Figure 6. TGA curves of complex **1** (——), a 1:1 physical mixture of **1** and β-CD (·····), a 1:1 physical mixture of **1** and TRIMEB (–·–·) and the inclusion compounds **3** (– – –) and **4** (–··–··).

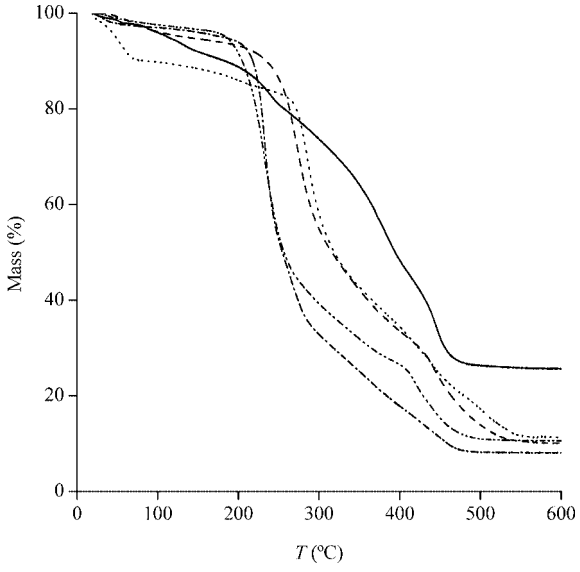

Figure 7. TGA curves of complex **2** (——), a 1:1 physical mixture of **2** and β-CD (·····), a 1:1 physical mixture of **2** and TRIMEB (–·–·) and the inclusion compounds **5** (– – –) and **6** (–··–··).

175 °C for TRIMEB. The TGA profile for the β-CD physical mixture exhibits an additional well-defined step from room temperature to 90 °C corresponding to the removal of water molecules located in the β-CD cavities and also in the interstices between the macrocycles. The TGA profiles for compounds **3** and **4** are very different from those for the physical mixtures. Neither individual steps for dehydration (in the case of the β-CD adduct) nor loss of the ligands from the organometallic complex were observed. Instead, both compounds exhibit a continuous and smooth weight loss from room temperature up to the points where the host macrocycles begin to decompose (230 °C for **3**, 155 °C for TRIMEB). This behaviour, coupled with the early degradation of the hosts (compared with the pure compounds β-CD hydrate and TRIMEB) is characteristic of true inclusion compounds comprising CDs and organometallic molecules. Comparable results were obtained for $[CpMo(H_2biim)(CO)_2](BF_4)$ (**2**) and its inclusion compounds (Figure 7), although the decomposition of the organometallic complex in the physical mixtures is not so obvious since the pure compound **2** decomposes in a series of overlapping steps which extend from room temperature to 475 °C.

The $^{13}C\{^1H\}$ CP/MAS NMR spectra of compounds **1**–**6** are shown in Figure 8 and Figure 9. Although the crystal structure of **1** contains two crystallographically independent $[CpMo(NCMe)_2(CO)_2]^+$ cations, with slightly different geometric features and distinct close-packing configurations, compound **1** gives rise to single peaks at 96.6, 145.1 and 252.6 ppm, assigned to the Cp, CN and CO groups, respectively. On the other hand, three partially revolved lines were observed between $\delta$ = 3 and 5 ppm for the methyl groups of the acetonitrile ligands. In the spectra of the inclusion compounds **3** and **4**, the guest species can be identified by a Cp resonance at about 96 ppm and a Me signal at about 3 ppm, which are essentially unshifted when compared with the resonances for nonincluded **1**. The β-CD carbon atoms in **3** give rise to four single peaks centred around 102.6, 80.6, 72.2 and 60.0 ppm, assigned to C1, C4, C2,3,5 and C6, respectively. This is in sharp contrast to plain β-CD hydrate, which exhibits a complex $^{13}C\{^1H\}$ CP/MAS NMR spectrum containing multiple sharp resonances for each type of carbon atom (not shown).[13] The multiple reso-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nances arise due to different torsion angles about the α(1→4) linkages[32] and the torsion angles describing the orientation of the hydroxy groups.[33] The appearance of single peaks in the $^{13}C\{^1H\}$ CP/MAS NMR spectrum of **3**, together with a lower dispersion in the chemical shift for each signal (i.e. the chemical shift range that comprises all of the resonances from the same carbon atom in distinct glycosidic units) are typically attributed to the β-CD macrocycle becoming symmetric, that is, the encapsulation of the guest molecule induces the ring to adopt a less distorted conformation, with each glucose unit in a more similar environment.[9e,13,34] The low crystallinity of compound **3** may also contribute to a broadening of the peaks.

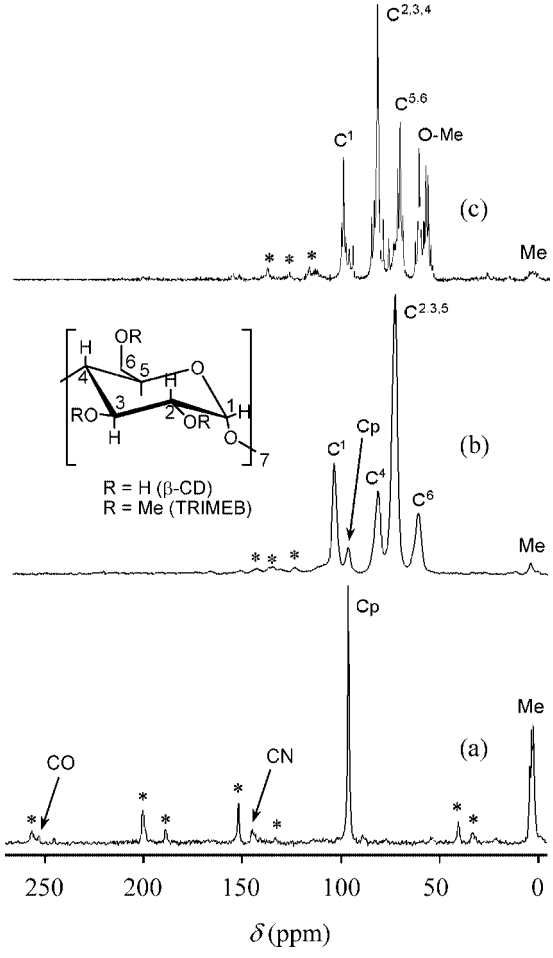

Figure 8. Solid-state $^{13}C\{^1H\}$ CP/MAS NMR spectra of (a) complex **1**, (b) the β-CD inclusion compound **3** and (c) the TRIMEB inclusion compound **4**. Spinning sidebands are denoted by asterisks.

Like plain β-CD hydrate, the $^{13}C\{^1H\}$ CP/MAS NMR spectrum of TRIMEB also contains multiple resonances for each type of carbon atom (not shown).[13] This is because the host assumes a severely collapsed conformation in the solid-state, which minimises the hydrophobic cavity in the absence of a hydrophobic guest.[35] Several resolved lines may also be observed for the inclusion compound **4** and this is consistent with the presence of an ordered crystal-packing arrangement of CD molecules. Indeed, the presence of at least ten sharp lines for the methyl carbon atoms shows that these groups exist in several different well-defined environments. The overall similarity of the spectrum with those previously reported for the adducts TRIMEB·[CpMoX(CO)$_3$] (X = Cl, $CH_2CONH_2$)[9e,13] is in line with the powder XRD results and confirms that the conformations of the host macrocycles and the crystal packing arrangements in the three compounds are similar. On the other hand, a comparison of these spectra with that for plain TRIMEB reveals considerable differences in the number, relative intensities and positions of peaks due to the host, which indicates that the conformation of the macrocycles in the inclusion compounds is different from that in plain TRIMEB.

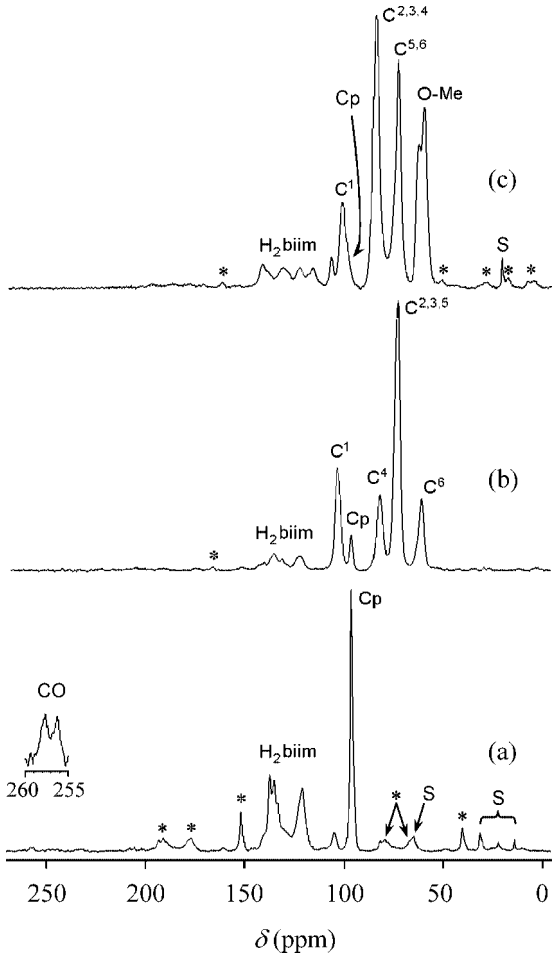

Figure 9. Solid-state $^{13}C\{^1H\}$ CP/MAS NMR spectra of (a) complex **2**, (b) the β-CD inclusion compound **5** and (c) the TRIMEB inclusion compound **6**. Spinning sidebands are denoted by asterisks and peaks due to the presence of residual solvents (diethyl ether, *n*-hexane or ethanol) are indicated by S.

Figure 9 shows the $^{13}C\{^1H\}$ CP/MAS NMR spectra of [CpMo($H_2$biim)(CO)$_2$](BF$_4$) (**2**) and the inclusion compounds β-CD·[CpMo($H_2$biim)(CO)$_2$](BF$_4$) (**5**) and TRIMEB·[CpMo($H_2$biim)(CO)$_2$](BF$_4$) (**6**). The resonances for the carbon atoms of the biimidazole ligand in **2** appear in the range 120–137 ppm and the Cp resonance can be found at $\delta$ = 96.1 ppm. The spectrum for compound **5** is

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

very similar to that of compound **3** with respect to the β-CD carbon resonances. Additional peaks for the guest molecule can be observed at $\delta$ = 95.6 ppm (Cp) and 122–139 ppm ($H_2$biim). For the TRIMEB adduct **6**, the $H_2$biim resonances appear in the range of 115–140 ppm, while the Cp resonance is obscured by a broad peak for the C1 carbon atoms of the host. In fact, in contrast to the spectrum of **4**, the resonances for the host carbon atoms in **6** appear mainly as single broad peaks, which are presumably related to the low crystallinity of the compound as revealed by the powder XRD studies.

For all the inclusion compounds studied, it was not possible to clearly identify the resonances (masked in the background) for the CO groups of the guest molecules, even when contact times of 2 ms were used. The presence of these groups was confirmed by IR spectroscopy. Thus, in addition to the intense and typical bands of the cyclodextrin hosts, the spectra contained two bands in the CO stretching region (1880–2000 $cm^{-1}$). These were mostly shifted by less than 10 $cm^{-1}$ compared with the corresponding bands for the nonincluded complexes **1** and **2**. Only in two cases (1971 $cm^{-1}$ for **3** vs. 1988 $cm^{-1}$ for **1**; 1891 $cm^{-1}$ for **5** vs. 1878 $cm^{-1}$ for **2**) were larger shifts observed. These shifts probably arise because the guest molecules in compounds **3**–**6** are isolated from one another by inclusion in the CD cavities.

### Concluding Remarks

β-CD and TRIMEB inclusion compounds containing the complexes $[CpMo(NCMe)_2(CO)_2](BF_4)$ and $[CpMo(H_2biim)(CO)_2](BF_4)$ have been prepared and characterised. Referring to previous work, we may conclude that neutral, cationic or anionic $\eta^5$-cyclopentadienyl metal carbonyl complexes of the type $[CpML_m(CO)_n]^{z-/z+}$ (M = Mo, Mn or Fe), with three-legged or four-legged piano stool geometries, are readily encapsulated by cyclodextrins. The available experimental and theoretical evidence suggests that the interaction geometries generally involve insertion of the Cp ligand into the host cavities, with the CO and L ligands (L = NCMe, $H_2$biim, Cl, $CH_2CONH_2$ etc) protruding outwards (on the wider secondary side of the host molecules). Indeed, the crystal-packing arrangements in the β-CD and TRIMEB inclusion compounds containing the $[CpMo(NCMe)_2(CO)_2]^+$ complex cation are evidently very similar to the arrangements found in the corresponding inclusion compounds containing the neutral tricarbonyl complex $[CpMoCl(CO)_3]$. We are currently studying how the behaviour of the organometallic complexes as, for example, CO-releasing molecules, catalyst precursors or anti-tumour agents is affected by cyclodextrin encapsulation.

## Experimental Section

**General Remarks:** All air-sensitive operations were carried out using standard Schlenk techniques under an oxygen- and water-free nitrogen atmosphere. Solvents were dried by standard procedures (diethyl ether and ethanol over Na, $CH_2Cl_2$ and NCMe over $CaH_2$), distilled under nitrogen and kept over 3 Å (NCMe) or 4-Å molecular sieves. Microanalyses for C, H and N were performed at the Instituto de Tecnologia Química e Biológica (Oeiras, Portugal) by C. Almeida and Mo was determined by ICP-OES at the Central Laboratory for Analysis (University of Aveiro) by E. Soares. TGA studies were carried out using a Shimadzu TGA-50 system at a heating rate of 5 °C $min^{-1}$ under air. Powder X-ray diffraction data were collected at ambient temperature on a X′Pert MPD Philips diffractometer (Cu-$K_\alpha$ X-radiation, $\lambda$ = 1.54060 Å) equipped with a curved graphite-monochromator and a flat-plate sample holder in a typical Bragg–Brentano *para*-focusing optics configuration (40 kV, 50 mA). Infrared spectra were recorded on a Unican Mattson Mod 7000 FTIR spectrometer. $^{13}C$ NMR spectra in solution were recorded on a Bruker Avance 500 spectrometer. $^{13}C\{^1H\}$ CP/MAS NMR spectra were recorded at 125.72 MHz on a (11.7 T) Bruker Avance 500 spectrometer, with an optimised $\pi/2$ pulse for $^1H$ of 4.5 μs, 2 ms contact time, a spinning rate of 7 kHz and 12 s recycle delays. Chemical shifts are quoted in parts per million relative to tetramethylsilane.

β-Cyclodextrin (Kleptose®) was kindly donated by laboratoires La Roquette (France) and heptakis-2,3,6-tris-*O*-methyl-β-CD was obtained from Fluka. 2,2′-Biimidazole was prepared from glyoxal and concentrated ammonia following the published method.[36] $[CpMo(\eta^3\text{-}C_3H_5)(CO)_2]$ was prepared as described in the literature[16b,16c] and characterised by elemental analysis and FTIR spectroscopy.

**$[CpMo(NCMe)_2(CO)_2](BF_4)$ (1):** A solution of $[CpMo(\eta^3\text{-}C_3H_5)(CO)_2]$ (0.35 g, 1.35 mmol) in $CH_2Cl_2$ was treated with 1 equiv. of $HBF_4{\cdot}Et_2O$. After 10 min, acetonitrile was added in excess and the reaction mixture was stirred for 2 h. The solution was then concentrated to about 5 mL and diethyl ether added to precipitate a red solid. The solid was filtered, washed with diethyl ether and *n*-hexane. Crystals suitable for X-ray analysis were obtained after slow diffusion at 4 °C of diethyl ether into a saturated solution of the crude product in acetonitrile. Yield: 0.48 g, 92%. $C_{11}H_{11}BF_4MoN_2O_2$ (385.96): calcd. C 34.23, N 7.26, H 2.87; found C 33.97, N 7.16, H 2.99. FTIR (KBr): $\tilde{\nu}$ = 3098 m, 3067 m, 3056 m (all $\nu_{CH}$ of Cp), 2972 m, 2965 m, 2915 m, 2902 m (all $\nu_{CH}$ of Me), 2325 w ($\nu_{N\equiv C}$), 2289 w ($\nu_{N\equiv C}$), 1988 vs. ($\nu_{CO}$), 1893 vs. ($\nu_{CO}$), 1621 m, 1434 m, 1422 m, 1366 w, 1352 w, 1305 w, 1300 w, 1083 vs. ($\nu_{BF}$), 1073 s, 1036 s, 928 w, 904 vw, 886 vw, 869 vw, 847 m, 824 w, 772 vw, 713 vw, 588 m, 542 m, 533 m, 522 m, 513 m, 488 m, 458 m, 433 m, 385 m $cm^{-1}$. $^1H$ NMR (300 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 5.80 (s, 5 H, Cp), 2.19 (s, 6 H, Me) ppm. $^{13}C\{^1H\}$ NMR (125.72 MHz, $CDCl_3$, 25 °C): $\delta$ = 249.7 (CO), 142.6 (CN), 96.1 (Cp), 4.8 (Me) ppm. $^{13}C\{^1H\}$ CP/MAS NMR: $\delta$ = 252.6 (CO), 145.1 (CN), 96.6 (Cp), 4.7 (Me) ppm

**$[CpMo(H_2biim)(CO)_2](BF_4)$ (2):** A solution of $[CpMo(\eta^3\text{-}C_3H_5)(CO)_2]$ (0.31 g, 1.19 mmol) in $CH_2Cl_2$ was treated with 1 equiv. of $HBF_4{\cdot}Et_2O$. After 10 min, dimethoxymethane was added in excess and the reaction mixture was stirred for 15 min. 2,2′-biimidazole (0.17 g, 1.30 mmol) was then added and the reaction mixture stirred for 4 h at room temperature. The resultant orange solution was filtered and, after concentrating to about 5 mL, diethyl ether was added to precipitate an orange microcrystalline solid. The solid was filtered and washed several times with diethyl ether and *n*-hexane. Crystals suitable for X-ray analysis were obtained after slow diffusion at 4 °C of diethyl ether into a saturated solution of the crude product in ethanol. Yield: 0.47 g, 90%. $C_{13}H_{11}BF_4MoN_4O_2$ (438.01): calcd. C 35.65, N 12.79, H 2.53; found C 35.52, N 12.51, H 2.38. FTIR (KBr): $\tilde{\nu}$ = 3360 s, br. ($\nu_{NH}$),

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

3265 sh ($\nu_{NH}$), 3156 m, 3140 s, 3122 s ($\nu_{NH}$, $\nu_{CH}$ of Cp and/or $H_2$biim), 2929 m, 2776 m, 1976 vs. ($\nu_{CO}$), 1878 vs. ($\nu_{CO}$), 1707 w, 1638 m, 1534 m, 1512 m, 1429 m, 1420 m, 1359 w, 1321 m, 1284 w, 1253 w, 1123 s, 1100 s, 1068 vs. ($\nu_{BF}$), 1004 m, 978 m, 919 w, 846 m, 822 m, 787 m, 761 s, 695 w, 679 m, 620 m, 612 w, 595 w, 538 m, 520 m, 484 m, 471 w, 435 m, 369 vw, 341 vw, 332 vw, 301 w cm$^{-1}$. $^1$H NMR (300 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 11.6 (NH, $H_2$biim), 7.75 (d, 2 H, $H_2$biim), 7.67 (d, 2 H, $H_2$biim), 5.85 (s, 5 H, Cp) ppm. $^{13}$C{$^1$H} NMR (125.72 MHz, $CDCl_3$, 25 °C): $\delta$ = 253.0 (CO), 136.7, 133.9, 120.7 (all $H_2$biim), 95.2 (Cp) ppm. $^{13}$C{$^1$H} CP/MAS NMR: $\delta$ = 257.6, 256.1 (CO), 137.3, 135.0, 133.3, 120.8 (all $H_2$biim), 104.8, 96.1 (Cp) ppm.

**β-CD·[CpMo(NCMe)$_2$(CO)$_2$](BF$_4$) (3):** A solution of [CpMo(NCMe)$_2$(CO)$_2$](BF$_4$) (**1**) (52.0 mg, 0.134 mmol) in acetonitrile (4.0 mL) was added to a solution of β-CD (152.5 mg, 0.134 mmol) in water (6.0 mL) at 40 °C. The resultant solution was stirred for 1 h and then frozen by immersion of the container in liquid nitrogen. The solvents were removed by freeze-drying to obtain a light-brown solid. FTIR (KBr): $\tilde{\nu}$ = 3375 s, br. ($\nu_{OH}$), 2939 m, 1971 s ($\nu_{CO}$), 1890 s ($\nu_{CO}$), 1640 m, 1536 m, 1509 w, 1422 m, 1367 m, 1334 m, 1300 m, 1244 m, 1157 s, 1101 sh, 1079 vs, 1027 vs, 1003 sh, 946 m, 938 m, 892 w, 860 w, 829 w, 821 w, 762 m, 706 m, 698 m, 670 w, 608 m, 577 m, 527 m, 484 m, 432 m, 356 w, 327 w, 302 w cm$^{-1}$. $^{13}$C{$^1$H} CP/MAS NMR: $\delta$ = 102.6 (β-CD, C1), 95.6 (guest Cp), 80.6 (β-CD, C4), 72.2 (β-CD, C2,3,5), 60.0 (β-CD, C6), 2.8 (guest Me) ppm.

**TRIMEB·[CpMo(NCMe)$_2$(CO)$_2$](BF$_4$) (4):** A solution of TRIMEB (0.558 g, 0.39 mmol) in $CH_2Cl_2$/water (20:1) was added to a solution of [CpMo(NCMe)$_2$(CO)$_2$](BF$_4$) (**1**) (103 mg, 0.26 mmol) in dichloromethane (10 mL) and the mixture was stirred for 48 h at 60 °C. After cooling to ambient temperature, the solution was evaporated to dryness under reduced pressure to obtain a dark-brown microcrystalline solid. FTIR (KBr): $\tilde{\nu}$ = 3463 s, 3106 m ($\nu_{CH}$ of Cp), 2989 s, 2935 s, 2842 s, 2322 vw ($\nu_{N\equiv C}$), 2290 vw ($\nu_{N\equiv C}$), 2074 w, 1988 s ($\nu_{CO}$), 1944 w, 1899 s ($\nu_{CO}$), 1840 w, 1631 m, 1458 m, 1384 m, 1370 m, 1325 m, 1307 m, 1263 m, 1196 s, 1163 s, 1145 s, 1107 vs, 1084 vs, 1072 vs, 1037 vs, 970 s, 951 m, 905 m, 856 m, 823 w, 805 w, 753 m, 734 m, 704 m, 671 vw, 553 m, 534 m, 522 m, 458 w, 434 w, 385 w, 348 w, 328 w, 313 w cm$^{-1}$. $^{13}$C{$^1$H} CP/MAS NMR: $\delta$ = 100.5, 99.6, 99.2, 98.3 (TRIMEB, C1), 96.8, 96.5 (TRIMEB, C1; guest Cp), 94.7 (TRIMEB, C1), 85.4, 84.0, 82.4, 81.9, 81.3, 79.2 (TRIMEB, C2,3,4), 76.4, 74.2, 72.2, 71.0, 69.6 (TRIMEB, C5,6), 63.0, 61.8, 61.2, 60.0, 58.9, 58.1, 57.0, 56.5, 55.4 (TRIMEB, O–Me), 3.8 (guest Me) ppm.

**β-CD·[CpMo(H$_2$biim)(CO)$_2$](BF$_4$) (5):** A solution of β-CD (311 mg, 0.27 mmol) and [CpMo(H$_2$Biim)(CO)$_2$](BF$_4$) (**2**) (120 mg, 0.27 mmol) in water (8 mL) was stirred for 50 min at 50 °C and then frozen with liquid nitrogen. The frozen water was removed by liophilisation to obtain a brick-coloured solid. FTIR (KBr): $\tilde{\nu}$ = 3377 s, br. ($\nu_{OH}$), 2928 m, 1973 s ($\nu_{CO}$), 1891 s ($\nu_{CO}$), 1640 m, 1534 m, 1507 w, 1422 m, 1368 m, 1334 m, 1300 w, 1245 w, 1157 s, 1099 sh, 1079 vs, 1050 sh, 1028 vs, 1005 sh, 944 m, 937 m, 861 w, 828 w, 820 w, 762 m, 706 m, 698 m, 668 m, 607 m, 577 m, 527 m, 483 m, 480 m, 433 m, 356 w, 335 w, 327 w, 302 w cm$^{-1}$. $^{13}$C{$^1$H} CP/MAS NMR: $\delta$ = 139.2, 134.5, 130.2, 122.1 (all guest $H_2$biim), 102.5 (β-CD, C1), 95.6 (guest Cp), 80.7 (β-CD, C4), 71.9 (β-CD, C2,3,5), 59.8 (β-CD, C6) ppm.

**TRIMEB·[CpMo(H$_2$biim)(CO)$_2$]BF$_4$ (6):** A solution of [CpMo(H$_2$biim)(CO)$_2$]BF$_4$ (**2**) (60.0 mg, 0.137 mmol) in a mixture of dichloromethane (12 mL) and ethanol (4 mL) was treated portionwise with TRIMEB (196 mg, 0.137 mmol), allowing each fraction to dissolve before adding the next. The mixture was stirred for 1 h and then evaporated to dryness under reduced pressure to obtain a solid product. FTIR (KBr): $\tilde{\nu}$ = 3142 m ($\nu_{NH}$, $\nu_{CH}$ of Cp and/or $H_2$biim), 2984 s, 2929 s, 2834 s, 2079 w, 1973 m ($\nu_{CO}$), 1885 m ($\nu_{CO}$), 1714 w, 1640 m, 1535 m, 1460 s, 1402 sh, 1369 m, 1322 m, 1304 m, 1259 sh, 1195 s, 1161 vs, 1141 vs, 1110 vs, 1095 vs, 1088 vs, 1072 vs, 1038 vs, 954 s, 937 s, 905 sh, 856 m, 821 w, 756 s, 706 m, 694 m, 666 w, 622 w, 599 sh, 551 m, 517 m, 468 w, 439 w, 377 vw, 346 w, 305 w cm$^{-1}$. $^{13}$C{$^1$H} CP/MAS NMR: $\delta$ = 140.3, 129.7, 121.1, 115.0 (all guest $H_2$biim), 105.0, 99.5 (TRIMEB, C1; guest Cp), 82.2 (TRIMEB, C2,3,4), 71.1 (TRIMEB, C5,6), 60.6, 57.8 (TRIMEB, O–Me) ppm.

**Single-Crystal X-ray Diffraction:** Suitable single-crystals of [CpMo(NCMe)$_2$(CO)$_2$](BF$_4$) (**1**) and [CpMo(H$_2$Biim)(CO)$_2$](BF$_4$) (**2**) were mounted on glass fibres using perfluoropolyether oil.[37] Data were collected at 180(2) K on a Nonius Kappa charge-coupled device area-detector diffractometer (Mo-$K_\alpha$ graphite-monochromated radiation, $\lambda$ = 0.7107 Å) equipped with an Oxford Cryosystems cryostream and controlled by the Collect software package.[38] Images were processed using the Denzo and Scalepack software packages[39] and data were corrected for absorption by the empirical method employed in Sortav.[40] Structures were solved by direct methods using SHELXS-97[41] and refined by full-matrix least-squares on $F^2$ using SHELXL-97.[42] All non-hydrogen atoms were directly located from difference Fourier maps and refined with anisotropic displacement parameters. Selected bond lengths and angles for the $Mo^{2+}$ coordination environments are given in Table 1 and Table 2 for compounds **1** and **2**, respectively. Table 3 summarises the hydrogen bonding geometries reported for compound **2**.

For the two crystal structures, hydrogen atoms bound to carbon were located in their idealised positions using appropriate HFIX instructions in SHELXL (43 for the aromatic and 137 for the terminal methyl groups of the coordinated NCMe moieties) and included in subsequent refinement cycles in the riding-motion approximation with isotropic thermal displacement parameters ($U_{iso}$) fixed at 1.2 (for the aromatic hydrogen atoms) or 1.5 (for the methyl moieties) times $U_{eq}$ of the carbon atom to which they were attached. For compound **1**, the two crystallographically independent $BF_4^-$ anions were found to be severely affected by structural disorder, which was directly reflected in the large thermal displacement parameters calculated for each fluorine atom. This disorder was modelled by considering, on the one hand, two distinct crystallographic positions for each $BF_4^-$ anion with fixed occupancy rates of $^1/_3$ and $^2/_3$ and, on the other, a geometry heavily restrained for each moiety with the B–F and F···F intramolecular distances restrained to variable common factors which ultimately refined to ca. 1.34 and 2.18 Å, respectively. This refinement strategy led to a more reasonable structural model for **1**, even though the checkCIF routines available with the PLATON software package still indicated a rather large discrepancy between the $U_{eq}$ values of the boron and fluorine atoms. The last difference Fourier map synthesis showed, for **1**, the highest peak (0.535 e Å$^{-3}$) and deepest hole (–0.790 e Å$^{-3}$) located at 1.37 Å from H(20C) and 0.79 Å from Mo(1), respectively, while, for **2**, the highest peak (0.616 e Å$^{-3}$) and deepest hole (–0.798 e Å$^{-3}$) were found at 1.65 Å from H(3) and 0.79 Å from Mo(1), respectively.

CCDC-604073 and -604074 (for **1** and **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Crystallographic Data for 1:** $C_{22}H_{22}B_2F_8Mo_2N_4O_4$, $M$ = 771.94, orthorhombic *Pbca*, $a$ = 12.871(3), $b$ = 19.222(4), $c$ = 23.849(5) Å, $V$ = 5900(2) Å$^3$, $Z$ = 8, $D_{calcd.}$ = 1.738 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) =

## Acknowledgments

The authors are grateful to FCT, OE and FEDER for funding (Project POCI//QUI/56109/2004). CCLP is grateful to the FCT for a postdoctoral grant. We wish to thank Professor João Rocha for access to research facilities and Paula Esculcas for assistance in the solid-state NMR experiments. We are also grateful to Celeste Azevedo for carrying out the TGA experiments and to Rosário Soares for collection of the powder diffraction data.

# Uranium(IV) Complexes of Calix[5]arene

Lionel Salmon,[a] Pierre Thuéry,[a] and Michel Ephritikhine*[a]

**Keywords:** Uranium / Calix[5]arene / Calixarenes

The μ-oxo uranium(V) compound $[Hpy]_2[\{U(calix[5]arene–5H)\}_2(\mu_2\text{-}O)]\cdot 4py$ (**1**·4py) was the sole product isolated from the reaction of $UCl_4$ and calix[5]arene unless the last traces of water were eliminated by thoroughly drying the macrocyclic molecule; under such strictly anhydrous conditions, the binuclear $U^{IV}$ complex $[Hpy]_3[U_2(calix[5]arene–5H)Cl_6]\cdot 4py$ (**2**·4py) was obtained. Treatment of $U(OTf)_3$ or $U(OTf)_4$ (OTf = $OSO_2CF_3$) with calix[5]arene gave the dimeric $U^{IV}$ complex $[U(calix[5]arene–4H)(py)]_2\cdot 4py$ (**3**·4py); compound **3** was also formed when no precautions were taken to avoid the presence of traces of water, together with compound **1**. The crystal structures of the complexes were determined.

## Introduction

We have recently reported on the synthesis and X-ray crystal structures of uranium(IV) complexes with calixarene ligands resulting from reactions of $UCl_4$ with calix[*n*]arenes (*n* = 4, 6 and 8),[1] and of $UX_4$ [X = Cl, MeCOCHCOMe (acac) and $OSO_2CF_3$ (OTf)] or $U(OTf)_3$ with the *O*-dimethylated *p*-*tert*-butylcalix[4]arene ($Me_2$-*t*Bucalix[4]arene).[2] As also outlined in the case of the preparation of the chloride-bridged trimeric complex $[\{U(Me_2\text{-}t\text{Bucalix[4]arene–2H})(\mu\text{-}Cl)_2\}_3]$,[3] the successful isolation of these compounds was critically dependent on the reaction conditions; in particular, the elimination of adventitious traces of water was of major importance to avoid the oxidation of the $U^{IV}$ ion. These difficulties explain why the first attempts to prepare uranium(IV) calixarene compounds by treatment of $UCl_4$ with *p*-*tert*-butylcalix[*n*]arenes (*n* = 4, 5, 6) resulted in the formation of a trinuclear, $\mu_3$-oxo-centred $[U^{VI}_2U^V]$ complex for *n* = 4, dinuclear, $\mu_2$-oxo-centred $U^V$ or $U^{VI}$ complexes for *n* = 5 and a mononuclear $U^{VI}$ homoleptic alkoxide complex for *n* = 6.[4] We encountered the same problems when we studied the reactions of $UX_4$ with calix[5]arene. These reactions seemed to be of special interest to us because metal complexes of calix[5]arene derivatives are rather scarce. A search of the Cambridge Structural Database (CSD, Version 5.27)[5] indicates that only six metal complexes of simple R-calix[5]arene (R = H, *tert*-butyl) have been crystallographically characterised.[4,6–9] Concerning the 5f-element compounds, apart from the binuclear $U^V$ and $U^{VI}$ derivatives cited above,[4] the mononuclear uranyl complex $[HNEt_3]_2[UO_2(p\text{-}tert\text{-butylcalix[5]arene–4H})]$ has also been described.[8] Here we present the synthesis and X-ray crystal structures of the $U^{IV}$ and $U^V$ compounds, which were obtained from reactions of $UX_4$ (X = Cl, OTf) with calix[5]arene.

## Results and Discussion

Reaction of $UCl_4$ with 1 molar equiv. of commercial calix[5]arene in pyridine at 20 °C afforded dark orange crystals of the μ-oxo uranium(V) compound $[Hpy]_2[\{U(calix[5]arene–5H)\}_2(\mu_2\text{-}O)]\cdot 4py$ (**1**·4py) in 63% yield. The synthesis of **1** is reminiscent of that of $[Hpy]_2[\{U(p\text{-}tert\text{-butylcalix[5]arene–5H)}\}_2(\mu_2\text{-}O)]$ from $UCl_4$ and *p*-*tert*-butylcalix[5]arene.[4] The crystal structures of both compounds are quite similar and do not merit further discussion; a view of **1** is shown in Figure 1, and selected bond lengths and angles are listed in Table 1.

As the $U^{IV} \rightarrow U^V$ oxidation during the formation of **1** likely resulted from the presence of water in the reaction mixture, it was suspected that commercial calix[5]arene was not anhydrous, and it was heated under vacuum at 130 °C for 1 d, but this had no effect on the course of the reaction. However, the TGA-DTA analysis of this macrocycle revealed a gradual endothermic process between 120 and 210 °C, with a weight loss of 0.9%, which would correspond to the release of half an included water molecule per calix[5]arene. Final drying of the latter was achieved by leaving a pyridine solution on molecular sieves (4 Å) for 5 d; the colourless solution turned pale blue and the $^1H$ NMR signal of the hydroxy protons shifted from $\delta$ = 10.57 to 13.75. Addition of 2 molar equiv. of $UCl_4$ into the anhydrous solution of calix[5]arene gave a green solution, which slowly deposited light green crystals of the uranium(IV) compound $[Hpy]_3[U_2(calix[5]arene–5H)Cl_6]\cdot 4py$ (**2**·4py) in 24% yield.

The trianionic complex, shown in Figure 2, represents a unique example of two metal atoms bound to a single calix[5]arene ligand. The structure shows a pseudosymmetry plane, which contains the U1, U2, O2, Cl1 and Cl5 atoms, with an rms deviation of 0.027 Å. Both uranium atoms are in six-coordinate environments with *fac*-$O_3Cl_3$ and *cis*-$O_2Cl_4$ octahedral geometry for U1 and U2, respectively. The five donor atoms of the calixarene define a mean $O_5$ plane with an rms deviation of 0.155 Å and the uranium atoms are located 1.125(4) (U1) and 1.626(6) Å (U2) from this mean plane. The macrocycle is in the distorted cone conformation, with dihedral angles between the four aromatic rings and the $O_5$ mean plane of 25.2(2), 87.4(3), 23.3(3), 73.1(3) and 82.9(3)°. These values, with two smaller angles corresponding to aromatic rings almost parallel to the $O_5$ plane, are analogous to those encountered in compound **1**. The mean values of the U–Cl (terminal) and U–$O_{phenoxy}$ bond lengths of 2.677(16) and 2.14(3) Å, respectively, are comparable to those measured in the other uranium(IV) complexes with calix[*n*]arenes (*n* = 4, 6, 8) previously reported.[1,2] The uranium atoms are further bonded to the bridging chlorine atom Cl1, with a U1–Cl1–U2 angle of 141.13(10)°, and they are at a distance of 5.2862(8) Å from one another. The charge of the trianionic complex is balanced by those of three pyridinium ions hydrogen bonded to three pyridine molecules [N1···N2 2.659(17) Å, N3···N4 2.665(10) Å, N5···N6 2.683(17) Å]. The pyridine molecule (or pyridinium ion) containing N3 is further encapsulated in the calixarene cavity, in which it is held by a π–π stacking interaction with the aromatic ring bearing O4 [centroid···centroid distance 3.69 Å, dihedral angle 13°, centroid offset 0.72 Å].

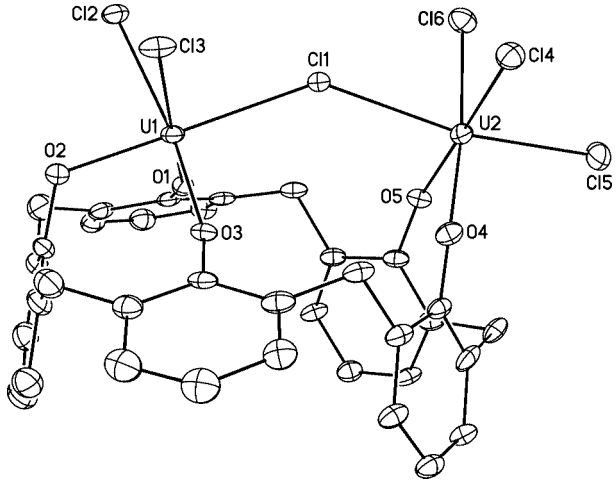

Figure 2. View of the trianion in complex **2**·4py with displacement ellipsoids drawn at the 15% probability level; hydrogen atoms have been omitted.

No reaction was observed between $U(acac)_4$ (acac = MeCOCHCOMe) and calix[5]arene in refluxing THF or pyridine while treatment of $U(acac)_4$ with the sodium salt of the macrocycle led to the sluggish formation of intractable

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

products. The lesser reactivity of $U(acac)_4$ with respect to $UCl_4$ was previously noted with the other calix[*n*]arenes (*n* = 4, 6, 8).[1]

Treatment of $U(OTf)_3$ with commercial calix[5]arene gave a mixture of red crystals of **1**·4py and green crystals of the dimeric complex $[U(calix[5]arene–4H)(py)]_2$·4py (**3**·4py). The latter was obtained from the reactions of $U(OTf)_3$ or $U(OTf)_4$ with the thoroughly dried macrocycle but was contaminated with a brown powder of an unidentified compound. Complex **3** could not be isolated in analytical purity because of its insolubility in organic solvents, a problem which was also encountered with most of the uranium(IV) compounds of calix[*n*]arenes (*n* = 4, 6, 8).[1] The formation of **3** from $U(OTf)_3$ implies oxidation of the uranium(III) centre, as in the case of the synthesis of a bis-calixarene $U^{IV}$ complex by treatment of $U(OTf)_3$ with *O*-dimethylated *p-tert*-butylcalix[4]arene.[2] Such oxidation reactions of trivalent uranium complexes by alcohols and phenols were assumed to proceed either by initial proton transfer followed by a valence disproportionation step,[10] or by the direct oxidation of uranium(III) with concomitant evolution of dihydrogen.[11] All the triflate ligands of $U(OTf)_3$ or $U(OTf)_4$ have been substituted by the phenoxide groups of the macrocycle, contrary to the chloride ligands of $UCl_4$, a difference which has already been noted with the reactions of $UX_4$ (X = Cl, OTf) and other calixarenes,[1,2] and which reflects the lesser coordinating ability of the triflate ligand.

A view of the centrosymmetric complex **3** is shown in Figure 3. The uranium atom is bound to five oxygen atoms from one calixarene, one oxygen atom from the second (O2′) and the nitrogen atom of the pyridine molecule. The resulting seven-coordinate uranium environment is pentagonal bipyramidal with the N1 and O2′ atoms in apical positions. The uranium atom is located 0.0354(11) Å from the $O_5$ mean plane defined by the five oxygen atoms of the ligand (rms deviation 0.313 Å) and is thus close to the centre of the $O_5$ coordination site, like the uranyl ion in the mononuclear complex $[HNEt_3]_2[UO_2$(*p-tert*-butylcalix[5]arene–4H)]. In this respect, complex **3** contrasts with complex **1** and the $U^V$ and $U^{VI}$ complexes with the same stoichiometry previously reported,[4] in which the two metal centres are bound to only two or three phenoxide groups from each calixarene and are located outside the lower rim array. Among the U–O bond lengths, those corresponding to the bridging atom O2 are dissymmetric and larger than the other ones, as well as that associated to atom O5, which is the protonated group (Table 1). The average value for the other bond lengths, 2.19(5) Å, is larger by 0.06 Å than the average value of the $U–O_{phenoxy}$ distances measured in uranium(IV) complexes of calixarenes.[1] Such an increase in the U–O bond length has already been observed in the $[U(Me_2calix)(H_2calix)]$ complex ($Me_2calix$ = *O*-dimethylated *p-tert*-butylcalix[4]arene) and has been attributed to the steric effects generated by the sandwich arrangement.[2] The hydroxy group is involved in a hydrogen bond with the pyridine molecule [O5···N2 2.626(4) Å, O5–H5···N2 157°]. While the uncomplexed calix[5]arene[12] and *p-tert*-butylcalix[5]arene[13] adopt shallow cone conformations, as well as the uranyl complex of *p-tert*-butylcalix[5]arene,[8] the dissymmetric coordination to two metal ions and the presence of an intermolecular hydrogen bond in **3** result in some distortion of the cone geometry; the two phenolic rings associated with metal bridging and hydrogen bonding are more tilted with respect to the $O_5$ mean plane [dihedral angles 12.5(2), 80.93(8), 15.9(2), 53.26(7) and 72.85(8)° for the rings bearing O1–O5, respectively]. This conformation differs from that encountered in the similar dimeric europium complex $[Eu($*p-tert*-butylcalix[5]arene–3H)$(dmso)_2]_2$, which has been described as a distorted 1,2-partial cone conformation.[7]

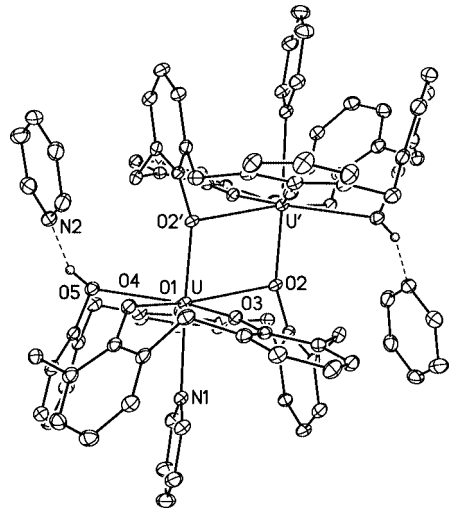

Figure 3. View of complex **3**·4py with displacement ellipsoids drawn at the 30% probability level; two solvent pyridine molecules and hydrogen atoms not involved in hydrogen bonds have been omitted; hydrogen bonds are shown as dashed lines; symmetry code: $2 - x$, $1 - y$, $2 - z$.

## Conclusions

Reactions of $UCl_4$ and $U(OTf)_4$ with calix[5]arene emphasise the extreme sensitivity of uranium(IV) calixarene complexes towards adventitious traces of water and oxygen and their easy oxidation into uranium(V) derivatives. The crystal structure of **2**·4py reveals a novel coordination mode of the calix[5]arene ligand, which was found to be able to accommodate two metal atoms as large as uranium.

## Experimental Section

**General:** All experiments were carried out under argon (<5 ppm oxygen or water) using standard Schlenk-vessel and vacuum-line techniques or in a glovebox. Solvents were dried by standard methods and distilled immediately before use. The $^1H$ NMR spectra were recorded with a Bruker DPX 200 instrument and referenced internally using the residual solvent $^1H$ resonances relative to tetramethylsilane ($\delta$ = 0 ppm). Elemental analyses were performed by Analytische Laboratorien at Lindlar (Germany). Calix[5]arene was purchased from Acros Organics; the TGA-DTA analysis was performed in dry air flow using a SETARAM TGDTA92 analyser; the temperature was increased from ambient to 300 °C applying

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

heating rates of 10 °C min$^{-1}$. $UCl_4$,[14] $U(OTf)_3$ and $U(OTf)_4$[15] were prepared by published methods.

**Crystals of $[Hpy]_2[\{U(calix[5]arene–5H)\}_2(\mu_2\text{-}O)]\cdot 4py$ (1·4py):** A flask was charged with $UCl_4$ (7.2 mg, 0.0188 mmol) and commercial calix[5]arene (10 mg, 0.0188 mmol) in pyridine (0.5 mL). The solution immediately turned orange and dark orange crystals of **1**·4py were deposited after 1 d at room temperature (11 mg, 63%).

**Synthesis of $[Hpy]_3[U_2(calix[5]arene–5H)Cl_6]\cdot 4py$ (2·4py):** Commercial calix[5]arene (50 mg, 0.094 mmol) was dried in pyridine (10 mL) with molecular sieves (4 Å) for 5 d and $UCl_4$ (71 mg, 0.188 mmol) was then added to the solution. After 5 d at 20 °C, the light green crystals of **2**·4py were filtered off and dried under vacuum (38 mg, 24%). $^1$H NMR (200 MHz, [D$_5$]pyridine, 23 °C): $\delta$ = –0.71 and 0.57 (2×2 H, –CH$_2$–), 1.16 (1 H, –CH$_2$–), 1.27 (2 H, –CH$_2$–), 4.46 (1 H, –CH$_2$–), 4.96 (2 H, –CH$_2$–), 7.43 (1 H, aromatic H), 8.51, 9.70, 11.95, 12.97, 13.22, 15.48 and 16.08 (7×2 H, aromatic H) ppm. The elemental analyses were in agreement with the formula $[Hpy]_3[U_2(calix[5]arene–5H)Cl_6]\cdot 3py$. $C_{65}H_{58}Cl_6N_6O_5U_2$ (1691): calcd. C 45.8, H 3.5, N 4.4; found C 46.1, H 3.4, N 4.3.

**Reaction of $U(OTf)_3$ with Calix[5]arene:** An NMR tube was charged with $U(OTf)_3$ (12.9 mg, 0.019 mmol) and commercial calix[5]arene (10 mg, 0.019 mmol) in pyridine (0.5 mL). After 12 h at 20 °C, dark orange crystals of **1**·4py and light green crystals of $[U(calix[5]arene–4H)(py)]_2\cdot 4py$ (**3**·4py) were deposited.

**Reaction of $U(OTf)_4$ with Calix[5]arene:** Commercial calix[5]arene (50 mg, 0.094 mmol) was dried in pyridine (10 mL) with molecular sieves (4 Å) for 5 d and $U(OTf)_4$ (78.7 mg, 0.094 mmol) was then added to the solution. After 5 d at 20 °C, green crystals of **3**·4py contaminated with a brown powder were deposited (35 mg, about 40%). Compound **3**·4py was identified by X-ray diffraction analysis but could not be characterised by $^1$H NMR because of its insolubility.

**X-ray Crystallography:** The data were collected at 100(2) K on a Nonius Kappa-CCD area detector diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The crystals were introduced into glass capillaries with a protecting "Paratone-N" oil (Hampton Research) coating. The unit cell parameters were determined from ten frames, then refined on all data. The data ($\varphi$- and $\omega$-scans)[16] were processed with HKL2000.[17] The structures were solved by direct methods or Patterson map interpretation with SHELXS-97 and subsequent Fourier-difference synthesis and refined by full-matrix least-squares on $F^2$ with SHELXL-97.[18] Absorption effects were corrected empirically with the program DELABS in PLATON[19] or with SCALEPACK.[17] All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms bound to N1 in **1**·4py and O5 in **3**·4py were found on Fourier-difference maps, but those bound to N atoms in **2**·4py were not found or introduced. All the other hydrogen atoms were introduced at calculated positions. All were treated as riding atoms with an isotropic displacement parameter equal to 1.2 times that of the parent atom. In **2**·4py, one pyridine molecule (containing N7) was affected with a 0.5 occupancy parameter so as to retain acceptable displacement parameters and four solvent pyridine molecules or pyridinium ions, being badly resolved, were refined as idealised hexagons; restraints on displacement parameters had to be applied for the atoms of some pyridine molecules or pyridinium ions. Crystal data and structure refinement details are given in Table 2. The molecular plots were drawn with SHELXTL.[20]

# Nonlinear, Resonance-Stabilized Pseudohalides: From Alkali Methanides to Ionic Liquids of Methanides

**Harald Brand,[a] Joel F. Liebman,[b] Axel Schulz,*[a] Peter Mayer,[a] and Alexander Villinger[a]**

*Dedicated to Professor Dr. Karl Otto Christe on the occasion of his 70th birthday*

**Keywords:** Ionic liquid / Methanides / Pseudohalides / Resonance / X-ray structure elucidation

New 1-ethyl-3-methylimidazolium (EMI) salts [EMI][X] (X = $[HC(NO_2)(CN)]^-$, $[C(NO_2)(NO)(CN)]^-$, $[HC(NO)_2]^-$ and $[HC(NO_2)_2]^-$) and 1-*n*-butyl-3-methylimidazolium (BMI) salts [BMI][Y] (Y = $[C(CN)_3]^-$ and $[C(NO_2)(NO)(CN)]^-$) were prepared and characterized. Different synthetic routes to these new resonance-stabilized methanide-based ionic liquids starting either from the explosive silver salts (except from $Ag[C(CN)_3]$) or the easily accessible potassium salts have been described. The melting points of all new salts are lower than 100 °C, in fact, most of them are ionic liquids at room temperature. These strongly colored ionic liquids (besides $[BMI][C(CN)_3]$ which is colorless) are neither heat nor shock sensitive, are thermally stable up to over 52 °C ($[EMI][C(NO_2)(NO)(CN)]$) and 270 °C ($[BMI][C(CN)_3]$) and can be prepared in large quantities. The structure and bonding of resonance-stabilized methanides ($[CR^1R^2R^3]^-$ with $R^{1,2,3}$ = H, $NO_2$, NO, and CN) is discussed on the basis of experimental and theoretical data. X-ray data of $Cs^+[HC(NO_2)(CN)]^-$, $K^+[HC(NO_2)_2]^-$, $[EMI]^+[C(NO_2)(NO)(CN)]^-$, and $[Me_4N]^+[C(NO_2)(NO)(CN)]^-$ reveal almost planar anions with strong cation···anion interactions in the alkali methanides resulting in three-dimensional network structures in the solid state. Only weak interionic interactions are found for the ammonium salts. As shown by different theoretical approaches (charge transfer, resonance energies and NLMO delocalization) resonance effects occur in all three classes of methanides ($NO_2$-, NO-, and CN-substituted), however, the magnitude of such effect strongly differs depending on the degree of substitution.

## Introduction

The term *pseudohalogen* was first introduced by Lothar Birckenbach[1a] in 1925 and further developed and justified in a series of papers in the following years.[1b–1d] The anions $CN^-$, $CNO^-$, $N_3^-$, $OCN^-$, and $SCN^-$ can be coined *classical linear pseudohalides*. A small species can be classified as a classical pseudohalogen when it fulfills the following criteria with respect to a halogen-like chemical behavior:[2,3] A pseudohalogen (X) forms (i) a strongly bound (linear) univalent radical ($X^{\cdot}$), (ii) a singly charged anion ($X^-$), (iii) a pseudohalogen hydrogen acid of the type HX, (iv) salts of the type $M(X)_n$ with silver, lead and mercuric salts of low solubility, (v) a neutral dipseudohalogen compound (X–X) which disproportionates in water and can be added to double bonds, and (vi) interpseudohalogen species (X–Y). However, not all criteria are always met. While many linear pseudohalogens (e.g. CN, OCN, CNO, $N_3$, SCN) are known, often the corresponding pseudohalide acids, dipseudohalogens, and interpseudohalogens are thermodynamically highly unstable (e.g. $HN_3$, OCN–NCO, NC–SCN) with respect to $N_2$/CO elimination or polymerization or indeed, remain unknown (e.g. $N_3$–$N_3$).

Starting from the binary non-metal hydrides $CH_4$, $NH_3$, $H_2O$ etc. a simple approach can be utilized to derive the hydrogen acids of the classical linear pseudohalides by combining or substituting isolobal (e.g. HC≡/≡N in HCN, HN=/=N=N in $HN_3$, HO–/–CN in HOCN), isosteric (e.g. $N_2$/CO in $HN_3$/HNCO) or isovalence electronic fragments (e.g. CO/CS in HOCN/HSCN).[2]

Nonlinear resonance-stabilized pseudohalides can be derived with the help of the Grimm hydride displacement law, a pseudoelement concept established as early as 1925.[4] This law describes the formation of a new pseudoelement $\cdot AH_n$ when *n* H (*n* = 1–4) atoms are formally added to the element A. The new complexes $\cdot AH_n$ (e.g. ·OH, $\cdot NH_2$ and $\cdot CH_3$) behave like pseudoatoms (in this case like halogens)

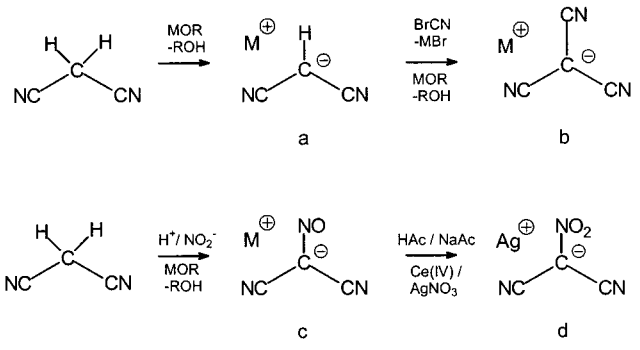
similar to elements of the group *n* positions to the right in the Periodic Table (e.g. they form singly charged anions: $OH^-$, $NH_2^-$, and $CH_3^-$, or neutral dimers: HO–OH, $H_2N$–$NH_2$ and $H_3C$–$CH_3$). However, chemically there is a significant difference in the basicity between these pseudohalides and the halides as the latter represent only very weak bases while these pseudohalides are strong bases. Only the successive substitution of the hydrogen atoms in $\cdot CH_3$ ($CH_3^-$) and $\cdot NH_2$ ($NH_2^-$) by electron-withdrawing groups such as CN, NO, and $NO_2$, leads to the class of resonance-stabilized, nonlinear pseudohalogens (pseudohalides). Important is also the capability of the electron-withdrawing groups to delocalize the single p-AO-type lone pair (AO = atomic orbital) of the C and N atom in $CH_3$ ($CH_3^-$) and $\cdot NH_2$ ($NH_2^-$), respectively, to decrease the basicity into the range of the halides. A compilation of all resonance-stabilized methanides, $[CR^1R^2R^3]^-$ ($R^{1,2,3}$ = H, $NO_2$, NO, and CN), is displayed in Table S0 (see Supporting Information).

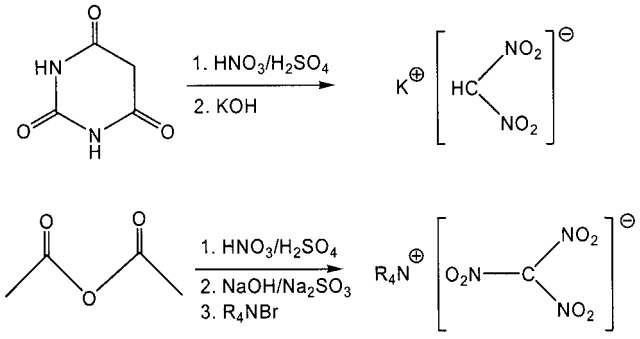
Generally, the synthesis of methanides starts from the free hydrogen acid which often is only generated in situ. Neutralization leads then to the according methanide salt. For instance malonodinitrile (Scheme 1, a)[5] is used to synthesize dicyanomethanides and tricyanomethanides (Scheme 1, b).[6] Nitrosation of malonodinitrile followed by a basic work up yields the nitrosodicyanomethanide, $[C(CN)_2(NO)]^-$, (Scheme 1, c).[7] Oxidation of the nitrosodicyanomethanides with ammonium cerium(IV) nitrate results in the formation of nitrodicyanomethanide, $[C(CN)_2(NO_2)]^-$, (Scheme 1, d),[7c,8] rather than the formation of the dimeric hexasubstituted ethane by radical coupling reactions. In the section "Results and Discussion" the following abbreviations are used: Nt = nitro, N = nitroso, C = cyano, M = methanide, combined with the multiplying prefixes D = di and T = tri; example: NtDCM = nitrodicyanomethanide (see Table S0 in the Supporting Information).



Scheme 1. Synthesis of dicyano, tricyano-, nitrosodicyano- and nitrodicyanomethanides.

Dinitromethanide (DNtM) can be prepared by nitration of barbituric acid followed by an alkaline work up procedure.[9] Access to trinitromethanides (TNtM) is possible by nitration of acetic anhydride followed by neutralization in the presence of sodium sulfite (Scheme 2).[10]

Recently, we have described the synthesis of the trisubstituted nitro(nitroso)cyanomethanides (NtNCM) and the disubstituted dinitrosomethanides (methylnitrosolates, DNM).[11,12] Nitro(nitroso)cyanomethanides can be generated by nitrosation of nitroacetonitrile followed by a basic work up, while treating formamidinium nitrate with hydroxylammonium nitrate and MO*t*Bu (M = alkali metal) in the presence of oxygen yields the deep blue alkali dinitrosomethanides.



Scheme 2. Synthesis of dinitro- and trinitromethanides.

Herein, we want to report on the synthesis, structure and properties of new ionic liquids based on some resonance-stabilized methanides and alkali methanides as well as on the resonance-stabilization and bonding of these methanides $[CR^1R^2R^3]^-$ ($R^{1,2,3}$ = H, $NO_2$, NO, CN; as well as all permutations of $R^{1,2,3}$).

## Results and Discussion

### Synthesis of Methanide-Based Ionic Liquids

Ionic liquids of resonance-stabilized methanides can easily be prepared from the alkali salts utilizing the properties of a pseudohalogen.[2] The first synthetic step includes the formation of the nearly insoluble silver salts in water (AgX, X = methanide, Scheme 3). Because the silver salts dissolve in 2 N $NH_3$(aq.), adding ethyl(methyl)imidazolium bromide ($EMI^+Br^-$)[13] results in the formation of a water soluble ethyl(methyl)imidazolium methanide ($EMI^+X^-$) which can be separated from the AgBr precipitate by filtration. A specific drying procedure involving stepwise addition and removal of dried methanol, THF and dichloromethane followed by removing traces of water or solvent molecules in high vacuum (HV) is necessary to obtain pure ionic liquids of the type $EMI^+X^-$.

A different approach has been used in case of NtNCM-based ionic liquids because the silver salt, AgNtNCM, is reasonably soluble in water. For this reason KNtNCM was treated with $AgNO_3$ in a 1:1 mixture of methanol and ethanol yielding dissolved AgNtNCM and $KNO_3$ as a white precipitate. Then this AgNtNCM solution is treated by a solution of ethyl(methyl)imidazolium ($EMI^+Br^-$) or *n*-butyl(methyl)imidazolium bromide ($BMI^+Br^-$) in THF resulting in the formation of the ionic liquids $EMI^+NtNCM^-$ and $BMI^+NtNCM^-$, respectively, and a AgBr precipitate which can be separated by filtration. Again, a specific drying procedure is needed to isolate pure NtNCM-based ionic liquids (see Scheme 3).

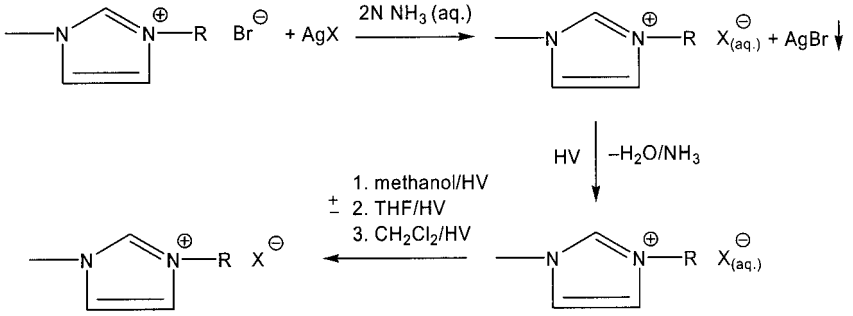

Scheme 3. Synthetic procedure for the isolation of pure, dry ionic liquids of resonance-stabilized methanides (R = Et, *n*Bu; X = methanide; HV = high vacuum, ± = addition and removal of solvent for several times).

An alternative route to ionic liquids of methanides avoiding the explosive silver salts (except from AgTCM) involves the use of imidazolium tetrafluoroborate salts (e.g. $EMI^+BF_4^-$). Because $KBF_4$ precipitates in a methanol/water solution, the reaction of potassium methanides with imidazolium tetrafluoroborate salts yields imidazolium methanides (e.g. $EMI^+X^-$) dissolved in methanol/water.

## Properties of Methanide-Based Ionic Liquids

In contrast to most of the high energy-density alkali and silver (NO- and $NO_2$-substituted) methanides,[11,12] the ionic liquids of methanides with a bulky organic cation are neither heat nor shock sensitive, and hence can be prepared and stored on a large scale. Nevertheless, this type of methanide-based ionic liquids can also be considered as "energetic ionic liquids" because the thermodynamically unstable methanide anion is only kinetically stabilized by the bulky organic cation such as $EMI^+$ or $BMI^+$.[14] Methanide-based ionic liquids are very hygroscopic and immediately absorb water when exposed to air. In the series of the alkali methanides it is mostly the lithium and sodium salts that are hygroscopic and to a much lesser extent are the heavy alkali salts (K, Cs).[11,12]

The decomposition temperature of methanide-based ionic liquids ranges, dependent on the counterion, between $T_{dec}$ = 52 °C [$EMI^+NNtCM^-$] and 270 °C [$BMI^+TCM^-$] (Table 1).[15] As expected, ionic liquids of methanides substituted solely by NO or by $NO_2$ are less stable compared to the pure cyanomethanide-based species. Furthermore, a slow decomposition of the NO- and $NO_2$-substituted methanides (both ionic liquids and alkali salts) is also observed when exposed to air.

Different decomposition reactions can be expected e.g. the oxidation or hydrolysis according to

$$HC(NO)_2^- + 1/2\ O_2 \rightarrow HC(NO)(NO_2)^- \rightarrow NO_2^- + HCNO$$

$$HC(NO)_2^- + H_2O \rightarrow HC(NO)NOH + OH^-$$

$$2\ HC(NO)NOH \rightarrow 2\ HCNO + H_2O + N_2O.$$

The formation of $N_2O$ was experimentally observed when traces of water were present. The decomposition of the free methylnitrosolic acid goes via a dimer. Dimerization of NO species is known for many NO compounds such as HNO and both alkyl and most aryl NO compounds.[16] Hence, NO- and $NO_2$-substituted methanide salts and ionic liquids should be stored under nitrogen at temperatures below –5 °C.

So far we have not been able to crystallize any of the discussed ionic liquids without solvent. Solidification resulted only in glass formation, a well-precedented phenomenon for ionic liquids.[17] However, storing saturated (e.g. ethanolic) solutions of ionic liquids at very low temperature often results in the formation of crystals suitable for single-crystal X-ray investigations (see section X-ray elucidation). The experimentally determined melting points varying between –48 °C ($BMI^+TCM^-$) and 48 °C ($EMI^+DNtM^-$) (Table 1), with the BMI salts always possessing the lower melting point. It can be assumed that both the number and the strength of interionic interactions (Coulomb and hydro-

gen bonding) as well as the size of the ions is responsible for the fairly wide range of observed melting points (see section X-ray elucidation).

On the basis of the characteristic group frequencies [NO (1200–1600 $cm^{-1}$), $NO_2$ (1230–1580 $cm^{-1}$), and CN (2100–2290 $cm^{-1}$)] methanides of the type $[CR^1R^2R^3]^-$ ($R^{1,2,3}$ = H, $NO_2$, NO, CN) are easily identified by Raman and IR spectroscopy.[2,7,11,12] Interestingly, the wavenumber of the characteristic frequency increases with the degree of substitution (Table 3 and Table 4).

As expected, the $^{13}C$ NMR resonance of the methanide C atom strongly depends on the substitution pattern (Table 2). The resonance signal of the methanide C atom attached to a CN group is always observed at smaller $\delta^{13}C$ values compared to the resonance signal of methanide C atoms attached to $NO_2$ and NO groups displaying a stronger deshielded $^{13}C$ nucleus in the latter cases (TCM: $\delta^{13}C$ = 5.1 ppm, NtCM: $\delta^{13}C$ = 80.5 ppm, NtNCM: $\delta^{13}C$ = 149.6 ppm). This is in accord with the larger charge transfer and a smaller negative partial charge localized at the methanide C atom when attached to NO or $NO_2$ groups (see section on bonding). $^{14}N$ NMR spectroscopic data can also be utilized to distinguish between CN, NO and $NO_2$ (NO: broad resonances $\delta^{14}N$ = 250–330, $NO_2$: $\delta^{14}N$ = –25 to –10, CN: $\delta^{14}N$ = –130 to –100 ppm; Table 2).

Nitrosomethanides are deeply colored ionic liquids (NtNCM: dark red, DNM: dark blue), while nitromethanides display a yellow/brown color (DNtM/NtCM) and pure cyanomethanides are colorless (UV/Vis data, Table 2 and Table S4). The UV/Vis spectra of alkali methanide salts, $[CR^1R^2R^3]^-$ exhibit one very strong characteristic $\pi\rightarrow\pi^*$ transition in the non-visible range below 300 nm. However, the color arises from weak $n\rightarrow\pi^*$ HOMO–LUMO electronic transition in the anion, where the HOMO describes a lone pair which lies in the anion plane. A closer inspection of the orbital coefficients composing the HOMO in $[CR^1R^2(NO)]^-$ ($R^1$, $R^2$ = H, $NO_2$, CN) show the largest coefficients for the nitroso group; hence it can be concluded that the nitroso group is mainly responsible for the color in the NO-substituted methanides.[11] We recall that monomeric, neutral nitroso compounds are usually intensely colored while their nitro counterparts and nitriles are generally colorless. It can be assumed that in the mixed-substituted methanides the color is "dominated" by NO > $NO_2$ > CN. Moreover, the color of most alkali methanide salts darkens with increasing heaviness of the alkali-metal counterion which can be attributed to strong cation···anion interactions

resulting in small (but visually significant) changes of the HOMO–LUMO gap.[11]

### Structure of Resonance-Stabilized Methanides

Carbanions of the type $[H_2CR^1]^-$, $[HCR^1R^2]^-$, and $[CR^1R^2R^3]^-$ ($R^{1,2,3}$ = CN, NO, $NO_2$ and all possible permutations of $R^{1,2,3}$) can be considered to be resonance-stabilized, nonlinear pseudohalides. All experimentally known resonance-stabilized methanides are reported to be planar or nearly planar (Table S0). To get further inside into the structure and bonding of these anions DFT calculations at the B3LYP/aug-cc-pvTZ level of theory have been carried out (Table 3 and Figures 1 and 2).

While the parent ion, the methanide anion $H_3C^-$, adopts a pyramidal structure [$\Delta E_{planar–pyramidal}$ = 2.35 kcal/mol; $d$(CH) = 1.099 Å, <(HCH) = 109.7°; cf. $d$(CH) = 1.093 Å, <(HCH) = 109.6°],[18] substitution of one H atom by any of the R groups results in planar anions (Figure 1 and Figure 2) other than $H_2C–CN^-$ for which the non-planar $C_S$-symmetric structure is favored by only 0.03 kcal/mol indicating a very flat potential energy surface [cf. 0.15 kcal/mol,

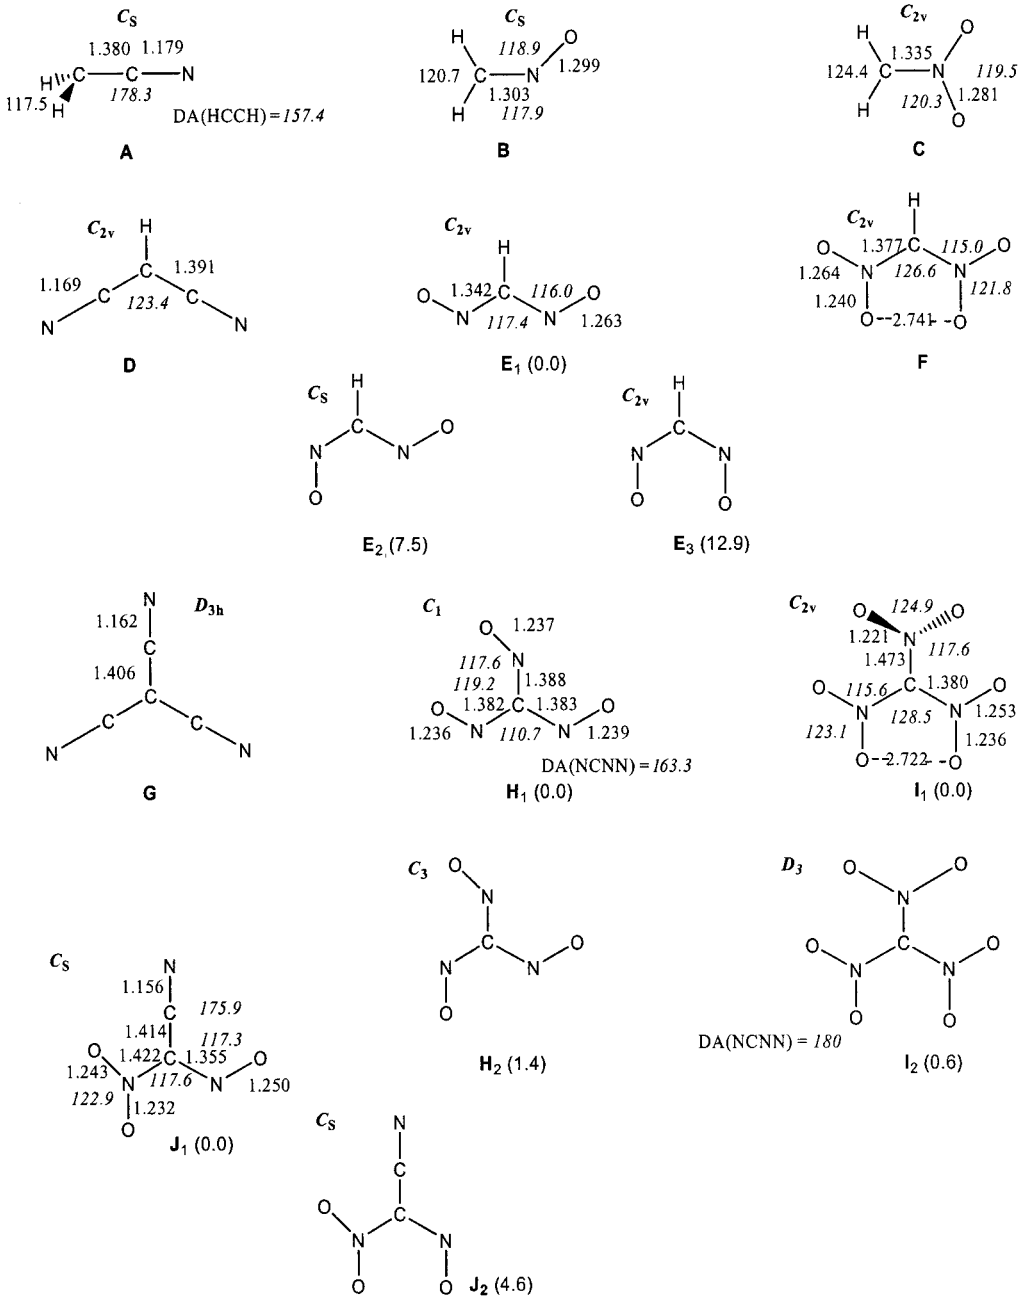

Figure 1. $[CR^1R^2R^3]^-$ ($R^{1,2,3}$ = H, CN, NO, $NO_2$): Molecular models of found isomers A–$J_2$ and selected optimized structural parameters for the global minima [B3LYP/aug-cc-pvTZ, angles in ° (*italics*), bond lengths in Å, DA = dihedral angle, in parenthesis relative energies of isomers in kcal/mol].

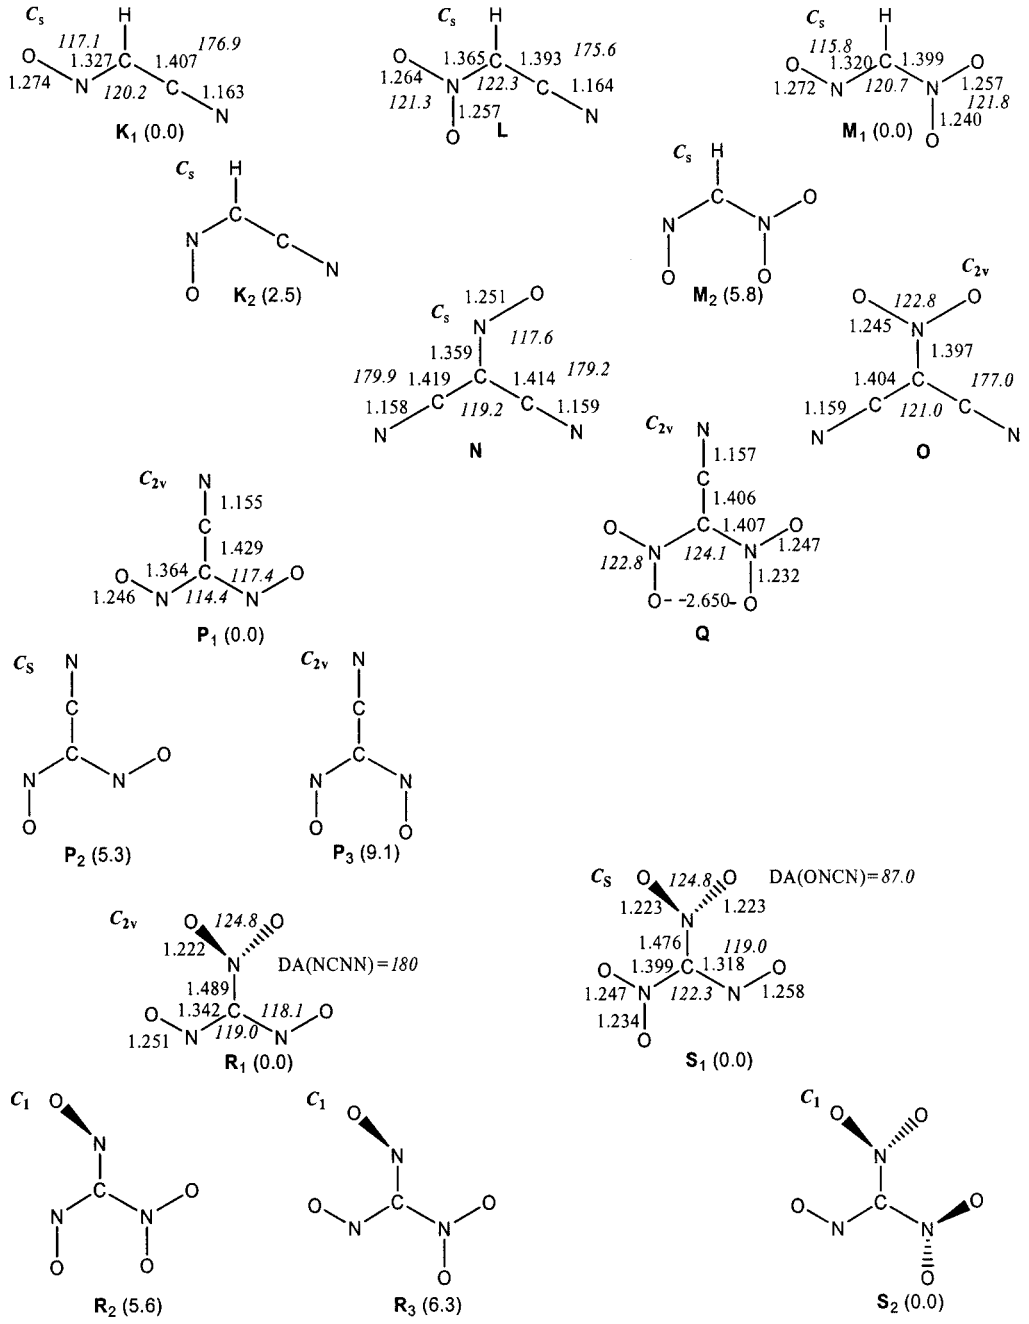

Figure 2. $[CR^1R^2R^3]^-$ ($R^{1,2,3}$ = H, CN, NO, $NO_2$): Molecular models of found isomers K–$S_2$ and selected optimized structural parameters for the global minima [B3LYP/aug-cc-pvTZ, angles in ° (*italics*), bond lengths in Å, DA = dihedral angle, in parenthesis relative energies of isomers in kcal/mol].

out-of-plane deformation angle $\alpha$ = 33.6° at MP2/6-31+G(d)].[19] Inclusion of zero-point vibrational energy at 0 K displays a different picture with the planar structure now being 0.25 kcal/mol [$\Delta(E^{tot}+zpe)$] favored over the non-planar structure. Thermal correction to 298 K slightly increases this value to 0.58 kcal/mol ($\Delta_{298}H$) while explicit consideration of the entropy again favors the non-planar structure with 0.42 kcal/mol ($\Delta_{298}G$). Experimentally, the $H_2C–CN^-$ carbanion was found non-planar with the hydrogen atoms slightly bent out of the molecular plane (out-of-plane deformation angle 30 ± 5°) and a very small inversion barrier of 0.28 ± 0.14 kcal/mol.[20]

The molecular models together with selected calculated data and relative energies are given in Figure 1 and Figure 2. Further substitution of the second H atom again results in planar anions, the same holds for the third substitution in case of R = CN, leading to the $D_{3h}$-symmetric TCM, the most prominent methanide. In case of R = NO and $NO_2$ the third substitution leads either to a propeller type ($D_3$ symmetry) structure with only a small distortion from plan-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

arity or one $NO_2$ group is twisted by 90°, nevertheless leaving the central carbon in an almost trigonal-planar environment.[21]

It is interesting to note that both the DNM and DNtM anions are planar ($C_{2v}$-symmetric) in the experiment (Figure 3) and theory (Figures 1 and 2), whereas the dinitramide, $[N(NO_2)_2]^-$ (isoelectronic with DNtM) adopts an non-planar ideal $C_2$-symmetric propeller-like structure (but only in the gas phase). Steric repulsion between the lone pairs on the nitrogen and oxygen atoms account for the typically non-planar geometry of the ion $[N(NO_2)_2]^-$, while cation···anion interactions are responsible for a different magnitude of distortions from $C_2$ symmetry (between 3–33°, X-ray data).[22] Consider the analog planar methanide $[HC(NO_2)_2]^-$: N is formally substituted by HC, which means instead of a lone pair a H–C bond is introduced. The electrostatic repulsion is decreased (by formation of two intramolecular C···H···O hydrogen bonds) resulting in a planar structure which allows a maximum of resonance stabilization.

