heterogeneity of the obtained materials and calls for prolonged soaking at high temperature.

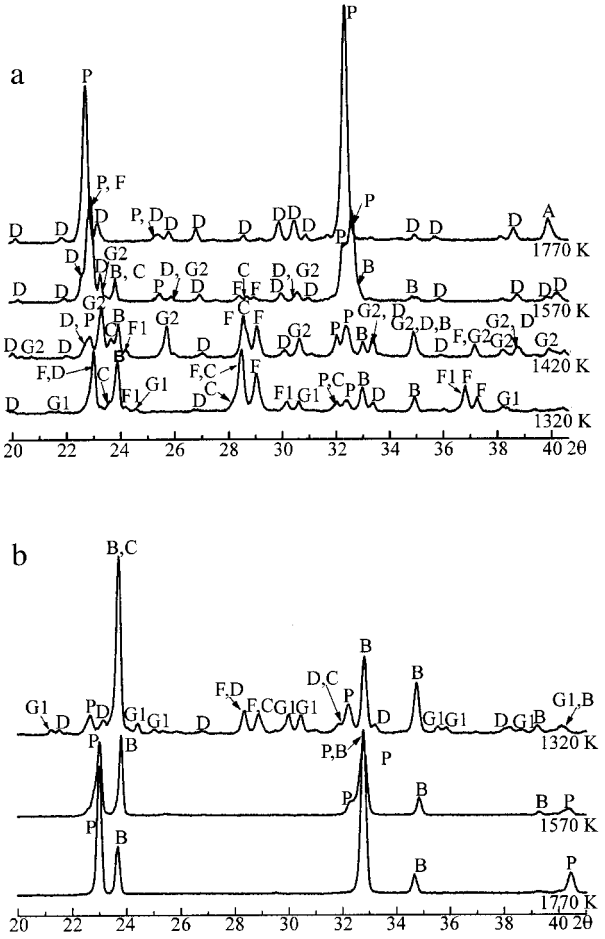

Figure 2. (a) Powder XRD spectra, recorded at room temperature, of $Li_{0.5}La_{0.5}Ta_2O_6$ prepared by the (SSR) technique and fired at different temperatures. P = perovskite, B = $LiTaO_3$, C = $LaTaO_4$, D = $LaTa_5O_{14}$, F = $Ta_2O_5$ (low temperature form), F1 = $Ta_2O_5$ (high temperature form), G1 = $LiTa_3O_8$ (monoclinic), G2 = $LiTa_3O_8$ (orthorhombic). (b) Powder XRD spectra, recorded at room temperature, of $Li_{0.3}La_{1.1}Ta_2O_6$ prepared by the (SSR) technique and fired at different temperatures. P = perovskite, B = $LiTaO_3$, C = $LaTaO_4$, D = $LaTa_5O_{14}$, F = $Ta_2O_5$ (low temperature form), G1 = $LiTa_3O_8$ (monoclinic).

### *Precipitation from Solution (PS) Method*

The results of the thermal investigation (DTA) of lanthanum and tantalum hydroxides and the product of their co-precipitation after addition of a stoichiometric amount of lithium hydroxide $(LLTaO)_{PS}$ are presented in Figure 3 (a). An examination of the heating curves for $(LLTaO)_{PS}$ (curve 3) showed the absence of thermoeffects inherent for individual hydroxides. Therefore it was suggested from thermal analysis that when the (PS) method is used the starting

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

powder of precursors $(LLTaO)_{PS}$ is not a mechanical mixture of hydroxides. The dehydration and decarbonation processes, which are accompanied by endothermic peaks observed in the thermogram of $(LLTaO)_{PS}$, occur until the crystallisation of the mixture and separation of a lithium metatantalate phase takes place (exothermic peak at 920 K) (see part a in Figure 3 and Table 2). In this case, the most intensive decrease in weight, resulting from the loss of $CO_2$ and $H_2O$, is accompanied by a broad endothermic peak with a maximum at 390 K. It should be noted that the $(LLTaO)_{PS}$ dehydration and decarbonation temperatures are lower than those for hydroxides [410 K and 450 K for $La(OH)_3{\cdot}nH_2O$ and $Ta_2O_5{\cdot}nH_2O$, respectively, Figure 3 (a)], which is apparently accounted for by the peculiar nature of the product obtained.

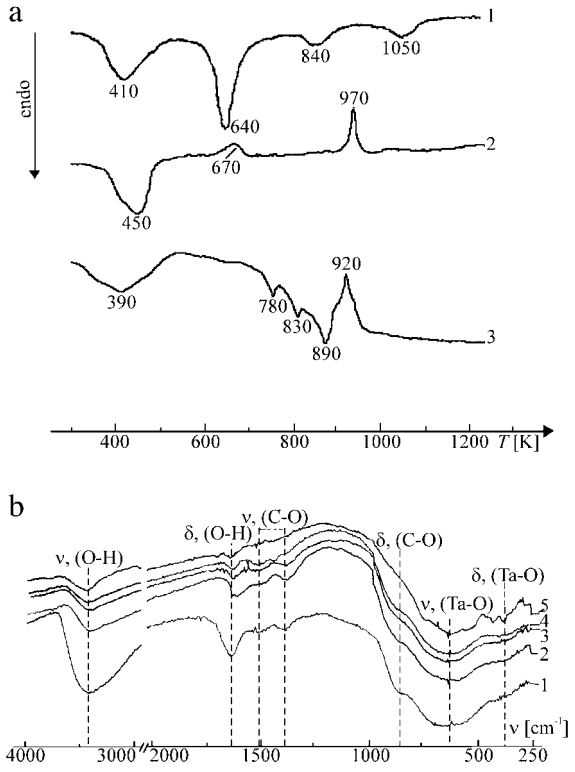

Figure 3. (a) Thermal analyses (DTA) of samples of (1) $La(OH)_3{\cdot}nH_2O$, (2) $Ta_2O_5{\cdot}nH_2O$ and (3) $Li_{0.5}La_{0.5}Ta_2O_6$, prepared by the (PS) route [$(LLTaO)_{PS}$]. (b) IR spectra, recorded at room temperature, of $Li_{0.5}La_{0.5}Ta_2O_6$ prepared by the (PS) route [$(LLTaO)_{PS}$] and fired at different temperatures: (1) 370 K, (2) 470 K, (3) 570 K, (4) 670 K and (5) 1020 K for 1 h.

The results of the IR spectroscopy of $(LLTaO)_{PS}$ over a wide-temperature range indicate the absence of the absorption bands that are characteristic of lanthanum and tantalum hydroxides,[18,19] which confirms the formation of new compounds during precipitation (Figure 3, b). The presence of a broad and intense absorption band with a maximum at 630 $cm^{-1}$, which corresponds to the Ta–O stretching vibration $\nu$ and shifts to 660 $cm^{-1}$ with increasing firing temperature, is typical of the octahedral coordination of Ta atoms and indicates the presence of O–Ta–O bridge bonds of the polymeric type.[20] The band of the Ta–O deformation vibration $\delta$ at 350–380 $cm^{-1}$ is poorly defined at low temperatures (part b of Figure 3, curves 1–4) but is well defined at 1020 K (part b of Figure 3, curve 5), which is the onset temperature for the formation of the defect perovskite structure (Table 2). The IR spectra of $(LLTaO)_{PS}$ are characterised by the presence of intense absorption bands at 3400–3440 $cm^{-1}$ and 1600–1640 $cm^{-1}$, which correspond to stretching and deformation vibrations of $H_2O$ molecules, respectively. Their frequencies depend weakly on the degree of hydration of samples, indicating that the bond energy of $H_2O$ molecules in $(LLTaO)_{PS}$ does not vary (Figure 3, b). The high adsorption power of this system with respect to $CO_2$ is corroborated by the existence of stretching vibrations ($\nu$) of the CO bond, at 1380–1520 $cm^{-1}$, and a shoulder at 850 $cm^{-1}$, which relates to deformation vibrations ($\delta$) of CO groups and undergoes a considerable high-frequency shift (to 930 $cm^{-1}$) in the crystalline sample containing the perovskite phase (part b of Figure 3, curve 5).

Table 2. Phase composition of the $Li_{0.5}La_{0.5}Ta_2O_6$ powder prepared by the (PS) route $(LLTaO)_{PS}$ as a function of firing temperature, $T$ (the firing time is 1 h). The different phases are given in the order of their decreasing amount.

| $T$ [K] | Phase composition |
|---|---|
| 770 | X-ray amorphous state |
| 920 | $LiTaO_3$ |
| | X-ray amorphous phase |
| 1020 | $LiTaO_3$ |
| | perovskite |
| | $LiTa_3O_8$ |
| | X-ray amorphous phase |
| 1070 | $LiTaO_3$ |
| | perovskite |
| | $LiTa_3O_8$ |
| 1120 | perovskite |
| | $LiTaO_3$ |
| | $LiTa_3O_8$ |
| 1170 | perovskite |
| | $LiTaO_3$ |
| | $LiTa_3O_8$ |
| 1270 | perovskite |
| | $LiTaO_3$ |
| 1320 | perovskite |
| | $LiTaO_3$ |
| 1370 | perovskite |
| | $LiTaO_3$ |
| 1570 | perovskite |
| | $LiTaO_3$ |
| 1670 | perovskite |

Thus on the basis of the results of the thermal analysis and IR spectroscopy it was concluded that when the PS method is used, the starting powder of precursors $(LLTaO)_{PS}$ obtained for the synthesis of lithium-containing lanthanum tantalate differs from the mechanical mixture of individual hydroxides and is an aquacomplex-type "inorganic polymer".[18]

The analysis of the XRD patterns of the $(LLTaO)_{PS}$ powders, fired at different temperatures (Figure 4 and Table 2), showed that the crystallization of the mixture, involving the formation of a lithium metatantalate phase, takes place at

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

920 K (Table 2). Several differences can be noted between the two synthetic methods. When the (PS) method is used, (i) the onset temperature of the defect-perovskite phase formation, from $(LLTaO)_{PS}$ powder, is 1020 K, which is 200 K lower than in the case for the synthesis by the SSR method (Table 1), (ii) the perovskite phase becomes predominant at 1120 K, instead of 1570 K for the (SSR) synthesis, (iii) the final firing temperature of the $Li_{0.5}La_{0.5}Ta_2O_6$ powder (1670 K) is decreased by 100 K (Table 1 and Table 2), (iv) the product obtained has a single phase, whereas the sample obtained by the SSR method contains a $LaTa_5O_{14}$ phase in addition to the perovskite (Table 1, Table 2; part a of Figure 2 and Figure 4). The observed considerable increase in the rate of chemical processes, when using the (PS) synthesis method, is because of the larger surface energy of the $(LLTaO)_{PS}$ powder and hence to a greater reactivity of the precursors.

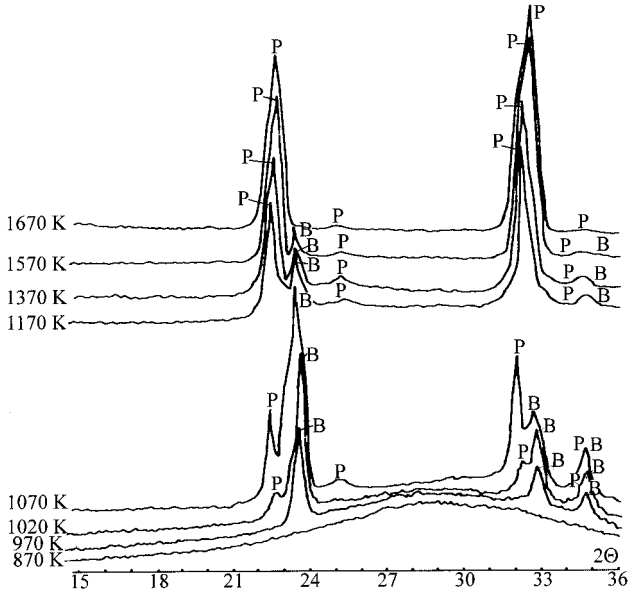

Figure 4. Powder XRD spectra, recorded at room temperature, of $Li_{0.5}La_{0.5}Ta_2O_6$ prepared by the (PS) route ($(LLTaO)_{PS}$) and fired at different temperatures. P = perovskite, B = $LiTaO_3$.

The Fullprof Rietveld analysis of the patterns collected from (SSR)[21] as well as from (PS) sintering samples indicated the formation of the defect-perovskite structure with tetragonal symmetry and the lattice parameters: $a = b = 3.903$ Å, $c = 7.831$ Å, $V = 119.29$ Å$^3$ and $a = b = 3.896$ Å, $c = 7.826$ Å, $V = 118.79$ Å$^3$, respectively.

## Microstructure

Figure 5 (a) shows TEM micrographs of the $(LLTaO)_{PS}$ powders fired at different temperatures for 1 h. In the temperature range corresponding to the amorphous region ($T < 900$ K) particles of about 5 nm in size form aggregates, as shown in Figure 5 (a). In the crystallization region ($970\ K < T < 1570$ K) the particle size increases from 15 nm to 140 nm (Figure 5, a). Part b of Figure 5 shows that the size increases linearly with firing temperature. The dilatometric curve shown in Figure 5 (c) reveals that the sintering process occurs at the same time when the grain growth takes place. Sintering begins at 1300 K leading to the shinkage of the pellet and to its compactness. The highest compactness (89%) has been achieved after a sintering at 1570 K for 2 h. Figure 6 shows a TEM image of a ceramic sintered at 1570 K for 2 h and the corresponding electron diffraction pattern. It confirms the good crystallinity of the sample and the absence of an amorphous phase. The powder is made up of grains of 150–200 nm in size with domains due to the cell-parameter values ($a_p$, $a_p$, $2a_p$).

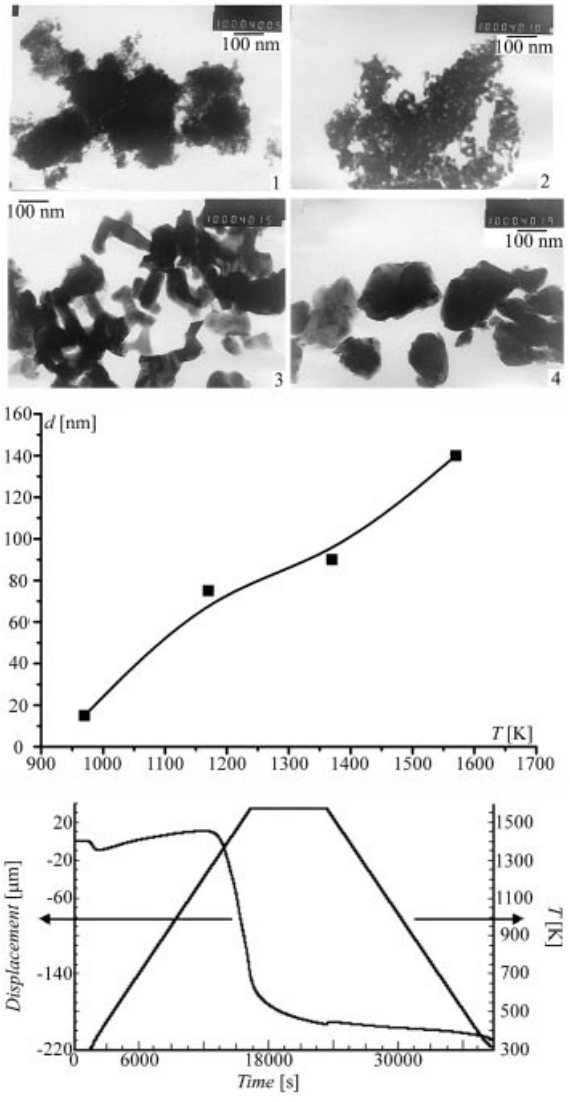

Figure 5. (a) TEM micrographs of the $Li_{0.5}La_{0.5}Ta_2O_6$ powder prepared by the (PS) route [$(LLTaO)_{PS}$)] and fired at different temperatures: (1) 370 K, (2) 970 K, (3) 1170 K, (4) 1570 K for 1 h. (b) Particle average size of the $Li_{0.5}La_{0.5}Ta_2O_6$ powder prepared by the (PS) route [$(LLTaO)_{PS}$] as a function of firing temperatures. (c) Dilatometric curve of a pellet of the $Li_{0.5}La_{0.5}Ta_2O_6$ powder prepared by the (PS) route [$(LLTaO)_{PS}$].

The peculiarities of the precipitation method employed in the synthesis of ceramic materials are known to enable preparation of a mixture of starting reagents at a "molecular level", which facilitates the formation of fine-grained ce-

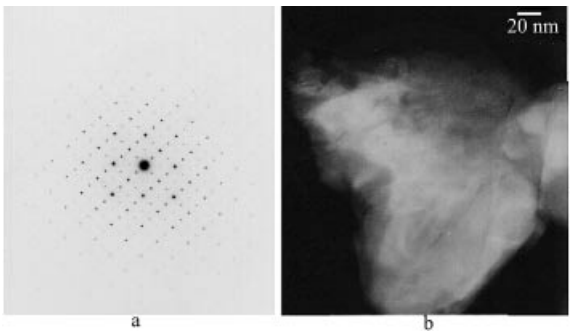

Figure 6. Electron diffraction pattern (a) and the corresponding TEM picture (b) of the $Li_{0.5}La_{0.5}Ta_2O_6$ powder prepared by the (PS) route [$(LLTaO)_{PS}$] fired at 1570 K for 2 h and ground.

ramics. A comparison can be made in Figure 7 that shows the microstructure of $Li_{0.5}La_{0.5}Ta_2O_6$ ceramics obtained by both synthetic methods. Figure 7 (a) shows the microstructure of a ceramic pellet obtained from powders prepared by the (PS) route and sintered at 1570 K for 2 h. It is characterised by a particle size of the order of 200 nm. Figure 7 (b) shows the microstructure of a ceramic pellet obtained by the (SSR) route and sintered at 1770 K for 1 h. A bigger grain size of about 6 μm is observed. Without doubt this result confirms the advantage of the precipitation method to prepare fine-grained ceramics.

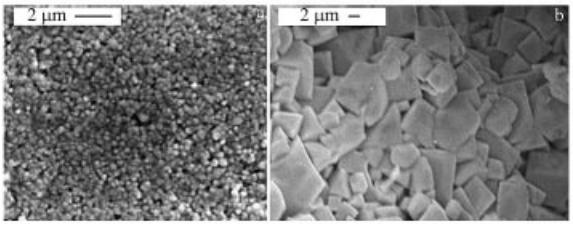

Figure 7. SEM micrographs of a sintered pellet of $Li_{0.5}La_{0.5}Ta_2O_6$ prepared (a) by the (PS) route and fired at 1570 K for 2 h and (b) by the (SSR) route and fired at 1770 K for 1 h.

## Electrical Properties of the Sintered Tantalates

For many electrochemical applications the resistance of the grain boundaries as well as the compactness of the sample are important parameters. The resistance of the grain boundaries generally limits the performance of an electrochemical device. To minimise the resistance of the grain boundaries and to increase the compactness of the pellet, sintering has been performed at 1570 K for 2 h for the pellet prepared by the (PS) method and at 1770 K for 1 h for the pellet prepared by the (SSR) route. It is obvious that such different sintering conditions will lead to different grain boundary properties. The electrical properties of these sintered ceramics have been studied by the impedance spectroscopy technique. Figure 8 shows typical impedance spectra obtained at 300 K under dry $N_2$, for both pellets. In order for comparisons to be made, the real and imaginary parts of the impedance have been normalised according to the geometric factor of the sample (l/s, l = thickness and s = geometric area). The high frequency part of the diagrams ($f > 10$ or 1 kHz) is attributed without doubt to the ionic relaxation in the bulk and the grain boundaries of the oxide. The low frequency part, which appears as a straight line, is attributed to the electrode polarisation. From Figure 8 it can be clearly observed that the total ionic impedance of the PS sample is higher than that for the SSR sample. This overall behaviour is observed for all the temperatures investigated. Figure 9 presents the total ionic conductivity (bulk and grain boundaries) as a function of temperature of sintered samples obtained from either the (SSR) or (PS) route. We attribute the deterioration of the transport properties of the fine-grained sample, prepared by the (PS) method, to an increase of the grain boundary impedance contribution, as previously observed with the 200 nm grain size $Li_{0.30}Ca_{0.35}TaO_3$ synthesised by a polymerised complex route.[20]

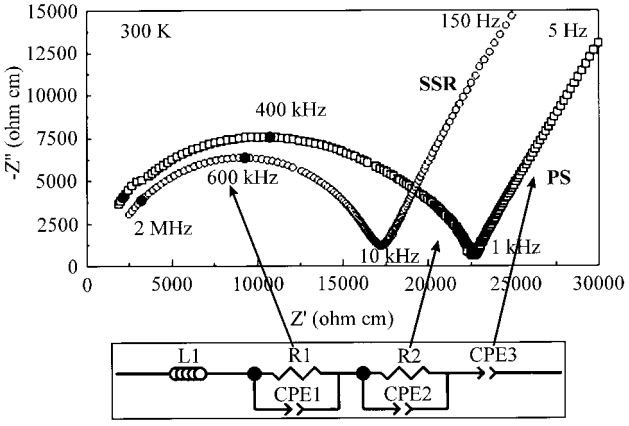

Figure 8. Normalised impedance spectra, recorded at 300 K, of $Li_{0.5}La_{0.5}Ta_2O_6$ prepared by the (PS) route and fired at 1570 K for 2 h and by the (SSR) route and fired at 1770 K for 1 h with the equivalent electrical circuit used for spectra refinement. The normalising factor is the pellet geometric factor (s/l).

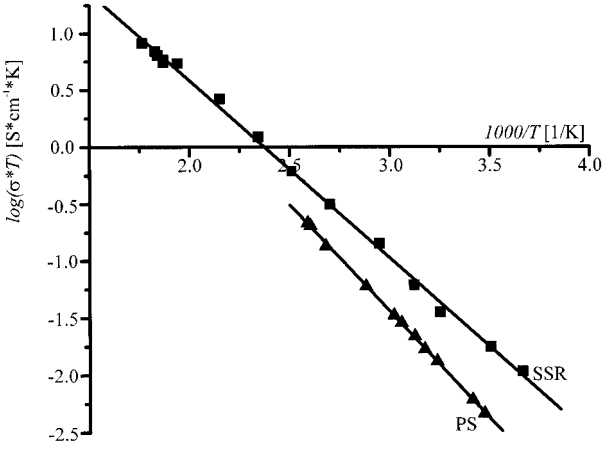

Figure 9. Arrhenius plots of the total ionic conductivity of sintered pellets of $Li_{0.5}La_{0.5}Ta_2O_6$ prepared by the (PS) route and fired at 1570 K for 2 h and by the (SSR) route and fired at 1770 K for 1 h.

In order to evaluate the importance of the grain boundary impedance of the sintered sample obtained by the (PS)

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

method, we performed the analysis of the impedance diagrams by means of an electrical model. Several possible electrical models were used, which were made up of series and parallel circuits. The model shown in Figure 8, below the impedance diagram, is the one which enabled us to fit all the impedance diagrams in the 175 K to 600 K temperature range. The analysis shows that two relaxations are necessary to fit the "semicircle" of the (PS) sample above room temperature, instead of only one for the (SSR) route. The high frequency relaxation is attributed to the ionic motion of $Li^+$ inside the grains and the low frequency relaxation to the ionic motion from grain to grain. The bulk conductivity of the sample is easily determined by using the high-frequency resistance $R_{Hf}$. Figure 10 shows the bulk conductivity, plotted in an Arrhenius fashion for both the (PS) and (SSR) sintered pellets. As found for the titanates,[22] the bulk conductivity is the same for both tantalates confirming that neither the synthesis method nor the grain size influence the nature and consequently the electrical properties of the oxide. On the other hand, the grain boundary resistance varies with the synthetic route. It is negligible when the sample is prepared by the (SSR) route and sintered at 1770 K for 1 h, whereas it becomes important when the sample is prepared by the (PS) route, sintered at 1570 K for 2 h and made up of particles of the order of 200 nm in size. It has to be noted that below room temperature thee relaxations are needed to fit the impedance data of the (PS) sample showing the presence of another electrical barrier that can be attributed to a boundary between the aggregates. The presence of this complex microstructure leads to an increase in the blocking effect and therefore to an increase in the total impedance of the (PS) pellet. This phenomenon has already been observed in $Li_{0.30}Ca_{0.35}TaO_3$[20] and in $Li_{3x}La_{2/3-x}TiO_3$[23] perovskites obtained by the sol-gel route, where both display a microstructure made up of grains and aggregates.

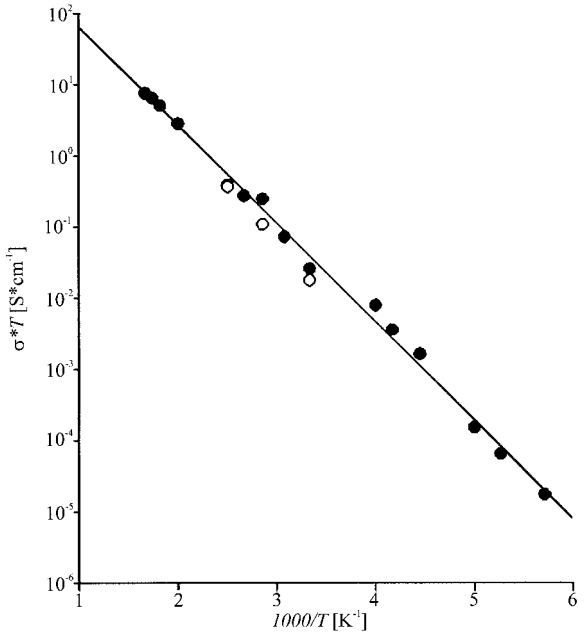

Figure 10. Arrhenius plots of the bulk conductivity of the (PS) ceramic sintered at 1570 K for 2 h (black dots) and of the (SSR) ceramic sintered at 1770 K for 1 h (white dots).

## Conclusion

The peculiarities of the preparation of lithium-containing lanthanum tantalates with a defect-perovskite structure using different synthetic methods have been studied. For the solid-state reaction (SSR) method it has been found that the formation of lanthanum metatantalate and lithium-containing lanthanum metatantalates proceeds via the formation of the intermediate phases $LaTaO_4$, $LaTa_5O_{14}$, $LaTa_7O_{19}$ and $LiTaO_3$, $LiTa_3O_8$, $LaTaO_4$, $LaTa_3O_9$, $LaTa_5O_{14}$, respectively. When using the precipitation from solution (PS) route, it has been shown that the precipitate formed is an aquacomplex of the polymeric type. The specific features of the (PS) method enabled the perovskite-phase formation temperature (1020 K) and the sintering temperature (1570 K) to be reduced by 200 K, as compared with the solid-state reaction method (1220 K and 1770 K, respectively). Furthermore, this chemical route facilitates the formation of fine-grained ceramics, even after sintering ($d \approx 200$ nm). The analysis of the impedance data reveals that the $Li^+$ motion inside the grains is not affected by the synthetic route. However, the complex microstructure of the ceramic obtained by the (PS) route, made up of fine grains and aggregates, leads to an increase of the grain- and aggregate-boundary blocking effect and to a slight decrease of the overall ionic conductivity.

## Experimental Section

Extra pure oxides and carbonates, $La_2O_3$, $Ta_2O_5$ and $Li_2CO_3$, were used as original reagents in the synthesis of $(Li_{3x}La_{2/3-x}v_{4/3-2x})$-$Ta_2O_6$ ($3x$ = 0, 0.50, 0.62, 0.74, 1.10, 1.85) by the SSR method. The synthesis and pellet sintering procedures have been described previously in detail.[7,8]

To synthesize $(Li_{3x}La_{2/3-x}v_{4/3-2x})Ta_2O_6$ ($3x$ = 0.5) by the PS method, alcoholic solutions of extra pure $La(NO_3)_3$ and $TaCl_5$ and aqueous solutions of LiOH and $NH_4OH$ were used. The $NH_4OH$ solution was added, at pH 9, to the mixture of $La(NO_3)_3$ and $TaCl_5$ solutions, taken in a stoichiometric ratio. The obtained precipitate was washed with a 2-propanol/distilled water mixture. The LiOH solution was then added to the precipitate, whilst stirring, and the solvents were evaporated. The obtained powder, hereafter named $(LLTaO)_{PS}$, was subjected to thermal treatment over a temperature range 770–1670 K for 1 h.

Differential thermal analysis (DTA), differential thermal gravimetry (DTG) and thermal gravimetry (TG) were performed with a Q-1000 OD-102 device at a heating rate of 10 K·min$^{-1}$, under dynamic conditions in air, using a Pt crucible. The infrared (IR) spectra were recorded with a Specord-M80 spectrometer over the 200–4000 cm$^{-1}$ frequency range. Samples used for the investigation were prepared as pellets with KBr. Powder X-ray diffraction (XRD) experiments were carried out with a DRON-4-07 diffractometer at room temperature using Cu-$K_\alpha$ radiation (40 kV, 18 mA). The data were recorded using a step-scanning mode in the $2\theta$ range from 10° to

150°, with a step size of 0.02° and an exposure time of 10 s for each point. $SiO_2$ ($2\theta$ standard) and NIST SRM1976-$Al_2O_3$ (certified intensity standard) were used as external standards.[24] The crystal parameters were refined using the Fullprof Rietveld analysis.

Microstructure studies were performed by scanning electron microscopy (SEM) using a JEM 10CX II (JEOL) electron microcope. Transmission Electron Microscopy (TEM) was also performed. Thin specimens for the TEM study were obtained by ultrasonically dispersing particles in ethanol and depositing one drop of the resulting suspension onto a Cu grid covered with a holey carbon film. After drying, the grid was fixed in a side-entry ±30° double-tilt specimen holder and introduced into a JEOL-2010 electron microscope operating at 200 kV.

A dilatometric experiment was performed with a vertical dilatometer (Setsys Evolution 1750 TMA equipment from Setaram). The dilatometer follows the continuous axial shinkage of the studied pellet as a function of temperature. Experiments were carried out in air with a 5 K·min$^{-1}$ sweep rate, from ambient temperature to 1570 K. This constant temperature was maintained for 2 h and then cooling to room temperature was performed at the same sweep rate as above. The probe used was that of an aluminium hemisphere. The density of the sintered pellets was estimated from the mass and the geometric dimensions of the sample. The compactness after sintering was then evaluated from the density, the molar mass and the cell parameters of the compound.

The electrophysical properties of the ceramic samples after sintering were investigated by complex impedance spectroscopy in the frequency range 1–10 MHz using a 1260 Frequency Response Analyzer and a 1296 Dielectric Interface from Solartron. The measurements were performed over the temperature range 135–600 K under vacuum at low temperature in a cryogenerator and under dry $N_2$ above room temperature in an oven (Dataline). We checked that the electrochemical system remains linear up to 1 V (rms), and therefore the applied ac voltage was 400 mV (rms).

The pellets were obtained from powders resulting from either the solid-state reaction or precipitation from the solution. The powders obtained from the (SSR) technique were pressed into pellets and then sintered for 1 h at 1700–1770 K in air. The powder obtained from the (PS) route [$(LLTaO)_{PS}$] was first mixed with an organic binder (Rhodoviol®) to prevent the breaking of the pellet owing to the presence of very fine grains. Pellets were then prepared by first pressing the powder uniaxially at ≈250 MPa and later pressing it isostatically at ≈500 MPa. The pellet was then heated at 670 K for 12 h in air to decompose the organic binder and then sintered for 2 h at 1570 K (with a sweeping rate of 5 K min$^{-1}$). Sputtered Pt films were deposited onto the pellets and used as ion-blocking electrodes in the measurement of the ionic conductivity. The same electrical model as described in ref.[22] was used to determine the bulk conductivity and the grain boundary conductance.

## Acknowledgments

We thank M.-P. Crosnier-Lopez for the help with the TEM micrograph and electron diffraction pattern of Figure 6.

# $Fe_3GeTe_2$ and $Ni_3GeTe_2$ – Two New Layered Transition-Metal Compounds: Crystal Structures, HRTEM Investigations, and Magnetic and Electrical Properties

**Hans-Jörg Deiseroth,*[a] Krasimir Aleksandrov,[a] Christof Reiner,[a] Lorenz Kienle,[b] and Reinhard K. Kremer[b]**

*Dedicated to Prof. Dr. Hanskarl Müller-Buschbaum on the occasion of his 75th birthday*

**Keywords:** Layered compounds / Crystal structures / Iron germanium telluride / Magnetism / Electron microscopy / Conductivity

$Fe_3GeTe_2$ and $Ni_3GeTe_2$ are two new air-stable, black-metallic solids. They were characterized by single-crystal X-ray crystallography, high resolution transmission electron microscopy (HRTEM), and preliminary magnetic measurements. Both compounds crystallize in the hexagonal system [$P6_3/mmc$, $Z = 2$; $Fe_3GeTe_2$: $a = 399.1(1)$ pm, $c = 1633(3)$ pm; $Ni_3GeTe_2$: $a = 391.1(1)$ pm, $c = 1602.0(3)$ pm], and represent a new structure type with a pronounced macroscopic and microscopic layer character. They show close structural relationships to iron/nickel germanium alloys. Each layer in the title compounds represents a sandwich structure with two layers of tellurium atoms covering a triple-layer $Fe_3Ge$ ($Ni_3Ge$) substructure on both sides. Assuming full occupancies for the Fe and Ni sites, a mixed-valence formulation for the transition-metal atoms according to $(M^{2+})(M^{3+})_2(Ge^{4-})(Te^{2-})_2$ (M = Fe, Ni) may be concluded. A slightly reduced occupancy for one Fe/Ni position, however, indicates a more complicated local structural situation. This is confirmed by weak residual electron density in the van der Waals gap and by the results of detailed HRTEM and electron-diffraction experiments for $Ni_3GeTe_2$. The latter results show variations in the arrangement of Ni atoms, as well as vacancies and a misfit of in-plane disordered hexagonal layers. $Fe_3GeTe_2$ shows Curie–Weiss behavior above and ferromagnetism below 230 K, while $Ni_3GeTe_2$ exhibits temperature-independent paramagnetism in the measured temperature range and a metallic behavior of the electrical resistance.

## Introduction

The title compounds represent two unexpected new solids. They were obtained from a series of experiments aimed at the syntheses of new mixed-valence compounds with *transition metals* related to those compounds with *main group elements* investigated in our group.[1,2]

$Fe_3GeTe_2$ is possibly identical to a solid obtained earlier[3] that could not, however, be structurally characterized. $Ni_3GeTe_2$ has not been reported previously. The crystal structures of both compounds exhibit a pronounced layer character with layered $Fe_3Ge$ ($Ni_3Ge$) substructures sandwiched by two layers of Te atoms and a van der Waals gap between adjacent Te layers. The $Fe_3Ge$ and $Ni_3Ge$ substructures are closely related to layered sections of the structures of alloys with the compositions $Fe_{1.67}Ge$[4] and $Ni_{1.67}Ge$.[5] From a general topological viewpoint, a close relationship with respect to the sandwich character is also obvious to a group of layered metal-rich Nb, Ta, and Hf chalcogenides and to $Pd_5AlI_2$ characterized earlier by different authors.[6–9] The latter solid is the earliest example to fit into this group of unconventional layer structures. In all these solids, at least three layers of metal atoms (or mixed-metal and semimetal atoms) are sandwiched between two layers of chalcogen (or halogen) atoms.

For both compounds there seems to be a simple mixed-valence formulation like $M_3GeTe_2 = (M^{2+})(M^{3+})_2(Ge^{4-})(Te^{2-})_2$, which is strongly supported by the crystallographic multiplicity of the respective atomic sites. However, disorder phenomena and structural inhomogeneity, in combination with the general properties of the new solids, make a simple formulation as type 1 mixed-valence solids[10] with clearly distinguishable oxidation states most unlikely, and complicate a concise description of these new compounds.

Here we present information about the preparation conditions and the crystal structures obtained by X-ray single-crystal and powder diffraction studies. Detailed discussions of the real structure based on results from HRTEM and SAED (Selected Area Electron Diffraction) studies of $Ni_3GeTe_2$ are also provided. In addition, preliminary temperature-dependent measurements of the magnetic susceptibility for powder samples of both compounds are presented.

## Results and Discussion

Tables 1, 2, and 3 contain the relevant crystallographic and crystal chemical results for the title compounds.

Table 2. Atomic coordinates, Wyckoff notations, site occupation factors, and equivalent isotropic displacement parameters $U_{eq}$ [$10^4$ pm$^2$] for $Fe_3GeTe_2$ and $Ni_3GeTe_2$ (printed in *italics*). $U_{eq}$ is defined as one-third of the trace of the orthogonalized $U_{ij}$ tensor.

### $Fe_3GeTe_2$

Figure 1 shows a projection of the crystal structure of $Fe_3GeTe_2$, emphasizing that layers of Te atoms sandwich 2D structural sections built from Fe and Ge atoms. The shortest distance $d$(Te–Te) between adjacent layers amounts to 374 pm. In order to illustrate the Fe/Ge substructure in more detail, the three atomic layers consisting of Fe, Fe/Ge, and Fe atoms are projected along [001] in part b of Figure 1. A comparison with structural data given in the literature for $Fe_{1.67}Ge$ (see earlier) reveals that this alloy contains similar hexagonal layers of Fe and Fe/Ge atoms, however, it forms a compact, isotropic 3D structure without any macroscopic layer character. It should be noted that the chemical composition as obtained by refinement of the crystallographic occupational parameters based on single-crystal X-ray data gives $Fe_{2.83}GeTe_2$ instead of $Fe_3GeTe_2$ (Table 2). This minor but significant difference was repeatedly found for different crystals. It stems from an occupational deficiency of the Fe2 site (forming a common layer with Ge), however, it differs from results obtained by analytical scanning electron microscopy for a variety of crys-

Table 3. Selected interatomic distances *d* [pm] for $Fe_3GeTe_2$ and $Ni_3GeTe_2$.

| | | $Fe_3GeTe_2$ | $Ni_3GeTe_2$ |
|---|---|---|---|
| Ge | –Fe2/Ni2 (3×) | 230.42(6) | 225.74(6) |
| | –Fe1/Ni1 (6×) | 263.4(1) | 261.9(1) |
| Fe1/Ni1 | –Fe1/Ni1 | 255.4(4) | 265.6(4) |
| | –Fe2/Ni2 (3×) | 263.4(1) | 261.9(1) |
| | –Ge (3×) | 263.4(1) | 261.9(1) |
| | –Te (3×) | 266.2(1) | 258.5(1) |
| | –Ni3 | – | 267.7(2) |
| Fe2/Ni2 | –Ge (3×) | 230.42(6) | 225.74(6) |
| | –Te (2×) | 261.1(1) | 266.59(7) |
| | –Fe1/Ni1 (6×) | 263.4(1) | 261.9(1) |
| Ni3 | –Te (6×) | – | 266.59(7) |
| | –Ni1 (2×) | – | 267.7(2) |

tals. These strongly support the composition $Fe_3GeTe_2$ for the series of tested crystals. A possible solution for this contradiction assumes a marginal fraction of 0.17 Fe atoms (per formula unit) statistically distributed over atomic positions in the van der Waals gap. This problem is even more pronounced for the corresponding Ni atoms in $Ni_3GeTe_2$, and is therefore discussed together with the character of the coordination polyhedra and further structural details later.

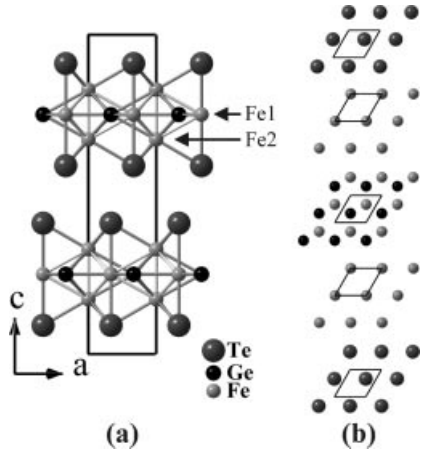

Figure 1. (a) Projection of the crystal structure of $Fe_3GeTe_2$ along [010]. (b) [001] projections of the single Te, Fe, and mixed Fe/Ge layers of the upper layer package.

## $Ni_3GeTe_2$

Figure 2 (a) shows a projection of the crystal structure of $Ni_3GeTe_2$ along [010], which is basically isotypic to $Fe_3GeTe_2$. Even more pronounced than for $Fe_3GeTe_2$, a significant residual electron density in the van der Waals gap is observed in the refinement of the single-crystal X-ray diffraction data. The reliability factor of the refinement significantly improves if we assume partial occupancy (0.25) of the Ni3 site located in the van der Waals gap between adjacent Te layers.

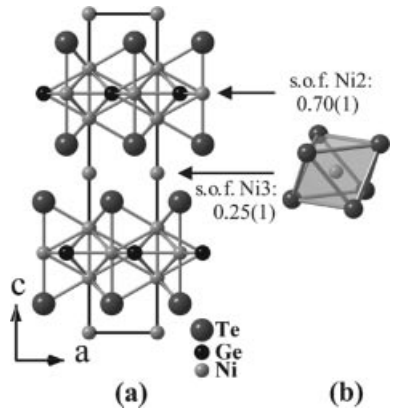

Figure 2. (a) Projection of the crystal structure of $Ni_3GeTe_2$ along [010]. (b) The octahedral coordination polyhedron for Ni3 (this Ni-position is located in the van der Waals gap with an approximate occupancy of 0.25).

In Figure 2 (b), the coordination polyhedron for Ni3 is displayed. It is similar to the coordination polyhedron found, for example, for Ni in $NiTe_2$ ($CdI_2$ type[11]). This Ni3–Te partial structure can be treated as a 2D section of a Ni-deficient $NiTe_2$ structure. Together with the reduced occupancy of Ni2 (Table 2), the occupancy of Ni3 completes the chemical composition to give $(Ni3)_{0.25}(Ni2)_{0.7}(Ni1)_2GeTe_2 = Ni_{2.95}GeTe_2$.

From the inspection of SEM images (Figure 3), it is most likely that the presence of Ni3 in the van der Waals gap causes a stronger cohesion between adjacent layers, and may be responsible for the more compact and less pronounced layer character of the $Ni_3GeTe_2$ sample in comparison with $Fe_3GeTe_2$.

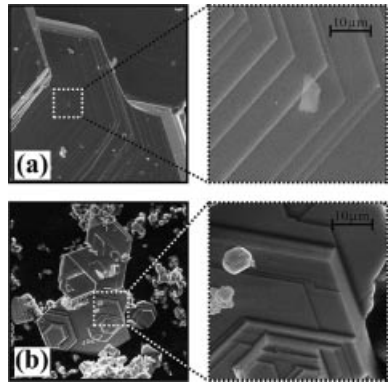

Figure 3. A comparison between SEM images of (a) $Fe_3GeTe_2$ and (b) $Ni_3GeTe_2$ showing the hexagonal platelets which are characteristic for both compounds. The platelets formed by the Ni compound are thicker and more compact.

## Further Crystal Chemical Aspects

The individual coordination polyhedra shown in Figure 4 for $Fe_3GeTe_2$ clearly demonstrate that there is no typical coordination geometry (for example, tetrahedral) around the germanium atoms that would formally allow a +4 oxidation number to be ascribed to the Ge atoms. In-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

stead, the germanium atoms are surrounded by iron atoms exclusively in their first coordination sphere, whereas tellurium atoms are typical constituents of the second coordination sphere [the shortest *d*(Ge–Te) = 348 pm in comparison with the shortest *d*(Ge–Fe) = 230 pm]. On the other hand, both types of iron atoms (Fe1 and Fe2) are coordinated by Ge, Fe, *and* Te atoms in their first coordination sphere (Figure 4), suggesting in particular significant Fe–Fe interactions [the shortest *d*(Fe–Fe) = 255 pm in comparison to *d*(Fe–Fe) = 250 pm in alpha-Fe]. At first glance, these structural details partly seem to support the earlier mentioned simple ionic description of $Fe_3GeTe_2$ as $(Fe^{2+})$-$(Fe^{3+})_2(Ge^{4-})(Te^{2-})_2$.

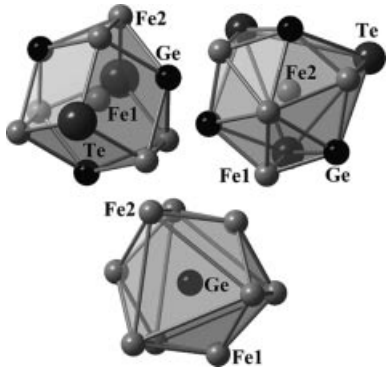

Figure 4. Coordination polyhedra around Fe1, Fe2, and Ge in $Fe_3GeTe_2$.

If we omit the enclosing Te atom layers and the Ni atoms located in the van der Waals gap, we can clearly see from Figure 5 that the Fe/Ge and Ni/Ge atoms form a 2D system of trigonal prisms $GeFe(2)_{6/3}$ interconnected by additional Fe(1) atoms, or alternatively as a system of trigonal prisms $Fe(1)Fe(2)_{6/3}$ interconnected by Ge atoms. The first view is reminiscent of the aspect that the 2D partial structure represented in this way can be interpreted as a stuffed 2D NiAs structure.

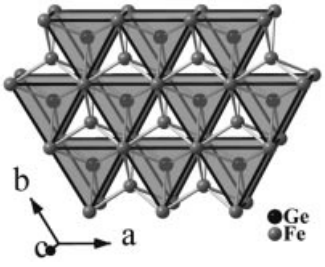

Figure 5. The 2D $Fe_3Ge$ ($Ni_3Ge$) partial structure of $Fe_3GeTe_2$ ($Ni_3GeTe_2$) visualized as a 2D arrangement of trigonal prismatic $GeFe_{6/3}$ units interconnected by Fe atoms or as a 2D system of trigonal prismatic $FeFe_{6/3}$ units interconnected by Ge atoms.

A comparison of $Fe_3GeTe_2$ and $Ni_3GeTe_2$ based on the statements given earlier shows that the most important difference between their crystal structures concerns the partially occupied atomic position Ni3 (0.25 Ni per formula unit) located in the van der Waals gap. In the case of the iron compound this position does not show any significant residual electron density. A supporting argument comes from the experimental observation that $NiTe_2$ crystallizes in the $CdI_2$ structure type[12] with Ni in a similar coordination as Ni3 in $Ni_3GeTe_2$. $FeTe_2$ on the other hand does *not* crystallize in this structure type. Instead, only a marcasite modification of $FeTe_2$ is known.[12] Thus, the crystal structure of $Ni_3GeTe_2$ can actually be treated as an intergrowth species between the two Ni-deficient constituting phases $Ni_xTe_2$ and $Ni_{1-x}Ni_2GeTe_2$ with $x = 0.25$.

In order to clarify the structural situation, it must be mentioned at this point that a completely *ordered* distribution of Ni3 (hypothetical Fe3) would require multiple lengths of *a* and *b* (not *c*). A fully (or partially) *ordered* distribution of Ni3 on the other hand would result in additional (diffuse) superstructure reflections. It was found that more detailed information on this subtle problem could only be derived from HRTEM and SAED investigations with $Ni_3GeTe_2$ (see later), and not from the X-ray structure analyses.

## HRTEM and SAED Investigations of $Ni_3GeTe_2$

Our study was specifically focused on the degree of structural disorder on the nanometer scale, and in particular on the examination of the Ni and Ge atomic disorder. Disorder phenomena resulting from X-ray analyses in many cases have been artificially generated by a superposition of ordered real structure components, like domains or stacks of layers with ordered structure. In fact, some peculiarities of the morphology could be addressed to layered components: see the well-defined microstructure in the bright field images of Figure 6 (part a, zone axis [001] and part b). Electron-diffraction patterns along zone axes [*uv*0] demonstrate that all stacks are strictly parallel to (001). Figure 6 (b) was recorded along zone axis [100], and hence displays the (001) stacks edge on. The lower limit of their thickness is in the range of several nanometers. The stacks separate at the outermost rims of the crystals, while they match perfectly at coherent boundaries in thicker areas. HRTEM proves that the stacks are not significantly shifted to each other; therefore, they are not part of a classical polytypic structure. EDX linescans indicate no noticeable changes in the average composition of adjacent stacks, particularly not of the Ni/Ge ratio. At first glance, SAED patterns (tilting experiments) are in good agreement with patterns simulated on the basis of the average structure. However, closer inspection reveals two kinds of intensities in addition to the main structure reflections. Both phenomena indicate marginal deviations of the real structure from the disordered average structure.

The first one includes weak diffuse rods parallel to [001]* intersecting all positions $^{h}/_{3}{}^{h}/_{3}0$ and $^{2h}/_{3}{}^{2h}/_{3}0$ of the reciprocal space which are equivalent for the hexagonal system. The rods are shown as diffuse lines in patterns containing [001]* (see for instance zone axis [210] in Figure 6, c), while they are cut into intersection points in [001] patterns (Figure 6, d). The diffuse intensity observed in different areas of the same crystallite is variable, as demonstrated by the

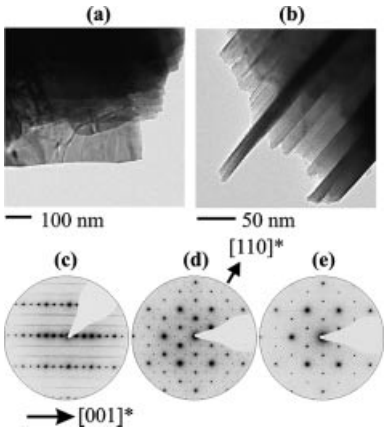

Figure 6. Bright field images of compact crystals, (a) zone axis [001] and (b) zone axis [100]. Electron-diffraction patterns with diffuse intensities, (c) for [210], and intersection points, (d) [001]. Pattern (e) was recorded on another selected area of the same crystal as (d).

existence or absence of intersection points, cf. Figure 6 (parts d and e). In some cases, we observed [001] patterns without any diffuse scattering in the precise zone axis orientation, however, when tilting the diffuse intensities became significant (see later).

Taking into account the high sensitivity of electron-diffraction experiments and the exceptionally weak diffuse intensity observed, the lack of such intensities in X-ray diffraction patterns can be rationalized. It was challenging to image the deviation from the average structure, especially because of the beam sensitivity of the sample under the conditions of HRTEM. However, with selection of low dose modes, we were at least able to record [001] micrographs with significant intersection points in the Fourier transforms. An interpretation of the scattering phenomena in real space is complicated as a result of moiré effects (see later). However, a basic interpretation is straightforward, that is, the existence of diffuse rods in reciprocal space correlates with the evolution of structural order within layers of direct space. For the modeling of such in-plane ordering, ordered arrangements of Ni atoms and vacancies in the Ni and (Ni, Ge) layers were introduced. Additionally, the occupancy factors were fixed to the average values. Prototypes for such ordering can be derived from the structures of (Ni, Ge) intermetallics. Those compounds show related disorder phenomena to those observed for $Ni_3GeTe_2$. A top view of a mixed (Ni, Ge) layer of $Ni_5Ge_3$[13] is characterized by an ordered vacancy distribution (see Figure 7).

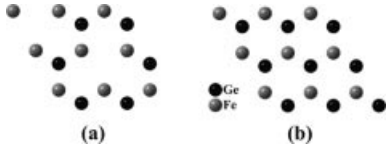

Figure 7. (a) Top view of the ordered (Ni, Ge) layer of $Ni_5Ge_3$. (b) Top view of the disordered (Ni, Ge) layer in $Ni_3GeTe_2$.

The composition of this layer is the same as that of the mixed and disordered (Ni2, Ge) layer in $Ni_3GeTe_2$. The ordered vacancies can be introduced in large supercells, which serve for simulation. The simulated [001] SAED pattern shows, like the experimental patterns, intensities in addition to the main structure reflections on all positions $^{h}/_{3}{}^{h}/_{3}0$ and $^{2h}/_{3}{}^{2h}/_{3}0$. The occurrence of diffuse scattering in the experimental patterns could be interconnected with a nonperiodic sequence of the ordered layers, for example by applying rotations of adjacent layers. In the case of disorder, the intensity distribution within the diffuse rods depends on the degree of structural order within the analyzed area. If the structure appears to be randomly arranged along [001], for instance by assuming equal numbers of ordered layers with 0°, ±60°, and ±120° rotation (rotation axis [001]), we expect no intersection points in the zero-order Laue zone of [001] patterns. However, diffuse intensity should be present in layers slightly above (001)*; hence, the formation of intersection points by tilting slightly from precise [001] zone axis orientation is rationalized. As shown by simulated micrographs, the significance of ordered vacancies in HRTEM micrographs is marginal, in particular for real structures containing a disorder of layers. Therefore, future projects are focusing on HRTEM on long-term annealed samples which may be long-range ordered crystals.

The second type of diffracted intensity, in addition to the main structure reflections, can be assigned to moiré effects based on a misfit of hexagonal layers (see later). In this case, no diffuse intensities were observed as evidence of an in-plane disordered arrangement of Ni atoms and vacancies. Along [001], the misfit produces characteristic patterns of double diffraction (see Figure 8).

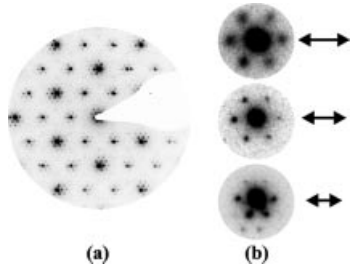

Figure 8. Double diffraction patterns in [001], (a) typical example and (b) enlarged sections of patterns, displaying distinct difference vectors ($\Delta d$, see arrows).

No multiple twinning (triplets) of stacks with a lower symmetry than hexagonal (for example, orthorhombic *C*) is shown. All [001] patterns as well as Fourier transforms of HRTEM images show perfect hexagonal symmetry and no splitting of the main structure reflections. As a rule, a translational moiré effect is observed, which is based on hexagonal layers with parallel orientation of all lattice vectors but with significant variations of the in-plane (*a*) lattice parameter. The changes of the lattice could be interconnected with strain, for example because of in-plane aggregation of Ni atoms on Ni2 and Ni3 positions within adjacent (001) stacks. The lattice mismatch varies from crystal to crystal: see the arrows in Figure 8 (b) which highlight the distinct

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

difference vectors of both lattices. Slight variations of the mismatch are also evident within the same crystallite. The in-plane aggregation could be interconnected with variations in the density of the Ni atoms in consecutive (001) layers containing Ni2 and Ni3 positions. To check for such real structures, the average density of the Ni atoms was split in terms of more or less occupied Ni2 and Ni3 positions within consecutive (001) layers. The significance of such separation in HRTEM micrographs is demonstrated for [100] in Figure 9 (a). The simulations were calculated close to Scherzer defocus. The black contrasts correspond to atoms (high projected potential), and the white contrasts correspond to cavities (low projected potential), with both superimposed in rows along [100]. The black and gray arrows highlight the layers containing Ni2 and Ni3 positions edge on. Starting from a ratio of occupied positions Ni2/Ni3 = 100:0, the average occupation of Ni2 layers was decreased while that of Ni3 was increased in steps of the same value. The series of simulations clearly demonstrates that the significance of HRTEM is limited to full separation which has never been experimentally observed, not even by selection of different focusing conditions (see Figure 9, b). On the contrary, all experimental images are in good agreement with the simulated images based on the average structure. The occupation of the position Ni3, for example, is in accordance to the average structure low, and a separation in layers with full and nonoccupied positions Ni3 can be excluded. Hence, the mismatch must be based on in-plane aggregations of Ni atoms without significant changes to the average occupancy factors.

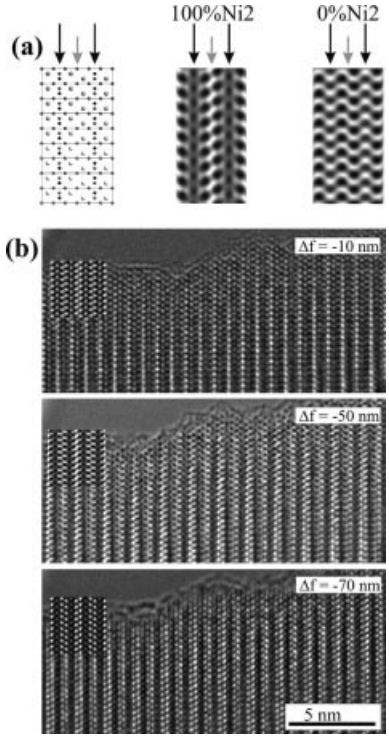

Figure 9. (a) Simulated micrographs for Scherzer defocus (zone axis [100]) with different densities on positions Ni2, Ni3; see text. (b) Defocus series with inserted simulations ([100], thickness: 3.2 nm).

To conclude, the ordering of Ni atoms and vacancies in the real structure is never complete. Two scattering phenomena demonstrate variations in the arrangement of Ni atoms and vacancies. The first one (diffuse intensities) indicates in-plane ordering, while the second one (double diffraction) is characterized by a misfit of in-plane disordered hexagonal layers.

### Magnetism of $Fe_3GeTe_2$ and $Ni_3GeTe_2$ and Electrical Conductivity of $Fe_3GeTe_2$

Preliminary measurements of the temperature dependence of the magnetic susceptibility reveal a spontaneous magnetization below 230 K, indicating ferro- or ferrimagnetic behavior of $Fe_3GeTe_2$ (Figure 10, a). The splitting of the zero-field cooled (zfc) and field-cooled (fc) susceptibility measured in an external field of 0.1 T below about 200 K closes for larger external fields (1 and 5 T). We ascribe the splitting of the fc-zfc susceptibilities to irreversible effects due to domain ordering. The inset in Figure 10a displays the magnetization of $Fe_3GeTe_2$ at 10 K. Saturation is observed for external fields above 5 T with a moment of about 1.2 $\mu_{Bohr}$ per Fe atom, about half of the saturated moment of elementary iron.

$Ni_3GeTe_2$ shows no indication of spontaneous magnetization. Rather, a weak temperature-independent susceptibility is observed above 100 K (Figure 10, b). The increase of the susceptibilities below 50 K can be understood as caused by traces of a paramagnetic impurity, and the field dependence of the susceptibilities as caused by traces of a ferromagnetic impurity.

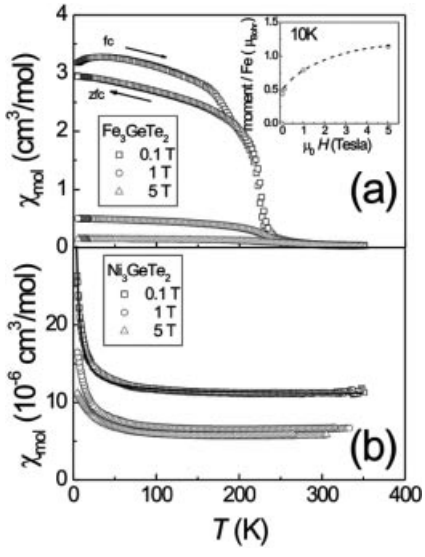

Figure 10. (a) Magnetic susceptibility for $Fe_3GeTe_2$ as a function of temperature and magnetic field. The inset displays the magnetic moment per Fe atom at 10 K. (b) Magnetic susceptibility for $Ni_3GeTe_2$ as a function of temperature and magnetic field. The solid line represents a fit of a modified Curie law (see text) to the susceptibility of $Ni_3GeTe_2$ measured in a field of 0.1 T. The increase in the susceptibility at low temperatures can be ascribed to a temperature-dependent paramagnetic impurity with a concentration of about 0.2% assuming $S = {}^1/_2$ entities with an effective moment of 1.73 $\mu_B$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The observed field dependence of the magnetic susceptibilities follows if the sample ($m$ = 135 mg) is assumed to contain about 400 μg of elementary ferromagnetic Ni (saturation magnetization 0.62 $\mu_{Bohr}$[14]).

The magnitude and temperature dependence of the electrical resistance (Figure 11) prove $Fe_3GeTe_2$ is a metal. The magnetic transition shows up as a kinklike anomaly at about 225 K (see inset in Figure 11) because of spin-flip scattering.

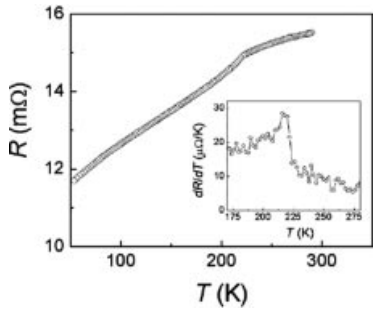

Figure 11. Temperature dependence of the in-plane electrical resistance of a small crystal (approximately $1 \times 1 \times 0.05$ mm$^3$) of $Fe_3GeTe_2$. The inset displays the derivative of the in-plane resistance with respect to temperature. A clear maximum of the derivative is seen at the magnetic ordering temperature.

In order to clarify the earlier mentioned valence problems of iron, more detailed magnetic measurements together with Moessbauer investigations are currently in progress.

## Experimental Section

$Fe_3GeTe_2$ was prepared by a direct solid-state reaction starting from an intimate mixture of the pure elements in the molar ratio 3:1:2 (Fe: 99.9%, powder, Heraeus; Ge: 99.99%, powder 250 μm, Chempur; Te: 99.999%, pieces, Chempur). The mixture of the starting materials was filled into a dry quartz glass ampoule, which was evacuated and sealed, heated up to 625 °C, and kept at this temp. for two weeks. The homogeneous gray, air-stable product did not show any impurities in standard X-ray diagrams, melted incongruently at 837 °C, and formed crystals with the shape of small hexagonal plates suitable for X-ray single-crystal experiments. Polycrystalline $Ni_3GeTe_2$ was prepared in an analogous way (Ni: 99.9%, powder, Heraeus). Bulk material and crystals, viewed under a light microscope, looked very similar to $Fe_3GeTe_2$, and melted incongruently at 879 °C. However, a more compact and less pronounced layer character of small crystals of the nickel compound became obvious in the scanning electron microscope. Standard powder X-ray diagrams for $Ni_3GeTe_2$ did not show any contaminations. Further details of the crystal structure investigation for $Fe_3GeTe_2$ and $Ni_3GeTe_2$ may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository numbers CSD 415616 or CSD 415617, respectively.

For the HRTEM investigations, crystals of $Ni_3GeTe_2$ were crushed and suspended in *n*-butanol (HRTEM measurements of $Fe_3GeTe_2$ were not possible because of unexpectedly emerging ferromagnetism already at ambient temp.). One drop of the *n*-butanol suspension was transferred to a perforated carbon/copper net which served as support of the crystallites after drying. HRTEM and SAED investigations were performed with a Philips CM30ST (300 kV, $LaB_6$ cathode, $C_S$ = 1.15 mm). Computer simulations of the HRTEM images (multislice formalism) and SAED patterns (kinematical approximation) were carried out with the EMS program package[15] (spread of defocus: 70 Å, illumination semiangle: 1.2 mrad). All images were collected with a Multiscan CCD Camera [software Digital Micrograph 3.6.1 (Gatan)]. EDX spectroscopy was performed in the scanning- and nanoprobe mode of CM30ST with a Si/Li-EDX detector (Noran, Vantage System).

Magnetic measurements for both compounds were carried out with the SQUID magnetometer (MPMS, Quantum Design, Dan Diego, USA) of the Max-Planck-Institut für Festkörperforschung (Stuttgart). The in-plane electrical resistance of $Fe_3GeTe_2$ was measured on a platelet-shaped crystal with dimensions $\approx 1 \times 1 \times 0.05$ mm$^3$ in the temp. range 50–300 K. Electrical contacts were made by four parallel Cr/Au stripe contacts which had been evaporated on a (110) face of the crystal.

## Acknowledgments

The authors would like to thank Mrs. V. Duppel for practical TEM work and Prof. Dr. Dr. h. c. mult. A. Simon for enabling the TEM experiments. The authors are grateful to the "Deutsche Forschungsgemeinschaft" and the "Fonds der Chemischen Industrie" for their financial support.

# Aminoethyl-Functionalized Cyclopentadienyliridium Complexes: Photochemical C–H Activation and Carbonylation of Cycloalkanes

**Pek Ke Chan,[a] Weng Kee Leong,*[a] Karl I. Krummel,[b] and Marc V. Garland*[b]**

**Keywords:** Carbonylation / C–H activation / Cyclopentadienyl ligands / Iridium / Photochemistry

The photochemical C–H activation of cycloalkanes by aminoethyl-functionalized cyclopentadienyliridium complexes proceeds in a broadly similar way to that for their unfunctionalized analogues. In a carbon monoxide atmosphere, there is evidence that carbonylation to form the carboxaldehyde occurred with both systems. In situ infrared spectroscopic studies on these reactions allow the identification of several species present in low concentrations in the reaction mixture. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

UV initiated photodissociation of CO or $H_2$ from group-9 organometallic compounds of the type [CpMLL′] or [Cp*MLL′] (M = Ir, Rh; L = CO, $PMe_3$; L′ = CO, $H_2$) have been known to generate intermediates that are capable of activating the otherwise inert C–H bonds in hydrocarbon solvents.[1] This has stimulated much interest due to the plentiful supply of alkanes and the potential of using alkanes as chemical feedstocks for catalytic syntheses of organic molecules. Over the last two decades there have been several studies on the mechanism, kinetics, and thermodynamics of this activation process in solution, the gas phase, low-temperature matrices, and liquid noble gases.[1d,2] For $[Cp^XM(CO)_2]$ ($Cp^X$ = Cp or Cp*; M = Ir or Rh), spectroscopic measurements have shown that the primary photoproduct is a coordinatively unsaturated 16-electron species $[Cp^XM(CO)]$ obtained by dissociation of a CO ligand. This species is extremely reactive and forms a solvent adduct complex $[Cp^XM(CO)\cdots S]$ before undergoing C–H activation to give the hydridoalkyl species $[Cp^XM(CO)(R)(H)]$.[2b,3]

Many functionalized cyclopentadienyl ligands containing side-chain donor groups (OR, NRR′, PRR′, $CH{=}CH_2$) are beginning to appear in the literature. In particular, we were interested in aminoethyl-functionalized cyclopentadienyl ligands because of their "hard-soft" combination of electron donors; the cyclopentadienyl ligand is known to stabilize transition metals in high as well as low oxidation states whereas the amino group favors coordination to metals in high oxidation states. Only weak interactions are anticipated to metals in low oxidation states, although these may be strengthened by the chelate effect.[4] As a result, aminoethyl-functionalized cyclopentadienyl ligands may be expected to behave as hemilabile ligands; under the conditions for the activation of hydrocarbons, the nitrogen donor on the side-arm of the aminoethyl-functionalized cyclopentadienyliridium complex may coordinate to the iridium center. This reversible coordination to a reactive metal center is of general interest in catalysis as it may stabilize a highly reactive, electronically and sterically unsaturated intermediate by weakly occupying the vacant coordination site until the actual substrate coordinates and replaces the amino group.[5] In this paper, we present the results of our study on the photolysis of $[Cp^*Ir(CO)_2]$ (**1b**), as well as its aminoethyl-functionalized analogue, in vacuo or under an argon or carbon monoxide atmosphere.

## Results and Discussion

The aminoethyl-functionalized cyclopentadienyliridium complexes $[Cp^{\wedge}Ir(CO)_2]$ (**1c**) and $[Cp^{*\wedge}Ir(CO)_2]$ (**1d**; $Cp^{\wedge}$ = $C_5H_4CH_2CH_2NMe_2$ and $Cp^{*\wedge}$ = $C_5Me_4CH_2CH_2NMe_2$) were synthesized by an analogous route to that reported for $[CpIr(CO)_2]$ (**1a**; Scheme 1).[6]

The UV absorption spectrum of **1d** shows absorption maxima at about 210 and 280 nm. Upon UV irradiation of a degassed solution of **1d** in cyclohexane, the solution darkened slowly from yellow to orange-brown. Monitoring the photolysis by infrared spectroscopy showed initial formation only of the corresponding hydridoalkyl species **2d** ($\nu_{CO}$ = 1981 $cm^{-1}$), the CO stretching vibration of which is essentially identical to that of the [Cp*IrCO(Cy)(H)] analogue ($\nu_{CO}$ = 1981 $cm^{-1}$ in cyclohexane).[7] As the photolysis progressed, a new species showing a carbonyl stretch at 1996 $cm^{-1}$ in the infrared spectrum and a hydride resonance at $\delta$ = –15.7 ppm ([$D_8$]toluene) in the $^1H$ NMR spectrum was formed (Scheme 2). This was assigned to the dihydride

[a] Department of Chemistry, National University of Singapore, 3 Science Drive 3, Singapore 117543, Singapore

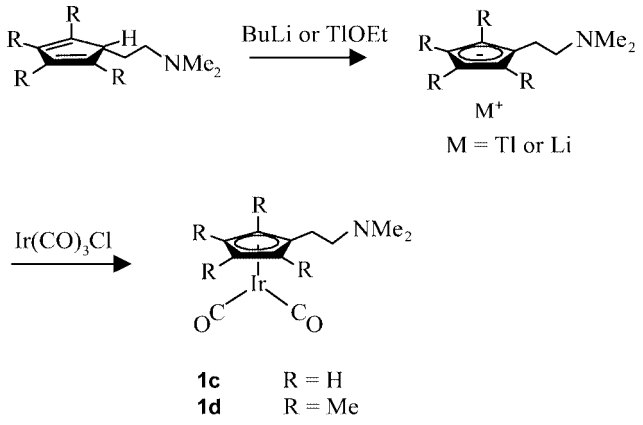
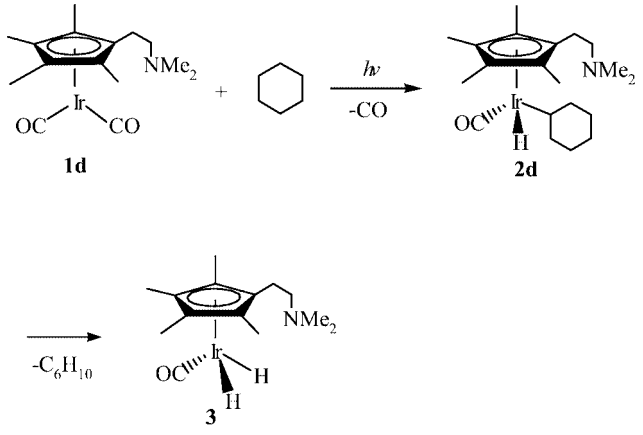


Scheme 1.

complex **3** by comparison of its spectroscopic data with the analogue [Cp*Ir(CO)$H_2$] ($\nu_{CO}$ = 1996 $cm^{-1}$ in cyclohexane; $\delta$ = –15.8 ppm in $C_6D_6$);[7,8] the latter was reported to form when **1b** was irradiated under a hydrogen atmosphere.[7]



Scheme 2.

Since our irradiation experiment was carried out in the absence of hydrogen gas, the formation of **3** may have resulted from β-hydrogen elimination of cyclohexene from **2d**. Indeed, cyclohexene was detected by GC-MS analysis of the reaction solution. Similar irradiation of **1c** in cyclohexane also resulted in the formation of the corresponding dihydride species, although in this case there appeared to be some decomposition during irradiation. Similar results could also be achieved in a shorter time by irradiation with a 266-nm laser; for **1c**, the ratio of **1c**/**2c**, as determined by the relative intensities of the CO absorbance, was 3.3 after 6 h of UV irradiation, while the ratio was 2.0 after irradiation with the laser for 45 minutes. We also found that with [($C_5H_4CH_2Ph$)Ir($CO)_2$] (**1e**), which has a benzyl group as the side-arm, a dihydride species was also obtained. It therefore appears that photolysis of the complexes carrying a side-arm results in the formation of dihydride complexes; this has not been reported to occur with [Cp*Ir($CO)_2$] itself. The $^1$H NMR spectrum of the reaction mixture also shows another hydride resonance at $\delta$ = –17.5 ppm, which could be due to intramolecular C–H activation of the amine group on the Cp ligand or CO insertion into the Ir–C bond to give the acyl species [Cp*^Ir(CO)(H)($COC_6H_{11}$)].

Under a CO atmosphere (1 bar), the activation of **1d** in cyclohexane to form **2d** was slower and occurred with lower yield; the ratio of the absorbance of the CO stretch for **2d**/**1d** was 0.43 after 5 h under a CO atmosphere, and 1.4 after 2 h in vacuo. The same difference in ratios was observed for the activation of **1b** in cyclohexane to form **2b**; the ratio of (absorbance of) **2b**/**1b** was essentially constant at 0.65 after 30 min under a CO atmosphere, while it increased steadily from 1.03 at 30 min to 1.61 at 60 min in vacuo, although there were signs of decomposition in the latter on prolonged photolysis. Instead of **3**, the cluster [$Ir_4(CO)_{12}$] (**4**; $\nu_{CO}$ = 2029, 2069 $cm^{-1}$) was obtained together with **2d**; cluster **4** was also obtained from **1b** under similar conditions. Cluster **4** was not formed when a cyclohexane solution of **1d** was stirred under a CO atmosphere without irradiation. However, if the cyclohexane solution of **1d** was first irradiated, and then a CO atmosphere introduced, a mixture of **1d**, **2d**, and **4** was obtained; the changes in the relative intensities in the infrared spectra suggest that **3** is completely converted into **4** while **2d** is only partially converted into **4**. If this mixture was degassed and then subjected to irradiation, a mixture of **1d**, **2d**, and **3** was obtained. All these are summarized by the scheme and spectra given in Figure 1, and suggest that **4** is formed by the decomposition of **2d** and **3**, and that this is reversible.

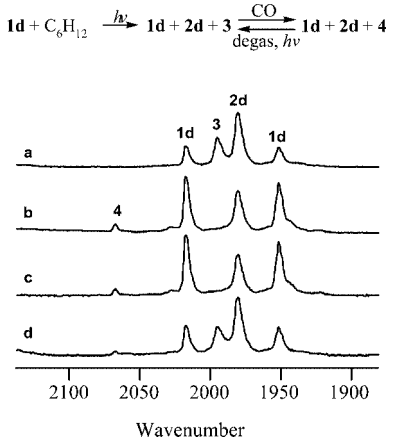


Figure 1. IR spectra of **1d** taken in cyclohexane: (a) after UV irradiation in vacuo for 6 h, followed by (b) stirring overnight under 1 atm of CO, (c) degassing and stirring overnight in vacuo, and (d) UV irradiation in vacuo for 3 h.

We confirmed the identity of **4** by an independent synthesis,[9] and also found that upon irradiation, a degassed suspension of **4** in cyclohexane in the presence of Cp*H or Cp*^H gave partial conversion to **1b** or **1d**, respectively, as identified by IR spectroscopy. Further irradiation of the reaction mixture containing **1b** and the starting materials resulted in the formation of the corresponding hydridoalkyl species **2b**; the yield of **2d** for the corresponding reaction was low. At the end of the 5 h irradiation, suspension of **4** in the reaction mixture was still observed, thus the low conversion rates may be attributed to the low solubility of **4** in cyclohexane.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In line with earlier findings that smaller rings show higher reactivity toward C–H activation,[1c,10] we found that the C–H activation of cyclopentane by **1d** was indeed more facile; the ratio of **2e**/**1d** (by absorbance) was 2.22 after 10 min, compared to a **2d**/**1d** ratio of 1.94 after the same period. These figures also indicate that the activation of **1d** is faster than that of **1b**. On stirring the resultant solution overnight under a CO atmosphere, both **2e** and **3** converted completely into **4** (Figure 2).

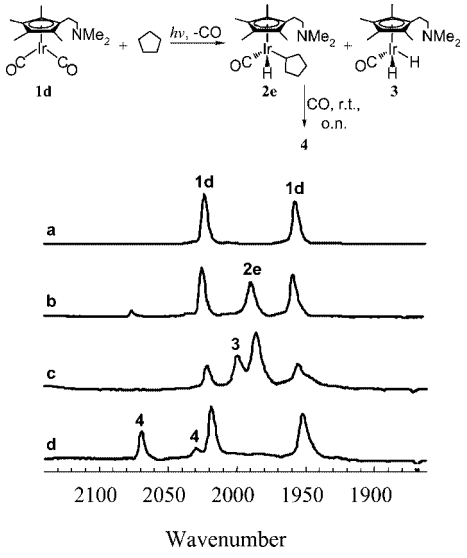

Figure 2. IR spectrum of **1d** in cyclopentane: (a) after stirring for 2 h under CO, followed by (b) 3 h UV irradiation under CO, (c) degassing and irradiation for 3 h in vacuo, and finally (d) stirring overnight under 1 atm of CO.

