All attempts to obtain solid complexes with $Ni^{II}$, $Co^{II}$ and $Zn^{II}$ were unsuccessful, as no homogeneous products were isolated. This fact could be attributed to the protonation of **L**, as was also observed in the titrations of other tertiary amine-containing ligands with these metal ions.[11]

## Spectrophotometric and Spectrofluorometric Studies

### *Ligand Protonation*

The absorption spectrum of a dichloromethane solution of **L** shows the characteristic band of the anthracene derivatives above 330 nm. The absorption band of **L** has a vibrational fine structure with maxima at 333, 350, 368 and 388 nm. The effect of the protonation on the absorption spectrum of this ligand was determined by titration with methanesulfonic acid (Figure 3, A). This absorption titration revealed seven isosbestic points at 335, 342, 352, 361, 371, 380 and 391 nm, which suggests the presence of two species in equilibrium. The protonation induced a red shift of the absorption maxima, as well as a decrease in the absorption coefficient of this band. As can be seen in the inset of Figure 3 (A), an equivalent amount of acid is required to complete the protonation of **L**.

The fluorescence emission and excitation spectra of **L** show the characteristic bands of the anthracene systems (Figure 3, B). An "off–on" behaviour is observed when a dichloromethane solution of **L** is titrated with acid, as the nonprotonated ligand is slightly emissive in dichloromethane, whereas the protonated form is at least 30 times more

Table 1. Quantum yields in dichloromethane at 298 K.

| | $\Phi$ |
|---|---|
| **L** | 0.010 |
| **L** + $H^+$ | 0.341 |
| **L** + $Pd^{2+}$ | 0.005 |
| **L** + $Zn^{2+}$ | 0.254 |
| **L** + $Ni^{2+}$ | 0.203 |
| **L** + $Co^{2+}$ | 0.208 |

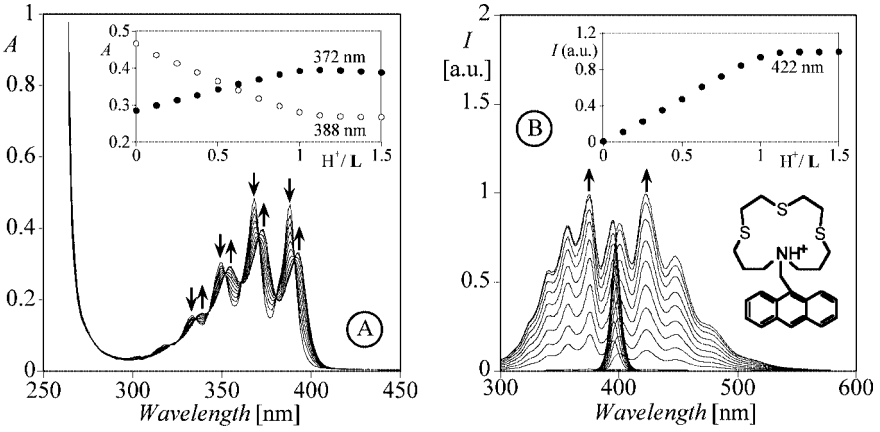

Figure 3. (A) Absorption spectra of a dichloromethane solution of **L** as a function of added $CH_3SO_3H$. The inset shows the absorbances at 372 and 388 nm. (B) Excitation and emission spectra of a dichloromethane solution of **L** as a function of added $CH_3SO_3H$. The inset shows the normalised fluorescence intensity at 422 nm ($[\mathbf{L}] = 5.14 \times 10^{-5}$ M, $T$ = 298 K, $\lambda_{exc}$ = 368 nm; $\lambda_{em}$ = 423 nm).

emissive than the free ligand. This increase in the fluorescence intensity is also reflected by comparing the quantum yield of the nonprotonated and protonated ligands (see Table 1), and is due to the fact that protonation prevents photoinduced electron transfer (PET) from the lone pair of electrons of the nitrogen atom to the anthracene moiety.

### *Metal Ion Titrations*

To explore the utility of **L** as a fluorescence device, titrations with several transition-metal ions were performed. Two different behaviours were observed as a function of the used metal ion.

### *$Pd^{II}$ Titrations*

To identify the absorption bands that exclusively resulted from the interactions between the $Pd^{II}$ cations and the macrocyclic moiety of **L**, we first performed a titration of the nonfunctionalised macrocycle **2** with this metal ion. The addition of $Pd(BF_4)_2 \cdot 4CH_3CN$ to a dichloromethane solution of **2** led to the formation of two absorption bands at 258 and 330 nm, assigned to MLCT and *d*–*d* bands respectively.[15] The inset of Figure 4 shows that the titration was completed after the addition of 1 equiv. of metal ion, which is in agreement with the formation of mononuclear species.

Figure 5 (A) shows the absorption spectra of the titration of **L** with $Pd(BF_4)_2$. The addition of the metal ion causes a

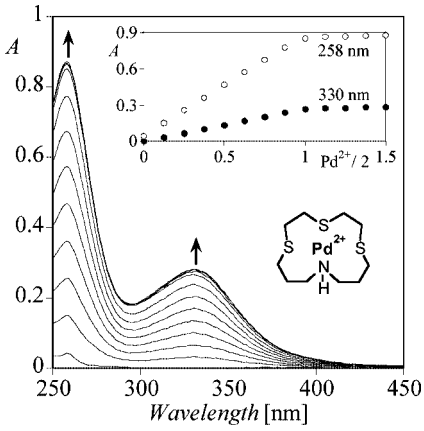

Figure 4. Absorption spectra of a dichloromethane solution of **2** as a function of added $Pd(BF_4)_2$. The inset shows the absorbances at 258 and 330 nm ([**2**] = $5.50 \times 10^{-5}$ M, $T$ = 298 K).

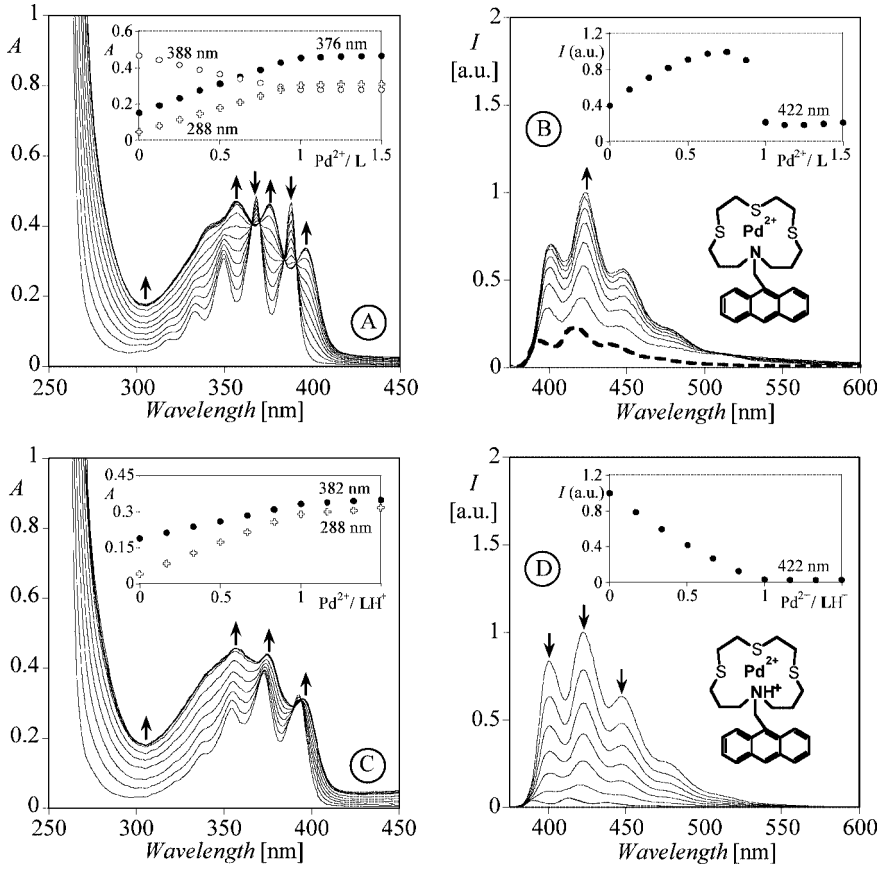

Figure 5. (A) Absorption spectra of **L** as a function of increasing amounts of $Pd(BF_4)_2$. The inset shows the absorbances at 288, 376 and 388 nm. (B) Emission spectra of **L** as a function of added $Pd(BF_4)_2$. Those spectra between the maximum and the end of the titration have been omitted for clarity. The last spectrum of each titration is shown as a dotted line. The inset shows the normalised fluorescence intensity at 422 nm. (C) Absorption spectra of $\mathbf{LH}^+$ as a function of increasing amounts of $Pd(BF_4)_2$. The inset shows the absorbances at 288 and 382 nm. (D) Emission spectra of $\mathbf{LH}^+$ as a function of added $Pd(BF_4)_2$. The inset shows the normalised fluorescence intensity at 422 nm (dichloromethane solution, [**L**] = [$\mathbf{LH}^+$] = $5.14 \times 10^{-5}$ M, $T$ = 298 K, $\lambda_{exc}$ = 368 nm).

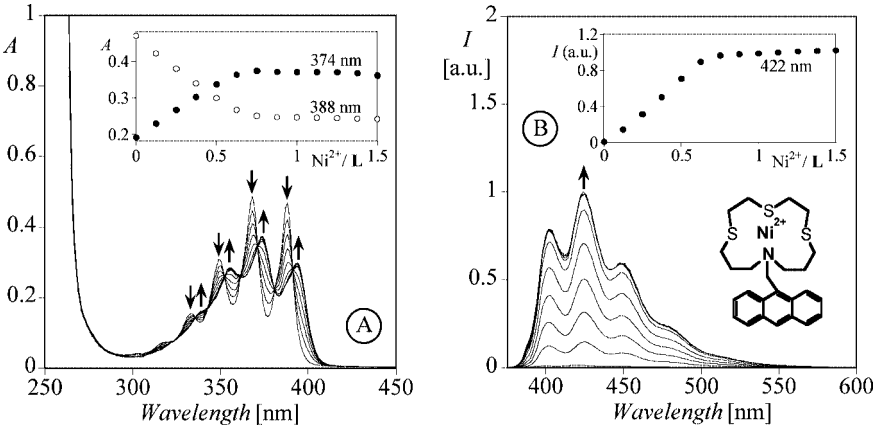

Figure 6. (A) Absorption spectra of a dichloromethane solution of **L** as a function of increasing amounts of $Ni(BF_4)_2$. The inset shows the absorbances at 374 and 388 nm. (B) Emission spectra of a dichloromethane solution of **L** as a function of added $Ni(BF_4)_2$. The inset shows the normalised fluorescence intensity at 422 nm. ([**L**] = $5.14 \times 10^{-5}$ M, $T$ = 298 K, $\lambda_{exc}$ = 368 nm).

red shift of the anthracene band, as well as an incremental increase in the molar absorption coefficient in the region around 300 nm. This increment is attributed to the formation of the absorption bands analogous to those observed in the titration of **2**. As can be seen in the inset of Figure 5 (A), a plateau is reached after the addition of an equivalent amount of metal ion, which suggests that each macrocyclic unit is coordinated to one metal ion. Figure 5 (B) shows the fluorescence titration of **L** with $Pd(BF_4)_2$. Although initial additions of the metal ion increase the fluorescence of the ligand, supplementary additions cause a strong quenching of the fluorescence, as well as a blue shift of about 6 nm. The *chelation enhancement of the quenching* (CHEQ) effect can be explained by assuming that $Pd^{II}$, as well as other transition-metal ions with partially filled d orbitals, is known to induce fluorescence quenching through photoinduced electron transfer or energy transfer mechanisms.[16] The initial increase of the fluorescence could be explained by the protonation of the amine, which prevents PET from its nitrogen atom to the anthracene moiety. This protonation is probably due to the presence of water in the metal ion solutions, which acts as an acid.

To verify this hypothesis, both absorption and fluorescence titrations of **L** were repeated in the presence of 1 equiv. of methanesulfonic acid (see parts C and D in Figure 5). The absorption titration of $\mathbf{LH}^+$ with $Pd(BF_4)_2$ followed the same pattern as that observed for **L**. On the other hand, the fluorescence titration of $\mathbf{LH}^+$ was significantly different from that of **L**, as the intensity of fluorescence decreased after each addition of metal ion. These results are in agreement with the simultaneous presence of protonated and complexed species in the early stages of the titration of **L** with $Pd(BF_4)_2$, and with the presence of only complexed species in the last stages of this titration. The insets of Figure 5 (parts C and D) show that 1 equiv. of $Pd^{II}$ is required to complete the complexation of $\mathbf{LH}^+$, which indicates that the $Pd^{II}$ ions can efficiently replace the protons of the $\mathbf{LH}^+$ moieties.

### *$Zn^{II}$, $Ni^{II}$ and $Co^{II}$ Titrations*

No significant differences were found in the absorption or in the fluorescence titrations of **L** when this ligand was titrated with $Zn(CF_3SO_3)_2$, $Ni(BF_4)_2$ or $Co(BF_4)_2$. As a representative example, Figure 6 shows both the absorption and fluorescence titrations of **L** with $Ni^{II}$. The addition of any of these salts causes a red shift in the anthracene absorption maximum of **L**, as well as a decrease in its molar absorption coefficient. These changes occur until the addition of 0.6 equiv. of $Zn^{II}$ or $Ni^{II}$ or 0.7 equiv. of $Co^{II}$.

As in the case of the fluorescence titration of **L** with $Pd^{II}$, initial additions of $Zn^{II}$, $Ni^{II}$ or $Co^{II}$ increase the fluorescence of **L**. However, further additions cause neither the shift nor the quenching of the emission band. These observations suggest that the addition of $Zn^{II}$, $Ni^{II}$ or $Co^{II}$ also leads to the initial protonation of **L**, after which no interaction between **L** and these metal ions can occur. This hypothesis was confirmed when the titrations were repeated in the presence of an equivalent amount of acid, as the addition of these ions to dichloromethane solutions of $\mathbf{LH}^+$ did not cause significant changes either in the absorption or in the emission spectrum of the ligand, which indicates that these metal ions cannot efficiently replace the protons in the protonated macrocycles.

The different behaviour observed between the titrations with $Pd^{II}$ and those with $Zn^{II}$, $Ni^{II}$ or $Co^{II}$ is probably due to the different affinity between the metal ion and the donor atoms of **L**. This is in agreement with the fact that the *soft* nature of the $NS_3$ set of **L** leads to the formation of complexes with only the *softest* of these metal ions, that of $Pd^{II}$.

## Conclusions

The azathiamacrocycle **2** can be synthesised by reacting *N*,*N*-bis(3-chloropropyl)amine with 2,2′-thiobis(ethanethiol) in the presence of CsOH. This new method allowed

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

us to obtain **2** without using any amine-protecting group, which decreases the number of synthetic steps and improves the final yield. The anthracene-containing macrocycle **L** can be obtained either by functionalisation of **2** with 9-(chloromethyl)anthracene or by cyclisation of *N*,*N*-bis(3-chloropropyl)-9-anthracenemethanamine with 2,2′-thiobis-(ethanethiol). Both methods allow the synthesis of **L** in moderately high yields.

As observed in the spectra of the fluorescence titration of **L** with methanesulfonic acid, the protonation of this ligand greatly increase its fluorescence. This protonation also occurs when **L** is titrated with $Pd^{II}$, $Zn^{II}$, $Ni^{II}$ or $Co^{II}$ solutions, as the water molecules present in such solutions are acidic enough to produce the protonation of the ligand, which reflects the basic nature of its tertiary amine group.

Only the $Pd^{II}$ ions can efficiently remove the protons from the protonated $\mathbf{LH}^+$ molecules to yield complexed species, which indicates that the interactions between **L** and the $Pd^{II}$ ions are stronger than those between **L** and protons, whereas the interactions between **L** and the $Zn^{II}$, $Ni^{II}$ or $Co^{II}$ ions are weaker than those between **L** and the proton ions. These differences explain why only characterisable species with $Pd^{II}$ could be isolated. The high affinity of **L** towards $Pd^{II}$ could be potentially useful in the development of new molecular devices.

## Experimental Section

**General Remarks:** Elemental analyses were performed with a Carlo–Erba EA-1108 instrument by the Chemical Analysis Service at the Universitat Autònoma de Barcelona. Mass spectra were recorded with a HP298S GC–MS system. NMR spectra were recorded with a Bruker 250 MHz AC instrument. Conductivity measurements were carried out with a Cyberscan 500 conductimeter. IR spectra were recorded with a Perkin–Elmer FT-1710 instrument. Organic reagents and transition-metal salts were purchased from Aldrich and used as received. All syntheses were carried out using standard Schlenk techniques. *N*,*N*-Bis(3-chloropropyl)amine (**1**) was prepared from 3-amino-1-propanol and 3-chloro-1-propanol according to the published method but using chloroform instead of benzene as solvent.[17] *N*,*N*-Bis(3-chloropropyl)-9-anthracenemethanamine (**3**) was prepared from **1** and 9-(chloromethyl)anthracene as previously reported in the literature.[11]

**X-ray Crystal Structure Determinations:** A single crystal of $[Pd(\mathbf{L})](BF_4)_2$ was mounted on a glass fibre and used for data collection. A summary of the crystallographic data is reported in Table 2. Crystallographic measurements were performed with a Bruker Smart CCD apparatus at 293 K, using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) in RIAIDT (University of Santiago de Compostela, Spain). Crystallographic data were corrected for Lorentz and polarisation effects. The frames were integrated with the Bruker SAINT Software package,[18] and the data were corrected for absorption using the SADABS program.[19] The structure was determined by direct methods using the SIR-97 program.[20] All non-hydrogen atoms were refined with anisotropic thermal parameters by full-matrix least-squares calculations on $F^2$ using the SHELXL97 program.[21] Hydrogen atoms were inserted at calculated positions and constrained with isotropic thermal parameters. Tetrafluoroborate anions and the S12 sulfur atom of the macrocyclic ligand were modelled with disorder. Special computations for the crystal structure discussions were carried out with PLATON.[22]

CCDC-266369 contains the supplementary crystallographic data for this paper. The data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.uk/data_request/cif.

**Spectrophotometric and Spectrofluorometric Measurements:** Absorption spectra were recorded with a Shimadzu UV-2501PC spectrophotometer and fluorescence emissions on a Horiba–Jobin–Yvon SPEX Fluorolog 3.22 spectrofluorimeter at the Universidade Nova de Lisboa. The linearity of the fluorescence emission versus concentration was verified for the concentration range used ($10^{-4}$ to $10^{-6}$ M). A correction for the absorbed light was performed when necessary. The absorption and fluorescence titrations were performed by adding microlitre amounts of acetonitrile, or ethanol solutions of the corresponding titrating agent, to dichloromethane solutions of the ligand. [**2**] = $5.50 \times 10^{-5}$ M. [**L**] = $5.14 \times 10^{-5}$ M, $\lambda_{exc}$ = 368 nm; $\lambda_{em}$ = 423 nm. Luminescence quantum yields were measured using a solution of sublimated anthracene in cyclohexane as a standard [$\Phi_F$ = 0.36].[23]

**1,4,7-Trithia-11-azacyclotetradecane (2):** A solution of **1** (3.32 g, 15.54 mmol) in deoxygenated DMF (50 mL) and a solution of 2,2′-thiobis(ethanethiol) (3.02 g, 15.54 mmol) in deoxygenated DMF (50 mL) were added simultaneously (at 2 mL/h using a perfusor) to a round-bottomed flask equipped with a magnetic stirrer and charged with CsOH (6.45 g, 39.06 mmol) and deoxygenated DMF (700 mL). Subsequently, the solvent was removed and the residue was dissolved in $CHCl_3$ (200 mL). The solution was filtered off and the solvent was removed to obtain a pale brown oil. This residue was purified by column chromatography on silica gel using a mixture of $CHCl_3$/$CH_3OH$ (10:1 v/v ratio) as eluent. Yield 3.07 g, 62%. $C_{10}H_{21}NS_3$ (251.48): calcd. C 47.76, H 8.42, N 5.57, S 38.25; found C 47.55, H 8.30, N 5.55, S 37.80. $^1$H NMR (250 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.18 (s, 1 H, -$CH_2$-N*H*-$CH_2$-), 1.72 (m, $^3J_{H,H}$ = 6.23 Hz, 4 H, -S-$CH_2$-C*H*$_2$-$CH_2$-NH-), 2.63–2.74 (m, 8 H, -S-C*H*$_2$-$CH_2$-C*H*$_2$-NH-), 2.74 (m, 8 H, -S-C*H*$_2$-C*H*$_2$-S-) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 25 °C): $\delta$ = 28.9 (-S-$CH_2$-*C*H$_2$-$CH_2$-NH-), 30.4 (-S-*C*H$_2$-$CH_2$-$CH_2$-NH-), 31.9 (-S-$CH_2$-*C*H$_2$-S-*C*H$_2$-$CH_2$-S-), 32.5 (-S-*C*H$_2$-$CH_2$-S-$CH_2$-*C*H$_2$-S-), 46.9 (-S-$CH_2$-$CH_2$-*C*H$_2$-NH-) ppm. UV/Vis ($CH_2Cl_2$): $\lambda$ = 258 nm ($\varepsilon$ = 769 M$^{-1}$/cm). ESI-MS: *m*/*z* (%) = 252.4 [**2** + H]$^+$. IR (KBr pellet): $\tilde{\nu}$ = 3316, 2925, 2819, 1675, 1424, 1265, 1191, 1122, 693 cm$^{-1}$.

**11-(9-Anthracenylmethyl)-1,4,7-trithia-11-azacyclotetradecane (L). Preparation from 2:** A mixture of anhydrous $Na_2CO_3$ (0.31 g, 2.94 mmol), KI (0.20 g, 1.20 mmol), 9-(chloromethyl)anthracene (0.49 g, 2.15 mmol) and **2** (0.65 g, 1.47 mmol) in $CH_3CN$ (100 mL) was refluxed for 4 h. The mixture was filtered off and the solvent was removed with a rotary evaporator. The resultant yellow residue was purified by column chromatography on silica gel using $CHCl_3$ as eluent. Yield 1.14 g, 73%.

**Preparation from 3:** A solution of 2,2′-thiobis(ethanethiol) (0.77 g, 4.98 mmol) in deoxygenated DMF (50 mL) and a solution of **3** (1.79 g, 4.98 mmol) in deoxygenated DMF (50 mL) were added simultaneously at 2 mL/h using a perfusor to a round-bottomed flask equipped with magnetic stirrer and charged with a solution of $Cs_2CO_3$ (1.78 g, 5.50 mmol) in deoxygenated DMF (700 mL). The solvent was removed and the residue was dissolved in $CHCl_3$. This solution was filtered off and the solvent was removed to yield a yellow oil that was purified by column chromatography on silica gel using $CHCl_3$ as eluent to afford 0.90 g (40% yield) of yellow solid. $C_{25}H_{31}NS_3$ (441.72): calcd. C 67.98, H 7.07, N 3.17, S 21.78; found C 67.55, H 7.10, N 3.10, S 21.40. $^1$H NMR (250 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.73 (m, 4 H, -S-$CH_2$-C$H_2$-$CH_2$-N-), 2.26 (t, $^3J_{H,H}$ = 7.93 Hz, 4 H, -S-C$H_2$-$CH_2$-$CH_2$-N-), 2.59 (t, $^3J_{H,H}$ = 6.19 Hz, 4 H, -S-$CH_2$-$CH_2$-C$H_2$-N-), 2.69 (s, 8 H, -S-C$H_2$-C$H_2$-S-), 4.51 (s, 2 H, An-C$H_2$-N-), 7.50 (m, 4 H, *An*-$CH_2$-N-), 8.00 (m, 2 H, *An*-$CH_2$-N-), 8.44 (m, 3 H, *An*-$CH_2$-N-) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 25 °C): $\delta$ = 28.5 (-S-$CH_2$-C$H_2$-$CH_2$-N-), 29.8 (-S-C$H_2$-$CH_2$-$CH_2$-N-), 31.1 (-S-$CH_2$-C$H_2$-S-C$H_2$-$CH_2$-S-), 31.8 (-S-C$H_2$-$CH_2$-S-$CH_2$-C$H_2$-S-), 52.0 (An-C$H_2$-N-), 53.7 (-S-$CH_2$-$CH_2$-C$H_2$-NH-), 124.8, 125.6, 127.6, 129.1, 130.1, 131.2, 131.4 (*An*-$CH_2$-N-) ppm. UV/Vis ($CH_2Cl_2$): $\lambda$ = 333 ($\varepsilon$ = 3024), 350 (5902), 368 (9418), 388 nm (9096 $M^{-1}$/cm). ESI-MS: *m*/*z* (%) = 442.7 [**L** + H]$^+$. IR (KBr pellet): $\tilde{\nu}$ = 3048, 2949, 2922, 2810, 1677, 1622, 1444, 1436, 1426, 1336, 1279, 1190, 1023, 893, 735, 541 $cm^{-1}$.

**[Pd(L)](BF$_4$)$_2$·2H$_2$O:** A dichloromethane solution of **L** (90 mg, 0.20 mmol, 4 mL) was added dropwise to an acetonitrile solution of $Pd(BF_4)_2$·4$CH_3CN$ (91 mg, 0.20 mmol, 4 mL). The resulting solution was stirred at room temperature for 2 h, and the solvent was partially removed to about 3 mL. Diethyl ether was slowly infused into the solution producing a powdery precipitate, which was filtered off and washed with diethyl ether. This complex was recrystallised by diffusion of diethyl ether into acetonitrile solutions. The yield was 130 mg (88%). Crystals suitable for X-ray diffraction were obtained by diffusion of hexane into a dichloromethane solution. $C_{25}H_{31}B_2F_8NPdS_3$·2$H_2O$ (757.72): calcd. C 39.63, H 4.66, N 1.85, S 12.69; found C 39.40, H 4.85, N 1.80, S 12.25. Conductivity ($CH_3CN$, $1 \times 10^{-3}$ M): 231 μS/cm. $^1$H NMR (250 MHz, $CD_3NO_2$, 25 °C): $\delta$ = 2.29 (m, 2 H, -S-$CH_2$-C$H_2$-$CH_2$-N-), 2.47 (m, 2 H, -S-$CH_2$-C$H_2$-$CH_2$-N-), 2.70 (m, 2 H, -S-$CH_2$-$CH_2$-C$H_2$-N-), 3.03 (m, 2 H, -S-C$H_2$-$CH_2$-$CH_2$-N-), 3.11 (m, 4 H, -S-C$H_2$-$CH_2$-C$H_2$-N-), 3.32 (m, 4 H, -S-$CH_2$-C$H_2$-S-C$H_2$-$CH_2$-S-), 3.35 (m, 2 H, -S-C$H_2$-$CH_2$-S-$CH_2$-C$H_2$-S-), 3.84 (m, 2 H, -S-C$H_2$-$CH_2$-S-$CH_2$-C$H_2$-S-), 5.02 (s, 2 H, An-C$H_2$-N-), 7.46 (m, 2 H, *An*-$CH_2$-N-), 7.63 (m, 2 H, *An*-$CH_2$-N-), 8.04 (d, $^3J_{H,H}$ = 8.40 Hz, 2 H, *An*-$CH_2$-N-), 8.56 (d, $^3J_{H,H}$ = 8.95 Hz, 2 H, *An*-$CH_2$-N-), 8.61 (s, 1 H, *An*-$CH_2$-N-) ppm. $^{13}$C{$^1$H} NMR ($CD_3NO_2$, 25 °C): $\delta$ = 24.6 (-S-$CH_2$-C$H_2$-$CH_2$-N-), 32.6 (-S-C$H_2$-$CH_2$-$CH_2$-N-), 39.8 (-S-$CH_2$-C$H_2$-S-C$H_2$-$CH_2$-S-), 41.1 (-S-C$H_2$-$CH_2$-S-$CH_2$-C$H_2$-S-), 57.5 (An-C$H_2$-N-), 61.0 (-S-$CH_2$-$CH_2$-C$H_2$-NH-), 123.3, 123.4, 125.9, 128.4, 130.1, 131.1, 131.7, 132.5 (*An*-$CH_2$-N-) ppm. # Hydrophosphanation of Phenolic Aldehydes as Facile Synthetic Approach to Catechol-Functionalized Phosphane Oxides and Phosphanes

**Samir Chikkali[a] and Dietrich Gudat*[a]**

**Keywords:** Phosphanes / Phosphane oxides / P,O ligands / Hydrophosphanation / Rearrangement

Reactions of diphenylphosphane with mono- and dihydroxybenzaldehydes yield as initial products α-phosphanyl-carbinols that exist according to NMR studies in dynamic equilibrium with the starting materials in solution but are stable in the solid state. The facile rearrangement of the initial products yields isomeric phosphane oxides which react with MeI and excess $LiAlH_4$ via deoxygenation to give the corresponding phosphanes. Phosphane oxides and phosphanes were isolated and characterized by analytical and spectroscopic data. The reactions described represent an improved synthesis for phosphanes with phenol and catechol functionalities that are useful for applications as ligands or supramolecular building blocks.

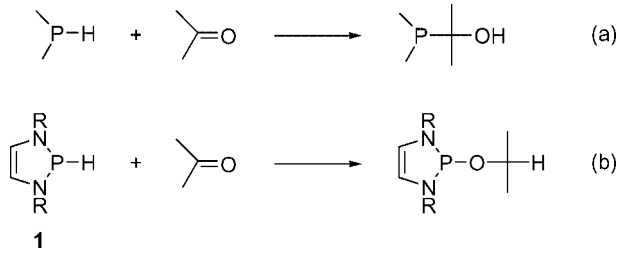
## Introduction

The addition of a P–H bond to a carbonyl group is a fundamental and synthetically useful reaction of phosphorus-hydrogen substituted phosphanes $PH_nR_{3-n}$. These transformations proceed normally strictly regioselective via P–C bond formation to give α-phosphanyl-carbinols (Scheme 1, a) and are used for the synthesis of functional tertiary phosphanes.[1] We have recently found that N-heterocyclic phosphanes **1** react with aldehydes and ketones via reduction rather than alkylation of the carbonyl moiety (Scheme 1, b).[2] The reversed regioselectivity ("umpolung") has been related to the unique hydride-like polarization of the P–H bond in **1** which owes to the special bonding situation in the heterocycle.[2]



Scheme 1. Possible reaction modes of phosphanes with carbonyl groups.

During a study on hydrophosphanation of carbonyl compounds we noticed that the reaction of diphenylphosphane with salicylic aldehyde affords a benzylphosphane oxide. Similar reactions were observed earlier and explained by a two-step sequence involving a "normal" hydrophosphanation followed by isomerization of the transient α-phosphanyl-carbinol [pathway (i), Scheme 2].[3] In the context of our studies on controlling the regioselectivity in hydrophosphanations[2] it was of interest to elucidate mechanistic aspects of this reaction in more detail. In particular, we wanted to exclude that the product was formed via "inverse" addition of the P–H bond of the phosphane and subsequent Michaelis–Arbuzov rearrangement of a transient phosphinite [pathway (ii) in Scheme 2] which might, in view of the reactivity of **1** and earlier observations of Michaelis–Arbuzov rearrangements under conditions similar to the ones applied here,[4] provide a conceivable alternative to the standard mechanism. We present here the results of studies of the transformations of diphenylphosphane and phenolic aldehydes into phenol-functionalized phosphane oxides, and demonstrate that these species can easily be converted into phosphanes. The products thus accessible belong to a class of multifunctional ligands that have recently attracted increasing attention as supramolecular building blocks[5]

and anchoring groups that are capable of immobilizing metal complexes on the surface of a metal oxide support.[6]

## Results and Discussion

The reaction of equimolar amounts of diphenylphosphane (**2**) and salicylic aldehyde (**3a**) in methanol or ethers ($Et_2O$, DME) in the presence of catalytic amounts of hydrochloric or *p*-toluenesulfonic acid affords directly the phosphane oxide **5a**[7] which has been isolated in good yield after work-up (Scheme 3).

| $R^2$ | H | OH | H | OH | OH |
| $R^3$ | H | H | OH | OH | H |

X = 4-$CH_3$–$C_6H_4SO_3^-$

Scheme 3.

$^{31}P$ NMR studies revealed that **5a** remained the only spectroscopically detectable species beside unreacted **2** and minor side products. The latter were not further characterized but their chemical shifts precluded assignment as an α-phosphanyl-carbinol. In order to elucidate mechanistic details we set out to find reaction conditions that facilitated the detection of a precursor to **5a**. In these studies it was established that treatment of an ethereal solution of **2** and **3a** with excess concd. hydrochloric acid lead to immediate precipitation of a colorless solid which was isolated by filtration. A solid-state $^{31}P$ CP/MAS NMR spectrum disclosed an isotropic shift ($\delta^{31}P_{iso}$ = –0.8) which differs clearly from that of **5a** ($\delta^{31}P_{iso}$ = 39.3) but resembles that of the α-phosphanyl-carbinol obtained from reaction of **2** and benzaldehyde. A spectrum recorded under conditions that allow to detect scalar couplings to protons revealed a doublet splitting attributable to a one-bond *J*-coupling (Figure 1, $J_{PH}$ = 501 Hz). Consequently, we assume that α-phosphanyl-carbinol hydrochloride **6a** is formed which is deemed to represent the initial product formed by attack of the phosphane on the protonated aldehyde. This structural assignment was further corroborated by satisfactory analytical data. Attempts to characterize **6a** by solution NMR spectroscopy revealed that the product decomposes upon dissolution in methanol to give a mixture of the starting materials and the phosphane oxide **5a**, an observation that emphasizes the character of a reaction intermediate for **6a**.

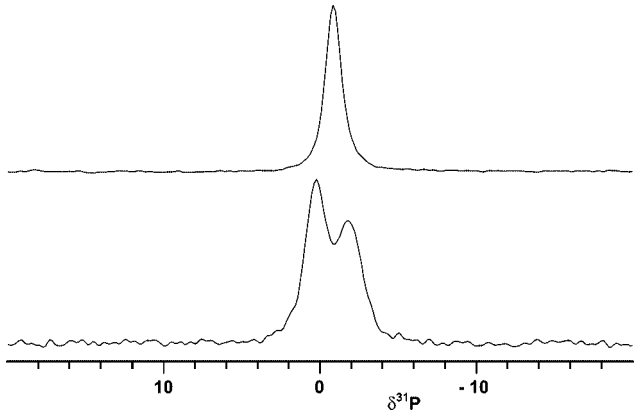

Figure 1. Isotropic line of the solid state CP/MAS $^{31}P$ NMR spectrum of **6a** at a spinning speed of 13.2 kHz recorded with high-power proton decoupling (top trace) and frequency-shifted Lee–Goldburg decoupling[9] (bottom trace) to suppress homonuclear dipolar coupling between protons. As the decoupling sequence scales the heteronuclear coupling by a factor of 0.577, the observed splitting of 289 Hz corresponds to a value of $^1J_{PH}$ = 501 Hz.

The above results allow to conclude that the reaction of **2** with salicylic aldehyde involves a "normal" hydrophosphanation as the key step. The same regioselectivity was observed in the acid-catalyzed reaction of **2** with 2,3-dihydroxybenzaldehyde (**3b**). NMR studies allowed in this case the direct detection of a small amount of the α-phosphanyl-carbinol **4b** and two further intermediates. The constitution of the latter was assigned as diastereomeric phosphonium salts **7b**, **7′b** by 2D NMR studies, and dynamic exchange between all four species was established by a 2D $^{31}P$ EXSY NMR spectrum. All products were eventually converted into the phosphane oxide **5b** which was isolated after work-up and characterized by analytical and spectroscopic data. Species similar to **7b**, **7′b** have previously been obtained by reaction of diphenylphosphane (**2**) with formaldehyde in the presence of strong acids.[1,8]

The reaction of **2** with 4-hydroxybenzaldehyde (**3c**) affords as primary product the α-phosphanyl-carbinol **4c** which was isolated by precipitation from methanol and characterized by $^{31}P$ CP/MAS NMR and analytical data. Key to the structural assignment was the observation of a single resonance ($\delta^{31}P$ = –7.2) which appears at somewhat higher field than that of **6a** and shows no splitting due to $^1J_{PH}$ coupling. In contrast to the elusive 2-hydroxy-substituted carbinol **4a**, the signal of **4c** is also observable in solution $^{31}P$ NMR spectra although in these solutions, even in the absence of additional acid, partial decomposition to **2** and **3c** occurs (obviously the acidity of the phenolic OH moiety is sufficient to promote an auto-catalytic reaction). Acidic catalysts promote the complete conversion to phos-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phane oxide **5c**. The same behavior can be observed in the reaction of **2** with 3,4-dihydroxybenzaldehyde (**3d**) which affords **5d** as final product. Both **5c** and **5d** were isolated after work-up and characterized by analytical and spectroscopic data.

Finally, the acid-catalyzed reaction of **2** with 3-hydroxybenzaldehyde (**3e**) gives a mixture of dynamically exchanging products the structures of which were assigned to the phosphanyl-carbinol **4e** and the diastereomeric phosphonium salts **7e/7e′** on the basis of a comparison of the observed $^{31}P$ chemical shifts with those of the products of the previously described reactions. A 1:1 mixture of **7e/7e′** precipitated from the reaction solution and was isolated by filtration. The constitution was confirmed by analytical data; a slow-spinning technique $^{31}P$ CP/MAS NMR spectrum shows the presence of two isotropic signals of equal intensity with negligible chemical shielding anisotropy. The precipitate dissolved again when the mixture was stirred for prolonged reaction times, and $^{31}P$ NMR studies allowed to detect the formation of the phosphane oxide **5e** as final product which eventually precipitated from the solution and was characterized by spectroscopic data.

In summary it can be stated that the reactions of the phosphane **2** with hydroxybenzaldehydes **3a**–**e** proceed via hydrophosphanation to yield α-phosphanyl-carbinols **4a**–**e** as initial products. These species are in dynamic equilibrium with the starting materials and phosphonium salts **7** resulting from acid-promoted reaction with further aldehyde. The composition of the equilibrium mixtures depends on the substitution pattern of the aldehydes and lies for **3a**–**d** which feature at least one OH substituent in 2- or 4-position largely on the side of the starting materials, whereas for **3e** the formation of the phosphonium salts **7e**,**e′** appears to be favored. As a consequence, the equilibrium concentration of the adducts **4a**–**e** is rather low, or these species may not be detectable at all. The reduced stability of the adducts with respect to the starting materials is attributable to the electron-releasing nature of the additional hydroxy-substituents which should render the aldehydes weaker electrophiles and the attack by the nucleophilic phosphane energetically less favorable. Aldehydes with 2-hydroxy substituents such as **3a**,**b** may further benefit from additional stabilization by strong intramolecular hydrogen bonding. The observation that all primary adducts may eventually rearrange quantitatively to the corresoponding phosphane oxides **5a**–**e** suggests that the latter are thermodynamically much more stable so that the isomerization is practically irreversible. The easy occurrence of this rearrangement is presumably also facilitated by the stabilization of the resulting transient intermediates by the electron-releasing phenolic OH substituents.

Deoxygenation of the phosphane oxides **4a**–**e** is readily achieved by adaptation of an established procedure[10] involving quaternization of the phosphane oxide moiety with methyl iodide and subsequent reduction with $LiAlH_4$ (Scheme 3). No special protection of the phenol groups is necessary, however, the use of a sufficient excess of the hydride to achieve complete deprotonation of the acidic OH groups is mandatory to obtain reasonable yields of products. Aqueous work-up of the reaction mixture and purification of the crude products by column chromatography affords the phosphanes **8a**–**d** as colorless, moderately oxygen-sensitive solids that were characterized by analytical and spectroscopic data.

## Conclusions

It has been confirmed that the reaction of diphenylphosphane with phenolic aldehydes is initiated by reversible formation of α-phosphanyl-carbinols. The presence of OH groups in *p*- or *o*-position appears to destabilize the adducts relative to the starting materials, thus keeping their concentration in the equilibrium mixtures low. The initial adducts rearrange easily to afford isomeric phosphane oxides which may further be reduced to the corresponding phosphanes. The overall reaction sequence permits to access the first alkylphosphane derivatives with tethered catechol and phenol moieties from readily available starting materials and without the necessity of additional efforts for the protection and deprotection of the reactive OH groups. This procedure constitutes a substantial improvement over previously known synthetic protocols which required often more complicated approaches.[4,11] The utilization of this procedure should prove useful for the preparation of functional phosphanes in applications as chelating ligands or supramolecular building blocks.

## Experimental Section

**General Remarks:** Manipulations were carried out under dry argon and solvents were dried by standard procedures if required. Solution NMR spectra were recorded at 30 °C on Bruker Avance 400 ($^1H$: 400.1 MHz, $^{13}C$: 100.5 MHz, $^{31}P$: 161.9 MHz) or AC 250 spectrometers ($^1H$: 250 MHz, $^{13}C$: 62.8 MHz, $^{31}P$: 101.2 MHz) at 303 K; chemical shifts are referenced to ext. TMS ($^1H$, $^{13}C$) or 85% $H_3PO_4$ ($\Xi$ = 40.480747 MHz, $^{31}P$). Solid state MAS NMR spectra were recorded on a Bruker Avance 400 instrument with spinning rates between 3 and 14 kHz. Cross polarization with a ramp-shaped contact pulse and mixing times between 3 and 5 ms was used for signal enhancement. MAS NMR spectra aiming at the determination of $^1J_{P,H}$ couplings were recorded under frequency-shifted Lee–Goldburg decoupling of homonuclear proton–proton interactions[9] which scales the visible splitting by a factor of 0.577. All coupling constants are given as absolute values; prefixes *i*, *o*, *m*, *p* denote phenyl ring positions of *P*-$C_6H_5$ substituents. The resonances of OH protons were not always detectable, presumably as a consequence of chemical exchange, and data are not listed when unequivocal assignment was unfeasible. MS: Varian MAT 711, EI, 70 eV. Elemental analyses: Perkin–Elmer 2400CHSN/O Analyser. Melting points were determined in sealed capillaries.

**General Procedure for the Synthesis of Phenol-Functionalized Phosphane Oxides:** Diphenylphosphane **2** (12 mmol) was added to a solution of the appropriate aldehyde **3a**–**e** (12 mmol) in DME (10 mL). The solution was stirred for five minutes at room temperature. A catalytic amount of *p*-toluenesulfonic acid (approx. 3–6 mmol) was added and the stirring continued for 48 h. The color-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

less precipitate formed was isolated by filtration, washed twice with 5 mL of DME, and dried in vacuo for 4 h.

**3-[(Diphenylphosphinoyl)methyl]phenol (5e):** Yield 2.22 g (60%); m.p. 198 °C; elemental analysis: $C_{19}H_{17}O_2P$ (308.32): calcd. C 74.02 H 5.56; found C 74.10 H 5.60. $^1$H NMR (250 MHz, $CD_3CN/CDCl_3$): $\delta$ = 7.55 (m, 4 H, *o*-H), 7.40 to 7.25 (m, 6 H, *m*/*p*-H), 6.80 (t, $^3J_{HH}$ = 8.0 Hz, 1 H, H-5), 6.59 (s, 1 H, H-2), 6.44 (d, $^3J_{HH}$ = 8.0 Hz, 1 H, H-4/6), 6.41 (d, $^3J_{HH}$ = 8.0 Hz, 1 H, H-4/6), 3.50 (d, $^2J_{PH}$ = 13.4 Hz, 2 H, $CH_2$) ppm. $^{13}$C{$^1$H} NMR (62 MHz, $CD_3CN/CDCl_3$): $\delta$ = 157.1 (d, $J_{PC}$ = 2.6 Hz), 132.4 (d, $J_{PC}$ = 2.9 Hz, *p*-C), 131.2 (d, $J_{PC}$ = 9.5 Hz, *o*-C), 131.0 (s), 130.9 (d, $J_{PC}$ = 102.3 Hz, *i*-C), 129.5 (d, $J_{PC}$ = 2.1 Hz), 128.9 (d, $J_{PC}$ = 11.8 Hz, *m*-C), 121.8 (d, $J_{PC}$ = 5.8 Hz), 117.5 (d, $J_{PC}$ = 5.0 Hz), 114.2 (d, $J_{PC}$ = 2.9 Hz), 37.1 (d, $J_{PC}$ = 67.1 Hz) ppm. $^{31}$P{$^1$H}NMR (101 MHz, $CDCl_3$): $\delta$ = 31.4 ppm.

**2-[(Diphenylphosphanyl)hydroxymethyl]phenol Hydrochloride (6a):** 2-Hydroxybenzaldehyde (**3a**) (0.64 mL, 6 mmol) was added to a solution of diphenylphosphane **2** (1.05 mL, 6 mmol) in diethyl ether (10 mL). This mixture was stirred for five minutes at room temperature and an excess of conc. hydrochloric acid (2 mL, 24 mmol) was added. A colorless precipitate formed immediately. The reaction mixture was then stirred for further 60 min, the precipitate filtered off, washed twice with diethyl ether (5 mL), and dried for 1 h in vacuo. Yield: 1.86 g (90%); m.p. 104 °C; elemental analysis: $C_{19}H_{18}ClO_2P$ (344.78): calcd. C 66.19 H 5.26 Cl 10.28; found C 66.76 H 5.38 Cl 8.54. $^{31}$P{$^1$H}NMR (solid, 162 MHz, CP/MAS): $\delta_{iso}$ = –0.8.

**4-[(Diphenylphosphanyl)hydroxymethyl]phenol (4c):** A solution of diphenylphosphane (**2**) (1.43 mL, 8.2 mmol) and 4-hydroxybenzaldehyde (**3c**) (1.00 g, 8.2 mmol) in methanol (10 mL) was stirred for 5 min at room temperature and conc. hydrochloric acid (0.25 mL, 3 mmol) was added. A colorless precipitate formed immediately. The reaction mixture was stirred for further 60 min, the precipitate filtered off and dried for 1 h in vacuo. Yield: 2.27 g (90%); m.p. 168 °C; elemental analysis: $C_{19}H_{17}O_2P$ (308.32): calcd. C 74.02 H 5.92; found 74.29 H 5.92. $^{31}$P NMR (101 MHz, THF): $\delta$ = –2.3 (s) ppm. $^{31}$P{$^1$H}NMR (solid, 162 MHz, CP/MAS): $\delta_{iso}$ = –7.2 ppm.

**Bis[hydroxy(3-hydroxyphenyl)methyl]diphenylphosphonium Toluenesulfonate (7e/7e′):** A solution of diphenylphosphane (**2**) (1.43 mL, 8.2 mmol) and 3-hydroxy benzaldehyde (**3e**) (1.00 g, 8.2 mmol) in DME (5 mL) was stirred for 5 min at room temperature and *p*-toluenesulfonic acid (0.60 g, 3.2 mmol) was added. A colorless precipitate began to form after 10 min. The reaction mixture was stirred for 12 h, the precipitate filtered off, washed twice with DME, and dried for 4 h in vacuo. Yield: 1.73 g (90%); m.p. 121 °C; elemental analysis: $C_{33}H_{31}O_7PS$ (602.64): calcd. C 65.77 H 5.19; found 65.39 H 5.30. $^{31}$P{$^1$H}NMR (solid, 162 MHz, CP/MAS): $\delta_{iso}$ = 30.5, 29.9 ppm.

**General Procedure for the Synthesis of Phenol-Functionalized Phosphanes:** The appropriate phosphane oxide **5a**–**d** (10 mmol) was dissolved in dry THF (100 mL). Methyl iodide (0.69 mL, 11 mmol) was added via a syringe and the solution stirred for 2 h at room temperature. The mixture was then cooled to 0 °C and solid $LiAlH_4$ (1.7 g, 45 mmol) added in several small portions. The reaction mixture was warmed to ambient temperature, and stirring was continued for another 5–6 h. The progress of the reaction was monitored by TLC. The reaction flask was again cooled to 0 °C, and 50 mL of 1 M hydrochloric acid were added in several portions (the first few drops had to be added very carefully until the exothermic reaction became less violent). The organic layer was separated and the aqueous layer washed with ethyl acetate (3 × 50 mL). The combined organic phases were dried overnight with $Na_2SO_4$ and all volatiles evaporated in vacuo. The crude products were purified by column chromatography (silica, petroleum ether:ethyl acetate = 7:3).

**2-[(Diphenylphosphanyl)methyl]phenol (8a):** Yield 1.81 g (62%); colorless oil, elemental analysis: $C_{19}H_{17}OP$ (292.32): calcd. C 78.07 H 5.86; found C 74.33 H 5.91. $^1$H NMR (250 MHz, [$D_8$]toluene): $\delta$ = 6.8 to 7.5 (m, 10 H, $C_6H_5$), 6.80 (t, 1 H, $^3J_{HH}$ = 7.7 Hz), 6.74 (d, 1 H, $^3J_{HH}$ = 7.7 Hz), 6.61 (d, 1 H, $^3J_{HH}$ = 7.8 Hz), 6.50 (t, 1 H, $^3J_{HH}$ = 7.5 Hz), 3.32 (s, 2 H, $CH_2$) ppm. $^{31}$P{$^1$H} NMR (101 MHz, [$D_8$]toluene): $\delta$ = –15.0 ppm. The $^1$H NMR spectroscopic data match those published earlier.[11]

**3-[(Diphenylphosphanyl)methyl]benzene-1,2-diol (8b):** Yield 1.85 g (60%); m.p. 82 °C; elemental analysis: $C_{19}H_{17}O_2P$ (308.32): calcd. C 74.02 H 5.56; found C 73.91 H 5.73. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 7.52 to 7.30 (m, 10 H, $C_6H_5$), 6.78 (dm, $^3J_{HH}$ = 7.9 Hz, 1 H, $C_6H_3$), 6.64 (tm, $^3J_{HH}$ = 7.9 Hz, 1 H, $C_6H_3$), 6.43 (dm, $^3J_{HH}$ = 7.9 Hz, 1 H, $C_6H_3$), 6.02 (br., 1 H, OH), 5.86 (br., 1 H, OH), 3.52 (d, $^2J_{PH}$ = 1.7 Hz, 2 H, $CH_2$) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $CDCl_3$): $\delta$ = 145.0 (d, $J_{PC}$ = 1.6 Hz), 141.7 (d, $J_{PC}$ = 3.7 Hz), 132.8

# Fluoromethyl Cations and Group XIV Congeners $AH_nF_{3-n}^+$ (A = Si, Ge, Sn, Pb; $n$ = 0–2): From Covalent Structures to Ion-Molecule Complexes

**Paola Antoniotti,[a] Stefano Borocci,[b] Nicoletta Bronzolino,[b] Maria Giordani,[b] and Felice Grandinetti*[b]**

**Keywords:** Ab initio calculations / Fluorinated cations / Group XIV elements / Ion-molecule complexes / Structure and stability

Ab initio calculations at the MP2 and CCSD(T) level of theory (triple-zeta quality basis sets for Si and Ge and effective core potentials plus DZ valence basis sets for tin and lead) have been performed to investigate the geometries, harmonic frequencies and relative stabilities of the $(Si,H,F)^+$, $(Ge,H,F)^+$, $(Si,F_3)^+$, $(Ge,F_3)^+$ and $(A,H_n,F_{3-n})^+$ (A = Si, Ge, Sn, Pb; $n$ = 1 and 2) isomeric ions. While the H–Si–F$^+$, F–$SiH_2^+$, H–$SiF_2^+$ and $SiF_3^+$ covalent structures are invariably predicted as the most stable isomers, the Ge$^+$–(HF), FA$^+$–($H_2$) and FA$^+$–(HF) complexes (A = Ge, Sn, Pb) are the global minima on the potential energy surfaces, more stable than the corresponding covalent structures by up to some tens of kilocalories per mole. For tin and lead, the HA$^+$–(HF) isomeric ions are also significantly more stable than F–$AH_2^+$ (A = Sn and Pb). Compared with the parent group XIV hydrides $(A,H_3)^+$, investigated so far by Schleyer and co-workers (*J. Am. Chem. Soc.* **1996**, *118*, 12154–12158) and found to possess, for A = Sn and Pb, energetically favoured HA$^+$–($H_2$) connectivities, the structural switch from covalent structures to ion-dipole complexes occurs, therefore, even earlier. This suggests that the "regular" covalent connectivity of even the simplest $AH_2X^+$ or $AHX_2^+$ cations of group XIV cannot be taken for granted, and, especially for germanium, tin and lead, the role of ion-molecule complexes must be carefully investigated.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

In 1996, Schleyer and co-workers performed a benchmark theoretical study[1] on the structure and stability of the heavier group XIV congeners of the methyl cation. Before that investigation, the $D_{3h}$ geometries of all the $AH_3^+$ ions (X = C, Si, Ge, Sn, Pb) had been taken for granted, as such species are expected to obey the Walsh rules for six valence electron compounds.[2] As a matter of fact, for $CH_3^+$ the $D_{3h}$ structure is the only energy minimum located at the highest levels of theory.[3] However, for the heaviest, Sn and Pb, the calculations show[1] that the HSn$^+$–($H_2$) and HPb$^+$–($H_2$) ion-molecule complexes are more stable than the $SnH_3^+$ and $PbH_3^+$ $D_{3h}$ covalent structures by about 5 and 23 kcal mol$^{-1}$, respectively. In addition, although $SiH_3^+$ and $GeH_3^+$ are more stable than HSi$^+$–($H_2$) and HGe$^+$–($H_2$), the energy difference between the covalent structure and the ion-molecule complex substantially reduces from about 28 to about 10 kcal mol$^{-1}$ passing from silicon to germanium.[1] The order of stability of the $GeH_3^+$ and HGe$^+$–($H_2$) isomers has been more recently confirmed by Schwarz and co-workers,[4] who have also found that the Ge$^+$–($H_2$) complex is nearly degenerate with the H–Ge–H$^+$ covalent structure ($C_{2v}$ symmetry) and plays an active role in the gas-phase ion chemistry of $GeH_2^+$. The order of stability of Si$^+$–($H_2$) and H–Si–H$^+$ is, however, opposite, and the latter species is more stable by about 12 kcal mol$^{-1}$.[5] From a general point of view, these theoretical and experimental findings are in line with the increased tendency, down group XIV, toward lower oxidation numbers, clearly evident, for example, in the thermodynamic instability of various Pb(IV) compounds.[6,7] Concerning the structure of cations such as $AHX^+$, $AX_2^+$, $AH_2X^+$, $AHX_2^+$ and $AX_3^+$ (A = C, Si, Ge, Sn, Pb; X = monovalent group), they are usually assumed to be "regular" covalent structures and the conceivable role of ion-molecule complexes such as A$^+$–(HX), AH$^+$–(HX) or AX$^+$–($H_2$) is still essentially unexplored. As a first step in this direction, stimulated by our continuing interest in the chemistry of fluorinated cations,[8] we report here an ab initio study on the heavier congeners of the fluoromethyl cations $CH_2F^+$, $CHF_2^+$ and $CF_3^+$, which are known to possess covalent structures of $C_{2v}$ or $D_{3h}$ symmetry,[9–12] as well as on the additional exemplary species $SiHF^+$ and $GeHF^+$. While the $(Si,H,F)^+$ and $(Si,H_n,F_{3-n})^+$ ($n$ = 0–3) isomeric ions are structurally similar to their carbon congeners, the global minima on the $(Ge,H,F)^+$,

$(A,H_2,F)^+$ and $(A,H,F_2)^+$ potential energy surfaces (A = Ge, Sn, Pb) are invariably ion-molecule complexes such as $Ge^+$–(HF), $HA^+$–(HF) or $FA^+$–($H_2$). Therefore, our calculations provide additional examples of only "seemingly familiar"[1] compounds of group XIV and confirm the crucial role of noncovalent isomers in the gas-phase ion chemistry of the heaviest elements: germanium, tin and lead.

## Results and Discussion

All the $(Si,H,F)^+$, $(Ge,H,F)^+$, $(Si,F_3)^+$, $(Ge,F_3)^+$ and $(A,H_n,F_{3-n})^+$ (A = Si, Ge, Sn, Pb; $n$ = 1 and 2) isomeric ions shown in Figure 1, Figure 2, Figure 3 and Figure 4 have been characterised as minimum points on the MP2(full)/6-311G(d,p) (Si and Ge) or MP2(full)/6-311G(d,p)/LANL2DZ (Sn and Pb) potential energy surfaces. Their harmonic frequencies are listed in Tables 1S–4S of the supporting information. The geometries of the silicon- and germanium-containing ions were also refined at the CCSD(T,full)/cc-pVTZ level of theory, finding however only minor differences with the MP2(full)/6-311G(d,p) bond lengths and bond angles. The CCSD(T,full)/cc-pVTZ-optimised structures were finally used to perform CCSD(T,full)/aug-cc-pVTZ single-point calculations, so as to obtain accurate estimates of the relative stability of the various isomers and to evaluate the accuracy of the corresponding values obtained by MP2 calculations. The obtained data, reported in Table 1 and Table 2, reveal that the MP2(full)/6-311G(d,p) level of theory invariably predicts the correct order of stability of the various isomers but in general overestimates the stability of the ion-molecule com-

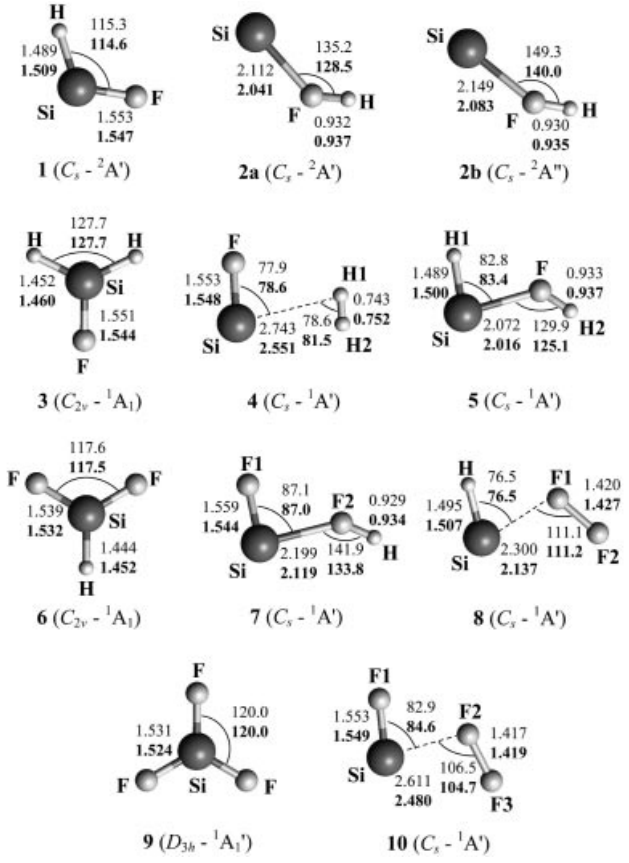

Figure 1. MP2(full)/6-311G(d,p) and CCSD(T,full)/cc-pVTZ-optimised (bold) geometries [Å and °] of the $(Si,H,F)^+$ and $(Si,H_n,F_{3-n})^+$ isomeric ions ($n$ = 0–3).

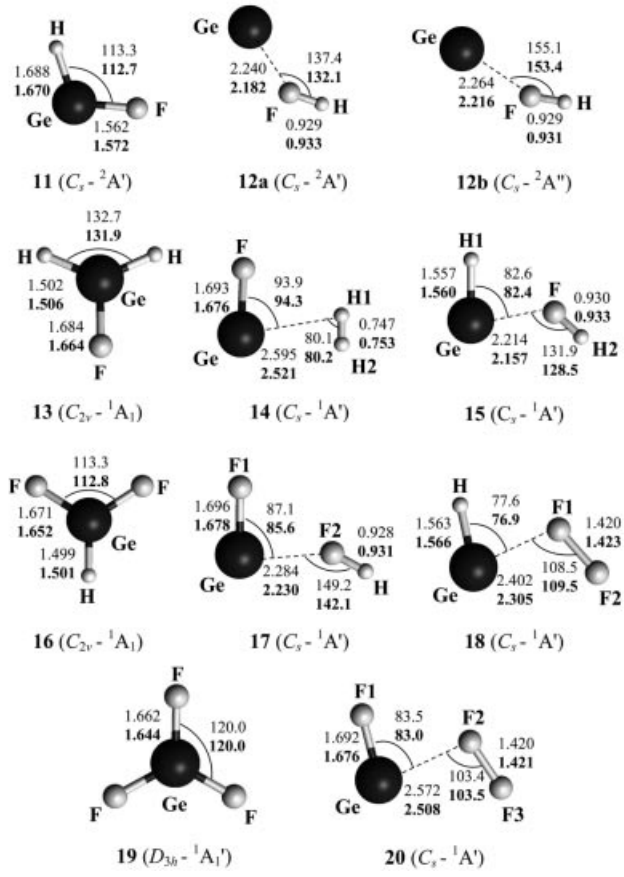

Figure 2. MP2(full)/6-311G(d,p) and CCSD(T,full)/cc-pVTZ-optimised (bold) geometries [Å and °] of the $(Ge,H,F)^+$ and $(Ge,H_n,F_{3-n})^+$ isomeric ions ($n$ = 0–3).

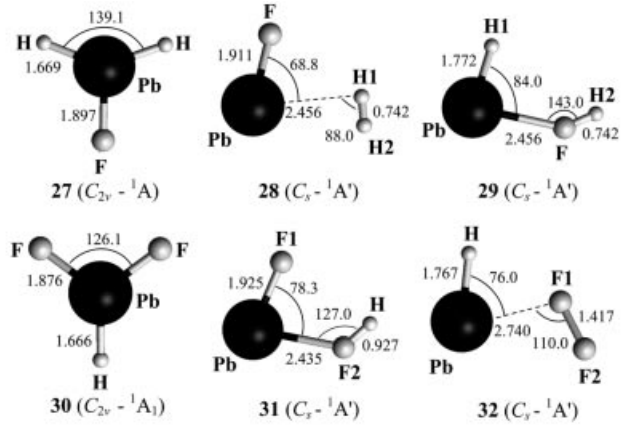

Figure 4. MP2(full)/6-311G(d,p)/LANL2DZ-optimised geometries [Å and °] of the $(Pb,H_2,F)^+$ and $(Pb,H,F_2)^+$ isomeric ions.

plexes by about 4–6 kcal mol$^{-1}$ for the silicon-containing ions and by about 10–12 kcal mol$^{-1}$ for the germanium-containing ions. On the other hand, from Table 3, the large energy differences of up to some tens of kilocalories per mole predicted at the MP2(full)/6-311G(d,p)/LANL2DZ level of theory between the various $(A,H_2,F)^+$ and-$(A,H,F_2)^+$ (A = Sn and Pb) isomeric structures are confirmed, within a few kilocalories per mole, by CCSD(T) single-point calculations.

## Structure and Stability of the $(Si,H,F)^+$ and $(Si,H_n,F_{3-n})^+$ Isomeric Ions ($n$ = 0–3)

The optimised parameters and the harmonic frequencies of the bent H–Si–F$^+$ isomer **1**[13] are in very good agreement with previous HF/6-31G(d) data[14,15] and identify the cat-

Table 1. Total energies (atomic units), zero-point energies (ZPE, atomic units), thermal corrections (TC, atomic units) and total entropies ($S$, cal·mol$^{-1}$ K$^{-1}$) of the $(Si,H,F)^+$ and $(Si,H_n,F_{3-n})^+$ ($n$ = 0–3) isomeric ions (see Figure 1).

[a] The values in parentheses are based on CCSD(T,full)/6-311G(d,p)/LANL2DZ single-point calculations.

ion as a typical covalent structure, with Si–H and Si–F bond lengths of about 1.5 Å and corresponding stretching frequencies around 2150 and 1050 cm$^{-1}$, respectively. On the other hand, the geometries and harmonic frequencies of the nearly degenerate $Si^+$–(HF) isomers **2a** and **2b**, located as distinct minima on the A′ and A″ doublet potential energy surface, point to ion-dipole complexes between $Si^+$ and HF. The Si–F bond lengths are longer than 2.0 Å, the corresponding stretching frequencies range around 250 cm$^{-1}$ and the CCSD(T,full)/aug-cc-pVTZ//CCSD(T,full)/cc-pVTZ dissociation energies into $Si^+(^2P)$ and HF amount to 22.3 kcal mol$^{-1}$ for isomer **2a** and 21.1 kcal mol$^{-1}$ for isomer **2b**. At the same computational level, the two ions are less stable than **1** by 23.1 and 24.3 kcal mol$^{-1}$, respectively. This difference is larger than the energy gap between $SiH_2^+$ ($C_{2v}$) and $Si^+$–($H_2$), obtained so far as 11.5 kcal mol$^{-1}$ at the complete active space SCF level of theory followed by second-order CI (CASSCF–SOCI)[5] and presently confirmed as 11.4 kcal mol$^{-1}$ at the CCSD(T,full)/aug-cc-pVTZ//CCSD(T,full)/cc-pVTZ level of theory.

The geometries and harmonic frequencies of the F–$SiH_2^+$ isomer **3** and of the H–$SiF_2^+$ isomer **6** of $C_{2v}$ symmetry are also in good agreement with previous HF,[14–16] MP2[10,17] and CASSCF[18] ab initio studies and are again typical of covalent structures. On the other hand, the bond lengths, harmonic frequencies and dissociation energies of the $(Si,H_2,F)^+$ isomers **4** and **5**, and of the $(Si,H,F_2)^+$ isomers **7** and **8**, point to ion-molecule complexes between ground-state $SiF^+(^1\Sigma^+)$[19] and $H_2$ (**4**) or HF (**7**), and ground-state $SiH^+(^1\Sigma^+)$[20] and HF (**5**) or $F_2$ (**8**). The bond lengths between the constituting moieties range from about 2.0 Å (isomer **5**) to about 2.6 Å (isomer **4**), and their CCSD(T,full)/aug-cc-pVTZ//CCSD(T,full)/cc-pVTZ interaction energies, computed as 3.3 kcal mol$^{-1}$ for isomer **4**, 8.4 kcal mol$^{-1}$ for isomer **8**, and 22.1 and 18.6 kcal mol$^{-1}$, respectively, for isomers **5** and **7**, parallel the increasing solvation ability of $H_2$, $F_2$ and HF. From Table 1, these ions are less stable than the corresponding covalent structures **3** or **6** by 9.3 kcal mol$^{-1}$ (isomer **4**), 38.0 kcal mol$^{-1}$ (isomer **5**), 16.9 kcal mol$^{-1}$ (isomer **7**) and 204.3 kcal mol$^{-1}$ (isomer **8**) (in the context of the protonation of $SiF_2$, the energy difference between isomers **6** and **7** has been obtained[21] as 15.9 kcal mol$^{-1}$ at the G2 level of theory). These energy differences and orders of stabilities, namely $FSi^+$–($H_2$) > $HSi^+$–(HF) and $FSi^+$–(HF) >> $HSi^+$–($F_2$), reflect a balance of several factors, including the different strength of the Si–$H^+$ and Si–$F^+$ covalent bonds[22] (75 vs. 151 kcal mol$^{-1}$), the different thermodynamic stability of $H_2$, HF and $F_2$, and the different solvation ability of these ligands. Consistently, the ion-molecule complex **10**, arising from the weak interaction [5.5 kcal mol$^{-1}$ at the CCSD(T,full)/aug-cc-pVTZ//CCSD(T,full)/cc-pVTZ level of theory] between $SiF^+$ and the highly unstable, poorly solvating $F_2$, is less stable than $SiF_3^+$ ($D_{3h}$) by more than 170 kcal mol$^{-1}$.

### Structure and Stability of the $(Ge,H,F)^+$ and $(Ge,H_n,F_{3-n})^+$ Isomeric Ions ($n$ = 0–3)

As already pointed out in the Introduction, the energy difference of about 28 kcal mol$^{-1}$ between $SiH_3^+$ ($D_{3h}$) and $HSi^+$–($H_2$)[1] is reduced to about 10 kcal mol$^{-1}$ for $GeH_3^+$ and $HGe^+$–($H_2$).[4] Similarly, H–Si–$H^+$ ($C_{2v}$) is more stable than $Si^+$–($H_2$) by about 11 kcal mol$^{-1}$,[5] but, according to highly accurate ab initio calculations,[4] H–Ge–$H^+$ and $Ge^+$–($H_2$) are nearly degenerate. Therefore, passing from $(Si,H,F)^+$ and $(Si,H_n,F_{3-n})^+$ ($n$ = 0–3) to $(Ge,H,F)^+$ and $(Ge,H_n,F_{3-n})^+$ ($n$ = 0–3), one expects an overall stabilisation of the ion-molecule complexes with respect to the corresponding covalent structures. From Table 2, the clearest confirmation of this qualitative expectation is the high stability of the $FGe^+$–(HF) isomer **17**, which is more stable than the covalent H–$GeF_2^+$ (**16**) by more than 17 kcal mol$^{-1}$ at the CCSD(T,full)/aug-cc-pVTZ//CCSD(T,full)/cc-pVTZ

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

level of theory. The $FGe^+$–($H_2$) isomer **14** is also more stable than F–$GeH_2^+$ (**13**) by about 2 kcal mol$^{-1}$, while the two $Ge^+$–(HF) isomers **12a** and **12b**, located as distinct energy minima on the A′ and A′′ doublet potential energy surfaces, are nearly degenerate with the H–Ge–$F^+$ cation **11**. Ions **12a**, **12b**, **14** and **17**, as well as the $HGe^+$–(HF) isomer **15** and the $HGe^+$–($F_2$) isomer **18** feature bond lengths, bond angles and harmonic frequencies that point to ion-molecule complexes between ground state $Ge^+(^2P)$, $GeH^+(^1\Sigma^+)$[23] and $GeF^+(^1\Sigma^+)$,[24] and $H_2$, HF or $F_2$. Similar to their silicon congeners, the distances between the constituting moieties range in fact from about 2.0 Å to more than 2.5 Å and the CCSD(T,full)/aug-cc-pVTZ//CCSD(T,full)/cc-pVTZ interaction energies regularly increase from the $H_2$ complex **14** (4.6 kcal mol$^{-1}$) to the $F_2$ complex **18** (8.6 kcal mol$^{-1}$), and arrive at about 20–22 kcal mol$^{-1}$ for the HF complexes **12**, **15** and **17**. In addition, the orders of stability of these isomers, namely $FGe^+$–($H_2$) > $HGe^+$–(HF) and $FGe^+$–(HF) >> $HGe^+$–($F_2$), parallel that of their silicon congeners and again reflect the increasing strength of Ge–$H^+$ and Ge–$F^+$ covalent bonds (68 vs. 125 kcal mol$^{-1}$), and the different thermodynamic stability and solvation ability of $H_2$, HF and $F_2$. It is therefore not surprising that the $FGe^+$–($F_2$) loosely bound complex **20** (the interaction between $GeF^+$ and $F_2$ amounts to 7.0 kcal mol$^{-1}$) is less stable than $GeF_3^+$ ($D_{3h}$) by 114.6 kcal mol$^{-1}$.

### Structure and Stability of the $(A,H_2,F)^+$ and $(A,H,F_2)^+$ Isomeric Ions (A = Sn and Pb)

Passing to the tin- and lead-containing ions $(A,H_2,F)^+$ and $(A,H,F_2)^+$ (A = Sn and Pb), with the only exception of the $HSn^+$–($F_2$) isomer **26** and the $HPb^+$–($F_2$) isomer **32**, all the $FA^+$–($H_2$), $HA^+$–(HF) and $FA^+$–(HF) isomers, **22**, **23**, **25**, **28**, **29** and **31** (A = Sn and Pb), become appreciably more stable than the corresponding covalent structures **21** (F–$SnH_2^+$), **24** (H–$SnF_2^+$), **27** (F–$PbH_2^+$) and **30** (H–$PbF_2^+$). The MP2(full)/6-311G(d,p)/LANL2D energy differences amount to about 17 kcal mol$^{-1}$ for $HSn^+$–(HF) and 26.0 kcal mol$^{-1}$ for $FSn^+$–($H_2$), range around 50 kcal mol$^{-1}$ for $FSn^+$–(HF), $FPb^+$–($H_2$) and $HPb^+$–(HF), and become as large as about 85 kcal mol$^{-1}$ for the $FPb^+$–(HF) isomer. The values obtained by CCSD(T) single-point calculations are essentially similar, but these estimates could be in principle appreciably affected by geometry optimisations. We note in fact from Figure 1 and Figure 2 that, for the Si and Ge analogues, the MP2 distances of the ion-neutral complexes are considerably larger than the CCSD(T) values.

From Figure 3 and Figure 4, any $FA^+$–($H_2$), $HA^+$–(HF), $HA^+$–($F_2$) and $FA^+$–(HF) isomeric structure (A = Sn and Pb) features bond lengths between the constituting moieties that are typical of ion-molecule complexes. In addition, similar to their silicon and germanium congeners, their stabilisation energies with respect to the separated ions and neutrals, computed as about 0.5 kcal mol$^{-1}$ for isomers **22** and **28**, about 3 kcal mol$^{-1}$ for isomers **26** and **32**, and about 17–24 kcal mol$^{-1}$ for isomers **23**, **25**, **29** and **31**, are again related to the increasing solvation ability of their constituting $H_2$, $F_2$ or HF neutral moieties. They also follow the orders of stability already noted for Si and Ge, namely $FA^+$–($H_2$) > $HA^+$–(HF) and $FA^+$–(HF) >> $HA^+$–($F_2$) (A = Sn and Pb).

## Concluding Remarks

The benchmark theoretical study by Schleyer and coworkers[1] on cationic hydrides of group XIV first disclosed a periodic structural switch from covalent structures to ion-molecule complexes, which results in particular in the higher stability of $HSn^+$–($H_2$) and $HPb^+$–($H_2$) with respect to $SnH_3^+$ and $PbH_3^+$. The results of our calculations indicate that, for the fluorine-substituted cations, this structural switch occurs even earlier and ion-molecule complexes such as $FGe^+$–($H_2$) and $FGe^+$–(HF), as well as $Ge^+$–(HF), are already more stable than their corresponding covalent structures. In addition, for the tin- and lead-containing analogues, the energy differences become as large as some tens of kilocalories per mole. From a general point of view, these findings suggest that the covalent structure of even the simplest $AH_2X^+$- or $AHX_2^+$-substituted cations of group XIV cannot be taken for granted, and, especially for the ions containing germanium, tin and lead, the role of ion-molecule complexes such as $A^+$–(HX), $AH^+$–(HX) or $AX^+$–($H_2$) must be carefully investigated.

## Computational Details

The quantum chemical calculations were performed using Unix versions of the Gaussian03[25] and MOLPRO 2000.1[26] sets of programs installed on an Alphaserver 1200 and an HP Proliant DL585 machine. The geometries of all the silicon- and germanium-containing ions were first optimised, using the 6-311G(d,p) basis set,[27] at the second-order Møller-Plesset level of theory with inclusion of the inner electrons, MP2(full),[28] and subsequently refined, using the Dunning's correlation consistent triple-zeta basis set (cc-pVTZ)[29] at the coupled cluster level of theory (full electrons), including the contribution from single and double substitutions and an estimate of connected triples, CCSD(T,full).[30,31] To evaluate the influence of diffuse functions, single-point calculations were finally performed at the CCSD(T,full) level of theory with the aug-cc-pVTZ basis set. For the doublet state species, we used the spin-restricted coupled cluster theory as implemented in MOLPRO.[32,33] The MP2(full)/6-311G(d,p) unscaled frequencies were used to calculate the zero-point vibrational energies (ZPE) and the vibrational contribution to the thermal correction (TC), obtained at 298.15 K by standard statistical mechanics formulas.[34] The overall TC term was finally obtained by adding the translational (3/2 RT) and rotational (RT) contributions at this temperature. The structure and harmonic frequencies of the tin- and lead-containing species were computed at the MP2(full) level of theory using the 6-311G(d,p) basis set for H and F and the Los Alamos ECP plus DZ (LANL2DZ) for Sn and Pb.[35]

# Synthesis, Characterization, and Crystal Structure Analysis of the First Terdentate [C,N,S] Thiosemicarbazone Complex with a Six-Membered Palladacycle: Influence of Steric Effects on Ring Size

**Adriana Amoedo,[a] Luis A. Adrio,[a] José M. Antelo,[a] Javier Martínez,[a] M. Teresa Pereira,[a] Alberto Fernández,[b] and José M. Vila*[a]**

*Dedicated to Professor Victor Riera on the occasion of his 70th birthday*

**Keywords:** Thiosemicarbazones / Cyclometalation / Palladium / Indole / Crystal structure

The reaction of the thiosemicarbazone ligands 1-(COMe)-3-[C(H)=NN(H)C(=S)NHR]$C_8H_5N$, (R = H **a**, Me **b**, Et **c**) with potassium tetrachloropalladate in an ethanol/water mixture led to the new tetranuclear palladium(II) compounds [Pd{1-(COMe)-3-[C(H)=NN=C(S)NHR]$C_8H_4N$-$k^3C5,N,S$}]$_4$ (R = H **1a**, Me **1b**, Et **1c**) which contain six-membered metallacycles. The thiosemicarbazone ligands in these complexes are terdentate through the C, N, and S atoms and are deprotonated at the NH group. The Pd–S bond formed is sufficiently strong to undergo reactions with nucleophiles without bond cleavage. Reaction of **1a** and **1b** with 1,2-bis(diphenylphosphanyl)ethane (dppe) gave the dinuclear species [{Pd[1-(COMe)-3-{C(H)=NN=C(S)NHR}$C_8H_4N$]}$_2$(μ-$Ph_2P(CH_2)_2PPh_2$)] (R = H **2a**, Me **2b**). The molecular structure of complex **1b** has been determined by X-ray diffraction analysis.

## Introduction

Cyclometalated compounds, which make up a fair portion of species pertaining to the organometallic family, are quite numerous and have been studied to a great degree, among other reasons owing to the great number of organic substrates that can undergo a cyclometalation reaction to form a stable five-membered ring.[1–7] In particular, thiosemicarbazone ligands are prominent in this process in view of the donor atoms they display, which is not only limited to the nitrogen and sulfur atoms of the thiosemicarbazide chain, or to additional donors set on the parent aldehyde or ketone, but also because metal–carbon bonding makes them appropriate terdentate [C,N,S] ligands. This makes them reminiscent of the related terdentate [C,N,N] Schiff bases[8–10] and [C,N,O] semicarbazones[11] in that compounds with two fused rings at the metal center are formed; recently, a further example of [C,N,N] pincer complexes has been reported.[12]

That thiosemicarbazone derivatives exhibit an altogether different chemical behavior is due to the strength of the Pd–$S_{chelate}$ bond, which hinders opening of the metalated and coordination rings at the metal center, thus making the ligands excellent pincer species that powerfully occupy three of the four coordination positions of the metal, thereby allowing only the fourth coordination site to undergo further reaction with nucleophiles.

Another interesting issue related to these ligands is that upon treatment with the corresponding palladium or platinum salt, tetrameric compounds bearing a central $Pd_4S_4$ or $Pt_4S_4$ central core are obtained, an outcome which, in the majority of cases, seems to be an inevitable consequence of their chemistry. In view of our previous results, and in efforts to progress further into the chemistry of cyclometalated thiosemicarbazones, we were interested in establishing if tetrameric compounds could also be obtained in the case of six-membered palladacycles, for which purpose we chose ligands derived from condensed systems where five- or six-membered metalated rings may be formed. It has been reported that in ligands with condensed rings, the site and/or the electronic properties of the substituents may force the formation of six-membered metalated rings as opposed to the more stable five-membered ones.[13,14] Furthermore, previous studies have also shown that bulky groups close to the potential metalation site impede metal–carbon bond formation by hindering approach of the metal to the carbon atom.[15] With this in mind we chose the thiosemicarbazones derived from the condensation of 1-acetyl-3-in-

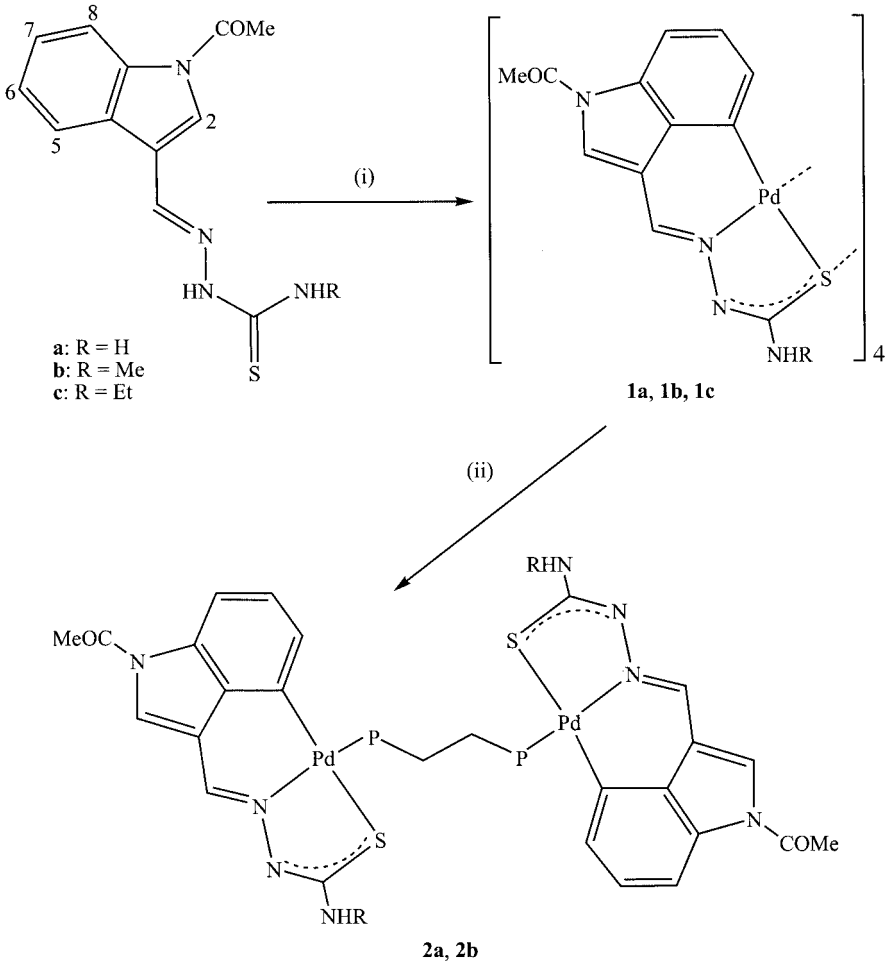
dolecarboxaldehyde and the corresponding thiosemicarbazide, where, although metalation could, in principle, be achieved through the pyrrole (C2) or the phenyl (C5) carbon atoms to give a five- or a six-membered metalated ring, respectively, the acetyl group on the pyrrole nitrogen atom should sufficiently hinder approach of the palladium atom to the C(2) carbon, in which case metalation of the ligand should occur at the C(5) carbon. This paper describes the results of this endeavor.

## Results and Discussion

The ligands **a**–**c** were prepared by reaction of 1-acetyl-3-indolecarboxaldehyde with thiosemicarbazide, 4-methylthiosemicarbazide, or 4-ethylthiosemicarbazide, respectively (see Exp. Sect.). The bands at around 3380 and 3140 $cm^{-1}$ in the IR spectra of these compounds are due to ν(N–H) absorption of the $NH_2$ and NH groups, respectively; the latter is not present in the spectra of the complexes.[15] The ligands also show characteristic ν(C=N) and ν(C=S) stretches in their IR spectra at around 1615 and 830 $cm^{-1}$, respectively. In the $^1H$ NMR spectra the resonances at around $\delta$ = 11.5 and 8.30 ppm were assigned to the NH and HC=N protons, respectively (see Exp. Sect.). New cyclometalated compounds were obtained from the ligands, as shown in Scheme 1. In a typical experiment, a suspension of $K_2PdCl_4$ in ethanol/water was treated with the corresponding thiosemicarbazone ligand to give complexes [Pd{1-(COMe)-3-[C(H)=NN=C(S)NHR]$C_8H_4$N-$k^3C5,N,S$}]$_4$ (R = H **1a**, Me **1b**, Et **1c**) as air-stable solids, which were fully characterized, with the ligand in the (*E*,*Z*) configuration. The mass spectrum (FAB) shows peaks at *m*/*z* 1458 (**1a**), 1515 (**1b**), and 1571 (**1c**) for the molecular ion, and the isotopic composition suggests a tetranuclear complex of formula $C_{48}H_{40}N_{16}O_4Pd_4S_4$ (**1a**), $C_{52}H_{48}N_{16}O_4Pd_4S_4$ (**1b**), and $C_{56}H_{56}N_{16}O_4Pd_4S_4$ (**1c**).

The IR data are in agreement with deprotonation of the ligand at the hydrazine nitrogen upon complex formation[16–19] (vide supra). The ν(C=N) band is shifted to lower wavenumbers,[20] contrary to the trend observed for other thiosemicarbazone complexes, which show a shift to higher wavenumbers.[15] The ν(C=S) band disappears, in agreement with loss of double-bond character upon deprotonation of the NH group. Although these data are in good accordance with metalation of the thiosemicarbazone, they give little insight as to the metalated carbon atom, for which definite proof was obtained from the $^1H$ NMR spectra, whose data are fully consistent with metalation of the C(1)



Scheme 1. (i) $K_2PdCl_4$/EtOH; (ii) $Ph_2P(CH_2)_2PPh_2$/$Me_2CO$, 1:2.

carbon atom. Thus, a singlet at $\delta$ = 7.41 (**1a**), 7.41 (**1b**) and 7.68 ppm (**1c**) was assigned to the pyrrole C(2)*H* proton resonance, which is shifted to lower frequency with respect to its position in the spectra of the free ligands ($\delta \approx$ 8.3 ppm). The complex ABCD spin system due to the H(5)–H(8) protons that is seen for the ligands is absent in the spectra of the complexes, where it gives way to a simple three-proton first-order spectrum that can be unambiguously assigned and clearly indicates loss of the H5 proton upon metalation. Thus, two doublets at around $\delta$ = 8.6 and 8.4–8.0 ppm were ascribed to the H6 and H8 protons, respectively, whereas a triplet at around $\delta$ = 7.1 ppm was assigned to the H7 resonance (see Exp. Sect.). Also relevant is the absence of the signal for the NH group and the high-field shift of the HC=N resonance by about 0.4–0.9 ppm.[21,22] Only one set of signals was detected in the $^1$H NMR spectra, thereby precluding mixtures of compounds bearing different metalated carbons and confirming the strong steric hindrance exerted by the C(O)Me group, which selectively directs the palladium atom towards the phenyl C5 atom.

### Crystal and Molecular Structure of 1b

Suitable crystals of complex **1b** were grown by slowly evaporating a DMSO solution. Crystal data are given in the Exp. Sect. An ORTEP illustration of the structure, with selected interatomic distances and angles, is shown in Figure 1.

The asymmetric unit of **1b** consists of two molecules of compound **1b** and eight DMSO solvent molecules. Although the overall structure for each molecule is only approximately $S_4$-symmetric, the four cyclometalated moieties are not symmetry-related. Nevertheless, discussion shall be limited to the data pertaining to one fourth of the molecule, i.e., the one involving Pd(1A); the structural data for the other three molecular units are very similar. The palladium atom exhibits a slightly distorted square-planar geometry with a central nucleus comprised of an eight-membered ring of alternating palladium and sulfur atoms, which adopts a boat conformation. Each palladium atom is bonded to four different donor atoms: three pertaining to a terdentate thiosemicarbazone, namely the aryl C(1) carbon, the imine N(2) nitrogen, and the thioamide S(1) sulfur atom, with a fourth donor being a sulfur atom S(1B) from a neighboring ligand. The plane formed by the ligating atoms at palladium [C(1A), N(2A), S(1A), S(1B): plane 1] is essentially planar (rms = 0.0132), with slight displacement of the metal atom by ±0.0395 Å. The remaining planes at palladium: the metallacycle [Pd(1A), C(1A), C(6A), C(10A), C(11A), N(2A): plane 2], the coordination ring [Pd(1A), N(2A), N(3A), C(12A), S(1A): plane 3], and the metalated phenyl ring [C(1A), C(2A), C(3A), C(4A), C(5A), C(6A): plane 4] are nearly coplanar [angles between planes 1 and 2 = 1.60(0.08)°, 1 and 3 = 1.13(0.08)°, 1 and 4 = 1.35(0.10)°, 2 and 3 = 2.70(0.08)°, 2 and 4 = 2.80(0.12)°, and 3 and 4 = 1.23(0.11)°]. All bond lengths are in their typical ranges, and the S(1A)–C(12A) [1.765(8) Å] and N(3A)–C(12A) bond lengths [1.299(7) Å] are consistent with increased single- and double-bond character, respectively. The Pd(1A)–S(1A) bond [2.3380(14) Å] is longer than the Pd(1A)–S(1B) bond [2.3208(13) Å], thus confirming the greater *trans* influence of the phenyl carbon as compared to the imine nitrogen atom. The Pd(1A)–C(1A) bond [2.021(5) Å] is shorter than the expected value of 2.081 Å,[23] probably due to partial multiple-bond character.[11,24] The Pd(1)–N(1) bond [2.064(4) Å] is longer than previous values found in related complexes (sum of the covalent radii for palladium and nitrogen: 2.01 Å[10]), due not only to the *trans* influence of the sulfur atom but also to the greater size of the met-

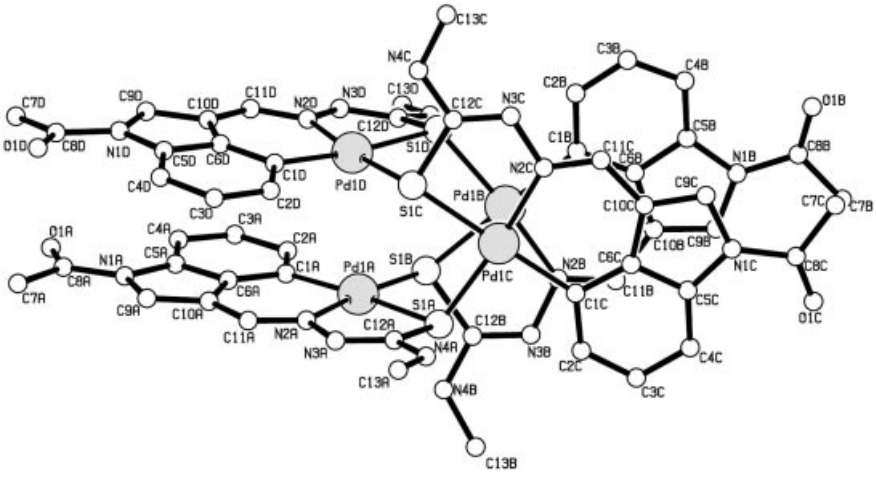

Figure 1. Molecular structure of **1b**, with labelling scheme. Hydrogen atoms have been omitted for clarity. Selected bond lengths and angles: Pd(1A)–C(1A) 2.021(5), Pd(1A)–N(2A) 2.064(4), Pd(1A)–S(1B) 2.3208(13), Pd(1A)–S(1A) 2.3380(14), S(1A)–C(12A) 1.749(6), N(3A)–C(12A) 1.299(7), N(3A)–N(2A) 1.439(5), N(2A)–C(11A) 1.292(6), C(1A)–C(6A) 1.390(6), C(11A)–C(10A) 1.410(7), C(10A)–C(6A) 1.457(6); C(1A)–Pd(1A)–N(2A) 94.27(18), C(1A)–Pd(1A)–N(2A) 94.27(18), N(2A)–Pd(1A)–S(1B) 173.23(12), C(1A)–Pd(1A)–S(1A) 176.29(14), N(2A)–Pd(1A)–S(1A) 83.45(12), S(1B)–Pd(1A)–S(1A) 89.92(5), C(6A)–C(1A)–Pd(1A) 118.7(4), C(1A)–C(6A)–C(10A) 130.4(5), C(11A)–C(10A)–C(6A) 125.2(4), N(2A)–C(11A)–C(10A) 123.5(5), C(11A)–N(2A)–N(3A) 112.1(4), C(11A)–N(2A)–Pd(1A) 128.0(4), N(3A)–N(2A)–Pd(1A) 119.9(3), C(12A)–N(3A)–N(2A) 113.6(4), N(3A)–C(12A)–S(1A) 127.2(4), C(12A)–S(1A)–Pd(1A) 95.4(2).

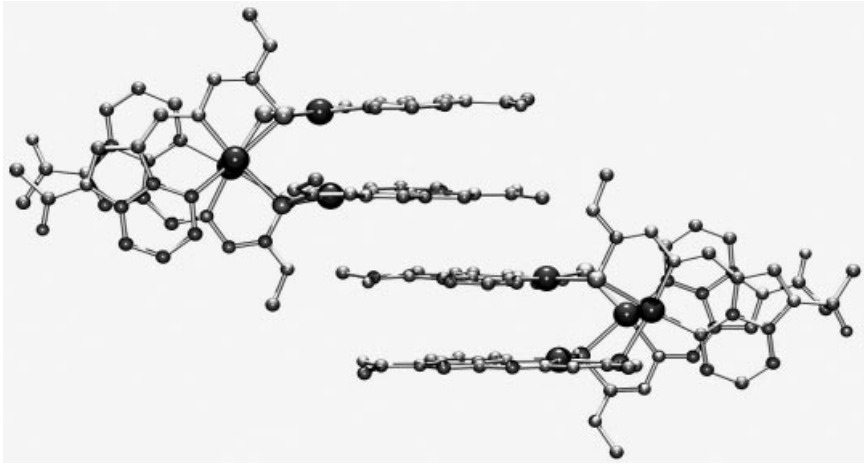

Figure 2. Packing diagram of compound **1b** showing the parallel arrangement of the cyclometalated units.

alated ring in the present compound. The angles between adjacent atoms in the coordination sphere are close to the expected value of 90°. However, as opposed to previous results where the C–Pd–N bite angle was less than 90°, due to formation of a five-membered metallacycle,[25,26] the six-membered ring in the present case allows a larger bite of the *C*,*N* chelate, thereby relieving strain on the angle at the metal; consequently, the C(1A)–Pd(1A)–N(1A) angle is 94.27°. On the other hand, inspection of the N(2A)–Pd(1A)–S(1A) bite angle of the five-membered Pd–N–N–C–S ring shows a similar value to that observed earlier in related complexes, with a value of 83.45°. The Pd–Pd bond lengths across parallel sets of cyclometalated moieties, which are in the range 3.8–4.1 Å, preclude any interaction between the metal atoms.

Two noteworthy observations regarding the structure are that pairs of metalated units are fixed in a nearly co-planar parallel mode (angle between planes of about 3.2°, with groups of parallel units separated by about 3.6 Å), and at an angle of 43° to the *a* axis (see Figure 2), thus indicating a possible weak π-stacking with the pyrrole rings set in an alternating disposition (see Figure 2).

### Reactivity of the Complexes

Reactions of **1a** and **1b** with $Ph_2P(CH_2)_2PPh_2$ (dppe) were tested in order to corroborate the behavior observed by us in related compounds. Thus, treatment of **1a** and **1b** with $Ph_2P(CH_2)_2PPh_2$ in a 1:2 molar ratio gave compounds [{Pd[1-(COMe)-3-[C(H)=NN=C(S)NHR]$C_8H_4N$]}$_2$(μ-$Ph_2P(CH_2)_2PPh_2$)] (R = H **2a**, Me **2b**) as pure, air-stable solids, which were fully characterized (Scheme 1). The $^1$H NMR spectra show a signal at $\delta$ = 8.79 (**2a**) and 8.32 ppm (**2b**), shifted to higher frequency with respect to the corresponding tetramers, which was assigned to the HC=N resonance. It appears as a doublet owing to coupling to the phosphorus nucleus. The H6 resonance [$\delta$ = 6.11 (**2a**) and 6.11 ppm (**2b**)] is shifted to lower frequency by about 1.5 ppm with respect to the parent complexes owing to shielding by the phosphane phenyl rings, in accordance with a phosphorus *trans* to nitrogen. The $^{31}$P NMR resonance is a singlet at $\delta$ = 70.41 (**2a**) and 70.34 ppm (**2b**), thus showing the equivalence of the two $^{31}$P nuclei. The $^{31}$P chemical shift values are also consistent with a phosphorus *trans* to nitrogen.[27–30]

## Conclusions

We have shown that thiosemicarbazones derived from condensed systems, such as indole, may behave as terdentate [C,N,S] pincer ligands in a cyclometalation reaction with palladium salts to give new tetranuclear species, which have been fully characterized in solution, as has one compound in the solid state. From a structural point of view they are closely related to similar systems reported by us previously, although in the present case the condensed rings seem to favor π stacking of the molecules in the unit cell. An added novelty to these compounds is the formation of a six-membered metallacycle, the first example with thiosemicarbazones, which is induced by the presence of bulky groups that hinder formation of the more common, and stable, five-membered metalated ring.

## Experimental Section

**General Remarks:** Solvents were purified by standard methods.[31] All chemicals were reagent grade. $K_2PdCl_4$ was purchased from Alfa Products and 1,2-bis(diphenylphosphanyl)ethane (dppe) from Aldrich-Chemie. Microanalyses were carried out at the Servicio de Análisis Elemental at the Universidad de Santiago using a Carlo Erba Elemental Analyzer (model 1108). IR spectra were recorded as Nujol mulls or KBr discs with a Perkin–Elmer 1330 or a Mattson spectrophotometer. NMR spectra were obtained for solutions in [$D_6$]DMSO with Bruker WM-250 and AMX-300 spectrometers and are referenced to $SiMe_4$ ($^1$H) or 85% $H_3PO_4$ ($^{31}$P{$^1$H}). All chemical shifts are reported downfield from standards. The FAB mass spectra were recorded with a Fisons Quatro mass spectrometer with a Cs ion gun; 3-nitrobenzyl alcohol was used as the matrix.

IR: ν(N–H) 3289 m, 3129 m $cm^{-1}$; ν(C=O) 1715 s; ν(C=N) 1612 s; ν(C=S) 823 m. $^1H$ NMR ([D$_6$]DMSO): δ = 11.50 (s, 1 H, NH), 8.37 (m, 2 H, H5,H8), 8.33 (s, 1 H, H2), 8.30 (s, 1 H, *H*C=N), 8.06 (br., 1 H, N*H*Me), 7.39 (m, 2 H, H6, H7), 3.08 (d, $^3J_{H,H}$ = 4.4 Hz, 3 H, NH*Me*), 2.68 ppm (s, 3 H, COMe).

**1-(COMe)-3-[C(H)=NN(H)C(=S)NHEt]$C_8H_5N$ (c):** Yield: 431 mg (89%). $C_{14}H_{16}N_4OS$ (288.37): calcd. C 55.8, H 5.6, N 19.4, S 11.1; found C 55.6, H 5.5, N 19.3, S 11.0. IR: ν(N–H) 3372 m, 3140 m $cm^{-1}$; ν(C=O) 1719 s; ν(C=N) 1615 s; ν(C=S) 831 m. $^1H$ NMR ([D$_6$]DMSO): δ = 11.45 (s, 1 H, NH), 8.36 (m, 2 H, H5, H8), 8.33 (s, 1 H, H2), 8.30 (s, 1 H, *H*C=N), 8.10 (br., 1 H, N*H*Et), 7.40 (m, 2 H, H6, H7), 3.65 (m, 2 H, NH*CH$_2$*CH$_3$), 2.67 (s, 3 H, COMe), 1.19 ppm (t, $^3J_{H,H}$ = 7.1 Hz, 3 H, NH CH$_2$*CH$_3$*).

**Preparation of 1a:** Ethanol (40 mL) was added to a stirred solution of $K_2PdCl_4$ (100 mg, 0.306 mmol) in water (6 mL) and the fine yellow suspension obtained was treated with **a** (80 mg, 0.306 mmol). The mixture was stirred for 24 h at room temperature. The brown precipitate was filtered off, washed with ethanol, and dried in vacuo. Yield: 264 mg (59%). $C_{48}H_{40}N_{16}O_4Pd_4S_4$ (1458.9): calcd. C 39.5, H 2.8, N 15.4, S 8.8; found C 39.8, H 2.8, N 15.2, S 8.7. IR: ν(N–H) 3331 m $cm^{-1}$; ν(C=O) 1709 s; ν(C=N) 1604 m. $^1H$ NMR ([D$_6$]DMSO): δ = 8.66 (br., 1 H, H6), 8.41 (s, 1 H, H2), 8.24 and 7.61 (br., 2 H, N$H_2$), 7.98 (br., 1 H, H8), 7.44 (s, 1 H, *H*C=N), 7.13 (t, $^3J_{H7,H6}$ = $^3J_{H7,H8}$ = 7.8 Hz, 1 H, H7), 2.72 ppm (s, 3 H, COMe). FAB-MS: *m*/*z* 1458 $[M]^+$.

Compounds **1b** and **1c** were synthesized following a similar procedure.

**1b:** Yield: 342 mg (62%). $C_{52}H_{48}N_{16}O_4Pd_4S_4$ (1515.0): calcd. C 41.2, H 3.2, N 15.0, S 8.5; found C 40.9, H 3.2, N 15.2, S 8.6. IR: ν(N–H) 3394 m $cm^{-1}$; ν(C=O) 1710 s; ν(C=N) 1600 m. $^1H$ NMR ([D$_6$]DMSO): δ = 8.58 (d, $^3J_{H7,H6}$ = 8.0 Hz, 1 H, H6), 7.98 (d, $^3J_{H7,H8}$ = 8.0 Hz, 1 H, H8), 7.86 (s, 1 H, *H*C=N); 7.41 (s, 1 H, H2), 7.05 (t, $^3J_{H7,H6}$ = $^3J_{H7,H8}$ = 8.0 Hz, 1 H, H7), 6.20 (br., 2 H, N*H*Me), 2.85 (d, $^3J_{H,H}$ = 4.4 Hz, 3 H, NH*Me*), 2.55 ppm (s, 3 H, COMe). FAB-MS: *m*/*z* 1515 $[M]^+$.

**1c:** Yield: 300 mg (55%). $C_{56}H_{56}N_{16}O_4Pd_4S_4$ (1571.10): calcd. C 42.8, H 3.6, N 14.3, S 8.2; found C 43.0, H 3.6, N 14.2, S 8.1. IR: ν(N–H) 3359 m $cm^{-1}$; ν(C=O) 1716 s; ν(C=N) 1603 m. $^1H$ NMR ($CDCl_3$): δ = 8.63 (d, $^3J_{H7,H6}$ = 8.1 Hz, 1 H, H6), 8.41 (d, $^3J_{H7,H8}$ = 8.1 Hz, 1 H, H8), 7.68 (s, 1 H, H2), 6.79 (t, $^3J_{H7,H6}$ = $^3J_{H7,H8}$ = 8.1 Hz, 1 H, H7), 6.33 (s, 1 H, *H*C=N), 4.83 (br., 2 H, N*H*Et), 3.39 (m, 2 H, NH*CH$_2$*CH$_3$), 2.76 (s, 3 H, COMe), 0.88 ppm (t, $^3J_{H,H}$ = 6.7 Hz, 3 H, NH CH$_2$*CH$_3$*). FAB-MS: *m*/*z* 1571 $[M]^+$.

**Complex 2a:** 1,2-Bis(diphenylphosphanyl)ethane (11 mg, 0.028 mmol) was added to a suspension of complex **1a** (20 mg, 0.014 mmol) in acetone (15 mL). The mixture was stirred for 3 h and the resulting orange solid filtered off and dried. Yield: 23.5 mg (76%). $C_{50}H_{44}N_8O_2P_2Pd_2S_2$ (1127.9): calcd. C 53.3, H 3.9, N 9.9, S 5.7; found C 53.1, H 4.0, N 9.8, S 5.8. IR: ν(N–H) 3344 m $cm^{-1}$; ν(C=O) 1714 s; ν(C=N) 1607 m. $^1H$ NMR ([D$_6$]DMSO): δ = 8.96 (s, 1 H, H2), 8.79 (d, $J_{H,P}$ = 2.7 Hz, 1 H, *H*C=N), 8.25 (d, $^3J_{H7,H8}$ = 8.4 Hz, 1 H, H8), 7.09 (t, 1 H, H7), 6.11 (d, $^3J_{H7,H6}$ = 8.4 Hz, 1 H, H6), 2.66 ppm (s, 3 H, COMe). $^{31}P\{^1H\}$ NMR ([D$_6$]DMSO): δ = 70.41 ppm (s). FAB-MS: *m*/*z* 1128 $[M]^+$.

Compound **2b** was synthesized following a similar procedure.

**2b:** Yield: 23.8 mg (78%). $C_{52}H_{48}N_8O_2P_2Pd_2S_2$ (1155.9): calcd. C 54.0, H 4.2, N 9.7, S 5.6; found C 53.8, H 4.1, N 9.8, S 5.5. IR: ν(N–H) 3375 m $cm^{-1}$; ν(C=O) 1710 s; ν(C=N) 1599 m. $^1H$ NMR ([D$_6$]DMSO): δ = 8.90 (s, 1 H, H2), 8.32 (d, $J_{H,P}$ = 2.7 Hz, 1 H, *H*C=N), 8.25 (d, $^3J_{H7,H8}$ = 8.8 Hz, 1 H, H8), 6.83 (t, 1 H, H7), 6.21 (br., 2 H, N*H*Me), 6.11 (d, $^3J_{H7,H6}$ = 8.8 Hz, 1 H, H6), 2.74 (s, 3 H, COMe), 2.50 ppm (d, $^3J_{H,H}$ = 4.4 Hz, 3 H, NH*Me*). $^{31}P\{^1H\}$ NMR ([D$_6$]DMSO): δ = 70.34 ppm (s). FAB-MS: *m*/*z* 1156 $[M]^+$.

**X-ray Crystallographic Study:** A single crystal of complex **1b** was mounted on a glass fiber and transferred to the diffractometer. Three-dimensional, room temperature X-ray data were collected on a Bruker SMART CCD diffractometer by the ω-scan method using graphite-monochromated Mo-$K_\alpha$ radiation (see Table 1 for details). All the measured reflections were corrected for Lorentz and polarization effects and for absorption by semi-empirical methods based on symmetry-equivalent and repeated reflections ($T_{max.}/T_{min.}$ = 0.816/0.587). The structure was solved by direct methods and refined by full-matrix least-squares on $F^2$. Hydrogen atoms were included in calculated positions and refined in a riding mode. The structure contains eight symmetry-related voids of 37 $Å^3$ containing unresolvable solven; this was treated using the squeeze method, which lowered the $R_1$ value by about 25%.[32] Refinement converged at a final $R$ = 0.0827 (observed data, $F$) and $wR_2$ = 0.1128

Table 1. Crystal data and structure refinement for compound **1b**.

# Synthesis, Structure and Magnetic Properties of a New Low-Spin Iron(III) Complex [$FeL_3$] {L = [$HNC(CH_3)]_2C(CN)$}

**Junichi Nishijo[a] and Nobuyuki Nishi*[a]**

**Keywords:** Iron / Magnetic properties / N ligands

High-temperature treatment of acetonitrile with $CaC_2$ and $FeCl_2$ afforded crystals of the new iron(III) $S = 1/2$ low-spin complexes [$FeL_3$]ROH (R = $CH_3$ or $C_2H_5$), whose crystal structures were determined by single-crystal X-ray structural analysis. The methanol complex consists of a one-dimensional arrangement of the iron moieties, while each methanol molecule is separated from each other by the complexes. On the other hand, the ethanol complex contains a two dimensional arrangement of the iron moieties and one dimensionally aligned ethanol molecules elongated perpendicular to the sheet. Because of the large difference in the inter-complex overlap patterns between the ligands, the two materials show quite different magnetic properties. The magnetism of the crystal containing ethanol is well described by the singlet–triplet model with the antiferromagnetic interaction $2J/k_B = -7.5$ K, while that containing methanol obeys the Curie law with a negligibly small Weiss temperature.

## Introduction

Transition-metal complexes of π-conjugated N-ligands have attracted much attention over the years. In these complexes, the strong coordination bonds with the lone pair of the nitrogen atoms bring the d-electrons of the transition metal and the π-electrons of the ligands close to each other, and the interaction between d- and π-electrons leads to several important properties, such as a modified reactivity of the center metal, high photon absorbance and efficient charge transfer. Previous studies with such complexes have revealed their usefulness as catalysts[1–7] and dye-sensitized solar cells.[8–10] From the viewpoint of molecule-based magnets, this kind of complex would offer a strong spin–spin interaction as the strong metal–nitrogen interaction brings about a high spin density at the nitrogen atom. On the other hand, it is known that the π-electrons can convey spin polarization from one side of the molecule to the other side through the π-conjugated system.[11–13] Because a π-conjugated N-ligand has both of these features, it is expected that transition-metal complexes based on these ligands would enable a strong, long-range spin–spin interaction.[14–18] Furthermore, the flat π-conjugated molecules tend to stack their molecular planes, which results in a large intermolecular orbital overlap and thus a strong intermolecular spin–spin interaction.[19,20]

The strong coordination bond is also essential to investigate the effect of the intermolecular arrangement on the magnetism. It is well known that the magnetism of molecule-based magnets largely depends on the intermolecular overlap patterns, and that some of them can be controlled by the absorption/desorption of solvent.[21–23] By using π-conjugated N ligands, the complex approximately keep its intra-complex structure thanks to the rigidness of the ligand and the strong coordination bonds, while the inter-complex arrangement is considerably rearranged upon changing the solvent molecules;[24,25] that is, we can investigate only the effect of the inter-complex arrangement.

Because of the features mentioned above, it is important to synthesize new transition-metal complexes of π-conjugated N-ligands. We decided to use the bidentate ligand 2-amino-3-cyanopent-2-en-4-imine (HL, Figure 1) for the following two reasons. First, its bidentate nature is promising to create magnetic complexes because they are likely to form stable coordination bonds like bipyridine. Secondly, the planer shape of the ligand and the protruding cyano group seem to ease the intermolecular orbital overlaps which causes inter-complex spin–spin interaction. However, although the structure of this ligand is attractive, its instability prevents the easy synthesis of complexes. Thus, although it was first synthesized more than 40 years ago,[26,27]

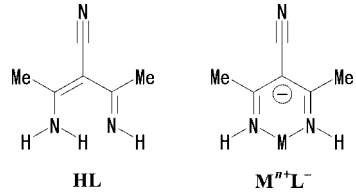

Figure 1. The molecular structure of 2-amino-3-cyanopent-2-en-4-imine (HL). The deprotonated form of the molecule behaves as a bidentate ligand ($M^{n+}L^-$).

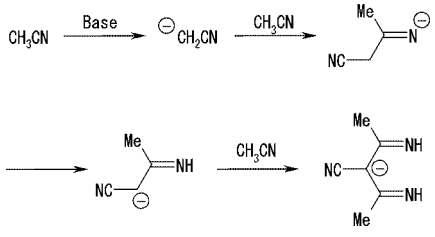
up to the present time only one complex of Co and a few complexes of Ga, Al, and In with the deprotonated ligand ($L^-$) have been synthesized.[28–30] In this paper, we report new transition-metal complexes based on this ligand synthesized by an unconventional method, and report the remarkable solvent dependency of their structure and magnetism.

## Results and Discussion

### Synthesis

To obtain the transition-metal complex based on the ligand, we tried to develop a new synthesis method by using a strong base under water-free conditions. It is known that the ligand can be synthesized by the trimerization of acetonitrile molecules in the presence of a strong base, as shown in Scheme 1.[28–30] Furthermore, the strong base stabilizes the deprotonated form of the ligand and enables complex formation. Because the ligand is easily decomposed in the presence of water molecules,[27] the synthesis should be done under strictly water-free conditions. In light of these two conditions, calcium carbide is one of the most suitable reagents as a strong base because it is an easily acquired water-free base that is strong enough to deprotonate acetonitrile molecules. A stainless-steel airtight vessel is appropriate for the synthesis as this not only allows exclusion of water from the air but also enables the synthesis to be performed at high temperature, where the trimerization of acetonitrile is accelerated. Despite the water-sensitivity of the free ligand molecule, the complex [$FeL_3$] is stable even in air. It should be noted that vigorous stirring, a longer reaction time, or a higher reaction temperature lead only to carbon-encapsulated iron nanoparticles due to the reductive nature of $C_2^{2-}$.[31] This one-pot synthesis method gives the complex [$FeL_3$].



Scheme 1.

### Crystal Structures

The complex was obtained as a racemic crystal regardless of the solvent molecules. The unit cells of [$FeL_3$]$CH_3OH$ and [$FeL_3$]$C_2H_5OH$ contain two crystallographically equivalent Δ- and Λ-[$FeL_3$] and one Δ- and one Λ-[$FeL_3$] moieties, respectively. Selected bond lengths and angles, and the molecular structures of [$FeL_3$]ROH can be found in Tables 1 and 2, and Figures 2 and 3, respectively. The intra-complex structures are nearly identical regardless of the solvent molecules. Each complex consists of an iron atom and three chelating ligand molecules such that the iron atom is surrounded by the six nitrogen atoms of the ligands to form an octahedral $FeN_6$ chromophore. The six Fe–N bonds have similar lengths, and no Jahn–Teller distortion was observed at room temperature despite the low-spin $d^5$ configuration of iron(III), as evidenced by the small Curie constant (discussed later). The Fe–N bond lengths of [$FeL_3$]ROH range from 1.916(4) to 1.957(3) Å and are in reasonable agreement with the values for other iron complexes with Schiff-base-type ligands.[32,33] The intra-ligand bond lengths are close to those of other complexes of the $L^-$ ligand reported previously.[28–30] The C–N bond lengths, which range from 1.292(6) to 1.316(5) Å, and the π-conjugated C–C bond lengths, which range from 1.406(7) to 1.433(6) Å, indicate that the negative charges are delocalized over the π-conjugated system of the ligand. Because of this aromaticity, the six-membered chelate rings tend to be planar except for a small inflection at the coordinated nitrogen atoms. For example, the torsion angles of Fe1–N1–N2–C3, Fe1–N4–N5–C9, and Fe1–N8–N7–C15 in the [$FeL_3$]$CH_3OH$ crystal have values [172.74(13)°, 155.84(13)°, and 166.69(13)°, respectively] that are slightly smaller than 180°, while the ligand molecules keep its almost flat structure.

Table 1. Selected bond lengths [pm] and angles [°] for [$FeL_3$]-$CH_3OH$.

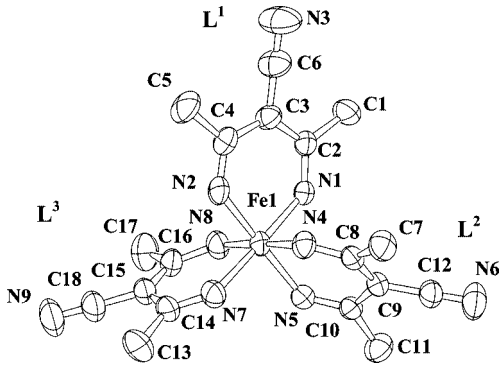

Figure 2. Thermal ellipsoid plot (50% probability) of $[FeL_3]$-$CH_3OH$. The labels $L^i$ identify the three crystallographically independent ligand molecules. A methanol molecule and hydrogen atoms have been omitted for clarity.

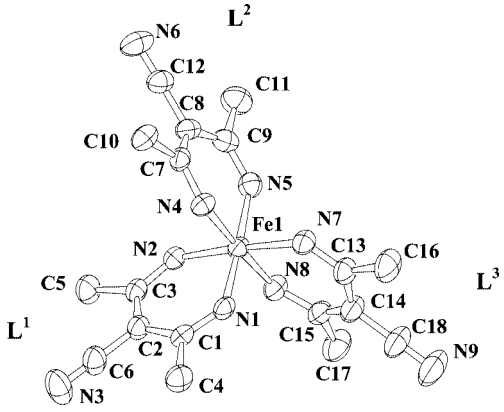

Figure 3. Thermal ellipsoid plot (50% probability) of $[FeL_3]$-$C_2H_5OH$. The labels $L^i$ identify the three ligand molecules. An ethanol molecule and hydrogen atoms have been omitted for clarity.

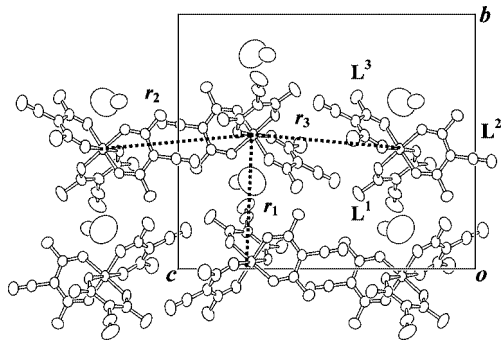

Figure 4. The crystal structure of $[FeL_3]CH_3OH$ viewed along the *a* axis. Hydrogen atoms have been omitted for clarity. The dotted lines indicate the short iron–iron distances (see text).

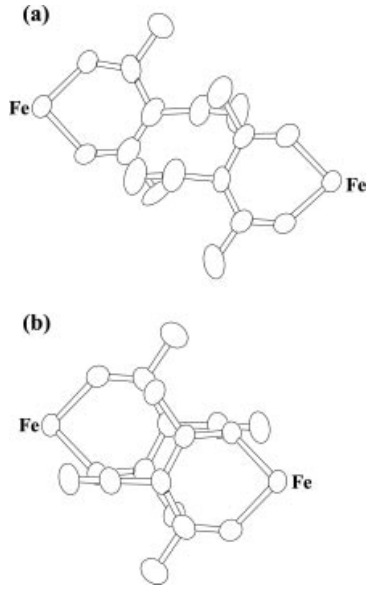

Figure 5. The two kinds of stacking modes between adjacent ligands viewed perpendicular to the six-membered chelate rings: a) Type A, b) Type B (see text). Hydrogen atoms have been omitted for clarify.

In contrast to the intra-complex structure, the inter-complex arrangement depends greatly on the solvent. In the crystal of $[FeL_3]CH_3OH$, each $[FeL_3]$ moiety has two short contacts with two adjacent complexes, as shown in Figure 4, and the ligands $L^2$ and $L^3$ face their counterparts in adjacent complexes. The complexes are connected to each other by these short ligand–ligand contacts and are arranged one-dimensionally parallel to the *c* axis. The cyano group of ligand $L^1$ is directed towards the hydroxy group of a neighboring methanol molecule. The stacking structures of $L^2$–$L^2$ and $L^3$–$L^3$ resemble each other. This stacking mode (type A) is shown in Figure 5 (a), where the cyano groups of the ligands are placed at the midpoints of the C–C bonds between the imine groups and methyl groups. In these contacts, the interatomic distance between the nitrogen atom of the cyano group and the carbon atom of the imine group is about 3.5 Å. In type-A stacking, the overlap between π-orbitals of the ligands is expected to be small due to the displacement of the two six-membered chelate rings, thus suggesting a weak spin–spin interaction between the complexes. The short iron–iron distances in the *bc* plane (Figure 4) are $r_1$ = 8.495(5), $r_2$ = 9.359(5), and $r_3$ = 9.337(5) Å, while that in the *a* direction is 8.099(5) Å.

The crystal structure of $[FeL_3]C_2H_5OH$ is characterized by a two-dimensional cage-like arrangement of the complexes and one-dimensionally aligned ethanol molecules. In the crystal, four complexes form a cage that encloses an ethanol molecule, as shown in Figure 6, and this cage-like structure spreads as a sheet in the *bc* plane. Each ligand in a sheet is close to a neighboring crystallographically equivalent ligand, and the stacking mode of the ligand pairs $L^1$–$L^1$ and $L^3$–$L^3$ is also classified as type A (see Figure 5), with an N–C interatomic contact of about 3.5 Å, while that of $L^2$–$L^2$ is of type B, with an interatomic distance of around 3.8 Å between the carbon atom of the cyano group and the carbon or nitrogen atom of the imine group. Although the interatomic distance of type B stacking is longer than that of type A, it is expected that the larger π-orbital overlap of type B stacking brings about a stronger spin–spin interaction than that of type A. The sheets of the cage-like structures are stacked along the *a* axis, where the adjacent sheets are weakly bonded by the inter-plane type A stacking of $L^2$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ligands. In short, one complex has two small intra-sheet overlaps (type A, $L^1$–$L^1$ and $L^3$–$L^3$), one small inter-sheet overlap (type A, $L^2$–$L^2$), and one large intra-sheet overlap (type B, $L^2$–$L^2$). The cavities of the cages are connected and form one-dimensional tunnel structures that are elongated parallel to the *a* axis; these are filled with ethanol molecules. The short iron–iron distances in the *bc* plane shown in Figure 6 are $r_1$ = 8.142(4), $r_2$ = 10.881(4), and $r_3$ = 9.337(4) Å, while that in the *a* direction is 8.195(3) Å. The shortest iron–iron distance in the crystal of $[FeL_3]C_2H_5OH$ is therefore slightly longer than that of $[FeL_3]CH_3OH$.

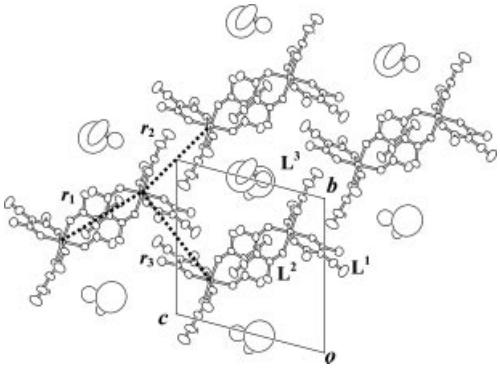

Figure 6. The crystal structure of $[FeL_3]C_2H_5OH$ viewed along the *a* axis. Hydrogen atoms have been omitted for clarify. The dotted lines indicate the short iron–iron distances (see text).

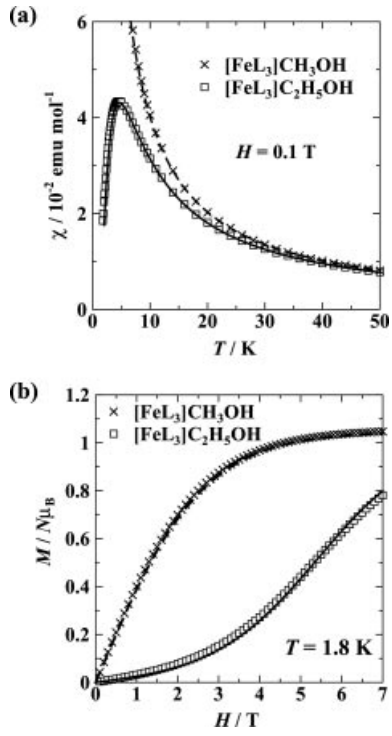

Figure 7. a) The magnetic susceptibilities and b) the reduced magnetization curves of $[FeL_3]ROH$. The dashed lines are the theoretical curves for the free $S$ = 1/2 spins having $g$ = 2.08, and the solid lines are the theoretical curves based on the singlet–triplet model with the values of $2J/k_B$ = –7.5 K and $g$ = 2.08 (see text).

## Magnetic Properties

The temperature dependencies of the magnetic susceptibilities, $\chi$, of $[FeL_3]ROH$ and the magnetization curves at 1.8 K are shown in Figure 7 (parts a and b), respectively. The magnetic susceptibility of $[FeL_3]CH_3OH$ follows the Curie–Weiss law in the whole temperature range, with a Curie constant, $C$, of 0.406 emu K mol$^{-1}$ and a negligibly small Weiss temperature, $\Theta$. The fact that $\Theta$ is almost zero indicates that the type A overlap of the ligands does not contribute to the spin–spin interaction due to the poor overlap of the π-orbitals. The observed value of $C$ roughly agrees with the spin-only value for a $S$ = 1/2 species (0.375), thereby indicating the low-spin nature of the iron(III). The small enhancement of $C$ from that of a free $S$ = 1/2 spin can be attributed to the slightly larger $g$ value predicted from the magnetization curve. The magnetization curve of $[FeL_3]CH_3OH$ is very close to the Brillouin curve of $S$ = 1/2 spins with a $g$ value of 2.08, which indicates that the inter-complex spin–spin interaction is negligible.

The magnetic susceptibility of $[FeL_3]C_2H_5OH$ can also be described by the Curie–Weiss law in the high-temperature region above 10 K ($C$ = 0.403 emu K mol$^{-1}$, $\Theta$ = –3.3 K). Below 10 K, $\chi$ reaches a peak at 4.6 K and then decreases rapidly with decreasing temperature. A linear extrapolation of $\chi$ to lower temperature gives $\chi$ = 0 at a finite temperature of 0.7 K, thus suggesting that the ground state of the spin system is a singlet. Despite the longer iron–iron distance and smaller spin density of $[FeL_3]C_2H_5OH$ relative to those of $[FeL_3]CH_3OH$, the inter-complex spin–spin interaction of $[FeL_3]C_2H_5OH$ is stronger than that of $[FeL_3]$-$CH_3OH$. This fact confirms that the spin–spin interaction is strongly dependent on the inter-ligand overlap of the π-orbitals, as predicted from the crystal structures, as in some previously reported materials, where ligand–ligand contacts play important roles.[34,35] Based on the crystal structure, where only one strong inter-complex interaction is expected, a singlet–triplet model is the appropriate for the spin system of $[FeL_3]C_2H_5OH$. In this model, the spin Hamiltonian, $H$, is described as shown in Equation (1), where $J$, $S_i$, $g$, $\mu_B$, and $H_{ex}$ are the interaction between spins, the spin values, the $g$ value, the Bohr magneton, and the external magnetic field, respectively.

$$H = -2JS_1 \cdot S_2 + g\mu_B \sum_i S_i \cdot H_{ex} \quad (1)$$

By using this spin Hamiltonian, the partition function $Z$ [Equation (2)], the free energy $F$ [Equation (3)], the magnetization, $M$, and $\chi$ can be calculated, as shown in Equations (4) and (5), where $N$ and $k_B$ are the Avogadro number and the Boltzmann constant, respectively. The best fit, shown as solid lines in parts a and b of Figures 7 is nearly indistinguishable from the observed values with the adjustable parameters of $2J/k_B$ = –7.5 K and $g$ = 2.08. This consistency offers evidence that only the type B overlap can bring about a strong spin–spin interaction.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$Z = T_r \exp(-H/k_B T) \quad (2)$$

$$F = -k_B T \cdot \ln Z \quad (3)$$

$$M(H_{ex},T) = -\frac{\partial F}{\partial H_{ex}} = \frac{Ng\mu_B \exp(2J/k_B T)\sinh(g\mu_B H_{ex}/k_B T)}{1+\exp(2J/k_B T)[1+2\cosh(g\mu_B H_{ex}/k_B T)]} \quad (4)$$

$$\chi(T) = \left(\frac{\partial M}{\partial H_{ex}}\right)_{H_{ex}=0} = \frac{Ng^2\mu_B{}^2}{k_B T}\frac{1}{3+\exp(-2J/k_B T)} \quad (5)$$

## Conclusions

Crystals of the new iron(III) complex $[FeL_3]$ containing ROH (R = $CH_3$ and $C_2H_5$) have been obtained. The crystal structure of $[FeL_3]CH_3OH$ is characterized by a one-dimensional arrangement of the $[FeL_3]$ moieties where the cyano groups are placed above the methyl groups of adjacent moieties. Because of the small overlap between the π-orbitals of the ligands, the inter-complex spin–spin interaction of $[FeL_3]CH_3OH$ is weak, as evidenced by the almost zero value of the Weiss temperature and the absence of a magnetic transition. On the other hand, the crystal of $[FeL_3]$-$C_2H_5OH$ consists of a two-dimensional sheet-like arrangement of $[FeL_3]$ moieties and one-dimensionally aligned ethanol molecules elongated perpendicular to the sheets. In this structure, $[FeL_3]$ moieties are dimerized by the large inter-ligand overlap and a cyano group is placed above an imine group of the neighboring complex. Owing to the dimerization of the complexes, the magnetic properties of $[FeL_3]C_2H_5OH$ are consistent with a singlet–triplet model with the inter-complex spin–spin interaction $2J/k_B$ = –7.5 K.

## Experimental Section

**Materials and Measurements:** $CaC_2$ (Kojundo Chemical Lab. Co.) was used after ball-milling under argon for 12 h, while $FeCl_2$ and anhydrous acetonitrile were used as supplied. IR spectra were recorded with a Shimadzu FTIR-8600PC for KBr disks. Elemental analysis was performed with a Yanaco MT-6. Single-crystal X-ray diffraction data were collected with a Rigaku AFC7R MERCURY CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71069 Å) and a rotating anode generator (50 kV, 100 mA). The structures were solved by direct methods (SHELXS-97), then refined with full-matrix least-squares (SHELXL-97).[36] Graphics were produced with ORTEP-III.[37] The positions of hydrogen atoms, except N-H groups, were refined with a "riding" model with $U_{iso}$ = 1.2 $U_{eq}$ of the connected non-hydrogen atom or as ideal $CH_3$ groups with $U_{iso}$ = 1.5 $U_{eq}$. The crystal data of $[FeL_3]$-ROH are shown in Table 3.

Table 3. Crystallographic data for $[FeL_3]$ROH.

| Residuals (all data) | $R_1$ = 0.0742 | $R_1$ = 0.0823 |
| | $wR_2$ = 0.1710 | $wR_2$ = 0.2183 |

CCDC-295169 and -295168 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

A Quantum Design MPMS-XL SQUID magnetometer was used to measure DC magnetic susceptibilities of $[FeL_3]$ROH between 300 and 1.8 K in a 0.1-T static magnetic field. The core temperature independent diamagnetic susceptibility was subtracted from the experimental values based on Pascal's constants for all constituent atoms.

**Reaction:** In a water- and oxygen-free glove box, $CaC_2$ (449 mg, 7 mmol) and $FeCl_2$ (634 mg, 5 mmol) were suspended in anhydrous acetonitrile (300 mL). The suspension was sealed in a SUS-316 stainless-steel high-temperature, high-pressure reactor (TPR-1, Taiatsu techno, Tokyo, Japan), then the solution was heated to 240 °C at around 3 MPa for 12 h with gentle stirring. After cooling to room temperature, the solution was exposed to air and absolute methanol (100 mL) was added. Vigorous stirring of the solution for 20 min under air resulted in a deep-blue solution, which was then filtered. The residue was extracted with methanol, and the extract was added to the filtrate. The solution was dried in vacuo, then the precipitate was washed with toluene (200 mL) and extracted with dichloromethane (300 mL). The solution was dried in vacuo again. The blue powder was dissolved in hot methanol (20 mL), then cooled to –10 °C. The purple crystalline product was collected by filtration. Recrystallization from hot methanol gave 85 mg of $[FeL_3]CH_3OH$ (4%) as reddish-purple block crystals. $C_{19}H_{28}FeN_9O$ (454.34): calcd. C 50.23, H 6.21, N 27.75; found C 50.18, H 6.40 N 27.61. IR (KBr): ν(N–H) = 3280 cm$^{-1}$; $\nu_2$(C≡N) = 2177; ν(C=N) = 1582 cm$^{-1}$. A single crystal of $[FeL_3]C_2H_5OH$ was obtained as follows. Pure $[FeL_3]CH_3OH$ crystals were dissolved in a mixture of THF (30 mL) and ethanol (10 mL). The solution was slowly evaporated at ambient pressure, and subsequent filtration gave small, deep-purple crystals. $C_{20}H_{30}FeN_9O$ (468.37): calcd. C 51.29, H 6.46, N 26.92; found C 51.23, H 6.25 N 26.99. IR (KBr): ν(N–H) = 3284 cm$^{-1}$; ν(C≡N) = 2182; ν(C=N) = 1579 cm$^{-1}$.

# New Dinuclear Face- and Edge-Sharing Bioctahedral Ruthenium Compounds Containing 1,2-Bis(diphenylphosphanyloxy)ethane

**Jorge Bravo,*[a] Jesús Castro,[a] Soledad García-Fontán,*[a] M. Carmen Rodríguez-Martínez,[a] and Pilar Rodríguez-Seoane[a]**

**Keywords:** Ruthenium / P ligands / Chelates / Bimetallic complexes

The bidentate diphosphinite ligand 1,2-bis(diphenylphosphanyloxy)ethane (L), $Ph_2P–O–(CH_2)_2–O–PPh_2$, can be sequentially incorporated into a series of dinuclear chloro-bridged ruthenium compounds using $[RuCl_2(DMSO)_4]$ as a precursor to give the new bioctahedral compounds $[Ru_2(\mu\text{-}Cl)_3(DMSO)_3Cl(\eta^2\text{-}L)]$ (**1**), $[Ru_2(\mu\text{-}Cl)_3(DMSO)Cl(\eta^2\text{-}L)_2]$ (**2**) and $[Ru_2Cl_2(\eta^2\text{-}L)_2\{\eta^1\text{-}L(O)\}_2(\mu\text{-}Cl)_2]$ (**3**). Compound **3** contains two partially oxidised diphosphinite ligands that act in a monodentate manner. These compounds can also be obtained by direct reaction of $[RuCl_2(DMSO)_4]$ with the appropriate stoichiometric amount of L but in the case of **3** (in which prolonged heating is necessary) the reaction affords two mononuclear compounds $[RuCl_2(\eta^2\text{-}L)(Ph_2POPPh_2)]$ (**7**) and $[RuCl(CO)(\eta^2\text{-}L)(Ph_2POCH_2)]$ (**8**), with ligand fragments coordinated to the metal probably originating in metal-mediated disruptions of L. Reaction of **2** with the monodentate ligands $PPh_{3-n}(OEt)_n$ ($n$ = 1–3) (L′) affords the dinuclear doubly chloro-bridged compound $[Ru_2(\mu\text{-}Cl)_2Cl_2(\eta^2\text{-}L)_2(L')_2]$ (**4**), the dinuclear triply chloro-bridged compound $[\{Ru(\eta^2\text{-}L)(L')\}_2(\mu\text{-}Cl)_3]Cl$ (**5**) and the mononuclear compound $[RuCl_2(\eta^2\text{-}L)(L')_2]$ (**6**). The solid-state structures of **2** (*transoid* isomer), **5** (*transoid* isomer), **6**, **7** and **8** are reported.

## Introduction

Ruthenium complexes continue to attract attention because they can be used in a range of applications in many different fields including catalytic processes[1] and bioinorganic processes.[2] Moreover, the discovery of the anticancer activity of $[RuCl_2(DMSO)_4]$ has increased interest in the properties of new Ru–DMSO complexes.[3] A number of chelating diphosphines have been used to stabilise transition-metal complexes but, surprisingly, studies on analogous diphosphinites are rare, although some such compounds have proved to be efficient catalysts.[4] Furthermore, the presence of halogeno bridges between the metal centres provides higher reactivity, thus enhancing their possibilities for successful use as new catalysts.[5]

We report here the results obtained in the reaction between $[RuCl_2(DMSO)_4]$ and 1,2-bis(diphenylphosphanyloxy)ethane (L) to yield a range of new mono- and dinuclear ruthenium complexes (Scheme 1). It is worth mentioning that, in contrast with the behaviour observed for other diphosphinite ligands,[6] it was possible to obtain different products when the stoichiometric relationship between the metal-containing precursor and the ligand was varied.

## Results and Discussion

### Reaction of $[RuCl_2(DMSO)_4]$ with L – Preparation of $[Ru_2(\mu\text{-}Cl)_3(DMSO)_3Cl(L)]$ (1)

Reaction of $[RuCl_2(DMSO)_4]$ with 1,2-bis(diphenylphosphanyloxy)ethane (L) in a 2:1 molar ratio in refluxing toluene for 1/2 h gave a yellow solid. The analytical data for this compound are consistent with the empirical formula $Ru_2LCl_4(DMSO)_3$. The IR spectrum shows a strong band at 1093 $cm^{-1}$, which is consistent with the presence of the $\eta^1$-*S* (DMSO) ligands.[7] The $^{31}P\{^1H\}$ NMR spectrum in $CDCl_3$ shows a singlet at $\delta$ = 158.2 ppm, indicating the magnetic equivalence of the two phosphorus atoms of the bidentate ligand L. The $^1H$ NMR spectrum shows, in the same solvent, three singlets at $\delta$ = 3.04, 3.12 and 3.43 ppm (integrating to 6 protons each), which can be assigned to the three DMSO ligands, and two multiplets at $\delta$ = 3.72 and 4.26 ppm (integrating to 2 protons each) corresponding to the methylene groups of L. Further evidence for the dinuclear nature of **1** comes from the FAB-MS spectrum, which shows signals corresponding to the molecular ion $[M^+]$ and to the fragments $[M^+ – Cl]$, $[M^+ – (DMSO)]$, $[M^+ – 3(DMSO)]$, $[M^+ – 3(DMSO) – Cl]$ and $[M^+ – Ru – 3(DMSO) – 2Cl]$. Two of the three isomers shown in Scheme 2 are compatible with this structural information.

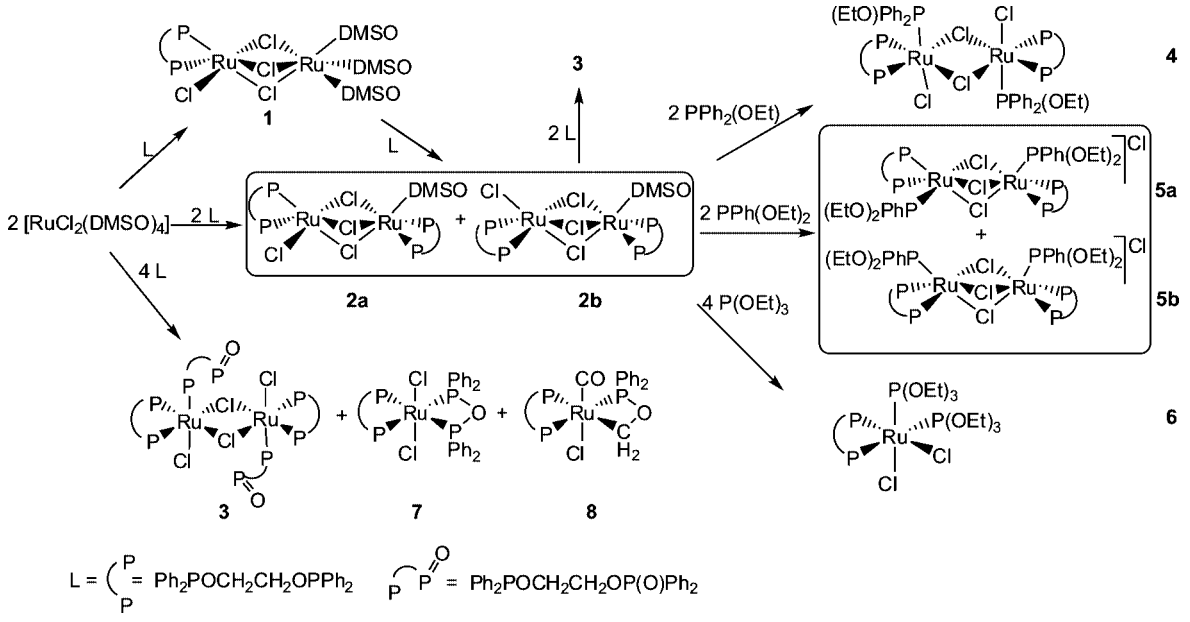
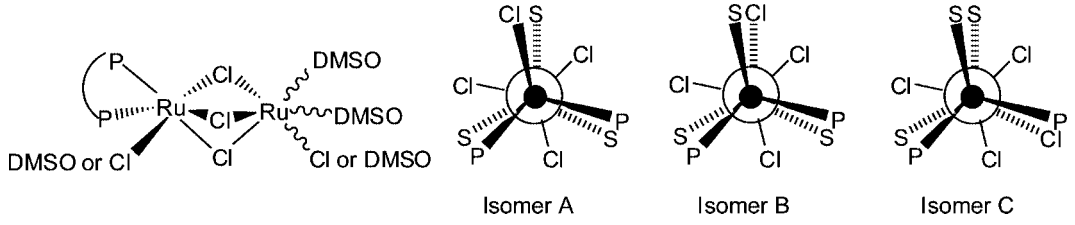


Scheme 1.



Scheme 2.

Isomer C can be ruled out because the two P nuclei are not equivalent. Isomer A is our preferred choice between isomers A and B because the chemical shift of P is similar to that observed for compounds with the same environment[8] and the methyl groups of each DMSO do not appear as two diastereotopic singlets (we carried out a 2D $^{1}H$, $^{13}C$ HSQC experiment to confirm this, see Supporting Information) as one would expect them to if they were in proximity to a bidentate ligand. Moreover, the 2D $^{1}H$, $^{31}P$ NMR HMBC experiments do not show any evidence of an interaction between the P atoms and the $CH_3$ protons of the DMSO ligands (although such negative evidence is not conclusive).

### Reaction of Compound 1 with L – Preparation of $[Ru_2(\mu\text{-}Cl)_3(DMSO)Cl(L)_2]$ (2)

Reaction of **1** with L in a 1:1 molar ratio in refluxing toluene for 1/2 h gave a yellow solid. The analytical data for this product are consistent with the formulation $[Ru_2(\mu\text{-}Cl)_3(\eta^2\text{-}L)_2Cl(DMSO)]$ (**2**).[9] The IR spectrum shows a strong band at 1093 $cm^{-1}$, which is consistent with the presence of a $\eta^1$-*S* sulfoxide ligand.[7]

The $^{31}P\{^{1}H\}$ NMR spectrum in $CDCl_3$ shows two sets of signals. The first set (indicated in Figure 1 by an asterisk) consists of a pair of doublets and a quartet [consistent with an AX spin system ($\delta$ = 160.7, 151.9 ppm, $J_{AX}$ = 54 Hz) and an AB spin system ($\delta$ = 148.3 ppm, $J_{AB}$ = 44 Hz), respectively]. This is a characteristic pattern of compounds of the type $[RuCl(PP)(\mu\text{-}Cl)_3Ru(PP)L]$[10] and can be assigned to the *transoid* form of **2** in which the four P atoms are not equivalent (see Scheme 3).

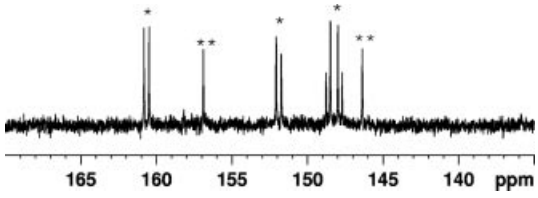


Figure 1. $^{31}P\{^{1}H\}$ NMR spectrum in $CDCl_3$ for compound **2**.

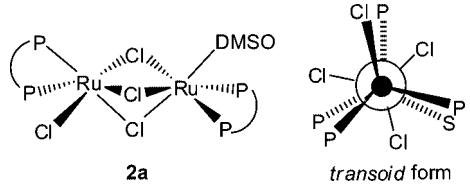
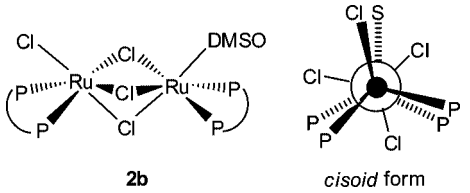


Scheme 3.

The second set of signals consists of two singlets [$\delta$ = 156.9, 146.4 ppm] (indicated by a double asterisk in Figure 1) and corresponds to the *cisoid* structure **2b** (see

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Scheme 4) in which both phosphorus nuclei, belonging to each bidentate ligand, are magnetically equivalent.



Scheme 4.

The $^1H$ NMR spectrum in $CDCl_3$ also presents signals that correspond to both structures. For example, two singlets at $\delta$ = 2.54 and 2.87 ppm can be assigned to the two diastereotopic methyl groups of DMSO corresponding to the *transoid* structure. At 3.22 ppm a singlet with a lower intensity can be assigned to the methyl groups of the DMSO ligand corresponding to the *cisoid* structure (there are no diastereotopic signals in this case because of its higher symmetry). A similar situation occurs with the signals corresponding to the methylene groups of the bidentate ligand. As observed in other halide compounds bearing this ligand,[11] these groups usually display one multiplet for each proton. In our case different multiplets were observed that integrate as one proton each and these coexist with other signals of lower intensity that may correspond to the *cisoid* structure.

An HMBC $^1H,^{31}P\{^1H\}$ NMR study (see Supporting Information) shows that there is a correlation between the signal at $\delta$ = 148.3 ppm (in $CDCl_3$) and that at $\delta$ = 2.54 ppm attributed to one of the DMSO methyl groups. This indicates that – in agreement with the assignment made by Bianchini for a similar complex – this resonance corresponds to the bidentate ligand coordinated to the Ru atom that bears the DMSO molecule.[8a] The relative intensities of the signals of the two isomers change significantly when benzene is used as the solvent, with the signals of the *cisoid* structure almost residual in this case. This must be due to the different solubility of the two isomers, because a VT NMR study carried out in $CDCl_3$ from 25 °C to –50 °C and in $C_6D_6$ from 25 °C to 45 °C did not provide any evidence for interconversion between them.

Finally, the $^{13}C\{^1H\}$ spectrum in $CD_2Cl_2$ shows two singlets at $\delta$ = 50.5 and 51.0 ppm, which can be assigned to the two inequivalent methyl groups of the DMSO ligand corresponding to the *transoid* structure. A signal with a lower intensity was also observed at $\delta$ = 51.3 ppm and this can be assigned to the two equivalent methyl groups of the *cisoid* structure.

We were able to obtain single crystals of the *transoid* isomer of compound **2** (**2a**) to carry out an X-ray diffraction analysis. Selected bond lengths and angles are reported in Table 1 and an ORTEP view is shown in Figure 2.

Table 1. Bond lengths [Å] and angles [°] for **2a**.

at each metal centre is a distorted octahedron. The structure is unsymmetrical, with Ru(2) bearing a DMSO and Ru(1) a chloride ligand. The structural features are similar to those found in previously reported face-sharing bioctahedral $Ru^{II}$–$Ru^{II}$ complexes.[7b,12] The Ru–$Cl_{terminal}$ distance is shorter than the Ru–$Cl_{bridge}$ distances. Of all the Ru–$Cl_{bridge}$ distances, those that are *trans* to a phosphorus atom are the longest. The shortest Ru–$Cl_{bridge}$ distance is that with the DMSO ligand in the *trans* position. It is worth noting that the Ru(1)–P distances (with Ru bound to a terminal chloro ligand) are significantly shorter than the Ru(2)–P distances (with Ru bound to the DMSO ligand).

The seven-membered chelate rings allow P–Ru–P angles of 91.21(19) and 90.14(19)°. The $Cl_{bridge}$–Ru–$Cl_{bridge}$ angles have values between 77.57(15) and 80.25(16)°, with this being the main source of distortion of the octahedron. As shown in Figure 3, the environment of the metal atoms corresponds with the $C_1$-symmetric *transoid* isomer, with the dihedral torsion angle Cl(4)–Ru(1)–Ru(2)–S(1) having a value of 122.4(2)°. The Ru–Ru distance of 3.371(2) Å lies in the range expected for this type of dinuclear $Ru^{II}$ complex (3.28–3.44 Å).[12a]

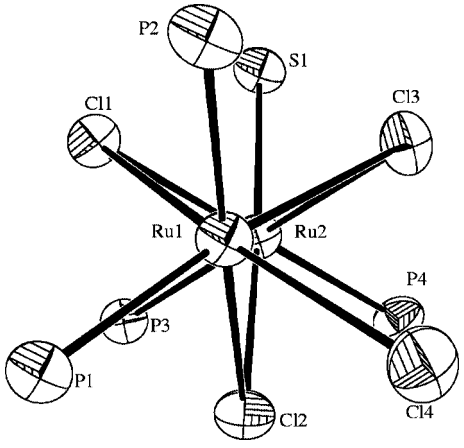

Figure 3. Environment of the Ru atoms in **2a**.

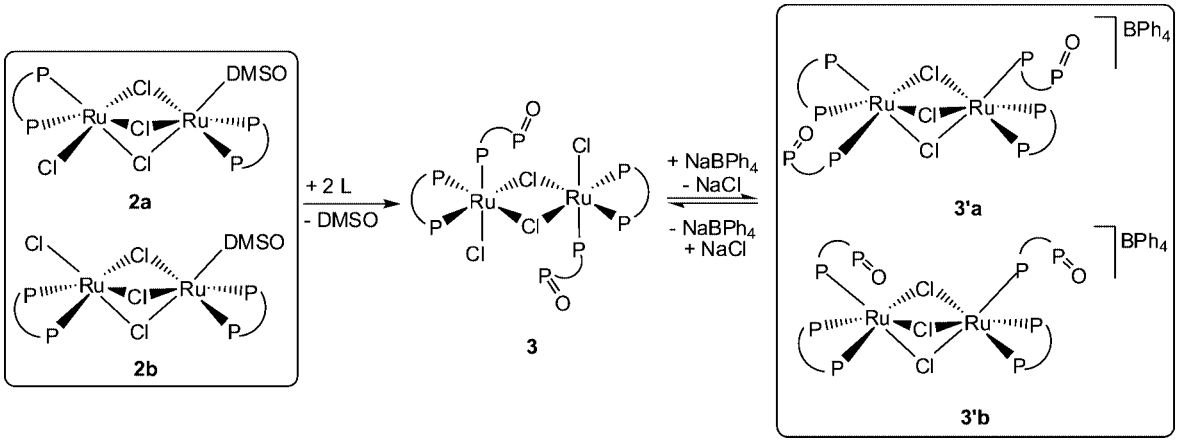
### Reaction of Compound 2 with L – Preparation of $[\{RuCl(\eta^2\text{-}L)[\eta^1\text{-}L(O)]\}_2(\mu\text{-}Cl)_2]$ (3)

The reaction of **2** with L (1:2 molar ratio) in refluxing toluene for 1 h gave the new compound **3**. The $^{31}P\{^1H\}$ NMR spectrum in $CDCl_3$ displays a doublet at $\delta$ = 159.0 ppm ($J$ = 46 Hz), a triplet at $\delta$ = 138.3 ppm and a singlet at $\delta$ = 32.5 ppm with an intensity ratio of 2:1:1, respectively. The singlet at higher field is consistent with the existence of a P=O group (corresponding to a partially oxidised molecule of L) that is not coordinated to the metal. The other two signals can be assigned to the P atoms of $\eta^2$-L and $\eta^1$-L(O), respectively. The $^1H$ NMR spectrum in $CDCl_3$ displays four multiplets at 3.68, 3.73, 4.17 and 4.49 ppm with an integral ratio 1:1:1:1. These signals correspond to the $CH_2$ groups of the two ligands. The 2D $^1H$, $^1H$ COSY and the 2D $^1H$, $^{31}P$ HMQC spectra allow full assignment of those signals (see Exp. Sect.). The FAB mass spectrum contains peaks at mass values for fragments of dinuclear species [$M^+$ – Cl – L(O)], [$M^+$ – 2Cl – L(O)], [$M^+$ – 2Cl – 2L(O)] and, interestingly, the strongest fragment was found at 1013, which corresponds exactly to the monomeric unit [RuClLL(O)]. Finally, treatment of a sample of **3** with excess $NaBPh_4$ in ethanol resulted in the precipitation of a new product, **3′**. The $^{31}P\{^1H\}$ NMR spectrum of this compound contains two sets of signals: three pseudotriplets integrating in a 1:1:1 ratio, and a triplet and a doublet integrating in a 1:2 ratio (the first set integrates to three times the second one) coexisting with traces of the original compound (very small signals at 159 and 138 ppm). When the sample in the NMR tube was stored for five days, evidence was observed that the reaction had gone backwards and the small signals had increased in intensity to levels similar to those observed at the beginning of the experiment.

All these data suggest the formation of neutral edge-sharing bioctahedra with two chloro bridges [{RuCl($\eta^2$-L)[$\eta^1$-L(O)]}$_2$($\mu$-Cl)$_2$] for compound **3** and this converts into the cationic face-sharing bioctahedral compound **3′** by reaction with $NaBPh_4$ – as depicted in Scheme 5.



Scheme 5.

**Reaction of 2 with L′ [L′ = $PPh_{3-n}(OEt)_n$; *n* = 1–3]**

In an effort to complement the results described above and to gather more information about the reactivity of complex **2**, we investigated the reaction of **2** with the monodentate phosphinite, phosphonite and phosphite ligands of formulae $PPh_{3-n}(OEt)_n$ (*n* = 1–3) (L′). Unexpectedly, different results were obtained when L′ was changed from a phosphinite (*n* = 1) to a phosphite (*n* = 3).

***L′ = $PPh_2(OEt)$ – Preparation of [{RuCl(η²-L)[$PPh_2(OEt)$]}₂(μ-Cl)₂] (4)***

When a mixture of **2** and $PPh_2(OEt)$ in a 1:2 molar ratio was heated under reflux in toluene for 1 h, the new compound [{RuCl(η²-L)[$PPh_2(OEt)$]}₂(μ-Cl)₂] (**4**) was obtained. Compound **4** shows spectral features that are very similar to those of compound **3**. The $^{31}P\{^1H\}$ NMR spectrum shows a doublet at $\delta$ = 159.7 ppm and a triplet at $\delta$ = 136.3 ppm (integrating to 2:1, $J$ = 46 Hz), which are very similar to the signals of **3**. The $^1H$ NMR spectrum also contains a set of signals that is consistent with this formulation. The signals at 4.31 (m, 4 H) and 3.86 (m, 4 H) ppm can be assigned to the –$CH_2$– groups of the bidentate ligand L, and those at 3.50 (m, 4 H) and 1.22 (t, 6 H) can be assigned to the ethoxy group of L′. The FAB mass spectrum of **4** displays (as observed for compound **3**) peaks that indicate the dinuclear nature of the compound: 1630 ($M^+$ – Cl), 1435 ($M^+$ – L′), 1400 ($M^+$ – L′ – Cl), 830 $[RuCl_2LL']^+$, 797 $[RuClLL']^+$.

Treatment of a sample of **4** with excess $NaBPh_4$ in ethanol gave similar results to those obtained in the case of complex **3**, with a new dinuclear face-shared bioctahedral complex, **4′**, formed as a mixture of both *cisoid* and *transoid* isomers.[13] However, in this case the proportion of the *transoid* isomer for the face-shared bioctahedra is significantly greater than in the case of compound **3**. In agreement with this situation, the $^{31}P\{^1H\}$ NMR spectrum of **4′** in $CDCl_3$ displays three pseudotriplets at 134.1, 141.9 and 145.7 ppm (corresponding to a *transoid* isomer) along with a doublet at $\delta$ = 143.3 ppm (the triplet is probably obscured by the signal at $\delta$ = 134.1 ppm) that corresponds to the *cisoid* form.

***L′ = $PPh(OEt)_2$ – Preparation of [{Ru(η²-L)[$PPh(OEt)_2$]}₂(μ-Cl)₃]Cl (5)***

When a mixture of **2** and $PPh(OEt)_2$ in a 1:2 molar ratio was heated under reflux in toluene for 1.5 h, we obtained a solid with $^{31}P\{^1H\}$ and $^1H$ NMR spectra consistent with a mixture (approx. 1:3) of both *cisoid* and *transoid* isomers of the cationic trichloro-bridged dinuclear compound [{Ru(η²-L)[$PPh(OEt)_2$]}₂(μ-Cl)₃]Cl (**5**) (see Scheme 1). The $^{31}P\{^1H\}$ NMR spectrum displays a doublet at $\delta$ = 151.7 ppm and a triplet at $\delta$ = 158.2 ppm ($J$ = 53 Hz) (*cisoid* isomer) and three pseudotriplets at 149.7, 153.0 and 156.1 ppm (*transoid* isomer). Careful inspection of the $^1H$ NMR spectrum also enables the signals of both isomers to be assigned (see Exp. Sect.). The mass spectrum shows the $[M^+]$ peak at $m/z$ = 1567, which is consistent with a dinuclear formulation. Moreover, treatment of a solution of this complex with excess $NaBPh_4$ in ethanol gave a tan solid with spectral features identical to those of the original product, thus confirming its ionic nature. We were also able to obtain suitable crystals for an X-ray diffraction study. The structure of the complex cation and the most relevant distances and angles are shown in Figure 4 and in Tables 2 and 3, respectively.

It can be seen that the cation complex **5a** adopts a *transoid* [dihedral torsion angle P(1)–Ru(1)–Ru(2)–P(2) of 115.5(2)°] triply chloride-bridged diruthenium structure similar to **2a** (Figure 5). The coordination geometry around each metal centre is a distorted octahedron, with the same coordination sphere at each ruthenium atom (three bridging chlorine atoms and three phosphorus atoms). The two met-

als maintain the same oxidation state (+II) as a disordered chloride ion is acting as a counterion. Two of the phosphorus atoms coordinated to each metal atom come from the bidentate phosphinite ligand L, and the third one comes from the monodentate ligand L′. In contrast to complex **2a**, the environment around each ruthenium atom is quite similar, with similar values for bond lengths and angles. The Ru–P bonds are slightly shorter, by 0.01 Å, when the ligand is the monodentate phosphonite ligand. The Ru–Cl bond lengths range from 2.473(2) to 2.535(3) Å, with the longer ones corresponding to those including the labelled Cl(2) atom, the only one that is simultaneously *trans* to two phosphinite phosphorus atoms. The Ru(1)–Cl(2)–Ru(2) angle, 86.02(8)°, is also the most acute of the three Ru–Cl–Ru angles.

The seven-membered chelate rings allows P–Ru–P angles of 89.89(11) and 90.05(10)°, which are virtually identical to one another and similar to those found in **2a**. The Cl–Ru–Cl angles involving the triple bridge have values between 76.66(9) and 79.05(8)° and once again this is the main source of distortion of the octahedron. The Ru–Ru separation of 3.4417(12) Å is in the upper limit of the range expected for this type of dinuclear $Ru^{II}$ complex, 3.28–3.44 Å.[12a]

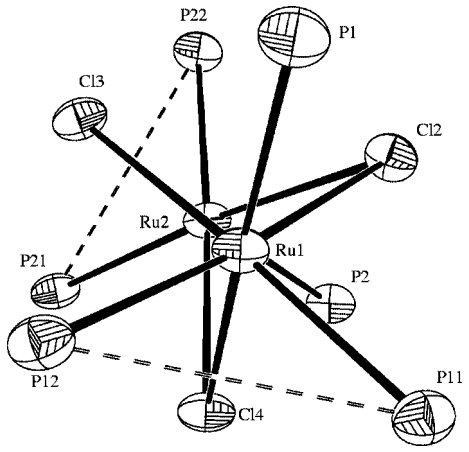

Figure 5. Environment of the Ru atoms in the complex cation **5a**.

### *L′ = P(OEt)$_3$ – Preparation of [RuCl$_2$(η$^2$-L){P(OEt)$_3$}$_2$] (6)*

When a mixture of **2** and $P(OEt)_3$ in a 1:2 molar ratio was heated under reflux in toluene for 1 h, we obtained a solid that has NMR features consistent with a mononuclear species of formula $[RuCl_2(\eta^2\text{-}L)\{P(OEt)_3\}_2]$ (**6**), in which one bidentate ligand and two phosphite ligands (mutually *cis*) are present. The $^{31}P\{^1H\}$ NMR spectrum consists of four double doublets of doublets at 97.8 ($P_1$), 122.0 ($P_4$), 129.8 ($P_2$) and 150.7 ($P_3$) ppm ($J_{12}$ = 48, $J_{13}$ = 24, $J_{14}$ = 544, $J_{23}$ = 47, $J_{24}$ = 64 and $J_{34}$ = 46 Hz). The $^1H$ NMR spectrum displays two triplets at $\delta$ = 0.90 and 1.22 ppm ($J$ = 7 Hz), which integrate to 9 protons each, and these signals can be assigned to the methyl groups of L′. These signals demonstrate the nonequivalence of the two ligands. The signals corresponding to the methylene protons of both L and L′ appear as seven multiplets of different intensity. These signals were fully characterised by 2D $^1H$, $^{13}C\{^1H\}$ HSQC correlation (see Figure 6). The methylene protons of the bidentate ligand L appear as four multiplets at 3.43, 3.98, 4.40 and 5.67 ppm, integrating to one proton each. On the other hand, the methylene protons of both L′ ligands appear as four multiplets centred at 3.26, 3.43, 4.23 and 4.46 and these signals integrate to three protons each because of the nonequivalence of the two L′ ligands and the diastereotopic nature of each pair of geminal $CH_2$ protons.

Crystals suitable for X-ray analysis were obtained. The structure of the complex is shown in Figure 7 and the most relevant distances and angles are given in Table 4. The compound consists of discrete units in which the ruthenium atom is in a slightly distorted octahedral environment, coordinated to two mutually *cis* chlorine atoms, two phosphorus atoms of a diphosphinite ligand and two phosphorus atoms of two monodentate phosphite ligands, which are also mutually *cis*. The *cis* angles range from 84.78(5) to 97.28(6)°, with the latter value corresponding to the chelate angle allowed by the seven-membered chelate ring. The *trans* angles range from 170.42(6) to 177.02(6)° and these show the regu-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

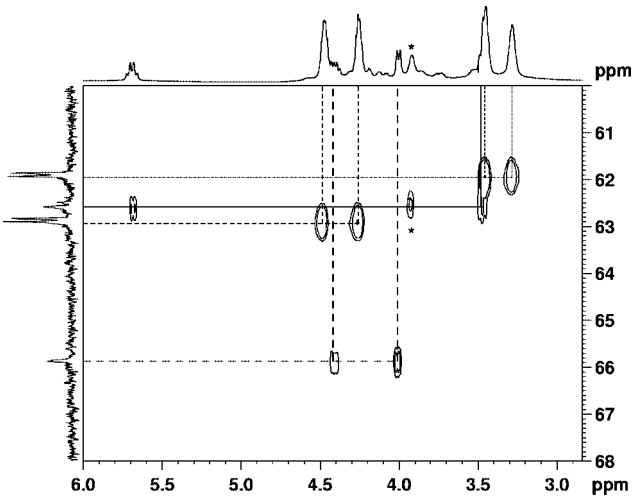

Figure 6. 2D $^{1}H,^{13}C\{^{1}H\}$ HSQC experiment in $CDCl_3$ for compound **6**. Signals in the $^{13}C$ spectrum can be assigned as follows: $\delta$ = 65.9, 62.6 (br. s, $CH_2$, L), 62.9, 61.9 (d, $J_{CP}$ = 10 Hz, $CH_2$, L′). Signals marked with an asterisk correspond to an impurity.

larity of the octahedron, which is probably only distorted due the steric hindrance of the diphosphinite ligand. The *cis* Cl–Ru–Cl angle, 86.81(5)°, is similar to those found in *cis* complexes $RuCl_2P_4$.[14] The Ru–Cl distances are similar to one another but the Ru–P distances show small differences in the order Ru–P4 < Ru–P1 < Ru–P3 < Ru–P2. This order is consistent with the greater *trans* influence of phosphorus ligands than Cl and the higher π-acceptor character of phosphite ligands as compared with phosphinites.

### Reaction of $[RuCl_2(DMSO)_4]$ with L in a 1:2 Molar Ratio

A mixture of $[RuCl_2(DMSO)_4]$ and L in a 1:2 molar ratio was heated under reflux in toluene for 2 h and the progression of the reaction was followed by $^{31}P$ NMR spectroscopy. A complicated spectrum was observed with different sets of signals, suggesting the presence of a mixture of several new compounds. The solution was evaporated to dryness and the residue was treated with $Et_2O$. An orange solid and a yellow solution were obtained. The solid was filtered off, washed with $Et_2O$ and dried to afford the same compound, $[\{RuCl(\eta^2\text{-}L)[\eta^1\text{-}Ph_2PO(CH_2)_2OP(O)Ph_2]\}_2(\mu\text{-}Cl)_2]$ (**3**), as was already obtained in the reaction of complex **2** with L.[15] The yellow solution was purified by column chromatography to yield the two new compounds $[RuCl_2(L)(Ph_2POPPh_2)]$ (**7**) and $[RuCl(CO)(L)(Ph_2PO-$

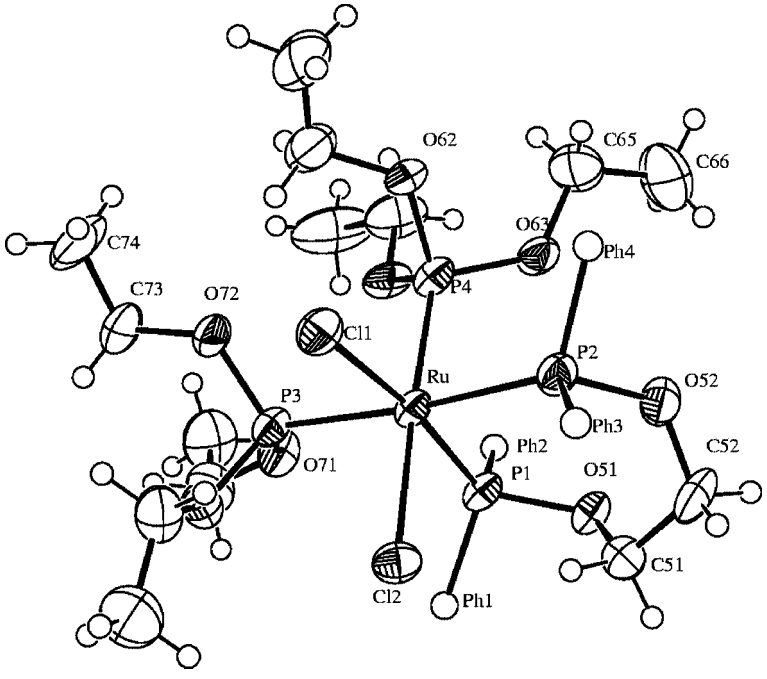

Figure 7. ORTEP representation of complex $[RuCl_2(\eta^2\text{-}L)\{P(OEt)_3\}_2]$ (**6**) drawn at the 30% probability level. The phenyl rings were replaced by spheres of arbitrary radius.

$CH_2$)] (**8**) (see Exp. Sect. for details). We were able to obtain single crystals of both compounds that were suitable for X-ray analysis.

### *[RuCl$_2$(L)(Ph$_2$POPPh$_2$)] (7)*

The reaction probably involves a metal-promoted disruption of the bidentate ligand to tetraphenyldiphosphoxane,[16] although in a somewhat similar reaction between $[Rh(COE)_2Cl]_2$ (COE = cyclooctene) and $P(NMe_2)_3$ in toluene, the generation of a diphosphoxane complex was attributed to a hydrolysis impurity present in the commercial $P(NMe_2)_3$.[17] This is probably not the situation in our case because we did not observe such a process in reactions between the same ligand and other metals such as Re and Mn.[18] Other authors have observed the same product (POP) and suggested a P–P(O) to P–O–P thermal rearrangement prior to metal coordination,[19] a process that is favoured when R groups bonded to P are inductively electron-withdrawing groups like OR groups (as in our case). A likely mechanism involves partial hydrolysis of the ligand due to the prolonged heating and the presence of adventitious moisture, followed by a tautomeric rearrangement from the P–P(O) to the P–O–P form.

The $^1$H NMR spectrum of **7** in $CDCl_3$ shows a multiplet centred at $\delta$ = 4.30 ppm, which is assigned to the methylene protons of the bidentate diphosphinite ligand, and signals between 6.90 and 7.50 ppm corresponding to the phenyl groups of the two chelating ligands. The $^{31}P\{^1H\}$ NMR spectrum in $CDCl_3$ shows two doublets of multiplets centred at $\delta$ = 106.8 and 133.0 ppm, corresponding to the two phosphorus nuclei of each bidentate ligand. The signal at lower field can be assigned to the bisphosphinite ligand L (as shown in the 2D $^1$H, $^{31}P\{^1H\}$ HMBC correlation experiment by the cross-peak present with the methylene signal of L at $\delta$ = 4.30 ppm, see Supporting Information) and the multiplet at $\delta$ = 106.8 ppm can be assigned to the phosphorus nuclei of the tetraphenyldiphosphoxane ligand. The IR spectrum contains a strong band at 791 cm$^{-1}$ and this is assigned to the P–O–P asymmetric stretching mode in accordance with its chelating nature (reported values of 775–800 cm$^{-1}$).[16,20]

An ORTEP view of compound **7** is shown in Figure 8 along with the labelling scheme. Selected distances and angles are given in Table 5. The compound consists of discrete units, although some intermolecular nonclassical Cl···HC hydrogen bonds can be found (Table 6). The ruthenium atom is in a distorted octahedral environment and is coordinated to two chlorine atoms that are mutually *trans*, two phosphorus atoms of a tetraphenyldiphosphoxane ligand and two phosphorus atoms of a diphosphinite ligand.

The four phosphorus atoms are located in the equatorial plane (rms = 0.057). The chelate ring angle of the tetraphenyldiphosphoxane ligand is only 66.37(2)° and is the main source of distortion. To the best of our knowledge, this is the first example of a ruthenium complex with this type of chelating ligand, but the chelate angle is similar to that found in the chromium, molybdenum and rhodium complexes.[17,21] The chelate angle allowed by the seven-membered chelate ring is close to the theoretical value of 90° [92.43(3)°] and, consequently, the other two angles in the equatorial plane increase to 98.56(2) and 102.76(3)°. The *trans* Cl–Ru–Cl angle is also slightly different than the expected value of 180° [171.40(2)°] and this is due to a small deviation of the chlorine atom labelled as Cl(1), as shown by the P–Ru–Cl angles. The four-membered chelate ring is almost planar, with the O(1) atom only 0.103(2) Å out of the P(3)–Ru–P(4) plane.

[a] Symmetry transformations used to generate equivalent atoms: $1 - x, y + 1/2, 1/2 - z$.

The angle P(4)–O(1)–P(3) has a value of 104.14(9)°, which is slightly less acute than those reported for the aforementioned complexes.[17,21] The ruthenium atom is only 0.0184(4) Å out of the equatorial plane defined by the four phosphorus atoms (rms = 0.057). The plane defined by the two phosphorus atoms and the two oxygen atoms of the diphosphinite ligand (rms = 0.088) forms a dihedral angle with the equatorial plane of 41.73(6)°. However, the plane P(3)–Ru–P(4) forms a dihedral angle of only 6.00(7)° with the equatorial plane and can essentially be considered as coplanar [the oxygen atom O(1) is only 0.096(2) Å out of the equatorial plane].

### *[RuCl(CO)(L)(Ph$_2$POCH$_2$)] (8)*

Compound **8** has a surprising structure in which the ruthenium centre is coordinated by an intact ligand L, Cl and CO ligands, and an anionic fragment $Ph_2POCH_2^-$ of this ligand. This arrangement stabilises, in spite of the strain, a ruthena-phospha-oxa-cyclobutane ring. As the only source of CO is the bis(phosphinite) L ligand, and we did not observe similar behaviour for L with other metals,[18] these fragments must come from a metal-promoted disruption of the bidentate ligand. Moreover, although the yields are low, the reaction is perfectly reproducible. The complex was characterised in solution by multinuclear NMR spectroscopy. The $^{31}P\{^1H\}$ NMR spectrum of **8** in $CDCl_3$ shows three doublet of doublets, which is consistent with a structure presenting two mutually *trans* phosphorus atoms [one on the $Ph_2POCH_2^-$ fragment ($\delta$ = 76.0 ppm) and one on the L ligand ($\delta$ = 133.3 ppm), $J_{trans}$ = 341 Hz] and the other in a *cis* disposition ($\delta$ = 131.5 ppm), $J_{cis}$ = 14 and 31 Hz. The $^1H$ NMR spectrum of **8** in $CDCl_3$ shows two groups of multiplets, one in the range 3.80–4.80 ppm that integrates to six protons and corresponds to the methylene groups of the two ligands, and other between 7.20–7.80 (30 H) that corresponds to the phenyl groups. An HMBC $^{31}P\{^1H\}$–$^1H$ correlation enabled identification of the dif-

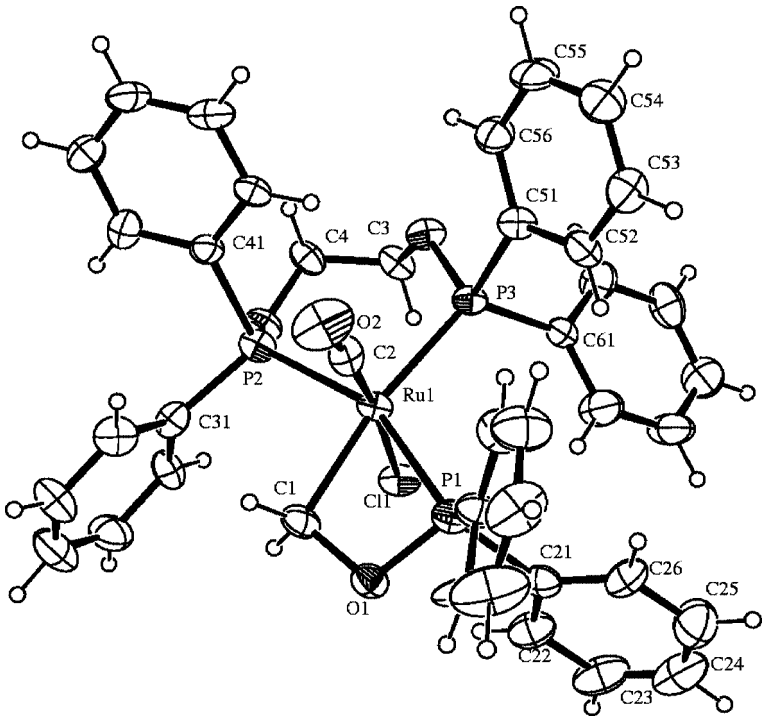

Figure 9. ORTEP drawing of complex **8**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ferent proton signals, showing that the multiplets at $\delta$ = 3.97 and 4.77 ppm (integrating to 2 protons each) can be assigned to the methylene groups of L, and the multiplets at $\delta$ = 4.52 and 4.68 ppm (integrating to one proton each) correspond to the $CH_2$ group bonded to the ruthenium. This observation shows that these two protons are diastereotopic.

An ORTEP view of compound **8** is shown in Figure 9 along with the labelling scheme. Selected distances and angles are given in Table 7. The compound consists of discrete units, although some intermolecular nonclassical Cl···HC hydrogen bonds can be found (see Table 8). The ruthenium atom is in a distorted octahedral environment, coordinated to one chlorine atom, two phosphorus atoms of a diphosphinite ligand, one phosphorus atom, a carbon atom of the diphenyl(oxymethyl-κ*C*)phosphinite-κ*P* ligand and a carbon atom of a carbonyl ligand. Two of the ligands act as bidentate systems (diphosphinite and phosphinite ligand) and these can be considered to be in the equatorial plane. The four-membered chelate ring is one of the main sources of distortion in the octahedron, with an angle of 62.9(3)°. The opposite seven-membered chelate angle in the equatorial plane is slightly larger than one would expect for this ligand, 93.59(9)°, but the two adjacent angles in the equatorial plane do not increase to the same extent [P(1)–Ru(1)–P(3) = 110.85(9)°, C(1)–Ru(1)–P(2) = 92.4(3)°]. The differences found in these angles are due to the steric effects of the phenyl rings on the phosphorus atoms. For the same reason, all the axial angles in the octahedron are close to the expected 180°, except for the P(2)–Ru(1)–P(1) angle [155.26(9)°]. The plane formed by the four atoms in the chelate ring (rms = 0.069) forms a dihedral angle of only 7.2(2)° with the equatorial plane of the donor atoms (rms = 0.047). The ruthenium atom is only 0.096(3) Å out of this plane.

Table 7. Selected bond lengths [Å] and angles [°] for complex **8**.

| Bond lengths | | | |
|---|---|---|---|
| Ru(1)–C(2) | 1.835(11) | Ru(1)–C(1) | 2.181(10) |
| Ru(1)–P(2) | 2.336(3) | Ru(1)–P(1) | 2.346(3) |
| Ru(1)–P(3) | 2.378(3) | Ru(1)–Cl(1) | 2.467(2) |
| P(1)–O(1) | 1.582(6) | O(1)–C(1) | 1.465(11) |
| **Bond angles** | | | |
| C(2)–Ru(1)–C(1) | 89.8(4) | C(2)–Ru(1)–P(2) | 91.9(3) |
| C(1)–Ru(1)–P(2) | 92.4(3) | C(2)–Ru(1)–P(1) | 88.8(3) |
| C(1)–Ru(1)–P(1) | 62.9(3) | P(2)–Ru(1)–P(1) | 155.26(9) |
| C(2)–Ru(1)–P(3) | 97.3(3) | C(1)–Ru(1)–P(3) | 170.5(3) |
| P(2)–Ru(1)–P(3) | 93.59(9) | P(1)–Ru(1)–P(3) | 110.85(9) |
| C(2)–Ru(1)–Cl(1) | 174.0(3) | C(1)–Ru(1)–Cl(1) | 84.3(3) |
| P(2)–Ru(1)–Cl(1) | 87.09(8) | P(1)–Ru(1)–Cl(1) | 89.60(8) |
| P(3)–Ru(1)–Cl(1) | 88.64(8) | O(2)–C(2)–Ru(1) | 176.2(9) |

To the best of our knowledge, the diphenyl(oxymethyl-κ*C*)phosphinite-κ*P* ligand has only previously been found to show this behaviour in the manganese complex tetracarbonyl-2,2-diphenyl-1-oxa-2-phospha-3-manganacyclobutane.[22]

## Conclusions

New dinuclear ruthenium complexes bearing the 1,2-bis(diphenylphosphinite)ethane ligand in different proportions were prepared and characterised. The compounds $[Ru_2(\mu\text{-}Cl)_3(DMSO)_3Cl(\eta^2\text{-}L)]$ (**1**) and $[Ru_2(\mu\text{-}Cl)_3(DMSO)\text{-}Cl(\eta^2\text{-}L)_2]$ (**2**) present a face-sharing bioctahedral structure while compound $[Ru_2Cl_2(\eta^2\text{-}L)_2\{\eta^1\text{-}L(O)\}_2(\mu\text{-}Cl)_2]$ (**3**) has an edge-sharing bioctahedral structure with two chelating L units and two monodentate ligands in which a phosphorus atom is oxidised and remains uncoordinated. Reaction of compound **2** [a mixture of both *cisoid* (**2a**, minor component) and *transoid* (**2b**, major component) isomers] with the monodentate ligands $PPh_{3-n}(OEt)_n$ ($n$ = 1–3) (L′) affords different compounds depending on the structure of L′. When L′ is structurally similar to L (both phosphinites), the resulting compound is the dinuclear doubly chloro-bridged complex $[\{RuCl(\eta^2\text{-}L)(L')\}(\mu\text{-}Cl)_2]$ (**4**), which is very similar to compound **3** – obtained by reacting compound **2** with L. Reaction of compound **2** with the phosphonite L′ ($n$ = 2) gave the face-sharing octahedral compound $[\{Ru(\eta^2\text{-}L)(L')\}_2(\mu\text{-}Cl)_3]Cl$ (**5**) as a mixture of both *cisoid* (**5a**) and *transoid* (**5b**) isomers. On the other hand, when L′ is a phosphite ($n$ = 3) the reaction with compound **2** yields the mononuclear compound $[RuCl_2(\eta^2\text{-}L)(L')_2]$ (**6**). Finally, compound **3** can also be obtained by reaction of $[RuCl_2(DMSO)_4]$ with L, but in this case two more products with formulae $[RuCl_2(L)(Ph_2POPPh_2)]$ (**7**) and $[RuCl(CO)(L)(Ph_2POCH_2)]$ (**8**) were also obtained. In these products a chelating diphosphinite L coexists with new phosphorus ligands formed in situ by metal-mediated disruptions of L.

## Experimental Section

**General:** All experimental manipulations were carried out under argon using Schlenk techniques. All solvents were purified by conventional procedures[23] and distilled prior to use. $[RuCl_2(DMSO)_4]$[24] and 1,2-bis(diphenylphosphanyloxy)ethane[18c] were prepared using published methods. All the other chemicals were commercial products and were used as received without further purification. 1D and 2D NMR spectra ($\delta$, ppm) were recorded in $CDCl_3$, $CD_2Cl_2$ or $C_6D_6$ (as indicated) with a Bruker ARX-400 spectrometer (161 MHz for $^{31}P\{^1H\}$, 100 MHz for $^{13}C\{^1H\}$, 400 MHz for $^1H$) using the solvent as the internal lock. $^{31}P\{^1H\}$ chemical shifts are referred to 85% $H_3PO_4$ with downfield values reported as positive. $^1H$ and $^{13}C\{^1H\}$ signals are referred to residual protonated solvents as internal standards. IR spectra of samples in KBr pellets were obtained with a Bruker Vector IFS28 FT spectrophotometer. Mass spectra were recorded with a Micromass Au-

tospec M LSIMS ($FAB^+$) system with 3-nitrobenzyl alcohol as matrix. Microanalyses were carried out with a Fisons EA-1108 apparatus. Merck silica gel 60 (0.040–0.063 mm) was used for column chromatography.

**Synthesis of $[Ru_2(\mu\text{-}Cl)_3(DMSO)_3Cl(L)]$ (1):** A solution of L (2.0 mL, 0.56 mmol) in toluene was added to a solution of $[RuCl_2(DMSO)_4]$ (0.5 g, 1.03 mmol) in toluene (20 mL). The solution was heated under reflux for 1/2 h, cooled to room temperature and concentrated under vacuum. The residue was treated with EtOH to give a yellow solid, which was washed with EtOH and dried under vacuum. Yield: 0.40 g (77%). $C_{32}H_{42}Cl_4O_5P_2Ru_2S_3$ (108.77): calcd. C 38.10, H 4.20, S 9.54; found C 37.97, H 4.19, S 9.50. $^1H$ NMR ($CDCl_3$): $\delta$ = 3.04 (s, 6 H, DMSO), 3.12 (s, 6 H, DMSO), 3.43 (s, 6 H, DMSO), 3.72 (m, 2 H, $CH_2$), 4.26 (m, 2 H, $CH_2$), 7.29 (m, 12 H, Ph), 7.49 (m, 4 H, Ph), 7.78 (m, 4 H, Ph). $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 158.2 (s). IR (KBr): $\nu$(SO) 1093 (s) $cm^{-1}$. $FAB^+$/MS: *m/z* (calculated for the most abundant isotopes) = 1010, ($M^+$), 975 ($M^+$ – Cl), 932 ($M^+$ – DMSO), 776 ($M^+$ – 3 DMSO), 741 ($M^+$ – 3 DMSO – Cl), 602 $[RuCl_2L]^+$.

**Synthesis of $[Ru_2(\mu\text{-}Cl)_3(DMSO)Cl(L)_2]$ (2):** Method (a): A solution of L (1.8 mL, 0.50 mmol) in toluene was added to a solution of **1** (0.50 g, 0.49 mmol) in toluene (20 mL). The solution was heated under reflux for 1/2 h and then cooled to room temperature. The solvent was removed under vacuum and EtOH was added to the oily residue. The resulting yellow precipitate was filtered off, washed with EtOH and dried under vacuum. Yield: 0.43 g (68%). Method (b): A solution of L (4.0 mL, 1.14 mmol) in toluene was added to a solution of $[RuCl_2(DMSO)_4]$ (0.5 g, 1.03 mmol) in toluene (20 mL). The reaction mixture was heated under reflux for 1 h and then cooled to room temperature. The solvent was removed under vacuum and EtOH was added to the oily residue. The resulting yellow precipitate was filtered off, washed with EtOH and dried under vacuum. Yield: 0.39 g (59%). $C_{54}H_{54}Cl_4O_5P_4Ru_2S$ (1282.92): calcd. C 50.55, H 4.24, S 2.50; found C 50.32, H 4.26, S 2.55. $^1H$ NMR ($CDCl_3$) (intensity ratio 1:4 *cisoid*/*transoid* isomers): $\delta$ = 2.54 (s, 3 H, $CH_3'SO$, *transoid*), 2.87 (s, 3 H, $CH_3''SO$, *transoid*), 3.22 (s, 6 H, DMSO, *cisoid*), 3.57–4.13 [m, (5 H, $CH_2$, *transoid* + 5 H, $CH_2$, *cisoid*)], 4.33 [m, (1 H, $CH_2$, *transoid* + 1 H, $CH_2$, *cisoid*)], 4.50 (m, 1 H, $CH_2$, *cisoid*), 4.59 (m, 1 H, $CH_2$, *cisoid*), 4.76 (m, 1 H, $CH_2$, *transoid*), 4.90 (m, 1 H, $CH_2$, *transoid*), 6.80–8.30 [m, (40 H, Ph, *cisoid* + 40 H, Ph, *transoid*)] ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 146.4 (s, *cisoid*), 148.3 (q, $J_{AB}$ = 44 Hz, *transoid*), 151.9 (d, $J_{AX}$ = 55 Hz), 156.9 (s, *cisoid*), 160.7 (d, $J$ = 55 Hz, *transoid*) ppm. $C_{54}H_{54}Cl_4O_5P_4Ru_2S$: calcd. C 50.55, H 4.24, S 2.50; found C 49.82, H 4.28, S 2.67. $FAB^+$/MS: *m/z* (calculated for the most abundant isotopes) 1284 ($M^+$), 1249 ($M^+$ – Cl), 1206 ($M^+$ – DMSO). X-ray quality crystals were obtained by slow evaporation of a $CH_2Cl_2/Et_2O$ (1:10 v/v) solution.

**Synthesis of $[Ru_2(\mu\text{-}Cl)_2Cl_2(L)_2\{L(O)\}_2]$ (3):** Method (a): A solution of compound **2** (0.150 g, 0.12 mmol) in toluene (20 mL) was added to a solution of L (0.75 mL, 0.26 mmol) in toluene and the mixture was heated under reflux for 1 h, cooled to room temperature and the solvent removed under vacuum. $Et_2O$ was added to the residue and the resulting yellow solid was filtered off, washed with $Et_2O$ and dried under vacuum. Yield: 0.18 g (92%). Method (b): A mixture of $[RuCl_2(DMSO)_4]$ (0.5 g, 1.03 mmol) and a solution of L (7.5 mL, 2.14 mmol) in toluene (20 mL) was heated under reflux for 2 h with stirring. The solution was cooled to room temperature and the solvent was removed under vacuum to give an oily residue. $Et_2O$ (5 mL) was added and the resulting yellow solid was filtered off. Compounds **7** and **8** were obtained from the filtrate (see below). The solid was washed with $Et_2O$ and dried under vacuum. Yield: 0.72 g (42%). $C_{104}H_{96}Cl_4O_{10}P_8Ru_2$ (2097.61): calcd. C 59.55, H 4.61; found C 59.20, H 4.63. $^1H$ NMR ($CDCl_3$): $\delta$ = 3.68 (m, 4 H, $CH_2$, L), 3.73 [m, 4 H, $CH_2$, L(O)], 4.17 [m, 4 H, $CH_2$, L(O)], 4.49 (m, 4 H, $CH_2$, L), 6.80–8.00 (m, 80 H, Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 32.5 [s, (P=O), L(O)], 138.3 [t, $J$ = 46 Hz, P, L(O)], 159.0 (d, $J$ = 46 Hz, 2P, L) ppm. $FAB^+$/MS: *m/z* (calculated for the most abundant isotopes) 1617 [$M^+$ – Cl – L(O)], 1580 [$M^+$ – 2 Cl – L(O)], 1013 $[RuClLL(O)]^+$.

**Synthesis of $[Ru_2(\mu\text{-}Cl)_2Cl_2(L)_2\{PPh_2(OEt)\}_2]$ (4):** $PPh_2(OEt)$ (0.05 mL, 0.24 mmol) was added to a solution of compound **2** (0.150 g, 0.12 mmol) in toluene (20 mL). The mixture was heated under reflux for 1 h and the solvent was removed under vacuum. Addition of $Et_2O$ gave an orange-yellow precipitate and this was filtered off, washed with $Et_2O$ and dried under vacuum. Yield: 0.15 g (75%). $C_{80}H_{78}Cl_4O_6P_6Ru_2$ (1665.27): calcd. C 57.70, H 4.72; found C 57.53, H 4.71. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.22 (t, $J$ = 7 Hz, 6 H, $CH_3$), 3.50 (m, 4 H, $OCH_2$), 3.86 (m, 4 H, $CH_2$), 4.31 (m, 4 H, $CH_2$), 6.50–7.90 (m, 60 H, Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 136.3 (t, $J$ = 46 Hz, P, L′), 159.7 (d, $J$ = 46 Hz, 2P, L) ppm. $FAB^+$/MS: *m/z* (calculated for the most abundant isotopes) 1631 ($M^+$ – Cl), 1436 ($M^+$ – L′), 1401 ($M^+$ – L′ – Cl), 832 $[RuCl_2LL']^+$, 797 $[RuClLL']^+$.

**Synthesis of $[Ru_2(\mu\text{-}Cl)_3(L)_2\{PPh(OEt)_2\}_2]Cl$ (5):** $PPh(OEt)_2$ (0.07 mL, 0.24 mmol) was added to a solution of compound **2** (0.150 g, 0.12 mmol) in toluene (20 mL). The mixture was heated under reflux for 1.5 h and the solvent was removed under vacuum. Addition of $Et_2O$ gave a yellow precipitate and this was filtered off, washed with $Et_2O$ and dried under vacuum. Yield: 0.13 g (67%). $C_{72}H_{78}Cl_4O_8P_6Ru_2$ (1601.18): calcd. C 54.01, H 4.91; found C 53.81, H 4.88. $^1H$ NMR ($CDCl_3$): $\delta$ = 0.83 (t, 6 H, $J$ = 7 Hz, $CH_3$, *transoid*), 0.97 (t, 6 H, $J$ = 7 Hz, $CH_3$, *transoid*), 1.25 (m, 12 H, $CH_3$, *cisoid*), 3.50–3.90 [m, 16 H, $CH_2$ (L + L′), *transoid*], 4.01 [m, 8 H, $CH_2$ (L′), *cisoid*], 4.26 [m, 4 H, $CH_2$, (L)], 4.51 [m, 4 H, $CH_2$, (L)], 6.40–8.00 [m, (50 H, Ph, *cisoid*) + (50 H, Ph, *transoid*)] ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 149.6 [$t_{apparent}$, $J_{app}$ = 48 Hz, 2P (L), *transoid*], 151.7 [d, $J$ = 53 Hz, 4P (L), *cisoid*], 153.0 [$t_{apparent}$, $J_{app}$ = 48 Hz, 2P (L), *transoid*], 156.1 [$t_{apparent}$, $J_{app}$ = 53 Hz, 2P (L′), *transoid*], 158.2 [t, $J$ = 53 Hz, 2P (L′), *cisoid*] ppm. $FAB^+$/MS *m/z* (calculated for the most abundant isotopes) 1567 ($M^+$), 1530 ($M^+$ – Cl), 765 $[RuClLL']^+$. X-ray quality crystals were obtained by slow evaporation of a $CH_2Cl_2/Et_2O$ (1:10 v/v) solution.

**Synthesis of $[RuCl_2L\{P(OEt)_3\}_2]$ (6):** $P(OEt)_3$ (0.08 mL, 0.48 mmol) was added to a solution of compound **2** (0.150 g, 0.12 mmol) in toluene (20 mL). The mixture was heated under reflux for 1 h and the solvent was removed under vacuum. Addition of $Et_2O$ gave a pale yellow precipitate and this was filtered off, washed with $Et_2O$ and dried under vacuum. Yield: 0.14 g (62%). $C_{38}H_{54}Cl_2O_8P_4Ru$ (934.71): calcd. C 48.83, H 5.82; found C 49.05, H 5.85. $^1H$ NMR ($CDCl_3$): $\delta$ = 0.90 (t, $J$ = 7 Hz, 9 H, $CH_3$), 1.22 (t, $J$ = 7 Hz, 9 H, $CH_3$), 3.26 [m, 3 H, $CH_2$ (L′)], 3.43 [m, 3 H, $CH_2$ (L′) + 1 H, $CH_2$ (L)], 3.98 [m, 1 H, $CH_2$ (L)], 4.23 [m, 3 H, $CH_2$ (L′)], 4.40 [m, 1 H, $CH_2$ (L)], 4.46 [m, 3 H, $CH_2$ (L′)], 5.67 [m, 1 H, $CH_2$ (L)] ppm. $^{31}P\{^1H\}$NMR ($CDCl_3$): $\delta$ = 97.8 (ddd, $J_{cis}$ = 24, 48 Hz, $J_{trans}$ = 544 Hz, $P_1$), 122.0 (ddd, $J_{cis}$ = 46, 64 Hz, $J_{trans}$ = 544 Hz, $P_4$), 129.8 (ddd, $J_{cis}$ = 47, 48, 64 Hz, $P_2$), 150.7 (ddd, $J_{cis}$ = 24, 46, 47 Hz, $P_3$) ppm. $FAB^+$/MS: *m/z* (calculated for the most abundant isotopes) 899 ($M^+$ – Cl), 733 [$M^+$ – Cl – $P(OEt)_3$]. X-ray quality crystals were obtained by slow evaporation of a $CH_2Cl_2/Et_2O$ (1:10 v/v) solution.

**Synthesis of $[RuCl_2(L)(Ph_2POPPh_2)]$ (7) and $[RuCl(CO)(L)(PPh_2OCH_2)]$ (8):** From the ether solution obtained during the synthesis of compound **3** [Method (b), see above], the solvent was re-

moved under vacuum, and the residue was treated with MeOH to give a yellow solid, which was washed with MeOH and dried under vacuum. This solid was a mixture of compounds **7** and **8** and these were separated by column chromatography using silica gel as the stationary phase. Complex **7** was eluted first using a mixture of $CH_2Cl_2/Et_2O$ (10:1, v:v). The eluent was removed under vacuum and the residue was treated with EtOH to give a yellow solid, which was filtered off, washed with EtOH and dried under vacuum. Yield: 0.012 g (12%). $^1H$ NMR ($CDCl_3$): $\delta$ = 4.30 (m, 4 H, $CH_2$), 6.90–7.50 (m, 40 H, Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 106.8 (m, $P_{3,4}$), 133.0 (m, $P_{1,2}$) ppm. $C_{50}H_{44}Cl_2O_3P_4Ru$ (988.75): calcd. C 60.74, H 4.49; found C 60.60, H 4.50. $FAB^+$/MS: *m*/*z* (calculated for the most abundant isotopes) 988 ($M^+$), 953 ($M^+$ – Cl), 602 $[RuCl_2L]^+$. X-ray quality crystals were obtained by slow evaporation of a $CH_2Cl_2$/EtOH (1:10 v/v) solution. Complex **8** was eluted using $CH_2Cl_2$ as eluent. The solvent was removed under vacuum and the residue was treated with EtOH. The resulting white solid was filtered off, washed with EtOH and dried under vacuum. Yield: 0.013 g (1.5%). IR (KBr disc): 1953 (s) ($\nu_{co}$) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 3.80–4.80 (m, 6 H, $CH_2$), 7.20–7.80 (m, 30 H, Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 76.0 (dd, $J_{12}$ = 341, $J_{13}$ = 14 Hz, $P_1$), 131.5 (dd, $J_{23}$ = 31 Hz, $P_3$), 133.3 (dd, $P_2$) ppm. $C_{40}H_{36}ClO_4P_3Ru$ (810.15): calcd. C 59.30, H 4.48; found C 59.46, H 4.46. $FAB^+$/MS: *m*/*z* (calculated for the most abundant isotopes) 782 ($M^+$ – CO), 775 ($M^+$ – Cl), 747 ($M^+$ – CO – Cl), 595 $[RuCl(CO)L]^+$. X-ray quality crystals were obtained by slow evaporation of a $CH_2Cl_2$/EtOH (1:10 v/v) solution.

CCDC-297717 to -297721 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Details of crystal data and structural refinement are given in Table 9. The data were collected with a SIEMENS Smart CCD area-detector diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation. Absorption correction was carried out using SADABS.[25]

The structures of **5a** and **8** were solved by Patterson methods and the structures of **2a**, **6** and **7** were solved by direct methods. All of the structures were refined by a full-matrix least-squares based on $F^2$.[26] In the case of **5a** and **7** the compounds crystallised with a solvent molecule and the Squeeze program was used to correct the reflection data for the diffuse scattering due to disordered solvent.[27] Non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in idealised positions and refined with isotropic displacement parameters. Atomic scattering factors and anomalous dispersion corrections for all atoms were taken from International Tables for X-ray Crystallography.[28]

Table 9. Crystallographic data for **2a**, **5a**, **6**, **7** and **8**.

# 2D and 3D Cadmium(II) Coordination Polymers from a Flexible Tripodal Ligand of 1,3,5-Tris(carboxymethoxy)benzene and Bidentate Pyridyl-Containing Ligands with Three-, Eight- and Ten-Connected Topologies

**Suna Wang,[a] Hang Xing,[a] Yizhi Li,[a] Junfeng Bai,*[a] Yi Pan,[a] Manfred Scheer,*[b] and Xiaozeng You[a]**

**Keywords:** Metal-organic frameworks / Tripodal ligands / Topology / Metal carboxylates

Four novel cadmium(II) coordination polymers, $[Cd_3(TCMB)_2(4,4'\text{-bipy})(H_2O)_{16}]_n$ (**1**), $[Cd_3(TCMB)_2(bpe)(H_2O)_{13}]_n$ (**2**), $[Cd_3(TCMB)_2(bpe)_2(H_2O)_4]_n$ (**3**), and $[Cd_3(TCMB)_2(dpp)_2(H_2O)_3]_n$ (**4**), [TCMB = 1,3,5-tris(carboxymethoxy)benzene, 4,4-bipy = (4,4-bipyridine), bpe = 1,2-bis(4-pyridyl)ethane, dpp = 1,3-bis(4-pyridyl)propane] have been hydrothermally synthesized by the self-assembly of the flexible tripodal acid TCMB and $Cd(OAc)_2{\cdot}2H_2O$ with pyridyl-containing ligands possessing different flexibilities. Single-crystal X-ray diffraction analysis reveals that the four polymers exhibit novel frameworks due to diverse coordination modes and different conformations of the flexible TCMB as well as pyridyl-containing ligands. Complex **1** shows a unique twofold parallel interpenetrating 2D honeycomb network structure with an unusual $6^3$ topology, in which two different large hexagonal rings are arranged alternately, with extraordinary dimensions of ca. 22.172(6) × 12.947(2) Å (A) and 17.233(2) × 12.947(2) Å (B) based on the distances of the atoms at the opposite positions of the rings. Complex **2** is almost isostructural to complex **1**, except that the bidentate bpe ligands bridge the cadmium centers in an *anti* conformation, rendering the network more flexible. Complex **3** features a 3D network with one of the scarce eight-connected $(4^6, 6^{14}, 8^8)(4^3)_2$ topologies based on the rare $CdI_2$-type layer constructed from secondary building units (SBUs) of rare $[Cd_3(CO_2)_4]^{2-}$ isosceles triangle cadmium clusters. Complex **4** possesses distorted $CdI_2$-type layers constructed from unprecedented ten-connected $Cd_3$ clusters which are linked by more flexible dpp ligands in a *trans-gauche* (TG) conformation in (4,4) networks, leading to another 3D framework of the unusual $(4^{18}, 6^{24}, 8^3)(4^3)_2$ topology. Such an arrangement represents the highest connected topology presently known for the frameworks. Among them, complex **1** displays photoluminescent properties at 460 nm due to the ligand-to-metal charge transfer (LMCT).

## Introduction

In recent years, self-assembly of metal-organic frameworks (MOFs) has attracted much attention not only for the potential discovery of novel functional materials, which may have applications in the areas including gas storage, molecular sieves, ion-exchange, catalysis, magnetism, and optoelectronics, but also for their intriguing variety of architectures and topologies, such as molecular grids, bricks, herringbones, ladders, rings, boxes, diamondoids, and honeycombs.[1–4] In particular, exploring highly symmetrical multi-topic ligands and suitable metal salts in order to construct supramolecular architectures is of great interest.[5,6] On the basis of $[Cp^*Fe(\eta^5\text{-}P_5)]$, we have synthesized the inorganic fullerene-like molecules and 1D or 2D coordination polymers.[7] Generally, rigid symmetrical multi-topic ligands which have been intensively investigated can lead to more predictable supramolecular structures, but the diversity of them has been limited to some extent due to the fact that little or even no conformational changes can be observed for these kinds of ligands when treated with metal ions. By contrast, flexible ligands can adopt different conformations and coordination modes according to the geometric requirements of different metal ions and may afford unpredictable and interesting supramolecular networks. Their reactivities and coordination chemistry have been less explored and the investigation of metal-organic frameworks is still a great challenge.[6]

In order to extend our work in this field, we have turned our attention to an unexplored tripodal ligand, 1,3,5-tris(carboxymethoxy)benzene (TCMB). In comparison with the more intensively investigated rigid ligand, 1,3,5-benzenetricarboxylic acid (BTC),[8] it exhibits additional interesting characteristics, such as more flexibility because of the

presence of a $–OCH_2–$ spacer between the benzene ring and carboxylate moiety, which may bend to enable it to coordinate metal centers, and the existence of the ether oxygen atom may function as an electron-donor forming hydrogen bonds to stabilize the entire structure. Thus, rich topologies, including coordination modes, packing fashions, and dimensionalities of supramolecular coordination solids, may result from this interesting ligand. Herein, we report four novel 2D and 3D cadmium(II) compounds with unusual topologies and different pyridyl-containing coligands, among which $[Cd_3(TCMB)_2(4,4'\text{-bipy})(H_2O)_{16}]_n$ (**1**) and $[Cd_3(TCMB)_3(bpe)(H_2O)_{13}]_n$ (**2**) exhibit a novel kind of 2D-twofold interpenetrating $6^3$ network with two types of large hexagonal rings arranged alternately, whereas $[Cd_3(TCMB)_2(bpe)_2(H_2O)_4]_n$ (**3**) shows a 3D compact network composed of rare 2D $CdI_2$-type layers linked by the bpe ligand, with a topology of $(4^6, 6^{14}, 8^8)(4^3)_2$ where the novel isosceles triangle $Cd_3$ SBUs are taken as eight-connected nodes and TCMB ligands as three-connected nodes. $[Cd_3(TCMB)_2(dpp)_2(H_2O)_3]_n$ (**4**) has ten-connected nodes similar to $Cd_3$ SBUs connected by more flexible dpp ligands with a different topology of $(4^{18}, 6^{24}, 8^3)(4^3)_2$. Moreover, the effects of the coligand, different pyridyl-containing coligands on the structures, and luminescent properties of the metal-organic frameworks have been investigated in detail.

## Results and Discussion

### Syntheses of the Complexes

Because of the low solubility of the TCMB ligand, the hydrothermal method was employed in our syntheses. The crystals cannot be obtained through general hydrothermal conditions above 100 °C and only comparably low temperatures such as 80 °C are appropriate for the isolation of good-quality crystals. Additionally, the polarity of the solvent may also influence the process of assembly and it has been proven that the addition of cosolvent $CH_3OH$ or $C_2H_5OH$ helps with the formation of the complexes.[9] For the rigid 4,4-bipy ligand the ratio of bases/acids is in the range 1:1 to 3:1 and seems to have no effect on the product. However, increasing the ratio of bpe ligand/acids from 1:1 to 3:1 extends the two-dimensional structure to the three-dimensional network, and dpp crystals can only be formed from reactions where this coligand is in excess. Other cadmium salts such as $Cd(NO_3)_2{\cdot}6H_2O$ were used instead of $Cd(OAc)_2{\cdot}2H_2O$, but only precipitates were afforded, indicating that the $OAc^-$ anion may play an important role in the formation of the crystals.

### Structural Description

#### *$[Cd_3(TCMB)_2(4,4'\text{-bipy})(H_2O)_{16}]_n$ (1)*

Single-crystal X-ray studies reveal that the fundamental building unit of complex **1** consists of two repeating crystallographically independent $Cd^{II}$ centers (Cd1 and Cd2) [Figure 1(a)]. Two chelating carboxylate groups (O4, O5, $O6^i$, $O7^i$: symmetry code i: $1+x, -1+y, z$) from different TCMB ligands as well as one nitrogen atom from the 4,4-bipy ligand occupy the equatorial positions around the Cd1 center, and two aqua molecules occur at the apical positions, leading to the heptacoordinated pentagonal-bipyramidal coordination geometry. The average Cd–O and Cd–N distances are ca. 2.376(4) Å and 2.338(5) Å, respectively. The coordinated carboxylate groups are statistically different in that for the O6 and O7 carboxylate group, the Cd–O distances are 2.350(4) Å and 2.507(4) Å, respectively, suggesting that the pentagonal bipyramid is significantly distorted. On the other hand, the Cd2 center exhibits an octahedral geometry, with two oxygen atoms from aqua molecules (O3w, $O3w^{ii}$) (symmetry code ii: $-x, -y, 2-z$) and two monodentate carboxylate groups of separated TCMB ligands (O9, $O9^{ii}$) in *trans* positions composing the equatorial plane, and two other aqua molecules (O4w, $O4w^{ii}$) in apical sites completing the coordination sphere. All the Cd–O and Cd–N distances are listed in Table 1; they are slightly larger than the results for other Cd–OFs.[10]

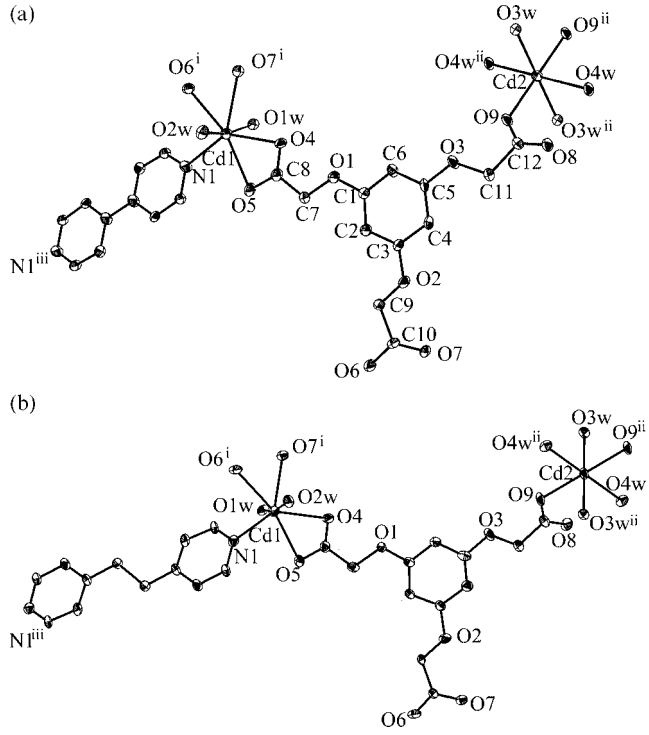

Figure 1. Coordination environments for the $Cd^{2+}$ centers in **1** (a) and **2** (b). Hydrogen atoms and solvent molecules have been omitted for clarity, and thermal ellipsoids are drawn at the 30% probability level. Selected bond information is listed in Table 1. Symmetry codes for **1**: (i) $1+x, -1+y, z$; (ii) $-x, -y, 2-z$; (iii) $3-x, 1-y, -z$: for **2**: (i) $1+x, -1+y, z$; (ii) $2-x, 1-y, 3-z$; (iii) $1-x, 3-y, -1-z$.

The TCMB ligand is completely deprotonated and acts as a $\mu^3$-bridge linking three cadmium centers, and ether oxygen atoms are not involved in the coordination spheres [Scheme 1(a)]. Two kinds of coordination fashions exist for the three carboxylate groups, in which two of them adopt bidentate chelating modes to connect Cd1 centers while the third bridges one Cd2 center through one carboxylate oxy-

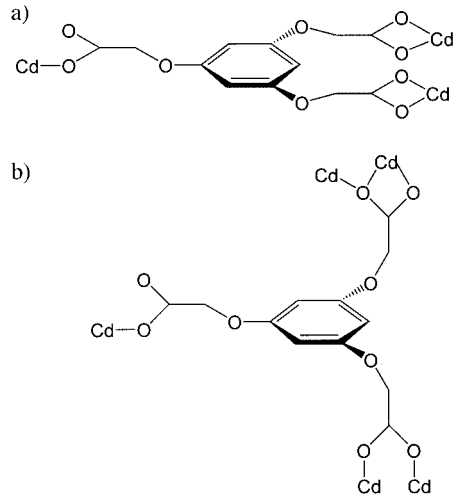
gen atom. One chelating carboxylate group is approximately coplanar with the aromatic ring, while the other chelating and monodentate groups form small dihedral angles of ca. 14.4° and 30.9°, respectively.



Scheme 1. Coordination modes of the TCMB ligand in the four complexes.

Furthermore, two-dimensional frameworks containing compact triple-metallic layers are afforded by two sheets of Cd1 centers bridged through 4,4′-bipy ligands and one of the Cd2 centers connected through TCMB ligands, in which all the same kinds of metal centers are arranged in straight lines as depicted in Figure 2(a). In this way, large hexagonal rings are formed and adjacent rings have extremely different environments, i.e. ring A and ring B. Four TCMB ligands are linked together by two Cd1 centers and two Cd2 centers alternately to form a 48-membered macrocycle (ring A). The distances between two opposite pairs of $Cd^{2+}$ centers on the macrocycle are Cd1···Cd1$^{ii}$ with a distance of 22.172(6) Å and Cd2···Cd2$^{i}$ with a distance of 12.947(2) Å (symmetry code i: 1 + *x*, –1 + *y*, *z*; ii: –*x*, –*y*, 2 – *z*). The second type of ring (B) is involved in Cd1 centers of adjacent layers bridged by the bidentate 4,4′-bipy ligand, which is also a macrocycle with 44 atoms, four Cd1 centers, and benzene rings of two TCMB ligands located at the vertexes of this hexagon as well as two 4,4-bipy ligands at the opposite edges. The distance between the opposite carbon atoms of the TCMB ligands at the vertexes is 17.233(2) Å, whilst the edges are separated by 12.947(2) Å based on the Cd2···Cd2$^{i}$ distance (symmetry code i: 1 + *x*, –1 + *y*, *z*). If only the Cd1 ions and the geometrical centers of the benzene ring of the TCMB ligands are considered as three-connected nodes, the structure can be best described as an infinite two-dimensional network with a $6^3$ topology in which two types of large hexagonal rings are arranged alternately. To the best of our knowledge, in most of the reported complexes with such topologies[11] only two examples with different cavities have been found,[12] whereas the others only contain haploid cavities.

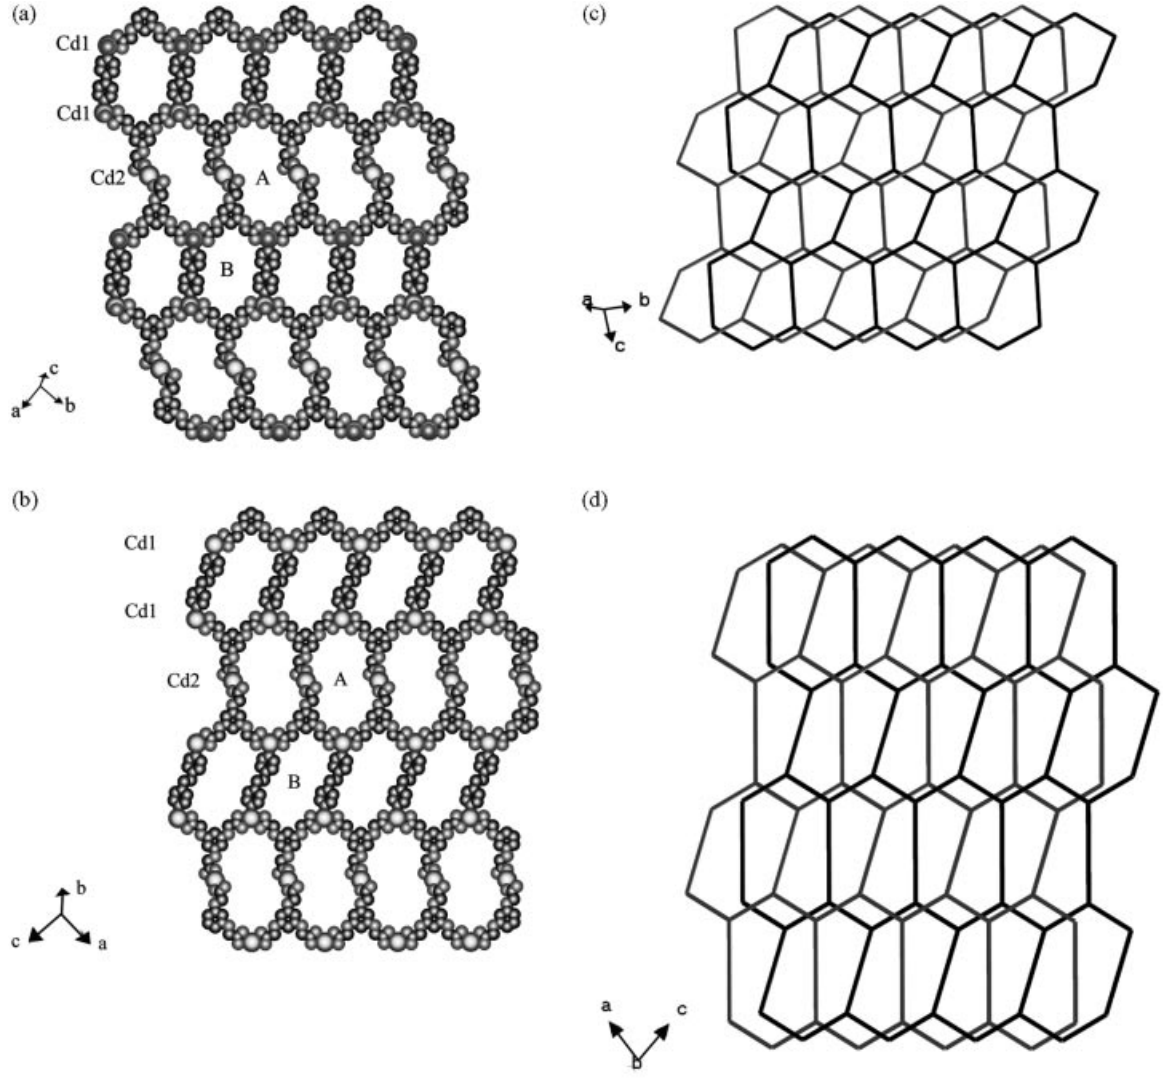

Figure 2. Space-filling representation of the 2D layer with a cross-section of the two different rings A and B for **1** (a) and **2** (b). Topological representation of the twofold interpenetration of the adjacent layers in **1** (c) and **2** (d). Cd1 centers and the geometrical centers of the benzene ring of the TCMB ligands are considered as three-connected nodes. Hydrogen atoms and the coordinated water molecules are omitted for clarity.

Because of the flexibility of the TCMB ligand, the metal atoms in one layer of the network do not lie in the same plane. All the atoms in ring B are almost coplanar while the Cd2 centers are located "above" and "below" alternately, with a dihedral angle between the monodentate carboxylate group and the plane of the aromatic ring of ca. 30.9°, leading to chair conformations for ring A. Such a bonding arrangement gives rise to a corrugated sheet topology and two undulating sheets pass through each other, forming the twofold interpenetrating 2D networks parallel to the *ac* plane with a layer thickness of ca. 3.50 Å [Figure 2(c)]. Furthermore, weak π···π interactions between the aromatic rings of adjacent layers lead to the 3D metal-organic framework, in which the composite 2D sheets are stacked in an ...ABC... fashion, with a mean distance between the double sheets of ca. 4.08 Å (Figure 3). Such an uncommon stacking mode for doubly interpenetrated sheets reduces the voids to a large extent, even though the single network contains large windows as described above. It is noteworthy that one-dimensional channels still exist along the *a* axis, and crystallographically unique uncoordinated water molecules are distributed freely in the network, which are involved in strong hydrogen bonds with the ether and carboxylate oxygen atoms between neighboring layers (see Supporting Information). Details of hydrogen bond parameters are summarized in Table 2. Interestingly, the hydrogen bonds influence the coordination environment of the Cd1 atom significantly. Because of the presence of the strong interaction between O7 and O1w with an O(1w)···O(7)$^{iii}$ (symmetry code iii: $-x+1, -y+1, -z+1$) distance of 2.689(6) Å and an O(1w)–H1(wB)···O(7)$^{iii}$ angle of 169.9°, which is a relatively strong hydrogen bond, the corresponding Cd1–O7$^{i}$ (symmetry code i: $1+x, -1+y, z$) bond is weakened and is rather long.

### *[$Cd_3$(TCMB)$_2$(bpe)($H_2O$)$_{13}$]$_n$ (2)*

Complex **2** is isostructural to complex **1**, which also consists of a 2D $6^3$ network with two types of hexagonal rings as described in Figure 2(b). In general, increased flexibility of the ligand may probably lead to the corresponding change of the dimensionality, void space, degree of interpenetration, or topology.[13] However, in this case, the introduction of two $CH_2$ groups into the bipy molecule results in a slightly changed framework, which may be attributed to the flexible TCMB ligand with the ability to bend in order to satisfy coordination to the metal centers. The bidentate bpe ligand in an *anti* conformation bridges two Cd1 centers with a Cd1···Cd1$^{iv}$ (symmetry code iv: $1-x$, $3-y$, $-1-z$) distance of 13.624(6) Å, which is slightly shorter than that of similar bridges.[14] Apparently, the orientations of the ligands adjust themselves to the requirements of the particular networks.

Comparing these two complexes, the distances of Cd–O and Cd–N have changed after the substitution of the flexible bpe for the rigid 4,4′-bipy ligand. The carboxylate groups in the TCMB ligand coordinate to the Cd1 centers with an average Cd–O distance of 2.378(3) Å, similar to that in complex **1**. The bond lengths of Cd1–O6$^{i}$ and Cd1–O7$^{i}$ (symmetry code i: $1+x$, $-1+y$, $z$) are 2.395(3) Å and 2.399(3) Å, respectively, showing approximately symmetrical chelating conformation of the O6 and O7 carboxylate group [Figure 1(b)]. Consequently, because of the flexibility of the bpe ligands and interpenetration of the sheets, the two types of hexagonal rings become distorted with a slightly expanded ring A and a seriously compressed ring B. The dimensions corresponding to those in complex **1** are changed to 22.905(0)×12.902(3) Å, and 18.887(4)×12.902(3) Å, respectively. Obviously, the comparable dimensions of the two different kinds of rings enable the two adjacent layers to interpenetrate more easily than those in complex **1** [Figure 2(d)].

In addition, hydrogen bonds are involved in the neighboring layers, which may play a crucial role in constructing the whole three-dimensional network (Table 3). The ether oxygen atom (O1) can form a weak hydrogen bond with the free water molecule O6w, where the O6w···O1$^{v}$ (symmetry code v: $1-x$, $1-y$, $1-z$) distance is 3.130(5) Å and the O6w–H6w···O1$^{v}$ angle is 146.9°. Three water molecules O5w, O6w, and O7w are bonded to each other through hydrogen bonds (Figure 4). The O5w atom acts as a double donor, while O6w and O7w act as single acceptors, and O5w can still form hydrogen bonds with another O5w$^{vi}$ water molecule (symmetry code vi: $-x$, $1-y$, $1-z$). Thus, hexameric water clusters are formed between the adjacent layers. Interestingly, the six O atoms of the hexameric unit assume a rather uncommon centrosymmetrical planar conformation, different from those in other reported hexameric water clusters.[15] Nonbonding Ow···Ow distances and neighboring Ow···Ow···Ow angles are listed in Table 4, and show wide variations commensurate with the MOF structure. The average Ow···Ow distance [2.883(5) Å] is slightly longer than that of liquid water with a value of 2.85 Å, determined from the X-ray diffraction radial distribution curve, and that of the gas phase value of 2.86 Å.[16]

oxygen atom (O8) of the TCMB ligand exist in this complex. The C(4)···O(8)$^{vii}$ interaction (symmetry code vii: $1-x$, $1-y$, $2-z$) with a distance of 3.310(6) Å and a C(4)–H(4A)···O(8)$^{vii}$ angle of 152.8°, together with the other hydrogen bonds mentioned above, extend the 2D layers into a 3D network.

### *[Cd$_3$(TCMB)$_2$(bpe)$_2$(H$_2$O)$_4$]$_n$ (3)*

The fundamental unit of complex **3** contains two crystallographically independent hexacoordinate Cd$^{II}$ centers (Figure 5). The Cd1 center adopts a distorted octahedral geometry {CdO$_5$N}, and is bonded to four carboxylate oxygen atoms from three separate TCMB ligands in the basal plane, one oxygen atom from the aqua molecule, and one nitrogen atom from the bpe ligand ligating the metal atoms in the two apical positions. The average Cd–O and Cd–N distances are 2.303(3) Å and 2.305(3) Å, respectively. Comparably, the Cd2 center {CdO$_4$N$_2$} is coordinated by four different monodentate carboxylate oxygen atoms from four distinct TCMB ligands and two nitrogen atoms from different bpe ligands, displaying a slightly distorted octahedral geometry. All the values are in good agreement with the reported Cd–OFs.[9]

Unlike that in complex **1** and **2**, the TCMB ligand exhibits essentially different coordination modes and the three carboxylate groups show large deviations from the plane of the central aromatic ring [Scheme 1(b)] due to the rotation of the OCH$_2$ groups; significantly more flexible than the corresponding coordination ability of the BTC ligand.[8] Among the three arms, only one is still almost coplanar with the aromatic ring, whereas the other two are arranged "above" and "below" the plane. Meanwhile, the three carboxylate groups show different coordination fashions: in the plane, the carboxylate group functions in a monodentate fashion with one oxygen atom bonding the Cd1 center; above the plane, the carboxylate group chelates to the Cd1 center and one oxygen atom also bridges the Cd1 and Cd2 centers, exhibiting the chelating-bridging mode, and the third one below the plane behaves in a bidentate bridging fashion, linking the Cd1 and Cd2 atoms. Thus, the TCMB ligand serves as a $\mu_5$-bridge, linking five Cd centers through its three arms in different fashions and losing the original planarity and $C_3$ symmetry observed in the free state.