Our calculated structural data display, that obviously only two NO or $NO_2$ groups fit into a planar structure in a methanide as long as $R^3$ is either H or CN. However, when a third NO or $NO_2$ group is introduced in the methanides (TNM, TNtM, DNtNM, NtDNM), the larger electrostatic repulsion forces the anion into a non-planar geometry. Here, the balance between resonance stabilization and steric repulsion results in the torsion of one $NO_2$ or NO group out of the anion plane. Moreover, a $D_3$ propeller-shaped isomer is found being 0.6 kcal/mol less stable (TNtM). In agreement with theory, experimentally for TNtM both isomers are found in single crystal X-ray investigations with dihedral angles between the $NO_2$ planes varying from 60–100°.[10,23]

Moreover, fairly small O···O distances (ranging between 2.60–2.75 Å) are found for all DNtM anions $[R–C(NO_2)_2^-$, Figures 1 and 2]. AIM analyses[24] of DNtM anions show in addition to the expected bond path network, a (3,–1)[25] unusual bond critical point (CP) along $O(NO_2^a)\cdots O(NO_2^b)$ lines (Figure 4). The origin of this bond CP has been described recently by Pinkerton et al. as a bonding closed-shell-type interaction between the negatively charged oxygen atoms belonging to different nitro groups.[26]

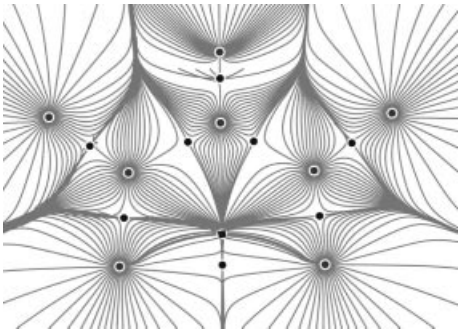

Figure 4. The gradient lines of the electron density in DNtM and the projection of the molecular graph onto the anion plane. The bond CP's are shown as circles and the ring CP's are shown as rectangles.

Balance between resonance and electrostatic repulsion seems to be the important structure factor not only to answer the question of a planar vs. non-planar structure but also to explain the energy differences between different isomers (see Figure 1 and Figure 2, e.g. TNM isomers $\mathbf{I}_1$ and $\mathbf{I}_2$ or NtNCM isomers $\mathbf{J}_1$, and $\mathbf{J}_2$) besides the aforementioned intramolecular hydrogen bonds (see Figures 1 and 2, e.g. DNM isomers $\mathbf{E}_1$, $\mathbf{E}_2$ and $\mathbf{E}_3$, or $\mathbf{R}_1$, $\mathbf{R}_2$ and $\mathbf{R}_3$). Isomeric anions are only found for the NO- and $NO_2$-substituted methanides. In NO-substituted methanides those isomers are energetically favored which adopt an *anti*/*anti* configuration with respect to a second NO or $NO_2$ group. The relative energy difference between different isomers is given in Figures 1 and 2.

All multiply substituted cyanomethanides (DCM, TCM, NCM, NDCM, DNCM, NtCM, NtDCM and DNtCM) adopt a planar structure at the theoretical level applied, nicely in agreement with experimental data.[7c,11,27–29]

A CN group attached to a methanide C atom forms always a linear or nearly linear [<(CCN) = 175°] CCN moiety. Upon further CN substitution the C–CN bond lengths increases (CM: 1.380, DCM: 1.391, TCM: 1.406 Å) while the CN bond lengths decreases (CM 1.179, DCM: 1.169, TCM: 1.162 Å). Similar trends for the C–NO bonds are found along the series NM, DNM and TNM (1.303, 1.342 and 1.380–1.388 Å) as well as for the nitromethanides (1.335, 1.377 and 1.380–1.470 Å), while the NO bonds decrease. The $C–N_{nitroso}$ bond length is significantly smaller than the $C–N_{nitro}$ bond length which again is smaller than the C–CN bond length indicating a stronger π interaction along the $C–N_{nitroso}–O$ moiety [Figure 1, e.g. $d([H_2C–R^1]^–)$: $R^1$ = NO 1.303, $NO_2$ 1.335 and CN 1.380 Å] which nicely agrees with experimental observations.[7c,11,12,29]

### X-ray Elucidation – Interaction between Alkali/Ammonium Cations and Resonance-Stabilized Methanides

In accord with the theoretically derived structural data of resonance-stabilized methanides, the experimental data of KDNtM, CsNtCM, $[Me_4N]$NtNCM and [EMI]NtNCM reveal nearly planar anions, with bond lengths and angles as discussed above. The asymmetric units along with selected bond lengths and angles are displayed in Figure 3. In the following discussion we would like to focus on the interaction between cations and anions.

As shown on numerous occasions, the solid-state structure of alkali methanides consists of an infinite three-dimensional network with coordination numbers between 8 (e.g. KDNtM) and 13 (e.g. CsDNM;[12] see Figures S1–S3 in the Supporting Information, displaying the coordination environment of KDNtM, CsNtCM and $[Me_4N]$NtNCM). Moreover, a great diversity of bonding modi is found. Usually the CN groups coordinate one or two neighboring cation centers, NO one to three cations through the oxygen and/or the nitrogen atoms whereas a $NO_2$ group exclusively coordinates through the oxygen atoms up to three cation centers in both mono and bidentate fashion. These strong cation···anion interactions lead to an interesting three-dimensional network arrangement of the ions (Figure 5, a–b) in the solid with chains of $M^+$ and $[CR^1R^2R^3]^–$ stacked one upon the other. If such interactions are suppressed by using almost non-coordinating cations such as $EMI^+$ or $Me_4N^+$ the anions still show this type of parallel anion arrangement in the solid state (Figure 5, c–d).

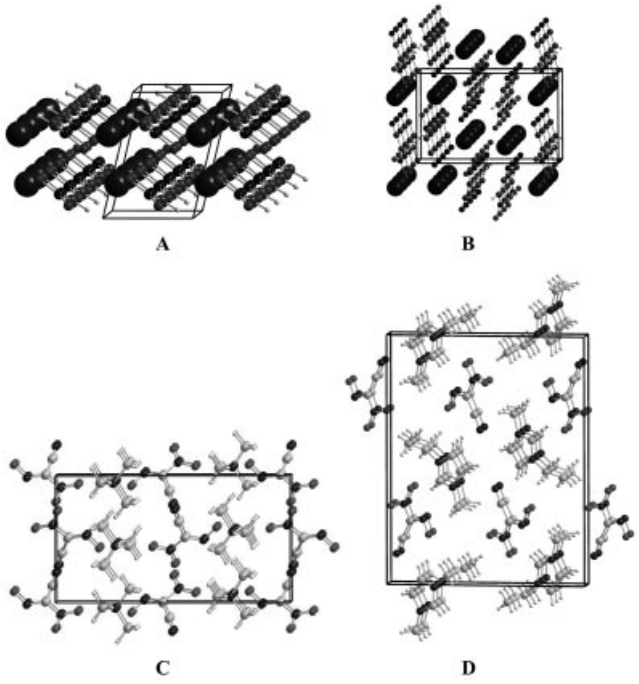

Figure 5. Packing diagram of **A** KDNtM: view along *c* axis, **B** CsNtCM: view along *a* axis, **C** $[Me_4N]$NtNCM: view along *c* axis, and **D** [EMI]NtNCM view along *a* axis.

So far we were not able to crystallize any of our ionic liquids from the melt, however, we succeeded in crystallizing $EMI^+NtNCM^–$ from a saturated ethanolic solution at –30 °C. The unit cell contains one crystallographically independent $EMI^+NtNCM^–$ species (Figure 3). Both the EMI

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cations and the NtNCM anions form two-dimensional layers which are nearly parallel to each other but two $EMI^+$ layers are always separated by one $NtNCM^-$ layer and vice versa (Figure 5, D). Only very small van der Waals interaction can be assumed between the anion and cation layers, as well as within the anion and cation layers, because fairly long interaction distances are observed [shortest $d(EMI^+\cdots EMI^+)$ = 3.1–3.5, $d(NtNCM^-\cdots NtNCM^-)$ = 3.3, and $d(EMI^+\cdots NtNCM^-)$ = 2.3–2.8 Å] (Figure 6). The interionic distances with 2.3–2.8 Å are significantly shorter than in $EMI^+TCM^-$ (3.05–3.2 Å)[13c] and can be partly attributed to the interionic Coulomb attractive forces; however, for $Me_4N^+NtNCM^-$ there are significantly more interionic interactions (of the type: C–H···O–N–O, C–H···O–N, C–H···N–O, C–H···N–C) in the range between 2.2 and 3.0 Å compared to $EMI^+NtNCM^-$ (cf. Figure 6 and Figure S1/Table S2 in Supporting Information). Hence, it can be assumed that the total interionic interaction decreases along $EMI^+TCM^- < EMI^+NtNCM^- < Me_4N^+NtNCM^-$. In accord with this, the lowest melting point is found for $EMI^+TCM^-$ ($T_m$ = –11 °C),[13c] followed by $EMI^+NtNCM^-$ ($T_m$ = 35 °C, $T_{dec,onset}$ = 52 °C) and $Me_4N^+NtNCM^-$ ($T_m > T_{dec,onset}$ = 70 °C).

### Bonding and Resonance Stabilization in Resonance-Stabilized Methanides

Structural parameters such as the fairly short C–NO, C–$NO_2$ and C–CN bond lengths together with the planarity, indicate the presence of over the whole anion delocalized π bonds. MO and NBO[30] calculations displayed the existence of an ($n$π-electron,$m$-center) bond unit in all methanides (Scheme 4, with $n = 2+4x+2y+2z$ and $m = 1+3x+2y+2z$; $x$ = number of $NO_2$ groups, $y$ = number of NO groups and $z$ number of CN groups in the anion plane).

To gain a quantitative view of the delocalization of the p-type lone pair (LP) localized at the central C atom, the partial charges, occupancies of the p-type LP {*occ*[LP(C)-$p_z$]} and the charge transfer upon substitution have

[a] The data of the mixed species are given in the supporting information. [b] Percent of localization of the methanide lone pair on the carbon atom according to the calculated NLMO (natural localized molecular orbital).

been carefully investigated. The overall charge transfer [$q_{CT}(\pi+\sigma)$] was divided into a π [$q_{CT}(\pi)$] and σ contribution [$q_{CT}(\sigma)$, Table 4]. As displayed in Table 4, the delocalization of the p-type lone pair, $q_{CT}(\pi)$, increases along the series CN < $NO_2$ < NO for all substitution patterns whereas the σ contribution increases along CN < NO < $NO_2$. Introduction of the second group R (R = NO, $NO_2$, CN) results once again in an increase of both the π and σ contribution, although the magnitude strongly decreases especially for the π contribution [e.g. $CH_2NO^-$: –0.75 and –0.15 $e$ for the second NO group in $CH(NO)_2^-$ resulting in an overall $q_{CT}(\pi)$ = –0.90 $e$]. Upon introducing a third group R, the π contribution increases very slightly for TCM but slightly decreases for TNM and TNtM. However, in all cases the σ contribution increases significantly. The dramatic decrease of the partial charge on the C atom (cf. –1.45 in $CH_3^-$ vs. +0.15 $e$ in TNtM) in the methanides is mainly attributed to the delocalization of the p-LP (π contribution) and the increase of the polarization in the σ bonds upon substitution. The σ contribution increases relatively to the π contribution the larger the degree of substitution. The best delocalization of the p-type LP is found in DNM with $q_{CT}(\pi)$ = –0.90 $e$. Molecular orbital, classical VB resonance structures and electron-charge arguments suggest that most of the negative charge in the NO- and $NO_2$-substituted methanides is located on the oxygen atom, which is also the more electronegative element.

To estimate the resonance stabilization energy we have computed the reaction energies of a series of isodesmic reactions[31] according to Equations (1), (2), and (3) (Table 5). The computed resonance stabilization energies reveal a similar picture like the charge transfer/delocalization consideration for the first substitution, displaying the largest resonance energy in $[HC–NO]^-$ followed by the $NO_2$- and CN-substituted methanides (–69.2, –62.6, and –44.8 kcal/mol). The order changes with the second substitution (NO: –44.16 > CN: –42.3 > $NO_2$: –36.7 kcal/mol) and third substitution (CN: –35.7 > $NO_2$: –13.2 > NO: –7.41 kcal/mol), with the cyano group now delivering the largest resonance energy. While the second and the third incremental resonance energies in the CN methanides decrease only very little, a dramatic decrease is observed for the NO and $NO_2$ methanides. However, although the resonance energy for the second substitution strongly decreases for NO and $NO_2$, the overall $\Delta_{res}E$ [Equation (1) + Equation (2)] values are still larger than for DCM (DNM > DNtM > DCM). Only with the third substitution, the cyano compound displays also the largest overall $\Delta_{res}E$ [Equation (1) + Equation (2) + Equation (3)] with –122.8 compared to –120.7 for TNM and –112.5 kcal/mol for TNtM, in accord

Table 5. Resonance energies according to Equations 1–3.[a,b]

| $\Delta_{res}E$ | $R^1 = R^2 = R^3 = CN$ | $R^1 = R^2 = R^3 = NO$ | $R^1 = R^2 = R^3 = NO_2$ |
|---|---|---|---|
| $\Delta_{res}E$ [Equation (1)] | –44.83[c] | –69.18 | –62.56 |
| $\Delta_{res}E$ [Equation (2)] | –42.33[c] | –44.16 | –36.75 |
| $\Delta_{res}E$ [Equation (3)] | –35.68 | –7.41 | –13.20 |
| $\Delta_{res}E$ [Equation (1) + Equation (2)] | –87.14 | –113.43 | –99.31 |
| $\Delta_{res}E$ [Equation (1) + Equation (2) + Equation (3)] | –122.82 | –120.75 | –112.51 |
| $\Delta_{res}E$ | $R^1 = CN$, $R^2 = NO$, $R^3 = NO_2$ | $R^1 = CN$, $R^2 = NO_2$, $R^3 = NO$ | $R^1 = NO$, $R^2 = NO_2$, $R^3 = CN$ |
| $\Delta_{res}E$ [Equation (3)] | –27.42 | –31.06 | –21.76 |

[a] Values according to Equation (1) and (2) for the mixed species are given in the supporting information. [b] All resonance energies refer to the best isomer of the H–C bound acid; see Equation (1)–(3). Note: For $R^{1,2,3}$ = H, NO the *aci* form represents always the global minimum while for $R^{1,2,3}$ = H, CN and $NO_2$ the H–C bound acid is the global minimum (values for the *aci* form are given in the supporting information). [c] For planar $C_{2v}$-symmetric $H_2C–CN^-$: $\Delta_{res}E$ [Equation (1)] = –44.80 and $\Delta_{res}E$ [Equation (2)] = –42.36 kcal/mol.

with experimental observations. TCM salts are known and thermally stable while TNtM salts are labile (highly explosive) species, and TNM are not known yet but can be expected to be very labile.

$$[H_3C]^- + H_3C–R^1 \rightarrow [H_2CR^1]^- + H_3C–H \quad (1)$$

$$[H_2CR^1]^- + H_2CR^1R^2 \rightarrow [HCR^1R^2]^- + H_3C–R^1 \quad (2)$$

$$[HCR^1R^2]^- + HCR^1R^2R^3 \rightarrow [CR^1R^2R^3]^- + H_2CR^1R^2 \quad (3)$$

Also the NBO approach[30] can be used to study delocalization effects quantitatively, especially the NLMO (natural localized molecular orbitals) are suitable to display delocalization of a localized natural bond orbital. Here, the contributions of the antibonds represent the delocalization of the bonding orbital, $\varphi_{AB}$, from an idealized, strictly localized Lewis structure, over antibonding orbitals due to non-covalent, hyperconjungative interactions. Thus, the localized MOs offer a direct description of delocalization. Again, the inspection of the delocalization effects in the NLMO describing the methanide lone pair displays similar trends as discussed for the charge transfer, nicely corresponding to the resonance energies (Table 5). While the localization of the p-type lone pair on the methanide C atom steadily decreases for the cyanomethanides (81.9 CM > 75.1 DCM > 72.6% TCM), only a small decrease is found for the second substitution along the $NO_2$- and NO-substituted methanides and an increase is found for the third substitution (e.g. 54.9 NtM > 52.5 DNtM < 66.7% TNtM).

## Conclusions

Different synthetic routes to six new resonance-stabilized methanide-based ionic liquids ($EMI^+NtCM^-$, $EMI^+NtNCM^-$, $BMI^+NtNCM^-$, $EMI^+DNM^-$, $EMI^+DNtM^-$, $BMI^+TCM^-$) starting either from the explosive silver salts (except from AgTCM) or the easily accessible potassium salts have been described. Four of them represent room temperature ionic liquids ($BMI^+TCM^-$, $EMI^+DNM^-$, $BMI^+NtNCM^-$, $EMI^+NtCM^-$) while $EMI^+NtNCM^-$ and $EMI^+DNtM^-$ melt at 35 and 48 °C, respectively. These strongly colored ionic liquids (blue $EMI^+DNM^-$, red $EMI^+NtNCM^-$ and $BMI^+NtNCM^-$, yellow $EMI^+DNtM^-$, brown $EMI^+NtCM^-$, but colorless $BMI^+TCM^-$) are neither heat nor shock sensitive, are thermally stable up to over 52–270 °C and can be prepared in large quantities.

The structure and bonding is discussed on the basis of experimental and theoretical data. X-ray data of $Cs^+NtCM^-$, $K^+DNtM^-$, $EMI^+NtNCM^-$, and $Me_4N^+NtNCM^-$ reveal almost planar anions piled up parallel to each. In case of the alkali metal methanides strong cation···anion interactions result in three-dimensional network type structures in the solid state, while $Me_4N^+NtNCM^-$ and $EMI^+NtNCM^-$ display no such 3D-network which can also be assumed for the other $EMI^+$ or $BMI^+$ salts, not have been structurally characterized. X-ray crystallography of the $EMI^+NtNCM^-$ salt reveals only weak cation/anion, cation/cation and anion/anion contacts.

Structural parameters of the methanides such as the fairly short C–NO, C–$NO_2$ and C–CN bond lengths together with the planarity, indicate the presence of over the whole anion delocalized π bonds. These methanide anions are stabilized relative to the corresponding acids due to resonance stabilization. Charge transfer from the methanide central C atom to the substituent leads to a decrease in the C–$R^{1,2,3}$ bond lengths with the introduction of double bond character and an increase in the bond lengths within the substituent groups ($R^{1,2,3}$). The charge transfer can be divided into a strong π and σ contribution. The π contribution displays the delocalization of the p-type lone pair at the methanide carbon leading to at ambient temperature stable methanide anions.

In summary, as shown by different theoretical approaches (charge transfer, resonance energies and NLMO delocalization) resonance effects occur in all three classes of methanides, however, the magnitude of such effects strongly differs depending on the degree of substitution: (i) For mono-substitution the largest resonance is found for the $NO_2$ and NO species (similarly strong) while a significantly smaller resonance is found for the CN species, $[H_2C–CN]^-$. Hence, geometry optimizations find planar $[H_2C–NO_2]^-$ and $[H_2C–NO]^-$ anions while $[H_2C–CN]^-$ is predicted to be

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

non-planar at the level of theory applied, in agreement with experiment. (ii) For double-substitution the picture changes. Introduction of a second CN group results in a better resonance and the magnitude of the effect of the second CN group only slightly decreases in contrast to the magnitude of the resonance effect of the second $NO_2$ or NO group which dramatically decreases. Combining the resonance effect of the first and the second group, the overall resonance effect is still larger for the $NO_2$ and NO anions (DNtM and DNM) compared to $[HC(CN)_2]^-$ (DCM). In agreement with these strong resonance effects all doubly substituted methanides adopt a planar geometry. (iii) In accord with experimental observations, for the triple-substitution only in case of the CN species a significant resonance effect is found and also for the overall effect (sum over all three resonance steps) the cyano species, $[C(CN)_3]^-$, represents the best stabilized methanide compared to $[C(NO)_3]^-$ (TNM) and $[C(NO_2)_3]^-$ (TNtM). In agreement between theory and experiment TCM salts are stable compounds with a planar TCM anion, while in the highly explosive known TNtM salts non-planar TNtM anions are observed. TNM salts are not known yet, but it can be assumed that according to theory (B3LYP/aug-cc-pvTZ) the TNM anion adopts a non-planar geometry similar to the TNtM salts.

## Experimental Section

**Caution:** Although alkali and silver nitro- and nitrosomethanides are kinetically stable compounds, they are nonetheless energetic materials and appropriate safety precautions (e.g. protection shield when dried substances are used, preparation of small quantities $< 2$ g, keep these salts wet when stored) should be taken, especially when these compounds are prepared on a larger scale.

**General Remarks:** The $^{14}N$ and $^{13}C/^{1}H$ NMR spectra were recorded with a Jeol Eclipse 400 instrument, and chemical shifts were referenced to TMS ($^{13}C/^{1}H$) and $CH_3NO_2$ ($^{14}N$). Raman spectra were recorded with a Perkin–Elmer Spectrum 2000R NIR FT-Raman instrument equipped with a Nd:YAG laser (1064 nm). Elemental analysis was performed with a VARIO-EL Analyser (ELEMENTAR). Melting points are uncorrected (Büchi B540). DSC experiments: Samples (ca. 0.25 mg) were analyzed in closed Al containers with a hole (1 μm) on the top for gas release and a 0.003 × 3/16-inch disk was used to optimize good thermal contact between the sample and container with a nitrogen flow of 20 mL/min. The reference sample was an Al container with air. Experiments were carried out from 30–420 °C. The sample and the reference pan were heated in a differential scanning calorimeter (Perkin–Elmer Pyris 6 DSC, calibrated by standard pure indium and zinc) at different heating rates of 2, 5 and 10 °C/min. For the removal of moisture, the sample was dried in vacuo for 7 d at room temp. and prepared in a dry-box.

**Materials:** Nitroacetonitrile,[32] KTCM,[33] $EMI^+TCM^-$,[13c] KDNM,[12] KNtNCM,[11] KDNtM[9] and $EMI^+BF_4^-$[34] were prepared according to the procedure given in the literature. The following silver salts, AgX [X = $C(CN)_3$, $CH(NO_2)CN$ and $CH(NO)_2$] were synthesized by metathetic reaction of $AgNO_3$ with the corresponding alkali salts (KTCM, CsNtCM and KDNM) in water under exclusion of light. All manipulations for the isolation of the EMI/BMI salts[35] were carried out under an inert atmosphere of nitrogen gas in a dry-box with the rigid exclusion of air and moisture ($H_2O$, $O_2 < 1$ ppm). Solvents (for drying and cleaning procudure) were dried, freshly distilled, and stored under nitrogen.

**Computational Details:** Our goal was to compare the structures and energetics of different substituted methane derivatives and methanide anions. Structural and vibrational data of all considered species were calculated by using the hybrid density functional theory (B3LYP) with the program package Gaussian 98.[36] Three different types of basis sets were used: (i) a 6-31G(d,p) and (ii) an aug-cc-pvDZ and (iii) an aug-cc-pvTZ basis. All stationary points were characterized by a frequency analysis (Table 3) at the B3LYP level. Selected computed geometrical parameters are displayed in Figures 1 and 2. Further details can be obtained in the Supporting Information. If not otherwise stated, all discussed computational data refer to the B3LYP/aug-cc-pvTZ level of theory. Comparison of these data sets shows differences in bond lengths no larger than 0.01–0.02 Å. The bond angles in all these molecules are rather constant and relatively independent of the basis sets.[37] NBO analyses[30] were carried out to investigate the bonding of the methanides at the SCF level utilizing the optimized aug-cc-pvTZ geometry. Details of the NBO analyses are summarized in Table 4. It should be emphasized that the computation was carried out for a single, isolated (gas-phase) anion. There may well be significant differences among gas-phase, solution, and solid-state data.

**X-ray Analysis:** X-ray quality crystals of KDNtM, CsNtCM, $[Me_4N]$NtNCM and [EMI]NtNCM were obtained by recrystallization from ethanol. Data for compound KDNtM were collected with a Nonius Mach3, data for CsNtCM and $[Me_4N]$NtNCM on a KappaCCD, and data for [EMI]NtNCM on a Oxford Excalibur III using Mo-$K_\alpha$ radiation. Crystallographic data are summarized in Table S1 (Supporting Information). The asymmetric unit along with selected bond lengths and angles are displayed in Figure 3. All structures were solved by direct methods (structure solution program: for KDNtM and [EMI]NtNCM SHELXS-97[38] and SIR97[39] for CsNtCM and $[Me_4N]$NtNCM) and refined by full-matrix least-squares methods with SHELXL-97. Hydrogen atoms were included at geometrically idealized positions and were not refined; the non-hydrogen atoms were refined anisotropically.

CCDC-606717 (for CsNtCM), -606718 (for [EMI]NtNCM), -606719 (for KDNtM), and -261892 (for $[Me_4N]$NtNCM) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of Cesium Nitrocyanomethanide (CsNtCM, $Cs[CH(NO_2)CN]$):** At 0 °C a solution of nitroacetonitrile (1.87 g, 21.7 mmol) in diethyl ether (70 mL) was slowly dropped to a stirred solution of cesium hydroxide monohydrate (3.60 g, 21.4 mmol) in 2-propanol (30 mL). The resulting suspension was stirred at 0 °C for 30 min and the brown precipitate (CsNTCM) was recrystallized from methanol. Yield 3.92 g (84%). $^1H$ NMR ([D$_6$]DMSO, 400 MHz, 25 °C): $\delta$ = 5.58 (*H*–C) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]DMSO, 101 MHz, 25 °C): $\delta$ = 120.6 (C–*C*N), 80.5 (*C*–CN) ppm. $^{14}N$ NMR ([D$_6$]DMSO, 28.9 MHz, 25 °C): $\delta$ = –14 (C–*N*O$_2$), –117 (C–C*N*) ppm. Raman (200 mW, 25 °C): $\tilde{\nu}$[cm$^{-1}$] = 3117 (1), 2187 (10), 1452 (7), 1341 (1), 1239 (0.5), 1084 (2), 1025 (0.5), 980 (4), 745 (0.5), 716 (1), 552 (3), 513 (0.5), 442 (0.5), 204 (2), 189 (3), 126 (1). $C_2HN_2CsO_2$ (217.95): calcd. C 11.02, H 0.46, N 12.85; found C 10.70, H 0.51, N 12.34.

**Synthesis of Tetramethylammonium Nitro(nitroso)cyanomethanide ($[Me_4N]$NtNCM, $[Me_4N][C(NO_2)(NO)(CN)]$):** At 0 °C a solution

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of $H_2SO_4$ (1.10 g, 11.2 mmol, 100%) in 3 mL water was slowly dropped to a stirred solution of nitroacetonitrile (1.80 g, 20.9 mmol) and sodium nitrite (1.50 g, 21.7 mmol) in water (30 mL). The resulting solution was stirred at 0 °C for 30 min and the cyanomethylnitrolic acid was extracted with diethyl ether (4 × 25 mL). The ether solution was dried with anhydrous calcium chloride and filtered. At 0 °C a solution of tetramethylammonium hydroxide pentahydrate (2.60 g, 14.3 mmol) in 10 mL 2-propanol was slowly dropped to the stirred, dried ether solution of cyanomethylnitrolic acid. After recrystallization of the red precipitate from methanol 2.48 g (63%) red crystals of $[Me_4N]$NtNCM were obtained. M.p. decomposition, $T_{dec.,onset}$ = 70 °C. $^{13}C\{^1H\}$ NMR ([D$_6$]DMSO, 101 MHz, 25 °C): $\delta$ = 119.5 (C–*C*N), 149.6 (*C*–CN) ppm. $^{14}N$ NMR ([D$_6$]DMSO, 28.9 MHz, 25 °C): $\delta$ = –107 (C–C*N*), –15 (C–*N*O$_2$), 265 (C–*N*O) ppm. Raman (200 mW, 25 °C): $\tilde{\nu}$[cm$^{-1}$] = 3035 (1), 2957 (1), 2922 (0.5), 2214 (2), 1506 (0.5), 1496 (0.5), 1474 (0.5), 1460 (0.5), 1394 (3), 1340 (10), 1229 (4), 1175 (2), 949 (1), 839 (2), 754 (1), 535 (0.5), 456 (0.5), 244 (2), 170 (2). $C_6H_{12}N_4O_3$ (188.19): calcd. C 38.30, H 6.43, N 29.77; found C 38.34, H 6.32, N 29.94.

**Synthesis of Potassium Dicyanomethanide (KDCM, K[CH(CN)$_2$]):** At 20 °C a solution of malonodinitrile (1.76 g, 26.6 mmol) in 30 mL 2-propanol was slowly dropped to a stirred solution of KO*t*Bu (2.70 g, 24.1 mmol) in 30 mL 2-propanol. After adding 200 mL dichloromethane, a white precipitate (KDCM) is obtained which was washed twice with 100 mL dichloromethane and dried in vacuo. Yield 2.19 g (87%). $^1H$ NMR ([D$_6$]DMSO, 400 MHz, 25 °C): $\delta$ = 3.38 (*H*–C) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]DMSO, 101 MHz, 25 °C): $\delta$ = 130.6 (s, C–*C*N), –1.9 (*C*–CN). $^{14}N$ NMR ([D$_6$]DMSO, 28.9 MHz, 25 °C): $\delta$ = –135 (C*N*) ppm. Raman (200 mW, 25 °C): $\tilde{\nu}$[cm$^{-1}$] = 3068 (3), 2175 (10), 2122 (1), 1552 (0.5), 1343 (1), 1144 (8), 635 (1), 420 (0.5), 197 (3). $C_3HKN_2$ (104.15): calcd. C 34.60, H 0.97, N 26.90; found C 34.21, H 1.25, N 26.58.

**Synthesis of *n*-Butyl(methyl)imidazolium Tricyanomethanide (BMI$^+$TCM$^-$):** A slight excess of AgTCM (0.59 g, 2.98 mmol) was added to a water solution of ammonia (30 mL, 2 N). This reaction mixture was treated with a solution of BMI$^+$Br$^-$ (0.62 g, 2.83 mmol) in 20 mL distilled water. The resulting suspension was stirred (1 h) in the dark at room temp. and filtered to remove AgBr. The solvent was evaporated in vacuo. The drying and cleaning procedure included successive adding, filtering and removing of 25 mL dried methanol, THF and dichloromethane. Remaining volatiles were evaporated in high-vacuum over a period of 7 d. Yield 0.59 g (91%) colorless liquid (transparent melt). M.p. –48 °C, $T_{dec.,onset}$ = 270 °C. $^{13}C\{^1H\}$ NMR ([D$_6$]DMSO, 101 MHz, 25 °C): $\delta$ = 121.0 (C–*C*N), 5.1 (*C*–CN) ppm. $^{14}N$ NMR ([D$_6$]DMSO, 28.9 MHz, 25 °C): $\delta$ = –122 (C–C*N*) ppm.[35] Raman (200 mW, 25 °C): $\tilde{\nu}$[cm$^{-1}$] = 3167 (0.5, br.), 3110 (0.5), 2962 (3), 2942 (2), 2914 (1), 2875 (1), 2864 (0.5, sh), 2210 (10), 2166 (5), 1418 (2), 1388 (1), 1340 (1), 1112 (0.5), 1024 (2), 600 (0.5), 325 (0.5), 175 (1). $C_{12}H_{15}N_5$ (229.29): calcd. C 62.86, H 6.59, N 30.54; found C 62.70, H 6.25, N 30.73.

**Synthesis of Ethyl(methyl)imidazolium Nitro(cyano)methanide (EMI$^+$NtCM$^-$):** A slight excess of AgNtCM (0.42 g, 2.18 mmol) was added to a water solution of ammonia (25 mL, 2 N). This reaction mixture was treated with a solution of EMI$^+$Br$^-$ (0.40 g, 2.10 mmol) in 10 mL distilled water. The resulting suspension was stirred (1 h) in the dark at room temp. and filtered to remove AgBr. The solvent was evaporated in vacuo. The drying and cleaning procedure included successive adding, filtering and removing of 25 mL dried methanol, THF and dichloromethane. Remaining volatiles were evaporated in high-vacuum over a period of 7 d. Yield 0.32 g (78%) brown liquid (transparent melt). M.p. 5 °C, $T_{dec.,onset}$ = 210 °C. $^1H$ NMR ([D$_6$]DMSO, 400 MHz, 25 °C): $\delta$ = 5.58 (*H*–C) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]DMSO, 101 MHz, 25 °C): $\delta$ = 120.6 (C–*C*N), 80.5 (*C*–CN). $^{14}N$ NMR ([D$_6$]DMSO, 28.9 MHz, 25 °C): $\delta$ = –13.9 (C–*N*O$_2$), –117 (C–C*N*) ppm.[35] Raman (200 mW, 25 °C): $\tilde{\nu}$[cm$^{-1}$] = 3160 (0.5), 3121 (0.5), 3114 (1), 3070 (0.5, br.), 2960 (1, br.), 2955 (1, br.), 2192 (10), 1454 (7), 1422 (0.5), 1340 (1), 1085 (2), 1021 (0.5), 976 (5), 717 (1), 601 (0.5), 550 (3), 200 (3). $C_8H_{12}N_4O_2$ (196.21): calcd. C 48.97, H 6.16, N 28.55; found C 48.26, H 6.17, N 27.97.

**Synthesis of Ethyl(methyl)imidazolium Dinitrosomethanide (EMI$^+$DNM$^-$):** AgDNM (0.67 g, 3.72 mmol) was added to a water solution of ammonia (35 mL, 2 N). This reaction mixture was treated with a solution of EMI$^+$Br$^-$ (0.71 g, 3.72 mmol) in 20 mL distilled water. The resulting suspension was stirred (1 h) in the dark at room temp. and filtered to remove AgBr. The solvent was evaporated in vacuo. The drying and cleaning procedure included successive adding, filtering and removing of 25 mL dried methanol, THF and dichloromethane. Remaining volatiles were evaporated in high-vacuum over a period of 7 d. Yield 0.61 g (89%) dark blue-violet liquid (transparent melt). M.p. –6 °C, $T_{dec.,onset}$ = 180 °C. $^1H$ NMR ([D$_6$]DMSO, 400 MHz, 25 °C): $\delta$ = 8.68 (*H*–C). $^{13}C\{^1H\}$ NMR ([D$_6$]DMSO, 101 MHz, 25 °C): $\delta$ = 190.0 (*C*–NO). $^{14}N$ NMR ([D$_6$]DMSO, 28.9 MHz, 25 °C): $\delta$ = 332 (C–*N*O).[35] Raman (200 mW, 25 °C): $\tilde{\nu}$[cm$^{-1}$] = 3161 (0.5), 3119 (0.5), 3068 (0.5, br.), 2994 (0.5, sh), 2961 (1, br.), 2952 (1, br.), 1402 (3), 1420 (0.5), 1391 (1), 1340 (1), 1305 (10), 1180 (0.5), 1122 (0.5), 861 (0.5), 601 (0.5), 576 (9), 145 (2). $C_7H_{12}N_4O_2$ (184.20): calcd. C 45.65, H 6.57, N 30.42; found C 44.96, H 6.44, N 29.78.

**Synthesis of *n*-Butyl(methyl)imidazolium Nitro(nitroso)cyanomethanide (BMI$^+$NtNCM$^-$):** KNtNCM (0.47 g, 3.10 mmol) was dissolved in a mixture of 15 mL dried methanol and 15 mL dried ethanol. After adding a solution of $AgNO_3$ (0.53 g, 3.10 mmol) dissolved in 15 mL dried methanol and 15 mL dried ethanol, $KNO_3$ precipitated. After filtration the solvents were evaporated yielding 0.59 g AgNtNCM. A solution of AgNtNCM (0.59 g, 2.65 mmol) in a mixture of 30 mL dried methanol and 30 mL dried ethanol was added to a solution of BMI$^+$Br$^-$ (0.58 g, 2.65 mmol) in 20 mL dried THF. After filtration of AgBr, all solvents were evaporated. The drying and cleaning procedure included successive adding, filtering and removing of 25 mL dried methanol, THF and dichloromethane. Remaining volatiles were evaporated in high-vacuum over a period of 7 d. Yield 0.53 g (68%) red liquid (transparent melt). M.p. –4 °C, $T_{dec.,onset}$ = 65 °C. $^{13}C\{^1H\}$ NMR ([D$_6$]DMSO, 101 MHz, 25 °C): $\delta$ = 119.5 (s, C–*C*N), 149.6 (*C*–CN). $^{14}N$ NMR ([D$_6$]DMSO, 28.9 MHz, 25 °C): $\delta$ = –107 (C–C*N*), –15 (C–*N*O$_2$), 265 (C–*N*O) ppm.[35] Raman (200 mW, 25 °C): $\tilde{\nu}$[cm$^{-1}$] = 3170 (1, br.), 3120 (0.5, br.) 2990 (1), 2964 (0.5, br.), 2880 (0.5, br.), 2209 (6), 1490 (4), 1474 (0.5, br.), 1458 (1), 1418 (3), 1381 (9), 1340 (10), 1346 (10), 1249 (2), 1231 (4), 1178 (2), 1022 (1), 960 (1), 839 (3, br.), 772 (1), 601 (1), 535 (2), 481 (0.5), 251 (4), 176 (2). $C_{10}H_{15}N_5O_3$ (253.26): calcd. C 47.43, H 5.97, N 27.65; found C 48.24, H 6.32, N 26.89.

**Synthesis of Ethyl(methyl)imidazolium Nitro(nitroso)cyanomethanide (EMI$^+$NtNCM$^-$):** KNtNCM (0.75 g, 4.90 mmol) was dissolved in 30 mL methanol and 2 mL water. After adding a solution of EMI$^+$BF$_4^-$ (0.97 g, 4.90 mmol) dissolved in 10 mL methanol, $KBF_4$ precipitated. After filtration the solvents were evaporated. The drying and cleaning procedure included successive adding, filtering and removing of 25 mL dried methanol, THF and dichloromethane. Remaining volatiles were evaporated in high-vacuum over a period of 7 d. Yield 0.95 g (86%) red glass. M.p. 35 °C, $T_{dec.,onset}$ = 52 °C. $^{13}C\{^1H\}$ NMR ([D$_6$]DMSO, 101 MHz, 25 °C): $\delta$ = 119.5

(C–*C*N), 149.6 (*C*–CN) ppm. $^{14}$N NMR ([D$_6$]DMSO, 28.9 MHz, 25 °C): $\delta$ = –107 (C–C*N*), –15 (C–*N*O$_2$), 265 (C–*N*O) ppm.[35] Raman (200 mW, 25 °C): $\tilde{\nu}$[cm$^{-1}$] = 3158 (1), 3112 (0.5, br.) 2987 (1), 2964 (0.5, br.), 2878 (0.5), 2211 (5), 1495 (3), 1476 (0.5), 1458 (1), 1417 (3), 1380 (9), 1346 (10), 1248 (2), 1232 (5), 1177 (2), 1021 (1), 959 (1), 838 (3, br.), 772 (1), 600 (1), 536 (2), 480 (0.5), 250 (4), 172 (2). $C_8H_{11}N_5O_3$ (225.21): calcd. C 42.67, H 4.92, N 31.10; found C 43.12, H 4.89, N 30.69.

**Synthesis of Ethyl(methyl)imidazolium Dicyanomethanide (EMI$^+$DCM$^-$):** Adding a solution of KDCM (0.90 g, 8.64 mmol) in 20 mL methanol and 1 mL water, to a solution of EMI$^+$BF$_4^-$ (1.71 g, 8.64 mmol) in 10 mL methanol results in a white precipitate of $KBF_4$. After filtration of $KBF_4$, all solvents were evaporated. The drying and cleaning procedure included successive adding, filtering and removing of 25 mL dried methanol, dried THF and dried dichloromethane. Remaining volatiles were evaporated in high-vacuum over a period of 1 h. Yield 1.27 g (83%) yellow-brown liquid (slowly decomposes at room temperature resulting in a black tar). Raman (200 mW, 25 °C, decomposition in Raman): $\tilde{\nu}$[cm$^{-1}$] = 3121 (1, br.), 2959 (3, br.), 2185 (10, br.), 2157 (8, br.), 2146 (5, br.), 1482 (3), 1420 (3), 1389 (2), 1337 (1), 1236 (0.5), 1091 (0.5), 1023 (1), 704 (0.5), 599 (1), 473 (0.5). $C_9H_{12}N_4$ (176.22): calcd. C 61.34, H 6.86, N 31.79; found C 60.53, H 6.31, N 30.86.

**Synthesis of Ethyl(methyl)imidazolium Dinitromethanide (EMI$^-$DNtM$^+$):** KDNtM (0.73 g, 5.10 mmol) was dissolved in a boiling mixture of 20 mL methanol and 5 mL distilled water. After adding a solution of 1.01 g (5.10 mmol) EMI$^+$BF$_4^-$ in 10 mL methanol, $KBF_4$ precipitated. After filtration of $KBF_4$, all solvents were evaporated. The drying and cleaning procedure included successive adding, filtering and removing of 25 mL dried methanol, THF and dichloromethane. Remaining volatiles were evaporated in high-vacuum over a period of 7 d. Yield 0.79 g (72%) yellow glass. M.p. 48 °C, $T_{dec.,onset}$ = 186 °C. $^1$H NMR ([D$_6$]DMSO, 400 MHz, 25 °C): $\delta$ = 8.17 (*H*–C). $^{13}$C{$^1$H} NMR ([D$_6$]DMSO, 101 MHz, 25 °C): $\delta$ = 121.7 (*C*–NO$_2$) ppm. $^{14}$N NMR ([D$_6$]DMSO, 28.9 MHz, 25 °C): $\delta$ = –21 (C–*N*O$_2$) ppm.[35] Raman (200 mW, 25 °C): $\tilde{\nu}$[cm$^{-1}$] = 3142 (1, br.), 3115 (1, br.), 2963 (10, br.), 2955 (9, br.), 2899 (5, sh), 1668 (1), 1570 (3), 1447 (10, br.), 1375 (5), 1334 (9, br.), 1092 (4), 1023 (5), 999 (4), 960 (3), 794 (3), 780 (3), 750 (2), 702 (2), 431 (3, br.), 255 (4), 162 (5). $C_7H_{12}N_4O_4$ (216.20): calcd. C 38.89, H 5.59, N 25.91; found C 39.27, H 6.08, N 25.39.

**Supporting Information** (see also the footnote on the first page of this article): References, crystallographic data for KDNtM, CsNtCM, [EMI]NtNCM, and [Me$_4$N]NtNCM, and extensive computational data.

# Modified Pyridine-Bis(imine) Iron and Cobalt Complexes: Synthesis, Structure, and Ethylene Polymerization Study

**Frédéric Pelascini,[a,b] Marcel Wesolek,*[b] Frédéric Peruch,*[a] and Pierre J. Lutz[a]**

**Keywords:** N ligands / Iron / Cobalt / Ethylene / Polymerization

In this paper, we describe the synthesis of two new pyridine-bis(imine)s {4-chloro-2,6-bis[1-(2,6-diisopropylphenylimino)-ethyl]pyridine and 2,6-bis[1-(2,6-dimethylcyclohexylimino)-ethyl]pyridine} and their complexation with iron and cobalt dichloride. The solid-state structure of the iron complexes was solved and found to be very close to catalysts already described by Brookhart and Gibson. Their ability to polymerize ethylene was investigated after activation with MAO. It was thus shown that the substitution of the pyridine ring of the ligand is unfavorable: their catalytic activity is rather low. The replacement of the aromatic rings on the imine functions by dimethylcyclohexyl rings resulted in a complete loss of activity of the iron complex for oligomerization and polymerization of ethylene. With the cobalt analog, polymerization of ethylene could be achieved under the same conditions.

## Introduction

In 1998, Brookhart and Gibson simultaneously described the synthesis of very active pyridine-bis(imine) iron- or cobalt-based catalysts for the oligomerization or the polymerization of ethylene.[1–3] When the substituents on the ligand were bulky enough, they were found to be extremely efficient for the synthesis of linear polyethylenes. Many modifications of these ligands have already been described, but it was almost always the $R^1$–$R^5$ (Figure 1) groups that were modified; some reviews are listed with the most recent of these references.[4–17] So far, less work has been done on other types of modifications (imine functions replaced by amine functions, aryl rings replaced by amines or pyrrolyl rings, pyridine ring replaced by thiophene or furan ring, and so forth).[18–23] In this paper, we report new kinds of modifications. We focus more specifically on the electronic factors through the synthesis of two new types of pyridine-bis(imine) ligands. With ligand **1**, the presence of the chlorine group in the *para* position of the pyridine ring in the well-known 2,6-bis[1-(2,6-diisopropylphenylimino)ethyl]-pyridine ligand ($R^1 = R^5$ = isopropyl) led us to study the effect of the electronic-withdrawing chlorine group. For ligand **2**, the replacement of the aryl groups by aliphatic rings of another well-known ligand, 2,6-bis-[1-(2,6-dimethylphenylimino)ethyl]pyridine ($R^1 = R^5$ = methyl), was performed. The iron and cobalt complexes, once synthesized, were activated with methylaluminoxane (MAO) and tested for the polymerization of ethylene.

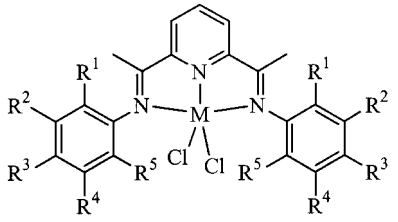

Figure 1. Pyridine-bis(imine) iron or cobalt complexes.

## Results and Discussion

### Synthesis and Characterization of Ligands

4-Chloro-2,6-bis[1-(2,6-diisopropylphenylimino)ethyl]pyridine (**1**) was synthesized according to already published procedures for the synthesis of pyridine-bis(imine).[1,2] The reaction is a condensation between 2,6-diacetyl-4-chloropyridine (synthesis described by Constable[24]) and 2,6-diisopropylaniline (Scheme 1, i). The yellow product was isolated and characterized by elemental analysis, and $^1H$ and $^{13}C$ NMR spectroscopy.

Concerning the synthesis of 2,6-bis[1-(2,6-dimethylcyclohexylimino)ethyl]pyridine (**2**), the same procedure was followed but the substituted aniline was replaced by the corresponding cyclohexylamine to yield aliphatic-substituted imines (Scheme 1, ii). Besides, substituted cycloalkanes exhibit several stereoisomers. In the case of 2,6-dimethylcyclohexylamine, three different stereoisomers can be identified: the

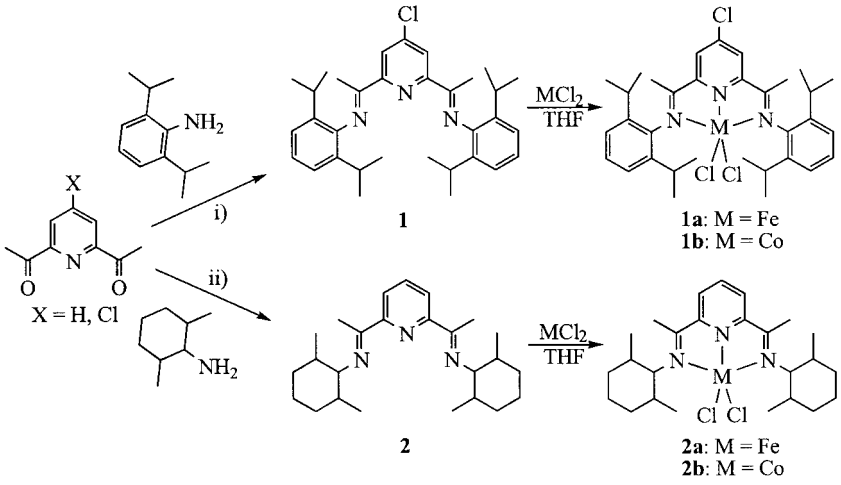

Scheme 1. Synthesis of ligands **1**, **2all-*cis***, **2all-*trans*** and complexes **1a**, **1b**, **2a**, **2b**.

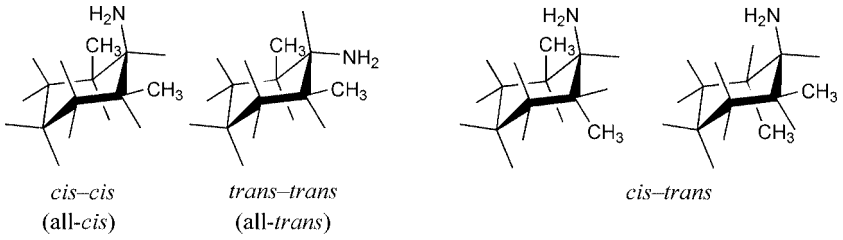

Figure 2. Most stable conformers for each stereoisomer of 2,6-dimethylcyclohexylamine.

*cis–cis* (all-*cis*), the *trans–trans* (all-*trans*), and the *cis–trans* one (Figure 2). It was decided to use only the pure all-*trans* and all-*cis* amines. After double condensation with diacetyl pyridine, these two products will give few conformers compared to the *cis–trans* one. Indeed, in the case of the *cis–trans* amine, the final pyridine-bis(imine) would probably be a mixture of isomers. Moreover, thanks to a thorough conformational analysis, it was shown that each stereoisomer had several conformers of different stabilization energy. For the all-*cis* and all-*trans* amines the most stable conformer is the one where the two methyl groups are in the equatorial position, thus minimizing steric repulsion. For the all-*cis* amine the amino group takes the axial position and for the all-*trans* amine the same group is in an equatorial position. Thus, normally only one conformer will be obtained for each selected amine. Condensation was carried out under ethanol reflux, with a slight excess of amine and some drops of acetic acid.

Both ligands based on the amine, hereafter named **2all-*cis*** and **2all-*trans***, were characterized by elemental analysis, and $^{1}H$ and $^{13}C$ NMR spectroscopy. In order to better allot the resonance peaks, a COSY spectrum was recorded. It was thus established that the molecule is in a blocked configuration at ambient temperature. Indeed, in the case of unsubstituted cyclohexane, it is known that there is a difference of 0.5 ppm between the chemical shifts of the axial and equatorial protons only at low temperature, when the exchange of cycle is slow compared to the timescale of the NMR spectroscopy. In our case, at ambient temperature, the conformational exchange is slow; we observe a difference of 0.3 ppm between the axial and equatorial protons, the equatorial protons being the most strongly shielded.

The attribution of the multiplet between 1.0 and 1.9 ppm was possible thanks to a 2D experiment ($^{1}H$–$^{13}C$). Three broad multiplets that integrate respectively for 10, 2, and 4 protons can be distinguished. One of the main differences between the two NMR spectra is the peak corresponding to the proton of the cycle carried by the carbon linked to the nitrogen atom of the imine function, whose chemical shift changes from 2.9 ppm for the **2all-*trans*** system to 3.7 ppm for the **2all-*cis*** system. Moreover, the coupling constant for the triplet goes from 9.3 Hz to 2.2 Hz. This difference may be easily explained with the Karplus and Conroy

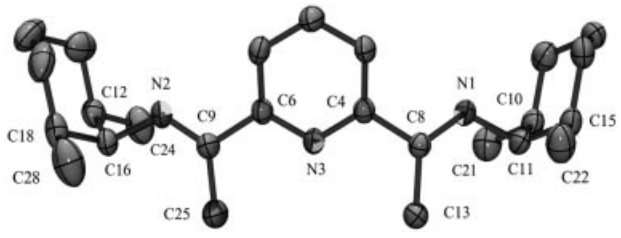

Figure 3. An ORTEP view of the crystal structure of **2all-*cis***. equation. Indeed, $^3J_{180°}$ coupling constants are always strictly higher than $^3J_{60°}$ ones.

The X-ray structure of the ligand **2all-*cis*** has been determined to complete the characterization and is represented in Figure 3. Only one conformer is observed, as expected.

## Synthesis and Characterization of Complexes

### *Synthesis and Structure of Iron and Cobalt Complexes with 4-Chloro-2,6-bis[1-(2,6-diisopropylphenylimino)ethyl]-pyridine (1a and 1b)*

The complexes were obtained from a stoichiometric reaction between the ligand and a suspension of anhydrous $FeCl_2$ or $CoCl_2$ in THF at room temperature. In order to recover the complexes, the solution was concentrated and hexane was added to the reaction medium. The iron complex was isolated with a yield of 83% as a blue-green powder. The cobalt complex was isolated with a yield of 81% as a green powder. The isolated complexes were paramagnetic (according to $^1$H NMR indicating chemical shifts from –40 to 170 ppm) and were characterized by elemental analysis, infrared and X-ray analysis (iron complex only). The elemental analysis results were in agreement with the formula $LMCl_2$.

Recrystallization of the iron complex redissolved in diethyl ether yields crystals suitable for X-ray analysis. In the solid state (Figure 4), the geometry of the metal center can be considered as distorted square-pyramidal. One of the chlorine atoms occupies the apical position, with an almost right angle with the iron and nitrogen of the pyridine [N(1)(2)(3)–Fe–Cl(2) ranging from 89.3° to 102.5°], whereas the second occupies one of the bases of the formed square. The apical bond seems to be the weaker, as the length of the Fe–Cl bond goes from 2.305 Å for the apical position to 2.247 Å for the longitudinal one. This is normally expected for that geometry. The iron atom is slightly above the base of the pyramid [N(3)–Fe–N(1) = 139.2°]. Predictably, the phenyl groups linked to the imine functions are almost perpendicular to the plane formed by the nitrogen atoms, although there is a slight deformation of the molecule, one of the phenyl groups having a dihedral angle of 94.7° and the other 85.1°.

We can examine the effect of the chlorine atom in the *para* position of the pyridine ring by comparing the lengths of the various bonds with X-ray data of the equivalent nonchlorinated iron complex.[2] The molecule is asymmetric in the solid state, one of the Fe–$N_{imine}$ bonds measuring 2.244 Å and the other 2.212 Å. This is probably due to the presence of a molecule of $Et_2O$ in the lattice, but the average value is 2.228(9) Å, very close to the average value 2.224(9) Å for the unsubstituted complex where the lengths of these same bonds are almost identical (in this case half a water molecule is present in the lattice). The decrease in length of the Fe–$N_{py}$ bond for the chlorinated ligand (2.080 instead of 2.091 Å) can be explained by the fact that the chlorine on the pyridine group enhances the π back donation of the iron to the pyridine group. Another expected

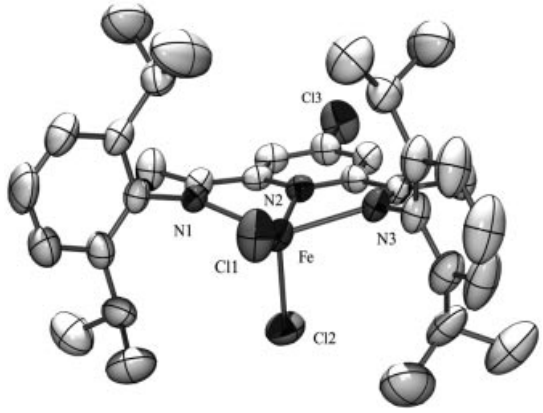

Figure 4. An ORTEP view of the crystal structure of **1a**. Selected bond lengths [Å] and angles [°] for the subunit Fe1: Fe1–N(1) 2.213(4), Fe1–N(2) 2.080(3), Fe1–N(3) 2.243(4), Fe1–Cl(1) 2.247(1), Fe1–Cl(2) 2.305(2), Cl(1)–Fe1–N(1) 100.8(1), Cl(1)–Fe1–N(2) 151.1(1), Cl(1)–Fe1–N(3) 97.2(1), Cl(2)–Fe1–N(1) 100.0(1), Cl(2)–Fe1–N(2) 89.3(1), Cl(2)–Fe1–N(3) 102.5(1), Cl(1)–Fe1–Cl(2) 119.55(7), N(1)–Fe1–N(2) 73.7(1), N(1)–Fe1–N(3) 139.2(1), N(2)–Fe1–N(3) 72.9(1).

difference is the reduction of the length of the Fe–Cl(1) bond *trans* to the pyridine group (2.247 instead of 2.263 Å), while the angle N(2)–Fe–Cl(1) where the chlorine and the nitrogen are *trans* to the basal plane varies from 147.9 to 151.1° (for the chlorinated ligand). The apical iron chlorine bond varies from 2.305 (for the chlorinated ligand) to 2.317 Å, in agreement with the expected electronic effect of the chlorine on the *para* position on the pyridine, that is a decrease of the electronic density on the iron atom. Nevertheless, the solid-state structures of the chlorinated and the nonchlorinated complexes are very close. Besides, as we will see in the structure of {2,6-bis[1-(2,6-dimethylcyclohexylimino)ethyl]pyridine}iron dichloride (**2a**), the crystal packing causes little difference in the structure.

### *Synthesis and Structure of Iron and Cobalt Complexes with 2,6-Bis[1-(2,6-dimethylcyclohexylimino)ethyl]pyridine (2a and 2b)*

With the ligand **2all-*cis***, no iron or cobalt complexes could be isolated. Indeed, during the reaction between iron chloride and the ligand in THF at ambient temperature, the solution became slightly pink, but no precipitation was observed, even after 24 h. The addition of hexane or diethyl ether did not lead to the precipitation of the complex. Evaporation of solvents to dryness yielded a pink powder. IR results prompted us to think that no complexation occurred, as free $FeCl_2$ and free ligand were detected. Similar observations were made when the reaction was run at 50 °C. Thus, the stoichiometric reaction between the ligand **2all-*cis*** and the metal chloride did not lead to the formation of the expected complex of formula $LMCl_2$. We first made the assumption that a steric factor could be the cause of this nonreactivity, but an X-ray of the free ligand shown in Figure 3 does not confirm this hypothesis.

On the contrary, the addition of 1 equiv. of the ligand **2all-*trans*** to 1 equiv. of metal chloride in THF at room

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

temperature led to the formation of the desired complex in good yield (75% for $LFeCl_2$ and 65% for $LCoCl_2$). Crystals suitable for X-ray analysis were obtained by slow crystallization in THF. The X-ray crystal structure contains two independent sets of iron complexes, Fe1 and Fe2, with slightly different angles and distances (Figure 5, Table 1).

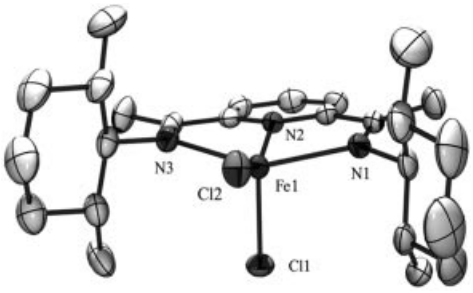

Figure 5. An ORTEP view of the crystal structure of **2a all-*trans***. Only one of the two distinct units is represented. The differences in lengths and angles are shown in Table 1.

Table 1. Selected bond lengths [Å] and angles [°] of the two subunits Fe1 and Fe2 for the complex **2a all-*trans***.

| Bond lengths [Å] | | | |
|---|---|---|---|
| Fe1–N(1) | 2.286(4) | Fe2–N(6) | 2.318(4) |
| Fe1–N(2) | 2.087(4) | Fe2–N(5) | 2.091(4) |
| Fe1–N(3) | 2.295(4) | Fe2–N(4) | 2.308(4) |
| Fe1–Cl(1) | 2.349(1) | Fe2–Cl(3) | 2.329(2) |
| Fe1–Cl(2) | 2.279(1) | Fe2–Cl(4) | 2.286(1) |
| Bond angles [°] | | | |
| Cl(1)–Fe1–N(1) | 97.9(1) | Cl(3)–Fe2–N(6) | 95.9(1) |
| Cl(1)–Fe1–N(2) | 91.8(1) | Cl(3)–Fe2–N(5) | 95.1(1) |
| Cl(1)–Fe1–N(3) | 95.1(1) | Cl(3)–Fe2–N(4) | 102.0(1) |
| Cl(2)–Fe1–N(1) | 103.2(1) | Cl(4)–Fe2–N(6) | 102.2(1) |
| Cl(2)–Fe1–N(2) | 153.4(1) | Cl(4)–Fe2–N(5) | 155.4(1) |
| Cl(2)–Fe1–N(3) | 101.0(1) | Cl(4)–Fe2–N(6) | 102.2(1) |
| Cl(1)–Fe1–Cl(2) | 114.7(1) | Cl(3)–Fe2–Cl(4) | 109.4(1) |
| N(1)–Fe1–N(2) | 73.7(2) | N(5)–Fe2–N(6) | 72.8(2) |
| N(1)–Fe1–N(3) | 144.5(1) | N(4)–Fe2–N(6) | 142.7(2) |
| N(2)–Fe1–N(3) | 73.0(2) | N(4)–Fe2–N(5) | 73.2(2) |

As in the complexes with an aryl group on the imine functions, the geometry of the metal center can be considered as distorted square-pyramidal, with one of the chlorine atoms occupying the apical position, with an almost 90-degree angle with the iron and the nitrogen atoms: N(1)(2)(3)–Fe1–Cl(1) ranging from 91.8° to 97.9° and N(4)(5)(6)–Fe2–Cl(3) ranging from 95.1° to 102.0°. The average apical Fe–Cl bond (2.35 Å) is longer than the average equatorial one (2.28 Å), as expected from this type of geometry. It is noticeable that these lengths are higher than for complexes bearing fully aromatic ligands. This seems to indicate that the electronic density on the iron becomes higher. The iron atom is slightly above the base of the pyramid: N(3)–Fe–N(1) 144.5°, which is close to the value found for the aromatic trimethyl analog described by Gibson et al.,[4] where the value is 145.5°. For comparison, in complex **1a** the angle is 139.2°.

The distances between the iron and both imines are almost identical (average 2.29 Å for Fe1 and 2.31 Å for Fe2). These bonds are a bit longer than for the complex with the 2,4,6-trimethyl aryl substituent[4] (average 2.27 Å), revealing the electronic effect generated by the replacement of an aryl by a cyclohexyl group. Besides, the Fe–$N_{py}$ bond length with an average of 2.09 Å in complex **2a** is shorter than for the aryl analog, where the value is 2.11 Å. The angle N–Fe–Cl where the nitrogen and the chlorine atom are *trans* to the basal plane is somewhat greater, with an average value of 154.4° in complex **2a** compared to 131.3° in the aryl one.[4]

Although the cyclohexyl groups are not planar and adopt a chair conformation with the two methyl substituents and the imine in the equatorial position, they are almost perpendicular to the plane of the square base, like aryl groups (dihedral angles: 117.1° and 111.8°). The average distance between the iron atom and the methyl substituents is about 4.3 Å, as already observed for the equivalent aromatic systems.

### Ethylene Polymerization with Complexes 1a, 1b, 2a, and 2b Activated with MAO

All the complexes were activated with methylaluminoxane and tested for the polymerization of ethylene. The results are summarized in Table 2 together with the experimental conditions.

With complexes **1a** and **1b**, polyethylene was produced with the same activity for the two metals, whereas, iron complexes generally present a higher catalytic activity than their cobalt analogs. This result might be due to faster deactivation processes of **1a** versus **1b**. The activities were compared with those observed for the nonchlorinated pyridine complexes (di*i*PrFe and di*i*PrCo). As indicated in Table 2, the presence of the chlorine atom in the *para* position of the pyridine decreases the catalytic activity, from 2220 to

Table 2. Ethylene polymerization with iron and cobalt complexes/MAO.

| Catalyst[a] | Yield [g] | Activity [g·mmol$^{-1}$·h$^{-1}$·bar$^{-1}$] | Productivity ($g_{PE}/g_{Cat.}$) | $M_n$[b] [g·mol$^{-1}$] | $M_w$[b] [g·mol$^{-1}$] | MMD[c] | $T_m$[d] [°C] | $\chi$[d] |

810 g·mmol$^{-1}$·h$^{-1}$·bar$^{-1}$ for the iron complexes and from 1410 to 810 g·mmol$^{-1}$·h$^{-1}$·bar$^{-1}$ for the cobalt one. It was thought that slightly decreasing the electronic density on the metal would render the interaction with the incoming ethylene more favorable and then would enhance the catalytic activity.

Actually, this is not what happens because lowering the electronic density on the metal simultaneously disfavors the π back donation of the metal to the incoming ethylene. Bennett did not observe significant falls of activity with a cobalt complex substituted by a trifluoromethyl group in the *para* position of the pyridine ring, but experimental conditions were not comparable.[25] As the decrease in the catalytic activity cannot be explained by the small differences in the structures of the chlorinated and the nonchlorinated complex, the possible interaction of the chlorine atom present on the pyridine with MAO, used in a large excess, was studied. To do this we have observed by $^1$H NMR the chemical shifts of chlorobenzene (to mimic the ligand, this one would coordinate first with the nitrogen groups) in deuterated toluene after addition of a quantity of MAO similar to that used in the polymerization experiment. No significant chemical shifts have been observed, which means that there is probably no interaction between the chlorine atom and the TMA present in the MAO, or the MAO itself. Eventually, the loss of activity observed for the chlorinated complexes could be attributed to the lack of stability of the complex. Indeed, as can be seen on the $^1$H NMR spectrum of the complex (Figure 6), a great amount of decomposition product appeared within 20 min; this quantity increases with time. The decomposition process has not been studied in detail.

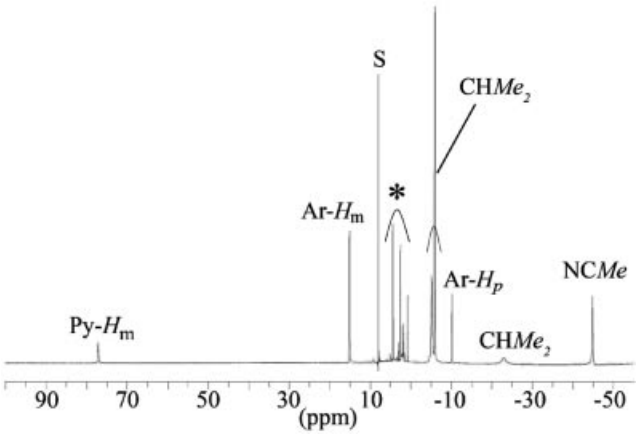

Figure 6. $^1$H NMR spectrum of complex **1a**. The peaks of the decomposition product are marked with * (300 MHz, 293 K, $CDCl_3$).

With the iron complex **2a** no polymers or oligomers have been detected. However, with the cobalt complex **2b** polymers are obtained (no oligomers could be detected by GC). Bianchini obtained oligomers with dissymmetric pyridine-bis(imine) ligands [the imine substituents being an aryl group and a (cyclo)alkyl group].[21] The proton NMR spectra of the iron complex (Figure 7, a) reveals that almost all the peaks are in the region from –8 to 11 ppm; only the peaks attributed to the protons on the pyridine are strongly shifted. Although the spectrum was obtained with a large window, from –55 to 250 ppm, some of the protons of the complex cannot be observed, probably because they are too large. Indeed the integration gives 35 protons instead of the 39 expected. An NMR study at low temperature, down to –90 °C, does not reveal new peaks. On the contrary, the broad peak at –11 ppm broadens even further at –70 °C and is invisible at –90 °C.

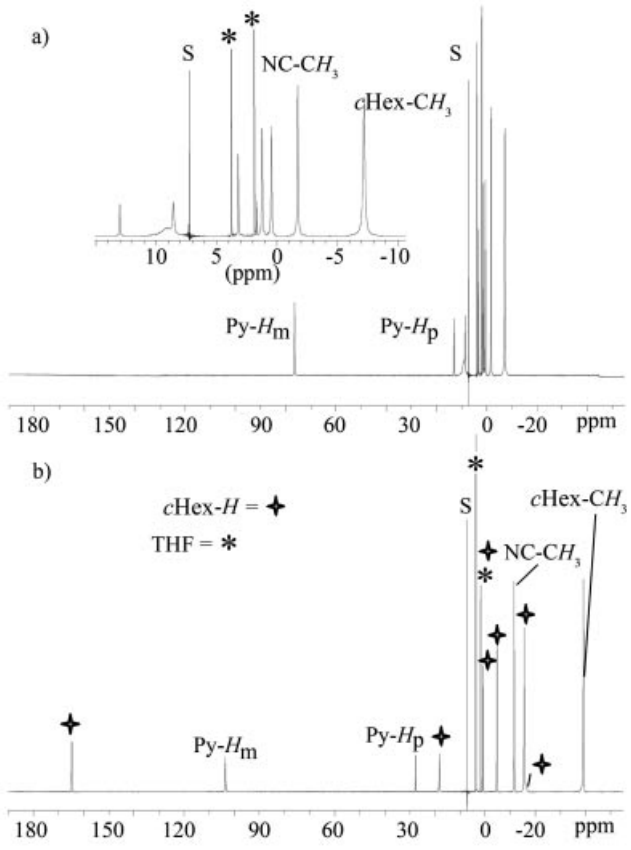

Figure 7. (a) $^1$H NMR spectrum of the iron complex **2a** containing THF marked with *; all the other nonmarked peaks are due to the protons on the cyclohexyl group. (b) $^1$H NMR spectrum of the cobalt complex **2b** containing THF marked with * (300 MHz, 293 K, $CDCl_3$).

All the spectra were recorded with pure crystals that contained THF of crystallization; this is the reason two relatively intense peaks of free THF can always be seen in the spectra. In the case of the cobalt complex the proton NMR shows us more important paramagnetic shift: the peaks are in the range –40 to 166 ppm (Figure 7, b). The integration of the peaks corresponds to what is expected.

These observations and the fact that there is a marked difference in the reactivity between the iron and the cobalt complexes bearing the same ligands prompted us to think that the ligand is in some way hemilabile in the case of iron.

The complete loss of activity can then be explained by the assumption that the addition of MAO can hinder the return of the imine group to the iron. On the contrary, for

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the cobalt complex **2b**, the spectrum of which is shown in Figure 7 (b), polymerization of ethylene is observed in the presence of MAO. Under 4 bar of ethylene and after 3 h, 150 mg of polyethylene was isolated. We will not go into more detail, as the subject is currently under investigation.

The polymers obtained with **1a** and **1b** were analyzed by $^1$H NMR, DSC, and HT SEC. $^1$H NMR spectra of polyethylenes ($C_2D_2Cl_4$, 130 °C) present a main peak at 1.3 ppm due to $CH_2$ groups, and a small one at 0.9 ppm due to $CH_3$ groups coming from chain ends or branching. Nevertheless, the intensity of the peak at 0.9 ppm is too small to allow reliable integration.

The results of SEC measurements are presented in Table 2. The chlorine atom seems to have no influence on the molar masses or the molar mass distributions when cobalt is employed. For the iron complexes, broad (even bimodal) molar mass distributions were obtained. It is now well established that this is due to transfer to aluminum (TMA present in MAO). It was nevertheless a bit surprising to get such broad distributions, as to avoid this transfer, the MAO we employed had most of its TMA removed by evaporation (5 mol-% residual TMA instead of 30 mol-% in commercial MAO). For cobalt complexes, molar mass distributions were much lower, because these catalytic systems are less sensitive towards transfer to aluminum.

The results of DSC measurements are also presented in Table 2. Like for SEC measurements, no huge differences were observed for the chlorinated and nonchlorinated ligands. The chlorine atom seems to have almost no influence on the melting temperatures and on the crystallinity rate. For all polyethylenes, the crystallinity rate (>0.8) is consistent with highly linear polymers. Polyethylenes obtained with the iron complexes exhibit two melting temperatures corresponding probably to two populations of polymers of different molar masses observed by HT SEC. With the cobalt complexes, only one melting temperature, very close to the one measured for highly linear polyethylene, was observed.

## Conclusion

In summary, two new pyridine-bis(imine)s were synthesized, by substituting the pyridine ring, or by replacing the aryl groups linked to the imine functions by an aliphatic ring. These ligands were complexed with iron and cobalt dichloride and two of these four new complexes were characterized by X-ray analysis. All the complexes were tested in the presence of MAO for the polymerization of ethylene. The introduction of a chlorine atom onto the pyridine ring was unfavorable; indeed the catalytic activity decreases compared to the unsubstituted ligand. For the other ligand two different results were observed. In the case of the iron complex, the loss of aromaticity led to a complete loss of catalytic activity towards ethylene polymerization and oligomerization. On the other hand, for the cobalt system, polyethylene could be obtained.

## Experimental Section

### General Considerations

Anhydrous $FeCl_2$ and $CoCl_2$, diacetylpyridine, chelidamic acid, thionyl chloride, Meldrum's acid, and 2,6-diisopropylaniline (all purchased from Aldrich) were used as received. 2,6-Dimethylcyclohexylamine was kindly provided by BASF AG. Methylaluminoxane (MAO) was purchased from Aldrich as a 10 wt.-% solution in toluene. Toluene and most of the trimethylaluminum (TMA) were removed under vacuum to yield a white powder, still containing 5 mol-% of TMA. Tetrahydrofuran, hexane, and toluene were distilled from sodium benzophenone ketyl. All complex syntheses were performed in a Jacomex glovebox or under thoroughly purified argon using a standard Schlenk technique. 2,6-Diacetyl-4-chloropyridine was prepared according to an already published procedure.[24]

### Characterization

$^1$H and $^{13}$C NMR spectra were recorded with a Bruker Avance-300 apparatus (300 MHz) at room temperature. IR spectra were recorded with a Perkin–Elmer 1600 FTIR spectrometer. Molar masses were measured by Size Exclusion Chromatography using an Alliance GPCV 2000 Permeation Chromatograph equipped with a differential refractive index detector and a viscosimeter in 1,2,4-trichlorobenzene (150 °C) using two Styragel HT 6E and one HT 2 columns. DSC measurements were performed with a Perkin–Elmer DSC4 or DSC7, with a heating rate of 10 °C·min$^{-1}$.

### Synthesis of Ligands

**4-Chloro-2,6-bis[1-(2,6-diisopropylphenylimino)ethyl]pyridine (1):** 2,6-Diacetyl-4-chloropyridine (0.5 g, 2.5 mmol), 2,6-diisopropylaniline (0.98 g, 5.5 mmol), and a small amount of *p*-toluenesulfonic acid were poured into a three-necked round-bottomed flask containing toluene (50 mL). The solution was refluxed for 24 h with a Dean–Stark trap. After lowering the temperature, the toluene was removed under vacuum to yield a brownish oil. The addition of hexane (20 mL) led to a yellow solution and a brown solid. After filtration and drying, a yellow solid was recovered (0.94 g, yield 72%). $^1$H NMR (300 MHz, $CDCl_3$, 293 K): $\delta$ = 8.48 (s, 2 H, py-$H_m$), 7.22–7.09 (m, 6 H, Ar-*H*), 2.74 (sept, $^3J_{H,H}$ = 6.9 Hz, 4 H, C*H*Me$_2$), 2.25 (s, 6 H, N=C-*Me*), 1.17 (d, $^3J_{H,H}$ = 6.9 Hz, 12 H, CH*Me*Me), 1.16 (d, $^3J_{H,H}$ = 6.9 Hz, 12 H, CHMe*Me*) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, 293 K): $\delta$ = 166.0 (N=*C*), 156.5 (Py-$C_o$), 146.0 (Ar-$C_{ip}$), 145.4 (Py-*C*-Cl), 135.7 (Ar-$C_o$), 123.8 (Ar-$C_p$), 123.0 (Py-$C_m$), 122.2 (Ar-$C_m$), 28.3 (N=C-*Me*), 23.3 (CH*Me*Me), 22.9 (CHMe*Me*), 17.2 (*C*HMe$_2$) ppm. IR: $\tilde{\nu}$ = 1640, 1557, 1317, 1260, 1228, 1189, 1104, 1016, 935, 885, 828, 762, 722, 692, 535, 438 cm$^{-1}$. $C_{33}H_{42}ClN_3$ (516.16): calcd. C 76.79, N 8.14, H 8.20; found C 73.23, N 7.21, H 8.35.

**2,6-Bis[1-(2,6-dimethylcyclohexylimino)ethyl]pyridine (2all-*cis*):** 2,6-Diacetylpyridine (2 g, 12.3 mmol), 2,6-dimethylcyclohexylamine all-*cis* (3.2 g, 25 mmol), and a few drops of acetic acid were poured into a three-necked round-bottomed flask containing ethanol (50 mL). The solution was refluxed for 18 h. After lowering the temperature, a white precipitate appeared. After filtration, washing with pentane and drying, a white solid was recovered (3.7 g, yield 82%). $^1$H NMR (300 MHz, $CDCl_3$, 293 K): $\delta$ = 8.18 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H, py-$H_m$), 7.68 (t, $^3J_{H,H}$ = 7.6 Hz, 1 H, py-$H_p$), 3.71 (t, $^3J_{H,H}$ = 2.2 Hz, 2 H, C$H_{c\text{Hex}}$-N=), 2.38 (s, 6 H, N=C-C$H_3$), 1.88–1.32 (br. m, 16 H, *c*Hex-C$H_2$-), 0.70 (d, $^3J_{H,H}$ = 6.6 Hz, 12 H, *c*Hex-C$H_3$) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, 293 K): $\delta$ = 164.0 (-*C*=N), 156.5 (py-$C_o$), 135.9 (py-$C_p$), 120.8 (py-$C_m$), 65.2 (C$H_{c\text{Hex}}$-N=), 38.6 (*c*Hex-$C_o$), 28.9 (*c*Hex-$C_m$), 27.1 (*c*Hex-$C_p$), 19.3 (*c*Hex-*C*H$_3$),

### Synthesis of the Complexes

**{4-Chloro-2,6-bis[1-(2,6-diisopropylphenylimino)ethyl]pyridine}iron Dichloride (1a):** $FeCl_2$ (36 mg, 0.28 mmol) and 4-chloro-2,6-bis[1-(2,6-diisopropylphenylimino)ethyl]pyridine (150 mg, 0.29 mmol) were dissolved in THF (25 mL). The reaction was let run for 16 h. After precipitation with hexane, filtration, and drying, a blue powder was recovered (150 mg, yield 83%). $^1$H NMR (300 MHz, $CDCl_3$, 293 K, $\delta_{solvent}$ = 7.26): $\delta$ = 76.46 (s, 2 H, $H_m$, Py), 14.40 (s, 4 H, $H_m$ Ar), –5.86 (br. s, 12 H, CH*Me*Me), –6.62 (s, 12 H, CHMe*Me*), –10.87 (s, 2 H, $H_p$ Ar), –23.70 (br. s, 4 H, C*H*Me), –45.57 (s, 6 H, NC*Me*) ppm. $C_{33}H_{42}Cl_3FeN_3$ (642.91): calcd. C 61.65, N 6.54, H 6.58; found C 61.88, N 6.01, H 7.35. IR: ṽ = 1689, 1574, 1500, 1320, 1282, 1237, 1115, 1015, 806, 722, 525, 365, 313 $cm^{-1}$.

**{4-Chloro-2,6-bis[1-(2,6-diisopropylphenylimino)ethyl]pyridine}-cobalt Dichloride (1b):** $CoCl_2$ (38 mg, 0.29 mmol) and 4-chloro-2,6-bis[1-(2,6-diisopropylphenylimino)ethyl]pyridine (150 mg, 0.29 mmol) were dissolved in THF (25 mL). The reaction was let run for 16 h. After precipitation with hexane, filtration, and drying, a green powder was recovered (150 mg, yield 81%). $C_{33}H_{42}Cl_3CoN_3$ (646.00): calcd. C 61.36, N 6.50, H 6.55; found C 59.52, N 5.42, H 6.70. IR: ṽ = 1582, 1325, 1264, 1204, 1103, 1057, 1028, 938, 858, 854, 838, 798, 768, 722, 590, 487, 440, 347, 309, 280, 213 $cm^{-1}$.