To gain further insight into the process, particularly with respect to the detection of compounds that we have hitherto not isolated or identified, we carried out in situ IR measurements on the C–H activation of cyclohexane, and used the band-targeted entropy minimization (BTEM) technique that one of us has developed for deconvolution of the data matrix.[11] The BTEM algorithm has been proven to be useful for picking up signals due to species that are present in low concentration, have low absorbance, are unstable, or have peaks that overlap with those due to other species.[11] The schematic diagram for the set-up used for the in situ IR measurements is shown below (Figure 3).

Measurements were made for both **1b** and **1d**; for each complex, spectra were collected at 5 min intervals, and a total of 232 spectra were collected.[12] For **1b**, the individual IR spectra of **1b**, **2b**, and **4**, in the CO stretching region (1650–2250 $cm^{-1}$) were recovered, together with the C=O stretch for cyclohexanecarboxaldehyde (Figure 4). Further confirmation of the aldehyde identity was obtained by NMR and GC-MS characterization. Formation of the corresponding carboxaldehyde in reactions carried out with cyclopentane was also observed by NMR spectroscopy. The carboxaldehyde could have been formed by carbonylation

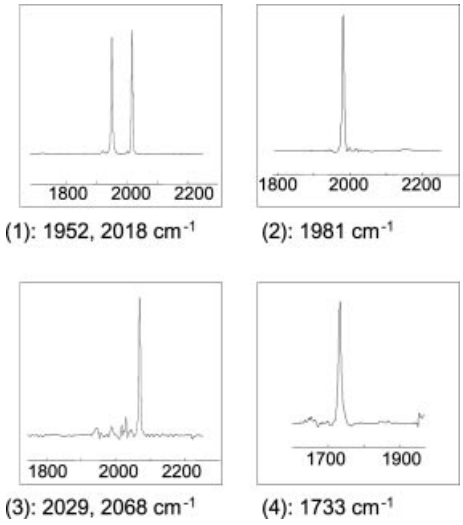

Figure 4. Pure component IR spectra of individual species recovered from deconvolution of the IR spectra of the reaction mixture: (1) $[Cp^*Ir(CO)_2]$ (**1b**), (2) $[Cp^*Ir(CO)(H)(C_6H_{11})]$ (**2b**), (3) $[Ir_4(CO)_{12}]$ (**4**), and (4) $C_6H_{11}CHO$.

of the hydridoalkyl species followed by reductive elimination. Carbonylation of hydrocarbons catalyzed by group-9 transition metal complexes such as $[RhCl(CO)(PMe_3)_3]$ under UV irradiation has been reported,[13] but 18-electron Cp*Ir complexes have not been known to carbonylate hydrocarbons as it was believed that coordination of an incoming CO ligand would result in dissociation of the hydrocarbon.[14] A FAB-MS analysis of the reaction mixture yielded a fragment at *m*/*z* 267 in the positive-ion mode, and the $^{13}C$ NMR spectrum also shows a resonance at $\delta$ = 210.54 ppm, both of which suggest the presence of an acyl species, which may be the intermediate in the carbonylation reaction, although we have yet to confirm its identity.

We analyzed the yield of carboxaldehyde by GC-FID and found that UV irradiation of **1b** in cyclohexane in vacuo for one hour (absence of external CO source) afforded 0.9% of cyclohexanecarboxaldehyde (wrt [Ir]). When the photolysis was carried out under CO (1 bar) for the same length of time, the yield of aldehyde was 71.8%. So far, however, the yield is still far from catalytic. A high CO pressure may inhibit the initial CO dissociation from the dicarbonyliridium complex while favoring the insertion of CO into the Ir–C bond to form the putative $[Cp^*Ir(CO)(COC_6H_{11})(H)]$ acyl intermediate. Photolysis at various CO pressures (1.3 to 7.4 bars) was carried out but we did not find any significant trend in the aldehyde yield with CO pressure.

## Conclusions

We have found that dicarbonylcyclopentadienyliridium complexes in which there is a side-arm carrying an amino group undergo photochemical C–H activation of alkanes in much the same way as the parent complexes without the side-arm. By employing in situ IR measurements and using iterative band-targeted entropy minimization to analyze the spectra, however, we have been able to detect the presence of many hitherto undetected products and intermediates in the C–H activation reaction of such iridium species, including a carboxaldehyde. The formation of the carboxaldehyde represents the first evidence that the cyclopentadienyliridium system can be photochemically activated to promote the carbonylation of alkanes.

## Experimental Section

**General:** All operations were carried out using standard Schlenk techniques under an inert argon atmosphere unless otherwise stated. Cyclopentane (99+%), cyclohexane (99.9%), and hexane were distilled under nitrogen from sodium/benzophenone ketyl. Chlorotricarbonyliridium (Strem) was purchased and used without further purification.

NMR spectra were recorded with either a Bruker ACF 300 MHz or Bruker DPX 300 MHz spectrometer. Chemical shifts are reported with respect to residual solvent peaks. UV absorption spectra of starting complexes were recorded in cyclohexane with a Shimadzu 160 spectrometer. Gas chromatography (GC) analyses were performed with a HP 6890 gas chromatograph equipped with an HP 5973 mass-selective detector and a ZB-1 (30 m × 0.25 mm × 0.25 μm) capillary column, or with an HP5890 Series II plus equipped with an FID detector and a DB-5 (30 m × 0.32 mm × 0.25 μm) capillary column. Photolyses were carried out with either a Hanovia 450-W UV lamp with a nominal $\lambda_{max}$ of 254 nm, or a continuum Surelite III 10-ns-pulse Nd-YAG laser operating at 3 mJ per pulse with 266-nm radiation.

IR spectra for routine analysis were recorded with a Bio-Rad FTS 165, a Digilab Excalibur Series FTS 3000MX, or a Shimadzu IR Prestige-21 FTIR-8400S FT-IR spectrometer at a resolution of 1 $cm^{-1}$ using a solution IR cell with NaCl windows and a path length of 0.1 mm. IR spectra for in situ studies under ambient pressure were recorded with a Perkin–Elmer 2000 FTIR spectrometer at a resolution of 4 $cm^{-1}$ using a high-pressure heatable liquid cell with ZnSe windows and a path length of 0.1 mm from Specac. IR spectra for high-pressure studies were taken in a thermostatted high-pressure cell constructed of 316 stainless steel and AMTIR windows with a path length of 0.5 mm; details of the design will be described elsewhere.[15] Only carbonyl stretches in the 1600–2200 $cm^{-1}$ region are reported.

The compounds Cp^H,[16] Cp*^H,[17] $C_5H_5CH_2Ph$ ($Cp^{Bz}H$),[18] and $[Cp^*Ir(CO)_2]$ (**1b**)[19] were prepared following published procedures. Thallium salts were prepared following a literature method.[20] The complexes $[Cp^{\wedge}Ir(CO)_2]$ (**1c**), $[Cp^{*\wedge}Ir(CO)_2]$ (**1d**), and $[Cp^{Bz}Ir(CO)_2]$ (**1e**) were synthesized by a procedure analogous to that used for the synthesis of $[CpIr(CO)_2]$ (**1a**).[6]

**Preparation of [Cp*^Ir(CO)$_2$]:** Cp*^Li was prepared in situ from Cp*^H (98.2 mg, 0.509 mmol) and *n*BuLi (0.3 mL of a 2.2 M solution, 0.66 mmol) in hexane. The suspension was cannula transferred into a suspension of $[Ir(CO)_3Cl]$ (102 mg, 0.327 mmol) in hexane (10 mL) in a Carius tube. The mixture was degassed and heated at 70 °C for 2 d. The resultant mixture was cooled and filtered through celite to remove unreacted starting materials. The yellow filtrate was vacuum-dried to give **1d** as a yellow oil. IR (cyclohexane): $\tilde{\nu}$ = 1954, 2020 $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.60–2.54 (m, 2 H, $CH_2$-N) 2.27 (s, 6 H, N-$CH_3$), 2.26–2.19 (m, 2 H, $CH_2$), 2.15 (s, 6 H, ring $CH_3$), 2.16 (s, 6 H, ring $CH_3$) ppm. The $^1H$ NMR spectroscopic data matched the literature values.[21,22]

**Preparation of [Cp$^{Bz}$Ir(CO)$_2$]:** A degassed suspension of $Cp^{Bz}Tl$ (55 mg, 0.154 mmol) and $[Ir(CO)_3Cl]$ (21.2 mg, 0.068 mmol) in hexane (20 mL) was heated in a Carius tube at 80 °C for 2 d. The resultant mixture was cooled and filtered through celite to remove unreacted starting materials. The yellow filtrate was vacuum-dried to give **1e** as a yellow oil. IR (cyclohexane): $\tilde{\nu}$ = 1969, 2036 $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.23 (m, 5 H, $C_6H_5$), 5.45 (m, 2 H, $C_5H_4$), 5.37 (m, 2 H, $C_5H_4$), 3.77 (s, 2 H, $CH_2$) ppm. The IR data matched the literature values.[20]

Complex **1c** was prepared from Cp^Tl (432 mg, 1.265 mmol) and $[Ir(CO)_3Cl]$ (217 mg, 0.696 mmol) in an analogous manner. IR (cyclohexane): $\tilde{\nu}$ = 1967, 2034 $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 5.52 (m, 2 H, $C_5H_4$), 5.37 (m, 2 H, $C_5H_4$), 2.58–2.36 (m, 4 H, $CH_2CH_2$), 2.26 (s, 6 H, N-$CH_3$) ppm. The $^1H$ NMR spectroscopic data matched the literature values.[20]

**Preparative Photolysis:** A solution of the metal complex in the hydrocarbon solvent (1 mg $mL^{-1}$) was placed in a closed quartz tube, degassed by three cycles of freeze-pump-thaw, and then irradiated with a 450-W water-cooled, medium-pressure mercury lamp placed approximately 15 cm away whilst being continuously stirred. For reaction under CO atmosphere, the quartz tube was refilled with 1 atm of CO from the Schlenk line after degassing. For the laser irradiation, dichroic mirrors were used to direct the pulses; cooling by water circulation was not necessary.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**In situ IR Measurements:** For measurements at ambient pressure, a well-stirred solution of **1b** or **1d** in cyclohexane was circulated between the quartz reactor and a ZnSe cell through Vitron (internal diameter 2.06 mm) and Tygon tubing using a peristaltic pump (MASTERflex C/L 5910 pump systems model 77120–62). UV irradiation was carried out through the quartz reactor. The reactor was fan-cooled and the temperature was not controlled. The atmosphere was either argon or carbon monoxide.

For the high-pressure measurements, a solution of **1b** in cyclohexane was circulated between a 100-mL stainless-steel autoclave type reactor, a high-pressure cell of original design (AMTIR windows), and an industrial sapphire tube (Almaz Optics, Inc., Marlton, New Jersey) of 5 mm internal diameter (I.D.) via stainless steel tubing of 1/16 inch i.d. under various CO pressures. UV irradiation was carried out through the sapphire tube. The temperature was kept at 20 °C by cryostatic control.

# Enolate-Phosphane Ligands Providing a Tool for the Selective Substitution of Triphenylphosphane by Carbon Monoxide or Trimethylphosphane in Complex {Ru(Cp)[$\eta^2$-*P*,*O*-$Ph_2PCH_2C(t$Bu)=O](PPh$_3$)}[$PF_6$], and Subsequent Reactivity Towards Terminal Alkynes

**Bernard Demerseman*[a] and Loïc Toupet[a]**

**Keywords:** Cyclopentadienyl ligands / Metallacycles / Phosphane ligands / Ruthenium / Vinylidene ligands

The deprotonation under basic conditions of the keto-phosphane ligand in complexes {Ru(Cp)[$\eta^1$-*P*-$Ph_2PCH_2C$(=O)-*t*Bu](PPh$_3$)(L)}[$PF_6$] (L = CO or $PMe_3$) that arise from the addition of L to {Ru(Cp)[$\eta^2$-*P*,*O*-$Ph_2PCH_2C(t$Bu)=O](PPh$_3$)}[$PF_6$] generates {$Ru^+$(Cp)[$\eta^1$-*P*-$Ph_2PCH$=C(*t*Bu)$O^-$](PPh$_3$)(L)} zwitterionic species, as shown by an X-ray crystal structure determination (L = CO). The removal of the triphenylphosphane ligand is subsequently achieved under thermal activation to afford the neutral derivatives Ru(Cp)[$\eta^2$-*P*,*O*-$Ph_2PCH$=C-(*t*Bu)O](L). A further protonation step is sufficient to complete the formation of the new complex {Ru(Cp)[$\eta^2$-*P*,*O*-$Ph_2PCH_2C(t$Bu)=O](PMe$_3$)}[$PF_6$], which reacts in methanol at reflux with 1,1-diphenyl-2-propyn-1-ol to afford the six-membered metallacyclic derivative {Ru(Cp)[$\eta^2$-*C*,*P*:C(CH=$CPh_2$)OC(*t*Bu)=CH–$PPh_2$](PMe$_3$)}[$PF_6$], as shown by an X-ray single crystal analysis. The synthesis of related $\eta^5$-indenyl ruthenium complexes and of {Ru(Cp)-(=C=$CH_2$)[$Ph_2PCH_2C$(=O)*t*Bu](PR$_3$)}[$PF_6$] ($PR_3$ = $PPh_3$ or $PMe_3$) vinylidene complexes is also reported.

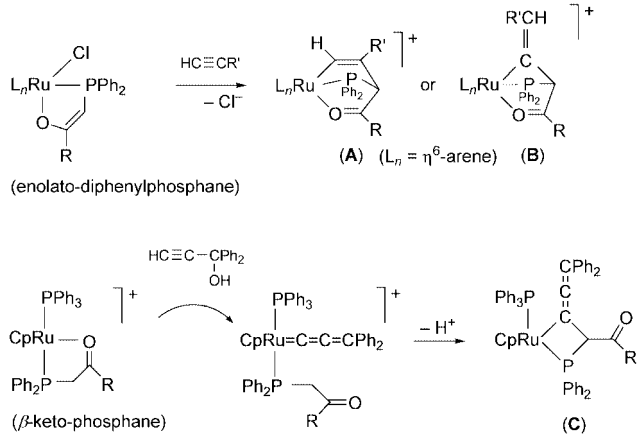
## Introduction

Enolato-phosphane chelates derived from β-keto-phosphanes associate an ancillary phosphorus coordinating centre with a strongly coordinating but reactive enolate moiety. Thus, the enolato function had been shown to interfere in the 1-alkyne to vinylidene rearrangement when coordination of 1-alkynes at a ruthenium centre was additionally instigated. As depicted on Scheme 1, carbon–carbon bond formation occurred and resulted in cationic metallacyclic derivatives **A** and **B**.[1–3]

On the other hand, protonation of the enolato function under acidic conditions converted the chelate into a hemilabile β-keto-phosphane one, where the oxygen atom might compare to a weakly coordinating ketone.[4–6] Taking advantage of the hemilabile property of β-keto-phosphanes in related cyclopentadienyl ruthenium complexes, the synthesis of allenylidene ruthenium derivatives had been achieved (Scheme 1).[7] A further deprotonation of the $\eta^1$-*P*-coordinated keto-phosphane still resulted in a formal carbon–carbon coupling reaction between an enolate moiety and the allenylidene ligand to afford a neutral ruthenaphosphacyclobutane derivative (**C**).

These results emphasised the nucleophilic character of the enolate moiety from functional enolato-phosphane chelate, or generated in situ under basic conditions from $\eta^1$-*P*-coordinated keto-phosphane. We wish to report now (i) an unusual $\eta^1$-*P* coordination mode of an enolate-phosphane ligand in new zwitterionic cyclopentadienyl ruthenium complexes, (ii) the reactivity of the uncoordinated anionic enolate moiety, which provides a new tool to cleanly achieve ligand-exchange reactions, and (iii) the formation of a ruthenaoxophosphacyclohexadiene ring, which may be formally summarised as an oxygen–carbon coupling reaction between an allenylidene ligand and an $\eta^1$-*P*-coordinated enol-phosphane.



Scheme 1. Carbon–carbon coupling reactions leading to ruthenacycles **A**–**C**.

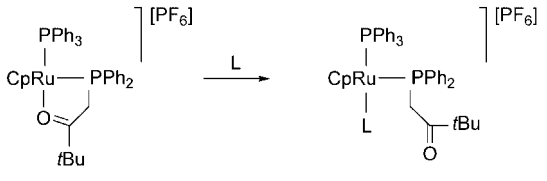
## Results and Discussion

The hemilabile property of the β-keto-phosphane in the cyclopentadienyl ruthenium complex {Ru(Cp)[η²-*P*,*O*-$Ph_2PCH_2C(tBu)$=O](PPh₃)}[PF₆] (**1a**) allowed the entrance not only of 1-alkynols or carbon monoxide as reported previously,[7] but also of phosphorus ligands such as trimethylphosphane or trimethyl phosphite [Equation (1)].

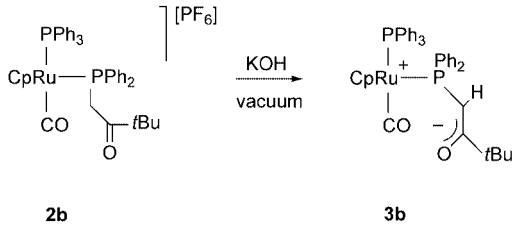


(1)

The new complexes **2c**,**d** were thus isolated as yellow solids in a nearly quantitative yield and were characterised by a combination of $^1H$, $^{13}C\{^1H\}$, $^{13}C$ and $^{31}P\{^1H\}$ NMR, IR spectroscopy, and elemental analysis. The $^1H$ and $^{31}P\{^1H\}$ NMR spectra accounted for the coordination of the phosphorus ligands besides the cyclopentadienyl one while IR spectroscopy indicated the η¹-*P*-coordination mode of the keto-phosphane.[7] Attempts to achieve a similar entrance of triphenylphosphane failed. Indeed, steric congestion in the putative expected complex {Ru(Cp)[η¹-*P*-$Ph_2PCH_2C(=O)tBu$](PPh₃)₂}[PF₆] was believed to be responsible for the easy synthesis of **1a**, by reacting the keto-phosphane $Ph_2PCH_2C(=O)tBu$ with RuCl(Cp)(PPh₃)₂ and $NH_4PF_6$ in methanol as solvent.[7] The loss of steric constraints in complexes **2b**–**d** provided thermal stability and complexes **2b**–**d** remained unchanged when they were heated in toluene at reflux. Unfortunately, such thermal stability precluded a removal of the triphenylphosphane ligand in **2b**–**d** and thus an easy recovery of the chelate coordination mode of the keto-phosphane.

The generation of an enolate anion might be expected to enhance the reactivity of the oxygen atom from the keto-phosphane when involved as an η¹-*P*-coordinated ligand, but such a formation would require basic conditions. No reaction was detected when an excess of KOH was added to a stirred solution of **2b** in methanol. However, a subsequent complete removal of volatiles under prolonged vacuum at room temperature resulted in the formation of the new enolate-phosphane complex **3b** [Equation (2)].

Complex **3b** was isolated in 79% yield as orange crystals that were found to be stable in air and could be kept at room temperature. IR spectroscopy indicated the retention of a carbon monoxide ligand ($\tilde{\nu}$ = 1959 cm⁻¹) and the conversion of the keto-function into an enolate one ($\tilde{\nu}$ = 1489 cm⁻¹). The $^{31}P\{^1H\}$ NMR spectrum of **3b** indicated the coordination of two phosphorus atoms with a normal coupling constant value ($^2J_{PP}$ = 26.7 Hz). More noteworthy was the observation by $^1H$ NMR spectroscopy of a doublet at $\delta$ = 3.66 ppm exhibiting a high $^2J_{PH}$ coupling constant



(2)

value of 27.1 Hz and assigned to the PCH= proton, whereas the $^{13}C\{^1H\}$ NMR resonance of the corresponding carbon nucleus displayed usual features ($\delta$ = 60.6 ppm, $^1J_{PC}$ = 70.9 Hz). Further characterisation of **3b** was obtained from an X-ray crystal structure determination. An ORTEP drawing of **3b** is shown in Figure 1, and selected bond lengths and angles are given in the caption.

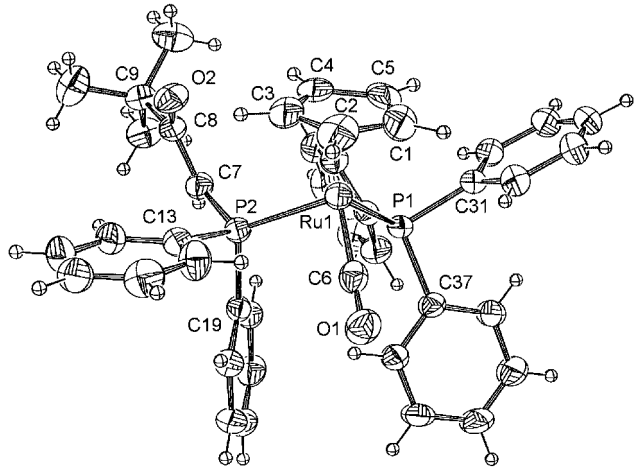


Figure 1. ORTEP drawing of **3b**·$CH_2Cl_2$ showing 50% probability thermal ellipsoids. The $CH_2Cl_2$ molecule is omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–C6 1.858(5), Ru1–P1 2.339(1), Ru1–P2 2.370(1), C7–C8 1.379(5), C8–C9 1.561(6), C8–O2 1.271(5), P2–C7 1.759(4); C7–C8–C9 120.1(4), C7–C8–O2 124.1(4), C8–C7–P2 123.7(3), C9–C8–O2 115.8(4), C7–P2–Ru1 120.7(1), C6–Ru1–P1 90.5(1), C6–Ru1–P2 91.3(1), P1–Ru1–P2 99.19(4).

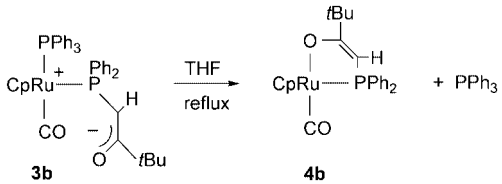
Complex **3b** disclosed a classical piano-stool geometry involving an η⁵-cyclopentadienyl ruthenium moiety. One carbon monoxide ligand and two phosphorus atoms complete the coordination of a formal $Ru^+$ centre. Moreover, the two Ru–P bond lengths are close [Ru1–P1: 2.339(1), Ru1–P2: 2.370(1) Å], thus providing straightforward evidence for a normal coordination of the functionalised phosphane. The C7–C8 and C8–O2 bond lengths [1.379(5) and 1.271(5) Å, respectively] clearly indicated a marked double bond character, as expected for an anionic enolate fragment. Therefore, complex **3b** is best described as a zwitterionic compound. Remarkably, the O2 oxygen atom lies in a *cis* position relative to the P2 phosphorus atom, thus in a favourable position for a subsequent coordination of the oxygen atom.

The removal of the triphenylphosphane ligand in **3b** was achieved by heating at reflux a solution of **3b** in THF monitored by $^{31}P\{^1H\}$ NMR spectroscopy as having a new sing-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

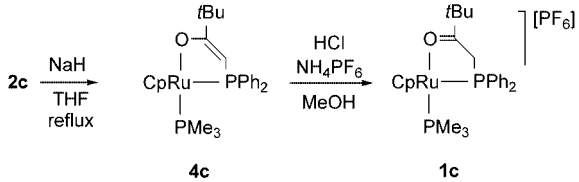
let resonance at $\delta$ = 61.4 ppm, besides a singlet resonance, as might be expected from the presence of free triphenylphosphane [Equation (3)].



**3b** **4b** (3)

Attempts to separate the enolato-phosphane derivative **4b** from free triphenylphosphane by generating under acidic conditions a less soluble cationic $\{Ru(Cp)[Ph_2PCH_2C(tBu)=O](CO)\}^+$ species immediately showed the additional coordination of triphenylphosphane leading to the recovery of cationic **2b**. The addition of $ICH_3$ to convert the free phosphane into the corresponding phosphonium salt was more successful. The neutral complex **4b** was then selectively extracted with diethyl ether and isolated as orange-yellow crystals in 72% yield. Of interest is the comparison of the $^1H$ and $^{13}C\{^1H\}$ NMR spectra of **4b** and **3b**, which showed in the case of **4b** the PCH= proton resonance as a doublet at $\delta$ = 4.85 ppm with a normal $^2J_{PH}$ coupling constant value of 4.1 Hz, while the corresponding $^{13}C\{^1H\}$ NMR resonance ($\delta$ = 74.0 ppm, $^1J_{PC}$ = 61.9 Hz) appeared moderately low-field shifted, relative to **3b**.

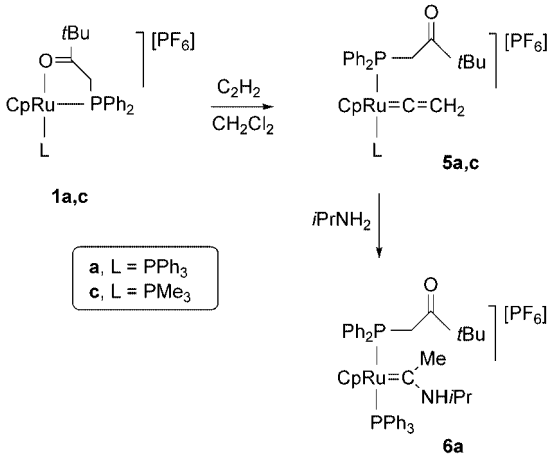
The study of the reaction between **2c** (L = $PMe_3$) and KOH in methanol as solvent under similar experimental conditions was disappointing, as the $^{31}P\{^1H\}$ NMR spectrum of the crude product showed a major presence of unreacted **2c**. However, a new set of resonances might indicate a partial formation of the expected zwitterionic intermediate and thus suggested that more drastic experimental conditions would allow completion of the reaction. Indeed, the enolato-diphenylphosphane complex **4c** was straightforwardly obtained when NaH was used as a base in THF at reflux [Equation (4)]. A subsequent treatment under acidic conditions (addition of anhydrous HCl and $NH_4PF_6$ in methanol as solvent) led to the new cationic derivative $\{Ru(Cp)[Ph_2PCH_2C(tBu)=O](PMe_3)\}[PF_6]$ (**1c**) [Equation (4)].



**4c** **1c** (4)

With the addition of trimethylphosphane to **1a** to generate **2c**, as a supplementary step, the whole process achieved the selective substitution of the triphenylphosphane ligand in **1a** by a trimethylphosphane one, to afford **1c** in 73% yield. NMR and IR spectroscopy, and elemental analysis accounted for the structure of the stable complexes **4c** and **1c**.

Further emphasising the usefulness of the hemilabile property of the keto-phosphane ligand to conveniently allow the entrance of an additional ligand, complexes **1a**,**c** reacted with ethyne under very mild conditions (1 atm, room temperature) to afford the new vinylidene complexes **5a**,**c** [Equation (5)].

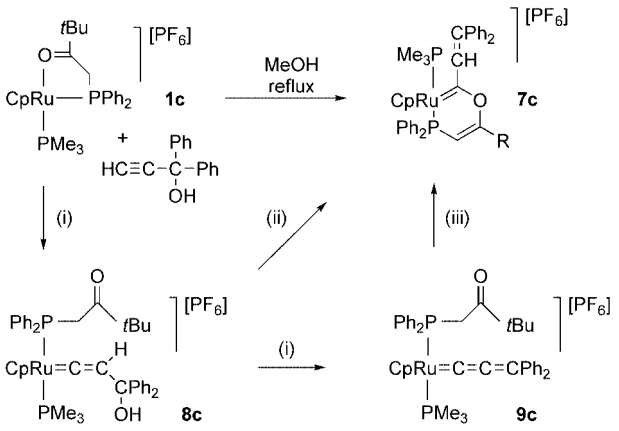


**1a,c** **5a,c** **6a** (5)

Complexes **5a**,**c** were isolated as yellow-brown crystals in 93% and 92% yield, respectively, and fully characterised by $^1H$, $^{13}C\{^1H\}$, $^{13}C$ and $^{31}P\{^1H\}$ NMR spectroscopy, and elemental analysis. Several unsubstituted vinylidene ruthenium complexes have been reported previously,[8] but the almost quantitative formation of **5a**,**c** using ethyne under mild conditions, and avoiding any formation of by-product, is noteworthy. Under the same experimental conditions, the parent complex $RuCl(Cp)(PMe_2Ph)_2$ reacted with ethyne in the presence of $TlBF_4$ to afford the $\eta^2$-ethyne complex $Ru(Cp)(\eta^2\text{-}C_2H_2)(PMe_2Ph)_2$, from which the 1-alkyne to vinylidene rearrangement needed a thermal activation to occur.[9] Similar observations were made starting from $RuCl(Cp)(PMe_3)_2$,[10] and the mechanism of the isomerisation has been fully investigated.[11] The $^{13}C\{^1H\}$ NMR spectra of **5a**,**c** showed a very low-field resonance at $\delta$ = 346.6 and 345.5 ppm, respectively, and thus unambiguously provided evidence for the presence of a vinylidene ligand. Furthermore, complexes **5a**,**c** easily added primary amines such as isopropylamine to afford amino-carbene derivatives, as emphasised by the formation of complex **6a** [Equation (5)]. Like the vinylidene ruthenium complexes **5a**,**c**, the amino-carbene derivative **6a** was a robust compound, which could be kept in air at room temperature.

The labile keto-oxygen ligand in complexes **1a**,**c** also allowed the entrance of 1-alkynols and the synthesis of the allenylidene derivative $\{Ru(Cp)(=C=C=CPh_2)[Ph_2PCH_2C(=O)tBu](PPh_3)\}[PF_6]$ by reacting **1a** with 1,1-diphenyl-2-propyn-1-ol in methanol at reflux has already been reported.[7] By contrast, a distinct complex **7c** was selectively formed when the same alkynol was treated with **1c** under similar experimental conditions (Scheme 2).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2. Reactivity of complex **1c** towards 1,1-diphenyl-2-propyn-1-ol: (i) in $CH_2Cl_2$ as solvent, (ii) in MeOH as solvent (room temperature), (iii) in $CH_2Cl_2$ as solvent and in the presence of aqueous $K_2CO_3$.

Such a formation of **7c** in methanol also occurred at room temperature but the completion of the reaction needed 10 days instead of 1 h under reflux conditions. The stable complex **7c** was isolated in 69% yield as dark-red crystals. The $^{31}P\{^1H\}$ NMR spectrum of **7c** indicated the retention of two coordinating phosphorus centres, while $^1H$ NMR and IR spectroscopy both indicated the transformation of the keto-phosphane into an enolate-phosphane. Furthermore, the $^{13}C\{^1H\}$ NMR spectrum of **7c** exhibited a very low-field resonance at $\delta$ = 286.1 ppm and thus suggested that a carbene ligand completed the coordination of the ruthenium centre. Finally, an X-ray crystal structure determination of **7c** showed a vinyl-carbene ligand to formally arise from an addition at the $C_\alpha$ position of an allenylidene ligand of the enol form of an $\eta^1$-*P*-coordinated keto-phosphane. An ORTEP drawing of **7c** is shown in Figure 2, and selected bond lengths and angles are given in the caption.

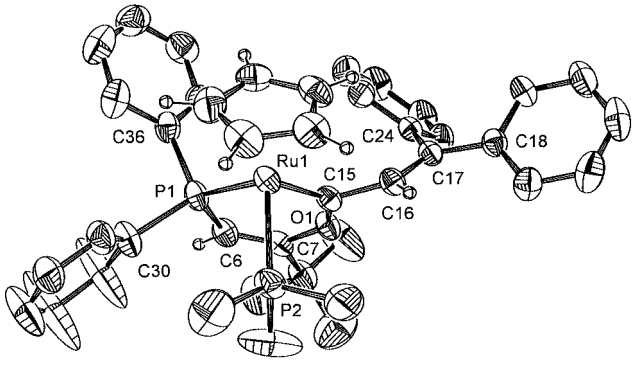


Figure 2. ORTEP drawing of **7c** showing 50% probability thermal ellipsoids. The hydrogen atoms and the $PF_6$ anion are omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–C15 1.924(3), Ru1–P1 2.2497(7), Ru1–P2 2.3197(8), C6–C7 1.319(4), C7–O1 1.393(3), P1–C6 1.776(3), C15–C16 1.472(4), C16–C17 1.354(4); C6–P1–Ru1 113.2(1), C7–C6–P1 125.6(2), C6–C7–O1 125.7(3), C7–O1–C15 128.1(2), O1–C15–Ru1 134.3(2), C15–Ru1–P1 90.21(8), C15–Ru1–P2 89.62(8), P1–Ru1–P2 95.57(3), Ru1–C15–C16 119.1(2), C15–C16–C17 129.0(3).

Figure 2 displays a piano-stool geometry where a carbene and two phosphorus ligands complete the coordination of a formal cationic $\eta^5$-cyclopentadienyl ruthenium fragment. One phosphorus and the (carbene)-carbon atoms are involved in a six-membered metallacycle that is closely planar, as monitored by a sum of internal angles of 717.1°, close to 720°. Furthermore, the ruthenacycle compares with a 1,4-cyclohexadiene ring wherein the Ru1–P1–C6 and C7–O1–C15 fragments are linked through two short C6–C7 and Ru1–C15 double bonds [1.319(4) and 1.924(3) Å, respectively].

The formation of **7c** was strongly dependent on the nature of the solvent and became almost negligible when the reaction between **1c** and 1,1-diphenyl-2-propyn-1-ol was conducted in dichloromethane at room temperature. As monitored by $^{31}P\{^1H\}$ NMR spectroscopy, the complete consumption of **1c** in dichloromethane as solvent was virtually achieved after 20 h and the reaction mixture disclosed a major presence (ca. 85% as determined by $^1H$ NMR spectroscopy) of the hydroxy-vinylidene complex **8c** (Scheme 2). Complex **8c** then gradually disappeared, leaving the allenylidene ruthenium complex **9c** as the final product after 3 days; no further change was detected after 10 days. Complex **9c** can be rapidly synthesised by reacting **1c** and the alkynol in THF at reflux. The structure of complexes **8c** and **9c** was inferred from $^1H$, $^{13}C\{^1H\}$, $^{13}C$ and $^{31}P\{^1H\}$ NMR spectroscopic studies. Thus, the $^1H$ NMR spectrum of **8c** showed two additional resonances relative to the spectrum of **9c**, at $\delta$ = 3.19 (s) and 5.25 (dd, $^4J_{PH}$ = 2.5 and 1.6 Hz) ppm, which might reasonably be assigned to the OH and Ru=C=CH protons, respectively.[12,13] The formation of the allenylidene complex $[Ru(Cp)(=C=C=CPh_2)(PMe_3)_2][PF_6]$ similarly involved a hydroxy-vinylidene intermediate when $RuCl(Cp)(PMe_3)_2$ was treated with 1,1-diphenyl-2-propyn-1-ol.[14] Moreover, several hydroxy-vinylidene complexes have been later isolated and characterised as pentamethylcyclopentadienyl ruthenium derivatives.[12,13]

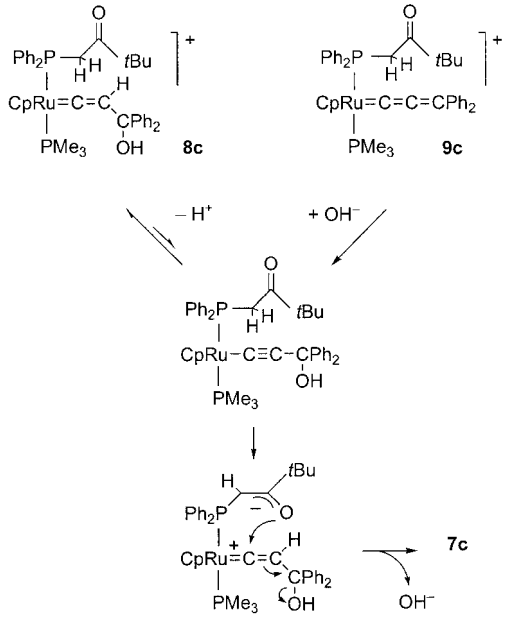
The formation of the isomeric complexes **7c** and **9c**, in methanol and in dichloromethane as solvent, respectively, was intriguing. Two supplementary experiments were significantly informative. First, a mixture of **8c** and **9c** in an approximately 1:1 molar ratio was formed in dichloromethane and the solvent was evaporated under vacuum. The residue was dissolved in methanol and the solution was stirred at room temperature for 20 h. The examination of the resulting solution by $^{31}P\{^1H\}$ NMR spectroscopy surprisingly disclosed a mixture of **7c** and **9c**, indicating a conversion of **8c** into **7c** but also a passiveness of the allenylidene complex **9c** (Scheme 2). However, a very slow isomerisation of **9c** into **7c**, needing 10 days to complete, was observed to occur in methanol at ambient temperature.

In the second experiment, a small amount of a 0.07 M $K_2CO_3$ aqueous solution was added to a solution of **9c** in dichloromethane. On stirring, the colour of the solution rapidly (<1 h) turned from violet to red and although a deprotonation of the keto-phosphane in **9c** under such mild heterogeneous conditions was unlikely, **7c** was observed to

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

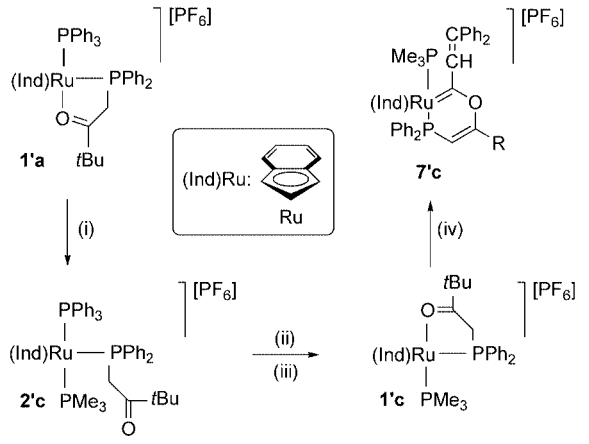
be quantitatively formed by $^{31}P\{^1H\}$ NMR spectroscopy (Scheme 2).

These observations suggested that the coupling process leading to **7c** preliminarily required the formation of an intermediate that would arise either from **8c** in methanol or from the addition of hydroxide anion to **9c**. As depicted in Scheme 3, a plausible candidate consisted of a neutral alkynyl complex arising from a deprotonation (requiring a solvent with proton-acceptor ability such as methanol) of the vinylidene ligand in **8c**, or from the addition of hydroxide anion at the γ position of the allenylidene ligand in **9c**. A subsequent proton migration from the keto-fragment to the alkynyl ligand would subsequently lead to **7c**. Finally, the presence of a bulkier triphenylphosphane ligand in **1a** might sufficiently hinder closeness between the keto function and the alkynyl chain to preclude a similar coupling process.



Scheme 3. Rationale accounting (i) for the formation of **7c** in methanol and (ii) for the isomerisation of **9c** into **7c** catalysed by hydroxide anions.

The reactions allowing the synthesis of the trimethylphosphane derivatives **2c**, **1c** and **7c** tolerated the presence of an indenyl ligand instead of the cyclopentadienyl one. As summarised in Scheme 4, the indenyl ruthenium precursor complex {Ru(Ind)[$\eta^2$-*P*,*O*-$Ph_2PCH_2C(tBu)$=O](PPh$_3$)}[PF$_6$] (**1′a**) (Ind = $\eta^5$-$C_9H_7$)[7] easily added trimethylphosphane to afford **2′c**, which was isolated as orange-red crystals, in 89% yield. Treatment of **2′c** with NaH in THF under reflux and subsequent work under acidic conditions (HCl + $NH_4PF_6$) led to **1′c**, which was isolated as orange crystals, in 77% yield. Finally, complex **1′c** reacted with 1,1-diphenyl-2-propyn-1-ol in methanol at reflux to afford **7′c** isolated as deep-red crystals, in 71% yield. The $^1H$, $^{13}C\{^1H\}$, $^{13}C$ and $^{31}P\{^1H\}$ NMR spectroscopic data collected for **7′c** unambiguously indicated a similar structure relative to complex **7c**.



Scheme 4. Synthesis of the new complexes **2′c**, **1′c** and **7′c**: (i) $PMe_3$, $CH_2Cl_2$, (ii) NaH, THF, reflux, (iii) HCl, $NH_4PF_6$, MeOH, (iv) HC≡CC(OH)$Ph_2$, MeOH, reflux.

## Conclusions

The deprotonation of an $\eta^1$-*P*-coordinated β-keto-phosphane in cyclopentadienyl or indenyl ruthenium complexes was achieved under basic conditions and was observed to enhance the affinity of the oxygen atom to coordinate the metal centre. Subsequent removal of a triphenylphosphane ligand was facilitated and allowed the chelate coordination mode of the functionalised phosphane. Thus, using the β-keto-phosphane as a tool, the substitution of a triphenylphosphane ligand by a less sterically demanding ligand such as carbon monoxide or trimethylphosphane was achieved. Furthermore, such a synthesis offered an opportunity to compare two analogous complexes but with distinct steric constraints. The presence of the hemilabile β-keto-phosphane not only allowed an easy additional coordination of ethyne but also facilitated further rearrangement into vinylidene derivatives. The coordination of 1-alkynols similarly led to allenylidene complexes, but the presence of a reactive functionalised phosphane might interfere in the process to afford new metallacyclic complexes.

## Experimental Section

**General Comments:** The reactions were performed under inert argon according to Schlenk-type techniques. THF, diethyl ether and dichloromethane were distilled after drying according to conventional methods. NMR spectra were recorded at 297 K with an AC 300 Bruker instrument and referenced internally to the solvent peak. IR spectra were recorded as Nujol mulls with Bruker IFS28. Elemental analyses were performed by the "Service de Microanalyse du CNRS", Vernaison, France. Complexes **1a** (as its dichloromethane adduct) and **1′a** were prepared as described previously.[7]

**{Ru(Cp)[$Ph_2PCH_2C$(=O)*t*Bu](PPh$_3$)(CO)}[PF$_6$] (2b):** In a 125 mL stainless steel vessel, a solution of **1a** (13.8 g, 14.6 mmol) in dichloromethane (70 mL) was stirred for 3 days at room temperature under carbon monoxide pressure (65 atm). The resulting solution was concentrated under vacuum (≈40 mL) before being covered with methanol (10 mL) and then diethyl ether (160 mL), to afford lemon-yellow crystals. Yield: 11.9 g, 92%. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CD_2Cl_2$): $\delta$ = 25.7 (s, $CMe_3$), 35.9 (d, $^1J$ = 29.4 Hz,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$PCH_2$), 45.5 (d, $^3J$ = 1.5 Hz, $CMe_3$), 90.9 (s, Cp), 129.0–135.1 (m, 5 Ph groups), 202.5 (t, $^2J \approx 17.8$ Hz, C≡O), 207.6 (d, $^2J$ = 8.2 Hz, C=O) ppm. $^1H$ and $^{31}P\{^1H\}$ NMR, and IR spectroscopic data were given elsewhere.[7]

**{Ru(Cp)[$Ph_2PCH_2C$(=O)*t*Bu](PPh$_3$)(PMe$_3$)}[PF$_6$] (2c):** A 1.0 M solution of trimethylphosphane in THF (8.0 mL, 8.0 mmol) was added to a stirred solution of **1a** (7.04 g, 7.47 mmol) in THF (40 mL). The mixture was further stirred overnight to obtain a yellow precipitate, which was collected by filtration, then washed with diethyl ether and dried under vacuum. Yield: 7.00 g, 100%. IR: $\tilde{\nu}$ = 1699 cm$^{-1}$, C=O. $^1H$ NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 0.64 (s, 9 H, *t*Bu), 1.45 (d, $^2J_{PH}$ = 8.6 Hz, 9 H, $PMe_3$), 2.99 (dd, $^2J_{HH}$ = 16.4, $^2J_{PH}$ = 8.5 Hz, 1 H, $PCH_2$, $H_a$), 3.16 (dd, $^2J_{HH}$ = 16.4, $^2J_{PH}$ = 4.0 Hz, 1 H, $PCH_2$, $H_b$), 4.68 (s, 5 H, Cp), 6.80–7.47 (m, 25 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = –10.4 (t, $^2J_{PP} \approx {}^2J_{PP'} \approx$ 38 Hz, PMe), 36.9 (t, $^2J_{PP} \approx {}^2J_{PP'} \approx$ 38 Hz), 43.9 (t, $^2J_{PP} \approx {}^2J_{PP'} \approx$ 38 Hz) ppm. $C_{44}H_{50}F_6OP_4Ru$ (933.84): calcd. C 56.59, H 5.40; found C 56.66, H 5.87.

**{Ru(Cp)[$Ph_2PCH_2C$(=O)*t*Bu](PPh$_3$)[P(OMe)$_3$]}[PF$_6$] (2d):** Trimethyl phosphite (0.80 mL, 6.78 mmol) was added to a solution of **1a** (3.00 g, 3.18 mmol) in dichloromethane (50 mL). After being stirred overnight, the solution was evaporated to dryness to leave the crude product. Recrystallisation from dichloromethane (20 mL) and diethyl ether (110 mL) afforded thin yellow needles that were collected by filtration. Yield: 3.05 g, 98%. IR: $\tilde{\nu}$ = 1703 cm$^{-1}$, C=O. $^1H$ NMR (300.13 MHz, $CDCl_3$): $\delta$ = 0.55 (s, 9 H, *t*Bu), 2.43 (dd, $^2J_{HH}$ = 16.1, $^2J_{PH}$ = 10.8 Hz, 1 H, $PCH_2$, $H_a$), 3.71 (d, $^3J_{PH}$ = 10.8 Hz, 10 H, POMe and hidden $PCH_2$, $H_b$), 4.71 (d, $^2J_{PH}$ = 0.7 Hz, 5 H, Cp), 6.92–7.61 (m, 25 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (121.50 MHz, $CDCl_3$): $\delta$ = 41.9 (dd, $^2J_{PP}$ = 63 and 32 Hz, PPh), 45.9 (dd, $^2J_{PP}$ = 63 and 32 Hz, PPh), 144.3 (t, $^2J_{PP} \approx {}^2J_{PP'} \approx$ 63 Hz, POMe) ppm. $C_{44}H_{50}F_6O_4P_4Ru$ (981.84): calcd. C 53.83, H 5.13, P 12.62; found C 53.73, H 5.10, P 12.34.

**Ru$^+$(Cp)[$\eta^1$-*P*-$Ph_2PCH$=C(*t*Bu)O$^-$](PPh$_3$)(CO)·$CH_2Cl_2$ (3b):** A mixture consisting of a sample of **2b** (3.00 g, 3.39 mmol), KOH (0.31 g, 5.54 mmol) and methanol (50 mL) was stirred for 3 days at room temperature. The resulting pale-yellow slurry was evaporated under vacuum until an orange colour was observed, and the residue was extracted with dichloromethane (20 mL). The solution was filtered and the orange filtrate was covered with diethyl ether (100 mL). The subsequent diffusion of solvents was conducted at –20 °C to avoid decomposition, and afforded large orange crystals, which were washed with hexane (20 mL). Yield: 2.20 g, 79%. IR: $\tilde{\nu}$ = 1489 cm$^{-1}$, C=CO; 1959 cm$^{-1}$, C≡O. $^1H$ NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 1.10 (s, 9 H, *t*Bu), 3.66 (d, $^2J_{PH}$ = 27.1 Hz, 1 H, PCH=), 4.98 (s, 5 H, Cp), 7.00–7.65 (m, 25 H, Ph) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CD_2Cl_2$): $\delta$ = 29.6 (s, $CMe_3$), 40.7 (d, $^3J$ = 10.7 Hz, $CMe_3$), 60.6 (d, $^1J$ = 70.9 Hz, PCH=), 90.4 (s, Cp), 127.8 (d, $^2J$ = 9.9 Hz, PPh, *ortho*), 127.8 (d, $^2J$ = 10.8 Hz, PPh, *ortho*), 128.1 (d, $^4J$ = 2.7 Hz, PPh, *para*), 128.5 (d, $^2J$ = 9.9 Hz, $PPh_3$, *ortho*), 128.7 (d, $^4J$ = 2.7 Hz, PPh, *para*), 130.6 (d, $^4J$ = 1.8 Hz, $PPh_3$, *para*), 131.7 (d, $^3J$ = 9.0 Hz, PPh, *meta*), 132.6 (d, $^3J$ = 10.8 Hz, PPh, *meta*), 134.0 (d, $^3J$ = 10.8 Hz, $PPh_3$, *meta*), 135.3 (d, $^1J$ = 48.5 Hz, $PPh_3$, *ipso*), 140.8 (d, $^1J$ = 53.0 Hz, PPh, *ipso*), 141.7 (d, $^1J$ = 50.3 Hz, PPh, *ipso*), 191.9 (s, =CO), 205.6 (dd, $^2J$ = 19.3 and 15.7 Hz, C≡O) ppm. $^{13}C$ NMR (75.47 MHz, $CD_2Cl_2$, selected values): $\delta$ = 60.6 (dd, $^1J_{HC}$ = 158, $^1J_{PC}$ = 70.5 Hz, PCH=) ppm. $^{31}P\{^1H\}$ NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = 19.5 (d, $^2J_{PP}$ = 27 Hz), 47.9 (d, $^2J_{PP}$ = 27 Hz). $C_{42}H_{40}O_2P_2Ru$·$CH_2Cl_2$ (824.73): calcd. C 62.62, H 5.13, Cl 8.60, P 7.51; found C 62.36, H 5.10, Cl 7.36, P 7.51.

**Ru$^+$(Cp)[$\eta^1$-*P*-$Ph_2PCH$=C(*t*Bu)O$^-$](PPh$_3$)(PMe$_3$):** A similar treatment of **2c** with KOH in methanol was attempted, but examination of the crude product after evaporation of the resulting dichloromethane solution by $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopy disclosed resonances corresponding to unreacted **2c** as well as a new set of resonances arising from the presence of the assumed zwitterionic complex. $^1H$ NMR (300.13 MHz, $CDCl_3$, available values): $\delta$ = 1.01 (s, 9 H, *t*Bu), 1.44 (d, $^2J_{PH}$ = 8.6 Hz, 9 H, $PMe_3$), 4.35 (s, 5 H, Cp) ppm. $^{31}P\{^1H\}$ NMR (121.50 MHz, $CDCl_3$, the additional presence of **2c** is omitted): $\delta$ = –5.3 (t, $^2J_{PP} \approx {}^2J_{PP'} \approx$ 42 Hz, PMe), 18.7 (dd, $^2J_{PP}$ = 42 and 35 Hz), 46.8 (dd, $^2J_{PP}$ = 42 and 35 Hz) ppm.

**Ru(Cp)[$\eta^2$-*P*,*O*-$Ph_2PCH$=C(*t*Bu)O](CO) (4b):** Crude **3b** was obtained from evaporation of the dichloromethane solution as described above starting from **2b** (13.0 g, 14.7 mmol), and then dissolved in THF (70 mL). The solution was heated at reflux for 20 h and then evaporated. Dichloromethane (60 mL) then methyl iodide (2.0 mL, 32.1 mmol, an excess) were added and this mixture was stirred overnight, then evaporated. The residue was extracted with diethyl ether (100 mL). The solution was filtered and the filtrate was evaporated to leave crude **4b**. Yield: 5.03 g, 72%. Heptane (60 mL) was added to a solution of crude **4b** in dichloromethane (30 mL) and this solution was slowly concentrated under vacuum to yield pure **4b** as a crystalline yellow powder. Orange-yellow crystals were also obtained by recrystallisation from hot hexane. IR: $\tilde{\nu}$ = 1494 cm$^{-1}$, C=CO; 1940 cm$^{-1}$, C≡O. $^1H$ NMR (300.13 MHz, $C_6D_6$): $\delta$ = 1.40 (s, 9 H, *t*Bu), 4.45 (s, 5 H, Cp), 4.85 (d, $^2J_{PH}$ = 4.1 Hz, 1 H, PCH=), 6.99–7.79 (m, 10 H, Ph) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CD_2Cl_2$): $\delta$ = 29.8 (s, $CMe_3$), 39.3 (d, $^3J$ = 12.1 Hz, $CMe_3$), 74.0 (d, $^1J$ = 61.9 Hz, PCH=), 84.5 (d, $^2J$ = 1.6 Hz, Cp), 128.6 (d, $^2J$ = 10.5 Hz, PPh, *ortho*), 128.6 (d, $^2J$ = 10.8 Hz, PPh, *ortho*), 129.2 (d, $^4J$ = 2.6 Hz, PPh, *para*), 130.3 (d, $^4J$ = 2.5 Hz, PPh, *para*), 130.7 (d, $^3J$ = 11.3 Hz, PPh, *meta*), 133.3 (d, $^3J$ = 10.8 Hz, PPh, *meta*), 136.9 (d, $^1J$ = 62.0 Hz, PPh, *ipso*), 143.4 (d, $^1J$ = 46.8 Hz, PPh, *ipso*), 202.7 (d, $^2J$ = 15.5 Hz, =CO), 203.6 (d, $^2J$ = 18.9 Hz, C≡O) ppm. $^{31}P\{^1H\}$ NMR (121.50 MHz, $C_6D_6$): $\delta$ = 61.4 (s) ppm. $C_{24}H_{25}O_2PRu$ (477.51): calcd. C 60.37, H 5.28; found C 60.54, H 5.28.

**Ru(Cp)[$\eta^2$-*P*,*O*-$Ph_2PCH$=C(*t*Bu)O](PMe$_3$) (4):** The slow concentration under vacuum of a solution of crude **4c** in methanol, the preparation of which is detailed below (see synthesis of **1c**), allowed the formation of orange crystals of analytical purity. IR: $\tilde{\nu}$ = 1492 cm$^{-1}$, C=CO. $^1H$ NMR (300.13 MHz, $C_6D_6$): $\delta$ = 0.91 (d, $^2J_{PH}$ = 9.0 Hz, 9 H, $PMe_3$), 1.42 (s, 9 H, *t*Bu), 4.21 (s, 5 H, Cp), 4.95 (d, $^2J_{PH}$ = 1.3 Hz, 1 H, PCH=), 6.98–7.74 (m, 10 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (121.50 MHz, $C_6D_6$): $\delta$ = 6.8 (d, $^2J_{PP}$ = 42 Hz, PMe), 64.8 (d, $^2J_{PP}$ = 42 Hz, PPh) ppm. $C_{26}H_{34}OP_2Ru$ (525.58): calcd. C 59.42, H 6.52, P 11.79; found C 59.72, H 6.71, P 12.12.

**{Ru(Cp)[$Ph_2PCH_2C$(*t*Bu)=O](PMe$_3$)}[PF$_6$] (1):** A mixture consisting of a sample of **2c** (6.13 g, 6.56 mmol), an excess of NaH (0.89 g, 37.1 mmol) and THF (80 mL) was heated at reflux for 20 h. The resulting mixture was filtered and the orange-yellow filtrate was evaporated to dryness to leave crude **4c** as a solid. The solid was dissolved in hot methanol (50 mL) to obtain an orange solution that was filtered. $NH_4PF_6$ (1.34 g, 8.22 mmol) and a 6 M solution of HCl in diethyl ether (2.0 mL, 12.0 mmol) were added to the filtrate, and the mixture was further stirred for 10 min. The resulting yellow precipitate was collected by filtration and washed with diethyl ether (50 mL), and then extracted with dichloromethane (60 mL). The solution was filtered and the filtrate was covered with methanol (20 mL) then diethyl ether (160 mL) to afford yellow crystals. Yield: 3.20 g, 73%. IR: $\tilde{\nu}$ = 1603 cm$^{-1}$, C=O. $^1H$ NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 1.16 (d, $^2J_{PH}$ = 9.1 Hz, 9 H, $PMe_3$), 1.26 (s, 9 H, *t*Bu), 3.32 (dd, $^2J_{HH}$ = 19.3, $^2J_{PH}$ = 7.2 Hz, 1 H, $PCH_2$,

0.9 Hz, =*C*Ph$_2$), 208.8 (dd, $^3J$ = 2.7 and 1.3 Hz, Ru=C=*C*), 208.9 (d, $^2J$ = 7.2 Hz, C=O), 293.2 (dd, $^2J$ = 18.4 and 16.6 Hz, Ru=C) ppm. $^{31}$P{$^1$H} NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = 9.6 (d, $^2J_{PP}$ = 36 Hz, PMe), 41.2 (d, $^2J_{PP}$ = 36 Hz, PPh).

**Isomerisation of 9c into 7c:** A solution of a sample of **9c** in methanol was stirred at room temperature and the isomerisation of **9c** into **7c** was monitored by $^{31}$P{$^1$H} NMR spectroscopy. Completion of the reaction was reached after 15 days. A 0.07 M aqueous solution of $K_2CO_3$ (2.0 mL, 0.14 mmol) was added to a solution of **9c** (1.80 g, 2.08 mmol) in dichloromethane (40 mL) and the mixture was stirred for 1 h. Examination of the resulting orange-red solution by $^{31}$P{$^1$H} NMR spectroscopy showed the isomerisation of **9c** into **7c** to be complete.

**{Ru(Ind)[Ph$_2$PCH$_2$C(=O)*t*Bu](PPh$_3$)(PMe$_3$)}[PF$_6$] (2′c):** A 1.0 M solution of trimethylphosphane in THF (8.0 mL, 8.0 mmol) was added to a solution of {Ru(Ind)[Ph$_2$PCH$_2$C(*t*Bu)=O](PPh$_3$)}[PF$_6$] (**1′a**) (6.00 g, 6.61 mmol) in dichloromethane (50 mL). The mixture was stirred overnight and then evaporated to dryness to leave the crude product that was recrystallised from dichloromethane (35 mL) and diethyl ether (140 mL) to afford orange-red crystals. Yield: 5.78 g, 89%. IR: $\tilde{\nu}$ = 1705 cm$^{-1}$, C=O. $^1$H NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 0.63 (s, 9 H, *t*Bu), 1.46 (d, $^2J_{PH}$ = 8.5 Hz, 9 H, PMe$_3$), 3.11 (m, 2 H, PCH$_2$), 4.51 (s, broad, 1 H, Ind), 5.44 (s, broad, 1 H, Ind), 5.57 (m, 1 H, Ind), 6.80–7.45 (m, 29 H, Ph and Ind) ppm. $^{31}$P{$^1$H} NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = –10.5. (t, $^2J_{PP} \approx {}^2J_{PP'} \approx$ 33 Hz, PMe), 42.8 (t, $^2J_{PP} \approx {}^2J_{PP'} \approx$ 33 Hz), 45.0 (t, $^2J_{PP} \approx {}^2J_{PP'} \approx$ 33 Hz) ppm. $C_{48}H_{52}F_6OP_4Ru$ (983.90): calcd. *C*$Ph_2$), 140.2 and 140.6 (2 s, C*Ph*$_2$, *ipso*), 141.8 (dd, $^1J$ = 55.7, $^3J$ = 2.7 Hz, PPh, *ipso*), 178.1 (d, $^2J$ = 3.6 Hz, O*C*tBu), 285.4 (dd, $^2J$ = 16.2 and 12.6 Hz, Ru=C) ppm. $^{13}$C NMR (75.47 MHz, $CD_2Cl_2$, selected values): $\delta$ = 85.1 (dd, $^1J_{HC}$ = 160, $^1J_{PC}$ = 58.5 Hz, PCH=), 137.9 (d, $^1J_{HC}$ = 160 Hz, *C*HCPh$_2$), 139.3 (d, $^2J_{HC}$ = 2.7 Hz, *C*Ph$_2$) ppm. $^{31}$P{$^1$H} NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = 1.6 (d, $^2J_{PP}$ = 31 Hz, PMe), 42.5 (d, $^2J_{PP}$ = 31 Hz, PPh) ppm. $C_{45}H_{49}F_6OP_3Ru$ (913.87): calcd. C 59.14, H 5.40, P 10.17; found C 58.29, H 5.17, Cl 0.73, P 10.34. The presence of chlorine indicated a slight retention of dichloromethane, which is likely responsible for the low carbon value.

**X-ray Crystallography:** Selected crystals of **3b**·$CH_2Cl_2$ and **7c** were studied with a NONIUS Kappa CCD diffractometer with graphite monochromator. Crystallographic data are given in Table 1. The cell parameters were obtained with Denzo and Scalepack,[15] and data collection with NONIUS KappaCCD Software.[16] Data reduction was carried out with Denzo and Scalepack.[15] The structures were solved with SIR-97, which revealed the non-hydrogen atoms.[17] After anisotropic refinement, many hydrogen atoms may be found with Fourier difference calculations. The whole structures were refined with SHELXL97 by full-matrix least-squares methods on $F^2$ ($x$, $y$, $z$, $\beta_{ij}$ for Ru, P, Cl, O and C atoms; $x$, $y$, $z$ in riding mode for H atoms).[18] ORTEP views were prepared with PLATON98.[19] Thermal ellipsoids for some atoms in the C30 ring in **7c** might suggest a disorder problem. Calculations to split these atoms in two positions to improve the structural model were unsuccessful, probably because this defect is not symmetrical relative to the phenyl ring axis.

CCDC-291347 (for **3b**) and -291348 (for **7c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Formation of Two 1D Polymeric Water Morphologies

Feng Li,[a] Tao-Hai Li,[a] Wei Su,[a] Shui-Ying Gao,[a] and Rong Cao*[a]

**Keywords:** Hosts / Water morphologies / Chains / Tapes

Two complexes with double- or triple-stranded chain structures, $\{[Cd(pg)(phen)]\cdot 3H_2O\}_n$ (**1**) and $\{[Cd_3(cpg)_3(phen)_2]\cdot 3H_2O\}_n$ (**2**), have been hydrothermally synthesized [$H_2pg$ = 3-phenylglutaric acid, $H_2cpg$ = 3-(4-chlorophenyl)glutaric acid, phen = 1,10-phenanthroline]. In the crystal lattices of **1** and **2**, two 1D polymeric water morphologies are observed (a treelike chain for **1** and a staircaselike tape for **2**), both of which contain $(H_2O)_6$ subunits. The geometrical parameters of water chains and tapes are similar to those in ice, $I_h$, and liquid water, respectively.

## Introduction

The fundamental importance of water in physical, biological, and chemical processes has prompted intensive research efforts, however, some properties of water still remain "anomalous".[1–4] The structural information of discrete water clusters is the first step to understanding the behavior of water.[5] In recent years, extensive structural studies on discrete water clusters have significantly advanced our preliminary comprehension of water.[6] A comparison between the physical properties of discrete water clusters and polymeric clusters, which structurally lie between small water clusters and bulk water/ice, shows that the properties of polymeric clusters are more closely associated with those of bulk water. Thus, studies involving polymeric water clusters are a further step towards understanding water. With the development of polymeric water clusters, three morphologies of polymeric water clusters[7] including infinite 1D-chain,[8] tape,[9] and 2D-layer[10] structures, have been observed. Among the three morphologies, 1D water chains and tapes are of great interest since many fundamental biological processes[11] and properties of materials[12] appear to depend on the unique properties of 1D water morphologies. Structural studies have shown that 1D water morphologies exist in gramicidin A membrane channels,[13] bacteriorhodopsin,[14] and α-amylase[15] for the rapid transport of protons and act as "proton wires". Thus, it is essential that 1D water morphologies can be rationally and predictably designed. However, most water clusters are obtained occasionally, and the rational design of such water morphologies still remains a challenge.

The lattices of crystal hosts offer environments for stabilizing various topologies of water clusters, which play important roles in the formation of different water morphologies. To obtain 1D water morphologies, it is necessary to construct suitable host frameworks for water molecules extending into chains or tapes. Without a doubt, a host channel, which can encapsulate the water chains or tapes, generated by organic or inorganic moieties is a good choice.[16] If a host chain can provide hydrogen-bond donors and/or acceptors, it may induce the free water molecules or discrete water clusters to extend with itself, and finally lead to 1D water morphologies. A metal–organic chain may be another good choice. In this paper, we report on two complexes, $[Cd_3(cpg)_3(phen)_2]\cdot 3H_2O$ (**1**) and $[Cd(cpg)(phen)]\cdot 3H_2O$ (**2**) [$H_2pg$ = 3-phenylglutaric acid, $H_2cpg$ = 3-(4-chlorophenyl) glutaric acid, phen = 1,10-phenanthroline], which both have 1D host frameworks and result in 1D water chains and tapes, respectively.

## Results and Discussion

Carboxyl groups can provide hydrogen-bond donors and/or acceptors, so we have chosen two similar benzoic carboxylates ($H_2pg$ and $H_2cpg$) as organic ligands to construct the host frameworks. In order to obtain 1D metal–organic chains, we selected 1,10-phen as a secondary ligand. The induction of the terminal ligand can prevent the chain from extending to intricate 2D and 3D architectures.

### Crystal Structure of $\{[Cd(pg)(1,10\text{-}Phen)]\cdot 3H_2O\}_n$ (1)

Single-crystal X-ray analysis reveals that **1** is a 1D double-stranded chain. As shown in Figure 1, each central cadmium ion is coordinated by two oxygen atoms from two monatomic bridging carboxylate groups (Scheme 1a), two

 InterScience © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

oxygen atoms from one chelating carboxylate group (Scheme 1b) and two nitrogen atoms from one 1,10-phen molecule. Two $pg^{2-}$ ligands link two cadmium ions forming a metal–organic ring, and these are bridged into a double-stranded chain through the monatomic bridging carboxylate groups (Figure 2).

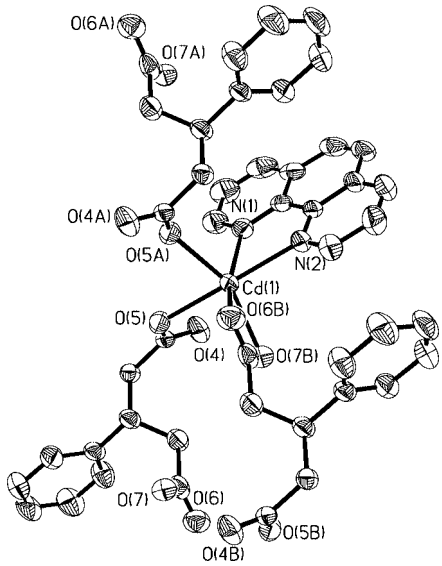

Figure 1. The coordination environment of cadmium ions in **1** with the thermal ellipsoids at the 50% probability level (all H atoms were omitted for clarity). Symmetry codes: #A: $-x + 1, -y + 1, -z$; #B: $-x + 1, -y + 2, -z$.

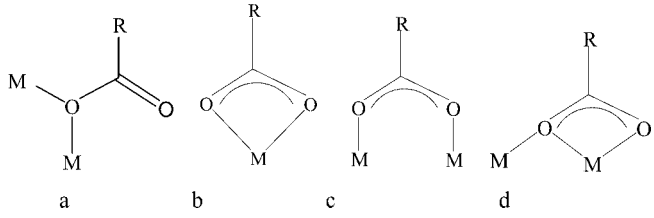

Scheme 1. The coordination modes assumed by the carboxylate ligands.

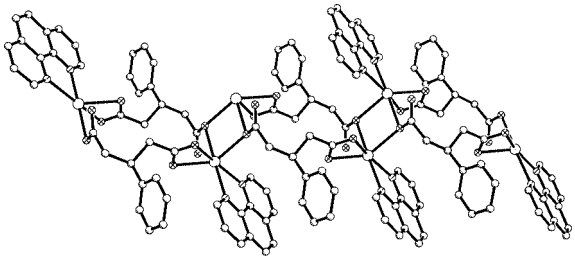

Figure 2. The double-stranded host chain of **1**.

In the crystal lattice of **1**, three crystallographically independent water molecules (O1w, O2w, and O3w) are observed, which are associated by hydrogen bonds to form a water trimer. The water trimer is hydrogen bonded to its equivalent, derived by the crystallographic $2_1$ axis along the [010] direction, forming a $(H_2O)_6$ unit. The geometric parameters of the hexamers are summarized in Table 1. The $2_1$ axis in symmetry operations of generating $(H_2O)_6$ clusters leads to a water hexamer with an opening structure. Such an open structure is different from any hexamer conformation revealed by theoretical calculations (ring, book, bag, cage, and prism).[19,20,6a] With O1w and equivalent molecules dangling at two sides, the hexamers are self-assembled into treelike chains along the [010] direction (Figure 3). The average O···O distance of 2.796 Å is very close to the corresponding value of 2.759 Å in ice, $I_h$, at –90 °C.[1] However, there is a wide variation in the O–O–O angles with an average of 131.2°, which deviates considerably from the corresponding value found in ice, $I_h$. The water chains link adjacent double-stranded metal–organic chains into a 2D network through the O1w–H···O6 and O3w–H···O4 hydrogen bonds. Neighbor layers are extended into a three-dimensional architecture through π–π interactions (3.367 Å) between two phenanthroline rings of the 1,10-phen ligand.

### Crystal Structure of $\{[Cd_3(cpg)_3(1,10\text{-Phen})_2]\cdot 3H_2O\}_n$ (2)

In the asymmetric unit of **2**, there are three crystallographically independent $Cd^{II}$ ions, three $cpg^{2-}$ ligands, two 1,10-phen ligands, and three water molecules, as revealed by X-ray crystallography. The coordination environments around the three $Cd^{II}$ ions are different, however, they all exhibit an octahedral-coordination geometry (Figure 4). Cd(1) is coordinated by two nitrogen atoms from one 1,10-phen ligand, one oxygen atom from one *syn*,*syn*-$\eta^1$:$\eta^1$:$\mu_2$ bridging carboxylate group (Scheme 1c), one oxygen atom from one monatomic bridging carboxylate group (Scheme 1a), and two oxygen atoms from one chelate bridging carboxylate group (Scheme 1d). Cd(2) is coordinated by two nitrogen atoms from one 1,10-phen ligand, two oxygen atoms from two *syn*,*syn*-$\eta^1$:$\eta^1$:$\mu_2$ bridging carboxylate groups (Scheme 1c), and two oxygen atoms from one chelate bridging carboxylate group (Scheme 1d). Cd(3) is coordinated by three oxygen atoms from three *syn*,*syn*-$\eta^1$:$\eta^1$:$\mu_2$ bridging carboxylate groups (Scheme 1c), two oxygen atoms from one chelate bridging carboxylate group (Scheme 1d), and one oxygen atom from one monatomic bridging carboxylate group (Scheme 1a). As a result of the coordination diversity of carboxylate groups, three $Cd^{II}$ ions are connected to form a trinuclear cluster. As a basic building unit, the trinuclear clusters are fused to an infinite triple-stranded chain bridged by the carboxylate groups of the $cpg^{2-}$ ligands. To accommodate the role of the bridging trinuclear clusters, the alkyl chain of the $cpg^{2-}$ ligands rotates from the most stable *anti* form to the gauche form, which is higher in energy. The rotation of the flexible $cpg^{2-}$ ligand allows each strand to twist in order to form a helical chain. By sharing cadmium ions, the three strands are attached to produce a novel triple-stranded helical chain (Figure 5). In the case of the infinite double and higher order helices there are two kinds of possibilities: (i) The strands of the helix are independent infinite chains held together by noncovalent forces, analogous to the situation in DNA;[21] and (ii) The strands are not independent, but are attached through coordinative bonds to a column of metal atoms, which form the axis of the helix. To the best of our knowledge, complex **1** is the first infinite triple-stranded helical chain of type (ii).

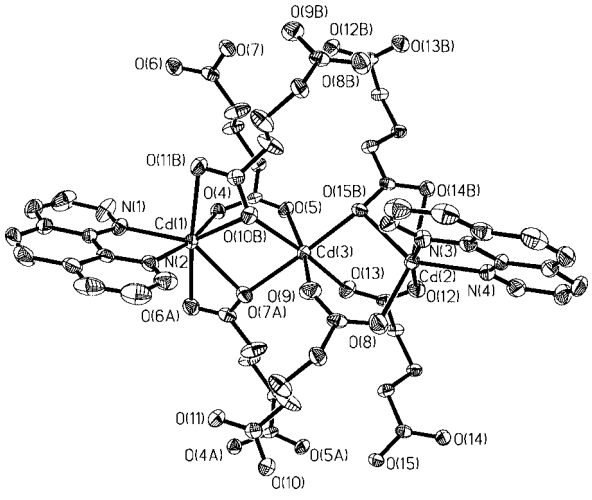

Figure 4. The coordination environment of cadmium ions in **2** with the thermal ellipsoids at the 30% probability level (all hydrogen atoms and the chlorophenyl groups of the $cpg^{2-}$ ligand were omitted for clarity). Symmetry codes: #A: $x + 1$, $y$, $z$; #B: $x - 1$, $y$, $z$.

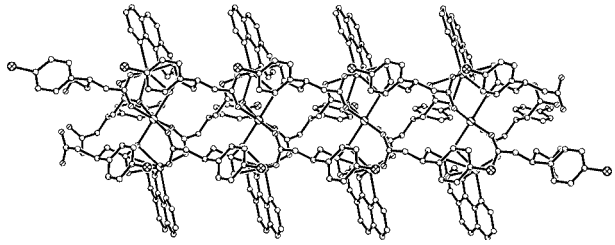

Figure 5. The triple-stranded host chain of **2**.

Similar to **1**, there are three crystallographically independent free water molecules in the crystal lattice of complex **2**. These three water molecules and their equivalents, generated by a crystallographic inversion center, are associated by O–H···O hydrogen bonds in a cyclic centrosymmetric hexamer. The mean deviation of the three atoms from the plane is 0.0088 Å, which shows that these atoms are almost located on the same plane and the hexamer ring exists as a planar conformation. The geometric parameters of the hexamers are summarized in Table 1. The average O···O distance of 2.858 Å is longer than the value of 2.759 Å in ice, $I_h$,[1] but very similar to the O···O distance of 2.85 Å in liquid water.[22] The average value of the O–O–O angles is 119.3°, which deviates considerably from the corresponding value found in liquid water. The hexamers are self-assembled by O3w–H···O1w hydrogen bonds into extended water tapes along the [100] direction, consisting of fused four- and six-membered water rings (Figure 6). The dihedral angle between four- and six-membered rings is 44.1°, which makes the water tape "staircase"-like. The interhexamer O1···O3B distance of 2.892 Å is also close to the corresponding O···O distance in liquid water. Additional O2w–H···O4 and O3w–H···O6 hydrogen bonds anchor the water tapes to two adjacent metal–organic chains, resulting in triple helical chain pairs. The triple chain pairs are extended

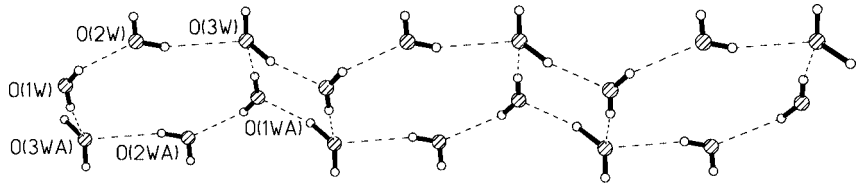

Figure 6. The staircaselike water tape in **2**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

into a three-dimensional architecture through π–π interactions (3.779 Å) between two phenanthroline rings of 1,10-phen ligands from neighboring chains.

### Thermal Analysis and X-ray Powder Diffraction

Samples of **1** and **2** were examined by TGA, which show similar TGA curves (Figure 7). TGA analyses of **1** show a 4.11% weight loss from 63 to 108 °C, which corresponds to 1.26 of the 3 free water molecules. The remaining water molecules are eventually lost at 345 °C. For **2**, the weight loss of 1.92% from 61 to 91 °C is equivalent to the loss of 1.57 of the three free water molecules. The remaining water molecules are lost slowly until a temperature of 268 °C is reached. After all the free water molecules were released from the structure the metal–organic host chains started to decompose. To confirm the TGA, the original samples and dehydrated samples of **1** and **2** were characterized by X-ray Powder diffraction (XRPD) at room temperature (Figure 8 and Figure 9). The patterns that were simulated from the single-crystal X-ray data of **1** and **2** were in good agreement with those that were observed. However, after water molecules were lost as a result of heat, total changes in the pattern were observed, suggesting decomposition of the metal–organic framework. This is expected, as the water chain or tape acts as a "glue" to assemble the overall structure.