As an effective intermetallic bridge, the bpe ligand always connects the same type of metal centers; however, in this case, it bridges two crystallographically independent centers

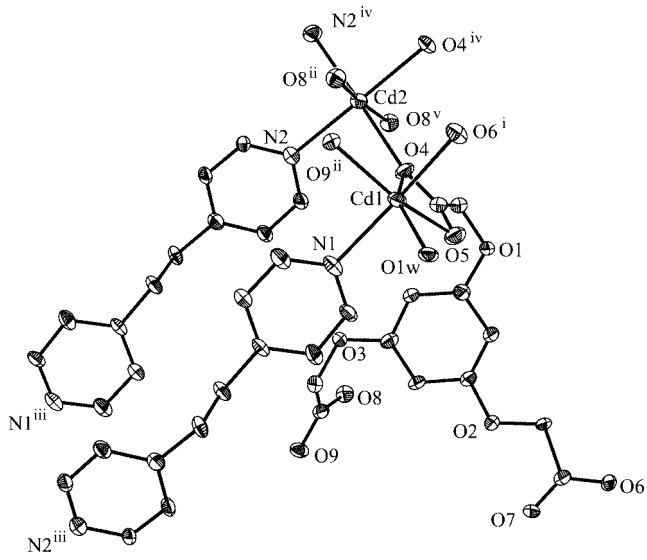

Figure 5. Schematic representation of the distorted octahedral coordination environments for the two crystallographically unique $Cd^{2+}$ metal centers in **3**. Thermal ellipsoids are drawn at the 30% probability level. Hydrogen atoms and other solvent molecules have been omitted for clarity. For bond lengths and angles see Table 1. Symmetry codes used to generate equivalent atoms: (i) $x$, $1-y$, $-1/2+z$; (ii) $x$, $2-y$, $-1/2+z$; (iii) $3/2-x$, $5/2-y$, $2-z$; (iv) $1-x$, $y$, $3/2-z$; (v) $1-x$, $2-y$, $2-z$.

of Cd1 and Cd2 from different $[Cd_3(CO_2)_4]^{2-}$ cores where the metal–metal separation for Cd1···Cd2$^{viii}$ (symmetry code viii: $3/2-x$, $5/2-y$, $2-z$) is ca. 13.883(6) Å. The interplanar angle between the pyridyl rings in bpe is ca. 9.9° and the C–CH$_2$–CH$_2$–C torsion angle is ca. 70.5°, suggesting a deviation from the normal *anti* conformation, which can be viewed as intermediate between the *anti* and the *gauche* conformations. Notably, the dihedral angles between the planes of the 4-pyridyl rings are obviously larger than those in complex **2**, which is probably one of the main causes of the dimensions of these two complexes.

The most interesting feature of the complex is the presence of the unreported isosceles triangle $[Cd_3(CO_2)_4]^{2-}$ cores [Figure 6(a)] in which the Cd2 atom is located at the vertex and doubly bridged to adjacent Cd1 metal atoms by bidentate carboxylate groups in a *syn-syn* conformation as well as one oxygen atom from the chelating-bridging group. The metal–metal separation of Cd1···Cd2 is 4.025(6) Å, significantly longer than those in some discrete dimeric cadmium tetracarboxylate complexes (3.278–3.452 Å),[17] but slightly larger than that in a similar bridge reported recently.[18] The two symmetrical Cd1 centers are separated by the long distance of Cd1···Cd1$^{ix}$ (symmetry code ix: $-x$, $1+y$, $3/2-z$) of ca. 6.731(1) Å. As far as we know, in the few reported Cd–OFs composed of Cd$_3$ SBUs,[19] the metal centers are mostly located in linear arrangements. The arrangement of six TCMB ligands around a $[Cd_3(CO_2)_4]^{2-}$ cluster is shown in Figure 6(b).

Thus, the assembly of these trinuclear SBUs leads to a 3D compact and neutral framework through the bridging of the *exo*-bidentate bpe and the TCMB ligands. On the one hand, each Cd$_3$ SBU is interlinked to other two SBUs

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

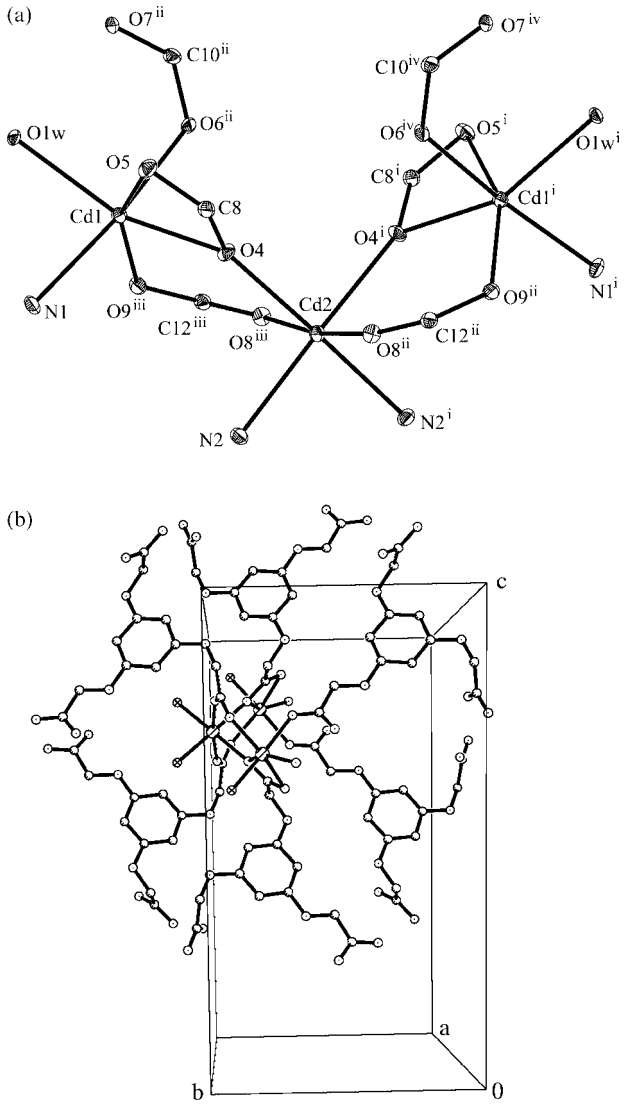

Figure 6. (a) Trinuclear secondary building unit (SBU) in **3**. All of the carboxylate groups are from different TCMB ligands and other parts of the ligand have been omitted for clarity. Nitrogen atoms are from the bpe ligand. Symmetry codes: (i) $1-x$, $+y$, $3/2-z$; (ii) $x$, $1-y$, $-1/2+z$; (iii) $x$, $2-y$, $-1/2+z$; (iv) $1-x$, $1-y$, $2-z$. (b) Perspective view showing the arrangement of six TCMB ligands around one $Cd_3$ cluster in the unit cell of **3**. Large and small open circles represent cadmium and carbon atoms, respectively. Oxygen and nitrogen atoms are shown as dotted and crossed circles, respectively. Solvent molecules, other parts of the bpe ligands and hydrogen atoms are omitted for clarity.

through four bpe ligands, resulting in the formation of one-dimensional doubly interlaced zigzag chains in the *ac* plane (Figure 7). On the other hand, two carboxylate groups "above" and "below" the plane of the aromatic ring from the TCMB ligand connect adjacent $Cd_3$ cores, which results in the helix structure along the *a* axis with a mean core distance of ca. 5 Å, and the third carboxylate groups link the neighboring helices to form the 2D networks in the *bc* plane. Accordingly, the 3D network can be interpreted as the result of inclination of 1D into 2D layers (Figure 8).

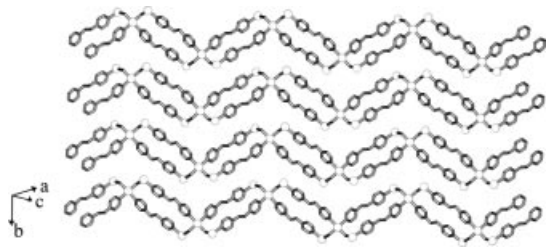

Figure 7. Doubly interlinked chains constructed from $Cd_3$ SBUs and bidentate bpe ligands in **3**.

In addition, C–H···O hydrogen bonds exist in the 3D networks. Carbon atoms with hydrogen atoms (C7–H7, C21–H21) from the $OCH_2$ groups of the TCMB ligand and aromatic rings of the bpe ligand can form C–H···O hydrogen bonds with the carboxylate oxygen atoms (O6, O7) from neighboring motifs. The C···O distance [3.280(5)–3.364(5) Å] and C–H···O angles (156.0–173.0°) of C–H···O hydrogen bonds are both within the ranges of those reported.[20] In spite of the close packing of the whole framework, small one-dimensional channels are still present and are viewed along the *c* axis (see Supporting Information).

In order to classify the network, suitable nodes should be confirmed. In this complex, every $Cd_3$ core is connected through six carboxylate groups and four bpe ligands, but two of the bpe ligands are parallel and can be considered as one linker from a topological view. Thus, the $Cd_3$ core can be viewed as an irregular eight-connected node. Additionally, taking the geometrical center of the benzene ring of the TCMB ligand as a three-connected node, the 3D framework can be represented simply by connecting these nodes according to the connectivity defined by the bpe ligand (Figure 8). When viewed along the *bc* plane, a 2D layer composed of tetragons sharing edges or vertexes can be formed, corresponding to the well-known $CdI_2$-type layer structure, which is quite common for inorganic compounds. To the best of our knowledge, except for several examples of metal alkoxides and hydroxides, few organic-inorganic hybrid materials have been reported with such a net topology.[21] Moreover, such 2D layers are linked by the linear bpe ligands. Thus, tetragons and hexagons as well as octagons can be identified in the projection, which represent the shortest circuit of the three essential rings that define the topology of the whole structure. Because the two kinds of nodes are arranged in a ratio of $Cd_3$/TCMB = 1:2, the short Schläfli symbol of the topology can be expressed as the unusual $(4^6, 6^{14}, 8^8)(4^3)_2$.[22] As far as we know, for the majority of 3D metal-organic framework structures, the connectivity of the building block does not exceed six and, in general, coordination networks with a local connectivity higher than six is very rare. Only some examples involving high coordination number lanthanide metal centers and polynuclear metal-cluster building blocks with eight-connected nodes have been reported.[23] Thus, the complex we report represents a scarce eight-connected topology, known for self-penetrating systems so far.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

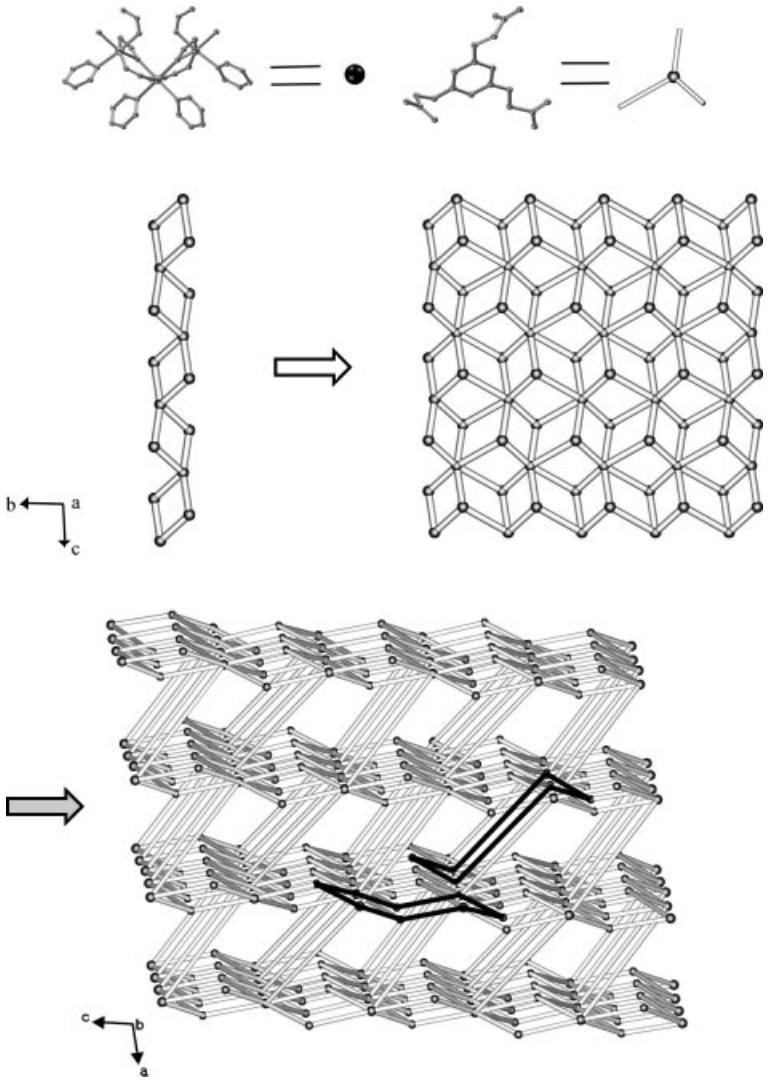

Figure 8. Topological representation of the formation of the whole structure of **3** from a 1D helical chain to a 3D network, showing the self-penetrating shortest circuits (black circles). By this notation, two parallel bpe ligands linking adjacent $Cd_3$ SBUs are viewed as one stick.

### *[Cd$_3$(TCMB)$_2$(dpp)$_2$(H$_2$O)$_3$]$_n$ (4)*

X-ray analysis reveals that in complex **4**, similar $Cd_3$ SBUs are also formed with metal–metal distances for Cd1···Cd2 and Cd1···Cd1$^{x}$ (symmetry code x: $1-x$, $+y$, $3/2-z$) of 3.967(5) Å and 6.459(8) Å, respectively, which are shorter than those in complex **3** (Figure 9). The largest difference lies in the connectivity of the more flexible dpp ligand. In general, the dpp ligand could assume a TT, TG, GG′, or GG conformation with relative orientations of the $CH_2$ groups.[24] In this case, the high flexibility of the dpp molecules enables them to join metal cores in different directions and one dpp ligand connects the Cd1 and Cd2 centers from adjacent cores with a metal–metal separation Cd1···Cd2$^{xi}$ (symmetry code xi: $3/2-x$, $-1/2+y$, $1/2-z$.) of ca. 12.368(7) Å, exhibiting significant dihedral angles of 70.5° between the two phenyl rings, which can be viewed as a *trans-gauche* (TG) conformation. Additionally, the C25 atom of the methylene group is disordered in this conformation. In this way, the dpp ligands establish a physical bridge between the separated $Cd_3$ cores and each $Cd_3$ core is linked to another four adjacent clusters, resulting in the (4,4) network (Figure 10).

Similarly, in this compound, the dpp ligands and the TCMB ligands also interact with each other through C–H···O hydrogen bonds that originate from the C atoms, with hydrogen atoms, (C17–H17, C19–H19, C24–H24) of the dpp ligands and the carboxylate oxygen atoms (O5, O8$^{xii}$, O5$^{xiii}$) (symmetry code xii: $x$, $2-y$, $-1/2+z$; xiii: $3/2-x$, $1/2+y$, $1/2-z$), where the C···O distances are in the range 3.209(7)–3.384(7) Å and the C–H···O angles in the range 132.0–172.0°.

Figure 11 illustrates the simplified self-assembly from 1D helical chains to the 3D network of complex **4**. Similar 2D layers composed of $Cd_3$ SBUs bridged by carboxylate groups can be formed, with significant distortion that is closer to that for the $HgBr_2$-type layer, which is another type of inorganic structure that is very similar to the $CdI_2$ type.[22] Interestingly, the $Cd_3$ cores are bridged to one an-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

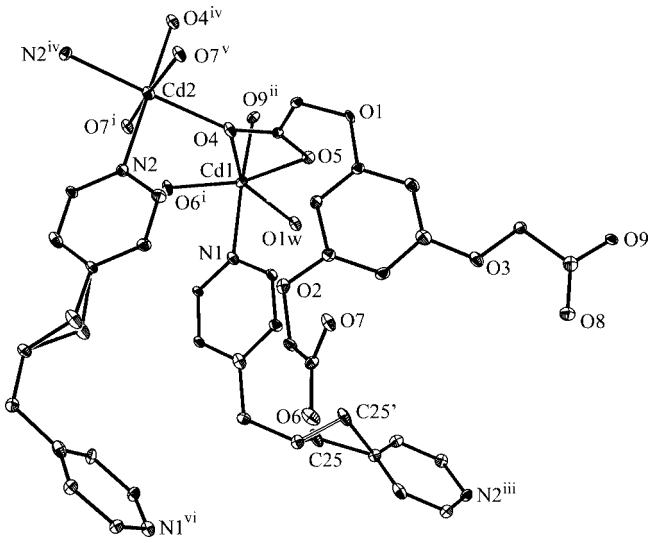

Figure 9. Schematic representation of the distorted octahedral coordination environments for the Cd metal centers in **4**. Hydrogen atoms have been omitted for clarity, and thermal ellipsoids are drawn at the 10% probability level. The disordered dpp ligand is represented in terms of C25 and C25′. For bond lengths and angles see Table 1. Symmetry codes used to generate equivalent atoms: (i) $x, 2-y, -1/2+z$; (ii) $x, 1-y, -1/2+z$; (iii) $-1/2+x, -1/2+y, +z$, (iv) $2-x, y, 1/2-z$; (v) $2-x, 2-y, 1-z$; (vi) $3/2-x, 1/2+y, 1/2-z$.

other by four nonparallel dpp ligands because of the flexibility of such ligands, and thus become a more irregular ten-connected node. The final 3D network of complex **4** can be viewed as the conversion of the parallel (4,4) sheets into the 2D sheet, and the topology defined by the dpp linking of ten-connected and three-connected nodes is rare $(4^{18}, 6^{24}, 8^3)(4^3)_2$.[22] To the best of our knowledge, the complex we report represents the highest connected topology of any known entangled species.

In summary, coligands in the reactions have a great influence on the final products. Firstly, the flexibility of the pyridyl-containing ligands can induce the structures and the acids to adopt diverse coordination modes and facilitate more complicated MOFs. Secondly, different amounts of the bases in the assembly process lead to different dimensions of the final network. Though the amounts of bases in the reactions are equal, for example, complexes **3** and **4**, different frameworks of the products may result from the adjustable conformations of the ligands to enable themselves to satisfy the coordination assemblies. Furthermore, more bases can coordinate to the metal centers competing with the aqua molecules, extending the networks from low-dimensional to high-dimensional structures, such as complex **3** in comparison with complex **2**.

### FT-IR Spectra and Thermogravimetric Analyses

The IR spectra show features attributable to the carboxylate stretching vibrations of the complexes. The absence of signals in the range 1760–1680 cm$^{-1}$ indicates complete deprotonation of the TCMB ligand. The characteristic bands of the carboxylate groups appear in the range 1560–1620 cm$^{-1}$ for the asymmetric stretching and 1370–1490 cm$^{-1}$ for the symmetric stretching. Weak absorptions observed over the range 2900–2950 cm$^{-1}$ can be attributed to the $\nu_{CH2}$ of the TCMB ligand. The broad bands at ca. 3300 cm$^{-1}$ correspond to the vibration of the water ligands in the complexes. The TGA curves of complex **1** and **2** have almost the same thermal characteristics: an obvious weight loss between 40 °C and 150 °C was attributed to the loss of all the solvent water molecules (8 $H_2O$ per unit for **1**: calcd. 10.47, found 10.49; 5 $H_2O$ for **2**: calcd. 6.67, found 7.54) and a rapid weight loss was observed from ca. 320 °C, indicating the decomposition of the whole structure. Complexes **3** and **4** also exhibit similar curves and the gradual decrease occurs from about 100 °C, which is involved in the release of guest water molecules. The complexes begin to decompose from this temperature and the obvious weight loss was observed at ca. 330 °C (see Supporting Information).

### Photoluminescent Properties

The emission spectra of all the complexes in the solid state were measured at room temperature (Figure 12). Complex **1** shows fluorescent emissions at 470 nm with a shoulder peak at about 530 nm, and no enhancement in the fluorescence intensity is realized compared with the free ligand.

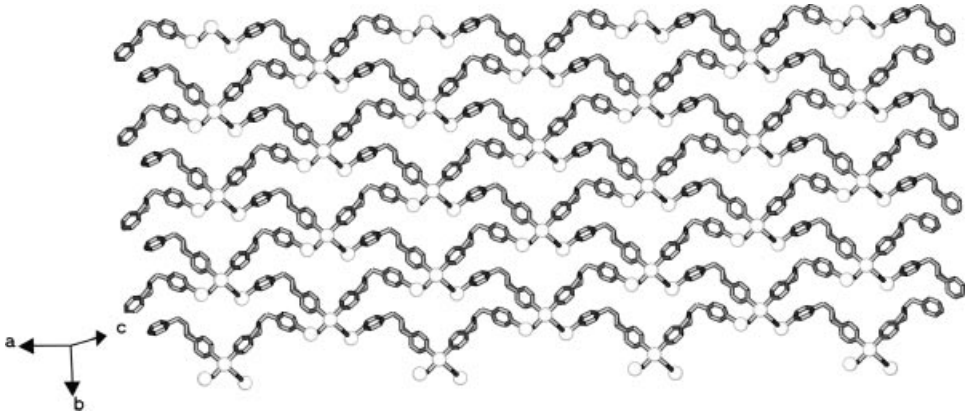

Figure 10. View of the two-dimensional (4,4) layer formed through bidentate dpp-bridging $Cd_3$ SBUs in **4**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

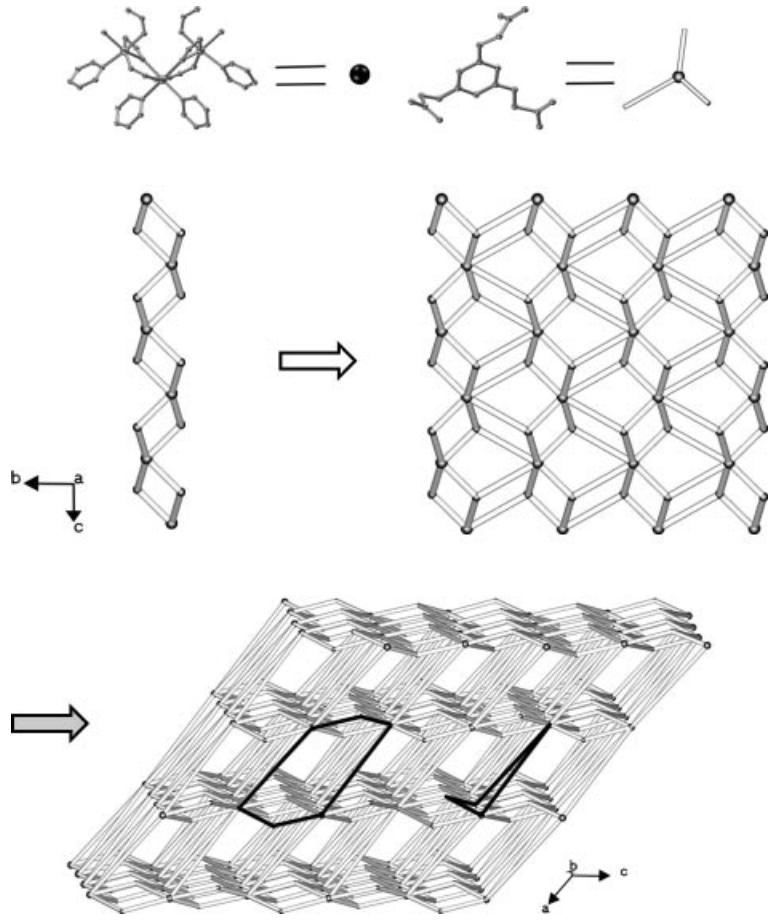

Figure 11. Topological representation of complex **4** from a 1D helical chain to a 3D network, showing the self-penetrating shortest circuits (black circles).

Since the free 4,4′-bipy ligand does not show any luminescence in the range 400–800 nm,[25] the main peak at 470 nm may be interpreted as a ligand-to-metal charge transfer (LMCT).[26] On the other hand, the shoulder peak is neither metal-to-ligand charge transfer (MLCT) nor ligand-to-metal charge transfer (LMCT) in nature, and can probably be attributed to the intraligand fluorescent emission because of the similar emission for the free ligand with the intraligand π-π* transition at 530 nm. Thus, this complex may be an excellent candidate for blue-fluorescent materials. For complexes **2** and **3**, the fluorescence is significantly decreased, and only weak absorptions were observed at 530 nm for the intraligand transition, while complex **4** shows no photoluminescent properties at room temperature. Apparently, this phenomenon is associated with the structure of this complex. In complex **1**, strong π···π interactions exist between the adjacent 2D layers, which is favorable for the reduction of the energy of the π-π* transition to some extent, while for complexes **2**–**4**, the gradually increasing flexibility of the coligands from bpe to dpp largely weakens such interactions, which is disadvantageous to the luminescence. In complex **4**, the interactions are reduced in such a way that even the luminescence was not observed.

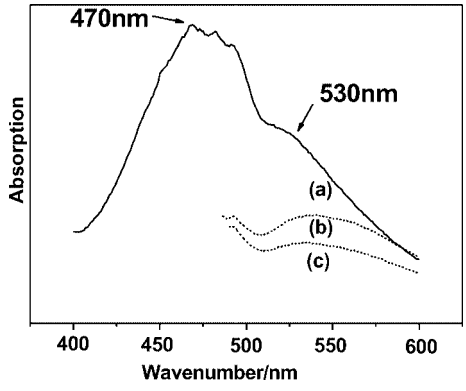

Figure 12. Photoluminescence spectra of (a) complex **1**, (b) complex **2**, and (c) complex **3** at room temperature.

## Conclusions

Four novel cadmium(II) coordination polymers based on an unexplored and flexible tripodal ligand, 1,3,5-tris(carboxymethoxy)benzene (TCMB) and bipyridyl ligands (rigid 4,4-bipy, flexible bpe, dpp) have been hydrothermally synthesized and structurally characterized, and all of them

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

show interesting topologies resulting from the different comformations and coordination modes of the flexible ligands. Complex **1** and **2** have similar unusual twofold parallel interpenetrating 2D $6^3$ networks with two types of hexagonal rings of large dimensions arranged alternately. An excess of the pyridyl-containing ligands leads to the formation of 3D frameworks of complexes **3** and **4** with scarce eight- and ten-connected topologies of $(4^6, 6^{14}, 8^8)(4^3)_2$ and $(4^{18}, 6^{24}, 8^3)(4^3)_2$, respectively, both of which contain rare 2D $CdI_2$ layers consisting of isosceles triangle $[Cd_3(CO_2)_4]^{2-}$ SBUs. They represent one of the few eight-connected and the highest connected topologies, respectively. Complex **1** exhibits luminescent properties resulting from an LMCT and may be a potential candidate for blue luminescent materials. In summary, our research demonstrates for the first time that 1,3,5-tris(carboxymethoxy)benzene (TCMB) could be a potential building block to construct novel cadmium supramolecular architectures with unusual topologies and luminescent properties. Further investigation is ongoing.

## Experimental Section

**General Methods:** TCMB was prepared according to the literature.[27] 4,4-Bipyridine (4,4-bipy), 1,2-bis(4-pyridyl)ethane (bpe), and 1,3-bis(4-pyridyl)propane (dpp) were purchased from Aldrich and used as received without further purification. All of the other reagents were commercially available and used as purchased. The elemental analysis was carried out with a Perkin–Elmer 240C elemental analyzer, at the Center of Materials Analysis, Nanjing University. The FT-IR spectra were recorded from KBr pellets over the range 4000–400 $cm^{-1}$ with a Vector 22 spectrometer. Thermal analyses were performed with a TGA V5.1A Dupont 2100 instrument from room temperature to 700 °C with a heating rate of 10 °C/min under a flow of nitrogen, and the data are consistent with the structures. The emission/excitation spectra were recorded with a Hitachi 850 fluorescence spectrophotometer.

**$[Cd_3(TCMB)_2(4,4'\text{-bipy})(H_2O)_{16}]_n$ (1):** In a general synthesis, an equimolar mixture of TCMB (0.030 g, 0.1 mmol), 4,4′-bipy (0.016 g, 0.1 mmol), and $Cd(OAc)_2{\cdot}2H_2O$ (0.026 g, 0.1 mmol) in $H_2O/C_2H_5OH$ (1:1, v/v) (10 mL) was placed in a Parr Teflon-lined stainless steel vessel and heated to 80 °C for 50 h. The reaction system was then slowly cooled to room temperature and colorless block crystals of **1** were obtained. After filtration, the crystals were washed with water and dried in air; yield 0.026 g [56%, based on $Cd(OAc)_2{\cdot}2H_2O$]. $C_{34}H_{58}Cd_3N_2O_{34}$ (1376.02): calcd. C 29.67, H 4.25, N 2.04; found C 29.98, H 4.36, N 1.98. IR (KBr pellet): $\tilde{\nu}$ = 3446 (s, br), 2924 (w), 1605 (s), 1418 (m), 1336 (w), 1262 (vw), 1165 (m), 1121 (w), 1075 (w), 807 (w), 726 (w), 629 (vw) $cm^{-1}$.

**$[Cd_3(TCMB)_2(bpe)(H_2O)_{13}]_n$ (2):** Similar procedures were performed to obtain colorless crystals of complex **2**, except that ligand bpe was used instead of 4,4′-bipy; yield 0.020 g [45%, based on $Cd(OAc)_2{\cdot}2H_2O$]. $C_{36}H_{56}Cd_3N_2O_{31}$ (1350.03): calcd. C 32.02, H 4.18, N 2.07; found C 32.06, H 4.38, N 2.04. IR (KBr pellet): $\tilde{\nu}$ = 3449 (s,br), 2924 (w), 1611 (s), 1509 (vw), 1422 (m), 1340 (w), 1264 (vw), 1165 (m), 1121 (w), 1075 (w), 807 (w), 726 (w), 671 (w), 629 (w) $cm^{-1}$.

**$[Cd_3(TCMB)_2(bpe)_2(H_2O)_4]_n$ (3):** A mixture of TCMB (0.030 g, 0.1 mmol), bpe (0.036 g, 0.2 mmol), and $Cd(OAc)_2{\cdot}2H_2O$ (0.026 g, 0.1 mmol) with a molar ratio of about 1:3:1 in $H_2O$ (10 mL) with several drops of $CH_3OH$ was placed in a Parr Teflon-lined stainless steel vessel and heated to 80 °C for 50 h. The reaction system was cooled to room temperature to give colorless block crystals of **3** that were filtered, washed with water and dried in air; yield 0.027 g [59%, based on $Cd(OAc)_2{\cdot}2H_2O$]. $C_{48}H_{50}Cd_3N_4O_{22}$ (1372.12): calcd. C 42.01, H 3.67, N 4.08; found C 41.72, H 3.92, N 3.89. IR (KBr pellet): $\tilde{\nu}$ = 3430 (m, br), 2923 (w), 1612 (s), 1474 (w), 1424 (m), 1320 (m), 1267 (vw), 1171 (s), 1157 (s), 1075 (w), 830 (w), 818 (w),712 (w) $cm^{-1}$.

**$[Cd_3(TCMB)_2(dpp)_2(H_2O)_3]_n$ (4):** Complex **4** was obtained in a similar manner to that of complex **3**, except that more flexible dpp (0.057 g, 0.3 mmol) was used instead of the bpe ligand; yield 0.033 g [72%, based on $Cd(OAc)_2{\cdot}2H_2O$]. $C_{100}H_{104}Cd_6N_8O_{42}$ (2764.31): calcd. C 43.44, H 3.79, N 4.05; found C 42.72, H 3.92, N 3.99. IR (KBr pellet): $\tilde{\nu}$ = 3447 (m), 2919 (w), 1615 (s), 1423

**X-ray Crystallographic Study:** Suitable single crystals were selected for indexing and intensity data were measured with a Siemens Smart CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 293 K. The raw data frames were integrated into SHELX-format reflection files and corrected using the SAINT program. Absorption corrections based on multiscans were obtained from the SADABS program. The structures were solved with direct methods and refined with full-matrix least-squares techniques using the SHELXS-97 and SHELXL-97 programs, respectively.[28] The coordinates of the non-hydrogen atoms were refined anisotropically, and the positions of the H atoms were generated geometrically, assigned isotropic thermal parameters, and allowed to ride on their parent carbon atoms before the final cycle of refinement. Basic information pertaining to crystal parameters and structure refinement is summarized in Table 5, and selected bond lengths and angles are listed in Table 1. The figures were obtained by using the SHELXP-97[28] and Olex program packages.[29] CCDC-294480 to -294483 for complexes **1**–**4** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Additional figures, and TGA and luminescent curves of complexes **1**–**4**.

# In Situ Synthesis, Characterization of SiPMo-X, and Different Catalytic Properties of SiPMo-X and SiPW-X

**Chunfeng Shi,[a,b] Runwei Wang,*[a] Guangshan Zhu,[a] Shilun Qiu,*[a] and Jun Long[b]**

**Keywords:** In situ synthesis / Heteropolyacids / Mesoporous materials / Encapsulation / Bulky molecule reactions / Zeolites

SBA-15 frameworks with encapsulated Keggin type heteropolyacids (HPAs) were synthesized in situ under strongly acidic conditions (pH < 0). During the hydrolysis of tetraethyl orthosilicate (TEOS), a P- and a Mo source were added into the initial sol–gel system to form Keggin type HPAs. The texture of the final products was studied by the $N_2$ adsorption–desorption isotherms and transmission electron microscopy (TEM), and their structure was systematically characterized by X-ray diffraction (XRD), UV/Vis diffuse reflectance- (DRS), infrared- (IR), and $^{31}P$ magic angle spinning nuclear magnetic resonance (MAS NMR) spectroscopy. Characterization results suggest that the samples show very ordered hexagonal mesostructure, and the HPAs that are incorporated into the framework of meso-silica are insoluble during catalysis. Results of catalytic tests indicate that the materials demonstrated catalytic activity comparable with or even surpassing those of the bulk HPAs in catalytic tests implementing chemical reactions of bulky molecules (1,3,5-triisopropylbenzene cracking, esterification of benzoic acid with *tert*-butyl alcohol, and 2,3,6-trimethylphenol hydroxylation with $H_2O_2$). Additionally, some other properties, such as easy separation and stability when recycled, ensure their potential applications in the chemical industries. Here, we report not only the in situ synthesis and characterization of SiPMo-X, but also the difference in the catalytic properties of SiPMo-X and SiPW-X.

## Introduction

In recent years, environmental and economic considerations have raised strong interest in the redesign of commercially important processes so that the use of harmful substances and the generation of toxic wastes could be avoided. In this respect, there is no doubt that heterogeneous catalysis, as an alternative to homogeneous catalysis, can play a key role in the development of environmentally benign processes both in petroleum chemistry and in the production of chemicals, for example, by substitution of liquid acid catalysts by solid materials.[1]

Most notably, zeolites and heteropoly compounds have attracted much attention not only as such acidic catalysts, but also as oxidation catalysts. First of all, zeolites, owing to their uniform intracrystalline microporosity that provides access to a very large and well-defined surface, the molecular sieve effect, and the strong electrostatic field centered at zeolite cations, promised unique opportunities from the start for important improvements in efficiency and economy in gas and liquid sorption and separation technologies. The unique catalytic sites can catalyze many reactions, but zeolites also have some restrictions in general applications, such as weaker acidity, lack of variability in pore size, and the limited number of the constituent elements.[2–12] For heteropoly compounds, peculiarly for HPAs, because their unique acidic and redox properties can be controlled at the atomic/molecular level, their catalytic function in the solid state as well as in solution has attracted much attention: the strong acidity or oxidizing properties of heteropoly compounds, the soft basicity of the polyanions, the high solubility in water and organic solvents, a moderately high thermal stability in the solid state, the relatively simple synthetic procedure, the ability to form pseudoliquid phases, and the possibility of the introduction of several different elements into polyanions and counter-cations. All the above-mentioned advantages of HPAs have led to a large body of work on their applications in homogeneous and heterogeneous catalysis.[3–19] Soluble heteropoly compound catalysts (HPAs are typically strong Brønsted acids and are very soluble in oxygen-containing polar solvents such as water, alcohols, ethers, and ketones.) can catalyze a large variety of reaction types but suffer from their inability to be recycled.[5–25] Much effort has been put into developing stable, water-tolerant solid acid catalysts, as such catalysts do not require a catalyst separation process after usage and are therefore much easier to use when compared with homo-

geneous acid catalysts. One approach to obtaining such a catalyst is to immobilize an active acidic species onto a solid support and to practically use this as a solid acidic catalyst. Moreover, the specific surface areas of solid HPAs are low (usually less than 10 $m^2/g$), leading to very few active sites on their surfaces. Thus, immobilization of HPAs onto stable solid supports to create hybrid catalysts is absolutely necessary for using HPAs as solid catalysts. At the same time, their catalytic activities are expected to be improved by this procedure.[10–28]

Mesoporous materials have attracted much attention because of their wide potential industrial applications as catalysts or catalyst supports and hosts since their discovery in the last decade, and it has been widely reported that mesoporous silica SBA-15 has been extensively used as a support and host because of its large pore size, thick walls, and high hydrothermal stability, which make it an excellent candidate for use as a stable solid support as mentioned above.[29–40]

In our previous work, we prepared a series of insoluble HPA-containing hybrid catalysts by incorporation of HPAs into mesoporous supports during the formation of a mesostructure through acid-base interactions or covalent bond formation.[23,25] We also investigated the heterogeneous catalytic behavior of these supported HPA catalysts in polar solvents. It was found that the catalytic activity of HPAs in the hybrid catalyst was significantly improved by the fascinating physical and chemical properties and the unusual internal surface topology of the mesoporous materials. Moreover, the separation and recovery of the HPAs from the reaction environment became easy.[10,21,23,25] We also presented an in situ synthetic method for incorporating HPAs directly into the framework of mesoporous materials without destruction of the mesostructure. For example, we introduced $Na_2HPO_4$ and $Na_2WO_4$ (a P and a W source) or $H_3PO_4$ and $Na_2MoO_4$ (a P and an Mo source) into the initial sol–gel during the preparation of SBA-15 and successfully synthesized in situ new mesoporous silica encapsulated with Keggin type HPAs. Here we report not only the in situ synthesis and characterization of SiPMo-X, but also the different catalytic properties of SiPMo-X and SiPW-X.

## Results and Discussion

### Spectroscopy

#### *X-ray Diffraction*

Low-angle powder XRD patterns of SiPMo-8, HPMo/SBA, and SBA-15 samples are shown in Figure 1. Obviously, the sample of SiPMo-8 (Figure 1b and Table 1) exhibits three clearly well-resolved peaks indexed as (100), (110), and (200), which may be associated with the *p6mm* hexagonal symmetry similar to that of pure silica SBA-15 (Figure 1a).[32] The three clearly well-resolved peaks may also indicate that SiPMo-8 is characterized by the presence of long-range ordering and that the ordering of SiPMo-8 may also be comparable to that of SBA-15. These results indicate that the formation and presence of HPMo in the framework of SBA-15, by the addition of $H_3PO_4$ and $Na_2MoO_4$ into the sol–gel during the hydrolysis of TEOS, does not affect the formation of the mesoporous structure of SBA-15. However, the ordering of conventionally supported HPMo (SBA-15 as the support) (Figure 1c) decreases significantly compared with that of SBA-15, which may be attributed to the fact that the conventional preparation method affects the ordering of the support. Moreover, from Figure 2, we can see that the wide-angle powder XRD

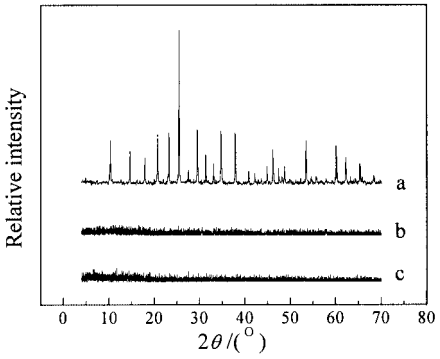

Figure 2. Wide-angle XRD patterns of samples: (a) HPMo, (b) SiPMo-8, and (c) HPMo/SBA.

Table 1. HPMo content and parameters of the pore structure of SiPMo-8, SBA-15, HPMo, and HPMo/SBA.

| Samples | HPW content (wt.-%) | | $d_{(100)}$ | $a$ | Pore size | Wall thickness | Surface area | Pore volume | Carbon residue[b] |
|---|---|---|---|---|---|---|---|---|---|
| | Sol–gel | Product | [nm] | [nm] | [nm] | [nm][a] | [$m^2/g$] | [$cm^3/g$] | |
| SiPMo-8 | 33.3 | 19.6 | 10.4 | 12.0 | 7.6 | 4.4 | 807 | 1.04 | 10.9 |
| SBA-15 | 0.0 | 0.0 | 10.3 | 11.9 | 7.9 | 4.0 | 860 | 1.15 | 8.8 |
| HPMo/SBA | 20.0 | 20.0 | 10.3 | 11.9 | 7.8 | 4.1 | 473 | 0.85 | 8.2 |
| HPMo | 100 | 100 | – | – | – | – | 5 | – | – |

[a] Pore size distributions were determined from $N_2$ adsorption isotherms and the wall thickness was calculated as: thickness = $a$ – pore size ($a = 2 \times d_{(100)}/3^{1/2}$). [b] The units for the carbon residue of samples are $\times 10^{-6}$ mmol/g.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

patterns of SiPMo-8 (Figure 2b) do not show any obvious characteristic signals for pure HPMo, indicating the very high dispersion of HPMo in the meso-silica matrix.[17,23,25,35]

### *Transmission Electron Microscopy*

Figure 3 shows the TEM images of SiPMo-8 and SBA-15; we can see that the pores of the modified sample SiPMo-8 (Figure 3a, b) represent a hexagonal analogue to that of pure silica SBA-15 (Figure 3c, d).[32] Compared with Figure 3c, d, the images shown in Figure 3a, b suggest that the ordering of the sample SiPMo-8 is only slightly less than that of the SBA-15 sample; these results are consistent with those from XRD.

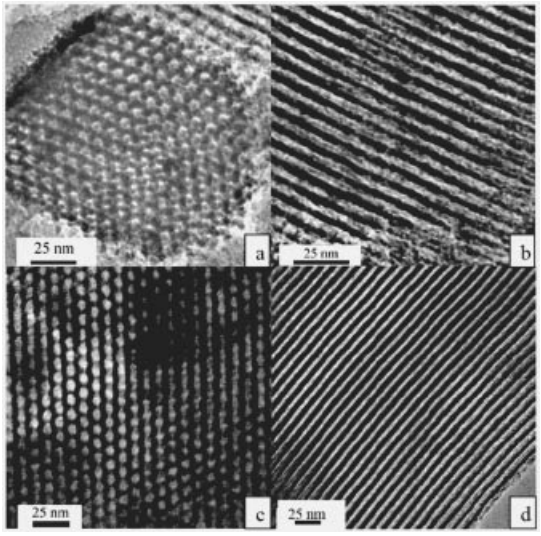

Figure 3. TEM images of samples: (a) SiPMo-8 in the [100] direction, (b) SiPMo-8 in the [110] direction, (c) SBA-15 in the [100] direction, and (d) SBA-15 in the [110] direction.

### *$N_2$ Adsorption Isotherms*

The $N_2$ adsorption isotherms of the SiPMo-8 and HPMo/SBA samples together with that of pure silica SBA-15 are shown in Figure 4, and the porosity parameters, such as the BET specific area, cumulative pore volume, and average pore diameter, are listed in Table 1. Evidently, SiPMo-8 shows a typical adsorption curve of type IV (according to the IUPAC classification) with an obvious hysteresis loop at a relative pressure of $0.70 < P/P_0 < 0.85$ (Figure 4b) that is very similar to that of pure silica SBA-15 (Figure 4a).[32] The hysteresis loop for the material starting at about 0.70 relative pressure suggests the presence of framework mesoporosity. In situ incorporation of HPMo into the framework of SBA-15 only leads to a very slight decrease in the values of surface area and pore volume. For example, the BET surface area and pore volume of SiPMo-8 are given as 807 $m^2/g$ and 1.04 $cm^3/g$, and the corresponding values for SBA-15 are 860 $m^2/g$ and 1.15 $cm^3/g$, so there is no clear difference between the porosity parameters of pure silica SBA-15 and the SiPMo-8 sample, implying the formation and presence of HPMo in the initial gel does not affect the formation of a mesostructure, which is also in agreement with the XRD results. However, the BET surface area and pore volume of HPMo/SBA (Figure 4c) are 473 $m^2/g$ and 0.85 $cm^3/g$, respectively, and comparing these results with the corresponding values for pure silica SBA-15, the BET surface area and pore volume of HPMo/SBA are significantly lower; these results also provide evidence that the conventional preparation method affects the ordering of the support.

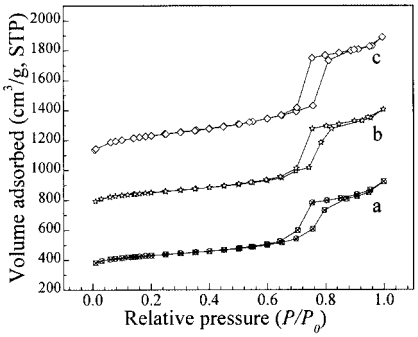

Figure 4. $N_2$ adsorption/desorption isotherms of samples at STP: (a) HPMo/SBA, (b) SiPW-8, and (c) SBA-15.

### *IR Spectra*

The infrared spectra of the samples are shown in Figure 5. It is well known that the Keggin structure of HPMo is composed of one $PO_4$ tetrahedron surrounded by four tri-metal groups of three edge-sharing $MoO_6$ octahedra and that HPMo gives several strong typical IR bands at ca. 1062 $cm^{-1}$ (stretching frequency of P–O in the central tetrahedron $PO_4$), 963 $cm^{-1}$ (terminal bands of Mo=O in the exterior octahedron $MoO_6$), 871, and 793 $cm^{-1}$ (Mo–$O_b$–Mo and Mo–$O_c$–Mo bridge band, respectively) (Figure 5a).[14] It has been widely reported that pure mesoporous silica of SBA-15 shows the framework bands at about 800 $cm^{-1}$ (symmetric stretching of Si–O–Si), 960 $cm^{-1}$ (stretching of Si–O–H), and 1030–1250 $cm^{-1}$ (*anti*-symmetric stretching of Si–O–Si) (Figure 5c).[23,25] In our case, SiPMo-8 gives three intense bands at 1098, 961, 803 $cm^{-1}$, and one shoulder band at 896 $cm^{-1}$ over 600–1400 $cm^{-1}$ regions (Figure 5b). It should be noted that some bands of HPMo in the region partially or fully overlapped with the bands of SBA-15, because of the strong contrast between the weak signals of HPMo in the framework of SiPMo-8 and the very strong signals of SBA-15. Three strong bands in the IR spectrum of SiPMo-8 appeared at 803, 961, and 1098 $cm^{-1}$, from the overlapping of the IR absorption bands of SBA-15 around 800, 960, and 1100 $cm^{-1}$, and those of HPMo at 793, 963, and 1062 $cm^{-1}$, respectively. Consequently, the Keggin unit could only be characterized by the stretching modes assigned to bridging bonds: a very low-intensity peak at about 896 $cm^{-1}$, with slightly shifted shoulder signals, may confirm that the Keggin structure of HPMo encapsulated into the framework of SBA-15 was slightly influenced during the synthesis procedure, in other words, this may indirectly prove that there are interactions

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

between the silicon species and the heteropolyanion in the framework of SiPMo-8, it can thus be deemed that the Keggin structure of HPMo is preserved in the framework of SiPMo-8.[14]

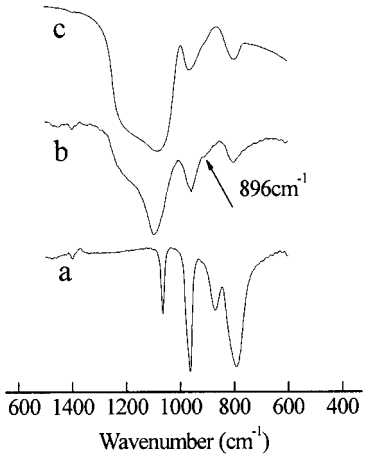

Figure 5. IR spectra of samples: (a) HPMo, (b) SiPMo-8, and (c) SBA-15.

### *UV/Visible Diffuse Reflectance Spectra*

The incorporation of HPMo into the framework of SBA-15 was further indirectly verified by UV/Visible spectra. The UV/Visible spectra of the samples are shown in Figure 6. Bulk HPMo (Figure 6a) shows a broad and strong UV absorption in the range of 200–300 nm, with a maximum centered at about 260 nm, which is a characteristic peak attributed to the oxygen–molybdenum charge-transfer absorption band for Keggin anions. The UV irradiation of the polyoxomolybdate cluster results in charge-transfer from an $O^{2-}$ ion to a $Mo^{6+}$ ion, and this occurs at Mo–O–Mo bonds corresponding to the formation of a pair consisting of a hole center ($O^{-}$) and a trapped electron center ($Mo^{5+}$). The process can be described as follows:[14]

$$[Mo^{6+}–O^{2-}–Mo^{6+}] \xrightarrow{h\nu} [Mo^{5+}–O^{-}–Mo^{6+}]^*$$

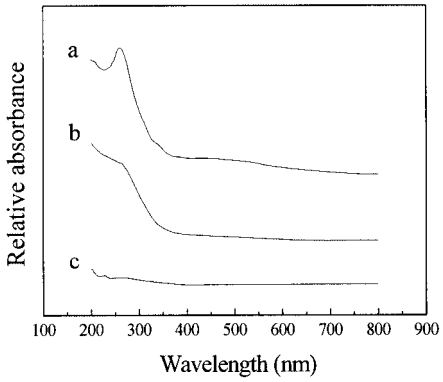

Figure 6. UV/Visible spectra of samples: (a) HPMo, (b) SiPMo-8, and (c) SBA-15.

SBA-15 did not show any signals in the wavelength region studied (Figure 6c). In our case, the SiPMo-8 (Figure 6b) sample has a broad UV absorption in the range 200–300 nm, with a characteristic peak centered at about 260 nm in the spectrum, similar to that of the $[PMo_{12}O_{40}]^{3-}$ species. These results indicate that the primary Keggin structure of HPMo has been introduced into the framework of the mesostructure and is very stable even after the extraction of surfactants and washing with deionized water, which is in agreement with IR results. Similar results can also be observed with $^{31}P$ MAS NMR measurements.

### *$^{31}P$ MAS NMR Spectra*

The $^{31}P$ MAS NMR spectra of bulk HPMo and SiPMo-8 are shown in Figure 7. It is well known that the $^{31}P$ MAS NMR chemical shift of bulk HPMo is strongly dependent on the number of crystallized water molecules, in our case bulk HPMo exhibits an intense and sharp line at a chemical shift of around –4.5 ppm in the $^{31}P$ MAS NMR spectrum (Figure 7b) pointing to a uniform phosphorus environment in the structure of HPMo. The $^{31}P$ MAS NMR spectrum of SiPMo-8 also shows an intense and sharp line at around –4.5 ppm and two low intense down-field and up-field chemical shifts (–5.1 and –3.8 ppm, respectively) are observed (Figure 7a). These could be deemed to represent very strong interactions between the molybdophosphoric anions and the framework of SBA-15, which is made up of a network of $SiO_2$, and could also be attributed to a significant distortion of the heteropoly anion symmetry, whereby the long-range order created by water molecules in the hydrated state of HPMo is lost because of strong chemical interactions between molybdophosphoric anions and the framework of SBA-15. It can be concluded that the Keggin unit (primary structure) is preserved after being incorporated into the framework of SBA-15, because HPMo microcrystallites deposited on the silica surface and heteropoly anions interacting with Si–OH groups have been observed when HPMo was supported on silica.[14]

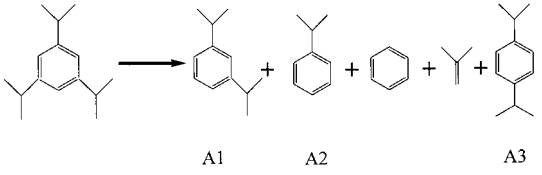
[a] Esterification reactions of benzoic acid with *tert*-butyl alcohol. [b] 2,3,6-Trimethylphenol hydroxylation with $H_2O_2$, acetonitrile as the solvent (polar solvent), 2,3,6-trimethylphenol/$H_2O_2$ = 3 (molar ratio); catalyst/2,3,6-trimethylphenol ≈0.05 (weight ratio), temperature: 353 K, reaction time: 2 h. The products are trimethylhydroquinone (C1, TMHQ), trimethylbenzoquinone (C2, TMBQ), others (C3). Conversion = 2,3,6-trimethylphenol converted to TMHQ, TMBQ and other products/2,3,6-trimethylphenol added in the system. [c] The catalysts were reused five times. [d] Turnover frequency of esterification is moles of *tert*-butyl benzoate yield per mol active site on the surface of the catalyst per hour, using the fresh catalysts. [e] Turnover frequency of hydroxylation is moles of 2,3,6-trimethylphenol converted per mol active site on the surface of the catalyst per hour, using the fresh catalysts. The active site numbers on the surface of SiPMo-8, SiPW-8, HPMo/SBA, and HPW/SBA were estimated on the basis of the amount of HPAs (moles) estimated by ICP analysis, and the surface areas were determined by $N_2$ adsorption methods. [f] The selectivity of hydroxylation is that of 2,3,6-trimethylphenol hydroxylation with $H_2O_2$ using the fresh catalysts.

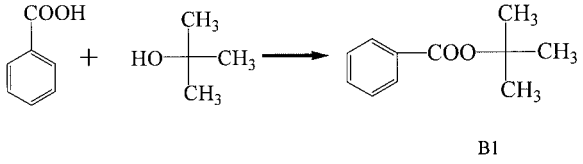
of SBA-15 with impregnation methods gives reaction conversion at 17.4%. In our case, SiPMo-8 shows high catalytic activity and gives reaction conversion at 50.6%, which is higher than that of HPMo/SBA, and the results suggest the potential use of SiPMo-8 as a catalyst for bulky molecule catalytic reactions. Similar phenomena have also been observed when using SiPW-8 and HPW/SBA samples as the catalyst, giving conversion at 61.3 and 18.8%, respectively. We can see that the activity of SiPW-8 in TIPB cracking is higher than that of SiPMo-8, the activity of HPW/SBA is higher than that of HPMo/SBA, and the activity of HPW is also higher than that of HPMo. It is well known that HPW is a stronger acid than HPMo, and TIPB cracking is a typical acidic catalytic reaction, so it is easy to understand the above results.[17]



Scheme 1. Catalytic cracking of 1,3,5-triisopropylbenzene (TIPB): [A1] 1,3-diisopropylbenzene; [A2] cumene; [A3] 1,4-diisopropylbenzene.

### *Esterification of Benzoic Acid with tert-Butyl Alcohol*

In esterification (see Scheme 2), as shown in Table 2, the SiPMo-8 sample gives conversion at 10.2% (TOF at 3.1 $h^{-1}$), HPMo/SBA prepared by the impregnation method shows very low catalytic activity (conversion at 4.8%, TOF at 1.5 $h^{-1}$) compared with the SiPMo-8 sample; the SiPW-8 sample gives conversion at 12.4% (TOF at 4.0 $h^{-1}$) and HPW/SBA prepared by the impregnation method shows conversion at 6.9% (TOF at 2.2 $h^{-1}$). Moreover, the SiPMo-8 and SiPW-8 samples still showed similar catalytic activity compared with the corresponding fresh catalysts after the catalysts were reused five times (Table 2), whereas the conversions with HPMo/SBA and HPW/SBA were reduced remarkably after the catalysts were used five times, to only 0.5 and 0.7%, respectively, which may be attributed to the leaching of the HPAs supported on the surface of SBA-15 during the reactions.[23,25] The above results suggest that SiPMo-8 and SiPW-8 are very stable in liquid reactions even when they are reused many times, and the leaching of HPAs is hardly observed, as compared with samples prepared by the impregnation method.[18] Similar phenomena can also be observed in the hydroxylation of 2,3,6-trimethylphenol with $H_2O_2$.



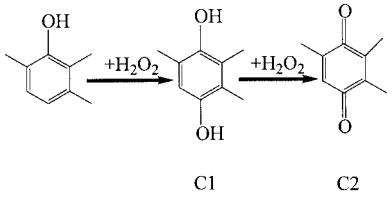
Scheme 2. Esterification of benzoic acid with *tert*-butyl alcohol: [B1] *tert*-butyl benzoate.

### *Hydroxylation of 2,3,6-Trimethylphenol with $H_2O_2$*

In hydroxylation (see Scheme 3),[41] also as shown in Table 2, SiPMo-8 gives conversion at 26.5% (TOF at 251.3 $h^{-1}$), and HPMo/SBA prepared by the impregnation method shows similar catalytic activity (conversion at 21.2%, TOF at 206.6 $h^{-1}$). SiPW-8 gives conversion at 17.9% (TOF at 180.2 $h^{-1}$), HPW/SBA shows similar catalytic activity (conversion at 15.8%, TOF at 113.0 $h^{-1}$). Moreover, after the catalysts were reused five times (Table 2), SiPMo-8 and SiPW-8 still showed similar catalytic activities (26.2 and 17.6%, respectively) compared with the corresponding fresh catalysts (26.5 and 17.9%, respectively), whereas the conversions with HPMo/SBA and HPW/SBA were reduced remarkably, to only 4.9 and 3.0%, respectively, after the catalysts were recycled five times.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Other properties of the SiPMo-8 and SiPW-8 samples, such as easy separation and stability when recycled, ensure their potential application in the chemical industries. This phenomenon is very similar to that in esterification and all of these could be attributed to the stability of the HPAs encapsulated into the framework of mesoporous materials and the preservation of the catalytic abilities of the HPAs when encapsulated. The XRD pattern of impregnated samples (Figure 1) reveals the effect of the conventional preparation method on the ordering of the support. For impregnated samples, some heteropolyacid clusters may block the channels of the SBA-15 substrate, which on the one hand reduce the BET surface area and pore volume (Table 1) and on the other hand prohibit bulky reactant molecules from entering the channels of the SBA-15 substrate, so that the heteropolyacids in the channels will not be able to perform their catalytic activity. The number of catalytically active heteropolyacids is reduced, and this leads to a reduction of their apparent total catalytic activity, which in turn gives the apparent result that the activity of impregnated samples is not as high as that of the in situ synthesized sample (SiPMo-8, SiPW-8). We also noticed that the catalytic properties of SiPMo-8 in the esterification and hydroxylation reactions are different from those of SiPW-8. Although both SiPMo-8 and SiPW-8 are very active, SiPMo-8 is more active in hydroxylation and SiPW-8 is more active in esterification; this is because esterification is an acidic catalytic reaction and hydroxylation is an oxidative catalytic reaction, and as HPW is a stronger acid than HPMo and the oxidation ability of HPW is less than that of HPMo. From Table 2, we may notice that, although the specific surface areas of solid HPAs are very low (usually less than 10 $m^2/g$), leading to very few active sites on their surfaces, HPAs are all active in the reactions of TIPB cracking, esterification, and hydroxylation. Properties of HPAs, such as the ability to form pseudo-liquid phases, the soft basicity of the polyanions, and the high solubility in water and organic polar solvents, make them active in reactions of some bulky molecules.[5–10]



Scheme 3. Hydroxylation of 2,3,6-trimethylphenol with $H_2O_2$: [C1] trimethylhydroquinone (TMHQ); [C2] trimethylbenzoquinone (TMBQ).

## Conclusions

SBA-15 frameworks with encapsulated Keggin type HPAs were synthesized in situ by adding P- and Mo sources into the initial sol–gel system during hydrolysis of TEOS under strongly acidic conditions. Characterization results suggest that samples synthesized in this manner show a very ordered hexagonal mesostructure, and HPAs that are incorporated in the meso-silica are insoluble during catalysis. The results of catalytic reactions suggest that these samples are very active in reactions of bulky molecules (1,3,5-triisopropylbenzene cracking, esterification of benzoic acid with *tert*-butyl alcohol, and 2,3,6-trimethylphenol hydroxylation with $H_2O_2$). We can prepare samples with different types of catalytic activity (such as acid, redox) by incorporating different types of HPA. Additionally, recycling results of the liquid reactions of esterification (polar solvent) and hydroxylation (polar solvent) indicate that these materials are easily separated and recycled as catalysts, which make them interesting for potential industrial applications.

## Experimental Section

**Materials:** Tetraethyl orthosilicate (TEOS), hydrochloric acid (HCl), $H_3PO_4$, benzoic acid, tertiary butyl alcohol, and $H_2O_2$ (30 wt.-%) were of analytical grade and purchased from Tianjin Chemical Co. (China). 12-Molybdophosphoric acid (HPMo) and sodium molybdate ($Na_2MoO_4$) were of analytical grade and supplied by Beijing Chemical Co. (China). $EO_{20}PO_{70}EO_{20}$ (Pluronic P123), 2,3,6-trimethylphenol, and 1,3,5-triisopropylbenzene are Aldrich products.

**Synthesis:** The typical in situ synthesis process of SiPMo-X was as follows: (1) Pluronic P123 (2.0 g) was dissolved in a solution of hydrochloric acid (10 mL, 36 wt.-%) in deionized water (50 mL) followed by the addition of TEOS (4.4 mL), and then the mixture was stirred at 40 °C for 3 h. (2) The requisite amount of $Na_2MoO_4$ and $H_3PO_4$ was added to the above mixture simultaneously to form a yellow precipitate. (3) The mixture was further stirred at 40 °C for 20 h and then transferred into a stainless steel autoclave for crystallization at 100 °C for 48 h. The obtained products were dried in vacuo ($<10^{-2}$ Pa) at 120 °C for 6 h and washed three times with an ethanol solution containing HCl and distilled water, and finally treated in vacuo ($<10^{-2}$ Pa) at 300 °C for 5 h again. The final products were designated as SiPMo-X, where X stands for the Si/Mo molar ratio in the initial gel, in this paper X is equal to 8.

For comparison, pure silica SBA-15 was synthesized according to literature procedures.[32] Conventional supported HPMo (SBA-15 as the support) was made by immersing SBA-15 powder into an HPMo solution under stirring for 3 h, drying at 120 °C for 24 h, and then calcination at 300 °C for 5 h. This product was denoted as HPMo/SBA. The methods of synthesis of HPW, SiPW-8, and HPW/SBA are the same as those in the literature.[23]

**Characterization:** The HPMo contents in solid samples and the carbon residue of the SBA 15 substrate and encaged HPAs were determined by the results of inductively coupled plasma analysis (ICP, Perkin–Elmer 3300DV). Powder X-ray diffraction (XRD) data were recorded with a Siemens D5005 instrument (30 kV, 30 mA) using nickel-filtered Cu-$K_a$ radiation with a wavelength of $\lambda$ = 0.15418 nm, diffraction patterns were collected under ambient conditions in the $2\theta$ range 0.6–4° at a scanning rate of 0.6°/min and in the $2\theta$ range 4–70° at a scanning rate of 6°/min. Transmission electron microscopy (TEM) experiments were performed with a JEM-3010F electron microscope (JEOL, Japan) with an acceleration voltage of 300 kV. The nitrogen isotherms at the temperature of liquid nitrogen were measured using a Micromeritics ASAP 2010M system. The samples were outgassed for 10 h at 300 °C before the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

measurements, the volume of adsorbed $N_2$ was normalized to standard temperature and pressure, specific surface areas were determined from the linear part of the BET equation, the average pore diameter was calculated by using the adsorption branches of the $N_2$ isotherms. Infrared (IR) spectroscopy was performed with a Bruker IFS 66v/S infrared spectrometer in the range 400–4000 $cm^{-1}$ by using KBr pellets in vacuo (<0.4 Pa) at ambient temperature. The diffuse reflectance UV/Visible spectra for powder samples were obtained with a Perkin–Elmer Lambda 20 UV/Visible spectrometer equipped with an integrating sphere, and $BaSO_4$ was used as the internal standard. Solid-state $^{31}P$ magic angle spinning nuclear magnetic resonance (MAS NMR) spectroscopy was performed with an Infinity Plus-400 spectrometer equipped with MAS at a frequency of 104.26 MHz, chemical shifts were referenced to 85% $H_3PO_4$ as an external standard.

**Catalytic Test**

**Catalytic Cracking of 1,3,5-Triisopropylbenzene**

Catalytic cracking of 1,3,5-triisopropylbenzene was carried out by using the pulse technique in a microreactor, and the analyses of the catalytic products were performed by a gas chromatograph (GC-17A, Shimadzu Co.) equipped with a flame ionization detector (FID) with a flexible, 30-m OV-17 quartz capillary column. The catalytic cracking was performed under the following standard conditions: the reaction temperature was 250 °C (no thermal cracking); the reaction pressure was atmospheric pressure; the mass of the catalyst was 0.050 g; 0.2 μL of TIPB was injected for each test; nitrogen was used as the carrier gas at a flow rate of 45 mL/min.

**Esterification of Benzoic Acid with *tert*-Butyl alcohol**

The esterification of benzoic acid with *tert*-butyl alcohol was performed under nitrogen at 80 °C in a flask (30 mL) containing suspended catalyst powder (60 mesh pass), benzoic acid (5 mmol), and *tert*-butyl alcohol (10 mmol). The amount of catalyst used was 0.150 g. After vigorous agitation for 4 h, the products were analyzed with a gas chromatograph (6890N, Agilent Co.) equipped with a flame ionization detector (FID) with a flexible, 30-m HP-5 quartz capillary column.

**Hydroxylation of 2,3,6-Trimethylphenol with $H_2O_2$**

The hydroxylation reaction of 2,3,6-trimethylphenol with $H_2O_2$ was performed at 80 °C in a flask (50 mL) containing suspended catalyst powder (0.150 g, 60 mesh pass), acetonitrile (5 mL) as the solvent, 2,3,6-trimethylphenol (0.156 mol), and $H_2O_2$ (0.052 mol), all added at the same time followed by vigorous agitation for 2 h. The products were analyzed with a gas chromatograph (6890N, Agilent Co.) equipped with a flame ionization detector (FID) with a flexible, 30-m INNOWAX quartz capillary column.

# Early Alkali Metal (Li, Na, K) and Tris(dimethylamino)sulfonium (TAS) Salts of [1,2,5]Thiadiazolo[3,4-*c*][1,2,5]thiadiazolidyl Radical Anion: Rational Syntheses, Structures and Magnetic Properties

**Vladimir N. Ikorskii,[c] Irina G. Irtegova,[a] Enno Lork,[b] Alexander Yu. Makarov,[a] Ruediger Mews,*[b] Victor I. Ovcharenko,*[c] and Andrey V. Zibarev*[a,d]**

**Keywords:** Magnetic properties / Nitrogen heterocycles / Radical anions / Sulfur heterocycles

Salts of the [1,2,5]thiadiazolo[3,4-*c*][1,2,5]thiadiazolidyl radical anion (**1**) and the early alkali metals, [Li(12-crown-4)$_2$][**1**] (**3**), [Na(15-crown-5)][**1**] (**4**), and [K(18-crown-6)][**1**] (**5**) as well as the salt [(Me$_2$N)$_3$S][**1**] (**6**) can be prepared by reduction of [1,2,5]thiadiazolo[3,4-*c*][1,2,5]thiadiazole (**2**) with PhS$^-$ anion followed by XRD and ESR characterization. These salts are thermally stable and soluble in MeCN. Low-temperature crystallization of salt **5** from MeCN or storage of **5** under MeCN for a few days at ambient temperature gives the solvate **5**·MeCN (**7**). The radical anion **1** acts as bridging ligand in salts **4** and **5** and as chelating ligand in salt **7**. In salt **3**, the radical anion **1** is not coordinated to the cation and can be considered as "naked" anion. In salt **6**, one of the two crystallographically independent **1** acts as bridging ligand, whilst the other is not coordinated to the cation. Magnetic susceptibility data obtained for salts **4** and **5** in the temperature range of 2–300 K revealed antiferromagnetic exchange interactions between paramagnetic centers: **4**, $J$ = –3.42, $\alpha J$ = –1.12 cm$^{-1}$; **5**, $J$ = –1.22 cm$^{-1}$.

## Introduction

The design, synthesis and investigation of new molecular materials, especially of conducting, superconducting, and magnetic materials, belong to the topical fields of current scientific and technological progress. Over the past two decades, there has been considerable interest in the syntheses, molecular and electronic structures, and physical properties of heterocyclic thiazyl radicals, neutral and charged, recognized as promising building blocks for new molecular magnets and/or molecular conductors.[1] Numerous neutral and positively charged heterocyclic thiazyl radicals (radical cations) have been carefully explored, while rather rare negatively charged systems (radical anions) have been less studied.[1] In this context, new preparative approaches to heterocyclic thiazyl radical anions are of obvious interest.

Recently, we have described the [K(18-crown-6)]$^+$ salt of the [1,2,5]thiadiazolo[3,4-*c*][1,2,5]thiadiazolidyl radical anion (**1**, Scheme 1) and its solvate with MeCN that was unexpectedly isolated in low yield as a result of spontaneous decomposition of the [K(18-crown-6)] [PhXNSN] (X = S, Se) salts in MeCN solution.[2] Since the radical anion **1** might be of interest to material science as a building block for molecular ion-based conductors and/or magnets,[1] in this work we report on the rational preparation of the early alkali metal (Li, Na, K) and tris(dimethylamino)sulfonium (TAS) salts of the radical ion **1** based on the reduction of [1,2,5]thiadiazolo[3,4-*c*][1,2,5]thiadiazole (**2**) with the PhS$^-$ anion. The salts were isolated in high yields, in the case of the alkali metals as complexes with the corresponding crown ethers (12-crown-4, 15-crown-5, and 18-crown-6), followed by XRD and ESR characterization as well as measurements of magnetic susceptibility in the temperature range of 2–300 K.

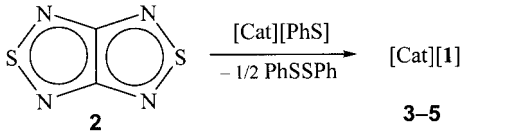
## Results and Discussion

In this work, salts of the radical anion **1** and the early alkali metals, [Li(12-crown-4)$_2$][**1**] (**3**), [Na(15-crown-5)][**1**] (**4**), and [K(18-crown-6)][**1**] (**5**), were prepared in a rational way by reduction of compound **2** with the PhS$^-$ anion in MeCN solution (Scheme 2). The corresponding PhSM thiolates (M = Li, Na, K) were used as a source of the PhS$^-$ anion.



Scheme 2.

For the in situ generation of the PhS$^-$ anion the desilylation of the Ph–S–SiMe$_3$ precursor was employed (Scheme 3). This approach allows to prepare salts of **1** not only with alkali metal cations, for example [K(18-crown-6)], but also with other cations including organic ones, for example the tris(dimethylamino)sulfonium (TAS) salt **6**.

The salts obtained were characterized by XRD (Table 3, Figure 1) and ESR (Figure 2) (for **5** XRD and ESR data were published before).[2] In MeCN solution for all salts the hfc constant $a(^{14}N \times 4)$ = 0.314 mT, and $g$ = 2.0045, are in accordance with previous measurements.[2]

Low-temperature crystallization of salt **5** from MeCN, or storage of **5** under MeCN for a few days at ambient temperature, gives the solvate **5**·MeCN (**7**, XRD and ESR data were published earlier).[2] In the case of **3** and **4**, under the same conditions only the initial salts are recovered, no inclusion of the MeCN solvent into the crystal lattices is observed. Transformation of **5** into **7** is reversible, and crystallization of **7** from boiling MeCN leads to **5**. The procedure can be repeated at least 3 times.

The salts **3**–**7** are thermally stable and soluble in MeCN. When protected from air, the salts **3**–**7** are stable in the crystalline state for several months, and in MeCN solution for several weeks, at least (under electrochemical conditions, a half-life time of **1** in MeCN solution was estimated as 74.5 s on the basis of the ESR data).[2] Upon contact with air,

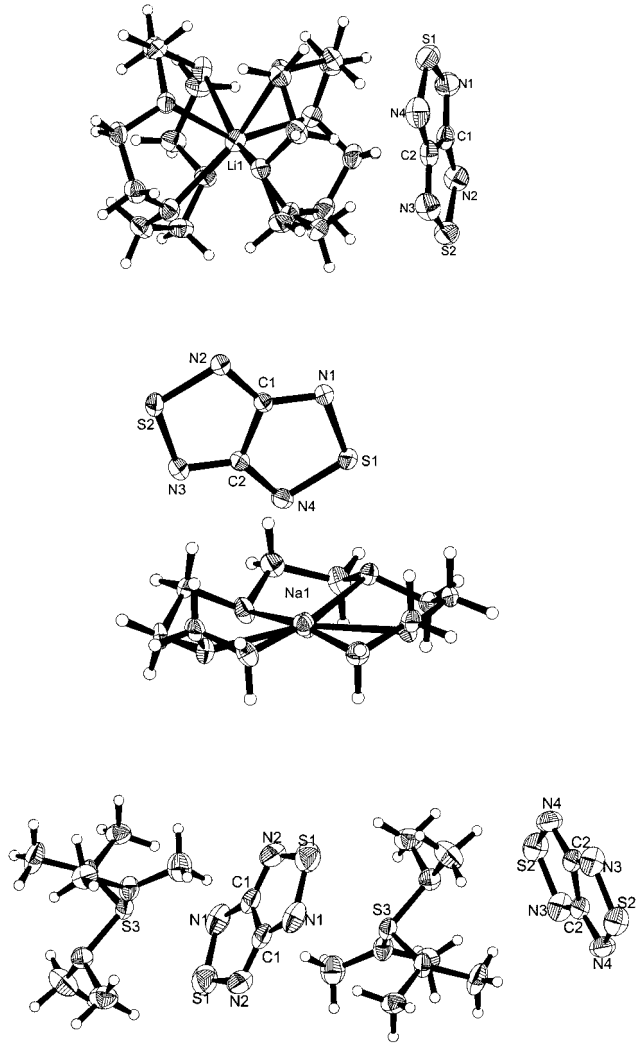


Figure 1. Structure of salts **3** (top), **4** (middle), and **6** (bottom). Crystallographic atom numbering is used; for selected bond lengths and bond angles, see Table 1.

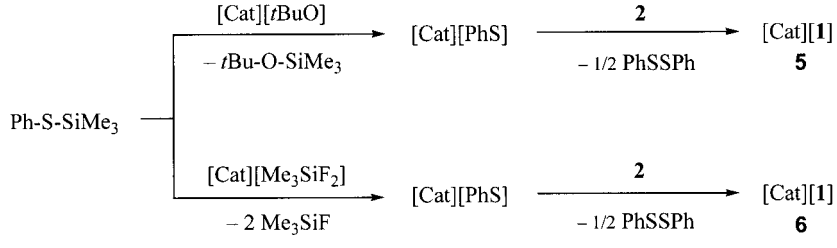
salts **3**–**7** decompose in both solid state and in solution. Among **3**–**7**, salt **3** is the most sensitive towards atmosphere.

It is known that the crystal packing of neutral thiazyl radicals (revealed general tendency to polymorphism)[1b,3] is crucial for their macroscopic magnetic properties.[1b] The crystal packing of salts **3**–**7** is different. The radical anion **1** acts as bridging ligand in salts **4** (Figure 3) and **5**,[2] and



Scheme 3.

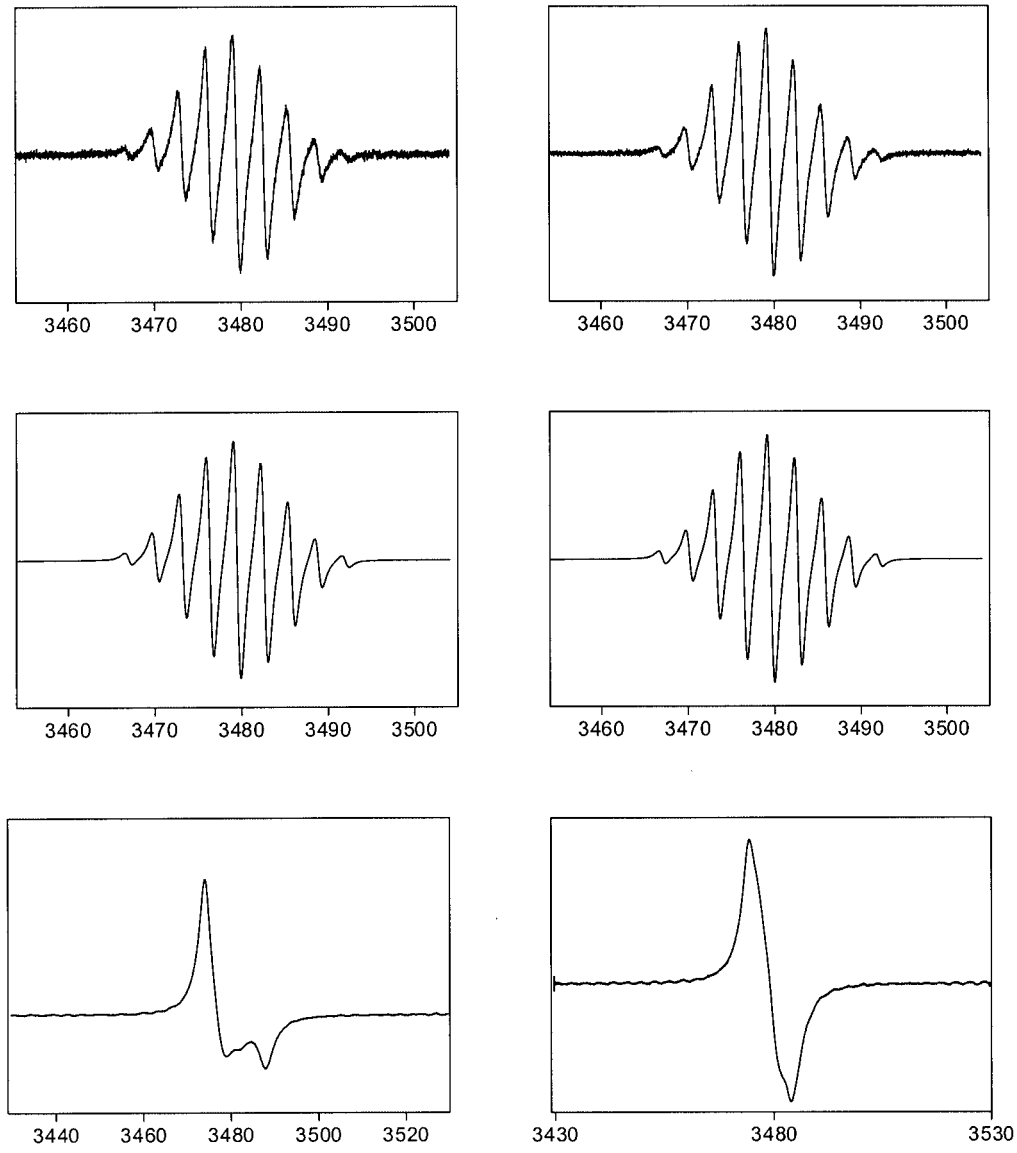

Figure 2. ESR spectra ($|H|\,10^4\,T^{-1}$). Salt **4** (left column): experimental in MeCN solution (top), simulated for solution (middle), and experimental in crystalline state (bottom). Salt **6** (right column): experimental in MeCN solution (top), simulated for solution (middle), and experimental in crystalline state (bottom).

as chelating ligand in salt **7**.[2] In contrast to salt **5** where **1** coordinates two cations symmetrically with N···K contacts of 288.5 pm, in salt **4** the bridging anion **1** coordinates the cations non-symmetrically via N···Na contacts of 251.1 and 283.7 pm, respectively. By these alternating contacts chains are formed along the crystallographic axis *b* (Figure 3).

In salt **3** the radical anion **1** is not coordinated to the Li cation (encapsulated in 2 crown ether molecules, Figure 4) and can be considered as "naked" anion. In salt **6** one of the two crystallographycally independent radical anions **1** acts as bridging ligand via S···S contacts of 361.2 pm, whilst the other is not coordinated to the cation (Figure 5).

Probably, the lack of stabilizing anion-cation interaction leads to the enhanced instability of salt **3** towards atmo-

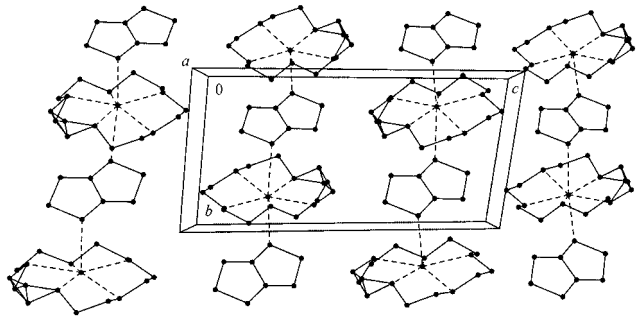

Figure 3. Crystal packing of salt **4** (dashed lines indicate shortened contacts).

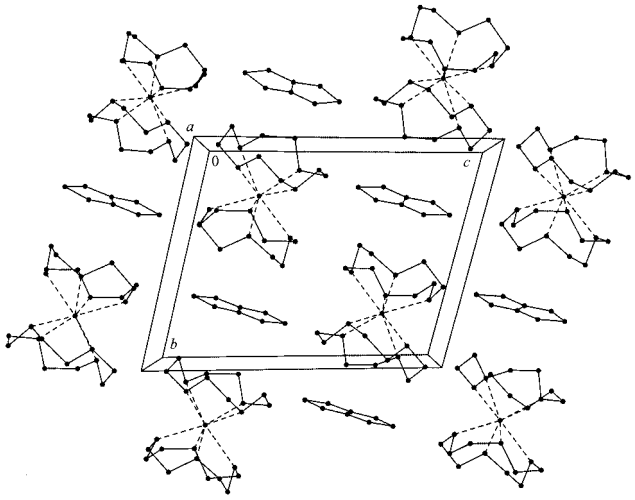

Figure 4. Crystal packing of salt **3** (dashed lines indicate shortened contacts).

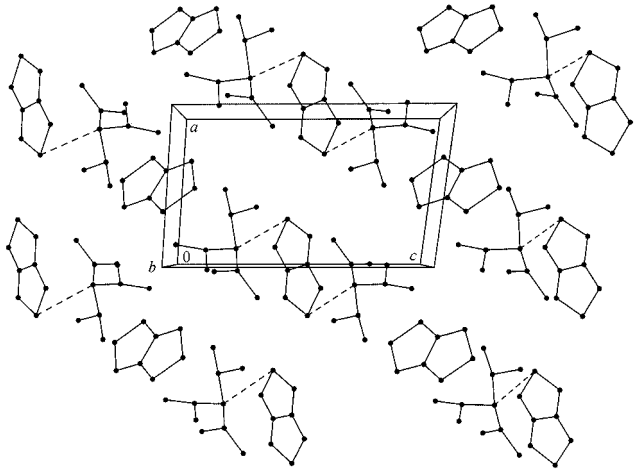

Figure 5. Crystal packing of salt **6** (dashed lines indicate shortened contacts).

sphere as compared with the other alkali metal salts **4**, **5**, and **7**. It should be noted, that the coordination chemistry of thiazyl radicals, both neutral and charged, is still in its infancy.[4]

Molecular geometry data of the radical anion **1** in salts **3**, **4**, and **6** are presented in Table 1 (data for salts **5** and **7** were published earlier).[2] Effects of the coordination of the radical anion **1** to the different cations on its geometry are rather minor.

Attempts to prepare salts with enlarged spin (negative charge) delocalization, for instance [Na(15-crown-5)][**1**][**2**] and [K(18-crown-6)][**1**][**2**], by low-temperature 1:1 co-crystallizations of salts **4** and **5** with the neutral precursor **2** were unsuccessful. The initial compounds were recovered.

The data of magnetic measurements for **4** and **5** are presented in Figure 6. For **4**, temperature dependence of magnetic susceptibility $\chi$ shows the maximum at 8 K. This is indicative of exchange coupling of radical anion clusters with even number of paramagnetic centers. For **5**, $\chi$ increases steadily with temperature lowering.

Table 1. Molecular geometry of **1** in salts **3**, **4**, and **6**.[a]

[a] Systematic atom numbering is used. [b] Two crystallographically independent molecules.

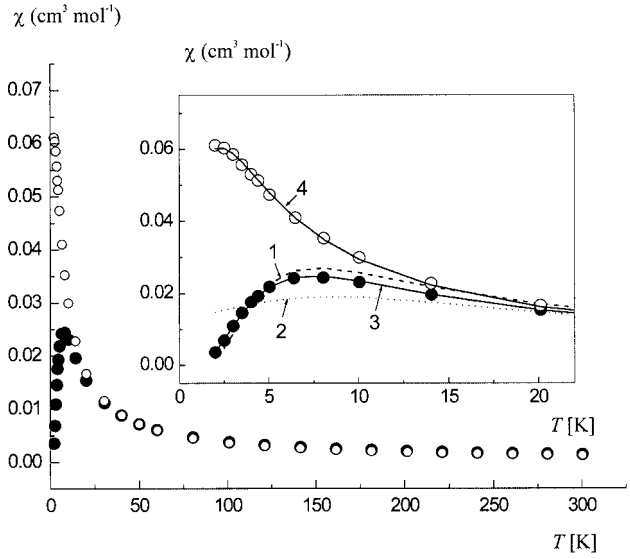

Figure 6. Dependence $\chi$(T) in the temperature ranges of 2–300 K and 2–20 K (insert) for **4** (black circles) and **5** (white circles). Theoretical curves (models) 1 (i), 2 (ii), 3 (iii) and 4 (ii) described in the text.

As mentioned above, crystal packing of **4** and **5** reveals linear chains formed by the N···M (**4**, M = Na; **5**, M = K) contacts, alternating for **4** (251.1 and 283.7 pm) and non-alternating for **5** (288.5 pm). To estimate the energy of exchange interaction $J$ between paramagnetic centers, analytical and numerical expressions of three different models were used, namely: i) the model of dimers,[5] $H = -2JS_1S_2$; ii) the Bonner–Fisher uniform chain model[6] with exchange parameters $J$ equal along the chain, $H = -2J\Sigma S_iS_{i+1}$; and iii) the alternating chain model[6] with exchange parameters $J$ and $aJ$ alternated along the chain, $H = -2J\Sigma(S_{2i}S_{2i-1} + a{\cdot}S_{2i}S_{2i+1})$. The optimized model parameters are given in Table 2. It is seen that the experimental data (Figure 6, in-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sert) are best fitted by the alternating chain model (iii) in the case of **4**, and by the Bonner–Fisher model (ii) in the case of **5** (Table 2), in both cases in accordance with the discussed features of the crystal packing. Corresponding theoretical curves are shown in Figure 6 (insert). Thus, despite long distances between radical anions **1** in the crystal lattices of salts **4** and **5**, weak antiferromagnetic exchange interactions are observed.

Table 2. Optimal parameters in modeling exchange interactions.

| Compound | Model | *g* factor | $J$ [cm$^{-1}$] | $-\alpha J$ [cm$^{-1}$] | $R^2$ |
|---|---|---|---|---|---|
| | i | 2.0(1) | 4.06(3) | | 0.9929 |
| **4** | ii | 2.2(2) | 4.9(8) | | 0.8159 |
| | iii | 2.003(7) | 3.46(2) | 1.12(2) | 0.9991 |
| **5** | ii | 1.98(1) | 1.22(2) | | 0.9997 |

One can conclude that even minor changes in the packing observed in going from **4** (this work) to **5**[2] affect the macroscopic magnetic properties of these salts. Overall, the crystal packing of the salts of the radical anion **1** seems to be important for their magnetic behavior.

## Conclusions

Early alkali metal (Li, Na, K) and tris(dimethylamino)-sulfonium (TAS) salts of the [1,2,5]thiadiazolo[3,4-*c*][1,2,5]-thiadiazolidyl radical anion are prepared in a rational way by chemical reduction of [1,2,5]thiadiazolo[3,4-*c*][1,2,5]thiadiazole with the $PhS^-$ anion. The salts, in the case of the alkali metals isolated in the form of complexes with the corresponding crown ethers (12-crown-4, 15-crown-5, and 18-crown-6), are characterized by XRD and ESR. Magnetic measurements confirmed the presence of unpaired electrons in the solids. The temperature dependence of the magnetic susceptibility $\chi$ indicates antiferromagnetic interactions in the solid state.

The salts prepared, which are thermally stable and soluble in MeCN, might be suitable starting materials (sources of the [1,2,5]thiadiazolo[3,4-*c*][1,2,5]thiadiazolidyl radical anion) in the synthesis of new molecular magnets and/or molecular conductors. The synthetic route based on Ph–S–$SiMe_3$ can obviously be generalized to preparation of salts of **1** with transition metal cations (including paramagnetic ones) since the chemistry of metal alkoxides (especially *tert*-butoxides) is well-developed.[7] On the other hand this approach can be expanded to many other π-heterocycles, especially nitrogen ones, possessing high electron affinity and forming stable radical anions.[1g]

## Experimental Section

**General:** Compound **2** was prepared as described earlier.[2] The syntheses described below were performed with exclusion of oxygen in absolutely dry solvents by using a glove box and standard vacuum line techniques. The pressure was normalized with argon where necessary. The GC-MS measurements were performed with a Hewlett–Packard G1800A GCD device for solutions in $CH_2Cl_2$. The ESR measurements were carried out with a Bruker ESP-300 spectrometer (MW power 265 mW, modulation frequency 100 kHz, modulation amplitude 0.005 mT), under anaerobic conditions. The spectral integration and simulation were performed with the Winsim 32 program. The *g* factors were measured using an MnO standard with an accuracy of ±0.0002. Magnetic measurements were carried out on an MPMS-5S Quantum Design SQUID magnetometer in the temperature range of 2–300 K in a magnetic field of 5000 Oe. The molar magnetic susceptibility $\chi$ was calculated using corrections for the diamagnetism equal to $-207 \cdot 10^{-6}$ cm$^3$ mol$^{-1}$ (for **4**) and $-243 \cdot 10^{-6}$ cm$^3$ mol$^{-1}$ (for **5**).

**Crystallographic Analysis:** The data collection for the single-crystal structure determinations (Table 3) were carried out on a Bruker P4 diffractometer with graphite-monochromated Mo-$K_\alpha$ (71.073 pm) radiation. The structures were solved by direct methods by use of the SHELXS-97 program[8] and refined by the least-squares method in the full-matrix anisotropic (isotropic for H atoms) approximation by use of the SHELXL-97 program.[8]

CCDC-293646 (for **3**), -293645 (for **4**), and -293647 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. For **5** and **7**, the data obtained in this work are in full agreement with those published previously.[2]

**Syntheses of Salts 3–5:** At –30 °C, a mixture of 0.144 g (0.001 mol) of **2**, 0.001 mol of PhSM (M = Li, Na, or K) and 0.001 mol (0.002 mol in the case of Li) of the corresponding crown ether was dissolved in 10 mL of MeCN. The wine-red solutions were warmed to 20 °C, stirred for 1 h, and filtered. The solvent was distilled off under reduced pressure, the residue washed with 10 mL of $Et_2O$, and dissolved in 5 mL of boiling MeCN under normal pressure. The solution was filtered and cooled to 20 °C in the case of salt **5**, or to –10 °C in the case of salt **4**. In the case of salt **3**, 10 mL of $Et_2O$ were recondensed onto the filtrate at –196 °C and the two-layered system was placed into cryostat at –40 °C. The solvent was removed with a syringe, and the crystals were washed with 10 mL of $Et_2O$ and dried in vacuo.

Salt **3** forms transparent red plates, yield 0.327 g (65%), m.p. (sealed capillary) 98 °C (dec.).

Salt **4** forms transparent red plates, yield 0.310 g (80%), m.p. (sealed capillary) 100 °C (dec.). $C_{12}H_{20}N_4NaO_5S_2$ (387.44): calcd. C 37.20, H 5.20, N 14.46, S 16.55; found C 37.37, H 5.12, N 14.38, S 16.36.

Salt **5** forms transparent ruby plates, yield 0.335 g (75%), m.p. (sealed capillary) 135 °C (dec.). $C_{14}H_{24}KN_4O_6S_2$ (447.64): calcd. C 37.57, H 5.40, N 12.52, S 14.33; found C 37.42, H 5.28, N 12.61, S 14.22.

In each case evaporation of the initially obtained $Et_2O$ solutions gave PhSSPh (95–98%) identified by GC-MS technique via comparison with an authentic sample.

At –30 °C, a solution of 0.182 g (0.001 mol) of Ph–S–$SiMe_3$[9] in 2 mL of THF was added to a solution of 0.376 g (0.001 mol) of [K(18-crown-6)][*t*BuO][10] in 5 mL of the same solvent. The solution was warmed to 20 °C, stirred for 1 h, and the solvent was distilled off under vacuum to give a white crystalline residue. Compound **2** (0.144 g; 0.001 mol) and 10 mL of MeCN were added at –30 °C, and the wine-red solution obtained was warmed to 20 °C, stirred for 1 h, filtered and the solvents evaporated under vacuum. The residue was washed with 10 mL of $Et_2O$, dissolved in 5 mL of boiling MeCN under normal pressure, and the solution was cooled to 20 °C. The solvent was removed with a syringe, and the crystals were washed with 10 mL of $Et_2O$ and dried in vacuo.

Salt **5** forms transparent ruby plates, yield 0.402 g (90%), m.p. (sealed capillary) 135 °C (dec.).

Evaporation of the initially obtained $Et_2O$ solution gave PhSSPh (97%) identified by GC-MS technique via comparison with an authentic sample.

**Synthesis of Salt 6:** At –30 °C, a solution of 0.182 g (0.001 mol) of Ph–S–$SiMe_3$[9] in 1 mL of MeCN was added to a solution of 0.275 g (0.001 mol) of $[(Me_2N)_3S][Me_3SiF_2]$ (TASF)[11] in 5 mL of the same solvent. The solution was warmed to 20 °C, stirred for 1 h, and the solvent was distilled off under vacuum to give a white crystalline residue. A solution of 0.144 g (0.001 mol) of **2** in 10 mL of MeCN was added at –30 °C, the wine-red reaction mixture was warmed to 20 °C, stirred for 1 h, filtered and the solvents evaporated under vacuum. The residue was washed with 10 mL of $Et_2O$ and dissolved in 5 mL of MeCN. Then 10 mL of $Et_2O$ were recondensed onto the solution at –196 °C and the two-layered system was placed into cryostat at –40 °C. The solvent was removed with a syringe, and the crystals were washed with 10 mL of $Et_2O$ and dried in vacuo.

Salt **6** forms transparent red needles, yield 0.230 g (75%), m.p. (sealed capillary) 92 °C (dec.). $C_8H_{18}N_7S_3$ (308.48): calcd. C 31.15, H 5.88, N 31.78, S 31.18; found C 31.30, H 5.74, N 31.85, S 31.06.

The PhSSPh by-product (95%) was identified as described above.

**Preparation of Salt 7:** Upon storage under mother liquor for a few days at ambient temperature, salt **5**, crystallized as described above, transformed slowly into salt **6** (ruby crystals turned to dark-brown). The solvent was removed with a syringe, and the crystals were washed with 10 mL of $Et_2O$ and dried under vacuum for a short time.

Salt **7** forms dark-brown prisms (orange in transmitting light), yield 0.333 g (65%), m.p. (sealed capillary) 125 °C (dec.).

At –196 °C, 10 mL of $Et_2O$ were recondensed onto a solution of 0.224 g (0.5 mmol) of salt **5** into 5 mL of MeCN and the system was placed into a cryostat at –40 °C. The solvent was removed with a syringe, and the crystals of salt **7** (0.243 g, 95%) were washed with 10 mL of $Et_2O$ and dried under vacuum for a short time.

## Acknowledgments

The authors are grateful to Prof. Yuri V. Gatilov for valuable discussions, to Mr. Peter Brackmann for his assistance in the XRD experiments, and to the Deutsche Forschungsgemeinschaft, Germany (grant 436 RUS 113/486/0-3 R), the Russian Foundation for Basic Research, Russia (grants 02-03-04001 and 06-03-32742), and the Siberian Division of the Russian Academy of Sciences (interdisciplinary project N 25) for financial support of this work. A. M. and A. Z. thank the Council for the President of Russian Federation's Grants for Young Scientists and Their Supervisors (grant MK-3178.2005.3), and A. M. thanks the National Science Support Foundation, Russia, for a postdoctoral scholarship.

# Spectroscopic, Structural and Theoretical Investigation of Alkenyl Ruthenium Complexes Supported by Sulfur–Nitrogen Mixed-Donor Ligands

**James D. E. T. Wilton-Ely,*[a] Ming Wang,[b] David M. Benoit,[c] and Derek A. Tocher[b]**

**Keywords:** Mixed-donor ligands / Ruthenium / Alkenyl / Thiolate / Ab initio / Density functional theory

A series of molecules bearing both sulfur and nitrogen donors has been investigated as ligands for σ-alkenyl ruthenium complexes. On deprotonation, the ligands, 4-amino-2-mercaptopyrimidine ($HL_1$), 2-amino-5-mercapto-1,3,4-thiadiazole ($HL_2$), 2-mercaptothiazoline ($HL_3$), 4-hydroxy-2-mercaptopyrimidine ($HL_4$) and 2-mercaptoquinoline ($HL_5$) all react with alkenyl complexes of the form [RuRCl(CO)(BTD)-$(PPh_3)_2$] [R = $CH{=}CHC_6H_5$, $CH{=}CHC_6H_4Me$-4, $C(C{\equiv}CPh){=}CHPh$; BTD = 2,1,3-benzothiadiazole] through loss of chloride and BTD ligands to yield [RuR(L)(CO)$(PPh_3)_2$]. Four of these ligands have alternative potential coordination modes and donor groups. In all cases complexation occurs to form four-membered nitrogen–sulfur chelates with the pendant amino or hydroxy functionality playing no role in coordination. In the case of the 4-aminopyrimidine-2-thiolate ($L_1$) ligand, this was confirmed by a single-crystal X-ray study. 2-Mercaptothiazoline ($L_3$) has the ability to coordinate through two sulfur donors, however, chelation to nitrogen and sulfur donors is preferred as demonstrated by a structural study. This observation is supported by theoretical calculations, which show that a complex displaying the nitrogen–sulfur chelate is of significantly lower energy than one bonded to the ligand through two sulfur donors, despite lone pairs being available in both cases.

## Introduction

The alkenyl ligand is an important member of the σ-organyl ligand family due to its presence as an intermediate in many catalytic reactions, and has attracted substantial interest over the last 40 years. Alkenyl complexes are known for many metals. This is largely due to well-established synthetic routes such as hydrometallation and the reaction of coordinated alkynes with electrophiles or nucleophiles (Scheme 1).[1]

Since the discovery of hydrometallation of alkynes by the compounds [RuHCl(CO)$L_{2/3}$] (L = P*i*$Pr_3$,[2] $PPh_3$[3]), the resulting alkenyl complexes have been the subject of much pioneering work by the groups of Werner,[10] Esteruelas[11] Santos,[12] and Caulton and Eisenstein[13] covering functional-group transformation, ligand exchange and theoretical calculations. The hydride complexes themselves are known for their ability to catalyse hydrogenation,[14,15] hydrocarbonylation[16] and hydrosilylation[15,17] reactions as well as the formation of diynes.[18]

Previous work from members of this group has concentrated on alkenyl complexes supported by bidentate and tridentate nitrogen and sulfur donor ligands and the reactions of these complexes.[19] This complemented work by other groups exploring the effect of polydentate donors on the structure and reactivity of alkenyl complexes. The majority of this research has concentrated on the use of symmetrical, bidentate phosphorus,[20] nitrogen[21] or chalcogen donors.[22] The investigation of mixed-donor ligands has been largely confined to simple, often homoleptic, coordination compounds. In particular, very few organometallic compounds bearing these ligands have been reported. The work reported here is part of a programme[23] to synthesise σ-

alkenyl complexes bearing mixed-donor bidentate ligands and to investigate their effect on migratory insertion reactions and hemilabile behaviour in these complexes.

Although the coordination chemistry of sulfur derivatives of nucleic bases has received sporadic attention due to the interest in metal-based drugs,[24] the potential of thionucleobases and related molecules as sulfur–nitrogen mixed-donor ligands for organotransition-metal compounds has been overlooked. The reactions of five such molecules with coordinatively-saturated σ-alkenyl ruthenium complexes bearing the labile 2,1,3-benzothiadiazole ligand are discussed below. Four of the ligands have alternative possible coordination modes to those adopted and this aspect is explored in one case using a combination of structural and computational methods.

## Results and Discussion

The organometallic starting materials used in this work are the 2,1,3-benzothiadiazole (BTD) complexes [Ru(alkenyl)Cl(CO)(BTD)($PPh_3$)$_2$],[25] which provide a useful alternative to the 16-electron starting materials, [Ru(alkenyl)Cl(CO)($PPh_3$)$_2$]. The BTD compounds do not suffer contamination by free triphenylphosphane and yield microcrystalline starting complexes of excellent purity, which can be easily (re)crystallized from dichloromethane/ethanol mixtures.

4-Amino-2-mercaptopyrimidine (2-thiocytosine) has been shown to play a role in *E. coli* transfer-RNA,[26] and its coordination chemistry has been explored with a number of metals.[27] Of the coinage metals, copper[28] and silver[29] coordination complexes have been reported, and work by members of our group has investigated its use in supramolecular networks of gold(I) based on hydrogen and aurophilic bonding.[30] In all these reports, the thionucleobase is bonded through sulfur, in many cases as a monodentate ligand. In one study,[31] the cisplatin analogue, [$PtCl_2(L_1)_2$], was prepared, in which 2-thiocytosine is bonded through the amino group, demonstrating the range of coordination options available. Only one organometallic complex (of tin) has been reported very recently.[32]

Treatment of a suspension of [Ru(CH=CHC$_6$H$_4$Me-4)Cl(CO)(BTD)($PPh_3$)$_2$] and 4-amino-2-mercaptopyrimidine in dichloromethane with an ethanolic solution of sodium methoxide led to an immediate colour change from red to yellow. A yellow microcrystalline solid was isolated. This gave rise to a singlet resonance in the $^{31}P\{^1H\}$ NMR spectrum at $\delta$ = 42.1 ppm, indicating a *trans* disposition of the two phosphane ligands; a feature common to all the complexes reported here. The retention of the alkenyl ligand was confirmed by a doublet at 5.84 ($J_{HH}$ = 16.4 Hz) for the β proton and a doublet of triplets to lower field for the α proton at $\delta$ = 7.77 ppm ($J_{HH}$ = 16.4 Hz, $J_{HP}$ = 4.3 Hz) in the $^1$H NMR spectrum. The tolyl substituent was observed as an $(AB)_2$ system at 6.46, 6.87 ppm ($J_{AB}$ = 7.9 Hz) and a methyl resonance at $\delta$ = 2.22 ppm. The mixed-donor ligand itself was identified by a singlet at 4.37 ($NH_2$) and doublet resonances at 4.98 and 6.65 ppm, showing a coupling of 6.3 Hz between the pyrimidine protons. These values are shifted to higher field compared to those at $\delta$ = 5.96 and 7.47 ppm ($J_{HH}$ = 7.15 Hz) in the free ligand.[33] A molecular ion at *m*/*z* = 897 in the Fast Atom Bombardment (FAB) mass spectrum and elemental analysis of the dichloromethane solvate confirmed the overall composition as [Ru(CH=CHC$_6$H$_4$Me-4)($L_1$)(CO)($PPh_3$)$_2$] (**1**) (Scheme 2).

Reaction of [Ru{C(C≡CPh)=CHPh}Cl(CO)(BTD)($PPh_3$)$_2$] with $HL_1$ in a similar manner yielded the disubstituted alkynyl derivative [Ru{C(C≡CPh)=CHPh}($L_1$)-

$(CO)(PPh_3)_2]$ (**2**), which gave rise to a ν(C≡C) absorption of low intensity at 2147 $cm^{-1}$ for the enynyl ligand. A broadened singlet at 4.5 ppm was observed in the $^1H$ NMR spectrum for the $NH_2$ group. In addition to a singlet for the vinylic proton ($\delta$ = 6.13 ppm) and resonances due to the aromatic protons of the alkenyl substituents, two doublets were observed at $\delta$ = 5.12 and 7.69 ppm ($J_{HH}$ = 6.3 Hz) in the $^1H$ NMR spectrum of **2**. The chemical shift of the latter resonance was shifted by approximately 1 ppm downfield with respect to the same feature in complex **1**. A possible explanation for this observation is provided by the crystal structure obtained from single crystals of **2**, grown by slow diffusion of ethanol into a dichloromethane solution of the complex (Figure 1).

An interaction of around 2.6 Å was observed between the triple bond of the enynyl ligand (C10–C11) and the closest proton of the pyrimidine ring (C19–H). The presence of this interaction in solution could explain the apparent deshielding of the proton and hence its shift to lower field. Such CH–π interactions are often found in terminal alkynes,[34] such as in (±)-3-phenylbut-l-ynol, where the distance to the midpoint of the triple bond is 2.62 Å.[34c] On the basis of this evidence, the proton resonances at $\delta$ = 5.12 and 7.69 ppm were assigned to the $H^5$ and $H^6$ protons, respectively.

Recent reports have shown 2-amino-5-mercapto-1,3,4-thiadiazole ($HL_2$) to be an effective corrosion inhibitor for copper[35] and bronze.[36] The properties of its metal complexes have been examined in the inhibition of carbonic anhydrase.[37] $[Ru(CH=CHPh)Cl(CO)(BTD)(PPh_3)_2]$ reacts with $HL_2$ in the presence of base to provide $[Ru(CH=CHPh)(L_2)(CO)(PPh_3)_2]$ (**3**) in good yield. The presence of the mixed-donor ligand was indicated in the $^1H$ NMR spectrum by a singlet at $\delta$ = 5.22 ppm for the $NH_2$ group, along with typical spectroscopic features for the alkenyl ligand. The formulation of the structure (Scheme 2) was based on these data, a molecular ion at $m/z$ = 889 and elemental analysis.

Thiazoline-2-thiolate ($L_3$) has been used as a bridging ligand for palladium centres[38] and to generate polymeric clusters of $Cu^I$ and $Ag^I$.[39] It has also been employed as a ligand in precursor complexes for the deposition of cadmium selenide.[40] However, the potential of the ligand as a bidentate donor has not been widely explored.[41]

The yellow compound $[Ru(CH=CHC_6H_4Me\text{-}4)(L_3)(CO)(PPh_3)_2]$ (**4**) was isolated from the reaction of $HL_3$ with $[Ru(CH=CHC_6H_4Me\text{-}4)Cl(CO)(BTD)(PPh_3)_2]$ and base (Scheme 2). Similar spectroscopic features for the alkenyl ligand were observed in the $^1H$ NMR spectrum as for **1**. Two triplets were also present in the spectrum at $\delta$ = 2.13 and 2.36 ppm, and these were assigned to the thiazoline ring protons showing mutual coupling of 8.2 Hz. The corresponding enynyl derivative, $[Ru\{C(C\equiv CPh)=CHPh\}(L_3)(CO)(PPh_3)_2]$ (**5**), was prepared in an identical manner. Co-

ordination of the ligand through a thiolate linkage was expected in view of the basic conditions employed and this assumption was reinforced by the observation of NaCl precipitation during the reactions. However, it was not clear whether a bidentate chelate would be achieved through the sulfur or the nitrogen donor on the thiazoline ring. A theoretical study was undertaken in order to examine the mode of coordination of $L_3$. This showed that the chelate should form through sulfur and nitrogen donors rather than both sulfur donors and revealed that there is a significant energy difference between the S,S and S,N coordination modes, favouring the latter (Computational Section). These calculations were found to be in good agreement with a later structural determination using single crystals of the enynyl derivative, [Ru{C(C≡CPh)=CHPh}($L_3$)(CO)($PPh_3$)$_2$] (**5**), which were grown by slow diffusion of ethanol into a dichloromethane solution of the complex (Figure 2).

The thionucleobase, 4-hydroxy-2-mercaptopyrimidine ($HL_4$), also known as 2-thiouracil, has been used to prepare coordination compounds with a number of metals.[42,27a,27k,31] Recent work has investigated the redox properties of complexes using 2-thiouracil as a bridging ligand between ruthenium centres.[27m] However, no organoruthenium species stabilized by this ligand have been reported as far as we are aware.

[Ru{C(C≡CPh)=CHPh}Cl(CO)(BTD)($PPh_3$)$_2$] reacted readily with $HL_4$ and base to yield [Ru{C(C≡CPh)=CHPh}($L_4$)(CO)($PPh_3$)$_2$] (**6**), the hydroxy analogue of the 4-aminopyrimidine-2-thiolate complex, **2**, in excellent yield (Scheme 2). The coordination of the ligand was assumed to be through the N1 and sulfur donors in order to minimize steric interaction between the hydroxy group and the carbonyl and enynyl ligands. Coordination of $L_4$ is also possible as an oxygen–nitrogen mixed-donor. This seemed unlikely, given the thiophilicity of ruthenium(II) and was ruled out by the observation of a broadened singlet at $\delta$ = 1.75 ppm for the hydroxy proton. A doublet for one of the pyrimidine protons was noted at $\delta$ = 5.22 ppm ($J_{HH}$ = 7.3 Hz) which was assigned to $H^5$ on the basis of HMQC and HMBC experiments. The $H^6$ resonance ($\delta$ = 7.43 ppm, $J_{HH}$ = 7.7 Hz in the free ligand[33]) was obscured by the aromatic resonances.

Walton and co-workers have investigated the coordination properties of quinoline-2-thiolate ($L_5$) with rhenium complexes[43] and a few examples have been isolated for molybdenum,[44] cobalt[45] and gold.[46] $HL_5$ has also been used as an analytical reagent for the determination of nickel, copper and palladium.[47] Reaction of a suspension of [Ru(CH=CH$C_6H_4$Me-4)Cl(CO)(BTD)($PPh_3$)$_2$] with $HL_5$ and sodium methoxide resulted in the formation of the yellow complex [Ru(CH=CH$C_6H_4$Me-4)($L_5$)(CO)($PPh_3$)$_2$] (**7**). The peaks observed in the $^1$H NMR spectrum for the alkenyl ligand are similar to those seen in the spectra of **1**, **3** and **4**. The protons of the quinoline rings are all obscured

by the resonances of the $PPh_3$ ligands with the exception of one proton, which gives rise to a doublet at $\delta$ = 7.92 ppm ($J_{HH}$ = 8.3 Hz). The overall formulation is based on these data, a molecular ion in the FAB mass spectrum at $m/z$ = 931 and elemental analysis.

## Structural Discussion

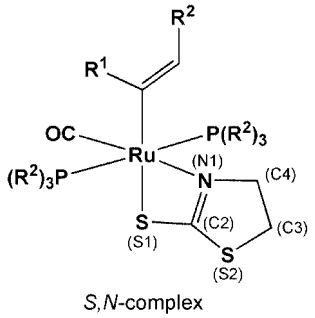
The structure of [Ru{C(C≡CPh)=CHPh}($L_1$)(CO)($PPh_3$)$_2$] (**2**) (Figure 1) has a distorted octahedral geometry with *cis*-interligand angles in the range 65.49(9)–104.98(13)°. The smallest of these angles corresponds to the bite angle, N1–Ru1–S1, of the 4-aminopyrimidine-2-thiolate ligand ($L_1$). The structure of 4-amino-5-methylmercaptopyrimidine has been determined[48] and can be assumed to be a direct analogue of the free ligand, $HL_1$. This report revealed that the molecule exists essentially in the thione form, however, on coordination to divalent ruthenium in our system, the bond lengths of $L_1$ were observed to be shifted towards the thiolate form. This is seen in the lengthening of the C–S distance from 1.710(4) to 1.730(4) Å in **2**, while the N1–C18 distance shortens from 1.371(5) to 1.346(5) Å on coordination. A complex with the related ligand, 4-methylpyrimidine-2-thiolate (mpymt), [Ru(mpymt)(bpy)$_2$]$^+$ (bpy = 2,2′-bipyridine) has been reported,[42e] in which the C–S distance [1.711(8) Å] is shorter, and the bond length corresponding to N1–C18 [1.367(9) Å] is approximately the same as that found in **2**. This indicates that complexation of $L_1$ in **2** represents a greater shift from the thione to thiolate form than observed in the literature complex. The Ru–S and Ru–N distances for the chelate in [Ru(mpymt)(bpy)$_2$]$^+$ [2.408(2) and 2.103(6) Å, respectively] are considerably shorter than the corresponding distances in **2** of 2.513(11) and 2.176(3) Å. This is likely to be due to the stronger *trans*-influence of the carbonyl and alkenyl donors in [Ru{C(C≡CPh)=CHPh}($L_1$)(CO)($PPh_3$)$_2$] (**2**) compared to 2,2′-bipyridine in the literature complex. The bite angle of $L_1$ in **2** [65.49(9)°] is also smaller than that of 68.2(2)° found in [Ru(mpymt)(bpy)$_2$]$^+$. The bond lengths associated with the alkenyl ligand were found to be unremarkable and fall within the typical range for these ligands.[49] As mentioned above (Results and Discussion), the close proximity of the $H^6$ proton of $L_1$ and the triple bond C10–C11 of the enynyl ligand appears to indicate an interaction that is also present in solution, as suggested by $^1$H NMR evidence.

The structure of 2-mercaptothiazoline ($HL_3$) was only reported very recently and revealed that the molecule adopts the expected thione form in the solid state with the C–S bond [1.6745(16) Å] displaying clear double bond character.[50] As was found for $HL_1$, coordination in the deprotonated form results in a shift of double bond character from the C–S bond to the N–C bond involved in the chelate. The C2–S1 distance of 1.720(2) Å found in the structure of [Ru{C(C≡CPh)=CHPh}($L_3$)(CO)($PPh_3$)$_2$] (**5**) (Figure 2) is considerably longer than that in the free ligand and the N1–C2 distance of 1.283(3) Å is shorter than the corresponding bond length in $HL_3$, 1.319(2) Å. These variations between bonding in the ligand in free and coordinated states are greater than those discussed for $HL_1$ above. The bond lengths between the donors and the ruthenium centre are essentially the same in both **2** and **5** with the exception of the Ru1–S1 bond length, which is around 0.03 Å longer in complex **5**. Unlike the 4-aminopyrimidine-2-thiolate ($L_1$) ligand, the thiazoline-2-thiolate ($L_3$) moiety is not planar due to the saturated C3–C4 linkage. The overall geometry of the structure of **5** is distorted octahedral with *cis*-interligand angles in the range 65.13(5) – 108.27(7)°, the smallest being due to the bite angle of the bidentate ligand. The bond lengths and distances of the enynyl ligand are similar to those found in [Ru{C(C≡CPh)=CHPh}($L_1$)(CO)($PPh_3$)$_2$] (**2**).

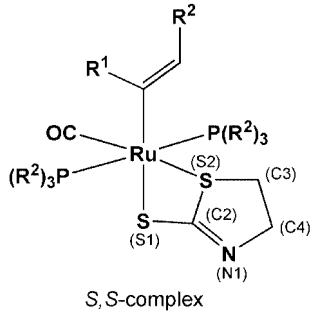
## Computational Study

In order to assess the relative stability of the S,N- and S,S-bonding modes available to the complex, [Ru{C(C≡CPh)=CHPh}($L_3$)(CO)($PPh_3$)$_2$] (**5**), it was decided to use ab initio and density functional theory calculations to compute the optimized geometry of two model complexes derived from structure **5**. The calculations were performed using the NWChem4.6 ab initio package[51] running on a dual processor Apple Xserve. Each optimization was performed using analytic gradients and the default convergence criteria of NWChem.

The simplest model for our computational study is obtained by substituting all phenyl groups and $R^2$ by hydrogen atoms, thus reducing the enynyl ligand to the parent alkenyl (Scheme 3).



*S,N*-complex



*S,S*-complex

Scheme 3. Computational model. Model A corresponds to $R^1$ = $R^2$ = H. Model B is for $R^1$ = C≡C$CH_3$ and $R^2$ = $CH_3$. Numbering scheme is the same as that used in the structural study.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The modest size of model A, along with the use of relativistic pseudo-potentials for each atom developed by Stevens, Basch and Krauss,[52] allowed us to perform fast exploratory calculations using both the Hartree–Fock (HF) method and the local density approximation (LDA) of density functional theory.

The results of our calculations are shown in Table 1, where we report a selection of metal–ligand distances. We observe that the HF distances are much larger than those measured in the experimental X-ray structure, in particular for the two phosphanes and the Ru–S bond. This is to be expected since this method does not take electronic correlation into account. The LDA results for the *S,N*-bonded structure on the other hand are in good agreement with the X-ray values, showing the importance of correlation in describing the electronic structure of transition metal complexes. Moreover, the good agreement with experiment suggests that the computed values for the S,S complex, which was not isolated experimentally, are a plausible representation of the geometrical environment around the ruthenium atom in the S,S system.

In particular, we note that for both levels of theory the S,S complex exhibits a strong degree of ring bending which is absent in the S,N complex. Indeed, Table 1 shows that, while the out-of-plane angle Ru1–S1–C2–C4 remains very low for the S,N complex (about 3° to 5°), the S,S complex has out-of-plane angles between –128° and –110° which indicate that the hybridization of the second sulfur atom (S2) is close to tetrahedral. This, in turn, forces the rest of the thiazoline ring to bend out of the equatorial plane to accommodate the bonding mode of both sulfur donors. The out-of-plane angle computed for the S,N complex on the other hand is in good agreement with that measured in the X-ray structure of –4.5°.

In Table 2, we observe that, for model A, the computed difference of total energy is in favour of the S,N complex in both types of calculations (HF and LDA), which is in line with the experimental observation. The HF method predicts a relatively large energy difference of about 92 kJ·mol$^{-1}$ which is likely to be an overestimation compared to the true value owing to the lack of an appropriate treatment of the electronic correlation. The correlated result computed using LDA brings the energy difference down to about 66 kJ·mol$^{-1}$ which still indicates a very strong preference of the ruthenium for S,N coordination over S,S complex formation.

Table 2. Total energy differences for the *S,N*- and *S,S*-bonded ruthenium structures computed at various levels of ab initio theory.

| | Level of theory | E(S,N complex) – E(S,S complex) |
|---|---|---|
| Model A | HF | – 92.35 kJ·mol$^{-1}$ |
| | LDA | – 65.93 kJ·mol$^{-1}$ |
| Model B | LDA | – 65.41 kJ·mol$^{-1}$ |
| | BP86 | – 64.91 kJ·mol$^{-1}$ |

It has been shown that steric effects can have a great influence on the energetics of ruthenium complexes[53] and, to assess the influence of bulkier phosphane and alkenyl ligands, we replaced the hydrogen atoms of our simple model by methyl and propynyl groups to generate Model B (Scheme 3). The influence of these groups on the stability of the bent ring in the S,S complex can result in an increase of the total energy difference between the S,N and S,S complexes. While these groups cannot account for the overall steric bulk of the phenyl groups used experimentally, we expect that any important steric effects would become apparent with this more limited substitution.

The model B compounds were optimized using local density functional theory and then further refined using a gradient-corrected exchange and correlation functional BP86, which has been developed by Becke and Perdew.[54] It has been shown that this exchange and correlation functional gives good results for transition-metal complexes[55] and ruthenium complexes containing carbonyl ligands in particular.[56]

Our results for these calculations are shown in Table 1 and Table 2. First, we see that the change from model A to model B has a small influence on the computed bond lengths and improves their agreement with the X-ray measurements. We note a slight elongation of the Ru–P bonds for both S,N and S,S complexes and a small contraction of the Ru–S distance for the structure with the S,N coordina-

Table 1. Selected metal–ligand distances for the *S,N*- and *S,S*-bonded ruthenium complex computed at various levels of ab initio theory. The atomic numbering scheme is identical to that in Figure 2.

tion mode. The values for the out-of-plane angle are also mildly affected and we see both types of complexes becoming slightly flatter. These observations suggest that the steric effects are small and indicate that our initial model (Model A) already provided a good description of both complexes. Second, we note that the energetics of both complexes are not perturbed by the increase in steric bulk of the substituents since the total energy differences between the S,N and S,S complexes remains at about 65 kJ·mol$^{-1}$, again in favour of the S,N complex.

To further investigate the effects of electron correlation on the structure and energetics of both types of complexes, the structures obtained from the LDA calculations on model B were re-optimized using BP86. The resulting geometries for both complexes are shown in Figure 3. As expected, since gradient-corrected functionals such as BP86 tends to elongate bonds in transition metal complexes,[55] we observe a lengthening of most bonds in both complexes. In the S,N complex, BP86 overestimates the Ru–P and the Ru–S distances compared with the experimental values, while the other distances and the out-of-plane angle are relatively unaffected (see Table 1). In the case of the S,S complex, the out-of-plane angle increases and the Ru–P, Ru–S bonds are longer than calculated previously using LDA.

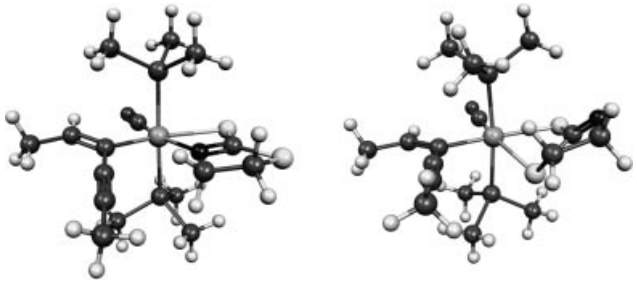

Figure 3. Optimised structures of the S,N complex (left) and S,S complex (right) for model B computed at the BP86/SBK level of theory. Note the large out-of-plane angle in the S,S structure.

Gradient-corrected functionals, such as BP86, provide a more reliable estimation of the binding energy of transition-metal complexes than the local density approximation.[55] Therefore, despite the lengthening of the metal–ligand bonds with BP86, it is interesting to note that the total energy difference between the S,N and the S,S complexes computed with this method remains similar to the value computed using LDA (about 65 kJ·mol$^{-1}$, see Table 2), again pointing to a marked preference for S,N coordination.

Both models and all levels of theory used in this study indicate that the S,N complex is thermodynamically favoured over the S,S complex. There are several possible reasons for the greater stability of a sulfur–nitrogen combination. First, the S,N configuration of the 2-mercaptothiazoline ligand is able to approach the metal centre more closely than the ligand in the S,S arrangement. Indeed, approach of an S,S donor combination is unfavourable due to the constraining bonding mode of the second sulfur atom (S2), which causes out-of-plane ring bending of the rest of the ligand. Second, the HOMO of the 2-mercaptothiazoline ligand is composed mainly of the $p_x$ orbital of the terminal sulfur atom but has a non-negligible contribution from the nitrogen atom, which allows a degree of π bonding with the ruthenium centre. The presence of π ligands in the complex already (e.g., the carbonyl group) means that an additional ligand that can act as a π donor will participate more efficiently in the bonding at the metal centre. Analysis of the molecular orbitals of the S,S complex shows that such π bonding is not possible when the metal centre is bonded to the ligand using the S,S-configuration.

In order to shed some light on a possible kinetic preference at the ligand-binding stage for the formation of the S,N complex over the S,S complex, we computed the charge distribution of the 2-mercaptothiazoline anionic ligand. This calculation was performed using the GAMESS-US suite of programs[57] at the Møllet-Plesset (MP2) level of theory with a TZV(d,p)++ basis set,[58] since it has been recognized that DFT can have problems describing anions.[59] It should be noted that there is a large negative region around the sulfur atom that protrudes out of the thiazoline ring (S1) and around the N atom (N1), while the sulfur atom within the thiazoline ring (S2) is mainly positively charged. This charge distribution could be responsible for a preferential formation of a S,N complex since the orientation of this anionic ligand with respect to a positively charged centre such as $Ru^{II}$ will naturally lead to a closer contact between the metal centre and the atoms S1 and N1.

## Conclusions

This report details the investigation of the coordination properties of five nitrogen–sulfur mixed-donor ligands with alkenyl complexes of ruthenium. We believe that these are the first organoruthenium examples to be reported. Although a number of alternative coordination modes are possible, all ligands adopt a four-membered nitrogen–sulfur chelate, a fact confirmed crystallographically for two examples. In the case of the thiazoline-2-thiolate ligand, the alternative sulfur–sulfur coordination mode was investigated computationally and found to be of much higher energy than the observed S,N coordination, which was confirmed by a structural determination. The excellent correlation of structural and computational data indicates the utility of this theoretical approach in the rationalization of such complexation behaviour.

## Experimental Section

All manipulations were carried out under aerobic conditions with commercially available solvents and reagents, which were used as received. Infrared and NMR spectroscopy was carried out at 25 °C using Shimadzu FTIR 8700 (KBr plates and nujol mulls) and Bruker AMX-300 ($^1$H: 299.87 MHz, $^{31}$P: 121.39 MHz) spectrometers respectively. Infrared spectroscopic features due to the triphenylphosphane ligands have been omitted to aid clarity. FAB-MS spectra (nitrobenzyl alcohol matrices) were measured using a VG 70-SB magnetic sector mass spectrometer. Elemental analysis

was performed at University College, London. Solvates were determined by integration of the $^1$H NMR spectra. The complexes [Ru(CH=CHC$_6$H$_4$CH$_3$-4)Cl(CO)(BTD)(PPh$_3$)$_2$],[25] [Ru(CH=CHPh)Cl(CO)(BTD)(PPh$_3$)$_2$],[25] [Ru{C(C≡CPh)=CHPh}Cl(CO)(PPh$_3$)$_2$],[60] were prepared according to published procedures. All other regents were obtained commercially.

**Preparation of [Ru(CH=CHC$_6$H$_4$Me-4)(L$_1$)(CO)(PPh$_3$)$_2$] (1):** [Ru(CH=CHC$_6$H$_4$Me-4)Cl(CO)(BTD)(PPh$_3$)$_2$] (100 mg, 0.106 mmol) and 4-amino-2-mercaptopyrimidine (HL$_1$) (15 mg, 0.118 mmol) were suspended in dichloromethane (20 mL) and ethanol (10 mL) and treated with sodium methoxide (11 mg, 0.204 mmol) in ethanol (10 mL). The reaction was stirred for 1 h, after which the solvent volume was concentrated under reduced pressure until precipitation of a pale yellow product was complete. This was washed with water (5 mL), ethanol (5 mL) and hexane (10 mL). Yield: 68 mg (72%). IR (KBr/nujol): $\tilde{\nu}$ = 1923 [ν(CO)], 1614, 1572, 1545, 1313, 1256, 1186 cm$^{-1}$. $^{31}$P{$^1$H} NMR (CDCl$_3$): $\delta$ = 42.1 ppm. $^1$H NMR (CDCl$_3$): $\delta$ = 2.22 (s, 3 H, CH$_3$), 4.37 (s, 2 H, NH$_2$), 4.98, 6.65 [d×2, $J_{HH}$ = 6.3 Hz, 2×1 H, C$_4$*H*$_2$(NH$_2$)N$_2$S], 5.84 (d, $J_{HH}$ = 16.4 Hz, 1 H, Hβ), 6.46, 6.87 [(AB)$_2$, $J_{AB}$ = 7.9 Hz, 4 H, C$_6$H$_4$], 7.25, 7.58 (m×2, 30 H, C$_6$H$_5$), 7.77 (dt, $J_{HH}$ = 16.4 Hz, $J_{HP}$ = 4.3 Hz, 1 H, Hα) ppm. FAB-MS: *m*/*z* (%) = 897 (1) [M]$^+$, 780 (1) [M – alkenyl]$^+$, 635 (2) [M – PPh$_3$]$^+$. C$_{50}$H$_{43}$N$_3$OP$_2$RuS·CH$_2$Cl$_2$ (981.93): calcd. C 62.4, H 4.6, N 4.3; found C 62.8, H 4.8, N 4.3.

**Preparation of [Ru{C(C≡CPh)=CHPh}(L$_1$)(CO)(PPh$_3$)$_2$] (2):** Synthesis as for **1** using [Ru{C(C≡CPh)=CHPh}Cl(CO)(BTD)(PPh$_3$)$_2$] (100 mg, 0.097 mmol) and 4-amino-2-mercaptopyrimidine (HL$_1$) (14 mg, 0.110 mmol) to provide a yellow product. Yield: 72 mg (76%). IR (KBr/nujol): $\tilde{\nu}$ = 2147 [ν(C≡C)], 1913 [ν(CO)], 1611, 1580, 1537, 1312, 1186, 972, 914 cm$^{-1}$. $^{31}$P{$^1$H} NMR (CDCl$_3$): $\delta$ = 40.1 ppm. $^1$H NMR (CDCl$_3$): $\delta$ = 4.5 (br. s, 2 H, NH$_2$), 5.12, 7.69 [d×2, $J_{HH}$ = 6.3 Hz, 2×1 H, C$_4$*H*$_2$(NH$_2$)N$_2$S], 6.13 (s, 1 H, RuC=CH), 6.78 (d, $J_{HH}$ = 7.4 Hz, 2 H, *ortho*-C$_6$H$_5$), 6.95 (t, $J_{HH}$ = 7.4 Hz, 1 H, *para*-C$_6$H$_5$), 7.27, 7.61 (m×2, 30 H + 7 H, PC$_6$H$_5$ + C$_6$H$_5$) ppm. glass fibre and all geometric and intensity data were taken from this sample with a Bruker SMART APEX CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data reduction and integration was carried out with SAINT+ and absorption corrections applied using the program SADABS. The structures were solved by direct methods and developed using alternating cycles of least-squares refinement and difference-Fourier synthesis. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions and their thermal parameters linked to those of the atoms to which they were attached (riding model). Structure solution and refinement used the SHELXTL PLUS V6.10 program package.[61] See Table 3 for selected crystal data.

CCDC-263406 and -263407 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

J. D. E. T. W.-E. gratefully acknowledges the Ramsay Memorial Trust for provision of a Fellowship and Merton College, Oxford, for a Fitzjames Fellowship. We thank the Department of Chemistry at UCL, the University of London Central Research Fund and the UCL Graduate School for funding and Johnson Matthey Ltd. for a generous loan of ruthenium salts.

# Symmetrisation in the Interaction of Chloro[2-(dimethylaminomethyl)phenyl-$C^1$]mercury(II) with Thiosemicarbazone Derivatives of Pyridine-2-carboxamide and Pyrazin-2-carboxamide

**Ulrich Abram,[b] Alfonso Castiñeiras,*[a] Isabel García-Santos,[a] and Raul Rodríguez-Riobó[a]**

**Keywords:** Mercury complexes / Symmetrisation / Thiosemicarbazones / Crystal structures / Weak hydrogen bonds / C–H···π interactions

Pyridine- and pyrazine-2-carboxamide thiosemicarbazones (HAm4DH and HAmpz4DH) or their $N^4$,$N^4$-dimethyl derivatives (HAm4DM and HAmpz4DM) react with chloro[2-(dimethylaminomethyl)phenyl-$C^1$]mercury(II), [Hg(damp)Cl], to give the tetrahedral [Hg(TSC)$_2$] complexes [TSC = Am4DH (**1**), Am4DM (**2**), Ampz4DH (**3**) or Ampz4DM (**4**)]. Spectroscopic studies and a X-ray structural analysis show that the potentially tridentate thiosemicarbazones adopt S,N coordination modes, with each deprotonated thiosemicarbazone binding to the $Hg^{II}$ centre through the azomethine nitrogen and the thiolate sulfur atoms, whereas the heterocyclic nitrogen atoms are free of coordination. Intra- and intermolecular hydrogen bonding in all complexes and specific C–H···π interactions with the chelate or pyridyl rings of the complexes **1** and **2** were found in the crystal structures. Furthermore, [Hg(damp)Cl] undergoes symmetrisation to give the symmetric unit [Hg(Hdamp)$_2$]$^{2+}$ in which the Hdamp is protonated at the nitrogen.

## Introduction

Thiosemicarbazones have been extensively studied due to their pharmacological properties and their coordinative behaviour towards transition-metal ions.[1] However, very few mercury(II) complexes with thiosemicarbazones are known.

The reaction of potentially tridentate thiosemicarbazones, such as 2-acetylpyridine thiosemicarbazone or pyridine-2-carboxamide thiosemicarbazone, with $Hg^{II}$ salts gives rise to five-coordinate compounds [Hg(HL)X$_2$] (X = Cl, Br or I) in which coordination to the metal centre occurs through the pyridine and azomethine nitrogen atoms and the thiocarbonyl sulfur atom (Scheme 1, a).[2–6] Furthermore, compounds such as 2-acetylpyridine *N*-oxide $N^4$,$N^4$-dimethylthiosemicarbazone can act as N,S-bidentate ligands for mercury halides in which the metal atom has a coordination number four with the same formula [Hg(HL)X$_2$] for the complexes (Scheme 1, b).[7] These thiosemicarbazones can also form dimeric or polymeric complexes in which the sulfur or the halogen acts as a bridge between metal centres and, in some cases, they also behave as S-monodentate ligands (Scheme 1, c) to form complexes of the formula [Hg(HL)$_2$X$_2$], where the mercury atom has a tetrahedral coordination geometry.[5,6,8,9]

Pyridine-2-carboxamide and pyrazine-2-carboxamide thiosemicarbazone derivatives (Figure 1) are almost always N,N,S-tridentate ligands[2–6] but are sometimes unidentate ligands that coordinate through the sulfur atom.[6] Only in two rhenium complexes does the 2-cyanopyridine thiosemicarbazone act as an N,N-bidentate ligand through the pyridine and azomethine nitrogen atoms (Scheme 2, a)[10] or through the amide and imine nitrogen atoms (Scheme 2, b).[11]

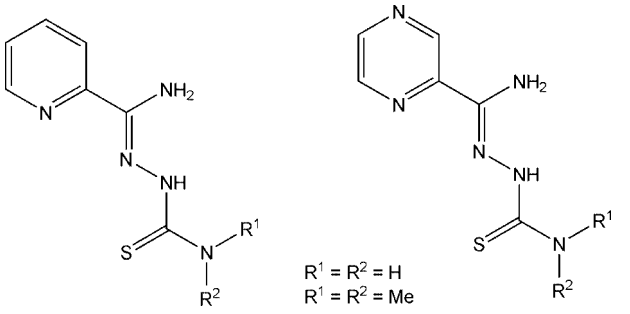

Figure 1. Pyridine-2-carboxamide and pyrazine-2-carboxamide thiosemicarbazone derivatives (left and right, respectively).

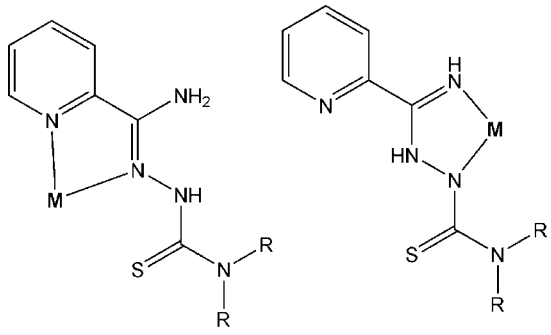

Scheme 2.

The coordination chemistry of organomercury(II) is not as extensive as that of mercury(II) salts such as halides or pseudohalides, probably because organomercury(II) derivatives have a lower tendency to increase their coordination by interaction with donor molecules. Organomercury(II) substrates, RHgX, are known to undergo symmetrisation to form symmetric diorganomercury $HgR_2$ and $Hg^{II}$ complexes.[12–15] Bidentate thiosemicarbazones react with organomercury(II) (RHgX) to form three-coordinate complexes [HgR(TSC)] (R = Ph or Me, TSC = thiosemicarbazone).[16–18]

When "TSC" is benzaldehyde or 4-methoxybenzaldehyde, the $^{199}$Hg NMR spectrum shows two signals, one corresponding to the formation of the aforementioned complex and another corresponding to the formation of $HgPh_2$, indicating that a symmetrisation reaction has occurred. However, when the "TSC" is cyclopentanone, cyclohexanone, 2-hydroxybenzaldehyde, *N*-phenyl pyrrole-2-carbaldehyde, *N*-phenyl thiophene-2-carbaldehyde, or furan-2-carbaldehyde thiosemicarbazonate, the $^{199}$Hg spectra show only one signal, indicating the presence of a single type of chemical environment around the mercury(II) atom. The reaction between acetophenone thiosemicarbazone (Hatsc) and PhHgCl gives compounds of formula $[HgCl_2(Hatsc)_2]$, where the proposed structure is a four-coordinate complex in which the "Hatsc" is bonded to the metal through the thiocarbonyl sulfur atom, and $Ph_2Hg$ as the products of the symmetrisation reaction.[19]

In this paper we report the first examples of the reactions between pyridine-2-carboxamide or pyrazine-2-carboxamide thiosemicarbazone (HAm4DH and HAmpz4DH) and their $N^4$,$N^4$-dimethyl derivatives (HAm4DM and HAmpz4DM), which are usually N,N,S-tridentate ligands, with chloro[2-(dimethylaminomethyl)phenyl-$C^1$]mercury(II) (Figure 2). These reactions give complexes $[Hg(Am4DH)_2]$ (**1**), $[Hg(Am4DM)_2]$ (**2**), $[Hg(Ampz4DH)_2]$ (**3**) and $[Hg(Ampz4DM)_2]$ (**4**), which contain two deprotonated ligands in a bidentate mode chelating to the $Hg^{II}$ through the azomethine nitrogen and thiolate sulfur atoms, a very unusual coordination mode for these potentially tridentate ligands. Furthermore, the $^{199}$Hg NMR spectroscopic data suggest a symmetrisation phenomenon, which is also supported by $^1$H NMR and IR data. In contrast to this behaviour, it was recently reported that thiosemicarbazonate complexes of gold(III) are formed in reactions of [Au(damp-$^1$C,N)$Cl_2$] with pyridine-2-carboxamide thiosemicarbazones, where the organometallic damp$^-$ ligand is protonated during the reactions and the Au–N bond is cleaved.[20]

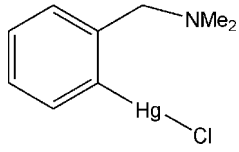

Figure 2. Chloro[2-(dimethylaminomethyl)phenyl-$C^1$]mercury(II).

## Results and Discussion

The reaction of chloro[2-(dimethylaminomethyl)phenyl-$C^1$]mercury(II), [Hg(damp)Cl], with pyridine-2-carboxamide or pyrazine-2-carboxamide thiosemicarbazone (HAm4DH and HAmpz4DH) and their $N^4$,$N^4$-dimethyl derivatives (HAm4DM and HAmpz4DM) give solids of formula $[Hg(TSC)_2]$ (TSC = deprotonated thiosemicarbazone). The products are consistent with the elemental analysis data and are colourless or yellow and quite soluble in common organic solvents.

The FAB$^+$ spectra of all complexes show peaks corresponding to $\{H_2L\}^+$, but only the $N^4$,$N^4$-dimethyl-substituted complexes show fragments that contain mercury. The spectra of **2** and **4** show peaks at *m*/*z* = 646 and *m*/*z* = 648, which can be assigned to a molecular ion of composition $\{HgHL_2\}^+$. Peaks at *m*/*z* = 423 can be assigned to the complex with a loss of a ligand, $\{HgL\}^+$. In the mass spectra of **1** and **3** only the signals due to the protonated ligand can be seen (at *m*/*z* 196 and 197, respectively).

### X-ray Crystal Structures

In the molecular structures of the complexes the geometry is essentially similar and contains four coordinate neutral $Hg(TSC)_2$ molcules. However, in the compounds **1**, **3** and **4** the mercury atom lies on a twofold axis and the asymmetric unit consists of half a molecule of complex and, as a consequence, a tetrahedral complex is formed with two chelating anionic ligands around the central metal (Figure 3). Complex **2** crystallises in the orthorhombic space group $Pna2_1$ and the Hg metal ion is tetrahedrally coordinated with two symmetrically independent thiosemicarbazone ligands as monoanionic bidentate N,S-chelators (Figure 4). Selected bond lengths and angles are listed in Table 1 and Table 2, respectively.

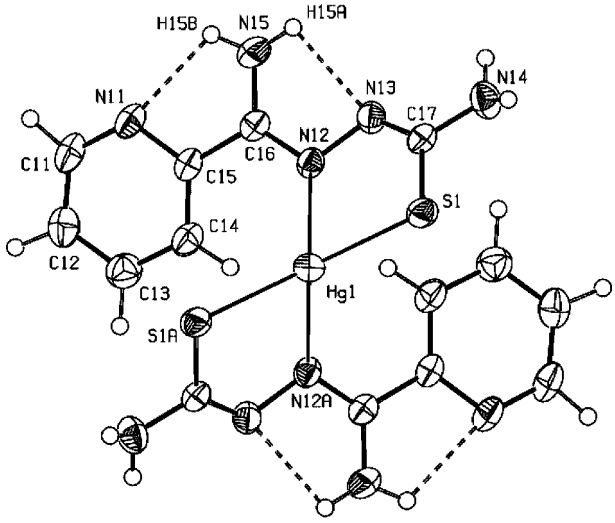

Figure 3. Structure of **1** showing the intramolecular hydrogen bonding. Symmetry codes are as given in Table 2.

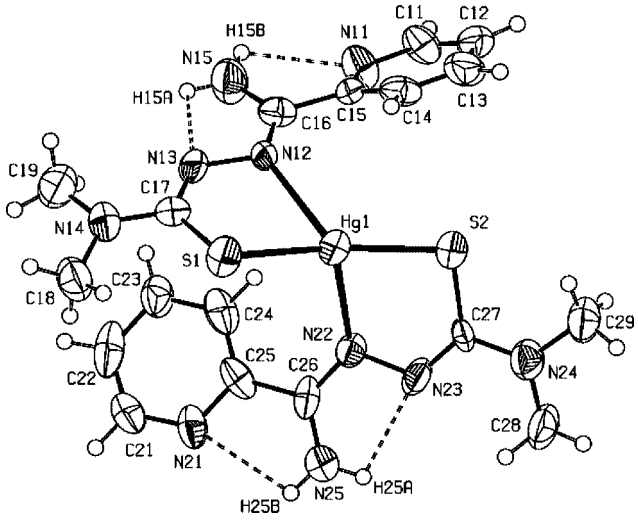

Figure 4. Asymmetric unit of **2** showing the intramolecular hydrogen bonding.

In the complexes **1**, **3** and **4** the tetrahedra are highly deformed with Hg–S bond lengths in the range 2.354(2)–2.362(1) Å, averaging 2.358(1) Å, which is a little shorter than the sum of the single-bond covalent radii (2.52 Å).[21] However, there is a significant difference between the two Hg–S distances in **2** [2.416(5) and 2.313(5) Å]. The Hg–N bond lengths [range 2.484(15)–2.540(3) Å] are somewhat longer than the Hg–N(hydrazinic) distances in tetracoordinate mercury(II) complexes, but in **1** this distance is 2.290(3) Å, which is significantly shorter. Thus, in **1** the thiolate sulfur and hydrazine nitrogen atoms are strongly bound to Hg.

Table 1. Selected bond lengths [Å] for complexes **1**–**4**.

| Bond | **1** | **2**[a] | | **3** | **4** |
|---|---|---|---|---|---|
| Hg1–N12 | 2.490(3) | 2.513(2) | 2.488(4) | 2.540(3) | 2.492(5) |
| Hg1–S1 | 2.363(1) | 2.417(1) | 2.312(1) | 2.356(1) | 2.354(2) |
| C17–S1 | 1.764(3) | 1.759(6) | 1.747(6) | 1.757(4) | 1.768(7) |
| C16–N12 | 1.311(4) | 1.35(2) | 1.302(7) | 1.304(4) | 1.305(8) |
| N12–N13 | 1.402(4) | 1.377(19) | 1.410(6) | 1.400(4) | 1.391(8) |
| N13–C17 | 1.290(4) | 1.332(7) | 1.307(7) | 1.295(4) | 1.308(9) |
| C17–N14 | 1.367(4) | 1.346(7) | 1.336(7) | 1.351(4) | 1.361(8) |
| C16–N15 | 1.340(5) | 1.342(7) | 1.334(7) | 1.347(5) | 1.340(9) |

| N13–C17–S1 | 129.6(2) | 128.2(4) | 126.0(5) | 129.5(3) | 127.6(5) |
| N14–C17–S1 | 112.9(2) | 116.8(4) | 116.9(4) | 113.3(3) | 115.4(5) |

[a] The second column corresponds to molecule II. [b] Symmetry transformations used to generate equivalent atoms: $-x$, $y$, $-z+1/2$ (**1**, **3**); $-x+1$, $y$, $-z+3/2$ (**4**).

The bond angles around the Hg centre vary over a wide range, and in any case the geometry is not clearly tetrahedral. The S–Hg–S bond angles [range 152.23(5)–159.8(2)°] deviate significantly from the ideal tetrahedral angle, but the main differences are in the N–Hg–N angles, which have values of 100.1(1) and 114.(5)° for compounds **1** and **2**, respectively, and 84.1(1) and 85.4(3)° for compounds **3** and **4**, respectively. These values seem to indicate that the pyrazine rings of the thiosemicarbazones have a significant influence on the packing.

The coordination polyhedra in the four complexes are to some extent reminiscent of those adopted by [Hg(H4DMLO)$X_2$] (X = Cl or Br, H4DMLO = 2-acetylpyridine *N*-oxide $N^4$,$N^4$-dimethyl thiosemicarbazone).[7] This can be described as a distorted trigonal pyramid with the mercury atom in the same mean plane as the nitrogen and sulfur atoms of the first thiosemicarbazone, and the sulfur atom of the symmetrical one (**1**, **3** and **4**) or of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

second thiosemicarbazone (**2**) [av. 0.2874(2) Å] (Figure 5). These coordination planes form angles in the range 5.5(1)–12.0(2)° (**1**, **3** and **4**) and 16.2(4)–36.2(2)° (**2**) with the mean plane of the thiosemicarbazone moiety.

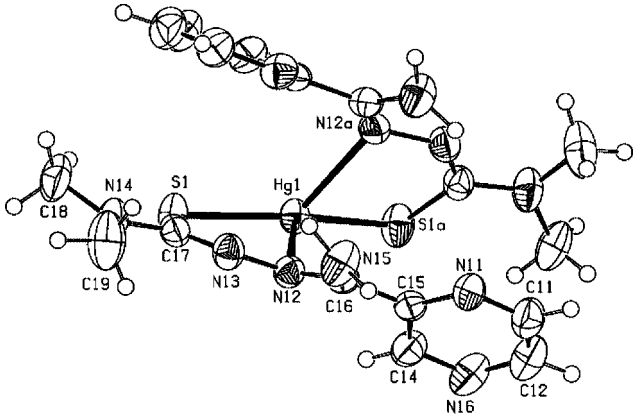

Figure 5. Perspective drawing of **4** oriented as a distorted trigonal pyramid. Symmetry codes are as given in Table 2.

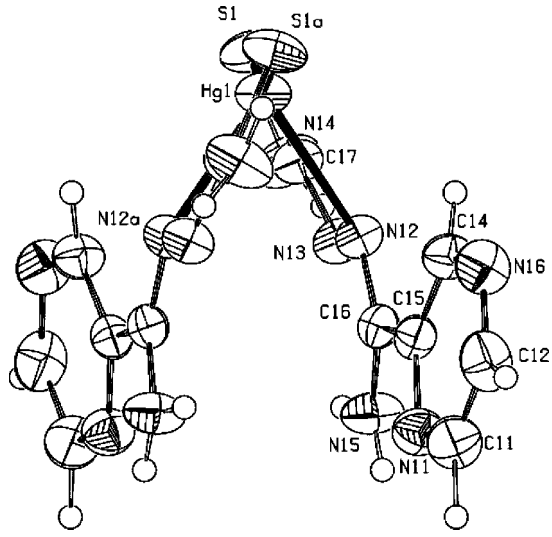

Figure 6. Parallel projection along the [101] direction showing the angle of the thiosemicarbazone moieties in the molecule of **3**. Symmetry codes are as given in Table 2.

The least-squares plane data and deviations from these planes for the complexes are listed in Table 3. In all four complexes the pyridyl and pyrazinyl rings are almost planar. In complex **1** the pyridine ring and the thiosemicarbazone moiety form a dihedral angle of 44.8(1)°, and the two thiosemicarbazonates bonded to the $Hg^{II}$ are nearly orthogonal, forming an angle of 85.3(1)°. However, in complex **2** the deviations are smaller and the angles between the pyridine and the thiosemicarbazone moieties are 25.6(8) and 29.6(7)° for the two non-symmetric ligands and the angle between the thiosemicarbazone main least-squares planes is 64.2(4)°. In complexes **3** and **4** the angles between the pyrazine ring and the thiosemicarbazone moieties are 33.3(1) and 42.7(2)°, respectively, whereas the angles between each thiosemicarbazone moiety and its symmetrical one are 46.8(1) and 45.8(2)°, respectively (Figure 6).

The bond lengths in the noncoordinating pyridine and pyrazine units remain unchanged upon metal-complex formation. These units therefore appear not to participate in the complexation process. The bond lengths for the thiosemicarbazone moieties are as one would expect and the bond lengths in the five-membered chelate rings are intermediate between the usual values for single and double bonds, thus demonstrating metalloaromaticity.[22]

A number of intra- and intermolecular hydrogen bonds are formed in the crystal packing arrangement (Table 4), and it is not only the amine and imine groups that take part but also the pyridine and pyrazine nitrogen atoms of the ligands (Figure 7). The most significant intramolecular interactions occur between the amino donor groups and the imine or pyrazine nitrogen atoms of neighbouring chains, which act as acceptors. These interactions give rise to a three-dimensional supramolecular network (Figure 8).

Table 3. Best least-squares planes for complexes **1**–**4**.

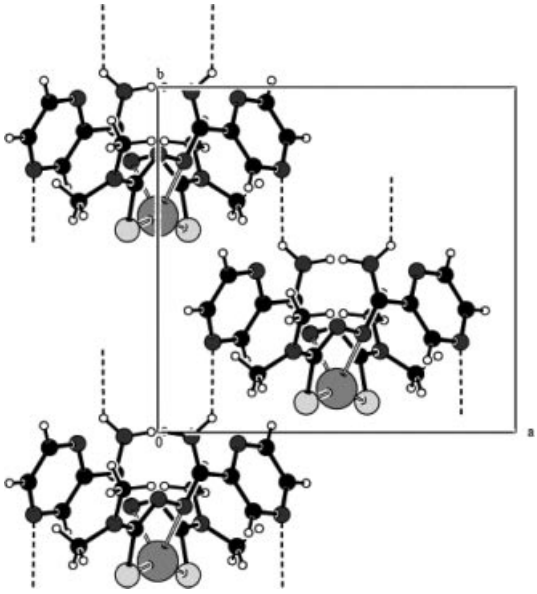

Figure 8. Partial representation of the unit cell of **4** showing the intermolecular hydrogen bonding.

Intermolecular CH···π(chelate ring) interactions between C–H bonds of the pyridyl ligand and the metal chelate ring are observed in complex **1** (Table 5). The H···ring centroid (H···*Ω*) distances are in the range 2.66–2.89 Å, and the *α* and *β* angles have values of 120° and 12.5–19.0°, respectively (Figure 9). These data are comparable with those found in crystal structures with weak C–H···π interactions between an organic moiety and a chelate ring in transition-metal complexes ($\alpha > 110°$, $\beta < 16°$ and $H\cdots\Omega < 3.0$ Å; α, *β*, and *Ω* are defined in Table 5).[23] The crystal structure of complex **2** also displays a weak C–H···π interaction between a methyl group and the pyridyl ring of neighbouring molecules.[24]

Table 5. Intermolecular CH···π ring interaction parameters for complexes **1** and **2**.[a]

| | CH···Ω | H···*Ω* [Å] | *α* [°] | *β* [°] |
|---|---|---|---|---|
| **1** | C11–H11···(Hg1/S1)[1] | 2.89 | 120.4 | 12.7 |
| | C14–H14···(Hg1/S1)[2] | 2.66 | 120.9 | 18.9 |
| **2** | C29–H29B···(N11/C15)[3] | 2.97 | 123.6 | 9.5 |

[a] *Ω* is the ring plane, *α* the angle C–H···centroid of *Ω* and *β* the angle defined by the H···centroid line and the perpendicular to this plane. Symmetry transformations used to generate equivalent atoms: 1: $-x$, $1-y$, $-z$; 2: $-x$, $y$, $½-z$; 3: $-x$, $1-y$, $-1/2+z$.

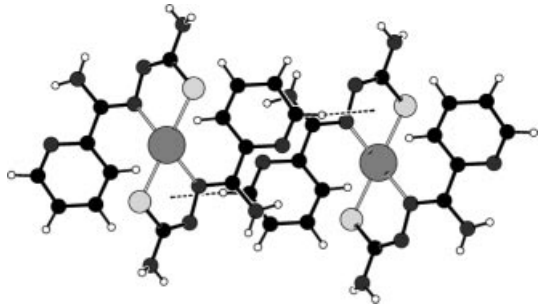

Figure 9. Perspective view of **1** showing an intermolecular C–H···π interaction with the π-system of the chelate ring.

## Spectral Data

The complexes exhibit bands due to ν(NH) vibrations in the range 3500–3146 $cm^{-1}$. The bands associated with ν(C=N) and ν(C=C) appear in the range 1609–1444 $cm^{-1}$ and are shifted to lower and higher frequencies, respectively, compared to those of the ligands. The ν(NH) band is shifted to slightly higher frequencies in the complexes with respect to the ligands, indicating the coordination of the azomethine nitrogen. The ν(CS) band appears at ca. 755 $cm^{-1}$ for the complexes with pyridine and ca. 850 $cm^{-1}$ for the pyrazine derivatives, which is in agreement with observed values for this series of compounds with the sulfur atom coordinated to the metal centre. Furthermore, coordination by the N azomethine and the S thiolate is supported by the localisation of the ν(Hg–N) modes around 405–418 $cm^{-1}$ and the ν(Hg–S) modes around 289–326 $cm^{-1}$, respectively.

In the $^1$H NMR spectra of the complexes, the absence of the $N^3$–H signal is consistent with the thiosemicarbazone

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in its deprotonated form. The pyridine proton signals appear at around 8.44–7.36 ppm and the pyrazine protons are in the range 9.67–8.48 ppm, which is normal for these aromatic protons. The $N^5H_2$ proton in both **1** and **2** appear as a singlet at $\delta$ = 6.60 ppm in each case and at $\delta$ = 7.06 and 6.51 ppm for **3** and **4**, respectively. The $N^4H_2$ protons appear at $\delta$ = 6.03 ppm in **1** and at 8.33, 8.22 ppm in **3**. The presence of two signals for the $N^4H_2$ protons in **3** must be due to the restriction of free-rotation around the $C^7$–$N^4H_2$ bond.[19,25] The variation in the shielding between the complexes must be related to a different arrangement of the complex in DMSO solution or to a different interaction between the $N^4H_2$ protons and DMSO.

The $^{199}$Hg NMR spectrum of **1** shows two peaks at –577 and –806 ppm (Figure 10). The peak at $\delta$ = –806 ppm is due to our four-coordinate complex, whereas the signal at $\delta$ = –577 ppm may be due to the coordination of the nitrogen atom of the pyridine ring in DMSO solution, a situation that increases the coordination number of the Hg atom and moves the $\delta(^{199}Hg)$ signal to higher frequencies. This observation is in agreement with literature data.[25,26] Furthermore, the $^1$H NMR spectra of the reaction between [Hg(damp)Cl] and HAm4DH in a [$D_6$]DMSO solution shows two peaks for the protons of the pyridine ring, which is also consistent with the suggested coordination of the heterocyclic nitrogen atom in solution.

The behaviour of the complexes in solution was followed by NMR spectroscopy of the reaction between two of the thiosemicarbazones and [Hg(damp)Cl]. The $^{199}$Hg NMR spectra were recorded for the reactions between [Hg(damp)Cl] and HAm4DM or HAmpz4DH in a MeOH/[$D_4$]MeOH mixture in 10-mm NMR tubes. The spectra for these two reactions each show two signals (Figure 11). The first signal is observed at –650 and –655 ppm for the two reactions, respectively, and this may indicate that, in solution, the heterocyclic nitrogen atom is also coordinated to the mercury centre in the complex $HgL_2$.[25,26] The second peak, which appears at –1162 and –1167 ppm, respectively, could correspond to the presence of $[Hg(Hdamp)_2]^{2+}$ as a secondary product formed by symmetrisation.[13,15] These signals are shifted to higher field with respect to that of [Hg(damp)Cl],

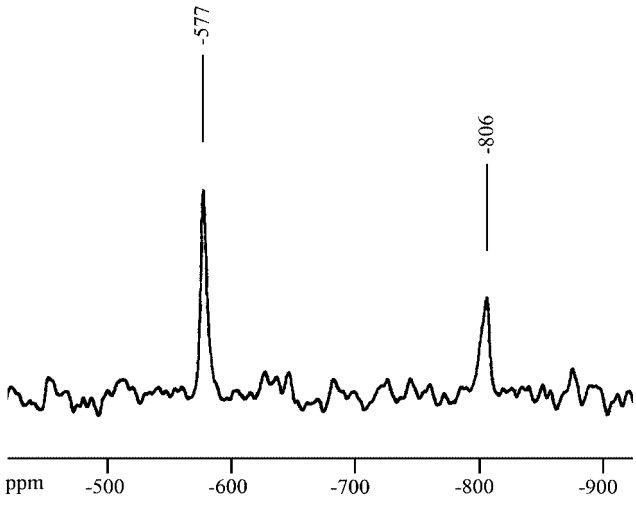

Figure 10. $^{199}$Hg NMR spectrum at room temperature of a solution of complex **1** in DMSO.

which appears at $\delta$ = –1109 ppm. Symmetrisation is a well known reaction in organometallic mercury compounds[27–29] and the occurrence of such a process would be consistent with the tendency for organomercury compounds to maintain linearity in $R_2Hg$ or RHgX systems. The overall reaction can be represented as follows:

It seems likely that the most stable form of the complex in solution is $Hg(TSC)_2^{(NNS)}$, that this is the form first produced when the reaction is carried out in methanol (Scheme 3, reaction **I**), and that its conversion to $Hg(TSC)_2^{(NS)}$ via equilibrium **II** (Scheme 3) is driven by the precipitation of $Hg(TSC)_2^{(NS)}$ as crystals. When $Hg(TSC)_2^{(NS)}$ is dissolved in DMSO, equilibrium **II** (Scheme 3) leads rapidly to the presence of both species.

The molar conductivity values for the solutions discussed above indicate that they are 2:1 electrolytes in MeOH,[30] a finding that is consistent with the presence of the species $[Hg(Hdamp)_2]^{2+}$ and 2 $Cl^-$, and consequently, the formation of a zwitterionic charge distribution in this ligand is not possible. The pH values of the solutions were also measured and significant variations were not found with respect

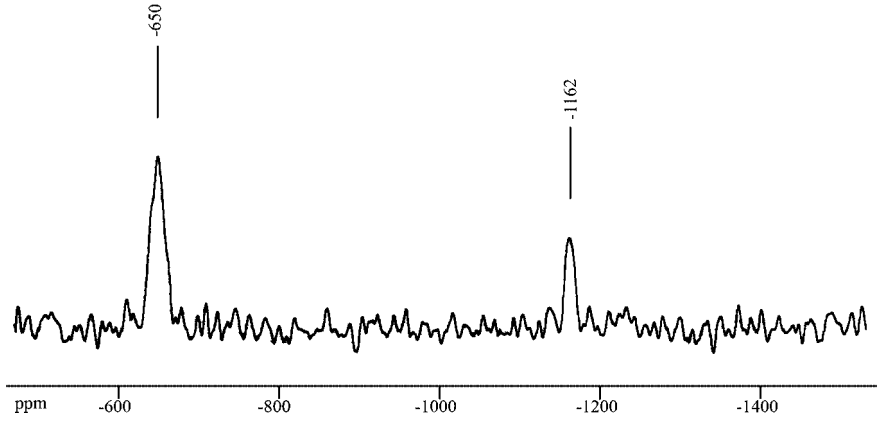

Figure 11. $^{199}$Hg NMR spectrum at room temperature of the reaction between [Hg(damp)Cl] and HA4DM in MeOH/[$D_4$]MeOH. The signal for $[Hg(Am4DM)_2]$ is on the left and that for $[Hg(Hdamp)_2]^{2+}$ on the right.

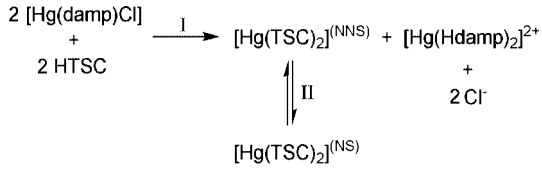

Scheme 3.

to the typical value for MeOH. This observation is consistent with the presence of the species $[Hg(Hdamp)_2]Cl_2$, which would retain the protons lost by the ligand upon coordination to mercury.

The reaction between [Hg(damp)Cl] and HAmpz4DH in DMSO was carried out and $^1H$ NMR spectra were acquired. It was found that, in addition to the signals corresponding to species **3** (as discussed above), a new set of signals appeared due to the presence of organometallic rings (in the range 7.17–7.48 ppm), $CH_2$ ($\delta$ =3.47 ppm) and the methyl groups of $[Hg(Hdamp)_2]Cl_2$ ($\delta$ = 2.23 ppm). Furthermore, the presence of a singlet at $\delta$ = 10.26 ppm in the reaction between [Hg(damp)Cl] and HAmpz4DH provides further evidence for protonation of the Hdamp nitrogen. Similarly, in the reaction between [Hg(damp)Cl] and HAm4DM in $CDCl_3$, as well as the signals described above, a signal was observed at $\delta$ = 11.60 ppm and this is probably due to protonation of the species $[Hg(Hdamp)_2]^{2+}$. Protonation of the ligand Hdamp is supported by IR spectra of damp, which show a band corresponding to ν(N–H) vibrations at around 2670 $cm^{-1}$, a value consistent with those found for other Hdamp complexes,[20,31,32] and with the N–H absorption of free tertiary ammonium salts (ca. 2700 $cm^{-1}$).

## Experimental Section

Elemental analyses were performed with a Carlo Erba 1108 microanalyser. The mass spectra were obtained using the FAB method with a Hewlett–Packard HP5988A mass spectrometer. IR spectra were recorded as KBr disks (4000–400 $cm^{-1}$) or polyethylene-sandwiched Nujol mulls (500–100 $cm^{-1}$) with a Bruker IFS-66v spectrometer. NMR spectra were obtained with a Bruker AMX 300 and AMX 500 spectrometers; chemical shifts are reported in ppm downfield from $Me_4Si$ or $Hg(CH_3)_2$. With the exception of $[Hg(Am4DH)_2]$, the $^{199}Hg$ NMR spectra of the other mercury complexes could not be registered due to their low solubility.

[Hg(damp)Cl] was synthesised according to the reported procedure.[33] The thiosemicarbazones were prepared by reduction of pyridine-2-carboxamide and pyrazine-2-carboxamide with sodium and subsequent reaction with the corresponding thiosemicarbazide as described previously.[6,34,35]

**Synthesis of $[Hg(Am4DH)_2]$ (1):** A mixture of HAm4DH (0.03 g, 0.15 mmol) and [Hg(damp)Cl] (0.06 g, 0.15 mmol) in methanol (25 mL) was heated under reflux for 1 h. The clear pale-yellow solution was left to crystallise and, after several days, colourless crystals suitable for crystal determination were obtained. Yield: 4.86 mg. $C_{14}H_{16}HgN_{10}S_2$ (589.06): calcd. C 28.5, H 2.7, N 23.8, S 10.9; found C 28.6, H 2.6, N 23.2, S 10.1. IR: $\tilde{\nu}_{max}$= 3479–3148 ν(NH), 1606–1552 ν(C=N and C=C), 1003 ν(NN), 795 ν(CS), 415 ν(Hg–N), 322 ν(Hg–S) $cm^{-1}$. $FAB^+$ MS, *m*/*z* (%), assignment: 196.09 (1.47), $[H_2Am4DH]$. $^1H$ NMR ([D$_6$]DMSO, ppm): $\delta$ = 8.44 (d, 1 H, 1-H), 7.83 (d, 1 H, 4-H), 7.67 (td, 1 H, 3-H), 7.36 (m, 1 H, 2-H), 6.60 (s, 2 H, $N5H_2$), 6.03 (s, 2 H, $N4H_2$).

**Synthesis of $[Hg(Am4DM)_2]$ (2):** HAm4DM (0.02 g, 0.1 mmol) in methanol was added to a stirred solution of [Hg(damp)Cl] (0.02 g, 0.1 mmol) in methanol (20 mL). The mixture was stirred for several hours and the resulting yellow solution was left to crystallise. A yellow crystalline solid formed after several days and crystals suitable for X-ray diffraction were obtained from the same solvent. Yield: 15.48 mg. $C_{18}H_{24}HgN_{10}S_2$ (645.17): calcd. C 33.5, H 3.7, N 21.7, S 9.9; found C 33.4, H 3.8, N 21.7, S 9.1. IR: $\tilde{\nu}_{max}$ = 3489–3358 ν(NH), 1609–1544 ν(C=N and C=C), 995 ν(NN), 797 ν(CS), 418 ν(Hg–N), 305 ν(Hg–S) $cm^{-1}$. $FAB^+$ MS, *m*/*z* (%), assignment: 646.27 (1.70), [Hg(HAmDM)(Am4DM)]; 559.26 (17.0), $[Hg(AmDM)(C_6H_8N_4)]$; 423.14 (0.73), [Hg(AmDM)]; 224.12 (3.12), $[H_2Am4DM]$. $^1H$ NMR ([D$_6$]DMSO, ppm): $\delta$ = 8.44 (d, 1 H, 1-H), 7.74 (d, 1 H, 4-H), 7.63 (td, 1 H, 3-H), 7.37 (m, 1 H, 2-H), 6.60 (s, 2 H, $N5H_2$), 3.08 (s, 6 H, 2Me).

**Synthesis of $[Hg(Ampz4DH)_2]$ (3):** A mixture of HAmpz4DH (0.02 g, 0.1 mmol) and [Hg(damp)Cl] (0.04 g, 0.1 mmol) in methanol (25 mL) was heated under reflux for 1 h. The resulting yellow-green precipitate was filtered off and dried under vacuum. Yellow crystals suitable for X-ray structural analysis were obtained from the liquors. Yield: 13.29 mg. Elemental analysis: $C_{12}H_{14}HgN_{12}S_2$ (591.04): calcd. C 24.4, H 2.4, N 28.4, S 10.8; found C 24.5, H 2.3, N 28.3, S 10.7. IR: $\tilde{\nu}_{max}$ = 3500–3146 ν(NH), 1608–1553 ν(C=N and C=C), 1017 ν(NN), 855 ν(CS), 417 ν(Hg–N), 326 ν(Hg–S). $FAB^+$ MS, *m*/*z* (%), assignment: 197.09 (1.64), $[H_2Ampz4DH]$. $^1H$ NMR ([D$_6$]DMSO, ppm): $\delta$ = 9.58 (s, 1 H, 4-H), 8.67 (s, 1 H, 1-H), 8.56 (d, 1 H, 2-H), 6.61 (s, 2 H, $N5H_2$), 6.37, 6.06 (1 H, 1 H, s, s, $N4H_2$).

**Synthesis of $[Hg(Ampz4DM)_2]$ (4):** HAmpz4DM (0.02 g, 0.09 mmol) in methanol was added to a stirred solution of [Hg(damp)Cl] (0.02 g, 0.09 mmol) in methanol (20 mL). The mixture was stirred for several hours and the resulting yellow solution was left to crystallise. A yellow crystalline formed after several days and was filtered off and dried under vacuum. Yellow crystals suitable for X-ray diffraction were obtained from the same solvent. Yield: 8.74 mg. $C_{16}H_{22}HgN_{12}S_2$ (647.14): calcd. C 29.7, H 3.4, N 26.0, S 9.9; found C 29.4, H 3.4, N 25.5, S 10.1. IR: $\tilde{\nu}_{max}$ = 3420–3312 ν(NH), 1607–1573 ν(C=N and C=C), 1019 ν(NN), 861 ν(CS), 405 ν(Hg–N), 289 ν(Hg–S). $FAB^+$ MS, *m*/*z* (%), assignment: 648.20 (34.03), [Hg(HAmpzDM)(Ampz4DM)]; 423.08 (2.01), [Hg(Ampz4DM)]; 225.10 (5.07), $[H_2Ampz4DM]$; 191.12 (55.29), $(C_8H_{11}N_6S)$. $^1H$ NMR ([D$_6$]DMSO, ppm): $\delta$ = 8.84 (s, 1 H, 4-H), 8.58 (s, 1 H, 1-H), 8.48 (s, 1 H, 2-H), 6.51 (s, 2 H, $N5H_2$), 3.14 (s, 6 H, 2Me).

**X-ray Crystallography:** Crystals of all complexes were mounted on glass fibres and used for data collection. Crystal data were obtained with a Bruker SMART CCD-1000 diffractometer at room temperature. X-ray data were processed using the SAINT program[36] and corrected for absorption using SADABS.[37] Structural solution and refinement was carried out using the SHELX suite of programs.[38,39] The hydrogen atoms were located unambiguously from difference Fourier maps (N–H hydrogen atoms) and included as fixed contributions riding on attached atoms or included in geometrically idealized positions employing appropriate riding models, all with isotropic displacement parameters constrained to 1.2 times those of their carrier atoms. Atom scattering factors were taken from the International Tables for Crystallography[40] and molecular graphics were obtained from PLATON[41] (see also Table 6).

# Synthesis, Isolation and Structural Investigation of Schiff-Base Alkoxytitanium Complexes: Steric Limitations of Ligand Coordination

**Andrew L. Johnson,*[a] Matthew G. Davidson,*[a] Matthew D. Lunn,[b] and Mary F. Mahon[c]**

**Keywords:** Titanium / Alkoxide / Steric effects / Schiff-base ligands / Coordination

This paper reports the reaction of Ti(O*i*Pr)$_4$ with a series of Schiff-base ligands. The Schiff-base proligands **1a–l** are synthesised by the condensation of salicylaldehyde with a range of primary alkylamine and aniline derivatives. The treatment of **1a–f** with Ti(O*i*Pr)$_4$ yields the octahedral bis(aryloxy–imine)Ti(O*i*Pr)$_2$ complexes **2a–f**. X-ray crystal structure analysis of **2c**, **2d** and **2e** reveals complexes with a *trans*-aldiminato oxygen atom and *cis*-N,*cis*-alkoxide ligand arrangement about the central metal atom. The reactions of Ti(O*i*Pr)$_4$ with the ligands **1g** and **1h** result in a sterically induced ligand rearrangement to form the octahedral complexes **2g** and **2h**, also characterised by X-ray diffraction experiments, in which the nitrogen atoms of the O,N-chelate are now *trans*-orientated at the titanium centre. $^1$H NMR analysis reveals significant deshielding of the isopropoxide methine proton, induced by this coordination mode. In contrast, reactions of **1i** and **1j** with Ti(O*i*Pr)$_4$ result in the formation and isolation of the complexes **2i** and **2j**. X-ray crystal structure analysis shows complex **2j** to have a previously unobserved ligand orientation, in which both ligands are *trans*-orientated, with respect to the aldiminato oxygen atoms, about the titanium centre, but steric bulk of the ligand inhibits the bidentate coordination of both O,N-ligands. Further increase in the steric bulk of the imine substituent results in a reduced reactivity for ligands **1k** and **1l**, such that Ti(O*i*Pr)$_4$ reacts with **1k** to form the dimeric mono(Schiff-base) complex **2k** (characterised by X-ray analysis). No reaction is observed for **1l**.

## Introduction

In recent years the development of new and increasingly active homogeneous catalysts for polymerisations has been one of the driving forces behind the advances in organometallic chemistry, the most significant progress having been made in the area of metallocene chemistry.[1–5] Much of this chemistry has focused on the development of new non-Cp ligands for alkyl d$^0$ metal compounds, which enhance α-olefin polymerisation, in the presence of co-catalysts, such as methylaluminoxane (MAO). A variety of ligands have been explored in recent years, including, for example, alkoxides and chelating alkoxides such as hydroxybenzaldehydes,[6–9,10] $N_2O_2$ Schiff-base ligands,[11–18] and bidentate N,O ligands such as 8-quinolinolato and pyridine–alkoxides.[19–22] Much of this work has focused on the formation of complexes that incorporate bidentate ligands to afford metal complexes possessing *cis*-located "active" sites, a prerequisite for effective olefin polymerisation. Recently, a family of group 4 transition-metal complexes, possessing just such a *cisoid* arrangement of two aryloxy–imine ligands, have been shown to be highly active catalysts for olefin polymerisation.[23–30] Considerable attention has also focused on the use of group 4 metal alkoxide complexes in the ring-opening polymerisations of cyclic esters such as lactic acid and ε-caprolactone.[31–35]

As part of a more general study of the chemistry of titanium alkoxides, we and others have been interested in the use of similar complexes for a range of Lewis acid mediated reactions and polymerisations.[31,32,36,37] Herein we report the results of a synthetic and structural investigation of the stereochemical control possible by steric variation of ligands, specifically at the imine substituent.

It has been shown previously that *ortho* substitution of the aryloxy–imine ligands (R position) can have a marked effect upon the structure and fluxional properties as well as the activity of the Schiff-base metal complexes as olefin polymerisation catalysts.[38,39]

Previous X-ray crystallographic studies have established that of the five possible isomeric structures of (bidentate)$_2$-$MX_2$ complexes (bidentate = aryloxy–imine ligand, X = unidentate ligand) (Figure 1) the preferred structure is a distorted octahedron with *trans*-O,*cis*-N,*cis*-X ligand arrangement [Figure 1(i)],[14,23–30,40,41] a feature that has also

been rationalised in terms of simple VSEPR concepts.[42] DFT calculations have also shown this conformation to be favoured in the gas phase.[23] Complexes with a *trans*-N,*cis*-O,*cis*-X ligand arrangement have also been reported.[29]

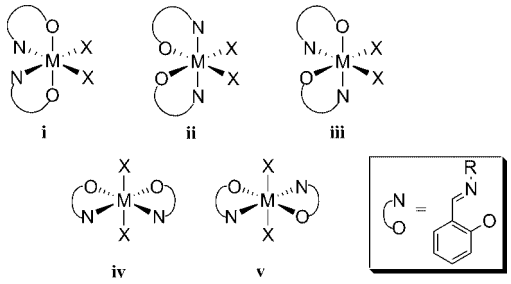

Figure 1. Depiction of the conformational isomers possible for (bidentate)$_2$MX$_2$ complexes.

## Results and Discussion

The aryloxy–imine ligands **1a**–**l** were readily prepared by the condensation of salicylaldehyde with commercially available primary amines or aniline derivatives in methanol using standard procedures (Scheme 1)[43] and isolated as sharp-melting white to yellow crystalline solids following recrystallisation in 70–98% yields. The range of amine and aniline derivatives used in this study were chosen because of their potential to impart different steric demands at metal centres.

### Synthesis and Structural Characterisation of Schiff Base Complexes

During the course of this study clear differences in the stereochemistry of metal complexes isolated, facilitate the

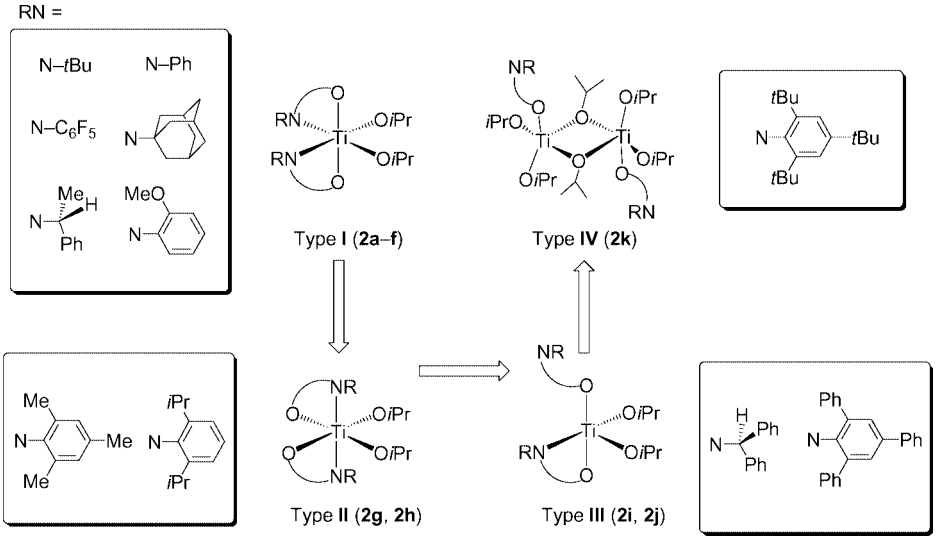

Figure 2. Structural classes of Schiff-base complexes **I**–**IV**.

division of their discussion into four distinct categories: bis($\eta^2$-*trans*-O,O) complexes, type **I**; bis($\eta^2$-*trans*-N,N) complexes, type **II**; bis($\eta^2$,$\eta^1$-*trans*-O,O) complexes, type **III**; and mono($\eta^1$) complexes, type **IV** (Figure 2). $^1$H NMR spectroscopic data and X-ray data are discussed below. $^{13}$C NMR spectroscopic data and elemental analyses are reported in the Experimental Section and are consistent with the structures proposed.

### Type I Complexes, Bis($\eta^2$-*trans*-O,O) Coordination

The reactions of Ti(O*i*Pr)$_4$ with 2 equiv. of **1a**–**f** proceed rapidly at room temperature in toluene to afford HO*i*Pr and the bis(ligand) complexes [{RN=C(C$_6$H$_4$O)}$_2$Ti(O*i*Pr)$_2$] (**2a**–**f**) in high yield (Scheme 1). The complexes **2** were isolated as analytically pure crystalline solids by recrystallisation from concentrated toluene solutions.

$^1$H NMR spectra of **2a**–**f** at room temperature contain one single set of sharp resonances, for both Schiff-base ligands and isopropoxide groups. Despite the variation in imine substituents in the complexes **2a**–**f**, signals due to the isopropoxide ligands do not vary significantly (i.e., $\delta$ = 4.6–4.9 ppm for the isopropoxide methine proton). It is well documented that six-cordinate bis(chelate) complexes of the structure types **I** and **II** (Figure 2) can undergo inversion of configuration at the metal centre, exhibiting rapid $\Delta \rightleftharpoons \Lambda$ isomerisation and isopropoxide rotation and/or exchange at ambient temperatures.[44–47] The observation of only one set of resonances for each ligand type in the $^1$H and $^{13}$C NMR spectra of **2a**–**f** is consistent with a $C_2$-symmetric structure. In the specific case of the complexes **2c**–**e**, single-crystal X-ray diffraction studies confirm the complexes to be type **I** (Figure 2) $C_2$-symmetric complexes in the solid state.

In order to probe this fluxional behaviour further, low-temperature $^1$H NMR spectra of **2c**, which incorporates an enantiomerically pure chiral ligand, are particularly informative, because the presence of chiral ligands leads to the formation of diastereoisomers.[20] Variable-temperature $^1$H NMR spectra for the imine CH region are shown in Figure 3. At room temperature (23 °C) the $^1$H NMR spectrum of **2c** shows one broad resonance each for the imine CH, the methine proton of the isopropoxide ligand, and the methine proton of the chiral imine substituent. Cooling of the sample to –20 °C results in resolution of each of these resonances into two peaks of intensity ratio 1:2.1, corresponding to the two diastereoisomers possible for complexes of type **I** shown in Figure 2. {It is likely that the two major isomers observed in solution correspond to the two diastereoisomers of the (*trans*,*cis*,*cis*) isomer [Figure 1(i)] as non-bulky ligands prefer a *trans*-O,*cis*-N conformation.} Cooling of the sample to –30 °C results in further changes in the relative intensities of these signals until at –80 °C the relative intensities are found in a 1:3.6 ratio. Although the absolute stereochemistry of the major diastereoisomer observed in the solution state cannot be determined unequivocally, it may be inferred from the molecular structure determination of **2c**. Compound **2c** crystallises in a chiral space group as only one diastereoisomer (see below), It is therefore likely that this is also the thermodynamically more stable isomer observed in solution.

The fluctional behaviour observed for **2c** at low temperatures is fully reversible, and warming of the sample to 60 °C shows a slight sharpening of the signals in the $^1$H NMR spectrum relative to the room-temperature spectrum, but no evidence for metal-based isomerisation is observed.

The molecular structures of **2c**, **2d**, and **2e** are shown in Figures 4, 5 and 6, respectively, and key parameters are summarised in Tables 1 and 5. All three complexes adopt a distorted octahedral structure of type **I**, with a *trans*-aldiminato,*cis*-alkoxide,*cis*-imine ligand arrangement.

The asymmetric unit of **2c** contains crystallographically independent molecules, both of which possess the same chirality but which differ marginally in the relative orientations of the isopropoxide groups. The coordination geometry

around the central titanium atom is close to octahedral. The axial O–Ti–O bond angle is distorted away from linearity [O(1)–Ti(1)–O(4), 161.65(8)°; O(6)–Ti(2)–O(8), 161.95(8)°] such that there is a displacement of the aldiminato ring away from the isopropoxide ligands. The Ti–O*i*Pr moieties exhibit bond lengths of 1.777(2) Å [Ti(1)–O(2)], 1.817(2) Å [Ti(1)–O(3)], 1.826(2) Å [Ti(2)–O(7)], and 1.778(2) Å [Ti(2)–O(9)], with O–Ti–O angles of 99.85(9)° and 101.04(8)° about Ti(1) and Ti(2), respectively. As expected, the Ti–N(imine) bonds are considerably longer: Ti(1)–N(1) 2.347(2), Ti(1)–N(2) 2.299(2), Ti(2)–N(3) 2.321(2), Ti(2)–N(4) 2.300(2) Å. The coordination geometries in complexes **2d** and **2e** are similar to that observed in **2c**, although subtle differences between the complexes are apparent (Table 1).

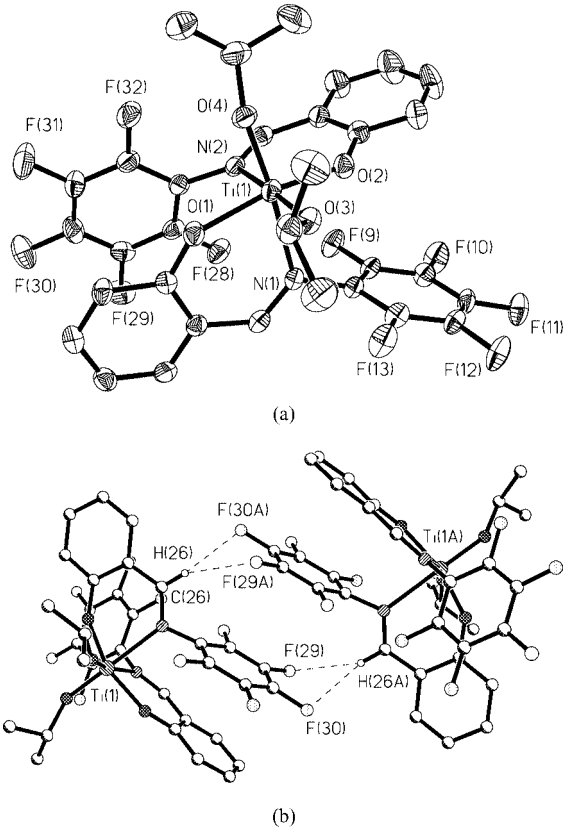

Figure 6. (a) Molecular structure of complex **2e**, shown with 50% displacement ellipsoids. Hydrogen atoms have been omitted for clarity. (b) Supramolecular structure of **2e** highlighting the intermolecular C–H···F interactions C(26)···F(29A) 3.550(4) Å, C(26)···F(30A) 3.406(4) Å, C(26)–H(26)···F(29A) 154.6°, C(26)–H(26)···F(30A) 140.1°.

Previous work has highlighted the role of the imine C–H group in promoting weak intermolecular interactions in the solid-state structures of Schiff-base complexes.[11] Of the titanium compounds described in this work, only **2e** exhibits significant intermolecular interactions involving this hydrogen-bond donor group: pairs of monomers are associ-

ated through mutual C–H···F interactions as shown in Figure 6(b). In related complexes, in which the imine group is an *ortho*-F-substituted phenyl ring, C–H···F interactions between the imine substituent and the β-H atoms of the growing polymer chain have been cited as the reason for the remarkable stability and catalytic behaviour of such complexes.[48,49]

### Type II Complexes, Bis($\eta^2$-*trans*-N,N) Coordination

Upon increasing the steric bulk of the imine substituent, beyond that of *o*-methoxyaniline, significant changes in the $^1$H NMR spectra are observed, such that the isopropoxide methine resonances shift from $\delta$ = 4.6–4.9 ppm in **2a**–**f** to $\delta$ = 3.4 and 3.7 ppm in **2g** and **2h**, respectively. We believe this change is indicative of a transformation from a type **I** to a type **II** structure. As with complexes **2a**–**f**, NMR spectra of **2g** and **2h** are consistent with $C_2$-symmetric complexes. A single-crystal X-ray structure of **2h** confirms the type **II** structure, in which the bidentate ligands adopt a mutually *trans*-N,*cis*-O(Ar),*cis*-O(R) arrangement, as shown in Figure 7; although there are no significant differences in Ti–N and Ti–O(Ar) bond lengths in **2h** relative to type **I** complexes **2c**–**e** (Tables 1 and 2), there is movement of the axial nitrogen atoms away from the isopropoxide ligands such that the N–Ti–N angle in **2h** is 164.61(8)°. As in the case of **2c**–**e**, the geometry of the aryloxy–imine ligands forces the chelate angles around the Ti atom to deviate from the ideal octahedral geometry, with a "bite" angle [N(1)–Ti(1)–O(1)] of 82.33(10)°, which is comparable to the average "bite" angles found in **2c**–**e** [81.02(7)° (**2cA**), 81.14(7)° (**2cB**), 81.06(6)° (**2d**) and 79.95(7)° (**2e**)]. Erker et al. have previously observed this unusual configuration in Schiff-base Ti and Zr chloride complexes of the ligand **1h**.[29]

The significant shift observed in the $^1$H NMR spectra of the isopropoxide ligands on changing from type **I** to type **II** complexes is not reflected in the Ti–O(isopropoxide) bond lengths, which remain similar in both type **I** and **II** complexes (see Tables 1 and 2). This suggests that the deshielding observed for type **II** complexes (**2g** and **2h**) is due to the proximity of the methine proton to an *N*-aryl group of the Schiff-base ligand rather than due to a differing *trans* effect

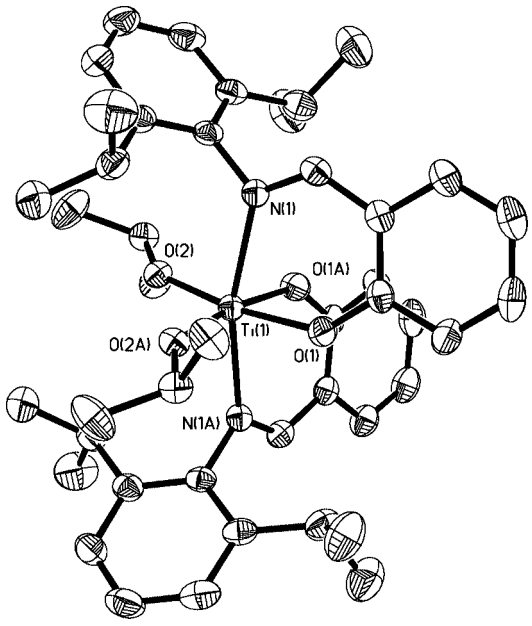

Figure 7. Molecular structure of **2h**. Ellipsoids are shown with 50% displacement probability. Hydrogen atoms have been omitted for clarity. Equivalent atoms (*A) are generated by the symmetry transformations $-x+1$, $y$, $-z+1/2$, and $-x+1/2$, $-y+1/2$, $-z+1$.

Table 2. Selected bond lengths [Å] and angles [°] for complex **2h**.

| | | | |
|---|---|---|---|
| Ti(1)–O(1) | 1.975(1) | O(1)–Ti(1)–O(1*) | 85.30(8) |
| Ti(1)–O(2) | 1.805(1) | O(1)–Ti(1)–O(2) | 171.27(6) |

caused by reorientation of the ligands. This inference is supported by the solid-state structures of type **I** and type **II** complexes, in which the isopropoxide methine proton is directed towards an aryl ring in type **II** complexes but not in type **I**. These orientations are apparent from Figures 5 and 7, type **I** and **II** complexes, respectively. Overall, the steric environment surrounding the metal centre is altered significantly because of the reorientation of the Schiff-base ligands as highlighted by the space-filling diagrams shown in Figure 8. It would be surprising if these changes did not influence the reactivity of the metal complexes, and it is interesting to note that a recent report by Matsui et al. suggests that very bulky imine substituents inhibit the activity of Schiff-base Zr complexes as polyolefin precatalysts.[23]

### Type III Complexes, Bis($\eta^2\eta^1$-*trans*-O,O) Coordination

An additional increase in the steric bulk of the imine substituents (ligands **1i** and **1j**) leads to the formation of complexes **2i** and **2j** (Scheme 1). Characterisation of **2i** and **2j** by $^1$H NMR spectroscopy indicates the presence of the same ligand set as for **2a**–**h**. However, for both complexes, the isopropoxide methine proton is only slightly deshielded in comparison to the type **I** complexes **2a**–**f** implying that the isopropoxide group no longer experiences the deshield-

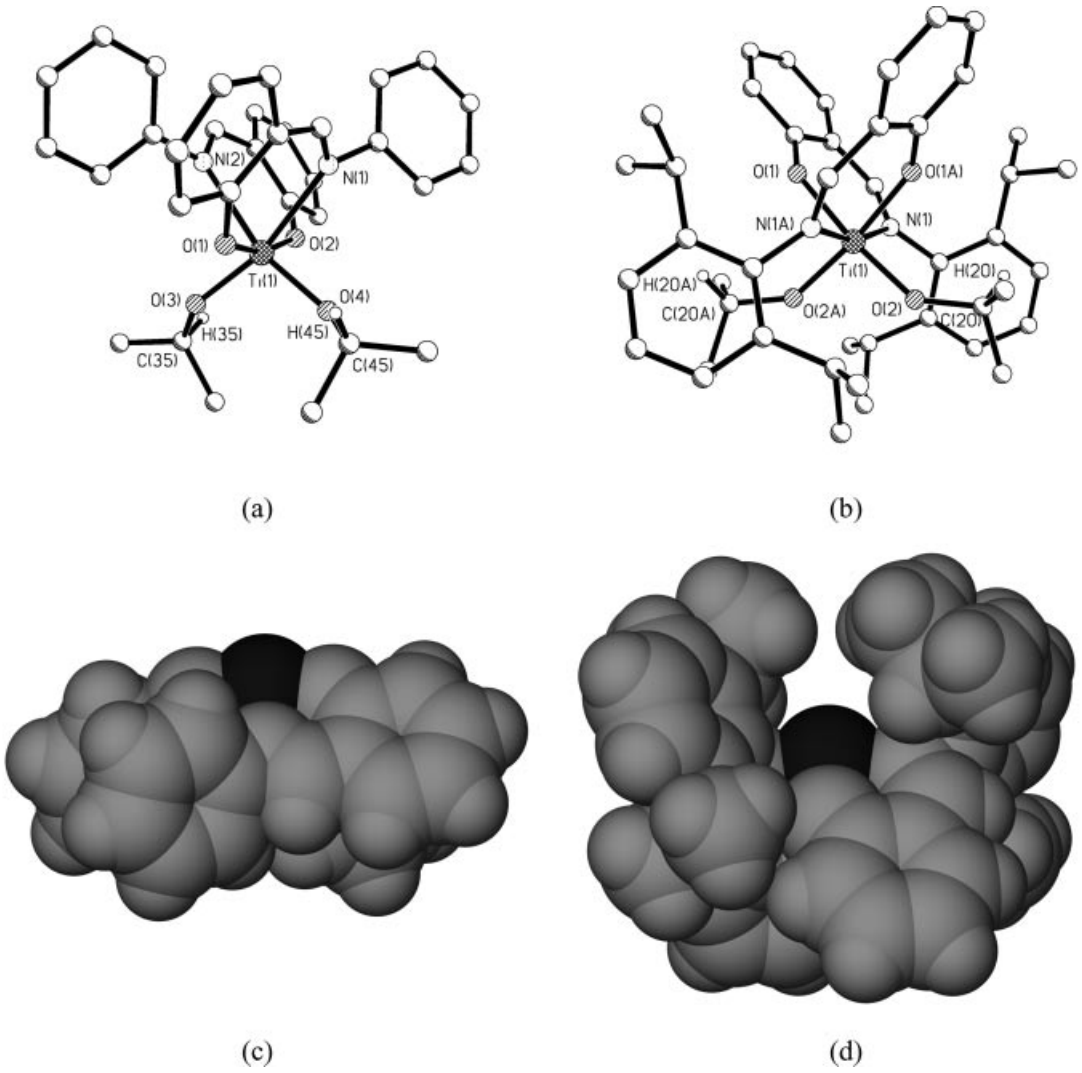

Figure 8. Complexes **2d** [(a) and (c)] and **2h** [(b) and (d)] highlighting orientation of the chelating ligands relative to the isopropoxide methine protons [(a) and (b)] and the difference in the steric environment of the active site in type **I** and type **II** complexes [isopropoxide groups have been omitted in (c) and (d) for clarity].

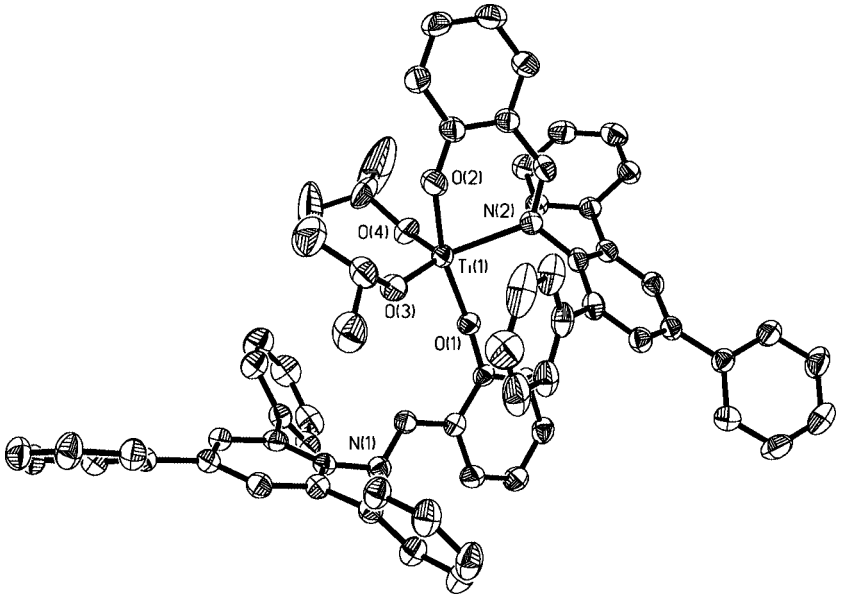

Figure 9. Molecular structure of complex **2j**, shown with 50% displacement ellipsoids; hydrogen atoms have been omitted for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ing effects observed in **2g** and **2h**, and that a further structural change has taken place.

X-ray structural analysis of complex **2j** (Figure 9) reveals the nature of this change and represents a previously uncharacterised structure for disubstituted Schiff-base titanium or zirconium complexes. Complex **2j** exhibits a five-coordinate titanium centre, with a distorted square-pyramidal geometry, supporting two alkoxide ligands and two aryloxide ligands, each exhibiting different bonding modes. One ligand forms a chelate to the metal centre in the expected $\eta^2$ fashion, while the second binds in $\eta^1$ mode solely through the aryloxide group. The 2,4,6-triphenylphenyl group of this monodentate ligand is orientated such that it is remote from the metal centre, thus relieving steric congestion. Selected bond lengths and angles for **2j** are given in Table 3. Complex **2j** may be viewed as a structural model for the proposed intermediate in the $\Delta \rightleftharpoons \Lambda$ enantiomerisation process of octahedral $(AB)_2MX_2$ complexes. The enantiomerisation process is reasoned to proceed via a five-coordinate intermediate formed by the rupture of a metal–ligand bond as shown in Figure 10.[19–21,44–47]

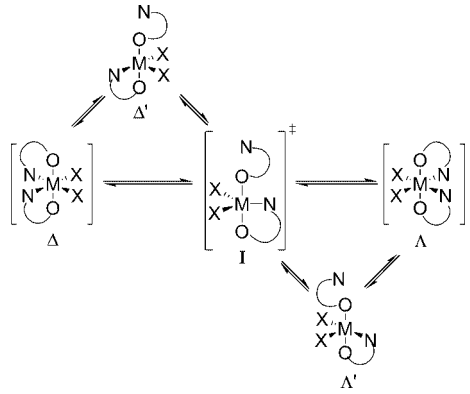

Figure 10. Proposed mechanism of racemisation for interchange of Δ and Λ forms of the bis(aryloxy–imine)titanium complexes. Complexes Δ′ and Λ′ represent the stable five-coordinate species, such as **2j**.[44–47]

### Type IV Complexes, Mono($\eta^1$) Coordination

Further increases in the steric bulk of the imine substituent (ligand **1k**, Scheme 1) inhibits formation of disubstituted complexes analogous to **2a**–**j**, and results in only monosubstitution of Ti(O*i*Pr)$_4$ to yield **2k**, even in the presence of excess **1k** and in refluxing toluene. Under similar reaction conditions, **1l** is recovered intact and no evidence for even monosubstitution is observed.

In the solid state, **2k** has a dimeric structure (Figure 11, Table 4) consisting of two terminal alkoxide and two bridging μ-O*i*Pr groups, as well as one monodentate aryloxide ligand coordinated to each Ti atom. This is structurally similar to the previously reported (alkoxide)(phenoxide)-titanium complex [$Ti_2$(O-2,4,6-$Me_3C_6H_2$)$_2$(O*i*Pr)$_4$(μ-O*i*Pr)$_2$].[18,50] Each titanium centre in **2k** possesses a trigonal-bipyramidal geometry, with one $\mu^2$-O*i*Pr group in an axial and one in an equatorial site (Figure 12). The terminal alkoxy–imine ligand occupies an equatorial site, and within

the dimer both ligands are arranged *trans* to each other such that the molecule has crystallographic $C_i$ symmetry. The bridging alkoxide ligands do so unsymmetrically, with the equatorial Ti–O bonds [Ti(1)–O(5) 1.929(2) Å, Ti(2)–O(4) 1.924(2) Å] being shorter than the axial [Ti(1)–O(4) 2.120(2) Å, Ti(2)–O(5) 2.112(2) Å] ones. Other bond lengths and angles found in the structure of **2k** are as expected.

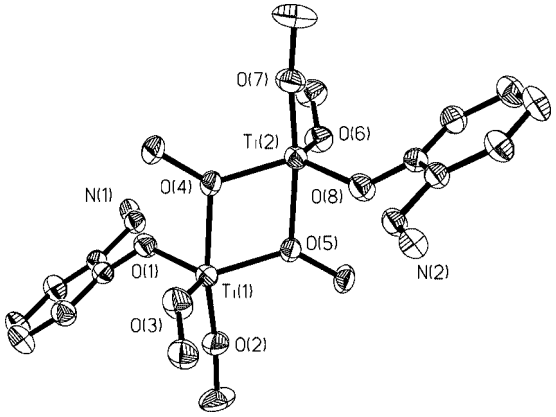

Figure 12. Structure of **2k**, showing the distorted trigonal-bipyramidal geometry about the two titanium centres, with 50% displacement ellipsoids; hydrogen atoms, methyl groups and the imine substituents have been omitted for clarity.

## Conclusions

We have synthesised, isolated and structurally characterised Schiff-base complexes of titanium with the previously observed $C_2$-symmetric type **I** (**2a**–**f**) and type **II** (**2g** and **2h**) structures. Type **II** complexes are characterised in their $^1$H NMR spectra by deshielding of the isopropoxide methine protons which highlights a significant change in the steric characteristics of the metal centre. A further increase in the steric demands of the imine substituent results in the isolation of complexes with the hitherto unknown five-coordinate type **III** structure (**2i** and **2j**), which can be viewed as a structural model for the proposed intermediate in $\Delta \rightleftharpoons \Lambda$ racemisation of $C_2$-symmetric complexes of this type. Increasing the steric bulk of the ligand still further induces a decrease in reactivity of the ligands towards Ti(O*i*Pr)$_4$. Thus, ligand **1k** substitutes only one alkoxide to form the bridged alkoxide complex **2k**, and **1l** is unreactive towards Ti(O*i*Pr)$_4$.

The ability to control molecular structure and particularly the environment about Lewis acidic metal centres, by steric variation at a ligands periphery, described here, clearly shows that, although somewhat distant from the metal centre, the choice of imine substituent is critical to the ligand coordination geometry about the central metal, and points to possible the rational design of metallo-organic complexes for use in catalysis.

## Experimental Section

**General Remarks:** All manipulations were carried out under dry argon using standard Schlenk and glove-box techniques. Solvents were purified by conventional procedures and distilled prior to use. Ti(O*i*Pr)$_4$ was purchased from Aldrich and used as received, without further purification. The ligands **1a**–**m** were prepared using the appropriate amine and salicylaldehyde, all purchased from Aldrich, using standard literature techniques.[51] Solution $^1$H, and $^{13}$C NMR experiments were performed at ambient temperature with a Bruker Avance-300. $^1$H NMR spectroscopic data are referenced to residual non-deuterated solvent.

**Syntheses of Complexes**

**[Ti(O*i*Pr)$_2${η$^2$-OC$_6$H$_4$C(H)N*t*Bu}$_2$] (2a):** To a stirred solution of **1a** (0.36 g, 2 mmol) in 20 mL of toluene was added Ti(O*i*Pr)$_4$ (0.3 mL, 1 mmol) dropwise by syringe, at 0 °C. The mixture was heated at reflux for 2 h. The solution was cooled to room temperature before removal of solvent under reduced pressure. The yellow residue was dissolved in a minimum of fresh toluene (6 mL), warmed to ca. 40 °C, and filtered through a Celite pad into a Schlenk flask. The filtrate was layered with 5 mL of dry pentane and allowed to stand at 4 °C for 2 days after which the solid microcrystalline product was collected by filtration, washed with 5 mL of cold hexane and dried in vacuo. Yield: 0.36 g (70%). $C_{28}H_{42}N_2O_4Ti$ (518.3): calcd. C 64.86, H 8.10, N 5.40; found C 65.1, H 8.17, N 5.41. $^1$H NMR (300 MHz, 23 °C, $CDCl_3$): $\delta$ = 1.17 [br. s, 12 H, OCH(C$H_3$)$_2$], 1.36 [s, 18 H, NC(C$H_3$)$_3$], 4.62 [sept, $^3J_{HH}$ = 6 Hz, OC$H$(CH$_3$)$_2$, 2 H], 6.6–6.85 (br. m, 4 H, CH$_{arom}$), 7.18–7.26 (br. m, 2 H, CH$_{arom}$), 7.27–7.45 (br. m, 2 H, CH$_{arom}$), 8.34 [s, 2 H, C($H$)=N] ppm. $^{13}$C NMR (75.5 MHz, 23 °C, $CDCl_3$): $\delta$ = 25.8, 30.9, 61.4, 77.6, 118.5, 119.3, 123.8, 132.5, 133.2, 160.1, 166.5 ppm.

Complexes **2b**–**2k** were prepared in a manner analogous to that of **2a**.

**[Ti(O*i*Pr)$_2${η$^2$-OC$_6$H$_4$C(H)N(C$_{10}$H$_{15}$)}$_2$] (2b):** Yield: 0.38 g (57%). $C_{40}H_{54}N_2O_4Ti$ (674.4): calcd. C 71.20, H 8.07, N 4.15; found C 71.60, H 8.01, N 4.09. $^1$H NMR (300 MHz, 23 °C, $CDCl_3$): $\delta$ = 1.22 [br . s, 12 H, OCH(C$H_3$)$_2$], 1.53–2.09 (br. m, 30 H, NC$_{10}H_{15}$), 4.69 [br. m, 2 H, OC$H$(CH$_3$)$_2$], 6.67–6.82 (br. m, 4 H, CH$_{arom}$), 7.14–7.28 (br. m, 2 H, CH$_{arom}$), 7.32–7.47 (br. m, 2 H, CH$_{arom}$), 8.32 [s, 2 H, C($H$)=N] ppm. $^{13}$C NMR (75.5 MHz, 23 °C, $CDCl_3$): $\delta$ = 25.9, 30.2, 36.7, 43.3, 78.4, 117.8, 118.7, 119.4, 131.7, 132.5, 160.4, 164.9 ppm.

**[Ti(O*i*Pr)$_2${η$^2$-OC$_6$H$_4$C(H)N[(*R*)-CHMePh]}$_2$] (2c):** Yield: 0.44 g (72%). $C_{36}H_{42}N_2O_4Ti$ (614.3): calcd. C 70.36, H 6.84, N 4.56; found C 69.60, H 6.84, N 4.42. $^1$H NMR (300 MHz, 23 °C, $CDCl_3$): $\delta$ = 1.02 [br. s, 12 H, OCH(C$H_3$)$_2$], 1.45 [br. s, 6 H, CH(C$H_3$)Ph], 4.67 [sept, OC$H$(CH$_3$)$_2$, $^3J_{HH}$ = 6 Hz, 2 H], 5.29 (br. m, 2 H, C$H$MePh) 6.58–6.66 (br. m, 2 H, CH$_{arom}$), 6.76–6.82 (br. m, 2 H, CH$_{arom}$), 6.97 (dd, $^3J_{HH}$ = 7.5 Hz, $^4J_{HH}$ = 1.5 Hz, 2 H, CH$_{arom}$), 7.06–7.15 (br. m, 10 H, CH$_{arom}$), 7.23 (ddd, $^3J_{HH}$ = 8 Hz, $^3J_{HH}$ = 7.2 Hz, $^4J_{HH}$ = 2.1 Hz, 2 H, CH$_{arom}$), 7.88 [s, 2 H, C($H$)=N] ppm. $^{13}$C NMR (75.5 MHz, 23 °C, $CDCl_3$): $\delta$ = 21.6, 25.7, 62.5, 78.6, 117.5, 119.4, 123.0, 126.9, 127.6, 128.8, 128.9, 134.18, 134.52, 163.7, 164.7 ppm.

**[Ti(O*i*Pr)$_2${η$^2$-OC$_6$H$_4$C(H)NC$_6$H$_5$}$_2$] (2d):** Yield: 0.38 g (68%). $C_{32}H_{34}N_2O_4Ti$ (558.2): calcd. C 68.80, H 6.09, N 5.01; found C 68.50, H 6.13, N 4.98. $^1$H NMR (300 MHz, 23 °C, $CDCl_3$): $\delta$ = 1.23 [br. s, 12 H, OCH(C$H_3$)$_2$], 4.9 [sept, $^3J_{HH}$ = 6 Hz, 2 H, OC$H$(CH$_3$)$_2$], 6.11–6.17 (m, 2 H, CH$_{arom}$), 6.49 (ddd, $^3J_{HH}$ = 9 Hz, $^3J_{HH}$ = 7.5 Hz, $^4J_{HH}$ = 1.2 Hz, 2 H, CH$_{arom}$), 6.78–7.04 (m, 14 H, CH$_{arom}$), 7.87 [s, 2 H, C($H$)=N] ppm. $^{13}$C NMR (75.5 MHz, 23 °C, $CDCl_3$): $\delta$ = 25.9, 79.0, 117.8, 119.8, 123.1, 126.2, 128.4, 134.3, 135.2, 154.3, 163.7, 166.3 ppm.

**[Ti(O*i*Pr)$_2${η$^2$-OC$_6$H$_4$C(H)NC$_6$F$_5$}$_2$] (2e):** Yield: 0.6 g (81%). $C_{32}H_{24}F_{10}N_2O_4Ti$ (738.1): calcd. C 52.03, H 3.25, N 3.79; found C

**X-ray Crystallographic Study:** Crystallographic data for compounds **2c**, **2d**, **2e**, **2h**, **2j** and **2k** are summarised in Table 5. All data collections were carried out with a Nonius KappaCCD diffractometer. Structure solution and refinement were performed using SHELX86[52] and SHELX97[53] software, respectively. Experimental data relating to all structure determinations are summarised in Table 5. Full-matrix anisotropic refinement was implemented in the final least-squares cycles throughout. All data were corrected for Lorentz and polarisation and, with the exceptions of **2d**, **2e** and **2j**, for extinction effects. Hydrogen atoms were included at calculated positions throughout. In **2d**, one of the phenyl groups was seen to exhibit positional disorder. In particular, C(1)–C(6) were found to be disordered in a 1:1 ratio with C(1A)–C(6A). All carbon–carbon distances therein were refined subject to rigid-bond restraints. In complex **2h**, the asymmetric unit consisted of one half of a molecule with the central titanium atom residing on a twofold rotation axis, in addition to half of a toluene molecule proximate to a crystallographic inversion centre. The methyl group in the solvent was disordered in a 1:1 ratio by virtue of straddling this inversion centre. One full toluene molecule was also seen to be present in the structure of **2j**. In addition, one of the isopropyl groups exhibited disorder whereby C(90)–(92) were disordered in a 1:1 ratio with C(90′)–(92′). Similarly, the asymmetric unit in **2k** was also observed to contain a solvent molecule (toluene) evenly disordered over two sites. In particular, C(101)–(106) exhibited 1:1 disorder with C(201)–C(206). Both partial rings were refined as rigid hexagons. Disordered toluene methyl groups were not included in the model. Moreover, one *tert*-butyl substituent was also found to be disordered in a 70:30 ratio, whereby C(95A)–(96C) were refined at 70% occupancy and C(95D)–(95F) were refined at 30% occupancy. CCDC-239547 to -239552 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Characterization of a Byproduct in the Alkylation of DMIT: Alkylation on the Least Nucleophilic Sulfur Atom

**Bo M. Petersen,[a] Jens K. Bjernemose,[a] and Jan O. Jeppesen*[a]**

**Keywords:** Alkylation / DMIT / Nucleophilic substitution / Sulfur heterocycles

It is generally accepted that the alkylation of $(Et_4N)_2$-$[Zn(DMIT)_2]$ (**1**) is a very clean reaction that produces 4,5-bis(alkylthio)-1,3-dithiole-2-thiones **4** in very high yields. Although this procedure has been widely used, we have found that, in addition to the 4,5-bis(alkylthio)-1,3-dithiole-2-thione products **4**, highly unexpected byproducts are formed during the alkylation reaction in which the thione functionalities of DMIT in $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) are alkylated instead of the more reactive thiolate groups. These byproducts were identified as a novel type of compounds, namely bis(2-alkylthio-1,3-dithiol-1-ium-4,5-dithiolato)zinc compounds **3**, being composed of two identical 2-alkylthio-1,3-dithiol-1-ium-4,5-dithiolate moieties coordinated to a single zinc(II) atom and were characterized by elemental analyses and different spectroscopic techniques as well as single-crystal X-ray structure analyses. A comparison of the physical properties of compounds **3** and $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) has been carried out. The outcome of these investigations revealed significant differences in the physical properties of these two systems.

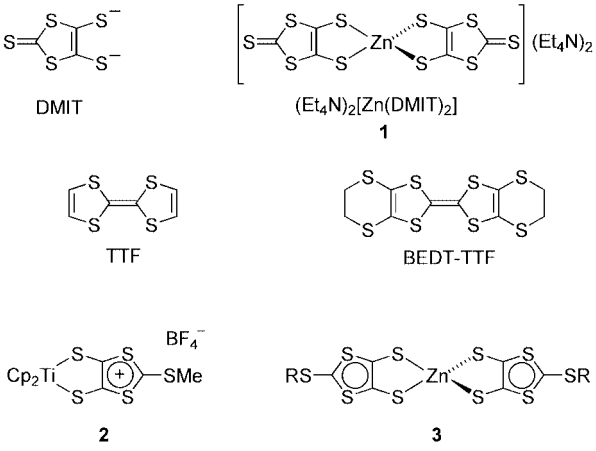
## Introduction

Among sulfur-containing heterocycles, derivatives of 2-thioxo-1,3-dithiole-4,5-dithiolate[1] (DMIT), have received a central position in organic and materials chemistry on account of the discovery of superconductivity in some of the metal complexes[2,3] of DMIT and its chalcogene analogs.[4] In addition, derivatives of DMIT are important building blocks for the synthesis[5] of tetrathiafulvalene[6–9] (TTF) systems, such as bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF) which has been employed for the preparation of an extensive range of conducting[10] and superconducting materials.[11,12] DMIT is commonly isolated as its zinc chelate[13] in the form of bis(tetraethylammonium) bis(2-thioxo-1,3-dithiole-4,5-dithiolato)zincate $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) and subsequent alkylation of the chelated thiolate groups can be accomplished with a variety of alkylating agents producing[14] in most cases 4,5-bis(alkylthio)-1,3-dithiole-2-thiones.



Although alkylation of the thione functionality of 1,3-dithiole-2-thione derivatives are favored by a gain in energy caused by aromatization of the 1,3-dithiole ring to a 1,3-dithiolium system simple alkylating agents, such as alkyl halides, are not sufficiently strong alkylating agents to accomplish this type of reaction for 4,5-bis(alkylthio)-1,3-dithiole-2-thiones. Instead, stronger alkylating agents, such as methyl fluorosulfate, methyl trifluorosulfonate, triethyloxonium tetrafluoroborate, triethyl orthoformate, boron trifluoride–diethyl ether, and dimethyl sulfate must be employed to produce[15] 2,4,5-tris(alkylthio)-1,3-dithiolium salts. Despite several reports on 2,4,5-tris(alkylthio)-1,3-dithiolium salts only one example[16] of a 2-alkylthio-1,3-dithiolium-4,5-dithiolate system – in the form of bis(cyclopentandienyl)(2-methylthio-1,3-dithiolium-4,5-dithiolato)-titanium(IV) (**2**) – has, to the best of our knowledge, been reported so far. In this paper, we present the synthesis and characterization of four systems **3** each containing two 2-alkylthio-1,3-dithiolium-4,5-dithiolate moieties coordinated to a single zinc(II) atom.

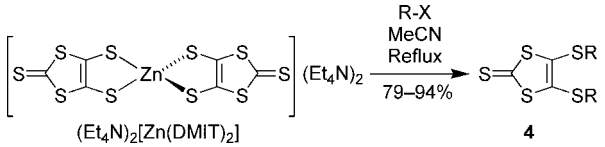
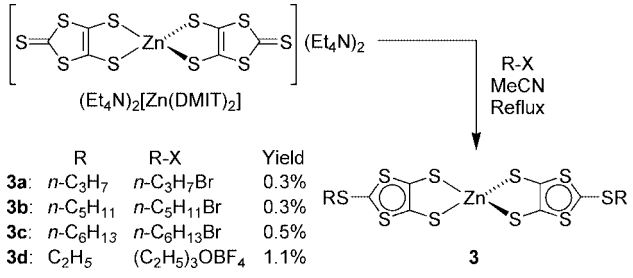
## Results and Discussion

In most cases, the reaction between $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) and an appropriate alkyl halide proceeds smoothly producing (Scheme 1) the corresponding 4,5-bis(alkylthio)-1,3-dithiole-2-thiones **4** in yields ranging from 79% to 94%.[14] In the present investigations, we have observed that, in addition to the desired 4,5-bis(alkylthio)-1,3-dithiole-2-thione products **4**, highly unexpected byproducts are formed during the reaction as a result of alkylation of the thione functionalities instead of the more reactive thiolate groups.



Scheme 1. Synthesis of 4,5-bis(alkylthio)-1,3-dithiole-2-thione products **4**.

In a typically alkylation experiment (Scheme 2), the zincate $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) and the alkyl halide were heated under reflux in MeCN followed by an aqueous workup. Subsequent purification by means of column chromatographic purification afforded a broad yellow fraction together with a weaker blue fraction. The first yellow fraction contained 4,5-bis(alkylthio)-1,3-dithiole-2-thione **4**, whereas it was identified (vide infra) that the second blue band contained the unexpected bis(2-alkylthio-1,3-dithiol-1-ium-4,5-dithiolato)zinc compound **3** as byproduct.



Scheme 2. Synthesis of bis(2-alkylthio-1,3-dithiol-1-ium-4,5-dithiolato)zinc compounds **3**.

As illustrated in Scheme 2, the isolated yields for **3a**–**c** are less than 0.5% when simple alkyl bromides are used as the alkylating agent. However, the yield can be improved by using the stronger alkylating agent triethyloxonium tetrafluoroborate. In this case, **3d** was isolated in a yield just above 1%. The fact that the yields of **3a**–**d** are very low can most likely be accounted for by the presence of the more nucleophilic thiolate groups in $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) which prevents the formation of any larger amounts of **3**. Although **3a**–**d** were isolated in very low yields, the alkylation reactions can be carried out on a large scale allowing substantial amounts (50–150 mg) of **3a**–**d** to be isolated.

The unexpected byproducts **3a**–**d** were all isolated as purple solids. $^1H$ and $^{13}C$ NMR spectroscopy, high-resolution mass spectrometry, and elemental analyses all support the proposed structures of **3a**–**d**. Furthermore, the structures of **3a** and **3b** were unequivocally determined by single-crystal X-ray structure analyses.

### X-ray Crystallographic Studies

Crystals of **3a** and **3b** were grown by letting cyclohexane diffuse into $CHCl_3$ solutions of **3a** and **3b**, respectively. Both compounds show very strong pleochroism with colors changing between bright blue and dark red under polarized light. Crystallographic data were collected with a Nonius KappaCCD diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and the structures were solved by direct methods using SIR97[17] followed by refinement with SHELXL97.[18] Table 1 summarizes the crystallographic data obtained for compound **3a** and **3b**.

The two chelating planes form angles of 85.1(4)° in **3a** and 89.58(13)° in **3b** as compared to 83–85° between the chelating planes in $(Et_4N)_2[Zn(DMIT)_2]$ (**1**). The molecular structure of **3b** with a partial labeling scheme is shown in Figure 1a. In both structures Zn is tetrahedrally coordinated with distortions on account of the limited bite angle of the bis(thiolato) ligand. The coordination geometry closely resembles that of $(Et_4N)_2[Zn(DMIT)_2]$ (**1**). However, in the case of **3b**, there is no crystallographically imposed symmetry contrasting with the twofold axial symmetry observed in about half of the known structures related to $(Et_4N)_2[Zn(DMIT)_2]$ (**1**).[19] This lack of restraint makes DOQXOW[20] the best candidate for comparison as it too is unrestrained and its data collected at 150 K (see Table 2 for a comparison of average bond lengths).

There is no apparent change in Zn–S distances despite the reduced charge of the ligand. The only significant geometric difference between the new ligand and $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) is the obvious lengthening of the C(3)–S(5) bond to a value somewhere between a double (DMIT) and single bond [S(5)–C(7)]. An accompanying shortening of S(3)–C(3) cannot be considered significant.

The packing of **3a** and **3b** is almost identical and the packing diagram of **3b** is depicted in Figure 1b. Both have an ordered alkyl chain in perfect staggered conformation in the plane of its attached dithiole ring. These ordered alkyl chains pack together with symmetry-equivalent copies to form layers parallel to the *ab* plane. The other alkyl chain is twisted and has bonds which are orthogonal to its attached dithiole ring. This twist results in a disorder that cannot readily be modeled wherefore large ADPs have been accepted instead. The disordered alkyl chains pack in a mixed layer in which one of the dithiole rings is sandwiched between the simple alkyl layers. The mixed layer is dominated by C–H···S interactions (minima are 2.9 Å and 2.7 Å in **3a** and **3b**, respectively) and S···S interactions (3.5 Å and 3.7 Å); **3b** shows an interaction between the C=C bond and a dithiole S atom (3.3 Å). The fact that the two dithiole rings are orthogonal in **3a** and **3b** precludes more than one alkyl chain from adopting the favorable all-staggered conformation. Thus, if both alkyl chains were supposed to

adopt a staggered conformation in the plane of their attached dithiole rings, one of them would penetrate into the next layer of molecules. Consequently, one of the alkyl chains is forced to twist to avoid such an unfavorable penetration. The molecule essentially makes the best of a bad lot. Only one alkyl chain can adopt the favorable all-staggered conformation and at the same time remain close packed. The other alkyl chain must then fend for itself without packing too loosely. This can apparently be done in a number of only slightly differing ways resulting in extensive disorder.