**{2,6-Bis[1-(2,6-dimethylcyclohexylimino)ethyl]pyridine}iron Dichloride (2a):** $FeCl_2$ (132 mg, 1.04 mmol) and 2,6-bis[1-(2,6-dimethylcyclohexylimino)ethyl]pyridine all-*trans* (400 mg, 1.04 mmol) were dissolved in THF (25 mL). The reaction was let run for 16 h. After precipitation with hexane, filtration, and drying, a blue powder was recovered (400 mg, yield 75%). $^1$H NMR (300 MHz, $CD_2Cl_2$, 298 K, $\delta_{solvent}$ = 5.32): $\delta$ = 78.34 (s, 2 H, py-$H_m$), 10.14 (v br. s, 2 H, $C_{c\mathrm{Hex}}$-*H*), 8.84 (s, 2 H, $C_{c\mathrm{Hex}}$-*H*), 8.58 (s, 1 H, py-$H_p$), 3.46 (s, 2 H, $C_{c\mathrm{Hex}}$-*H*), 1.73 (s, 4 H, $C_{c\mathrm{Hex}}$-*H*), 1.02 (s, 4 H, $C_{c\mathrm{Hex}}$-*H*), –1.29 (s, 6 H, N=C-C$H_3$), –6.99 (br. s, 12 H, $C_{c\mathrm{Hex}}$-C$H_3$) ppm. $C_{25}H_{39}Cl_2FeN_3$ (508.35): calcd. C 59.07, N 8.27, H 7.73; found C 58.52, N 8.40, H 7.71. IR: ṽ = 1582, 1268, 1198, 1020, 948, 842, 816, 718, 639, 568, 314, 285 $cm^{-1}$.

**{2,6-Bis[1-(2,6-dimethylcyclohexylimino)ethyl]pyridine}cobalt Dichloride (2b):** $CoCl_2$ (136 mg, 1.04 mmol) and 2,6-bis[1-(2,6-dimethylcyclohexylimino)ethyl] all-*trans* (400 mg, 1.04 mmol) were dissolved in THF (25 mL). The reaction was let run for 16 h. After precipitation with hexane, filtration, and drying, a green powder

was recovered (350 mg, yield 65%). $^1$H NMR (300 MHz, $CDCl_3$, 293 K, $\delta_H$ = 7.26): $\delta$ = 164.79 (s, 2 H, $C_{cHex}$-*H*), 103.50 (s, 2 H, py-$H_m$), 27.73 (s, 1 H, py-$H_p$), 18.21 (s, 2 H, $C_{cHex}$-*H*), 3.70 (s, 2 H, $C_{cHex}$-*H*), 0.79 (s, 2 H, $C_{cHex}$-*H*), –4.72 (s, 4 H, $C_{cHex}$-*H*), –11.59 (s, 6 H, N=C-C$H_3$), –15.58 (s, 4 H, $C_{cHex}$-*H*), –16.02 [s (v br. sh), 2 H, $C_{cHex}$-*H*], –39.19 (s, 12 H, $C_{cHex}$-C$H_3$) ppm. $C_{25}H_{39}Cl_2CoN_3$ (511.44): calcd. C 58.71, N 8.20, H 7.69; found C 58.41, N 8.49, H 7.69. IR: $\tilde{\nu}$ = 1620, 1582, 1266, 1248, 1198, 1115, 1023, 948, 864, 823, 816, 746, 716, 638, 568, 317, 287 cm$^{-1}$.

**Polymerization Procedure:** Polymerizations were conducted in a 250-mL glass Büchi reactor equipped with a magnetic stirrer and a temperature controller. Ethylene pressure was maintained constant in the reactor during the reaction. A typical procedure was: catalyst (10 μmol) in solution in toluene (30 mL) was added to the reactor under nitrogen. The reactor was heated to the reaction temperature and charged with ethylene. A solution of the desired amount of MAO dissolved in toluene (10 mL) was then added to the system. The reactor was charged with the desired differential pressure of ethylene. The reaction was let run for a period of 15 min, after which acidified ethanol (20 mL) was added to the miniclave to stop the polymerization. The content of the reactor was then precipitated in ethanol. The precipitated polymer was washed with ethanol and dried overnight in a vacuum oven at 60 °C.

**X-ray Crystallography:** Crystals of **1a**, **2a**, and **2all-*cis*** coated with vaseline were mounted onto the goniometer and placed on a Nonius Kappa CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved using the Nonius OpenMoleN package and refined against $F^2$ using the SHELXL-97 software[25] with anisotropical thermal parameters for all non-hydrogen atoms (except for one THF and the $H_2O$ in **2a**) and hydrogen atoms were introduced as fixed contribution (SHELXL-97[26]) (except for one THF and the $H_2O$ in **2a**) (see Table 3).

CCDC-255729 (for $C_{33}H_{42}Cl_3FeN_3{\cdot}C_4H_{10}O$, **1a**), -255730 (for $C_{100}H_{156}Cl_8Fe_4N_{12}{\cdot}3OC_4H_8{\cdot}H_2O$, **2a**), and -613556 (for $C_{25}H_{39}N_3$, **2all-*cis***) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

The authors want to thank the CNRS for financial support, Prof. Richard Blackborow, BASF, and Dr. Rath for providing the 2,6-dimethylcyclohexylamines, Suzanne Zehnacker for DSC measurements, Emmanuel Ibarboure and Prof. Henri Cramail (LCPO, Bordeaux, France) for HT SEC measurements, Jean-Daniel Sauer for the low-temperature NMR measurements, Nathalie Kyritsakas-Gruber for X-ray refinements of the complexes, Dr. André De Cian for all the X-ray measurements and the X-ray refinement of the free ligand, and Dr. Marie-Thérèse Youinou for her helpful advice.

# Synthesis, Structures, and Luminescent Properties of $d^{10}$ Group 12 Metal Complexes with Substituted 2,2′-Bipyridine Ligands

**Xiao-ming Liu,[a] Xiao-yue Mu,[a] Hong Xia,[a,b] Ling Ye,[a] Wei Gao,[a] Hao-yu Wang,[a] and Ying Mu*[a]**

**Keywords:** Group 12 metal complexes / 2,2′-Bipyridine / Solid-state structures / Luminescence

Four $d^{10}$ group 12 metal complexes, 6-(2-methoxyphenyl)-2,2′-bipyridinezinc dichloride (**2a**), -mercury dichloride (**2b**), 6-[2-(dimethylamino)phenyl]-2,2′-bipyridinezinc dichloride (**2c**), and -mercury dichloride (**2d**), were synthesized and the structures determined by single-crystal X-ray crystallography. Complexes **2a** and **2b** are four-coordinate and adopt a distorted tetrahedral geometry, while complexes **2c** and **2d** are five-coordinate with a distorted trigonal bipyramidal geometry for the metal center. Luminescent properties of complexes **2a**–**2d** in both solution and the solid state were studied.

## Introduction

Luminescent coordination complexes have attracted increasing attention because of their potential application in areas of optoelectronic devices and chemical sensors.[1] One of the most important considerations in organic light-emitting diodes (OLEDs) is the design and synthesis of molecules capable of tuning luminescent properties through the modification of ligands.[2,3] The organic compounds with aromatic nitrogen heterocycles, which can be receptors for metal ions, have been studied extensively because they are capable of performing useful light- and/or redox-induced tasks. For example, a large number of complexes based on 8-hydroxyquinoline, 7-azaindole, pyridyl-phenol, and phenyl-pyridine have been investigated during the last decades.[3–5] Particularly, luminescent complexes of $Re^{I}$,[6] $Ru^{II}$,[7] and $Os^{II}$[8] containing bipyridine type ligands have attracted much attention because of their high luminescent efficiency. However, the lower synthetic yields and higher costs of these complexes are disadvantages for their use as optoelectronic materials. The lower-cost $d^{10}$ metal complexes with the nitrogen-containing ligands are of interest because of their photoluminescent and/or electroluminescent properties.[9–11] To develop new complexes of this type with improved luminescent performance, we have synthesized four new complexes of zinc(II) and mercury(II) with modified bipyridine ligands that are synthesized by introducing an aromatic group with a donor at its α position to the 3-position of 2,2′-bipyridine. The ligands were selected considering that larger conjugating systems can be formed in their complexes and better luminescent properties might be expected. We herein report on the preparation, structural characterization, and photoluminescence of these zinc(II) and mercury(II) complexes.

## Results and Discussion

### Synthesis of Compounds

Ligand **1a** was prepared according to a known procedure (Scheme 1)[12] and ligand **1b** was synthesized by the reaction of dry 2,2′-bipyridine with the aryllithium reagent, obtained from the treatment of 2-bromo-*N*,*N*-dimethylaniline with *n*BuLi, in moderate yield after oxidative rearomatization. Ligand **1a** is a known compound while **1b** is a new compound. The new ligand **1b** was characterized by $^1$H NMR spectroscopy along with elemental analysis. The $^1$H NMR spectrum of **1b** exhibits resonance at $\delta$ = 2.77 ppm for the $CH_3$ proton. Compound **1b** is soluble in most organic solvents. Treatment of $ZnCl_2$ and $HgCl_2$ with equivalent free ligands in methanol at ambient temperature afforded the corresponding $d^{10}$ metal complexes **2a**–**2d** in good yields (>80%) as light yellow or white crystalline solids (Scheme 1). Complexes **2a**–**2d** were all characterized by elemental analyses, $^1$H NMR spectroscopy, and IR spectroscopy, and satisfactory analytic results were obtained on all compounds. All complexes are moderately soluble in DMSO, slightly soluble in dichloromethane, methanol, DMF, and THF, and insoluble in saturated hydrocarbon solvents.

### Crystal Structure

The molecular structures of complexes **2a**, **2b**, **2c**, and **2d** were determined by X-ray crystallographic analysis. Crystals of all four complexes suitable for X-ray crystal structure

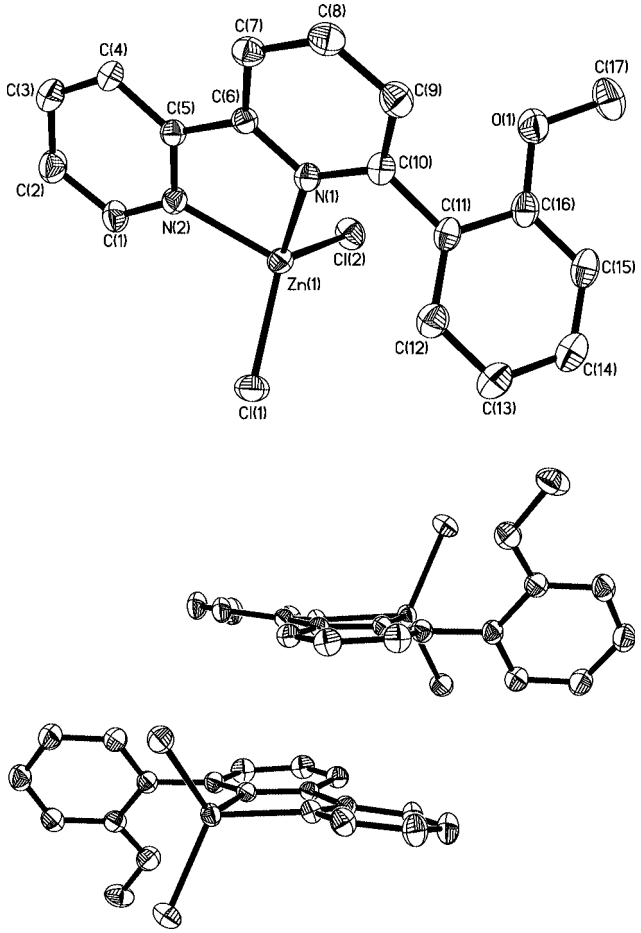

Figure 1. Top: molecular structure of complex **2a**; bottom: crystal packing diagram between two adjacent molecules of **2a** showing the lack of a π–π stacking interaction in the solid state. (Thermal ellipsoids are drawn at the 30% probability level.)

determination were grown from dichloromethane or $CH_3CN$ at room temperature. The ORTEP drawings of the molecular structures of **2a** and **2b** are shown in Figure 1 and Figure 2, respectively. Selected bond lengths and angles for the two complexes are given in Table 1. The X-ray analysis reveals that both complexes adopt a distorted tetrahedral geometry with the metal center chelated by the ligand **1a** through the pyridine nitrogen atoms, and the oxygen atom does not coordinate to the metal center in either complex because of the weak donating ability of the –OMe group. The Zn–N bond lengths in **2a** are 2.071 Å (average), which is close to the values previously reported for similar tetrahedral zinc complexes.[13] In complex **2b**, the two Hg–N bond lengths are slightly different [2.363(3) Å for Hg(1)–N(1) and 2.356(3) Å for Hg(1)–N(2)]. The values are consistent with bond lengths found in other four-coordinate $Hg^{II}$ complexes.[13c,14] The average $M^{II}$–N(pyridyl) bond distances (2.071 Å for Zn–N < 2.359 Å for Hg–N) are consistent with ionic radii. The N–Zn–N bite angle in **2a** [80.27(10)°] is smaller than those found in other pyridyl-containing four-coordinate $Zn^{II}$ complexes,[13a] but larger than the one [70.04(10)°] in its mercury analog **2b**. The dihedral angles between the two pyridyl rings are 10.1° for **2a** and 2.2° for **2b**, and the dihedral angles between the aromatic ring and the adjacent pyridyl ring are 61.0° for **2a** and 50.7° for **2b**. The data of the dihedral angles in two complexes indicate that the conjugated extent of **2b** is larger than that of **2a**. In addition, there is π–π stacking between the pyridyl rings of two neighboring molecules for complex **2a** in the solid state, forming an antiparallel dimeric structure (Figure 1 bottom). The distance between two pyridyl planes is 3.51 Å.[15] In contrast, a π–π stacking column structure was observed in **2b** (Figure 2 bottom). In the column each molecule of **2b** forms antiparallel π–π stacking with two adjacent molecules. The distances between the stacked aromatic planes are 3.46 Å and 3.50 Å, respectively. A similar π–π stacking column structure was also observed in $Hg^{II}$ complexes.[13c]

The molecular structures of complexes **2c** and **2d** are given in Figure 3 and Figure 4, respectively. Important bond lengths and angles are listed in Table 1. The crystal structure analysis reveals that complexes **2c** and **2d** are five-coordinate and adopt distorted trigonal bipyramidal geometry for the metal center. The ligand **1b** binds to the metal center in tridentate form by three nitrogen atoms, and there-

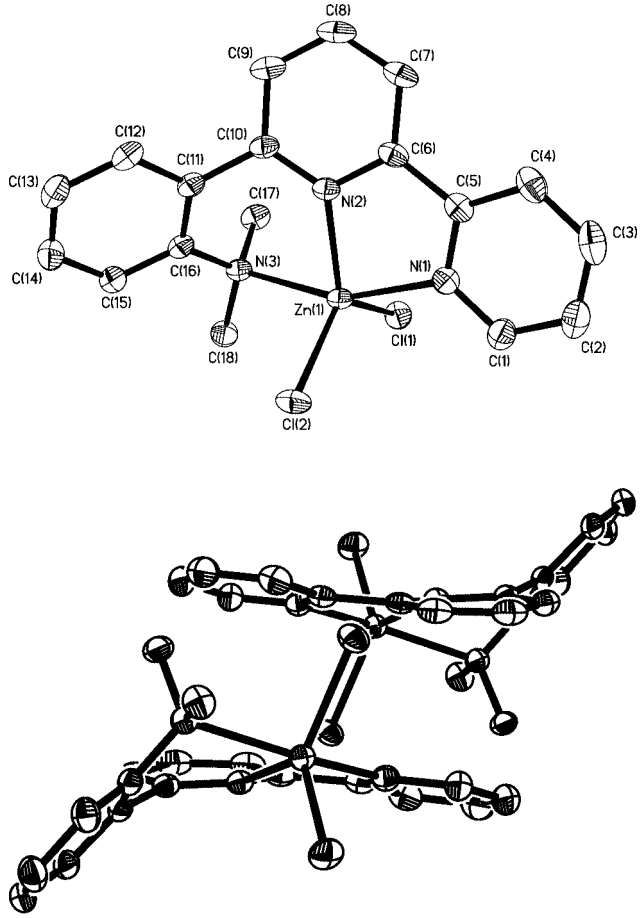

Figure 3. Top: molecular structure of complex **2c**; bottom: the π–π stacking dimer structure of complex **2c**. (Thermal ellipsoids are drawn at the 30% probability level.)

fore a five-membered metallacycle and a six-membered metallacycle are constructed. The N(1)–Zn(1)–N(2), N(2)–Zn(1)–N(3), and Cl(1)–Zn(1)–Cl(2) angles are 76.34(6), 84.17(6), and 118.74(3)° in **2c**, respectively. The Zn–N bond lengths, ranging from 2.1413(16) Å [Zn(1)–N(1)] to 2.3076(16) Å [Zn(1)–N(3)], are within the range of 2.098–2.321 Å observed for similar complexes,[16] while they are longer than those (2.079 and 2.062 Å) in the four-coordinate complex **2a**. The dihedral angles between the two pyridyl rings, and between the pyridyl ring and the adjacent aromatic ring are 18.0° and 47.7° for **2c** and 19.1° and 56.3° for **2d**, respectively. In solid state, molecules of **2c** are paired up through intermolecular π–π stacking of the ligand, resulting in the formation of a dimeric structure (Figure 3, bottom). The distance between the planes of the π–π stacked ligand is 3.53 Å. Similar to complex **2b**, a π–π stacking column structure was also observed in the mercury complex **2d** (Figure 4, bottom). The distances between the stacked aromatic planes are 3.42 and 3.65 Å, respectively. The intermolecular π–π interactions suggest that complexes **2a**–**2d** can possess charge transport property, which is essential for electroluminescent material.[17]

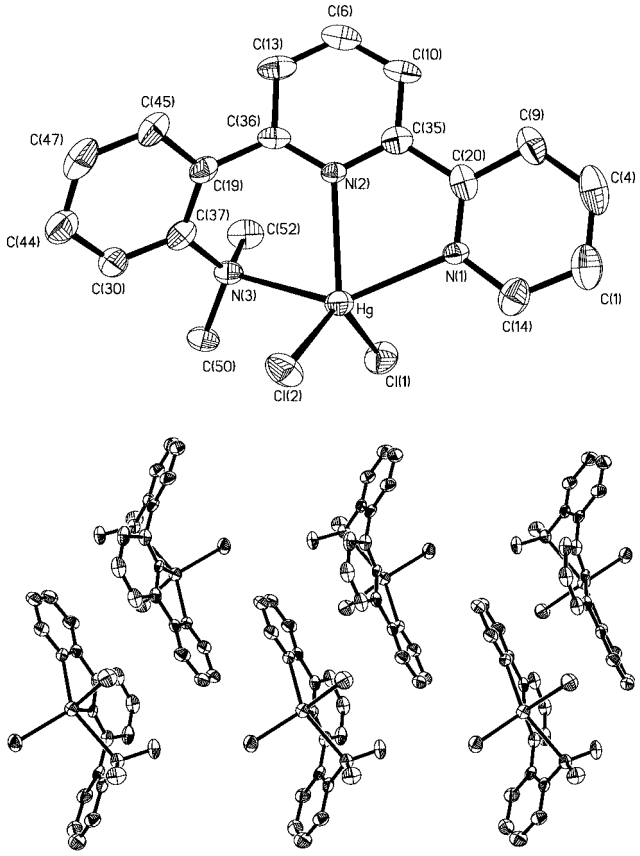

Figure 4. Top: molecular structure of complex **2d**; bottom: the π–π stacking column structure of complex **2d**. (Thermal ellipsoids are drawn at the 30% probability level.)

## Luminescence Properties

Table 2 summarizes the UV/Vis and fluorescent properties of compounds **1a**, **1b** and **2a**–**2d** determined in both solution and the solid state. In solution, the free ligands **1a** and **1b** have emission bands at $\lambda_{max}$ = 431 and 396 nm, respectively. In comparison with the free ligand **1a**, complexes **2a** and **2b** in solution give a broad emission band (bandwidth at half-height = 80–95 nm) with $\lambda_{max}$ = 447 nm and 452 nm, respectively, as shown in Figure 5. The emission maxima of the two complexes are slightly red-shifted compared to that of the free ligand. In contrast to complexes **2a** and **2b**, the emission maxima of **2c** and **2d** in solution are almost the same as that of the free ligand **1b** (see Figure 6). The luminescence of these complexes should be attributed to the transition from π* to π of their ligands. In solution, complex **2a** shows a strongly solvent-dependent emission band and its emission maximum shifts toward a shorter wavelength with the increase in polarity of the solvent. As shown in Figure 7, the emission maximum of **2a** is 461 nm in dichloromethane, while it becomes 358 nm in the polar solvent DMF. This is a rare case, as a red-shift of the emission maximum would be expected for most compounds when solvent polarity increases. The observed blue-shift phenomenon might be attributed to the presence of a highly polarized ground state.[18] The quantum yields of all compounds have been determined in solution. It was found that the quantum yields of the $Zn^{II}$ complexes **2a** and **2c** are slightly higher than those of their free ligands, while the quantum yields of the $Hg^{II}$ complexes **2b** and **2d** are lower than those of their free ligands. These results can be easily understood considering the following factors: the ligand becomes more rigid after coordination with a metal atom, which can reduce the loss of energy by vibrational motions and therefore increase the emission efficiency. On the other hand, the $Hg^{II}$ cation and the chloride anions can quench the fluorescence and result in luminescence decay. The quantum yields of complexes **2a** and **2b** are similar to those of four-coordinate zinc(II) complexes.[13b] The efficiency of **1a** and its corresponding complexes is about 20 times higher than that of **1b** and its corresponding complexes, probably because, in comparison with the –OMe group, the bulkier $–NMe_2$ group reduces the conjugated length and increases vibrational motion in **1b**, **2c**, and **2d**. The emission spectra of compounds **1a**, **1b**, **2a**, **2b**, and **2c** in the solid state are

shown in Figure 8. Except for **2d**, all compounds in solid state emit bright fluorescence when irradiated by exciting light. The emission maxima of **1a**, **2a**, and **2b** are 536, 397, and 410 nm, respectively. The emission maxima of **2a** and **2b** in the solid state are blue-shifted compared to emission maximum of their ligand **1a**, while the emission maximum of complex **2c** ($\lambda_{max}$ = 564 nm) in the solid state is red-shifted compared to that ($\lambda_{max}$ = 444 nm) of its corresponding ligand **1b**. These properties are probably a result of their π-stacking structures in the solid state.

## Conclusions

We have described the syntheses and X-ray structures of a number of d[10] group 12 metal complexes supported by two substituted 2,2′-bipyridine ligands. Crystal structure analysis reveals crystal structures of these complexes are different from each other. It was found that antiparallel dimeric structures are formed for complexes **2a** and **2c** while one-dimensional supramolecular structures are constructed for complexes **2b** and **2d** by π–π stacking in the solid state. These complexes produce fluorescence in both solution and the solid state, and the emission color in the solid state is dramatically affected by their packing structures.

## Experimental Section

All reactions were performed using standard Schlenk techniques in high-purity nitrogen or glovebox techniques. Toluene and diethyl ether were dried by refluxing over sodium and benzophenone and distilled under nitrogen prior to use. $CDCl_3$ was dried with $CaH_2$ for 48 h and vacuum-transferred to an air-free flask. $ZnCl_2$, $HgCl_2$, and *n*BuLi were purchased from Aldrich and used as received. NMR spectra were measured using a Varian Mercury-300 NMR spectrometer. The elemental analysis was performed with a Perkin–Elmer 2400 analyzer. UV/Vis absorption spectra were recorded with a UV-3100 spectrophotometer. Fluorescence measurements were carried out on an RF-5301PC.

**6-[2-(Dimethylamino)phenyl]-2,2′-bipyridine (1b):** A solution of *n*BuLi (30.32 mL, 48.5 mmol) in hexanes was added to a solution of 2-bromo-*N*,*N*-dimethylaniline (9.7 g, 48.5 mmol) in $Et_2O$ (30 mL) under nitrogen at –78 °C. The mixture was allowed to warm to room temperature and stirred overnight. The resulting

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mixture was added dropwise to an ice-cooled solution of 2,2′-bipyridine (7.57 g, 48.5 mmol) in degassed $Et_2O$ (30 mL), and a wine-red solution was obtained immediately. The resultant mixture was refluxed for 24 h and cooled in an ice bath, then deionized water (25 mL) was added to hydrolyze the products. The yellow organic phase was separated and stirred with $MnO_2$ for 24 h, then filtered and dried with $MgSO_4$. The solid was obtained upon concentration of the solution, and chromatography on silica gel with dichloromethane as eluent afforded a light yellow solid. Yield: 6.7 g (50%). $C_{18}H_{17}N_3$ (275.35): calcd. C 78.52, H 6.22, N 15.26; found C 78.32, H 6.41, N 15.10. $^1$H NMR (300 MHz, $CDCl_3$, 293 K): $\delta$ = 2.77 (s, 6 H, C$H_3$), 7.17 (d, 1 H), 7.32–7.40 (m, 2 H), 7.76–7.84 (m, 4 H), 7.99 (d, 1 H, $J$ = 7.8 Hz), 8.30 (d, 1 H, $J$ = 7.8 Hz), 8.49 (d, 1 H, $J$ = 5.4 Hz), 8.71 (d, 1 H, $J$ = 4.8 Hz) ppm.

**6-(2-Methoxyphenyl)-2,2′-bipyridinezinc Dichloride (2a):** A methanol solution (10 mL) of **1a** (0.2 g, 0.76 mmol) was added to a methanol solution (10 mL) of $ZnCl_2$ (0.11 g, 0.77 mmol). The reaction mixture was stirred for 4 h at room temperature. After filtering, the light yellow precipitate was collected and washed with cold methanol. Pure product was obtained in 81% yield (0.25 g) by recrystallization from $CH_3CN/CH_2Cl_2$. $C_{17}H_{14}Cl_2N_2OZn$ (398.60): calcd. C 51.22, H 3.54, N 7.03; found C 51.40, H 3.67, N 7.15. $^1$H NMR (300 MHz, [$D_6$]DMSO, 293 K): $\delta$ = 3.34 (s, 3 H, C$H_3$), 7.13 (t, 1 H), 7.21 (d, 1 H), 7.41–7.52 (m, 2 H), 7.91–7.99 (m, 4 H), 8.30 (d, 1 H), 8.48 (d, 1 H), 8.72 (d, 1 H) ppm. recrystallization from $CH_3CN/CH_2Cl_2$. $C_{18}H_{17}Cl_2HgN_3$ (546.84): calcd. C 39.53, H 3.13, N 7.68; found C 39.32, H 3.26, N 7.89. $^1H$ NMR (300 MHz, [D$_6$]DMSO, 293 K): $\delta$ = 2.58 (s, 6 H, C$H_3$), 7.15–7.21 (m, 2 H), 7.41 (s, 1 H), 7.58 (m, 2 H), 7.98–8.09 (m, 3 H), 8.41 (s, 1 H), 8.53 (d, 1 H), 8.72 (d, 1 H) ppm. IR (KBr): $\tilde{\nu}$ = 3064 w, 3013 w, 2964 w, 2869 w, 2835 w, 2795 w, 2364 w, 1594 s, 1568 s, 1443 s, 1288 m, 1259 w, 1233 w, 1185 m, 1159 m, 1126 w, 1110 w, 1049 w, 1008 m, 931 m, 891 w, 826 m, 777 s, 696 w, 630 m, 561 w, 543 w.

**X-ray Structure Determinations of 2a, 2b, 2c, and 2d:** Single crystals of **2a**, **2b**, **2c**, and **2d** suitable for X-ray structural analysis were obtained from dichloromethane or $CH_3CN$. Diffraction data were collected at 293 K on a Rigaku R-AXIS RAPID IP diffractometer equipped with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) for **2a**, **2b**, **2c**, and **2d**. Details of the crystal data, data collections, and structure refinements are summarized in Table 3. The structures were solved by direct methods[19] and refined by full-matrix least-squares on $F^2$. All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were included in idealized position. All calculations were performed using the SHELXTL[20] crystallographic software packages. For **2d**, the final difference maps revealed residual electron density near the mercury atoms (2.85 and 2.81 e Å$^{-3}$) but no regions of electron density that could be attributed to additional atomic sites.

CCDC-602363 (for **2a**), -602364 (for **2b**), -602365 (for **2c**), and -602366 (for **2d**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Chemical and Electrochemical Behaviours of a New Phenolato-Bridged Complex $[(L)Mn^{II}Mn^{II}(L)]^{2+}$. Pathways to Mononuclear Chlorido $[(L)Mn^{II/III/IV}Cl]^{0/1/2+}$ and Dinuclear Mono-μ-Oxido $[(L)Mn^{III}(\mu\text{-}O)Mn^{III/IV}(L)]^{2+/3+}$ Species

**Laurent Sabater,[a] Christelle Hureau,*[a,b] Guillaume Blain,[a] Régis Guillot,[a] Pierre Thuéry,[c] Eric Rivière,[a] and Ally Aukauloo*[a]**

**Keywords:** Manganese / N,O Ligands / Chloride ions / Electrochemistry / EPR spectroscopy

The X-ray structure of a new dinuclear phenolato-bridged $Mn_2^{II}$ complex abbreviated as $[(L)MnMn(L)]^{2+}$ (**1**), where LH is the $[N_4O]$ phenol containing ligand *N*,*N*-bis(2-pyridylmethyl)-*N*′-salicylidene-ethane-1,2-diamine ligand, is reported. A *J* value of –3.3 $cm^{-1}$ ($H = -J\hat{S}_1\cdot\hat{S}_2$) was determined from the magnetic measurements and the 9.4 GHz EPR spectra of both powder and frozen acetonitrile solution samples were analyzed with temperature. The cyclic voltammetry of **1** displays a reversible anodic wave at $E^{1/2}$ = 0.46 V vs. SCE associated with the two-electron oxidation of **1** yielding the dinuclear $Mn_2^{III}$ complex $[(L)MnMn(L)]^{4+}$ (**2**). The easy air oxidation of **1** gives the mono-μ-oxido $Mn_2^{III}$ complex $[(L)Mn(\mu\text{-}O)Mn(L)]^{2+}$ (**3**). A rational route to the formation of the mixed-valence $Mn_2^{III,IV}$ complex $[(L)Mn(\mu\text{-}O)Mn(L)]^{3+}$ (**4**) starting from **1** by bulk electrolysis at $E^{p}$ = 0.75 V vs. SCE in the presence of one equiv. of base per manganese ion is also briefly reported. Addition of chloride ions to **1** led to the cleavage of the phenolato bridges to give the mononuclear $Mn^{II}$ complex [(L)MnCl] (**5**). Cyclic voltammetry of **5** displays two reversible anodic waves at $E^{1/2}$ = 0.21 and $E^{1/2}$ = 1.15 V vs. SCE, assigned to the two successive one-electron abstractions giving the $Mn^{III}$ and $Mn^{IV}$ species $[(L)MnCl]^{+}$ (**6**) and $[(L)MnCl]^{2+}$ (**7**), respectively. The electronic signatures from UV/Visible and EPR spectroscopy of the electrochemically prepared samples of **6** and **7** confirmed the respective oxidation states. For instance, **7** displays a broad and intense absorption band characteristic of a phenolato to $Mn^{IV}$ charge-transfer transition at 690 nm (2000 $M^{-1}cm^{-1}$) and its 9.4 GHz EPR spectrum shows a strong transition at $g$ = 5.2 consistent with a rhombically distorted $S$ = 3/2 system with a zero-field splitting dominating the Zeeman effect.

## Introduction

Manganese ions are involved in the structure and activity of numerous metalloenzymes.[1,2] Their nuclearities may vary from 1 to 4 metal ions and they often carry out multielectron redox reactions. A mononuclear Mn core is encountered in superoxide dismutase[3–5] and in oxalate oxidase[6,7] and oxalate decarboxylase,[6,8] while dinuclear centres are the most common[9] and are found in catalase,[3,9,10] arginase,[11,12] and ribonucleotide reductase.[13] A tetranuclear Mn core is the heart of the oxygen-evolving complex of photosystem II.[14,15] The fact that these manganese containing enzymes perform crucial reactions in different processes for the maintenance of terrestrial life has encouraged the chemists to pay particular attention to their functioning mode together with their intimate structures and spectroscopic characterizations. Furthermore, bioinorganic chemists have set the challenge to devise synthetic low molecular weight models[16–18] to either reproduce the coordination spheres of these Mn containing active sites or even more challenging, to mimic the activity of the target enzyme (see for examples ref.[19–23]).

Results on both bases have until now been encouraging but a great effort is still needed to reach our objectives. Research along this field is being pursued in our laboratory. Recently, we have reported on the metalation of the ligand LH, where LH is the $[N_4O]$ phenol-containing ligand *N*,*N*-bis(2-pyridylmethyl)-*N*′-salicylidene-ethane-1,2-diamine, with $Mn^{II}$ salt giving the $[(LH)MnCl_2]$ complex where the phenol was still in a protonated state.[24] We have shown through various spectroscopic characterizations that upon the first one-electron oxidation process a concerted chemical reaction took place with the concomitant expulsion of one chloride ion from the manganese coordination sphere together with the deprotonation of the phenol and the coor-

dination of the phenolate group. The reversibility of this process was also evidenced. We believe that such an electrochemical process is essential to delineate the highly intricate manganese chemistry. Herein we report on the synthesis of the dinuclear phenolato-bridged $Mn_2^{II}$ species $[(L)Mn\text{-}Mn(L)]^{2+}$ (**1**), which has been characterized by X-ray diffraction studies, EPR spectroscopy, and cyclic voltammetry. We show that complex **1** can withstand a two-electron oxidation leading to complex $[(L)MnMn(L)]^{4+}$ (**2**) keeping the phenolate groups as bridging ligands. However, upon air oxidation of **1**, the mono-μ-oxido-bridged $Mn_2^{III}$ complex $[(L)Mn(\mu\text{-}O)Mn(L)]^{2+}$ (**3**) is obtained while the corresponding mixed-valence $Mn_2^{III,IV}$ complex $[(L)Mn(\mu\text{-}O)\text{-}Mn(L)]^{3+}$ (**4**) is electrochemically generated. A more detailed study on the reaction of complex **1** with the biologically ubiquitous chloride ions is described. After addition of chloride ions the mononuclear $Mn^{II}$ species [(L)MnCl] (**5**) is formed. The electrochemical behaviour of **5** exhibits two one-electron reversible-oxidation processes, changing the initial $Mn^{II}$ to $Mn^{III}$ and $Mn^{IV}$ oxidation states, respectively. Spectroscopic characterizations of the $Mn^{III}$ $[(L)\text{-}MnCl]^{+}$ (**6**) and $Mn^{IV}$ $[(L)MnCl]^{2+}$ (**7**) complexes in the $[N_4OCl]$ environment are reported.

## Results

### Characterization of Complex $[(L)MnMn(L)]^{2+}$ (1)

The reaction of ligand LH with $Mn(ClO_4)_2{\cdot}6H_2O$ in ethanol, and in the presence of one equiv. of 2,6-dimethylpyridine gives the complex $\mathbf{1}(ClO_4)_2{\cdot}2H_2O$. In order to attenuate the extremely fast air oxidation of **1** into the mono-μ-oxido-bridged $Mn_2^{III}$ complex $[(L)Mn(\mu\text{-}O)Mn(L)]^{2+}$ (**3**) (see Exp. Sect. for details), the preparation and handling of complex **1**, except for the magnetic measurements, were performed under an argon flux. Nevertheless, unavoidable contamination of solution and solid samples of complex **1** by complex **3** were observed by cyclic voltammetry and by UV/Visible spectroscopy.

### X-ray Crystal Structure of $\mathbf{1}(ClO_4)_2{\cdot}2CH_3CN$

The X-ray structure of complex **1** is shown in Figure 1, and principal bond lengths and angles are listed in Table 1. The structure consists of a discrete cation $[(L)Mn\text{-}Mn(L)]^{2+}$ (**1**), two perchlorate anions, and two acetonitrile solvent molecules. The two $Mn^{II}$ centres are bridged by the phenolato groups of the two $L^-$ ligands. Therefore, a $[N_4O_2]$ donor set forms the distorted octahedral coordination environment of each Mn ion. Bond lengths and angles listed in Table 1 show the distortion from octahedral geometry due to constraints imposed by the ligand.

The Mn···Mn distance of 3.383 Å is slightly longer than those reported for phenolato-bridged $Mn_2^{II}$ complexes of closely related $mL^-$, $Li^-/La^-$ ligands (see Scheme 1),[25–27] but shorter than those obtained for phenolato-bridged $Mn_2^{II}$ complexes obtained with the $[N_3O_2Cl]$ metal environment.[28] As a matter of fact, the $Mn_2O_2$ diamond core structure of **1** differs from those of complexes $[(mL)Mn\text{-}Mn(mL)]^{2+}$ and $[(Li/La)MnMn(Li)]^{2+}$.[29] Values of the average Mn–O–Mn angle and of the dihedral angle are slightly greater than those observed in $[(mL)Mn\text{-}Mn(mL)]^{2+}$ and $[(Li/La)MnMn(Li)]^{2+}$ systems: 103.7° vs. 100.0° and 101.4°, and 17.9° vs. 11.3° and 11.5°, respectively.[26,27] This can be tentatively attributed to the conjugation of the bridging phenolato group to an imine function in the present case.

The wrapping of the Mn ion by the ligand $L^-$ is identical to that observed in the structures of related Mn[24,30] and Fe[31] complexes, with the two pyridine functions in a *trans* position to one another.

### Magnetic Susceptibility Measurements

The molar magnetic susceptibility $\chi_M$ of a powder sample of $\mathbf{1}(ClO_4)_2{\cdot}2H_2O$ was measured between 300 and 2 K. At 300 K the $\chi_M T$ value is equal to 6.8 $cm^3\,mol^{-1}\,K$ and decreases slowly down to 5.0 $cm^3\,mol^{-1}\,K$ at 50 K. Below 50 K the $\chi_M T$ value decreases more rapidly and is equal to 0.3 $cm^3\,mol^{-1}\,K$ at 2 K (Figure S1, open circles). This behaviour is indicative of a weak antiferromagnetic interaction between two high-spin $Mn^{II}$ ions ($S = 5/2$). The best simulation performed on the $\chi_M$ vs. $T$ curve is obtained with a fixed $g$ value of 1.95[32] and $J = -3.2\ cm^{-1}$ ($H = -J\hat{S}_1{\cdot}\hat{S}_2$) (Figure S1, solid line).[33] The best simulation performed on the $\chi_M T$ vs. $T$ curve is obtained with $g = 1.95$[32] and $J = -3.4\ cm^{-1}$ (Figure S1, solid line).[34] The two sets of parameters are in agreement and lead to a $J$ value that is close to $-3.3(0.1)\ cm^{-1}$. This value is consistent with reported $J$ values for systems where the two $Mn^{II}$ ions are bridged by two phenolato groups,[35–38] and is slightly higher than the one published for the closely related $[(mL)MnMn(mL)]^{2+}$ complex.[27]

### EPR Spectroscopy

The 9.4 GHz (X band) EPR spectra recorded at 5 and 30 K, and the 10 K 34 GHz (Q-band) EPR spectrum of a powder sample of $\mathbf{1}(ClO_4)_2{\cdot}2H_2O$ are shown in Figure 2(a,b). The evolution of the 9.4 GHz EPR signatures as a function of temperature was monitored between 5 and 50 K and is given in the Supporting Information (Figure S2). All spectra exhibit features extending from 0–800 mT at 9.4 GHz and from 400–1500 mT at 34 GHz, the intensities of which depend on the temperature. This behaviour is strongly indicative of dinuclear $Mn_2^{II}$ species.[35,38–42] The observed features originate from the superimposition of signatures from the five $S = 1$ to $S = 5$ paramagnetic spin states.[43] The 9.4 and 34 GHz EPR spectra that were

obtained are slightly different from those previously reported for the $[(mL)MnMn(mL)]^{2+}$ complex.[27] More precisely, the 34 GHz EPR spectrum of the $[(mL)MnMn(mL)]^{2+}$ complex shows several lines below 600 mT, which are attributed to inter-S-spin transitions from the competitive effect between the Zeeman and the Heisenberg interactions ($J = -1.8\ cm^{-1}$).[27] Here, the 34 GHz EPR spectrum of **1** shows only one transition below 600 mT, in agreement with the higher $J$ value of $-3.3\ cm^{-1}$.

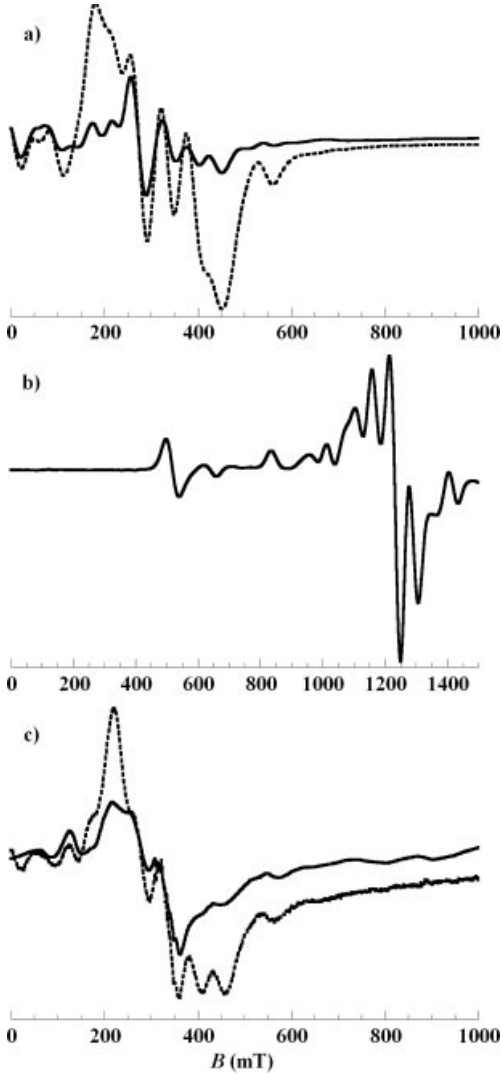

Figure 2. (a) 9.4 GHz EPR spectra recorded on a powder sample of $\mathbf{1}(ClO_4)_2{\cdot}2H_2O$ at 5 K (solid line) and 30 K (dotted line). (b) 34 GHz EPR spectra recorded on a powder sample of $\mathbf{1}(ClO_4)_2{\cdot}2H_2O$ at 10 K. (c) 9.4 GHz EPR spectra recorded on a millimolar solution sample of **1** in acetonitrile containing 0.1 M tetrabutylammonium perchlorate at 5 K (solid line) and 30 K (dotted line). Note that the product of the absorption by the temperature $T$ is plotted as a function of the magnetic field. 9.4 GHz EPR recording conditions: 9.38 GHz microwave frequency, 2.0 mW microwave power, 0.5 mT modulation amplitude, 100 kHz modulation frequency. 34 GHz EPR recording conditions: 34.18 GHz microwave frequency, 2.3 mW microwave power, 1.0 mT modulation amplitude, 100 kHz modulation frequency.

The 9.4 GHz EPR spectra recorded at 5 and 30 K of a frozen acetonitrile solution sample of **1** in the presence of 0.1 M tetrabutylammonium perchlorate are shown in Figure 2 (c). Evolution of the 9.4 GHz EPR signatures as a function of temperature is given in the Supporting Information (Figure S3). The EPR signatures as well as the modifications in the relative intensities of the observed EPR features as a function of temperature conform to that of a dinuclear $Mn_2^{II}$ species. The evolution of the EPR features is similar to the one observed in the powder sample of complex **1**. More precisely, in both powder and solution samples, the features near 200 and 400 mT increase with the temperature. Therefore, we can rationally propose that the dinuclear phenolato-bridged $Mn_2^{II}$ core structure is maintained upon dissolution in acetonitrile. However, no characteristic $^{55}Mn$ hyperfine pattern is observed. This can be attributed either to the superimposition in the same magnetic field range of several lines originating from different transitions that exhibit slightly distinct Mn hyperfine structures, or to a structural heterogeneity that would induce a distribution in the EPR parameters.

### UV/Visible Spectroscopy

The UV/Visible spectrum of complex **1** is shown in Figure 3 (a, dashed line) and the UV/Visible data are reported in Table 2. As expected for $Mn^{II}$ species no transition is observed in the visible region. An intense band is detected at 348 nm, which can be tentatively attributed to the phenolato to $Mn^{II}$ charge-transfer transition by comparison with data obtained from the related $[(L')Mn]^-$ complex, where $L'H_3$ is a triphenol containing ligand with a $[N_2O_3]$ donor set.[25,44] The band detected at 300 nm and indicated by an asterisk in Figure 3 (a) is assigned to the contaminant species **3** (see Table 2).

### Cyclic Voltammetry

The cyclic voltammogram of complex **1** is shown in Figure 4 (a) and its redox data are reported in Table 3. Anodic and cathodic processes assigned to the soil species **3** are indicated by a star in Figure 4 (a). The cyclic voltammetry trace of **1** exhibits a reversible anodic process at $E^{1/2} = 0.46$ V vs. SCE ($\Delta E^P = 133$ mV),[45] and an irreversible anodic peak at $E^P = 1.44$ V vs. SCE. The square wave voltammetry shows that two and one electrons are involved in the first and the second anodic process, respectively. These data indicate that the first anodic process is associated with the formation of the dinuclear phenolato-bridged $Mn_2^{III}$ complex $[(L)MnMn(L)]^{4+}$ (**2**), while the second anodic process is associated with the formation of a $Mn^{IV}$ containing species. Irreversibility of the second anodic process is probably due to the generation of a $Mn^{IV}$ ion, which would spontaneously engender the opening of the dinuclear structure. For comparison purposes redox data of complex **1** together with other related dinuclear phenolato-bridged $Mn_2^{II}$ complexes are given in Table 3. The potential value of the first

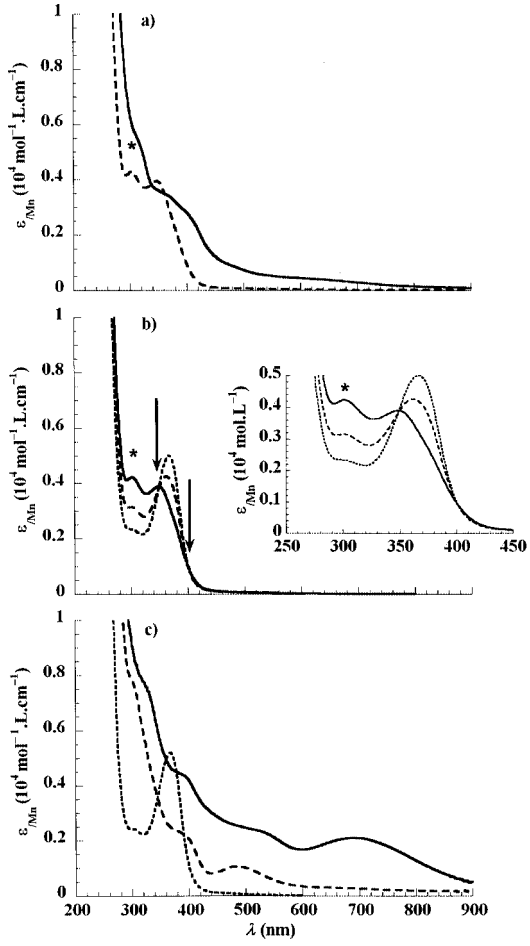

Figure 3. (a) UV/Visible spectrum of complex **1** in acetonitrile containing 0.1 M tetrabutylammonium perchlorate (dashed line) and of complex **2**, generated by exhaustive electrolysis of **1** at $E$ = 0.8 V vs. SCE (solid line); (b) UV/Visible spectrum of 1 mM solution of **1** in acetonitrile containing 0.1 M tetrabutylammonium perchlorate, upon addition of chloride ions. No chloride ion added (solid line), 0.5 equiv. of chloride ion per Mn (dashed line) and 1.0 equiv. of chloride ion per Mn ion (dotted line); (c) UV/Visible spectrum of complex **5**,[60] (dotted line); of complex **6**, generated by exhaustive electrolysis of complex **5** at $E$ = 0.85 V vs. SCE (dashed line), and of complex **7**, generated by exhaustive electrolysis of complex **5** at $E$ = 1.45 V vs. SCE (solid line). (l = 1 mm, $T$ = 20 °C). Note that unless specified the total conversions of **1** were assumed to draw the absorption spectrum. The asterisks * in (a) and (b) indicate the presence of the contaminant species **3**.

anodic process of **1** is lower than those of related phenolato-bridged dinuclear $Mn_2^{II}$ complexes, and the peak-to-peak separation $\Delta E^P$ is distinctly smaller. The possible origins of these differences will be discussed below.

An irreversible cathodic peak is detected at $E^P$ = –1.91 V vs. SCE, while in the related $[(Li/La)MnMn(Li)]^{2+}$ complex[29] reduction of the imine function of the $Li^-$ ligand (see Scheme 1) was observed at $E^P$ = –1.38 V vs. SCE.[26] The conjugation of the imine function to a phenolato group in the $L^-$ is anticipated to render the reduction more difficult, and therefore explain the lower potential value detected here.

### Electrochemical Oxidation of Species 1 into Complex [(L)MnMn(L)]$^{4+}$ (2)

The square wave and the cyclic voltammetry experiments recorded on complex **1** indicate that oxidation of **1** will lead to the dinuclear phenolato-bridged $Mn_2^{III}$ species $[(L)MnMn(L)]^{4+}$ (**2**). Exhaustive electrolysis was performed at $E$ = 0.8 V vs. SCE. The cyclic voltammetry trace recorded after consumption of one electron per Mn ion displays one reversible cathodic process at $E^{1/2}$ = 0.46 V vs. SCE and one irreversible anodic peak $E^P$ = 1.44 V vs. SCE (Figure S4). These data are consistent with the formation of complex **2** in solution. An insignificant amount of the dinuclear mono-μ-oxido-bridged complexes was generated during the electrolysis.

The UV/Visible spectrum recorded after completion of the electrolysis is shown in Figure 3 (a, solid line), and the UV/Visible data reported in Table 2, together with those of related phenolato $Mn^{III}$ complexes. Upon comparison, it is possible to attribute the broad transition detected near 600 nm to $Mn^{III}$ d–d transitions and the shoulder observed at 480 nm to the superimposition of $Mn^{III}$ d–d transitions and phenolato to $Mn^{III}$ charge-transfer transitions. Both the position and the intensity of the two absorption bands detected near 405 nm agree with values reported in the literature for bridging phenolato to $Mn^{III}$ charge-transfer transitions.[44,46–49] The shift of the phenolato to $Mn^{II}$ electronic transition detected in **1** at 348 nm to a lower energy upon oxidation of the Mn ion is reminiscent of what was observed for the successive oxidations of the dinuclear $Mn_2^{II}$ complex $[Mn_2(2\text{-}OHsalpn)_2]^{2-}$.[25,50] The UV/Visible signature of complex **2** is very close to that of complex **3**, except for the strong absorption band at 300 nm only detected in **3**.

9.4 GHz EPR spectra were recorded on the electrolyzed solution using the perpendicular and the parallel detection modes (data not shown). No signal was detected.

### Electrochemical Conversion of Species 1 into Complex [(L)Mn(μ-O)Mn(L)]$^{3+}$ (4)

The electrochemical conversion of mono- and dinuclear $Mn^{II}$ complexes into mixed-valence oxido-bridged $Mn_2^{III,IV}$ systems has been recently described.[27,51,52] An exhaustive electrolysis of the $Mn^{II}$ species is performed in acetonitrile, where the presence of residual water together with an external base leads to the formation of the oxido-bridged species. This method was applied here to obtain the mixed-valence complex $[(L)Mn(\mu\text{-}O)Mn(L)]^{3+}$ (**4**).

The cyclic voltammetry trace of species **1** upon addition of one equiv. of base per Mn ion is shown in Figure 4 (b). When scanning towards anodic potentials, the first oxidation process of species **1** is still partially detected, but at a slightly lower potential value. Furthermore, two new reversible processes are seen at $E^{1/2}$ = 0.55 and $E^{1/2}$ = 1.0 V vs. SCE, which correspond to the two sequential one-electron oxidations of the dinuclear $Mn_2^{III}$ complex $[(L)Mn(\mu\text{-}O)Mn(L)]^{2+}$ (**3**). Both the detection of the oxidation

peak of **1** at a lower potential value and of the cyclic voltammetry signature of a new species are symptomatic of an EC (Electrochemical Chemical) mechanism. Oxidation of species **1** leading to the corresponding dinuclear $Mn_2^{III}$ species **2** is followed by the formation of complex **3** at the electrode, because of the presence of residual water and of base in the medium.[53] This EC mechanism is illustrated in Scheme 2.

The cyclic voltammogram, the UV/Visible spectrum, and the 100 K 9.4 GHz EPR spectrum recorded after bulk electrolysis at 0.75 V vs. SCE (Figure 4(c), Figures S5, and S6, respectively, in the Supporting Information) are identical to those reported for the mixed-valence complex **4** obtained by the one-electron oxidation of the chemically prepared species **3**.[30] Both the number of consumed electrons during the electrolysis (3 $e^-$ per complex **1**) and the extinction coefficient values are consistent with the total conversion of species **1** into **4**. This is confirmed by quantification of the EPR trace recorded after the electrolysis of **1** (Figure S6), which shows the formation of **4** with a 95% (±5%) yield (see Exp. Sect. for details).

### Transformation of Complex 1 upon Addition of Chloride Ions

Evolution of the cyclic voltammetry trace of complex **1** upon addition of 0.5 and 1.0 equiv. of chloride ion per Mn ion is shown in Figure 4 (d dashed and solid lines, respectively). The anodic process corresponding to the oxidation of free chloride ions is not observed. Concomitantly with the loss of the anodic processes related to complex **1**, two new reversible anodic processes were detected at $E^{1/2}$ = 0.21 ($\Delta E^P$ = 95 mV) and $E^{1/2}$ = 1.15 V vs. SCE ($\Delta E^P$ = 94 mV). By comparing the potential values with those of related complexes with $[N_4Cl_2]$[52] and $[N_4O_2]$[54] Mn environments (see Table 3) we propose that the coordination sphere of the Mn ion is $[N_4OCl]$ provided by the $L^-$ ligand and one exogenous chloride anion, leading to the neutral $Mn^{II}$ species [(L)MnCl] (**5**). In this hypothesis, the two anodic processes are attributed to the successive one-electron oxidation of species **5** into the mononuclear $Mn^{III}$ $[(L)MnCl]^+$ (**6**) complex and then into the mononuclear $Mn^{IV}$ $[(L)MnCl]^{2+}$ (**7**) complex.

The spectral changes of the UV/Visible spectrum of complex **1** upon addition of 0.5 and 1.0 equiv. of chloride ion per Mn ion are shown in Figure 3 (b, dashed and dotted lines, respectively). The phenolato to $Mn^{II}$ charge transfer transition detected at 348 nm for complex **1** is shifted to lower energies ($\lambda_{max}$ = 367 nm) in species **5**. This spectral modification can be related to the change in the coordination mode of the phenolato arm from bridging to monodendate.

By contrast to the modifications observed by cyclic voltammetry and UV/Visible spectroscopy at room temperature, the EPR signature of complex **1** recorded at 100 K is virtually unmodified upon the addition of one equiv. of chloride ion per Mn ion (Figure 5, a,b). It totally vanishes upon the addition of five equiv. of chloride ions per Mn ion (Figure 5, d). The new spectral features consist of an intense transition at 330 mT ($g$ = 2) and three other transitions of lower intensity at 50 mT, 130 mT, and 225 mT. This signature is consistent with a mononuclear $Mn^{II}$ species, where the Zeeman effect dominates the zero-field splitting interaction.[55–59] The EPR study gives a first insight into the presence of an equilibrium between species **1**, **5**, and the chloride ions, which should be modified by the temperature. The detection of this equilibrium at room temperature was monitored by cyclic voltammetry. Upon addition of two and five equiv. of chloride ions per Mn ion, the cyclic voltammetry trace shows that the potential of the anodic peak is slightly shifted to lower values, whereas the position of the associated cathodic peak observed on the reverse scan remains virtually identical (Figure S7). This behaviour is reminiscent of a CE (Chemical-Electrochemical) mechanism, which is illustrated in Scheme 3. As a working hypothesis, we propose that the chemical reaction, which precedes the electrochemical oxidation of species **5** into **6**, is an equilibrium between species **1** and **5**.

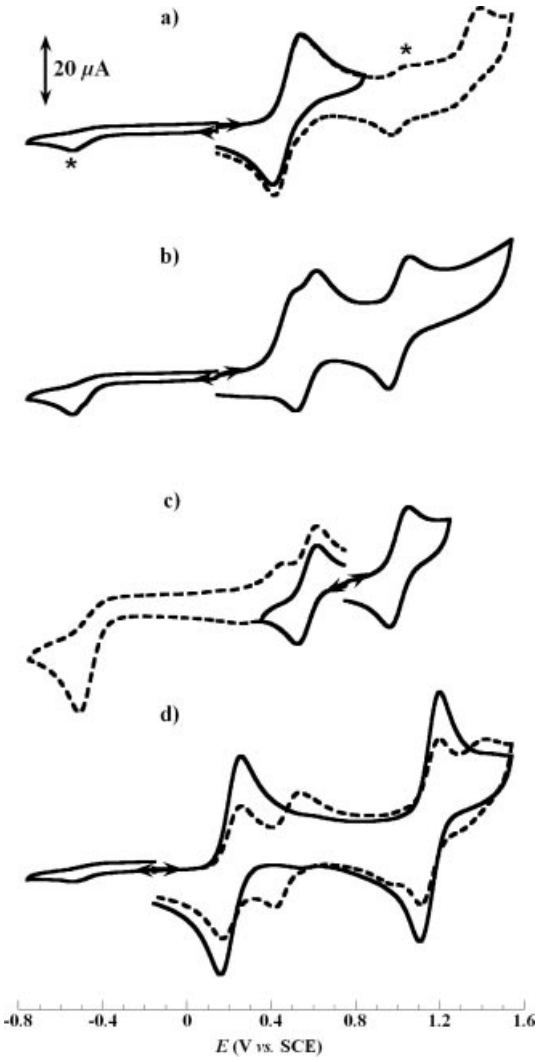

Figure 4. (a) Cyclic voltammograms of 1 mM solution of **1** in acetonitrile containing 0.1 M tetrabutylammonium perchlorate. (b) Cyclic voltammograms of 1 mM solution of **1** in acetonitrile in presence of one equiv. of 2,6-dimethylpyridine per Mn ion. (c) Cyclic voltammograms of 1 mM solution of **1** in acetonitrile in the presence of one equiv. of 2,6-dimethylpyridine per Mn ion, and after bulk electrolysis at $E$ = 0.7 V vs. SCE. ($T$ = 20 °C, scan rate = 100 mV). (d) Cyclic voltammograms of 1 mM solution of **1** in acetonitrile in the presence of 0.5 equiv. of chloride ion per Mn ion (dashed line), and in the presence of 1.0 equiv. of chloride ion per Mn ion (solid line). The stars in (a) indicate the presence of the contaminant species **3**.

It is worth noting that upon the addition of chloride ions, the intensity of anodic and cathodic processes corresponding to the contaminant species **3** fades significantly, as well as the UV band detected at 300 nm and assigned to species **3**. The dissipation of species **3** upon addition of chloride ions will be considered below.

### Electrochemical Oxidations of Complex 5 into Species $[(L)MnCl]^+$ (6) and $[(L)MnCl]^{2+}$ (7)

The cyclic voltammetry signature of complex **5**,[60] which is shown in Figure 4(d), suggests that complex **5** can be oxidized twice electrochemically to generate the corresponding $Mn^{III}$ $[(L)MnCl]^+$ (**6**) and $Mn^{IV}$ $[(L)MnCl]^{2+}$ (**7**) species. Two successive bulk electrolysis of species **5** were performed at $E$ = 0.85 (20 °C) and $E$ = 1.45 V vs. SCE (–30 °C), respectively, and were monitored by UV/Visible and EPR spectroscopy.

The cyclic voltammetry trace recorded after the first consumption of one electron per Mn ion displays one reversible anodic process at $E^{1/2}$ = 1.15 V vs. SCE and one reversible cathodic process at $E^{1/2}$ = 0.21 V vs. SCE (Figure S8, dashed line). These data are consistent with the one-electron oxidation of species **5** leading to the mononuclear $Mn^{III}$ complex **6**.

The UV/Visible spectrum recorded after the first bulk electrolysis is shown in Figure 3 (c, dashed line). Three new transitions are detected in the region from 390 to 495 nm. The UV/Visible data of complex **6** are reported in Table 2, together with other related phenolato and chlorido $Mn^{III}$ complexes. Upon comparison, it is possible to attribute the 390 nm absorption band to the superimposition of chlorido and phenolato to $Mn^{III}$ charge-transfer transitions, and the two transitions detected at 479 and 494 nm to both $Mn^{III}$ d–d transitions and phenolato to $Mn^{III}$ charge-transfer transitions.

No EPR signal was detected using the conventional perpendicular detection mode. However, the 5 K 9.4 GHz EPR spectrum of the electrolyzed solution, recorded in the parallel detection mode displays six ill-resolved hyperfine lines centred at 79 mT ($g$ = 8.5) and spaced by 5.4 mT (Figure 6, a). As previously described in the literature, 9.4 GHz parallel mode EPR spectra are expected for an $S$ = 2 quasi-axial system with a strong zero-field splitting.[61,62] More specifically, the spectroscopic signatures detected here are characteristic of a high-spin $Mn^{III}$ species, where the Jahn–Teller distortion is an elongation.[52,63–69]

The cyclic voltammetry trace recorded after the second one-electron electrolysis of **5** displays two reversible cathodic processes at $E^{1/2}$ = 1.15 and $E^{1/2}$ = 0.21 V vs. SCE (Figure S8, solid line), underlying that the one-electron oxidation of species **6** into the mononuclear $Mn^{IV}$ complex **7** was successful. However, a slightly weaker intensity is observed for the two electrochemical processes, indicating a partial evolution of the $Mn^{IV}$ species, even at –30 °C. It is worth noting that the possibility of a ligand-centred oxidation of species **6** leading to the mononuclear $Mn^{III}$-phenoxyl complex was given some thought. However, it was considered to be an unlikely hypothesis[70] on the basis of the reported oxidation of the $Mn^{III}$ centre at a potential that was 1 V lower than the phenolate ligand in the $Mn^{III}$ species with a phenolate-containing ligand.[71]

The electronic absorption spectrum recorded after the second bulk electrolysis is shown in Figure 3 (c, solid line). Three new intense absorption bands appear at 390, 523, and 690 nm, respectively. The UV/Visible data of complex **7** are reported in Table 3,[72] and compared with related phenolato and chlorido $Mn^{IV}$ complexes. The intense absorption band observed near 400 nm can be attributed to phenolato and chlorido to $Mn^{IV}$ charge-transfer transi-

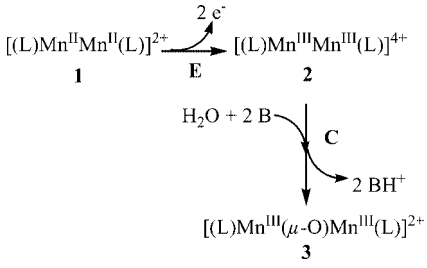
[a] irr. = irreversible. [b] The two potential values correspond to the sequential one-electron oxidation of the $Mn_2^{II}$ complex leading to the $Mn_2^{III}$ complex.



Scheme 2. Proposed Electrochemical Chemical (EC) mechanism to explain the evolution of the cyclic voltammetry trace of **1** upon addition of base.

tions,[71,73] while the shoulder detected at 530 nm may be assigned to $Mn^{IV}$ d–d transitions.[74] However, both the intensity and the position of the broad absorption band observed near 690 nm are reminiscent of absorption features reported for phenolato-containing $Mn^{IV}$ complexes,[27,30,54,71,75–79] and is therefore attributed to a phenolato to $Mn^{IV}$ charge-transfer transition. Therefore, the UV/Vis signature of species **7** also strongly supports the formation of a $Mn^{IV}$ complex instead of a $Mn^{III}$-phenoxyl one. Indeed, in the latter case, the two observed bands at 400 and 690 nm are expected with stronger and much weaker intensities, respectively.[71]

The 5 K 9.4 GHz EPR spectrum of the electrolyzed solution recorded using the perpendicular detection mode is shown in Figure 6 (b). The EPR spectrum exhibits a multiline signal centred at $g$ = 2 due to the presence of traces of uncoordinated $Mn^{II}$ ions. Quantification of this signal (see Exp. Sect.) indicates that uncoordinated $Mn^{II}$ ions account for approximately 5% of the total Mn-based species. Three other broad transitions are detected at 130 mT ($g$ = 5.2), 220 mT ($g$ = 3.0), and 580 mT ($g$ = 1.2), showing no evidence of $^{55}Mn$ hyperfine coupling (Figure 6, b). This EPR signature is indicative of an $S$ = 3/2 $Mn^{IV}$ ion, where the zero-field splitting interaction dominates the Zeeman effect.[54,79–86] For an axial $Mn^{IV}$ system (E/D = 0) the low-field transition is expected at $g_{eff}$ = 4. The diver-

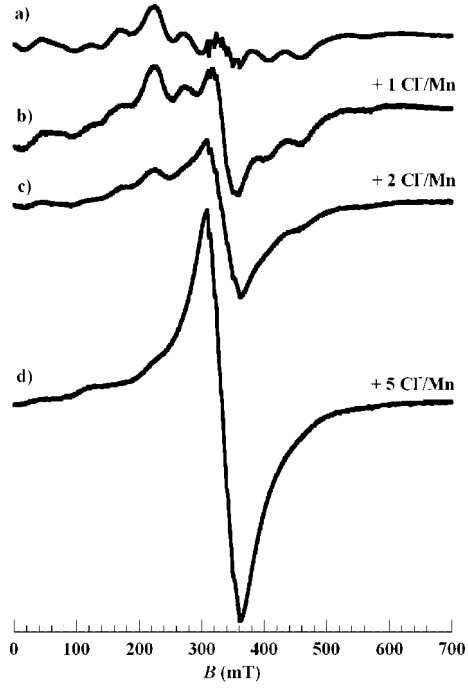


Figure 5. Evolution of the 100 K, 9.4 GHz EPR spectrum of 1 mM solution of **1** in acetonitrile containing 0.1 M tetrabutylammonium perchlorate, upon addition of chloride ions. Recording conditions: 9.38 GHz microwave frequency, 2.0 mW microwave power, 0.5 mT modulation amplitude, 100 kHz modulation frequency.

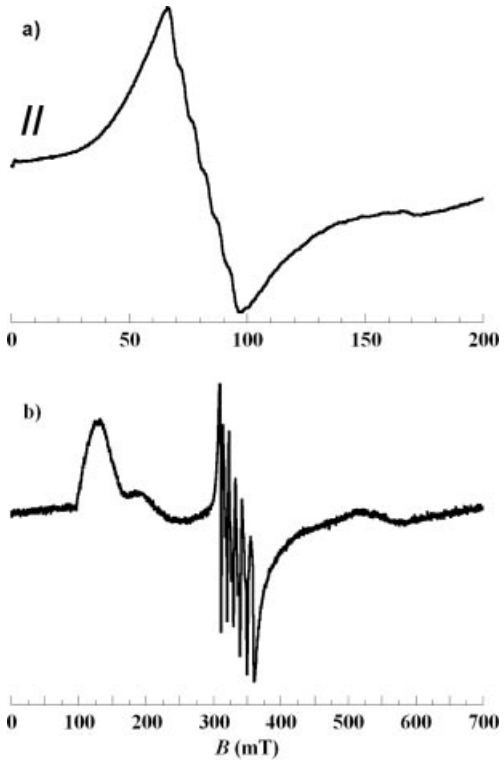

Figure 6. 5 K 9.4 GHz EPR spectra recorded on a 2 mM solution sample of **5**,[60] in acetonitrile containing 0.1 M tetrabutylammonium perchlorate, after bulk electrolysis at $E$ = 0.85 V vs. SCE (a), and after bulk electrolysis at $E$ = 1.45 V vs. SCE (b). Recording conditions: (a) parallel detection mode, 9.42 GHz microwave frequency, 0.8 mW microwave power, 0.5 mT modulation amplitude, 100 kHz modulation frequency, 10 scans. (b) 9.38 GHz microwave frequency, 0.12 mW microwave power, 0.5 mT modulation amplitude, 100 kHz modulation frequency.

gence from this value is characteristic of the rhombicity of the system. In the present case, according to the diagram showing the evolution of the $g_{eff}$ values for the Kramer doublets as a function of E/D,[87] the $g_{eff}$ = 5.2 and $g_{eff}$ = 3.0 values lead to an E/D ratio of 0.20(±0.04).

## Discussion

In the first part of this discussion, we will demonstrate the unique physicochemical properties of the dinuclear phenolato-bridged $Mn_2^{II}$ complex (**1**). As it is not our intention here to make an exhaustive comparison among all dinuclear phenolato-bridged $Mn_2^{II}$ complexes,[26,28] we will limit the comparative study to the recently published [(mL)Mn-Mn(mL)]$^{2+}$ system where the Mn ions have almost the same first coordination spheres as in **1**.[27]

Two main structural differences are observed between complex **1** and complex [(mL)MnMn(mL)]$^{2+}$. In the present case, the two pyridine rings are in a *trans* position, and the nitrogen atoms holding the bridging phenolato groups belong to the plane of the $Mn_2O_2$ core.

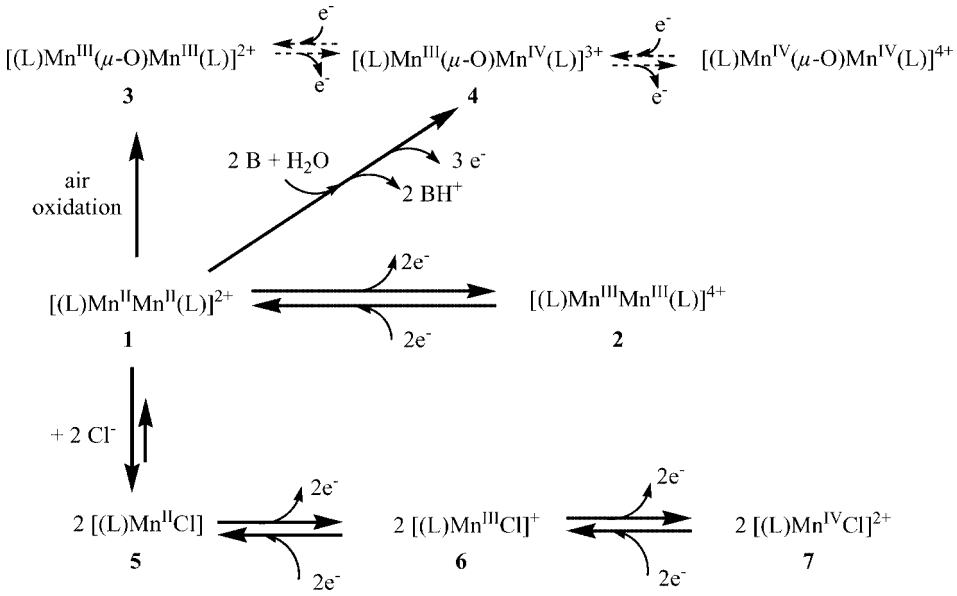
These structural peculiarities may support the distinct behaviour found for **1** in solution. More precisely, the enhanced reversibility of the anodic process detected for **1** is assigned to both an easier and nondestructive structural rearrangement from the dinuclear $Mn_2^{II}$ to the dinuclear $Mn_2^{III}$ systems. In the case of complex [(mL)Mn-Mn(mL)]$^{2+}$, it has been proposed that the two successive one-electron oxidations of the dinuclear $Mn_2^{II}$ complex led to the formation of the mononuclear $Mn^{III}$ species.[27] Here, we have shown that the dinuclear structure of complex **1** is maintained upon oxidation. Therefore, we can postulate that the Jahn–Teller distortion axis of the $Mn_2^{III}$ species is along the Py–Mn–Py axis, a direction that is not involved in the bridging motif. Furthermore, oxidation of **1** into **2** is detected at lower potential values than those of the related dinuclear $Mn_2^{II}$ phenolato-bridged complexes (see Table 3). The main difference in the [$N_4O$] donor set of the ligand $L^-$ compared to the one of ligand $mL^-$ (see Scheme 1) is the conjugation of the phenolate group to an imine function. This is in good agreement with the fact that the imine-phenolate fragment stabilizes the high oxidation states of the metal centres.

A two-electron oxidation process was detected for **1** whereas two successive one-electron oxidations were reported for the [(mL)MnMn(mL)]$^{2+}$ complex. The detection of a two-electron oxidation process is in line with what was observed and analyzed by Romero et al.[42] for the $Mn_2^{II}$ complex [$Mn_2(\mu\text{-}Cl)_2(bpea)_2Cl_2$] where bpea is a tetradentate ligand with a [$N_4$] donor set.[25] It was interpreted as arising from the independency of the two Mn ions because of a strong insulating effect of the bridging chloride ions. Indeed the two metal centres in the [$Mn_2(\mu\text{-}Cl)_2(bpea)_2Cl_2$] complex must be electronically uncoupled in order not to bring about any stabilization of the mixed-valence state. In the present case, we favour the hypothesis of an inversion of the potentials of the first- and second-electron transfers during the oxidation of **1**, i.e. the oxidation of the mixed-valence $Mn_2^{II,III}$ complex occurs at a lower potential value than that of complex **1**. Hapiot et al. have illustrated the inversion potential phenomenon in polyconjugated systems. Oxidation of the polyconjugated system leads to the dication, which is stabilized by interaction with the solvent, whereas the radical cation, which is delocalized over the molecular framework and thus less stabilized by interactions with the solvent, is not isolated.[88] We thus propose that in our case the easier oxidation of the mixed-valence $Mn_2^{II,III}$ state than that of the $Mn_2^{II}$ state arises from the better stabilization by the solvent of the $Mn_2^{III}$ state than that of the mixed-valence $Mn_2^{II,III}$ system.

Another clear cut difference is the cyclic voltammetry response upon addition of base to a solution of **1** or a solution of the [(mL)MnMn(mL)]$^{2+}$. In the former case, the dinuclear oxido-bridged species **3** is formed on the time scale of the cyclic voltammetry, whereas the intermediate mononuclear $Mn^{III}$ [(mL)Mn(OH)]$^+$ species was proposed in the latter case.[27] This result clearly indicates that the formation of species **3** is faster than that formed in the corresponding $Mn^{III}$ complex [(mL)Mn($\mu$-O)Mn(mL)]$^{2+}$.

In the second part of the discussion we will examine the various chemical and electrochemical reactions involved be-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4. Scheme of the various chemical or electrochemical reactions involved between species **1** to **7**. Solid arrows correspond to the reactions evidenced in the present work. Dashed arrows correspond to electrochemical processes described in a previous paper.[30]

tween the various Mn species obtained with the ligand $L^-$, which are depicted in Scheme 4. The X-ray structures of complexes **1**, **3**, **4**, and **6** are available in the present study and in the literature.[24,30]

The presence of the contaminant complex **3** in solution and powder samples of complex **1** has been evidenced by various techniques and comes from the air oxidation of **1**. Since all the experiments are not run in a glove box this impurity is hardly avoidable. The mechanism of this air oxidation is still unknown. The fast air oxidation of **1** may be related to the fast electrochemical oxidation of **1** into **3** in the presence of base as evidenced by the cyclic voltammetry study. We have also shown that the phenolato-bridged dinuclear $Mn_2^{III}$ complex **2** is accessible after a two-electron oxidation of **1** and that it does not evolve directly to the formation of the mono-μ-oxido complex **3** under an argon flux. Such an intermediate will certainly provide hints for the mechanistic pathway of the formation of the mono-μ-oxido species.

We have also checked that the mixed-valence mono-μ-oxido complex **4** can be generated by the exhaustive electrolysis of complex **1** in the presence of residual water and one equiv. of base per Mn ion, following a recently described procedure.[27]

The addition of chloride ions to complex **1** leads to the formation of the mononuclear chlorido $Mn^{II}$ species **5**. One more intriguing result is that upon addition of chloride ions to a solution sample of **1** containing species **3** as an impurity (indicated by an asterisk in parts a,b of Figure 3 and part a of Figure 4) leads to the fading of the absorption transition and of the redox waves characteristic of the mono-μ-oxido species. Furthermore, no other signal except that of species **3** was detected. For now, we can only speculate that species **5** is able to reduce species **3**, leading to the breaking of the oxido bridge by a mechanism that has still to be determined.

More importantly, we have shown that complex **5** can be oxidized twice electrochemically into the corresponding $Mn^{III}$ (**6**) and $Mn^{IV}$ (**7**) complexes. To the best of our knowledge no other (X-ray characterized) mononuclear complexes with a $[N_4OCl]$ coordination sphere are reported in the literature. The spectroscopic data for a $Mn^{IV}$ ion in an unusual coordination sphere with four nitrogen atoms, one oxygen, and a chloride ion are reported.[70] Hence, complex **5** is an interesting example of manganese mononuclear systems where three distinct oxidation states are observed and characterized.

## Conclusion

We have shown in this paper the chemical and electrochemical reactivities of a dinuclear phenolato-bridged $Mn_2^{II}$ complex. We have shown that the dinuclear $Mn_2^{II}$ compound could be oxidized in the +III states without alteration of the dinuclear structure of the starting compound. However, addition of chloride ions led to the formation of mononuclear species, which were oxidized and characterized in the +III and the rare +IV oxidation states. Future work will consist of the elucidation of the mechanistic pathways involving the formation of the mono-μ-oxido $Mn_2^{III}$ dinuclear complex.

## Experimental Section

**General Remarks:** Reagents and solvents were purchased commercially and used as received except for the electrochemical experiments for which acetonitrile was distilled under argon over granular $CaCl_2$. Argon U was used in the various experiments.

**Caution:** Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small quantities of these compounds should be prepared and handled behind suitable protective shields.

### Synthesis

***N*,*N*-Bis(2-pyridylmethyl)-*N'*-salicylidene-ethane-1,2-diamine:** Salicyladehyde (210 μL, 2 mmol) was added to a solution of *N*,*N*-bis(2-pyridylmethyl)ethane-1,2-diamine[89] (484 mg, 2 mmol) in methanol (20 mL). The solution was stirred at room temp for 3 h, evaporated, and dried under vacuum to give a pale brown oil (98% yield). $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 8.48 (d, 2 H, $J$ = 5 Hz, *H*–$C_6H_3N$), 8.24 (s, 1 H, Ar–C*H*=N), 7.60–6.80 (m, 10 H, *H*–Ar), 3.88 [s, 4 H, N–(C*H*$_2$–Py)$_2$], 3.70 (t, 2 H, $J$ = 6 Hz, CH=N–C*H*$_2$–$CH_2$), 3.46 (s, 1 H, O*H*), 2.90 (t, 2 H, $J$ = 6 Hz, $CH_2$–*N*–C*H*$_2$–$CH_2$) ppm; $^1$H NMR details are given in the Supporting Information. IR: $\tilde{\nu}$ = 3360 (broad), 2944 (strong), 2832 (s), 1634 (medium), 1596 (weak), 1450 (m), 1280 (w), 1028 (s), 762 (w), 660 (br) cm$^{-1}$. ESI-MS: $m/z$ (%) = 347.2 (100) $[M + H]^+$.