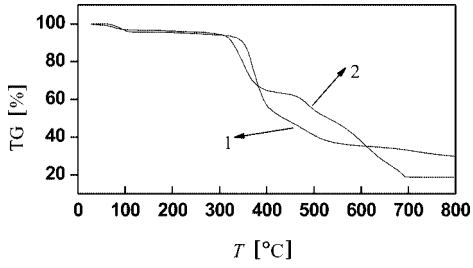

Figure 7. TGA curves for **1** and **2**.

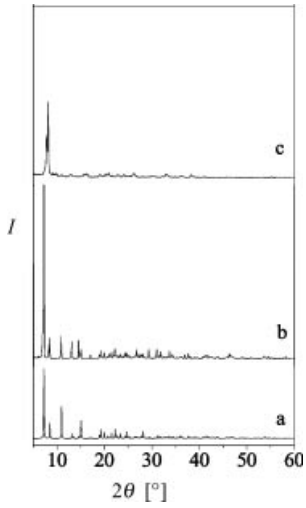

Figure 8. XRPD patterns for **1**: (a) calculated from single-crystal X-ray data; (b) taken at room temperature; (c) after heating at 350 °C for 2 h.

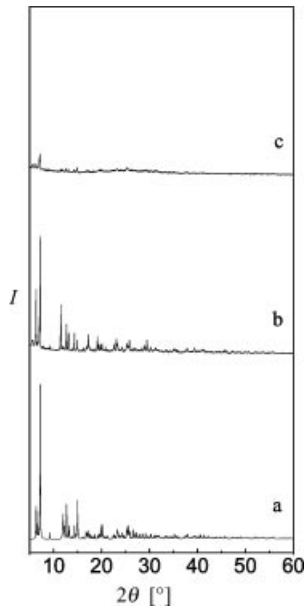

Figure 9. XRPD patterns for **2**: (a) calculated from single-crystal X-ray data; (b) taken at room temperature; (c) after heating at 300 °C for 2 h.

### Vibrational Spectra

The FT-IR spectroscopy of **1** shows strong bands at 1574 and 1428 $cm^{-1}$ due to the $\upsilon_{asym}(CO_2)$ and $\upsilon_{sym}(CO_2)$ stretching vibrations, respectively. For **2**, the $\upsilon_{asym}(CO_2)$ and $\upsilon_{sym}(CO_2)$ stretching vibrations appear at 1585 $cm^{-1}$ and 1402 $cm^{-1}$, respectively. The spectra of **1** and **2** exhibit broad bands centered around 3375 and 3406 $cm^{-1}$, respectively. The O–H stretching vibration for the quasiplanar water hexamer appears[23] as a broad band centered around 3400 $cm^{-1}$; the O–H stretching vibration for the same cluster in a helium droplet appears at 3325 $cm^{-1}$.[6b] In comparison, this vibration of the planar hexamers in the ice I and II phases occurs at 3220 $cm^{-1}$.[1] After removing the water from the crystal lattices of **1** and **2** by heating, the bands centered around 3375 and 3406 $cm^{-1}$ disappear. Therefore, in the case of **1** and **2**, these bands are attributable to the O–H stretching frequency of the $(H_2O)_6$ core structure. The difference in the stretching vibration may arise from their different conformations and environments. Deliberate exposure to water vapor for 3 d does not lead to reabsorption of water into the lattice as monitored by FTIR spectroscopy.

## Conclusions

In conclusion, two complexes with metal–organic host chains have been synthesized successfully, in which two 1D water morphologies are observed. When the host chains change from double stranded to triple stranded, the water morphologies are observed as treelike chains and staircaselike tapes, respectively, which contain $(H_2O)_6$ subunits with different conformations. The water morphologies act as building blocks extending the host frameworks into a higher dimensionality. In this sense, the water chains and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tapes are different from other 1D water morphologies encapsulated in the host channels generated by organic or inorganic moieties. We propose that the metal–organic chain, with selected hydrophilic groups, may be a good host framework to induce the formation of 1D water morphologies. This discovery may be helpful in the rational design of 1D water morphologies.

## Experimental Section

**General Methods:** All chemicals were obtained commercially and used without further purification. Elemental analyses were carried out with an Elementar Vario EL III analyzer. Infrared (IR) spectra were recorded with a PerkinElmer Spectrum One as KBr pellets in the range 4000–400 $cm^{-1}$. Thermogravimetric analyses were carried out with a NETZSCH STA 449C unit at a heating rate of 10 °C $min^{-1}$ under nitrogen. X-ray Powder diffraction measurements were recorded with a RIGAKU DMAX2500PC diffractometer using Cu-$K_\alpha$ radiation.

**Preparation of Complexes**

**{[Cd(pg)(1,10-Phen)]·3H$_2$O}$_n$ (1):** A mixture of $H_2$pg (0.021 g, 0.1 mmol), 1,10-phen (0.020 g, 0.1 mmol), and $Cd(NO_3)_2$·4$H_2O$ (0.031 g, 0.1 mmol) in distilled water (15 mL) was sealed in a Teflon-lined Stainless autoclave and heated at 165 °C for 3 d under autogenous pressure and then cooled to room temperature for 2 d. Colorless crystals (26 mg) were isolated in 47% yield and washed with distilled water. $C_{23}H_{24}N_2O_7Cd$ (552.84): calcd. C 49.81, H 4.37, N 5.05; found C 49.80, H 4.38, N 5.06. IR (KBr): $\tilde{\nu}$ = 3375 (m), 3063 (w), 1574 (vs), 1515 (s), 1428 (vs), 1251 (w), 1103(w), 973(w), 864 (s), 854 (vs), 775 (m), 729 (s) $cm^{-1}$.

**{[Cd$_3$(cpg)$_3$(1,10-Phen)$_2$]·3H$_2$O}$_n$ (2):** A mixture of $H_2$cpg (0.024 g, 0.1 mmol), 1,10-phen (0.020 g, 0.1 mmol), and $Cd(NO_3)_2$·4$H_2O$ (0.031 g, 0.1 mmol) in distilled water (15 mL) was sealed in a Teflon-lined Stainless autoclave and heated at 165 °C for 3 d under autogenous pressure and then cooled to room temperature for 2 d. Yellow prism-like crystals (47 mg) suitable for X-ray analysis were isolated in 32% yield and washed with distilled water. $C_{57}H_{49}N_4O_{15}Cl_3Cd_3$ (1473.55): calcd. C 46.46, H 3.35, N 3.80; found C 46.48, H 3.34, N 3.81. IR (KBr): $\tilde{\nu}$ = 3406 (m), 1581 (vs), 1518 (m), 1493 (m), 1402 (s), 1281 (w), 1092 (w), 1014 (w), 976 (w), 866 (m), 831 (m), 729 (s) $cm^{-1}$.

**X-ray Crystallography**

X-ray diffraction data were collected with a Rigaku diffractometer with a Mercury CCD area detector (Mo-$K_\alpha$; $\lambda$ = 0.71073 Å) for **1** and **2** at 173(2) K. Empirical absorption corrections were applied to the data using the CrystalClear program.[17] The structures were solved by the direct method and refined by the full-matrix least-squares on $F^2$ using the SHELXTL-97 program.[18] The hydrogen atoms on the organic ligands were generated by the riding mode (C–H = 0.95 Å), and hydrogen atoms on water molecules were located from difference maps. Bond lengths and bond angles are listed in Table 2. Crystallographic data and other pertinent information for **1** and **2** are summarized in Table 3.

CCDC-289131 and CCDC-281815 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# The UV/Vis Spectrum of Potassium Heptacyanovanadate(III): A Theoretical Multi-Reference Configuration Interaction Study Combined with Low-Temperature Experiments

Volker Schmid,[a] Rolf Linder,[a] and Christel M. Marian*[a]

**Keywords:** Cyanide ligands / Electronic structure / Quantum chemistry / UV/Vis spectroscopy / Vanadium

The electronic spectrum of $K_4[V(CN)_7]$ has been calculated by means of a combined quantum chemical density functional and multi-reference configuration interaction scheme. In addition to the states known so far, our calculations predict the existence of two low-lying triplet electronic states with excitation energies of 13600 and 13700 $cm^{-1}$, respectively. Both result from $d_{e''_1} \rightarrow d_{e'_2}$ excitations in the slightly distorted pentagonal-bipyramidal ligand field. To validate these theoretical results we measured a UV/Vis spectrum at low temperatures. In the wavelength range between 800 and 500 nm we observed a broad band with vibrational substructure (peak positions: 13661, 14450, 15243, 16051, and 16807 $cm^{-1}$). The origin transition at 13661 $cm^{-1}$ is in excellent agreement with our theoretical predictions.

## Introduction

Six- and fourfold coordination of a central atom by ligands is the most common coordination scheme observed in transition metal complexes. Ligand-field parameters have been derived from experimental d–d spectra for a variety of these complexes.[1–3] To be able to adjust ligand parameters in a meaningful way, the character of a spectral band observed in absorption or emission has to be assigned properly. In some instances, the assignment, and thus also the parameter adjustment, is hampered because electronic d–d transitions in highly symmetric complexes are dipole forbidden and thus tend to be weak.

In the past decade, quantum chemical methods have made enormous progress, such that the properties of molecular ground states, for example the electronic structure or the molecular geometry, can be computed routinely with high confidence. In contrast, electronically excited states pose a much harder challenge, particularly for large molecules. Here, only a few methods are applicable. Among the ab initio approaches, presently the most common one is time-dependent density functional theory (TDDFT)[4] because of its computational efficiency. However, its has been shown recently that TDDFT, when used with standard functionals, may give dramatic failures for charge-transfer (CT) states.[5,6] The reliable prediction of the electronic excitation spectra of transition metal complexes has come into reach through the development of multi-reference second-order perturbation theory methods, such as CASPT2[7] and MRMP2,[8] as well as variational procedures that combine density functional theory and multi-reference configuration interaction schemes such as the DFT/MRCI approach.[9] These methods do not suffer from the flaws of TDDFT and offer the possibility to compute absorption spectra of transition metal complexes and thus help assign fragmentary experimental data.

Vanadium is one of the few transition metals that forms hexa- as well as heptacoordinate complexes, although knowledge of the heptacoordinate vanadates is patchy. Until recently, only two d–d transitions at 20600 and 22800 $cm^{-1}$ had been observed in a solid-state spectrum of $K_4[V(CN)_7]\cdot 2H_2O$,[10] although Bennett and Nicholls have prepared crystals with the approximate chemical composition $K_4[V(CN)_7]\cdot H_2O$ for which they found d–d transitions at 22300 and 28900 $cm^{-1}$.[11] Bands at approximately 14700 $cm^{-1}$ have also been seen in aqueous solutions of $K_4[V(CN)_7]$.[12,13] However, $[V(CN)_7]^{4-}$ ions are known to disproportionate in water and the bands were assigned to originate either from a spin-forbidden transition in $[V(CN)_6]^{4-}$[13] or to $VO(CN)_5^{4-}$ complexes.[11] Thus, the assignment of the 14700 $cm^{-1}$ band to a heptacyanovanadate(III) complex in water was rather uncertain. Bands at 36400 $cm^{-1}$ and higher energies have been ascribed to CT transitions in crystals of $K_4[V(CN)_7]\cdot H_2O$.[11]

The $d^2$ configuration of the $V^{3+}$ ion yields nine singlets and six triplets for the free complex in $D_{5h}$ symmetry, i.e., the symmetry point-group of a pentagonal bipyramid. From EPR spectra, the electronic ground state of $K_4[V(CN)_7]$ is known to be a high-spin state,[11] therefore only triplet states are considered here. In the solid state, the

Table 1. Triplet states resulting from a $d^2$ occupancy in a pentagonal-bipyramidal ligand field and distorted towards $C_{2v}$ symmetry.

| $D_{5h}$ Symmetry Orbital product | Electronic state(s) | $C_{2v}$ Symmetry Electronic state(s) |
|---|---|---|
| $d_{e_1''} \otimes d_{e_1''}$ | $^3A_2'$ | $^3B_2$ |
| $d_{e_1''} \otimes d_{e_2'}$ | $^3E_1'' \oplus {}^3E_2''$ | $2\,{}^3A_2 \oplus 2\,{}^3B_1$ |
| $d_{e_1''} \otimes d_{a_1'}$ | $^3E_1''$ | $^3A_2 \oplus {}^3B_1$ |
| $d_{e_2'} \otimes d_{e_2'}$ | $^3A_2'$ | $^3B_2$ |
| $d_{e_2'} \otimes d_{a_1'}$ | $^3E_2'$ | $^3A_1 \oplus {}^3B_2$ |

high symmetry of the ligand field is distorted because of the tetrahedral arrangement of potassium counterions in the unit cell.[14] This reduction to $C_{2v}$ symmetry results in a splitting of degenerate electronic energies to yield 10 nondegenerate triplet states. The electronic configurations originating from a $d^2$ configuration and their irreducible representations in the $D_{5h}$ and $C_{2v}$ molecular point-groups are displayed in Table 1. In addition to these states, CT states will occur at higher energies in the electronic spectrum.

## Results and Discussion

The optimized complex geometry (OptGeo) corresponds to a slightly distorted pentagonal bipyramid with nearly equal axial and equatorial ligand bond lengths (see Figure 1). Crystal water that is present in the unit cell of $K_4[V(CN)_7]\cdot 2H_2O$[10] has been ignored in the calculations. The computed vanadium–carbon distances range from 218 to 220 pm, in fair agreement with the X-ray diffraction data (213–216 pm).[10] The CN ligand bonds are slightly longer in the optimized structure (116–117 pm) than in the experimental one (114–115 pm). In the fully optimized structure, the bond angles between equatorial ligands range between 70.6° and 73.5°. These values agree with the experimentally derived data within ±1°. The C–V–C angle of the two axial ligands, on the other hand, comes out somewhat too large. For this angle we compute a value of 177° compared to 171° in the X-ray structure. The energetic splitting of electronic states that are degenerate in the ideal $D_{5h}$ symmetry might therefore be somewhat underestimated in our calculations.

Although the $[V(CN)_7]^{4-}$ moiety is nearly $C_{2v}$ symmetric, the overall symmetry of the experimental X-ray structure is $C_1$ because two of the potassium counterions are slightly distorted out of the equatorial plane by the crystal water. In our calculations, we find the two equatorial $K^+$ ions at a distance of 462 pm from the central vanadium compared to values of 479 or 480 pm from the X-ray data. The two $K^+$ ions located below and above the equatorial plane, respectively, are separated from the vanadium nucleus by 393 pm according to our calculations, whereas these distances are 442 and 445 pm in the crystal.

To get an idea of the influence of the nuclear geometry on the electronic excitation energies, we performed two additional calculations. In the first one, $C_{2v}$ symmetry was retained but the C–V–C angle of the two axial ligands was set to the experimental value of 171°. The corresponding V–C–N angles were set to 173°. The coordinates of the potassium ions and the equatorial ligands were left unchanged with respect to the optimized geometry. This structure will be denoted as (AxLGeo). The second nuclear arrangement (ExpGeo) exhibits no symmetry at all. Here, the coordinates of all $CN^-$ ligands and the potassium counterions were fixed at their experimental X-ray positions.[14] It differs from the experimental unit-cell only by the lack of crystal water.

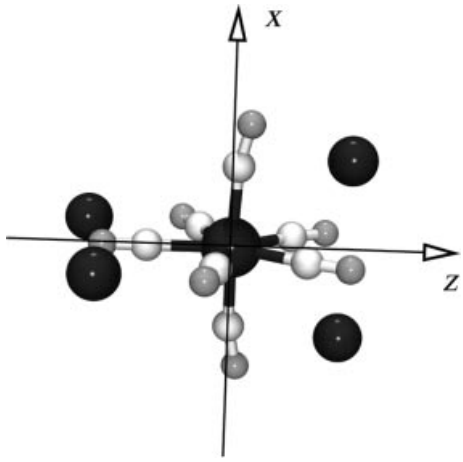

Figure 1. Optimized structure of the free potassium heptacyanovanadate(III) complex and orientation of the Cartesian coordinate system. The *y*-axis points toward the viewer.

The electronic ground-state corresponds to a configuration in which the d orbital of $e_1''$ symmetry is doubly occupied. As the *z*-axis has been chosen to coincide with the $C_2$ rotation axis of the $C_{2v}$ subgroup, $d_{e_1''}$ correlates with the Cartesian $d_{xz}$ and $d_{xy}$ orbitals. According to Table 1, this occupation gives rise to a triplet state of $A_2'$ symmetry in the undistorted pentagonal bipyramid or a $^3B_2$ state in the actual $C_{2v}$ point group.

A collection of measured and computed spectroscopic data is displayed in Table 2. Theoretical values correspond to vertical excitation energies at the optimized geometry (OptGeo). UTDDFT entries are not displayed in energetical order but are identified according to their symmetry labels and have been sorted to match the order of the corresponding DFT/MRCI entries. The lowest excited triplet states arise from d–d single excitations and combinations thereof. The first two states with DFT/MRCI excitation energies around 14000 $cm^{-1}$ are derived from the $d_{e_1''} \rightarrow d_{e_2'}$ ($^3E_2''$) state in $D_{5h}$ point-group symmetry. The lower one, $1\,{}^3A_2$, exhibits a $d^1_{xz}\,d^1_{yz}$ occupation, while its nearly degenerate partner state of $B_1$ symmetry has a leading configura-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion with $d_{xz}$ and $d_{y^2-z^2}$ open shells. The electronic structures of the states originating from the two $^3E_1''$ states are considerably more involved because their $d^1_{e_1''}\,d^1_{e_2'}$ and $d^1_{e_1''}\,d^1_{a_1'}$ configurations are allowed to interact even in a perfect pentagonal-bipyramidal arrangement. A simple molecular orbital picture is therefore not appropriate in this case. In addition to d–d single excitations, we find some contributions from excitations into vanadium p and ligand σ orbitals. As a result, we observe a marked energetic splitting of the $^3E_1''$ components due to the $C_{2v}$-symmetric ligand field. The four members belonging to this group of states span an energy range from approximately 20600 cm$^{-1}$, where the second $^3B_1$ state is located, to the fourth $^3A_2$ state at about 31400 cm$^{-1}$. In between, and extending well above this energy regime, we find several CT states. The third, fifth, and sixth $^3A_2$ states, the fourth to seventh $^3B_1$ states, all $^3A_1$ as well as the second and third $^3B_2$ states correspond to CT excitations from a vanadium d orbital to a $CN^-$ ligand π* orbital. The seventh $^3A_2$ state also exhibits CT character, but in a reversed sense. Here, the excitation originates from the highest occupied $a_1$ ligand-orbital and the electron is placed in the $d_{e_1''}$ orbital of vanadium. No indication for states arising from double excitations within the d shell (corresponding to the orbital products $d_{e_2'} \otimes d_{e_2'}$ and $d_{e_2'} \otimes d_{a_1'}$, respectively) are found in the energy regime below 40000 cm$^{-1}$.

When we started the present investigation, the lowest experimentally known band was located at about 20600 cm$^{-1}$.[10] In our theoretical spectrum, we find a transition exactly at this wavenumber. However, this band corresponds to the third excited electronic state (2 $^3B_1$). Since the dipole moments of the d–d excited states are all very similar (see Table 2), we do not expect considerable solvent shifts. Could our computed excitation energies of the $K_4[V(CN)_7]$ complex be so erroneous? In order to answer this question, a UV/Vis spectrum of $K_4[V(CN)_7]$ was recorded at liquid helium temperatures. This spectrum is shown in Figure 2. In the wavelength range between 800 and 500 nm we observe a broad band with substructure (peak positions: 13661, 14450, 15243, 16051, and 16807 cm$^{-1}$). Our calculations predict two electronic transitions ($^3B_2 \rightarrow {}^3A_2$ and $^3B_2 \rightarrow {}^3B_1$) in this spectral area. Their small crystal-field splitting presumably prevents the resolution of these electronic transitions in the experimental spectrum. The regular spacing of the substructure (approx. 800 cm$^{-1}$) leads us to the conclusion that it is caused by a vibrational progression,

Table 2. Electronic triplet states of $K_4[V(CN)_7]$. Excitation energies $\Delta E$ are given in wavenumber units and dipole moments, $\mu$, in Debye units. Oscillator strengths $f(r)$ were computed in the length form and are dimensionless.

and the first peak at 13661 $cm^{-1}$ is assumed to be the origin of the electronic transition. Its position is in excellent agreement with our predictions. In view of the typical error bars of the DFT/MRCI method (approx. ±2000 $cm^{-1}$)[9] such a close match must be considered somewhat fortuitous. The fourth electronically excited state ($2\ ^3A_2$) in our theoretical spectrum is located 1300–1900 $cm^{-1}$ above the corresponding experimental band, depending on the reference.

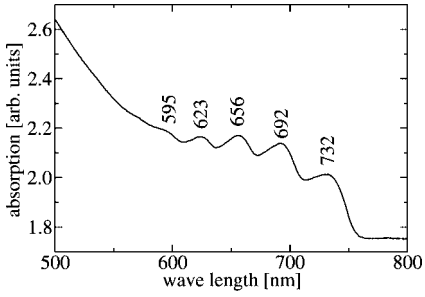

Figure 2. UV/Vis spectrum of $K_4[V(CN)_7]\cdot 2H_2O$ dispersed in silicon paste and recorded at 5 K.

The assignment of the higher-lying d–d states is less certain. In a solid-state spectrum of the (possibly eightfold coordinated) $K_4[V(CN)_7]\cdot H_2O$, Bennett and Nicholls[11] found a band with d–d character at 28900 $cm^{-1}$. In our theoretical spectrum, we only obtain a CT state with moderate oscillator strength in this energy regime. The d–d excited third $^3B_1$ state lies about 3000 $cm^{-1}$ below this transition. However, since the pure electronic transition is dipole forbidden, this state might be difficult to locate.

The DFT/MRCI calculations yield many more CT states than experimentally observed bands. However, this is not thought to be an artifact of our quantum chemical method. The MRCI treatment includes the nonlocal exchange interaction that is required for a correct asymptotic behavior of CT states.[6] The experimental spectra exhibit broad, poorly resolved bands. As the theoretical density of states is very high, we refrained from specifying the particular orbital excitations and labeled these states either as CT (d→L) or CT (L→d), depending on the direction of the charge transfer. Our assignment can only be tentative as it rests on the observation that the extinction coefficients of the CT bands in a solution spectrum (4 M KCN)[11] are larger than those of the d–d bands by two orders of magnitude.

It is difficult to judge the quality of the UTDDFT results. Overall, UTDDFT in combination with the B3LYP functional performs quite well for the d–d transitions, although it appears that the interaction between electronic configurations with a $d_{e_1''} \otimes d_{e_2'}$ open-shell structure is somewhat underestimated. This becomes apparent in the smaller splitting between the corresponding $^3E_2''$ and $^3E_1''$ states compared to the DFT/MRCI results and in the higher excitation energies of the first two excited states. CT states that involve predominantly ligand orbitals of $a_2$, $b_1$, or $b_2$ symmetries are located at comparable excitation energies in the UTDDFT and DFT/MRCI treatments, whereas excitations into totally symmetric ligand orbitals appear at considerably lower energies in the UTDDFT spectrum. The largest energy difference (more than 8000 $cm^{-1}$) is found for the $5\ ^3A_2$ state. This state is dominated by a single excitation from the vanadium $d_{e_1''}$ ($b_1$) orbital to unoccupied $a_1$ ligand orbitals. To a lesser extent, similar observations are made for other $A_2$ and $B_2$ CT states. We suppose that this difference is related to the above-mentioned wrong asymptotic behavior of the local exchange correlation functional and the fact that B3LYP contains only 20% exact exchange, although we cannot prove this hypothesis.

DFT/MRCI excitation energies obtained at the (AxLGeo) geometry, where the deflection of the axial ligands from the $z$ axis is identical to the X-ray structure, differ by, at most, 600 $cm^{-1}$ from the corresponding (OptGeo) values (see Table 2). The splitting between the $^3A_2$ and $^3B_1$ components of the lowest $^3E_2''$ and $^3E_1''$ states increase only slightly when proceeding from (OptGeo) to (AxLGeo). The oscillator strengths have the same order of magnitude at the two geometries and are therefore not listed. The energetic location of the CT states remains nearly unchanged. However, dramatic changes are observed in the spectrum if the electrostatic interaction with the counterions is not optimized (ExpGeo). In this case, diffuse electron-density distributions are stabilized to an extent that the first CT transitions appear already at about 20000 $cm^{-1}$, whereas all d–d transitions are blue-shifted. The first two d–d transitions are found at 18029 and 18995 $cm^{-1}$, respectively, in this DFT/MRCI calculation, followed by four CT states before the next d–d transition appears at 26351 $cm^{-1}$. This situation is aggravated if the counterions are moved even further out, eventually leading to an electron detachment from the central $[V(CN)_7]^{4-}$ unit. In that case, the solutions become heavily dependent on the AO basis set and are meaningless.

## Summary and Conclusions

We have computed the electronic spectrum of $K_4[V(CN)_7]$ by means of the DFT/MRCI method, which is a combined density functional and multi-reference configuration interaction approach. In addition to the states known so far from experiment, our quantum chemical calculations predict the existence of two low-lying excited electronic states that result from single excitations within the vanadium d shell. The configurations of the higher d–d excitations are considerably mixed so that a simple molecular orbital picture is not applicable.

The theoretical prediction of additional low-lying d–d states is confirmed by low-temperature optical spectroscopy measurements. For $K_4[V(CN)_7]\cdot 2H_2O$, a broad band with vibrational substructure in the wavelength range between approximately 750 and 600 nm is observed for the first time.

Concerning the excitation energies, we obtain excellent agreement between theory and experiment. Taking all measured transitions into account, the root mean square deviation (RMSD) from experiment amounts to merely 600 $cm^{-1}$. These findings suggest that the DFT/MRCI method, which was originally devised for organic molecules,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

can equally well be applied to determine the electronic spectra of transition metal complexes. The theoretical prediction of d–d excitations has thus become a valuable complement to the measurement of these weak bands.

We have shown that d–d transitions of transition metal coordination compounds in the solid state can be modeled successfully by calculations on isolated clusters. However, at least for highly negatively charged coordination complexes such us $[V(CN)_7]^{4-}$, single-point calculations at the experimental geometry of the unit cell are not sufficient. Before the vertical spectrum can be computed, it is necessary to relax the geometry of the complex, including the counterions, thus optimizing the electrostatic interactions of the surrounding.

## Experimental Section

**Theoretical Methods:** The geometry of the free $K_4[V(CN)_7]$ complex was optimized utilizing the B3LYP density functional[15,16] as implemented in the TURBOMOLE package.[17,18] The search for a minimum on the potential-energy surface started from the experimentally known X-ray structure[14] of the crystalline unit cell, i.e., a slightly distorted pentagonal bipyramid of $[V(CN)_7]^{4-}$ tetrahedrally surrounded by four potassium ions. Carbon and nitrogen atomic orbitals (AOs) were described by the TZVPP basis (valence triple zeta plus 2d1f polarization) of the TURBOMOLE library. For vanadium, we employed a 13-electron relativistic effective core potential.[19] The corresponding valence basis was augmented with two f functions with exponents 1.14 and 0.52, optimized in scalar relativistic calculations[20] on $V^+(^5D_g)$ for the description of s–d and d–d correlation effects, respectively. We chose to represent even the potassium ions by (large-core) pseudopotentials[21] instead of point charges to prevent an artificial drain of electrons from the fourfold negatively charged complex.

The electronic spectrum was computed by means of the DFT/MRCI method by Grimme and Waletzke.[9] For comparison, a spin-unrestricted time-dependent DFT (UTDDFT) calculation was carried out at the optimized geometry. For this task we utilized the ESCF module of TURBOMOLE[22] employing the B3LYP density functional. In the DFT/MRCI approach, major parts of dynamic electron correlation are included by density functional theory whereas moderate multi-reference configuration interaction expansions take account of static correlation effects. To this end, the determinants in the CI expansion are built up from Kohn–Sham (KS) orbitals and an effective Hamiltonian is employed that contains five empirical parameters. Optimized parameter sets are currently available in combination with the BHLYP[16,23] functional. Double counting of electron correlation is obviated by scaling off-diagonal CI matrix elements with a factor that depends exponentially on the energy difference between the diagonal energies of the two configuration state functions. For further technical details we refer to the original publication.[9]

The DFT/MRCI calculations were carried out in a somewhat reduced AO basis set: we employed a TZVP basis (valence triple zeta plus 1d polarization) for carbon and nitrogen while keeping the vanadium and potassium basis sets unchanged. KS orbitals were optimized for the lowest lying closed-shell determinant, which served also as a starting point for the automated generation of the CI reference space. A common set of reference configurations was used for all spatial symmetries. The first set comprised all single and double excitations involving eight electrons in the four energetically highest-lying occupied orbitals and the four lowest unoccupied orbitals. In $C_{2v}$ symmetry, CI energies and vectors were determined for the three lowest triplet states in the $A_1$ and $B_2$ irreducible representations, respectively. As many of the low-lying triplet states exhibit $A_2$ or $B_1$ symmetry, seven roots were computed for these irreducible representations. The CI expansion was kept moderate by extensive configuration selection: all excitations into MO with orbital energies above 8 $E_H$ (anti-core) and all configurations with energies 0.75 $E_H$ above the energy of the highest reference vector were discarded. The original reference space was then iteratively improved (two times) by adding all configurations contributing at least 0.001 to the norm of any of the CI vectors. This procedure resulted in a final reference set of 543 configurations and CI expansion lengths of approximately 1.1 million configuration state functions per irreducible representation. In $C_1$ symmetry, the number of roots was confined to 12 due to the lack of symmetry blocking.

**Experimental Details:** The compound was prepared at the Institute of Inorganic Chemistry of the Heinrich Heine University following the procedure of Müller et al.[24] The elemental analysis confirmed the chemical composition of $K_4[V(CN)_7]\cdot 2H_2O$.

The optical spectra were recorded with a Cary 4E instrument containing a tungsten lamp as light source, a 25-cm double monochromator, and a photomultiplier with an S20 photocathode as detector. The substance was dispersed in silicon paste and applied to a sapphire sample carrier. The samples were cooled by immersion in superfluid helium using a Konti bathcryostat type Spectro C of CryoVac.

## Acknowledgments

We are grateful to the Institute of Inorganic Chemistry of the Heinrich Heine University (Prof. Kläui) for the preparation of the potassium heptacyanovanadate complex. Volker Schmid cordially thanks Georg Jansen (University of Essen-Duisburg) and Reinhold Fink (Ruhr-University Bochum) for helpful discussions.

# Fe(Cu)-Containing Coordination Polymers: Syntheses, Crystal Structures, and Applications as Benzyl Alcohol Oxidation Catalysts

**Huayun Han,[a] Sujuan Zhang,[a] Hongwei Hou,*[a] Yaoting Fan,[a] and Yu Zhu[a]**

**Keywords:** Fe(Cu)-coordination polymers / Benzyl alcohol oxidation / Catalysts

In this paper three coordination polymers, $\{[Fe(fcz)_2Cl_2]\cdot 2CH_3OH\}_n$ (**1**), $\{[Cu(fcz)_2(H_2O)]\cdot SO_4\cdot DMF\cdot 2CH_3OH\cdot 2H_2O\}_n$ (**2**), and $\{[Cu(fcz)_2Cl_2]\cdot 2CH_3OH\}_n$ (**3**) {fcz = 1-(2,4-difluorophenyl)-1,1-bis[(1*H*-1,2,4-triazol-l-yl)methyl]ethanol}, were synthesized. Crystallographic analysis reveals that polymer **1** exhibits a 2-D rhombohedral grid structure with (4, 4) nets, while polymer **2** has a 1-D double-chain framework. The structure of polymer **3** is similar to that of **1**. We found that polymers **1**–**3** could effectively catalyze the oxidation of benzyl alcohol to benzaldehyde with $H_2O_2$ (30 mass-%) as oxidant in aqueous medium. Various reaction conditions were studied, and optimal reaction conditions were obtained. Under the optimal conditions, the selectivity to benzaldehyde was almost up to 100 % and the conversion of benzyl alcohol was 87 % for **1**, 79 % for **2**, and 68 % for **3**. The results of the recycling test showed that the catalytic activity decreased by only about 7 % after three consecutive reaction cycles. However, under similar conditions, when we used the corresponding metal salt instead of the polymer as catalyst, or replaced the water with acetonitrile as solvent, neither the selectivity nor the conversion was the same.

## Introduction

In the past decade, the investigation of coordination polymers has been intensified because of their promising perspectives toward the development of new functional materials with various structural features and properties for applications in such areas as magnetic and optical materials, gas storage, molecular recognition devices, and so on.[1–6] However, little attention has been paid to their catalytic activities.[7–9] In principle, coordination polymers would be expected to be one of the new candidates for catalysts.[10–12] First, the success of metal complexes in catalysis is largely dependent on their structures and electronic properties.[13–15] Coordination polymers offer a variety of molecular structures and electronic properties that can be obtained by changing the metal ions, ligands, anions, coordination modes, etc. For example, the d orbitals of some transition metals may interact with organic π electrons to provide a localized electronic system within a polymer.[16–19] This diversity should give one an opportunity to tune the electronic properties of the molecules, and hence to tune the catalytic activity. On the other hand, the high stability and large number of active metal centers of coordination polymers are advantageous for practical applications as catalysts.[20] Meanwhile, the structures of the catalysts should be characterized in order to fine-tune both catalytic activity and selectivity; however, the structures of the traditional heterogeneous catalysts are usually not very clear.

Benzaldehyde is a very important raw material and intermediate which is used in the perfumery, pharmaceutical, dyestuff, and agrochemical industry, and the market demands have been steadily increasing over the last years.[21–22] The selective oxidation of benzyl alcohol to benzaldehyde is one of the most fundamental reactions both for laboratory-scale experiments and in the manufacturing processes. Up to now, catalytic vapor-phase oxidation of benzyl alcohol to benzaldehyde has been widely investigated.[23–25] The few studies on the liquid-phase oxidation of benzyl alcohol mainly focus on expensive metals, such as Ru, Pd, or Pd–Ag,[26–27] heteropolyacids[28] and some Cu, Fe, and Mn complexes.[29–34] In addition, the traditional reactions are often performed in environmentally undesirable solvents.[35–36]

On the basis of the above considerations, we synthesized three coordination polymers, $\{[Fe(fcz)_2Cl_2]\cdot 2CH_3OH\}_n$ (**1**), $\{[Cu(fcz)_2(H_2O)]\cdot SO_4\cdot DMF\cdot 2CH_3OH\cdot 2H_2O\}_n$ (**2**), and $\{[Cu(fcz)_2Cl_2]\cdot 2CH_3OH\}_n$ (**3**) {fcz = 1-(2,4-difluorophenyl)-1,1-bis[(1*H*-1,2,4-triazol-l-yl)methyl]ethanol}, Scheme 1], and characterized their structures as well as their catalytic activities in the oxidation of benzyl alcohol with $H_2O_2$ as oxidant in aqueous medium. The results show that the selectivity to benzaldehyde was almost 100% for the three polymers, and the conversion of benzyl alcohol was 87% for **1**, 79% for **2**, and 68% for **3**. When we used the corresponding metal salts as catalysts, or acetonitrile as solvent, neither the selectivity nor the conversion was the same.

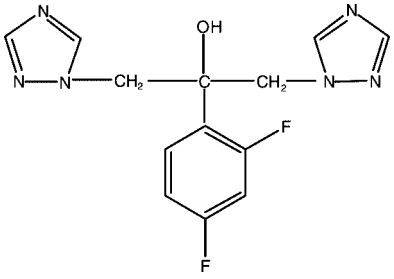

Scheme 1.

## Results and Discussion

### Crystal Structure of Polymer $\{[Fe(fcz)_2Cl_2]\cdot 2CH_3OH\}_n$ (1)

Coordination polymer **1** crystallizes in the monoclinic space group *C*2/*c* and exhibits a 2-D rhombohedral grid network structure with (4, 4) nets. Each $Fe^{II}$ ion is located at the center of an elongated octahedron. Two chlorine anions occupy the axial positions. Four nitrogen atoms from four fcz ligands occupy the equatorial positions (Figure 1). The axial Fe–Cl bond lengths [2.560(2) Å] are substantially longer than the equatorial Fe–N bond lengths (average: 2.174 Å). The bond angles around the $Fe^{II}$ ion are 180° (Cl1A–Fe1–Cl1, N4B–Fe1–N4C, N1A–Fe1–N1) or close to 90° (N1A–Fe1–Cl1A, N1A–Fe1–N4B, Cl1A–Fe1–N4C, etc.).

In the structure, all fcz ligands are equivalent. Every fcz ligand binds with two $Fe^{II}$ ions leading to a rhombohedral grid unit. Each grid consists of a 40-membered ring, $Fe_4(fcz)_4$, the four $Fe^{II}$ ions serving as four nodes and the four fcz groups acting as four sides. The rhombohedral grids have the dimensions 11.210 Å × 11.210 Å, the diagonal distances 9.430 Å × 20.337 Å, and the interior angles 49.8° and 130.2°. Two methanol molecules occupy the cavity of the (4, 4) network. Moreover, the solid-state structure of polymer **1** exhibits the layered packing mode.

### Crystal Structure of Polymer $\{[Cu(fcz)_2(H_2O)]\cdot SO_4\cdot DMF\cdot 2CH_3OH\cdot 2H_2O\}_n$ (2)

Crystallographic analysis reveals that polymer **2** crystallizes in the monoclinic space group $P2_1/n$ and exhibits a 1-D polymeric double-chain structure as shown in Figure 2. Each $Cu^{II}$ ion is at the center of a distorted tetragonal pyramid. Four nitrogen atoms from four fcz ligands occupy the basal sites, and one oxygen atom from a terminally coordinated water molecule fills the apical position. The Cu–O bond length of 2.365(4) Å is longer than the average Cu–N bond length (2.032 Å). The bond angles around the $Cu^{II}$ ion deviate from 180° or 90° (172.6 –177.1° or 86.9–96.8°), which differs from the structure of **1**.

In contrast to polymer **1**, in polymer **2** there are two kinds of fcz ligands, fcz1 and fcz2. In fcz1, the dihedral angle between two triazole rings is 107.0°, and the dihedral angle between the triazole ring and the phenyl ring is 59.1° or 48.9°. In fcz2, the corresponding dihedral angles are 112.2° and 56.1° or 56.3°, respectively. The dihedral angle between the two benzyl rings from two different fcz ligands is 6.8°. These ligands twist to meet the requirement of steric exclusion. The torsion angles are 179.2(3) Å for N3A–C3A–C4A–C11A and 177.4(3) Å for C3A–C4A–C11A–N4A in fcz1, and 163.0(3) Å for N9A–C16A–C17A–C24A and –177.6(3) Å for C16A–C17A–C24A–N10A in fcz2.

The twisted fcz ligands link two $Cu^{II}$ ions, resulting in a bimetallic ring as building block in which the Cu···Cu distance is 10.958 Å. The bimetallic rings are extended

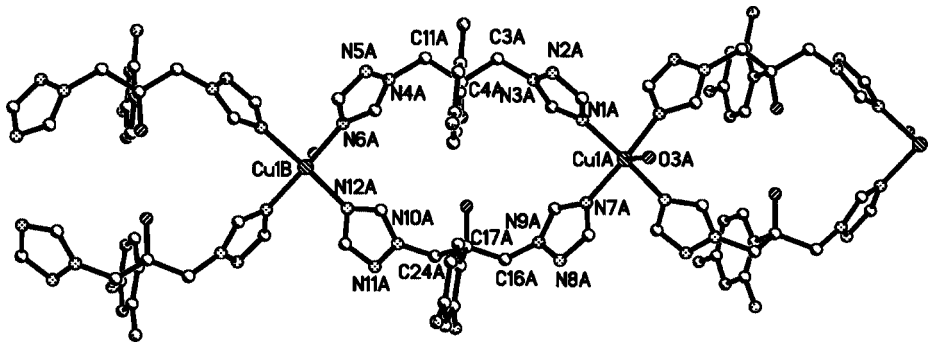

Figure 2. The double-chain structure of polymer **2** (cation part). Hydrogen atoms and solvent molecules have been omitted for clarity.

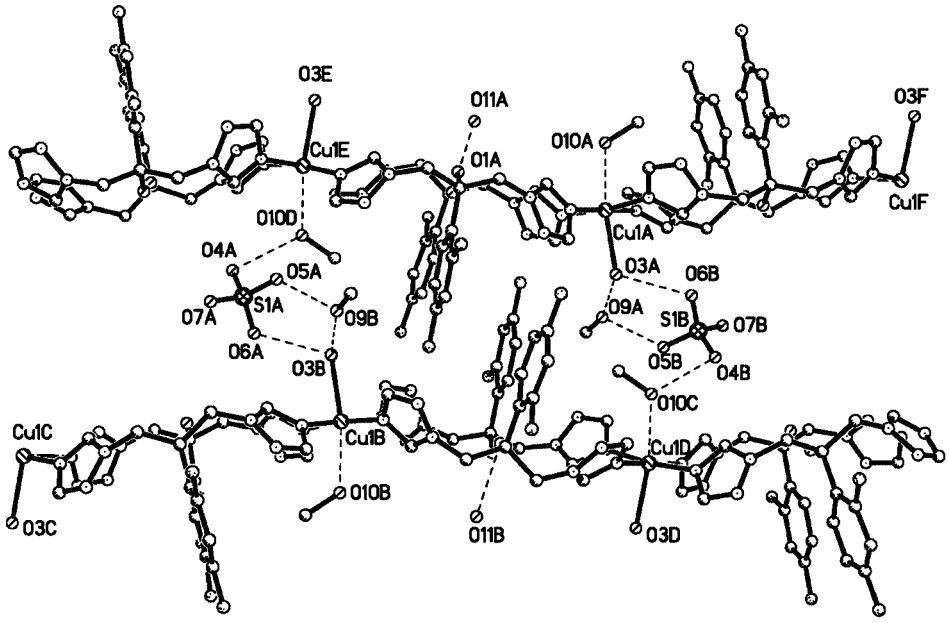

Figure 3. The crystal-packing diagram of polymer **2** with hydrogen bonds.

through co-$Cu^{II}$ to generate an infinite double chain. These chains are further connected through intermolecular hydrogen bonds and π–π stacking interactions of the phenyl rings, as shown in Figure 3. The sulfate anions and solvent molecules are located at the vacancy among the 1-D chains and hold the cationic chains together to generate a layered architecture. In this architecture, the shortest Cu···Cu distance between adjacent chains is 9.242 Å

The structure of polymer **3**[37] is similar to that of **1**. However, the average Cu–N bond length (2.032 Å) in **3** is shorter than that of Fe–N in **1**, and the Cu–Cl bond lengths [2.793(4) Å] are longer than those of Fe–Cl because of the Jahn–Teller effect.

### Catalytic Activities of the Polymers

To evaluate the catalytic properties of coordination polymers **1**–**3**, we selected the oxidation of benzyl alcohol as a probe reaction. The crystal polymers (1 mg/FW of **1** = $1.25 \cdot 10^{-3}$ mmol, 1 mg/FW of **2** = $2.08 \cdot 10^{-3}$ mmol, and 1 mg/FW of **3** = $1.23 \cdot 10^{-3}$ mmol[20]) were ground well into appropriate sizes. The effects of various reaction conditions such as temperature and amount of catalyst and oxidant $H_2O_2$ were investigated in detail by fixing the amount of benzyl alcohol at 4.6 mmol in 10 mL aqueous medium.

Figure 4 shows the effect of temperature on the oxidation with polymer **1**. It can be seen that the conversion of benzyl alcohol increases with increasing temperature. Especially when the temperature was raised from 30 to 40 °C, there was a significant increase in the conversion. At higher temperatures, rapid decomposition of hydrogen peroxide may take place and selectivity to benzaldehyde will decline, which are undesirable. Therefore, the optimal reaction temperature is 40 °C.

Figure 5 shows the effect of the amount of polymer **1**. When 0.005 mmol polymer **1** was employed in the reaction system, about 48% conversion of benzyl alcohol was achieved in 4 h. However, when the catalyst amount was increased to 0.01 mmol, the conversion was greatly improved and reached about 51% in 1 h and 87% in 4 h. A steady state of the catalytic reaction was observed after 4 h. Further increase in the amount of catalyst could not im-

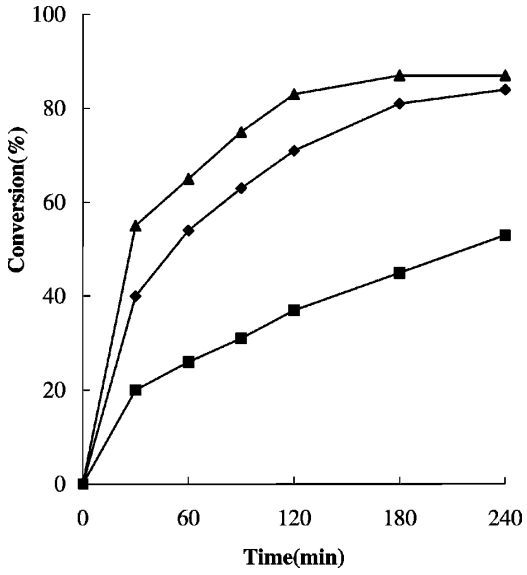

Figure 4. Effect of reaction temperature on conversion with polymer **1**: (■) 30 °C, (♦) 40 °C, (▲) 50 °C with fixed amounts of benzyl alcohol (4.6 mmol), $H_2O_2$ (6.0 mmol), and catalyst (0.01 mmol).

prove the conversion of benzyl alcohol significantly. The trend for polymer **2** or **3** as a catalyst was similar to that for **1**.

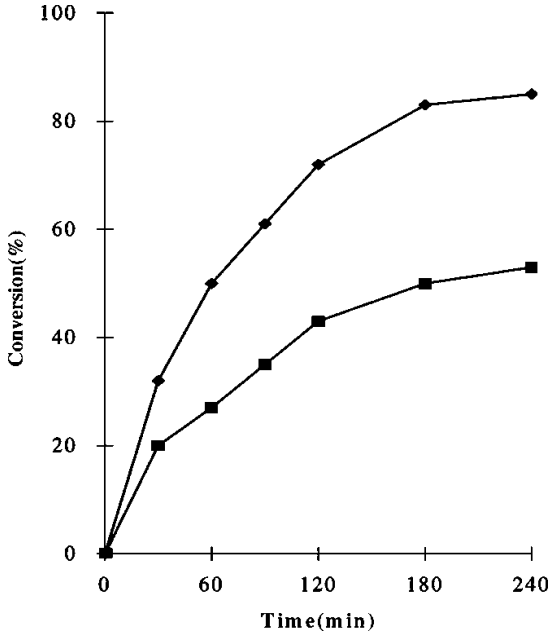

Figure 5. Effect of the amount of polymer **1** on benzyl alcohol oxidation: (■) 0.005 mmol, (♦) 0.01 mmol, with fixed amounts of benzyl alcohol (4.6 mmol) and $H_2O_2$ (6.0 mmol) at 40 °C in aqueous medium.

Moreover, the effect of the amount of oxidant was studied by using different concentrations of $H_2O_2$, viz. 4.6, 6.0, and 6.9 mmol (the molar ratio of $H_2O_2$ to benzyl alcohol was 1:1, 1:1.3, and 1:1.5). When the amount of $H_2O_2$ was increased from 4.6 to 6.9 mmol, the conversion of benzyl alcohol increased. Although excess $H_2O_2$ can increase the conversion, we chose 6.0 mmol $H_2O_2$ as the oxidant in order to avoid the formation of byproducts. In addition, the solvent was also taken into consideration for the oxidation of benzyl alcohol. The selectivity and conversion are better in aqueous medium than in acetonitrile, as shown in Table 1. The results are consistent with those in the literature,[38] in which benzyl alcohol was used as the substrate for the oxidation in a triphase using water with about sevenfold increase in conversion as compared with that obtained in a biphase using acetonitrile as solvent with titanium silicate catalyst.

Table 1. Results of oxidation of benzyl alcohol to benzaldehyde.[a]

| Catalysts | Solvent | Conversion (%) | Selectivity (%) |
|---|---|---|---|
| Polymer **1** | $H_2O$ | 87[a] | 100 |
| | | 85[b] | 100 |
| | | 81[c] | 100 |
| | $CH_3CN$ | 38 | 62 |
| Polymer **2** | $H_2O$ | 79[a] | 100 |
| | | 77[b] | 100 |
| | | 73[c] | 100 |
| | $CH_3CN$ | 29 | 56 |
| Polymer **3** | $H_2O$ | 68[a] | 100 |
| | | 66[b] | 100 |
| | | 63[c] | 100 |
| | $CH_3CN$ | 36 | 59 |
| $FeCl_2 \cdot 4H_2O$ | $H_2O$ | 32 | 85 |
| $CuCl_2 \cdot 2H_2O$ | $H_2O$ | 34 | 82 |
| $CuSO_4 \cdot 5H_2O$ | $H_2O$ | 35 | 84 |

[a] The superscripts "a, b, c" show the results of recycling from the first (fresh), to the second, and third runs, respectively.

Finally, the recycling of the catalysts was investigated. The organic phase was separated when the oxidation of benzyl alcohol was over. The aqueous phase and catalysts were reused for the subsequent oxidation reaction. The conversion of benzyl alcohol decreased by only about 7% after three consecutive cycles (Table 1). In order to prove that the Fe(Cu)-containing coordination polymers were heterogeneous catalysts, we filtered the catalysts and allowed the filtered catalysts and the filtrate to catalyze other benzyl alcohol oxidations. About 80–85% of the original conversion was achieved by using the filtered catalyst, while the filtrate showed only 10–15% conversion under similar conditions. This result suggests that the dominant reactive species is the heterogeneous catalyst.

Figure 6 presents the conversions of benzyl alcohol using polymers **1**–**3** as catalysts under optimized conditions. Obviously, polymer **2** exhibits the best catalytic activity in the first 2 h. However, the catalytic activity of polymer **1** improves later and surpasses that of polymer **2**. All relevant data, i.e. the conversion of benzyl alcohol and the selectivity to benzaldehyde, are collected in Table 1. We can find that the catalytic activities of these polymers are better than those of the corresponding salts. For example, the selectivity of polymer **1** to benzaldehyde was almost 100%, while the selectivity with $FeCl_2$ reached only 85%. This may be explained by the stabilizing effect of the fcz ligands. On the other hand, free metal ions resulted in rapid decomposition

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of hydrogen peroxide, and poor selectivity was observed. Also, it can be seen that the conversion of benzyl alcohol using Fe-containing polymer **1** as catalyst is higher than those using Cu-containing polymers, and the Cu-containing polymers **2** and **3** exhibit different catalytic activities, which can be ascribed to the difference in the coordination environment of their $Cu^{II}$ centers. The results suggest that both the central metals and the structures of the polymers have great influence on their catalytic activities.

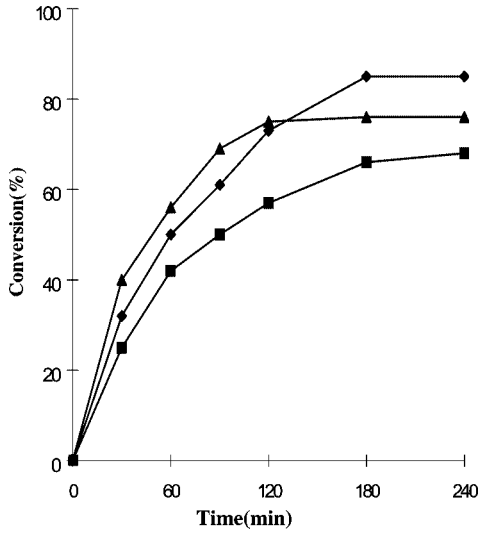

Figure 6. Dependence of the conversion of benzyl alcohol on the reaction time with different polymers: (♦) polymer **1**, (▲) polymer **2**, (■) polymer **3**, under the optimized conditions with fixed amounts of benzyl alcohol (4.6 mmol), $H_2O_2$ (6.0 mmol), and catalyst (0.01 mmol) at 40 °C in aqueous medium.

## Conclusions

The present study shows that polymers **1**–**3** are potential catalysts for the oxidation of benzyl alcohol to benzaldehyde. In addition, central metals and structures of the polymers have great influence on their catalytic activities.

## Experimental Section

**Materials and General Details:** Fcz was supplied by Zhongshuai Pharmaceutical Sci. & Tech. Development Co. Ltd., Henan Province, China. All the solvents and chemicals were used without further purification. IR spectroscopy was performed with a PE 1710 spectrophotometer in the 400–4000-$cm^{-1}$ region. Carbon, hydrogen, and nitrogen analysis were performed with a Carlo–Erba 1106 elemental analyzer.

**Synthesis of Polymer $\{[Fe(fcz)_2Cl_2]\cdot 2CH_3OH\}_n$ (1):** A methanol solution of fcz (0.2 mmol, 6 mL) was added dropwise into an aqueous solution of $FeCl_2\cdot 4H_2O$ (0.1 mmol, 1 mL) to give a clear solution. The resulting solution was allowed to stand at room temperature for two weeks. Yellow crystals formed; yield 56 mg (ca. 70%). The crystals are insoluble in water and most organic solvents. $C_{28}H_{32}Cl_2F_4FeN_{12}O_4$ (803.41): calcd. C 41.84, H 3.98, N 20.92; found C 41.72, H 4.07, N 20.76. IR (KBr): $\tilde{\nu}$ = 3446 (s), 1619 (s), 1502 (s), 1277 (s), 1129 (s), 967 (m), 677 (m) $cm^{-1}$.

**Synthesis of Polymer $\{[Cu(fcz)_2(H_2O)]\cdot SO_4\cdot DMF\cdot 2CH_3OH\cdot 2H_2O\}_n$ (2):** A mixture of methanol and DMF solution of fcz (0.2 mmol, 6 mL) was slowly added into an aqueous solution of $CuSO_4\cdot 5H_2O$ (0.1 mmol, 1 mL) to give a clear solution. The resulting solution was allowed to stand at room temperature for two weeks. Blue crystals formed; yield 30 mg (ca. 60%). The crystals are insoluble in water and most organic solvents. $C_{31}H_{45}CuF_4N_{13}O_{12}S$ (963.40): calcd. C 38.61, H 4.67, N 18.89; found C 38.52, H 4.67, N 18.76. IR (KBr): $\tilde{\nu}$ = 3445 (s), 3131 (s), 1620 (s), 1500 (m), 1279 (m), 1130 (s), 675 (m) $cm^{-1}$.

**Synthesis of Polymer $\{[Cu(fcz)_2Cl_2]\cdot 2CH_3OH\}_n$ (3):** Polymer **3** was synthesized according to the literature[37] as blue crystals; yield 50 mg (ca. 60%). The crystals are insoluble in water and most organic solvents. $C_{28}H_{32}CuCl_2F_4N_{12}O_4$ (811.10): C 41.43, H 3.95, N 20.72; found C 41.49, H 3.90, N 20.74. IR (KBr): $\tilde{\nu}$ = 3448 (s), 1619 (s), 1501 (s), 1278 (s), 992 (m), 673 (m) $cm^{-1}$.

**Crystal-Structure Determination:** Crystallographic data for the polymers **1** and **2** were collected with a Rigaku R-AXIS-IV image plate area detector with graphite-monochromatized Mo-$K_\alpha$ *X*-radiation ($\lambda$ = 0.71073 Å). The data were corrected for Lorentz and polarization effects and for absorption by using empirical scan data. All calculations were performed using the SHELXL-97 crystallographic software package,[39] and refined by full-matrix least-squares methods based on $F^2$ with isotropic thermal parameters for the non-hydrogen atoms. The hydrogen atoms were located theoretically. Processing parameters and the crystal data for polymers **1** and **2** are summarized in Table 2, and selected bond lengths and bond angles are listed in Table 3.

CCDC-262170 and -262172, for polymers **1** and **2**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Catalytic Experiments:** Catalytic experiments were carried out in a 50-mL, three-necked, round-bottom reaction flask fitted with a water condenser. One neck of the flask was equipped with a mercury thermometer for measuring the reaction temperature. The crystal polymer catalysts were ground well into appropriate sizes to increase the surface area, but not too small for a convenient filtration. Benzyl alcohol and water were mixed in the reactor with a magnetic stirrer and heated to a given temperature. Then, hydrogen peroxide (concentration determined by iodometric titration before use) was added to the reaction system. Samples of 0.2 mL were removed every 30 min and diluted (1:10) with $CH_3OH$ to be analyzed by HPLC (HP 1100 high-pressure liquid chromatogram analyzer). A reversed-phase Eclipse×DB-C8 (4.6×150 mm) column was used at ambient temperature, and a methanol/water mixture (70:30 vol-%, 0.5 mL·$min^{-1}$) was used as the eluent. The UV detector was employed at 253 nm. All reactions were run at least in triplicate, and the data reported represent the average of these reactions. Commercial products were used for all chromatographic standardizations.

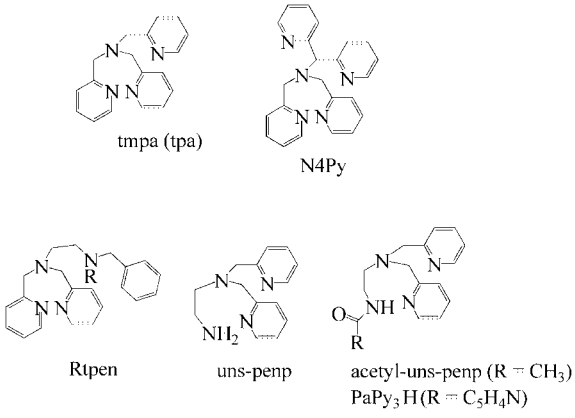
## Introduction

Tripodal ligands such as tris[(2-pyridyl)methyl]amine (tmpa, also abbreviated as tpa in the literature) as well as derivatives, e.g. N4Py (Scheme 1), have been used successfully in experimental studies to model copper and iron enzymes.[1–5] Iron(II) complexes of the related ligand Rtpen (R = Me, Bz etc.) were shown to react with an excess of hydrogen peroxide to form an end-on hydroperoxo complex that can convert to a side-on peroxo complex at higher pH values.[6–10] More recently it was demonstrated that iron complexes with the ligand Bztpen as well as N4Py can form an iron(IV) oxo species that is able to oxidise alkanes such as cyclohexane.[11]

Rtpen can be prepared in two different synthetic procedures. The first described previously starts from a monosubstituted ethylendiamine that is reacted with picolylchloride.[6–8] The second takes advantage of the amine *N*′,*N*′-bis[(2-pyridyl)methyl]ethylenediamine (uns-penp; Scheme 1), a versatile tripodal ligand described previously,[12,13] as a starting material. Interestingly, so far only an iron(II) complex of uns-penp has been described in the literature that has been investigated with regard to its spin crossover properties.[14] Furthermore, very recently an iron(II) complex of a derivative of uns-penp was described.[15] However, so far no iron(III) complexes have been described in the literature. Therefore, we decided to study the appropriate iron(III) complexes of this ligand as well as of its acetyl derivative *N*-acetyl-*N*′,*N*′-bis[(2-pyridyl)methyl]ethylenediamine (acetyl-uns-penp; Scheme 1), an amide that was obtained during the synthesis of uns-penp.



Scheme 1. The ligands discussed in the text.

## Results and Discussion

Only recently have different research groups started to use uns-penp as a versatile ligand in different areas of coor-

dination chemistry and different synthetic procedures have been described.[12,13,15–19] However, most of the authors unfortunately do not refer to the original synthesis of this ligand by Mandel and co-workers[12] and in one case it is presented a second time and described incorrectly as a new compound (ten years later in the same journal).[14] Some of us have used this ligand previously in studies within the field of copper chemistry and have improved its preparation.[13] During the two-step synthesis of uns-penp its protected form, *N*-Acetyl-*N*′,*N*′-bis[(2-pyridyl)methyl]ethylenediamine (acetyl-uns-penp), was easily obtained in pure form in high yields. Recrystallisation from petroleum ethers afforded single crystals that were suitable for X-ray diffraction studies. Acteyl-uns-penp crystallises with two molecules per unit cell. Those are dimerised by hydrogen bonding between the carboxamido group and one of the pyridine groups. The molecular structure of one of these dimers is presented in Figure 1 (see Table 2 for a summary of the crystallographic data and refinement parameters). Besides the hydrogen bonding, the crystal structure shows no extraordinary features.

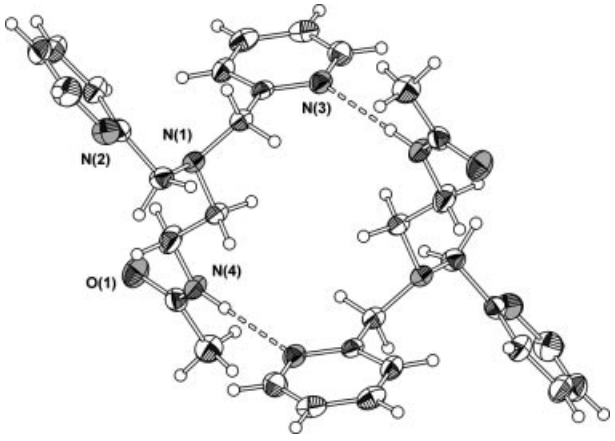

Figure 1. Thermal ellipsoid plot of an acetyl-uns-penp dimer (50% probability).

Furthermore, iron complexation with carboxamide ligands has attracted the interest of inorganic chemists to gain better understanding of metal–peptide bond coordination chemistry in life sciences[20] and to use such complexes as model compounds for the anti-tumor drug bleomycin[21,22] or nitrile hydratase.[23–25] Important in that regard are the results reported by Mascharak and co-workers, who have investigated in detail the structures and properties of $Fe^{II}/Fe^{III}$ complexes of a number of carboxamide ligands, several based on a pyridine-2-carboxamide framework, e.g. *N*-{[bis(2-pyridylmethyl)amino]ethyl}pyridine-2-carboxamide ($PaPy_3H$).[22,25–31] The ligand $PaPy_3H$ (Scheme 1) is related to acetyl-uns-penp; instead of the methyl group in acetyl-uns-penp it contains an additional coordinating pyridyl unit.

### $[Fe_2(acetyl\text{-}uns\text{-}penp)_2O](ClO_4)_2\cdot H_2O$ (1)

Acetyl-uns-penp has so far only been used to synthesise and characterise a copper(II) complex with this ligand. Herein the amide is not deprotonated, however, the carboxamido function of acetyl-uns-penp is no longer truly $sp^2$ hybridised and the nitrogen atom undergoes a weak interaction with the metal centre.[13] The copper complex of $PaPy_3H$ forms a dimer in which the oxygen atom of the amide is coordinated to the copper(II) ion.[32] In contrast, the iron amide complexes of $PaPy_3H$ described by Mascharak and co-workers contained the deprotonated ligand form.[27,30,32,33] However, our own efforts to synthesise the mononuclear deprotonated iron(III) complex [Fe(acetyl-uns-penp)]$(ClO_4)_2$ were only partially successful. Instead of the mononuclear species we obtained the dinuclear complex $[Fe_2(acetyl\text{-}uns\text{-}penp)_2O](ClO_4)_2\cdot H_2O$ (**1**). It is interesting to note at this point that the stoichiometrically identical compound $[Fe_2(PaPy_3H)_2O](ClO_4)_2$ (containing additional ethanol solvent molecules) derived through oxidation of the iron(II) complex is structurally completely different from **1**.[30] In this complex the oxo-bridge assembles two mononuclear amide complexes (with coordinated deprotonated amide nitrogen atoms while the oxygen atoms are not coordinated) to form the dimer (as one would expect). In contrast and as discussed below, in **1** the ligand acetyl-uns-penp additionally bridges the two iron(III) ions and involves the amide nitrogen as well as the oxygen atom in the coordination.

Crystals of **1** were at first obtained from the reaction of $Fe(ClO_4)_3$, acetyl-uns-penp and $NaN_3$ in methanol followed by recrystallisation of the precipitate in acetonitrile. In contrast to our expectations no azide complex was formed but instead deprotonation of the amide occurred under these conditions and because of the presence of water the oxo-bridged dinuclear complex **1** was obtained. Taking this result into account it was furthermore possible to crystallise **1** successfully by replacing the $NaN_3$ by $Et_3N$ or NaOH as the deprotonating agent. The cation of **1**, as depicted in Figure 2, shows that the crystallographically equivalent iron(III) centres are triply bridged by one oxo and two carboxamido groups from two acetyl-uns-penp ligands, respectively, leading to an intramolecular Fe–Fe distance of 2.992 Å and an Fe–O–Fe angle of 113.1°. A summary of the crystallographic data and refinement parameters for the structures is presented in Table 2. Selected bond lengths and angles for the iron(III) complexes are reported in Table 1.

It is interesting to note that in **1**, the acetyl-uns-penp ligand shows an unusual pentadentate coordination mode displaying deprotonated carboxamido NCO bridging groups ($\eta^2$, $\mu_2$) involving the delocalisation of π-bonding [*d*(C–O) = 1.283, *d*(C–N) = 1.306 Å], which is in agreement with the values of a related ($\eta^2$, $\mu_2$) NCO-bridged iron complex reported previously.[34] However, in contrast, structural properties of **1** are quite different to a related iron(III) complex with a bridging urea anion.[35] Compared to other di-iron(III) complexes with three bridging ligands, of which at least one is a μ-oxo unit, **1** exhibits some unique structural features. The Fe–Fe separation is significantly shorter than those of other μ-oxo-tribridged diiron(III) complexes (range 3.048–3.335 Å) and the Fe–O–Fe angle is among the smallest of them all (range 113.8–134.7°).[36] Each iron(III) ion

[a] X = Br(1) in **2** or O(4) in **3** A: *x*, *y*, –*z* + 1/2 (for **1**); –*x*, –*y*, –*z* (for **5**).

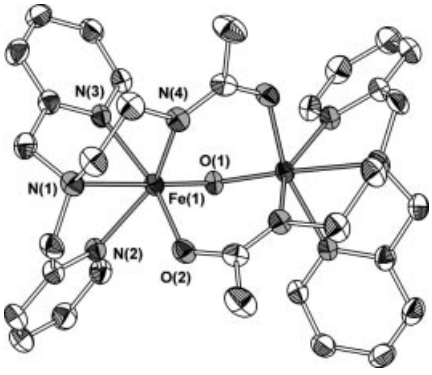

Figure 2. Thermal ellipsoid plot of the dinuclear complex in **1** (50% probability; hydrogen atoms omitted for clarity).

adopts a distorted octahedron coordination geometry by a $N_4O_2$ donor set, in which two pyridine nitrogen atoms (N2 and N3), one carboxamido nitrogen atom (N4) and a carboxamide oxygen atom (O2A) from the second acetyl-uns-penp ligand reside in the equatorial plane while oxo-bridged O(1) and the tertiary amino N(1) atoms occupy the axial positions. The negative charge of the μ-oxo-bridge leads to a rather short Fe(1)–O(1) bond [1.792(2) Å] and likewise because of the *trans* effect, the opposing Fe(1)–N(1) bond is weakened with a distance of 2.245(2) Å. All *cis* angles around O(1) are larger than the ideal 90°, with values of 98.35(5)° for O(1)–Fe(1)–O(2A), 102.11(6)° for O(1)–Fe(1)–N(2), 96.96(5)° for O(1)–Fe(1)–N(3) and 103.62(6)° for O(1)–Fe(1)–N(4). Obviously, deprotonation of the carboxamide groups facilitates the increase of bond lengths around the $Fe^{III}$ ions (Table 1).

### Model Complexes for Intradiol Catechol Dioxygenases

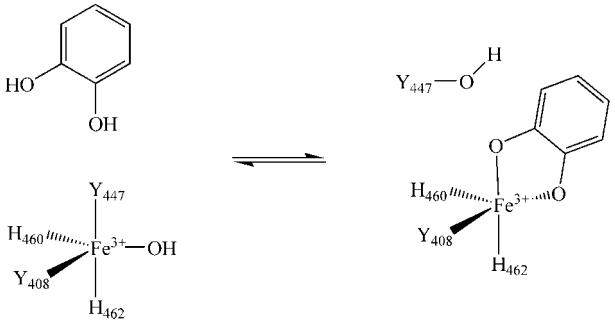
One reason for our efforts to obtain the mononuclear iron(III) complex with the deprotonated acetyl-uns-penp as ligand was our hope that this complex might be an excellent functional model for intradiol catechol dioxygenases. These mononuclear nonheme iron enzymes catalyse the oxidative cleavage of catechol derivatives by insertion of both atoms of dioxygen into the substrate—a key step in the degradation of aromatic compounds.[4,37,38]

Since Funabiki et al. reported the first functional models for catechol dioxygenases, increased efforts have been made by bioinorganic chemists to mimic the structure and function of these enzymes.[4,37–42] Besides macrocyclic ligands,[43–45] especially tetradentate tripodal ligands have shown considerable abilities to regulate the properties of model complexes, indicating that dioxygenase activity strongly depends on the nature of the ligand. The most effective biomimetic catalyst to date is the iron(III) tmpa (tpa) complex that was first reported by Que and co-workers.[4,46] Furthermore, several other systems with tripodal $N_4$ donor ligands showed considerable catechol dioxygenase activity.[47,48] Complexes with enzyme-analogous $N_2O_2$ donor sets represent good structural and spectroscopic model compounds, however, they are poor functional models so far.[49–56] Our recent efforts to reach higher activities than

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the iron(III) tmpa complex by increasing or decreasing the chelate ring sizes in this system were unsuccessful.[57]

The substrate-binding process in the reaction cycle of the catechol cleavage involves protonation of two ligands at the active site, Tyr447 and a hydroxide.[58,59] These two proton acceptors dissociate from the metal ion and thereby enable the proton donor molecule, the catechol, to coordinate in its dianionic form (see Scheme 2).



Scheme 2. Proposed substrate-binding process in catechol-1,2-dioxygenases.

The special electronic properties of the leaving Tyr447 group have been studied extensively using spectroscopic methods and seem to influence the reactivity of the enzyme to a large extent.[60] In previous work some of us used a tmpa-derived ligand [(6-bromo-2-pyridyl)methyl]bis[(2-pyridyl)methyl]amine (brtpa) to mimic the weak bonding of one of the donor groups, however, again it was observed that catechol dioxygenase reactivity decreased compared to the iron tmpa system, most likely because of steric hindrance.[61]

Replacing one pyridyl moiety of the tmpa ligand with a deprotonated carboxamide function we had hoped to finally increase reaction rates of the oxidation of catecholates compared to the tmpa system. However, as discussed below we did not reach this goal and furthermore, in contrast to the synthesis of complex **1**, we did not succeed in the preparation of deprotonated amide complexes when using acetyl-uns-penp, catecholates and base.

### [Fe(acetyl-uns-penp)(tcc)Br]·$(C_2H_5)_2O$ (2)

When iron(III) bromide, acetyl-uns-penp, tetrachlorocatechol and triethylamine were mixed in acetone the complex [Fe(acetyl-uns-penp)(tcc)Br]·$(C_2H_5)_2O$ (**2**) was obtained. Slow diffusion of diethyl ether into the complex solutions allowed the precipitation of single crystals that were suitable for X-ray diffraction studies. Four complex molecules and four diethyl ether molecules form the unit cell of compound **2**. The diethyl ether molecules are attached to the complex via hydrogen bonding to the noncoordinating carboxamide function of the ligand. The structure of **2** is depicted in Figure 3 (the solvate molecule has been omitted for clarity; crystallographic data are presented in Table 2 and Table 1).

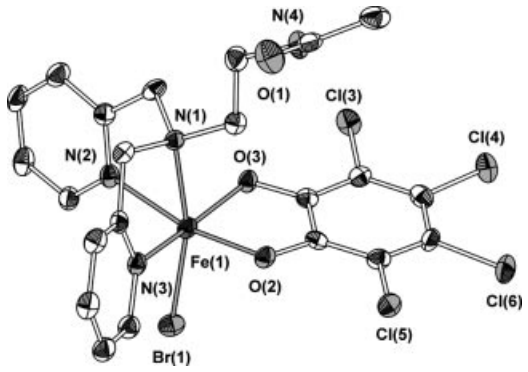


Figure 3. Thermal ellipsoid plot of the iron(III) complex in **2** (50% probability; hydrogen atoms omitted for clarity).

The iron(III) core is ligated by three nitrogen atoms, two catecholate oxygen atoms and one bromide atom. The longest bonds formed by iron and its donor atoms are found for Fe(1)–Br(1) and Fe(1)–N(1) with 2.4813(9) and 2.266(4) Å, respectively. This causes stretching of the coordination octahedron along the Br(1)–Fe(1)–N(1) axis. The *cis* angles around the bromide ion are widened to an average angle of 96.2°. On the other hand, the formation of five-membered chelate rings leads to small values for the N(1)–Fe(1)–N(2) and N(1)–Fe(1)–N(3) angles of 76.2(2) and 76.8(2)°, respectively.

### [{Fe(acetyl-uns-penp)(tcc)}$_2$O]·$(C_2H_5)_2O$·$CH_3OH$ (3)

Interestingly, applying the same experimental conditions as for the synthesis of **2**, though using a slightly larger amount of base, the dinuclear oxo-bridged complex [{Fe(acetyl-uns-penp)(tcc)}$_2$O]·$(C_2H_5)_2O$·$CH_3OH$ (**3**) was obtained (the syntheses of **2** and **3** could be reproduced applying these conditions). The molecular structure of the cation of **3** is shown in Figure 4 (crystallographic data are presented in Table 2 and Table 1).

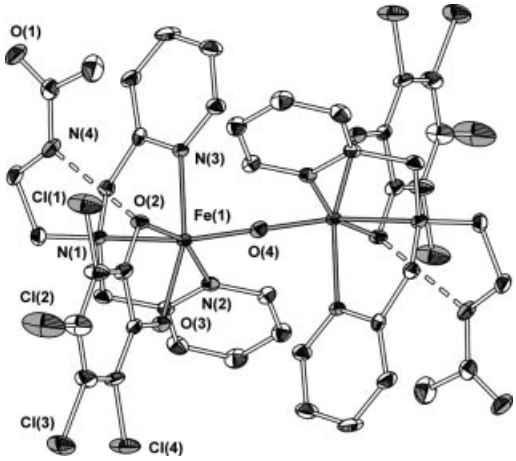

Figure 4. Thermal ellipsoid plot of the dinuclear complex in **3** (50% probability; hydrogen atoms omitted for clarity).

The unit cell contains two complexes as well as four diethyl ether and two disordered methanol molecules. Since

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the bridging oxygen atom O(4) is located on a symmetry centre, one half of the dinuclear complex is generated by inversion. The metal–metal distance is 3.586 Å and both iron ions are surrounded by an $N_3O_3$ donor set. The nitrogen donor atoms are provided by the ligand acetyl-uns-penp, whereas the oxygen atoms belong to the dianionic tetrachlorocatecholate ligand and the μ-oxo-bridge. The coordination sphere of the iron centre has a distorted octahedral geometry. The negative charge of the μ-oxo-bridge leads to a rather short Fe(1)–O(4) bond (1.793 Å) and because of a *trans* effect, the opposing Fe(1)–N(1) bond is weakened. All *cis* angles around O(4) are larger than the ideal 90°. Especially those to the catecholate oxygen atoms are widened, since this effect can be attributed to electrostatic repulsion. The negative charge of O(2) is reduced by the intramolecular hydrogen bond and therefore the corresponding O(2)–Fe(1)–O(4) angle has a value of only 98.25(6)° compared to 106.29(9)° for O(3)–Fe(1)–O(4).

The most striking feature of **3** is the intramolecular hydrogen bond between the carboxamide nitrogen N(4) and O(2) of the catecholate. The donor acceptor distance has a typical value of 2.755(3) Å and the distance between Fe(1) and N(4) is 3.692 Å. This is in good agreement with similar intramolecular hydrogen bonding reported recently.[61] In a way this hydrogen bonding indicates a possible pathway for the deprotonation of the catechol similar to the enzyme reaction shown in Scheme 1.