Table 2. Average bond lengths [Å] for selected chemically equivalent bonds (a few chemically equivalent bonds do deviate more than 3 e.s.d.s). Data for $(Et_4N)_2[Zn(DMIT)_2]$ was taken from the literature.[20]

| | **3a** | **3b** | $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) |
|---|---|---|---|
| Zn(1)–S(1) | 2.342(5) | 2.3410(12) | 2.345 |
| S(1)–C(1) | 1.724(16) | 1.728(4) | 1.735 |
| C(1)–C(2) | 1.42(2) | 1.372(7) | 1.362 |
| C(1)–S(3) | 1.722(16) | 1.739(4) | 1.753 |
| S(3)–C(3) | 1.707(16) | 1.688(5) | 1.721 |
| C(3)–S(5) | 1.701(16) | 1.721(5) | 1.661 |
| S(5)–C(7) | 1.811(17) | 1.818(7) | |

The absence of good hydrogen-bond donors (and hence of strong X–H···S hydrogen bond interactions) may account for the very different appearance of these compounds in the solid state (dark red) and in solution (dark blue).

## NMR Investigations

A comparison of the $^{13}C$ NMR spectra recorded of compound **3c** with those recorded of $(Et_4N)_2[Zn(DMIT)_2]$ and 4,5-bis(hexylthio)-1,3-dithiole-2-thione (**4c**) reveal significant chemical shift differences for the resonances associated with the carbon atoms in the 1,3-dithiole moiety. The chemical shift values summarized in Table 3, suggest that the 1,3-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dithiole moiety gains some aromatic character upon alkylation of the thione functionality. This observation is also supported by the bond lengths listed in Table 2.

Table 3. Selected $^{13}C$ NMR spectroscopic data ($\delta$ values in ppm) for $(Et_4N)_2[Zn(DMIT)_2]$ (**1**), 4,5-bis(hexylthio)-1,3-dithiole-2-thione (**4c**), and **3c** at 298 K.

| Compound | Solvent | C=C | S–C–S |
|---|---|---|---|
| $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) | $CD_3CN$ | 136.4 | 210.2 |
| **4c** | $CDCl_3$ | 136.5 | 211.6 |
| **3c** | $CDCl_3$ | 158.5 | 168.5 |

### Photophysical Investigations

The photophysical properties have been studied in $CHCl_3$ solutions at room temperature using absorption spectroscopy. The UV/Vis spectroscopic data of **3a**–**d** are listed in Table 4, together with those of $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) and 4,5-bis(pentylthio)-1,3-dithiole-2-thione (**4b**). A comparison of the absorption spectra of **3b**, $(Et_4N)_2[Zn(DMIT)_2]$ (**1**), and 4,5-bis(pentylthio)-1,3-dithiole-2-thione (**4b**) is displayed in Figure 2.

Table 4. UV/Vis absorption band maxima ($\lambda_{max}$) and molar extinction coefficients ($\varepsilon$) for compounds **1**, **3a**–**d**, and 4,5-bis(pentylthio)-1,3-dithiole-2-thione (**4b**) in $CHCl_3$ at room temperature.

| Compound | $\lambda_{max}$ [nm] ($\varepsilon$ [$M^{-1}$ $cm^{-1}$]) |
|---|---|
| $(Et_4N)_2[Zn(DMIT_2)]$ (**1**) | 315 ($26\cdot10^3$), 494 ($21\cdot10^3$) |
| **3a** | 308 ($20\cdot10^3$), 597 ($19\cdot10^3$) |
| **3b** | 308 ($20\cdot10^3$), 598 ($19\cdot10^3$) |
| **3c** | 308 ($21\cdot10^3$), 598 ($20\cdot10^3$) |
| **3d** | 308 ($19\cdot10^3$), 598 ($19\cdot10^3$) |
| **4b** | 278 ($6.4\cdot10^3$) 386 ($11\cdot10^3$) |

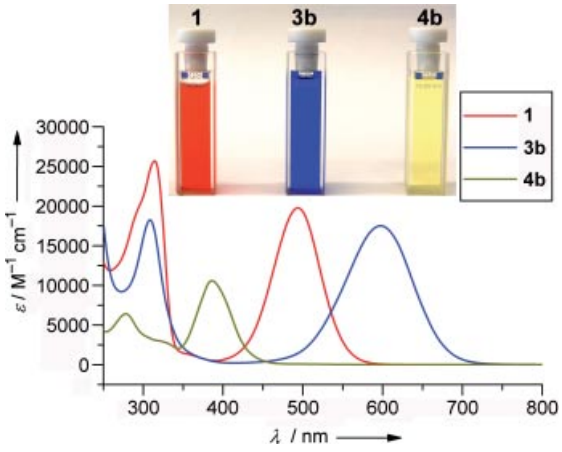

Figure 2. Absorption spectra recorded of $(Et_4N)_2[Zn(DMIT)_2]$ (**1**), **3b**, and 4,5-bis(pentylthio)-1,3-dithiole-2-thione (**4b**). The inset shows the actual color of the solutions of **1**, **3b**, and 4,5-bis(pentylthio)-1,3-dithiole-2-thione (**4b**).

The absorption spectrum of compound 4,5-bis(pentylthio)-1,3-dithiole-2-thione (**4b**) exhibits relative weak absorptions in the 250–450 nm region and no absorptions at $\lambda \geq 500$ nm, consistent with the observed pale yellow color (Figure 2, inset) of 4,5-bis(pentylthio)-1,3-dithiole-2-thione (**4b**) in $CHCl_3$. Dissolving $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) in $CHCl_3$ produced a red solution (Figure 2, inset) with a concomitant strong absorption band being observed at $\lambda_{max}$ = 494 nm ($\varepsilon = 21\cdot10^3$ $M^{-1}$ $cm^{-1}$) in the absorption spectrum, whereas a blue solution (Figure 2, inset) was obtained upon dissolving **3b** in $CHCl_3$. The absorption spectrum recorded of this blue solution of **3b** shows a strong absorption band centered at $\lambda_{max} \approx 598$ nm ($\varepsilon = 20\cdot10^3$ $M^{-1}$ $cm^{-1}$). This band can most likely be assigned to an intramolecular charge transfer (CT) taking place between the relative electron-rich thiolate groups and the 1,3-dithiolium moieties present in **3b**. To support this hypothesis, we carried out some molecular modeling calculations.[21] For simplicity, these investigations were conducted on **3a** which indicate that the two degenerated HOMO and HOMO–1 orbitals (Figure 3) mainly are located on the thiolate groups and the C=C bond, whereas the degenerated LUMO and LUMO+1 orbitals are located on the 1,3-dithiolium moieties. This led us to conclude that the Zn atom has only a minor contribution to the 598 nm absorption band. Instead, this absorption band can most likely be ascribed to an intramolecular electron transfer occurring between the thiolate groups and the 1,3-dithiolium moieties.

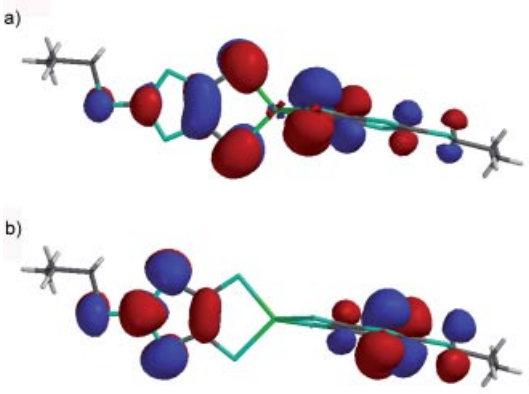

Figure 3. HOMO and LUMO orbitals of **3a**. (a) The degenerated HOMO and HOMO–1 orbitals are mainly located on the thiolate groups and the C=C bond, whereas (b) the degenerated LUMO and LUMO+1 orbitals are located on the 1,3-dithiolium moieties.

## Conclusions

In conclusion, we have shown that alkylation of $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) not only affords 4,5-bis(alkylthio)-1,3-dithiole-2-thiones **4**, but also takes place at the less nucleophilic thione functionalities producing a novel class of compounds **3** in which a Zn atom is coordinated to two aromatic 2-alkylthio-1,3-dithiolium-4,5-dithiolate moieties. Formation of **3** can be detected by the naked eye since solutions of $(Et_4N)_2[Zn(DMIT)_2]$ (**1**) and **3** display different colors, red and blue, respectively. Although the isolated yields of **3** generally were low, it seems that the formation of **3** is a common feature upon alkylation of $(Et_4N)_2[Zn(DMIT)_2]$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(**1**). Consequently, it can be expected that the method can be extended to produce more elaborate derivatives of **3**. The findings reported herein are undoubtedly not unimportant given the amount of research devoted to DMIT and its corresponding metal complexes.

## Experimental Section

**General Procedures:** Chemicals and solvents were purchased from Aldrich and were used as received. Bis(tetraethylammonium) bis(2-thioxo-1,3-dithiole-4,5-dithiolato)zincate (**1**) was prepared according to a literature procedure.[13] Thin-layer chromatography (TLC) was carried out using aluminium sheets pre-coated with silica gel 60F (Merck 5554). The plates were inspected under UV light and, if required, developed in $I_2$ vapor. Column chromatography was carried out using silica gel 60F (Merck 9385, 0.040–0.063 mm). Melting points were determined with a Büchi melting point apparatus and are uncorrected. $^1$H (300 MHz) and $^{13}$C NMR (75 MHz) spectra were recorded at 298 K with a Gemini-300BB instrument, using tetramethylsilane (TMS) or the residual solvent as the internal standard. All chemical shifts are quoted on the $\delta$ scale, and all coupling constants (*J*) are expressed in Hertz (Hz). Samples were prepared using $CDCl_3$ or $CD_3CN$ purchased from Cambridge Isotope Labs. High-resolution Fourier transform matrix-assisted laser-desorption/ionization mass spectrometry (HiRes-FT-MALDI-MS) was performed with an IonSpec 4.7 Tesla Ultima Fourier Transform mass spectrometer, utilizing a 2,5-dihydroxybenzoic acid (DHB) matrix. Infrared (IR) spectra were recorded with a Perkin–Elmer 580 spectrophotometer, while absorption spectra (UV/Vis) were recorded with a Shimadazu 1601 spectrophotometer. Elemental analyses were performed by the Atlantic Microlab, Inc., Atlanta, Georgia.

**General Method for the Preparation of the Bis(2-alkylthio-1,3-dithiol-1-ium-4,5-dithiolato)zinc Compounds 3:** Bis(tetraethylammonium) bis(2-thioxo-1,3-dithiole-4,5-dithiolato)zincate (**1**) (21.5 g, 30 mmol) was suspended in anhydrous MeCN (200 mL), whereupon the appropriate alkyl bromide (120 mmol) was added. The dark red reaction mixture was heated under reflux for 1 h until no more starting material could be detected by TLC analysis ($R_f$ = 0.70; eluent: EtOAc/MeCN, 3:2). After being cooled to room temperature, the reaction mixture was concentrated in vacuo, and the resulting dark green oil was dissolved in $CH_2Cl_2$ and purified by column chromatography (750 mL of silica; diameter: 13.5 cm; eluent: $CH_2Cl_2$/petroleum ether, 1:9). The broad yellow band was collected, and the solvent evaporated to afford the 4,5-bis(alkylthio)-1,3-dithiole-2-thiones **4**. Thereafter, the eluent was changed to $CH_2Cl_2$ and a blue band was collected and concentrated to provide the title compounds **3a**–**c** as purple powders. Crystals suitable for X-ray analysis were prepared by diffusion of cyclohexane into $CHCl_3$ solutions of **3a** and **3b**, providing **3a** and **3b** as fine purple plates.

**Bis(2-propylthio-1,3-dithiol-1-ium-4,5-dithiolato)zinc (3a):** Yield: 46 mg (0.28%); $R_f$ = 0.45 (eluent: $CH_2Cl_2$); m.p.183–184 °C (dec.). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 1.09 (t, *J* = 7.2 Hz, 6 H), 1.84 (sext, *J* = 7.2 Hz, 4 H), 3.18 (t, *J* = 7.2 Hz, 4 H). UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon$) = 308 ($20{\cdot}10^3$ M$^{-1}$ cm$^{-1}$), 597 nm ($19{\cdot}10^3$ M$^{-1}$ cm$^{-1}$). IR (KBr): $\tilde{\nu}$ = 2960, 2923, 2866, 2013, 1363, 1285, 1013, 979, 906, 469 cm$^{-1}$. $C_{12}H_{14}S_{10}Zn$ (544.3): calcd. C 26.48, H 2.59, S 58.91; found C 26.15, H 2.55, S 58.39.

**Bis(2-pentylthio-1,3-dithiol-1-ium-4,5-dithiolato)zinc (3b):** Yield: 60 mg (0.33%); $R_f$ = 0.46 (eluent: $CH_2Cl_2$); m.p. 148.5–149.5 °C (dec.). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 0.93 (t, *J* = 7.1 Hz, 6 H), 1.34–1.46 (m, 8 H), 1.80 (q, *J* = 7.4 Hz, 4 H), 3.20 (t, *J* = 7.4 Hz, 4 H). $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 14.0, 22.2, 28.2, 30.8, 40.4, 158.8 (one line for the trithiocarbonate carbon atom is missing). UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon$) = 308 ($20{\cdot}10^3$ M$^{-1}$ cm$^{-1}$), 598 nm ($19{\cdot}10^3$ M$^{-1}$ cm$^{-1}$). IR (KBr): $\tilde{\nu}$ = 2946, 2925, 2854, 2008, 1453, 1424, 1349, 1022, 903, 730, 467 cm$^{-1}$. HiRes-FT-MALDI-MS: calcd. for $C_{16}H_{22}S_{10}Zn$ [$M^{+\cdot}$] 597.8215; found: 597.8209. $C_{16}H_{22}S_{10}Zn$ (600.4): calcd. C 32.01, H 3.69, S 53.41; found C 32.01, H 3.60, S 53.60.

**Bis(2-hexylthio-1,3-dithiol-1-ium-4,5-dithiolato)zinc (3c):** Yield: 75 mg (0.49%); $R_f$ = 0.45 (eluent: $CH_2Cl_2$); m.p. 161.5–163.0 °C (dec.). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 0.91 (t, *J* = 6.7 Hz, 6 H), 1.25–1.50 (m, 12 H), 1.79 (q, *J* = 7.4 Hz, 4 H), 3.20 (t, *J* = 7.4 Hz, 4 H). $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 14.1, 22.6, 28.3, 28.5, 31.2, 40.4, 158.5, 168.5 cm$^{-1}$. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon$) = 308 ($21{\cdot}10^3$ M$^{-1}$ cm$^{-1}$), 598 nm ($20{\cdot}10^3$ M$^{-1}$ cm$^{-1}$). IR (KBr): $\tilde{\nu}$ = 2946, 2922, 2851, 2006, 1462, 1421, 1357, 1009, 904, 725, 465 cm$^{-1}$. HiRes-FT-MALDI-MS: calcd. for $C_{18}H_{26}S_{10}Zn$ [$M^{+\cdot}$] 625.8528; found 625.8522. $C_{18}H_{26}S_{10}Zn$ (628.4): calcd. C 34.40, H 4.17, S 51.02; found C 34.38 H 4.29, S 51.31.

**Bis(2-ethylthio-1,3-dithiol-1-ium-4,5-dithiolato)zinc (3d):** Bis(tetraethylammonium) bis(2-thioxo-1,3-dithiol-1-ylium-4,5-dithiolato)-zincat (**1**) (21.5 g, 30 mmol) was suspended in MeCN (200 mL), whereupon triethyloxonium tetraflouroborate (25.0 g, 120 mmol) was added. The dark red reaction mixture was heated under reflux for 5 min until no more starting material could be detected by TLC analysis ($R_f$ = 0.70; eluent: EtOAc/MeCN, 3:2). The reaction mixture was cooled to room temperature and concentrated in vacuo. The resulting dark red oil was dissolved in $CH_2Cl_2$. Column chromatography (800 mL of silica; diameter: 13.5 cm; eluent: $CH_2Cl_2$/petroleum ether, 1:4) gave a yellow band and a red band which was discarded. The bis(2-ethylthio-1,3-dithiol-1-ium-4,5-dithiolato)zinc (**3d**) was then eluted as a blue band with $CH_2Cl_2$. Removal of the solvent provided the title compound **3d** as a purple microcrystalline powder. Yield: 169 mg (1.1%); $R_f$ = 0.20 (eluent: $CH_2Cl_2$); m.p. 164.0–165.0 °C (dec.). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 1.49 (t, *J* = 7.4 Hz, 6 H), 3.22 (q, *J* = 7.4 Hz, 4 H). UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon$) = 308 ($19{\cdot}10^3$ M$^{-1}$ cm$^{-1}$), 598 nm ($19{\cdot}10^3$ M$^{-1}$ cm$^{-1}$). IR (KBr): $\tilde{\nu}$ = 2923, 2011, 1445, 1348, 1288, 1262, 1061, 1016, 905, 787, 466 cm$^{-1}$. HiRes-FT-MALDI-MS: $C_{10}H_{10}S_{10}Zn$ [$M^{+\cdot}$]: calcd. 513.7276; found 513.7265. $C_{10}H_{10}S_{10}Zn$ (516.23): calcd. C 23.27, H 1.95, S 62.11; found C 23.36, H 1.89, S 62.30.

**X-ray Crystallography:** Details are listed in Table 1. CCDC-601004 (**3a**) and -601005 (**3b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis, Crystal Structure, and Second-Order Nonlinear Optical Properties of Ruthenium(II) Complexes with Substituted Bipyridine and Phenylpyridine Ligands

**Laurence Labat,[a] Jean-François Lamère,[a] Isabelle Sasaki,[a] Pascal G. Lacroix,*[a] Laure Vendier,[a] Inge Asselberghs,[b] Javier Pérez-Moreno,[b] and Koen Clays[b]**

**Keywords:** Ligand design / Donor–acceptor systems / Ruthenium / Nonlinear optics / Density functional calculations

Two new ruthenium(II) complexes of formula $[Ru(bpy)_2(L^1)][PF_6]$ and $[Ru(bpy)_2(L^2)][PF_6]_2$ are reported. $HL^1$ is a (nitrophenyl)ethenyl-substituted phenylpyridine ligand, and $L^2$ is the bipyridine analogue of $HL^1$. The X-ray crystal structure of $[Ru(bpy)_2(L^1)][PF_6]$ has been solved, and the compound is found to crystallize in the monoclinic *C*2/*c* space group. The electronic spectrum of the cyclometalated derivative $[Ru(bpy)_2(L^1)][PF_6]$ exhibits a low-lying transition that is red-shifted from 454 to 546 nm relative to that of the parent bipyridine-based complex, which reveals an important charge-transfer character. To support this assumption, the nonlinear optical properties were investigated by the hyper-Rayleigh scattering technique and indicate a molecular static hyperpolarizability ($\beta_0$) equal to $230 \times 10^{-30}$ cm$^5$ esu$^{-1}$.

## Introduction

Molecules with π-conjugated electronic structures have been attracting considerable interest due to their potential nonlinear optical (NLO) properties and applications in optoelectronic and photonic devices.[1,2] While the first investigations were initially focused on purely organic systems,[3] the search for alternative organometallic and inorganic derivatives has gradually intensified in the last fifteen years.[4–6] Incorporation of metal atoms into π-conjugated systems introduces many new variables, such as diversity of oxidation states, intensely colored charge-transfers, additional magnetic capabilities, and a diversity of new topologies, which leads to NLO chromophores of much greater complexity than that of the first generation of "push-pull" organic molecules.[6]

For instance, ruthenium complexes have provided intriguing molecular materials with unusual electronic capabilities since the 1960s, in particular as mixed-valence $Ru^{II}Ru^{III}$ complexes.[7] In (pyridine)ruthenium(II) complexes, for example, the metal center is engaged in π-bonding with the organic ligating groups and can be involved in strongly allowed metal-to-ligand charge-transfer (MLCT), and hence provides various candidates for NLO applications. Indeed, ruthenium has led to the most investigated family of (pyridine)metal complexes in nonlinear optics.[8] The reasons for this interest are the possibility of designing various promising octupolar topologies,[9,10] and the observation of switchable NLO responses upon metal oxidation in some cases,[11] a possibility which could attract great interest in relation with the concept of molecular switches.[12,13]

In the last few years several cyclometalated counterparts of (polypyridine)ruthenium complexes have been prepared and their physical properties reported.[14–17] In fact, cyclometalated complexes have found widespread interest as species with promising properties in various research fields[15c] owing to the strong σ-donor ability of the cyclometalating ligand. Basically, replacement of a nitrogen donor by a formal carbanion donor drastically increases the electron density around the metal atom and the crystal-field strength.[14,15a] As a consequence, the d→π* back-donation is reinforced, which leads to a potential enhancement of the overall intramolecular charge transfer, a property which is highly desirable for the design of NLO chromophores. The enhancement of the donating capabilities of the ruthenium(II) center has been evidenced experimentally by the observation of intense charge-transfer properties in $Ru^{II}/Ru^{III}$ complexes with bis(cyclometalating) ligands,[15b,18] and by a shift of the value of the $Ru^{II}/Ru^{III}$ oxidation potential of about 900 mV upon replacement of one nitrogen atom by one carbon atom in tris(bipyridine)ruthenium(II)-like complexes.[14]

Recently, we have developed a new synthetic strategy aimed at providing an access to numerous phenylpyridine ligands substituted in *para* ($R^1$) and *meta* ($R^2$) positions with respect to the nitrogen atom (Scheme 1).[19] In the perspective of nonlinear optics, the presence of an acceptor (A) in the *meta* position is the most desirable to favor an intense

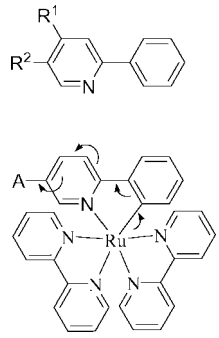
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

charge-transfer process from electron-rich metal–carbon moieties, as indicated in this scheme, and finally to provide a sizeable NLO response.



Scheme 1.

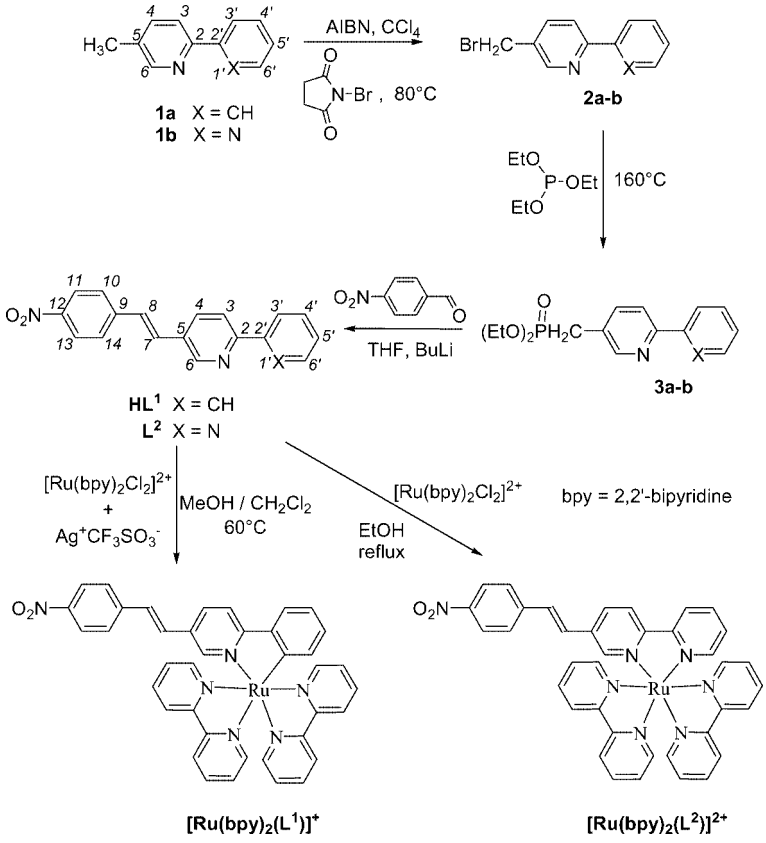
Following this idea, we report here our attempt to design a set of two (phenylpyridine and bipyridine)ruthenium complexes with potential MLCT capabilities. In the first section, their synthesis and characterizations will be presented. Then, the crystal structure of the cyclometalated complex will be discussed. Finally, the optical and nonlinear optical properties of both derivatives will be compared in relation to the enhanced "push-pull" character induced by the Ru–C linkage. The investigated molecules of formula $[Ru(bpy)_2(L^1)][PF_6]$ and $[Ru(bpy)_2(L^2)][PF_6]_2$ are shown in Scheme 2.

## Results and Discussion

### Synthesis and Characterization

Two methods for the synthesis of $HL^1$ and $L^2$, which contain the electron-withdrawing substituent $NO_2$, were envisioned: by condensing formylbipyridine or formyl(phenyl)pyridine with the appropriate phosphonate (method A) or by condensing the phosphonate **3a**,**b** derived from the bipyridine or the phenylpyridine with *p*-nitrobenzaldehyde (method B). Method B was chosen as the synthesis of 5-(bromomethyl)-2,2′-bipyridine (**2b**) from **1b**[20] has already been described[21] and was extended here to 5-methyl-2-phenylpyridine (**1a**). The first step involves the conversion of the methyl group to the corresponding bromomethyl group by treatment with *N*-bromosuccinimide (NBS) and azoisobutyronitrile (AIBN). The bromomethyl derivatives **2a**,**b** were then converted into the phosphonate derivatives **3a**,**b**.[22] The final step was the Wadsworth–Emmons reaction of compounds **3a**,**b** with the commercially available *p*-nitrobenzaldehyde, which leads to the styryl derivatives $HL^1$ and $L^2$ in 29% and 37% yields, respectively.[22] The double-bond linkages were confirmed to be (*E*) by $^1H$ NMR analysis based on the value of the $J_{CH=CH}$ coupling constant (ca. 16 Hz).

The syntheses of the two complexes are not similar. The tris(bipyridine) complex was obtained by the classical method, i.e., heating of 1 equiv. of $[Ru(bpy)_2]Cl_2$ with



Scheme 2.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1 equiv. of $L^2$ in ethanol, whereas for the cyclometalated complex 1 equiv. of $[Ru(bpy)_2]Cl_2$ was treated with 5 equiv. of the phenylpyridine $HL^1$ in the presence of silver triflate.[19] The complexes were characterized by the usual methods. The labelling of the atoms is the one used for the X-ray structure. Characteristic peaks of cyclometalated compounds were observed in the NMR spectra of $[Ru(bpy)_2(L^1)][PF_6]$ and the peaks of the spectra were fully assigned.[14,23,24] Nevertheless, for complex $[Ru(bpy)_2(L^2)][PF_6]_2$, the unambiguous assignment of all the signals was not possible: since the electronic environments of numerous pyridine hydrogen atoms are nearly similar, their signals occur in a very narrow chemical-shift range.

## Structural Data

The crystallographic data are summarized in the Experimental Section, and the X-ray molecular structure of $[Ru(bpy)_2(L^1)][PF_6]$ is presented in Figures 1 and 2. The compound crystallizes in the monoclinic *C*2/*c* space group ($Z = 8$). The asymmetric unit cell (Figure 1) is built up from one ruthenium complex, one $PF_6^-$ anion, and one molecule of diethyl ether. In the crystal, $[Ru(bpy)_2(L^1)][PF_6]$ is organized in extended layers of complexes in the *bc* plane (Figure 2). The π-conjugated skeleton of the substituted phenylpyridine ligands lies parallel to the layers, the direction of highest polarizability (phenyl → $NO_2$) being roughly [001].

The ruthenium atom lies in a distorted octahedral environment. Metal–ligand bond lengths are presented in Table 1. Interestingly, and in contrast with previously reported X-ray data,[16] the Ru–C(1) distance of 2.033(4) Å is not significantly shortened with respect to the average Ru–N distance 2.036(4) Å observed for the bipyridine N(3), N(4) atoms. Nevertheless, a tendency for increased ruthenium–nitrogen bond lengths in the *trans* position with respect to the Ru–C bond is unambiguously seen [Ru–N(6) = 2.133(4) Å]. Along this line, the increase of this latter bond length is indeed the most noticeable geometrical change introduced in the coordination sphere of the metal atom by the presence of a carbon atom, in agreement with the

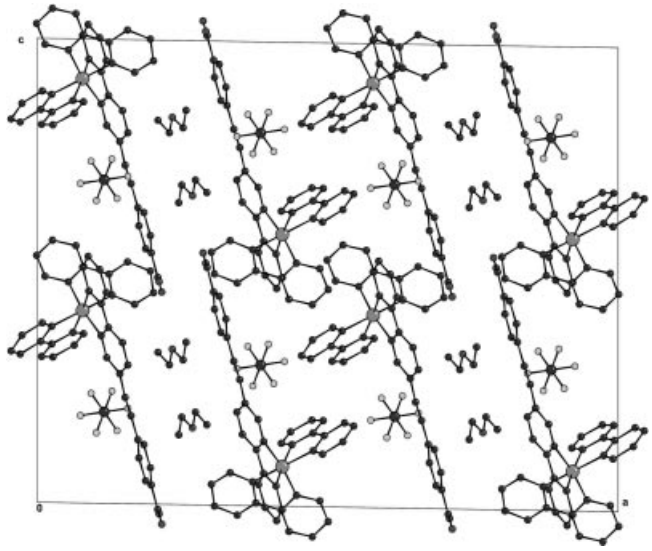


Figure 2. View of the crystal cell of $[Ru(bpy)_2(L^1)][PF_6]$ in the *ac* plane.

$[Ru(bpy)_2(nitrophenpy)]^+$ structure reported in the literature.[16] Another, more surprising, structural feature is the angle of 37.0(3)° observed between the phenyl group carrying the nitro substituent and the pyridine ring of the phenylpyridine ligand. This rotation suggests that the nitrophenyl group is not significantly involved in the charge-transfer process in the solid state. In order to verify whether the torsion arises from crystal packing or from intrinsic electronic effects, the gas-phase geometries of $[Ru(bpy)_2(L^1)][PF_6]$ and $[Ru(bpy)_2(L^2)][PF_6]_2$ were investigated within the framework of density functional theory (DFT).

The calculated coordination spheres are compared in Table 1. The tendency for slightly increases bond lengths obtained by DFT is observed here, as is the case in model Ru(phenpy) complexes (see Experimental Section). In the case of the bipyridine-based derivative, the six bond lengths are very similar, with an average value of 2.1175 Å. By contrast, the coordination sphere of the cyclometalated derivative exhibits the usual structural features of $[Ru(bpy)_2$-

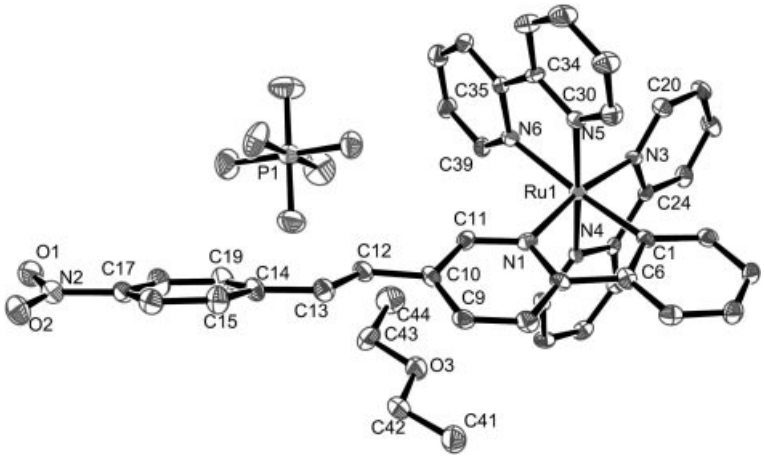

Figure 1. Asymmetric unit cell of $[Ru(bpy)_2(L^1)][PF_6]$. Hydrogen atoms are omitted for clarity.

Table 1. Ruthenium–ligand bond lengths [Å] in $[Ru(bpy)_2(L^1)][PF_6]$ and $[Ru(bpy)_2(L^2)][PF_6]_2$.

| | $[Ru(bpy)_2(L^1)][PF_6]$ | | $[Ru(bpy)_2(L^2)][PF_6]_2$ | |
|---|---|---|---|---|
| | X-ray | DFT | X-ray | DFT |
| Ru–C(1) | 2.033(4) | 2.049 | n.a. | 2.117 |
| Ru–N(1) | 2.072(3) | 2.131 | n.a. | 2.120 |
| Ru–N(3) | 2.033(3) | 2.088 | n.a. | 2.118 |
| Ru–N(4) | 2.039(4) | 2.096 | n.a. | 2.116 |
| Ru–N(5) | 2.068(4) | 2.124 | n.a. | 2.116 |
| Ru–N(6) | 2.133(4) | 2.233 | n.a. | 2.118 |

$(phenpy)]^+$ complexes, namely a shortening of the Ru–C bond (2.049 Å) and elongation of the Ru–N bond (2.233 Å) *trans* to the Ru–C bond. Importantly, the angles between the nitrophenyl and pyridine rings are 4.4° and 3.1° for $[Ru(bpy)_2(L^1)]^+$ and $[Ru(bpy)_2(L^2)]^{2+}$, respectively. This result suggests that, to a large extent, the torsion angle of 37° observed in the crystal structure arises from a solid-state effect and is not an intrinsic electronic behavior of the chromophores.

## Optical Properties

The UV/Vis spectra of $[Ru(bpy)_2(L^1)][PF_6]$ and $[Ru(bpy)_2(L^2)][PF_6]_2$ are shown in Figure 3. At first glance, both spectra are grossly similar and reveal three intense transitions located at 296 (65150), 370 (51850), and 546 (14500 $mol^{-1}\,L\,cm^{-1}$) nm for the cyclometalated complex, and at 288 (64850), 365 (44900), and 454 (12250 $mol^{-1}\,L\,cm^{-1}$) nm for the parent bipyridine-based derivative. It is interesting to note that the only significant difference in both spectra is a redshift of 92 nm (3711 $cm^{-1}$) observed for the low-lying transition depending on the presence of an Ru–N or Ru–C linkage. This considerable shift suggests that the low-energy transition is the main signature of the charge transfer arising between the ruthenium atom and the substituted bipyridine or phenylpyridine ligand.

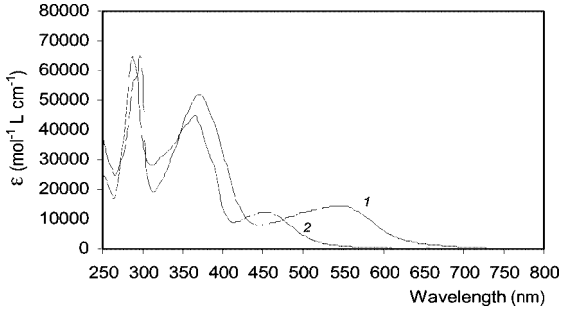

Figure 3. UV/Vis spectra of $[Ru(bpy)_2(L^1)][PF_6]$ (**1**) and $[Ru(bpy)_2(L^2)][PF_6]_2$ (**2**) recorded in acetonitrile.

In order to further analyze the nature of the electronic transitions of ruthenium complexes, the solvatochromic properties have been investigated. Solvatochromism is usually associated with a large dipole moment change upon electronic excitation, and is therefore an interesting probe of large charge-transfer capabilities. The absorption maxima recorded in solvents of different polarities are gathered in Table 2 and presented in Figure 4, where the energy transitions are drawn vs. the Reichardt solvent parameter $E_T^N$.[25] A first comparison conducted on the two transitions of the cyclometalated complex, located at 370 and 546 nm, confirms that the low-lying transition exhibits the largest solvatochromic shift (slope equal to 499 in Figure 4b, vs. 414 in Figure 4a). This is consistent with the anticipation of an intense charge-transfer effect associated with the low-lying transition of these ruthenium complexes. In a second comparison, the low-energy transitions are compared for $[Ru(bpy)_2(L^1)][PF_6]$ (Figure 4b) and the bipyridine-based $[Ru(bpy)_2(L^2)][PF_6]_2$ (Figure 4c). A reduction of the slope to 369 in Figure 4c clearly shows that the solvatochromic shift (and hence the charge transfer properties) are limited in $[Ru(bpy)_2(L^2)][PF_6]_2$. All together, these experimental data confirm the initial intuition that cyclometalated derivatives are promising candidates for the design of molecules with enhanced charge-transfer capabilities.

Table 2.Absorption maxima ($\lambda_{max}$ [nm]) of the lowest-energy optical transitions for $[Ru(bpy)_2(L^1)][PF_6]$ and $[Ru(bpy)_2(L^2)][PF_6]_2$ in solvents of different polarities.

[a] Reichardt parameter.

A theoretical support is provided from the calculated electronic spectra. Functionals specifically designed for TD-DFT calculations of electronic spectra (LB94, SOAP, GRAC) are not implemented in our version of Gaussian, therefore the spectra were calculated with ZINDO on the basis of the gas-phase DFT structures. The data are gathered in Table 3, where they are compared to the experimental values. There is an important blueshift in the computed wavelengths for both complexes. However, this seems to be a general tendency frequently observed in the calculated spectra of inorganic chromophores.[26] The fact that the magnitude of this shift is especially pronounced in the case of the low-energy transition of $[Ru(bpy)_2(L^1)][PF_6]$, which is assumed to arise from an intense metal–phenyl charge transfer, may be additionally related to an enhancement of the ruthenium–ligand distance within the DFT computation. Apart from these energy differences, a qualitative agreement between experiment and calculation is observed on two important points: (i) both complexes exhibit a very intense high-energy transition and a less intense one located at lower energy; (ii) while the high-energy transitions are grossly located at the same energy range in both derivatives, the low-lying transition is considerably red-shifted in the case of the cyclometalated compound.

To further understand the nature of the charge-transfer behavior, the low-lying transitions can be analyzed at the

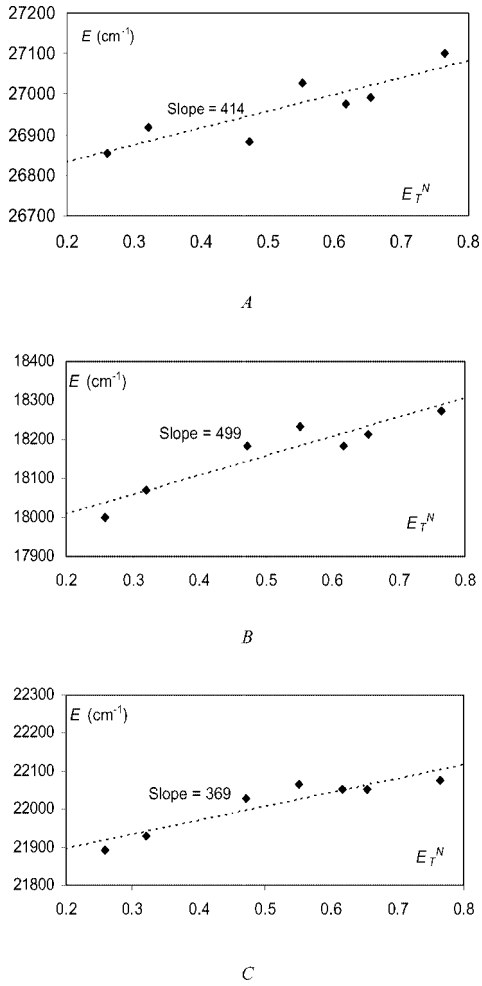

Figure 4. Absorption maxima [$cm^{-1}$] in solvents of different polarity (Reichardt constant $E_T^N$) for $[Ru(bpy)_2(L^1)][PF_6]$ [band at 370 (A) and 546 nm (B)] and for $[Ru(bpy)_2(L^2)][PF_6]_2$ [band at 454 nm (C)].

orbital level. In the case of $[Ru(bpy)_2(L^2)][PF_6]_2$, three dominant excitations contribute to the $1 \rightarrow 2$ transition (Table 3), which leads to 47% of the ground-state electron density in orbital 117. However, this orbital is located on the $L^2$ fragment only (98.1% of the electron density), which results in a ligand-to-ligand charge-transfer process. The contribution of the metal atom to $1 \rightarrow 2$ is weak and is provided by orbital 114 (70.0% centered on the ruthenium atom). In the case of $[Ru(bpy)_2(L^1)][PF_6]$, the dominant excitations involved in the $1 \rightarrow 7$ transition lead to the same 47% of ground-state electron density in orbital 117. However, and in striking contrast with $[Ru(bpy)_2(L^2)][PF_6]_2$, the electron density in orbital 117 is shared between $L^1$ (61.5%) and the ruthenium atom (31.8%). An additional donating contribution of the ruthenium atom is provided by orbital 115 (70.0% ruthenium-based). These differences lead to a significant enhancement of the donating character of the ruthenium atom in $[Ru(bpy)_2(L^1)][PF_6]$. The overall charge-transfer behavior associated with the $1 \rightarrow 7$ transition is shown in Figure 5, which clearly indicates that the ruthenium–phenyl fragment is deeply involved as the donating moiety of the chromophore.

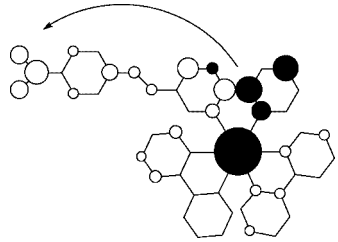

Figure 5. Charge transfer associated with the low-lying electronic transition of $[Ru(bpy)_2(L^1)][PF_6]$. White (black) contributions are indicative of increase (decrease) of electron density occurring upon electron transition.

Additional experimental evidence revealing the enhancement of the electron density around the metal center is provided by the electrochemical studies of the $Ru^{II}/Ru^{III}$ oxidation process. Single-electron waves are observed in both complexes, leading to $E^{1/2}$ values equal to 0.49 and 1.30 V for $[Ru(bpy)_2(L^1)][PF_6]$ and $[Ru(bpy)_2(L^2)][PF_6]_2$, respectively. The effect of cyclometalation on the stability of the $Ru^{III}$ state is illustrated by a cathodic shift of about 810 mV. This behavior demonstrates the strong σ-donating character of the anionic ligand, and the enhancement of the donating ability upon replacement of a nitrogen atom by a carbon atom, in the coordination sphere of the ruthenium atom.[19]

## Nonlinear Optical Properties

Before describing the NLO response of $[Ru(bpy)_2(L^1)][PF_6]$ and $[Ru(bpy)_2(L^2)][PF_6]_2$, it is important to emphasize that the values are not overestimated by multiphoton fluorescence. This is experimentally verified by performing femtosecond hyper-Rayleigh scattering (HRS) ex-

Table 3. Experimental and ZINDO calculated spectra for $[Ru(bpy)_2(L^1)][PF_6]$ and $[Ru(bpy)_2(L^2)][PF_6]_2$.

| Compound | UV/Vis spectra | | ZINDO data | | Assignment | Composition of CI expansion of the low-lying transitions[a] | Orbitals (% electron density on $Ru^{II}$) |
|---|---|---|---|---|---|---|---|
| | λ [nm] | ε [$mol^{-1}Lcm^{-1}$] | λ [nm] | *f* | | | |

| | 370 | 51900 | 344 | 0.72 | $1 \rightarrow 11$ | | |
| $[Ru(bpy)_2(L^2)][PF_6]_2$ | 454 | 12300 | 397 | 0.42 | $1 \rightarrow 2$ | 0.529 $\chi_{117\rightarrow118}$ – 0.454 $\chi_{114\rightarrow118}$ – 0.434 $\chi_{117\rightarrow119}$ | 118 (0.2%), 119 (4.2%), 114 (70.0%), 117 (1.6%) |
| | 364 | 44900 | 358 | 0.87 | $1 \rightarrow 10$ | | |

[a] Orbital 117 is the HOMO and orbital 118 the LUMO in both compounds.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

periments as a function of modulation frequency.[27] The finite lifetime associated with any fluorescence results in a demodulation (reduction of amplitude) for higher frequencies.[28] As exemplified in Figure 6, no such demodulation is observed in the case of $[Ru(bpy)_2(L^1)][PF_6]$, thus implying that the HRS signal is not comprised of any multiphoton fluorescence contribution.[29]

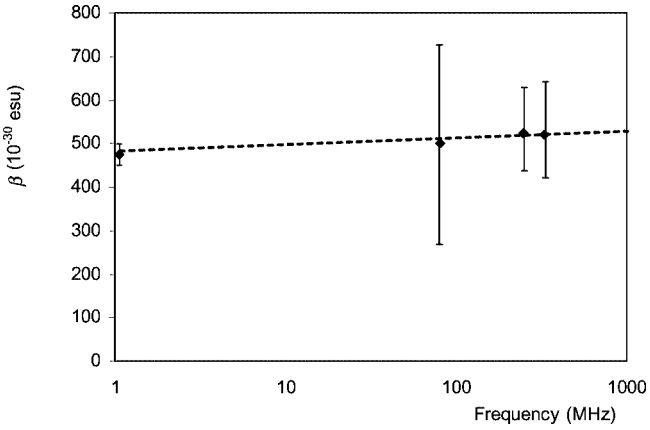

Figure 6. Experimental $\beta$ values as a function of modulation frequency for $[Ru(bpy)_2(L^1)][PF_6]$, showing the frequency-independent response of the multiphoton-fluorescence-free HRS signal.

The HRS data are gathered in Table 4 for both derivatives. In the case of $[Ru(bpy)_2(L^2)][PF_6]_2$, the detected signal falls within the limit of the uncertainty of the present HRS setup; therefore the hyperpolarizability was not determined with full accuracy and the reported data are the upper $\beta$ limit only. It must be pointed out that, as the second harmonic (400 nm) is close to the charge-transfer band located at 546 and 454 nm for $[Ru(bpy)_2(L^1)][PF_6]$ and $[Ru(bpy)_2(L^2)][PF_6]_2$, respectively, the experimental $\beta$ values are necessarily overestimated by resonance. Therefore, the parameter to take into account as the intrinsic hyperpolarizability (independent of the laser frequency) is $\beta_0$ (vide infra). An examination of Table 4 reveals a significant enhancement of the NLO response in the cyclometalated derivative, with an intrinsic hyperpolarizability equal to $230 \times 10^{-30}$ cm$^5$ esu$^{-1}$.

Table 4. Experimental hyperpolarizabilities [$10^{-30}$ cm$^5$ esu$^{-1}$] for the ruthenium complexes, recorded using the hyper-Rayleigh scattering method at 800 nm ($\beta$) and at zero frequency ($\beta_0$).

| | $\beta$ | $\beta_0$ |
|---|---|---|
| $[Ru(bpy)_2(L^1)][PF_6]$ | 500 | 230 (±50) |
| $[Ru(bpy)_2(L^2)][PF_6]_2$ | < 200 | < 40 |

## Conclusions

Two related ruthenium(II) complexes have been investigated to compare their MLCT capabilities and hence the hyperpolarizabilities of metal–phenylpyridine- vs. metal–bipyridine-based chromophores. We have reported on a set of computational, spectroscopic, electrochemical, and nonlinear optical measurements which all prove that a strongly enhanced MLCT behavior takes place in a cyclometalated derivative with respect to the parent metal–bipyridine molecule. The last few years have witnessed a growing interest in (pyridine)ruthenium(II) complexes in relation with the concept of NLO switching obtained by a redox effect.[11] It therefore seems promising to design such cyclometalated ruthenium chromophores that exhibit large NLO responses in addition to reversible and accessible redox properties. Along these lines, these complexes could undoubtedly attract potential interest from the perspective of materials science.

## Experimental Section

**Starting Materials and Equipment:** Reagents and solvents are commercially available and were used as received. **1a**,[19] **1b**,[20] and $[Ru(bpy)_2Cl_2]$[30] were prepared according to literature procedures. $^1$H and $^{13}$C NMR spectra were recorded at 298 K with a Bruker AM 250 spectrometer (250 MHz for $^1$H NMR and 62.9 MHz for $^{13}$C) or a Bruker Avance 500 spectrometer for 2D NMR. The atom labelling used for the assignment is given in Scheme 2. DCI and EI mass spectra were obtained with a Thermo Finnigan TSQ 7000 and FAB mass spectra were recorded with a quadrupolar Nermag R 10-10 instrument using an NBA matrix. UV/Vis spectra were recorded with a Hewlett Packard 8452A spectrophotometer. Elemental analyses were performed by the "Service de Microanalyses du Laboratoire de Chimie de Coordination" (Toulouse) with a Perkin–Elmer 2400 Serie II instrument. Cyclic voltammetry data were recorded with an Autolab PGSTAT 100 potentiostat, in acetonitrile using a Pt disk (1 mm diameter) as the working electrode, a Pt gauze as the auxiliary electrode, and SCE as the reference electrode. $n$Bu$_4$NPF$_6$ (0.1 M) was used as the supporting electrolyte (purum electrochemical grade Fluka, purified by sublimation). All voltammetric experiments were performed at ambient temperature in a home-made, airtight three-electrode cell connected to a vacuum/argon line. The solutions used for the electrochemical studies were typically $10^{-3}$ M in ruthenium complex. Prior to measurements, the solutions were deoxygenated by bubbling with argon gas for 15 min and the working electrode was polished with a polishing machine (Presi P230); during experiments, a stream of argon was passed over the solution.

**5-(Bromomethyl)-2-phenylpyridine (2a):** 5-Methyl-2-phenylpyridine (**1a**; 2.11 g, 12.5 mmol), NBS (2.22 g, 12.9 mmol), and AIBN (36 mg) were refluxed in dry $CCl_4$ (58 mL) for 2 h. After cooling, the suspension was filtered. The solvent was removed in vacuo and $n$-hexane (30 mL) was added to the remaining paste. The mixture was stirred in an ice bath for 1 h, whereupon a white fleecy precipitate appeared. This was filtered off to yield the pure product (837 mg, 27%). $^1$H NMR ($CDCl_3$): $\delta$ = 8.68 (s, 1 H), 7.97 (m, 2 H), 7.75 (m, 2 H), 7.45 (m, 3 H), 4.52 (s, 2 H) ppm. $C_{12}H_{10}BrN$ (248.1) + 0.25 $H_2O$: calcd. C 57.05, H 4.19, N 5.54; found C 56.81, H 3.95, N 5.57. DCI MS ($NH_3$): $m/z$ (%) = 248.1 (33), 250.1 (34) $[MH]^+$.

**5-(Bromomethyl)-2,2′-bipyridine (2b):** Same procedure as for the synthesis of **2a**, starting from 5-methyl-2,2′-bipyridine (**1b**). Yield: 68%. The $^1$H NMR spectrum is identical to those of previous reports.[31,32]

**Diethyl (2-Phenylpyridin-5-yl)methylphosphonate (3a):** Under nitrogen, **2a** (1.01 g, 4 mmol) was dissolved in triethyl phosphite (7 mL) and the mixture was refluxed for 1 d. After cooling, the brown oil was purified by two successive chromatographic separations on alumina (99% $CH_2Cl_2$/1% $CH_3OH$). Yellow oil (1.31 g, 87%). The

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

compound was used in the next step without further purification (triethyl phosphite could not be totally eliminated). $^1$H NMR ($CDCl_3$): $\delta$ = 8.55 (s, 1 H), 7.95 (m, 2 H), 7.70 (m, 2 H), 7.42 (m, 3 H), 4.05 (m, 4 H), 3.14 (d, $J_{H,P}$ = 21.6 Hz, 2 H), 1.26 (t, $J$ = 7.2 Hz, 6 H) ppm.

**Diethyl (2,2′-Bipyridin-5-yl)methylphosphonate (3b):** Same procedure as for the synthesis of **3a**, starting from **2b** and using 98% $CH_2Cl_2$/2% $CH_3OH$ as eluent for the two chromatographic separations. Some traces of triethyl phosphite remained and the compound was used without any further purification (Yield: 76%). $^1$H NMR ($CDCl_3$): $\delta$ = 8.66 (d, $J$ = 4.2 Hz, 1 H), 8.56 (s, 1 H), 8.36 (d, $J$ = 3.6 Hz, 1 H), 8.33 (d, $J$ = 3.8 Hz, 1 H), 7.80 (m, 2 H), 7.28 (m, 1 H), 4.08 (q, $J$ = 7 Hz, 4 H), 3.18 (d, $J_{H,P}$ = 22 Hz, 2 H), 1.35 (t, $J$ = 6.8 Hz, 6 H) ppm.

**5-(*p*-Nitrostyryl)-2-phenylpyridine ($HL^1$):** In a Schlenk flask, **3a** (348 mg, 1.14 mmol) was dissolved in THF (21 mL) and cooled in an ice bath. *n*-Butyllithium (1.6 M in hexane; 0.72 mL, 1.15 mmol) was added dropwise and the solution was stirred at room temperature for 1 h. A THF solution (6 mL) of *p*-nitrobenzaldehyde (174 mg, 1.15 mmol) was then added slowly and the color changed from yellow to brown. The mixture was refluxed for 3 h. After cooling to room temperature, the mixture was hydrolyzed with water (10 mL). The precipitate was filtered off, washed with diethyl ether, and purified by column chromatography on alumina (80% $CH_2Cl_2$/20% *n*-pentane). The product was recovered as a lemon-yellow powder (200 mg, 37% yield). $^1$H NMR ($CDCl_3$): $\delta$ = 8.86 (d, $J$ = 2.1 Hz, 1 H, H6), 8.27 (d, $J$ = 8.8 Hz, 2 H, H11, H13), 8.07 (dd, $J$ = 8.7 and 1.4 Hz, 2 H, H2′, H6′), 7.98 (dd, $J$ = 8.3 and 2.3 Hz, 1 H, H4), 7.81 (d, $J$ = 8.3 Hz, 1 H, H3), 7.70 (d, $J$ = 8.8 Hz, 2 H, H10, H14), 7.53 (dd, $J$ = 7.6 and 7.1 Hz, 2 H, H3′, H5′), 7.47 (t, $J$ = 7.3 Hz, 1 H, H4′), 7.31 (d, $J$ = 16.3 Hz, 1 H, H7), 7.26 (d, $J$ = 16.3 Hz, 1 H, H8) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 155.22 (C2), 148.96 (C6), 147.08 (C12), 143.18 (C9), 138.59 (C1′), 133.87 (C4), 130.36 (C5), 129.41 (C4′), 129.35 (C7), 128.91 (C5′), 127.89 (C8), 127.10 (C10, C14), 126.89 (C6′), 124.27 (C11, C13), 120.48 (C3) ppm. $C_{19}H_{14}N_2O_2$ (302.3): calcd. C 75.48, H 4.67, N 9.27; found C 75.14, H 4.59, N 9.12. DCI MS ($NH_3$): $m/z$ = 303 $[MH]^+$.

**5-(*p*-Nitrostyryl)-2,2′-bipyridine ($L^2$):** According to the procedure described above for the synthesis of $HL^1$, **3b** yielded compound $L^2$ (29% yield) after purification by chromatography on alumina with 0.5% MeOH in $CH_2Cl_2$. $^1$H NMR ($CDCl_3$): $\delta$ = 8.84 (d, $J$ = 1.9 Hz, 1 H, H6), 8.73 (ddd, $J$ = 4.7, 1.6 and 0.8 Hz, 1 H, H6′), 8.51 (d, $J$ = 8.3 Hz, 1 H, H3), 8.47 (d, $J$ = 8 Hz, 1 H, H3′), 8.29 (d, $J$ = 8.9 Hz, 2 H, H11, H13), 8.06 (dd, $J$ = 8.3 and 2.3 Hz, 1 H, H4), 7.88 (td, $J$ = 7.8 and 1.6 Hz, 1 H, H4′), 7.71 (d, $J$ = 8.8 Hz, 2 H, H10, H14), 7.37 (ddd, $J$ = 5.9; 4.9 and 1 Hz, 1 H, H5′), 7.34 (d, $J$ = 16.5 Hz, 1 H, H7), 7.30 (d, $J$ = 15.5 Hz, 1 H, H8) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 155.70 (C2), 155.32 (C2′), 149.15 (C6′), 148.56 (C6), 147.16 (C12), 143.07 (C9), 137.25 (C4′), 133.99 (C4), 131.99(C5) 129.27 (C7), 128.50 (C8), 127.18 (C10, C14), 124.28 (C11, C13), 124.05 (C5′), 121.36 (C3′), 121.22 (C3) ppm. $C_{18}H_{13}N_3O_2$ (303.3): calcd. C 71.28, H 4.32, N 13.85; found C 70.78, H 3.94, N 13.53. EI-MS: $m/z$ = 303 $[M]^+$.

**$[Ru(bpy)_2(L^1)][PF_6]$:** $[Ru(bpy)_2Cl_2]$ (40 mg, 0.073 mmol) and AgOTf (41 mg, 0.16 mmol) were added to a hot solution of $HL^1$ (110 mg, 0.36 mmol) in MeOH/$CH_2Cl_2$ (1:1, 10 mL) and the mixture was heated at 60 °C for 1 h. After cooling, the AgCl precipitate was filtered through glass fiber. The filtrate was concentrated and the crude product was purified by chromatography on alumina using two eluents: 0.5% MeOH in $CH_2Cl_2$ to recover the unreacted excess of ligand, then 3% MeOH in $CH_2Cl_2$ to isolate a dark-violet complex. A second chromatographic purification of this complex was carried out on alumina (3% MeOH in $CH_2Cl_2$) to yield the pure complex (15 mg, 24%). $^1$H NMR ($CD_3COCD_3$): $\delta$ = 8.78 (td, $J$ = 8.2 and 1.1 Hz, 1 H, H36), 8.68 (ddd, $J$ = 8.1, 1.1 and 0.6 Hz, 1 H, H33), 8.62 (ddd, $J$ = 8.2, 1.3 and 0.8 Hz, 1 H, H23), 8.60 (ddd, $J$ = 8.3, 1.2 and 0.8 Hz, 1 H, H26), 8.21 (d, $J$ = 8.8 Hz, 2 H, H16, H18), 8.24–8.17 (m, 3 H, H11, H37, H9), 8.16 (ddd, $J$ = 5.7, 1.5 and 0.7 Hz, 1 H, H30), 8.10 (ddd, $J$ = 5.4, 1.5 and 0.8 Hz, 1 H, H39), 8.06 (ddd, $J$ = 5.8, 1.4 and 0.8 Hz, 1 H, H29), 8.00–7.90 (m, 6 H, H22, H32, H8, H5, H27, H20), 7.71 (d, $J$ = 8.9 Hz, 2 H, H15, H19), 7.64 (ddd, $J$ = 7.6, 5.4 and 1.2 Hz, 1 H, H38), 7.42–7.38 (m, 3 H, H21, H31, H28), 7.29 (d, $J$ = 16.4 Hz, 1 H, H13), 7.21 (d, $J$ = 16.4 Hz, 1 H, H12), 6.92 (dt, $J$ = 7.2 and 1.2 Hz, 1 H, H4), 6.85 (dt, $J$ = 7.2 and 1.3 Hz, 1 H, H3), 6.52 (dd, $J$ = 7.4 and 1 Hz, 1 H, H2) ppm. $^{13}$C NMR ($CD_3COCD_3$): $\delta$ = 194.27 (C1), 167.39 (C7), 157.90 (C34), 157.09 (C24), 156.80 (C25), 155.34 (C35), 154.27 (C30), 150.56 (C29), 150.04 (C20) 149.95 (C8), 149.23 (C39), 147.10 (C17), 145.26 (C6), 143.34 (C14), 136.59 (C37), 135.37 (C2), 135.19 (C32), 134.04 (C22), 133.77 (C27), 132.22 (C9), 131.17 (C10), 128.62 (C3), 128.46 (C12), 127.98 (C13), 127.37 (C38), 127.27 (C15, C19), 126.57 (C21), 126.40 (C31), 126.27 (C28), 124.85 (C5), 123.97 (C16, C18), 123.63 (C33), 123.41 (C36), 123.09 (C26), 123.08 (C23), 120.95 (C4), 118.39 (C11) ppm. The metathesis was carried out as follows: the complex with the triflate counterion was dissolved in the minimum amount of methanol then a saturated aqueous solution of $NH_4PF_6$ was added until no more precipitation occurred. The precipitate was filtered off, rinsed with distilled water and dried under vacuum. $C_{39}H_{29}F_6N_6O_2PRu$ (859.7) + $H_2O$: calcd. C 52.41, H 3.50, N 9.40; found C 52.38, H 3.30, N 9.12. FAB-MS: $m/z$ = 715 $[M-PF_6]^+$.

**$[Ru(bpy)_2(L^2)][PF_6]_2$:** $L^2$ (48 mg, 0.158 mmol) was dissolved in EtOH (25 mL) under $N_2$ and the mixture heated to reflux. $[Ru(bpy)_2Cl_2]$ (85 mg, 0.158 mmol) was then added and the mixture refluxed for 3 h. After cooling in an ice bath, addition of $NH_4PF_6$ (saturated solution in water) led to the precipitation of the complex. The orange precipitate was filtered off, rinsed with water and diethyl ether, and dried in vacuo (115 mg). The compound was obtained by two successive chromatographic purifications on alumina ($CH_3CN$) and finally crystallization from acetone, which yielded the pure, brick-red complex (80 mg, 50%).$^1$H NMR ($CD_3COCD_3$): $\delta$ = 8.88–8.82 (m, 6 H, H8, H5, H26, H23, H33, H36), 8.60 (dd, $J$ = 8.5, 1.9 Hz, 1 H, H9), 8.30–8.06 (m, 7 H, H11, H4, H27, H25, H32, H37, H39), 8.24 (d, $J$ = 9 Hz, 2 H, H16, H18), 8.11 (dd, $J$ = 5.6, 7 Hz, 1 H, H2), 8.09–8.06 (m, 3 H, H29, H20, H30), 7.76 (d, $J$ = 8.8 Hz, 2 H, H15, H19), 7.64–7.58 (m, 5 H, H3, H31, H38, H21, H28), 7.57 (d, $J$ = 16.4 Hz, 1 H, H12), 7.21 (d, $J$ = 16.5 Hz, 1 H, H13) ppm. $^{13}$C NMR ($CD_3COCD_3$): $\delta$ = 157.33, 157.24, 157.21, 157.04, 156.30, 152.07 (C11), 151.92 and 151.83 and 151.75 (C2, C29, C20, C30), 151.05, 147.62, 142.51, 138.09, and 138.00 (C37, C32, C25, C27), 136.53, 133.84 (C9), 132.01 (C12), 127.93, 127.88, 127.86, 127.84 (C15, C19), 127.75, 127.04 (C13), 124.60, 124.50, 124.48, 124.44, 124.35, 124.04, 114.38 ppm. $C_{38}H_{29}F_{12}N_7O_2P_2Ru$ (1006.7): calcd. C 45.34, H 2.90, N 9.74; found C 45.19, H 2.77, N 9.49. FAB-MS: $m/z$ = 862 $[M-PF_6]^+$, 717 $[M-2PF_6]^+$.

**Crystallographic Studies:** Single crystals of $[Ru(bpy)_2(L^1)][PF_6]$ suitable for X-ray structure determination were grown by slow diffusion of diethyl ether into a concentrated solution of the complex in acetonitrile. Data were collected at 180 K with a Stoe Imaging Diffraction System (IPDS) equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å) and an Oxford Cryosystems Cryostream Cooler Device. Empirical absorption corrections were applied ($T_{min}$ = 0.811, $T_{max}$ = 0.963).[33] The structure was solved by direct methods using SIR92,[34] and refined by means of least-squares procedures on $F^2$ with the aid of the program

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

SHELXL97[35] included in the software package WinGX version 1.63.[36] Final unit-cell parameters were obtained by means of a least-squares refinement of a set of well-measured reflections. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[37] All non-hydrogen atoms were refined anisotropically, and in the last cycles of refinement a weighting scheme was used, where weights are calculated with the following formula: $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$. Further details are listed in Table 5. The drawing of the molecule was produced with the program ORTEP32[38] with 50% probability displacement ellipsoids for non-hydrogen atoms. CCDC-602439 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 5. Crystal data for $[Ru(bpy)_2(L^1)][PF_6]$ (**1**).

**Theoretical Methods:** Gas-phase geometries for cations $[Ru(bpy)_2(L^1)]^+$ and $[Ru(bpy)_2(L^2)]^{2+}$ were fully optimized using the Gaussian-03 program package[39] within the framework of DFT at the B3LYP/6-31G*/LANL2DZ(Ru) level.[40,41] The starting metrical parameters for the calculations were taken from the present crystal structure of $[Ru(bpy)_2(L^1)]^+$. In the absence of a crystal structure for $[Ru(bpy)_2(L^2)][PF_6]_2$, the starting model was built up from the previously reported structures of $[Ru(bpy)_3][PF_6]_2$,[42] and 4-hydroxy-4′-nitrobiphenyl.[43] Due to the large size of the molecule, time-consuming vibrational analyses were not performed on the ruthenium complexes. Nevertheless, we checked that the DFT approach provides an accurate description of the molecular geometry in the case of the few previously reported $[Ru(bpy)(phenpy)]^+$ complexes,[16,19] although with a tendency for slightly inflated coordination spheres in the DFT-computed structures. The all-valence INDO (intermediate neglect of differential overlap) method[44] was employed to calculate the electronic transitions in order to analyze the origin of the charge transfer at the atomic level. Calculations were performed using the INDO/1 Hamiltonian incorporated in the commercially available MSI software package ZINDO.[45] The monoexcited configuration interaction (MECI) approximation was employed to describe the excited states. The 100 lowest-energy transitions between the 10 highest occupied molecular orbitals and the 10 lowest unoccupied ones were chosen to undergo CI mixing.

**NLO Measurements:** The experimental $\beta$ measurements were performed with the frequency-resolved femtosecond hyper-Rayleigh scattering (HRS)[46] technique at 800 nm. This setup was used as described before.[27] The samples were dissolved in acetonitrile and crystal violet (CV) dissolved in methanol was used as the reference ($\beta_{xxx} = 338 \times 10^{-30}$ cm$^5$ esu$^{-1}$).[27] A concentration series ws measured and the slopes of the linear fitting compared. The internal field-correction factor $[(n^2+2)/3]^3$, where *n* is the refractive index at the $Na_D$ line, was applied to correct for the difference in solvent ($n_{MeOH} = 1.328$ and $n_{MeCN} = 1.343$). The compounds were analyzed as dipolar structures with $C_{\infty v}$ symmetry. To correct for the difference in symmetry between the dipolar compound and octupolar reference, the following appropriate correction factors were used:[46b,47]

$$\beta^2_{zzz,dipole} = \frac{slope_{dipole}}{slope_{octupole}} \times \frac{28}{9} \times \frac{\left[\left(n^2_{MeOH}+2\right)/3\right]^6}{\left[\left(n^2_{MeCN}+2\right)/3\right]^6} \times \beta^2_{xxx,octupole} \quad (1)$$

The determined apparent hyperpolarizability was found to be independent of the modulation frequency, and the fluorescence-free hyperpolarizability was calculated by averaging the obtained hyperpolarizabilities at different modulation frequencies. Due to the weakness of the $2\omega$ light intensity in the HRS phenomenon, measurements have to be performed close to the resonance, which leads to an artificial enhancement of the NLO signal. In this case, the parameter of interest is the intrinsic hyperpolarizability $\beta_{(0)}$, which is independent of the laser frequency and can be estimated within a two-level model according to the following expressions:[48]

$$\beta_\omega = \frac{3e^2\hbar^2 f_{ge}(\Delta\mu)_{ge}}{2mE_{ge}^3} \times \frac{E_{ge}^4}{\left(E_{ge}^2 - (2\hbar\omega)^2\right)\left(E_{ge}^2 - (\hbar\omega)^2\right)} \quad (2)$$

$$\beta_{(0)} = \frac{3e^2\hbar^2 f_{ge}(\Delta\mu)_{ge}}{2mE_{ge}^3} \quad (3)$$

## Acknowledgments

# What a Difference One Electron Makes! Generating Low-Coordinate Ti–C and V–C Multiply Bonded Frameworks through One Electron Oxidatively Induced α-Hydrogen Abstractions

**Daniel J. Mindiola,*[a] Brad C. Bailey,[a] and Falguni Basuli[a]**

**Keywords:** Alkylidenes / Alkylidynes / Titanium / Vanadium / Hydrogen abstraction / Oxidation

Low-coordinate, high oxidation state titanium and vanadium complexes containing terminal metal–carbon multiply bonded functionalities have been prepared directly or indirectly through one electron oxidatively induced α-hydrogen abstraction reactions. This synthetic approach offers a mild entry to reactive M=C and M≡C motifs, and does not depend on external stimulants such as heat, light or base to promote the α-hydrogen-abstraction step. In addition, this strategic protocol avoids the use of powerful electrophiles, thus generating terminal and nucleophilic M–C multiple bonds in low-coordination environments. In some cases terminal alkylidenes containing β-hydrogen atoms can also be introduced through this route. This microreview surveys the synthesis and chemistry surrounding isolable titanium and vanadium complexes bearing terminal alkylidene and alkylidyne ligands. Particular emphasis will be placed on the synthesis of the high oxidation state M–C multiple bond.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Metal–carbon multiple bonds are an important functionality given their utilization in important industrial processes such as metathesis, in particular cross-metathesis, ring-closing metathesis, ring-opening metathesis, ring-opening metathesis polymerization, acyclic diene metathesis polymerization, acetylene polymerization, and Wittig-type (alternatively referred to as group-transfer) reactions.[1] Seminal papers and reviews by Chauvin,[2] Grubbs,[3] and Schrock[4] exemplify both the fundamental and practical use of the M–C multiple bond. The combination of their efforts clearly portray how critical fundamental research addressing the bonding and structure of the M–C linkage can rapidly evolve into a more applied area of chemistry such as catalysis.[1,3,4] Consequently, a cascade of applications such as the synthesis of pharmaceutical fine chemicals, natural products, and the formation of polymers have evolved from a fundamental study involving the M–C multiple bond.[1,3,4] Not surprisingly, the contribution by Chauvin, Grubbs, and Schrock resulted in their winning of the 2005 Nobel Prize in Chemistry.[5]

Extensive reviews covering advances in the field of metal–carbon multiple bonds have been published,[3,4,6] with one of the most comprehensive reviews for high oxidation state transition-metal alkylidenes and alkylidynes being published in 2002 by R. R. Schrock.[4c] For this reason, we will limit our attention to the synthesis and chemistry of high oxidation state alkylidenes and alkylidynes of group 4 and 5 transition metals, since in recent years there has been a dramatic advancement in this group of elements.[4c] More specifically, we will discuss only compounds which have been fully characterized, and that invoke a nucleophilic or "Schrock-like" M–C multiply bonded linkage. We refer the reader to comprehensive reviews discussing the "in situ" preparation of alkylidenes.[1f,6] This microreview will focus on the synthesis, structure, and small-molecule chemistry invoking alkylidene and alkylidyne ligands of group 4 and 5 transition metals, in particular the lighter 3d congeners for each group. Catalytic reactions will not be covered in this review, nor the synthesis and chemistry of bridging alkylidenes or alkylidynes. Given the extensive literature covering this popular field, we apologize in advance for any omission of relevant work pertaining to the subject we are discussing.

### Synthesis of Group 4 and 5 High Oxidation State Alkylidenes

High oxidation state transition-metal alkylidenes are commonly prepared through an α-hydrogen-abstraction route with the first prototypical examples $(t\mathrm{BuCH_2})_3$-Ta=CH*t*Bu[7] and $(\eta^5\text{-}C_5H_5)_2$Ta=$CHCH_3$[8] being reported by Schrock. For instance, $d^0$ metal complexes containing an alkyl group can often be subjected to heat or light [Equation (1)], sterically imposing Lewis bases [Equation (2)], or Brønsted bases [Equation (3)] to assist in the α-hydrogen abstraction or deprotonation of the alkyl α-hydrogen.[4]

$$L_mM^n(CH_2R)_2 \xrightarrow{\Delta \text{ or } h\nu} L_mM^n{=}CHR + CH_3R \quad (1)$$

$$L_mM^n(CH_2R)_2 \xrightarrow{x\ PR_3} L_mM^n{=}CHR(PR_3)_x + CH_3R \quad (2)$$

$$L_mM^n(CH_2R)X \xrightarrow{2\ Base} L_mM^n{=}CHR(Base) + HX(Base) \quad (3)$$

In most cases, the Lewis base is often restricted to non-nucleophilic reagents such as bulky amides, neutral amines, phospha-ylides, in order to avoid displacement of the alkyl and subsequent redox chemistry from taking place.[4] In addition, the metal–alkyl ligand must lack β-hydrogen atoms, albeit with some exceptions, in order to avoid β-hydrogen-elimination or -abstraction pathways.[4] Alternate routes to the M=C linkage involve the in situ $2e^-$ reduction reactions of diazoalkanes, "$CH_2$" group-transfer reactions using phosphoranes such as $Ph_3P{=}CH_2$ [Equation (4)],[9] or two-electron reduction reactions to promote α-hydrogen elimination [Equation (5)].[10]

$$LM^n(LG) \xrightarrow{\text{"CHR"}} L_mM^{n+2}(CHR) + LG \quad (4)$$
LG = leaving group

$$LM^n(CH_2R)X_2 \xrightarrow[-2X^-]{x\ PR_3,\ +2e^-} L_mM^n(CHR)(H)(PR_3)_x \quad (5)$$
$X^-$ = halide or pseudohalide

Another elegant and rare transformation leading to alkylidene formation is the isomerization of terminal and 1,2-disubstituted olefins using low-valent metal centers [Equation (6)].[4c,11] The microscopic reverse, rearrangement of an alkylidene to an olefin, is not surprising given the intrinsic instability of β-hydrogen atoms with respect to the bound olefin. The latter rearrangement has been recognized as a potentially damaging side-reaction within the alkene metathesis cycle, but quite possibly, an important step in processes such as "alkane metathesis".[12] Recently, two new protocols to assemble low-coordinate metal–carbon multiple bonds have been reported. One applies a one-electron oxidation to promote the α-hydrogen abstraction [Equation

*Daniel Mindiola was born in San Cristóbal, Venezuela, in 1974. In 1996 he received a B.S. degree in chemistry with honors from Michigan State University (East Lansing, Michigan, USA), and then completed a Ph.D. in chemistry from the Massachusetts Institute of Technology under the tutelage of Prof. C. C. Cummins (2000). Following an NIH and Ford postdoctoral fellowship under the direction of Prof. G. L. Hillhouse at the University of Chicago, he then began his independent work in 2002 as an Assistant Professor at Indiana University in Bloomington, Indiana (USA). His research interests include synthesis, reactivity, and mechanistic studies involving low-coordinate early transition metal complexes containing metal–ligand multiple bonds, in particular their development as synthons or catalysts for unusual organometallic transformations.*

*Brad Bailey was born in Clarkston, Michigan, USA on June 10th 1980. In 2002, he received his B.S. from the University of Michigan while working under Dr. David Curtis on the synthesis of polythiophenes for their use as conducting polymers. Brad is currently working under the supervision of Dr. Daniel Mindiola on the preparation of highly reactive terminal titanium alkylidenes and alkylidynes, and exploring the reactivity of these unusual motifs.*

*Falguni Basuli was born in Panskura a small town of Midnapore district of west Bengal, India, in 1972. After completing her Master's (M.Sc.) in chemistry from Vidyasagar University, she received her Ph.D. degree in 2001 from Jadavpur University, Kolkata, in synthetic inorganic chemistry under the supervision of Prof. Samaresh Bhattacharyya. In 2002 she joined Prof. Daniel J. Mindiola's group as a post-doctoral researcher at Indiana University, Bloomington, USA. She continues to work on the syntheses of early transition metal complexes containing metal–ligand multiple bonds (e.g. alkylidenes, alkylidynes, imides, and phosphanylidenes), as well as their reactivity towards different substrates.*

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(7)],[13] while the second method utilizes a highly reducing metal center to promote P–C bond rupture of a bound trimethylphosphane [Equation (8)].[14]

$$L_mM^n(\eta^2\text{-HRC=CHR'}) \rightleftharpoons L_mM^{n+2}(CRCH_2R') \quad (6)$$

$$L_mM^n(CH_2R)_2 \xrightarrow[-A^0]{[A][X]} L_mM^{n+1}(CHR)(X) + CH_3R \quad (7)$$

$$L_mM^n[P(CH_3)_3] \longrightarrow L_mM^{n+2}(CH_2) + HP(CH_3)_2 \quad (8)$$

The former synthetic strategy has been referred to as an oxidatively induced α-hydrogen abstraction.[13] One advantage to this process is that bis(alkyl) complexes composed of 3d elements such as Ti and V can be readily transformed to the high-valent alkylidene by a single-electron oxidation. Most notably, this protocol can generate low-coordinate complexes bearing terminal M=C linkages with substitutionally labile ligands or counter anions such as $OTf^-$, $I^-$, $Br^-$, $Cl^-$, and $BPh_4^-$. As a result, $d^0$ transition-metal alkylidenes prepared by this route are poised for a subsequent α-hydrogen abstraction or α-hydrogen deprotonation to generate the alkylidyne ligand. Another rare, but known method to generate the terminal alkylidene ligand involves the breaking of dimers (composed of bridging alkylidenes) with donor ligands such as phosphanes [Equation (9)].[15a]

$$[L_mM^n]_2(\mu_2\text{-CHR})_2 \xrightarrow{2\ PR_3} 2\ L_mM^n(CHR)(PR_3) \quad (9)$$

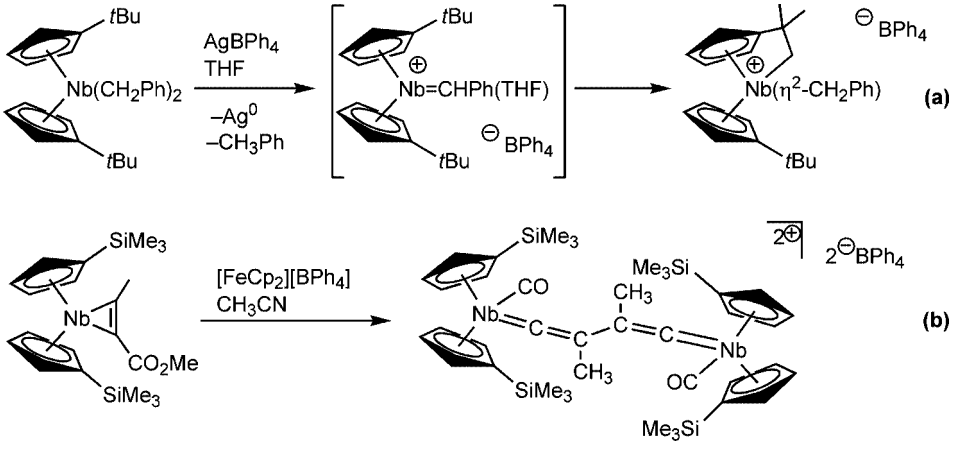
This same strategy can be used for Lewis acid decomplexation of heterobimetallic $\mu_2$-alkylidene systems using strong donors such as HMPA.[15b]

### Alkylidenevanadium and -titanium Complexes

Despite the extensive number of alkylidenetantalum complexes,[4] fewer examples exist for the lighter congener, Nb, while even less cases have been reported for V.[4,6] Table 1 lists high oxidation state alkylidene complexes for V (isolated) along with some diagnostic features. The lower number of V and Nb alkylidenes vs. those for tantalum, can arguably be correlated to the propensity of the former metals to generate low-valent oxidation states.

Theoretical studies by Nugent and co-workers have uncovered that the charge on the atom multiply bonded to the metal (e.g. imides, alkylidenes, oxo groups) decreases as we go up and to the right within the periodic table.[16] Consequently, high-valent $Nb^V$ and $V^V$ are more likely to be reduced by Grignard compounds or alkyllithium compounds as opposed to $Ta^V$. Hence, if one plans to incorporate the M=C linkage onto a lighter congener in a high oxidation state, then perhaps one should work retrosynthetically from the low-valent state by subsequent oxidation reactions. Gratifyingly, two examples for the later hypothesis have been reported (Scheme 1).[17,18] In 1995, McCamley and co-workers trapped a transient niobium alkylidene by a redox route.[17] Their studies described the one-electron oxidation of $Nb^{IV}(\eta^5\text{-}C_5H_4t\text{Bu})_2(CH_2Ph)_2$ with $AgBPh_4$ to generate a $Ag^0$ mirror along with the kinetically unstable benzylidene salt $[Nb^V(\eta^5\text{-}C_5H_4t\text{Bu})_2(CHPh)][BPh_4]$ (Scheme 1, a).[17] The latter intermediate underwent facile C–H activation reactions in toluene to afford the cyclometallated product (Scheme 1, a), but the mechanism of the C–H activation reaction was not discussed in this work. The second example involving one-electron oxidation to generate M=C linkages was reported by Otero and co-workers.[18] In their studies, one-electron oxidation of the $Nb^{IV}$ alkyne $Cp'_2Nb[\eta^2\text{-MeOC(O)C}\equiv\text{CMe}]$ ($Cp' = C_5H_4SiMe_3$) with $[FeCp_2][BPh_4]$ generated a binuclear vinylidene complex (Scheme 1, b).[18] Albeit a fascinating transformation, the mechanism of the latter reaction remains unclear.

Schwartz and co-workers are likely the first group to report the synthesis and characterization (NMR spectroscopic data) of group 4 alkylidenes $Cp_2M=CHR(PR_3)$ (M = Ti and Zr).[9d,15b] Their seminal work was followed-up by Bickelhaupt and co-workers in 1986.[15a] However, it was not until 1992 that Krüger and co-workers structurally characterized the $d^0$ Ti=C bonded complex $(PMe_3)$-



Scheme 1.

$Cp_2Ti{=}C{=}C{=}TiCp_2(PMe_3)$ [Ti=C, 2.051(2) Å].[19] In 1993, Fryzuk and co-workers[20] reported the synthesis and structural elucidation of the first mononuclear and terminal alkylidene $[\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_2CH_2P\textit{i}Pr_2)_2]Zr{=}CHPh(Cl)$. Not surprisingly, alkylidene complexes of group 4 are often represented as $^{+}M\text{–}CR_2^{-} \leftrightarrow M{=}CR_2$, much like ylides resonate. This feature explains why common reagents such as Tebbe's complex[21] are much more stable than Lewis acid free and terminal alkylidenes. Table 1 depicts isolable titanium complexes bearing a terminal alkylidene ligand along with diagnostic features.

## Synthesis of Group 4 and 5 High Oxidation State Alkylidynes

High oxidation state alkylidyne transition-metal complexes are far more rare than the corresponding alkylidenes, in particular for the early transition metals prior to group 6.[4c] This fact is not surprising because most $d^0$ alkylidynes are commonly prepared from alkylidenes by an α-hydrogen abstraction or deprotonation reaction [Equation (10)].

$$L_mM^n(CHR)(LG) \longrightarrow LM^n(CR) + H(LG) \quad (10)$$

Some elegant but rare entries to the terminal alkylidyne functionality invoke two-electron reduction of an alkyl group to promote α,α′-dehydrogenation and elimination of $H_2$ [Equation (11)],[11f] or α-hydrogen elimination of a reduced alkylidene–metal complex to generate the alkylidyne–hydride product [Equation (12)].[10,11f]

$$L_mM^n(CH_2R) \longrightarrow L_mM^{n+2}(CR) + H_2 \quad (11)$$

$$L_mM^n(CHR)(X)_2 \xrightarrow[-2X^-]{x\ PR_3} L_mM^n(CR)(H)(PR_3)_x \quad (12)$$

If one includes group 6 alkylidynes, other elegant entries would be methine (CH) group transfer to a low-valent metal center [Equation (13)],[22] trimethylsilyl migration of $\eta^2$-vinyl groups [Equation (14)],[23] and alkyne or nitrile metathesis with $W_2^{(III,III)}$ dimers [Equation (15)].[24]

$$L_mM^n + \text{"CH"} \longrightarrow L_mM^{n+3}(CH) \quad (13)$$

$$L_mM^n(\eta^2\text{-}H_2CCSiMe_3) \xrightarrow{\Delta} L_mM^n(CCH_2SiMe_3) \quad (14)$$

$$L_mM^n{\equiv}M^nL_m + XCR \longrightarrow L_mM^{n+3}(X) + L_mM^{n+3}(CR) \quad X = N \text{ or } CR \quad (15)$$

An extensive description of protocols to achieve group 6 M≡C linkages have been reported, and we refer the reader to this work.[6h] However, prior to group 6 transition metals, M≡CR linkages are far more scarce.[4c] As mentioned previously, our group has developed a novel technique applying one-electron oxidation to promote α-hydrogen abstraction. This strategy can also be applied to alkylidene(alkyl) species of vanadium(IV) thus giving rise to the first example of an alkylidynevanadium complex [Equation (16)].[13f]

$$L_mM^n(CHR)(R') \xrightarrow[-A^0]{[A][X]} L_mM^{n+1}(CR)(X) + HR' \quad (16)$$

Schrock and co-workers reported the first examples of group 5 alkylidynes, which were composed of tantalum(V),[10b,25] but it was not until 2004 that Mindiola and co-workers[13f] reported the only examples of alkylidynevanadium(V) complexes (both in neutral and cationic forms). The latter complexes are derived from two subsequent one-electron oxidation and α-H abstraction steps commencing from a bis(alkyl)vanadium(III) precursor (vide infra). Table 2 compiles a list of terminal alkylidynevanadium complexes.

Not surprisingly, isolable and terminal group 4 alkylidynes are unknown.[4c] Mena and co-workers have reported $\mu_3$-bridging alkylidynes of titanium where the hybridization at the α-C is best described as $sp^3$.[26] Very recently however, transient titanium(IV) complexes bearing terminal alkylidynes can be smoothly generated, mechanistically studied, and also trapped with various substrates (vide infra).[27] Interestingly, the latter alkylidyne precursors have been indirectly derived from a one electron oxidatively induced α-hydrogen abstraction. Table 2 compiles a list of well-defined alkylidynetitanium complexes.

### Oxidatively Induced α-Hydrogen Abstraction to Prepare M–C Multiple Bonds of Ti and V.

#### *a. Synthesis of Alkylidenetitanium Complexes*

An attractive entry towards the assembly of low-coordinate systems possessing metal–ligand multiple bonds can be derived from a redox reaction where the low-valent metal is alkylated, then oxidized. Accordingly, the protocol to prepare low-coordinate and terminal alkylidenetitanium complexes involved the use of a $d^1$ precursor complex (nacnac)-$TiCl_2$ (**1**) {nacnac$^-$ = [ArNC(Me)]$_2$CH, Ar = 2,6-(CHMe$_2$)$_2$-C$_6$H$_3$}, reported previously by Budzelaar.[28] The β-diketiminate ancillary ligand, nacnac$^-$, was chosen given its precedence to generate low-coordination environments in both early- and late metal complexes.[29] Hence, the THF base adduct of **1** can be readily alkylated with 2 equiv. of $LiCH_2tBu$ to afford the bis(alkyl)titanium(III) complex (nacnac)Ti($CH_2tBu$)$_2$ (**2**) in excellent yield.[13a] This compound is remarkably stable to heat, but when treated with oxidants such as AgOTf or $I_2$, the four-coordinate alkylidene complexes (nacnac)Ti=CH*t*Bu(X) [X$^-$ = OTf, (**3**)–OTf; X$^-$ = I, (**3**)–I] are readily obtained (Scheme 2).[13a,13b] Complex **3** displays $^1$H and $^{13}$C NMR spectroscopic signatures consistent with $C_s$ symmetry in solution. The alkylidene $C_\alpha$ resonance is centered at $\delta$ ca. 271–272 ppm with a $J_{CH}$ coupling constant of 95–85 Hz. The latter parameters are consistent with these molecules having a terminal alkylidene functionality in which there is a significant α-hydrogen agostic interaction with the metal center.[4c] The low-coordination number of **3** was confirmed by single-crystal X-ray crystallographic studies.[13a,13b] Conveniently, anion exchange or transmetallation in compounds such as **3**-OTf is facile (Scheme 2), thus giving rise to a family of alkylidenes where X$^-$ can be varied from halides (Cl and Br), to alkyl groups ($CH_2SiMe_3$), to a borohydride ($\eta^3$-$BH_4$). These alkylidenes have been thoroughly characterized, but all these compounds are kinetic products inasmuch as they can undergo intramolecular C–H activation transformations[13a] or intramolecular Wittig-like rearrangements to afford compounds such as **4**-OTf and **4**-I (Scheme 2 shows only the Wittig-like conversion of **3**-X to **4**-X, where X$^-$ = OTf or I).[13a,13b] However, the intramolecular Wittig-like rearrangement can be readily blocked by replacing the β-methyl groups on the β-diketiminate NCCCN framework with *t*Bu.[28] As a result, kinetically stable alkylidenetitanium complexes such as ($^{t\text{Bu}}$nacnac)Ti=CH*t*Bu(X) (X$^-$ = OTf, **5**–OTf; X$^-$ = I, **5**–I; $^{t\text{Bu}}$nacnac$^-$ = [Ar]NC(*t*Bu)]$_2$CH) can also be prepared from the corresponding bis(alkyl) precursor ($^{t\text{Bu}}$nacnac)Ti($CH_2tBu$)$_2$ (**6**) (Scheme 3).[13b] Structural and spectroscopic features for **5** are similar to those observed for **3**. With the bulkier $^{t\text{Bu}}$nacnac$^-$ framework, one can also incorporate the isobutylidene ligand onto titanium by oxidizing precursors such as ($^{t\text{Bu}}$nacnac)Ti($CH_2i$Pr)$_2$ (**7**) with AgOTf (Scheme 3).[30] This implies that oxidatively induced α-hydrogen abstraction is the preferred pathway as opposed to the more common β-hydrogen elimination and α-hydrogen abstraction themes. Although isolable, complex ($^{t\text{Bu}}$nacnac)Ti=CH*i*Pr(OTf) (**8**) is a kinetic product since

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

solutions decompose gradually over 24 h at 25 °C to afford the product ($\eta^2$-H*i*PrC=C(*t*Bu)CHC(*t*Bu)N[Ar])Ti=NAr-(OTf) (**9**): a complex resulting from an intramolecular Wittig-like rearrangement.[30] Despite complex **8** having *t*Bu groups to block the intramolecular [2+2]cycloaddition, the alkylidene functionality is apparently far less crowded and therefore more prone to group-transfer processes (Scheme 3).

Oxidatively induced α-hydrogen abstraction is a versatile process because terminal titanium alkylidene ligands can be readily assembled utilizing another ancillary ligand framework such as PNP (PNP = N[2-P(CHMe$_2$)$_2$-4-methylphenyl]$_2^-$).[31] PNP as an ancillary support provides a "hybrid type" coordination environment where both a hard amide and two soft phosphane donors are oriented in a meridional geometry. In addition, this ancillary support is impervious to intramolecular Wittig-like rearrangements often observed with sterically imposing β-diketiminate ligands.[13] Consequently, both (trimethylsilylmethylidene)- and (neopentylidene)titanium (PNP)Ti=CHR(OTf) (**10**: R = SiMe$_3$, **11**: R = *t*Bu),[13d] as well as isobutylidene (PNP)-Ti=CH*i*Pr(OTf) (**12**)[30] complexes can be constructed with this robust and rigid pincer system (Figure 1 shows their synthesis along with their corresponding X-ray structures). Unlike **3**, **5**, and **8**, compounds **10**–**12** display weaker α-hydrogen agostic interactions ($J_{C-H}$ = 85–99 Hz), presumably due to the greater coordination number at titanium. Distinct from **8**, complex **12** is remarkably stable despite having a less hindered and terminal alkylidene with a β-hydrogen.[30] This demonstrates that alkyl reagents that commonly reduce, such as *i*Bu$^-$, can be easily transformed into never-before seen isobutylidene "M=CH*i*Pr" functionalities on titanium. Compounds like **12** might offer an excellent opportunity to study the reverse: alkylidene to olefin conversion (vide supra).

### *b. Synthesis of Alkylidenevanadium Complexes*

Our success in preparing the first four-coordinate neopentylidenetitanium by an oxidatively induced α-abstraction reaction[13] motivated us to pursue other 3d transition metals, which lack such a motif. Unlike titanium, vanadium displays more diverse redox chemistry, which could result in more redox couples as opposed to the more general one-electron oxidation observed with $Ti^{3+}$. Terminal alkylidene

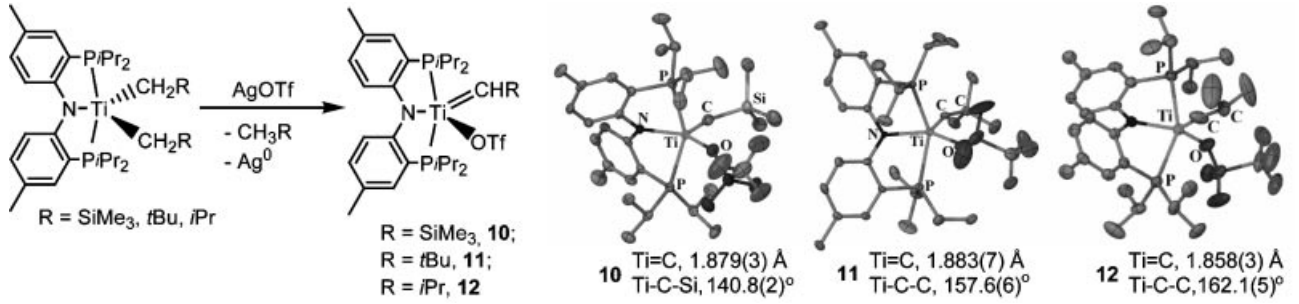

Figure 1. Synthesis of the terminal alkylidenetitanium(IV) complexes **10**–**12**. Single-crystal X-ray structures are displayed to the right with H atoms omitted for clarity. Selected metrical parameters are displayed under each structure.

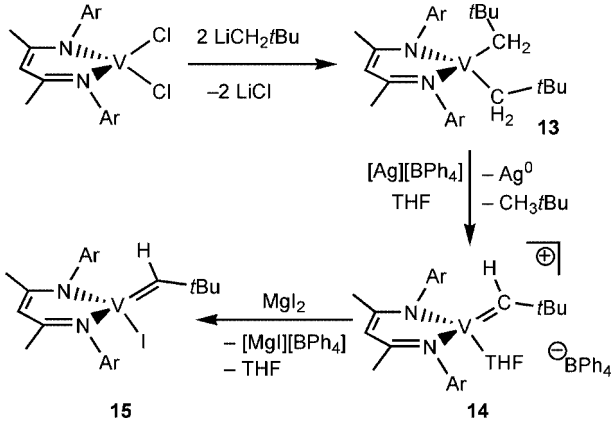
complexes of vanadium are rare,[32] with the first example being reported by Teuben and co-workers, namely CpV=CH*t*Bu(dmpe) [dmpe = bis(dimethylphosphanyl)ethane].[32a] For us, alkylating Budzelaar's precursor (nacnac)-$VCl_2$[28] with 2 equiv. of $LiCH_2tBu$ afforded the bis-neopentyl complex (nacnac)V($CH_2tBu$)$_2$ (**13**) as dark brown needles. Subsequent one-electron oxidation with $AgBPh_4$ generated a $Ag^0$ mirror along with the alkylidenevanadium(IV) complex [(nacnac)V=CH*t*Bu(THF)][$BPh_4$] (**14**) (Scheme 4).[13e] Complex **14** can readily disproportionate, but anion exchange using $MgI_2$ (or $I_2$) yielded the much more stable alkylidenevanadium(IV) (nacnac)V=CH*t*Bu(I) (**15**).[13e] Not only is the neutral complex **15** far more stable than the corresponding cation, but the $I^-$ ligand can also be readily substituted (vide infra). Compounds **14** and **15** are $d^1$ paramagnets as well as EPR active. More specifically, these compounds display an 8-line hyperfine coupling pattern resulting from coupling of the unpaired electron to the vanadium center ($I$ = 7/2, 99.6%, Figure 2).[13e] Single-crystal X-ray diffraction analysis for each system reveal four-coordinate vanadium complexes bearing a terminal neopentylidene ligand with short V=C distances [**14**, 1.795(3) Å; **15**, 1.787(3) Å], obtuse V=C–C angles [**14**, 159.8(4)°; **15**, 158.7(3)°], and in each case an α-H agostic interaction with the $d^1$-metal center.



Scheme 4.

### *c. Synthesis of Alkylidynetitanium Complexes*

Terminal alkylidynetitanium complexes are unknown, and the only isolable examples reported in the literature are $\mu^3$-alkylidynes restricted to cubane $Ti^{IV}_4$ clusters.[26] In 2004, Ozerov and co-workers reported remarkably stable alkylidene(alkyl)zirconium complexes of the type (PNP)-Zr=CHR($CH_2$R) (R = Ph or *p*-tolyl), which were prepared by α-hydrogen abstraction through thermolysis of the corresponding tris(alkyl) species.[33] However, α-hydrogen abstraction for the latter complex was not reported. Inspired by their work, we reasoned whether analogous $Ti^{IV}$ derivatives could undergo not one, but two α-hydrogen abstractions given the more congested environment for the $Ti^{4+}$ center. Our hypothesis proved fruitful inasmuch as four-co-

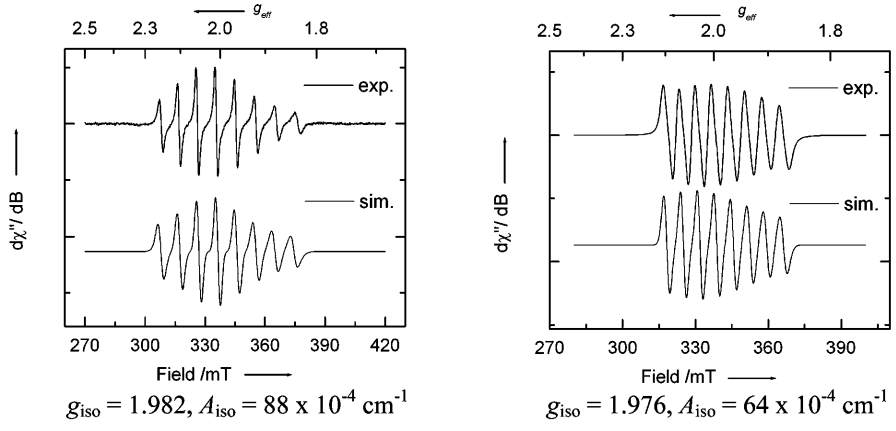


Figure 2. X-Band isotropic EPR spectra of complexes **14** (left) and **15** (right) in a 0.1 mM toluene solution.

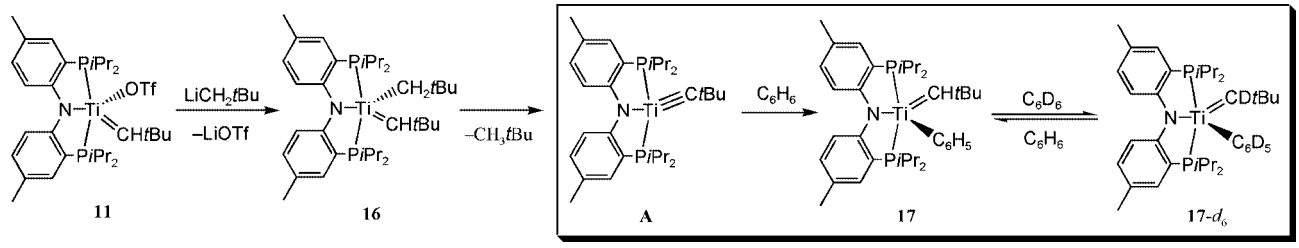
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ordinate alkylidynetitanium complexes can be readily generated by α-hydrogen abstraction reactions utilizing precursors such as **10** and **11**.[27] Accordingly, when complex **11** is treated with $LiCH_2tBu$ in pentane at low temperatures, the neopentylidene–neopentyltitanium complex (PNP)Ti=CH-*t*Bu($CH_2tBu$) (**16**) can be obtained upon rapid work-up of the reaction mixture (Scheme 5). Complex **16** reacts rapidly with benzene at 27 °C within 11.9 hours (4.5 half lives) to afford (PNP)Ti=CH*t*Bu($C_6H_5$) (**17**) quantitatively.[27] The combination of high-level density functional theory (DFT), labeling, and kinetic studies have demonstrated that complex **16** first undergoes α-H abstraction concomitant with elimination of $CH_3tBu$, to afford a transient alkylidynetitanium intermediate (PNP)Ti≡C*t*Bu (**A**), which experiences 1,2 addition of the benzene C–H bond across the reactive Ti≡C*t*Bu linkage to provide **17** (Scheme 5). The reaction energy profile for the C–H activation of benzene has been probed using high-level DFT calculations and is depicted in Figure 3.[27] The post rate-determining step suggests that the reverse process (liberation of benzene to generate alkylidyne, **17** → **A**), is associated with a barrier of 32.8 kcal/mol. In fact, this theoretical prediction can be experimentally proven under elevated temperature conditions. For example, complex **17**-$d_6$ can undergo clean conversion to **17** in $C_6H_6$ (95 °C, 48 hours), and vice-versa, thus linking intermediate **A** to complex **17** in the reaction profile.[27] This paradigm is particularly interesting because complex **17** can potentially be a synthon of **A** (albeit slow), in benzene, at ca. 95–120 °C. We have also found another alkylidyne source. Compound **10** can also be alkylated with $LiCH_2SiMe_3$ to afford (PNP)Ti=CHSiMe$_3$($CH_2SiMe_3$) (**18**). Compound **18** has been shown to generate the transient alkylidyne (PNP)Ti≡CSiMe$_3$ (**B**) in $C_6H_6$, albeit at higher temperatures, to afford the phenyl derivative (PNP)-Ti=CHSiMe$_3$($C_6H_5$) (**19**) (Scheme 6). As observed with **17**, thermolysis of **19** in $C_6D_6$ also leads to complete conversion to **19**-$d_6$, thus consistent with **19** being in equilibrium (at higher temperatures) with the alkylidyne intermediate **B**.[27]



Scheme 5.

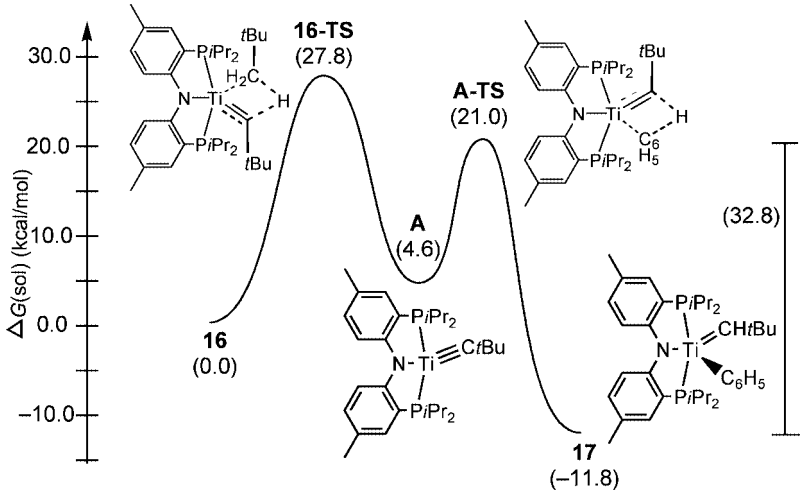


Figure 3. Reaction profile for the **15** → **16** conversion, whereby intermediate **A** is generated. The two transition-state geometries (**TS**) are depicted below.

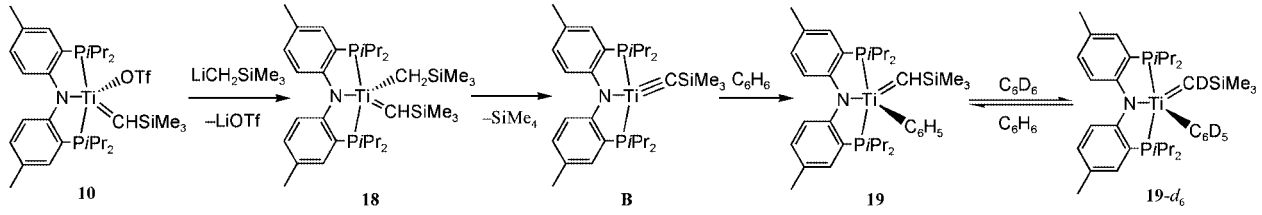

Scheme 6.

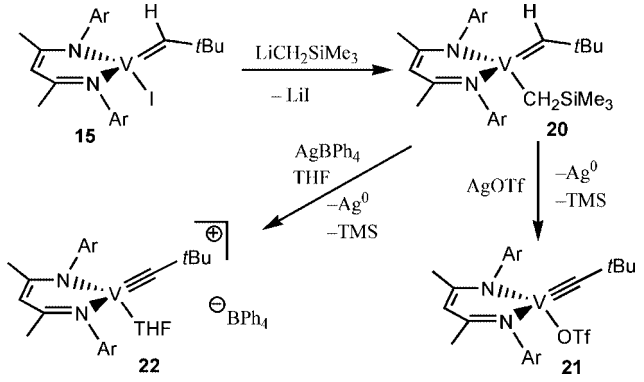
### *d. Synthesis of Vanadium Alkylidynes*

In 1991, Lippard and Protasiewicz reported the only example of a terminal V≡C linkage, namely the Fischer carbyne $(CO)(dmpe)_2V{\equiv}COSiPh_3$ [V≡C, 1.754(8) Å].[34] However, it was not until recently that the first examples of alkylidynes $d^0$, 3d transition metal complexes of group 5 were reported.[13f] This achievement was in part possible given our access to low-coordinate alkylidenevanadium complexes having labile ligands, namely compounds **14** and **15**.[13e] Accordingly, the four-coordinate neopentylidene complex **15** can be readily alkylated with $LiCH_2SiMe_3$ to afford the neopentylidene(alkyl) species (nacnac)-V=CH*t*Bu($CH_2SiMe_3$) (**20**) (Scheme 7). Complex **20** exhibits an EPR spectrum and a solution magnetic moment in accordance with a $V^{IV}$ radical center,[13f] and when oxidized with AgOTf or $AgBPh_4$, the neutral (nacnac)V≡C*t*Bu(OTf) (**21**) or cationic [(nacnac)V≡C*t*Bu(THF)][$BPh_4$] (**22**) neopentylidynes can be readily obtained, respectively (Scheme 7).[13f] $^1$H NMR spectra are consistent with **21** and **22** retaining $C_s$ symmetry in solution, while the combination of $^{13}$C ($\delta$: **21**, 375 ppm; **22**, 374 ppm)[7] and $^{51}$V (**21**: δ = –882 ppm, **22**: δ = –956 ppm) NMR spectra unambiguously confirms the presence of a terminal neopentylidynevanadium(V) functionality.[13f] In contrast to Schrock's two-electron reduction reactions of high-valent 5d metals to form Ta≡C linkages (vide supra),[10] our work involves two, one electron oxidatively induced α-hydrogen abstraction steps to prepare vanadium alkylidynes. While compounds **21** and **22** are remarkably stable at room temperature, they remain kinetic products from the reaction, since extensive thermolysis at ca. 80 °C results in quantitative conversion to the imidovanadium complex supported by the chelating amido–vinyl ligand, (*t*BuC=C(Me)CHC(Me)N[Ar])V=N-Ar(OTf) (**23**) and [(*t*BuC=C(Me)CHC(Me)N[Ar])-V=NAr(THF)][$BPh_4$] (**24**). Compounds **23** and **24** are best described as azametalacyclohexatriene systems resulting from an intramolecular cross-metathesis transformation involving an azametalacyclobutene transition state **21-TS** (Figure 4).[13f] The conversion **21** → **23** in $C_7D_8$ was determined to be first-order in vanadium with activation parameters $\Delta S^{\ddagger}$ = –6(3) cal/mol·K, $\Delta H^{\ddagger}$ = 25.4(3) kcal/mol. Formation of **23** was also found to be independent of solvent ($C_7D_8$ vs. [$D_8$]THF), which rules out dissociative or associative mechanisms from playing a role in this transformation.[13f] A similar transformation was observed for the analogous alkylidenetitanium systems bearing the same β-diketiminate ligand framework (vide supra).[13a,13b]



Scheme 7.

## Conclusions and Future Outlook

In this microreview we have compiled a series of synthetic strategies that incorporate the terminal alkylidene and alkylidyne ligands onto the early transition metal series. One particular method which we have focused our attention to has been a reaction denoted "oxidatively induced α-hydrogen abstraction". This protocol combines a one-electron oxidation step with Schrock's seminal α-hydrogen abstraction method. One-electron oxidation does not only promote α-hydrogen abstraction, but also generates metal–carbon multiple bonds in low-coordination environments while in-

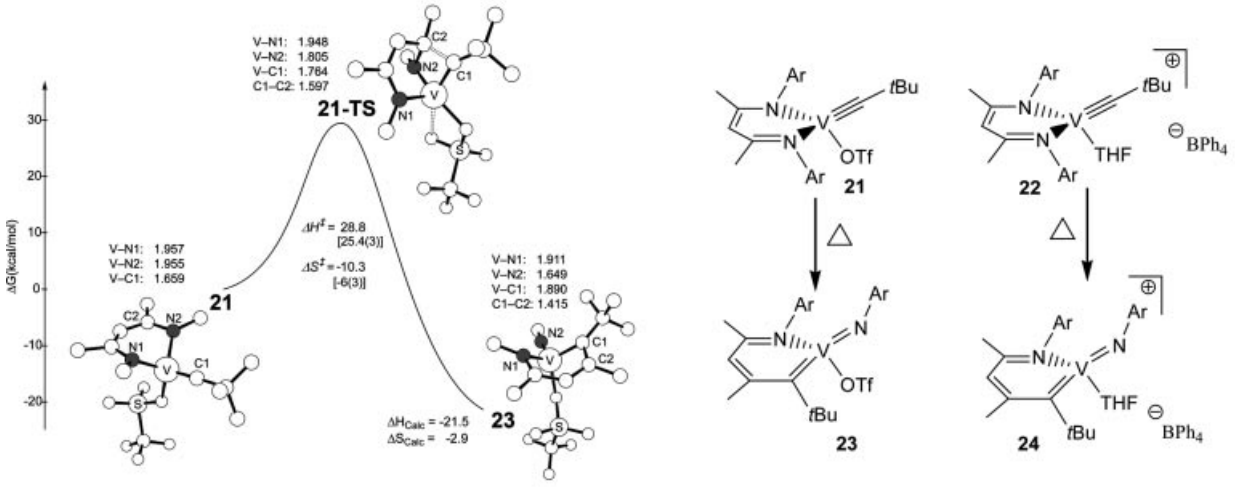


Figure 4. Transformation of the alkylidynevanadium complexes. corporating labile ligands such as $OTf^-$, $I^-$, or $BPh_4^-$. This feature unavoidably places these compounds along a cascade of other reactions which will ultimately lead to other novel functionalities. For example, terminal alkylidyne ligands can be incorporated onto titanium by an α-hydrogen abstraction pathway, while alkylidynevanadium complexes can be generated by a subsequent one-electron α-hydrogen abstraction reaction stemming from the alkylidene(alkyl) $V^{IV}$ precursor. In addition, the polarized nature of the M=C bond renders alkylidenetitanium and -vanadium functionalities exceedingly nucleophilic thus readily engaging in α-hydrogen migration or deprotonation reactions of primary phosphides to generate novel functionalities such as terminal phosphanylidenetitanium and -vanadium complexes.[13d,35] Fine tuning of the ancillary support has created kinetically robust systems capable of undergoing interesting intermolecular reactions such as C–H activation. The chemistry surrounding high-oxidation M=C and M≡C linkages for group 4 and 5 metals is an immature, yet emerging field in organotransition metal chemistry despite the first alkylidenetantalum being reported by Schrock in the early 70's.[7,8]

With these synthetic strategies now available to generate a library of M=C and M≡C linkages, we are now in position to probe these reactive functionalities and hopefully, pull alongside with the prototypical group 6 alkylidene/alkylidyne reagents commonly used today in catalysis.

## Acknowledgments

This work is dedicated to my former mentors Prof. C. C. Cummins and Prof. G. L. Hillhouse. Their dedication, originality, and level of expertise in fundamental chemistry have been a true inspiration throughout my scientific career. D.J.M. thanks Indiana University-Bloomington, the Camille and Henry Dreyfus Foundation, the Ford Foundation, the Alfred P. Sloan Foundation, and the U.S. National Science Foundation (CHE-0348941, PECASE award) for financial support of this research. D.J.M is also indebted to Dr. Falguni Basuli and Brad C. Bailey for achieving most of the results discussed in this microreview. Other contributors to the science which merit mentioning are Guangyu Zhao, Uriah J. Kilgore, Ingrid Castro-Rodriguez, Xile Hu, and Rodney Clark. Prof. Mu-Hyun Baik, Prof. Kenneth G. Caulton, Prof. Gang Wu, Prof. Karsten Meyer, and Prof. Oleg V. Ozerov are also acknowledged for insightful discussions and fruitful collaborations. The authors thanks Mrs. Jeannette E. Silvers for editing and Dr. John C. Huffman, Dr. John Bollinger, and Dr. Maren Pink for their contribution to X-ray analysis over the last 3.5 years.

# One-Pot Synthesis of a New High-Aluminium-Content Super-Microporous Aluminosilicate

**Lenin Huerta,[a,b] Francisca Romero-Sarria,[c] Olivier Marie,[c] Carmen Guillem,[a] Aurelio Beltrán,[a] Julio Latorre,[a] Daniel Beltrán,[a] and Pedro Amorós*[a]**

**Keywords:** Super-microporous / Aluminosilicates / Surfactants

A new super-microporous aluminosilicate having a high aluminium content (Si/Al ca. 1) has been prepared through a surfactant-assisted procedure with the use of a commercially available binary precursor (di-*sec*-butoxyaluminooxytriethoxysilane) as a single source of both Al and Si. The formation of super-micropores is a result of a significant network shrinkage associated with the thermal elimination of the surfactant. This solid has been studied by X-ray powder diffraction, electron microscopy, nuclear magnetic resonance spectroscopy and porosimetry. A preliminary analysis of the acidity and the catalytic activity of the super-microporous solid for the selective catalytic reduction of $NO_x$ is also presented. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

The discovery of the M41S family of mesoporous silicas by Mobil's researchers was a major step towards the expansion of the typical sizes of uniform micropores in zeotypes.[1] Since then, considerable effort has been devoted to the systematization of processing routes for the manufacture of silica-based mesoporous derivatives that contain pore sizes in the 2–10 nm range. The use of surfactants with alkyl chains of different lengths is the typical procedure employed for this endeavour.[2] While many investigations have been aimed at establishing the most suitable strategies to achieve large mesopores, the number of publications dealing with porous solids in which the pore sizes range between micropores and small-mesopores is limited.[3] The scarcity of results, however, is not an indication of the lack of interest in super-microporous solids since they are in high demand for their potential use in a large variety of applications, such as molecular recognition, adsorption, drug delivery and catalysis.[4] In fact, materials with uniform pore sizes in the 1–2 nm range (i.e. super-microporous) are expected to exhibit interesting shape- and size selectivity in the conversion of large organic substrates.

As mentioned above, there are few reports on super-microporous materials. Sung et al.[5] described the synthesis of porous niobium oxide with pore diameters below 2 nm. Shpeizer et al.[6] have recently reported on a general non-surfactant-assisted procedure to prepare super-microporous mixed oxides. With the exception of these two contributions, all of the remaining publications on super-microporous materials are centred on silica-based compositions. Super-microporous pure silicas have been prepared by different one-pot procedures, which implies the use of "structure-directing agents" or "templates". These templates vary greatly and range from micellar aggregates of surfactants (e.g. ω-hydroxy-bolaform[7] or long chain alkyl amines[8]) to simple, but bulky, organic molecules (e.g. adamantanamine[9]). Besides surfactant-assistance strategies, some strategies are based on the use of a single Si source (α-sodium disilicate[4]) or on a more complex multistep process (pore-entrance size decreases after post-synthetic treatment[10]). In some cases, mesoporous materials can be progressively altered to microporous materials through the incorporation of heteroelements such as Al or Zr.

Porous aluminosilicate compositions have traditionally attracted great interest owing to their capability to act as acid catalysts for bulky hydrocarbon conversion.[11] In practice, a solid acid material in the super-microporous domain could bridge the gap between zeolites and mesoporous aluminosilicates. Incorporation of Al centres in the framework of mesoporous silicas usually leads to a certain pore size decrease. Hence, aluminosilicates with pore sizes at the lower end of the mesoporous range have been obtained with high Al content materials.[12] However, pores in the super-microporous range usually cannot be achieved even with Si/Al ratios as low as 7.[13] In this case, the preparation of super-microporous aluminosilicates requires the combined effects of short-tail surfactants and high Al content in the starting solution[14] or, alternatively, the use of post-syn-

thetic strategies of Al-grafting.[15] Following these synthetic procedures, super-microporous silicas with a maximum Al content in the Si/Al = 2.5–7 range have been described.[16]

We report here on a new, direct and reproducible procedure that has allowed us to prepare a new porous silica with a very high Al content and with pore sizes in the super-microporous range.

## Results and Discussion

### Synthesis Strategy

Our surfactant-assisted strategy is based on the use of a "single-source molecular precursor" (i.e. a molecular precursor that simultaneously contains all the required oxide forming elements, Al and Si in this case). Under the synthetic conditions selected, and working in a water/triethanolamine medium, the use of such a precursor leads to poorly condensed mesostructured solids. Subsequently, the thermal treatment required to eliminate the surfactant also induces a significant network shrinkage, which leads to the formation of the super-micropores. The final material shows a high proportion of tetrahedral Al, and consequently a high acidity, and reasonable catalytic properties in the selective catalytic reduction (SCR) of nitrogen oxides ($NO_x$).

The use of bimetallic complexes, employed extensively by the Tilley group,[17,18] as inorganic precursors constitutes a polished approach towards the synthesis of a variety of mesoporous oxides. Although the composition of the final mixed oxide depends on that of the precursor, this approach is advantageous as it ensures an intimate mixture of the reactive elements from the initial preparative steps. In our case, we have additionally benefited from the complexing ability of triethanolamine (leading to atrane complexes), which in turn plays an essential role as the cosolvent.[19] The first step in our strategy involves the transesterification of commercially-available alkoxy derivatives (primary source of the oxide forming elements) through their treatment with dried triethanolamine at moderate temperatures (130–170 °C). This reaction leads to the formation of atrane complexes (real hydrolytic precursors). In fact, the use of atranes as precursors has allowed us to successfully prepare a diverse range of mesoporous single- and mixed oxides.[19–25] The additional use of triethanolamine as the cosolvent[19] is also supported by its use in the preparation of mesoporous materials in water/alcohol media;[26] however, atrane complex formation does not occur in water-rich media. The atrane alkoxy complexes are, in general, unstable but they are relatively inert towards hydrolysis. In many cases, this resistance towards hydrolysis (induced by the triethanolamine-like ligands) aids in the orchestration of the self-assembling processes (between the inorganic moieties and the surfactant aggregates) that lead to stable mesostructured phases.[19] In fact, the nucleophilic displacement of triethanolamine-related ligands, which occurs as a result of the attack of water on the silicon or aluminium centres, becomes more difficult than for monodentate alkoxo groups. In short, the combined effects of: (1) the use of a rigid binary "single-source molecular precursor", (2) the intrinsic "hydrolysis retarding effect" associated with the formation of atrane complexes, and (3) the buffered water/alcohol medium generated by the triethanolamine favours the formation of a low-condensed mesostructured material. The subsequent thermal evolution of the surfactant (to open the pore system) occurs together with a significant network shrinkage because of the completion of the condensation reactions, which leads to pores in the super-micropore domain.

### Characterization

As expected, the Si/Al molar ratio in the final material [$1.2 \pm 0.2$ from electron probe microanalysis (EPMA)] is very close to that present in the mother liquor. This fact indicates that there is no degradation of the bimetallic precursor under the working conditions. EPMA shows that the samples are chemically homogeneous at the micrometer level (spot area ca. 1 μm) with a regular distribution of Al and Si atoms throughout the inorganic walls. We can conclude that there is no preferential incorporation of Al or Si into the final net.

The mesophasic nature of both the as-synthesized and the super-microporous materials is illustrated by their X-ray powder diffraction (XRD) patterns and TEM images (Figure 1 and Figure 2). Both solids show low-angle XRD patterns with only one strong and relatively broad diffraction peak, which is typical of mesostructured/mesoporous materials prepared through surfactant-assisted procedures (Figure 1). This signal is usually associated with the (100) reflection if a MCM-41-like lattice is assumed. The observation of only one broad signal is characteristic of highly disordered pore systems. The absence of additional signals in the XRD pattern of the as-synthesized material could be due to the incorporation of Al into the walls. In fact, similar XRD patterns were recorded for Al-containing silica materials prepared from independent Si and Al molecular precursors under similar conditions.[12] In general, the incorporation of heteroelements into silica-based hexagonal porous frameworks implies a progressive lowering of the order in the pore array. After calcination, the intensity of the signal decreases, while it also appears significantly broadened. Moreover, calcination also results in a significant shift in the maximum towards high $2\theta$ values.

Hence, the value of the $a_0$ parameter (cell parameter assuming an MCM-41-like hexagonal array; $a_0 = 2 \cdot d_{100}/3^{1/2}$) pronouncedly decreases after calcination (from 5.77 to 5.05 nm). This behaviour indicates that surfactant elimination results in a significant reorganization of the porous walls. A relative loss of order together with a significant network shrinkage occur as a consequence of the calcination process.

While the TEM images (Figure 2) fully correlate to the XRD observations, the $N_2$ adsorption–desorption isotherms confirm the shrinkage of the framework (Figure 3).

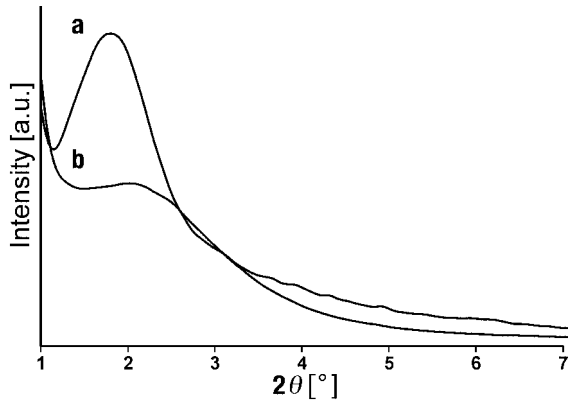

Figure 1. XRD patterns of (a) as-synthesized and (b) super-microporous materials.

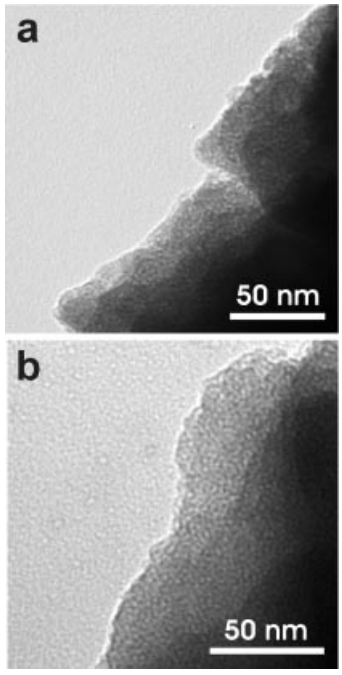

Figure 2. Representative TEM images of (a) as-synthesized and (b) super-microporous materials.

Thus, although the surfactant used (CTMABr) usually leads to the formation of mesopores (i.e. pores usually in the 2–3 nm range), the pore size estimated in this case falls in the microporous domain. In fact, the mean pore size resulting from the $D = 4V/S$ equation (which maintains a certain validity for super-micropores)[16] indicates a pore dimension of 1.3 nm, i.e. in the super-micropore range [pore volume ($V$) = 0.18 $cm^3 g^{-1}$, BET surface area ($S$) = 519 $m^2 g^{-1}$]. Application of the BJH method also indicates pore sizes in the super-micropore range, although these are slightly out of the optimum working range of the instrument. Indeed, we can observe a small maximum in the BJH pore size distribution at ca. 1.45 nm (see Figure 4). Also, the high value of the thickness of the average pore wall (3.8 nm, defined as wall thickness = $a_0$ – pore size) suggests a certain tendency to increase the wall condensation by calcination.

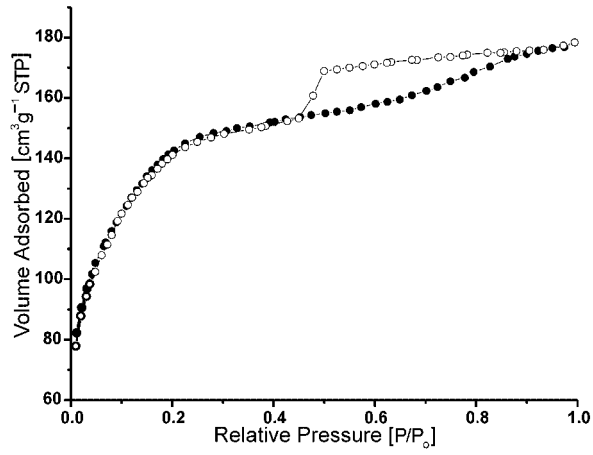

Figure 3. $N_2$ adsorption–desorption isotherms of the super-microporous aluminosilicate.

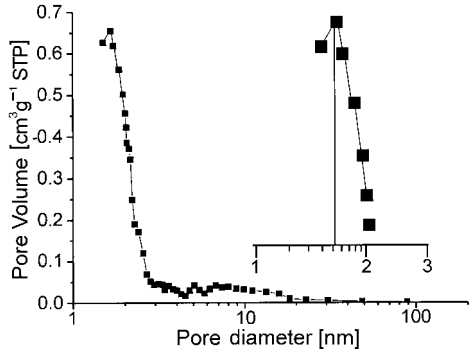

Figure 4. BJH pore size distribution on the adsorption branch of the isotherm.

Besides the above observations, the NMR results provide further evidence and confirm the theory that the condensation occurs in the inorganic walls as a consequence of the thermal treatment. Thus, in the case of the as-synthesized solid, the $^{27}Al$ MAS NMR spectrum shows essentially only one resonance signal at ca. $\delta$ = 57.0 ppm (Figure 5a), which is characteristic of tetrahedral Al sites. On the other hand, its $^{29}Si$ MAS NMR spectrum shows a very strong and broad signal whose centre appears to be shifted downfield ($\delta$ = –80.9 ppm, Figure 5c) when compared to that of a pure siliceous MCM-41. This signal displacement is in accordance with the resonance of $Q^4$ (4Al) environments. The broadness of the signal might be a consequence of other resonances that result from additional minority Si environments [such as $Q^4$ (3Al) and other $Q^3$ sites]. Thus, the MAS NMR results are consistent with the Si/Al = 1.2 ± 0.2 molar ratio determined from EPMA. The evolution of the NMR spectra indicates the occurrence of a significant conversion from a tetrahedral Al to an octahedral Al, which is a consequence of the surfactant removal (Figure 5b). This process also affects the Si sites. In fact, the $^{29}Si$ MAS NMR signal shifts from $\delta$ = –80.9 ppm to $\delta$ = –89.4 ppm (Figure 5d). This is consistent with an increase in $Q^4$ (3Al) centres. In short, the thermal surfactant removal also induces a reorganization, by way of a condensation reaction, of the inor-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ganic walls, and this shrinkage is responsible for the formation of the super-micropores. A similar behaviour (evolution from meso to micropores through calcination) has been recently reported in the preparation of pure porous silicas from hydrated α-sodium disilicate as a Si source.[4] In our case, we propose that the geometrical constraints imposed by the use of a single Si–Al molecular source lead to the framework in the as-synthesized material. In fact, when independent Si and Al precursors were used under similar working conditions, the final pore contraction was significantly lower, which resulted in solids with pore sizes that fall within the low limit of the mesoporous range.[12]

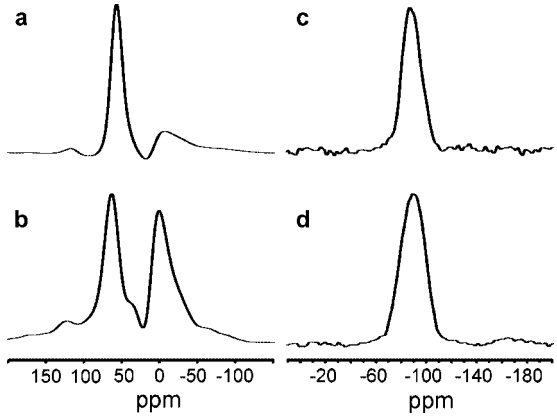

Figure 5. $^{27}$Al MAS NMR spectra of (a) as-synthesized and (b) super-microporous sample. $^{29}$Si MAS NMR spectra of (c) as-synthesized and (d) super-microporous sample.

Although ca. 50% of the Al centres have evolved from tetrahedral to octahedral sites after calcination, the final super-microporous material shows significant acidity, with a total number of acid sites of 800 mmol g$^{-1}$ (determined by nonselective $NH_3$ adsorption), – 375 mmol g$^{-1}$ corresponding to Lewis acid sites (estimated from Lewis selective acetonitrile adsorption) and the remaining 425 mmol g$^{-1}$ to Brønsted acid sites. This result is consistent with the $^{27}$Al MAS NMR spectrum, which shows both tetrahedral Al (responsible for Brønsted acidity) and octahedral Al (responsible for Lewis acidity) after calcination. A preliminary study on the use of this super-microporous aluminosilicate as a catalyst for the low-temperature (433 K) SCR of $NO_x$ with $NH_3$ gives a reasonable conversion level (ca. 72%) with little ammonia leakage. Comparatively, under the same temperature and flow conditions, the use of $NH_4Y$ (Si/Al = 5.7), whose Brønsted acidic strength is higher than that of our super micro-porous aluminosilicate, leads to 100% $NO_x$ conversion without $NH_3$ leakage; this result is in accordance with the acidity values.

## Conclusions

We report here on a simple and reproducible one-pot surfactant-assisted procedure for obtaining a new high-Al-content super-microporous aluminosilicate with well-dispersed Al and Si centres throughout the inorganic walls. Our strategy to diminish the pore size is based on the intermediate formation of a low-condensed framework starting from a binary (Al and Si) rigid precursor. Super-micropores are then formed as a consequence of the structure shrinkage induced by calcination. The final material presents with a high acidity and a reasonable catalytic activity in the SCR of $NO_x$. This strategy can be extended to the preparation of other bimetallic super-microporous oxides.

## Experimental Section

**Chemicals:** All the synthetic reagents were analytically pure and were used as received from Aldrich and Gelest. The Si and Al primary source used was di-*sec*-butoxyaluminooxytriethoxysilane (from Gelest). 2,2′,2′′-Nitrilotriethanol or triethanolamine [$N(CH_2–CH_2–OH)_3$] was used for obtaining the binary (Si and Al) atrane precursor. The templating agent used was cetyltrimethylammonium bromide (CTMABr).

**Synthesis:** The method was a modification of the so-called "atrane route", a simple preparative technique whose main points have been described previously in detail.[19] In a typical synthesis di-*sec*-butoxyaluminooxytriethoxysilane (13.20 g, 0.0375 mol) was slowly added to liquid triethanolamine (33.5 mL, 0.255 mol), and heated at 150 °C for 5 min. After the solution was cooled to 90 °C, CTMABr surfactant (6.84 g, 0.0187 mol) was added. The solution containing the binary (Si and Al) atrane complex (with the triethanolamine-related species as ligands) and the templating agent (CTMABr) was cooled to 60 °C and mixed with water (120 mL, 6.66 mol). After a few seconds, a white powder appeared. The resulting suspension was kept at room temperature for 12 h. The final (mesostructured) powder was filtered off, washed with water and ethanol, and air dried. In order to open the pore system (by surfactant removal), both calcination and chemical extraction procedures were tested. Typical extraction protocols, such as the suspension of the mesostructured solid in an HCl/ethanol solution (about 1 g of powder, 15 mL of 35% HCl and 150 mL of 96% ethanol), were unsuccessful. In practice, this process results in a significant mesostructure degradation or collapse that is provoked by the leaching of a large proportion of the Al atoms in the form of chloride complexes. This result indicates a high accessibility of the Al centres in the mesostructure, which provides evidence for a relatively low condensation in its inorganic walls. Removal of the surfactant was carried out by calcination. The as-synthesized solid was heated at 50 °C under static air for 5 h, thus yielding the final super-microporous material.

**Physical Measurements:** Both the as-synthesized and the super-microporous solids were analyzed for Si and Al content by electron probe microanalysis (EPMA, Philips SEM-515 instrument). X-ray powder diffraction (XRD) data were recorded with a Seifert 3000TT θ-θ diffractometer with Cu-$K_\alpha$ radiation. TEM images were obtained with a Philips CM10 microscope operated at 120 kV. $N_2$ adsorption–desorption isotherms were recorded with a Micromeritics ASAP2010 automated sorption analyzer. $^{29}$Si- and $^{27}$Al MAS NMR spectra were recorded with a Varian Unity 300 spectrometer operating at 79.5 MHz, and with a magic angle spinning speed of at least 4.0 KHz. Acidity was estimated from in situ FTIR experiments with a Nicolet Nexus FTIR instrument equipped with a quartz cell for the $NH_3$ or acetonitrile adsorption. Activity for the SCR of $NO_x$ with $NH_3$ was determined from operando FTIR experiments with a homemade infrared reactor cell.[27] More procedural details about both in situ and operando experiments are given in ref.[28]

# A Silver(I) Coordination Polymer Containing Tridentate *N*- and *P*-Coordinating 1,3,5-Triaza-7-phosphaadamantane (PTA) Ligands

**Fabian Mohr,*[a][‡] Larry R. Falvello[a] and Mariano Laguna*[a]**

*Dedicated to Prof. Victor Riera on the occasion of his retirement for his contribution to inorganic chemistry*

**Keywords:** Silver / Coordination polymer / Phosphane / Self-assembly

A silver(I) coordination polymer containing 1,3,5-triaza-7-phosphaadamantane (PTA) in an unprecedented bridging, tridentate *P,N,N′*-coordination mode is formed by the reaction of PTA with $AgNO_3$ in water.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

The synthesis of the air-stable, water-soluble phosphane ligand 1,3,5-triaza-7-phosphaadamantane (PTA) was first reported in 1974[1] but only recently has this phosphane been used as a ligand in a variety of inorganic and organometallic compounds.[2] An important driving force for the sudden interest in this ligand has been due to further developments in "green chemistry" and the need for inorganic/organometallic compounds that are soluble and stable in aqueous media.[3,4] One strategy to solubilise metal compounds is by the coordination of water-soluble ligands to a metal centre, which then may impart water solubility to the entire complex. In almost all of the known PTA metal complexes, the phosphane acts as a *P*-donor ligand (Figure 1, **A**). Very recently, the first examples of transition metal compounds that contain *N*-coordinated PTA (Figure 1, **B**) have been observed in manganese complexes $[MnX_2(PTA)_2(H_2O)_2]$ (X = Cl, Br).[5] In 2005, the organometallic Ru/Ag coordination polymers $[CpRu(L)(\mu\text{-}P,N\text{-}PTA)_2AgCl_2]_n$ (L = dmso, $H_2O$) were reported, which constitute the first, and so far only, examples of a PTA complex in which the ligand adopts a bridging *N,P*-coordination mode (Figure 1, **C**).[6]

In the past, we have utilised silver(I) phosphane salts of the type [AgX(P)] (P = tertiary phosphane; X = OTf, $ClO_4$, $NO_3$) as phosphane transfer reagents in the preparation of gold(II) complexes by metathesis reactions.[7] Recently, we reported the synthesis and characterisation of a series of water-soluble and water-stable gold complexes, which includes a gold(II) PTA derivative that was prepared with [Ag(OTf)(PTA)].[8,9] During our studies of various [AgX(PTA)] derivatives, we isolated and structurally characterised the nitrate derivative $[Ag(PTA)(H_2O)]NO_3$. X-ray quality crystals of $[Ag(PTA)(H_2O)]NO_3$[10] were formed when aqueous solutions containing equimolar amounts of PTA and $AgNO_3$ were mixed. This compound is the first example of a complex that contains PTA in a triply bridging *P,N,N′*-coordination mode (Figure 1, **D**). The basic unit of this complex consists of a molecule of *P*-coordinated PTA and water coordinated to the silver atom (Figure 2).

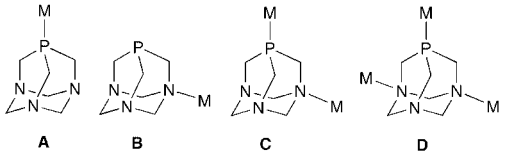

Figure 1. Observed coordination modes of PTA.

These monomers are then arranged such that two of the PTA nitrogen atoms, N-2 and N-3, coordinate to other silver atoms, i.e. each silver atom is connected to one phosphorus atom, P-1, and two nitrogen atoms, N-2 and N-3, from three different PTA molecules in a T-shaped arrangement. The coordinated water molecule completes the distorted tetrahedral coordination geometry about the silver atom. The network structure of the complex can be described as a polymeric net that contains hexagonal units (Figure 3).

In the crystal, these polymeric nets are stacked above each other, and the resulting channels are occupied by the nitrate anions (Figure 4).

In this complex, the PTA ligand behaves very similarly to its all-nitrogen analogue hexamethylenetetramine

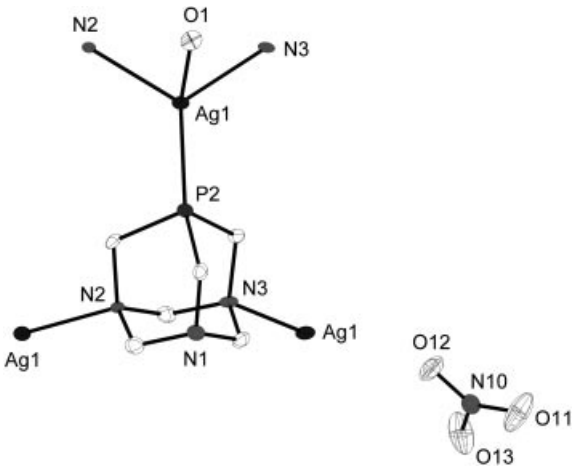

Figure 2. Structure of $[Ag(PTA)(H_2O)]NO_3$ which shows the atom-labelling scheme. Displacement ellipsoids are drawn at 50% probability and hydrogen atoms are omitted for clarity.

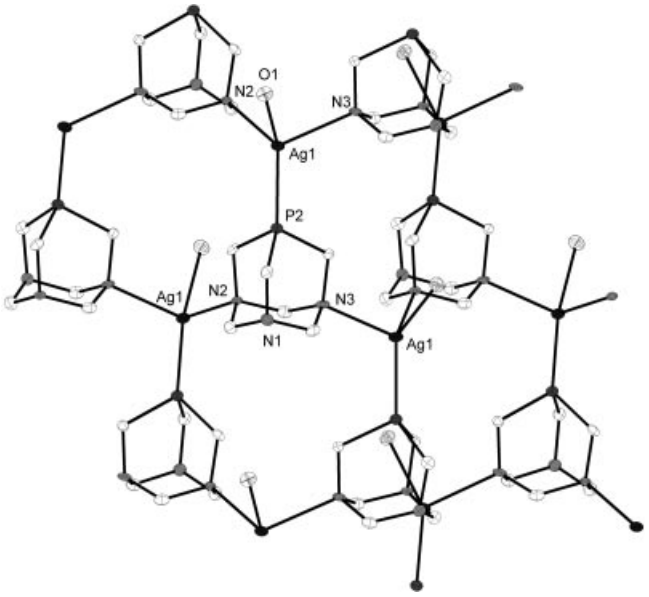

Figure 3. Polymeric net structure of $[Ag(PTA)(H_2O)]NO_3$ which illustrates the *P*,*N*,*N*′-coordination mode of the PTA ligand. Hydrogen atoms, as well as the nitrate anions, are omitted for clarity.

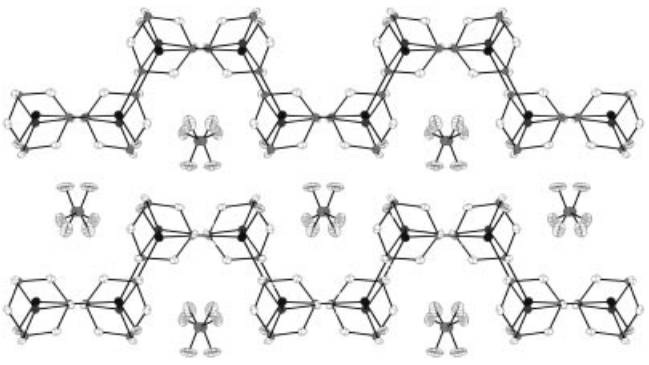

Figure 4. View of $[Ag(PTA)(H_2O)]NO_3$ along the *c*-axis which shows three polymer nets and the nitrate anions located in the channels. Hydrogen atoms are omitted for clarity.

(HMT). A variety of [AgX(HMT)] complexes have been prepared and structurally characterised and, depending on the metal/HMT ratios, the solution pH and the type of counterions, many different two- and three-dimensional network polymers have been observed.[11–13] In particular, the polymeric net structure of $[Ag(NO_3)(HMT)]$[14] is almost identical to that of $[Ag(PTA)(H_2O)]NO_3$, with the exception that a nitrato ligand is *O*-coordinated to the silver atom instead of a water molecule, hence the channels in the 3D network of $[Ag(NO_3)(HMT)]$ are vacant. The Ag–P bond length in $[Ag(PTA)(H_2O)]NO_3$ [2.3822(12) Å] is shorter than the Ag–P distances in other silver(I) nitrate complexes that contain bulky phosphane ligands such as $[Ag(NO_3)(PPh_3)_2]$ and $[Ag(NO_3)\{P(m\text{-}MeC_6H_4)_3\}]$ [2.443(1) and 2.4128(8) Å, respectively].[15] However, if the bulkiness of the phosphane group is decreased, the Ag–P bond length becomes shorter as is evident in $[Ag\{P(CH_2CH_2CN)_3\}_2]NO_3$, whose Ag–P bond length is 2.3832(9) Å.[15] This bond length is very similar to that observed in $[Ag(PTA)(H_2O)]NO_3$ in this work, which illustrates the small steric bulk of PTA. The two Ag–N distances [2.441(4) and 2.468(4) Å] are slightly longer than those observed in $[Ag(NO_3)(HMT)]$ [2.406(5) and 2.335(6) Å] and $[CpRu(H_2O)(\mu\text{-}P,N\text{-}PTA)_2AgCl_2]_n$ [2.423(6) Å].[6]

In summary we present here the first example of a PTA ligand that adopts a tridentate, bridging *P*,*N*,*N*′-coordination mode, which results in a polymeric net structure that contains hexagonal cavities occupied by nitrate anions.

**Keywords:** Asymmetric catalysis / Cycloadditions / Ruthenium / Phosphanyloxazolines / Half-sandwich complexes

Ruthenium complexes of formula $[(\eta^6\text{-arene})Ru(LL^*)(H_2O)][SbF_6]_2$ (arene = $C_6H_6$, *p*-$MeC_6H_4iPr$, $C_6Me_6$; $LL^*$ = bidentate chelate chiral ligand with PN, PP or NN donor atoms) have been tested as catalyst precursors for the asymmetric 1,3-dipolar cycloaddition of nitrones to methacrolein. The reaction occurs quantitatively with perfect *endo* selectivity and moderate enantioselectivity (up to 74 % *ee*). The ruthenium aqua complexes can be prepared from the corresponding chlorides, $[(\eta^6\text{-arene})RuCl(LL^*)][SbF_6]$. Dipolarophile intermediates $[(\eta^6\text{-arene})Ru(PNiPr)(methacrolein)][SbF_6]_2$ {PN*i*Pr = (4*S*)-2-(2-diphenylphosphanylphenyl)-4-isopropyl-1,3-oxazoline} as well as nitrone-containing complexes $[(p\text{-}MeC_6H_4iPr)Ru(PNiPr)(nitrone)][SbF_6]_2$ (nitrone = *N*-benzylidenephenylamine *N*-oxide, *N*-benzylidenemethylamine *N*-oxide, 3,4-dihydroisoquinoline *N*-oxide) have been also isolated and characterised. The crystal structures of the chlorides $(R_{Ru})$-$[(\eta^6\text{-}C_6Me_6)RuCl(PNiPr)][SbF_6]$, $(R_{Ru})$-$[(\eta^6\text{-}C_6H_6)RuCl(PNInd)][SbF_6]$ {PNInd = (3a*R*,8a*S*)-2-[2-(diphenylphosphanyl)phenyl]-3a,8a-dihydroindane[1,2-*d*]oxazole} and those of the aqua solvates $(R_{Ru})$-$[(\eta^6\text{-arene})Ru(PNiPr)(H_2O)][SbF_6]_2$ (arene = $C_6H_6$, $C_6Me_6$) were determined by X-ray diffraction methods.

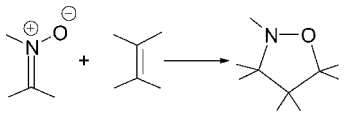
## Introduction

Asymmetric catalysis has achieved a position as one of the most important areas of modern organic chemistry.[1] Among the wide variety of organic reactions that are used in asymmetric synthesis, cycloaddition processes are one of the most attractive synthetic methodologies because they allow the construction of new molecular skeletons with several stereogenic centres in a single step.[2] 1,3-Dipolar cycloaddition reactions represent a highly atom-efficient and elegant method for the synthesis of five-membered ring systems and, depending on the choice of dipolar reagent and dipolarophile, a large variety of heterocycles can be prepared.[3] Nitrones, in particular, have attracted much attention since they are readily available and easy to handle and their reactions with olefins give convenient access to isoxazolidine derivatives (Scheme 1).[4] Because its N–O bond is readily cleaved to form 3-amino alcohol equivalents under mild reducing conditions, these cyclic compounds have been applied as synthetic intermediates for the synthesis of useful compounds such as alkaloids, β-lactams, amino acids or amino sugars.[3a,5] However, asymmetric versions of this reaction are scarce. Furthermore, alkenoyloxazolidinones are usually employed as bidentate dipolarophiles[3b,4a] and only a few studies on monodentate α,β-unsaturated aldehydes have been reported so far.[6]



Scheme 1. Reaction of nitrones with alkenes.

On the other hand, it has been shown that chiral pseudo-tetrahedral metal half-sandwich complexes[7] are efficient catalysts for the asymmetric Diels–Alder[8] and hydrogen-transfer reactions.[9] In this context, we have reported that the single-coordination-site transition-metal chiral Lewis acids $[(\eta^5\text{-}C_5Me_5)M(R\text{-Prophos})(H_2O)][SbF_6]_2$ [M = Rh, Ir;

*R*-Prophos = 1,2-bis(diphenylphosphanyl)propane] efficiently promote enantioselective 1,3-dipolar cycloaddition reactions (DCR) of nitrones with methacrolein.[10]

Taking into consideration all these data, we planned to test chiral half-sandwich ruthenium complexes of the general formula $[(\eta^6\text{-arene})Ru(LL^*)(H_2O)]^{2+}$ (LL* = bidentate chelate chiral ligand) as catalysts in enantioselective 1,3-dipolar cycloadditions of nitrones with methacrolein. In this paper we report the preparation of new chloride complexes of general formula $[(\eta^6\text{-arene})RuCl(LL^*)][SbF_6]$ (**1**–**4**) which are precursors of aqua solvates (**7**–**16**, Scheme 2) and the use of the latter as catalysts in the above-mentioned process. The molecular structural details of four representative complexes, determined by X-ray diffraction methods, are also included.

## Results and Discussion

### Preparation and Characterisation of the Diastereomeric Complexes 1–16

The aqua complexes **7**, **8**, **10** and **11** were prepared by treating the corresponding chloride complexes **1**–**4** with equimolar amounts of $AgSbF_6$. The latter, in turn, were prepared from the dimers[11] $[\{(\eta^6\text{-arene})RuCl\}_2(\mu\text{-}Cl)_2]$ [Equation (1)]. The previously reported chloride **5** and solvates **9**, **12** and **15** were similarly prepared.[8u,8x] The pyridylamino derivatives **6** and **16**, also prepared according to Equation (1), will be reported elsewhere.[12] The diphosphanyl complexes **13** and **14** were prepared by treatment of the dimer $[\{(\eta^6\text{-}p\text{-}MeC_6H_4iPr)RuCl\}_2(\mu\text{-}Cl)_2]$ with $AgSbF_6$, filtration of the AgCl formed and subsequent addition of the corresponding diphosphane.

$$\begin{array}{l} {}^1/_2[\{(\eta^6\text{-arene})RuCl\}_2(\mu\text{-}Cl)_2] \;+\; LL^* \\ \quad\downarrow -NaCl \;\; NaSbF_6 \\ [(\eta^6\text{-arene})RuCl(LL^*)][SbF_6] \\ \textbf{1-6} \\ \quad\downarrow -AgCl \;\; AgSbF_6 \\ [(\eta^6\text{-arene})Ru(LL^*)(H_2O)][SbF_6]_2 \\ \textbf{7-12, 15, 16} \end{array} \qquad (1)$$

The new complexes were characterised by IR and NMR spectroscopy, circular dichroism (CD), elemental analysis (see Exp. Sect.) and by the X-ray crystal structure determination of one of the epimers at the metal atom of complexes **2**, **3**, **7** and **8**.

During the formation of the chloride complexes, the ruthenium atom becomes a chiral centre and, as the chiral LL* ligand used is enantiopure, the new compounds are prepared as diastereomeric mixtures of both epimers at the metal atom. Variable degrees of diastereoselectivity are achieved, ranging from 10 to 96% *de* (see Exp. Sect.). Concerning the stereochemistry of the metal centres, it should be noted that due to the ligand priority rules,[13] different descriptors are assigned to the chlorides and to their derived aqua complexes, although both display identical spatial disposition of the ligands around the metal atom.

The absolute configurations of the new complexes were assigned through NMR spectroscopic and CD measurements. Thus, for example, irradiation of the arene protons in the $R_{Ru}$ chloride complexes (or in the $S_{Ru}$ aqua solvates) induces NOE enhancements of the $H_g$ or $H_a$ protons for

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

PN*i*Pr- or PNInd-containing complexes, respectively (see Scheme 2). Similarly, this irradiation induces, in the $S_{Ru}$ chlorides (or in the $R_{Ru}$ aqua solvates), NOE enhancements of the $H_i$ or $H_n$ protons for PN*i*Pr- or PNInd-containing complexes, respectively.

Proton shielding by aromatic ring currents can also be used to distinguish between the two epimers at the metal atom of these chiral complexes. For example, the chemical shift of the $C_6Me_6$ protons differs by 0.43 ppm for the two epimers of the PNInd-containing complex **4**. Inspection of molecular models indicates that these protons can only be efficiently shielded by the aromatic indane ring current in the $R_{Ru}$ epimers. Therefore, we assign the high-field resonance to the *R* epimer.

On the other hand, the difference in the chemical shift (ca. 1 ppm) between the signals of the two methyl protons of the PN*i*Pr ligand in complexes **1**, **2**, **7** and **8** could be explained by assuming that in these complexes the six-membered metallacycle adopts an $^1S_2$ screw boat conformation.[8v,8x,14] Such a conformation has been found in the solid state for complexes **7** and **8** (see below). In this conformation, one methyl group of the *i*Pr group lies over the *pro-R*-phenyl group of the $PPh_2$ group, becoming shielded by its aromatic ring current.

The aqua solvates **8**, **10** and **11** are fluxional. Although we have not measured the kinetic parameters for the dynamic process, the spectroscopic features encountered in the $^{31}P$ and $^1H$ NMR spectra strongly indicate that it likely consists of a flip of the phosphanyloxazoline metallacycle between the $^1S_2$ and $^2S_1$ screw boat conformations as has been previously found in the related phosphanyloxazoline aqua solvates of ruthenium, **9** and **12**.[8x]

The CD spectra of these complexes corroborate the above-assigned configurations. The main feature of the CD spectra of the $S_{Ru}$ chlorides ($R_{Ru}$ aqua complexes) is a maximum with a positive Cotton effect centred in the 360–390 nm range. The CD spectra of corresponding diastereomers with opposite configuration at the metal atom display a pseudo-enantiomorphic relationship, showing that the major contribution to the spectra corresponds to the metal atom. This transition thus gives direct insight into differences in the configurations at the metal atoms.

[a] There were two independent molecules in the crystal. [b] Data are included for the Ru–Cl (**2** and **3**) and the Ru–O(2) (**7** and **8**) bond lengths. [c] G represents the centroid of the arene ligand C(19)–C(24).

### Molecular Structures of $R_{Ru}$-2, $R_{Ru}$-3, $R_{Ru}$-7, and $R_{Ru}$-8

Single crystals of the chlorides **2** and **3** and of the aqua complexes **7** and **8** were grown by slow diffusion of diethyl ether into dichloromethane solutions of the complexes. Their structures were determined by diffraction methods. Molecular representations of the cations of the four complexes are depicted in Figure 1 and selected structural parameters are listed in Table 1. The coordination around the ruthenium atom is pseudo-octahedral. The $\eta^6$-arene ligand ideally occupies three *fac*-coordination positions. The phosphanyloxazoline ligand, coordinated through the phosphorus and the nitrogen atoms and one chlorine atom (**2**, **3**) or one water molecule (**7**, **8**) complete the coordination sphere of the metal atom. The absolute configuration of the ruthenium centre in the four complexes is *R*, in accordance with the ligand priority sequence[13] $\eta^6$-arene > Cl > P > N (chlorides) or $\eta^6$-arene > P > O > N (aqua solvates).

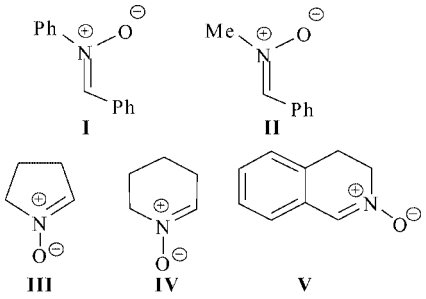
The six-membered Ru–P(1)–C(1)–C(2)–C(29)–N(1) metallacycle of complexes **3**, **7** and **8** adopts a $^1S_2$ screw-boat conformation[14] with the metal and phosphorus atoms above and below the best plane, respectively. This conformation forces the *pro-R*- and *pro-S*-phenyl groups to adopt pseudo-axial and pseudo-equatorial arrays, respectively. In particular, in the solvate complexes **7** and **8**, the C(33) carbon atom of the isopropyl group lies over the *pro-R*-phenyl group of the $PPh_2$ group at 3.260(6) (**7**) and 3.405(9) Å (**8**) from the plane of the pseudo-axial phenyl group. In compound **2**, the metallacycle adopts a $^2S_1$ screw-boat conformation,[14] with the metal and phosphorus atoms below and above the best plane, respectively.

### Catalytic Reactions

Firstly, we tried the (*p*-methylisopropylbenzene)ruthenium complexes **9** and **13**–**16**, which differ in the LL* bidentate chelate chiral ligand, as catalyst precursors for the cycloaddition reaction between methacrolein and the nitrone *N*-benzylidenephenylamine *N*-oxide (nitrone **I**, Scheme 3) (Table 2). These aqua complexes efficiently catalyse the proposed cycloaddition. The catalyst precursors were treated with methacrolein in the presence of molecular sieves (4 Å) before the addition of the nitrone (see Exp. Sect.). Under these conditions, the formation of active methacrolein complexes of formula $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)\text{-}Ru(LL^*)(methacrolein)]^{2+}$ is strongly favoured at the expense of the initial aqua complexes (see below) which prevents hydrolysis of the nitrone catalysed by trace amounts of the latter.[10b] Quantitative conversions with moderate *ee* values were achieved at –25 °C after a few hours. The best results in this series were obtained when the hybrid P,N-donor phosphanyloxazoline ligand (PN*i*Pr, complex **9**) was employed as chiral source (Entry 1, Table 2). Therefore, we focused on complex **9** in subsequent catalytic experiments (Table 3). Temperature variations slightly affected both product distribution and enantioselectivity, the latter smoothly increasing as temperature decreases. The pre-

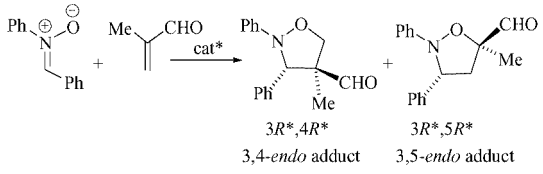
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

viously reported[8x] tetrafluoroborate and triflate complexes $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru(PNiPr)(H_2O)][BF_4]_2$ (**9·BF$_4$**) and $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru(PNiPr)(H_2O)][CF_3SO_3]_2$ (**9·CF$_3$SO$_3$**) were also tested as catalysts. As shown in Entries 5 and 6, the use of more coordinating anions decreased the yield, probably due to competition of the anion and the substrate for the Lewis acid site.[8o,15] The catalyst can be easily recovered and reused.



Scheme 3. Nitrones employed in the catalytic experiments.

Table 2. Enantioselective 1,3-dipolar cycloadditions of methacrolein with nitrone **I** catalysed by $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru(LL^*)(H_2O)][SbF_6]_2$ complexes.[a]



| Entry | Complex | *t* [h] | Yield [%][b,c] | 3,4-*endo*[c] | 3,5-*endo*[c] | *ee* [%][d] |
|---|---|---|---|---|---|---|
| 1 | **9** | 15 | 100 | 69 | 31 | 54:40 |
| 2 | **13** | 48 | 40 | 40 | 60 | 43/–42 |
| 3 | **14** | 15 | 90 | 32 | 68 | 6:3 |
| 4[e] | **15** | 48 | 98 | 36 | 64 | –18/–31 |
| 5[e] | **16** | 48 | 100 | 91 | 9 | –6/–4 |

[a] Reaction conditions: catalyst (0.06 mmol, 5.0 mol-%), methacrolein (1.68 mmol), molecular sieves (4 Å) (100 mg) and nitrone (1.2 mmol) in $CH_2Cl_2$ (5 mL). [b] Based on nitrone. [c] Determined by $^1$H NMR spectroscopy. [d] Determined by integration of the $^1$H NMR signals of the 3-H proton of the diastereomeric *R*-methylbenzylimine derivatives. Positive *ee* values correspond to the *endo*-3*R*,4*R* adduct. For the 3,5-*endo* adduct, positive values are arbitrarily assigned to the *ee* in the lower-field $^1$H NMR signal diastereomer. [e] Methacrolein (8.4 mmol) was used.

Consecutive runs of up to three more times were performed, producing a smooth decrease in the conversion rate. However, neither the 3,4-*endo*/3,5-*endo* ratio nor the *ee* were significantly affected (Entries 7.1–7.4).

To investigate the stereoelectronic influence of the $\eta^6$-coordinated arene ligand, we used the new benzene (**7**, **10**) and hexamethylbenzene (**8**, **11**) derivatives with PN*i*Pr or PNInd ligands as catalyst precursors for the cycloaddition of methacrolein with nitrone **I** (Table 4). Reactions carried out at –25 °C gave nearly quantitative conversions after 15 h. It seems that the PN*i*Pr ligand performs better than its PNInd congener with *ee* values of up to 74% being achieved with the former. On the other hand, no obvious trends were observed within the arene series.

Table 3. Enantioselective 1,3-dipolar cycloadditions between methacrolein and nitrone **I** catalysed by $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru(PNiPr)(H_2O)]^{2+}$.[a]

[a] Conditions were those indicated in footnote of Table 2 but using methacrolein (8.4 mmol). [b] Total reaction time; addition of nitrones was accomplished over 15 h. [c] Determined by integration of the $^1$H NMR signals of the 3-H proton of the diastereomeric *R*-methylbenzylimine (nitrone **II**) derivative, the CHO proton of the (+)-*S*-mandelic acid (nitrone **IV**) derivative or the CHO proton observed after addition of the chiral shift reagent Eu(hfc)$_3$ (nitrones **III** and **V**). Positive *ee* values correspond to the (+)-*endo*-3*R*,5*R* (nitrone **III**), (–)-*endo*-3*R*,5*R* (nitrone **IV**) and (–)-*endo*-3*S*,5*R* (nitrone **V**) adducts. For the adducts of nitrone **II**, positive values are arbitrarily assigned to the *ee* in the lower-field $^1$H NMR signal diastereomer. [d] 2% of the 3,5-*exo* isomer was also obtained. [e] 4% of the 3,4-*endo* isomer was also obtained.

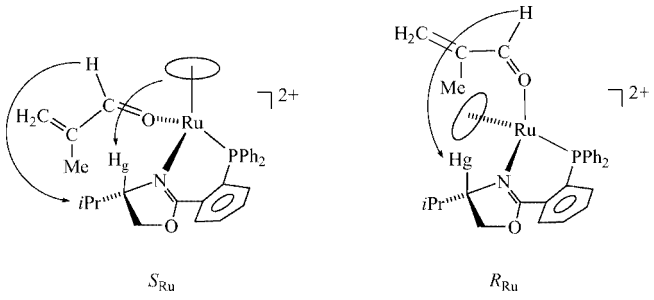
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

perfect regio- and diastereoselectivity for the 3,5-*endo* isomer. In all cases, low to moderate *ee* values were achieved. The hexamethylbenzene complex $[(\eta^6\text{-}C_6Me_6)Ru(PN\text{-}i\text{Pr})(H_2O)][SbF_6]_2$ (**8**) is the least active catalyst precursor tried but the most enantioselective (61% *ee*) and the acyclic nitrone **II** generates the least active system even at higher temperature (0 °C).

### The Methacrolein Complexes $[(\eta^6\text{-arene})Ru(PN\textit{i}Pr)(methacrolein)][SbF_6]_2$ [arene = $C_6H_6$ (17), *p*-$MeC_6H_4\textit{i}Pr$ (18), $C_6Me_6$ (19)]

To obtain a deeper insight into the catalytic systems, we studied the solution behaviour of mixtures of aqua complexes $[(\eta^6\text{-arene})Ru(PN\textit{i}Pr)(H_2O)]^{2+}$ with methacrolein by NMR spectroscopy. When 4 equiv. of methacrolein were added to solutions of complexes **7**–**9** at 0 °C, the new complexes $[(\eta^6\text{-arene})Ru(PN\textit{i}Pr)(methacrolein)]^{2+}$ were formed according to $^{31}P$ NMR spectroscopic measurements. Both complexes are in equilibrium, but in the presence of molecular sieves (4 Å) the position of equilibrium is completely shifted towards the formation of the methacrolein complex. In fact, pure complexes **17**–**19** were isolated from these solutions in about 40% *de*. The new complexes were characterised by analytical and spectroscopic means. An IR band at ca. 1650 $cm^{-1}$ along with $^1H$ NMR peaks at $\delta \approx 9.50$ (CHO) and 6.60 ($=CH_2$) ppm and a $^{13}C$ NMR resonance at $\delta \approx 213$ ppm are diagnostic of coordinated methacrolein. NOE measurements allowed us to assign the absolute configuration at the metal atom in these complexes. Thus, irradiation of the arene or the CHO protons in the $S_{Ru}$ epimers produced NOE enhancement in the $H_g$ or the isopropyl methyl protons of the PN*i*Pr ligand, respectively. On the other hand, irradiation of the CHO proton in the $R_{Ru}$ epimers gave enhancement in the $H_g$ proton (Scheme 4). From these data we propose that the major epimer is the $R_{Ru}$ isomer for the benzene and hexamethylbenzene complexes **17** and **19** and the $S_{Ru}$ isomer for the *p*-$MeC_6H_4\textit{i}Pr$ complex **18**.

On the other hand, the considerable difference in the chemical shift between the two *i*Pr methyl protons of the phosphanyloxazoline ligand of the complexes ($\Delta\delta \approx 1.0$ ppm) at low temperature, could be explained by assuming that the six-membered chelate ring of the phosphanyloxazoline ligand adopts a $^1S_2$ screw-boat conformation[14] in the ground state. At higher temperature, the NMR spectroscopic data again indicate a fluxional process, most probably involving a flip of the phosphanyloxazoline metallacycle between the $^1S_2$ and $^2S_1$ screw boat conformations.

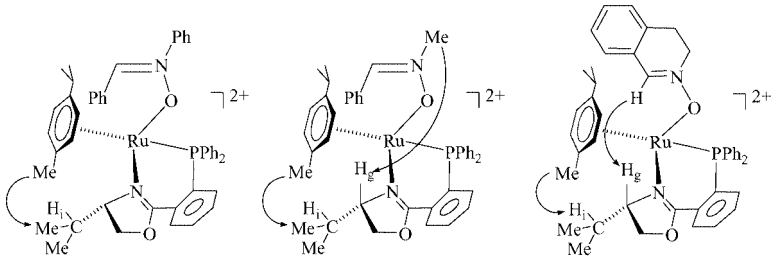


$S_{Ru}$ $R_{Ru}$

Scheme 4. NOEs observed in complexes **17**–**19**.

### Complexes $[(\eta^6\text{-}p\text{-}MeC_6H_4\textit{i}Pr)Ru(PN\textit{i}Pr)(nitrone)][SbF_6]_2$ [nitrone = I (20), II (21) and V (22)]

The reaction of the nitrone with the coordinated alkene is usually the rate- and enantio-determining step for the DCR between nitrones and enals.[7b] We therefore studied, by NMR spectroscopy, the system generated after addition of a nitrone to the methacrolein-containing complex $[(\eta^6\text{-}p\text{-}MeC_6H_4\textit{i}Pr)Ru(PN\textit{i}Pr)(methacrolein)]^{2+}$. While a partial displacement of coordinated methacrolein was observed when nitrone **I** was added to complex **18**, nitrone **II** readily substituted the coordinated enal, affording the new nitrone-containing complex $[(\eta^6\text{-}p\text{-}MeC_6H_4\textit{i}Pr)Ru(PN\textit{i}Pr)(\mathbf{II})]^{2+}$. It is important to note that in normal-electron-demand DCR, the reaction must occur by dipole attack at the coordinated dipolarophile. To circumvent this problem, we have carried out the catalysis with slow addition of nitrones **II**–**V** (see Exp. Sect.). From the solution, we have isolated and characterised the nitrone complexes **20**–**22**. One singlet in the $\delta$ = 8–8.5 ppm region of the $^1H$ NMR spectrum, along with a peak at $\delta \approx 150$ ppm in the $^{13}C$ NMR spectrum (attributed to the N=CH proton and C atom, respectively) strongly support the coordination of the nitrone ligand. Only one epimer at metal atom has been detected for these complexes from –90 °C to room temperature. NOE experiments (see Scheme 5) allow us to propose that the solely detected isomer is the $R_{Ru}$ epimer. According to the observed $\Delta\delta$ value



$R_{Ru}$-**20** $R_{Ru}$-**21** $R_{Ru}$-**22**

Scheme 5. NOEs observed in complexes **20**–**22**.

in the chemical shift of the isopropyl methyl protons of the phosphanyloxazoline ligand (see above) the metallacycle Ru–P–C–C–C–N should adopt a $^1S_2$ screw-boat conformation.[14]

## Conclusions

The half-sandwich ruthenium complexes $[(\eta^6\text{-arene})Ru(LL^*)(H_2O)]^{2+}$ are efficient catalyst precursors for the DCR of methacrolein with a series of nitrones. Typically, quantitative conversions are achieved at –25 °C in a few hours. Perfect diastereoselectivity for the *endo* adducts can be observed but only low to moderate enantioselectivity is obtained. Some structural features of the complexes involved in catalysis are illustrative. Firstly, the methacrolein complexes, presumably the active catalysts, are formed as mixtures of both epimers at the metal atom. Secondly, the metallacycle formed by coordination of the LL* ligand is conformationally labile. Thirdly, the methacrolein rotamer around the Ru–O bond is not fixed. In the related $[(\eta^5\text{-}C_5Me_5)M(R\text{-Prophos})(\text{methacrolein})]^{2+}$ (M = Rh, Ir) system, (i) only $S_M$ epimers can be detected, (ii) the metallacycle coordination only presents the $\lambda$ conformation and is not labile, (iii) O=CH···π attractive interactions set the conformation around the M–O bond in both the solid state and solution. In particular, a very strong shielding of the O=CH proton (about 2.5 ppm) indicates that this rotamer is fixed in solution. However, no significant shielding has been observed for the CHO proton of coordinated methacrolein in the ruthenium complexes reported in this work. In summary, all these structural differences could explain the distinct enantioselective behaviour encountered for these otherwise closely related half-sandwich complexes. The structural analysis carried out in this work provides a useful guide for the a priori selection of new enantioselective catalytic systems. In this context, the isolation of pure $R_{Ru}$ epimers for the nitrone complexes $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru(PNiPr)(\text{nitrone})]^{2+}$ opens the door to new enantioselective processes that will be investigated in our laboratory in due course.

## Experimental Section

**General Comments:** All solvents were dried with appropriate drying agents, distilled under argon and degassed prior to use. All preparations were carried out under argon. Infrared spectra were obtained as Nujol mulls with a Perkin–Elmer 1330 spectrophotometer. Carbon, hydrogen and nitrogen analyses were performed using a Perkin–Elmer 240C microanalyser. NMR spectra were recorded with a Bruker AV-400 (400.16 MHz) or 300-ARX (300.10 MHz) instrument. Chemical shifts are expressed in ppm upfield from $SiMe_4$ or 85% $H_3PO_4$ ($^{31}P$). NOEDIFF, $^{13}C$, $^{31}P$ and $^1H$ correlation spectra were obtained using standard procedures. CD spectra were determined in acetone or dichloromethane (ca. $5\times10^{-4}$ mol L$^{-1}$ solutions) in a cell with 1 cm path length using a Jasco-710 apparatus. The nitrones were prepared according to literature procedures.[16]

**Preparation of the Complexes $[(\eta^6\text{-arene})RuCl(LL^*)][SbF_6]$ (1–4):** A mixture of the appropriate $[\{(\eta^6\text{-arene})RuCl\}_2(\mu\text{-}Cl)_2]$ (0.25 mmol), $NaSbF_6$ (129.4 mg, 0.50 mmol) and the corresponding LL* ligand (0.50 mmol) in methanol (10 mL) was stirred for 5 h. During this time, the precipitation of an orange solid was observed. The resultant suspension was vacuum-concentrated to dryness. The residue was extracted with dichloromethane (3 × 5 mL) and the solution partially concentrated under reduced pressure. Slow addition of diethyl ether gave an orange solid which was filtered off, washed with diethyl ether and air-dried. By recrystallisation from methanol/diethyl ether, pure $R_{Ru}$-**4** and mixtures of molar compositions $S_{Ru}$-**1**/$R_{Ru}$-**1** (95:5) and $S_{Ru}$-**4**/$R_{Ru}$-**4** (95:5) were obtained.

**Catalytic Procedure:** The complexes [($\eta^6$-arene)Ru(LL*)($H_2O$)][A]$_2$ (0.06 mmol, 5 mol-%) were dissolved in $CH_2Cl_2$ (3 mL) at 0 °C. Freshly distilled methacrolein [0.14 mL (1.68 mmol) or 0.70 mL (8.40 mmol)] and activated molecular sieves (4 Å) (100.0 mg) were added and the suspension was stirred for 30 min. A solution of the corresponding nitrone (1.20 mmol) in $CH_2Cl_2$ (2 mL) was added. For nitrones **II**–**V**, the nitrone solution was added dropwise with a syringe pump over 15 h. After stirring at the appropriate temperature for the reaction time indicated in the tables, hexanes (20 mL) were added. After filtration through diatomaceous earth, the solution was concentrated to dryness. The residue was purified by chromatography ($SiO_2$) to provide a mixture of the corresponding isomers. Regioselectivity was determined on the crude mixture by $^1H$ NMR spectroscopic analysis in $C_6D_6$ (nitrones **I**, **II**, and **V**) or $CDCl_3$ (nitrones **III** and **IV**). Enantioselectivity was determined as indicated in the footnote of Tables 2 and 5.

**Preparation of the Complexes [($\eta^6$-arene)Ru(PN*i*Pr)(methacrolein)][$SbF_6$]$_2$ [arene = $C_6H_6$ (17), *p*-$MeC_6H_4$*i*Pr (18), $C_6Me_6$ (19)]:** To a solution of the corresponding aqua complex [($\eta^6$-arene)Ru(PN-*i*Pr)($H_2O$)][$SbF_6$]$_2$ (0.10 mmol) in $CH_2Cl_2$ (5 mL) at 0 °C under argon, methacrolein (33.0 μL, 0.395 mmol) and molecular sieves (4 Å) (200.0 mg) were added. The solutions were stirred for 20 min and the solvent was then vacuum-evaporated. The residues were extracted with $CH_2Cl_2$ (3 × 2 mL). Addition of dry hexane (20 mL) to the yellow filtrate afforded yellow solids which were washed with hexane and vacuum-dried.

(*Me*MeCH), 15.89 ($C_6Me_6$), 17.85 (Me*Me*CH), 30.22 (MeMe*C*H), 70.38 ($CH_cH_t$), 74.67 ($CH_g$), 100.90 (d, $J_{P,C}$ = 2.3 Hz, $C_6Me_6$), 123–135 (Ph), 144.77 [CHO*C*(CH$_3$)CHH], 149.58 [CHOC(CH$_3$)*C*HH], 167.83 (d, $J_{P,C}$ = 9.1, Hz, C=N), 210.68 (CHO) ppm.

**Preparation of the Complexes [(η$^6$-*p*-MeC$_6$H$_4$*i*Pr)Ru(PN*i*Pr)(nitrone)][SbF$_6$]$_2$ [nitrone = I (20), II (21), V (22)]:** A solution of [(η$^6$-*p*-MeC$_6$H$_4$*i*Pr)Ru(PN*i*Pr)(H$_2$O)][SbF$_6$]$_2$ (0.1 mmol) in $CH_2Cl_2$ (4 mL) was stirred in the presence of molecular sieves (4 Å) (200.0 mg) at 0 °C under argon for 20 min. The corresponding nitrone **I**, **II** or **V** (0.1 mmol) was then added and the suspension stirred for 20 min. Addition of hexanes (20 mL) caused the precipitation of a solid. The solvents were separated by decantation and the residue was washed with hexanes (3 × 20 mL). After washing, the residue was extracted with $CH_2Cl_2$ (5 mL). Addition of hexanes (20 mL) to the resultant solution gave an orange-red solid which was washed with hexanes and vacuum-dried.

**Crystal Structure Determination of Complexes $R_{Ru}$-2, $R_{Ru}$-3, $R_{Ru}$-7 and $R_{Ru}$-8:** X-ray data were collected for all complexes at low temperature [100(2) K] with a Bruker SMART APEX CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data were corrected for absorption using a multiscan method applied with the SADABS program.[17] The structures were solved by direct methods with SHELXS-86.[18] Refinement, by full-matrix least squares on $F^2$ with SHELXL97,[18] was similar for all complexes, including isotropic and subsequently anisotropic displacement parameters for all non-hydrogen nondisordered atoms. Particular details concerning the existence of static disorder and hydrogen refinement are listed below. All the highest electronic residuals (smaller than 1.0 e Å$^{-3}$) were observed in close proximity to the metal or Sb atoms and have no chemical significance. In all structures, in addition to the internal configuration reference of the oxazoline ligand, the Flack parameter was refined as a check of the correct absolute configuration determination.[19] CCDC-297912, -297913, -297914 and -297915 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via http://www.ccdc.cam.ac.uk/data requested/cif.

**Crystal Data for $R_{Ru}$-2:** $C_{36}H_{42}ClF_6NOPRuSb$, $M$ = 907.95; red prism, 0.10 × 0.09 × 0.08 mm; orthorhombic, $P2_12_12_1$; $a$ = 11.7929(9), $b$ = 14.0329(10), $c$ = 21.8518(16) Å; $Z$ = 4; $V$ = 3616.2(5) Å$^3$; $D_c$ = 1.668 g cm$^{-3}$; $\mu$ = 1.334 mm$^{-1}$, min/max transmission factors 0.8762/0.9013; $2\theta_{max}$ = 57.74°; 43058 reflections collected, 8852 unique ($R_{int}$ = 0.0395); number of data/restrains/parameters = 8852/0/510; final $GoF$ = 1.103, $R_1$ = 0.0360 [8516 reflections, $I > 2\sigma(I)$], $wR_2$ = 0.0807 for all data; Flack parameter $x$ = –0.025(18); three electron residual peaks above 1 e Å$^{-3}$ were located close to the fluorine atoms (distances shorter than 1 Å) and have no chemical significance. Most of the hydrogen atoms were observed in the difference Fourier maps and included in the model as free isotropic atoms; hydrogen atoms of the terminal methyl groups were included in calculated positions and refined with positional and thermal riding parameters.

**Crystal Data for $R_{Ru}$-3:** $C_{34}H_{28}ClF_6NOPRuSb$, $M$ = 869.81; orange prism, 0.18 × 0.07 × 0.04 mm; orthorhombic, $P2_12_12_1$; $a$ = 11.1353(11), $b$ = 16.1491(16), $c$ = 17.6001(18) Å; $Z$ = 4; $V$ = 3164.9(5) Å$^3$; $D_c$ = 1.825 g cm$^{-3}$; $\mu$ = 1.531 mm$^{-1}$, min/max transmission factors 0.7669/0.9357; $2\theta_{max}$ = 57.8°; 21412 reflections collected, 7573 unique ($R_{int}$ = 0.0648); number of data/restrains/parameters = 7573/12/475; final $GoF$ = 1.059, $R_1$ = 0.0557 [6161 reflections, $I > 2\sigma(I)$], $wR_2$ = 0.0963 for all data; Flack parameter $x$ = 0.00(3); largest difference peak 1.26 e Å$^{-3}$ (close to Sb atom). Most of the hydrogen atoms were observed in the difference Fourier maps and included in the model as free isotropic atoms; the remaining hydrogen atoms were included in calculated positions and refined with positional and thermal riding parameters.

**Crystal Data for $R_{Ru}$-7:** $C_{30}H_{32}F_{12}NO_2PRuSb_2$, $M$ = 1042.11; amber irregular block, 0.15 × 0.09 × 0.06 mm; orthorhombic, $P2_12_12_1$; $a$ = 10.1400(17), $b$ = 17.020(3), $c$ = 19.899(3) Å; $Z$ = 4; $V$ = 3434.1(10) Å$^3$; $D_c$ = 2.016 g cm$^{-3}$; $\mu$ = 2.138 mm$^{-1}$, min/max trans-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mission factors 0.7398/0.8771; $2\theta_{max}$ = 57.96°; 23407 reflections collected, 8218 unique ($R_{int}$ = 0.0570); number of data/restrains/parameters = 8218/2/451; final *GoF* = 1.052, $R_1$ = 0.0455 [7064 reflections, $I > 2\sigma(I)$], $wR_2$ = 0.0790 for all data; Flack parameter $x$ = –0.02(2). Hydrogen atoms were included in calculated positions and refined with a positional and thermal riding model. The two hydrogen atoms of the coordinated water molecule were included from observed positions and refined as free isotropic atoms.

**Crystal Data for $R_{Ru}$-8·$C_4H_{10}O$:** $C_{80}H_{84}F_{24}N_2O_6P_2Ru_2Sb_4$, $M$ = 2376.57; red lamina, 0.23 × 0.19 × 0.01 mm; monoclinic, $P2_1$; $a$ = 11.145(5), $b$ = 17.873(5), $c$ = 23.274(5) Å; $\beta$ = 103.139(5)°; $Z$ = 2; $V$ = 4515(3) Å$^3$; $D_c$ = 1.748 g cm$^{-3}$; $\mu$ = 1.640 mm$^{-1}$, min/max transmission factors 0.7072/0.9774; $2\theta_{max}$ = 57.7°; 30335 reflections collected, 19946 unique ($R_{int}$ = 0.0297); number of data/restrains/parameters = 19946/3/1036; final *GoF* = 1.076, $R_1$ = 0.0564 [18151 reflections, $I > 2\sigma(I)$], $wR_2$ = 0.1275 for all data; Flack parameter $x$ = 0.03(2). Two independent molecules were observed in the crystal. Two of the $SbF_6^-$ anions were observed disordered and a similar model was built for both anions using two $F_6$ moieties in each case; they were refined with complementary occupancy factors. Even with this model there was some residual electronic density left in the proximity of these groups. Hydrogen atoms were included in calculated positions and refined as free isotropic atoms. At this point, several residual peaks were still present in the difference Fourier maps, clearly separated from anions and cations. They were interpreted as originated from two heavily disordered diethyl ether solvent molecules. After several attempts to include these peaks in geometrically reasonable positions without success, the highest residuals were included to take account of solvent ($C_4H_{10}O$) presence.

# Transfer of Chirality in Complexes with $D_3$ Symmetry: Kinetics of the Formation Reaction of Chiral Tris[*O*,*O*′-bis(2-methylbutyl)-dithiophosphato]chromium(III) Complexes (Λ,Δ)-[Cr{(±)-Mebdtp}$_3$], Δ-(+)$_{589}$- and Λ-(–)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$]

**Paolo Biscarini,*[a] Michele Benedetti,[a][‡] Reiko Kuroda,[b] and Francesco Ferranti*[a]**

*Dedicated to Prof. Stephen F. Mason on the occasion of his 85th birthday*

**Keywords:** Chirality / Circular dichroism kinetics / UV/Vis spectroscopy / Dithiophosphate / Chromium complexes

The formation reaction of chiral racemic and diastereoisomeric title complexes, (Λ,Δ)-[Cr{(±)-Mebdtp}$_3$] and Λ-(–)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$], was monitored by absorption, UV/Vis, and circular dichroism, CD, spectroscopy, in the presence of either an excess of the racemic, (±)-Mebdtp$^-$, or the enantiopure ligand, (+)-(*S*)(*S*)-Mebdtp$^-$ = *O*,*O*′-bis[(+)-(*S*)-2-methylbutyl] dithiophosphate ion, at 25 °C in various solvents (ethanol, tetrahydrofuran, chloroform/ethanol, 9:1) and at various pH values and reactant concentrations. The kinetics of the formation reaction of the racemic complex, (Λ,Δ)-[Cr{(±)-Mebdtp}$_3$], shows three consecutive reaction steps. The relative pseudo first-order rate constants depend in different ways on the ligand and $H^+$ concentrations. Circular dichroism measurements during the formation reaction using the enantiopure ligand, as well as in the final equilibrium state, show a prevalence of the Λ-(–)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] over the Δ-(+)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] diastereoisomer in all solvents used. A mechanism is proposed which involves two parallel pathways each consisting of three consecutive reactions of solvent substitution by a chiral chelated ligand, interconnected by some reversible inversion reactions to obtain in solution the thermodynamic and kinetic Λ-(–)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] as the major diastereoisomeric compound. From the equilibrated solution the more stable solid (Λ,Δ)-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] crystallizes as a ca. 1:1 compound of a pair of the two diastereoisomers, undergoing a crystallization-induced second-order asymmetric transformation. Δ-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] is the thermodynamically stable diastereoisomer in the solid state, though in solution this inverts to the more stable Λ-(–)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$].

## Introduction

Transfer of chirality from a chiral ligand to a coordination centre is an interesting probe to follow in the field of asymmetric catalysis, as well as in supramolecular and bioinorganic chemistry.[1] Intrinsic chirality at the metal centre can be determined by an enantiopure A[*R*] or A[*S*] ligand forming a tris-chelated octahedral OC-6 metal complex of $D_3$ symmetry, resulting as a left- or right-handed helical coordination, i.e. Λ-M(A[*R*]^A[*R*])$_3$ or Δ-M(A[*R*]^A[*R*])$_3$.[2–4] Chiral discrimination in the formation of diastereoisomeric octahedral tris-chelate complexes can be considered as the difference in the interaction of the chiral ligand molecules with the two chiral forms of intermediate complexes.

In the past, circular dichroism, CD, has been very useful to study the kinetics of the configurational inversion reaction, Λ-M(A[*R*]^A[*R*])$_3$ ⇄ Δ-M(A[*R*]^A[*R*])$_3$, of optically labile diastereoisomeric complexes, as well as to follow qualitatively the formation reaction of Λ- or Δ-M[(*R*,*R*)-bdtp]$_3$ diastereoisomers in various solvents, $M^{III}$ = Cr, Co, Rh, Ir.[3,4] Chiroptical spectroscopy is a sensitive probe for studying electronic transitions and stereochemistry of chiral transition-metal complexes. CD spectra of chiral tris-(bidentate chelate) metal complexes having octahedral coordination can show the intrinsic configurational chirality of the coordinating metal ion. Chiral octahedral complexes of $D_3$ symmetry give positive or negative differential optical density, ΔOD, during the formation reaction with enantiomeric ligands, so the kinetic of these reactions can be observed.

The aim of this work is to show the influence of the chiral ligand *O*,*O*′-bis[(+)-(*S*)-2-methylbutyl]dithiophosphate, (+)-(*S*)(*S*)-Mebdtp$^-$ (**1**) on the kinetics and thermodynamics of the formation reaction of diastereoisomeric coordination compounds, showing, if possible, the chirality transfer mechanisms from the ligand (**1**) to the metal centre. Our current interest is also to reveal the influence of the solvent on the formation reaction of the diastereoisomers, as well as on the configurational inversion reaction during the crystallization, to predetermine chirality on the coordination centre.

The addition of the ligand to solvated metallic ions in solution may occur in a typical three-step mechanism for octahedral tris-bidentate complexes. Two- or three-chelate ligands coordinated to a metal ion form a left-handed (Λ) or a right-handed (Δ) helix. Two-chelate ligands form a segment of helices if the two bidentate ligands do not form a common mean plane. With the title chiral ligand **1** the preferential formation of the Λ-(*S*,*S*)(*S*,*S*)(*S*,*S*) diastereoisomer in solution has been shown by CD spectroscopy.[3a]

Here we report the results of a kinetic study on the formation reaction of the title complexes, as followed by absorption (OD) and by circular dichroism (CD) to clarify the mechanism of transfer of chirality from the ligand to the metal centre and the solvent effect in this type of coordination compound.

## Results and Discussion

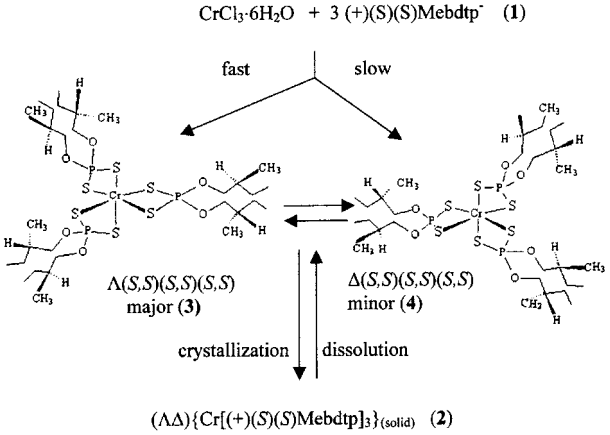
### Formation Reaction

The formation reaction of the chiral octahedral complex was carried out at 25 °C using either the enantiomeric dithiophosphinic acids, (+)-(*S*)(*S*)-MebdtpH or the racemic form, (±)-MebdtpH, as well as their lithium salts, as bidentate ligands, to react with $Cr^{3+}$ solvated ion in three different solvents [ethanol (EtOH), chloroform/ethanol ($CHCl_3$/EtOH, 90:10), and tetrahydrofuran (THF)] following Equation (1) and Scheme 1.

$$Cr^{3+}_{(sol)} + 3\ (\pm)\text{-Mebdtp}^-_{(sol)} \rightarrow Cr[(\pm)\text{-Mebdtp}]_{3(sol)} \quad (1)$$

This reaction was studied using an enantiopure chiral ligand by CD and UV/Vis spectroscopy to determine the influence of absolute ligand configuration and of the solvent on the kinetics and thermodynamics of diastereoselective octahedral complex formation.[3a] A faster formation of the tris{*O*,*O*′-bis[(+)-(*S*)-2-methylbutyl]dithiophosphato}chromium(III) complex, Λ-(–)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] (**3**), than Δ-(+)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] (**4**), was observed in solution, but in the solid phase a chiral complex (ΛΔ)-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] (**2**), is formed as a ca. 1:1 crystalline mixture of diastereoisomers **3** and **4** (Scheme 1).

Chiral discrimination occurs during formation of complexes in solution and also during their crystallization, as characterized by CD spectroscopy.



Scheme 1.

In solution the major diastereoisomer is the Λ-(–)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] (**3**), which is in equilibrium with the minor Δ-(+)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] (**4**).

Preferential crystallization of Δ- (**4**) together with Λ- (**3**) resulted in the formation of the hetero-chiral 1:1 complex (ΛΔ)-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$]$_{(solid)}$ (**2**). This complex is evidently less soluble than the single diastereoisomers Λ-(**3**) or Δ- (**4**). We deduce that an inversion reaction of the major Λ-(**3**) towards the minor Δ-(**4**) complex of the equilibrium occurs during crystallization, undergoing a crystallization-induced second-order asymmetric transformation, which finally yields crystals of (ΛΔ)-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$]$_{(solid)}$ (**2**), due to more stable hetero-chiral diastereoisomeric crystal packing as known also for some enantiomers and racemates.[2,5,6] As seen in the past, changing the stereochemical arrangement of the ligand groups and atoms causes various different dispersion forces or hydrogen bonding and different chiral discrimination forces between the molecules, in solution as well as in the solid state.[4a]

To clarify the nature of compound **2** we examined CD and absorbance spectra in solution and in the solid state (nujol, KBr pellets, thin film) or as microcrystalline powder by diffuse reflectance circular dichroism, DRCD.[7] When the solid complex **2** was dissolved in $CH_2Cl_2$, the absorption spectrum of the solution showed two bands in the range 500–700 nm. OD measures the total concentration of the complex in solution and did not change over time.[3a] In contrast, its CD spectra changed drastically: it showed a very weak almost flat spectrum at the time of dissolution, but the intensity of a positive Cotton effect at ca. 675 nm increased substantially to reach a maximum after 5–23 h (Figure 1, A). This corresponds to an equilibrium state between the major (**3**) and the minor (**4**) in $CH_2Cl_2$ solution reached through a Δ-(**4**) → Λ-(**3**) configurational inversion (Figure 1, A). This indicates the formation in the solid state of intermolecular weak interactions between hetero chiral diastereoisomers. Until now crystals suitable for X-ray structural investigation have not been obtainable, but hetero-chiral packing of a pair of octahedral enantiomeric complexes has been established in the crystalline racemic

compound (ΛΔ)-[Cr{ddtp}$_3$] with ddtp$^-$ = diethyl dithiophosphate ion, when the enantiomers are more soluble than the racemic compound.[2,3a,6] Hetero-chiral packing of a pair of octahedral diastereoisomeric complexes are also known.[2] The solubility of the two diastereoisomers is very high and ΛΔ-(**2**) is the less soluble complex. During crystallization the Λ-(**3**)–Δ-(**4**) packing-energy or the temperature favour the Λ → Δ configurational inversion and formation of the less soluble solid ΛΔ-(**2**).

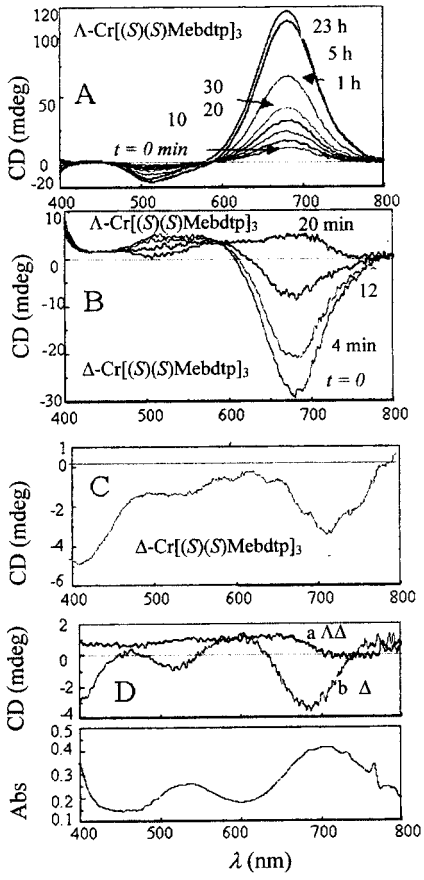

Figure 1. (A) CD spectra of ΔΛ-Cr[(*S*)(*S*)-Mebdtp]$_3$ (**2**) dissolved in $CH_2Cl_2$, positive at 678 nm at $t$ = 0 and inverted to Λ-Cr[(*S*)(*S*)-Mebdtp]$_3$ after 5–23 h. (B) CD spectra of Δ-Cr[(*S*)(*S*)-Mebdtp]$_3$ (**4**) obtained maintaining the solid ΔΛ-Cr[(*S*)(*S*)-Mebdtp]$_3$ (**2**) under vacuum at 100 °C for 3 h. The compound after dissolution in $CH_2Cl_2$ inverts from Δ to Λ showing changes at 678 nm from a negative CD at $t$ = 0, 4, 12 min to a positive CD after 20 min and over up to 5 h. (C) CD spectrum in nujol mull of solid Δ-Cr[(*S*)(*S*)-Mebdtp]$_3$ (**4**) obtained under vacuum at 100 °C for 3 h. (D) CD and UV/Vis spectra of a film over quartz: (a) ΔΛ-Cr[(*S*)(*S*)-Mebdtp]$_3$ (**2**) and (b) Δ-Cr[(*S*)(*S*)-Mebdtp]$_3$ (**4**) obtained after fast evaporation of a solution in $CH_2Cl_2$.

CD spectra of the solid **2** in nujol, KBr pellet and as a solid film (Figure 1, D, a) show a flat line in the 400–800 nm range, proving that the crystallized complex **2** is optically inactive as a ca. 1:1 solid mixture of the two diastereoisomers Λ-(**3**) and Δ-(**4**). DRCD of **2** also shows no Cotton effect in the same region as a result of the hetero-chiral equimolecular composition of the complex.

Heating of the solid **2** causes the thermodynamic Δ-(**4**) solid diastereoisomer to form. So the last complex **2**, maintained 3 h under vacuum at 100 °C, shows an inversion of configuration Λ → Δ of the inherent chiral coordination centre in the solid diastereoisomeric mixture **2**. Δ-Cr[(+)-(*S*)(*S*)-Mebdtp]$_3$ (**4**) is the major component in the new solid mixture. CD spectra of this mixture with major (**4**) and minor (**3**) diastereoisomers in nujol mull (Figure 1, C) and as a film (Figure 1, D, b) clearly show a stable negative Cotton effect in the range 680–710 nm, compared with the flat spectrum of (ΛΔ)-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$]$_{(solid)}$ (**2**) (Figure 1, D, a).

The CD spectrum of the solution of the major (**4**) and minor (**3**) mixture shows a negative Cotton effect at 678 nm at $t$ = 0 min, immediately after dissolution in $CH_2Cl_2$; this is caused by the presence of the diastereoisomer Δ-(*S*,*S*)(*S*,*S*)(*S*,*S*) (**4**) as the major component (Figure 1, B). The CD spectrum is opposite and about enantiomeric to that of the major diastereoisomer Λ-(*S*,*S*)(*S*,*S*)(*S*,*S*) (**3**) in solution (Figure 1A). In a solution of $CH_2Cl_2$, EtOH, $CHCl_3$, or THF, the major diastereoisomer Δ- (**4**) inverts the absolute configuration of the coordination metal centre from Δ to Λ (Figure 1B) and the equilibrium between major (**3**) and minor (**4**) is once again established. In the solid state the complex Δ- (**4**) is thermodynamically more stable, but after 5 h in solution it reaches an equilibrium between the kinetic and thermodynamic major Λ- (**3**) and minor Δ- (**4**), diastereoisomeric complexes (Scheme 1, Figure 1A, B).

The less soluble complex **2** is characterized by different interconversion equilibria between the **3** and **4** diastereoisomeric species, depending on the different conditions of temperature, pressure and solvent.[3]

The preferential formation of kinetic and thermodynamic Λ-(–)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] complex (**3**) in solution, or of thermodynamic Δ-Cr[(+)-(*S*)(*S*)-Mebdtp]$_3$ (**4**) in the solid state, can be achieved by kinetically diastereoselective steps and/or equal formation of the two Λ-(**3**), and Δ- (**4**) diastereoisomers with a parallel or consecutive Δ → Λ or Λ → Δ inversion reaction.

### Absorption and Circular Dichroism Spectra

The absorption spectra of the formation reaction solution in EtOH show two bands at ca. 675 and 530 nm, which increase with the reaction time (Figure 2). Two points in the spectra near 450 nm look somewhat like isosbestic points. However, accurate examination shows that as time increases the spectra shifts to higher wavelengths, excluding the presence of real isosbestic points and suggesting the presence of some reaction steps in the formation mechanism (see enlargement in the small window reported in Figure 2).

In the CD spectra at the beginning of the reaction a weak positive Cotton effect, growing with time, is observed, and attributed to the $^4A_{2g} \rightarrow {}^4T_{2g}$ transition corresponding to the absorbance at ca. 675 nm. Figure 3 reports the variation with time of the differential absorbance, ΔOD, in the CD spectrum in ethanol.

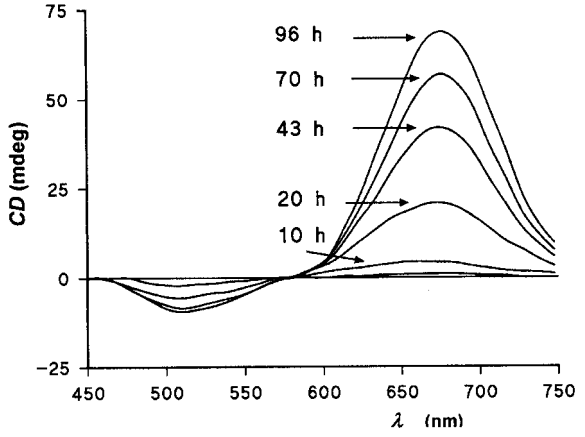

Figure 3. Variation of the CD during the formation reaction of Λ-Cr[(*S*)(*S*)-Mebdtp]$_3$ (**3**). Initial concentrations: $Cr(ClO_4)_3$ 0.002 mol dm$^3$, LH 0.1 mol dm$^3$, EtOH as the solvent.

### Kinetics by Absorption Spectra

The kinetics of the formation reaction [Equation (1) and Scheme 1] have been studied by UV/Vis and CD spectroscopy in an attempt to understand the reaction pathway of the stereoselective formation of the Λ- (**3**) diastereoisomer in solution, as well as the configuration inversion of diastereoisomeric compounds in solution and in the solid state.

Kinetic measurements of very high accuracy can offer reliable information on the formation mechanism in complex systems. OD measurements can give information on the total stoichiometric reaction. CD contributes information on the presence and reactivity of intermediate stereoisomers.

Figure 4 reports the variation in optical density with time, at 675 nm, and shows the influence on the reaction rate of three different solvents. Experimentally we measured and stored in a binary file one point OD/time every minute, so in the figure the results appear as continuous lines. OD values for the three runs at the beginning and at the end of the reactions are nearly equal, so the plot affords direct comparison of the reaction rates in the three solvents.

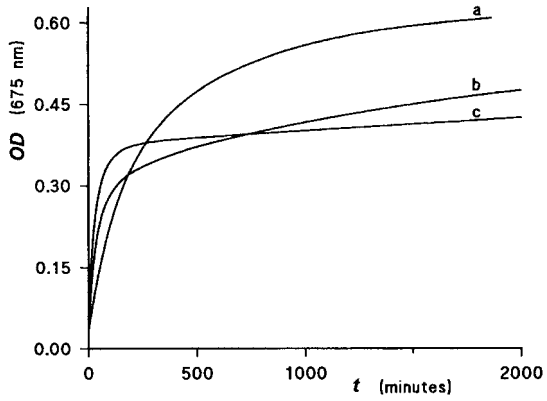

Figure 4. Increase of the optical density at 675 nm with reaction time in different solvents. (a) EtOH; (b) $CHCl_3$/EtOH, 90:10; (c) THF, initial concentrations: $Cr(ClO_4)_3$ 0.002 mol dm$^3$, LH 0.1 mol dm$^3$.

At the beginning of the reaction the OD signals in various different solvents increase with time, showing that the initial rate values differ according to the solvent in the sequence: THF > ($CHCl_3$/EtOH, 90:10) > EtOH. In the last part of the reaction the sequence is inverted, showing a lower reaction rate for THF and a higher one for EtOH.

The rate of a reaction between two ions of opposite charges, i.e. $Cr^{3+}$, $CrL^{2+}$, $CrL_2^+$ and $L^-$, should decrease with an increase in the dielectric constant of the solvent ($\varepsilon_{EtOH}$ = 25.1, $\varepsilon_{THF}$ = 7.6, $\varepsilon_{CHCl3}$ = 4.8), because the electrostatic interactions are lowered.[8] The measured rates in the solvents used do not agree well with this statement and thus, we cannot attribute the rate difference to the dielectric constants of the solvents. The more important reason for the solvent-dependent reaction rates is probably due to at least partial substitution of the water molecules in the hydration sphere of $Cr^{III}(H_2O)_6$ by solvent molecules, changing the characteristics of the activated complexes and of the reaction intermediates.

The experimental results were analyzed by applying a method of minimization of bi- or tri-exponential equations, similar to that used by N. W. Alcock et al.[9]

There are two types of mechanism, I and II, that can be hypothesized. The three rate constants, $k_a$, $k_b$, $k_c$, and the extinction coefficients, $\varepsilon_B$ and $\varepsilon_C$, of the intermediates $CrL(sol)_4^{2+}$ and $CrL_2(sol)_2^+$ were considered as adjustable parameters. The extinction coefficients $\varepsilon_A$ and $\varepsilon_D$ of the first $Cr(sol)_6^{3+}$ and the last $CrL_3$ species are accessible from the observed optical density at the beginning and at the end of the reaction.

The experimental data of the reaction in THF of Figure 4 (c) are reported in Figure 5 and Figure 6. Similar plots were obtained for reactions in other solvents.

Figure 5 shows a first-order plot, $-\log(OD_{inf} - OD)$ as a function of time. The curve only becomes linear after a rather long reaction time, while the first part of the reaction, by the nonlinearity of the curve, suggests the presence of consecutive steps.

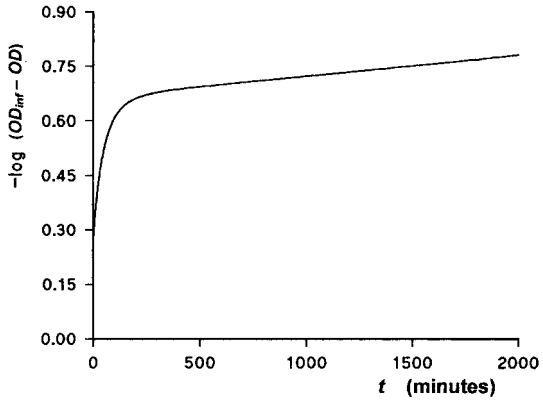

Figure 5. First-order plot of the formation reaction of Cr[(±)-Mebdtp]$_3$ in THF as the solvent. $Cr(ClO_4)_3$ 0.002 mol·dm$^{-3}$, LH 0.1 mol dm$^3$.

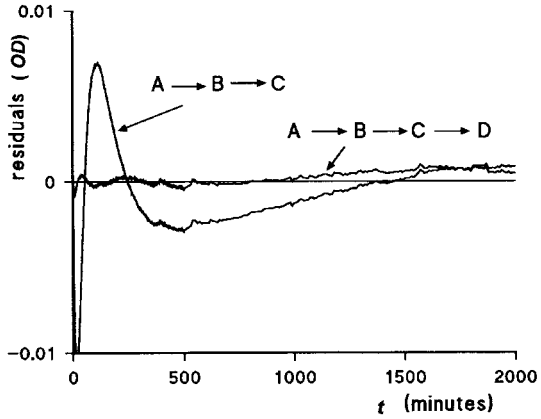

Figure 6. Differences between the observed optical density at 675 nm and that calculated according to mechanisms (I) and (II). $Cr(ClO_4)_3$ 0.002 mol dm$^3$, LH 0.1 mol dm$^3$, THF as the solvent.

Figure 6 reports the residuals (differences between the observed and calculated OD values) obtained applying the method of minimization to the three- and two-step mechanism, (I) and (II) respectively.

There is a much better agreement with mechanism (I), particularly in the first part of the reaction, the residuals being about 0.001 OD units, ca. 0.2%, of a total absorbance variation of about 0.6 OD units. The optical density varia-

tion as a function of time, in all runs made in THF and $CHCl_3$/EtOH (90:10), is in agreement with mechanism (I) comprehending three consecutive pseudo first-order reactions to $Cr^{III}$.

By contrast, some of the runs performed in EtOH as the solvent show a good agreement with the two-step mechanism II. Nonlinear least-square calculations, according to mechanism (I), afford poor accuracy, different results being obtained if one changes the initial set of adjustable parameters.

This discrepancy can be attributed to the too small differences between the values of the rate constants of the first and second step. To improve the reliability of the results for runs in EtOH, supposing that the reaction always occurs in three steps, the extinction coefficient, $\varepsilon_b$, of the first intermediate, $CrL^{2+}$, was measured, performing some runs with an excess of $Cr^{3+}$ over the ligand, $L^-$. The value obtained, $\varepsilon_{CrL^{2+}} = 46.7\ dm^3\,mol^{-1}\,cm^{-1}$, was then imposed as a nonadjustable parameter in mechanism I. The extinction coefficient, $\varepsilon_c$, of the second intermediate, $CrL_2^+$, was calculated as an adjustable parameter for the runs more in agreement with mechanism II. The mean value obtained, $\varepsilon_{CrL^{2+}} = 186.9 \pm 5.8\ dm^3\,mol^{-1}\,cm^{-1}$ was imposed as a nonadjustable parameter for all the runs made in EtOH following mechanism I. In every case the $k_c$ calculated values were nearly equal to the obtainable values from first-order diagrams in the last part of the reaction. We inferred that the three steps observed do correspond to the complexation of one, two and three molecules of the ligand to chromium ion, as shown in mechanism I.

In Table 1 pseudo first-order rate constants for the formation reaction of $[Cr\{(+)\text{-}(S)(S)\text{-Mebdtp}\}_3]_{(sol)}$ following the three-step mechanism I are reported. Where possible the ionic strength was maintained constant at $0.212\ mol\,dm^{-3}$, by adding tetrabutylammonium trifluoromethanesulfonate. The $H^+$ concentration was adjusted with tetrabutylammonium hydroxide or perchloric acid or using lithium salt as the ligand. The ligand LH was considered to be a strong acid, as shown by pH measurements. From the results obtained at constant ionic strength in ethanol as the solvent, it is possible to derive some information as to the reaction orders with respect to the ligand and to the $H^+$ ion.

### Reaction Order with Respect to the Ligand

The reaction order with respect to the ligand (proves 1–5 of Table 1) is bigger than one for $k_a$ and $k_b$ and smaller than one for $k_c$, in good agreement with Equations (2), (3), and (4).

$$k_a = a\,[L] + b\,[L]^2 \quad (2)$$

$$k_b = a'\,[L] + b'\,[L]^2 \quad (3)$$

$$k_c = a''\,[L]/(1 + b''\,[L]) \quad (4)$$

From the values of rate constants measured at constant $[H]^+$, $0.200\ mol\,dm^{-1}$, and a ligand concentration ranging from 0.05 and $0.2\ mol\,dm^{-1}$, values of $a = (7.49 \pm 1.70) \times 10^{-4}\ mol^{-1}\,dm^3\,s^{-1}$, $b = (7.08 \pm 1.34) \times 10^{-3}\ mol^{-2}\,dm^6\,s^{-1}$, $a' = (2.65 \pm 0.32) \times 10^{-4}\ mol^{-1}\,dm^3\,s^{-1}$, $b' = (1.88 \pm 0.25) \times 10^{-3}\ mol^{-2}\,dm^6\,s^{-1}$, $a'' = (2.7 \pm 2.9) \times 10^{-4}\ mol^{-1}\,dm^3\,s^{-1}$ and $b'' = 4.8 \pm 1.3\ mol^{-1}\,dm^3$ were calculated. A mechanism for the third reaction step in agreement with Equation (4) could involve a fast pre-equilibrium followed by a slow reaction, as in equations Equations (5) and (6).

$$CrL_2^+ + L^- \rightleftarrows CrL_2^+\cdots L^- \quad (5)$$

$$CrL_2^+\cdots L^- \rightarrow CrL_3 \quad (6)$$

In the intermediate $CrL_2^+\cdots L^-$, where we have not indicated the solvent molecules, ligand $L^-$ could be bonded to the metal by a single bond and the slow step should be a ring closure with solvent substitution. Similar mechanisms should be present in the first and second reaction steps too. The presence of a quadratic term in Equations (2) and (3) suggests parallel reaction paths of a second order with respect to the ligand. These second-order paths could be attributed to the possibility, forbidden for the third step, of forming intermediates with more than one mono-bonded ligand, followed by slow ring closure.

Alternatively these intermediates, $Cr^{3+}\cdots L^-$, $CrL^{2+}\cdots L^-$, $CrL_2^+\cdots L^-$, could be ionic pairs with the ligands and the metal somehow linked between them through the solvent molecules of the coordination sphere of the metal. In this case the rate-determining step should be substitution of a solvent molecule by the ligand, followed by a fast ring closure. The value of $b''$ seems to support the last hypothesis. In fact in the mechanism we propose, $b''$ is the formation constant of the $CrL_2^+\cdots L^-$ and corresponds, according to the Fuoss theory,[10] to a distance between the metal and the ligand in the ionic pair of 10.1 Å, a value that seems to be of the right order of magnitude.

### Reaction Order with Respect to the $H^+$ Ion

The rate constants for the first and second steps, $k_a$ and $k_b$, depend inversely on the hydrogen ion concentration in all the solvents used, taking very large values when $[H^+]$ is almost absent (proves 6–10, Table 1). Probably at the beginning of the reaction not all the water molecules in the coordination sphere of the $Cr^{3+}$ ion are substituted by the solvent and the mechanism could involve de-protonated species as shown for the first step of the reaction in Equations (7), (8) and (9).

$$Cr(OH_2)^{3+} \overset{K_a}{\rightleftarrows} Cr(OH)^{2+} + H^+ \quad (7)$$

$$k'\text{: } Cr(OH_2)^{3+} + L^- \rightarrow CrL^{2+} + H_2O \quad (8)$$

$$k''\text{: } Cr(OH)^{2+} + L^- \rightarrow CrL^{2+} + OH^- \quad (9)$$

The deprotonated species, $Cr(OH)^{2+}$ and analogously $CrL(OH)^+$ for the second step, are normally more reactive

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

than nondeprotonated species in substitution reactions.[11] The observed pseudo-first-order rate constants $k_{obs}$ should depend on the hydrogen ion concentration as in Equation (10).

$$k_{obs} = (k'\ K_a + k''\ [H^+])/([H^+] + K_a) \quad (10)$$

The experimental results of Table 1, (proves 3, 6–10, $[L^-]$ constant, 0.100 mol dm$^{-3}$, and $[H^+]$ varying from 0.025 and 0.200 mol dm$^3$) are qualitatively in agreement with Equation (10). The attempt to test Equation (10) quantitatively, however, leads to values of the acid ionization constants for $Cr(OH_2)^{3+}$, $K_a = 0.026 \pm 0.020$ mol dm$^{-3}$, and for $Cr(OH_2)$-$L^{2+}$ of the second step, $K_a = 0.018 \pm 0.008$ mol dm$^3$, that are too high compared to the value of $1.4 \cdot 10^{-4}$ mol dm$^3$ measured in aqueous solution for $Cr(OH_2)_6^{3+}$.[12] The rate constants of the third step depend very little on the hydrogen ion concentration, probably because of the low charge of the complex ion $CrL_2^+$.

### Kinetics by CD

Kinetic measurements performed by optical density cannot distinguish between Λ and Δ configuration. We then repeated the same runs as shown in Figure 4 recording the CD signal at 675 nm against time, as shown in Figure 7. The positive Cotton effect observed throughout the reaction and in all solvents used indicates a higher production in solution of the Λ-(–)$_{589}$- (**3**) than the Δ(+)$_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] (**4**) complex; see Figure 1 (A), 3 and 7.

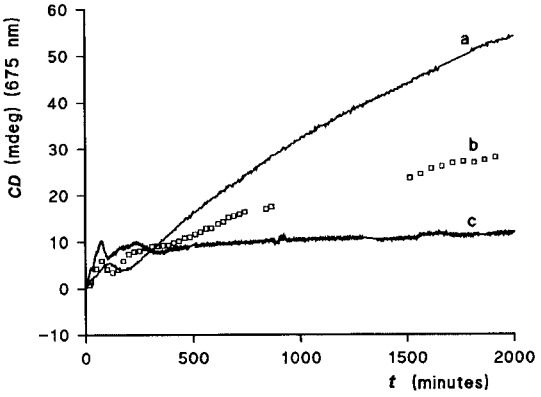

Figure 7. Variation of the CD signal at 675 nm with formation reaction time in different solvents: (a) EtOH; (b) $CHCl_3$/EtOH, (c) THF. Initial concentrations: $Cr(ClO_4)_3$ 0.002 mol dm$^3$, LH 0.1 mol dm$^3$.

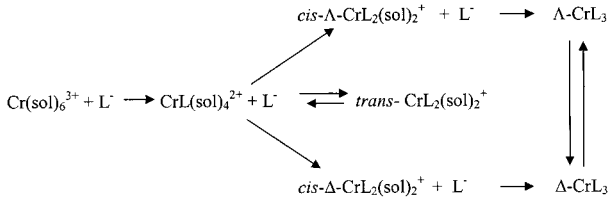
The Λ-(–)$_{589}$-(**3**) is present at the final equilibrium as a major complex being stabilized by the solvent in the order: EtOH > ($CHCl_3$/EtOH, 90:10) > THF. In the first part of the reaction the positive curve is not monotonic, but shows some oscillations, with the formation of one maximum and one minimum in the case of EtOH as the solvent (Figure 7, a) and two maxima and two minima in the other two cases (Figure 7b, c). Afterwards the CD signal grows quite regularly to the end of the reaction. These oscillations can be attributed to the formation of Equilibria (11) and (12) between the Λ and Δ forms of $CrL_2^+$ (1:2) and $CrL_3$ (1:3).

$$\Lambda\text{-}CrL_2^+ \rightleftarrows \Delta\text{-}CrL_2^+ \quad (11)$$

$$\Lambda\text{-}CrL_3 \rightleftarrows \Delta\text{-}CrL_3 \quad (12)$$

Taking into account, (i) the profile of reaction (Figure 7), (ii) the three consecutive reaction steps of mechanism (I), supported by the OD measurements, and (iii) Λ and Δ, *cis* and *trans* stereoisomery of intermediates $CrL_2^+$ and final $CrL_3$ complexes, a probable mechanism of the reaction studied could be that reported in Scheme 2.



Scheme 2.

The free octahedral coordination positions, are occupied by the solvent molecules. Every reaction step, indicated by an arrow, should be of pseudo-first order with respect to $Cr^{III}$, which is very complicated because of the presence of metal complex ions that are differently solvated, protonated and forming ion pairs. The planar *trans*-intermediate $CrL_2(sol)_2^+$ in this Scheme was hypothesized as having to go back to the diastereoisomer 1:1, $CrL(sol)_4^{2+}$, to form the *cis*-Λ- or the *cis*-Δ-$CrL_2^+$, 1:2 diastereoisomer. Considering Equations (5)–(12), moreover, Scheme 2 must be considered as a simplified version of more complicated ones.

The number of parameters of Scheme 2, that influence the CD signal, e.g. rate constants and CD values, is too large for any quantitative evaluation, because of the formation of various chiral species during the reaction. Nevertheless many computer simulations have been performed to test the compatibility of the proposed reaction mechanism with the CD values oscillating in the first part of the reaction (Figure 7). We compared the experimental results of the three runs reported in Figure 7 during the first 700 min of reaction also with some other mechanisms with different numbers of intermediates and reaction steps. Every simulation used CD values of Λ-Cr[(+)-(*S*)(*S*)-Mebdtp]$_3$, (**3**) measured at the end of the reactions as a known value, and assumed approximated values for all the other parameters. The differential equations involved were resolved numerically and the theoretical values of the CD signals were compared with experimental ones. The calculation was repeated many times, alternately and by small amounts changing the values of all the parameters, until it reached the minimum possible value of the standard deviation.

Numerical values of the parameters thus obtained are not reliable because they strongly depend on the initial values used in the calculations. However, the standard deviation and the shape of the CD signal/time curve obtained with different sets of adjustable initial parameters were practically identical. One can always obtain better agreement between observed and calculated values, if more intermediate species are used, even if some levelling effect has

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

been noted. However, we think that these calculations could be useful for selecting the simplest mechanism of the hypothetical ones, which could be in sufficiently good agreement with the experimental results. Figure 8 uses continuous lines to report the calculated runs according to Scheme 2. In EtOH (Figure 8, a) the agreement is better than was the case in other solvents, though simulation cannot really reproduce the nonmonotonic behaviour of CD with time. It is interesting to note that this agreement gets worse if we try to compare the experimental results with a mechanism with only two consecutive paths instead of one with three consecutive paths. This fact supports the choice of mechanism (I) over mechanism (II) in the kinetic runs in EtOH deduced by absorbance measurements.

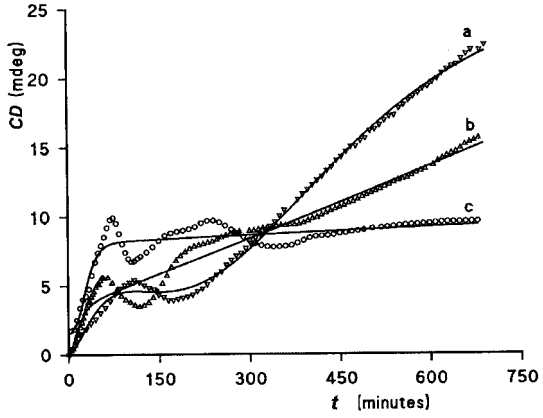


Figure 8. Simulated curves (continuous lines) CD/time, for Scheme 2 compared with experimental ones: (a) in EtOH (triangles); (b) in $CHCl_3$/EtOH, 90:10 (delta symbols); (c) in THF (circles).

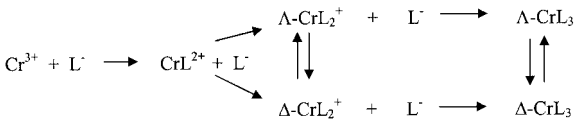
The other two runs performed in the other two solvents are not in agreement with Scheme 2 and must be compared with some more complicated Schemes. Similar computer simulations were carried out for Schemes 3–5.



Scheme 3.

The oscillations of CD observed in THF as the solvent are more complicated and difficult to resolve but they should contain a greater amount of information about the mechanism. As the complexity of the mechanism increases, so does the agreement between the experimental points and the calculated line.

Simulated curves (see 2 in Figure 9) obtained following Scheme 2 does not agree with the experimental curve in THF (see 1 in Figure 9).

In Scheme 3 we do not consider the intermediate *trans*-$CrL_2^+$, but, instead, we suppose an interconnecting direct equilibrium between Λ- and Δ-$CrL_2(sol)_2^+$. The little improvement in respect of calculations with Scheme 2, where there is one more intermediate as *trans*-$CrL_2^+$, suggests that

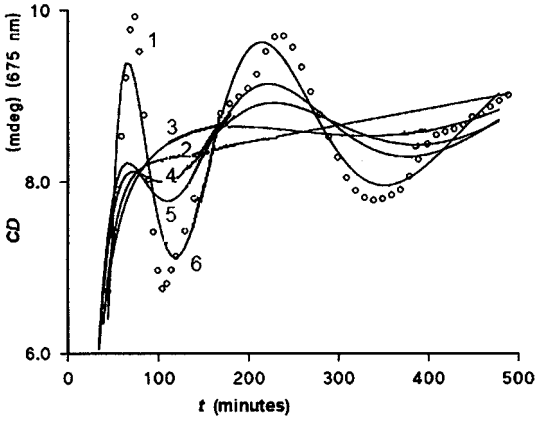


Figure 9. Experimental curve CD/time, in THF (1, line of circles), compared with simulated curves (2–6, continuous lines), obtained from various schemes of formation reaction: Scheme 2; Scheme 3, without the intermediate *trans*-$CrL^{2+}$; Scheme 4, with all intermediates and equilibria; Scheme 5, where the *cis*- and *trans*-$CrL^{2+}\cdots L^-$ intermediates were considered kinetically important; curve 6 refers to a scheme not reported here, but similar to Scheme 5, where the Λ- and Δ-$CrL^{2+}\cdots L^-$ were also considered.

the new equilibrium is an important responsible factor in the oscillations observed (see 3 in Figure 9).