**[(L)MnMn(L)](ClO$_4$)$_2$·2(H$_2$O):** Ligand LH (173 mg, 0.5 mmol) and 2,6-dimethylpyridine (58 μL, 0.5 mmol) were mixed in air-free absolute ethanol (10 mL) and placed under an argon atmosphere. $Mn(ClO_4)_2$·$6H_2O$ (181 mg, 0.5 mmol) was dissolved in air-free absolute ethanol (10 mL) and placed under an argon atmosphere. This was then added to the previous mixture. A white precipitate appeared rapidly. It was then filtered under an argon atmosphere, and washed with air-free ether (15 mL). A white powder (105 mg, yield = 42%) was then obtained and kept in a glove box until use. Crystallization of complex **1** was performed in the glove box by slow diffusion of diethyl ether in an acetonitrile solution of **1**, and crystals of **1**$(ClO_4)_2$·$2CH_3CN$ suitable for X-ray crystallography study were obtained. It is worth noting that solution and powder samples of **1** are highly sensitive to air oxidation. When not handled under inert atmosphere, complex **1** spontaneously converts into a dark purple species. An X-ray diffraction study revealed that this species is the previously studied mono-μ-oxido dinuclear $Mn_2^{III}$ complex $[(L)Mn(\mu\text{-}O)Mn(L)]^{2+}$ (**3**).[30] **1**$(ClO_4)_2$·$2H_2O$ (powder) ($C_{42}H_{46}Cl_2Mn_2N_8O_{12}$): calcd. C 48.7, H 4.5, Mn 10.6, N 10.8; found C 49.1, H 4.4, Mn 10.3, N 10.6. Note that in the case of the elemental analysis the contamination by species **3** is unapparent. IR: $\tilde{\nu}$ = 3421 (s, strong), 2918 (w, weak), 1634 (s), 1602 (s), 1570 (w), 1552 (w), 1541 (w), 1471 (m, medium), 1442 (m), 1400 (w), 1342 (w), 1295 (m), 1144 (m), 1115 (m), 1089 (s), 1048 (w), 1016 (w), 907 (w), 766 (m), 637 (m), 625 (w), 594 (w) cm$^{-1}$. ESI-MS: A major peak was detected at $m/z$ = 400 corresponding to $[(L)Mn]^+$.

**Infrared Spectroscopy:** Spectra were recorded on KBr pellets in the range 4000–400 cm$^{-1}$ with a Perkin–Elmer Spectrum 1000 spectrophotometer.

**Electrospray Ionization Mass Spectrometry:** Mass spectra were recorded with a Finnigan Mat95 in a BE configuration at low resolution on a micromolar acetonitrile solution.

**Elemental Analysis:** Analysis was performed by the Service de Microanalyse of the CNRS (Gif-Sur-Yvette, France) for carbon, nitrogen, and hydrogen and by the Service Central d'Analyse (Vernaison, France) for manganese.

**X-ray Crystallography:** Crystal data for $[(L)MnMn(L)](ClO_4)_2$·$2CH_3CN$ [**1**$(ClO_4)_2$·$2CH_3CN$] and the parameters of data collection are summarized in Table 4. Crystal data for **1**$(ClO_4)_2$·$2CH_3CN$ were collected with a Nonius Kappa-CCD area detector diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation. The lattice parameters were determined from ten images recorded with 2 $\varphi$-scans and later refined on all data. The data were recorded at 100°K with an Enraf–Nonius FR558NH nitrogen cryostat. A 180° $\varphi$-range was scanned with two steps with a crystal to detector distance fixed at 40 mm. Data was corrected for Lorentz polarization. The structures were solved by the direct methods with SHELXS-97 and refined by full-matrix least-squares on $F$[2] with anisotropic thermal parameters for all non-H atoms with SHELXL-97. H atoms were found in a difference Fourier map and were introduced at calculated positions as riding atoms, with C–H bond lengths of 0.93 (aromatic CH), 0.98 (aliphatic CH), 0.97 ($CH_2$), and 0.96 Å ($CH_3$), and with $U_{iso}$(H) values of 1.2 $U_{eq}$(C) for CH and $CH_2$ hydrogen atoms, and 1.5 $U_{eq}$(C) for $CH_3$ hydrogen atoms.

CCDC-279908 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Magnetic Susceptibility Measurements:** Magnetic susceptibility data were recorded with an MPMS5 magnetometer (Quantum Design Inc.). The calibration was made at 298 K using a palladium reference sample furnished by Quantum Design Inc. The data were collected over a temperature range of 2–300 K. Above 100 K, a 1 T magnetic field was applied, while below 100 K, the amplitude was 0.1 T. Data were further corrected for diamagnetism. The $\chi_M$ vs. $T$ and $\chi_M T$ vs. $T$ curves were fitted by the van Vleck formula assuming the same $g$ factor for each $S$-spin state. The total spin $S$ runs from $|S_1 - S_2|$ to $(S_1 + S_2)$ by unit steps. The exchange Hamiltonian used was $H = -J\hat{S}_1 \cdot \hat{S}_2$, where $J$ stands for the exchange coupling constant and $\hat{S}_1$, $\hat{S}_2$ for the spin operators associated with the electronic spin of the $Mn^{II}$ sites ($S_1 = S_2 = 5/2$).

**EPR Spectroscopy:** 9.4 and 34 GHz EPR spectra were recorded with a Bruker ELEXSYS 500 spectrometer. For low temperature studies, an Oxford Instrument continuous-flow liquid helium cryostat and a temperature-control system were used. Solutions spectra

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were recorded in acetonitrile containing 0.1 M tetrabutylammonium perchlorate. Quantification of uncoordinated $Mn^{II}$ was performed by comparison of the intensities of the $g = 2$ signal with those obtained using solutions of known concentrations of $Mn(ClO_4)_2 \cdot 6H_2O$ under the same recording conditions. Quantification of complex **4** in situ generated by bulk electrolysis of complex **1** in the presence of base was performed by a comparison of the intensities of the signal with those obtained using solutions of known concentrations of **4** (electrochemically prepared from the one-electron oxidation of **3**, and first isolated as a powder) under the same recording conditions.

**UV/Visible Spectroscopy:** UV/Visible spectra were recorded with a Varian Cary 300 Bio spectrophotometer at 20 °C with 0.1-cm quartz cuvettes.

**Cyclic Voltammetry and Bulk Electrolysis:** All electrochemical experiments were run under an Ar atmosphere. Cyclic voltammetry and coulometry measurements were recorded with an EGG PAR potentiostat (M273 model). For the cyclic voltammetry, the counter electrode was a Pt wire and the working electrode a glassy carbon disk carefully polished before each voltammogram with diamond paste (1 μm), sonicated in an ethanol bath and then washed carefully with ethanol. The reference electrode was a $Ag/AgClO_4$ electrode (0.53 V vs. NHE electrode), isolated from the rest of the solution by a fritted bridge. For bulk electrolysis, the counter electrode was a piece of Pt, separated from the rest of the solution with a fritted bridge. The working electrode was a grid of Pt. The solvent used was distilled acetonitrile and tetrabutylammonium perchlorate was added to obtain a 0.1 M supporting electrolyte (20 °C) or a 0.2 M supporting electrolyte (–30 °C). Low temperature regulation was ensured by a Julabo circulation cryostat.

[70] As pointed out by one of the referees, the one-electron oxidation of species **6** may also lead to the formation of the $Mn^{III}$-phenoxyl species. For the reason given in the text and from the data previously reported in the literature concerning related complexes (see ref. [54,71,75–78]), we strongly favor the formation of a $Mn^{IV}$-phenolate as the predominant species. Therefore, for the sake of clarity, we describe species **7** as the $Mn^{IV}$-phenolate species. However, we acknowledge that we have no conclusive argument to definitively rule out the presence in solution of the $Mn^{III}$-phenoxyl as a minor species. More generally, the correct description of the one-electron oxidation product of the $Mn^{III}$-phenolate species is still an open debate. As suggested by the referee, XAS studies would help to disentangle this issue and should be the subject of future reports.

# A Density Functional Study of the Hydrogenation of Ketones Catalysed by Neutral Rhodium-Diphosphane Complexes

**Francine Agbossou-Niedercorn*[a] and Jean-François Paul*[b]**

**Keywords:** Density functional calculations / Hydrogenation / Ketones / Rhodium / Asymmetric catalysis

The potential energy profile of $Rh^I$-catalysed hydrogenation of ketones has been computed for the simple model system [Rh{$H_3POCH_2CH_2N(H)PH_3$}(Cl)] using DFT calculations. The general sequence of the catalytic cycle involves coordination of the carbonyl derivative to the neutral $Rh^I$ complex followed by oxidative addition of molecular hydrogen providing rhodium dihydride intermediates. The latter are converted into alkoxy hydrides by a migratory insertion reaction. Reductive elimination of the alcohol and substitution of the latter by the incoming substrate completes the catalytic cycle. Intermediates and transition states of all catalytic steps have been located. Two isomeric derivatives bearing the model substrate have been found for the [Rh{$H_3POCH_2CH_2N(H)PH_3$}(Cl)($H_2CO$)] complex. Eight diastereomeric pathways have been followed for the *cis* addition of molecular hydrogen to [Rh{$H_3POCH_2CH_2N(H)PH_3$}(Cl)($H_2CO$)] leading to eight distinct isomeric dihydride intermediates. Four dihydride complexes can be considered as the more accessible compounds. The site preference for migratory insertion and transition states discriminates the main path of the catalytic reaction. Migratory insertion to form the alkoxy hydride constitute the turn over limiting step of the process. The potential energy profile has been found to be smooth without excessive activation barriers.

## Introduction

The enantioselective hydrogenation of prochiral ketones, which is one of the most exiting and powerful methods of synthesising chiral alcohols, has been receiving increased attention and has led to notable successes.[1] When ruthenium-based catalysts have been applied in the enantioselective hydrogenation of prochiral ketones,[2] rhodium complexes have proven to lead to very efficient processes along with potential industrial applications.[2–4] Likewise, asymmetric transfer hydrogenation of ketones has been well investigated over the last few decades[5], prompted by the very important contribution of Noyori's group.[6]

The most actively explored asymmetric hydrogenation mechanism has been the enantioselective hydrogenation of C=C bonds catalysed by cationic $Rh^I$-diphosphane complexes. Chemical,[7–14] kinetic[9] and theoretical[15,16] studies have been carried out. As a result, the rhodium-catalysed hydrogenation of dehydroamino acids leading to enantiomerically pure α-amino acids is considered to be a thoroughly understood reaction based on work carried out in the research groups of Halpern[7] and Brown[8] who revealed the underlying steps of the process. It has been demonstrated that the minor diastereomer resulting from the coordination of the enamide to the cationic Rh-diphosphane precursor reacts more rapidly with molecular hydrogen providing the observed prevailing hydrogenated product.[9–13] However, the reason for this increased reactivity is still not clearly understood. In addition, a complete understanding of the stereoselection has not yet been achieved. Finally, as highlighted recently by Rossen,[17] this classical mechanism of Rh-catalysed hydrogenation might not definitely be valid for all bisphosphane and metal combinations.

Much effort has been devoted to characterising transient intermediates in the C=C hydrogenation reactions. Among them, the cationic Rh-diphosphane-enamide complex[7,10,14] and the alkyl monohydride species[8,12] have been characterised by various spectroscopic and X-ray-based methods. Also, the presumed dihydride intermediate has been investigated by PHIP (*para*-hydrogen induced polarisation) NMR spectroscopy, which is a powerful tool for studying hydrogenation reactions.[18] Thus, while utilising *para*-hydrogen and appropriate complexes, elusive species could be detected. In this way, Selke and Bargon[19] observed a rhodium dihydride complex while using a sugar-based bisphosphinite ligand (Scheme 1). More recently, Bargon and Brown[20] reported the observation of an agostic complex which is encountered on the path of hydride transfer to the coordinated substrate (Scheme 1).

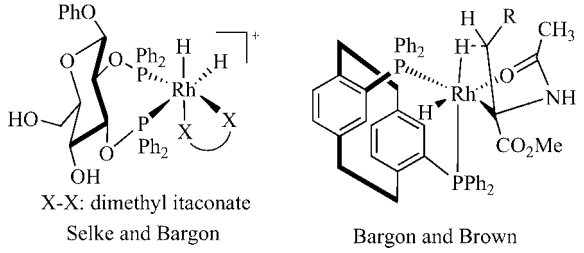
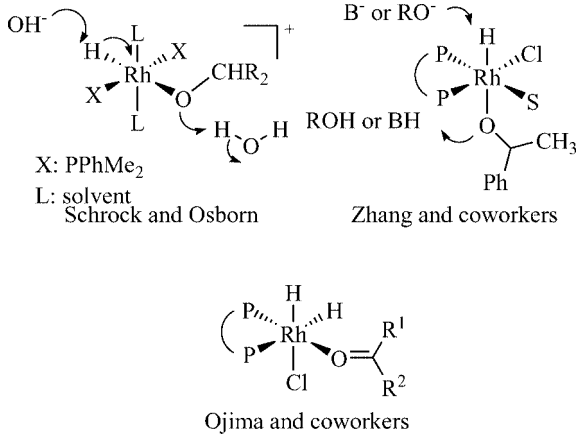


Scheme 1. Characterised dihydride-Rh complexes.

A second mechanism of hydrogenation that has been studied to some extent is related to the transfer hydrogenation of C=O bonds catalysed by $Rh^{I}$[21,22] and $Ru^{II}$ complexes.[23] However, much less is known about the mechanism of the molecular hydrogen-based hydrogenation of ketones catalysed by rhodium species. Although the catalytic results are quite satisfactory in terms of efficiency, little is known experimentally about intermediates and reaction steps and the reaction mechanism has not been elucidated so far. Nevertheless, mechanistic hypotheses have been made in order to take into account the several experimental observations. Primarily, Schrock and Osborn[24] proposed a mechanism for the hydrogenation of ketones catalysed by cationic rhodium complexes bearing basic monophosphanes. One step of the catalytic cycle is an oxidative addition of molecular hydrogen providing a rhodium-dihydride complex. The reported catalytic system is promoted by small quantities of water (ca. 1% of $H_2O$). A study carried out either in the presence of $D_2$ or $D_2O$ gave rise to a mechanism involving an active participation of water that would account for the determined incorporation of deuterium from $D_2O$. Actually, the key points are (1) the participation of a rhodium dihydride intermediate and (2) the promotion of the second hydrogen atom transfer by the small quantity of water as depicted in Scheme 2.



Scheme 2. Examples of reported rhodium-hydride intermediates.

More recently, Zhang[25] proposed a mechanism to take into account the beneficial effect provided by the use of amines which promoted both the activity and selectivity ($\Delta ee$ up to 38%) of the hydrogenation of simple ketones. In the catalytic cycle, an oxidative addition of molecular hydrogen on the rhodium precursor is considered prior to substrate coordination followed by hydride transfer to the coordinated substrate (Scheme 2). Yet, the reaction is carried out in methanol and the possibility of cationic rhodium catalytic intermediates has not been envisioned, the proposed mechanism being based only on noncharged intermediates.

Ojima described the efficient enantioselective hydrogenation of α-keto esters catalysed by neutral Rh–BPPM complexes [BPPM: (2*S*,4*S*)-*N*-*tert*-butoxycarbonyl-4-(diphenylphosphanyl)-2-[(diphenylphosphanyl)methyl]pyrrolidine][26] and proposed a mechanism based on results obtained while varying the solvent.[27] Dry aprotic solvents bestowed the best results both in terms of activity and enantioselectivity. These authors propose that both hydrides (Scheme 2) resulting from the oxidative addition of hydrogen onto the Rh–substrate adduct are successively transferred to the substrate. Meaningfully, it has been suggested that a retention of chloride on rhodium might be the clue for the increased efficiency of the catalyst.

In previous studies, we have shown that the enantioselective hydrogenation of functionalised ketones can be carried out very efficiently in the presence of neutral rhodium precursors bearing aminophosphane phosphinite ligands (AMPP).[28] The potential of such ligands has further been assayed in the highly enantioselective hydrogenation of fluorinated ketones including simple ketones.[29] We have also reported on the use of a combination of molecular mechanics-based methods and extended Hückel calculations in order to have access to the most stable catalytic intermediates and to their reactivity.[30]

Modern efforts have emphasised the potential of computational methods for organometallic catalysis investigations.[31] We became interested in using such methods to examine the catalytic cycle of the hydrogenation of ketones assisted by rhodium-aminophosphanephosphinite catalysts. To address the catalytic cycle, several computational approaches are possible. One deals with the general mechanism and the associated energetic profile while considering neutral catalytic intermediates and a second deals with the quest of the enantiodetermining step of the cycle. Both types of information require different levels of computation and consequently different ranges of calculation times. The aim of this study was to obtain an insight into the most probable energy profile of the catalytic cycle of ketone hydrogenation involving neutral rhodium diphosphane catalysts. Such an approach has not been undertaken to the best of our knowledge. Here, we report on the results of DFT computations of the catalytic reaction potential energy surface for a simple achiral aminophosphane phosphinite-based model system. In this paper, we describe the model system used, the computational method applied, and the overall reaction pathways explored.

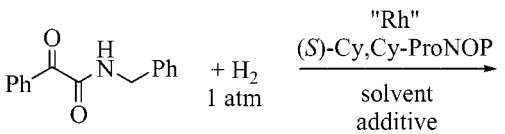
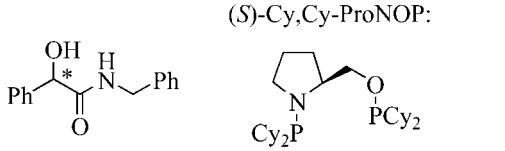
## Background and Calculation Methods

Despite our many attempts, we were unable to characterise, by NMR, catalytic intermediates under our classical ketone hydrogenation conditions (room temperature, 1 atm $H_2$, toluene). Indeed, only the starting rhodium dimeric complexes of the type $[Rh\{AMPP\}Cl]_2$ could be observed by $^{31}P$ NMR spectroscopy. However, the hydrogenation experiments carried out under various catalytic conditions did provide evidence for the participation of neutral intermediates bearing the chiral diphosphane along with a nonchiral ancillary ligand. For example, when the hydrogenation of benzylbenzoylformamide was run in ethanol in the presence of a cationic precatalyst, a slow reaction ($t_{1/2}$ = 4 h) with a very low *ee* was achieved (5.5% *ee*) (Table 1, entry 1).[32]

Table 1. Enantioselective hydrogenation of benzylbenzoylformamide.[a]





Cy: cyclohexyl

| Entry | "Rh" | Solvent | Additive | $t_{1/2}$ [min][b] | *ee* (%) (conf.) |
|---|---|---|---|---|---|
| 1 | $[Rh(COD)_2]BF_4$ | EtOH | – | 240 | 5.5 (*R*) |

[a] Substrate/Rh = 200:1. [b] Time of half conversion of the substrate. [c] F. Agbossou-Niedercorn, unpublished results. [d] n.d.: not determined, substrate/Rh = 45:1, total conversion after 3 d.

Interestingly, if the hydrogenation occurs in ethanol in the presence of a neutral precursor, an enhanced efficiency is attained as the chiral alcohol is produced in ca. 65% *ee* and with a higher rate ($t_{1/2}$ = 28 min) (Table 1, entry 2). The behaviour of diphosphane-rhodium complexes in various solvents deserves some comment. For instance, the reaction of neutral rhodium complexes with an amidophosphane phosphinite results in the formation of a mixture of cationic and neutral compounds in methanol, as shown by Pregosin.[33] Also, an earlier study of Bakos[34] outlined the behaviour of complexes of type "$Rh(P_2)$(diolefin)Cl" in various solvents (dichloromethane, benzene, methanol). Equilibrium between a cationic and a neutral complex could account for the $^{31}P$ NMR features of the corresponding solution. Therefore, the efficiency improvement observed while comparing the two above-mentioned hydrogenations can be reasonably related to the active participation of neutral catalytic species. As further evidence, a reaction carried out in toluene with a neutral precatalyst provides the alcohol with 74 and 67% *ee* and with higher rates for Cl and I, respectively (Table 1, entries 3 and 4). This compares well with hydrogenations carried out while using a cationic precatalyst in toluene in the presence of either LiI or LiBr (Table 1, compare entries 7 and 4). This is consistent with retention of the halide on the catalytic intermediates throughout the entire process. The weak dielectric constant of aromatic solvents is in favour of retention of the halide on the rhodium during catalysis.[35] Finally, note that the reaction performed with a cationic precursor in toluene proceeds with a low rate and an extremely low enantioselectivity (Table 1, entry 5).

Additional earlier results prove the benefit obtained when the hydrogenations of ketopantolactone are performed in the presence of neutral rhodium-halide complexes in toluene, essentially on the enantioselectivity (compare all entries of Table 2).[36] As a matter of fact, 98% *ee* was reached for Rh-iodide-based catalysts.

The reality of neutral Rh-dihydride-chloride complexes has been shown through the use of PHIP NMR techniques. Indeed, Eisenberg found a way to detect new mononuclear neutral dihydride-rhodium-phosphane-olefin complexes that appear to be intermediates in the catalytic hydrogenation of olefins (Scheme 3).[37]

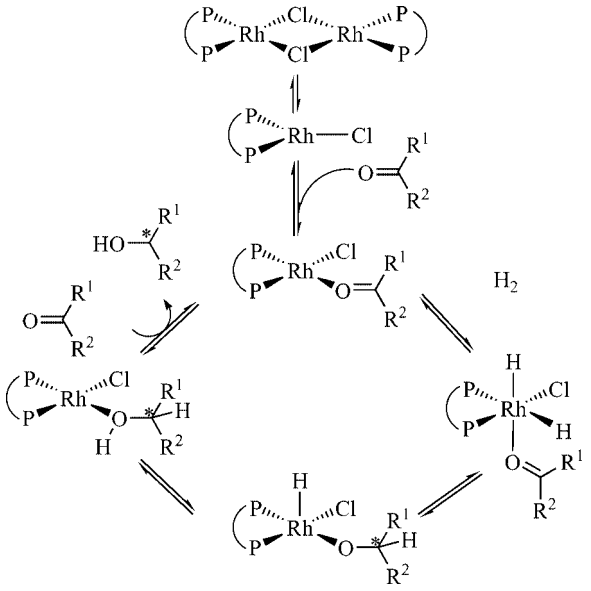
On the basis of these data, a plausible catalytic cycle depicted in Scheme 4 has been proposed for the hydrogenation of ketones catalysed by neutral rhodium complexes in aprotic solvents. Hereafter, we will focus on the computation of the various elementary steps of this catalytic cycle.



Scheme 4. Proposed reaction mechanism.

### Computational Methods

The calculations were based on the density functional theory (DFT) using Becke's three-parameter hybrid functional (B3) and the Lee, Yang and Parr (LYP) correlation functional for the correlation energies (B3LYP). This method[38] exhibits accuracy comparable to that of sophisticated post-Hartree–Fock methods in transition-metal studies. They were performed using the Gaussian 98 program package (version A9).[39] For the rhodium atom, we used the relativist effective core potential of Hay and Wadt (with 4s and 4p in the valence) and the corresponding double-ζ basis set.[40] For the carbon, oxygen, nitrogen and hydrogen atoms of the ligand a 6–3lG* basis set was used. For the hydrogen atoms on the rhodium and those of the reactant (formaldehyde) and product (methanol) a *p*-orbital of Gaussian type ζ = 1.1 was added. For the chlorine and the phosphorus atoms, a 6-311G* basis set was used. All the used basis sets were implemented in the Gaussian 98 program.

Geometries of reactants and products were fully optimised without any symmetry or internal coordinate constrains. All transition states were characterised by determining the number of imaginary frequencies and a further characterisation of the transition state was achieved by calculation of the intrinsic reaction coordinate (IRC) leading to the corresponding reactants and products.

### Models Used for the Calculation of the Complexes

**The Ligand:** The skeleton of the AMPP ligand {(*S*)-Cp$^s$,Cp$^s$-oxoProNOP} is replaced by an ethanolamine-bridged diphosphane [$H_2POCH_2CH_2N(H)PH_2$] (Scheme 5). Thus, the electronic effects of the oxygen and nitrogen atoms are maintained. In addition, the $CH_2CH_2$ spacer provides the constraint on the carbon backbone of the ligand which mimics the skeleton of the pyrrolidine ring present in the most efficient ligands studied. Hydrogen atoms replace the phosphorus substituents in order to reduce computational time.

AMPP model for computations

Scheme 5. AMPP and the model compound.

**Ketopantolactone:** Calculations were performed by using a model hydrogenation reaction of formaldehyde and when necessary with larger carbonyl compounds.

## Computational Results

### Coordination of the Substrate: Structures of Catalyst–Substrate Adducts

The $d^8$ complex [Rh(Cl){PO∩NP}] is a model for the product expected from the cleavage of the dimeric precursor [Rh{PO∩NP}Cl]$_2$ which leads to the formation of the active species. It is well known that $ML_3$ complexes can be stable in a T-shaped trigonal structure. Nevertheless, the contribution of solvent coordination through a C=C bond providing a square-planar complex has been computed by means of optimisation of Rh(Cl){PO∩NP}($C_6H_6$). The calculations show that the coordination energy of a benzene in the $\eta^2$ mode is almost thermoneutral (around 2 kcal/mol depending upon the geometry). Consequently, and taking into consideration the results related next, the eventual intermediate square-planar complex bearing a solvent molecule was not considered further in the catalytic cycle.

As T-shaped trigonal complexes present a $C_1$ symmetry, two isomeric compounds have to be considered that present the chloride either *trans* to $P_N$ (**1a**) or *trans* to $P_O$ (**1b**) (Figure 1). The energy difference between both optimised complexes is very small (0.2 kcal/mol). The activation energy on going from one isomer to the other is only 4.5 kcal/mol. Furthermore, both experimentally and theoretically, the length of the Rh–$P_O$ and Rh–$P_N$ bonds present only a small difference (0.02–0.03 Å experimentally, 0.03 Å by calculation).[41] Because of these small differences, it can be foreseen that the coordination of the carbonyl substrate *trans* of both moieties, i.e., $P_O$ and $P_N$, will be alike. The relative

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

stabilities are consistent with a larger *trans* influence of the $P_O$ group, an effect which can be observed in the Rh–Cl bond lengths: 2.348 Å when *trans* to $P_N$ and 2.363 Å when *trans* to $P_O$.

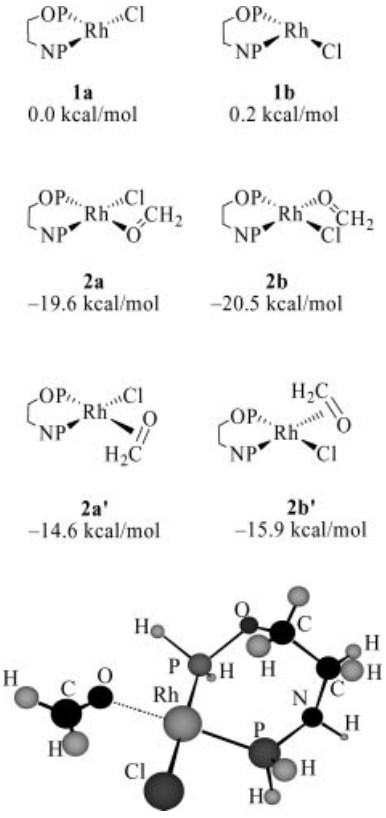

Figure 1. Schematic representation of the intermediates **1** and **2**. Values indicating the relative energies compared to **1a** + $CH_2O$ (top). Geometry of the most stable complex (bottom).

Carbonyl substrates can adopt two fundamental coordination modes on a transition metal complex: end-on coordination ($\eta^1$) by a lone pair of the oxygen atom or side-on coordination ($\eta^2$) through the CO π system.[42] Both modes have been taken into consideration (Figure 1). The $\eta^1$ coordination mode (structures **2a**–**b**) of the substrate provides more stable complexes than the $\eta^2$ one (structures **2a′**–**b′**). As anticipated, the *trans* to $P_N$ $\eta^1$-coordinated formaldehyde complex **2b** is only slightly more stable than **2a** by 0.9 kcal/mol.

The energy differences between the two coordination modes are due to two main effects of the same importance: the deformation energy of the organic molecule and the orbital interaction. The deformation energy of the organic molecule is more important in the $\eta^2$ coordination mode, destabilising the latter. For energetic reasons, the main orbital interaction is between the metal orbital and the $CH_2O$ nonbonding orbital located on the oxygen atom, which is also in favour of the $\eta^1$ coordination. Furthermore, as a test, we considered also acetone coordination on complex **1**. Starting with the molecule coordinated in a $\eta^2$ coordination mode invariably ends with a displacement towards the $\eta^1$ mode. These calculations confirm that the most stable coordination mode on these complexes is $\eta^1$. It should be mentioned that coordination energies of the acetone on the T-shape trigonal complexes are similar to those of the model system (18.2 kcal/mol on complex **1a** and 19.4 kcal/mol on **1b** as compared to 19.5 and 20.6 kcal/mol for the formaldehyde coordination).

### Addition of Molecular Hydrogen

The next elementary step of the proposed mechanism is the hydrogen addition, leading to the formation of a dihydride intermediate. As both complexes **2a** and **2b** bearing the $\eta^1$-coordinated substrate are of equivalent stability, the oxidative addition of molecular hydrogen has to be considered on the two complexes. Furthermore, the oxidative addition of molecular hydrogen to a square-planar complex may occur on either side of the plane, with the molecular hydrogen parallel to either the Rh–$P_O$ or Rh–$P_N$ bond, which leads to eight different dihydrides with *cis* configuration.[15,43] Thus, the addition of molecular hydrogen along eight diastereomeric pathways must be considered in the modelling. These pathways are designated A, B, C, D, E, F, G and H (Figure 2). The search for stable rhodium-dihydrogen intermediates and the transition states for the addition of molecular hydrogen were performed along these pathways. The energy profiles of the approach of molecular hydrogen along the pathways located above and below the square plane are very similar. In fact, the energy difference between the two corresponding transition states (TS) is less than 1.5 kcal/mol. In the TS, the main interaction occurs between the HOMO of the complex ($dz^2$), which is symmetric with respect to the plane, and the LUMO of the molecular hydrogen (σ*) and is therefore independent from the approaching face. Molecular hydrogen complexes of rhodium are not computed as stable intermediates in the process of oxidative addition of molecular hydrogen to the square planar rhodium complex. As a matter of fact, IRC calculations do not end on such complexes but rather on the dissociated species or on the rhodium-dihydride compounds. Interestingly, the activation energies which lead to the displacement of either the chloride or the carbonyl from the square plane are quite different as this motion generates large electronic barriers due to extensive nuclear reorganisation. Indeed, the out-of-plane displacement of the chloride is ca. 5 kcal/mol more energy demanding than the out-of-plane displacement of the carbonyl moiety. Thus, energeti-

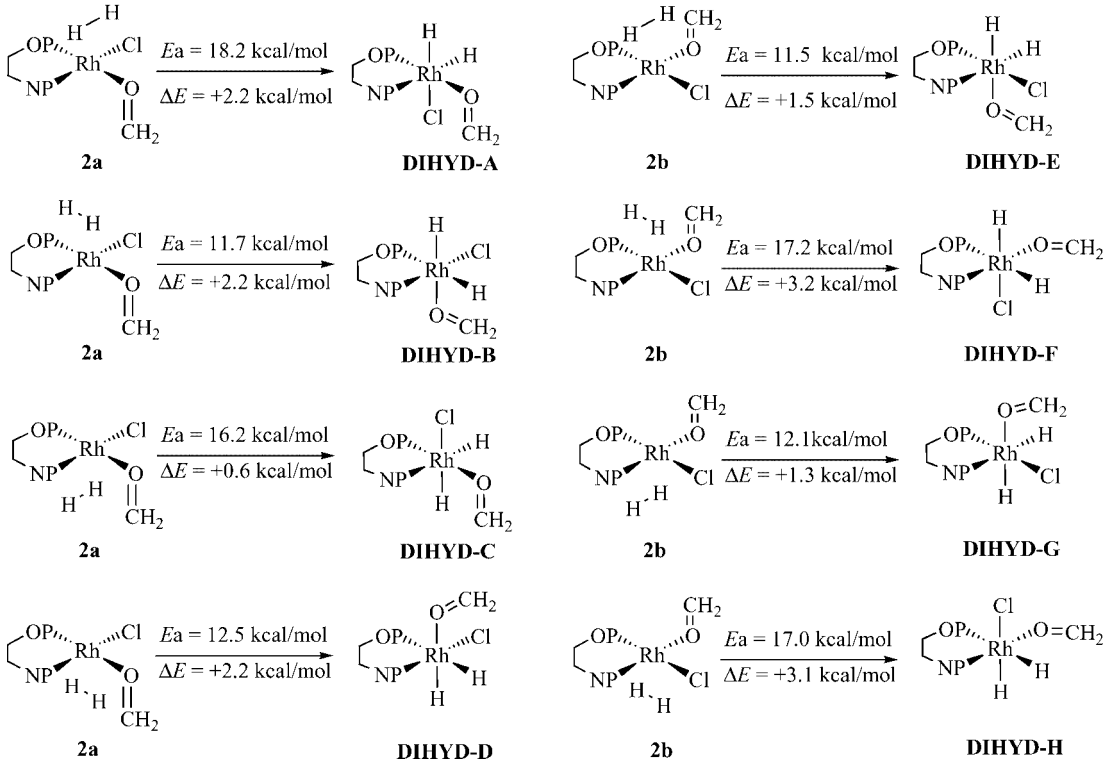
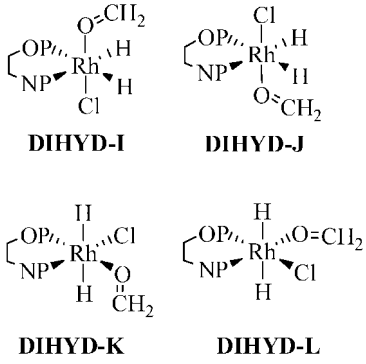


Scheme 6. Reaction and activation energy of the dihydride formation starting from complexes **2a** and **2b**.

cally lower transition states arise from the electronic preference for the chloride to remain in the rhodium-diphosphane plane (Scheme 6).

The transition states in going from **2a** to **DIHYD-B** and **DIHYD-D** and from **2b** to **DIHYD-E** and **DIHYD-G** are favoured. This result supports the final formation of only four isomers under the normal conditions of hydrogenation (room temperature and 1 atm of $H_2$). The geometries of these four transition states are similar: the H–H bond is almost broken while the Rh–O distance is increased to ca. 2.6 Å. The displaced group ($OCH_2$) is almost located in its position in the final products. In the case of the formation of **DIHYD-D**, the geometry of the transition state exhibit a H–H distance of 1.10 Å with the O–Rh length of 2.65 Å ($\Delta d$ = 0.36 Å) (Figure 2). In conclusion, only four dihydride complexes, which result from a *cis* addition of molecular hydrogen, are kinetically accessible minima on the reaction potential surface and are thus viable intermediates. Formation of dihydrides from **2** and molecular hydrogen is ap-



Scheme 7. Schematic representation of the dihydride that cannot be formed in one step, by hydrogen addition on complex **2**.

proximately thermoneutral; reaction enthalpies range from 0.6 to 3.2 kcal/mol.

The complexes possessing either *trans* hydrides or the chlorine and carbonyl in apical positions gave structures much less stable by 18.0 to 20.4 kcal/mol. The transition states to those improbable species have not been studied and these intermediates have not been further considered in the calculations (Scheme 7), as their formation activation energies will be larger than 20 kcal/mol. The relative energies of all intermediates are given in Table 3.

### Transfer of the First Hydride: Conversion of the Dihydrides into Alkoxy Hydrides via Migratory Insertion

A variety of alkoxy hydrides can be obtained by migratory insertion of the C=O bond into the Rh–H bond of a dihydride. As mentioned above, we did not consider structures presenting a *trans* arrangement of the dihydrides nor the structures presenting the *cis* arrangement of the dihydrides in the plane defined by the Rh and the two P atoms; not because they could not give insertion products but because of the improbable participation of such species in the hydrogenation process. The alkoxy formation starting from dihydride without the Cl atom in the RhPP plane has also not been considered as they are much more slowly formed. In conclusion, only the four dihydride complexes **DIHYD-B**, **DIHYD-D**, **DIHYD-E** and **DIHYD-G** have been taken into consideration for this step (Scheme 8). They present *cis* coplanar orientations of the coordinated C=O and one Rh–H being systematically located in the plane containing the diphosphane ligand. The activation energies are reported in Scheme 8 and the relative energies of the obtained intermediates in Table 3. The transition state corresponds to the intramolecular hydride transfer of a H atom into the C–Rh bond that could be created in the case of a $\eta^2$ coordination mode. However, it is not the H atom, which moves toward the C atom, but the opposite. After the H addition, the complexes have an empty coordination site that can be located either in a *trans* position to the H atom or in a *trans* position to one of the phosphorus atoms. The latter geometries are not stable and evolve without activation energies to the one possessing the emty coordination site *trans* to the H atom. The geometry of one transition state is represented in Figure 3.

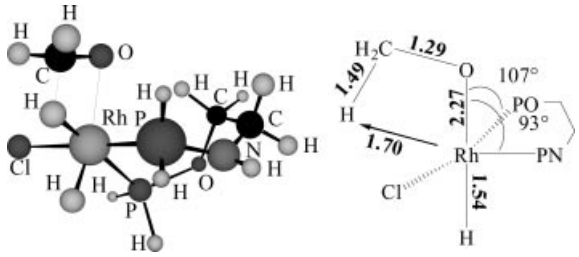

Figure 3. Transition-state geometry for the conversion of **DIHYD-D** into **4d**.

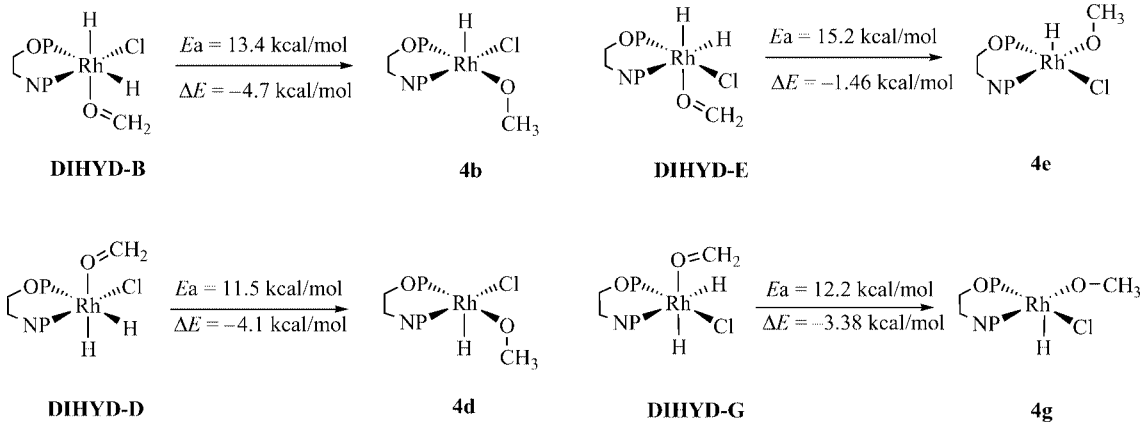
An IRC calculation was carried out for one of the transition-state structures. The final points are, on one side, the 18-electron starting complex with the C=O in a $\eta^2$ coordination mode, and on the other side, a complex with the alkoxy species. This calculation suggests that the substrate changes from a $\eta^1$ coordination to a $\eta^2$ coordination just prior to hydride insertion. The activation energy of this isomerisation is only 4.8 kcal/mol, the resulting dihydride being less stable than the starting one by 3.6 kcal/mol. This step will become improbable with larger carbonyl substrates. For this reason, we have not decomposed the C–H bond formation into two steps in the energetic diagram. This almost elementary step is slightly exothermic ($\Delta E$: –1.4 to –4.7 kcal/mol). The stable intermediates have square-planar pyramidal structures with the alkoxy fragment located in the square plane. The resulting stable structures all have a *cis* arrangement of the remaining H and alkoxy moieties. The site in the *trans* position to the H ligand is empty.

### Conversion of the Alkoxy Hydride into the Hydroxy Complex: Reductive Elimination

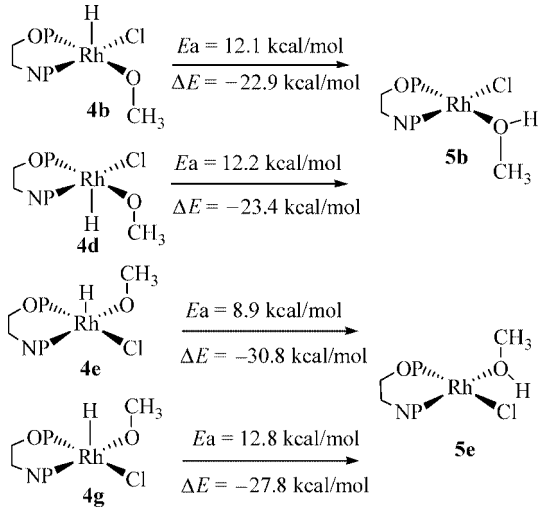
The next step is the reductive elimination starting from the four intermediates (**4b**, **4d**, **4e**, **4g**) (Scheme 9). The reductive elimination of the alkoxy hydride provides a square-



Scheme 8. Reaction and activation energies for the alkoxy formation.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

planar structure in which the hydroxy species is coordinated to the rhodium.



Scheme 9. Reaction and activation energies for the formation of the alcohol.

This structure is closely related to the starting complexes bearing the coordinated substrate C=O. Two structures are obtained with the hydroxy located either *trans* to the $P_O$ moiety or *trans* to the $P_N$ end. The energies are slightly in favour of a *trans* to $P_N$ location as in the case of the complexes resulting from the first step, i.e., coordination of the substrate.

The calculation indicates that the process of reductive elimination resulting in the reduction of $Rh^{III}$ to $Rh^{I}$ is highly exothermic (from –22.9 to –30.0 kcal/mol) (Scheme 9). The reaction coordinate is constituted almost exclusively by the H–Rh–O angle, which decreases from 90° to 15°. The transition state is reached for a value of that angle close to 50° (Figure 4). The activation energy is smaller than 13 kcal/mol for the four reactions path we have studied.

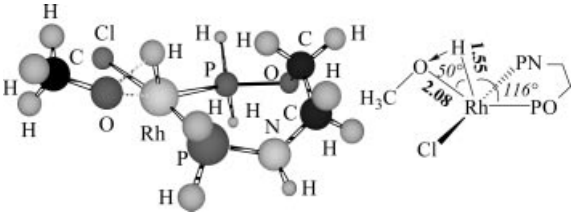


Figure 4. Representation of the transition state between **4b** and **5b**.

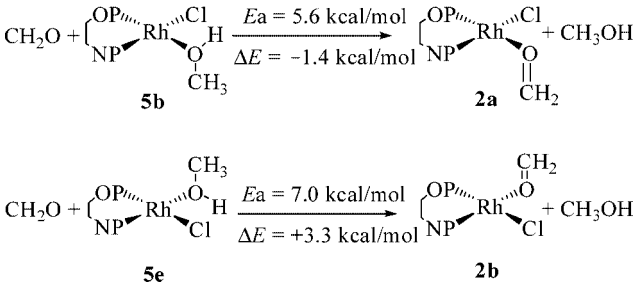
Because of the similar energies of the C=O-coordinated structures and the hydroxy coordinated one, it is not unreasonable to consider that the reaction could be inhibited by an excess of hydroxy compounds which might occur in high conversions of the hydrogenation reaction or when the concentration in the produced hydroxy compound becomes higher than that of the ketonic substrate. However, as the partial order of the reaction has not been performed, it is rather difficult to know if such an inhibition effect is observed experimentally.

**Alcohol-Carbonyl Substrate Substitution**

In the catalytic cycle, the last step is a substitution of the hydroxy compound by the carbonyl substrate. This step is almost athermic: slightly exothermic from **5b** and slightly endothermic from **5e** (Scheme 10) and can take place in one step (concerted mechanism). In the transition state, the two Rh–O distances are almost the same [2.60 Å for Rh–O(hydroxy) and 2.54 Å for Rh–O (carbonyl)] (Figure 5). The activation energy of that step is small (5.6 kcal/mol, Scheme 10). An alternative mechanism would be the associative one. However, the reaction involving the carbonyl coordination prior to hydroxy rhodium bond cleavage is an overall endothermic process and the energy loss is similar to the activation energy of the direct exchange reaction, indicating that the substitution should occur in one step.



Scheme 10. Reaction and activation energies for the ligand exchange.

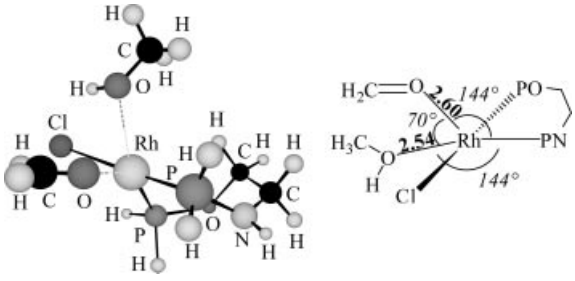


Figure 5. Transition-state geometry for the $CH_3OH/CH_2O$ exchange reaction.

**Catalytic Cycle**

Figure 6 and Figure 7 present the calculated energy profile for the entire catalytic cycle starting from the two complexes presenting the carbonyl substrate in a *trans* position to **2a** or **2b**. All activation energies are reported on the Figures. The energy difference between the final state (**2** + methanol) and the initial state (**2** + formaldehyde + $H_2$) of the cycle is the energy of hydrogenation of formaldehyde. The overall energy profile is smooth. This reaction is highly exothermic. The migratory insertion step [from **2** to the **DIHYD-D** complexes has the most important activation barrier (12.5 kcal/mol)] and might be considered as the rate-limiting step. For the two types of complexes, for steric in-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

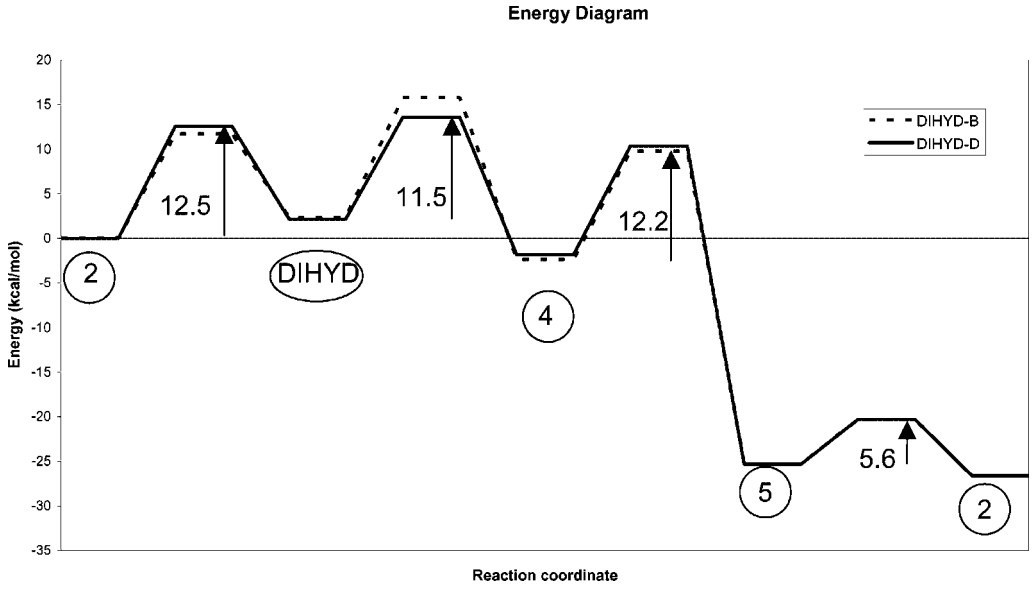

Figure 6. Calculated reaction profile (kcal/mol) of the entire catalytic cycle for the hydrogenation of C=O starting from **2a** (the two last stationary points are common for the two reaction paths).

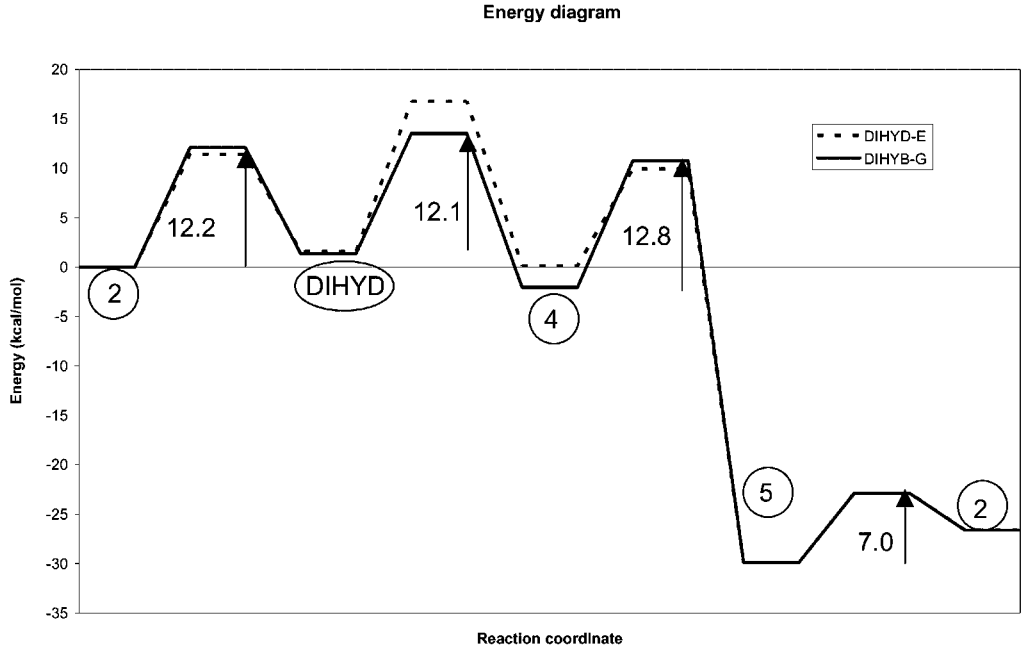

Figure 7. Calculated reaction profile (kcal/mol) of the entire catalytic cycle for the hydrogenation of C=O starting from **2b** (the two last stationary points are common for the two reaction paths).

teraction reasons the C–H formation is favoured when the substrate is located on the same side of the RhPP plane as the C2 chain. These interactions will play an important role for prochiral substrates.

## Conclusions

In this paper, we have presented the possible pathways of the mechanism of hydrogenation of C=O bonds catalysed by neutral rhodium complexes employing the B3LYP density functional method. This theoretical study is the first one carried out on neutral rhodium-based C=O bond hydrogenation. Our purpose was to calculate the most probable pathway for the catalytic reaction. Thus, new insight into our understanding of the reaction is provided here. We performed geometry optimisation for all isomers of intermediates and transition states. Eight diastereomeric pathways have been followed for the *cis* addition of molecular hydrogen to [Rh{$H_2POCH_2CH_2N(H)PH_2$}(CI)($H_2CO$)] leading to eight distinct isomeric dihydride intermediates. The postulated intermediates are minima on the potential surface. Four resulting dihydride complexes have been con-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sidered as the more accessible intermediates. In addition, we showed that even if one isomer can be considered as the most stable within a series, several isomeric structures are able to be involved in every step of the cycle and have to be examined in future studies. For formaldehyde hydrogenation, the rate-determining step is difficult to determine on the basis of the energy diagram. However, the calculation of one similar energy path for methanal and propanone indicate that the migratory path of hydride to the carbonyl moiety is the rate-determining step.[44] The overall energy profile of the catalytic cycle is smooth and corresponds to an exothermic process. On the basis of experimental data and on calculations, the hydrogenation of ketones with the participation of only neutral catalytic intermediates bearing a chloride atom during the entire process and without chelation of the substrate is thus likely to proceed. This is strongly supported by the efficiency of such catalysts in the highly efficient hydrogenation of even simple ketones under neutral conditions.[29]

# Morphology Control of CdSe Submicrostructures with High Hierarchy in Solution

**Benxia Li,[a] Meng Jing,[a] Guoxin Rong,[a] Yang Xu,[a] and Yi Xie*[a]**

**Keywords:** Morphology control / Cadmium selenide / Submicrostructures / Semiconductor

A series of CdSe submicrostructures, including rods, fringy structures, and fasciculate tubes with high hierarchy, have been selectively prepared by a facile one-step solution-based strategy without using any organic surfactants, simply by changing the feeding quantity of aqueous ammonia (25 % $NH_3$). The growth mechanism based on kinetic control is discussed for the selective formation of the CdSe submicrostructures with special morphologies. In the present reaction system, ammonia plays a dual role: providing an alkaline medium for the formation of $Se^{2-}$ and acting as a coordinating agent for cadmium cations in either the solution or the solid phase. The feeding quantity of aqueous ammonia greatly influences the rate of formation of the $Se^{2-}$ anion, and thus determines the final morphology of CdSe crystals. Compared with previous methods of preparing CdSe structures, this concise and novel one-step route has special advantages, suggesting a new path for convenient synthesis of CdSe materials with novel morphology.

## Introduction

Recently, the synthesis of higher ordered functional materials with specific orientation, complex form, and hierarchy has been an area of active research.[1] More and more studies are focused on synthesizing one-dimensional (1D) nanostructures and their hierarchical assemblies, which are expected to play an important role in fabricating the next generation of microelectronic devices because they can function as both building units and interconnections.[2] The architectural control of functional materials with well-defined shapes between nanoscale and microscale is a key for the success of "bottom-up" approaches toward future microdevice fabrication.[3] In addition, the fabrication of semiconducting metal chalcogenides with micro- or nanosize has attracted intense interest because of the unusual optical and electrical properties of these compounds and their potential applications in microdevices.[4] CdSe is one of the most studied subjects because of its extensive applications in solar cells, luminescent materials, lasing materials, and biomedical imaging.[5] In the past several years, most of the studies on the synthesis of CdSe materials were focused on various 1D nanostructures[6] and tetrapod-branched nanocrystals.[7] Peng et al. have reported the shape control and size distributions of colloidal CdSe nanocrystals and proposed morphological evolution from 0D to 1D nanocrystals.[8] These studies were mostly focused on the synthesis of CdSe nanocrystals with diameters below 100 nm. Little attention was paid to the fabrication of submicro- or micrometer-sized CdSe materials with novel morphology. Recently, Zhang's group has demonstrated that the shapes of CdSe crystals with diameters of 150–1000 nm could be manipulated sequentially from rods to particles to tetrapod structures by a vapor-solid (VS) process at high temperatures.[9] Yet, the controllable synthesis of CdSe materials including 1D, quasi-1D, and 3D microstructures with high hierarchy through a direct low-temperature, solution-based route without the use of any organic additives or the aid of other techniques has been rarely reported.

Because of its easily controlled reaction conditions and facile manipulation, the solution-based route might provide an attractive option for large-scale production of micro- or nanomaterials with special morphology. In as-reported solution-based approaches for controlled synthesis of CdSe nanostructures, a curious feature of the systems has been the ubiquitous use of some organic additives as complexing agents or capping ligands.[10] For the purpose of property studies and future applications, it is desirable to develop convenient strategies to obtain new nanomaterials with desired shapes. Moreover, to meet the needs of designed synthesis of micro- or nanostructures with novel morphology, it is vital to systematically find experimental conditions under which the desired materials with controlled morphology are synthesized in large quantities. In this work, a series of CdSe submicrostructures, including rods, fringy structures, and fasciculate tubes, have been selectively prepared by a facile one-step solution-based strategy without using any

organic surfactants, by simply changing the feeding quantity of aqueous ammonia (25% $NH_3$). Concerning the use of ammonia in the synthetic architecture, a dual role can be identified: providing an alkaline medium for the formation of $Se^{2-}$ anions and acting as a coordinating agent for cadmium cations in either solution or solid phase. This synthetic method provides a simple, environmentally friendly, and reproducible route for the controllable synthesis of CdSe materials.

## Results and Discussion

### Morphologies of the Products

The morphologies of the products obtained in the reaction systems containing different volume ratios of aqueous ammonia (25% $NH_3$) and distilled water were examined by a field-emission scanning electron microscope (FESEM). The FESEM images are shown in Figure 1. As shown in Figure 1 (a), the product obtained by feeding 20 mL aqueous ammonia (25% $NH_3$) was mainly composed of submicrorods with diameters around 500 nm and lengths ranging from 5 μm to 10 μm. When the volume of aqueous ammonia fed into the system was increased to 30 mL, fringy structures with high hierarchy assembled by nanorods was formed with about 85% morphological yield (Figure 1, b). A magnified SEM image in Figure 1 (c) clearly shows that the fringy assembly is formed by many smaller nanorods with diameters of 150 nm growing on a trunk. When aqueous ammonia (25%) was used as the only solvent, the obtained product was a large scale of 3D radial assemblies with an average diameter of about 5 μm, as depicted by the panoramic image (Figure 1, d). Interestingly, these 3D radial assemblies, different from those formed by aggregated nanorods that were reported previously,[11] are formed by fasciculate submicrotubes with diameters of 0.5–1 μm, and the open ends of some submicrotubes can be observed in Figure 1 (d). Parts e and f of Figure 1 show the magnified FESEM images of the assemblies with two representative shapes in the sample. The 3D assembly in Figure 1 (e) is composed of several thick tubes with diameters around 900 nm and wall thickness about 160 nm, which clearly manifests the tubular structure. The other assembly in Figure 1 (f) consists of more tubes with smaller diameters of 500 nm, in which these submicrotubes have cracked ends (arrowheads A) and rough interior walls (arrowhead B).

### Phase and Composition of the Products

The structure and bulk phase of the products were determined by XRD analysis. Figure 2 shows the XRD patterns of as-obtained samples of submicron rods, fringy structures, and fasciculate tubes. All diffraction peaks in these XRD patterns can be well indexed to those of the pure phase of wurtzite CdSe (space group $P6_3mc$, JCPDS card No.2–330). No peaks due to impurities were detected, indicating the high purity of the product. The intense and sharp diffraction peaks suggest that the obtained products are well crystallized. In addition, it is notable that the intensity of {100} and {101} diffraction peaks is degressive and that of the

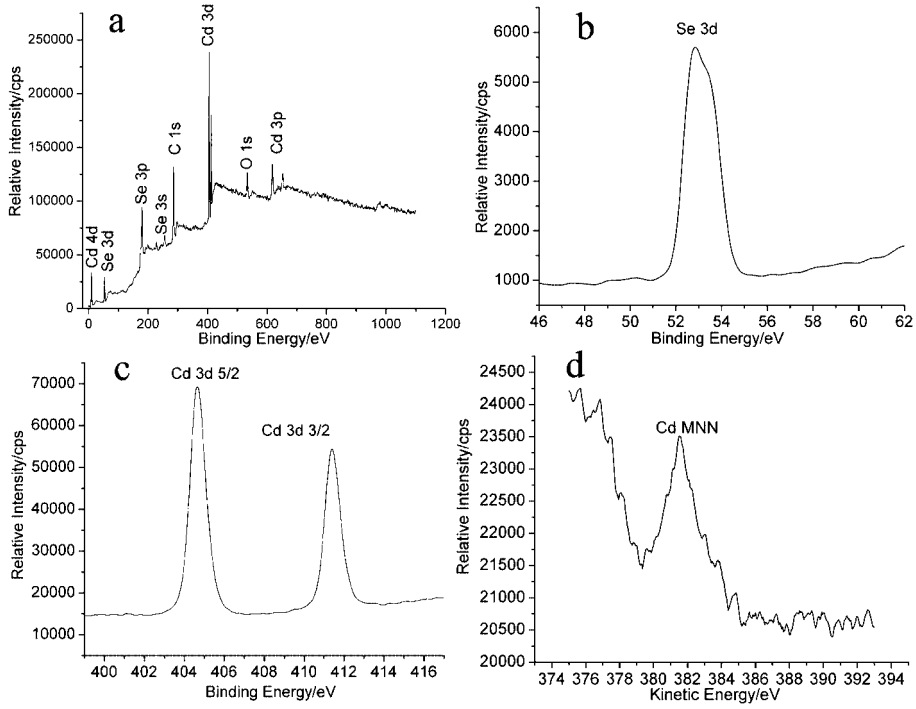

Figure 3. XPS spectra of the as-prepared CdSe fasciculate submicrotubes: (a) survey spectrum, (b) Se 3d, (c) Cd 3d, and (d) Cd MNN. The XPS spectra of other CdSe samples are similar.

{002} diffraction peak strengthens gradually from pattern a to pattern c, which results from the different arrangement of the rods in these CdSe submicrostructures. Thus, the XRD pattern can be indicative of the anisotropic shapes of the three CdSe samples.

In order to obtain the information about the electronic structure of the external ions and the relative composition of the product, three as-prepared CdSe samples with special morphologies were characterized by the XPS technique. Figure 3 shows the XPS spectra of CdSe fasciculate submicrotubes, in which the binding energies were corrected for specimen charging by referencing C 1s to 284.60 eV. The binding energies of Se 3d and Cd 3d were found to be 52.9 and 405.7 eV, respectively. The signals at 10.4 and 381.6 eV can be attributed to the binding energy of Cd 4d and the kinetic energy of Cd MNN. The Auger parameter, defined as the sum of the binding energy of the Cd 3d 5/2 level and the kinetic energy of Cd MNN, is approximately 786 eV, which is consistent with that of the CdSe material.[12]

### Formation Process and Possible Mechanism of CdSe Submicrostructures

To better clarify the nucleation and anisotropic growth of these CdSe submicrocrystals, the morphology and microstructure of their intermediates were further studied by using transmission electron microscopy (TEM) and high-resolution transmission electron microscopy (HRTEM). As shown in Figure 4 (a), the 1-h reaction starting with 20 mL aqueous ammonia engendered very short CdSe rods with different diameters. After 5 h, well-shaped CdSe rods (Figure 4, b) had been formed. The electron diffraction (ED) (Figure 4, b1) and HRTEM image (Figure 4, b2) of a single CdSe rod in Figure 4 (b) indicate that the nanorod has a single-crystalline structure and grows along the <0001> direction. When 30 mL aqueous ammonia was fed into the system, the 1-h reaction gave primary CdSe fringy structures with fewer branches (Figure 4, c). After 5 h, the CdSe fringy structures (Figure 4, d) were almost achieved and resembled their corresponding final products. Figure 4d1 and Figure 4d2 show the ED pattern and HRTEM image taken from a branch (marked with a white rectangle) of the CdSe fringy structure in Figure 4 (d). The ED pattern can be indexed as the [100] zone axis of a wurtzite CdSe crystal, and the lattice spacings of 0.705 nm and 0.372 nm in the HRTEM image correspond to the (0001) and (01$\bar{1}$0) planes of hexagonal CdSe, respectively, indicating that the branches of the CdSe fringy structures grow along the <0001> direction. The ED pattern and HRTEM image of the trunk in the CdSe fringy structure are similar to those from the branch, indicating that the trunk of the CdSe fringy structures also grow along the <0001> direction. In addition, time-dependent experiments for the synthesis of the fasciculate submicrotubes were typically carried out to investigate the formation of the special tubular shapes. TEM images of the intermediate products are shown in Figure 4 (e–f). The 1-h reaction resulted in CdSe aggregations that consisted of many small whiskers (Figure 4, e). After 5 h, the whiskers grew into nanorods with diameters of 200 nm, and the aggregations became 3D radial architectures assembled by nanorods (Figure 4, f). The ED pattern (Figure 4, f1) and HRTEM image (Figure 4, f2), taken form the nanorod marked with a white rectangle in Figure 4 (f), indicate that the nanorods in CdSe are fasciculate crystal-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

line nanorods that grow along the <0001> direction. The sample obtained after 12 h consists of larger 3D architectures assembled by nanorods, as revealed by its SEM images in Figure 5 (a–b). The magnified image of a typical architecture (Figure 5, b) indicates that the nanorods have very rough and cracked ends.

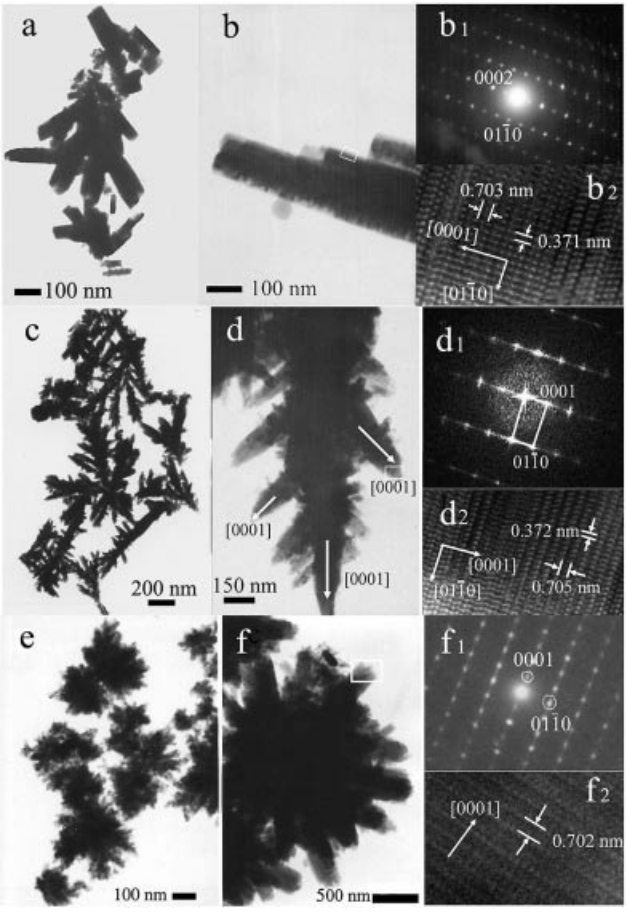

Figure 4. TEM images of the intermediate products of three CdSe submicrostructures: (a) rods obtained after 1 h; (b) rods obtained after 5 h, (b1,2) ED pattern and HRTEM image taken from the rod in Figure b; (c) fringy structure obtained after 1 h; (d) fringy structure obtained after 5 h; (d1,2) ED pattern and HRTEM image taken from the branch of the fringy structure in Figure d; (e) aggregations obtained after 1 h; (f) fasciculate rods obtained after 5 h, (f1,2) ED pattern and HRTEM image taken from the rod marked with a white rectangle in Figure f.

On the basis of the above experimental results, it can be seen that the most important factor that influences the morphology of CdSe crystals in the present approach is the concentration of ammonia in the reaction system. On one hand, our experimental results have indicated that the feeding quantity of aqueous ammonia (25%) in the reaction system also determined the composition of the final product (Figure S1–S2). Moreover, the presence of residual Se in the intermediate products (Figure S3) clarifies the formation process of the CdSe phase in the reaction, which can be illustrated by the series of reactions in Figure 6 (a): First,

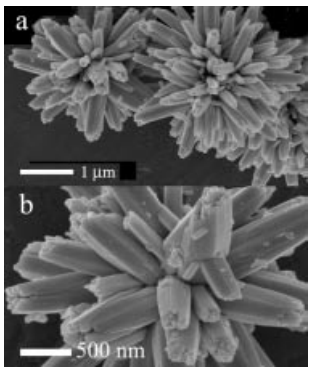

Figure 5. SEM images of CdSe fasciculate rods obtained after 12 h with using aqueous ammonia (25%) as the only solvent (40 mL).

$SeO_3^{2-}$, formed by the dissolution of $SeO_2$ in the solution, is reduced by $NaBH_4$ to Se. Then, under alkaline conditions, Se dismutates into $Se^{2-}$ and $SeO_3^{2-}$,[13] and the latter reacts again as the Se source. Finally, $Se^{2-}$ anions combine with $Cd^{2+}$ cations to form the CdSe phase. The formation of $Se^{2-}$ anions needs proper alkaline conditions, provided by ammonia in our reaction system. On the other hand, it is well known that shape control of the crystals can be achieved by manipulating the growth kinetics.[14] In the present case, the contributing growth-driving force for CdSe crystals is primarily the $Se^{2-}$ concentration, which is determined by the alkalinity of the reaction solution. In our reaction system, the alkalinity was manipulated by changing the feeding quantity of aqueous ammonia. The mechanism of formation of the CdSe submicrostructures with different morphologies is schematically described in Figure 6 (b). When the added volume of aqueous ammonia (25%) was as small as 20 mL, the alkalescence of the reaction solution was relatively weak, and the rate of formation of $Se^{2-}$ anions was low, leading to a lower concentration in solution, which favored the anisotropic nucleation and growth of CdSe crystals. CdSe building units are inclined to grow along the <0001> axis because of the intrinsic structure of CdSe {0001} planes, where $Cd^{2+}$ cations are rich on the positive facet (0001) and $Se^{2-}$ anions are rich on the negative facet (000$\bar{1}$). Thus, one-dimensional nucleation and growth of CdSe nanorods along the <0001> axis took place, and the final CdSe submicrorods were obtained by feeding 20 mL aqueous ammonia (25%) into the present reaction system. With an increased volume of the aqueous ammonia (30 mL), both the alkalinity and the concentration of $Se^{2-}$ anions in the reaction solution increased, giving more CdSe building units. Besides the one-dimensional growth, more nucleation sites around initial CdSe nanorods provided the growth along the <0001> direction of the new CdSe nanorods on the trunks. As a result, the fringy CdSe structures were obtained. When aqueous ammonia (25%) was used as the only solvent (40 mL), both the alkalinity and the concentration of $Se^{2-}$ anions in the reaction solution increased further. The high monomer concentration led to a fast initial nucleation of CdSe, and many newly formed CdSe colloids aggregated together. Then, the concentration

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the monomer became lower as the reaction proceeded. The nuclei around the initial CdSe aggregations would grow along the <0001> direction to form 1D nanorods as long as the chemical environment constantly provides reactants. 3D-fasciculate submicrorods were obtained after 12 h. As for the CdSe fasciculate submicrotubes obtained in 40 mL aqueous ammonia (25%) after 24 h, it was deemed that they were formed by a coordination-assisted dissolution and recrystallization process.[15] Because $Cd^{2+}$ cations are rich on the (0001) facet of the CdSe crystal, ammonia molecules tend to be adsorbed on the (0001) plane and coordinate with $Cd^{2+}$ cations [$CdSe + 4\,NH_3 \rightarrow Cd(NH_3)_4^{2+} + Se^{2-}$], leading to the dissolution of solid CdSe. The selective adsorption of ammonia molecules on the tips [plane (0001)] of the CdSe rods would result in selective "etching" on the rods from the tips toward the interior along the <0001> axis. As observed from Figure 5 (b), the tips of these fasciculate rods are very rough and porous, which may be the "etching" effect of ammonia molecules. The transformation from the fasciculate nanorods to the fasciculate submicrotubes was achieved by partial dissolution of CdSe rods from the tips toward the interior along the long axis (<0001> axis). In addition, the diameters of the final tubes are larger than those of the rodlike precursors, indicating that recrystallization accompanied the "etching" process. Thus, final fasciculate submicrotubes were obtained through such a coordination-assisted dissolution and recrystallization process. However, in the rods and the fringy assemblies, obtained with 20 mL and 30 mL aqueous ammonia (25%), respectively, the CdSe crystals cannot adsorb enough ammonia molecules on their surfaces because of the low concentration of $NH_3$, and no tubular structures are formed in either system. Therefore, by adjusting the feeding quantity of aqueous ammonia, the morphology of the CdSe submicrostructures can be varied sequentially from 1D rods to 3D-fasciculate tubes.

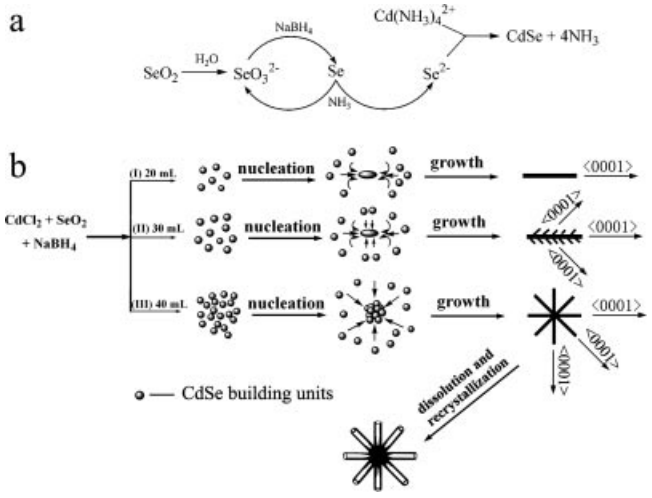

Figure 6. Schematic illustrations: (a) the formation process of CdSe phase in present reaction system; (b) the formation mechanism of CdSe submicrorods, fringy structures, and fasciculate tubes.

## Conclusions

In summary, various morphologies of CdSe, including rods, fringy structures, and fasciculate tubes in submicroscale have been synthesized by a facile one-step, solution-based strategy without using any organic surfactants. The morphology of the CdSe submicrocrystals can be varied sequentially from rods to fringy structures and then to fasciculate tubes by manipulating the volume ratio of aqueous ammonia (25% $NH_3$) and distilled water. In the present reaction system, ammonia acts as a coordinating reagent as well as providing a suitable alkaline environment for the transformation from Se to $Se^{2-}$. The feeding quantity of aqueous ammonia greatly influenced the rate of formation of the $Se^{2-}$ anion and thus its concentration in the reaction solution, which determined the final morphology of CdSe crystals. The rational mechanism based on kinetic control was discussed for the selective formation of these CdSe submicrocrystals with different morphologies. Compared with previous methods of preparing CdSe crystals, this concise one-step route has special advantages, which suggests a new path for the convenient synthesis of CdSe crystals with novel morphology.

## Experimental Section

**Materials and Preparation:** All chemicals were of analytical grade and were used as received without further purification. In a typical procedure, $CdCl_2{\cdot}2.5H_2O$ (ca. 4 mmol), $SeO_2$ (ca. 4 mmol), and $NaBH_4$ (ca. 10 mmol) were dissolved in the solvent (40 mL) containing different volume ratios of aqueous ammonia (25% $NH_3$) and distilled water. The mixed solution was then transferred to a Teflon-lined autoclave with a total capacity of 50 mL. The autoclave was sealed and maintained at 180 °C for 24 h, and then cooled naturally to room temperature. The precipitates were carefully collected and washed with distilled water and absolute ethanol for several times, and then dried in vacuo at 60 °C for 4 h.

**Characterization:** XRD patterns of the products were obtained with a Japan Rigaku DMax-γA rotation anode X-ray diffractometer equipped with graphite-monochromatized Cu-$K_\alpha$ radiation ($\lambda$ = 1.54178 Å). SEM images were taken with a field-emission scanning electron microscope (JEOL JSM-6700F, 15 kV). TEM photographs were taken with a Hitachi Model H-800 transmission electron microscope at an accelerating voltage of 200 kV. The HRTEM images and the corresponding SAED patterns were taken with a JEOL 2010 high-resolution TEM operating at 200 kV. The X-ray photoelectron spectra (XPS) were collected with an ESCALab MKII X-ray photoelectron spectrometer with non-monochromatized Mg-$K_\alpha$ X-ray as the excitation source.

**Supporting Information** (see also the footnote on the first page of this article): XRD patterns of the products obtained under different reaction conditions (Figure S1–S3), room-temperature photoluminescence (PL) emission spectra (Figure S4), and room-temperature Raman spectra (Figure S5).

# Chiral Recognition of Mesoporous SBA-15 with an Incorporated Chiral Porphyrin

**Huan-Bao Fa,[a,d] Lang Zhao,[b] Xing-Qiao Wang,*[a] Ji-Hong Yu,[b] Yi-Bing Huang,[c] Min Yang,[a] and De-Jun Wang[a]**

**Keywords:** Chiral recognition / Porphyrins / Mesoporous materials / SBA-15

The incorporation of a chiral porphyrin into the mesoporous molecular sieves SBA-15 by reactions of the surface OH group with an amino group of the porphyrin and its chiral recognition were studied. The resultant material was analyzed by a combination of techniques and it was confirmed that the channels of SBA-15 have been filled with chiral porphyrins, leaving the mesopores unaffected. The investigation of chiral recognition of the porphyrin and the composite SBA-15 shows that the incorporated SBA-15 has a clear CD spectral signal of the chiral porphyrin and exhibits different chiral recognition abilities for small amino acids. The D-alanine is more tightly bound to the mesoporous composite SBA-15 than its optical antipode.

## Introduction

Chiral recognition is an attractive subject in the area of host-guest chemistry, since it is a fundamental process for a range of chemical and biological phenomena.[1–3] Several types of host molecules for chiral recognition studies have been reported[4–10] because of their biological and chemical importance. Among them, porphyrins are relatively accessible molecules and have been used in recognition studies for the past two decades.[11–16] However, the use of porphyrins for chiral recognition has been restricted due to their poor stability in solution. A useful means to improve the stability of porphyrins is by encapsulating them into microporous materials such as zeolites, since molecular encapsulating is an emerging technology with potential applications in separation, chemical sensing, and catalysis.[17] However, for natural faujasite and synthetic zeolites X and Y the supercage diameter and the aperture to the cages are only 0.7–1.3 nm, which is too small for big complexes such as porphyrin substrates and products to diffuse in and out.[18] The discovery of the mesoporous material SBA-15[19,20] by Zhao and coworkers in 1998 provided the materials needed to achieve porphyrin incorporation since the SBA-15 has a regular hexagonal array of uniform channels with diameters 4.6–30 nm, high internal surface area of about 700–1000 $m^2 g^{-1}$, and high thermal and hydrothermal stabilities.

Incorporation of metal complexes into mesoporous SBA-15 for catalytic purposes has been extensively investigated.[21–26] However, studies on the incorporation of chiral metal complexes into SBA-15 and their chiral recognitions are limited[27] and there are no reports on incorporation of chiral porphyrins and their chiral recognitions. It is, therefore, important to study this system and to focus on chiral recognition of the host for small chiral molecules. It has been proposed that the enantioselectivity of the host for amino acids could be effectively enhanced by constructing a specific chiral environment derived from protected amino acids on the host porphyrin. In this research, we designed and synthesized a porphyrin that contains an amino acid on the porphyrin plane (Figure 1) and incorporated the porphyrin molecule with chiral recognition into the channels of SBA-15 to give it chiral recognition functions. Methods reported to date for organic complex fixation include: (a) impregnation,[28,29] (b) attachment to amine ligands provided by the modification of a mesoporous material surface with an organosilane,[29–31] (c) encapsulation during hydrothermal synthesis,[32] (d) ion exchange between the organic complex cation and the template surfactant species in the non-calcined mesoporous material,[32] and (e) covalent bonding of the amine-functionalized porphyrin to sites created in mesoporous material by doping with Nb.[33] It is well known that the interior surface of SBA-15 is covered with OH groups, so reduction of the nitro group on the porphyrin circumference led to the formation of aminogen with amino groups linking to OH groups of the SBA-15 through hydrogen bonding. In this paper, we report the results of our studies on the incorporation of a chiral porphy-

rin into SBA-15, and chiral recognition of the mesoporous composite SBA-15/porphyrin using a combination of techniques such as X-ray diffraction (XRD), transmission electron microscopy (TEM), UV/Vis spectroscopy, nitrogen adsorption, and circular dichroism (CD) spectroscopy. At the same time, the enantioselectivity of the chiral porphyrin for an amino acid ester in solution was studied for comparison with the SBA-15/porphyrin.

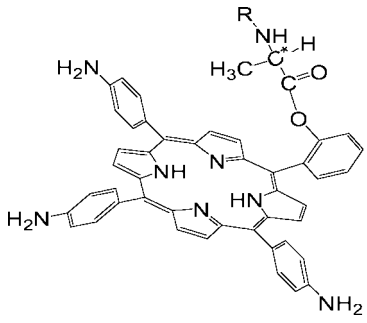

Figure 1. Chemical structure of the chiral porphyrin (R = Boc).