### Spectrophotometric Titrations

To gain a better understanding of the influence of the base and furthermore to achieve optimised conditions for catechol cleavage by molecular dioxygen it is necessary to provide a high concentration of the mononuclear iron complex with one coordinated catecholate dianion ([Fe(L)(3,5-dbc)]$^+$). To determine these ideal conditions for the catechol cleavage experiments, spectrophotometric titrations were performed (see Figure 5 and Exp. Sect.) as described previously for related systems.[61]

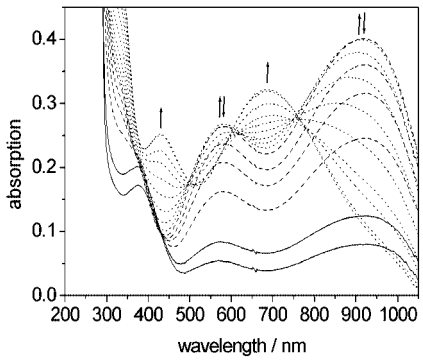

Figure 5. Spectrophotometric titration of a solution of iron(III) perchlorate hydrate, acetyl-uns-penp and 3,5-dbc against piperidine; solid lines: 0.0 and 0.5 equiv.; dashed lines: 1.0–1.6 equiv.; dotted lines: 1.8–4.0 equiv..

This analysis allowed us to gain insight into the species distribution in solution depending on the amount of external base that was added to a mixture of iron salt, the ligand and the substrate 3,5-dbc. At the beginning of the titration (0.0–0.5 equiv. of piperidine; piperidine was used for comparison with previous studies, however triethylamine works in the same way) an absorption band at 375 nm can be observed that is assigned to an oxo-iron(III)-CT transition.

We suggest that the main species in solution is a μ-oxo-bridged dinuclear compound without coordinated substrate. Such dinuclear complexes are thermodynamically favoured in the presence of water and many examples have been reported in the literature.[62–72] With regard to previous results it is possible that the carboxamido group of the ligand already undergoes a very weak interaction with the metal centre and is not truly $sp^2$ hybridised, however is not yet deprotonated.[13] Furthermore, two weak transitions occur at 580 and 920 nm which are typical for catecholate-iron(III)-CT transitions and indicate the presence of a low concentration of the desired mononuclear substrate adduct. Upon further addition of base (1.0–1.6 equiv.) these two absorption bands rise dramatically and so does the concentration of the mononuclear substrate adduct. In the last part of the titration (1.8–4.0 equiv.) the bands at 580 and 920 nm disappear and two new bands are seen at 430 and 690 nm that are also assigned to catecholate-iron(III)-CT transitions. The shift to higher energies indicates a higher electron density on the iron(III) core that makes the charge transfer from the catecholate more difficult. In accordance to the crystal structure of **3** we suggest that a dinuclear μ-oxo-bridged substrate adduct is formed in which the large electron density of the oxo-group is partially transferred to the metal ions and one ligand arm is detached. Finally, the amount of base that is necessary to reach optimal reaction conditions for the catechol cleavage was determined from a plot of the absorption of the lower energy CT band vs. the amount of base added (see Figure 6). The maximum of this plot is located at 1.7 equiv..

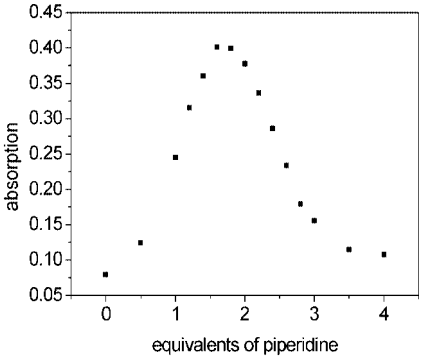

Figure 6. Absorbance vs. base equivalents plot ( $\lambda$ = 980 nm).

### Catechol 1,2-Dioxygenase Activity

An in situ prepared complex solution containing equimolar amounts of iron(III) perchlorate hydrate and acetyl-uns-penp was treated with 1 equiv. of 3,5-dbc and 1.7 equiv. of piperidine. The decrease in the lower energy LMCT band

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

was monitored by UV/Vis-spectroscopy. The reaction was performed in air-saturated methanol, resulting in a more than tenfold excess of dioxygen that ensures pseudo-first-order kinetics for the complete reaction. From the slope of the ln(absorbance) vs. time plot, the reaction rate was determined to be 0.05 $M^{-1}s^{-1}$, which is more than two orders of magnitude lower than that reported for the iron-tmpa system under similar reaction conditions.[46] Because of this low reactivity no further experiments were performed with this system.

### [Fe(uns-penp)$Cl_2$]$ClO_4$·$CH_3CN$ (4)

The ligand uns-penp was obtained in good yields according to the procedures described in the literature. Mixing uns-penp together with iron(III) salts in methanol afforded a yellow material that could be recrystallised from acetonitrile by ether diffusion to yield crystals suitable for X-ray structural analysis. The ORTEP representation of [Fe(uns-penp)$Cl_2$]$^+$ is shown in Figure 7.

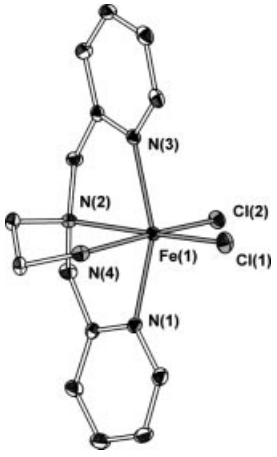

Figure 7. Thermal ellipsoid plot of the cation of **4** (50% probability; hydrogen atoms omitted for clarity).

The structure of the cation of **4** shows a distorted octahedral geometry coordinated with four N atoms of the uns-penp ligand and two chloride ions, as represented by the *trans* ligand angles of 153.61(6)° for N(1)–Fe(1)–N(3), 167.56(5)° for N(2)–Fe(1)–Cl(1), and 169.15(4)° for N(4)–Fe(1)–Cl(2). Moreover, the angle for Cl(1)–Fe(1)–Cl(2) is 100.38(2)°, which is significantly larger than 90°. As is often the case with a tripodal ligand that forms five-membered chelate rings, the coordination geometry is distorted toward the tertiary amino group (average $N_{amine}$–Fe–$N_{py/amine}$ = 77.55°). The Fe–$N_{py}$ bonds (av. 2.132 Å) are shorter than the Fe–N(amine) bond (av. 2.193 Å), which are comparable to the values of $Fe^{III}$ tmpa complexes.[46,73,74] Consequently the Fe(1)–Cl(1) bond which is *trans* to the tertiary amino group [2.2622(5) Å] is shorter than the Fe(1)–Cl(2) bond *trans* to a primary amino nitrogen [2.3081(6) Å].

### {[Fe(uns-penp)Cl]$_2$O}$(ClO_4)_2$·$2CH_3CN$ (5)

It is well known that a general problem in iron(III) chemistry is the formation of oxo-bridged dimers during the synthesis of the complexes such as for example the iron(III) tmpa complex or the acetyl-uns-penp ligand system described above. Addition of base can accelerate this reaction and therefore when base was added during the synthesis of **4** the dinuclear oxo-bridged complex **5** was obtained instead. The thermal ellipsoid representation of the cation of **5** is shown in Figure 8. The molecular structure is composed of centrosymmetric dimeric cations with a linear Fe–O–Fe unit. Each iron centre is in a distorted octahedral environment ligated by the two pyridine nitrogen atoms, the primary and tertiary amine nitrogen atoms, as well as the oxygen atom which is bound to the second iron centre. The Fe–O bond length of 1.798(1) Å is in keeping with the mean values of 1.79(6) (with a range of 1.73–1.82 Å) for such bond lengths in oxo-bridged iron(III) complexes.[75] The Fe–$N_{py}$ bonds of 2.141(2) Å and 2.147(2) Å are considerably shorter than the Fe–$N_{amine}$ bonds [2.213(2) and 2.235(2) Å]. This is analogous to the structures of the respective (μ-oxo) diiron(III) complexes of tmpa. The chloride ligands coordinate *trans* to the tertiary amine nitrogen on each iron centre and *anti* to each other relative to the Fe–O–Fe axis. The Fe–Cl bond lengths of 2.3166(4) Å are slightly longer than the values of **4** arising from steric hindrance in the dimer. The Fe–Fe distance of 3.596 Å is typical for complexes with singly bridged Fe–O–Fe cores, which are usually in the range 3.4–3.6 Å, whereby the longer distances are associated with Fe–O–Fe angles that are linear or close to linearity.

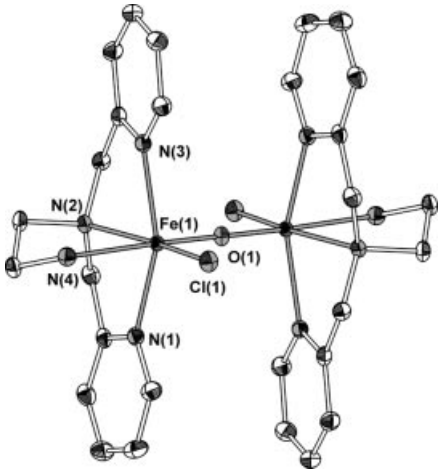

Figure 8. Thermal ellipsoid plot of the cation of **5** (50% probability; hydrogen atoms omitted for clarity).

### Catechol 1,2-Dioxygenase Activity of the Iron(III)-uns-penp System

The iron(III)-uns-penp complex was investigated under the same conditions used previously for the iron(III) tmpa catecholate (3,5-dbc) system.[57] Stopped-flow kinetic investigations revealed again that the rate of the reaction of the iron tmpa system is faster under these conditions, however, at least the iron-uns-penp complex was only slower by a factor of 20. No further detailed kinetic studies were

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

performed on this system because of the fact that the rate could not be increased and that no reactive intermediates could be detected spectroscopically.

## Conclusion

Acetyl-uns-penp has not been used in coordination chemistry so far despite its interesting ligand properties and in contrast to related ligands (in which additional pyridine or phenol donor groups are present) that have attracted a lot of interest in amide chemistry recently.[18,27–33,76–78] A copper(II) complex was recently reported, where the carboxamido function of acetyl-uns-penp is no longer truly $sp^2$ hybridised and the nitrogen atom undergoes a weak interaction with the metal centre.[13] In our present work, we demonstrated that acetyl-uns-penp is capable of influencing coordination chemistry by building hydrogen bonds with hydrogen acceptors in the vicinity of the carboxamido function. The intramolecular hydrogen bond between one arm of the tripodal ligand and a coordinated substrate molecule in **3** suggests a pathway for the second substrate deprotonation step in the reaction cycle of intradiol cleaving catechol dioxygenases according to Scheme 2. Taking into account that the carboxamide can also undergo strong binding interactions with a metal centre upon deprotonation, as demonstrated in **1**, acetyl-uns-penp is a very versatile ligand. Furthermore, structural characterization of two iron(III) complexes of the ligand uns-penp and its catechol dioxygenase reactivity provided additional information on the chemistry of this interesting ligand.

## Experimental Section

**Materials:** All chemicals were obtained from commercial sources and used without further purification.

***Caution!*** *The syntheses and procedures described below involve compounds that contain perchlorate and azide ions, which can detonate explosively and without warning. Although we have not encountered any problems with the compounds used in this study, they should be handled with extreme care.*

**Physical Measurements:** UV/Vis spectroscopy was performed with a Hewlett–Packard 8453 diode array spectrometer. Elemental analyses were carried out with an Elementar Vario EL III analyzer at the University of Münster.

### Syntheses

**Ligand Syntheses:** The ligand acetyl-uns-penp as well as uns-penp were prepared according to literature procedures.[13]

**$[Fe_2$(acetyl-uns-penp)$_2O](ClO_4)_2\cdot H_2O$ (1):** Iron(III) perchlorate hexadrate (177 mg, 0.5 mmol) and acetyl-uns-penp (142 mg, 0.5 mmol) were combined in methanol (10 mL). After 10 min of stirring, to the resulting brown solution $NaN_3$ (49 mg, 0.75 mmol) was added, immediately leading to a very dark red suspension. After 2 h a brown precipitate was filtered off, washed with methanol and diethyl ether, and dried under vacuum. Dark brown prism crystals, air stable and suitable for X-ray diffraction analysis, were obtained by slow evaporation of an acetonitrile solution after 1 week (69 mg, 0.03 mmol, 30%). $C_{16}H_{20}ClFeN_4O_6$ (455.66): calcd. C 42.2, H 4.4, N 12.3; found C 42.6, H 4.2, N 12.7.

**1** could also be prepared analogously to the former synthesis except that $Et_3N$ (101 mg, 1.0 mmol) or NaOH (40 mg, 1.0 mmol) were used instead of $NaN_3$.

**[Fe(acetyl-uns-penp)(tcc)Br]$\cdot(C_2H_5)_2O$ (2):** Anhydrous iron(III) bromide (30 mg, 0.1 mmol) and acetyl-uns-penp (28 mg, 0.1 mmol) were dissolved in acetone (7 mL). After addition of tetrachlorocatechol hydrate (27 mg, 0.1 mmol) and triethylamine (24 μL, 17 mg, 0.17 mmol) the reaction mixture was stirred for 10 min and filtered. Vapor diffusion of diethyl ether into the complex solution yielded single crystals of **2** (58 mg, 0.09 mmol, 90%), m.p. 181 °C (decomposition). $C_{22}H_{20}BrCl_4FeN_4O_3$ (without solvent, 666.0): calcd. C 39.7, H 3.0, N 8.4; found C 39.0, H 3.9, N 7.9.

**[{Fe(acetyl-uns-penp)(tcc)}$_2$O]$\cdot(C_2H_5)_2O\cdot CH_3OH$ (3):** The synthetic procedure is identical to the preparation of **2** with the only difference being that a slightly larger amount of triethylamine (28 μL, 20 mg, 0.2 mmol) was used. Vapor diffusion of diethyl ether into the complex solution yielded single crystals of **3** (37 mg, 0.03 mmol, 60%), m.p. 223 °C (decomposition). $C_{44}H_{40}Cl_8Fe_2N_8O_7$ (without solvent, 1188.2): calcd. C 44.5, H 3.4, N 9.4; found C 43.8, H 3.7, N 9.1.

**[Fe(uns-penp)Cl$_2$]$\cdot ClO_4\cdot CH_3CN$ (4):** To a solution of uns-penp (219 mg, 0.9 mmol) in methanol (10 mL) was added a solution of $Fe(ClO_4)_3\cdot xH_2O$ (139 mg, 0.3 mmol) and $FeCl_3$ (109 mg, 0.6 mmol) in methanol (10 mL). The resulting brown solution was stirred for 1 h at room temperature during which time a greenish yellow solid precipitated, which was then filtered. The precipitate was washed with methanol and diethyl ether, and dried under vacuum. Yellow prism crystals for crystallographic studies were obtained by vapor diffusion of diethyl ether into the acetonitrile solution. Yield: 221 mg (ca. 50%). $C_{16}H_{21}Cl_3FeN_5O_4$ (509.58): calcd. C 37.71, H 4.15, N 13.75; found C 37.59, H 4.13, N 13.68.

**[{Fe(uns-penp)Cl}$_2$O]$\cdot(ClO_4)_2\cdot 2CH_3CN$ (5):** To a methanol suspension (15 mL) of $Fe(ClO_4)_3\cdot xH_2O$ (115 mg, 0.25 mmol), $FeCl_3$ (41 mg, 0.25 mmol) and uns-penp ligand (122 mg, 0.5 mmol) was added $Et_3N$ (51 mg, 0.5 mmol) in methanol (5 mL) whilst stirring. After 1 h, the resulting greenish brown slurry was filtered and the precipitate was washed with methanol and diethyl ether. Dark brown cubic crystals suitable for X-ray diffraction analysis were obtained by slow evaporation of an acetonitrile solution about 1 week. Yield: 200 mg (ca. 42%). $C_{32}H_{42}Cl_4Fe_2N_{10}O_9$ (964.26): calcd. C 39.86, H 4.39, N 14.53; found C 39.62, H 4.24, N 14.41.

**X-ray Crystallographic Studies:** Intensity data for **1** were collected with a Siemens SMART CCD 1000 diffractometer using graphite monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) by the ω-scan technique. The collected reflections were corrected for absorption effects.[79] The structure was solved by direct methods and refined by least-squares techniques using the SHELX97 programme package.[80] Further data collection parameters are summarised in Table 2.

Intensity data for acetyl-uns-penp, **2** and **3** were collected with a Bruker AXS SMART 6000 CCD diffractometer (Cu-$K_\alpha$, $\lambda$ = 1.54178 Å, Göbel mirror) using the ω-scan technique. The collected reflections were corrected for absorption effects.[79] The structure was solved by direct methods and refined by full-matrix least-squares methods on $F^2$.[80] Further data collection parameters are summarised in Table 2.

Intensity data for **4** and **5** were collected at a temperature of 100 K with a Bruker-Nonius KappaCCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data were corrected for Lorentz and polarization effects. Absorption effects were corrected numerically[81] for **4** and by semi-empirical methods

based on multiple scans[79] for **5**. The structures were solved by direct methods; full-matrix least-squares refinement was carried out on $F^2$ using SHELXTL NT 6.12.[82] All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were geometrically positioned; their isotropic displacement parameters were tied to those of their corresponding carrier atoms by a factor of 1.2 or 1.5.

CCDC-266956 (acetyl-uns-penp), -263645 (for **1**), -266957 (for **2**), -266958 (for **3**), -283894 (for **4**), and -283895 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Determination of the Catechol 1,2-Dioxygenase Activity:** The catechol cleaving activity of an in situ prepared complex solution was tested using piperidine as an external base as described previously.[61] The amount of base needed to reach the highest reaction rates was determined according to the spectrophotometric titration method described below. To 2 mL of a $2\cdot10^{-4}$ M methanolic solution of $Fe(ClO_4)_3\cdot H_2O$ and the ligand was added a $2\cdot10^{-2}$ M (1 equiv.) solution of 3,5-$H_2$dbc (0.02 mL). The proper amount of base was added to the reaction mixture from a $2\cdot10^{-2}$ M stock solution. To limit errors, the oxidation of the complex was followed three times by UV/Vis spectroscopy. It is important to note that during these studies iron salts with noncoordinating ions (such as perchlorate or triflate) were used and besides the catecholate ligand no additional coordinating ions (such as bromide used in the crystallographic studies) were present.

**Spectrophotometric Titrations:** The spectrophotometric titrations were carried out with the same solutions as described above for the activity determinations. To avoid cleavage of the substrate, all manipulations were carried out under argon. A sample of the 3,5-$H_2$dbc solution (0.1 mL) was added to the complex solution (10 mL). The resulting mixture was titrated with piperidine and the UV/Vis-spectra were monitored using a flow cell (1 cm).

# Supramolecular Trapping of Phosphanes by Cyclodextrins: A General Approach to Generate Phosphane Coordinatively Unsaturated Organometallic Complexes

**Cécile Binkowski-Machut,[a] Michaël Canipelle,[a] Hervé Bricout,[a] Sébastien Tilloy,[a] Frédéric Hapiot,[a] and Eric Monflier*[a]**

**Keywords:** Phosphane ligands / Cyclodextrins / Molecular recognition / Palladium / Platinum

As shown by $^{31}P\{^1H\}$ NMR spectroscopy, addition of the native β-cyclodextrin or randomly methylated β-cyclodextrin to an aqueous solution of $Cl[Pt\{(p\text{-}tBuC_6H_4)P(m\text{-}C_6H_4SO_3Na)_2\}_3Cl]$ or $[Pd\{(p\text{-}tBuC_6H_4)P(m\text{-}C_6H_4SO_3Na)_2\}_3]$ allows us to generate the phosphane coordinatively unsaturated $[Pt\{(p\text{-}tBuC_6H_4)P(m\text{-}C_6H_4SO_3Na)_2\}_2Cl_2]$ or $[Pd\{(p\text{-}tBuC_6H_4)P(m\text{-}C_6H_4SO_3Na)_2\}_2]$ complexes, respectively. The existence of second-sphere coordination adducts between the organometallic complex and the cyclodextrin, in which the local bulkiness around the metallic centre is high, appears to be the essential prerequisite for the dissociation of one $(p\text{-}tBuC_6H_4)P(m\text{-}C_6H_4SO_3Na)_2$ phosphane ligand from the metal centre. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

One of the most challenging aspects of organometallic catalysis is to generate phosphane unsaturated species. Indeed, these complexes are generally accepted as the catalytically active species in numerous transition-metal-catalysed reactions.[1] An efficient strategy that favours the formation of such compounds consists of using hindered phosphanes. Actually, because of the bulkiness generated around the metallic centre, coordination of numerous ligands to the metal is prohibited and low-coordinated species are obtained. Thus, the use of hindered phosphane has proved to be efficient in generating coordinatively unsaturated complexes that are well known as active catalysts in hydroformylation[2] and carbon–carbon or carbon–heteroatom bond formation.[3] Unfortunately, these catalytic entities have often remained experimentally inaccessible in large amounts because of their low stability, and have required the synthesis of elaborate phosphanes.

We have recently put forward the remarkable properties of cyclodextrins to form inclusion complexes with water-soluble phosphane ligands used to dissolve the organometallic catalyst in water.[4] In particular, the native β-cyclodextrin (β-CD, Scheme 1) and the randomly methylated β-cyclodextrin (RAME-β-CD, Scheme 1) have proved to strongly interact with the disodium bis(3-sulfonatophenyl)(4-*tert*-butylphenyl)phosphane $[(p\text{-}tBuC_6H_4)P(m\text{-}C_6H_4SO_3Na)_2$ (**1**) ] (Scheme 1) as a result of the well-known ability of the *tert*-butylphenyl group to fit tightly into the β-CD cavity.[5] Thus, the association constants for the β-

CD/**1** and RAME-β-CD/**1** inclusion complexes were found to be notably higher than those measured for the inclusion complexes formed with trisulfonated triphenylphosphane (TPPTS); a phosphane currently used in aqueous organometallic catalysis (400000 and 250000 $M^{-1}$ at 25 °C for β-CD/**1** and RAME-β-CD/**1** inclusion complexes, respectively; 1200 and 1000 $M^{-1}$ at 25 °C for β-CD/TPPTS and RAME-β-CD/TPPTS inclusion complexes, respectively).

Interestingly, the strong interaction between **1** and CD derivatives can be used to generate phosphane low-coordinated rhodium species.[5] Indeed, we have demonstrated that $[HRh(CO)(\mathbf{1})_3]$ can be partially converted in the presence of β-CD or RAME-β-CD into the hydroxy complex $[HORh(CO)(\mathbf{1})_2]$ under nitrogen, or into the hydrido complex $[HRh(CO)_2(\mathbf{1})_2]$ under carbon monoxide.

In this paper, we would like to demonstrate that the use of a hydrosoluble phosphane, very strongly interacting with CDs such as **1**, could be a general approach to generate phosphane coordinatively unsaturated complexes under mild conditions. The feasibility of our approach was exam-

ined using platinum or palladium complexes of **1** and β-CD or RAME-β-CD as phosphane trapping agents.

## Results and Discussion

Initial experiments were performed using β-CD whose well-defined $^1$H NMR signals are easier to read than the signals of RAME-β-CD, where the overlapped resonances are often noninterpretable. The Cl[Pt(**1**)$_3$Cl] platinum complex (**2**) was prepared by mixing $K_2PtCl_4$ with 3 equiv. of **1** according to a procedure previously described in the literature for the synthesis of the analogous complex Cl[Pt(TPPTS)$_3$Cl].[6] Figure 1 shows the $^{31}P\{^1H\}$ NMR spectra relative to **2** without β-CD (Figure 1, a) and in the presence of 1 equiv. of β-CD at 25 °C (Figure 1, b), 60 °C (Figure 1, c) and 85 °C (Figure 1, d).

Since only one third of the platinum ($^{195}$Pt) has a spin of 1/2, the phosphorus of the square-planar structure of **2** exhibits a 1:4:1 triplet of doublets centred at $\delta$ = 23.0 ppm ($^1J_{Pcis–Pt}$ = 2494 Hz; $^2J_{Pcis–Ptrans}$ = 18.6 Hz) corresponding to the two phosphorus atoms *cis* to the chloride and a 1:4:1 triplet of triplets centred at $\delta$ = 12.4 ppm ($^1J_{Ptrans–Pt}$ = 3718 Hz; $^2J_{Pcis–Ptrans}$ = 18.6 Hz) corresponding to the phosphorus atom *trans* to the chloride (Figure 1, a). At 25 °C, addition of β-CD leads to the appearance of new resonances and a broadening of all signals (Figure 1, b). No peak is detected in the chemical shift region of the free or CD-included phosphane (from 0 ppm to –12 ppm). This can be explained by assuming that β-CD interacts with **2** without inducing the dissociation of phosphane **1** from the metal. The nature of the interactions between both species **1** and **2** with β-CD has been established by $^1$H NMR spectroscopic measurements. Figure 2 shows the $^1$H NMR spectra of β-CD, both alone and also as a stoichiometric β-CD/**2** mixture (Figure 2).

Upon addition of **2** to the β-CD solution, strong upfield chemical shifts are observed for the internal 3-H and 5-H CD protons suggesting the formation of inclusion complexes between **2** and β-CD. It should be noted that the other protons of the CD are also shielded upfield by the presence of **2**, indicating that they are also affected by the inclusion process. The formation of inclusion complexes between **2** and β-CD was unambiguously demonstrated by a 2D NMR T-ROESY spectrum of a 1:1 mixture of **2** and β-CD, which revealed intense cross-peaks between the *t*Bu group of the phosphane and the internal CD protons 3-H, 5-H and 6-H (Figure 3).

Nevertheless, the absence of correlations between the 3-H, 5-H or 6-H protons and $H_\alpha$ shows that the penetration of the phosphane into the CD cavity was not deep (Scheme 2).

This observation is opposite to what has previously been established for the β-CD/**1** inclusion complex. Indeed, a detailed study has clearly demonstrated that phosphane **1** was

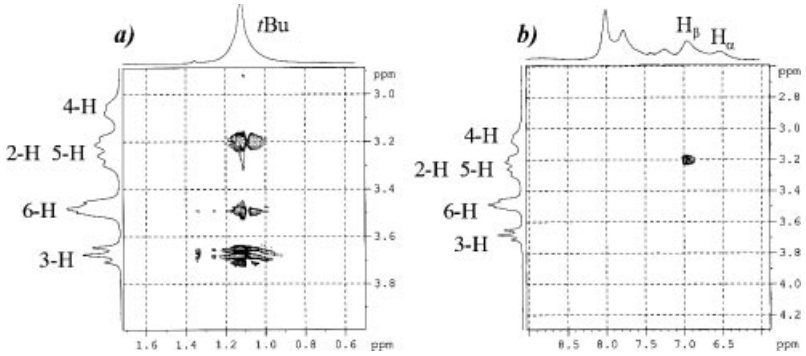

Figure 3. Partial contour plot of the T-ROESY spectrum of a solution containing β-CD (10 mM) and **2** (10 mM) in $D_2O$ at 25 °C with a 300 ms mixing time. (a) Cross-peaks between the β-CD protons and protons of the *tert*-butyl group. (b) Cross-peaks between the β-CD protons and the aromatic protons of phosphane **1**.

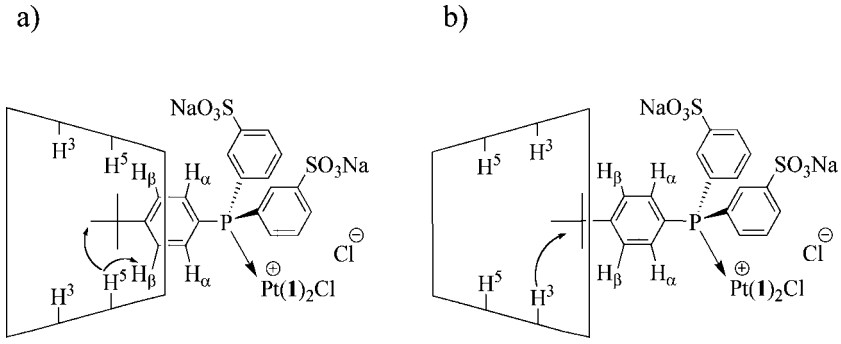
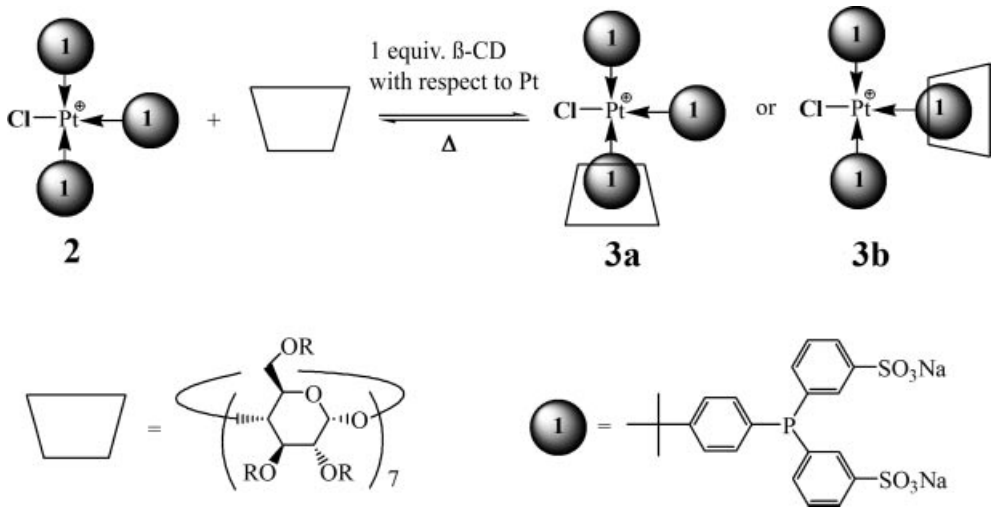


Scheme 2. Second-sphere coordination adducts between β-CD and **2** with a recognition process (a) at the primary face and (b) at the secondary face. The interactions observed in the T-ROESY spectrum between the different protons and the deduced orientation of the phosphane **1** in the CD cavity are also shown.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. Equilibrium between the platinum complexes of **1** in the presence of 1 equiv. β-CD (inclusion of **1** at the secondary face is also possible).

deeply included in the β-CD cavity at the primary face (intense cross-peaks between $H_\alpha$ and 5-H or 6-H, see Supporting Information). Therefore, **1** interacted very differently with β-CD when free in solution and when coordinated to the platinum complex. Furthermore, the presence of intense cross-peaks between the *t*Bu group of the phosphane and the 3-H, 5-H and 6-H CD protons strongly suggests that inclusion occurred at the primary face (Scheme 2, a) but also at the secondary face of the β-CD (Scheme 2, b). Indeed, a low-deep inclusion of **2** at the primary face of the β-CD cannot rationalise the intense cross-peak observed between the *t*Bu and 3-H proton. Finally, it must be pointed out that the inclusion of the phosphane **1** into the cavity at the secondary face was so small that no contact was detected between the 3-H and $H_\beta$ (or a fortiori $H_\alpha$) protons.

Knowing that **2** and β-CD were supramolecularly interacting, the splitting and broadening of the peaks of Figure 1 (b) are attributed to the existence of two possible inclusions of **2** in β-CD (Scheme 3), either by one of the two ligands **1** *cis* to the chloride (species **3a**) or by the ligand **1** *trans* to the chloride (species **3b**). Although inclusion of **2** at the secondary face also occurred, only the structures obtained with an inclusion at the primary face have been represented for clarity in Scheme 3.

Interestingly, the splitting of the signal at $\delta$ = 23.0 ppm, corresponding to the two phosphorus atoms *cis* to the chloride, into two broad signals in the 25–20 ppm region in the presence of β-CD (see parts a and b in Figure 1) indicates that the coordinated *cis* phosphanes **1** become inequivalent when β-CD binds to complex **2**. As only 1 equiv. of β-CD was added to a solution of **2**, this phenomenon probably finds its origin in the fact that when one of the two *cis* phosphanes **1** is included into the β-CD cavity, the other remains nonincluded. Finally, the important and unusual upfield shifts observed in the $^1$H NMR spectrum for the external protons of the CD (1-H, 2-H and 4-H) might be explained by the closeness in species **3** of nonincluded coordinated ligands **1** with the edges of a β-CD bound to a coordinated ligand **1**, suggesting an overcrowded environment at the periphery of the CD.

Consequently, at room temperature, it appears that β-CD acts as a host for a ligand that was directly coordinated to the platinum. Although the formation of second-sphere coordination adducts between CD derivatives and organometallic complexes is a well-known phenomenon,[7] it is worth mentioning that the formation of such adducts between CD and organometallic complexes bearing phosphane ligands has rarely been observed. Indeed, to the best

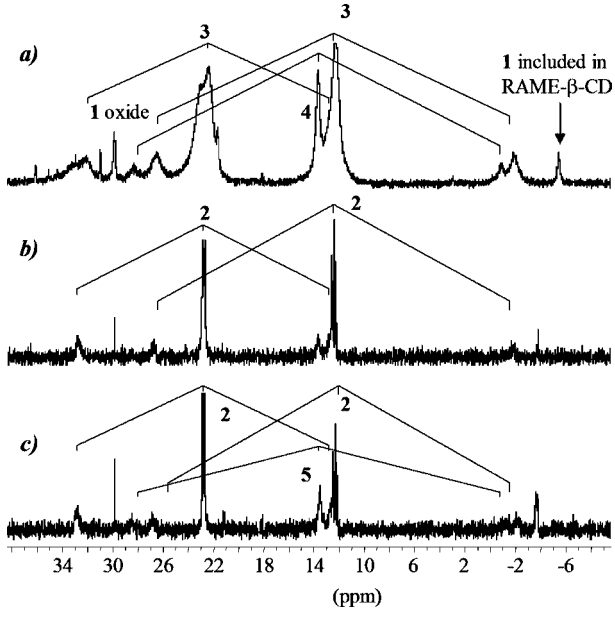


Figure 4. $^{31}$P{$^1$H} NMR spectra of the platinum complex Cl[ClPt((*p*-*t*BuC$_6$H$_4$)P(*m*-C$_6$H$_4$SO$_3$Na)$_2$)$_3$] (**2**) (10 mM) in $D_2O$ with 12 equiv. RAME-β-CD with respect to the platinum at (a) 25 °C; (b) 60 °C; (c) 85 °C.

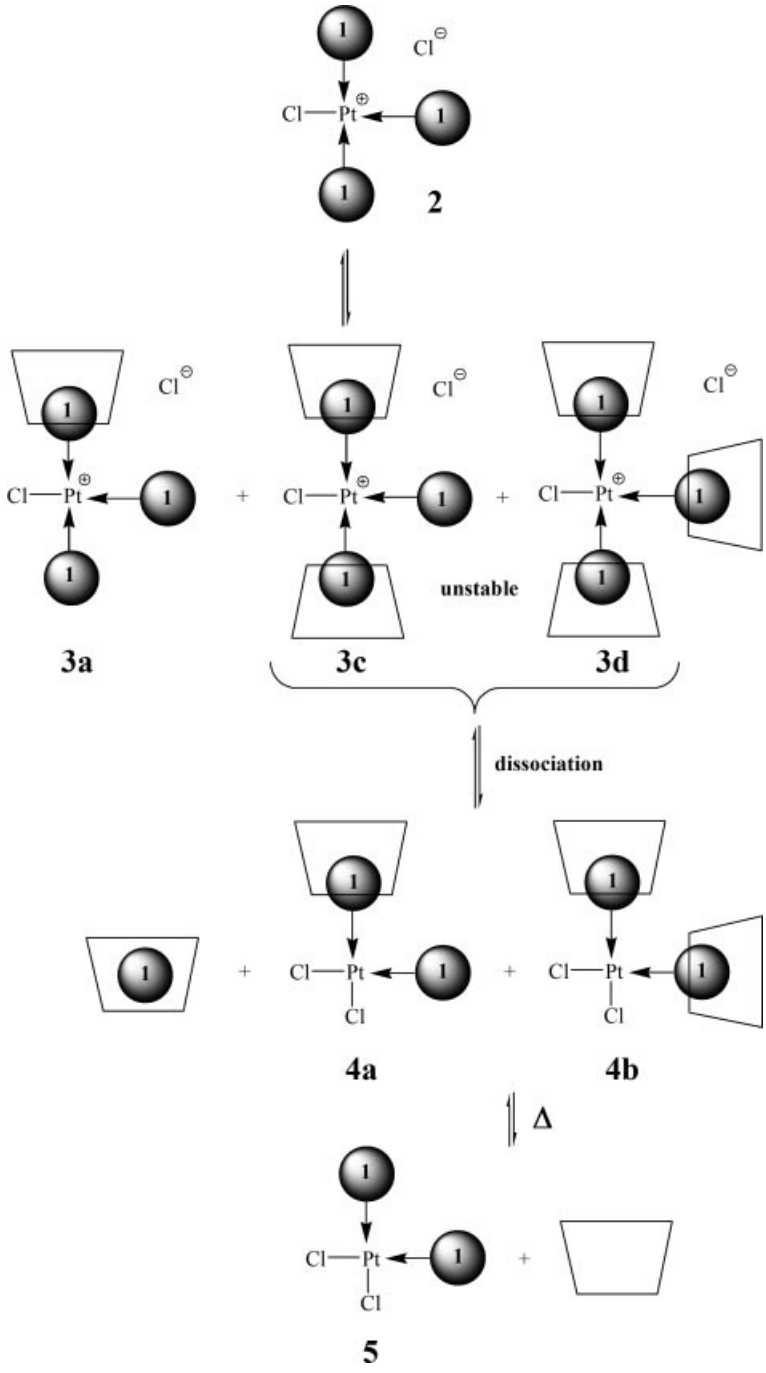
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of our knowledge, there are only four reports in the literature on the formation of such adducts in organic or aqueous media.[8]

Information concerning the thermal stability of second-sphere coordination adducts **3** was obtained by carefully examining the $^{31}P\{^{1}H\}$ NMR spectra recorded at various temperatures. Increasing the temperature to 60 and 85 °C gave more resolved spectra (see parts c and d in Figure 1). In particular, the $^{31}P\{^{1}H\}$ NMR spectrum recorded at 85 °C (Figure 1, d) strongly resembles that recorded at 25 °C (Figure 1, a), indicating that the second-sphere coordination adducts **3a** and **3b** disappeared when the temperature was increased. Actually, an increase in the temperature decreased the association constant between β-CD and **1**, which found expression in a dissociation of β-CD from the organometallic complex. Interestingly, the spectrum recorded at 60 °C suggests that the β-CD interacted more strongly with the *cis* ligands than with the *trans* ligand. Indeed, the signal at $\delta$ = 12.4 ppm corresponding to the *trans* phosphane is well resolved whereas the signal corresponding to the *cis* phosphanes remains broad at 60 °C. This result can easily be rationalised by considering that the steric



Scheme 4. Equilibria between the platinum complexes of **1** in the presence of 12 equiv. RAME-β-CD (inclusion of **1** at the secondary face is also possible). Some second-sphere coordination adducts are not represented for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

congestion around the *trans* ligand is more important than it is around the *cis* ligand.

The stability of the second-sphere adducts in the presence of various amounts of β-CD or RAME-β-CD was also investigated. Similar results were obtained with 3 equiv. β-CD and with 1 or 3 equiv. RAME-β-CD. However, the results were very different when 12 equiv. RAME-β-CD was used. Indeed, along with the numerous changes already observed above, the $^{31}P\{^{1}H\}$ NMR spectrum also revealed a broad 1:4:1 triplet centred at $\delta$ = 13.8 ppm ($^{1}J_{P,Pt}$ = 3700 Hz) assigned to a new platinum species (**4**) and a resonance characteristic of an inclusion complex between **1** and the RAME-β-CD at $\delta$ = –5.5 ppm (Figure 4, a).

This new platinum species **4** was identified by comparing its chemical shift and platinum-phosphorus coupling constant values with those for the known water-soluble platinum complexes and by integration of the $^{31}P$ NMR signals. Actually, we found that the spectroscopic data of **4** are very similar to those of [*cis*-Pt(TPPTS)$_2$Cl$_2$][6] and that the intensity of the $^{31}P$ NMR signal of the species **4** was twice as high as the intensity of the signal relative to the RAME-β-CD/**1** inclusion complex. These two findings led us to assume that the new platinum species **4** corresponds to second-sphere coordination adducts between [Pt(**1**)$_2$Cl$_2$] and the RAME-β-CD obtained by dissociation of **1** from adducts **3** according to Scheme 4.

As previously observed with adducts **3** (vide infra), dissociation of RAME-β-CD from platinum species **4** occurred at high temperatures, leading to nonincluded [Pt(**1**)$_2$Cl$_2$] (**5**). Indeed, increasing the temperature led to the destabilisation of the second-sphere coordination adducts (well-defined peaks at 60 and 85 °C) and additionally to a larger proportion of the signal corresponding to free phosphane **1** in interaction with RAME-β-CD (Figure 4, parts b and c) (Scheme 4). As the intensity of the signal relative to the RAME-β-CD/**1** inclusion complex is directly proportional to the $^{31}P$ NMR signal of the new species **4** and **5**, the percentage (**4** and **5**) could be determined starting from the integration of the peak assigned to the free phosphane **1** that is included into RAME-β-CD (see Supporting Information). At 85 °C, an amount of 22% (**4** and **5**) was calculated.

In order to confirm that the formation of the phosphane coordinatively unsaturated platinum complexes **4** and **5** was a result of the RAME-β-CD similar experiments have been performed with methyl-α-D-glucopyranoside, which constitutes the monomeric "building block" of RAME-β-CD. No modification of the spectra could be observed in this case, proving that the molecular recognition ability of RAME-β-CD plays a fundamental role in the formation of **4** and **5**.

Throughout these experiments, it was clear that an excess of RAME-β-CD was necessary to generate the phosphane coordinatively unsaturated platinum complexes. The explanation of such a phenomenon not only lies in the strength of the RAME-β-CD/**2** interaction, but also in the steric hindrance generated by the presence of RAME-β-CD on the first-sphere ligands. Indeed, below 3 equiv. of RAME-β-CD with respect to the amount of platinum, it is reasonable to assume that the equilibrium between the nonincluded and included **2** remained possible as the steric hindrance around the metallic centre should not be very important when one CD is bound to a coordinated phosphane **1** (Scheme 3). By contrast, when a large amount of RAME-β-CD was added, the equilibrium was displaced towards the second-sphere coordination adducts containing two and three CDs. The local bulkiness around the metallic centre of the obtained supramolecular adducts probably became too high and a steric decongestion by dissociation of the phosphane/CD inclusion complex from the platinum occurred leading to phosphane low-coordinated complexes **4** or **5**, depending on the temperature (Scheme 4). These observations are perfectly consistent with those already made above with β-CD for which a hindered structure for the β-CD/**2** complex has been thought of (vide infra). So, the existence of second-sphere coordination adducts in which the local bulkiness around the metallic centre is high appears to be an intermediate step in the formation of phosphane coordinatively unsaturated complexes.

The NMR study has been widened to the palladium complex [Pd{(*p*-*t*BuC$_6$H$_4$)P(*m*-C$_6$H$_4$SO$_3$Na)$_2$}$_3$] (**6**) whose $^{31}P\{^{1}H\}$ NMR spectrum is depicted in Figure 5 (a).

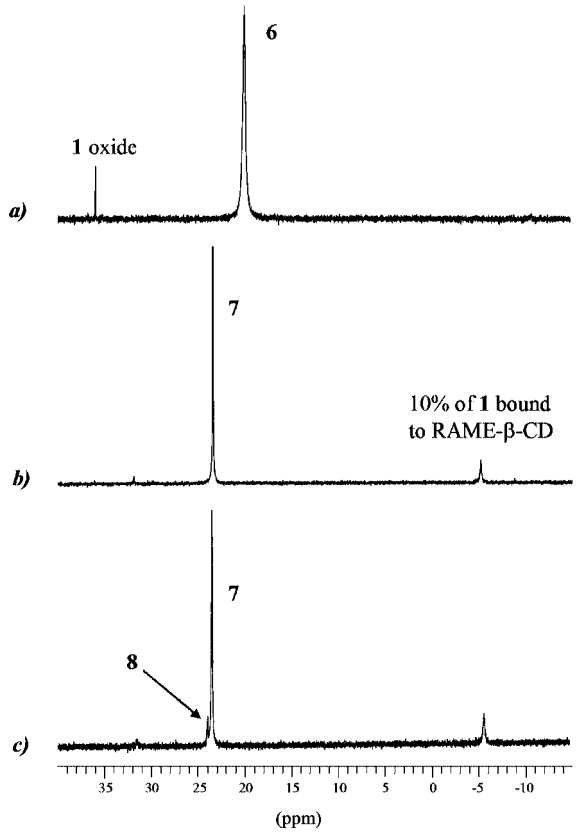


Figure 5. $^{31}P\{^{1}H\}$ NMR spectra of palladium complex [Pd((*p*-*t*BuC$_6$H$_4$)P(*m*-C$_6$H$_4$SO$_3$Na)$_2$)$_3$] (**6**) (20 mM) in D$_2$O at 25 °C (a) without cyclodextrin; (b) after addition of 3 equiv. RAME-β-CD with respect to palladium; (c) after addition of 12 equiv. RAME-β-CD with respect to palladium.

Besides the minor resonance of the phosphane oxide impurity ($\delta$ = 36 ppm), a broad signal was detected at $\delta$ =

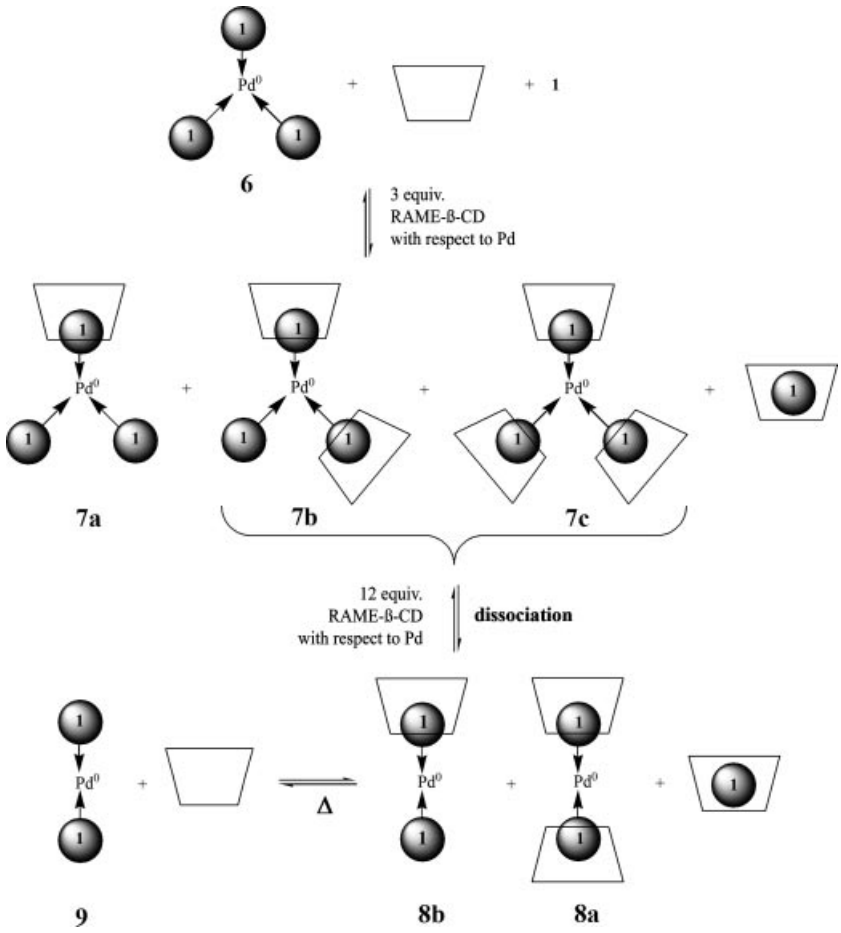

Scheme 5. Equilibria between the palladium complexes of **1** in the presence of various amounts of RAME-β-CD (inclusion of **1** at the secondary face is also possible).

20.1 ppm. As an excess of phosphane **1** was present in the medium (10%, see Exp. Sect.), this broad peak is an average signal resulting from the fast equilibrium between free phosphane **1** and the palladium complex **6**.[9] By addition of 3 equiv. of RAME-β-CD with respect to **6**, two distinct signals are observed at $\delta$ = 24 and $\delta$ = –5.5 ppm (Figure 5, b). Integration of the $^{31}$P NMR signals at $\delta$ = –5.5 ppm shows that the amount of noncoordinated **1** is 10%, which corresponds to the excess of phosphane **1** initially present in the medium. This last result indicates that 3 equiv. of RAME-β-CD were insufficient to induce the formation of the phosphane coordinatively unsaturated species. Consequently, the signal at $\delta$ = 24 ppm has been assigned to the second-sphere coordination adducts of the palladium complex **6** with the RAME-β-CD (species **7**) and the signal at $\delta$ = –5.5 ppm to the phosphane **1** in interaction with RAME-β-CD (Scheme 5). Moreover, it can be concluded that RAME-β-CD decreased the exchange rate between phosphane **1** and the palladium species since the excess of the phosphane **1** complex is visible.

Much more interesting were the results obtained when 12 equiv. of RAME-β-CD, with respect to the palladium complex, were added to an aqueous solution of **6** (Figure 5, c). Indeed, a new species at $\delta$ = 24.5 ppm (**8**) was observed and the amount of phosphane **1** bound to RAME-β-CD was higher than the previous one (16% compared with 10%). Furthermore, calculations showed that the intensity of the $^{31}$P NMR signal of the new species **8** was twice as high as the intensity of the phosphane **1** signal that appeared. By analogy with the platinum complexes, this outstanding result led us to assume that **8** was the palladium species [(**1**)$_2$Pd$^0$] containing two phosphane ligands included in the RAME-β-CD cavities. As observed for platinum species **4** and **5**, the steric hindrance generated by two or three CDs around the metallic centre of **6** could be invoked to explain the formation of the phosphane low-coordinated palladium species **8** (Scheme 5).

Here again, the amounts of included phosphane **1** and complex **8** were found to be dependent on the temperature. Indeed, when the solution containing 12 equiv. of RAME-β-CD with respect to **6** was heated at 40 °C (Figure 6, b) and 60 °C (Figure 6, c), the signals corresponding to the palladium complex **8** and phosphane **1** included into RAME-β-CD notably increased. Although no evidence has been obtained contrary to that for the platinum species, it is reasonable to think that, at higher temperatures, dissociation of the second-sphere adducts **8** could lead to the formation of species [(**1**)$_2$Pd$^0$] (species **9**, Scheme 5).

Calculations revealed that the amount of phosphane **1** that appeared was directly connected to the amount of spe-

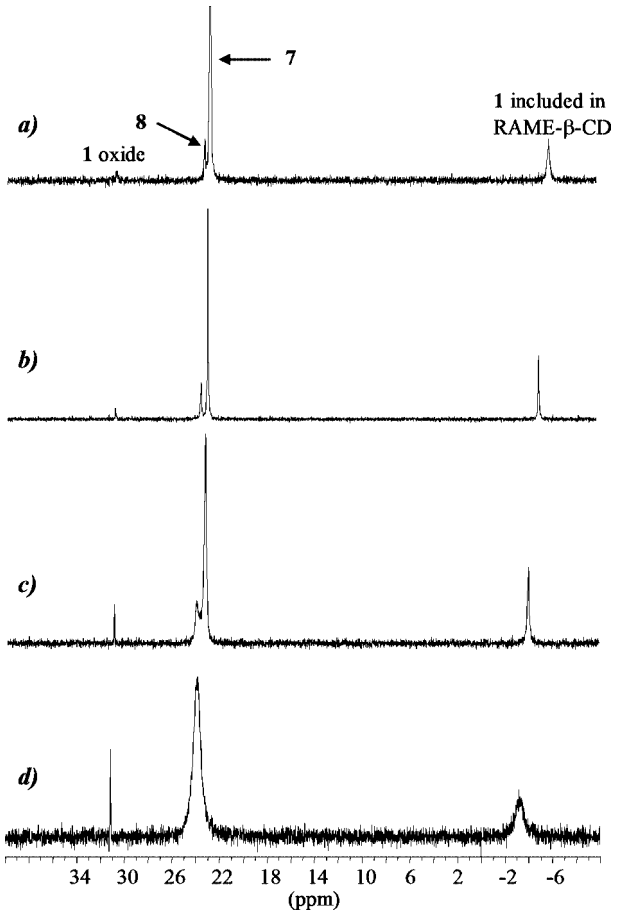

Figure 6. $^{31}P\{^{1}H\}$ NMR spectra of a mixture of [Pd((*p*-*t*BuC$_6$H$_4$)P(*m*-C$_6$H$_4$SO$_3$Na)$_2$)$_3$] (**6**) (20 mM) and RAME-β-CD (240 mM) in $D_2O$ at various temperatures: (a) 25 °C; (b) 40 °C; (c) 60 °C; (d) 85 °C.

cies **8** and **9** (see Supporting information). The percentage of **8** and **9** relative to the total amount of palladium could reach 40% at 85 °C (Figure 7).

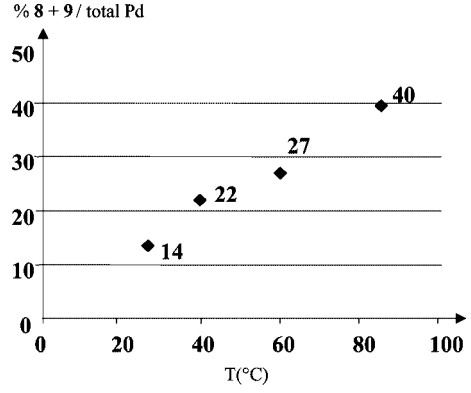

Figure 7. Percentage of palladium species (**8** and **9**) relative to the total palladium amount [% complex (**8** and **9**)/total Pd] as a function of the temperature [Pd((*p*-*t*BuC$_6$H$_4$)P(*m*-C$_6$H$_4$SO$_3$Na)$_2$)$_3$ (20 mM) and RAME-β-CD (240 mM)].

Finally, it must be pointed out that the above phenomena were reversible since a new $^{31}P\{^{1}H\}$ NMR spectrum recorded at 27 °C, after the heating period, was identical to that observed before heating the sample.

To confirm that the formation of the phosphane coordinatively unsaturated palladium complexes **8** and **9** was due to RAME-β-CD, similar experiments were also performed with methyl-α-D-glucopyranoside. As previously reported with the platinum species, no modification of the spectra could be observed in this case, proving that the molecular recognition ability of RAME-β-CD plays a fundamental role in the formation of **8** and **9**.

## Conclusion

This work has clearly demonstrated that the strong interaction between RAME-β-CD and the especially designed phosphane **1** can be used for generating phosphane coordinatively unsaturated platinum and palladium complexes, which are spectroscopically evidenced by $^{31}P$ NMR measurements. This constitutes the first example of the existence of low-coordinated palladium species in water. The existence of second-sphere coordination adducts in which the local bulkiness around the metallic centre is high appeared to be the essential prerequisite leading to the dissociation of the sulfonated ligand from the metal. Studies are currently underway in our laboratory to examine the catalytic activity of these supramolecularly generated species.

## Experimental Section

**General Remarks:** The $^{1}H$ and $^{31}P\{^{1}H\}$ NMR spectra were recorded with a Bruker Avance 300 DPX instrument at 300.13 and 75.46 MHz, respectively. The 2D T-ROESY experiments were run using the software supplied by Bruker. Mixing times for T-ROESY experiments were set at 300 ms. The data matrix for the T-ROESY was made from 512 free induction decays, 1 K points each, resulting from the coaddition of 32 scans. The real resolution was 1.5–6.0 Hz/point in the F2 and F1 dimensions. They were transformed in the nonphase, sensitive mode after QSINE window processing. Palladium acetate, potassium chloro-platinate and randomly methylated β-cyclodextrin (RAME-β-CD) were purchased from Aldrich. RAME-β-CD was a native β-CD partially methylated; statistically 1.8 OH groups per glucopyranose unit were modified. The synthesis of the disodium bis(3-sulfonatophenyl)(4-*tert*-butylphenyl)phosphane [(*p*-*t*BuC$_6$H$_4$)P(*m*-C$_6$H$_4$SO$_3$Na)$_2$ (**1**)] was described in one of our previous publications.[10]

**$^{31}P\{^{1}H\}$ NMR Study on the Complex Cl[Pt{(*p*-*t*BuC$_6$H$_4$)P(*m*-C$_6$H$_4$SO$_3$Na)$_2$}$_3$Cl] (2):** $K_2Pt_2Cl_4$ (21 mg, 0.05 mmol) was dissolved in degassed deuterated water (5 mL). Three equiv. of **1** (7.9 mg, 0.15 mmol) were added to the solution, which was then stirred for 30 min at room temperature under nitrogen. Complex **2** was quantitatively obtained. Studies in the presence of β-CD or RAME-β-CD were conducted as follows: the required amount of cyclodextrin was introduced into 1 mL of the above solution. After 15 min. of stirring the solution was transferred into a 5 mm NMR tube.

**$^{31}P\{^{1}H\}$ NMR Study on the Complex [Pd{(*p*-*t*BuC$_6$H$_4$)P(*m*-C$_6$H$_4$SO$_3$Na)$_2$}$_3$] (4):** [Pd{(*p*-*t*BuC$_6$H$_4$)P(*m*-C$_6$H$_4$SO$_3$Na)$_2$}$_3$] in a $D_2O$ solution was synthesized according to a modified literature procedure.[9a] Pd(PPh$_3$)$_4$ (412 mg, 0.36 mmol) was dissolved in degassed toluene (8 g) in a Schlenk tube under nitrogen. (*p*-*t*BuC$_6$H$_4$)-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

P(*m*-$C_6H_4SO_3Na)_2$ (277 mg, 0.53 mmol) was dissolved in $D_2O$ (8 g) and cannulated into the palladium solution. The mixture was stirred for 30 min at room temperature. After decantation, the aqueous phase was recovered. The obtained [Pd{(*p*-*t*Bu$C_6H_4$)P(*m*-$C_6H_4SO_3Na)_2$}$_3$] solution was then used for the $^{31}P\{^1H\}$ NMR spectroscopic study. This solution contained the expected palladium complex [Pd{(*p*-*t*Bu$C_6H_4$)P(*m*-$C_6H_4SO_3Na)_2$}$_3$] and an excess of about 10% of free (*p*-*t*Bu$C_6H_4$)P(*m*-$C_6H_4SO_3Na)_2$ {with regard to the initial amount of (*p*-*t*Bu$C_6H_4$)P(*m*-$C_6H_4SO_3Na)_2$}. A study in the presence of RAME-β-CD was conducted as follows: the required amount of RAME-β-CD was introduced, under nitrogen, to 1 mL of the above [Pd{(*p*-*t*Bu$C_6H_4$)P(*m*-$C_6H_4SO_3Na)_2$}$_3$] solution. After 15 min. of stirring, the solution was transferred via a cannula into a nitrogen pressurized 5 mm NMR tube.

# Synthesis, Crystal Structures, and Photophysical Properties of Two Novel Lead(II)–SIP Coordination Polymers ($NaH_2SIP$ = 5-Sulfoisophthalic Acid Monosodium Salt) Containing Tetranuclear Lead(II) Units

**Qing-Yan Liu[a,b] and Li Xu*[a]**

**Keywords:** Tetranuclear lead / Hydrothermal synthesis / Crystal structures / Photophysical properties

Two new $Pb^{II}$–SIP coordination polymers, $\{[Pb_4(OH)_2(SIP)_2(H_2O)](H_2O)_5\}_n$ (**1**) and $[Pb_3(SIP)_2(H_2O)_5]_n$ (**2**), have been synthesized by hydrothermal reactions of $Pb(OH)_2$ or $Pb(NO_3)_2$ and 5-sulfoisophthalic acid monosodium salt ($NaH_2SIP$) at 160 °C, respectively. Single-crystal X-ray diffraction reveals that compound **1** has a 2D brick-wall-like architecture constructed from 1D tapes containing the basketlike tetranuclear $[Pb_4(\mu_3\text{-}OH)_2(COO)_2]$. Compound **2** has a 2D-layered structure, which is constructed from a 1D-ladder structure composed of the cyclic $[Pb_4(SIP)_2(COO)_2]$ grid with the four Pb atoms nearly coplanar. In the solid state, compound **1** exhibits blue photoluminescence with the maximum emission intensity at 436 nm upon excitation at 335 nm. Compound **2** shows phosphorescence with the maximum emission intensity at 603 nm upon excitation at 426 nm. Both compounds have also been characterized by elemental analysis, IR spectra, TG analysis, and powder X-ray diffraction.

## Introduction

The design and construction of coordination polymers is one of the most active areas of materials research. The intense interest in these materials is driven by both their interesting network topologies and potential applications such as catalysis, molecular magnets, sensors, ion exchange, adsorption, and phase separation.[1–4] Many of the efforts have so far been devoted to the study of transition-metal-based coordination polymers.[5–7] However, relatively little attention has been paid to the coordination polymers of main group metal ions despite their important applications in electroluminescent devices or organic light-emitting diode (OLED) technology.[8–11] $Pb^{2+}$ is employed in the present work for several reasons: (1) it has a $6s^2$ outer electron configuration and large radius, which can lead to interesting topological arrangements;[12–14] (2) the absence of crystal field stabilization energy effects allows the $Pb^{2+}$ ion to adopt varied coordination geometries including octahedra, tetrahedra, or square planes amongst others, which give rise to novel coordination networks;[15–17] and (3) it has interesting photochemical and photophysical properties.[18–21] On the other hand, the SIP ligand, with three functional groups, exhibits multiple coordinating modes facilitating the formation of multi-dimensional structures and diversified topologies.[22–24] Recently, we have reported a series of lanthanide–SIP coordination polymers wherein SIP proves to be a sensitive probe in examining the role of the lanthanide contraction effect in crystal structure formation.[25] In this contribution, SIP will serve as a probe to examine the coordination polymer chemistry of $Pb^{2+}$, and the two novel polymeric materials with $Pb_4$ secondary building blocks, $\{[Pb_4(OH)_2(SIP)_2(H_2O)](H_2O)_5\}_n$ (**1**) and $[Pb_3(SIP)_2(H_2O)_5]_n$ (**2**), will be described with regard to syntheses, crystal structures, TG analysis, powder X-ray diffraction, IR spectra, and photoluminescent properties. An unprecedented coordinating mode of SIP (Scheme 1, b) is observed in polymer **1**.

## Results and Discussion

### Preparation of the Complexes

Hydrothermal synthesis is widely employed to produce new structures, but is still a kind of "black box". This method can minimize the problems associated with ligand solubility and enhance the reactivity of reactants in favor of efficient molecular building during the crystallization process. The two $Pb^{II}$–SIP polymers, $\{[Pb_4(OH)_2(SIP)_2(H_2O)](H_2O)_5\}_n$ (**1**) and $[Pb_3(SIP)_2(H_2O)_5]_n$ (**2**), are obtained from hydrothermal reactions of the lead(II) salts and $NaH_2SIP$ in aqueous solution. The preparative reactions

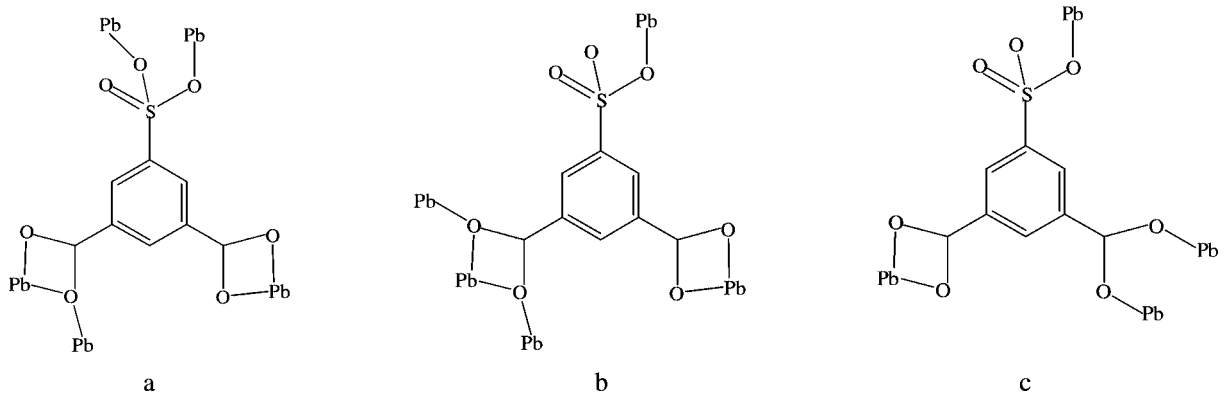

Scheme 1. Coordination modes of SIP observed in compound **1** and **2**.

were carried out under different temperatures (140, 160, and 180 °C) to examine the temperature-dependence of their solid structures. X-ray diffraction analyses of the reaction products indicate that the same results were obtained under these reaction temperatures although the purity and yields are slightly different, indicative of the thermodynamic nature of the hydrothermal reactions. Compounds **1** and **2** cannot be obtained from the reaction of the corresponding lead(II) salts and $NaH_2SIP$ in aqueous solution at room temperature (in contrast to hydrothermal conditions), indicating the kinetic nature of this conventional method. The dramatic difference in reaction products between conventional and hydrothermal reactions is attributable to their different reaction mechanisms that are shifted from a kinetic domain for conventional solution reactions to a thermodynamic domain for hydrothermal reactions.[26–28]

### Crystal Structure of $\{[Pb_4(OH)_2(SIP)_2(H_2O)](H_2O)_5\}_n$ (1)

Compound **1** features a two-dimensional brick-wall-like architecture constructed from unusual tetranuclear lead(II) motifs as a secondary building block. As depicted in Figure 1 (a), the asymmetric unit of **1** contains four crystallographically independent lead(II) ions. Pb(1) is surrounded by six oxygen atoms, of which four are from three surrounding SIP ligands, one is from a water molecule, and one is from a $\mu_3$-hydroxy group. The coordination geometry of Pb(1) can be described as a distorted pentagonal bipyramid with the seventh coordination site occupied by its lone pair of electrons. The atoms O(17) and O(6B) (B: $-x + 1$, $y + 1/2$, $-z + 2/3$) occupy the axial positions (Figure 1, a). The Pb(1)–O distances range from 2.469(8) to 2.714(8) Å, comparable to those observed in the related lead(II) compounds.[7–9] The Pb(3) atom has a similar coordination geometry to that of Pb(1) with the two apical positions occupied by the carboxylate and hydroxy oxygen atoms [O(2E) (E: $-x + 1$, $y - 1/2$, $-z + 3/2$) and O(16)], and they both have similar Pb–O distances [Pb–O = 2.425(8)–2.752(8) Å]. Pb(2) has a distorted [:PbO4] tetragonal-pyramid geometry with the four basal positions occupied by a chelating carboxylate group and two $\mu_3$-hydroxy groups and the apical position occupied by the lone pair of electrons. The Pb(2)–O distances [2.328(8)–2.612(9) Å] are slightly shorter than those around the six-coordinate Pb(1) center. The Pb(4) atom has a similar coordination geometry to that of Pb(2) as illustrated in Figure 1 (a). As shown in Figure 1 (b), the four $Pb^{2+}$ ions are capped by two $\mu_3$-hydroxy groups generating a butterfly $[Pb_4(\mu_3\text{-}OH)_2]$ cluster. The Pb(1)Pb(2) Pb(3) and Pb(1)Pb(4)Pb(3) triangles are each capped by an additional carboxylate group to form a basketlike structure with a weak Pb(1)–O(4) (3.18 Å) interaction. The basal plane [Pb(2), Pb(4), O(15), and O(16)] of the basket is almost planar with the Pb(4)–O(15)–Pb(2) and Pb(4)–O(16)–Pb(2) angles of 104.6(3) and 103.1(3)°, respectively (Table 1). The Pb(2)···Pb(4) separation of about 3.8 Å is longer than the sum of the van der Waals radii (3.20 Å).[29] The dihedral angles between the side faces and the basal plane are 67.8(2), 97.2(1), 112.8(2), 106.1(1), 88.2(1), and 64.8(3)°, respectively. Interestingly, the basketlike structure of the tetranuclear cluster $[Pb_4(\mu_3\text{-}OH)_2(COO)_2]$ core resembles many cubanelike structures that are commonly found in many other compounds. However, in the current compound the carboxylate groups make the cluster more open instead of the bridging oxygen atoms.[30–31] Several complexes containing $[Pb_4(\mu_3\text{-}OH)_2]$ have been documented, but the $[Pb_4(\mu_3\text{-}OH)_2]$ cluster has a chair structure with the two Pb atoms above and below the $[Pb_2(\mu_3\text{-}OH)_2]$ plane.[32–34] Therefore, this is a rare example concerning lead(II) complexes.

As shown in Figure 1 (a), the two independent SIP ligands exhibit different coordinating modes. SIP(a) acts as a pentadentate ligand (Scheme 1, a) with the bidentate sulfonate group, one chelating carboxylate group, and one $\mu_2$-$\eta^2$:$\eta^1$ carboxylate group (one oxygen atom bridges two metal atoms, the other connects one metal atom, and the carboxylate group coordinates to two metal atoms). The unprecedented coordinating mode of SIP(b) is depicted in Scheme 1 (b) wherein one carboxylate group chelates to one $Pb^{2+}$ ion and the other displays an unusual $\mu_3$-$\eta^2$:$\eta^2$ coordinating mode (each oxygen atom coordinates to two metal atoms and the carboxylate group coordinates to three metal atoms). To the best of our knowledge, this type of coordinating mode of the SIP ligand is not observed in the previously reported SIP complexes. Unlike that of SIP(a), the sulfonate group of the SIP(b) ligand is unidentate.

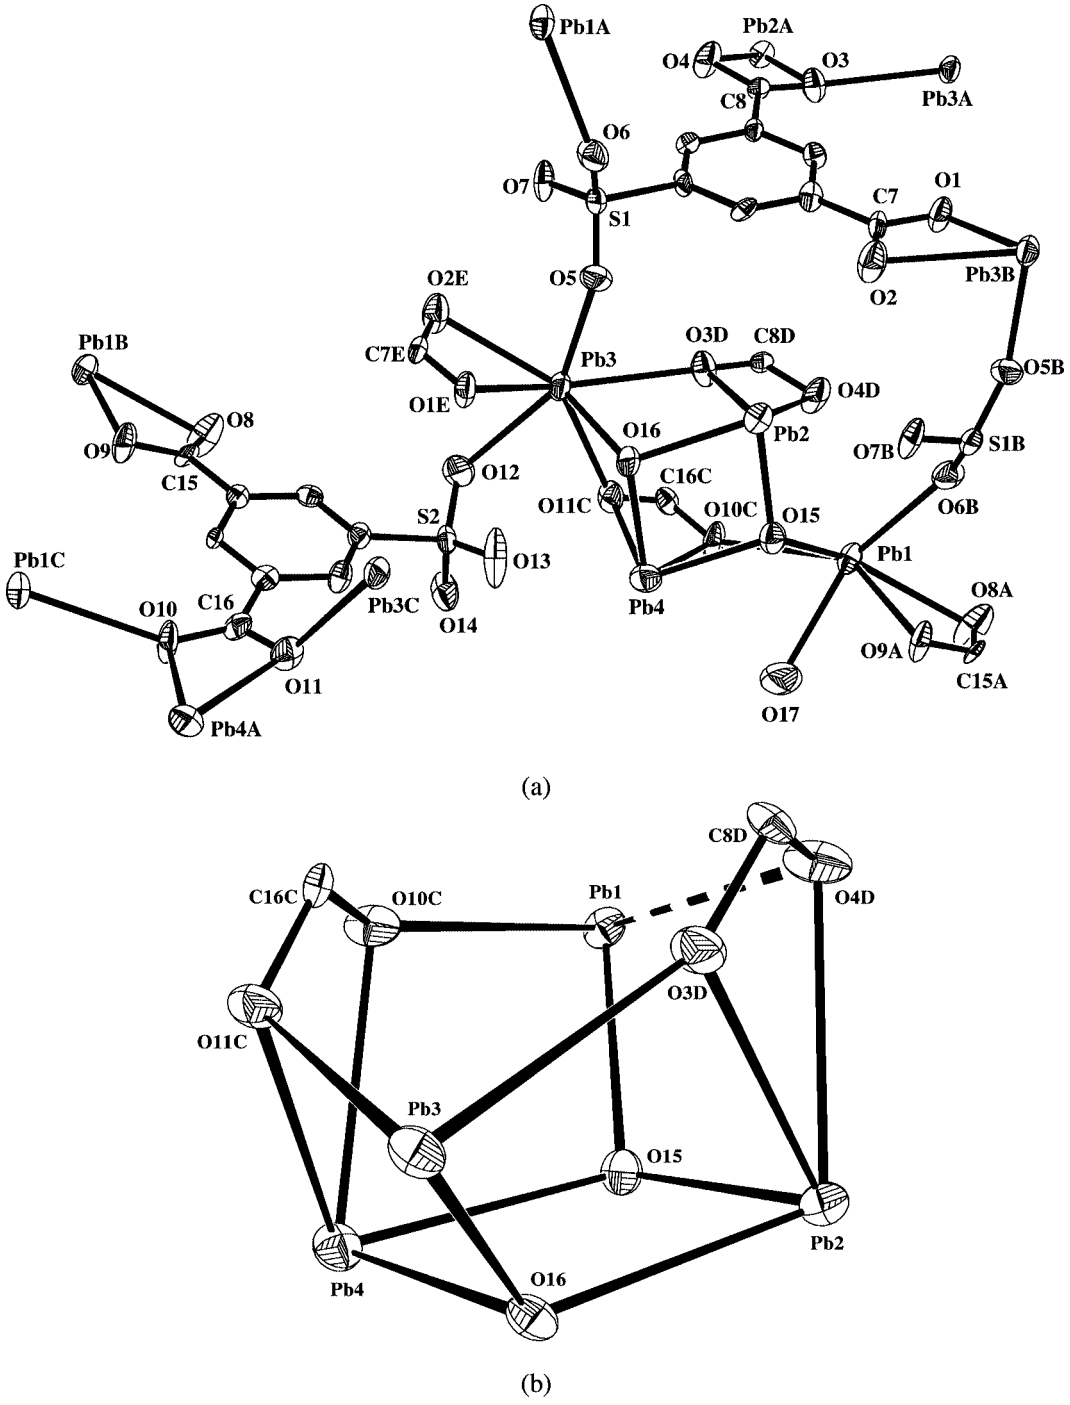

Figure 1. (a) Molecular structure of compound **1**. (b) The basketlike tetranuclear $[Pb_4(\mu_3\text{-}OH)_2(COO)_2]$ cluster as a secondary building block.

The $[Pb_4(\mu_3\text{-}OH)_2(COO)_2]$ secondary building blocks are interconnected into a one-dimensional tape structure propagating along the crystallographic *b* axis (Figure 2) by the SIP ligand through the chelating carboxylate and sulfonate groups. Two types of 16-membered rings are observed in the 1D tape; ring A is composed of two SIP ligands and two Pb atoms and ring B consists of one $[Pb_4(\mu_3\text{-}OH)_2(COO)_2]$, one Pb atom, one SIP ligand, and one sulfonate group. Such cyclic structures are characteristic of the SIP coordination polymers.[25] The separation between the two neighboring $Pb_4$ units, linked by ring A, is 15.3 Å, comparable to the length of the *b* axis. As described above, the two independent SIP ligands use four of their six functional groups to form a 1D tape. The remaining two carboxylate groups link the 1D tapes along the *c* axis into a 2D brick-wall-like layered structure where the cavities have an approximate dimension of 12.8×6.5 Å, as depicted in Figure 3. The layers are parallel and do not slip in the crystal

packing. So, the intralayer pores form a channel along the *a* axis. The lattice water molecules occupying the voids of the 2D layered structure serve as receptors or donors of the extensive O–H···O hydrogen bonds with O···O distances of 2.701(1)–3.096(3) Å. The layers are further held together by π-stacking interactions between the parallel neighboring phenyl rings with a face-to-face distance of 3.337(3) Å, and the neighboring phenyl rings have a dihedral angle of 8.2(1)° with a centroid–centroid distance of 3.728(4) Å. Similar π–π stacking interactions have also been reported in a number of cadmium– and copper–SIP complexes.[35,36]

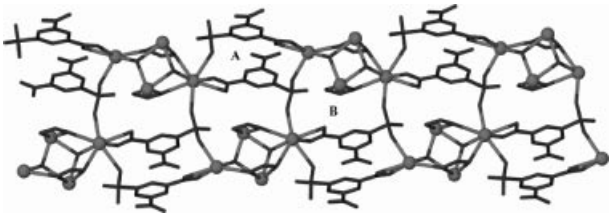

Figure 2. View of the tetranuclear $[Pb_4(\mu_3\text{-}OH)_2(COO)_2]$ bridged by SIP to form a one-dimensional tape structure propagating along the *b* axis (Pb atoms are represented as balls).