In Scheme 4 it is suggested that the *trans*-$CrL_2^+$ intermediate could react further, forming equilibria with Λ- and Δ-$CrL_2(sol)_2^+$ diastereoisomers as well. The agreement grows and the two maxima and minima observed experimentally begin to appear (Figure 9 and Figure 4).

On increasing the number of direction routes (arrows) in Scheme 4, we did not obtain a much better agreement, so we have tried to increase the number of intermediates alone.

Scheme 5 supports the hypothesis, just suggested in Equations (2)–(6) of the kinetic importance of intermediates $CrL^{2+}\cdots L^-$, which should be present under two forms, one with $L^-$ mono-bonded in the *cis* position with respect to the plane of the first chelated ligand, the other linked in the *trans* position. The *cis* species should form Λ- or Δ-$CrL_2(sol)_2^+$, while the *trans* species should form Λ-$CrL_2(sol)_2^+$, Δ-$CrL_2(sol)_2^+$, or planar *trans*-$CrL_2(sol)_2^+$ (see 5 in Figure 9)

If we suppose that ion pairs of the type $CrL_2^+\cdots L^-$ are also present in the third reaction step, the agreement between calculated and experimental data increases (Figure 9, 6). However, increasing the number of intermediates we can obtain better agreement between observed and calculated values, but some levelling effect has been noted.

The experimental results point to a more complicated mechanism in THF than in EtOH. The solvent confirms its effect on the kinetic and in the thermodynamic stabilization of the various diastereoisomers formed during the reaction. All our experimental results strongly hint at the last tested mechanisms. However, Scheme 4 must be considered as a good exemplification of some more complicated mechanisms that we cannot evaluate quantitatively. For every step shown in Scheme 4 there may be a corresponding reaction path and various intermediates, as in Scheme 5 or more complicated Schemes.

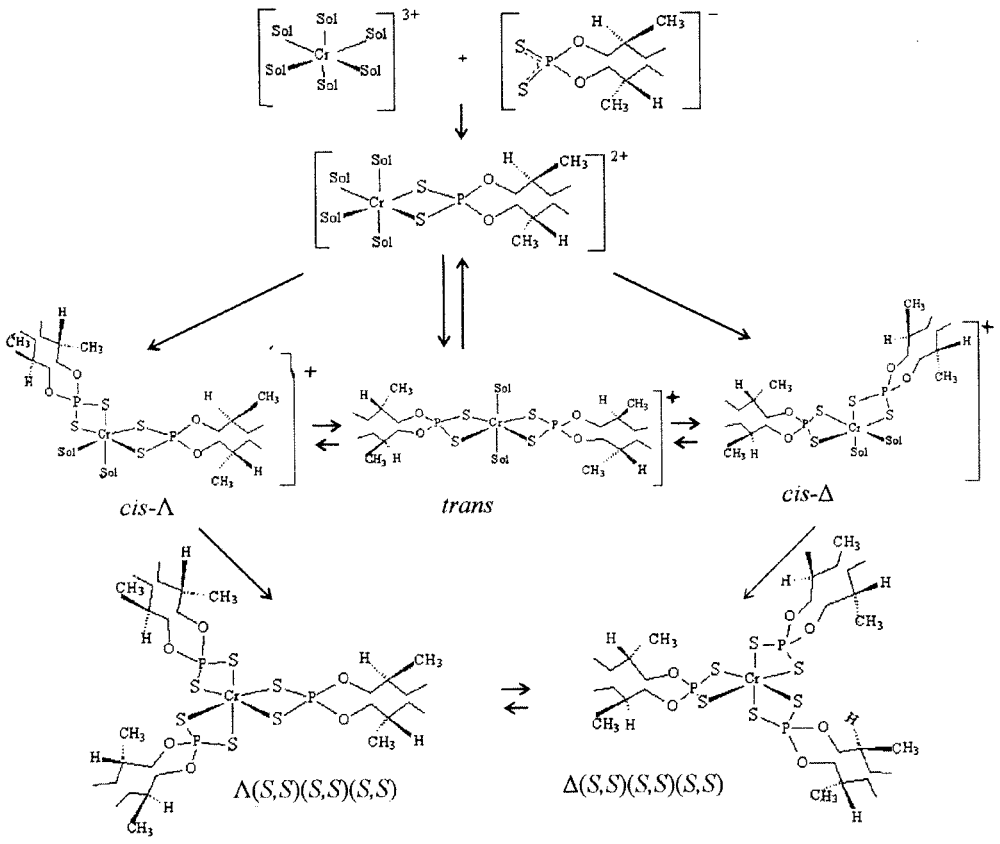
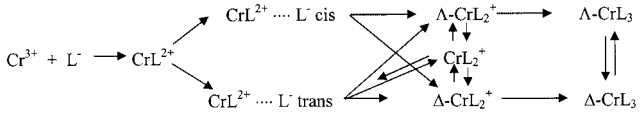


Scheme 4.



Scheme 5.

In the formation of diastereoisomeric octahedral tris-chelate complexes, chiral discrimination is active because of the difference in the interaction of the chiral chelating ligand molecules with the pro-chiral metal centre of the 1:1 ion, $CrL^{2+}$ and/or with the two chiral intermediate 1:2, *cis* bis-chelated complexed ions, Λ- or Δ-$CrL_2^+$, forming Λ- or Δ-$CrL_3$ diastereoisomeric helical complexes 1:3.

The shape and stereochemical features of the ligand molecules lead to diastereoselectivity in the formation reaction of complexes. The structure of the resulting complex and the interactions with the solvent causes thermodynamic stability of the diastereoisomers as well as chiral discrimination/recognition between molecules.

We are currently trying quantitative analysis of the configurational inversion reactions from Λ-$CrL_3$ to Δ-$CrL_3$ shown in all Schemes proposed.[13,14]

## Conclusions

This paper reports the kinetic study of the formation reaction of chiral octahedral coordination compounds by isotropic and chiroptical spectroscopy. The diastereoselective synthesis of the complex was followed kinetically by UV/Vis and CD measurements. The OD spectra suggest a three-step consecutive mechanism for tris-chelate complex formation. However, a mono-bonded ligand or ion pair could be formed before chelation and substitution of the solvent. CD spectroscopy shows new observables and adds a remarkable new contribution to the knowledge of the chirality transfer and stereoselective synthesis mechanism of chiral inorganic diastereoisomeric coordination compounds, when an enantiopure ligand is used. The CD spectra show preferential formation of Λ-(**3**) diastereoisomer in solution, and of Δ-(**4**) in the solid state. The mechanisms hypothesized on the basis of the kinetic measurements enable one to show the formation in solution of the kinetic and thermodynamic Λ-$(-)_{589}$-[Cr{(*S*)(*S*)-Mebdtp}$_3$] (**3**) complex in equilibrium with Δ-$(+)_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] (**4**) through two parallel three-step consecutive pathways interconnected by some configurational inversion reactions at the metal centre.

Our experimental results show that diastereoselective synthesis of Λ-(*S*,*S*)(*S*,*S*)(*S*,*S*) or Δ-(*S*,*S*)(*S*,*S*)(*S*,*S*) can be achieved using the chiral enantiopure dithiophosphate ligand (+)-(*S*)(*S*)-Mebdtp$^-$ (**1**). The diastereoselective reaction of chiral enantiopure ligand **1** with a $Cr^{III}$ ion occurs through kinetically diastereoselective steps during the formation reaction of 1:2 metal/ligand complex, Λ-Cr[(*S*)(*S*)-Mebdtp]$_2^+$ or Δ-Cr[(*S*)(*S*)-Mebdtp]$_2^+$, and of 1:3 complex,

**3** or **4**. A hetero-chiral recognition occurs during crystallization, giving $(\Lambda\Delta)$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$]$_{(solid)}$ (**2**) which by configurational inversion gives the thermodynamic complex $\Delta$-$(+)_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] (**4**) in the solid phase. Crystal packing favours a crystallization-induced second-order asymmetric transformation, shifting all equilibria towards formation of the more stable and less soluble $(\Lambda\Delta)$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$]$_{(solid)}$ diastereoisomer.

The transfer of chirality from the enantiomeric ligand (+)-(*S*)(*S*)-Mebdtp$^-$ to the $Cr^{III}$ centre is achieved during the formation process by stereoselecting the kinetic and thermodynamic diastereoisomer $\Lambda$-$(+)_{589}$-[Cr{(*S*)(*S*)-Mebdtp}$_3$] in all the solvents used and the thermodynamic complex $\Delta$-$(+)_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] in the solid phase. The (*S*)(*S*) configuration of the chiral ligand predetermines $\Lambda$ configuration on the chromium(III) centre in solution and $\Delta$ configuration in the solid state.

## Experimental Section

### Preparation of the Compounds

Hydrated chromium(III) chloride, 2-methyl-1-butanol, and phosphorus pentasulfide (Carlo Erba and Aldrich) were used without further purification. Solvents were purified by standard methods and dehydrated to a spectroscopic degree.

Lithium *O*,*O*′-bis[(*S*)-(+)-2-methyl butyl]dithiophosphate, (+)-(*S*)(*S*)-MebdtpLi, and MebdtpLi were obtained as described, using lithium carbonate to neutralize the acid formed.[3]

$(\Lambda\Delta)$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] (**2**) and the diastereoisomers $\Lambda$-$(-)_{589}$- (**3**) and $\Delta$-$(+)_{589}$-[Cr{(+)-(*S*)(*S*)-Mebdtp}$_3$] (**4**) were prepared as described.[3]

### Measurement of Formation Reaction Rates

Kinetics of the formation reaction of the complexes were analyzed by absorption, UV/Vis, and CD spectroscopy, through measurement of optical density OD and ellipticity, $\psi$, or differential absorption, $\Delta OD$, at 675 nm, with various concentrations in different solvents at 25.00 ± 0.01 °C. The ligand was always in great excess so as to maintain pseudo first-order conditions for the $Cr^{3+}$ ion.

Solutions of hydrated chromium ion, $CrCl_3 \cdot 6H_2O$ ($2 \cdot 10^{-3}$ mol dm$^3$), containing a minimum of water (ca. $10^{-2}$ mol dm$^3$), were mixed with solutions of the other reagents, in a thermostatted cell ($l$ = 1 cm), controlled by a thermocouple in contact with the same cell. In chloroform solutions it was necessary to add 10% of absolute ethanol to dissolve the chromium trichloride. Formation reactions were followed up to a state of equilibrium between the two diastereoisomers formed, and many days later a stable absorption band at 675 nm and a correspondingly stable Cotton effect were observed. The total concentration of the complexes formed, $C_{tot}$, was determined by isotropic absorbance spectra. The concentration of the major diastereoisomer formed, $C_A$, was determined by the intensity of the relative Cotton effect in CD spectra.

### Spectroscopic Measurements

The kinetics were followed at a fixed wavelength (675 nm) with a Cary/4 spectrophotometer and with a Jasco J-500 A spectropolarimeter using a 1-cm cell. UV/Vis spectra were measured with a Jasco UVIDEC 650 spectrophotometer in various solvents, between 750 and 200 nm. Circular dichroism spectra were obtained in freshly prepared solutions and in nujol mull, KBr pellets, and film between 750 and 200 nm on a Jasco J-810 spectropolarimeter.

# Synthesis, Structure, and Magnetic Behavior of Two New 1D Polymeric Manganese Azido Complexes

**Morsy A. M. Abu-Youssef,*[a] Albert Escuer,[b] and Vratislav Langer[c]**

**Keywords:** Manganese / Coordination polymers / Azido complexes / Aqua complexes / Magnetic properties

Two new $Mn^{II}$ one-dimensional compounds with formulae $[Mn(\mu\text{-}N_3)_2(pyzamid)_2]_n$ (**1**) and $[Mn_2(3\text{-}ampy)_4(\mu\text{-}N_3)_2(N_3)_2(H_2O)_2]_n$, (**2**) (pyzamid = pyrazineamide and 3-ampy = 3-aminopyridine) were structurally and magnetically characterized. Compound **1** crystallizes in the monoclinic system, *P*2/*c* space group, and polymerizes through double end-on azido bridges giving 1D chains with the $Mn^{II}$ atoms in a $MnN_6$ environment. Compound **2** crystallizes in the triclinic system, $P\bar{1}$ space group, and consists of alternate $[Mn(3\text{-}ampy)_2(\mu\text{-}N_3)_2(N_3)_2]$ and $[Mn(3\text{-}ampy)_2(\mu\text{-}N_3)_2(H_2O)_2]$ octahedrons ($MnN_6$ – $MnN_4O_2$ environments), linked by single end-to-end azido bridges. Both chains show very uncommon topologies. Attemps to obtain manganese/azido derivatives with the qux = quinoline-4-carboxylato anion gave the recently reported compound $[Mn(\mu\text{-}qux)_2(\mu\text{-}H_2O)]_n$ (**3**), which consists of a chain with only carboxylato and aqua bridges with the $Mn^{II}$ atoms in a $MnO_6$ slightly distorted octahedron. In good agreement with the expected behavior, magnetic susceptibility measurements show weak ferromagnetic interactions for **1**, whereas compound **2** exhibits moderate antiferromagnetic coupling.

## Introduction

The flexidentate azide ion has been demonstrated as not only an extremely versatile ligand but also an excellent magnetic mediator, which provides complexes of great structural variety with interesting physical properties.[1–4] The versatility of this ligand is a direct consequence of its ability to link transition metal cations in $\mu\text{-}_{1,1}$ (end-on, EO), $\mu\text{-}_{1,3}$ (end-to-end, EE), $\mu\text{-}_{1,1,3}$, $\mu\text{-}_{1,1,1}$, or still other modes, easily yielding polynuclear, one-, two-, or three-dimensional species with specific topologies.[5–8] The simultaneous presence of more than one of these coordination modes in the same compound, increasing the connectivity possibilities, is not rare.[9] The interest of the magnetochemists in this ligand lies in the well-established relationship between the coordination mode and the resulting magnetic properties, which covers a wide range of ferro-, ferri-, and antiferromagnetic responses.[1] It should be pointed out that the topology of the resulting systems is far from under control because of the similar stabilities of the different coordination modes, which permit other factors such as packing forces or weak supramolecular interactions to be determinant.[10] One of the most complete series of compounds reported to date, with the general formula $[Mn(N_3)_2(R\text{-}py)_2]_n$ (R-py, substituted pyridyl ligands), is a good example of how minor differences in R can drastically change the dimensionality or the coordination mode of the azido bridges, generally because of weak effects such as hydrogen bonds, steric hindrance, or supramolecular π-π stacking interactions in the solid state. As part of our investigation on metal-azido derivatives, we have recently reported a number of transition metal coordination polymers with bidentate or tetradentate neutral organic ligands to built coordination supramolecular frameworks.[8–10]

In this paper we have studied the reaction of azido ligands with $Mn^{II}$ and several polytopic ligands such as the coligands pyzamid = pyrazineamide, 3-ampy = 3-aminopyridine, and qux = quinoline-4-carboxylato anion. These coligands, with almost one aromatic N donor, closely related with previously reported systems such as pyrimidine,[8b] nicotinate anion,[10b] 2-acetylpyridine,[10a,10e] or the same 3-aminopyridine,[10f] were chosen in order to combine the azido versatility with the possibility of a second bridging donor group such as the N pyrazinic or the amide in pyzamid, the amino function in 3-ampy or the carboxylate in qux, in a trial experiment to obtain new topologies. As a result, we present the synthesis, X-ray, and magnetic char-

acterization of two new polymeric manganese azido derivatives with the formula $[Mn(\mu\text{-}N_3)_2(pyzamid)_2]_n$ (**1**) and $[Mn_2(3\text{-}ampy)_4(\mu\text{-}N_3)_2(N_3)_2(H_2O)_2]_n$ (**2**). For compound **1** the pyrazineamide ligand coordinates through only one of its donor N atoms in a similar way to a classical pyridine ligand. In this case double EO azido bridges provide the second example[8a] of an EO-azido one-dimensional system. Compound **2** also has monodentate 3-aminopyridine ligands such as in $[Mn(3\text{-}ampy)_4(N_3)_2]$[10f] but the topology of the resulting system is very uncommon: alternating $[Mn(3\text{-}ampy)_2(\mu\text{-}N_3)_2\ (N_3)_2]$ and $[Mn(3\text{-}ampy)_2(\mu\text{-}N_3)_2\text{-}(H_2O)_2]$ coordination polyhedra, linked by single EE azido groups gives the 1D arrangement. The reaction with the qux ligand gave the very recently reported compound $[Mn(\mu\text{-}qux)_2(\mu\text{-}H_2O)]_n$ (**3**).[11] In this case the qux ligand only coordinates by means of the carboxylato groups while azido groups do not coordinate to the manganese atoms. The structure of **3** is closely related to the similar $[Cd(qux)_2\text{-}(H_2O)]_n$ complex.[12] The magnetic response agrees with the expected properties for the different kinds of bridges, that is to say, weak ferromagnetic interactions for the 1D EO-azido chain **1** and moderately weak antiferromagnetic coupling for the EE-azido chain **2**. Compound **3** shows weak antiferromagnetic coupling as was reported.[11]

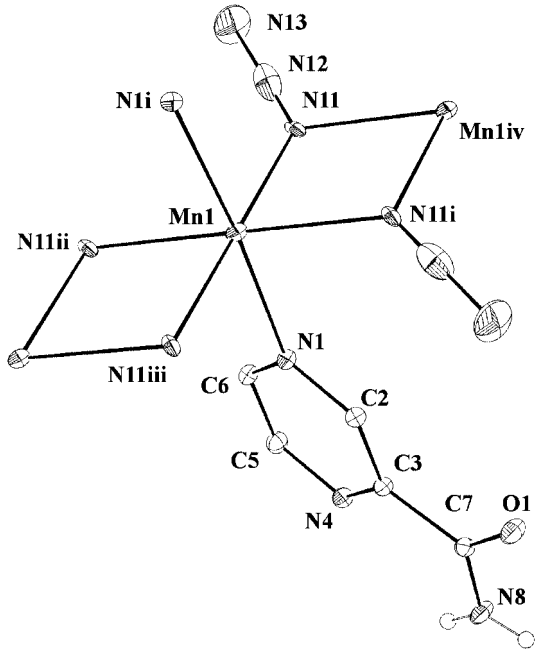

Figure 1. Numbering scheme for $[Mn(\mu\text{-}N_3)_2(pyzamid)_2]_n$ (**1**) with atomic displacement parameters shown at the 30% probability level. Symmetry codes are given in Table 1.

## Results and Discussion

### Structure of $[Mn(\mu\text{-}N_3)_2(pyzamid)_2]_n$ (1)

A labeled ORTEP plot of the structure is shown in Figure 1. Selected distances and angles are listed in Table 1.

The structure consists of neutral 1D chains of $Mn^{II}$ cations linked by double end-to-end azido bridges, along the *b* axis, see Figure 2. The manganese ions, positioned on twofold axes, are placed in a distorted octahedral geometry, $MnN_6$, linked to four bridging azides in the equatorial plane and two terminal *trans* pyzamid-groups in the apical positions. Mn–N(azido) and Mn–N(pyrazine) bond lengths are very similar lying in the range 2.328(3)–2.349(3) Å. The four-membered ring Mn1–N11–$Mn1^{iv}$–$N11^{i}$ is fully planar with Mn–N–Mn bond angles of 97.1(1)°. The Mn···Mn distance is 3.510(1) Å along the chain in the *b* direction. Aromatic rings coordinated at the *trans* sites to the manganese atoms shows a distance between the centroids of 3.510 Å, as result of the short Mn···Mn distances through the double end-on bridges, Figure 2.

The structure is stabilized in the (*a*,*c*) plane by hydrogen bonds involving the N4 atoms from the pyrazine ligands, as well as the N8 and O1 from the amide function, Table 2. The strongest interchain H bonds corresponds to N8–H···O1 [donor–acceptor distance is 2.907(4) Å with a hy-

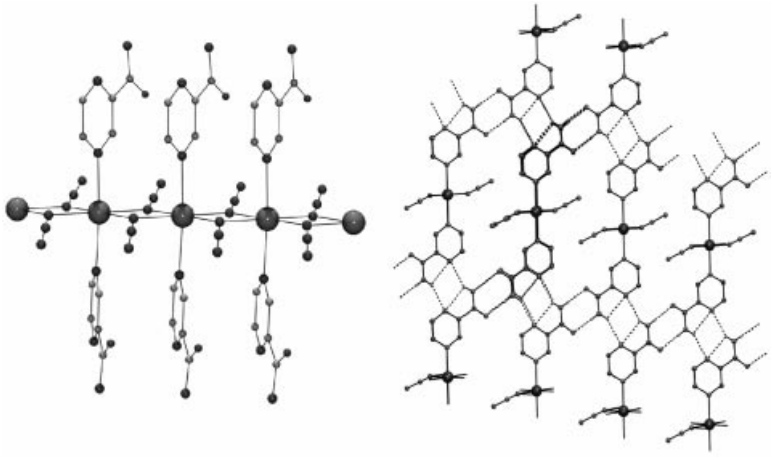

Figure 2. Left, view along the *c*-axis of the one-dimensional compound **1**, showing the double end-on azido bridges between the manganese atoms and the parallel arrangement of the pyrazine rings along the chain in the *b*-direction. Right, view of the structure of **1** projected along the *b*-direction, showing the intra and interchain H-bond network. H bonds involve the N4 atom from the pyrazine ring, O1 from the amide function, and N8 ($-NH_2$) from the same function.

Symmetry transformations used to generate equivalent atoms: (i): $-x+1$, $y$, $-z+1/2$; (ii): $x$, $y-1$, $z$; (iii): $-x+1$, $y-1$, $-z+1/2$; (iv): $x$, $y+1$, $z$

drogen bond angle of 180(6)°], weaker H bonds correspond to the bifurcated N8···N4 [donor–acceptor distances 2.762(4) and 3.112(4) Å, with hydrogen bond angles of 103(4)° and 146(4)°, respectively], see Figure 2, whereas weak intrachain contacts are given by the bifurcated interaction C6–H···N13. Coordination as a monodentate ligand of the pyrazine ring can be justified by two reasons: the steric hindrance of the amide group, too close to N4, and the additional stabilization of the structure provided by the H-bond network.

### Structure of $[Mn_2(3\text{-ampy})_4(\mu\text{-}N_3)_2(N_3)_2(H_2O)_2]_n$ (2)

A labeled ORTEP plot of the structure is shown in Figure 3. Selected distances and angles are listed in Table 3. The structure consists of neutral 1D chains of $Mn^{II}$ along the *a* axis, in which the coordination environment around the manganese atoms shows a regular alternating chain (Figure 4).

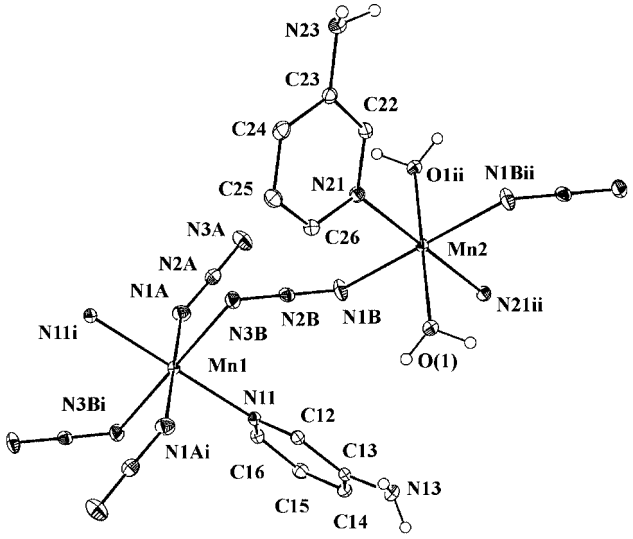

Figure 3. Numbering scheme for $[Mn_2(3\text{-ampy})_4(\mu\text{-}N_3)_2(N_3)_2(H_2O)_2]_n$ (**2**). Atomic displacement parameters are shown at the 30% probability level. Symmetry codes are given in Table 3.

Table 3. Selected bond lengths [Å] and bond angles [°] for complex $[Mn_2(3\text{-ampy})_4(\mu\text{-}N_3)_2(N_3)_2(H_2O)_2]_n$ (**2**).

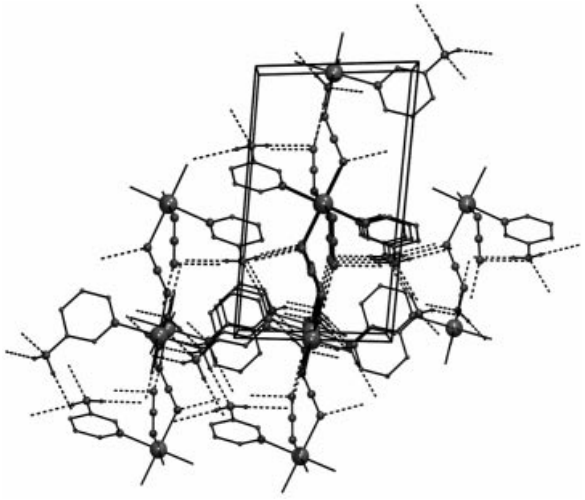

Figure 4. View of the one-dimensional compound **2** showing the interchain H bridges involving terminal azido ligands and the $-NH_2$ functions.

try, $MnN_6$. The equatorial plane is defined by two end-to-end μ-bridging azides and two terminal azides, and the axial sites are occupied by two terminal 3-ampy groups in a *trans* arrangement. The Mn1–N1A bond length (terminal azido ligand) is slightly shorter than the Mn1–N (bridging azido or 3-ampy) distances. The Mn2 ion is placed in a slightly distorted $MnN_4O_2$ octahedral environment with two end-to-end μ-bridging azides, two 3-ampy ligands in the equatorial plane, and two water molecules in the apical positions. The end-to-end azido bridge gives two slightly different bond angles with the manganese atoms, Mn1–N3B–N2B of 129.9(2)° and Mn2–N1B–N2B of 143.5(2)°, and a Mn–N–N–N–Mn dihedral angle of 165.1°.

The Mn1···Mn2 distance is 6.3507(2) Å along the chains, whereas the minimum interchain distance is equal to 7.8105(2) Å.

The structure is stabilized by a large number of strong hydrogen bonds that involve O1 from the water molecules, N13 and N23 from the amino functions, the terminal azido atoms N3A, and also one of the atoms of the bridging azido group, N3B, Table 2. One of them is an intrachain contact between the aminated groups N23–H23B···N13$^{ii}$ whereas the other contacts, involving the water molecules and the azido ligands, are all interchain contacts, Figure 4. This H-bond network gives a 3D supramolecular arrangement as occurs in compound **1**. The aromatic rings of neighbor chains interact between them by means of π-π interactions with distances between centroids of 3.394 and 3.510 Å.

### Structure of $[Mn(\mu\text{-qux})_2(\mu\text{-}H_2O)]_n$ (3)

A schematic plot of the structure of **3** is shown in Figure 5. The structure of this compound can be described as 1D chains of manganese atoms along the *c* axis, linked by two *syn-syn* carboxylates and one μ-$OH_2$ molecule. The manganese ions, positioned on inverse centers, are placed in a slightly distorted octahedral geometry, $MnO_6$, linked to four bridging quinoline-4-carboxylato ligands and two axial O atoms from bridging water molecules. The $Mn^{II}$–O(carboxylate) bond lengths lie in the range 2.103(2)–2.171(2) Å and they are shorter than the $Mn^{II}$–O(water) distances, 2.286(2) Å. The bond angle Mn–O(water)–Mn′ has a value of 114.1(2)°.

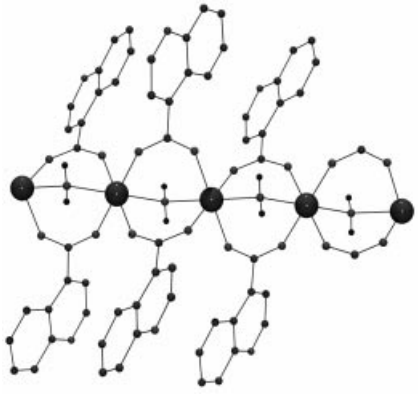

Figure 5. Schematic view of $[Mn(\mu\text{-qux})(\mu_2\text{-}H_2O)]_n$ (**3**).

The structure is stabilized in the (*a*,*b*) plane by strong interchain $O_{water}$···$N_{quinoline}$ hydrogen bonds [donor–acceptor distance is 2.742(3) Å with a hydrogen-bond angle of 179(4)°]. Each water molecule participates in two H bonds with *N*-quinoline atoms from two different chains. The aromatic rings from neighboring chains show π-π stacking with interplanar distances of 3.381(3) Å.

### Synthetic and Structural Features

Polymeric systems with exclusively end-on azido bridges, all of them characterized by $Mn^{II}$ cations, are very uncommon and only three related compounds have been reported to date. One of them is also a one-dimensional compound with the formula $[Mn(N_3)_2(2\text{-bzpy})]_n$, 2-bzpy = 2-benzoylpyridine, which stabilizes the system by means of interchain π-π stacking of the aromatic rings.[8a]

The other two are bidimensional systems in which the one-dimensional manganese-azido chains are linked between them by means of a second bridging coligand such as bis-monodentate pyrazine[5d] (pyz) or the bis-bidentate 2,2′-bipyrimidine (bpym).[13] The compound $[Mn(N_3)_2(pyz)]_n$ also shows an extensive π-π stacking of parallel pyrazine rings (distance between the rings is 3.412 Å), which contributes to stabilize the structure, Scheme 1.

Less clear are the factors that stabilize the other compound, with formula $[Mn_2(N_3)_4(bpym)]_n$, for which π-π stacking or H bonds cannot be found, but this case is not totally comparable because the coligand is bis-bidentate. In our case, compound **1** exhibits the same kind of interaction between the aromatic rings, which seems to be a quasi general factor that favors these types of compounds.

The variety of compounds that can be obtained with other pyrazines or the 3-ampy ligand are much more difficult to rationalize. As is shown in Scheme 1, nonsubstituted

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 1.

pyrazine is able to coordinate both nitrogen atoms but steric hindrance in substituted pyrazines prevents this kind of coordination and only one of the N ring atoms can act as a donor. If the function attached to the pyrazine ring contains coordinating groups, the ligand can act as bidentate, as occurs with pyrazinecarbozylate[14a] and methyl-imidopyrazinecarboxylate,[14b] which gives high-dimensional compounds in both cases. In our case, compound **1**, pyrazineamide coordinates by only one N-ring donor following the general trend for substituted pyrazines, but the poor coordinating amido functions do not act as donors and are involved in intrachain H bonds.

It should be pointed out that small differences in the synthetic procedure can produce very different compounds as occurs in the case of the ligand 3-ampy: an excess of 3-ampy (ratios of $Mn^{II}$, 3-ampy, and sodium azide 1:7:2) yield the mononuclear compound $[Mn(3\text{-ampy})_4(N_3)_2]$, which is to be expected from the large 3-ampy concentration.[10f] In contrast, similar ratios 1:2.5:2.5 or 1:2:3 give either the $[Mn_2(3\text{-ampy})_4(\mu_{1,1}\text{-}N_3)_2(\mu_{1,3}\text{-}N_3)(N_3)(H_2O)]_n$ system[15] with alternating coordination modes of the azido bridge or the above described $[Mn_2(3\text{-ampy})_4(\mu_{1,3}\text{-}N_3)_2(N_3)_2(H_2O)_2]_n$ (**2**) with alternating coordination polyhedra. This pair of compounds that differs by only one water molecule in their empirical formula, are a nice example of the similar stability of end-on and end-to-end coordinations for the azido ligand.

### Magnetic Measurements and Coupling Constant Calculations

The magnetic measurements were performed on powdered crystalline samples in the 2–300 K temperature range. The shape of the plots indicate that the overall interaction is weakly ferromagnetic for compound **1** and moderately antiferromagnetic for **2** and **3**.

Compound **1** shows a $\chi_M T$ room temperature value of 4.78 $cm^3 \cdot K \cdot mol^{-1}$, greater than the expected value of 4.375 $cm^3 \cdot K \cdot mol^{-1}$ for an isolated manganese atom. $\chi_M$ increases continuously on cooling and $\chi_M T$ also increases up to a maximum value of 8.31 $cm^3 \cdot K \cdot mol^{-1}$ at 8 K, decreasing down to 4.5 $cm^3 \cdot K \cdot mol^{-1}$ at 2 K, Figure 6. Fitting the $\chi_M T$ data as a homogeneous $S = 5/2$ chain in the 300–15 K temperature range, applying the analytical expression for a regular chain derived from the Hamiltonian $H = -JS_i \cdot S_{i+1}$ (for local $S = 5/2$),[16] gives the best fit parameters $J = +1.1(1)\ cm^{-1}$, $g = 2.045(3)$. The weak ferromagnetic response is in good agreement with the expected properties. End-on azido bridges with M–N–M bond angles around 100° gives typically ferromagnetic coupling and the $J$ value is similar to that reported for the related compound $[Mn(\mu_{1,1}\text{-}N_3)_2(2\text{-bzpy})_2]_n$ (2-bzpy = 2-benzoylpyridine), previously reported by us,[8a] and also agrees with the calculated values for the ferromagnetic interaction in $[Mn(N_3)_2(pyz)]_n$[5d] and $[Mn_2(N_3)_4(bpym)]_n$.[13] Also, the $g$ value, slightly greater than 2.00, agrees with this previously reported chain.[8a] The only difference for the $[Mn(\mu_{1,1}\text{-}N_3)_2(2\text{-bzpy})_2]_n$ compound lies in the H bonds that afford weak antiferromagnetic interchain interactions at very low temperatures; their effect can be seen in the decrease of $\chi_M T$ below 8 K. As can be expected, magnetization measurements, performed at 2 K, show a fast increase in the magnetization, reaching a value equivalent to five electrons for the manganese atom under moderate external fields, Figure 6.

In contrast, compound **2** shows a different response, with a maximum molar susceptibility at 13 K, Figure 7. On the basis of the structural data, compound **2** is an alternating one-dimensional system, which shows similar bond lengths, quite similar Mn–N–N bond angles, and identical torsion angles in the bridging region. A fit of the system was performed assuming that the two $J$ coupling constants have

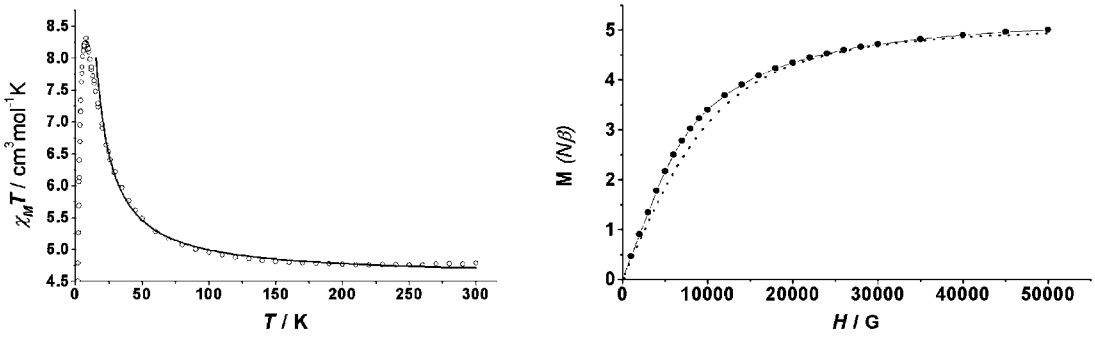

Figure 6. Plot of $\chi_M T$ for compound **1** (left plot). Solid line corresponds to the best fit (see text). Right, magnetization of compound **1**; dotted line shows the Brillouin plot for an uncoupled $S = 5/2$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the same value under these conditions and by applying the analytical expression for a regular $S = 5/2$ chain; best fit parameters were $J = -3.15(2)\ cm^{-1}$ and $g = 2.000(5)$. Attempts to differentiate between the two $J$ values by means of the analytical expression for an alternating $S = 5/2$ chain[17] were unsuccessful. For the manganese–azido bridges, theoretical and experimental work on end-to-end coordination modes indicates that the coupling should be antiferromagnetic in all cases and that the large bond or torsion angles in the bridging region always give a lower interaction. Compound **2** shows one large Mn–N–N bond angle (143.5°) and a moderate dihedral angle in the Mn–N–N–N–Mn bridging region. Under these conditions a moderately low coupling can be expected, mainly derived from the large Mn–N–N bond angle.

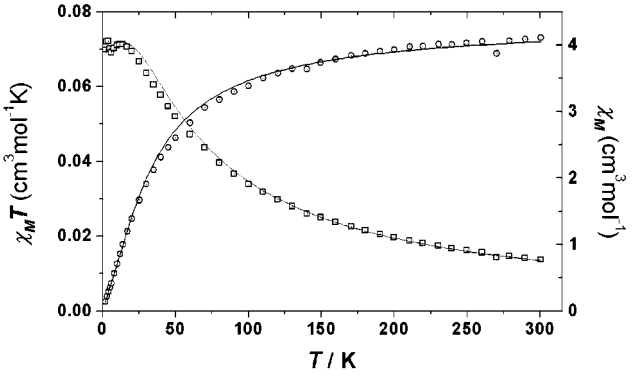

Figure 7. Plot of $\chi_M$ (open squares) and $\chi_M T$ (dot centered circles) for compound **2**. Solid line corresponds to the best fit (see text).

Remeasurement of the magnetic properties of compound **3** fully agree with the recently reported[11] data for this compound: molar susceptibility shows a maximum at 17 K, and a fit of the experimental data gives the best fit parameter $J = -2.75(2)\ cm^{-1}$. This $J$ value agrees with the values reported in the literature for simultaneous carboxylato–aqua bridges, which are always weakly antiferromagnetic.[18]

## Conclusions

Two new one-dimensional systems of $Mn^{II}$ have been obtained and characterized from structural and magnetic points of view. The effect of the coligands employed in the synthesis play a fundamental role in the topology of the final compounds: with 3-pyrazineamide (compound **1**) and 3-aminopyridine (compound **2**) the expected azido chains were obtained but weak packing interactions (π-π stacking and H-bond networks) induce either end-on or end-to-end azido derivatives. In contrast, when the coligand was quinoline-4-carboxylato (compound **3**), the azido ligand did not coordinate to the manganese atoms and one 1D system with *syn-syn* carboxylato and aqua bridges was obtained. Magnetic measurements have been performed for all of them, showing a variety of interactions closely related to the topology of the chains: ferromagnetic interactions for **1**, alternating antiferromagnetic coupling for **2**, and homogeneous antiferromagnetic interactions for **3**.

## Experimental Section

**General Remarks:** Elemental analyses (C,H,N) were carried out using a Perkin–Elmer analyzer, $Mn^{2+}$ was analyzed by a Perkin–Elmer Analyst 300, AAS atomic absorption spectrometer. Infrared spectra (4000–400 $cm^{-1}$) were recorded with a Bruker IFS-125 model FT-IR spectrophotometer using KBr pellets. Quinoline-4-carboxylic acid, pyrazineamide, and 3-aminopyridine were purchased from Aldrich and other chemicals were of analytical grade quality and used as received. Magnetic susceptibility measurements were carried out on polycrystalline samples with a Quantum Design susceptometer working in the range 20–300 K under magnetic fields of 0.3 T and under a field of 0.03 T in the range 20–2 K at the Magnetochemistry Service of the University of Barcelona. Diamagnetic corrections were estimated from Pascal Tables.

**$[Mn(\mu\text{-}N_3)_2(pyzamid)_2]_n$ (1):** A methanolic solution (10.0 mL) of manganese nitrate tetrahydrate (0.5 g, 2 mmol) was mixed with an aqueous/methanolic (1:1) solution (15 mL) of pyrazinamide (0.5 g, ca. 4 mmol). The mixture was stirred for ca. 5 min. A solution of sodium azide (0.65 g, 10 mmol) in water (10 mL) was added dropwise with vigorous stirring. The resulting clear solution was allowed to stand in a refrigerator for several weeks. Colorless needles of the ligand were formed, several days latter yellow needles suitable for X-ray measurements were collected and dried in air with a yield of ca. 45%. $C_{10}H_{10}MnN_{12}O_2$ (385.2): calcd. C 31.18, H 2.62, Mn 14.26, N 43.63; found C 31.0, H 2.5, Mn 14.4, N 43.5. IR (KBr; v: very, s: strong, m: medium, w: weak): $\tilde{\nu}$ = 3393 (s), 3294 (m), 3170 (s), 3091 (s), 2100 (vs), 1718 (vs), 1611 (s), 1590 (s), 1432 (s), 1379 (vs), 1330 (s), 1275 (m), 1187 (m), 1166 (ms), 1100 (m), 1061 (s), 1026 (s), 811 (wm), 787 (ms), 706 (w), 643 (w), 567 (s), 507 (s), 440 (s), 408 (w), 386 (w), 365 (vw), 342 (vw), 315 (vw), 292 (vw), 268 (s) $cm^{-1}$.

**$[Mn_2(3\text{-}ampy)_4(\mu\text{-}N_3)_2(N_3)_2(H_2O)_2]_n$ (2):** 3-Aminopyridine (0.19 g, ca. 2 mmol) in methanol (10.0 mL) was added to a solution (10.0 mL) of $MnCl_2{\cdot}4H_2O$ (0.20 g, ca. 1.0 mmol) in methanol. The mixture was stirred for ca. 5 min. Aqueous solutions of sodium azide (0.2 g, 3 mmol) and a few drops of saturated L-ascorbic acid, to prevent oxidation, were added successively and continuously stirred. The resulting clear solution was allowed to stand in a dark place at room temperature for several weeks. Yellowish-brown crystals suitable for X-ray measurements were collected and dried in air with a yield of ca. 65%. $C_{10}H_{14}MnN_{10}O$ (345.2): calcd. C 34.79, H 4.09, Mn 15.91, N 40.57; found C 34.7, H 3.9, Mn 15.9, N 40.5. IR (KBr; v: very, s: strong, m: medium, w: weak, br: broad): $\tilde{\nu}$ = 3343 (vs, br), 3286 (vs, br), 3062 (s), 2631 (m), 2532 (m), 2351 (w), 2310 (w), 2082 (vs), 1661 (s), 1644 (vs), 1605 (vs), 1580 (m), 1488 (vs), 1445 (vs), 1354 (m), 1313 (s), 1277 (s), 1195 (m), 1143 (m), 1096 (m), 1051 (m), 1024 (m), 989 (w), 911 (m), 858 (m), 813 (s), 797 (s), 700 (vs), 644 (s), 610 (s), 594 (s), 477 (m), 407 (m), 388 (m), 343 (w), 315 (w), 292 (w), 268 (s), 232 (s) $cm^{-1}$.

**$[Mn(\mu\text{-}qux)_2(\mu\text{-}H_2O)]_n$ (3):** Colorless crystals suitable for X-ray measurements were collected from a 2:1:4 aqueous/methanolic 1:1 solution of quinoline-4-carboxylic acid, manganese nitrate tetrahydrate, and sodium azide. From this mixture that contains a large excess of azido, the neutral chain $[Mn(\mu\text{-}qux)_2(\mu\text{-}H_2O)]_n$, containing only carboxylato bridges, was obtained instead of the expected azido derivative. $C_{20}H_{14}MnN_2O_5$ (417.3): calcd. C 57.57, H 3.38, Mn 13.17, N 6.71; found C 57.4, H 3.3, Mn 13.0, N 6.8. IR (KBr;

v: very, s: strong, m: medium, w: weak, br: broad): $\tilde{\nu}$ = 3439 (m, br,) 2765 (m, br), 2353 (m), 1604 (vs), 1579 (vs), 1506 (ms), 1460 (s), 1427 (vs), 1408 (vs), 1377 (vs), 1302 (s), 1267 (m), 1206 (wm), 1153 (m), 1075 (m), 1026 (m), 995 (m), 961 (m), 874 (ms), 802 (s), 784 (s), 765 (s), 740 (ms), 652 (s), 593 (ms), 532 (wm), 510 (wm), 458 (m), 398 (s), 375 (s), 343 (m), 316 (m), 294 (m), 269 (vs) cm$^{-1}$.

**X-ray Crystallographic Study:** All diffraction data were collected using a Siemens SMART CCD diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å, graphite monochromator). The crystals were cooled to 173(2) K by a flow of nitrogen gas using the LT-2A device. A full sphere of reciprocal lattices were scanned by 0.3° steps in $\omega$ with a crystal-to-detector distance of 3.97 cm. Preliminary orientation matrices were obtained from the first frames using the SMART program.[19] The collected frames were integrated using the preliminary orientation matrices, which were updated every 100 frames. Final cell parameters were obtained by refinement on the positions of reflections with $I > 10\sigma(I)$ after integration of all the frames using the SAINT program.[19] The data were empirically corrected for absorptions and other effects using the SADABS program.[20] The structures were solved by direct methods and refined by full-matrix least-squares on all $F^2$ data using SHELXTL.[21] The non-H atoms were refined anisotropically, while hydrogen atoms were refined isotropically with the use of geometrical restraints. The crystallographic and refinement data are summarized in Table 4. Molecular graphics were prepared using the programs Diamond[22] and ORTEP3.[23] Structural determination for **3** was recently reported[11] but with a lower quality. Our refinement led to the same formula $C_{20}H_{14}MnN_2O_5$ and $C2/c$ space group with the parameters $a$ = 15.0903(7) Å, $b$ = 14.3131(7) Å, $c$ = 7.6708(4) Å, $\beta$ = 92.513(2)°, $V$ = 1655.2(1) Å$^3$, $Z$ = 4, $R_1$ = 0.0484, and $wR_2$ = 0.0772.

CCDC-291400 to -291402 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Layered Double Hydroxides Containing Intercalated Zinc Sulfide Nanoparticles: Synthesis and Characterization

**Guoqing Wu,[a] Lianying Wang,[a] David G. Evans,[a] and Xue Duan*[a]**

**Keywords:** Layered compounds / Intercalations / Zinc complex / Organic–inorganic hybrid composites / ZnS nanoparticles

Nanosized ZnS has been synthesized in the interlayer galleries of Mg–Al layered double hydroxides (LDHs) by a process involving ion exchange of a $Mg_2Al$-$NO_3$ LDH precursor with a zinc–citrate complex $\{Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O\}$ followed by reaction between the intercalated $[Zn(C_6H_4O_7)]^{2-}$ anions and $H_2S$. The materials have been characterized by elemental analysis, powder X-ray diffraction (XRD), transmission electron microscopy, FTIR spectroscopy, MAS $^{13}C$ NMR spectroscopy, and UV/Vis diffuse reflectance spectroscopy, and structural models have been proposed. The XRD diffraction patterns indicate that the layered structure is maintained and that the basal spacing in the intercalated materials depends on the orientation of the citrate moiety. The results confirm that cubic ZnS (sphalerite) is formed in the interlamellar domain rather than on the external surfaces and is co-intercalated with citrate dianions. The growth of ZnS particles is constrained by the layers of the LDH resulting in a large blue shift in the bandgap compared with the bulk material. The thermal decomposition process of the hybrid material has been characterized by in situ high-temperature powder XRD and thermogravimetry-differential thermal analysis (TG/DTA) coupled with mass spectrometry. The thermal stability of the zinc–citrate complex anions intercalated in LDHs is lower than that in the sodium salt. Thermal treatment below 270 °C leads to a reorientation of the citrate anions in the interlayer galleries associated with a significant interlayer contraction. No obvious changes in the XRD peaks corresponding to ZnS are apparent below 400 °C, indicating that sintering to form larger particles is successfully inhibited by the layered host; at higher temperatures the ZnS is oxidized with evolution of $SO_2$.

## Introduction

In recent years, semiconductor nanocrystals have attracted considerable attention because of their size- and shape-dependent optical and electronic properties as well as their potential for applications in nanodevices. ZnS is one of the most important II–VI semiconductors and has potential applications in numerous areas including optoelectronics,[1] photocatalysis,[2] and thin-film electroluminescent devices.[3] There have been many reports of attempts to control the size and morphology of ZnS including solvothermal routes,[4] thermal evaporation,[5] reverse micelle templates,[6] as well as intercalation in zeolites,[7] and mesoporous silica MCM-41.[8–10] Layered compounds have also been shown to be potential hosts: by virtue of confining the growth of nanoparticles inside the interlamellar galleries, the reaction zone is spatially constrained by the layers,[11–13] giving rise to conditions similar to those in two-dimensional nanoreactors such as Langmuir–Blodgett (LB) films and self-assembled monolayers.[14,15] One great advantage of such methods compared with lithographic fabrication is that regular nanoscale arrays of materials can be obtained with drastically reduced production costs.[16,17]

Layered double hydroxides (LDHs) are a family of lamellar solids that can be represented by the general formula $[M^{II}_{1-x}M^{III}_x(OH)_2]^{x+}A^{n-}_{x/n}\cdot mH_2O$. The structure of this class of compound, based on the stacking of positively charged layers with hydrated anions in the interlamellar domains, allows relatively high mobility of these anions.[18] It is possible to modulate their properties by changing the nature of the $M^{II}$ and $M^{III}$ cations, their molar ratio, and/or the size of the $A^{n-}$ anion.[19,20] One of the most important properties of such compounds is their high anion-exchange capacities. The lamellar structure and the anion-exchange properties of LDHs make them attractive for technological applications such as ion-exchangers, adsorbents, pharmaceutical stabilizers, and precursors of new catalytic materials.[21–23] There have been many examples of LDHs containing intercalated metal complex anions such as permanganate,[24,25] and coordination complexes.[26–30] In the case of metal oxide species, Suib et al.[24] have reported that manganese oxide species ($MnO_x$) can be prepared in LDH interlayer galleries by ion exchange followed by in situ post-treatment, whilst Lukashin et al.[31] have reported the synthesis of iron oxide nanoparticles with different morphologies and composition using an LDH as the template. However, synthesis of semiconductor nanoparticles using

LDHs as the host structure has not been extensively studied. Sato et al.[12,13] have reported that extremely small particles of CdS and CdS–ZnS mixtures less than 0.4 nm in thickness could be prepared by liquid–liquid reactions in the interlayers of LDH and their photocatalytic properties in respect of hydrogen evolution from $Na_2S$, $Na_2SO_3$, and/or 2-aminoethanol under irradiation by visible light have been studied. The interlayer distance of their proposed $[Cd(EDTA)]^{2-}$-intercalated LDH precursor is only 0.762 nm however, which is substantially lower than that subsequently reported for $[Ni(EDTA)]^{2-}$-intercalated LDHs.[26,32] Therefore, the $[Cd(EDTA)]^{2-}$ anions in the precursor, and hence presumably also the resulting CdS in the product, are located on the external surfaces of the LDH rather than in the interlayer galleries.

In this work, we report the synthesis of cubic ZnS (sphalerite) nanoparticles by gas–solid reaction in the confined interlayer gallery space of LDHs and the characterization of the resulting hybrid materials. An anionic zinc citrate complex $\{[Zn(Cit)]^{2-}\}$ [Cit = $C_6H_4O_7^{4-}$] is first intercalated into the LDH by ion exchange with a $Mg_2Al$-$NO_3$ LDH precursor, giving a material we denote LDH-Zn(Cit). Subsequent reaction with $H_2S$ at atmospheric pressure affords a material, denoted LDH-ZnS-$H_2$Cit, containing ZnS nanoparticles in the interlayer galleries of the LDH. Subsequent treatment of LDH-ZnS-$H_2$Cit with aqueous sodium carbonate solution gives a material, denoted LDH-$CO_3$-ZnS, containing interlayer carbonate anions and ZnS on the external surfaces of the crystallites. This method provides a simple approach for the synthesis of semiconductor particles in layered double hydroxide materials.

## Results and Discussion

The preparation of LDH-ZnS-$H_2$Cit involves four steps: preparation of $Na_2[Zn(Cit)]\cdot 3H_2O$, synthesis of an LDH-nitrate precursor, intercalation of $[Zn(Cit)]^{2-}$ by anion exchange, and, finally, reaction between $[Zn(Cit)]^{2-}$ and $H_2S$ in the interlayer galleries. The coordination chemistry of citrate is rather complex and a variety of mononuclear and polynuclear complexes have been structurally characterized.[33–37] Generally, trianionic $HCit^{3-}$ is the predominant form above pH 5.8, but it is possible to remove the proton from the hydroxy group to give a tetra-anionic $Cit^{4-}$ species at higher pH; the pH required is lowered considerably when the citrate is coordinated to a transition-metal cation. On the basis of elemental analysis (see Exp. Sect.), FTIR spectroscopy, and solid-state NMR spectroscopy (see below), it can be concluded that the tetra-anionic species was present in the zinc complex prepared under the reaction conditions employed in our work. Citrate coordination presumably involves the alkoxy group, the central carboxylate group, and one terminal carboxylate group with the octahedral coordination shell around zinc being completed by three water molecules. This is consistent with the results from both solution and structural studies of related complexes.[38,39]

### Elemental Analysis

Elemental compositions of the precursors and intercalated materials are given in the Experimental Section. The Mg/Al molar ratio in LDH-Zn(Cit) (2.00) and LDH-ZnS-$H_2$Cit (2.02) is essentially the same as that in the LDH-$NO_3$ precursor (2.03); the value is slightly lower in LDH-HCit (1.87), suggesting that part of the magnesium is leached from the layers during the synthesis of the LDH-HCit. This is commonly observed during ion-exchange reactions with LDHs.[20,21] Elemental analysis confirms that the nitrate anion in the LDH-$NO_3$ precursor is completely displaced during the exchange reactions with $[Zn(Cit)]^{2-}$ or $[HCit]^{3-}$, as no detectable amounts of nitrogen are present in either material. The data also suggest that the stoichiometry of the zinc citrate complex is unchanged after intercalation, although a small amount of carbonate anion is co-intercalated along with $[Zn(Cit)]^{2-}$. The analytical data for LDH-Zn(Cit) are consistent with the formula $[Mg_{0.69}Al_{0.33}(OH)_2][Zn(C_6H_4O_7)]_{0.16}(CO_3)_{0.01}\cdot 0.58\,H_2O$. In the case of the $[HCit]^{3-}$ intercalate, the data suggest a stoichiometry $[Mg_{0.65}Al_{0.35}(OH)_2](C_6H_5O_7)_{0.11}(CO_3)_{0.01}\cdot 0.57\,H_2O$.

When solid LDH-Zn(Cit) is reacted with gaseous $H_2S$ for 5 min, 20 min, and 1 h, the measured S/Zn molar ratio is 0.34, 0.55, and 0.70 respectively. The deviation of the S/Zn ratio from 1:1 implies that the reaction between $Zn^{2+}$ and $H_2S$ is not fully complete. However, when the reaction time was extended to 8 h, the observed S/Zn molar ratio in the resulting sample (LDH-ZnS-$H_2$Cit) was 0.96, close to the ideal value of unity. The analytical data for LDH-ZnS-$H_2$Cit are consistent with the formula $[Mg_{0.67}Al_{0.33}(OH)_2][ZnS]_{0.16}(C_6H_6O_7)_{0.16}(CO_3)_{0.01}\cdot 0.70\,H_2O$.

### X-ray Diffraction

The XRD patterns of the LDH materials are shown in Figure 1. The patterns are typical of lamellar materials, with a basal reflection and associated harmonics at low angle $2\theta$ and weaker nonbasal reflections at a higher angle. The reflections for LDHs are generally indexed in a three-layer 3R polytype with rhombohedral symmetry (space group $R\bar{3}m$), based on the structure of the mineral hydrotalcite.[40] In this case, the unit cell $c$-parameter corresponds to three times the basal spacing $d(003)$ and the value of the unit cell $a$-parameter is calculated from the position of the $d(110)$ reflection near 60° $2\theta$. The values of the cell parameters and basal spacing ($d_{obs}$) in the LDH materials are compared in Table 1. The XRD pattern of LDH-$NO_3$ shows a basal reflection at 0.867 nm, which is similar to that reported in the literature[41,42] for LDHs with Mg/Al of about 2. Intercalation of $HCit^{3-}$ leads to an increase in basal spacing to 1.15 nm, which is also comparable to the values in the literature.[43] The values of the basal spacing in LDH-Zn(Cit) and LDH-ZnS-$H_2$Cit are very similar to each other (1.21–1.22 nm) and slightly larger than that in LDH-HCit, which may indicate a different orientation of the citrate moiety within the interlayer galleries. The values of the unit cell $a$-parameter are very similar for LDH-$NO_3$,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

LDH-Zn(Cit), LDH-ZnS-$H_2$Cit, and LDH-$CO_3$-ZnS, with a slightly smaller value being observed for LDH-HCit. The value of *a* corresponds to the average distance between metal ions in the layers and as the Shannon crystal radius of $Al^{3+}$ is smaller than that of $Mg^{2+}$, a decrease in Mg/Al ratio should lead to a lower value of *a*; the XRD data are therefore consistent with the analytical data described above.

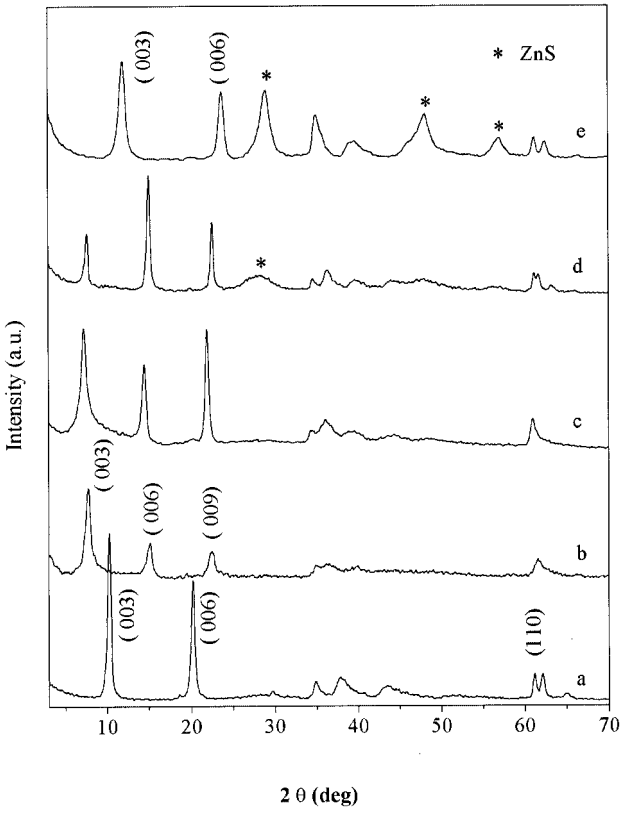

Figure 1. Powder X-ray diffraction patterns of (a) LDH-$NO_3$, (b) LDH-HCit, (c) LDH-Zn(Cit), (d) LDH-ZnS-$H_2$Cit, and (e) LDH-$CO_3$-ZnS.

Table 1. Values of unit cell parameters *a* and *c* and basal spacing *d*(003) for the LDH materials.

| Sample | *a* [nm] | *c* [nm] | *d*(003) [nm] |
|---|---|---|---|
| LDH-$NO_3$ | 0.303 | 2.601 | 0.867 |
| LDH-Zn(Cit) | 0.304 | 3.651 | 1.217 |
| LDH-ZnS-$H_2$Cit | 0.304 | 3.633 | 1.211 |
| LDH-HCit | 0.301 | 3.441 | 1.147 |
| LDH-$CO_3$-ZnS | 0.303 | 2.235 | 0.745 |

Figure 1 shows the XRD patterns of the LDH-Zn(Cit) precursor and the materials obtained after exposure to $H_2S$ for 8 hours. Although the positions of the (00*l*) (*l* = 3, 6, 9) reflections of LDH-Zn(Cit) and LDH-ZnS-$H_2$Cit are almost identical, as noted above, there is a significant variation in the relative intensities of the peaks, suggesting that structural changes have occurred within the interlayer galleries. When the interlayer anions in LDHs do not contain any atoms with large scattering power, intensities of the basal (00*l*) reflections are mainly governed by the X-ray intensity scattered by metal cations in the host layers and the intensities generally decrease as *l* increases, as is observed in Figure 1 for LDH-$NO_3$, LDH-HCit, and LDH-$CO_3$-ZnS. If the interlayer contains a transition-metal complex anion as the guest, the intensity of the (006) reflection is generally greater than that of (003), which has been attributed to an increased electron density at the midpoint of the interlayers, where the metal is presumed to be located. Reported examples include chromate or vanadate anions intercalated in [Mg–Al] LDHs,[44,45] $[MO_2]^{2-}$ (M = Co, Cu) and $[MOx_3]^{3-}$ (M = Cr, Mn, Ga) (Ox = oxalato) anions in [Zn–Al] and [Mg–Al] LDHs,[29,35] and hexachloro/hydroxoplatinum(IV) anions in [Zn–Al], [Mg–Al], and [Cu–Al] LDHs.[46] It has been reported that 1,1′-ferrocenedicarboxylate and ferrocenecarboxylate anions can be intercalated in [Zn–Al] LDHs giving materials with basal spacings of 1.55 and 2.00 nm respectively.[47] On the basis of modeling studies, these values were interpreted in terms of a monolayer and bilayer of guest species respectively. In the former case, the iron atom is located at the midpoint of the interlayer galleries and, consistent with this picture, the intensity of the (006) reflection is larger than that of (003) and (009). In the bilayer arrangement, alternate iron atoms are shifted along the *c* axis above and below the midpoint of the interlayer galleries, and in this case the intensity of the (009) reflection is larger than that of (006). In the case of LDH-Zn(Cit) (Figure 1, c), the intensity of the (009) reflection is also greater than that of (006), suggesting a similar displacement of the zinc atoms along the *c* axis. On treatment with $H_2S$, the intensity of the (006) reflection increases, with a concomitant decrease in the relative intensity of the (009) reflection. This indicates that reaction with $H_2S$ involves a change in the one-dimensional electron density distribution alone the *c* axis, which can be ascribed to the migration of the zinc atoms to the midpoint of the interlayer galleries and incorporation of sulfur.

In the case of LDH-ZnS-$H_2$Cit, a weak broad diffraction peak centered around $2\theta = 28°$ is apparent, which corresponds to the (111) lattice planes of cubic ZnS (sphalerite, JCPDS Card 5-566). The broadness of the peak is indicative of very small nanoparticles; using the Scherrer formula,[48] an average particle diameter of about $2.0 \pm 0.2$ nm in the direction perpendicular to the (111) lattice planes can be estimated.

It is well known that LDHs have a very strong affinity for carbonate anions. After treatment of LDH-ZnS-$H_2$Cit with an aqueous solution of sodium carbonate, the resulting solid has a basal spacing of 0.745 nm, which agrees with that reported in the literature for $Mg_2Al$-$CO_3$ LDH.[41,49] This indicates that the citrate ions have been displaced by carbonate from the interlayer galleries. Furthermore, the XRD pattern of the resulting material LDH-$CO_3$-ZnS (Figure 1, e) shows a series of strong and sharp diffraction peaks corresponding to cubic ZnS. This indicates the ZnS nanoparticles have also been liberated from the interlayer galleries by treatment with carbonate anions and, free of the constraint imposed by the layers, grow into larger crys-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tallites on the external surfaces of the LDH. An average particle diameter of about 6.0 nm can be estimated according to the Scherrer formula.[48]

### Transmission Electron Microscopy

The transmission electron microscopy (TEM) images of LDH-ZnS-$H_2$Cit and LDH-$CO_3$-ZnS are shown in Figure 2. The diameter and shape of the LDH-$CO_3$-ZnS particles are essentially identical to those of the LDH-ZnS-$H_2$Cit, which indicates that the extraction of ZnS from the interlamellar galleries does not lead to the destruction of the lamellar structure (see parts a and b in Figure 2). Even at higher magnification (Figure 2, c), there is no obvious indication of the presence of ZnS nanoparticles on the external surfaces of LDH-ZnS-$H_2$Cit. It is difficult to confirm directly the presence of ZnS in the galleries of the LDHs by the TEM method however; this is probably a result of the weak contrast between the LDH frameworks and the nanosized ZnS, as is the case for ZnS and $Fe_2O_3$ inside mesoporous hosts.[8,50] In the case of LDH-$CO_3$-ZnS however, as shown in Figure 2 (d), many ZnS crystallites of about 6.0 nm are observed on the external surfaces. The particle sizes are in agreement with those estimated from the XRD data. The above results show that the small ZnS nanoparticles can only grow in the two-dimensional gallery spaces, where they experience the confinement effect of the layers.

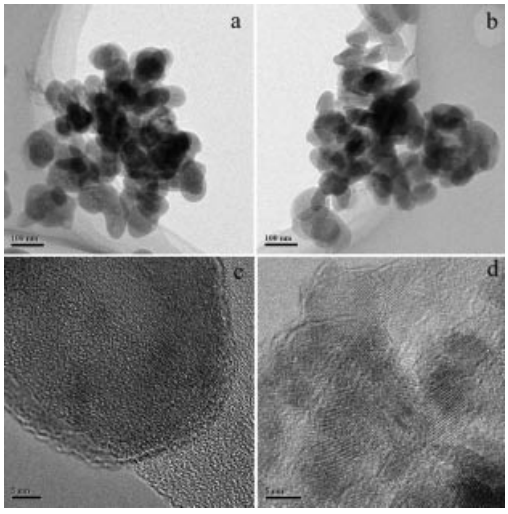

Figure 2. Transmission electron microscopy images of (a) LDH-ZnS-$H_2$Cit, (b) LDH-$CO_3$-ZnS at low magnification, (c) LDH-ZnS-$H_2$Cit, and (d) LDH-$CO_3$-ZnS at high magnification.

### FTIR Spectroscopy

FTIR spectroscopy is very helpful in the study of LDHs, especially those containing interlayer organic anions (or anions with organic moieties), as it is very sensitive to the symmetry of the organic anion and to the interactions of the anion with its environment such as hydrogen bonding and coordinate bonding.[28,39,45,51,52] The FTIR spectra of the $Na_2$[Zn(Cit)]·3$H_2O$ and $Mg_2$Al-$NO_3$ LDH precursors together with those of LDH-Zn(Cit) and LDH-ZnS-$H_2$Cit are illustrated in Figure 3. For the LDH nitrate precursor (Figure 3, a), the intense and broad absorption band centered at 3445 $cm^{-1}$ corresponds to the stretching vibrations of the hydroxy groups of both the layer hydroxide moieties and interlayer water. The broadening of this band is due to hydrogen-bond formation.[53] The band close to 1640 $cm^{-1}$ corresponds to the deformation mode ($\delta H_2O$) of water molecules. The absorption peaks at 1384 and 839 $cm^{-1}$ are usually assigned to the $v_3$ and $v_2$ vibration modes, respectively, of $NO_3^-$ with $D_{3h}$ symmetry[42,46] whilst bands around 447 and 675 $cm^{-1}$ are due to Al–O and Mg–O lattice vibrations respectively.[23] The slight broadening of the 1384 $cm^{-1}$ peak and the relatively low wavenumber for the $v_2$ mode (at 827 $cm^{-1}$) are indicative of an interaction of $NO_3^-$ anions with their surroundings,[54] namely with intercalated water, hydroxy groups, and metal cations in the brucite-type layers.

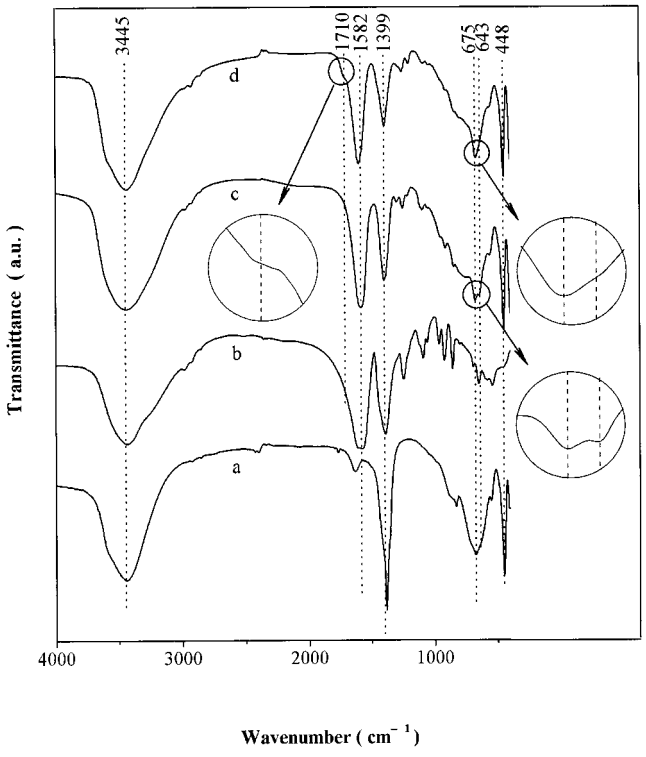

Figure 3. FTIR spectra of (a) LDH-$NO_3$, (b) $Na_2$[Zn(Cit)]·3$H_2O$, (c) LDH-Zn(Cit), and (d) LDH-ZnS-$H_2$Cit.

The FTIR spectra of the $Na_2$[Zn(Cit)]·3$H_2O$ precursor (Figure 3, b) exhibits strong characteristic absorptions of the carboxylate group of the citrate ligands in the asymmetric and symmetric vibration regions. Specifically, $v_{as}$(COO) vibrations appear at 1604 (shoulder) and 1576 $cm^{-1}$ and $v_s$(COO) vibrations are observed at 1436 (shoulder) and 1393 $cm^{-1}$. These assignments are in good agreement with those in $K_4$[$MoO_3$(Cit)]·3$H_2O$,[39] which has been structurally characterized and shown to have the same citrate coordination geometry about the metal as that proposed above for $Na_2$[Zn(Cit)]·3$H_2O$. The asymmetric $v_{as}$(COO) and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

symmetric $\nu_s$(COO) stretching modes in the complexes are shifted to lower frequencies compared to those of free citrate, denoting the changes in the environment of the ligand upon complexation to metals. The wavenumber difference $\Delta\nu = \nu_{as} - \nu_s$ gives information about the coordination environment of the carboxylate group.[51,55] The value of $\Delta\nu$ for $Na_2[Zn(Cit)]\cdot 3H_2O$ is 183 $cm^{-1}$, indicating that the carboxylate groups are either free or coordinated to the metal in a monodentate fashion, rather than in bridging or bidentate modes. This is consistent with the structure proposed above for $Na_2[Zn(Cit)]\cdot 3H_2O$.

After exchange of $Mg_2Al\text{-}NO_3$ LDH with $Na_2[Zn(Cit)]\cdot 3H_2O$, the $\nu_3$ vibration of $NO_3^-$ disappears, and the asymmetric $\nu_{as}$(COO) and symmetric $\nu_s$(COO) stretching modes of the carboxylate groups, at 1582 and 1399 $cm^{-1}$ respectively, appear (Figure 3, c). The value of $\Delta\nu$ for LDH-Zn(Cit) (189 $cm^{-1}$) is similar to that in $Na_2[Zn(Cit)]\cdot 3H_2O$, indicating that the coordination mode of the carboxylate groups is unchanged after intercalation. The slight difference in the value of $\Delta\nu$ may be a reflection of the different intermolecular hydrogen-bonding environments experienced by the anion in the sodium salt and in the interlayer galleries of the LDH.[55–57]

After LDH-Zn(Cit) is exposed to $H_2S$, the IR spectrum of the resulting material shows a number of changes. The asymmetric $\nu_{as}$(COO) stretching mode shows a shift to 1596 $cm^{-1}$, comparable to the value for LDH-HCit (1593 $cm^{-1}$, spectrum not shown). Furthermore, the band at 643 $cm^{-1}$ (see inset of part c in Figure 3) due to the Zn–O vibration mode[23,47] is no longer detected, and an additional IR absorption band at around 1710 $cm^{-1}$, assigned to the free COOH vibration mode,[34,58,59] appears (see part d in Figure 3, inset), suggesting that (at least) one of the carboxylate groups has been protonated. In $K_4[(MoO_2)_2O(HCit)_2]\cdot 4H_2O$, where the central carboxylate group is protonated, the free COOH vibration mode is observed[39] at around 1715 $cm^{-1}$. These data all indicate that reaction of intercalated $[Zn(Cit)]^{2-}$ with $H_2S$ leads to cleavage of the Zn–O coordinate bonds in the complex, consistent with the formation of ZnS in the interlayers, according to Equations (1) and (2).

$$H_2S\ (gas) + H_2O\ (interlayer\ water) \rightarrow H_3O^+ + HS^- \quad (1)$$

$$[Zn(Cit)]^{2-} + HS^- + H_3O^+ \rightarrow ZnS + H_2Cit^{2-} + H_2O \quad (2)$$

### Solid-State NMR Spectroscopy

Figure 4 shows the solid-state MAS $^{13}C$ NMR spectra of $Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O$, LDH-Zn(Cit), and LDH-ZnS-$H_2$Cit. In the spectrum of $Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O$ there are resonances at $\delta$ = 184.4 and 181.4 due to the carboxyl groups, and in addition there are two signals of lower frequency at $\delta$ = 76.3 due to the alkoxy carbon and at $\delta$ = 47.9 due to the methylene carbons. The close correspondence between the MAS $^{13}C$ NMR spectra of $Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O$ and LDH-Zn(Cit) indicates that the coordination mode of $[Zn(C_6H_4O_7)]^{2-}$ is preserved in LDH-Zn(Cit). In comparison with LDH-Zn(Cit), the corresponding $^{13}C$ NMR resonances for LDH-ZnS-$H_2$Cit are all shifted to high field. In particular, the α-carboxyl carbon and β-carboxyl carbon signals show large shifts of $\Delta\delta$ 7.0 and 6.7 ppm, which is a clear indication[39] of the loss of coordination of carboxyl groups to the zinc(II) cation. MAS $^{13}C$ NMR spectroscopy is unable to confirm whether the central C–O group of the citrate anion is coordinated to the zinc cation as an alcohol or alkoxide group however. Zhou et al.[39] have reported the solid-state NMR spectra of structurally characterized oxomolybdenum(VI) citrate complexes, concluding that the coordination of a deprotonated alkoxide group to molybdenum is characterized by a downfield shift in the $^{13}C$ resonance to 82–84 ppm compared with that for $KH_3Cit$ ions ($\delta$ =74 ppm). It has been reported however[60,61] that the solid-state NMR spectrum of a structurally characterized gallium citrate complex with a deprotonated alkoxide group coordinated to gallium has a peak at $\delta$ = 76 ppm. This latter value is very close to those reported for the chemical shifts (73–75 ppm) of a C–OH group in citrate coordinated to cadmium in the solid-state NMR spectra of structurally characterized $Cd^{II}$ complexes.[62] The small difference in chemical shift $\Delta\delta$ between LDH-Zn(Cit) ($\delta$ = 76.6 ppm) and LDH-ZnS-$H_2$Cit ($\delta$ = 74.6 ppm) is consistent with the presence of coordinated citrate in the former and free citrate in the latter, although whether the coordination mode in the former involves (C–O–Zn) or [C–O(H)–Zn] linkages cannot be determined. It is noteworthy that the $^{13}C$ NMR spectrum of LDH-ZnS-$H_2$Cit is similar to that of the free anion $KH_3Cit$ {$^{13}C$ NMR ($D_2O$): $\delta$ = 177.6 [$(CO_2)_\alpha$], 174.0 [$(CO_2)_\beta$], 73.6 (≡CO), 43.0 (=$CH_2$)},[39] which is consistent with the IR data.

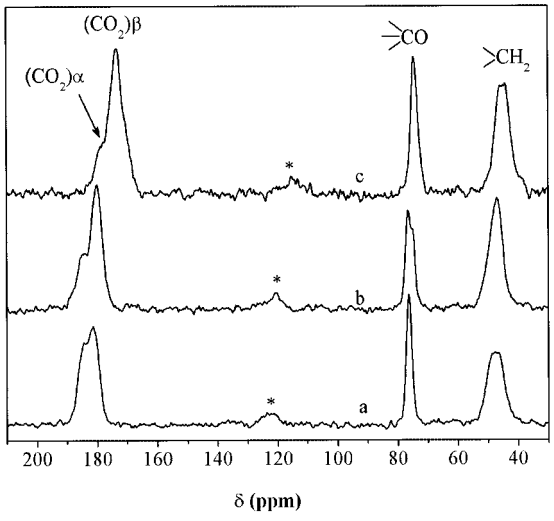

Figure 4. Solid-state $^{13}C$ MAS NMR spectra of (a) $Na_2[Zn(Cit)]\cdot 3H_2O$, (b) LDH-Zn(Cit), and (c) LDH-ZnS-$H_2$Cit; spinning sidebands are indicated with an asterisk. α, central carboxylate; β, terminal carboxylate.

### Optical Properties of the ZnS Nanoparticles

UV/Vis diffuse reflectance spectroscopy was used to investigate the optical properties of the ZnS nanoparticles. As shown in Figure 5, the LDH-Zn(Cit) precursor has negligible absorption above 250 nm, whereas, in contrast, both LDH-ZnS-$H_2$Cit and LDH-$CO_3$-ZnS have significant absorption in the range 250–350 nm, consistent with the presence of ZnS. In comparison with that of bulk ZnS, the absorption onset of LDH-ZnS-$H_2$Cit shows a blue shift of about 50 nm, whereas the absorption edge of LDH-$CO_3$-ZnS shows a smaller blue-shift of about 25 nm. The blue shift in UV/Vis spectra, indicating an increase in the bandgap of the material, is associated with a decrease in the particle size, characteristic of the so-called quantum size effects.[63] The smaller blue shift of LDH-$CO_3$-ZnS relative to that of LDH-ZnS-$H_2$Cit implies that the former contains larger ZnS particles,[14,64] which is consistent with the XRD data discussed above. The absorption onset for the ZnS nanoparticles is followed by a peak generally referred to as the excitonic peak. The excitonic peak position of the as-prepared ZnS particles in LDH-ZnS-$H_2$Cit is at 276 nm, corresponding to a bandgap of 4.52 eV, which is some 0.87 eV higher than that in bulk ZnS (3.65 eV).[65] The diameter of the ZnS particles in LDH-ZnS-$H_2$Cit, as calculated by the Wang equation,[4,63] is about 2.0 nm, which is comparable to the value estimated from XRD (2.0 ± 0.2 nm) as noted above.

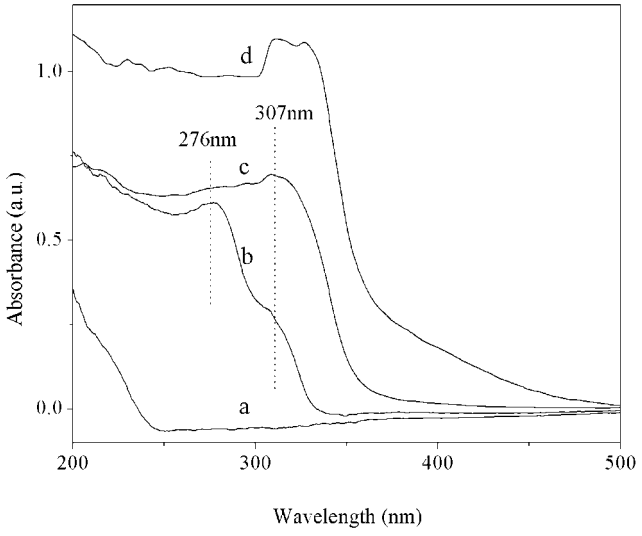

Figure 5. UV absorption spectra of (a) LDH-Zn(Cit), (b) LDH-ZnS-$H_2$Cit, (c) LDH-$CO_3$-ZnS, and (d) bulk ZnS (with particles diameter above 1 mm).

The presence of the shoulder (307 nm) on the long wavelength side of the excitonic peak in LDH-ZnS-$H_2$Cit may be an indication of an anisotropic disk or plate-like morphology of the ZnS particles induced by their confinement in the interlayer galleries. Li et al.[66] have prepared ZnS/octylamine hybrid nanosheets that show two such absorption features, and a similar phenomenon has been observed for CdS nanoparticles in LB films.[14] Alternatively, a high wavelength shoulder may be caused by a large concentration of defect sites (vacancies and interstitial anions).[67,68] Li et al.[69] reported that ZnS nanoparticles with <3 nm average diameter have two absorption features, concluding that the weak shoulder that appeared at 320 nm was caused by sulfur vacancy defects. Similar features have been observed and discussed in the literature for ZnS nanoparticles.[70,71] The spectra of our ZnS nanoparticles thus suggest that the organic component present in the sample may interact with the ZnS particles. The interface induced by the interaction between the ZnS clusters and the organic component in LDH-ZnS-$H_2$Cit may possess a large number of sulfur vacancy defects, which is consistent with the results of chemical analysis of the S/Zn ratio. Therefore, the optical properties of our ZnS nanoparticles may be similarly influenced by the presence of sulfur vacancy defects.

### Structural Model of the Intercalated Materials

All of the experimental results given above indicate that the $[Zn(Cit)]^{2-}$ anion is intercalated in the interlayer galleries and that ZnS nanoparticles are synthesized in situ by reaction with $H_2S$. If the thickness of the LDH layer ($T_{Layer}$ = 0.21 nm) and the hydrogen-bonding space between the layers and anions ($2L_H$ = 0.27 nm) are subtracted[72] from the observed basal spacing of LDH-Zn(Cit) (see Table 1), the gallery height is calculated to be 0.74 nm. As the estimated length[73] of the $[Zn(Cit)]^{2-}$ anion (with three $H_2O$ molecules) is about 0.79 nm, its long axis is probably oriented perpendicular to the layers (Figure 6, a) with the pendant carboxylate group of adjacent anions hydrogen-bonded to opposite layers. This locates the Zn atoms away from the center of the interlayer galleries, consistent with the relative intensities of the XRD reflections discussed

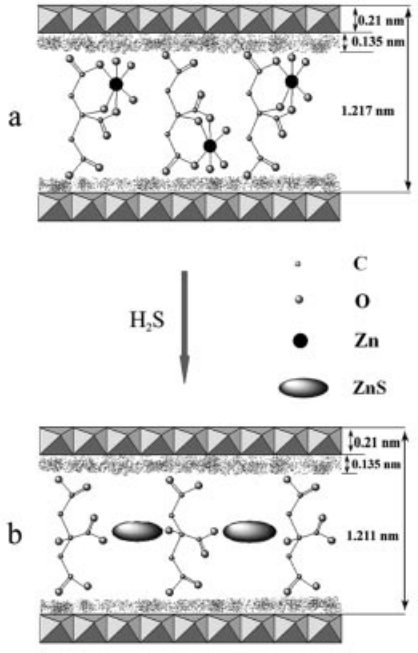

Figure 6. Schematic illustration of the structures of (a) LDH-Zn(Cit) and (b) LDH-ZnS-$H_2$Cit.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

above [$I(009) > I(006)$]. On reaction with $H_2S$, a change in the one-dimensional electron-density distribution alone the *c* axis occurs, consistent with the formation of ZnS nanoparticles in the center of the interlayer galleries, along with co-intercalated $H_2Cit^{2-}$ anions, as shown schematically in part b of Figure 6.

As discussed above, on the basis of XRD and UV/Vis spectroscopic data, the estimated diameter of the ZnS particles is about 2.0 nm. As the gallery height in LDH-ZnS-$H_2$Cit is only 0.73 nm, this implies that the particles have a disc- or plate-like morphology. A similar observation has been reported in the literature[14,15,58,74,75] for semiconductor nanoparticles formed in the layers within LB films, where the particles adopt a disc-like morphology as result of the constraints imposed by the two-dimensional nanoreactors.

## Thermal Behavior of the Materials

### *In Situ Variable Temperature XRD Study of LDH-Zn(Cit) and LDH-Zns-$H_2$Cit*

The in situ variable temperature powder X-ray diffraction patterns of LDH-Zn(Cit) and LDH-ZnS-$H_2$Cit in the temperature range 30–900 °C are shown in Figure 7 and Figure 8 respectively. In each case, as the temperature is increased above ambient, the basal reflections move to higher angles, indicating a contraction in interlayer spacing. The magnitudes of the contraction observed on heating the two samples are very different however. The value of the basal spacing of LDH-Zn(Cit) decreases from 1.217 nm at 30 °C to 1.148 nm at 240 °C. The observed contraction of 0.069 nm can be interpreted in terms of the destruction of the hydrogen-bonding space as a result of removal of interlayer water molecules and the loss of coordinated water molecules from the complex anion (TG measurements on the $Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O$ precursor show that it becomes completely dehydrated below 150 °C). It is worth mentioning that the inversion of intensity between the (006) peak and (009) peak in LDH-Zn(Cit) disappears on heating from 30 °C to 150 °C. This probably results from a disorder in the arrangement of the guests associated with the loss of water molecules from the hydrogen-bonded framework in the interlayer galleries, as water molecules play an important role in preserving interlayer order.[28,41] On further heating above 270 °C, the layer structure collapses completely, indicative of decomposition of the $[Zn(Cit)]^{2-}$ complex and dehydroxylation of the layers. At 400 °C, reflections characteristic of a cubic MgO-like phase begin to appear as a result of decomposition of the layers and at 900 °C reflections from a $MgAl_2O_4$ spinel phase and MgO are present, as is generally observed for calcined [Mg–Al] LDHs.[49,76] In addition, peaks that can be assigned to ZnO (JCPDS Card 01-1136), resulting from the decomposition of $[Zn(Cit)]^{2-}$, can be observed.

In comparison with LDH-Zn(Cit), the value of the basal spacing of LDH-ZnS-$H_2$Cit shows a much larger contraction of about 0.25 nm on heating from ambient temperature

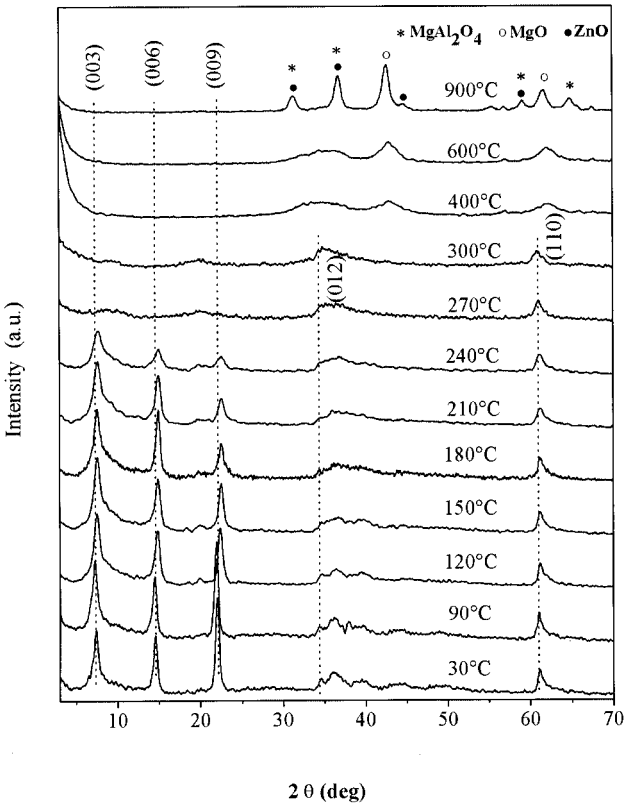

Figure 7. In situ powder X-ray diffraction patterns of LDH-Zn(Cit) in the temperature range 30–900 °C.

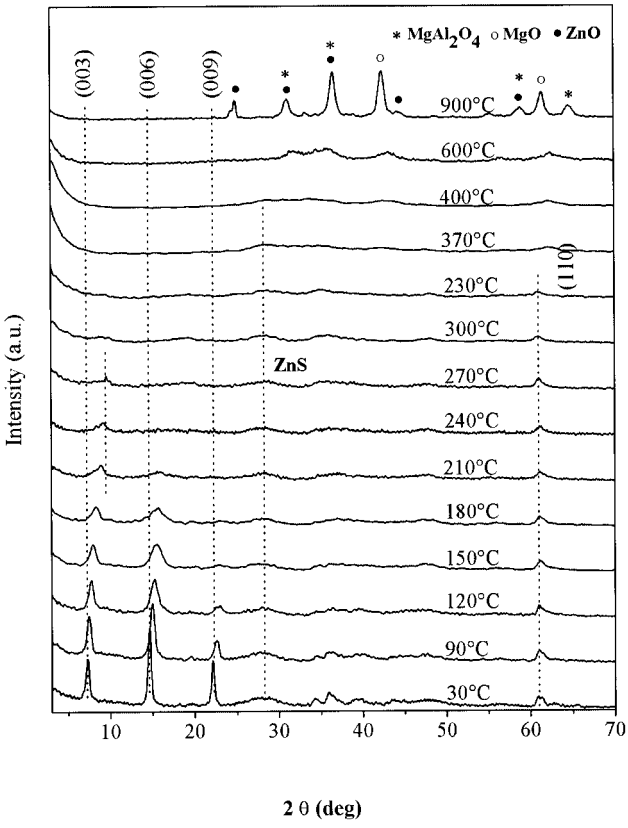

Figure 8. In situ powder X-ray diffraction patterns of LDH-ZnS-$H_2$Cit in the temperature range 30–900 °C.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to 240 °C, as shown in Figure 8. At 240 °C, evolution of $CO_2$ is not observed in the MS curve for LDH-ZnS-$H_2$Cit (see below), implying that decomposition of the intercalated citrate anions does not occur at this temperature. The significant decrease in basal spacing therefore probably results from a reorientation of the free citrate anions from being essentially perpendicular to the layers to being parallel to the layers; a similar phenomenon has been observed for tartrate anions intercalated in LDHs.[77] At 900 °C, peaks attributed to MgO, $MgAl_2O_4$, and ZnO appear, as for LDH-Zn(Cit).

It is noteworthy that the width of the broad diffraction peak centered around $2\theta = 28°$ corresponding to ZnS is essentially unchanged on heating from 30 to 240 °C, implying that there is no growth in particle size with increasing temperature. This provides further evidence that the ZnS nanoparticles are formed in the interlayer galleries rather on the external surfaces of the LDH, as in the latter case considerable sintering would be expected.[8] At 400 °C, the broad diffraction peak of ZnS is no longer observed, which is in agreement with the evolution of $SO_2$ observed in the MS data for LDH-ZnS-$H_2$Cit at a similar temperature (see below).

### *TG/DTA Analysis Coupled with Mass Spectrometry*

The results of the thermal analysis of the materials are presented in Figure 9, Figure 10, and Figure 11. Generally, four steps are observed in the thermal evolution of LDHs: desorption of physically adsorbed water, removal of the interlayer structural water, dehydroxylation of the brucite-like sheets, and the decomposition of the interlayer anions, although the first two steps may overlap in the temperature range 30–200 °C and the latter two steps may also overlap at higher temperatures.

For the complex $Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O$ (Figure 9), the thermal decomposition clearly consists of three distinct steps. The first one (30–300 °C, 14.8% mass loss) corresponds to the removal of coordinated water. The sharp mass loss observed in the range 300–400 °C (21.1% mass loss) is due to combustion of the organic ligand, with a corresponding sharp endothermic peak ($T_m$ = 377 °C) in the DTA curve (Figure 9, a). There is a third sharp mass loss step in the range 400–600 °C (10.1% mass loss), with a corresponding strong endothermic peak ($T_m$ = 524 °C) in the DTA curve. Mass spectrometric analysis (Figure 9, b) shows that the first endothermic peak is associated with evolution of both water and carbon dioxide (*m/e* 44, $CO_2^+$), whilst the second endothermic process involves liberation of $CO_2$ alone. On this basis $Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O$ decomposes on heating in air by three steps, as in Equations (3), (4), and (5).

$$Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O \rightarrow Na_2Zn(C_6H_4O_7) + 3\ H_2O \quad (3)$$

$$Na_2Zn(C_6H_4O_7) + 9\ O_2 \rightarrow Na_2CO_3 + ZnCO_3 + 2\ H_2O + 4\ CO_2 \quad (4)$$

$$ZnCO_3 \rightarrow ZnO + CO_2 \quad (5)$$

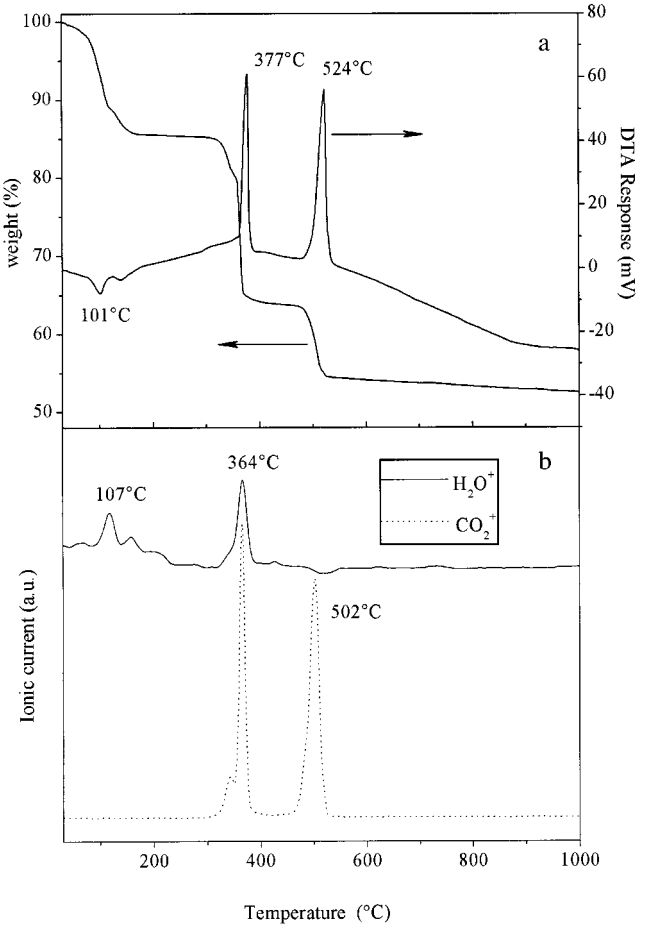

Figure 9. TG/DTA curve (a) and coupled with mass spectrometry curve (b) of $Na_2[Zn(Cit)]\cdot 3H_2O$.

The thermal decomposition of LDH-Zn(Cit) is characterized by three mass loss steps (Figure 10, a). The reduction in mass between 30 and 200 °C ($T_m$ = 120 °C, 9.9% mass loss) is due to loss of surface adsorbed and interlayer water resulting in the decrease in interlayer spacing observed in Figure 7. The latter two mass loss steps overlap to some extent (total weight loss of 37.7%) and are accompanied by exothermic peaks in the DTA at 319 and 417 °C (Figure 10, a). These two exothermic peaks occur some 58 and 107 °C below the temperatures of the corresponding DTA peaks for $Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O$. Typically, the thermal stability of a complex anion intercalated in LDHs is higher than that of the precursor salt.[41] However, the opposite has been reported in the literature,[78,79] as is the case here. Although intercalation of the anion gives rise to a hydrogen-bonding interaction between the pendant terminal $COO^-$ group of the citrate ligand and the layer hydroxy groups, the strongly hydrogen-bonded network of hydrated cations and anions in the precursor salt, clearly demonstrated in the single-crystal structure of $Cu_2(C_6H_4O_7)\cdot 3H_2O$,[33] is lost on intercalation and this may be the origin of the greater thermal stability of the precursor salt. The MS trace (Figure 10, b) shows that both water and carbon dioxide are evolved simultaneously over the entire

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

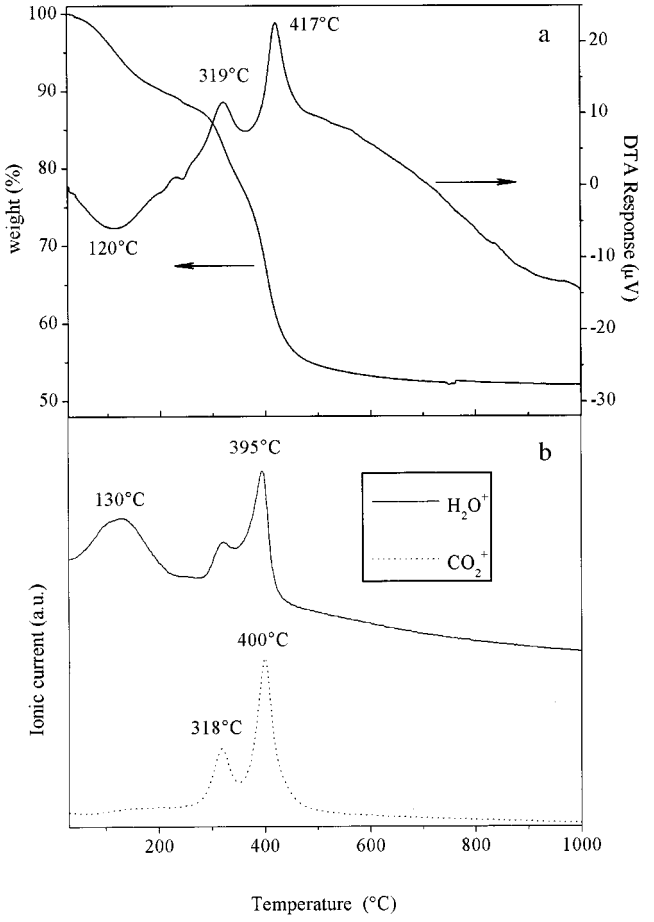

Figure 10. TG/DTA curve (a) and coupled with mass spectrometry curve (b) of LDH-Zn(Cit).

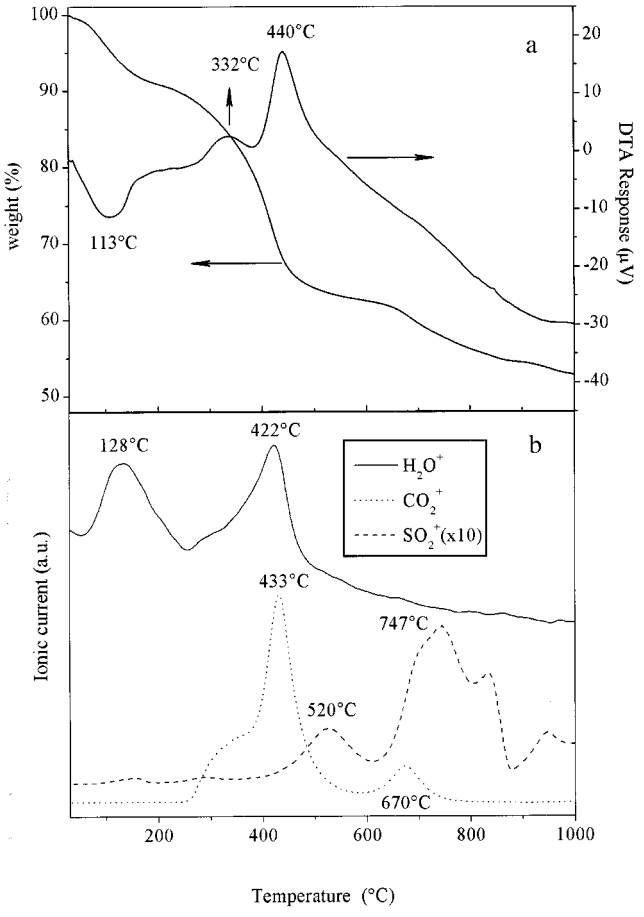

Figure 11. TG/DTA curve (a) and coupled with mass spectrometry curve (b) of LDH-ZnS-$H_2$Cit.

decomposition range, rather than in discrete steps as seen for $Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O$ (Figure 9, b).

The TG trace for LDH-ZnS-$H_2$Cit (Figure 11, a) shows also three mass loss events. The first step, corresponding to the removal of surface adsorbed and interlayer water, extends from room temperature to approximately 240 °C ($T_m$ = 113 °C, 10.8% mass loss). The second step (240–540 °C, 25.9% mass loss), with two corresponding exothermic maxima at 332 and 440 °C in the DTA curve, can be assigned to partial decomposition of the citrate ligands and the dehydroxylation of the hydroxide layers. The MS trace (Figure 11, b) shows evolution of both carbon dioxide and water during this process. During the final step (540–950 °C 16.2% mass loss), a gradual weight loss is observed and the MS trace shows that both $SO_2$ (*m*/*e* 64, $SO_2^+$) and $CO_2$ are evolved. The former presumably arises from oxidation of ZnS according to Equation (5) [see Equation (6)]

$$2\ ZnS + 3\ O_2 \rightarrow 2\ ZnO + 2\ SO_2 \quad (6)$$

and is consistent with the absence of the peak assigned to ZnS from the X-ray diffraction patterns recorded above 400 °C. The $CO_2$ arises from oxidation of residual organic material and as all organic material is lost below 550 °C

Table 2. Results and interpretation of thermogravimetric measurements on precursors and products.

| Sample | Temperature range [°C] | Observed step | Experimental mass loss [%] | Calculated[a] mass loss [%] |
|---|---|---|---|---|
| $Na_2[Zn(Cit)]$ | 30–300 | dehydration | 14.8 | 15.2 |
| | 300–600 | ligand decomposition | 31.2 | 31.8 |
| LDH-Zn(Cit) | 30–200 | dehydration | 9.9 | 9.7 |
| | 200–700 | dehydroxylation + anion decomposition | 37.7 | 38.9 |
| LDH-ZnS-$H_2$Cit | 30–240 | dehydration | 10.8 | 9.2 |
| | 240–950 | dehydroxylation + anion decomposition | 42.1 | 42.9 |

[a] Mass losses are calculated based on the stoichiometries $Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O$ for $Na_2[Zn(Cit)]$, $[Mg_{0.67}Al_{0.33}(OH)_2][Zn(C_6H_4O_7)]_{0.16}(CO_3)_{0.01}\cdot 0.58H_2O$ for LDH-Zn(Cit) and $[Mg_{0.67}Al_{0.33}(OH)_2][ZnS]_{0.16}(C_6H_6O_7)_{0.16}(CO_3)_{0.01}\cdot 0.70H_2O$ for LDH-ZnS-$H_2$Cit.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

on heating LDH-Zn(Cit), this may indicate that complete combustion of intercalated citrate in LDH-ZnS-$H_2$Cit is hindered by the presence of co-intercalated ZnS.

The mass losses expected for materials with stoichiometries proposed on the basis of chemical analysis and TGA results are listed in Table 2 and correspond closely to the experimental values.

## Conclusions

Cubic sphalerite ZnS nanoparticles can be synthesized by an in situ reaction between a pre-intercalated $[Zn(Cit)]^{2-}$ anion and $H_2S$ in the interlayer galleries of an LDH. The LDH precursor is obtained by an ion-exchange reaction of $Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O$ and a nitrate-containing LDH. The synthesis of the ZnS nanoparticles, involving a gas–solid reaction between the LDH and $H_2S$, provides a simple approach for the synthesis of such semiconductors in layered hosts. Structural data show that $[Zn(Cit)]^{2-}$ anions are accommodated vertically in the interlayer region as a monolayer with the zinc center in adjacent anions located alternately above and below the midpoint of the interlayer galleries. Reaction with $H_2S$ leads to the formation of co-intercalated ZnS in the interlayer galleries and citrate dianions. The ZnS nanoparticles grow only gradually in the two-dimensional gallery spaces because of the confinement effect of the layers. The material exhibits an excitonic peak at 276 nm corresponding to a bandgap of 4.52 eV, which is some 0.87 eV higher than that in the bulk. The diameter of the ZnS particles (≈ 2 nm), as estimated from XRD and UV/Vis spectroscopic data, is larger than the gallery height of the LDH (0.73 nm), demonstrating that the ZnS nanoparticles have a disc- or plate-like morphology.

## Experimental Section

**Synthesis:** In order to prevent contamination by carbonate ions arising from atmospheric $CO_2$, all procedures were carried out under constant nitrogen flow using freshly decarbonated, deionized water.

**Preparation of $Na_2[Zn(Cit)]\cdot 3H_2O$:** A mixture of ZnO (3.91 g, 0.048 mol) and citric acid monohydrate, $C_6H_8O_7\cdot H_2O$ ($H_4Cit$) (10.09 g, 0.048 mol), was stirred in water (100 mL) until the solids had completely dissolved. The reaction mixture was subsequently stirred overnight at 60 °C. Aqueous sodium hydroxide solution (1.0 M) was added until the pH reached 8.5. After concentration and slow evaporation, a white solid was obtained. The produced solid was redissolved in a water/ethanol mixture, 8:1 (v/v), under mild heating. The derived reaction mixture was allowed to slowly evaporate at room temperature. A few days later, a white crystalline material appeared at the bottom of the flask. The white crystals were isolated by filtration and dried under vacuum. $Na_2[Zn(C_6H_4O_7)]\cdot 3H_2O$ (353.43): calcd. C 20.37, H 2.83, $H_2O$ 15.28, Na 13.02, Zn 18.51; found C 20.58, H 2.56, $H_2O$ 14.87, Na 13.36, Zn 18.93 ($H_2O$ was determined by thermogravimetry as described below). $^{13}C$ MAS NMR: $\delta$ = 47.9 (=$CH_2$), 76.3 (≡CO), 181.3 [$(CO_2)_\beta$], 184.4 [$(CO_2)_\alpha$] ppm.

**LDH-Nitrate Precursor:** $Mg_2Al$-$NO_3$ LDH was prepared by a co-precipitation method at controlled pH as described in the literature.[80] The resulting white precipitate was collected by centrifugation, washed several times, and stored moist under nitrogen. $[Mg_{0.67}Al_{0.33}(OH)_2](NO_3)_{0.31}(CO_3)_{0.01}\cdot 0.47H_2O$ (87.32): calcd. C 0.15, H 3.36, Al 10.24, $H_2O$ 8.66, Mg 18.39, N 4.99; found C 0.15, H 3.25, Al 10.35, $H_2O$ 9.68, Mg 18.70, N 5.18.

**LDH-Zn(Cit):** LDH-Zn(Cit) was prepared starting from the as-synthesized LDH-nitrate without drying the solid. The wet LDH-$NO_3$ (13.75 g, about 10.0 mmol of $NO_3^-$) was suspended in a solution of $Na_2[Zn(Cit)]\cdot 3H_2O$ (14.14 g, 40.0 mmol) in water (100 mL). The mixture was stirred at room temperature for 8 h in nitrogen. The resulting product was separated by centrifugation, extensively washed, and finally air-dried at 65 °C. $[Mg_{0.67}Al_{0.33}(OH)_2]$-$[Zn(C_6H_4O_7)]_{0.16}(CO_3)_{0.01}\cdot 0.58H_2O$ (109.81): calcd. C 10.28, H 3.49, Al 8.16, $H_2O$ 9.76, Mg 14.60, Zn 9.23; found. C 10.44, H 3.47, Al 8.18, $H_2O$ 9.90, Mg 14.62, Zn 9.22. $^{13}C$ MAS NMR: $\delta$ = 47.1 (=$CH_2$), 76.6 (≡CO), 180.1 [$(CO_2)_\beta$], 184.9 [$(CO_2)_\alpha$] ppm. For comparison purposes, the $(C_6H_5O_7)^{3-}$-containing LDH (LDH-HCit) was prepared by an analogous procedure. $[Mg_{0.65}Al_{0.35}$-$(OH)_2](C_6H_5O_7)_{0.11}(CO_3)_{0.01}\cdot 0.57H_2O$ (90.62): calcd. C 8.86, H 4.07, Al 10.40, $H_2O$ 10.13, Mg 17.24; found C 8.81, H 3.94, Al 10.32, $H_2O$ 11.30, Mg 17.12.

**LDH-ZnS-$H_2$Cit:** Powdered LDH-Zn(Cit) samples were treated with gaseous $H_2S$ for 8 h. The sample is denoted LDH-ZnS-$H_2$Cit. $[Mg_{0.67}Al_{0.33}(OH)_2][ZnS]_{0.16}(C_6H_6O_7)_{0.16}(CO_3)_{0.01}\cdot 0.70H_2O$ (117.06): calcd. C 9.70, H 3.71, Al 7.63, $H_2O$ 9.65, Mg 13.70, S 4.19, Zn 8.72; found C 9.98, H 3.58, Al 7.26, $H_2O$ 10.79, Mg 13.07, S 3.97, Zn 8.39. $^{13}C$ MAS NMR: $\delta$ = 44.3 (=$CH_2$), 74.6 (≡CO), 173.4 [$(CO_2)_\beta$], 177.9 [$(CO_2)_\alpha$] ppm.

**LDH-$CO_3$-ZnS:** The reaction of LDH-ZnS-$H_2$Cit with aqueous $Na_2CO_3$ solution was carried out at 60 °C with a tenfold excess of $CO_3^{2-}/Al^{3+}$ for 2 h. The resulting product was separated by centrifugation, extensively washed, and finally air-dried at 65 °C. The sample is denoted LDH-$CO_3$-ZnS.

**Characterization:** Elemental analyses for metals and sulfur were performed by ICP emission spectroscopy using a Shimadzu ICPS-7500 instrument. Carbon, hydrogen, and nitrogen analyses were carried out using an Elementarvario elemental analysis instrument.

The in situ powder X-ray diffraction (in situ XRD) data were recorded with a Shimadzu XRD-6000 powder diffractometer in the temperature range 30–900 °C in air, using Cu-$K_\alpha$ radiation ($\lambda$ = 0.154 nm) at 40 kV and 30 mA. The samples, as unoriented powders, were step-scanned in steps of 5°/min in the $2\theta$ range from 3 to 70° using a count time of 4 s per step. The rate of temperature increase was 10 °C/min with a holding time of 5 min before each measurement.

FTIR spectra of samples in KBr matrix were recorded with a Bruker Vector 22 spectrophotometer in the range 4000–400 $cm^{-1}$. UV/Vis diffuse reflectance spectra were recorded at room temperature with a Shimadzu UV-2101PC instrument with $BaSO_4$ powder as the reference.

$^{13}C$ solid-state magic-angle spinning nuclear magnetic resonance (MAS NMR) spectra were recorded with a Bruker AV300 spectrometer operating at a frequency of 75.467 MHz for $^{13}C$ at a spinning rate of about 4500 Hz with a 5 s pulse delay.

TEM images were obtained with a JEOL 2010 FasTEM at an accelerating voltage of 200 kV. Powder samples were ultrasonically dispersed in ethanol, and the suspension was deposited on a copper grid coated with a holey carbon film.

Thermogravimetric analysis coupled to mass spectrometry was performed using a Perkin–Elmer Diamond TG apparatus linked to a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ThermoStar mass spectrometer by a quartz capillary transfer line heated at 190 °C. The heating rate was 10 °C/min, with an air flow rate of 200 $cm^3$/min. The TG apparatus was at atmospheric pressure, and the mass spectrometer at a working pressure of $6 \times 10^{-6}$ Torr. The mass of sample used was 10 mg in each case.

# Platinum Complexes with One Monodentate Ligand (1-Methylbenzimidazole or Antiviral Ribavirin) Flanked by Two *cis*-$NMe_2$ Groups: Informative Models for Assessing Interligand Interactions

**Leonardo Cerasino,*[a] and Giovanni Natile[a]**

**Keywords:** Platinum / Pentamethyldiethylenetriamine / 1-Methylbenzimidazole / Ribavirin / Interligand interactions

Platinum complexes with a tridentate amine ligand ($A_3$) and a nucleobase (L) represent very useful models for investigating nucleobase/*cis*-amine interactions without the complications arising from nucleobase/nucleobase interferences present in the more frequently used *cis*-$A_2PtL_2$ model systems ($A_2$ = two monodentate amines or a diamine). In this context, the $Me_3$dienPtL complexes ($Me_3$dien = *N1*,*N4*,*N7*-trimethyldiethylenetriamine), previously investigated, were particularly informative. The presence of a methyl group on each terminal nitrogen atom renders the rotation of L about the Pt–L bond slow on the NMR timescale and the two half spaces defined by the coordination plane inequivalent. Thus, guanine and deoxyguanine derivatives were found to have comparable rates of rotation by way of a H-bond interaction between the O6 atom of the rotating guanine and the NH group of the *cis*-amine. We have now extended the investigation to $Me_5$dien complexes ($Me_5$dien = *N1*,*N1′*,*N4*,*N7*,*N7′*-pentamethyldiethylenetriamine). The results indicate that the absence of a proton on the terminal nitrogen atoms not only reduces the rate of rotation of L by a factor of $10^{10}$, but also dramatically increases the difference in the rates between the L ligands mimicking guanine and deoxyguanine.

## Introduction

Cisplatin [*cis*-$PtCl_2(NH_3)_2$] displays exceptional anticancer activity when employed in the treatment of testicular, ovarian, cervical, head and neck, oesophageal, and non-small-cell lung cancers.[1,2] Continued research into the mechanism for the action of cisplatin[3–5] is being carried out in order to understand why it is so extraordinarily effective, especially against testicular cancer, and to allow for the rational design of new derivatives that could overcome the toxic side effects and the resistance to cisplatin of several tumors.

The major DNA adduct formed by cisplatin, the intrastrand cross-link between adjacent G groups, is mimicked by *cis*-$A_2PtG_2$ models, where $A_2$ stands for two monodentate or a bidentate amine and G is a guanine derivative. Models with bulky $A_2$ ligands, designed to reduce the rate of rotation around the Pt–G bonds, have been extensively investigated in our laboratories and have contributed to the elucidation of some relevant features of cisplatin adducts.[6–12] In some instances, in order to investigate the role of nucleotide/*cis*-amine interactions without the complications arising from interactions between *cis*-nucleotides, model compounds containing only one G group have also been constructed.

The most widely used model compound for platinum adducts with just one coordinated purine base is represented by dienPtL (dien = 1,4,7-triazaheptane = diethylenetriamine). *N4*-methyldien, *N1*,*N4*,*N7*-trimethyldien, and *N1*,*N1′*,*N4*,*N7*,*N7′*-pentamethyldien (abbreviated as Medien, $Me_3$dien, and $Me_5$dien, respectively) are systems of increasing steric bulk, which can differently affect the rate of rotation of a purine base about the Pt–N7 bond. All these ligands are nonsymmetrical with respect to the platinum coordination plane. In particular the single Me group on the N4 atom occurs only on one side of the platinum coordination plane. Therefore, coordination of a nonsymmetrical ligand L, such as a purine base, can lead to the formation of two $Me_n$dienPtL conformers differing in the orientation of the purine base with regard to the $Me_n$dien ligand (Scheme 1). The six-membered ring of the purine base and the central *N*-methyl group of $Me_n$dien can be either on the same side (*endo* rotamer) or on opposite sides (*exo* rotamer) of the platinum coordination plane.[13–17]

MedienPtL complexes[18] are very dynamic and the four hydrogen atoms on the terminal nitrogen atoms exert negligible hindrance to the *endo*/*exo* interconversion process; therefore, similar to the case of dienPtL complexes, only one set of signals, which is the coalescence of the sets of signals of the two conformers, is observed in the NMR spectra.[19]

$Me_3$dienPtL complexes represent a case in which the interconversion is sufficiently slow (already at ambient temperature) to be studied by NMR spectroscopic techniques.

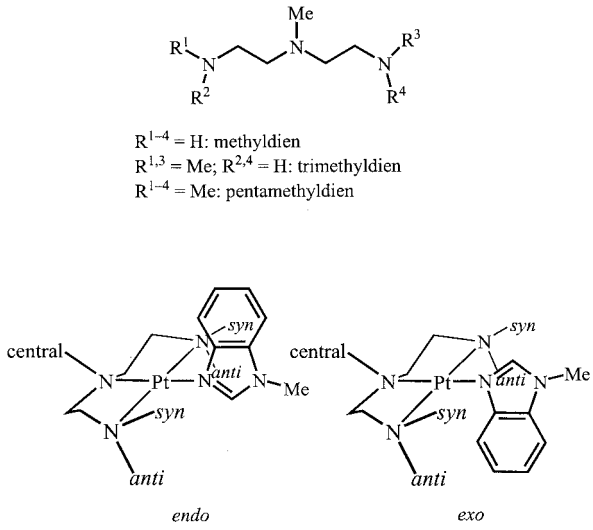


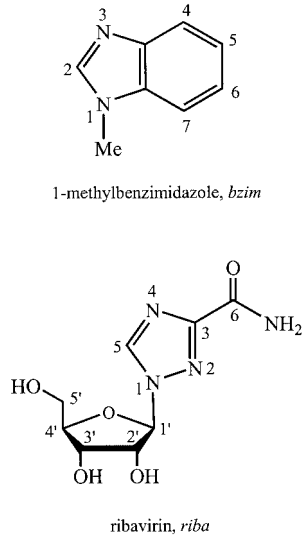
Scheme 1. Schematic view of the $Me_n$dien ligands (top) and of the two possible conformers (*endo* and *exo*) for $Me_5$dienPt(1-methylbenzimidazole) (bottom).

The rate of *endo*/*exo* interconversion has been found to depend upon the nature of the purine derivative investigated, and the factors influencing the rotation around the Pt–L bond have been elucidated.[11–14]

In particular, $Me_3$dienPtL compounds could be prepared in the form that has all three methyl groups of $Me_3$dien on the same side of the platinum coordination plane [*syn*-(*R*,*S*) isomer];[12] moreover, under acidic or neutral conditions no change in ligand configuration could be detected after several days in aqueous solution. $Me_3$dienPtL complexes were found to be the most informative for assessing steric, solvation, and electronic factors influencing stability and dynamic behavior.

A first interesting result of the investigation was the large tendency of a coordinated 5′-nucleotide to place the phosphate group on the same side of the platinum coordination plane as the NH groups of $Me_3$dien; such a conformation allows for phosphate/*cis*-amine H-bonding. Therefore, the *endo* rotamer was the exclusive form in adducts with 5′-GMP, while in adducts with 9-EtG and 3′-GMP, in which such an interaction cannot take place, the *endo* and *exo* rotamers were present in comparable amounts. The effect of the substituent at the 6-position of the purine ring on the rate of rotation about the Pt–N7 bond was also investigated. The rate of interconversion between rotamers was comparable for guanine and deoxyguanine derivatives notwithstanding the greater bulk of the C6 substituent in the guanine complex. In contrast, the rate of rotation was far slower for the adenine derivative although the bulk of the C6 substituent is comparable for adenine and guanine. Activation parameters for rotation suggest that an attractive interaction between the negatively charged O6 atom of the guanine (an H-bond acceptor) and the positively charged *N*-hydrogen atom of the *cis*-amine (an H-bond donor) could lower the rotational barrier and render the rate of rotation of guanine only one order of magnitude slower than that of deoxyguanine. Finally, in the case of adenine derivatives in which the substituent at the 6-position of the purine ring is bulky and positively charged (as positively charged as the *N*-hydrogen atoms of the triamine) the barrier to rotation could be expected to be far greater than that observed for guanine and deoxyguanine derivatives with the consequence that the interconversion between rotamers becomes very slow.

In order to prove further the correctness of the explanation given above, we extended the investigation to fully methylated dien derivatives ($Me_5$dienPtL compounds) lacking protons on the terminal aminic groups. Some $Me_5$dienPtL complexes have already been investigated (L = a guanine derivative such as 9-EtG, guanosine, 5′-dGMP, 5′-GMP,[11] and penciclovir,[10] or a deoxyguanine such as famciclovir[10]); however, in none of the cases was it possible to observe an interconversion between rotamers and the *endo*/*exo* ratio was in the range 0.6–1 in the case of the guanine derivatives and ca. 2 in the case of the deoxyguanine derivative. We therefore looked at other N-donor heterocycles that could mimic guanine and deoxyguanine derivatives but be more reactive and allow for the detection of a kinetically controlled composition, which could possibly be different from that at thermodynamic equilibrium. The search has been successful. We found two bases (Scheme 2), 1-methylbenzimidazole (bzim) and 1-D-ribose-1*H*-[1,2,4]triazole-3-carboxamide (ribavirin, riba) for which the reaction was completed in 2 d at ambient temperature. Moreover, the initially formed rotamer composition appears to be under kinetic control (*endo*/*exo* ratio of 7–8) and in one case (bzim) it has been possible to measure the rate of isomerization to the thermodynamically controlled composition and to evaluate the activation parameters.



Scheme 2. Structures and numbering schemes for the two ligands L used in this work.

New insights into steric, electronic, and solvation factors influencing the dynamic behavior of these model compounds have been gained.

## Results

### $Me_5$dienPt(bzim)

The reaction of $[Pt(Me_5dien)(NO_3)](NO_3)$ with bzim was complete after 48 h at room temperature. In the $^1H$ NMR spectrum two sets of signals of very different intensities (ca. 8:1) were detected. For each set of signals the resonance at the lower field belongs to H2 and reveals a downfield shift with respect to the corresponding signal for the free bzim of ca. 0.8 ppm. This is a clear indication that both sets of signals belong to complex species in which bzim is *N3*-coordinated to the platinum atom. Therefore, most likely, the two sets of signals arise from the presence of two conformers, *endo* and *exo* (Table 1).

A 2D NOESY experiment showing connectivities between bzim protons and *N*-Me protons of $Me_5$dien enabled the assignment of the two sets of signals to the corresponding conformers (Figure 1). Previous investigations on strictly related compounds have demonstrated that *syn*-*N*-Me signals of $Me_5$dien are always at a higher field with respect to *anti*-*N*-Me signals and the latter are at a higher field with respect to the central *N*-Me signals.[13–17]

The major conformer exhibits intense NOE crosspeaks between bzim-H2 and *anti*-*N*-Me groups of $Me_5$dien and between bzim-H4 and *syn*-*N*-Me groups of $Me_5$dien, therefore it is identified as the *endo* rotamer (the six-membered ring of bzim is on the same side of the platinum coordination plane as the central *N*-Me group of $Me_5$dien). Consequently, the minor form is identified as the *exo* rotamer (the six-membered ring and the central *N*-Me group are on opposite sides of the platinum coordination plane). A common feature of the $Me_n$dienPtL compounds is a signal for the L proton adjacent to the coordinating nitrogen atom,

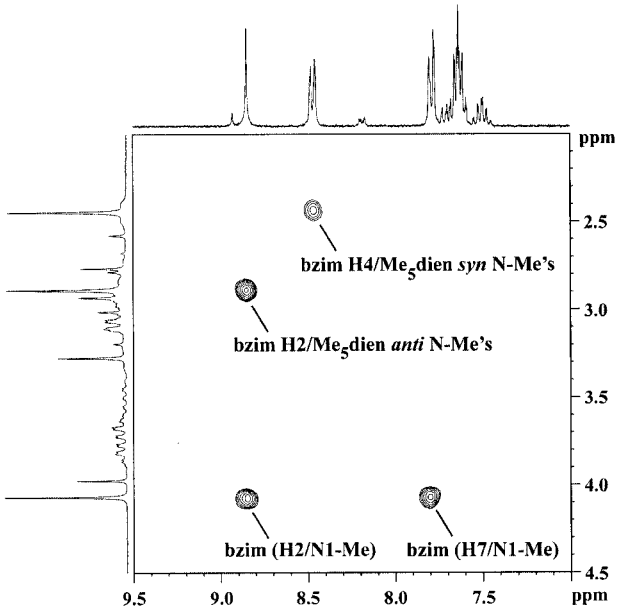

Figure 1. 2D NOESY spectrum of $Me_5$dienPt(bzim). All crosspeaks belong to the major set of signals that result from the *endo* conformer. The second set of signals has intensities that are too weak to generate observable crosspeaks, and, by exclusion, it is assigned to the *exo* rotamer.

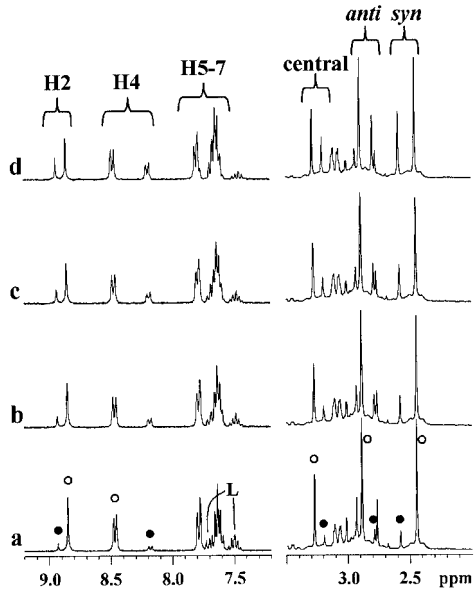

Figure 2. $^1H$ NMR spectra of $Me_5$dienPt(bzim) after standing for different times in $D_2O$ solution at 353 K (a, b, c, and d correspond to 0, 1800, 3600, and 12000 s, respectively). The signals of the bzim aromatic protons fall in the region δ = 9–7 ppm, while the $Me_5$dien protons fall in the region δ = 4–2 ppm. The intensity of the aromatic proton signals is increased by a factor of two with respect to the intensity of the aliphatic proton signals. Peaks labeled with ○ belong to the *endo* rotamer, peaks labeled with ● belong to the *exo* rotamer, and peaks labeled with L belong to unreacted bzim.

Table 1. Chemical shift values (ppm) for the $Me_5$dienPtL complexes (L = riba or bzim), and the starting $[Pt(Me_5dien)(D_2O)]^{2+}$, bzim, and riba compounds. The sugar protons of $Me_5$dienPt(riba) not listed in the table underwent rather small chemical shift changes (values for free riba are given in parenthesis): H2′ 4.75 (4.66), H3′ 4.46 (4.50), H4′ 4.30 (4.22), H5′/5′′ 3.91/3.76 (3.87/3.76).

more shielded in the *endo* rotamer than in the *exo* rotamer.[13,14,16,17]

The 8:1 ratio between rotamers reflects a kinetic rather than a thermodynamic preference for the *endo* form. As a matter of fact, with time, the *endo*/*exo* ratio decreases until a constant value (representing the thermodynamic equilibrium) is reached (Figure 2). The rate of isomerization is very slow at room temperature, requiring weeks; however, it can be increased by increasing the temperature. In order to evaluate the activation parameters ($\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$), the rates of isomerization were measured at different temperatures in the range 323–363 K (Table 2).

The $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values for the rate of isomerization of the *endo* ($k_{endo}$) and *exo* ($k_{exo}$) conformers were found to be almost identical ($\Delta H^{\ddagger} = 118 \pm 9$ and $119 \pm 9$ kJ mol$^{-1}$ for the *endo* and *exo* rotamers, respectively; and $\Delta S^{\ddagger} = 15 \pm 20$ J K$^{-1}$ mol$^{-1}$), indicating that the two rotamers have very similar ground-state enthalpy and entropy values (Table 3).

Table 3. Collection of activation enthalpies ($\Delta H^{\ddagger}$ [kJ mol$^{-1}$]) and entropies ($\Delta S^{\ddagger}$ [J K$^{-1}$ mol$^{-1}$]) for interconversion between rotamers in $Me_{3/5}$dienPtL complexes. Standard deviations are given at the 95% confidence limit.

[a] Penciclovir = 9-[4-hydroxy-3-(hydroxymethyl)but-1-yl]guanine.[17] [b] 9-EtG = 9-ethylguanine.[16] [c] Deoxypenciclovir = 6-deoxy-9-[4-hydroxy-3-(hydroxymethyl)but-1-yl]guanine.[17]

### $Me_5$dienPt(riba)

The reaction of [Pt($Me_5$dien)($NO_3$)]($NO_3$) with riba was also complete after 48 h at room temperature. Two sets of signals (intensity ratio 7:1) were observed. For both sets of signals the chemical shift of the aromatic proton of riba (H5) is more than 1 ppm at a lower field with respect to the corresponding signal for the free ligand indicating that in both cases the riba ligand is *N4*-coordinated to the platinum atom. Therefore, the two sets of signals have to be ascribed to two conformers, most likely the *endo* and *exo* rotamers (Table 1).

As in the the case of bzim, a 2D NOESY experiment enabled the assignment of the two sets of signals to the corresponding conformers. In particular, the presence of a crosspeak between the riba H5 proton and the *anti*-*N*-Me signal of $Me_5$dien for the more intense set of signals indicates that in this case the major rotamer also has the *endo* conformation (Figure 3). No isomerization was observed for this compound, even after prolonged heating at 363 K.

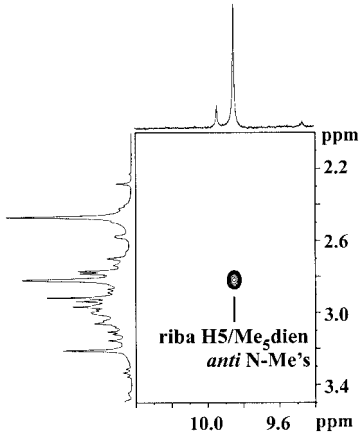

Figure 3. 2D NOESY spectrum of $Me_5$dienPt(riba). The crosspeak belongs to the major set of signals and this set is assigned to the *endo* rotamer. The second set of signals has intensities that are too weak to generate observable crosspeaks and, by exclusion, it is assigned to the *exo* rotamer.

## Discussion

In Table 3 we compare the activation parameters for rotamer interconversion in the series of $Me_{3/5}$dienPtL complexes investigated so far. In the case of $Me_3$dien complexes the most remarkable difference was between the guanine

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and deoxyguanine derivatives. The enthalpy of activation was ca. 50 $kJ\,mol^{-1}$ higher in the case of the deoxyguanine derivative, notwithstanding the fact that deoxyguanines carry a much smaller group (H) in the 6-position of the purine ring as compared to guanines for which the substituent at the 6-position is much bulkier (O). We argued that in the transition state (in which the purine base is dragged through the platinum coordination plane) the O6 atom of the guanine ligand (negatively charged) and the *N*-hydrogen atom of the *cis*-amine (positively charged) can give rise to an attractive interaction which helps in lowering the rotational barrier. In contrast, in the case of deoxyguanine derivatives, both the purine H6 and the *cis*-amine *N*-hydrogen atom carry a partial positive charge; therefore, the electrostatic repulsion between the two positively charged moieties, when coming close to one another, would increase the rotational barrier, notwithstanding the small size of H6 as compared to O6 of guanine. In the case of deoxyguanine the greater enthalpy of activation is also accompanied by a rather large entropy of activation (average $170 \pm 4$ as compared to $-18 \pm 4\ J\,mol^{-1}\,K^{-1}$ for guanine derivatives). We suggested that, in the presence of an electrostatic repulsion between the two groups, there could be a large desolvation process (particularly of the amine groups) with the consequent release of water molecules and increase of activation entropy. The explanation given for the $Me_3$dien derivatives is fully confirmed by the behavior of the $Me_5$dien derivatives reported in this paper. The major difference between $Me_3$dien and $Me_5$dien derivatives is the absence, in the latter case, of positively charged *N*-hydrogen atoms on the *cis*-amine groups. In principle, there could also be a change in steric bulk of the terminal amines (an additional methyl group attached to each terminal nitrogen atom in the case of $Me_5$dien); however, such a change in steric bulk could be rather small. It has been widely demonstrated that the rotation of a coordinated purine base is mainly affected by substituents on the *cis*-amine, which have "quasi-equatorial" character, and $Me_3$dien and $Me_5$dien both have one "quasi-equatorial" methyl group on each terminal nitrogen atom.[14]

The $Me_5$dienPt(bzim) complex has an activation enthalpy for rotamer interconversion that is very similar to that observed for the $Me_3$dienPt(deoxyguanine) derivative. The stereochemistry of the H4 proton of bzim is coincident with that of the H6 proton of deoxyguanines; therefore, it is expected to generate a similar steric interaction with the "quasi-equatorial" *N*-Me group on the *cis*-amine, while it is dragged through the platinum coordination plane. Accordingly, the measured $\Delta H^{\ddagger}$ value for rotation is very similar for $Me_3$dienPt(deoxyguanine) and $Me_5$dienPt(bzim) complexes. In contrast, the $\Delta S^{\ddagger}$ value was much greater for $Me_3$dienPt(deoxyguanine) (average $170 \pm 4\ J\,K^{-1}\,mol^{-1}$) than for $Me_5$dienPt(bzim) (average $15 \pm 20\ J\,K^{-1}\,mol^{-1}$). The large value of $\Delta S^{\ddagger}$ for the former complex was explained by a desolvation (particularly of the amine NH group) taking place in the transition state; such a desolvation cannot occur in the $Me_5$dienPt(bzim) complex lacking amine *N*-hydrogen atoms.

The rate of interconversion was found to be extremely low for the $Me_5$dienPt(riba) complex in which the riba ligand has the O6 substituent stereochemically equivalent to the O6 atom of a guanine group. In the case of $Me_3$dienPt(guanine) derivatives the $\Delta H^{\ddagger}$ value for rotamer interconversion was found to be lowered by an electrostatic attraction between the negatively charged O6 atom and the positively charged *N*-hydrogen atom of the *cis*-amine. Such an interaction cannot take place in the $Me_5$dienPt(riba) complex lacking amine *N*-hydrogen atoms. Therefore, contrary to the case of $Me_3$dienPtL derivatives (for which the $\Delta H^{\ddagger}$ value was significantly lower for guanine as compared to deoxyguanine derivatives), $Me_5$dienPtL compounds are expected to have a much larger $\Delta H^{\ddagger}$ value for guanine-type derivatives (like the riba complex) having a bulkier substituent at the C6 position than for deoxyguanine-type derivatives (like the bzim complex) having a small proton at the C6 position. This fully explains the much slower rate of rotation observed in $Me_5$dienPt(riba) as compared to $Me_5$dienPt(bzim).

## Conclusions

This investigation has highlighted two features of $Me_5$dienPtL compounds (a kinetic preference for the *endo* rotamer and a rate of rotation depending upon the substituent at the *peri* position with respect to the coordinated L nitrogen atom) that further contribute to deepening our understanding of interactions between a rotating platinum(II)-coordinated ligand L and *cis*-amine groups. For the first time in $Me_n$dienPtL complexes, it has been shown that the kinetically preferred product has the bulkier portion of the ligand L on the sterically less hindered side of the platinum coordination plane (that is the side where the "quasi-equatorial" *N*-methyl substituents are located). In the case of $Me_3$dienPtL derivatives, the rate of rotamer interconversion was too fast to enable the observation of the kinetically controlled composition.

The investigation of rotamer interconversion in the case of $Me_5$dienPt(bzim) has fully confirmed the previous observation that an amine proton can play a key role in modulating the rate of rotation of a *cis* ligand, also in the case in which an alkyl substituent is attached to the same nitrogen atom (as in the case of $Me_3$dienPtL compounds). The presence of such a proton can increase the rate of L rotation by 10 orders of magnitude [compare the rates of rotation of L in $Me_3$dienPt(deoxyguanine)[17] and in $Me_5$dienPt(bzim)] and can greatly reduce the difference in the rate of rotation between ligands L having a bulky oxygen atom or a small proton substituent in the *peri* position with respect to the coordinated nitrogen atom. Therefore, for $Me_3$dienPtL complexes the rate of rotation is only ten times smaller in guanine than in deoxyguanine derivatives (at ambient temperature), while for $Me_5$dienPtL derivatives the rate is far smaller in the case of riba (mimicking a guanine) than in the case of bzim (mimicking a deoxyguanine).

Recent results from studies on oligomers led to the hypothesis that the very small size of the NH group, and not its hydrogen-bonding ability, is responsible for the good activity exhibited by antitumor Pt compounds with amine carrier ligands bearing multiple NH protons.[7,8,22] In contrast, for amines lacking NH groups, bulky substituents projecting out of the coordination plane could clash with neighboring nucleobases. Since the biological activity of cisplatin is widely considered to be associated with a definite arrangement of the nucleic bases (guanines in first place) linked by the metal center,[6–12] the lack of significant biological activity for platinum complexes bearing bulky ligands can be attributed to the conformational restrictions that the coordinated bases are subjected to in these compounds. On the other hand, it has been recently demonstrated that platinum complexes with specially designed bulky ligands can sort out other interesting effects in the case of coordination to single-strand oligonucleotides.[23] In particular, the negatively charged phosphate groups of the oligonucleotide are no longer able to wrap around the positively charged metal core with the consequence of favoring the hybridization of the oligonucleotide with the complementary strand and tightening the double-strand form. Therefore, we can envisage a possible employment of the platinum complex with $Me_5$dien in the modification of single-strand oligonucleotides to be used in antisense and antigene therapy.

## Experimental Section

**Materials:** [Pt($Me_5$dien)($NO_3$)]($NO_3$) was prepared as previously described.[20] Bzim was purchased from Sigma–Aldrich, riba was a gift from Joze Kobe of the Institute of Chemistry of Ljubljana, Slovenia.

**Preparation of the Adducts:** Solutions of the adducts were prepared by treatment of [Pt($Me_5$dien)($NO_3$)]($NO_3$) (5 mM solution in $D_2O$) with a stoichiometric amount of ligand. The reactions were monitored by $^1$H NMR spectroscopy. When the reaction was complete, the pD of the solution was found to be 7.2 in the case of both bzim and riba.

**NMR Spectroscopy:** Spectra were collected in $D_2O$ at 298 K with a Bruker DPX 300 MHz spectrometer. $^1$H NMR chemical shifts were referenced to internal TSP. For 2D NOESY experiments a standard pulse program with gradient pulses during the mixing time was used. 2048 complex points in the direct detection dimension and 256 in the indirect dimension were collected. A 3000 Hz spectral width was used in both dimensions with a 500 ms mixing time. Chemical shift values are reported in Table 1.

**Kinetic Measurements:** NMR tubes containing solutions of the bzim adduct were sealed and kept at a fixed temperature in a water bath. $^1$H NMR spectra were taken from time to time by collecting 64 scans. Selected nonexchangeable proton signals were integrated and used to determine the relative abundance of the two rotamers. Equilibrium was considered reached when the changes in signal intensities became negligible (after a time that was five-fold larger than the estimated half life at a given temperature). The kinetic constants were determined at six different temperatures covering a range of 40° (323, 333, 343, 348, 353, and 363 K). At equilibrium the *exo*/*endo* ratio ($K$) was found to be rather constant (comprised between 0.56 and 0.60). The kinetic equation for the $endo \underset{k_{exo}}{\overset{k_{endo}}{\rightleftarrows}} exo$ process has the following expression:

$$\ln \frac{KC^{t}_{endo} - C^{t}_{exo}}{KC^{0}_{endo} - C^{0}_{exo}} = -(k_{endo} + k_{exo})t$$

[in which $k_{endo}$ and $k_{exo}$ are the kinetic constants for the *endo* → *exo* and the *exo* → *endo* conversions, respectively; $K = (C^{\infty}_{exo}/C^{\infty}_{endo}) = (k_{exo}/k_{endo})$ is the equilibrium constant; $C^t$, $C^0$, and $C^\infty$ are the concentrations of a given rotamer (*endo* or *exo*) at time $t$, at time 0, and at equilibrium]. The graphical representation of the logarithmic term as a function of time (Figure 4) corresponds to a straight line whose slope gives $k_{endo} + k_{exo}$. From the values of $k_{endo}/k_{exo}$ (corresponding to the equilibrium constant $K$) and of $k_{endo} + k_{exo}$ (kinetically determined) the individual $k_{endo}$ and $k_{exo}$ constants

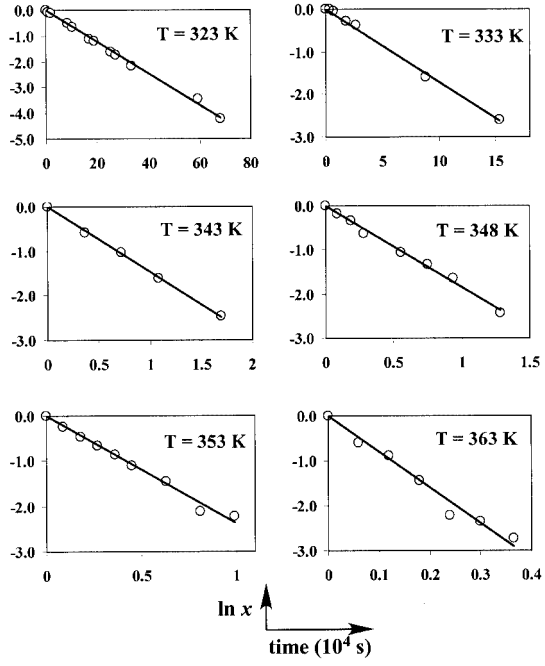

Figure 4. Plots of $\ln x$ {$x = [(KC^t_{endo} - C^t_{exo})/(KC^0_{endo} - C^0_{exo})]$} as a function of time for the isomerization of $Me_5$dienPt(bzim) at different temperatures.

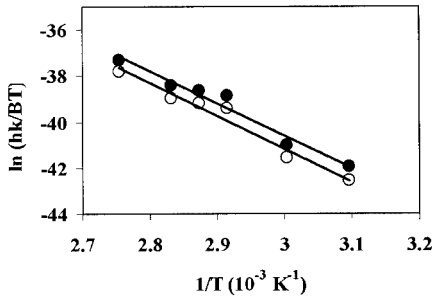

Figure 5. Plots of $\ln(h/B)\cdot(k/T)$ as a function of $1/T$ for the *endo* → *exo* (○) and *exo* → *endo* (●) interconversion of $Me_5$dienPt(bzim). According to the Eyring equation, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ can be derived from the slope $[(\Delta H^{\ddagger})/R]$ and intercept $[(\Delta S^{\ddagger})/R]$ of the straight line fitting the experimental points.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

could be determined. Enthalpies and entropies of activation ($\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$) were estimated (for direct and inverse reactions) from plots of $\ln(h/B)\cdot(k/T)$ vs. $1/T$ (Figure 5), according to the Eyring equation:

$$\ln\frac{h}{B}\frac{k}{T} = -\frac{\Delta H^{\#}}{RT} + \frac{\Delta S^{\#}}{R}$$

[$k$ = kinetic constant ($k_{endo}$ or $k_{exo}$) at temperature $T$; $h$, $B$, and $R$, are the Planck, Boltzmann, and gas constants, respectively].[21] Values of $C_{endo}/C_{exo}$ at different time intervals for a given temperature together with the estimated values of $K$, $k_{endo}$, and $k_{exo}$ are reported in Table 2. Activation parameters are reported in Table 3.

## Acknowledgments

# Methoxyphenyl-Functionalized Diiron Azadithiolates as Models for the Active Site of Fe-Only Hydrogenases: Synthesis, Structures, and Biomimetic $H_2$ Evolution

**Li-Cheng Song,*[a] Jian-Hua Ge,[a] Xiao-Guang Zhang,[a] Yang Liu,[a] and Qing-Mei Hu[a]**

**Keywords:** Biomimetic chemistry / Diiron azadithiolate / Iron-only hydrogenases / Structural elucidation / Catalytic $H_2$ evolution

A series of methoxyphenyl-functionalized diiron azadithiolate (ADT) complexes, [{(μ-$SCH_2$)$_2$N($C_6H_4$OMe-*p*)}$Fe_2(CO)_5$L] [L = CO (**2**); $PPh_3$ (**3**); $PPh_2H$ (**4**)] and [{(μ-$SCH_2$)$_2$N-($C_6H_4$OMe-*p*)}$Fe_2(CO)_4(CN)_2$][$Et_4N$]$_2$ (**5**) as the active site models of Fe-only hydrogenases has been investigated. While model **2** was prepared in 67 % yield by a condensation reaction of *N*,*N*-bis(chloromethyl)-*p*-methoxyaniline (**1**) with [(μ-LiS)$_2Fe_2(CO)_6$], models **3**–**5** were prepared in 49–75 % yields by a CO substitution reaction of **2** with $PPh_3$, $PPh_2H$, or $Et_4NCN$, respectively. The X-ray crystal structures of **2** and **3** revealed that the methoxyphenyl substituent is attached to the N atom by an axial bond and the nitrogen lone electron pair in an equatorial position. On the basis of cyclic voltammetric studies of **2** and **4**, it was found that **2** is a catalyst for proton reduction, and an EECC mechanism is proposed for such electrocatalytic $H_2$ production catalyzed by the ADT-type models.

## Introduction

Hydrogen evolution and uptake in the biological energy cycle is mostly catalyzed by two types of metalloenzymes: Fe-only hydrogenases and NiFe hydrogenases.[1,2] Fe-only hydrogenases (hereafter referred to as FeHases) have recently received much more attention than NiFe hydrogenases, primarily owing to their much higher efficiency than NiFe hydrogenases in the production of hydrogen,[3] a clean and highly efficient fuel. The high-quality crystal structures of FeHases isolated from *C. pasteurianum* and *D. desulfuricans* have indicated[4] that the active site of FeHases (so-called H cluster) comprises a butterfly 2Fe2S cluster with one of the Fe atoms linked to a cuboidal 4Fe4S cluster through the S atom of a cysteinyl ligand. There are also three other ligands, namely CO, $CN^-$, and dithiolate coordinated to Fe atoms of the butterfly 2Fe2S cluster (Scheme 1). It is noteworthy that the dithiolate ligand bridged between the two iron atoms of the 2Fe2S cluster was recently suggested as an azadithiolate (ADT) $SCH_2NHCH_2S$,[5] in which the bridgehead N atom plays an important role for the heterolytic cleavage or formation of $H_2$ in the enzymatic process.[6] In spite of the biological importance of the bridgehead N atom in the H cluster, the synthetic and functional studies regarding azadithiolate (ADT) model complexes[7] have been much less investigated than diiron 1,3-propanedithiolate (PDT) model compounds.[8] So far, the PDT-type models [(μ-H)(μ-PDT)$Fe_2(CO)_4(L)_2]^+$ (L = $Me_3P$, *t*BuNC) have been reported to be catalysts for H/D exchange reactions.[9] In addition, the PDT- and ADT-type models [(μ-PDT)$Fe_2(CO)_4(CN)(Me_3P)]^-$,[10] [(μ-PDT)$Fe_2$-$(CO)_4L_2$] (L = CO, $Me_3P$),[11] and [{(μ-$SCH_2$)$_2$N(*p*-$BrC_6H_4CH_2$)}$Fe_2(CO)_6$][12] have been demonstrated to be catalysts for proton reduction to $H_2$ under electrochemical conditions. To further develop the biomimetic chemistry of FeHases, we initiated a study on the synthesis, structures and properties of a new series of diiron ADT-type model complexes, in which some substituents are attached to the N atom and Fe atoms in the diiron ADT framework [{(μ-$SCH_2$)$_2$N}$Fe_2(CO)_n$] (*n* = 4, 5). Herein we report our results obtained from this study.

## Results and Discussion

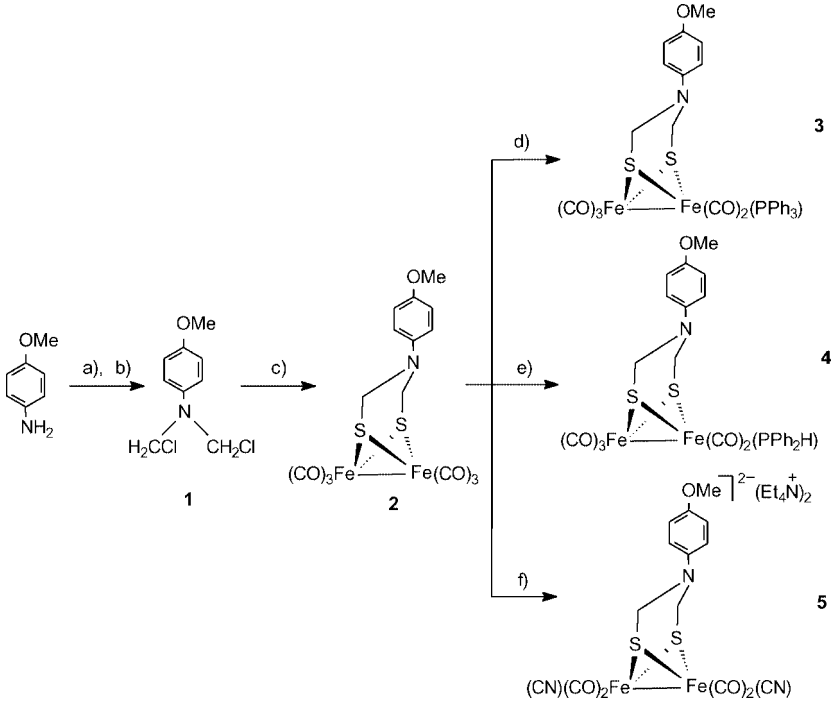
### Synthesis and Spectroscopic Characterization of Compounds 1–5

The synthetic methods for our target compounds **2**–**5** and their precursor **1** are based on those previously reported by Rauchfuss[13] and the well-known CO substitution reactions with various 2e ligands[14] (Scheme 2). Treatment of *p*-methoxyaniline with paraformaldehyde in $CH_2Cl_2$ at room temperature followed by treatment with an excess of $SOCl_2$ gave *N*,*N*-bis(chloromethyl)-*p*-methoxyaniline (**1**) in 91% yield. Further reaction of **1** with lithium salt $[(\mu\text{-}LiS)_2Fe_2(CO)_6]$ {generated in situ from $[(\mu\text{-}S)_2Fe_2(CO)_6]$ and $Et_3BHLi$ in THF at –78 °C}[15] afforded the ADT-type model **2** in 67% yield. Models **3**–**5** could be prepared in 49–75% yields through CO substitution reactions of **2** in MeCN with $PPh_3$ in the presence of the decarbonylating agent $Me_3NO$, with $PPh_2H$ in toluene at reflux, or with $Et_4NCN$ in MeCN from 0 °C to room temperature, respectively.

Compounds **1**–**5** have been characterized by elemental analysis and IR and $^1H$ NMR spectroscopy. The $^1H$ NMR spectra of **1**–**5** each show a singlet at $\delta \approx 3.7$ ppm for their MeO groups and an AB quartet between $\delta = 6.5$ and 7.2 ppm for their *para*-disubstituted $C_6H_4$ benzene rings. While precursor **1** displays a singlet at $\delta = 5.44$ ppm for its $CH_2$ groups, **2** exhibits a singlet, **3** two doublets, **4** a multiplet, and **5** a singlet for their $CH_2$ groups at a relatively higher field. In addition, the IR spectra of **2**–**5** show three absorption bands around 2000 $cm^{-1}$ for their terminal carbonyl groups and the $\tilde{\nu}(C{\equiv}O)$ values of **3**–**5** are markedly shifted towards lower frequencies relative to those of their parent complex **2**. It follows that the $PPh_3$, $PPh_2H$, and $CN^-$ ligands in **3**–**5** are all stronger electron-donating ligands than CO.[16]

### Crystal Structures of Compounds 2 and 3

The structures of **2** and **3** have been unambiguously confirmed by X-ray crystal diffraction analysis. ORTEP diagrams of **2** and **3** are given in Figures 1 and 2, and Tables 1 and 2 list selected bond lengths and angles, respectively. Models **2** and **3**, as illustrated in Figures 1 and 2, indeed consist of a *p*-methoxyphenyl-substituted azadithiolate group that is bridged between two iron atoms to form a butterfly 2Fe2S cluster. The Fe–Fe bond of **3** [2.554(2) Å] is longer than those of **2** [2.5076(16) Å], $[\{(\mu\text{-}SCH_2)_2\text{-}NMe\}Fe_2(CO)_6]$ [2.4924(7) Å][7a] and $[(\mu\text{-}PDT)Fe_2(CO)_6]$ [2.5103(11) Å],[17] but somewhat shorter than those in the structures of enzymes *C. pasteurianum* and *D. desulfuricans* (ca. 2.6 Å).[4] The sum of the C–N–C angles around the N atom is 354.8° for **2** and 355.9° for **3**. This means that the p–π conjugation exists between the substituted benzene ring and the p-orbital of the bridgehead N atom, although it is weakened because the N atom is slightly deviated from the plane defined by the N(1), C(7), C(8), and C(9) atoms (for **2**) or by the N(1), C(24), C(25), and C(26) atoms (for **3**). Both **2** and **3** contain two fused six-membered rings: N(1)-C(7)S(1)Fe(2)S(2)C(8) and N(1)C(7)S(1)Fe(1)S(2)C(8) for **2**; N(1)C(24)S(1)Fe(1)S(2)C(25) and N(1)C(24)S(1)Fe(2)-S(2)C(25) for **3**. The former six-membered ring in **2** or **3** is in a chair conformation, while the latter ring in **2** or **3** is in a boat conformation. It should be noted that the phenyl group attached to the N(1) atom of **2** and **3** resides in an



Scheme 2. (a) $(CH_2O)_n$, $CH_2Cl_2$, room temp.; (b) $SOCl_2$, room temp.; (c) $[(\mu\text{-}LiS)_2Fe_2(CO)_6]$, THF, –78 °C; (d) $PPh_3$, $Me_3NO$, MeCN, room temp.; (e) $PPh_2H$, toluene, reflux; (f) $Et_4NCN$, MeCN, 0 °C.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

axial position and the nitrogen lone electron pair is in an equatorial position. In fact, such a conformation is also observed in other phenyl-substituted ADT-type models.[7c] Furthermore, the $PPh_3$ ligand in **3** is in an axial position of the square-pyramidal geometry of the Fe(1) atom and *trans* to the substituted benzene ring in order to reduce the steric repulsion between these two bulky structural units.

### Electrochemistry of Compounds 2 and 4

The electrochemical behavior of the representative models **2** and **4** was studied in MeCN by cyclic voltammetric techniques. Table 3 lists their electrochemical data, and Figures 3 and 4 show their cyclic voltammograms, respectively.

Table 3. Electrochemical data of **2** and **4**.[a]

| Compound | $E_{pc}$ | $E_{pa}$ [V] | $E_{pa}$ | $E_{pc}$ [V] |
|---|---|---|---|---|
| **2** | –1.61 | –1.48 | +0.48 | – |
| | –2.10 | – | +0.81 | – |
| **4** | –1.78 | –1.50 | +0.26 | – |
| | –2.22 | – | +0.49 | – |

[a] All potentials in Table 3 are vs. $Fc/Fc^+$.

It has been demonstrated that **2** displays one quasi-reversible reduction, one irreversible reduction and two irreversible oxidations, whereas **4** exhibits two irreversible reductions and two irreversible oxidations. The first and second reduction peaks of **2** (–1.61 V, –2.10 V) and **4** (–1.78 V, –2.22 V) can be assigned to the one-electron reduction processes from $Fe^IFe^I$ to $Fe^IFe^0$ and $Fe^IFe^0$ to $Fe^0Fe^0$ (supported by bulk electrolysis). Similarly, the first and second oxidation peaks of **2** (+0.48 V, +0.81 V) and **4** (+0.26 V, +0.49 V) should be attributed to the one-electron oxidation processes from $Fe^IFe^I$ to $Fe^IFe^{II}$ and $Fe^IFe^{II}$ to

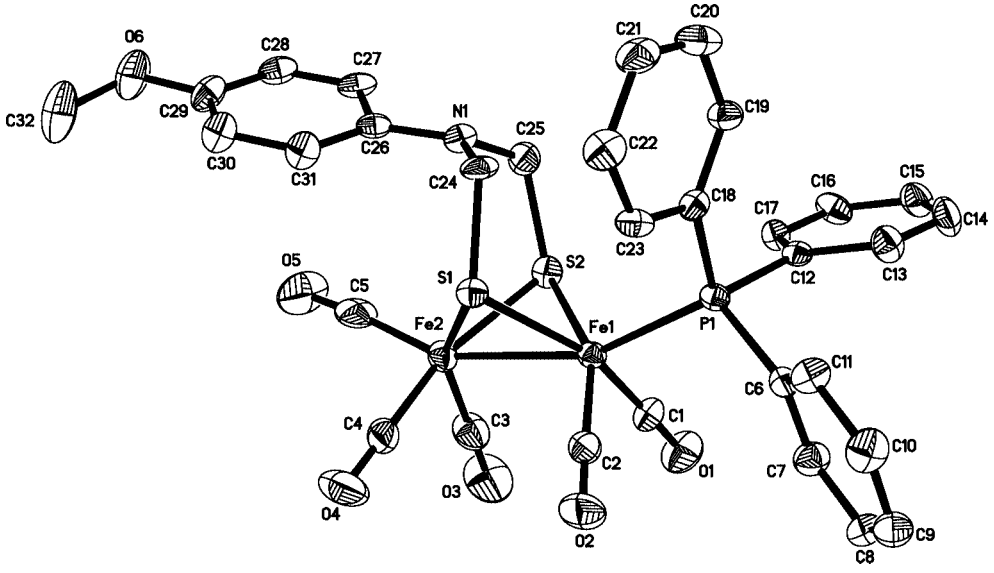

Figure 2. ORTEP view of **3** with 30% probability level ellipsoids.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

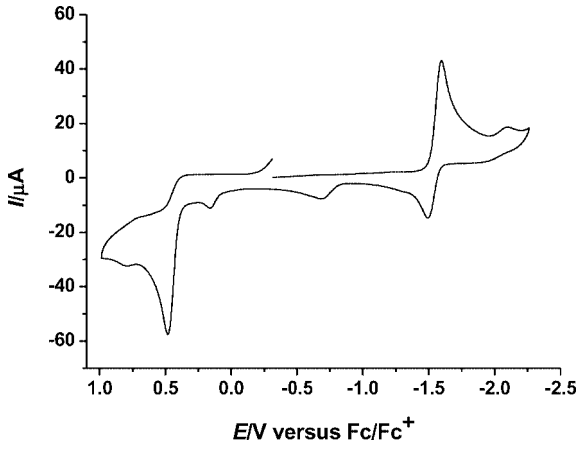

Figure 3. Cyclic voltammogram of **2** (1 mM) in 0.1 M $nBu_4NPF_6$/MeCN at a scan rate of 100 $mVs^{-1}$.

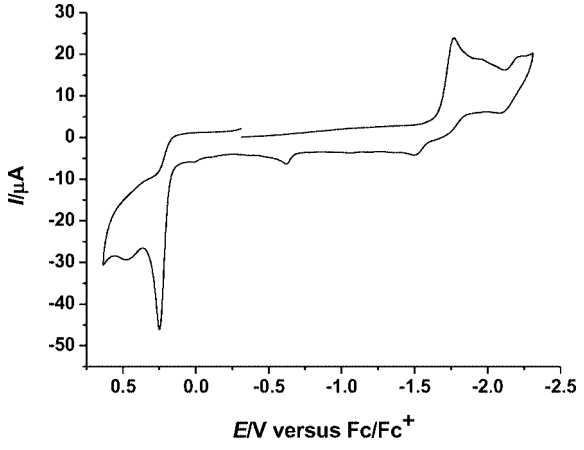

Figure 4. Cyclic voltammogram of **4** (1 mM) in 0.1 M $nBu_4NPF_6$/MeCN at a scan rate of 100 $mVs^{-1}$.

$Fe^{II}Fe^{II}$, respectively. It can be seen that the reduction and oxidation peaks of **4** (Figure 4) are apparently shifted towards more negative potentials than those corresponding to **2**. This is consistent with the substituent $PPh_2H$ being a stronger electron-donating ligand than CO. Actually, the electrochemical behavior described above resembles that displayed by those reported for ADT-, PDT-, and ODT-(oxadithiolate)-bridged analogs.[10–12,18]

We further studied the electrochemical behavior of model **2** by cyclic voltammetric techniques in the presence of HOAc (0–10 mM) in MeCN. As shown in Figure 5, the current intensity of the initial first peak at –1.61 V slightly increased when the first amount of HOAc (2 mM) was added, but it did not increase further with sequential increments of the acid concentration. However, when the first 2 mM HOAc was added, the initial second peak at –2.10 V grew considerably and increased linearly with increasing acid concentration. It is evident that such cyclic voltammetric behavior features an electrocatalytic proton reduction process.[10–12,18–21] This catalytic process was further confirmed by electrolysis of a MeCN solution of **2** (0.33 mM) with excess HOAc (6.6 mM) at –2.18 V (Figure 6). The initial rate of electrolysis is more than twice as much as it is in the absence of the catalyst. A total of 10.2 F/mol passed in 0.5 h, which corresponds to 5.1 turnovers. In such a large-scale experiment, $H_2$ evolution could clearly be seen. Gas chromatographic analysis showed that the hydrogen yield was about 90%.

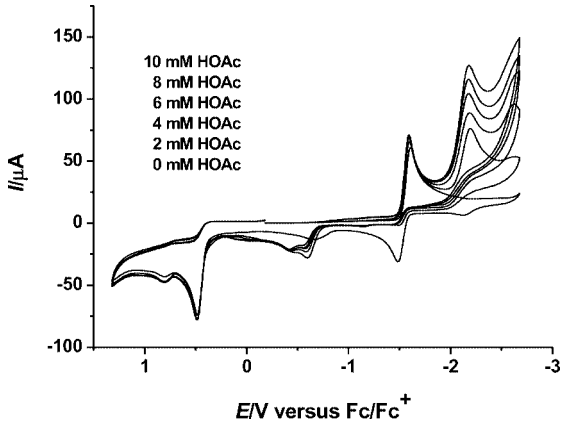

Figure 5. Cyclic voltammogram of **2** (1.0 mM) with HOAc (0–10 mM).

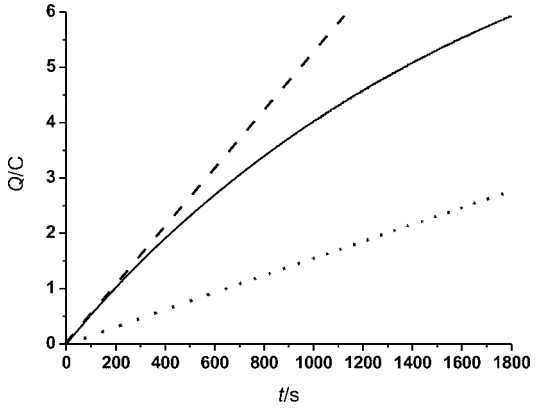

Figure 6. Bulk electrolysis of HOAc at a vitreous carbon rod electrode in the presence of **2** (——) and without **2** (·····); extrapolation of the catalytic reduction at the initial electrolysis rate (------).

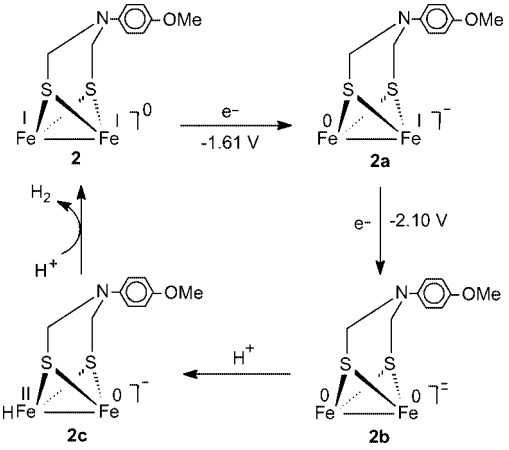
On the basis of previously reported, similar cases[10–12,18–21] and the above-mentioned electrochemical observations, we can propose an EECC (E = electrochemical, C = chemical) mechanism to account for the above-described electrocatalytic $H_2$ production process. As shown in Scheme 3, model **2** can undergo a one-electron reduction at –1.61 V to give the intermediate **2a**. Further one-electron reduction of **2a** at –2.10 V affords intermediate **2b**, which is then protonated to give intermediate **2c**. Final protonation of **2c** results in $H_2$ evolution to accomplish the catalytic cycle. Apparently, this mechanism is different from the CECE mechanism for $H_2$ production from $HClO_4$ catalyzed by the benzyl-substituted model $[\{(\mu\text{-}SCH_2)_2N(p\text{-}BrC_6H_4CH_2)\}Fe_2(CO)_6]$.[12] In the CECE mechanism the bridged N atom of the benzyl-substituted model is first protonated by strong acid, $HClO_4$, whereas in our EECC mechanism the bridged N atom of model **2** is not protonated by weak acid, HOAc. In fact, the protonation of the benzyl-substituted model and the nonprotonation of **2** were

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

all confirmed by spectroscopic studies. That is, the $^1H$ NMR and IR spectroscopic data of the benzyl-substituted model determined in $HClO_4$ were obviously changed due to protonation of its bridged N atom,[12] while the corresponding data of model **2** determined by us in HOAc were almost the same as those determined in the absence of HOAc.[22] Finally, it should be noted that model **2** undergoes serious decomposition in $HClO_4$. The decomposition could be observed by its color changes from red to orange and then to light yellow. In addition, some bubbles were liberated upon addition of 5–30 equiv. of $HClO_4$ to a solution of **2** in $CD_3CN$. In fact, it is the decomposition that precluded us from further studies on its electrochemical behavior in the presence of $HClO_4$.



Scheme 3. Suggested EECC mechanism for $H_2$ production catalyzed by **2**. All carbonyl groups attached to Fe are omitted for clarity.

## Experimental Section

**General Comments:** All reactions were carried out under prepurified nitrogen with standard Schlenk and vacuum-line techniques. All solvents were dried and distilled prior to use. Paraformaldehyde, $SOCl_2$, $Et_3BHLi$ (1 M in THF), *p*-$MeOC_6H_4NH_2$, $Et_4NCN$, $Me_3NO{\cdot}2H_2O$, and $PPh_3$ were available commercially and used as received. $[(\mu\text{-}S)_2Fe_2(CO)_6]$[15] and $PPh_2H$[23] were prepared according to published procedures. Preparative TLC was carried out on glass plates (26 × 20 × 0.25 cm) coated with silica gel H (10–40 μm). IR spectra were recorded with a Nicolet Magna 560 FTIR or a Bruker Vector 22 infrared spectrophotometer. $^1H$ NMR spectra were recorded with a Bruker AC-P 300 NMR spectrometer. Elemental analyses was performed with an Elementar Vario EL analyzer. Melting points were determined with a Yanaco MP-500 apparatus.

**Preparation of *N*,*N*-$(ClCH_2)_2N(C_6H_4OMe\text{-}p)$ (1):** A suspension consisting of paraformaldehyde (1.50 g, 50 mmol), *p*-$MeOC_6H_4NH_2$ (2.46 g, 20 mmol), and $CH_2Cl_2$ (30 mL) was stirred at room temperature for 5 h, and then treated dropwise with $SOCl_2$ (9.52 g, 80 mmol). After the gas evolution had ceased, solvent and unreacted $SOCl_2$ were removed in vacuo. The residue was purified by extraction into $Et_2O$. Removal of $Et_2O$ afforded **1** as an orange solid (3.99 g, 91%). M.p. 38–40 °C. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.15, 7.12, 6.84, 6.81 (AB q, 4 H, $C_6H_4$), 5.44 (s, 4 H, $2CH_2$), 3.70 (s, 3 H, $CH_3$) ppm. IR (KBr disk): $\tilde{\nu}$ = 1507 (s), 1280 (m), 1245 (s), 1183 (m), 1154 (s), 1098 (m), 1052 (m), 1023 (s), 943 (s), 820 (s) $cm^{-1}$. $C_9H_{11}Cl_2NO$ (220.10): calcd. C 49.11, H 5.04, N 6.36; found C 49.12, H 5.19, N 6.40.

**Preparation of $[\{(\mu\text{-}SCH_2)_2N(C_6H_4OMe\text{-}p)\}Fe_2(CO)_6]$ (2):** A solution of $[(\mu\text{-}S)_2Fe_2(CO)_6]$ (0.344 g, 1 mmol) in THF (20 mL) was cooled to –78 °C and treated dropwise with $Et_3BHLi$ (1 M in THF, 2 mL, 2 mmol) to give a green solution. After stirring for 15 min, **1** (0.55 g, 2.50 mmol) was added to cause an immediate color change from green to red. The mixture was warmed to room temperature and stirred for 8 h. The crude product was separated by TLC using $CH_2Cl_2$/petroleum ether (1:5) as the eluent. Compound **2** was obtained from the main band as a red solid (0.329 g, 67%). M.p. 132–135 °C. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 6.90, 6.87, 6.72, 6.69 (AB q, 4 H, $C_6H_4$), 4.26 (s, 4 H, 2 $CH_2$), 3.78 (s, 3 H, $CH_3$) ppm. IR (KBr disk): $\tilde{\nu}$ = 2073 (s), 2027 (vs), 1969 (s) (C≡O) $cm^{-1}$. $C_{15}H_{11}Fe_2NO_7S_2$ (493.07): calcd. C 36.54, H 2.25, N 2.84; found C 36.42, H 2.30, N 2.86.

**Preparation of $[\{(\mu\text{-}SCH_2)_2N(C_6H_4OMe\text{-}p)\}Fe_2(CO)_5(PPh_3)]$ (3):** A mixture of **2** (0.124 g, 0.25 mmol), $PPh_3$ (0.065 g, 0.25 mmol), $Me_3NO{\cdot}2H_2O$ (0.029 g, 0.25 mmol), and MeCN (20 mL) was stirred at room temperature for 3 h. The resulting dark-brown mixture was concentrated to dryness in vacuo and the residue was separated by TLC using $CH_2Cl_2$/petroleum ether (1:2) as the eluent. Compound **3** was obtained from the main band as a red solid (0.136 g, 75%). M.p. 134 °C (dec). $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.73–7.44 (m, 15 H, $3C_6H_5$), 6.76, 6.73, 6.49, 6.46 (AB q, 4 H, $C_6H_4$), 3.82 (d, $J$ = 12.3 Hz, 2 H, 2 C*H*H), 3.73 (s, 3 H, $CH_3$), 2.90 (d, $J$ = 12.3 Hz, 2 H, 2 C*H*H) ppm. IR (KBr disk): $\tilde{\nu}$ = 2041 (vs), 1984 (vs), 1923 (s) (C≡O) $cm^{-1}$. $C_{32}H_{26}Fe_2NO_6PS_2$ (727.33): calcd. C 52.84, H 3.60, N 1.93; found C 52.80, H 3.45, N 1.87.

**Preparation of $[\{(\mu\text{-}SCH_2)_2N(C_6H_4OMe\text{-}p)\}Fe_2(CO)_5(PPh_2H)]$ (4):** A mixture of **2** (0.124 g, 0.25 mmol), $PPh_2H$ (0.047 g, 0.25 mmol), and toluene (20 mL) was stirred and refluxed for 4.5 h. The same workup used for **3** gave **4** as a red solid (0.080 g, 49%). M.p. 126–127 °C. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.62–7.34 (m, 10 H, 2 $C_6H_5$), 6.72, 6.69, 6.51, 6.48 (AB q, 4 H, $C_6H_4$), 6.20 (d, $J$ = 349.8 Hz, 1 H, PH), 4.03–3.92 (m, 4 H, $2CH_2$), 3.68 (s, 3 H, $CH_3$) ppm. IR (KBr disk): $\tilde{\nu}$ = 2045 (vs), 1984 (vs), 1924 (s) (C≡O) $cm^{-1}$. $C_{26}H_{22}Fe_2NO_6PS_2$ (651.25): calcd. C 47.95, H 3.40, N 2.15; found C 47.92, H 3.32, N 2.19.

**Preparation of $[\{(\mu\text{-}SCH_2)_2N(C_6H_4OMe\text{-}p)\}Fe_2(CO)_4(CN)_2]\text{-}[(Et_4N)]_2$ (5):** A solution of $Et_4NCN$ (0.156 g, 1 mmol) in MeCN (5 mL) was added to a solution of **2** (0.247 g, 0.5 mmol) in MeCN (20 mL) at 0 °C, causing an immediate gas evolution. The mixture was warmed to room temperature and stirred for 4 h. The resulting brown-red solution was concentrated to dryness and the product was washed with hexane and diethyl ether, and finally dried in vacuo. Compound **5** was obtained as a red solid (0.266 g, 71%). M.p. 82–83 °C. $^1H$ NMR (300 MHz, $CD_3CN$): $\delta$ = 6.86, 6.83, 6.72, 6.68 (AB q, 4 H, $C_6H_4$), 4.16 (s, 3 H, $OCH_3$), 3.74 (s, 4 H, 2 $CH_2S$), 3.44 (q, $J$ = 6.9 Hz, 16 H, 8 C$H_2$CH$_3$), 1.14 (t, $J$ = 6.9 Hz, 24 H, 8 $CH_2CH_3$) ppm. IR (KBr disk): $\tilde{\nu}$ = 2066 (s), 2027 (s) (C≡N), 1968 (vs), 1933 (vs), 1893 (vs) (C≡O) $cm^{-1}$. $C_{31}H_{51}Fe_2N_5O_5S_2$ (749.59): C 49.67, H 6.86, N 9.34; found C 49.50, H 7.02, N 9.21.

**X-ray Structure Determination of 2 and 3:** Single crystals of **2** and **3** suitable for X-ray diffraction analyses were grown by slow concentration of their $CH_2Cl_2$/haxane solutions at about –25 °C. Each single crystal was mounted on a Bruker SMART 1000 automated diffractometer. Data were collected at room temperature, using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) in the $\omega$-2$\theta$ scanning mode. Absorption corrections were performed with the SADABS program.[24] The structures were solved by direct

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

methods using the SHELXS-97[25] program and refined by full-matrix least-squares techniques (SHELXL-97[26]) on $F^2$. Hydrogen atoms were located by using the geometric method. Details of crystal data, data collections, and structure refinements are summarized in Table 4. CCDC-293719 (**2**) and -293720 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Electrochemistry:** Acetonitrile (Fisher Chemicals, HPLC grade) was the solvent used for the electrochemistry. A solution of 0.1 M $n$Bu$_4$NPF$_6$ in MeCN was used as the electrolyte in all of the cyclic voltammetric experiments. The electrolyte solution was degassed by bubbling $N_2$ through it for 10 min before measurements were taken. Electrochemical measurements were made using a BAS Epsilon potentiostat. All voltammograms were obtained in a three-electrode cell with a 3-mm-diameter glassy carbon working electrode, a platinum counter electrode and an Ag/Ag$^+$ (0.01 M AgNO$_3$/0.1 M $n$Bu$_4$NPF$_6$ in MeCN) reference electrode under $N_2$ or CO. The working electrode was polished with 0.05 μm alumina paste and sonicated in water for 10 min. Bulk electrolysis was run on a vitreous carbon rod (ca. 3 cm$^2$) in a two-compartment, gas tight, H-type electrolysis cell containing ca. 18 mL of MeCN. All potentials are quoted against the ferrocene/ferrocenium (Fc/Fc$^+$) potential.

# Cationic Brønsted Acids for the Preparation of $Sn^{IV}$ Salts: Synthesis and Characterisation of $[Ph_3Sn(OEt_2)][H_2N\{B(C_6F_5)_3\}_2]$, $[Sn(NMe_2)_3(HNMe_2)_2][B(C_6F_5)_4]$ and $[Me_3Sn(HNMe_2)_2][B(C_6F_5)_4]$

**Yann Sarazin,[a] Simon J. Coles,[b] David L. Hughes,[a] Michael B. Hursthouse,[b] and Manfred Bochmann*[a]**

**Keywords:** Tin / Cations / N ligands / Anions

$Ph_3SnN(SiMe_3)_2$ (**1**) was prepared in good yields by reaction of $[\{NaN(SiMe_3)_2\}_2{\cdot}THF]$ (**2**) with $Ph_3SnF$. Treatment of **1** with $[H(OEt_2)_2][H_2N\{B(C_6F_5)_3\}_2]$ (**4**) in dichloromethane afforded the stannylium cation $[Ph_3Sn(OEt_2)][H_2N\{B(C_6F_5)_3\}_2]$ (**5**), which was characterised by $^1H$, $^{13}C\{^1H\}$, $^{11}B$, $^{19}F$ and $^{119}Sn$ NMR spectroscopy. The reaction of $Sn(NMe_2)_4$ with $[Ph_2MeNH][B(C_6F_5)_4]$ (**3**) gave the amidotin(IV) compound $[Sn(NMe_2)_3(HNMe_2)_2][B(C_6F_5)_4]$ (**6**) which proved very stable towards ligand substitution and resisted treatment with $Et_2O$, THF, TMEDA and pyrazine. Two new Brønsted acid salts $[H(NMe_2H)_2][B(C_6F_5)_4]$ (**7**) and $[(C_4H_4N_2)H{\cdot}OEt_2][H_2N\{B(C_6F_5)_3\}_2]$ (**8**) were synthesised. The reaction of **7** with $Sn(NMe_2)_4$ in $Et_2O$ allowed the preparation of **6** in a much improved yield (83 %). The treatment of **7** with $Me_3SnN(SiMe_3)_2$ in $Et_2O$ yielded $[Me_3Sn(HNMe_2)_2][B(C_6F_5)_4]$ (**9**) nearly quantitatively. Compounds **1**, **2**, **6**, **8** and **9** were characterised by single-crystal X-ray diffraction analyses; **6** is the first example of a structurally characterised amidotin(IV) cation.

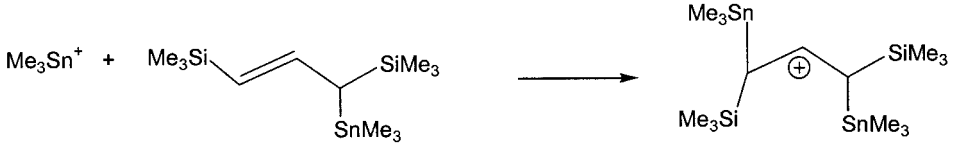
## Introduction

Organotin(IV) compounds have long attracted interest due to their reactivity, their industrial applications and their intriguing biological activity.[1,2] In particular, organotin(IV) cations are thought to play an essential part in the cytotoxicity of organotin compounds[3] or in their catalytic activity for esterification reactions,[4] and the search for stable examples of $Sn^{IV}$ cations was initiated over half a century ago.[5–19] However, to this date only few cationic complexes of tin have been isolated. Even though in the past decade or so fundamental breakthroughs have been achieved where tin cations free of donor atoms have been characterised in the solid state,[20–25] stannylium cations stabilised by donor heteroatoms appear to be more readily accessible.[2] For instance, cationic tin species stabilised by a Y,C,Y-chelating pincer-type ligand (where Y is an heteroatom such as oxygen or nitrogen) have been prepared very successfully in the past 15 years.[26–32] The utilisation of N,C,N-coordinating ligands has even enabled the preparation of air-stable organotin cations.[33,34] Our interest in the chemistry of cationic tin species is based on our recent isolation of a thermally remarkably stable sec-alkyl carbocation that was generated by the attack of a $Me_3Sn^+$ intermediate on a suitably substituted propene (Scheme 1).[35,36]



Scheme 1. Involvement of $Me_3Sn^+$ in the formation of a tin-stabilised carbocation.

This prompted us to investigate the chemistry of cationic tin species in more detail. We report here the reactions of a number of tin amides with cation-generating agents. To the best of our knowledge, simple $Sn^{IV}$-amide precursors have never been employed efficiently for this purpose.

A convenient way of generating cationic metal species is the reaction of protolysis-sensitive metal complexes with

Brønsted acidic salts of very weakly coordinating anions. For example, the oxonium ions $[H(L)_x]^+$ [L = $Et_2O$, THF, $x$ = 2; L = $(MeC{=}NC_6H_3\text{-}iPr_2\text{-}2,6)_2$, $x$ = 1] as salts of perfluorinated anions have been synthesised and used with great success in recent years;[37–43] we have shown that they can be applied as a very clean way to abstract alkyl, alkoxy and amido groups from various metals such as Mg, Zr, Zn or Cd.[43–47] For instance, the reactions of $ZnR_2$ [R = $C_6F_5$, Me, Et, $N(SiMe_3)_2$], $MgR_2$ [R = Bu, $N(SiMe_3)_2$], or $Cp_2Zr(O\text{-}iPr)_2$ with $[H(OEt_2)_2]^+[X]^-$ [X = $H_2N\{B(C_6F_5)_3\}_2$ or $B(C_6F_5)_4$] allowed the characterisation of, respectively, $[(Et_2O)_3ZnR][X]$,[44–45] $[(Et_2O)_3MgR][X]$[45] and $[Cp_2Zr(O\text{-}iPr)(HO\text{-}iPr)][X]$.[46] In addition, the anilinium salts $[PhNMe_2H][B(C_6F_5)_4]$ and $[Ph_2NMeH][B(C_6F_5)_4]$ have long been known and used as activating agents in olefin-polymerisation catalysis.[48–49]

As part of our ongoing studies on the preparation and the reactivity of main-group element cations,[43–45,47,50] we describe here the preparation and reactions of the stannylium compounds $[Ph_3Sn(OEt_2)][H_2N\{B(C_6F_5)_3\}_2]$, $[Sn(NMe_2)_3(HNMe_2)_2][B(C_6F_5)_4]$ and $[Me_3Sn(HNMe_2)_2]$-$[B(C_6F_5)_4]$. The structures of $[\{NaN(SiMe_3)_2\}_2{\cdot}THF]$, $Ph_3SnN(SiMe_3)_2$ and $[(C_4H_4N_2)H{\cdot}OEt_2][B(C_6F_5)_4]$ are also presented.

## Results and Discussion

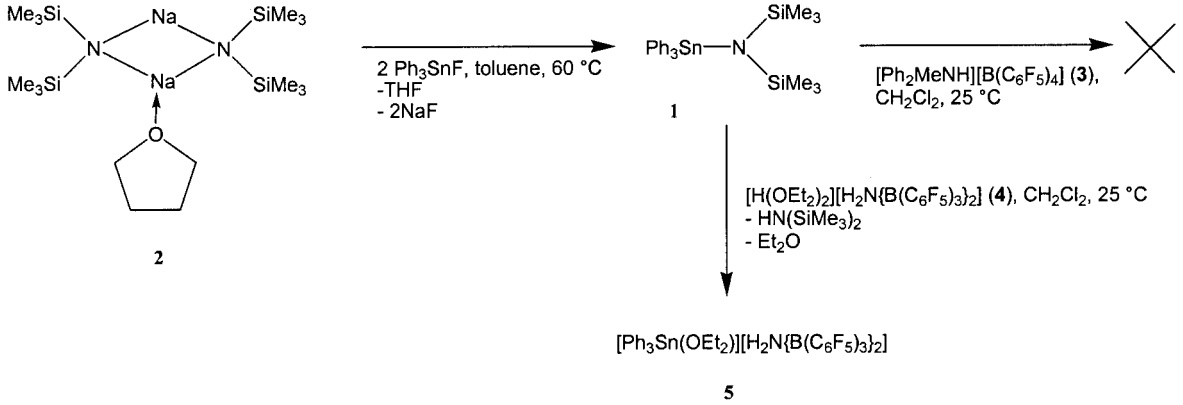
### Synthesis and Structure of $Ph_3SnN(SiMe_3)_2$

First attempts to generate a sterically relatively unencumbered stannyl cation involved the reaction of $Ph_3SnN(SiMe_3)_2$ (**1**) with one equiv. of $[Ph_2MeNH][B(C_6F_5)_4]$ (**3**). Compound **1** is conveniently accessible from $Ph_3SnF$ and 0.5 equiv. of $[\{NaN(SiMe_3)_2\}_2{\cdot}THF]$ (**2**) in hot toluene (Scheme 2). The $^{119}Sn$ NMR spectrum of **1** exhibited a single peak at $\delta$ –106.4 ppm, i.e. there was a noticeable highfield shift of ca. 145–185 ppm when compared to other known $R_3Sn{-}NR'_2$ trialkyltin amides.[1] **1** is very soluble both in polar ($CH_2Cl_2$, $Et_2O$, THF) and non-polar (toluene, light petroleum) organic solvents.

Crystals of **1** suitable for X-ray diffraction crystallography were isolated as large colourless blocks by recrystallisation from a concentrated toluene solution stored at –26 °C. The tin atom in **1** has a tetrahedral coordination geometry, while the nitrogen atom is trigonal planar coordinated. A view of a molecule of **1** is depicted in Figure 1. Viewed down the N(4)–Sn bond, the N(4)–Si(5) bond eclipses the Sn–C(11) bond. The Si(5)–N(4)–Sn–C(11) torsion angle is 0.8(4)°. The Sn–C(11), Sn–C(21) and Sn–C(31) bond lengths in **1** of 2.149(6), 2.154(6) and 2.114(6) Å, respectively, are typical of $Sn^{IV}$–aryl bonds.[31–32,51] The Sn–N(4) bond is 2.060(5) Å, i.e. greater than the two Sn–N bond lengths reported for $(Me_2N)_2Sn(O\text{-}2,6\text{-}tBu_2\text{-}C_6H_3)_2$ [1.980(4) and 1.997(4) Å][52] and the Sn–$NMe_2$ bond length [2.013(3) Å] found in $\{(2,2,6,6\text{-}Me_4C_5H_6N){-}P{=}C(SiMe_3)\}$-$Sn\{NMe_2\}\{N(SiMe_3)_2\}_2$,[53] but comparable to the two Sn–$N(SiMe_3)_2$ bond lengths [2.070(2) and 2.080(2) Å] also identified in the latter compound. In the crystal packing, there is no stacking of parallel phenyl rings; instead, the principal packing features are those of hydrogen atoms (both of phenyl and methyl groups) pointing into the centre of phenyl rings, and of methyl–methyl interactions.

During the course of this work large crops of the crystalline sodium amide **2** were obtained fortuitously from a concentrated light petroleum solution stored at –26 °C. The molecular structure of **2** was determined and, interestingly, confirmed the presence of only 0.5 molecules of THF per sodium atom.

The molecule of **2** contains a $Na_2N_2$ ring with a $C_2$ axis passing through the two sodium atoms (Figure 2). Na(1) is bound only to the two bridging nitrogen atoms, whereas Na(2) is coordinated to the same N atoms as well as to one THF ligand. Examination of the region on the "open" side of Na(1) shows its closest neighbours to be two C(21) methyl groups of neighbouring molecules, with Na(1)···C(21′′) and Na(1)···C(21′′′) distances of 3.104(6) Å; the closest H atoms are the H(21c) atoms of these methyl groups, at 2.61 Å. The shortest distances between the methyl groups (about the twofold symmetry axis) are: C(21′′)···C(21′′′) 3.756(9), H(21b′′)···H(21b′′′) 2.62, and H(21b′′)···H(21c′′′) 2.79 Å. Because the contact distance between two hydrogen atoms is ca. 2.4 Å, there is negligible space for any other atom or group in this region; the methyl groups cover this 'open' side of Na(1). There are other short



Scheme 2. Synthesis of $Ph_3SnN(SiMe_3)_2$ (**1**) and its subsequent reactions with Brønsted acids $[Ph_2MeNH][B(C_6F_5)_4]$ (**3**) and $[H(OEt_2)_2][H_2N\{B(C_6F_5)_3\}_2]$ (**4**).

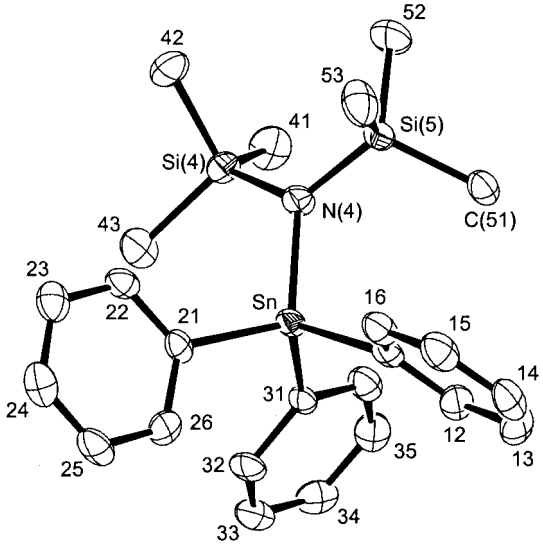

Figure 1. View of a molecule of **1**, indicating the atom numbering scheme; atoms labelled '*n*' represent the carbon atoms C(*n*). Hydrogen atoms have been omitted for clarity. Thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: Sn–C(11) 2.149(6), Sn–C(21) 2.154(6), Sn–C(31) 2.114(6), Sn–N(4) 2.060(5), N(4)–Si(4) 1.738(5), N(4)–Si(5) 1.743(5); C(11)–Sn–C(21) 102.5(2), C(31)–Sn–C(11) 109.5(2), C(31)–Sn–C(21) 114.0(2), N(4)–Sn–C(11) 112.9(2), N(4)–Sn–C(21) 112.8(2), N(4)–Sn–C(31) 105.3(2).

Na···H contacts of similar distance in this structure, viz. Na(1)···H(12a) 2.62, Na(1)···H(12c) 2.64 and Na(2)···H(22a) 2.66 Å. There are also Me···Me contacts between each of these C(21) groups and methyl groups of the Na(1) complex, e.g. H(12a)···H(21b′) 2.76 Å, H(21a)···H(21a′) 2.80 Å and H(11c)···H(21a′) 2.73 Å. These contacts effectively shield Na(1) from approach by any other ligand. The arrangement around Na(2) is trigonal planar, while each of the two nitrogen atoms are in a slightly distorted tetrahedral environment. The two N–Na(1)–N and N–Na(2)–N angles are almost identical [99.7(2)° and 99.0(2)°, respectively]. The presence of a THF molecule coordinated to Na(2) has very little influence on the N–Na(2) distance, because the N–Na(1) bond length of 2.388(5) Å is only marginally shorter than the 2.400(5) Å found for N–Na(2). It is remarkable that despite the presence of a unique molecule of THF in the dimeric **2**, all bond lengths and angles correspond closely to those already reported for the bis-THF adduct [{$NaN(SiMe_3)_2$}$_2$·2THF].[54] For instance, the N–Na(1), N–Na(2) and Na(2)–O(3) bond lengths of 2.388(5), 2.400(5) and 2.285(6) Å, respectively in **2** compare very well with the Na(1)–N(1) and Na(1)–O(1) lengths of 2.399 and 2.267 Å given for [{$NaN(SiMe_3)_2$}$_2$·2THF], and the N–Na(2)–N in **2** [99.0(2)°] is very close to the 101.7° found for N(1)–Na(1)–N(1) in the bis-THF adduct.

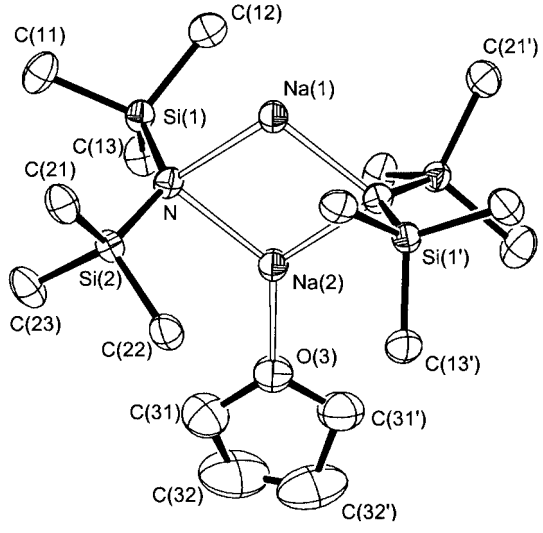

Figure 2. View of a molecule of [{$NaN(SiMe_3)_2$}$_2$·THF] (**2**), indicating the atom numbering scheme. Hydrogen atoms have been omitted for clarity. Thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: Na(1)–N 2.388(5), Na(2)–N 2.400(5), Na(2)–O(3) 2.285(6), N–Si(1) 1.696(5), N–Si(2) 1.688(6); N–Na(1)–N′ 99.7(2), N–Na(2)–N′ 99.0(2), N–Na(2)–O(3) 130.5(1).

### Synthesis of [$Ph_3Sn(OEt_2)$][$H_2N\{B(C_6F_5)_3\}_2$] (5)

Treatment of **1** with an equimolar amount of [$H(OEt_2)_2$]-[$H_2N\{B(C_6F_5)_3\}_2$][38] (**4**) in dichloromethane yielded a viscous oil, from which a fine white powder was obtained upon repeated washing with light petroleum. NMR spectroscopic data of this solid were consistent with the formulation [$Ph_3Sn(OEt_2)$][$H_2N\{B(C_6F_5)_3\}_2$] (**5**), and the composition was confirmed by elemental analysis. Compound **5** is very soluble in chlorinated solvents and diethyl ether, but is only sparingly soluble in toluene and insoluble in light petroleum. The $^{119}Sn$ NMR resonance for **5** was found at $\delta$ –76.0 ppm, i.e. at much higher field than reported for the free ions (mesityl)$_3Sn^+$ ($\delta$ +806 ppm)[21] and (2,4,6-triisopropylphenyl)$_3Sn^+$ ($\delta$ +714 ppm).[23] All attempts to determine the molecular structure of **5** proved unsuccessful, possibly due to its high air- and moisture-sensitivity. It was not possible to remove the coordinated $Et_2O$ molecule, even upon heating under vacuum.

Attempts to generate a stannyl cation free of coordinating ether by reacting **1** with [$Ph_2MeNH$][$B(C_6F_5)_4$] (**3**) in dichloromethane at room temperature gave dark blue mixtures from which no tractable material could be isolated.

### Synthesis, Characterisation and Reactivity of [$Sn(NMe_2)_3$-$(HNMe_2)_2$][$B(C_6F_5)_4$] (6), [$H(HNMe_2)_2$][$B(C_6F_5)_4$] (7) and [$(C_4H_4N_2)H\cdot OEt_2$][$H_2N\{B(C_6F_5)_3\}_2$] (8)

To the best of our knowledge simple amidotin(IV)–amide complexes have never been used for the preparation of organotin cations, and it prompted us to investigate the potential of these simple precursors for such purposes.

The sterically very hindered amide $MeSn[N(SiMe_3)_2]_3$ was treated with the cation-generating agents **3**, **4**, [$Ph_3C$][$H_2N\{B(C_6F_5)_3\}_2$] or $B(C_6F_5)_3$ in dichloromethane. However, none of these reactions proceeded to give the expected organotin cations, but instead the starting material $MeSn[N(SiMe_3)_2]_3$ was recovered in all cases.[55]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

By contrast, the less encumbered $Sn(NMe_2)_4$ can be employed effectively for reactions with Brønsted acids. On addition of one equiv. of $Sn(NMe_2)_4$ to a colourless solution of **3** in dichloromethane, a pale yellow, slightly cloudy solution was obtained (Scheme 3, Method A). The crude product was isolated as a viscous yellow oil. Attempts to purify the compound adequately with light petroleum failed. Nevertheless, crystals were grown from a concentrated dichloromethane solution, and crystallographic studies carried out on these colourless plates indicated the structure $[Sn(NMe_2)_3(HNMe_2)_2][B(C_6F_5)_4]$ (**6**), with two molecules of dimethylamine coordinated to the metal centre. Elemental analysis and NMR characterisation were in agreement with the proposed structure. The $^1H$ NMR spectrum displayed a single sharp singlet for all methyl groups at $\delta$ 2.76 ppm, while the N–H protons gave rise to a broad singlet centred at $\delta$ 3.25 ppm. Whereas in the $^{119}Sn$ NMR spectrum the starting material $Sn(NMe_2)_4$ exhibited a resonance at $\delta$ –122.4 ppm, the peak for **6** was high-field shifted by about 190 ppm, to $\delta$ –311.4 ppm. The borate anion showed an $^{11}B$ NMR signal at $\delta$ –13.6 ppm, while the $^{19}F$ NMR resonances at $\delta$ –133.4, –160.6 and –166.1 ppm are typical of a noncoordinated borate. Compound **6** is highly soluble in diethyl ether, THF and dichloromethane, moderately soluble in toluene and insoluble in light petroleum. It is very air- and moisture-sensitive, but is thermally stable for periods of weeks at room temperature, and does not show any sign of deterioration upon prolonged exposure to light.

The structure of the $[Sn(NMe_2)_3(HNMe_2)_2]^+$ cation ($\mathbf{6^+}$) is shown in Figure 3. The complex is trigonal-bipyramidal, with the two dimethylamine ligands *trans* to one another [angle N(11)–Sn–N(12) 176.0(2)°; angle sum for $N_{eq}$–Sn–$N_{eq}$ 360.0°]. The Sn–N distances to the axial $HNMe_2$ ligands [Sn–N(11) 2.382(7), Sn–N(12) 2.321(7) Å] are substantially longer than those to the equatorial amido groups [Sn–N(13) 2.013(7) Å, Sn–N(14) 2.005(6) and Sn–N(15) 1.990(7) Å]. The average Sn–$N_{eq}$ length in $\mathbf{6^+}$ (2.003 Å) is somewhat shorter than the average Sn–$N_{eq}$ length of 2.038 Å found in the geometrically comparable neutral complex $Me_2NSn(MeNCH_2CH_2N)_3N$,[56] which presumably reflects the influence of the positive charge on the metal centre in $\mathbf{6^+}$. To the best of our knowledge, **6** is the first example of a structurally characterised five-coordinate amido $Sn^{IV}$-cation paired with a noncoordinating counteranion.

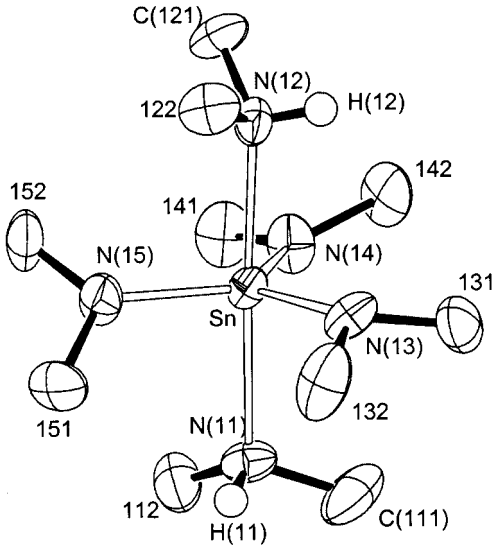

Figure 3. View of the $[Sn(NMe_2)_3(HNMe_2)_2]^+$ cation ($\mathbf{6^+}$), indicating the atom numbering scheme. Atoms labelled 'n' represent the carbon atoms C(n). Hydrogen atoms (except for the amino H atoms) have been omitted for clarity. Thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: Sn–N(11) 2.382(7), Sn–N(12) 2.321(7), Sn–N(13) 2.013(7), Sn–N(14) 2.005(6), Sn–N(15) 1.990(7); N(12)–Sn–N(11) 176.0(2), N(13)–Sn–N(11) 91.4(3), N(14)–Sn–N(11) 90.4(3), N(15)–Sn–N(11) 89.9(3), N(13)–Sn–N(12) 84.6(3), N(14)–Sn–N(12) 92.1(3), N(15)–Sn–N(12) 91.5(3), N(14)–Sn–N(13) 120.8(3), N(15)–Sn–N(13) 118.7(3), N(15)–Sn–N(14) 120.5(3).

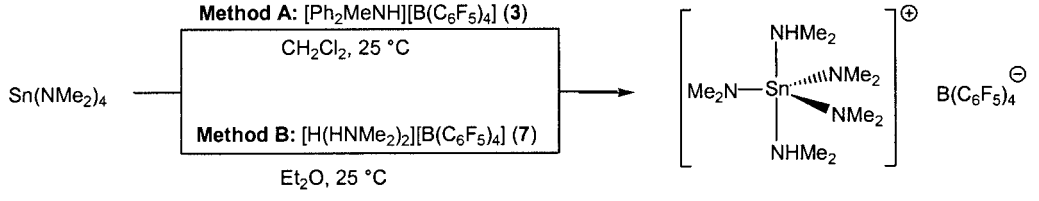
The preparation described above gave **6** in low yield (24% based on Sn). Consequently, a more economical route was developed, which consisted of protonating $Sn(NMe_2)_4$ while at the same time offering a second molecule of dimethylamine (Scheme 3, Method B). For this purpose, the new Brønsted acid $[H(HNMe_2)_2][B(C_6F_5)_4]$ (**7**) was prepared. The low basicity of $NMePh_2$ compared to that of $HNMe_2$ was exploited for the nearly-quantitative synthesis of **7** (Scheme 4, top). Thus, the straightforward reaction of **3** with a large excess of $HNMe_2$ in diethyl ether at room temperature yielded a white solid after removal of the volatiles. Upon thorough washing with light petroleum, a fine white powder was obtained, and the composition of **7** was confirmed by elemental analysis and NMR spectroscopy. In the $^1H$ NMR spectrum (in $CD_2Cl_2$), all four methyl groups appear as a sharp singlet at $\delta$ 2.61 ppm, while the three N–H protons are equivalent and give rise to a sharp singlet at



**6**

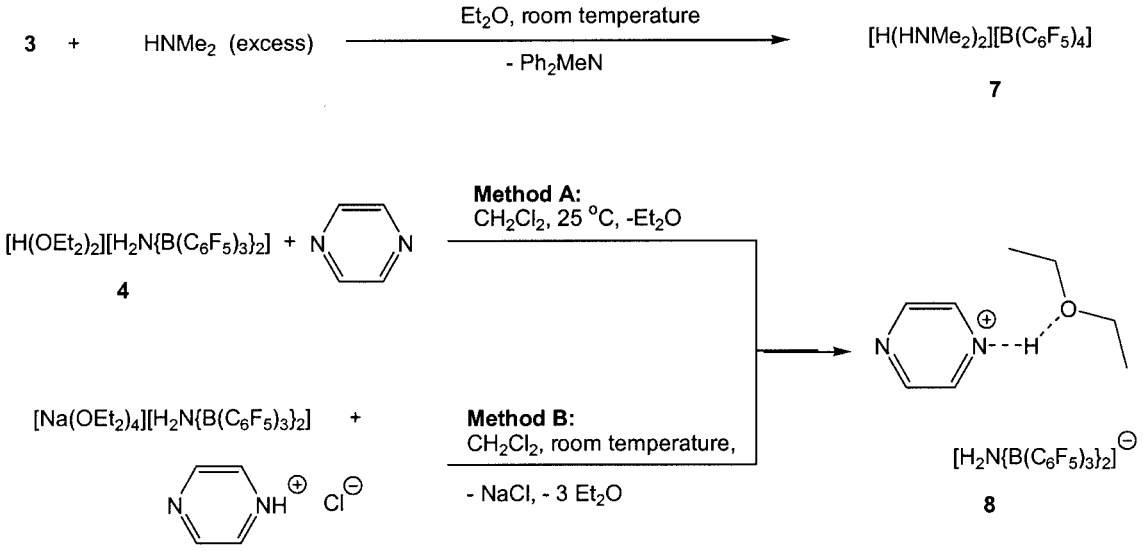

Scheme 4. Preparation of new Brønsted acids stabilised by weakly coordinating perfluorinated anions.

$\delta$ 7.04 ppm. It is worth noting that this reaction must not be conducted in dichloromethane, as in this case crystalline $Me_2NH{\cdot}HCl$ is slowly formed in quantitative yield. For this reason, highly concentrated solutions of **7** and short acquisition times were used to record its NMR spectra. Compound **7** dissolves in $Et_2O$ and THF but is hardly soluble in toluene and insoluble in light petroleum. As anticipated, the reaction of $Sn(NMe_2)_4$ with an equimolar amount of **7** in diethyl ether proceeded cleanly to yield ether-free **6** in a substantially improved yield (83%; Scheme 3, Method B).

The stability of **6** was demonstrated by its remarkable inertness towards ligand substitution. There is no reaction with diethyl ether, THF or even a chelating ligand such as tetramethylethylenediamine (TMEDA). Moreover, **6** was also isolated as the only product of the reaction between **3** and $Sn(NMe_2)_4$ carried out in $Et_2O$ or THF instead of $CH_2Cl_2$ (yield 10–20% with respect to Sn).

Because adding an excess of pyrazine to **6** proved ineffective in displacing one of the dimethylamine ligands, we envisaged adding $[(C_4H_4N_2)H{\cdot}OEt_2][H_2N\{B(C_6F_5)_3\}_2]$ (**8**) to $Sn(NMe_2)_4$, with the rationale that such reaction would lead to the formation of a $Sn^{IV}$ cation coordinated by at least one bifunctional pyrazine ligand. Thus, the new Brønsted acid **8** was conveniently prepared by addition of pyrazine to a solution of **4** in dichloromethane (Scheme 4, bottom, Method A). After removal of the volatile fraction and several washings with light petroleum, analytically pure **8** was recovered in high yield (88%). Product **8** was also readily obtained in 77% yield by reaction of solid pyrazinium chloride with $[Na(OEt_2)_4][H_2N\{B(C_6F_5)_3\}_2]$ in dichloromethane (Scheme 4, bottom, Method B). Compound **8** can easily be dissolved in $Et_2O$ and chlorinated solvents, but shows poor solubility in aromatic solvents and light petroleum. Unexpectedly, no clean product could be recovered from the reaction of $Sn(NMe_2)_4$ and **8** performed in $CH_2Cl_2$; instead a complicated mixture of products was obtained.

The anion $[H_2N\{B(C_6F_5)_3\}_2]^-$ was chosen in preference to $B(C_6F_5)_4^-$ because of its better crystallisation properties, and indeed crystals of **8** suitable for X-ray crystallography were grown as colourless shards from a concentrated

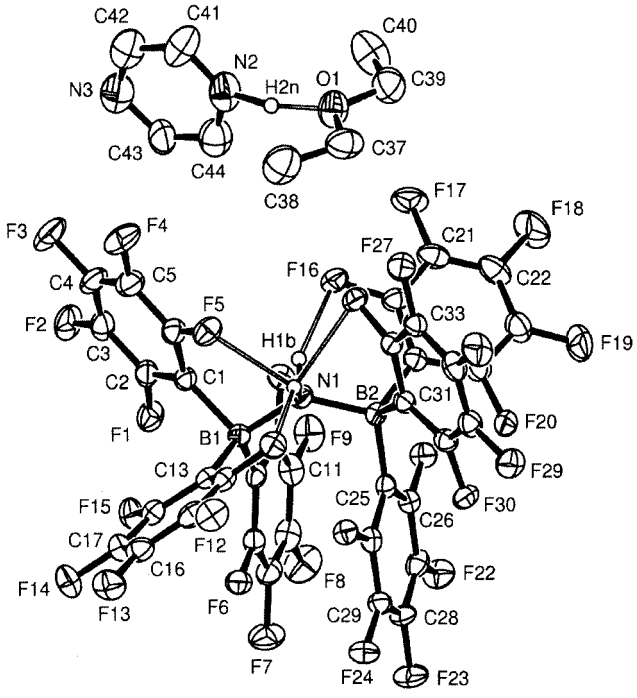

Figure 4. View of the salt $[(C_4H_4N_2)H{\cdot}OEt_2][H_2N\{B(C_6F_5)_3\}_2]$ (**8**), indicating the atom numbering scheme. Hydrogen atoms (except for the amido and acidic atoms) have been omitted for clarity. Thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: N(2)–H(2n) 1.27(5), O(1)–H(2n) 1.38(5), N(2)–C(41) 1.335(6), N(2)–C(44) 1.337(6), N(3)–C(42) 1.321(6), N(3)–C(43) 1.331(6), N(1)–B(1) 1.627(4), N(1)–B(2) 1.638(4), N(1)–H(1a) 0.90, N(1)–H(1b) 0.90, H(1a)–F(5) 2.24, H(1a)–F(11) 2.13, H(1a)–F(26) 2.32, H(1b)–F(16) 1.98; N(2)–H(2n)–O(1) 156(5), C(41)–N(2)–C(44) 120.6(4), C(42)–N(3)–C(43) 114.9(4), B(1)–N(1)–B(2) 133.2(2).

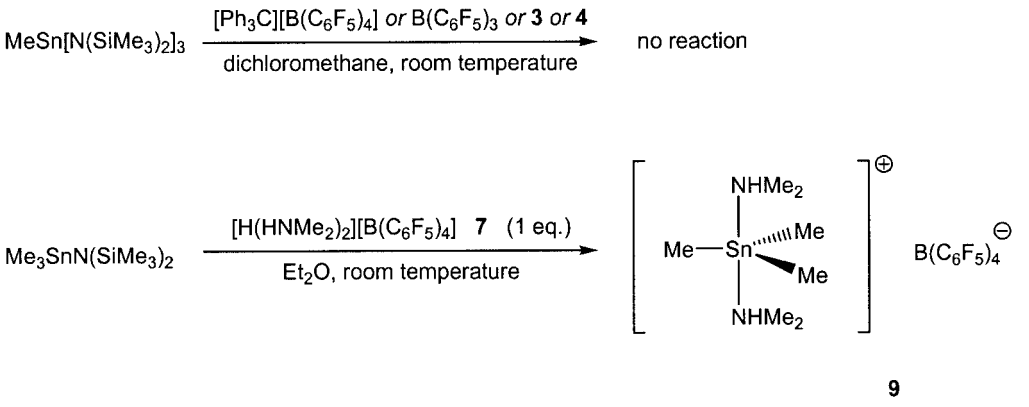
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dichloromethane solution cooled to –26 °C (Figure 4). The acidic proton in the cation was refined freely. It lies between the oxygen and nitrogen atoms and is located somewhat closer to the latter [N(2)–H(2n) 1.27(5) Å, O(1)–H(2n) 1.38(5) Å]; the N(2)–H(2n)–O(1) angle is 156(5)°. The C–N bonds of the protonated nitrogen [1.335(6) and 1.337(6) Å] are marginally longer than those to the nonprotonated nitrogen atom [1.321(6) and 1.331(6) Å]. The structure of the anion resembles strongly that in $[Na(OEt_2)_2][H_2N\{B(C_6F_5)_3\}_2]$ reported previously.[38]

### Synthesis and Characterisation of $[Me_3Sn(HNMe_2)_2][B(C_6F_5)_4]$ (9)

As discussed above, no stannyl cation could be generated from $MeSn[N(SiMe_3)_2]_3$ upon treatment with various cation-generating agents. On the other hand, the sterically less hindered mono-amide $Me_3SnN(SiMe_3)_2$ reacted successfully with one equiv. of **7** in $Et_2O$ to yield $[Me_3Sn(HNMe_2)_2][B(C_6F_5)_4]$ (**9**) in a near-quantitative yield (Scheme 5). Compound **9** was fully characterised by NMR



Scheme 5. Preparation of $[Me_3Sn(HNMe_2)_2][B(C_6F_5)_4]$ (**9**).

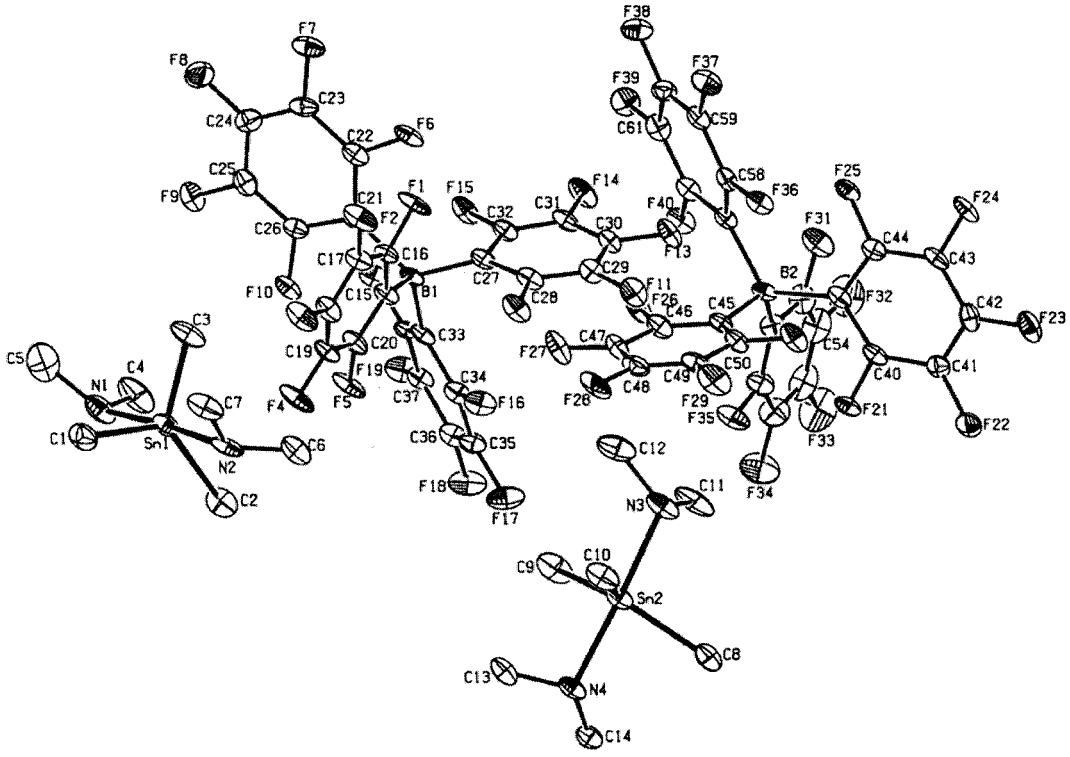


Figure 5. View of the two independent ion pairs in the salt $[Me_3Sn(HNMe_2)_2][B(C_6F_5)_4]$ (**9**), indicating the atom numbering scheme. Hydrogen atoms have been omitted for clarity. Thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: For the first cation, Sn(1)–N(1) 2.405(6), Sn(1)–N(2) 2.323(6), Sn(1)–C(1) 2.036(6), Sn(1)–C(2) 2.404(6), Sn(1)–C(3) 2.085(6); N(1)–Sn(1)–N(2) 176.3(2), N(1)–Sn(1)–C(1) 78.4(2), N(1)–Sn(1)–C(2) 93.0(2), N(1)–Sn(1)–C(3) 94.0(2), N(2)–Sn(1)–C(1) 100.2(2), N(2)–Sn(1)–C(2) 84.9(2), N(2)–Sn(1)–C(3) 89.7(2), C(1)–Sn(1)–C(2) 124.5(2), C(2)–Sn(1)–C(3) 127.9(2), C(1)–Sn(1)–C(3) 107.5(3). For the second cation, Sn(2)–N(3) 2.263(5), Sn(2)–N(4) 2.272(4), Sn(2)–C(8) 2.417(7), Sn(2)–C(9) 2.049(6), Sn(2)–C(10) 2.154(6); N(3)–Sn(2)–N(4) 177.0(2), N(3)–Sn(2)–C(8) 98.8(2), N(3)–Sn(2)–C(9) 80.2(2), N(3)–Sn(2)–C(10) 91.7(2), N(4)–Sn(2)–C(8) 84.0(2), N(4)–Sn(2)–C(9) 97.7(2), N(4)–Sn(2)–C(10) 87.3(2), C(8)–Sn(2)–C(9) 116.8(3), C(9)–Sn(2)–C(10) 116.1(3), C(8)–Sn(2)–C(10) 127.1(3).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spectroscopy in $CD_2Cl_2$, and its composition was confirmed by elemental analysis. It is readily soluble in ethers and chlorinated solvents, but only poorly soluble in aromatic hydrocarbons and totally insoluble in light petroleum. It is air- and moisture-sensitive, but is thermally stable and does not deteriorate when exposed to light.

The $^{119}Sn$ NMR spectrum of **9** consists of a single peak located at $\delta$ –25.3 ppm, i.e. it has undergone a high-field shift of about 77 ppm when compared to the starting material ($\delta$ +52.1 ppm). By contrast, the $^{119}Sn$ NMR resonance for the free $Bu_3Sn^+$ appears at the much higher frequency ($\delta$ +454 ppm).[22] In the $^1H$ NMR spectrum, the resonance for the nine Sn–$CH_3$ protons is found at $\delta$ 0.60 ppm, exhibiting a $^2J_{H,Sn}$ coupling of 30.7 Hz; the two N–H protons display a resonance at $\delta$ 2.14 ppm, and are considerably more shielded than the two analogous protons in **6** ($\delta$ 3.25 ppm). The $^{11}B$ ($\delta$ –13.6 ppm) and $^{19}F$ ($\delta$ –133.6, –164.0 and –168.0 ppm) NMR spectra are characteristic of the noncoordinating nature of the counteranion.

Single crystals of **9** were readily grown from a dichloromethane/light petroleum mixture at –28 °C as colourless slabs, suitable for X-ray diffraction. The crystal structure (Figure 5) indicates the presence of two independent ion pairs per asymmetric unit. The arrangement around the tin atoms of the two cations in **9** resembles that in **6**. Each of the cations has a distorted trigonal-bipyramidal environment, where the two dimethylamine ligands are situated in apical positions [N(1)–Sn(1)–N(2) 176.3(2)°; N(3)–Sn(2)–N(4) 177.0(2)°]. The average angle sums for $C_{eq}$–Sn(1)–$C_{eq}$ [359.9(2)°] and $C_{eq}$–Sn(2)–$C_{eq}$ [360.0(3)°] confirm the planarity of the trigonal $SnMe_3$ subunits. In both cations, one of the three equatorial Sn–C bonds is significantly longer than the other two [Sn(1)–C(2) 2.404(6) compared to Sn(1)–C(1) 2.036(6) and Sn(1)–C(3) 2.085(6) Å; Sn(2)–C(8) 2.417(7) compared to Sn(2)–C(9) 2.049(6) and Sn(2)–C(10) 2.154(6) Å], and there are considerable variations in the $C_{eq}$–Sn–$C_{eq}$ angles [$C_{eq}$–Sn(1)–$C_{eq}$ 107.5(3)–127.9(2)°; $C_{eq}$–Sn(2)–$C_{eq}$ 116.1(3)–127.1(3)°]. The axial Sn–N bond lengths in **9** differ slightly between the two independent cations [Sn(1)–N(1) 2.405(6) and Sn(1)–N(2) 2.323(6) Å; Sn(2)–N(3) 2.263(5) and Sn(2)–N(4) 2.272(4) Å], but overall compare well with those found in **6** [2.382(7) and 2.321(7) Å] and in the related ammonia complex $[Me_3Sn(NH_3)_2][N(SO_2Me)_2]$ (Sn–N 2.328 and 2.383 Å; N–Sn–N 179.2°).[57] The equatorial Sn–C bond lengths in **9** are comparable to those reported for the latter compound (Sn–C 2.117–2.124 Å).

## Conclusions

We have shown that Brønsted acids paired with weakly coordinating perfluorinated counteranions can be employed as an effective way to generate cationic tin(IV) complexes. With this aim in mind two new nitrogen-based Brønsted acids have been developed. The $Sn^{IV}$ cations formed in such fashion are highly electrophilic. In particular, $[Sn(NMe_2)_3(HNMe_2)_2]^+$ $[B(C_6F_5)_4]^-$ was synthesized as the first example of a structurally characterised cationic amidotin complex. The dimethylamine ligands exhibit a surprising resistance to substitution by other Lewis bases. Future work will involve tailor-made cationic Brønsted acids and their use in combination with other main group precursors for the development of new architectures built around cationic metal centres and weakly coordinating anions.

## Experimental Section

**General:** All manipulations were performed under argon using standard Schlenk techniques. Solvents were pre-dried, and distilled under inert atmosphere over sodium (low-sulfur toluene), sodium–benzophenone (diethyl ether, THF), sodium–potassium alloy (light petroleum, boiling point 40–60 °C) or calcium hydride (dichloromethane). NMR solvents were dried with activated 4-Å molecular sieves and degassed by several freeze–thaw cycles. NMR spectra were recorded with a Bruker Avance DPX-300 spectrometer. Chemical shifts are reported in ppm. $^1H$ NMR spectra (300.13 MHz) are referenced to the residual protons of the deuterated solvent used. $^{13}C$ NMR spectra (75.47 MHz) were referenced internally to the D-coupled $^{13}C$ resonances of the NMR solvent. $^{11}B$ (96.29 MHz), $^{19}F$ (282.38 MHz) and $^{119}Sn$ (111.91 MHz) NMR spectra were referenced externally to $BF_3{\cdot}Et_2O$, $CFCl_3$ and $SnMe_4$, respectively. $HN(SiMe_3)_2$, $NMePh_2$, $Ph_3SnF$, $SnCl_4$, $Me_3SnCl$, $MeSnCl_3$, $C_4H_4N_2$, $HNMe_2$ and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine were used as purchased without further purification. $B(C_6F_5)_3$,[58–59] $[Ph_2MeNH][B(C_6F_5)_4]$ (**3**),[49] $[Na(OEt_2)_4][H_2N\{B(C_6F_5)_3\}_2]$,[38] $[H(OEt_2)_2][H_2N\{B(C_6F_5)_3\}_2]$ (**4**),[38] $[Ph_3C][H_2N\{B(C_6F_5)_3\}_2]$,[38] $MeSn[N(SiMe_3)_2]_3$,[60] $Me_3SnN(SiMe_3)_2$[61] and $Sn(NMe_2)_4$[62] were prepared according to the literature methods.

**Synthesis of $Ph_3SnN(SiMe_3)_2$ (1):** $Ph_3SnF$ (5.0 g, 13.5 mmol) was added rapidly at –78 °C to a suspension of $[\{NaN(SiMe_3)_2\}_2{\cdot}THF]$ (6.0 g, 13.5 mmol) in light petroleum (80 mL). The mixture was warmed slowly to room temperature and was stirred overnight. The volatiles were removed under vacuum, giving a white solid which was suspended in toluene (60 mL). The reaction mixture was stirred at 60 °C for 5 hours. The precipitate of NaF was then removed by filtration, and the supernatant was concentrated to 20 mL. X-ray quality crystals were obtained by recrystallisation at –26 °C. Yield: 4.8 g (70%). $^1H$ NMR ($CD_2Cl_2$, 25 °C, 300.13 MHz): $\delta$ = 7.66 (m, 6 H, Ar–*H*), 7.44 (m, 9 H, Ar–*H*), 0.10 (s, 18 H, Si*Me*$_3$) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 25 °C, 75.48 MHz): $\delta$ = 142.5 ($C_i$, $^1J_{C,Sn}$ = 298.9 Hz, Sn*Ph*$_3$), 137.0 ($C_o$, $^2J_{C,Sn}$ = 20.6 Hz, Sn*Ph*$_3$), 129.6 ($C_p$, $^4J_{C,Sn}$ = 6.2 Hz, Sn*Ph*$_3$), 129.1 ($C_m$, $^3J_{C,Sn}$ = 28.9 Hz, Sn*Ph*$_3$), 5.6 (Si*Me*$_3$) ppm. $^{119}Sn$ NMR ($CD_2Cl_2$, 25 °C, 111.91 MHz): $\delta$ = –106.4 ppm. $C_{24}H_{33}NSi_2Sn$ (510.4): calcd. C 56.48, H 6.52, N 2.74; found C 56.71, H 6.52, N 2.87.