## Results and Discussion

### General Features of the Synthesized Material

The X-ray powder diffraction (XRD) patterns of SBA-15 before (Figure 2, b) and after (Figure 2, a) the incorporation of the chiral porphyrin are given in Figure 2. The XRD patterns of pure SBA-15 and SBA-15/porphyrin show strong (100) peaks, suggesting that framework stability of the mesoporous material is well maintained when the chiral porphyrin is incorporated into the channels of SBA-15. It is to be noted that the relative intensities of (110) and (200) scattering reflections were dramatically decreased for the composite consisting of both the porphyrin and SBA-15 when compared to the same bands for pure SBA-15. The change is interpreted as indicating that the porphyrins are dispersed in the mesoporous channels. TEM measurements were used to analyze the structure of the SBA-15. From the TEM image (Figure 3), it is seen that large ordering domains with highly ordered hexagonal (Figure 3, b) and

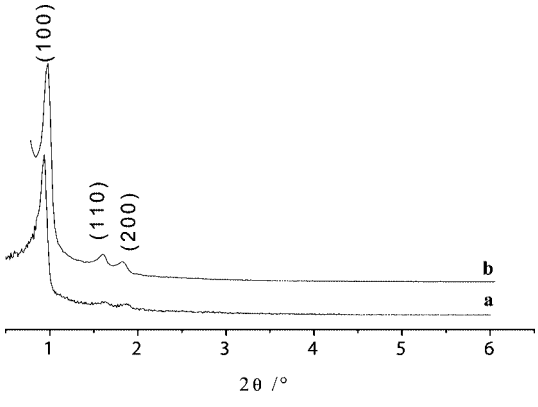

Figure 2. XRD patterns of SBA-15 samples with (a) and without (b) the incorporated chiral porphyrin.

strutlike arrays (Figure 3, a) exist. The SBA-15 after incorporation of chiral porphyrin is shown in Figure 4. When comparing this to Figure 3, it is clear that the hexagonal structure of SBA-15 is preserved after the chiral porphyrin incorporation. However, the TEM images of Figure 4 (part b [110], and part a [100]) show that the hexagonal channels of SBA-15/porphyrin become shaggier. The observed difference can probably be attributed to incorporation of the chiral porphyrin into the channels of SBA-15.

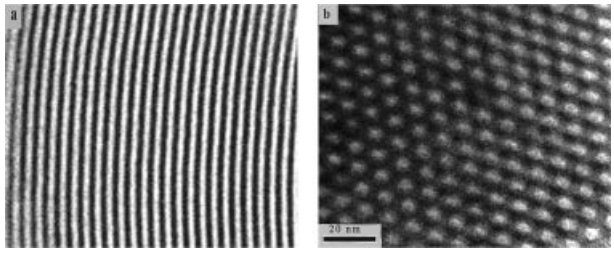

Figure 3. TEM images of SBA-15 along the (a) [100] and (b) [110] directions.

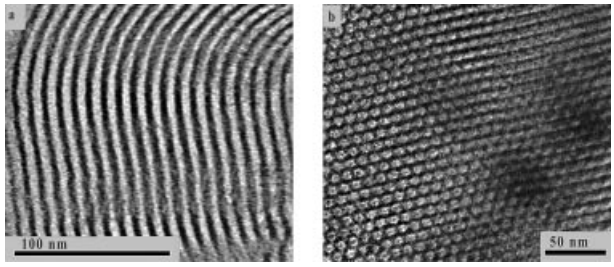

Figure 4. TEM images of SBA-15 with incorporated chiral porphyrin along the (a) [100] and (b) [110] directions.

UV/Vis diffuse reflectance spectrum of the chiral porphyrin, SBA-15/porphyrin, and pure SBA-15 are given in Figure 5. The pure SBA-15 has no characteristic absorption bands over the entire spectral region (Figure 5, a). The chiral porphyrin itself has the Soret bands (438 nm) and four Q-bands (526, 573, 662, 729 nm) (Figure 5, c). The SBA-15/porphyrin has absorption bands at 425 (Soret band), 518, 560, and 698 nm (Figure 5, b). Compared with the pure complex, the Soret band of the chiral porphyrin in SBA-15 is shifted toward shorter wavelengths. This can be attributed to interactions of the porphyrin with the interior surface hydroxyl groups of SBA-15. It has been shown that oxide supports have strong perturbations on the absorption maxima and molar absorption coefficients.[34] A comparison of the characteristic absorption bands of the chiral porphyrin incorporated SBA-15 with that of the chiral porphyrin confirms the incorporation of the chiral porphyrin into the SBA-15 channels. When the chiral porphyrin was incorporated, interactions of the ligands of the porphyrin with their local chemical environment changed the symmetry of the porphyrin. Because of these interactions, the polarity of the surroundings of the porphyrin is increased, as evidenced by the shifts of the absorption bands toward higher energy (shorter wavelength) in the UV/Vis spectra given above.

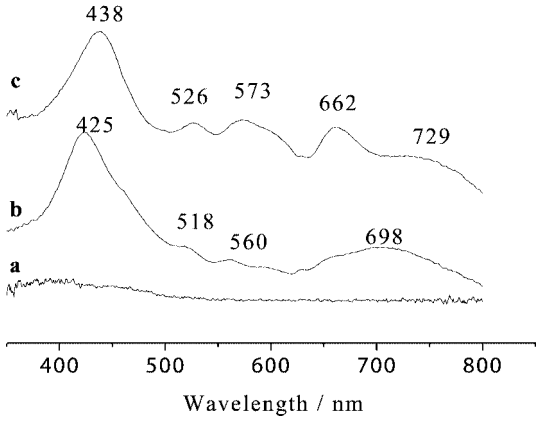

Figure 5. UV/Vis absorption spectra of SBA-15 before (a) and after (b) the incorporation of chiral porphyrin, and also the chiral porphyrin on its own (c).

In order to understand better the texture of the mesoporous composite SBA-15/porphyrin, the nitrogen isothermal adsorption technique was employed. Nitrogen adsorption/desorption isotherms for SBA-15 and SBA-15/porphyrin are shown in Figure 6. When porphyrins were incorporated into SBA-15, the sharpness of the inflection was significantly reduced at the $P/P_0$ range from 0.45 to 0.9, and the inflections were shifted slightly toward lower $P/P_0$ ranges. The inflection point of the relative pressure is related to a diameter in the mesopore range, and the sharpness of these steps indicates the uniformity of the mesopore size distribution.[35,36] Compared to pure SBA-15, the mesoporous composite SBA-15/porphyrin showed a reduction of sharpness, indicating less uniformity of the mesopore size distribution. Table 1 summarizes the results of $N_2$ adsorption analyses. After incorporation of chiral porphyrin into SBA-15, the $S_{BET}$, $V_t$, and $D_{BJH}$ values for SBA-15/porphyrin were 427 $m^2 g^{-1}$, 0.66 $cm^3 g^{-1}$, and 9.0 nm, respectively, and 540 $m^2 g^{-1}$, 0.88 $cm^3 g^{-1}$, and 9.8 nm for pure SBA-15, respectively. Therefore, all parameters of SBA-15/porphyrin decreased compared with pure SBA-15. This is fully consistent with the results of the XRD, UV/Vis, and TEM studies and confirms that the porphyrin was successfully incorporated into the interior surface of the channels of SBA-15. There is a slight decrease of the average pore size ($D_{BJH}$) from 9.8 to 9.0 nm (Figure 6, B), which indicates that some of the nanometer-shaggier void space of the host silica is open, although a portion of the channels may be blocked by the porphyrin molecules. The space is important for guest molecules to diffuse into the host silica, and to contact chiral porphyrin molecules for reactions to proceed.

Table 1. Physical and surface properties of selected samples.

| Sample | $S_{BET}$[a] [$m^2 g^{-1}$] | $V_t$ [$cm^3 g^{-1}$] | $D_{BJH}$ [nm] |
|---|---|---|---|
| SBA-15 | 540 | 0.88 | 9.8 |
| SBA-15/porphyrin | 427 | 0.66 | 9.0 |

[a] $S_{BET}$, BET specific surface area; $V_t$, total pore volume; $D_{BJH}$, pore diameter calculated using the BJH method.

The CD spectra of the chiral porphyrin in solution and the SBA-15/porphyrin in the solid phase are given in Figure 7. The SBA-15 incorporating chiral porphyrin gives CD signals while the pure SBA-15 does not have CD signals. This also confirms the results that the porphyrin has been

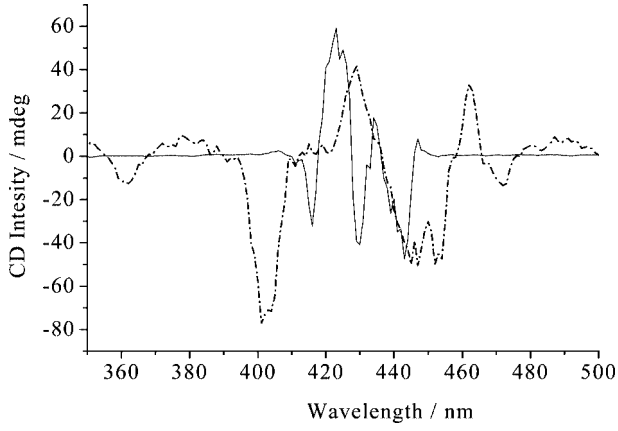

Figure 7. Circular dichroism spectra of the chiral porphyrin (solid line) ($1 \times 10^{-6}$ M) in chloroform and the SBA-15/porphyrin (dash dot line) (solid state) at 298 K.

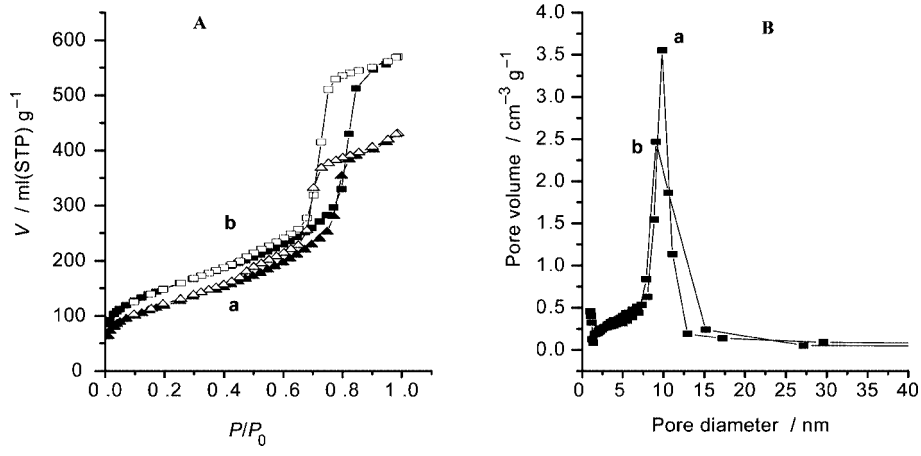

Figure 6. A: Nitrogen adsorption isotherms of pure SBA-15 (a) and SBA-15/porphyrin (b). B: Pore size distribution of the samples calculated from the adsorption branch of the isotherms using the BJH algorithm.

successfully incorporated into the channels of SBA-15. The great change in peak shape of the chiral porphyrin upon incorporation also demonstrates that incorporation has indeed occurred. Difference in peak shape is likely attributable to the influence of the channel of mesoporous material by interactions of porphyrins with OH groups of the SBA-15.

### Chiral Recognition

To investigate comparatively the chiral recognition of the chiral porphyrin and mesoporous composite SBA-15/porphyrin for chiral amino acids, visible spectroscopy and circular dichroism spectra were employed to study the enantioselectivity of L and D amino acids.

Figure 8 shows circular dichroism spectra of porphyrin 1 before and after linking L-BocAla. The porphyrin 1 has no spectral signal, but porphyrin 3 has a strong CD spectral signal with a split Cotton effect around its Soret band when chiral amino acid is linked with porphyrin 1 by covalent bonding. The interaction between the excited states of chromophores in unsymmetrical environments gives circular dichroism curves with split Cotton effects.[37] There is strong exciton-coupled action between the porphyrin ring and the acylamide group. Porphyrin 3 exhibits complex curves around its Soret band (Figure 8, b). According to the Tinoco law,[38] the coupling between the electric and magnetic transition moments of the acylamide group and the electric transition moments of porphyrin chromophores leads to the observed Cotton effects.[13,39]

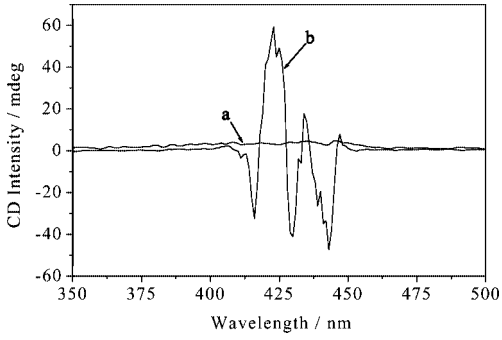

Figure 8. Circular dichroism spectra of porphyrin 1 (a) and chiral porphyrin 3 (b) ($1 \times 10^{-6}$ M).

Absorption spectra of chiral porphyrins binding with amino acid esters of varying concentrations are shown in Figure 9 and Figure 10, which suggest a stepwise binding of the chiral porphyrin with D- and L-alanine methyl ester ($AlaOCH_3$), respectively. The absorption spectral change in the Soret region shows an increase in intensity of the absorption band at 465 nm with a decrease of the absorption at 425 nm, displaying an isosbestic point at 440 nm, which indicates 1:1 complexation between the host and guest molecules. The association constant $K$ is given by Equation (1).

$$\frac{1}{A_0 - A} = \frac{1}{K \cdot a} \cdot \frac{1}{C_L} + \frac{1}{a} \quad (1)$$

where $A_0$ is the absorbance of the porphyrin 3 solution at 425 nm, $A$ is the absorbance in the presence of a guest at concentration $C_L$, and $a$ is a constant. The quantity $1/(A_0 - A)$ has a linear relation to $1/C_L$; the association constant, $K$, can be obtained from the ratio of the intercept to the slope. The results of the association constant of D- and L-$AlaOCH_3$, are $K_D$ = 9526 and $K_L$ = 3834, respectively, which are much larger than that of ZnTPP.[40,41] This is because the electronic effect is more significant than the steric repulsion between the side chain of the amino acid ester and the branch group of the porphyrin. The association constant of D-$AlaOCH_3$ is larger than that of its optical antipode. The structure of the D-enantiomer of the guest molecules can be better aligned with the chiral porphyrin. The steric repulsion between the larger groups in the porphyrin and the L-enantiomer is unfavorable for "close binding" of the host and guest. Accordingly, the association of the porphyrin with the L-guest becomes weaker and the association constant smaller than that with the D-guest.

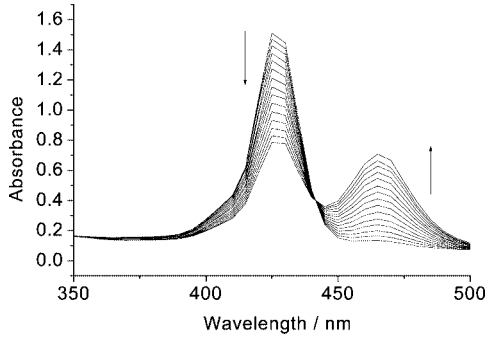

Figure 9. UV/Vis titration of the chiral porphyrin with L-$AlaOCH_3$ in chloroform at 298 K: [3] = $2 \times 10^{-6}$ M; [L-$AlaOCH_3$] = 0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 1.1, 1.2, 1.3, and $1.4 \times 10^{-4}$ M.

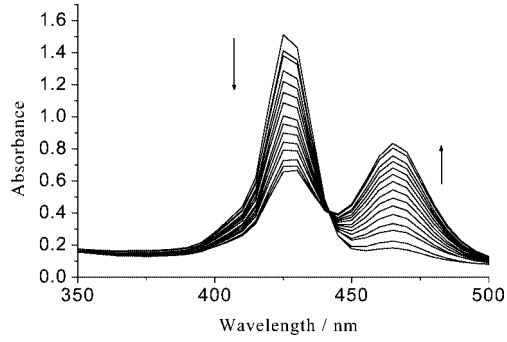

Figure 10. UV/Vis titration of chiral porphyrin with D-$AlaOCH_3$ in chloroform at 298 K: [3] = $1 \times 10^{-6}$ M; [D-$AlaOCH_3$] = 0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 1.1, 1.2, 1.3, and $1.4 \times 10^{-4}$ M.

The chiral porphyrin has a higher enantioselectivity in organic solutions, however, the tedious preparation, high cost, and weak stability of the porphyrin, and also the weak solubility of some amino acids in organic solutions obstruct the application of porphyrins in chiral recognition for amino acids. A good approach to circumvent this problem

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

is to incorporate porphyrins into SBA-15, facilitating the host-guest separation. To investigate the enantioselectivity of the mesoporous material SBA-15/porphyrin for chiral amino acids, a $10^{-3}$ M solution of L-alanine and D-alanine in distilled water was prepared. This solution (10 mL) of L-alanine and D-alanine was mixed with SBA-15 (5.6 mg) after incorporation of chiral porphyrin 3. While the mixture was stirred in a round-bottomed flask at room temperature, the solution was monitored by the CD technique. The changes in the CD spectra with time are shown in Figure 11 and Figure 12. Figure 11 gives the CD spectra of L-alanine with a positive response. As time passes, the response intensity of the solution of L-alanine decreases. The intensity at 30 min is half the intensity at 0 min. This indicates that L-alanine is absorbed into the channel and onto the surface of the mesoporous material.

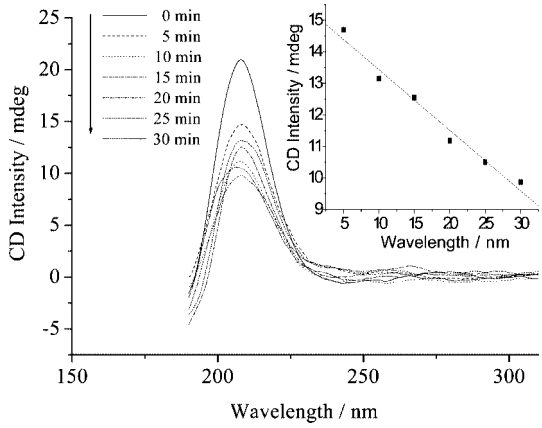

Figure 11. CD spectra of L-alanine at different times after being stirred with SBA-15/porphyrin. Inset shows the CD decrease (ΔCD) vs. time (min).

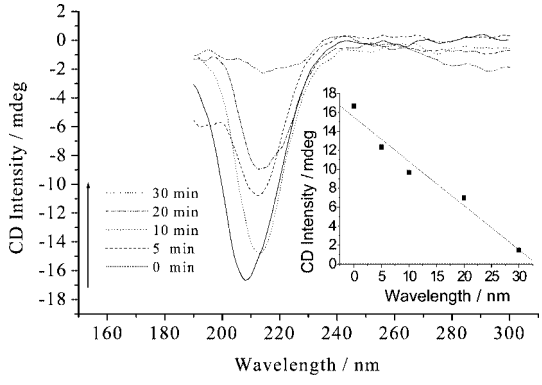

Figure 12. CD spectra of D-alanine solution at different times after being stirred with SBA-15/porphyrin. Inset shows the CD decrease (ΔCD) vs. time (min).

Comparing this with Figure 12, the CD spectra of D-alanine exhibit a negative response and a mirror image of L-alanine. The signal intensity of D-alanine also decreases with time. However, the difference is obvious compared with L-alanine in that the intensity at 30 min is very weak, nearly one ninth of that at 0 min (Figure 12). Also for the same 30 min, the changes of concentration of alanines in their liquid phase are evidently different (inset of Figure 11 and Figure 12). The linear regression parameter for L-alanine is 0.19, and –0.47 for D-alanine. All these results indicated that D-alanine couples more strongly with the mesoporous material, which is consistent with the results of the porphyrin with the amino acid ester. When the porphyrin was not incorporated into the SBA-15, the changes in the CD spectra of the alanines were the same. The observed difference is attributed to incorporation of the chiral porphyrin. The branch groups of the chiral porphyrin provide a chiral cavity for the guest molecules (small amino acids).

## Conclusions

A combination of techniques such as XRD, TEM, UV/Vis, nitrogen adsorption, and CD spectroscopy was employed to confirm that we have successfully incorporated chiral porphyrins into the interior surface of the channels of mesoporous molecular sieves SBA-15. The SBA-15 has a clear CD spectra signal after the incorporation and shows different chiral recognition abilities for small amino acids such as L- and D-alanine. The above experiments demonstrate that the D-alanine is more tightly bound to the host than its optical antipode, which is consistent with the results of porphyrins in organic solutions. The investigation provides an available model for the application of chiral recognition.

## Experimental Section

**Materials and Physical Measurements:** All reagents and solvents were of commercial reagent grade and used without further purification. Boc-alanine(BocAla) was purchased from Aldrich. The SBA-15 was synthesized according to ref.[19]

The powder diffraction of the solid materials was examined by using a Rigaku D/MAX X-ray powder diffractometer with a Cu-$K_\alpha$ X-ray source ($\lambda$ = 0.154 18 nm). Transmission electron microscopic (TEM) images were performed with a JEOL JEM2011 electron microscope operating at 200 kV. UV/Vis spectra of solutions were collected with a Perkin–Elmer Lambda 2 spectrometer. Diffuse reflectance UV/Vis spectra of solids were recorded with a Perkin–Elmer Lambda 9 spectrometer. Circular dichroism (CD) spectra were performed with a JASCO-715 spectropolarimeter equipped with a thermostat cell compartment. Nitrogen adsorption measurements at 77 K were performed with a NOVA 2000e volumetric adsorption analyzer, samples were outgassed for 6 h in the degas port of the adsorption apparatus.

**Synthesis of the Chiral Porphyrin:** The synthesis procedure for the chiral porphyrin is illustrated in Scheme 1.The synthesis was based on the following procedures: The unsymmetrically phenyl-substituted porphyrin **1** was synthesized according to an adaptation of the general Rothemund method for synthesis of *meso*-tetraphenylporphyrins.[42] *o*-Hydroxybenzaldehyde (4.9 g, 1 equiv.) and *p*-nitrobenzaldehyde (6.1 g, 3 equiv.) were added to refluxing propionic acid (300 mL). Once the aldehydes had completely dissolved, freshly distilled pyrrole (6 mL, 4 equiv.) was added within 20 min and refluxed for 1 h. The reaction mixture was then cooled and allowed to stand overnight. After diluting with distilled water (500 mL) and adjusting the pH to 6–7 with aqueous sodium hy-

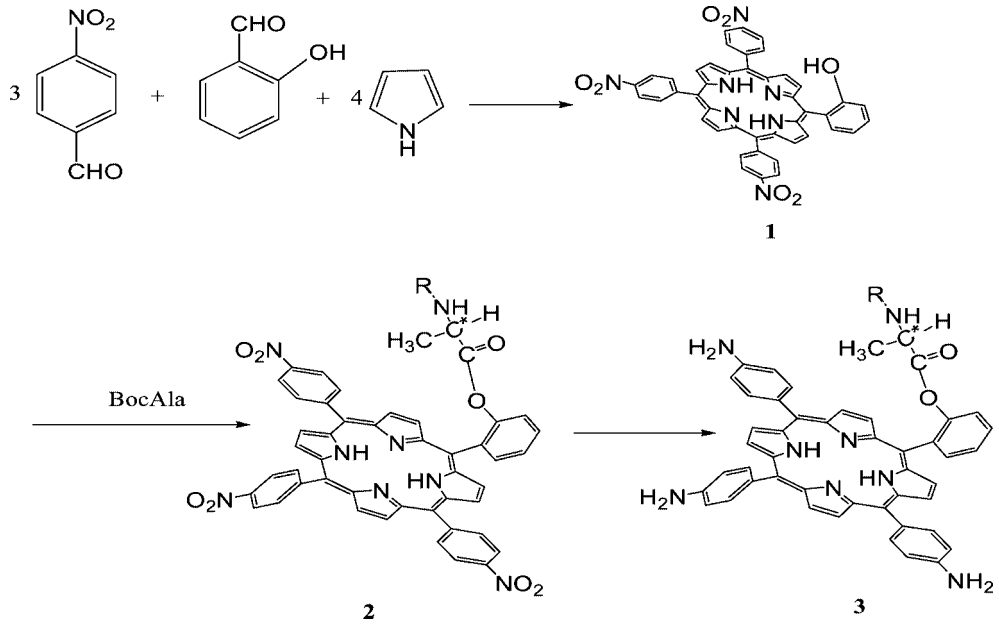

Scheme 1. Synthesis of the tailed chiral amino acid porphyrin chloroform at 298 K.

droxide (6 mol $L^{-1}$), filtration and hot water washing was performed five times. The obtained powder mixture, which was black-purple in color, was then dried in a vacuum oven at 80 °C overnight. The dried powder was extracted with chloroform until the extracts became colorless. After distilling off the solvents under a reduced pressure with a rotary evaporator, a black-purple crude product was obtained. The crude product was separated using silica gel column chromatography eluted first with dichloromethane followed by elution with a chloroform solution. The second elution was collected and the solvents evaporated to dryness, and the product was chromatographed a second time by column chromatography and then TLC. Porphyrin **1** was obtained at the end and dried in a vacuum oven at 80 °C overnight.

$C_{44}H_{27}N_7O_7$ (765.20): calcd. C 69.02, H 3.55, N 12.80; found C 68.85, H 3.50, N 12.63. Visible spectrum ($CHCl_3$): $\lambda$ = 650, 590, 550, 515, 425 nm. IR (KBr): $\tilde{\nu}$ = 3442 (–OH), 3317 (pyrrole N–H) 2921 (C–H), 2850, (–$CH_2$–), 1515, 1346 (–$NO_2$) $cm^{-1}$. MALDI-TOF-MS: *m*/*z* = 765.5 $[M + 1]^+$.

BocAla (30 mg) was dissolved in thionyl chloride (50 mL). This solution was stirred at reflux for 12 h. Thionyl chloride was then removed by distillation under reduced pressure. The crude product was redissolved in benzene (60 mL) and triethylamine (5 mL). A solution of porphyrin 1 (50 mg) in benzene (10 mL) was added. The reaction was stirred for 10 h at reflux. The mixture separated into benzene and water. The organic layer was evaporated under reduced pressure. Flash column chromatography (silica gel, dichloromethane/ethanol, 3:1) afforded 14.1 mg (23%) of pure porphyrin 2.

$C_{52}H_{40}N_8O_{10}$ (936.29): calcd. C 66.66, H 4.30, N 11.96; found C 66.57, H 4.23, N 12.01. Visible spectrum ($CHCl_3$): $\lambda$ = 650, 590, 550, 515, 425 nm. IR (KBr): $\tilde{\nu}$ = 3375 (CON–H), 3317 (pyrrole N–H), 2923 (–$CH_3$), 2852 (–$CH_2$–), 1699 (C=O) $cm^{-1}$. MALDI-TOF-MS: *m*/*z* = 937.2 $[M + 1]^+$.

Porphyrin **2** (24 mg) was dissolved in concentrated hydrochloric acid (36%, 20 mL) at room temperature, in a beaker, followed by addition of excess $SnCl_2{\cdot}2H_2O$ (100 mg). The resulting green mixture was quickly heated to 65–70 °C for 25 min, then cautiously neutralized with concentrated aqueous ammonia. Chloroform (20 mL) was added to the hot suspension and the mixture was stirred for 1 h. The chloroform layer was separated, the aqueous layer extracted several times with chloroform, and all chloroform extracts were combined and filtered. The chloroform solution was reduced in volume (10 mL) on a rotary evaporator, washed first with dilute aqueous ammonia then twice with water, dried with anhydrous sodium sulfate, and evaporated under reduced pressure. Flash column chromatography (silica gel, chloroform, the second elution) afforded 21.7 mg (89%) of pure porphyrin 3.

$C_{52}H_{46}N_8O_4$ (846.36): calcd. C 73.74, H 5.47, N 13.23; found C 73.58, H 5.39, N 13.34. Visible spectrum ($CHCl_3$): $\lambda$ = 650, 590, 550, 515, 425 nm. IR (KBr): $\tilde{\nu}$ = 3429 (N–H), 3359 (CON–H), 3216 (pyrrole N–H), 2921 (–$CH_3$), 2850 (–$CH_2$–), 1700 (C=O) $cm^{-1}$. MALDI-TOF-MS: *m*/*z* = 847.4 $[M + 1]^+$.

**Incorporation of Chiral Porphyrin into SBA-15:** SBA-15 (100 mg) was mixed with porphyrin **3** (10 mg) in a round-bottomed flask (20 mL), and then chloroform (10 mL) was added and stirred for 48 h at room temperature. The solid was filtered and washed with chloroform until no absorption of porphyrin in the UV/Vis spectrum was seen from the solution. The solid was dried at room temperature. The original white powders of SBA-15 turned jade-green after adding the chiral porphyrin, which indicated inclusion of the porphyrins into the SBA-15 frameworks.

For quantitative determination of the porphyrin incorporated into the SBA-15, a mesoporous composite SBA-15/porphyrin sample (14 mg) was dissolved in aqueous sodium hydroxide solution (8 M) to destroy the framework. Thus the porphyrin in the mesoporous composite was released. The porphyrin was extracted with chloroform (10 mL), and the solution was diluted to 1/5 its concentration with chloroform. The OD value of the porphyrin at 425 nm is 0.3141. A reference solution was made with chiral porphyrin (0.5 mg) dissolved in chloroform (100 mL) and its OD value at 425 nm was measured to be 0.5022. By comparing this with the reference, the amount of porphyrin encapsulated in SBA-15 was determined to be 11.2 mg $g^{-1}$ using Beer's law. Because there is no C element in pure SBA-15, the C elemental analysis of the mesopo-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rous composite was employed to obtain 0.83%. The amount of porphyrin was estimated to be 11.4 mg g$^{-1}$, which agrees with that obtained by Beer's law.

# Reactions of Trimethylphosphane-Supported Cobalt Complexes with Salicylaldimines – Formation and Structures of Cobalt Compounds Containing Salicylaldiminato [*N*:*O*] Ligands

**Xiaoyan Li,*[a] Fengli Yu,[a] Hongjian Sun,[a] Liye Huang,[a] and Haoqing Hou[b]**

**Keywords:** Cobalt / Salicylaldimines / Trimethylphosphane / Imines

The reactions of low-valent cobalt complexes $CoMe(PMe_3)_4$, $CoCl(PMe_3)_3$ and $Co(PMe_3)_4$ with salicylaldimines are described to give tetrahedral complexes **7**–**12**, an octahedral complex **13** and a π-coordinated imine complex **15**. The crystal structures of **13** and **15** are reported. The formation and likely mechanisms are discussed.

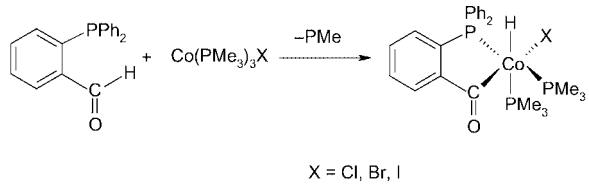
## Introduction

At present, there is increasing interest in N-containing chelate ligands forming metallacyclic compounds.[1–6] Large numbers of complexes of transition metals with Schiff bases, which are used as agents in organic synthesis, catalysts and anticancer or antitoxin drugs, have been synthesized and studied in many laboratories.[7–12] Recent progress has been made in the study of Schiff base–Co(II) complexes as dioxygen carriers. These reports have considerable significance in chemical and biochemical processes.[13–15]

Chelate-assisted oxidative addition is a reaction of potential utility for the selective activation of organic functional groups.[16–18] 2-Phosphanylacyl ligands or 2-phosphanylphenol groups containing weakly acidic protons react with metal halides to afford metal hydrides with the oxidative addition of an O–H or C–H bond at the metal centre.[19] According to Equation (1), acylcobalt(III) hydrides are obtained by the reaction of halogenotris(trimethylphosphane)-cobalt(I) complexes with 2-diphenylphosphanylbenzaldehyde.[20] There is increasing interest in this process, since it is generally accepted that acyl hydride intermediates are involved in certain metal-catalyzed carbonylation[21] and decarbonylation processes.[22]

Recently, we have introduced the salicylaldimine ligands, which are isoelectronic to 2-diphenylphosphanylbenzaldehyde. We now report the reactions of electron-rich, low-valent cobalt complexes $CoMe(PMe_3)_4$, $CoCl(PMe_3)_3$ and $Co(PMe_3)_4$ with salicylaldimines, which have afforded tetrahedral bis(chelate) cobalt(II) imine complexes (**7**–**12**), an octahedral tris(chelate) cobalt(III) imine complex **13** as well as a π-coordinate imine complex **15**, which includes trimethylphosphane as a supporting ligand. The neighbouring N-donor of the salicylaldimine ligand plays an active part in the formation of these complexes . The molecular structures of **13** and **15** were determined by X-ray diffraction. Possible formation routes are proposed.



X = Cl, Br, I (1)

## Results and Discussion

### 1. Reactions of $CoMe(PMe_3)_4$ with Salicylaldimines

The reaction between $CoMe(PMe_3)_4$ and salicylaldimines **1**–**4** liberated methane and utilized both the phenolato and N-donor functions to form the paramagnetic cobalt(II) complexes **7**–**10**, which include two salicylaldiminato[*N*:*O*] chelating ligands. The reaction occurs by a disproportionation route, with the concomitant production of tetrakis(trimethylphosphane)cobalt(0) (Scheme 1, route a). Analogous reactions, e.g., leading to a five-membered metallacycle (route b), did not occur, and the corresponding iminoacyl(hydrido)cobalt(III) species was not detected among the products.

In the infrared spectra of complexes **7**–**10**, the characteristic ν(C=N) bands are found between 1600 and 1634 $cm^{-1}$. Complex **10** has pseudo-tetrahedral geometry; the crystal structure of this complex was reported in our previous work.[23]

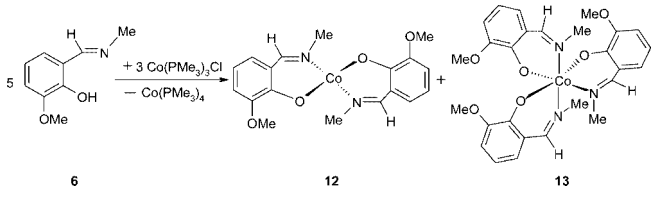
Scheme 1.

An oxidative addition of salicylaldimine iminoacyl C–H bonds did not occur upon reaction with methyltetrakis(trimethylphosphane)cobalt(I) (Scheme 1, route b). It appears that the preferred coordination of the N-donor prevents the attack of cobalt at the C–H bond. This assumption would also explain the scarcity of iminoacyl metal complexes arising from C–H activation.[24,25]

## 2. Reactions of $CoCl(PMe_3)_3$ with Salicylaldimines

Chloridotris(trimethylphosphane)cobalt(I) reacts with salicylaldimines **3**–**5** to afford the cobalt(II) complexes **9**–**11**, which include two salicylaldiminato[*N:O*] ligands, together with tetrakis(trimethylphosphane)cobalt(0) (Scheme 2). A cobalt hydride is suggested as a plausible intermediate. This unstable species undergoes a reductive elimination reaction liberating hydrogen chloride and giving rise to a reactive cobalt(I) complex, which disproportionates to afford complexes **9**–**11** and tetrakis(trimethylphosphane)cobalt(0).

3-methoxy-*N*-methylsalicylaldimine [ligand **6**, Equation (2)] reacts with chloridotris(trimethylphosphane)cobalt(I) to afford not only the cobalt(II) complex **12** containing salicylaldiminato[*N:O*] ligands but also the cobalt(III) complex **13** containing three salicylaldiminato[*N:O*] ligands [Equation (2)]. To the best of our knowledge, complex **13** is the first cobalt(III) complex with three Schiff base anions.



(2)

The $^1$H NMR spectrum of complex **13** shows a resonance at $\delta$ = 7.72 ppm clearly representing the protons of the imino groups. Protons of the benzene rings lie in the range 6.39–6.80 ppm. The $CH_3O$ protons are found at $\delta$ = 3.75 ppm, and the $CH_3N$ protons of are located at $\delta$ = 3.55 ppm. In the $^{13}$C NMR spectrum, resonances at 164.9–166.5 ppm are assigned to the imino carbon atoms. The $CH_3O$ and $CH_3N$ carbon atoms are situated at $\delta$ = 48.0 and 56.0 ppm, respectively. As only the NMR resonances of a single aldimine ligand are observed, the spectra suggest that **13** undergoes a rapid ligand exchange process in $CDCl_3$ solution. It is insoluble in pentane and diethyl ether. Crys-

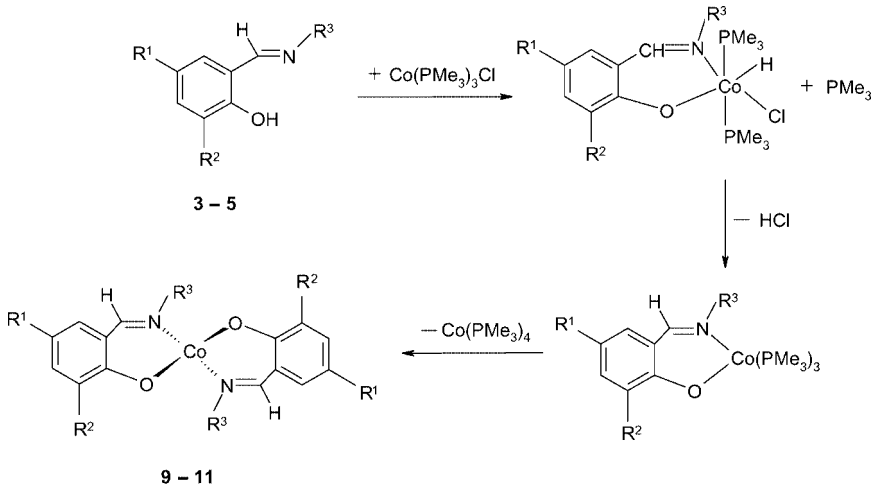

Scheme 2.

tals of **13** were obtained from THF and were analysed by X-ray diffraction. The structure of **13** is shown in Figure 1.

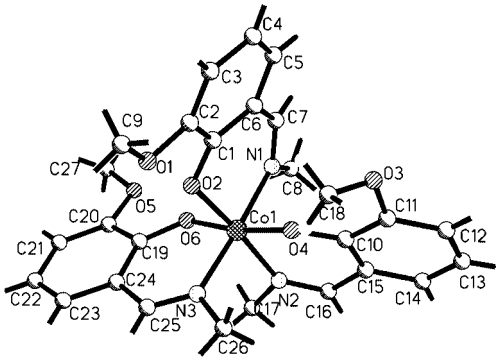

Figure 1. Molecular structure of **13**; selected distances [Å] and angles [°]: Co1–O4 1.883(3), Co1–O6 1.892(3), Co1–O2 1.900(3), Co1–N3 1.935(4), Co1–N2 1.947(3), Co1–N1 1.948(4), N1–C7 1.277(6), N1–C8 1.457(6), N2–C16 1.260(6), N2–C17 1.469(6), N3–C25 1.290(7); O4–Co1–O6 172.33(15), O6–Co1–N3 93.80(16), O4–Co1–N2 92.50(14), O2–Co1–N2 174.11(15), O2–Co1–N1 91.93(15), N3–Co1–N1 176.79(15).

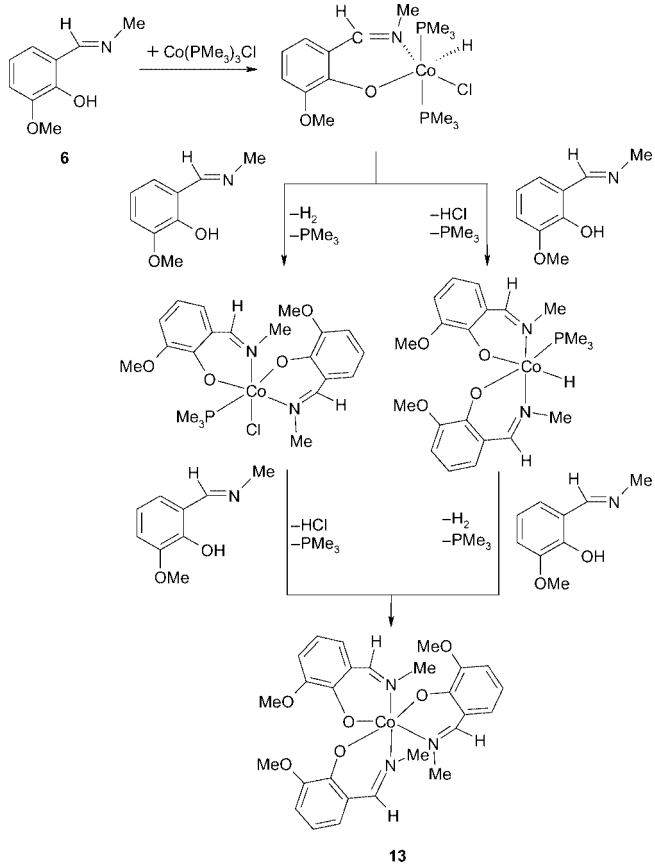
The cobalt atom occupies the central position in an octahedral geometry. Three equivalent salicylaldimine ligands have Co–O and Co–N bond lengths of Co1–O2 1.900(3), Co1–O4 1.883(3), Co1–O6 1.892(3), Co1–N1 1.948(4), Co1–N2 1.947(3), Co1–N3 1.935(4) Å, respectively. Average Co–O and Co–N bond lengths are 1.892 and 1.943 Å, respectively. Complex **13** is a chiral molecule with a meridional configuration. There are two pairs of enantiomers in every crystal cell.

The formation of the cobalt(II) complex **12** is similar to that of complexes **9**–**11** in Scheme 2. A proposed mechanism for the generation of cobalt(III) complex **13** via a cobalt hydride intermediate is illustrated in Scheme 3. The hydridocobalt(III) intermediate, initially formed by oxidative addition of an imino C–H group, reacts with two molecules of Schiff base to afford the cobalt(III) complex **13** with concomitant elimination of hydrogen and hydrogen chloride.



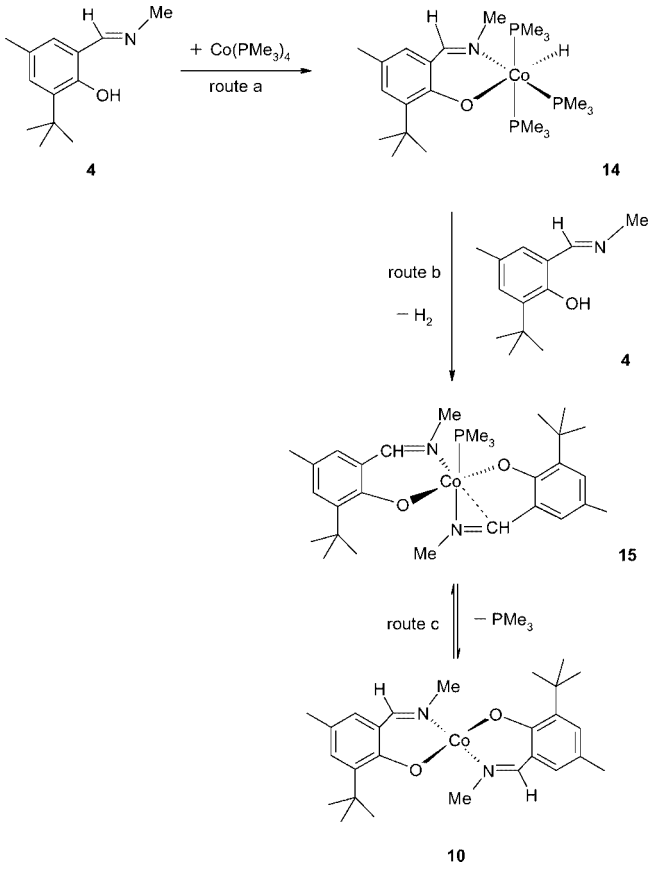
Scheme 3.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The formation of complexes **12** and **13** is a competitive process. The stability of the intermediate hydride complex is advantageous for the formation of complex **13**. In Scheme 2, the steric hindrance of groups $R^1$, $R^2$ and $R^3$ and the electronegativities of the substituents have an effect on the stability of the hydride intermediate and therefore on the relative proportions of complexes **12** and **13**. The details of this dependence are not clear and should be further studied with a greater selection of ligands.

### 3. Reactions of $Co(PMe_3)_4$ with Salicylaldimines

Reaction of tetrakis(trimethylphosphane)cobalt(0) with 3-*tert*-butyl-*N*,5-dimethylsalicylaldimine (ligand **4**) should afford a cobalt(II) hydride complex **14** if oxidative addition of the phenolic hydoxy group at the cobalt centre prevails (Scheme 4, route a). However, in the experiment two products were obtained, i.e., the cobalt(II) complex **10** and the π-imine cobalt(II) complex **15**.



Scheme 4.

The proposed mechanism through an intermediate cobalt(II) hydride complex **14** is illustrated in Scheme 4. The Co–H bond of the reactive hydrido cobalt(II) complex **14** reacts with a phenolic OH group of a further salicylaldimine. Meanwhile, the C=N donor of salicylaldimine π-coordinates to the cobalt atom affording **15** with the elimination of $H_2$ (Scheme 4, route **b**). Dissociation of trimethylphosphane from **15** affords the cobalt(II) complex **10** (Scheme 4, route **c**). We propose that the presence of a trimethylphosphane ligand in complex **15** results from π-imine coordination at the cobalt centre, which competes with the usual N-coordination. In the presence of trimethylphosphane, the interconversion of complexes **15** and **10** is a reversible process.

Yellow crystals of **15** were obtained from pentane at 0 °C. A view of the molecular structure of crystal **15** is given in Figure 2. The cobalt atom occupies the central position of a square plane in a pseudo-square-pyramidal configuration with P1 in the apical position. Two salicylaldimine ligands lie in the square plane with out-of-plane distortion of the π-coordinated C=N bond. The distance between Co1 and C25 [1.929(5) Å] is shorter than that between Co1 and N2 [1.980(4) Å]. Few reports on π-imine compounds of cobalt(II) have appeared.[26]

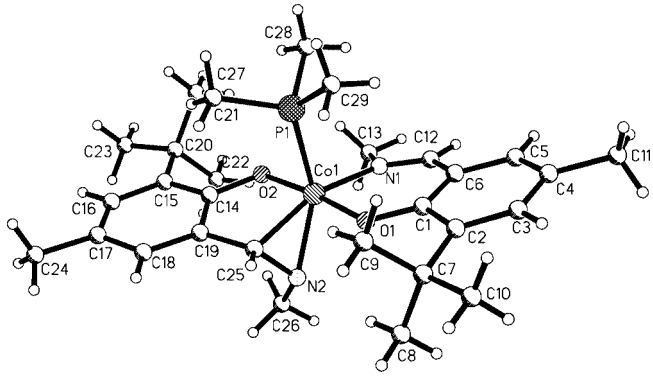


Figure 2. Molecular structure of **15**; selected distances [Å] and angles [°]: Co1–O1 1.918(3), Co1–O2 1.923(3), Co1–C25 1.929(5), Co1–N2 1.980(4), Co1–N1 1.992(4), Co1–P1 2.1954(13); O1–Co1–O2 174.93(13), O1–Co1–C25 89.84(16), O2–Co1–C25 85.28(16), O1–Co1–N2 84.78(15), O2–Co1–N2 90.70(14), C25–Co1–N2 43.15(17), O1–Co1–N1 91.73(14), C25–Co1–N1 156.72(18), N2–Co1–N1 113.91(16), O1–Co1–P1 94.88(10), O2–Co1–P1 87.76(10), C25–Co1–P1 105.46(15), N2–Co1–P1 148.55(13), N1–Co1–P1 97.54(12).

## Conclusions

Methyltetrakis(trimethylphosphane)cobalt(I) and chloridotris(trimethylphosphane)cobalt(I) react with salicylaldimines to form cobalt(II) complexes **7**–**12** which bond to both the phenolato and N-donor functions of two salicylaldiminato[*N*:*O*] ligands. The reaction involves the liberation of methane or hydrochloric acid and subsequent disproportionation to give complexes **7**–**12** and tetrakis(trimethylphosphane)cobalt(0). Steric hindrance and the electronegativities of substituents in the ligands influence the ratio of products in the reaction between chloridotris(trimethylphosphane)cobalt(I) and salicylaldimines. 3-methoxy-*N*-methylsalicylaldimine reacts with chloridotris(trimethylphosphane)cobalt(I) to afford not only cobalt(II) complex **12**, which includes two salicylaldiminato[*N*:*O*] li-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

gands, but also the cobalt(III) complex **13**, which includes three salicylaldiminato[*N:O*] ligands. Tetrakis(trimethylphosphane)cobalt(0) reacts with salicylaldimine to afford the π-imine cobalt(II) complex **15** and the cobalt(II) complex **10** through a possible cobalt hydride intermediate. However, a chelate-assisted oxidative addition of the OC–H bond, that has been shown to proceed with 2-donor substituted benzaldehydes in complexes of low-valent cobalt,[27] could not be observed for the NC–H group of salicylaldimines under otherwise similar conditions. Such a reaction is probably suppressed by the greater stability of the N-coordination in comparison to an O-coordination in the six-membered cobaltacycle.

## Experimental Section

**General Procedures and Materials:** Standard vacuum techniques were used in manipulations of volatile and air-sensitive materials. Microanalyses: Elemental analysis (C, H and N) was carried out at Shandong University by using a Vario ELIII elemental analyzer. Melting points/decomposition temperatures were determined by using sealed capillaries, uncorrected values are reported. Literature methods were used in the preparation of methyltetrakis(trimethylphosphane)cobalt(I), tetrakis(trimethylphosphane)cobalt(0)[28] and chloridotris(trimethylphosphane)cobalt(I).[29] Salicylaldimines were obtained by the condensation of salicylaldehyde or substituted salicylaldehydes with amines. Other chemicals were used as purchased. All solvents were dehydrated and degassed before use. IR samples were prepared as Nujol mulls and placed between KBr discs; samples were analyzed with a Bruker spectrophotometer of type VECTOR 22. $^1$H NMR spectra were recorded with a Bruker AV 400 MHz spectrometer. X-ray crystallography was performed with a Bruker Smart 1000 diffractometer.

**Bis(*N*-methylsalicylaldiminato)cobalt(II) (7):** Methyltetrakis(trimethylphosphane)cobalt(I) (1.82 g, 4.81 mmol) was dissolved in pentane (50 mL). *N*-Methylsalicylaldimine (0.65 g, 4.81 mmol) in pentane (10 mL) was then added to this solution. The resulting solution was stirred at ambient temperature for 17 h. During this period the solution turned orange, indicating that a reaction had occurred. The mixture was then filtered. The filtrate afforded red crystals of complex **7** (0.57 g, 36.5%). M.p. 165.2–170.5 °C. $C_{16}H_{14}CoN_2O_2$ (325.23): calcd. C 5.91, H 4.34, N 8.61; found C 5.82, H 4.24, N 8.64. IR (Nujol): 1634 s ν(C=N) cm$^{-1}$.

**Bis(*N*-*tert*-butylsalicylaldiminato)cobalt(II) (8):** Methyltetrakis(trimethylphosphane)cobalt(I) (1.0 g, 2.65 mmol) was dissolved in pentane (50 mL). *N*-*tert*-Butylsalicylaldimine (0.47 g, 2.66 mmol) dissolved in pentane (10 mL) was then added to this solution. After being stirred for 18 h at 20 °C, the red-brown mixture was filtered. The filtrate that was stored at –20 °C afforded red microcrystals of complex **8** (0.17 g, 41%). M.p. 208.7–212.5 °C. $C_{22}H_{28}CoN_2O_2$ (411.40): calcd. C 64.23, H 6.86, N 6.81; found C 64.20, H 6.81, N 6.78. IR (Nujol): 1600 (s) ν(C=N) cm$^{-1}$.

**Bis(*N*-phenylsalicylaldiminato)cobalt(II) (9): Method a:** Methyltetrakis(trimethylphosphane)cobalt(I) (0.68 g, 1.80 mmol) was dissolved in pentane (50 mL). *N*-Phenylsalicylaldimine (0.35 g, 1.80 mmol) dissolved in pentane (10 mL) was then added to this solution. The resulting solution was stirred at ambient temperature for 18 h. During this period the reaction solution turned coffee brown. After filtration, the precipitate was recrystallized from diethyl ether at 4 °C to afford red-brown crystals of complex **9** (0.25 g, 31%). **Method b:** *N*-Phenylsalicylaldimine (1.17 g, 5.94 mmol) in diethyl ether (10 mL) was combined with chloridotris(trimethylphosphane)cobalt(I) (1.92 g, 5.95 mmol) in diethyl ether (50 mL) at room temperature. The mixture was stirred for 18 h, during which time a brown-yellow solution formed. The solution was filtered. The filtrate at –27 °C gave red crystals of complex **9** (0.23 g, 17.2%). M.p. 152–155.4 °C. $C_{26}H_{20}CoN_2O_2$ (451.38): calcd. C 69.1, H 4.47, N 6.21; found C 69.08, H 4.52, N 6.31. IR (Nujol): 1604 ν(C=N), 1582 ν(C=C) cm$^{-1}$.

**Bis(3-*tert*-butyl-*N*,5-dimethylsalicylaldiminato)cobalt(II) (10): Method a:** See ref.[23] **Method b:** A solution of 3-*tert*-butyl-*N*,5-dimethylsalicylaldimine (0.67 g, 3.27 mmol) in diethyl ether (10 mL) was added to a stirred solution of chloridotris(trimethylphosphane)cobalt(I) (1.05 g, 3.26 mmol) in diethyl ether (50 mL) at –80 °C. After being warmed up, the mixture was stirred for 18 h at 20 °C. The turbid yellow-brown solution was filtered. The solid residue was then extracted with diethyl ether. The filtrate and ether extracts were combined and kept at 0 °C to afford red crystals **10** (0.16 g, 21%). **Method c:** 3-*tert*-Butyl-*N*,5-dimethylsalicylaldimine (0.90 g, 4.39 mmol) in pentane (10 mL) was combined with tetrakis(trimethylphosphane)cobalt(0) (0.80 g, 2.20 mmol) in pentane (50 mL) at –80 °C. After being warmed up, the mixture was kept stirring for 18 h at 20 °C, during which time a brown-yellow solution formed. The solution was filtered, and the filtrate afforded red crystals of complex **10** (0.20 g, 39%) and yellow crystals of complex **15** (0.27 g, 45%) at 4 °C, respectively, which were separated manually. Crystals of **10**: dec.>159 °C. $C_{26}H_{36}CoN_2O_2$ (467.5): calcd. C 56.6, H 9.44, N 3.15; found C 56.5, H 9.49, N 3.24. IR (Nujol): 1615 ν(C=N), 1538 ν(C=C) cm$^{-1}$.

**Bis(3-methoxy-*N*-phenylsalicylaldiminato)cobalt(II) (11):** 3-methoxy-*N*-phenylsalicylaldimine (1.30 g, 5.73 mmol) in diethyl ether (10 mL) was combined with chloridotris(trimethylphosphane)cobalt(I) (0.62 g, 1.92 mmol) in diethyl ether (50 mL) at room temperature. The mixture was stirred for 18 h, during which time a brown-yellow solution formed. The solution was filtered, and the solid residue was recrystallized from THF at –27 °C affording red crystals of complex **11** (0.13 g, 27%). M.p. ≈ 250 °C (dec.). $C_{28}H_{24}CoN_2O_4$ (511.43): calcd. C 65.76, H 4.73, N 5.48; found C 65.59, H 4.78, N 5.36. IR (Nujol): 1604 ν(C=N), 1582 ν(C=C) cm$^{-1}$.

**Bis(3-methoxy-*N*-methylsalicylaldiminato)cobalt(II) (12) and Tris(3-methoxy-*N*-methylsalicylaldiminato)cobalt(III) (13):** A solution of 3-methoxy-*N*-methylsalicylaldimine (1.25 g, 7.58 mmol) in diethyl ether (10 mL) was added to a stirred solution of chloridotris(trimethylphosphane)cobalt(I) (0.80 g, 2.48 mmol) in diethyl ether (50 mL) at room temperature. After stirring for 18 h, a brown-yellow turbid solution was obtained. The suspension was filtered, and the filtrate was stored at –27 °C to give red crystals of complex **12** (0.06 g, 19%). The solid residue was recrystallized from THF at –27 °C to afford dark green crystals of **13** (0.10 g, 20%). Crystals of **12**: m.p. >250 °C. $C_{18}H_{20}CoN_2O_4$ (387.29): calcd. C 55.82, H 5.20, N 7.23; found C 55.66, H 5.27, N 7.20. IR (Nujol): $\tilde{\nu}$ = 1616 ν(C=N); 1599, 1543 ν(C=C) cm$^{-1}$. Crystals of **13**: m.p. dec.>140 °C. $C_{29}H_{34}CoN_3O_{6.5}$ (587.52): calcd. C 59.32, H 5.83, N 7.15; found C 59.34, H 5.79, N 7.22. IR (Nujol): $\tilde{\nu}$ = 1633 ν(C=N); 1597, 1546 ν(C=C) cm$^{-1}$. $^1$H NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 3.55 (s, 3 H, $NCH_3$), 3.75 (s, 3 H, $OCH_3$), 6.39, 6.64, 6.80 (3 H, CH), 7.72 (s, 1 H, N=CH) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$, 298 K): $\delta$ = 47.715, 48.381 (s, $NCH_3$), 56.354, 56.678 (s, $OCH_3$), 112.7, 115.4, 116.4, 116.9, 123.3, 124.9, 125.4, 125.5 (s, CH), 153.3, 153.8, 155.5 (s, C–O), 164.9, 166.5 (s, C=N) ppm.

# Synthesis and Structural Characterization of a New Alkaline Earth Imide: $MgCa(NH)_2$

**Yongfeng Liu,[a] Tao Liu,[a] Zhitao Xiong,[a] Jianjiang Hu,[a] Guotao Wu,[a] Ping Chen,*[a,b] Andrew T. S. Wee,[a] Ping Yang,[c] Kenji Murata,[d] and Ko Sakata[d]**

**Keywords:** Solid-state reactions / Amides / Hydrides / EXAFS spectroscopy / Ternary imide

The ternary imide of $MgCa(NH)_2$ has been successfully synthesized for the first time by the mechanochemical reaction of $Mg(NH_2)_2$ and $CaH_2$ at a molar ratio of 1:1. It was found that ca. four H atoms were desorbed per $Mg(NH_2)_2$-$CaH_2$ after 72 h of ball milling leaving a solid residue with the chemical composition of $MgCa(NH)_2$. The solid residue exhibits an imide N–H stretching vibration at 3151 $cm^{-1}$ and a cubic CaNH-like structure. In addition, X-ray Absorption Fine Structure examination at the Ca *K*-edge indicates that six N atoms occupy the first coordination shell of the Ca center in an anticipated octahedral geometry, and Ca(Mg) atoms occupy the second coordination shell. The distances of Ca–N and Ca–Ca(Mg) in the newly formed $MgCa(NH)_2$ structure calculated by ESDs are 2.46 and 3.47 Å, respectively.

## Introduction

Significant progress in metal nitride research has been made in the past few decades.[1–6] Binary nitrides of the Group 1 and 2 elements, such as $Li_3N$, $Be_3N_2$, $Mg_3N_2$, and $Sr_3N_2$ have been extensively studied[2–3] and used as solar control coatings for windows,[6] reagents for solid-state metathesis reaction,[7–9] and hydrogen storage materials.[10–12] More recently, ternary and multinary nitrides have also been synthesized and investigated due to the unusual crystal and coordination chemistry.[3–6] Unlike nitrides, however, less work has been performed on metal imides. Some basic structural and electronic properties of binary imides such as $Li_2NH$, $Na_2NH$, CaNH, and BaNH are still unknown or controversial.[13–16] As for ternary imides, limited research was done on $Li_2Mg(NH)_2$ and $Li_2Ca(NH)_2$ only in the past two years, motivated by their remarkable hydrogen storage performances.[17–18] Theoretically, the chemical nature of the –NH group enables it to bond with elements from Groups 1–13. A variety of novel ternary or multinary metal imides with unique physical and chemical properties are expected if suitable synthetic routes can be established. Our recent studies showed that a solid-state reaction between metal amides and hydrides could result in the formation of ternary imides. For example, $Li_2Mg(NH)_2$ was synthesized successfully by reacting $LiNH_2$ with $MgH_2$ (molar ratio 2:1) at around 250 °C.[17] The chemical driving force of the above-mentioned solid-state reaction lies in the strong interaction between $H^{\delta+}$ in amide and $H^{\delta-}$ in hydride. However, the thermal instability of the starting amides may lead to self-decomposition at elevated temperatures, which will inevitably result in synthesis failure especially for reactions with slow kinetics. As thermal decomposition of the starting amides is a highly endothermic process, the synthesis of ternary imides may be favored at lower temperature if the overall interaction is mildly endothermic or exothermic. The mechanochemical route, which can perturb surface-bonded species by pressure and enable uniform occurrence of solid-state reaction with poor kinetics at relatively low temperatures,[19–20] could be advantageously used in such synthesis. In this paper, a novel ternary alkaline earth imide, $MgCa(NH)_2$, has been synthesized for the first time by a mechanochemical reaction. FTIR, XRD, and XAFS characterizations were performed to determine the structure of this newly developed imide.

## Results and Discussion

A gaseous product gradually evolved from the mixture of $Mg(NH_2)_2$ and $CaH_2$ (1:1) during the mechanical ball milling treatment, and was identified to be pure hydrogen by a mass spectrometer (Hiden, HPR20). The corresponding amount of hydrogen released from the starting chemicals was calculated by measuring the pressure of hydrogen and the volume of the ball mill vessel. As shown in Figure 1, the amount of hydrogen desorbed increases with ball

milling time. After 12 h ball milling, 11 psi of hydrogen, which is equivalent to ca. 0.5 H atoms per mixture of $Mg(NH_2)_2$–$CaH_2$, was desorbed. After 72 h ball milling, ca. 3.8 H atoms were found to be detached from the mixture. Taking into consideration the purities of the starting chemicals, the number of H atoms released is close to four, being equivalent to the hydrogen storage capacity of ca. 4.0 wt.-%, which is higher than that of most of the traditional metal hydrides, such as $LaNi_5H_6$ (1.4 wt.-%), $FeTiH_{1.9}$ (1.8 wt.-%), and $Mg_2NiH_4$ (3.6 wt.-%). Moreover, EDS analysis reveals that the Mg/Ca atomic ratio in the solid product is 1.03:1, no other metal contamination, such as Fe, was introduced from the stainless steel ball mill jar and balls during the mechanochemical reaction of ball milling.

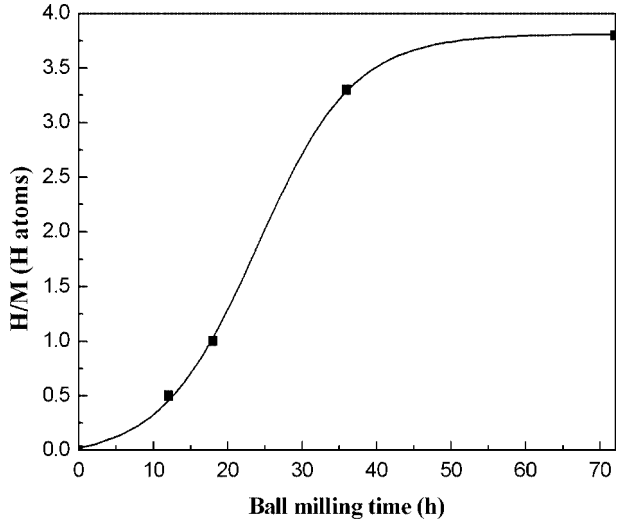

Figure 1. Dependence of the amounts of hydrogen desorption on the ball milling time.

It is well known that $CaH_2$ hardly decomposes to hydrogen at temperatures lower than 600 °C.[21] $Mg(NH_2)_2$, on the other hand, decomposes to $NH_3$ and MgNH at temperatures above 200 °C following the reaction (1).[22–23]

$$Mg(NH_2)_2 \rightarrow MgNH + NH_3 \rightarrow \frac{1}{3}Mg_3N_2 + \frac{4}{3}NH_3 \quad (1)$$

Therefore, hydrogen desorption during the mechanical ball milling should come from the chemical reaction between $Mg(NH_2)_2$ and $CaH_2$ in the present study. Since ca. four H atoms detached from the mixture and no other element was consumed during ball milling, the overall chemical process can be expressed by the following reaction (2).

$$Mg(NH_2)_2 + CaH_2 \rightarrow [MgCa(NH)_2] + 2H_2 \quad (2)$$

The chemical composition of the solid residue indicates that it may be a new ternary imide of Ca and Mg.

It is known that hydrogen atoms in $Mg(NH_2)_2$ are positively charged, while in $CaH_2$ they are negatively charged. The abnormally high enthalpy of the following reaction (3).

$$H^+ + H^- \rightarrow H_2 \ (\Delta H = -17.37 \text{ eV}) \quad (3)$$

is probably the driving force leading reaction (2) to take place under the mechanical ball milling condition.[17] Similar reactions were also observed in other systems such as $LiNH_2$–LiH, $Mg(NH_2)_2$–2LiH, and $LiNH_2$–$CaH_2$ etc. However, it is worth mentioning that it took 72 h for the completion of the reaction under the severe ball milling condition. So the kinetics of the reaction should be very slow. Such slow kinetics will inevitably bring problems to the conventional high temperature synthesis if the starting chemical [like $Mg(NH_2)_2$] or product (the newly developed imide) easily decomposes at elevated temperatures. Therefore, the mechanochemical method developed in the paper could be one of the viable routes for the synthesis of those thermally unstable ternary or multinary imides.

Figure 2 shows the FTIR spectra of the starting chemicals and the solid residues collected at different ball milling times. It can be seen that the N–H symmetric and asymmetric stretching vibrations of $Mg(NH_2)_2$ appear at 3272 and 3326 $cm^{-1}$, respectively. Ca–H vibration in $CaH_2$ is out of the wavenumber range of 3600–2500 $cm^{-1}$. After 12 h ball milling, in addition to the two absorption peaks of $Mg(NH_2)_2$, a broad absorbance at 3151 $cm^{-1}$ was observed, which is located in the N–H vibration range of imide.[13–16] After 72 h ball milling, the characteristic N–H vibrations of $Mg(NH_2)_2$ were almost undetectable. The broad imide-like N–H vibration at 3151 $cm^{-1}$ was enhanced. This result reveals that $Mg(NH_2)_2$ was gradually consumed and an imide-like compound was gradually formed during the ball milling treatment. More importantly, the N–H stretching vibration of the newly developed product of $MgCa(NH)_2$ differs considerably from that of MgNH and CaNH as shown in Figure 2, indicating it is possibly a new ternary imide of Ca and Mg rather than a mixture of MgNH and CaNH.

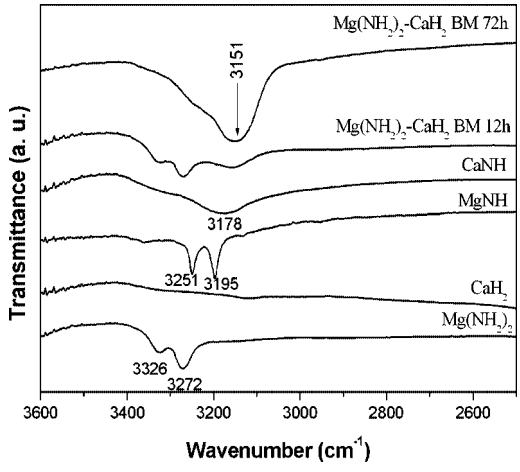

Figure 2. FTIR spectra of the starting chemicals and the Mg–Ca–N–H solid residues after ball milling.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Consumption of $CaH_2$ with ball milling was also manifested by the XRD measurements. As shown in Figure 3, the XRD pattern of the post-12 h milled solid residue is mainly composed of the diffraction peaks of orthorhombic $CaH_2$ (refer to the PDF-2 of the JCPDS-ICDD). As $Mg(NH_2)_2$ is easily deformed into an amorphous phase under the energetic ball milling condition,[22] no distinct diffraction peak can be seen. After 72 h ball milling, a new and single phase structure with main diffraction peaks at 30.5, 35.2, and 50.7° was formed (see Figure 3). Matched with the PDF-2 database of the JCPDS-ICDD, the above newly developed solid product possesses a cubic CaNH-like structure. However, compared with CaNH, the diffraction peaks of this product shift to higher angles, revealing a reduction in the unit cell volume. The diffraction pattern is also different from that of MgNH. No other structure assignable to Mg–N or Ca–N can be detected. Combined with the FTIR analyses, it is deducible that this newly developed solid product should be a ternary imide of Ca and Mg, i.e., $MgCa(NH)_2$. Further supportive evidences were obtained from the Temperature-Programmed-Decomposition (TPD) measurements on the $MgCa(NH)_2$, and the mixture of CaNH and MgNH, respectively. Distinct thermal decomposition features were detected. As shown in Figure 4, the solid product decomposes at a peak temperature of 590 °C but the decomposition of the mixture of MgNH and CaNH (1:1) presents two peaks at 650 and 720 °C, respectively.

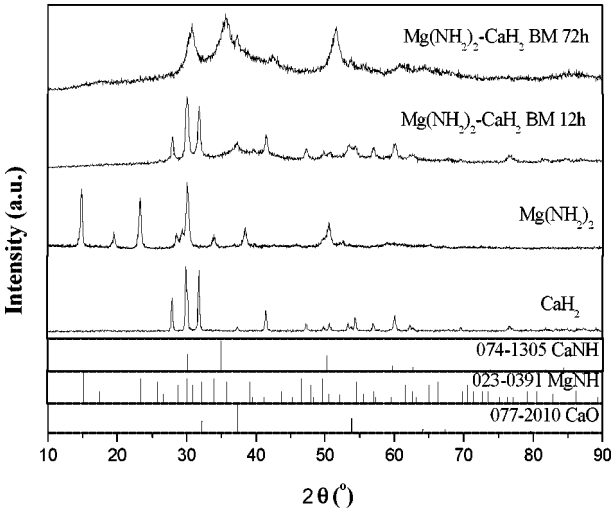

Figure 3. XRD patterns of the starting materials and the Mg–Ca–N–H samples after ball milling.

As can be seen in Figure 3, however, the newly developed imide exhibits rather broad diffraction peaks revealing poor crystallinity in the sample, which is the consequence of the long mechanical ball milling treatment. Because of the poor crystallinity, local structural information could not be convincingly derived from XRD data. The thermal instability of the imide [$MgCa(NH)_2$ decomposes to $NH_3$ at temperatures above 350 °C] defeated our attempt on sample annealing. In order to obtain more structural information on the

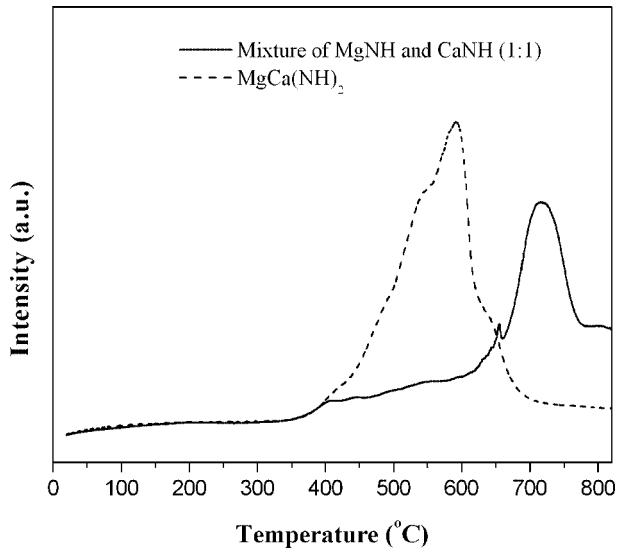

Figure 4. TPD behavior of $MgCa(NH)_2$ and the mixture of MgNH and CaNH.

novel ternary imide, XAFS measurements were conducted. Data of Ca *K*-edge of CaO, CaNH, $Ca(NH_2)_2$, and $MgCa(NH)_2$ were collected and analyzed.

Figure 5 shows the XANES spectra of CaO, CaNH, $Ca(NH_2)_2$, and $MgCa(NH)_2$ samples at Ca *K*-edge, respectively. Obviously all samples exhibit similar spectral features, revealing that they possess the octahedral geometry local structure.[24] Four features can be identified and labeled as A, B, C, and D in Figure 5. Peak A at 4.039 keV can be assigned to the characteristic electron transition from 1*s* to 3*d*.[25] This quadruple transition is usually very weak. However, it is enhanced by the deviation from local centrosymmetry with respect to the central atom (Ca). Compared with CaO, peak A is more obvious in $MgCa(NH)_2$, indicating that the Ca–N octahedrons are somehow distorted. As Mg is more likely to partially replace Ca positions in the second neighboring shell of Ca, the mismatch of atomic radii may result in the distortion of the Ca–N octahedrons. The peak B at 4.042–4.044 keV and peak C at 4.050 keV are ascribed to the dipolar $1s \rightarrow 4p$ transition.[26] Peak B is usually sharp for perfect octahedral sites as shown in CaO.[27] The asymmetry of peak C could be due to the nonequivalent $p_x$, $p_y$, and $p_z$ orbitals of Ca bonded to neighboring nitrogen atoms. Peak C for $MgCa(NH)_2$ shows a shift towards higher energy from 4.049 to 4.050 keV, an indication of a reduced distance between Ca and N compared with that of CaNH. Peak D at 4.058–4.062 keV is related to a middle range ordering as previously demonstrated.[27] Comparatively the ternary $MgCa(NH)_2$ has less middle range ordering, which may be due to its poor crystallinity.

EXAFS looks only at the radial structures of coordination shells around the absorbing atoms. N or O atoms sit in the first coordination shell surrounding the Ca center, and Ca or Mg atoms occupy the second coordination shell. Figure 6 (a) shows Fourier transformed spectra of the various Ca-containing samples. The first peak is assigned to the distance between Ca and the atoms in the first coordination

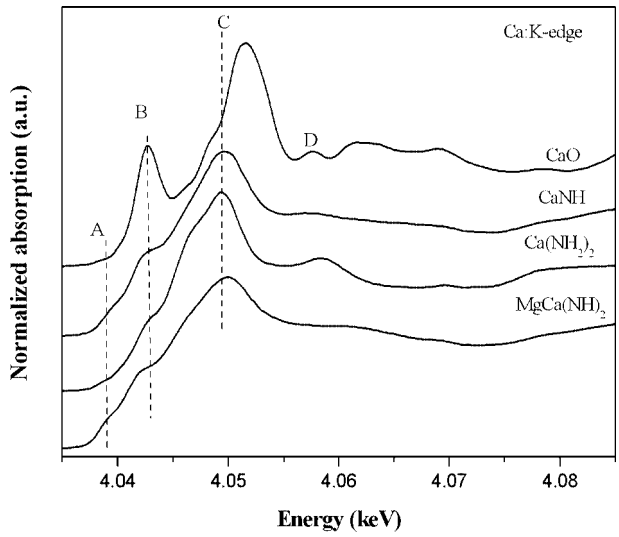

Figure 5. XANES transmission spectra at Ca *K*-edge of the CaO, CaNH, $Ca(NH_2)_2$, and $MgCa(NH)_2$ samples.

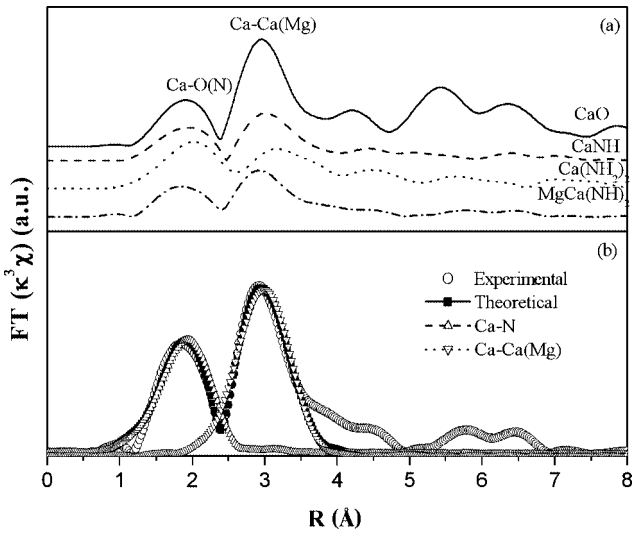

Figure 6. Fourier transformations of the EXAFS spectra of the various Ca-containing samples. (a) Experimental data; (b) fitting results.

shell, i.e., Ca–N or Ca–O; the second peak is attributed to the distance between Ca and the atoms in the second coordination shell, i.e., Ca–Ca and/or Ca–Mg. It should be noted that EXFAS cannot distinguish the positions of Ca and Mg in the second coordination shell of the Ca center. Ca and Mg are more likely to evenly occupy the octahedral center of N in the lattice to minimize energy. Two to three peaks can be identified arising from higher order shells. Figure 6 (b) shows the experimental data and fitting result of $MgCa(NH)_2$, which shows good agreement in the range of 1 to 4 Å. Similar fitting was also performed on CaNH and $Ca(NH_2)_2$, and the results are summarized in Table 1. It is noted that the coordination number (N) of Ca in the first coordination shell is close to 6 for all samples, indicating that octahedral geometry is retained in the first coordination shell, in good agreement with the XRD results. However, the coordination numbers of the second coordination shell are obviously lower than the actual values due to the disorder effects at high coordination shells. Meanwhile, it should be noted that the value of $Ca(NH_2)_2$ (4.4) is lower than that of $MgCa(NH)_2$ (8), which can be attributed to the vacancies of Ca in the second coordination shell due to the lower ratio of the metal atom and N atom (1:2) in the $Ca(NH_2)_2$ structure compared to that in the $MgCa(NH)_2$ structure (1:1).[13] The Ca–N and Ca–Ca distances of CaNH are calculated to be 2.49 and 3.53 Å, respectively, which match well with the values (Ca–N: 2.50 Å, Ca–Ca: 3.54 Å) obtained from the known crystallographic data. On the other hand, the Ca–N and Ca–Ca(Mg) distances of $MgCa(NH)_2$ are calculated to be 2.46 and 3.47 Å, respectively, which are the shortest among the three Ca–N-based structures in the present study. This contraction of atomic distances is in good agreement with the reduction of lattice parameters detected by XRD, which is probably due to the smaller ionic radius of Mg (0.72 Å) compared to Ca (1.0 Å).

Table 1. Structural parameters of CaNH, $Ca(NH_2)_2$, and $MgCa(NH)_2$ obtained from XAFS.[a,b]

| Sample | Shell | Coordination | R [Å] | *N* | $\sigma^2$ [Å$^2$] | Residual [%] |
|---|---|---|---|---|---|---|
| CaNH | 1 | Ca–N | 2.49 | 6.0 | 0.0173 | 9.2 |
| | 2 | Ca–Ca | 3.53 | 6.4 | 0.0132 | |
| $Ca(NH_2)_2$ | 1 | Ca–N | 2.51 | 6.7 | 0.0130 | 16.0 |
| | 2 | Ca–Ca | 3.67 | 4.4 | 0.0078 | |
| $MgCa(NH)_2$ | 1 | Ca–N | 2.46 | 5.9 | 0.0118 | 10.6 |
| | 2 | Ca–Ca(Mg) | 3.47 | 8.0 | 0.0174 | |

[a] Error bars for *R* are 0.01 Å, for *N* and $\sigma^2$, 10%. [b] Data fitting does not include the effects of the H atoms and the oxide contamination.

According to the above discussions, it can be seen that the newly formed ternary imide of $MgCa(NH)_2$ possesses a CaNH-like cubic structure. The half substitution of Ca by Mg does not substantially change the lattice configuration of CaNH, but the lattice has shrunk considerably compared with CaNH, because of the smaller ionic radius of Mg. Figure 7 illustrates a structural model of $MgCa(NH)_2$, in which Ca(Mg) occupies the 4a site (0,0,0) and N occupies the 4b site (1/2,1/2,1/2) of space group Fm-3m, and the N atoms sit in the octahedral holes made of Ca(Mg). However, it is difficult to determine the position of H in the ternary imide by means of XRD and XAFS. There are a number of investigations on the position of H in binary imides, such as CaNH and BaNH.[16,28] As Jacobs et al. pointed out the NH group in CaNH is dynamically disordered at room temperature, and the maximum possibility for the location of hydrogen is the eightfold split position along <111> directions in Ca-octahedra.[16,28] In other words, there are eight possible positions for the H atoms in the structure of CaNH, and every H atom points to the relevant face of the octahedron of Ca. According to the XRD and XAFS analyses, the crystal structure of the newly formed

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$MgCa(NH)_2$ resembles that of CaNH. Therefore, it is suggested that the situation of the H atoms in $MgCa(NH)_2$ is similar to that in CaNH as shown in Figure 7.