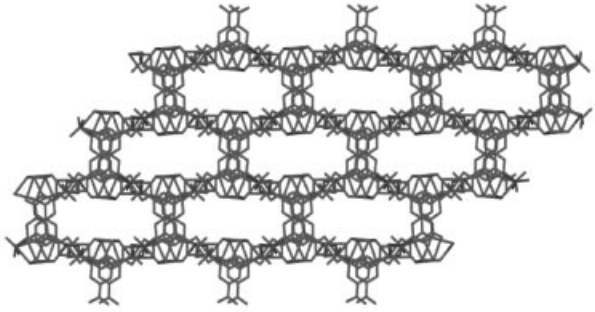

Figure 3. View of the two-dimensional brick-wall-like architecture of **1** along the *bc* plane.

### Crystal Structure of $[Pb_3(SIP)_2(H_2O)_5]_n$ (2)

Compound **2** has a 2D-layered structure with the tetranuclear $[Pb_4(SIP)_2(H_2O)_6]$ unit. As shown in Figure 4, the asymmetric unit of **2** consists of three $Pb^{2+}$ ions, two SIP ligands, and five coordinating water molecules. The Pb(1) atom coordinates to three carboxylate oxygen atoms from two SIP ligands and two water molecules, with Pb(1)–O distances of 2.460(15)–2.680(14) Å. The coordination geometry of Pb(1) can be described as a distorted pentagonal

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

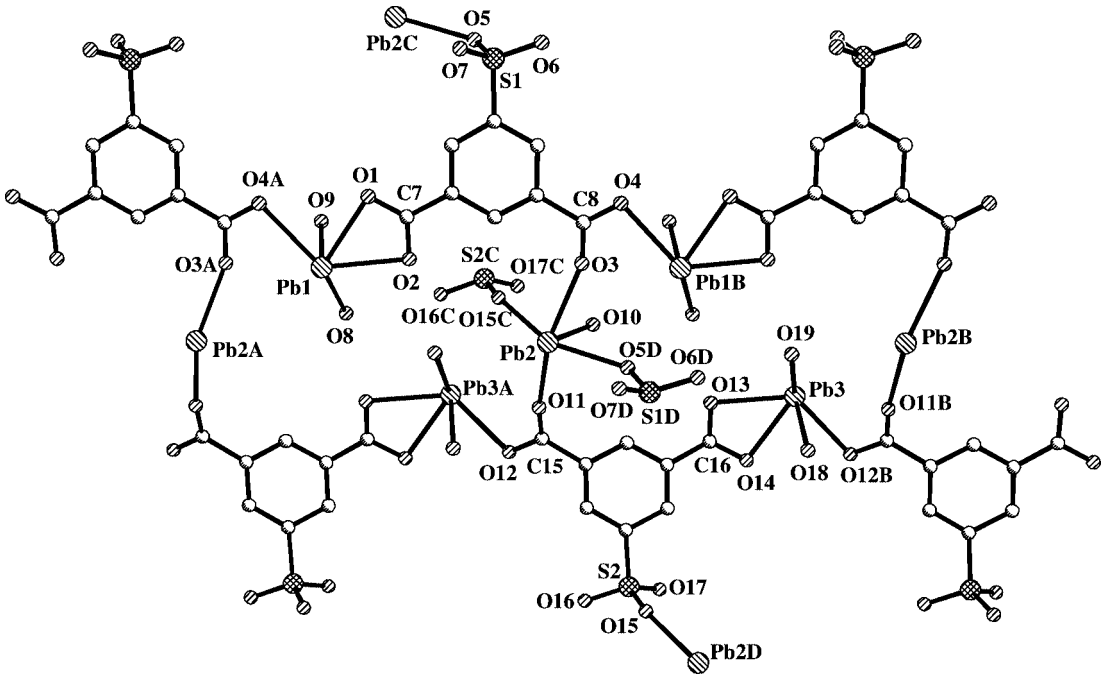

Figure 4. Crystal structure of compound **2**.

pyramid with the lone pair of electrons completing the pentagonal plane and the water molecule [O(9)] lying at the apical position. Pb(3) is crystallographically independent but geometrically similar to Pb(1) with the apical position occupied by the O(18) atom of the water molecule. The Pb(3)–O distances of 2.437(13)–2.715(15) Å are similar to those around Pb(1). Pb(2) has a distorted [:PbO5] octahedral coordination geometry with equatorial positions occupied by two carboxylate and two sulfonate oxygen atoms, and the apical positions taken up by one water molecule and the lone pair of electrons. The Pb(2)–O distances [2.26(2)–2.562(13) Å] are within the normal experimental limitation (Table 3)[12,13] but slightly shorter than those around the seven-coordinate Pb(1) and Pb(3) atoms. The two independent SIP ligands have similar coordinating modes as illustrated in Scheme 1 (c).

As illustrated in Figure 5, the $Pb^{2+}$ ions are interconnected by the SIP ligands into a 1D-ladder structure featuring the cyclic $[Pb_4(SIP)_2(COO)_2]$ with an approximate dimension of $10.2 \times 5.8$ Å$^2$. The four Pb ions [Pb(1), Pb(2), Pb(3A), and Pb(2A), A: $x$, $y + 1$, $z$] are nearly coplanar with a maximum deviation of 0.377(1) Å for [Pb(1)] and a mean deviation of 0.344(1) Å. This type of coplanar $Pb_4$ unit is, to the best our knowledge, uncommon. The 1D ladder can also conveniently be regarded as resulting from two 1D $[Pb(SIP)(H_2O)_2]_n$ single chains bridged by Pb(2) (Figure 5). As mentioned above, the SIP ligands use the carboxylate groups to form the 1D ladder. The remaining sulfonate groups further link the 1D ladders into a 2D layer through Pb(2)–sulfonate bonding [Pb(2)–O(5D), 2.452(15); Pb(2)–O(15C), 2.511(14) Å; C: $x$, $y - 1$, $z$, D: $x$, $y + 1$, $z$] (see Figure 6). The stacking of the 1D ladders is clearly affected by π interactions between the SIP ligands. The phenyl rings between the ladders are almost parallel and closely stacked [the dihedral angle is 1.5(1)° and the centroid–centroid distance is 3.559(1) Å]. The coordinating water molecules fill the cavities of the neighboring ladders preventing interpenetration.

### FT-IR Spectra, Thermogravimetric Analyses, and Powder X-ray Diffraction

The FT-IR spectra of **1** and **2** exhibit broad absorptions centered at 3390 and 3410 $cm^{-1}$ for **1** and **2**, respectively, occurring because of the existence of water molecules in the structures. The IR spectrum of **1** shows the typical asymmetric (1597 $cm^{-1}$) and symmetric (1542 and 1431 $cm^{-1}$) stretching bands of carboxylate groups. The respective values of [$\nu_{as}(CO_2) - \nu_s(CO_2)$] clearly indicate the presence of chelating (55 $cm^{-1}$) and bridging (166 $cm^{-1}$) coordination modes of the carboxylate groups in **1**.[37] The strong bands at 1598 $cm^{-1}$, and 1522 and 1434 $cm^{-1}$, respectively, correspond to the asymmetric and symmetric stretching bands of the carboxylate groups in the IR spectrum of **2**. Similar to those in **1**, the values of [$\nu_{as}(CO_2) - \nu_s(CO_2)$] are 76 $cm^{-1}$ and 164 $cm^{-1}$ in **2**, which supports the presence of chelating and bridging coordination modes of the carboxylate groups. The absorptions in the region 1000–1200 $cm^{-1}$ for the two complexes are typical of the sulfonate group. The strong absorption bands at 621 and 623 $cm^{-1}$ for **1** and **2**, respectively, are because of the $\nu_{S-O}$ stretching.

To examine the thermal stability of the two compounds and their structural variation as a function of the temperature, thermogravimetric analyses (TGA) were performed on single-phase polycrystalline samples of these materials (see Figure S1 in the Supporting Information). Results from the TGA measurements of **1** exhibit two distinct weight loss steps. The first weight loss occurs between 60 and 290 °C because of the release of all water molecules (weight loss: measured 7.2%, theoretical 7.4%). The need for such an unusually high temperature for the removal of the water molecules is because of the hydrogen bonding with the carboxylate or sulfonate oxygen atoms. The second weight loss in the temperature range 410–800 °C corresponds to the decomposition of the SIP ligand. The thermogravimetric analysis of **2** shows that the initial weight loss occurs in the temperature range 110–240 °C, attributable to the release of all coordinating water molecules (observed, 7.3%, calculated 7.5%). Increasing the temperature led to the decomposition of the SIP ligand at 420 °C.

The X-ray powder diffraction patterns (XRPD) of both compounds are illustrated in Figure S2 and S3. The different structures of compounds **1** and **2** have also been indicated by their different XRPD patterns. Their XRPD patterns are in good agreement with those simulated from single crystal structural data, thus both compounds **1** and **2** were obtained as a single phase.

### Photoluminescent Properties

Photoluminescent properties of $s^2$-metal complexes are not well studied as compared with those of $d^{10}$-metal complexes, although there are reports on the photoluminescent properties of lead-containing materials.[38–41] The photoluminescence properties of **1** and **2**, as well as the free ligand, were examined in the solid state at room temperature. The free $Na_2HSIP$ displays photoluminescent emission at 320 nm under 286 nm radiation.[42] Compound **1** exhibits intense photoluminescent emission with a maximum at 436 nm upon excitation at 335 nm (Figure 7). In the case of **2**, photoluminescence with a maximum emission at 603 nm upon excitation at 426 nm is observed. The emission wavelength of **1** (436 nm) is much longer than that of the free SIP ligand (320 nm) and similar to those of the reported $s^2$-metal cluster complexes.[43–46] Therefore, this emission can be assigned to the lead(II) cluster complex. A remarkable bathochromic shift is also observed in compound **2**. As seen from Figure 7, the emission of **2** occurs at a much lower energy of 603 nm with a large Stokes shift. The low-energy emissions associated with large Stokes shifts have been commonly observed for other $s^2$-metal complexes, which can be assigned to a metal-centered transition involving the s and p metal orbital as proposed by Vogler.[39,43,47] With these concerns in mind, the emission band at 603 nm of **2** can be assigned to a metal-centered s → p transition. The large Stokes shift is caused by the elimination of the ground-state distortion in the excited state.[39] The further lifetime measurements at room temperature of each emission maximum give the results of 2.43 ns for **1** and 3.47 μs for **2**. The long emission lifetime of **2** can be assigned to phosphorescence, which is consistent with the general idea that the appearance of a room-temperature phosphorescence requires the presence of a heavy metal ion, which re-

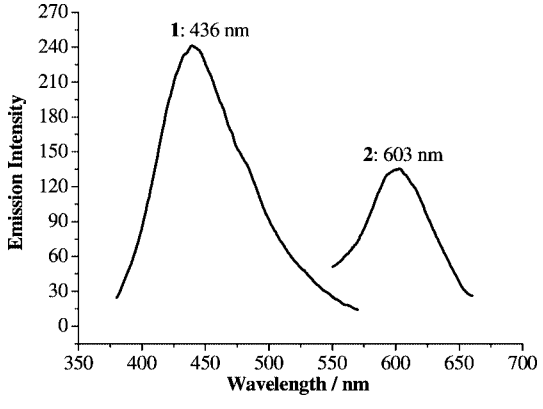

Figure 7. The solid-state emission photoluminescent spectra of **1** ($\lambda_{ex}$ = 335 nm) and **2** ($\lambda_{ex}$ = 426 nm) at room temperature.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

duces the radiative lifetime of triplets by increased spin-orbit coupling.[21] As described above, we can conclude that the different emission spectra of **1** and **2** can be significantly influenced by their crystal structures.

## Conclusion

In conclusion, the self-assembly of the lead(II) ions with SIP affords two novel $Pb^{II}$–SIP coordination polymers **1** and **2** containing tetranuclear lead(II) motifs. Because of the diversity of the SIP ligand in bridging metal ions, the metal–SIP complexes are expected to show various novel, interesting structures and desired properties. In the present case, compounds **1** and **2**, obtained with the same SIP ligand and under almost the same synthetic procedures, are distinct from each other, with regard to composition, topology, and photoluminescent properties. Compound **1** displays a 2D brick-wall-like structure featuring a unique basketlike tetranuclear $[Pb_4(\mu_3\text{-}OH)_2(COO)_2]$ motif. Compound **2** has a 2D layered structure containing 1D ladders characteristic of the cyclic $[Pb_4(SIP)_2(COO)_2]$ unit. Therefore, the multiple coordinating modes of the SIP ligand, together with the varied coordination geometry of $Pb^{2+}$, exhibit diverse structural topologies of the $Pb^{II}$–SIP system. In addition, the lone pair of electrons usually leads to the asymmetric coordination geometry of $Pb^{II}$, which probably disfavors the formation of high-dimensional structures. So, lead(II) materials usually have low-dimensional structures. Compound **1** displays fluorescent emission and **2** shows phosphorescence emission at room temperature, indicating structure-dependent photoluminescent properties of the Pb–SIP coordination polymers, and revealing potential for application in OLED technology.

## Experimental Section

**General Remarks:** 5-Sulfoisophthalic acid monosodium salt (Alfa) was purchased commercially and used without further purication. Elemental analyses were carried out with an Elementar Vario EL III analyzer and IR spectra (KBr pellets) were recorded with a PerkinElmer Spectrum One. Fluorescent spectra were measured at room temperature with an Edinburgh FL-FS90 TCSPC system. The thermogravimetric measurements were performed with a Netzsch STA449C apparatus under a nitrogen atmosphere with a heating rate of 10 °C/min from 25 to 800 °C. X-ray powder diffraction patterns were performed with a RIGAKU DMAX2500PC diffractometer using Cu-$K_\alpha$ radiation. All complexes were synthesized by the hydrothermal method under autogenous pressure.

**Synthsis of $\{[Pb_4(OH)_2(SIP)_2(H_2O)](H_2O)_5\}_n$ (1):** A mixture of $Pb(OH)_2$ (0.048 g, 0.2 mmol) and 5-sulfoisophthalic acid monosodium salt (0.027 g, 0.1 mmol) in a 2:1 molar ratio in $H_2O$ (18 mL) was introduced into a Parr Teon-lined stainless steel vessel (30 mL). The vessel was sealed and heated to 160 °C. This temperature was kept for 5 d and then the mixture was cooled at a rate of 5 °C/h to form colorless crystals of **1**. A pale yellow crystalline product was filtered, washed with distilled water, and dried at ambient temperature (yield: 0.47 g, 64% on the basis of Pb). $C_{16}H_{20}O_{22}S_2Pb_4$ (1457.20): calcd. C 13.18, H 1.37; found C 13.11, H 1.33. IR (KBr): $\tilde{\nu}$ = 3390 (s), 1597 (vs), 1542 (vs), 1431(s), 1355 (vs), 1197 (s), 1149 (s), 1107 (s), 1036 (s), 925 (w), 872 (w), 771 (m), 719(s), 677 (w), 621 (s), 447 (m) $cm^{-1}$.

**Synthsis of $[Pb_3(SIP)_2(H_2O)_5]_n$ (2):** A mixture of $Pb(NO_3)_2$ (0.033 g, 0.1 mmol), 5-sulfoisophthalic acid monosodium salt (0.041 g, 0.15 mmol), and triethyl amine (0.1 mL) in a 2:3:6 molar ratio in $H_2O$ (18 mL) was introduced into a Parr Teon-lined stainless steel vessel (30 mL). The vessel was sealed and heated to 160 °C. This temperature was kept for 5 d and then the mixture was cooled at a rate of 5 °C/h to form colorless crystals of **1**. A pale yellow crystalline product was filtered, washed with distilled water, and dried at ambient temperature (yield: 0.40 g, 56% on the basis of Pb). $C_{16}H_{16}O_{19}S_2Pb_3$ (1197.98): calcd. C 16.04, H 1.35; found C 16.01, H 1.34. IR (KBr): $\tilde{\nu}$ = 3410 (s), 1598 (vs), 1522 (vs),

**X-ray Crystallographic Study:** X-ray diffraction data of compound **1** and **2** were collected with a Rigaku Mercury CCD diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The CrystalClear software was used for data reduction and empirical absorption corrections.[48] The structures were solved by direct methods and successive Fourier difference syntheses, and refined by the full-matrix least-squares method on $F^2$ (SHELXTL Version 5.1[49]). All non-hydrogen atoms except for the carbon atoms of compound **2** were refined with anisotropic thermal parameters. Aromatic hydrogen atoms were assigned to calculated positions with isotropic thermal parameters fixed at 1.2 times that of the attached carbon atom. Hydrogen atoms attached to oxygen atoms for compound **1** were located from difference maps and refined with O–H distances restrained to 0.90 Å, and isotropic thermal parameters fixed at 1.5 times that of the respective oxygen atom. Water hydrogen atoms for compound **2** could not be located in the difference Fourier map. The final Fourier map had a maximum and a minimum electron density of 2.153/–1.675 e·Å$^{-3}$, 2.438/–3.797 e·Å$^{-3}$ for compound **1** and **2**, respectively, and are within 1.0 Å of the lead atoms. The $R_1$ values are defined as $R_1 = \Sigma||F_o| - |F_c|| / \Sigma|F_o|$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. The selected bond lengths and bond angles are listed in Table 2 and details of the crystal parameters, data collection, and refinement are summarized in Table 3.

# A Radical-Radical and Metal–Metal Coupling Tetrathiafulvalene Derivative in which Organic Radicals Directly Coordinate to $Cu^{II}$ Ions

**Wen Lu,[a] Yong Zhang,[a] Jie Dai,*[a,b] Qin-Yu Zhu,[a] and Guo-Qing Bian,[a] and De-Qing Zhang[b]**

**Keywords:** Tetrathiafulvalenes / Copper(II) complexes / Magnetic coupling

A new dinuclear metal complex including tetrathiafulvalene (TTF) radicals as ligands has been prepared and characterized, $[\{DMT\text{-}TTF(CONH_2)_2\}_2Cu_2Cl_6]$ (**1**), DMT-$TTF(CONH_2)_2$ = *o*-bis(amido)-appended dimethylthio-tetrathiafulvalene. The compound is an uncommon example in which TTF radicals directly coordinate to the copper(II) halide by the amido group. Crystal structure analysis shows that it is a unique coordination bond/H-bond/S···S stacking cooperative system with two radicals and two paramagnetic transition metal ions, $TTF^{+\cdot}$–$Cu^{II}$–$Cu^{II}$–$TTF^{+\cdot}$. In the structure of **1**, the DMT-TTF units form dimers with very strong S···S interactions. The $Cu^{II}$–O(amide) distance of the coordination bond is 2.271(2) Å and the S···S stacking distances between the radicals are in the range 3.345–3.489 Å. The metal–metal ions are mildly antiferromagnetically coupled ($2J_1$ = –58.4 $cm^{-1}$), while the radical pairs are strongly antiferromagnetically coupled ($2J_2 > -1000$ $cm^{-1}$).

## Introduction

Until the end of the twentieth century, the work on tetrathiafulvalene (TTF) chemistry was mostly concerned with the radical salts of magnetic molecular conductors.[1–5] In the crystals of these salts, the organic radicals and paramagnetic inorganic counterions are discretely arranged. Therefore, the interaction between them could only occur through space by weak intermolecular interactions, such as hydrogen bonding and stacking of atoms. With increasing light being shed on the interactions of TTFs with transition metals, recent interests of inorganic chemists are devoted to organic–inorganic hybrid TTF materials in which the synergy between organic and inorganic parts are through stronger covalent or coordination bonds. The incorporation of TTF units into dithiolate ligands ($TTFS_4^{4-}$ and $TTFS_2^{2-}$) is one of the successful strategies, and systems of single molecular complexes with d–π interactions have been reported.[6–10] Another strategy that has been popular is the design and synthesis of TTF derivatives that are substituted with heteroatom-based groups capable of coordinating to a metallic center, such as thioethers,[11–14] phosphanes,[15–18] pyridines,[19–24] alkylsilyls,[25] and stibines.[26] The corresponding coordination compounds have also been reported. The metal coordination of complexes with the TTF ligand offers a novel perspective on the modulation of the architecture and collective properties of molecular solids. However, to the best of our knowledge, the TTF moieties in most of the reported complexes are in the neutral state. Therefore, their direct applications as electronic or magnetic materials are limited. Very recently, an important step was reached by the synthesis and characterization of a radical electron/d electron directly cooperative complex, $[Cu^{II}(hfac)_2(TTF\text{-}py)_2][PF_6]\cdot 2CH_2Cl_2$, which has metal–radical and radical-radical couplings.[22] Besides the metal coordination, hydrogen bonds are also one of the successful strategies used to promote the properties of molecular solids. Some amide-functionalized TTFs have been prepared and their radical salts involving N–H···Cl/O hydrogen bonds were studied.[27–31]

What follows is a report on the preparation, crystal structure, and magnetic properties of a new TTF-amide derivative with two radicals and two paramagnetic transition metal ions, $[\{DMT\text{-}TTF(CONH_2)_2\}_2Cu_2Cl_6]$ (**1**), DMT-$TTF(CONH_2)_2$ = *o*-bis(amide)-appended dimethylthio-tetrathiafulvalene. Complex **1** is a new dinuclear $TTF^{+\cdot}$–$Cu^{II}$–$Cu^{II}$–$TTF^{+\cdot}$ system with coordination bonds, H-bonds and S···S stacking, which is different from $[Cu^{II}(hfac)_2(TTF\text{-}py)_2][PF_6]\cdot{}_2CH_2Cl_2$, which has a mono-nuclear TTF–$Cu^{II}$–$TTF^{+\cdot}$ coordination system. The radical-radical and metal–metal magnetic couplings are also discussed.

## Results and Discussion

### Synthesis and General Discussion

The TTF derivative DMT-$TTF(CONH_2)_2$ was synthesized by a similar procedure described in the literature.[27]

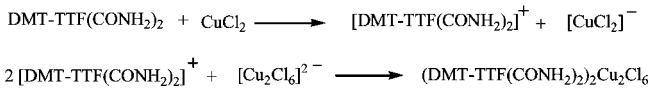
Compound **1** was prepared by the reaction of the TTF precursor with excess $CuCl_2$ using a diffusing method in ambient conditions (Scheme 1). The details are given in the experimental section. During the reaction the ligands are oxidized by $Cu^{II}$ ions forming the radical cations and, hence, the charge distribution of **1** might be deduced as [{DMT-TTF$(CONH_2)_2^{+\cdot}$}$_2(Cu_2Cl_6)^{2-}$].



Scheme 1.

Copper(II) halides readily oxidize the TTF derivatives, providing a variety of charge-transfer (CT) salts that have conductive or semiconductive properties. Although a number of TTF CT compounds with copper(II) halides have been prepared, no cation-anion coordinated model has been found.[32–37] Due to the weak coordination of the TTF radicals with the $Cu^{II}$ center (by the thioether or alkylthio group), the paramagnetic copper(II) halides, such as the familiar $Cu_2Cl_6^{2-}$ anion, are arranged discretely as counterions. However, anions of copper(I) halides, which can be formed from the reduction of $Cu^{II}$ halides, are easily coordinated by the alkylthio group of the TTFs or its radicals. Some copper(I) halide-TTF complexes[11–14] or CT compounds[38–40] having S–$Cu^{I}$ coordination bonds have been obtained. Compound **1** is an uncommon example where direct coordination of the copper(II) halide with the TTF radical occurs. In the case of **1** the TTF moieties are appended by two amido groups, which enable the $Cu^{II}$ center to be bonded by the oxygen atom of the amide group.

## Description of the Structures

The single crystal structure of **1** was solved by direct methods. A summary of the experimental details and crystal data for compound **1** is given in Table 1. Selected bond lengths, contact distances, bond angles, and torsion angles are listed in Table 2. The ligand, DMT-TTF$(CONH_2)_2$, in **1** adopts a conformation with an intramolecular hydrogen bond [N(1)–H···O(2), Figure 1], which has been observed for several TTF amides and their radical salts.[27–31] As a consequence of the intramolecular hydrogen bond, the two *ortho*-amido groups are fixed and form a seven-membered ring fused with the TTF moiety, which enables the conjugated π system to extend to the oxygen atoms of the amide groups.

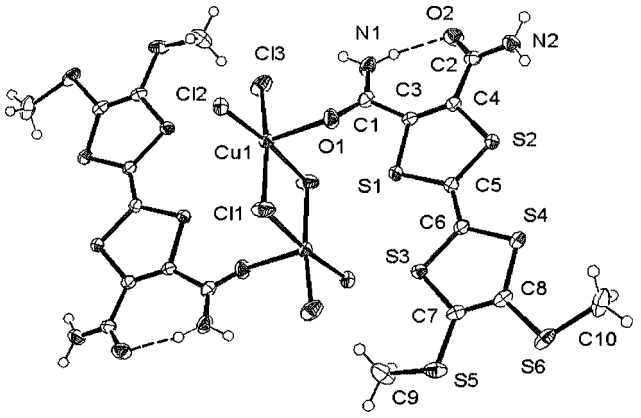

Figure 1. ORTEP view of **1**, showing the atom-labeling scheme. Displacement ellipsoids are drawn at the 50% probability level.

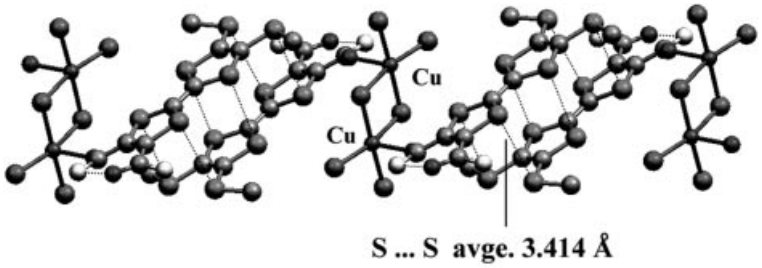
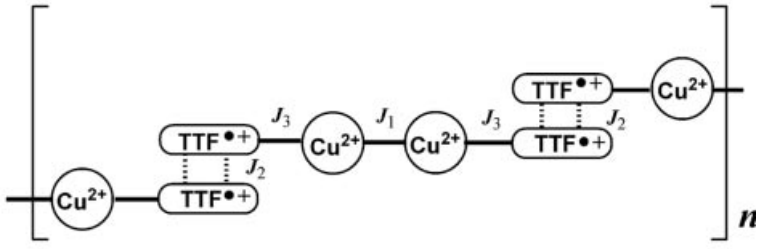
The center of **1** is a dinuclear moiety of $Cu_2Cl_6^{2-}$, in which the $Cu^{II}$ ions take on a quasi-square coordination and the two squares share a common edge of Cl(1)–Cl(1$^i$). The Cu–Cl distances are in the range 2.254–2.335 Å, and are comparable to those reported for the $Cu_2Cl_6^{2-}$ ion. However, the Cu(1)–Cl(1)–Cu(1$^i$) angle of 97.12(3)° is located at the top of the angle range compared with those of the corresponding compounds.[36,41,42] In addition to the coordination of chloride ions, the DMT-TTF$(CONH_2)_2$ coordinates to the $Cu^{II}$ ions by the amide oxygen atom O(1), perpendicular to the square planes of the $CuCl_4$ moieties (see Figure 1). The 2.271(2) Å distance of Cu(1)–O(1) undoubtedly shows the formation of a strong coordination bond, which forces the $Cu_2Cl_6^{2-}$ ion to take on a quasi-planar geometry [atom Cl(3) is somewhat out of the square plane]. In contrast, the discrete $Cu_2Cl_6^{2-}$ ion adopts a structure with two distorted tetrahedra sharing a common edge.[36,43,44] The central C=C distance of the TTF moiety [C(5)–C(6), 1.379(4) Å], however, is longer than that found in the neutral TTF compounds (1.331 Å) but in accordance with that of the $TTF^{+\cdot}$ radicals (1.373–1.383 Å).[27]

All of the TTF units form dimers in the crystal structure **1** with very strong S···S stacking [Figure 2 (a)]. There are six S···S interactions between the TTF units of the dimer, in which the shortest one is 3.345 Å and the longest is 3.489 Å (average 3.414 Å, Table 2). The S···S interactions are considerably shorter than the sum of the van der Waals radii (3.60–3.70 Å), and they are related to the strong antiferromagnetic coupling of the organic radical dimer (vide infra).



(a)



(b)

Figure 2. (a) One-dimensional structure of the molecules assembled by S···S stacking and metal coordination. (b) Schematic diagram of the two TTF radicals with the $Cu^{II}$ system and the magnetic coupling constants.

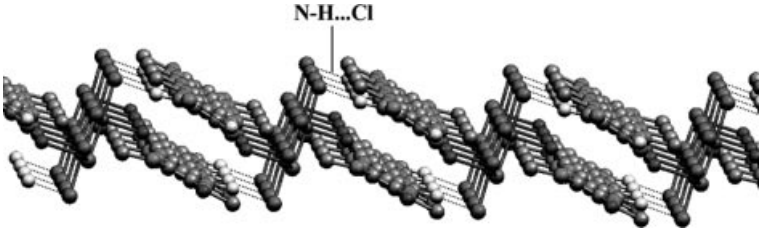


Figure 3. The inter-chain N(2)–H···Cl(2) (3.288 Å) hydrogen bonds of the assembled two-dimensional structure of the title compound.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Assembled by S···S stacking and Cu–O metal coordination, compound **1** forms an infinite chain propagating in the [101] direction. The crystal structure of **1** is further stabilized by inter-chain N(2)–H···Cl(2) hydrogen bonds (3.288 Å) and S(6)···O(2) contacts (3.317 Å), which assemble the molecules into two-dimensional slabs parallel to the plane (1–11) (Figure 3). It has been shown that the hydrogen-bond network is correlated with the density of states at the Fermi level and the spin susceptibility behavior.[31]

### Magnetic Properties

Until now, work on TTF-containing π–d-type magnetic compounds has mostly been concerned with radical salts, except for the example reported recently by Ouahab et al., which has a mono-nuclear TTF–$Cu^{II}$–$TTF^{+\cdot}$ coordination system.[22] Compound **1**, reported here, has a new dinuclear $TTF^{+\cdot}$–$Cu^{II}$–$Cu^{II}$–$TTF^{+\cdot}$ coordination system [Figure 2 (b)]. The magnetic properties of **1** were measured with a SQUID magnetometer in the range 4–260 K (Figure 4). The magnetic moment (2.40 B. M. at room temperature) is considerably lower than the spin-only value, 6.92 B. M., for a noncoupling four-spin system (1.73 B. M. × 4), but the value of 2.40 B. M. corresponds to the value which is expected for a two-spin ($S$ = 1/2) system with antiferromagnetic (AF) coupling (3.46 B. M. for a noncoupling two-spin system).

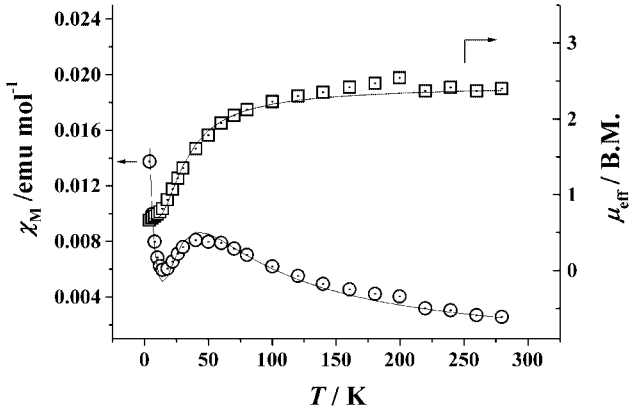

Figure 4. Variable-temperature magnetic susceptibility data and effective magnetic moments of **1** collected by a SQUID magnetometer in the range 4–260 K. The solid lines were calculated based on a singlet-triplet model.

A solid-state EPR spectrum (polycrystalline sample), which strongly supports the speculation, was measured at 110 K (Figure 5). Because the organic radicals are dimerized with very short S···S stacking and are strongly antiferromagnetically coupled no sharp radical signal is observed in the EPR spectrum. The spectrum only shows a parallel and perpendicular split of $Cu^{II}$ character with $g$ values of 2.045 and 2.246 for $g_{\|}$ and $g_{\perp}$, respectively. This result means that the two TTF radicals are AF coupled with $2J_2 > -1000\ cm^{-1}$. In addition, because the spin density of the radical is mainly located on the central TTF core and the amide oxygen atom of **1** coordinates to the $Cu^{II}$ center of the $Cu_2Cl_6$ plane along the axial position, the interaction of the radicals with the metal ions should be very weak. Therefore, the $J_3$ coupling can be neglected in the fitting procedure. Consequently, this compound can be described as a system that has a strongly coupled $TTF^{+\cdot}$ ($J_2$) dimer and a mildly coupled $Cu_2Cl_6$ ($J_1$) dimer with very weak radical-metal interaction ($J_3$) [Figure 2 (b)]. From a simplified calculation, considering the antiferromagnetic coupling intensity, the magnetic susceptibility of compound **1** can be fitted by a $Cu_2Cl_6$ dimer model with spin-exchange Hamiltonian $\hat{H} = -2J_1\hat{S}_{Cu1}\hat{S}_{Cu2}$, where $J_1$ is the spin-exchange coupling constant between the two $Cu^{II}$ ions (Figure 4). The susceptibility data were fitted using Equation (1) containing the paramagnetic impurity term ρ. The best least-squares fit gave $J_1 = -29.2\ cm^{-1}$, $g = 2.08$, $\rho = 0.08$ and the consistent factor $R = \Sigma(\chi_{obsd} - \chi_{calcd})^2/\Sigma\chi_{obsd}^2 = 3.85 \times 10^{-3}$. The structural-magnetic correlation for the $Cu_2Cl_6^{2-}$ ion has been intensively discussed elsewhere.[45,46] The present result of $2J_1 = -58.4\ cm^{-1}$ supports the structure in which the copper(II) center adopts a square-planar geometry.

$$\chi_M = \frac{2Ng^2\beta^2}{KT}\left[\frac{1}{3+\exp(-2J_1/KT)}\right](1-\rho) + \frac{Ng^2\beta^2}{2KT}\rho + N_\alpha \quad (1)$$

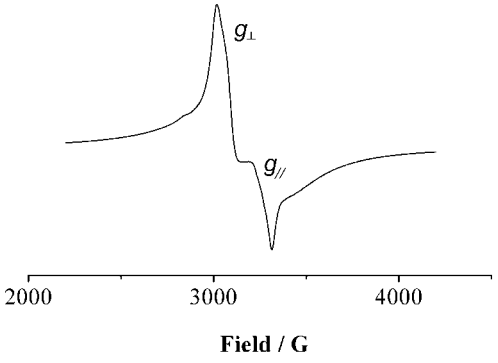

Figure 5. Solid-state EPR spectrum of the title compound measured at 110 K.

## Conclusion

Prior to the report of Ouahab et al., where the TTF radicals directly coordinate to the paramagnetic ions,[22] the charge transfer TTF compounds containing paramagnetic inorganic ions were radical salts in which the cations and anions are discretely arranged. The compound **1** reported here is a new example in which the TTF radicals directly coordinate to the paramagnetic ions. Crystal structure analysis showed that it is a unique coordination bond/H-bond/S···S stacking cooperative system with two radicals and two paramagnetic transition metal ions, $TTF^{+\cdot}$–$Cu^{II}$–$Cu^{II}$–$TTF^{+\cdot}$. Although the direct coordination of the $TTF(CONH_2)_2^{+\cdot}$ radical to the paramagnetic transition metal anion, $(Cu_2Cl_6)^{2-}$, does not improve the interaction of the radical electrons and the d electrons in this case, because

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the strong antiferromagnetic coupling within the radical pairs (TTF radical couples) the preparation of materials with direct coordination of TTF radicals to transition metal anions is still an attractive strategy for chemists in molecular design.

## Experimental Section

**General Remarks:** All analytical grade chemicals were obtained commercially and used for synthesis directly without further purification. Elemental analyses of C, H, and N were performed using an MOD 1106 elemental analyzer. The IR spectra were recorded as KBr discs with a Nicolet Magma 550 FT-IR spectrometer. Solid-state EPR spectra were recorded with an EMX-10/12 spectrometer at 110 K and at a frequency of 9.4852 GHz. The magnetic properties were measured with a SQUID magnetometer (Quantum Desigen, MPMS-2) in the range 3.99–278 K, with an applied field of 10000 gauss.

**Synthesis of Compounds**

**DMT-TTF(CONH$_2$)$_2$ (Ligand):** The ligand was synthesized by a similar procedure described in the literature.[27] A purple powder was obtained (yield 79%). $C_{10}H_{10}N_2O_2S_6$ (382.56): calcd. C 31.24, H 2.64, N 7.33; found C 32.09, H 2.87, N 6.60. IR (KBr): $\tilde{\nu}$ = 3375–3189 ($NH_2$), 1675–1662 (C=O) cm$^{-1}$.

**(C$_{10}$H$_{10}$N$_2$O$_2$S$_6$)$_2$Cu$_2$Cl$_6$ (1):** Well-defined black platelet crystals of **1** were obtained by a diffusing method with an acetonitrile solution of $CuCl_2$ ($4 \times 10^{-2}$ M) and a THF solution of the ligand ($5 \times 10^{-3}$ M). $C_{20}H_{20}Cl_6Cu_2N_4O_4S_{12}$ (1104.93): calcd. C 21.83, H 1.83, N 5.09; found C 21.56, H 2.05, N 4.89. IR (KBr): $\tilde{\nu}$ = 3329–3149 ($NH_2$), 1671–1660 (C=O) cm$^{-1}$.

**X-ray Crystallographic Study:** All measurements were carried out with a Rigaku Mercury CCD diffractometer at 193 K with graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation. X-ray Crystallographic data of compounds **1** were collected and processed using CrystalClear (Rigaku).[47] The structures were solved by direct methods with SHELXS-97[48] and the refinements against all reflections of the compound were performed using SHELXL-97.[49] The non-hydrogen atoms were refined anisotropically and hydrogen atoms were refined using the theoretical riding model. The final cycle of full-matrix least-squares refinement was done on the basis of 3371 independent reflections and 220 variable parameters. The weighted $R$ factor ($wR$) and goodness of fit ($S$) were obtained on the basis of 2996 [$I > 2\sigma(I)$] reflections. The calculations were performed using the CrystalStructure software package.[50]

CCDC-268681 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# The First Example of a Dinuclear Platinum(III) Complex with Three Bridging Ligands

**Raffaella Z. Pellicani,[a] Francesco P. Intini,[a] Luciana Maresca,[a] Ernesto Mesto,[b] Concetta Pacifico,[a] and Giovanni Natile*[a]**

**Keywords:** Bridging ligands / Hydrogen bonds / Metal–metal interactions / N ligands / Platinum(III)

The first triply bridged dinuclear platinum(III) compound with acetamidate ligands, $X[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$ ($X = K^+$ or $AsPh_4^+$), has been isolated in the solid state and characterized by one- and two-dimensional NMR spectroscopy and X-ray crystallography. Owing to the asymmetry of the bridging acetamidate ligands, three isomers can be formed (HHH, HHT, and HTH), although only two are found in the crude reaction product: HHT and HTH. The HTH species is thermodynamically less stable and slowly (half life of around two days at room temperature) isomerizes into the HHT form. The more stable and less symmetric HHT isomer crystallizes from chloroform/pentane ($AsPh_4^+$ counter ion). The two $[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]^-$ anions of the unit cell are linked by two strong N–H···O H-bonds while contiguous anions of adjacent cells are linked together by two, slightly weaker N–H···Cl H-bonds. The result is a chain of anions running along the *a* direction. The crystal packing allows for the formation of one-dimensional pore channels, also running along the *a* direction, which are filled with disordered pentane molecules.

## Introduction

The chemistry and reactivity of platinum(III) compounds has not yet been explored to the same extent as those of platinum(II) and platinum(IV) species. The majority of platinum(III) complexes have dinuclear structures supported by two[1–3] or four[4–6] bridging ligands. The chelating chain is usually made up of three atoms of the type NCO, NCS, NCN, POP, or OYO (Y = C, S, P), with these three atoms forming a five-membered metallacycle with the two metal centers.[7–9] A few examples of mononuclear platinum(III) species[10] and dinuclear complexes unsupported by covalent bridges have also been reported.[11–13]

Very recently, further interest in dinuclear compounds of platinum(III) has arisen from their potential use as catalysts for the oxidation of olefins.[14–18] This property is fostered by the unusual reactivity of the axial ligands. The axial metal–ligand distances are longer than those found in octahedral platinum(IV) and square-planar platinum(II) complexes but much shorter than distances sometimes found for ligands interacting with platinum(II) species from axial sites.[1]

In spite of the large number of platinum(III) dimers with two or four bridging ligands, very few reports have so far dealt with platinum(III) dimers supported by three covalent bridges. In two NMR investigations, it was shown that species with three acetate bridging ligands can be formed as intermediates in the synthesis of quadruply bridged complexes[19] or as decomposition products of the latter compounds in water,[20] however such species were not isolated or fully characterized.

In this paper, we report the synthesis, NMR characterization, and X-ray structure of the first example of a triply bridged platinum(III) compound with acetamidate ligands, namely $X[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$ ($X = K^+$ or $AsPh_4^+$).

## Results and Discussion

### Synthesis and Spectroscopic Characterization

When $K_2PtCl_4$ and $K_2PtCl_6$ (1:1 ratio) are allowed to react with a large excess of free amide at high temperature (90 °C) and for a long time (5 h), quadruply bridged dimeric lantern-type complexes are formed. These complexes are insoluble in water and precipitate soon after formation. Full accounts of their synthesis and characterization have already been published.[5,6]

In order to obtain platinum(III) dimers with a smaller number of bridging ligands, we used the same procedure but shortened the reaction time until incipient precipitation of the quadruply bridged species (one instead of five hours). The reaction solution was then filtered and the solvent evaporated to dryness to leave an orange residue. Purification of the crude reaction product was performed by washing with chloroform to remove the excess of acetamide li-

gand, extraction with methanol to remove insoluble KCl and trace amounts of unreacted platinum(II) and platinum(IV) species, and finally precipitation with diethyl ether. The orange precipitate was characterized by elemental analysis and IR and NMR spectroscopy, and was found to be the triply bridged species $K[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$ (**1a**). The corresponding tetraphenylarsonium salt, $(AsPh_4)[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$ (**1b**), which is soluble in chloroform − **1a** is only soluble in protic solvents such as water and methanol − and precipitates as well-shaped orange crystals from a mixture of chloroform and pentane (1:1, v/v), was also prepared and characterized by elemental analysis, NMR spectroscopy, and X-ray crystallography.

The reaction conditions (90 °C and 1 h reaction time) appear to be critical to maximize the yield of triply bridged species. Longer reaction times result in greater formation of undesired quadruply bridged complexes, while shorter reaction times (0.5 h) leave significant amounts of unreacted platinum(II) and platinum(IV) species. Moreover, if the temperature is lowered the reaction becomes slower and at room temperature does not appear to take place at all.

Since the reaction can lead to formation of several interconverting isomers of the same species (for instance the triply bridged species can be present in three isomeric forms depending upon the relative orientations of the three amidates: HHH, HHT, and HTH), we analyzed the reaction products before and after purification. The latter will be described first.

A solution of **1b** in $CDCl_3$ gives a $^1H$ NMR spectrum characterized by the presence of two sets of three signals. One set falls in the region of amidic protons ($\delta$ = 6.5–5.5 ppm), while the second set falls in the region of aliphatic protons ($\delta$ = 2.5–2.0 ppm). The three signals have equal intensities within each set, and the relative intensities of the two sets is 1:3.

The correlations between the two sets of signals were established by a 2D NOESY experiment, which shows a cross peak between the less-shielded amidic proton signal at $\delta$ = 6.41 ppm (A) and the less-shielded methyl proton signal at $\delta$ = 2.29 ppm (D) and two overlapping cross peaks between the amidic proton signals at $\delta$ = 5.75 (B) and 5.73 (C) ppm and the methyl proton signals at $\delta$ = 2.03 (F) and 2.05 (E) ppm, respectively (Figure 1).

Three isomers are possible for a dinuclear species with three acetamidate bridging ligands (Figure 2). Two of them, HHH and HTH, have magnetically equivalent acetamidate bridges in *trans* positions, while the third isomer, HHT, has all three acetamidate bridges in different magnetic environments. Since the $^1H$ NMR spectrum exhibits distinct signals for each of the three acetamidate ligands, we can conclude that the isolated product has an HHT configuration.

The $^{195}Pt$ NMR spectrum of compound **1b** in $CDCl_3$ reveals the presence of two platinum resonances, one at $\delta$ = 241 ppm and the other at $\delta$ = –437 ppm. Each resonance is flanked by $^{195}Pt$ satellites with a $^1J_{Pt,Pt}$ coupling of 6660 Hz (Figure 3).[14,21,22]

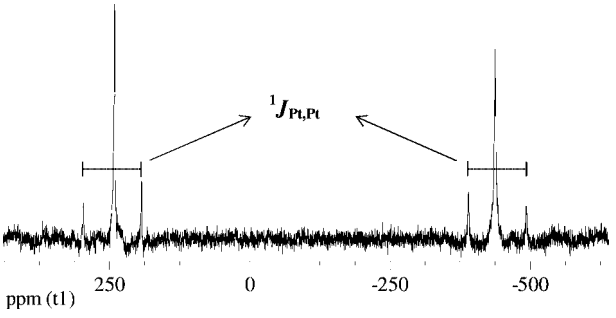

Figure 3. $^{195}Pt$ NMR spectrum of $(AsPh_4)[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$ in $CDCl_3$ ($4.6\times10^{-3}$ M) at 295 K.

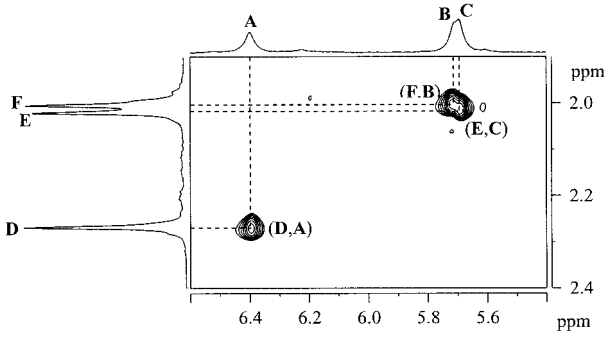

Figure 1. 2D NOESY spectrum of $(AsPh_4)[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$ in $CDCl_3$ ($4.6\times10^{-3}$ M) at 295 K.

On the basis of the established correlations between $^{195}Pt$ chemical shifts and electronegativities of the donor atoms,[23] the less-shielded signal, at $\delta$ = 241 ppm, can be assigned to the Pt atom with $Cl_2NO_2$ set of donor atoms while the most-shielded signal, at $\delta$ = –437 ppm, can be assigned to the Pt atom with $Cl_2N_2O$ set of donor atoms. This assignment is also supported by the broader profile of the peak at $\delta$ = –437 ppm as compared to that at $\delta$ = 241 ppm. Such a broadening is caused by the N donors, which

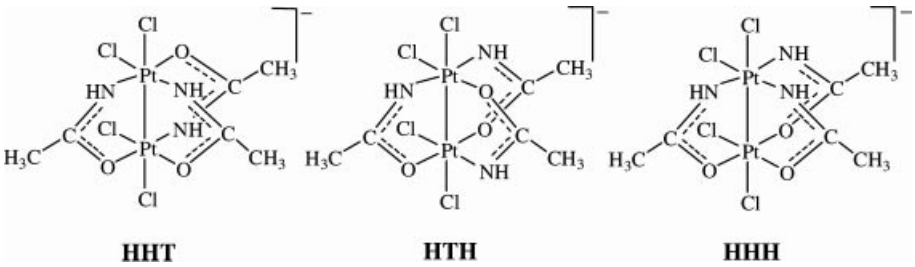

Figure 2. The three possible isomers for the complex $[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]^-$. HH and HT stand for equal (head-to-head) or opposite (head-to-tail) orientation of adjacent amidates, respectively.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

number two for the platinum resonating at $\delta$ = –437 ppm and only one for the platinum resonating at $\delta$ = 241 ppm. It is worth noting that, differently from the present case, where only a broadening of the signals has been observed, the Pt–N couplings are well resolved in some mononuclear complexes with terminal amides.[24]

Compounds **1a** and **1b** in aqueous solution (**1a** is not soluble in $CDCl_3$) give identical $^{195}Pt$ NMR spectra, with resonances at $\delta$ = 220 and –430 ppm indicating that the two compounds contain the same complex anion.

The presence of only one isomer in the purified product indicates that this isomer is the end product of the purification procedure but not necessarily that it is the only product formed in the reaction. For this reason we performed an NMR investigation on the crude reaction product obtained by evaporation of the aqueous reaction solution to dryness. The $^{195}Pt$ NMR spectrum (due to the presence of a very large excess of free amide the $^1H$ NMR spectrum is not informative; moreover, water was used as solvent in order to ensure complete dissolution of the raw material) showed the presence of two sets of signals: one corresponding to that of the purified product (signals at $\delta$ = 220 and –430 ppm) and the other (signals at $\delta$ = 161 and –86 ppm) indicating the presence of a second isomer. The intensity of this second set of signals was initially similar to that of the other isomer (about 0.7 times its intensity). However, on standing in solution at room temperature its intensity decreased and after eight days became negligible (Figure 4). Therefore, we can conclude that two major dinuclear species are initially formed and that with time, under the experimental conditions used for this investigation (water solution of the raw material still containing a large excess of free acetamide), one isomer converts into the other.

It has already been demonstrated that the thermodynamically favored isomer has an HHT configuration, therefore the second isomer observed in the crude reaction product can have either an HTH or an HHH configuration. For the HTH isomer the chemical-shift difference between the two platinum atoms and the peak profiles are expected to be similar to those observed for the HHT isomer since both have similar sets of donor atoms for platinum ($Cl_2NO_2$ and $Cl_2N_2O$). In contrast, for the HHH isomer the chemical-shift difference between the two platinum atoms is expected to be greater than for the HHT and HTH isomers due to the greater difference between the sets of donor atoms ($Cl_2N_3$ and $Cl_2O_3$). Furthermore, the peak profile is expected to be much broader for $Pt(Cl_2N_3)$ than for $Pt(Cl_2O_3)$. Since the chemical-shift difference between the two platinum atoms and the peak profiles for the second isomer present in the raw material are very similar to those observed for the HHT isomer, we propose that this second isomer has HTH configuration.

## X-ray Diffraction Analysis of $(AsPh_4)[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$

### *Bond Lengths and Angles*

Orange crystals of $\{(AsPh_4)[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]\}_2 \cdot C_5H_{12}$ were obtained by crystallization from $CHCl_3$/pentane (1:1, v/v). The asymmetric unit comprises two independent complex molecules **A** and **B**. The two $[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]^-$ ions are very close to one another, implying the formation of hydrogen bonds between the NH groups of one anion and the O atoms of the second anion. Since the amidate groups in each independent anion are in an HHT arrangement, four different models can be drawn for the pair of independent anions in the asymmetric unit: Z1, Z2, Z3, and Z4 (Scheme 1). The four models converged to $R_1$ = 0.0375 and $wR_2$ = 0.0772 for Z1, $R_1$ = 0.0376 and

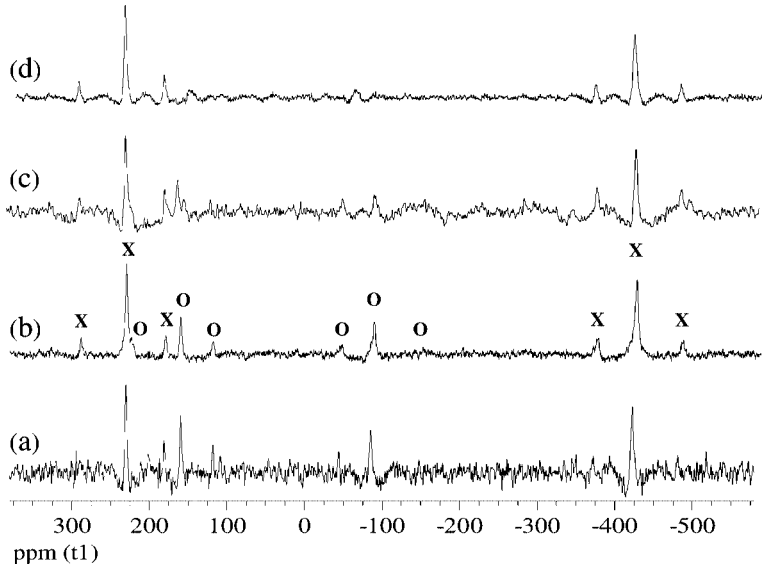

Figure 4. $^{195}Pt$ NMR spectrum of the crude reaction product dissolved in $D_2O$ and kept at 295 K. The spectra were registered soon after dissolution (a) and after one (b), three (c), and eight (d) days. Resonances of the HHT and HTH isomers are labeled with x and o, respectively.

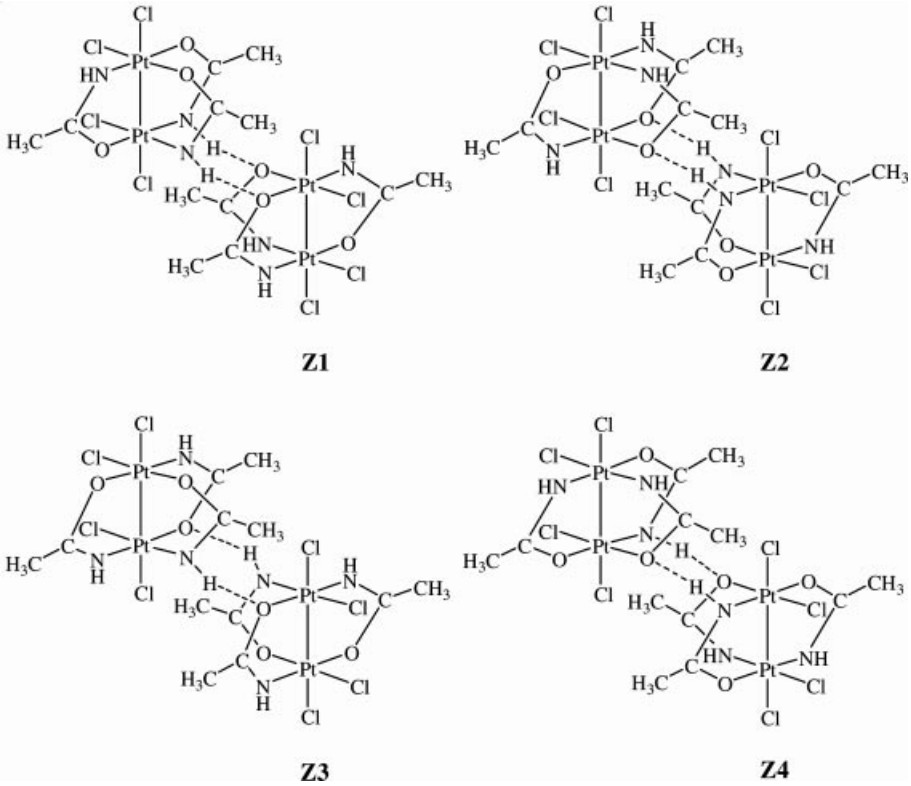
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1.

$wR_2$ = 0.0778 for Z2, $R_1$ = 0.0374 and $wR_2$ = 0.0766 for Z3, and $R_1$ = 0.0383 and $wR_2$ = 0.0811 for Z4. Among these four models, Z3 has the lowest value of $wR_2$, the best values of thermal parameters for all the N and O atoms of the acetamidate bridging ligands, and the best geometry for the hydrogen bonds between NH and O groups of the two independent anions within the unit cell. On this basis, Z3 was chosen as the correct model. However, clear-cut evidence in favor of Z3 came from analysis of the short contacts between anions of adjacent unit cells. While the Z3 model leads to short (<3.5 Å) N···Cl contacts, indicative of N–H···Cl H-bond interactions, all other models lead to short O···Cl distances, which imply unfavorable electrostatic repulsion between the two electron-rich atoms (see following discussion on intermolecular interactions).

Within a dinuclear complex molecule, each platinum(III) atom has a distorted octahedral geometry with three amidates and a chloride ligand in equatorial positions and a chloride ligand and the second platinum atom in axial positions (Figure 5). Selected bond lengths and angles are reported in Table 1.

The equatorial Pt–Cl [2.27(1)–2.35(1) Å], Pt–N [1.97(2)–2.07(2) Å], and Pt–O distances [2.03(2)–2.08(2) Å] are in the range of those reported for doubly and quadruply bridged dinuclear platinum(III),[5,6,25,26] four-coordinate platinum(II), and six-coordinate platinum(IV) complexes.[11] The axial Pt–Cl distances [2.43(1)–2.47(1) Å] are significantly longer (ca. 0.14 Å) than the equatorial Pt–Cl distances and are comparable to those already reported for axial Pt–Cl distances in dinuclear complexes of platinum(III) (average Pt–Cl distance of 2.44 Å).[5,25–27] The Pt–Pt distances [2.533(2) and 2.527(2) Å] are in between the Pt–Pt distances observed for

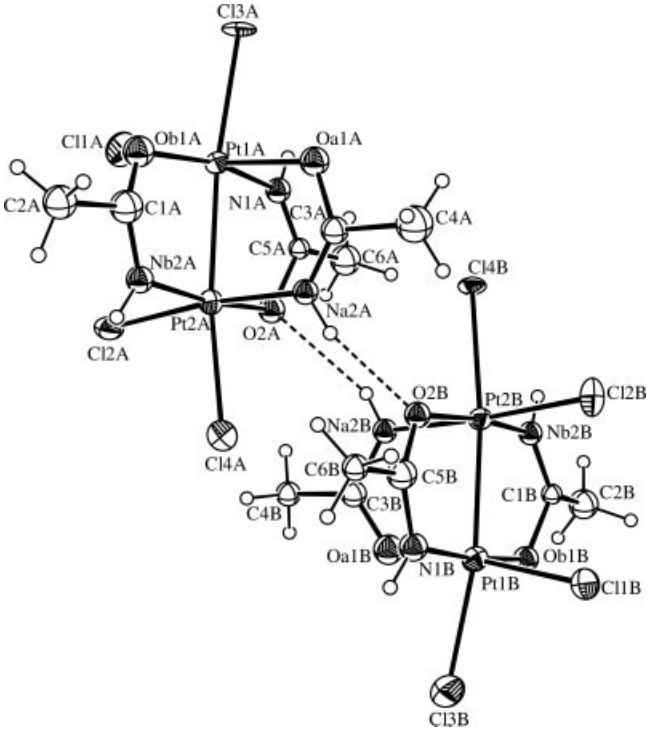


Figure 5. ORTEP view, with labelling scheme, of the two independent $[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]^-$ ions within the unit cell. Ellipsoids enclose 30% probability.

doubly bridged (ca. 2.58 Å)[25–27] and quadruply bridged platinum(III) complexes [2.448(2) Å][5] having bridging amidates and terminal Cl ligands.

The dihedral angles between equatorial planes are 15.3(4)° for molecule **A** and 15.9(4)° for molecule **B**. The bow-like distortion of the Cl3–Pt1–Pt2–Cl4 axis, as indicated by the sum of the deviations from 180° of the angles Cl3–Pt1–Pt2 and Pt1–Pt2–Cl4, is 18.1(4)° for both molecules **A** and **B** and corresponds roughly to the dihedral angle between the equatorial planes. It should be noted that the dihedral angle between the equatorial planes in triply bridged acetamidate species is smaller than in the corresponding doubly bridged species (ca. 20°).[25,26]

### *Intermolecular Interactions*

Compound **1b** crystallizes with one molecule of pentane per asymmetric unit. The molecules of solvent are located in pores of the crystal lattice running along the *a* direction, which appear to be specific for this solvent. For a better understanding of how these pores are formed a detailed description of the crystal packing is given in this section. As already anticipated, two strong H-bonds link the two independent anions (**A** and **B**) within the asymmetric unit. The atoms involved in H-bonding are the nitrogen Na2 and the oxygen O2 [Na2A···O2B = 2.92(2), (Na2A)H···O2B = 2.09(1) Å, Na2A–H···O2B = 162(1)°; Na2B···O2A = 3.09(2), (Na2B)H···O2A = 2.36(2) Å, Na2B–H···O2A = 142(1)°].

Anions **A** and **B** of one cell are hydrogen-bonded with anions of adjacent cells. These H-bonds involve the Cl4 and Nb2 atoms of anion **A** of one cell and the Nb2 and Cl4 atoms of anion **B** of the adjacent cell [Nb2A···Cl4B($x$ + 1, +$y$, +$z$) = 3.49(2), (Nb2A)H···Cl4B($x$ + 1, +$y$, +$z$) = 2.664(7) Å, Nb2A–H···Cl4B($x$ + 1, +$y$, +$z$) = 162(1)°; Nb2B···Cl4A($x$ – 1, +$y$, +$z$) = 3.46(2), (Nb2B)H···Cl4A($x$ – 1, +$y$, +$z$) = 2.615(9) Å, Nb2B–H···Cl4A($x$ – 1, +$y$, +$z$) = 170(1)°].

As already anticipated, all the models other than Z3 reported in Scheme 1 (Z1, Z2, and Z4) would result in very short O···Cl nonbonding distances between contiguous **A** and **B** anions of adjacent cells. The resulting O···Cl distances (ca. 3.46 Å) would be very close to the sum of the van der Waals radii for oxygen and chlorine atoms and would lead to unfavorable electrostatic repulsion between

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

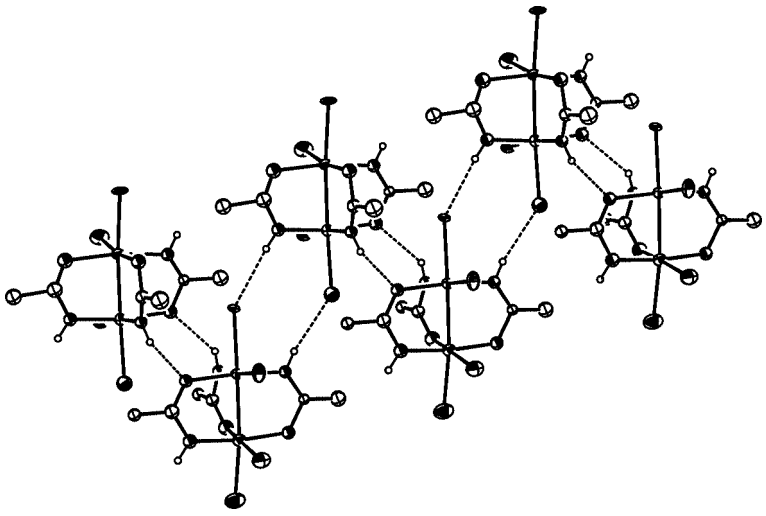

Figure 6. View of the hydrogen-bonding network.

the two electron-rich atoms. This observation gives strong support to the choice of model Z3 for describing the positioning of the two anions within the unit cell.

The N–H···O hydrogen bonds linking the **A** and **B** molecules within the same cell and the N–H···Cl bonds linking the **A** molecule of one cell with the **B** molecule of the adjacent cell make a chain of $[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]^-$ anions extending along the *a* axis (Figure 6).

The tetraphenylarsonium cations are located between the chains of anions extending along the *a* direction, which results in columns running parallel to the chains of anions. There are no direct interactions between these cations, however there are H-bonds between the Cl atoms of the chains of anions and the H atoms of the cations [Cl1A···C20A = 3.46(2), Cl1A···H(C20A) = 2.72(1) Å, Cl1A···H–C20A = 137(1)°; Cl1A···C29B($x-1, y-1, z-1$) = 3.77(2), Cl1A···H(C29B)($x-1, y-1, z-1$) = 3.00(1) Å, Cl1A···H–C29B($x-1, y-1, z-1$) = 141(1)°; Cl2A···C11A = 3.55(2), Cl2A···H(C11A) = 2.79(1) Å, Cl2A···H–C11A = 140(1)°; Cl2A···C27A($x+1, y, z$) = 3.60(2), Cl2A···H(C27A)($x+1, y, z$) = 2.72(1) Å, Cl2A···H–C27A($x+1, y, z$) = 158(1)°; Cl3A···C30B($x-1, y-1, z-1$) = 3.46(2), Cl3A···H(C30B)($x-1, y-1, z-1$) = 2.77(1) Å, Cl3A···H–C30B($x-1, y-1, z-1$) = 132(1)°; Cl4A···C15B($x, y, z-1$) = 3.63(2), Cl4A···H(C15B)($x, y, z-1$) = 2.73(1) Å, Cl4A···H–C15B($x, y, z-1$) = 162(1)°; Cl1B···C8B = 3.55(2), Cl1B···H(C8B) = 2.72(1) Å, Cl1B···H–C8B = 149(1)°; Cl2B···C15A($x, y, z+1$) = 3.56(2), Cl2B···H(C15A)($x, y, z+1$) = 2.70(1) Å, Cl2B···H–C15A($x, y, z+1$) = 153(1)°; Cl3B···C30A($x+1, y+1, z+1$) = 3.67(2), Cl3B···H(C30A)($x+1, y+1, z+1$) = 2.99(1) Å, Cl3B···H–C30A($x+1, y+1, z+1$) = 132(1)°; Cl4B···C27B($x-1, y, z$) = 3.80(2), Cl4B···H(C27B)($x-1, y, z$) = 2.99(1) Å, Cl4B···H–C27B($x-1, y, z$) = 146(1)°; Cl4B···C14A($x, y, z+1$) = 3.67(2), Cl4B···H(C14A)($x, y, z+1$) = 2.95(1) Å, Cl4B···H–C14A($x, y, z+1$) = 135(1)°]. The packing of the chains of anions and columns of cations extending along the *a* direction leaves some channels, which also extend along the *a* direction; the pentane molecules of crystallization are located in these channels (Figure 7).

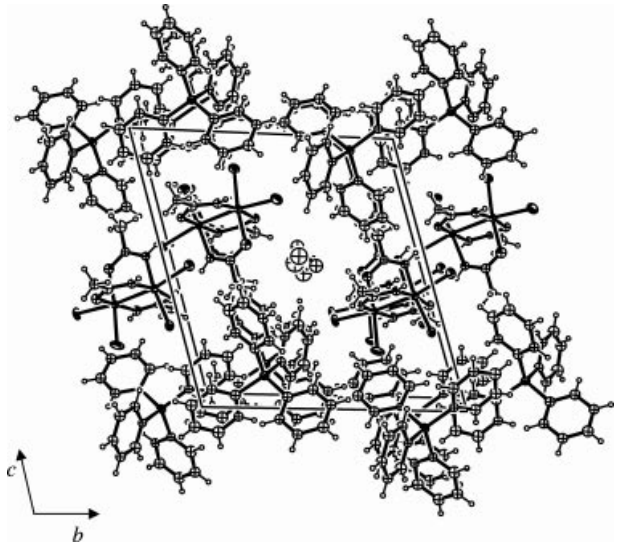

Figure 7. Crystal packing of $\{(AsPh_4)[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]\}_2 \cdot C_5H_{12}$, showing the location of the solvent molecules in the pores of the crystal lattice.

## Conclusions

Dimeric platinum(III) complexes supported by three covalent bridges between the two metal centers have generally been considered as transient species in the reaction leading to quadruply bridged species starting from a 1:1 mixture of $Pt^{II}$ and $Pt^{IV}$ chloro species and excess bridging ligand. We have proven that, by reducing the reaction time, the triply bridged compound can become the major reaction product.

Due to the asymmetry of the acetamide ligand, three isomers can be formed (HHH, HHT, and HTH), although only two major species were found in the crude reaction product: HHT and HTH. Moreover, the HTH species is

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thermodynamically less stable and slowly (half life of about two days at room temperature) isomerizes into the HHT form. A possible explanation for the observed preference is the more homogeneous sets of donor atoms for the two platinum atoms provided by the HHT and HTH isomers ($Cl_2N_2O$ and $Cl_2NO_2$) as compared to the HHH isomer ($Cl_2N_3$ and $Cl_2O_3$). The HHT isomer is favored over the HTH isomer by a statistical factor of two. It should be noted that the greater stability of the HHT isomer is also in agreement with the configurations found in the quadruply bridged dimers prepared by a similar reaction procedure.[5] The preferred configurations were usually found to be HHTH and HHTT. These two configurations can both be generated from the triply bridged HHT species by addition of a fourth bridge in an H or T orientation. In contrast, the HTH isomer can generate, upon the addition of a fourth bridge, only one observed configuration (HTHH) and a second, never observed, configuration (HTHT).

The crystal structure of the more stable and less symmetric HHT isomer is made up of chains of $[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]^-$ ions running along the *a* direction and columns of tetraphenylarsonium cations also running along the *a* direction. A curious aspect of the crystal packing is the presence of one-dimensional pore channels filled with disordered pentane molecules. The dimension of the pore is probably such that only molecules of *n*-pentane can be accommodated, leaving out completely the molecules of chloroform which, in principle, should give stronger interactions (H bonds) with the aromatic protons on the surface of the pores.

## Experimental Section

**Physical Measurements:** Elemental analyses were obtained with an Elementar Analyser mod. 1106 Carlo Erba instrument. $^1H$ and $^{195}Pt$ NMR spectra were recorded with a Bruker Avance DPX 300 WB spectrometer. $^1H$ chemical shifts are referenced to TMS and $^{195}Pt$ chemical shifts to $K_2PtCl_4$ (1 M in water, $\delta$ = –1614 ppm).

**Preparation of $K[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$ (1a):** $K_2PtCl_4$ (500 mg, 1.2 mmol) and $K_2PtCl_6$ (585 mg, 1.2 mmol) were dissolved in water (25 mL) and treated with an excess of acetamide (2.8 g, 48 mmol). The reaction mixture was stirred for 1 h at 90 °C. The resulting red solution was cooled to room temperature and then taken to dryness under reduced pressure. The orange solid residue was washed several times with small portions of chloroform in order to remove the excess of acetamide and then extracted with methanol, which solubilizes only the desired compound (**1a**) while leaving KCl and unreacted $K_2PtCl_6$ and $K_2PtCl_4$ as insoluble residue. Orange microcrystals of $K[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$ precipitated from the methanolic solution upon addition of diethyl ether. Yield: 45% (400 mg). $K[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]\cdot 2H_2O$, $C_6H_{16}Cl_4KN_3O_5Pt_2$ (780.9): calcd. C 9.21, H 2.05, N 5.38; found C 8.83, H 1.83, N 5.54. $^{195}Pt$ NMR (64.3 MHz, $D_2O$, 22 °C): $\delta$ = –430 ($PtCl_2N_2O$) and 220 ($PtCl_2NO_2$) ppm ($^1J_{Pt,Pt}$ = 7020 Hz).

**Preparation of $(AsPh_4)[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$ (1b):** $K[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$ (400 mg, 0.54 mmol) and $AsPh_4Cl$ (339 mg, 0.81 mmol) were dissolved in chloroform (70 mL) and stirred for a few minutes. The white precipitate of KCl was removed while the filtered mother liquor was concentrated to a smaller volume (10 mL) and then layered with pentane (10 mL). Under these conditions, orange crystals of the desired product $(AsPh_4)[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]$ separated from solution. Yield: 23% (135 mg). $\{(AsPh_4)[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]\}_2\cdot C_5H_{12}$, $C_{65}H_{76}Cl_8N_6O_6Pt_4As_2$ (2249.4): calcd. C 34.69, H 3.40, N 3.73; found C 34.78, H 3.27, N 3.50. $^1H$ NMR (300 MHz, $CDCl_3$, 22 °C): $\delta$ = 2.03 (s, 3 H, $CH_3$), 2.05 (s, 3 H, $CH_3$), 2.29 (s, 3 H, $CH_3$), 5.73 (s, 1 H, NH), 5.75 (s, 1 H, NH), 6.41 (s, 1 H, NH) ppm. $^{195}Pt$ NMR (64.3 MHz, $CDCl_3$, 22 °C): $\delta$ = –437 ($PtCl_2N_2O$) and 241 ($PtCl_2NO_2$) ppm ($^1J_{Pt,Pt}$ = 6660 Hz).

**X-ray Crystal Structure Determination of $\{(AsPh_4)[Pt_2Cl_4\{N(H)C(CH_3)O\}_3]\}_2\cdot C_5H_{12}$:** Compound **1b**, which crystallizes from $CHCl_3$/pentane with half a molecule of pentane per molecule of compound, was investigated by X-ray diffraction analysis. X-ray data were collected on a BrukerAXS X8 APEX CCD system equipped with a four-circle Kappa goniometer and a 4 K CCD detector (Mo-$K_\alpha$ radiation). A Miracol fiber optics capillary collimator (0.3 mm) was used to enhance the intensity of the Mo-$K_\alpha$ radiation and to reduce X-ray beam divergence. The diameter of the active imaging area was 90 mm and the data were collected at a resolution of 512 × 512 pixels. The crystal-to-detector distance was 40 mm. The SAINT-IRIX package was employed for data reduction and unit-cell refinement.[28]

A total of 53118 reflections ($\Theta_{max}$ = 25.00°) were indexed, integrated, and corrected for Lorentz, polarization, and absorption effects using the program SADABS.[29] The number of independent reflections was 12139. The unit-cell dimensions were calculated from all reflections. The structure was solved by direct methods technique in the *P*1 space group. A pseudo center of inversion is present between the two dinuclear independent molecules **A** and **B**, which is reminiscent of a virtual $P\bar{1}$ space group, although attempts to refine in this group were unsuccessful.

The model was refined by full-matrix least-square methods. Only the Pt, Cl, and As atoms were refined anisotropically; the remaining atoms needed isotropic treatment in order to maintain satisfactory thermal displacement parameters. Furthermore, the phenyl groups were treated as rigid, idealized hexagons. Hydrogen atoms were placed at calculated positions and refined given isotropic parameters equivalent to 1.2-times (for phenyl groups) or 1.5-times (for methyl groups) those of the atom to which they are attached.

The pentane solvent molecule of crystallization was disordered. The final difference-Fourier map showed electron density peaks (up to 0.966 e $Å^{-3}$) lying near the Pt atoms. All calculations and molecular graphics were carried out using the SIR2002,[30] SHELXL97,[31] PARST97,[32] WinGX,[33] or ORTEP-3 for Windows packages.[34] The crystallographic data are listed in Table 2.

CCDC-288044 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

# Facile Synthesis of $SnO_2$ Hollow Nanospheres and Applications in Gas Sensors and Electrocatalysts

Qingrui Zhao,[a] Yang Gao,[a] Xue Bai,[a] Changzheng Wu,[a] and Yi Xie*[a]

**Keywords:** Tin oxides / Room-temperature sensitivity / Electrocatalysts

Tin oxide ($SnO_2$) hollow nanospheres have been successfully synthesized from mixed ethanol and water systems containing the surfactants sodium dodecyl benzenesulfonate (SDBS) and terephthalic acid. Systematic studies reveal that terephthalic acid plays pivotal roles in the formation of hollow nanospheres. In the present work, the as-synthesized $SnO_2$ hollow nanospheres exhibit excellent room-temperature ethanol sensitivity and potential catalytic ability towards the electrooxidation of ethanol, and thus are expected to be economical alternative catalysts and useful in industrial applications such as room-temperature gas sensors.

## Introduction

Tin oxide ($SnO_2$), an n-type semiconductor with a wide bandgap ($E_g$ = 3.62 eV), is a key functional material, which has attracted a lot of interest as an excellent candidate for optoelectronic devices,[1] gas sensors,[2] transparent conducting electrodes,[3] and catalyst supports.[4] With specific morphologies, the hollow structures are more desirable because of their potential for encapsulation of large quantities of guest molecules or large-sized guests within the empty core domain.[5] For example, hollow $SnO_2$ microspheres offer enhancement in sensitivity to methanol, carbon monoxide, benzene, and water over compact chemical vapor deposition (CVD) films at high temperatures.[6] On the basis of this, hollow spheres of $SnO_2$ have been produced with sizes ranging in the submicrometer regime. For example, Xia et al. used polystyrene particles as templates to fabricate mesoscale hollow spheres of $SnO_2$ with an average diameter of 400 nm.[7] Qian et al. synthesized $SnO_2$ hollow microspheres with a diameter of several micrometers by hydrolysis of $SnCl_4$ in alkaline media.[8]

Although various types of gas sensors have been investigated, great effort has focused on exploring the high temperature sensitivity of sensors.[9] However, the sensors working at lower temperatures, especially room temperature, no doubt have wider and more practical applications such as in the detection of drunk drivers by measuring ethanol concentrations of their breath. Therefore, it becomes more important to explore the room-temperature sensitivity of $SnO_2$. One useful strategy for increasing the poor sensitivity of tin oxide at room temperature may be realized by controlling the morphology as well as decreasing the size of the sensor materials. However, little work has been reported on the production of hollow $SnO_2$ nanospheres, which are expected to show superior properties. Thus, the exploration of a simple and easily scaled-up route to hollow nanostructures is still a great challenge so far.