**Preparation of $[\{NaN(SiMe_3)_2\}_2{\cdot}THF]$(2):** The solvent was removed from a solution of $NaN(SiMe_3)_2$ (12.0 g, 65.4 mmol) in THF (125 mL) under vacuum and the resulting solid extracted with light petroleum (2×100 mL). The filtrate was concentrated to 50 mL and stored overnight at –26 °C, affording a large crop of colourless crystals suitable for X-ray diffraction crystallography. Yield 10.0 g, 22.8 mmol, 70%. $^1H$ NMR ($CD_2Cl_2$, 25 °C, 300.13 MHz): $\delta$ = 3.41 (t, 4 H, $J$ = 6.6 Hz, $CH_2$–C*H*$_2$–O), 1.22 (m, 4 H, C*H*$_2$–$CH_2$–O), 0.26 (s, 36 H, Si*Me*$_3$) ppm. $^{13}C$ NMR ($CD_2Cl_2$, 25 °C, 75.48 MHz): $\delta$ = 68.4 ($CH_2$–*C*$H_2$–O), 25.4 (*C*$H_2$–$CH_2$–O), 7.0 (Si*Me*$_3$) ppm. $C_{16}H_{44}N_2Na_2OSi_4$ (438.9): calcd. C 43.79, H 10.11, N 6.38; found C 43.01, H 10.10, N 6.40.

**$[Ph_3Sn(OEt_2)][H_2N\{B(C_6F_5)_3\}_2]$ (5):** A colourless solution of **1** (0.5 g, 1.0 mmol) and **4** (1.2 g, 1.0 mmol) in $CH_2Cl_2$ (8 mL) was stirred at room temperature for 12 hours. The solvent was then removed under vacuum, leaving a sticky foam. Upon repeated washing with light petroleum a white powder was obtained which was suspended in 3 mL of light petroleum, and dichloromethane (ca. 2 mL) was added until the solid was completely dissolved. Cooling to –26 °C for several days gave a white microcrystalline solid, yield 0.5 g (30%). $^1$H NMR ($CD_2Cl_2$, 25 °C, 300.13 MHz): $\delta$ = 7.92–7.70 (m, 15 H, Ar–*H*), 5.70 (br. s, 2 H, $H_2$N), 3.61 (q, $^3J_{H,H}$ = 7.0 Hz, 4 H, $CH_3$–C$H_2$–O), 0.99 (t, $^3J_{H,H}$ = 7.0 Hz, 6 H, C$H_3$–$CH_2$–O) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$, 25 °C, 75.48 MHz): $\delta$ = 149.8, 146.7, 141.2, 138.7, 137.8, 135.5 (all $ArF_5$–*C*), 136.9 ($C_i$, Sn*Ph*$_3$), 136.6 ($^2J_{C,Sn}$ = 22.8 Hz, $C_o$, Sn*Ph*$_3$), 131.1 ($C_p$, Sn*Ph*$_3$), 131.0 ($^3J_{C,Sn}$ = 33.8 Hz, $C_m$, Sn*Ph*$_3$), 67.5 ($CH_3$–*C*$H_2$–O), 13.9 (*C*$H_3$–$CH_2$–O) ppm. $^{11}$B NMR ($CD_2Cl_2$, 96.29 MHz, 25 °C): $\delta$ = –5.3 ppm. $^{19}$F NMR ($CD_2Cl_2$, 282.38 MHz, 25 °C): $\delta$ = –133.4 (d, $^3J_{F,F}$ = 19.8 Hz, 12 F, $F_o$), –160.7 (t, $^3J_{F,F}$ = 19.8 Hz, 6 F, $F_p$), –166.0 (t, $^3J_{F,F}$ = 19.8 Hz, 12 F, $F_m$) ppm. $^{119}$Sn NMR ($CD_2Cl_2$, 25 °C, 111.91 MHz): $\delta$ = –76.0 ppm. $C_{58}H_{27}B_2F_{30}NOSn$ (1464.1): calcd. C 47.58, H 1.86, N 0.96; found C 47.45, H 2.02, N 1.04.

**$[Sn(NMe_2)_3(HNMe_2)_2][B(C_6F_5)_4]$ (6). Method A:** To a colourless solution of **3** (1.3 g, 1.5 mmol) in $CH_2Cl_2$ (15 mL) was added neat $Sn(NMe_2)_4$ (0.5 g, 1.7 mmol). The solution was stirred at room temperature for 5 h, when it gradually turned pale yellow and cloudy. It was then concentrated to ca. 5 mL and crystals suitable for X-ray crystallography were obtained after several days at –26 °C. Yield 0.4 g (24% relative to Sn). $^1$H NMR ($CD_2Cl_2$, 25 °C, 300.13 MHz): $\delta$ = 3.25 (br., 2 H, N–*H*), 2.76 (s, 30 H, N–C$H_3$) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$, 25 °C, 75.48 MHz): $\delta$ = 150.0, 146.8, 140.2, 138.2, 136.9, 135.0 (all $ArF_5$–*C*), 42.0 (br., N–*C*$H_3$) ppm. $^{11}$B NMR ($CD_2Cl_2$, 96.29 MHz, 25 °C): $\delta$ = –13.6 ppm. $^{19}$F NMR ($CD_2Cl_2$, 282.38 MHz, 25 °C): $\delta$ = –133.6 (d, $^3J_{F,F}$ = 19.8 Hz, 8 F, $F_o$), –164.1 (t, $^3J_{F,F}$ = 19.8 Hz, 4 F, $F_p$), –168.0 (t, $^3J_{F,F}$ = 19.8 Hz, 8 F, $F_m$) ppm. $^{119}$Sn NMR ($CD_2Cl_2$, 25 °C, 111.91 MHz): $\delta$ = –311.4 ppm. $C_{34}H_{32}BF_{20}N_5Sn$ (1020.2): calcd. C 40.03, H 3.16, N 6.87; found C 39.52, H 2.95, N 6.48.

**Method B:** Neat $Sn(NMe_2)_4$ (0.4 g, 1.4 mmol) was added to a solution of **7** (0.9 g, 1.2 mmol) in $Et_2O$ (30 mL). A white precipitate formed within 2 min. The reaction mixture was stirred overnight, and light petroleum (10 mL) was added, yielding a white precipitate. The supernatant was filtered off. The white solid residue was washed with light petroleum (4 × 30 mL) and dried in vacuo. The product proved to be identical to that prepared by Method A. Yield 1.0 g (83% relative to Sn).

**$[H(HNMe_2)_2][B(C_6F_5)_4]$ (7):** Dimethylamine (6.6 g, 14.6 mmol) was condensed into a Schlenk tube at –35 °C and transferred rapidly to a solution of **3** (1.2 g, 1.4 mmol) in $Et_2O$ (25 mL). The resulting colourless solution was stirred overnight at room temperature. The volatiles were then removed in vacuo, yielding a white solid which was washed thoroughly with light petroleum (5 × 20 mL) and dried under vacuum. Yield 0.9 g (86%). $^1$H NMR ($CD_2Cl_2$, 25 °C, 300.13 MHz): $\delta$ = 7.04 (s, 3 H, N–*H*), 2.61 (s, 12 H, N–C$H_3$) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$, 25 °C, 75.48 MHz): $\delta$ = 150.0, 147.1, 140.1, 138.0, 136.7, 135.0 (all $ArF_5$–*C*), 36.7 (N–*C*$H_3$) ppm. $^{11}$B NMR ($CD_2Cl_2$, 96.29 MHz, 25 °C): $\delta$ = –11.7 ppm. $^{19}$F NMR ($CD_2Cl_2$, 282.38 MHz, 25 °C): $\delta$ = –131.8 (d, $^3J_{F,F}$ = 19.8 Hz, 8 F, $F_o$), –161.9 (t, $^3J_{F,F}$ = 19.8 Hz, 4 F, $F_p$), –165.9 (t, $^3J_{F,F}$ = 19.8 Hz, 8 F, $F_m$) ppm. $C_{28}H_{15}BF_{20}N_2$ (770.2): calcd. C 43.66, H 1.96, N 3.64; found C 43.92, H 1.82, N 3.65.

**$[(C_4H_4N_2)H{\cdot}OEt_2][H_2N\{B(C_6F_5)_3\}_2]$ (8). Method A:** Pyrazine (0.1 g, 1.2 mmol) was weighed under inert atmosphere and rapidly added to a solution of **4** (1.0 g, 0.8 mmol) in $CH_2Cl_2$ (25 mL). The colourless mixture was stirred at room temperature overnight, and the solvent was pumped off under vacuum to leave a white solid which was washed with light petroleum (3 × 25 mL) and dried in vacuo. Crystals suitable for X-ray diffraction were obtained by recrystallisation from a concentrated $CH_2Cl_2$ solution at –26 °C. Yield 0.8 g (88%). $^1$H NMR ($CD_2Cl_2$, 25 °C, 300.13 MHz): $\delta$ = 16.46 (br., 1 H, N–*H*), 10.36–8.10 (v br, 4 H, C–*H*), 5.70 (br. s, 2 H, $H_2$N), 3.86 (q, $^3J_{H,H}$ = 7.0 Hz, 4 H, $CH_3$–C$H_2$–O), 1.34 (t, $^3J_{H,H}$ = 7.0 Hz, 6 H,C$H_3$–$CH_2$–O) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$, 25 °C, 75.48 MHz): $\delta$ = 148.8, 146.6, 141.1, 138.6, 137.8, 135.4 (all $ArF_5$–*C*), 142.7 ($C_4H_4N_2$), 67.7 ($CH_3$–*C*$H_2$–O), 15.0 (*C*$H_3$–$CH_2$–O) ppm. $^{11}$B NMR ($CD_2Cl_2$, 96.29 MHz, 25 °C): $\delta$ = –5.3 ppm. $^{19}$F NMR ($CD_2Cl_2$, 282.38 MHz, 25 °C): $\delta$ = –133.4 (d, $^3J_{F,F}$ = 19.8 Hz, 12 F, $F_o$), –160.6 (t, $^3J_{F,F}$ = 19.8 Hz, 6 F, $F_p$), –166.1 (t, $^3J_{F,F}$ = 19.8 Hz, 12 F, $F_m$) ppm. $C_{44}H_{17}B_2F_{30}N_3O$ (1195.2): calcd. C 44.22, H 1.43, N 3.52; found C 43.91, H 1.58, N 3.43.

**Method B:** $[Na(OEt_2)_4][H_2N\{B(C_6F_5)_3\}_2]$ (1.9 g, 1.4 mmol) was added at room temperature to a suspension of solid $C_4H_4N_2{\cdot}HCl$ (0.15 g, 1.3 mmol) in 25 mL of $CH_2Cl_2$. The pyrazinium chloride reacted immediately, and the resulting solution turned pale yellow while small amounts of NaCl precipitate persisted. The solution was filtered off after 6 h, and the volatiles were removed under vacuum. A white powder was isolated, the composition of which was essentially identical to that of the solid obtained with Method A above. Yield 1.2 g (77%).

**$[Me_3Sn(HNMe_2)_2][B(C_6F_5)_4]$ (9):** Compound **7** (0.8 g, 1.0 mmol) was rapidly added to a solution of $Me_3SnN(SiMe_3)_2$ (0.6 g, 1.8 mmol) in $Et_2O$ (30 mL). The resulting colourless solution was stirred at room temperature for 1 h. Upon removal of the volatiles in vacuo a white solid was obtained which was washed thoroughly with light petroleum (2 × 50 mL) and dried in vacuo to constant weight. Yield 0.9 g (96%). Recrystallisation from a dichloromethane/light petroleum mixture (4:1) kept at –26 °C afforded single crystals of **9** as colourless slabs. $^1$H NMR ($CD_2Cl_2$, 25 °C, 300.13 MHz): $\delta$ = 2.42 (s, 12 H, N–C$H_3$), 2.14 (br., 2 H, N–*H*), 0.60 (s, 9 H, Sn–C$H_3$) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$, 25 °C, 75.48 MHz): $\delta$ = 150.1, 146.9, 140.2, 138.3, 137.0, 135.0 (all $ArF_5$–*C*), 37.8 (N–*C*$H_3$), –5.4 (Sn–*C*$H_3$) ppm. $^{11}$B NMR ($CD_2Cl_2$, 96.29 MHz, 25 °C): $\delta$ = –13.6 ppm. $^{19}$F NMR ($CD_2Cl_2$, 282.38 MHz, 25 °C): $\delta$ = –133.6 (d, $^3J_{F,F}$ = 19.8 Hz, 8 F, $F_o$), –164.0 (t, $^3J_{F,F}$ = 19.8 Hz, 4 F, $F_p$), –168.0 (t, $^3J_{F,F}$ = 19.8 Hz, 8 F, $F_m$) ppm. $^{119}$Sn NMR ($CD_2Cl_2$, 25 °C, 111.91 MHz): $\delta$ = –25.3 ppm. $C_{31}H_{23}BF_{20}N_2Sn$ (933.0): calcd. C 39.91, H 2.48, N 3.00; found C 40.07, H 2.40, N 3.06.

**X-ray Crystallography:** Crystal data and refinement results for compounds **1**, **2**, **6**, **8** and **9** are collated in Table 1. In each case, crystals were mounted on glass fibres, either in oil and fixed in the cold nitrogen stream on a Rigaku/MSC AFC7R diffractometer (samples **1**, **2** and **6**) or with epoxy resin on a Nonius KappaCCD diffractometer (samples **8** and **9**). Data were processed with the TeXsan/PROCESS[63] or DENZO program,[64] and absorption corrections applied. The structures were determined by heavy atom methods (compounds **1** and **2**) or direct methods (compounds **6**, **8** and **9**) in SHELXS.[65] Refinement was by full-matrix least-squares methods in SHELXL.[65] In all, non-hydrogen atoms were refined anisotropically; hydrogen atoms were included in idealised positions and their isotropic thermal parameters were set to ride on the $U_{eq}$ values of the parent carbon or nitrogen atoms. Scattering factors for neutral atoms were taken from ref.[66]. The relatively large difference peaks and holes were located close to the tin atoms and arise from inadequate absorption correction. No absorption correction was applied in the case of compound **1**.

# Pentafluorosulfanyl ($SF_5$) Containing Energetic Salts

Haixiang Gao,[a] Chengfeng Ye,[a] Rolf W. Winter,[b] Gary L. Gard,[b] Michael E. Sitzmann,[c] and Jean'ne M. Shreeve*[a]

**Keywords:** Ionic liquids / Pentafluorosulfanylnitramide / Quaternization / Salts / Heats of formation / Energetic materials

New quaternary salts of pentafluorosulfanyl-substituted ($SF_5$) *N*-methylimidazole (**1**), 4-amino-1,2,4-triazole (**3**) or pyridine (**5**) were prepared and characterized. Most of the salts exhibit good thermal stabilities and low melting points placing them in the ionic liquid class. Their densities range between 1.4 and 1.8 g/cm$^3$. The standard enthalpies of formation for the new salts were calculated by the use of computationally feasible DFT(B3LYP) and MP2 methods in conjunction with an empirical approach based on densities of salts.

## Introduction

Energetic materials are vital to the improvement and advancement in our lives; essential in peace and in armed conflict. These materials are controllable energy sources which deliver power as a function of the rate at which the energy is liberated. Propellants that release energy over a period of a few milliseconds to seconds by evolving gases are useful for driving turbines or propelling rockets. However, explosives, which evolve energy at rapid rates are employed to produce intense shock waves and find great value in mining, cutting, and initiation of detonation phenomena. Nearly all of the industrially used energetics are based on ammonium nitrate, while for military purposes nitroglycerin, nitrocellulose, HMX, TNT, or RDX are most frequently used. Currently, the research in the field of energetic materials has tended to be directed towards the synthesis of simple molecules with high energy, high density, high heat resistance and low sensitivity by often focusing on the design of nitrogen-containing heterocyclic-based, energetic, low-melting salts.[1,2] Energetic materials that are salts often possess advantages over molecular analogues since they tend to exhibit lower vapor pressures and higher densities.

High on the list of important characteristics for energetic materials are density and energy released. Earlier we reported new thermally stable, pentafluorosulfanyl polyfluoroalkyl-substituted quaternary salts whose melting points were less than 0 °C and where the presence of the pentafluorosulfanyl group markedly increased the densities of these room-temperature ionic liquids vis-à-vis most of their perfluoroalkyl or alkyl analogues.[3] Based on those results and the following observations: (1) indications that the $SF_5$ group can provide energetic salts with improved properties, i.e., increased density, decreased sensitivity and good thermal stability; and (2) the larger energy release found due to formation of HF in the detonation of $SF_5$ explosives [compare the average S–F bond energy (79 kcal/mol) to that of H–F (136 kcal/mol)],[4] we examined the impact of the pentafluorosulfanyl group on the properties of energetic salts. In the present work, we report the preparation and characterization of pentafluorosulfanylalkyl-substituted imidazolium, triazolium and pyridinium salts that contain highly oxidizing anions.

## Results and Discussion

Initially, we attempted to quaternize *N*-methylimidazole (**1**), 4-amino-1,2,4-triazole (**3**) or pyridine (**5**) with $SF_5CH_2CH_2Br$ or $SF_5CH_2CH_2OTs$, but failed because major decomposition of the pentafluorosulfanyl-containing precursor occurred due to the loss of HBr or HOTs. In sharp contrast, by simply elongating the alkyl chain in the $SF_5$ electrophile from ethyl to propyl, excellent yields resulted. For example, reaction of $SF_5CH_2CH_2CH_2Br$ with *N*-methylimidazole (**1**) in a 1:1 molar ratio without solvent at 65 °C for 12 h led to the formation of the quaternary salt **2** in 90% isolated yield (Scheme 1). Analogously, reactions of $SF_5CH_2CH_2CH_2Br$ with 4-amino-1,2,4-triazole (**3**) and pyridine (**5**) gave the monoquaternary bromides **4** and **6** in >85% isolated yields. Nitrate, perchlorate, dinitramide, and pentafluorosulfanylnitramide salts were synthesized by metathesis of the monoquaternary salts with silver nitrate, silver perchlorate, ammonium dinitramide, and potassium pentafluorosulfanylnitramide,[5] respectively, in aqueous

Scheme 1.

solution (Scheme 1). Because some of the nitrate salts were hygroscopic, they were dried under vacuum for 24 h and stored in a desiccator for further analysis.

Phase-transition temperatures [midpoints of melting points ($T_m$) or glass phase transition temperatures ($T_g$)] were determined by differential scanning calorimetry (DSC), and decomposition points ($T_d$) were recorded using thermogravimetric analysis (TGA) (Table 1). It is seen that the decomposition temperatures and heats of formation for the perchlorate salts are higher than those of the nitrate and dinitramide salts. The melting points of the imidazolium (**2**) and pyridinium (**6**) salts are considerably lower than that of triazolium salts (**4**).

Density is one of the important physical properties of energetic salts. Some of the experimental densities obtained by using a helium pycnometer for the new salts are also listed in Table 1. For all of the compounds, densities exceeded 1.40 g cm$^{-3}$, likely arising from the presence of the $SF_5$ moiety. This is particularly noticeable in the case of **4d**, which exhibits a density of 1.82 g/cm$^3$ due to the $SF_5$ functional groups found in both anion and cation, which markedly enhance this property.

Table 1. Structure and properties of $SF_5$-containing salts.

### Thermochemistry

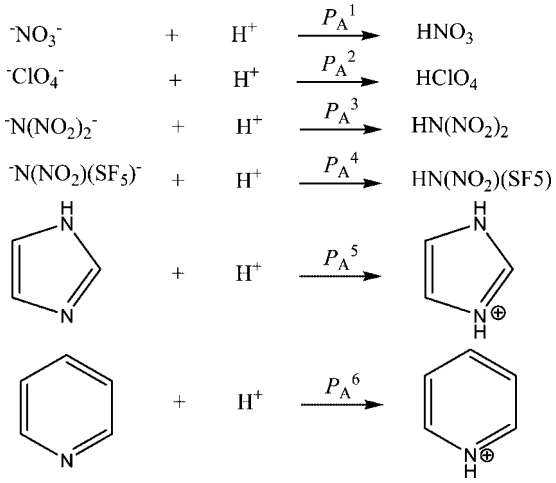
According to Born–Haber energy cycles, heats of formation of ionic salts can be simplified by the formula:

$\Delta H_f^o$ (ionic salts, 298 K) = $\Delta H_f^o$ (cation, 298 K) + $\Delta H_f^o$ (anion, 298 K) – $\Delta H_L$

where $\Delta H_L$ is the lattice energy of the ionic salts. For 1:1 salts and considering the nonlinear nature of the cation and anion we currently used, $\Delta H_L$ [kJ/mol] can be predicted by the formula suggested by Jenkins et al.[6] as:

$\Delta H_L = 1981.2 \cdot (\rho_m/M_m)^{1/3} + 108.8$

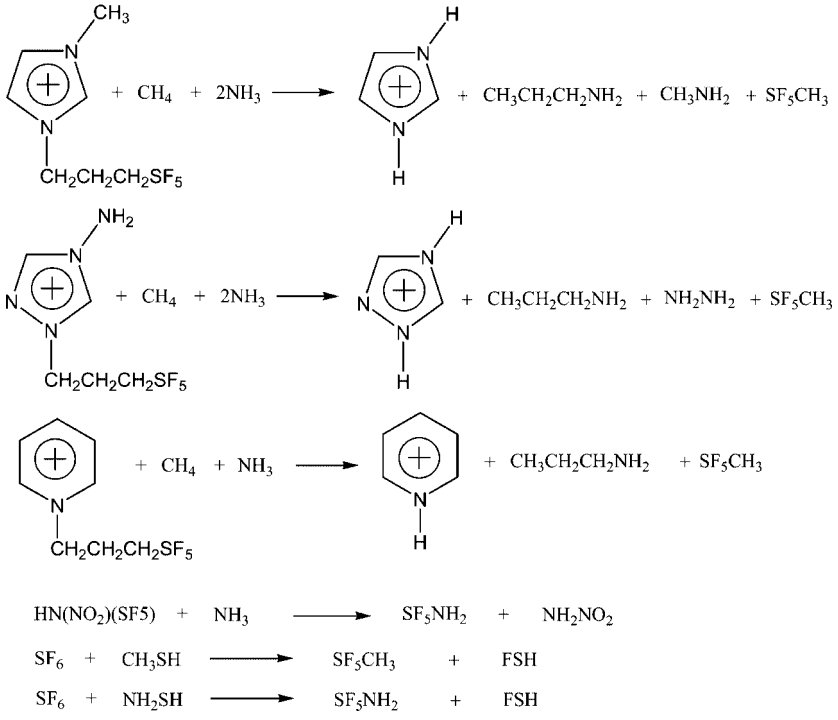
Heats of formation of the $NO_3^-$, $ClO_4^-$ and $N(NO_2)_2^-$ anions can be easily obtained by the reactions in Scheme 2.



Scheme 2.

The proton affinities ($P_A$) were calculated using the G2 method or taken from the literature.[7] A value of 1528.085 kJ mol$^{-1}$ with correction of 6.197 kJ mol$^{-1}$ was adopted for $\Delta H_f^o$ ($H^+$, 298 K).[8,9] Heats of formation of $HNO_3$ and $HN(NO_2)_2$ in the gas phase are available (–32.1 and 29.9kcal/mol, respectively),[7] while the heat of formation of $HClO_4$ (g) is a little uncertain. In this work, 0.6 kcal mol$^{-1}$ was used. This was derived by computation using W1 and W2 methods.[10] This molecule exhibits particularly severe degrees of inner polarization, and as such obtaining a basis-set limit SCF component to the total atomization energy becomes a challenge. However, the G2 calculation gives 10.8 kcal/mol. Heats of formation of $NO_3^-$, $ClO_4^-$ and $N(NO_2)_2^-$ were calculated to be –73.6, –66.4, and –26.9 kcal/mol, respectively.

Then the remaining task was to determine the heats of formation of the cations, and of $N(NO_2)(SF_5)^-$, which were computed using the method of isodesmic reactions (Scheme 3). The 1,2,4-triazolium species was purposely conserved, because its heat of formation has been experimentally determined to be 835 kJ mol$^{-1}$.[8] With the experimental heat of formation of imidazole and pyridine, the imidazolium and pyridinium cations were calculated by the proton-affinity reactions shown in Scheme 2 using the G2 method. The enthalpies of reactions ($\Delta H_r^o{}_{,298}$) are obtained by combining the MP2(full)/6-311++G** energy difference for the reactions, the scaled zero-point energies, and other thermal factors. Thus, the heats of formation of the cations and of $N(NO_2)(SF_5)^-$ can be readily extracted. The results are listed in Table 1. The calculated enthalpies of formation ($\Delta_f H_m$) range from –419.5 kcal mol$^{-1}$ to –161.5 kcal mol$^{-1}$.



Scheme 3.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

All of the values are negative mainly as a result of the large negative heat of formation of $SF_5$ (–216.3 kcal/mol).[11]

The expected detonation pressures ($P$) and detonation velocities ($D$) based on the traditional Chapman–Jouget thermodynamic detonation theory were calculated (Table 1).[12] For all the salts, the calculated detonation pressures lie in the range between $P$ = 10.4 GPa (**2b**) and $P$ = 16.7 GPa (**4d**). These values are similar to that of tetranitromethane (14.4 GPa).[13] Detonation velocities range between $D$ = 5538 m s$^{-1}$ and $D$ = 6630 m s$^{-1}$ (**4d**), higher than those of ammonium dinitramide ($D \geq$ 5300 m s$^{-1}$) and lead azide ($D$ = 5300 m s$^{-1}$).

Of all of the new energetic compounds, **4b** is thermally considerably more stable than **4d**, but its density is lower by 0.4 g/cm$^3$. Also, the pentafluorosulfanylnitramide derivative **4d** has a melting point which is 71 °C lower than **4b**. The densities of the new (pentafluorosulfanyl)alkyl quaternary salts are surprisingly low compared to their (pentafluorosulfanyl)polyfluoroalkyl quaternary analogs that exhibit densities around 2 g/cm$^{-3}$ making them among the most dense of any of the non-chloroaluminate salts reported to date.[14] Comparisons must be made carefully because the (pentafluorosulfanyl)polyfluoroalkyl derivatives were only studied with bis(trifluoromethanesulfonyl)amide as the anion.[3] However, it may be concluded that density may be enhanced by the presence of fluorine in fluoroalkyl and/or pentafluorosulfanyl moieties.

## Conclusions

Syntheses of $SF_5$-propyl derivatives of imidazole, 4-amino-1,2,4-triazole, and pyridine and their subsequent quaternization led to new energetic salts. Most of the new salts exhibit good physical properties, including moderately high density (>1.40 g/cm$^3$), good thermal and hydrolytic stabilities and low melting points (<100 °C). The molar enthalpies of formation were calculated by theoretical methods. Perchlorate salts have slightly higher molar enthalpies of formation than the analogous nitrates. The calculated heats of formation for dinitramide-containing salts are the highest. Utilization of pentafluorosulfanylnitramide as the anion contributes to a decrease in the melting point because of its asymmetry and of the tendency for the negative charge to be dispersed over the entire anionic structure, as is the case for dinitramide.

## Experimental Section

**Caution:** While we have experienced no difficulties with shock and friction sensitivity of these compounds with high nitrogen content and rather high heats of formation, they should be synthesized in mmol amounts and handled with extreme care.

**General Methods:** All the reagents used were analytical reagents purchased from commercial sources and used as received. $^1$H, $^{19}$F NMR and $^{13}$C NMR spectra were recorded with a 300-MHz NMR spectrometer operating at 300.13, 282 and 75.48 MHz, respectively. Chemical shifts are reported relative to $Me_4Si$ or $CCl_3F$. The solvent was $D_2O$ unless otherwise specified. The melting and decomposition points were recorded with a differential scanning calorimeter and a thermogravimetric analyzer at a scan rate of 10 °C/min, respectively. IR spectra were recorded using NaCl plates for neat liquids and KBr pellets for solids. Densities of ionic liquids were measured at room temperature using a pycnometer. Densities of solid salts were measured at room temperature using a Micromeritics Accupyc 1330 gas pycnometer. Elemental analyses were performed with an EXETER CE-440 Elemental Analyzer.

**Theoretical Study:** Computations were performed with the Gaussian03 (Revision D.01) suite of programs.[15] The geometric optimization and the frequency analyses are carried out using B3-LYP functional analyses with 6-31+G** basis set.[16] Single energy points were calculated at the $MP_2$(full)/6-311++G** level.[17,18] All of the optimized structures were characterized to be true local energy minima on the potential energy surface without imaginary frequencies.

**General Procedure:** *N*-Methylimidazole (**1**), 4-amino-1,2,4-triazole (**3**), or pyridine (**5**) (2 mmol) and $SF_5CH_2CH_2CH_2Br$ were sealed in a Pyrex glass tube in vacuo by cooling to liquid nitrogen temperature and then heated at 65 °C for 12 h. After cooling to room temperature, the tube was opened and the volatile materials were removed at reduced pressure. Washing of the crude products with an acetone/pentane mixture (1:3) gave **2**, **4**, and **6** in good yields. The nitrate, perchlorate, dinitramide and pentafluorosulfanylnitramide salts were synthesized by metathesis of the monoquaternary bromides with silver nitrate, silver perchlorate, ammonium dinitramide, and potassium pentafluorosulfanylnitramide[5] in water. Reactions of these bromides with silver salts in water in a 1:1 molar ratio were carried out at 25 °C. After 2 h, silver bromide was removed by filtration. The filtrate was concentrated and dried in vacuo to give **2a**–**b**, **3a**–**b** in high yields. Reactions of analogous substrates with ammonium dinitramide or potassium pentafluorosulfanylnitramide in water were stirred at room temperature for 2 h to give a heterogeneous mixture. The water was removed under reduced pressure at 50 °C until constant weight was reached. To the remaining suspension were added chloroform and anhydrous magnesium sulfate. After 1 h, the suspension was filtered and the volatile material was removed under reduced pressure at 30 °C for 2 h to afford the dinitramide or pentafluorosulfanylnitramide salts.

**1-Methyl-3-[3-(pentafluorosulfanyl)propyl]imidazolium Bromide (2):** Yield 90% (0.596 g). IR (KBr pellet): $\tilde{\nu}$ = 3433, 3146, 3069, 2982, 2858, 2750, 2069, 1749, 1639, 1574, 1462, 1379, 1286, 1244, 1169, 1073, 831, 624, 595, 563 cm$^{-1}$. $^1$H NMR: $\delta$ = 8.78 (s, 1 H), 7.53 (s, 1 H), 7.48 (s, 1 H), 4.34 (t, $J$ = 0.79 Hz, 2 H), 3.91 (m, 5 H), 2.58 (m, 2 H) ppm. $^{13}$C NMR: $\delta$ = 124.84, 123.05, 68.90 (m), 48.15, 36.69, 27.36 (m) ppm. $^{19}$F NMR: $\delta$ = 85.65 (m, 1 F), 64.84, (d, m, 4 F) ppm. $C_7H_{12}BrF_5N_2S$ (331.14): calcd. C 25.39, H 3.65, N 8.46; found C 25.46, H 3.59, N 8.41.

**1-Methyl-3-[3-(pentafluorosulfanyl)propyl]imidazolium Nitrate (2a):** Yield 90% (0.282 g). IR (KBr pellet): $\tilde{\nu}$ = 3433, 3149, 3092, 2395, 2289, 2067, 1631, 1571, 1377, 1169, 1082, 1037, 829, 758, 655, 627, 595, 563, 482 cm$^{-1}$. $^1$H NMR: $\delta$ = 8.80 (s, 1 H), 7.56 (s, 1 H), 7.50 (s, 1 H), 4.36 (t, $J$ = 4.82 Hz, 2 H), 3.94 (m, 5 H), 2.60 (m, 2 H) ppm. $^{13}$C NMR: $\delta$ = 137.16, 124.96, 123.14, 69.01 (m), 48.22, 36.78, 27.36 (m) ppm. $^{19}$F NMR: $\delta$ = 85.43 (m, 1 F), 64.78, (d, m, 4 F) ppm. $C_7H_{12}F_5N_3O_3S$ (313.25): calcd. C 26.84, H 3.86, N 13.41; found C 26.54, H 4.02, N 12.97.

**1-Methyl-3-[3-(pentafluorosulfanyl)propyl]imidazolium Perchlorate (2b):** Yield 89% (0.312 g). IR (KBr pellet): $\tilde{\nu}$ = 3429, 3088, 2379, 1716, 1566, 1388, 1087, 826, 754, 625, 598, 544 cm$^{-1}$. $^1$H NMR: $\delta$

# Correlation Between Structure and Magnetic and Magnetotransport Properties of $La_{0.7}Pb_{0.3}(Mn_{1-x}Co_x)O_3$ ($0.1 \leq x \leq 0.3$) CMR Manganites

**Alazne Peña,[a] Jon Gutiérrez,*[b] Izaskun Gil de Muro,[a] Javier Campo,[c][‡] Jose Manuel Barandiarán,[b] and Teófilo Rojo[a]**

**Keywords:** Manganites / Crystal structure / Magnetic properties / Magnetoresistance / Metal–insulator transition / Perovskite phases

Structural and magnetic properties of $La_{0.7}Pb_{0.3}(Mn_{1-x}Co_x)O_3$ ($0.1 \leq x \leq 0.3$) manganites are reported. Samples were fabricated by the sol-gel low temperature method. At room temperature, the first structural characterisation of all phases gave as a result the rhombohedral space group ($R\bar{3}c$). All compositions show ferromagnetic behaviour and magnetoresistance. The measured low-temperature magnetic moment and the Curie temperature continuously decrease with respect to the undoped composition, as Mn ions are substituted progressively by Co. This is interpreted in terms of substitution of $Mn^{3+}$ by $Co^{3+}$ and the appearance of a small amount of $Co^{4+}$. The measured magnetoresistance reaches 40 % for the 10 % Co-doped one at the corresponding Curie temperature. The resistivity behaviour of all the studied compounds is determined by the intra- and intergrain conduction mechanisms, with grain sizes in the range of 10–25 nm.

## Introduction

Perovskite-like phases with the general formula $Ln^{3+}_{1-x}A^{2+}_xMnO_3$ ($Ln^{3+}$ = La, Pr, Nd, Sm… and $A^{2+}$ = Ca, Sr, Ba, Pb…) have attracted the attention of the scientific community because of the magnetotransport properties exhibited.[1,2] The double exchange mechanism[3] is used to explain the ferromagnetic behaviour of these phases, while the simultaneous presence of ferromagnetism and a metallic state brings about colossal magnetoresistance (CMR) when the magnetic field is changed.[4] These generic magnetic and transport properties in this type of doped manganites mainly arise from a strong on-site exchange interaction (Hund's-rule couple $J \approx 2$–$3$ eV[5]) between the localised $t_{2g}$ spins and itinerant $e_g$ electrons.[6] The rhombohedral and orthorhombic distortion of the actual crystallographic structure of the classic cubic symmetry is also an essential factor to understand the magnetic and transport properties of these samples.[7]

The substitution of the Mn ions by other transition-metal ions in perovskites of composition $Ln_{0.7}A_{0.3}Mn_{1-y}TM^{3+}_yO_3$ (TM = transition metal) gives rise to changes in the $Mn^{3+}$:$Mn^{4+}$ ratio, with important modifications in their magnetic and transport properties.[8–12] The $y = 0$ sample shows ferromagnetism and CMR. In this sense, the effect of different trivalent ions from the iron group (partially filled 3d shells) as $Fe^{3+}$ ($3d^5$), $Co^{3+}$ ($3d^6$) or $Ni^{3+}$ ($3d^7$) substitution in the Mn site is still an interesting subject.

We have shown, in previous works,[9,13] that iron enters as high-spin $t_{2g}^3\ e_g^2$ (HS, $S = 5/2$) $Fe^{3+}$ in the $La_{0.7}Pb_{0.3}Mn_{1-x}Fe_xO_3$ family of compositions because it is the most stable oxidation state for this cation, and its ionic radius is very similar to that of the $Mn^{3+}$ ion. Iron couples antiferromagnetically with Mn ions and weakens progressively the double exchange mechanism and so the ferromagnetic character (decrease of both Curie temperature and low-temperature magnetic moment value) of the compounds as the doping level increases. A 20–30% substitution of Fe leads to magnetic frustration and insulating behaviour in these compositions.[13]

The electronic and magnetic properties of the $LaCoO_3$ perovskite is still a matter of research in the scientific community. Goodenough determined that the spin state of the $Co^{3+}$ ions presents a $t_{2g}^6\ e_g^0$ diamagnetic low-spin configuration at low temperatures (LS, $S = 0$), which changes as temperature increases to a $t_{2g}^4\ e_g^2$ high-spin (HS, $S = 2$) state. The possibility of having $Co^{3+}$ in different spin states as a function of temperature arises from the close values of the intra-atomic exchange energy ($J_H$) and the crystal field splitting (10Dq) at the Co sites. The low-temperature spin state of the $Co^{III}$ ion is due to the large crystal field, which stabilises its low-spin configuration and is energetically

more favourable. Increasing temperature, a thermally activated spin transition from the low-temperature LS state to a paramagnetic HS state occurs; in the range 100–350 K both populations are stabilised in a dynamical equilibrium.[14,15] More recently different authors[16,17] have evidenced the existence of a transition that develops from the low-temperature $Co^{3+}$ (LS, $t_{2g}^6 e_g^0$) to an intermediate spin (occupation $t_{2g}^5 e_g^1$) state, as temperature increases, with energy differences about 10–12 meV between the ground and the first excited state. Also, in Co containing perovskite-like compounds and in particular in cobaltites, the coexistence of those ions with high-spin tetravalent $Co^{4+}$ ($t_{2g}^3 e_g^2$) has also been proposed.

In order to study such a transition and the effect of these different tri- or tetravalent Co cations, we present the results concerning the magnetic and structural properties of the $La_{0.7}Pb_{0.3}(Mn_{1-x}Co_x)O_3$ manganites when Mn is substituted progressively by Co up to 30% doping levels. Similar research work was performed in a family of manganites having Ca instead of Pb occupying the A site.[15] Briefly, it was found that even for small doping levels of Co (as low as $x = 0.05$) the ferromagnetic order of the pure manganite is severely modified. The magnetic-order temperature decreases quickly in the Mn–Co mixed compounds, with almost a constant value of 165–170 K for doping levels ranging from $x = 0.1$ to 0.3. But $Ca^{2+}$ and also $Sr^{2+}$ are cations with ionic character and when cations with a more covalent character, such as $Pb^{2+}$[13] and $Bi^{3+}$,[18] are used, the observed magnetic behaviour indicates a soft and progressive decrease of the magnetic-order temperatures in each family of compounds.

Neutron diffraction, magnetic and transport measurements have been used in order to perform this study. We have been especially careful in the analysis of the chemical and structural properties of the studied compositions, and tried to explain the observed magnetic and magnetotransport properties on the basis of those previously determined characteristics.

## Results and Discussion

The morphology of the $La_{0.7}Pb_{0.3}Mn_{0.9}Co_{0.1}O_3$ compound is shown as representative in the SEM photograph (taken with 8500 times magnification) of Figure 1. The microstructure reveals uniform and fine grain growth, less than 1 μm size, as expected from the sol-gel fabrication process used to synthesise the samples. The observed agglomeration of such fine grains is also a direct consequence of the fabrication process used.

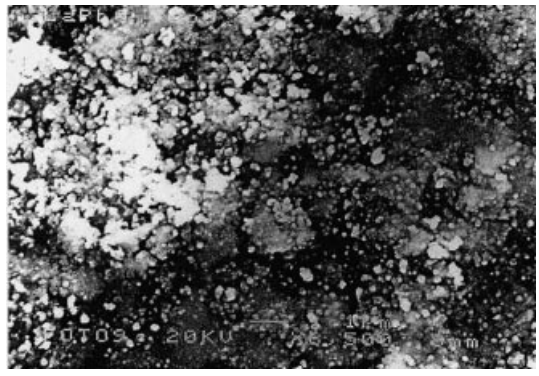

Figure 1. SEM photograph of the $La_{0.7}Pb_{0.3}Mn_{0.9}Co_{0.1}O_3$ compound.

The crystal structure of this family of compounds has been analysed in the trigonal space group ($R\bar{3}c$) (see Figure 2), hexagonal setting ($Z = 6$), using the D1B neutron powder diffraction data.

The Co cation undergoes a spin-state transition, in the range 125–230 K, that is directly correlated with the ionic radius of the cations and is reflected in the thermal evol-

ution of the Mn/Co–O bond length obtained from the neutron diffraction patterns (see Figure 3). We attribute this transition to be from nonmagnetic (LS) to magnetic intermediate state (IS) of the Co cations, with the appearance of orbital ordering of occupied $e_g$ orbitals, as has been previously observed by other authors in the related compound $LaCoO_3$.[16,17] A very recent work[19] on this subject has proved that Co–O hybridisation has to be taken into account, giving rise to a "covalent" IS, $Co(t_{2g}^5\ e_g^{1.5})$–$O(2p^{5.5})$. However, in our case the Co quantity is small enough to give a precise picture of this transition.

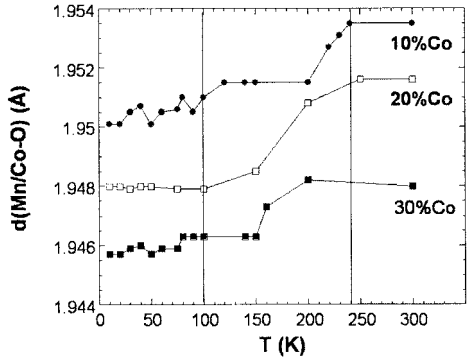

Figure 3. Thermal evolution of the bond length Mn/Co–O for these compounds.

The oxygen stoichiometry of the samples was determined by thermogravimetric analysis, the oxides being heated up to 900 °C in flowing 5% $H_2$/Ar. The samples were reduced to MnO and CoO and the observed weight losses allowed us to determine the oxygen contents of $La_{0.7}Pb_{0.3}Mn_{0.9}Co_{0.1}O_{3.10}$, $La_{0.7}Pb_{0.3}Mn_{0.8}Co_{0.2}O_{3.17}$ and $La_{0.7}Pb_{0.3}Mn_{0.7}Co_{0.3}O_{3.20}$ for the synthesised samples. The obtained excess of oxygen for all the samples is in good agreement with the quantities obtained from the redox titration, the oxygen excess being a direct consequence of the fabrication process used.

Two losses of consecutive weight based on the temperature for all the samples are observed (see Figure 4). The first loss occurs at a temperature of 437 °C. This temperature increases as the Co doping level in the sample increases, while the second loss happens at approximately the same temperature in all cases.

According to this we can affirm that first the $Mn^{4+}$ and $Co^{4+}$ ions (this one only for the 20% and 30% Co-containing compositions) are reduced to $Mn^{3+}$ and $Co^{3+}$ respectively and when all components appear in the form $Mn^{3+}$ and $Co^{3+}$ (constant amount in all the samples) the second reduction takes place, that is to say, the $Mn^{3+}$ and $Co^{3+}$ ions are reduced to $Mn^{2+}$ and $Co^{2+}$ respectively.

The obtained ZFC–FC curves, for all the compositions, are shown in Figure 5. From ZFC curves, a continuous decrease of the magnetic-order or Curie temperature from 240 K for the 10% Co-doped composition to 180 K for the 30% Co-doped one is clearly observed. This decrease in those magnetic-ordering temperatures can be directly attributed to the progressive suppression of the double exchange

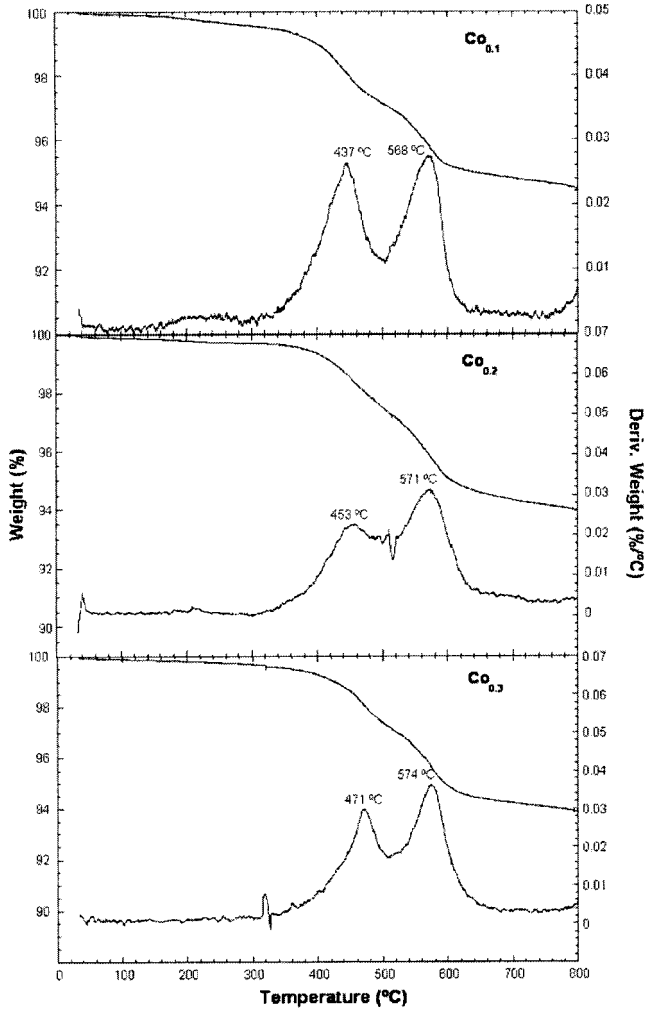

Figure 4. Thermogravimetric curves in $H_2$. It shows two steps of reduction indicating a reduction process of $TM^{4+} \rightarrow TM^{3+} \rightarrow TM^{2+}$ (TM = Mn and Co).

interaction present in the Mn host as Co content increases in the composition of the samples.

There is a remarkable similarity between this low-field magnetisation behaviour, indicating that the magnetisation process is basically the same. The degree of irreversibility of such processes is high, as indicated by the splitting between ZFC and FC curves. This bifurcation of both curves occurs at a temperature $T_b$ corresponding to the blocking temperature of the largest particles in the assembly. That is, $T_b$ defines also a temperature above which magnetisation processes are fully reversible. It is worth mentioning that the drop of the ZFC magnetisation below $T_C$ for each composition can be interpreted as a feature of cluster glass behaviour. On the other hand, a clear weakening of the ferromagnetic character of these compounds on Co substitution is observed, reflecting a decrease of the measured Curie temperature value as Co content increases in the composition of the samples.

The hysteresis loops, measured at 10 K and up to 7 T (see Figure 6), show the usual ferromagnetic behaviour, quickly reaching magnetic saturation, and the measured values of

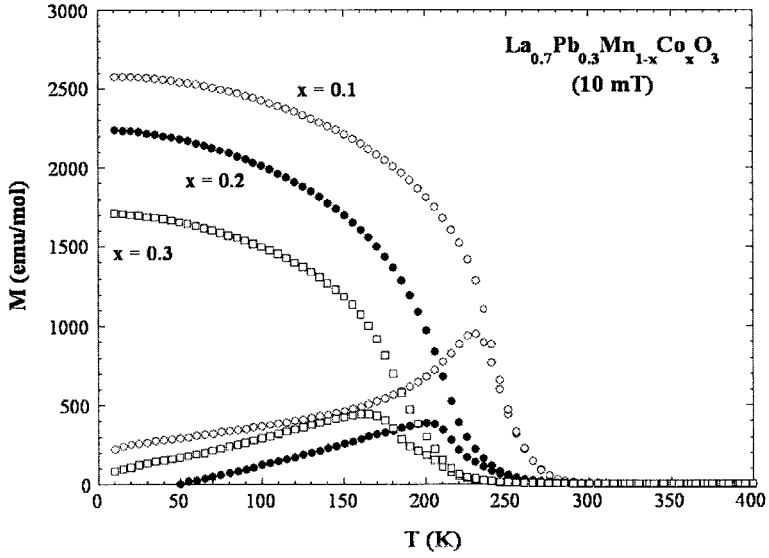

Figure 5. Zero-field cooling (ZFC) and field cooling (FC) curves measured at 10 mT.

the coercive field are 95.5, 114 and 243 kA/m for the 10, 20 and 30% Co-doped compositions, respectively. This high magnitude of the coercive field measured at low temperature can be understood as arising from the strong anisotropic nature of the Co ion.[20] The experimental value of the low-temperature magnetic moment was also determined by using Arrott plots.[21] All measured magnetic data are summarised in Table 1. Previous work from the authors[13] determined the following values for the undoped $La_{0.7}Pb_{0.3}MnO_3$ composition: low temperature $<\mu_{Mn}>_{LT}$ = 3.4 $\mu_B$, $T_C$ = 345 K, high-temperature effective moment $<\mu_{Mn}>_{HT}$ = 5.9 $\mu_B$. For the $x$ = 0.1 composition the measured low-temperature magnetic moment supports our previous supposition that Co enters in the composition only as $Co^{3+}$ (LS) (diamagnetic at low temperatures). However, this is not the case for the $x$ = 0.2 and 0.3 samples. The measured moment values do not agree with the supposition that all Co is $Co^{3+}$. To account for those measured values (and in particular for the $x$ = 0.2 composition, in which a higher degree of ferromagnetic coupling is observed) we need to assume that also $Co^{4+}$ (HS, $S$ = 5/2) is present in those compositions. In fact, a simple calculation gave us a good fit for the measured low-temperature magnetic moment values taking into account small percentages of about 9% high-spin $Co^{4+}$ for the 20% and 5% for the 30% Co-containing compositions. The existence of $Co^{4+}$ has been observed in other manganite phases.[22] Thus, the low-temperature magnetic properties of these compounds can be understood on the basis of a competition between positive $Co^{3+}$–O–$Co^{4+}$ and negative $Co^{3+}$–O–$Co^{3+}$ and $Co^{3+}$–O–$Mn^{4+}$ interactions, in which it concerns Co ions. Furthermore, a scenario in which $Co^{3+}$ ions cluster around $Co^{4+}$ ions is plausible and justifies the observed zero-field cooled magnetisation behaviour.

| Co0.3 | 2.38 | 2.63 | 180 | 2.11[e] | 190 | 5.22 | 230 | 5.2 |

[a] Expected values if only $Co^{3+}$ enters in the compositions. [b] Values obtained from magnetic measurements. [c] Values obtained from neutron diffraction. [d] $T$ = 1.5 K. [e] $T$ = 10 K. [f] Values from Curie–Weiss law in the paramagnetic regime. [g] Values calculated as explained in the text.

We can check the validity of this guess by analysing the high-temperature magnetisation behaviour. In Figure 7 we show the $\chi^{-1}_{dc} = H/M_{ZFC}$ versus $T$ behaviour measured in the paramagnetic phase for the different samples. A Curie–Weiss law is clearly followed above $T_C$ and in the temperature range over which the data were taken. The effective moments $\mu_{eff}$ obtained from the Curie constants are shown in Table 1, together with the obtained paramagnetic Curie temperatures, $\theta_C$. We have also calculated the expected value $\mu_t$ of that effective moment as $\mu_t = [(1 - x)<\mu_{Mn}>^2_{HT} + x<\mu_{Co}>^2]^{1/2}$, taking into account the previous percentages of $Co^{4+}$ (HS) and that only $Co^{3+}$ (covalent IS, 2.5 $\mu_B$[19]) is present for each composition (see Table 1). As expected, all calculated values are slightly higher than the experimental ones, except for the $x$ = 0.3 compound, which shows an excellent agreement between both experimentally determined and calculated values. This sample has the lowest paramagnetic Curie temperature and as a first consequence a better accuracy in the experimental determination of $\mu_{eff}$ than the other two compounds because the temperature range used for the fitting extends to temperatures far above $T_C$.

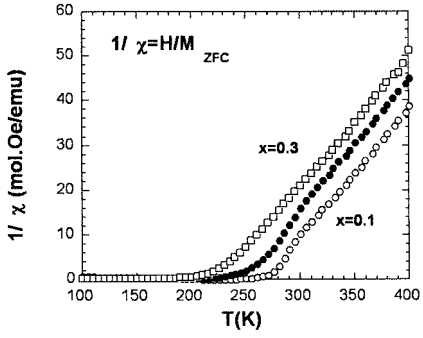

Figure 7. Curie–Weiss plot of the dc susceptibility.

The proposed magnetic behaviour for this family of Co-doped manganites is also supported by our neutron diffraction experiments. The thermal evolution of the neutron diffraction patterns for these samples was also recorded (see Figure 8). In all cases, two reflections with magnetic contribution at the same $d$ values are observed. This feature is indicative of an equivalent magnetic structure for the compounds. That is, the magnetic order does not change its structure when including 10, 20 or 30% of Co in these La-based phases. Furthermore, all magnetic reflections can be indexed with the same cell as the nuclear one, indicating an equivalent type of ferromagnetic structure with collinear magnetic moments. The magnetic contribution appears at about 275, 230 and 190 K for the 10, 20 and 30% Co-doped compositions, respectively. The best solution for the fits was obtained with a collinear magnetic structure in which the magnetic moment of the Mn ion is placed into the (101) crystallographic plane, in the hexagonal setting (parallel to the [111] direction of the perovskite cubic cell) (see Figure 9). The obtained values of the magnetic moment at the lowest temperature of the measurement (1.5 or 10 K) are 2.74, 2.72 and 2.11 $\mu_B$ for the 10, 20 and 30% Co-doped compositions, respectively. Figure 10 shows the temperature dependence of the refined magnetic moment value for the studied Co-containing compositions.

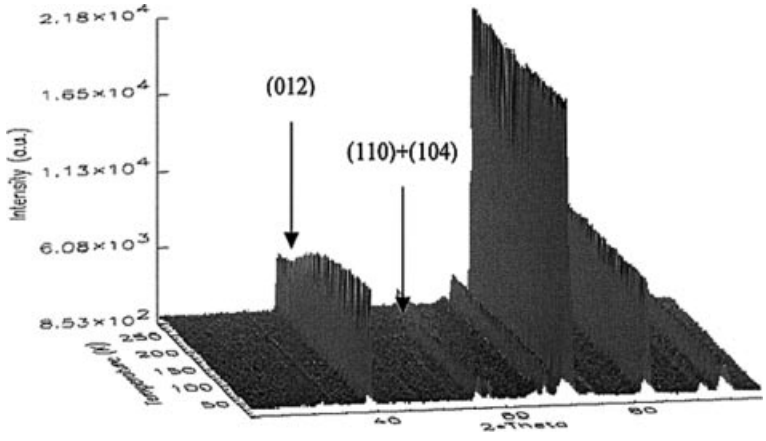

Figure 8. Thermal evolution of the neutron diffraction patterns for the $La_{0.7}Pb_{0.3}Mn_{0.8}Co_{0.2}O_3$ compound.

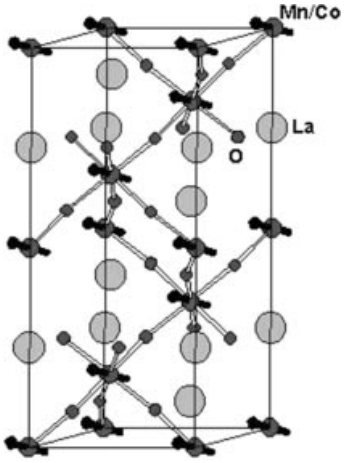

Figure 9. Magnetic structure obtained from neutron diffraction analysis for the $La_{0.7}Pb_{0.3}Mn_{0.8}Co_{0.2}O_3$ compound.

Finally, the room-temperature measured values of the resistivity are 0.098, 0.617 and 0.981 Ω·cm for the 10, 20 and 30% Co-containing samples, respectively. That is, conductivity of the samples decreases as the amount of cobalt that enters into the composition of the samples increases.

From the measured resistivity values as a function of temperature and applied magnetic field we can calculate the magnetoresistance at 6 T as MR (%) = [1 – $R$(6 T)/$R$(0 T)] × 100. The magnitude of this magnetoresistance (see Figure 11) is about 25% for the 30% Co-containing sample and reaches 40% for the 10% Co-containing one (with a local maximum arising from an intragrain magnetoresistance mechanism) at the corresponding Curie temperature of each compound. As the doping level of the cobalt increases, a progressive decrease of the MR value is observed (see Table 2).

It is already well established that the zero-field resistivity data obtained for $T > T_C$ obey the Mott variable range hoping (VRH) mechanism[23] when the carriers are localised near the Fermi energy, as it is in the case of hole-doped manganites. Previous works[24,25] have determined also that the exponent $n = 1/2$ is the most adequate one for this law. Indeed our zero-field resistance data obey Equation (1).

$$\frac{R(T)}{R_0} \propto \exp\left(\frac{T_0}{T}\right)^{1/2} \quad (1)$$

Efros and Shklovskii[26] explained that such resistance behaviour is directly related to a form of hopping favoured by the Coulomb repulsion between carriers. Its most important consequence is the existence of an energy or Coulomb gap, which basically reflects the differences between the minimum energies of adding an electron and subtracting one from the system, without disturbing the other charges. From the obtained $T_0$ values, we have estimated values for these energy gaps ranging between 1 and 5 eV (see Table 2). In particular, the sample containing 20% of doping element exhibits a gap value higher than that obtained when $Ln_{0.7}A_{0.3}MnO_3$-type perovskites are synthesised by using the ceramic method.[27,28] Other authors have already identified such resistivity behaviour, specially at low temperatures, as arising in samples with low grain size (around 20–30 nm).[29] As previously discussed, our perovskites prepared by the sol-gel method present as one of their characteristics the fine grain obtained,[30] typically below 1 μm (see Figure 1). It is already well established that tunnelling of electric charge into small nanoparticles increases the Coulomb energy by the charging effect, strongly enhancing the tunnel resistance. The grain sizes of our compounds can be roughly estimated by using the measured values of the blocking temperature in ZFC–FC curves. This can be written as $T_b = KV/(25k_B)$, where $K$ is the anisotropy constant and $V$ is the grain volume [$V = (3\pi/4)(d/2)^3$, $d$ being the diameter of the grains, assumed to be spherical for simplicity]. From ferromagnetic resonance experiments in a similar $La_{0.67}Ba_{0.33}MnO_3$ oxide,[31] we used $K$ values in the range $2–4 \times 10^4$ J/m$^3$. Thus, from the values of $T_b = 215$ K (30% Co, the lowest one) and 255 K (10% Co, the highest one) we infer grain sizes of 10–25 nm for both compositions, in good agreement with the grain sizes obtained from our structural study. But the presence of those nanosized grains in our samples is strongly supported also by the low-temperature behaviour of the resistivity of these compounds.

Table 2. Values of the magnetoresistance at the corresponding Curie temperature and calculated energy gap for the $La_{0.7}Pb_{0.3}(Mn_{1-x}Co_x)O_3$ ($0.1 \le x \le 0.3$) family of compounds.

| Sample | $\rho_0$[a] [Ω·cm] | MR [%] | $\Delta E$ [eV][b] |
|---|---|---|---|
| Co0.1 | 0.098 | 40 | 1.9 |
| Co0.2 | 0.617 | 38 | 3.5 |
| Co0.3 | 0.981 | 25 | 4.0 |

[a] At 300 K and $H = 0$ applied field. [b] Data fitted to the variable range hopping model, $T > T_C$ range.

The resistivity of the 10% Co-doped sample shows typical features of grain boundary (intergrain) effects, that is a maximum of $\rho(T)$ at a temperature well below $T_C$ that is not shifted to higher temperatures by applying an external magnetic field (see Figure 10, a); but at low temperatures and because of the small size of the grains, it is increasingly difficult to activate this intergrain mechanism. In this situation, transport is effectively blocked, giving, as a result, a much higher upturn in the low-temperature resistivity. This is the so-called Coulomb blockade,[32] and appears much more enhanced in the 20% Co-doped composition.

Along this line of reasoning, our experimental data below 100 K fit well to the expression for granular metals [Equation (2)].[33]

$$\rho(T) \approx \exp\sqrt{(\Delta/T)} \quad (2)$$

In Equation (2) Δ is proportional to the activation or charging energy, $E_C$, of a single grain. From our fits we have obtained values of $\Delta^{1/2} = 2.4$ and 8.5 K$^{1/2}$, and gap energies of 0.5 and 6.2 meV for the Co-10% and Co-20% doped compositions, respectively, that agree with results from other authors[29,34] obtained for related compounds. We also have to mention that the fit to the $T^{-1/2}$ law is better than that to the $T^{-1}$ dependence postulated for a pure Coulomb blockade effect.

## Conclusions

In the light of our experimental work, we can conclude that Co enters in the $La_{0.7}Pb_{0.3}Mn_{1-x}Co_xO_3$ family of perovskites, giving rise to low distortion in the structure of these compounds. The measured low-temperature saturation magnetic moments are mainly due to the coexistence of $Co^{3+}$ (LS) and high spin $Co^{4+}$, as confirmed by susceptibility measurements in the paramagnetic region. The cluster glass behaviour indicated by zero-field cooled magnetisation curves is due to the fact that $Co^{3+}$ probably clusters around $Co^{4+}$ ions. A progressive increase in the doping level of Co gives rise to a subsequent decrease in the measured Curie temperature values, indicating that the long-range ferromagnetism is sensitive even to small amounts of Co.

Because of the sol-gel fabrication process used, we have obtained very homogeneous and small size of the grains (about 10–25 nm as obtained by structural methods and confirmed by magnetic measurements) for all samples. This makes the measured resistivity behaviour to be determined both by the intra- and intergrain carrier tunnelling mechanism that evolve at low temperatures to strong Coulomb blockade for the 20% Co-doped sample.

All compounds show magnetoresistance with magnitudes, at the Curie temperatures, of 40 and 25% for the 10 and 20% Co-doped samples, respectively.

## Experimental Section

Mixed oxides of nominal composition $La_{0.7}Pb_{0.3}(Mn_{1-x}Co_x)O_3$ ($0 \le x \le 0.3$) were prepared by the sol-gel method with the required

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

quantities of analytical grade of $La_2O_3$, $Pb(NO_3)_2$, $Co(NO_3)_2{\cdot}6H_2O$ and $Mn(C_2H_3O_2)_2{\cdot}4H_2O$ as the starting materials. Citric acid and ethylene glycol were used as gelling agents for the metallic ions in a nitrate solution. After drying in a sand bath for 24 h, the gel obtained was subjected to successive heat treatments at temperatures of 773, 973 and 1073 K, each of 10 h. In order to measure the electrical resistivities of the samples, the powder thus obtained was pelletised with a pressure of 7.2 MPa prior to final sintering at 1173 K for 10 h in flowing oxygen.

The $Mn^{3+}/Mn^{4+}$ content of each sample was determined by redox titration using an excess of $FeSO_4$ solution and back titration with $KMnO_4$. We have observed small deviations from the theoretical stoichiometries that could be due to an excess in the oxygen concentration, in accordance with the preparation method, or more probably to the presence of cation vacancies in the samples. We have obtained a ratio $Mn^{3+}/Mn^{4+}$ of 0.37/0.53 for the $x = 0.1$ compound that changes progressively to 0.10/0.60 for the $x = 0.3$ one. That is, as expected, the $Mn^{3+}$ content decreases as the Co doping level increases in the nominal composition of our samples.

Thermogravimetric measurements were performed in a TA instruments SDT 2960 thermobalance. Approximately 50 mg of sample was placed on an alumina crucible and heated to 900 °C at 5 °C/min in a 5% $H_2$/Ar current flow.

Scanning electron microscopic (SEM) observations were also performed to give an indication of the compound morphology and compactness using a JEOL JSM-6400 instrument.

The first crystallographic characterisation of the phases was performed by X-ray powder diffraction analysis using a Philips X-Pert diffractometer, working with Cu-$K_\alpha$1 and Cu-$K_\alpha$2 radiation, Soller slits of 0.04 rad and receiver and divergence slits of 1°. Powder diffraction patterns were Rietveld fitted using the FULLPROF program.[35]

Magnetic and resistance measurements were conducted in a Quantum Design MPMS-7 SQUID magnetometer. The zero-field cooling (ZFC) and field cooling (FC) curves were performed under an applied field of 10 mT. The order temperature, $T_C$, was determined from the ZFC curves as the temperature where the minimum of the d$M$/d$T$ derivative occurs. Hysteresis loops at 10 K and up to 7 T were also obtained. The resistance and magnetoresistance versus temperature measurements were taken by using a conventional dc four-wire system, with the magnetic field applied parallel to the current.

Neutron diffraction measurements were performed at the high-flux reactor at the Institut Laue-Langevin, Grenoble, France. In order to trace the temperature dependence of the structural and magnetic properties, measurements were carried out on D1B. We used a wavelength of 2.519 Å to study the range $2\theta$ = 20–100° at temperatures ranging from 10 to 300 K. The Rietveld analysis of the diffraction data was performed using the FULLPROF program. The line shape of the diffraction peaks was generated by a pseudo-Voigt function and the background interpolated between some fixed background points of the diagrams. In the final run the following parameters were refined: unit-cell parameters, zero-point, half-width, pseudo-Voigt and asymmetric parameters, scale factor, atomic coordinates and thermal isotropic factors. The occupancy factors were also allowed to vary in the last steps of the refinements. Because of the high correlation between the thermal and occupancy factors, in some cases the refinements did not reach the convergence. In those cases, the occupancy factors were fixed to the theoretical ones.

All structural parameters obtained from neutron diffraction experiments together with the tolerance factor ($t$) of the perovskite structure, $t = (d_{La–O})/\sqrt{2}(d_{Mn/Co–O})$ (with $d_{La–O}$ and $d_{Mn/Co–O}$ the La–O and Mn/Co–O bond lengths), are summarised in Table 3. A previous study of the related parent compound $La_{0.7}Pb_{0.3}MnO_3$ gave as the main structural parameters the following: $V$ = 353.01 Å$^3$, $t$ = 0.995, Mn–O–Mn = 166.8° and O–Mn–O = 90.71°.[13] We have observed that for our compounds the unit-cell volume decreases with increasing Co content according to the smaller size of this ion. However, this substitution produces only a minor distortion in the $MnO_6$ octahedra, the O–Mn/Co–O and Mn/Co–O–Mn/Co angles remaining rather constant. The tolerance factor does not suffer any appreciable change for the different compositions. These geometrical characteristics indicate that the distortion of the $La_{0.7}Pb_{0.3}Mn_{1-x}Co_xO_3$ perovskite structure is nearly independent of the $x$ value, in good agreement with the comparable size of $Co^{3+}$ and $Mn^{3+}$ ions. From our structural fits and using the Scherrer formula[36] we have estimated a grain size between 16 and 20 nm.

Table 3. Atomic parameters for the $La_{0.7}Pb_{0.3}(Mn_{1-x}Co_x)O_3$ ($0.1 \leq x \leq 0.3$) family of compounds after the Rietveld refinements of the D1B neutron powder diffraction data. La and Pb atoms are at 6a positions (0, 0, 1/4); Mn and Co atoms are at 6b (0, 0, 0); O atoms are at 18e ($x$, 0, 1/4). $Z$ = 6 in all cases.

# A Ruthenium(II) Complex with a Tripodal Ligand Containing Three Imidazole Groups

**Tomoka Yamaguchi,[a] Kazutoshi Harada,[a] Yukinari Sunatsuki,[a] Masaaki Kojima,*[a] Kiyohiko Nakajima,[b] and Naohide Matsumoto[c]**

**Keywords:** Ruthenium/ Redox chemistry / Chirality / Schiff bases / N ligands / Tripodal ligands

The orange $[Ru^{II}(H_3L)](ClO_4)_2 \cdot 3H_2O$ (**1**) complex was synthesized from *cis*-$[RuCl_2(dmso)_4]$ and $H_3L$, where $H_3L$ (tris{[2-{(imidazol-4-yl)methylidene}amino]ethyl}amine) is a tripodal ligand obtained by condensation of tris(2-aminoethyl)-amine and 4-formylimidazole in a 1:3 mol ratio. The X-ray crystal structure analysis revealed that the complex has an octahedral structure coordinated by three imidazole nitrogen atoms and three Schiff base (imine) nitrogen atoms. The uncoordinated NH groups of the imidazole moieties of **1** are easily deprotonated by the action of a base. The effect of deprotonation on the $Ru^{III}/Ru^{II}$ redox potential was studied by cyclic voltammetry in methanol containing 0.1 M $LiClO_4$. Complete deprotonation shifts the $Ru^{III}/Ru^{II}$ potential to a much more negative value from –0.18 to –0.72 V vs. $Ag/Ag^+$, making it easier to oxidize. The bluish-purple $Ru^{III}$ complex, $[Ru^{III}(H_3L)]^{3+}$, was formed by controlled-potential electrolysis of **1**, and the electronic spectrum is reported.

## Introduction

Ruthenium complexes containing imidazole and its derivatives have attracted great attention in recent years since several of them serve as antitumor drugs.[1] For example, $(H_2im)[Ru^{III}Cl_4(Him)(dmso)]$ (Him = imidazole) and $(H_2ind)[Ru^{III}Cl_4(Hind)(dmso)]$ (Hind = indazole) are on clinical trials, the first as an antimetastatic drug and the second as an anticancer agent against primary tumors and metastases and, in particular, colon carcinomas. As a mode of antitumor action of the $Ru^{III}$ complexes, the "activation by reduction" hypothesis was proposed. The $Ru^{III}$ complexes were suggested to serve as prodrugs that are activated by reduction to $Ru^{II}$ in order to coordinate more rapidly to biomolecules.[1d] In other words, the $Ru^{III}$ complexes should possess biologically accessible reduction potentials to be active in vivo.

Recently, we reported the structures and properties of $Fe^{II}$ and $Fe^{III}$ complexes with a tripodal ligand containing three imidazole groups, $H_3L$; $H_3L$ (tris{[2-{(imidazol-4-yl)methylidene}amino]ethyl}amine) is a potentially heptadentate Schiff-base ligand derived from 1:3 condensation of tris(2-aminoethyl)amine and 4-formylimidazole (Figure 1).[2] The X-ray crystal structure analysis of $[Fe^{II}(H_3L)](BF_4)_2 \cdot 3H_2O$ revealed that the $Fe^{II}$ ion is surrounded by three Schiff base (imine) nitrogen and three imidazole nitrogen atoms in an octahedral fashion, where the tertiary amine nitrogen atom is uncoordinated. The uncoordinated imidazole NH hydrogen atoms of $[Fe^{II}(H_3L)]^{2+}$ are easily deprotonated; upon addition of up to three equiv. of NaOH, $[Fe^{II}(H_3L)]^{2+}$ in methanol under aerobic conditions shows a drastic color change from yellowish-orange, through reddish-orange and green, to deep blue.[2c] $Fe^{II}$ species are oxidized to $Fe^{III}$ by air under basic conditions, and from the final blue solution, we obtained the iron(III) complex, $[Fe^{III}(L)]$, containing the deprotonated ligand $L^{3-}$. Deprotonation of $[Fe^{II}(H_3L)]^{2+}$ induces oxidation of the metal center to generate the $[Fe^{III}(L)]^0$ species. Thus, this reaction is an example of a proton-coupled electron-transfer (PCET) reaction.[3] If we study a ruthenium complex with a ligand containing several imidazole groups such as $H_3L$, we should be able to control the redox potential by adjusting the pH of the solution because the complex will have several different $pK_a$ values. PCET is the basic mechanism of bioenergetic conversion. Small-molecule activation, redox-driven proton pumps, and hydrogen atom abstraction reactions of a wide variety of oxidases and reductases all involve the coupling of electrons to protons.[1d] Thus, $[Ru^{II}(H_3L)]^{2+}$ should be an ideal system to study the pH-dependent metal-based couples as models for PCET reactions because deprotonation should affect the stability of the oxidation state of the Ru complex.

We report here the synthesis, structure, and properties of a $Ru^{II}$ complex with a tripodal ligand containing three

imidazole groups, $[Ru(H_3L)](ClO_4)_2$ (Figure 1), with emphasis being placed on the effect of deprotonation on the cyclic voltammogram (CV) and on the electronic spectrum.

## Results and Discussion

### Synthesis and Characterization

The tripodal $H_3L$ ligand was prepared by the condensation reaction of tris(2-aminoethyl)amine and 4-formylimidazole in a 1:3 mol ratio in methanol (Figure 1). The $H_3L$ ligand was not isolated and a solution containing this ligand was used for the synthesis of $[Ru(H_3L)](ClO_4)_2\cdot 3H_2O$ (**1**). Orange $[Ru(H_3L)]^{2+}$ was prepared by mixing the ligand and *cis*-$[RuCl_2(dmso)_4]$[4] in a 10:1 mol ratio. It should be noted that the ligand/$[RuCl_2(dmso)_4]$ ratio is not 1.0, but 10. We tried to prepare the complex in different ligand/Ru ratios. A large excess of the ligand seems to be necessary to yield the desired complex. At present, we cannot explain why complex **1** does not form under the equivalent mol ratio (ligand/Ru = 1.0).

The IR spectrum of complex **1** ($4d^6$, $t_{2g}^6$) shows an intense band assignable to the Cl–O vibration of the perchlorate ion at 1088–1143 $cm^{-1}$ and an intense characteristic absorption at 1607 $cm^{-1}$ assignable to the C=N stretching vibration of the tripodal Schiff-base ligand. The position of the C=N stretching band is close to that of $[Fe^{II}(H_3L)](BF_4)_2\cdot 3H_2O$ (1610 $cm^{-1}$) in the low-spin state ($3d^6$, $t_{2g}^6$).[2f] It has been reported that the position of the C=N stretching band is sensitive to the electronic state of the complex. For example, $[Fe^{II}(H_3L)](BF_4)_2\cdot 3H_2O$ exhibits a spin crossover behavior and the high-spin species ($t_{2g}^4e_g^2$) shows the C=N stretching vibration in the Raman spectrum at a higher energy (1638 $cm^{-1}$, $T > 200$ K) than the low-spin one (1610 $cm^{-1}$, $T < 100$ K).[2f] Complex **1** in $D_2O$ shows a very simple $^1H$ NMR spectrum, and it conforms to the high symmetry ($C_3$) of the complex confirmed by X-ray crystallography.

### Crystal Structure

The crystal structure consists of a ruthenium(II) complex cation, $[Ru(H_3L)]^{2+}$, and two perchlorate ions as the counteranions. Figure 2 shows an ORTEP drawing of the cation of complex **1** with the atom numbering scheme. Selected distances and angles, with their estimated standard deviations in parentheses, are listed in Table 1. A ruthenium(II) ion with the $4d^6$, $t_{2g}^6$ electron configuration assumes an octahedral coordination environment with the $N_6$ donor set of the tripodal ligand including three imidazole and three Schiff base nitrogen atoms. The tertiary amine nitrogen atom (N1) is not coordinated, the Ru···N1 distance being 3.161(6) Å. The lengths of the six Ru–N bonds are 2.151(7)–2.232(8) Å, and are in the expected range for the given coordination number and donor atoms. The corresponding M–N bond lengths for $[Co^{III}(H_3L)](ClO_4)_3\cdot H_2O$ ($3d^6$, $t_{2g}^6$) and $[Fe^{II}(H_3L)](BF_4)_2\cdot 3H_2O$ ($3d^6$, $t_{2g}^6$) are as follows: $Co^{III}$ 1.88(1)–1.98(1) Å,[5] $Fe^{II}$ 1.981(3)–1.989(4) Å.[2f] Ionic radii (Shannon) for six-coordinate $Co^{III}$ and $Fe^{II}$ are reported to be 0.69 and 0.75 Å, respectively.[6] The ionic radius (Shannon) for $Ru^{II}$ is not available. However, on the basis of the above M–N bond lengths, we can estimate the ionic radius for $Ru^{II}$ to be ca. 0.95 Å, assuming the nature of the bonding is similar for each one of the three complexes.

The crystal consists of a dimeric unit. Two adjacent complex cations with the opposite absolute configurations (Δ and Λ) are connected in a tail-to-tail fashion by N–H···O($ClO_4^-$)···H–N hydrogen bonds through two counter-$ClO_4^-$ anions, with N(imidazole)···O($ClO_4^-$) dis-

## Electronic and CD Spectra

The electronic spectrum of complex **1** in methanol is shown in Figure 4. The complex is fairly stable in methanol under aerobic conditions and the spectrum stays unchanged for at least five hours. The complex shows an intense band attributable to a metal-to-ligand charge transfer (MLCT) transition in the visible region at 424 nm (13900 $M^{-1}cm^{-1}$), which obscures the weak d–d bands. The MLCT band is unsymmetrical, which may be related to the less than octahedral local symmetry ($C_3$) of the complex that leads to loss of the degeneracy of the MLCT transitions. The bands in the UV region are mainly due to intraligand transitions. The electronic spectrum of the $H_3L$ ligand in methanol is also shown in Figure 4. Comparison of the two spectra indicates that the shoulder around 330 nm of **1** is attributable to the Schiff base π–π* transition and that the intense band at 248 nm is mainly due to the imidazole moiety.

The uncoordinated NH groups of the imidazole moieties of **1** can be deprotonated by the action of a base. With the addition of $NaOCH_3$ to $[Ru(H_3L)]^{2+}$ in methanol, a slight color change from yellow to yellowish-orange was observed: aliquots of the methanolic $NaOCH_3$ solution were added up to three equiv. to $[Ru(H_3L)]^{2+}$ in methanol, and the reaction was followed spectrophotometrically (Figure 5). Although isosbestic points were observed at 375 and 440 nm, the latter is not sharp. This behavior can be ex-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

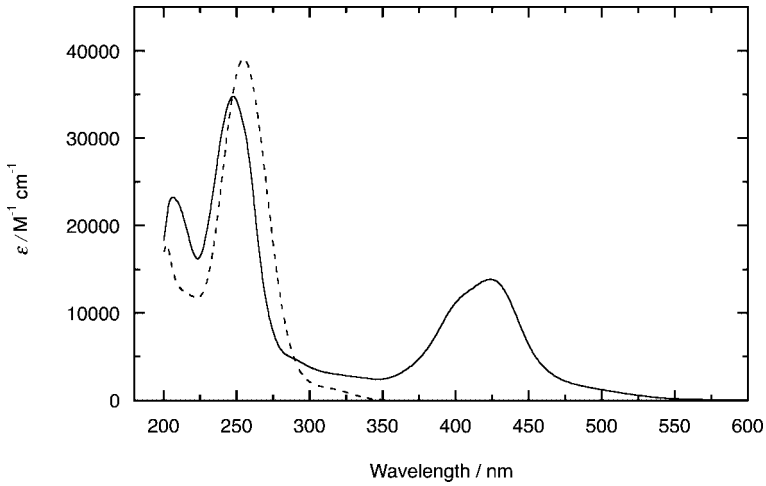

Figure 4. Electronic spectra of $[Ru(H_3L)](ClO_4)_2 \cdot 3H_2O$ (**1**, ——) and the $H_3L$ ligand (- - -) in methanol.

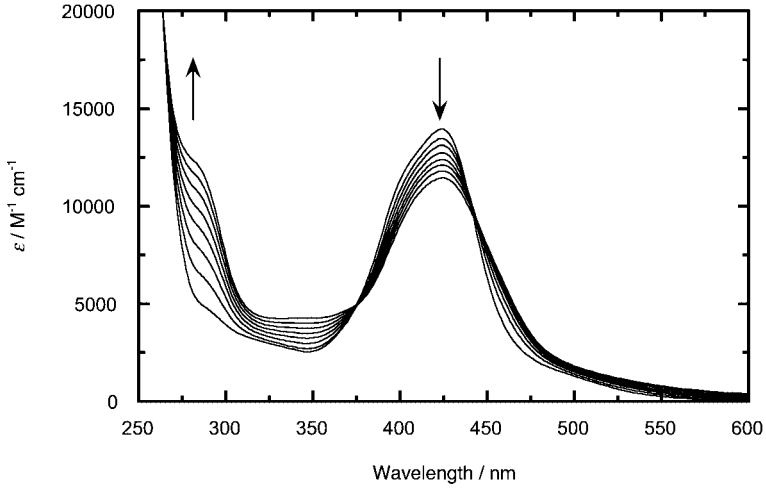

Figure 5. Electronic spectral changes of $[Ru(H_3L)](ClO_4)_2 \cdot 3H_2O$ (**1**) upon addition of $NaOCH_3$. $NaOCH_3$ in methanol was added stepwise to a methanol solution of **1** ($3.4 \times 10^{-5}$ M) up to 3.0 equiv.

plained as follows : The p$K_a$ values for $[Ru(H_3L)]^{2+}$, $[Ru(H_2L)]^{+}$, and [Ru(HL)] are similar to each other, and many species ($[Ru^{II}(H_3L)]^{2+}$, $[Ru^{II}(H_2L)]^{+}$, $[Ru^{II}(HL)]^{0}$, and $[Ru^{II}(L)]^{-}$) exist in equilibrium to obscure the isosbestic points [Equation (1)].

$$[Ru^{II}(H_3L)]^{2+} \underset{-H^+}{\overset{+H^+}{\leftrightarrows}} [Ru^{II}(H_2L)]^{+} \underset{-H^+}{\overset{+H^+}{\leftrightarrows}} [Ru^{II}(HL)] \underset{-H^+}{\overset{+H^+}{\leftrightarrows}} [Ru^{II}(L)]^{-} \quad (1)$$

In order to examine the stability of the deprotonated species under aerobic conditions, we measured the spectral change with the passage of time. After the addition of one equiv. of $NaOCH_3$, the spectrum stayed almost unchanged for at least 90 min. However, with the addition of two equiv. of $NaOCH_3$, a slight spectral change was observed after 90 min. This spectral change may be due to oxidation of $Ru^{II}$ to $Ru^{III}$. This behavior is in agreement with the cyclic voltammetry results described later. Thus, the above deprotonation reaction was carried out under an inert atmosphere. The reaction is reversible: protonation of $[Ru^{II}(L)]^{-}$ in methanol takes place upon sequential addition of $HClO_4$ in methanol, and the complex is finally converted to $[Ru^{II}(H_3L)]^{2+}$ [Equation (1)].

$[Ru(H_3L)]^{2+}$ is chiral because of a spiral coordination arrangement of the achiral $H_3L$ ligand around the $Ru^{II}$ ion. Optical resolution was carried out by column chromatography on SP-Sephadex, with 0.15 M sodium (+)-tartrate being used as the eluent.[7] The eluate was collected fractionally. The first and last fractions show CD patterns that are enantiomeric to each other, as shown in Figure 6. A strong CD band around 330 nm is attributable to the Schiff base π–π* transition. Recently, we have reported that the $Fe^{II}$ complex containing the $H_3L$ ligand, $[Fe^{II}(H_3L)](BF_4)_2 \cdot 3H_2O$, is spontaneously resolved, and X-ray crystallography revealed that the complex showing negative CD around 320 nm, attributable to the Schiff base π–π* transition, has the Δ absolute configuration.[2f] We have also resolved

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

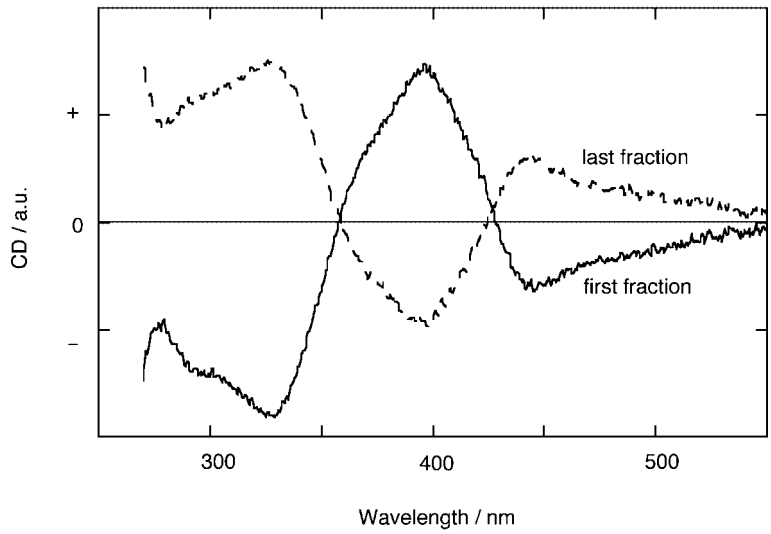

Figure 6. Circular dichroism (CD) spectra of $[Ru^{II}(H_3L)]^{2+}$ (**1**) resolved by SP-Sephadex column chromatography [eluent: 0.15 M $Na_2$(+)-tart], the first (——) and the last (- - -) fraction showing patterns that are enantiomeric to each other.

$[Co^{III}(H_2L)]^{2+}$ by fractional crystallization of the diastereomeric salt with $[Sb_2\{(+)\text{-tart}\}_2]^{2-}$ [tart = tartrate(4) ion] and have determined the absolute configuration by X-ray crystallography.[8] The less soluble diastereomeric salt, $[Co^{III}(H_2L)][Sb_2\{(+)\text{-tart}\}_2]\cdot 4H_2O$, has the Λ configuration and exhibits positive CD around 320 nm. From these results, we conclude that the faster-eluted enantiomer of $[Ru(H_3L)]^{2+}$ showing negative CD around 330 nm has the Δ absolute configuration. Exciton theory has been applied to tris(chelate)- or *cis*-bis(chelate)-type metal complexes, where chelate denotes such ligands as 2,2-bipyridine, 1,10-phenanthroline, or Schiff-base ligands, and the relationship between the CD pattern in the ligand π–π* transition region and the absolute configuration around the metal ion has been established.[9] The conclusion described above for the present complex is in agreement with the assignment based on exciton theory.

## Electrochemistry

The electrochemical properties of $[Ru^{II}(H_3L)]^{2+}$ and its deprotonated forms, $[Ru^{II}(H_2L)]^{+}$, $[Ru^{II}(HL)]^{0}$, and $[Ru^{II}(L)]^{-}$, were studied by cyclic voltammetry (CV). The measurements were performed under nitrogen using methanol solutions containing $LiClO_4$ (0.1 M) as the supporting electrolyte. The redox couple of $[Ru^{II}(H_3L)]^{2+}$ appears at –0.18 V ($E_{pc}$ = –0.21 V, $E_{pa}$ = –0.15 V) vs. $Ag/Ag^+$ irrespective of the scan rate ($10 \leq v \leq 200$ mV s$^{-1}$), the peak current ratio $i_{pa}/i_{pc}$ was found to be 1.0, ($i_{pa}$ or $i_{pc}$)/$v^{1/2}$ was independent of $v$, and the peak separation ($\Delta E_p$) was 0.060 V (Figure 7). These results are consistent with an electrochemically reversible one-electron redox process, see Equation (2).

$$[Ru^{III}(H_3L)]^{3+} + e^- \leftrightarrows [Ru^{II}(H_3L)]^{2+} \quad (2)$$

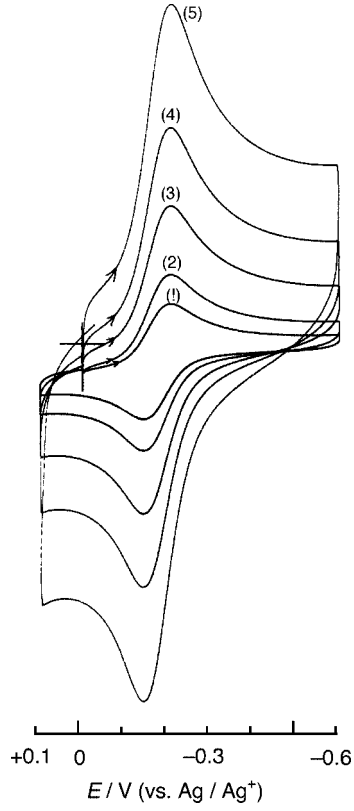

Figure 7. Cyclic voltammograms of $[Ru(H_3L)](ClO_4)_2\cdot 3H_2O$ (**1**, 0.2 mM) in methanol containing 0.1 M $LiClO_4$ at a glassy carbon electrode at sweep rates of (1) 10, (2) 20, (3) 50, (4) 100, and (5) 200 mV s$^{-1}$.

The bluish-purple $Ru^{III}$ complex, $[Ru^{III}(H_3L)]^{+}$, was formed by controlled-potential electrolysis of $[Ru^{II}(H_3L)]^{2+}$ at 0.0 V vs. $Ag/Ag^+$ in methanol containing 0.1 M ($n$-$C_4H_9)_4NBF_4$. The progress of the oxidation reaction was monitored spectrophotometrically (Figure 8). The band at

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

424 nm decreased while two bands appeared at 320 and 580 nm, and isosbestic points were observed at 370 and 480 nm. The broad moderately intense band at 580 nm can be assigned as an LMCT band.[10]

$[Ru^{II}(H_3L)]^{2+}$ in methanol undergoes reversible deprotonation and protonation upon addition of a base and an acid, respectively, as described above (deprotonation–protonation is associated with the imidazole moieties). Figure 9 shows the progress of the deprotonation reaction as monitored by cyclic voltammetry. Upon addition of one equiv. of $NaOCH_3$ to $[Ru^{II}(H_3L)]^{2+}$ in methanol (Figure 9, b), the current intensity of the initial redox couple at –0.18 V ($E_{pc}$ = –0.21 V, $E_{pa}$ = –0.15 V; Figure 9, a) diminishes and the couple shifts slightly to a more negative potential ($E_{pc}$ = –0.29 V, $E_{pa}$ = –0.18 V), and a new redox couple attributable to $[Ru^{III/II}(H_2L)]^{2+/+}$ appears at –0.67 V ($E_{pc}$ = –0.72 V, $E_{pa}$ = –0.61 V). Upon addition of one more equiv. of $NaOCH_3$ (Figure 9, c), the second redox couple shifts to a more negative potential ($E_{pc}$ = –0.75 V, $E_{pa}$ = –0.62 V) and grows at the expense of the first redox couple, and the initial redox couple shifts to a more negative potential ($E_{pc}$ = –0.35 V, $E_{pa}$ = –0.24 V). Full deprotonation at the imidazolate nitrogen moieties is achieved by adding three equiv. of base to produce $[Ru^{II}(L)]^{-}$ (see part d in Figure 9, $E^{0\prime}$ = –0.72 V, $E_{pc}$ = –0.77 V, $E_{pa}$ = –0.66 V). Complete deprotonation of the ligand shifts the $Ru^{III}/Ru^{II}$ redox potential to a more negative value from –0.18 V to –0.72 V, i.e. 180 mV per proton. Carina et al.[11] reported that deprotonation of the uncoordinated NH groups of the imidazole moieties switches the redox potential of iron by as much as 345 mV per proton. A series of reverse reactions was observed when an acid (HCl) was added to $[Ru^{II}(L)]^{-}$. These results are consistent with the acid–base equilibrium [Equation (1)]. Analysis of the CVs in Figure 9 (a–d), suggests that each $[Ru^{II}(H_{3-n}L)]^{(2-n)+}$ ($n$ = 0–3) species is characterized by a different potential of the redox couple although the redox couple for $[Ru^{III/II}(HL)]^{+/0}$ was not clearly observed; as the degree of deprotonation increases, the redox potential becomes more negative (i.e. the compound becomes easier to oxidize). These results are in accordance with the instability of the deprotonated species under aerobic conditions, as observed by electronic spectroscopy. It is worth noting that, for a metal complex with a ligand exhibiting acid–base properties in aqueous solution, the redox potential value is pH dependent; usually, however, each species (fully deprotonated, monodeprotonated, etc.) does not show an independent redox couple, but only an averaged couple is observed.[12] The $[Ru^{II}(L)]^{-}$ species exhibits another redox couple at +0.12 V (Figure 9d, $E_{pc}$ = +0.08 V,

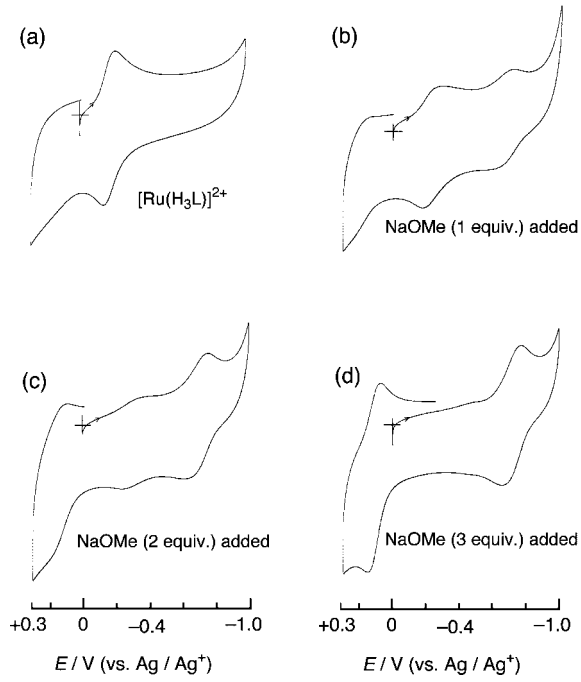

Figure 9. Progress of the deprotonation of $[Ru(H_3L)](ClO_4)_2{\cdot}3H_2O$ as monitored by cyclic voltammetry. (a)–(d): stepwise addition (0, 1, 2, and 3 equiv.) of $NaOCH_3$ in methanol to 0.2 mM $[Ru(H_3L)](ClO_4)_2{\cdot}3H_2O$ in methanol containing $LiClO_4$ (0.1 M).

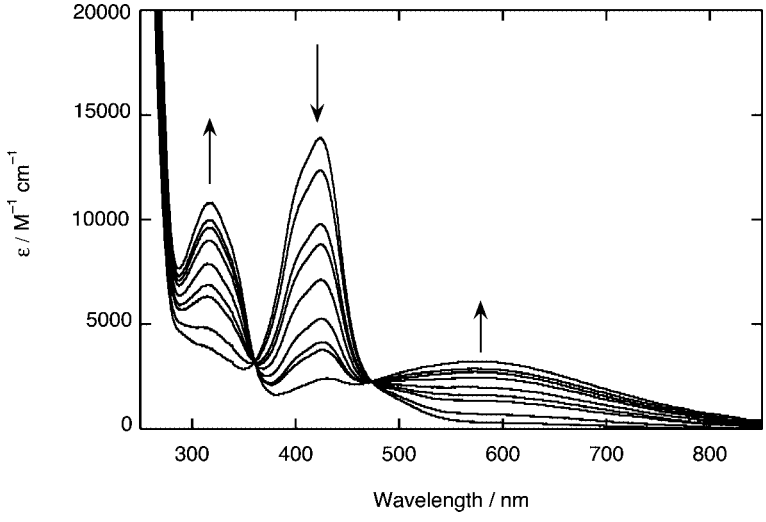

Figure 8. Electronic spectral changes accompanied by the progress of controlled-potential electrolysis (oxidation) of $[Ru(H_3L)]^{2+}$ in methanol containing 0.1 M $(n\text{-}C_4H_9)_4NBF_4$ at 0.0 V vs. $Ag/Ag^+$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$E_{pa}$ = +0.16 V), and this couple may be assigned as the $Ru^{IV/III}$ process.[10]

We have demonstrated that the uncoordinated NH groups of the imidazole moieties of **1** can easily be deprotonated by the action of a base, and that deprotonation stabilizes the oxidized form, $Ru^{III}$.

## Experimental Section

**Caution!** Perchlorate salts of metal complexes are potentially explosive. Only small quantities of material should be prepared, and the samples should be handled with care.

**Materials:** All reagents and solvents in the syntheses were of reagent grade and were used without further purification. *cis*-$[RuCl_2(dmso)_4]$ was prepared according to the literature procedure.[4]

**$[Ru(H_3L)](ClO_4)_2\cdot 3H_2O$ (1):** A methanol solution (20 $cm^3$) containing tris(2-aminoethyl)amine (0.73 g, 5 mmol) and 4-formylimidazole (1.44 g, 15 mmol) was heated under reflux for 20 min to give a yellow-orange solution. This methanol solution contains the $H_3L$ ligand, and the solution was used for the preparation of the Ru complex. Nitrogen (or argon) gas was bubbled through the solution for 15 min to remove oxygen (Solution A). *cis*-$[RuCl_2(dmso)_4]$ (0.242 g, 0.5 mmol) was dissolved in oxygen-free methanol (20 $cm^3$), and the ligand solution (Solution A) was added to this solution by a syringe. The mixture was heated under reflux for 6 h. The color of the solution changed from orange to dark brown. The solution was cooled to room temperature, and a methanol solution (50 $cm^3$) of $NH_4BF_4$ (1.6 g, 15 mmol) was added to give a brown precipitate, which was collected by filtration. This product is not soluble in common organic solvents, and it is not the desired compound, but seems to be an oligomer. The filtrate was diluted with 0.01 M HCl (300 $cm^3$). The solution was passed through a column (2.7 cm I.D. × 15 cm) of SP-Sephadex C-25. The adsorbed cationic species were eluted with 0.2 M NaCl/0.01 M HCl. The eluate containing the fastest eluted orange-red band was collected, and mixed with an aqueous solution (5 $cm^3$) of $NaClO_4$ (0.2 g). The orange crystals that deposited were collected by filtration. They were recrystallized from water under nitrogen. Yield 15 mg. $C_{18}H_{30}Cl_2N_{10}O_{11}Ru_1$ = $[Ru(H_3L)](ClO_4)_2\cdot 3H_2O$: calcd. C 29.44, H 4.11, N 19.07; found C 29.34, H 3.74, N 18.88. $^1H$ NMR ($D_2O$, ref. DSS): $\delta$ = 2.8–3.5 (m, 4 H, $CH_2$), 7.25 (s, 1 H), 7.80 (s, 1 H), 8.52 (s, 1 H) ppm. IR (KBr pellet): $\tilde{\nu}$ = $\nu_{C=N}$(Schiff base), 1607 $cm^{-1}$; $\nu_{Cl-O}(ClO_4^-)$, 1088, 1115, 1143 $cm^{-1}$. UV/Vis ($CH_3OH$): $\lambda$ ($\varepsilon$) = 424 nm (13900 $M^{-1}$ $cm^{-1}$), 248 nm (34800 $M^{-1}$ $cm^{-1}$). Crystals suitable for X-ray analysis were obtained by adding a diethyl ether layer to an acetonitrile solution of the complex.

**Optical Resolution:** An aqueous solution (20 $cm^3$) of $[Ru(H_3L)](ClO_4)_2\cdot 3H_2O$ (3 mg) was adsorbed onto SP-Sephadex (1 $cm^3$) and the SP-Sephadex was placed on top of an SP-Sephadex column (1 cm ID × 30 cm). The complex was eluted with 0.15 M sodium (+)-tartrate, and the eluate was fractionally collected.[7]

**Physical Measurements:** UV/Vis absorption spectra were recorded with a JASCO Ubest-550 spectrophotometer. Infrared spectra were measured on a JASCO FT/IR-550 spectrophotometer. CD spectra were recorded with a JASCO J-720 spectropolarimeter. $^1H$ NMR spectra were recorded with a Varian Mercury 300 spectrometer ($^1H$ at 300 MHz) at ambient temperature. Cyclic voltammetry measurements were performed under nitrogen using a Fuso HECS 321B potential sweep unit with methanol solutions containing $LiClO_4$ (0.1 M) as the supporting electrolyte. The electrochemical cell was a three-electrode system consisting of a glassy-carbon working electrode, a platinum wire auxiliary electrode, and an $Ag/Ag^+$ (Ag/0.01 M $AgNO_3$) reference electrode. As an external standard, the $Fc/Fc^+$ (Fc = ferrocene) couple was observed at –0.170 V vs. $Ag/Ag^+$ under the same conditions. Controlled-potential electrolysis experiments were carried out with a platinum-gauze working electrode, with the use of a Fuso HECS 312B DC-pulse polarograph and a Model 1109 integrator. The reference electrode was the same $Ag/Ag^+$ (Ag/0.01 M $AgNO_3$) electrode used for the cyclic voltammetric experiments, and the auxiliary electrode was a platinum wire separated from the test solution by a salt bridge.

**X-ray Data Collection, Reduction, and Structure Determination:** An orange crystal of **1**, with the approximate dimensions 0.5 × 0.2 × 0.1 mm, was mounted by a loop method, and the X-ray data were collected with a Rigaku R-AXIS RAPID II imaging plate area detector using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The crystallographic data are summarized in Table 3. The structure was solved by direct methods, and was refined using full-matrix least-squares procedures with the CrystalStructure crystallographic software package.[13] There are two possible space groups, *C*2/*c* (No.15) and *Cc* (No.9). We tried to solve the structure in both space groups. Only the space group *C*2/*c* gave rational results.

# A Supramolecular Assembly of Organotin Complexes: Syntheses, Characterization and Crystal Structures of Organotin Complexes with *meso*-2,3-Dimercaptosuccinic Acid

**Chunlin Ma*[a,b] and Qingfu Zhang[a]**

**Keywords:** S ligands / Self-assembly / Supramolecular chemistry / Tin

A series of two types of organotin complexes, namely $[(R_3Sn)_4(dmsa)]$ (R = Ph **1**, $PhCH_2$ **2**, $CH_3$ **3**, *n*Bu **4**; $H_4$dmsa = *meso*-2,3-dimercaptosuccinic acid) and $[(R_2Sn)_2(dmsa)(Y)]\cdot L$ (R = Ph, Y = $2H_2O$, L = $H_2O$, $Et_2O$ **5**; R = $PhCH_2$ **6**; R = $CH_3$ **7**; R = *n*Bu **8**; R = *n*Bu, Y = 0.5MeOH **9**) have been synthesized. All complexes were characterized by elemental analysis and FT-IR and NMR ($^1H$, $^{13}C$ and $^{119}Sn$) spectroscopy. Among them, the strucrtures of complexes **1**, **3**, **5**, and **9** were also determined by X-ray crystallography. The structural analyses show that complexes **1** and **3** are tetranuclear triorganotin monomers, complex **5** is a dinuclear diphenyltin monomer, and complex **9** is a 3D di-*n*-butyltin coordination polymer with a metal-organic framework structure. The supramolecular structure analyses reveal that the type of organic substituent attached to the tin atoms can apparently affect the supramolecular assembly: when the substituents attached to the tin atom are aromatic groups (**1** and **5**) the supramolecular structures are dominated by intermolecular π–π (C–H···π) weak interactions, whereas when the substituents attached to the tin atom are alkyl groups (**3** and **9**) the supramolecular structures are dominated by intermolecular Sn←X (X = S, O) coordination interactions.

## Introduction

Recently, the design and self-assembly of metal compounds into one-, two-, or three-dimensional supramolecular architectures has been attracting considerable attention due to their potential applications and intriguing architectures.[1–9] Two main lines of study are adopted, based on the different nature and bonding energy of the interactions responsible for networking, namely (i) frameworks comprised of metal centers and di- or polydentate ligands connected through chemical (covalent or coordination) bonds, which have been widely studied in the crystal engineering of microelectronic, nonlinear optical, ferromagnetic, and catalytic materials,[2,3] (ii) networks derived by the assembly of mono- or polynuclear metal complexes through intermolecular weak interactions such as hydrogen bonds, π–π interactions, electrostatic interactions, and so on, where it has been found that these weak interactions play vital roles in highly efficient and specific biological reactions and are essential for molecular recognition and the self-organization of molecules in supramolecular chemistry.[4,5]

Both systems mentioned above have recently been widely investigated in the supramolecular chemistry of organometallic complexes[6–9] because the supramolecular structures of such complexes can be more rationally controlled by tailoring the type and number of organic substituents attached to the metal center. Among these complexes, organotin complexes are attracting more and more attention due to their wide industrial applications and antitumor activities,[10] as well as their interesting and varied supramolecular structures.[7–9] In our previous work, we have also reported several interesting supramolecular structures assembled from organotin complexes.[9] To continue our research in this area, we selected another interesting ligand − *meso*-2,3-dimercaptosuccinic acid ($H_4$dmsa). This ligand was chosen based on the following considerations: first, both the carboxy and thiol groups in this ligand can form strong covalent bonds with the organotin moiety, thus providing sufficient thermodynamic stability for them to be stable in the solid state, including toward corrosive substances such as oxygen and water; second, $H_4$dmsa is a polyfunctional chelate ligand with two carboxy and two thiol groups, so it has a rich coordination chemistry and can help to construct multidimensional coordination polymers by acting as a multidentate bridging linker; third, the conformational flexibility of this ligand will allow for the formation of various and interesting molecular and supramolecular structures; fourth, $H_4$dmsa can bond more than one organotin moiety in one discrete molecule, which will increase the opportunities for supramolecular assembly from these complexes through intermolecular weak interactions between substituents (such as π–π interactions); fifth,

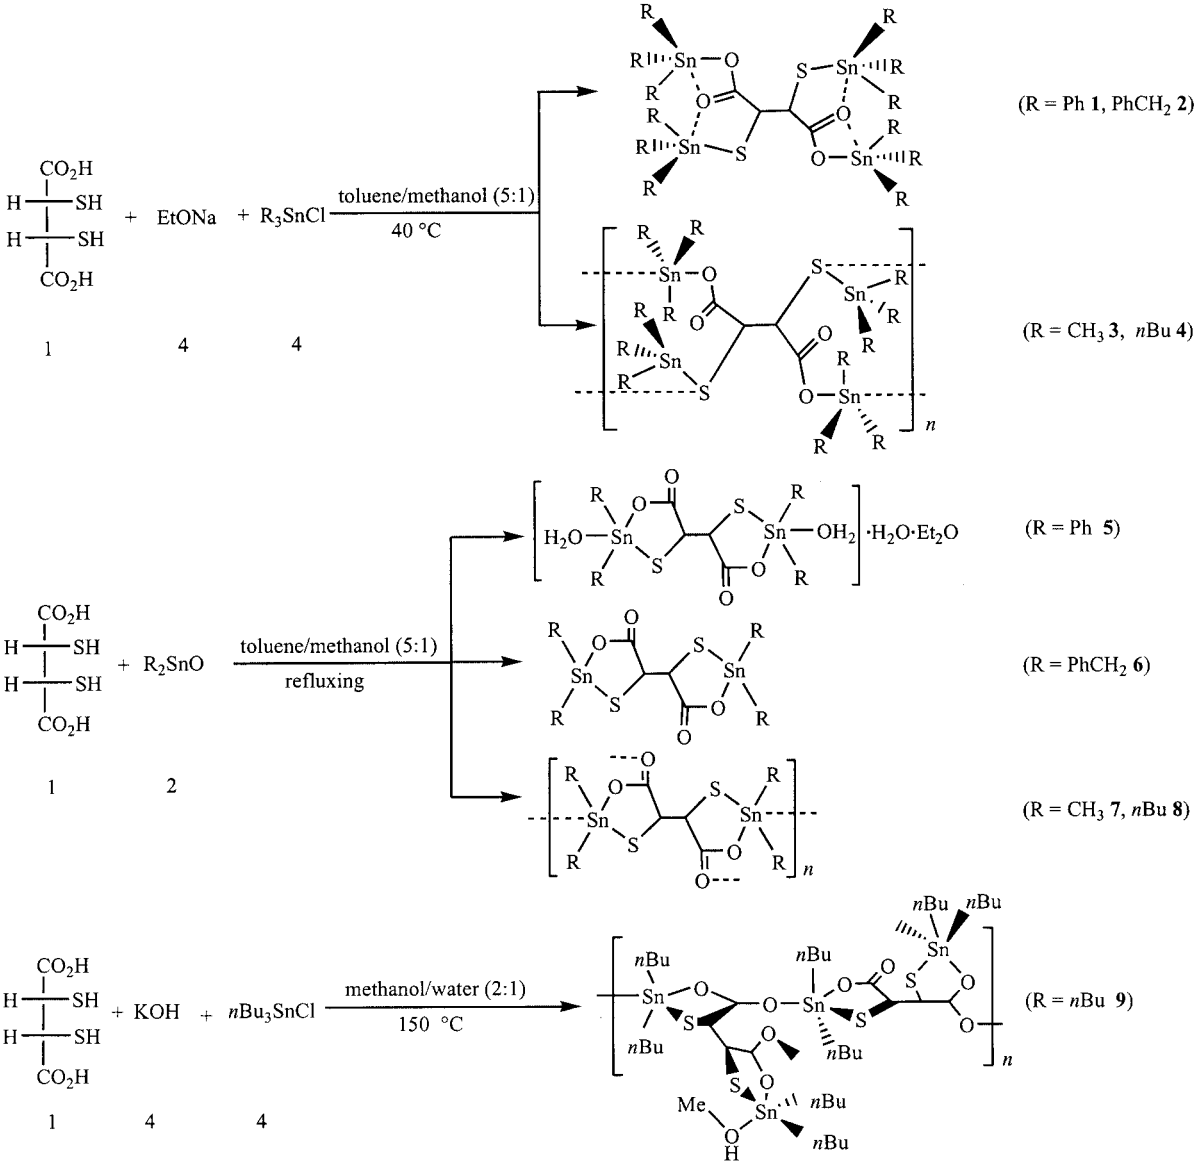
$H_4$dmsa is a simple linear ligand without a complicated inner structure, which makes it easy to analyze the electronic and steric influence of the organic substituents attached to the tin atom on the supramolecular structure. In addition, although $H_4$dmsa is a mercapto-containing, water-soluble, nontoxic, orally administered metal chelator that has been used as an antidote to heavy metal (lead, mercury, arsenic, and cadmium) toxicity for more than 50 years,[11] few metal complexes with this ligand have been determined by X-ray crystallography so far.[12] Recently, we began to treat $H_4$dmsa with organotin compounds with the hope of obtaining interesting supramolecular structures by assembly of this polyfunctional ligand with different organotin compounds. Here we report the detailed syntheses of eight new organotin complexes of *meso*-2,3-dimercaptosuccinic acid of two types: $[(R_3Sn)_4(dmsa)]$ (R = Ph **1**, $PhCH_2$ **2**, $CH_3$ **3**, *n*Bu **4**) and $[(R_2Sn)_2(dmsa)(Y)]\cdot L$ (R = Ph Y = $2H_2O$ L = $H_2O$, $Et_2O$ **5**; R = $PhCH_2$ **6**; R = $CH_3$ **7**; R = *n*Bu **8**; R = *n*Bu Y = 0.5MeOH **9**). All complexes were characterized by elemental analysis and FT-IR and NMR ($^1H$, $^{13}C$, and $^{119}Sn$) spectroscopy. The structures of complexes **1**, **3**, **5**, and **9** were also determined by X-ray crystallography.

## Results and Discussion

### Syntheses

Complexes **1**–**4** were obtained by reaction of $H_4$dmsa/EtONa/$R_3SnCl$ in a 1:4:4 molar ratio in toluene/methanol (5:1) at 40 °C, while complexes **5**–**8** were obtained by reaction of $H_4$dmsa/$R_2SnO$ in a 1:2 molar ratio in toluene/methanol (5:1) at reflux. Crystals of complex **9** were obtained by solvothermal reaction of $H_4$dmsa/KOH/$R_3SnCl$ in a 1:4:4 molar ratio in methanol/water (2:1) at 150 °C. The synthetic procedures are shown in Scheme 1.



Scheme 1.

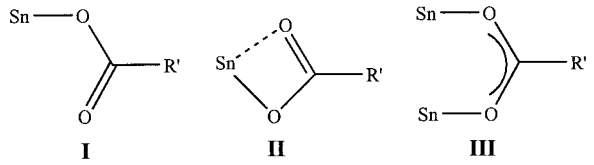
## Spectroscopic Studies

### *IR*

The main feature in the IR spectra of complexes **1**–**9** is the absence of bands in the region 3120–2980 and 2560–2410 $cm^{-1}$, which appear in the free ligand as $CO_2H$ and SH stretching vibrations, thus indicating metal–ligand bonding through these sites. The typical absorptions for Sn–C, Sn–O, and Sn–S vibrations in complexes **1**–**9** are all located in the normal range of similar organotin complexes.[13,14]

IR spectroscopy can provide useful information concerning the coordination of the carboxyl groups in organotin carboxylates.[15,16] When the carboxylic group coordinates the tin atom in a monodentate manner (mode **I**), the difference between the wavenumbers of the asymmetric and symmetric carboxylic stretching bonds, $\Delta\tilde{\nu}$ [$\Delta\tilde{\nu} = \tilde{\nu}(\nu_{as}CO_2^-) - \tilde{\nu}(\nu_sCO_2^-)$], is larger than that observed for ionic complexes. When the ligand chelates (mode **II**), $\Delta\tilde{\nu}$ is considerably smaller than that for ionic complexes, while in the asymmetric bidentate coordination mode the value is in the range characteristic of monodentate coordination. The characteristic wavenumber difference for mode **III** is larger than that for chelating groups and nearly the same as that observed for ionic complexes (Scheme 2).



Scheme 2. Different coordination modes of the carboxylate group.

Based on the above results, it was possible to distinguish the coordination mode of the $CO_2^-$ group. The magnitude of $\Delta\tilde{\nu}$ (about 242–268 $cm^{-1}$) for **1**–**6**, compared with that for the corresponding sodium salts, reveals that the carboxylate ligands are monodentate, while the value of about 200 $cm^{-1}$ for **7**–**9** suggests a bidentate coordination mode. The conclusions drawn from the IR data are consistent with the X-ray crystallography study.

### *NMR*

The $^1H$ NMR spectra show the expected integration and peak multiplicities. In the spectra of the free ligand, the resonances observed at $\delta \approx 10.50$ and 1.65 ppm, which are absent in the spectra of the complexes, indicate removal of the $CO_2H$ and SH protons and formation of Sn–O and Sn–S bonds. This conclusion accords well with the IR data. Moreover, the $^1H$ NMR spectroscopic data show that the chemical shifts of the phenyl groups in complexes **1** and **5** ($\delta$ = 7.36–7.79 ppm), the methyl groups in complexes **3** and **7** ($\delta$ = 0.84–0.91 ppm), and the methylene groups connected directly to the tin atom in complexes **2**, **4**, **6**, **8**, and **9** ($\delta$ = 1.25–3.26 ppm) undergo an upfield shift relative to those of their precursors.

The $^{13}C$ NMR spectra of all compounds show a significant downfield shift of all carbon resonances compared with the free ligand because of an electron-density transfer from the ligand to the metal atom. Although at least two different types of carboxy groups are present, only one single resonance is observed for the $CO_2$ group in the $^{13}C$ spectra. A possible reason for this is that either accidental magnetic equivalence of the carbonyl carbon atoms occurs or the separation between the sets of resonance is too small to be resolved.

The $^{119}Sn$ NMR spectroscopic data show two signals for complexes **1**–**4** ($\delta$ = –95.1, –125.5 ppm for **1**; $\delta$ = –93.5, –118.8 ppm for **2**; $\delta$ = –96.4, –121.6 ppm for **3**; $\delta$ = –98.2, –126.1 ppm for **4**) and both of them are in the normal range for four-coordinate tin complexes,[17] thus indicating the existence of two different coordination environments around the tin atoms for complexes **1**–**4** in solution, which is similar to that found in the complexes [$(Ph_3Sn)_2$(*p*-mpspa)] and [$(Ph_3Sn)_2$(cpa)].[18] The $^{119}Sn$ NMR spectroscopic data of complexes **5**–**8** ($\delta$ = –150.2, –165.8, –175.7, and –173.8 ppm for **5**–**8**, respectively) show signals in the normal range for five-coordinate tin complexes.[17] However, complex **9** shows two signals at $\delta$ = –126.8 and –170.5 ppm, which are in the range corresponding to the coordination number 5 ($\delta$ = –90 to –190 ppm),[17] thus it can reasonably be assumed that there are also two different coordination environments around the tin atoms of complex **9** in solution.

## Crystal Structures

### *X-ray Crystallographic Study of 1 and 3*

Crystals of **1** suitable for an X-ray crystallography study were grown from dichloromethane, while crystals of **3** were grown from diethyl ether. The most relevant crystallographic data for **1** and **3** are summarized in the Experimental Section. Selected bond lengths and bond angles for **1** and **3** are given in Tables 1 and 2, respectively.

Table 1. Selected bond lengths and angles for complex **1**.

| Bond lengths [Å] | | | |
|---|---|---|---|
| Sn1–C3 | 2.122(5) | Sn1–C9 | 2.135(5) |
| Sn1–C15 | 2.114(4) | Sn1–S1 | 2.4373(13) |
| Sn1–O1 | 2.071(3) | Sn1–O2 | 2.838(3) |

ety containing two symmetrical $(Ph_3Sn)_2(SCHCO_2)$ moieties (inversion center: $-x+2$, $-y+1$, $-z$). Each tin atom in complex **1** forms four primary bonds: three from the phenyl C atoms and one from the O (for Sn1) or S (for Sn2) atom of the bridging ligand. The bond angles around the Sn1 and Sn2 atoms range from 101.51(15) to 120.23(18)° and from 95.68(13) to 116.78(13)°, respectively, suggesting apparent distortion from an ideal tetrahedron. The Sn1–O1 (2.071 Å) and Sn2–S1 [2.4373(13) Å] distances are in the normal range for Sn–O[19] and Sn–S[20] covalent bonds. There are also two weak intramolecular Sn···O interactions in complex **1** [Sn1–O2 = 2.838(3) and Sn2–O2 = 2.849(3) Å]. Although these distances are considerably longer than the normal Sn–O covalent bond, they lie in the range of Sn···O distances of 2.61–3.02 Å that have been confidently reported for intramolecular bonds.[21] As the oxygen atoms of the carboxylate groups in complex **1** are involved in weak coordination interactions with the tin atoms along one of the tetrahedral faces, the structural distortion for the tin atoms in **1** is best described as a capped tetrahedron.

Analysis of the supramolecular structure in the crystal lattice of **1** reveals that weak intermolecular C–H···π interactions play important roles in the supramolecular arrangements. The C–H···π interaction can also be viewed as an edge-to-face (as opposed to point-to-face or T-shaped) π–π interaction, and now is usually assigned to non-conventional weak hydrogen bonds.[5c,5g] Although this interaction is much weaker than covalent and coordinative interactions, and even than typical hydrogen bonds (such as O–H···O and N–H···O etc.), it clearly governs the supramolecular assembly in many compounds.[5g,22] In complex **1**, a series of parallel molecular chains connected by weak intermolecular C8–H8···Cg1 interactions (Cg1 is the centroid of the phenyl ring C9–C14) is found along the horizontal direction. Interestingly, these parallel molecular chains are further interlinked by weak intermolecular C6–H6···Cg2 interactions (Cg2 is the centroid of phenyl ring C27–C32) to form a 2D network structure in the defined plane (see Figure S1 in the Supporting Information). These C–H···π interactions in complex **1** (C8···Cg1 = 3.270, H8···Cg1 = 3.860 Å, C8–H8···Cg1 = 112.67°; C6···Cg2 = 3.752, H6···Cg2 = 2.867 Å, C6–H6···Cg2 = 159.41°) are close to those found in bis(*N*-pyridoxy-L-amino acidato)cobalt(III) complexes,[23] thereby suggesting they are strong enough to assemble these tetranuclear tin molecules into a 2D network in the solid state.

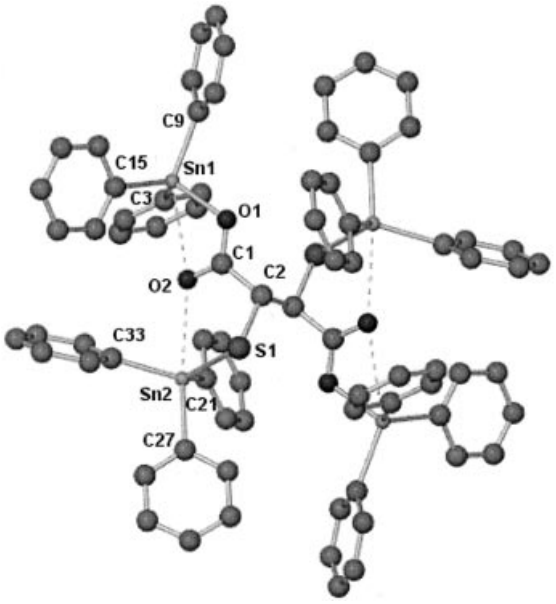

Figure 1. Molecular structure of complex **1** (all hydrogen atoms have been omitted for clarity).

A perspective view of the molecular structure of **3** is shown in Figure 2. Complex **3** is also a tetranuclear tin moiety containing two symmetrical $(Me_3Sn)_2(SCHCO_2)$ moieties (inversion center: $x$, $1-y$, $-1/2+z$). The molecular structure of **3** is similar to that of **1**, so we will not deal with many structural details here. However, a comparison of the molecular conformations and configurations of complexes **1** and **3** should be noted: first, the two intramolecular Sn···O weak interactions (Sn1···O2 = 3.092, Sn2···O2 = 3.165 Å) in complex **3** are weaker than in **1** and are out of the range of typical intramolecular Sn–O bonds (2.61–3.02 Å).[21] Therefore, these distances are almost sufficient to make this oxygen atom stereochemically inactive around the two Sn atoms; second, the Sn2 atom in complex **3** displays a distorted tetrahedral coordination sphere, with six angles ranging from 98.3(2) to 116.0(3)°. The bond angles around Sn1 (from 92.84 to 121.6°) show a larger deviation from the ideal value for a tetrahedron (109.5°), thereby indicating that there may be intermolecular contacts around Sn1 in the crystal lattice (vide infra). Finally, all the Sn–C and covalent Sn–O and Sn–S bonds around each tin atom in complex **3** are unremarkable, as expected.

To our surprise, the common intermolecular C=O→Sn interactions that can give rise to either polymeric or cyclo-oligomeric structures in trimethyltin compounds[24] are not found in complex **3**. In fact, the supramolecular structure of complex **3** is a 2D network linked by weak intermolecular Sn←S coordination interactions. As shown in Figure 3, the asymmetric unit of complex **3** is linked by weak intermolecular Sn1···S1 coordination interactions along the

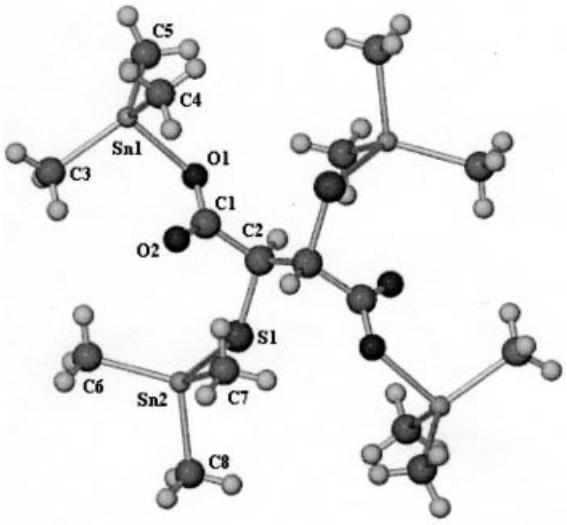

Figure 2. Molecular structure of complex **3**.

*b* and *c* axes to form a 2D layer with a 24-membered cavity in the *bc* plane. Although the loose cavities provided by these intermolecular Sn–S weak coordination interactions are large enough (7.525 × 11.265 Å) and are not completely filled by the methyl groups on the tin atoms that protrude into the interior, there are no solvent molecules in these cavities. This is not surprising in view of the fact that packing of such layers along the *a* axis produces a genuine no-cavity structure in the crystal lattice of complex **3** (see Figure S2 in the Supporting Information). Although the weak intermolecular Sn···S coordination distance in complex **3** is 3.286 Å, it still falls in the range proposed for secondary Sn···S coordination bonds (2.79–3.81 Å)[6] and is even close to the C=S···Sn distance [3.2274(8) Å] found in (5-mercapto-3-phenyl-1,3,4-thiadiazoline-2-thionato)trimethyltin.[25] If the weak Sn···S interaction is also considered, the coordination environment around the Sn1 atom in complex **3** can best be described as a distorted trigonal bipyramid.

### *X-ray Crystallographic Study of 5 and 9*

Crystals of **5** suitable for an X-ray crystallography study were grown from dichloromethane/diethyl ether, while crystals of **9** were obtained from the mother liquor of the solvothermal reaction. The most relevant crystallographic data for **5** and **9** are summarized in the Experimental Section. Selected bond lengths and bond angles for **5** and **9** are given in Tables 3 and 4, respectively.

Table 3. Selected bond lengths and angles for complex **5**.

| Bond lengths [Å] | | | |
|---|---|---|---|
| Sn1–C11 | 2.11(2) | Sn1–C5 | 2.13(2) |
| Sn1–O1 | 2.37(1) | Sn1–S1 | 2.416(4) |
| Sn1–O5 | 2.443(6) | Sn2–C23 | 2.130(9) |
| Sn2–C17 | 2.16(2) | Sn2–O3 | 2.36(1) |

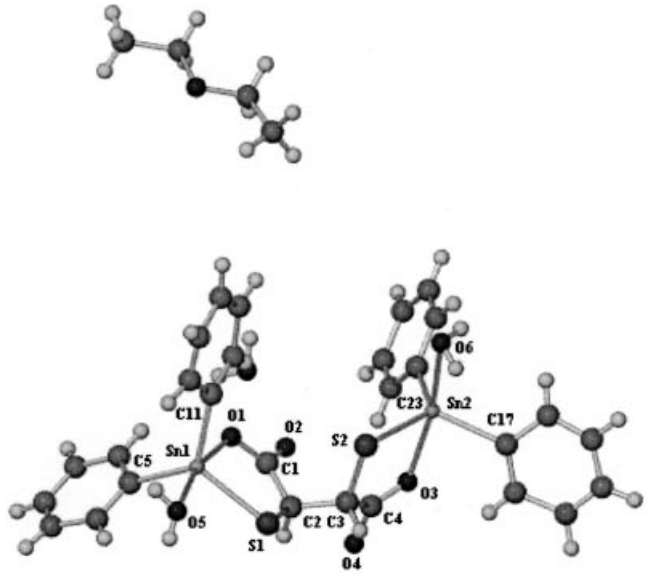

Figure 4. Molecular structure of complex **5**.

conformation, which is similar to the anion of the diorganotin carboxylate $[(n\text{Pr})_3\text{NH}][\text{Me}_2\text{Sn}(\mu^2\text{-SCH}_2\text{COO})\text{Cl}]$.[26] Each tin atom in complex **5** is a five-coordinate trigonal bipyramid, with two phenyl groups and the sulfur atom of dmsa occupying the equatorial plane and one of the carboxyl oxygen atoms (O1 or O3) and one coordinated water molecule (O5 or O6) in axial positions. Because there is a strong (O,S) chelate effect (O1–Sn1–S1 = 78.64°, O3–Sn2–S2 = 78.75°), the corresponding axial–Sn–axial angles (167.20° for Sn1 and 167.24° for Sn2) and equatorial angles (116.80°, 118.40°, 121.69° for Sn1 and 116.51°, 118.67°, 122.15° for Sn2) suggest the geometries of both tin atoms in complex **5** are distorted trigonal pyramids. The two coordinative Sn–$OH_2$ bonds (Sn1–O5 = 2.443, Sn2–O6 = 2.406 Å) are slightly longer than the corresponding covalent Sn–O bonds (Sn1–O1 = 2.367, Sn2–O2 = 2.360 Å) and are in the range of known Sn–$OH_2$ bonds [2.14(3)–2.47(2) Å].[27] Both Sn–O (Sn1–O1 = 2.367, Sn2–O2 = 2.360 Å) and Sn–S (Sn1–S1 = 2.415, Sn2–S3 = 2.413 Å) bond lengths are close to those found in diorganotin carboxylates and thiolates.[9a] In addition, there are co-crystallized water and diethyl ether molecules in complex **5**.

The supramolecular structure of complex **5** is dominated by a 1D helical molecular chain along the *c* axis linked by intermolecular C–H···π (C3–H3···Cg3, Cg3 is the centroid of phenyl C5–C10) weak hydrogen-bonding interactions (see Figure S3 in the Supporting Information); the pitch of this helix (13.337 Å) is longer than that found in $(Ph_3Sn)_2(SC_6H_4CO_2)$ (9.991 Å).[20b] The corresponding C3···Cg3, H3···Cg3, and C3–H3···Cg3 values (3.866 Å, 3.019 Å, and 145.31°) in complex **5** are close to the C–H···π values in the $CH_4/C_6H_6$ system[5g] but larger than that found in complex **1**, which is in good agreement with theoretical calculations that predict that C–H···π interactions in aliphatic/aromatic systems are weaker than in aromatic/aromatic systems.[5g]

A perspective view of the molecular structure of **9** is shown in Figure 5; for clarity, the somewhat disordered β, γ and δ carbon atoms of the butyl groups have been omitted. The structure analysis for **9** reveals that it is a 3D metal-organic framework constructed by the S-shaped building block $[(n\text{Bu}_2\text{Sn})_2(\text{dmsa})]_2\cdot\text{MeOH}$. The S-shaped asymmetric unit consists of two $[(n\text{Bu}_2\text{Sn})_2(\text{dmsa})]$ moieties and one coordinated MeOH molecule. Interestingly, every two five-membered SnSCCO chelate metallacycles in the asymmetric unit that are connected by the same dmsa ligand, such as pSn1 and pSn2, pSn3 and pSn4,[28] are not coplanar (dihedral angles between pSn1 and pSn2 and pSn3 and pSn4 are 71.51° and 60.69°, respectively), while pSn2, pSn3, and the bridging O4 atom are almost in the same plane (largest deviation: 0.071 Å; mean deviation: 0.035 Å). Each $[(n\text{Bu}_2\text{Sn})_2(\text{dmsa})]$ moiety in complex **9** also contains two five-membered SnSCCO chelate metallacycles, similar to those found in complex **5**. The coordination environment around each tin atom in complex **9** is also distorted trigonal-bipyramidal, with the equatorial positions occupied by two *n*-butyl groups and one thiol sulfur atom from the dmsa ligand and the axial positions shared by one coordinated oxygen atom from the dmsa ligand and an additional Lewis base, which may be a solvent molecule (for Sn1) or an intermolecular C=O→Sn bond (for Sn2, Sn3, and Sn4). The corresponding axial–Sn–axial skeletons are bent (ranging from 162.51° to 167.51°; av. 164.53°) due to the strong chelate effect of the O and S atoms (O–Sn–S chelate angles ranging from 80.31° to 82.68°; av. 81.36°), which is similar to that found in complex **5**. All the Sn–S and Sn–O distances lie in the range 2.389(4)–2.408(4) and 2.156(13)–2.259(9) Å, respectively, except for Sn1–O9, which is consistent with the situation reported in other organotin compounds.[9a,29] Moreover, the solvent-coordinated Sn–O bond (Sn1–O9) is only 2.264(15) Å, which is close to the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

corresponding covalent Sn–O bond [Sn1–O1 = 2.156(13) Å] formed with carboxylate groups (the difference between these two Sn–O bonds is only 0.108 Å) and shorter than that found in [($Me_3Sn$)(TMA)]·2MeOH (2.462 and 2.586 Å),[9b] thus showing the strong coordinative interactions between guest methanol molecules and the host framework.

The supramolecular structure of complex **9** is a 3D metal-organic framework built by {[($n$Bu$_2$Sn)$_2$(dmsa)]$_2$·MeOH} units. As shown in Figure 6a, each {[($n$Bu$_2$Sn)$_2$-(dmsa)]$_2$·MeOH} unit is linked by intermolecular C=O→Sn coordination interactions along the 110 and 0$\bar{1}$1 directions, thus forming a 2D layer with 53-membered organotin rings in the defined plane. Furthermore, these layers are linked to form a 3D framework along the 010 direction to give 56-membered rhombic channels (Figure 6b). The size of the 53-membered ring channel is 26.83×11.50 Å (transannular Sn4···Sn4′ and Sn2···Sn3), while the 56-membered ring rhombic channels are only 13.551×9.658 Å in size (transannular Sn4···Sn4′′ and Sn2′···Sn3′). The solvent methanol molecules reside in the 53-membered ring channels because they are strongly coordinated to the framework Sn1 atoms. A strong H-bonding interaction is also found between the methanol molecule and the framework oxygen atom O9 (O9···O6 = 2.525 Å). These coordinating and H-bonding interactions between the methanol molecules and the framework are believed to be responsible for the formation of the framework structure. It is worth mentioning here that, although the channels in this complex are ostensibly large enough to capture the guest methanol molecules, they constitute only 4.3% of the crystal volume and are almost com-

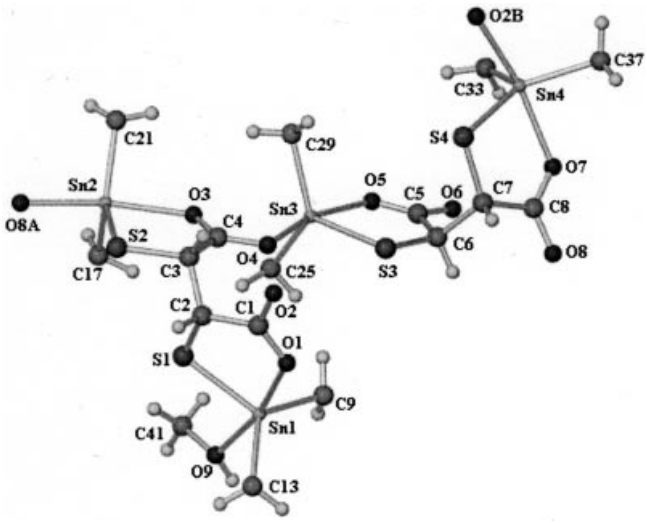

Figure 5. Molecular structure of complex **9** (the β, γ, and δ carbon atoms of the butyl groups on the tin atom have been omitted for clarity).

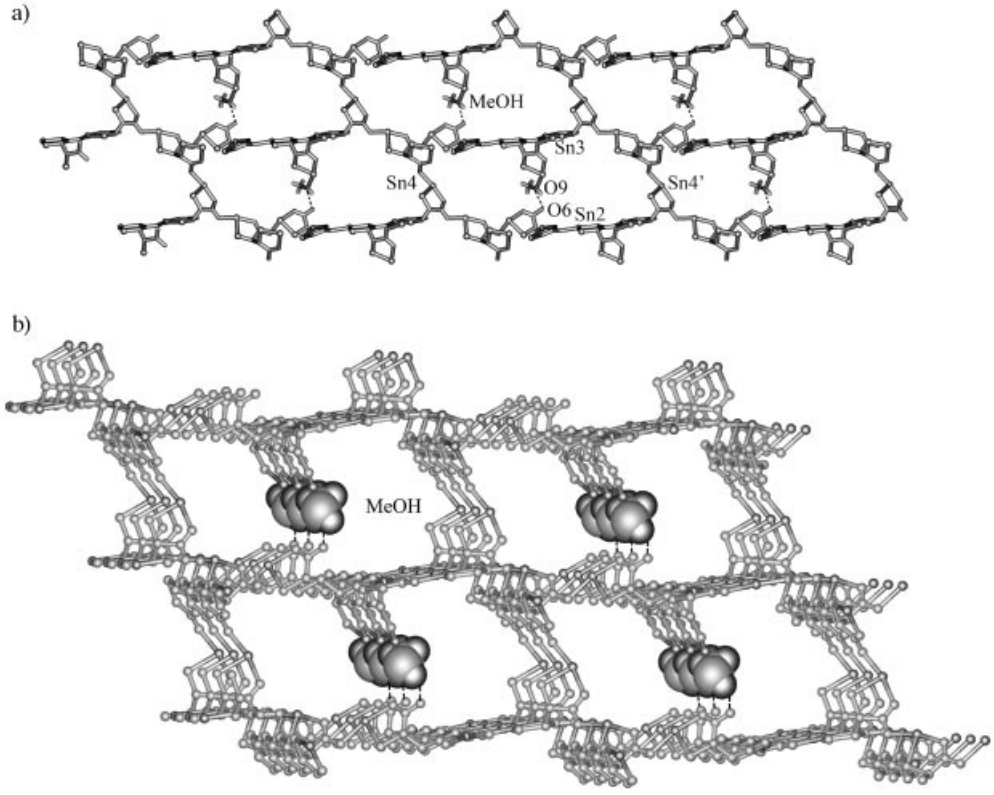

Figure 6. a) 2D "wall-like" layer and b) 3D metal-organic framework of complex **9**. The O–H···O hydrogen bonds between guest methanol molecules and the host organotin framework are shown with a broken line (the *n*-butyl groups on the tin atoms have been omitted for clarity).

pletely filled by the butyl groups on the tin atoms that protrude into the interior (if *n*Bu groups are omitted they constitute up to 69.7%; see Figure S4, Supporting Information).[30] This is apparently different to ionic complexes with a 3D open-framework structure, such as [{Mn(dcbp)}·$2H_2O$]$_n$ (dcbp = 4,4′-dicarboxylato-2,2′-bipyridine)[31] and [Co(bix)$_2$($H_2O$)$_2$]($SO_4$)·$7H_2O$ [bix = 1,4-bis(imidazol-1-ylmethyl)benzene],[32] which all have a large pore aperture for guest molecules (18.2% and 27%, respectively) and show reversible "desorption-adsorption" processes.

The TGA of **9** shows a continuous weight loss (found: 2.7%) from 77 to 135 °C, which is attributed to the loss of guest methanol molecules (calcd. 2.5%); the host framework is stable up to 280 °C, at which point decomposition starts. However, during thermal treatment under vacuum the crystal lattice collapses at relatively low temperatures (< 100 °C). X-ray crystallography proved that the crystalline 3D framework is transformed into an amorphous material, which is similar to that found in the organotin complex [{(*n*Bu)$_2$Sn(2,5-pdc)($H_2O$)}$_3$·$3H_2O$·*y*EtOH]$_n$.[8a] To evaluate the porosity of this material, crystals of **1** were thermally treated for a period of 1 h (100 °C at 10 Torr) and then exposed to vapors of $H_2O$, EtOH, MeOH, and $NH_3$. In all cases no solvent molecules were found by elemental analysis or integration of the $^1$H NMR spectrum in $CD_3COCD_3$, thus showing the irreversibility of the removal of the enclathrated guest molecule within the host framework. This is well in agreement with the crystal structure analysis.

## Conclusions

In summary, a series of organotin complexes based on *meso*-2,3-dimercaptosuccinic acid have been synthesized. All complexes were characterized by elemental analysis and FT-IR and NMR ($^1$H, $^{13}$C and $^{119}$Sn) spectroscopy. The structures of complexes **1**, **3**, **5**, and **9** have also been determined by X-ray diffractometry. Both the spectra and crystal structures show that when *meso*-2,3-dimercaptosuccinic acid reacts with triorganotin compounds it can form tetranuclear monomers, whereas when it reacts with diorganotin compounds it can form dinuclear monomers or 3D polymers with a metal-organic framework structure.

The supramolecular structures described in this paper demonstrate that the type of substituent attached to the tin atom has an influence on the supramolecular arrangement: when the groups attached to the tin atom are aromatic groups (**1** and **5**), the supramolecular structures are dominated by intermolecular C–H···π weak interactions, whereas when the groups attached to the tin atom are alkyl groups (**3** and **9**), the supramolecular structures are dominated by intermolecular Sn←X (X = S, O) coordination interactions. In diorganotin complexes, it also shows that the number of solvent molecules coordinated to the tin atom is crucial for the supramolecular assembly. This contribution adds several new features to the fast developing field of supramolecular chemistry and aids the fundamental understanding of molecular recognition and systematic rationalization of molecular aggregation in crystal engineering of organometallic complexes.

## Experimental Section

**Materials and Measurements:** Commercially available starting materials and solvents were used. Tribenzyltin chloride,[33] dimethyltin oxide, and dibenzyltin oxide[34] were prepared by standard methods reported in the literature. The melting points were obtained with a Kofler micro-melting point apparatus and are uncorrected. IR spectra were recorded with a Nicolet-460 spectrophotometer using KBr discs and sodium chloride optics. $^1$H, $^{13}$C, and $^{119}$Sn NMR spectra were recorded with a Varian Mercury Plus 400 spectrometer operating at 400, 100.6, and 149.2 MHz, respectively. The spectra were acquired at room temperature (298 K) unless otherwise specified; $^{13}$C NMR spectra were broadband-proton-decoupled. The chemical shifts are reported in ppm with respect to the references and are quoted relative to external tetramethylsilane (TMS) for $^1$H and $^{13}$C NMR, and to neat tetramethyltin for $^{119}$Sn NMR spectroscopy. Elemental analyses were performed with a PE-2400II apparatus.

**[($Ph_3Sn$)$_4$(dmsa)] (1):** This reaction was carried out under nitrogen. *meso*-2,3-Dimercaptosuccnic acid (0.182 g, 1 mmol) and sodium ethoxide (0.272 g, 4 mmol) were added to a mixed solution of toluene and methanol (5:1) in a Schlenk flask and stirred for 0.5 h. After the addition of triphenyltin chloride (1.542 g, 4 mmol), the mixture was stirred at 40 °C for 12 h and then filtered. The solvent was gradually removed by evaporation under vacuum until a solid product was obtained. This solid was then recrystallized from dichloromethane to give colorless crystals of **1**. Yield: 1.294 g (82%). M.p. 212–214 °C. $C_{76}H_{62}O_4S_2Sn_4$ (1578.1): calcd. C 57.84, H 3.96, S 4.06; found C 57.75, H 4.05, S 4.00. IR (KBr): $\tilde{\nu}$ = 1594 cm$^{-1}$ $\nu(COO)_{as}$, 1352 $\nu(COO)_s$, 560 $\nu$(Sn–C), 447 $\nu$(Sn–O), 320 $\nu$(Sn–S). $^1$H NMR ($CDCl_3$): $\delta$ = 4.25 (s, 2 H, CH), 7.46–7.79 (m, 60 H, $C_6H_5$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 53.1, 128.1, 129.3, 136.5, 148.6, 177.4 ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –95.1, –125.5 ppm.

**[{($PhCH_2$)$_3$Sn}$_4$(dmsa)] (2):** Complex **2** was prepared in the same way as compound **1**, by adding tribenzyltin chloride (1.710 g, 4 mmol) to *meso*-2,3-dimercaptosuccinic acid (0.182 g, 1 mmol) and sodium ethoxide (0.272 g, 4 mmol). The solvent was gradually removed by evaporation under vacuum until a solid product was obtained. Yield: 1.484 g (85%). M.p. 200–202 °C. $C_{88}H_{86}O_4S_2Sn_4$ (1746.6): calcd. C 60.51, H 4.96, S 3.70; found C 60.55, H 5.00, S 3.75. IR (KBr): $\tilde{\nu}$ = 1595 cm$^{-1}$ $\nu(COO)_{as}$, 1358 $\nu(COO)_s$, 575 $\nu$(Sn–C), 438 $\nu$(Sn–O), 335 $\nu$(Sn–S). $^1$H NMR ($CDCl_3$): $\delta$ = 3.24 (s, 24 H, $CH_2$), $\delta$ = 4.25 (s, 2 H, CH), 7.25–8.05 (m, 60 H, $C_6H_5$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 34.8, 54.2, 126.6, 128.7, 129.7, 134.2, 135.0, 176.3 ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –93.5, –118.8 ppm.

**[($Me_3Sn$)$_4$(dmsa)] (3):** Complex **3** was prepared in the same way as compound **1**, by adding trimethyltin chloride (0.800 g, 4 mmol) to *meso*-2,3-dimercaptosuccinic acid (0.182 g, 1 mmol) and sodium ethoxide (0.272 g, 4 mmol). The solvent was gradually removed by evaporation under vacuum until a solid product had formed. The solid was then recrystallized from ethanol to give colorless crystals of **3**. Yield: 0.733 g (88%). M.p. 108–110 °C. $C_{16}H_{38}O_4S_2Sn_4$ (833.34): calcd. C 23.06, H 4.60, S 7.69; found C 23.10, H 4.65, S 7.65. IR (KBr): $\tilde{\nu}$ = 1598 cm$^{-1}$ $\nu_{as}$(COO), 1360 $\nu_s$(COO), 583 $\nu$(Sn–C), 476 $\nu$(Sn–O), 357 $\nu$(Sn–S). $^1$H NMR ($CDCl_3$): $\delta$ = 0.84 (s, 36 H, $CH_3$), 4.25 (s, 2 H, CH) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = –5.0, 2.5, 53.4, 175.5 ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –96.4, –121.6 ppm.

**[($n$Bu$_3$Sn)$_4$(dmsa)] (4):** Complex **4** was prepared in the same way as compound **1**, by adding tri-*n*-butyltin chloride (1.302 g, 4 mmol)

to *meso*-2,3-dimercaptosuccinic acid (0.182 g, 1 mmol) and sodium ethoxide (0.272 g, 4 mmol). The solvent was gradually removed by evaporation under vacuum until a solid product was obtained. Yield: 1.137 g (85%). M.p. 152–154 °C. $C_{52}H_{110}O_4S_2Sn_4$ (1338.4): calcd. C 46.70, H 8.25, S 4.75; found C 46.66, H 8.28, S 4.79. IR (KBr): $\tilde{\nu}$ = 1590 $cm^{-1}$ $\nu_{as}$(COO), 1358 $\nu_s$(COO), 575 ν(Sn–C), 450 ν(Sn–O), 365 ν(Sn–S). $^1H$ NMR ($CDCl_3$): $\delta$ = 0.92 (t, $^3J_{H,H}$ = 7.2 Hz, 36 H, $CH_3$), 1.25–1.71 (m, 72 H, $CH_2CH_2CH_2$), 4.27 (s, 2 H) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 13.4, 25.8, 26.5, 27.0, 54.0, 177.2 ppm. $^{119}Sn$ NMR ($CDCl_3$): $\delta$ = –98.2, –126.1 ppm.

**[(Ph$_2$Sn)$_2$(dmsa)(2H$_2$O)]·H$_2$O·Et$_2$O (5):** A mixture of *meso*-2,3-dimercaptosuccinic acid (0.182 g, 1 mmol) and $Ph_2SnO$ (0.580 g, 2 mmol) in toluene/methanol (5:1) was refluxed in a Dean–Stark trap for 10 h. After cooling to room temperature, the solvent was removed under vacuum to give **5** as a colorless solid. This solid was then recrystallized from diethyl ether to give colorless crystals of **5**. Yield: 0.732 g (86%). M.p. > 300°C (dec.). $C_{32}H_{38}O_8S_2Sn_2$ (852.1): calcd. C 45.10, H 4.50, S 7.55; found C 45.08, H 4.45, S 7.60. IR (KBr): $\tilde{\nu}$ = 1585 $cm^{-1}$ $\nu_{as}$(COO), 1352 $\nu_s$(COO), 558 ν(Sn–C), 460 ν(Sn–O), 375 ν(Sn–S). $^1H$ NMR ($CDCl_3$): $\delta$ = 7.68–7.36 (m, 20 H, $C_6H_5$), 4.26 (s, 2 H, CH) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 51.8, 128.4, 128.8, 131.5, 150.8, 176.5 ppm. $^{119}Sn$ NMR ($CDCl_3$): $\delta$ = –150.2 ppm.

**[{(PhCH$_2$)$_2$Sn}$_2$(dmsa)] (6):** Complex **6** was prepared in the same way as complex **5**, by refluxing $(PhCH_2)_2SnO$ (0.634 g, 2 mmol) and *meso*-2,3-dimercaptosuccinic acid (0.182 g, 1 mmol). After cooling to room temperature, the solvent was removed under vacuum to give **6** as a colorless solid. Yield: 0.647 g (83%). M.p. 205–207 °C. $C_{32}H_{30}O_4S_2Sn_2$ (780.13): calcd. C 49.27, H 3.88, S 8.22; found C 49.30, H 3.85, S 8.20. IR (KBr): $\tilde{\nu}$ = 1578 $cm^{-1}$ $\nu_{as}$(COO), 1310 $\nu_s$(COO), 552 ν(Sn–C), 460 ν(Sn–O), 336 ν(Sn–S). $^1H$ NMR ($CDCl_3$): $\delta$ = 3.26 (s, 8 H, $CH_2$), 4.27 (s, 2 H, CH), 7.24–7.58 (m, 20 H, $C_6H_5$) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 56.3, 125.8, 128.7, 129.3, 143.7, 177.1 ppm. $^{119}Sn$ NMR ($CDCl_3$): $\delta$ = –165.8 ppm.

**[(Me$_2$Sn)$_2$(dmsa)] (7):** Complex **7** was prepared in the same way as complex **5**, by refluxing $Me_2SnO$ (0.330 g, 2 mmol) and *meso*-2,3-dimercaptosuccinic acid (0.182 g, 1 mmol). After cooling to room temperature, the solvent was removed under vacuum to give **7** as a colorless solid. Yield: 0.418 g (88%). M.p. 221–223 °C. $C_8H_{14}O_4S_2Sn_2$ (475.74): calcd. C 20.20, H 2.97, S 13.48; found C 20.25, H 3.00 S 13.55. IR (KBr): $\tilde{\nu}$ = 1635 $cm^{-1}$ $\nu_{as}$(COO), 1326 $\nu_s$(COO), 543 ν(Sn–C), 480 ν(Sn–O), 345 ν(Sn–S). $^1H$ NMR ($CDCl_3$): $\delta$ = 0.91 (s, 12 H), 4.27 (s, CH) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = –0.6, 54.8, 177.5 ppm. $^{119}Sn$ NMR ($CDCl_3$): $\delta$ = –175.7 ppm.

**[(*n*Bu)$_2$Sn]$_2$(dmsa) (8):** Complex **8** was prepared in the same way as complex **5**, by refluxing $(nBu)_2SnO$ (0.498 g, 2 mmol) and *meso*-2,3-dimercaptosuccinic acid (0.182 g, 1 mmol). After cooling to room temperature, the solvent was removed under vacuum to give **8** as a colorless product. Yield: 0.515 g (80%). M.p. 310–312 °C. $C_{20}H_{38}O_4S_2Sn_2$ (644.1): calcd. C 37.30, H 5.95, S 9.96; found C 37.32, H 5.80, S 10.00. IR (KBr): $\tilde{\nu}$ = 1632 $cm^{-1}$ $\nu_{as}$(COO), 1330 $\nu_s$(COO), 558 ν(Sn–C), 464 ν(Sn–O), 328 ν(Sn–S). $^1H$ NMR ($CDCl_3$): $\delta$ = 0.80–0.93 (t, $^3J_{H,H}$ = 6.8 Hz, 12 H, $CH_3$), 1.35–1.82 (m, 24 H, $CH_2CH_2CH_2$), 4.22 (s, 2 H, CH) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 13.5, 25.8, 26.3, 27.5, 52.0, 175.4 ppm. $^{119}Sn$ NMR ($CDCl_3$): $\delta$ = –173.8 ppm.

**{[(*n*Bu)$_2$Sn]$_4$(dmsa)$_2$(MeOH)}$_n$ (9):** A mixture of *meso*-2,3-dimercaptosuccinic acid (0.091 g, 0.5 mmol), KOH (0.112 g, 2 mmol), tri-*n*-butyltin chloride (0.651 g, 2 mmol), $CH_3OH$ (10 mL) and $H_2O$ (5 mL) was heated in a Teflon-lined autoclave at 150 °C for 3 d. After cooling to room temperature, colorless crystals of **9** were collected and washed with hexane. Yield: 0.280 g (85%). M.p. 298°C (dec.). $C_{41}H_{81}O_9S_4Sn_4$ (1320.5): calcd. C 37.30, H 6.11, S 9.72; found C 37.25, H 6.20, S 9.70. IR (KBr): $\tilde{\nu}$ = 3195 $cm^{-1}$ $\nu_{as}$(OH), 1625, 1555 $\nu_{as}$(COO), 1532, 1326 $\nu_s$(COO), 556 ν(Sn–C) 470 ν(Sn–O), 330 ν(Sn–S). $^1H$ NMR ($CD_3COCD_3$, $D_2O$): $\delta$ = 0.82–0.96 (t, $^3J_{H,H}$ = 7.0 Hz, 24 H, $CH_3$), 1.33–1.85 (m, 48 H, $CH_2CH_2CH_2$), 4.25 (s, 4 H, CH) ppm. $^{13}C$ NMR ($CD_3COCD_3$): $\delta$ = 13.8, 25.5, 26.2, 27.1, 52.4, 176.8 ppm. $^{119}Sn$ NMR ($CD_3COCD_3$): $\delta$ = –126.8, –170.5 ppm.

**X-ray Crystallography:** Crystals were mounted in Lindemann capillaries under nitrogen. All X-ray crystallographic data were collected with a Bruker SMART CCD 1000 diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 298(2) K. A

semiempirical absorption correction was applied to the data. The structures were solved by direct methods using SHELXS-97 and refined against $F^2$ by full-matrix least squares using SHELXL-97. Non-hydrogen atoms were refined anisotropically, while hydrogen atoms were placed in geometrically calculated positions using a riding model. Crystal data and experimental details of the structure determinations are listed in Table 5. The molecular and supramolecular structures in this paper were created with the X-Seed software package.[35] CCDC-238964 (**1**), -254168 (**3**), -254166 (**5**), and -254171 (**9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

# Metal Atom Vibrational Amplitudes in Decamethylferrocene and Related Organometallics

**Rolfe H. Herber,*[a] Israel Nowik,[a] Volker Kahlenberg,[b] Holger Kopacka,[c] and Herwig Schottenberger[c]**

**Keywords:** Sandwich complexes / Iron / Vibrational amplitudes / Mössbauer spectroscopy / Isotopic enrichment

Recent experiments have shown that root-mean-square amplitudes-of-vibration (rmsav) for iron atoms in organometallic complexes at various temperatures can be extracted from temperature-dependent $^{57}$Fe Mössbauer spectroscopic data related to the recoil-free fraction of the metal atom. The applicability of this procedure has been validated by comparison with rmsav data extracted from $U_{ij}$ values obtained from single-crystal X-ray diffraction parameters at various temperatures. This analysis has been applied in detail to a study of decamethylferrocene (DMFc), for which the agreement between the rmsav values derived from the two experimental procedures is compared in the present study. A comparison of these rmsav values for a number of related structures is also reported over a similar temperature range. An improved method for the quantitative preparation of isotopically enriched DMFc is described.

## Introduction

In a number of recent publications from this laboratory (HU),[1–4] it has been shown that temperature-dependent $^{57}$Fe Mössbauer effect spectroscopy (ME) can serve to elucidate the root-mean-square-amplitude-of-vibration (rmsav) of the metal atom in ferrocene-type organometallics. While such studies have led to reasonably self-consistent values for this parameter, detailed validation has only been accomplished in the case of the parent ferrocene, for which single-crystal X-ray data are available at a number of different temperatures. However, in the case of ferrocene, not only are the details of the molecular structure and arrangement complicated by the existence of a number of different crystallographic forms, but the particular crystallographic form assumed at a given temperature depends on the thermal history of the sample.[5] References to these reported X-ray data have been reported earlier.[4]

To place the inference concerning the iron atom rmsav in iron organometallics on a more reliable basis, in the present study both the X-ray structure and the detailed ME parameters of decamethylferrocene (DMFc) have been determined at a number of different temperatures, thus allowing a comparison of the values obtained by the two techniques.

[c] Institut für Anorganische Chemie, Universität Innsbruck, Innrain 52a, 6020, Innsbruck, Austria

There have been a number of X-ray studies of DMFc reported in the literature, but the early work of Struchkov et al.[6] has been re-examined by Raymond et al.[7] and in neither case are the thermal parameters of the metal atom extractable from the available data. In the present study, single-crystal X-ray diffraction data for DMFc (**1**) have been acquired at 123, 173, 232, and 298 K and the rmsav data calculated from the corresponding anisotropic displacement parameters $U_{ij}$ are compared to detailed ME spectroscopic results over the range $88 < T < 385$ K. In addition, lattice dynamical parameters have been extracted from ME data for $DMFc^{+}BF_4^{-}$ (**2**), the co-crystalline solid-state adduct (intercalate) of $C_{60}$ and DMFc reported by Stanghellini et al.[8] (**3**), and the mononuclear bucky ferrocene $CpFe(CH_3)_5C_{60}$ reported by Nakamura and Matsuo et al.[9] (**4**). The details of the rmsav data for the metal atom in these structurally related complexes are described in detail in the present study.

## Results and Discussion

A representative ME spectrum of **1** at 298 K is shown in Figure 1. It consists of a single quadrupole doublet with a line width (*fwhm*) of $0.243 \pm 0.005$ mm s$^{-1}$ at room temperature. The resonance effect under these conditions is about 2.8%, and the data were treated with the "thin absorber" approximation. The hyperfine parameters [isomer shift (IS) and quadrupole splitting (QS)] for **1** have been reported earlier.[10] The area ratio of the two components of the doublet spectrum are essentially temperature independent over the range $90 < T < 370$ K, thus indicating no appreciable anisotropy in the metal atom motion parallel and perpendicu-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lar to the symmetry axis passing through the two five-membered rings and the Fe atom. This is in contrast to the observations made in the case of the parent ferrocene,[3,4] in which this anisotropy is significant over a similar temperature range.

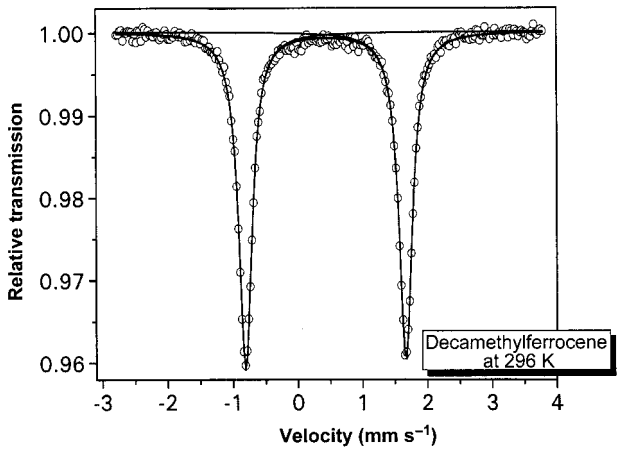

Figure 1. $^{57}$Fe Mössbauer spectrum of decamethylferrocene (**1**) at room temperature. The velocity scale is with respect to the centroid of an α-Fe absorber spectrum at room temperature.

The recoil-free fraction scales with the area ($A$) under the resonance curve in the "thin absorber" approximation; that is $\ln[A(T)/A(\mathrm{r})]$ [where $A(T)$ is the area under the resonance curve at temperature $T$, and $A(\mathrm{r})$ is a reference temperature] scales with $\ln f$. The recoil-free fraction, $f$, in turn, is given by

$$f = \exp(-k^2 \langle x_{ave}^2 \rangle)$$

where $k$ is the wave vector of the ME gamma ray (7.3039 Å$^{-1}$) and $\langle x_{ave}^2 \rangle$ is the mean square amplitude of the metal atom motion. It follows that an estimate of the msav can be extracted from the temperature-dependent spectral area values extracted from the ME data. The temperature dependence of the logarithm of the area under the resonance curve is summarized graphically in Figure 2. It is immediately obvious from these data that there is significant curvature in this dependence, especially at higher temperatures (i.e. above about 300 K), in contrast to what is usually observed in organometallic solids. Moreover, the highest temperature at which reliable ME data can be acquired is approximately 385 K, which is some 165 K below the melting point of this compound. It may be postulated that the onset of ring rotation at higher temperatures, which increases the metal–ring distances, increases the rmsav of the iron atom to the point where the ME is no longer observable. However, this assumption has been questioned on the basis of a density of states (DOS) study at 25 K, carried out at ESRF by Chumakov and van Buerck.[11] This study showed that the DOS is almost completely defined by the data within the first 9 meV and that at higher temperatures (above 100 K) all these modes are effectively populated. However, their DOS data do not directly elucidate the reason for the non-linearity referred to above except to indicate that an additional effect sets in at higher temperatures. Moreover, the X-ray data in the range $123 \leq T \leq 298$ K show that the distance from the metal atom to the centers of the five-membered rings increases by only 0.45% with increasing temperature. Extrapolation of the linear low-temperature dependence of $-\ln[A(T)]$ to 298 K shows that this extrapolation gives a value some 10% smaller than what is observed experimentally. Thus, the decrease in $f$ is not well accounted for by the onset of ring-rotation, and this dynamic may not be solely responsible for the non-linearity in the $\ln A(T)$ vs. $T$ data summarized in the figure. A "softening" of the lattice (as probed by the Fe ion) well below $T_{mp}$ must be accounted for by another mechanism. Differential scanning calorimetry data by Kobayashi et al.[12] have shown the existence of two solid phase transitions at $397 \pm 1$ and $501 \pm 2$ K involving uniaxial reorientation of the whole molecule about its $C_5$ axis. NMR spectroscopic data by Waugh et al.[13] and Pines et al.[14] have been interpreted in terms of a $2\pi/5$ jump process involving an energy barrier of about 143 and 140 meV, respectively, but these processes would not be significant in the solid in the low-temperature regime. The barrier to internal rotation for the gas-phase molecule has been reported[7b] to be 43.4 meV.

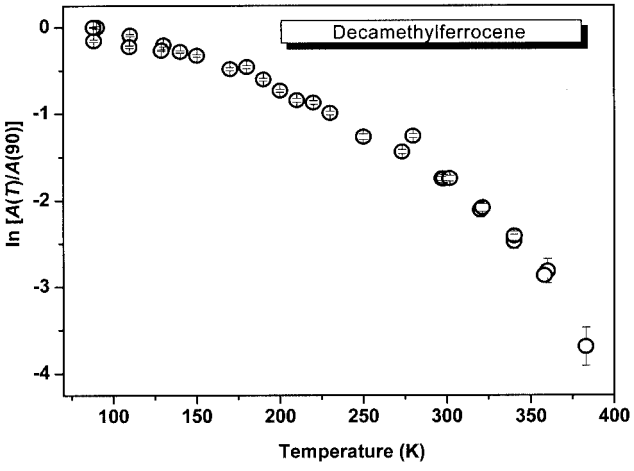

Figure 2. Temperature dependence of $\ln[A(T)/\mathrm{A}(90)]$ for **1**. The low-temperature data were obtained with a natural abundance $^{n}$Fe sample and were fitted using the optically "thin" absorber approximation. The high-temperature data were acquired using an enriched $^{57}$Fe sample as discussed in the text.

The $\ln[A(T)]$ data have been scaled so that the low-temperature regime passes through (0,0) at $T = 0$ K. The resulting curve can be well fitted by a second-order polynomial function from which $\ln A$, and hence the msav of the metal atom, can be calculated at all temperatures. These values, in turn, can be compared to those extracted from the anisotropic displacement parameters of the single-crystal X-ray diffraction experiment, and are shown in Figure 3 by the filled data points. The agreement between these two sets of values, at least up to 298 K, appears to be quite satisfactory, and validates the interpretation of the Mössbauer data in terms of $\langle x_{ave}^2 \rangle$. A similar comparison for ferrocene, based on the data of Brock and Fu,[15] has been reported earlier.[3]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

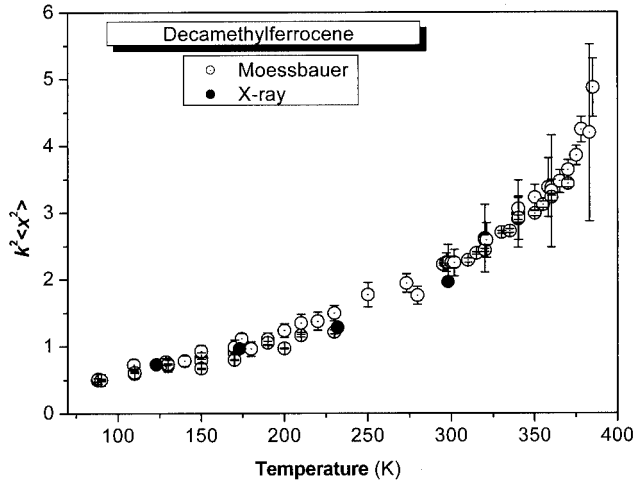

Figure 3. Temperature-dependence of the $k^2<x_{ave}^2>$ values for **1** extracted from the ME data (open circles) and from the single-crystal X-ray diffraction data (filled circles). The average errors in the X-ray values are ±0.00064, ±0.00112, ±0.0014, and ±0.00138 Å$^2$ at 298, 223, 173, and 123 K, respectively.

A summary of the rmsav of the metal atom in **1** at five different temperatures calculated from the X-ray data and the ME experiments is given in Table 1, which includes the comparable data for related systems to be discussed below. Thus, despite the uncertainty concerning the origin of the non-linearity in the ln$f$ vs. $T$ data shown in Figure 2, it is clear that the ME data can be used to estimate the rmsav of the metal atom in such organometallic solids.

Table 1. Root-mean-square amplitudes-of-vibration (rmsav; Å) of the iron atom in a number of structurally related organometallics discussed in the text.

| Ferrocene | **4** | **3** | **2** | DMFc (ME) | DMFc (X-ray) | Temp. [K] |
|---|---|---|---|---|---|---|
| 0.131 | 0.102 | 0.115 | 0.105 | 0.107 | 0.104 | 100 |
| 0.154 | 0.120 | 0.140 | 0.126 | 0.122 | 0.125 | 150 |
| 0.183 | 0.137 | 0.157 | 0.145 | 0.143 | 0.143 | 200 |
| 0.202 | 0.156 | 0.182 | 0.162 | 0.182 | 0.165 | 250 |
| 0.222 | 0.174 | 0.202 | 0.177 | 0.205 | 0.191 | 300 |

A molecular system closely related to the neutral species **1** is that obtained by one-electron oxidation of **1**, in which the cationic charge is balanced by the presence of either $BF_4^-$ or $PF_6^-$ anions. The ME spectra of the former compound, **2**, consist of a single broad resonance line which arises from spin-lattice relaxation of the paramagnetic metal site. The ME hyperfine parameters of **2** are listed in Table 2, and are similar to those of the corresponding $BF_4^-$ salt. It is, however, interesting to note that the ln[$A(T)$/$A$(90)] vs. $T$ data are well fitted by a linear regression over the temperature range 90 ≤ $T$ ≤ 360 K, in contrast to the data for **1** discussed above. The ln$A(T)$ data for **2** are shown graphically in Figure 4 (filled data points) together with those for **3** and **4** (to be discussed below). The rmsav data for **2** listed in Table 1 are very similar to those reported for **1** at a given temperature, except at 300 K, which is indicative of a similarity in the Fe–ligand interaction, especially in the lower temperature regime. Unfortunately, the relevant iron atom $U_{ij}$ data are not available in the literature, so no direct comparison with X-ray data for the cationic complex **2** can be effected at the present time.

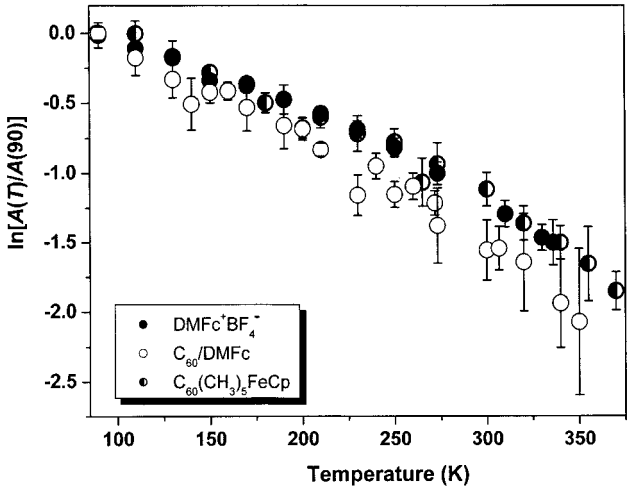

Figure 4. Temperature-dependence of the ln($A$) data (normalized to the 90 K value) for **2**, **3**, and **4**.

The data in Table 1 includes rmsav results obtained from ME experiments on the co-crystalline product $C_{60}$·DMFc (**3**) reported by Stanghellini et al.,[8] which is similar to the $C_{60}$ ferrocene intercalate reported by Crane et al.[16] for which the ME characterization has been reported from this laboratory.[17] The ME hyperfine parameters of **3** are included in Table 2. The $U_{ij}$ values for the iron atom in **3** have been determined at 150 K by Stanghellini et al.[8] and the calculated $k^2<x_{ave}^2>$ value of 1.10 is in good agreement with the ME extracted value of 1.02 at the same temperature. The remainder of the rmsav data for **3** listed in Table 1 are those derived from the ME data as described for **1** above. It is noted from these data that the rmsav of the metal atom in **3** is comparable to that in **1** at the same temperature, suggesting that this parameter reflects *intra*- rather than *inter*molecular forces. It is also worth noting

Table 2. Mössbauer effect (ME) hyperfine parameters at 90 K and related values for the compounds discussed in the text. The parenthetical number(s) are the errors associated with the last figure(s) for each entry.

that the temperature dependence of the $\ln[A(T)/A(90)]$ data for **3** over the temperature range $89 \leq T \leq 350$ K are well accounted for by a linear regression (cc = 0.994 for 23 data points) so that the lattice "softening" observed in **1** is again absent in **3**. Since both the isomer shift and the recoil-free fraction data show a linear temperature-dependence over the total temperature range, it is possible to calculate[18] both an "effective vibrating mass" ($M_{eff}$) and a "Mössbauer lattice temperature" ($\Theta_M$) of 85 ± 3 D and 116 ± 5 K, respectively. Clearly, these data refer to the high-temperature limiting values, i.e. $T_{exp} > \Theta_M/2$. The difference between the calculated $M_{eff}$ (85 D) and the "bare" atom mass (57 D) reflects the covalency of the metal atom–ligand interaction, as discussed earlier.[19] The $[k^2<x^2>]^{1/2}$ values at five different temperatures, calculated from the $\ln A(T)$ data as noted above, and making the assumption that the high-temperature limiting slopes extrapolate to $f = 0$ as $T \rightarrow 0$, are summarized graphically in Figure 5.

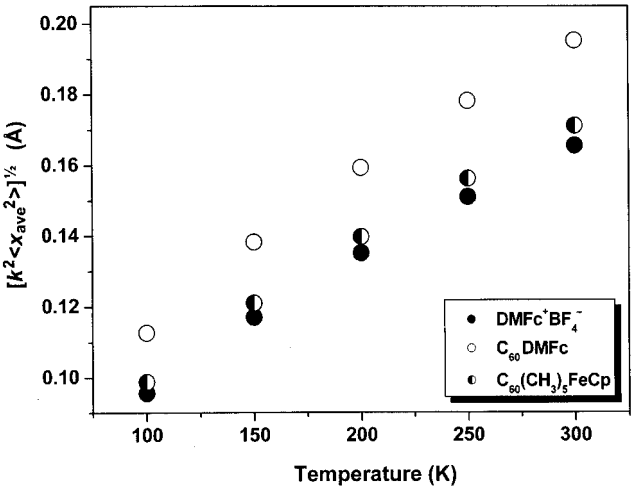

Figure 5. The $[k^2<x^2>]^{1/2}$ parameters for **2**, **3**, and **4** at five different temperatures calculated from the high temperature ($T > \Theta_M/2$) slopes of the data shown in Figure 4, as discussed in the text.

Finally, a related organometallic structure in which the iron atom is ligated to two five-membered rings and in which there are five methyl groups on the $C_{60}$ sphere, in near proximity to the metal center, is provided by the "bucky ferrocene" compound **4**, for which the details of the ME parameters have been reported earlier.[4] In this molecule the iron atom "sees" an unsubstituted Cp ring in one direction and a similar Cp ring in the opposite direction, with, however, five methyl groups attached to the next neighbor carbon atoms of the $C_{60}$ sphere. The ME hyperfine parameters and derived data are included in Table 1 and the rmsav values for the iron atom are listed in Table 2 and included in Figure 5. As in the case of **2** and **3**, the $\ln f$ vs. $T$ plot is linear over the temperature range $210 \leq T \leq 370$ K as already noted.[1] As indicated in Figure 5, the rmsav of the metal atom in **4** is very nearly identical to that in **1** and **3**. Presumably the massive fullerene moiety ligated to the Fe center plays no critical role in the magnitude of the rmsav of the metal atom in these complexes.

## Summary and Conclusions

An improved efficient synthesis of $^{57}$Fe-labeled decamethylferrocene ($^{57}$Fe DMFc) has been developed. The resulting product has been characterized by elemental and isotopic composition, single-crystal X-ray diffraction, and IR and NMR spectroscopic data. The availability of $^{57}$Fe DMFc, in turn, has made it possible to use temperature-dependent Mössbauer effect spectroscopy to elucidate the hyperfine interactions in this material at high temperatures, as well as the temperature-dependence of the recoil-free fraction of the metal atom. From these data it is possible to determine the mean-square-amplitude-of-vibration of the iron atom motion, and to compare these results with those extracted from single-crystal X-ray diffraction data. The agreement between these two data sets in the temperature range 80 to 300 K is quite satisfactory within the quoted experimental errors. The origin of the non-linearity observed in the recoil-free fraction data, as well as the vanishingly small value of this parameter at temperatures about 165 K below the melting point of DMFc is assumed to be due in part to the onset of ring rotation in the solid, but may have an additional contribution not well elucidated by the presently available data. The comparison of the Fe vibrational amplitude as a function of temperature for a number of structurally related ferrocene-type systems should lead to a clearer understanding of the relationship between the microscopic architecture and the dynamic behavior of the metal atom in these structures.

## Experimental Section

A commercial sample of **1** was recrystallized from trichloroethylene and used without further purification for the ME studies. A sample of $^{57}$Fe-enriched **1** was prepared as described below and used for acquiring data in the high-temperature regime ($T \geq 300$ K) where the recoil-free fraction values ($f$), which determine the area under the resonance curve, become so small that natural abundance samples would require inordinately long data acquisition times. Single crystal samples of **1** for the X-ray diffraction studies were grown as described below. A sample of **2** was prepared in the Innsbruck laboratory and used for Mössbauer studies as received. Complex **3** was similarly made available by Profs. Stanghellini and Viterbo and used as received. A sample of **4** was provided by Profs. Nakamura and Matsuo, and again used as received.

Temperature-dependent ME studies were carried out as described previously[1–5] and spectrometer calibration was effected using a 10.52 mg cm$^{-2}$ α-Fe foil at room temperature, which also served as the isomer-shift reference point. Temperature control was monitored using the DASWIN program of Glaberson and Brettschneider,[20] and confirmed that the indicated temperatures were constant to better than ±0.2 K over the data acquisition periods (typically 8–24 hours) at each temperature.

For the structural investigations of **1**, a rhomb-shaped crystal of good optical quality ($0.14 \times 0.14 \times 0.16$ mm$^3$ in size) was selected and mounted on a glass fiber. Data collections at four different temperatures were performed using graphite-monochromated Mo-$K_\alpha$ radiation on a Stoe IPDS-II diffractometer equipped with a 700 Series Oxford Cryostream nitrogen gas stream cooler. The mor-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phology of the crystals was described by external faces and an analytical absorption correction based on the indexed faces was applied. Further data reduction included Lorentz and polarization corrections. The subsequent least-squares refinements were accomplished with the program SHELX97.[21] The corresponding X-ray data for **3** have been reported in the literature.[8]

**Synthesis and Characterization of [$^{57}$Fe]Decamethylferrocene**

**Instrumentation:** Microwave reactor: Synthos 3000, Anton Paar GmbH, Austria; Kugelrohr apparatus: Buechi GKR-51, Switzerland. IR spectra were measured with a Nicolet 5700 FT-IR with an ATR diamond window, and $^{1}$H and $^{13}$C NMR spectra were recorded in $CDCl_3$ solution with a Bruker Avance DPX 300 spectrometer. All organometallic reactions were carried out under an inert atmosphere using standard Schlenk techniques. Solvents were distilled, dried, and deoxygenated prior to use. Starting compounds not specifically referred to are commercially available by several suppliers. Purchased chemicals were used without any further purification.

$^{57}$Fe-enriched iron powder (95%) was purchased from ATM, Advanced Materials Technologies. From this starting material, enriched $^{57}FeCl_2$ was prepared by oxidation with methanolic hydrogen chloride in a microwave reactor by the novel procedure described below. This synthesis is also a low-temperature preparation in solution,[22] but avoids the concomitant formation of chlorobutanol from HCl and THF, which is difficult to separate from methylated ferrocenes during workup. The $^{57}$Fe-labeled decamethylferrocene was then prepared from $^{57}FeCl_2$ by complexation with the $[CpMe_5]^-$ anion in analogy to the synthesis of [$^{57}$Fe]octamethylferrocene.[23] In contrast to octamethylferrocene, decamethylferrocene is very easily oxidized on silica and alumina-packed chromatography columns, which results in extremely reduced yields if any chromatographic purification is required. The elemental and isotopic composition of [$^{57}$Fe]decamethylferrocene was determined by means of HR mass spectrometry (Finnigan MAT 95). The exact monoisotopic molecular weight was measured using the following HR-FAB-MS conditions: Cs gun: 20 kV, 2 μA; glycerol matrix, resolution $R$ = 8000, E-scan, average over 20 scans. The determination of the $^{57}$Fe/$^{56}$Fe isotope ratio of the target compound gave a $^{57}$Fe content of >95.0%.

**Synthesis of Anhydrous $^{57}FeCl_2$:** $^{57}$Fe powder (35 mg, 0.62 mmol) was fixed on a magnetic stirring bar and placed in a Teflon-lined microwave reactor along with 6 mL of a 1.25 M solution of hydrochloric acid in methanol (6 mL required to immerse the internal temperature probe), whereupon a slight evolution of hydrogen was observable. The reaction mixture was heated to 150 °C within 1 min and held at this temperature for 50 min. Afterwards, it was cooled by the fan-device for 20 min. The liner was opened under a stream of nitrogen and the contents transferred to a Schlenk tube. The $^{57}$Fe powder was completely dissolved, although the yellowish coloration indicated the presence of iron(III) salts. Subsequently, the solvent and excess hydrogen chloride were stripped off on a vacuum line (oil pump) whilst heating to 40 °C in a water bath, and the crude iron chlorides triturated for 5 min with chlorotrimethylsilane (1 mL) in order to remove protic solvent residuals. The chlorotrimethylsilane was then pumped off whilst shaking the Schlenk tube in such a way that the crude iron chloride was deposited in a layer covering the lower part of the tube. Afterwards, the remainder was rinsed with hexamethyldisilane (1 mL) and evacuated again to yield an off-white material. Anhydrous THF (40 mL) was added to the Schlenk tube and the solution was stirred magnetically with an additional 5 mg of excess $^{57}$Fe powder adhered to the stirring bar to give a clear white solution of $FeCl_2$ within 2 min. The THF solution was cooled to –40 °C under nitrogen and used for the complexation step below.

**Synthesis of [$^{57}$Fe]Decamethylferrocene:** Anhydrous THF (60 mL) was placed in a second Schlenk tube and 1,2,3,4,5-pentamethyl-1,3-cyclopentadiene (0.95 mL, 170 mg, 1.26 mmol; Chem. Abstr. registry no. 4045-44-7) was added from a syringe. The solution was cooled to –40 °C under nitrogen and butyllithium (0.80 mL, 1.6 M in hexane) was added to give a yellowish cloudy suspension. After 30 min the external cooling bath was removed and the reaction mixture was warmed to 10 °C whilst stirring. Afterwards, the reaction mixture was again recooled to about –30 °C. The $^{57}FeCl_2$/THF solution obtained by the procedure described above was added with a cannula and the stirring bar holding the excess elemental iron powder was also transferred. The resulting reaction mixture gradually turned black. After 90 min, the cooling bath was removed and the reaction mixture was ultrasonicated for 30 min. The solvents were removed on the vacuum line and the remainder was partitioned between diethyl ether (30 mL) and water (40 mL) in a separating funnel. The aqueous layer was washed with diethyl ether (30 mL) and the combined organic phases again extracted with water (2 × 30 mL). The organic phase was dried with anhydrous sodium sulfate and filtered. Evaporation (rotary evaporator) and drying (oil pump) yielded 105 mg of crude decamethylferrocene as a yellow-orange powder (52% of theoretical yield based on $^{57}$Fe). Finally, the crude product was sublimed[24] in a Kugelrohr apparatus at 200 °C on a vacuum line. HR-MS calcd. for $C_{20}H_{30}{}^{57}Fe_1$ (DMFc): 327.1696; found 327.1705 (cation; rel. intensity 27.4); calcd. for $C_{19}{}^{13}CH_{30}{}^{57}Fe_1$ (DMFc): 328.1730; found 328.1699 (cation; rel. intensity 6.2). IR data (ATR): $\tilde{\nu}$ = 2962.5 cm$^{-1}$ s, 2943.2 m, 2891.5 s, 2851.7 m, 2712.0 w, 1473.4 m, 1448.0 m, 1424.2 m, 1371.9 s, 1353.0 w, 1259.3 m, 1068.8 s, 1024.6 vs, 867.5 w, 796.5 s, 698.7 ws, 589.4 w, 536.1 w, 507.2 w, 449.4 vs, 416.6 m. $^{1}$H NMR ($CDCl_3$): $\delta$ = 1.67 ppm (s, methyl-*H*). $^{13}$C NMR ($CDCl_3$): $\delta$ = 9.59, (methyl-*C*, $^{1}J_{C,H}$ = 125.4 Hz), 79.70 ppm (Cp-C). DMFc is only sparingly soluble in methanol; alternatively, suspending the crude material by ultrasonication then centrifuging the mixture allows removal of any organic impurities. Crystals suitable for X-ray structure determinations were grown by slow evaporation of the solvent from a solution in 2-methylbutane at ambient temperature. In order to recover any residual unreacted $^{57}$Fe material, the aqueous extracts containing precipitated iron(III) hydroxide (formed by oxidation with ambient oxygen during workup) were centrifuged. Iron(III) chloride may be reconverted to iron(II) chloride by dissolving the separated $Fe(OH)_3$ in methanolic hydrogen chloride and drying/reducing with trimethylchlorosilane/hexamethyldisilane as described above.

## Acknowledgments

The authors are indebted to Prof. H. Schottenberger both for the single crystals of **1** used in the acquisition of the X-ray data and also for providing the $^{57}$Fe-labeled samples used in the ME experiments. Similarly, we are grateful to Profs. Nakamura and Matsuo for providing a sample of **4** for study, and Profs. P. L. Stanghellini and D. Viterbo not only for providing the sample of **3** for the ME experiments but also for sharing the results of their X-ray investigation with us.

# Controlling the Size of $BaF_2$ Nanocubes from 1000 to 10 nm

Peng Gao,[a] Yi Xie,*[a] and Zhen Li[a]

**Keywords:** $BaF_2$ Nanocubes / Nanostructures / Electron diffraction / X-ray diffraction

Size control of $BaF_2$ nanocubes has been achieved by varying reaction time and pH value, thus producing nanocubes with a controllable edge length in the range 10–1000 nm. A linear relationship between cube size and reaction time has been revealed. Furthermore, a process has been developed to separate the growing $BaF_2$ nanocubes from the remaining solid products at different stages of the synthesis. On the basis of the observed crystallite morphologies, we have elucidated an "extension growing" mechanism to describe the size-controlled growth of $BaF_2$ nanocubes using this method. Photoluminescence results demonstrate that the deoxidant selenite ions prevent the incorporation of oxygen into the $BaF_2$ nanocubes effectually, which will greatly affect their performance as scintillators.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Solid inorganic fluorides have a number of uncommon properties, for example, electron-acceptor behavior, a large optical-transmission domain, high resistivity, and anionic conductivity. Inorganic nanoscale fluorides and rare-earth-doped inorganic nanoscale fluorides have attracted much interest recently because of their unique properties,[1] such as optical, electrical, and magnetic, which result from the size and shape of their particles.[2] Barium fluoride is one of the dielectric fluorides (along with $CaF_2$ and $SrF_2$) that have a wide range of potential applications in microelectronic and optoelectronic devices, such as wide-gap insulating overlayers, gate dielectrics, insulators, and buffer layers in semiconductor-on-insulator structures and more advanced 3D devices.[3] $BaF_2$ salts activated with rare-earth ions have also been reported to display unique luminescence properties and can be used as scintillators.[4] Recently, $BaF_2$ nanowires and nanocubes with arching sheet-like dendrites have been prepared in quaternary microemulsions and reverse micelles, respectively.[5] Li et al. have reported the preparation of $CaF_2$ nanocubes by a hydrothermal method in the absence of surfactants.[6] Monodispersed noble-metal and $Cu_2O$ nanocubes[7] have also been synthesized by controlled oxidation–reduction reactions. However, to the best of our knowledge, there have been no reports on large-scale preparations of $BaF_2$ nanocubes to date. Therefore, the development of simple methods for the synthesis on a large scale is a challenge. It was reported that oxygen may be incorporated into $BaF_2$ as oxygen–vacancy pairs and detrimentally affect the performance of the resulting nanocubes as scintillators,[8] thus avoiding the incorporation of oxygen into the products will be necessary in industry. We have synthesized single-crystalline $BaF_2$ nanocubes through a simple hydrothermal precipitation procedure in the presence of selenite ions, which act as deoxidants and prevent the incorporation of oxygen effectively. The morphology and size of the final products can be manipulated through controlling the synthesis parameters such as reaction time and pH value.

## Results and Discussions

### Structural and Compositional Analysis

Figure 1 shows a representative XRD pattern of samples prepared with this approach, which indicates that all the products are phase-pure crystalline $BaF_2$ [in cubic symmetry; space group (SG) *Fm*3*m*, lattice constant *a* =

6.19 ± 0.01 Å].[9] No other impurities have been found in the synthesized products.

Further evidence for the quality and composition of the samples was obtained by X-ray photoemission spectroscopy (XPS) of the products. An XPS measurement of the crystals shows peaks corresponding to Ba, F, O, and C (Figure 2), which agrees with results previously reported in the literature.[10] The oxygen detected in the XPS measurement may come from the atmosphere. Furthermore, low amounts of oxygen (about two percent) are frequently observed in XPS spectra. Both the results of the XRD and XPS studies leave no doubt that the product is $BaF_2$.

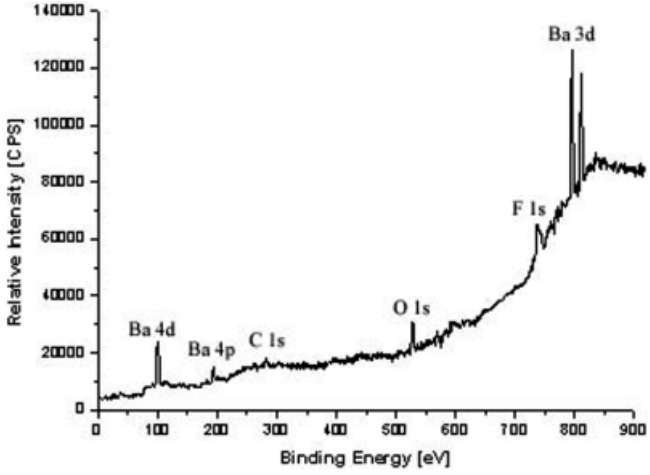

Figure 2. XPS spectrum of the $BaF_2$ nanocubes with an edge length of 55 nm.

### Morphology of the $BaF_2$ Nanocubes

As shown in Figure 3a, the $BaF_2$ products described above have perfect cubic morphology. It is also clear that more than 95% of the $BaF_2$ particles have a regular cubelike structure with a mean edge length of 55 nm. The excellent crystallinity of the $BaF_2$ nanocubes is also confirmed by an electron diffraction (ED) experiment. Figure 3c shows a spot pattern from a single-crystalline $BaF_2$ nanocube (Figure 3b). In this case, the electron beam is incident along the [001] direction, and the spot array has a fourfold axis that can be indexed with *hk*0 (i.e. [001] zone spots, in accordance with the extinction rule of electron diffraction for the space group *Fm*3*m*), which indicates cubic symmetry for the $BaF_2$ nanocubes. Figure 3d shows a typical FESEM image of the $BaF_2$ nanocubes. The inset shows a FESEM image at higher magnification that clearly displays the sharp corners and edges of these nanocubes. All these observations confirm that the particles are indeed cubelike. Moreover, the nanocubes obtained from this approach are very uniform in size.

### Size-Controlled Growths

In this work, size control of $BaF_2$ nanocubes has been achieved by varying the reaction time and adjusting the pH, and this produces $BaF_2$ nanocubes with a controllable edge length in the range 10–1000 nm.

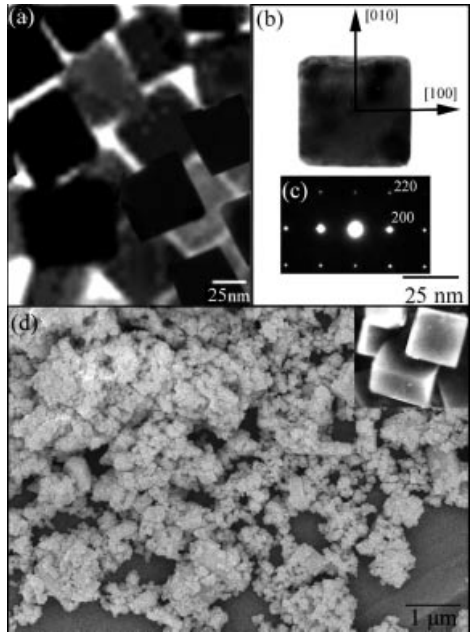

Figure 3. (a) TEM image of the $BaF_2$ nanocubes (pH = 2, 0.002 mol $SeO_2$ for 24 h). (b) TEM image of one $BaF_2$ single-crystalline nanocube. (c) Electron diffraction pattern of the nanocube in (b). (d) Typical FESEM images of the as-synthesized $BaF_2$ nanocubes. The inset shows a magnified FESEM image that illustrates the sharp corners and edges of these nanocubes.

With a simple variation in the reaction time (or ageing time), the size of these nanocubes can be controlled easily. In fact, we have obtained nanocubes as small as 10 nm (average edge length) with an ageing time of 3 h, as reported in Figure 4 and Figure 5a. After a reaction time of only 3 h, these $BaF_2$ nanoparticles started to show cubic type morphology, although they are not as well-faceted as samples obtained with longer ageing times. In principle, it is possible to capture even smaller particles by drawing samples at ageing times shorter than 3 h. However, the extremely low yield makes it impractical to do so. Nonetheless, the possibility of synthesizing even smaller (a few nanometers) and yet uniform nanocubic $BaF_2$ is positively indicated. With ageing times of 12 and 24 h (as shown in

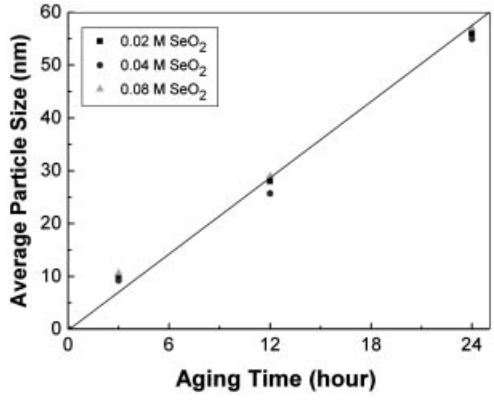

Figure 4. Average size of $BaF_2$ nanocube edges as a function of ageing time and $SeO_2$ added. The line is linearly fitted with $R^2$ = 0.98.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Figure 5b and Figure 3a, respectively), the particles gradually increase in size and are better faceted. As can be seen in Figure 4, the size kinetics appears to be linear with respect to time and independent of the amount of $SeO_2$ added under the synthesis conditions investigated (i.e. 0.02 M of $SeO_2$ was sufficient to generate the cubelike morphology). On the basis of the TEM image statistics, it is found that the amount of $SeO_2$ used (either 0.02 or 0.08 M) does not have a substantial influence on the sizes of the nanoparticles. Although our primary focus in this work is on $BaF_2$ nanocubes in the range 10–50 nm, this linear relationship is likely to extend further. TEM image statistics also indicate an improvement in size uniformity for the long-aged samples.

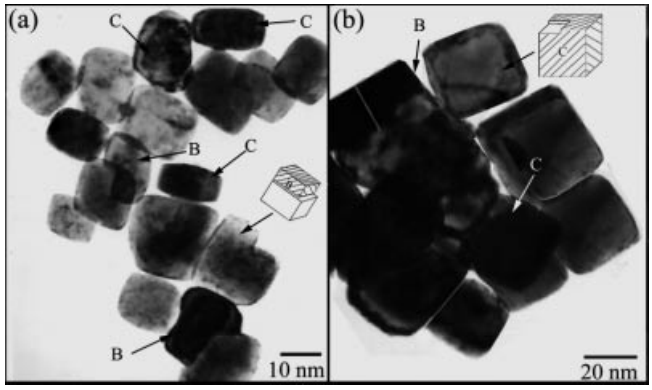

Figure 5. TEM images of $BaF_2$ nanocubes prepared (0.04 M $SeO_2$, pH = 2) with ageing times of: (a) 3 h and (b) 12 h (crystallite types B and C have been marked).

Varying the pH value of the system, while keeping other synthesis parameters unchanged, leads to a dramatic change in the size and shape of the particles. Figure 6 and Table 1 show the morphologies and sizes of the particles obtained by increasing the pH value of the system. It is found that when the pH value is small (≈2), the nanoparticles are smaller, and their shapes are cubic; When pH value ≥ 2, only larger nanocubes form; in the pH value range 2–6, a clear transition from small cubic particles is observed. Only octahedral particles with a mean edge length of 1 μm form when the pH value is raised to 7.

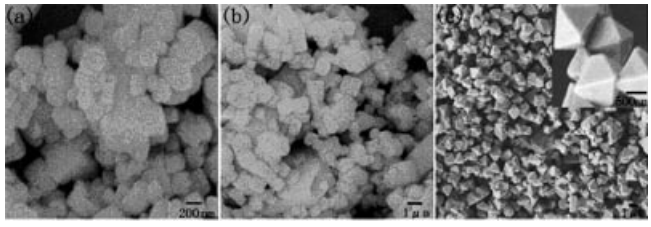

Figure 6. FESEM images of $BaF_2$ nanoparticles prepared (0.04 M $SeO_2$, ageing time 24 h) with different pH values: (a) pH = 4, (b) pH = 6 and (c) pH = 7.

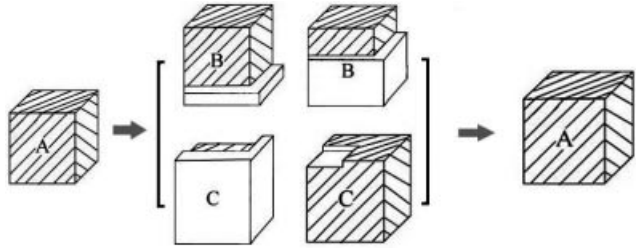
Table 1. The morphologies and mean sizes of $BaF_2$ nanoparticles at different pH values.

| pH value | Morphology | Mean size [nm] |
|---|---|---|
| 2 | Cube | 55 |
| 4 | Cube | 200 |
| 6 | Cube | 1000 |
| 7 | Octahedron | 1000 |

### Growth Mechanism

In Figure 5, a considerable amount of $BaF_2$ nanoparticles (marked with arrows) show special morphologies, although the majority of the $BaF_2$ crystallites are highly symmetrical nanocubes with equal edges. Aside from the normal, perfect nanocubes (type A), there are two types of "abnormally grown" nanocubes. As illustrated further in Scheme 1, the first one, type B, indicates some sidewall extension. The second one, type C, results largely from an in-plane completing growth. All crystallites observed can be broadly classified as either type A, type B, or type C, a finding also reported for $Co_3O_4$ nanocubes.[11] As depicted in the literature, a correct sequential arrangement of these crystallite types would naturally disclose the nanocube growth mechanism, a logical repetition of the three types of nanocrystallites, i.e. $\cdots\rightarrow A_{smaller} \rightarrow B \rightarrow C \rightarrow A_{larger} \rightarrow\cdots$. Thus, the growth does not proceed in a layer-by-layer manner (atomically), but with multiple-layer growth, i.e. nucleation and growth take place simultaneously in different atomic layers.



Scheme 1. Schematic illustration of the "extension growing" process based on the morphologies of intermediate crystallites (B and C) observed. The crystallite types B and Chave also been referred to in Figure 5.

In this approach, $SeO_2$ plays a critical role in the formation of the $BaF_2$ nanocubes. Firstly it acts as deoxidant, to prevent the incorporation of oxygen, which will affect the luminescence properties of $BaF_2$.[8] Photoluminescence experiments were carried out at room temperature on a Perkin–Elmer Model LS-55 fluorescence spectrometer with a Xe lamp. Photoluminescence results, as shown in Figure 7, display a weak emission peak at 453 nm (2.74 eV), which is excited at 270 nm (4.59 eV). The luminescence band at 2.74 eV results from an oxygen–vacancy complex with an oxygen on a fluorine site with a next-nearest fluorine vacancy on the surface of the nanocrystals.[12] It is believed that the deoxidant selenite ions prevent the incorporation of oxygen into $BaF_2$ effectively during the growth process, as the emission peak is so weak that it is difficult to be detected. Under the same conditions, the PL spectrum of $BaF_2$ with oxygen incorporated displays an intense peak

(several hundred times that of $BaF_2$ prepared by using $SeO_2$) at the same position. The trace oxygen may come from the atmosphere when the products were examined. Secondly, it is believed that $SeO_2$ which is tetragonal in symmetry ($a$ = 8.3 Å, $c$ = 5.1 Å) acts as a seed for the growth of the $BaF_2$ nanocubes. The [001]-oriented $BaF_2$ has a fourfold-symmetric $a$ plane with $a$ = 6.2 Å, which matches well to the fourfold-symmetric $SeO_2$ (001) substrate, $4a_{BaF_2} \approx 3a_{SeO_2}$, and this results in a $c$-axis-oriented growth of $BaF_2$ on $SeO_2$ (001). A small quantity of crystalline $SeO_2$ was also found in the sample prior to washing with distilled water and anhydrous alcohol. In this solution system, $SeO_2$ undergoes a recrystallization process, which is illustrated in Scheme 2.

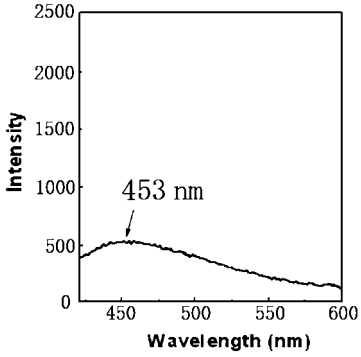

Figure 7. Photoluminescence (PL) spectra acquired from the 55-nm $BaF_2$ nanocubes excited at 270 nm.

When the pH value is lowered, more crystalline $SeO_2$ seeds form, which provides more nucleation points for the $BaF_2$ nanoparticles. This prevents the nanoparticles from aggregating and leads to the formation of smaller nanocubes, as illustrated in Table 1. When the pH value is increased to 7, only octahedral crystals are obtained. This is considered to be related to the enhanced surface energy of the $BaF_2$ nanooctahedra in the absence of $SeO_2$ seeds, which leads to more stable {111} faces being exposed. These results also indicate that the growth rate along <100> relative to that along <111> can be manipulated by adjusting the pH value, which will dictate whether nanocubes or nanooctahedra are formed. The concentration of $SeO_2$ (either 0.02 or 0.08 M) does not have a substantial influence on nanoparticle size (Figure 4) probably because at either of these concentrations, the solution is already saturated with small crystalline seeds of $SeO_2$. No $BaSeO_3$ is found in the product as a result of the acidic conditions.

## Conclusions

In summary, by controlling the reaction time and pH values, $BaF_2$ nanocubes of different sizes have been prepared in the range 10–1000 nm with high crystallite-monodispersity. The relationship between the size of the cube and reaction time is found to be linear. Furthermore, on the basis of the observed crystallite morphologies, an "extension growing" growth mechanism has been elucidated for the formation of the $BaF_2$ nanocubes. The growth of the $BaF_2$ nanocubes proceeds in a multiple-layer manner. This work may uncover new ways for preparing other nano-polyhedra.

## Experimental Section

**Preparation of $BaF_2$ Nanocubes:** In a typical growth procedure for $BaF_2$ nanocubes, $BaCl_2$ (0.002 mol), $SeO_2$ (0.002 mol), and NaF (0.004 mol) powders were combined in distilled water (30 mL) and stirred for 2 min. The solution pH was then adjusted with hydrochloric acid solution until its pH value was about 2. The sample (about 50 mL) was placed in a 60 mL autoclave with a Teflon liner, which was maintained at 140 °C for 24 h and then air cooled to room temperature. After reaction, the white precipitate was collected and washed thoroughly with distilled water and anhydrous alcohol. The product was dried in a vacuum at 50 °C for 4 h.

**Sample Characterization:** The samples were characterized by X-ray powder diffraction using a Rigaku D/max-Rapid X-ray diffractometer equipped with a copper anticathode and secondary graphite monochromator (Cu–$K_{\alpha 1,2}$, λ = 1.54178 Å). A scan rate of 0.05°/s was used to record the patterns in the 2$\theta$ range 20–70°. TEM images and ED patterns were taken on a Hitachi Model H-800 instrument with a tungsten filament, with an accelerating voltage of 200 kV. The FESEM image was obtained with a JSM-6700F field emission scanning electron microanalyser (JEOL, Japan), where the resulting powders were mounted on a copper slice. X-ray photoelectron spectroscopy (XPS) was performed with an ESCALab MKII X-ray photoelectron spectrometer, using Mg-$K_\alpha$ X-ray radiation as the excitation source. The binding energies obtained in the XPS analysis were calibrated against the C 1s peak at 284.2 eV.

# Molecular Structures and NMR Studies of Lithium and Germanium(II) Complexes of a New Chelating Amido–Imino Ligand Obtained by Addition of *n*BuLi to 1,2-Bis(arylimino)acenaphthene

**Igor L. Fedushkin,*[a] Markus Hummert,[b] and Herbert Schumann[b]**

*Dedicated to Prof. Vladimir K. Cherkasov on the occasion of his 60th birthday*

**Keywords:** Lithium / N ligands / Germanium / Structure elucidation

The reaction of 1,2-bis[(2,6-diisopropylphenyl)imino]acenaphthene (dpp-bian, **1**) with 1 equiv. of *n*BuLi in diethyl ether or with 2 equiv. of *n*BuLi in hexane produces [{dpp-bian(*n*Bu)}Li($Et_2O$)] (**3**) and [{dpp-bian(*n*Bu)Li}*n*BuLi]$_2$ (**4**), respectively. Complexes **3** and **4** are formed by the transfer of an *n*Bu anion to one of the imine carbon atoms of the dpp-bian ligand. Treatment of **3** and **4** with $H_2O$ affords the *C*-alkylated *N*-protonated amino-imino compound dpp-bian(H)(*n*Bu) (**5**). The reaction of **3** with $GeCl_2$(dioxane) affords the three-coordinate germylene complex [{dpp-bian(*n*Bu)}GeCl] (**6**). The molecular structures of **3**–**6** were determined by single-crystal X-ray structure analysis. The lack of symmetry in the alkylated bian system in **3**–**6** causes the non-equivalence of all protons except those of the $CH_3$ groups of the *i*Pr substituents.

## Introduction

In many respects, progress in organometallic and coordination chemistry is determined by the type of organic ligands used for the preparation of these metal complexes. The use of a new ligand system usually leads to complexes with more or less novel chemical properties. During the last decade, acenaphthene-1,2-diimines (bian) have become widely used as ligands in coordination chemistry. Diimine transition metal complexes serve as catalysts in alkyne hydrogenation,[1] C–C bond formation,[2] cycloisomerization,[3] hydrosilylation,[4] polymerization of alkenes[5] and acrylic monomers,[6] as well as in the copolymerization of $CO_2$[7] and $CH_2$=$CH_2$[8] with methylenecyclopropene, of ethylene with norbornene,[9] and of CO with styrene.[10] Thus, acenaphthene-1,2-dimine late transition metal complexes, the so-called Brookhart catalysts,[11] are some of the most effective catalysts for olefin polymerization known until now. The π-acceptor capability of the acenaphthene-1,2-dimine ligand causes an electron deficiency at the respective metal center that makes these complexes highly reactive towards organic substrates.

Recently, we have demonstrated for the first time that main group metals also readily form stable bian complexes. The most widely used ligand in this field is 1,2-bis[(2,6-diisopropylphenyl)imino]acenaphthene (dpp-bian, **1**). One of the remarkable features of the dpp-bian ligand in its main group metal complexes is its ability to adopt variable oxidation states. The reduction of dpp-bian with alkali metals in diethyl ether affords the mono-, di-, tri- and tetra-anions of the ligand, i.e. [(dpp-bian)$M_n(Et_2O)_m$] (M = Li, Na; $n$ = 1–4),[12] whereas with alkaline-earth metals the reduction of dpp-bian provides only dianions, forming the complexes [(dpp-bian)M$(THF)_n$] (M = Mg, Ca; $n$ = 2–4).[13] Depending on the reaction medium, the reduction of dpp-bian with aluminum in the presence of its halides gives the complexes [(dpp-bian)$AlCl_2$], [(dpp-bian)AlI($Et_2O$)], and [(dpp-bian)AlCl($Et_2O$)].[14] Alkylaluminum complexes with dpp-bian as a radical-anionic as well as a dianionic ligand are obtained by treating (dpp-bian)Na with $R_2AlX$ (R = Me, Et, *i*Bu; X = Cl, Br).[15] Similarly, the metal-exchange reactions of (dpp-bian)$Na_2$ or (dpp-bian)Na with $GeCl_2$ give the germanium(II) derivatives [(dpp-bian)Ge][16] and [(dpp-bian)-GeCl],[17] respectively. The variability of the oxidation state of the dpp-bian ligand is impressively demonstrated by the decomposition of [(dpp-bian)Mg(*i*Pr)($Et_2O$)], which occurs with elimination of *i*Pr radicals and simultaneous reduction of the dpp-bian radical anion to the dianion.[18] The oppo-

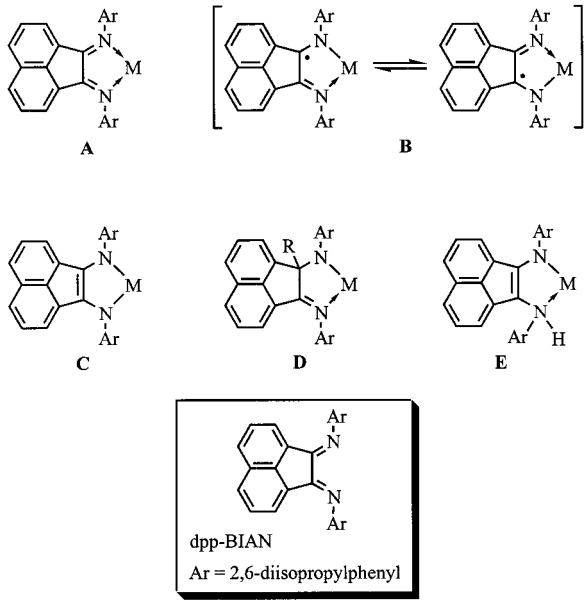
site process, namely oxidation of the dpp-bian dianion to the radical anion, is observed in the reactions of [(dpp-bian)-$Mg(THF)_3$] (**2**) with organic substances such as aromatic ketones.[19] The course of the reactions of **2** with ethyl halides further demonstrates the non-innocence of the dpp-bian ligand in its metal complexes. They proceed by single-electron transfer from the dianionic dpp-bian ligand to EtX to yield an ethyl radical, which, in turn, attacks the ligand, which is now a radical anion, at one of the imino carbon atoms to give [(dpp-bian)(Et)MgX$(THF)_n$].[20] Acidic substances such as aliphatic ketones, terminal alkynes, and nitriles add to complex **2** with protonation of one of the ligand nitrogen atoms to produce complexes with unsymmetrical amido–imino dpp-bian ligands.[21] The different modes of the dpp-bian ligand (**A**: neutral; **B**: radical-anion; **C**: dianion) in the reactions of **2** with organic substrates, as well as the resulting modifications of the dpp-bian ligand (**D**: amino/imine and **E**: amido/amine), are shown below.

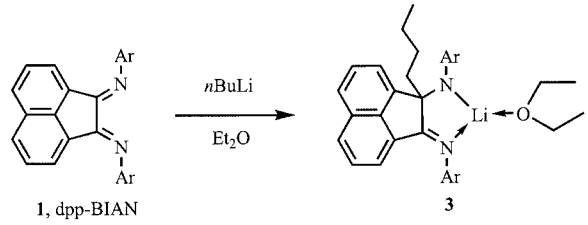


In this paper, we report on the alkylation of dpp-bian with *n*BuLi to provide the ligand system **D** and its subsequent reaction with $GeCl_2$.

## Results and Discussion

### Alkylation of dpp-bian with *n*BuLi

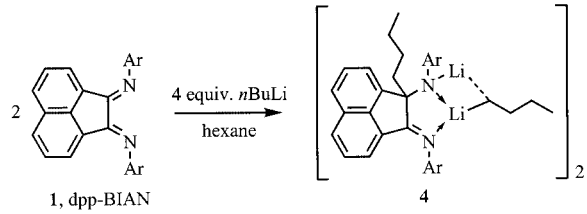
Addition of 1 equiv. of *n*BuLi to a suspension of dpp-bian in diethyl ether caused immediate dissolution of dpp-bian and a change in the color of the reaction mixture from yellow to blue. Crystallization of the foamy residue, remaining after removal of the solvents, from hexane afforded [dpp-bian(*n*Bu)]Li($Et_2O$) (**3**) in the form of blue, crystalline plates in 44% yield (Scheme 1).



Scheme 1.

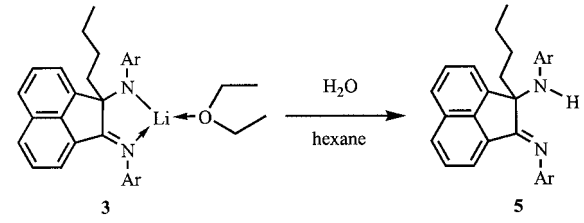
The reaction of equivalent amounts of dpp-bian and *n*BuLi also proceeded easily in hexane but produced yellow instead of blue crystals, the characterization of which by $^1H$ NMR spectroscopy in $C_6D_6$ is seriously hindered by multiple overlaps of the numerous signals. However, $[D_{10}]Et_2O$ solutions of both the blue and the yellow crystals give identical $^1H$ NMR spectra.

Addition of a twofold molar amount of *n*BuLi to a suspension of dpp-bian in hexane caused immediate precipitation of [{dpp-bian(*n*Bu)Li}*n*BuLi]$_2$ (**4**) as red crystals in 81% yield (Scheme 2).



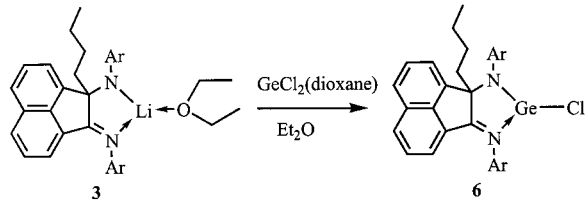
Scheme 2.

Hydrolysis of **3** and **4** resulted in the formation of the yellow, crystalline amino-imine [dpp-bian(H)(*n*Bu)] (**5**; Scheme 3).



Scheme 3.

The anionic amido–imino ligand [dpp-bian(*n*Bu)]$^-$ of the lithium complex **3** can be transferred to other metal ions such as $Ge^{2+}$. Thus, the reaction of equimolar amounts of **3** and $GeCl_2$(dioxane) in $Et_2O$ afforded almost quantitative yields of red, crystalline [{dpp-bian(*n*Bu)}GeCl] (**6**), which contains three-coordinate $Ge^{II}$ (Scheme 4).



Scheme 4.

### Molecular Structures of Compounds 3–6

The molecular structures of **3**–**6** were determined by single-crystal X-ray analysis and are presented in the figures. Selected bond lengths and angles for **4**–**6** are presented in Tables 1 and 2, respectively. The low quality of the X-ray data obtained for **3** ($R_1$ = 0.1231) does not allow detailed information of bond lengths and angles. However, the X-ray structure of **3** (Figure 1) is good enough to indicate clearly that the reaction of *n*BuLi with dpp-bian (1:1 molar ratio) occurs with the transfer of the butyl group to the imino carbon atom C(2) of the dpp-bian ligand, thus making this carbon atom a chiral center.

Table 1. Selected bond lengths [Å] for **4**–**6**. M[a] = Li(2) for compound **4** and Ge for compound **6**.

In the solid state, compound **4** (Figure 2) is the centrosymmetric dimer of the 1:1 adduct of solvent-free **3** with *n*BuLi. This dimer is formed by interaction of all four lithium atoms with the two $\mu_3$-bridging *n*Bu(Li) carbanions. Within the monomeric units, the bonding modes of the two lithium atoms relative to the [dpp-bian(*n*Bu)]$^-$ anion are different. Li(2) is connected with both N(1) and N(2) of the amido[N(2)]–imino[N(1)] ligand, while Li(1) is linked only to N(2). The amido–imino character of the alkylated dpp-bian ligand is manifested by the bond length within the N(1)–C(1)–C(2)–N(2) fragment. The length of the C(1)–N(1) bond [1.285(3) Å] is close to that of the C=N double

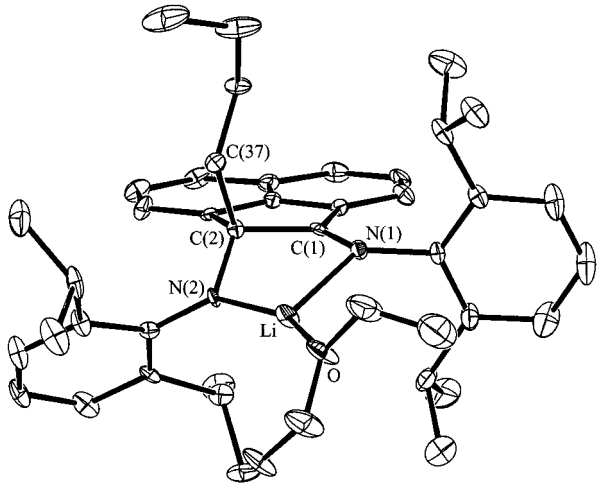

Figure 1. Molecular structure of **3**. Hydrogen atoms are omitted for clarity. Thermal ellipsoids are drawn at 30% probability.

bond in free dpp-bian [1.282(4) Å],[22] whereas the C(2)–N(2) distance [1.485(3) Å] corresponds well with the average value of carbon–nitrogen single bonds. In spite of the different functionality of the nitrogen atoms in the [dpp-bian(*n*Bu)]$^-$ anion, the N(1)–Li(2) and N(2)–Li(2) distances are very similar [2.007(5) and 1.978(5) Å, respectively]. The distance of the Li(1) atom to the amido atom N(2) is 2.071(5) Å. Both *n*-butyl carbanions act as $\mu_3$-bridges between Li(2) and the symmetry-equivalent Li(1) and Li(1a) atoms (symmetry operation: *–x*, *–y*, *–z*). The same bridging mode of *n*-butyl anions has been observed in [{(*n*BuLi)$_4$(TMEDA)}$_\infty$],[23] which exhibits a TMEDA-linked tetrameric cubane structure. The distances C(41)–Li(1) [2.321(6) Å] and C(41)–Li(1a) [2.265(6) Å], which are in the range of the Li–C distances in [{(*n*BuLi)$_4$(TMEDA)}$_\infty$], are significantly longer than the C(41)–Li(2) distance [2.087(6) Å].

The molecular structure of the metal-free amino-imine compound **5** (Figure 3) shows C–N distances that differ significantly, thus indicating an N(1)–C(1) double bond [1.274(3) Å] and an N(2)–C(2) single bond [1.497(3) Å]. The sum of the bond angles at N(2) (340°) points to a more tetrahedral (327°) than trigonal-planar (360°) arrangement.

The molecular structure of **6** (Figure 4) corresponds to a monomeric three-coordinate germylene. Because of the three different groups (chloride ion, amido- and imino-nitrogen atoms) bonded to the germanium atom and its lone electron-pair, the germanium atom is a chiral center. Taking into account that the C(2) atom in **6** is also chiral, one may expect the existence of two diastereomeric pairs of molecules, whereas in fact only one diastereomeric pair is present in the unit cell. In these two diastereomeric molecules the *n*Bu group and the chlorine atom are positioned at the same side of the plane formed by the metallacycle Ge–N(1)–C(1)–C(2)–N(2). Again, the difference between the amido and the imino functionality of the ligand is evident from the C–N distances [N(1)–C(1) = 1.286(3) and N(2)–C(2) = 1.468(3) Å]. However, in contrast to compound **4**,

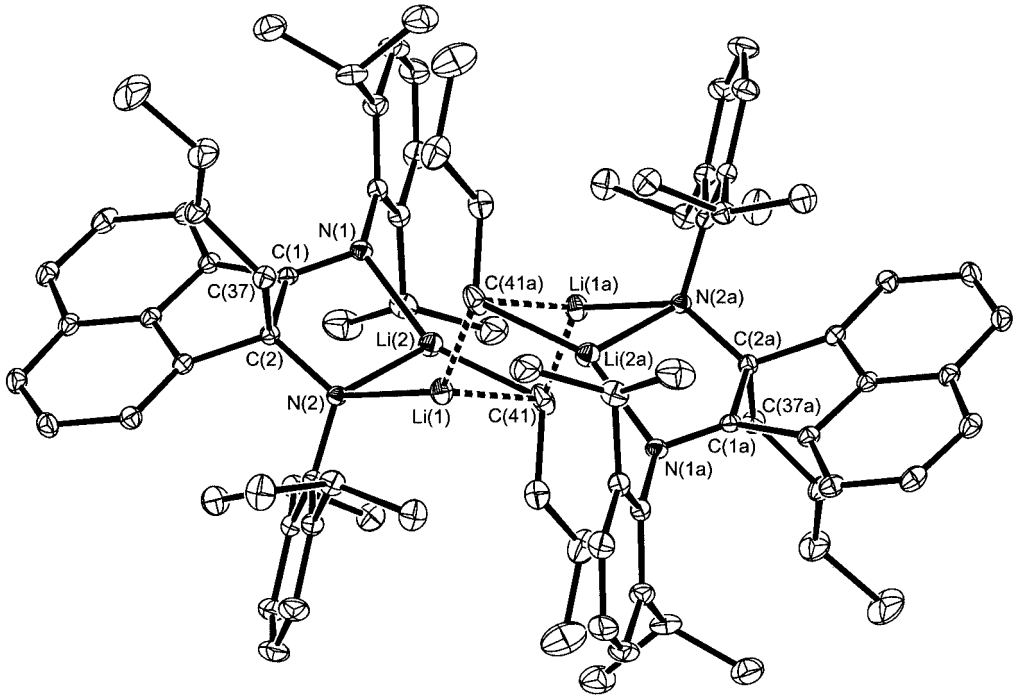

Figure 2. Molecular structure of **4**. Hydrogen atoms are omitted for clarity. Thermal ellipsoids are drawn at 30% probability.

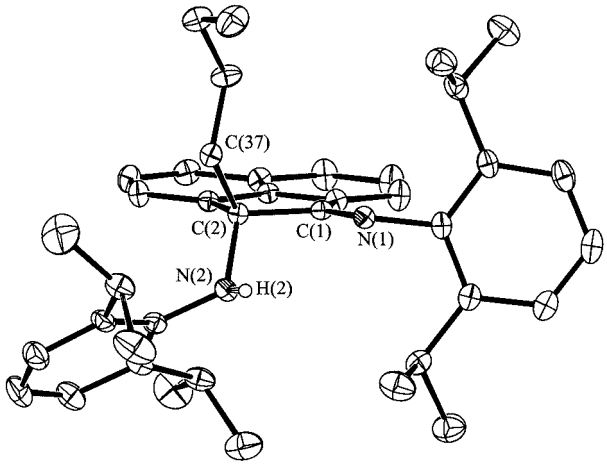

Figure 3. Molecular structure of **5**. Hydrogen atoms are omitted for clarity. Thermal ellipsoids are drawn at 30% probability.