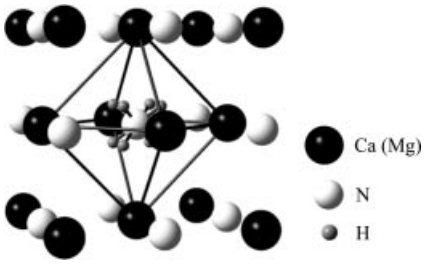

Figure 7. Structural model of $MgCa(NH)_2$.

## Conclusions

In this paper, a novel ternary alkaline earth imide has been synthesized by the mechanochemical reaction of $Mg(NH_2)_2$ and $CaH_2$ with a molar ratio of 1:1. The newly formed ternary imide of $MgCa(NH)_2$ has a CaNH-like cubic structure. Mg atoms partially substitute Ca atoms in the lattice resulting in a distorted local centro-symmetry and poor near and middle range ordering. The Ca–N and Ca–Ca(Mg) distances of $MgCa(NH)_2$ were calculated by ESDs to be 2.46 and 3.47 Å, respectively.

## Experimental Section

All samples were handled in a glovebox (MBRAUN) filled with purified argon ($H_2O$: <1 ppm, $O_2$: <1 ppm). The starting chemicals for the mechanochemical reaction were $Mg(NH_2)_2$ and $CaH_2$. $Mg(NH_2)_2$ was synthesized by reacting pre-milled metallic Mg (99%, Riedel-De Haen) with $NH_3$ (99.98%, BOC GASES) at 300 °C, and its purity was estimated by XRD analyses and measured by thermogravimetric methods, i.e., by measuring the weight loss of a $Mg(NH_2)_2$ sample during the thermal decomposition. Only the diffraction patterns of $Mg(NH_2)_2$ can be detected by XRD examination; and the weight loss was 39.7% as the self-made $Mg(NH_2)_2$ was heated from 25 to 720 °C. The theoretical weight loss was 40.5% when $Mg(NH_2)_2$ was decomposed to $Mg_3N_2$ and $NH_3$. Thus, the purity of the self-made $Mg(NH_2)_2$ is about 98%. $CaH_2$ powder with 95% purity was purchased from Sigma–Aldrich. The mechanochemical reactions were performed on a Retsch PM400 planetary ball mill. In a typical procedure, the starting chemicals of $Mg(NH_2)_2$ (1.4 g) and $CaH_2$ (1.05 g) (molar ratio 1:1) were mixed and then milled at 200 rpm. The ball milling treatment was stopped at different intervals (12–72 h) to measure the pressure changes within the ball mill vessel. After 72 h of mechanochemical reaction, the sample was collected and weighed. Although some of the product adhered to the milling balls and the inner surface of the ball mill vessel, ca. 2.2 g of gray powder was ultimately obtained. The Mg/Ca atomic ratio in the solid product was examined by EDS with a Philips XL30 Scanning Electron Microscope (SEM).

The thermal decomposition of the solid product and the mixture of MgNH and CaNH was carried out with the home-made Temperature-Programmed-Decomposition (TPD) system with an online mass spectrometer (MS) and gas chromatograph (GC) attached. Argon was used as the carrier gas. About 100 mg of sample was loaded and tested each time. The temperature was raised gradually from 20 to 820 °C at 2 °C/min.

N–H vibrations of all samples were detected with a Perkin Elmer FTIR-3000 unit in DRIFT mode. The phase identification was carried out by X-ray diffraction (XRD). A Bruker D8-advance X-ray diffractometer with Cu-$K_\alpha$ radiation at 40 kV and 40 mA equipped with an in-situ cell was used. X-ray absorption fine structure (XAFS) experiments at the Ca *K*-edge (4.038 keV) were performed in transmission mode at room temperature at the XDD beamline in the Singapore Synchrotron Light Source (SSLS).[29] CaO, CaNH, and $Ca(NH_2)_2$ were used as reference samples measured under the same experimental conditions. CaO with 99.9% purity was purchased from Sigma–Aldrich; $Ca(NH_2)_2$ was synthesized by reacting metallic Ca (98.5%, Merck) with $NH_3$ at room temperature.[30] CaNH was obtained by the thermal decomposition of $Ca(NH_2)_2$.[13,31] Each sample was pressed into a pellet by mixing with LiF powder (99%, Fluka) in a weight ratio of 1:10 under a pressure of 2.5 tons; the pellets were subsequently coated with solid wax under an inert atmosphere to protect against air contamination during XAFS measurements. The thickness of the samples was adjusted to achieve a jump of about 1 in absorption coefficient at the absorption edge. Ca *K*-edge XAFS spectra were analyzed following the standard methods using the WINXAS code.[32] The extracted $\chi(k)$ in the range 2.2–9.2 $Å^{-1}$ was weighted by $k^3$ and Fourier transformed into *R* space using the Bessel window function. Data fitting was performed in *R* space without considering the effects of H atoms by filtering out the first and second coordination shells. The other possible error may be generated from the impurities of the reference sample. For all systems, we used the amplitude reduction factor of $S_0^2 = 0.73$, a theoretical value extracted from the fit of CaNH by fixing the known crystallographic data.

# Selective Phosphoramidite Cleavage as a Route to Novel Chiral and Achiral Pentacoordinated Nickel(II) PNP Pincer Complexes

David Benito-Garagorri,[a] Kurt Mereiter,[b] and Karl Kirchner*[a]

**Keywords:** Nickel complexes / Tridentate ligands / Square-pyramidal complexes / Hydrolysis

Treatment of $NiBr_2$(DME) (DME = 1,2-dimethoxyethane) or anhydrous $NiBr_2$ with 2 equiv. of PNP pincer ligands featuring phosphoramidites in $CH_2Cl_2$ yields the novel neutral pentacoordinate complexes [Ni(PNP){$\kappa^1$(P)-$R_2P$=O}Br]. Over the course of this reaction the P–N bonds of the phosphoramidite units of one PNP ligand are selectively cleaved due to hydrolysis affording an anionic $\kappa^1$-(P)-coordinated phosphinite ligand $[R_2P{=}O]^-$, while a second PNP ligand remains intact and is coordinated in a $\kappa^3$-(P,N,P) fashion. The X-ray structure of one [Ni(PNP){$\kappa^1$(P)-$PR_2$=O}Br] complex has been determined.

## Introduction

Tridentate PNP ligands in which the central pyridine-based ring donor contains $–CH_2PR_2$ substituents in the two *ortho* positions are widely utilized ligands in transition metal chemistry (e.g., Fe, Ru, Rh, Ir, Pd, Pt).[1–10] We have recently designed an alternative and versatile modular approach for the high-yield synthesis of a new generation of tridentate PNP pincer-type ligands based on 2,6-diaminopyridine and $R_2PCl$. The latter may contain both bulky and/or electron-rich dialkylphosphanes as well as various P–O bond containing achiral and chiral phosphite units derived from diols or amino alcohols (Scheme 1).[11] With this synthetic route it is possible to modify both electronic, steric, and stereochemical parameters of the PNP ligands in a simple and straightforward manner avoiding tedious multistep syntheses and expensive starting materials.

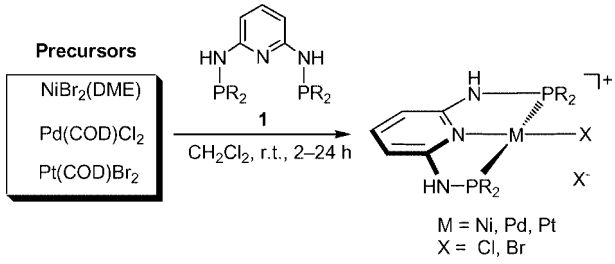
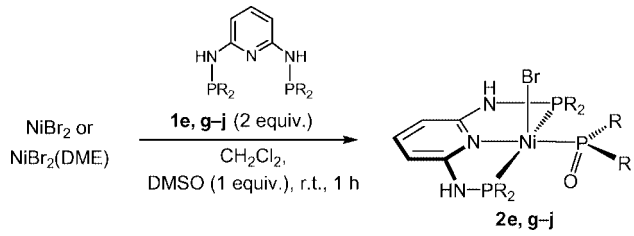
Several of these new PNP ligands have recently been successfully applied to the synthesis of square-planar $Ni^{II}$, $Pd^{II}$, and $Pt^{II}$ PNP complexes as shown in Scheme 2.[11] While in the case of palladium and platinum there were no limitations as to the nature of the PNP ligands, surprisingly with nickel the synthesis of square-planar PNP complexes was limited to the alkyl- and aryl-substituted phosphane ligands **1a**–**c**, which lack P–O bonds. In the particular case of phosphite ligands hydrolysis of the P–N bond(s) took place presumably because of the presence of small amounts of water in the solvents leading to the formation of decomposition products. It has to be noted that indeed in some instances $P^{III}$–N bonds turned out to be sensitive towards acid- or base-catalyzed hydrolysis during complexation reactions.[12] In this paper we utilize one such decomposition pathway as a selective high-yield synthetic route to obtain novel pentacoordinated Ni PNP complexes featuring chiral and achiral PNP ligands together with $\kappa^1$-(P)-coordinated phosphinite ligands $R_2P{=}O^-$.



Scheme 2.

## Results and Discussion

Treatment of $NiBr_2$(DME) (DME = 1,2-dimethoxyethane)[13] with 1 equiv. of the PNP ligands **1e**, (*S*,*S*)-**1g**, (*R*,*R*)-**1h**, (*S*,*S*)-**1i**, and (*S*,*R*)-**1j** (see Scheme 1) in $CH_2Cl_2$ at room temperature for 16 h afforded the novel neutral pentacoordinate complexes [Ni(PNP){$\kappa^1$(P)-$PR_2{=}O$}Br] (**2e**,**g**–**j**) (Scheme 3). The isolated yields were typically less than 50%. There was no evidence for the formation of other products such as square-planar complexes of the type [Ni(PNP)Br]Br. The isolated yields of **2e**,**g**–**j** could be significantly improved up to 89% when $NiBr_2$(DME) was treated with ≥1.5 equiv. of PNP ligand in $CH_2Cl_2$ as the solvent for 16 h. The same reaction took place if anhydrous $NiBr_2$ was treated with 2 equiv. of the respective PNP ligands in $CH_2Cl_2$ in the presence of 1 equiv. of DMSO (or DMF). The addition of these solvents resulted in immediate dissolution of the otherwise insoluble nickel precursor accompanied by a color change of the solution from colorless to bright orange indicating the formation of **2e**,**g**–**j**. It has to be emphasized that DMSO does not participate in the reaction as an oxygen-transfer agent but merely increases the solubility of the stated materials. Under these conditions the reaction time could be reduced to 1 h.



Scheme 3.

All complexes have been characterized by a combination of elemental analysis and $^1H$, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectroscopy. Most diagnostic is the $^{31}P\{^1H\}$ NMR spectrum exhibiting an $A_2X$ pattern with a doublet in the range of δ = 116–147 ppm, assignable to the intact PNP ligand, and a triplet in the range of δ = 74–87 ppm, assignable to the $\kappa^1$-(P)-coordinated phosphinite ligand $R_2P{=}O^-$. The $J_{PP}$ coupling constant ranges from 90 to 115 Hz.

In order to unequivocally establish the ligand arrangement around the metal center, the structure of **2i** (in the form of **2i**·MeOH) has been determined by X-ray crystallography. A structural view is depicted in Figure 1 with selected bond lengths and angles given in the caption. The nickel atom exhibits a square-pyramidal coordination with the Br atom in the apical position. The diphenylphosphinite ligand is clearly coordinated through the lone-pair at the P atom rather than through the oxygen lone-pairs. The PNP ligand is coordinated in the typical meridional $\kappa^3$-(P,N,P) fashion. Nickel pentacoordination is rare in organometallic chemistry and only about 9% of all complexes adopt this coordination number of which about half belong to the trigonal-bipyramidal and the rest to the square-pyramidal type (Cambridge Structural Data base, CSD, version 5.27, release 2006).[14] Only one compound was found in this database with a square-pyramidal Ni(PNP)(P)Br coordination, however, with the Br atom in the basal and the N atom in the apical position.[15] Another example with a coordination related to **2i**·MeOH is dibromo{bis[2-(diphenylphosphanyl)ethyl]amine}nickel(II)[16] having a Ni(PNP)$Br_2$ square pyramid with a basal Ni–Br bond of 2.33 Å and an apical Ni–Br bond of 2.70 Å, whereas in **2i**·MeOH the latter measures 2.54 Å on average for the two independent complexes.

Over the course of this reaction, the P–N bonds of one PNP ligand were selectively cleaved to afford a complex with one anionic phosphinite ligand $PR_2{=}O^-$ and one intact $\kappa^3$-(P,N,P)-coordinated PNP ligand. Only a few examples of mononuclear complexes with a single $PR_2{=}O^-$ ligand are reported in the literature including [RuCp{=C($CH_2$Ph)-NHPh}($PPh_2$NHPh){$\kappa^1$(P)-$PPh_2{=}O$}],[17] [Pt($PPh_3$)(Ph)-(NC-9-anthracenyl){$\kappa^1$(P)-$PPh_2{=}O$}],[18] and $HNEt_3$-[$W(CO)_5${$\kappa^1$(P)-$PPh_2{=}O$}].[19] However, in many cases phosphinite ligands are found in conjunction with the corresponding phosphinous acids $PR_2OH$ to form $R_2P$–O–H···O=$PR_2$ moieties with very strong and almost symmetric hydrogen bonds of O···O distances as low as 2.40 Å.[20–22]

A proposed and plausible mechanism for the formation of **2e**,**g**–**j** supported by $^1$H and $^{31}$P{$^1$H} NMR spectroscopic studies is depicted in Scheme 4. NMR monitoring of the reaction of $NiBr_2$(DME) with varying amounts of PNP-BIPOL (**1e**) ranging from 0.8 to 4 equiv. in $CD_2Cl_2$ revealed in all cases the formation of an intermediate species that exhibits a characteristic $A_2X$ pattern in the $^{31}$P{$^1$H} NMR spectrum with a doublet centered at $\delta$ = 145.7 ppm and a triplet centered at $\delta$ = 122.4 ppm ($J_{PP}$ = 109.8 Hz). This pattern is consistent with a square-pyramidal five-coordinate species **D** where, in contrast to the final product **2e**, the phosphinite ligand is coordinated in the apical position and the Br atom in a basal position. This intermediate isomerizes at room temperature within 16 h to afford quantitatively the final product **2e** exhibiting a doublet centered at $\delta$ = 145.8 ppm and a triplet centered at $\delta$ = 95.4 ppm ($J_{PP}$ = 104.2 Hz). Surprisingly, in all cases there was no evidence for the formation of any additional phosphorus-containing species as a result of PNP decomposition. In fact, if $NiBr_2$(DME) was treated with 0.8 equiv. of **1e**, complex **2e** was cleanly formed after 16 h but the conversion was not quantitative and substantial amounts of the unreacted poorly soluble nickel precursor remained in the NMR tube. If $NiBr_2$(DME) was treated with 1.5 equiv. of **1e**, complete consumption of both $NiBr_2$(DME) and **1e** took place, while with an excess of **1e** (>1.5 equiv.) $NiBr_2$(DME) was completely converted to afford **2e** but unreacted PNP ligand was still present. In the course of all these experiments a white precipitate was formed, which was removed by filtration. Upon dissolution in $CD_3CN$ this compound was unequivocally identified as the 2,6-diaminopyridinium salt **G** giving rise to signals at $\delta$ = 7.46 (t, $J$ = 7.5 Hz, 1 H, H$^5$) and 5.92 (d, $J$ = 7.5 Hz, 2 H, H$^{3,4}$) ppm and broad signals at $\delta$ = 13.4 (1 H, pyN-H) and 7.2 (4 H, $NH_2$) ppm, which is in agreement with an authentic sample[23] of the 2,6-diaminopyridinium cation [cf. the three p$K_a$ values of 2,6-diaminopyridine are 2.16 and 2.90 ($NH_2$ protonation), and 7.22 (protonation of the pyridine nitrogen atom)].[24]

In line with the observed stoichiometry (2 equiv. of nickel salt requires 3 equiv. of PNP ligand for quantitative conversion), despite the absence of other detectable intermediates, the reaction may be initiated by the formation of the cationic square-planar [Ni(PNP)Br]$^+$ complex **A**. Nucleophilic attack of water at one of the two electrophilic phosphorus atoms of the coordinated PNP ligand leads to P–N bond cleavage affording **B**. This compound reacts readily with another PNP ligand to afford **D**. Thereby the monophosphanylated 2,6-diaminopyridine ligand **C** is released, which in turn reacts with $NiBr_2$(DME) to give complex **E** adopting either a square-planar or tetrahedral geometry. The latter reacts again with water to give **F**. The 2,6-diaminopyridine ligand is readily replaced by the tridentate PNP ligand to yield **D** with concomitant release of 2,6-diaminopyridine in the form of its pyridinium cation **G**.

Additional evidence for intermediate **B** comes from the fact that a similar square-planar palladium chloride complex, viz. [Pd{κ$^2$(P,N)-$NH_2$-PN-BIPOL}{κ$^1$(P)-BIPOL-P=O}Cl] (**4**), was obtained during an attempt to obtain crystals of [Pd(PNP-BIPOL)Cl]Cl (**3**) (Scheme 5). Small amounts of pale-yellow crystals of **4** were repeatedly formed by slow solvent evaporation of a DMF solution of **3** at room temperature over a period of 10 d. The molecular structure of this compound (in the form of **4**·DMF) is shown in Figure 2 with selected bond lengths and angles reported in the caption. The Pd center adopts a distorted square-planar geometry defined by two phosphorus atoms, the central nitrogen atom of the PNP ligand, and a chlorine atom. The $PdNP_2Cl$ coordination deviates significantly from planarity most likely because of a short intramolecular contact between C(28)H and Cl (Figure 1). Moreover, there is a stabilizing short intramolecular hydrogen bond N(3)–H···Cl with N···Cl = 3.15 Å. It has to be mentioned

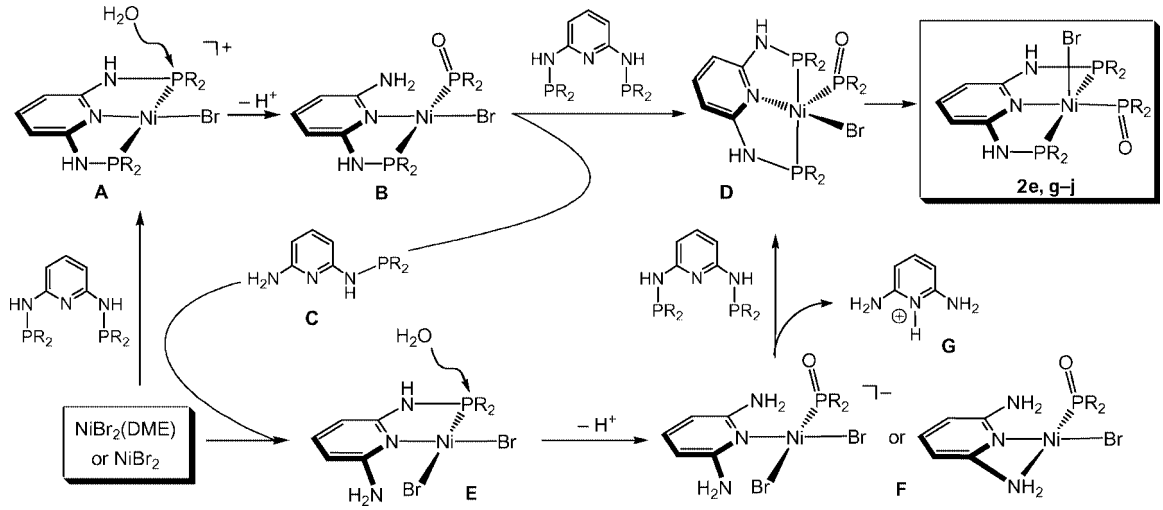
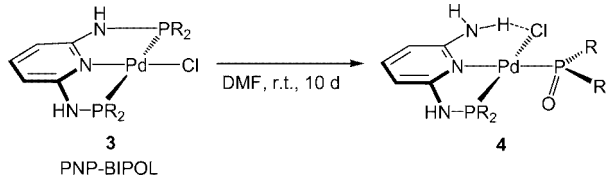


Scheme 4.

that structurally related "one-armed" pincer-type platinum complexes have been reported recently.[25]



Scheme 5.

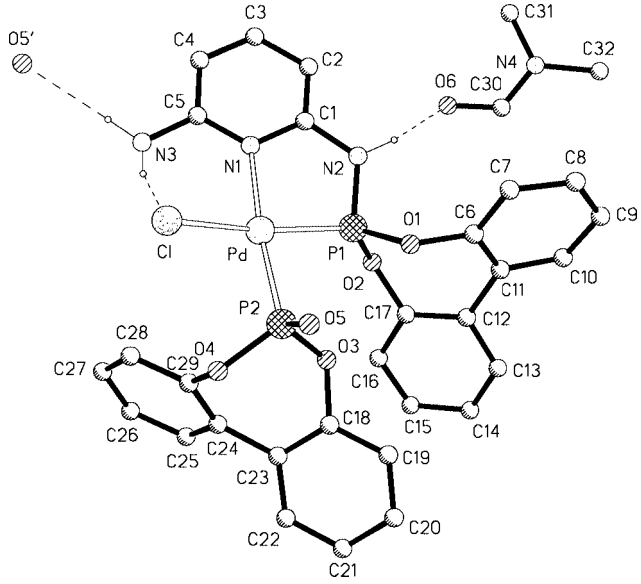


Figure 2. Structural view of [Pd{κ²(P,N)-NH₂-PN-BIPOL}{κ¹(P)-BIPOL-P=O}Cl]·DMF (**4**·DMF) (*C*-bonded H atoms omitted for clarity). Selected bond lengths [Å] and bond angles [°]: Pd–N(1) 2.171(2), Pd–P(1) 2.1787(5), Pd–P(2) 2.2276(6), Pd–Cl 2.3505(5); P(1)–Pd–P(2) 91.78(2), Cl–Pd–P(2) 86.76(2), N(1)–Pd–P(2) 173.51(5), Cl–Pd–P(1) 165.39(2).

Finally, it has to be noted that phosphoramidite PNP ligands are very stable in $CH_2Cl_2$ and comparatively stable also in neat DMSO. In the case of PNP-BIPOL (**1e**) about 50% decomposition is observed at room temperature after 16 h leading to the formation of several intractable materials giving rise to signals in the range of $\delta$ = 6–20 ppm in the $^{31}P\{^1H\}$ NMR spectrum [cf. BIPOL-P(OH)=O, a possible decomposition product, gives rise to a signal at $\delta$ = 5.71 ppm].[26]

## Experimental Section

**General:** All manipulations were performed under argon by using Schlenk techniques. The solvents were purified according to standard procedures. The starting materials (4*S*,5*S*)-2-chloro-4,5-diphenyl-1,3,2-dioxaphospholane,[27] (4*S*,5*R*)-2-chloro-3,4-dimethyl-5-phenyl-1,3,2-oxazaphospholidine,[28] PNP-BIPOL (**1e**), PNP-TAR$^{Me}$ (**1g**), PNP-TAR$^{Pr}$ (**1h**), and [Pd(PNP-BIPOL)Cl]Cl (**3**) were prepared according to literature procedures.[11] The deuterated solvents were purchased from Aldrich and dried with molecular sieves (4 Å). $^1H$, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were recorded with a Bruker AVANCE-250 spectrometer and were referenced to $SiMe_4$ and $H_3PO_4$ (85%), respectively. $^1H$ and $^{13}C\{^1H\}$ NMR signal assignments were confirmed by $^1H$-COSY, 135-DEPT, and HMQC($^1H$-$^{13}C$) experiments.

***N*,*N*′-Bis[(4*S*,5*S*)-4,5-diphenyl-1,3,2-dioxaphospholan-2-yl]-2,6-diaminopyridine (PNP-HBz) (1i):** (4*S*,5*S*)-2-Chloro-4,5-diphenyl-1,3,2-dioxaphospholane (500 mg, 1.8 mmol) was dissolved in toluene (5 mL) and added to a mixture of 2,6-diaminopyridine (98 mg, 0.9 mmol) and triethylamine (0.25 mL, 1.8 mmol) dissolved in toluene (15 mL). The reaction mixture was stirred at 80 °C for 16 h and insoluble materials were removed by filtration. After removal of the solvent under reduced pressure, **1i** was obtained in an analytically pure form as a white solid. Yield: 363 mg (68%). $C_{33}H_{29}N_3O_4P_2$ (593.56): calcd. C 66.78, H 4.92, N 7.08; found C 66.81, H 4.89, N 7.15. $^1H$ NMR ($CDCl_3$, 20 °C): $\delta$ = 7.38–7.11 (m, 21 H, Ph and py[4]), 6.43 (d, $J$ = 8.0 Hz, 2 H, py[3,5]), 6.05 (d, $J$ = 8.2 Hz, 2 H, N*H*), 5.24–5.15 (m, 2 H, C*H*), 5.00–4.81 (m, 2 H, C*H*) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 20 °C): $\delta$ = 157.6 (py[2,6]), 140.2 (py[4]), 136.5 (Ph[1]), 129.0 (Ph[2,6]), 128.5 (Ph[4]), 126.7 (Ph[3,5]), 100.7 (py[3,5]), 87.2 (*C*H) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 20 °C): $\delta$ = 130.0 ppm.

***N*,*N*′-Bis[(4*S*,5*R*)-3,4-dimethyl-5-phenyl-1,3,2-oxazaphospholidin-2-yl]-2,6-diaminopyridine (PNP-Ephe) (1j):** This ligand was prepared analogously to **1i** with (4*S*,5*R*)-2-chloro-3,4-dimethyl-5-phenyl-1,3,2-oxazaphospholidine (500 mg, 2.2 mmol), 2,6-diami-

nopyridine (118 mg, 1.1 mmol), and triethylamine (0.30 mL, 2.2 mmol). Yield: 283 mg (52%). $C_{25}H_{31}N_5O_2P_2$ (495.50): calcd. C 60.60, H 6.31, N 14.13; found C 60.54, H 6.42, N 14.25. $^1$H NMR ($CDCl_3$, 20 °C): $\delta$ = 7.37–7.15 (m, 13 H, Ph, py$^{3,5}$ and py$^4$), 5.86 (d, $J$ = 7.8 Hz, 2 H, N*H*), 4.71–4.60 (m, 2 H, C*H*Ph), 3.77–3.60 (m, 2 H, C*H*$CH_3$), 2.84–2.63 (m, 6 H, NC*H*$_3$), 0.84–0.63 (m, 6 H, CHC*H*$_3$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 20 °C): $\delta$ = 157.0 (py$^{2,6}$), 140.1 (py$^4$), 139.6 (Ph$^1$), 128.5 (Ph$^{2,6}$), 126.8 (Ph$^4$), 125.8 (Ph$^{3,5}$), 99.7 (py$^{3,5}$), 81.7 (*C*HPh), 60.2 (*C*HCH$_3$), 29.1 (NCH$_3$), 14.6 (CH*C*H$_3$) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$, 20 °C): $\delta$ = 119.0 ppm.

**[Ni(PNP-BIPOL){κ$^1$(P)-BIPOL-P=O}Br] (2e):** $NiBr_2$ (150 mg, 0.46 mmol) was suspended in a solution of **1e** (500 mg, 0.93 mmol) in $CH_2Cl_2$ (5 mL). Upon addition of DMSO (33 μL, 0.46 mmol), the solution turned deep orange. The mixture was stirred at room temperature for 1 h and the volume of the solution was reduced under vacuum. The orange product was precipitated with $Et_2O$ and dried under vacuum. Yield: 371 mg (89%). $C_{41}H_{29}BrN_3NiO_7P_3$ (907.23): calcd. C 54.28, H 3.22, N 4.63; found C 54.24, H 3.16, N 3.35. $^1$H NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 7.33–7.09 (m, 20 H, Ph), 6.93–6.88 (m, 4 H, Ph), 6.70 (t, $J$ = 7.3 Hz, 1 H, py$^4$), 6.36 (d, $J$ = 7.3 Hz, 2 H, py$^{3,5}$), 5.80 (d, $J$ = 8.0 Hz, 2 H, N*H*) ppm. $^{13}$C{$^1$H} NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 155.1 (Ph), 154.3 (py$^{2,6}$), 142.2 (py$^4$), 132.3–124.4 (Ph), 100.8 (py$^{3,5}$) ppm. $^{31}$P{$^1$H} NMR ([D$_6$]-DMSO, 20 °C): $\delta$ = 147.7 (d, $J$ = 98.6 Hz, BIPOL-*P*N*P*), 86.6 (t, $J$ = 98.6 Hz, BIPOL-*P*O) ppm.

**[Ni(PNP-TAR$^{Me}$){κ$^1$(P)-TAR$^{Me}$-P=O}Br] (2g):** This complex was prepared analogously to **2e** with $NiBr_2$ (205 mg, 0.94 mmol), **1g** (980 mg, 1.87 mmol), and DMSO (68 μL, 0.94 mmol) as the starting materials. Yield: 672 mg (81%). $C_{35}H_{53}BrN_3NiO_{19}P_3$ (1051.35): calcd. C 39.99, H 5.08, N 4.00; found C 40.09, H 5.00, N 4.10. $^1$H NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 7.44 (t, $J$ = 8.0 Hz, 1 H, py$^4$), 6.40 (d, $J$ = 8.0 Hz, 2 H, py$^{3,5}$), 5.83 (d, $J$ = 8.3 Hz, 2 H, N*H*), 5.03–4.89 (m, 4 H, C*H*), 4.80–4.61 (m, 2 H, C*H*), 1.23–1.14 (m, 18 H, C*H*$_3$) ppm. $^{13}$C{$^1$H} NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 170.2 (*C*O), 166.3 (*C*O), 159.6 (py$^{2,6}$), 142.1 (py$^4$), 100.8 (py$^{3,5}$), 95.1 (*C*H), 76.7 (*C*H), 45.9 (*C*H$_3$), 45.3 (*C*H$_3$) ppm. $^{31}$P{$^1$H} NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 146.2 (d, $J$ = 104.2 Hz, TAR$^{Me}$-*P*N*P*), 85.3 (t, $J$ = 104.2 Hz, TAR$^{Me}$-*P*=O) ppm.

**[Ni(PNP-TAR$^{Pr}$){κ$^1$(P)-TAR$^{Pr}$-PO}Br] (2h):** This complex was prepared analogously to **2e** with $NiBr_2$ (290 mg, 1.33 mmol), **1h** (1.6 g, 2.7 mmol), and DMSO (96 μL, 1.33 mmol) as the starting materials. Yield: 979 mg (70%). $C_{23}H_{29}BrN_3NiO_{19}P_3$ (883.03): calcd. C 31.28, H 3.31, N 4.76; found C 31.21, H 3.40, N 4.66. $^1$H NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 7.42 (t, $J$ = 7.8 Hz, 1 H, py$^4$), 6.41 (d, $J$ = 7.8 Hz, 2 H, py$^{3,5}$), 5.81 (d, $J$ = 8.2 Hz, 2 H, NH), 5.06–4.40 [m, 12 H, C*H* and C*H*(CH$_3$)$_2$], 1.23–1.12 (m, 36 H, [CH(C*H*$_3$)$_2$] ppm. $^{13}$C{$^1$H} NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 170.2 (*C*O), 168.3 (*C*O), 159.8 (py$^{2,6}$), 145.1 (py$^4$), 100.8 (py$^{3,5}$), 95.2 (*C*H), 80.0 (*C*H), 69.1 [*C*H(CH$_3$)$_2$], 68.8 [*C*H(CH$_3$)$_2$], 21.9 [CH(*C*H$_3$)$_2$], 21.7 [CH(*C*H$_3$)$_2$] ppm. $^{31}$P{$^1$H} NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 146.1 (d, $J$ = 100.8 Hz, TAR$^{Pr}$-*P*N*P*), 85.5 (t, $J$ = 100.8 Hz, TAR$^{Pr}$-*P*=O) ppm.

**[Ni(PNP-HBz){κ$^1$(P)-HBz-P=O}Br] (2i):** This complex was prepared analogously to **2e** with $NiBr_2$ (54 mg, 0.24 mmol), **1i** (300 mg, 0.49 mmol), and DMSO (18 μL, 0.24 mmol) as the starting materials. Yield: 132 mg (55%). $C_{47}H_{41}BrN_3NiO_7P_3$ (991.39): calcd. C 56.94, H 4.17, N 4.24; found C 57.04, H 4.19, N 4.31. $^1$H NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 7.29–7.00 (m, 33 H, Ph, py$^4$ and py$^{3,5}$), 5.70 (d, $J$ = 8.0 Hz, 2 H, N*H*), 5.24–4.90 (m, 6 H, C*H*) ppm. $^{13}$C{$^1$H} NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 152.6 (py$^{2,6}$), 144.3 (Ph), 142.5 (py$^4$), 130.1–127.3 (Ph), 98.8 (py$^{3,5}$), 95.1 (*C*H), 87.0 (*C*H) ppm. $^{31}$P{$^1$H} NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 143.4 (d, $J$ = 107.2 Hz, *P*N*P*-HBz), 87.8 (t, $J$ = 107.2 Hz, HBz-*P*=O) ppm.

**[Ni(PNP-Ephe){κ$^1$(P)-Ephe-P=O}Br] (2j):** This complex was prepared analogously to **2e** with $NiBr_2$ (175 mg, 0.40 mmol), **1j** (400 mg, 0.80 mmol), and DMSO (29 μL, 0.40 mmol) as the starting materials. Yield: 213 mg (63%). $C_{35}H_{44}BrN_6NiO_4P_3$ (844.31): calcd. C 49.79, H 5.25, N 9.95; found C 49.69, H 5.09, N 10.05. $^1$H NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 7.40–7.02 (m, 18 H, Ph, py$^4$ and py$^{3,5}$), 5.60 (s, 2 H, N*H*), 4.90–4.74 (m, 3 H, C*H*Ph), 3.64–3.47 (m, 3 H, C*H*CH$_3$), 3.22–3.11 (m, 9 H, NC*H*$_3$), 0.94–0.72 (m, 9 H, CHC*H*$_3$) ppm. $^{13}$C{$^1$H} NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 155.7 (py$^{2,6}$), 143.9 (py$^4$), 141.3 (Ph), 128.6–126.1 (Ph), 99.7 (py$^{3,5}$), 84.5 (*C*HPh), 81.6 (*C*HPh), 65.2 (*C*HCH$_3$), 59.2 (*C*HCH$_3$), 30.9 (NCH$_3$), 28.8 (NCH$_3$), 15.5 (CH*C*H$_3$), 9.5 (CH*C*H$_3$) ppm. $^{31}$P{$^1$H} NMR ([D$_6$]DMSO, 20 °C): $\delta$ = 116.8 (d, $J$ = 114.1 Hz, *P*N*P*-Ephe), 74.5 (t, $J$ = 114.1 Hz, Ephe-*P*=O) ppm.

**X-ray Structure Determination:** Crystals of **2i** were obtained as **2i**·$CH_3OH$ from diethyl ether diffusion into a saturated $CH_3OH$ solution of **2i**. Crystals of **4** were obtained as **4**·DMF by slow concentration of a DMF solution. X-ray data were collected with a Bruker Smart APEX CCD area detector diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and 0.3° $\omega$-scan frames. Corrections for absorption, $\lambda$/2 effects, and crystal decay were applied.[29] The structures were solved by direct methods using the program SHELXS97.[30] Structure refinement on $F^2$ was carried out with the program SHELXL97.[27] Non-hydrogen atoms were refined anisotropically (for **2i**·MeOH isotropically for C, N, and O atoms). Hydrogen atoms were inserted in idealized positions and were refined riding with the atoms to which they are bonded, except for *N*-bound hydrogen atoms, which were refined in $x$,$y$,$z$ if permitted by data quality. Salient crystallographic data are: **2i**·$CH_3OH$: $C_{48}H_{45}BrN_3NiO_8P_3$, $M_r$ = 1023.40 g mol$^{-1}$, orthorhombic, space group $P2_12_12_1$, $a$ = 15.043(12), $b$ = 19.159(12), $c$ = 33.21(3) Å, $V$ = 9572(12) Å$^3$, $Z$ = 8, $\mu$ = 1.396 mm$^{-1}$, $T$ = 173 K. 11282 independent reflections, reflections were collected up to $\theta_{max}$ = 23.1°; final $R$ indices: $R_1$ = 0.131 [5725 reflections with $I > 2\sigma(I)$], $wR_1$ = 0.365 (all data). All available crystals were thin and bent blades (<0.03 mm), giving broad reflection profiles and poor intensities. Therefore, anisotropic displacement parameters were used only for Ni, Br, and P, and the phenyl rings were refined as idealized rigid groups. Despite the relatively large $R$ values, the structure is sound and hydrogen bonding as well as absolute structure [Flack absolute structure parameter = 0.00(3)] could safely be clarified. The asymmetric unit of the structure contains two independent Ni complexes and methanol molecules mutually linked through hydrogen bonds with N–H and O–H as donors and the Br and phosphinite O atoms as acceptors. Only one of the two independent Ni complexes is shown in Figure 1. **4**·DMF: $C_{32}H_{29}ClN_4O_6P_2Pd$, $M_r$ = 769.38 g mol$^{-1}$, monoclinic, space group $P2_1/c$, $a$ = 9.4778(4), $b$ = 13.7127(6), $c$ = 24.2252(10) Å, $\beta$ = 94.642(1)°, $V$ = 3138.1(2) Å$^3$, $Z$ = 4, $\mu$ = 0.831 mm$^{-1}$, $T$ = 173 K. 9147 independent reflections, reflections were collected up to $\theta_{max}$ = 30.0°; final $R$ indices: $R_1$ = 0.0330 [7211 reflections with $I > 2\sigma(I)$], $wR_1$ = 0.0768 (all data). A view of the molecular structure with all hydrogen bonds is shown in Figure 2. CCDC-608245 (**2i**·$CH_3OH$) and -608246 (**4**·DMF) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Properties of Organometallic $Pt^{II}$ and $Pt^{IV}$ Complexes with Acyclic Selenoether and Telluroether Ligands and Selenoether Macrocycles

**William Levason,[a] Joanna M. Manning,[a] Paul Pawelzyk,[a] and Gillian Reid*[a]**

**Keywords:** Selenoether / Telluroether / Platinum / Macrocycles / Organometallic complexes

The first series of planar dimethyl(selenoether)$Pt^{II}$ complexes, $[PtMe_2L]$ [L = $MeSe(CH_2)_nSeMe$ ($n$ = 2 or 3), $o$-$C_6H_4(CH_2SeMe)_2$, [8]ane$Se_2$ (1,5-diselenacyclooctane), or [16]ane$Se_4$ (1,5,9,13-tetraselenacyclohexadecane)], have been obtained by treatment of $[PtMe_2(SMe_2)_2]$ with L in $Et_2O$ solution and characterised by VT $^1H$, $^{13}C\{^1H\}$, $^{77}Se\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR spectroscopy, electrospray MS and microanalysis. The corresponding dimethyl(telluroether)$Pt^{II}$ complexes do not form under similar reaction conditions. The distorted octahedral $[PtMe_3I(L)]$ [L = $o$-$C_6H_4(CH_2SeMe)_2$, [8]ane$Se_2$, [16]ane$Se_4$ or $MeC(CH_2SeMe)_3$] form as stable complexes in good yield from reaction of $PtMe_3I$ with L in refluxing $CHCl_3$ and have been characterised similarly. These all show bidentate selenoether coordination, with fast pyramidal inversion occurring at room temperature. The distorted octahedral coordination environment at $Pt^{IV}$ is also confirmed from a crystal structure of $[PtMe_3I\{o\text{-}C_6H_4(CH_2SeMe)_2\}]$. Rare examples of (telluroether)$Pt^{IV}$ complexes, $[PtMe_3I\{o\text{-}C_6H_4(CH_2TeMe)_2\}]$ and the dinuclear $[Me_3Pt(\mu^2\text{-}I)_2(\mu^2\text{-}MeTeCH_2TeMe)PtMe_3]$, have also been prepared and characterised similarly (and also by $^{125}Te\{^1H\}$ NMR spectroscopy). The [8]ane$Se_2$ and [16]ane$Se_4$ species are the first examples of alkyl $Pt^{II}$ or $Pt^{IV}$ complexes with (macro)cyclic selenoether coordination. Halide abstraction ($TlPF_6$) from $[PtMe_3I(\kappa^2\text{-}[16]aneSe_4)]$ affords $[PtMe_3(\kappa^3\text{-}[16]aneSe_4)]PF_6$; a rare example of a cationic $Pt^{IV}$ selenoether. The (diselenoether)$Pt^{II}$ complexes undergo oxidative addition of MeI to yield the corresponding $Pt^{IV}$ species $[PtMe_3I(diselenoether)]$.

## Introduction

The chemistry of the neutral ligands derived from the heavier group 16 elements, i.e. selenoethers and telluroethers, is of interest because these are less electronegative than their thioether or ether counterparts, and hence are better σ-donor ligands to transition-metal ions in medium oxidation states compared to their O- and S-donor counterparts.[1,2] The vast majority of transition-metal species involving the selenoether or telluroether ligands are based upon transition-metal halide systems, although we have also shown that homoleptic hexaselenoether or hexatelluroether coordination can be achieved under certain conditions.[3] In contrast, examples of organometallic complexes (involving ligands other than carbonyls) with selenoether and telluroether coordination are rare.[4–7] Abel and Orrell and co-workers have reported some such species based upon $PtMe_3X$ (X = Cl, Br or I) as part of their extensive investigation of the solution dynamics in complexes with dichalcogenoether ligands, in order to understand the fluxional processes occurring and to establish the invertomer populations.[8] However, the reaction chemistry of alkyl(chalcogenoether)transition-metal species has not been investigated. The only examples of dimethyl(chalcogenoether)-$Pt^{II}$ complexes are those involving the $E(CH_2CH{=}CH_2)_2$ ligands (E = S, Se), in which both the chalcogen atom and the alkene functions are coordinated to Pt at low temperature.[9] The preparation of $[PtMeBr\{MeSe(CH_2)_2SeMe\}]$ has also been described.[10]

Here we describe the syntheses and spectroscopic characterisation of a series of methylplatinum(II) and methylplatinum(IV) complexes involving a selected range of acyclic di- and triseleno- and telluroether ligands and macrocyclic selenoethers incorporating between two and four chalcogen atoms and containing a range of linkages between the chalcogen atoms. The $^1H$, $^{13}C\{^1H\}$, $^{77}Se\{^1H\}$, $^{125}Te\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR shifts and coupling constants are discussed and the crystal structure of $[PtMe_3I\{o\text{-}C_6H_4(CH_2SeMe)_2\}]$ described, together with some reaction chemistry.

## Results and Discussion

### Platinum(II) Complexes

Initial attempts to prepare the dimethyl(selenoether)$Pt^{II}$ complexes by treatment of $[PtMe_2(cod)]$ (cod = 1,5-cyclooctadiene) with the ligand in refluxing $CHCl_3$ failed. The $^1H$ NMR spectra of the products show that displacement of the cod is not achieved cleanly, presumably owing to the

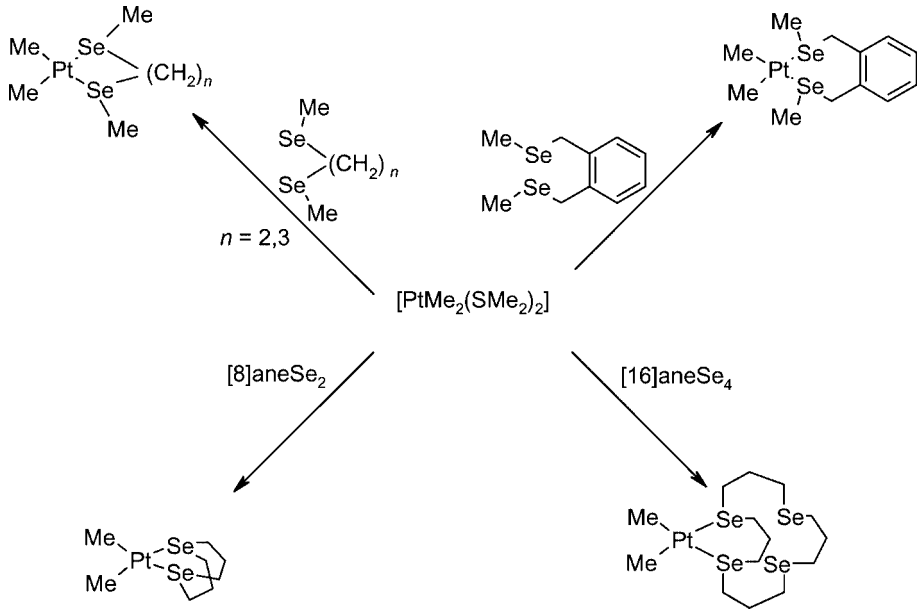
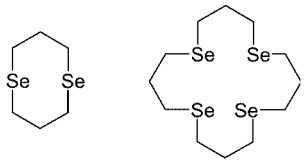


Scheme 1. Synthesis of dimethyl$Pt^{II}$ complexes (note that only one of the possible stereoisomers is shown in each case).

strong σ-donor properties of the Me ligands which occupy the coordination sites *trans* to the cod. However, the (selenoether)$Pt^{II}$ species $[PtMe_2(L\text{-}L)]$ (L-L = $MeSe(CH_2)_nSeMe$, $n$ = 2 or 3, *o*-$C_6H_4(CH_2SeMe)_2$, [8]$aneSe_2$ or [16]$aneSe_4$) were successfully prepared (Scheme 1) by initially treating $[PtCl_2(Me_2S)_2]$ with two mol. equivs. of MeLi in cold $Et_2O$ solution (–78 °C), followed by hydrolysis with water to give $[PtMe_2(SMe_2)_2]$ in situ. Addition of one mol. equiv. of the selenoether to this two-phase mixture and stirring at room temperature gave the products either as solutions in the $Et_2O$ or as yellow solids at the interface. Treatment of [16]$aneSe_4$ with two mol. equivs. of the (dimethyl)$Pt^{II}$ source under these conditions also yielded the 1:1 species $[PtMe_2([16]aneSe_4)]$, hence the product appears to be independent of the ratio used (although this may be a result of the poor solubility of the 1:1 complex which precipitates from the solution and may prevent further complexation to a second $PtMe_2$ unit). The compounds were characterised thoroughly by spectroscopic methods (IR, electrospray MS and variable temperature multinuclear NMR spectroscopy – see Table 1) and microanalysis. On the basis of the *m*/*z* values and the isotopic distributions observed, the electrospray MS show the highest mass peaks corresponding to $[PtMe(L\text{-}L)]^+$ in each case. Attempts to isolate a pure complex from reaction of $[PtMe_2(Me_2S)_2]$ with the $MeSeCH_2SeMe$ under similar conditions were not successful.



[8]$aneSe_2$ [16]$aneSe_4$

The $^1H$ NMR spectra of $[PtMe_2\{MeSe(CH_2)_nSeMe\}]$ ($n$ = 2 or 3) are consistent with fast pyramidal inversion occurring in chloroform solution at room temperature. Cooling to 223 K reveals sharp resonances associated with both the *meso* and DL forms of the complexes being present in unequal amounts, resulting in two sets of PtMe, SeMe and $SeCH_2$ resonances. Similar behaviour is seen by both $^{13}C\{^1H\}$ and $^{77}Se\{^1H\}$ NMR spectroscopy (Table 1). When recorded at 223 K, the $^{77}Se$ NMR spectra show two distinct Se resonances to high frequency of the uncoordinated selenoether, with $^{195}Pt$ couplings of ca. 420–460 Hz. The relative intensities of the $^{77}Se\{^1H\}$ resonances for $[PtMe_2\{MeSe(CH_2)_2SeMe\}]$ are ca. 1:2, i.e. rather disparate quantities of the *meso* and DL forms, whereas a ratio of ca. 1:1 occurs for $[PtMe_2\{MeSe(CH_2)_3SeMe\}]$. The $^{195}Pt$ NMR spectra (223 K) show resonances for both stereoisomers at approximately –4400 ppm. These resonances are significantly to low frequency of the corresponding $[PtCl_2\{MeSe(CH_2)_nSeMe\}]$, reflecting the better σ-donating properties of the Me ligands.

In separate work we have established that incorporation of the *o*-xylyl linkage in a range of ligand types (diphosphane, distibane, ditelluroether) leads to an increased tendency towards *cis*-chelation compared to aliphatic $C_4$-linked analogues. Therefore, despite the seven-membered ring chelate, these turn out to be very effective ligands for a range of transition-metal ions. We have also reported recently the first series of (alkyl)$Pt^{II}$ and (alkyl)$Pt^{IV}$ complexes involving stibane ligands of this type.[11,12] Furthermore, complexes involving *o*-xylyl-linked wide-angle diphosphanes provide very efficient catalysts for a range of processes such as hydroformylation and hydrocyanation.[13] A number of macrocyclic thioether and selenoethers containing *o*-xylyl linkages have also been reported.[2] We were

[a] The temperature quoted is that required to clearly resolve the invertomers (see text). [b] Spectra not obtained due to very poor solubility. [c] Coordinated Se. [d] Uncoordinated Se.

therefore interested to investigate the chemistry of *o*-xylyl-linked ligands in this work. Using the wide-angle diselenoether ligand $o\text{-}C_6H_4(CH_2SeMe)_2$ in the procedure described above gives the seven-membered chelate complex $[PtMe_2\{o\text{-}C_6H_4(CH_2SeMe)_2\}]$ in good yield. For square planar $[PtMe_2(L–L)]$ (L–L = bidentate chalcogenoether) two NMR distinguishable forms arise from the chirality at the coordinated chalcogen atom (*meso* and DL). The incorporation of the xylyl linker (which lies out of the square plane) may give rise to further invertomers depending upon the orientation of the SeMe groups with respect to the xylyl backbone. In our recent work on xylyl distibane complexes[11,12] several different conformations of the backbone were identified crystallographically, which serve to illustrate the effect of the backbone. The VT NMR spectroscopic data confirm *cis*-chelation in $[PtMe_2\{o\text{-}C_6H_4(CH_2SeMe)_2\}]$, with two invertomers clearly identifiable, one of which, the DL form, results in two $\delta(^{77}Se)$ resonances of equal intensity (each with $^{195}Pt$ satellites) and one $\delta(^{195}Pt)$ resonance. The other major form is attributed to a *meso*-1 form [one $\delta(^{77}Se)$ and one $\delta(^{195}Pt)$].

The $Pt^{II}$ complexes of the cyclic selenoethers were less soluble, although $[PtMe_2([8]aneSe_2)]$ dissolved in DMF, enabling $^1H$, $^{13}C\{^1H\}$, $^{77}Se\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR spectra to be obtained. The $[PtMe_2([16]aneSe_4)]$ was much less soluble and hence only the $^1H$ NMR spectroscopic data were obtained for this compound, although the formulation was supported by microanalysis and positive ion electrospray MS measurements. The $^1H$ NMR spectra of these cyclic selenoether complexes show resonances associated with coordinated selenoether as well as a singlet around 0.5 ppm due to the Pt–Me groups. The Pt–H couplings (≈ 80 Hz) are in agreement with the expected values. For $[PtMe_2([8]aneSe_2)]$, the $\delta(^{13}C)$ for the Me groups is a singlet at $\delta$ = –7.6 ppm with $^{195}Pt$ satellites (794 Hz). The $^{77}Se$ NMR spectrum is a singlet at 140.8 ppm, thus there is only a very small shift from "free" $[8]aneSe_2$ ($\delta$ = 138 ppm) upon coordination, although the appearance of clear coupling to $^{195}Pt$ ($^1J_{PtSe}$ = 323 Hz) unambiguously confirms the assignment. This compares to $\delta(^{77}Se)$ of 194 ppm ($^1J_{PtSe}$ = 680 Hz) for the corresponding dichloro species $[PtCl_2([8]aneSe_2)]$,[14] consistent with replacement of the chloro ligands with

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

strong σ-donor Me groups which have a much greater *trans* influence and hence substantially reduce the Pt–Se coupling constants. The $^{195}$Pt NMR shift for [$PtMe_2$([8]ane$Se_2$)], –4325 ppm, also compares with a value of –3825 ppm for [$PtCl_2$([8]ane$Se_2$)], reflecting the incorporation of the much stronger σ-donating Me ligands in the former. We note that the cyclic structure of the [8]ane$Se_2$ ligand eliminates the possibility of stereoisomers, hence only one form of the complex is evident. All of the dimethyl(selenoether)$Pt^{II}$ complexes are rather unstable – the solids deteriorate with significant darkening of the powders over a period of days to weeks even when stored under $N_2$. Solutions in chlorocarbons are even less stable, and substantial sample degradation was clearly evident from the NMR spectra recorded after standing in solution for a few hours. Data quoted were therefore recorded from freshly prepared samples.

Attempts to prepare analogous dimethyl(ditelluroether)-$Pt^{II}$ complexes by reaction of [$PtCl_2(SMe_2)_2$] with MeLi in situ, followed by hydrolysis and addition of either $MeTe(CH_2)_3TeMe$ or *o*-$C_6H_4(CH_2TeMe)_2$ gave dark brown, poorly soluble materials which were not the desired species. We also investigated reaction of isolated [$PtMe_2(SMe_2)_2$] with ditelluroether in anhydrous $Et_2O$ both at room temperature and low temperature. These reactions yielded orange/brown materials whose NMR spectra show clear evidence for TeMe units, but no PtMe groups. The electrospray mass spectra from these reaction show common features consistent with diplatinum compounds involving TeMe ligands, strongly indicating significant Te–C bond fission occurs in these reactions.

### Platinum(IV) Complexes

Freshly prepared solutions of the $Pt^{II}$ complexes [$PtMe_2${*o*-$C_6H_4(CH_2SeMe)_2$}] and [$PtMe_2${$MeSe(CH_2)_3$-SeMe}] in $CH_2Cl_2$ were stirred overnight with excess MeI, giving light yellow solids after work-up. The $^1$H and $^{77}$Se{$^1$H} NMR spectra of solutions of these products show that oxidative addition of MeI occurs cleanly, with complete conversion of the $Pt^{II}$ complexes to [$PtMe_3$I{*o*-$C_6H_4(CH_2SeMe)_2$}] and [$PtMe_3$I{$MeSe(CH_2)_3SeMe$}] respectively.

Six-coordinate trimethyl $Pt^{IV}$ complexes with both selenoether and telluroether ligands, [$PtMe_3$I(L-L)] [L-L = *o*-$C_6H_4(CH_2EMe)_2$; E = Se or Te], were obtained in good yield as soluble yellow/orange powdered solids through reaction of $PtMe_3$I with one mol. equiv. of L-L in refluxing $CHCl_3$ (Scheme 2). Surprisingly, these $Pt^{IV}$ compounds are much more stable both as solids and in solution than the $Pt^{II}$ species described above. The formulations follow from variable temperature $^1$H, $^{13}$C{$^1$H}, $^{77}$Se{$^1$H}, $^{125}$Te{$^1$H} and $^{195}$Pt NMR spectroscopic studies, electrospray MS and microanalyses. For bidentate chalcogenoethers coordinated to $PtMe_3$I three NMR distinguishable diastereoisomers are possible (*meso*-1, *meso*-2 and a pair of NMR indistinguishable DL enantiomers – Scheme 3) depending upon the orientations of the Me substituents relative to both the iodo and methyl ligands on Pt. The fact that the planar aromatic unit in the *o*-$C_6H_4(CH_2EMe)_2$ complexes lies out of the $ME_2$ plane leads to further possible stereoisomers for these particular complexes. From the NMR studies we observe that the telluroether complex is undergoing relatively slow pyramidal inversion at 298 K compared to the selenoether analogue. Cooling the solution of [$PtMe_3$I{*o*-$C_6H_4(CH_2SeMe)_2$}] leads to the observation of two significant $\delta$($^{195}$Pt) NMR resonances, while four $\delta$($^{77}$Se) NMR resonances with $^{195}$Pt satellites are evident, albeit one of these is weak, indicating that one isomer (probably a rather sterically crowded *meso*-2 form) has a very low percentage population. Thus, the DL form gives rise to two $\delta$($^{77}$Se) resonances and the *meso* form gives one resonance. Figure 1 shows the low temperature $^{125}$Te{$^1$H} NMR spectrum of [$PtMe_3$I{*o*-$C_6H_4(CH_2TeMe)_2$}], which clearly shows the presence of three invertomers all in significant amounts.

The crystal structure of [$PtMe_3$I{*o*-$C_6H_4(CH_2SeMe)_2$}] (Figure 2) confirms a distorted octahedral coordination sphere at $Pt^{IV}$ derived from three facial Me groups, an iodo ligand and a chelating diselenoether, *d*(Pt–C) = 2.080(3)–2.114(4) Å, *d*(Pt–Se) = 2.5530(4), 2.5629(4) Å, *d*(Pt1–I) = 2.7663(3) Å. The seven-membered chelate ring gives rise to a Se1–Pt1–Se2 angle of 98.317(12)°, and somewhat longer Pt–Se bonds than in [$PtMe_3$I(MeSeCH=CHSeMe)] [2.525(4), 2.532(4) Å],[9] reflecting the considerable steric demands of the wide-angle diselenoether. The selenoether adopts a DL configuration in which the SeMe substituents lie on opposite sides of the $PtSe_2$ plane, and the aromatic ring is oriented towards the Me ligand opposite the sterically large iodo ligand.

Using the ditelluromethane ligand, $MeTeCH_2TeMe$, with two mol. equivs. of $PtMe_3$I gives the dinuclear [($PtMe_3I)_2$-($MeTeCH_2TeMe$)] in good yield. The spectroscopic data are in full accord with a diiodo-bridged species in which the telluroether also bridges between the Pt atoms, i.e. [$Me_3Pt(\mu^2$-I)$_2(\mu^2$-$MeTeCH_2TeMe)PtMe_3$], which leads to two NMR distinguishable invertomers.

In order to investigate the effect of ligand architecture further, reactions were also conducted using the cyclic selenoethers [8]ane$Se_2$ and [16]ane$Se_4$, as well as the tripodal $MeC(CH_2SeMe)_3$. The distorted octahedral (trimethyl)$Pt^{IV}$ complexes, [$PtMe_3$I([8]ane$Se_2$)] and [$PtMe_3$I([16]ane$Se_4$)] were obtained in good yield by treatment of [$PtMe_3$I] with one molar equivalent of the cyclic selenoether in refluxing $CHCl_3$. The products were characterised by IR and multinuclear NMR spectroscopy, electrospray MS and microanalyses and represent the first examples of alkyl $Pt^{IV}$ complexes with (macro)cyclic selenoether coordination. The electrospray MS show clusters of peaks with the correct *m*/*z* and isotope patterns for [$PtMe_3$(L)]$^+$ (L = [8]ane$Se_2$ or [16]-ane$Se_4$). For the [8]ane$Se_2$ complex an additional cluster of peaks corresponding to [PtMe([8]ane$Se_2$)]$^+$ is also clearly evident, presumably a result of facile reductive elimination of ethane from the parent complex in the MS experiment. The NMR spectroscopic data for these species are also summarised in Table 1. The presence of three mutually *fac*

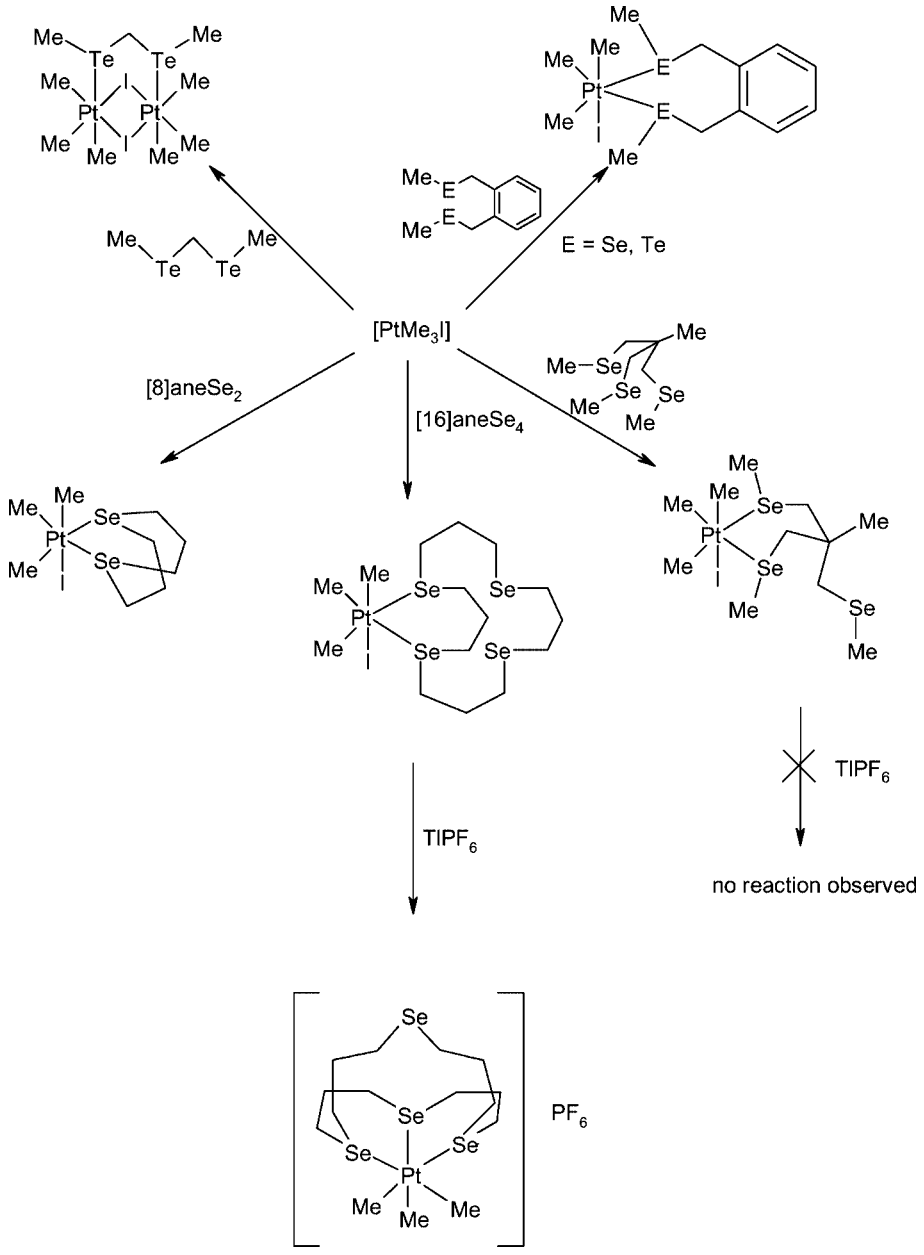
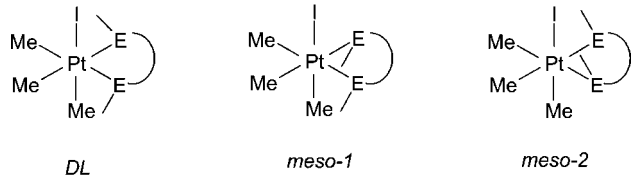


Scheme 2. Synthesis of (trimethyl)$Pt^{IV}$ complexes (note that only one of the possible stereoisomers is shown in each case).



Scheme 3. Diasteroisomers for [$PtMe_3I$(L–L)] (L–L = bidentate dichalcogenoether). Note that the planar phenylene unit present in the xylyl derivatives leads to further stereoisomers depending upon its orientation with respect to the rest of the molecule.

Me groups was confirmed by the $^1H$ and the $^{13}C\{^1H\}$ NMR spectra which show two Me singlets in a 1:2 ratio at low frequency, each with $^{195}Pt$ satellite couplings as expected. The Me group *trans* to I is to low frequency of Me *trans* to Se, as observed for the small number of known examples of (trimethyl)$Pt^{IV}$ complexes with acyclic diselenoethers, and the Pt–H and Pt–C couplings are in also in accord.[7] For [$PtMe_3I$([8]ane$Se_2$)] we find that the coupling constants are consistently smaller than for the planar [$PtMe_2$([8]ane$Se_2$)] described above, as expected based upon the different coordination environments. The absence of axial symmetry in the $Pt^{IV}$ compounds leads to inequivalencies in the macrocyclic $CH_2$ environments, giving rise to four distinct $\delta(CH_2)$ resonances in the $^{13}C\{^1H\}$ NMR spectrum for the [8]ane$Se_2$ complex. For [$PtMe_3I$([16]ane$Se_4$)] seven $\delta(CH_2)$ resonances are clearly evident, consistent with bidentate coordination of the tetraselenoether ligand, giving a six-coordinate $Pt^{IV}$ species with a vertical plane of symmetry. The $^{77}Se$ NMR shifts for the $Pt^{IV}$ species are

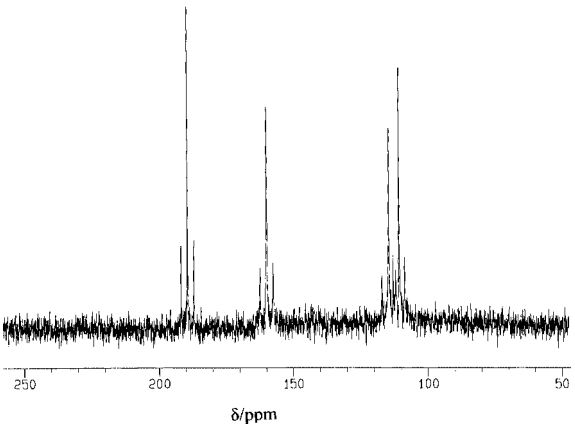

Figure 1. $^{125}Te\{^1H\}$ ($CH_2Cl_2/CDCl_3$, 243 K) spectrum of $[PtMe_3I\{o\text{-}C_6H_4(CH_2TeMe)_2\}]$ showing the presence of all three invertomers.

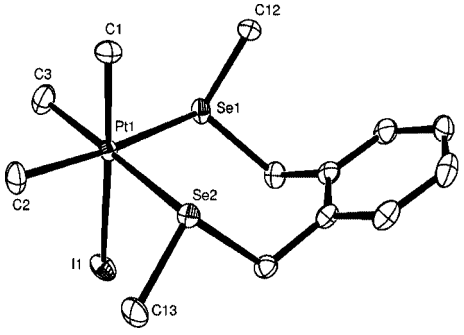

Figure 2. View of the crystal structure of $[PtMe_3I\{o\text{-}C_6H_4(CH_2SeMe)_2\}]$ with numbering scheme adopted. Ellipsoids are drawn at the 50% probability level and H atoms are omitted for clarity.

substantially to low frequency of the "free" ligand values, and surprisingly even the resonance arising from the two uncoordinated Se atoms of the $[16]aneSe_4$ ring is also some 40 ppm to low frequency of $[16]aneSe_4$ itself. This suggests that the presence of the (trimethyl)$Pt^{IV}$ fragment bound to the other two Se atoms significantly influences the electronic environment at the remote, "free" Se atoms – this may suggest that the uncoordinated Se atoms lie near to the iodo ligand.

As with all of the compounds in this study, $^{195}Pt$ NMR spectroscopy in principle provides an excellent and convenient direct probe of the electronic environment at platinum. Each of the $Pt^{IV}$ compounds shows a single resonance at ca. –3600 ppm, to high frequency of that for the planar $[PtMe_2([8]aneSe_2)]$ above. The macrocycle ring size has very little influence on the $^{195}Pt$ chemical shift. These compare with values of –3458 and –3530 ppm for the *meso*-1 and DL forms of $[PtMe_3I\{MeSe(CH_2)_3SeMe\}]$.[7]

Treatment of $[PtMe_3I(\kappa^2\text{-}[16]aneSe_4)]$ with one mol. equiv. of $TlPF_6$ in $CHCl_3$ results in clean abstraction of the iodo ligand, giving $[PtMe_3([16]aneSe_4)]PF_6$, as a white solid. This is the first cationic (alkyl)$Pt^{IV}$ complex with selenoether coordination. Electrospray MS shows intense peaks for the parent $[PtMe_3([16]aneSe_4)]^+$ cation, with lower intensity peaks corresponding to $[PtMe([16]aneSe_4)]^+$, i.e. loss of two Me groups (Figure 3). The generation of a $Pt^{IV}$ cation involving a *fac*-octahedral $Me_3Se_3$ donor set is confirmed by NMR spectroscopy. Although the cation still has $C_s$ local symmetry at $Pt^{IV}$, thus giving rise to two $\delta(^1H)$ and $\delta(^{13}C)$ resonances, this time both the chemical shift values and the Pt–H and Pt–C couplings are similar as the Me ligands are all *trans* to Se. The $^{13}C\{^1H\}$ and $^{77}Se\{^1H\}$ NMR spectra for this cation–anion system show only very broad resonances at room temperature. Upon cooling the sample to 223 K, the spectra sharpen. The dynamic process probably involves "ring-whizzing", resulting in rapid interchange between the "free" and coordinated Se atoms. Abel and coworkers proposed a similar mechanism for the thioether complex $[PtMe_3(\kappa^3\text{-}[12]aneS_4)]^+$ ([12]aneS$_4$ = 1,4,7,10-tetrathiacyclododecane).[15] The occurrence of a $\kappa^3$-bonding mode for $[16]aneSe_4$ is very unusual, the only other known examples are in the carbonyl complexes *fac*-$[M(CO)_3(\kappa^3\text{-}[16]aneSe_4)]^+$ (M = Mn or Re) and *fac*-$[M'(CO)_3(\kappa^3\text{-}[16]aneSe_4)]$ (M′ = Mo or W).[16] At 223 K the $^{77}Se\{^1H\}$ NMR spectrum for $[PtMe_3([16]aneSe_4)]PF_6$ reveals two Se environments at 70 (coordinated Se) and 138 ppm ("free" Se), once again these are both to low frequency of $[16]aneSe_4$ itself ($\delta$ =158 ppm). Replacement of the iodo ligand with a third Se atom leads to a small change in the $^{195}Pt$ NMR spectrum, which is now a singlet at $\delta$ = –3648 ppm. The only other examples of $Pt^{IV}$ complexes involving $[16]aneSe_4$ are the *trans*-$[PtX_2([16]aneSe_4)](PF_6)_2$ (X = Cl or Br) which we have described previously, obtained by halogen oxidation of the planar $[Pt([16]aneSe_4)](PF_6)_2$.[17] Spectroscopic studies of the yellow material obtained following treatment of the dicationic $Pt^{II}$ species, $[Pt([16]aneSe_4)](PF_6)_2$ with excess MeI in either refluxing $CH_2Cl_2$ or acetone solution showed no evidence for oxidative addition of the MeI, contrasting with the halogen oxidation described above.

The successful preparation of the cationic $[PtMe_3([16]aneSe_4)]^+$ with an unusual $Me_3Se_3$ donor set prompted us to investigate the chemistry of the tripodal $MeC(CH_2SeMe)_3$ with $[Me_3PtI]$. The preparation of $[PtMe_3I\{MeC(CH_2SeMe)_3\}]$ was achieved in good yield and the product was characterised by electrospray MS, microanalysis, IR and VT multinuclear NMR spectroscopy. The data are consistent with bidentate coordination of the tripod selenoether at the distorted octahedral $Pt^{IV}$ centre. For $[PtMe_3I\{\kappa^2\text{-}MeC(CH_2SeMe)_3\}]$ at room temperature both the $^1H$ and $^{77}Se\{^1H\}$ NMR spectra were broad and ill-defined. Upon cooling the sample to 223 K, the $^1H$ NMR resonances are sharp and several Pt–Me resonances are clearly evident, consistent with the presence of several invertomers (*meso*-1, *meso*-2 and DL forms, with further isomers arising depending upon the orientation of the uncoordinated arm either towards the iodo ligand or towards a Me group), and the presence of both coordinated and "free" SeMe groups. The mixture of invertomers, together with the low symmetry of the molecule make it very difficult to assign the spectra in detail. The structurally simpler (but spectroscopically still rather complicated)

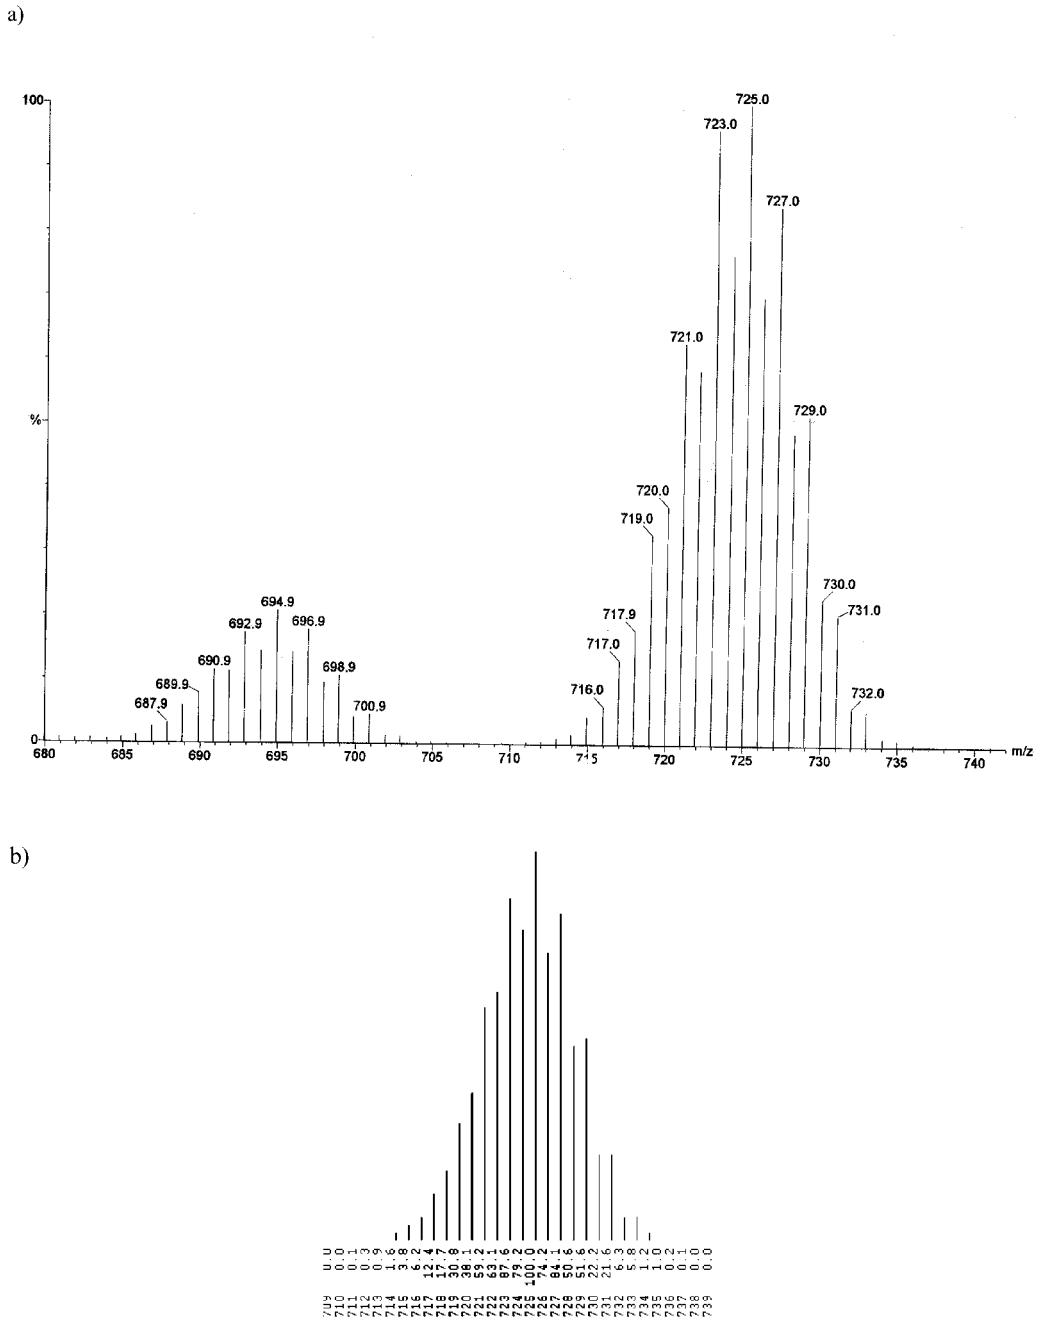

Figure 3. a) Positive ion electrospray MS (MeCN) of $[PtMe_3([16]aneSe_4)]PF_6$ (the cluster of peaks centred at $m/z$ = 725 corresponds to $[PtMe_3([16]aneSe_4)]^+$, while that centred at $m/z$ = 695 corresponds to $[PtMe([16]aneSe_4)]^+$). b). Simulated isotope pattern for $[PtMe_3([16]aneSe_4)]^+$.

$[PtMe_3X\{MeE(CH_2)_nEMe\}]$ ($n$ = 2 or 3) systems have been studied in detail by Abel and co-workers by VT NMR spectroscopy and band-shape analysis.[6–8] However, the identity of the complex as $[PtMe_3I\{\kappa^2\text{-}MeC(CH_2SeMe)_3\}]$ is not in doubt.

At 223 K the $^{13}C\{^1H\}$ NMR spectrum of $[PtMe_3I\{\kappa^2\text{-}MeC(CH_2SeMe)_3\}]$ is extremely complicated owing to the presence of varying amounts of the possible invertomers, the low symmetry of the complexes and the fact that the C atoms of the Pt–Me units occur in the same region of the spectrum as the SeMe groups of the uncoordinated arm of the tripod, resulting in overlapping resonances which are not readily assigned.

The observation of three $^{195}Pt\{^1H\}$ NMR resonances at ca. –3500 ppm at 223 K is consistent with the presence of three significant, NMR distinguishable invertomers. The $^{77}Se\{^1H\}$ NMR spectrum at 223 K is also very complex, revealing three coordinated Se environments in the range 49–53 ppm, each with $^{195}Pt$ satellites, three further coordinated Se environments in the range 37–39 ppm with satellites, and four resonances in the range 27–35 ppm which show no $^{195}Pt$ coupling and hence are attributed to the Se

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atoms of the uncoordinated arm of the tripod selenoether [$\delta(^{77}Se)$ for $MeC(CH_2SeMe)_3$: +24]. These data strongly suggest that the orientation of the uncoordinated arm of the tripod (either towards the iodide or towards the Me group *trans* to I) are also distinguishable by NMR spectroscopy.

Attempts to promote tridentate selenoether coordination to give $[PtMe_3\{MeC(CH_2SeMe)_3\}]^+$ through treatment of the bidentate complex with $TlPF_6$ either in refluxing MeCN or $CHCl_3$ were not successful. The NMR spectra of the resulting solutions show that $[PtMe_3I\{MeC(CH_2SeMe)_3\}]$ is still the only significant species after the reaction. This suggests that the tripodal $Se_3$-donor ligand is not well-suited to facial coordination on the small trimethylPt$^{IV}$ fragment. The different reactivities of the Pt$^{IV}$ complexes containing the tripodal $Se_3$-donor ligand compared to that containing the macrocyclic selenoether may be due to the different constraints of the two ligands and the different ring-strain effects.