Tin oxide materials have been known for a long time to display good catalytic activity towards the synthesis of vinyl ketone,[10] oxidation of methanol,[11] and so on. Recently, the demands for alternative energy sources such as fuel cells have attracted great interest in the studies on nanostructured materials. Among various candidates for catalysts of ethanol fuel cells, carbon-supported $PtSnO_2$ catalysts have exhibited excellent catalytic activity for ethanol electrooxidation, in which $SnO_2$ can enhance the catalytic activity for alcohol electrooxidation.[11] Therefore, nanomaterials with $SnO_2$ alone are believed to display potential catalytic activity for ethanol electrooxidation. In this paper, the electrochemical properties of the prepared hollow $SnO_2$ nanospheres for ethanol electrooxidation were examined.

Among many preparative methods for hollow nano- and mesoscaled structures, template-assisted synthesis is an effective approach in which hard templates[12,13] and soft templates[14] have been utilized. Surfactants tend to self-assemble to form micelles with desired structures and have been widely used as soft templates.[15] However, in many systems, the aggregated micelles may be very sensitive to the solvents and become unstable, which may not facilitate their use as templates in the microreactors. Thus, the complex surfactant systems are introduced to fabricate hollow structures.[16,17] For example, Qi et al. reported the synthesis of micrometer-sized hollow $CaCO_3$ spheres by using the complex surfactant of poly(ethylene oxide)-*block*-poly(methacrylic acid)–sodium dodecylsulfate (PEO-*b*-PMAA-

SDS) micelles as templates,[16] in which the additive of PEO-*b*-PMAA could hold $Ca^{2+}$ ions and assisted with the precipitation of $CaCO_3$. However, the large steric hindrance of the surfactant polymer PEO-*b*-PMAA-SDS made it difficult to restrict the size to the nanometer regime. Here, we suppose a simple coordination agent, which can hold metal ions without the large steric hindrance, may help to increase the stability of the soft template and thus further increase the formation of the hollow nanospheres. $SnO_2$ hollow nanospheres are successfully synthesized from a micelle system that is made up of the surfactants terephthalic acid along with sodium dodecyl benzenesulfonate (SDBS) in an ethanol and water (volume ratio 1:1) solution. Terephthalic acid can hold $Sn^{2+}$ ions without a large steric hindrance, which is helpful for the growth of $SnO_2$ hollow nanospheres. We found that the as-synthesized $SnO_2$ hollow nanospheres show good room-temperature sensitivity to ethanol vapors and potential catalytic activity for electrooxidation of ethanol, which offers promising applications in the fields involving sensors and catalysts.

## Results and Discussion

The phase and purity of the sample was determined by X-ray powder diffraction (XRD), and the typical diffraction pattern is shown in Figure 1. All the peaks were readily indexed to the tetragonal phase of $SnO_2$ (JCPDS card No. 41-1445), with lattice constants of $a$ = 4.738 Å and $c$ = 3.187 Å. No characteristic peaks were observed for the other impurities.

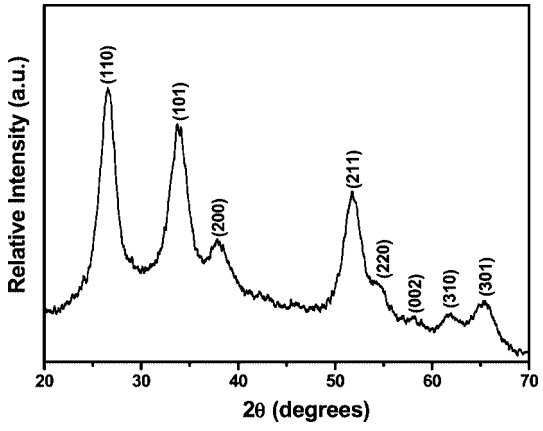

Figure 1. XRD pattern of the $SnO_2$ hollow nanospheres.

To further characterize the product, XPS was carried out to investigate the surface compositions and chemical state of the as-prepared products, and the results are shown in Figure 2. The binding energies obtained in the XPS analysis were corrected for specimen charging by referencing $C_{1s}$ to 284.75 eV. The sample appeared as a spin-orbit doublet at ca. 486.85 eV ($3d_{5/2}$) and ca. 495.25 eV ($3d_{3/2}$) (Figure 2, a), which is in agreement with the reported value in the literature.[18] The $O_{1s}$ binding energy of 531.00 eV (Figure 2, b) indicates that the oxygen atoms exist as $O^{2-}$ species in the compounds. Quantification gave the atomic ratio of O and Sn elements as 1.93 on the basis of the areas of the O and Sn peaks within experimental error. Consequently, from the results of the XRD and XPS measurements the as-synthesized products could be determined as $SnO_2$.

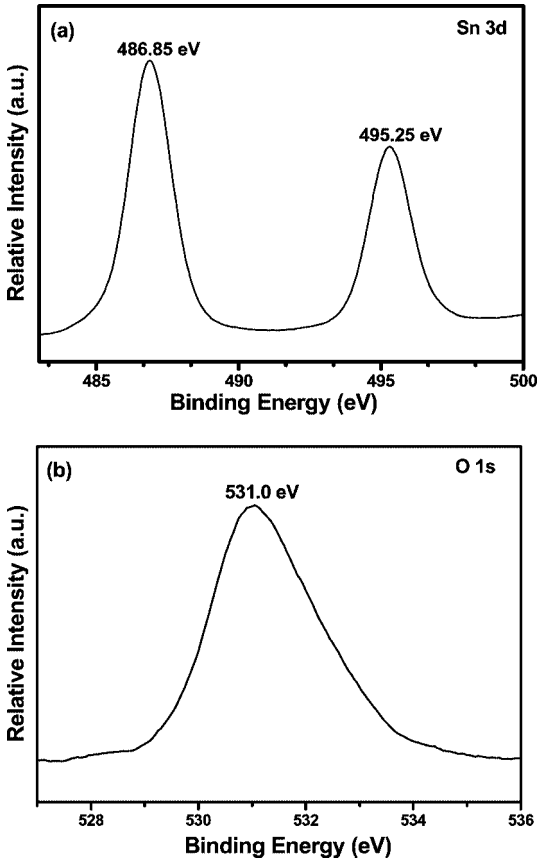

Figure 2. XPS spectra of the $SnO_2$ hollow nanospheres: (a) Sn region; (b) O region.

The structure and morphology of these hollow $SnO_2$ nanostructures were investigated by TEM. From the panoramic morphology shown in Figure 3 (a), a bright contrast (dark/bright) between the boundary and the center of the spheres is seen, confirming their hollow nature. The external diameter of the hollow spheres is 80–120 nm and the thickness of the shell is ca. 10–20 nm. The inset in Figure 3 (a) corresponds to the SAED pattern performed on the shell, and the circular character indicates the polycrystalline $SnO_2$ shell. The structural details were investigated from a high-magnification TEM image (Figure 3, b), revealing that the shells of hollow $SnO_2$ nanospheres seem to be rough and consist of nanoparticles with sizes in the range of 3–5 nm. The high-resolution transmission electron microscopy (HRTEM) images (Figure 3, c) further confirm the hollow nanostructures. FE-SEM observations also revealed that the $SnO_2$ nanospheres are hollow, which was learned from the broken regions of the spheres, as indicated by the arrows (see part d of Figure 3 and the inset).

It is known that SDBS is an anionic surfactant, which tends to self-assemble to form aggregates and further lead to the formation of microemulsions with desired structures because of its bulky hydrophobic tail compared with the

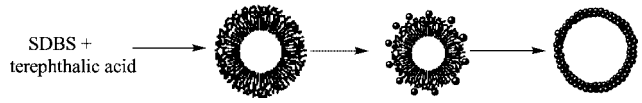
hydrophilic group.[19] However, in many systems SDBS micelles become unstable. Thus, terephthalic acid is added to play the important role of facilitating the formation of more stable aggregates to provide chemical microenviroments. Previous investigations of the interaction between SDS, poly(ethylene glycol) (PEG), and poly(methacrylic acid) (PMAA) showed that ionic headgroups of SDS repelled the charged PMAA chains and only hydrocarbon chains of SDS partitioned into the PEG core of the polymer aggregates. Then PMAA as a shell may be adsorbed onto the surface of the core, which is made up of PEG and SDS, through the interaction between the PMAA and PEG.[20] Thus, we could speculate that the mixture of SDBS and terephthalic acid in the mixed ethanol and water solutions could form complex micelles similar to that of the PEG-PMAA-SDS complex. In this case, ethanol with ethyl and ethylene oxide groups could interact with anionic SDBS to form micelles.[21] Terephthalic acid as a shell might be adsorbed onto the surface of the micelles through the interaction between ethanol and terephthalic acid. Such micelles would function as soft templates and provide the microenviroment in which nucleation and growth of $SnO_2$ could occur. In this approach, $SnO_2$ was synthesized by the chemical reaction of $SnCl_2$ and $KClO_3$ in ethanol and water solutions of terephthalic acid and SDBS, on the basis of the following equation:

$$3\,Sn^{2+} + ClO_3^- + 3\,H_2O \rightarrow 3\,SnO_2 + Cl^- + 6\,H^+$$

Terephthalic acid provides the nucleation sites for the crystallization of $SnO_2$ owing to the interaction of terephthalic acid and $Sn^{2+}$, which leads to a high local supersaturation of $Sn^{2+}$ over the micelle periphery.[20] The crystallization of $SnO_2$ started from these nucleation sites on the surface of the micelles and the crystals developed outwards until they collided with each other, leading to the final hollow structures. A schematic pattern of the formation process was shown in Scheme 1. It is worth noting that the $SnO_2$ hollow nanospheres, which are attributed to the simple coordination agent terephthalic acid that can hold $Sn^{2+}$ ions, formed without a large steric hindrance.

The complex surfactant system was critical in the formation of hollow nanospheres. If the reaction was carried out in the absence of terephthalic acid the products were found to be large amounts of $SnO_2$ nanoparticles and a few hollow nanospheres; whereas if the experiment was carried out without SDBS under similar conditions, only $SnO_2$ nanoparticles were obtained. The results above indicate that single SDBS-micelles as soft templates ae unstable, but the presence of terephthalic acid favored the formation of stable

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1. Schematic illustration of the formation process of $SnO_2$ hollow nanospheres: a mixture of SDBS and terephthalic acid complexes in the system → complex micelles were formed → $SnO_2$ particles formed on the surface of the micelles → $SnO_2$ hollow nanospheres emerged as the final product.

micelles, and thus further helped the growth of the $SnO_2$ hollow nanospheres. The synergistic effect of terephthalic acid and SDBS as the soft templates in the formation of $SnO_2$ hollow nanospheres has been confirmed.

It is known that the solvent composition has a great effect on the formation of the micelle structures.[15] The solvent composition influences the difference in solubility of the hydrophilic head and hydrophobic tail of the surfactant, thus affecting the formation and aggregation of the micelles. To investigate the effect of the solvent composition, a series of comparative experiments were carried out. When keeping other experimental conditions unchanged, the absence of ethanol would only produce irregular $SnO_2$ particles. When trace ethanol was introduced into the system, a few hollow nanospheres appeared in the products. If the volume ratio of ethanol and water was increased to 1:1 all the samples had a hollow nanosphere morphology. These results demonstrate that ethanol seems to perform the function of bridging the SDBS and terephthalic acid, which is consistent with the proposed mechanism above. Moreover, the addition of ethanol could have increased the solubility of terephthalic acid in this approach, which facilitated the formation of micelles and was necessary for the formation of $SnO_2$ hollow nanospheres. However, at a high percentage of the ethanol solvent only a few $SnO_2$ hollow nanospheres formed. This may be caused by the lower solubility of $KClO_3$ at a high ethanol percentage, leading to incomplete reaction.

The room-temperature PL spectrum of hollow $SnO_2$ nanospheres, as shown in Figure 4, was obtained with an excitation wavelength of 340 nm. It can be seen that the spectrum of the sample is characterized by one strong emission band at 410 nm. Earlier reports indicated that $SnO_2$ thin films exhibit a broad dominant peak near 396 nm (3.1 eV),[22] and that $SnO_2$ nanoribbons synthesized by self-catalyst growth have a strong emission band centered at ca. 500 nm because of other luminescence centers, such as crystal defects.[23] The newly observed peaks at 410 nm might result from other luminescence centers, such as oxygen vacancies or tin interstitials in the obtained hollow $SnO_2$ nanospheres.

The hollow structure of the $SnO_2$ hollow nanospheres was expected to offer advantages in fabricating gas sensors at room temperature. The room-temperature sensitivity of the obtained $SnO_2$ hollow nanospheres in response to $C_2H_5OH$ was investigated, which is shown in Figure 5 (a). The gas sensitivity, $S_g$, was defined as $R_{air}/R_{gas}$, where $R_{air}$ and $R_{gas}$ are the electrical resistances for the sensor in air and in gas.[24] It can be seen from Figure 5 (a) that the sensitivity of the $SnO_2$ hollow nanospheres gradually increases with an increase in ethanol gas concentration. To evaluate the sensitivity of the $SnO_2$ hollow nanospheres, solid $SnO_2$ nanoparticles with a diameter of 5 nm were fabricated according to ref.[25] The room-temperature sensitivity of 5 nm $SnO_2$ nanoparticles is displayed in Figure 5 (b) and compared with that of the hollow nanospheres. As shown in Figure 5, the sensitivity of the $SnO_2$ hollow nanospheres versus ethanol concentration was much greater than that for the $SnO_2$ nanoparticles under the same conditions. For the sensors, we believe that the higher sensitivity might be attributed to the hollow structures of the sample, which has more chance to adsorb and desorb the gas molecules.[24] In addition, in order to test the reversibility of the sample, the measurements were repeated more than 10 times and no major changes in the signals were observed.

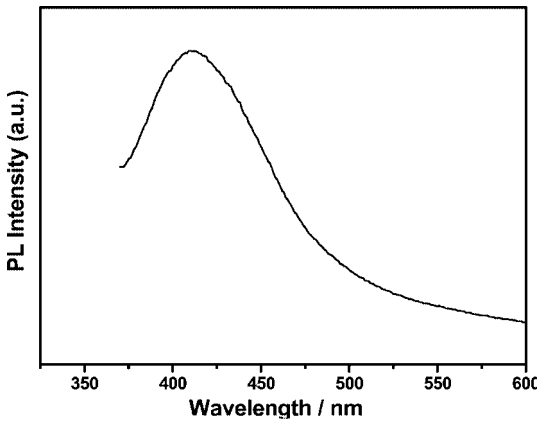


Figure 4. PL spectrum of the $SnO_2$ hollow nanospheres.

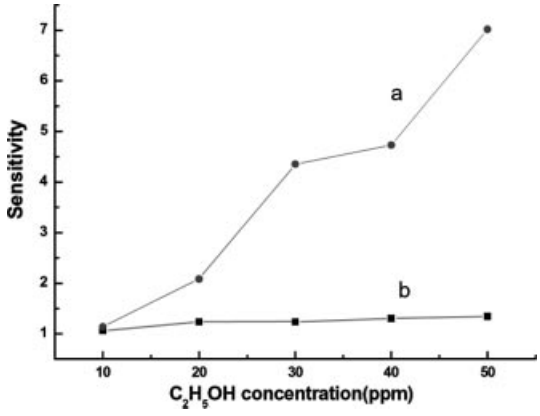

Figure 5. Room-temperature sensor sensitivity to ethanol of (a) the as-prepared $SnO_2$ hollow nanospheres and (b) nanoparticles.

Brunauer–Emmett–Teller (BET) nitrogen adsorption-desorption measurements showed that the surface area of the hollow $SnO_2$ nanospheres is 44 $m^2 g^{-1}$, whereas the surface area of $SnO_2$ nanoparticles is 31 $m^2 g^{-1}$. The small difference between the BET surface area of the $SnO_2$ hollow nanospheres and the nanoparticles may be attributed to the fact that the surface of the $SnO_2$ hollow nanospheres is composed of compact nanoparticles. The superior sensing properties of the obtained hollow $SnO_2$ nanospheres could

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

be because of its porous structure associated with the small grain size,[6] which enables ethanol gas to access almost all of the surfaces of the hollow $SnO_2$ nanospheres contained in the sensing unit. Therefore, hollow $SnO_2$ nanospheres with a higher surface area have more chances to adsorb and desorb ethanol gas molecules, which leads to higher sensitivity at room temperature.

In previous reports, $SnO_2$ nanoparticles were employed to synthesize the carbon-supported $PtSnO_2$ catalyst, which promoted catalytic activity of the ethanol electrooxidation in fuel cells.[11] However, a critical problem with Pt-based catalysts is their prohibitive cost. Therefore, economical and effective alternative catalysts are required. Thus, in the current work the electrooxidation of ethanol of $SnO_2$ hollow nanospheres was investigated without Pt, using a well-used electrochemical reaction in a solution of $H_2SO_4$,[26] and the result indicated that $SnO_2$ hollow nanospheres exhibit a good electrocatalytic performance for the electrooxidation of ethanol. Figure 6 shows the cyclic voltammetric responses of the bare glass carbon electrode (GCE) (a) and also the $SnO_2$ hollow nanospheres on the glass carbon electrode surface (b) in the presence of ethanol. From the voltammograms in Figure 6 (b), it can be seen that $SnO_2$ hollow nanospheres show catalytic behavior for electrooxidation of ethanol by the appearance of an oxidation current in the positive potential region. The peak potentials for the oxidation of ethanol were approximately 0.46 V, in agreement with the literature values of ethanol oxidation for the formation of acetaldehyde.[27,28] The electrochemical reaction can be described by the following equations:

$$SnO_2(CH_3CH_2OH)_{ads} \rightarrow SnO_2(CH_3CHO)_{ads} + 2\,H^+ + 2\,e^-$$

$$SnO_2(CH_3CHO)_{ads} \rightarrow CH_3CHO + SnO_2$$

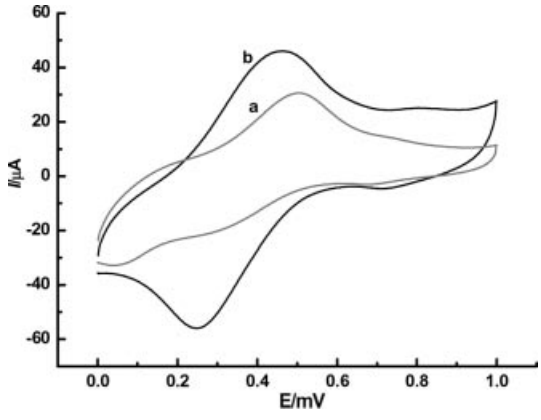

Figure 6. Cyclic voltammograms of the (a) bare glass carbon electrode and (b) $SnO_2$ hollow nanospheres on the glass carbon electrode surface in $H_2SO_4$ (0.5 M) and ethanol (0.6 M). Scan rate = 50 mV $s^{-1}$.

The scission of the alcohol bond occurred at the tin dioxide site with the breaking of the C–H bonds. The potential was about 40 mV more negative than the oxidation peak at the bare GCE. The peak currents of the hollow nanospheres loading onto the bare GCE and the bare GCE are 46 μA and 31 μA, respectively. The reduction of potential and the enhancement of the peak current indicates that the modified electrode can effectively catalyze the electrooxidation of ethanol. Most probably, the catalytic performance may be ascribed to the hollow structures. More chemicals (ions) can be stored in the hollow structures of the sample with a greater chance of participating in the reactions, thus greatly improving the catalytic efficiency of the obtained nanostructures. To test the recycling performance of the sample, two runs were reperformed under the same conditions. It was found that the catalytic efficiency in the third cycle was still the same, revealing its excellent recycling performance. Therefore, the $SnO_2$ hollow nanospheres exhibited potential catalytic behavior for the electrooxidation of ethanol.

## Conclusions

The present study describes a micelle system for the preparation of $SnO_2$ hollow nanospheres on a large scale, which is made up of SDBS and terephthalic acid in mixed ethanol and water solutions. Their cooperative functions contribute to the final morphology of the $SnO_2$ hollow nanospheres. Such a system may represent a promising microreactor for the synthesis of other inorganic materials with unique properties. The obtained $SnO_2$ hollow nanospheres exhibit not only good room-temperature sensitivity to ethanol, but also potential electrocatalytic activity towards electrooxidation of ethanol, which may be useful in industrial applications including catalytic nanoreactors and gas sensors.

## Experimental Section

In a typical experimental process, sodium dodecyl benzenesulfonate (SDBS) (1.4 g, 4 mmol) in distilled water (25 mL) and terephthalic acid (0.3 g, 2 mmol) in ethanol (25 mL) were loaded into a 60 mL Teflon-lined stainless steel autoclave, which was stirred for half an hour. Then $SnCl_2$ (0.45 g, 2 mmol) and $KClO_3$ (0.49 g, 4 mmol) were added under constant stirring to the solution to form a homogeneous solution, which was maintained at 180 °C for 12 h. After the reaction was completed, the white products were collected from solution, rinsed several times with distilled water and absolute ethanol, and then dried under vacuum at 40 °C for 4 h.

The samples were characterized by X-ray powder diffraction (XRD) with a Japan Rigaku D/max rA X-ray diffractometer equipped with graphite-monochromatized high-intensity Cu-$K_\alpha$ radiation ($\lambda$ = 1.54178 Å), recorded with $2\theta$ ranging from 10 to 70°. The transmission electron microscopy (TEM) images and electron diffraction (ED) patterns were performed with a Hitachi Model H-800 instrument with a tungsten filament, using an accelerating voltage of 200 kV. High-resolution transmission electron microscopy (HRTEM) images were carried out with a JEOL-2010 TEM at an acceleration voltage of 200 kV. The field emission scanning electron microscopy (FE-SEM) images were taken with a FEI Sirion-200 SEM. XPS was performed with a ESCALAB MKII with Mg-$K_\alpha$ ($h\nu$ = 1253.6 eV) as the excitation source. The binding energies obtained from the XPS spectral analysis were corrected for specimen charging by referencing $C_{1s}$ to 284.75 eV. The room-temperature photoluminescence (PL) spectra were performed with a Jobin Yvon-Labram Steady-State/Lifetime Spectrofluorometer with a He-Cd laser. Gas-sensing measurements were performed with a

*WS-30A* system (Weisheng Instruments Co., Zhengzhou, China). Brunauer–Emmett–Teller (BET) surface area measurements was performed with a Micromeritics ASAP-2000 nitrogen adsorption apparatus. The as-prepared samples were cast as a thin film spanning across the two gold electrodes for test. Electrochemical measurements were performed with a CHI 832 electrochemical station (ChenHua Instruments Co., Shanghai, China). A conventional three-electrode system was used, consisting of a glassy carbon (4 mm diameter) working electrode (GCE), platinum wire auxiliary electrode, and a saturated calomel reference electrode (SCE). The working electrode was polished with $Al_2O_3$ paste and washed ultrasonically in distilled water, loading 0.3 mg cm$^{-2}$. Electrocatalytic oxidation measurements were carried out in a solution of $H_2SO_4$ (0.5 M) and ethanol (0.6 M).

# Syntheses, Structures, and Characterization of Two Manganese(II)-Aminobenzoic Complexes

**Ruihu Wang,[a] Daqiang Yuan,[a] Feilong Jiang,[a] Lei Han,[a] Song Gao,[b] and Maochun Hong*[a]**

**Keywords:** Manganese / Aminobenzoic acid / Magnetic properties

A discrete tetranuclear manganese(II) complex, $\{(H_3O)_2Mn_4(4\text{-Haba})_2(4\text{-aba})_6(SCN)_4(H_2O)_2\}$ (**1**) and a two-dimensional coordination polymer $[Mn(3\text{-aba})_2]_n$ (**2**) (4-Haba = 4-aminobenzoic acid, 3-Haba = 3-aminobenzoic acid), have been synthesized and characterized by elemental analyses, IR, X-ray crystallography, and magnetic susceptibility. In complex **1**, 4-aba in three types of coordination modes connects $Mn^{II}$ centers to form a discrete tetranuclear anionic molecule. Hydrogen bonding interaction links the tetranuclear units to generate a one-dimensional supramolecular chain. In complex **2**, 3-aba in an *exo*-tridentate mode bridges six-coordinate $Mn^{II}$ centers forming a two-dimensional coordination architecture. Studies of the magnetic susceptibilities of **1** and **2** reveal weak antiferromagnetic exchange interactions between adjacent $Mn^{II}$ centers.

## Introduction

A significant amount of research has been dedicated to the study of the magnetic behavior of discrete polynuclear entities and molecule-based coordination polymers with extended structures.[1–3] The increasing interest in this field is justified not only by the intellectual challenge of understanding the fundamental relationship between structures and magnetic properties, but also by the development of new types of functional molecule-based magnetic materials.[4–7] In this context, one of the points to be seriously considered for the preparation of these magnetic solids is the choice of appropriate bridging ligands, since they mediate superexchange interactions between the paramagnetic metal centers. The type, size, shape, flexibility, conformation, and symmetry of the ligands along with their connective patterns are all important parameters, affecting the type and magnitude of the magnetic exchange interaction.[5–8] In the course of formation of desirable magnetic complexes, certain features of the organic ligands connecting paramagnetic metal centers can be utilized and tuned. For example, the carboxyl group can not only bridge two or more metal centers to produce a wide variety of complexes ranging from zero-dimensional discrete molecules to three-dimensional architectures, but also can adopt various types of bridging conformation modes, such as the so-called *syn-syn*, *syn-anti*, and *anti-anti* modes (Scheme 4). The magnetic properties are closely related to the bridging modes adopted by the carboxyl group in these complexes.[9,10] Thus, in terms of constructing the extended structural motifs, either di- and muti-carboxyl ligands, or multifunctional carboxyl-containing ligands incorporating other coordination groups, such as N, and S, have been employed;[5,11,12] the N or S donor atoms coordinating to metal centers can result in fascinating extended complexes with beautiful aesthetics and useful functional properties.[13,14c] However, owing to the presence of many subtle factors in the assembly process and the difficulty in predicting the final architectures, the rational design of coordination complexes from multifunctional organic ligands and metal ions is still a challenge to chemists, and a great deal of work is required to extend the knowledge of relevant magnetic solids and establish proper synthetic strategies leading to desirable architectures and useful properties.

As a part of our work towards rational design and preparation of functional supramolecular complexes with intriguing structures and potential applications in optics, electrical conductivity, magnetism, and host-guest chemistry,[14,15] we have successfully prepared a series of $Cd^{II}$ and $Ag^{I}$ complexes from the multifunctional organic ligands 4-aminobenzoic acid (4-Haba) and 3-aminobenzoic acid (3-Haba) through combination of their amino and carboxyl groups.[15b,15c] It is known that high-spin manganese(II) contains five unpaired electrons and is quite oxophilic, and

that the assembly of manganese(II) with organic ligands containing the carboxyl group is inclined to the formation of larger clusters and extended solids.[16] Moreover, carboxyl-bridged manganese(II) complexes have been known to exist at the active centers of some $Mn^{II}$-containing enzymes.[17] Recently, we have reported a three-dimensional manganese(II) complex from 4-Haba exhibiting ferrimagnetic and metamagnetic behavior.[15a] Considering the versatile bridging modes of the carboxyl group and efficient mediation of magnetic coupling in 4-aba and 3-aba, herein, we wish to report the syntheses and characterization of a discrete tetranuclear manganese(II) complex $\{(H_3O)_2[Mn_4(4\text{-Haba})_2(4\text{-aba})_6(SCN)_4(H_2O)_2]\}$ (**1**) and a two-dimensional coordination architecture $[Mn(3\text{-aba})_2]_n$ (**2**).

## Result and Discussion

### Synthesis and Characterization

Reaction of $MnCl_2{\cdot}4H_2O$, 4-Haba, and $NaN_3$ at room temperature produced a three-dimensional complex $[Mn_3(4\text{-aba})_6]_n$ (**3**),[15a] in which $N_3^-$ is not involved in coordination to the $Mn^{II}$ ion and acts as a base to deprotonate 4-Haba. Previous research demonstrates that the assembly process of 4-Haba and transitional metal ions has been highly influenced by counter anions, pH value, solvent system, and metal-to-ligand ratio besides the coordination nature of the metal ions.[15,18] In some cases, a subtle alteration in any of these factors can result in new complexes with different structural topologies and different functions. The successful isolation of **3** prompted us to prepare other $Mn^{II}$ complexes from 4-Haba and 3-Haba through altering reaction-influencing factors. Instead of $N_3^-$, the use of $SCN^-$ in the presence of NaOH led to a tetranuclear $Mn^{II}$ complex (**1**), and the reaction of 3-Haba and $MnCl_2{\cdot}4H_2O$ in the presence of either $NaN_3$ or $NH_4SCN$ and NaOH afforded the complex **2**. In the preparation of compounds **1**–**3**, the counter anions obviously have an important effect on their assembly process even if they are not present in the complexes. We presume that these counter anions coordinate to a part of the metal ions in solution and remain soluble species, whereas only the insoluble crystalline material can be isolated and identified. It is possible therefore, that the presence of these counter anions is important for the equilibrium that leads eventually to the isolation of the polynuclear carboxylates. It is well known that the relative orientation of the coordination sites in organic ligands is also one of the most important factors in controlling the construction of supramolecular architectures.[19] The assembly of organic ligands with different orientations of coordination sites and metal ions can produce different structural frameworks. Thus, the difference between complex **2** and complex **1** and **3** can be ascribed to the different stereochemistry of the ligands.

The C≡N stretching vibration of the thiocyanate group in **1** appears as a single strong peak at 2085 $cm^{-1}$, which is consistent with the occurrence of thiocyanate-N coordination.[20] The characteristic bands of the carboxyl group of 4-aba are shown at 1608 $cm^{-1}$ for antisymmetric stretching and at 1406 and 1396 $cm^{-1}$ for symmetric stretching. The separations ($\Delta$) between $\nu_{asym}$(–COO) and $\nu_{sym}$(–COO) are 202 and 212 $cm^{-1}$, respectively, revealing that the carboxyl group of 4-aba functions in different bridging modes. The IR spectrum of complex **2** shows typical antisymmetric and symmetric stretching bands of the carboxyl group at 1579 and 1394 $cm^{-1}$, respectively, the $\Delta$ value is 185 $cm^{-1}$.

### Structural Description

**$\{(H_3O)_2[Mn_4(4\text{-Haba})_2(4\text{-aba})_6(SCN)_4(H_2O)_2]\}$ (1):** Single-crystal X-ray diffraction analysis reveals that **1** consists of a tetranuclear $[Mn_4(4\text{-Haba})_2(4\text{-aba})_6(SCN)_4(H_2O)_2]^{2-}$ anion and two lattice water molecules; the two lattice water molecules or two of the total eight amino groups of the tetranuclear unit are required to be protonated to achieve overall charge balance. These protons were not located crystallographically and could reside on any of the eight amino groups or two lattice water molecules. Since the amino group is more basic than the water molecule, the protonation likely occurs at the amino groups of some ligands. As shown in Figure 1 (a), there are two crystallographically independent $Mn^{II}$ centers in the tetranuclear anionic framework. Mn(1) is coordinated by two carboxyl oxygen atoms and one chelating carboxyl group from three different 4-aba, one water molecule, and one nitrogen atom of the terminal $SCN^-$. However, Mn(2) is coordinated by four carboxyl oxygen atoms from different 4-aba, one carboxyl oxygen atom from 4-Haba, and one nitrogen atom of the terminal $SCN^-$. Thus, Mn(1) and Mn(2) are in a highly distorted octahedral geometry. Mn(1)–O(21)–Mn(2) and Mn(1)–O(41)–Mn(2) bond angles are 94.30(14) and 98.59(15)°, respectively. The $SCN^-$ groups are almost linear with the N(1)–C(1)–S(1) and N(2)–C(2)–S(2) bond angles being 177.8(6) and 179.0(8)°, respectively. The connections between $Mn^{II}$ and $SCN^-$ groups are slightly bent with the C(1)–N(1)–Mn(2) and C(2)–N(2)–Mn(1) bond angles being 151.5(5) and 168.4(6)°, respectively. 4-Haba acts as a monodentate ligand through one carboxylic oxygen atom coordinating to Mn(2) (Scheme 1, a). However, 4-aba has three distinctly different coordination modes, in which the amino nitrogen atom is not involved in coordination with $Mn^{II}$: one behaves in a $\mu_2$-$\eta^2$-carboxyl bridging mode (Scheme 1, b); the second adopts a $\mu_2$-chelating/bridging mode (Scheme 1, c); and the third acts as a $\mu_3$-carboxyl bridge (Scheme 1, d). Thus, Mn(1) and Mn(2) are linked together by three different types of 4-aba through one *syn-syn* μ-carboxyl bridge (Scheme 1, b), two μ-O atoms from the $\mu_2$-chelating/bridging carboxyl group (Scheme 1, c), and the $\mu_3$-carboxyl group (Scheme 1, d), respectively. The separation of Mn(1)···Mn(2) is 3.407 Å. A similar molecular geometry to this kind of connection has been found in $[Mn_3(HCOO)_6]$, where the Mn–Mn connectivity is 3.625 Å.[21] The other oxygen atom in the $\mu_3$-carboxyl group of 4-aba (Scheme 1, d) coordinates to Mn(2) and further links the two independent $Mn^{II}$ into a tetranuclear $Mn^{II}$

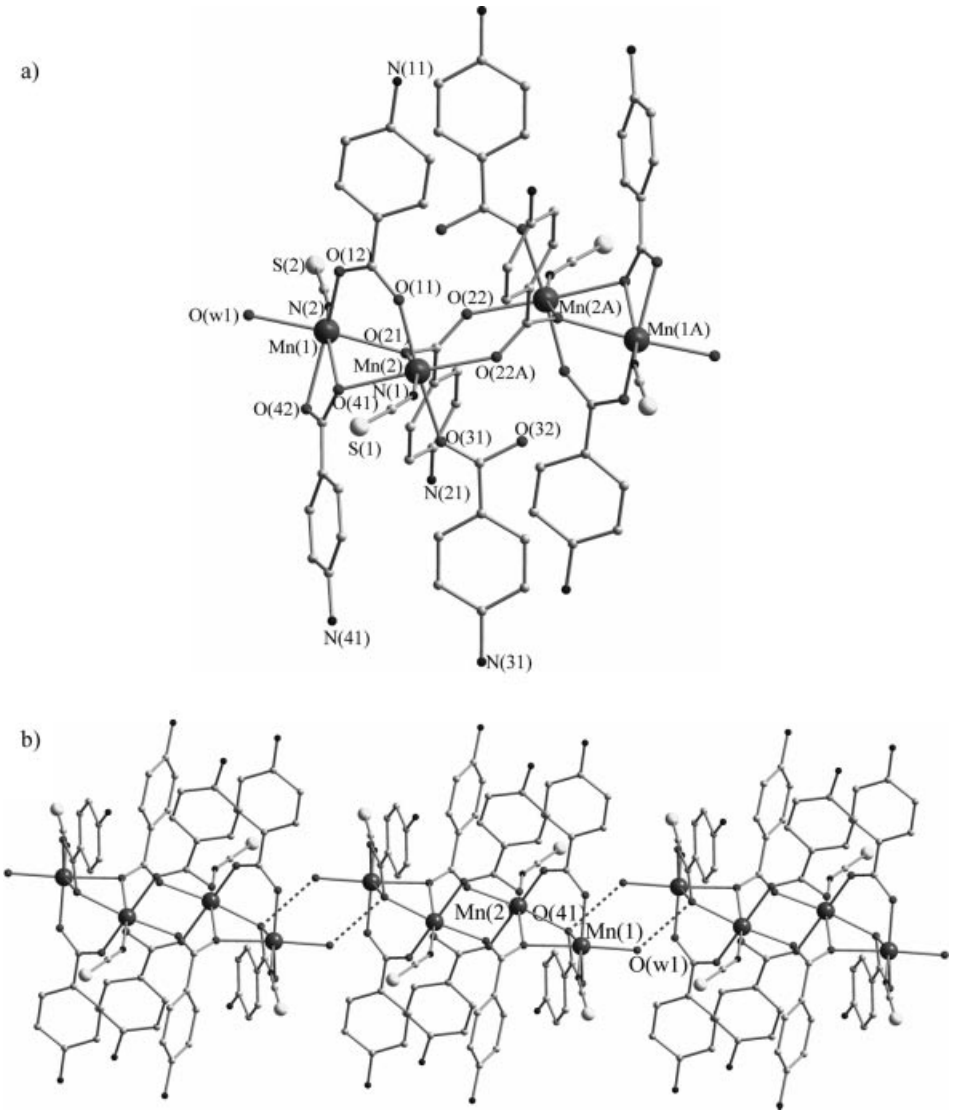

Figure 1. (a) View of the tetranuclear $Mn^{II}$ anionic framework in **1**. (A) $2 - x$, $1 - y$, $1 - z$. (b) View of a one-dimensional hydrogen bonding chain consisting of tetranuclear $Mn^{II}$ anions in **1**.

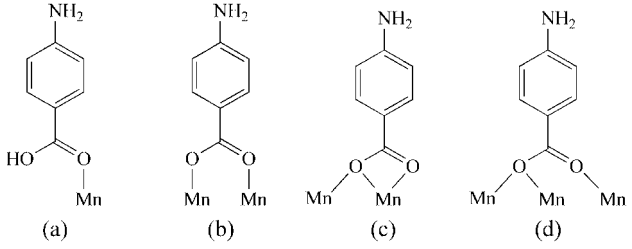
cluster, in which the Mn(2)···Mn(2A) and Mn(1)···Mn(2A) separations bridged by the carboxyl group of 4-aba are 5.058 and 6.150 Å, respectively. The topology of the rhombic tetranuclear $Mn^{II}$ cluster is rather unusual, and it has an unprecedented $[Mn_4(\mu_3\text{-4-aba})_2(\mu_2\text{-}\eta^2\text{-4-aba})_2]$ core, which is different to several rhombic or butterfly-like tetranuclear Mn clusters with an $[Mn_4(\mu\text{-carboxylic})]$ or $[Mn_4(\mu_3\text{-phth})_2]$ core that have been reported.[22] The hydrogen bonding interaction between the coordinated water molecule and the μ-O atom in the $\mu_3$-carboxyl of 4-aba [OW1–H(1)···O(41)$^i$ 2.854(7) Å; symmetry code (i) $-x + 1$, $-y + 1$, $-z + 1$] cross-links the tetramers into a one-dimensional supramolecular chain. The closest Mn···Mn distance between adjacent tetramers in the chain is 4.994 Å (Figure 1, b).



Scheme 1. Coordination modes of 4-Haba and 4-aba in **1**.

**$[Mn(3\text{-aba})_2]_n$ (2):** Complex **2** is a two-dimensional coordination polymer based on infinite Mn–O–C–O chains. As shown in Figure 2 (a), Mn(1) is in a slightly distorted octahedral coordination environment and is coordinated by four carboxyl oxygen atoms and two nitrogen atoms from six different 3-aba. Four carboxyl oxygen atoms comprise the equatorial plane and $Mn^{II}$ is coplanar with the mean plane of four equatorial carboxyl oxygen atoms, and the two amino nitrogen atoms occupy the axial positions. The bond angles between the *cis* donors around $Mn^{II}$ range from

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

85.27(17) to 94.73(17)°. The Mn–N bond length of 2.290(5) Å is slightly longer then the Mn–O bond lengths of 2.150(4) and 2.201(4) Å, suggesting an elongated octahedron. In addition, 3-aba acts as an *exo*-tridentate bridge through the amino nitrogen atom and $\mu_2$-$\eta^2$-carboxyl group (Scheme 2). The carboxyl group is slightly distorted with respect to the phenyl ring with the dihedral angle between them being 11.8°. The double *syn-syn* mode $\mu_{1,3}$-carboxyl bridges coming from two different 3-aba ligands exist between neighboring $Mn^{II}$ ions forming an infinite Mn–O–C–O chain with the C–O–Mn bond angles being 124.6(3) and 133.8(3)°. The closest Mn···Mn distance within the chain is 4.607 Å. As shown in Figure 2 (b), the chains are cross-linked into a two-dimensional layer structure through the amino nitrogen atom of 3-aba coordinating to the remaining coordination sites of $Mn^{II}$. The shortest inter-chain Mn···Mn distance is 8.129 Å. There are no other short contacts or noteworthy aryl-aryl interactions between the adjacent two-dimensional layers.

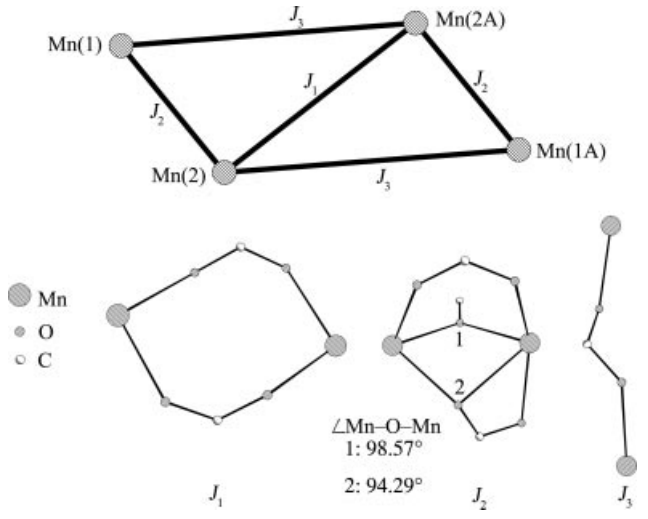
## Magnetic Properties

The magnetic susceptibilities of complexes **1** and **2** were measured in the 2–300 K temperature range and are shown in Figure 3 and Figure 4, respectively. The experimental $\chi_m T$ values of **1** and **2** at room temperature are 4.66 and 4.24 $cm^3 \cdot mol^{-1} \cdot K$ per $Mn^{II}$, respectively, close to the spin-only value expected for an uncoupled high-spin $Mn^{II}$ ion (4.38 $cm^3 \cdot mol^{-1} \cdot K$). As the temperature is lowered to 2 K, the $\chi_m T$ products decrease first slowly and then rapidly. The behavior suggests that antiferromagnetic interactions are operative in the two complexes. The temperature dependence of the reciprocal susceptibilities ($1/\chi_m$) obeys the Curie–Weiss law above 5 K for **1** and 15 K for **2** with $\theta$ = –8.9 and –13.9 K for **1** and **2**, respectively. The negative $\theta$ values support the presence of overall antiferromagnetic interactions in the two complexes.

The crystallographic data of **1** suggest that there are three different types of superexchange pathways within the tetranuclear unit, which can be schematized as shown in Scheme 3. Therefore, the magnetic data of **1** should be analyzed by an analytical expression based on the Hamiltonian in Equation (1).

$$H = -2J_1S_1S_2 - 2J_2(S_1S_3 + S_2S_4) - 2J_3(S_1S_4 + S_2S_3) \quad (1)$$



Scheme 3. Spin topology for **1** assuming three different *J* values.

Calculations were performed with the magnetism package MAGPACK.[23] The best-fit parameters obtained were $J_1$ = –1.84(1) $cm^{-1}$, $J_2$ = –0.18(2) $cm^{-1}$, $J_3$ = 0.02(1) $cm^{-1}$, $g$ = 2.090(2) and $R = 2.6 \cdot 10^{-4}$ ($R = \Sigma[(\chi_m T)_{obs}^2 - (\chi_m T)_{calc}^2]/\Sigma[(\chi_m T)_{obs}^2]$). As expected from the structural parameters depicted in Scheme 3, the results show the presence of two antiferromagnetic and one very weak ferromagnetic interaction. The difference in the magnetic exchange interactions found for **1** can be satisfactorily explained in terms of the conformation modes of the carboxyl bridge. The exchange

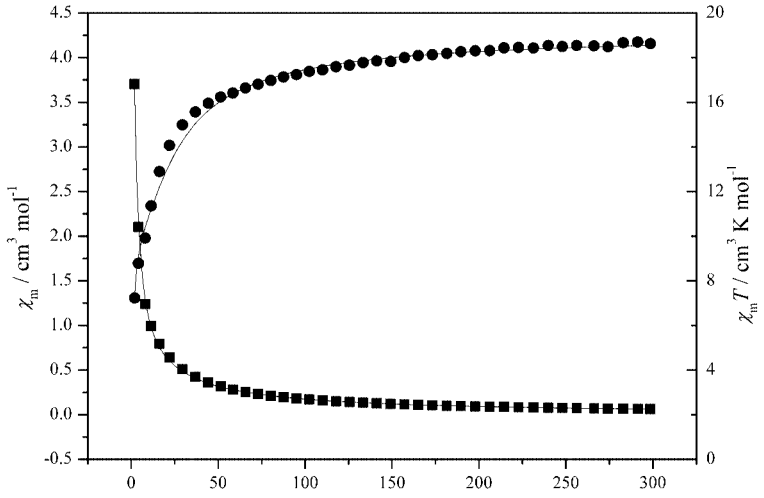

Figure 3. Temperature dependence of $\chi_m$ (■) and $\chi_m T$ (●) values for complex **1**. The solid lines correspond to the best-fit curves using the parameters described in the text.

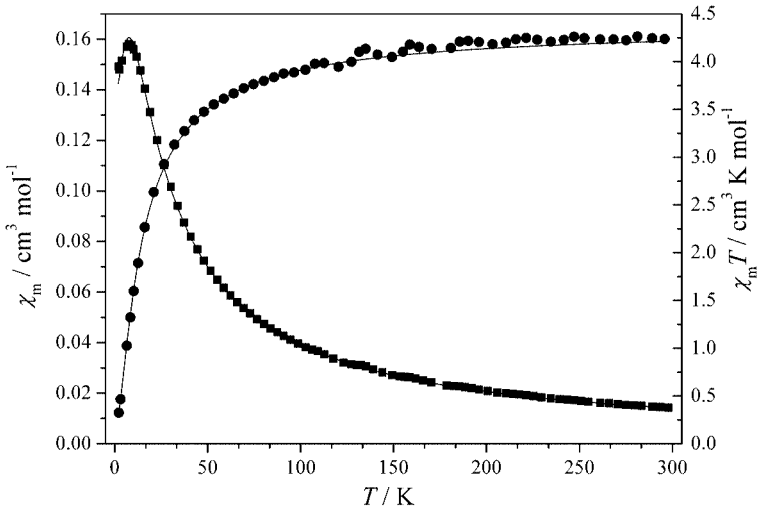

Figure 4. Temperature dependence of $\chi_m$ (■) and $\chi_m T$ (●) values for complex **2**. The solid lines correspond to the best-fit curves using the parameters described in the text.

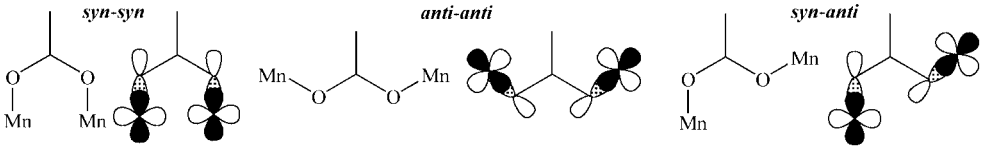
coupling through the carboxyl bridge is highly dependent on the conformation modes (Scheme 4) of the bridge between the metal centers.[16b] The *syn-syn* mode provides small metal–metal distances and a good overlap of magnetic orbitals, which usually induces antiferromagnetic coupling in $Mn^{II}$ polynuclear complexes.[24] The *syn-anti* mode induces much smaller $J$ values because of the expanded metal center and a mismatch in the orientation of magnetic orbitals.[8b,9] The few examples involving the *anti-anti* mode indicated that this coupling is weakly ferromagnetic or antiferromagnetic.[9,25] Coupling $J_1$ arises from the double *syn-syn* carboxyl bridge and gives a weak antiferromagnetic coupling in this case, but coupling $J_3$ through the single *anti-anti* carboxyl bridge gives very weak ferromagnetic coupling. The $J_1$ value is larger than the $J_3$ value, which shows that the *syn-syn* carboxyl bridge is more favorable than the *anti-anti* mode for transmission of the magnetic coupling interaction.[9,26] In the coupling $J_2$, the effect of the two carboxyl bridges in *syn-syn* and *syn-anti* configuration is antiferromagnetic, but the two μ–O bridges with Mn–O–Mn angles of 98.59° and 94.30° may show weak ferromagnetic coupling and will reduce the antiferromagnetic contribution.[27]

The situation for **2** is much simpler. Magnetically, **2** is a uniform chain, in which there is only one type of superexchange pathway: the double *syn-syn* mode carboxyl bridge. The interchain magnetic interactions should be much weaker. The magnetic interaction within the chain can be expressed by the isotropic Hamiltonian $H = -2J\Sigma S_i S_{i+1}$, where $J$ is the coupling constant between neighboring metal ions. To simulate the experimental magnetic behavior, we used the analytical expression derived by Fisher[28] for a one-dimensional Heisenberg chain of classical spins [$S = 5/2$, Equation (2)].

$$\chi_{chain} = [Ng^2\beta^2 S(S + 1)/(3kT)][(1 + u)/(1 - u)] \quad (2)$$

where $N$ is Avogadro's number, $\beta$ is Bohr's magneton, $k$ is Boltzmann's constant, and $u$ is the well-known Langevin

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4. Schematic representations of the coordination modes for the carboxylate bridges and the overlap of *d-p* magnetic orbitals.

function: $u = \coth[2JS(S + 1)/kT] - kT/[2JS(S + 1)]$. To take into account the interchain interaction, we applied the molecular field approximation [Equation (3)].[29]

$$\chi = \chi_{chain}/[1 - (2zJ'/Ng^2\beta^2)\chi_{chain}] \quad (3)$$

The best least-squares fit of the theoretical equation to experimental data leads to $J = -0.640(3)\ cm^{-1}$, $2zJ' = 0.070(1)\ cm^{-1}$, and $g = 2.000(2)$. The $J$ value suggests that a weak antiferromagnetic interaction between neighboring $Mn^{II}$ ions is mediated through the double *syn-syn* mode $\mu_2$-carboxyl bridges. It is comparable to those reported for other $Mn^{II}$ species with similar double carboxyl bridges.[16c]

## Conclusions

One tetranuclear manganese(II) complex and one two-dimensional coordination polymer based on infinite Mn–O–C–O chains from 4-Haba and 3-Haba, respectively, have been synthesized and characterized crystallographically and magnetically. The structural difference between **1** and **2** is ascribed to the relatively different orientation of coordination sites of 4-aba and 3-aba. The analysis of the magnetic properties of **1** and **2** suggests weak antiferromagnetic interactions. Three types of magnetic interaction operative in complex **1** result in an overall antiferromagnetic behavior, as indicated by the temperature dependence of the magnetic susceptibility. Complex **2** exhibits weak antiferromagnetic interactions through double $\mu_2$-$\eta^2$-carboxyl bridges within the chain.

## Experimental Section

**General:** All reagents were commercially available and used as purchased. The IR spectra (KBr disk) were recorded with a Magna 750 FT-IR spectrophotometer. C, H, and N elemental analyses were determined with an Elementary Vario ELIII elemental analyzer. Variable-temperature magnetic susceptibilities were measured with a Quantum Design MPMS SQUID magnetometer equipped with a 5 kOe magnet in the temperature range 2–300 K. The observed susceptibility data were corrected for underlying diamagnetism by using Pascal's constants.[1b]

**Synthesis of $\{(H_3O)_2[Mn_4(4\text{-Haba})_2(4\text{-aba})_6(SCN)_4(H_2O)_2]\}$ (1):** A solution of $MnCl_2{\cdot}4H_2O$ (0.10 g, 0.5 mmol) and $NH_4SCN$ (0.08 g, 1.0 mmol) in $H_2O$ (10 mL) was added slowly to a solution of 4-aminobenzoic acid (0.07 g, 0.5 mmol) in ethanol (10 mL) under stirring, then 0.1 mol·$L^{-1}$ NaOH aqueous solution was added dropwise to the reaction mixture until a small amount of precipitate was formed (pH = 4.0–4.5). The precipitate was filtered off and the filtrate was allowed to stand at room temperature for about 2 weeks, yellow crystals were produced. Yield: 0.13 g (61%). $C_{30}H_{30}Mn_2N_6O_{10}S_2$ (808.60): calcd. C 44.56, H 3.71, N 10.39; found C 44.51, H 3.67, N 10.35. IR (KBr): $\tilde{\nu}$ = 3460 (w), 3365 (s), 3271 (m), 2085 (s), 1608 (s), 1574 (w), 1528 (s), 1508 (s), 1406 (vs), 1396 (vs), 1327 (w), 1292 (w), 1261 (w), 1184 (w), 1174 (w), 1128 (vw), 1093 (vw), 1014 (vw), 978 (w), 957 (vw), 850 (vw), 789 (m), 700 (vw), 621 (w), 552 (vw), 492 (vw) $cm^{-1}$.

**Synthesis of $[Mn(3\text{-aba})_2]_n$ (2):** The procedure is similar to the synthesis of **1** except that 3-aminobenzoic acid (0.07 g, 0.5 mmol) was used instead of 4-aminobenzoic acid. Yield: 0.09 g (55%). $C_{14}H_{12}MnN_2O_4$ (327.2): calcd. C 51.39, H 3.67, N 8.56; found C 51.35, H 3.61, N 8.53. IR (KBr): $\tilde{\nu}$ = 3358 (m), 3284 (w), 1579 (m), 1547 (s), 1454 (m), 1394 (s), 1311 (vw), 1246 (w), 1120 (vw), 1074 (vw), 976 (m), 924 (w), 912 (w), 901 (w), 787 (m), 775 (s), 690 (vw), 669 (vw), 565 (vw), 546 (vw), 517 (vw) $cm^{-1}$. Compound **2** can also be obtained through the directed reaction of 3-Haba, $MnCl_2{\cdot}4H_2O$, and $NaN_3$ in EtOH/$H_2O$ at room temperature.

**X-ray Crystallography:** Intensity data for **1** and **2** were measured with a Siemens Smart CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at room temperature. All empirical absorption corrections were applied using the SADABS program.[30] The structures were solved by direct methods[31] and refined on $F^2$ by full-matrix least-squares using the SHELXL-97 program package.[32] The positions of H atoms were generated geometrically (C–H bond fixed at 0.96 Å), assigned isotropic thermal parameters, and allowed to ride on their parent carbon atoms before the final cycle of refinement. No attempt was made to locate the hydrogen atoms of water. The selected bond lengths and angles for **1** and **2** are listed in Table 1.

**Crystal Data for 1:** $C_{30}H_{30}Mn_2N_6O_{10}S_2$, $Mr$ = 808.60, 0.46 × 0.34 × 0.26 mm, triclinic, space group $P\bar{1}$ (No. 2), $a$ = 12.2553(2), $b$ = 12.28000(10), $c$ = 12.2833(2) Å, $\alpha$ = 80.774(1), $\beta$ = 85.798(1), $\gamma$ = 67.587(1)°, $V$ = 1686.68(4) Å$^3$, $Z$ = 2, $D_c$ = 1.592 g/cm$^3$, $F$(000) = 828, Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, $T$ = 173(2) K, $2\theta_{max}$ = 50.1°, 8783 reflections collected, 5900 unique ($R_{int}$ = 0.0320). Final $GooF$ = 1.088, $R1$ = 0.0738, $wR2$ = 0.1414, $R$ indices based on 4667 reflections with $I > 2\sigma(I)$ (refinement on $F^2$), 455 parameters, $\mu$ = 0.938 mm$^{-1}$.

**Crystal Data for 2:** $C_{14}H_{12}MnN_2O_4$, $Mr$ = 327.20, 0.30 × 0.26 × 0.20 mm, monoclinic, space group $P2_1/n$ (No. 14), $a$ = 8.8522(17), $b$ = 4.6071(9), $c$ = 15.377(3) Å, $\beta$ = 105.279(3)°, $V$ = 604.9(2) Å$^3$, $Z$ = 2, $D_c$ = 1.796 g/cm$^3$, $F$(000) = 334, Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, $T$ = 293(2) K, $2\theta_{max}$ = 50.2°, 1785 reflections collected, 1054 unique ($R_{int}$ = 0.0400). Final $GooF$ = 1.247, $R1$ = 0.0603, $wR2$ = 0.1243, $R$ indices based on 866 reflections with $I > 2\sigma(I)$ (refinement on $F^2$), 121 parameters, $\mu$ = 1.110 mm$^{-1}$.

CCDC-288647 and -288648 (for **1** and **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (for details see the footnote on the first page of this article): Figure S1, packing diagram of **1** along the $c$ axis and Figure S2, packing diagram of **2** along the $b$ axis.

# Synthesis and Metallation of the Diphosphanylsilane $i$Pr$_2$Si(PHMe)$_2$

Carsten von Hänisch*[a] and Oliver Rubner[b]

**Keywords:** Clusters / Phosphorus / Silicon / Tin / Zinc

The reaction of [LiAl(PHMe)$_4$] with $i$Pr$_2$SiCl$_2$ yields the dialkyldiphosphanylsilane $i$Pr$_2$Si(PHMe)$_2$ (**1**). This compound is formed as a diastereomeric mixture and was identified by NMR spectroscopy and mass spectrometry. Silane **1** reacts with [Sn{N(SiMe$_3$)$_2$}$_2$] and [Zn{N(SiMe$_3$)$_2$}$_2$] to form the polycyclic compounds [Sn{SnN(SiMe$_3$)$_2$}$_2${$i$Pr$_2$Si(PMe)$_2$}$_2$] (**2**) and [{ZnN(SiMe$_3$)$_2$}$_3${$i$Pr$_2$Si(PMe)$_2$}$_2$H] (**3**), respectively. The tricyclic compound **2** possesses one Sn–Sn bond and contains tin atoms in the formal oxidation states +1, +2 and +3. The central structural motif of the zinc–phosphorus cluster **3** is a Zn$_3$P$_4$Si$_2$ cage. The compounds [$i$Pr$_2$Si{P(Me)MEt$_2$}$_2$]$_2$ (**4**: M = Al; **5**: M = Ga), which feature an adamantane-like cage formed by four metal, four phosphorus and two silicon atoms can be obtained by the reaction of **1** with MEt$_3$ (M = Al, Ga).

## Introduction

In the last few years reactions of primary silylphosphanes or -arsanes (R$_3$SiEH$_2$; E = P, As) with amide or alkyl compounds of different main- and subgroup metals have been applied several times to synthesise metal–phosphorus and metal–arsenic compounds.[1–3] Cyclic and cage-like species were obtained by these reactions. The molecular structures of the reaction products can be influenced by the silyl groups attached to the P or As atom. The reactions of [Sn{N(SiMe$_3$)$_2$}$_2$] with R$_3$SiEH$_2$ (E = P, As) serve as an example. Thus, the hexagonal-prismatic compounds [SnESi$i$Pr$_3$]$_6$ (E = P, As) are formed starting from $i$Pr$_3$SiEH$_2$, whereas the reaction of $t$Bu$_3$SiPH$_2$ with [Sn{N(SiMe$_3$)$_2$}$_2$] yields the heterocubane [SnPSi$t$Bu$_3$]$_4$.[2] Recently, it was shown that the diisopropyldiphosphanylsilane $i$Pr$_2$Si(PH$_2$)$_2$ is a very promising starting compound for the formation of novel ternary clusters. For example, it reacts with MEt$_3$ (M = Al, Ga, In) to form the ternary compounds [$i$Pr$_2$Si{P(H)MEt$_2$}$_2$]$_2$ (M = Al, Ga, In), which exhibit an M$_4$P$_4$Si$_2$ adamantane cage as the central structural motif.[3] In this paper, the synthesis of the new diphosphanylsilane $i$Pr$_2$Si(PHMe)$_2$ and its reactions with the metal amides [Sn{N(SiMe$_3$)$_2$}$_2$] and [Zn{N(SiMe$_3$)$_2$}$_2$], as well as with the alkyl compounds AlEt$_3$ and GaEt$_3$, are described.

## Results and Discussion

A solution of [LiAl(PHMe)$_4$] in DME was treated with $i$Pr$_2$SiCl$_2$ and furnished the dialkyldiphosphanylsilane $i$Pr$_2$Si(PHMe)$_2$ (**1**) in about 30% yield. Because of the high inversion barrier of the phosphorus atoms, compound **1** forms as a diastereomeric mixture. Therefore, the $^{31}$P{$^1$H} NMR spectrum of **1** shows two singlet signals at $\delta$ = –190.2 and –193.1 ppm. Two triplets at $\delta$ = 19.3 and 21.3 ppm, with $^1J_{Si,P}$ coupling constants of 44 and 45 Hz, can be observed in the $^{29}$Si{$^1$H} NMR spectrum. In the $^1$H NMR spectrum, the signals of the diastereomers are superposed. One can observe a multiplet for the methyl groups at $\delta$ = 0.93 ppm, a multiplet for the isopropyl groups at $\delta$ = 1.06 ppm, and a quadruplet of doublets for the PH protons at $\delta$ = 2.20 ppm. The phosphorus-decoupled $^1$H NMR spectrum shows two doublets at $\delta$ = 0.94 and 0.93 ppm for the methyl groups, with $^3J_{H,H}$ coupling constants of 7.4 Hz. The mass spectrum of **1** shows the molecular peak at $m/z$ = 208, as well as peaks for the fragments [M$^+$ – Me], [M$^+$ – PHMe] and [M$^+$ – C$_3$H$_6$].

Compound **1** reacts with [Sn{N(SiMe$_3$)$_2$}$_2$] in heptane to give a red solution from which orange crystals can be obtained at –35 °C. An X-ray crystal structure determination revealed that [Sn{SnN(SiMe$_3$)$_2$}$_2${$i$Pr$_2$Si(PMe)$_2$}$_2$] (**2**) (Figure 1) has been formed.[4] This compound shows a polycyclic Sn$_3$P$_4$Si$_2$ core structure, which is formed by two Sn$_2$P$_2$Si rings and one Sn$_2$P$_2$ ring. Two of the tin atoms bear one N(SiMe$_3$)$_2$ substituent each, whereas the central tin atom has no exocyclic ligands. Remarkably, a tin–tin bond [Sn(1)–Sn(3)] appears in the molecular structure of **2**, hence compound **2** contains three electronically different tin atoms.[5] The $^{119}$Sn Mössbauer spectrum (recorded at 77 K with a BaSnO$_3$ source) could be fitted with six Lorentzian lineshape components at 4.0, 3.3, 2.5, 2.1, 1.6, and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1.3 mm s$^{-1}$ with approximately equal intensities. The linewidths of these components (0.8 mm s$^{-1}$) are close to the expected natural linewidth. These six Lorentzians most likely comprise three spectral components that are split into doublets by nuclear electronic quadrupolar interactions with the spin 3/2 nuclear excited state of $^{119}$Sn, consistent with the expectation of three distinct crystallographic sites. As there is currently no body of suitable reference data, we cannot identify the specific sets of lines making up these three quadrupolar doublets with certainty. In view of the crystallographic information, it appears plausible, however, to group these six lines into one doublet centred near 1.5 mm s$^{-1}$, characterised by a rather small quadrupolar splitting [this doublet is most likely assignable to the four-coordinate Sn(3) site], and two doublets having relatively large quadrupolar splittings, which are assigned to the three-coordinate Sn(1) and Sn(2) sites. While we cannot specify isomeric shifts and quadrupolar splitting parameters of Sn(1), Sn(2) and Sn(3) beyond doubt at the present time, we can nevertheless conclude that the Mössbauer spectrum is consistent with the proposed structure.

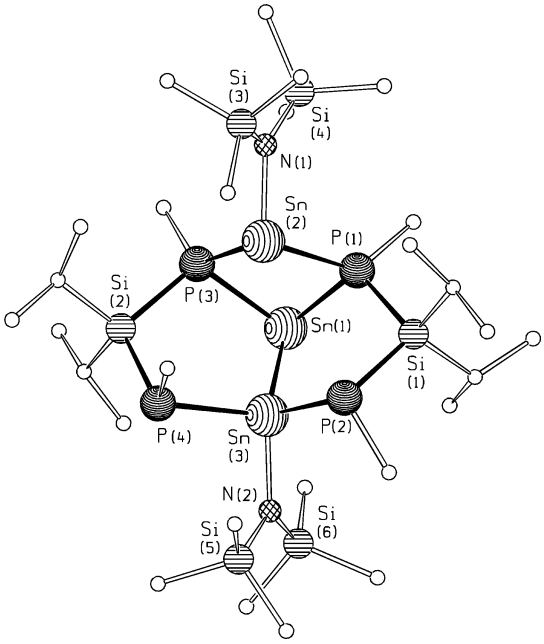

Figure 1. Molecular structure of **2**. Selected bond lengths [pm] and angles [°]: Sn(1)–Sn(3) 288.1(1), Sn(1)–P(1) 263.2(1), Sn(1)–P(3) 261.5(1), Sn(2)–N(1) 210.6(4), Sn(2)–P(1) 266.9(1), Sn(2)–P(3) 270.1(1), Sn(3)–N(2) 210.4(3), Sn(3)–P(2) 256.1(1), Sn(3)–P(4) 256.9(1), Si(1)–P(1) 226.4(1), Si(1)–P(2) 226.8(1), Si(2)–P(3) 226.8(2), Si(2)–P(4) 224.8(2); P(1)–Sn(1)–Sn(3) 84.66(3), P(3)–Sn(1)–Sn(3) 86.03(3), P(1)–Sn(1)–P(3) 84.47(3), P(2)–Sn(3)–P(4) 107.93(4), P(2)–Sn(3)–Sn(1) 111.26(3), P(4)–Sn(3)–Sn(1) 110.33(3), P(1)–Sn(2)–P(3) 82.12(4), P(1)–Si(1)–P(2) 105.73(5), P(3)–Si(2)–P(4) 111.33(3), Sn(1)–P(1)–Sn(2) 93.46(4), Si(1)–P(2)–Sn(3) 101.16(5), Sn(1)–P(3)–Sn(2) 93.09(3), Si(2)–P(4)–Sn(3) 100.13(5).

In the $^{31}P\{^1H\}$ NMR spectrum of **2** one signal with one pair of Sn satellites at $\delta$ = –181.5 ppm ($^1J_{P,Sn}$ = 948 Hz), which corresponds to P(2) and P(4), and another signal with two pairs of Sn satellites at $\delta$ = –176.6 ppm ($^1J_{P,Sn}$ = 1105 and 935 Hz), which corresponds to P(1) and P(3), can be observed. The $^{117}$Sn NMR spectrum shows three broad signals with a triplet structure at $\delta$ = 39, 172 and 290 ppm.

The Sn(1)–Sn(3) bond length of 288.1 pm is within the usual range for Sn–Sn single bonds; the Sn–P bonds in compound **2** are between 256.1 and 266.9 pm. In the mixed-valence Sn/P cluster $[Sn_8(PSi\textit{i}Pr_3)_6Cl_2]$ described recently, the Sn–Sn bonds are in the range 283.4–288.8 pm and the Sn–P bonds are in the range 253.8–272.8 pm.[6]

The reaction of **1** with the zinc amide $[Zn\{N(SiMe_3)_2\}_2]$ in heptane yields a colourless solution from which crystals of $[\{ZnN(SiMe_3)_2\}_3\{\textit{i}Pr_2Si(PMe)_2\}_2H]$ (**3**) can be obtained. Compound **3** crystallises in the orthorhombic space group $Pna2_1$ and was refined as an inversion twin (Figure 2). The molecular structure contains a heavily folded six-membered $Zn_3P_3$ ring. Each zinc atom binds to one exocyclic $N(SiMe_3)_2$ substituent, and each phosphorus atom bears one methyl group. Two of the phosphorus atoms [P(1) and P(2)] of this ring are further connected by an Si*i*Pr$_2$ group to form a four-membered $ZnP_2Si$ ring. The third phosphorus atom [P(3)] binds to an Si*i*Pr$_2$PHMe fragment. The phosphorus atom of this PHMe group [P(4)] coordinates the opposite zinc atom of the ring [Zn(1)]. Therefore, Zn(1) has a coordination number of four, whereas Zn(2) and Zn(3) have a trigonal-planar coordination. Due to the lower coordination, the Zn–P and Zn–N bonds at Zn(2) and Zn(3) are significantly shorter than to Zn(1) [Zn(1)–P = 246.6–250.1 ppm, Zn(1)–N = 192.3 pm, Zn(2,3)–P = 234.9–241.2 ppm, Zn(2,3)–N = 189.8 and 189.2 pm]. In the zinc–phosphorus ring compound $[MeZn\{\mu\text{-}P(SiMe_3)_2\}]_3$, in which the coordination of all Zn atoms is trigonal-planar, the Zn–P bonds are, on average, 238 pm long.[7] The ring compound $[Zn_2Cl_2\{\mu\text{-}P(SiMe_3)_2\}_2(P\textit{n}Pr_3)_2]$ shows Zn atoms with coordination number four due to the coordination of additional phosphane ligands. In this compound, the Zn–P($\mu_2$) bonds are 242.6 to 244.7 pm long, whereas the terminal Zn–P bonds amount to 240.8–243.0 pm.[8] The hydrogen atom at P(4) could not be satisfactorily fitted in the difference map; however, the $^1$H and $^{31}$P NMR spectra of **3** give clear evidence for the presence of a hydrogen atom. Beside the signals of the PMe, $SiMe_3$ and Si*i*Pr$_2$ groups, the $^1$H NMR spectrum shows a weak doublet of multiplets with a $^1J_{P,H}$ coupling constant of 270 Hz; in the $^1H\{^{31}P\}$ NMR spectrum this signal appears as a quadruplet with a $^3J_{H,H}$ coupling constant of 7.5 Hz. In the $^{31}P\{^1H\}$ NMR spectrum four multiplets for the four different phosphorus atoms in **3** can be observed in the range from $\delta$ = –150 to –200 ppm (ABCD spin system). In the $^{31}$P NMR spectrum the signal at $\delta$ = –155 ppm is further split by a $^1J_{P,H}$ coupling (see Figure 3a,b), therefore this signal can be assigned to P(4). Quantum chemical calculations with the Turbomole program package were applied to allocate the three remaining multiplets to specific P atoms. The method applied was DFT with the BP86 functional and a TZVPP basis set for all atoms;[9,10] for performance reasons the resolution-of-identity (RI) approximation was used.[11] The reference for the chemical shifts was $H_3PO_4$, computed with the same parameters as were used for the cluster. Those calculations that gave chemical shifts closest to the experimental values

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were performed as single-point calculations with the geometry obtained from the X-ray structure analysis. As the position of the hydrogen atom at P(4) could not be determined by the experiment, its distance to the phosphorus atom was varied systematically. Geometry optimisations with different basis sets led to deviations from the experimental values of about $\delta$ = 15–30 ppm, although the order of peaks for P(1), P(2) and P(3) was always retained. For a given geometry of the cluster, the shift of P(4) is extremely sensitive to the P–H distance and the H–P–C bond angle. Thus, the correct combination of distance and angle could not definitely be fixed. The best agreements were achieved for a distance of about 150 pm at an angle of 100°. The resulting chemical shifts are given in Table 1.

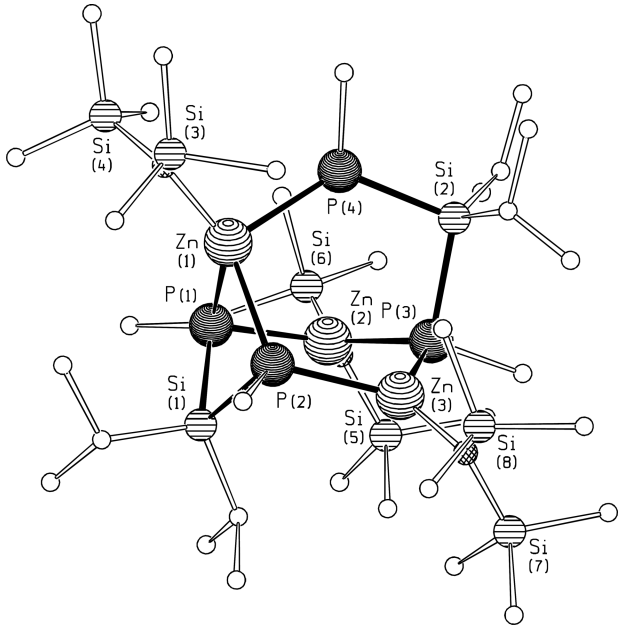

Figure 2. Molecular structure of **3**. Selected bond lengths [pm] and angles [°]: Zn(1)–P(1) 250.1(2), Zn(1)–P(2) 246.6(3), Zn(1)–P(4) 249.5(4), Zn(1)–N(1) 192.3(7), Zn(2)–P(1) 236.7(2), Zn(2)–P(2) 241.2(2), Zn(2)–N(2) 189.8(6), Zn(3)–P(2) 234.9(3), Zn(3)–P(3) 238.8(2), Zn(3)–N(3) 189.2(6), P(1)–Si(1) 224.6(4), P(2)–Si(1) 227.4(4), P(3)–Si(2) 224.2(3), P(4)–Si(2) 219.5(5); P(1)–Zn(1)–P(2) 81.13(8), P(1)–Zn(1)–P(4) 95.47(13), P(2)–Zn(1)–P(4) 109.15(12), P(1)–Zn(2)–P(3) 109.66(8), P(2)–Zn(3)–P(3) 106.56(8), Si(1)–P(1)–Zn(2) 106.42(12), Si(1)–P(1)–Zn(1) 87.65(10), Si(1)–P(2)–Zn(3) 107.44(12), Si(1)–P(2)–Zn(1) 87.88(11), Si(2)–P(3)–Zn(3) 103.96(11), Si(2)–P(4)–Zn(1) 124.61(18), P(1)–Si(1)–P(2) 91.21(12), P(3)–Si(2)–P(4) 102.54(14).

A complete analysis of the $^{31}$P NMR spectrum by an iterative optimisation of the coupling constants yielded the values $J_{P1,P2}$ = 302.4, $J_{P1,P3}$ = 202.4, $J_{P1,P4}$ = 168.8, $J_{P2,P3}$ = 217.3, $J_{P2,P4}$ = 134.1, $J_{P3,P4}$ = 93.2 Hz and $^1J_{P4,H}$ = 272.7 Hz; the simulated spectrum is shown in Figure 3c.[12]

Compound **1** reacts with $MEt_3$ (M = Al, Ga) in heptane at ambient temperature with elimination of ethane. Recrystallisation from benzene yielded colourless crystals of the composition [$i$Pr$_2$Si{P(Me)MEt$_2$}$_2$]$_2$·2C$_6$H$_6$ (**4**: M = Al; **5**: M = Ga). The molecular structures of **4** and **5** (Figure 4) are almost identical to the compounds [$i$Pr$_2$Si{P(H)-MEt$_2$}$_2$]$_2$ (M = Al, Ga, In), described recently, but with methyl groups bound to the phosphorus atoms instead of hydrogen atoms.[3] The central structural motif is an adamantane-like cage of four aluminium or gallium atoms, four phosphorus and two silicon atoms. The phosphorus atoms are in the bridgehead positions and the metal and silicon atoms are in the secondary positions. This results in an eight-membered M$_4$P$_4$ (M = Al, Ga) ring where the opposite phosphorus atoms [P(1), P(3) and P(2), P(4)] are bridged by $i$Pr$_2$Si groups on different sides of the ring. The M$_4$P$_4$ ring is therefore strongly distorted and shows a boat-like conformation. The observed P–M and P–Si bond lengths are in the typical range for single bonds between these elements [**4**: Al–P = 242.8(1)–244.3(1), P–Si = 228.5(1)–228.8(1) pm; **5**: Ga–P = 241.5(1)–243.5(1), P–Si = 228.2(2)–229.3(2) pm]. Each of the metal atoms is bound to two exocyclic ethyl groups, and the silicon atoms possess two isopropyl groups each.