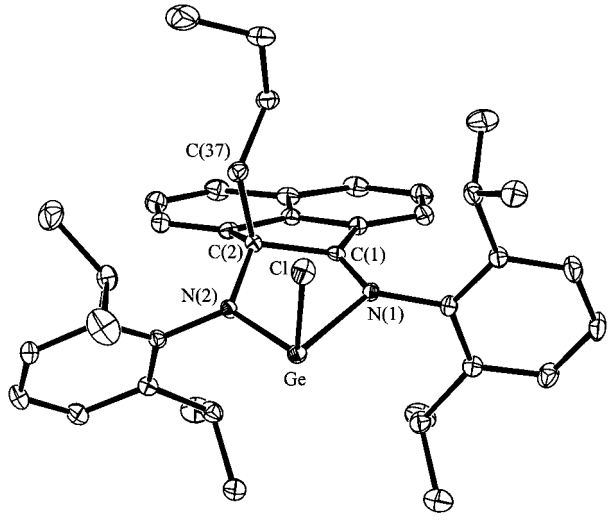

Figure 4. Molecular structure of **6**. Hydrogen atoms are omitted for clarity. Thermal ellipsoids are drawn at 30% probability.

there is also a pronounced difference in the length of the Ge–N(amido) bond [Ge–N(2) = 1.872(1) Å] and the Ge–N(imino) bond [Ge–N(1) = 2.118(1) Å]. The Ge–N(amido) distance compares well with the two Ge–N(amido) bonds in the germylene [(dpp-bian)Ge] [1.896(3) and 1.885(3) Å].[16] The Ge–Cl distance [2.3500(7) Å] is noticeably longer than the corresponding distance in the three-coordinate $Ge^{II}$ compound [(dpp-bian)GeCl] [2.2693(8) Å], which contains dpp-bian as a radical-anionic ligand.[17a] The sum of the bond angles (277.2°) at the germanium atom [81.46(8), 93.06(5), 102.68(6)°] is almost the same as in [(dpp-bian)GeCl] (276.8°).[17a]

## NMR Spectroscopy of 3–6

The addition of *n*BuLi to one of the C=N bonds of dpp-bian results in the formation of an asymmetric amido–imino structure, which, in turn, causes the inequivalence of all aromatic protons as well as of all methine protons of the isopropyl substituents (Figure 5).

The $^1$H NMR spectrum of a solution of the blue crystals of **3** in $C_6D_6$ contains twelve signals for the aromatic protons, ranging from $\delta$ = 7.48 to 6.53 ppm, and four signals for the methine protons at $\delta$ = 5.12, 3.44, 3.33, and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

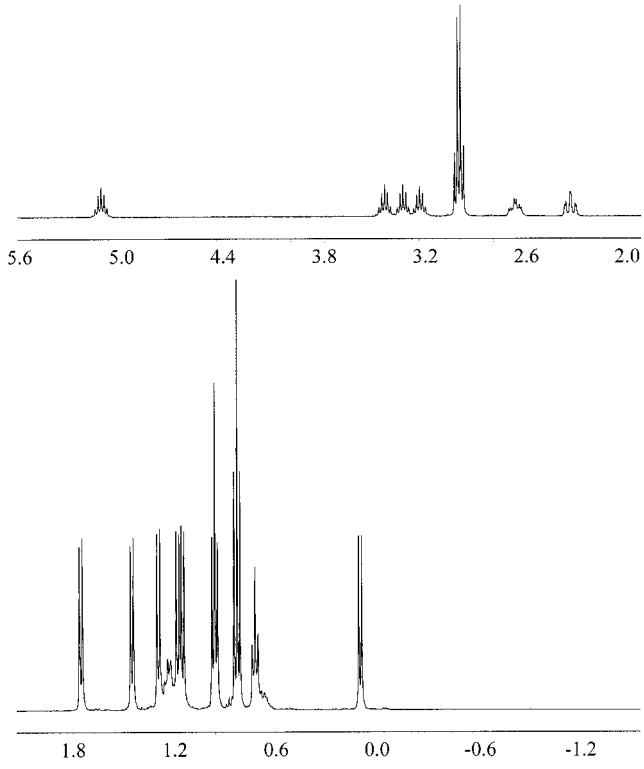

Figure 5. $^1$H NMR spectrum of **3** divided into two sections ($C_6D_6$, 400 MHz, 20 °C). The aromatic region is not shown.

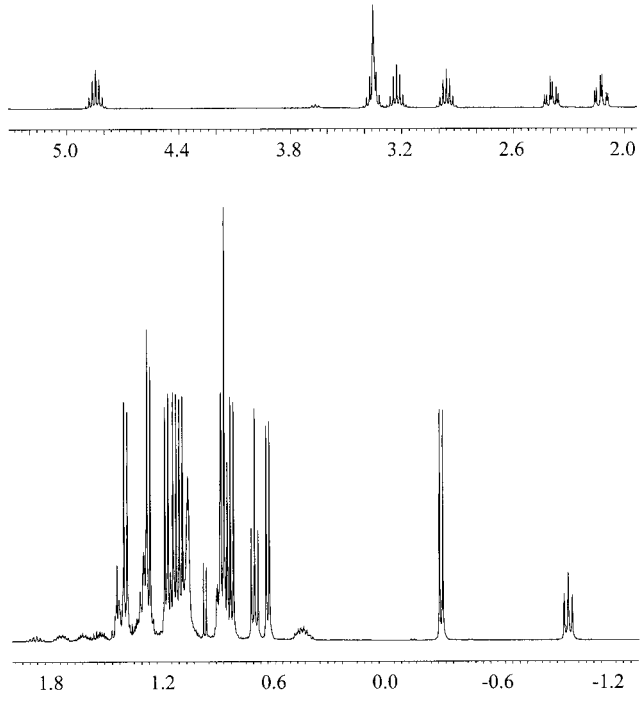

Figure 6. $^1$H NMR spectrum of **4** divided into two sections ([$D_{10}$]-$Et_2O$, 400 MHz, 20 °C). The aromatic region is not shown.

3.23 ppm (Figure 5a). Due to the restricted rotation around the N–C(*ipso*-Ph) bonds, all eight methyl groups become unequal and appear as eight doublets in the range from $\delta$ = 1.75 to 0.09 ppm (Figure 5b). The presence of the chiral carbon atom C(2) next to the methylene protons of the *n*Bu group causes the inequivalence of the α-$CH_2$(*n*Bu) protons and the appearance of two triplets of doublets at $\delta$ = 2.67 and 2.33 ppm. The $CH_3$(*n*Bu) group gives rise to a triplet at $\delta$ = 0.72 ppm, whereas the β- and γ-$CH_2$(*n*Bu) protons appear as multiplets at $\delta$ = 1.23 and 0.68 ppm. The signals of the coordinated $Et_2O$ molecule are centered at $\delta$ = 3.00 (q) and 0.83 (t) ppm. Dissolution of **3** in [$D_{10}$]$Et_2O$ does not cause significant changes in the $^1$H NMR spectrum. Thus, the four signals of the methine protons appear as septets at $\delta$ = 4.84, 3.35, 3.23 and 2.96 ppm, the nonequivalent α-$CH_2$(*n*Bu) protons give rise to two triplets of doublets at $\delta$ = 2.40 and 2.12 ppm, and the eight doublet signals for the unequal methyl groups are found between $\delta$ = 1.40 and –0.30 ppm.

The $^1$H NMR spectrum of **4** recorded in $C_6D_6$ (red solution) reveals only broadened signals, which could not be assigned. However, a simple $^1$H NMR spectrum (Figure 6) was obtained from a solution of compound **4** in [$D_{10}$]$Et_2O$ (blue solution) in which the positions of all signals of the amido–imino ligand are identical with those of the $^1$H NMR spectrum of solutions of compound **3** in [$D_{10}$]$Et_2O$.

Unexpectedly, the $^1$H NMR spectrum of compound **5** in [$D_8$]THF (Figure 7) shows signals for only eight of the twelve aromatic protons, and of the total of four methine protons belonging to the isopropyl substituents only two give distinguishable signals which are superimposed upon each other and centered at $\delta$ = 3.08 and 3.01 ppm (Figure 7). Also, only four of the eight doublet signals expected for the $CH_3$(*i*Pr) protons can be located. However, it should be noted that in the aromatic and aliphatic regions in which the missing signals would be expected, a visible raising of the baseline is observed. We attribute this to a significant broadening of those signals due to a slow (on the NMR timescale) dynamic process within the molecules of **5** in solution and suggest an umbrella-like inversion at the amino nitrogen atom N(2). Such a process affects all the protons of the 2,6-*i*$Pr_2$Ph ring bonded to N(2) and leads to a broadening of the $^1$H resonances of this substituent. In contrast, the signal of the proton connected directly to N(2)

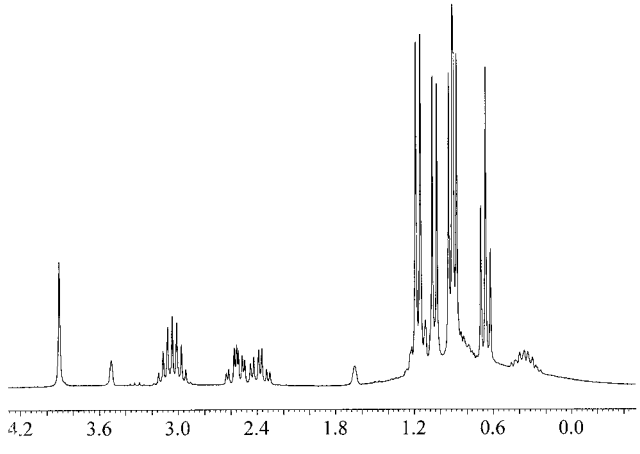

Figure 7. $^1$H NMR spectrum of **5** ([$D_8$]THF, 200 MHz, 20 °C). The aromatic region is not shown.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

appears as a sharp singlet at $\delta$ = 3.91 ppm. The α-$CH_2$(*n*Bu) protons give rise to two triplets of doublets at $\delta$ = 2.56 and 2.38 ppm and the $CH_3$(*n*Bu) signal appears as a triplet at $\delta$ = 0.66 ppm.

The $^1$H NMR spectrum of compound **6** in [$D_8$]THF shows analogous signal sets to the $^1$H NMR spectrum of compound **3** recorded in [$D_{10}$]$Et_2O$, which differ only with respect to the chemical shifts of the signals. Nevertheless, the spectrum has one noticeable feature. In the $^1$H NMR spectrum of **6**, the α-$CH_2$(*n*Bu) protons appear at $\delta$ = 3.90 and 2.41 (2 td) ppm, thus displaying a much larger diastereotopic splitting constant (1.49 Hz) than those observed in the spectra of **3** (0.28 Hz in $Et_2O$), **4** (0.28 Hz in $Et_2O$), and **5** (0.18 Hz in THF). We believe that the high value of the splitting constant of **6** is caused by the chirality at the germanium atom.

## Conclusions

We have been able to demonstrate that the addition of *n*BuLi to one C=N bond of dpp-bian produces a new, asymmetrically chelating amido–imino ligand system which is expected to be useful for the preparation of new metal-based reagents for organic synthesis.

## Experimental Section

**General Remarks:** All manipulations were carried out under nitrogen using standard Schlenk techniques. Hexane, diethyl ether, and benzene were dried by distillation from sodium/benzophenone. *n*BuLi (2.5 M in hexane) was purchased from ACROS. The deuterated solvents [$D_8$]THF (Aldrich), $C_6D_6$ (Aldrich), and [$D_{10}$]$Et_2O$ (Euriso-top) used for NMR experiments were dried with sodium/benzophenone at ambient temperature and, just prior to use, were condensed under vacuum into the NMR tubes already containing the respective compound. Melting points were measured in sealed capillaries. IR spectra were recorded with an FTIR FSM-1201 spectrometer (Monitoring Ltd.), and $^1$H NMR spectra were obtained with Bruker DPX-200 and Bruker DRX-400 NMR spectrometers.

**[{dpp-bian(*n*Bu)}Li($Et_2O$)] (3):** Addition of 0.8 mL of *n*BuLi (2.5 M in hexane; 2.0 mmol) to a stirred suspension of dpp-bian (1.0 g, 2.0 mmol) in $Et_2O$ (20 mL) at room temperature caused immediate dissolution of dpp-bian and formation of a clear blue-green solution. The foamy residue left after evaporation of the solvent was recrystallized from hexane. The thin blue plates of compound **3** formed within 20 h were collected by decantation of the mother liquor. Yield: 0.56 g (44%); m.p. > 120 °C (dec.). $C_{44}H_{59}LiN_2O$ (638.91): calcd. # A Route to Multi-Clusters Containing Half-Sandwich Rh and Ir Complexes of Chelating 1,2-Dicarba-*closo*-dodecaborane(12)-1,2-dithiolate Ligands

**Jian-Qiang Wang,[a] Chun-Xia Ren,[a] and Guo-Xin Jin*[a]**

*Dedicated to Professor Max Herberhold on the occasion of his 70th birthday*

**Keywords:** Iridium / Rhodium / Carboranes / N ligands / Cluster compounds

Reaction of the 16-electron half-sandwich rhodium and iridium complexes [Cp*M{$S_2C_2(B_{10}H_{10})$}] [M = Rh (**1a**), Ir (**1b**)] with multidentate ligands (L) such as 5,10,15,20-tetra(4-pyridyl)porphyrin) ($H_2$TPyP), 2,4,6-tri(4-pyridyl)-1,3,5-triazine (tpt), and 4,4′-azopyridine, gave the corresponding multicluster complexes [Cp*$MS_2C_2(B_{10}H_{10})]_n$(L) [M = Rh, Ir; $n$ = 4, L = $H_2$TPyP (**2**); 3, L = tpt (**3**); 2, L = 4,4′-azopyridine (**4**), *N*,*N*′-bis(4-pyridinylmethylene)biphenyl-4,4′-diamine (**5**), pyrazine, (**6**), 2,5-di(4-pyridyl)-1,3,4-oxadiazole (**7**), 1,2-di(4-pyridyl)ethylene) (**8**), diisonicotinic acid 1,4-phenylene diester (**9**), 4,4′-bipyridine (**10**)]. The X-ray structure of **2a** reveals that an $H_2$TPyP unit bridges four [Cp*$RhS_2C_2(B_{10}H_{10})$] fragments to form a tetranuclear [Cp*$RhS_2C_2(B_{10}H_{10})]_4$($H_2$TPyP) complex and the [Cp*$RhS_2C_2(B_{10}H_{10})$] units adopt a tail-to-tail contact mode, rather than a head-to-tail mode, in spite of the large steric repulsion between the two carborane ligands. In complex **3a**, three [Cp*$RhS_2C_2(B_{10}H_{10})$] units are symmetrically arranged around the periphery of one tpt core, thus forming a "bowl-shaped" structure. In **4a**, **5a**, **6a**, **8b**, and **9b**, two [Cp*$RhS_2C_2(B_{10}H_{10})$] fragments take a *trans* conformation around the linear or pseudo-linear pyridyl-based ligand core, while in **7a** they are in a *cis* conformation. All new complexes **2**–**10** were characterized by $^1$H and $^{11}$B NMR spectroscopy, and X-ray structural analyses are reported for complexes **2a**, **3a**, **4a**, **5a**, **6a**, **7a**, **8b**, and **9b**.

## Introduction

During the last decade, a series of mononuclear 16-electron Cp* half-sandwich complexes of Co, Rh, and Ir have been prepared that contain didentate, chelating 1,2-dicarba-*closo*-dodecaborane(12)-1,2-dichalcogenolate ligands $[(B_{10}H_{10})C_2E_2]^{2-}$ (E = S, Se).[1] These complexes exhibit a rich coordination chemistry due to both their unsaturation at the metal atom and the bridging or chelating properties of the sulfur or selenium atoms.[2] Among the types of target structures attracting attention are highly symmetrical, aesthetically appealing architectures such as star-shaped molecules.[3] The efforts to build cluster-supported molecular or supramolecular structures are expected to offer many fascinating research problems with potentially significant ramifications.[4] To the best of our knowledge, only a few examples of *ortho*-carboranyl-functionalized highly branched molecules have been reported in the search for efficient methods for assembling suitable organic or inorganic linkers into desired target metallodendrimers.[5–7] Carboranes are obvious candidates for such applications because of their synthetic versatility and well-developed derivative chemistry. Our laboratory and Herberhold et al. have already reported the synthesis of the 16-electron "pseudo-aromatic" half-sandwich complexes [Cp*M{$E_2C_2(B_{10}H_{10})$}] (M = Co, Rh, Ir; E = S, Se),[8] and a recent publication from our laboratory suggests that this species may be promising for further transformations owing to its electron deficiency at the metal center.[9] This has allowed the construction of a polycarborane molecular architecture that takes advantage of special attributes, such as an addition reaction at the metal center in a dichalcogenolato metal heterocycle.[8]

Here, we describe the assembly of soluble, air-stable supramolecular structures based on the metal-containing moieties [Cp*M{$S_2C_2(B_{10}H_{10})$}] (M = Rh **1a**; M = Ir **1b**), bridged by nitrogen-based, star-shaped organic spacers (Scheme 1).

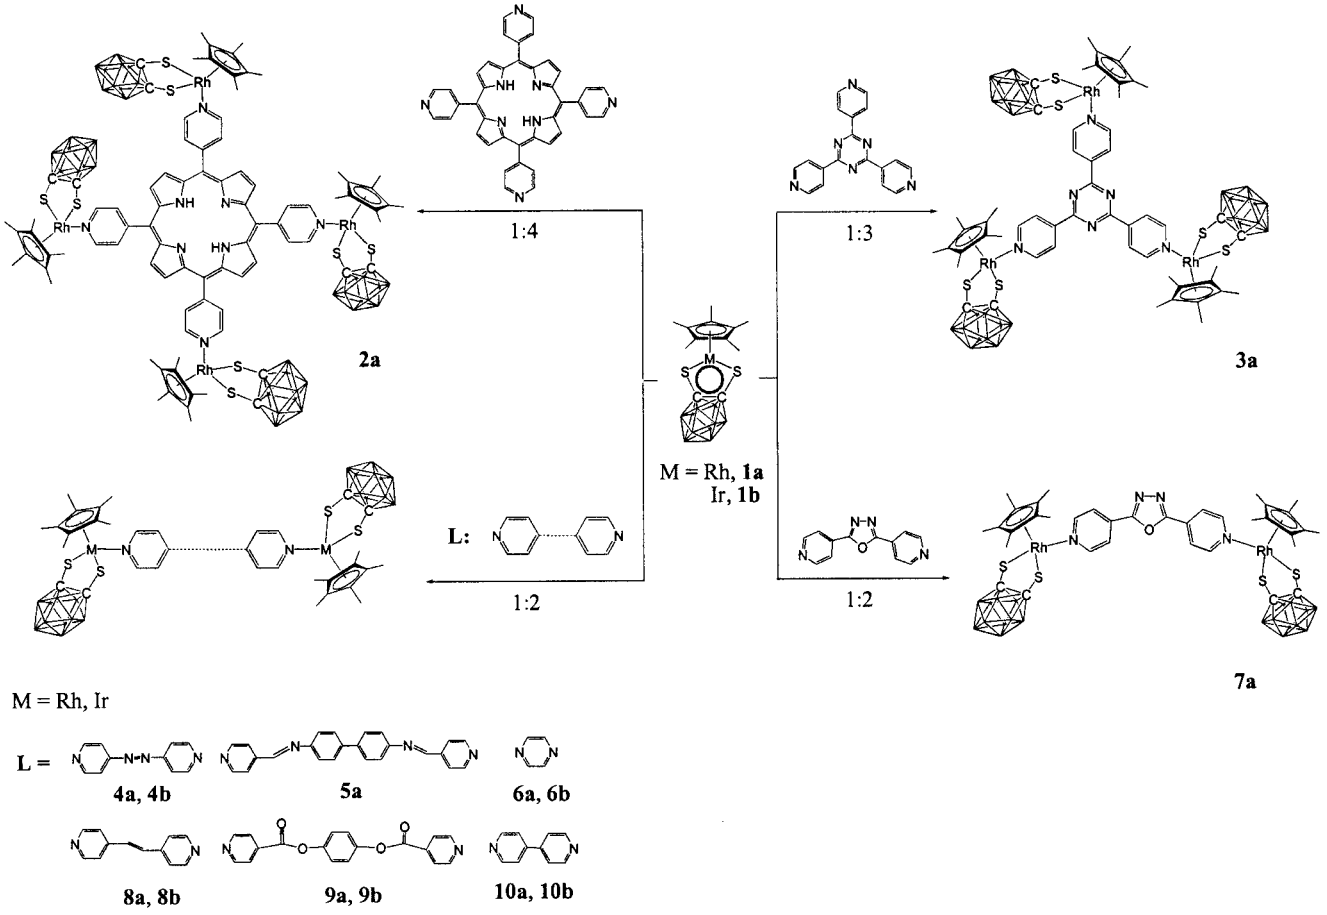

Scheme 1. Reaction of $[Cp^*MS_2C_2(B_{10}H_{10})]$ with a pyridyl-based ligand to give complexes **2**–**10**.

## Results and Discussion

### Synthesis and Characterization

We recently reported the reaction of the iridium precursor $[Cp^*IrS_2C_2(B_{10}H_{10})]$ (**1b**) with 2,4,6-tri(4-pyridyl)-1,3,5-triazine (tpt) and 4,4′-bipyridine, which leads to the formation of the multi-cluster $[Cp^*IrS_2C_2(B_{10}H_{10})]_n(L)$ [$n$ = 3, L = tpt; 2, L = 4,4′-bipyridine].[6] By using different metal complexes (**1a**, **1b**) and the linear or pseudo-linear pyridyl-based ligand that have been used as building blocks for discrete supramolecular assemblies[10] as starting materials, further neutral star-shaped molecules with $[Cp^*MS_2C_2(B_{10}H_{10})]$ (M = Rh or Ir) units can be synthesized. Scheme 1 shows the formation of star-shaped molecules **2**–**10**, which were characterized by single-crystal X-ray analysis, elemental analysis, and $^1$H NMR, $^{11}$B NMR and IR spectroscopy.

Stirring a mixture of $[Cp^*Rh\{S_2C_2(B_{10}H_{10})\}]$ (**1a**) and 5,10,15,20-tetra(4-pyridyl)porphyrin ($H_2TPyP$) in $CH_2Cl_2$ at room temperature for 24 h produced a red solution of **2a** in high yield. The IR spectrum shows a strong band at approximately 2559 cm$^{-1}$ due to the carborane group. The formation of **2a** was confirmed by the appearance of signals at $\delta$ = –2.89, 1.78, 8.20, 9.02, and 9.38 ppm in the $^1$H NMR spectrum, which are ascribed to the $H_2TPyP$ and Cp* ligands; the $^{11}$B NMR spectrum exhibits carborane (B–H) resonances at $\delta$ = –5.8, –8.2, –9.0, and –10.8 ppm.

Trinuclear complex **3a**, formulated as $[Cp^*Rh\{S_2C_2(B_{10}H_{10})\}]_3(tpt)$ from elemental analysis and $^1$H NMR spectroscopy, was formed when **1a** was treated with tpt in a 3:1 molar ratio in $CH_2Cl_2$ at room temperature (Scheme 1). The $^1$H NMR spectrum shows two kinds of resonances for each of the Cp* and tpt ligands, at $\delta$ = 1.77 ppm and $\delta$ = 8.67, 8.96 ppm respectively, suggesting the presence of configurational isomers. The signals at $\delta$ = –7.9 and –10.3 ppm in the $^{11}$B NMR spectrum suggest B–H activation.

The 16-electron "pseudo-aromatic" half-sandwich complexes **1a** and **1b** react readily with two equivalents of 4,4′-azopyridine to give dimeric complexes formulated as $[Cp^*M\{S_2C_2(B_{10}H_{10})\}]_2(C_{10}H_8N_4)$ (M = Rh **4a**, Ir **4b**). The IR spectra of **4a** and **4b** show B–H bands for the carboranes at 2568 and 2562 cm$^{-1}$, respectively. The $^1$H NMR spectrum of **4a** shows a singlet at $\delta$ = 1.77 ppm due to the methyl groups of the Cp* ligands and resonances at about $\delta$ = 7.76 and 8.85 ppm due to the 4,4′-azopyridine protons; that for **4b** has a singlet at $\delta$ = 1.87 and $\delta$ = 7.80 and 8.92 ppm. The $^{11}$B NMR spectrum exhibits a carborane (B–H) resonance at $\delta$ = –6.1, –7.5, –8.7, and –10.9 ppm for **4a** and $\delta$ = –6.2, –7.5, –8.6, and –10.5 ppm for **4b**. Detailed structures were confirmed by X-ray analysis of **4a** (see below), which re-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vealed that the complex is a dimer bridged by a 4,4′-azopyridine molecule.

Analogously, treatment of **1a** or **1b** with *N*,*N*′-bis(4-pyridinylmethylene)biphenyl-4,4′-diamine, pyrazine, 2,5-di(4-pyridyl)-1,3,4-oxadiazole, 1,2-di(4-pyridyl)ethylene, diisonicotinic acid 1,4-phenylene diester, or 4,4′-bipyridine also generated the dinuclear complexes $[Cp^*Rh\{S_2C_2(B_{10}H_{10})\}]_2(C_{24}H_{18}N_4)$ (**5a**), $[Cp^*M\{S_2C_2(B_{10}H_{10})\}]_2(C_4H_4N_2)$ (M = Rh **6a**, Ir **6b**), $[Cp^*Rh\{S_2C_2(B_{10}H_{10})\}]_2(C_{12}H_8N_4O)$ (**7a**), $[Cp^*M\{S_2C_2(B_{10}H_{10})\}]_2(C_{12}H_{10}N_2)$ (M = Rh **8a**, Ir **8b**), $[Cp^*Rh\{S_2C_2(B_{10}H_{10})\}]_2(C_{18}H_{12}N_2O_4)$ (M = Rh **9a**, Ir **9b**), $[Cp^*M\{S_2C_2(B_{10}H_{10})\}]_2(C_{10}H_8N_2)$ (M = Rh **10a**, Ir **10b**), respectively. All the $^1H$ NMR spectra in $CDCl_3$ show two resonances for each of the Cp* and pyridyl or pyrazine ligands and the $^{11}B$ NMR spectra in $CDCl_3$ exhibit a carborane (B–H) resonance. In the IR spectra, the B–H vibration bands of the carborane group appear at 2575–2580 $cm^{-1}$ for all of the complexes, and the C=O band appears at 1690 $cm^{-1}$ for **9a** and 1692 $cm^{-1}$ for **9b**.

### Molecular Structures

The crystal structure of **2a** consists of quadridentate units in which there are two crystallographically independent $Rh^{III}$ atoms and the $H_2TPyP$ ligand adopts a bridging mode (Figure 1, a). All of the rhodium centers adopt a three-legged piano-stool conformation with a six-coordinate geometry, assuming that the Cp* ligand functions as a three-coordinate ligand. The angles between adjacent atoms around the rhodium atoms are nearly 90°. All of the Cp* atoms fall in a fairly good plane, and the Cp* ligands are symmetrically bound to the rhodium atoms. The distances between Rh and the least-squares plane of the Cp* ring are 1.78 and 1.82 Å, which compare well with those for other rhodium complexes containing Cp*.[11,12] The dihedral angle along the S···S vector in the rhodadithiolato metallacycle ($RhS_2C_2$) is about 173° and 169°, compared to 180° in **1a**.[8b] An $H_2TPyP$ unit bridges four $[Cp^*RhS_2C_2(B_{10}H_{10})]$ fragments to form the tetranuclear $[Cp^*RhS_2C_2(B_{10}H_{10})]_4(H_2TPyP)$ complex. An interesting feature of this solid-state structure is that the $[Cp^*RhS_2C_2(B_{10}H_{10})]$ units adopt a tail-to-tail contact mode, rather than a head-to-tail mode, in spite of the large steric repulsion between the two carborane ligands, similar to that reported previously.[5] In the crystal lattice, molecules of **2a** form an extended two-dimensional layered structure. Within each layer, the molecules of **2a** interdigitate through the four legs, as depicted inpart b of Figure 1. The dihedral angle between neighboring porphyrins is 46.8°. The shortest distance between Cp* ligands in the same layer is 3.75 Å, and there is a very weak π–π interaction between the molecules. In addition, four dendrimer complexes in the same layer form a parallelogram with dimensions 15.4×18.0 $Å^2$. As illustrated in Figure 1 (b), there are channels running along the *b* axis. The overall free voids are 35.0% of the cell volume, omitting solvent molecules and hydrogen atoms.

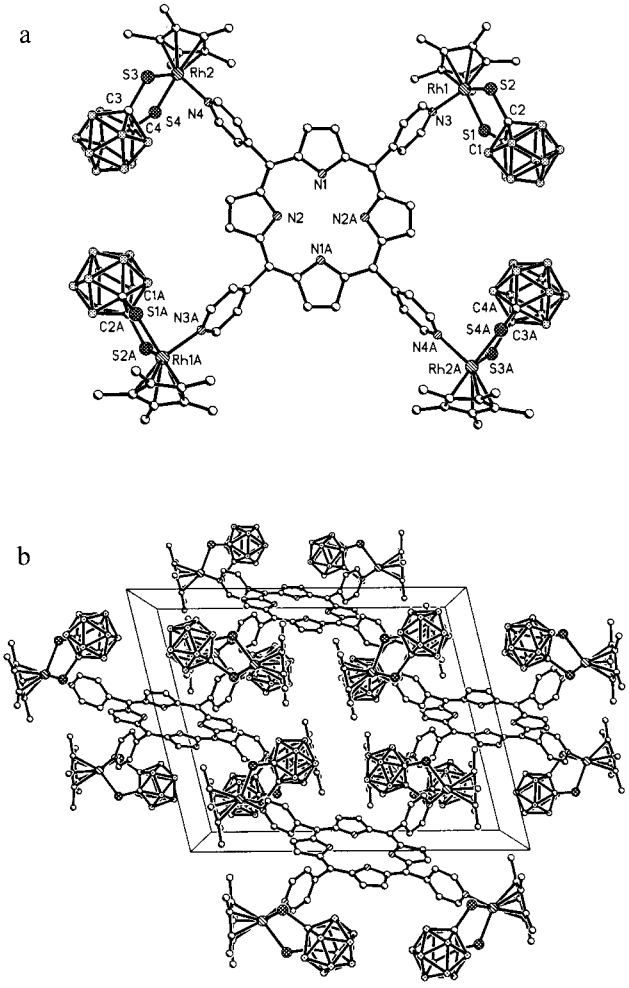

Figure 1. (a) Molecular unit of $[Cp^*RhS_2C_2(B_{10}H_{10})]_4(H_2TPyP)$ (**2a**). (b) Stacking of the molecules in crystals of **2a**, as viewed along the *b* axis. Selected distances [Å] and angles [°]: Rh(1)–N(3) 2.127(7), Rh(1)–S(1) 2.358(3), Rh(1)–S(2) 2.360(3), Rh(2)–N(4) 2.134(7), Rh(2)–S(4) 2.353(3), Rh(2)–S(3) 2.357(3), S(4)–C(4) 1.803(10), S(1)–C(1) 1.788(10), S(2)–C(2) 1.769(11), S(3)–C(3) 1.795(11), C(1)–C(2) 1.655(14), C(3)–C(4) 1.658(14); N(3)–Rh(1)–S(1) 89.3(2), N(3)–Rh(1)–S(2) 89.7(2), S(1)–Rh(1)–S(2) 90.62(10), N(4)–Rh(2)–S(4) 88.6(2), N(4)–Rh(2)–S(3) 91.9(2), S(4)–Rh(2)–S(3) 90.28(10), C(4)–S(4)–Rh(2) 106.4(3), C(1)–S(1)–Rh(1) 105.7(3), C(2)–S(2)–Rh(1) 106.0(3), C(3)–S(3)–Rh(2) 106.3(3).

Changing the ligand from $H_2TPyP$ to tpt gives **3a**, whose structure was established by X-ray structure analysis (Figure 2) and is very similar to that of $[Cp^*IrS_2C_2(B_{10}H_{10})]_3(tpt)$.[6] Three $[Cp^*RhS_2C_2(B_{10}H_{10})]$ units are symmetrically arranged around the periphery of one tpt core to form a "bowl-shaped" structure. All of the rhodium centers adopt a three-legged piano-stool conformation, which has six-coordinate geometry, assuming that the Cp* ligand functions as a three-coordinate ligand. The Rh–N bond lengths are 2.125(6)–2.144(9) Å, which are similar to those of **2a**. Each tpt ligand connects three Rh atoms related by crystallographic threefold symmetry in the tetragonal space group $P4_2/ncm$. It is interesting that the tpt ligand acts in a bifunctional tridentate fashion in **3a** through three N-donor atoms of the oligopyridyl and one triazine group. Two

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

neighboring molecules of **3a** are paired and staggered in a face-to-face fashion, with the separation between the central triazine rings being 3.46 Å, which is indicative of the presence of π–π stacking interactions. The two neighboring molecules within the stack are rotated by about 60° with respect to each other, just like two buckled bowls.

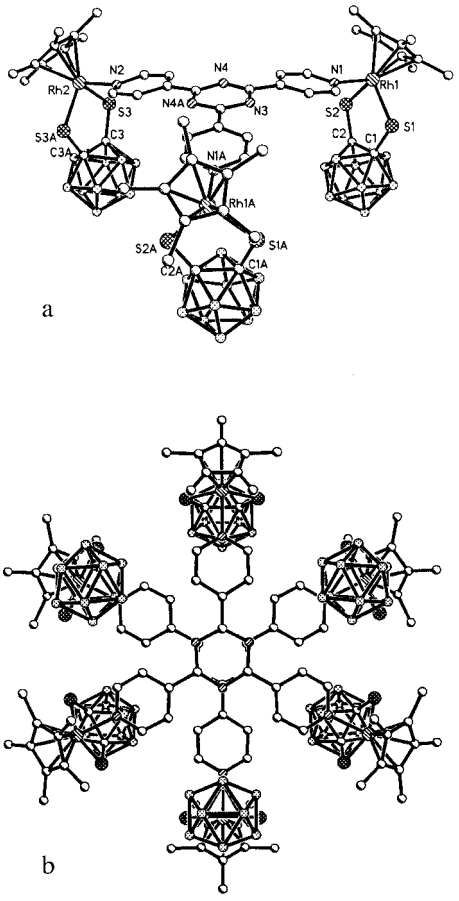

Figure 2. (a) Molecular unit of $[Cp^*RhS_2C_2(B_{10}H_{10})]_3(tpt)$ (**3a**). (b) Two units of **3a** in a staggered disposition. Selected distances [Å] and angles [°]: Rh(1)–N(1) 2.125(6), Rh(1)–S(1) 2.361(2), Rh(1)–S(2) 2.371(2), Rh(2)–N(2) 2.144(9), Rh(2)–S(3a) 2.360(3), Rh(2)–S(3) 2.360(3), S(1)–C(1) 1.765(8), S(2)–C(2) 1.776(8), S(3)–C(3) 1.760(11), C(1)–C(2) 1.690(12), C(3)–C(3a) 1.65(2); N(1)–Rh(1)–S(1) 90.72(18), N(1)–Rh(1)–S(2) 90.54(17), S(1)–Rh(1)–S(2) 91.05(8), N(2)–Rh(2)–S(3a) 90.0(2), N(2)–Rh(2)–S(3) 90.0(2), S(3a)–Rh(2)–S(3) 90.66(15), C(1)–S(1)–Rh(1) 106.0(3), C(2)–S(2)–Rh(1) 105.8(3), C(3)–S(3)–Rh(2) 105.7(4); symmetry transformation for the generation of equivalent atoms *a*: $-x+2, -y, -z+1$.

Another remarkable feature of **3a** is the packing pattern along the *c* axis. These "buckled bowls" stack along the *c* axis to form an interesting stacking structure. As shown in Figure 3, each of the eight molecules of **3a** is paired up to form two types of channels with the dimensions ranging from 3.6–4.0 Å. In other words, each molecule of **3a** is locked into position by pairing up with neighboring molecules in the crystal lattice. The packing in the crystals is such as to create infinite tunnels. It is interesting that such channels are constructed with a double-stranded helix, which consists of repeating "buckled bowl" molecules. Overall, the free voids form 40.1% of the cell volume, omitting hydrogen atoms.

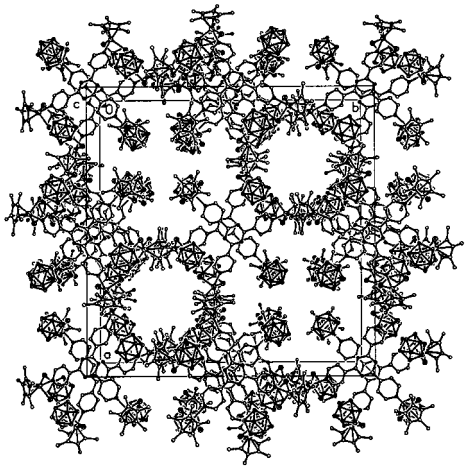

Figure 3. Crystal structure of **3a** viewed down the *c* axis. All hydrogen atoms have been omitted for clarity.

A perspective drawing of **4a** is given in Figure 4. The crystal unit has a crystallographically imposed inversion center in the middle of the Rh···Rh vector. The molecule has a dimeric structure connected by a 4,4′-azopyridine ligand. The plane of the rhodacycle has a dihedral angle of

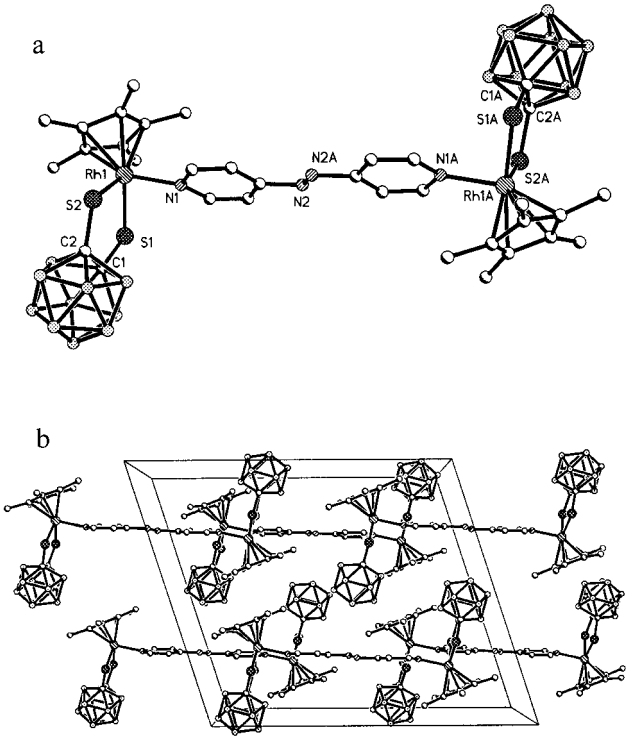

Figure 4. (a) Molecular unit of $[Cp^*Rh\{S_2C_2(B_{10}H_{10})\}]_2(C_{10}H_8N_4)$ (**4a**). (b) Crystal structure of **4a** viewed down the *b* axis. Selected distances [Å] and angles [°]: Rh(1)–N(1) 2.121(3), Rh(1)–S(2) 2.3487(11), Rh(1)–S(1) 2.3526(11), S(1)–C(1) 1.781(4), S(2)–C(2) 1.781(3), C(1)–C(2) 1.658(5); N(1)–Rh(1)–S(2) 90.23(9), N(1)–Rh(1)–S(1) 90.50(9), S(2)–Rh(1)–S(1) 91.06(4), C(1)–S(1)–Rh(1) 105.71(12), C(2)–S(2)–Rh(1) 106.30(13).

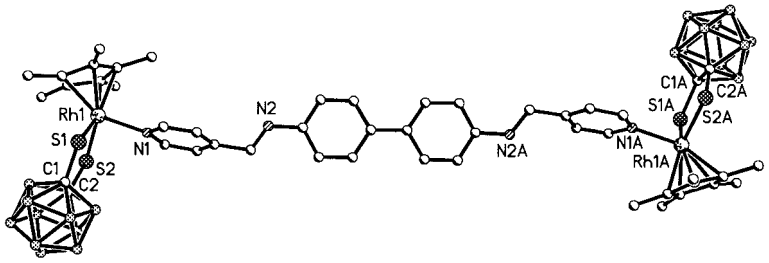

Figure 5. (a) Molecular unit of $[Cp^*Rh\{S_2C_2(B_{10}H_{10})\}]_2(C_{24}H_{18}N_4)$ $2(CHCl_3)$ (**5a**). All hydrogen atoms have been omitted for clarity. Selected distances [Å] and angles [°]: Rh(1)–N(1) 2.140(4), Rh(1)–S(2) 2.3530(17), Rh(1)–S(1) 2.3553(17), S(1)–C(1) 1.778(6), S(2)–C(2) 1.785(6), C(1)–C(2) 1.661(8); N(1)–Rh(1)–S(2) 91.32(14), N(1)–Rh(1)–S(1) 89.90(14), S(2)–Rh(1)–S(1) 91.30(6), C(1)–S(1)–Rh(1) 105.7(2), C(2)–S(2)–Rh(1) 105.7(2).

102.3° with 4,4′-azopyridine, and the Rh···Rh distance is 13.195 Å. Two neighboring molecules of **4a** are staggered in a face-to-face fashion, with the separation between the central Cp* rings being 3.64 Å, which is indicative of the presence of weak π–π stacking interactions (Figure 4, b).

The crystal structures of **5a** and **6a** are similar to that of **4a**, and also consist of $[Cp^*RhS_2C_2(B_{10}H_{10})]$ and *N*,*N*′-bis(4-pyridinylmethylene)biphenyl-4,4′-diamine or pyrazine adducts in a 2:1 molar ratio. As shown in Figures 5 and 6, each Rh is also in a three-legged piano-stool conformation. The Rh–N bond lengths are 2.129(3)–2.140(4) Å, similar to those of **2a**, **3a**, and **4a**. The crystal unit has a crystallographically imposed inversion center in the middle of the Rh···Rh vector. The molecule has a dimeric structure connected by a *N*,*N*′-bis(4-pyridinylmethylene)biphenyl-4,4′-diamine or pyrazine ligand, respectively. The plane of the rhodacycle has a dihedral angle of 100.7° with *N*,*N*′-bis(4-pyridinylmethylene)biphenyl-4,4′-diamine for **5a** and 86.7° with pyrazine for **6a**, and the Rh···Rh distance is 23.980 Å for **5** and 7.019 Å for **6a**.

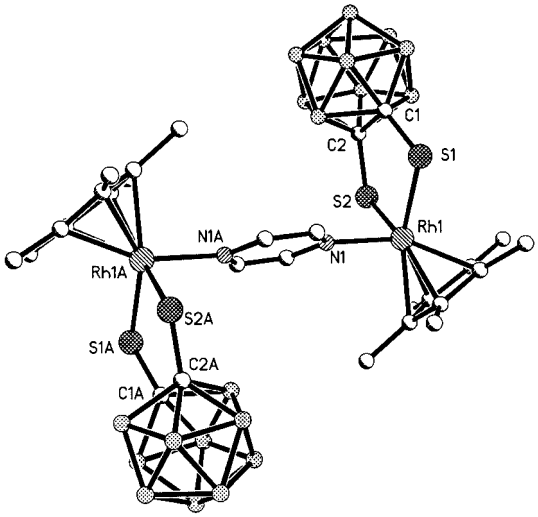

Figure 6. Molecular unit of $[Cp^*Rh\{S_2C_2(B_{10}H_{10})\}]_2(C_4H_4N_2)$ (**6a**). All hydrogen atoms have been omitted for clarity. Selected distances [Å] and angles [°]: Rh(1)–N(1) 2.129(3), Rh(1)–S(2) 2.3528(12), Rh(1)–S(1) 2.3662(12), S(1)–C(1) 1.784(4), S(2)–C(2) 1.769(4),C(1)–C(2), 1.665(5); N(1)–Rh(1)–S(2) 89.32(8), N(1)–Rh(1)–S(1) 91.26(9), S(2)–Rh(1)–S(1) 90.01(5), C(1)–S(1)–Rh(1) 105.97(14).

As shown in Figure 7, there are two crystallographically independent rhodium(III) atoms in the crystal of complex **7a**, and the stoichiometry of $[Cp^*Rh\{S_2C_2(B_{10}H_{10})\}]_2$-$(C_{12}H_8N_4O)$ is 2:1. Each $Rh^{III}$ is also located in a three-legged piano-stool conformation. The two metal atoms Rh(1) and Rh(2) are interconnected by 2,5-di(4-pyridyl)-1,3,5-oxadiazole groups to form a dimeric structure. The plane of each rhodacycle forms a dihedral angle of 88.4° and 91.6° with 2,5-di(4-pyridyl)-1,3,5-oxadiazole, respectively; the Rh(1)···Rh(2) distance is 13.820 Å. It is interesting to note that the two $[Cp^*RhS_2C_2(B_{10}H_{10})]$ fragments

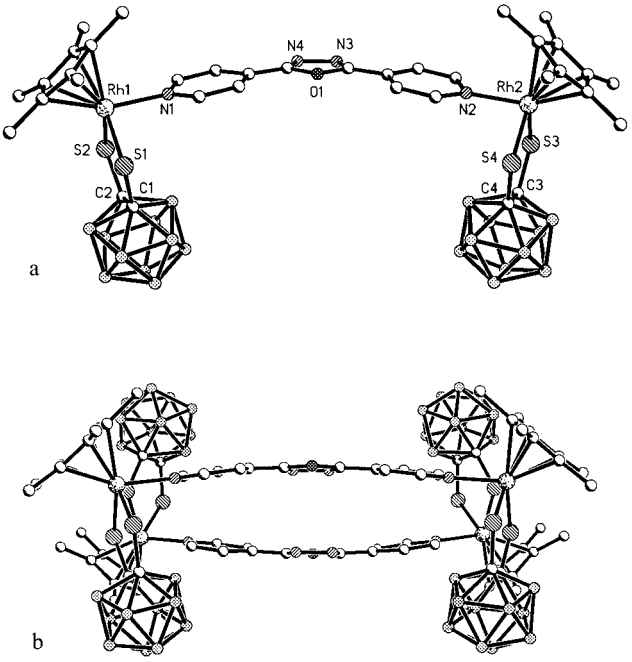

Figure 7. (a) Molecular unit of $[Cp^*Rh\{S_2C_2(B_{10}H_{10})\}]_2$-$(C_{12}H_8N_4O)\cdot(THF)$ (**7a**). (b) Two units of **7a** in a staggered disposition. All hydrogen atoms have been omitted for clarity. Selected distances [Å] and angles [°]: Rh(1)–N(1) 2.148(7), Rh(1)–S(1) 2.356(3), Rh(1)–S(2) 2.363(2), Rh(2)–N(2) 2.126(7), Rh(2)–S(4) 2.343(3), Rh(2)–S(3) 2.369(3), S(1)–C(1) 1.792(9), S(2)–C(2) 1.782(10), S(3)–C(3) 1.785(9), S(4)–C(4) 1.766(9), C(1)–C(2) 1.687(13), C(3)–C(4) 1.637(12); N(1)–Rh(1)–S(1) 91.7(2), N(1)–Rh(1)–S(2) 88.94(19), S(1)–Rh(1)–S(2) 90.38(10), N(2)–Rh(2)–S(4) 91.5(2), N(2)–Rh(2)–S(3) 88.8(2), S(4)–Rh(2)–S(3) 90.30(9), C(1)–S(1)–Rh(1) 106.7(3), C(2)–S(2)–Rh(1) 107.2(3), C(3)–S(3)–Rh(2) 105.7(3), C(4)–S(4)–Rh(2) 106.6(3).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

are in a *cis* conformation, which is different from the *trans* conformation in **4a**, **5a**, and **6a**. It is also interesting that the 2,5-bis(4-pyridyl-1,3,5-oxadiazole) ligand is bifunctional didentate in **7a** through two N-donor atoms of the oligopyridyl and one oxadiazole group. Two neighboring molecules of **7a** are paired and staggered in a face-to-face fashion, with the separation between the central oxadiazole rings being 3.15 Å, which is indicative of the presence of strong π–π stacking interactions (Figure 7, b). The two neighboring molecules within the stack are rotated by about 180° with respect to each other, just like two buckled boxes.

The crystal structures of complexes **8b** and **9b** are quite similar to those of **4a**, **5a**, and **6a**. As shown in Figures 8 and 9, respectively, X-ray crystallographic analysis reveals that the complexes are dimers bridged by pyridyl ligands with an Ir···Ir distance of 13.461 Å for **8b** and 19.654 Å for **9b**. The plane of the iridacycle forms a dihedral angle with the pyridyl ring of 107.7° for **8b** and 97.5° for **9b**. It is interesting to note that the two [Cp*IrS$_2$C$_2$(B$_{10}$H$_{10}$)] fragments in **8b** and **9b** are in a *trans* conformation, similar to **4a**, **5a**, and **6a**.

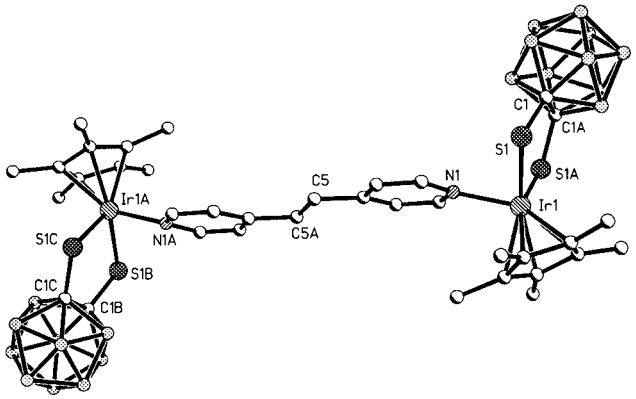

Figure 8. Molecular unit of [Cp*IrS$_2$C$_2$(B$_{10}$H$_{10}$)]$_2$(C$_{12}$H$_{10}$N$_2$) (**8b**). All hydrogen atoms have been omitted for clarity. Selected distances [Å] and angles [°]: Ir(1)–N(1) 2.115(5), Ir(1)–S(1) 2.3568(14), S(1)–C(1) 1.774(5), C(1)–C(1a) 1.662(10); N(1)–Ir(1)–S(1) 87.70(11), N(1)–Ir(1)–S(1a) 87.70(11), S(1)–Ir(1)–S(1a) 90.79(7), C(1)–S(1)–Ir(1) 105.50(17).

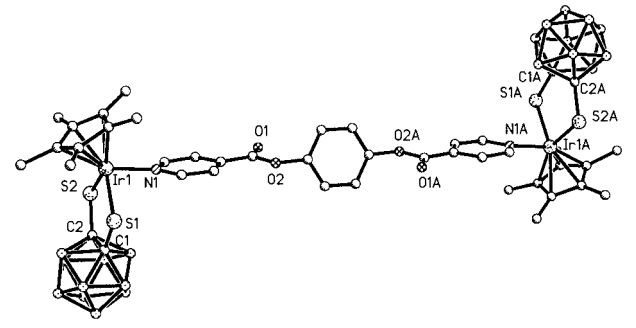

Figure 9. Molecular unit of [Cp*IrS$_2$C$_2$(B$_{10}$H$_{10}$)]$_2$(C$_{18}$H$_{12}$N$_2$O$_4$)·2(CH$_2$Cl$_2$) (**9b**). All hydrogen atoms have been omitted for clarity. Selected distances [Å] and angles [°]: Ir(1)–N(1) 2.132(8), Ir(1)–S(2) 2.3551(18), Ir(1)–S(1) 2.359(3), S(1)–C(1) 1.782(8), S(2)–C(2) 1.768(10), C(1)–C(2) 1.652(13); N(1)–Ir(1)–S(2) 90.35(17), N(1)–Ir(1)–S(1) 88.2(3), S(2)–Ir(1)–S(1) 90.71(7), C(1)–S(1)–Ir(1) 106.3(3), C(2)–S(2)–Ir(1) 105.6(3).

In summary, a new set of multi-cluster molecules has been synthesized from half-sandwich rhodium(III) and iridium(III) complexes bearing 1,2-dicarba-*closo*-dodecaborane(12)-1,2-dithiolate chelate ligands and different multidentate pyridyl ligands. This synthetic approach, which is based upon stepwise building-up of metal clusters with organic fragments, offers the potential for exquisite control over the detailed architecture of the materials, which may lead to a variety of unusual shapes.

## Experimental Section

All manipulations were performed under nitrogen using standard Schlenk techniques or in a glove box. Solvents were dried by refluxing over sodium/benzophenone ketyl (toluene, hexane, cyclohexane) and distilled just before use. [Cp*Rh{S$_2$C$_2$(B$_{10}$H$_{10}$)}] (**1a**),[12] [Cp*Ir{S$_2$C$_2$(B$_{10}$H$_{10}$)}] (**1b**),[13] 2,4,6-tri(4-pyridyl)-1,3,5-triazine,[14] 4,4′-azopyridine,[15] *N*,*N*′-bis(4-pyridinylmethylene)biphenyl-4,4′-diamine,[16] diisonicotinic acid 1,4-phenylene diester,[17] 2,5-di(4-pyridyl)-1,3,4-oxadiazole[18] were prepared by methods reported previously. IR spectra were recorded with a Nicolet AVATAR-360IR spectrometer, whereas $^1$H (500 MHz) and $^{11}$B (160 MHz) NMR spectra were obtained with a Bruker DMX-500 spectrometer in CDCl$_3$ solution. Elemental analyses were performed with an Elementar vario EI Analyzer.

**Caution!** *Perchlorate salts are explosive (especially when dry) and should be handled with care.*

**Synthesis of [Cp*Rh{S$_2$C$_2$(B$_{10}$H$_{10}$)}]$_4$(H$_2$TPyP) (2a):** A mixture of **1a** (178 mg, 0.4 mmol) and H$_2$TpyP (62 mg, 0.1 mmol) in CH$_2$Cl$_2$ (30 mL) was stirred for 24 h, whereupon the green-colored mixture gradually changed to red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a violet solid of **2a** (190 mg, 79%). C$_{88}$H$_{126}$B$_{40}$N$_8$Rh$_4$S$_8$ (2396.6): calcd. C 44.10, H 5.30, N 4.68; found C 43.85, H 5.16, N 4.57. $^1$H NMR (500 MHz, CDCl$_3$, 20 °C): $\delta$ = –2.89 (s, porphine NH, 2 H), 1.78 (s, C$_5$Me$_5$, 60 H), 8.20 (d, $^3J_{H,H}$ = 5 Hz, 3,5-pyridyl, 8 H), 9.02 (m, pyrrole, 8 H), 9.38 (d, $^3J_{H,H}$ = 5 Hz, 2,6-pyridyl, 8 H) ppm. $^{11}$B NMR (160 MHz, CDCl$_3$, 20 °C): $\delta$ = –5.8, –8.2, –9.0, –10.8 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2581, 2559 ($\nu_{B-H}$), 1578, 1420, 986, 792 cm$^{-1}$.

**Synthesis of [Cp*Rh{S$_2$C$_2$(B$_{10}$H$_{10}$)}]$_3$(C$_{18}$H$_{12}$N$_6$) (3a):** A solution of **1a** (133 mg, 0.3 mmol) in CH$_2$Cl$_2$ (30 mL) was added to tpt (31 mg, 0.1 mmol) in CH$_2$Cl$_2$ (30 mL). The green-colored mixture was stirred for 24 h, whereupon it gradually changed to violet. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a violet solid of **3a** (143 mg, 82%). C$_{54}$H$_{87}$B$_{30}$N$_6$Rh$_3$S$_6$ (1645.8): calcd. C 39.41, H 5.33, N 5.11; found C 39.28, H 5.27, N 5.10. $^1$H NMR (500 MHz, CDCl$_3$, 20 °C): $\delta$ = 1.77 (s, 30 H, C$_5$Me$_5$), 8.67 (br., 6 H, 3,5-pyridyl), 8.96 (br., 6 H, 2,6-pyridyl) ppm. $^{11}$B NMR (160 MHz, CDCl$_3$, 20 °C): $\delta$ = –7.9, –10.3 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2573, 2559 cm$^{-1}$ ($\nu_{B-H}$).

**Synthesis of [Cp*Rh{S$_2$C$_2$(B$_{10}$H$_{10}$)}]$_2$(C$_{10}$H$_8$N$_4$) (4a):** A solution of **1a** (89 mg, 0.2 mmol) in CH$_2$Cl$_2$ (30 mL) was added to 4,4′-azopyridine (21 mg, 0.1 mmol) in CH$_2$Cl$_2$ (30 mL). The green-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **4a** (85 mg, 79%).

$C_{34}H_{58}B_{20}N_4Rh_2S_4$ (1073.1): calcd. C 38.05, H 5.45, N 5.22; found C 37.87, H 5.39, N 5.17. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.77 (s, 30 H, $C_5Me_5$), 7.76 (d, $^3J_{H,H}$ = 5 Hz, 4 H, 3,5-pyridyl), 8.85 (d, $^3J_{H,H}$ = 5 Hz, 4 H, 2,6-pyridyl) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 20 °C): $\delta$ = –6.1, –7.5, –8.7, –10.9 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2568 ($\nu_{B-H}$), 1657, 1600, 1491, 1450 cm$^{-1}$.

**Synthesis of [Cp*Ir{$S_2C_2(B_{10}H_{10})$}]$_2$($C_{10}H_8N_4$) (4b):** A solution of **1b** (106 mg, 0.2 mmol) in $CH_2Cl_2$ (30 mL) was added to 4,4′-azopyridine (21 mg, 0.1 mmol) in $CH_2Cl_2$ (30 mL). The blue-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **4b** (100 mg, 80%). $C_{34}H_{58}B_{20}Ir_2N_4S_4$ (1251.8): calcd. C 32.62, H 4.67, N 4.48; found C 32.39, H 4.61, N 4.43. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.87 (s, 30 H, $C_5Me_5$), 7.80 (d, $^3J_{H,H}$ = 5 Hz, 4 H, 3,5-pyridyl), 8.92 (d, $^3J_{H,H}$ = 5 Hz, 4 H, 2,6-pyridyl) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 20 °C): $\delta$ = –6.2, –7.5, –8.6, –10.5 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2562 ($\nu_{B-H}$), 1653, 1610, 1491, 1438 cm$^{-1}$.

**Synthesis of [Cp*Rh{$S_2C_2(B_{10}H_{10})$}]$_2$($C_{24}H_{18}N_4$) (5a):** A solution of **1a** (89 mg, 0.2 mmol) in $CH_2Cl_2$ (30 mL) was added to *N*,*N*′-bis(4-pyridinylmethylene)biphenyl-4,4′-diamine (36 mg, 0.1 mmol) in $CH_2Cl_2$ (30 mL). The green-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **5a** (91 mg, 73%). $C_{48}H_{68}B_{20}N_4Rh_2S_4$ (1251.4): calcd. C 46.07, H 5.48, N 4.48; found C 45.77, H 5.39, N 4.41. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.76 (s, 30 H, $C_5Me_5$), 7.2–7.5 (m, 8 H, biphenyl), 7.69 (s, 2 H, CH), 8.25 (br., 4 H, 3,5-pyridyl), 9.12 (br., 4 H, 2,6-pyridyl) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 20 °C): $\delta$ = –6.1, –7.5, –8.9, –10.6, –12.2 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2551, 2573 cm$^{-1}$($\nu_{B-H}$).

**Synthesis of [Cp*Rh{$S_2C_2(B_{10}H_{10})$}]$_2$($C_4H_4N_2$) (6a):** A solution of **1a** (178 mg, 0.4 mmol) in $CH_2Cl_2$ (30 mL) was added to pyrazine (17 mg, 0.2 mmol) in $CH_2Cl_2$ (30 mL). The green-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **6a** (159 mg, 82%). $C_{28}H_{54}B_{20}N_2Rh_2S_4$ (969.03): calcd. C 34.70, H 5.62, N 2.89; found C 34.59, H 5.58, N 2.83. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.79 (s, 30 H, $C_5Me_5$), 8.80 (s, 4 H, pyrazine) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 20 °C): $\delta$ = –7.7, –10.2 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2563 cm$^{-1}$ ($\nu_{B-H}$).

**Synthesis of [Cp*Ir{$S_2C_2(B_{10}H_{10})$}]$_2$($C_4H_4N_2$) (6b):** A solution of **1b** (213 mg, 0.4 mmol) in $CH_2Cl_2$ (30 mL) was added to pyrazine (17 mg, 0.2 mmol) in $CH_2Cl_2$ (30 mL). The green-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **6b** (197 mg, 86%). $C_{28}H_{54}B_{20}Ir_2N_2S_4$ (1147.66): calcd. C 29.30, H 4.74, N 2.44; found C 29.01, H 4.71, N 2.42. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.86 (s, 30 H, $C_5Me_5$), 8.81 (s, 4 H, pyrazine) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 20 °C): $\delta$ = –7.3, –10.1 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2558 cm$^{-1}$ ($\nu_{B-H}$)

**Synthesis of [Cp*Rh{$S_2C_2(B_{10}H_{10})$}]$_2$($C_{12}H_8N_4O$) (7a):** A solution of **1a** (89 mg, 0.2 mmol) in $CH_2Cl_2$ (30 mL) was added to 2,5-di(4-pyridyl)-1,3,5-oxadiazole (22 mg, 0.1 mmol) in $CH_2Cl_2$ (30 mL). The green-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **7a** (86 mg, 77%). $C_{36}H_{58}B_{20}N_4ORh_2S_4$ (1113.2): calcd. C 38.84, H 5.25, N 5.03; found C 38.49, H 5.17, N 4.98. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.76 (s, 30 H, $C_5Me_5$), 7.67 (d, $^3J_{H,H}$ = 5 Hz, 4 H, 3,5-pyridyl), 8.76 (d, $^3J_{H,H}$ = 5 Hz, 4 H, 2,6-pyridyl) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 20 °C): $\delta$ = –5.7, –7.3, –8.9, –10.6 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2555, 2576 cm$^{-1}$ ($\nu_{B-H}$).

**Synthesis of [Cp*Rh{$S_2C_2(B_{10}H_{10})$}]$_2$($C_{12}H_{10}N_2$) (8a):** A solution of **1a** (89 mg, 0.2 mmol) in $CH_2Cl_2$ (30 mL) was added to 1,2-di(4-pyridyl)ethylene (18 mg, 0.1 mmol) in $CH_2Cl_2$ (30 mL). The green-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **8a** (76 mg, 71%). $C_{36}H_{60}B_{20}Rh_2N_2S_4$ (1071.2): calcd. C 40.37, H 5.65, N 2.62; found C 40.19, H 5.53, N 2.55. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.77 (s, 30 H, $C_5Me_5$), 7.20 (m, 2 H, CH), 7.56 (br., 4 H, 3,5-pyridyl), 8.81 (m, 4 H, 2,6-pyridyl) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 20 °C): $\delta$ = –5.8, –7.2, –8.5, –10.3 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2559, 2580 cm$^{-1}$ ($\nu_{B-H}$).

**Synthesis of [Cp*Ir{$S_2C_2(B_{10}H_{10})$}]$_2$($C_{12}H_{10}N_2$) (8b):** A solution of **1b** (106 mg, 0.2 mmol) in $CH_2Cl_2$ (30 mL) was added to 1,2-di(4-pyridyl)ethylene (18 mg, 0.1 mmol) in $CH_2Cl_2$ (30 mL). The blue-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **8b** (94 mg, 75%). $C_{36}H_{60}B_{20}Ir_2N_2S_4$ (1249.8): calcd. C 34.60, H 4.84, N 2.24; found C 34.31, H 4.79, N 2.21. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.87 (s, $C_5Me_5$, 30 H), 7.26 (m, CH, 2 H), 7.71 (br., pyridyl, 4 H), 8.92 (br., pyridyl, 4 H) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 20 °C): $\delta$ = –5.9, –7.1, –8.5, –10.5 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2561, 2579 cm$^{-1}$ ($\nu_{B-H}$).

**Synthesis of [Cp*Rh{$S_2C_2(B_{10}H_{10})$}]$_2$($C_{18}H_{12}N_2O_4$) (9a):** A solution of **1a** (89 mg, 0.2 mmol) in $CH_2Cl_2$ (30 mL) was added to diisonicotinic acid 1,4-phenylene diester (32 mg, 0.1 mmol) in $CH_2Cl_2$ (30 mL). The green-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **9a** (98 mg, 81%). $C_{42}H_{62}B_{20}N_2O_4Rh_2S_4$ (1209.2): calcd. C 41.72, H 5.17, N 2.32; found C 41.59, H 5.08, N 2.25. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.78 (s, $C_5Me_5$, 20 H), 7.26 (s, phenyl, 4 H), 7.79 (d, $^3J_{H,H}$ = 5 Hz, 4 H, 3,5-pyridyl), 8.95 (s, $^3J_{H,H}$ = 5 Hz, 4 H, 2,6-pyridyl) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 20 °C): $\delta$ = –3.2, –5.3, –7.0, –8.2, –9.7, –12.8 ppm (signal overlap). IR (KBr pellet): $\tilde{\nu}$ = 2563, 2575 cm$^{-1}$ ($\nu_{B-H}$), 1692 ($\nu_{C=O}$).

**Synthesis of [Cp*Ir{$S_2C_2(B_{10}H_{10})$}]$_2$($C_{18}H_{12}N_2O_4$) (9b):** A solution of **1b** (106 mg, 0.2 mmol) in $CH_2Cl_2$ (30 mL) was added to diisonicotinic acid 1,4-phenylene diester (32 mg, 0.1 mmol) in $CH_2Cl_2$ (30 mL). The blue-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **9b** (115 mg, 83%). $C_{42}H_{62}B_{20}Ir_2N_2O_4S_4$ (1387.9): calcd. C 36.35, H 4.50, N 2.02; found C 36.07, H 4.39, N 1.93. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.89 (s, $C_5Me_5$, 20 H), 7.31 (s, phenyl, 4 H), 7.89 (d, $^3J_{H,H}$ = 5 Hz, 4 H, 3,5-pyridyl), 9.01 (d, $^3J_{H,H}$ = 5 Hz, 4 H, 2,6-pyridyl) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 20 °C): $\delta$ = –3.2, –5.3, –7.0, –8.2, –9.7, –12.8 ppm (signal overlap). IR (KBr pellet): $\tilde{\nu}$ = 2562, 2575 cm$^{-1}$ ($\nu_{B-H}$), 1690 ($\nu_{C=O}$).

**Synthesis of [Cp*Rh{$S_2C_2(B_{10}H_{10})$}]($C_{10}H_8N_2$) (10a):** A solution of **1a** (89 mg, 0.2 mmol) in $CH_2Cl_2$ (30 mL) was added to 4,4′-bipyridine (16 mg, 0.1 mmol) in $CH_2Cl_2$ (30 mL). The green-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **10a** (85 mg, 81%). $C_{34}H_{58}B_{20}N_2Rh_2S_4$ (1045.1): calcd. C 39.07, H 5.59, N 2.68; found C 38.92, H 5.46, N 2.60. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.78 (s, $C_5Me_5$, 30 H), 7.53 (d, $^3J_{H,H}$ = 5 Hz, 2,6-pyridyl, 4 H),

8.71 (d, $^3J_{H,H}$ = 5 Hz, 3,5-pyridyl, 4 H) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 25 °C): $\delta$ = –6.5, –7.7, –8.1, –10.8 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2582, 2571 cm$^{-1}$ ($\nu_{B-H}$).

**Synthesis of [Cp*Ir{$S_2C_2(B_{10}H_{10})$}]($C_{10}H_8N_2$) (10b):** A solution of **1b** (106 mg, 0.2 mmol) in $CH_2Cl_2$ (30 mL) was added to 4,4′-bipyridine (16 mg, 0.1 mmol) in $CH_2Cl_2$ (30 mL). The blue-colored mixture was stirred for 24 h, whereupon it gradually became dark red. The solvent was then evaporated under vacuum. The residue was washed with toluene to give a red solid of **10b** (106 mg, 87%). $C_{34}H_{58}B_{20}Ir_2N_2S_4$ (1223.75): calcd. C 33.37, H 4.78, N 2.29; found C 32.98, H 4.57, N 2.23. $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.86 (s, $C_5Me_5$, 30 H), 7.57 (d, $^3J_{H,H}$ = 5 Hz, 3,5-pyridyl, 4 H), 8.77 (d, $^3J_{H,H}$ = 5 Hz, 2,6-pyridyl, 4 H) ppm. $^{11}$B NMR (160 MHz, $CDCl_3$, 25 °C): $\delta$ = –6.3, –8.1, –8.7, –10.3 ppm. IR (KBr pellet): $\tilde{\nu}$ = 2583, 2571 cm$^{-1}$ ($\nu_{B-H}$).

**X-ray Crystallographic Analysis:** Diffraction intensity data were collected with a Bruker Smart Apex CCD diffractometer. The determination of the unit cell and the collection of intensity data were performed with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). All the data were collected at room temperature using the $\omega$-scan technique. The structures were solved by direct methods using Fourier techniques, and refined on $F^2$ by a full-matrix least-squares method. SADABS[19] absorption corrections were applied to the data. All non-hydrogen atoms were refined with anisotropic

# Can the Clusters $Zr_6O_4(OH)_4(OOCR)_{12}$ and $[Zr_6O_4(OH)_4(OOCR)_{12}]_2$ Be Converted into Each Other?

**Michael Puchberger,[a] Franz René Kogler,[a] Myhedin Jupa,[a] Silvia Gross,[a][‡] Helmut Fric,[a] Guido Kickelbick,[a] and Ulrich Schubert*[a]**

**Keywords:** Zirconium / Zirconium oxo cluster / Hafnium oxo cluster / Metal carboxylate / Ligand exchange

Upon reaction of zirconium alkoxides, $Zr(OR)_4$, with carboxylic acids, the clusters $Zr_6O_4(OH)_4(OOCR)_{12}$ (**Zr6**) or $[Zr_6O_4(OH)_4(OOCR)_{12}]_2$ (**Zr12**) were obtained, depending on the employed carboxylic acid. The structures of **Zr12** clusters with acetate, propionate, vinyl acetate or 3,3′-dimethylacrylate ligands were determined by single-crystal X-ray diffraction, as well as that of methacrylate/acetate and methacrylate/propionate mixed-ligand clusters. The structure of the hafnium cluster $[Hf_6O_4(OH)_4(acetate)_{12}]_2$ is also reported for comparison. The **Zr12** clusters are structurally related to the **Zr6** clusters since they are composed of two **Zr6** sub-units which are bridged by four carboxylate ligands. In each compound, carboxylic acid molecules interact with the cluster by hydrogen bonding to part of the $\mu_3$-OH ligands. The clusters are highly dynamic in solution, due to site exchange of the carboxylate ligands; low-temperature NMR spectra of the clusters correspond to the solid-state structures. The **Zr6** and **Zr12** clusters can be clearly distinguished by their solution NMR spectra. Reactions between selected **Zr12** clusters and carboxylic acids led to the conclusion, that only part of the ligands is accessible for ligand exchange reactions. In contrast, all ligands were exchanged when the **Zr6** cluster $Zr_6O_4(OH)_4(methacrylate)_{12}$ was treated with an excess of propionic acid, and $Zr_6O_4(OH)_4(propionate)_{12}$ was formed. However, the **Zr12** cluster $[Zr_6O_4(OH)_4(propionate)_{12}]_2$ was obtained from the reaction of $Zr(OBu)_4$ with propionic acid. The **Zr6** and **Zr12** clusters thus do not interconvert at the given reaction conditions.

## Introduction

We have previously prepared a variety of carboxylate-substituted titanium and zirconium oxo clusters, mainly to use the (meth)acrylate derivatives for the preparation of cluster-crosslinked polymers.[1] During this work, we obtained several types of zirconium oxo clusters, among them $Zr_6O_4(OH)_4(OOCR)_{12}$ (**Zr6**) and the dimer $[Zr_6O_4(OH)_4(OOCR)_{12}]_2$ (**Zr12**), having the same overall stoichiometry. Previous to this work, we obtained crystalline **Zr6** clusters for RCOO = methacrylate (**1**)[2] and 5-norbornene-2-carboxylate,[3] and the **Zr12** type for RCOO = acrylate.[4] The crystal structures of both cluster types additionally contain carboxylic acid molecules interacting with the ligand shell of the clusters by hydrogen bonding (see below).

The **Zr6** clusters consist of a $Zr_6O_4(OH)_4$ cluster core in which the triangular faces of a $Zr_6$ octahedron are alternatively capped by $\mu_3$-O and $\mu_3$-OH groups. The structure of the **Zr12** cluster consists of two **Zr6** sub-units which are connected by four carboxylate bridges. This will be discussed below in more detail. In a formal manner, the **Zr12** clusters can be constructed by opening two $\mu_2$-(edge-bridging) carboxylate ligands of **Zr6** and letting two such units dimerize as shown in Figure 1.

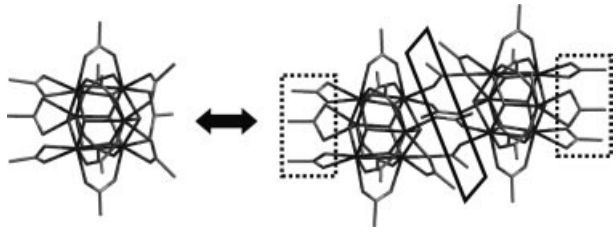

Figure 1. The schematic structures of **Zr6** $[Zr_6O_4(OH)_4(OOCR)_{12}$, left] and **Zr12** ($[Zr_6O_4(OH)_4(OOCR)_{12}]_2$, right) showing that the molecular structure of **Zr12** is derived from the **Zr6** structure. The dashed boxes mark the chelating ligands, and the box drawn with solid lines the carboxylate bridges connecting the $Zr_6$ sub-units.

The clusters were obtained when $Zr(OR')_4$ was treated with the corresponding carboxylic acid. In each case, only one cluster type was obtained, mostly in very high to quantitative yields, i.e. we never obtained mixtures of both clusters. This raises the question whether the formation of either cluster is controlled by the particular reaction conditions or by the different carboxylate ligands including the hydrogen-bonded carboxylic acid molecules. Differences in the electronic and/or steric properties could determine which cluster is formed. A related question of practical im-

portance, is whether the **Zr6** and **Zr12** clusters can be converted into each other once they are formed. Since carboxylate-substituted metal alkoxides play an important role in sol-gel chemistry,[1,5] the conversion of intra-cluster bridges to inter-cluster bridges could result in the formation of oligomers or polymers made of cluster units, which could severely influence the structure of the networks formed during sol-gel processing.

We report in this article experiments proving that the two cluster types are not interconverted under the conditions employed during their synthesis. First, we will describe new **Zr12** clusters with different carboxylate ligands than previously described. Second, we will demonstrate that the **Zr6** and **Zr12** clusters can be clearly distinguished in solution by their NMR spectra. Third, we will show that each cluster type is retained when the ligands are exchanged; this renders possible the preparation of **Zr6** and **Zr12** clusters with the same ligands.

## Results and Discussion

### Preparation and Structures of New Zr12 Clusters

Cluster **1** was previously prepared by reaction of $Zr(OPr)_4$ in propanol or $Zr(OBu)_4$ in butanol with four equivalents of methacrylic acid.[2] The reported procedure is very reliable, and it is possible to prepare large quantities of this cluster per run for materials syntheses.[1] However, minor changes in the kind of employed carboxylic acid resulted in the formation of **Zr12** clusters instead. The crystalline clusters $[Zr_6O_4(OH)_4(OOCMe)_{12}]_2 \cdot 6MeCOOH \cdot 3.5CH_2Cl_2$ (**2**), $[Zr_6O_4(OH)_4(OOCCH_2Me)_{12}]_2 \cdot 6MeCH_2COOH$ (**3**), $[Zr_6O_4(OH)_4(OOCCH_2CH{=}CH_2)_{12}]_2 \cdot 6CH_2{=}CHCH_2COOH$ (**4**) and $[Zr_6O_4(OH)_4(OOCCH{=}CMe_2)_{12}]_2 \cdot 4Me_2C{=}CHCOOH$ (**5**) were formed in high yields when an 80% solution of $Zr(OBu)_4$ in *n*-butanol was treated with acetic acid (10 molar equivalents), propionic acid (2–10 molar equivalents), vinylacetic acid (7 molar equivalents) or 3,3′-dimethylacrylic acid (4 molar equivalents), respectively. Methylene chloride was used as a co-solvent in the reaction of acetic acid to obtain crystals suitable for single crystal measurements. These reactions show that the **Zr12** cluster type is obviously obtained with a much broader range of carboxylic acids than the **Zr6** cluster type.

We have previously shown that the carboxylate ligands of the **Zr6** clusters can be partially or fully exchanged, when the **Zr6** clusters are reacted with a carboxylic acid. Partial exchange resulted in mixed-ligand clusters, which can alternatively be prepared by reaction of the metal alkoxide with mixtures of two carboxylic acids.[8,6] Mixed-ligand **Zr12** clusters can also be obtained by both methods. Crystalline $[Zr_6O_4(OH)_4(OOCCH_2Me)_3\{OOC(Me){=}CH_2\}_9]_2 \cdot CH_2{=}C(Me)COOH \cdot 5MeCH_2COOH$ (**6**) was obtained by reaction of $Zr(OBu)_4$ with a 2:5 or 1:6 mixture of propionic and methacrylic acid, and $[Zr_6O_4(OH)_4(OOCMe)_8\{OOC(Me){=}CH_2\}_4]_2 \cdot 6MeCOOH$ (**7**) by reacting $Zr(OBu)_4$ with five equivalents of a 1.4:3.6 mixture of methacrylic acid and acetic acid.

The cluster $[Hf_6O_4(OH)_4(OOCMe)_{12}]_2 \cdot 6MeCOOH \cdot 6CH_2Cl_2$ (**8**) was similarly prepared by reaction of $Hf(OBu)_4$ with 10 molar equivalents of acetic acid in $CH_2Cl_2$. This **Hf12** cluster is isostructural to the zirconium cluster **2** and is therefore included in the discussion.

The solid-state structures of the **Zr12** clusters are fairly similar; differences are only observed for the carboxylic acids which are hydrogen-bonded to the cluster. We will therefore first discuss the structure of the vinyl acetate-substituted cluster **4** (Figure 2) as an example before we turn to the mixed-ligand clusters and point out differences among the different **Zr12** clusters.

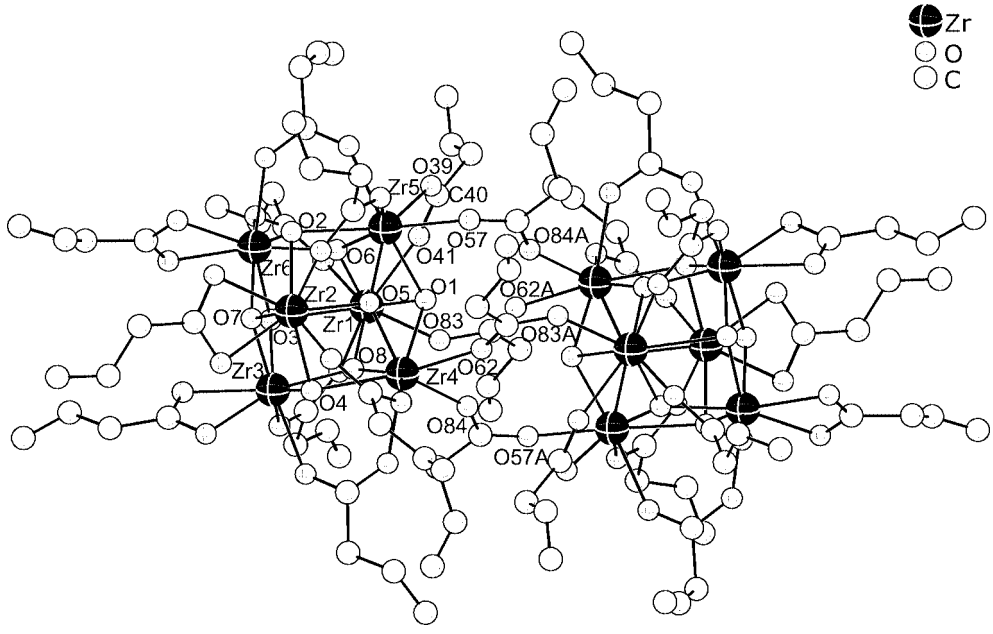

Figure 2. Structure of $[Zr_6O_4(OH)_4(OOCCH_2CH{=}CH_2)_{12}]_2$ (**4**).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The structure of **Zr6** (Figure 1, left) consists of a $Zr_6O_4(OH)_4$ core in which the triangular faces of a $Zr_6$ octahedron are alternatively capped by $\mu_3$-O and $\mu_3$-OH groups. The same cluster core was found in $Ce_6(OH)_4O_4$(acetylacetonate)$_{12}$.[7] Three carboxylate ligands of **Zr6** chelate the zirconium atoms at one $\mu_3$-O capped face ("chelated face"), while the other nine OOCR groups bridge all edges of the $Zr_6$ octahedron except the edges of the chelated face. Each zirconium atom is coordinated by eight oxygen atoms. The cluster core thus has a $C_{3v}$ symmetry with the $C_3$ axis passing through the center of the chelated face and the triangular face opposite to it.

The basic structural features of **Zr6** are retained in the sub-units of centrosymmetric **4** and all the other clusters of the **Zr12** type (Figure 1, right and Figure 2). The carboxylate ligands opposite the chelated face in the **Zr6** unit appear to be somewhat activated. For example, we previously obtained modifications of the **Zr6** structure, where *one* carboxylate ligand opposite the chelated face was opened to a monodendate coordination and the vacated coordination site occupied by a coordinated alcohol or a water molecule $[Zr_6O_4(OH)_4(OOCR)_{12}\cdot XOH$, X = R, H].[4,8] In **Zr12**, *two* of the bridging carboxylate ligands per $Zr_6$ unit opposite the chelated face are opened and are converted to inter-cluster bridges, i.e. the **Zr12** clusters are thus dimers of **Zr6** in which $Zr_6$ sub-units are connected by four inter-cluster carboxylate bridges. The third bridging carboxylate ligand opposite the chelated face [O(39)/C(40)/O(41)] stays bridging. This change of the coordination mode of two carboxylate units per $Zr_6$ unit from edge-bridging to inter-cluster bridging has only little effect on the geometrical parameters of the cores of the $Zr_6$ sub-units and the remaining carboxylate ligands.

The $\mu_3$-O and $\mu_3$-OH groups capping the $Zr_6$ core can be easily distinguished by their Zr–O distances. In **4**, the oxygen atoms O(5)–O(8) were $\mu_3$-O (Zr–O distances between 203.5(2) and 210.7(2) pm, where the Zr–O distances at the chelated face were slightly longer [209.0–210.7 pm]), while O(1)–O(4) were $\mu_3$-OH. While the Zr–O(1) distances (the $\mu_3$-OH group opposite the chelated face) were quite uniform [229.8(2)–233.1(2) pm], that of the other three capping OH groups showed a pattern of two short [218.3(2)–221.7(2) pm] and one long [233.1(2)–239.1(2) pm] Zr–O distance, i.e. the groups are in fact between $\mu_2$ and $\mu_3$.

The Zr–O distances of the intra-cluster bridging carboxylate ligands (218.3–223.6 pm) in **4** were in the same range as the inter-cluster bridging ligands (216.6–222.3 pm) while the distances of the chelating ligands were distinctly longer. Remarkably, each chelating carboxylate ligand had a longer [229.7(2)–230.8(2) pm] and a significantly shorter [225.3(2)–227.4(2) pm] Zr–O bond length, which is due to the hydrogen bonds described below, the *shorter* distance being the oxygen atom interacting with the hydrogen-bonded acid.

The crystal lattice of **4** contains three vinylacetic acid molecules per asymmetric unit, which interact with the cluster subunits via hydrogen bridges. The OH group of each carboxylic acid is hydrogen-bonded to an oxygen atom of a *chelating* vinyl acetate ligand [O(9)···O(87) 265.8 pm, O(15)···O(93) 262.9 pm, O(23)···O(99) 263.8 pm] and the carbonyl oxygen of each carboxylic acid is hydrogen-bonded to one of the three $\mu_3$-OH groups surrounding the chelating face [O(2)···O(85) 271.8 pm, O(3)···O(91) 275.0 pm, O(4)···O(97) 273.1 pm]. The hydrogen-bonding pattern in **4** is schematically shown in Figure 3.

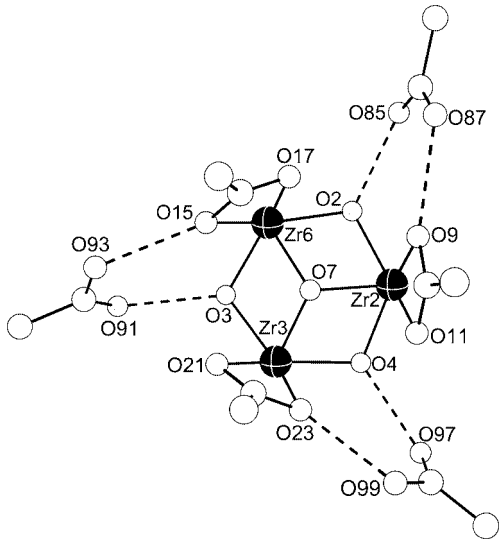

Figure 3. Hydrogen bonding patterns in **4**. The vinyl groups are omitted for clarity.

The hydrogen-bonding pattern of **4** (similar for the other **Zr12** clusters) is remarkable, as it shows that the $\mu_3$-OH groups in the clusters are efficient proton donors in hydrogen bonds and thus enable the coordination of carboxylic acid molecules at the periphery of the clusters. This may be important for carboxylate-exchange reactions as discussed below (see also ref.[8]). As we have already pointed out in a related case,[9] the simultaneous action of carboxylic acids as hydrogen donors *and* hydrogen acceptors may stabilize unusual bonding situations.

The inorganic core of the mixed-ligand clusters **6** and **7** was the same as that of the other **Zr12** clusters, but the distribution of the ligands needs to be discussed. In the following discussion we distinguish between (i) the chelating ligands, (ii) the ligands bonded to zirconium atoms at the face of the $Zr_6$ octahedron opposite the chelated face ("opposite ligands"), which are the carboxylate bridges connecting the $Zr_6$ sub-units and the remaining edge-bridging ligand at the "opposite" face, and (iii) the ligands bridging the zirconium atoms of the "chelated" face and the "opposite" face ("belt ligands", see Figure 1). Cluster **6** is again centrosymmetric and contains three propionate and nine methacrylate ligands per $Zr_6$ sub-unit. All propionate groups were "opposite" ligands (Figure 4). In the acetate/methacrylate-substituted cluster **7**, with a lower proportion of methacrylate ligands, the saturated (acetate) ligands occupied again the "opposite" ligand positions and in addition part of the "belt" positions, while the methacrylate ligands were at the chelating and part of the "belt" positions (as a matter of fact, part of the belt positions contained disordered acetate and methacrylate ligands in the

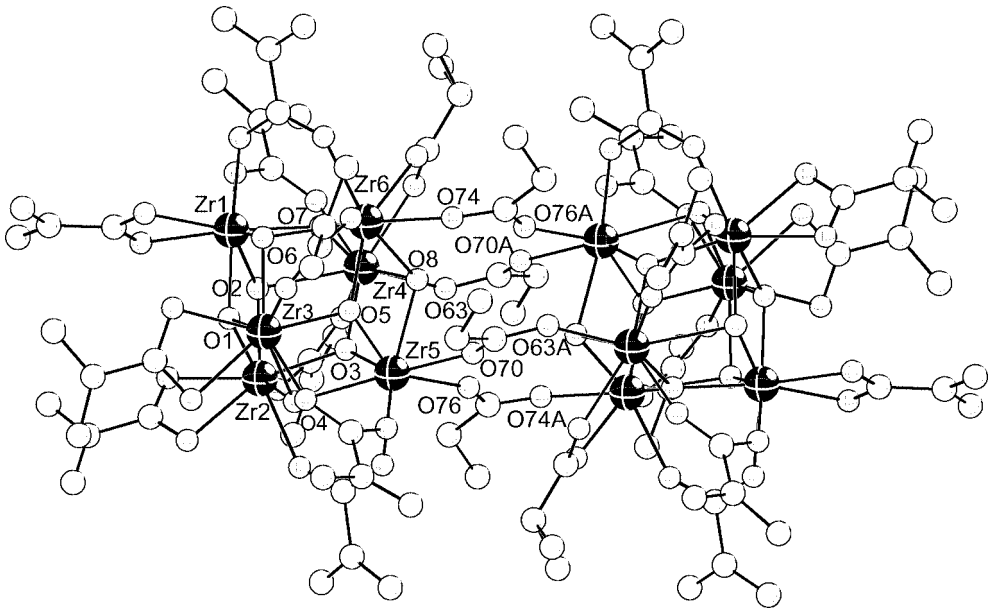

Figure 4. Structure of $[Zr_6O_4(OH)_4(OOCCH_2Me)_3\{OOCC(Me)=CH_2\}_9]_2$ (**6**).

solid-state structure). There is obviously a clear preference of the methacrylate ligands in the order chelating > belt > opposite. The reason for this preference is currently speculative. One possibility is that the $pK_a$ of methacrylic acid is slightly lower (4.66) than that of propionic acid (4.88) and acetic acid (4.76), and the site preference is thus due to the basicity of the anions. Another reason could be the slightly different steric demand of the ligands.

The molecular structures of all **Zr12/Hf12** clusters were essentially the same. However, different hydrogen-bonding patterns of the carboxylic acids were observed. In the clusters **2** and **8**, the hydrogen bonding was the same as in **4** discussed above. A second type of hydrogen bonding pattern was observed in **3**, **6** and **7**. Again, three carboxylic acid molecules are hydrogen-bonded per $Zr_6$ unit with the $\mu_3$-OH groups neighboring the chelated face as the hydrogen donors to the carbonyl oxygen atoms. However, the OH groups of the carboxylic acid molecules interact in a different manner with the chelating ligands. In **6**, two carboxylic acid molecules interact with the two oxygen atoms of *one* chelating ligand. The second chelating ligand is hydrogen-bonded as in **4**, while the third is not involved in hydrogen bonding. The structure of **3** contained two half **Zr12** molecules in the asymmetric unit. One of them had the same hydrogen-bonding pattern as in **4**, and the other as in **6**. In **7**, the OH group of one acetic acid molecule interacted with *two* chelating carboxylate ligands (with rather long O···O interactions, 286–301 pm), the second oxygen atom of which was hydrogen-bonded to the other acetic acid molecules. The dimethylacrylate derivative **5** had only four hydrogen-bonded acid molecules, probably because of their greater steric bulk. One of the dimethylacrylic acid molecules is hydrogen-bonded as described above, i.e. the carbonyl oxygen interacts with one of the $\mu_3$-OH groups [O(1)] and an oxygen of a chelating carboxylate ligand [O(30)]. The carbonyl group of the second hydrogen-bonded dimethylacrylic acid molecule interacts with the $\mu_3$-OH group O(3), but the hydrogen atom of the carboxylic OH group interacts in a bifurcated manner with one oxygen atom of both other chelating carboxylate ligands.

### NMR Spectra of Zr6 and Zr12 Clusters

For the NMR spectroscopic investigation of the clusters, the solvate molecules of the crystalline compounds were nearly completely removed by repeated dissolution/evaporation cycles, as described in the Experimental Section. We have previously reported the $^1H$ and $^{13}C$ NMR spectroscopic data of **1**,[8] where the signals in the room temperature spectra can be clearly assigned to three nonequivalent ligand positions (one chelating and two different bridging positions) according to the $C_{3v}$ symmetry of the cluster in the crystalline state. The signal ratio of the olefinic $CH_2$ protons should therefore be 2:1:1, which was approximately found by integrating the corresponding signals of the solution $^1H$ NMR spectrum; the proton signals of all methyl groups were overlapping. The three different ligands can be easily distinguished in the $^1H/^{13}C$ HMBC spectrum of **1** (Figure 5), where long-range correlations between the olefinic $CH_2$ and $CH_3$ protons to the corresponding carboxylate carbon atoms were observed. The signals at $\delta$ = 6.10/5.65 ppm ($^1H$ NMR) and 184.7 ppm ($^{13}C$ NMR) were therefore assigned to the chelating ligands, and those at 5.97/5.39 ppm ($^1H$ NMR) and 171.9 ppm ($^{13}C$ NMR) as well as those at 6.04/5.60 ppm ($^1H$ NMR) and 169.6 ppm ($^{13}C$ NMR) to the two inequivalent bridging ligands. This sequence of chemical shifts shows that $^{13}C$ NMR signals of chelating carboxylates are distinctly shifted to a lower field.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

This is in line with previous work on zinc carboxylate clusters, where this was explained by electronic effects of the bound metal(s).[10]

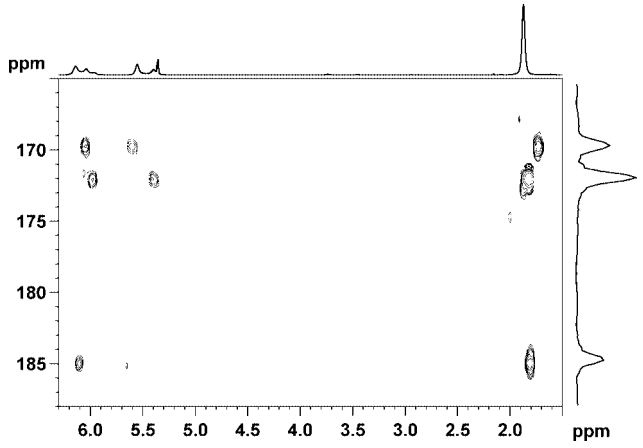

Figure 5. $^1H/^{13}C$ HMBC spectrum of **1** at room temperature in $CD_2Cl_2$.

We start the discussion of the NMR spectra of the **Zr12/Hf12** clusters with the simpler cases, i.e. the acetate-substituted clusters $[Zr_6O_4(OH)_4(OOCMe)_{12}]_2$ (**2**) and $[Hf_6O_4(OH)_4(OOCMe)_{12}]_2$ (**8**), which both show the same features in the NMR spectra. Six of the 24 acetate ligands are chelating ligands, 14 are bridging ligands within the same $Zr_6$ sub-unit and four ligands are inter-cluster bridging. The symmetry of the cluster in the crystalline state is $C_i$ with 12 inequivalent ligand positions. Neglecting a slight perturbation of the symmetry by crystal packing or slightly different conformations of the acetate ligands, the molecular symmetry is in fact $C_{2h}$ (Figure 6 (a)]. This results in seven nonequivalent ligand positions, i.e. two chelating, four bridging and one inter-cluster bridging, with a signal ratio of 1:1:2:2:2:2:2. In the case of a $C_i$ symmetry three of the 12 ligand positions are chelating, seven are bridging and two are inter-cluster bridging. Their signal intensity should be the same. A comparison of these two cases is shown in Figure 6. In passing, it should be pointed out that, in the worst case for NMR investigations, all ligands may become inequivalent due to different ligand conformations. This may lead to different isomers and an even greater number of signals or broader resonances.

Temperature-dependent $^1H$ NMR spectra of solvate-free $[Zr_6O_4(OH)_4(OOCMe)_{12}]_2$ (**2**) in $CD_2Cl_2$ are shown in Figure 7. Five separated methyl signals were observed at 20 °C. Upon cooling the solution to –40 °C two additional signals appeared; the seven nonequivalent ligand signals in an approximate ratio of 1:1:2:2:2:2:2 indicate that the cluster has indeed $C_{2h}$ symmetry in solution.

A tentative assignment of the signals was reached from a $^1H/^{13}C$ HMBC spectrum (Figure 8) and by comparison of the chemical shifts with those of compound **1**. The signal at $\delta$ = 1.75 ppm, which shows a long-range correlation to the most down-field shifted carboxylate at $\delta$ = 181.1 ppm, was assigned to a chelating acetate ligand, whereas the signal at $\delta$ = 2.05 ppm, showing a long-range correlation to

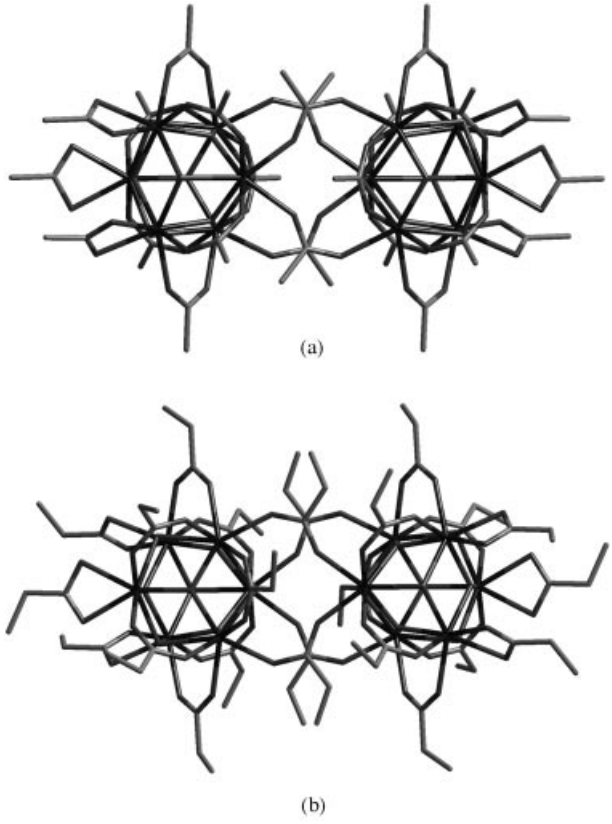

Figure 6. $[M_6O_4(OH)_4(OOCMe)_{12}]_2$ [M = Zr (**2**) or Hf (**8**); (a)] has a mirror plane whereas $[Zr_6O_4(OH)_4(OOCCH_2Me)_{12}]_2$ [**3**; (b)] only has an inversion center due to the different conformation of the ethyl groups.

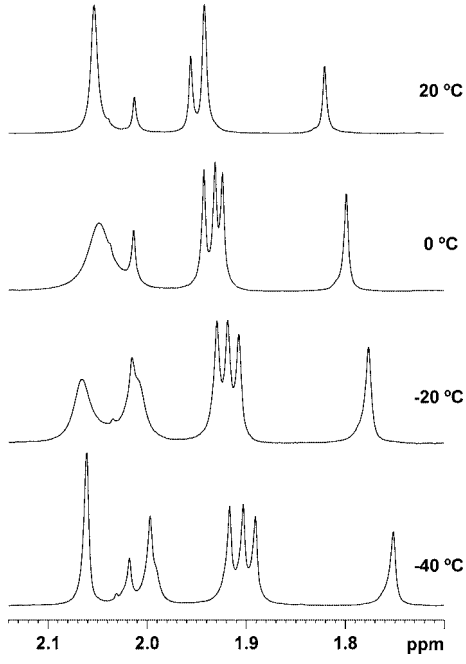

Figure 7. Temperature-dependent $^1H$ NMR spectra of $[Zr_6O_4(OH)_4(OOCMe)_{12}]_2$ (**2**) in $CD_2Cl_2$.

the most high-field shifted carboxylate at $\delta$ = 175.9 ppm, should correspond to a bridging ligand. The signals with long-range correlations between 2.02 ppm ($^1$H) and 176.6 ppm ($^{13}$C) as well as 2.00 ppm ($^1$H) and 176.6 ppm ($^{13}$C) appear in the $^1$H NMR spectrum only with 50% intensity and can therefore be assigned to the set of intercluster bridging ligands and to the set of chelating ligands. The remaining three signals at 1.91 ($\delta$ = 177.4 ppm), 1.90 ($\delta$ =177.3 ppm) and 1.89 ($\delta$ = 177.5 ppm) must then be signals of the other bridging acetate ligands. The carbon signals of the methyl groups are listed in the Experimental Section.

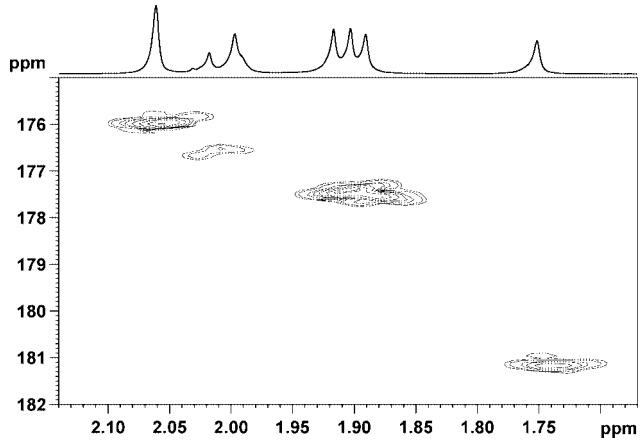

Figure 8. $^1$H/$^{13}$C HMBC spectrum of **2** at –40 °C in $CD_2Cl_2$.

A different picture was obtained for the propionate-substituted cluster $[Zr_6O_4(OH)_4(OOCCH_2Me)_{12}]_2$ (**3**) in [D$_8$]-toluene (Figure 9). The $^1$H NMR spectrum at room temperature showed sharp lines, and signals for six different ligands were observed. Five of them showed long-range correlations to carboxylate carbon atoms at 184.0, 179.9, 179.8, 179.7 and 178.4 ppm in a $^1$H/$^{13}$C HMBC spectrum, whereas no long-range correlation was observed for the broad $CH_3$ signal at $\delta$ = 1.02 ppm. This is common for fast exchanging ligands in such cluster compounds.

Cooling the sample to –40 °C changed the picture, and signals for at least ten inequivalent ligands were observed in the $^1$H NMR spectrum (not shown). This means that the symmetry of **3** is reduced to at least $C_i$ or even $C_1$ at lower temperatures. In the $^1$H/$^{13}$C HMBC spectrum at this temperature, six carboxylate signals were now resolved, and the signal, which formerly gave no long-range correlation, was shifted from 1.02 to 0.89 ppm and split into two proton signals, both of which gave a long-range correlation to the same carbon at $\delta$ = 192.0 ppm. This signal was also tentatively assigned to a chelating ligand. When the sample was further cooled to –80 °C (not shown) the lines in the spectrum became broad and unstructured. This indicated that at room temperature the symmetry is approximately $C_{2h}$ because the ligand conformations are averaged on the NMR time scale. At lower temperature, the ligand motion is restricted, and the symmetry of the cluster is thus lowered, resulting in a larger number of signals.

These examples show that the **Zr6** and **Zr12** clusters can be clearly distinguished by their molecular symmetry and therefore by their NMR spectra in solution. While the $C_{3v}$ symmetric **Zr6** cluster **1** has three sets of nonequivalent carboxylate ligands, the **Zr12** clusters have either $C_{2h}$ or $C_i$ symmetry and should therefore have either seven or 12 nonequivalent ligands. The symmetry of the cluster may even be reduced to $C_1$ and therefore the number of signals in the NMR spectra increases when the ligand motion is restricted. The NMR spectrum of **1** at room temperature had already shown signals for all three nonequivalent ligands (Figure 5). In the case of the **Zr12** clusters **2** and **3**, the room temperature NMR spectra show signals for five or six nonequivalent ligands, respectively. This indicates that site exchange of the ligands in **2** and **3** is much easier than that in the **Zr6** cluster **1**. Furthermore, it was observed that in the case of **3** the most dynamic region in this **Zr12** cluster is that of the chelating ligands.

It is worth noting at this point that the ability to distinguish clearly between a **Zr6** and a **Zr12** cluster is already a clear indication that there is no equilibrium between these two different clusters at room temperature in solution.

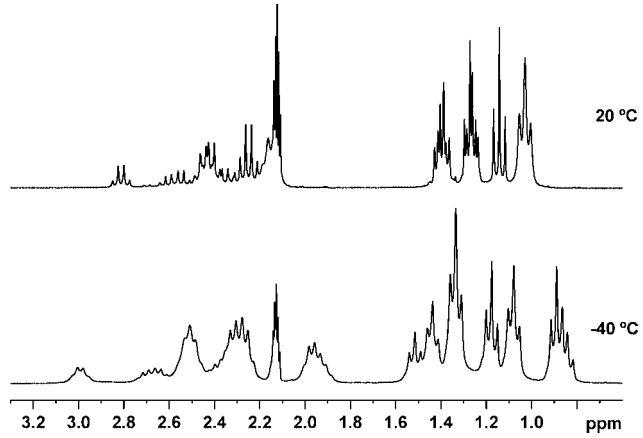

Figure 9. Temperature-dependent $^1$H NMR spectra of $[Zr_6O_4(OH)_4(OOCCH_2Me)_{12}]_2$ (**3**) in [D$_8$]toluene.

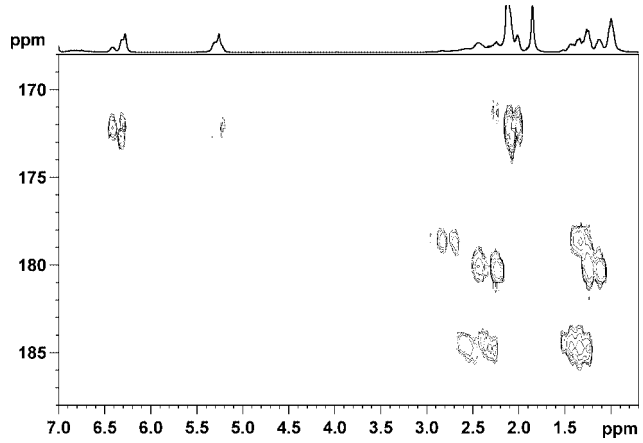

Figure 10. $^1$H/$^{13}$C HMBC spectrum of $[Zr_6O_4(OH)_4(OOCCH_2Me)_3\{OOCC(Me)=CH_2\}_9]_2$ (**6**) at room temperature in [D$_8$]toluene.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

To explore the ability of the **Zr12** clusters to undergo ligand exchange reactions and to compare this with the already known exchange behavior of the **Zr6** clusters[8,6] we analyzed the mixed propionate-methacrylate cluster **6**. The $^1H$ NMR spectrum of **6** in [$D_8$]toluene at room temperature showed broad and unstructured lines, due to ligand exchange. The corresponding $^1H/^{13}C$ HMBC spectrum (Figure 10) of **6** showed signals for only three different methacrylate ligands and six different propionate ligands. The carboxylate carbons of the methacrylate groups appeared at 171.5, 172.0 and 172.5 ppm, and that of the propionate ligands at 178.3, 178.4, 179.7, 179.8, 184.1 and 184.2 ppm.

### Reaction of $[Zr_6O_4(OH)_4(OOCCH_2Me)_3\{OOCC(Me)=CH_2\}_9]_2$ (6) and $Zr_6O_4(OH)_4\{OOCC(Me)=CH_2\}_{12}$ (1) with Propionic Acid

Cluster **6** was treated with a large excess of propionic acid in $CH_2Cl_2$. After careful workup of the reaction product and excessive drying in vacuo, the $^1H$ NMR spectra (Figure 11) showed a complete exchange of the cluster-bonded methacrylate ligands against propionate ligands. The obtained spectrum is very similar to that of **3** directly prepared from $Zr(OBu)_4$ and propionic acid (see above). This indicated that in **Zr12** clusters at least the "outer" parts of the cluster, to which the 18 methacrylate ligands are bonded, are accessible to ligand exchange in solution.

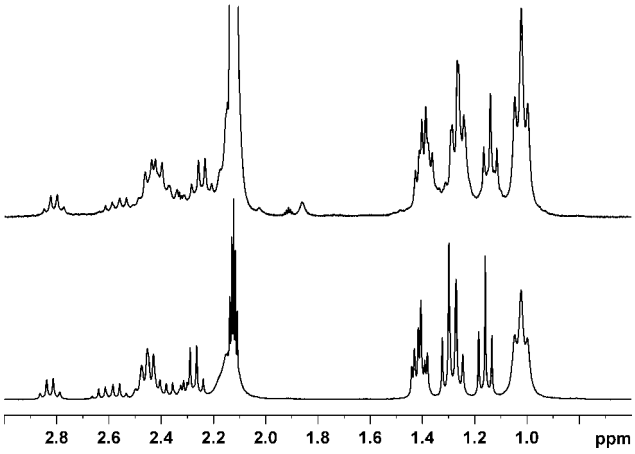

Figure 11. Top: $^1H$ NMR spectrum (in [$D_8$]toluene) of the reaction product of **6** with an excess of propionic acid in [$D_8$]toluene at room temperature. Bottom: $^1H$ NMR spectrum of solvate-free **3** for comparison.

To check whether all ligands can be exchanged, we used the propionate-substituted cluster **3**. Treatment with an excess of acetic acid should yield the acetate cluster $[Zr_6O_4(OH)_4(OOCMe)_{12}]_2$ (**2**) when all ligands are exchanged. The $^1H$ NMR spectrum of the reaction product is compared in Figure 12 (center) with the starting compound **3** (top) and **2** (bottom). It is easy to see that even after excessive treatment with acetic acids signals from propionate ligands were retained. The integration of the signals showed that the ratio of acetate to propionate was 3:1. This leads to the conclusion, that the "opposite ligands" of the **Zr12** cluster are not accessible for ligand exchange reactions in solution.

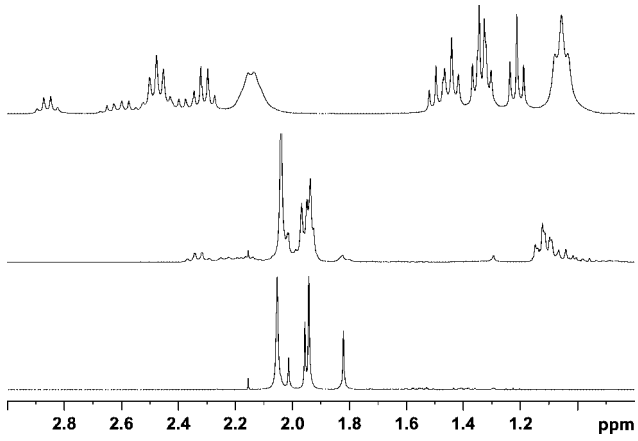

Figure 12. Top: $^1H$ NMR spectrum of $[Zr_6O_4(OH)_4(OOCCH_2Me)_{12}]_2$ (**3**). Bottom: $^1H$ NMR spectrum of $[Zr_6O_4(OH)_4(OOCMe)_{12}]_2$ (**2**), the expected reaction product. Center: Reaction product of **3** with an excess of acetic acid. All spectra were recorded at room temperature in $CD_2Cl_2$.

In contrast, when the **Zr6** cluster **1** was treated with a large excess of propionic acid, the NMR spectra clearly showed that no methacrylate ligands were left and therefore all ligands were exchanged against propionate.[8] In the $^1H/^{13}C$ HMBC spectrum of the reaction product (Figure 13), long-range correlations between the $CH_2$ and $CH_3$ protons of three different propionate groups to the corresponding carboxylate carbon atoms were observed. A comparison with the $^1H/^{13}C$ HMBC spectrum of **1** (Figure 5) showed a similar peak pattern of the signals; two of the signals appeared at a higher field (180.0 and 180.4 ppm), whereas one signal was shifted to lower field ($\delta$ = 184.0 ppm). The intensity ratio of the protons is also approximately 2:1:1 as found for **1**. This indicates strongly that the cluster core of the **Zr6** cluster was preserved during the exchange reaction, that the overall symmetry $C_{3v}$ was retained and that $Zr_6O_4(OH)_4$-(propionate)$_{12}$ was formed.

One of the key steps in the formation of zirconium oxo clusters from $Zr(OR')_4$ and carboxylic acids is the esterification reaction of the acid with the cleaved alcohol.[11] The thus-generated water is the source of the oxo and hydroxo ligands in the clusters. When mixed-ligand clusters are prepared from two different acids, the question is whether two esters were formed or just one. We therefore also monitored the formation of **6** in solution starting from $Zr(OBu)_4$ and a mixture of propionic and methacrylic acid by NMR spectroscopy, concentrating on signals from either butyl propionate or butyl methacrylate. After 6 h, the reaction was almost complete and no more ester was formed. The TOCSY spectrum (Figure 14, top) showed that the sharp triplet at $\delta$ = 3.93 ppm (marked by an arrow) can be assigned to the $CH_2O$ moiety of a butyl residue, and the $^1H/^{13}C$ HMBC spectrum (Figure 14, bottom) shows a long-range correlation from this triplet to a propionate group at $\delta$ = 173.7 ppm. The other signals in the $^1H/^{13}C$ HMBC spec-

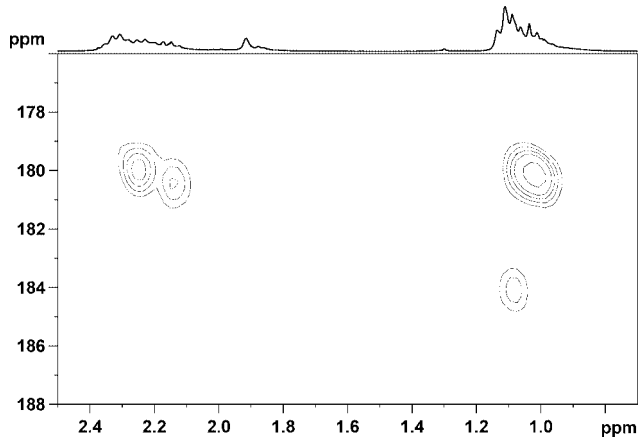

Figure 13. $^{1}H/^{13}C$ HMBC spectrum of the reaction product of **1** treated with an excess of propionic acid at room temperature in $[D_8]$toluene.

trum were due to methacrylic acid ($\delta$ = 173.0 ppm) and propionic acid ($\delta$ = 179.8 ppm). No butyl-methacrylate was formed during the reaction. This experiment shows that the formation rate of ester, and thus water, may play a key role in the formation of different cluster types.

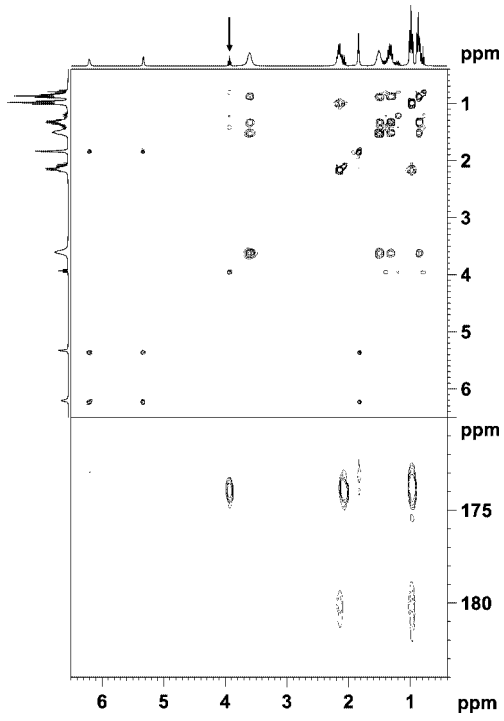

Figure 14. TOCSY spectrum (top) and $^{1}H/^{13}C$ HMBC spectrum (bottom) of the formation of $[Zr_6O_4(OH)_4(propionate)_3(methacrylate)_9]_2$ (**6**) after 6 h in $[D_8]$toluene.

## Conclusions

The most important conclusion of this work is that **Zr6** and **Zr12** clusters, despite their structural similarity, are not converted into each other in solution under the employed conditions. The first proof is that their solution NMR spectra are clearly different, especially at low temperatures. The spectra are in agreement with the molecular symmetries obtained from the solid-state structures. Second, exchange experiments showed that both $Zr_6O_4(OH)_4(propionate)_{12}$ and $[Zr_6O_4(OH)_4(propionate)_{12}]_2$ can be obtained, depending on the preparation route. The **Zr6** cluster $Zr_6O_4(OH)_4(propionate)_{12}$ was obtained by treatment of $Zr_6O_4(OH)_4(methacrylate)_{12}$ (**1**) with a large excess of propionic acid and clearly identified by NMR spectroscopy. On the other hand, the **Zr12** cluster $[Zr_6O_4(OH)_4(propionate)_{12}]_2$ was formed either when $[Zr_6O_4(OH)_4(propionate)_3(methacrylate)_9]_2$ (**6**) was treated with a large excess of propionic acid or directly from $Zr(OBu)_4$ and propionic acid. In either case, the cluster symmetry is retained upon ligand exchange.

From a structural point of view, the **Zr12** clusters are dimers of **Zr6** in which the $Zr_6$ sub-units are connected by four inter-cluster carboxylate bridges. The **Zr12** clusters could be constructed by opening two $\mu_2$- (edge-bridging) carboxylate ligands of **Zr6** and letting two such units dimerize by formation of four inter-cluster bridges. The notion that the **Zr12** clusters could be formed in this manner was imposed by the previous observation that *one* carboxylate ligand opposite the chelated face can be opened to a monodentate coordination and the vacated coordination site occupied by a coordinated alcohol or a water molecule. NMR spectra indicated that this process is reversible.[8] The process leading to the **Zr12** clusters is obviously not related to this. Why *either* **Zr6** *or* **Zr12** clusters are formed when $Zr(OR)_4$ is reacted with carboxylic acids is still an open question. The key to answering this question could be the acidity of the employed carboxylic acids. This influences both the rate of ester plus water formation and also the bond strength of the coordinated carboxylate ligands. The interplay of both probably determines how the cluster formation proceeds in the early stages of the reaction.

## Experimental Section

Acetic acid (99%, Aldrich) was dried with $CaSO_4$ and distilled before use. Methacrylic acid (99%, Aldrich) and propionic acid (99.5%, Aldrich) were distilled. $Zr(OBu)_4$ (80% in BuOH, Aldrich), $Hf(OBu)_4$ (95%, ABCR), vinylacetic acid (97%, Aldrich) and dimethylacrylic acid (97%, Aldrich) were used as received. All experiments were carried out in a moisture- and oxygen-free argon atmosphere. To remove the solvate molecules from the crystalline clusters, the compounds were dissolved in $CH_2Cl_2$ and all volatiles were removed in vacuo. This process was repeated with toluene and once more with $CH_2Cl_2$. The obtained solids were dried at room temperature and ca. $10^{-5}$ mbar.

All NMR spectra were recorded with a Bruker *Avance* 300 ($^{1}H$ at 300.13 MHz, $^{13}C$ at 75.47 MHz) equipped with a 5 mm, inverse-broadband probe head with a *z*-gradient unit. 2D experiments were measured with Bruker standard pulse sequences: COSY (Correlated Spectroscopy), TOCSY (Total Correlation Spectroscopy), HSQC (Heteronuclear Single Quantum Correlation) and HMBC (Heteronuclear Multiple Bond Correlation). Gas-tight Young tubes were used for all measurements. Solvents were either $CD_2Cl_2$ (99.8%, euriso-top) or $[D_8]$toluene (99.8%, euriso-top).

**Synthesis of $[Zr_6O_4(OH)_4(OOCMe)_{12}]_2$·6MeCOOH·3.5$CH_2Cl_2$ (2):** Acetic acid (2.62 g, 43.66 mmol) was added dropwise at room temperature to a solution of $Zr(OBu)_4$ (4.44 mmol, 2.13 g of a 80% solution in BuOH) in $CH_2Cl_2$ (5 mL) whilst stirring in a Schlenk tube. Within 3 h at room temperature colorless crystals were obtained. The crystals were separated and dried in vacuo. Yield: 864 mg (68%). $C_{63.5}H_{111}Cl_7O_{76}Zr_{12}$ (3433.2): calcd. C 22.22, H 3.26; found C 22.37, H 3.21. IR-ATR: $\tilde{\nu}$ = 2960 (w), 2776 (w), 2607 (w), 1757 (w), 1709 (m), 1599 (s), 1556 (s), 1449 (s), 1346 (m), 1258(m), 1046 (m), 1026 (m), 910 (w), 883 (w), 791 (w), 735 (w), 669 (m) $cm^{-1}$. $^1H$ NMR (Figure 7) ($C_7D_8$, 25 °C): $\delta$ = 1.82, 1.94, 1.96, 2.01, 2.05 (Me), 10.01 (O*H*). At –40 °C: 1.75, 1.89, 1.90, 1.92, 1.99, 2.02, 2.06 (C$H_3$), 11.51 ppm (O*H*). $^{13}C$ NMR ($C_7D_8$, 25 °C): $\delta$ = 181.0, 177.5, 176.6 (*C*O); 23.5, 23.8, 23.7, 22.9, 20.9 (Me). At –40 °C: 181.1, 177.4, 177.3, 177.5, 176.5, 175.9, 175.9 (*C*O); 23.6, 24.1, 23.9, 23.9, 22.8, 23.5, 21.0 ppm (Me).

**Synthesis of $[Zr_6O_4(OH)_4(OOCCH_2Me)_{12}]_2$·6$MeCH_2COOH$ (3):** Propionic acid (1.8 g, 24.2 mmol) was added dropwise at room temperature to a stirred mixture of $Zr(OBu)_4$ (2.37 mmol, 1.14 g of a 80% butanol solution). After 7–8 h at room temperature, colorless crystals (0.53 g) were formed. The crystals were separated and dried in vacuo. Yield 0.53 g (75%). $C_{90}H_{164}O_{76}Zr_{12}$ (3556.9): calcd. C 30.39, H 4.65; found C 29.30, H 4.30. IR-ATR: $\tilde{\nu}$ = 3402 (w), 3259 (w), 2978 (m), 2942 (w), 1717 (m, COOH), 1600 (s, sh, COO), 1533 (s, COO), 1468 (s), 1439 (s, COO), 1374 (m), 1300 (s), 1211 (m), 1078 (m), 1014 (w), 910 (w), 882 (w), 810 (m) $cm^{-1}$. $^1H$ NMR (Figure 8) ($C_7D_8$, 25 °C): $\delta$ = 1.06, 1.23, 1.35, 1.37, 1.47, 1.49 (Me); 2.20, 2.36, 2.39, 2.55, 2.69, 2.95 (C$H_2$); 11.96 ppm (O*H*). $^{13}C$ NMR ($C_7D_8$, 25 °C): $\delta$ = 180.2, 180.8, 179.9, 184.3, 178.6 (*C*O); 28.4, 30.5, 30.5, 30.6, 30.0, 30.2 (*C*$H_2$); 8.5, 9.8, 9.5, 9.5, 9.9, 10.2 ppm (Me).

**Synthesis of $[Zr_6O_4(OH)_4(OOCCH_2CH{=}CH_2)_{12}]_2$·6$CH_2$=CH-$CH_2COOH$ (4):** Vinylacetic acid (966 mg, 11.22 mmol) was added dropwise to $Zr(OBu)_4$ (1.62 mmol, 776 mg of a 80% solution in BuOH). A microcrystalline precipitate was obtained after 5 min which formed colorless crystals within 2 d at room temperature. The crystals were separated and dried in vacuo. Yield: 332 mg (63%). $C_{120}H_{164}O_{76}Zr_{12}$ (3917.2): calcd. C 36.79, H 4.22, $ZrO_2$ 37.75; found C 36.54, H 4.06, $ZrO_2$ 38.39 (TGA). IR-ATR: $\tilde{\nu}$ = 3396 (w, OH), 3080 (w, CH), 3020 (w, CH), 2982 (w, CH), 1711 (m, C=O), 1641 (w, C=C), 1603 (m, $COO_{as.}$), 1547 (sh, $COO_{as}$), 1537 (s, $COO_{as}$), 1436 (s, $COO_s$), 1417 (s, $COO_s$), 1392 (s, $COO_s$), 1314 (w), 1295 (w), 1268 (m), 1199 (m), 1121 (w), 994 (m), 914 (m, C=C), 893 (sh), 811 (m), 782 (sh), 762 (w), 724 (m, CH), 676 (sh), 627 (s, OCO) $cm^{-1}$. $^1H$ NMR ($C_7D_8$, 25 °C): $\delta$ = 6.43, 6.34, 6.32, 6.30, 5.94 (=C*H*); 5.30/5.14, 5.27/5.11, 5.26/5.17, 5.23/5.09, 5.27/5.12, 5.04/4.96 (C$H_2$=); 3.61/3.30, 3.57/3.27, 3.33/3.17, 3.29/3.14, 3.28/3.14, 3.00/2.90 (C$H_2$); 11.55, 7.36, 7.32, 6.88 ppm (O*H*). $^{13}C$ NMR ($C_7D_8$, 25 °C): $\delta$ = 182.7, 182.5, 182.3, 178.7, 176.9 (*C*O); 135.1, 133.7, 131.0 (=*C*H-); 118.5, 117.1, 115.8 (*C*$H_2$=); 42.1, 41.8, 41.6, 39.5 ppm (*C*$H_2$).

**Synthesis of $[Zr_6O_4(OH)_4(OOCCH{=}CMe_2)_{12}]_2$·4$Me_2C$=CHCOOH (5):** Dimethylacrylic acid (1.23 g, 12.3 mmol) was added to a solution of $Zr(OBu)_4$ (3.25 mmol, 1.56 g of a 80% solution in BuOH) in toluene (5 mL) whilst stirring. The mixture was allowed to stir for an additional 30 min. After 20 days at room temperature colorless crystals separated, which were dried in vacuo. Yield: 0.985 g (88%). $C_{140}H_{208}O_{72}Zr_{12}$ (4137.8): calcd. C 40.64, H 5.07, $ZrO_2$ 35.73; found C 40.58, H 4.87, $ZrO_2$ 35.29 (TGA). IR-ATR: $\tilde{\nu}$ = 3648 (w), 3355 (w, OH), 2911 (w, CH), 1696 (m, C=O), 1651 (s, C=C), 1577 (s), 1520 (br. s, $COO_{as}$), 1419 (s, $COO_s$), 1370 (m), 1314 (s), 1234 (m), 1183 (m), 1161 (m), 1077 (m), 862 (m), 819 (m), 722 (m), 638 (m) $cm^{-1}$. $^1H$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 5.57, 5.56, 5.52, 5.57, 5.53, 5.44, 5.37 (C*H*); 2.1, 2.08, 2.07, 1.92, 1.88, 1.79, 1.47 (Me); 10.63 ppm (O*H*). $^{13}C$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 171.5, 174.3, 171.7 (*C*O); 150.7, 152.5, 157.0 (*C*H); 118.3, 120.2, 120.5, 121.7, 121.4, 121.9, 121.1 (*C*$Me_2$), 20.0, 19.9, 20.7, 19.7, 27.0, 27.0, 27.0 ppm (Me).

**Synthesis of $[Zr_6O_4(OH)_4(OOCCH_2Me)_3\{OOCC(Me){=}CH_2\}_9]_2$·$CH_2$=C(Me)COOH·5$MeCH_2COOH$ (6):** Propionic acid (1.37 g, 18.49 mmol) and methacrylic acid (0.618 g, 7.17 mmol) were added dropwise at room temperature to a stirred mixture of $Zr(OBu)_4$ (3.72 mmol, 1.78 g of a 80% butanol solution). After 24 h at room temperature colorless crystals were formed. The crystals were separated and dried in vacuo. Yield: 995 mg (85%). $C_{109}H_{164}O_{76}Zr_{12}$ (3785.1): calcd. C 34.59, H 4.37, $ZrO_2$ 39.06; found C 33.08, H 3.87, $ZrO_2$ 39.49 (TGA). IR-ATR: $\tilde{\nu}$ = 3393 (w, OH), 2979 (m), 1718 (m, COOH), 1595 (s, sh, $COO_{as}$), 1543 (s, $COO_{as}$), 1462 (s), 1421 (s, $COO_s$), 1372 (m), 1302 (s), 1244 (m), 1203 (m), 1080 (m), 936 (m, C=$CH_2$), 826 (m), 617 (m) $cm^{-1}$. $^1H$ NMR (Figure 10) ($C_7D_8$, 25 °C): $\delta$ = 0.99, 1.11, 1.24, 1.34, 1.40 (C$H_3$ propionate); 2.11, 2.24, 2.43, 2.57, 2.71 (C$H_2$ propionate); 6.30, 5.20, 6.40, 5.29, 6.26, 5.25 (C$H_2$ methacrylate); 11.70 ppm (O*H*). $^{13}C$ NMR ($C_7D_8$, 25 °C): $\delta$ = 178.3, 179.8, 184.1 (*C*O, methacrylate); 179.8, 179.6, 178.2, 184.2, 183.7 (*C*O, propionate); 137.5, 140.1, 139.9 (*C*Me, methacrylate); 123.1; 123.2; 125.5 (*C*$H_2$, methacrylate); 27.8, 30.2, 30.3, 29.9, 30.2 (*C*$H_2$, propionate); 18.2, 18.5, 18.4 (*C*$H_3$, methacrylate); 8.3, 9.6, 9.3, 9.7, 9.8 (*C*$H_3$, propionate) ppm.

**Synthesis of $[Zr_6O_4(OH)_4(OOCMe)_8\{OOCC(Me){=}CH_2\}_4]_2$·6MeCOOH (7):** Methacrylic acid (239 mg, 2.78 mmol) and acetic acid (423 mg, 7.04 mmol) were added dropwise to $Zr(OBu)_4$ (1.97 mmol, 945 mg of a 80% solution in BuOH) whilst stirring. Colorless needles were formed after 12 h at room temperature. The crystals were washed twice with *n*-heptane (1 mL) and dried in vacuo. Yield: 540 mg (98%). IR-ATR: $\tilde{\nu}$ = 3221 (w, OH), 2980 (vw, CH), 2956 (vw, CH), 2927 (vw, CH), 2875 (vw, CH), 1711 (m, C=O), 1643 (w, C=C), 1595 (sh), 1547 (s, $COO_{as.}$), 1448 (sh), 1422 (s, $COO_s$), 1373 (m, $COO_s$), 1344 (w), 1298 (w), 1245 (s), 1207 (sh), 1179 (w), 1047 (w), 1029 (w), 1007 (w), 937 (w), 902 (w), 883 (w), 852 (w), 827 (m), 798 (m), 674 (sh), 644 (vs, OCO), 631 (sh), 612 (vs, OCO) $cm^{-1}$. $^1H$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 6.17/5.66, 6.08/5.59, 6.06/5.59, 5.92/5.39 (C$H_2$=); 1.82, 1.77, 1.75, 1.68 (Me, methacrylate); 2.00, 1.95, 1.62, 1.47 (Me, acetate); 11.48 ppm (O*H*). $^{13}C$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 189.5, 180.1, 176.4, 175.4, 174.1 (*C*O, acetate); 183.5, 180.1, 171.1 (*C*O, methacrylate); 138.5, 135.9, 135.7, 135.6 (-*C*-); 127.2, 127.1, 126.9, 123.8 (*C*$H_2$=); 22.9, 23.1, 20.5 (Me, acetate); 17.8, 16.6 ppm (Me, methacrylate).

**Synthesis of $[Hf_6O_4(OH)_4(OOCMe)_{12}]_2$·6MeCOOH·3$CH_2Cl_2$ (8):** Acetic acid (1.92 g, 32.0 mmol) was added dropwise at room temperature to a stirred solution of $Hf(OBu)_4$ (3.2 mmol, 1.57 g of a 95% solution in BuOH) in $CH_2Cl_2$ (3 mL). After 24 h at room temperature colorless crystals were formed. The crystals were separated and dried in vacuo. Yield: 1.15 g (98%). $C_{63}H_{110}Cl_6Hf_{12}O_{76}$ (4438.1): calcd. C 17.05, H 2.50; found C 17.00, H 2.29. IR-ATR: $\tilde{\nu}$ = 3663 (w), 3387 (w), 1710 (m), 1558 (s), 1453 (s), 1261 (m), 1029 (m), 804 (m), 652 (s), 615 (s) $cm^{-1}$. $^1H$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 1.84, 1.94, 2.01, 2.04, 2.05 (Me), 10.32 (O*H*) ppm. $^{13}C$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 181.9, 177.8, 176.7 (*C*O); 23.5, 23.8, 23.0, 21.8, 21.1 (Me) ppm.

**Reaction of $[Zr_6O_4(OH)_4(OOCCH_2Me)_3\{OOCC(Me){=}CH_2\}_9]_2$ (6) with Propionic Acid:** An excess (1.94 g, 26.2 mmol) of propionic acid was added to a solution of **6** (165 mg, 0.043 mmol) in benzene (5 mL). The solution was stirred for 10 min, and then all volatile

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

compounds were removed in vacuo. This process was repeated twice.

**Reaction of $Zr_6O_4(OH)_4(OMc)_{12}$ (1) with Propionic Acid:** An excess (ca. 20 mmol) of propionic acid was added to a solution of **1** (226 mg, 0.133 mmol) in toluene (15 mL). The solution was stirred for 10 min, and then all volatile compounds were removed in vacuo. This process was repeated twice.

**X-ray Structure Analyses of 2–8:** Data collection (Table 1): The crystals were mounted on a Siemens SMART diffractometer (area detector) and measured in a nitrogen stream. Mo-$K_\alpha$ radiation ($\lambda$ = 71.069 pm, graphite monochromator) was used for all measurements. The data collection covered a hemisphere of the reciprocal space, by a combination of three or four sets of exposures. Each set had a different $\varphi$ angle for the crystal, and each exposure took 15 or 20 s and covered 0.3° in $\omega$. The crystal-to-detector distance was 5 cm. The data were corrected for polarization and Lorentz effects, and an empirical absorption correction (SADABS[12]) was employed. The cell dimensions were refined with all unique reflections. The structures were solved by the direct or the Patterson method (SHELXS97[13]). Refinement was performed by the full-matrix least-squares method based on $F^2$ (SHELXL97) with aniso-

# Facile Synthesis of Cyclometalated Ruthenium Complexes with Substituted Phenylpyridines

**Isabelle Sasaki,*[a] Laure Vendier,[a] Alix Sournia-Saquet,[a] and Pascal G. Lacroix[a]**

**Keywords:** Metallacycles / N ligands / Ruthenium

We have developed a new strategy that uses the Kröhnke synthesis for the preparation of various substituted phenylpyridines in excellent yields (up to 88 %). Starting with the appropriate commercially available acetophenone, a variety of phenylpyridines substituted by either electron-donating (i.e. methyl, methoxy) or -withdrawing groups (i.e. bromide, nitro) on the phenyl ring are obtained in a two-step synthesis. The corresponding functionalized cyclometalated ruthenium complexes can be prepared with unusually high yields by using methanol as reaction solvent. The electrochemical data of the complexes demonstrate the strong σ-donating character of the anionic phenylpyridine ligand. X-ray analyses of four complexes show a shortening of the Ru–C bond associated with the elongation of only one of the five Ru–N bonds (*trans* effect).

## Introduction

(Polypyridine)ruthenium(II) complexes have attracted much interest as light absorbers, photoluminescent sensors or switches, and intermolecular energy- and electron-transfer agents.[1] Some cyclometalated counterparts of these complexes have been prepared and their physical properties reported.[2–6] In fact, cyclometalated complexes have found widespread interest as species with promising properties in various fields[7] owing to the strong σ-donor ability of the cyclometalated ligand. Typically, the coordinating ligand forms a bond to the metal center and then intramolecular C–H activation takes place to yield a five-membered chelate ring. Replacement of a nitrogen donor by a formal carbanion donor drastically increases the electron density around the metal atom[4] and the crystal-field strength.[5]

A variety of synthetic methodologies[8] for the synthesis of new pyridine derivatives have been developed. One of the most important is the transition-metal-catalyzed cross-coupling reactions of precursors developed by Negishi, Suzuki, and Stille (see refs.[9–11]). In fact, all these methods entail the preparation of functionalized intermediates.[12] In the course of our studies we have prepared a number of polypyridine ligands[13] by using the Kröhnke method.[14] By extending this procedure to aromatic ketones, we propose an easy and versatile synthesis of substituted phenylpyridines.[15] Starting from commercially available acetophenones, a variety of mono- or difunctionalized phenylpyridines substituted by electron-donating (i.e. methyl, methoxy) or -withdrawing groups (i.e. bromide, nitro) on the phenyl ring can be obtained with very good yields.

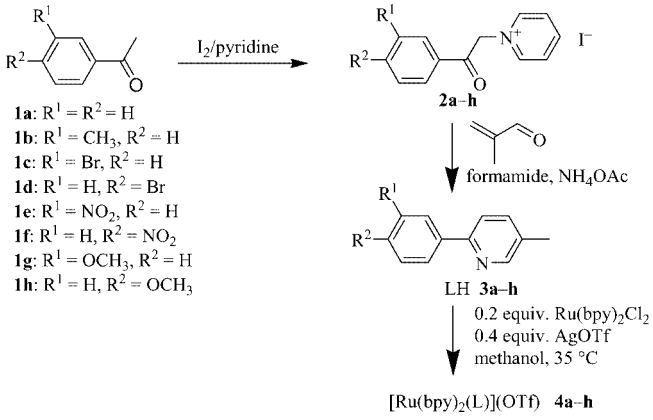
## Results and Discussion

### Synthesis

Our synthetic route starts with the preparation of the pyridinium derivative of the appropriate aromatic methyl ketone.[14] Condensation of these derivatives with methacrolein gives the corresponding phenylpyridines, as described in Scheme 1. We also checked this synthesis with tiglic aldehyde[16] to show that this methodology can be extended to other α,β-unsaturated carbonyl compounds.



Scheme 1.

The different ligands synthesized in this work are summarized together with the few previously reported molecules in Table 1. To the best of our knowledge, no crystal structure of a phenylpyridine has been published (vide infra).

Table 1. List and yields of ligands LH prepared by this method.

| | | Yield [%] | Ref. |
|---|---|---|---|
| **3a**: | $R^1 = R^2 = R^3 = H$ | 88 | [15,17,18] |
| | $R^1 = R^2 = H$, $R^3 = CH_3$ | 84 | [21] |
| **3b**: | $R^1 = CH_3$, $R^2 = R^3 = H$ | 88 | [10] |
| **3c**: | $R^1 = Br$, $R^2 = R^3 = H$ | 62 | |
| **3d**: | $R^1 = R^3 = H$, $R^2 = Br$ | 82 | [20] |
| **3e**: | $R^1 = NO_2$, $R^2 = R^3 = H$ | 77 | |
| **3f**: | $R^1 = R^3 = H$, $R^2 = NO_2$ | 79 | |
| **3g**: | $R^1 = OCH_3$, $R^2 = R^3 = H$ | 81 | |
| **3h**: | $R^1 = R^3 = H$, $R^2 = OCH_3$ | 76 | [19,20] |

The different products were obtained in good yields and their characterizations were carried out by $^1H$ and $^{13}C$ NMR spectroscopy as well as by mass spectrometry (FAB or DCI) and microanalysis (see Experimental Section). These compounds offer the possibility for further reactions on both aromatic rings; for example, the Br atom on the phenyl ring can be replaced in various reactions and the $NO_2$ group can be reduced, whereas the pyridine ring can be functionalized thanks to the methyl group.[22]

The synthesis of five cyclometalated $Ru^{II}$ complexes was carried out by Constable's method[4] with a modification proposed by Coudret,[23] which uses only 5 equiv. of ligand instead of a 15-fold excess.[4] We obtained much higher yields of cyclometalated complexes (up to 90%) than according to the literature procedure by using methanol instead of dichloromethane[4] as solvent. Constable[24] has studied the effect of different solvents in the reactions of 6-phenyl-2,2′-bipyridine with ruthenium(II) and concluded that the higher the dielectric constant of the solvent the greater the proportion of the metalated product formed (as is the case with methanol compared to dichloromethane). Purification of the complexes was carried out by column chromatography, which enables recovery of the unreacted excess of ligand. This synthesis yields the corresponding functionalized ruthenium complexes directly, whereas in the literature functionalization was carried out on the ruthenium complexes. Using 3,5-dipyridylbenzene, Collin et al. converted the corresponding cyclometalated complex into the nitro derivative and subsequently into the amino derivative.[25] More recently, Coudret was able to obtain the corresponding bromo-substituted complex upon treatment of $[Ru(bpy)_2L]^+$ (L = phenpy) with NBS.[25] The synthesis of the amino derivative was also carried out.[26] The different direct functionalizations of the complex were possible only at the position *para* to the carbanion.[27] In our case, by using the appropriate starting material (acetophenone), other positions of the substituent on the ligand and therefore in the complex are accessible.

Complete assignment of the $^1H$ and $^{13}C$ NMR spectra of the complexes required 1D, 2D $^1H$-$^1H$ COSY, HMQC $^1H$-$^{13}C$ and HMBC $^1H$-$^{13}C$ experiments. The labelling of the atoms is that of the X-ray structures. For the five complexes, comparison of the $^1H$ NMR spectra shows that the peaks corresponding to the phenylpyridine ring are influenced by the electronic character of the substituents on the phenyl ring. More precisely, in the high-field region between $\delta$ = 7.3 and 5.9 ppm, the most high-field-shifted doublet is assigned to the proton of the phenyl ring (8-H) in the *ortho* position and its chemical shift varies from $\delta$ = 5.95 (methoxy derivative **4h**) to 7.3 ppm (nitro derivative **4f**). The upfield shift of the proton adjacent to the site of metalation is a common feature of compounds of this type.[4,24,28] The other shielded doublet (between $\delta$ = 6.45 and 7.05 ppm) is attributed to the proton *meta* (9-H, complex **4a**) or *para* (10-H, complexes **4b**, **4d**, and **4h**) to the metalated carbon atom. An exception is observed for **4f**, for which the proton 10-H is highly deshielded ($\delta$ = 7.69 ppm) due to the electron-withdrawing character of the nitro substituent.

## X-ray Analysis

Single crystals of ligands **3a** and **3b** were obtained after slow concentration of a mixture of pentane and ethyl acetate. The ORTEP diagrams of **3a** and **3b** are shown in Figure 1.

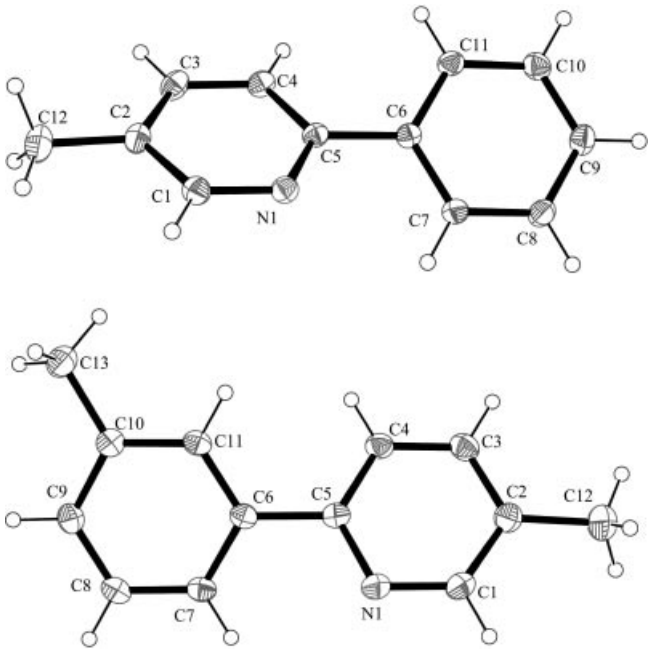

Figure 1. X-ray molecular structures of **3a** (top) and **3b** (bottom).

Ligand **3a** crystallizes in the $P2_12_12_1$ orthorhombic space group. The two aromatic rings are not planar, with an N(1)–C(5)–C(6)–C(7) torsion angle of 32.3°. Ligand **3b** crystallizes in the $P2_1/n$ monoclinic space group. The molecule is slightly more planar than **3a**, with an N(1)–C(5)–C(6)–C(7) torsion angle of 28.4°. As these compounds are not symmetrical, and as the exact position of the substituents can be unambiguously determined by NMR spectroscopy and because of the synthetic scheme, the position of the nitrogen atom is well defined. This is important for the analysis of the X-ray data of the complexes.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Crystals of the four complexes **4b′**, **4d**, **4f**, and **4h** were obtained for X-ray analysis (Figure 2). In one case (**4b**), good-quality crystals were available only after exchange of the trifluoromethanesulfonate counteranion by hexafluorophosphate to give complex **4b′**. Crystallization occurred upon slow diffusion of diethyl ether into acetonitrile solutions of the complexes at 5 °C.

The ruthenium complex **4b′** crystallizes in the $P2_1/n$ monoclinic space group. The asymmetric unit cell contains one ruthenium complex, one $PF_6^-$ anion, and one molecule of acetone. The phenylpyridine ligand is almost perfectly planar in the complex, with an N(1)–C(5)–C(6)–C(7) torsion angle of 0.59° against torsion angles of 2.69° and 1.73° in the bipyridine ligands with N(2)/N(3) and N(4)/N(5), respectively. The brominated complex **4d** crystallizes in the $C2/c$ monoclinic space group. The unit cell contains eight molecules of complex ($Z = 8$), and four molecules of water. The phenylpyridine ligand is roughly planar, with an N(1)–C(5)–C(6)–C(7) torsion angle of 2.95° against torsion angles of 3.00° and 0.27° in the bipyridine ligands with N(2)/N(3) and N(4)/N(5), respectively. Complex **4f** crystallizes in the $P2_1/n$ monoclinic space group, with one molecule in the asymmetric unit cell. The bipyridine ligands are nearly perfectly planar in the complex, with torsion angles of 0.30° and 0.40° for the bipyridine ligands with N(2)/N(3) and N(4)/N(5), respectively. By contrast, the torsion angle in the phenylpyridine ligand is 1.63°. Complex **4h** crystallizes in the $P\bar{1}$ triclinic space group. The asymmetric unit cell contains one ruthenium complex, one $CF_3SO_3^-$ anion, and one molecule of acetonitrile. The phenylpyridine ligand is perfectly planar (torsion angle of 0.17°), whereas the bipyridine ligands are slightly distorted, with torsion angles of 5.96° and 4.46° for the bipyridine ligands with N(2)/N(3) and N(4)/N(5), respectively.

The Cambridge Crystallographic Database contains 156 entries with a (phenylpyridine)metal unit, most of them containing platinum (55) and palladium (24). However, structures containing a $(bpy)_2$(phenpy)metal unit are far

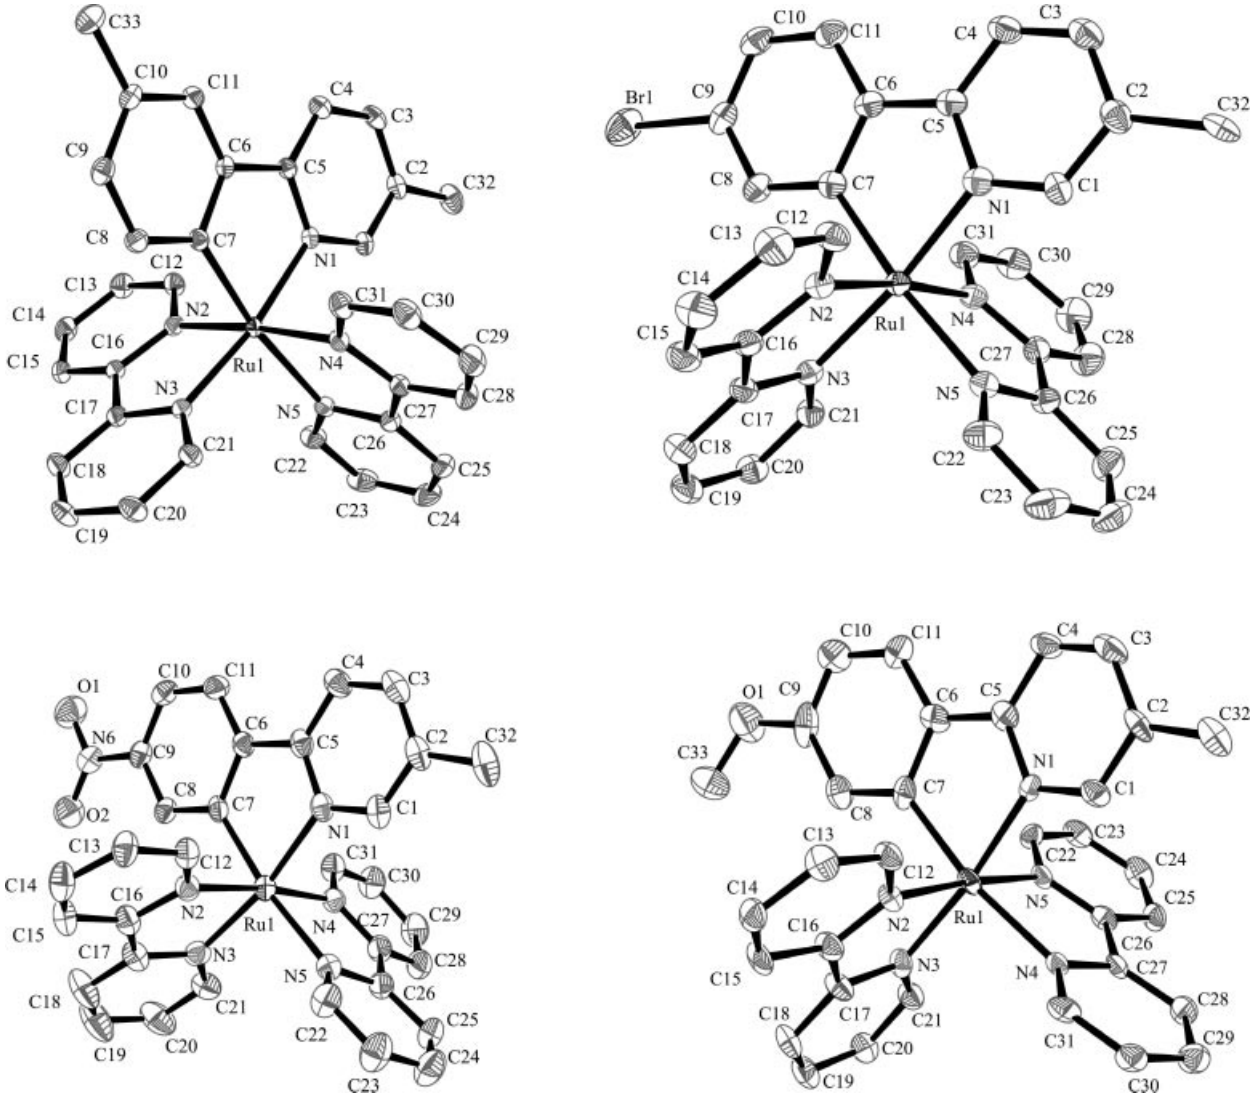

Figure 2. ORTEP representation of the X-ray structureS of **4b′** (top left), **4d** (top right), **4f** (bottom left), and **4h** (bottom right). The hydrogen atoms, solvent molecules, and counteranions are omitted for clarity.

| Av. value | 2.029(5) | 2.074(4) | 2.045(4) | 2.046(4) | 2.064(4) | 2.125(4) |
| **a**[a] | 1.997(7) | 2.075(5) | 2.040(5) | 2.056(5) | 2.086(5) | 2.140(5) |
| **b**[a] | 2.044(1) | 2.069(4) | 2.067 | 2.046 | 2.037 | 2.075 |

[a] **a**: $[Ru(bpy)_2(NPP)][BF_4]$[6] [NPP = 2-(3-nitrophenyl)pyridine]. **b**: $[Ru(bpy)_2(ppy)][PF_6]$[28] (ppy = phenylpyridine).

less common, with only four entries.[6,29–31] In two of them, namely $[Ru(bpy)_2(phenpy)][CrMn(ox)_3]$[30] and $[Rh(bpy)_2(phenpy)](PF_6)$,[31] the localization of the carbon atom was not possible. In the third complex, $[Ru(bpy)_2(phenpy)](PF_6)$,[29] the carbon atom was arbitrarily localized because its distribution was equal on the six atomic sites bonded to the Ru atom. Finally, the only crystal structure in which the carbon–metal bond was unambiguously identified is that of $[Ru^{II}(bpy)_2\{2\text{-(nitrophenyl)pyridine}\}](BF_4)$, reported by Reveco et al.[6] The description of the coordination sphere of the four new complexes **4b′**, **4d**, **4f**, and **4h** is compared to the previously reported structures in Table 2. First of all, it must be pointed out that the position of the carbon atom is unambiguous as the positions of the substituents in the unsymmetrical ligands are definite. The average metal–ligand distances for the four available structures were calculated and show the following general features: (1) whereas the Ru(1)–C(7) bond is shorter than the other metal–ligand bonds, the Ru–N bonds to both the nitrogen atom *trans* to the carbon atom [N(5)] and the one *cis* to the carbon atom [N(1)] are slightly elongated, which leads to a distorted octahedral geometry around the metal atom; (2) the Ru(1)–N(4) bond is also slightly elongated, but less than Ru(1)–N(5), probably because it belongs to the same bipyridine ligand; (3) the Ru(1)–N(2) and Ru(1)–N(3) bond lengths have similar values, thus showing that this bipyridine ligand is the least disturbed by the cyclometalating ligand. Interestingly, comparison of the Ru(1)–C(7) bond length [1.997(7) Å] in $[Ru^{II}(bpy)_2\{2\text{-(3-nitrophenyl)pyridine}\}](BF_4)$[6] and that in complex **4f** [2.020(4) Å, the smallest value in the series of complexes **4**], in which the nitro substituent is at the 4-position, demonstrates the influence of the electron-withdrawing character of the substituent. More precisely, in the *para* position, both inductive and mesomeric effects are transmitted to C(9) whereas in the *meta* position (complex **4f**) only an inductive effect is in operation.

## Electrochemistry

The ligands and ruthenium complexes were examined by cyclic voltammetry (Figure 3) and Osteryoung square-wave voltammetry (Table 3).

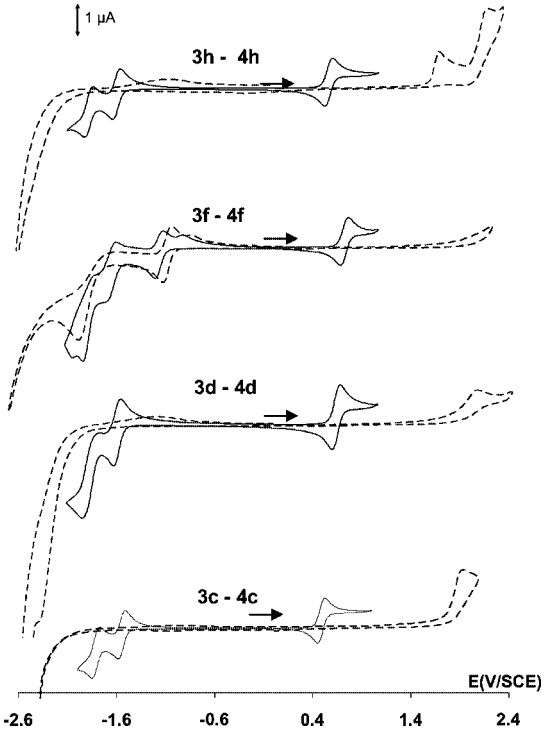

Figure 3. Cyclic voltammograms at room temperature of ruthenium complexes **4c**, **4d**, **4f**, **4h** (solid line) and ligands **3c**, **3d**, **3f**, **3h** (dashed line) in $CH_3CN$ with 0.1 M $TBABF_4$ as supporting electrolyte (Pt electrode, $v = 0.1\ V\,s^{-1}$).

Ligands **3c**, **3d**, and **3h** exhibit two processes: one in oxidation (ca. 1.9 V) and one in reduction (ca. –2.4 V). However, ligand **3h** presents another oxidation (1.55 V) due to the methoxy substituent. Ligand **3f** displays two reduction processes: a reversible redox couple at –1 V assigned to the $NO_2$ substituent and an irreversible reduction at –1.84 V (much higher than those of other ligands). This suggests that because of the electron-withdrawing properties of the $NO_2$ group, the oxidation is also dramatically shifted to higher potentials that are not measurable under the experimental conditions.

Cyclic voltammetry of the complexes exhibits three characteristic processes: one oxidation process and two reduction processes.

First, the reversible redox couple at around 0.5 V is readily assigned to the $Ru^{III}/Ru^{II}$ process.[4,32] A comparison of the potentials in Table 3 indicates that the first metal-cen-

|---|---|---|---|---|---|---|---|
| | $E_{1/2}$[a] | $E_{1/2}$[b] | $E_{1/2}$[b] | $E_{1/2}$[a] | $E_{1/2}$[a] | $E_{1/2}$[a] | $E_{1/2}$[b] |
| **3c** | | | 1.90 | | | | –2.44 |
| **3d** | | | 1.91 | | | | –2.19 |
| **3f** | | | n.d.[c] | –1.04 | | | –1.84 |
| **3h** | | 1.55 | 1.99 | | | | –2.55 |
| **4c** | 0.48 | | 1.73 | | –1.54 | –1.82 | –2.40 |
| **4d** | 0.60 | | 1.77 | | –1.51 | –1.76 | –2.24 |
| **4f** | 0.67 | | 1.99 | –1.12 | –1.57 | –1.81 | –1.94 |
| **4h** | 0.52 | 1.63 | n.d.[c] | | –1.53 | –1.79 | –2.37 |
| $Ru(bpy)_3$[33] | 1.29 | | | | –1.35 | –1.54 | –1.73 |

[a] The $E_{1/2}$ values were estimated as the average of the cathodic and anodic peak potentials in cyclic voltammetry with a scan rate of 100 mV $s^{-1}$. [b] The $E_{1/2}$ values were obtained from the square-wave voltammogram: frequency 20 Hz, step potential 5 mV, amplitude 20 mV. [c] Not observed or badly defined under the experimental conditions.

tered oxidation of the complex is shifted by about 800 mV to more cathodic potentials than that of $[Ru(bpy)_3]$.[33] This behavior demonstrates the strong σ-donating character of the phenylpyridine ligands, which stabilize $Ru^{III}$ by increasing the electron density on the metal atom.[4,7c] Moreover, the nature of the substituents affects the shift of the $Ru^{III}/Ru^{II}$ potential. The methyl and methoxy substituents with electron-donating character induce the most significant shift, whereas the electron-withdrawing groups (Br and $NO_2$), which decrease the electron density on $Ru^{III}$, lower the magnitude of the shift.

Second, the complexes exhibit two reduction processes at around –1.55 and –1.80 V (–1.35 and –1.54 V for $[Ru(bpy)_3]$). Complex **4f** displays an additional first reduction process at –1.12 V assigned to the $NO_2$ substituent. Generally, compared to $[Ru(bpy)_3]$, the bpy-centered quasi-reversible reductions are shifted to more negative potentials and are also strongly affected by the presence of the cyclometallating ligand,[7c] but the nature of the substituents does not affect significantly these processes. Moreover, the most cathodic potentials near the solvent/electrolyte limit were resolved in the square-wave experiment and were assigned to the phenylpyridine ligand.

## Conclusions

We have been able to synthesize new substituted phenylpyridines in high yields by a very simple general method from cheap, commercially available starting materials. Functionalized cyclometalated ruthenium(II) complexes were obtained in much higher yields than the few examples described in the literature. As crystals for four of them were obtained, an X-ray study highlighted specific features of the Ru–C and the *trans*-Ru–N bonds. The easiness in obtaining first the ligands and then the cyclometalated complexes is a breakthrough for the application of these complexes. By a "building block" approach, involving convergent synthesis, these compounds could lead to various polynuclear complexes[34] or to new compounds with potential NLO properties.[22]

## Experimental Section

**General:** Reagents and solvents were commercially available and were used as received. $[Ru(bpy)_2Cl_2]$ was prepared according to a literature procedure.[35] $^1H$ and $^{13}C$ NMR spectra were obtained at 298 K in $CDCl_3$, $CD_3COCD_3$, or $(CD_3)_2SO$ with a Bruker AM 250 spectrometer (250 MHz for $^1H$ NMR and 62.9 MHz for $^{13}C$) or a Bruker Avance 500 spectrometer for 2D NMR. DCI and EI mass spectra were recorded with a Thermo Finnigan TSQ 7000 and FAB mass spectra were recorded with a quadrupolar Nermag R 10-10 instrument with NBA as matrix. Elemental analyses were performed at the LCC with a Perkin–Elmer 2400 Serie II instrument. Electrochemistry data: Voltammetric measurements were carried out with a potentiostat Autolab PGSTAT 100. A home-made, airtight three-electrode cell connected to a vacuum/argon line made up of a Pt disk (0.5 mm diameter) as working electrode, a Pt gauze as auxiliary electrode, and an SCE as reference electrode. All experiments were performed at ambient temperature in $CH_3CN$ solution, with 0.1 M $nBu_4NBF_4$ as supporting electrolyte (purum electrochemical grade Fluka, purified by sublimation). The solutions used for the electrochemical studies were typically $10^{-3}$ M in ruthenium complex. Prior to measurements, the solutions were deoxygenated by bubbling with argon gas for 15 min and the working electrode was polished with a polishing machine (Presi P230); during experiments, a stream of argon was passed over the solution. All potentials are reported vs. SCE.

**X-ray Analysis:** Data collection (Table 4) was performed at low temperature (180 K) with an IPDS STOE diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å) and an Oxford Cryosystems Cryostream Cooler Device. The final unit-cell parameters were obtained by means of a least-squares refinement performed on a set of 5000 well-measured reflections. Crystal decay was monitored during the data collection; no significant fluctuations of intensities were observed. The structures were solved by direct methods using SIR92,[36] and refined by means of least-squares procedures on $F^2$ with the aid of the program SHELXL97[37] included in the software package WinGX version 1.63.[38] Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[39] All hydrogen atoms were located geometrically and refined by using a riding model. All non-hydrogen atoms were refined anisotropically, and in the last cycles of refinement a weighting scheme was used, where weights are calculated from the following formula: $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$. Drawings of the molecules were produced with the program ORTEP32,[40] with 30% probability displacement ellipsoids for non-hydrogen atoms. CCDC-603013 to -603018 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Typical Procedure for the Preparation of the Pyridinium Derivatives 2a–h:** A solution of sublimated iodine (5.25 g, 20.5 mmol) in 8 mL of dry pyridine was added to a solution of 20 mmol of acetophenone in 5 mL of dry pyridine. After heating at 80 °C for 6 h, then cooling, the precipitate was filtered off, rinsed once with pyridine, dried, and recrystallized from boiling ethanol. The corresponding pyridinium derivative was isolated as a beige powder.

**Compound 2a:** Yield: 4.03 g (62%). $^1$H NMR ([D$_6$]DMSO): $\delta$ = 9.01 (d, $J$ = 5.5 Hz, 2 H), 8.75 (dt, $J$ = 7.9 and 1.2 Hz, 1 H), 8.29 (t, $J$ = 7.4 Hz, 2 H), 8.07 (dd, $J$ = 7 and 1.4 Hz, 2 H), 7.79 (m, 1 H), 7.67 (dt, $J$ = 7.6 and 1.7 Hz, 2 H), 6.51 (s, 2 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 190.6, 146.4, 146.2, 134.7, 133.4, 129.1, 128.2, 127.8, 66.3 ppm. $C_{13}H_{12}INO$ (325.14): calcd. C 48.02, H 3.72, N 4.31; found C 47.92, H 3.38, N 4.09. FAB-MS: $m/z$ = 198 [M–I]$^+$.

**Compound 2b:** Yield: 4.27 g (63%). $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.98 (d, $J$ = 5.5 Hz, 2 H), 8.71 (t, $J$ = 7.8 Hz, 1 H), 8.24 (dd, $J$ = 7.3 and 6.6 Hz, 2 H), 7.86 (s, 1 H), 7.84 (d, $J$ = 6.3 Hz, 1 H), 7.54 (m, 2 H), 6.44 (s, 2 H), 2.44 (s, 3 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 190.6, 146.3, 146.2, 138.5, 135.3, 133.5, 129.0, 128.4, 127.8, 125.5, 66.2, 20.8 ppm. $C_{14}H_{14}INO$ (339.17): calcd. C 49.58, H 4.16, N 4.13; found C 49.58, H 4.27, N 4.00. FAB-MS: $m/z$ = 212 [M–I]$^+$.

**Compound 2c:** Yield: 6.30 g (78%). $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.97 (d, $J$ = 5.5 Hz, 2 H), 8.76 (t, $J$ = 7.8 Hz, 1 H), 8.30 (dd, $J$ = 7.2 and 6.8 Hz, 2 H), 8.22 (m, 1 H), 8.1–8.0 (m, 2 H), 7.65 (t, $J$ = 7.9 Hz, 1 H), 6.48 (s, 2 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 189.8, 146.5, 146.2, 137.1, 135.5, 131.4, 130.7, 127.9, 127.2, 122.3, 66.2 ppm. $C_{13}H_{11}BrINO$ (404.04): calcd. C 38.65, H 2.74, N 3.47; found C 38.71, H 2.55, N 3.33. FAB-MS: $m/z$ = 277 [M–I]$^+$.

**Compound 2d:** Yield: 6.30 g (78%). $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.97 (d, $J$ = 5.5 Hz, 2 H), 8.74 (t, $J$ = 7.8 Hz, 1 H), 8.28 (dd, $J$ = 7.1 and 7 Hz, 2 H), 8.00 (d, $J$ = 8.6 Hz, 2 H), 7.90 (d, $J$ = 8.6 Hz, 2 H), 6.45 (s, 2 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 190.0, 146.4, 146.2, 132.5, 132.2, 130.1, 128.8, 127.8, 66.1 ppm. $C_{13}H_{11}BrINO$ (404.04): calcd. C 38.65, H 2.74, N 3.47; found C 38.55, H 2.50, N 3.24. FAB-MS: $m/z$ = 277 [M–I]$^+$.

**Compound 2e:** Yield: 5.55 g (75%). $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.98 (d, $J$ = 5.7 Hz, 2 H), 8.76 (m, 2 H), 8.63 (dd, $J$ = 8.2 and 2 Hz, 1 H), 8.48 (d, $J$ = 7.8 Hz, 1 H), 8.31 (dd, $J$ = 7.1 and 7 Hz, 2 H), 7.98 (t, $J$ = 8 Hz, 1 H), 6.55 (s, 2 H) ppm. $^{13}$C NMR ([D$_6$]-DMSO): $\delta$ = 189.6, 148.0, 146.6, 146.2, 134.8, 134.3, 131.0, 128.6, 127.9, 122.5, 66.3 ppm. $C_{13}H_{11}IN_2O_3$ (370.14): calcd. C 42.18, H 3.00, N 7.57; found C 42.22, H 2.92, N 7.45. FAB-MS: $m/z$ = 243 [M–I]$^+$.

**Compound 2f:** Yield: 5.33 g (72%). $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.97 (d, $J$ = 5.5 Hz, 2 H), 8.76 (t, $J$ = 7.8 Hz, 1 H), 8.48 (d, $J$ = 8.8 Hz, 2 H), 8.27–8.32 (m, 4 H), 6.51 (s, 2 H) ppm. $^{13}$C NMR ([D$_6$]-DMSO): $\delta$ = 190.0, 146.4, 146.2, 132.5, 132.2, 130.1, 128.8, 127.8, 66.1 ppm. $C_{13}H_{11}IN_2O_3$ (370.14): calcd. C 42.18, H 3.00, N 7.57; found C 42.33, H 2.95, N 7.46. FAB-MS: $m/z$ = 243 [M–I]$^+$.

**Compound 2g:** Yield: 5.82 g (82%). $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.99 (d, $J$ = 5.5 Hz, 2 H), 8.75 (t, $J$ = 7.8 Hz, 1 H), 8.29 (dd, $J$ = 7.5 and 6.6 Hz, 2 H), 7.70–7.55 (m, 2 H), 7.54 (s, 1 H), 7.39 (md, $J$ = 7.7 Hz, 1 H), 6.48 (s, 2 H), 3.87 (s, 3 H) ppm. $^{13}$C NMR ([D$_6$]-DMSO): $\delta$ = 190.4, 159.4, 146.3, 146.2, 134.7, 130.3, 127.8, 120.6, 120.4, 112.7, 66.3, 55.5 ppm. $C_{14}H_{14}INO_2$ (355.17): calcd. C 47.34, H 3.97, N 3.94; found C 47.39, H 3.97, N 4.00. FAB-MS: $m/z$ = 228 [M–I]$^+$.

**Compound 2h:** Yield: 5.11 g (72%). $^1$H NMR ([D$_6$]DMSO): $\delta$ = 9.00 (d, $J$ = 5.5 Hz, 2 H), 8.74 (t, $J$ = 7.8 Hz, 1 H), 8.27 (dd, $J$ = 7.5 and 6.7 Hz, 2 H), 8.05 (d, $J$ = 8.8 Hz, 2 H), 7.19 (d, $J$ = 8.8 Hz, 2 H), 6.45 (s, 2 H), 3.90 (s, 3 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 188.8, 164.2, 146.2, 130.7, 127.7, 126.2, 114.4, 66.9, 55.8 ppm. $C_{14}H_{14}INO_2$ (355.17): calcd. C 47.34, H 3.97, N 3.94; found C 47.22, H 3.60, N 3.72. FAB-MS: $m/z$ = 228 [M–I]$^+$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Typical Procedure for the Preparation of the Phenylpyridines 3a–h:** $NH_4OAc$ (4 equiv., 8 mmol) and methacrolein (4 mmol) were added to a solution of the pyridinium derivative (2 mmol) in 5 mL of formamide. The reaction mixture was heated at 80 °C for 6 h and, after cooling, the ligand precipitated and was filtered off and rinsed with water. If the ligand did not precipitate it was extracted with $Et_2O$ (3×20 mL), the organic phase was dried with $MgSO_4$, concentrated to dryness, and purified by chromatography on silica gel with EtOAc in pentane (10:90) or methanol in dichloromethane (3:97) as eluent.

**5-Methyl-2-phenylpyridine (3a):** $^1$H NMR ($CDCl_3$): $\delta$ = 8.51 (d, $J$ = 1.2 Hz, 1 H), 7.96 (m, 2 H), 7.62 (d, $J$ = 8 Hz, 1 H), 7.54 (dd, $J$ = 8 and 2.1 Hz, 1 H), 7.49–7.35 (m, 3 H), 2.36 (s, 3 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 154.7, 150.0, 139.3, 137.4, 131.6, 128.7, 128.6, 126.7, 120.0, 18.2 ppm. $C_{12}H_{11}N$(169.23): calcd. C 85.21, H 6.51, N 8.28; found C 85.29, H 6.37, N 8.21. DCI-MS: $m/z$ = 170 $[MH]^+$.

**5-Methyl-2-(3-methylphenyl)pyridine (3b):** $^1$H NMR ($CDCl_3$): $\delta$ = 8.51 (s, 1 H), 7.79 (s, 1 H), 7.71 (d, $J$ = 7.5 Hz, 1 H), 7.61 (d, $J$ = 8 Hz, 1 H), 7.53 (dd, $J$ = 8.1 and 1.9 Hz, 1 H), 7.34 (t, $J$ = 7.6 Hz, 1 H), 7.19 (d, $J$ = 7.5 Hz, 1 H), 2.42 (s, 3 H), 2.35 (s, 3 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 154.9, 150.0, 139.3, 138.3, 137.3, 131.5, 128.6, 127.4, 123.8, 120.1, 21.5, 18.1 ppm. $C_{13}H_{13}N$ (183.25): calcd. C 85.21, H 6.51, N 8.28; found C 85.29, H 6.37, N 8.21. DCI-MS: $m/z$ = 184 $[MH]^+$.

**2-(3-Bromophenyl)-5-methylpyridine (3c):** $^1$H NMR ($CDCl_3$): $\delta$ = 8.51 (s, 1 H), 7.87 (td, $J$ = 7.8 and 1.5 Hz, 1 H), 7.58 (m, 2 H), 7.50 (ddd, $J$ = 8, 1.7 and 0.8 Hz, 1 H), 7.32 (t, $J$ = 8 Hz, 1 H), 2.38 (s, 3 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 152.9, 150.1, 141.3, 137.4, 132.3, 131.4, 130.2, 129.7, 125.1, 123.0, 120.0, 18.2 ppm. $C_{12}H_{10}BrN$ (248.12): calcd. C 58.09, H 4.06, N 5.65; found C 58.15, H 3.74, N 5.52. DCI-MS: $m/z$ (%) = 248 (96), 250 (100) $[MH]^+$.

**2-(4-Bromophenyl)-5-methylpyridine (3d):** $^1$H NMR ($CDCl_3$): $\delta$ = 8.49 (d, $J$ = 0.6 Hz, 1 H), 7.83 (m, 2 H), 7.58 (m, 4 H), 2.35 (s, 3 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 153.5, 150.1, 138.2, 137.5, 132.0, 131.8, 128.2, 123.0, 119.8, 18.2 ppm. $C_{12}H_{10}BrN$ (248.12): calcd. C 58.09, H 4.06, N 5.65; found C 58.14, H 3.93, N 5.59. DCI-MS: $m/z$ (%) = 248 (100), 250 (95) $[MH]^+$.

**5-Methyl-2-(3-nitrophenyl)pyridine (3e):** $^1$H NMR ($CDCl_3$): $\delta$ = 8.81 (s, 1 H), 8.54 (s, 1 H), 8.33 (d, $J$ = 7.7 Hz, 1 H), 8.22 (dd, $J$ = 8 and 1.1 Hz, 1 H), 7.70 (d, $J$ = 8 Hz, 1 H), 7.62 (m, 2 H), 2.40 (s, 3 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 152.0, 150.4, 148.7, 141.0, 137.7, 133.1, 132.5, 129.6, 123.2, 122.5, 120.1, 18.2 ppm. $C_{12}H_{10}N_2O_2$ (214.22): calcd. C 67.28, H 4.70, N 13.08; found C 67.13, H 4.44, N 12.97. DCI-MS: $m/z$ = 215 $[MH]^+$.

**5-Methyl-2-(4-nitrophenyl)pyridine (3f):** $^1$H NMR ($CDCl_3$): $\delta$ = 8.57 (s, 1 H), 8.31 (d, $J$ = 8.9 Hz, 2 H), 8.15 (d, $J$ = 8.9 Hz, 2 H), 7.71 (d, $J$ = 8.1 Hz, 1 H), 7.62 (dd, $J$ = 8.1 and 1.8 Hz, 1 H), 2.41 (s, 3 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 152.0, 150.4, 148.7, 141.0, 137.7, 133.1, 132.5, 129.6, 123.2, 122.5, 120.1, 18.2 ppm. $C_{12}H_{10}N_2O_2$ (214.22): calcd. C 67.28, H 4.70, N 13.08; found C 67.41, H 4.34, N 12.95. DCI-MS: $m/z$ = 215 $[MH]^+$.

**2-(3-Methoxyphenyl)-5-methylpyridine (3g):** $^1$H NMR ($CDCl_3$): $\delta$ = 8.51 (d, $J$ = 1.5 Hz, 1 H), 7.60 (t, $J$ = 8 Hz, 1 H), 7.55 (m, 2 H), 7.36 (t, $J$ = 8 Hz, 1 H), 6.93 (dd, $J$ = 8.2 and 2.5 Hz, 1 H), 3.88 (s, 3 H), 2.36 (s, 3 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 160.0, 154.5, 150.0, 140.9, 137.3, 131.7, 129.6, 120.1, 119.1, 114.7, 111.7, 55.3, 18.2 ppm. $C_{13}H_{13}NO$ (199.25): calcd. C 78.39, H 6.53, N 7.03; found C 78.08, H 6.60, N 6.83. DCI-MS: $m/z$ = 200 $[MH]^+$.

**2-(4-Methoxyphenyl)-5-methylpyridine (3h):** $^1$H NMR ($CDCl_3$): $\delta$ = 8.47 (s, 1 H), 7.90 (dd, $J$ = 8.7 and 1.6 Hz, 2 H), 7.6–7.5 (m, 2 H), 6.97 (dd, $J$ = 8.8 and 1.8 Hz, 2 H), 3.86 (s, 3 H), 2.34 (s, 3 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 160.1, 154.3, 149.8, 137.2, 133.0, 130.8, 127.8, 119.2, 114.0, 55.2, 18.0 ppm. $C_{13}H_{13}NO$ (199.25): calcd. C 78.39, H 6.53, N 7.03; found C 78.30, H 6.59, N 6.96. DCI-MS: $m/z$ = 200 $[MH]^+$.

**General Procedure for the Preparation of the Complexes:** [Ru(bpy)$_2$Cl$_2$] (0.15 mmol) and AgOTf (0.30 mmol) were added to a solution of the ligand (0.75 mmol) in 5 mL of MeOH, and the mixture was refluxed in the dark for 2 h. After cooling and filtration of a brown precipitate, the filtrate was concentrated off and purification was carried out by chromatography on alumina. Elution with EtOAc/pentane (10:90) provided unreacted ligand and further elution with MeOH/$CH_2Cl_2$ (3:97) gave the pure complex.

**Complex 4a:** Yield: 98 mg (90%). $^1$H NMR ($CD_3COCD_3$): $\delta$ = 8.77 (dt, $J$ = 8.2 and 1 Hz, 1 H, H25), 8.68 (dt, $J$ = 8 and 1.1 Hz, 1 H, H28), 8.61 (dt, $J$ = 8 and 1 Hz, 1 H, H18), 8.59 (dt, $J$ = 8 and 1 Hz, 1 H, H15), 8.16 (ddd, $J$ = 5.7, 1.5 and 0.7 Hz, 1 H, H31), 8.13 (ddd, $J$ = 9.2, 5.6 and 1.5 Hz, 1 H, H24), 8.06 (d, $J$ = 8.3 Hz, 1 H, H4), 8.05 (m, 1 H, H22), 7.98–7.93 (m, 3 H, H12, H29, H19), 7.92–7.86 (m, 3 H, H11, H14, H21), 7.62 (ddd, $J$ = 8.7, 2.1 and 0.7 Hz, 1 H, H3), 7.59 (ddd, $J$ = 7.5, 5.4 and 1.2 Hz, 1 H, H23), 7.56 (m, 1 H, H1), 7.39–7.34 (m, 3 H, H20, H30, H13), 6.88 (dd, $J$ = 7.2 and 1.3 Hz, 1 H, H10), 6.81 (td, $J$ = 7.3 and 1.3 Hz, 1 H, H9), 6.18 (ddd, $J$ = 7.3, 1.3 and 0.4 Hz, 1 H, H8), 2.08 (s, 3 H, $CH_3$py) ppm. $^{13}$C NMR ($CD_3COCD_3$): $\delta$ = 191.79 (C7), 164.97 (C5), 157.88 (C27), 157.15 (C17), 156.81 (C16), 155.36 (C26), 154.15 (C31), 150.24 (C29), 149.98 (C11), 149.77 (C1), 149.10 (C22), 145.57 (C6), 136.73 (C3), 136.41 (C24), 135.18 (C8), 134.98 (C29), 133.78 (C19), 133.53 (C14), 132.07 (C2), 128.10 (C9), 127.22 (C23), 126.48 (C20), 126.29 (C30), 126.14 (C13), 123.73 (C11), 123.58 (C28), 123.34 (C25), 123.06 (C15), 123.04 (C18), 120.74 (C10), 118.39 (C4), 17.15 ($CH_3$py) ppm. FAB-MS: $m/z$ = 582 $[M–OTf]^+$.

**Complex 4b:** Yield: 98 mg (88%). Metathesis: the complex with the triflate counterion was dissolved in the minimum amount of methanol, then a saturated solution of $NH_4PF_6$ was added until no more precipitation was observed. The precipitate was filtered off, rinsed with distilled water, and dried under vacuum. $^1$H NMR ([D$_6$]-DMSO): $\delta$ = 8.76 (d, $J$ = 8.2 Hz, 1 H, H25), 8.68 (d, $J$ = 8.2 Hz, 1 H, H28), 8.61 (d, $J$ = 8.8 Hz, 1 H, H15), 8.59 (d, $J$ = 8.8 Hz, 1 H, H18), 8.09 (td, $J$ = 7.5 and 0.9 Hz, 1 H, H24), 8.04 (d, $J$ = 8.3 Hz, 1 H, H4), 7.99 (d, $J$ = 5.4 Hz, 1 H, H31), 7.91 (t, $J$ = 8.1 Hz, 1 H, H29), 7.89 (t, $J$ = 8 Hz, 1 H, H19), 7.86 (t, $J$ = 8.1 Hz, 1 H, H14), 7.81 (d, $J$ = 5.3 Hz, 1 H, H22), 7.72 (d, $J$ = 5.6 Hz, 1 H, H12), 7.68 (s, 1 H, H11), 7.62 (d, $J$ = 5.6 Hz, 1 H, H21), 7.58 (d, $J$ = 8.8 Hz, 1 H, H3), 7.56 (t, $J$ = 6.5 Hz, 1 H, H23), 7.38 (t, $J$ = 6.5 Hz, 1 H, H30), 7.36 (m, 1 H, H20), 7.35 (t, $J$ = 7 Hz, 1 H, H13), 7.28 (s, 1 H, H1), 6.61 (d, $J$ = 7.4 Hz, 1 H, H9), 6.18 (d, $J$ = 7.5 Hz, 1 H, H8), 2.22 (s, 3 H, $CH_3$phe), 2.04 (s, 3 H, $CH_3$py) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 187.54 (C7), 164.74 (C5), 157.72 (C27), 157.0 (C16), 156.65 (C17), 155.22 (C26), 153.91 (C31), 150.03 (C21 or C12), 149.78 (C12 or C21), 149.55 (C1), 148.99 (C22), 145.55 (C10), 137.21 (C3), 136.86 (C24), 135.45 (C29), 134.94 (C8), 134.20 (C14 or C19), 133.89 (C19 or C14), 132.14 (C2), 129.78 (C9), 129.33 (C6), 127.83 (C23), 127.05 (C20 or C13), 126.87 (C13 or C20), 126.77 (C30), 124.99 (C11), 124.21 (C28), 123.94 (C25), 123.69 (C15), 123.64 (C18), 118.86 (C4), 21.27 ($CH_3$ph), 18.17 ($CH_3$py) ppm. ## COVER PICTURE

**The cover picture shows** the supramolecular structure of an inclusion complex between the trisilanol 1,3,5-$(HOiPr_2Si)_3C_6H_3$ and *trans*-bis(4-pyridyl)ethylene (bpe). The trisilanol molecules are associated by SiO−H···O(H)Si hydrogen bonds, giving rise to the formation of 1D (horizontal) chains. The bpe molecules resemble pillars that are situated perpendicularly to the 1D chains and linked by SiO−H···N hydrogen bonds. The supramolecular motif is somewhat reminiscent of the Acropolis of Selinunte built 650 BC in Sicily, a masterpiece of classical Greek architecture. Details of synthesis and structures of supramolecular complexes between the trisilanol 1,3,5-$(HOiPr_2Si)_3C_6H_3$ and a number of 4,4′-bis(pyridine) compounds are described in the article by J. Beckmann and S. L. Jänicke on p. 3351 ff.

# Osmium- and Ruthenium-Based Phosphorescent Materials: Design, Photophysics, and Utilization in OLED Fabrication

**Pi-Tai Chou*[a] and Yun Chi*[b]**

**Keywords:** Osmium / Ruthenium / N ligands / Phosphorescence / Luminescence

Osmium(II) complexes possessing β-diketonate, quinolinate, diimine, and C-linked pyridyl azolate chelates reveal interesting structural and photophysical properties. Spectroscopic and dynamic measurements, in combination with theoretical analyses, have provided an important understanding of the electronically excited state properties of these complexes, such as the energy gap and nature of the lower lying states, rate for intersystem crossing, and the efficiency of corresponding radiative decay and nonradiative deactivation processes. This review also reports on the synthetic processes that lead to the neutral $Os^{II}$ and $Ru^{II}$ complexes that possess two *trans*-substituted phosphane donor ligands together with two *anti*-parallel, aligned azolate chromophores. Considerable efforts have been made to focus on utilizing these emitting materials as phosphorescent dopants for practical PLED and OLED fabrication. Consequently, the interplay between these emitting materials and device configurations is discussed.

## 1. Introduction

Owing to their versatility and potential in optical sensing and sensitization,[1] as well as in constructing a wide variety of photoresponsive molecular electronics,[2] research on the photophysics and photochemistry of transition-metal complexes has been revitalized and has attracted much recent attention. Particularly, a wide range of metal elements with distinctive d-shell configurations have been employed in order to study their luminescent properties. The influence of metal atoms, together with the modification of ligand architectures, continuously provides an attractive theme for further investigations. There has been an intensive investigation into the emissive $Re^{I}$ complexes, in particular those with a functionalized diimine ligand attached to the *fac*-$[Re(CO)_3]$ unit.[3] The diimine group, exhibiting diversified electronic properties, has rendered a possibility for fine-tuning the excited state properties and luminescent efficiencies. In sharp contrast, relatively less attention has been focused on the behavior of their isoelectronic and isostructural $Os^{II}$ analogues. In an attempt to explore their chemistry and corresponding photophysical properties, we have directed our research efforts specifically to the preparation and charac-

*Pi-Tai Chou received his Ph.D. degree from Florida State University, Tallahassee, in 1985, and is currently a Chair Professor at National Taiwan University. He was an assistant professor at University of South Carolina (1988–1994) and a professor of National Chung Cheng University, where he was the departmental chairman from 1997 to 1999. His research interests span the area of ultrafast laser spectroscopy, syntheses, and photophysics of materials suited for OLED, solar energy cell, and nanotechnology.*

*Yun Chi obtained his Ph.D. degree from UIUC, Illinois, in 1986, and was promoted to Professor of Natural Sciences at National Tsing Hua University in 2003. His past academic endeavors cover the chemistry of polymetallic carbonyl clusters, which is important for understanding the catalysts used by petroleum industries for production of new polymers and commodity organics. His current research focuses on subjects involving preparation of metal-containing thin films and nanomaterials by using chemical vapor deposition, as well as synthesis of transition-metal complexes for OLEDs and photovoltaics.*

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

terization of a great range of $Os^{II}$ complexes. With an ingenious design of ligated chromophores, we believe that the luminescent $Os^{II}$ complexes may serve as new models for probing a variety of fundamental characteristics in both ground and excited states (vide infra).

From the application point of view, organometallic complexes possessing heavy transition-metal elements are crucial for the fabrication of phosphorescent organic light-emitting diodes (OLEDs).[4] The strong spin–orbit coupling effectively promotes singlet-to-triplet intersystem crossing, as well as enhances the subsequent transition from the triplet excited state to the ground state, the results of which then facilitate strong electroluminescence by harnessing both singlet and triplet excitons. Theoretically, an internal phosphorescence quantum efficiency ($\eta_{int}$) that can be as high as 100% could be achieved,[5] such that these emitting materials would be superior to their fluorescence-only counterparts for which only singlet excitons can be utilized. This superiority leads to a continuous trend of shifting research endeavors to the heavy transition-metal-based emitters, among which intense research has been carried out on the system involving $Ir^{III}$ complexes ever since the seminal study on [Ir(ppy)$_3$] (ppy = 2-phenylpyridine).[6] In comparison, although much less explored, Os(II) complexes may gain certain advantages, such as the reduction of radiative lifetime and hence a possibility of higher luminescent efficiency, over the traditional $Ir^{III}$ and $Pt^{II}$ emitting materials in OLED applications.

On one hand, this is probably due to the fact that Os in all emissive Os complexes possesses the unique +2 oxidation state. Hence, luminescent $Os^{II}$ complexes, in general, are expected to exhibit lower electrochemical oxidation potentials in dπ orbitals relative to those of the iso-electronic $Ir^{III}$ complexes. Thus, unless $Os^{II}$ complexes are incorporated with strong π-accepting ancillary ligands such as CO, the osmium dπ orbitals will be destabilized, which results in an increase in the metal-to-ligand charge transfer (MLCT) contribution relative to typical π–π* transitions. Such a property, i.e. a short radiative decay time, may also improve the OLED device efficiencies by minimizing the unwanted triplet-triplet annihilation that occurs at a higher operating current density.[7] On the other hand, in comparison to the luminescent Pt complexes possessing a similar $Pt^{II}$ +2 oxidation state, the octahedral ligand arrangement of the $Os^{II}$ complexes would provide a prevailing environment for reducing the intermolecular interaction. This is mainly due to the fact that the planar arrangement and the $d^8$ electronic configuration of the $Pt^{II}$ complexes are subject to aggregation, which leads to a possible π–π stacking interaction in both fluid and solid solutions.[8]

Another subject of current interest is the development of luminescent, neutral $Ru^{II}$ complexes.[9] Despite the fruitful progress on the transition-metal complexes above, a practical barrier to the commercialization of phosphorescent OLED technologies may result from the prohibitive cost of noble metals. With regard to the viability of application, there is an urgent need to develop phosphorescent emitting materials from less expensive precursors, among which $Ru^{II}$ serves as an alternative. Skepticism to this approach, however, might arise as a result of the weaker ligand field strength of $Ru^{II}$ as well as its smaller heavy-atom-effect, i.e. weak spin–orbit coupling, relative to the third-row transition metals.[10] Nevertheless, recent progress has shown that $Ru^{II}$ complexes are suitable for decent OLED/PLED performance. Such success is apparently credited to the rational design of ligand structures through the standpoint of fundamental chemistry and photophysics. Accordingly, in this review, a certain focus will also be directed towards the synthesis, characterization, and utilization of the $Ru^{II}$ complexes, their excitation behavior, and the fabrication of efficient phosphorescent OLED devices.

## 2. [Os(CO)$_3$] Derivatives

### 2.1 Diketonate Complexes

Photophysical studies of lower oxidation state rhenium(I) complexes with the structural formula *fac*-[Re(CO)$_3$X(L)] (X = halides and L = bidentate heterocycles such as 2,2′-bipyridine) have received considerable attention over the past two decades.[3,11] The observed emission could originate from the ligand-centered π–π*, intra- or interligand charge transfer, or even from the metal-to-ligand charge transfer (MLCT) states, depending on the nature of heterocyclic ligands. Moreover, the central metal cation would also impose notable influence on the photophysical properties of the complexes. This gives us the motivation to initiate the heretofore unexplored osmium(II) tricarbonyl analogues.

Accordingly, a series of β-diketonate complexes with the formula [Os(CO)$_3$(tfa)(LX)] (**1**–**7**) were synthesized from the Os dimer [Os$_2$(CO)$_6$(tfa)$_2$] (tfa = trifluoroacetate) with the appropriate diketone reagent (LX)H in a Carius tube.[12]

$$[Os_2(CO)_6(tfa)_2] + (LX)H \rightarrow [Os(CO)_3(tfa)(LX)] + H_2$$

The remarkable variation in the photophysical properties of complexes **1**–**7** is summarized in Table 1. For the hexafluoroacetylacetate complex **1**, the lowest energy absorption at 336 nm, with an extinction coefficient as low as 3000 $M^{-1}cm^{-1}$, is assigned to the $^1$MLCT transition, while the corresponding emission appears at $\lambda_{max}$ = 545 nm. The phosphorescent character is ascertained by its large Stokes shift and long radiative lifetime, $\tau_r$, of ca. 7 μs, which is calculated by $\tau_r = \tau_p/\Phi$ ($\tau_p$: observed decay time, $\Phi$: emission yield). Upon replacing one $CF_3$ substituent with a *tert*-butyl or a phenyl group to form complexes **2** or **3**, respectively, the emission is still dominated by phosphorescence, as indicated by its large Stokes shifted peak wavelength and drastic $O_2$ quenching effect.

Replacement of the aromatic pendant with either α- or β-naphthalene to form **4** or **5**, respectively, also gives rise to a unique phosphorescence with a peak wavelength at 560 and 540 nm, respectively. However, in contrast to the sole phosphorescence for complexes **1**–**3** in both degassed and aerated $CH_2Cl_2$, dual emission that consists of fluorescence, i.e. 462 nm (**4**) and 455 nm (**5**), and phosphorescence was

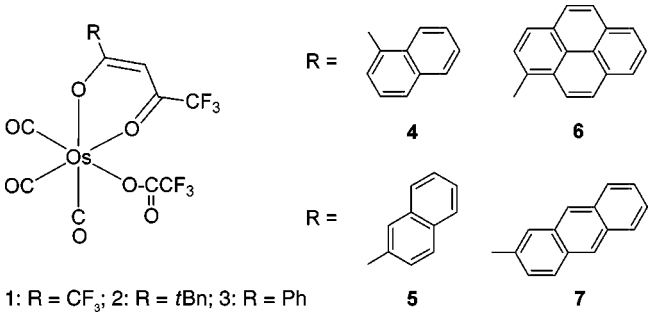
| **7** | 378 (20.7), 453 (11.3) | 575, 740[e] | 11.0 | 2100 | –[f] | $^1\pi\pi^*$ (≈0%) |

[a] The solution was degassed with at least three freeze-pump-thaw cycles. For **6**, the reported $\Phi$ value is the sum of florescence and phosphorescence. [b] Values in parentheses are the percentage of $^3$MLCT/$^3\pi\pi$. [c] $\tau_f$ is shorter than the system response of 150 fs. [d] The emission band was only detectable in an aerated solution. [e] The phosphorescence was acquired by laser (355 nm) excitation in a 77-K methylcyclohexane glass. [f] The phosphorescence intensity was too weak to resolve the lifetime.



resolved for **4** and **5** under aerated conditions, which indicates their relatively slow $S_1$–$T_1$ intersystem crossing rate, $k_{isc}$. Further substitution of pyrene (**6**) reveals drastically different excitation behaviors. This is confirmed by the observation of dual fluorescence (550 nm) and phosphorescence (690 nm) with a ca. 1:1.2 intensity ratio. In contrast, complex **7** exhibits only fluorescence, regardless of whether it is in degassed or aerated $CH_2Cl_2$, as supported by the excessive short radiative lifetime of 2.1 ns. Nevertheless, weak phosphorescence with a peak wavelength at ca. 740 nm was resolved for **7** in a 77 K methylcyclohexane glass matrix.

The changes of the lowest energy excited state character can be rationalized by the π-electron conjugation introduced by the polyaromatic pendant at the diketonate chromophore, which increases (decreases) the π (π*) energy of both $S_1$ and $T_1$ states in a qualitative manner. The fast $k_{isc}$ observed in **1**–**3** can be rationalized by mixed MLCT and π–π* character in both $S_1$ and $T_1$ manifolds. If intersystem crossing takes place mainly from the $S_1 \rightarrow T_1$ pathway, the corresponding rate constant, $k_{isc}$, is proportional to $\frac{<T_1|H_{SO}|S_1>^2}{(\Delta E_{S_1-T_1})^2}$, where $H_{so}$ is the Hamiltonian for the spin–orbit coupling and $\Delta E_{S_1-T_1}$ is the energy difference between singlet ($S_1$) and triplet ($T_1$) states. The mixing of π–π* and MLCT in both $S_1$ and $T_1$ states leads to the $S_1 \rightarrow T_1$ intersystem crossing that incorporates the $<^1d_\pi\pi^*|H_{so}|^3\pi\pi^*>$ or $<^3d_\pi\pi^*|H_{so}|^1\pi\pi^*>$ term. The net result induces the change in orbital angular momentums, i.e. $d\pi \rightarrow \pi$ coupled with the flip of the electron spin, so that the transition has a significantly large first-order spin–orbit coupling term, which results in a drastic enhancement of the intersystem crossing.[13]

Accordingly, among complexes **1**–**7**, as shown in Table 1, the greatest MLCT/π–π* mixing in **1** and **2** gives rise to ultrafast, system-response–limited ($>10^{13}$ $s^{-1}$) $k_{isc}$. Because of the lack of MLCT/π–π* state mixing in **6**, $k_{isc}$ decreases drastically to $9.2 \times 10^9$ $s^{-1}$. Apparently, because of the lack of MLCT, complexes **6** and **7** mainly undergo a $^1\pi\pi^* \rightarrow {}^3\pi\pi^*$ intersystem crossing, in which the coupling between orbital and spin angular momentum, and hence the $<^1\pi\pi^*|H_{so}|^3\pi\pi^*>$ term, should be rather small owing to negligible changes in orbital angular momentum that can couple with the flip of electron spin. In other words, there is a small first-order spin–orbit coupling to enhance the intersystem crossing.

To investigate the effect of the anionic ligands X in this class of osmium(II) complexes, we prepared the dibenzoylmethanate complexes using the reaction sequence and the corresponding anion exchange protocols that is depicted.

$[Os_2(CO)_6(\mu\text{-}X)_2] + (dbm)H \rightarrow [Os(CO)_3X(dbm)]$, X = tfa (**8**) and I (**11**)

(**8**) + NaCl, NaBr or $NH_4SCN \rightarrow [Os(CO)_3X(dbm)]$, X = Cl (**9**), Br (**10**), and SCN (**12**)

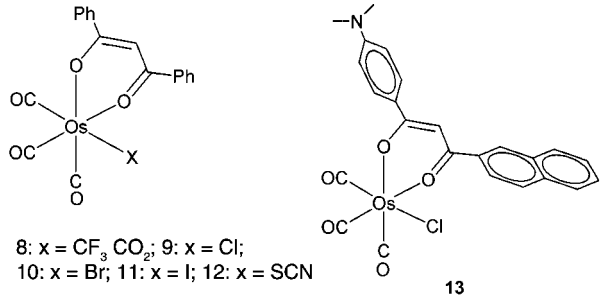


Table 2 shows their photophysical data, for which the lowest-energy absorption band in the region of ca. 367–380 nm can be assigned as an intraligand π–π* transition of the chelating dbm ligand, together with a small proportion of MLCT character.[14] The emission lifetime is unusually long (≥29 μs), giving characteristics of the long-lived phosphorescent emission and quantum yields approaching the level 0.08–0.13. The only exception is the iodide complex **11** ($\Phi$ = 0.007) − which could originate from photoinduced dissociation involving the weak Os–I bond − which exhibits a decrease in phosphorescence upon prolonged photolysis. The hypsochromic shift of the emission peak maximum follows the order tfa ≈ SCN > Cl > Br >

[a] Excitation wavelength: 380 nm. [b] Data in parenthesis were obtained in the thin solid films. Note that a faster decay component (<0.2 μs) was observed for **8**–**12** in the solid state possibly due to the defective sites. Its integrated intensity is <10% and is thus neglected. [c] $k_r = \Phi_{em}/\tau$.

I, which is proportional to the electron-donor strength of the anion that destabilizes the metal-centered HOMO, hence decreasing the energy gap.

We also made an attempt to probe the fundamentals of the triplet-state properties based on this inherent molecular design involving the related *fac*-$[Os(CO)_3]$ unit.[15] One intriguing topic relevant to triplet-state properties should be ascribed to the triplet-state intramolecular charge transfer (TSICT) process.[16] It has been reported that the micelle or polymer encapsulated organic chromophore, together with the external heavy atom effect, may resolve room-temperature phosphorescence.[17] However, the resulting heterogeneous and rigid environments make the investigation of the solvation-associated properties impractical. As a result, photophysical properties associated with TSICT, such as the solvation relaxation dynamics and the steady-state consequence, e.g. the phosphorescence solvatochromism, are not attainable in solvents with a low viscosity. Our strategic design, in contrast, is much more simple (c.f. complex **13**) and involves the utilization of the $[Os(CO)_3Cl]$ fragment to support an asymmetrical β-diketonate ligand, composed of an *N*,*N*-dimethylaniline and a 2-naphthylene substituent that serve as the electron donor and the acceptor, respectively.[18] As the attached heavy-metal fragment $[Os(CO)_3Cl]$ generally possesses a large energy gap for the metal dd and MLCT transitions,[19] the organic chromophore of interest, i.e. β-diketonate, is expected to lie in the lower-lying excited states.

Figure 1 shows the absorption and emission spectra of **13** in various solvents. The different relaxation dynamics of fluorescence and phosphorescence allowed us to resolve each component.[15] In aerated cyclohexane, this molecule exhibits distinct dual fluorescence at 470 nm and phosphorescence at 570 nm with a sum of near unitary quantum efficiency. As the solvent polarity increases, drastic polarity dependence in emission spectra is observed. Evidently, both the fluorescence and phosphorescence undergo notable bathochromatic shift and give rise to an exceedingly broad emission signal. Changes in dipole moment for the $S_1$ and $T_1$ states with respect to the ground state are deduced to be 18.0 and 11.9 Debye, respectively, with the Lippert–Mataga equation.[20] The appreciable difference in dipolar changes implies the intrinsic difference in the electron-density distribution between $S_1$ and $T_1$ states. Further theoretical analysis indicates that the $T_1$ state possesses a substantial contribution (≈10%) from the MLCT transition originating from the osmium dπ orbital to the π system of the 2-naphthyl moiety, whereas the $S_1$ state is dominated by a ππ* configuration. Thus, the redistribution of π electron density because of the charge transfer should be less emphasized in the $T_1$ state, rationalizing its smaller dipolar change. Such intrinsic, subtle differences in charge-transfer properties are intriguing and worthy to pursue further from a theoretical standpoint.

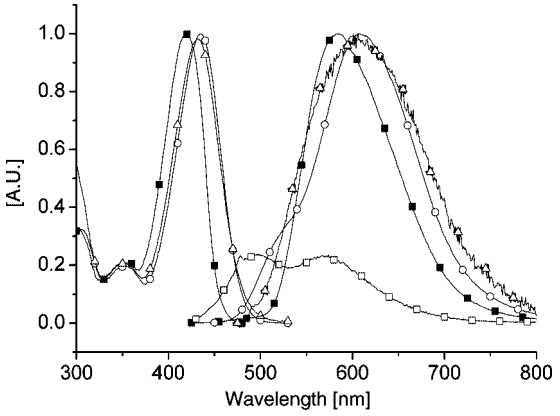

Figure 1. The absorption and steady-state emission spectra of **13** at 298 K in degassed cyclohexane (-■-), dichloromethane (-○-), and acetonitrile (-Δ-). The trace (-□-) denotes the emission spectrum of **13** in aerated cyclohexane.

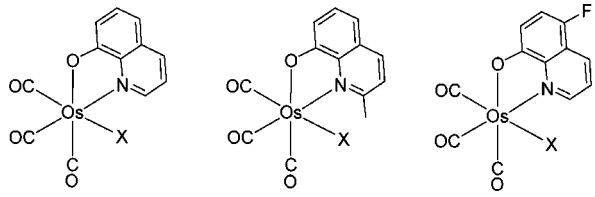
### 2.2. Quinolinolate Complexes

Providing that the osmium fragment $[Os(CO)_3X]$ of β-diketonate complexes serves as a prototype to facilitate the intersystem crossing, other chelating anions such as quinolinolate have also been explored in an attempt to reveal their phosphorescent characters.[21] This issue is motivated by the consideration that aluminum quinolinolate and its homologues were extensively tested for applications as the emitting or the electron-transporting materials in OLEDs.[22]

Four osmium(II) quinolinolate complexes **14**–**17** were synthesized, which provide a good example of the structural modifications that influence the basic photophysical properties. Table 3 summarizes the peak wavelengths of the lowest-energy absorption and other important photophysical data. The room-temperature absorption and emission spectra of complexes **14**–**17** in toluene are shown in Figure 2. The lower-lying absorption peak located at near 420–450 nm is derived from a π–π* transition with a significant contribution from the intraligand charge transfer (ILCT)

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

transition.[23] This delineation is in good agreement with the ca. 20-nm bathochromic shift of a similar absorption band of **17**, for which fluorine substitution at the 5-position is expected to markedly lower the π–π energy gap of the quinolinolate fragment because of the resonance (i.e. mesomeric) effect.[24] The assignment to the MLCT band is discarded owing to the lack of electronic dependence on the metal environment in the iodide complex **15**.



**14:** X = $CF_3CO_2$ **16:** X = $CF_3CO_2$ **17:** X = $CF_3CO_2$

**15:** X = I

As depicted in Figure 2, except for the fluorine-substituted complex **17** in which only fluorescence could be resolved, complexes **14**–**16** revealed two distinct bands, the intensity ratios of which varied according to the quinolinolate ligands and the anionic ancillary ligands. The shorter-wavelength band, showing characteristics of a short lifetime (<2 ns, see Table 3), is classified as fluorescent emission, while the longer-wavelength band can be assigned to the respective phosphorescence on the basis of its relatively much longer lifetime (>1 μm) and drastic quenching effect under oxygen. It is believed that both of these emissions are dominated by typical π–π* transition in combination with ILCT [phenolate site (π) → pyridine site (π*)] character. The latter transition, in part, incorporates the transfer of electron densities from the oxygen atom of the phenolate fragment to the π* orbitals of the fused ring system. The fluorine atom in complex **17** exhibits the mesomeric effect,[24] which results in the decrease in electronic transition energy, with a consequent bathochromic shift in both the absorption and emission bands.

The variation in the intensity of dual emissions, i.e. fluorescence vs. phosphorescence, can be correlated with the relaxation dynamics of the $S_1 \rightarrow T_1$ intersystem crossing. In comparison with complex **14**, the addition of a 2-methyl group in **16** enhances $k_{isc}$ threefold, which may be rationalized by the increase in density of the final vibronic states ($T_1$) having the same energy as the initial states ($S_1$). For complex **17**, the mesomeric effect introduced by the fluorine atom at the 5-position of the quinolinolate would result in the retardation of intersystem crossing in a qualitative manner and hence give the reduction of $k_{isc}$. However, in the case of iodide-substituted complex **15**, the phosphorescence is significantly increased, plausibly because of the additional iodide heavy-atom effect that drastically increases the rate of intersystem crossing (vide infra).[25]

Table 3. Photophysical properties of complexes **14**–**17** in degassed toluene at room temperature.

| | Abs. $\lambda_{max}$ [nm] ($\varepsilon \times 10^3$) | PL $\lambda_{max}$ [nm] | $\Phi$ [%][a] | Fluorescence [ns] | Phosphorescence [μs][b] |
|---|---|---|---|---|---|
| **14** | 424 (3.3) | 526, 635 | 1.4 | 0.55 | 33.1 |
| **15** | 430 (4.1) | 520, 650 | 2.4 | 0.15 | 3.8 |
| **16** | 421 (3.4) | 520, 650 | 0.2 | 0.21 | 21.6 |
| **17** | 443 (2.9) | 560, 689 | 1.1 | 1.10 | – |

[a] The solution was degassed with at least three freeze-pump-thaw cycles. The reported $\Phi$ value is the sum of fluorescence and phosphorescence. [b] The phosphorescence lifetime was measured by a direct laser flash experiment.

## 3. [Os(CO)$_2$] Derivatives

### 3.1 Diimine Complexes

Dicarbonyl osmium(II) complexes of the type [Os(diimine)(CO)$_2$I$_2$] contain both π-donating iodide ligands and an accepting diimine ligand with low energy π* orbitals. These osmium(II) complexes exhibit pseudo-octahedral geometry, and the iodide and carbonyl ligands are located at the *trans* and *cis* positions, respectively.[26] The main interest in initiating this investigation was to shed light on the nature of the lowest excited state; for example, whether these complexes display the basic characteristics of the usual metal-to-ligand charge transfer excited state (MLCT) or a state with a substantial amount of the halide-to-ligand charge transfer (XLCT) character.

It is noted that these Os$^{II}$ complexes exhibit much stronger room-temperature iodide-to-ligand phosphorescence than that of their ruthenium analogues. Such a difference is attributed to an increase in the all osmium ligand bonding strength relative to that of the second row ruthenium counterparts, which affords an increase in the energy of the metal-centered dd state. Therefore, this dd state is more difficult to populate in the osmium derivatives, which shows a notable increase in luminous intensity. Conversely, if the metal-centered dd state is more easily populated, which is more likely to occur in the ruthenium complexes, the complex may relax back to the ground state through nonradiative means and exhibit a great loss in the emission efficiency.[27] DFT calculations on complex **18b** confirm that the room-temperature emission originates from mixed XLCT (≈70%) and MLCT (≈30%) as a result of the lower oxidation potential of the iodide ligand. Replacing the diimine ligand from bipyridine (or phenanthroline) with the pyridyl benzoxazole ligand leads to a significant bathochromatic shift of the emission signal. The result implies that the benzoxazole ligand of **19** possesses a lower energy π* orbital relative to that of the bipyridine (or phenanthroline) ligands, which in turn gives a reduction in the energy gap for the MLCT/XLCT excited states.

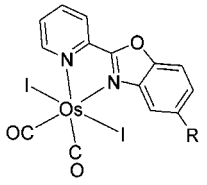
**18b**

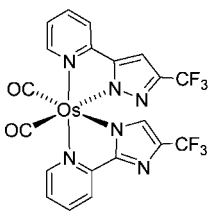


**19:** R = H; **19a:** R = *t*Bu

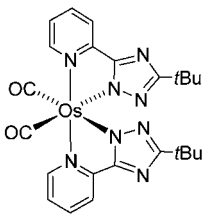
### 3.2 Pyridyl Azolate Complexes

The C-linked 2-pyridyl azolate belongs to a class of chelating ligands for which the large difference in the electronic properties of the pyridyl and the azolate fragment would render a larger ligand-centered π–π* energy gap. Such a property is very desirable for the generation of rarely observed blue phosphorescence. Furthermore, the disparity in electron distribution between the azolate and pyridyl fragments may provide a synergic effect such that the electron density transfers from the azolate to the cationic metal center and back to the pyridyl fragment, giving a delocalized and stabilized metal–chelate bonding interaction.

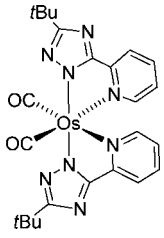
Treatment of 3-trifluoromethyl-5-(2-pyridyl)pyrazole (fppz)H and Os$_3$(CO)$_{12}$ afforded only one complex, **20**, in moderate yield.[28] For reactions with the related triazole chelate, two isomeric complexes, **21** and **22**, were observed for the direct treatment of 3-*tert*-butyl-5-(2-pyridyl)triazole (bptz)H with Os$_3$(CO)$_{12}$.[29] Separation of products was achieved by using their marked solubility differences in acetone, where the less soluble isomer **21**, which is structurally related to complex **20**, can readily be obtained as a crystalline solid, while isolation of the second complex **22** required repeated extraction and slow diffusion of hexane vapor into a saturated acetone solution at room temperature.



**20**



**21**



**22**

It is notable that the pyridyl fragments in complexes **20** and **21** are both located at the mutual *trans* position, while the pyridyl groups in complex **22** are located *trans* to the *cis*-oriented carbonyl ligands.

The corresponding photophysical data are summarized in Table 4. For complex **20**, the lowest-energy absorption bands at ca. 310 nm are ascribed to the ligand-centered π–π* transitions, while the corresponding MLCT transitions could be hidden under the more intense π–π* transitions. The emission spectrum exhibits a distinct vibronic feature with $\lambda_{max}$ at 430, 457, and ca. 480 nm in $CH_3CN$. The fact that the entire emission band originates from a common excited-state species is ascertained by the same fluorescence excitation spectra throughout the monitored wavelengths of 420–600 nm. This observation leads us to propose that the emissive state mainly possesses a ligand-centered $^3\pi\pi^*$ character.

Table 4. Photophysical properties of complexes **20**–**22** in degassed $CH_3CN$ at room temperature.

| | Abs. $\lambda_{max}$ [nm] | PL $\lambda_{max}$ [nm] | Q.Y. $\Phi$ | $\tau$ [μs] |
|---|---|---|---|---|
| **20** | 311 | 430, 457, 480 | 0.14 | 18.5 |
| **21** | 333 | 455, 480, 507 | 0.42 | 39.9 |
| **22** | 340 | 460, 483, 515 | 0.00046 | 0.026 |

Figure 3 shows the UV/Visible absorption and emission spectra of both **21** and **22** in acetonitrile. Similarly, a structureless band with a maximum at 310–334 nm can be assigned to a triazolate-to-pyridine intraligand π–π* transition. For their emission spectra, complex **21** exhibits strong

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

emission, with a quantum yield of 0.42, for which distinct vibronic peak maxima appear at ca. 455, 480, and 507 nm in degassed $CH_3CN$ at 298 K. Remarkable differences in emission properties were observed for **22**. Although its emission profile looks quite similar to that of **21**, this complex is nearly nonemissive with a quantum efficiency as low as $4.6\times10^{-4}$ in degassed $CH_3CN$ solution at 298 K. This weak phosphorescence also correlates well with the observed fast relaxation dynamics, in which the lifetime of phosphorescence for **22** is measured to be as short as 26 ns. It is also worth noting that a small but non-negligible fluorescence shoulder ($\lambda_{max} \approx 420$ nm, $\tau_f < 200$ ps) could be resolved in **22** (Figure 3), although the rate of intersystem crossing is very fast, as indicated by the system-response-limited rising component of the phosphorescence (<200 ps).

One possibility to account for the distinctive difference in emission behavior of **22** is that there exist certain excited states, possibly a metal-centered d–d transition (i.e. ligand field, LF, transition), which results in weakening of the metal–ligand interaction as a result of their *anti*-bonding character and may thus act as an activator for the overall radiationless transition.[30] However, this possibility was ruled out as none of the four lowest excited states, including two singlet and two triplet manifolds that were examined, possess the anticipated dd character. The inaccessibility of the dd excited state is believed to result from the strong ligand field strength of the triazolate chelates as well as of the CO ligands.

On the other hand, according to our TD–DFT calculation, a $T_1$ configuration in **22** could be reasonably attributed to a $^3\pi\pi^*$ manifold, mixed to a great extent with small amounts of the $^3$MLCT character.[31] By populating the $T_1$ excited state, a shift in the electron density from the metal center, CO ligands, and the triazolate moiety to the pyridine moiety occurs, which results in a further reduction of the already weakened Os–pyridine interactions in **22**, for which the weakened bond lengths have been confirmed by single-crystal X-ray analysis. As a result, in **22**, the potential energy surface (PES) of $T_1$ might be so shallow that, under extreme conditions, a surface crossing of PESs between $T_1$ and $S_0$ is possible. As shown in Figure 4, upon excitation, fast $S_1$–$T_n$ intersystem crossing (ISC) must take place. It is plausible that ISC proceeds from $S_1$ to $T_2$ because of their closeness in energy, followed by a fast rate for $T_2$ to $T_1$ internal conversion ($\leq 1$ ps$^{-1}$). After population equilibrium, **22** can be thermally activated to certain vibrational levels close to the section of surface crossing to execute the radiationless deactivation through facile metal–ligand bond stretching. Thus, a dominant $T_1 \rightarrow S_0$ radiationless transition caused by a "loose-bolt" effect might take place upon thermal activation.[32]

This discovery may allow a parallel comparison with the behavior of tris(cyclometalated) iridium complexes for which isolation of two geometrical isomers has been documented in the literature.[33] Structural and spectroscopic data suggest that the facial isomers have stronger and more evenly distributed metal–ligand bond interactions, and are highly emissive in both fluid and solid states at room temperature. In contrast, the meridional isomers have much greater bond length alternations caused by the differing *trans* influences of anionic phenyl and neutral nitrogen donors such as pyridine or pyrazolate, and are significantly less emissive under identical conditions at room temperature. We speculate that this greater bond strength alternation then induces a similar effect upon electronic excitation, which is more likely to be responsible for the rapid radiationless deactivation observed in this $Ir^{III}$ system.

Moreover, treatment of complex **20** with a nitrogen donor ligand led to the formation of a new series of $Os^{II}$ complexes with formula $[Os(fppz)_2(CO)(L)]$ (**23**, L = 4-dimethylaminopyridine; **24**, L = pyridine; **25**, L = 4,4′-bipyridine;

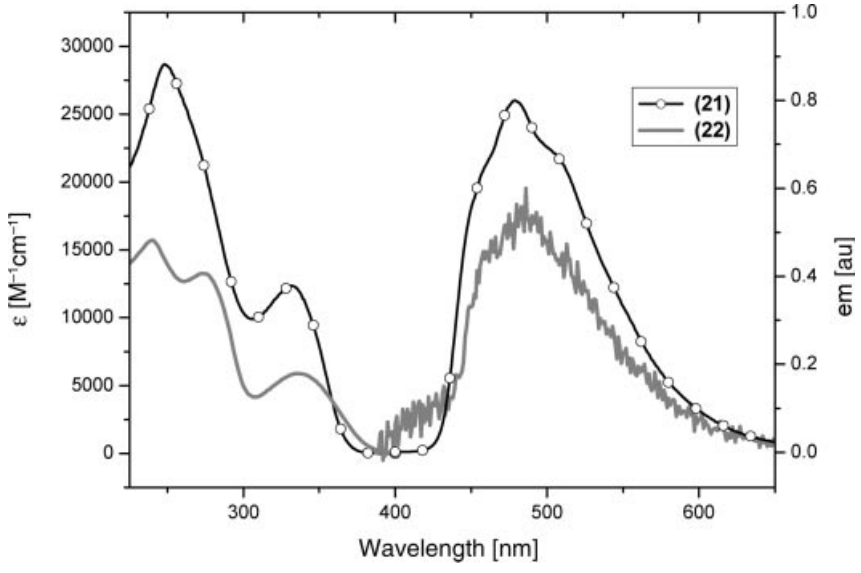


Figure 3. UV/Vis absorption and emission spectra of **21** (-o-) and **22** (—) in $CH_3CN$ solution at room temperature.

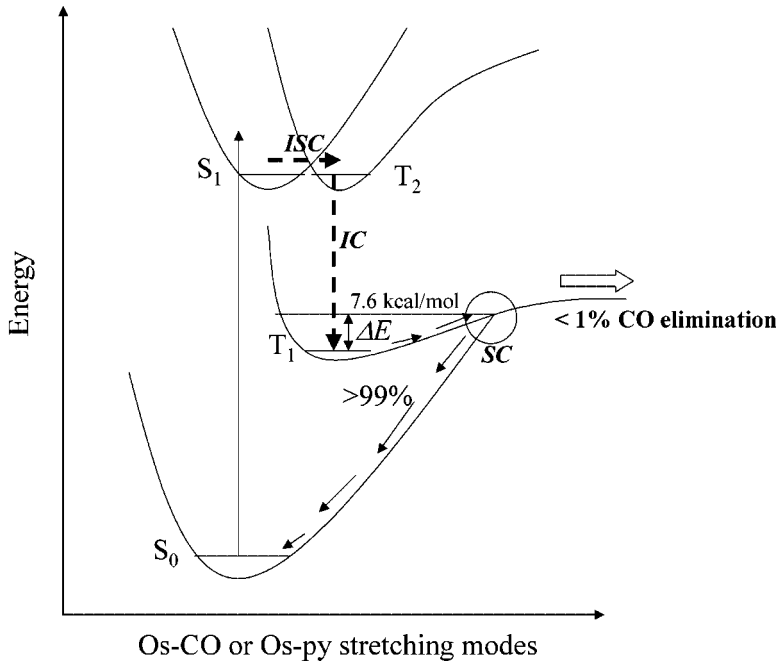

Figure 4. Energy levels of the lower-lying excited states and the proposed relaxation pathway for complex **22**. ISC: intersystem crossing, IC: internal conversion. SC: surface crossing.

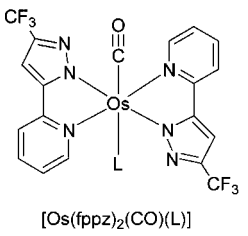
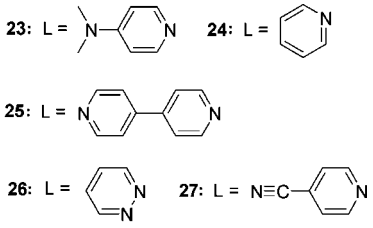
**26**, L = pyridazine; **27**, L = 4-cyanopyridine); the remaining carbonyl ligands and the N-heterocyclic ligand are located at the axial positions.[34] Variation in the axial N-heterocyclic ligand leads to remarkable changes in photophysical properties such that the energy gap and the phosphorescence peak wavelength can be fine-tuned.