It has been shown that $[PtMe_3I(L–L)]$ (L–L = diphosphane or distibane)[18,12] undergo clean reductive elimination of ethane upon thermolysis. We have therefore probed the thermolysis of the $[PtMe_3I\{o\text{-}C_6H_4(CH_2EMe)_2\}]$ complexes prepared in this work. The telluroether complex $[PtMe_3I\{o\text{-}C_6H_4(CH_2TeMe)_2\}]$ does not melt on heating, but undergoes decomposition at ≈ 130 °C giving a black solid. The corresponding Pt$^{IV}$ selenoether complex melts at ca. 150 °C and then darkens slowly as the temperature is increased, indicating the onset of decomposition. A solid sample of this complex was heated at ca. 160 °C for 1 h and the residue investigated by $^1H$ NMR spectroscopy, which revealed loss of the PtMe and SeMe resonances. Thus, it is clear that these species do not undergo clean reductive elimination under these conditions. This may be a consequence of the well-known susceptibility of group 16 ligands to undergo dealkylation.[1]

## Conclusions

We have developed routes for the synthesis of the first series of dimethyl(selenoether)Pt$^{II}$ complexes, as well as a range of trimethyl(selenoether)Pt$^{IV}$ complexes (including the first macrocyclic examples) and rare examples involving ditelluroethers. The Pt$^{IV}$ species are less reactive than the Pt$^{II}$ complexes, possibly due to the very strong ligand field imparted by the Me ligands in the Pt$^{IV}$ species, together with the fact that these compounds are coordinatively saturated, hence providing limited possibility for metal-assisted E–C bond fission (cf. the Pt$^{II}$ species). The donor type, ligand architecture and denticity clearly play major roles in determining the invertomer populations in these compounds. Using the macrocyclic [16]aneSe$_4$ we have been able to obtain the first cationic trialkyl(selenoether)Pt$^{IV}$, $[PtMe_3(\kappa^3\text{-}[16]aneSe_4)]^+$, whereas surprisingly this was not possible under similar conditions using the tripodal $MeC(CH_2SeMe)_3$. This may also be a consequence of the ligand architecture which for the tripodal $Se_3$ ligand results in low stability on the small Pt$^{IV}$ centre. The new dimethyl(selenoether)Pt$^{II}$ complexes, $[PtMe_2(L\text{-}L)]$, undergo clean and complete oxidative addition of MeI to afford the corresponding Pt$^{IV}$ species $[PtMe_3I(L\text{-}L)]$.

## Experimental Section

Infrared spectra were recorded as Nujol mulls between CsI plates with a Perkin–Elmer 983G spectrometer over the range 4000–200 cm$^{-1}$. Mass spectra were run by positive ion electrospray (MeCN solution) with a VG Biotech platform. $^1H$ NMR spectra were recorded with a Bruker AV300 spectrometer or Bruker DPX400 spectrometer. $^{13}C\{^1H\}$, $^{77}Se\{^1H\}$, $^{125}Te\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR spectra were recorded with a Bruker DPX400 spectrometer operating at 100.6, 76.3, 126.3 or 85.7 MHz, respectively, and are referenced to TMS, external neat $Me_2Se$, external neat $Me_2Te$ and external 1 mol·dm$^{-3}$ $Na_2[PtCl_6]$ in water, respectively. Microanalyses were undertaken by the University of Strathclyde microanalytical service. Solvents were dried prior to use, and all preparations were undertaken using standard Schlenk techniques under $N_2$. The precursors $[PtCl_2(Me_2S)_2]$[19] and $[PtMe_3I]$[20] were prepared by literature methods and the selenoethers and telluroethers were prepared as described previously.[21–24]

### Preparations

#### Pt$^{II}$ Compounds

**$[PtMe_2([8]aneSe_2)]$:** A 1.6 M solution of MeLi (0.2 mL, 0.32 mmol) in $Et_2O$ was slowly added to an ice-cold suspension of $[PtCl_2(SMe_2)_2]$ (0.050 g, 0.128 mmol) in 20 cm$^3$ dry $Et_2O$. After 5 min a further 0.1 mL MeLi (1.6 M in $Et_2O$, 0.16 mmol) were added and the solution was warmed to room temperature. After ca. 10 min the yellow colour disappeared and a white precipitate formed. At this stage 10 mL of $H_2O$ and 1 equiv. of [8]aneSe$_2$ (0.031 g, 0.128 mol) were added. The mixture was stirred for 2.5 h giving a beige precipitate which was filtered off and washed with $Et_2O$. The solid was then dissolved in $CH_2Cl_2$ (10 mL), filtered and the solvent was removed in vacuo. Yield 0.075 g, 64%. $C_8H_{18}PtSe_2$ (467.2): calcd. C 20.6, H 3.9; found C 21.3, H 4.2. Electrospray MS (MeCN): found 494, 453; calcd. for $[^{195}PtMe([8]ane^{80}Se_2)(MeCN)]^+$ *m*/*z* = 495, $[^{195}PtMe([8]ane^{80}Se_2)]^+$ 454. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 0.5 (s, $^2J_{PtH}$ = 82 Hz, 6 H, PtMe), 2.2 (m, 4 H, $CH_2CH_2CH_2$), 2.8 (m, 8 H, $SeCH_2$) ppm. $^{13}C\{^1H\}$ NMR (DMF/$[D_6]Me_2CO$, 298 K): $\delta$ = –7.6 ($^1J_{PtC}$ = 794 Hz, 2 C, PtMe), 24.0 (4 C, $SeCH_2$), 27.3 (2 C, $CH_2CH_2CH_2$) ppm. $^{77}Se\{^1H\}$ NMR (DMF/$[D_6]Me_2CO$, 298 K): $\delta$ = 140.8 ($^1J_{PtSe}$ = 323 Hz) ppm. $^{195}Pt$ NMR ($CH_2Cl_2$/$CDCl_3$, 298 K): $\delta$ = –4318 ppm.

**$[PtMe_2([16]aneSe_4)]$:** Method as above using [16]aneSe$_4$. Yellow solid. Yield 61%. $C_{14}H_{30}PtSe_4$ (709.3): calcd. C 23.7, H 4.3; found C 23.1, H 4.2. Electrospray MS (MeCN): found *m*/*z* = 695; calcd. for $[^{195}PtMe([16]ane^{80}Se_4)]^+$ *m*/*z* = 700. $^1H$ NMR (300 MHz, $[D_6]$-DMSO, 298 K): $\delta$ = 0.48 (s, $^2J_{PtH}$ = 81 Hz, 6 H, PtMe), 1.92 (m, 8 H, $CH_2CH_2CH_2$) 2.61 (t, 16 H, $SeCH_2$) ppm.

**$[PtMe_2\{MeSe(CH_2)_2SeMe\}]$:** Method as above using $MeSe(CH_2)_2SeMe$. Yellow solid. Yield 41%. $C_6H_{16}PtSe_2$ (441.2): calcd. C 16.3, H 3.7; found C 15.9, H 3.3. Electrospray MS (MeCN): found *m*/*z* = 468, 453, 426, 411; calcd. for $[^{195}PtMe\{Me^{80}Se(CH_2)_2{}^{80}SeMe\}(MeCN)]^+$ *m*/*z* = 469, $[^{195}Pt\{Me^{80}Se(CH_2)_2{}^{80}SeMe\}(MeCN)]^+$ 454, $[^{195}PtMe\{Me^{80}Se(CH_2)_2{}^{80}SeMe\}]^+$ 428, $[^{195}Pt\{Me^{80}Se(CH_2)_2{}^{80}SeMe\}]^+$ 413. $^1H$ NMR (400 MHz, $CDCl_3$, 273 K): $\delta$ = 0.72 (s, $^2J_{PtH}$ = 84 Hz, PtMe), 0.77 (s, $^2J_{PtH}$ = 85 Hz, PtMe), 2.16 (s, $^3J_{PtH}$ = 22 Hz, SeMe), 2.36 (s, $^3J_{PtH}$ = 21 Hz,

SeMe), 2.55–3.25 (m, 4 H, $SeCH_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 223 K): $\delta$ = –12.8 ($^1J_{PtC}$ = 760 Hz, PtMe), –12.6 ($J$ = 735 Hz, PtMe), 9.9, 11.1 (SeMe), 29.2, 29.5 ($SeCH_2$) ppm. $^{77}Se\{^1H\}$ NMR ($CDCl_3$, 223 K): $\delta$ = 247.9 (major form, $^1J_{PtSe}$ = 457 Hz), 250.1 (minor form, $J$ = 438 Hz) ppm. $^{195}Pt$ NMR ($CDCl_3$, 223 K): $\delta$ = –4383 (major), –4395 (minor) ppm.

**[$PtMe_2\{MeSe(CH_2)_3SeMe\}$]:** Method as above using $MeSe(CH_2)_3SeMe$. Beige solid. Yield 64%. $C_7H_{18}PtSe_2$ (455.2): calcd. C 18.5, H 4.0; found C 18.6, H 4.2. Electrospray MS (MeCN): found $m/z$ = 482, 466, 425; calcd. for $[^{195}PtMe\{Me^{80}Se(CH_2)_3{}^{80}SeMe\}(MeCN)]^+$ $m/z$ = 483, $[^{195}Pt\{Me^{80}Se(CH_2)_3{}^{80}SeMe\}(MeCN)]^+$ 468, $[^{195}PtMe\{Me^{80}Se(CH_2)_3{}^{80}SeMe\}]^+$ 427. $^1H$ NMR (400 MHz, $CDCl_3$, 248 K): $\delta$ = 0.51 (s, $^2J_{PtH}$ = 84 Hz, PtMe), 0.55 (s, $J$ = 84 Hz, PtMe), 2.20 (br., 2 H, $CH_2CH_2CH_2$), 2.31, 2.33 (s, 6 H, SeMe), 2.83, 2.99 (m, 4 H, $SeCH_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 223 K): $\delta$ = –8.9 ($^1J_{PtC}$ = 749 Hz, PtMe), –8.7 ($J$ = 748 Hz, PtMe), 10.5, 10.9 (SeMe), 26.0, 26.7, 27.6 ($CH_2$) ppm. $^{77}Se\{^1H\}$ NMR ($CDCl_3$, 223 K): $\delta$ = 114.0 ($^1J_{PtSe}$ = 427 Hz), 102.1 ($J$ = 429 Hz) ppm. $^{195}Pt$ NMR ($CDCl_3$, 223 K): $\delta$ = –4247 (major), –4309 (minor) ppm.

**[$PtMe_2\{o\text{-}C_6H_4(CH_2SeMe)_2\}$]:** Method as above using $o$-$C_6H_4(CH_2SeMe)_2$. Yellow solid. Yield 56%. $C_{12}H_{20}PtSe_2$ (517.3): calcd. C 27.9, H 3.9; found C 28.6, H 3.7. Electrospray MS (MeCN): found $m/z$ = 506; calcd. for $[^{195}PtMe\{o\text{-}C_6H_4(CH_2{}^{80}SeMe)_2\}]^+$ $m/z$ = 504. $^1H$ NMR (400 MHz, $CDCl_3$, 298 K): $\delta$ = 0.34 (s, $^2J_{PtH}$ = 83 Hz, 6 H, PtMe), 2.3 (s, 6 H, SeMe), 4.3 (br., 4 H, $SeCH_2$), 7.0–7.2 (br. m, 4 H, $o$-$C_6H_4$) ppm; (213 K): $\delta$ = 0.23 (s, $^2J_{PtH} \approx$ 80 Hz, PtMe), 0.25 (s, $J \approx$ 80 Hz, PtMe), 1.89, 2.21, 2.44 (s, SeMe), 3.8–5.0 (m, $SeCH_2$), 6.9–7.3 (m, 4 H, $o$-$C_6H_4$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 298 K): $\delta$ = –8.6 ($^1J_{PtC}$ = 779 Hz, PtMe), 11.0 (SeMe), 29.8 ($SeCH_2$), 126.0–134.5 ($o$-$C_6H_4$) ppm; (193 K): $\delta$ = –8.8 ($^1J_{PtC}$ = 760 Hz, PtMe), –8.3 (PtMe, $J$ = 751 Hz), –7.4 ($J$ = 763 Hz, PtMe), 10.3, 11.1, 13.2 (SeMe), 27.8, 28.6, 31.3 ($SeCH_2$), 127.4–134.6 ($o$-$C_6H_4$) ppm. $^{77}Se\{^1H\}$ NMR ($CDCl_3$, 298 K): $\delta$ = 171.6 ($^1J_{PtSe}$ = 520 Hz) ppm; (193 K): $\delta$ = 169.1 ($J$ = 526 Hz), 160.6 ($J$ = 492 Hz), 155.9 ($J$ = 438 Hz) ppm. $^{195}Pt$ NMR ($CDCl_3$, 298 K): $\delta$ = –4275; (193 K): $\delta$ = –4308, –4316 ppm.

**Platinum(IV) Compounds**

**[$PtMe_3I([8]aneSe_2)$]:** [$PtMe_3I$] (0.10 g, 0.27 mmol) was dissolved in $CHCl_3$ (10 mL). [8]$aneSe_2$ (0.068 g, 0.28 mmol) in $CHCl_3$ (10 mL) was added slowly. The pale yellow solution was refluxed for 7 h, then stirred at room temperature overnight. The solution was concentrated in vacuo to approximately 5 mL. Diethyl ether (10 mL) was added, producing a cream-coloured solid, which was collected by filtration, washed with diethyl ether and dried in vacuo. Yield 0.075 g, 45%. $C_9H_{21}IPtSe_2$ (609.2): calcd. C 17.7, H 3.4; found C 17.8, H 3.3. Electrospray MS (MeCN): found 494, 483, 453; calcd. for $[^{195}PtMe([8]ane^{80}Se_2)(MeCN)]^+$ 495, $[^{195}PtMe_3([8]ane^{80}Se_2)]^+$ 484, $[^{195}PtMe([8]ane^{80}Se_2)]^+$ 454. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 1.0 (s, $^2J_{PtH}$ = 71.8 Hz, 3 H, PtMe *trans* I), 1.6 (s, $J$ = 65.2 Hz, 6 H, PtMe *trans* Se), 2.1–3.4 (m, 12 H, $CH_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 3.5 ($^1J_{PtC}$ = 612 Hz, 1 C, PtMe *trans* I), 3.9 ($J$ = 674 Hz, 2 C, PtMe *trans* Se), 20.8 (2 C), 21.4 (2 C, $SeCH_2$), 22.5 (1 C), 26.8 (1 C, $CH_2CH_2$) ppm. $^{77}Se\{^1H\}$ NMR ($CDCl_3$, 298 K): $\delta$ = 65 ($^1J_{PtSe}$ = 244 Hz) ppm. $^{195}Pt$ NMR ($CDCl_3$): $\delta$ = –3589 ppm.

**[$PtMe_3I([16]aneSe_4)$]:** Method as above, but using [16]$aneSe_4$. Cream solid. Yield 59%. $C_{15}H_{33}IPtSe_4.CHCl_3$ (970.6): calcd. C 19.8, H 3.5; found C 19.4, H 3.8. Electrospray MS (MeCN): found 724; calcd. for $[^{195}PtMe_3([16]ane^{80}Se_4)]^+$ 728. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 1.15 (s, $^2J_{PtH}$ = 71.6 Hz, 3 H, PtMe *trans* I), 1.55 (s, 6 H, PtMe *trans* Se, $J$ = 66.5 Hz), 2.5–3.1 (m, 24 H, $CH_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 243 K): $\delta$ = 3.7 ($^1J_{PtC}$ = 619 Hz, 2 C, PtMe *trans* Se), 4.35 (1 C, PtMe *trans* I, 654 Hz), 22.1 (1 C), 22.7 (2 C, $SeCH_2$), 23.0 (2 C), 25.7 (2 C), 26.3 (2 C), 29.3 (2 C), 29.9 (1 C, $CH_2$) ppm. $^{77}Se\{^1H\}$ NMR ($CDCl_3$, 243 K): $\delta$ = 116.6 ($^1J_{PtSe}$ = 266 Hz, 1 Se), 119.5 (1 Se) ppm. $^{195}Pt$ NMR ($CDCl_3$, 243 K): $\delta$ = –3616 ppm.

**[$PtMe_3([16]aneSe_4)]PF_6$:** $TlPF_6$ (0.063 g, 0.18 mmol) was added to a solution of [$PtMe_3I$] (0.06 g, 0.163 mmol) and [16]$aneSe_4$ (0.079 g, 0.163 mmol) in $CHCl_3$ (8 mL). The reaction mixture was refluxed under $N_2$ for 2.5 h to give a fine yellow precipitate (TlI) and an almost colourless solution which was separated via cannula. After concentrating the solution in vacuo to ca. 2 mL, $Et_2O$ was added to give a white solid which was collected by filtration, washed with $Et_2O$ and dried in vacuo. Yield 0.049 g, 35%. $C_{15}H_{33}F_6PPtSe_4$ (869.3): calcd. C 20.7, H 3.8, found C 21.3, H 3.7. Electrospray MS (MeCN): found 725, 695; calcd. for $[^{195}PtMe_3([16]ane^{80}Se_4)]^+$ 728, $[^{195}PtMe([16]ane^{80}Se_4)]^+$ 698. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 1.06 (s, $^2J_{PtH}$ = 61 Hz, 3 H, PtMe), 1.13 (s, $J$ = 66 Hz, 6 H, PtMe), 1.8–3.3 (br. m, 24 H, $CH_2$) ppm. $^{13}C\{^1H\}$ NMR ($CH_2Cl_2$/$CDCl_3$, 298 K): very broad (223 K): $\delta$ = 2.4 ($^1J_{PtC}$ = 612 Hz, 1 C, PtMe), 3.0 ($J$ = 647 Hz, 2 C, PtMe), 22.3–29.1 ($CH_2$) ppm. $^{77}Se\{^1H\}$ NMR ($CDCl_3$, 298 K): no spectrum; (223 K): $\delta$ = 138 (1 Se), 70 ($^1J_{PtSe}$ = 249 Hz, 3 Se) ppm. $^{195}Pt$ NMR ($CH_2Cl_2$/$CDCl_3$, 298 K): $\delta$ = –3648 ppm. IR (Nujol): $\tilde{\nu}$ = 840 [$\nu(PF_6^-)$], 557 [$\delta(PF_6^-)$] $cm^{-1}$.

**[$PtMe_3I\{MeC(CH_2SeMe)_3\}$]:** Method as for [$PtMe_3I([16]aneSe_4)$] above, but using $MeC(CH_2SeMe)_3$. Yellow solid. Yield 63%. $C_{11}H_{27}IPtSe_3$ (718.2): calcd. C 18.4, H 3.8, found C 18.7, H 3.5. Electrospray MS (MeCN): found $m/z$ = 591, 561; calcd. for $[^{195}PtMe_3\{MeC(CH_2{}^{80}SeMe)_3\}]^+$ $m/z$ = 594; $[^{195}PtMe\{MeC(CH_2{}^{80}SeMe)_3\}]^+$ 564. $^1H$ NMR (400 MHz, $CDCl_3$, 298 K): very broad (223 K): $\delta$ = 0.9–1.6 (overlapping resonances, PtMe, CMe), 2.0–3.7 (overlapping resonances, SeMe and $SeCH_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 223 K): $\delta$ = 0.35–1.06 (s, PtMe *trans* I), 5.9–6.8 (s, PtMe *trans* Se), 7.8–12.4 (SeMe), 25.2–25.5 (MeC), 31.5–42.5 ($SeCH_2$) ppm. $^{77}Se\{^1H\}$ NMR ($CDCl_3$, 298 K): no spectrum; (223 K): $\delta$ = 53.0 ($^1J_{PtSe}$ = 252 Hz), 51.6 ($J$ = 160 Hz), 49.3 ($J$ = 258 Hz), 38.5 ($J$ = 252 Hz), 37.4 ($J$ = 162 Hz), 37.3 ($J$ = 256 Hz), 35.1, 33.0, 29.0, 27.3 (uncoordinated Se) ppm. $^{195}Pt$ NMR ($CDCl_3$, 223 K): $\delta$ = –3446, –3543, –3550 ppm.

**[$PtMe_3I\{o\text{-}C_6H_4(CH_2SeMe)_2\}$]:** Method as above, but using $o$-$C_6H_4(CH_2SeMe)_2$. Cream solid. Yield 75%. $C_{13}H_{23}IPtSe_2{\cdot}1/2Et_2O$ (696.3): calcd. C 25.9, H 4.0, found C 26.3, H 3.8. Electrospray MS (MeCN): found 533; calcd. for $[^{195}PtMe_3\{o\text{-}C_6H_4(CH_2{}^{80}SeMe)_2\}]^+$ 534. $^1H$ NMR (400 MHz, $CDCl_3$, 298 K): broad (223 K): $\delta$ = 0.90 (s, $^2J_{PtH}$ = 79 Hz, PtMe), 1.12 (s, $J$ = 70 Hz, PtMe), 1.20 (s, $J$ = 70 Hz, PtMe), 1.22 (s, $J$ = 70 Hz, PtMe), 1.36 (s, $J$ = 68 Hz, PtMe), 2.3 (sh), 2.55, 2.6 (sh, 6 H, SeMe), 3.9–5.2 (m, 4 H, $CH_2$), 7.05–7.45 (m, 4 H, $o$-$C_6H_4$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 298 K): broad (213 K): $\delta$ = 1.8 ($^1J_{PtC}$ = 628 Hz, PtMe), 2.6 ($J$ = 622 Hz, PtMe), 5.2 ($J$ = 616 Hz, PtMe), 5.85 ($J$ = 624 Hz, PtMe), 6.2 ($J$ = 660 Hz, PtMe), 13.7, 14.5, 14.69, 14.72 (SeMe), 27.7, 28.6, 34.3 (sh), 34.6 ($SeCH_2$), 126.8–139.9 ($o$-$C_6H_4$) ppm. $^{77}Se\{^1H\}$ NMR ($CDCl_3$, 298 K): not observed; (213 K): $\delta$ = 114.0 ($^1J_{PtSe}$ = 289 Hz) ppm; 98.7 ($J$ = 280 Hz), 97.8 ($J$ = 312 Hz), 95.5 ($J$ = 286 Hz) (minor isomer) ppm. $^{195}Pt$ NMR ($CDCl_3$, 298 K): not observed; (213 K): $\delta$ = –3382, –3468 (the minor isomer is not observed) ppm.

**[$PtMe_3I\{o\text{-}C_6H_4(CH_2TeMe)_2\}$]:** Method as above, but using $o$-$C_6H_4(CH_2TeMe)_2$. Orange solid. Yield 60%. $C_{13}H_{23}IPtTe_2{\cdot}1/2Et_2O$ (793.6): calcd. C 22.7, H 3.6, found C 23.1, H 3.5. Electrospray MS (MeCN): found 629; calcd. for $[^{195}PtMe_3\{o\text{-}C_6H_4(CH_2{}^{130}TeMe)_2\}]^+$

634. $^1$H NMR (400 MHz, $CDCl_3$, 298 K): broad (248 K): $\delta$ = 0.85–1.6 (s, PtMe), 2.1–3.1 (s, TeMe), 3.9–5.0 (m, 4 H, $CH_2$), 6.9–8.1 (m, 4 H, *o*-$C_6H_4$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 298 K): broad (243 K): $\delta$ = –12.45, –12.4, –6.7, –5.7 (TeMe), 1.8 ($^1J_{PtC}$ = 638 Hz, PtMe), 2.9 ($J$ = 635 Hz, PtMe), 3.9 ($J$ = 687 Hz, PtMe), 4.3 ($J$ = 607 Hz, PtMe), 7.3 ($J$ = 592 Hz, PtMe), 10.4, 12.4, 16.7, 16.9 ($TeCH_2$), 126.5–135.3 (*o*-$C_6H_4$) ppm. $^{125}Te\{^1H\}$ NMR ($CDCl_3$, 243 K): $\delta$ = 189.5 ($^1J_{PtTe}$ = 602 Hz) ppm; 159.9 ($J$ = 618 Hz), 114.5 ($J$ = 638 Hz), 110.8 ($J$ = 537 Hz) ppm. $^{195}$Pt NMR ($CDCl_3$, 298 K): not observed; (223 K): $\delta$ = –3968, –4022, –4119 ppm.

**[($PtMe_3I)_2$(MeTe$CH_2$TeMe)]:** Method as above, but using 0.5 mol. equivs. of MeTe$CH_2$TeMe. Orange solid. Yield 68%. $^1$H NMR (400 MHz, $CDCl_3$, 298 K): broad (248 K): $\delta$ = 1.06 (s, $^2J_{PtH}$ = 76 Hz, PtMe), 1.14 (s, $J$ = 72 Hz, PtMe), 1.16 (s, $J$ = 74 Hz, PtMe), 1.22 (s, $J$ = 76 Hz, PtMe), 2.06 (s, $J$ = 68 Hz, PtMe), 2.07 (s, $J$ = 68 Hz, PtMe), 2.01, 2.18 (s, TeMe), 4.46, 4.55 (m, $TeCH_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 298 K): broad (243 K): $\delta$ = –18.7 (major form, $TeCH_2$) –16.1 (minor form, $TeCH_2$), –8.5 (major form, TeMe), –7.95 (minor form, TeMe), 6.55 ($^1J_{PtC}$ = 670 Hz, PtMe), 7.0 ($J$ = 678 Hz, PtMe), 7.7 ($J$ = 600 Hz, PtMe), 7.8 ($J$ = 660 Hz, PtMe), 9.1 ($J$ = 607 Hz, PtMe) ppm. $^{125}Te\{^1H\}$ NMR ($CDCl_3$, 243 K): $\delta$ = 173.2 ($^1J_{PtTe}$ = 713 Hz) ppm. 171.1 ($J$ = 605 Hz) ppm. $^{195}$Pt NMR ($CDCl_3$, 223 K): $\delta$ = –3430 (major), –3451 (minor) ppm.

**X-ray Crystallography:** Selected bond lengths and angles for this species are presented in Table 2. Details of the crystallographic data collection and refinement parameters are given in Table 3. Yellow/orange single crystals of [$PtMe_3I${*o*-$C_6H_4(CH_2SeMe)_2$}] were obtained by diffusion of hexane into a solution of the complex in $CH_2Cl_2$. Data collection used a Nonius Kappa CCD diffractometer ($T$ = 120 K) and with graphite-monochromated Mo-$K_\alpha$ X-radiation ($\lambda$ = 0.71073 Å). Structure solution and refinement were routine.[25,26]

CCDC-609594 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 2. Selected bond lengths [Å] and angles [°] for [$PtMe_3I${*o*-$C_6H_4(CH_2SeMe)_2$}].

# Synthesis and Properties of Complexes of Vanadium(V) Oxide Trichloride with Nitrogen- and Oxygen-Donor Ligands

**Charlotte D. Beard,[a] Rosalind J. Barrie,[b] John Evans,[a] William Levason,*[a] Gillian Reid,[a] and Mark D. Spicer[b]**

**Keywords:** Vanadium / Coordination complexes / Multinuclear NMR spectroscopy

Intensely coloured, extremely moisture sensitive complexes $[VOCl_3(L)]$ (L = pyridine, quinoline, $Ph_3PO$, $Ph_3AsO$, pyridine *N*-oxide), $[VOCl_3(L)_2]$ (L = pyridine, $Me_3PO$, pyridine *N*-oxide), $[VOCl_3(L–L)]$ [L–L = 2,2′-bipyridyl, 1,10-phenanthroline, $Ph_2P(O)CH_2P(O)Ph_2$, $MeOCH_2CH_2OMe$, 15-crown-5 or $Me_2NCH_2CH_2NMe_2$] and $[Cl_3OV(\mu\text{-}L–L)VOCl_3]$ [L–L =18-crown-6 or $Ph_2P(O)CH_2P(O)Ph_2$] have been prepared from $VOCl_3$ and the appropriate ligands in dichloromethane solution. These constitute the first extended series of complexes of vanadium(V) with neutral donor ligands. They have been fully characterised by analysis, IR, UV/Visible and multinuclear ($^1H$, $^{31}P$, $^{51}V$) NMR spectroscopy, and their solution behaviour probed as a function of temperature using $^{51}V$ NMR spectroscopy. Reducing ligands including phosphanes, arsanes, thio- and selenoethers immediately reduce $VOCl_3$ to give $V^{IV}$ or $V^{III}$ species. Oxygen atom transfer reactions of some of the complexes with $Ph_3P$, $Ph_3As$, $Me_2Se$ and $Bu_2S$, leading to the corresponding ligand oxides are also described.

## Introduction

The chemistry of vanadium(V) is dominated by oxido species including $V_2O_5$, iso- and hetero-polyvanadates and alkoxides.[1] The only binary halide is $VF_5$; early claims for the existence of $VCl_5$ having been shown to be erroneous,[2] and there are three oxide trihalides $VOX_3$ (X = F, Cl or Br).[1] Adducts of $VOCl_3$ with a variety of neutral ligands have been explored by in situ $^{51}V$ NMR studies,[3–5] but structurally characterised examples are limited to the nitriles, $[VOCl_3(PhCN)_2]$ (octahedral, but with Cl/O disorder) and $[VOCl_3(RCN)]$ (R = Me, Ph, $PhCH_2$),[6–8] the surprisingly robust carbene $[VOCl_3\{(mes)N^aCH_2CH_2N(mes)\text{-}C^a(N^a–C^a)\}]$,[9] and $[VOCl_3(adamantan\text{-}2,2'\text{-}homoadamantan\text{-}3\text{-}one)]$,[10] all of which approximate to square pyramids with the V=O apical. In the six-coordinate $[VOCl_3\{(2\text{-}nitrophenyl)pyridine\text{-}2\text{-}carboxamide\}]$ the chlorines are *mer* and the V=O *trans* to the amide oxygen.[11] The isolation of other complexes has been reported from time to time,[12–17] but the data are very limited and frequently inconsistent. The problems arise both from the extreme moisture sensitivity of $VOCl_3$ and many of its complexes, and from the ease with which the vanadium is reduced to $V^{IV}$ or $V^{III}$. In passing, we note that $VOBr_3$ is reported to be reduced by all *neutral* ligands examined.[18,19] We are currently exploring the use of molecular high-valent vanadium complexes as single source CVD precursors, and to provide comparator compounds for that work we have investigated complexes of $VOCl_3$ with a range of neutral group 15 and 16 donor ligands. We have also explored the solution chemistry using $^{51}V$ NMR spectroscopy and investigated some oxygen atom transfer reactions of the resulting complexes. The chemistry of high-valent vanadium species is also of relevance to vanadium in biological systems such as the vanadate-dependent haloperoxidases most of which occur in marine organisms.[20]

## Results and Discussion

$VOCl_3$ is extremely easily hydrolysed, and all reactions were carried out in rigorously dried glassware using freshly dried ligands and solvents. Many of the complexes are also photochemically unstable and typically were stored in foil-wrapped containers in a dry-box. Even with these precautions, many of the solid samples deteriorate over a few days, hence all measurements were made on freshly prepared samples. Decomposition in solution is faster and, despite many attempts, X-ray quality crystals of the complexes have not proved to be obtainable. The two commonest products of hydrolysis are the dark red $[VOCl_4]^-$ and yellow $[VO_2Cl_2]^-$ anions,[21,22] which are readily detected by $^{51}V$ NMR spectroscopy [$^{51}V$:[23] 99.76%, I = 7/2, $\Xi$ = 26.29 MHz, $Q = -5.2\cdot10^{-30}$ m$^2$, $D_c$ (receptivity relative to $^{13}C$) = 2150], (Table 1). The $^{51}V$ chemical shift of the former is slightly solvent-dependent and lies in the range $\delta$ = +45 to +50 ppm, which is to high frequency of the resonances of

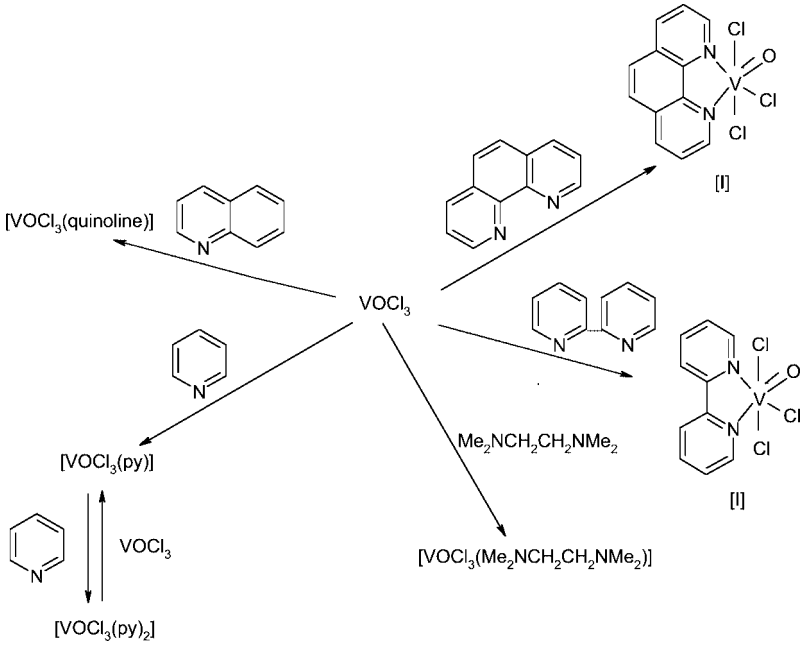
[a] Nujol mull. [b] $^{51}$V Chemical shift in $CH_2Cl_2$ solution at 298 K relative to neat $VOCl_3$, $w_{1/2}$ (Hz) in parenthesis. [c] Diffuse reflectance UV/Vis spectra. [d] See text. [e] Not obtained analytically pure, see text. [f] Insufficiently soluble.

the neutral complexes prepared in this study. The $[VO_2Cl_2]^-$ anion is relatively resistant to further hydrolysis and the $^{51}$V chemical shift ($\delta \approx -362$ ppm) is less solvent-dependent. It seems probable that resonances at ca. $\delta = -360$ to $-370$ ppm originally ascribed to oligomeric $\{VOCl_3L\}_n$ adducts in in situ studies,[4] are in fact due to hydrolysis to $[VO_2Cl_2]^-$. Reduction of $VOCl_3$ to blue-green $[VOCl_2L_n]$ species is also common in the presence of reducing ligands, but the $VO^{2+}$ species are easily identified by the presence of a strong, broad feature at ca. 12000–15000 cm$^{-1}$ in their UV/Visible spectra.[24]

**N-Donor Ligands** (Scheme 1): The reaction of $VOCl_3$ with 2,2′-bipyridyl or 1,10-phenanthroline (L–L), in anhydrous $CH_2Cl_2$ or toluene produced [$VOCl_3$(L–L)] in good yield, as diamagnetic, very dark red-brown powders. These two complexes are amongst the more stable simple adducts of $VOCl_3$, although even these solids decompose in a few weeks at room temperature, hydrolyse rapidly in air, and decompose quite rapidly in solution. The solids show strong υ(VO) bands at 978 and 973 cm$^{-1}$, respectively, and three strong features in the region 300–400 cm$^{-1}$ assigned as υ(VCl) (Table 1). In $VOCl_3$ complexes υ(VO) ranges from ca. 950–1040 cm$^{-1}$ and, comparing data only on structurally characterised compounds, the value falls from the four-coordinate $VOCl_3$ (1035 cm$^{-1}$), to five-coordinate [$VOCl_3$(RCN)], $[VOCl_4]^-$, [$VOCl_3${(mes)N$^a$$CH_2CH_2$N(mes)-C$^a$($N^a$–$C^\alpha$)}] (1025–1016 cm$^{-1}$), to six-coordinate [$VOCl_3(RCN)_2$] (below ca. 1000 cm$^{-1}$).[6–9,25,26] This is



Scheme 1.

clearly consistent with the two diimine complexes containing six-coordinate vanadium. In solution the $^1H$ NMR spectra show significant high-frequency shifts of the ring protons and the complex pattern (see Exp. Sect.) shows that the isomer present is the unsymmetrical I (see Scheme 1), rather than the isomer with both N atoms *trans* to Cl which would have given a maximum of four resonances of equal intensity for each complex. The $^{51}V$ NMR resonances are relatively sharp lines some 100 ppm to low frequency from $VOCl_3$ (Table 1). The UV/Visible spectra in anhydrous $CH_2Cl_2$ solution consist of strong broad features at ca. 21000 $cm^{-1}$ which are assigned as $\pi(Cl)\rightarrow V$ charge transfer, with several strong overlapping features at higher energy. The diffuse reflectance spectra are similar although the bands are broader and the first bands have weak shoulders to lower energy. Several attempts to produce crystals of the deep red 2,2′-bipy complex reproducibly formed a few very small orange crystals identified as the oxido-bridged dimeric hydrolysis product. The structure (Figure 1) consists of two six-coordinate V atoms linked through a bridging oxido group. The V–O2 distances favour an oxido rather than hydroxo bridge [compare the V–O(H) distance in $[VOCl_3(OH)]^-$ 2.033(4) Å[22]] leading to $V^V$ and on each V the two Cl atoms are in *trans* position. There are two molecules in the asymmetric unit which are very similar.[27] Several X-ray data sets were obtained from crystals grown both in Strathclyde and Southampton, and all showed the same rather poor crystal quality. The origin of this is probably related to the similarity of the triclinic cell to a monoclinic C-lattice cell and the occurrence of twinning, which was particularly marked for one data set.

Quinoline and $VOCl_3$ react in dry $CH_2Cl_2$ to form dark red $[VOCl_3(quinoline)]$ which has the $\upsilon(VO)$ at 1022 $cm^{-1}$ and $\upsilon(VCl)$ at 409, 375 and 330 $cm^{-1}$, the higher frequency of $\upsilon(VO)$ is in agreement with five-coordination at the vanadium centre based on the trends described above [if significant V=O···V interactions occur such that a six-coordinate oligomer description is appropriate $\upsilon(VO)$ would be much lower]. At ambient temperature the $^{51}V$ NMR spectrum is a broad ($w_{1/2}$ = 2500 Hz) line at $\delta$ = –39 ppm, which sharpens on cooling the solution, but with little change in the chemical shift. In contrast, the $VOCl_3$–pyridine system is more complicated and initial attempts to isolate reproducible materials from the reaction of $VOCl_3$ with pyridine in either a 1:1 or 1:2 molar ratio in anhydrous $CH_2Cl_2$ were unsuccessful. Using a 2:1 $VOCl_3$/py ratio led to red-brown $[VOCl_3(py)]$, whilst a 1:4 ratio gave $[VOCl_3(py)_2]$, but with stoichiometric ratios of the reagents only mixtures are produced. In this respect the pyridine systems seem to resemble the nitrile complexes.[6–8] The IR spectra show $\upsilon(VO)$ at 1020 and 978 $cm^{-1}$ for the 1:1 and 1:2 complexes, respectively (Table 1), consistent with assignment as five- and six-coordinate vanadium. The $\upsilon(VCl)$ modes in $[VOCl_3(py)_2]$ have a very similar pattern to those in $[VOCl_3(L–L)]$ (L–L = 2,2′-bipy or 1,10-phenanthroline) and strongly suggest the same isomer is present with *mer* chlorines and one pyridine ligand *trans* to Cl and the second *trans* to O. The diffuse reflectance spectra are similar, although the lowest energy feature in the 1:1 complex is at slightly lower energy than that of the 1:2 complex. It seems that the charge-transfer spectra are not suited to distinguishing reliably five- and six-coordination in these systems. The solution spectroscopic data obtained from either $[VOCl_3(py)]$ or $[VOCl_3(py)_2]$ are similar, consistent with equilibrium mixtures in solution. In particular, the $^{51}V$ NMR spectra show only single resonances for solutions of either complex, which vary with concentration and temperature. However, at –90 °C $CH_2Cl_2$ solutions of $[VOCl_3(py)_2]$ containing excess pyridine show a relatively sharp resonance at $\delta$ = –58 ppm, which broadens and drifts to higher frequency on warming. This is probably due to the 1:2 complex. Similarly, at –90 °C a $CH_2Cl_2$ solution of $[VOCl_3(py)]$ containing excess $VOCl_3$ shows two resonances at $\delta$ = –6 and –38 ppm, which broaden and then coalesce (–40 °C) on warming. These are tentatively attributed to $VOCl_3$ and $[VOCl_3(py)]$ respectively, although the lines are still broad, indicating that the low temperature limit has not been reached. However, further cooling results in precipitation of the complex. The reaction of $VOCl_3$ with amines was violent and generated considerable heat and decomposition. We were unable to obtain pure complexes with $Et_3N$ or $Et_2NH$, but adding a $CH_2Cl_2$ solution of $VOCl_3$ to a solution of $Me_2NCH_2CH_2NMe_2$ in $CH_2Cl_2$ frozen in liquid nitrogen, and slowly allowing the mixture to thaw, gave dark brown $[VOCl_3(Me_2NCH_2CH_2NMe_2)]$. The complex is very poorly soluble in chlorocarbons, preventing useful solution-phase spectroscopic data being obtained, but the IR and UV/Visible data (Table 1) are consistent with six-coordinate $V^V$.

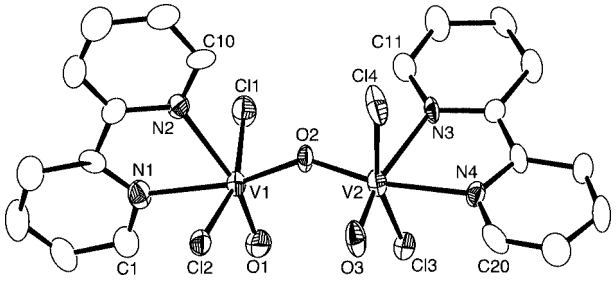

Figure 1. Structure of one of the two vanadium-containing molecules in the asymmetric unit of $[V_2Cl_4O_3(2,2'\text{-bipy})_2]\cdot 1.75CH_2Cl_2$. Displacement ellipsoids are drawn at the 50% probability level and H atoms omitted for clarity. Selected bond lengths [Å] and angles [°]: V1–Cl1 2.308(4); V1–Cl2 2.330(3); V1–O1 1.578(8); V1–N1 2.164(10); V1–N2 2.258(10); V1–O2 1.783(7); V2–Cl3 2.309(4); V2–Cl4 2.290(4); V2–O3 1.595(8); V2–N3 2.228(9); V2–N4 2.167(9); V2–O2 1.785(8); Cl1–V1–Cl2 163.6(2); N1–V1–N2 72.1(4); N1–V1–O2 163.0(4); N2–V1–O1 164.3(4); V1–O2–V2 145.8(5); Cl3–V2–Cl4 163.2(2); N3–V2–N4 72.7(4); N4–V2–O2 164.1(3); N3–V2–O3 164.8(4). The second molecule involving V3 and V4 has very similar bond lengths and angles.

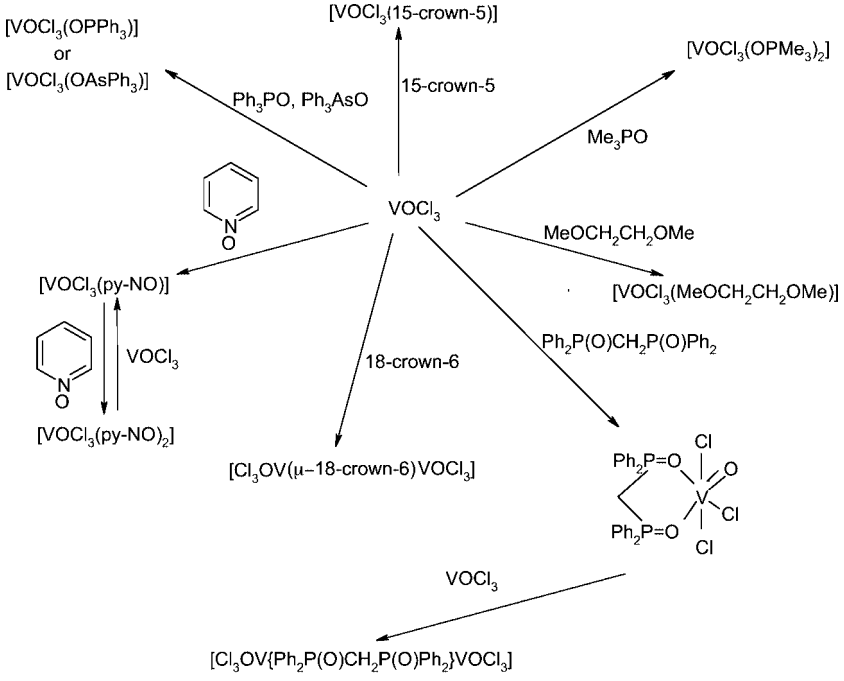
Comparison of the data above shows that adducts of $VOCl_3$ with nitrogen heterocycles form readily under anhydrous conditions. For the rigid chelates, 2,2′-bipyridyl and 1,10-phenanthroline, the complexes are six-coordinate, whilst for the bulky monodentate quinoline, five-coordina-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion is preferred. The formation of both 1:1 and 1:2 complexes with the smaller pyridine suggests that electronically the stability of the five- and six-coordinate complexes are similar. Paul et al.[16] reported dark brown $[VOCl_3(L)_3]$ (L = py, 1-, 2-, or 3-picoline, or quinoline), described as hygroscopic and insoluble in common solvents. We have been unable to reproduce these results, and the coordination of seven monodentate ligands to the small $V^V$ centre seems highly unlikely. The only examples of "seven-coordinate" $V^V$ are with small-angle chelates such as $[VO(NO_3)_3]$ or $[VO(S_2CNR_2)_3]$, or in "side-on" peroxido complexes.[1] The complexes described above are easily soluble in organic solvents, although some insoluble decomposition or hydrolysis products we have obtained include dark brown or sometimes green solids, which often show evidence of protonation of the heterocycle in the IR spectra.

**O-Donor Ligands** (Scheme 2): Reaction of excess $VOCl_3$ with 15-crown-5 and 18-crown-6 in $CH_2Cl_2$ under rigorously anhydrous conditions gave dark red-brown solutions from which removal of the solvent and excess $VOCl_3$ in vacuo, left very moisture sensitive, red-brown powders. The products were identified as $[VOCl_3(15\text{-crown-5})]$ and $[(VOCl_3)_2(18\text{-crown-6})]$ by analysis. Repeated attempts to obtain a pure complex with 12-crown-4 were unsuccessful. The presence of $V^V$ was confirmed by their diamagnetism, and by broad features in the UV/Visible spectra of both the solids and $CH_2Cl_2$ solution at ca. 21000 $cm^{-1}$ assigned as $(\pi)Cl\rightarrow V^V$ charge transfer, the absence of features to lower energy ruling out lower oxidation states of vanadium.[24] The IR spectra show broad, intense features in the regions between ca. 1100 and ca. 800 $cm^{-1}$ attributable to $(COC)_{asym}$ and $(COC)_{sym}$ vibrations, respectively, of the crowns. ν(VO) is assigned as the broad medium intensity features at 983 $cm^{-1}$ (15-crown-5) or 993 $cm^{-1}$ (18-crown-6) and ν(VCl) as overlapping bands at ca. 360–430 $cm^{-1}$. The compounds are extremely moisture sensitive and labile in solution. In rigorously dry $CD_2Cl_2$ the $^1H$ NMR spectra show singlet methylene resonances over the range +25 to –95 °C, indicating reversible ligand dissociation or "ring whizzing". The $^{51}V$ NMR spectrum of $[VOCl_3(15\text{-crown-5})]$ shows a single line at $\delta$ = –21 ppm and that of $[(VOCl_3)_2$-(18-crown-6)] a broad feature at $\delta$ = –6 ppm, both of which drift upfield on cooling the solutions, the effects reversing on warming to ambient temperatures. This is consistent with reversible dissociation on the vanadium NMR timescale, and from mixtures with added $VOCl_3$ we were unable to observe separate resonances for the complex and $VOCl_3$ even at –90 °C. The data are consistent with six-coordinate vanadium centres, with the $VOCl_3$ coordinated to two crown ether oxygen atoms. The behaviour of these complexes is reminiscent of the $[TiCl_4(crown)]$ systems,[28] although in these the exchange processes were slowed sufficiently at low temperatures for the different methylene environments to be observed in the $^1H$ NMR spectra, consistent with the stronger Lewis acidity of $TiCl_4$ compared with $VOCl_3$. Hydrolysis of the $V^V$ complexes with traces of water in chlorocarbon solvents produce $[VO_2Cl_2]^-$ $\delta(^{51}V)$ = –363 ppm, and the $^{51}V$ resonance of a $CH_2Cl_2$ solution of $[Ph_4As][VO_2Cl_2]$ is unshifted on adding 18-crown-6 showing no interaction with the crown in solution.

The acyclic ether, 1,2-bis(methoxy)ethane (dme) gave a dark red complex $[VOCl_3(dme)]$, which was also very labile in solution and deliquescent in the solid state. The very similar IR and $^{51}V$ NMR spectra of this complex (Table 1) to those of the two crown ethers is strong evidence for the $\kappa^2$-coordination of the crown proposed above.



Scheme 2.

The reaction of $VOCl_3$ with $Ph_3PO$ and $Me_3PO$ gave $[VOCl_3(Ph_3PO)]$ and $[VOCl_3(Me_3PO)_2]$ irrespective of the V/L ratio used. The former is a dark brown solid which exhibits υ(PO) at 1050 $cm^{-1}$ and υ(VO) at 1020 $cm^{-1}$, whilst the latter is dark red-brown and has υ(PO) at 1085 $cm^{-1}$ and υ(VO) at 952 $cm^{-1}$, the differences in υ(VO) suggesting these are five- and six-coordinate species, respectively. The dry solids are relatively resistant to hydrolysis and may be handled briefly in air, although in solution hydrolysis to chlorido-oxidovanadates occurs readily ($^{51}V$ NMR evidence). In solution the complexes exhibit large high-frequency coordination shifts in the $^{31}P\{^1H\}$ NMR spectra, consistent with coordination to a high-valent metal centre, and have $\delta(^{51}V)$ at –83 and –92 ppm, respectively. The observation of single $^1H$ and $^{31}P$ NMR resonances for $[VOCl_3(Me_3PO)_2]$ even at low temperatures, suggests a single isomer with equivalent phosphane oxides is present, and the single υ(PO) vibration tentatively suggests the $R_3PO$ groups are mutually *trans*. The corresponding reaction of $VOCl_3$ with $Ph_3AsO$ in $CH_2Cl_2$ produced an extremely moisture-sensitive dark red solid $[VOCl_3(Ph_3AsO)]$, which from its spectroscopic signature [υ(VO) at 1016 $cm^{-1}$, υ(AsO) at 803 $cm^{-1}$, $\delta(^{51}V)$ = –141 ppm] appears to be analogous to the $OPPh_3$ complex.

The diphosphane dioxide $Ph_2P(O)CH_2P(O)Ph_2$, reacts with 1 equiv. of $VOCl_3$ to form dark brown $[VOCl_3\{Ph_2P(O)CH_2P(O)Ph_2\}]$. In the solid state the complex exhibits bands at 1164 and 1080 $cm^{-1}$ assigned as υ(PO) and 970 υ(VO), suggesting a six-coordinate vanadium centre. In $CH_2Cl_2$ solution the complex is labile and exhibits a $^{31}P$ NMR resonance only on cooling, and at –70 °C the spectrum reveals doublets of equal intensity at $\delta$ = 48.2 and 34.5 ppm ($^2J$ = 12 Hz) ["free" $Ph_2P(O)CH_2P(O)Ph_2$ has $\delta(^{31}P)$ = 25 ppm]. The $^{51}V$ ($\delta$ = –81 ppm) resonance is broad ($w_{1/2}$ ca. 2500 Hz) at room temperature, and sharpens on cooling, although the chemical shift varies only slightly with temperature. The large difference in υ(PO) in the IR spectrum and the inequivalence of the phosphorus centres in solution strongly suggest the structure of this complex has the phosphinoyl groups *trans* to VO and VCl, respectively, and hence has *mer*-Cl atoms. Evaporation of a $CH_2Cl_2$ solution of $[VOCl_3\{Ph_2P(O)CH_2P(O)Ph_2\}]$ with excess $VOCl_3$ and pumping to dryness in vacuo, gave a second complex which was not obtained analytically pure, but which appears to be $[(VOCl_3)_2\{\mu\text{-}Ph_2P(O)CH_2P(O)Ph_2\}]$ with υ(PO) at 1094 $cm^{-1}$ and υ(VO) at 1023 $cm^{-1}$, and which from NMR studies was undergoing ligand exchange in solution even down to very low temperatures. The data show that like the pyridine systems above, the balance between five- and six-coordination in the phosphane oxide systems is subtle. In the case of the $Ph_2P(O)CH_2P(O)Ph_2/VOCl_3$ system the relative mismatch of the small vanadium centre and the large chelate bite in the six-membered ring is probably responsible for the dynamic behaviour in solution. Attempts to isolate a complex of $VOCl_3$ with the diphosphane dioxide $o\text{-}C_6H_4\{P(O)Ph_2\}_2$, which is both more rigid and sterically larger, were unsuccessful.

Pyridine *N*-oxide afforded two complexes, red $[VOCl_3(pyNO)]$ and darker red-black $[VOCl_3(pyNO)_2]$, depending upon the experimental conditions. The υ(VO) at 976 $cm^{-1}$ in the latter is within the range of other six-coordinate complexes, whilst for the former the υ(VO) at 1006 $cm^{-1}$ is at the lowest frequency observed for an (assumed) five-coordinate vanadium centre. The complexes also show strong υ(NO) at 1195 and 1200 $cm^{-1}$, lowered from the value of 1228 $cm^{-1}$ in pyridine *N*-oxide.[29] The $^{51}V$ NMR spectrum of $[VOCl_3(pyNO)_2]$ in anhydrous $CH_2Cl_2$ solution at ambient temperatures is a very broad resonance at $\delta$ = –67 ppm ($w_{1/2}$ = 800 Hz) which on cooling the solution sharpens and shows a small low-field shift. In the presence of added pyNO the limiting chemical shift is $\delta$ = –72 ppm ($w_{1/2}$ = 1000 Hz) at –70 °C, which probably corresponds to the 1:2 complex. In contrast, a $CH_2Cl_2$ solution of $[VOCl_3(pyNO)]$ only shows a $^{51}V$ NMR resonance below ca. –30 °C as a very broad feature at ca. $\delta$ = –25 ppm, which does not sharpen appreciably on cooling the solution, although as expected, addition of excess pyNO replicates the behaviour observed from $[VOCl_3(pyNO)_2]$. Overall, the data suggest that neutral O-donor ligand complexes of $VOCl_3$ are less stable, particularly in solution, than the N-donor adducts, and with the exception of the phosphane oxides, the lability precludes using solution NMR spectroscopic data to identify the isomer present in the six-coordinate complexes. Again examples of both five- and six-coordination are found, the coordination number presumably largely driven by steric factors.

**S-, Se-, P- and As-Donor Ligands:** The reaction of $VOCl_3$ with $R_2S$ (R = Me, Et or Bu) in chlorocarbons or hydrocarbons even at low temperatures gave dark solutions, which became blue-green in seconds. The UV/Visible spectrum of the latter ($E_{max}$ = 13500 $cm^{-1}$) showing reduction to a vanadyl $VO^{2+}$ species, as reported by Baker et al.[15] Similar reduction occurred with $Ph_2S$ and $PhSCH_2CH_2SPh$. The reaction of $Me_2Se$, $MeSeCH_2CH_2SeMe$, $Ph_3P$, $Ph_2PCH_2CH_2PPh_2$, or $o\text{-}C_6H_4(AsMe_2)_2$ with $VOCl_3$ even at –78 °C caused instant reduction to $V^{IV}$ or $V^{III}$ (identified by in situ UV/Visible spectroscopy).

**Oxygen Atom Transfer Reactions:** The results above clearly show that the $V^V$ complexes are extremely reactive and unstable towards reduction. Hence we have investigated their possible utility as O-atom transfer reagents towards $R_3E$ (E = P or As) and $R_2E'$ (E′ = S or Se). Many high valent metal oxido complexes have been shown to behave as O-atom transfer reagents to organic molecules.[30] The addition of 1 equiv. of $Ph_3P$ to $CH_2Cl_2$ solutions of $[VOCl_3(2,2'\text{-bipy})]$, $[VOCl_3(py)_2]$ or $[VOCl_3(quinoline)]$ resulted in instant loss of the dark red $V^V$ complexes, leaving pale pink solutions, and in situ $^{31}P$ NMR studies showed clean conversion to $Ph_3PO$ ($\delta$ = +28 ppm). The corresponding reactions with $Me_3As$ and $Ph_3As$ with $[VOCl_3(quinoline)]$ also resulted in rapid discharge of the colour, and after hydrolysis with aqueous ammonia, a mixture of the corresponding $R_3AsO$ and quinoline were isolated from the organic extracts, and identified by comparison of their IR and $^1H$ NMR spectra with literature data.[31] The reaction

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of [$VOCl_3$(quinoline)] with $Me_2Se$ was also rapid, and in this case the product was identified as $Me_2SeO$ by its $^{77}Se$ NMR [$\delta$($CH_2Cl_2$ solution) = +825 ppm; ref.[32] +812 ppm (in $H_2O$)] which, given the solvent-dependence of selenium chemical shifts, is good agreement. In contrast, the reactions of [$VOCl_3$(quinoline)] with thioethers, including $nBu_2S$ and $Ph_2S$, were slow, taking several hours to discharge the deep red colour (contrast the rapid reduction of $VOCl_3$ by these ligands described above). In these cases, after hydrolysis with aqueous ammonia and extraction with $CH_2Cl_2$, evaporation of the organic solvents left the corresponding[33] colourless liquid sulfoxides, $R_2SO$.

## Conclusions

A range of five- and six-coordinate oxido $V^V$ complexes incorporating neutral N- and O-donor ligands has been isolated and characterised spectroscopically and analytically. This represents the first detailed characterisation of an extended series of adducts of $VOCl_3$. The compounds are highly reactive and undergo moderately rapid degradation both in solution and in the solid state even in the dark. They are immediately decomposed by water or alcohols and reduced by ligands containing the heavier groups 15 or 16 donors, and for selected examples we have shown that this decomposition involves oxygen atom transfer to the group 15/16 atom. $^{51}V$ NMR studies show resonances to low frequency of $VOCl_3$ for all of the complexes reported here. Variable temperature studies have shown that most of the complexes are labile in chlorocarbon solvents. Although for some of the monodentate ligands both 1:1 and 1:2 ligand/metal complexes have been isolated as solids, in solution these are in fast equilibrium.

## Experimental Section

All reactions were conducted under anhydrous conditions under dry dinitrogen using standard vacuum line, Schlenk and glove-box techniques. $VOCl_3$ (Aldrich) was used as received. Solvents were dried by distillation from $CaH_2$ ($CH_2Cl_2$), Na/benzophenone ketyl (hexane and diethyl ether). 2,2′-Bipyridyl, 1,10-phenanthroline, $Ph_3PO$, $Ph_3AsO$ and pyridine *N*-oxide were dried by heating in vacuo, $Me_3PO$ was freshly sublimed in vacuo. 18-crown-6, 15-crown-5 and 12-crown-4 were dried by refluxing with excess $SOCl_2$, followed by vacuum drying at 60 °C. 1,2-bis(methoxy)ethane was dried by distillation from Na pellets. Quinoline, pyridine and $Me_2NCH_2CH_2NMe_2$ were refluxed over BaO and freshly distilled. [$Ph_4As$][$VOCl_4$] and [$Ph_4As$][$VO_2Cl_2$] were made by literature methods.[20,21] $^{51}V$ NMR spectra were recorded in 10-mm o.d. tubes from dry $CH_2Cl_2$ solutions containing 5% $CD_2Cl_2$ as lock, with a Bruker DPX400 operating at 105.2 MHz, and referenced to external neat $VOCl_3$ ($\delta$ = 0 ppm). Other physical measurements were made as described.[9,28] Analytical data were obtained from the microanalytical laboratory of Strathclyde University.

**[$VOCl_3$(2,2′-bipy)]:** A solution of $VOCl_3$ (0.23 g, 1.3 mmol) in dry $CH_2Cl_2$ (5 mL) was added to a solution of 2,2′-bipyridyl (0.2 g, 1.3 mmol) in dry $CH_2Cl_2$ (10 mL). The dark red solution was concentrated to ca. 5 mL in vacuo, dry hexane (5 mL) added and the red-black solid isolated by filtration, and dried in vacuo. Yield 0.30 g, 70%. $C_{10}H_8Cl_3N_2OV$ (329.5): calcd. C 36.5, H 2.5, N 8.5; found C 37.1, H 2.1, N 8.2. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 7.6 (m, 2 H), 8.5 (m, 4 H), 9.35 (s, H), 9.70 (s, H) ppm. IR (Nujol): $\tilde{\nu}$ = 1314 (m), 1261 (m), 1157 (w), 1104 (w), 1026 (m), 978 (s), 802 (m), 763 (s), 658 (m), 381 (s), 358 (s), 348 (s) $cm^{-1}$. UV/Vis: $E_{max}$ [$cm^{-1}$] ($\varepsilon_{mol}$, $cm^{-1}$ $dm^3$ $mol^{-1}$) = 19250 (sh), 21550 (1325), 22730 (1300), 26310 (sh), ca. 33000 (ca. 20000).

**[$VOCl_3$(1,10-phen)]:** Prepared similarly from $VOCl_3$ (0.29 g, 1.6 mmol) and 1,10-phenanthroline (0.29 g, 1.6 mmol). A dark red-brown solid was isolated. Yield 0.32 g, 55%. $C_{12}H_8Cl_3N_2OV$ (353.2): calcd. C 40.7, H 2.3, N 7.9; found C 39.8, H 2.0, N 7.5. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 8.0 (m, 4 H), 8.65 (s, 2 H), 9.75 (s, H), 9.95 (s, H) ppm. IR (Nujol): $\tilde{\nu}$ = 1308 (w), 1258 (w), 1171 (m), 1140 (s), 1023 (w), 973 (s), 839 (s), 776 (m), 431 (m), 386 (s), 347 (s), 319 (sh) $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $E_{max}$ [$cm^{-1}$] ($\varepsilon_{mol}$, $cm^{-1}$ $dm^3$ $mol^{-1}$) = 18200 (sh), 21505 (1680), 22730 (1730), ca. 33000 (ca. 15000).

**[$VOCl_3(py)_2$]:** A solution of pyridine (0.4 g, 5.0 mmol) in $CH_2Cl_2$ (5 mL) was added to $VOCl_3$ (0.21 g, 1.2 mmol) in $CH_2Cl_2$ (5 mL) producing an immediate precipitate. The mixture was stirred briefly, concentrated in vacuo to small volume and hexane (5 mL) added. The red solid was filtered off, rinsed with hexane, and dried in vacuo. Yield 0.23 g, 51%. $C_{10}H_{10}Cl_3N_2OV$ (331.5): Calcd. C 36.2, H 3.0, N 8.5; found C 36.3, H 3.9, N 8.3. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 7.3–7.5 (m) ppm. IR (Nujol): $\tilde{\nu}$ = 1604 (m), 1375 (m), 1325 (w), 1263 (w), 1161 (w), 1054 (m), 978 (s), 800 (s), 750 (s), 671 (s), 426 (s), 393 (m), 372 (m), 347 (m) $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $E_{max}$ [$cm^{-1}$] = 19800 (sh), 21740, 28730.

**[$VOCl_3$(py)]:** A solution of pyridine (0.2 g, 2.5 mmol) in $CH_2Cl_2$ (5 mL) was added to $VOCl_3$ (0.84 g, 4.8 mmol) in $CH_2Cl_2$ (25 mL) producing an immediate precipitate. The solution was stirred for 30 min and then pumped to dryness in vacuo at room temperature. The dark brown powder produced was rinsed with hexane (5 mL), the solid filtered off and dried in vacuo. Yield 0.40 g, 64%. $C_5H_5Cl_3NOV$ (252.4): calcd. C 23.8, H 2.0, N 5.6; found C 23.1, H 2.1, N 5.4. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 7.5 (s, 2 H), 8.0 (s, H), 8.9 (s, 2 H) ppm. IR (Nujol): $\tilde{\nu}$ = 1604 (w), 1361 (m), 1250 (w), 1236 (w), 1158 (m), 1071 (m), 1020 (s), 964 (w), 869 (m), 757 (s), 734 (s), 687 (s), 642 (m), 419 (s), 385 (s), 344 (s) $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $E_{max}$ [$cm^{-1}$] = 21500, 29110.

**[$VOCl_3$(quinoline)]:** A solution of quinoline (0.26 g, 2.0 mmol) in $CH_2Cl_2$ (10 mL) was added to $VOCl_3$ (0.52 g, 3.0 mmol) in $CH_2Cl_2$ (25 mL) producing an immediate red-black precipitate. The solution was stirred for 30 min and then pumped to dryness in vacuo at room temperature. The dark brown powder produced was stirred with hexane (5 mL) for 15 min, the solid filtered off and dried in vacuo. Yield 0.45 g, 74%. $C_9H_7Cl_3NOV$ (302.5): calcd. C 35.7, H 2.3, N 4.6; found C 35.5, H 2.4, N 4.5. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 7.7 (s, H), 7.9 (s, H), 8.1 (s, 2 H), 8.4 (s, H), 8.7 (s, H), 9.4 (s, H) ppm. IR (Nujol): $\tilde{\nu}$ = 1610 (w), 1354 (m), 1298 (w), 1261 (m), 1091 (m),1022 (s), 798 (s), 771 (m), 710 (s), 634 (w), 596 (m), 496 (s), 458 (m), 409 (sh), 375 (s), 330 (sh) $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $E_{max}$ [$cm^{-1}$] = 21600, 27700.

**[$VOCl_3(Me_2NCH_2CH_2NMe_2)$]:** A solution of $Me_2NCH_2CH_2NMe_2$ (0.12 g, 1.0 mmol) in $CH_2Cl_2$ (20 mL) was frozen in liquid nitrogen and a solution of $VOCl_3$ (0.17 g, 1.0 mmol) in $CH_2Cl_2$ (10 mL) syringed in. The mixture was allowed to thaw and then warm slowly to room temperature to produce a dark brown solution. The solution was stirred for 30 min and then concentrated to ca. 10 mL in vacuo. The dark red-brown solid was filtered off and dried in vacuo. Yield 0.25 g, 86%. $C_6H_{16}Cl_3N_2O_3V$ (281.5): calcd. C 24.9, H 5.6, N 9.7; found C 24.3, H 6.0, N 9.5. IR (Nujol): $\tilde{\nu}$ = 1590

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(w), 1260 (m), 1161 (w), 1080 (sh), 993 (s), 946 (m), 914 (w), 803 (s), 733 (s), 525 (w), 360 (sh), 343 (s), 290 (sh) $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $E_{max}$ [$cm^{-1}$] = 20830, 32100.

**[$VOCl_3$(15-crown-5)]:** $VOCl_3$ (0.14 g, 0.8 mmol) in dry $CH_2Cl_2$ (5 mL) was added to 15-crown-5 (0.17 g, 0.77 mmol) in dry $CH_2Cl_2$ (10 mL) and the solution pumped to dryness under vacuum. The solid was washed with pentane (10 mL), filtered off and dried in vacuo. Yield 0.2 g, 64%. $C_{10}H_{20}Cl_3O_6V$ (393.5): calcd. C 30.5, H 5.2; found C 29.4, H 5.7. IR (Nujol): $\tilde{\nu}$ = 1304 (w), 1261 (m), 1098 (vs), 1022 (s), 983 (m), 940 (m), 802 (s), 610 (w), 428 (m), 395 (m), 351 (m) $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $E_{max}$ [$cm^{-1}$] = 22420. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 3.6 (br. s) ppm. $^{51}V$ NMR ($CH_2Cl_2$, 223 K): $\delta$ = –54 ($w_{1/2}$ = 1000 Hz) ppm.

**[{$VOCl_3$}$_2$(18-crown-6)]:** Excess $VOCl_3$ (0.42 g, 2.4 mmol) in dry $CH_2Cl_2$ (5 mL) was added to 18-crown-6 (0.2 g, 0.76 mmol) in dry $CH_2Cl_2$ (10 mL) and worked up as described for [$VOCl_3$(15-crown-5)]. Red-brown solid. Yield 0.2 g, 30%. $C_{12}H_{24}Cl_6O_8V_2$ (610.9): calcd. C 23.6, H 4.0; found C 24.3, H 4.6. IR (Nujol): $\tilde{\nu}$ = 1300 (w), 1260 (m), 1146 (w), 1098 (vs), 1027 (s), 993 (m), 927 (m), 803 (s), 563 (m), 408 (sh), 359 (s,br), 306 (m) $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $E_{max}$ [$cm^{-1}$] = 22320. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 3.66 (s) ppm. $^{51}V$ NMR ($CH_2Cl_2$, 203 K): $\delta$ = –47 ($w_{1/2}$ = 2000 Hz) ppm.

**[$VOCl_3$($Ph_3PO$)]:** A solution of triphenylphosphane oxide (0.56 g, 2.0 mmol) in $CH_2Cl_2$ (5 mL) was added to $VOCl_3$ (0.35 g, 2.0 mmol) in $CH_2Cl_2$ (5 mL), the dark solution stirred briefly and then concentrated in vacuo. The solution was treated with hexane (5 mL) and refrigerated to give a red-brown solid, which was filtered off and dried in vacuo. Yield 0.53 g, 58%. $C_{18}H_{15}Cl_3PO_2V$ (451.6): calcd. C 47.9, H 3.3; found C 48.5, H 3.3. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 7.4–7.8 (m, Ph) ppm. $^{51}V$ ($CH_2Cl_2$, 200 K): $\delta$ = –102 ($w_{1/2}$ = 850 Hz) ppm. $^{31}P\{^1H\}$ ($CH_2Cl_2$, 295 K): $\delta$ = 56 ppm. IR (Nujol): $\tilde{\nu}$ = 1312 (w), 1260 (m), 1182 (m), 1119 (s), 1050 (s, PO), 1020 (s), 992 (m), 749 (s), 688 (s), 535 (vs), 432 (m), 403 (m), 372 (m), 336 (m), 311 (m) $cm^{-1}$. UV/Vis ($CH_2Cl_2$) $E_{max}$ [$cm^{-1}$] ($\varepsilon_{mol}$, $cm^{-1}\,dm^3\,mol^{-1}$) = 17000 (110), 23250 (500), 31000 (15000).

**[$VOCl_3$($Me_3PO$)$_2$]:** A solution of trimethylphosphane oxide (0.09 g, 1.0 mmol) in $CH_2Cl_2$ (5 mL) was added to $VOCl_3$ (0.09 g, 0.5 mmol) in $CH_2Cl_2$ (5 mL), the dark brown solution which was stirred briefly, filtered, and the solvents evaporated to dryness in vacuo. Yield 0.16 g, 88%. $C_6H_{18}Cl_3O_3P_2V$ (357.5): calcd. C 20.1, H 5.0; found C 20.6, H 5.3. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 2.0 (br., $CH_3$) ppm. $^{31}P\{^1H\}$ ($CH_2Cl_2$, 295 K): $\delta$ = 74 ppm, essentially unchanged on cooling to 210 K. IR (Nujol): $\tilde{\nu}$ = 1297 (s), 1260 (m), 1085 (vs, PO), 1016 (s), 952 (s), 863 (m), 801 (m), 757 (w), 608 (w), 468 (sh), 431 (m), 381 (sh), 367 (br., m) $cm^{-1}$. **[$VOCl_3$($Ph_3AsO$)]:** Triphenylarsane oxide (0.32 g, 1.0 mmol) was melted in vacuo after 20 min the melt was cooled to room temperature, dissolved in dry $CH_2Cl_2$ (10 mL) and added to $VOCl_3$ (0.35 g, 2.0 mmol) in $CH_2Cl_2$ (5 mL). (Unless rigorously anhydrous conditions are used this reaction gives the product as a black oil which appears spectroscopically identical to the solid complex.) The dark solution stirred briefly and then concentrated in vacuo. The solution was treated with hexane (5 mL) to give a red-black solid, which was filtered off and dried in vacuo. Yield 0.40 g, 80%. $C_{18}H_{15}AsCl_3O_2V{\cdot}CH_2Cl_2$ (580.5): calcd. C 39.3, H 3.0; found C 39.6, H 2.7. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 7.4–7.8 (m, Ph), 5.4 (s, $CH_2Cl_2$) ppm. $^{51}V$ ($CH_2Cl_2$, 298 K): $\delta$ = –142 ($w_{1/2}$ = 400 Hz) ppm. IR (Nujol): $\tilde{\nu}$ = 1363 (m), 1260 (m), 1087 (s), 1016 (s), 801 (m, AsO), 735 (s), 684 (m), 530 (w), 461 (m), 393 (m), 365 (m), 347 (sh) $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $E_{max}$ [$cm^{-1}$] ($\varepsilon_{mol}$, $cm^{-1}\,dm^3\,mol^{-1}$) = 16000 (sh) (ca. 200), 21550 (3100), 30490 (2295).

**[$VOCl_3$($MeOCH_2CH_2OMe$)]:** A solution of dme (0.18 g, 2.0 mmol) in $CH_2Cl_2$ (10 mL) was added to $VOCl_3$ (0.19 g, 1.0 mmol) in $CH_2Cl_2$ (25 mL) producing a very dark solution. The solution was stirred for 30 min, and then pumped to dryness in vacuo at room temperature. The dark red-black powder produced was stirred with hexane (5 mL) for 15 min, the solid filtered off and dried in vacuo. Yield 0.35 g, 66%. $C_4H_{10}Cl_3O_3V$ (263.4): calcd. C 18.3, H 3.8; found C 18.7, H 4.2. $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 3.8 (br) ppm; (220 K): $\delta$ = 4.01 (s, 2 H, $CH_2$), 4.05 (s, 3 H, $CH_3$) ppm. IR (Nujol): $\tilde{\nu}$ = 1346 (m), 1278 (w), 1260 (m), 1240 (m), 1190 (m), 1107 (s), 1076 (s), 1026 (s), 999 (s), 983 (s), 864 (m), 820 (m), 770 (m), 421 (m), 359 (s), 348 (vbr), 282 (w) $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $E_{max}$ [$cm^{-1}$] = 19840, 26050 (sh), 32000.

**[$VOCl_3$(pyNO)]:** A solution of pyridine *N*-oxide (0.55 g, 5.8 mmol) in toluene (50 mL) was treated dropwise with $VOCl_3$ (1.0 g, 5.8 mmol). A dark red precipitate was formed immediately and the mixture stirred for 2 h. The supernatant was removed by cannula and the solid residue washed with hexane (15 mL). Filtration yielded a red solid which was dried in vacuo. Yield 0.96 g, 62%. $C_5H_5Cl_3NO_2V$ (268.4): calcd. C 22.4, H 1.9, N 5.2; found C 22.1, H 1.7, N 5.7. $^1H$ NMR (400 MHz, $CDCl_3$, 298 K): $\delta$ = 8.85 (s, 2 H), 9.20 (s, 1 H), 9.65 (s, 2 H). IR (Nujol): $\tilde{\nu}$ = 1605 (w), 1258 (m), 1197 (s), 1172 (m), 1092 (m), 1006 (s), 979 (m), 836 (m), 768 (s), 727 (m), 690 (m), 393 (m), 371 (s), 330 (s) $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $E_{max}$ [$cm^{-1}$] = 16000 (sh), 19700, 22000, 31700.

**[$VOCl_3$(pyNO)$_2$]:** A solution of pyridine *N*-oxide (0.55 g, 5.8 mmol) in $CH_2Cl_2$ (30 mL) was treated with $VOCl_3$ (0.5 g, 2.8 mmol). A very dark red-black solution resulted. After stirring for 1 h. the mixture was taken to dryness in vacuo at room temperature. The resulting dark red solid was suspended in hexane (10 mL) and stirred for 15 min, the solid filtered off and dried in vacuo. Yield 0.86 g, 82%. $C_{10}H_{10}Cl_3N_2O_3V$ (363.5): calcd. C 33.0, H 2.8, N 7.7; found C 32.7, H 2.6, N 7.1 $^1H$ NMR (400 MHz, $CDCl_3$, 298 K): $\delta$ = 8.82 (s, 2 H), 9.15 (s, 1 H), 9.60 (s, 2 H). IR (Nujol): $\tilde{\nu}$ = 1605 (w), 1258 (m), 1200 (s), 1175 (m), 1092 (s), 996 (s), 976 (m), 830 (m), 768 (s), 727 (m), 695 (m), 373 (m), 348 (s), 325 (s) $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $E_{max}$ [$cm^{-1}$] = 18000 (br), 27200.

**Oxidation Reactions:** General method: $Ph_3P$ (0.026 g, 0.1 mmol) was dissolved in $CH_2Cl_2$ (5 mL) and a solution of the vanadium complex (0.1 mmol) in $CH_2Cl_2$ (5 mL) added. After 5 min the mixture was pumped to dryness in vacuo, and the residue shaken up with aqueous ammonia (5 mL of 4 mol·$dm^{-3}$) and $CH_2Cl_2$ (5 mL). The organic phase was separated and used for $^{31}P$ NMR studies. The reactions with $Me_3As$, $Ph_3As$, $Me_2Se$, $nBu_2S$ and $Ph_2S$ were

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

conducted similarly, the products being identified by $^{1}H$, $^{77}Se$ NMR and IR spectroscopy as appropriate.

**X-ray Data:** CCDC-608276 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

We thank EPSRC for support and Dr M. Webster for assistance with the X-ray crystallographic studies.

# Studies on Chromium(III) and Vanadium(III) Complexes with Crown Ether and Crown Thioether Coordination – Synthesis, Properties and Structural Systematics

**Charlotte D. Beard,[a] Loretta Carr,[a] Martin F. Davis,[a] John Evans,[a] William Levason,[a] Louise D. Norman,[a] Gillian Reid,*[a] and Michael Webster[a]**

**Keywords:** Chromium / Crown ether / Thioether macrocycle / Vanadium

A series of six-coordinate chloro $Cr^{III}$ and $V^{III}$ complexes involving crown ether, crown thioether and mixed ether/thioether crowns, $[MCl_3(crown)]$ (M = Cr or V; crown = 12-crown-4, 15-crown-5,18-crown-6, [12]aneS$_4$, [15]aneS$_5$, [9]aneS$_2$O, [15]aneS$_2$O$_3$, [18]aneS$_3$O$_3$) has been prepared by the reaction of $[MCl_3(thf)_3]$ with rigorously dried crown in anhydrous $CH_2Cl_2$. In the presence of small amounts of water the monoaquo species $[MCl_3(H_2O)$(15-crown-5)] and $[MCl_3(H_2O)$(18-crown-6)] are obtained. The products have been characterised by IR and UV/Visible spectroscopy, microanalyses and for $[CrCl_3(H_2O)$(18-crown-6)], $[VCl_3(H_2O)$(15-crown-5)] and $[CrCl_3$([15]aneS$_5$)], by X-ray crystallography. The unexpected affinity of specifically the 15-crown-5 and 18-crown-6 complexes to pick up $H_2O$ is rationalised in terms of the strain within the two adjacent five-membered chelate rings in the anhydrous ($\kappa^3$-coordinated) species, and a wider survey of the structures reported for six-coordinate $M^{III}$ crown complexes (M = Sc – Cr) with RECH$_2$CH$_2$ER (E = O or S) reveals that while the S–M–S angles in five-membered chelate rings are typically around 82°, those involving O–M–O are very substantially more acute at around 75°. Thus, the $[MCl_3(\kappa^3$-crown ether)] complexes are much less stable and can alleviate some of this significant ring strain by switching to $\kappa^2$-crown coordination with the $H_2O$ ligand completing the six coordination. In contrast, the crown thioether complexes have much less tendency to do this and hence appear to be more stable. Furthermore, using the structurally related (dimethylene linkages) mixed thia/oxa crowns to probe the M–O vs. M–S binding competitively, strongly indicates that the $Cr^{III}$ and $V^{III}$ preferentially coordinate to the thioether rather than the ether donor atoms, contrary to normal expectation based upon HSAB theory.