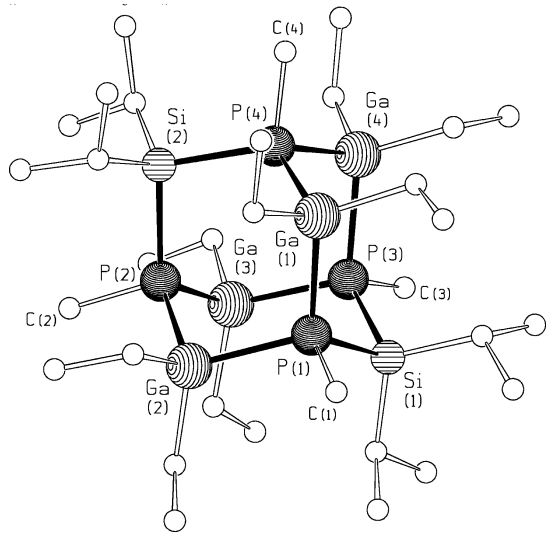

Figure 4. Molecular structure of **5**. Selected bond lengths [pm] and angles [°]: Ga(1)–P(1) 243.5(1), Ga(1)–P(4) 241.5(1), Ga(2)–P(1) 242.1(1), Ga(2)–P(2) 242.2(1), Ga(3)–P(2) 242.0(1), Ga(3)–P(1) 241.5(1), Ga(4)–P(3) 242.4(1), Ga(4)–P(4) 241.5(1), P(1)–Si(1) 228.7, P(3)–Si(1) 228.9(2), P(2)–Si(2) 229.3(2), P(4)–Si(2) 228.2(2); Si–P–Ga 114.23(6)–115.63(6), Ga–P–Ga 109.32(5)–110.28(5), P–Ga–P 110.47(5)–101.24(4).

## Experimental Section

**General:** All manipulations were performed under nitrogen, with rigorous exclusion of oxygen and moisture, using a Schlenk line. Solvents were dried and freshly distilled before use. NMR spectra were recorded with a Bruker DPX Avance 300 or with a Bruker AC 250 instrument. $[LiAl(PHMe)_4]$ and $GaEt_3$ were prepared according to the literature.[13] $AlEt_3$, $[Sn\{N(SiMe_3)_2\}_2]$ and $[Zn\{N(SiMe_3)_2\}_2]$ were obtained from Aldrich and used as received. Crystallographic data of **2**–**5** are shown in Table 2.[4]

**1:** $i Pr_2SiCl_2$ (3.0 g, 0.016 mol) was added to 50 mL of a 0.16 M solution of $[LiAl(PHMe)_4]$ in DME at 0 °C. The reaction mixture was warmed to room temperature and stirred for 16 h. Subsequently, pentane (50 mL) was added and the yellow precipitate was removed by filtration. Finally, the solvent was distilled off under reduced pressure at room temperature and the residue was distilled under vacuum. Compound **1** was obtained as a colourless liquid at 40 °C ($10^{-3}$ mbar). Yield: 1.0 g (32%). $^1H\{^{31}P\}$ NMR ($C_6D_6$): $\delta$ = 0.93 (d, $^3J_{H,H}$ = 7.4 Hz, 6 H, P–Me), 0.94 (d, $^3J_{H,H}$ = 7.4 Hz, 6 H, P–Me), 1.15 (m, 14 H, *i*Pr), 2.20 (qd, $^3J_{H,H}$ = 7.4, $^1J_{P,H} \approx$ 194 Hz, 2 H, P–H) ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$): $\delta$ = –3.2 (m, P–Me), 14.0 [m, $CH(CH_3)_2$], 19.4 [s, $CH(CH_3)_2$] ppm. $^{29}Si\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 19.3 (t, $^1J_{P,Si}$ = 44 Hz), 21.3 (t, $^1J_{P,Si}$ = 45 Hz) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = –190.2 (d, $^1J_{P,H}$ = 194 Hz), –193.1 (d, $^1J_{P,H}$ = 195 Hz) ppm. MS (EI, 70 eV): *m*/*z* (%) = 208 (90) [$M^+$], 193 (10) [$M^+$ – Me], 161 (80) [$M^+$ – PHMe], 119 (100) [$M^+ - C_3H_6$], 43 (60) [$iPr^+$].

**2:** $[Sn\{N(SiMe_3)_2\}_2]$ (0.51 g, 1.15 mmol) was added to a solution of $iPr_2Si(PHMe)_2$ (0.12 g, 0.58 mmol) in heptane (5 mL) at 0 °C. The reaction mixture was warmed to room temperature and stirred for 16 h. During this time the colour of the solution changed from orange to red, and small amounts of a precipitate appeared. After filtration, the solution was cooled to –35 °C. Orange crystals of compound **2** appeared within 2 d. Yield: 0.25 g (79%). $C_{28}H_{76}N_2P_4Si_6Sn_3$ (1089.4): calcd. C 30.87, H 7.03, N 2.57; found C 30.91, H 7.05, N 2.44. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.51 [s, 18 H, $N(SiMe_3)_2$], 0.58 (s, 9 H, $SiMe_3$), 0.80 (s, 9 H, $SiMe_3$), 1.07–1.33 (m, 28 H, *i*Pr), 1.83 (d, $^2J_{P,H}$ = 5.0 Hz, 6 H, PMe), 1.96 (d, $^2J_{P,H}$ = 8.1 Hz, 6 H, PMe) ppm. $^{31}P\{^1H\}$ NMR ([D$_8$]toluene, 50 °C): $\delta$ = –176.6 (br.), –181.5 (br.) ppm. $^{117}Sn\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 39 (t, $^1J_{Sn,P} \approx$ 1000 Hz), 172 (t, $^1J_{Sn,P} \approx$ 935 Hz), 290 (t, $^1J_{Sn,P} \approx$ 1340 Hz) ppm.

**3:** $[Zn\{N(SiMe_3)_2\}_2]$ (0.22 g, 0.57 mmol) was added to a solution of $iPr_2Si(PHMe)_2$ (0.06 g, 0.29 mmol) in 5 mL of heptane at 0 °C. The reaction mixture was warmed to room temperature and stirred for 3 h. The solution was then cooled to 6 °C. Colourless crystals of **3** appeared after 2 d. Yield: 0.13 g (62%). $C_{34}H_{95}N_3P_4Si_8Zn_3$ (1090.9): calcd. C 37.44, H 8.78, N 3.85; found C 37.10, H 8.51, N 3.69. $^1H\{^{31}P\}$ NMR ([D$_8$]toluene): $\delta$ = 0.27 [s, 18 H, $Si(CH_3)_3$],

0.31 [s, 36 H, Si(C$H_3$)$_3$], 1.19 (d, $^3J_{H,H}$ = 7.3 Hz, 3 H, C$H_3$PH), 1.20–1.35 (m, 28 H, Si$iPr_2$), 1.46 (s, 3 H, C$H_3$P), 1.50 (s, 3 H, C$H_3$P), 151 (s, 3 H, C$H_3$P), 3.03 (q, $^3J_{H,H}$ = 7.3 Hz, 1 H, CH$_3$P$H$) ppm. $^{29}$Si{$^1$H} NMR ([D$_8$]toluene): $\delta$ = –4.9 (s, SiMe$_3$), –4.5 (s, SiMe$_3$), –3.9 (s, SiMe$_3$), 2.1 (s, Si$i$Pr$_2$) ppm. $^{31}$P{$^1$H} NMR ([D$_8$]-toluene): $\delta$ = –154 (m), –164 (m), –179 (m), –193 (m) ppm. Raman: $\tilde{\nu}$ = 2950 (s), 2918 (s), 2899 (vs), 2342 (w), 1461 (w), 1230 (w), 879 (w), 681 (m), 627 (m), 467 (w), 397 (m), 180 (m), 114 (m) cm$^{-1}$.

**4:** A solution of AlEt$_3$ (1.2 mL, 1.0 M) in hexane (1.2 mmol) was added, with stirring, to a solution of $i$Pr$_2$Si(PHMe)$_2$ (0.13 g, 0.60 mmol) in heptane (5 mL). After 16 h, all volatile compounds were removed under vacuum. Recrystallisation of the residue from 2 mL of benzene yielded **4**·2C$_6$H$_6$ as large, colourless crystals within 3 d. Yield: 0.18 g (66%). $C_{32}H_{80}Al_4P_4Si_2$ (909.16): calcd. C 51.04, H 10.71; found C 50.03, H 10.58. $^1$H NMR (C$_6$D$_6$): $\delta$ = 0.73 (q, $^3J_{H,H}$ = 7.8 Hz, 16 H, C$H_2$CH$_3$), 1.33 [d, $^3J_{H,H}$ = 7.5 Hz, 24 H, CH(C$H_3$)$_2$], 1.56 (m, 36 H, CH$_2$C$H_3$, PC$H_3$), 1.70 [sept, $^3J_{H,H}$ = 7.5 Hz, 4 H, C$H$(CH$_3$)$_2$] ppm. $^{31}$P NMR (C$_6$D$_6$): $\delta$ = –181.3 (s) ppm.

**5:** GaEt$_3$ (0.18 g, 1.16 mmol) was added, with stirring, to a solution of $i$Pr$_2$Si(PHMe)$_2$ (0.123 g, 0.58 mmol) in heptane (5 mL). After 16 h, all volatile compounds were removed under vacuum. Recrystallisation of the residue from 2 mL of benzene yielded **5**·2C$_6$H$_6$ as large, colourless crystals within 3 d. Yield: 0.20 g (64%). $C_{32}H_{80}Ga_4P_4Si_2$ (1080.1): calcd. C 41.60, H 8.73; found C 42.67, H 8.92. $^1$H NMR (C$_6$D$_6$): $\delta$ = 1.15 (q, $^3J_{H,H}$ = 7.2 Hz, 16 H, C$H_2$CH$_3$), 1.36 [d, $^3J_{H,H}$ = 7.5 Hz, 24 H, CH(C$H_3$)$_2$], 1.60 (m, 36 H, CH$_2$C$H_3$, PC$H_3$), 2.20 [sept, $^3J_{H,H}$ = 7.5 Hz, 4 H, C$H$(CH$_3$)$_2$] ppm. $^{31}$P NMR (C$_6$D$_6$): $\delta$ = –167.2 (s) ppm.

**Supporting Information** (see footnote on the first page of this article): Details about the $^{119}$Sn Mössbauer spectrum of compound **2**.

# Structural Studies of β-Cyclodextrin and Permethylated β-Cyclodextrin Inclusion Compounds of Cyclopentadienyl Metal Carbonyl Complexes

**Susana S. Braga,[a] Filipe A. Almeida Paz,[a] Martyn Pillinger,[a] João D. Seixas,[b,c] Carlos C. Romão,*[b,c] and Isabel S. Gonçalves*[a]**

**Keywords:** Ab initio calculations / Cyclodextrins / Inclusion compounds / Iron / Molybdenum / Sandwich complexes

[CpM(CO)$_n$Cl] complexes with M = Fe ($n$ = 2) and Mo ($n$ = 3) have been immobilised in plain β-cyclodextrin (β-CD) and permethylated β-CD (TRIMEB) by methods tailored according to the stabilities and solubilities of the individual components. Four adducts were obtained with a 1:1 host/guest stoichiometry. The compounds were studied by powder X-ray diffraction (XRD), thermogravimetric analysis (TGA), $^{13}C\{^1H\}$ CP/MAS NMR and FTIR spectroscopy. A comparison of the experimental powder XRD data for the TRIMEB/[CpMo(CO)$_3$Cl] inclusion compound with reference patterns revealed that the crystal packing is very similar to that reported previously for a TRIMEB/ethyl laurate inclusion compound. The unit-cell parameters refined to $a$ = 14.731, $b$ = 22.476, $c$ = 27.714 Å (volume = 9176.3 Å$^3$), and the space group was confirmed as $P2_12_12_1$. A hypothetical structural model of the inclusion compound was subsequently obtained by global optimisation using simulated annealing.

## Introduction

Cyclodextrins (CDs) are water-soluble cyclic oligosaccharides that are capable of forming inclusion compounds with a wide range of organic molecules, inorganic ions and metallo-organic species.[1] Suitable guests include transition metal complexes and organometallic compounds bearing hydrophobic ligands such as cyclopentadienyl (Cp = $\eta^5$-$C_5H_5$) and $\eta^6$-arene groups.[2] With these ligands, the weaker categories of non-covalent bonding, such as van der Waals and charge-transfer interactions, assume considerable importance. CDs are known to bind ferrocene and its derivatives,[3] metallocene dihalides,[4] aromatic ruthenium complexes,[5] mixed-sandwich complexes such as [($\eta^5$-$C_5H_5$)Fe($\eta^6$-$C_6H_6$)]($PF_6$),[6] and half-sandwich complexes such as [CpFe(CO)$_2$X] (X = Cl, Me, CN),[7] [CpFe(CO)$_2$-$NH_3$]($PF_6$),[8] [CpMn(CO)$_3$],[9] [($\eta^6$-$C_6H_6$)Cr(CO)$_3$],[10] [Cp′Mo($\eta^3$-$C_3H_5$)(CO)$_2$],[11] [Cp′Mo($\eta^3$-$C_6H_7$)(CO)$_2$] and [Cp′Mo($\eta^4$-$C_6H_8$)(CO)$_2$]($BF_4$) (Cp′ = Cp, Ind).[12] Encapsulated metallo-organic complexes often exhibit markedly different physical and chemical characteristics compared to the bulk material, for example in their nonlinear optical properties,[13] electrochemical behaviour,[3b,3g,3i,3j,14] ligand substitution/insertion reactions,[7a,7b] and catalysis.[15] In the present work, we describe the synthesis and solid-state characterisation of inclusion compounds formed between the cyclopentadienyl metal carbonyl complexes [CpFe(CO)$_2$Cl] (**1**) and [CpMo(CO)$_3$Cl] (**2**) (Figure 1) and unmodified β-cyclodextrin and 2,3,6-tri-*O*-methyl-β-CD (TRIMEB). The encapsulation of the tricarbonylmolybdenum complex is of particular interest because this molecule is a precursor to the dioxomolybdenum(VI) complex [CpMoO$_2$Cl], which has been shown to be a very effective catalyst for the epoxidation of olefins using *tert*-butyl hydroperoxide as the oxidising agent.[16]

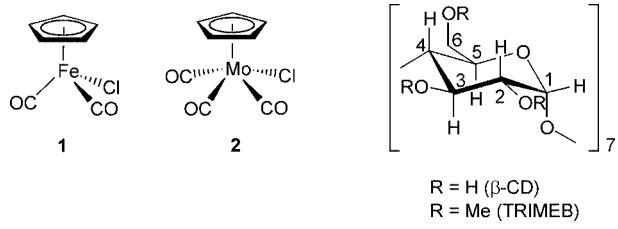

Figure 1. Guests and hosts used in this work.

Among the organometallic–cyclodextrin inclusion compounds described in the literature, only a few have been successfully characterised by single-crystal X-ray diffraction,[3e,3f,5,6] mainly because of the difficulty in preparing crystals of appropriate size that exhibit stability under the X-ray beam over the period of data collection. Useful structural information can, however, be obtained through a combination of other techniques such as powder XRD and NMR spectroscopy.[17–19] In particular, Caira described a

few years ago a reliable empirical technique based on the visual comparison of X-ray powder patterns, which can almost unambiguously identify the type of crystal-packing arrangement of CD molecules in a typical host–guest inclusion compound.[17] This method can be envisaged as a "manual" (in some cases not very effective) direct-space approach to finding a hypothetical structural model. Even though it gives a rather reasonable first approach, this technique is also limited in its essence as it cannot explore all of the possible combinations in direct space. In this paper, we use conventional powder X-ray data, in combination with the technique proposed by Caira, to produce a hypothetical structural model of the inclusion compound TRIMEB·[CpMo(CO)$_3$Cl], obtained by global optimisation using simulated annealing. The calculations were performed using the recently developed FOX program,[20,21] which has proven to be a reliable, fast and robust software package for the solution of many different types of compounds.[22–26] This kind of ab initio model idealisation is unusual among compounds typically composed of light atoms (such as carbon, hydrogen and oxygen), and, to the best of our knowledge, is completely unprecedented among cyclodextrin inclusion compounds.

## Results and Discussion

The relative solubilities of β-CD, TRIMEB, and the complexes [CpFe(CO)$_2$Cl] (**1**) and [CpMo(CO)$_3$Cl] (**2**) determined the method used for the preparation of the respective inclusion compounds. An initial CD/complex molar ratio of 1:1 was always used. The iron complex **1** is slightly water soluble, and so the encapsulations were carried out using a mixture of water and ethanol. The compound β-CD·[CpFe(CO)$_2$Cl] (**3**) precipitated as an orange microcrystalline solid upon slow cooling of a hot water/ethanol solution. The high solubility of the modified cyclodextrin TRIMEB meant that the corresponding adduct, TRIMEB·[CpFe(CO)$_2$Cl] (**4**), could only be isolated by complete evaporation of the solvents. For the molybdenum complex **2**, dichloromethane had to be used to solubilise the guest. β-CD inclusion was achieved by mixing a dichloromethane solution of **2** with an aqueous solution of β-CD. After stirring at 40 °C for 2 h, a microcrystalline brick-red precipitate formed at the interface between the two solutions, designated as β-CD·[CpMo(CO)$_3$Cl] (**5**). Inclusion of the molybdenum complex **2** in TRIMEB was performed by dissolving the guest in a dichloromethane solution of the host followed by vacuum-drying to isolate TRIMEB·[CpMo(CO)$_3$Cl] (**6**). This uncommon technique works particularly well for the methylated cyclodextrin TRIMEB due to its high solubility in organic solvents. In fact, the same method has been successfully used by some of us in previous work.[27] Elemental analysis of compounds **3**–**6** confirmed that the final host/guest molar ratios were close to 1:1.

X-ray diffraction studies allow the identification of true inclusion complexes of cyclodextrins, mainly based on the empirical evidence that the powder XRD patterns of these complexes should be clearly distinct from those obtained by the superimposition of the diffractograms of each individual component.[1b] Figure 2 shows the patterns for complexes **1** and **2**, β-CD, and the adducts **3** and **5**. The diffractograms for the adducts are clearly different from the sum of the individual patterns of β-CD and either the iron complex **1** or the molybdenum complex **2**. For compound **3**, the overall pattern matches reasonably well with the reference pattern reported by Caira for the isostructural series characterised by channel-type packing of β-CD dimers ($C_2$ space group).[17] This type of packing has been previously identified in several β-CD inclusion complexes of organometallic molecules, such as ferrocene derivatives,[3k] mixed-sandwich complexes,[6] and half-sandwich molybdenum carbonyl complexes.[11,12] Most of the reflections in the powder XRD pattern of compound **5** match those present in the corresponding pattern for the parent β-CD hydrate, even though substantial changes in relative intensities are markedly visible along with some slight displacements in the 2$\theta$ values. The reflection centred at about 4.5° 2$\theta$ is characteristic of cage-type packing, as observed for β-CD hydrate or β-CD inclusion complexes of relatively small guests.[17] The existence of this type of crystal packing for compound **5** would therefore be surprising, although it is known that a molecule at least as large as benzyl alcohol can be accommodated by the host without a change in the packing arrangement.[17]

Figure 3 shows the powder XRD patterns for complexes **1** and **2**, TRIMEB, and adducts **4** and **6**. Compound **4** is poorly crystalline, making it difficult to deduce the type of crystal packing arrangement. Nevertheless, a comparison of this pattern with those for the iron complex **1** and the parent TRIMEB indicates that a true inclusion compound has been isolated. The adduct TRIMEB·[CpMo(CO)$_3$Cl] (**6**) exhibits a better defined diffractogram, which could also be attributed to a new phase corresponding to a true inclusion compound. A careful inspection of this pattern suggests that the crystal packing should share close similarities with that found by Mentzafos et al. for a 1:1 inclusion compound comprising TRIMEB and ethyl laurate (in which the macrocycles are arranged along the *b* axis in a zigzag mode to form a distorted column structure).[28] This allowed us to perform a more in-depth structural evaluation using ab initio calculations. As typically observed for this type of compounds, the overall crystallinity of TRIMEB·[CpMo(CO)$_3$Cl] (**6**) is low due to structural orientation disorder of the host and/or the guest molecules, and the existence of several solvent molecules also highly affected by thermal disorder. Compound **6** diffracts very weakly at high angles and the diffractogram is generally characterised by poorly resolved lines (with large full-width-at-half-maximum). This creates, a priori, several limitations for a typical ab initio structural determination, and several approximations based on empirical evidence had to be taken into account (see below).

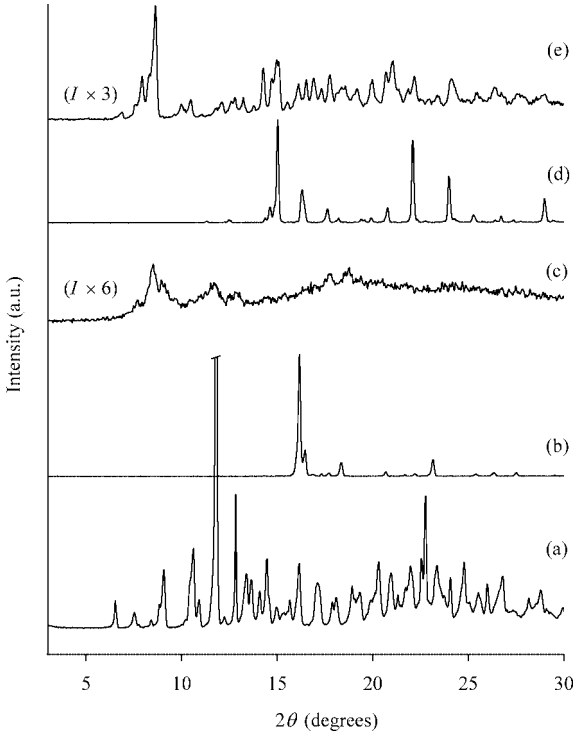

Figure 3. Powder XRD patterns of (a) TRIMEB, (b) [CpFe(CO)$_2$Cl] (**1**), (c) the inclusion compound TRIMEB·[CpFe(CO)$_2$Cl] (**4**), (d) [CpMo(CO)$_3$Cl] (**2**) and (e) the inclusion compound TRIMEB·[CpMo(CO)$_3$Cl] (**6**).

The ab initio determination of a hypothetical structural model for the inclusion compound TRIMEB·[CpMo(CO)$_3$Cl] (**6**) started by comparing the experimental data with the TRIMEB/ethyl laurate model compound, which has the Cambridge Structural Database (CSD)[29,30] refcode PINMAA [crystal data: $a$ = 14.796(2), $b$ = 22.444(6), $c$ = 27.720(8) Å, $V$ = 9205.03 Å$^3$, and space group $P2_12_12_1$]. Collected data were examined using the software package CHECKCELL,[31] and the unit-cell parameters refined to $a$ = 14.731, $b$ = 22.476, and $c$ = 27.714 Å (volume = 9176.3 Å$^3$), using 33 reflections for the CELREF subroutines.[32] By cross-examining the collected powder XRD pattern with the refined cell parameters, the space group of $P2_12_12_1$ for the inclusion compound **6** was unambiguously confirmed using CHECKCELL.

The modelling of compound **6** using FOX[20,21] started by assuming that the interactions between the guest [CpMo(CO)$_3$Cl] and the host TRIMEB molecules are mainly weak (van der Waals and hydrogen-bonding interactions) and mediated by close-packing principles. We assumed that the molecular geometries of the individual molecules remain relatively unchanged upon interaction to form the inclusion complex. In this case, FOX is particularly robust as individual molecules can be added as mathematical objects in the form of a Fenske–Hall Z-matrix, thus retaining some tacit knowledge of their geometry for the optimisation algorithm. Moreover, as the guest molecule contains a heavy atom (Mo), whose electron density contrasts well with the smeared-out density coming from the organic component, we assumed that the crystallographic position of [CpMo(CO)$_3$Cl] would be easily determined from the powder XRD pattern.

Firstly, the atomic coordinates of [CpMo(CO)$_3$Cl] were taken from the structure reported by Bueno et al. (deposited in the CSD with the refcode CPDMOC01),[33] and a Fenske–Hall Z-matrix (without hydrogen atoms) was created using BABEL.[34] The pivot atom was selected to be the central Mo in order to facilitate the mobility of the rigid molecule inside the unit cell. A Monte Carlo optimisation (using the optimised parallel tempering algorithm), in which the parameters of the Z-matrix were fixed (i.e., the molecule was treated as a rigid body), was launched in FOX and, after nearly 1,300,000 movements, the initial location of the crystallographically independent [CpMo(CO)$_3$Cl] complex was found (calculated weighted residual of $R_{wp}$ = 0.412). Starting from random initial positions, individual optimisations converged to nearly the same final crystallographic location, with comparable $R_{wp}$ factors. Figure 4 (b) shows the simulated powder XRD pattern for the hypothetical unit cell containing just the [CpMo(CO)$_3$Cl] complexes.

In the next stage of the global optimisation, the position of the [CpMo(CO)$_3$Cl] moieties was fixed and a second crystallographic object composed of a Fenske–Hall Z-matrix (also without hydrogen atoms) of the cyclodextrin TRIMEB, as reported by Mentzafos et al.,[28] was added to the unit cell. In the subsequent Monte Carlo optimisation steps using FOX (once again using the more efficient parallel tempering algorithm), the PINMAA residue was allowed to

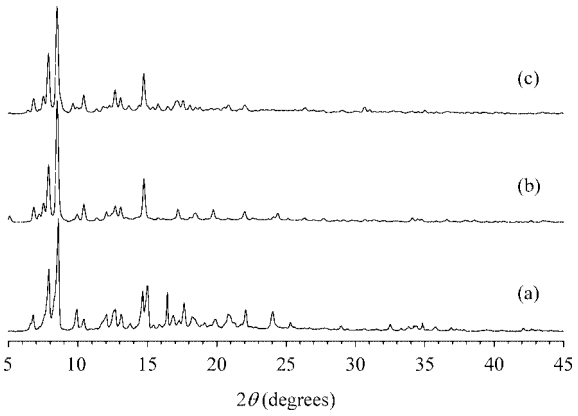

Figure 4. Powder XRD patterns of: (a) the as-synthesised inclusion compound TRIMEB·[$CpMo(CO)_3Cl$] (**6**), (b) the unit cell containing just the individual [$CpMo(CO)_3Cl$] complexes and (c) the hypothetical structural model for the inclusion compound **6**.

freely move as a rigid body and, after just four million moves, the model converged to that shown in Figure 5. Figure 4 (c) shows the simulated powder XRD pattern with a calculated weighted residual of $R_{wp}$ = 0.386. Apart from the general low crystallinity of the inclusion complex, the powder pattern is also affected by textural effects such as preferred orientation. To minimise such effects a refineable March–Dollase correction[35,36] was applied in FOX. The model obtained using the Monte Carlo optimisation clearly proves the existence of a true inclusion complex, with the final convergence being achieved without the use of any antibump restraints. Since this model was obtained by treating the molecules as rigid entities, some groups of atoms are closer together than they would be in a real crystal structure. This is particularly evident for the methyl groups of TRIMEB, which, in some cases, nearly overlap. Such "structural errors" could be eliminated by performing a Rietveld refinement in the present model. However, as high-resolution powder XRD data were not available due to the low crystallinity of the material, and probably could only be obtained using synchrotron radiation, preliminary studies using FULLPROF[37] did not produce the expected results (data not shown).

Thermogravimetric analysis was also useful for the recognition of inclusion complex formation in compounds **3**–**6** (Figure 6). The β-CD adducts β-CD·[$CpFe(CO)_2Cl$] (**3**) and β-CD·[$CpMo(CO)_3Cl$] (**5**) exhibit a step from room temperature up to about 65 °C, assigned to the removal of water molecules located in the β-CD cavities, and also in the interstices between the macrocycles. The corresponding weight losses are 10.7% for **3** and 6.2% for **5**, which are in agreement with the microanalysis results and indicate that the approximate number of water molecules per β-CD molecule in **3** and **5** are eight and six, respectively. For comparison, plain β-CD hydrate shows a similar well-defined step from room temperature up to about 80 °C (not shown), with a mass loss of 14.6% (11 water molecules per β-CD molecule). The reduction in the number of water molecules

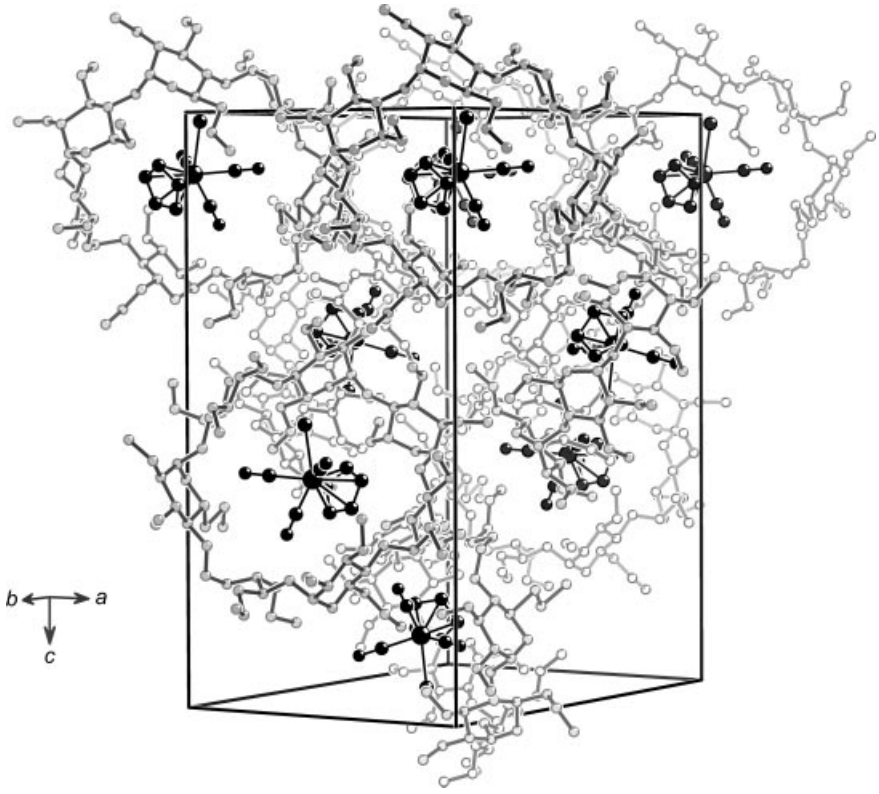

Figure 5. Unit cell contents, viewed in perspective towards the (1 7 0) plane, of the Monte Carlo optimised structural model of the inclusion compound TRIMEB·[$CpMo(CO)_3Cl$] (**6**). TRIMEB and [$CpMo(CO)_3Cl$] residues are represented with grey- and black-filled bonds, respectively.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

per β-CD molecule in the inclusion compounds is consistent with at least partial occupation of the β-CD cavities by the hydrophobic organometallic guests. After the dehydration step, the TG curves for **3** and **5** are very similar. There is a gradual mass loss in the temperature range of 65–200 °C (7.8% for **3** and 9.8% for **5**), attributed to the loss of CO and/or Cl ligands from the included guest molecules (since plain β-CD hydrate exhibits insignificant mass loss in the temperature range of 80–200 °C). The corresponding steps for the non-included complexes **1** and **2** are much more abrupt (not shown): 16.3% between 90 and 120 °C for **1**, and 23.6% between 100 and 160 °C for **2**. Finally, the host molecules in the two inclusion compounds start to decompose at about 205 °C, while plain β-CD hydrate starts to decompose around 270 °C. This difference is attributed to the promoting effects of iron and molybdenum on the decomposition of β-cyclodextrin, and is further evidence for the existence of a significant host–guest interaction in the inclusion compounds.[10] A similar result was obtained for the TRIMEB inclusion compounds TRIMEB·[CpFe(CO)$_2$Cl] (**4**) and TRIMEB·[CpMo(CO)$_3$Cl] (**6**). Thus, while pure TRIMEB starts to melt and decompose at about 175 °C (not shown), compounds **4** and **6** start at 135 and 150 °C, respectively (Figure 6). In the low-temperature range of the thermogram compound **6** exhibits a weight loss between 75 and 130 °C (2.8%), presumably due to the partial loss of CO and/or Cl ligands from the included guest molecules. No such step is evident for compound **4**, and only a minor mass loss of about 1% is observed from room temperature up to the onset of decomposition. Finally, it is worth noting that the residual masses at 500 °C are 6.1% for the inclusion compounds containing the Fe complex and 9.5% for the compounds containing the Mo complex.

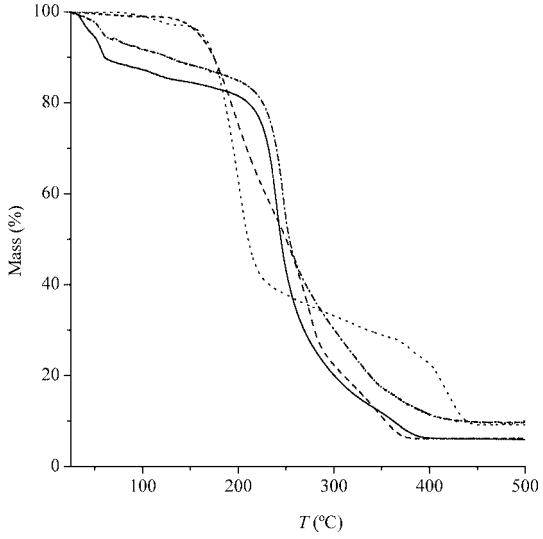

Figure 6. TGA curves of the inclusions compounds β-CD·[CpFe(CO)$_2$Cl] (**3**) (——), TRIMEB·[CpFe(CO)$_2$Cl] (**4**) (– – –), β-CD·[CpMo(CO)$_3$Cl] (**5**) (– · – ·), and TRIMEB·[CpMo(CO)$_3$Cl] (**6**) (· · · · ·).

The $^{13}C\{^1H\}$ CP/MAS NMR spectra of complexes **1** and **2**, and their corresponding inclusion compounds with β-CD and TRIMEB, are shown in Figure 7 for the [CpFe(CO)$_2$Cl] series and in Figure 8 for the [CpMo(CO)$_3$Cl] series. Plain β-CD hydrate exhibits a complex $^{13}C\{^1H\}$ CP/MAS NMR spectrum (not shown), with multiple sharp resonances for each type of carbon atom. These features have been correlated with different torsion angles about the α(1→4) linkages,[38] and with torsion angles describing the orientation of the hydroxy groups.[39] Upon inclusion to give β-CD·[CpFe(CO)$_2$Cl] (**3**) and β-CD·[CpMo(CO)$_3$Cl] (**5**), the resonances due to the C1, C4, C2,3,5, and C6 host carbon atoms (Figure 1) appear mainly as single broad peaks, with little or no structure, centred around $\delta$ = 104, 81, 73, and 61 ppm, respectively. Furthermore, the dispersion in the chemical shift for each signal (i.e., the chemical-shift range that comprises all of the resonances from the same carbon atom in distinct glycosidic units) decreases with respect to the β-CD spectrum. These observations are typically attributed to a symmetrisation of the β-CD macrocycle, that is, the encapsulation of the guest molecule induces the ring to adopt a less distorted conformation, with each glucose unit in a more similar environment.[3k,3l,4b,7d,11,12,40] For the inclusion compound **3** (Figure 7), the Cp carbon atoms of the guest molecule give rise to one weak resonance at $\delta$ = 89.2 ppm, which is shifted downfield by 2.5 ppm relative to the resonance for non-included [CpFe(CO)$_2$Cl] (**1**). The Cp carbon atoms of the mo-

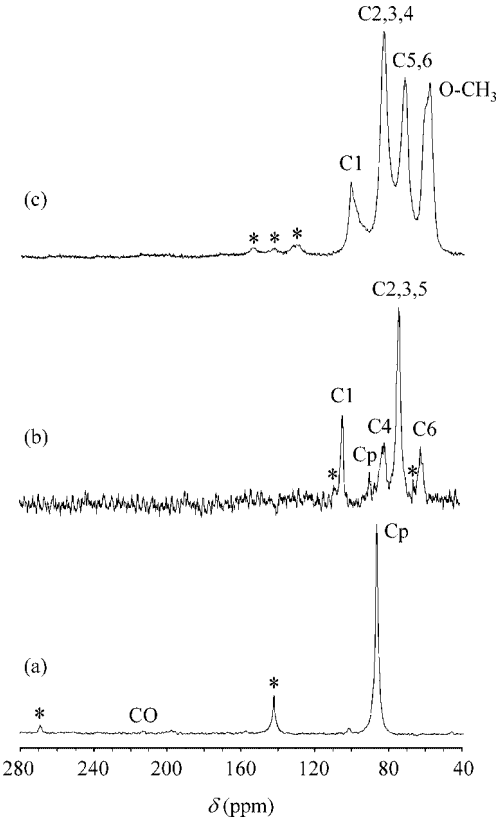

Figure 7. Solid-state $^{13}C\{^1H\}$ CP/MAS NMR spectra of (a) [CpFe(CO)$_2$Cl] (**1**), (b) the inclusion compound β-CD·[CpFe(CO)$_2$Cl] (**3**) and (c) the inclusion compound TRIMEB·[CpFe(CO)$_2$Cl] (**4**). Spinning sidebands are denoted by asterisks.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lybdenum complex in **5** give rise to two resolved peaks at $\delta$ = 94.8 and 96.1 ppm, which are shifted slightly upfield relative to the sharp line exhibited by non-included [$CpMo(CO)_3Cl$] (**2**) (Figure 8). The presence of two peaks may mean that there are two distinct inclusion modes for the guest molecule, comprising, for example, different orientations of the guest relative to the host and/or different degrees of penetration of the guest in the host cavity.

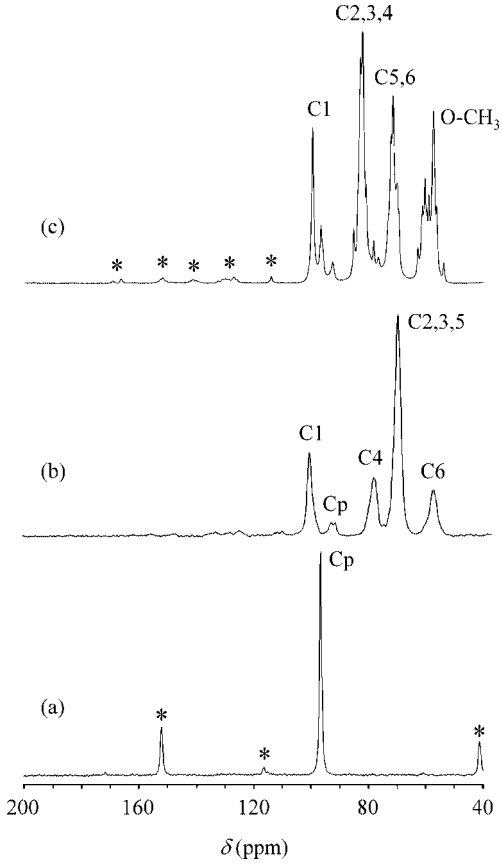

Figure 8. Solid-state $^{13}C\{^1H\}$ CP/MAS NMR spectra of (a) [$CpMo(CO)_3Cl$] (**2**), (b) the inclusion compound β-CD·[$CpMo(CO)_3Cl$] (**5**) and (c) the inclusion compound TRIMEB·[$CpMo(CO)_3Cl$] (**6**). Spinning sidebands are denoted by asterisks.

Like plain β-CD hydrate, the $^{13}C\{^1H\}$ CP/MAS NMR spectrum of TRIMEB also shows multiple resonances for each type of carbon atom (not shown).[27] This is because the host assumes a severely collapsed conformation in the solid state, which minimises the hydrophobic cavity in the absence of a hydrophobic guest. This multiplicity is lost for the inclusion compound TRIMEB·[$CpFe(CO)_2Cl$] (**4**) and only broad peaks are observed, indicating a change in the conformation of the host macrocycle (Figure 7).[27,41] The spectrum for the inclusion compound TRIMEB·[$CpMo(CO)_3Cl$] (**6**) is slightly different, exhibiting several resolved lines for each type of carbon atom (Figure 8). This could be related to the fact that the overall crystallinity of compound **6** is higher than that for compound **4**, as evidenced by powder XRD. For compound **6**, at least seven resonances are discernible for the methyl carbon atoms, indicating that these groups exist in several different well-defined environments. The expected Cp resonances for the guest molecules in compounds **4** and **6** cannot be confidently assigned due to overlap with the resonances for the C1 carbon atoms of the host. Also, for all of the inclusion compounds studied, even with a contact time of 2 ms, it was not possible to clearly identify the resonances (masked in the background) for the CO groups of the guest molecules. The presence of these groups was confirmed by IR spectroscopy. Thus, in addition to the intense and typical bands of the cyclodextrin hosts, the spectra contain strong bands in the CO stretching region (1940–2060 $cm^{-1}$). As expected, two bands are observed for compounds **3** and **4**, while three bands were identified for compounds **5** and **6**. These are slightly shifted relative to the corresponding bands for the non-included complexes **1** and **2** in the solid state. The spectra for the inclusion compounds also contain bands in the range 800–850 $cm^{-1}$ (out-of-plane CH deformation of the Cp ring) and 1420–1430 $cm^{-1}$ (C–C stretching vibration of the Cp ring).

## Concluding Remarks

Inclusion compounds comprising cyclodextrins and half-sandwich complexes of iron and molybdenum have been prepared with a 1:1 host-to-guest stoichiometry and characterised in the solid state by various techniques. The results support the existence of true inclusion compounds. By reference to previous molecular modelling and crystallographic studies of related organometallic–cyclodextrin adducts, it is reasonable to conclude that the interaction geometries in the studied compounds probably involve insertion of the Cp ligands inside the host cavities. The ab initio determination of a hypothetical structural model for the inclusion compound TRIMEB·[$CpMo(CO)_3Cl$] using X-ray studies in direct space has afforded a reliable structural model which is, on the one hand, in good agreement with the results obtained using the other techniques (such as TGA and solid-state NMR) and, on the other, a systematic implementation of the empirical technique previously described by Caira.[17] The low crystallinity of the sample under study, largely reflected in the generally poorly resolved powder XRD pattern, prevents a more precise structural refinement. However, we are currently applying the strategies described in this manuscript to other more crystalline cyclodextrin inclusion compounds. As mentioned in the introduction, oxidative decarbonylation of [$CpMo(CO)_3Cl$] yields a dioxomolybdenum(VI) complex which is an active catalyst for the epoxidation of olefins. We are investigating the effect that CD encapsulation has on the reactivity of the tricarbonyl complex towards oxidative decarbonylation, that is, the possibility of forming a CD·[$CpMoO_2Cl$] complex. Molecular encapsulation of the tricarbonyl complex with TRIMEB may be advantageous in several ways from a catalytic point of view, such as enhancing the solubility of the pre-catalyst in different solvents, and improving the stability of the resultant dioxomolybdenum(VI) complex.

## Experimental Section

**General Remarks:** β-CD was kindly donated by Laboratoires La Roquette (France), and heptakis-2,3,6-tri-*O*-methyl-β-CD was obtained from Fluka. All air-sensitive operations were carried out using standard Schlenk techniques under nitrogen. Solvents were dried by standard procedures, distilled under nitrogen or argon, and kept over 4-Å molecular sieves. Microanalyses for CHN were performed at the ITQB, Oeiras, Portugal (by C. Almeida), and Fe/Mo were determined by ICP-OES at the Central Laboratory for Analysis, University of Aveiro (by E. Soares). TGA studies were carried out using a Shimadzu TGA-50 system at a heating rate of 5 °C min$^{-1}$ under air. Powder XRD data were collected at ambient temperature on an X′Pert MPD Philips diffractometer (Cu-$K_\alpha$ X-radiation) with a curved graphite monochromator. Routine examination of compounds **1**–**6** was performed with quick scans with variable slit opening (Figures 2 and 3). Data for the structure optimisation (Figure 4) were collected with a fixed divergence slit of 1/8°, and a flat plate sample holder, in a Bragg–Brentano parafocusing optics configuration. Intensity data were collected by the step counting method (step 0.03° and time 35 s) in the $5° \leq 2\theta \leq 45°$ range. Infrared spectra were recorded with a Unican Mattson Mod 7000 FTIR spectrophotometer. $^{13}C\{^1H\}$ CP/MAS NMR spectra were recorded at 125.72 MHz on a (11.7 T) Bruker Avance 500 spectrometer, with an optimised π/2 pulse for $^1H$ of 4.5 μs, 2-ms contact time, a spinning rate of 7 kHz and 12-s recycle delays. Chemical shifts are quoted in parts per million from tetramethylsilane. The complexes $[CpFe(CO)_2Cl]$ (**1**) and $[CpMo(CO)_3Cl]$ (**2**) were prepared as described in the literature,[42] and characterised by elemental analysis and FTIR spectroscopy.

**β-CD·[CpFe(CO)$_2$Cl] (3):** A solution of β-CD (110 mg, 0.09 mmol) in water (2 mL) at 70 °C was added dropwise to a solution of $[CpFe(CO)_2Cl]$ (**1**; 20 mg, 0.09 mmol) in ethanol (1 mL), and the resultant brick-red solution was stirred for 30 min. After cooling slowly inside a Dewar flask, an orange microcrystalline precipitate was formed, which was separated from the mother liquor and dried. $(C_{42}H_{70}O_{35})\cdot(C_7H_5ClFeO_2)\cdot 8H_2O$ (1491.5): calcd. C 39.46, H 6.15, Fe 3.74; found C 39.52, H 6.54, Fe 3.31. TGA up to 65 °C revealed a sample weight loss of 10.7% (calcd: for loss of 8 $H_2O$, 9.7%). FTIR (KBr): $\tilde{\nu}$ = 3375 cm$^{-1}$ vs, 2967 sh, 2925 m, 2040 s, 1995 s, 1639 m, 1429 m, 1370 m, 1334 m, 1305 m, 1245 w, 1206 w, 1157 s, 1103 s, 1080 s, 1054 vs, 1027 vs, 1003 vs, 945 m, 937 m, 860 m, 841 m, 836 m, 757 m, 703 m, 669 m, 606 m, 635 m, 592 m, 576 m, 542 sh, 504 w, 476 m, 442 w, 412 m, 355 w. $^{13}C\{^1H\}$ CP/MAS NMR: $\delta$ = 104.2 (β-CD, C1), 89.2 (guest, Cp), 81.0 (β-CD, C4), 73.0 (β-CD, C2,3,5), 61.3 ppm (β-CD, C6).

**TRIMEB·[CpFe(CO)$_2$Cl] (4):** A solution of TRIMEB (1.55 g, 1.08 mmol) and $[CpFe(CO)_2Cl]$ (**1**; 230 mg, 1.08 mmol) in a mixture of water and ethanol (10 + 10 mL) was stirred for 1 h. The solution was then evaporated to dryness to give an orange solid. $(C_{63}H_{112}O_{35})\cdot(C_7H_5ClFeO_2)\cdot 2H_2O$ (1678.0): calcd. C 50.11, H 7.27, Fe 3.33; found C 50.00, H 6.08, Fe 3.34. FTIR (KBr): $\tilde{\nu}$ = 3480 cm$^{-1}$ m, 2984 s, 2931 s, 2841 m, 2050 s, 2004 s, 1792 w, 1751 w, 1717 m, 1623 m, 1418 sh, 1460 m, 1404 sh, 1368 m, 1324 m, 1304 m, 1196 sh, 1164 vs, 1141 vs, 1107 vs, 1087 vs, 1071 vs, 1035 vs, 968 s, 950 sh, 937 s, 907 m, 857 m, 785 vw, 755 m, 706 m, 605 m, 596 w, 567 m, 548 m, 470 vw, 376 vw, 348 m. $^{13}C\{^1H\}$ CP/MAS NMR: $\delta$ = 99.7 (TRIMEB, C1), 82.4 (TRIMEB, C2,3,4 and overlapping guest Cp), 71.3 (TRIMEB, C5,6), 58.1 ppm (TRIMEB, O-$CH_3$).

**β-CD·[CpMo(CO)$_3$Cl] (5):** A solution of $[CpMo(CO)_3Cl]$ (**2**; 32 mg, 0.12 mmol) in dichloromethane (1 mL) was added to a solution of β-CD (150 mg, 0.12 mmol) in water (4 mL) at 40 °C, and the resultant biphasic mixture was stirred for 2 h. During this period, a pale brick-red precipitate formed at the interface between the two solutions. The solid was recovered, washed with dichloromethane (2 mL) and water (10 mL), and dried. $(C_{42}H_{70}O_{35})\cdot(C_8H_5MoO_3Cl)\cdot 6H_2O$ (1523.6): calcd. C 39.42, H 5.76, Mo 6.30; found C 39.50, H 6.03, Mo 5.45. TGA up to 65 °C revealed a sample weight loss of 6.2% (calcd: for loss of 6$H_2O$, 7.1%). FTIR (KBr): $\tilde{\nu}$ = 3345 cm$^{-1}$ vs, 2923 s, 2853 sh, 2044 s, 1968 s, 1944 s, 1642 m, 1426 m, 1380 m, 1369 m, 1334 m, 1248 m, 1202 m, 1157 s, 1104 s, 1082 s, 1055 vs, 1028 vs, 1004 s, 945 m, 937 m, 860 m, 837 sh, 827 w, 759 m, 703 m, 606 m, 594 m, 576 m, 528 m, 499 vw, 474 w, 445 w, 435 w, 407 m, 404 sh, 378 vw, 359 m, 358 sh. $^{13}C\{^1H\}$ CP/MAS NMR: $\delta$ = 104.0 (β-CD, C1), 96.1, 94.8 (guest, Cp), 81.5 (β-CD, C4), 73.0 (β-CD, C2,3,5), 60.6 ppm (β-CD, C6).

**TRIMEB·[CpMo(CO)$_3$Cl] (6):** $[CpMo(CO)_3Cl]$ (**2**; 29.4 mg, 0.12 mmol) was added stepwise to a solution of TRIMEB (150 mg, 0.12 mmol) in dichloromethane (3 mL), allowing each fraction to dissolve before adding the next. The mixture was stirred for 2 h and then evaporated to dryness under reduced pressure to obtain a bright brick-red solid product. $(C_{63}H_{112}O_{35})\cdot(C_8H_5MoO_3Cl)\cdot 5H_2O$ (1800.1): calcd. C 47.37, H 7.11, Mo 5.33; found C 47.93, H 7.55, Mo 5.36. FTIR (KBr): $\tilde{\nu}$ = 3112 cm$^{-1}$ m, 3101 m, 3094 m, 2979 vs, 2929 vs, 2831 s, 2050 vs, 1962 vs, 1941 vs, 1641 m, 1464 s, 1420 sh, 1404 m, 1368 m, 1322 m, 1303 m, 1258 sh, 1194 vs, 1161 vs, 1143 vs, 1109 vs, 1090 vs, 1073 vs, 1041 vs, 970 vs, 951 s, 910 m, 877 sh, 856 m, 838 w, 824 m, 785 w, 754 m, 736 m, 704 m, 658 w, 602 m, 564 s, 524 s, 470 m, 432 w, 419 sh, 407 m, 399 sh, 377 w, 357 w, 350 w. $^{13}C\{^1H\}$ CP/MAS NMR: $\delta$ = 99.8, 96.9, 92.8 (TRIMEB, C1), 85.5, 83.1, 82.3, 81.0, 78.6, 76.8 (TRIMEB, C2,3,4), 73.6, 72.6, 71.8, 70.6, 70.3, 69.8 (TRIMEB, C5,6), 63.2, 61.6, 60.9, 60.1, 59.3, 57.8, 56.7, 54.1 ppm (TRIMEB, O-$CH_3$).

## Acknowledgments

This work was partly funded by the FCT, POCTI, and FEDER (project POCTI/CTM/46780/2002). We wish to thank Prof. João Rocha for access to research facilities and Paula Esculcas for assistance with the solid-state NMR experiments. We are also grateful to Celeste Azevedo for carrying out the TGA experiments and to Rosário Soares for collection of the powder diffraction data.

# Peroxotungstates and Their Citrate and Tartrate Derivatives

Shu-Ya Hou,[a,b] Zhao-Hui Zhou,*[a] Tao-Ran Lin,[a] and Hui-Lin Wan[a]

**Keywords:** Bioinorganic chemistry / Peroxo ligands / Polyoxometalates / Tungsten

The reaction of potassium tungstate with the biologically relevant ligands citric and tartaric acid, in the presence of hydrogen peroxide, was investigated to discover the effect of pH variation on the product pattern. The reaction with citric acid led to the formation of the dimer $K_5[WO(O_2)_2(Hcit)H(Hcit)(O_2)_2OW]\cdot 6H_2O$ (**1**; $H_4cit$ = citric acid) due to carboxyl-carboxylic acid hydrogen bonding in the pH range 2–5; this complex can also be obtained by an exchange reaction between the oxo ligands of the dimeric hydrogencitrate tungstate $K_4[W_2O_5(Hcit)_2]\cdot 4H_2O$ (**6**) and $H_2O_2$. Interestingly, a novel dimeric peroxotungstate $K_3[W_2O_3(O_2)_4(OH)]\cdot H_2O$ (**2**), without the coordination of citrate ligands, was isolated in the pH range 7–9, as confirmed by $^{17}O$ NMR solution studies. The reaction of potassium tungstate with (*R*,*R*)-tartaric acid afforded the tartratoperoxotungstate $K_4[W_2O_2(O_2)_4\{(R,R)\text{-tart}\}]\cdot 3H_2O$ [**3**; $H_4tart$ = (*R*,*R*)-tartaric acid] in the pH range 1–3. The dimeric peroxotungstate $K_2[W_2O_3(O_2)_4(H_2O)_2]\cdot 2H_2O$ (**4**) was found to react with citric or tartaric acid at pH 2–5 or 2–3, respectively, to give species **1** and **3**. Evidence that **1** exists as a dimer in solution is presented. The three complexes were characterized by elemental analysis, IR and NMR spectroscopy, and X-ray structural analyses. The formation of these complexes is dictated by pH, and the thermal stabilities of **1** and **3** vary with the coordinated ligands.

## Introduction

Due to their catalytic activity and specialized redox behavior, peroxotungstates have received special attention in a variety of industrial, pharmaceutical, and biological processes as they can be regarded as an environmentally friendly alternative to traditional oxidation reactions that represents an improvement in terms of pollution prevention.[1] They are widely used in stoichiometric as well as catalytic oxidation in organic chemistry,[2] for example in the oxidation of alcohols,[3,4] internal alkenes,[5] amines,[6] sulfides,[4,7,8] isobutyraldehyde,[9] hydroquinones,[2] bromide,[10] benzyl chlorides,[11] epoxidation of chiral allylic alcohols,[12] geraniol, linalool[13] and also in olefin epoxidations,[14–17] such as cyclohexene,[18] propylene,[19] alkene,[20] and *cis*-1-propenylphosphonic acid.[21] To better understand these catalytic processes, a more detailed characterization of peroxotungstates is necessary. It appears that $[W(O_2)_4]^{2-}$ predominates at high pH (>7) and in the presence of excess $H_2O_2$,[22] whereas at intermediate pH (1.3–7.0) the dimer $[W_2O_3(O_2)_4(H_2O)_2]^{2-}$ is the major species,[23] and at lower pH the solution become unstable and lose oxygen.[24] Although other peroxotungstates have also been observed in the solid state[25–27] and solution,[28,29] the key to stabilizing peroxotungstates is to incorporate a ligand that can effectively coordinate to tungsten. The reactivity of peroxo complexes also depends on both the number and nature of the auxiliary ligands.

A variety of peroxotungstates with oxygen and nitrogen donors have been studied in solution and in the solid state.[28–39] However, unlike peroxomolybdates(VI), which have been investigated extensively,[40–47] fewer peroxotungstate species with other ligands have been structurally reported. Known compounds include dimeric oxalate and tetranuclear carbonate complexes such as $M_2[WO(O_2)_2(C_2O_4)]$ (M = $K^+$, $NH_4^+$)[48,49] $[(n\text{-}C_4H_9)_4N]_2[W_2O_2(O_2)_4(C_2O_4)]$,[50] $K_6[W_4O_8(O_2)_6(CO_3)]\cdot 6H_2O$,[51] or isoperoxotungstates like $K_2[W(O_2)_4]$,[22] $K_2[W_2O_3(O_2)_2(H_2O)_2]\cdot 2H_2O$,[23] $(Me_3CNH_3)_4[W_4O_{12}(O_2)_2]$,[25] $[(n\text{-}C_4H_9)_4N]_2[W_4O_6(O_2)_6(OH)_2(H_2O)_2]\cdot H_2O$,[26] and $Cs_2(CN_3H_6)_3[(C_2H_5)_2NH_2][W_7O_{22}(O_2)_2]\cdot 3H_2O$.[27]

Citrate ions are present in most plant and animal tissues where they regulate various fundamental physiological processes and are intermediates in carbohydrate metabolism, such as in the Krebs cycle. (*R*,*R*)-Tartaric acid, which is also widely distributed in nature and is classified as a fruit acid, is another example of an α-hydroxycarboxylic acid that is involved in many biochemical processes. Our study in this field has been undertaken in order to answer one fundamental question, namely whether a pH variation can act as the sole factor to induce structural changes in isolable peroxotungstates in a hydrogen peroxide solution containing both tungstate and citrate or tartrate ions. It should be

noted that peroxotungstates are much more unstable and their isolation is more difficult than their peroxomolybdate homologs.

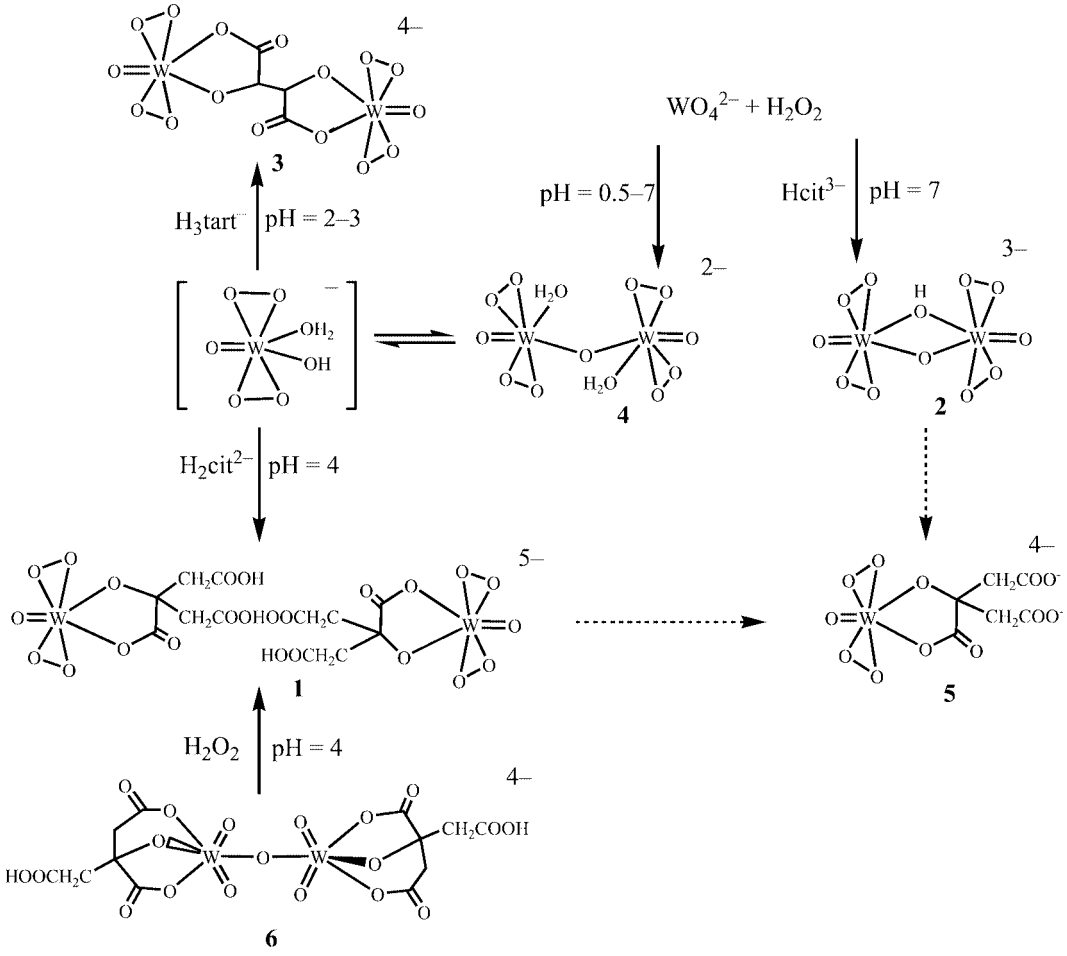
Here we report the isolation and characterization of the dimeric citrato and tartrato peroxotungstates $K_5[WO(O_2)_2(Hcit)H(Hcit)(O_2)_2OW]\cdot 6H_2O$ (**1**) and $K_4[W_2O_2(O_2)_4\{(R,R)\text{-tart}\}]\cdot 3H_2O$ (**3**). The hydroxy-bridged dinuclear peroxotungstate $K_3[W_2O_3(O_2)_4(OH)]\cdot H_2O$ (**2**) was also isolated serendipitously from a weakly basic solution and is the first example of an isolated dimeric $W_2O_3(O_2)_4(OH)$ skeleton.

## Results and Discussion

Scheme 1 shows the different pathways that lead to peroxo compounds **1**–**4**. The compound numbers shown correspond both to the potassium salts and the anions of the complexes, which are used interchangeably in this description. It appears that pH acts as a decisive factor in dictating the structural features of the isolated complexes. When the pH of an aqueous solution containing potassium tungstate, potassium citrate, and excess hydrogen peroxide was adjusted to 2–5, the dimer **1** was isolated, and this compound could also be isolated by the treatment of **4** with citric acid under comparable conditions. The dimeric peroxotungstate **4** is in equilibrium with the monomeric species in aqueous solution,[29] and it is possible that the monomeric species reacts directly with the citrate or tartrate to form **1** or **3**. Alternatively, complex **1** was prepared at pH 4 by the reaction of $H_2O_2$ with the dimeric hydrogencitratodioxotungstate $K_4[W_2O_5(Hcit)_2]\cdot 4H_2O$ (**6**), which was isolated from a solution of potassium tungstate and citric acid at pH 3.0–3.5. This is a clear demonstration that the β-carboxylate in complex **6** is relative weakly coordinated and can be detached by a peroxo group, which results in the formation of a more stable didentate citrate peroxotungstate at pH 2–5.

It is significant that **1** is a centrosymmetric dimer formed through the linear hydrogen bonding of a β-carboxy to a β-carboxylic acid group [O···O = 2.502(8) Å]. In view of the intramolecular hydrogen-bonding distance [O···O = 2.636(7) Å] in salicylic acid,[52] and the ordinary OH bond of 0.96 Å, the hydrogen bonding in **1** must be very strong as an intramolecular mode. This, in turn, reveals the stability of dimer **1**. In light of its low solubility and its $^{13}C$ and $^{1}H$ NMR signals, which will be discussed later, **1** probably exists as a dimer both in the crystalline state and in solution due to this strong hydrogen bonding.

When the pH of the same solution that formed **1** was changed to 7–8, it slowly deposited $K_2[W_2O_3(O_2)_4(OH)]\cdot H_2O$ (**2**) instead of the molybdate(VI) analog $[WO(O_2)_2(cit)]^{4-}$ (**5**).[45] Here, citric acid acts as both reactant and buffer



Scheme 1. Synthesis and transformation of citrato- and tartratoperoxotungstates.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

agent to capture this species. As the pH value increases, the coordination ability of citrate with peroxotungstate decreases and therefore complex **5** is not isolated. Reversible dimerization and dissociation do not occur. It is known that the monomeric species $[W(O_2)_4]^{2-}$ is the principal species at high pH (7–9) in the presence of excess $H_2O_2$,[22] while the dimeric anion $[W_2O_3(O_2)_4(H_2O)_2]^{2-}$ (**4**) is the major species at intermediate pH (1.3–7.0). Complex **2** could be an intermediate between the two peroxotungstates mentioned above, and it can also be considered as the product of deprotonation of the coordinated water molecule in $K_2[W_2O_3(O_2)_4(H_2O)_2]\cdot 2H_2O$ (**4**). Complex **4** exhibits high catalytic activity for the epoxidation of various allylic alcohols using hydrogen peroxide in water.[53]

The pH is also critical in the formation of the tartratoperoxotungstate **3**. The reaction of potassium tungstate, (*R*,*R*)-tartaric acid, and excess hydrogen peroxide in aqueous solution at pH 2–3 gave **3**, which can also be obtained by treating **4** with (*R*,*R*)-tartaric acid under comparable conditions via the monomeric peroxo species. The higher pH only led to the formation of potassium tartrate. Complex **3** is efflorescent, and can easily be converted into a powder by dehydration.

An equilibrium between dimeric and monomeric peroxotungstate species like $[WO(O_2)_2(OH_2)]$ and $[W_2O_3(O_2)_4(H_2O)_2]^{2-}$ has been proposed,[28,29] therefore it does not seem necessary that **1** and **3** are directly formed from **4**. Although the detailed structures of the monomeric peroxotungstates remain controversial,[32] some monomeric species like $[WO(O_2)_2(OH_2)_2]$, $[WO(O_2)_2(OH)(OH_2)]^-$, $[WO(O_2)_2(OH)_2]^{2-}$, and $[WO(O_2)(OH)_3(OH_2)]$ are suggested.

Selected bond lengths and angles for the three compounds are summarized in Table 1, and further crystallographic data can be found in the Experimental Section. The structure of the anion in complex **1** is shown in Figure 1. Each tungsten atom is seven-coordinate with a pentagonal-bipyramidal geometry. The axial positions are occupied by the oxo ligand and the oxygen atom from an α-carboxy group. The equatorial positions are occupied by the two bonded peroxo groups and a deprotonated α-alkoxy group. The didentate ($\eta^2$-$O_2^{2-}$) ligand is a π-donor-like oxo ligand,[30] thus each peroxo and oxo ligand in this complex are in the *cis* configuration and interact with different metal orbitals. The citrate ion acts as a didentate ligand with the α-alkoxy and α-carboxy oxygen coordinated to the tungsten atom, while one of the β-carboxy groups is free to bind as a centrosymmetric dimer through a linear $[CO_2^-\cdots HO_2C]$ hydrogen bond, that is, one of the β-carboxylates of the citrate unit is bonded to the β-carboxylic acid group of the other unit.

Table 1. Selected bond lengths [Å] and angles [°] for $K_5[WO(O_2)_2(Hcit)H(Hcit)(O_2)_2OW]\cdot 6H_2O$ (**1**), $K_3[W_2O_3(O_2)_4(OH)]\cdot H_2O$ (**2**), and $K_4[W_2O_2(O_2)_4\{(R,R)\text{-tart}\}]\cdot 3H_2O$ (**3**).

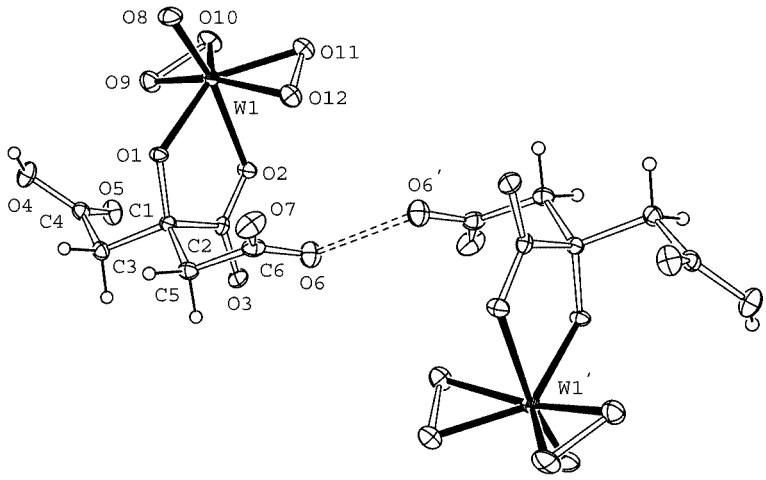

Figure 1. Perspective view of the anion structure of $K_5[WO(O_2)_2(Hcit)H(Hcit)(O_2)_2OW]\cdot 6H_2O$ (**1**).

As shown in Table 1, the W–O distances in complex **1** vary systematically. The distance of the W=O double bond is 1.707(4) Å, and the W–O(peroxo) bond lengths are in the range 1.927(4)–1.976(4) Å, which suggests that they are bonded asymmetrically. The slightly shorter W–O(alkoxy) bond [2.015(3) Å] indicates the deprotonation of the hydroxy group. The W–O(carboxy) bond is the longest [2.190(4) Å] due to the strong *trans* influence of the terminal oxo group.

An ORTEP diagram of the anion of **2** is shown in Figure 2. The dimeric complex **2** has a *cis* configuration and is bridged by two oxygen atoms. The existence of such a dimeric anion has been predicted previously by an $^{17}O$ NMR study.[28,29] The structure of **2** shows that one of the two bridged oxygen atoms is protonated, which represents a new isolated structural example of peroxotungstates. The coordination about the tungsten is essentially pentagonal bipyramidal. The equatorial place is defined by the five oxygen atoms corresponding to the two peroxo groups and one bridging oxygen atom. None of the atoms deviate more than 0.08 Å from the mean plane, and the tungsten atom is placed 0.23 Å above this plane. The axial positions are occupied by the oxo ligand and the hydroxy group. As shown in Table 1, the W–O6(hydroxy) bond [2.219(6) Å] is longer than the W–O7 bridge bond. The ligand binding is inferred to be significantly weaker at the axial position than the equatorial position due to the *trans* influence of the terminal oxygen.

The X-ray structure of the (*R*,*R*)-tartratoperoxotungstate **3** consists of discrete anions, potassium cations, and water molecules. As shown in Figure 3, the two $WO(O_2)_2$ moieties are spanned by a tartrato ligand that is didentate at each end, giving a pentagonal-bipyramidal coordination at the tungsten atoms. The tungsten is bound by a terminal oxo group, two didentate peroxo groups, and a didentate tartrate ligand that binds through its α-alkoxy and α-carboxy groups. The axial positions are occupied by the terminal oxo ligand [W–O = 1.707(9) Å] and an oxygen atom from the deprotonated carboxy group [W–O(2) = 2.224(8) Å]. The equatorial positions are occupied by the two slightly

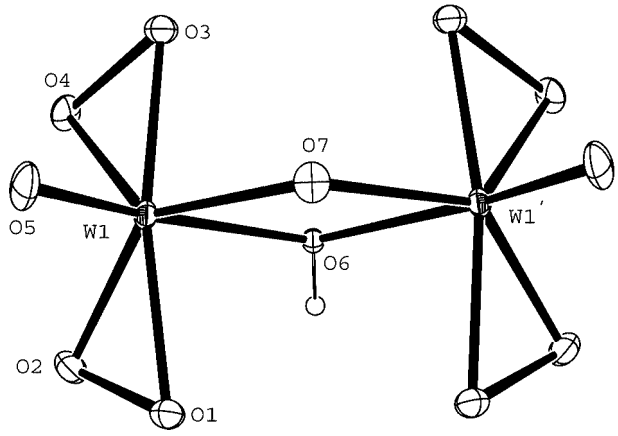

Figure 2. Perspective view of the anion structure of $K_3[W_2O_3(O_2)_4(OH)]\cdot H_2O$ (**2**).

asymmetrically bound peroxo ligands, while the α-alkoxy group of the tartrate makes up the distorted pentagon [W–O = 1.964(7) Å]. It appears that the α-alkoxy group assumes the equatorial rather than the axial position so as to form a strong bond. The W–O(peroxo) distances in **3** vary only slightly. The W–$O_2$, W=O, and O–O distances in the peroxo groups are all within the range of distances previously observed for this class of peroxo complexes. Moreover, the potassium ions in complexes **1**–**3** are coordinated by water molecules, the oxygen atoms of the peroxo groups, and citrate or tartrate ligands. The coordination numbers of the potassium ions are between 7 and 9 and the coordination bond lengths of K–O between 2.65–3.30 Å. These ions are important for the stabilities of the overall structures: replacing the counterion with $Na^+$ results in no isolation of peroxotungstates **1**–**3**, which suggests that the sodium salt is more soluble in water than the potassium salt.

Table 2 shows a comparison of Mo–O and W–O distances. The W–O distances of α-alkoxy group in the peroxotungstates are longer than those in their molybdate homologs, although the W–O distances of the α-carboxy groups are shorter than the Mo–O distances of the α-carboxy group.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

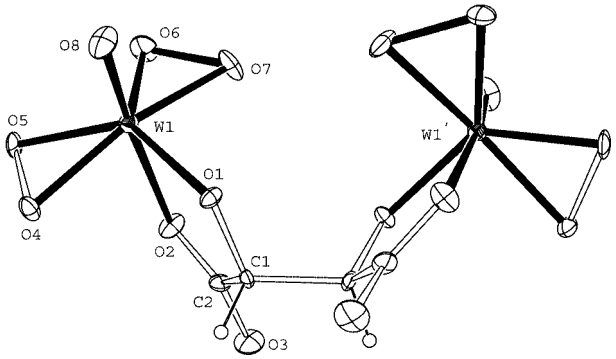

Figure 3. Perspective view of the anion structure of $K_4[W_2O_2(O_2)_4\{(R,R)\text{-tart}\}]\cdot 3H_2O$ (**3**).

O–O bond activation is a major feature of the reactivity of peroxo complexes, therefore it is instructive to compare the O–O distances in peroxotungstates and peroxomolybdates. The peroxo bonds in tungstates are slightly longer than those in molybdates, which indicates that activation of the peroxo group is much more effective with the peroxotungstates.

Complexes **1** and **3** display characteristic features of the coordinated citrate or tartrate ligand in their IR spectra. The coordinated carboxy frequencies are shifted to lower values compared to those of the free ligands. Specifically, absorptions for the antisymmetric stretching carboxy vibrations $\nu_{as}$(COOH) and/or $\nu_{as}$(COO) appear at 1731 and 1654 $cm^{-1}$ for **1** and 1642 and 1612 $cm^{-1}$ for **3**, and those of the symmetric stretching vibrations $\nu_s$(COO) appear at 1440–1330 $cm^{-1}$. For the peroxotungstates without a carboxy ligand there is an obvious band at 703 or 763 $cm^{-1}$, which is assigned to the W–O–W vibration for **2** or **4**, respectively. The W=O vibrations appear as strong bands at 950/970, 928, and 947 $cm^{-1}$ for **1**–**3**, respectively. The ν(O–O) vibration appears as a clearly defined strong band at around 840 $cm^{-1}$, which is a higher frequency than in the spectra of simple peroxide salts (800 $cm^{-1}$). Additional bands in the range 650–560 $cm^{-1}$ belong to $\nu_{as}$W(O–O) and $\nu_s$W(O–O).

Owing to their dissociation on dissolution in $H_2O$ ($D_2O$) the NMR spectra of **1** and **3** show additional peaks, although the major peaks could be interpreted. The $^{13}C$ NMR spectrum of $K_5[WO(O_2)_2(Hcit)H(Hcit)(O_2)_2OW]\cdot 6H_2O$ (**1**) displays four groups of resonance, with two close signals for each group. Complex **1** shows large low-field shifts of some $^{13}C$ resonances upon coordination relative to the corresponding carbons in the $KH_3cit$ ion at a similar pH (3.4). For example, the shifts of the α-alkoxy carbons at $\delta$ = 88.1 and 85.6 ppm are 14.5 and 12 ppm, respectively, and those of the α-carboxy carbons at $\delta$ = 189.0, 187.4 ppm are 11.4 and 9.8 ppm, respectively (Figure 4). It also shows several AB quartets for the methylene protons of the coordinated citrate ligand in the $^1H$ NMR spectrum. The proton of the methylene belonging to the β-carboxy that forms hydrogen bonds is shifted to lower field than the others. These data do not conflict with the existence of **1** as a dimer in solution.

In the tartrate complex $K_4[W_2O_2(O_2)_4((R,R)\text{-tart})]\cdot 3H_2O$ (**3**), two singlets appear at around $\delta$ = 186 and 88 ppm in the $^{13}C$ NMR spectrum due to the α-carboxy and α-alkoxy groups. These low-field shifts relative to (*R*,*R*)-tartaric acid ($\delta$ = 177.1 and 72.0 ppm) imply the involvement of coordination (Figure 5). These results prove that the tartrate serves as a tetradentate ligand to form a dinuclear complex. The $^1H$ NMR spectrum of **3** shows multiple signals around $\delta$ = 5.3 ppm. These shifts occur at lower fields than in the free ligand. When these complexes are dissolved in $D_2O$ they emit bubbles, thus the $^1H$ and $^{13}C$ NMR spectra display several additional peaks derived from the liberated ligand in addition to the signals of the complexes themselves.