[Os(fppz)$_2$(CO)(L)]

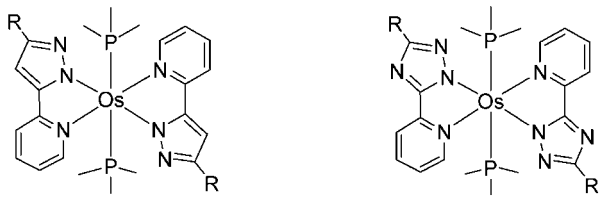


For complexes **23** and **24**, the axial nitrogen donor ligand possesses an electron-rich aromatic π system, which discourages its participation in the lowest-energy electronic transition. As a result, the phosphorescence originates from a combination of intraligand $^3\pi\pi^*$ ($^3$ILCT) and metal-to-ligand charge transfer transitions ($^3$MLCT) to the pyridyl fragments of the fppz chelates, and its peak wavelength is independent of the polarity of the solvent. This is confirmed by the observation of an only 18-nm red-shifted emission wavelength for complex **24** upon changing solvents from cyclohexane (487 nm) to acetonitrile (≈505 nm). In sharp contrast, complexes **25**–**27** exhibit mainly ligand-to-ligand charge transfer (LLCT) transitions, with a transfer of electron density from the equatorial pyrazolate fragment to the axial nitrogen donor ligand because of the excessive stabilization produced by either the extended π conjugation (4,4′-bipyridine) or the presence of an extra electronegative nitrogen atom (pyridazine and 4-cyanopyridine). The phosphorescence thus reveals strong solvent-polarity dependence, which results in a large shift in emission wavelength, e.g. from 560 (in $C_6H_{12}$) to 665 nm (in $CH_3CN$) and from 603 (in $C_6H_{12}$) to 710 nm (in $CH_3CN$) for complexes **25** and **27**, respectively. These results clearly demonstrate that a simple derivatization of the axial N-heterocyclic ligand drastically alters the excitation properties per se from intraligand charge transfer (ILCT) to the LLCT transition. The latter exhibits remarkable LLCT phosphorescence solvatochromism, so that a broad range of color tunability was achieved. Future applications to probe molecular/metal ion recognition will be of great interest and these can be achieved by applying the mechanism that incorporates solvent-polarity dependent interplay between ILCT and LLCT.[35]

## 4. Diphosphane Osmium Derivatives

An optimized synthesis was performed by the treatment of $Os_3(CO)_{12}$ with at least 6 equiv. pyridyl azole in anhydrous diethylene glycol monoethyl ether (DGME) at 180–190 °C, followed by the addition of a decarbonylation reagent, $Me_3NO$, and the phosphane ligands in sequences.[36] This one-pot synthesis strategy gives the desired $Os^{II}$ complexes **28**–**33** in good yields (>70%), and hence has a great advantage as it can be scaled up for possible industrial application.[37]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



**28**: R = $CF_3$, P = $PPh_2Me$

**29**: R = $CF_3$, P = $PPhMe_2$

**30**: R = *t*Bu, P = $PPh_2Me$

**31**: R = $CF_3$, P = $PPh_2Me$

**32**: R = $C_3F_7$, P = $PPh_2Me$

**33**: R = $C_3F_7$, P = $PPhMe_2$

Figure 5 shows an ORTEP diagram of **28**, in which the metal atom is located at a crystallographic center of inversion. The two chelating pyrazolate ligands establish a nearly planar $OsN_4$ basal arrangement, together with two $PPh_2Me$ ligands located at the *trans* positions. The planar ligand arrangement is analogous to those of the porphinato ligand in metalloporphyrins such as [Os(TTP)($PPh_3$)$_2$] (TTP = *meso*-tetraphenylporphinate) and [Os(TPP)(CO)(Im)] (Im = 1-methylimidazole).[38] The measured Os–$N_{(pz)}$ distances of 2.073(2) Å in **28** are slightly shorter than the respective Os–$N_{(py)}$ bond lengths of 2.090(2) Å; both bond lengths fall in the range expected for a typical N→$Os^{II}$ dative bond. Of particular interest are the relatively weak nonbonding contacts (N3A···C1 = 3.305 Å and N3A···H1 ca. 2.50 Å) observed between the *ortho*-hydrogen atom of the pyridyl moiety and the N atom of the nearby pyrazolate fragment. It is speculated that this H-bonding, to a certain extent, is akin to that observed in the cobaloxime complexes.[39]

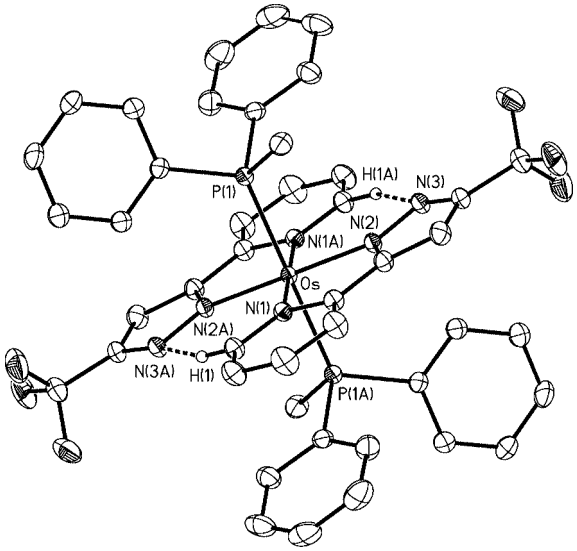


Figure 5. ORTEP diagram of **28**; selected distances: Os–P(1) = 2.3616(5), Os–N(1) = 2.090(2), Os–N(2) = 2.073(2), N(2)–N(3) = 1.349(2), N(3)···H(1A) = 2.508 Å and angles: N(1)–Os–N(2) = 76.48(7), N(1)–Os–N(2A) = 103.52(7)°.

As indicated in Table 5, the UV/Vis spectra of these osmium complexes show similar patterns, with three notable absorption maxima. The highest energy band, observed at ca. 400 nm, is naturally assigned to the spin-allowed $^1\pi\pi^*$ transition. The next lower energy absorption band, around 454–466 nm, can be ascribed to a spin-allowed metal-to-ligand charge transfer ($^1$MLCT) transition, while the third lowest energy band can be assigned to a state involving a mixture of both $^3\pi\pi^*$ and $^3$MLCT characters.

Table 5. Photophysical properties of complexes **28**–**33** in $CH_2Cl_2$ and solid state at room temperature.

| | Abs. $\lambda_{max}$ [nm] | PL $\lambda_{max}$ [nm] | Q.Y. $\Phi$[a] | $\tau$ [ns][a] |
|---|---|---|---|---|
| **28** | 405, 454, 542 | 617 (618)[a] | 0.50 (0.21) | 855 (631) |
| **29** | 411, 456, 553 | 632 (655) | 0.19 (0.29) | 725 (610) |
| **30** | 406, 466, 560 | 649 (670) | 0.25 (0.10) | 634 (440) |
| **31** | 405, 457, 543 | 617 (631) | 0.62 (0.24) | 960 (180) |
| **32** | 403, 457, 545 | 614 (618) | 0.76 (0.36) | 940 (580) |
| **33** | 410, 465, 550 | 629 (634) | 0.50 (0.21) | 810 (910) |

[a] Data in parentheses are measured in the solid state at room temperature.

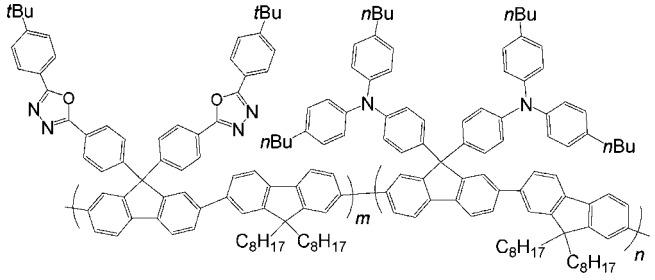
For the emission spectra, in comparison with **28**, which is coordinated by two $PPh_2Me$ ligands, complex **29**, bearing the $PPhMe_2$ groups, reveals a ca. 15-nm bathochromic shift in $\lambda_{max}$ that can qualitatively be rationalized by an increase in the $Os^{II}$ d$\pi$ energy level as a result of the poor $\pi$-accepting strength of the $PPhMe_2$ ligands (see Table 5). Complexes **28** and **31**, both possessing two $PPhMe_2$ ligands, exhibit nearly identical emission in solution, $\lambda_{max}$ =617 nm. This is due to the fact that the triazolate fragment, which is more electron withdrawing relative to pyrazolate, exerts an equal amount of stabilization to both HOMO and LUMO, which are located at the $Os^{II}$ metal center and the adjacent pyridyl site, respectively. Moreover, changing the substituent on the triazolate from *tert*-butyl (**30**) to $CF_3$ (**31**) and then to $C_3F_7$ (**32**) causes a notable blue-shift as a result of the increase in the MLCT gap by lowering the metal d$\pi$ energy level.

Moreover, the observed lifetimes of ca. 0.6–0.9 μs in degassed $CH_2Cl_2$ solution are considerably shorter than those of other reported red emitting $Ir^{III}$ complexes.[40] This, in combination with decent quantum yields >0.1, implies that the OLED devices fabricated using this class of osmium complexes could exhibit reduced triplet-triplet annihilation at the higher driving voltage.[7,41]

For the preparation of light-emitting devices, we incorporated the osmium phosphor **29** into a tailor-made blue-emitting polyfluorene derivative **PF-TPA-OXD**.[42] This host polymer, which contains both hole- and electron-transporting side chains, is capable of facilitating charge injection and transport and is suitable for matching the dopant-host energy level to achieve the direct formation and confinement of an exciton at the dopant. This configuration leads to a reduction in the electrical excitation of the host polymer, which in turn decreases the degree of exciton loss arising from nonradiative decay of the host triplet. In practice, PLED devices having the configuration ITO/poly(styrenesulfonate)-doped poly(3,4-ethylenedioxythiophene) (PEDOT) (35 nm)/polymer emitting layer (50–70 nm) and dopant **29**/TPBI (30 nm)/Mg:Ag (100 nm)/Ag (100 nm) were fabricated, and the optimized dopant concentration of **29** was kept at ca. 1 mol-%. The PL profile of this device

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

contains two components, which are attributed to the polyfluorene emission of the **PF-TPA-OXD** host and the triplet emission of **29**, while the corresponding EL spectra indicate an exclusively dopant emission. The dramatic difference between the PL and EL spectra reveals that the emission would result from direct charge trapping, followed by recombination with opposite charges at the dopant sites.[43] To understand the details of the charge–transport mechanism, the HOMO and LUMO energy of **29** were estimated by using the onset potentials of the oxidations and reductions obtained with cyclic voltammetry (CV). As shown in Figure 6, holes in this device can easily be injected from PEDOT (–5.2 eV)[44] into the HOMOs (–5.3 eV) of the **PF-TPA-OXD** host upon overcoming a small energy barrier (0.1 eV). For complex **29**, the ionization potential is 0.8 eV below the HOMO of **PF-TPA-OXD**; therefore, holes can be trapped at the dopant site, followed by recombination of opposite charges (electrons) to form excitons. For comparison, this device reached a maximum external quantum efficiency of 8.37% with a peak brightness of 16720 cd m$^{-2}$. Moreover, a maximum $\eta_{ext}$ of 12.8% is reached by using a similar device configuration and by employing a tetraphenylenebiphenyldiamine (TPD) based cross-linkable hole-transport layer, as well as a layer of 1,3,5-tris(*N*-phenylbenzimidazol-2-yl)benzene (TPBI) as an electron-transport layer and complex **29** as a dopant emitter.[45]



**PF-TPA-OXD**

In contrast, ionic red-emitting osmium(II) incorporating various substituted bipyridine ligands were also synthesized and tested for OLED applications.[46] The schematic drawing of two representative osmium(II) complexes, **34** and **35**, are shown.

This class of complexes features strong red MLCT phosphorescent emission ranging from 611 to 651 nm and the best quantum yields, up to 45%.[47] Electrophosphorescent

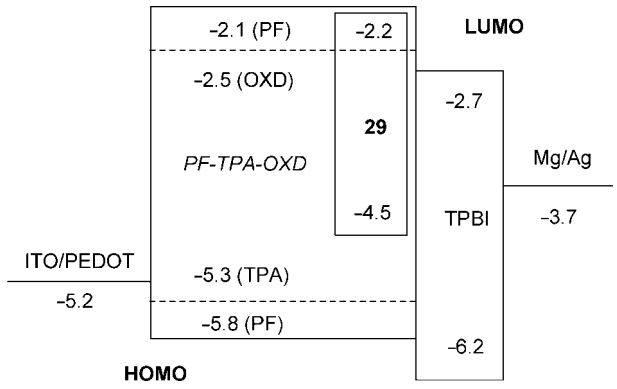


Figure 6. Proposed energy level for the devices having the configuration ITO/PEDOT/**29**: **PF-TPA-OXD**/TPBI/Mg:Ag.

devices were demonstrated by using poly(*N*-vinylcarbazole) and 2-*tert*-butylphenyl-5-biphenyl-1,3,4-oxadiazole (PVK:PBD) as the emitting layer, which give a brightness of 1400 cd m$^{-2}$. The best external quantum efficiency of 2.2%, which corresponds to a photometric efficiency of 1.9 cd A$^{-1}$, was achieved when switching the host matrix from PVK:PBD to a blend host of poly(2-vinylnaphthalene) (PVN) and PBD.[48] Moreover, it is understood that the analogous cationic osmium complexes are capable of trapping both electrons and holes, which facilitates the direct recombination of holes and electrons on the complex sites; however, the resulting devices failed to show any device data comparable to those of previously mentioned neutral osmium complexes such as **29**, even under the conditions using the copolymer **PF-TPA-OXD**, which is well known for its carefully balanced charge injection and transporting properties.[45] It is obvious that the counterions presented in this class of bipyridine complexes have seriously deteriorated the performance of the device, presumably by affecting the charge trap/transport property of the osmium complexes; hence, the use of ionic emitting materials must be avoided.

For a further comparison, we also took advantage of the high volatility of the neutral osmium(II) complexes to prepare OLEDs using direct thermal evaporation.[37] In this approach, complex **31** was selected for fabricating a series of multilayer devices with the configuration ITO/HTL(40 nm)/CBP:**31**(30 nm)/BCP(10 nm)/$Alq_3$(30 nm)/LiF(1 nm)/Al(150 nm), where CBP, BCP, and $Alq_3$ are the ab-

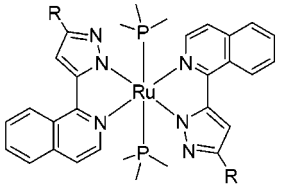
breviations for 4,4′-*N*,*N*′-dicarbazolyl-1,1′-biphenyl, 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline, and tris(8-hydroxyquinolinato) aluminum(III), respectively. Interestingly, upon switching the hole-transport layer (HTL) from 4,49-bis[*N*-(1-naphthyl)-*N*-phenylamino]biphenyl (NPB) and 9,9-bis{4-[bis(*p*-biphenyl)aminophenyl]}fluorene (BPAPF),[49] a very high initial external quantum efficiency of ca. 20% and luminous efficiency of 27.8 cd $A^{-1}$ are obtained at 1 mA $cm^{-2}$. These examples stand as some of the best red-emitting phosphorescent OLED devices ever fabricated.

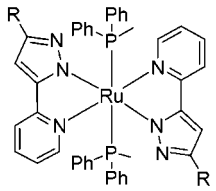
## 5. Diphosphane Ruthenium Derivatives

It is indispensable to have neutral $Ru^{II}$ complexes that are suitable for serving as efficient phosphorescent emitters. However, the weaker ligand field strength for the second row transition elements requires the use of strong field ancillary ligands such as phosphane to increase the energy gap of the metal-centered d–d transition, such that the radiationless deactivation associated with the metal–metal and/or metal–ligand bond stretching motion can be significantly suppressed.[19,50] Moreover, the relatively high oxidation potential in $Ru^{II}$ versus that of its third-row $Os^{II}$ analogues demands the employment of extensively conjugated 1-isoquinolyl-substituted chromophores to compensate for the unfavorable metal oxidation potential for the generation of saturated red emission.

Conversely, a series of $Ru^{II}$ complexes **36**–**40** were synthesized following the synthetic scheme established for their osmium counterparts.[9] Their emission spectra are depicted in Figure 7, while photophysical data are listed in Table 6. Moderate to highly intense luminescence in the solid state is obtained for complexes **36**–**38**, with $\lambda_{max}$ at 709, 682, and 632 nm, respectively. In good agreement with the $^3$MLCT emission, the $PPh_2Me$ derivative **37** exhibits a ca. 27-nm hypsochromic shift in $\lambda_{max}$ relative to the $PPhMe_2$ anchored **36**; this result can qualitatively be rationalized in terms of a decrease in the $Ru^{II}$ dπ energy level as a result of the increase in π-accepting strength. For complex **38**, an even more notable hypsochromic shift of 50 nm is achieved. This is apparently caused by the electron-withdrawing effect of the $CF_3$ substituents on pyrazolate, which has a function of lowering the electron density at the $Ru^{II}$ metal center.



**36**: R = *t*Bu, P = $PPhMe_2$
**37**: R = *t*Bu, P = $PPh_2Me$
**38**: R = $CF_3$, P = $PPh_2Me$



**39**: R = *t*Bu
**40**: R = $CF_3$

With the aim of reducing ligand π conjugation, replacement of the 1-isoquinolyl pyrazolate ligands with less-conjugated 2-pyridyl pyrazolate counterparts afforded the pyridyl complexes **39** and **40**.[51] Although **39** has a low chemical stability upon contact with chlorinated solvents in air, its solid sample gives a faint orange emission at $\lambda_{max}$ = 568 nm at room temperature – a result of increasing the emission gap from that of **36** ($\lambda_{max}$ = 709 nm) by reducing the π-conjugation of the LUMO orbital.

A further increase in the energy gap for **40** is expected owing to the presence of an electronegative $CF_3$ substituent on the chelating pyrazolate, which is expected to stabilize the metal dπ orbitals by lowering the electron density. This viewpoint can be firmly supported by TD–DFT calcula-

[a] Data in parentheses are measured in the solid state at room temperature.

tions. As shown by the absorption data listed in Table 6, complex **40** apparently exhibits the highest $^1$MLCT absorption (ca. 460 nm) among all other $Ru^{II}$ complexes prepared (493–580 nm). The TD–DFT results of **40** show that the lowest-energy triplet state involves metal dd character (≈64%), while the typical $^3$MLCT state increases in energy and becomes a second lowest excited state.[51]

As for the OLED applications, a multilayer device using 24 wt.-% of **38** as a dopant emitter in a CBP host and with NPB as a hole transport layer exhibits saturated red emission with an external quantum efficiency of 5.10%, luminous efficiency of 5.74 cd $A^{-1}$, and power efficiency of 2.62 lm $W^{-1}$, while incorporation of a thin layer of PEDOT/PSS between ITO and NPB gives an optimized result with external quantum efficiency of 7.03%, luminous efficiency of 8.02 cd $A^{-1}$, and power efficiency of 2.74 lm $W^{-1}$ at 20 mA $cm^{-2}$. The nonionic nature, high emission quantum efficiency, and short radiative lifetime are believed to be the key factors responsible for this unprecedented behavior. In contrast, fabrication of OLED devices using the ionic emitting materials can only produce devices with poor performances,[52] although the related $Ru^{II}$ complexes have been extensively utilized in light-emitting electrochemical cells (LECs),[53] in which the excessive mobile counterions facilitate the electrochemical redox processes required for generation of high efficiency steady-state radiance.

## 6. Concluding Remarks

With the aim of optimizing the performance of organic light-emitting diodes, research on the transition-metal complexes evidently still offers great prospects. In this review, we demonstrate the power of $Os^{II}$ and $Ru^{II}$ fragments in supporting a variety of ligands, such as those of $[Os(CO)_3]$-substituted diketonate or quinolinolate complexes, $[Os(CO)_2]$ derivatives involving diimine or pyridyl azolate complexes, diphosphane-substituted osmium and ruthenium derivatives, which result in complexes with great luminescent properties. We also show the importance of merging theoretical and experimental observations, providing timely feedback for further rational design of numerous functionalized luminescent complexes. In this regard, we formulate a fundamental issue regarding a generalized radiationless deactivation process, i.e. the first-order perturbation incorporating the spin–orbit coupling from various orbital configurations (e.g. $^3\pi\pi^*$ or $^3d_\pi\pi^*$). In this approach, mixing between $^3\pi\pi^*$ and $^3d_\pi\pi^*$ apparently gains a certain preference for facilitating the $S_1 \rightarrow T_1$ intersystem crossing rate (and likewise the $T_1 \rightarrow S_1$ process). As a result, the intersystem crossing rate can be qualitatively predicted through theoretical frontier orbital analyses in combination with, for example, X-ray structural determination. As for the case of neutral $Ru^{II}$ complexes, we trust that the design of ligands for averting the incorporation of metal dd character into the lowest triplet state plays a key role in increasing the luminescent behavior; this strategy should be equally applicable to other systems incorporating second-row transition-metal elements.

In view of OLED applications, a broad range of color tuning from red to blue has been achieved by derivatization of either pyridine or azolate segments as well as by variation in the electronic properties of the central metal atom by adjusting the ancillary ligands. Accordingly, we have reviewed a number of C-linked pyridyl azolate based $Os^{II}$ and $Ru^{II}$ complexes with regard to making OLEDs with excellent performance. It is thus possible that these pyridyl azolate based metal complexes, after full optimization, will eventually meet the expected industrial demand. Further extension of the chapter of $Os^{II}$ transition-metal complexes is also of great interest. On the basis of a similar principle, coarse as well as fine-tuning of ligands, especially the pyridyl azolate based complexes, toward the near-IR region with high luminescent efficiency is feasible, making possible their future applications in other fields such as near-IR imaging, optical communication, and photovoltaic systems, etc. We thus believe that the results as well as the perspectives presented in this review should spur continuous interest in the design and preparation of luminescence materials incorporating both $Os^{II}$ and $Ru^{II}$ elements.

# The Two-Step Spin Conversion in a Supramolecular Triple Helicate Dinuclear Iron(II) Complex Studied by Mössbauer Spectroscopy

**Yann Garcia,*[a] C. Matthias Grunert,[b] Sergey Reiman,[b] Olivier van Campenhoudt,[a] and Philipp Gütlich*[b]**

*Dedicated to Professor Hans-Georg von Schnering on the occasion of his 75th birthday*

**Keywords:** Spin crossover / Molecular bistability / Supramolecular chemistry / Iron(II) dinuclear compounds / Two-step conversion / Mössbauer spectroscopy

The triple helicate dinuclear iron(II) complex, $[Fe_2(L)_3](ClO_4)_4 \cdot 2H_2O$ (**1**), previously reported by Tuna et al. (*Chem. Eur. J.* **2004**, *10*, 5737), was prepared and characterised by detailed SQUID and $^{57}Fe$ Mössbauer measurements. Compound **1** exhibits a thermochromic two-step spin conversion at $T_{SC}^{(1)}$ ca. 240 K and $T_{SC}^{(2)}$ ca. 120 K, but does not switch its spin state further below 20 K as proven by Mössbauer spectroscopy. The sharp variation of the susceptibility below 20 K is due to zero-field splitting of the remaining iron(II) high-spin species. Applied field $^{57}Fe$ Mössbauer spectroscopy experiments at 4.2 K indicate that the gradual thermal spin conversion from [HS–HS] pairs to [LS–LS] pairs is complete for one half of the $Fe^{II}$ active sites. The presence of a step tracked in the spin-conversion curve and through the variation of the Mössbauer parameters of an uncoupled iron(II) site call for the occurrence of an [LS–HS] intermediate spin state in the plateau region.

## Introduction

The spin crossover (SCO) phenomenon presumably belongs to one of the most exciting and active field of research in molecular and coordination chemistry[1] as probed by the constantly increasing amount of papers.[2] This phenomenon has been observed for coordination compounds of 3d transition metals such as $d^4$ ($Cr^{II}$, $Mn^{III}$), $d^5$ ($Fe^{III}$, $Mn^{II}$), $d^6$ ($Fe^{II}$, $Co^{III}$) and $d^7$ ($Co^{II}$) ions.[3] Yet, most of the synthetic efforts and physical investigations have been carried out for $Fe^{II}$ mononuclear complexes displaying a wide range of SCO behaviours.[1,2] Recently, synthetic approaches combining the tools of supramolecular and coordination chemistry have been developed because it was realised that bridging active sites through noncovalent and/or covalent bonds could enhance cooperative effects associated to the spin-state change of individual molecules.[4] Such strategy is appealing because it can lead to the observation of a bistability domain that is of great importance for potential applications.[5] It should, however, be used with caution as strong cooperative interactions between spin-changing molecules in the crystal lattice can disfavour, in some cases, the occurrence of spin-state crossover itself.[6,7] The understanding of complex magnetic behaviour as developed in SCO coordination polymers[8] requires a full understanding of the SCO occurring in much simpler compounds such as monomers and oligomers.[9–10] As such, dinuclear $Fe^{II}$ complexes exhibiting a SCO between the high-spin (HS, $^5T_{2g}$) state and the low-spin (LS, $^1A_{1g}$) state in the liquid and solid state have been the subject of intensive preparation and investigations during the last three years.[11–19] The quest for new complexes is motivated by the understanding of the nature and the determination of the proportion of the existing spin pairs for these materials exhibiting gradual, abrupt or stepwise spin conversions. Another motivation stems from the possibility to combine both magnetic exchange and SCO phenomena in the same dinuclear unit[20] leading to multifunctional materials.[21]

Several modules have been used to link the active SCO sites in these binuclear systems: one bridging ligand such as μ-bpym (bpym = 2,2′-bipyrimidine)[11,12,17b] or μ-dicyanamide,[15] two ligands constituting a μ-pyrazolato[16,17] or μ-triazolato bridge,[18] or three benzimidazole bridging ligands leading to an helicate structure presenting a spin con-

version in solution.[19] A new series of triple helicate dinuclear $Fe^{II}$ complexes of the type $[Fe_2(L)_3]A_4 \cdot n$Solvent with A = $PF_6^-$, $BF_4^-$ and $ClO_4^-$ was also recently communicated.[22] L is a Schiff base resulting from the condensation of 3*H*-imidazole-4-carbaldehyde with 4,4′-methylenedianiline in methanol. Their crystal structure reveals that the $Fe^{II}$ centres are in a six-coordinate pseudo-octahedral coordination environment bound to three imidazolimine units originating from three different ligand strands. Each ligand strand binds to two metals, and the three ligands wrap around the metal–metal axis leading to a triple helical dinuclear structure (Figure 1). CH···π interactions are noted in the centre of the helix, the Fe···Fe distance being of 11.584(3) Å.[22] These compounds, that were investigated by SQUID measurements over the temperature range 1.8–340 K, where shown to display a thermally induced spin-state conversion. The perchlorate complex of formula $[Fe_2(L)_3](ClO_4)_4 \cdot 2H_2O$ (**1**) attracted our special interest, because it was reported to exhibit a two-step spin conversion with one gradual step at $T_{sco} \approx 180$ K and another very abrupt spin conversion was proposed to take place below ca. 20 K. On this basis, the authors concluded on the existence of a "tristability" phenomenon[22] although no hysteresis effect was observed. Our attention has been drawn to this compound for two main reasons:

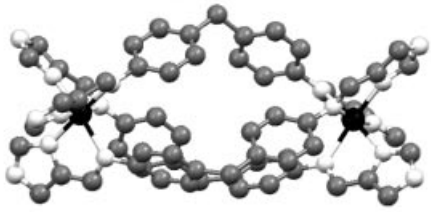

Figure 1. View of the triple-helicate cation in complex **1** adapted from ref.[22]. Hydrogen atoms and perchlorate anions are omitted for clarity. White and grey small spheres correspond to nitrogen and carbon atoms, respectively. The larger black spheres correspond to $Fe^{II}$ ions.

(i) To our experience it is very unlikely, for kinetic reasons, that thermal spin conversion occurs at such low temperatures as below 20 K. The sharp decrease of the $\chi_M T$ values below 20 K may be rather due to zero-field splitting (ZFS) of the approximately 50% of the $Fe^{II}$ ions in the HS state still present in the plateau around 50 K.

(ii) The spin conversion observed between 260 and 50 K gives rise to the question whether it takes place simultaneously in the $Fe^{II}$ dinuclear units, viz. via [HS–HS] ↔ [LS–LS] pairs, or via the intermediate [HS–LS] pairs in the sequence [HS–HS] ↔ [HS–LS] ↔ [LS–LS], as demonstrated to occur in other dinuclear $Fe^{II}$ complexes.[11a,12,14]

We thus re-synthesised and characterised compound **1** in order to clarify its thermally induced spin conversion by a set of precise SQUID and $^{57}$Fe Mössbauer measurements over the temperature range 1.8–300 K. The full differentiation of the existing spin pairs is not a routine exercise, and can only be solved using applied field Mössbauer spectroscopy,[23] which has also been carried out at 4.2 K.

## Results

### Synthesis and Characterisation

Complex **1** was prepared according to the described procedure.[22] The ligand L was first obtained as shown by $^1$H NMR and IR spectroscopy. The complex was also successfully obtained, as an orange powder, as shown by electrospray ionisation mass spectrometry (ESI), C,H,N analysis, IR and UV/Vis spectroscopy. No thermogravimetric measurement was carried out due to the presence of perchlorate anions in this complex. The use of $^{57}$Fe Mössbauer spectroscopy (vide infra), confirmed the nonoxidation of this material since no ferric species were observed for this $Fe^{II}$ compound. Interestingly, this material reveals a distinct colour change on cooling from orange (293 K) to wine brown (77 K). This reversible thermochromic phenomenon was not previously reported.[22]

### Magnetic Susceptibility Measurements

The magnetic data were collected every K over the temperature range 300–1.8 K on cooling and warming modes with an applied field of 10 kOe. The temperature dependence of the molar magnetic susceptibility is displayed in Figure 2 in the form of a $\chi_M T$ vs. $T$ plot, $\chi_M$ being the molar magnetic susceptibility corrected for diamagnetic contributions and $T$ the temperature. At room temperature, $\chi_M T$ is equal to 7.23 $cm^3 mol^{-1} K$, which indicates $Fe^{II}$ ions in the HS state with a $g$ value of 2.197. As $T$ is lowered, $\chi_M T$ initially remains constant down to ca. 280 K and then smoothly decreases in two steps as a result of a HS to LS conversion, reaching a plateau value of 3.43 $cm^3 mol^{-1} K$ at 66 K. The conversion is thus incomplete, ca. 50% of molecules remaining in the HS state. Between 65 and 30 K, the $\chi_M T$ product decreases very slightly, a behaviour that might be attributed to weak antiferromagnetic interactions between paramagnetic spin carriers, as confirmed by applied field $^{57}$Fe Mössbauer spectroscopy. Below 20 K, $\chi_M T$ decreases sharply and falls to 0.96 $cm^3 mol^{-1} K$ at 1.8 K. This behaviour can be attributed to the presence of ZFS splitting due to spin-orbit coupling of the HS $Fe^{II}$ ions, and the preferred Boltzmann population of the lowest levels with decreasing temperatures. The absence of any spin-state crossover at this temperature is unambiguously demonstrated by zero-field $^{57}$Fe Mössbauer spectroscopy (see next section). The spin conversion occurs in two steps with transition temperatures near 240 K and 120 K, respectively. It is of interest to note that the mean transition temperature around 180 K roughly corresponds to the transition temperature deduced from the gradual spin conversion of the first step presented in.[22] As $T$ is increased, the same magnetic behaviour was observed indicating no hysteresis effect in none of the spin conversion branches. This measurement thus confirms the absence of a bistability domain for **1** and does not support the tristability behaviour interpreted in ref.[22]. The calculated $\chi_M T$ values for the nonsolvated dinuclear complex in ref.[22] of 7.70 $cm^3 K mol^{-1}$ and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

3.81 $cm^3 K mol^{-1}$ at room temperature and 66 K, respectively, are noticeably higher than in Figure 2 of the present study. These magnetic data were not calculated for the non-solvated complex as indicated in the caption to Figure 1 in ref.[22] because considering the molecular mass (1718.93 $g mol^{-1}$) and diamagnetic correction (–220.68·$10^{-6}$ $cm^3 mol^{-1}$) for the crystals of $[Fe_2(L)_3](ClO_4)_4 \cdot 4MeOH \cdot H_2O$, we could fully recover the magnetic data presented in ref.[22]. The calculations in ref.[22] are thus not correct because these SQUID measurements were performed on powders of $[Fe_2(L)_3](ClO_4)_4 \cdot 2H_2O$ as done in our study.

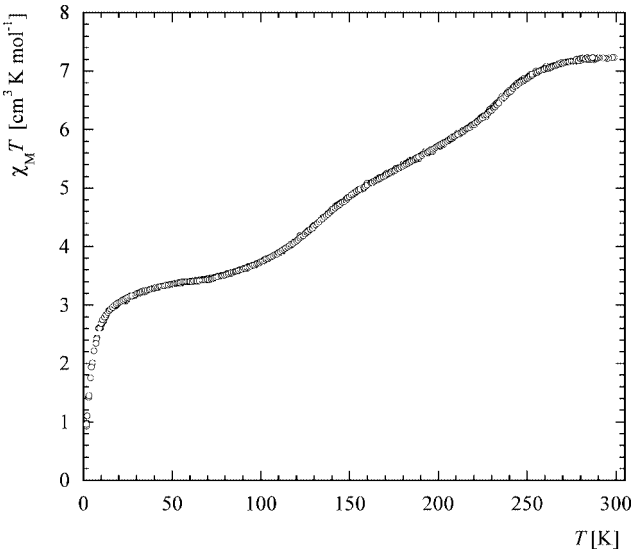

Figure 2. $\chi_M T$ vs. $T$ plot for **1** over the 300–1.8 K range.

### Zero-Field $^{57}Fe$ Mössbauer Spectroscopy

$^{57}Fe$ Mössbauer spectra were recorded for **1** at variable temperatures between 300 K and 4.2 K. Selected spectra are displayed in Figure 3, and detailed values of the Mössbauer parameters at 19 temperatures deduced from least-squares fitting procedures are listed in Table S1 (supp. inf.; for supporting information see also the footnote on the first page of this article). The spectrum at 300 K could be fitted best with two quadrupole doublets. The isomer shift, $\delta$, is 0.98 mm/s for both doublets, the quadrupole splitting, $\Delta$, is 1.20 mm/s and 0.79 mm/s, respectively. Both signals refer to $Fe^{II}$ in the HS state, one denoted as HS(A) with area fraction of ca. 10% and the other as HS(B) with area fraction of ca. 90%. This result is consistent with the magnetic measurements recorded at 300 K that also indicated 100% of HS $Fe^{II}$ ions. On decreasing the temperature the quadrupole splitting of these two $Fe^{II}$ HS species increases (see Figure 4); this is typical for $Fe^{II}$ HS species, where the electric field gradient is dominated by the temperature-dependent valence-electron contribution. The difference between the quadrupole-splitting values of HS(A) and HS(B) is caused by different lattice contributions of opposite sign to that of the valence-electron contributions. The HS(B) signal loses intensity on lowering the temperature at the favour of

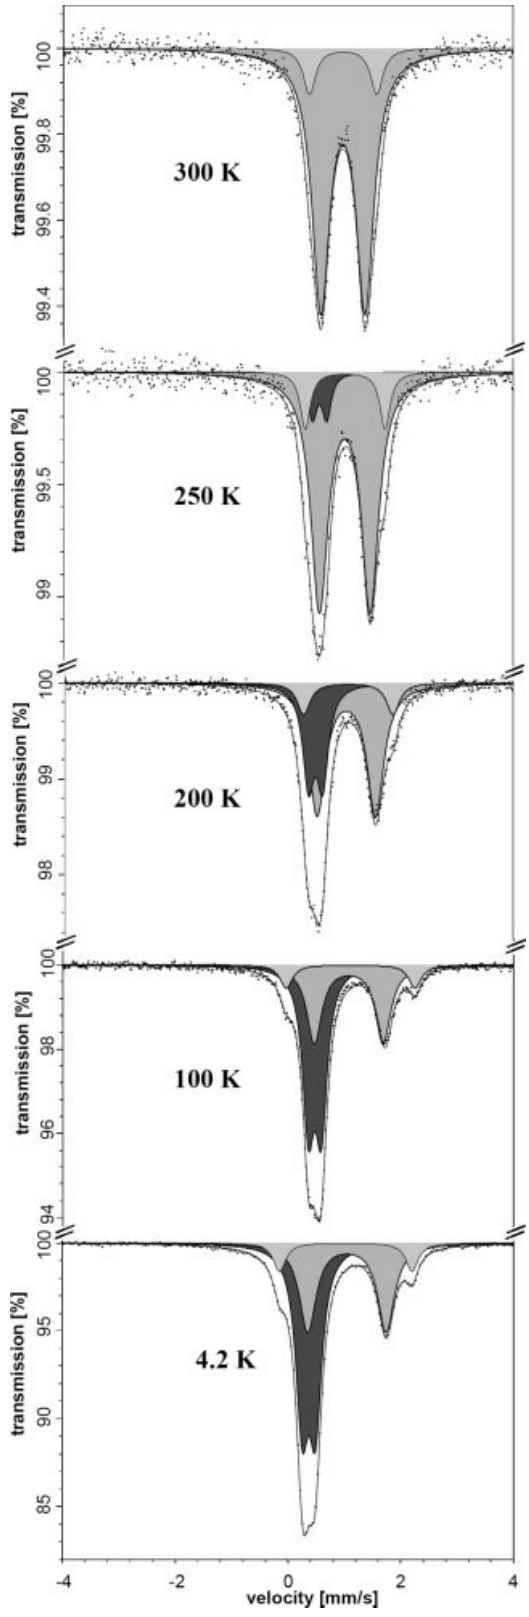

Figure 3. Selected $^{57}Fe$ Mössbauer spectra for **1** over the temperature range 300–4.2 K. The integrals of HS species (A and B) are filled in light grey and grey, respectively, and the LS species (B) in black.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a new signal, a poorly resolved quadrupole doublet with parameter values $\delta$ = 0.57 mm/s and $\Delta$ = 0.25 mm/s typical of iron(II) in the LS state, LS(B) that is seen from 270 K downwards. Thus HS(B) undergoes partial thermal spin conversion to reach a plateau, that is also seen in the $\chi_M T$ curve, corresponding to ca. 40% HS(B) and ca. 50% LS(B) at 4.2 K, while the ca. 10% of HS(A) remains essentially constant over the whole temperature range (Figure 5). The partial spin conversion is completed at about 80 K as noted in the $\chi_M T$ curve. The spectrum obtained at 4.2 K shows, in comparison to the spectrum at 61 K, that the strong decrease of the $\chi_M T$ values to very low temperatures, seen in Figure 2, is not caused by a further decrease of the HS molar fraction and, therefore, not caused by a spin transition. The ZFS with increasing Boltzmann population of the lowest electronic levels on lowering the temperature is responsible for the abrupt decrease below 20 K.

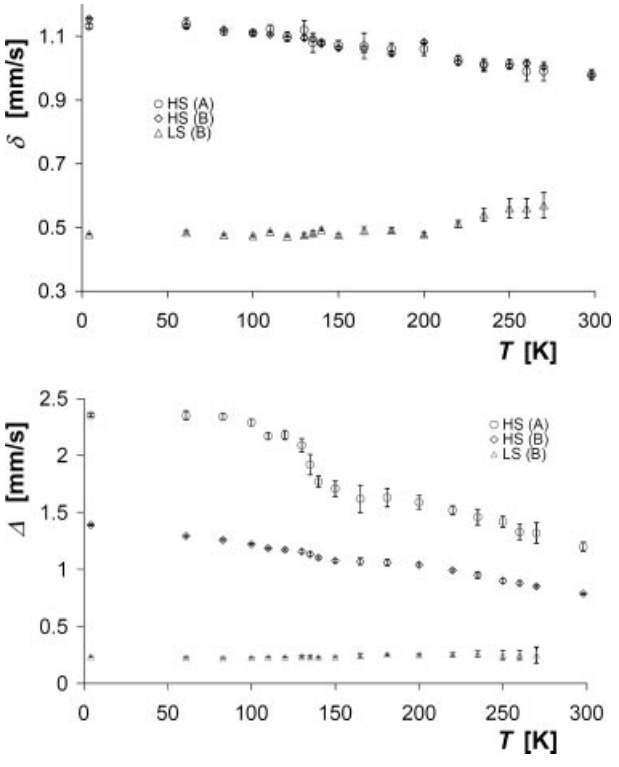

Figure 4. Temperature dependence of isomer shift ($\delta$) and quadrupole splitting values $\Delta$ for site A: ○ (HS) and site B: ◊ (HS), Δ (LS) in **1** over the temperature range 300–4.2 K.

The SCO dinuclear units are thus represented by the HS(B) site. But the nature of the HS(A) site should be discussed. The HS(A) site does not refer to an impurity as a result of oxidation because no ferric species were detected (the isomer shift corresponds to $Fe^{II}$ ions[24] and signal A is present over the whole temperature range of investigation – see Figure 5). It cannot be attributed to the iron starting material, too, for two reasons: (i) The isomer shift of HS(A) is exactly the same as the one of the dinuclear units HS(B) (see Figure 4) (ii) We did not observed a gradual replacement of the lines for this site between ca. 200 K and 250 K, as reported for $[Fe(H_2O)_6](ClO_4)_2$.[25] Therefore,

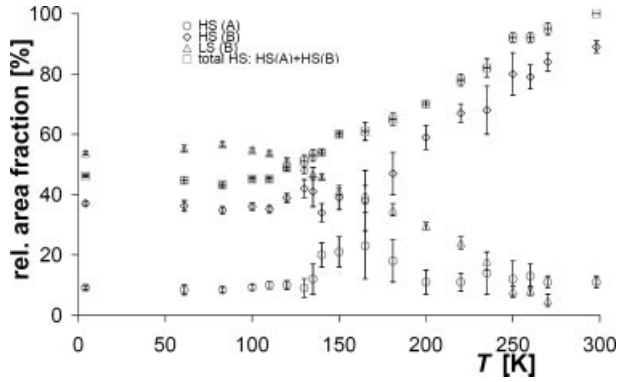

Figure 5. Temperature dependence of the relative area fraction for site A: ○ (HS) and site B: ◊ (HS), Δ (LS) in **1** over the temperature range 300–4.2 K. The HS molar fraction (□) is also given.

HS(A) should correspond to nonswitched complexes that could be either $[Fe_2L_3]^{4+}$ dinuclear units or dinuclear units with one vacant metal centre. Applied field Mössbauer experiments (see next section) have revealed that these species are uncoupled at 4.2 K. We thus favour the hypothesis of the presence of mononuclear species, that is interestingly supported by the detection of mononuclear species in the ESI analysis of **1**.

### Applied Field $^{57}$Fe Mössbauer Spectroscopy

To answer the second question of this study, whether the spin conversion occurs via intermediates of [HS–LS] pair formation or directly from [HS–HS] to [LS–LS] pairs, we have performed a $^{57}$Fe Mössbauer experiment in applied parallel magnetic field (50 kOe) at 4.2 K (Figure 6), as the zero-field Mössbauer spectrum gives only access to the fraction of HS and LS components, irrespective of the nature of the spin pairs involved. The effective hyperfine magnetic field $H_{eff}$ at the iron nuclei of a paramagnetic nonconducting sample in an external field $H_{ext}$ may be estimated as $H_{eff} \approx H_{ext} - [220 - 600(g-2)]\langle S \rangle$, where $\langle S \rangle$ is the atomic spin moment and $g$ the Landé splitting factor.[26,27] The difference between the expectation values of $S$ for $Fe^{II}$ in the LS and in the HS states in [LS–LS], [HS–LS] and [HS–HS] pairs enables one to distinguish unambiguously between the dinuclear units consisting of two possible spin states in an external magnetic field.[11a] To do so, the strength of the external magnetic field should be sufficiently high, and the temperature sufficiently low, in order to avoid magnetic relaxation taking place within the characteristic time window of a Mössbauer experiment ($\approx 10^{-7}$ s). The black spectrum with area fraction of 57% refers to $Fe^{II}$–LS split by a local effective field of 49.4 kOe, which corresponds to the applied magnetic field of 50 kOe, as expected for $\langle S \rangle = 0$ of the LS centres in the [LS–LS]. The grey doublet with area fraction of 37% shows considerable line broadening arising from the interaction with the external field. The value of the effective field calculated from this spectrum is 13 kOe. The two iron HS centres of the [HS–HS] pairs are antiferromagnetically coupled and the resulting spin ladder is thermally popu-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lated leading to the expectation value <S> of ca. 0.4, derived from the formula above. This value results from a weak antiferromagnetic coupling between the two HS $Fe^{II}$ centres of the dinuclear species. The light-grey magnetically split spectrum with area fraction of ca. 6% is typical for uncoupled $Fe^{II}$–HS centres with S = 2 each. This fraction corresponds to the HS(A) site. The calculated effective field is 56 kOe. Thus, no [HS–LS] pairs were detected at 4.2 K.

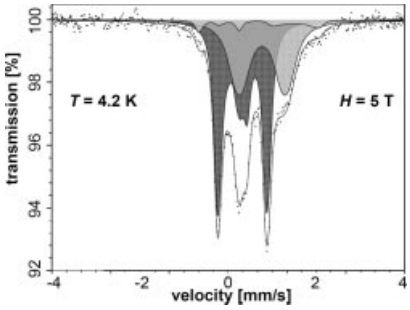

Figure 6. $^{57}$Fe Mössbauer spectrum of **1** recorded at 4.2 K in an external magnetic field of 50 kOe. The signals in black, grey, and light grey refer to LS ions in [LS–LS] pairs, HS ions in [HS–HS] pairs and to uncoupled HS ions, respectively.

## Discussion

The field experiments at 4.2 K may call for the occurrence of thermal spin conversion in the present triple helicate dinuclear system directly from [HS–HS] to [LS–LS] species, contrary to what was observed for the series {[Fe(L)(NCX)$_2$]$_2$(μ-bpym)} (L = bpym, X = S or Se) and (L = bt = 2,2′-bithiazoline and X = S)[23] and for {[Fe(phdia)(NCS)$_2$]$_2$(phdia)} (phdia = 4,7-phenanthroline-5,6-diamine)[14] using the same physical method. According to Real, the predominant factor that determines the existence of [HS–LS] pairs is the strength of intermolecular interactions in these compounds.[28] Indeed, weak intermolecular interactions were taken responsible for the direct [HS–HS] to [LS–LS] transformation observed by applied field Mössbauer spectroscopy in {[Fe(dpa)(NCS)$_2$]$_2$-(bpym)} (dpa = 2,2′-dipyridylamine),[13] but such interactions can be hardly evaluated because this material was not structurally characterised. This is in line with a density functional theory (DFT) study recently reported by Zein and Borshch.[29] These authors have studied the energetics of five binuclear SCO complexes exhibiting different ligand-field strength and different structural arrangements of the bridging ligands. It could be shown that spin transition via the intermediate [HS–LS] pairs occurs only in those cases, where the energy of the [HS–LS] pairs lies below the halfway point between the energies of [LS–LS] and [HS–HS] states. Favourable for this to occur seems to be a planar bridging structure. On the contrary, a strong distortion of the bridging ligand breaks the electronic communication between the metal centres and destabilises the [HS–LS] spin-state shifting it above the halfway point. In such systems, a direct spin transition from [HS–HS] to [LS–LS] is expected and has indeed been observed on the basis of X-ray measurements, for two other binuclear complexes: [(pypzH)(NCSe)Fe(μ-pypz)$_2$Fe(NCSe)(pypzH)]·2H$_2$O displaying an abrupt spin transition[17a] and [{Fe(NCBH$_3$)(4-phpy)}$_2$(μ-bpypz)$_2$] (4phpy = 4-phenylpyridine) presenting a stepwise transition.[16a] This also appears to be the case in the triple helicate system under study that displays a gradual spin conversion despite the fact that all noncoordinated species (perchlorate anions, water and methanol solvent molecules) are involved in hydrogen bonding with the triple-helicate cation in the crystal structure of [Fe$_2$(L)$_3$](ClO$_4$)$_4$·4MeOH·H$_2$O.[22] The use of the very flexible L thus does not propagate efficiently cooperative effects associated with the spin-state change within the dinuclear unit as earlier observed for some Fe coordination polymers exhibiting a gradual SCO behaviour.[30] Interestingly, according to the above mentioned DFT calculations,[29] the step in the spin conversion curve around 180 K (see Figure 2) calls for the presence of an intermediate spin state involving [LS–HS] pairs. This situation is supported by the Zero-field Mössbauer study looking at the evolution of the HS(A) fraction as well as its Mössbauer parameters. On cooling, in the region slightly below the step, the quadrupole splitting increases rather abruptly and follows from then on the usual increase of the quadrupole splitting with decreasing temperature (Figure 4). The jump in quadrupole splitting falls together with the formation of the [LS–LS] pairs. If we consider that the transition would directly occur from [HS–HS] to [LS–LS], we would then rather expect a continuous increase in quadrupole splitting as is commonly observed for iron(II) HS compounds. The ca. 50% gradual spin conversion of **1** thus occurs via [LS–HS] pairs formation and is complete for the involved fraction since these pairs are not present at 4.2 K. A quantitative evaluation of the population of these mixed species could not be obtained by applied field Mössbauer spectroscopy due to the high temperature range of the plateau (≈ 180 K) that would have prevented the trapping of the sample to 4.2 K by rapid cooling. During the pronounced change of the quadrupole splitting of HS(A) the area fraction of this site increases and decreases again (see Figure 5). This indicates transient stiffening of the nearby lattice which shows that these HS sites, although presumably not directly linked to the dinuclear complexes, may take part in the cooperative elastic interactions accompanying the spin conversion process.

## Conclusions

The spin-state-crossover phenomenon in [Fe$_2$(L)$_3$](ClO$_4$)$_4$·2H$_2$O (**1**) investigated by precise SQUID magnetic measurements performed over the temperature range (300–1.8 K) occurs in two steps at ca. 240 K and ca. 120 K. $^{57}$Fe Mössbauer data recorded at 4.2 K have demonstrated that half of the $Fe^{II}$ ions remains in the HS state, and that the second drop of $\chi_M T$ observed below ca. 20 K cannot be attributed to a spin-state conversion. The absence of any hysteresis effect also disapproves the "multistability" char-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

acter reported for **1**,[22] and confirms the noncooperative character of the spin conversion. Applied field Mössbauer measurements demonstrate the occurrence of a complete thermal spin conversion for half of the iron(II) ions from [HS–HS] to [LS–LS] species because no [LS–HS] species were identified at 4.2 K. The mechanism of this spin-state conversion should, however, involve [LS–HS] species that should be responsible of the presence of the plateau around 180 K in the magnetic measurements (Figure 2) and which are sensed in the Mössbauer parameters of an uncoupled iron(II) site. Further experiments are planned to confirm the presence of these mixed species in this novel system.

## Experimental Section

**General:** All reagents and solvents were used as received from commercial sources. $^1$H NMR spectra were recorded with a Gemini 200–92, 200 MHz spectrometer. The solvent residual peak has been set as a reference. CHN analyses have been performed by the Zentrale Analytik of the Institute für Organische Chemie (Mainz). IR spectra were collected with a BioRad FTS-135 spectrometer using KBr pellets. UV spectra in solution were recorded with a Cary 50 spectrometer and diffuse reflectance spectra on solids were recorded with a CARY 5E spectrophotometer using polytetrafluoroethylene as a reference. Mass spectra were recorded with a Thermo Finnigan LCQ Ion Trap spectrometer using ESI mode and detecting positive ions. Magnetic susceptibilities were measured over the temperature range 1.8–300 K with a cooling and heating rate of 2 K/min with a Quantum Design MPMS*XL* SQUID magnetometer equipped with a 50-kOe magnet operating at 10 kOe. Magnetic data were corrected for diamagnetic contributions, which were estimated from Pascal's constants. $^{57}$Fe Mössbauer spectra were recorded in transmission geometry with a conventional constant-acceleration spectrometer with a room temperature $^{57}$Co(Rh) source over the temperature range (300–83 K). The samples were sealed in a Plexiglas sample holder. For the 4.2 K experiment, the samples were mounted in a helium-bath cryostat with a $^{57}$Co(Rh) source that was kept at 4.2 K. A superconducting magnet was applied to create a magnetic field directed parallel to the wave vector of the $\gamma$-quanta. The spectra were fitted to Lorentzians using Recoil 1.05 Mössbauer Analysis Software[31] assuming equal Debye–Waller factors of the HS and LS states of the $Fe^{II}$ ions. All isomer shifts refer to natural Fe at room temperature.

**Synthesis of L:** The L ligand has been prepared as a white solid by a condensation reaction of 4,4′-methylenedianiline and 3*H*-imidazole-4-carboxaldehyde in methanol according to ref.[22]. $^1$H NMR (200 MHz, DMSO, 25 °C): $\delta$ = 8.43 (s, 1 H, $H^{im}$), 7.82 (s, 1 H, $H^{2/4}$); 7.64 (s, 1 H, $H^{2/4}$), 7.24 (d, $J$ = 7.6 Hz, 2 H, $H^{Ph}$), 7.15 (d, $J$ = 7.6 Hz, 2 H, $H^{Ph}$), 3.96 ppm (s, 1 H, $CH_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3021 (w), 2907 (w), 2827 (*w*), 1629 (vs), 1600 (s), 1541 (vw), 1501 (s), 1437 (m), 1414 (*w*), 1351 (w), 1330 (*w*), 1299 (w), 1222 (*m*), 1201 (*w*), 1170 (w), 1148 (sh), 1109 (w), 1093 (m), 1014 (w), 990 (m), 977 (sh), 918 (w), 873 (m), 844 (m), 808 (w), 787 (w), 753 (w), 709 (w), 622 (s), 601 (w), 539 (m) cm$^{-1}$.

**Synthesis of 1:** The complex $[Fe_2L_3](ClO_4)_4{\cdot}2H_2O$ was prepared as an orange powder according to a procedure slightly adapted from that in ref.[22] substituting the addition of $LiClO_4$ by $Fe(ClO_4)_2{\cdot}6H_2O$ to avoid the presence of unwanted cationic species and a few mg of ascorbic acid to prevent oxidation of $Fe^{II}$ ions. Yield: 0.097 g (67%). $C_{63}H_{58}Cl_4Fe_2N_{18}O_{18}$ (1608.77): calcd. C 47.04, H 3.63, N 15.67; found C 47.10, H 3.67, N 15.58. IR (KBr): $\tilde{\nu}$ = 3131 (br), 2932 (w), 2853 (w), 1620 (vs), 1599 (s), 1558 (w), 1540 (w), 1506 (s), 1501 (sh), 1437 (m), 1294 (m), 1232 (w), 1207 (w), 1090 (vs), 1009 (m), 935 (vw), 892 (m), 861 (w), 814 (m), 756 (w), 708 (w), 625 (s), 544 (w) cm$^{-1}$. UV/Vis (PTFE): $\lambda_{max}$ = 470 nm (MLCT), 880 nm ($^5E \leftarrow {}^5T_2$). # "To Bend or not To Bend?" Both! The Planar and Bent Structures of $[(Ph_3P)_4Rh_2(\mu\text{-}F)_2]$

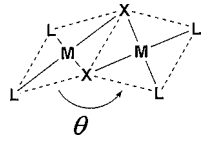
**William J. Marshall,*[a] Gabriel Aullón,*[b] Santiago Alvarez,[b] Kerwin D. Dobbs,[a] and Vladimir V. Grushin*[a]**

**Keywords:** Isomerism / Rhodium / Fluorine / X-ray diffraction / Theoretical calculations

The first experimental evidence is presented for planar–bent isomerism of complexes of the type $[L_4M_2(\mu\text{-}X)_2]$. Both the planar and bent forms have been detected for *the same composition*, $[(Ph_3P)_4Rh_2(\mu\text{-}F)_2]$, with full exclusion of any variation in such factors as the nature of the metal, ligand, counterion, and solvent of co-crystallization. Computational studies point to weak C–H···F intramolecular bonding as an additional factor affecting the choice between the planar and bent geometries.

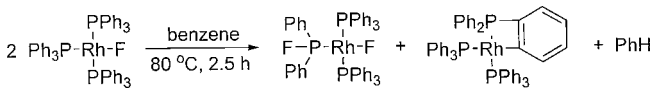
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

In 1998, two of us published a paper entitled "To Bend or Not To Bend: Dilemma of the Edge-Sharing Binuclear Square Planar Complexes of $d^8$ Transition Metal Ions".[1] This publication provided a structural and theoretical analysis of complexes of the type $[L_4M_2(\mu\text{-}X)_2]$ which are ubiquitous in the chemistry of catalytically important metals such as Ni, Pd, Pt, Rh, and Ir.[1–3] A remarkable feature of such dinuclear complexes is their ability to exist in either planar or bent forms, with the bending angle $\theta$ (Scheme 1) showing a bimodal distribution with maxima at 130 and 180°. Analysis of well over 100 X-ray structures of $[L_4M_2(\mu\text{-}X)_2]$ (X = halogen or chalcogen) indicated that for M = Rh, Pd, and Pt, both bent and planar geometries are commonly observed.[1] The energy cost of bending for such complexes is normally low, often only a few kcal mol$^{-1}$,[1,4] suggesting that both forms could be found experimentally for a single species. Both almost planar and more bent molecules have been found in the crystal structure of *non-square-planar* $[Co_2(\mu\text{-}PPh_2)_2(CO)_6]$.[5] The $Pt_2(\mu\text{-}S)_2$ moiety in complexes of the type $[L_4Pt_2(\mu\text{-}S)_2]$ is commonly bent,[1] though for L = 2-(diphenylphosphanyl)pyridine, a planar structure was reported.[6] Depending on the nature of the counterion X in $[Pt_2(NH_3)_4(\mu\text{-}OH)_2]X_2$, both the planar (X = $NO_3$[7] or 1/2$CO_3$, dihydrate[8]) and bent (X = $ClO_4$[9]) forms of the cation can exist in the crystalline state. The angle $\theta$ for these structures is apparently governed by H-bonding interactions involving the anion, as well as by different packing requirements for different X. There have been no literature reports describing a compound of the type $[L_4M_2(\mu\text{-}X)_2]$, for which *both* planar and bent forms have been detected for *the same composition*, with full exclusion of any variation in the ligand, counterion, solvent of crystallization, and so forth. In this communication, we report the first example of such a complex, $[(Ph_3P)_4Rh_2(\mu\text{-}F)_2]$.



Scheme 1.

Some of us recently reported[10,11] that the fluoro congener of Wilkinson's catalyst, $[(Ph_3P)_3RhF]$, exhibits intriguing reactivity patterns. For instance, heating of $[(Ph_3P)_3RhF]$ in benzene (at 80 °C for 2.5 h) leads to F transfer to one of the P atoms, as shown in Equation (1).[10]



(1)

The reaction occurs by reversible Ph/F exchange as the first key step.[11] In order to determine if the resulting fluoride complex, *trans*-$[(Ph_3P)_2(Ph_2PF)RhF]$, was also capable of undergoing such Ph/F exchange, the thermolysis was conducted for longer periods of time. After 5–6 h at 80 °C, complex reaction mixtures were produced, as judged by $^{19}F$

and $^{31}P$ NMR analysis. Because the NMR spectroscopic data did not allow for unambiguous characterization of new compounds, a series of attempts were made to isolate some of the products by fractional crystallization. After the reaction solutions were concentrated and treated with ether and/or hexane, single crystals were obtained. X-ray analysis of one of the gold-yellow square plates revealed the structure of ideally planar ($\theta$ = 180°) $[(Ph_3P)_4Rh_2(\mu\text{-}F)_2]$ (**1**).[12] Poor quality, disordered structures of $\mathbf{1}\cdot 2C_6H_6$ and $\mathbf{1}\cdot 2C_6H_5CH_3$ have been mentioned before.[10] The formation of $[(PPh_3)_4Rh_2(\mu\text{-}F)_2]$ is easily accounted for by dissociation and decomposition of the (in its free form[13,14]) unstable $Ph_2PF$ from $[(Ph_3P)_2(Ph_2PF)RhF]$ to give "$[(PPh_3)_2RhF]$" which would undergo dimerization to **1**.

In another experiment under similar reaction and crystallization conditions, growth of very thin, "two-dimensional" looking yellow plates was noticed. Although the bulkiest crystal in the batch appeared to be only ca. 0.005 mm thick, its X-ray analysis was achieved with a Bruker Smart Apex-II CCD instrument. To our surprise, the crystal was comprised of the same dimer $[(Ph_3P)_4Rh_2(\mu\text{-}F)_2]$ but in a *bent* form ($\theta$ = 133.7°). The planar (**1-p**) and bent (**1-b**) structures are shown in Figures 1 and 2, respectively.[12] The quality of the structure of **1-b** was limited by the crystal size/shape, and structure subtleties such as bond lengths and angles should be looked at with care. Most importantly, the bent geometry was established beyond any doubt.

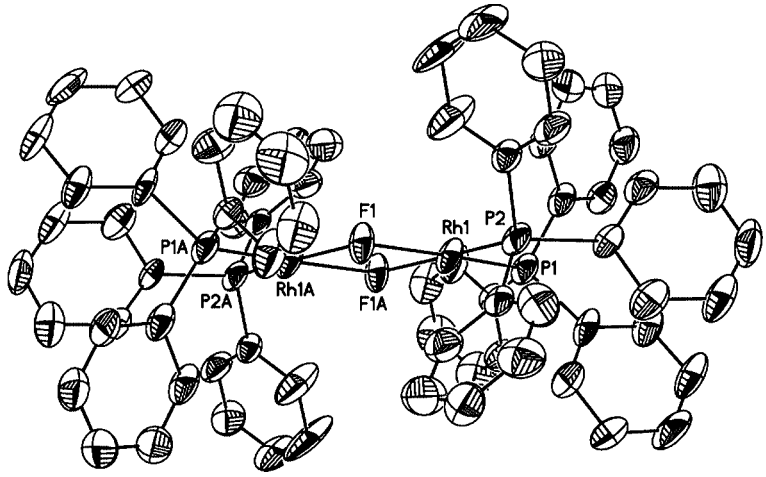

Figure 1. ORTEP view of the planar form of **1** (**1-p**) with thermal ellipsoids drawn to the 50% probability level. Selected bond lengths [Å] and angles [°]: Rh(1)–F(1) 2.131(5), Rh(1)–F(1A) 2.141(5), Rh(1)–P(1) 2.161(3), Rh(1)–P(2) 2.185(3); F(1)–Rh(1)–F(1A) 77.3(2), F(1)–Rh(1)–P(1) 171.4(2), F(1A)–Rh(1)–P(1) 94.2(1), F(1)–Rh(1)–P(2) 93.2(2), F(1A)–Rh(1)–P(2) 170.1(1), P(1)–Rh(1)–P(2) 95.4(1).

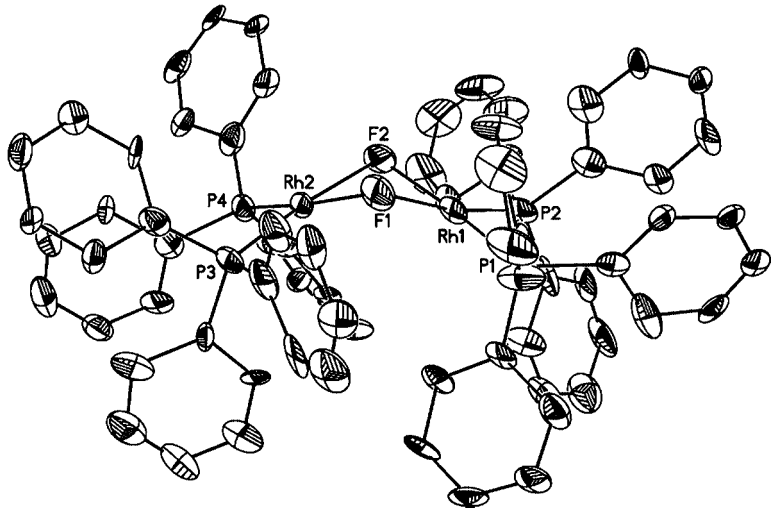

Figure 2. ORTEP view of the bent form of **1** (**1-b**) with thermal ellipsoids drawn to the 50% probability level. Selected bond lengths [Å] and angles [°]: Rh(1)–F(1) 2.02(1), Rh(1)–F(2) 2.07(1), Rh(1)–P(2) 2.116(6), Rh(1)–P(1) 2.146(7), Rh(1)–Rh(2) 2.972(6), Rh(2)–F(1) 2.04(1), Rh(2)–F(2) 2.08(1), Rh(2)–P(4) 2.109(6), Rh(2)–P(3) 2.115(6); F(1)–Rh(1)–F(2) 76.1(5), F(1)–Rh(1)–P(2) 169.8(4), F(2)–Rh(1)–P(2) 95.7(3), F(1)–Rh(1)–P(1) 93.9(4), F(2)–Rh(1)–P(1), 170.0(3), P(2)–Rh(1)–P(1) 94.3(2), F(1)–Rh(1)–Rh(2) 43.1(4), F(2)–Rh(1)–Rh(2) 44.5(3), P(2)–Rh(1)–Rh(2) 133.0(2), P(1)–Rh(1)–Rh(2) 126.82(14), F(1)–Rh(2)–F(2) 75.6(5), F(1)–Rh(2)–P(4) 167.7(3), F(2)–Rh(2)–P(4) 92.1(4), F(1)–Rh(2)–P(3) 95.6(4), F(2)–Rh(2)–P(3) 170.6(4), P(4)–Rh(2)–P(3) 96.6(2), F(1)–Rh(2)–Rh(1) 42.8(3), F(2)–Rh(2)–Rh(1) 44.3(4), P(4)–Rh(2)–Rh(1) 126.6(2), P(3)–Rh(2)–Rh(1) 126.6(2).

The structures of **1-p** and **1-b** were carefully examined to see if the Rh centers could be bridged by OH, rather than F. There was no evidence from the X-ray data that either structure contained OH based upon occupancy refinement or the location of hydrogen atoms from difference maps. However, the X-ray data from structures of this quality cannot rule out completely the presence of OH either partially or fully occupied in the bridging position. While direct X-ray evidence cannot be obtained for the lack of OH in the crystals, a number of experimental facts support the formulation $[(Ph_3P)_4Rh_2(\mu\text{-}F)_2]$. Complex **1** has been found[15a] uncommonly stable toward hydrolysis. Rigorously anhydrous conditions[11] were used all through the experiments, from the thermolysis to the fractional crystallization steps. The starting material, $[(Ph_3P)_3RhF]$, was free of $[(Ph_3P)_4Rh_2(\mu\text{-}OH)_2]$ (NMR), the "would-be" product of its hydrolysis. Because there is no fast exchange between $[(Ph_3P)_3RhF]$ and $[(Ph_3P)_4Rh_2(\mu\text{-}OH)_2]$,[15a] the presence of the latter would have been easily detected. The reaction mixtures were studied by $^{19}F$ and $^{31}P$ NMR prior to fractional crystallization in a dry-box. The NMR spectra indicated the presence of **1**[10] and no detectable amounts of $[(Ph_3P)_4Rh_2(\mu\text{-}OH)_2]$ with the characteristic chemical shift and $J$(Rh–P) coupling constant.[15b] It is also noteworthy that unlike **1**, $[(Ph_3P)_4Rh_2(\mu\text{-}OH)_2]$ crystallizes with 2 molecules of benzene under similar conditions.[15c] Measuring NMR spectra of the crystals in bulk supported the formulation $[(Ph_3P)_4Rh_2(\mu\text{-}F)_2]$.[10] The ultimate solution to the problem, however (as also suggested by a referee), would be obtaining NMR spectroscopic data for the very crystals used in the X-ray determination. This, however, is not experimentally feasible. The masses of the crystals of **1-p** ($0.420 \times 0.420 \times 0.030$ mm; $d = 1.454$ g cm$^{-3}$) and **1-b** ($0.320 \times 0.300 \times$ ca. 0.005 mm; $d = 1.618$ g cm$^{-3}$) were ca. 0.0077 mg and 0.00078 mg, respectively. Such quantities are not amenable to a solution NMR study.

The difference in energy between the planar and bent forms ($\Delta E$) of **1** is expected to be small. For instance, the $\Delta E$ value from the ab initio (MP2) study of the planar ($\theta = 180°$) and bent ($\theta = 139.1°$) forms of $[(PH_3)_4Rh_2(\mu\text{-}F)_2]$ has been computed at about 3 kJ mol$^{-1}$,[1] the smallest difference among the series of analogous halide-bridged rhodium complexes. This small value suggests that the observed deviation from the planar geometry of **1** may be easily forced by weak ligand–ligand interactions or different crystal-packing requirements, e.g., due to co-crystallization with different solvents. Remarkably, however, both X-ray-analyzed crystals contained only molecules of **1** and no other co-crystallized species. Examination of the X-ray structures of **1-p** and **1-b** did not reveal any conclusive evidence that the crystal packing might influence the bending along the F···F hinge.

Both structures exhibit intramolecular CH···F close contacts, as defined by being shorter than the sum of the van der Waals radii (2.67 Å). Such CH···F interactions are common for late transition metal fluoride complexes.[16] In the planar form (**1-p**) each F atom interacts with *two ortho*-hydrogen atoms of two different phenyl groups of the same phosphane ligand with the H···F distances of 2.45 and 2.49 Å and corresponding C···F distances of 3.11 and 3.21 Å. In contrast, each fluorine atom of the bent form (**1-b**) exhibits only *one* short CH···F contact. Within the bent molecule, the two non-symmetry related H···F distances are observed at 2.26 and 2.64 Å with C···F distances of 3.02 and 2.92 Å, respectively. At difference with the planar form, the bent form (**1-b**, Figure 2) presents three intermolecular contacts shorter than 3.0 Å to the bridging fluorine atoms. It should be emphasized that because of the limited quality of the structures the presented H···F distances should be interpreted with care.

The unusual existence of both the planar and the bent forms of $[(Ph_3P)_4Rh_2(\mu\text{-}F)_2]$ prompted us to perform exploratory electronic structure calculations in search for an explanation, using DFT at the B3LYP level.[17] First, we verified that the DFT calculations do reproduce the qualitative expectations of the higher level MP2 calculations, using the simplified model complexes $[(R_3P)_4Rh_2(\mu\text{-}F)_2]$ (R = H, Me) in which the phenyl rings in the phosphane ligands were substituted by the computationally affordable H atoms or Me groups. Energy optimization of their bent and planar forms tells us that the two geometries correspond to two nearly isoenergetic minima (characterized through a vibrational analysis; geometries provided in the Supporting Information). We note also that B3LYP calculations have been shown to provide excellent results for the analysis of bending of dinuclear complexes similar to the ones studied here.[18]

These results, combined with the structural information of the short contacts between the bridging fluoride ions and the phenyl groups of the phosphanes, suggest that the F···Ph interactions may govern the choice between the planar and bent forms. Therefore, we studied the interaction between $[(H_3P)_4Rh_2(\mu\text{-}F)_2]$ and an independent benzene molecule. Two energy minima were found for the $[(H_3P)_4Rh_2(\mu\text{-}F)_2]\cdots C_6H_6$ adduct. In one of them, one C–H···F contact is formed while the $Rh_2F_2$ core remains practically planar ($\theta = 165°$). The slight degree of bending is most likely an artefact of the choice of only one benzene ring to study this interaction, because in the experimental planar structure each fluorine atom interacts with one phenyl proton at each side of the molecular plane. In the other minimum found for the adduct, two C–H···F contacts appear between two *ortho*-hydrogen atoms of the *exo*-phenyl group and the two bridging fluorine atoms, quite similar to the intermolecular interaction found in the experimental bent structure **1b**. Moreover, the optimized adduct presents a minimum only at a bent geometry ($\theta = 148°$), thus giving support to the idea that the intermolecular C–H···F contacts favor the bent structure.[19] Further support to the effect of the weak hydrogen bonds governing the molecular geometry comes from calculations on $[(H_2PhP)_4Rh_2(\mu\text{-}F)_2]$, in which the phenyl substituents pointing to the central part of the molecule have been retained. This complex has only one energy minimum with a planar geometry and two short intramolecular F···H contacts (2.14 Å) per fluorine atom.

Let us concisely review the factors influencing the bending in $[L_4M_2(\mu\text{-}X)_2]$,[1] as applied to **1**.

**The Nature of the Metal.** Of the metals that may present both planar and bent structures (Rh, Ir, Pd, and Pt), rhodium is the one that favors the most diverse distribution. For the other metals, planar structures prevail for palladium and platinum, while only bent structures are found for iridium.

**The Nature of the Bridging Atom.** Of all the halogens, fluorine is apparently the one, for which the smallest $\Delta E$ value is expected. The ab initio (MP2) calculated values for $\Delta E$ in $[(PH_3)_4Rh_2(\mu\text{-}X)_2]$ are 3, 17, 26, and 31 kJ mol$^{-1}$, for X = F, Cl, Br, and I, respectively.[1]

**The Nature of the Terminal Ligand.** It has been concluded[1] that bent structures for $[L_4M_2(\mu\text{-}X)_2]$ are favored by monodentate ligands L that are good σ-donors/π-acceptors. Strongly σ-donating organic tertiary phosphanes $R_3P$ are also recognized[20] as π-acids, the combination of electronic properties that might be important for stabilization of the M–F bond in late transition metal fluorides.[15a] With regards to steric properties, the bending in **1** is surprising due to the presence of four bulky $PPh_3$ ligands which normally favor only planar structures.[1]

**The Substituents of the Phosphane Ligand.** Given the small energy difference between the planar and bent forms to be expected for the $[(PR_3)_4Rh_2(\mu\text{-}F)_2]$ compounds, the ability of the R groups to form weak hydrogen bonds with the bridging fluorine atoms, combined with the different orientation of the $PR_3$ groups in the planar and bent forms, may stabilize the form with the larger number of short H···F contacts for R = Ph, but not for R = Me.[19]

Very poor solubility of **1** precludes its low-temperature NMR studies in solution. More easily soluble Werner's Rh–F dimer $[(i\text{Pr}_3P)_4Rh_2(\mu\text{-}F)_2]$[21] has been found[11,15a] planar in the solid state. A detailed solution NMR study[21] did not reveal the presence of two or more isomers of $[(i\text{Pr}_3P)_4Rh_2(\mu\text{-}F)_2]$ at room temperature. Because the $^{19}F$ and $^{31}P$ spectral parameters of **1** are similar,[10] the barrier to planar–bent isomerization of both $[(i\text{Pr}_3P)_4Rh_2(\mu\text{-}F)_2]$ and **1** may be low enough to regard **1-p** and **1-b** as conformational isomers.

It is worth mentioning in this communication one more unexpected result obtained during our studies of decomposition of $[(Ph_3P)_3RhF]$ at prolonged heating. After a benzene solution of $[(Ph_3P)_3RhF]$ in glass had been kept at 80 °C for 48 h, the formation of well-shaped yellow crystals was noticed. Although the amount of these crystals was insufficient for full characterization in bulk, single-crystal X-ray analysis was carried out to reveal the astounding structure of a cationic $Rh^I$ complex $[(dppbz)_2Rh]^+X^-$ (**2**)[12] where dppbz = 1,2-bis(diphenylphosphanyl)benzene [Equation (2); Figure 3].[22] The nature of the counterion $X^-$ could not be established unambiguously. In the X-ray analysis, the anion refined well as tetrahedral $[F_3SiO]^-$. Indeed, when the experiment was repeated in a teflon reactor, no precipitation was observed, indicating that the bis(chelate) was not produced. Although the formation of $[(dppbz)_2Rh]^+$ from $[(Ph_3P)_3RhF]$ in glass is certainly remarkable, we did not carry out a detailed study of this reaction [Equation (2)], as it was beyond the scope of this project. It is noteworthy, however, that monitoring the long-term decomposition of $[(Ph_3P)_3RhF]$ by $^{31}P$ and $^{19}F$ NMR spectroscopy indicated intermediate formation of several Rh species bearing $PhPF_2$ as a ligand, i.e. triplets of multiplets with large triplet coupling constants of ca. 900–1100 Hz in the $^{31}P$ NMR spectra. Hence, the originally formed $Ph_2PF$ ligand [Equation (1)] is apparently capable of undergoing further Ph/F exchange with fluoride on Rh, albeit at considerably slower rates.

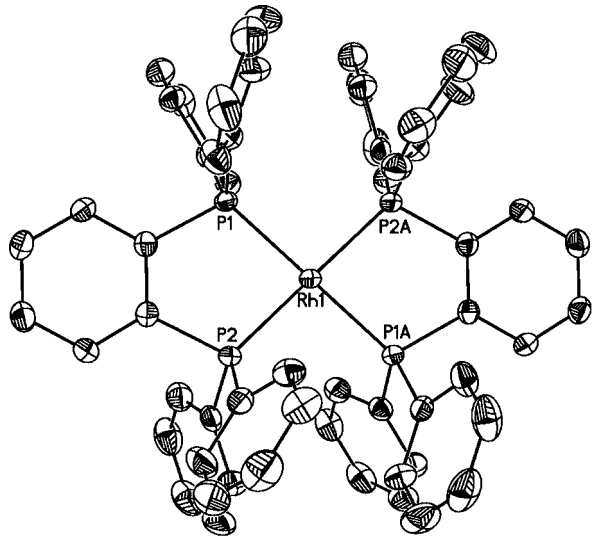

Figure 3. ORTEP view of the cation of **2** with thermal ellipsoids drawn to the 50% probability level. Selected bond lengths [Å] and angles [°]: Rh(1)–P(2A) 2.2807(7), Rh(1)–P(2) 2.2807(7), Rh(1)–P(1) 2.2975(7), Rh(1)–P(1A) 2.2976(7); P(2A)–Rh(1)–P(2) 174.93(3), P(2A)–Rh(1)–P(1) 95.03(2), P(2)–Rh(1)–P(1) 85.00(2), P(2A)–Rh(1)–P(1A) 85.00(2), P(2)–Rh(1)–P(1A) 95.03(2), P(1)–Rh(1)–P(1A) 179.29(3).

In conclusion, we have obtained the first experimental evidence for the existence of a single compound of the type $[L_4M_2(\mu\text{-}X)_2]$ in *both* planar and bent forms. Most importantly, the two forms have been detected for *the same composition*, $[(Ph_3P)_4Rh_2(\mu\text{-}F)_2]$, with full exclusion of any varia-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion in such factors as the nature of the metal, ligand, counterion, and solvent of co-crystallization. For the first time, experimental support has been provided to the previous theoretical results predicting a very small difference in energy between the planar and bent forms for dimers of the type $[L_4M_2(\mu\text{-}X)_2]$. The preliminary DFT study suggests that the hydrogen bonding pattern will govern whether the planar or bent form is isolated.

**Supporting Information** (see footnote on the first page of this article): Tables containing atomic coordinates of the B3LYP optimized geometries of $[(H_3P)_4Rh_2(\mu\text{-}F)_2]$ and $[(Me_3P)_4Rh_2(\mu\text{-}F)_2]$ in their planar and bent conformations, of the adducts formed by benzene and $[(H_3P)_4Rh_2(\mu\text{-}F)_2]$ in the *exo* and *endo* orientations, and of $[(H_2PhP)_4Rh_2(\mu\text{-}F)_2]$. Figures showing the energy of interaction between a benzene molecule and $[Rh_2(\mu\text{-}F)_2(PH_3)_4]$ as a function of the intermolecular F···H distance, calculated at the B3LYP and MP2 levels, and the relative B3LYP energy of $[(Me_3P)_4Rh_2(\mu\text{-}F)_2]$ as a function of the bending angle $\theta$.

## Acknowledgments

This is DuPont CRD Contribution No. 8618. We thank Professor Agustí Lledós for fruitful discussions. Support from Dirección General de Investigación (MEC, project CTQ2005-08123-C02-01/BQU) to G. A. and S. A. is thankfully acknowledged.

[12] Data for all structures were collected at –100 °C using a Bruker APEX-II CCD system equipped with Mo-$K_\alpha$ radiation. Indexing and integration were performed using the Bruker APEX-II software suite and the structures were solved and refined on $|F^2|$ using the SHELXTL software suite. All of the hydrogen atoms were idealized using a riding model. Extra redundant reflections were collected and a SADABS correction was applied to help minimize absorption effects. Specific parameters are as follows. **1-p:** Square plate, $0.42\times0.42\times0.03$ mm, triclinic, $P\bar{1}$, $a$ = 9.130(7), $b$ = 13.311(10), $c$ = 14.106(11) Å, $\alpha$ = 67.872(14), $\beta$ = 71.577(16), $\gamma$ = 72.832(18)°, $V$ = 1476(2) Å$^3$, $\rho_{calcd.}$ = 1.454 g/cm$^3$, $\mu$(Mo) = 0.72 mm$^{-1}$, total data = 18279, unique data = 5507, $2\theta$ range = 3.20–51.40°, parameters = 362, $R$ indices [$I>4\sigma(I)$]: $R_1$ = 0.089, $wR_2$ = 0.203, $R$ indices (all data): $R_1$ = 0.166, $wR_2$ = 0.223, max. difference peak/hole = 2.55/–2.11 e/Å$^3$. **1-b:** Thin plate, $0.320\times0.300\times$ca. 0.005 mm, monoclinic, $P21/c$, $a$ = 13.32(3), $b$ = 34.39(8), $c$ = 13.04(3) Å, $\beta$ = 117.31(4)°, $V$ = 5307(21) Å$^3$, $\rho_{calcd.}$ = 1.618 g/cm$^3$, $\mu$(Mo) = 0.80 mm$^{-1}$, total data = 32033, unique data = 10735, $2\theta$ range = 3.64–52.74°, parameters = 716, restraints = 1365, $R$ indices [$I>4\sigma(I)$]: $R_1$ = 0.168, $wR_2$ = 0.347, $R$ indices (all data): $R_1$ = 0.274, $wR_2$ = 0.381, max. difference peak/hole = 2.97/–2.62 e/Å$^3$. The overall quality of this structure was poor due to the small crystal size. A number of restraints were used to help stabilize the refinement including SAME, FLAT, SIMU and ISOR commands. **2:** Irregular block, $0.17\times0.17\times0.12$ mm, monoclinic, $C2/c$, $a$ = 16.062(3), $b$ = 15.054(3), $c$ = 23.422(4) Å, $\beta$ = 104.797(3)°, $V$ = 5475.6(18) Å$^3$, $\rho_{calcd.}$ = 1.425 g/cm$^3$, $\mu$(Mo) = 0.50 mm$^{-1}$, total data = 21929, unique data = 6807, $2\theta$ range = 3.60–56.66°, parameters = 383, restraints = 13, $R$ indices [$I>4\sigma(I)$]: $R_1$ = 0.039, $wR_2$ = 0.094, $R$ indices (all data): $R_1$ = 0.064, $wR_2$ = 0.101, max difference peak/hole = 0.62/–0.60 e/Å$^3$. CCDC-295809 (**1-p**), -295810 (**1-b**), and -295811 (**2**) contain the supplementary crystallographic data for this paper. [19] Calculations on the corresponding methane adduct $[(H_3P)_4Rh_2(\mu\text{-}F)_2]\cdots CH_4$ at the B3LYP level gives an interaction energy of less than 1 kJ mol$^{-1}$, pointing to an almost negligible effect of the C–H···F contact. This is in contrast with the non-negligible effect (4 kJ mol$^{-1}$ at the same level of theory) for the benzene adduct $[(H_3P)_4Rh_2(\mu\text{-}F)_2]\cdots C_6H_6$. The attractive nature of the weak hydrogen bonds in the $[(H_3P)_4Rh_2(\mu\text{-}F)_2]\cdots C_6H_6$ adduct has been verified by re-calculating the interaction energy curve at the MP2 level (with correction for the basis set superposition error), that indicates a bonding interaction of some 13 kJ mol$^{-1}$ at an optimum distance of 2.5 Å, and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

still significant interaction (11 kJ mol$^{-1}$) at 3.0 Å (see Supporting Information, Figure S1).

# Actinide-Transition Metal Heteronuclear Ions and Their Oxides: $\{IrUO\}^+$ as an Analogue to Uranyl

**Marta Santos,[a] Joaquim Marçalo,*[a] António Pires de Matos,[a] John K. Gibson,*[b] and Richard G. Haire[b]**

**Keywords:** Actinides / Ion–molecule reactions / Isolobal relationship / Mass spectrometry / Metal–metal interactions / Uranium

Recent theoretical calculations have shown that Ir should behave as a chemical analogue to N, with the result that $IrUO^+$, like known $NUO^+$, is predicted to be a stable species isoelectronic with $UO_2^{2+}$, the uranyl dication. The target heterometallic analogue to uranyl has now been prepared by direct laser desorption/ionization of a U/Ir alloy, and by oxidation of $UIr^+$ with $N_2O$ and $C_2H_4O$. Properties of $UIr^+$, $UPt^+$, and $UAu^+$ bimetallic ions have been studied. They demonstrate direct actinide–transition metal bonding, and support the concept of "autogenic isolobality".
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Despite that actinide–transition metal (An–$M_{nd}$) bonding has been an important goal in molecular actinide chemistry, remarkably few complexes have been characterized in which an An–$M_{nd}$ bond has been clearly identified (An = Th, U).[1,2] In these complexes, the An–$M_{nd}$ bonding is either mediated by phosphido bridges,[1] or is between the An and a $M_{nd}$-containing fragment, $M_{nd}Cp(CO)_2$ (Cp = *cyclo*-$C_5H_5$),[2] which can be considered an "organometallic pseudohalogen".[3] Accordingly, there to date seem to be no well-established molecular complexes with a direct, unsupported covalent An–$M_{nd}$ bond.

Gaseous $AnM_{nd}$ bimetallics are elementary molecular species incorporating distinct An–$M_{nd}$ bonding. The ThRu, ThRh, ThIr, ThPt, and URh molecules, synthesized in high-temperature vapors, have bond energies of 500 to 600 kJ mol$^{-1}$.[4] Direct An–$M_{5d}$ bonding was also demonstrated with the preparation of the $ThFe^+$ and $UFe^+$ ions by collision-induced dissociation (CID) of $AnFe(CO)_x^+$ ($x$ = 2, 3).[5] In a recent theoretical study, Gagliardi and Pyykkö[6] predicted several stable triatomic species which would incorporate covalent bonds between uranium and 5d transition metals ($M_{5d}$), including $IrUO^+$. According to the concept of "autogenic isolobality",[6,7] Au can behave as a pseudohalogen, Pt as a pseudochalcogen, and Ir as a pseudopnictogen. Thus, $IrUO^+$ can be formally represented as $\{Ir{\equiv}U{=}O\}^+$, which is nominally isoelectronic with $\{N{\equiv}U{=}O\}^+$ and $\{O{=}U{=}O\}^{2+}$ (the uranyl dication);[6] both of the latter have been prepared in the gas phase.[8,9]

In view of recent theoretical predictions of strong U–$M_{5d}$ covalent bonds and stable triatomic species incorporating such bonds, we employed laser desorption/ionization (LDI) of binary An/$M_{5d}$ alloys to synthesize gaseous $AnM_{5d}^+$ bimetallic ions. The synthesis of these ions, and their reactions with nitrous oxide, ethylene oxide, and ethane, are interpreted in the context of "autogenic isolobality",[6,7] and the nature of An–$M_{5d}$ bonds.[6]

## Results and Discussion

In the initial experiments that employed dilute (≈ 2–5 wt.-%) An/Pt alloys (An = Th, Pa, U, Np, Pu, Am, Cm),[10] several diatomic and triatomic ions were produced. These included the bimetallics, $ThPt^+$, $PaPt^+$, $UPt^+$, $NpPt^+$, $PuPt^+$, $AmPt^+$ and $CmPt^+$, the trimetallics $ThPt_2^+$ and $UPt_2^+$, and the bimetallic oxides $OThPt^+$, $OPaPt^+$, $OUPt^+$ and $ONpPt^+$. The appearance of the $OAnPt^+$ (from O contamination in the alloys) only for Th through Np reflects the particularly strong O–$An^+$ bonds there;[10] the suggested atomic connectivities of the oxides are consistent with this strong bonding.

Generation of the $AnPt^+$ ions motivated a LDI study of U/$M_{5d}$ alloys ($M_{5d}$ = Os, Ir, Pt, Au; ≈ 20 wt.-% U). The following three bimetallics were produced in the indicated order of relative yields: $UAu^+ > UPt^+ > UIr^+$; $UOs^+$ was not observed. Illustrative LDI spectra are shown in Figure 1. For each U/$M_{5d}$ ($M_{5d}$ = Au, Pt, Ir) alloy, $U^+$ and $M_{5d}^+$ were produced by LDI, both in an abundance very roughly an order of magnitude greater than that of $UM_{5d}^+$.

In analogy with high-temperature synthesis of $AnM_{nd}$,[4] the $UM_{5d}^+$ (and other $AnM_{5d}^+$) are presumably formed by coalescence of a neutral atom and monopositive ion in the laser-desorption plume. As the four IE[$M_{5d}$] are in the range of 8.7 eV (Os) to 9.2 eV (Au) and IE[U] = 6.2 eV,[11] electron transfer from U to $M_{5d}^+$ is exothermic by ≥ 2.5 eV and should predominate over U/$M_{5d}^+$ coalescence. A probable mechanism for generation of the $UM_{5d}^+$ is instead association of $U^+$ with $M_{5d}$. It is not possible to be conclusive regarding the bimetallic formation mechanism(s) or the relative yields. However, several atomic properties that might account for the relative $UM_{5d}^+$ yields vary monotonically between Os and Au; for example, the electron affinities {EA/eV}[11] are: Os {1.1} < Ir {1.6} < Pt {2.1} < Au {2.3}. Another factor that likely affects the propensity for coalescence during alloy LDI is the relative volatilities of the transition-metal constituents, as indicated by their vapor pressures at 2500 K{P/Torr}:[12] Os {3·10$^{-6}$} < Ir {6·10$^{-4}$} < Pt {0.04} < Au {17}. In a general sense, the relative yields can be considered to be related to the different electronic structures of the $M_{5d}$. LDI also resulted in the formation of the trimetallics $UAu_2^+$ and (minor) $UPt_2^+$, but not $UIr_2^+$ or $UOs_2^+$. Bimetallic monoxides were also produced by LDI, with the following average relative abundances: $OUAu^+ > OUPt^+ > OUIr^+$ ($OUOs^+$ was not observed). The $OUIr^+$ ion has been predicted as a species comprising a strong formally triple U≡Ir bond, which renders it isoelectronic with dipositive uranyl, $O{=}U{=}O^{2+}$,[6] and $N{\equiv}U{=}O^+$.[8]

Some bimetallic ions were subjected to collision-induced dissociation (CID). Whereas $UAu^+$ fragmented into $U^+$ and Au, there was no evidence for dissociation of $UPt^+$ or $UIr^+$. Although these results suggest a relatively weak $U^+$–Au bond, consistent with single- rather than multiple-bond character, such CID studies are only qualitative. Electronic structure calculations should be performed to assess the validity of these somewhat speculative interpretations of the CID results regarding the relative bond energies. The CID of $OUAu^+$ and $OUPt^+$ resulted exclusively in fragmentation to $OU^+$ and Au or Pt, suggesting that the U–$M_{5d}$ bonds are weaker than the U–O bonds (there was insufficient $OUIr^+$ for a CID study). These latter CID results support the proposed O–U–$M_{5d}$ connectivity – for both the U–$M_{5d}$–O and U–O–$M_{5d}$ connectivities, some $M_{5d}O$ loss would be expected.

To further probe the nature of these $UM_{5d}^+$, they and the constituent atomic metal ions were treated with $N_2O$, $C_2H_4O$ (ethylene oxide) and $C_2H_6$. The results of the primary ion–molecule reactions are summarized in Table 1. In some cases, secondary and higher order reactions were observed, but these are not discussed here.

For a reaction of thermalized ions to occur, the overall process must be exothermic regardless of kinetic considerations. If a reaction does not proceed it may be due to a kinetic barrier rather than endothermicity. Here we only consider thermodynamic limits based on the requirement for exothermicity; no assumptions are made regarding kinetics. In accord with previous results, both $Ir^+$[13a] and $Pt^+$[13] were oxidized to the monoxides by $N_2O$, consistent with the requirement that $D[Ir^+–O]$ ca. 250 kJ mol$^{-1}$[14] and $D[Pt^+–O]$ ca. 322 kJ mol$^{-1}$[15] exceed $D[N_2–O]$ = 167 kJ mol$^{-1}$.[14] That $Au^+$ is unreactive with $N_2O$[13a] may reflect a kinetic or thermodynamic barrier. As reported previously,[8,10a] $U^+$ reacts with $N_2O$ to give $UO^+$ and $UN^+$. The three $UM_{5d}^+$ ions react with $N_2O$ to give $OUAu^+$, $OUPt^+$ and $OUIr^+$, along with $UO^+$ (and $AuN_2$, $PtN_2$ and $IrN_2$ as presumed neutral products). Given the inert charac-

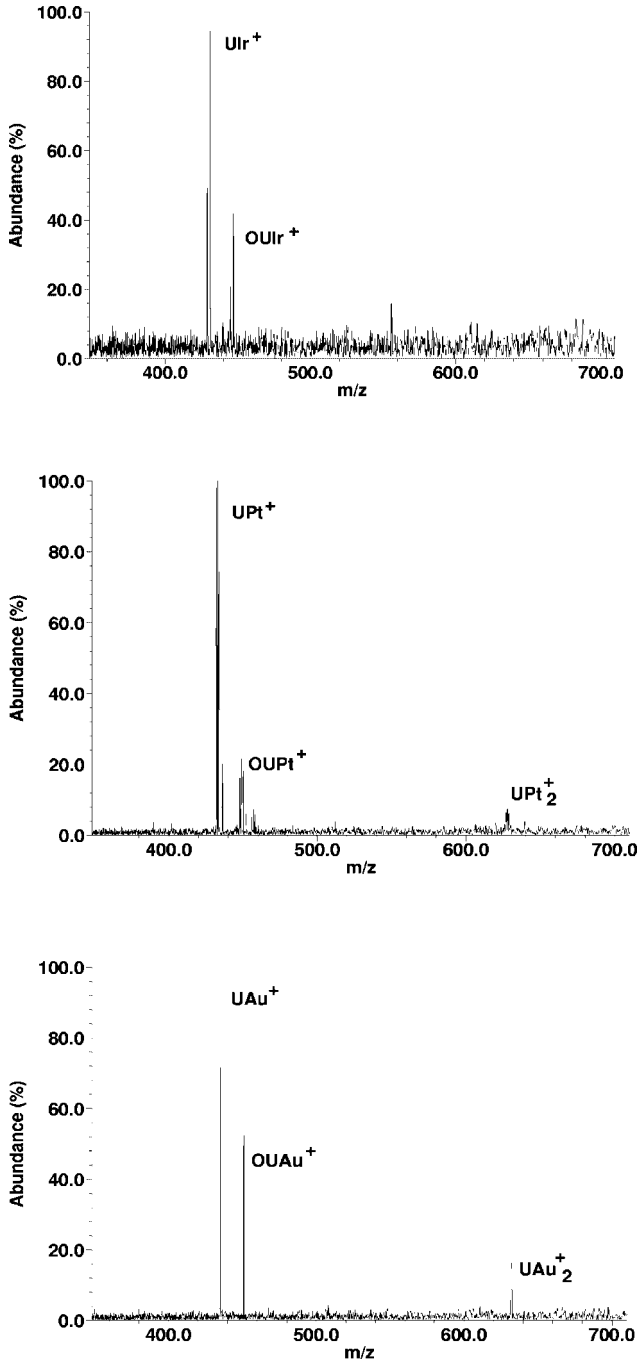

Figure 1. Direct LDI mass spectra for U/Ir (top), U/Pt (middle), and U/Au (bottom) alloys. The two isotopes of Ir and several isotopes of Pt are evident. The minor peaks in the middle spectrum at $m/z$ = 456–460 correspond to the composition $UPtC_2^+$.

[a] Where more than one product was formed, the relative abundances (%) are indicated in parentheses. Rate constants ($k$) are in units of $10^{-10}$ $cm^3 molecule^{-1} s^{-1}$; $k/k_{COL}$ are the reaction efficiencies.[10c] Absolute rate constants are uncertain by ±50%; relative uncertainties are ±20%. [b] Results for the $U^{+}/N_2O$ and $U^{+}/C_2H_4O$ reactions are from ref.[10a].

ter of bare $Au^{+}$ toward $N_2O$, the formation of $OUAu^{+}$ supports the proposed atomic connectivity. The $OUIr^{+}$ connectivity had been predicted from theory.[6] The $UAu^{+}/N_2O$ reaction produced $NUAu^{+}$, for which the thermodynamic requirement is $D$[N–$UAu^{+}$] ≥ {$D$[N–NO] = 482 kJ mol$^{-1}$}.[14] That both $UO^{+}$[8,10a] and $UPt^{+}$ are oxidized by $N_2O$ is in agreement with the isolobal analogy between $UPt^{+}$ and $UO^{+}$.[6,7] The observation that $UN^{+}$ is unreactive with $N_2O$, while formally isoelectronic $UIr^{+}$ is oxidized to $OUIr^{+}$ by $N_2O$, illustrates that the "autogenic isolobality" concept does not imply absolute correspondence, but rather chemical analogy.[6,7]

Whereas $U^{+}$ is oxidized to $UO^{+}$ by $C_2H_4O$,[10a] the three $M_{5d}^{+}$ react to give carbenes, $M_{5d}CH_2^{+}$ (Table 1). Thus, if the neutral product of the $M_{5d}^{+}/C_2H_4O$ reactions is formaldehyde ($CH_2O$), the thermodynamic requirement is $D$[$M_{5d}^{+}$–$CH_2$] ≥ 334 kJ mol$^{-1}$; if instead the neutral products are CO + $H_2$, the thermodynamic requirement is $D$[$M_{5d}^{+}$–$CH_2$] ≥ 332 kJ mol$^{-1}$.[14] Previous experimental studies have established $D$[$Ir^{+}$–$CH_2$] = 474 ± 3 kJ mol$^{-1}$,[16] $D$[$Pt^{+}$–$CH_2$] ≥ 464 kJ mol$^{-1}$,[17] and $D$[$Au^{+}$–$CH_2$] ≥ 397 kJ mol$^{-1}$.[18] The formation of the triatomic oxides, rather than carbenes, from the $UM_{5d}^{+}/C_2H_4O$ reactions is reminiscent of the $U^{+}/C_2H_4O$ reaction. This suggests that the reactivities of the $UM_{5d}^{+}$ are dominated by the oxophilicity of the uranium metal center, and that the product oxides can be represented as $OUM_{5d}^{+}$. In analogy with the ethane results discussed below, the $U^{+}$-like, rather than $M_{5d}^{+}$-like, reactivity of the $UM_{5d}^{+}$ with $C_2H_4O$ suggests that the transition-metal center has been rendered inert. The thermodynamic requirement for the $C_2H_4O$ oxidation reactions is $D$[O–$UM_{5d}^{+}$] ≥ 354 kJ mol$^{-1}$[14] ($M_{5d}$ = Ir, Pt, Au). The oxidation of the three $UM_{5d}^{+}$ in a similar manner to bare $U^{+}$ provides a further indication of the O–U–$M_{5d}$ connectivities proposed above. Additional calculations are required to establish the energy differences between the different isomers, as well as whether the species are linear (like $UO_2^{2+}$) or bent (like $ThO_2$). The calculations by Gagliardi and Pyykkö[6] indicate that some triatomic uranium-transition metal species adopt a linear structure but the bond angle for $OUIr^{+}$ (or other $OUM_{5d}^{+}$) was not reported.[6]

The appearance of $UO^{+}$ (+ $AuC_2H_4$) from the $UAu^{+}/C_2H_4O$ reaction is consistent with a weaker $U^{+}$-Au bond as compared with the $U^{+}$–Ir and $U^{+}$–Pt bonds. Neither the $UIr^{+}/C_2H_4O$ nor $UPt^{+}/C_2H_4O$ reactions result in $UO^{+}$ (+ $M_{5d}C_2H_4$). This distinctive behavior of $UAu^{+}$ supports the interpretation of the CID results discussed above in terms of the relative U–$M_{5d}$ bond strengths.

The results in Table 1 for reactions with ethane are in agreement with earlier reports for $U^{+}/C_2H_6$,[19] $Ir^{+}/C_2H_6$,[17] and $Au^{+}/C_2H_6$;[18] in an ion beam study of the $Pt^{+}/C_2H_6$ reaction,[20] only $PtC_2H_4^{+}$ (+ $H_2$) was reported, not $PtC_2H_2^{+}$ (+ $2H_2$). In contrast to the bare $M_{5d}^{+}$, but like bare $U^{+}$, the three $UM_{5d}^{+}$ were unreactive towards $C_2H_6$: the reactivity of the transition metal center is evidently "shut off" in the $UM_{5d}^{+}$, in distinct contrast to $Pt_2^{+}$, which is as effective at dehydrogenating $C_2H_6$ as is atomic $Pt^{+}$.[20] The reduced reactivity of $UM_{5d}^{+}$ also contrasts with ions such as $PtCu^{+}$, $PtAg^{+}$ and $PtAu^{+}$, which dehydrogenate methane with an efficiency comparable to that of $Pt_2^{+}$.[21] According to the concept of "autogenic isolobality",[6,7] it can be considered that there are no non-bonding valence electrons at the transition metal centers in Au–$U^{+}$, Pt =$U^{+}$ and Ir≡$U^{+}$. With the lack of available valence electrons at the $M_{5d}$ center, reactivity would disappear, as is observed.

In conclusion, we have synthesized several new $AnPt^{+}$ (An = Th through Cm), and examined the chemistries of $UIr^{+}$, $UPt^{+}$, and $UAu^{+}$ in the general context of "autogenic isolobality", and the prediction of strong actinide–transition metal bonds.[6,7] Our experimental results are consistent with the predicted bonding for these species – specifically, the reactivities of the transition-metal centers are apparently "shut off" in the $UM_{5d}^{+}$ bimetallics. With each of the three reagents, $N_2O$, $C_2H_4O$ and $C_2H_6$, the reactivities of the $UM_{5d}^{+}$ ions were evidently dominated by the U metal center, in agreement with the concept of "autogenic isolobality".[6] To further probe Ir as a pseudopnictogen, Pt as a pseudochalcogen, and Au as a pseudohalogen or pseudohydrogen,[22,23] our future efforts will compare directly reactivities of the $UM_{5d}^{+}$ ($M_{5d}$ = Ir, Pt, Au) and isoelectronic $UX^{+}$, where X is a pnictogen, chalcogen, or halogen (or H). One noteworthy result of the present work was the synthesis

of $IrUO^+$, which was predicted to exist as a stable species isoelectronic with uranyl, $OUO^{2+}$.[6]

## Experimental Section

The experimental procedures, described in detail elsewhere,[5,9,10] are briefly summarized here. The atomic and bimetallic ions were produced by direct LDI of arc-melted actinide–transition metal alloys,[10] An/Pt (An = natural Th-232, Pa-231, depleted U, Np-237, Pu-242, Am-243, Cm-248) and $U/M_{5d}$ ($M_{5d}$ = Os, Ir, Pt, Au). The LDI ions directly entered the source cell of a dual cell Finnigan FT/MS 2001-DT FTICR mass spectrometer equipped with a 3-T magnet and controlled by an Odyssey data system; all experiments were performed in the source cell. The $N_2O$ and $C_2H_6$ were commercial gases (>99%); the $C_2H_4O$ was a commercial liquid (>99%) degassed prior to use. The reagents were introduced into the spectrometer through a leak valve to pressures of $3{\cdot}10^{-8}$ to $2{\cdot}10^{-7}$ Torr. Isolation of ions was achieved using single-frequency, frequency-sweep, or SWIFT excitation. The reactant ions were thermalized by collisions with argon, introduced through a leak valve to a constant pressure in the range of $(1–5)\times10^{-6}$ Torr, concurrent with the reagent gas. Thermalization of the reactant ions was confirmed by standard procedures.[5,9,10] The CID experiments were carried out by ion excitation and collision with argon.[5] The pseudo-first-order rate constants, $k$, were determined from the reactant ion decay as a function of time; the collisional rate constants, $k_{COL}$, were calculated as described previously.[10c]

# Supramolecular Silanol Chemistry: Inclusion Complexes of 1,3,5-Tris(diisopropylhydroxysilyl)benzene and 4,4′-Bis(pyridines)

**Jens Beckmann*[a] and Sanna L. Jänicke[a]**

**Keywords:** Supramolecular chemistry / Crystal engineering / Inclusion compounds / Hydrogen bonds / Silicon

The trisilanol 1,3,5-(HO*i*Pr$_2$Si)$_3$C$_6$H$_3$ (**5**), a novel building block for applications in supramolecular chemistry, has been prepared via the intermediates 1,3,5-(H*i*Pr$_2$Si)$_3$C$_6$H$_3$ (**6**) and (Cl*i*Pr$_2$Si)$_3$C$_6$H$_3$ (**7**). The inclusion complexes **5**·0.5H$_2$O, **5**·bpy·0.5H$_2$O, **5**·bpe, **5**·azpy and **5**·bpa have been investigated by X-ray crystallography [bpy = 4,4′-bipyridine, bpe = (*E*)-bis(4-pyridyl)ethylene, azpy = 4,4′-azopyridine, bpa = bis(4-pyridyl)aceylene]. The ratio between donor and acceptor molecules is always 1:1 and the crude supramolecular motifs are very similar for **5**·bpy·0.5H$_2$O, **5**·bpe, **5**·azpy and **5**·bpa. The trisilanol molecules form 1D chains, which are connected by nearly perpendicular 4,4′-bis(pyridine) molecules to give rise to formation of 2D grid networks featuring O–H···O(H)Si and O–H···N hydrogen bonds. Differences are observed in the shape and size of the voids defined by the 2D grids. The smaller voids are blocked by trisilanol molecules of adjacent 2D networks in case of **5**·bpy·0.5H$_2$O and **5**·bpe. In case of **5**·azpy, the larger voids are filled by interpenetration of the same 2D networks.

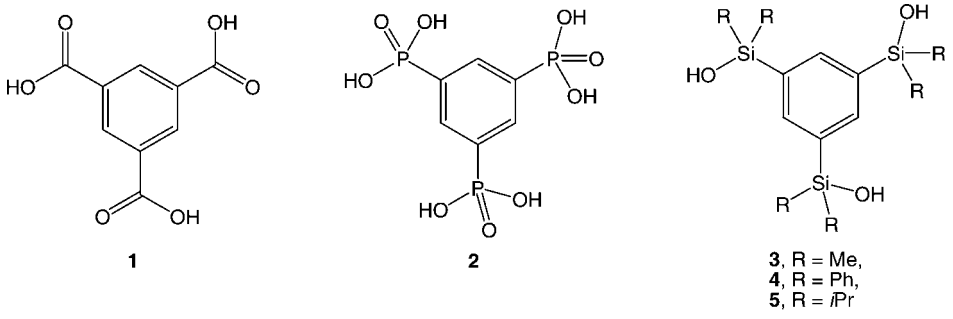
## Introduction

Organosilanols are well known for their extensive self-organisation in the solid state, which has led to the observation of a great variety of different hydrogen-bond patterns.[1] In most cases organosilanols form hydrogen bonds with themselves, but occasionally co-crystals with alcohols,[2] ethers[3] and amines[4] have been observed. Whilst the majority of these complexes has been formed inadvertently with solvent and reagent molecules, recently a small number of inclusion complexes has been prepared deliberately by co-crystallisation studies.[5] However, the vast potential of organosilanols in molecular recognition has not yet been exploited for applications in supramolecular chemistry and crystal engineering. The organosilanols used in previous studies lack topological pre-organisation of the silanol sites on a molecular level, a prerequisite for genuine control of supramolecular structures.

Gaining control over solid-state structures requires the judicious choice of molecular building blocks ("synthons") possessing adhesive functional groups ("tectons") with prefixed directionality.[6] 1,3,5-Trimesic acid, 1,3,5-(HOOC)$_3$C$_6$H$_3$ (**1**), the prime building block for organic supramolecular chemistry fulfils this criterion and gives rise to formation of honeycomb ("chicken-wire") networks containing nano-dimensional cavities in the solid state, which may be useful for applications in host–guest chemistry (Scheme 1).[7] Organometallic chemistry can extend the range of useful building blocks for supramolecular chemistry by a wealth of adhesive functional groups.[8] For instance, 1,3,5-benzenetriphosphonic acid, 1,3,5-(H$_2$O$_3$P)$_3$C$_6$H$_3$ (**2**), has been used for co-crystallisation studies with



Scheme 1.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a number of amines, which has given rise to formation of inclusion complexes revealing N–H···OP hydrogen-bond contacts (Scheme 1).[9]

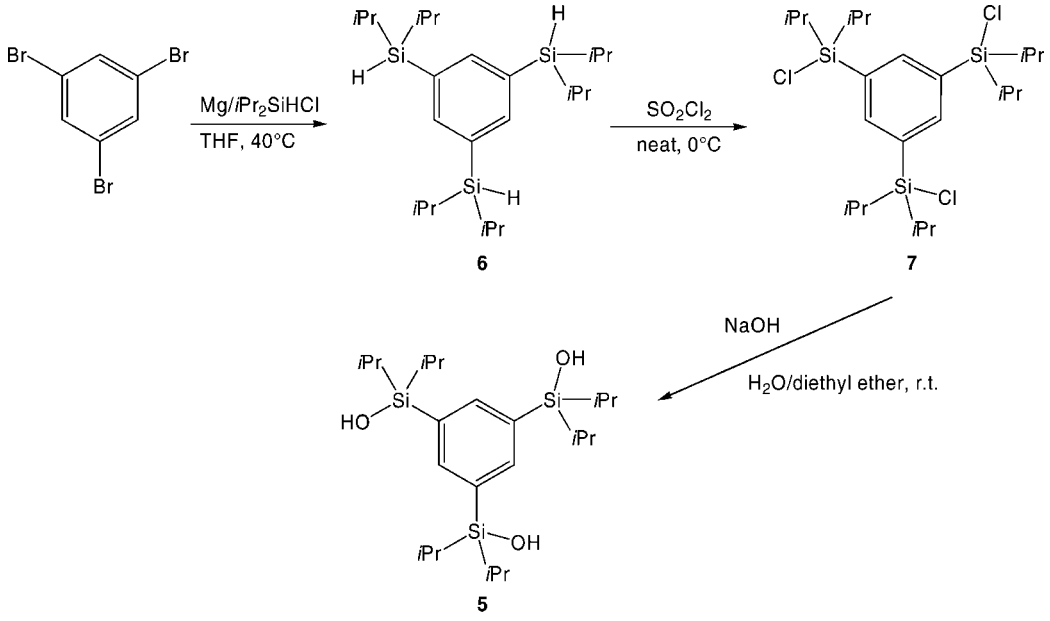
Recently, we have prepared 1,3,5-(hydroxydiorganosilyl)-benzenes, 1,3,5-$(HOR_2Si)_3C_6H_3$ (**3**, R = Me; **4**, R = Ph) and investigated their supramolecular structures (Scheme 1).[10] Unfortunately, all attempts to prepare inclusions complexes of 1,3,5-(hydroxydiorganosilyl)benzenes and amines have not yet been successful. In case of **3**, the amines have base-catalysed the condensation and formation of siloxanes, whereas in case of **4**, C–H···π stacking is presumably the predominant crystal-packing force, precluding the formation of inclusion complexes with amines.[11] We have now prepared a novel 1,3,5-(hydroxydiorganosilyl)benzene, 1,3,5-$(HO{i}Pr_2Si)_3C_6H_3$ (**5**) possessing bulky and aliphatic isopropyl groups, which are able to circumvent the difficulties encountered with **3** and **4** in co-crystallisation studies with amines. Herein, we describe co-crystals of **5** with 4,4′-bipyridine (bpy), (*E*)-bis(4-pyridyl)ethylene (bpe), 4,4′-azopyridine (azpy) and bis(4-pyridyl)aceylene (bpa) that exhibit similar supramolecular motifs featuring 2D grid networks of O–H···O(H)Si and O–H···N hydrogen bonds.

## Results and Discussion

The synthesis of the trisilanol 1,3,5-$(HO{i}Pr_2Si)_3C_6H_3$ (**5**) has been achieved in three steps starting from commercially available 1,3,5-tribromobenzene (Scheme 2). The diisopropylsilyl groups have been introduced by the in situ Grignard reaction of 1,3,5-$Br_3C_6H_3$ with $i$Pr$_2$SiHCl/Mg affording 1,3,5-$(H{i}Pr_2)_3C_6H_3$ (**6**) as a distillable oil. Chlorination of **6** using $SO_2Cl_2$ has provided the corresponding chlorosilane 1,3,5-$(Cl{i}Pr_2)_3C_6H_3$ (**7**) as distillable oil that solidifies upon standing at room temperature. The base hydrolysis of **7** provides the trisilanol 1,3,5-$(HO{i}Pr_2Si)_3C_6H_3$ (**5**) as a low-melting crystalline solid.

### Solid-State Structure of 5

After recrystallisation from $CH_2Cl_2$/hexane, the trisilanol 1,3,5-$(HO{i}Pr_2Si)_3C_6H_3$ (**5**) has been obtained free of crystal water. The IR spectrum (KBr pellet) of this material exhibits two absorptions at 3694 cm$^{-1}$ (sharp, intense) and 3345 cm$^{-1}$ (broad, very intense), which were assigned to stretching vibrations of hydroxy groups that are free and involved in hydrogen bonding, respectively.[12] This assignment is supported by a preliminary X-ray structure analysis,[13] which reveals that only one silanol group is engaged in hydrogen bonding, whereas the other two are free. Unfortunately, severe disorder or twining has precluded the satisfying refinement of the X-ray data. When slowly crystallised from toluene the trisilanol was isolated as a hemihydrate, **5**·0.5$H_2O$, which has been investigated by X-ray diffraction. A perspective view of the supramolecular structure of **5**·0.5$H_2O$ is shown in Figure 1. Crystal and refinement data are collected in Table 6. The asymmetric unit contains three crystallographically independent molecules of **5** (denoted A, B and C) and water. Twelve O···O distances between 2.684(3) and 2.871(3) Å are indicative for weak to medium-strength hydrogen bonding and are listed in Table 1. The exact donor–acceptor relationship could not be established from the erratic refinement of the hydrogen positions. However, from the close proximity of the water molecules (O11–O12) to four oxygen atoms of the silanol groups it can be deduced that each water molecule serves twice as donor and acceptor for a total of four hydrogen bonds. The supramolecular motif around the water molecules can be described best as a spirocyclic arrangement of two eight-membered rings each consisting of four oxygen



Scheme 2.

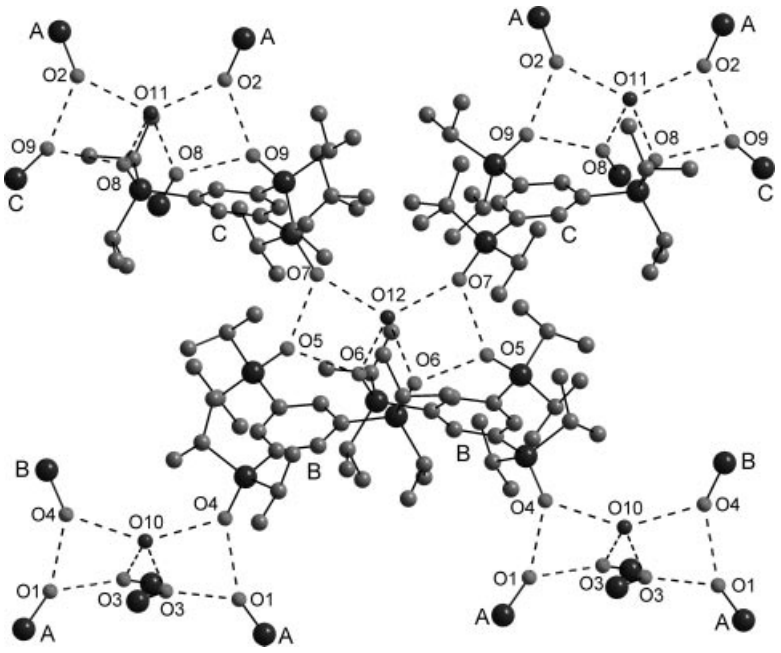

Figure 1. Perspective view of the inclusion complex **5**·0.5$H_2O$ (only SiO groups of the outer trisilanol molecules are shown for clarity).

and four hydrogen atoms. The eight-membered rings feature one water molecule and three silanol groups and therefore somewhat resemble the hydrogen-bond motif observed for the hydrate of **4**.[10] The participation of all silanol groups in hydrogen bonding is confirmed by an IR spectrum (KBr) of **5**·0.5$H_2O$, which shows one absorption at 3357 $cm^{-1}$ (broad, very intense).

Table 1. Donor acceptor distances [Å] of the hydrogen bonds of **5**·0.5$H_2O$.

| O–H···O(H)Si | | O–H···$OH_2$ | |
|---|---|---|---|
| O1···O3 | 2.719(2) | O2···O11 | 2.757(5) |

| O2···O9 | 2.700(3) | O4···O10 | 2.791(5) |
| O5···O6 | 2.739(3) | O6···O12 | 2.861(3) |
| O5···O7 | 2.675(3) | O7···O12 | 2.809(5) |
| O8···O9 | 2.771(3) | O8···O11 | 2.783(3) |

### Inclusion Complexes of 5 with 4,4′-Bis(pyridines)

Co-crystals of **5** with 4,4′-bipyrdine (bpy), (*E*)-bis(4-pyridyl)ethylene (bpe), 4,4′-azopyridine (azpy) and bis(4-pyridyl)acetylene (bpa) have been obtained and investigated by X-ray crystallography. Crystal and refinement data are collected in Table 6. To account for the fact that the trisilanol **5** and the 4,4′-bis(pyridines) contain three potential H-donors sites and two potential H-acceptor sites, respectively, the ratio of the reactants was originally intended to be 2:3. However, all isolated co-crystals consist of equimolar amounts of the trisilanol **5** and the acceptor molecule, which has been confirmed by microanalyses and $^1H$ NMR spectroscopy. The same co-crystals are also formed when an excess of the trisilanol **5** is used.

A perspective view of the inclusion complex **5**·bpy·0.5$H_2O$ is shown in Figure 2. Hydrogen-bond parameters are collected in Table 2. The asymmetric unit contains two crystallographically independent molecules of **5** (denoted as A and B) and bpy as well as one water molecule, which are associated through hydrogen bonding. The donor–acceptor relationship has been unambiguously established by complete refinement of all relevant hydrogen atoms. The trisilanol molecules are linked by hydrogen bonds (O3–H3···O4/O6–H6···O1) into 1D chains, in which the benzene rings are nearly coplanar. These 1D chains are connected by two bpy pillars and one water molecule giving rise to the formation of a 2D grid structure. The connection between the 1D chains and the bpy pillars is realised by two hydrogen-bond junctions (O1–H1···N1/O7–H7A···N2/O2–H···O7 and O4–H4···N3/O5–H5···N4) running approximately in parallel. This 2D grid network is linked to adjacent networks by an additional hydrogen bond (O7–H7B···O5) being associated with the water molecule. Adjacent network layers are aligned parallel without penetration and are shifted with respect to each other by half length of the supramolecular repeating unit, so that the 1D chains are situated in close proximity to the bpy pillars of the adjacent layers. This crystal packing avoids larger cavities in the lattice.

A perspective view of the inclusion complex **5**·bpe is shown in Figure 3. Hydrogen-bond parameters are collected in Table 3. The asymmetric unit contains only one molecule of **5** and one bpe molecule, which are linked by hydrogen bonding. The position of all relevant hydrogen atoms has been located during the X-ray data refinement. The supramolecular motif can be described best as 2D brick-wall structure. Therein, the trisilanol **5** forms 1D chains, in which the individual molecules are linked by hy-

work are approximately 10 × 10 Å and blocked mostly by trisilanol molecules of adjacent layers running parallel.

A perspective view of the inclusion complex **5**·azpy is shown in Figure 4. Hydrogen-bond parameters are collected in Table 4. The asymmetric unit contains two crystallographically independent molecules of **5** (denoted as A and B) and azpy. All hydrogen atoms related to hydrogen bonds have been located during the X-ray data refinement. Similar as observed for the two previous structures, the trisilanol molecules are associated through hydrogen bonds (O1–H1···O3/O6–H6···O4) and give rise to the formation of 1D chains. However, unlike the two previous structures, the phenyl rings are not coplanar. The overall supramolecular motif may be also described as 2D brick-wall structure. The azpy pillars occur pair-wise and are situated approximately perpendicular to the 1D chains to which they are associated through hydrogen bonds (O2–H2···N3/O3–H3···N1/O4–H4···N4/O5–H5···N2). The almost square-like voids defined by the supramolecular arrangement are approximately 16 × 16 Å and filled by the same interpenetrating 2D brick-wall network. To the best of our knowledge interpenetrating networks[14] have not yet been observed for silanol structures.[1]

A perspective view of the inclusion complex **5**·bpa is shown in Figure 5. Hydrogen-bond parameters are collected in Table 5. The asymmetric unit contains one molecule of **5** and bpa. All hydrogen atoms associated with hydrogen bonding have been located during the refinement. As observed in the structures before, the trisilanol molecules are associated through hydrogen bonds (O3–H3···O2) giving rise to the formation of 1D chains, in which the phenyl groups are not coplanar. The bpa pillars are situated approximately perpendicular to the 1D chains to which they are associated through hydrogen bonding (O1–H1···N1/O2–H2···N2). The almost square-like voids defined by the supramolecular pattern are approximately 8 × 8 Å.

The close examination of hydrogen-bond parameters (Tables 1–5) reveals no significant difference between O–H···O(H)Si and O–H···N hydrogen bonds. The donor–acceptor distances of the hydrogen bridges of all four structures range from 2.684(3) to 2.91(1) Å with an average of 2.78(1) Å and compare well with previously reported experimental values[1–5] as well as parameters established computationally in the gas phase for $H_3SiOH\cdots O(H)SiH_3$ (2.863 Å) and $H_3SiOH\cdots$pyridine (2.815 Å) at the B3LYP/6-311+(2d,p) level of theory.[15]

Applications in supramolecular chemistry and crystal engineering require that the molecular building blocks are rigid and that the functional groups possess a pre-fixed directionality.[7] In an effort to qualitatively examine the conformational flexibility of the silanols groups, the O–Si–C–C torsion angles have been assessed and compared for all structures. The absolute torsion angles can vary between 2.5(2) and 70.3(2)°; however, most values are close to the average of 25.5(2)° for all structures. The average of these values for each individual trisilanol molecule varies only between 20.6(2) and 31.4(2)°, which apparently suggests that the silanol groups cannot adopt conformations that are entirely independent from the influence of the other two silanol groups attached to the same phenyl ring.

## Conclusions

Regardless of the stoichiometric ratio of the reactants applied, the inclusion complexes between **5** and 4,4′-bis(pyridines), namely **5**·bpy·0.5$H_2O$, **5**·bpe and **5**·azpy, contain the same number of donor and acceptor molecules, which are associated by hydrogen bonding. The thermodynamic driving force of the co-crystallisation is the energy gain associated with the formation of O–H···N hydrogen bonds. This energy gain needs to be higher than that of the competitive O–H···O(H)Si hydrogen bonds. We have recently shown that the BSSE-corrected hydrogen-bond energies of the model compounds $H_3SiOH\cdots O(H)SiH_3$ and $H_3SiOH\cdots$pyridine are –3.47 and –6.47 kcal mol$^{-1}$, respectively, at the B3LYP/6-311+(2d,p) level of theory.[15] These values suggest that the highest energy gain should be observed when the ratio between trisilanol and 4,4′-bis(pyridine) is 2:3, allowing a maximum of three O–H···N hydrogen bridges. However, the loss of symmetry in a 2:3 complex and the associated increase of entropy, apparently, cannot be compensated entirely by the O–H···N hydrogen-bond energy. The formation of 1:1 complexes might be a compromise between the gain of hydrogen-bond energy and the loss of symmetry.

One of the more ambitious goals in supramolecular chemistry is the prediction of solid-state architectures.[6] Interestingly, the crude supramolecular motifs are very similar for **5**·bpy·0.5$H_2O$, **5**·bpe and **5**·azpy. In all three structures, the trisilanol molecules form 1D chains, which are interconnected by nearly perpendicular 4,4′-bis(pyridine) pillars to give rise to formation of 2D grid networks. However, the inevitable voids between the 2D grids differ substantially in size and shape for all four structures. The small voids of **5**·bpa (8 × 8 Å) are unfilled, the medium-sized voids of **5**·bpy·0.5$H_2O$ (10 × 12 Å) and **5**·bpe (10 × 10 Å) are blocked by trisilanol molecules of adjacent 2D networks, whereas the larger voids of **5**·azpy (16 × 16 Å) are filled by interpenetration. It might be interesting to see if these voids can be also filled with guest molecules that may possibly interact with the C–C and N–N double bonds of the bpe and azpy pillars.

## Experimental Section

**General:** 1,3,5-Tribromobenzene, chlorodiisopropylsilane, 4,4′-bipyridine (bpy) and (*E*)-bis(4-pyridyl)ethylene (bpe) are commercially available, whereas 4,4′-azopyridine (azpy) and bis(4-pyridyl)-acetylene (bpa) have been prepared according to known routes.[16] NMR spectra were collected using a Jeol JNM-LA 400 FT spectrometer and are referenced against $Me_4Si$. IR spectra were recorded with a 5 SXC Nicolet DTGS FT-IR spectrometer. Microanalyses were obtained with a Vario EL elemental analyser.

**1,3,5-Tris(diisopropylsilyl)benzene (6):** A 250-mL three-neck flask equipped with a septum, dropping funnel and reflux condenser was

charged with Mg turnings (4.75 g, 195 mmol), *i*$Pr_2$SiHCl (24.0 g, 159 mmol) and THF (100 mL). The Mg was activated by addition of 1,2-dibromoethane (250 μL) through a syringe. 1,3,5-Tribromobenzene (15.3 g, 49.0 mmol) dissolved in THF (100 mL) was slowly added. The temperature was maintained at 40 °C for 12 h, before the mixture was hydrolysed by the addition of $H_2O$ (50 mL). The organic layer was washed with water (3 × 20 mL) and dried with $Na_2SO_4$. Removal of the solvent and fractional distillation of the crude product in vacuo afforded **6** as an almost colourless viscous oil [11.5 g, 27.3 mmol (56%); b.p. 200–220 °C/7.5 $10^{-3}$ Torr]. $^1$H NMR ($CDCl_3$, 399.65 MHz): $\delta$ = 7.56 (s, 3 H, Ph), 3.86 [s, $^1J(^1H-^{29}Si)$ = 182 Hz, 3 H, Si*H*], 1.16 (m, 6 H, C*H*Me$_2$), 0.98, 0.90 (d, 36 H, CH*Me$_2$*) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 100.40 MHz): $\delta$ = 143.4, 131.8 (Ph), 18.7, 18.4 (*C*HMe$_2$), 10.8 (CH*Me$_2$*) ppm. $^{29}Si\{^1H\}$ NMR ($CDCl_3$, 79.30 MHz): $\delta$ = 5.3 [s, $^1J(^{29}Si-^1H)$ = 184 Hz] ppm. IR (KBr plates): $\tilde{\nu}$ = 2101 (SiH) $cm^{-1}$. $C_{24}H_{48}Si_3$ (420.52): calcd. C 68.55, H 11.41; found C 68.53, H 11.45.

**1,3,5-Tris(chlorodiisopropylsilyl)benzene (7):** A 50-mL Schlenk flask with gas outlet was charged with **6** (10.5 g, 25 mmol) and sealed with a septum. An excess of $SO_2Cl_2$ (7 mL, 93 mmol) was slowly added through a syringe. After a short induction delay, a strongly exothermic reaction occurred and $SO_2$ gas vigorously evolved. During the reaction, the mixture was cooled with an ice bath. After the addition was complete, the mixture was stirred at room temperature for 24 h and at 40 °C for 1 h. Unreacted $SO_2Cl_2$ was removed in vacuo and the remaining crude product was purified by kugelrohr distillation to give **7** as a colourless low-melting solid [9.37 g, 17.9 mmol (72%); b.p. 220–240 °C/7.5 $10^{-3}$ Torr]. $^1$H NMR ($CDCl_3$, 399.65 MHz): $\delta$ = 7.89 (s, 3 H, Ph), 1.45 (m, 6 H, C*H*Me$_2$), 1.09, 1.01 (d, 36 H, CH*Me$_2$*) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 100.40 MHz): $\delta$ = 141.6, 130.7 (Ph), 16.9, 16.7 (*C*HMe$_2$), 13.7 (CH*Me$_2$*) ppm. $^{29}Si\{^1H\}$ NMR ($CDCl_3$, 79.30 MHz): $\delta$ = 26.4 (s) ppm. $C_{24}H_{45}Cl_3Si_3$ (523.87): calcd. C 54.99, H 8.65; found C 54.90, H 9.03.

**1,3,5-Tris(hydroxydiisopropylsilyl)benzene (5):** Compound **7** (8.23 g, 16 mmol) dissolved in diethyl ether (40 mL) was treated with an aqueous solution (40 mL) of NaOH (5.28 g, 132 mmol). The mixture was stirred at room temperature for 3 h before the layers were separated. The organic layer was washed with $H_2O$ (3 × 40 mL) and dried with $Na_2SO_4$. The removal of the solvent in vacuo produced a colourless solid that was recrystallised from $CH_2Cl_2$/hexane to furnish **5** as colourless crystals [3.2 g, 6.8 mmol (43%); m.p. 90–91 °C]. $^1$H NMR ($CDCl_3$, 399.65 MHz): $\delta$ = 7.74 (s, 3 H, Ph), 2.39 (s, OH), 1.20 (m, 6 H, C*H*Me$_2$), 1.00, 0.92 (d, 36 H, CH*Me$_2$*) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 100.40 MHz): $\delta$ = 140.7, 132.7 (Ph), 17.1, 16.9 (*C*HMe$_2$), 12.4 (CH*Me$_2$*) ppm. $^{29}Si\{^1H\}$ NMR ($CDCl_3$, 79.30 MHz): $\delta$ = 7.0 (s) ppm. IR (KBr pellet): $\tilde{\nu}$ = = 3694, 3345 (OH) $cm^{-1}$. $C_{24}H_{48}O_3Si_3$ (468.89): calcd. C 61.48, H 10.32; found C 61.53, H 10.62. Slow recrystallisation from toluene afforded **5**·0.5$H_2O$. $C_{48}H_{98}Si_6O_7$ (955.80): calcd. C 61.32, H 10.33; found C 60.13, H 10.50.

**Synthesis of the Inclusion Complexes of 5 with 4,4′-Bis(pyridines):** Compound **5** (50 mg, 0.107 mmol) and the appropriate amount of the 4,4′-bis(pyridines) (byp: 10.7 mg, bpe: 13.0 mg, azpy: 13.7 mg, 0.070 mmol) were dissolved in $CH_2Cl_2$/hexane (3:2). Slow concentration of the solution furnished colourless or orange crystals. The yields were not optimised. **5·byp·0.5$H_2O$:** Yield 20 mg (30%). $C_{68}H_{113}N_4O_7Si_6$ (1267.19): calcd. C 64.40, H 9.06, N 4.42; found

C 63.78, H 9.40, N 4.06. **5·bpe:** Yield 30 mg (43%). $C_{36}H_{58}N_2O_3Si_3$ (651.13): calcd. C 66.41, H 8.98, N 4.30; found C 66.35, H 9.19, N 4.27. **5·azpy:** Yield 40 mg (57%). $C_{34}H_{56}N_4O_3Si_3$ (653.09): calcd. C 62.53, H 8.64, N 8.58; found C 62.31, H 8.58, N 8.44. **5·bpa:** Yield 40 mg (57%). $C_{36}H_{56}Si_3N_2O_3$ (648.10): calcd. C 66.61, H 8.70, N 4.32; found C 66.12, H 8.71, N 4.19.

**X-ray Crystallography:** Intensity data were collected with a Bruker SMART 1000 CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ (0.7107 Å) radiation. Data were reduced using the program SAINT.[17] The structures were solved by direct methods and difference Fourier synthesis using SHELXS-97 implemented in the program WinGX 2002.[18] Full-matrix least-squares refinements on $F^2$, using all data, were carried out with anisotropic displacement parameters applied to all non-hydrogen atoms. Disorder of an isopropyl group in **5**·0.5$H_2O$ was resolved with split occupancies of 0.6 and 0.4 for C81 and C81′. The large residual electron density (2.498 e·Å$^{-3}$) might be indicative for disorder (of O12) or an unaccounted solvent molecule; however, all attempts of modelling failed. Hydrogen atoms attached to carbon atoms were included in geometrically calculated positions using a riding model and were refined isotropically. Hydrogen atoms attached to oxygen atoms were located from the electron-density maps of **5**·bpy·0.5$H_2O$, **5**·bpe, **5**·azpy and **5**·bpa and refined isotropically without restraints. The absolute configuration of **5**·azpy has been determined by the refinement of the Flack parameter [0.00(8)]. Figures were created using DIAMOND.[19] Further details are listed in Table 6. CCDC-605353 (**5**·0.5$H_2O$), -605354 (**5**·bpy·0.5$H_2O$), -605355 (**5**·bpe), -605356 (**5**·azpy) and -605357 (**5**·bpa) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Structural and Magnetic Studies of Copper(II) and Zinc(II) Coordination Complexes Containing Nitroxide Radicals as Chelating Ligands

**Akihiro Ito,[a] Yoshiaki Nakano,[a] Masashi Urabe,[a] Kazuyoshi Tanaka,*[a,b] and Motoo Shiro[c]**

**Keywords:** Copper / Density functional calculations / Magnetic properties / Radicals / Zinc

The mononuclear transition metal complexes $[Cu(CF_3SO_3)_2\mathbf{1}_2]$ (**1a**), $[Zn(CF_3SO_3)_2\mathbf{1}_2]$ (**1b**), $[Cu(CF_3SO_3)_2\mathbf{2}_2]\cdot 2CH_3CN$ (**2a**), and $[Zn(CF_3SO_3)_2\mathbf{2}_2]\cdot 2CH_3CN$ (**2b**) have been prepared from the newly synthesized doxyl nitroxide ligands 4,4-dimethyl-2,2-di(2-pyridyl)oxazolidine-*N*-oxyl (**1**) and 4,4-dimethyl-2,2-bis[2-(3-methylpyridyl)]oxazolidine-*N*-oxyl (**2**) and $M(CF_3SO_3)_2$ (M = $Cu^{II}$ or $Zn^{II}$). These metal–nitroxide complexes have been structurally and magnetically characterized. In all complexes, the four pyridyl groups coordinate in equatorial coordination sites and the two nitroxide groups in axial coordination sites, which means that the central metal ion acquires a distorted $N_4O_2$ octahedral configuration. The variable-temperature magnetic susceptibility data show that complexes **1b** and **2b** exhibit paramagnetic behavior, and hence a very weak intraligand magnetic interaction could be estimated [$J_{NO-NO}$ = –0.64 (**1b**) and 0.14 $cm^{-1}$ (**2b**)]. The $\chi_m T$ values of **1a** and **2a** decrease continuously with decreasing temperature until they reach a nearly constant value at around 50 K, thereby indicating an intramolecular antiferromagnetic interaction between the $Cu^{II}$ ion and the nitroxide ligands for both **1a** and **2a** [$J_{Cu-NO}$ = –81.6 (**1a**) and –78.1 $cm^{-1}$ (**2b**)]. These magnetic behaviors are supported by density functional theory calculations and are discussed in connection with the specific structural features.

## Introduction

Studies in multi-spin systems consisting of paramagnetic metal ions and organic radicals are drawing much attention in the field of molecular magnetism.[1] The advantage of using metal–radical compounds resides not only in the fact that both building blocks afford spin centers but also that a higher dimensional molecular architecture can be constructed by versatile coordination patterns of paramagnetic metal ions. Moreover, the radical ligands have the possibility of mediating a stronger magnetic interaction between the adjacent paramagnetic metal ion centers even though the metal–metal distance is large. Therefore, the metal–radical approach has become one of the most promising strategies for large hetero-spin assemblies of exchange-coupled species.

On the other hand, as is the case with metal–radical complexes in which the radical centers are directly bound to the paramagnetic metal ions, intramolecular magnetic interactions are governed by direct overlap between their magnetic orbitals.[2,3] Hence, the nature of the magnetic interaction depends strongly on the coordination geometry around the paramagnetic metal ion. For example, the magnetic interactions in copper(II)–radical complexes range from strong antiferromagnetic interactions to weak ferromagnetic ones.[2] Therefore, the development of organic radical ligands is important to control the magnetic interaction. Several kinds of organic radical ligands have been studied in this context.[4–7] In particular, nitroxide radicals have often been used as paramagnetic ligand molecules because of their stability and ease of chemical modification.[3] However, nitroxides are generally considered as weak Lewis bases and hence they cannot coordinate to metal ions unless the Lewis acidity of the metal center is enhanced by using electron-withdrawing co-ligands such as hexafluoroacetylacetonato (hfac). Consequently, their weak ligating ability to metal ions prevents the formation of metal–nitroxide complexes with high-dimensional structures.[3] Actually, the dimensionality is restricted due to the prior occupation of coordination sites by the electron-withdrawing co-ligands.[8,9] Two strategies have been developed to overcome this difficulty. One approach is to use a high-spin poly(nitroxide radical) as a polydentate bridging ligand to connect the paramagnetic metal ions.[10,11] The other approach is to incorporate nitroxide groups into normal organic ligands with powerful ligating ability such as pyridine,[12] 2,2′-bipyridine,[13] triazole,[14] imidazole,[15] and piperazine,[16]

which allows a facile coordination to metal ions through the chelate effect.

In the present work, two new organic radical ligands bearing pyridyl groups, namely 4,4-dimethyl-2,2-di(2-pyridyl)oxazolidine-*N*-oxyl (**1**) and 4,4-dimethyl-2,2-bis[2-(3-methylpyridyl)]oxazolidine-*N*-oxyl (**2**), were synthesized to have a suitable ligating ability to metal ions. The selection of copper(II) and zinc(II) as the metal ion centers stems from two reasons: (i) $Cu^{II}$ has a $d^9$ configuration with spin-1/2, which simplifies the magnetic interaction between the metal ion and the organic radical ligand,[3] and (ii) $Zn^{II}$ has a closed-shell $d^{10}$ configuration with no unpaired electrons, and hence we can extract the direct magnetic interaction between the paramagnetic ligand molecules. More conveniently, the ionic radius for $Cu^{II}$ (0.87 Å) is almost the same as that for $Zn^{II}$ (0.88 Å).[17] Structural characterization by X-ray crystallographic studies and measurement of the magnetic properties with a SQUID magnetometer for the newly prepared metal–radical complexes were performed. For the $Cu^{II}$ and $Zn^{II}$ complexes with **1**, a theoretical analysis was also carried out on the basis of density functional calculations.

## Results and Discussion

### Synthesis

The novel radical ligands **1** and **2** were synthesized as illustrated in Scheme 1.

Coupling of the dipyridyl ketone **3** (or **4**), with 2-amino-2-methylpropan-1-ol in toluene gives the oxazolidine **5** (or **6**), in high yield. A long reaction time (several days) and continuous water removal by means of a Dean–Stark trap were needed for successful preparation of **5** and **6**. Dipyridyl ketone **4** was prepared by reaction of ethyl chloroformate with lithiated 2-bromo-5-methylpyridine, whereas **3** is commercially available. Oxidation of **5** and **6** with MCPBA in $Et_2O$ finally gave **1** and **2** in relatively high yield. The four complexes **1a**, **1b**, **2a**, and **2b** were obtained by treatment of an acetonitrile solution of $M(CF_3SO_3)_2$ (M = $Cu^{II}$ and $Zn^{II}$) with the corresponding radical ligand, **1** and **2**; vapor diffusion of $Et_2O$ into the reaction mixtures afforded single crystals of these complexes. Elemental analyses of complexes **1a** and **1b** confirmed that the two radical ligands coordinate to a single metal ion. On the other hand, efflorescence was observed with complexes **2a** and **2b**, which suggests that some solvent molecules are included in the crystals. Consequently, we could not determine the chemical formulae of **2a** and **2b** from the elemental analyses; they were finally determined by the X-ray structure analyses, as discussed below.

### Crystal Structures

The structures of complexes **1a**, **1b**, **2a**, and **2b** were determined by X-ray crystallography at 103 or 123 K. All the

complexes crystallize in the triclinic system with space group $P\bar{1}$; they are isostructural. The nitroxide ligand molecule **1** or **2** in these complexes behaves as a tridentate ligand through two pyridyl N-atoms ($N_{pyridyl}$) and one nitroxide O-atom ($O_{NO}$). All the equatorial coordination sites around the central metal ion are occupied by the $N_{pyridyl}$ atoms, with the remaining axial coordination sites occupied by $O_{NO}$ atoms. As a result, the central metal ion has a distorted $N_4O_2$ octahedral configuration. The triflate anions are not coordinated. Selected bond lengths, bond angles, and dihedral angles are given in Table 1, where the dihedral angle, $\varphi$, is defined as that between the equatorial plane (defined by the central metal ion and the four $N_{pyridyl}$ atoms) and the nitroxide plane (defined by the nitroxide N- and O-atoms and two carbon atoms adjacent to the nitroxide N-atom). The tilt angle, $\theta$, is defined as the difference between the line along the $Cu^{II}$–$O_{NO}$ coordination bond and the line perpendicular to the equatorial plane of the $Cu^{II}$ ion.

### *[Cu(CF$_3$SO$_3$)$_2$1$_2$] (1a) and [Zn(CF$_3$SO$_3$)$_2$1$_2$] (1b)*

The molecular structures of **1a** and **1b** are shown in Figure 1. The central $Cu^{II}$ and $Zn^{II}$ ions reside at the inversion center of a distorted octahedron. In the equatorial plane, a considerable deviation from the ideal square geometry is seen in **1a**: the two kinds of $Cu^{II}$–$N_{pyridyl}$ bond lengths are Cu–N2 = 2.001(1) and Cu–N3 = 2.033(1) Å, and the N2–Cu–N3 angle is 86.52(6)°. The axially coordinated $Cu^{II}$–$O_{NO}$ bond [Cu–O1 = 2.333(1) Å] is longer than the equatorially coordinated $Cu^{II}$–$N_{pyridyl}$ bonds. As is well-known for a $d^9$ electron configuration like the $Cu^{II}$ ion, the octahedral geometry does not remain perfect at equilibrium and is inevitably distorted along one axis (the Jahn–Teller effect).[18]

A similar deviation from the ideal square geometry is also observed in **1b** [Zn–N2 = 2.101(1), Zn–N3 = 2.144(1) Å; N2–Zn–N3 = 85.24(5)°]. The elongation along the axial axis is not conspicuous due to the $d^{10}$ electron configuration of the $Zn^{II}$ ion [Zn–O1 = 2.163(1) Å]. The dihedral ($\varphi$) and tilt ($\theta$) angles in **1a** (and **1b**) are 90.5° (91.4°) and 6.0° (5.6°), respectively. As the elongation axis is through O1–Cu1–O1*, the magnetic orbital of $Cu^{II}$ is considered to be $d_{x^2-y^2}$, which is directed toward the nitrogen atoms of the pyridyl groups. As shown in part a of Figure 2, neighboring complex molecules in **1a** (and also **1b**) are well separated in the crystal [the shortest distances between the adjacent metal ions for **1a** and **1b** are 7.5928(5) and 7.6792(4) Å, respectively]. The shortest $O_{NO}$–$O_{NO}$ distances between intermolecular nitroxide groups for **1a** and **1b** are 5.680(2) and 5.953(2) Å, respectively. There is a short C–C contact [3.337(3) Å for **1a** and 3.323(3) Å for **1b**] that is less than the sum of the van der Waals radii (3.40 Å)[19] between the adjacent complex molecules along the *a*-axis.

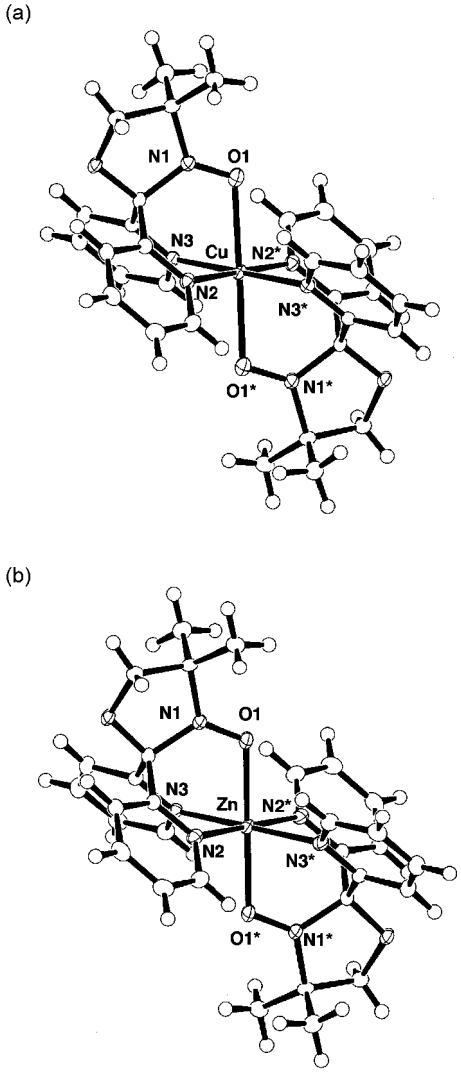

Figure 1. ORTEP view (50% probability ellipsoids) and atom labeling scheme of a) [Cu(CF$_3$SO$_3$)$_2$**1**$_2$] (**1a**) and b) [Zn(CF$_3$SO$_3$)$_2$**1**$_2$] (**1b**). The non-coordinated triflate anions have been omitted for clarity. The atom labeling for compounds **2a** and **2b** is identical.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As described later, however, the spin density on the C atoms with the short contact is so small that a strong magnetic interaction via this molecular contact cannot be expected. Consequently, the magnetic systems of **1a** and **1b** can be considered to be an assemblage of well-isolated three- and two-spin systems, respectively. Moreover, **1a** and **1b** have similar molecular and crystal structures, and therefore we can compare the magnetic interactions in the three-spin systems with those in the two-spin system without the central spin-1/2 moiety within the same geometrical configuration.

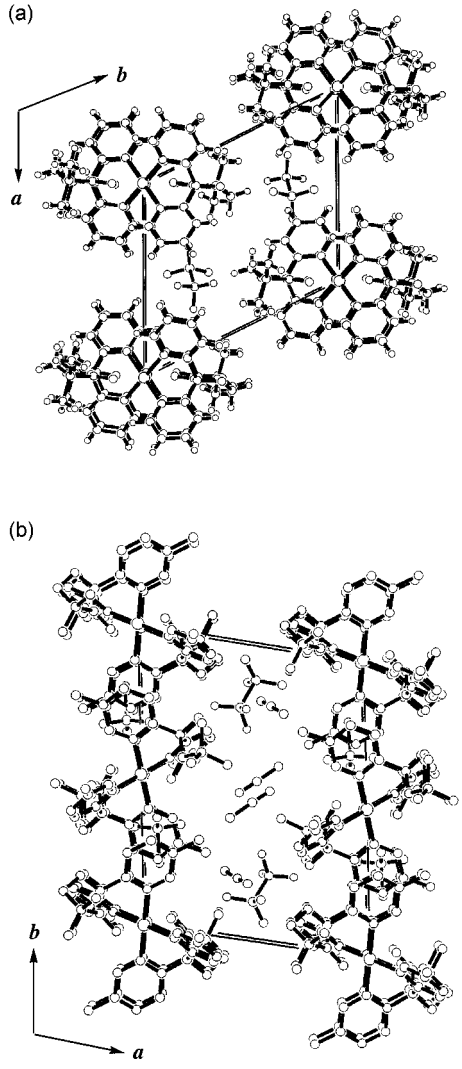

Figure 2. Views of the crystal packing for **1a** (a) and **2a** (b).

### *[Cu(CF$_3$SO$_3$)$_2$2$_2$]·2CH$_3$CN (2a) and [Zn(CF$_3$SO$_3$)$_2$2$_2$]·2CH$_3$CN (2b)*

The crystal structure of **2a** is shown in Figure 2 (b). The crystal of **2a** (and also **2b**) contains two acetonitrile molecules per molecular unit and is different from **1a** (and **1b**) as there are two crystallographically independent molecules in which the central metal ion resides on the inversion center. The molecular structures of **2a** and **2b** are similar to those of **1a** and **1b**. The characteristic geometrical parameters of **2a** are as follows: Cu–O1 = 2.333(2) [2.309(2)], Cu–N2 = 2.014(2) [2.025(2)], Cu–N3 = 2.028(2) Å [2.001(2) Å]; the N2–Cu–N3 angle is 86.53(8)° [87.66(8)°]. The corresponding parameters in **2b** are also similar to those of **1b**: Zn–O1 = 2.165(1) [2.155(2)], Zn–N2 = 2.101(2) [2.096(2)], Zn–N3 = 2.134(2) Å [2.119(2) Å], N2–Zn–N3 = 85.03(7)° [86.46(6)°]. Moreover, the dihedral ($\varphi$) and tilt ($\theta$) angles in **2a** (and **2b**) are 94.8° [83.8°] (85.5° [96.4°]) and 5.9° [4.7°] (5.8° [5.1°]), respectively. The deviation of the dihedral angle between the equatorial plane and the nitroxide plane from 90° in **2a** and **2b** is larger than that in **1a** and **1b**. The intermolecular distances in **2a** and **2b** are larger than those in **1a** and **1b** due to the steric hindrance of the crystallized acetonitrile molecules and the methyl group of ligand **2** (the shortest distances between the adjacent metal ions for **2a** and **2b** are 7.97 and 8.16 Å, respectively). The shortest $O_{NO}$–$O_{NO}$ distances between intermolecular nitroxide groups for **2a** and **2b** are 7.477(3) and 7.465(3) Å, respectively. In addition, there is no intermolecular contact less than the sum of the van der Waals radii (3.40 Å for C–C; 3.22 Å for C–O)[19] between the adjacent complex molecules. Therefore, the intermolecular magnetic interactions in **2a** and **2b** are expected to be weaker than those in **1a** and **1b**.

### Magnetic Properties

The temperature-dependent magnetic susceptibility of complexes **1a**, **1b**, **2a**, and **2b** was measured in the temperature range 2–300 K; $\chi_m T$ values are plotted as a function of

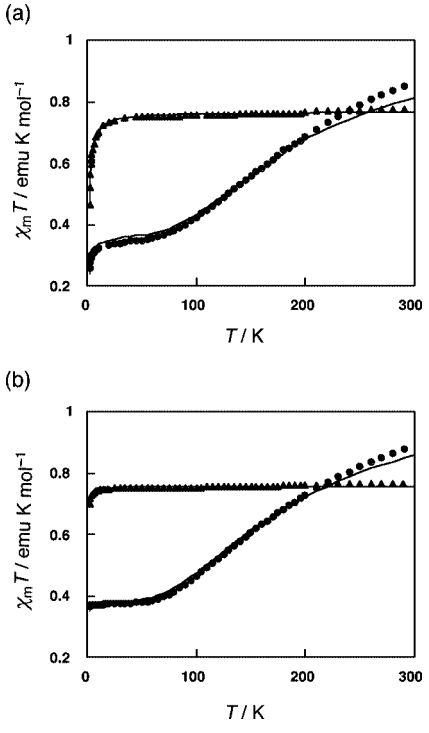

Figure 3. Temperature-dependence of the magnetic susceptibilities of a) **1a** (solid circle) and **1b** (solid triangle) and b) **2a** (solid circle) and **2b** (solid triangle). The solid curves represent the best theoretical fit to the data (see text).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the temperature in Figure 3, where $\chi_m$ is the molar magnetic susceptibility per molecular unit.

### *[Cu(CF$_3$SO$_3$)$_2$I$_2$] (1a) and [Zn(CF$_3$SO$_3$)$_2$I$_2$] (1b)*

As shown in Figure 3 (a), the $\chi_m T$ value for **1b** is nearly constant at around 0.75 emu K mol$^{-1}$, which corresponds to two magnetically uncoupled spins-1/2 per molecular unit. This result is reasonable for the complex of a diamagnetic $Zn^{II}$ ion with two spin-1/2 radical ligands. Moreover, the crystal structural analysis shows that the shortest $O_{NO}$–$O_{NO}$ distance between intermolecular nitroxide groups (5.95 Å) is longer than that between intramolecular nitroxide groups (4.33 Å). This indicates that the spin system in **1b** can be regarded as an assemblage of approximately isolated two-spin clusters. Taking these results into account, the magnetic data for **1b** were analyzed by using the Bleaney–Bowers equation[20] for a two-spin cluster composed of a pair of nitroxide radical ligands ($H = -2J_{NO-NO}\boldsymbol{S}_{NO}\cdot\boldsymbol{S}_{NO}$, where $\boldsymbol{S}_{NO}$ is the spin-1/2 operator for the nitroxide radical ligand and $J_{NO-NO}$ is the exchange coupling constant between two intramolecular nitroxide spins). Furthermore, the Curie–Weiss law can be used to describe inter-cluster magnetic interactions [Equation (1)], where $f$ is the purity factor of the sample, $N_A$ the Avogadro number, $g$ the isotropic $g$-factor (assuming $g = 2$), $\theta$ the Weiss temperature, $k_B$ the Boltzmann constant, and $\mu_B$ the Bohr magneton.

$$\chi_m T = f\frac{2N_A g^2 \mu_B^2 T}{k_B(T-\theta)}\frac{1}{3+exp\left(-\frac{2J_{NO-NO}}{k_B T}\right)} \quad (1)$$

The best fit parameters were found to be $f = 1.02$, $J_{NO-NO} = -0.64$ cm$^{-1}$, and $\theta = -0.4$ K ($-0.26$ cm$^{-1}$). The small values of $J_{NO-NO}$ and $\theta$ indicate that the intra- and intermolecular magnetic interaction between the nitroxide radical spins in **1b** can be ignored as compared to the magnetic interaction between the d$^9$ $Cu^{II}$ spin and the nitroxide radical spin in the complex molecule of **1a**, as discussed below.

In contrast, the $\chi_m T$ value for **1a** at room temperature is smaller than the theoretical value ($\chi_m T$ = 1.125 emu K mol$^{-1}$) for three spins-1/2 per molecular unit. Furthermore, on lowering the temperature, the $\chi_m T$ value decreases gradually and reaches a nearly constant value close to a theoretical value for a single spin-1/2 per molecular unit ($\chi_m T$ = 0.375 emu K mol$^{-1}$) at around 50 K. These results indicate that a relatively strong antiferromagnetic interaction is present in the crystal of **1a**. As indicated by the crystal structure analysis of **1a**, the shortest intra- and intermolecular $O_{NO}$–$O_{NO}$ distances between the nitroxide radical ligands (4.67 and 5.68 Å, respectively) and the shortest intermolecular $Cu^{II}$–$Cu^{II}$ distance (7.59 Å) are longer than the $Cu^{II}$–$O_{NO}$ distance (2.333 Å). This indicates that the spin system in **1a** can be regarded as an assemblage of approximately isolated three-spin clusters consisting of a $Cu^{II}$ ion and two nitroxide radical ligands. Moreover, the direct intramolecular magnetic interaction between the nitroxide ligand molecules in **1a** can be neglected due to the magnetic behavior of **1b**. Therefore, the arrangement of the three-spin clusters in complex **1a** can be regarded as a linear three-spin model [$\boldsymbol{S}_{NO(1)}$–$\boldsymbol{S}_{Cu}$–$\boldsymbol{S}_{NO(2)}$]. The spin Hamiltonian can be written as shown in Equation (2) using an exchange coupling constant, $J_{Cu-NO}$, between the $Cu^{II}$ spin and the nitroxide radical spin.

$$H = -2J_{Cu-NO}[\boldsymbol{S}_{NO(1)}\cdot\boldsymbol{S}_{Cu} + \boldsymbol{S}_{Cu}\cdot\boldsymbol{S}_{NO(2)}] \quad (2)$$

for which the eigenvalues are

$$E_1(S = 1/2) = 2\,J_{Cu-NO}$$

$$E_2(S = 1/2) = 0$$

$$E_3(S = 3/2) = -\,J_{Cu-NO}$$

Hence, the temperature dependence of $\chi_m T$ is given by Equation (3).

$$\chi_m T = f\frac{N_A g^2 \mu_B^2 T}{4k_B(T-\theta)}\frac{1+exp\left(-\frac{2J_{Cu-NO}}{k_B T}\right)+10exp\left(\frac{J_{Cu-NO}}{k_B T}\right)}{1+exp\left(-\frac{2J_{Cu-NO}}{k_B T}\right)+2exp\left(\frac{J_{Cu-NO}}{k_B T}\right)} \quad (3)$$

The parameters in this equation are the same as in Equation (1). This equation was fitted well to the experimental data, and the best-fit parameters were $f = 0.99$, $J_{Cu-NO} = -81.6$ cm$^{-1}$, and $\theta = -1.1$ K ($-0.77$ cm$^{-1}$). The sign of $J_{Cu-NO}$ is opposite to that found for $Cu^{II}$–nitroxide complexes where the $O_{NO}$ atoms occupy the axial positions (+10 to +70 cm$^{-1}$).[2,21] However, the magnitude of $J_{Cu-NO}$ is smaller than that observed for $Cu^{II}$–nitroxide complexes where the $O_{NO}$ atoms occupy the equatorial positions (ca. $-600$ cm$^{-1}$).[2,21] This discrepancy in the sign of $J_{Cu-NO}$ suggests that the overlap mode between the π* orbital of the nitroxide group and the magnetic orbital ($d_{x^2-y^2}$) of the $Cu^{II}$ ion differs between the present complex and the previously reported axially coordinated $Cu^{II}$–nitroxide complexes.[22] The relatively small $J_{Cu-NO}$ value arises from the fact that the Cu–$O_{NO}$ distance is fairly long (ca. 2.3 Å) owing to the Jahn–Teller distortion as compared to that for the equatorially coordinated $Cu^{II}$–nitroxide complexes (ca. 2.0 Å).[21,23,24]

### *[Cu(CF$_3$SO$_3$)$_2$2$_2$]·2CH$_3$CN (2a) and [Zn(CF$_3$SO$_3$)$_2$2$_2$]·2CH$_3$CN (2b)*

The $\chi_m T$ vs. $T$ plots for **2a** and **2b** are shown in Figure 3 (b). The temperature dependence of the $\chi_m T$ value for **2a** and **2b** is similar to those for **1a** and **1b**, respectively. The X-ray structural analysis shows that the intermolecular distance and shortest contacts in **2a** and **2b** are larger than those in **1a** and **1b**. However, the temperature dependence of their magnetic properties remains unchanged. This means that the main magnetic interaction observed in the crystals of **1a** and **2a** can be ascribed to the intramolecular antiferromagnetic interaction between the $Cu^{II}$ spin and the nitroxide radical spin. Hence, the magnetic data were again fitted to Equations (1) and (3). The best fit, shown in Figure 3 (b) as a solid line, afforded the following parameters:

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$f$ = 1.03, $J_{Cu-NO}$ = –78.1 cm$^{-1}$, and $\theta$ = –0.2 K (–0.15 cm$^{-1}$) for **2a** and $f$ = 1.01, $J_{NO-NO}$ = 0.14 cm$^{-1}$, and $\theta$ = –0.3 K (–0.19 cm$^{-1}$) for **2b**. The value of $J_{Cu-NO}$ is similar to that for **1a**, which supports the assumption that the spin alignment in **1a** and **2a** is governed by an intramolecular antiferromagnetic interaction between the Cu$^{II}$ ion and the nitroxide ligands.

### Theoretical Considerations

On the basis of the obtained X-ray structures of **1a** and **1b** we performed quantum chemical calculations in order to examine the electronic structures of the present metal–radical complexes. First of all, we investigated the spin-density distribution of complexes **1a** and **1b**. As density functional theory (DFT) calculations often give good results for both signs and magnitudes of spin densities of open-shell molecules, we carried out calculations using the hybrid HF/DF method (B3LYP/LANL2DZ).[25] The partially occupied spin-free natural orbitals from the B3LYP/LANL2DZ calculations for the $^4A_u$ state of **1a** and the selected spin densities of the low- and high-spin states of **1a** and **1b** are shown in Figures 4 and 5, respectively. In both of the doublet and quadruplet states of **1a**, the spin densities are mainly localized on the Cu$^{II}$ ion and the nitroxide groups. In **1b**, the spin densities for the singlet and triplet states are localized only on the nitroxide groups of the two ligands. On the other hand, the spin densities over the peripheral pyridyl groups of **1a** and **1b** are quite small. These results are consistent with the experimental result that the intermolecular magnetic interactions in all four complexes are very weak.

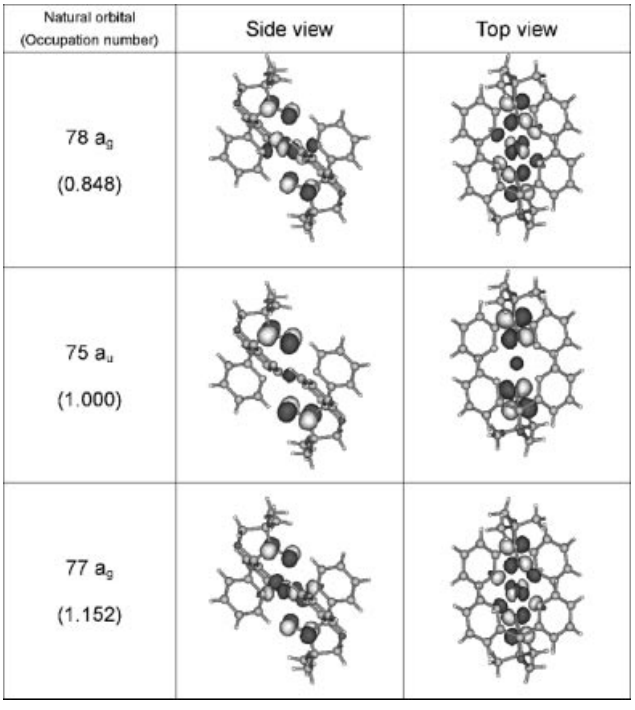

Figure 4. Three partially occupied natural orbitals for the $^2A_u$ state of **1a** at the UB3LYP/LANL2DZ level of theory.

Moreover, the sign of the spin density on the Cu$^{II}$ ion in the doublet state of **1a** is opposite to that in the quadruplet state, while the magnitudes of the spin densities on the Cu$^{II}$ and nitroxyl groups remain unchanged. This indicates that an antiferromagnetic spin alignment occurs in the doublet state of **1a**, while a ferromagnetic spin alignment occurs in the quadruplet state of **1a**. In addition, the natural orbital occupation number indicates that the $^2A_u$ state of **1a** has a doublet triradical character.

Energetically, the doublet state ($^2A_u$) in **1a** was estimated to be more stable than the quadruplet state ($^4A_u$) by 223 cm$^{-1}$. In addition, the exchange coupling constant, $J$, can be estimated to be 110 cm$^{-1}$ by using the approximate spin projection method[26–29] given by Equation (4),

$$J = \frac{E(^2A_u) - E(^4A_u)}{\langle S^2\rangle(^4A_u) - \langle S^2\rangle(^2A_u)} \quad (4)$$

where $E(^2A_u)$ and $E(^4A_u)$ are the total energies for the $^2A_u$ and $^4A_u$ states and $<S^2>(^2A_u)$ and $<S^2>(^4A_u)$ the expectation values for the total spin angular momentums of $^2A_u$ and $^4A_u$ states. The estimated $J$ value gives a good agreement with the $J_{Cu-NO}$ value determined from the magnetic

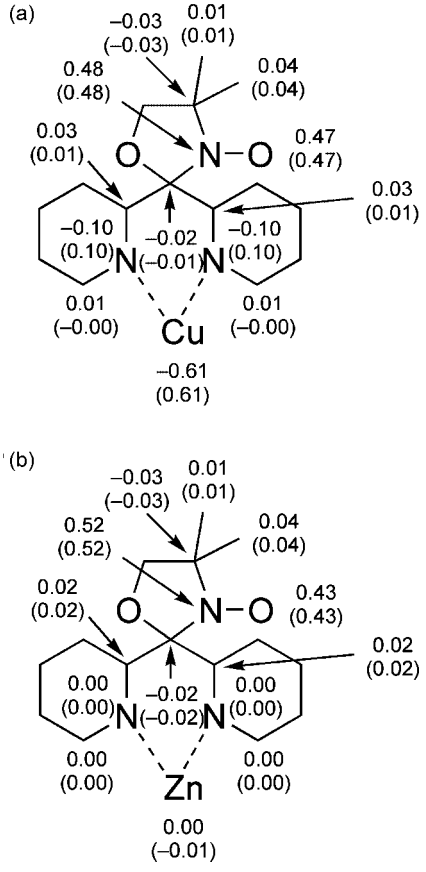

Figure 5. Mulliken spin density for a) the doublet and quadruplet states (in parentheses) of **1a** and b) the singlet and triplet states (in parentheses) of **1b** at the UB3LYP/LANL2DZ level of theory. The centrosymmetric atoms have the same spin density (having the opposite sign only for the singlet state of **1b**), hence one of the two ligands has been omitted for clarity.

measurements. On the other hand, the singlet ($^1A_u$) and triplet ($^3A_u$) states of **1b** were found to be virtually degenerate. This indicates that effective magnetic interactions between the two nitroxide ligands via the diamagnetic $Zn^{II}$ ion do not occur.

The present axially coordinated $Cu^{II}$–nitroxide complexes **1a** and **2a** show antiferromagnetic coupling between the metal center and the nitroxide ligand molecule, although the $Cu^{II}$–nitroxide magnetic interaction in the axially coordinated $Cu^{II}$–nitroxide complexes is usually ferromagnetic.[3,22] Schweizer and co-workers have clearly shown the spin-density distribution of an axially coordinated $Cu^{II}$–nitroxide complex on the basis of a neutron diffraction analysis; their results strongly suggest that the ferromagnetic interaction between the $Cu^{II}$ ion and the nitroxide ligand is derived from orthogonality between the corresponding magnetic orbitals (the $3d_{x^2-y^2}$ atomic orbital for $Cu^{II}$ and the π* orbital for the nitroxide).[30] In general, the exchange parameter is approximately expressed as Equation (5),

$$J_{dir} \approx \rho_{x^2-y^2} J(3d_{x^2-y^2}, \pi^*) \quad (5)$$

$$J(3d_{x^2-y^2}, \pi^*) \sim < 3d_{x^2-y^2}\,\pi^* \mid \pi^*\,3d_{x^2-y^2} > + 2S < \pi^* \mid h \mid 3d_{x^2-y^2} > - S^2 [\, \varepsilon_{xy} + \varepsilon_{\pi^*} + < 3d_{x^2-y^2}\,3d_{x^2-y^2} \mid \pi^*\,\pi^* > ]$$

where $\rho_{x^2-y^2}$ is the density of the unpaired electron on the $3d_{x^2-y^2}$ atomic orbital, $S = <3d_{x^2-y^2}|\pi^*>$ is the overlap integral between the magnetic orbitals, $\varepsilon_{xy}$ and $\varepsilon_{\pi^*}$ are the orbital energies, $<3d_{x^2-y^2}\pi^*|\pi^*\,3d_{x^2-y^2}>$ and $<3d_{x^2-y^2}\,3d_{x^2-y^2}|\pi^*\,\pi^*>$ are the two-electron integrals of the exchange and Coulomb types, respectively, and $h$ is the one-electron Hamiltonian. According to Musin and co-workers,[31] the strong antiferromagnetic coupling ($J \approx -500\ cm^{-1}$)[3] in equatorially coordinated $Cu^{II}$–nitroxide complexes can be explained by the above-mentioned direct exchange interaction $J_{dir}$. The third term of $J(3d_{x^2-y^2}, \pi^*)$ in Equation (5) becomes dominant due to the large overlap integral $S \approx 10^{-1}$ ($J_{dir} \approx -500\ cm^{-1}$).

On the other hand, in axially coordinated $Cu^{II}$–nitroxide complexes, slight delocalization of the unpaired electron from the π* orbital of the nitroxide group to the $3d_{z^2}$ atomic orbital of the $Cu^{II}$ ion takes place. Hence, the delocalized π* orbital is approximately expressed as $\pi^* + c_{z^2}3d_{z^2}$. As a result, the exchange parameter contains two main contributions, $J \approx J_{dir} + J_{del}$. The exchange parameter due to the delocalization mechanism $J_{del}$ takes the form shown in Equation (6),

$$J_{dir} \approx \rho_{x^2-y^2}\rho_{z^2} <3d_{x^2-y^2}\,3d_{z^2}|3d_{z^2}\,3d_{x^2-y^2}> \quad (6)$$

where $\rho_{z^2} = c_{z^2}$, the spin density due to delocalization from the nitroxide group to $Cu^{II}$. In the axially coordinated $Cu^{II}$–nitroxide complexes, the values of $S$ are estimated to be very small because of orthogonality between the $3d_{x^2-y^2}$ atomic orbital for the $Cu^{II}$ ion and the π* orbital of nitroxide group. Hence, the direct exchange term $J_{dir}$ only gives a very small positive value. On the other hand, in spite of the smallness of the delocalization $\rho_{z^2}$, the large intra-atomic exchange integral [Equation (6)] leads to a major contribution from the delocalized exchange term $J_{del}$ (ca. 10–65 $cm^{-1}$).[31]

In the present complexes **1a** and **1b** the nitroxide groups are axially coordinated to the $Cu^{II}$ ion. However, the determined exchange parameter is antiferromagnetic ($J_{exp} \approx 80\ cm^{-1}$), which is contrary to the expected ferromagnetic interaction in axially coordinated $Cu^{II}$–nitroxide complexes. This can be explained by the difference of overlap mode between the magnetic orbitals of the $Cu^{II}$ ion and the nitroxide groups. As shown in Figure 6 (a), when the symmetry plane containing the π* orbital of the nitroxide group is orthogonal to the equatorial plane of the $Cu^{II}$ ion, the tilting of the $Cu^{II}$–$O_{NO}$ coordination bond from the line

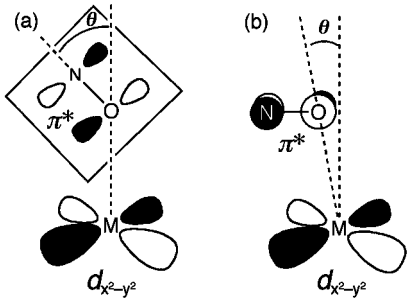

Figure 6. Schematic views of possible orbital interactions between the magnetic orbitals ($3d_{x^2-y^2}$) of the $Cu^{II}$ ion ($3d_{x^2-y^2}$) and the nitroxide radical (π*). $\theta$ is the tilt angle of the $Cu^{II}$–$O_{NO}$ coordination bond from the line perpendicular to the equatorial plane of the $Cu^{II}$ ion.

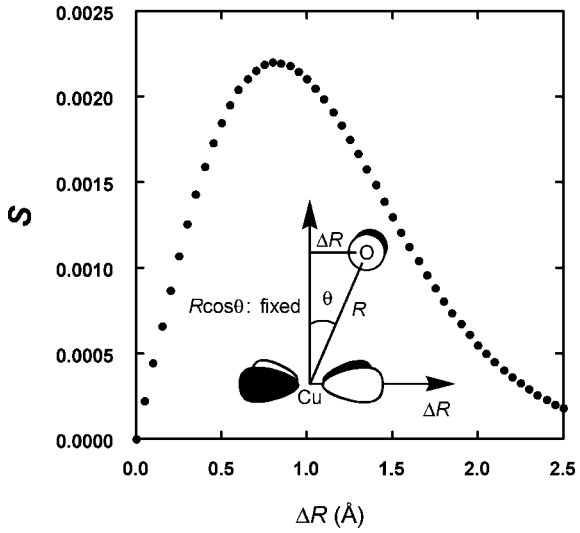

Figure 7. Dependence of the overlap integral between the Slater 2p atomic orbital of the oxygen atom and the Slater $3d_{x^2-y^2}$ atomic orbital of the Cu atom on the distance $\Delta R$ (in Å) defined in the inset ($R\cos\theta$ was fixed to 2.3202 Å, which corresponds to complex **1a**). $\Delta R$ can be related to the tilt angle $\theta$ in Table 1 and Figure 6 by the formula $\sin\theta = \Delta R/R$. We adopted 2.275 and 2.95 for the values of $\zeta$ of the oxygen 2p orbital and the copper 3d orbital, respectively [see: J. A. Pople, D. L. Beveridge, *Approximate Molecular Orbital Theory*, McGraw-Hill, New York, **1970**.]. In the case of complex **1a**, the corresponding overlap integral was estimated to be 0.001 [$\Delta R = 0.2438$].

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

perpendicular to the equatorial plane causes an effective overlap between the π* orbital of the nitroxide group and the $3d_{z^2}$ atomic orbital of the $Cu^{II}$ ion. Therefore, the delocalization mechanism [Equation (6)] leads to a relatively large ferromagnetic interaction. On the other hand, as shown in Figure 6 (b), in the present $Cu^{II}$–nitroxide complexes the symmetry plane containing the π* orbital of the nitroxide group is nearly parallel to the equatorial plane of the $Cu^{II}$ ion. Hence, the overlap integral between the π* orbital of the nitroxide group and the $3d_{z^2}$ atomic orbital of the $Cu^{II}$ ion is virtually negligible. Thus, we can ignore the above-mentioned delocalization mechanism in complexes **1a** and **1b**. More importantly, the $Cu^{II}$–$O_{NO}$ coordination bond tilts from the line perpendicular to the equatorial plane ($\theta \approx 5°$) in the present coordination mode [Figure 6 (b)]. Therefore, the finite overlap integral between the π* orbital of the nitroxide group and $3d_{x^2-y^2}$ atomic orbital of the $Cu^{II}$ ion is expected. However, the overlap integral is expected to be small compared to the equatorially coordinated $Cu^{II}$–nitroxide complexes, as shown in Figure 7 ($S \approx 0.001$). Such a specific overlap mode leads to a relatively weak antiferromagnetic interaction ($J \approx 80\ cm^{-1}$) in complexes **1a** and **1b** due to the direct exchange mechanism.

## Concluding Remarks

The synthesis, magnetic properties, and theoretical analysis of $Cu^{II}$ complexes **1a** and **2a** and $Zn^{II}$ complexes **1b** and **2b** containing radical ligands **1** and **2** have been described. It has been shown that the combination of the metal ion and these radical ligands results in formation of isostructural mononuclear complexes. The magnetic properties of the $Zn^{II}$ complex indicate that there is a weak intramolecular magnetic interaction between two nitroxide ligands. On the other hand, the exchange coupling constant $J_{Cu–NO}$ between the $Cu^{II}$ and the nitroxide ligands for **1a** and **2a** was determined to be –81.6 and –78.1 $cm^{-1}$, respectively, thereby indicating an antiferromagnetic interaction. The DFT calculations show that the ground $^2A_u$ state of **1a** has a doublet triradical character and give a reasonable exchange coupling constant $J_{Cu–NO}$ (–110 $cm^{-1}$). Although the present axially coordinated $Cu^{II}$–nitroxide complexes show an antiferromagnetic interaction, this interaction can be attributed to the specific structural features of the coordination pattern of the nitroxide ligand molecules. Unfortunately, the present nitroxide ligand molecules **1** and **2** are contained in mononuclear transition metal complexes. However, it may be possible to build highly dimensional magnetic materials by using radical ligands containing 3- or 4-pyridyl groups to avoid coordination of all the pyridyl groups to a single metal ion.

## Experimental Section

**General Procedures and Materials:** $^1H$ and $^{13}C$ NMR spectra were recorded with a JEOL AL-300 spectrometer, and chemical shifts are given in ppm relative to internal tetramethylsilane (TMS; $\delta$ = 0.0 ppm) for $^1H$ and to $CDCl_3$ for $^{13}C$ NMR spectroscopy. Elemental analyses were performed by the Center for Organic Elemental Microanalysis of Kyoto University. Toluene was distilled from over calcium hydride. 2-Amino-2-methylpropan-1-ol was distilled from over calcium hydride under reduced pressure. THF was distilled from over potassium/benzophenone under argon. *m*-Chloroperbenzoic acid (MCPBA) was obtained commercially (70–75% purity) and used without further purification. All the other purchased reagents and solvents were used without further purification.

**4,4-Dimethyl-2,2-di(2-pyridyl)oxazolidine (5):** This compound was prepared by a modified literature procedure.[32,33] A mixture of bis(2-pyridyl) ketone (9.71 g, 51.7 mmol), freshly distilled 2-amino-2-methylpropan-1-ol (110 mL, 1130 mmol), and concentrated $H_2SO_4$ (25 drops) in toluene (200 mL) was refluxed for 4 d. The water generated was removed by means of a Dean–Stark trap containing 4-Å molecular sieves. The reaction mixture was then cooled to room temperature and concentrated under reduced pressure. Water (200 mL) and $Et_2O$ (100 mL) were added to the resulting residue and then the organic layer was separated. The aqueous layer was extracted with $CH_2Cl_2$ (2 × 100 mL). The combined organic layers were dried with $MgSO_4$ and the solvents evaporated in vacuo. The residue was recrystallized from cyclohexane to afford **5** (4.39 g, 33%) as a white solid. The mother liquor was evaporated and chromatographed on aluminum oxide (ethyl acetate/*n*-hexane = 1:1 as eluent) to afford additional **5** (8.54 g, 65%). The total yield was 98%. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 8.55 (d, $J$ = 4.0 Hz, 2 H), 7.75 (d, $J$ = 7.9 Hz, 2 H), 7.63 (td, $J$ = 7.7, 1.6 Hz, 2 H), 7.11–7.16 (m, 2 H), 4.26 (br., 1 H), 3.68 (s, 2 H), 1.21 (s, 6 H) ppm. $^{13}C$ NMR (75.5 MHz, $CDCl_3$): $\delta$ = 162.3, 148.5, 136.3, 122.3, 121.2, 98.9, 77.9, 59.6, 26.6 ppm. $C_{15}H_{17}N_3O$: calcd. C 70.56, H 6.71, N 16.46, O 6.27; found C70.28, H 6.71, N 16.55, O 6.30.

**4,4-Dimethyl-2,2-di(2-pyridyl)oxazolidine-*N*-oxyl (1):** This compound was also prepared by a modified literature procedure.[32] Thus, a solution of MCPBA (4.34 g, ca. 17.6 mmol) in $Et_2O$ (40 mL) was added dropwise to an ice-cooled solution of **5** (3.01 g, 11.8 mmol) in $Et_2O$ (40 mL). The resulting solution was allowed to stand for 4 h. Cold 5% $Na_2CO_3$ aqueous solution (40 mL) was then added to the reaction mixture and the aqueous layer was separated. The organic layer was extracted with cold 5% $Na_2CO_3$ aqueous solution (4 × 40 mL) and the aqueous phases were combined. The aqueous phase was extracted with $CH_2Cl_2$ (5 × 40 mL). The combined organic phase was washed with cold 5% $Na_2CO_3$ solution (2 × 40 mL), dried with $MgSO_4$, and the solvents evaporated in vacuo. The resulting orange solid was chromatographed on silica gel (acetone as eluent). A fraction ($R_f$ = 0.61) afforded **1** as an orange solid (1.99 g, 62%). ESR (X-band, toluene): $g$ = 2.0094 and $a_N$ = 13.7 G. $C_{15}H_{16}N_3O_2$: calcd. C 66.65, H 5.97, N 15.55, O 11.84; found C66.74, H 5.92, N 15.48, O 11.84.

**Bis[2-(3-methylpyridyl)] Ketone (4):** Compound **4** was prepared by a modified literature procedure.[34] *n*BuLi (10.5 mmol, 1.5 M in hexane) was added dropwise to a solution of 2-bromo-5-methylpyridine (1.93 g, 11.0 mmol) in THF (15 mL) at –90 °C (petroleum ether/liquid nitrogen) under argon. The resulting solution was stirred at –90 °C for 1 h, and then a solution of ethyl chloroformate (0.58 g, 5.18 mmol) in THF (2 mL) was added rapidly. After stirring overnight, the reaction mixture was concentrated and $CH_2Cl_2$ (100 mL) and water (100 mL) were added. The organic layer was separated and the aqueous layer was extracted with $CH_2Cl_2$ (4 × 50 mL). The combined organic layer was washed with 10% aqueous $NaHCO_3$, dried with $MgSO_4$, and the solvents evaporated in vacuo. The crude product was chromatographed on silica gel (ethyl acetate as eluent). A fraction ($R_f$ = 0.38) afforded **4** as a pale-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

yellow solid (yield 0.40 g, 36%). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 8.57 (dd, $J$ = 1.5, 0.7 Hz, 2 H), 8.01 (d, $J$ = 7.9 Hz, 2 H), 7.67 (ddd, $J$ = 7.9, 2.2, 0.7 Hz, 2 H), 2.43 (s, 6 H) ppm. $^{13}$C NMR (75.5 MHz, CDCl3): $\delta$ = 192.8, 152.1, 149.7, 137.0, 136.7, 125.0, 18.7 ppm. $C_{13}H_{12}N_2O$: calcd. C 73.56, H 5.70, N 13.20, O 7.54; found C73.28, H 5.85, N 13.06, O 7.48.

**4,4-Dimethyl-2,2-bis[2-(3-methylpyridyl)]oxazolidine (6):** Compound **6** was obtained from **4** by the same procedure as **5**. The reaction mixture was chromatographed on aluminum oxide (ethyl acetate as eluent) to afford **6** as a pale-yellow solid ($R_f$ = 0.83, yield 97%). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 8.37 (s, 2 H), 7.60 (d, $J$ = 7.9 Hz, 2 H), 7.43 (d, $J$ = 8.1 Hz, 2 H), 4.21 (br., 1 H), 3.67 (s, 2 H), 2.27 (s, 6 H), 1.20 (s, 6 H) ppm. $^{13}$C NMR (75.5 MHz, $CDCl_3$): $\delta$ = 159.7, 148.9, 136.9, 131.6, 120.7, 98.9, 77.9, 59.7, 26.7, 18.0 ppm. $C_{17}H_{21}N_3O$: calcd. C 72.06, H 7.47, N 14.83, O 5.65; found C 72.15, H 7.68, N 14.58, O 5.52.

**4,4-Dimethyl-2,2-bis[2-(3-methylpyridyl)]oxazolidine-*N*-oxyl (2):** Compound **2** was obtained from **6** by the same procedure as **1**. The reaction mixture was chromatographed on a silica gel column (acetone as eluent) to afford **2** as an orange solid ($R_f$ = 0.72, yield 73%). $C_{17}H_{20}N_3O_2$: calcd. C 68.43, H 6.76, N 14.08, O 10.72; found C 68.25, H 6.84, N 13.91, O 10.54.

**General Procedure for the Synthesis of Complexes 1a, 1b, 2a, and 2b:** A solution of the radical ligand (2.0 mmol) in acetonitrile (10 mL) was added to a solution of the appropriate triflate salt (1.0 mmol) in acetonitrile (15 mL). The color of the solution changed to dark green (for the $Cu^{II}$ complexes) or pale yellow (for the $Zn^{II}$ complexes). The resulting solution was filtered and $Et_2O$ vapor was slowly diffused into the solution. The single crystals obtained were suitable for X-ray studies.

**[Cu(CF$_3$SO$_3$)$_2$2$_2$] (1a):** Dark green blocks. $C_{32}H_{32}CuF_6N_6O_{10}S_2$: calcd. C 42.60, H 3.57, N 9.31; found C 42.68, H 3.57, N 9.34.

**[Cu(CF$_3$SO$_3$)$_2$2$_2$]·2CH$_3$CN (2a):** Efflorescent dark-green needles. $C_{40}H_{46}CuF_6N_8O_{10}S_2$: calcd. C 46.17, H 4.46, N 10.77; found C 44.19, H 4.31, N 8.39.

**[Zn(CF$_3$SO$_3$)$_2$1$_2$] (1b):** Yellow blocks. $C_{32}H_{32}F_6N_6O_{10}S_2Zn$: calcd. C 42.51, H 3.57, N 9.30; found C 42.57, H 3.59, N 9.19.

**[Zn(CF$_3$SO$_3$)$_2$2$_2$]·2CH$_3$CN (2b):** Efflorescent yellow needles. $C_{40}H_{46}F_6N_8O_{10}S_2Zn$: calcd. C 46.09, H 4.45, N 10.75; found C 44.55, H 4.26, N 9.15.

**X-ray Crystallographic Studies:** The measurements were performed on a Rigaku/MSC Mercury CCD diffractometer (for **1a**) or a Rigaku RAXIS imaging plate area detector (for **1b**, **2a**, and **2b**) with graphite-monochromated Mo-$K_\alpha$ radiation. The data were collected at a temperature of 103 K (for **1a**) or 123 K (for **1b**, **2a**, and **2b**) to a maximum $2\theta$ value of 54.9° (for **1a** and **2a**) or 60.1° (for **1b** and **2b**). After correction of the raw data for Lorentz and polarization effects, the structure was solved by direct methods (SIR97[35]). The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. For **2a**, hydrogen atoms were refined isotropically. However, for **1a**, **1b**, and **2b** hydrogen atoms were included but not refined. Crystallographic data for these complexes are listed in Table 2.

CCDC-267140 (for **1a**), -267141 (for **2a**), -267142 (for **1b**), and -267143 (for **2b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Magnetic Susceptibility Measurements:** The magnetic susceptibility was measured on polycrystalline samples of **1a** and **1b** or powder samples of **2a** and **2b** in the 2–300 K temperature range under a field of 500 G with a SQUID magnetometer (Quantum Design MPMS-5S). The data were corrected for magnetization of the sample holder and the magnetic susceptibility was corrected for diamagnetism of the constituent atoms using the Pacault method.[36]

**Calculational Methods:** Density functional theory (DFT) calculations were carried out by using a hybrid method (B3LYP) that combines Becke's three-parameter non-local exchange functional[21] with the non-local correlation functional of Parr and co-workers.[37] All of the computations were performed with the Gaussian 98 package[38] using the LANL2DZ basis set where the pseudopotential proposed by Hay and Wadt[39] is applied to the Cu atom, and the Dunning/Huzinaga valence double-ζ basis set[40] to the H, C, O, and N atoms. We employed the geometrical parameters of the isolated complex molecules of **1a** and **1b** determined by the X-ray crystallography as the geometry for the quantum chemical calculations, without geometry optimizations. DFT doublet, triplet, and quadruplet energies were calculated in straightforward unrestricted fashion (UB3LYP). The open-shell singlet energy for **1b** was estimated by the sum method.[41] Generally speaking, the UB3LYP calculations for the open-shell singlet state give the so-called

broken-symmetry state.[42] In the weak bonding regime, the following relationship is deduced between the energies of the broken-symmetry state ($E_{BS}$) and those of the pure (open-shell) singlet ($E_S$) and triplet states ($E_T$) from which we can estimate the pure singlet energy for complex **1b** [see Equation (7)].

$$E_{BS} = (E_S + E_T)/2 \quad (7)$$

# Synthesis, Crystal Structures, Cation-Binding Properties and the Influence of Intramolecular C–H···O Interactions on the Complexation Behaviour of a Family of Cone *p-tert*-Butylcalix[4]arene-crown-5 Compounds

**Pragati Agnihotri,[a] Eringathodi Suresh,[a] Parimal Paul,*[a] and Pushpito K. Ghosh*[a]**

**Keywords:** Calixarenes / Crown compounds / Selectivity / Association constants

A family of cone *p-tert*-butylcalix[4]arene-crown-5 compounds with various substituents (H, $COCH_3$, $CH_2CO_2C_2H_5$ and $CH_2CO_2H$) appended at the opposite phenolic oxygen atoms have been synthesised to evaluate their efficiency and selectivity towards different alkali and alkaline-earth metal ions, and also to ascertain the role of the appended side-arms in the complexation process. The selectivity of these ionophores towards $Na^+$, $K^+$, $Mg^{2+}$, and $Ca^{2+}$ has been evaluated with an aqueous solution containing an equimolar mixture of these ions. The concentration of metal ion in the extract (organic phase) has been estimated by ion chromatographic assay. Among these ions, $K^+$ shows the highest selectivity in all cases except one, where the two phenolic oxygen atoms contain $COCH_3$ substituents. All the ionophores show poor selectivity towards $Mg^{2+}$ and $Ca^{2+}$. Association constants ($K_a$) for the binding of $Na^+$ and $K^+$ to these ionophores have been determined spectrophotometrically. $K_a$ ($7.2\times10^7$) is highest for the binding of $K^+$ to the ionophore with $CH_2CO_2C_2H_5$ substituents. The molecular structures of four of the ionophores and four of the metal complexes have been established by single-crystal X-ray crystallography. Analysis of the structures revealed that in case of the ionophore with two $COCH_3$ substituents, the C–H···O interactions form an eight-membered zigzag ring almost perpendicular to the crown ring, which prevents entry of the metal ions into the calix-crown cavity. The ionophore with $CH_2CO_2C_2H_5$ substituents, where no such interaction is observed, forms metal complexes easily and exhibits the highest association constant. $^1H$ and $^{13}C$ NMR studies have also been carried out to investigate the conformational behaviour of these ionophores and their metal complexes in solution.

## Introduction

Calixarenes, which are macrocyclic oligomers made up of phenol units linked by a methylene bridge, are receiving increasing attention because of their ability to bind guest molecules or ions.[1] In the calixarene family, calix[4]arenes are most popular because of their rigid structures, which make them ideal candidates for the complexation of neutral molecules or ions.[1,2] This chemistry has become even more versatile because of the ease with which calix[4]arenes can be modified with functional groups at either the lower or upper rims, or both, depending on the requirements. These modified calixarenes provide a highly pre-organized architecture for the assembly of converging binding sites.[3] Among these calixarene derivatives, calix[4]arene-crown ethers have attracted intense interest as selective alkali metal extractants.[4] The ion selectivity of this class of compounds is controlled mainly by the conformation of the calixarene platform, the size of the crown ether ring, the substituents at the upper rim of the calixarene and the appended functional groups at the two sides of the crown ring. Among various conformations of the calixarene, 1,3-alternate conformers have been studied more extensively as complexing agent for alkali metal ions.[4b,4c,4f,5] Other conformers have also been prepared but metal ion complexation studies are rare.[4a,4d] Among various crown ether rings, crown-5- and crown-6-containing calixarene derivatives have been found to be more suitable for complexation with alkali metal ions.[4] A number of calix[4]-bis(crown ethers) and their complexation behaviour, mainly with cations of large size, have also been reported.[6]

It has been observed that the substituents at the lower rim determine the conformations of the calixarenes. Calix[4]arene-crown ether derivatives in 1,3-alternate conformation have been studied most since they are more efficient and selective in the complexation of potassium ions.[5] The ionophores *p-tert*-butylcalix[4]arene-crown derivatives, which have not been studied extensively, exist in cone, partial cone and 1,3-alternate conformations.[4a,4g,7] In the latter case, the desired conformation can be obtained by manipulating the experimental conditions and reagents.[4g,8] It should be noted that the selectivity and efficiency of extraction of alkali and alkaline-earth metal ions is maximal with

the cone conformation of *p-tert*-butylcalix[4]arene-crown derivatives, except for one report in which a partial cone conformation was reported to exhibit high $K^+/Na^+$ selectivity.[4a]

As part of our effort to identify suitable options for selective extraction of $K^+$ from natural sources such as brine and bittern, which mainly contain $Na^+$, $K^+$, $Ca^{2+}$ and $Mg^{2+}$,[9] we here report our studies on competitive binding of these ions with *p-tert*-butylcalix[4]arene-crown-5 derivatives in the cone conformation (Figure 1). The effect of appended substituents on complexation and the structural features of the ionophores before and after complexation in solution and the solid state, as probed by NMR spectroscopic and single-crystal X-ray studies, are reported. These studies have enabled us to unravel structural features of the ionophores and their complexes; in particular, the influence of intramolecular hydrogen bonding on complexation.

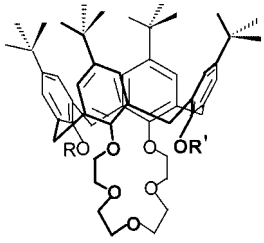

Figure 1. Structures of the ionophores (**1**–**5**) used in this study.

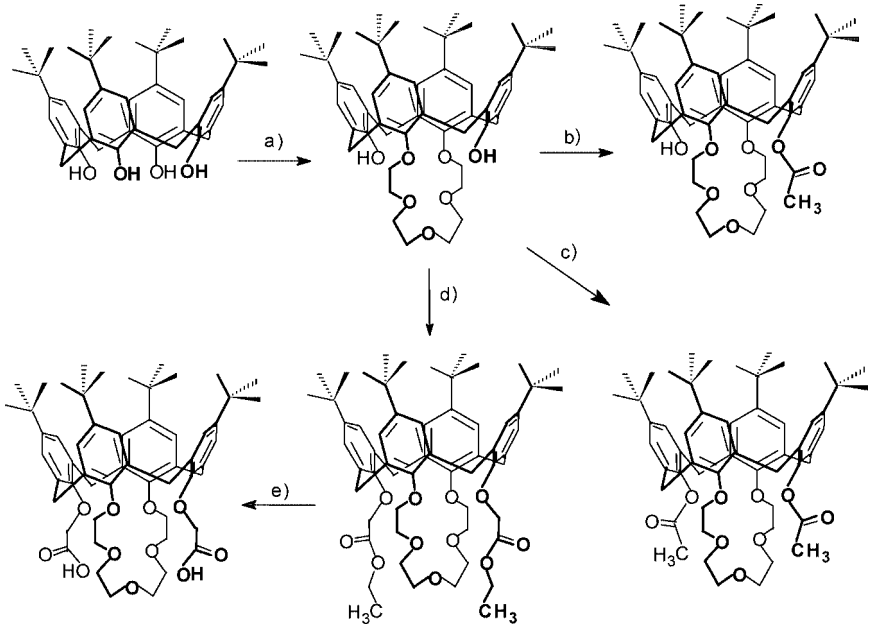
## Results and Discussion

### Synthesis of Ligands 1–5

The compound *p-tert*-butylcalix[4]arene-crown-5 (**1**) was synthesised by the reaction of *p-tert*-butylcalix[4]arene, tetraethylene glycol ditosylate and *t*BuOK (Scheme 1) according to a modified literature procedure.[4a] The conformation of the calix-crown products depends on the reaction conditions and reagents used; the cone conformation needed for the complexation study could be obtained in good yield. For the synthesis of acetyl derivatives of **1**, we attempted the reaction at room temperature with acetyl chloride and acetyl bromide, using NaH as base and diethyl ether as solvent. However, a mixture of mono- and diacetyl derivatives was obtained, with the former as the major product even after extended (3 d) stirring. We optimised the reaction conditions in diethyl ether to maximize the yield of the monoacetyl derivative, and compound **2** was obtained in cone conformation after purification by column chromatography. By switching the solvent from diethyl ether to THF and conducting the synthesis under reflux conditions, we were successful in obtaining the diacetyl derivative **3** in good yield. Compound **4** was obtained in cone conformation by the reaction of **1** with ethyl bromoacetate in the presence of $K_2CO_3$ under reflux in acetonitrile. Hydrolysis of **4** yielded the corresponding acid **5** in good yield. During preparation of this manuscript, a paper has appeared on the synthesis of **4** and **5** and use of the latter as a proton di-ionisable extractant for $Mg^{2+}$, $Ca^{2+}$, $Sr^{2+}$ and $Ba^{2+}$; however, this study is quite different from that reported here.[10]



Scheme 1. Synthesis of *p-tert*-butylcalix[4]arene-crown-5 compounds; a) $OTsCH_2(CH_2OCH_2)_2CH_2OTs$, *t*BuOK, benzene; b) $CH_3COBr$, NaH, diethyl ether; c) $CH_3COBr$, NaH, THF; d) $BrCH_2CO_2C_2H_5$, $K_2CO_3$, $CH_3CN$; e) NaOH, ethanol.

### Synthesis of $Na^+$ and $K^+$ Complexes of 1–5

Reaction of the ligands with a ten-fold excess of metal picrate in chloroform resulted in the formation of 1:1 metal complexes. In the case of **3**, however, the $Na^+$ complex (**3**·$Na^+Pic^-$, Pic = picrate) was only obtained in poor yield, and virtually no complex formation took place with $K^+$, as evident from the $^1H$ NMR spectrum. Hence, the $K^+$ complex of **3** is not discussed further.

All of these ligands and metal complexes gave satisfactory C, H, and N analyses. The mass spectra of all these ligands and metal complexes were recorded and the observed *m*/*z* values show excellent agreement with the calculated values. It may be noted that the *m*/*z* values (100%) of all ligands correspond to the $Na^+$ adduct [ligand + Na]$^+$, which is a well-known phenomenon in LC mass spectrometry. The potassium and sodium complexes of the ligands (complex formation was confirmed by NMR studies and X-ray structure determination; vide infra) exhibit molecular ion peaks corresponding to [ligand + K]$^+$ and [ligand + Na]$^+$, respectively.

### NMR Study

The $^1H$ and $^{13}C$ NMR spectra of all compounds were recorded in $CDCl_3$ and the data are presented in the Experimental Section. The NMR spectroscopic data established the conformation of the ligands and complexes in solution. The $^1H$ NMR spectra of these compounds exhibit two signals for the aromatic protons, two doublets for the bridging methylene groups of the calixarene unit and two singlets for the *tert*-butyl groups. In the case of **2** and its complexes, however, the spectra are more complex because of asymmetric substituents at the *p*-hydroxy positions of the opposite benzene rings (OH and $COCH_3$). In all of these ionophores and complexes, a typical AB pattern was observed for the methylene bridge (Ar$CH_2$Ar) protons, that is, two widely separated doublets at $\delta$ = 3.90–4.65 and 3.12–3.36 ppm ($J$ = 12–13.8 Hz), which suggests that these ionophores exist in a cone conformation in solution.[4a,11] The low-field doublet is due to the axial H atom and the high-field doublet is due to the equatorial H atom of the methylene bridge. The chemical shift difference ($\Delta\delta$) between $H_{axial}$ and $H_{equatorial}$ serves as a measure of the "flattening" of each phenyl unit.[1a,12] In general, $\Delta\delta$ = 0.9 ppm for a system in the regular cone conformation, and for a more "flattened" conformation the value of $\Delta\delta$ decreases. For compounds **1**–**5**, the $\Delta\delta$ values are 0.78, 0.89 (1.31 for another ring), 0.78, 1.48 and 1.10 ppm, respectively. These data indicate that the "flattening" of the phenyl rings is greater in **1** and **3** and lesser in **4** and **5** than that of the regular cone conformation.[4a] The reduced "flattening" in **4** and **5** is because of steric crowding caused by bulky substituents at the narrow lower rim of the calix[4]arene-crown moiety. The $\Delta\delta$ values for the metal complexes of **1**–**3** could not be calculated because of the overlapping of signals from the high-field doublet and crown moiety. However, for the complexes of **4** and **5** these values are in the range 1.07–1.12 ppm, thus indicating that the structures of the metal complexes in solution are close to a regular cone conformation. The difference between the two signals due to phenyl groups and also due to *tert*-butyl groups observed for the free ligand are significantly reduced ($\leq$0.1) in the complexed state. This is presumably because insertion of a metal ion into the crown cavity provides a similar geometrical shape of the complexed molecule. It should be noted that the two appended $CH_2CO_2C_2H_5$ groups of **4**·$Na^+Pic^-$ and **4**·$K^+Pic^-$ exhibit one set of signals [$\delta$ = 4.77 (s), 4.32 (q) and 1.33 (t) ppm for **4**·$Na^+Pic^-$ and $\delta$ = 4.57 (s), 4.32 (q) and 1.33 (t) ppm for 4·$K^+Pic^-$ (Figure 2)] thus indicating that both groups in each compound are chemically equivalent in solution. A similar observation was also noted for the complexes of **3** and **5**, in which two appended $COCH_3$ and $CH_2CO_2H$ groups are present, respectively. Interestingly, the crystal structures of **4**·$Na^+Pic^-$, **4**·$K^+Pic^-$ and **5**·$K^+Pic^-$ (see below) show that only one of the two appended groups in each complex is connected to a metal ion through its oxygen atom. Therefore, two sets of signals for two non-equivalent appended groups in each complex are expected. The appearance of only one set of signals suggests exchange of coordination between the appended groups and the metal ion in solution. This exchange process is fast enough on the NMR timescale to make them indistinguishable. Another unprecedented observation is noted for the signals for the phenyl and *tert*-butyl protons of the complexes of **1**. Ligand **1** shows two signals for the phenyl protons and two signals for the *tert*-butyl protons. However, in the complexes one of the signals (high-field) of the phenyl protons is found to split to produce two signals at $\delta$ = 6.73 (1 H) and 6.63 (3 H) ppm for **1**·$Na^+Pic^-$ and $\delta$ = 6.74 (1 H) and 6.61 (3 H) ppm for **1**·$K^+Pic^-$. The high-field signal for *tert*-butyl is also seen to split to produce signals at $\delta$ = 1.20 (3 H), 0.92 (3 H) and 0.83 (12 H) ppm for **1**·$Na^+Pic^-$ and $\delta$ = 1.20 (3 H), 0.93 (3 H) and 0.81 (12 H) ppm for **1**·$K^+Pic^-$. The possibility of the formation of other conformations can be ruled out on the basis of full NMR spectroscopic data. The crystal structure of **1**·$K^+Pic^-$ shows that the picrate anion is coordinated to the metal ion in a bidentate fashion through the oxygen atoms of the deprotonated phenolic group and one of the nitro groups. Beer et al. have noted similar observations in the lanthanide picrate complexes of their *tert*-butylcalix[4]arene diamide ligand.[13]

Analysis of the crystal structure of **1**·$K^+Pic^-$ shows that the benzene ring of the picrate anion is in proximity, and almost parallel to, one of the benzene rings of the calixarene ($C_g$–$C_g$ distance is 3.76 Å and the dihedral angle between the planes of the rings is 13.72°). The structural analysis shows that one of the phenyl protons and a few of the *tert*-butyl protons of one of the benzene rings of the calixarene are pointed towards the deshielding zone of the benzene ring of the picrate anion, which results in a splitting of the signals for the phenyl and *tert*-butyl protons.[14] Because of this deshielding effect, the signals of one of the phenyl protons and two methyl groups of the *tert*-butyl moiety are shifted downfield; the shift of one of the methyl groups is quite pronounced.

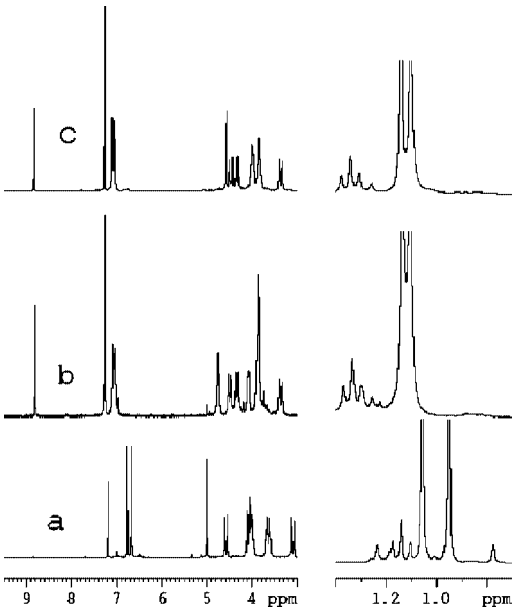

Figure 2. $^1$H NMR spectra of ionophore **4** (a), its $Na^+$ (**4**·$Na^+Pic^-$) (b) and $K^+$ complexes (**4**·$K^+Pic^-$) (c), recorded in $CDCl_3$ at room temperature.

In the $^{13}$C NMR spectra, the signals of the carbon atoms of the four methylene bridges (Ar$CH_2$Ar) appear at the same position (one peak), with a chemical shift of $\delta \approx$ 31 ppm, which is typical for the cone conformation of *tert*-butylcalix[4]arene derivatives.[4g,15] The other observation is that the C-1 and C-4 carbon atoms (see Figure 3 for the numbering scheme) show two signals each, which could be due to different substituents attached to the carbon atoms at the lower rim of the calixarene. In the metal complexes, the $^{13}$C NMR signals are consistent with the cone conformation of the calixarene moiety albeit with some changes in chemical shift for the carbon atoms of the crown moiety, due to complex formation, compared to the free ligand.

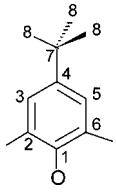

Figure 3. Numbering scheme for carbon atoms of the *p-tert*-butylcalix[4]arene used in the NMR discussion.

## Crystal Structures

X-ray crystal structures of four ionophores and four complexes have been determined; ORTEP views of the ionophores are displayed in Figure 4. The structures of the ionophores clearly show the flattened cone conformation, as suggested by the NMR spectroscopic data. However, the extent of flattening differs from ligand to ligand. The interplanar angles between the two opposite rings are 71.89° and 41.10° (82.67° and 35.60° for the other molecule in the unit cell) for **1**, 87.00° and 7.40° for **2**, 60.66° and 39.82° for **3** and 78.10° and 29.18° for **4**. The opposite benzene rings, which are connected to the crown moiety, are less flattened, as evident from their low inter-planar angles. The wide variations in flattening of the rings are due to steric overcrowding of the bulky substituents at the lower rim of the rings and also due to intramolecular C–H···O interactions. It should be noted that the oxygen atoms of the CO groups of the $COCH_3$ substituent in **2** and **3** and the $CH_2COOC_2H_5$ substituent of **4** are directed away from the polyether rings, which could be due to minimisation of the electrostatic repulsion between the lone pairs of the oxygen atoms of the CO and polyether rings. Most of the appended groups show hydrogen-bonding interactions with the oxygen atoms of the polyether rings. There are many examples of hydrogen-bonding interactions involving OH groups at the lower rim of the calixarene,[16] although hydrogen-bonding interactions involving other groups are not common. In case of **1**, the hydrogen atoms of the OH groups (O6–H6 and O7–H7) make strong O–H···O interactions with O5 and O1, which act as donors; O7, on the other hand, acts as an acceptor, making C–H···O interactions with H48A and H50B of the methylene groups of the polyether ring. The interesting feature of the packing is the dimeric association of the two ligands A and B present in the asymmetric unit. This occurs by an intermolecular C–H···O interaction involving H10K attached to C101 and the phenolic oxygen atom O6. Two such hydrogen-bonded dimers are further associated by a C–H···π interaction to form a tetrameric unit (Figure 5). Details of C–H···O, C–H···N, and C–H···π interactions of **1**–**3** and **4** are given in Table S1 in the Supporting Information. In the case of **2**, the hydrogen atom (H1) of the phenolic oxygen atom O1 is involved in a strong intramolecular O–H···O interaction with O4. Two of the methyl hydrogen atoms of the acetyl moiety (H46B and H46C) make intramolecular C–H···O interactions with O4 and O8 of the crown moiety. A packing diagram of **2** showing the one-dimensional array formed by intermolecular hydrogen-bonding interactions between adjacent molecules is depicted in Figure S1 (Supporting Information).

The intramolecular hydrogen-bonding pattern of **3** is interesting and provides important information regarding its robustness towards complexation with $K^+$. In this compound, it has been observed that the two H atoms of each methyl group of the two appended $COCH_3$ groups (H46B, H48C and H46C, H48B) are close to the oxygen atoms of the polyether ring and are held strongly by C–H···O interactions with O6 and O8 of the crown moiety (Table 1) In fact, this hydrogen bonding forms an eight-membered puckered ring, which is nearly perpendicular to the crown ring (79.33°) and crosses it through the middle (Figure 6). We believe this interaction also exists in solution and, therefore, metal ions such as $K^+$ cannot enter into the cavity to form metal complexes. The packing diagram of **3**, which shows a dimeric association of the molecule through intermolecular interactions involving surrounding lattice solvent molecules, is shown in Figure S2 (Supporting Information).

In the case of **4** the C–H···O interactions involving the crown ring are not significant. The only interaction observed is that between the hydrogen atoms (H49A) of the $CH_2COOC_2H_5$ moiety and O9 of the crown ring. However, the oxygen atoms of the CO groups of both $CH_2COOC_2H_5$ moieties form C–H···O interactions with the hydrogen atoms of the bridging methylene group. The packing diagram of **4** is also available as Supporting Information (Figure S3).

All of the above ligands contain lattice solvent molecule(s) and these appear to play a role in crystal formation. One of the acetonitrile molecules present in the crystal occupies the cone cavity of the calixarene unit in all cases. This acetonitrile molecule is held in the cavity and forms C–H···N interactions with the hydrogen atom of one of the bridging ethylene groups and C–H···π interactions with the benzene rings of the calixarene moiety.

The crystal structures of the metal complexes reveal that the $K^+$ ion is coordinated to eight oxygen atoms in all complexes whereas the $Na^+$ ion in **4**·$Na^+Pic^-$ is coordinated to six oxygen atoms (Figure 7). In **1**·$K^+Pic^-$, where eight coordination sites with oxygen atoms as donor are not available,

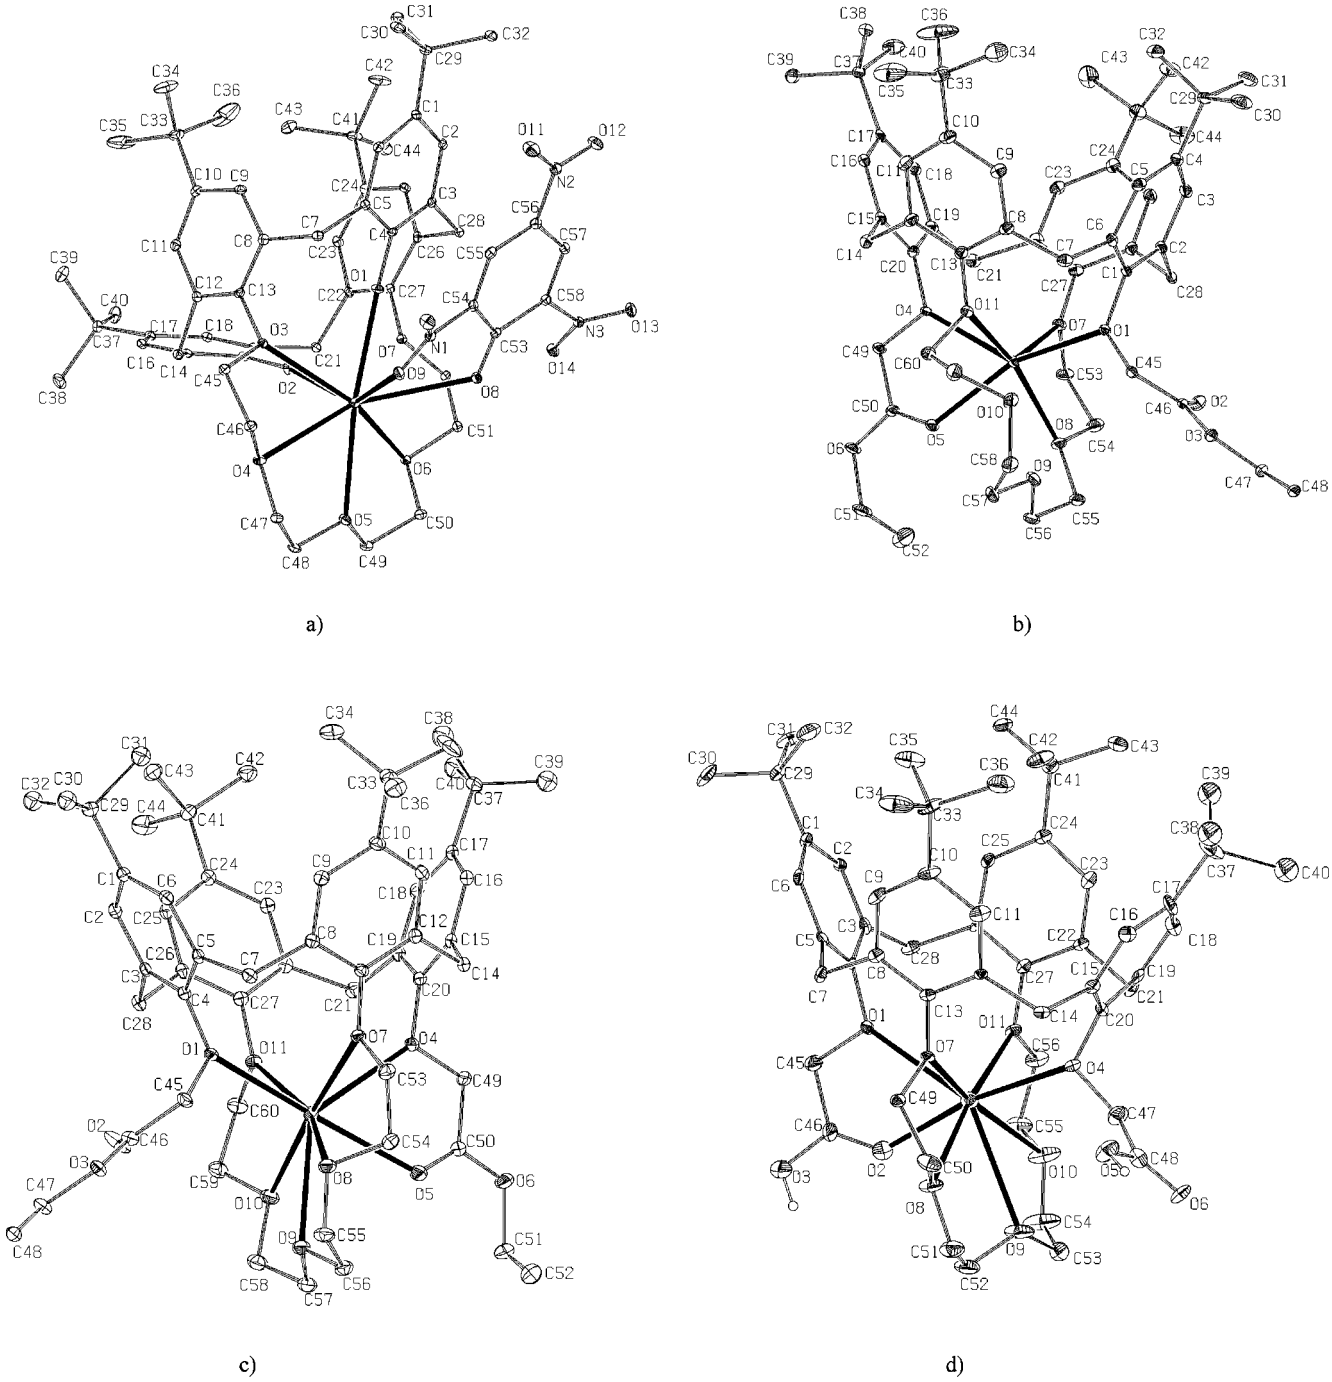

Figure 7. ORTEP views of complexes **1**·$K^+Pic^-$ (a), **4**·$Na^+Pic^-$ (b), **4**·$K^+Pic^-$ (c), and **5**·$K^+Pic^-$ (d).

the picrate anion acts as a bidentate ligand to make $K^+$ octacoordinate. For complexes **4**·$Na^+Pic^-$, **4**·$K^+Pic^-$ and **5**·$K^+Pic^-$, out of two $CH_2CO_2C_2H_5$ and $CH_2CO_2H$ appended arms, the oxygen atom of the CO group of one arm is coordinated to $K^+$. In the case of **4**·$Na^+Pic^-$, however, two oxygen atoms (O9 and O10) of the crown moiety are not coordinated to $Na^+$. The M–O distances of all complexes are given in Table 2. In the metal complexes, the cone conformations of the calixarene moieties are more symmetric than those of the corresponding free ligands. For example, all the four phenyl rings of **4**·$K^+Pic^-$ make similar angles of intersection with the plane of the four rim methylene groups (64.50–69.92°) and the inter-planar angles between the two opposite rings are 45.63° and 54.25°, which suggests an almost symmetric cone conformation of the calixarene unit.

Analysis of the crystal structures revealed that each of these structures make a number of intra- and intermolecular C–H···O interactions, leading to layered or zigzag chain network of packing. Packing diagrams (Figures S4–S7) and a table of hydrogen-bonding interactions (Table S2) for all these complexes are available as Supporting Information. Some of the solvent molecules and picrate anions are highly disordered, as discussed in the Experimental Section.

## Selectivity

The selectivities of these ionophores toward metal ions such as $Na^+$, $K^+$, $Mg^{2+}$ and $Ca^{2+}$ were determined by a two-phase extraction method followed by ion chromatographic assay of the metal ions in the extract.[9] The experiments were carried out with an aqueous solution containing equimolar amounts of $Na^+$, $K^+$, $Mg^{2+}$ and $Ca^{2+}$ as their picrate salts, as described in the Experimental Section. Chromatograms of the original solution and that of the extract obtained using **4** are given in Figure 8. The distributions of metal ions in the organic extracts, together with values of the observed selectivity ratios, are given in Table 3. As can be seen from the data, all ionophores except **3** show high selectivity towards $K^+$, this selectivity being highest for **4** (82.1%). From the crystal structures it appears that the calix-crown cavity fits well with $K^+$, allowing it to coordinate to all the oxygen donors of the cavity. $Na^+$ also coordinates, but it does not fit well in the cavity and leaves two oxygen atoms of the crown ring uncoordinated. $Mg^{2+}$ and $Ca^{2+}$ show poor selectivity.

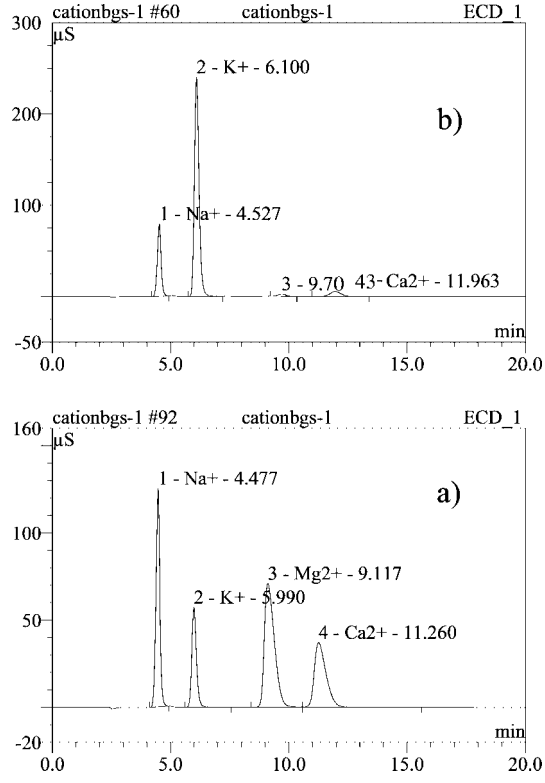

Figure 8. Ion chromatograms of a) a solution containing an equimolar mixture of $Na^+$, $K^+$, $Mg^{2+}$, and $Ca^{2+}$ and b) the extract obtained from the equimolar mixture by two-phase extraction using ionophore **4**.

Apart from cavity size, the C–H···O interactions involving oxygen atoms of the crown ring observed in some of these compounds play an important role in complex formation. In the ionophores **2**–**5**, the main coordination core (calix-crown moiety) for all of them is the same, with one of the appended arms taking part in coordination. However, the selectivity for a particular metal ion (e.g. $K^+$) differs significantly. The crystal structures show that in the case of **2**, one side of the crown ring is blocked by strong C–H···O interactions between two of the methyl protons of $COCH_3$ and the oxygen atoms of the crown rings. For **3**, both the sides are blocked (Figure 6), and in this case the effect is so severe that $K^+$ cannot enter into the cavity for complex formation. For **4**, however, the C–H···O interaction involving oxygen atoms of the crown ring is not significant and the metal ion can interact easily with the calix-

| **4** | 17.9 | 82.1 | –[c] | –[c] | 2.7 | – | – |
| **5** | 26.6 | 69.4 | 0.7 | 4.2 | 1.5 | 60.9 | 16.9 |

[a] Concentration [%] of metal ion in the original solution (before extract): $Na^+$ = 18.2, $K^+$ = 30.9, $Mg^{2+}$ = 19.9, $Ca^{2+}$ = 31.7. [b] Ratio calculated by [% of $K^+$ in the extract][% of $M^{n+}$ in the original solution]/[% of $M^{n+}$ in the extract][% of $K^+$ in the original solution]. [c] Trace amount.

crown moiety. This is consistent with the selectivity data and the association constants determined. It should be noted that apart from the appended arms, the remainder of all five ionophores is identical, therefore the observed variation in complex formation/selectivity is obviously due to the effect of the appended arms. Steric crowding is not a significant factor in this case as the ionophore with the most bulky appended arms (**4**) shows the highest selectivity. This suggests that the intramolecular hydrogen-bonding interactions involving the lower rim of the ionophore play an important role in complex formation with metal ions. The appended functional groups, which are expected to act cooperatively as an axial ligand to stabilise the complex, may not always work in this manner and could even inhibit complex formation.

### Association Constants

The association constants ($K_a$) of the ionophores **1**–**5** with $Na^+$ and $K^+$ picrates were determined spectrophotometrically, as described in the Experimental Section. Metal picrates in aqueous solution were extracted with chloroform both in the presence and absence of host. The amount of picrate ion in the chloroform layer was determined from its extinction coefficient at 380 nm after appropriate dilution in $CH_3CN$. The association constants were determined using Equation (1), where $K_a$ is the association constant, $K_d$ the distribution constant, $R$ the molar ratio of picrate to host in the organic layer, $[G_i]_{H_2O}$ the initial concentration of the guest (metal ion/picrate), $[H_i]_{CHCl_3}$ the initial concentration of the host (ionophore) in chloroform, $V_{CHCl_3}$ the volume of the organic layer (chloroform) and $V_{H_2O}$ the volume of the aqueous layer.[17]

$$K_a = \frac{R}{(1-R)K_d\{[G_i]_{H_2O} - [H_i]_{CHCl_3}(V_{CHCl_3}/V_{H_2O})\}^2} \quad (1)$$

The molar ratios of picrate to host ($R$) were determined from Equation (2), where $A$ is the observed absorbance in the aqueous phase, $D$ the dilution factor, $\varepsilon$ the extinction coefficient of the picrate salt at 380 nm in $CH_3CN$ ($\varepsilon$ = 16900), $[G_i^+]$ the initial concentration of guest in the aqueous phase, $V_{aq}$ the volume of the aqueous phase, $V_{org}$ the volume of the organic phase, and $[H_i^*]$ the initial concentration of the host in the $CHCl_3$ phase.[18]

$$R_{CHCl_3} = \frac{\{[G_i^+] - A(D/\varepsilon)\}(V_{aq}/V_{org})}{[H_i^*]} \quad (2)$$

The distribution constants were determined using Equation (3).[17]

$$K_d = \frac{[G^+X^-]_{CHCl_3}}{[G^+]_{H_2O}[X^-]_{H_2O}} \quad (3)$$

The values of association constants ($K_a$) and $R$ for all ionophores are given in Table 4. The data show that the values of $K_a$ for $K^+$ with various ionophores decrease in the order **4** > **5** > **1** > **2** >> **3**, which is consistent with the selectivity data and the C–H···O interactions observed in the crystal structures. For $Na^+$, the values of $K_a$ are approximately 10–100 times lower than those for $K^+$, in line with the selectivity data.

Table 4. Molar ratio of picrate/host in the organic layer ($R$) and association constants ($K_a$) with $Na^+$ and $K^+$.

| Ionophore | $R$ | | $K_a$ | |
|---|---|---|---|---|
| | $Na^+$ | $K^+$ | $Na^+$ | $K^+$ |
| **1** | 0.02 | 0.24 | $1.06\times10^4$ | $1.82\times10^6$ |
| **2** | 0.02 | 0.08 | $8.70\times10^4$ | $3.25\times10^5$ |
| **3** | 0.01 | – | $5.17\times10^4$ | – |
| **4** | 0.26 | 0.68 | $3.12\times10^6$ | $7.20\times10^7$ |
| **5** | 0.34 | 0.66 | $5.96\times10^6$ | $5.80\times10^7$ |

## Conclusions

A series of *p*-*tert*-butylcalix[4]arene-crown ethers with various substituents attached to the opposite phenolic oxygen atoms have been synthesised in the cone conformation to evaluate their performance as ionophores towards $Na^+$, $K^+$, $Mg^{2+}$ and $Ca^{2+}$. NMR and crystal structure studies suggest that these ionophores exist in a "flattened" cone conformation both in solution and the solid state. $Na^+$ and $K^+$ complexes of these ionophores have been synthesised and the crystal structures show that, in all cases, one of the two appended substituents coordinates to the metal ion and the size of the calix-crown cavity is most suited to $K^+$ among the ions studied. The $^1H$ NMR study also revealed that there is fast exchange of coordination between the two appended groups and the metal ion in solution. The selectivity study with a mixture of cations showed the highest

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

selectivity towards $K^+$; the association constants also follow the same order. The one exception is compound **3**, where access to the metal ion is blocked as a result of strong C–H···O interactions between the pendant $COCH_3$ substituents and the crown moiety. Such deleterious interactions are apparently nonexistent in the case of the $CH_2CO_2C_2H_5$ substituents as the ligand interacts strongly with the metal ions. Evidently, although appended functional groups (like "lariat" crown ethers) are known to act as a stabilizing axial ligand, these may, in fact, act in the opposite way if strong intramolecular hydrogen bond involving the crown ring is operational. The X-ray structure determination of the ionophores therefore provides an insight into the effect of intramolecular interactions on the structure–selectivity correlation.

## Experimental Section

**Reagents and Methods:** The ligand *p-tert*-butylcalix[4]arene was synthesised according to a literature procedure.[19] Metal picrate salts were prepared by the reaction of picric acid and the metal hydroxide in aqueous media. All the reagents used in this study were purchased from Aldrich and S. D. Fine Chemicals. All solvents were of analytical grade and purified by standard procedures before use.[20] Milli-Q (Millipore Corporation) water was used for extraction and ion chromatographic study. Elemental analyses (C and H) were performed with a model 2400 Perkin–Elmer elemental analyzer. NMR spectra were recorded with a model DPX 200 Bruker FT-NMR instrument. Infrared spectra were recorded with a Perkin–Elmer Spectrum GX FT-IR system. Mass spectra were recorded with a Q-TOF Micro™ LC-MS instrument. The UV/Vis spectra were recorded with a model 8452A Hewlett–Packard diode array spectrophotometer. Cation concentration was measured with a Dionex 500 ion chromatograph. Single crystal structures were determined using a Bruker SMART 1000 (CCD) diffractometer.

**Synthesis of 1:** A mixture of *p-tert*-butylcalix[4]arene (1.46 g, 2.25 mmol) and *t*BuOK (0.23 g, 2 mmol) in 150 mL of dry benzene was refluxed under an inert gas with stirring for 1.5 h, then tetraethylene glycol ditosylate (1.06 g, 2 mmol) was added. After refluxing for 24 h, a second portion of *t*BuOK (0.23 g, 2 mmol) was added, and the reaction mixture was refluxed for an additional 24 h. It was then cooled to room temperature, treated with 1 N HCl (125 mL), and extracted five or six times with 30 mL of diethyl ether each time. The combined organic layers were finally washed three times with water (100 mL each time) and the solvent was removed by rotary evaporation. The crude product was purified by column chromatography using silica gel as packing material and dichloromethane/ethyl acetate (4:1) as eluent. Yield: 0.75 g (43%). $^1$H and $^{13}$C NMR spectroscopic data are similar to those reported earlier.[4a,10] LC-MS: *m*/*z* = 829.51 (calcd. for [**1** + $Na^+$] 829.50). $C_{52}H_{71}O_{7.5}$ (**1**·0.5$H_2O$, 815.50): calcd. C 76.59, H 8.78; found C 76.48, H, 8.69.

**Synthesis of 2:** Compound **1** (0.27 g, 0.3 mmol), NaH (0.04 g, 1.75 mmol), and acetyl bromide (0.4 mL, 5.4 mmol) were dissolved in 70 mL of diethyl ether and the mixture was stirred at room temperature under an inert gas for 3 d. After removing the solvent with a rotary evaporator, the solid mass was treated with 10% HCl (50 mL) and extracted with dichloromethane (50 mL). The organic layer was washed twice with water (50 mL each time) and the solvent was removed by rotary evaporation. The product was purified by column chromatography using silica gel as packing material and ethyl acetate/hexane (1:5) as eluent. Initially, some starting materials were separated and then the desired product was eluted. The solvent was removed from the desired fraction and the solid compound was dried in vacuo. Yield: 0.11 g (39%). $^1$H NMR (200 MHz, [$D_3$]chloroform): $\delta$ = 7.20 (s, 2 H, ArH), 7.08 (s, 2 H, ArH), 6.79 (s, 1 H, OH), 6.64 (d, *J* = 2.4 Hz, 2 H, ArH), 6.59 (d, *J* = 2.4 Hz, 2 H, ArH), 4.55 (d, *J* = 13.0 Hz, 2 H, Ar*CH*$_2$Ar), 4.13 (d, *J* = 12.8 Hz, 2 H, Ar*CH*$_2$Ar), 4.07–3.46 (m, 16 H, crown-*CH*$_2$), 3.24 (dd, $J_1$ = 13.1, $J_2$ = 3.6 Hz, 4 H, Ar*CH*$_2$Ar), 2.90 (s, 3 H, O*CH*$_3$), 1.35 (s, 9 H, *t*Bu), 1.34 (s, 9 H, *t*Bu), 0.83 (s, 18 H, *t*Bu) ppm. $^{13}$C NMR: $\delta$ = 171.18 (*CO*$CH_3$), 151.45, 151.25, 150.44 (C-1), 147.43, 146.24 (C-4), 135.71, 135.44, 133.11, 132.01, 131.96 (C-2, C-6), 128.47, 126.05, 125.58, 125.36, 125.33, (C-3, C-5), 74.98, 72.39, 71.69, 71.52, 70.99, 70.38, (O*CH*$_2$*CH*$_2$O*CH*$_2$*CH*$_2$O), 32.49, 32.29, (C-7), 32.40, 31.62 (C-8), 31.97 (Ar*CH*$_2$Ar), 22.10 (CO*CH*$_3$) ppm. LC-MS: *m*/*z* = 871.7 (calcd. for [**2** + $Na^+$]: 871.53). $C_{54}H_{73}O_{8.5}$ (**2**·0.5$H_2O$, 857.53): calcd. C 75.63, H 8.58; found C 75.64, H 8.55.

**Synthesis of 3:** NaH (0.02 g, 0.8 mmol) was added to a solution of **1** (0.20 g, 0.25 mmol) in THF (70 mL) and the reaction mixture was refluxed. After 30 min of reflux, a solution (10 mL) of acetyl bromide (0.5 mL, 7.0 mmol) in THF was added dropwise to the reaction mixture and refluxing was continued. After 6 h, the solution was cooled to room temperature, filtered and the solvent of the filtrate was removed by rotary evaporation. The residue was treated with 2 N HCl (50 mL), the mixture filtered and the solid mass washed twice with water (25 mL each time). The product thus obtained was recrystallised from dichloromethane/acetonitrile. Yield: 0.16 g (81%). $^1$H NMR (200 MHz, [$D_3$]chloroform): $\delta$ = 7.06 (s, 4 H, ArH), 6.48 (s, 4 H, ArH), 4.28–4.06 (m, 8 H, crown-*CH*$_2$), 3.90 (d, *J* = 12.8 Hz, 4 H, Ar*CH*$_2$Ar), 3.77–3.61 (m, 8 H, crown-*CH*$_2$), 3.12 (d, *J* = 12.8 Hz, 4 H, Ar*CH*$_2$Ar), 2.56 (s, 6 H, O*CH*$_3$), 1.25 (s, 18 H, *t*Bu), 0.78 (s, 18 H, *t*Bu) ppm. $^{13}$C NMR: $\delta$ = 171.39 (*CO*$CH_3$), 154.95, 152.44 (C-1), 146.66, 145.43 (C-4), 135.53 (C-2), 132.16 (C-6), 126.68, 125.51 (C-3, C-5), 74.02, 73.62, 71.89, 71.57 (O*CH*$_2$*CH*$_2$O*CH*$_2$*CH*$_2$O), 32.42, 31.82, 31.74 (C-7, C-8), 32.04 (Ar*CH*$_2$Ar), 22.25 (CO*CH*$_3$) ppm. LC-MS: *m*/*z* = 913.53 (calcd. for [**3** + $Na^+$]: 913.52). $C_{56}H_{76}O_{10}$ (**3**·$H_2O$, 908.52): calcd. C 74.03, H 8.43; found C 74.12, H, 8.07.

**Synthesis of 4:** A mixture of **1** (0.20 g, 0.25 mmol) and $K_2CO_3$ (0.08 g, 0.53 mmol) in 70 mL of acetonitrile was refluxed with stirring for 3 h, then ethyl bromoacetate (0.09 g, 0.53 mmol) was added dropwise and refluxing was continued for 24 h. The reaction mixture was then cooled to room temperature, treated with 5% HCl (50 mL) and extracted with 50 mL of dichloromethane. The organic layer thus obtained was washed twice with water (50 mL in each time) and the solvent was removed by rotary evaporation. The crude product was recrystallised from dichloromethane/acetonitrile. Yield: 0.18 g (71%). $^1$H NMR (200 MHz, [$D_3$]chloroform): $\delta$ = 6.84 (s, 4 H, ArH), 6.74 (s, 4 H, ArH), 5.07 (s, 4 H, O*CH*$_2$CO), 4.65 (d, *J* = 12.6 Hz; 4 H, Ar*CH*$_2$Ar), 4.20–4.05 (m, 8 H, crown-*CH*$_2$), 3.76–3.66 (m, 8 H, crown-*CH*$_2$), 3.17 (d, *J* = 12.6 Hz, 4 H, Ar*CH*$_2$Ar), 1.21 (t, *J* = 6.8 Hz, 6 H, $CH_3$), 1.13 (s, 18 H, *t*Bu), 1.01 (s, 18 H, *t*Bu) ppm. $^{13}$C NMR: $\delta$ = 171.53 (OCH$_2$*CO*OCH$_2$CH$_3$) 153.98, 152.79 (C-1), 145.28, 145.13 (C-4), 134.67 (C-2), 134.09 (C-6), 125.46 (C-3, C-5), 73.40, 71.81, 71.49, 71.18, (O*CH*$_2$*CH*$_2$O*CH*$_2$-*CH*$_2$O), 70.98 (O*CH*$_2$COOCH$_2$CH$_3$), 60.69 (OCH$_2$COO*CH*$_2$CH$_3$), 34.37, 34.25 (C-7), 32.68 (Ar*CH*$_2$Ar), 32.18, 31.83 (C-8), 14.82 (OCH$_2$COOCH$_2$*CH*$_3$) ppm. **Synthesis of 5:** An aqueous solution (0.25 mL) of NaOH (15%) was added to an ethanolic solution (70 mL) of **4** (0.10 g, 0.1 mmol) and the reaction mixture was heated under reflux. After 24 h, it was cooled to room temperature and the solvent was removed by rotary evaporation. Then, 50 mL of cold water was added to the solid mass and 30% HCl was added dropwise with vigorous stirring until the pH of the solution reached 1. The solid product thus produced was isolated by filtration. The crude product was then dissolved in chloroform (50 mL) and washed with HCl (30%) followed by concentrated brine. The organic layer was separated, the solvent removed, and the product dried in vacuo. Yield: 0.065 g (70%). $^1$H NMR (200 MHz, [D$_3$]chloroform): $\delta$ = 7.12 (s, 4 H, ArH), 6.60 (s, 4 H, ArH), 5.29 (s, 4 H, O*CH$_2$*CO), 4.37 (d, *J* = 12.0 Hz, 4 H, Ar*CH$_2$*Ar), 4.08–3.85 (m, 16 H, crown-CH$_2$), 3.27 (d, *J* = 12.0 Hz, 4 H, Ar*CH$_2$*Ar), 1.33 (s, 18 H, *t*Bu), 0.83 (s, 18 H, *t*Bu) ppm. $^{13}$C NMR: $\delta$ = 172.99 (OCH$_2$*CO*OH), 153.69, 152.18 (C-1), 146.69, 146.19 (C-4), 135.49 (C-2), 132.89 (C-6), 126.39, 126.19 (C-3, C-5), 74.09, 71.13, 71.07, 70.99 (O*CH$_2$CH$_2$*O*CH$_2$CH$_2$*O), 70.44 (O*CH$_2$*-COOH), 34.89, 34.39 (C-7), 32.89 (Ar*CH$_2$*Ar), 32.39, 31.99 (C-8) ppm. LC-MS: *m*/*z* = 945.52 (calcd. for [**5** + Na$^+$]: 945.51). $C_{56}H_{80}O_{14}$ (**5**·3H$_2$O, 976.51): calcd. C 68.87, H 8.26; found C 69.14, H, 8.32.

**General Procedure for the Synthesis of Na$^+$ and K$^+$ Complexes of 1–5:** A mixture of 0.05 mmol of the required ionophore (**1**–**5**) and Na$^+$/K$^+$ picrate (0.5 mmol, ten-fold excess) was stirred in chloroform at room temperature for 24 h. The reaction mixture was then filtered to remove unreacted picrate salt and the complex was obtained by removing the solvent from the filtrate by rotary evaporation. The yellow complex thus obtained was dissolved in a minimum amount (ca. 3 mL) of dichloromethane (in which Na$^+$/K$^+$ picrate is almost insoluble) and filtered to remove trace quantities of unreacted Na$^+$/K$^+$ picrate. The solvent was then removed from the filtrate and the yellow product was dried in vacuo. The $^1$H NMR spectra of the product did not show any signal corresponding to free ligand or excess picrate anion. Yield: 90–95%.

**Sodium Complex of 1 (1·Na$^+$Pic$^-$):** $^1$H NMR (200 MHz, [D$_3$]chloroform): $\delta$ = 8.69 (s, 2 H, picrate), 7.03 (s, 2 H, OH), 7.03 (s, 4 H, ArH), 6.73 (s, 1 H, ArH), 6.63 (s, 3 H, ArH), 4.22–4.16 (m, 12 H, Ar*CH$_2$*Ar and crown-*CH$_2$* overlapped), 3.98–3.80 (m, 8 H, crown-*CH$_2$*), 3.30 (d, *J* = 13.6 Hz, 4 H, Ar*CH$_2$*Ar), 1.29 (s, 18 H, *t*Bu), 1.20 (s, 3 H, *t*Bu), 0.92, 0.83 (s, 15 H, *t*Bu) ppm. $^{13}$C NMR: $\delta$ = 150.15, 148.15 (C-1), 143.27, 142.18 (C-4), 132.61 (C-2), 128.62 (C-6), 127.50 (C-3), 126.35 (C-5), 125.99 (picrate), 75.84, 71.27, 70.24 (O*CH$_2$CH$_2$*O*CH$_2$CH$_2$*O), 34.59 (C-7), 32.40, 32.24, 31.60 (C-8), 31.93 (Ar*CH$_2$*Ar) ppm. **Determination of Selectivity of the Ionophores:** The selectivity of the ionophores towards $Na^+$, $K^+$, $Mg^{2+}$, and $Ca^{2+}$ was determined using an equimolar mixture of the picrate salts of these ions according to a procedure described in the literature.[9] In a typical procedure, equal volumes (15 mL) of an aqueous solution of an equimolar mixture of picrate salts ($Na^+$, $K^+$, $Mg^{2+}$, $Ca^{2+}$; 0.005 M each) and a $CH_2Cl_2$ solution (15 mL) of the required ionophore (0.005 M) were mixed and vigorously shaken in a vortex mixer for 15 min. The solution was then transferred to a separating funnel and allowed to stand for 4–5 h. The dichloromethane layer was then separated and transferred to a crucible, stripped of solvent by gentle heating in a water bath, and then heated in a furnace at 550 °C for 4–5 h. The residue was dissolved in deionized water (ca. 5 mL) and filtered through 0.2-μm filter paper. The relative concentrations of the cations in the filtrate were determined by ion chromatography on an Ion Pac CS12 (2 mm) analytical column and 20 mM methylsulfonic acid as eluent with a flow rate of 0.25 mL min$^{-1}$. Quantification was made using a standard solution containing a mixture of NaCl, KCl, $MgCl_2$, and $CaCl_2$ (15 ppm each). A blank experiment, without added ionophore, was carried out under similar experimental conditions; no detectable amount of picrate was observed in the dichloromethane layer.

**Determination of Association Constants ($K_a$) with $Na^+$ and $K^+$ Picrate:** Association constants of the ionophores **1**–**5** with $Na^+$ and $K^+$ were determined according to a published procedure using picrate as anion.[17,18] This involves two-phase (water/chloroform) extraction of the metal complex followed by determination of the ratios of picrate to host ($R$) in the organic phase and determination of the distribution constants ($K_d$) of the picrate salts between water and chloroform [Equations (1)–(3)].

**Determination of Molar Ratio of Picrate/Host in the Organic Layer ($R$):** Aqueous solutions were prepared that were 0.01 M in the picrate of $Na^+$ and $K^+$. Into each of two 10-mL centrifuge tubes was transferred 1 mL of the appropriate picrate solution with a syringe; 1-mL aliquots of a previously prepared chloroform solution that was 0.01 M in host were then added with a syringe to each tube. The tube was covered immediately with a rubber septum to prevent evaporation and the two layers in each tube were mixed thoroughly with a Vortex Genie mixer for 5 min. The tubes were then placed in a centrifuge for 15 min. Aliquots of 0.5 mL of the organic phase were carefully removed from each phase with a syringe and transferred to a 10-mL volumetric flask, which was brought to the mark with acetonitrile. The absorbance of each sample was then determined ($\lambda$ = 380 nm) after appropriate dilution (to make absorbance within measuring limit). The molar ratio of picrate/host ($R$) was then calculated from Equation (2).

**Determination of Distribution Constants ($K_d$) of Picrate Anion:** A 0.02 M metal picrate solution in 100 mL of water was added to 100 mL of chloroform and the mixture was shaken in a separating funnel for 5–6 h. The layers of the mixture were then allowed to separate overnight (ca. 12 h). The lower layer (chloroform) was then carefully transferred into a round-bottomed flask and the solvent evaporated with a rotary evaporator. The residue was quantitatively transferred with acetonitrile to a 10-mL volumetric flask and diluted with acetonitrile up to the mark. The absorbance of the organic layer was measured spectrophotometrically and the value of $K_d$ was determined from Equation (3).

**X-ray Crystallography for 1–4, 1·$K^+Pic^-$, 4·$Na^+Pic^-$, 4·$K^+Pic^-$ and 5·$K^+Pic^-$:** Crystal data collection and refinement parameters for all eight compounds are given in Table 5. A suitable crystal of each compound was selected, coated with Paratone oil and mounted with epoxy cement on the tip of a fine glass fibre. Data sets were obtained with a Bruker Smart APEX diffractometer with a CCD area detector using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at liquid nitrogen temperature (100 K). Data frames were processed using the Bruker SAINT program.[21] Intensities were corrected for Lorentz, polarisation, decay effects and an absorption correction was applied using SADABS.[22] The structure was solved by direct methods using SHELXS-97[23] and refined on $F^2$ using SHELXL-97.[24] The non-hydrogen atoms were located directly by successive Fourier calculations and were refined anisotropically in all the solvated ligand structures except for **2**. In **2**, three of the *tert*-butyl groups attached to the phenyl rings were found to be disordered over two positions (with occupancy factor 0.50) and these disordered *tert*-butyl groups were refined only isotropically. In the case of **1**·$K^+Pic^-$, the lattice THF molecule is disordered extensively, and in the case of **4**·$K^+Pic^-$ two of the *tert*-butyl groups, the lattice solvent molecules (benzene and THF) and the nitrate groups of the picrate anions showed dynamic disorder; all these disordered atoms were refined isotropically. Since it was very difficult to determine the dynamic disorder present in both the *tert*-butyl groups and lattice solvent molecules, these disorders were taken care of by assigning a tentative occupancy factor for the reasonably good peaks appearing in the difference Fourier map depending upon their peak heights. Anisotropic full-matrix refinement of all atoms, except the disordered atoms, was carried out using SHELXL-97 until convergence was reached (no significant peaks in the difference Fourier map). The inclusion of all the disordered atoms with the occupancy factor tentatively assigned, depending upon the peak height, significantly reduced the refinement parameters, thus implying the correct treatment of the disorder; a constrained or rigid model refinement was not possible in this case. In the case of **4**·$Na^+Pic^-$, it was not possible to locate the picrate anions and severely disordered solvents (THF and toluene from which crystals for X-ray study were grown) present in the lattice from the difference Fourier map. A suitable disorder model was not obtained and the picrate anion and solvent contribution was subtracted from the reflection data using the program SQUEEZE.[25] A combination of SQUEEZE and PLATON was applied to resolve severely disordered molecules of solvents (THF and toluene) within the asymmetric unit, which also contains one

crystallographically independent picrate anion. Within the 3460 Å$^3$ void space occupied by solvent molecules and the unresolved anion, a total of 810 electrons were calculated per unit cell. After correction for the one unresolved counteranion per asymmetric unit, corresponding to 115 electrons, the rest of the electron density per asymmetric unit (87.6) can be equated for by the presence of approximately one molecule of THF and one molecule of toluene in the asymmetric unit. A refinement using reflections modified by the SQUEEZE procedure behaved well, and the geometry of **4**·$Na^+Pic^-$ and, of course, the *R* factors and GOF values were significantly improved. H atoms (except for the H atoms attached to the disordered non-hydrogen atoms and some of the lattice solvent hydrogen atoms) were calculated on the basis of geometric criteria and were treated with a riding model in subsequent refinements using the SHELXL default parameters. The molecular graphics of the crystal structures were generated using ORTEP, PLATON and Mercury.[26–28] CCDC-297554 to -297561 (for complexes **1**–**4**, **1**·$K^+Pic^-$, **4**·$Na^+Pic^-$, **4**·$K^+Pic^-$, and **5**·$K^+Pic^-$, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information Available** (see footnote on the first page of this article): Tables S1 and S2 contain hydrogen-bonding parameters of the ionophores and metal complexes, respectively. Figures S1–S7 show packing diagrams of **2**–**4**, **1**·$K^+Pic^-$, **4**·$Na^+Pic^-$, **4**·$K^+Pic^-$, and **5**·$K^+Pic^-$, respectively.

# Encouraging Chromium(III) Ions to Form Larger Clusters: Syntheses, Structures, Magnetic Properties and Theoretical Studies of Di- and Octametallic Cr Clusters

**Caytie E. Talbot-Eeckelaers,[a] Gopalan Rajaraman,[a] Joan Cano,*[b,c,d] Guillem Aromí,[b] Eliseo Ruiz,[b,c] and Euan K. Brechin*[a,e]**

**Keywords:** Exchange coupling / Density functional theory / Polynuclear chromium complexes / Magnetic properties / Magneto-structural correlation

Reaction of anhydrous $CrCl_2$ with the tripodal ligands 1,1,1-tris(hydroxymethyl)ethane ($H_3$thme), 1,1,1-tris(hydroxymethyl)propane ($H_3$tmp) and pentaerythritol ($H_4$peol) produces three new $Cr^{III}$ clusters that have been structurally and magnetically characterised. The dimeric complex $[Cr_2(H_2tmp)_2Cl_4]\cdot 2MeOH$ (**1**·2MeOH) is generated under reflux. An analogous reaction, but under solvothermal conditions produces the octametallic species $[Cr_8O_2(thme)_2(Hthme)_4Cl_6]\cdot 2MeOH$ (**2**·2MeOH) and $[Cr_8O_2(Hpeol)_2(H_2peol)_4Cl_6]\cdot 3MeOH$ (**3**·3MeOH). Complex **1** is a simple dimeric species whereas the structures of **2** and **3** are based on the decametallate $\{M_{10}O_{28}\}^{26-}$ ion. Variable-temperature direct-current (dc) magnetic susceptibility data were collected for complexes **1** and **2** in the 1.8–300 K temperature range in fields up to 5.0 T. Complex **1** has a ground state of S = 0 with the best-fit parameters $J = -12.30 \pm 0.04$ cm$^{-1}$ and $g = 1.990 \pm 0.003$. Electronic structure calculations based on density functional theory (DFT) on **1** and **2** have been carried out and good agreement with the experimental data was found for **1**. For **2**, the theoretical results have been used as starting point to fit the $J$ values to the experimental data, revealing the presence of competing antiferromagnetic ($J_{4,7} = -39.0$ cm$^{-1}$; $J_{3,7} = J_{4,6} = +1.1$ cm$^{-1}$, $J_{4,5} = J_{3,4} = -20.0$ cm$^{-1}$, $J_{3,6} = -16.0$ cm$^{-1}$ and $J_{1,3} = J_{1,6} = J_{1,4} = J_{1,7} = -4.8$ cm$^{-1}$) exchange interactions between the $Cr^{III}$ centres that suggests a singlet ground state with very close S = 1, 2, 3 and 4 excited states. Magneto-structural correlations developed on a model complex based on **1** show a strong dependence of $J$ with Cr–O–Cr angle. A similar magneto-structural correlation is found for the $J$ values obtained by theoretical calculations on **2**.

## Introduction

Polymetallic clusters of chromium remain relatively rare, and in terms of nuclearity, relatively small. Whereas clusters of Mn, Fe, Ni, Co and Cu have, in some cases, contained more than eighty metal centres, the largest known $Cr^{III}$ clusters contain only twelve metal ions.[1–20] The kinetically inert nature of the $Cr^{III}$ ion usually requires reactions to be carried out at high temperatures, and the most successful synthetic routes have involved either the direct heating of the basic Cr carboxylates $[Cr_3O(O_2CR)_6(H_2O)_3]^+$ or the heating of the $Cr^{III}$ salt in the presence of a carboxylic acid. For example, the use of a combination of $CrF_3$ and pivalic acid leads to a family of clusters based on wheels,[1] as does the solvothermal heating of $[Cr_3O(O_2CR)_6(H_2O)_3]^+$ in alcohol.[2] An interesting aspect of this chemistry is that homometallic Cr clusters all contain bridging carboxylates, the majority have topologies that are based on either cubes or wheels, and most are characterised by S = 0 spin ground states. The exceptions to this are a $Cr_{12}$ centred-pentacapped trigonal prism with S = 6,[3] a ferromagnetic $Cr_{10}$ wheel,[2] and a tetrametallic cluster with S = 6.[4]

Theoretical calculations based on density functional theory of magnetic exchange coupling constants ($J$) in binuclear and polynuclear transition-metal complexes have gained much attention recently because these methods have proven to give good numerical estimates of $J$ values as well as providing insight into the electronic structure of the molecule of interest.[11,21–40] For polynuclear transition-metal complexes, the best way to experimentally obtain a good set of $J$ values (or other spin Hamiltonian parameters such as zero-field splitting) is Inelastic Neutron Scattering (INS) or Frequency Domain Magnetic Resonance Spec-

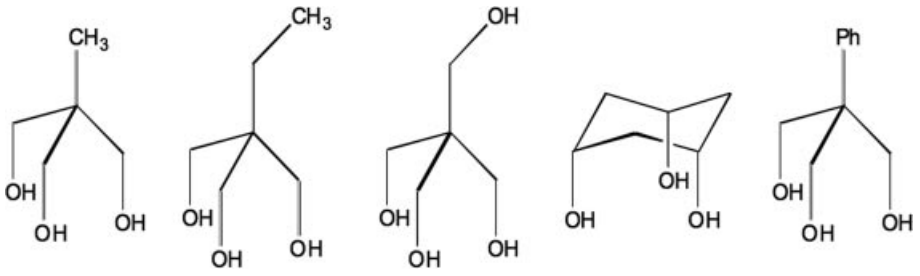

Scheme 1.

troscopy (FDMRS).[5–7] INS allows the direct spectroscopic determination (in zero-applied field) of such parameters, but unfortunately these measurements are somewhat uncommon because of restrictive sample requirements.[5] These constants can also be evaluated from magnetic susceptibility (fitting of $\chi_M$ or $\chi_M T$ vs. $T$ curves), heat capacity or EPR measurements, but the obtained values are only correct if certain requirements are fulfilled, namely: (i) as well as in the INS experiments, the choice of an accurate spin Hamiltonian that properly describes the magnetic properties of the system; (ii) the presence of critical points in the experimental curves that allow for a better assessment of the variable parameters in the fitting; and (iii) avoidance of over-parameterisation, i.e. using too many parameters ($J$ constants) in the spin Hamiltonian. In this latter case, obtaining a set of $J$ values from theoretical calculations as a starting point for the fitting procedure is a very useful alternative.

We have been using the tripodal ligand 1,1,1-tris(hydroxymethyl)ethane ($H_3$thme, Scheme 1) and its analogues in the synthesis of Mn, Fe, Ni and Co clusters[8] and herein report our first attempts to make polymetallic $Cr^{III}$ clusters including a novel dinuclear cluster and a related octametallic $Cr^{III}$ cluster whose structure is based on the decametallate $\{M_{10}O_{28}\}^{26-}$ ion. Both complexes are formed from similar reaction schemes, but the dimeric cluster is isolated under reflux and the octametallic species isolated under solvothermal conditions. In order to elucidate the magnetic properties of these compounds, we have also studied their electronic structure. The relevant exchange coupling constants have been calculated and several magneto-structural correlations have been found and interpreted according to the Cr–O–Cr angle for different families displaying several bridging ligands (oxo, alkoxo).

## Results and Discussion

### Synthesis

When $CrCl_2$, $H_3$tmp and NaOMe are stirred in MeOH at room temperature no isolable products are obtained, even if the solvent is evaporated and the resultant solid extracted into a variety of solvents. When the reaction is repeated, but under reflux, the dimeric species **1** is obtained when the original MeOH solution is stripped off and the resultant solid redissolved in MeCN. No isolable product is obtained from the initial MeOH solution or from any other solvents, or when the reaction is repeated with the tripodal ligands $H_3$thme or $H_4$peol. Superheating a methanolic solution containing equivalent amounts of $CrCl_2$, $H_3$thme or $H_4$peol and NaOMe in a sealed high-pressure vessel at 100 °C for 12 h followed by slow cooling to room temperature generates crystals of compounds **2** and **3**, respectively, directly from the reaction mixture in high yield. It is likely that the $Cr^{II}$ ions are oxidised almost immediately upon dissolution, but the analogous reactions – under both refluxing and solvothermal conditions – using $Cr^{III}$ halides failed to yield any isolable products.

### Structure Description

Complex **1** (Figure 1) crystallises in the monoclinic space group $P2_1/c$. Selected bond lengths and angles are given in Table 1. The structure consists of two $Cr^{III}$ ions related by an inversion centre, bridged by two singly deprotonated $H_2tmp^-$ ligands. The deprotonated arms (O1 and O1A) act as μ-bridges with the protonated arms (O2, O3A and symmetry equivalents), each bonding in a terminal fashion. These are H-bonded to the MeOH solvent molecules [e.g. O4···O2, 2.552(3) Å] and their bonds to Cr are slightly longer [1.983(2)–2.017(2) Å] than the bridging Cr–O distances [1.954(2)–1.964(2) Å]. Two terminal chloride ions (Cl1, Cl2 and symmetry equivalents) complete the coordination spheres of the $Cr^{III}$ ions, and these H-bond to the

oxygen arms of the tripodal ligands on neighbouring molecules (Cl···O, 3.06–3.18 Å). The $Cr^{III}$ ions are in distorted octahedral geometries with *cis* angles in the range 79.1(1)–94.43(7)° and *trans* angles of 171.77(7)–177.25(9)°. In the crystal the $Cr_2$ units pack in 2D sheets as mediated by the Cl···O and O(tripod)···O(MeOH) H-bonds, with these "metallic" sheets separated from each other by the organic tails of the tripodal ligands and the chloride ions. Here, the closest intermolecular interactions are of the order 3.5–4.0 Å. Complex **1** is structurally related to the vanadium dimers of general formula $[V_2O_2(H_2tripod)_2Cl_2]$, in which one of the chloride ions on each metal has been replaced by an oxygen.[9]

Complex **2**, $[Cr_8O_2(thme)_2(Hthme)_4Cl_6]$ crystallises in the triclinic space group $P\bar{1}$, whereas complex **3**, $[Cr_8O_2(Hpeol)_2(H_2peol)_4Cl_6]$ crystallises in the monoclinic space group $C2/c$. Both structures are essentially the same, and thus we will confine our discussion to complex **2** (Table 2 and Table 3). Differences in the packing arrangements between **2** and **3** are discussed afterwards (Figure S1). The core of **2** (Figure 2) consists of two $[Cr_5O]^{13+}$ square-based pyramids, related by an inversion centre, which share one edge forming a central $[Cr_8O_2]^{20+}$ unit. The core can be regarded as part of the decametallate $\{M_{10}O_{28}\}^{26-}$ ion of two edge-sharing octahedra, but with two of the apical metal centres missing and with the bridging and terminal oxo groups replaced by a combination of oxygen atoms from tripodal ligands and chloride ions. The tripodal ligands are of two types: the two fully deprotonated $thme^{3-}$ ligands, each bound to the open triangular face of the square-based pyramid with each oxygen (O5, O6, O10A) arm bridging in a $\mu_2$-fashion between either the apical $Cr^{III}$ ion (e.g. Cr3A) and basal ion (e.g. Cr2) or between two basal $Cr^{III}$ ions (e.g. Cr4A, Cr2). The remaining four tripodal ligands are doubly deprotonated, $Hthme^{2-}$, and occupy four of the "faces" surrounding the vacant apical Cr sites: one deprotonated arm bonds in a $\mu_2$-fashion between apical and basal $Cr^{III}$ ions (e.g. O9) – thus linking the two square-based pyramids together; the second deprotonated arm bridges between two basal sites (e.g. O8), with the third protonated arm (e.g. O7) binding in a terminal fashion to a basal $Cr^{III}$ site. There are six chloride ions in the structure which each bond terminally to $Cr^{III}$ ions on the open triangular faces of the square-based pyramids. The two $O^{2-}$ ions are five-coordinate and square-based pyramidal, each bound to four basal and one apical $Cr^{III}$ ion, with *cis* angles in the range 89.2–95.3° and *trans* angles 170.8–172.0° (Table 2). The result is an $\{M_8L_{26}\}$ unit, equivalent to the $\{M_{10}O_{28}\}^{26-}$ decametallate ion minus the two {ML} apices. The terminal Cr–O bonds of the $Hthme^{2-}$ ligand are significantly longer (2.020–2.064 Å) than the μ-bridging oxygen

bond lengths (1.949–1.984 Å), with O4 and O7A hydrogen bonded both to each other and a MeOH solvate molecule (e.g. O4···O7A, 2.737 Å; O4···O11, 2.662 Å) (Table 2). All the $Cr^{III}$ ions are in distorted octahedral geometries with their oxidation states confirmed by a combination of BVS calculations, bond lengths and overall charge balance considerations.

In the crystal the molecules pack in columns with one $Cr_8$ unit sitting directly above and below its nearest neighbours. Here, the closest intermolecular interactions are between the terminal chloride ions and the tripodal ligands (≈ 3.5–3.7 Å). Intermolecular interactions between the columns are mediated through a combination of Cl···C (tripod) H-bonds (in the region of ≈ 3.5–3.7 Å), and the Cl···O (MeOH) H-bonds. For complex **3**, the pendant alcohol group of the pentaerythritol ligand is found to greatly influence the packing within the crystal lattice. These additional OH groups form hydrogen bonds to molecules in adjacent planes (e.g. O11···O13, O11A···O13A) at a distance of ca. 2.65 Å and result in these planes packing in a perpendicular fashion. The terminal chloride ions are also involved in two intermolecular H-bonding interactions; one OH···Cl interaction with an uncoordinated $H_2peol^-$ ligand arm (e.g. O12···Cl3, 3.25 Å), and the other with a MeOH solvent molecule (O17···Cl2, 3.21 Å).

The edge-sharing $[M_8(\mu_5\text{-}O_2)]^{n+}$ core adopted by **2** and **3** is somewhat unusual. Other examples of this octanuclear fragment are restricted to the Ba clusters $[Ba_8O_2]^{12+}$, $[Sr_6Ba_2O_2]^{12+}$ and $[Ba_8Eu_2O_2]^{12+}$ where the principal bridging ligand is also an alkoxo group.[10,11] Similar cores can, however, be found in the decanuclear transition-metal

clusters $[Fe_{10}O_2Cl_8(tmp)_6]$, $[(VO)_2Fe_8O_2Cl_6(tmp)_6]$ and $(NEt_4)_2[Mn_{10}O_2Cl_8(thme)_6]$.[9,12,13]

### Magnetic Measurements

Solid-state dc magnetisation measurements were performed on **1** and **2** in the temperature range 1.8–300 K in a field of 5.0 kG and the Irreducible Tensor Operator (ITO) formalism was employed to fit the experimental data by means of the programme VPMAG.[14] For complex **1**, the room temperature $\chi_M T$ value of approximately 3.75 $cm^3 \cdot K \cdot mol^{-1}$ is that expected for two non-interacting $Cr^{III}$ centres (Figure 3). As the temperature is lowered, the value of $\chi_M T$ drops very gradually until approximately 100 K where it begins to fall more dramatically, reaching a value close to 0 $cm^3 \cdot K \cdot mol^{-1}$ at 1.8 K. At 27 K a maximum in $\chi_M$ is reached ($\chi_M$ = 0.0512 $cm^3 \cdot K \cdot mol^{-1}$). This behaviour is indicative of relatively weak antiferromagnetic exchange coupling between the $Cr^{III}$ ions with an $S = 0$ spin ground state. Using the spin Hamiltonian $\hat{H} = -J\hat{S}_1 \cdot \hat{S}_2$, the best fit (Figure 3 solid line) was obtained for the following parameters: $J = -12.30 \pm 0.04$ $cm^{-1}$ and $g = 1.990 \pm 0.003$, resulting in an S = 0 spin ground state. The agreement factor of the fit, defined as

$F = \{\Sigma[\chi_i^{exp.} - \chi_i^{calcd.}]^2\}/\{\Sigma[\chi_i^{calcd.}]^2\}$, is good ($F = 1.1 \cdot 10^{-5}$).

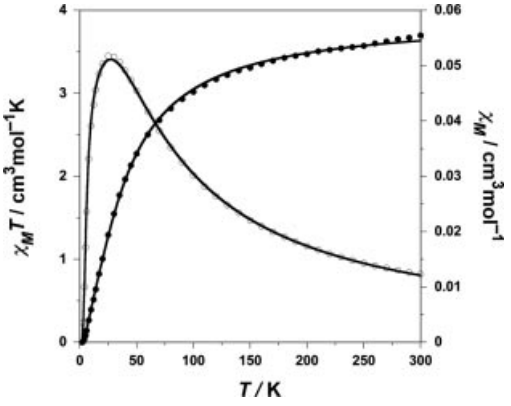

Figure 3. Plot of $\chi_M$ and $\chi_M T$ vs. $T$ for complex **1**. The solid lines are fits to the experimental data. See text for details.

For complex **2**, the $\chi_M T$ value of approximately 10.8 $cm^3 \cdot K \cdot mol^{-1}$ at 300 K is smaller than that expected for eight noninteracting $S = 3/2$ metal centres (15 $cm^3 \cdot K \cdot mol^{-1}$, with $g = 2.0$). Below 300 K, the value of $\chi_M T$ drops gradually with temperature reaching a pseudo-plateau with a value of approximately 3.2 $cm^3 \cdot K \cdot mol^{-1}$ at 10 K (Figure 4). This behaviour is indicative of dominant antiferromagnetic exchange between the $Cr^{III}$ ions, resulting in a relatively small spin ground state ($S = 2$). Below 10 K the $\chi_M T$ value falls again to approximately 2 $cm^3 \cdot K \cdot mol^{-1}$ at 1.8 K. The decrease of $\chi_M T$ in this last region is probably due to intermolecular interactions, the magnetic anisotropy of the ground spin state, or (less probably) the presence of more stable states displaying lower spin angular momenta.

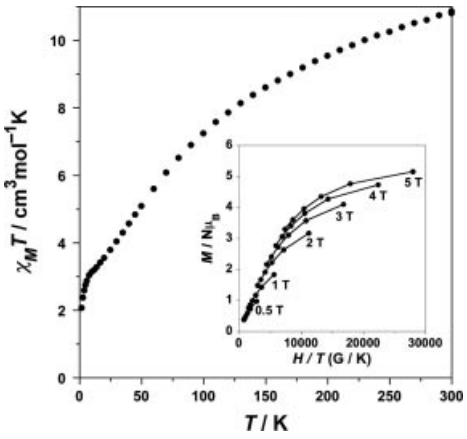

Figure 4. Plot of $\chi_M T$ vs. $T$ for complex **2** and (inset) magnetisation ($M$) vs. field ($H$) data taken in the ranges 1.8–6.2 K and 0.5–5.0 T.

Magnetisation measurements in the 1.8–6.2 K temperature range were performed under constant magnetic fields of 0.5–5.0 T (Figure 4, inset). The isofield lines are not superimposable and the values of reduced magnetisation ($M/N\mu_B$) become higher than expected for the postulated spin ground state ($M/N\mu_B \approx 4$ for $S = 2$). This is probably caused by population of low-lying excited states with higher spin numbers which become more stable with increasing fields. For this reason a fit of the magnetisation data to a Brillouin equation was not attempted, because a well-isolated spin ground state is required for such a model to apply. The possibility of slow relaxation of the magnetisation was investigated by collection of ac susceptibility data taken in a range of frequencies. However, no out-of-phase ($\chi_M''$) signal was observed over the whole temperature range (1.8–6.2 K) indicating that **2** is not a single-molecule magnet.

Unfortunately, there are few examples of $Cr^{III}$ compounds in the literature that actually possess similar bridging ligands to the ones found in **2** and **3**, and even these contain other bridging co-ligands (e.g. carboxylates etc.).[15–23] Moreover, there exists little magnetic characterisation of these species and/or their magnetic properties have not been quantitatively analysed because the complexity of the system.[24–30] Thus, it is very difficult to compare and contrast any results with other $Cr^{III}$ complexes. In addition, in such complicated multiple $J$ systems it is usually possible to find several sets of $J$ values that can reproduce the experimental magnetic behaviour equally well. We therefore decided to carry out calculations based on DFT in order to either have good estimated $J$ values to use them as a starting point in a fit.

### Theoretical Study of the Magnetic Exchange Coupling

#### *Complex 1*

An exchange coupling constant, $J = -7.5$ $cm^{-1}$, has been obtained from DF calculations on complex **1** using the broken symmetry approach. Although the theoretical study correctly reproduces the nature of the magnetic interaction, the magnitude of the $J$ constant is slightly lower than the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

experimental value (–12.3 $cm^{-1}$). Despite the fact that only a few compounds display the $[Cr_2(OX)_2]^{4+}$ core (X = H, Me or Et), there does exist a magneto-structural correlation for this unit based on experimental structural parameters which relates the magnetic exchange constant to the Cr–O–Cr angle ($\alpha$), the Cr–O distance ($d_{CrO}$), and the dihedral angle formed between the OR group and $Cr_2O_2$ plane ($\theta$).[31] Here, we have revisited this correlation bringing up to date the experimental data (Table 4), as well as performing a theoretical analysis by electronic structure calculations. The Cr–O distance remains essentially unchanged along the series of compounds, so we have focused our efforts in the study of the influence of the $\alpha$ and $\theta$ angles. We have used the model complex $[Cr_2(OMe)_2(H_2O)_4Cl_4]$ (**1A**) built from the experimental structural parameters of **1** (Figure S2). In this magneto-structural correlation only the $\alpha$ angles have been modified with the remaining parameters constant. It is important to stress that the molecular geometry of the most stable compound corresponds to an $\alpha$ angle equal to 100.85° – similar to that experimentally found (100.93°, Figure 5). This $\alpha$ value is the same in the singlet (ground state) and triplet state. The thermal energy at room temperature allows the $\alpha$ angle to achieve any value between 98.8 and 102.8° and so, in agreement with the experimental data (Table 4), we can conclude that the experimental $\alpha$ angles in the $[Cr_2(OR)_2]^{4+}$ complexes will take similar values.

At $\alpha$ = 101.3° ($\alpha_{min}$), near the more stable molecular geometry, the antiferromagnetic exchange coupling reaches a minimum value ($J$ = –5.2 $cm^{-1}$). At lower $\alpha$ angles the exchange coupling becomes strongly antiferromagnetic because the inter-metal distance is short enough to allow direct interaction between the paramagnetic centres ($\alpha < 95°$). However, as has been observed in bis-alkoxo dinuclear copper(II) complexes,[32,33] there is an experimental and theoretical correlation between the $\alpha$ and $\theta$ (dihedral) angles (Figure S3). However, no qualitative changes occur in the magneto-structural correlation between the $J$ constant and the $\alpha$ angle (Figure 5). Most complexes display an $\alpha$ value of around 100–101°, but in some cases where bulky alkoxo bridging ligands are used, the $\alpha$ angle can take larger values.

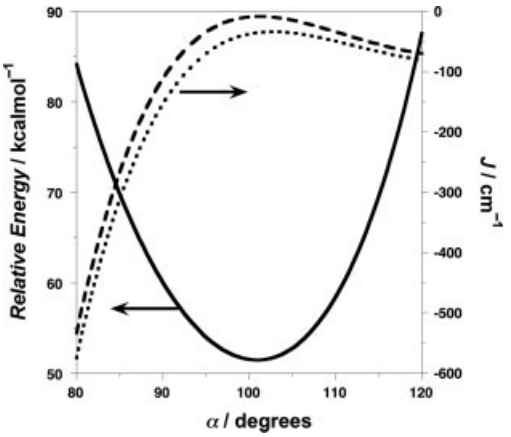

Figure 5. Relative energy (in kcal/mol, solid line) of the singlet ground state and magnetic exchange coupling as a function of the bridging angle Cr–O–Cr ($\alpha$) angle. The dotted and dashed lines correspond to the $J$ values obtained on model **1A** when the $\theta$ angle is or is not optimised, respectively.

In these cases the alkoxo group is almost coplanar with the $[Cr_2(OR)_2]^{4+}$ unit and the antiferromagnetic coupling becomes stronger (Table 4), as predicted by theoretical calculations.[22,34–41] We have analysed this magneto-structural correlation in order to find the electronic factors that govern it (Figure S4). In agreement with previous work, we have concluded that the contribution from the $d_{xy}$ magnetic orbitals is responsible for the correlation between the $J$ constant and the $\alpha$ angle.[31] A more detailed analysis can be found in the Supporting Information.

The thme ligand provides two possible exchange pathways to mediate the magnetic exchange coupling between the $Cr^{III}$ centres: (a) by one alkoxo oxygen only; and (b) by the more extended O–C–C–C–O network (see Figure 1). In previous work, we demonstrated that the more extended pathway is an inefficient route for magnetic communication between $Fe^{III}$ ions where $t_{2g}$ and $e_g$ magnetic orbitals are present.[42] In this case, calculations on the full experimental molecule and on the simpler model lead to the same conclusion. The calculations on the model, where only the shortest pathway is present, give a theoretical $J$ value (–5.2 $cm^{-1}$)

Table 4. Experimental structural data and exchange coupling constants[a] for $[Cr_2(OR)_2]^{4+}$ compounds.

| Compound | $d_{CrO}$ | $\alpha$ | $\theta$ | $J$[b] | Refcode[c] | Ref. |

[a] All angles in °; distance in Å and constants in $cm^{-1}$. [b] Because various magnetic models have been used in the literature, $J$ refers to the energy of the triplet states as calculated from the observed susceptibility data. Theoretical value obtained from electronic structure calculations is in parentheses. [c] Codes for locating structural data in the Cambridge Structural Database.[58]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

similar to that obtained for the full molecule (–7.5 $cm^{-1}$). Moreover, the experimental $J$ value of **1** (–12.3 $cm^{-1}$) agrees well with those observed in previous complexes presenting similar $\alpha$ angles via the shortest M–O–M pathway only (–9.8 $cm^{-1}$). Therefore, the longest M–O–C–C–C–O–M pathway should not be relevant in these complexes as it leads to weak contributions. The contribution of $e_g$ magnetic orbitals – not present in the $Cr^{III}$ ion – are mainly responsible for the magnetic exchange coupling in $Fe^{III}$ complexes and it is strongly weakened when the exchange pathway is lengthened.

### *Complex 2*

As was shown in the structural section, the metal ions in complexes **2** and **3** are connected in three different ways: (a) by two $\mu_5$-oxo bridging ligands ($J_1$); (b) by one $\mu_5$-oxo ion ($J_2$); and (c) by one $\mu_5$-oxo ion and one μ-alkoxo ($J_3$). However, this simple model infers a higher molecular symmetry than that experimentally found (Figure 6). The lower molecular symmetry is related to the different Cr–O bond lengths and Cr–O–Cr angles, and in reality we can take into account ten possible exchange coupling constants and, thus, the spin Hamiltonian (Equation (1):

$$\hat{H} = -J_{4,7}\hat{S}_4 \cdot \hat{S}_7 - J_{3,7}(\hat{S}_3 \cdot \hat{S}_7 + \hat{S}_4 \cdot \hat{S}_8) - J_{4,6}(\hat{S}_4 \cdot \hat{S}_6 + \hat{S}_5 \cdot \hat{S}_7) - J_{4,5}(\hat{S}_4 \cdot \hat{S}_5 + \hat{S}_6 \cdot \hat{S}_7) - J_{3,4}(\hat{S}_3 \cdot \hat{S}_4 + \hat{S}_7 \cdot \hat{S}_8) - J_{3,6}(\hat{S}_3 \cdot \hat{S}_6 + \hat{S}_5 \cdot \hat{S}_8) - J_{1,3}(\hat{S}_1 \cdot \hat{S}_3 + \hat{S}_2 \cdot \hat{S}_8) - J_{1,6}(\hat{S}_1 \cdot \hat{S}_6 + \hat{S}_2 \cdot \hat{S}_5) - J_{1,4}(\hat{S}_1 \cdot \hat{S}_4 + \hat{S}_2 \cdot \hat{S}_7) - J_{1,7}(\hat{S}_1 \cdot \hat{S}_7 + \hat{S}_2 \cdot \hat{S}_4) \quad (1)$$

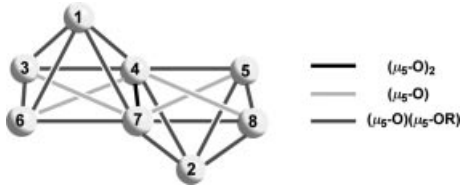

Figure 6. Scheme of the interactions employed in the study of the magnetic properties of **2** and **3**.

where the subindex in the $J$ constants refers to the paramagnetic centres involved in the exchange coupling. We have performed a least-squares fitting to the fourteen-equation system obtained from the differences in the energy between the fifteen spin distributions ($SD_i$) shown in Table S1. The results are shown in the Table 5. In Figure 7 is displayed a spin density map of the most stable configuration, $SD_3$. A more detailed description of this study is able in the Supporting Information.

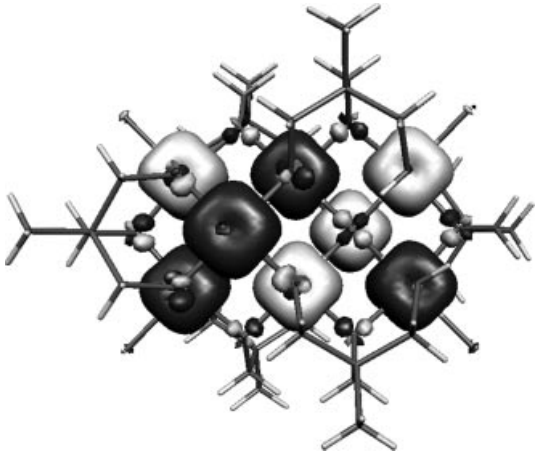

Figure 7. Spin density map calculated at the B3LYP level for the spin ground state of **2** (light and dark contours indicate positive and negative spin populations, respectively). The isodensity surface corresponds to a value of 0.005 $e^-/bohr^3$.

Although the $[Cr_2O_2]$ unit has a relatively low symmetry, a good magneto-structural correlation is found between the exchange coupling constants and the Cr–O–Cr angle in the cases where one oxo and one alkoxo groups act as bridges between metal ions (interaction 4–5, 3–4, 3–6, 1–3. 1–6, 1–4, 1–7; see Table 5). A change of the nature of the magnetic interaction is observed at $\alpha$ ca. 98°, where the ferro- and antiferromagnetic contributions are counter-balanced and a zero value for the $J$ constant is expected (Figure 8). This correlation is also found with the metal–metal distance because the Cr–O distances are almost constant within this small family. Only one system is not in accord with this correlation, displaying a weaker antiferromagnetic interaction than that expected, probably due to the longer Cr–O bond length (2.026 Å, Table 5) weakening the metal–ligand overlap and thus the magnetic exchange.

Table 5. Description of the bridging ligands, average Cr···Cr distances, Cr–O bond lengths, Cr–O–Cr bond angles and calculated exchange coupling constants $J_{i,j}$ (in $cm^{-1}$).

| $i,j$ | Bridging ligands | $d$(Cr···Cr)[a] | $d$(Cr–O)[a] | Cr–O–Cr ($\alpha$)[a] | $J_{i,j}$ |
|---|---|---|---|---|---|
| 4,7 | $(\mu_5\text{-}O^{2-})_2$ | 2.930 (2.930) | 2.085 (2.087) | 89.3 (89.2) | –52.7 |

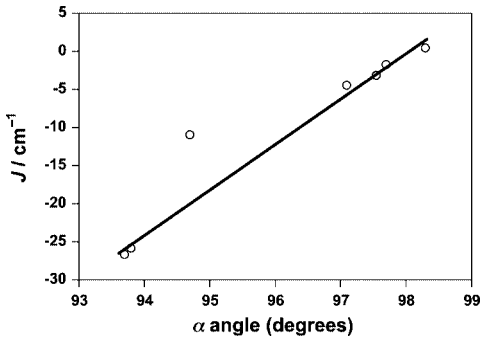

Figure 8. Dependence of the calculated exchange coupling constant ($J$) in **2** for the $[Cr_2O_2]^{2+}$ core with the Cr–O–Cr($\alpha$) angle.

There are two exchange interactions that mediate only through one $\mu_5$-oxo bridge (interaction 3–7, 4–6; see Table 5) where the $J$ constants are found to be –3.8 $cm^{-1}$ and –2.8 $cm^{-1}$. These values are very similar because both $[Cr_2O_2]$ units have similar $\alpha$ values (170.9° and 172.1°). The magnetic coupling in this case is expected to be governed by the Cr–O distance, so the stronger of the two $J$ constants is the one with the shortest Cr–O bond length. The stronger magnetic interactions found in **2** where two $\mu_5$-oxo bridges are present (interaction 4–7) should thus be due to the extremely small $\alpha$ values (Table 5).

Unfortunately, it is difficult to find similar compounds in the literature that have been structurally and magnetically characterised. In fact, only two such dinuclear complexes and one dodecanuclear $Cr^{III}$ complex exist.[17,29,30] For the dinuclear complexes there are no reported magnetic measurements and for the $Cr_{12}$ cluster the measurements have not been analysed due to the complexity of the system. The crystal structures of two $Cr^{III}$ dimers displaying a linear or quasi-linear $[Cr_2O]^{4+}$ core are known,[24,25] but, as is often the case, there are no studies of the magnetic properties, meaning we have no way to check the validity of our theoretical results.

The magnetic behaviour of **2** can be simulated by exact diagonalisation of the energy matrix built using the irreductible tensors operator approach. We have obtained the $\chi_M T$ vs. $T$ curve for **2** from the calculated $J$ values and find that they are in qualitatively acceptable agreement with the experimental curve (Figure 9). We have also carried out a fit using these $J$ values as starting point and to avoid overparameterisation, we have reduced the number of variables in the way shown in Table 6. The best fit was obtained for the following parametes: $J_{4,7}$ = –39.0 $cm^{-1}$; $J_{3,7}$ = $J_{4,6}$ = +1.1 $cm^{-1}$, $J_{4,5}$ = $J_{3,4}$ = –20.0 $cm^{-1}$, $J_{3,6}$ = –16.0 $cm^{-1}$, $J_{1,3}$ = $J_{1,6}$ = $J_{1,4}$ = $J_{1,7}$ = –4.8 $cm^{-1}$ and $g$ = 1.919. The $J$ values are in good agreement with the calculated ones. However, the $g$ factor is slightly smaller than that expected for a chromium(III) ion (1.98–1.99). This fact can be explained by a partial hydration of the sample observed when it is exposed to the environment modifying the formula mass. According to the magneto-structural correlation observed in **2** (Figure 8), when one oxo and one alkoxo group act as bridges, a strong antiferromagnetic coupling is expected for small angles (89.3°) such as it occurs for $J_{4,7}$. Probably, for this $\alpha$ value a short metal–metal distance is found favouring the direct interaction between two metal ions, as proposed in the previous theoretical study on dinuclear models (compound **1**). It is also possible to find a set of $J$ parameters with a $g$ factor near to 1.98–2.00; however, this set is discarded because the obtained $J_{4,7}$ value is too large (–122.9 $cm^{-1}$). In fact, the $J_{4,7}$ value expected from the magneto-structural correlation shown in Figure 8 (–53.3 $cm^{-1}$) is lower and closer to that obtained from DF calculations. In the curves obtained with the calculated and fitted $J$ values, as the temperature decreases the value of $\chi_M T$ is close to reaching a plateau ($\chi_M T \approx 3.2$ $cm^3 \cdot K \cdot mol^{-1}$) in agreement with the experimental curve. At lower temperatures the value of $\chi_M T$ falls to reach a value equal to zero corresponding to a singlet ground state. Thus, we can reject possible intermolecular interactions or magnetic anisotropy as a cause of the magnetic behaviour at lower temperature. Regardless, the chosen set of $J$ values must explain the be-

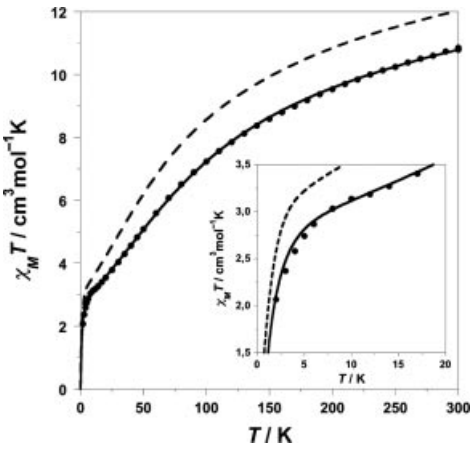

Figure 9. Magnetic susceptibility curves for **2** obtained from the calculated $J$ values (dashed line) and fitted $J$ values (solid line) that are shown in Table 6. The experimental data is displayed as black circles.

Table 6. Exchange coupling constants ($J_{i,j}$, $cm^{-1}$) obtained for **2** from theoretical calculations (A) and fitted values (B) in the temperature range 300–20 K. We also indicate the $g$ factor, agreement factor ($F$), the spin ground state (GS) and the relative energy of first excited state ($E_1$, in $cm^{-1}$).

haviour observed for the dependence of the magnetisation with magnetic field at several temperatures. From an energy-level diagram obtained from calculated $J$ values (Figure S5), we observe that some singlet, triplet, quintet and septet states are very close to the ground spin state. At slightly higher energy we can also find the first nonet state. Thus, when the applied magnetic field is increased some *ms* eigenfunctions of low-lying excited states with higher multiplicity will be populated reaching a non-zero-saturation value. In this situation the shape of the magnetisation curve and the saturation value are dependent on the temperature, because low-lying excited states will be populated at higher temperature. A similar behaviour is observed with the parameters obtained in the fit.

## Conclusions

In conclusion, the reactions between $CrCl_2$ and the tripodal ligands $H_3$thme, $H_3$tmp, and $H_4$peol have produced new di- and octanuclear $Cr^{III}$ clusters. Complex **1** can only be made under reflux and complexes **2** and **3** only under solvothermal conditions. Complexes **2** and **3** represent rare examples of "large" Cr clusters containing no bridging carboxylates with structures derived from the decametallate core commonly seen in polyoxometallate chemistry. As such, **1**–**3** may represent the first examples in a large family of Cr clusters and variations of the above reaction schemes may lead to the isolation of diverse metal polyhedra exhibiting novel magnetic properties. Magneto-structural correlations for $[Cr_2(OR)_2]^{4+}$ and $[Cr_2O_2]^{2+}$ complexes have been found, which we hope will help the analysis of the magnetic properties in new polynuclear $Cr^{III}$ clusters. Electronic-structure calculations based on density functional theory have allowed us to understand the electronic factors that govern these correlations. Electronic structure calculations have been performed on **1** and **2** and good estimates of the $J$ values have been obtained. Different sets of $J$ values have been found to reproduce the magnetic behaviour of **2**. An analysis of the theoretical results and those obtained in the fitting procedure by diagonalisation of the Hamiltonian matrix allowed us to select one among the fitted $J$ value sets.

## Experimental Section

**$[Cr_2(H_2tmp)_2Cl_4]\cdot 2MeOH$ (1·2MeOH):** Anhydrous $CrCl_2$ (0.5 g, 4.0 mmol), $H_3$tmp (0.545 g, 4.0 mmol) and NaOMe (0.110 g, 2.0 mmol) were heated at reflux in MeOH (30 mL) for 3 h. The reaction mixture was filtered and the resulting dark green solution cooled. The solvent was then removed under reduced pressure and the resulting dark green solid recrystallised from MeCN (20 mL). Green crystals of **1** appeared upon $Et_2O$ diffusion over 2 weeks. Yield based on $Cr^{III}$: 0.230 g (20%). $C_{14}H_{32}Cl_4Cr_2O_8$ (574.22): calcd. C 29.18, H 5.95; found C 28.99, H 5.85. IR (KBr pellet): $\tilde{\nu}$ = 3424 (s), 3170 (s), 2978 (s), 2604 (m), 1630 (w), 1453 (m), 1384 (m), 1299 (m), 1265 (w), 1189 (w), 1100 (s), 1040 (s), 940 (s), 773 (w), 592 (m), 560 (s), 509 (m), 443 (w) $cm^{-1}$. $[Cr_2(H_2tmp)_2Cl_4]\cdot$ 2MeOH (576.22): calcd. C 29.18, H 5.95; found: C 28.99, H 5.85.

**$[Cr_8O_2(thme)_2(Hthme)_4Cl_6]\cdot 2MeOH$ (2·2MeOH):** This complex was synthesised by heating $CrCl_2$ (0.3 g, 2.4 mmol), $H_3$thme (0.29 g, 2.4 mmol) and NaOMe (0.13 g, 2.4 mmol) in MeOH (9 mL) in a teflon-lined autoclave at 100 °C for 12 h. Slow cooling to room temperature yielded dark green crystals of **2**. Yield based on $Cr^{III}$: 0.130 g (30%). $C_{32}H_{62}Cl_6Cr_8O_{29}$ (1427.28): calcd. C 26.85, H 4.65; found C 26.28, H 4.67. IR (KBr pellet): 3420 (s), 2930 (s), 2361 (m), 1636 (w), 1464 (w), 1385 (w), 1124 (m), 1044 (s), 630 (m), 580 (s), 536 (m), 468 (w) $cm^{-1}$.

**$[Cr_8O_2(Hpeol)_2(H_2peol)_4Cl_6]\cdot 3MeOH$ (3·3MeOH):** The complex was synthesised as **2**, replacing $H_3$thme with $H_4$peol. $C_{33}H_{60}Cl_6Cr_8O_{22}$ (1549.27): calcd. C 25.31, H 4.89; found C 25.63, H 4.97. IR (KBr pellet): $\tilde{\nu}$ = 3450 (s), 2931 (m), 2874 (m), 1636 (w), 1472 (w), 1388 (w), 1224 (w), 1115 (s), 1060 (s), 653 (m), 593 (s), 537 (m), 506 $cm^{-1}$ (w).

**X-ray Crystallography:** Data were collected with either Bruker SMART APEX CCD (1) or Oxford Diffraction Crysalis CCD diffractometers (**2**, **3**) at 100(2) K using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Both structures were solved by direct methods and refined (on $F^2$ for all reflections) using SHELXTL.[43,44] Absorption corrections were applied using SADABS (**1**) and software built into the Crysalis CCD program (**2**, **3**). All non-hydrogen atoms were refined anisotropically. Excessive thermal motion of the chlorine atoms in **1** required thermal and angular restraints to be applied. Neither refinement nor absorption corrections reduced the residual electron density in the core of **2**. The hydrogen atoms in **2** could not be found so were added in calculated positions. Relevant crystallographic information for the compounds is summarised in Table 7. CCDC-285702–285704 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Magnetic Measurements:** Variable-temperature, solid-state direct current (dc) magnetic susceptibility data down to 1.80 K were collected with a Quantum Design MPMS-XL SQUID magnetometer equipped with a 5.5-T dc magnet at the University of Barcelona. Diamagnetic corrections were applied to the observed paramagnetic susceptibilities using Pascal's constants.

**Computational Details:** All theoretical calculations were carried out with the hybrid B3LYP method,[45–47] as is implemented in the Gaussian03 program.[48] Double-ζ (SV) and triple-ζ (TZV) quality basis sets proposed by Ahlrichs and co-workers have been used for all atoms.[49,50] For the chromium ions, two extra p functions have been added. The electronic configurations used as starting points have been created using Jaguar 6.0 software. The broken-symmetry approach has been employed to describe the unrestricted solutions of the antiferromagnetic spin states.[51–53] No molecular modelling has been done, with the full experimental geometry of **2** used for the calculations. A quadratic convergence method was employed to determine the more stable wave functions in the SCF process.[54] The atomic spin densities were obtained from Natural Bond Orbital (NBO) analysis.[55–57]

**Other Measurements:** Elemental analyses were performed by the University of Manchester Microanalysis Service. IR spectra were recorded as KBr pellets on a Nicolet model 510P spectrophotometer.

## Acknowledgments

This work was supported by the Lloyds of London Tercentenary Foundation (UK), EPSRC (UK), The Leverhulme Trust (UK), Dirección General de Enseñanza Superior (DGES) and Comissió Interdepartamental de Ciència i Tecnologia (CIRIT) through the grants CTQ2005-08123-C02-02/BQU and 2005SGR-00036, respectively. The computing resources were generously made available in the Centre de Computació de Catalunya (CESCA) with a grant provided by Fundació Catalana per a la Recerca (FCR) and the Universitat de Barcelona.

# Synthesis of a New Tetrakis(2-pyridinyl)pyrazine Complex of Gold(III) and Its Computational, Spectroscopic and Electrochemical Characterization

**Marco Bortoluzzi,*[a] Eddy De Faveri,[b] Salvatore Daniele,[b] and Bruno Pitteri[a]**

**Keywords:** Gold / N ligands / Density functional calculations / Electrochemistry

The cationic dinuclear (hydroxo)$Au^{III}$ complex $[Au_2(OH)_2(tppz)]Cl_4$ [tppz = 2,3,5,6-tetrakis(2-pyridinyl)pyrazine] was prepared by allowing the ligand tppz to react with $K[AuCl_4]\cdot 2H_2O$ in refluxing methanol. Its NMR and IR spectra support the formation of a symmetric hydroxo derivative instead of the expected chloro complex. DFT B3PW91 calculations were performed with various basis sets to give better insights into the properties of the prepared complex and to compare it with the known derivative $[Au(OH)(terpy)]^{2+}$ (terpy = 2,2′:6′,2′′-terpyridine). The electrochemical behaviour of $[Au_2(OH)_2(tppz)]Cl_4$ was investigated by cyclic voltammetry and it was found that two main irreversible reduction processes occurred. In particular, a four-electron process, leading to the formation of gold(I) complex species in solution, and a two-electron process affording metallic gold were observed. The electronicity involved in the two processes was verified by macroelectrolysis at controlled potential.

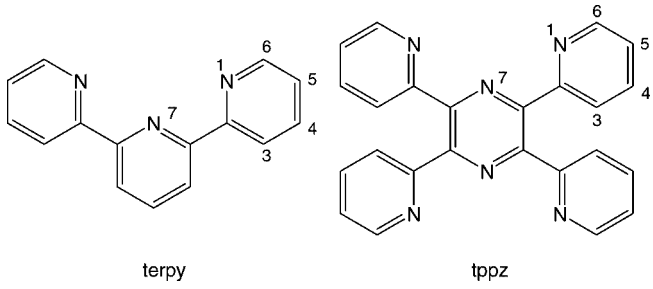
## Introduction

Pyridine-derived polydentate ligands play a fundamental role in inorganic chemistry and one of the most interesting molecules of this kind is the terdentate ligand 2,2′:6′,2′′-terpyridine (terpy; Scheme 1), whose coordination chemistry with $Au^{III}$ has been studied in the past few years. In particular, chloro- and hydroxogold(III)–terpy complexes of the type $[AuL(terpy)]^{2+}$ (L = Cl, OH) are known that have been structurally characterized.[1,2] In the field of gold complexes with pyridine-based polydentate ligands, much less attention has been devoted to the ligand 2,3,5,6-tetrakis(2-pyridinyl)pyrazine (tppz; Scheme 1), even though it can be approximately considered as a "double terpyridine" and, therefore, is suited to coordinate two metal fragments to form complexes having a strong electronic delocalization.

A number of tppz complexes of transition metals such as ruthenium and osmium,[3] iron,[4] rhodium,[5] iridium,[6] nickel,[7] palladium,[8] copper[7,9,10] and zinc[10] have been prepared, whereas, to the best of our knowledge, no example of a gold derivative of 2,3,5,6-tetrakis(2-pyridinyl)pyrazine has been published in the literature. The previous works regarding tetrakis(2-pyridinyl)pyrazine coordination chemistry demonstrated that both mono- and dinuclear tppz complexes can be synthesized and that it is also possible to obtain mixed-metal tppz derivatives. Many of these tetrakis(2-pyridinyl)pyrazine complexes have shown intriguing spectroelectrochemical and electrochemical properties due to the characteristics of the tppz ligand.



Scheme 1. 2,2′:6′,2′′-Terpyridine (terpy) and 2,3,5,6-tetrakis(2-pyridinyl)pyrazine (tppz) and the numbering of their hydrogen and nitrogen atoms.

In this paper the synthesis of a tetrakis(2-pyridinyl)pyrazine derivative of gold, the dinuclear hydroxo complex $[Au_2(OH)_2(tppz)]Cl_4$, is reported for the first time. DFT B3PW91 calculations are also performed to give better insights into the electronic and steric properties of the prepared compound and to compare it with the known $[Au(OH)(terpy)]^{2+}$ cation. Cyclic voltammetric experiments and macroelectrolysis at controlled potential are performed to understand the redox properties of $[Au_2(OH)_2(tppz)]Cl_4$ and to ascertain an eventual formation of stable tetrakis(2-pyridinyl)pyrazine derivatives of gold(I) in solution.

## Results and Discussion

### Preparation and Characterization of the Complex

The hydroxo complex $[Au_2(OH)_2(tppz)]Cl_4$ was prepared by treating the ligand 2,3,5,6-tetrakis(2-pyridinyl)pyrazine

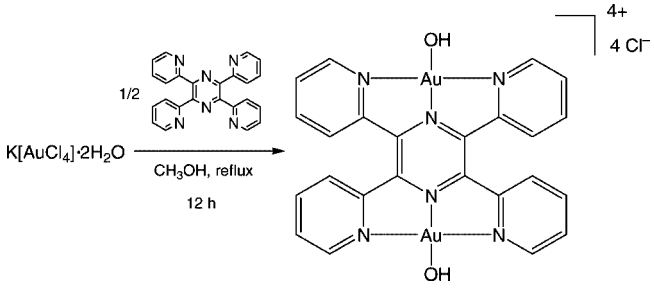
(tppz) with potassium tetrachloroaurate dihydrate $K[AuCl_4]\cdot 2H_2O$ in refluxing methanol (see Scheme 2). On the basis of previous works with the terpy ligand,[1,2] the formation of the chloro complex $[Au_2Cl_2(tppz)]^{2+}$ was expected. However, both the IR and the $^1H$ NMR spectra of the reaction product support the presence of a coordinated hydroxo ligand. Thus, an O–H stretching is observable in the IR spectrum (3412 $cm^{-1}$) and the hydrogen atoms of the OH ligands give a broad signal in the $^1H$ NMR spectrum. The chemical shift of this signal is, as expected, quite dependent upon the temperature. The formation of a hydroxo ligand is probably due to the presence of water in the reaction mixture coming from the starting precursor $K[AuCl_4]\cdot 2H_2O$. All the pyridine rings are magnetically equivalent, and only four signals attributable to coordinated tppz can be observed in the $^1H$ NMR spectrum. Also, the $^{13}C\{^1H\}$ NMR spectrum shows signals of only four primary carbon atoms and two quaternary carbon atoms. This means that the prepared compound is dinuclear and that both the gold atoms have the same coordination environment. Finally, the elemental analyses (C, H, Cl, N) are also in agreement with the proposed formulation, the deviations between found and calculated values being less than 0.4%.



Scheme 2. Synthesis of $[Au_2(OH)_2(tppz)]Cl_4$.

## DFT Studies

To better understand the electronic and steric properties of the prepared compound, computational geometry optimisations of the cations $[Au(OH)(terpy)]^{2+}$ and $[Au_2(OH)_2(tppz)]^{4+}$ were performed using the DFT B3PW91 method. Table 1 shows the $r_{Au-O}$, $r_{Au-N7}$ and the average $r_{Au-N1}$ bond lengths of $[Au(OH)(terpy)]^{2+}$ and $[Au_2(OH)_2(tppz)]^{4+}$. The average C6–N1–Au–O dihedral angle and the Mulliken charge of the coordinated [AuOH] fragments are also included. The differences between the DFT-calculated bond lengths and the bond lengths found in the X-ray structure analysis of $[Au(terpy)(OH)](ClO_4)_2$[2] are always less than 2.2%; the greatest deviation between calculated and experimental $r_{Au-O}$ bond lengths is less than 1.2%.

The average $r_{Au-N1}$ and $r_{Au-O}$ bond lengths for both optimised cations are almost identical to within three significant figures, whereas the Au–N7 bond in the $[Au_2(OH)_2(tppz)]^{4+}$ complex is about 0.03 Å longer than that in the monomer. The coordination of two gold fragments strongly twists the molecule from planarity because of the steric hindrance between the H3 atoms of the pyridine rings. The degree of twisting can be quantified by comparing the C6–N1–Au–O dihedral angles of $[Au(OH)(terpy)]^{2+}$ and $[Au_2(OH)_2(tppz)]^{4+}$: the terpy derivative is approximately planar, with an average C6–N1–Au–O dihedral angle of less than 1°, while the dinuclear [tetrakis(2-pyridinyl)pyrazine]gold derivative has an average C6–N1–Au–O dihedral angle of between 9.0° and 9.8°, depending upon the basis set. A similar deviation of the tetrakis(2-pyridinyl)pyrazine ligand from planarity has already been observed in the X-ray structures of dinuclear tppz derivatives of various transition metals.[3,5–10]

From the calculated geometries, a $C_{2h}$ symmetry can be ascribed to the $[Au_2(OH)_2(tppz)]^{4+}$ cation, which is in agreement with the corresponding $^1H$ NMR and $^{13}C\{^1H\}$ NMR spectra. The DFT B3LYP/BS3 optimised geometry of $[Au_2(OH)_2(tppz)]^{4+}$ is shown in Figure 1.

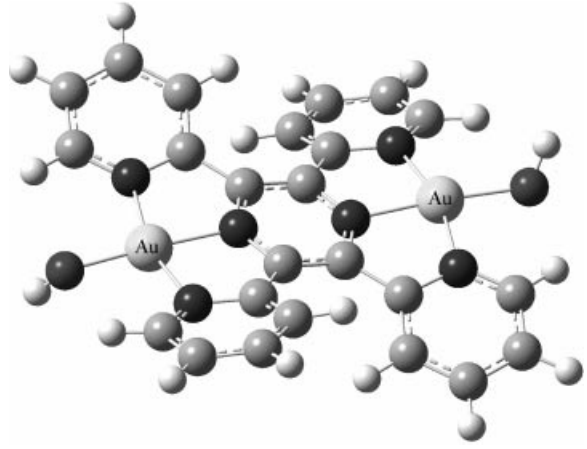


Figure 1. DFT B3LYP/BS3 optimised geometry of the $[Au_2(OH)_2(tppz)]^{4+}$ cation.

Table 1. Selected bond lengths and angles for the cations $[Au(OH)(terpy)]^{2+}$ and $[Au_2(OH)_2(tppz)]^{4+}$ and the Mulliken charge of the coordinated [AuOH] fragment. **BS1**: CEP-121G, CEP-31G on Au; **BS2**: D95V, SDD on Au; **BS3**: D95, LANL2DZ on Au.

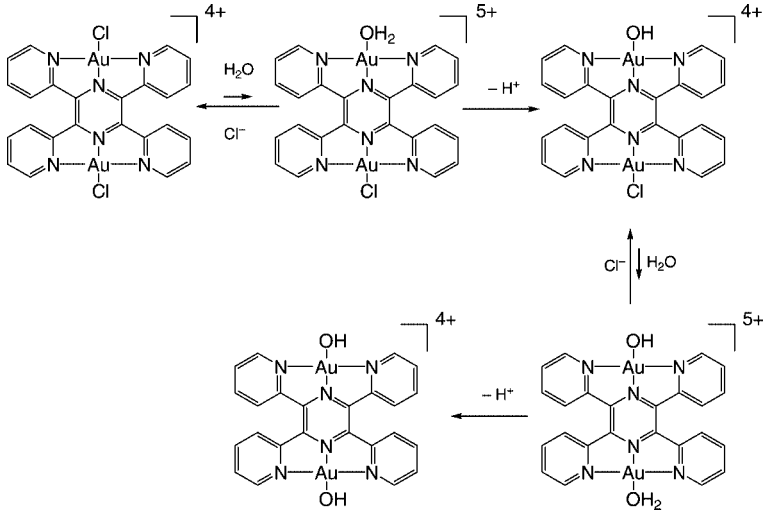
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The Mulliken charge of the [AuOH] fragments in the $[Au_2(OH)_2(tppz)]^{4+}$ cation is always higher than that calculated for the $[Au(OH)(terpy)]^{2+}$ complex (see Table 1). This means that the tetrakis(2-pyridinyl)pyrazine derivative has less basic hydroxo ligands and more electrophilic gold centres and this fact can be ascribed to the lower ability of the tppz ligand, if compared with two terpy molecules, to delocalize the positive charge on its aromatic rings. The mechanism of formation of the mononuclear $[Au(OH)(terpy)]^{2+}$ cation from the chloro complex $[AuCl(terpy)]^{2+}$ and the equilibrium between this hydroxo derivative and the corresponding aqua complex $[Au(OH_2)(terpy)]^{3+}$ has been studied in a previous paper.[2] It was found that the water molecule coordinated to the $[Au(terpy)]^{3+}$ fragment behaves as a strong acid ($K_a \geq 0.8$ M). It therefore seems reasonable to hypothesise that the mechanism leading to the $[Au_2(OH)_2(tppz)]Cl_4$ complex could be similar to that of the analogous terpy derivative. Thus, the reaction between tppz and $AuCl_4^-$ probably leads to the initial formation of an intermediate chloro species. This may react with water present in the reaction medium to give a very acidic aqua species which, on the basis of the DFT calculations, would be even more acidic than the corresponding $[Au(OH_2)(terpy)]^{3+}$ complex and, consequently, would deprotonate to provide the final $[Au_2(OH)_2(tppz)]Cl_4$ hydroxo species. It must be considered that, although the formation of (aqua)-$Au^{III}$–tppz derivatives is disfavoured by the experimental conditions, the driving force of the whole reaction is the immediate deprotonation of the coordinated water molecules. The $[Au_2(OH)_2(tppz)]Cl_4$ product should be very stable as the square-planar hydroxo species is known to be inert towards nucleophilic substitution.[11] Besides, the very similar values of the calculated $r_{Au-O}$ bond lengths in $[Au_2(OH)_2(tppz)]^{4+}$ and $[Au(OH)(terpy)]^{2+}$ (see Table 1) and the fact that the terpy derivative is rather stable allowed us to conclude that the same lack of reactivity occurs for the dinuclear $Au^{III}$ complex prepared in this work.

On the other hand, because the formation of a 6+ diaquo intermediate of the type $[Au_2(OH_2)_2(tppz)]^{6+}$ in solution is rather improbable as its acidity should be even higher than that of a 5+ aquo species like $[Au_2Cl(OH_2)(tppz)]^{5+}$ or $[Au_2(OH)(OH_2)(tppz)]^{5+}$, a possible reaction pathway leading to the hydroxo derivative from the intermediate chloro species is that summarized in Scheme 3.

## Electrochemical Characterisation

The redox properties of $[Au_2(OH)_2(tppz)]Cl_4$ were investigated by cyclic voltammetry (CV) with both conventional and microelectrodes.[13,14] Figure 2 shows a typical cyclic voltammogram recorded for $[Au_2(OH)_2(tppz)]Cl_4$ at 50 mV s$^{-1}$ with a 3 mm glassy carbon electrode, displaying a rather complex pattern. In particular, in the forward scan, two main irreversible cathodic processes occurring at –0.030 and –0.70 V (**A** and **B**, respectively, in Figure 2), and a series of smaller processes, which occur over the potential region from –1.5 to –2.2 V, are observed. In the reverse scan, apart from the small peaks associated with the latter processes, two major peaks, occurring at 0.56 and 1.16 V (**C** and **D**, respectively, in Figure 2), are observed. Direct anodic scans, starting from 0.3 V, also displayed peak **D**, which is characterised by its much smaller height (see Figure 2 dashed line). This finding suggests that a bulk solution species is responsible for the latter electrode process. Voltammetric measurements performed in DMF solutions containing the supporting electrolyte and increasing amounts of $[BzEt_3N]Cl$ allowed us to assign peak **D** as being due to the oxidation of free $Cl^-$ ions. Similarly, the series of small cathodic and anodic patterns over the potential region from –1.5 to –2.2 V were assigned to an electrode process involving free tppz ligand, as checked in solutions of pure sample. Peaks **A** and **B** probably involve the metal centres and our attention was therefore mainly devoted to these processes. It should be noted that peak **B** is rather broad, and a closer examination of its shape suggests that at least two overlapping peaks are present in it.



Scheme 3. Mechanism of formation of the $[Au_2(OH)_2(tppz)]Cl_4$ complex.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

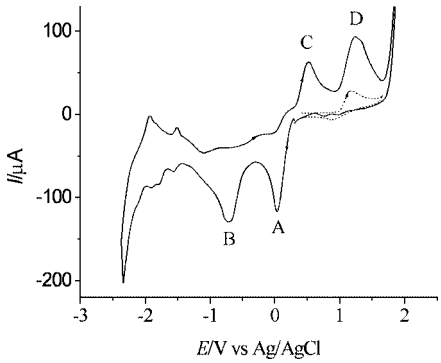


Figure 2. Cyclic voltammograms of 2 mM $[Au(OH)_2(tppz)]Cl_4$ in DMF + 0.1 M TBAP; (—) direct cathodic scan, (- - -) direct anodic scan. Glassy carbon electrode (3 mm diameter); scan rate: 50 mV s$^{-1}$.

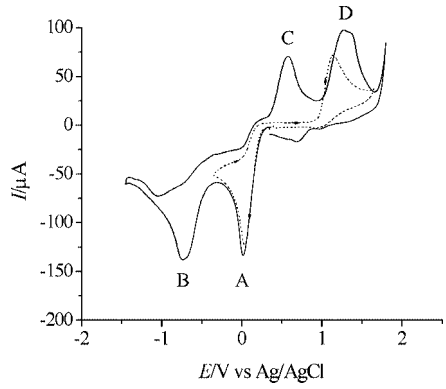

Figure 3. Cyclic voltammograms of 2 mM $[Au(OH)_2(tppz)]Cl_4$ in DMF + 0.1 M TBAP; (—) reversal of the scan direction after peak **B**, (- - -) reversal of the scan direction after peak **A**. Glassy carbon electrode (3 mm diameter); scan rate: 50 mV s$^{-1}$.

Figure 3 shows the cyclic voltammograms obtained for the $[Au_2(OH)_2(tppz)]Cl_4$ solution on reversal of the scan direction soon after either peak **A** or **B** were traversed. It is evident that peak **C** originates from the second cathodic process, while peak **D** increases strongly in current height after peak **A** has been traversed. This current increase indicates that a larger amount of $Cl^-$ ions is formed at the electrode surface following the first reduction process. This circumstance, along with the conductivity value found for a $10^{-3}$ M $[Au_2(OH)_2(tppz)]Cl_4$ solution in DMF at 25 °C ($\Lambda_M$ = 159 $\Omega^{-1}$ mol$^{-1}$ cm$^2$), which is lower than that expected for a 4:1 electrolyte (i.e. in the range 250–300 $\Omega^{-1}$ mol$^{-1}$ cm$^2$[12]), suggests that the $[Au_2(OH)_2(tppz)]^{4+}$ cation forms relatively stable ionic couples with chloride ions in DMF. Evidence for association of cationic gold(III) complexes of the type $[AuCl_2(N–N)]^+$ (N–N = sp$^2$-nitrogen-donating chelate ligands like 2,2′-bipyridine and 1,10-phenanthroline) with chloride in solution is known in the literature;[17] therefore, both the low conductivity value and the growth of peak **D** after the first reduction process were not unexpected. The above scenario did not change when performing cyclic voltammetric measurements at different scan rates over the range 0.01–0.5 V s$^{-1}$. The analysis of peak current ($I_p$) as a function of the square root of scan rate ($v^{1/2}$) was linear for both peaks **A** and **B**, thus indicating that they are diffusion-controlled processes.[13] An analysis of the peak potential ($E_p$) and the half-peak potential ($E_p - E_{p/2}$) ($E_{p/2}$ is the potential at $I_p/2$) as a function of scan rate over the above range was also performed. However, because of the complex nature of peak **B**, only the characteristics of peak **A** were examined from a quantitative point of view. It was found that $E_{p(A)}$ shifts by about 90 mV towards more negative potentials with a tenfold change of scan rate, although ($E_{p(A)} - E_{p/2}$) is equal to 106(±7) mV regardless of the scan rate. These findings are consisent with the occurrence of an irreversible electrode process.[13] The irreversible character of process **A** was further confirmed by CV measurements performed at higher scan rates with a platinum microdisk electrode. In fact, no oxidation process was directly associated to peak **A**, even when performing CV measurements at scan rates up to 500 V s$^{-1}$.[13]

Cyclic voltammetric measurements with the microelectrodes were also performed at low scan rates, and Figure 4 shows a typical CV obtained at 20 mV s$^{-1}$. Under these conditions sigmoidal waves, which are typical for microelectrodes working under steady-state conditions, were obtained.[14] The number of both cathodic and anodic processes observed, and their positions, are identical to those obtained with the conventional electrode. The shape of the voltammogram either confirmed or gave additional information with respect to that obtained with the conventional electrode. In particular, the analysis of wave **A** in terms of the Tomes difference ($E_{1/4} - E_{3/4}$)[15] (i.e. the difference between the potentials recorded at 1/4 and 3/4 of the steady-state limiting current of the forward waves) gave a value of 81(±2) mV, which is considerably higher than the value of 56.5/$n$ mV ($n$ is the number of electrons) expected theoretically for a reversible process at 24 °C.[13] This confirms the irreversible character of process **A**. The CV pattern on reversal of the scan direction from the second cathodic wave displays a current cross-over to which wave **C** is associated (see Figure 4). This behaviour is typical for metal deposition and growth on the electrode surface.[16] Therefore, the formation of metallic gold is conceivably occurring over the reduction process of the second wave. Consequently, wave **C** could be assigned to the stripping of metallic gold from the electrode surface.

The involvement of metallic gold in the correspondence of peak **C** was verified by performing a series of measurements with a conventional gold electrode in DMF solutions containing TBAP and, in consecutive steps, $[BzEt_3N]Cl$ and the tppz ligand. It was observed that the anodization of the gold electrode in the presence of $[BzEt_3N]Cl$ provided the peak at 0.56 V (peak **C**), probably due to the formation of gold chloride species.

The number of electrons involved in the two cathodic processes **A** and **B** was evaluated by preparative macroelectrolysis at controlled potential.[13] Exhaustive reduction performed at –0.4 V (where only **A** is reduced) yielded a charge consumption corresponding to a total of four electrons per mol of $[Au_2(OH)_2(tppz)]Cl_4$, i.e. an overall two-electron

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

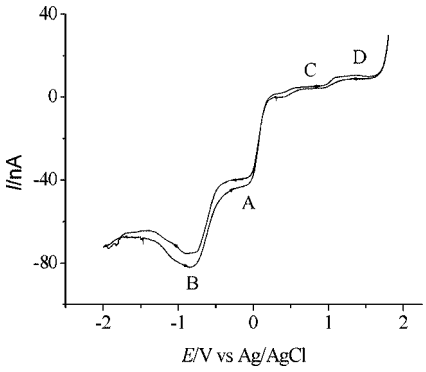

Figure 4. Cyclic voltammogram of 2 mM $[Au_2(OH)_2(tppz)]Cl_4$ in DMF + 0.1 M TBAP at a 12.5-μm Pt disk; scan rate: 20 mV s$^{-1}$.

process for each Au centre. During this experiment the solution turned from bright yellow to colourless. Cyclic voltammetric analysis of the electrolysed solution performed with a glassy carbon electrode displayed peak **B** in the cathodic scan and peaks **C** and **D** upon reversal of the scan direction. Only peak **D** was present in the direct anodic scan. It is also interesting to note that the voltammetric analysis performed on an electrolysed solution after a charge consumption corresponding to a an overall two electrons per mol of $[Au_2(OH)_2(tppz)]Cl_4$ still displays peak **A** with a height equal to half of its initial value, while peak **B** maintains almost the same height as in Figure 2. This suggests that the reduction of $[Au_2(OH)_2(tppz)]Cl_4$ provides only the species responsible for peak **B**, and that the electrons consumed are shared between the two $Au^{III}$ centres, conceivably providing $Au^{I}$ species.

Macroelectrolysis performed at –1.5 V (i.e. at peak **B**) required an overall two electrons per mol of the $[Au_2(OH)_2(tppz)]Cl_4$ complex, thus indicating a one-electron reduction process for each central atom. This reduction process affords metallic gold, as indicated by the fact that during electrolysis the platinum gauze becomes covered by a yellow film, conceivably due to a thick deposit of metallic gold,

Peak **A**

$$[Au^{III}_2(OH)_2(tppz)]Cl_4 \rightleftharpoons [Au_2(OH)_2(tppz)]Cl_{(4-i)}^{i+} + i\,Cl^-$$

$$[Au_2(OH)_2(tppz)]Cl_{(4-i)}^{i+} \xrightarrow{4\,e^-} Au_2(OH)_2(tppz) + (4-i)\,Cl^-$$

$$Au_2(OH)_2(tppz) \xrightarrow[fast]{} [Au_2(tppz)]^{2+} + 2\,OH^-$$

$i$ = number of free $Cl^-$

Peak **B**

$$[Au_2(tppz)]^{2+} \xrightarrow{e^-} [Au_2(tppz)]^{+}$$

$$[Au_2(tppz)]^{+} \xrightarrow[fast]{} [Au(tppz)]^{+} + Au$$

$$[Au(tppz)]^{+} \xrightarrow{e^-} Au(tppz)$$

$$Au(tppz) \xrightarrow[fast]{} tppz + Au$$

Scheme 4. Reduction pathway at peaks **A** and **B**.

and at the same time the colour of the solution turned from almost colourless to yellow-orange. Voltammetric analysis of the electrolysed solution displayed only a series of peaks from –1.5 to –2.5 V in the cathodic region, and peak **D** during the anodic scan. The latter peak was also observed by direct scan in the anodic potential window. Consequently, the final reduction products are metallic gold, free tppz ligand and $Cl^-$ ions.

On the basis of the voltammetric and macroelectrolysis experiments, the possible reduction pathways for processes **A** and **B** can be described as shown in Scheme 4.

## Concluding Remarks

The first gold complex of 2,3,5,6-tetrakis(2-pyridinyl)-pyrazine has been synthesized and spectroscopically characterised. DFT B3PW91 calculations have allowed us to understand some steric and electronic properties of the prepared compound, while electrochemical measurements have allowed us to determine the tetraelectronic nature of the reduction process, which leads to the formation of a stable gold(I)–tppz derivative in solution. Further studies will be carried out in order to obtain new complexes having a gold ion linked by the bridging ligand tppz to another transition metal ion, which could be really interesting from an electrochemical point of view.[3]

## Experimental Section

**Materials:** The salt $K[AuCl_4]\cdot 2H_2O$ was prepared according to a standard procedure starting from metallic Au (99.99%). The ligand 2,3,5,6-tetrakis(2-pyridinyl)pyrazine, the supporting electrolyte tetrabutylammonium perchlorate (TBAP) and benzyltriethylammonium chloride $[BzEt_3N]Cl$ were purchased from Aldrich. Solvents were dried using standard techniques.

**Preparation of $[Au_2(OH)_2(tppz)]Cl_4$:** This complex was prepared by adding solid 2,3,5,6-tetrakis(2-pyridinyl)pyrazine (0.194 g, 0.5 mmol) to a solution of $K[AuCl_4]\cdot 2H_2O$ (0.414 g, 1.0 mmol) in methanol (25 mL). The reaction mixture was heated to reflux for 12 h. During this time the white, insoluble ligand slowly changed to a bright yellow precipitate, which was filtered after cooling the reaction mixture to room temperature and dried in vacuo. The product was purified by dissolving the solid in the minimum volume of DMF (ca. 6 mL) and filtering the resulting solution. Dropwise addition of diethyl ether (ca. 20 mL) caused the product to precipitate, and this solid was filtered, washed with diethyl ether and dried in vacuo. The complex was obtained in nearly quantitative yield. $C_{24}H_{18}Au_2Cl_4N_6O_2$ (958.18): calcd. C 30.08, H 1.89, Cl 14.80, N 8.77; found C 30.20, H 1.90, Cl 14.85, N 8.80. $^1$H NMR [$(CD_3)_2SO$, 298 K]: $\delta$ = 8.53 (dd, $^3J_{H,H}$ = 5.1, $^4J_{H,H}$ = 1.2 Hz, 4 H, 6-H), 8.26 (dd, $^3J_{H,H}$ = 7.2, $^4J_{H,H}$ = 1.5 Hz, 4 H, 3-H), 8.21 (ddd, $^3J_{H,H}$ = 7.2, $^3J_{H,H}$ = 6.9, $^4J_{H,H}$ = 1.2 Hz, 4 H, 4-H), 7.66 (ddd, $^3J_{H,H}$ = 5.1, $^3J_{H,H}$ = 6.9, $^4J_{H,H}$ = 1.5 Hz, 4 H, 5-H), 6.01 (br. s, 2 H, OH) ppm. $^{13}C\{^1H\}$ NMR [$(CD_3)_2SO$, 298 K]: $\delta$ = 153.5, 147.6 (tppz quaternary C atoms), 147.1, 140.2, 125.7, 125.5 ppm (tppz primary C atoms). IR (nujol): $\tilde{\nu}$ = 3412 [$\nu$(O–H)] cm$^{-1}$. $\Lambda_M$ (DMF, 298 K) = 159 $\Omega^{-1}$ mol$^{-1}$ cm$^2$.

**Physical Measurements:** Infrared spectra (4000–400 cm$^{-1}$, nujol mulls) were recorded with a Perkin–Elmer Spectrum One spectro-

photometer. $^1$H NMR, $^1$H COSY and $^{13}$C{$^1$H} NMR spectra were obtained with an Avance 300 Bruker spectrometer in $(CD_3)_2SO$ at temperatures between 298 and 338 K. $^1$H and $^{13}$C{$^1$H} NMR spectra are referenced to internal tetramethylsilane. The SwaN-MR and MestRe-C software packages were used to treat the NMR spectroscopic data.[18] Elemental analyses (C, H, Cl, N) were performed by the microanalytical laboratory at the Department of Pharmaceutical Sciences, University of Padua. The conductivity of $10^{-3}$ M solutions of the complexes in DMF at 25 °C was measured with a Radiometer CDM 83 instrument.

**Computational Details:** Computational geometry optimisation of the cations $[Au(OH)(terpy)]^{2+}$ and $[Au_2(OH)_2(tppz)]^{4+}$ was performed in vacuo using the restricted DFT B3PW91 method[19,20] without symmetry constraints. The basis sets used were CEP-121G (CEP-31G on the Au atom) (**BS1**),[21] D95V (SDD on the Au atom) (**BS2**) and D95 (LANL2DZ on the Au atom) (**BS3**).[22] Geometry convergence was accelerated using the GDIIS algorithm. All of the resultant stationary points were characterized as true minima (i.e., no imaginary frequencies). Atomic charges were derived from a Mulliken population analysis. All calculations were carried out with computers equipped with Intel Pentium 4 660 processors (Prescott 2M) operating at 3.6 GHz. The software used was Gaussian 98.[23]

**Electrochemical Apparatus and Procedure:** Voltammetric experiments were performed in an air-tight, three-electrode cell, which was located in a Faraday cage to avoid external noise. Working electrodes of both conventional and micrometric dimensions were employed. The working electrodes of conventional size were either a glassy carbon or a platinum disk of about 3 mm diameter. Preliminary voltammetric tests showed that similar results were obtained whether conventional glassy carbon or platinum disk electrodes were employed as working electrodes, therefore the general voltammetric behaviour of the investigated complex at the conventional glassy carbon electrode is discussed in the text. The microelectrode was a Pt microdisk (25 μm diameter), which was prepared by sealing a 25-μm-diameter wire directly in glass, as reported elsewhere.[16] A platinum spiral was used as counter electrode, and aqueous Ag/AgCl saturated with KCl was used as reference electrode. It was separated from the cell by a salt bridge containing the same solvent and supporting electrolyte solution as used in the cell. All working electrodes were polished mechanically with graded alumina powder (1, 0.3 down to 0.05 μm) on a polishing microcloth. Cyclic voltammetric experiments were performed with a potentiostat/galvanostat PAR 283 A (EG&G) controlled by 270 PAR (EG&G) software using a PC. For experiments with conventional electrodes, positive feedback corrections of the uncompensated resistance (i.r. drop) were performed. Steady-state voltammograms with the microelectrode were recorded at 20 mV s$^{-1}$. Macroelectrolyses were carried out in an H-shaped cell with the cathodic and anodic compartments separated by a sintered glass disk. As the compound examined displayed comparable voltammetric behaviours on glassy carbon and platinum electrodes, the working electrode used in macroelectrolysis was a large-area platinum gauze, while a platinum spiral served as counter electrode. In controlled-potential electrolyses, an Amel model 552 potentiostat coupled to an Amel model 731 integrator was employed. Unless otherwise stated, voltammetric and coulometric measurements were performed at room temperature using 2 mM $[Au_2(OH)_2(tppz)]Cl_4$ and 0.1 M supporting electrolyte (TBAP) DMF solutions. The cells were degassed with pure nitrogen (99.99%), which was first passed through sulfuric acid solution to remove traces of water and then equilibrated to the vapour pressure of DMF, prior to the measurements.

# Synthesis, Structure and Magnetic Properties of a Tetranuclear Copper(II) Complex on the Basis of a 2-Substituted Glucopyranoside Schiff Base Ligand

**Anja Burkhardt,[a] Axel Buchholz,[a] Helmar Görls,[a] and Winfried Plass*[a]**

*Dedicated to Professor Ernst-Gottfried Jäger on the occasion of his 70th birthday*

**Keywords:** Carbohydrates / Schiff base ligands / Copper(II) complexes / Magnetic properties

Condensation of a derivatized 2-aminoglucose fragment with salicylaldehyde affords the new sugar-based Schiff base ligand benzyl 4,6-*O*-benzylidene-2-deoxy-2-salicylideneamino-α-D-glucopyranoside ($H_2L$). The reaction of the dibasic ligand $H_2L$ with $[Cu(CH_3COO)_2]\cdot H_2O$ leads to the formation of the tetranuclear copper(II) complex $[\{Cu(L)\}_4]$ (**3**) by a self-assembly process. The X-ray structural analysis of complex **3** which crystallizes together with two molecules of chloroform and one molecule of ethanol in the space group $P2_12_12_1$ revealed for all copper atoms a $NO_3$ coordination environment with a square-planar geometry. The tetranuclear molecule **3** consists of four chiral building blocks {Cu(L)} with the rare 2,3-coordination of the *trans*-configured donor atoms of the sugar backbone. The observed coordination mode of the building blocks exemplifies how chitosan-derived polysaccharide ligands can act as a chiral support for transition-metal complexes. The C-3 alcoholate oxygen atoms of the carbohydrate unit is bridging adjacent {Cu(L)} moieties resulting in an eight-membered $Cu_4O_4$ ring with a boat-like conformation. Temperature-dependent magnetic measurements of **3** indicate moderate antiferromagnetic interactions between the four copper(II) ions with a coupling constant of $J = -130\ cm^{-1}$.

## Introduction

Carbohydrates are the most abundant biogenic class of compounds involved in a wide range of functions in living organisms. In case of cellulose, sugars act as scaffolding material in plants. Monosaccharide fragments are participating in glycolipids and glycoproteins and play an important role in various biological processes e.g. as building blocks for nucleotides and of the ADP/ATP energy-storage system.[1] Many sugar-metabolizing enzymes have been revealed to function with alkaline earth and transition metal ions in the active sites.[2–10]

Although the importance of sugar–metal interaction is known for many years, the field of sugar–metal complexes is still largely unexplored. Only for the past two decades, sugars received a growing interest as ligand components in bioorganic chemistry due to their enantiomerically pure natural abundance and their polyfunctionality. The vicinal functional groups feature many donor atoms forming stable chelate complexes.[11–15] Furthermore, carbohydrates combine interesting properties like stable chiral scaffold and supramolecular arrangement. Well-known modification strategies for introducing additional donor groups into the sugar backbone are *N*-glycosylation with polyamines[16–22] and nucleophilic substitution of bromoethyl-*O*-glycosides.[23–28] A further method is the condensation of amino saccharides and carbonyl components resulting in tridentate Schiff base ligands.[29–31]

The corresponding transition-metal complexes show a large tendency for coordinative saturation via coligation or self-assembly to polynuclear compounds by oxo-bridging. Many naturally available copper-containing enzymes like catechol oxidase[32] or ascorbate oxidase[33] exhibit a polynuclear active site. Thus, polynuclear sugar-modified copper(II) complexes are interesting concerning their biorelevance as structural and/or functional models for various metalloenzymes. However, the rare examples described in literature are linear trinuclear and cyclic di- or tetranuclear copper(II) complexes which are based on either C-1 or C-6 amino functionalized carbohydrate fragments.[34–38]

Amino precursors have to be synthesized by *N*-glycosylation or a laborious six-step synthesis with participation of various protecting groups. 2-Aminoglucose is the monomer unit of chitosan which could be obtained from acidic deacetylation of chitin (see Scheme 1). The β-(1-4)-linked polysaccharide is the structural element in the exoskeleton of crustaceans. The vision of creating polymeric catalysts provoked us to more detailed studies of the coordination

## Results and Discussion

### Synthesis and Characterization

Starting from benzyl 2-amino-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside (**1**)[39,40] the Schiff base ligand $H_2L$ (**2**) was prepared by condensation with salicylaldehyde in methanol as depicted in Scheme 2. The synthesized Schiff base ligand **2** was characterized by IR, NMR and ESI-MS studies as well as elemental analysis. The IR band at 1637 $cm^{-1}$ is attributed to the valence vibration of the imino group. In the NMR spectra the corresponding resonances of the imino group are present at $\delta$ = 167.8 ppm ($^{13}C$ NMR) and at $\delta$ = 9.91 ppm ($^{1}H$ NMR). The proton on C-1 of the D-glucose moiety leads to a doublet in the $^{1}H$ NMR spectrum with $^{3}J_{12}$ = 3.7 Hz indicative for the exclusive presence of the α-anomer of the saccharide unit associated with the *cis* position of the protons attached to C-1 and C-2. Due to its hydrophobic phenyl groups the sugar ligand **2** is soluble in less polar solvents.

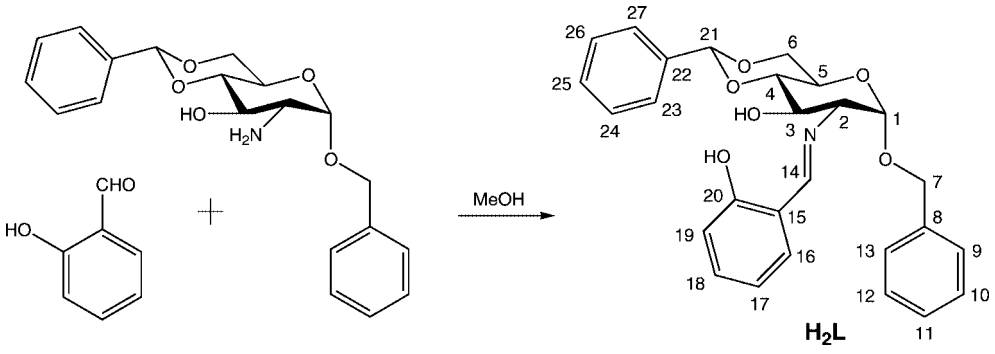
For complexation an aqueous solution of $[Cu(CH_3COO)_2]\cdot H_2O$ was added to a chloroform solution of **2** in a 1:1 molar ratio at room temperature. Ethanol was added under vigorous stirring for homogenization of the generated two-phase system. Slow evaporation of the dark green solution affords crystals of $[\{Cu(L)\}_4]\cdot 2CHCl_3\cdot EtOH$ (**3**·$2CHCl_3$·EtOH) as green prisms after 4 d. Due to its volatility, chloroform is removed first from the reaction mixture leading to an increasing polarity of the remaining solution. Owing to the poor solubility of **3** in polar solvents the formed copper(II) complex can be isolated in very high yields.

In accordance with the molecular ion peaks at 2092 ($[\{Cu(L)\}_4+H]^+$) and 2113 ($[\{Cu(L)\}_4+Na]^+$) obtained from ESI-MS measurements, complex **3** also appears to exist as undissociated tetranuclear species in solution. UV/Vis studies of the green copper(II) complex **3** performed in chloroform solution exhibit two charge–transfer bands at 277 and 370 nm and a third band at 628 nm attributed to a d–d transition. No weight loss can be found up to the decomposition temperature by TGA measurement indicating that all solvent molecules are removed during the air-drying process consistent with the formula $[\{Cu(L)\}_4]$ for complex **3**. This is further corroborated by the results obtained from elemental analysis.

To the best of our knowledge complex **3** is the first tetranuclear transition-metal complex derived from the monomeric chitosan unit 2-aminoglucose. Copper(II) structures on the basis of C-1-salicylidene-functionalized Schiff base ligands of 1-amino-D-sorbitol[35] and 1-amino-4,6-*O*-ethylidene-β-D-glucopyranose[38] have recently been reported. Furthermore, **3** is the first transition-metal complex characterized by X-ray crystallography featuring a *trans*-configured coordination of donor atoms at C-2 and C-3 of the sugar moiety. From literature 2-aminoglucose-derived *cis*-dioxomolybdenum(VI) complexes are known with the metal center coordinated by the imino nitrogen atom and the alcoholate oxygen atom at the anomeric carbon atom C-1.[41]

### Structure Description

Figure 1 shows the molecular structure of the complex $[\{Cu(L)\}_4]$ (**3**) which was found in crystals of **3**·$2CHCl_3$·EtOH. The observed space group $P2_12_12_1$ is consistent with the appearance of only one diastereomer formed by self-assembly of the four neutral mononuclear chiral building blocks {Cu(L)}. Selected distances and angles are given in Table 1. Each copper(II) center is coordinated in a square-planar environment by a phenolate oxygen atom of the salicylidene residue, a nitrogen atom of the C-2 imino group and a C-3 alcoholate oxygen atom of the sugar backbone. The fourth position is occupied by an additional C-3 alcoholate group from an adjacent sugar unit.



Scheme 2. Reaction scheme for the synthesis of ligand $H_2L$ (**2**).

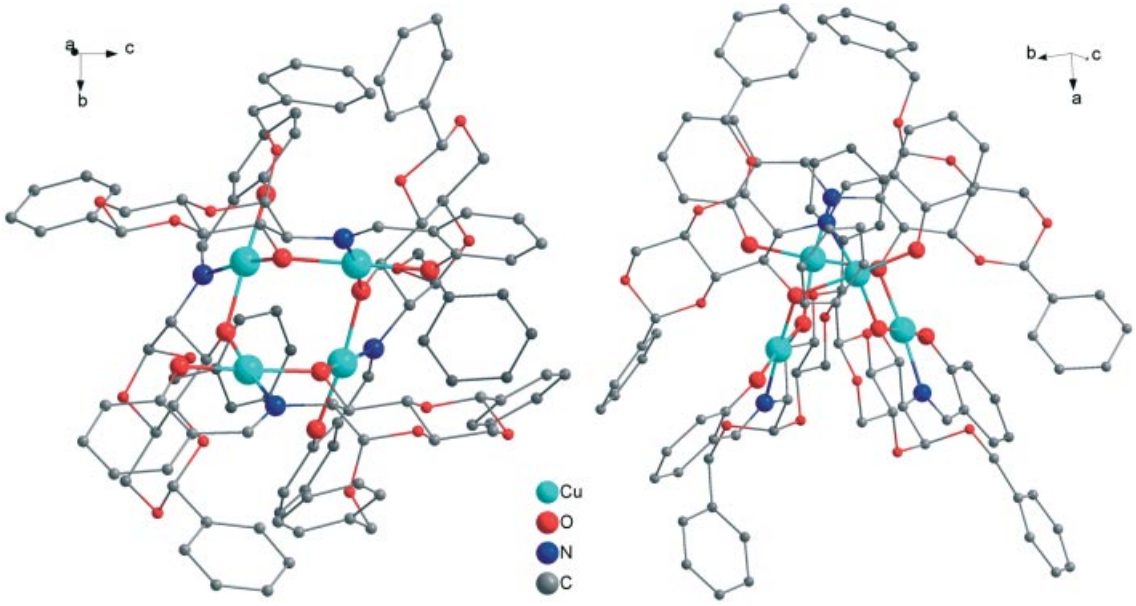

Figure 1. Molecular structure of [{Cu(L)}$_4$] (**3**) in crystals of **3**·2CHCl$_3$·EtOH. Solvent molecules and hydrogen atoms are omitted for clarity. (left) View approximately along the pseudo $S_4$ axis of the central Cu$_4$ tetrahedron. (right) Side view, indicating the boat-like conformation of the Cu$_4$O$_4$ metallocycle.

All 2-aminoglucose moieties adopt the more stable $^4C_1$ chair conformation. The copper(II) centers are included well in each NO$_3$ coordination plane with deviations less than 0.05 Å from the corresponding mean planes. The N–Cu–O and O–Cu–O angles are varying from 83.9 to 94.5° and from 170.5 to 177.1°, which is consistent with a slightly distorted square-planar geometry at the copper atoms.

The tetranuclear complex **3** is formed by a self-assembly process of four chiral building blocks {Cu(L)}, with the C-3 alcoholate oxygen atoms being the bridging links between adjacent {Cu(L)} moieties. The resulting eight-membered Cu$_4$O$_4$ ring depicted in Figure 2 is folded in a boat-like conformation. The metal centers occupy the vertices of a distorted tetrahedron which is bisected by the distorted tetragonal plane [torsion angle $\tau$(O13–O23–O33–O43) = 51.8°] composed of the linker alcoholate oxygen atoms O*i*3 (*i* is the running number assigned to the {Cu(L)} moieties) with its normal vector almost collinear to the pseudo $C_2$ axis of the [{Cu(L)}$_4$] molecule. This results in a non-coplanar orientation of the coordination planes of the four {Cu(L)} moieties given by Cu*i*, N*i*, O*i*3, O*i*6 and O*j*3 (*i* and *j* are the running numbers of the {Cu(L)} moieties). The angles between adjacent planes are ranging from 68.4 to 88.9°, whereas the angles between opposite planes are 43.0 (Cu1 and Cu3) and 45.7° (Cu2 and Cu4).

In accordance with the Cu*i*–O*i*3 distances ranging from 1.917 to 1.957 Å the C-3 alcoholate groups are deprotonated affording a dianionic ligand unit and finally complex **3** as a neutral species. All bond lengths and angles of complex **3** are in the expected range (see Table 1). Unlike the square-planar coordination found for the metal centers in **3**, the only two other sugar-based tetranuclear copper(II) complexes described in literature[35,38] exhibit a square-pyramidal coordination environment at the copper(II) ions. In the latter cases, the apical position is occupied by an additional alcoholate group from the sugar backbone. The absence of an auxiliary accessible donor function in H$_2$L (**2**) may be the reason for the observed coordination number four in complex **3**. Unsaturated copper(II) centers are interesting with respect to catalysis due to a possible substrate binding at the unoccupied fifth position.

## Magnetic Properties

Magnetic susceptibility measurements of powder samples of **3** were carried out in the temperature range of 2–300 K at an applied magnetic field of 500 Oe. The magnetic data are represented as $\chi_M$ vs. $T$ and $\chi_M T$ vs. $T$ plots in Figure 3. The molar paramagnetic susceptibility $\chi_M$ is corrected for the diamagnetic contributions using Pascal's constants. $\chi_M$ goes through a maximum at about 150 K and is increasing again below 25 K due to the presence of paramagnetic impurities. The observed low-temperature value of $\chi_M T$ is in accordance with an $S = 0$ ground state of **3**. The high-temperature value of 1.41 $cm^3 K mol^{-1}$ at 300 K is slightly below the expected spin-only value for four independent copper(II) ions. The temperature dependence of $\chi_M T$ clearly indicates antiferromagnetic exchange interactions within the tetranuclear core of complex **3**.

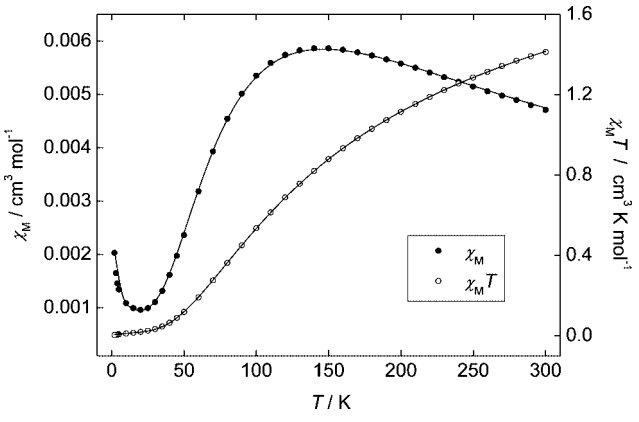

Figure 3. Plots of $\chi_M$ vs. $T$ (●), $\chi_M T$ vs. $T$ (○) for **3**. The solid lines represent the best fit to the experimental data (see text).

On the basis of the Cu···Cu distances ranging from 3.39 to 3.88 Å and the unfavorable relative orientations of the copper coordination planes, direct interactions between the metal centers are not very likely. Therefore, the prominent interaction is most likely superexchange through the alcoholate bridges. In the majority of cases the central $Cu_4O_4$ unit of tetranuclear copper(II) complexes exhibits a cubane-like structure treated as a dimer of $Cu_2O_2$ fragments. In complex **3** the $Cu_4O_4$ metallocyclic core unit adopts the unusual boat-like conformation found for only two other magnetically studied examples.[35,42]

Because of the similarity of the Cu*i*–O*i*3 distances ranging from 1.917 to 1.957 Å and the Cu*i*–O*i*3–Cu*j* bridging angles ranging from 121.2 to 127.3°, only one coupling constant $J$ is employed. This assumption is confirmed by the obtained quality of the best fit (solid lines in Figure 3) on the basis of the Heisenberg spin Hamiltonian given in Equation (1)[43] to the experimental data, which results in a coefficient of determination of $r^2 = 0.99999$. The fit parameters $g = 2.15$, $J = -130\ cm^{-1}$, $\rho = 0.0024$ and $\chi_{TIP} = 6.9 \cdot 10^{-4}\ cm^3 mol^{-1}$ were obtained by least-square methods utilizing Equation (2) ($\chi_{TIP}$ = temperature-independent paramagnetism). To account for small amounts of paramagnetic impurity in the sample indicated by the $\chi_M$ vs. $T$ plot, the additional constant $\rho$ (fraction of paramagnetic impurity) was included in Equation (2). The contributions of $\rho$ become significant at temperatures below 20 K.

$$H = -J\,(S_1 S_2 + S_2 S_3 + S_3 S_4 + S_1 S_4) \tag{1}$$

$$\chi_M \cdot T = \frac{2Ng^2\beta^2}{k}\left[(1-\rho)\left(\frac{e^{\frac{J}{kT}} + 2e^{\frac{2J}{kT}} + 5e^{\frac{3J}{kT}}}{1 + 3e^{\frac{J}{kT}} + 7e^{\frac{2J}{kT}} + 5e^{\frac{3J}{kT}}}\right) + \frac{\rho}{2}\right] + \chi_{TIP} \cdot T \tag{2}$$

For dinuclear copper complexes with a planar $Cu_2O_2$ core magneto-structural correlations between the Cu–O(R)–Cu bridging angle ($\alpha$) and the singlet-triplet splitting ($J$) have been reported depending on the nature of the bridging unit (R = H, alkyl, aryl).[44] On the basis of the Cu*i*–O*i*3–Cu*j* bridging angles observed for complex **3**, ranging from 121 to 127°, the relationship found for alcoholate-bridged copper(II) complexes ($J = 82.1\alpha - 7857$) would estimate a very strong antiferromagnetic interaction of about 2000 $cm^{-1}$, which is a rather poor prediction. Although this difference may be related to the variation of the number of bridges, this cannot account for the overall effect. More important is the fact that for planar $Cu_2O_2$ arrangements the bridging angle is a sufficient parameter to describe the interaction of the magnetic orbitals based on their given coplanar orientation, whereas this is not the case for complexes with single alcoholate bridges. Therefore, additional parameters are essential in order to describe the relative orientation of the magnetic orbitals for systems with single alcoholate bridges, as found in the case of complex **3**. An important structural feature in this context is the torsion angle between adjacent copper coordination planes.[45] For complex **3** the relevant torsion angles range from 68 to 89°. This missing coplanarity of the adjacent Cu coordination planes is associated with poor overlap of the magnetic orbitals.[46] Hence, this can explain the comparatively low value of $J$ observed for complex **3**.

## Conclusions

The reaction of the sugar-derived Schiff base ligand $H_2L$ (**2**), obtained from the condensation of benzyl 2-amino-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside (**1**) and salicylaldehyde, with $[Cu(CH_3COO)_2]\cdot H_2O$ affords the tetranuclear complex $[\{Cu(L)\}_4]$ (**3**) by a self-assembly process of the chiral building blocks {Cu(L)}. The structure determination by X-ray crystallography revealed the exclusive presence of square-planar coordination environments for the copper(II) ions, which to the best of our knowledge is as yet unprecedented in literature for oligonuclear complexes with sugar-derived Schiff base ligands. The square-planar coordination of the copper centers is given by a phenolate oxygen atom of the salicylidene residue, a nitrogen atom of the C-2 imino group and a C-3 alcoholate oxygen atom of the sugar backbone as well as the bridging C-3 alcoholate oxygen atom of the adjacent {Cu(L)} building block. The four adjacent {Cu(L)} moieties are linked by the C-3 alcoholate oxygen atoms resulting in an eight-membered $Cu_4O_4$ metallocycle adopting a boat-like conformation. This is uncommon for such a tetranuclear oxygen atom bridged core unit, for which usually a cubane-like structure is observed. Magnetic studies of complex **3** show moderate antiferromagnetic interactions between the copper(II) centers with a coupling constant of $J = -130\ cm^{-1}$. Regarding to the obtuse Cu*i*–O*i*3–Cu*j* bridging angles of more than 120° much larger exchange interactions would be predicted on the basis of magneto-structural correlations derived from binuclear complexes. This is mainly because of the missing coplanarity of the adjacent Cu coordination planes and hence the magnetic orbitals. As first example for 2-amino sugar-derived transition-metal complexes exhibiting a 2,3-coordination of the *trans*-configured donor atoms of the sugar backbone, **3** provides useful insight to the opportunity of constructing polysaccharide-based coordination compounds, in particular chitosan-derived polymer complexes.

## Experimental Section

**Material:** The precursor ligand benzyl 2-amino-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside (**1**) was obtained by a three-step synthesis starting from *N*-acetyl-α-D-glucopyranosamine following reported procedures.[39,40] All other chemicals were purchased from commercial suppliers and used without further purification.

**Physical Measurements:** Melting points are given uncorrected and were determined with a VEB Analytik Dresden HMK 72/41555. Thermogravimetric analysis (TGA) for powdered samples was performed with a Netzsch STA409PC Luxx apparatus under constant flow of nitrogen ranging from room temperature up to 1000 °C with a heating rate of 1 °C/min. Infrared and Raman spectra were recorded with a Bruker IFS55/EQUINOX spectrometer. $^1H$ and $^{13}C$ NMR experiments were carried out with a Bruker AVANCE DRX 400 spectrometer. The exact interpretation was accomplished by additional two-dimensional experiments. For the labeling scheme see Scheme 2. UV/Vis spectra were recorded with a Varian CARY 5000 UV/Vis-NIR spectrometer. Mass spectra were measured with a Bruker MAT SSQ 710 spectrometer. Elemental analyses were determined with a Leco CHNS/932 elemental analyzer and a VARIO EL III. Magnetic susceptibilities were obtained from powdered samples using a Quantum-Design MPMSR-5S SQUID magnetometer equipped with a 5-Tesla magnet in the range from 300 to 2 K. The diamagnetic correction of the sample was estimated from Pascal's constants.

**Crystallographic Study:** Crystallization of complex **3** from a mixture of chloroform, ethanol and water afforded green prismatic crystals of $[\{Cu(L)\}_4]\cdot 2CHCl_3\cdot EtOH$ (**3**·$2CHCl_3$·EtOH) suitable for X-ray measurements. Single crystals were selected while still covered with mother liquor under a polarizing microscope and fixed on fine glass fibers. X-ray measurements were carried out with a Nonius Kappa CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda = 0.71073$ Å). The crystallographic data is summarized in Table 2. The structure was solved by direct methods with SHELXS-97[47] and was full-matrix least-squares refined against $F^2$ using SHELXL-97.[47] The refinement afforded a Flack parameter of 0.004(8). Anisotropic thermal parameters were used for all non-hydrogen atoms except the ethanol solvent molecules. Hydrogen atoms were calculated and treated as riding atoms with fixed thermal parameters. CCDC-602321 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Centre via www.ccdc.cam.ac.uk/data-request/cif.

# Designed Assembly and Structures and Photoluminescence of a New Class of Discrete $Zn^{II}$ Complexes of 1*H*-1,10-Phenanthroline-2-one

**Jie-Peng Zhang,[a] Yan-Yong Lin,[a] Xiao-Chun Huang,[a] and Xiao-Ming Chen*[a]**

**Keywords:** Zinc / Cluster compounds / Metallacycles / Photoluminescence / Solvothermal synthesis

The hydrothermal reaction of 1*H*-1,10-phenanthroline-2-one (Hophen), zinc acetate, benzoic acid (Hba), and triethylamine (3.0 mL) yields the tetranuclear complex $[Zn_4(\mu_3\text{-}OH)_2(ophen)_4(ba)_2]$ (**2**), which features a chair-like $Zn_4(\mu_3\text{-}OH)_2$ cluster with two ba ligands centrosymmetrically oriented. $[(OAc)\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(ox)\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(OAc)]$ (**3**; ox = oxalate) was isolated when less triethylamine (1.0 mL) was used. Two $Zn_3(\mu_3\text{-}OH)(ophen)_3$ clusters in **3** are linked together by an oxalate to form a dumbbell-like structure in which the acetate and oxalate ligands point outward from the $Zn_3(\mu_3\text{-}OH)(ophen)_3$ cluster with an acute bending angle. A geometric analysis reveals that $Zn_3(\mu_3\text{-}OH)(ophen)_3$ and dicarboxylate with an obtuse bending angle cannot form an infinite zigzag chain, whereas the ring isomer can. With isophthalate (ipa), thiophene-2,5-dicarboxylate (tda), and 4,4′-oxybis(benzoate) (oba) instead of the acetate of **3** three new complexes, namely $[\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(ipa)_2\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}]\cdot 0.5H_2O$ (**4**), $[\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(tda)_2\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}]$ (**5**), and $[\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(oba)_2\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}]$ (**6**), were obtained in which two $Zn_3(\mu_3\text{-}OH)(ophen)_3$ clusters are linked by a pair of ipa, tda, or oba ligands to form isostructural, cluster-based 2:2 metallomacrocycles. Photoluminescence studies of **2**–**6** revealed that their luminescent properties are derived from ophen-based $\pi\text{-}\pi^*$ excited states.

## Introduction

The rational design of supramolecular metal–organic compounds has received considerable attention. Due to the lack of control over the self-assembly of individual metal ions or ligands, chemists have introduced metal clusters as molecular building blocks as they offer greater structural rigidity and predictable coordination geometries.[1] This strategy has been successfully combined with net-based or reticular approaches to assemble many pre-designed cluster-based coordination polymers,[2] and has recently been extended to discrete metal–organic polyhedra.[3] Discrete metal–organic polygons and polyhedra have been widely studied[4] and continue to be one of the most interesting research topics.[3,5–9] Generally, the vertices or the edges of these polygons and polyhedra are occupied by single metal ions such as *cis*-protected $Pt^{II}$ and $Pd^{II}$,[4–7] while reported cluster-based polygons or polyhedra are rare.[3,8,9] Systematic studies of cluster-based polygons have mainly been concerned with *cis*-protected $Mo_2^{4+}$ and $Rh_2^{4+}$ dimetal units.[8] It should be noted that common metal clusters can possess more than two leaving groups, for example there are six substitutable acetates in $[Zn_4O(OAc)_6]$, whereas a polygon requires uniquely two-connected building blocks. Therefore, known cluster-based metal–organic polygons are extremely rare, especially for trinuclear or larger metal clusters. In this context, the key strategy for the rational construction of cluster-based polygons is to select metal clusters with only two substitutable monotopic ligands.

Another problem in the controlled assembly of metal–organic polygons comes from the phenomenon of supramolecular isomerism. Both polygons and infinite zigzag chains as possible extended superstructures can be obtained for a given set of two-connected angular and/or linear molecular building blocks.[10] The kinetically favored infinite framework structures are usually the dominant species for highly insoluble metal–organic systems, especially those neutral ones such as metal polyazolates/polycarboxylates. Therefore, the reaction conditions should also be controlled to avoid the formation of infinite chain isomers.

Recently, we discovered a novel chelating/bridging ligand, namely 1*H*-1,10-phenanthroline-2-one (Hophen), which tends to form polynuclear metal clusters such as $[Cu_2(ophen)_2]$,[11] $[Cd_3(ophen)_5Cl]$, and $[Zn_4(\mu_4\text{-}O)(ophen)_4(OAc)_2]$ (**1**).[12] Obviously, the two acetate ligands located on two opposite sides of the centrosymmetric cluster of **1** might be substituted by angular dicarboxylates to form infinite chains or finite rings. Unfortunately, our preliminary trials of substituting the acetates in **1** by dicarbox-

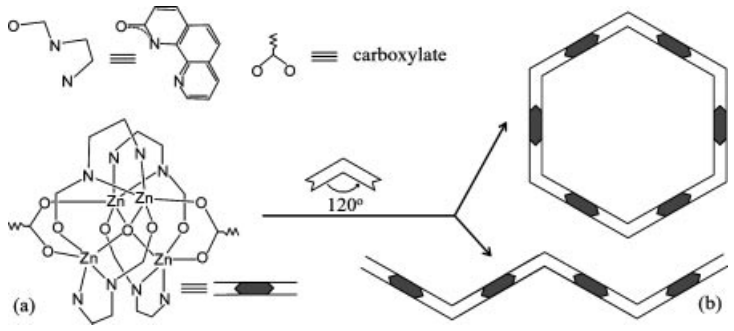

Scheme 1. Simplification of **1** as a linear two-connected building block (a) and two typical supramolecular isomers formed by using a bent dicarboxylate to substitute the two acetates of **1** (b).

ylates failed. From a geometrical point of view, centrosymmetric $Zn_4(\mu_4\text{-}O)(ophen)_4$ is a linear two-connector since the two acetates are located on two opposite sides of the $Zn_4(\mu_4\text{-}O)$ core. When a common rigid angular dicarboxylate such as isophthalate is used, the hypothetical cluster-based hexagonal ring of $Zn_4(\mu_4\text{-}O)(ophen)_4$ should be expected. Similar to the approaches for copper(I) imidazolate rings,[6a] the inner cavity of this hexagon is too large for common templates. Although we can use dicarboxylates with smaller bending angles (much smaller than 120°) to reduce the difficulty, such rigid angular dicarboxylates are not readily available. Alternatively, we can also shift our attention to reducing the bending angle by modifying the $Zn^{II}$ cluster.

Since acidity can play an important role in controlling the degree of aggregation and the structure of oxo/hydroxo-bridged $Zn^{II}$ clusters, we anticipated being able to synthesize new $Zn^{II}$ clusters by varying the reaction conditions, especially the pH. Simple carboxylates like acetate and benzoate were used as the potential leaving groups. Herein, we report our step-by-step approach toward the rational design and synthesis of a new series of cluster-based metallacycles (Scheme 1).

## Results and Discussion

### Synthesis and Structure

We first obtained the discrete, tetranuclear cluster $[Zn_4(\mu_3\text{-}OH)_2(ophen)_4(ba)_2]$ (**2**; ba = benzoate) using triethylamine (3.0 mL) as base, while the oxo-bridged **1** was synthesized by using the very strong base $NaOCH_3$. The four $Zn^{II}$ ions of **2** are bridged by two $\mu_3$-$OH^-$ groups [Zn–O1 1.932(2)–2.018(2) Å] to form a centrosymmetric, chair-like $Zn_4(\mu_3\text{-}OH)_2$ core. The $Zn^{II}$ ions are also chelated by the bipyridyl fragments of ophen ligands [Zn–N 2.028(2)–2.127(2) Å] (Figure 1). The ketone oxygen atoms of the ophen ligands further bridge the $Zn_4(\mu_3\text{-}OH)_2$ core either by coordinating to $Zn^{II}$ ions [Zn1–O3 2.018(2) Å] or by hydrogen bonding to the hydroxo groups (O1···O2 2.562(2) Å, O1–H···O2 166(3)°]. The outer $Zn^{II}$ ions are further coordinated by ba ligands in a chelating mode [Zn2–O4 2.247(2), Zn2–O5 2.088(2) Å]. According to the above discussion, **2** is not a good candidate for the construction of cluster-based metallacycles as the ba ligands are oriented centrosymmetrically, as in **1**.

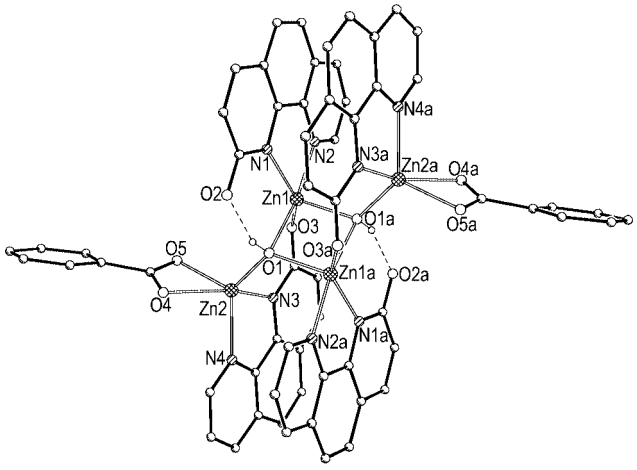

Figure 1. Perspective view of the molecular structure of **2** (a: $-x$, $1-y$, $-z$).

The chair-like $Zn_4(\mu_3\text{-}OH)_2$ cluster is composed of two edge-sharing triangular $Zn_3(\mu_3\text{-}OH)$ clusters. One may expect that changing the pH value would either prevent or promote the expansion of the $Zn_3(\mu_3\text{-}OH)$ cluster, and consequently modify the size and symmetry of the $Zn^{II}$ cluster. For example, $Zn_4(\mu_4\text{-}O)$ or $Zn_5(\mu_3\text{-}OH)_2$ might be generated at higher pH, while $Zn_3(\mu_3\text{-}OH)$ might be generated at lower pH. When the experiments were carried out using less triethylamine (1.0 mL), we managed to isolate several new complexes with the expected $Zn_3(\mu_3\text{-}OH)(ophen)_3$ clusters. A discrete, hexanuclear complex $[(OAc)\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(ox)\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(OAc)]$ (**3**; ox = oxalate) was isolated in 20% yield by the solvothermal reaction of $Zn(OAc)_2$, Hophen, triethylamine, and benzoic acid in water. We subsequently found that **3** could also be synthesized in a higher yield (40%) in the absence of benzoic acid. The $Zn_3(\mu_3\text{-}OH)$ cluster in **3** [Zn–O1 1.983(2)–2.037(2) Å] replicates part of the $Zn_4(\mu_3\text{-}OH)_2$ core in **2**. Each of the three $Zn^{II}$ ions is also chelated by a corresponding ophen ligand through its bipyridyl fragment [Zn–N 2.062(2)–2.193(2) Å]. Each ketone oxygen atom of the ophen ligands further ligates another $Zn^{II}$ ion [Zn–O 1.962(2)–2.125(2) Å]. An acetate ligand coordinates to the outer sphere of $Zn_3(\mu_3\text{-}OH)(ophen)_3$ by ligation to the $Zn^{II}$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ion [Zn–O 2.053(2) Å] and hydrogen bonding to the hydroxy ion (O1···O8 2.594(3) Å, O1–H···O8 170(3)°]. Finally, two $\{Zn_3(\mu_3\text{-OH})(phen)_3\}(OAc)$ moieties are linked by a bis-chelating, *exo*-tetradentate oxalate ligand [Zn–O 2.011(2)–2.169(2) Å]. This unexpected oxalate ligand must be derived from an acetate since no oxalic acid or oxalate was added. An oxalate ligand can be generated by oxidation of ethanol or oxidative coupling of methanol under solvothermal conditions using nitrate as the oxidant.[13] It has also been reported that oxalate can be generated by the decarboxylative coupling of isonicotinates under solvothermal conditions.[14] Since no obvious oxidant was added in our experiment, we believe that the oxalate in **3** might be derived from the decarboxylative coupling of an acetate (Figure 2).

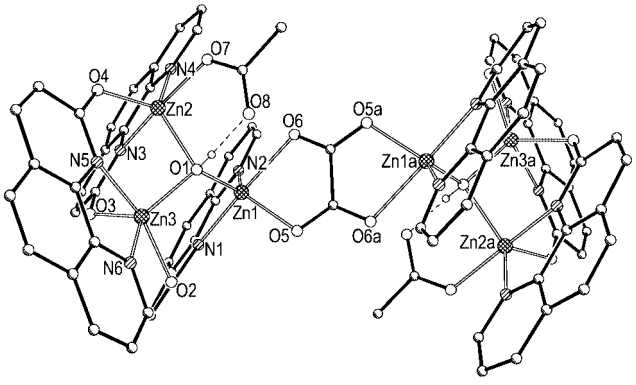

Figure 2. Perspective view of the molecular structure of **3** (a: $-x$, $-y$, $1 - z$).

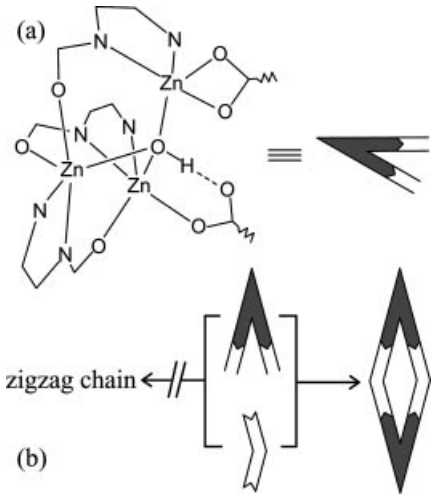
Two carboxylate vectors ($OAc^-$ and $ox^{2-}$) in **3** point outward from $Zn_3(\mu_3\text{-OH})(phen)_3$ with a bending angle of around 30° (or turning angle of around 150°). Therefore, we can construct a 2:2 cluster-based metallacycle by substituting the carboxylates by dicarboxylates with a bending angle of about 150° (or turning angle of about 30°). Interestingly, these two types of two-connected molecular building blocks, which individually contain an acute or an obtuse bending angle, cannot be self-assembled into an infinite zigzag chain, as illustrated in Scheme 1. Geometrically, this phenomenon can be explained by considering the geometric criteria for these isomers. For the ring isomers, the overall turning angle is equal to $360° = n(x + y)$ ($x \geq 0$, $y \geq 0$, $x \neq y$, $n \geq 2$), whereas for the zigzag chain isomers the overall turning angle is equal to $0° \neq n(x - y)$ ($x \geq 0$, $y \geq 0$, $x \neq y$, $n \geq 2$), where $x$ and $y$ are the turning angles of the molecular building blocks and $n$ is the number of repeat units. In other words, a finite ring-like structure would be much more easily obtained in such a self-assembly system because it does not contain infinite zigzag chain isomers (Scheme 2).

We therefore used isophthalate (ipa), thiophene-2,5-dicarboxylate (tda), and 4,4′-oxybis(benzoate) (oba) as the obtuse dicarboxylates to replace the acetate and oxalate. Three new, isostructural, centrosymmetric, cluster-based metallacycles, namely $[\{Zn_3(\mu_3\text{-OH})(phen)_3\}(ipa)_2\{Zn_3(\mu_3\text{-OH})(phen)_3\}]\cdot 0.5H_2O$ (**4**), $[\{Zn_3(\mu_3\text{-OH})(phen)_3\}(tda)_2\{Zn_3(\mu_3\text{-OH})(phen)_3\}]$ (**5**), and $[\{Zn_3(\mu_3\text{-OH})(phen)_3\}(oba)_2\{Zn_3(\mu_3\text{-OH})(phen)_3\}]$ (**6**), were obtained in high yields under solvothermal conditions similar to that of **3**. It should be noted that no zigzag chain isomer or other crystalline product was isolated in these experiments (Figure 3).



Scheme 2. Simplification of the $Zn_3(\mu_3\text{-OH})(phen)_3$ cluster as an angular building block (a) and possible extended structures for combining two different types of angular building blocks (b).

The $Zn_3(\mu_3\text{-OH})(phen)_3$ clusters in **4**–**6** are isostructural to that of **3** with similar structural parameters [Zn–OH 1.950(1)–2.059(1), Zn–N 2.022(2)–2.177(2), $Zn–O_{ophen}$ 1.968(2)–2.196(2) Å], while the acetate and oxalate ligands in **3** are now replaced by dicarboxylate ligands. The coordination/hydrogen-bonding mode of the carboxylate group of the acetate in **3** is retained in **4**–**6** [Zn2–O7a 2.042(2)–2.056(2), O1···O8a 2.613(2)–2.668(3) Å; O1–H···O8a 160(3)–168(3)°]. The stable five-membered chelating mode of the oxalate in **3** is not available for ipa, tda, or oba, and is replaced by four-membered chelating carboxylate groups in **4**–**6**. Two Zn–O bond lengths of the chelating carboxylate groups in **4**–**6** show remarkable structure-related differences. Two carboxylate groups in an ipa moiety are oriented with a bending angle of about 120°, which is significantly smaller than the required angle of 150°. This structural deviation is compensated for by distorting the very energetically stable, ideal chelating carboxylate to a quasi-monodentate one [Zn1–O5 1.946(2), Zn1–O6 2.560(2) Å]. On the other hand, two carboxylate groups in tda are oriented with a bending angle of about 140°, and the difference in the Zn–O bond lengths in **5** [Zn1–O5 2.039(2), Zn1–O6 2.283(2) Å] is much smaller than that in **4**. A short intramolecular S···S contact [3.461(2) Å] is also found in **5**. Furthermore, the bending angle of oba (ca. 130°) and the difference in Zn–O bond lengths in **6** [Zn1–O5 2.002(2), Zn1–O6 2.366(2) Å] lies between those of ipa and tba.

Two $Zn_3(\mu_3\text{-OH})(phen)_3$ clusters are linked by different dicarboxylates to give nanosized supermolecules. According to the lengths of the dicarboxylates, the sizes of **3**–**6** vary from 1.76 to 2.15, 2.20, and 2.72 nm, respectively. Similar to **1**, intermolecular, head-to-tail π-π stacking interactions are the major supramolecular interactions between the dis-

crete molecules in **2**–**6**. Significant intramolecular, head-to-head π-π stacking interactions are also found in **1**–**6**. Although **2**–**6** are discrete, neutral molecules, they are barely soluble in common solvents. This interesting phenomenon has also been observed in other solvothermally synthesized discrete complexes and may be partially ascribed to the significant three-dimensional packing of the molecules (see Supporting Information).

## Photoluminescence

Compounds **2**–**6** display bright blue to green photoluminescence upon UV irradiation. The photoluminescence parameters of **2**–**6** are summarized in Table 1 and the emission and excitation spectra of **2**–**6** are shown in Figure 4. The solid-state photoluminescent properties of **2**–**6** are very similar to those of **1**,[12] thus implying that the carboxylate ligands may not influence the nature or energy of the luminescence-related electronic ground state or excited state. The carboxylate ligands in **1**–**6** have much smaller π-conju-

Table 1. Photoluminescence properties of **2**–**6**.

| | Excitation [nm] | Emission [nm] | Lifetime [ns] |
|---|---|---|---|
| **2** | 383 sh, 402 sh, 418 | 487 | 3.43(5) |
| **3** | 375, 404 sh | 464 | 3.58(4) |
| **4** | 383, 402 sh, 409 sh | 468 | 6.97(1) |
| **5** | 383, 401 sh, 413 | 469 | 7.70(2) |
| **6** | 376, 393 sh, 406 | 477 | 7.57(4) |

gated systems than that of the ophen ligand, therefore the lowest lying HOMO–LUMOs should be mainly localized on the ophen ligand, which results in an ophen-based π-π* excitation mechanism. Compared with that of oxo-bridged **1** (15 ns), the shorter luminescence lifetime of **2**–**6** (3.4–7.7 ns) may be attributed to the quenching effect of the OH stretch.

## Conclusions

Based on geometrical considerations and a strategy of controlling the reaction condition, we have successfully synthesized a new series of cluster-based metallacycles. Our results demonstrate that the degree of aggregation of the hydroxy- or oxo-bridged Zn–ophen cluster can be simply controlled by varying the reaction conditions, generating $[Zn_4(\mu_4\text{-}O)(ophen)_4]^{2+}$, $[Zn_4(\mu_3\text{-}OH)_2(ophen)_4]^{2+}$, or $[Zn_3(\mu_3\text{-}OH)(ophen)_3]^{2+}$ from very high (NaOMe) to relatively low basicity (triethylamine). Although the above Zn clusters are potential candidates for the construction of cluster-based metallacycles, we have demonstrated that $[Zn_3(\mu_3\text{-}OH)(ophen)_3]^{2+}$, which binds two carboxylate groups in an acute angle, can easily form 2:2 metallacycles with different dicarboxylate ligands with obtuse bending angles. The self-assembly principle has been rationalized in the context of supramolecular isomerism, in which the infinite zigzag chain isomer is excluded by the geometrical requirements of the molecular building blocks. Owing to its tendency to form metal clusters, ophen may be an excellent ligand for paramagnetic transition metal ions to form metal clusters of significance in molecular magnetism.

## Experimental Section

**General Remarks:** Commercially available reagents were used as received without further purification. Hophen was prepared by our previously reported method.[12] IR spectra were obtained from KBr pellets on a Bruker EQUINOX 55 FT IR spectrometer in the 400–4000 $cm^{-1}$ region. Elemental analyses (C, H, N) were performed with a Perkin–Elmer 240 elemental analyzer. The steady-state fluorescent and fluorescence lifetimes were determined with an Edinburgh Instrument FLS920 fluorescence spectrophotometer. Single-crystal samples were used in photoluminescence analyses.

**Synthesis of $[Zn_4(\mu_3\text{-}OH)_2(ophen)_4(ba)_2]$ (2):** Reaction of a mixture of $Zn(OAc)_2{\cdot}2H_2O$ (0.220 g, 1.0 mmol), Hophen (0.196 g, 1.0 mmol), benzoic acid (0.060 g, 0.5 mmol), triethylamine (3.0 mL), and water (10.0 mL) in a 23-mL Teflon-lined bomb at 160 °C for 80 h afforded yellow, block-like crystals (yield: 0.20 g, 60%). $C_{62}H_{40}N_8O_{10}Zn_4$ (1318.6): calcd. C 56.47, H 3.06, N 8.50; found C 56.34, H 3.09, N 8.39. IR: $\tilde{\nu}$ = 3059 $cm^{-1}$ w, 1624 s, 1593 s, 1560 s, 1534 s, 1483 s, 1391 s, 1313 w, 1136 m, 845 s, 723 m, 657 m, 473 w.

**Synthesis of $[(OAc)\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(ox)\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(OAc)]$ (3):** Reaction of a mixture of $Zn(OAc)_2{\cdot}2H_2O$ (0.220 g, 1.0 mmol), Hophen (0.196 g, 1.0 mmol), triethylamine (1.0 mL), and water (10.0 mL) in a 23-mL Teflon-lined bomb at 160 °C for 80 h afforded yellow, block-like crystals (yield: 0.12 g, 40%). $C_{76}H_{44}N_{12}O_{16}Zn_6$ (1773.6): calcd. C 51.47, H 2.50, N 9.48; found C 51.36, H 2.54, N 9.40. IR: $\tilde{\nu}$ = 3409 $cm^{-1}$ w, 3057 w, 2921 w, 1652 s, 1624 s, 1560 s, 1526 s, 1481 s, 1389 s, 1309 m, 1138 m, 943 w, 846 s, 734 m, 659 m, 496 m.

**Synthesis of $[\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(ipa)_2\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}]{\cdot}0.5H_2O$ (4):** Reaction of a mixture of $Zn(OAc)_2{\cdot}2H_2O$ (0.220 g, 1.0 mmol), Hophen (0.196 g, 1.0 mmol), isophthalic acid (0.041 g, 0.25 mmol), triethylamine (1.0 mL), and water (10.0 mL) in a 23-mL Teflon-lined bomb at 160 °C for 80 h afforded yellow, block-like crystals (yield: 0.19 g, 80%). $C_{88}H_{53}N_{12}O_{16.5}Zn_6$ (1934.8): calcd. C 54.63, H 2.76, N 8.69; found C 54.67, H 2.68, N 8.72. IR: $\tilde{\nu}$ = 3411 $cm^{-1}$ w, 3057 w, 1624 s, 1561 s, 1528 s, 11484 s, 1388 s, 1307 w, 1140 w, 944 w, 846 s, 737 m, 657 m, 496 w.

**Synthesis of $[\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(tda)_2\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}]$ (5):** Reaction of a mixture of $Zn(OAc)_2{\cdot}2H_2O$ (0.220 g, 1.0 mmol), Hophen (0.196 g, 1.0 mmol), thiophene-2,5-dicarboxylic acid (0.043 g, 0.25 mmol), triethylamine (1.0 mL), and water (10.0 mL) in a 23-mL Teflon-lined bomb at 160 °C for 80 h afforded yellow, block-like crystals (yield: 0.16 g, 65%). $C_{84}H_{48}N_{12}O_{16}S_2Zn_6$ (1937.8): calcd. C 52.06, H 2.50, N 8.67, S 3.31; found C 52.17, H 2.51, N 8.59; S 3.18. IR: $\tilde{\nu}$ = 3421 $cm^{-1}$ w, 3059 w, 1624 s, 1563 s, 1526 s, 1482 s, 1391 s, 1141 w, 943 w, 846 s, 735 m, 656 w, 498 w.

**Synthesis of $[\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}(oba)_2\{Zn_3(\mu_3\text{-}OH)(ophen)_3\}]$ (6):** Reaction of a mixture of $Zn(OAc)_2{\cdot}2H_2O$ (0.220 g, 1.0 mmol),

**X-ray Crystallographic Study:** Diffraction intensities were collected at 293(2) K on a Bruker Smart APEX CCD area-detector diffractometer (Mo-$K_\alpha$, $\lambda$ = 0.71073 Å). Absorption corrections were applied by using the multi-scan program SADABS.[15] The structures were solved by direct methods and refined with a full-matrix least-squares technique with the SHELXTL program package.[16] Anisotropic thermal parameters were applied to all non-hydrogen atoms. The organic hydrogen atoms were generated geometrically (C–H: 0.96 Å); hydroxy hydrogen atoms were located from difference maps and refined with isotropic temperature factors. Crystal data as well as details of data collection and refinements for the complexes are summarized in Table 2.

CCDC-291301 to -291305 (for **2**–**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# In situ HT-XRD Study on the Formation of Hexagonal Ammonium Tungsten Bronze by Partial Reduction of Ammonium Paratungstate Tetrahydrate

**Imre Miklós Szilágyi,*[a] Ferenc Hange,[b] János Madarász,[a] and György Pokol[a]**

**Keywords:** Tungsten / Reduction / In situ studies / X-ray diffraction / X-ray photoelectron spectroscopy / Solid-state $^1$H NMR spectroscopy

Hexagonal ammonium tungsten bronze, $(NH_4)_{0.33-x}WO_{3-y}$, is a possible constituent of the intermediate "tungsten blue oxide" in non-sag (NS) tungsten production and a material of chromogenic and sensor interest. Its formation has been studied by in situ high-temperature powder X-ray diffraction (HT-XRD) accompanied by semiquantitative phase analysis through the partial thermal reduction of ammonium paratungstate tetrahydrate, $(NH_4)_{10}[H_2W_{12}O_{42}]\cdot 4H_2O$, in flowing 10 % $H_2$/He. The effect of the heating program on the formation of the title compound has been discussed. Highly crystalline, monophasic hexagonal ammonium tungsten bronze prepared by partial reduction of ammonium paratungstate tetrahydrate has been characterised by high-precision powder XRD, X-ray photoelectron spectroscopy (XPS), chemical analysis and solid-state $^1$H NMR spectroscopy ($^1$H-MAS-NMR).

## Introduction

Hexagonal ammonium tungsten bronze (HATB), $(NH_4)_{0.33-x}WO_{3-y}$, is one of the compounds that may be intermediates in the powder metallurgical production of tungsten lamp filaments. Partial reduction of the starting material, ammonium paratungstate tetrahydrate (APT), $(NH_4)_{10}[H_2W_{12}O_{42}]\cdot 4H_2O$, between 400 and 600 °C produces an intermediate product (called "tungsten blue oxide"), which is a possible mixture of different phases. It is doped with K, Al and Si that ensure, after complete reduction in hydrogen, an overlapping crystallite structure of tungsten powder, which finally provides appropriate mechanical stability (a so-called "non-sag" feature) to tungsten filaments even at high operating temperatures in lamps.[1–3] Among the possible constituents of "tungsten blue oxide" (an X-ray amorphous phase, $WO_3$, $WO_{2.9}$, $WO_{2.72}$, $WO_2$ and tungsten bronzes[1,2,4–7]), hexagonal ammonium tungsten bronze may have an important role in the doping process because of its ion-exchange property.[4,5,8,9]

Furthermore, for applications in electrochromic devices,[1,10–14] humidity[15,16] and gas sensors[17–21] as well as secondary batteries,[22] metastable tungsten oxides and oxide bronzes have attracted much attention in the past decades due to their open-tunnel structures.[1,2,23,24] Hexagonal ammonium tungsten bronze is an interesting member of these compounds because of its mixed proton and electron conductivity[25] and, in addition, hexagonal $WO_3$ can be produced by its oxidation,[26] the latter being one of the most studied tungsten oxides.[22,27–29] Besides hydrothermal[25,30] and solvothermal[31,32] synthetic methods, the partial reduction of APT is also a viable way of preparing the hexagonal ammonium tungsten bronze for these fields of interest.

For further studies on the various aforementioned reactions and applications of the title compound, it is advisable to obtain a deeper insight into its formation through the partial reduction of APT. In previous studies, when heating APT at a rate of 5–10 °C min$^{-1}$, hexagonal ammonium tungsten bronze readily appeared between 350 and 600 °C but was accompanied by some other phases (monoclinic, orthorhombic or hexagonal $WO_3$ in air,[1,2,33–37] tetragonal hydrogen tungsten bronze, $WO_{2.9}$, $WO_{2.72}$ and $WO_2$ in reducing gases[1,2,7,37–40] and X-ray amorphous phase in all cases). On the other hand, a monophasic, crystalline and/or partly amorphous hexagonal ammonium tungsten bronze could be produced when APT was decomposed in a furnace between 300 and 500 °C in reducing[41–45] or inert gases.[46]

In an attempt to explain the effect of the heating conditions on the partial reduction of APT, we report here our results obtained by in situ high-temperature powder X-ray diffraction (HT-XRD) in flowing 10 % $H_2$/He on the formation and thermal stability of hexagonal ammonium tungsten bronze. Supported by the results of our HT-XRD measurements and also by earlier studies,[1,2,7,37–46] we have proposed a model for the formation of the title compound through the partial reduction of APT. In harmony with this model, HATB has been prepared in a monophasic, highly

crystalline form and its composition and structure have been studied by high-precision powder XRD, X-ray photoelectron spectroscopy (XPS), chemical analysis and solid-state $^1$H NMR spectroscopy ($^1$H-MAS-NMR).

## Results and Discussion

### Formation and Thermal Stability of Hexagonal Ammonium Tungsten Bronze

On the basis of earlier studies,[43–45] an annealing temperature of 400 °C seemed to be the most suitable for the formation of the monophasic title compound when heating APT in a furnace in a reducing gas. This process (fast heating of APT followed by an isothermal period) has been modelled by in situ HT-XRD measurements in flowing 10% $H_2$/He.

Straight after (1 min) rapid heating (100 °C min$^{-1}$) of APT to 400 °C, hexagonal ammonium tungsten bronze, HATB (ICDD 42-0452), tetragonal hydrogen tungsten bronze, THTB, $H_xWO_{3-y}$ (ICDD 23-1448), and an X-ray amorphous phase were identified in the XRD pattern (Figure 1). The $2\theta$ = 23.702° reflection of HATB ($I/I_0$ = 65%) and the $2\theta$ = 22.980° reflection of THTB ($I/I_0$ = 50%) were used for semiquantitative phase analysis. The amounts of crystalline hexagonal bronze and tetragonal bronze were 69% and 31%, respectively (Figure 2). This is much higher than in the case of heating APT slowly (5 °C min$^{-1}$) to 450 °C, whereby the proportion of HATB was 34%.[47]

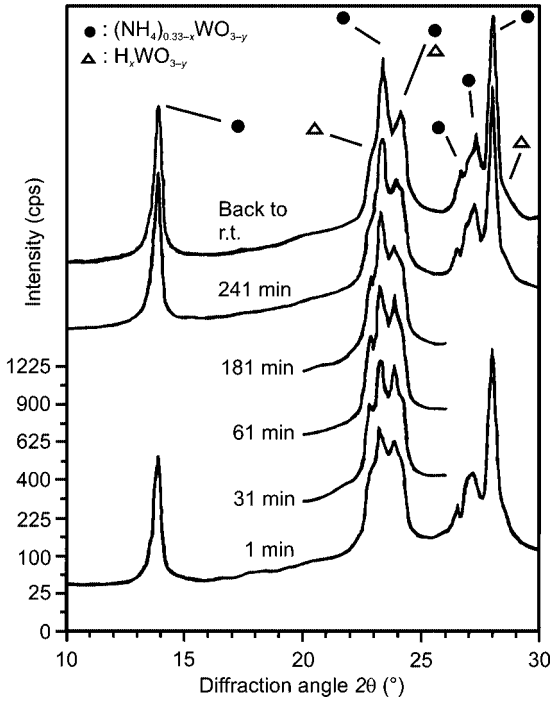

Figure 1. In situ HT-XRD patterns at 400 °C after rapid heating (100 °C min$^{-1}$) of APT in 10% $H_2$/He.

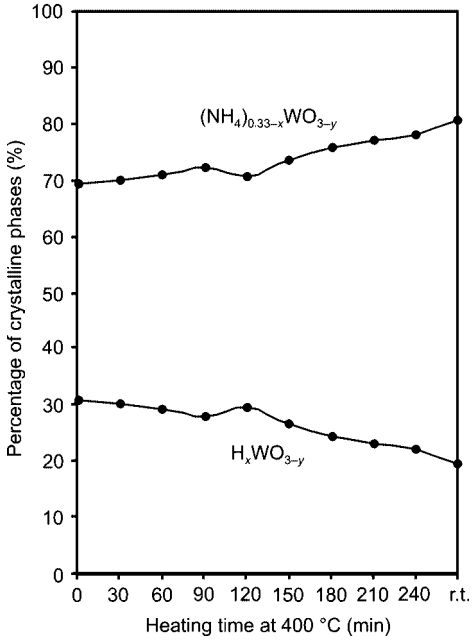

Figure 2. Amount of the formed crystalline tungsten bronzes from APT at 400 °C after rapid heating (100 °C min$^{-1}$) in 10% $H_2$/He.

During consecutive heating at 400 °C, the sample became more crystalline. This is indicated by the growth in intensity of reflections from both the hexagonal and tetragonal bronzes (Figure 1). On the other hand, the ratio of the hexagonal phase increased steadily (Figure 2). A further increase in the crystallinity of the sample and the amount of the hexagonal bronze (80%) accompanied cooling of the sample to room temperature (r.t.), which followed the 4 h isothermal heating period.

Our present study, as well as a comparison of earlier results,[1,2,7,37–46] shows that the heating conditions of APT in a reducing gas influence the formation of the bronzes, i.e. formation of the hexagonal bronze is favoured when APT is heated rapidly whereas for the formation of the tetragonal bronze, slow heating is favourable. We propose an explanation in terms of structure for this phenomenon.

The structure of APT is basically determined by the paratungstate ion, $[H_2W_{12}O_{42}]^{10-}$, which is built up from twelve $WO_6$ octahedra. These large ions are bound together by water molecules and ammonium ions.[48] When annealing APT at 250–300 °C (in fact this is the third main decomposition step of APT[1,2,37]), ammonia and water are released, structural collapse and rearrangement take place, i.e. some $WO_6$ octahedra from separate paratungstate ions become linked together and an amorphous phase is formed.[49] In this structure, a certain number of water molecules, ammonium ions as well as ammonia molecules are trapped and therefore cannot be released in this temperature region. From the amorphous phase, tungsten bronzes and then tungsten oxides form on further heating at 300–600 °C.

We suppose that the heating rate of APT determines the process of $WO_6$ octahedra linking and the amount of trapped molecules and ions. This then also determines the possibility of the formation of hexagonal and tetragonal

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bronzes. Ammonia molecules and ammonium ions fit in the hexagonal channels of HATB the best. Therefore, the faster APT is heated, the more ammonia molecules and ammonium ions (as well as water molecules) are trapped in the cages between the $WO_6$ octahedra. This results in a higher proportion of hexagonal bronze.

The growth in the amount of HATB during the isothermal period must also be explained. One solution might be that the tetragonal bronze becomes transformed into the hexagonal material.[39] The other possibility is that right after (1 min; Figure 2) the rapid heating of APT, only a part of the sample crystallised. Since under such circumstances the formation of the hexagonal phase seems to be favoured, during the isothermal period, when the other part of the sample also crystallised, HATB was formed to a greater extent than THTB resulting in a growth in the percentage of the hexagonal bronze.

It should be mentioned that we observed only a phase mixture at all stages of the reaction and that the hexagonal bronze was accompanied by small amounts of the tetragonal bronze even after 4 h of annealing. We assume that the difference of the decomposition conditions for APT in a furnace and in a high-temperature camera may be the reason why a monophasic HATB finally did not form in our experiments.

However, we clearly detected that during fast heating and then during isothermal heating of APT, much more hexagonal bronze than tetragonal bronze formed. We also observed that during the isothermal stage the sample became more crystalline. Our results and assumptions together with earlier studies[41–46] thus show that when HATB is required in a highly crystalline, monophasic form, APT has to be heated rapidly, preferably at 400 °C in a reducing gas, and kept under these conditions for several hours, which in practice corresponds to heating APT in a furnace.

It is very interesting that in air formation of the tetragonal hydrogen tungsten bronze was not observed as described earlier and that hexagonal ammonium tungsten bronze was accompanied by an X-ray amorphous phase and/or by crystalline monoclinic, orthorhombic or hexagonal $WO_3$.[1,2,33–37] In this case, oxidation might also have an effect on the linking process of paratungstate ions, which should be responsible for the absence of the tetragonal bronze during the decomposition sequence of APT in air.

## Characterisation of Hexagonal Ammonium Tungsten Bronze

In order to check our model of how highly crystalline, monophasic hexagonal ammonium tungsten bronze is formed through the partial reduction of APT, ammonium paratungstate tetrahydrate was annealed at 400 °C for 6 h in $H_2$. The structure and composition of the resultant HATB sample were determined by high-precision powder XRD, XPS, chemical analysis and $^1$H-MAS-NMR spectroscopy.

### *Characterisation of Hexagonal Ammonium Tungsten Bronze by High-Precision XRD*

XRD analysis showed that the HATB sample contained only the hexagonal ammonium tungsten bronze phase, which was identified by the ICDD 42-0452 card in space group $P6_3/mcm$, no. 193.[46] The sample was highly crystalline [the signal/background ratio for the (2,0,0) reflection was 6050 cps/60 cps] and an X-ray amorphous phase was not detected. Thus, a monophasic, highly crystalline hexagonal ammonium tungsten bronze could be successfully produced by partial thermal reduction of APT, in agreement with our model.

To check the cell parameter refining program, we recalculated the cell parameters of the title compound on the basis of the measured reflections of HATB found in the literature[8,44,46] and this showed the reliability of our program (Table 1). The slight difference in literature cell parameters[8,44,46] might have been caused mostly by the differences in the compositions of hexagonal ammonium tungsten bronze samples.[5]

In order to obtain precise XRD data, we used all the simulated reflections of the $P6_3/mcm$, no. 193 space group for finding and indexing the reflections in the measured XRD pattern of the HATB sample. The simulated reflections were calculated with PulverX using cell parameters of HATB reported by Dickens et al.[44] Deconvolution of peaks, base line correction, splitting of peaks from Cu-$K_{\alpha1}$ and -$K_{\alpha2}$ radiation, profile fitting and, finally, correction of reflections on the basis of an Si internal standard were then performed. The obtained reflections of HATB are listed in Table 2.

The following cell parameters of the HATB sample were obtained: $a = 0.7381 \pm 0.0001$ nm, $c = 0.7540 \pm 0.0002$ nm.

While we could detect all the measurable 77 reflections of HATB, Kiss et al.[8] observed 49 reflections, Dickens et al.[44] listed 20 and Volkov[46] detected 25 of them. Interestingly, Kiss et al.[8] reported indices (3,0,1) and (5,0,3), which are in contrast to the extinction rule of the space group $P6_3/mcm$, no. 193.

### *Characterisation of Hexagonal Ammonium Tungsten Bronze by XPS*

In tungsten bronzes, the tungsten atoms may appear in different oxidation states.[1,2] To check this for our HATB

sample, the $WO_3$ reference sample was investigated first. Besides O atoms (O1s = 530.7 eV) only $W^{VI}$ atoms were detected (Figure 3a), the W4f values of which ($W4f_{7/2}$ = 36.9 eV and $W4f_{5/2}$ = 34.8 eV) were in agreement with earlier results.[27,50,51]

After refining the XPS spectrum belonging to the HATB sample (Figure 3b), $W^{IV}$ atoms ($W4f_{7/2}$ = 35.2 eV and $W4f_{5/2}$ = 33.2 eV) and $W^{V}$ atoms ($W4f_{7/2}$ = 35.9 eV and $W4f_{5/2}$ = 33.5 eV) were also observed besides $W^{VI}$ atoms.[52–54] Zhan et al.[32] also investigated a hexagonal ammonium tungsten bronze sample by XPS but they did not report the presence of $W^{IV}$ and $W^{V}$ atoms.

Furthermore, in our HATB sample, $NH_3$ molecules (N1s = 399.7 eV) were also detected in addition to $NH_4^+$ ions (N1s = 401.9 eV).[50,51] Up to this time ammonia molecules were only detected in HATB by $^1$H-MAS-NMR spectroscopy[4,5] whereas they were not detected by XPS.[32]

Depth profiling by $Ar^+$ ion sputtering was not informative because sputtering distorted the structure so much that, due to oxygen loss, even $W^0$ species ($W4f_{7/2}$ = 32.5 eV and $W4f_{5/2}$ = 30.5 eV) appeared.[54–56]

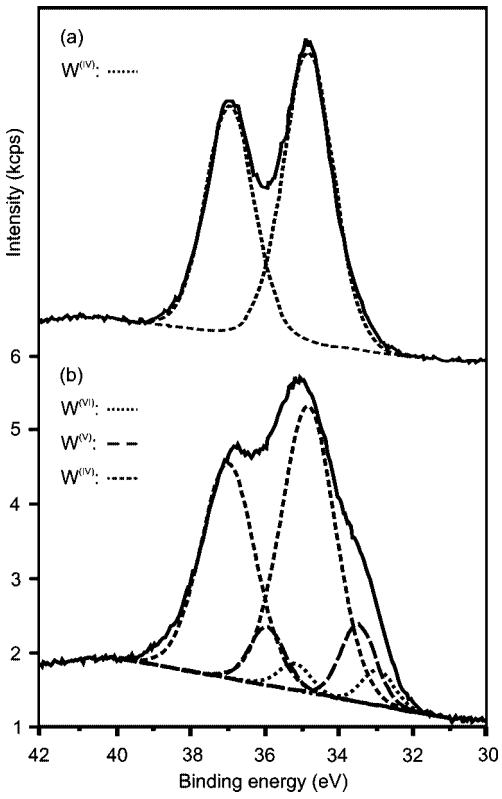

Figure 3. XPS spectra of (a) $WO_3$ and (b) HATB.

### *Chemical Analysis of Hexagonal Ammonium Tungsten Bronze*

In order to determine the composition of the HATB sample, it was first heated at 800 °C in argon in a Setaram TG-DTA 92 thermobalance to form $WO_{3-x}$ and was then heated at 800 °C in air to form $WO_3$. From the corresponding weight changes, the W and O contents of the sample were calculated. The N content was determined by titration of the ammonia released when the HATB sample was heated in nitrogen. The ratio of $NH_4^+$ ions to $NH_3$ molecules was measured by XPS. The total amount of $H_2O$ present in the sample was calculated by complementing to 100% (m/m). The weight loss of the sample up to 100 °C, i.e. corresponding to adsorbed water was not taken into account when calculating the stoichiometry. Thus, the formula of the HATB sample was determined as $(NH_4)_{0.07}(NH_3)_{0.04}(H_2O)_{0.09}WO_{2.95}$. XPS analysis showed no impurities in the sample.

In the case of HATB samples, for which cell parameters and *d* values were published previously[8,44,46] (Table 1), the chemical analysis of samples was not detailed enough. The presence of $NH_3$ molecules was not checked in any of the reports corresponding to refs.[8,44,46] and the rate of reduction, i.e. the oxygen index, was not taken into account in refs.[44,46].

### *Characterisation of Hexagonal Ammonium Tungsten Bronze by $^1$H-MAS-NMR Spectroscopy*

Because of the possible presence of some proton-containing species ($NH_3$, $NH_4^+$, $H_2O$ and OH group) in hexagonal

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ammonium tungsten bronze, the HATB sample was also characterised by solid-state $^1$H NMR spectroscopy.

In the $^1$H-MAS-NMR spectrum of the $WO_3$ reference sample, only a small peak was observed at $\delta$ = 0.8 ppm, which was also noticeable in the $^1$H-MAS-NMR spectrum of HATB (Figure 4). Since this peak was also present in the $^1$H-MAS-NMR spectrum of the sample holder, we could not check the presence of OH groups on the surface of $WO_3$ and HATB particles.[4,5,57]

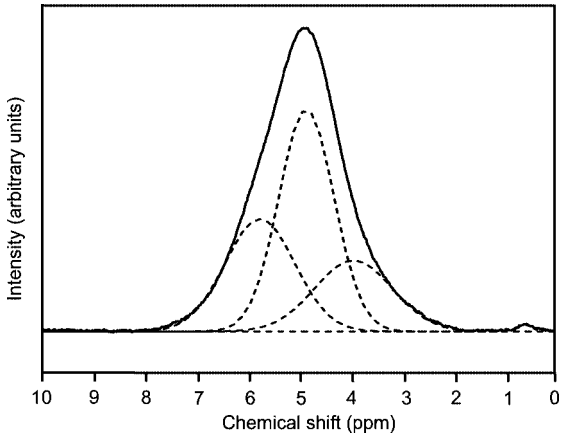

Figure 4. $^1$H-MAS-NMR spectrum of HATB.

In the$^1$H-MAS-NMR spectrum of HATB, the large peak at $\delta \approx 5$ ppm seemed to be asymmetric and we could not fit it properly with one or two but only with three peaks. The peak at $\delta$ = 4.9 ppm was assigned to the ammonium ions situated in the hexagonal channels, in accordance with ref.[5] We suppose that the peak at $\delta$ = 5.8 ppm is due to ammonia molecules in the hexagonal channels, an idea which is also supported by our XPS measurements and also by earlier results.[5] The peak at $\delta$ = 4.0 ppm may come from water molecules bound to the surface of or inside the bronze particles.

## Conclusions

On the basis of in situ HT-XRD measurements and earlier results,[1,2,7,37–45] we propose that the heating program of APT influences the process of linking of $WO_6$ octahedra of paratungstate ions. This probably determines the likelihood, as a result of structural factors, of the formation of hexagonal ammonium tungsten bronze. Formation of monophasic hexagonal bronze is favoured the most when APT is heated rapidly at 400 °C in a reducing gas. On the basis of this model, the preparation of a highly crystalline, monophasic HATB sample was successful.

Chemical analysis of the resultant hexagonal ammonium tungsten bronze sample showed a composition of $(NH_4)_{0.07}(NH_3)_{0.04}(H_2O)_{0.09}WO_{2.95}$. The presence of $W^{IV}$, $W^{V}$ and $W^{VI}$ species detected by XPS supports the electron-conducting properties while the presence of $NH_3$ molecules and $NH_4^+$ ions detected by XPS and $^1$H-MAS-NMR spectroscopy supports the proton-conducting properties of the title compound. With powder XRD analysis more reflections of hexagonal ammonium tungsten bronze were detected than previously observed.

## Experimental Section

**Ammonium Paratungstate Tetrahydrate:** Ammonium paratungstate tetrahydrate (H. C. Starck GmbH), $(NH_4)_{10}[H_2W_{12}O_{42}]\cdot 4H_2O$ (ICDD 40-1470) was used as purchased (analysis: measured $WO_3$ 89.6%, $NH_3$ 5.1%; calculated $WO_3$ 88.8%, $NH_3$ 5.4%). XRD measurements did not show any impurities in the APT sample.

**Hexagonal Ammonium Tungsten Bronze:** Hexagonal ammonium tungsten bronze was produced by annealing APT at 400 °C for 6 h in $H_2$ since, on the basis of earlier results[43–45] and our HT-XRD measurements, these conditions seemed to be the best for the formation of highly crystalline, monophasic HATB.

**Tungsten Trioxide:** Monoclinic tungsten trioxide, $WO_3$ (ICDD 83-0951), was produced as a reference sample for XPS and $^1$H-MAS-NMR spectroscopic analysis by heating APT at 600 °C for 2 h in air. XRD, XPS and $^1$H-MAS-NMR spectroscopic measurements did not show any impurities in the $WO_3$ sample.

**In situ High-Temperature Powder X-ray Diffraction (HT-XRD):** HT-XRD patterns were recorded with a device consisting of a Müller Mikro 111 generator, a Philips PW 1710 diffractometer control unit and a Philips PW 1050 goniometer between $2\theta$ = 10–30° and 20–26° at (0.02° per 0.5 s) with Cu-$K_{\alpha 1,2}$ radiation. Heating of samples was performed in an Anton Paar HTK 16 high-temperature camera in flowing 10% $H_2$/He. Deconvolution of peaks, base-line correction, splitting of peaks from Cu-$K_{\alpha 1}$ and -$K_{\alpha 2}$ radiation as well as profile fitting were carried out using Profit for Windows 1.0. The relative ratio of the crystalline phases was calculated by semiquantitative phase analysis.

**Powder X-ray Diffraction (XRD):** X-ray diffraction pattern of the title compound was recorded with a Philips MPD 1880 X-ray diffractometer using Si (ICDD 27-1402) as an internal standard between $2\theta$ = 5 and 100° at (0.01° per 3 s) with Cu-$K_{\alpha 1,2}$ radiation. The same program and method were used to obtain the Cu-$K_{\alpha 1}$ reflections as in the case of in situ HT-XRD experiments. Measured reflections were indexed on the basis of simulated reflections of the $P6_3/mcm$, no. 193 space group, which were calculated by PulverX using cell parameters of HATB reported by Dickens et al.[44] A linear interpolation was made between the deviations of measured and standard $d$ values at each Cu-$K_{\alpha 1}$ reflection belonging to the Si internal standard and, using the function obtained this way, the $d$ values of HATB sample were corrected. The cell parameters of hexagonal ammonium tungsten bronze were refined using a gwbasic language program, which used non-linear fitting (least square of $1/d^2$, Gauss–Newton–Marquardt method) without weighting.[58]

**X-ray Photoelectron Spectroscopy (XPS):** XPS data were collected with a VG Microtech instrument consisting of an XR3E2 X-ray source, a twin anode (Mg-$K_\alpha$ and Al-$K_\alpha$) and a CLAM 2 hemispherical analyser using Mg-$K_\alpha$ radiation. Survey scans were obtained in the 0–1100 eV range with a 20 eV pass energy at 0.4 eV per 0.1 s. Detailed scans were recorded with a 50 eV pass energy at 0.05 eV per 1.5 s. The spectrometer was calibrated by using the binding energy of the C 1s line (284.5 eV).

**Solid-State $^1$H NMR Spectroscopy ($^1$H-MAS-NMR):** $^1$H-MAS-NMR spectra were recorded with a Varian Unity 300 spectrometer supplied with a Doty XC5 solid-phase $^1$H head at a rotor spinning frequency of 4000 Hz in an XC5 insert (special sample holder), which was set inside an $Si_3N_4$ rotor.

# Chemical Oxidation of 1,3,2-Diazaboroles and 1,3,2-Diazaborolidines

**Lothar Weber,*[a] Imme Domke,[a] Jan Kahlert,[a] and Hans-Georg Stammler[a]**

**Keywords:** Diazaboroles / Diazaborolidines / Diazaborolium salts / Nitrosonium hexafluorophosphate

Oxidation of the 1,3,2-diazaborole *t*BuN$^a$CH=CHN$^b$(*t*Bu)-BBr(*N$^a$*–*B*) (**1h**) with $NO^+PF_6^-$ afforded the diazaborolium salts [*t*BuN$^a$=CH–CH=N$^b$(*t*Bu)$BF_2$(*N$^a$*–*B*)]$^+X^-$ (X = $Br^-$, $Br_3^-$, $PF_6^-$) (**3h**) as the result of different oxidation processes. The same product was obtained when the 1,3,2-diazaborolidine *t*BuN$^a$$CH_2CH_2$N$^b$(*t*Bu)BBr(*N$^a$*–*B*) (**2h**) was subjected to reaction with $NO^+PF_6^-$. In contrast to this, oxidation of **1h** and **2h** with $NO^+BF_4^-$ cleanly furnished [*t*BuN$^a$CH–CH=N$^b$(*t*Bu)-BFBr(*N$^a$*–*B*)]$^+BF_4^-$ (**6h**). Treatment of the 1,3,2-diazaboroles *t*BuN$^a$CH=CHN$^b$(*t*Bu)BR(*N$^a$*–*B*) [R = H (**1e**), CN (**1i**), C≡CH (**1j**)] with $NO^+PF_6^-$ under comparable conditions led to the borolium salts [*t*BuN$^a$=CH–CH=N$^b$(*t*Bu)BRF(*N$^a$*–*B*)]$^+PF_6^-$ [R = H (**3e**), CN (**3i**), C≡CH (**3j**)]. All the borolium salts investigated in this study were reversibly reduced by cyclic voltammetry. The novel products were characterized by elemental analyses and NMR spectra ($^1$H, $^{11}$B, $^{13}$C, $^{19}$F, $^{31}$P). The X-ray structure analysis of **3h** reveals two independent planar cations in the asymmetric unit, accompanied by one bromide and one tribromide ion.

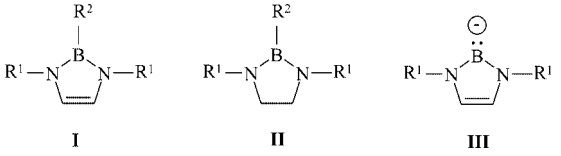
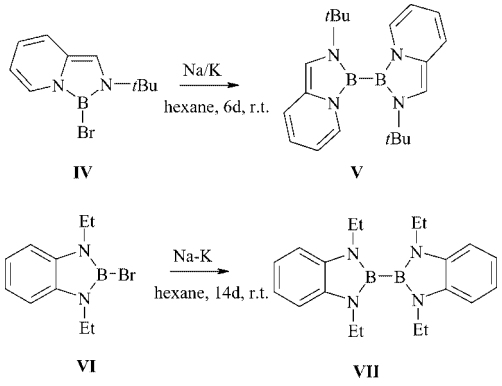
## Introduction

The reactivity of the 1,3,2-diazaboroles **I** towards a broad range of nucleophiles has been investigated intensively and described in detail in the literature some years ago.[1] More recently, the redox chemistry of these compounds and of their saturated analogs, the 1,3,2-diazaborolidines **II** (Scheme 1), has been studied by cyclic voltammetry and He(I)-UV-photoelectron spectroscopy.[2]



Scheme 1. Diazaborole **I**, diazaborolidine **II** and boranide ion **III**.

The electrochemical reduction of diazaboroles to afford the boranide ion **III**, however, has never been observed. This is consistent with the results of their chemical reduction with sodium/potassium alloy, which also did not lead to anions of the type **III**. The latter would be analogous to Denk's silylene[3] or to the related germylene.[4] The alkali metal reduction of **IV**[5] and **VI**[6] afforded the diboranes(4) **V** and **VII**. Treatment of diazaborole **1h**, however, did not furnish the corresponding diborane(4) (Scheme 2).



Scheme 2. Chemical reduction of 1,3,2-diazaboroles **IV** and **VI**.

The electrochemical oxidation of *N*,*N*-di-*tert*-butyldiazaboroles **1a**–**i** by cyclic voltammetry displayed clean, but irreversible waves, whereby the oxidation potentials $E_{ox,1/2}$ vary strongly in dependence of the substitution pattern at the boron center (Table 1). Thus, the amino-substituted borole **1a** as well as the methoxy-substituted heterocycle **1c** were oxidized much easier than the cyano- or bromodiazaboroles, **1h** or **1i**, which was rationalized by the donor and acceptor abilities of the functional groups at the boron atom. The corresponding saturated 1,3,2-diazaborolidines with identical ligands at the boron atom exhibited the same trend, but in general they were less easy oxidized. This trend was confirmed by photoelectron spectroscopy of the heterocycles in the gas phase.[2]

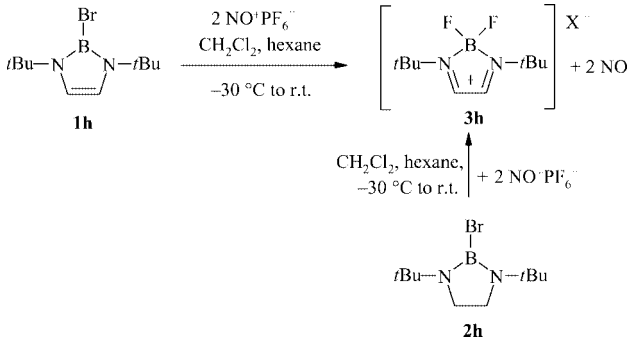
## Results and Discussion

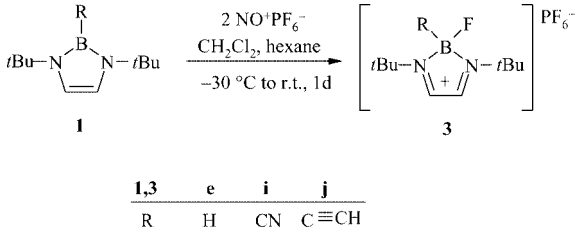
With respect to the irreversible electrochemical oxidation of diazaboroles, we were interested in the nature of the oxidation products and thus decided to oxidize these heterocycles chemically. The reaction of 1 equiv. of bromoborole **1h** with 2 equiv. of $NO^+PF_6^-$ in $CH_2Cl_2$/hexane led to the quantitative formation of the difluoroborolium salt **3h** as yellow crystals (Scheme 3). The counterion in the product, however, was not uniform. Obviously, the bromo ligand of **1h** was displaced by fluoride, which was released from a $PF_6^-$ ion before, and serves now as a counterion in the salt in addition to the $PF_6^-$ ion and the tribromide ion. The presence of a $Br_3^-$ anion indicates that additional redox processes have taken place. It could be formed from $Br^-$ by the oxidation with excessive $NO^+PF_6^-$. In contrast to other 1,3,2-diazaborolium salts with bromo or chloro substituents, **3h** was excellently soluble in dichloromethane and moderately soluble in toluene.



Scheme 3. Oxidation of the bromoborole **1h** and bromoborolidine **2h** with $NO^+PF_6^-$ (X = Br, $Br_3$, $PF_6$).

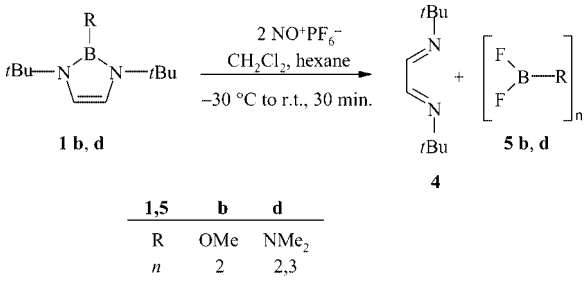
The reaction of the 1,3,2-diazaborolidine **2h** with $NO^+PF_6^-$ under the same conditions also led to the formation of product **3h** (Scheme 3). The employment of 4 equiv. of $NO^+PF_6^-$ did not lead to an improved yield. Instead 2 equiv. of the nitrosonium salt were recovered unaffected after the reaction.

Another situation was encountered when the 1,3,2-diazaborole was substituted by poor leaving groups, like the hydrido, ethynyl or cyano units. Here, only one fluoride atom was added to the boron center and borolium ions with two different ligands were formed. Thus, the reaction of the hydroborole **1e**, the cyanoborole **1i** or the ethynylborole **1j** with 2 equiv. of $NO^+PF_6^-$ afforded the intensely yellow (**3e**) or red borolium salts (**3i** and **3j**) in moderate to high yields (Scheme 4).



Scheme 4. Oxidation of diazaborole **1e**, **i**, **j** with $NO^+PF_6^-$.

Here, the hexafluorophosphate was observed as the sole counterion. The formation of the different diazaborolium salts studied here requires a twofold electron transfer. Principally, this could lead to the liberation of 2 equiv. of NO. At the top of the reaction vessel, where the released gases came into contact with air, an acidic reaction at a moist indicator paper was observed ($HNO_3$). The oxidation of the diazaborolidine **2h** to **3h**, however, required the removal of four electrons. According to experimental evidence this is accomplished by only 2 equiv. of the nitrosonium salt. Obvioulsy, here $NO^+$ is reduced to a nitrogen species with an oxidation number smaller than +II ($N_2$?). The treatment of diazaboroles containing electron-donating substituents on the boron atom, like dimethylamino- or methoxy-functionalized derivatives **1d** and **1b** with $NO^+PF_6^-$, did not lead to the borolium salts. Here, a ring opening took place with the formation of *N*,*N*′-di-*tert*-butyldiazabutadiene (**4**), $[Me_2NBF_2]_2$ (**5d**) or $[MeOBF_2]_n$ (**5b**), which were identified by comparison of their $^1H$ and $^{11}B$ NMR spectra with those of authentic samples (Scheme 5).

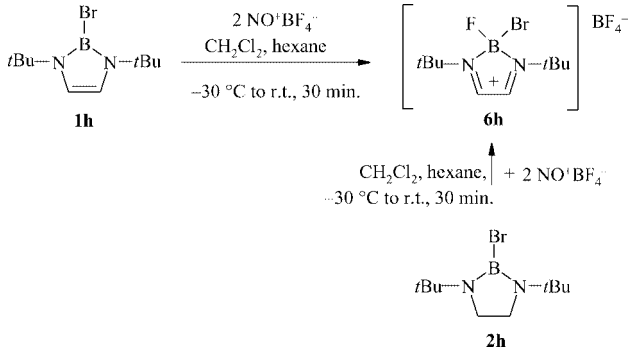


Scheme 5. Oxidation of diazaboroles **1b**, **d** with $NO^+PF_6^-$.

The 1,3,2-diazaboroles **1c**, **1k** (R = Ph) with methyl or phenyl substituents at the boron center were reluctant towards oxidation with $NO^+PF_6^-$ despite the fact that the methyl-substituted diazaborole **1c** and its saturated analog were easily oxidized electrochemically. Even an excess of the oxidant and stirring in boiling toluene for hours did not lead to the oxidation of the heterocycle.

Some of these experiments were repeated with $NO^+BF_4^-$ and $AgPF_6$ With the hexafluorophosphate, the results of the reaction with $NO^+PF_6^-$ were reproduced. In contrast to this, the reaction of **1h** and **2h** with $NO^+BF_4^-$ led to the mixed borolium salt **6h** (Scheme 6). In addition to elemental analysis, the identity of **6h** was evidenced by ESI mass spectroscopy. The signal of the cation of **6h** (*m*/*z* = 356 [M$^+$]) was observed with the correct isotopic distribution.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 6. Reaction of **1**, **2h** with $NO^+BF_4^-$.

With $AgPF_6$ as an oxidation agent, side reactions were observed depending on the stoichiometry of both reactants. Equimolar amounts of bromoborole **1h** and $AgPF_6$ led to the formation of equal portions of *t*BuN$^a$CH=CHN$^b$(*t*Bu)-BF($N^a$–*B*) (**1l**) and salt **3h**. The formation of the fluoroborole **1l** was avoided by the use of 2 equiv. of $AgPF_6$, and borolium salt **3h** was then isolated as the only product.

## Spectra and Structural Data

The $^{11}B\{^1H\}$ NMR spectrum of **3h** displays several signals in the typical area for tetracoordinate boron ($\delta \approx$ 6 ppm), due to the various borolium salts present.[7] In the $^1H$ NMR spectrum the ring protons absorb as broad singlets at $\delta$ = 8.87 ppm. The NMR spectroscopic data of the other borolium salts **3e**,**i**,**j** and **6h** are similar. ESI mass spectra of all the different borolium salts were obtained, whereby the cations represent the base peak. The products of the reaction of 1,3,2-diazaboroles with electron-donating groups (**1b**,**d**) were identified by comparison of the $^1H$ and $^{11}B\{^1H\}$ NMR spectroscopic data with authentic samples. In both cases, the $^1H$ NMR spectrum displays two characteristic singlets at $\delta$ = 1.10 and 8.09 ppm for the free *N*,*N*′-di-*tert*-butyldiazabutadiene. In addition to that, in the $^1H$ NMR spectrum of the reaction of **1b** with $NO^+PF_6^-$, another singlet at $\delta$ = 1.24 ppm is present, which belongs to the boron-bound methoxy group of the difluoro(methoxy)-borane **5b**. The product of the reaction of **1d** with $NO^+PF_6^-$, the difluoro(dimethylamino)borane **5d**, shows in the $^1H$ NMR spectrum a singlet at $\delta$ = 1.36 ppm. In the $^{11}B\{^1H\}$ NMR spectrum, the signals for $[F_2BOMe]_n$ ($n$ = 2,3) are observed at $\delta$ = 0.66 ppm and for $[F_2BNMe_2]_2$ at $\delta$ = 1.08 ppm, in agreement with the data of authentic samples.

## X-ray Structural Analysis of 3h

Yellow single crystals of **3h** suitable for an X-ray diffraction study (Table 2) were grown from a dichloromethane/hexane (1:1) mixture. Two independent diazaborolium cations are in the asymmetric unit in addition to one bromide and one tribromide anion. There are no bonding contacts between the cations and anions. The tribromide ion is slightly bent [Br(3)–Br(2)–Br(4) 175.65(1)°] with bond lengths Br(2)–Br(3) of 2.5811(4) Å and Br(2)–Br(4) of 2.5325(4) Å. In the symmetric anion of $(Me_3NH)Br_3$ the Br–Br bond length amounts to 2.54 Å (Br–Br–Br 171°), whereas in the nonsymmetric anion of $(PBr_4)Br_3$ (Br–Br–Br 177.3°) the Br–Br bond lengths are 2.39(1) and 2.91(1) Å.[8]

As the bonding parameters of both cations do not differ significantly, only the ring constructed of the atoms B(1), N(1), N(2), C(1) and C(2) is discussed in detail (Figure 1). The structure features a planar five-membered heterocycle (sum of bond angles 539.9°) with a tetracoordinate boron atom. The bond lengths B(1)–F(1) [1.366(3) Å] and B(1)–F(2) [1.369(3) Å] are slightly shorter than the B–F contacts in the $BF_4^-$ ion of $[\{Mes^*P{=}C(NMe_2)\}_2Cu]BF_4$, which range from 1.379(2) to 1.403(2) Å.[9] The boron–nitrogen bonds [B(1)–N(1) 1.607(3) Å, B(1)–N(2) 1.611(3) Å] are significantly longer than the average B–N single-bond of 1.59 Å found in amine–boranes.[10] Consistently, in compound **VIII** the B–N distance amounts to 1.588(3) Å.[11] An extremely long B–N bond was found in the Dewar borazine **IX** [1.752 Å].[12]

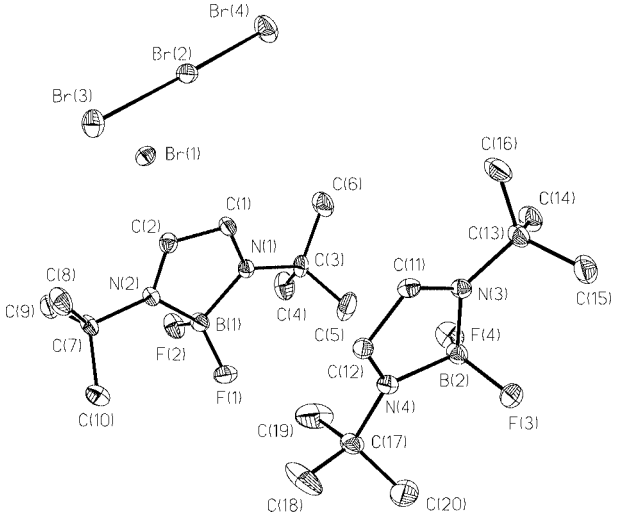


Figure 1. Crystal structure of **3h**; H atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: B(1)–N(1) 1.607(3), B(1)–N(2) 1.611(3), B(1)–F(1) 1.366(3), B(1)–F(2) 1.369(3), N(1)–C(1) 1.282(3), N(2)–C(2) 1.290(3), N(1)–C(3) 1.513(3), N(2)–C(7) 1.511, C(1)–C(2) 1.491(3); N(1)–B(1)–N(2) 97.2(2), B(1)–N(1)–C(1) 110.4(2), B(1)–N(2)–C(2) 109.8(2), N(1)–C(1)–C(2) 111.0(2), N(2)–C(2)–C(1) 111.2(2), N(1)–B(1)–F(1) 110.9(2), N(1)–B(1)–F(2) 112.1(2), N(2)–B(1)–F(1) 112.4(2), N(2)–B(1)–F(2) 109.7(2), F(1)–B(1)–F(2) 113.3(2), B(1)–N(1)–C(3) 124.9(2), B(1)–N(2)–C(7) 125.2(2), C(1)–N(1)–C(3) 124.7(2), C(2)–N(2)–C(7) 124.4(2).

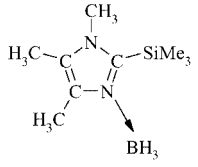
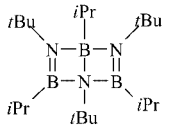


**VIII**

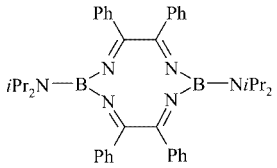


**IX**

In the precursor molecules, the 1,3,2-diazaborole B–N bond lengths range from 1.40–1.45 Å [e.g., (trimethylstannyl)diazaborole **1g**: B–N 1.439(7) and 1.450(7) Å].[1b] The

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

endocyclic C–N bond lengths [C(1)–N(1) 1.282(3) Å; C(2)–N(2) 1.290(3) Å] are characteristic for double bonds which are well comparable with those in the cyclic ketiminoborane **X** [1.273(3)–1.277(2) Å].[13]



**X**

The carbon–carbon bond length in the cation [1.491(3) Å] indicates a bond order of unity, whereas in the precursor diazaboroles double bonds [e.g., 1.344(8) Å in **1g**] are typical. In the course of the oxidation process the angle at the boron atom N(1)–B(1)–N(2) (in diazaboroles ca. 105°) was compressed to 97.42(16)° in **3h**, whereas the endocyclic angles B(1)–N(1)–C(1) [110.41(17)°], B(1)–N(2)–C(2) [109.8(2)°], N(1)–C(1)–C(2) [111.0(2)°] and N(2)–C(2)–C(1) [111.2(2)°] are similar to those in **1g** [107.1(4)–110.2(5)°].

### Electrochemical Data

The established protocol for the synthesis of 2-halo-1,3,2-diazaboroles involves the reduction of the corresponding diazaborolium salts with a strong reducing agent, e.g. sodium amalgam.[1d] This preparative result is supported by reductive cyclovoltammetric experiments. All borolium salts **3e**,**h**,**i**,**j** and **6h** show a clean, reversible curve in the range of 0 to –2 V, performed in dichloromethane or acetonitrile as a solvent. The reductive cyclovoltammogram of **3j** is shown as a representative in Figure 2 with scan rates from 10 to 100 mV/s.

The distance between the two extrema (120 mV) exceeds the theroretical value of 58 mV and could be an indicator for quasireversibility.

The reductive potentials $E_{1/2}$ of the various borolium salts, taken from square-wave voltammetry, vary from –731 mV (**3e**) to –742 mV (**3j**), vs. the ferrocene/ferrocinium standard. As expected, no electrochemical oxidation was observed in the range of 0–3.2 V.

## Conclusions

A number of 1,3,2-diazaboroles with different substituents at the boron atom can be irreversibly oxidized using cyclic voltammetry; the potentials $E^o$, taken from square-wave voltammetry, vary strongly, subject to the functional group at the boron atom. We were interested in the nature of the oxidation products and decided to study the chemical oxidation of a series of 1,3,2-diazaboroles **1b**–**e** and **1h**,**i**,**j**. The products were either borolium salts with two fluoride ligands at the boron atom as given with **3h**, or borolium salts with one fluoride substituent in addition to the functional group at the boron center. The latter situation was observed with diazaboroles containing poor leaving groups as given in **1e**,**i**,**j**. With electron-donating groups at the boron atom (**1b**,**d**) oligomers of difluoroboranes were detected as products. Interestingly, the alkyl- or aryl-substituted diazaboroles can not be oxidized chemically, although the oxidative cyclovoltammogram of the methyl-substituted borole **1c** shows a clean, irreversible signal. The chemical oxidation of the 2-bromodiazaborolidine **2h** suprisingly led to the same product **3h** as in the case of the unsaturated analog.

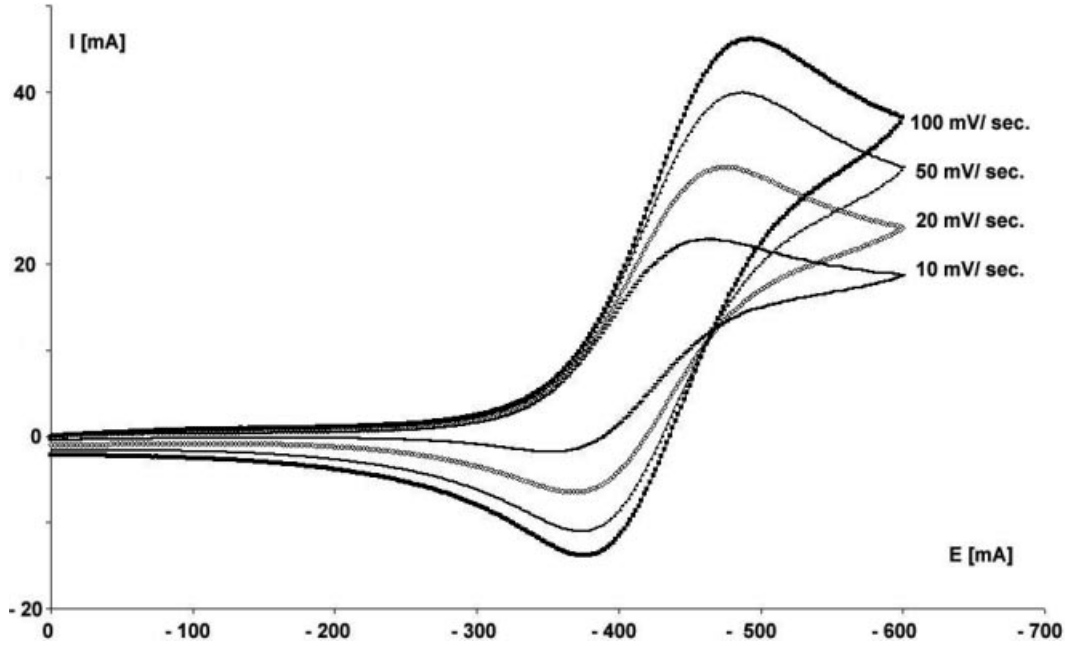


Figure 2. Reductive multiscan cyclovoltammogram of the borolium salt **3j**, 0 to –700 mV, $CH_2Cl_2$ with TBAPF at scan rates 10, 20, 50 and 100 mV/s.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The borolium salts **3e**,**h**,**i**,**j** and **6h** are deeply colored, air-stable compounds and prone for reduction by cyclic voltammetry. Hereby, the values of $E_{1/2}$ [ca. –735 mV] do not vary significantly.

## Experimental Section

**General:** All manipulations were performed under dry nitrogen. Solvents were rigorously dried with appropriate drying agents and distilled before use. The boron-containing heterocycles were prepared as described in the literature: *t*BuN$^a$=CH–CH=N$^b$(*t*Bu)-BR(*N*$^a$–*B*) (**1b**–**e**,**h**,**i**,**j**; R = OMe,[5] Me,[14] NMe$_2$,[1a] H,[1b] Br,[1d] CN,[1a] C$_2$H[1a]) and *t*BuN$^a$CH$_2$CH$_2$N$^b$(*t*Bu)BBr(*N*$^a$–*B*) (**2h**).[2] NMR spectra were recorded in $CD_2Cl_2$ with a Bruker AM Avance DRX 500 spectrometer ($^1$H, $^{11}$B, $^{13}$C, $^{19}$F) using $SiMe_4$, $BF_3{\cdot}OEt_2$ and $CFCl_3$ as external standards, mass spectra with a VG Autospec sector-field mass spectrometer (Micromass). The electrochemical experiments were performed with a PAR Model 270A instrument and the relevant software (Model 270). A system of microelectrodes with a three-electrode array was used. As working electrode a platinum wire was used (1.5 cm length, 0.5 mm diameter), which was formed to a helix around the counter electrode. A silver wire (1.5 cm length, 1 mm diameter) served as pseudo-reference electrode. All experiments were conducted in a glass device, which was flame dried prior to use and filled with dry dinitrogen. The determinations were performed in a 0.1 M solution of tetrabutylammonium hexafluorophosphate (TBAPF) in $CH_2Cl_2$ and MeCN with concentrations of the analyte of ca. $1{\cdot}10^{-4}$ mol L$^{-1}$ in the range of 0–3 V. The cyclovoltammograms were recorded with scan rates of 5–700 mV s$^{-1}$, whereby the results presented here were obtained with scan rates of 10, 20, 50 and 100 mV s$^{-1}$. All published potentials were confirmed by square-wave voltammetry (frequency: 5 Hz). The oxidation potentials were referenced vs. the ferrocene/ferrocinium couple ($E_{ox}$ = 0 eV) as a standard.

**[(*t*BuN$^a$=CH–CH=N$^b$*t*Bu)BF$_2$(*N*$^a$–*B*)]X (X = Br$^-$, Br$_3^-$, PF$_6^-$) (3h). Path a:** Compound **1h** (1.00 g, 3.86 mmol) was dissolved in a mixture of 20 mL of $CH_2Cl_2$ and 20 mL of hexane and cooled to –30 °C. Then solid $NOPF_6$ (1.36 g, 7.72 mmol) was added. The color of the solution turned pale yellow and after 2 h at 20 °C to orange. After 2 d at 4 °C, the product **3h** crystallized with different counterions (1.61 g). **Path b:** Analogous protocol with **2h** instead of **1h**. **Path c:** Analogous protocol with $AgPF_6$ instead of $NOPF_6$. $^1$H NMR: $\delta$ = 1.54 (s, 18 H, *t*Bu), 8.87 (s, 2 H, NCH) ppm. $^{13}$C NMR ($CD_2Cl_2$): $\delta$ = 27.7 [s, C(*C*H$_3$)$_3$], 60.8 [s, *C*(CH$_3$)$_3$], 151.2 (s, NCH) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = 6.1 ppm. $^{19}$F{$^1$H} NMR: $\delta$ = –69.7 (d, $^2J$ = 710.0 Hz, PF$_6^-$), –148.8 (s, BF) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = –144 (sept, $^2J$ = 710.0 Hz, PF$_6$) ppm. Due to different counterions the elemental analysis was meaningless. ESI MS: *m*/*z* = 217 [*t*BuN$^a$=CH–CHN$^b$(*t*Bu)BF$_2$(*N*$^a$–*B*)]$^+$.

**[(*t*BuN$^a$=CH–CH=N*t*Bu)BBrF(*N*$^a$–*B*)]BF$_4$ (6a):** To a chilled solution (–30 °C) of **1h** (1.00 g, 3.86 mmol) in a mixture of $CH_2Cl_2$ (20 mL) and hexane (20 mL), solid $NOBF_4$ (0.90 g, 7.72 mmol) was added. The color of the solution turned pale yellow and after 2 h at room temp. it changed to orange. After 3 d at 4 °C, pure **6a** (1.24 g, 88%) was collected as yellow crystals. $^1$H NMR: $\delta$ = 1.44 (s, 18 H, *t*Bu), 8.80 (s, 2 H, NCH) ppm. $^{13}$C NMR: $\delta$ = 27.9 [s, C(*C*H$_3$)$_3$], 61.2 [s, *C*(CH$_3$)$_3$], 151.7 (s, NCH) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = 5.2 ppm. $^{19}$F{$^1$H} NMR: $\delta$ = –69.7 (d, $^2J$ = 710.0 Hz, PF$_6^-$), –148.5 (s, BFBr) ppm. $C_{10}H_{20}B_2BrF_5N_2$ (364.80): calcd. C 32.92, H 5.53, N 7.68; found C 33.44, H 6.13, N 7.99. ESI MS: *m*/*z* = 278 [*t*BuN$^a$=CH–CHN$^b$(*t*Bu)BBrF(*N*$^a$–*B*)]$^+$.

**[(*t*BuN$^a$=CH–CH=N$^b$*t*Bu)BHF(*N*$^a$–*B*)]PF$_6$ (3e):** Solid $NOPF_6$ (1.94 g, 11.10 mmol) was added to a solution (–30 °C) of **1e** (1.00 g, 5.55 mmol) in $CH_2Cl_2$ (20 mL) and hexane (20 mL). Again, the color of the solution changed during the reaction from colorless to orange. After 2 d of stirring at room temp., the solution was stored at –4 °C for 4 d, and 1.28 g (67%) was obtained as yellow crystals. $^1$H NMR: $\delta$ = 1.41 (s, 18 H, *t*Bu), 3.75 (br. s, BH), 8.53 (s, 2 H, NCH) ppm. $^{13}$C NMR: $\delta$ = 27.3 [s, C(*C*H$_3$)$_3$], 60.8 [s, *C*(CH$_3$)$_3$], 158.3 (s, NCH) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = 5.2 ppm. $^{19}$F{$^1$H} NMR: $\delta$ = –69.7 (d, $^1J$ = 710.0 Hz, PF$_6^-$), –147.7 (s, BFBr) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = –144 (sept, $^1J$ = 710.0 Hz, PF$_6^-$) ppm. No reliable analysis was obtained. ESI MS: *m*/*z* = 199 [*t*BuN$^a$=CH CHN$^b$(*t*Bu)-HBF(*N*$^a$–*B*)]$^+$.

**[(*t*BuN$^a$=CH–CH=N$^b$*t*Bu)B(CN)F(*N*$^a$–*B*)]PF$_6$ (3i):** A solution of **3i** (1.00 g, 4.88 mmol) and $NOPF_6$ (1.70 g, 9.76 mmol) was stirred in a mixture of $CH_2Cl_2$/hexane (1:1) for 3 d, whereby the color changed from yellow to red. The solution was stored at 4 °C for at least 5 d; then 1.39 g of the product (77%) was obtained as a red solid. $^1$H NMR: $\delta$ = 1.45 (s, 18 H, *t*Bu), 7.81 (s, 2 H, NCH) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 28.9 [s, C(*C*H$_3$)$_3$], 59.6 [s, *C*(CH$_3$)$_3$], 155.1 (s, NCH) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = 5.1 ppm. $^{19}$F{$^1$H} NMR: $\delta$ = –69.7 (d, $^1J$ = 710.0 Hz, PF$_6^-$), –148.5 (s, BFCN) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = –144 (sept, $^1J$ = 710.0 Hz, PF$_6$) ppm. $C_{11}H_{20}BF_7N_3P$ (369.11): calcd. C 35.79, H 5.46, N 11.38; found C 35.38, H 6.11, N 11.99. ESI MS: *m*/*z* = 224 [*t*BuN$^a$=CH CHN$^b$(*t*Bu)B(CN)F(*N*$^a$–*B*)]$^+$.

**[(*t*BuN$^a$=CH–CH=N$^b$*t*Bu)B(C$_2$H)F(*N*$^a$–*B*)]PF$_6$ (3j):** Neat $NOPF_6$ (1.72 g, 9.80 mmol) and **3j** (1.00 g, 4.90 mmol) were stirred in a mixture of $CH_2Cl_2$/hexane (1:1) for 1 d, whereby the solution turned from colorless to cherry-red. After 4 d at 4 °C, 1.25 g of the product was collected as a red solid (69%). $^1$H NMR: $\delta$ = 1.69 (s, 18 H, *t*Bu), 2.51 (s, C$_2$CH), 8.77 (s, 2 H, NCH) ppm. $^{13}$C NMR: $\delta$ = 29.0 [s, C(*C*H$_3$)$_3$], 66.0 [s, *C*(CH$_3$)$_3$], 89.8 (s, C$_2$H), 161.3 (s, NCH) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = 5.1 ppm. $^{19}$F{$^1$H} NMR: $\delta$ = –69.7 (d, $^1J$ = 710.0 Hz, PF$_6^-$), –148.5 (s, BFC$_2$H) ppm. $^{31}$P{$^1$H} NMR: $\delta$

# Third-Order Nonlinear Optical Properties of DA-salen-Type Nickel(II) and Copper(II) Complexes

João Tedim,[a][‡] Sónia Patrício,[a] Rosa Bessada,[a] Rui Morais,[b,c] Carla Sousa,[a][‡‡] Manuel B. Marques,[b,c] and Cristina Freire*[a]

**Keywords:** Third-order NLO properties / Z-scan technique / UV/Vis spectroscopy / Schiff bases

Third-order nonlinear and linear optical properties of nickel(II) and copper(II) complexes with salen ligands, functionalised with electron donor/acceptor groups (DA-salen), have been investigated in solution by the Z-scan technique using an Nd:YAG laser ($\lambda_{inc}$ = 1064 nm) and UV/Vis spectroscopy. The [M(DA-*salen*)] complexes exhibit positive nonresonant nonlinear refractive indexes ($n_2^I$) in the range 27.0–8.50·$10^{-21}$ $m^2 W^{-1}$ and nonlinear absorption coefficients ($\alpha_2^I$) within the range 1.80–26.0·$10^{-17}$ $m W^{-1}$. The latter values correspond to less than 10 % of the overall magnitude of the third-order susceptibility, $|\chi_3|$, which is the result of the absence of electronic transitions near $\lambda_{inc}$ = 1064 nm. For the group of $Ni^{II}$ complexes, the highest $n_2^I$ values are exhibited by the complexes with aromatic diimine bridges and large π-electron delocalisation, which leads to intense electronic charge-transfer bands ($\varepsilon > 16000$ $mol^{-1} dm^3 cm^{-1}$) in the region $\lambda$ = 275–500 nm. The complexes that exhibit charge-transfer bands near $\lambda_{inc}/2$ = 532 nm, also show the highest $\alpha_2^I$ values, a consequence of multiphoton absorption processes. For the group of $Cu^{II}$ complexes, the highest $n_2^I$ value is also observed by the complex that exhibits the most intense charge-transfer bands in the region $\lambda$ = 275–475 nm. Between $Ni^{II}$ and $Cu^{II}$ complexes with the same DA-salen ligands, those of copper show always higher $n_2^I$ values, indicating that NLO responses can also be fine-tuned by the metal centre.

## Introduction

During the last decade there has been a continuous demand for new materials capable of faster responses in optical information processing.[1] More specifically, the search has been focused on materials possessing high nonresonant nonlinear optical (NLO) responses. This implies that the materials must have not only high nonlinear refractive indexes, but also small linear and nonlinear absorptions; otherwise the slow photothermal effects arising from absorptive processes dominate the desirable fast photorefractive effects.[2]

Molecules with high NLO responses must possess small differences between the ground and low excited states; the corresponding electronic transitions should also correspond to strong absorptions and there must be a large difference between the dipole moments of the ground and excited states.[3] These properties can be accomplished by compounds with a D-π-A structure, where an electron donor (D) group and an electron acceptor (A) group are placed away from each other in the molecule through a π-conjugated system, therefore creating a high asymmetry in the electronic density.

Organic compounds with extensive π-delocalisation have emerged as promising NLO materials instead of inorganic solids, due to their ultrafast NLO responses, good processability as thin-film devices and enhanced nonresonant NLO responses.[4] More recently, transition metal complexes have appeared as an important alternative for the design of NLO materials, since the metal centre can impart important structural and electronic properties to the organic ligands, and consequently to the NLO responses.[5] Among transition-metal complexes, those with porphyrins and their derivatives exhibit great potential application due to their two-dimensional structures and unique electronic properties.[6] The $N_2O_2$ Schiff-base ligands derived from salicyladehyde and diamines (generically named as salen ligands) can be used as alternative building blocks for the design/preparation of NLO compounds owing to their synthetic versatility relative to the introduction of electron donor/acceptor functionalities and creation of extensive π-delocalisation to in-

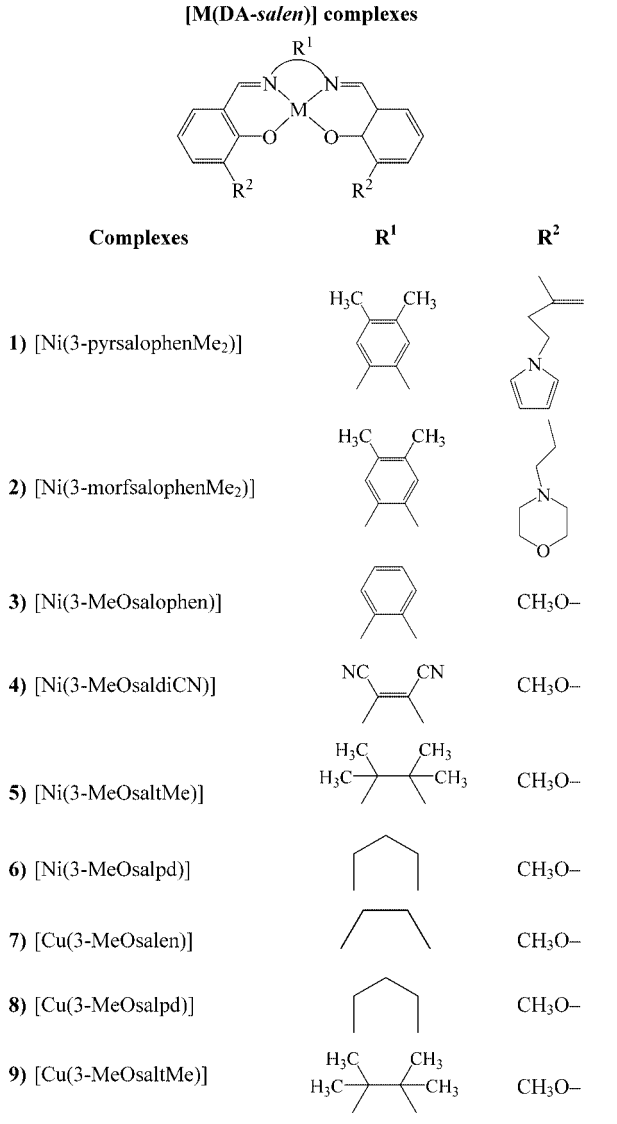
duce large electron asymmetry.[7] Furthermore, they can also coordinate several transition metal cations, in different oxidation states, which can additionally fine-tune the NLO responses.

The second-order NLO properties of metal complexes with salen-type ligands functionalised with electron donor and acceptor groups with a D-π-A structure have been extensively studied by Di Bella and Lacroix[8–14] and some important conclusions have been presented on the relationship between complex molecular structure and second-order NLO properties. It has been shown that second-order NLO responses of salen-type complexes were related to the presence of intense low-energy metal-to-ligand, ligand-to-metal charge transfer and intraligand transitions. The importance of the metal centre in these complexes was shown in the surveys carried out by the same authors and others.[11,14,15] Inclusion of metal centres in Schiff-base ligands was always accompanied by an enhancement of second-order NLO responses, compared to that of the free ligands and the role of the metal centre could be twofold, as it could act as both the donor of the D-π-A structure and/or as part of the π-bridging moiety.

With the work presented here we endeavour to extend the previous study on NLO properties of salen complexes to third-order and exploit the potential application of these compounds as building blocks for the preparation of materials with NLO properties suitable for ultrafast switching technologies. Several nickel(II) and copper(II) complexes with salen-type ligands functionalised with electron donor/acceptor groups – denoted here by [M(DA-salen)] complexes (Scheme 1) – were investigated by the Z-scan technique and their nonlinear refractive index and nonlinear absorption determined and the relationship between molecular NLO properties and complex molecular structure exploited. To the best of our knowledge, this is the first study on third-order NLO properties of (salen)nickel(II) and -copper(II) complexes in solution, although recently, the third-order NLO properties of some related bis(salicylaldiminato)$Ni^{II}$ and -$Cu^{II}$ complexes were measured by a coupling Z-scan technique and degenerate four-wave mixing.[16] The study presented here can also be the starting point for a survey of the NLO properties of electroactive films based on the same [M(DA-salen)] complexes, as previous works have shown that (salen)nickel(II) and -copper(II) complexes can be electropolymerized as electroactive films that exhibit interesting electrochromic properties.[17]

The potential application of these compounds/films in ultrafast switching technologies has determined the choice of the wavelength to study the third-order NLO responses, $\lambda_{inc}$ = 1064 nm, as the operating wavelength in ultrafast switching technologies is generally in the near infrared region ($\lambda$ = 1000–1500 nm).[18] It must be mentioned that very few of the organic materials reported so far are suitable for implementation in devices working in the near infrared.[4] In fact, the absolute magnitude of the nonlinear refractive index can be enhanced by one- or two-photon resonant transitions when the compound has strong absorptions close to $\lambda_{in}$ (1064 nm) and $\lambda_{in}/2$ (532 nm), and for the organic compounds with the largest nonlinear refractive index, strong electronic transitions are usually observed at $\lambda$ = 500–600 nm, leading to strong absorption losses.[19] In this context, the attempt to produce new molecular compounds with the referred and desired properties still remains an actual area of research. The divalent transition-metal complexes with salen ligands have square-planar geometries leading to strong electronic transitions (CT and intraligand) in the UV/Vis region and medium-intense d–d bands in the far visible region;[20] these electronic characteristics make them potential candidates for the preparation of materials with third-order nonlinear optical properties to be used in ultrafast optical communications.



Scheme 1. Structures of [M(DA-salen)] complexes, M = Ni and Cu.

## Results and Discussion

The linear and nonlinear optical properties of the $Ni^{II}$ and $Cu^{II}$ complexes with DA-salen ligands summarised in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Scheme 1 have been investigated as a function of the different combinations of the electron donor/acceptor groups introduced in the ligand in the 3-position of the aldehyde fragment (methoxy group, pyrrol or morpholine derivatives) and in the diimine bridge (several aromatic and aliphatic diimine bridges). These $N_2O_2$ tetradentate ligands with delocalised π-systems impart strong ligand fields leading to almost square-planar geometries and low-spin ground states for the metal complexes (for those that have more than one spin ground state), inducing high degrees of covalence/delocalisation within the metal–ligand bonds. The presence of these electronic properties, which are important in the design of molecules with high nonlinear optical properties, can be firstly surveyed from the study of the linear optical properties of the metal complexes.

## UV/Vis Spectra

The UV/Vis spectra of $Ni^{II}$ and $Cu^{II}$ complexes with DA-salen ligands are very similar and present typically high intense bands ($\varepsilon$ higher than 1000 $mol^{-1}\,dm^3\,cm^{-1}$) occurring at $\lambda < 400$ nm, due to metal-to-ligand and ligand-to-metal charge transfer and intra-ligand transitions and one broad band in the visible region at $\lambda$ = 500–650 nm with $\varepsilon$ values ranging from 70 to 400 $mol^{-1}\,dm^3\,cm^{-1}$, corresponding to the nonresolved d-d transitions from the four low-lying d orbitals ($d_{xz}$, $d_{yz}$, $d_{z^2}$, $d_{x^2-y^2}$) to the empty (in the case of Ni) or half filled (in the case of Cu) $d_{xy}$ orbital.[20] This latter broad electronic band is not observed in the nickel complexes that have an extended π-system including the aldehyde moiety and the diimine bridge, as the more intense CT bands are shifted to higher wavelengths, therefore preventing its observation. This is a general trend that is observed for nickel and copper complexes with salen ligands that have an extended π-system and is a consequence of the high degree of π-delocalisation between the metal centre and the ligand, which in turn induces an increase in $\varepsilon$ values. The $\lambda_{max}$ bands for all the complexes and the corresponding $\varepsilon$ values are summarised in Table 1. The electronic spectra of nickel and copper complexes with salen complexes functionalised with methoxy groups are shown in Figures 1 and 2 as examples.