Thermogravimetric (TG) and differential thermal analysis (DTA) were carried out for **1**–**4** under $N_2$; they indicated that the different ligands in the peroxo complexes give dif-

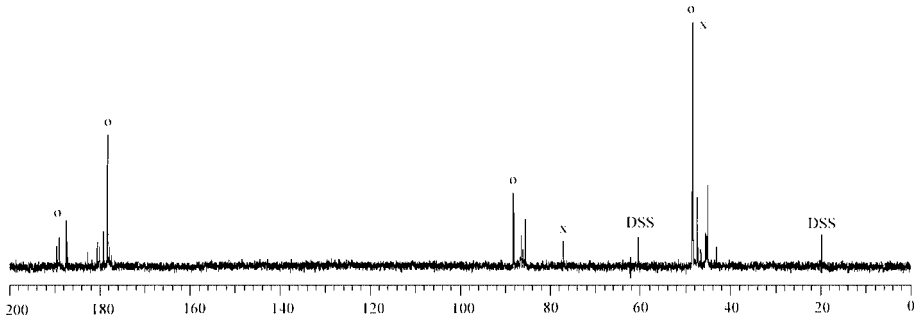

Figure 4. $^{13}C$ NMR spectra of the citratoperoxotungstate $K_5[WO(O_2)_2(Hcit)H(Hcit)(O_2)_2OW]\cdot 6H_2O$ (**1**). Labels: (x) free citrate; (o) coordinated citrate complex.

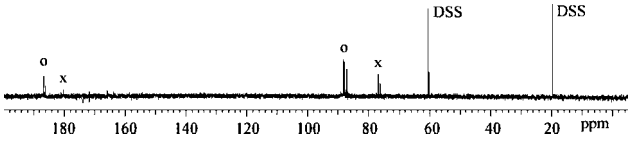

Figure 5. $^{13}C$ NMR spectra of the tartratoperoxotungstate $K_4[W_2O_2(O_2)_4\{(R,R)\text{-tart}\}]\cdot 3H_2O$(**3**). Labels: (x) free tartrate; (o) coordinated tartrate complex.

ferent thermal stability. The first decomposition in $K_5[WO(O_2)_2(Hcit)H(Hcit)(O_2)_2OW]\cdot 6H_2O$ (**1**), which is an endothermic process occurring at 112 °C, is believed to be associated with the loss of three $H_2O$ molecules, and is followed by the loss of another three $H_2O$ and peroxo groups at 166 °C. It is probable that **1** undergoes complete dehydration at this temperature and that this is followed by the rearrangement of the crystal lattice through an exothermic process, as confirmed by the TG and DTA plots, to form an anhydrous species such as $K_5[WO_3(Hcit)H(Hcit)O_3W]$. It then undergoes extensive decomposition at 301 °C to form potassium tungstate and carbonaceous matter due to the combustion of the citrate groups. The observed decomposition temperatures for the dehydration and decomposition of the peroxo groups of **1** are lower than for the corresponding Mo analogues, which may be related to the electrostatic interaction between $M^{6+}$ and $O_2^{2-}$.

The dimeric peroxotungstate $K_2[W_2O_3(O_2)_4(OH)]\cdot H_2O$ (**2**) dehydrates in air and no water-loss step is observed. It is stable up to 158 °C, where it loses two peroxo groups. $K_4[W_2O_2(O_2)_4((R,R)\text{-tart})]\cdot 3H_2O$ (**3**) is not particularly stable and decomposes at 108 and 138 °C in exothermic processes that correspond to the loss of three water molecules and the loss of peroxo groups, respectively. $K_2[W_2O_3(O_2)_4(H_2O)_2]\cdot 2H_2O$ (**4**) first loses $H_2O$ at 114 °C and then begins to lose its peroxo groups at 145 °C. These four complexes all showed rearrangement with exothermic process around 380 – 390 °C. From the data above, it is concluded that complexes **1** and **2** are much stable.

## Experimental Section

**Physical Measurements:** Infrared spectra were recorded as Nujol mulls between KBr plates with a Nicolet 360 FT-IR spectrometer. Elemental analyses were performed with an EA 1110 elemental analyzer. $^1H$ and $^{13}C$ NMR spectra were recorded in $D_2O$ on a Varian UNITY 500 NMR spectrometer using DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) as the internal reference. Thermogravimetric (TG) and differential thermal analysis (DTA) were carried out using a Netzsch Sta 449C thermal analyzer.

All experiments were carried out in the open air. All chemicals were analytical-grade reagents and were used without further purification. Nanopure-quality water was used throughout this work.

**Preparation of $K_5[WO(O_2)_2(Hcit)H(Hcit)(O_2)_2OW]\cdot 6H_2O$ (1):** Potassium tungstate, prepared from the reaction of tungsten trioxide (0.92 g, 4.0 mmol) and potassium hydroxide (2 M, 9 mL), was added dropwise to a solution containing citric acid (0.93 g, 4.4 mmol) and an excess of 30% hydrogen peroxide (1 mL). The resulting reaction mixture was adjusted to pH 4 with hydrochloric acid solution (1 M) in an ice-bath. Colorless crystals deposited gradually from the solution after several days in a refrigerator. They were collected and washed with ethanol to give **1** (0.87 g, 36%) as a white solid. $C_{12}H_{23}K_5O_{30}W_2$ (1210.5): calcd. C 12.3, H 1.7; found C 11.9, H 1.9. IR (KBr): $\nu_{as}$(C=O) = 1731 s, 1654 vs; $\nu_s$(C=O) = 1437 m, 1387 s, 1335 m; ν(W=O) = 950 s; ν(O–O) = 837 s; $\nu_{as}$W(O–O) = 637 s; $\nu_s$W(O–O) = 571 m $cm^{-1}$. $^1H$ NMR (500 MHz): $\delta$ = 2.86 (d, $J$ = 15.0 Hz, 1 H, $CH_2$), 2.83 (d, $J$ = 15.0 Hz, 1 H, $CH_2$), 2.76 (d, $J$ = 16.5 Hz, 1 H, $CH_2$), 2.72 (d, $J$ = 15.5 Hz, 1 H, $CH_2$) ppm. $^{13}C$ NMR (125 MHz): $\delta$ = 189.0, 187.4 $(CO_2)_\alpha$, 179.3, 178.4 $(CO_2)_\beta$, 88.1, 85.6 (≡CO), 48.5, 47.3 (=$CH_2$) ppm.

**Preparation of $K_3[W_2O_3(O_2)_4(OH)]\cdot H_2O$ (2):** Potassium tungstate (4 mmol), prepared in situ as above, and citric acid (0.92 g, 4.4 mmol) were dissolved in 5 mL of water and an excess of 30% hydrogen peroxide (1 mL) was added dropwise in an ice-bath. Potassium hydroxide was added to give a light-yellow solution of pH 7. Colorless crystals were obtained from EtOH/$H_2O$ solution after cooling in a refrigerator for several weeks and these were washed with ethanol to give **2** (8.2 mg, 0.5%) as a white solid. IR (KBr): ν(OH) = 3641 vs, 3409 vs; ν(W=O) = 970 s, 928 vs; ν(O–O) = 841 vs; ν(W–O–W) = 703 s; $\nu_{as}$W(O–O) = 605 s; $\nu_s$W(O–O) = 564 s $cm^{-1}$.

**Preparation of $K_4[W_2O_2(O_2)_4\{(R,R)\text{-tart}\}]\cdot 3H_2O$ (3):** An aqueous solution of (*R*,*R*)-tartaric acid (0.36 g, 2.4 mmol) and an excess of 30% hydrogen peroxide (1 mL) were added slowly to a stirred solution of potassium tungstate (4.0 mmol) in an ice-bath. Hydrochloric acid was then added to adjust the solution to pH 3. To induce precipitation, 95% ethanol solution was added dropwise until a permanent turbidity was obtained. The ethanol solution was kept in a refrigerator for several days to give colorless crystals, which were filtered and washed with ethanol to give **3** (0.60 g, 34%) as a white solid. $C_4H_8K_4O_{19}W_2$ (884.2): calcd. C 5.4, H 0.9; found C 5.0, H 0.7. IR (KBr): $\nu_{as}$(C=O) = 1642 vs, 1612 vs; $\nu_s$(C=O) = 1382 s; ν(W=O) = 926 s; ν(O–O) = 844 m; $\nu_{as}$W(O–O) = 627 m; $\nu_s$W(O–

O) = 577 m cm$^{-1}$. $^1$H NMR (500 MHz): $\delta$ = 4.456 (s, 2 H, CH) ppm. $^{13}$C NMR (125 MHz): $\delta$ = 186.6, 186.2 $(CO_2)_\alpha$, 88.2, 87.0 (≡CO) ppm.

**Transformation of $K_2[W_2O_3(O_2)_4(H_2O)_2]\cdot 2H_2O$ (4) into 1:** The dimeric peroxotungstate **4** (0.50 g, 0.7 mmol), prepared by the published method,[23] was dissolved in 5 mL of water. Citric acid (0.34 g, 1.5 mmol) was added to this solution followed by a small amount of 30% $H_2O_2$. The resulting mixture was stirred and the pH adjusted to 4 with potassium hydroxide (1 M). Colorless crystals of **1** (0.28 g, 33%) were obtained after one day in the refrigerator.

**Transformation of 4 into 3:** Peroxotungstate **4** (0.65 g, 0.94 mmol) in water was added to (*R*,*R*)-tartaric acid (0.15 g, 0.56 mmol) in an ice-bath. Hydrochloric acid was added followed by a small amount of 30% $H_2O_2$ to get a solution of pH 3. The solution was kept in a refrigerator for two days to give colorless crystals of **3** (0.092 g, 11%).

**Transformation of $K_4[W_2O_5(Hcit)_2]\cdot 4H_2O$ (6) into 1:** A solution of dimeric hydrogendioxocitratotungstate (**6**; 1.79 g, 1.4 mmol), prepared as reported previously,[56] in water was added to excess 30% hydrogen peroxide (1 mL) to give a solution of pH 4. The solution was kept in a refrigerator for two days to afford yellow crystals of **1** (0.94 g, 55%).

**X-ray Structure Determination:** Diffraction data were collected on a Bruker Smart Apex CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation at 296 K. Further details can be found in Table 3. The structures were solved with SHELXS-97 and refined by full-matrix least-squares procedures with anisotropic thermal parameters for all the non-hydrogen atoms. H-atoms were located from a difference Fourier map. All calculations were performed with the programs SHELXL-97 and SHELXS-97.[57,58]

CCDC-284258 to -284260 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (for details see the footnote on the first page of this article): Details of IR spectra, $^1$H NMR spectra, and thermogravimetric analyses.

## Acknowledgments

We thank the Ministry of Science & Technology (2005CB221408, 2001CB108906) and the National Natural Science Foundation of China (20571061, 20021002, 20423002) for their generous support of this research.

Treatment of the tridentate (*NN′N*) *N*-alkylaminopyrazole ligands bis[2-(3,5-dimethyl-1-pyrazolyl)ethyl]ethylamine (ddae), bis[2-(3,5-dimethyl-1-pyrazolyl)ethyl]isopropylamine (ddai) and bis[2-(3,5-dimethyl-1-pyrazolyl)ethyl]*tert*-butylamine (ddat) with [$PdCl_2(CH_3CN)_2$] in a 1:1 M/L ratio in $CH_2Cl_2$ produces [$PdCl_2$(*NN′N*)]. Treatment of the corresponding ligand with [$PdCl_2(CH_3CN)_2$] in a 1:2 M/L ratio in the presence of $AgBF_4$ in $CH_2Cl_2$/methanol (6:1) gives [PdCl(*NN′N*)]($BF_4$). The complexes [$PdCl_2$(*NN′N*)] were again obtained when the complexes [PdCl(*NN′N*)]($BF_4$) were heated under reflux in a solution of $NEt_4Cl$ in acetonitrile, which means that ligands ddae, ddai and ddat in complexes **1**–**6** are hemilabile. These $Pd^{II}$ complexes have been characterised by elemental analyses, conductivity measurements and IR and $^1H$ and $^{13}C\{^1H\}$ NMR spectroscopy. The $^1H$ NMR spectroscopic studies for compounds [$PdCl_2$(*NN′N*)] give evidence of $\kappa^2(N_{pz},N_{pz})$ coordination in acetonitrile and $\kappa^3(N_{pz},N_{amino},N_{pz})$ coordination in methanol. The X-ray structure of the complex [PdCl(ddae)]Cl·$H_2O$ has been determined. The $Pd^{II}$ is coordinated to the ddae ligand by two nitrogen atoms of the pyrazolyl groups and one nitrogen atom of the amine, along with one chlorine atom, in a slightly distorted square-planar geometry.

## Introduction

In the course of a study of pyrazole-derived ligands we have studied and reported the synthesis and characterisation of ligands combining a pyrazolyl group with some other functions containing O (alcohol or ether),[1] S (thiol or thioether),[2] P (phosphane or phosphinite)[3] or N (amine)[4] as donor atoms. The synthesis of pyrazolyl-N(amine) ligands has been developed by Driessen et al. and, so far, the study of their coordinating ability has been mainly focused on the design of chelating systems to mimic metalloenzymes.[5]

In our group, we have investigated the reactivity of bi- (*NN′*) and tridentate (*NN′N*) *N*-(alkylamino)pyrazole ligands {1-[2-(ethylamino)ethyl]-3,5-dimethylpyrazole, 1-[2-(isopropylamino)ethyl]-3,5-dimethylpyrazole and bis[(3,5-dimethylpyrazolyl)methyl]ethylamine} with $Rh^I$ and obtained the complexes [$Rh_2Cl_2(COD)_2$(*NN′*)],[4b] [Rh(COD)(*NN′*)]($BF_4$)[4e] and [$Rh(CO)_2$(*NN′N*)]($BF_4$), [4c] respectively. In a recent publication some of us have shown that bis[(3,5-dimethylpyrazolyl)methyl]ethylamine is a very flexible ligand with $\kappa^2(N,N)$ or $\kappa^3(N,N',N)$ bonding modes depending on the electronic configuration and the steric constrains around the metal.[4c] The hemilabile centre of the ligand is the nitrogen atom of the amine function.

Recently, we have synthesised the new $Pd^{II}$ complexes [$PdCl_2$(*NN′*)],[6] and [$Pd(NN')_2$]($BF_4$)$_2$[7] {*NN′* = 1-[2-(ethylamino)ethyl]-3,5-dimethylpyrazole, 1-[2-(isopropylamino)-ethyl]-3,5-dimethylpyrazole and 1-[2-(*tert*-butylamino)-ethyl]-3,5-dimethylpyrazole}; the NMR studies of the complexes have shown the rigid conformation of the ligands when they are complexed.

This paper extends this work to a new family of *NN′N* ligands with $Pd^{II}$. We report the synthesis of the ligands bis[2-(3,5-dimethyl-1-pyrazolyl)ethyl]ethylamine (ddae), bis[2-(3,5-dimethyl-1-pyrazolyl)ethyl]isopropylamine (ddai) and bis[2-(3,5-dimethyl-1-pyrazolyl)ethyl]*tert*-butylamine (ddat), and the study of their reactivity with $Pd^{II}$. The ligands contain two pyrazole nitrogens and one amine nitrogen as potential N-donor atoms (Scheme 1).

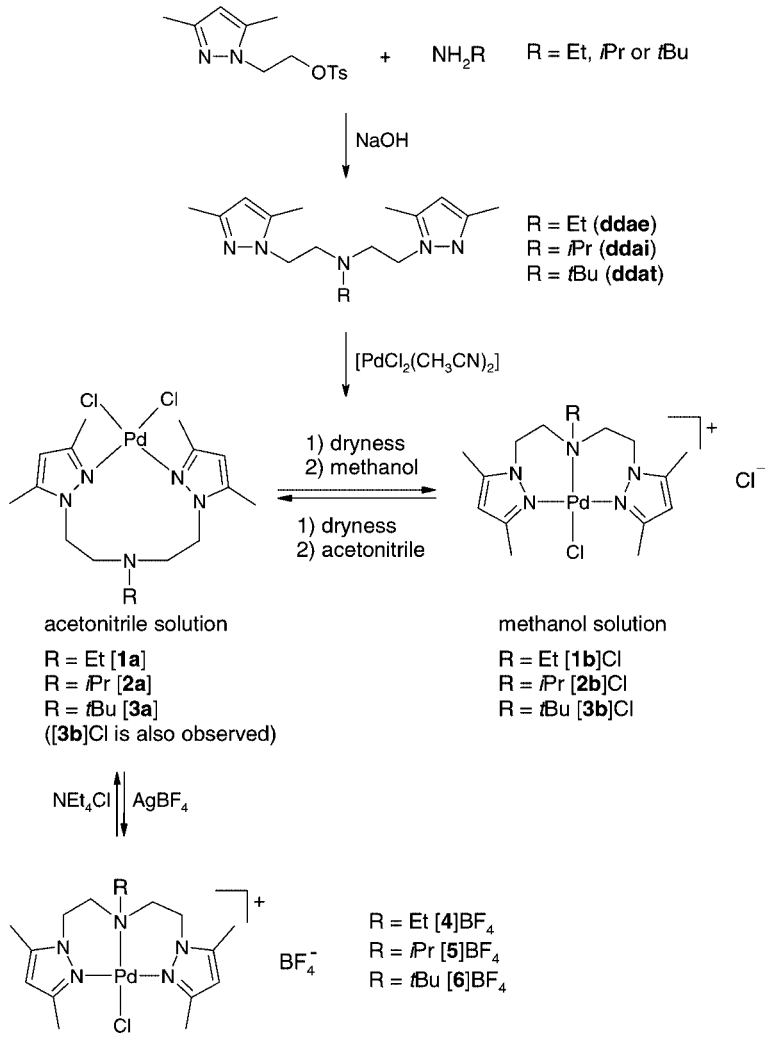
## Results and Discussion

### Synthesis and Spectroscopic Properties

Although bis[2-(3,5-dimethyl-1-pyrazolyl)ethyl]ethylamine (ddae) has already been described,[5g] an alternative

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1.

pathway for its synthesis is presented here. This new method is also useful to develop two new ligands that had not been described previously: bis[2-(3,5-dimethyl-1-pyrazolyl)ethyl]-isopropylamino (ddai) and bis[2-(3,5-dimethyl-1-pyrazolyl)-ethyl]*tert*-butylamino (ddat), neither of which could be synthesised by the same method that was used in the literature for ddae.

Synthesis of the three ligands consists of the treatment of 3,5-dimethyl-1-(2-toluene-*p*-sulfonyloxyethyl)pyrazole[8] with the appropriate primary amine (ddae: ethylamine; ddai: isopropylamine; ddat: *tert*-butylamine) in the presence of sodium hydroxide in water.

Each product was obtained as a yellow oil. This oil consists of a mixture of the mono- and bis(pyrazolyl)alkylamine ligands. The ligands were further purified by chromatography (silica gel 60) with ethyl acetate as eluent. The proportions of the bis(pyrazolyl)alkylamine/mono(pyrazolyl)alkylamine were 3:1 for ddae, 1:1 for ddai and 4:1 for ddat.

The ligands were characterised by elemental analysis, mass spectrometry and IR, $^1$H and $^{13}$C{$^1$H} NMR spectroscopy. The NMR signals were assigned by reference to the literature[9] and from DEPT, COSY and HMQC NMR experiments.

Complexes [$PdCl_2(NN'N)$] [$NN'N$ = ddae (**1**), ddai (**2**) and ddat (**3**)] were obtained by treatment of the corresponding ligand with [$PdCl_2(CH_3CN)_2$] in a 1:1 M/L ratio in $CH_2Cl_2$. Complexes [$PdCl(NN'N)$]($BF_4$) [$NN'N$ = ddae (**4**), ddai (**5**) and ddat (**6**)] were obtained by reaction of the corresponding ligand with [$PdCl_2(CH_3CN)_2$] in a 1:1 M/L ratio in the presence of $AgBF_4$ in $CH_2Cl_2$/methanol (6:1). When complexes **4**–**6** were heated under reflux in a solution of $Et_4NCl$ in $CH_3CN$ for 24 h complexes **1**–**3** were again obtained. The elemental analyses of products **1**–**3** are consistent with the formula [$PdCl_2(NN'N)$] and those for compounds **4**–**6** with [$PdCl(NN'N)$]($BF_4$).

Depending on the solvent used, different values of conductivity were found for complexes **1**–**3**. The conductivity values in methanol are 83–95 $\Omega^{-1}cm^2mol^{-1}$ (consistent with a 1:1 electrolyte), whereas those in acetonitrile are 78–80 $\Omega^{-1}cm^2mol^{-1}$ for **1** and **2** (in agreement with the non-electrolyte nature of the complexes) and 118 $\Omega^{-1}cm^2mol^{-1}$ for **3** (higher than for **1** and **2** due to the presence of a mixture of neutral and cationic isomers, as seen in the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

NMR section). The conductivity values for complexes **4**–**6** in acetonitrile and methanol are in agreement with 1:1 electrolytes. The reported values for $10^{-3}$ M solutions of non-electrolyte complexes are lower than 120 $\Omega^{-1}cm^2mol^{-1}$ or 80 $\Omega^{-1}cm^2mol^{-1}$ in acetonitrile or methanol, respectively, while the range of conductivity values for $10^{-3}$ M solutions of 1:1 electrolyte compounds in methanol is between 80–115 $\Omega^{-1}cm^2mol^{-1}$ and in acetonitrile between 120 and 160 $\Omega^{-1}cm^2mol^{-1}$.[10]

The IR spectra of all complexes are similar to those of the ligands, the most characteristic bands being those attributable to the pyrazolyl group: ν(C=C) and ν(C=N) between 1556 and 1554 $cm^{-1}$ and $\delta(C–H)_{oop}$ between 820 and 801 $cm^{-1}$. The ν(B–F) band between 1060–1053 $cm^{-1}$ is characteristic for **4**–**6**.

The IR spectra of the complexes in the 500–100 $cm^{-1}$ region were also recorded and show a well-defined band corresponding to ν(Pd–Cl) between 342 and 335 $cm^{-1}$. The number and energy of the bands is consistent with the presence of terminal chlorine. Bands attributable to ν(Pd–N) between 460 and 426 $cm^{-1}$ are also present.[11]

The $^1H$ NMR, $^{13}C\{^1H\}$ NMR, HMQC and NOESY spectra were recorded in $CD_3CN$ and methanol for **1**–**3**, and $CD_3CN$ for **4**–**6**, and show the signals of the ligands (ddae, ddai, and ddat). NMR spectroscopic data are reported in the Exp. Sect.

The $^1H$ NMR spectra of **1** and **2** in acetonitrile at room temperature show the presence of one isomer (**1a** and **2a**, respectively), whereas the spectrum of **3** shows the presence of two isomers (**3a** and **3b**$^+$) in a 1:3 ratio (Scheme 1). The $^1H$ NMR spectra of **1**–**3** in methanol at room temperature show the presence of one isomer (**1b**$^+$, **2b**$^+$ and **3b**$^+$, respectively). The most significant feature for probing structural difference is provided by the $N_{pz}CH_2CH_2N_{amine}$ resonances: the $CH_2$ signals of the isomers **1b**$^+$–**3b**$^+$ are more deshielded than those of **1a**–**3a**. This observation suggests that the nitrogen of the amine group is bonded to palladium in **1b**$^+$–**3b**$^+$. For isomers **1a**–**3a**, at 298 K, the methylene protons appear as four poorly defined broad bands. This led us to record variable-temperature spectra for **1** in acetonitrile. At higher temperatures (313 K) only one signal can be observed for each $CH_2$ of the $N_{pz}CH_2CH_2N_{amine}$ chain, whereas lowering of the temperature induces a progressive broadening and splitting of the two signals corresponding to each $CH_2$. At 283 K, four well-defined bands are observed at $\delta$ = 4.95, 4.31, 3.09 and 2.72 ppm. This suggests that at 313 K there is a fluxional process in which, with ring-flipping, the two hydrogens of each $CH_2$ are interconverted and only one signal can be observed. This process would take place with a $\Delta G^{\ddagger}$ value of about 60 $kJ\,mol^{-1}$, as deduced from the coalescence behaviour of the methylene resonances.[12]

The $^1H$ NMR spectra at room temperature for **4**–**6** complexes in acetonitrile show the presence of one isomer (**4b**$^+$, **5b**$^+$ and **6b**$^+$, respectively).

The NMR spectra of complexes **1**–**3** in methanol and **4**–**6** in acetonitrile were studied in detail. Treatment of the $N_{pz}CH_2CH_2N_{amino}$ fragment as an AA′XX′ system gave a set of coupling constants for each compound. These constants are consistent with the simulated spectra for compounds **1**–**6** obtained with the aid of the *g* NMR program.[13] All these results are reported in Tables 1 and 2. Figures 1 and 2 show the experimentally determined and simulated spectra for **2** and **5**, respectively. HMQC spectra were used to assign the signals of protons H-6 and H-7. The two protons of each $CH_2$ group in a $N_{pz}CH_2$-$CH_2N_{amino}$ chain are diastereotopic and thus give rise to four groups of signals, each attributable to a single hydrogen atom of one $N_{pz}CH_2CH_2N_{amino}$ chain. Each group of signals can be assigned as a doublet of doublets of doublets for H-6 and H-7.

In the NOESY spectra of compounds **1**–**3** in methanol and **4**–**6** in acetonitrile, it was observed that the methyl linked to the pyrazole at $\delta$ = 2.66 (**1b**$^+$), 2.63 (**2b**$^+$) 2.58 (**3b**$^+$), 2.63 (**4b**$^+$), 2.61 (**5b**$^+$) and 2.58 ppm (**6b**$^+$) shows an NOE with the doublet of doublets of doublets at $\delta$ = 4.58, 4.71, 4.71, 4.54, 4.55 and 4.48 ppm (**1b**$^+$–**6b**$^+$, respectively), but not with the ones at $\delta$ = 5.21, 5.30, 5.44, 5.10, 5.17 and 5.22 ppm (**1b**$^+$–**6b**$^+$, respectively). This allowed us to assign H-6a to the first set of doublet of doublets of doublets. From the NOESY spectra it can also be observed that the methyl groups from the ethylamino [$\delta$ = 1.65 (**1b**$^+$), 1.57 ppm (**4b**$^+$)], isopropylamino [$\delta$ = 1.55 (**2b**$^+$), 1.47 ppm (**5b**$^+$)] and *tert*-butylamino [$\delta$ = 1.22 (**3b**$^+$), 1.17 (**6b**$^+$)] moieties show NOEs with the doublet of doublets of doublets at $\delta$ = 2.87 (**1b**$^+$), 2.96 (**2b**$^+$), 3.30 (**3b**$^+$), 2.78 (**4b**$^+$), 2.85 (**5b**$^+$) and 3.08 ppm (**6b**$^+$). This information allowed us to assign H-7b to these signals. These assignments were possible thanks to the X-ray crystal structure of (**1b**)Cl·$H_2O$ (Fig-

ure 3), which shows that the shortest distances are between the methyl linked to the pyrazole at $\delta$ = 2.66 ppm and the doublet of doublets of doublets at $\delta$ = 4.67 ppm (H6b···H5a = 2.03, H11a···H15a = 2.01 Å) and between the methyl group from the ethylamino group and H-7b (H10b···H9c = 2.09 Å).

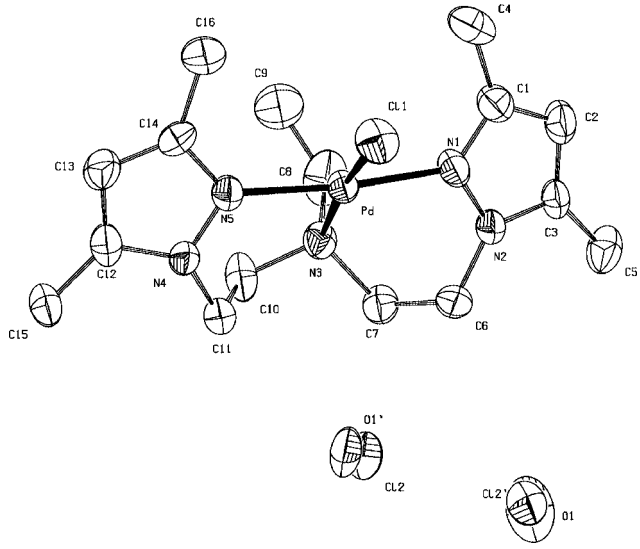

Figure 3. ORTEP drawing of [PdCl(ddae)]Cl·$H_2O$, showing all non-hydrogen atoms and the atom-numbering scheme; 50% probability amplitude displacement ellipsoids are shown.

### Crystal Structure of [PdCl(ddae)]Cl·$H_2O$

The crystal structure consists of discrete $[PdCl(ddae)]^+$ units, chloride anions and solvent molecules ($H_2O$) (Figure 3). The $H_2O$ and chloride ions are disordered.

The cation complex is mononuclear, and the $Pd^{II}$ is coordinated to the ddae ligand by its three donor atoms (two nitrogen atoms of the pyrazolyl group and one nitrogen atom of the amine moiety), along with one chlorine atom, in a slightly distorted square-planar geometry. The tetrahedral distortion can be observed from the bond angles and from the mean separation (0.0045 Å) of the atoms coordinated to the Pd atom in relation to the mean plane that contains these four atoms and the Pd atom. The dihedral angle between the planes N5–Pd–N3 and N1–Pd–N3 is 37.1(3)°. The ddae ligand acts as a tridentate chelate and forms two six-membered rings, with a boat conformation for Pd–N1–N2–C6–C7–N3 and a twist-boat conformation for Pd–N5–N4–C11–C10–N3, which share an edge (Pd–$N_{amino}$). The boat distortions in the six-membered rings are $\Delta C_s[(N3–C7)] = \Delta C_s[(N1–N2)] = 19.4(6)°$ for Pd–N1–N2–C6–C7–N3 and $\Delta C_s[(N3–C10)] = \Delta C_s[(N5–N4)] = 52.2(6)°$ for Pd–N5–N4–C11–C10–N3.

A $PdN_3Cl$ core is present in 89 complexes in the literature.[14] Some selected bond lengths and bond angles for this complex are listed in Table 3. The Pd–$N_{pz}$ bond lengths [2.019(6) and 2.027(6) Å], the Pd–$N_{amino}$ bond length [2.113(5) Å] and the Pd–Cl bond length [2.2991(18) Å] can be regarded as normal compared with the distances found

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in the literature. For Pd–$N_{pz}$, the literature describes values between 1.979 and 2.141 Å,[1a,1b,1f,2a–2d,2g,6,15] for Pd–$N_{amino}$ between 2.017 and 2.280 Å,[16] and for Pd–Cl between 2.280 and 2.341 Å.[1a,1b,1f,2a–2d,6,15b,15c]

Table 3. Selected bond lengths [Å] and angles [°] for [PdCl(ddae)]Cl·$H_2O$.

| | | | |
|---|---|---|---|
| Pd–N(1) | 2.019(6) | Pd–N(3) | 2.113(5) |
| Pd–N(5) | 2.027(6) | Pd–Cl(1) | 2.2991(18) |
| N(1)–Pd–N(5) | 172.3(2) | N(1)–Pd–Cl(1) | 90.44 (17) |
| N(1)–Pd–N(3) | 87.3(2) | N(5)–Pd–Cl(1) | 92.30(17) |
| N(5)–Pd–N(3) | 90.8(2) | N(3)–Pd–Cl(1) | 173.15(15) |

The $N_{pyrazole}$–$N_{amino}$ bite angles of the ligand are 87.3(2)° and 90.8(2)°, respectively, and are similar to the corresponding bite angles in the complexes [$PdCl_2$(*NN′*)] [*NN′* = deae, deat; 89.3(2)° and 88.16(18)°, respectively][6] and [Pd(*NN′*)$_2$]($BF_4$)$_2$ [*NN′* = deat; 87.3(2)°].[7]

## Conclusion

The *N*-alkylaminopyrazole ligands ddae, ddai, and ddat can coordinate $Pd^{II}$ centres in different ways. In complexes **1**–**3** these ligands show didentate coordination (*NN*) in acetonitrile and tridentate coordination (*NN′N*) in methanol. Furthermore, we have demonstrated the hemilabile properties of these ligands when coordinated to $Pd^{II}$.

Complexes **4**–**6**, where the ligand uses *NN′N* coordination, are obtained from **1**–**3** by treatment with $AgBF_4$. When complexes **4**–**6** are heated under reflux in a solution of $Et_4NCl$ in $CH_3CN$, **1**–**3** are obtained once again. This could be considered as type-III hemilability.[17]

## Experimental Section

**General Details:** The reactions were carried out under nitrogen using vacuum-line and Schlenk techniques. Solvents were dried and distilled according to standard procedures and stored under nitrogen. Elemental analyses (C, H, N) were carried out by the staff of the Chemical Analyses Service of the Universitat Autònoma de Barcelona on a Carlo Erba CHNS EA-1108 instrument. Conductivity measurements were performed at room temperature in $10^{-3}$ M acetonitrile and methanol, employing a CyberScan CON 500 (Euthech Instruments) conductimeter. Infrared spectra were run on a Perkin–Elmer FT spectrophotometer, series 2000 $cm^{-1}$ as NaCl pellets, KBr pellets or polyethylene films in the range 4000–100 $cm^{-1}$. $^1H$, $^{13}C\{^1H\}$, DEPT, COSY, HMQC, and NOESY NMR spectra were recorded with an NMR-FT Bruker 250 MHz spectrometer in $CDCl_3$, $CD_3CN$ or [$D_4$]methanol solutions at room temperature. All chemical-shift values ($\delta$) are given in ppm. Mass spectra were obtained with an Esquire 3000 ion-trap mass spectrometer from Bruker Daltonics. The complex [$PdCl_2(CH_3CN)_2$][18] was synthesised according to published methods. The precursor 3,5-dimethyl-1-[2-(*p*-tosyloxy)ethyl]pyrazole was prepared as described in the literature.[8]

**Synthesis of the Ligands Bis[2-(3,5-dimethyl-1-pyrazolyl)ethyl]ethylamine (ddae), Bis[2-(3,5-dimethyl-1-pyrazolyl)ethyl]isopropylamine (ddai) and Bis[2-(3,5-dimethyl-1-pyrazolyl)ethyl]-*tert*-butylamine (ddat):** The synthesis consists of the reaction between 3,5-dimethyl-1-[2-(*p*-tosyloxy)ethyl]pyrazole (6.17 g, 21 mmol), 11 mmol of the appropriate primary amine (ddae: 0.88 mL of 70% ethylamine; ddai: 0.98 mL of 97% isopropylamine; ddat: 1.18 mL of 98% *tert*-butylamine), and sodium hydroxide (0.96 g, 24 mmol). The reaction was carried out in 20 mL of water with continuous stirring at reflux for 4 h. The mixture was then cooled down to room temperature and extracted three times with 6 mL of $CH_3Cl$. The organic phase was collected and dried overnight with anhydrous $MgSO_4$. The solution was filtered off and the solvent removed under vacuum. Each product was obtained as a yellow oil. This oil consisted of a mixture of the mono- and bis(pyrazolylalkyl)amine ligands. The proportions of the bis(pyrazolylalkyl)amine and the mono(pyrazolylalkyl)amine were 3:1 for ddae, 1:1 for ddai and 1:4 for ddat.

In order to separate the two ligands, a silica gel column with ethyl acetate as eluent was used. The mono(pyrazolylalkyl)amine ligand stayed on top of the column whereas the bis(pyrazolylalkyl)amine ligand eluted. The solvent was removed under vacuum to give ddae as a pale-yellow oil, ddai as a pale-yellow solid (m.p. 25 °C) and ddat as a white solid (m.p. 30 °C).

**X-ray Crystal Structure for Compound [PdCl(ddae)]Cl·$H_2O$:** Crystals suitable for X-ray diffraction were obtained by crystallisation from methanol. A prismatic crystal was selected and mounted on a Enraf–Nonius CAD4 four-circle diffractometer. Unit-cell parameters were determined from automatic centring of 25 reflections ($12 < \theta < 21°$) and refined by least-squares method. Intensities were collected with graphite-monochromated Mo-$K_\alpha$ radiation using the $\omega/2\theta$ scan technique. 6425 Reflections were measured in the range $2.41 \le \theta \le 29.96°$, 6085 reflections of which were non-equivalent by symmetry [$R_{int}$(on $I$) = 0.031]. 4431 Reflections were assumed as observed by applying the condition $I > 2\sigma(I)$. Three reflections were measured every two hours as orientation and intensity control; significant intensity decay was not observed. Lorentz-polarisation but no absorption corrections were made. The structure was solved by direct methods using the SHELXS computer program,[19] and refined by full-matrix least-squares method with SHELX-97 [20] using 6425 reflections (very negative intensities were not assumed). The function minimised was $\Sigma w||F_o|^2 - |F_c|^2|^2$ where $\omega = [\sigma^2(I) + (0.0818P)^2 + 10.1890\ P]^{-1}$, and $P = (|F_o|^2 + 2|F_c|^2)/3$. All H-atoms were computed and refined using a riding model, with an overall temperature factor equal to 1.2-times the equivalent temperature factor of the atom to which they are linked. The final $R(F)$ factor and $R_w(F^2)$ values, as well as the number of parameters and other details concerning the refinement of the crystal structure, are gathered in Table 4.

# Synthesis of Novel α-Aminoboronate Complexes of Aminoboranes and Aminocyanoboranes

Amal Shibli[a] and Morris Srebnik*[a]

**Keywords:** Amines / Aminoboranes / Aminocyanoboranes / Boranes / Lewis acids

Tertiary amines activated either by borane ($BH_3$) or cyanoborane ($BH_2CN$) groups were α-C lithiated with *s*BuLi (2 equiv.) and then treated with 2-isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane to produce the α-aminoboronate complexes of aminoboranes and aminocyanoboranes **2**–**7** in 70–85 % yields.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

During the last 30 years much effort has been focused in the area of pharmaceutical chemistry on the synthesis and biological activity studies of boron analogues of α-amino acids (α-aminoboronic acids **1**), in which the carboxylic acid moiety is replaced by a boronic acid moiety, as they are highly effective inhibitors of serine proteases.[1] In addition, α-aminoboronic acids have been shown to be inhibitors for proteosomes, arginase, NOS,[2] and cysteine enzymes.[3] The incorporation of a Lewis basic amine and a Lewis acidic boronic acid functionality into the same molecule is a notoriously difficult procedure, and synthetic routes to these compounds are scarce. It is known that primary and secondary derivatives of α-aminoboronic acids are not stable in their neutral form; however, they can be stabilized either by forming their hydrochloride salts or by converting the molecules into their amide derivatives.[4–6] In this context, new effective methods to prepare amino and related boron compounds will have a tremendous impact on synthetic, bioinorganic, and pharmaceutical chemistry.[7–12] The first synthesis of an α-amidoboronic ester was reported by Matteson et al.,[13] and remains the standard method for synthesis of α-aminoboronic acids; however, it is a multistep method and is time consuming.

**1**

Deprotonation of tertiary amines can be promoted by a Lewis acid, since on forming a complex a positive charge develops on the nitrogen to inductively facilitate the removal of a proton from the α-C position. This concept of tertiary amine activation using Lewis acid activators was introduced by Kessar and co-workers in 1991. These authors used $BF_3$ as an activator that facilitated the α-metalation of several tertiary amine complexes.[14] Based on these results, in 1995 Ebden and co-workers applied a similar approach to aminoborane complexes, which underwent interesting metalation reactions.[15]

Trimethylaminocyanoboranes can also be easily α-deprotonated at the α-carbon and treated with various electrophiles to give more complicated aminocyanoboranes, as was recently reported by Takrouri et al.[16] The biological and pharmaceutical activities of aminocyanoboranes ($A{\cdot}BH_2CN$) and aminocarboxyboranes ($A{\cdot}BH_2COOH$) and their amide, ester, peptide, and transition metal derivatives have been investigated;[17] they have been shown to possess anticancer,[18] antiosteoporotic,[19] antiinflammatory,[20] and hypolipidemic properties.[20b,21] These molecules have also been mentioned as possible boron carriers to tumor cells for boron neutron capture therapy (BNCT).[22]

Based on the above results, we have now applied these methods with a more complex electrophile. Thus, the boron-containing electrophile 2-isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane was mainly used to give the α-aminoboronic ester attached to the cyano ($BH_2CN$) or borane ($BH_3$) groups on the same molecule. In this work, we report a novel, short, simple, and direct method to prepare novel α-aminoboronate complexes of aminoboranes and aminocyanoboranes in very good yields. Our method starts from tertiary amines that are activated either by borane or cyanoborane groups. This, in turn, leads to selective α-deprotonation. Reaction of the lithiated complexes with a boron-containing electrophile gives the title compounds.

## Results and Discussion

### Preparation of Aminoborane Derivatives

We initially focused on 2-isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane as an electrophile in our study. Treat-

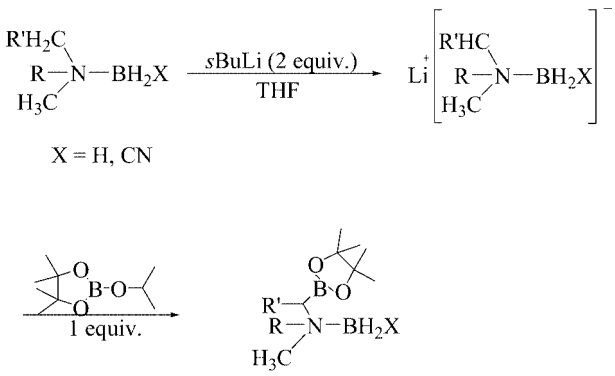
ment of the borane adduct with two equivalents of *s*BuLi in THF at –78 °C, warming to the room temperature, followed by recooling to –78 °C and addition of the electrophile gave good yields of the desired α-aminoboronic acid products **2** and **3** (Scheme 1, Table 1).



Scheme 1. Synthesis of α-aminoboronate complexes of aminoboranes and aminocyanoboranes.

Table 1. α-Aminoboronic acid derivatives **2**–**7** prepared from aminoboranes or aminocyanoboranes.

| Product | X | R′ | R | Yield [%][a] |
|---|---|---|---|---|
| **2** | H | Ph | $CH_3$ | 85 |
| **3** | H | 2-naph | $CH_3$ | 84 |
| **4** | CN | H | $CH_3$ | 83 |
| **5** | CN | H | $C_4H_9$ | 70 |
| **6** | CN | H | $C_9H_{19}$ | 80 |
| **7** | CN | H | $C_{12}H_{25}$ | 70 |

[a] Yields after column chromatography.

The use of an excess of *s*BuLi is necessary to get high yields, as using a lower amount of *s*BuLi resulted in reduced conversion to product and recovery of unreacted starting material. We suspect that this may be due to the known instability of organolithium reagents in THF.[23] It is also possible that some limited destruction of the borane complexes occurs by nucleophilic attack of *s*BuLi, resulting in partial consumption of the base. Adventitious water may also be involved.[15]

The products were stable enough to be purified on silica gel and were isolated as solids. However, these products should be stored at low temperature, otherwise they decompose slowly to give back the starting material.

### Preparation of Aminocyanoborane Derivatives

In an analogous manner, trialkylaminocyanoboranes were lithiated with *s*BuLi and then treated with 2-isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane to give the oily alkyl α-aminoboronic acid derivatives **4**–**7**. The desired products were purified on silica gel in high yields and in high purity (Scheme 1, Table 1).

Products **2**–**7** were fully characterized by $^1H$, $^{13}C$, and $^{11}B$ NMR spectroscopy, GC/MS, FT-IR spectroscopy, and elemental analysis. In the borane products **2** and **3** a new stereogenic center is created in the benzylic position, which means that the methyl groups attached to the nitrogen become diastereotopic and peaks for each group are evident in both the $^1H$ and $^{13}C$ NMR spectra. The methyl groups on the pinacol are also diastereotopic and peaks for each of the two methyls appear in the $^1H$ and $^{13}C$ NMR spectra.

The 4,4,5,5-tetramethyl-1,3,2-dioxaborolane group causes a high-field shift of the benzylic proton in the $^1H$ NMR spectra in products **2** and **3** and also for the methylenic protons in products **4**–**7** in comparison with the starting materials. In the $^{13}C$ NMR spectra of all products typical pinacol peaks are observed at $\delta$ = 24 [C($CH_3$)$_2$] and 84 ppm [$C$(CH$_3$)$_2$]. No peaks are observed for the carbon in the α-position to the boron due to the rapid relaxation of this boron-bound carbon.[24] Two peaks are observed in the $^{11}B$ NMR spectra of all the products: a positive boron chemical shift appears as a singlet at $\delta$ = 29–30 ppm, which is typical for a boron substituted with two oxygens, and a negative boron chemical shift, which is typically associated with tetracoordinate boron, appears as a quartet for products **2** and **3** at $\delta$ = –9 ppm or as a triplet for products **4**–**7** at $\delta$ = –14 ppm. These results agree with results published in the literature.[25] Typical peaks are also observed in the FT-IR spectra [2236–2407 (B–H), 2196–2199 (C≡N), 653–752 cm$^{-1}$ (B–N)].

## Conclusions

A series of novel α-aminoboronic acids **2**–**7** that also bear a borane or cyanoborane group have been prepared in a one-pot reaction in very good yields. This method involves short reaction times and is applicable to prepare diverse α-aminoboronic acids.

## Experimental Section

**Materials and Instrumentation:** Solvents were dried with sodium/benzophenone and freshly distilled before use. All reactions were carried out under dry nitrogen in oven-dried glassware. Melting points were determined on a Fisher scientific melting point apparatus. Infrared spectra were run for samples as neat films for liquids and in KBr disks for solids on a Bruker Vector 22 FT-IR spectrophotometer. $^1H$, $^{13}C$, and $^{11}B$ NMR spectra were recorded with a Varian Unity spectrometer (300, 75, and 96 MHz, respectively). Elemental analysis was performed in-house at the Hebrew University Microanalysis laboratory. Chemical shifts were recorded relative to an internal standard ($SiMe_4$) for $^1H$ and $^{13}C$ NMR and an external standard ($Et_2O{\cdot}BF_3$) for $^{11}B$ NMR spectroscopy. Liquid chromatography was performed by column chromatography with the indicated solvent system on Merck silica gel 60 (0.040–0.063 mm).

**Synthesis:** All aminoboranes complexes were prepared from borane methylsulfide and the corresponding amine using the literature method.[15] Trimethylaminocyanoborane was prepared from trimethylamine hydrochloride and sodium cyanoborohydride using the literature method.[26] All other cyanoboranes were prepared analogously as in the literature.[16] The electrophile 2-isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane was prepared using the literature method.[27] All other chemicals were obtained from Sigma–Aldrich and used as received without any further purification.

**General Procedure. Synthesis of 2:** A solution of *s*BuLi in cyclohexane (1.3 M, 2 mmol) was added dropwise to a solution of (dimethylbenzylamino)borane (0.149 g, 1 mmol) in THF (2.5 mL) at –78 °C. The solution was stirred for 30 min at –78 °C, then it was warmed up to room temperature for 30 min, before cooling down to –78 °C again and addition of 2-isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (0.186 g, 1 mmol) in one portion. After 2 min the cooling bath was removed, and the reaction mixture was stirred for 30 min at room temperature. A saturated $NaHCO_3$ solution (10 mL) was then added, the layers were separated, and the aqueous layer was extracted with diethyl ether (2 × 10 mL); the combined organic layers were dried with sodium sulfate. After evaporation of all the volatiles the residue was purified by column chromatography on silica gel (2.5% EtOAc in petroleum ether) to give *N*,*N*-dimethyl-*N*-[phenyl(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)methyl]aminoborane (**2**) as a white solid, m.p. 93–95 °C, (0.235 g; yield: 85%). $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 1.22 [s, 6 H, $C(CH_3)_2$], 1.28 [s, 6 H, $C(CH_3)_2$], 2.36 (s, 3 H, $NCH_3$), 2.70 (s, 3 H, $NCH_3$), 3.83 (s, 1 H, PhC*H*), 7.35 (m, 5 H, Ph) ppm; BH could not be detected. $^{11}$B NMR ($CDCl_3$, 25 °C): $\delta$ = –9.1 (q, $J$ = 96.25 Hz), 29.4 ppm (s). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25 °C): $\delta$ = 24.7, 24.8, 47.0, 52.1, 84.3, 128.6, 129.0, 132.5, 132.9 ppm; BC could not be detected. IR (KBr): $\tilde{\nu}$ = 2363 cm$^{-1}$ (B–H), 2321 (B–H), 2270 (B–H), 1469 (C–N) 664 (B–N) ppm. MS (EI): *m*/*z* = 275 [M$^+$], 261, 246, 231, 217, 202, 187, 172, 157, 132, 127. $C_{15}H_{27}B_2NO_2$ (275): calcd. C 65.45, H 9.81, N 5.09; found C 66.25, H 9.80, N 5.12.

**Preparation of *N*,*N*-Dimethyl-*N*-[naphthalen-2-yl(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)methyl]aminoborane (3):** White solid, m.p. 108–110 °C, (0.275 g; yield 84%). $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 1.23 [s, 6 H, $C(CH_3)_2$], 1.30[s, 6 H, $C(CH_3)_2$], 2.42 (s, 3 H, $NCH_3$), 2.78 (s, 3 H, $NCH_3$), 4.01 (s, 1 H, PhC*H*), 7.54 (m, 4 H), 7.84 (m, 2 H), 7.95 (s, 1 H) ppm; BH could not be detected. $^{11}$B NMR ($CDCl_3$, 25 °C): $\delta$ = –9.0 (q, $J$ = 94.38 Hz), 29.1 ppm (s). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25 °C): $\delta$ = 24.5, 24.6, 46.9, 52.0, 84.1, 126.3, 126.7, 127.5, 127.9, 128.1, 129.91, 129.95, 132.4, 133.0, 133.1 ppm; BC could not be detected. # Facile and Reliable Synthesis of Tetraphenoxyborates and Their Properties

Itamar M. Malkowsky,[a] Roland Fröhlich,[b] Ulrich Griesbach,[c] Hermann Pütter,[c] and Siegfried R. Waldvogel*[a]

**Keywords:** Borates / Sodium / Anions / Phenolates

Tetraphenoxyborates are reliably prepared in a two-step sequence, exploiting less corrosive reagents like boric acid and the corresponding phenols. The broad scope of this transformation is demonstrated in 22 examples. Several solid-state structures reveal the preferential conformation of the phenoxy moieties allowing cation interaction. Furthermore, a novel architecture of a phenoxy-substituted tetraborate was found. Surprisingly, the tetraphenoxyborates exhibit a good stability in neutral and basic media.

## Introduction

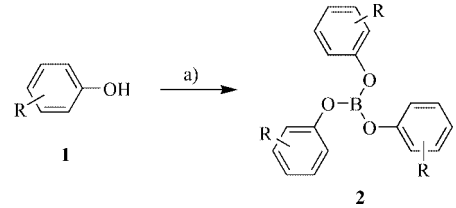
Tetracoordinated borates play an important role in nature.[1] In particular, these natural products are involved in the communication among bacterial microorganisms.[2] Size, oxophilic nature, and a maximum coordination number of four predestine boron for templating alkoxy or phenoxy moieties in an efficient manner. The synthesis and properties of tetracoordinated borates are well established, whereas the corresponding tetraphenoxy derivatives are only little explored. Tetraphenoxyborates are commonly used as bulky and inert counterions for catalysts[3] or as electrolytes in batteries.[4]

The formation of such tetragonal-coordinated compounds involves the reaction of Lewis acidic boron species with a nucleophilic phenoxy system. If very electron-deficient boranes are applied with no additional base, a tetragonal boron derivative is observed, incorporating an unusual tautomeric form of the phenolate.[5] Treatment of the corresponding phenol with boron trichloride in the presence of a nitrogen base leads to the triphenoxyborane by a direct displacement of chlorine and subsequently to the anionic tetragonal derivative. This approach requires very electron-deficient phenols and a highly corrosive boron reagent.[6] When employing sodium tetrahydridoborate as boron source in the reaction with phenol a variety of different borates is observed. Herein the counterion plays a crucial role, because the sodium cations link the borate subunits to infinite polymeric structures.[7] The stepwise formation of tetraphenoxyborates requires the prior construction of the triesters of boric acid followed by the conversion with phenolates. In order to obtain soluble phenolate equivalents of divalent cations like barium, sophisticated reagent mixtures were applied.[8] However, the direct use of barium metal ameliorated the process to barium-linked dimeric borates.[9]

We present a reliable protocol for the synthesis of a wide scope of tetraphenoxyborates. The simple two-step sequence can be performed in a one-pot process and is feasible for large quantities of the desired tetragonal boron compound.

## Results and Discussion

The synthesis of tetraphenoxyborates began with the esterification of the corresponding phenol with boric acid (Scheme 1). The transformation was performed in refluxing toluene with the use of a Dean–Stark trap. With the removal of water the reaction mixture became homogeneous. The amount of water received was slightly lower than anticipated from a stoichiometric condensation reaction.



Scheme 1. a) $B(OH)_3$, toluene, 12 h reflux with a Dean–Stark trap.

Removal of the solvent under reduced pressure yielded a mixture of phenyl esters of boric acid. Mass spectrometric investigation of the crude product indicated the presence of several trigonal boron species as depicted in Figure 1.

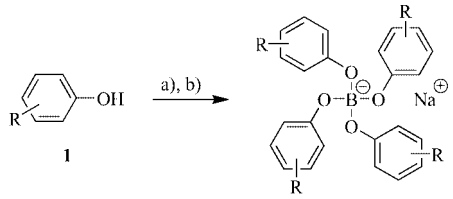
Figure 1. Major products by the condensation reaction of **1** with boric acid.

The presence of abundant **1** gives rise to a fast equilibrium among the ester species **2**–**4**.[10] When the crude material was carefully distilled under high vacuum ($10^{-4}$–$10^{-5}$ mbar), the pure triester **2** could be obtained. However, this step turned out to be time-consuming. Furthermore, it was only feasible on smaller quantities, limited to substrates of low molecular weight and involved an unacceptable loss of material. Therefore, the crude mixture was directly subjected to the corresponding phenolate in THF (Scheme 2).



1 5

Scheme 2. a) $B(OH)_3$, toluene, 12 h reflux with a Dean–Stark trap; b) Na, **1**, THF, room temp.

THF proved to be the appropriate solvent for this particular transformation including the reaction of phenol with sodium as well as the formation of the desired tetraphenoxyborate **5**, which precipitated and could easily be isolated by simple filtration. The formation of anionic borates results in a fast equilibrium of the corresponding trigonal compounds **2**–**4** and strongly favours the formation of the mononuclear borate species **5**. Noteworthy, performing the transformation at high concentration led almost exclusively to **5**. However, application of 4-methoxyphenol in this reaction sequence yielded the desired borate **9** besides the tetranuclear borate **28** as by-product in very low yields. Fortunately, a suitable single crystal for X-ray analysis was obtained (Figure 2). Further spectroscopic investigation was not possible because not sufficient pure material of **28** was available.

Compound **28** represents an intermediate in the formation of **5** from higher aggregates similar to **3** or **4**. The molecular structure reveals a mixed tetraborate. In the centre, a trigonal boric anhydride unit is connected to three tetragonal anionic borate moieties. The tetrahedral symmetry of the borates is distorted and shows two pairs of angles

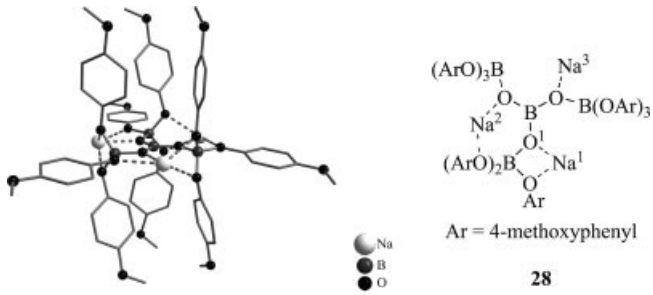


Figure 2. Left: X-ray structure of the tetraborate **28**; right: coordination pattern.

(Table 1). Three sodium cations link the borate fragments through the phenol oxygen atoms and compensate the negative charge. In addition, each sodium cation is coordinated by two THF molecules, which are omitted in Figure 2 for clarity. The architecture of the depicted tetraborate **28** is unique. Remarkably, **28** exhibits no $C_3$ symmetry, due to the deviated orientation of the methoxy substituents in its periphery.

As shown in Table 2, the parent phenol (Entry 1) as well as mono-, di- and trisubstituted substrates were applied in the synthesis of their tetraphenoxyborates in moderate to excellent yields. The reaction outcome is determined by the steric demand and electronic nature of the individual phenol derivative. The conversion of *para*- and *ortho*-cresol to the corresponding borates **7** and **14**, respectively, shows a lower yield for the latter one, due to the steric demand close to the borate centre (Entries 2 and 9). This trend is reflected in the conversion of almost all *ortho*-alkyl-substituted phenols compared to the congeners with free *ortho* positions. Interestingly, thymol and 4-chlorothymol, both exhibiting an isopropyl group at C-2, provide the borates **16** and **26** in high yields (Entries 11 and 21).

Phenols with a single *tert*-butyl substituent were successfully subjected to the condensation reaction with boric acid followed by salt formation to yield **8**, **17**, **19** or **25** in good yields (Entries 3, 12, 14 and 20), whereas two *tert*-butyl groups dramatically disfavour the arrangement of four phenolates around the boron centre (Entry 13). Furthermore, electronic effects can lower the nucleophilicity of the intermediate sodium phenolate, resulting in a lower yield for the desired borate. Therefore, substrates like 4-fluorophenol, 4-chlorophenol and 2-bromo-4-methylphenol were converted into the corresponding borates **10**, **11** and **20**, respectively, in moderate yields (Entries 5, 6 and 15). In contrast, tetraphenoxyborates of electron-rich phenols were obtained in good to excellent yields (Entries 4, 7 and 17).

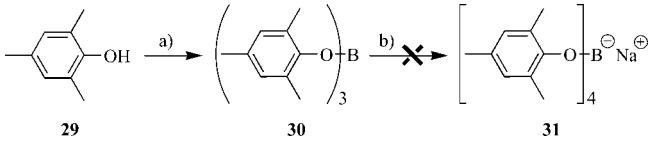
Phenols with two *ortho* substituents smoothly undergo the condensation reaction to the triphenoxyborane, whereas the subsequent formation of the tetraphenoxyborates was not observed (Scheme 3).

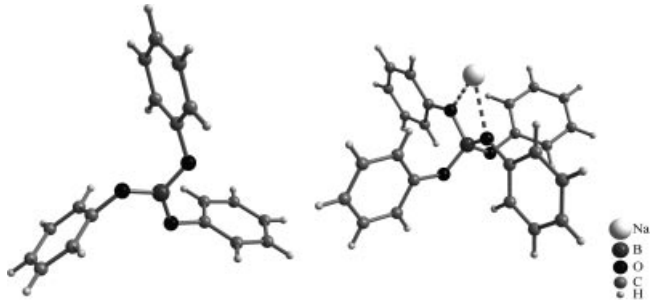


**29** **30** **31**

Scheme 3. a) $B(OH)_3$, toluene, 24 h reflux with a Dean–Stark trap; b) **29**, NaH, THF.

The conversion of 2,4,6-trimethylphenol (**29**) with sodium metal was sluggish, therefore sodium hydride was employed for deprotonation. Still, the addition of **30** to the phenolate of **29** gave no indication for the formation of the sodium tetraphenoxyborate **31**. The reaction mixture was analyzed by $^{11}B$ NMR spectroscopy, as the signals for a trigonal and a tetragonal boron atom clearly differ from each other. Only a broad signal at $\delta$ = 15.89 ppm was observed, indicating the triphenoxyborane **30**. Remarkably, compound **30** could easily be separated from the phenolate of **29** by chilling the reaction mixture. Compound **30** was filtered off and obtained as pure colourless solid. Thus, triphenoxyboranes of phenol derivatives exhibiting two alkyl substituents in the *ortho* positions are far too shielded to undergo addition with a further phenolate equivalent.

Because suitable crystals for X-ray analysis of both, triphenoxyborane (**6a**) and the corresponding tetraphenoxyborate (**6b**) were available, a direct comparison of the structural features was possible (Figure 3). The obtained geometric data are representative for most analogues.



**6a** **6b**

Figure 3. Molecular structure of triphenoxyborane (**6a**) and the tetraphenoxyborate (**6b**) determined by X-ray analysis.

Triphenoxyborane (**6a**) exhibits a trigonal-planar boron centre with three phenyl units symmetrically arranged around the boron atom. The planes of the aromatic rings are oriented almost perpendicular to the $BO_3$ plane, resulting in a water-wheel-shaped molecule. Three almost similar distances of about 2.35 Å between the oxygen atoms of **6a** emphasise the expected $C_3$ symmetry of **6a**. In contrast, the tetraphenoxyborate (**6b**) reveals a slight deviation from the tetrahedral symmetry by elongation in one direction. The pair of oxygen atoms bridged by the sodium cation forms the shorter side of the tetrahedron and exhibits an interatomic distance of about 2.26 Å. Interestingly, the opposite side shows the same oxygen–oxygen distance without a coordinating counterion. The corresponding interatomic distances on the longer side are in the range of 2.44–2.48 Å. Compared to **6a**, neighboured *ortho*-carbon atoms come closer to each other up to 4.28 Å. The sodium cation in **6b** has in fact a coordination number of five. Two positions are held by phenoxy oxygen atoms, represented in Figure 3 by dashed lines. The remaining three ligands are THF molecules, which are omitted for clarity. Almost the same assembly can be found in the X-ray structure of tetraphenoxyborate **10** as shown in Figure 4. Again, THF molecules are not depicted for clarity.

The tetraphenoxyborate **10** exhibits very similar structural features compared to **6b** according to geometry and complexation of the sodium cation by the substrate and three THF molecules. In contrast, the tetranaphthoxyborate **27** (Figure 4) is no longer able to coordinate to the sodium cation itself, due to the highly crowded boron centre. Therefore, the cation is coordinated by five THF molecules

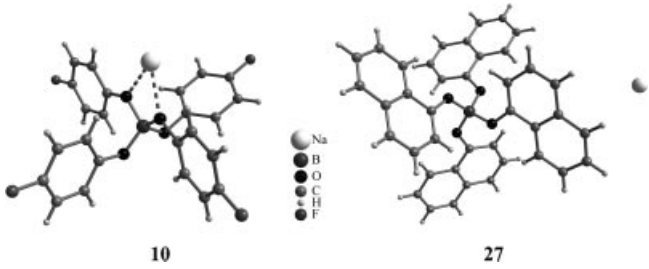

Figure 4. Molecular structures of tetraphenoxyborates **10** and **27** determined byX-ray analysis.

and reveals a boron–sodium distance of 8.97 Å, which is about 3 times longer than for **6b** or **10**. The boron–oxygen bond lengths in **27** are comparable with those observed for **6b** and **10**, whereas the distance between the phenoxy carbon atoms increases by 6% (Table 3). The oxygen atoms in **27** are almost equidistant, resulting in a consistent tetrahedral symmetry of the $BO_4$ unit.

[a] Sodium-bridged pair of oxygen atoms. [b] Non-bridged pair of oxygen atoms.

The geometric data for the described sodium tetraphenoxyborates correspond to earlier reports on complex architectures of sodium hydrido(phenoxy)borates concerning oxygen–boron and oxygen–sodium bond lengths as well as the angle for the sodium-chelating oxygen–boron–oxygen cleft at about 100°.[7] In contrast to sodium borates, the non-coordinating oxygen atoms in barium-linked dimeric borates span a significantly wider oxygen–boron–oxygen angle than the opposite angle between the cation-bridged oxygen atoms.[9]

It turned out that tetraphenoxyborates are much less prone to hydrolysis than the corresponding trigonal triphenoxyborane species. Consequently, **5** can be handled for short times at ambient conditions,[11] whereas the triphenyl ester of boric acid is almost immediately affected by moisture. The enhanced stability of the tetragonal boron systems is based on the saturated coordination sphere of the boron centre. However, protic media or strongly coordinating solvents like methanol or acetonitrile might affect the stability of **5**. In this context, $^{11}$B NMR studies proved to be a versatile tool. Besides the chemical shift as an indicator for the electronic properties, the line full width at half maximum can individually characterize the structure of a specific borate derivative. The comparison of different triphenoxyboranes is not facile to accomplish, due to extremely broad signals. However, triphenoxyboranes and tetraphenoxyborates can easily be distinguished as presented in Figure 5.

The $^{11}$B NMR spectrum of triphenoxyborane in chloroform (Figure 5, top) shows a broad signal at $\delta \approx 15$ ppm with a line full width at half maximum of 320 Hz, which represents a typical value for a trigonal boron species. When the same substrate is recorded in methanol, a shift to $\delta \approx 18$ ppm is observed accompanied by a significantly decreased line full width at half maximum of 85 Hz. Methanol is a particular solvent since an adduct formation with the ester of boric acid can occur.[12] Thus, the electrophilic boron centre experiences a tetragonal environment which is clearly supported by the NMR spectroscopic data. Interestingly, only a single species is detected revealing that no exchange of the phenolate groups occurs. When recording the corresponding tetraphenoxyborate in methanol, the protic and nucleophilic properties have no significant impact on the NMR spectroscopic data. The chemical shift as well as the line width of the signal correspond to the data collected for a THF solution. Furthermore, the typical line full width at half maximum for a tetraphenoxyborate of 20–40 Hz in THF or MeOH was also observed in acetonitrile (Figure 5, bottom).

## Conclusion

A reliable and easy to perform two-step-one-pot sequence for the synthesis of tetraphenoxyborates was elaborated. The protocol is applicable to a broad scope of phenols and useful for larger scale as well. Interestingly, the tetraphenoxyborates exhibit a much higher stability than the trigonal congeners. Consequently, tetraphenoxyborates can be handled in methanol, THF and acetonitrile.

Furthermore, a novel tetranuclear borate system was found, consisting of trigonal and tetragonal boron moieties. The structural comparison of the corresponding tetraphenoxyborates and triphenyl esters of boric acid reveals that the tetragonal arrangement yields in a superb organisation of the *ortho* positions in the aryl moieties. Oxidative coupling reactions of these boron-templated phenolates are currently studied and will be reported in due course.

## Experimental Section

**General Remarks:** All reagents were used in analytical grades. Solvents were desiccated if necessary by standard methods. Microanalyses were performed with a Vario EL III (Elementar-Analysensysteme, Hanau, D). $^1$H and $^{13}$C NMR spectra were recorded at 25 °C with a Bruker ARX 300, AM 360 or AMX 400. Chemical shifts ($\delta$) are reported in parts per million (ppm) relative to traces of $CHCl_3$, [$D_7$]THF or $CD_2HCN$ in the corresponding deuterated solvents. $^{11}$B NMR spectra were recorded at 25 °C with a Bruker AC 200 by external calibration. Mass spectra were obtained with a Quattro LC (Waters-Micromass) or Micro TOF (Bruker) by employing ESI and HRMS (negative mode).

**Triphenoxyborane (6a):** Phenol (9.4 g, 0.10 mol) and boric acid (2.1 g, 0.03 mol) were suspended in toluene (50 mL) and the reaction mixture was heated for a period of 12 h (Dean–Stark trap). Toluene was removed under reduced pressure and the crude product was purified by distillation to yield a colourless oil, which solidified upon cooling; yield 5.8 g, 67%. B.p. 150 °C, $5\cdot10^{-6}$ mbar; m.p. 82 °C. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 6.94–6.99 (m, 3 H, 4-H), 7.00–7.04 (m, 6 H, 2-H), 7.15–7.21 (m, 6 H, 3-H) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 120.20 (C-2), 123.50 (C-4), 129.26 (C-3), 152.85 (C-1) ppm. $^{11}$B NMR (64 MHz, $CDCl_3$): $\delta$ = 15.65 ppm. MS (EI = 70 eV): *m/z* (%) = 290.0 (100) $[M]^{+\cdot}$, 197.0 (44) $[M - C_6H_5O]^{+\cdot}$, 94.0 (75) $[C_6H_5O]^{+\cdot}$, 77.0 (81) $[C_6H_5]^{+\cdot}$.

**General Procedure for the Preparation of Sodium Tetraphenoxyborates:** A suspension of the corresponding phenol derivative (0.32 mol) and boric acid (0.10 mol) in toluene (200 mL) was heated for a period of 12 h (Dean–Stark trap). Toluene was removed under reduced pressure and the excess of phenol was removed by distillation, solid phenols were removed by sublimation. The crude product was dissolved in THF (40 mL) and added dropwise to a solution of the sodium phenolate, which was prepared by deprotonation of the corresponding phenol (0.09 mol) with 1 equiv. of sodium (0.09 mol) in THF (70 mL). After stirring for additional 1–12 h, the precipitated product was filtered off and washed subsequently with diethyl ether (40 mL) and pentane (40 mL). The filtrate was stored at 4 °C for another 12 h and a second crop was isolated as described above. Drying under high vacuum provided the desired products as colourless solids that were stored under inert conditions at ambient temperature. For **10**, **11**, **12**, **17**, **20**, **21** and **26** the scale of the protocol was reduced by a factor of three. All borates decomposed at temperatures above 200 °C under change of colour. The obtained tetraphenoxyborates exhibit good stability. However, the microanalyses of most borates show slight deviations from ±0.4% and therefore, HRMS data are given.[13]

**Sodium Tetraphenoxyborate (6b):** 33.3 g, 82%. $^1$H NMR (300 MHz, $CD_3CN$): $\delta$ = 6.64–6.70 (m, 4 H, 4-H), 7.06–7.08 (m, 16 H, 2-H, 3-H) ppm. $^{13}$C NMR (75 MHz, $CD_3CN$): $\delta$ = 119.26 (C-4), 120.14 (C-2), 129.64 (C-3), 158.93 (C-1) ppm. $^{11}$B NMR (64 MHz, $CD_3CN$): $\delta$ = 2.79 ppm. HRMS: calcd. for $C_{24}H_{20}BO_4$ 383.1453 $[M - Na^+]^-$; found 383.1417.

**Sodium Tetrakis(4-methylphenoxy)borate (7):** 38.8 g, 84%. $^1$H NMR (400 MHz, [$D_8$]THF): $\delta$ = 2.14 (s, 12 H, $CH_3$), 6.74–6.78 (m, 8 H, 2-H), 6.87–6.91 (m, 8 H, 3-H) ppm. $^{13}$C NMR (75 MHz, [$D_8$]-THF): $\delta$ = 20.76 ($CH_3$), 120.62 (C-2), 127.56 (C-4), 129.53 (C-3), 156.62 (C-1) ppm. $^{11}$B NMR (64 MHz, $CD_3CN$): $\delta$ = 2.34 ppm. HRMS: calcd. for $C_{28}H_{28}BO_4$ 439.2080 $[M - Na^+]^-$; found 439.2066.

**Sodium Tetrakis(4-*tert*-butylphenoxy)borate (8):** 35.9 g, 57%. $^1$H NMR (300 MHz, [$D_8$]THF): $\delta$ = 1.22 (s, 36 H, $CH_3$), 6.90–6.93 (m, 8 H, 2-H), 6.99–7.02 (m, 8 H, 3-H) ppm. $^{13}$C NMR (75 MHz, [$D_8$]-THF): $\delta$ = 32.16 ($CH_3$), 34.45 [$C(CH_3)_3$], 120.27 (C-2), 125.64 (C-3), 141.07 (C-4), 156.67 (C-1) ppm. $^{11}$B NMR (64 MHz, [$D_8$]-THF): $\delta$ = 2.04 ppm. HRMS: calcd. for $C_{40}H_{52}BO_4$ 607.3971 $[M - Na^+]^-$; found 607.3979.

**Sodium Tetrakis(4-methoxyphenoxy)borate (9):** 34.7 g, 66%. $^1$H NMR (300 MHz, $CD_3CN$): $\delta$ = 3.79 (s, 12 H, $OCH_3$), 6.75–6.78 (m, 8 H, arom. H), 7.07–7.10 (m, 8 H, arom. H) ppm. $^{13}$C NMR (75 MHz, $CD_3CN$): $\delta$ = 56.16 ($OCH_3$), 114.92, 120.65 (C-2, C-3), 152.69, 153.33 (C-1, C-4) ppm. $^{11}$B NMR (64 MHz, $CD_3CN$): $\delta$ = 2.30 ppm. MS (ESI): *m/z* (%) = 503 (100) $[M - Na^+]^-$. $C_{28}H_{28}BNaO_8$ (526.2): calcd. C 63.90, H 5.36; found C 63.60, H 5.26.

**Sodium Tetrakis(4-fluorophenoxy)borate (10):** 5.9 g, 37%. $^1$H NMR (300 MHz, $CD_3CN$): $\delta$ = 6.77–6.83 (m, 8 H, 2-H), 6.97–7.02 (m, 8 H, 3-H) ppm. $^{13}$C NMR (75 MHz, $CD_3CN$): $\delta$ = 115.61 [d, $^2J$(F,C) = 24.8 Hz, C-3], 120.79 [d, $^3J$(F,C) = 7.9 Hz, C-2], 155.20 (C-1), 156.85 [d, $^1J$(F,C) = 247.4 Hz, C-4] ppm. $^{11}$B NMR (64 MHz, $CD_3CN$): $\delta$ = 2.66 ppm. HRMS: calcd. for $C_{24}H_{16}BF_4O_4$ 455.1072 $[M - Na^+]^-$; found 455.1103.

**Sodium Tetrakis(4-chlorophenoxy)borate (11):** 7.4 g, 41%. $^1$H NMR (300 MHz, $CD_3CN$): $\delta$ = 6.98–7.06 (m, 16 H, 2-H, 3-H) ppm. $^{13}$C NMR (75 MHz, $CD_3CN$): $\delta$ = 121.51 (C-2), 123.41 (C-4), 129.38 (C-3), 157.75 (C-1) ppm. $^{11}$B NMR (64 MHz, $CD_3CN$): $\delta$ = 2.57 ppm. HRMS: calcd. for $C_{24}H_{16}BCl_4O_4$ 517.9927 $[M - Na^+]^-$; found 517.9906.

**Sodium Tetrakis(4-methylthiophenoxy)borate (12):** 19.5 g, 99%. $^1$H NMR (400 MHz, $CD_3CN$): $\delta$ = 2.05 (s, 12 H, $SCH_3$), 6.64–6.70 (m, 16 H, 2-H, 3-H) ppm. $^{13}$C NMR (100 MHz, $CD_3CN$): $\delta$ = 18.37 ($SCH_3$), 120.85 (C-2), 126.78 (C-3), 130.66 (C-4), 157.09 (C-1) ppm. $^{11}$B NMR (128 MHz, $CD_3CN$): $\delta$ = 4.07 ppm. HRMS: calcd. for $C_{28}H_{28}BO_4S_4$ 567.0969 $[M - Na^+]^-$; found 567.0955.

**Sodium Tetrakis(3,4-dimethylphenoxy)borate (13):** 43.0 g, 83%. $^1$H NMR (300 MHz, $CD_3CN$): $\delta$ = 2.04 (s, 12 H, 4-$CH_3$), 2.07 (s, 12 H, 3-$CH_3$), 6.72–6.76 (m, 8 H, 5-H, 6-H), 6.78 (s, 4 H, 2-H) ppm. $^{13}$C NMR (75 MHz, $CD_3CN$): $\delta$ = 18.84 (3-$CH_3$), 20.18 (4-$CH_3$), 117.27 (C-6), 121.35 (C-2), 126.54 (C-4), 130.49 (C-5), 137.19 (C-3), 156.94 (C-1) ppm. $^{11}$B NMR (64 MHz, $CD_3CN$): $\delta$ = 2.60 ppm. HRMS: calcd. for $C_{32}H_{36}BO_4$ 495.2718 $[M - Na^+]^-$; found 495.2720.

[10] Maldi-TOF analysis of the crude product. $^{11}$B NMR studies turned out to be less useful since the equilibration is fast on the NMR timescale and the particular shifts are very similar.
[11] For longer times and storage purposes, an anhydrous environment is recommended to avoid hydrolysis.