## Introduction

The coordination chemistry of crown ether ligands is dominated by the group 1 and 2 metals and the lanthanides.[1–3] Two main types of metal–crown ether complex are known – primary coordination, where the crown bonds directly to the metal by some or all of the ether oxygen atoms, and secondary coordination, where the crown is not directly bonded to the metal, but interacts through H bonding with the metal complex. Relatively few studies of transition metal crown ether complexes have been reported. For the early 3d metals, scandium(III) forms primary coordination complexes under anhydrous conditions, including $[ScCl_2$(15-crown-5)][SbCl$_6$], [ScCl(15-crown-5)(MeCN)]-[SbCl$_6$]$_2$, $[ScCl_2$(18-crown-6)][SbCl$_6$] and $[Sc(12\text{-crown-}4)_2]^{3+}$, whilst in the presence of water secondary coordination occurs as in $[ScCl_3(H_2O)_3]\cdot$crown (crown = 15-crown-5, 18-crown-6).[4–6] Titanium(IV) halides produce the very moisture sensitive $[TiX_4(\kappa^2$-crown)] (crown = 12-crown-4, 15-crown-5, 18-crown-6; X = Cl or Br) and $[TiCl_3$(15-crown-5)(MeCN)][SbCl$_6$]; two hydrolysis products $[Ti_2Cl_6(\mu$-O)(18-crown-6)$_2$] and $[Ti_4(\mu$-O)$_4$Cl$_8$(15-crown-5)$_4$] have also been structurally characterised.[7–9]

Titanium(III), vanadium(III) and chromium(III) are represented by some scattered structurally characterised complexes, viz. $[MCl_3(H_2O)$(18-crown-6)] (M = Ti or V),[10,11] [VCl$_2$(15-crown-5)][VOCl$_4$],[12] $[CrCl_3(H_2O)$(15-crown-5)],[13] and $[CrCl_3(H_2O)_3]\cdot$(15-crown-5),[14] but the systematic chemistry with these trivalent metals has not been investigated. We have also been probing the chemistry of early transition-metal centres with softer thioether ligands and macrocycles in order to explore the effects of combining these soft ligands with hard metals. In this context we have described previously the preparations and properties of a series of neutral $Cr^{III}$ and $V^{III}$ halide complexes of the form $[MX_3(L)]$ (X = Cl or Br; L = [9]aneS$_3$, [10]aneS$_3$ [1,4,7-trithiacyclodecane] or [18]aneS$_6$ [1,4,7,10,13,16-hexathiacyclooctadecane]) and the cationic $[CrX_2([n]$aneS$_4$)]PF$_6$ ($n$ = 14 or 16) ([14]aneS$_4$ = 1,4,8,11-tetrathiacyclotetradecane, [16]aneS$_4$ = 1,5,9,13-tetrathiacyclohexadecane).[15] The crystal structure of $[CrCl_3(\kappa^3$-[18]aneS$_6$)] has also been described by Grant and co-workers.[16] Chromium(III) complexes with thioether-containing ligands, e.g.

$[CrCl_3\{RS(CH_2)_2NH(CH_2)_2SR\}]$ (R = Me, Et, *n*Bu, *n*-decyl) have also been shown to be important catalyst precursors which, when combined with methylaluminoxane, promote the selective trimerisation of ethene to produce 1-hexene.[17] The nature of the ligand plays an important role in determining the product distribution in these processes.

Here we report the results of our systematic studies on the synthesis, characterisation and structures of complexes of the three crown ethers 12-crown-4, 15-crown-5 and 18-crown-6, the thiamacrocycles [12]ane$S_4$ (1,4,7,10-tetrathiacyclododecane) and [15]ane$S_5$ (1,4,7,10,13-pentathiacyclopentadecane) and the mixed thia-oxa macrocycles [9]ane$S_2O$ (1-oxa-4,7-dithiacyclononane), [15]ane$S_2O_3$ (1,4,7-trioxa-10,13-dithiacyclopentadecane) and [18]ane$S_3O_3$ (1,4,7-trioxa-10,13,16-trithiacyclooctadecane) with $Cr^{III}$ and $V^{III}$ chlorides. The macrocyclic ligands were specifically chosen to provide a direct comparison between ether and thioether coordination and the mixed S/O systems to probe the ligation to S or O competitively. The crystal structures of three complexes are reported and an analysis of the structural parameters of these species, together with the structurally characterised examples in the literature reveal some quite marked trends in the angles subtended at the metal. These are discussed in terms of donor atom type, ring size and complex stability.

## Results and Discussion

The reaction of $[MCl_3(thf)_3]$ with rigorously dry (either by prolonged heating in vacuo or by pre-treatment with $SOCl_2$ in refluxing $CH_2Cl_2$) 15-crown-5 in $CH_2Cl_2$ under anhydrous conditions yields pink-purple (Cr) and pink (V) powders $[MCl_3(\kappa^3\text{-15-crown-5})]$, whilst in the presence of small amounts of water the products are $[MCl_3(H_2O)(\kappa^2\text{-15-crown-5})]$. The structure of $[CrCl_3(H_2O)$(15-crown-5)] has been reported[13] and consists of a pseudo-octahedral chromium centre bonded to three facial chlorines, a water molecule and $\kappa^2$ to the crown. The anhydrous and aqua complexes are readily distinguishable by their IR spectra (the presence or absence of water bands), have distinguishable spectra in the fingerprint region and also differ in the far IR ν(M–Cl) vibrations (Experimental Section). The anhydrous $[MCl_3(\kappa^3\text{-15-crown-5})]$ readily convert to $[MCl_3(H_2O)(\kappa^2\text{-15-crown-5})]$ upon stirring in $CH_2Cl_2$ solution with small amounts of added water under $N_2$ (larger amounts of water completely displace the crown – see below). Crystals of $[VCl_3(H_2O)(\kappa^2\text{-15-crown-5})]$ were obtained from $CH_2Cl_2$/hexane. The structure shows (Figure 1, Table 1) the V coordinated to three facial Cl atoms 2.309(2)–2.335(2) Å, one $H_2O$ ligand [2.064(5) Å] and two adjacent ether O atoms from the crown [2.070(4) and 2.122(4) Å]. The O–V–O angle within the chelate ring is 76.23(18)°. The O5···O6···O4a angle is a plausible 102.3°. The structure of $[VCl_3(H_2O)(\kappa^2\text{-18-crown-6})]$ reported by Atwood and co-workers shows similar geometric parameters.[8] Although the H atoms bonded to the water O6 were not convincingly identified, there are only two suitable O···O distances for O–H···O H-bonding interactions. Thus O6···O5 [2.784(6) Å] is an intramolecular H-bond and O6···O4a [2.676(6) Å, a: *y*, *x*, –*z*] an intermolecular interaction to crown O atoms.

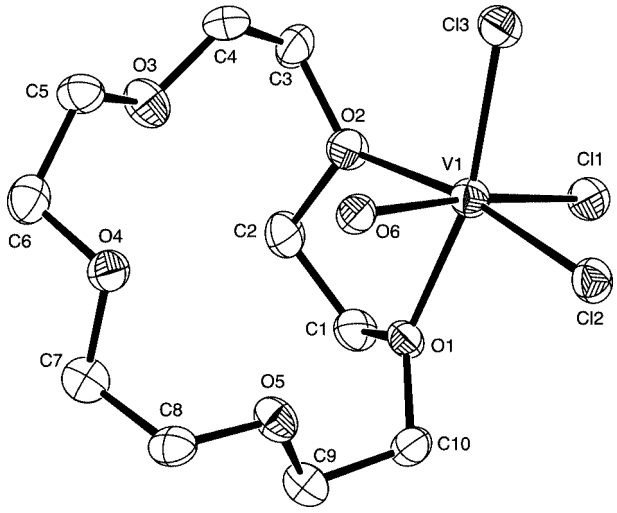

Figure 1. View of the structure of $[VCl_3(H_2O)$(15-crown-5)] with numbering scheme adopted. H atoms have been omitted for clarity and the ellipsoids are drawn at the 50% probability level.

| O2–V1–Cl2 | 170.10(14) | Cl3–V1–Cl2 | 96.98(8) |
| Cl1–V1–Cl2 | 91.89(8) | | |

Stirring a $CH_2Cl_2$ solution of this complex overnight with a further added water leads to deposition of blue crystals. These were shown (unit cell determination) to be the $V^{IV}$ species $[VOCl_2(H_2O)_2]$·(15-crown-5) whose structure has been determined previously and shows secondary bonding interactions between the $H_2O$ ligands on the vanadyl centre and the crown ether.[18]

The corresponding reactions of $[MCl_3(thf)_3]$ with 12-crown-4 gave $[MCl_3(\kappa^3\text{-12-crown-4})]$. Similarly, reaction of $[MCl_3(thf)_3]$ with 18-crown-6 affords $[MCl_3(\kappa^3\text{-18-crown-6})]$ and $[MCl_3(H_2O)(\kappa^2\text{-18-crown-6})]$ (the latter with M = Cr was characterised by an X-ray study – below), while using a 2:1 ratio of M/crown gives the binuclear $[(MCl_3)_2$(18-crown-6)]. The anhydrous $[MCl_3(\kappa^3\text{-18-crown-6})]$ are particularly moisture sensitive, much more so than $[MCl_3(\kappa^3$-12-crown-4)], which may indicate that the water is first associated with the "free" O atoms of the crown and then transferred to the metal, which will be less easy in the smaller ring. The structure of $[CrCl_3(H_2O)$(18-crown-6)] shows two

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

independent molecules in the asymmetric unit, one of which is shown in Figure 2, Table 2. The $Cr^{III}$ is in a distorted octahedral environment, coordinated to three facial Cl atoms, two adjacent ether O atoms from the crown and a water molecule. For the Cr1 molecule (see Figure 2) each of the O13 H atoms is involved in an intramolecular H bond to a crown O atom [O13···O4 2.813(4), O13···O6 2.842(4) Å]. A similar situation applies to the Cr2 containing-molecule and O14. The Cr–O distances within the crown are ca. 2.05 Å, while the Cr–$OH_2$ distances are slightly shorter in each case. The O–Cr–O angles within the chelate rings are notable at only 79.22(11) and 76.93(12)°. The structural features in this species parallel those in $[CrCl_3(H_2O)(\kappa^2\text{-15-crown-5})]$ reported by Dehnicke and co-workers,[13] which shows intramolecular H-bonding interactions between the coordinated $H_2O$ ligand and two of the uncoordinated O atoms of the crown.

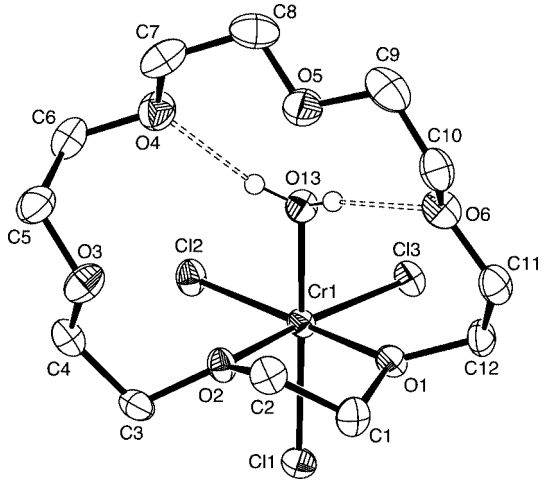

Figure 2. View of the structure of one of the two independent $[CrCl_3(H_2O)(18\text{-crown-6})]$ molecules with numbering scheme adopted. H atoms on C have been omitted for clarity and the ellipsoids are drawn at the 50% probability level. The other molecule is very similar.

As before, the anhydrous and the aqua complexes can be distinguished by their IR spectra, and the IR spectra of the dinuclear complexes are quite distinct in the fingerprint region. All of the $M^{III}$ complexes contain pseudo-octahedral metal centres, as shown by their diffuse reflectance spectra (Table 3) (some solution spectra were obtained but a combination of poor solubility and extreme moisture sensitivity of the dilute solutions meant they were poorly reproducible and are not quoted).

The $d^3$ chromium complexes typically showed two d–d bands assigned (in $O_h$ symmetry) as $^4A_{2g}\rightarrow{}^4T_{2g}$ and $^4A_{2g}\rightarrow{}^4T_{1g}(F)$, respectively, and a third band was usually evident of the edge of intense features in the UV, which may be the $^4A_{2g}\rightarrow{}^4T_{1g}(P)$ transition (Table 3).[19] Although the actual metal-centre symmetry is lower than $O_h$, no clearly resolved splitting of the bands was observed, although the lowest energy feature was often asymmetric. The band maxima show small shifts consistent with the ligand field strengths $Cl < O_{crown} < H_2O$. For the $d^2$ vanadium complexes the two transitions observed are assigned to $^3T_{1g}\rightarrow{}^3T_{2g}$, and $^3T_{1g}\rightarrow{}^3T_{1g}(P)$, respectively, based on $O_h$ symmetry and trends are discussed below.

Table 2. Selected bond lengths [Å] and angles [°] for $[CrCl_3(H_2O)(18\text{-crown-6})]$.

Grant and co-workers have described the reaction of $CrCl_3\cdot6H_2O$ with the thioether macrocycles [12]aneS$_4$ and [15]aneS$_5$ in refluxing MeCN; however, unsurprisingly, in the presence of water the substitutions are not clean and no pure products were isolated.[16] We have obtained the thioether macrocyclic complexes $[CrCl_3(\kappa^3\text{-[12]aneS}_4)]$ and $[CrCl_3(\kappa^3\text{-[15]aneS}_5)]$ readily and in good yield from $[CrCl_3(thf)_3]$ and the thiamacrocycle in anhydrous $CH_2Cl_2$ solution and isolated them as purple/blue solids. Despite the softer nature of the ligand donor atoms, once isolated these compounds show a much reduced tendency to pick up $H_2O$ in the metal coordination sphere cf. the crown ethers above (IR evidence). $[VCl_3(\kappa^3\text{-[12]aneS}_4)]$ was obtained similarly.

A crystal structure of $[CrCl_3([15]aneS_5)]$ confirms (Figure 3, Table 4) the distorted octahedral coordination at Cr through three facial Cl atoms and three facial and mutually adjacent S atoms of the macrocycle, $d$(Cr–Cl) = 2.2849(8)–2.3028(9) Å; $d$(Cr–S) = 2.4161(10)–2.4942(8) Å, the bond lengths and angles compare well with those in the crystallographically characterised neutral $[CrCl_3([18]aneS_6)]$[16] and the cationic *cis*-$[CrX_2([14]aneS_4)]PF_6$.[15] The UV/Visible spectra show clearly that the thioether donors present a stronger ligand field than the O–donor ligands, giving the overall order $Cl^- < O_{crown} < H_2O < S_{thiacrown}$ (Table 3).

The mixed thia-oxa macrocyclic complexes $[MCl_3(\kappa^3\text{-[9]aneS}_2O)]$, $[MCl_3(\kappa^3\text{-[15]aneS}_2O_3)]$ and $[MCl_3(\kappa^3\text{-[18]aneS}_3O_3)]$ were obtained from similar reactions as purple/blue (Cr) or pink (V) coloured solids. These compounds have a much lower tendency to pick up $H_2O$ compared to the crown ether complexes.

The diffuse reflectance UV/Visible spectra for the thia and thia-oxa macrocyclic complexes are also consistent

with distorted octahedral geometries. For the $[MCl_3$([9]ane$S_2O$)] complexes, $S_2O$ coordination of the macrocycle is imposed, giving the metal an $S_2OCl_3$ donor set overall, and as expected, the UV/Visible spectra of $[MCl_3$([9]ane$S_2O$)] (Table 3) much more closely resemble those of the thioether crown analogues ($S_3Cl_3$ donor set) rather than the crown ether analogues ($O_3Cl_3$ donor set). Importantly, comparison of the energies of the d-d transitions in the $Cr^{III}$ thia-oxa species clearly shows that even the [15]ane$S_2O_3$ and [18]ane$S_3O_3$ systems involve S-coordination (although this technique does not readily discriminate between $S_3$ vs. $S_2O$ vs. $SO_2$ coordination). Unfortunately, despite repeated efforts to obtain single crystals of one or more of the complexes with these ligands to provide definitive proof of the metal donor set, we have not been successful.

## Analysis of Structural Data

Evidence from this work shows that the $\kappa^3$-coordinated crown ether complexes may be obtained only under stringently anhydrous conditions, with traces of water leading to partial hydrolysis and isolation of the mono-aqua complexes, with the crown now only $\kappa^2$-coordinated. On the other hand, the thiamacrocycles readily yield $S_3$-coordinated species, which appear to be considerably less susceptible to hydrolysis. At first sight this seems surprising because on the basis of Pearson's HSAB theory, one would antici-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pate that the crown ether ligands (O-donor) would result in more stable complexes than the softer thioether macrocycles. In order to explain these results we have therefore examined the structural parameters in these species, together with the crystallographically determined parameters in all other reported six-coordinate (octahedral) complexes of early transition metals (Sc, Ti, V and Cr) with ether and thioether ligands of the form $RE(CH_2)_2ER$ and $RE(CH_2)_2E(CH_2)_2ER$ (E = O or S; R = alkyl) and S- or O-donor macrocycles involving dimethylene linkages. The results obtained using the Cambridge Crystallographic Database[20,21] are presented in Figure 4, which shows histograms depicting the E–M–E angles within the five-membered chelate rings for E = O (a) and for E = S (b). The average O–M–O angles in these species are 74.8°, with values ranging from 68.6–79.0°, while the average S–M–S chelate angles are 82.2°, with values ranging from 75.7–86.8°. The data obtained from the three crystal structures presented above are consistent with the data in Figure 4. This surprisingly large difference is consistent with the crown ether complexes being more strained, and may well explain why the $\kappa^3$-crown complexes are so readily hydrolysed – incorporating two adjacent very acute five-membered chelates leads to a very strained species which will readily scavenge another donor ligand such as $H_2O$ and convert to $\kappa^2$-crown to relieve the strain within the coordination sphere. In contrast, the S–M–S chelate angles of ca. 82° are closer to the idealised 90° angle in a regular octahedron. In support of this we note that the O–Cr–O angles in *mer*-$[CrCl_3(thf)_3]$ are 86.0(1) and 86.5(1)° – the monodentate thf ligands remove chelate constraints as a consideration, and hence presumably reflect the preferred relative positioning of the ligands.[22]

The magnitude of the chelate angle subtended at the metal M is a consequence of both the M–E distances and the E–C distances. The M–S distances are ca. 0.4 Å longer than *d*(M–O) in these species. The reason for the large difference in E–M–E angles presumably originates from the difference between *d*(O–C) (typically ca. 1.47 Å) vs. *d*(S–C) (typically ca. 1.83 Å) – thus an O–C–C–O linkage is too short to accommodate idealised octahedral angles at a coordinated early transition metal without introducing significant angle strain at the O and the C atoms.

We previously reported the preparation and properties of the $Ti^{IV}$ complex $[TiCl_4(\kappa^2\text{-}[15]aneS_2O_3)]$, the $^1H$ NMR spectrum of which unexpectedly showed that coordination to Ti is through the two thioether S atoms, not the ether O atoms.[9] This result, together with the results of the present studies, suggest that the substantially different ring-strain effects introduced upon chelation of $–OCH_2CH_2O–$ cf. $–SCH_2CH_2S–$ linkages plays a dominant role in determining the donor set at Ti and offsets the fact that the thioethers are softer donor ligands than the ethers.

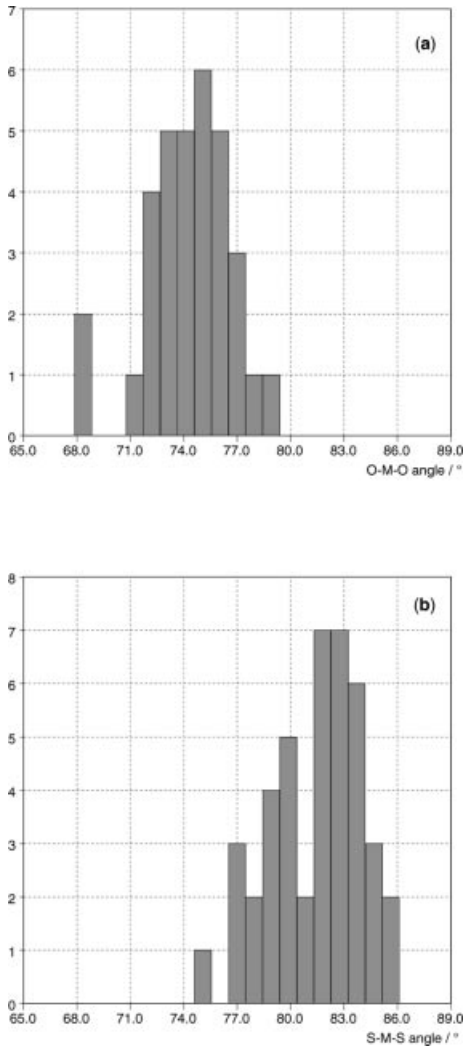

Figure 4. Histograms showing the crystallographically determined E–M–E angles within saturated five-membered chelate rings on an octahedral metal centre (M = Sc, Ti, V, Cr). (**a**) E = O, mean O–M–O angle 74.8(2.4)°. The lowest angles are for $[Sc(CH_2SiMe_3)_3$-(12-crown-4)] which contains two adjacent five-membered chelate rings.[28] (b) E = S, mean S–M–S angle 82.2(2.6)°. The lowest angles are for those complexes involving the macrocycle [9]ane$S_3$ containing three adjacent five-membered chelate rings.

## Conclusions

We describe here a series of neutral chloro $Cr^{III}$ and $V^{III}$ complexes with crown ether, crown thioether and mixed thia-oxa crown ligands. The $\kappa^3$-crown ether complexes show a marked tendency to dissociate one O atom and pick up a $H_2O$ ligand – an observation also noted for other early transition-metal crown ether complexes both by ourselves and by other workers. Furthermore, competitive binding studies using mixed S/O crowns with various ring sizes, but still maintaining the dimethylene linking groups strongly suggest that *S*-coordination is preferred.

This work has shown that despite the prediction that the hard, oxophilic early transition metals are likely to coordinate more favourably with ether-based ligands than the softer thioethers, ring strain within the resulting five-membered chelates plays a critical role and destabilises the crown ether complexes cf. the crown thioether analogues in these systems. This result suggests that the linkage between the O atoms of crown ether ligands may be of fundamental

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

importance in determining complex stability and that judicious choice of crown design (ring size and substitution pattern) may influence significantly the stability of transition metal–crown ether complexes and allow a much wider range of transition metal complexes with this important family of ligands to be prepared. Work is underway in our laboratories currently to investigate this more fully. Finally, we note that these considerations are not relevant to the *endo*-coordinated crowns in the seven-coordinate species such as $[ScCl_2(\kappa^5\text{-15-crown-5})]^+$, $[ScCl(\kappa^5\text{-15-crown-5})(MeCN)]^{2+}$ [4–6] and $[VCl_2(\kappa^5\text{-15-crown-5})]^+$,[12] since in these species the crown occupies five positions in a pentagonal plane, with idealised O–M–O angles of 72° which can be easily accommodated by the five-membered chelate rings.

## Experimental Section

**Physical Measurements:** Infrared spectra were recorded as Nujol mulls between CsI discs with a Perkin–Elmer 983G spectrometer over the range 4000–180 $cm^{-1}$. UV/Visible spectra were obtained in diffuse reflectance mode from samples diluted with $BaSO_4$ using a Perkin–Elmer Lambda19 spectrometer or as solutions in $CH_2Cl_2$ using quartz cells. Microanalyses were performed by the University of Strathclyde micro-analytical service. In some cases the compounds retained some $CH_2Cl_2$ which was evident from the microanalyses, IR and by $^1H$ NMR spectroscopy; partial $CH_2Cl_2$ is also evident in some of the crystal structures. $[CrCl_3(thf)_3]$ was made by the literature route.[23] $[VCl_3(thf)_3]$ and the macrocycles 12-crown-4, 15-crown-5, 18-crown-6, [12]ane$S_4$ and [15]ane$S_5$ were obtained from Aldrich. The mixed thia-oxa crowns, [9]ane$S_2O$, [15]ane$S_2O_3$ and [18]ane$S_3O_3$ were prepared by the literature methods.[24] The anhydrous crown ethers were obtained either by prolonged heating in vacuo or by refluxing the crown with thionyl chloride in $CH_2Cl_2$. The aqua complexes either used the crowns treated as above and subsequent addition of small amounts of water, or using crowns which were "dried" by pumping in vacuo at room temperature for a few hours (under these conditions $^1H$ NMR and IR spectra provide evidence for retention of some water). The anhydrous crowns were stored in Schlenk flasks and manipulated in a dry box. All complexes were manipulated in a dry box (<5 ppm water).

### Chromium(III) Complexes

**$[CrCl_3(12\text{-crown-4})]$:** $[CrCl_3(thf)_3]$ (0.4 g, 1.1 mmol) in dry $CH_2Cl_2$ (5 mL) was combined with dry 12-crown-4 (0.2 g, 1.1 mmol) in dry $CH_2Cl_2$ (5 mL). A precipitate was formed; this was then filtered off and dried in vacuo. The product was a pink solid. Yield 0.10 g, 24%. $C_8H_{16}Cl_3CrO_4\cdot 1/2CH_2Cl_2$ (377.0): calcd. C 27.1, H 4.5; found C 27.5, H 4.9. IR (Nujol): $\tilde{\nu}$ = 1299 (s), 1261 (m), 1228 (m), 1145 (s), 1063 (s), 1026 (vs), 934 (m), 908 (s), 838 (s), 363 (sh), 356 (s), 340 (sh) $cm^{-1}$.

**$[CrCl_3(15\text{-crown-5})]$:** $[CrCl_3(thf)_3]$ (0.13 g, 0.34 mmol) in dry $CH_2Cl_2$ (5 mL) was added to anhydrous 15-crown-5 (0.07 g, 0.34 mmol) in dry $CH_2Cl_2$ (5 mL) and the solution was stirred for 30 min. A solid was produced and then filtered off and dried in vacuo. Pink solid. Yield 0.06 g, 38%. $C_{10}H_{20}Cl_3CrO_5\cdot CH_2Cl_2$ (463.5): calcd. C 28.5, H 4.8; found C 27.5, H 5.8. IR (Nujol): $\tilde{\nu}$ = 1304 (m), 1263 (m), 1231 (m), 1147 (s), 1126 (s), 1111 (s), 1081 (s), 1064 (vs), 1021 (vs), 934 (s), 928 (sh), 906 (sh), 841 (s), 798 (s), 728 (s), 380 (sh), 362 (s), 349 (s) $cm^{-1}$.

**$[CrCl_3(H_2O)(15\text{-crown-5})]$:** $[CrCl_3(thf)_3]$ (0.10 g, 0.27 mmol) in dry $CH_2Cl_2$ (5 mL) was added to 15-crown-5 (0.17 g, 0.28 mmol) in dry $CH_2Cl_2$ (5 mL) and the solution was stirred for 1 h. The precipitate was filtered off and dried in vacuo. The product was a pink solid. Yield 0.05 g, 37%. $C_{10}H_{22}Cl_3CrO_6$ (396.6): calcd. C 30.3, H 5.6; found C 29.5, H 6.1. IR (Nujol): $\tilde{\nu}$ = 3300 (br), 1630 (m), 1303 (m), 1249 (m), 1140 (s), 1120 (s), 1110 (s), 1073 (vs), 1035 (vs), 1006 (m), 933 (s), 919 (m), 854 (s), 828 (w), 786 (w), 365 (sh), 343 (m), 321 (m) $cm^{-1}$.

**$[CrCl_3(18\text{-crown-6})]$:** $[CrCl_3(thf)_3]$ (0.3 g, 0.8 mmol) in dry $CH_2Cl_2$ (5 mL) was combined with dry 18-crown-6 (0.2 g, 1.0 mmol) in dry $CH_2Cl_2$ (5 mL). The solution was stirred for 5 min the solid produced was then filtered off and dried in vacuo. The product produced was a pink solid. Yield 0.05 g, 10%. $C_{12}H_{24}Cl_3CrO_6\cdot 1/2CH_2Cl_2$ (465.1): calcd. C 32.3, H 5.4; found C 32.5, H 6.0. IR (Nujol): $\tilde{\nu}$ = 1306 (m), 1260 (w), 1120 (s), 1166 (s), 1022 (s), 937 (m), 922 (m), 822 (m), 797 (m), 377 (m), 352 (s) $cm^{-1}$.

**$[CrCl_3(H_2O)(18\text{-crown-6})]$:** $[CrCl_3(thf)_3]$ (0.14 g, 0.37 mmol) in dry $CH_2Cl_2$ (10 mL) was combined with 18-crown-6 (0.1 g, 0.4 mmol) in dry $CH_2Cl_2$ (10 mL). The solution was stirred for 1 h. Addition of dry *n*-hexane (5 mL) produced a precipitate, which was then filtered off and dried in vacuo. The product produced was a pink solid. Yield 0.03 g, 19%. $C_{12}H_{26}Cl_3CrO_7$ (440.7): calcd. C 32.7, H 6.0; found C 31.9, H 7.0. IR (Nujol): $\tilde{\nu}$ = 3300 (br), 1617 (m), 1299 (w), 1261 (m), 1148 (m), 1093 (vs), 1046 (sh), 1019 (s), 951 (w), 865 (s), 810 (m), 356 (m), 323 (m) $cm^{-1}$.

**$[(CrCl_3)_2(18\text{-crown-6})]$:** $[CrCl_3(thf)_3]$ (0.19 g, 0.50 mmol) was dissolved in anhydrous $CH_2Cl_2$ (20 mL) and a solution of dry 18-crown-6 (0.06 g, 0.23 mmol) in anhydrous $CH_2Cl_2$ (10 mL) added and the mixture stirred for 30 min. The solution was concentrated in vacuo to 10 mL, and dry hexane (10 mL) added dropwise to the vigorously stirred solution. After stirring for 10 min the purple solid which had separated was filtered off and dried in vacuo. Yield 0.09 g, 67%. $C_{12}H_{24}Cl_6Cr_2O_6$ (581.0): calcd. C 24.8, H 4.2; found C 25.7, H 5.9. IR (Nujol): $\tilde{\nu}$ = 1346 (w), 1306 (w), 1258 (m), 1210 (w), 1147 (sh), 1092 (s), 1064 (s), 1018 (s), 936 (m), 921 (sh), 852 (m), 821 (m), 707 (m), 587 (w), 367 (sh), 350 (s) $cm^{-1}$.

**$[CrCl_3([12]aneS_4)]$:** [12]ane$S_4$ (0.03 g, 0.13 mmol) was dissolved in $CH_2Cl_2$ (5 mL) and combined with a solution of $[CrCl_3(thf)_3]$ (0.05 g, 0.13 mmol) in $CH_2Cl_2$ (5 mL). The solution turned blue immediately and a small amount of blue precipitate formed. The solution was concentrated further to ca. 3 mL in vacuo. The resulting blue solid was then filtered off and dried in vacuo. Yield 0.04 g, 76%. $C_8H_{16}Cl_3CrS_4$ (398.8): calcd. C 24.1, H 4.0; found C 24.4, H 4.6. IR (Nujol): $\tilde{\nu}$ = 1300 (w), 1262 (m), 1093 (m), 1017 (m), 951 (w), 923 (w), 861 (m), 802 (m), 744 (m), 366 (m), 329 (w) $cm^{-1}$.

**$[CrCl_3([15]aneS_5)]$:** Prepared similarly to $[CrCl_3([12]aneS_4)]$ using [15]ane$S_5$. Purple solid. Yield 88%. $C_{10}H_{20}Cl_3CrS_5$ (459.0): calcd. C 26.2, H 4.4; found 25.6, H 4.9. IR (Nujol): $\tilde{\nu}$ = 1260 (s), 1096 (s), 1021 (s), 800 (m), 340 (m), 315 (sh) $cm^{-1}$.

**$[CrCl_3([9]aneS_2O)]$:** Prepared similarly to $[CrCl_3([12]aneS_4)]$ using [9]ane$S_2O$. Purple solid. Yield 58%. $C_6H_{12}Cl_3CrOS_2\cdot 1/4thf$ (340.67): calcd. C 24.7, H 4.1; found 25.0, H 4.0. IR (Nujol): $\tilde{\nu}$ = 1297 (w), 1200 (w), 1188 (w), 1056 (m), 1012 (m), 989 (s), 934 (m), 912 (s), 836 (m), 772 (w), 686 (w), 487 (w), 358 (s), 343 (sh) $cm^{-1}$.

**$[CrCl_3([15]aneS_2O_3)]$:** Prepared similarly to $[CrCl_3([12]aneS_4)]$ using [15]ane$S_2O_3$. Purple solid. Yield 40%. $C_{10}H_{20}Cl_3CrO_3S_2$ (410.8): calcd. C 29.2, H 4.9; found C 28.9, H 5.3. IR (Nujol): $\tilde{\nu}$ = 1304 (m), 1260 (m), 1095 (s), 1021 (s), 917 (w), 868 (w), 802 (m), 366 (m), 345 (w) $cm^{-1}$.

**$[CrCl_3([18]aneS_3O_3)]$:** $[CrCl_3(thf)_3]$ (0.18, 0.52 mmol) was dissolved in anhydrous $CH_2Cl_2$ (15 mL) and added to a solution of

[18]ane$S_3O_3$ (0.16 g, 0.52 mmol) in anhydrous $CH_2Cl_2$ (15 mL), when an intensely blue solution formed immediately which rapidly deposited a blue solid. The mixture was stirred for 30 min, dry hexane (10 mL) was added dropwise and the mixture stirred for a further 1 h. The deep blue solid was filtered off and dried in vacuo. Yield 0.16 g, 82%. $C_{12}H_{24}Cl_3CrO_3S_3 \cdot 1/2CH_2Cl_2$ (513.3): calcd. C 29.2, H 4.9; found C 28.9, H 5.3. IR (Nujol): $\tilde{\nu}$ = 1348 (w), 1295 (m), 1260 (m), 1130 (sh), 1101 (s), 1070 (sh), 1023 (s), 914 (w), 849 (w), 801 (s), 470 (w), 355 (sh), 345 (s) $cm^{-1}$.

**Vanadium(III) Complexes**

**[$VCl_3$(12-crown-4)]:** [$VCl_3(thf)_3$] (0.38 g, 1.0 mmol) and dry 12-crown-4 (0.18 g, 1.0 mmol) were combined in dry $CH_2Cl_2$ (10 mL). The pink powder that precipitated was filtered off after 2 h and dried in vacuo. Yield 0.28 g, 33%. $C_8H_{16}Cl_3O_4V$ (333.5): calcd. C 28.8, H 4.8; found C 28.8, H 5.6. IR (Nujol): $\tilde{\nu}$ = 1298 (s), 1261 (w), 1231 (m), 1145 (s), 1066 (s), 1027 (s), 937 (m), 909 (s), 837 (s), 483 (m), 364 (m), 339 (s) $cm^{-1}$.

**[$VCl_3$(15-crown-5)]:** Prepared similarly to [$VCl_3$(12-crown-4)] using anhydrous 15-crown-5. Pink powder. Yield 0.15 g, 25%. $C_{10}H_{20}Cl_3O_5V \cdot CH_2Cl_2$ (462.5): calcd. C 28.5, H 5.2; found C 27.5, H 5.3. IR (Nujol): $\tilde{\nu}$ = 1304 (m), 1262 (w), 1228 (w), 1149 (m), 1113 (m), 1080 (sh), 1068 (vs), 1027 (s), 933 (m), 918 (m), 846 (m), 793 (m), 367 (m), 342 (s), 324 (s) $cm^{-1}$.

**[$VCl_3(H_2O)$(15-crown-5)]:** [$VCl_3(thf)_3$] (0.17 g, 0.48 mmol) in dry $CH_2Cl_2$ (5 mL) was added to 15-crown-5 (0.11 g, 0.48 mmol) in dry $CH_2Cl_2$ (5 mL) and the solution was stirred for 1 h. The pink precipitate was filtered off and dried under vacuo. Yield 0.15 g, 38%. $C_{10}H_{22}Cl_3O_6V \cdot CH_2Cl_2$ (480.5): calcd. C 27.5, H 5.0; found C 27.5, H 6.1. IR (Nujol): $\tilde{\nu}$ = 3300 (br), 1630 (m), 1303 (m), 1260 (m), 1140 (s), 1120 (s), 1110 (s), 1073 (vs), 1035 (vs), 1006 (m), 933 (s), 919 (m), 854 (s), 828 (w), 786 (w), 362 (sh), 331 (m), 321 (m) $cm^{-1}$.

**[$VCl_3$(18-crown-6)]:** [$VCl_3(thf)_3$] (0.37 g, 1.0 mmol) was dissolved in anhydrous $CH_2Cl_2$ (20 mL) and added to a solution of 18-crown-6 (0.26 g, 1.0 mmol) in anhydrous $CH_2Cl_2$ (10 mL), and the purple-pink solution stirred for 1 h. The pink solid which separated on concentration of the solution to ca. 15 mL in vacuo, was filtered off and dried. Yield 0.21 g, 50%. $C_{12}H_{24}Cl_3O_6V \cdot CH_2Cl_2$ (506.5): calcd. C 30.8, H 5.2; found C 31.2, H 6.5. IR (Nujol): $\tilde{\nu}$ = 1350 (w), 1297 (m), 1261 (m), 1240 (w), 1100 (sh), 1057 (s), 1033 (s), 928 (s), 833 (s), 799 (s), 485 (w), 432 (w), 359 (sh), 340 (s) $cm^{-1}$.

**[$VCl_3(H_2O)$(18-crown-6)]:** The filtrate from the [$VCl_3$(18-crown-6)] preparation above was treated with 0.1 mL $H_2O$ and stirred for 1 h, concentrated in vacuo to ca. 10 mL to give a pink solid which was filtered off and dried in vacuo. Yield 35%. $C_{12}H_{26}Cl_3O_7V$ (439.6): calcd. C 32.8, H 6.0; found C 32.4, H 6.3. IR (Nujol): $\tilde{\nu}$ = 3400 (br), 1630 (m), 1290 (m), 1256 (m), 1150 (sh), 1093 (br.,s), 1000 (s), 952 (s), 920 (m), 837 (m), 808 (m), 389 (w), 333 (s), 310 (sh) $cm^{-1}$.

**[($VCl_3$)$_2$(18-crown-6)]:** Prepared similarly to [$VCl_3$(18-crown-6)] from anhydrous 18-crown-6 and two mol. equiv. [$VCl_3(thf)_3$]. Pink solid. Yield 45%. $C_{12}H_{24}Cl_6O_6V_2$ (578.9): calcd. C 24.9, H 4.2; found C 24.4, H 4.4. IR (Nujol): $\tilde{\nu}$ = 1298 (m), 1275 (m), 1097 (sh), 1056 (s), 1031 (s), 930 (m), 833 (m), 794 (w), 365 (sh), 341 (s) $cm^{-1}$.

**[$VCl_3$([12]ane$S_4$)]:** Prepared similarly to [$VCl_3$(18-crown-6)], using [12]ane$S_4$. Pink solid. Yield 30%. $C_8H_{16}Cl_3S_4V$ (397.8): calcd. C 24.2, H 4.1; found C 25.1, H 5.3. IR (Nujol): $\tilde{\nu}$ = 1345 (w), 1260 (s), 1090 (s), 1041 (m), 1015 (s), 925 (w), 841 (m), 801 (s), 677 (w), 361 (w), 346 (m) $cm^{-1}$.

**[$VCl_3$([9]ane$S_2O$)]:** Prepared similarly to [$VCl_3$(18-crown-6)] using [9]ane$S_2O$. Pink solid. Yield 52%. $C_6H_{12}Cl_3OS_2V$ (321.6): calcd. C 22.4, H 3.8; found C 22.4, H 3.7. IR (Nujol): $\tilde{\nu}$ = 1300 (w), 1260 (m), 1182 (w), 1096 (s), 1072 (sh), 1051 (m), 1013 (s), 998 (w), 976 (w), 935 (m), 910 (m), 797 (s), 483 (w), 356 (sh), 339 (m) $cm^{-1}$.

**[$VCl_3$([15]ane$S_2O_3$)]:** [$VCl_3(thf)_3$] (0.21 g, 0.55 mmol) was dissolved in anhydrous $CH_2Cl_2$ (15 mL) and added to a solution of [15]ane$S_2O_3$ (0.14 g, 0.55 mmol) in anhydrous $CH_2Cl_2$ (10 mL), and the purple-pink solution stirred for 1 h. The pink solid which separated on standing was filtered off and dried in vacuo. Yield 0.12 g, 54%. $C_{10}H_{20}Cl_3O_3S_2V \cdot 2CH_2Cl_2$ (579.5): calcd. C 24.8, H 4.2; found C 24.6, H 4.9. IR (Nujol): $\tilde{\nu}$ = 1290 (m), 1260 (m), 1208 (w), 1190 (m), 1126 (s), 1116 (s), 1064 (s), 1015 (sh), 917 (m), 905 (m), 811 (s), 796 (sh), 485 (w), 416 (w), 360 (s), 322 (s) $cm^{-1}$.

**[$VCl_3$([18]ane$S_3O_3$)]:** [$VCl_3(thf)_3$] (0.11 g, 0.29 mmol) was dissolved in anhydrous $CH_2Cl_2$ (15 mL) and added to a solution of

[18]aneS$_3$O$_3$ (0.09 g, 0.29 mmol) in anhydrous $CH_2Cl_2$ (10 mL), and the pale purple-pink solution stirred for 1 h. The solution was concentrated in vacuo to 10 mL, and dry hexane (10 mL) was added dropwise to the vigorously stirred solution. After stirring for 10 min the pale pink solid which had separated was filtered off and dried in vacuo. Yield 0.07 g, 52%. $C_{12}H_{24}Cl_3O_3S_3V$ (469.8): calcd. C 30.7, H 5.2; found C 31.2, H 5.6. IR (Nujol): $\tilde{\nu}$ = 1346 (w), 1300 (m), 1258 (s), 1210 (w), 1100 (s), 1072 (s), 1033 (s), 919 (m), 848 (w), 805 (s), 477 (m), 355 (sh), 343 (s) cm$^{-1}$.

**X-ray Crystallography:** Details of the crystallographic data collection and refinement parameters are given in Table 5. Crystals of [$CrCl_3(H_2O)$(18-crown-6)], [$CrCl_3$([15]aneS$_5$)] and [$VCl_3(H_2O)$(15-crown-5)]·3/4$CH_2Cl_2$ were obtained by layering $CH_2Cl_2$ solutions of the complexes with hexane. Data collection used a Nonius Kappa CCD diffractometer ($T$ = 120 K) and with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Structure solution and refinement were routine.[25,26] H atoms bonded to C were introduced in calculated positions (C–H 0.99 Å). H atoms on the water molecules (O13 and O14) were located in [$CrCl_3(H_2O)$(18-crown-6)] from later electron-density maps and introduced into the model and refined using DFIX commands on the four O–H distances [target 0.84(2) Å]. Refinement converged leaving satisfactory H–O–H and H–O–Cr angles. Water H atoms were not identified on O6 in the V compound. The $U_{iso}$ for H atoms was either a common refined parameter or 1.2$U_{eq}$ of the bonded C atom (in [$CrCl_3$([15]aneS$_5$)] only). The absolute structures of the crystals used for [$VCl_3(H_2O)$(15-crown-5)] and [$CrCl_3$([15]aneS$_5$)] were established from the Flack parameter.[27] Selected bond lengths and angles are given in Table 1, 2 and 4.

CCDC-607029 (for Cr/O), -607030 (for V), and -607031 (for Cr/S) contain supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# DFT Investigation of the Potential of [H-M{$(NHCH_2CH_2)_3X$}] Catalysts (M = Mo, Ru, Os; X = N, P) for the Reduction of $N_2$ to $NH_3$ by $H_2$

**Markus Hölscher[a] and Walter Leitner*[a]**

**Keywords:** DFT calculations / Nitrogen fixation / Nitrogen activation / Nitrogen reduction / Ammonia / Homogeneous catalysis

DFT calculations of model complexes [H-M{$(NHCH_2CH_2)_3$-X}] (M = Mo, Ru, Os; X = N, P) were carried out to investigate the catalytic potential of these complexes towards the reduction of $N_2$ to $NH_3$ using only $H_2$ as the reducing agent. Closed catalytic cycles were calculated for all three metal hydrides. The calculations showed that [H-Mo{$(NHCH_2CH_2)_3$-N}], **1**-Mo, is not an appropriate catalyst due to very high activation barriers for several steps of the reaction ($\Delta H^{\ddagger}_{max}$ = 69.1 kcal/mol). Much lower activation barriers were found for the Ru and Os catalysts [H-Ru{$(NHCH_2CH_2)_3N$}], **1**-Ru, and [H-Os{$(NHCH_2CH_2)_3P$}], **1**-Os(P). With $\Delta H^{\ddagger}_{max}/\Delta G^{\ddagger}_{max}$ = 29.3/35.7 kcal/mol, **1**-Os(P) shows potential for future theoretical work. QM/MM calculations were used to investigate some properties of the Ru system empolying the hexaisopropylterphenyl ligand (HIPT). The results indicate that an HIPT substituent at the ligand core has a benefical influence on some reaction steps by lowering the activation barriers, while for other steps the activation energies increase.

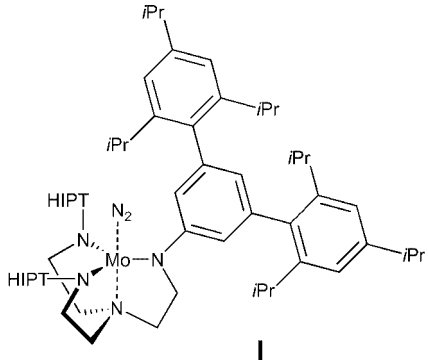
## Introduction

The reduction of dinitrogen ($N_2$) to ammonia ($NH_3$) has been of significant importance to chemical research for many years.[1] The conversion of the very inert $N_2$ molecule to $NH_3$ is currently put into practice by both natural and manmade processes, which have some important differences, such as the following: For the in vivo reaction of $N_2$ with the FeMoco-Cofactor of nitrogenase, protons and reducing agents are required. This process can be considered as a homogeneously catalyzed reaction. Conversely, the industrial reduction of $N_2$ to $NH_3$ (Haber–Bosch process) is a hetereogeneously catalyzed reaction in which $N_2$ is directly reduced by $H_2$. Any kind of synthetic, well-defined transition metal complex that catalyzes either of these reactions ($H^+$/reducing agent, or $H_2$ reduction) is of general interest, allowing for a greater understanding of the natural and technical processes, as they can provide important information about the individual reaction steps on the molecular level. Furthermore, routes to new processes might be identified in this way.

Especially important in this context is the seminal work published very recently by Schrock et al., who showed [$N_2$–Mo{$(N(HIPT)CH_2CH_2)_3N$}] (HIPT = hexaisopropylterphenyl) **I** to be an active catalyst for the reduction of $N_2$ to $NH_3$.[2] In the presence of **I**, protons, and a reducing agent, $N_2$ can be reduced in a stepwise protonation/reduction cycle to yield $NH_3$.



**I**

These experimental results were recently rationalized by Tuczek and Studt using DFT calculations.[3] The reaction mechanism as postulated by Schrock et al. was supported by these calculations, and the energetic requirements for the reaction were related to the energetics of the reducing agent ATP which led to an experimentally, and theoretically, well-rounded picture of this synthetic $N_2$ reduction. Independently, Reiher et al. investigated, by means of DFT calculations, the geometries and electronic structures of complexes that participate in this type of nitrogen activation/transformation reaction and considered how the structures vary as a function of the ligand structure. The authors were able to prove the assumptions that were postulated by the Schrock

group with regards to some of the individual reaction steps.[4,5] Also, the work by Reiher et al. made it clear that the ligand structures (that is the HIPT substituent or other substituents at the trisamidoamine core of the ligand) can lead to significantly different energy profiles over multiple reaction steps. Furthermore, it was shown that the charge of the complex is crucial in enabling the catalyst to release $NH_3$ at the end of the reaction cycle, and for coordination to a new $N_2$ molecule. Cao et al. also reported DFT calculations using model complexes derived from **I**.[6] On the whole there is agreement between experimental and theoretical results that the reaction at the molybdenum center can take place because firstly, the HIPT substituent at the amido nitrogen centers of the ligand core efficiently shields the metal center and thus prevents the formation of nitrogen-bridged, unreactive complex dimers, and secondly, it leaves enough space to allow $N_2$ and $H^+$ to approach the metal center thus enabling the reaction to take place. For the release of $NH_3$ at the end of the catalytic cycle Reiher et al. suggested that a neutral or anionic pathway would be the most probable way for re-establishment of the original catalyst. Furthermore, experiments made it clear that the substituent at the trisamidoamine ligand core exerts a significant electronic influence, as Schrock et al. showed that changing the HIPT substituent to the HTBT substituent (HTBT = hexa-*tert*-butylterphenyl) results in a significant lowering of the catalytic activity, while the activities of catalysts with *para*-BrHIPT substituents are similar to the those catalysis carrying the HIPT substituent.[2e] Electronically, molybdenum seems to be a mandatory component of the catalyst as it was shown experimentally that the corresponding tungsten compound [$N_2$-W{(N(HIPT)$CH_2CH_2)_3$N}] **II** does not catalyze $NH_3$ formation under identical reaction conditions.[7]

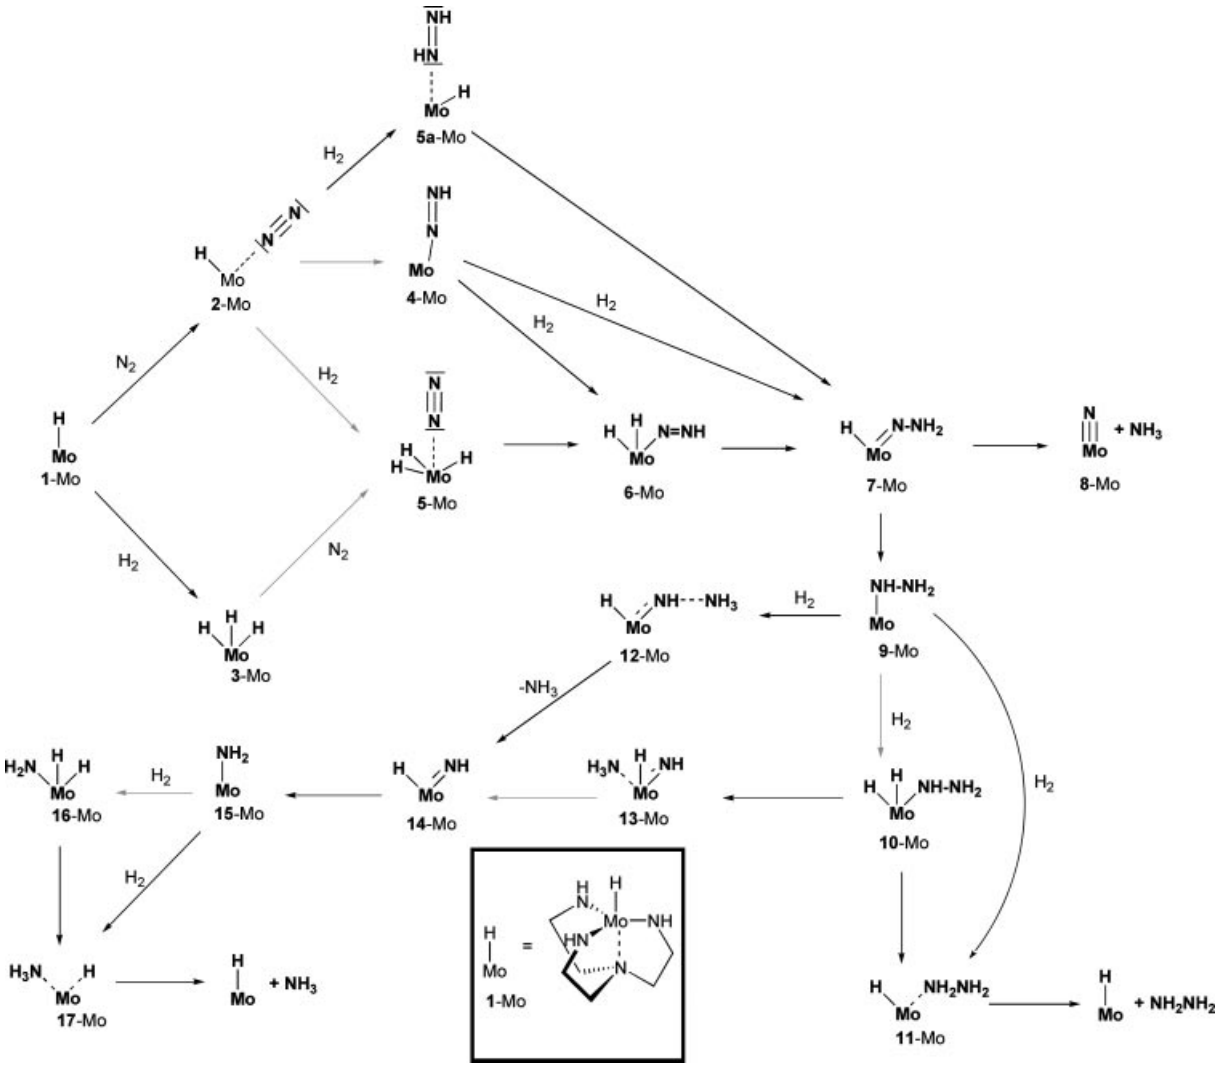
Stimulated by these fascinating experimental and theoretical results, we became interested in finding out if complexes of the general formula [H-M{$(NHCH_2CH_2)_3$X}] (M = Mo, Ru, Os; X = N, P) could be suitable general catalysts for the reduction of $N_2$ to $NH_3$ using *only* $H_2$. If this is the case, the gap that presently exists in catalytic $N_2$ reduction chemistry could be closed, and one could arrive at the homogeneously catalyzed reduction of $N_2$ to $NH_3$ using a $N_2$/$H_2$ reactant gas mixture and well-defined transition metal complexes as catalysts, without the presence of any other reagents. As Schrock et al. have already reported the synthesis of, and analytical data for, [H-Mo{(N(HIPT)-$CH_2CH_2)_3$N}][2d] we considered model complexes [H-Mo{$(NHCH_2CH_2)_3$N}] (**1**-Mo), [H-Ru{$(NHCH_2$-$CH_2)_3$N}] (**1**-Ru) and [H-Os{$(NHCH_2CH_2)_3$P}] (**1**-Os(P)) to be potentially useful catalyst candidates for DFT investigations aimed at exploring the $N_2$ reduction reaction. Our aim was to check if closed catalytic cycles can be found in all cases, and if they exist, which energy profiles one would have to expect. To the best of our knowledge calculations of this kind have not yet been carried out.[8] We found for all three complexes, **1**-Mo, **1**-Ru and **1**-Os(P) that catalytic cycles do exist, but differ from one another, in some parts significantly so. With regards to a potential experimental application of catalysts of this kind, we postulate in accordance with our calculations and the experimental work by Schrock et al.[9] that **1**-Mo will not be a suitable catalyst for the generation of $NH_3$ using $N_2$/$H_2$. Whether or not complexes **1**-Ru and **1**-Os(P) will be suitable cannot be answered conclusively at this point; however, there is a higher probability that these compounds will be of potential use. Furthermore, they should be interesting starting points for theoretical and experimental investigations of modified ligands (vide infra). Our main aim in this first theoretical catalyst screening is to answer the following question: can an experimental search for potential catalysts be considered profitable in view of the high activation barriers that must be expected for this reaction?

DFT calculations using the B3LYP hybrid function were carried out successfully by Tuczek and Studer,[3] and by Reiher and co-workers,[4,5] using models of molybdenum complexes relevant to the $N_2$ reduction reaction, as reported by Schrock et al. Yates and co-workers compared the results of B3LYP and CCSD(T) calculations for nitrogen activation at model trigonal coordinated molybdenum complexes, and found both calculation methods yielded energies being well in accord with each other.[10] Thus, calculations using the B3LYP hybrid function can be considered a reasonable compromise between justifiable computer time for the calculations of model complexes, and the degree of accuracy with which the structures and energies are obtained from these calculations. Moreover, calculations of this kind are considered to predict reactivity trends correctly. A multitude of theoretical investigations of transition metal hydrides,[11] among them ruthenium[12] and osmium hydrides[13] also show the B3LYP hybrid function to be appropriate for obtaining plausible structures and energy trends. For this reason we used the B3LYP hybrid function in this work.[14] In a few selected cases we used QM/MM calculations to estimate the influence of the HIPT substituent on the calculated properties (see Computational Details). In the following discussion of energies and energy differences we refer to the reaction enthalpy, $H$,[15] as well as the Gibb's free energy, $G$ (as well as to the activation enthalpies $H^{\ddagger}$ and Gibb's free activation energies $G^{\ddagger}$).

## Results and Discussion

The catalytic cycle that was obtained using **1**-Mo is shown in Scheme 1 and an energy profile is depicted in Figure 1. Figures showing the structures and selected structural parameters are included in the supporting information. Complex **1**-Mo is more stable, by –14.2 kcal/mol, in the triplet state than in the singlet state, which is in accord with the experimentally observed paramagnetism of **1**-Mo.[2d,16] However, all other compounds of the Mo cycle are either significantly more stable in the singlet state, or they could not be located in the triplet state. To start the reaction cycle, $N_2$ or $H_2$ could be added to **1**-Mo, resulting in the formation of **2**-Mo and **3**-Mo, respectively. With regard to a closed catalytic cycle, only the addition of $N_2$ would be successful. A low lying transition state for the conversion of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1. Catalytic cycle as calculated for **1**-Mo. Arrows in grey denote reactions for which a transition state could not be located.

**1**-Mo to **3**-Mo was located, but the addition of $N_2$ to **3**-Mo to give **5**-Mo is not feasible as a transition state leading to **5**-Mo could not be located. There is a transition state for the conversion of **1**-Mo to **2**-Mo ($\Delta H^{\ddagger}$ = 17.8 kcal/mol), but not for the oxidative addition of $H_2$ to **2**-Mo leading to **5**-Mo. As a result **5**-Mo cannot be formed in this way. Also the transfer of the metal bound hydride in **2**-Mo to a coordinated $N_2$ molecule does not seem to be possible. The corresponding product **4**-Mo, which has been characterized crystallographically,[2f] is a stable local minimum, however no transition state for the conversion of **2**-Mo to give **4**-Mo exists. However in an interesting, though energetically very unfavorable, σ-bond metathesis process $H_2$ can be added to **2**-Mo thus generating **5a**-Mo.

During this reaction the metal bound hydride is transferred to one of the nitrogen atoms of the $N_2$ molecule that is coordinated to the metal, while one of the hydrogen atoms of the $H_2$ molecule is transferred to the other nitrogen atom, and the second hydrogen atom is transferred to the metal center. However, the activation enthalpy $\Delta H^{\ddagger}$ for this step is extremely high (69.1 kcal/mol). A local minimum in which the incoming $H_2$ molecule initially coordinates in a non-classical manner to the metal center of **2**-Mo without being cleaved, was searched for, but not located. Complex **7**-Mo can be obtained from **5a**-Mo by hydrogen migration from the internal N atom of the Mo–NH=NH unit to the external N atom. Energetically speaking this reaction is slightly more unfavorable than the reaction of **4**-Mo with $H_2$ that also generates **7**-Mo, in both cases transition states were located. The activation enthalpies for both reactions are very high (52.3 and 43.4 kcal/mol, respectively). However, the reaction of $H_2$ and **4**-Mo to produce **6**-Mo is not possible. Complexes **6**-Mo and **5**-Mo can only be formed from **7**-Mo. With **7**-Mo as the staring material, two reactions can take place, either the metal bound hydrogen is transferred to the $NH_2$ unit generating one molecule of ammonia and the extremely stable molybdenum nitride complex **8**-Mo, or the H atom is transferred to the internal N atom of the $N{=}NH_2$ unit generating **9**-Mo. The latter reaction is kinetically preferred with respect to the formation of **8**-Mo due to its lower activation enthalpy ($\Delta H^{\ddagger}$ = 21.7 kcal/mol); the formation of **8**-Mo and $NH_3$ requires

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

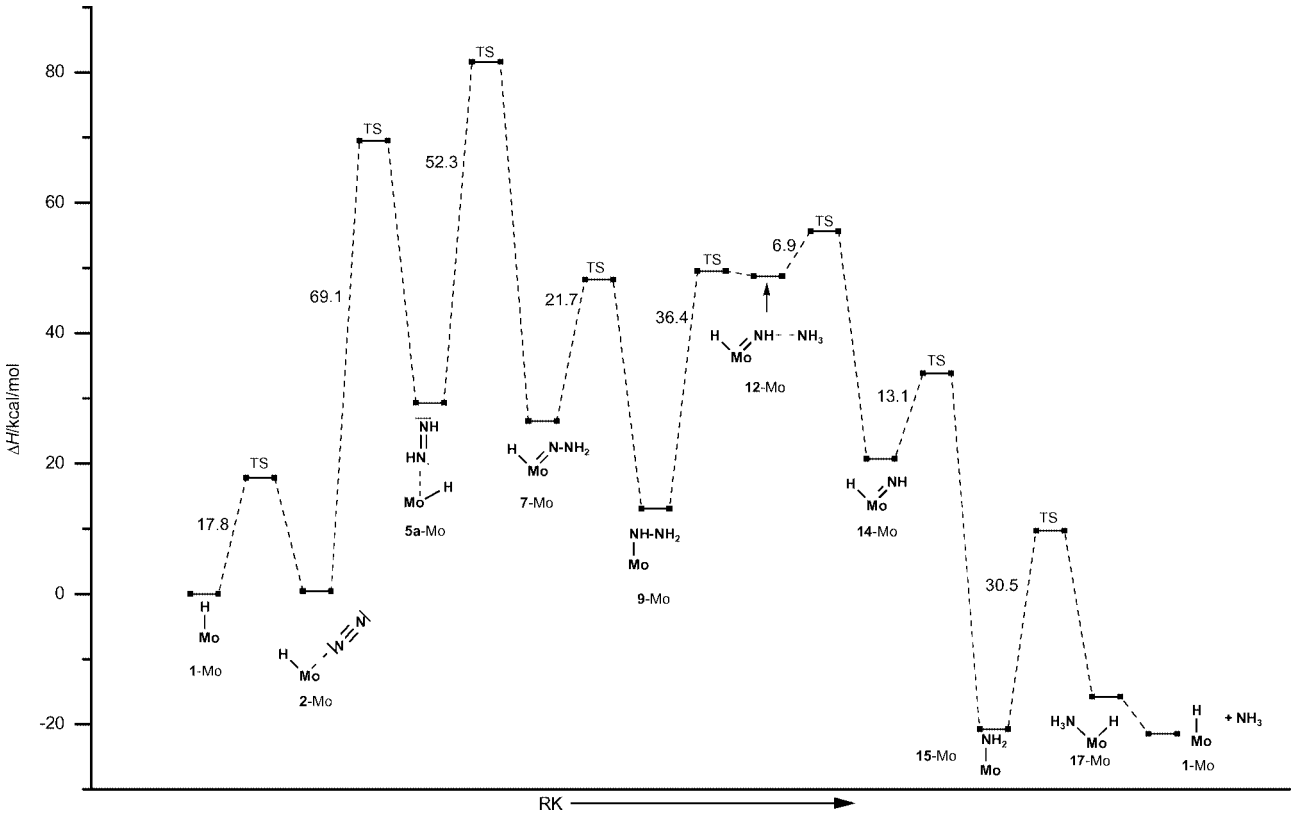


Figure 1. Energy profile ($\Delta H$/kcal/mol) as calculated for the only completely closed cycle obtained with **1**-Mo. Relative activation energies ($\Delta H^{\ddagger}$/kcal/mol) are noted at the corresponding barriers.

an activation enthalpy higher by ca. 20 kcal/mol ($\Delta H^{\ddagger}$ = 39.7 kcal/mol). However, thermodynamically speaking the formation of **8**-Mo and $NH_3$ is clearly preferred. The reintroduction of **8**-Mo into the catalytic cycle by the addition of $H_2$ is impossible.

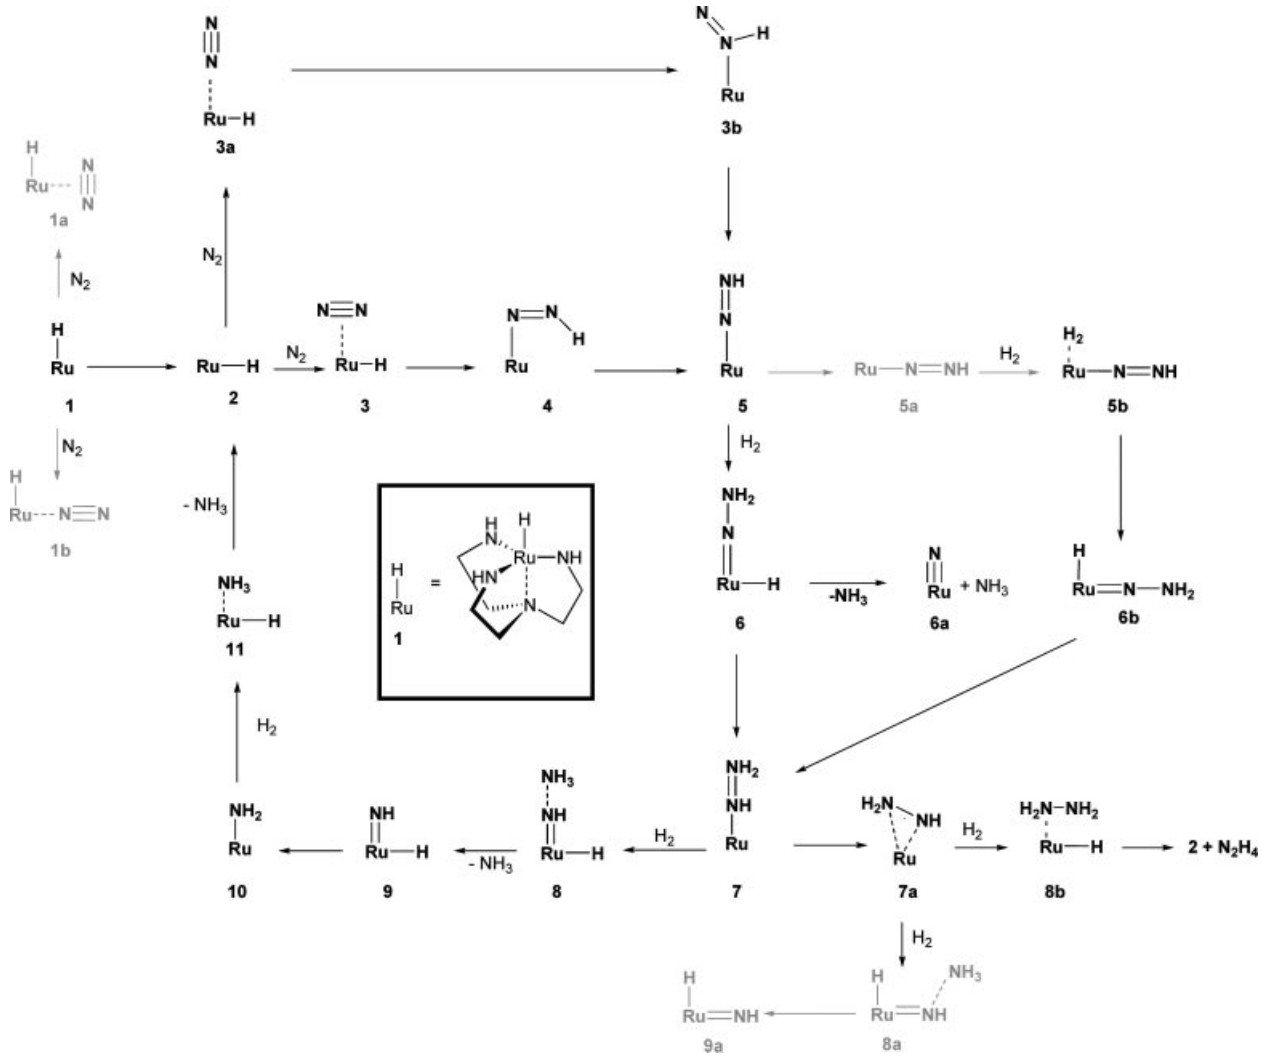
Complex **9**-Mo can also react in two ways. The addition/cleavage of $H_2$ generates **11**-Mo, which can be considered as the adduct of **1**-Mo and hydrazine. Hydrazine can leave the complex while the catalytic cycle is endothermically closed ($\Delta H$ = 57.8 kcal/mol). The oxidative addition of $H_2$ to **9**-Mo does not seem to be possible, as the reaction product **10**-Mo exists on the hyper surface, but this is not case for the corresponding transition state that leads to **10**-Mo. However, the transfer of one metal bound hydride of **10**-Mo to the NH–$NH_2$ unit to form **11**-Mo is possible, and the corresponding activation enthalpy is comparatively low ($\Delta H^{\ddagger}$ = 16.2 kcal/mol).

Alternatively, **9**-Mo can react with one $H_2$ molecule to produce **12**-Mo. By cleavage of $H_2$ one molecule of $NH_3$ is generated, which participates in attractive interactions with a neighboring N atom. The $NH_3$ molecule can be cleaved off easily ($\Delta H^{\ddagger}$ = 6.9 kcal/mol) thus forming **14**-Mo. The rearrangement of **14**-Mo to give **15**-Mo requires only a comparatively small amount of energy ($\Delta H^{\ddagger}$ = 13.1 kcal/mol), and the product **15**-Mo is significantly more stable than **14**-Mo ($\Delta H$ = –37.8 kcal/mol).

Complex **15**-Mo cannot participate in an oxidative addition reaction with $H_2$ to produce **16**-Mo, as the corresponding transition state does not exist. Instead, the $H_2$ molecule is cleaved directly upon reaction with **15**-Mo generating **17**-Mo, which is an adduct of $NH_3$ and **1**-Mo. The activation enthalpy for this reaction that generate **17**-Mo amounts to 30.5 kcal/mol. In the last step $NH_3$ is cleaved off from the complex, and **1**-Mo is regenerated.[17]

Due to the high activation enthalpies, which amount to very high values at the beginning of the reaction cycles (i.e. **2**-Mo → **5a**-Mo, **5a**-Mo → **7**-Mo), it cannot be expected that **1**-Mo would be a useful catalyst for the reduction of $N_2$ to $NH_3$ using only $H_2$, this is in accordance with experimental results.[9] As an alternative to molybdenum, we considered ruthenium to be interesting, as a variety of molecular ruthenium hydrides have been synthesized[18] and have been employed as catalysts by us[19] and others.[20] Furthermore, novel heterogeneous ruthenium catalysts[21] have been developed recently, and Haber–Bosch ruthenium-containing catalysts are also known. Additionally, by keeping the formal oxidation state of the metal center the same, by exchanging molybdenum with ruthenium (and also osmium, vide infra) one obtains a catalyst system possessing an additional two electrons. This should enable direct information to be generated as to whether or not, for the given ligand core, an electron-rich metal center is most useful for promoting the $N_2$ reduction reaction. Interestingly, a closed catalytic cycle for the $N_2$ reduction reaction could also be calculated using **1**-Ru as the catalyst. However, this cycle is different from the molybdenum cycle in some ways.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2. Catalytic cycle as calculated for **1**-Ru. Compounds and arrows in grey denote structures and reactions which were not located, respectively.

The catalytic cycle obtained with **1**-Ru is shown in Scheme 2 and Figure 2 contains the corresponding energy profile (the supporting information contains graphical representations of the calculated structures). The cycle for the Ru catalyst was calculated with all compounds being in the singlet spin state (this was also the case for the cycle incorporating Os compounds, vide infra). Both the side-on and end-on addition of $N_2$ to **1**-Ru forming **1a**-Ru and **1b**-Ru, respectively, are not possible ($H_2$ could not be coordinated side-on, or end-on, to **1**-Ru either).

However, in contrast to **1**-Mo, the hydride in **1**-Ru can flip from the axial to the equatorial position generating **2**-Ru. This flipping requires a significant amount of energy ($\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 43.5/43.2 kcal/mol) and product **2**-Ru is significantly richer in energy ($\Delta H$ = 42.9) than the reactant. Dinitrogen can coordinate to **2**-Ru at the axial position in either end-on (**3a**-Ru) or side-on (**3**-Ru) fashion, with end-on-addition clearly being exergonic relative to **2**-Ru ($\Delta H/\Delta G$ = –24.1/–13.3 kcal/mol), while side-on addition yields only a small energy gain ($\Delta H$ = –5.0 kcal/mol), which is compensated for by the unfavorable entropic contribution ($\Delta G$ = 4.7 kcal/mol). Transfer of the Ru bound hydride in **3**-Ru to the coordinated $N_2$ molecule leads to **4**-Ru, and the activation enthalpy for this reaction amounts to $\Delta H^{\ddagger}$ = 19.4 kcal/mol ($\Delta G^{\ddagger}$ = 20.9 kcal/mol). This is clearly different to the molybdenum system in which hydride transfer is not possible in this way. Complex **4**-Ru can rearrange to give the slightly more stable complex **5**-Ru, which is also obtainable via **3a**-Ru. The transfer of the hydride of **3a**-Ru to form **3b**-Ru is possible, however, energetically it is much more unfavorable than the reaction sequence already described, namely the transformation of **3**-Ru to **5**-Ru via **4**-Ru. Indeed, the activation barrier for the formation of **3b**-Ru from **3a**-Ru is higher by ca. 20 kcal/mol ($\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 42.0/41.9 kcal/mol), and the barrier for the reaction of **3b**-Ru to give **5**-Ru is very high with $\Delta H^{\ddagger}$ and $\Delta G^{\ddagger}$ values of 47.2 and 46.8 kcal/mol, respectively. The sequence **3**-Ru → **4**-Ru → **5**-Ru requires much less energy.

It can be envisaged that the reaction continues from **5**-Ru via the equatorial conformer **5a**-Ru. For the subsequent steps (reaction of **5b**-Ru to **6b**-Ru and **7**-Ru) the corresponding minima and transition states were located, and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

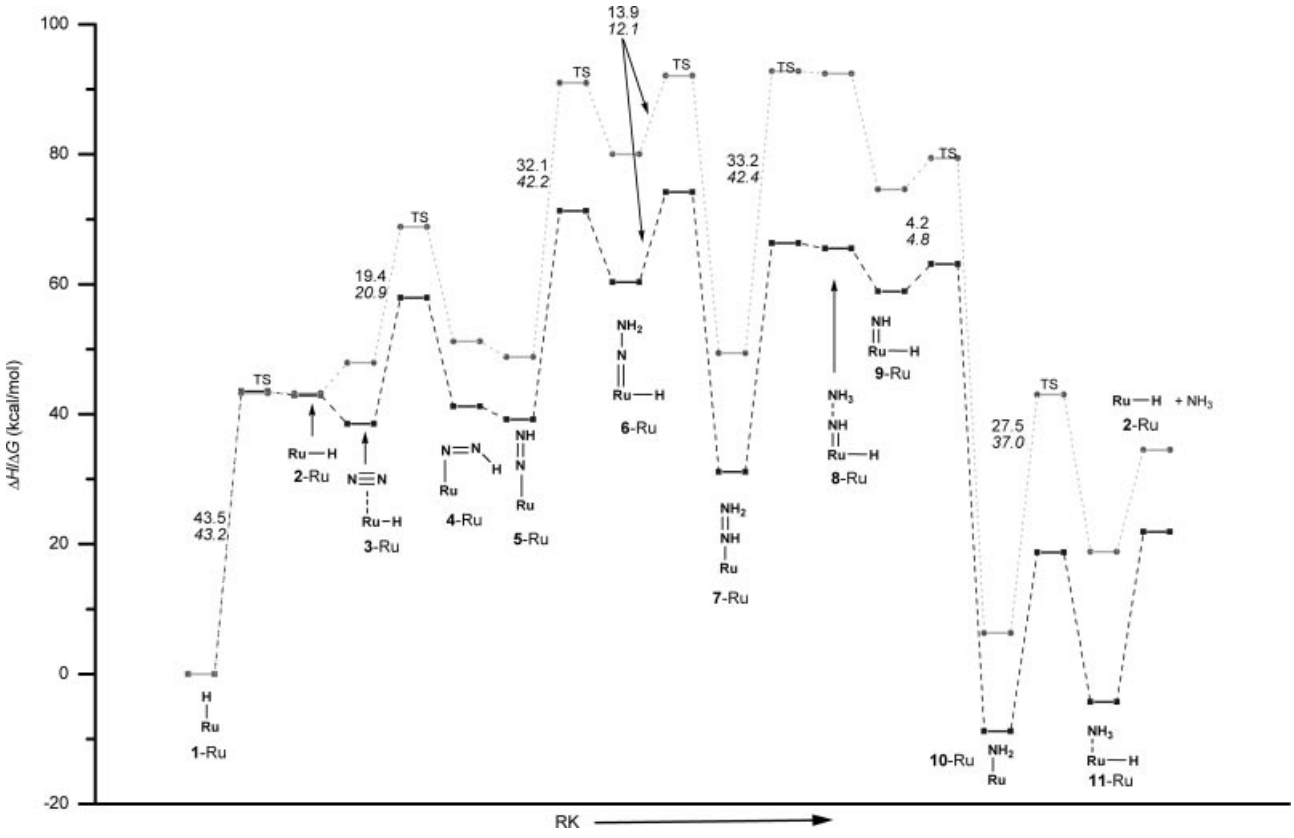


Figure 2. Energy profile ($\Delta H$ [squares; broken lines] and $\Delta G$ [circles; dotted lines], all in kcal/mol) as calculated for the main cycle obtained for **1**-Ru. Relative activation energies ($\Delta H^{\ddagger}/\Delta G^{\ddagger}$ plain/italics) are noted at the corresponding barriers.

the energies of these were low. For example, the activation energies for the conversion of **5b**-Ru to **6b**-Ru are $\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 9.5/10.5 kcal/mol. Complex **6b**-Ru can then be transformed to **7**-Ru, a process that also has a low activation barrier ($\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 9.4/9.5 kcal/mol). However, it was not possible to locate compound **5a**-Ru, making the reaction sequence **5**-Ru → **5a**-Ru → **5b**-Ru → **6b**-Ru → **7**-Ru questionable.

Conversely, if an $H_2$ molecule approaches **5**-Ru, the H–H bond is cleaved and **6**-Ru is formed. One hydrogen atom is transferred to the terminal NH group, and the other hydrogen atom migrates to the metal. Transfer of the Ru bound hydride of **6**-Ru to the terminal $NH_2$ group of the $NNH_2$ unit generates the first $NH_3$ molecule of this cycle. In an analogous manner to the molybdenum system, the corresponding ruthenium nitride complex **6a**-Ru is formed. In a similar way to the molybdenum system, this reaction step has a large activation energy ($\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 43.6/43.3 kcal/mol), however, the reaction products are strongly endothermic ($\Delta H/\Delta G$ = 51.7/58.2 kcal/mol) relative to the sum of the energies for **1**-Ru, $N_2$ and $H_2$, and this is in clear contrast to the molybdenum system. According to these results ruthenium nitride, **6a**-Ru, is significantly less stable than the analogous molybdenum nitride complex, **8**-Mo.

Alternatively, the hydride in **6**-Ru can be transferred from the metal center to the internal N atom of the $NNH_2$ unit generating complex **7**-Ru ($\Delta H/\Delta G$ = 31.1/49.4 kcal/mol) that is significantly lower in energy. The Gibb's free energy required for the formation of **7**-Ru from **6**-Ru is relatively small ($\Delta G^{\ddagger}$ = 12.1 kcal/mol), and clearly differs from the Gibb's free energies for the steps described so far. The even less energy consuming complex **7**-Ru is obtained following the alternative route (which is not completely closed) **5b**-Ru to **6b**-Ru, and then from **6b**-Ru complex **7**-Ru can be obtained, with a Gibb's free energy of only 9.5 kcal/mol.

By rotating the $NHNH_2$ unit that is bound to the metal center in **7**-Ru to a side-on coordination mode, complex **7a**-Ru is formed in which both N atoms of the $NHNH_2$ unit have bonding interactions with the ruthenium center, as can be deduced from the N–Ru distances of 2.081 ($NH_2$–Ru) and 2.186 Å (NH–Ru). With **7a**-Ru as a starting material one can arrive at **8b**-Ru (the adduct of **2**-Ru and hydrazine), and the imidoruthenium complex **8a**-Ru can also be formed, from which the second ammonia molecule of the cycle is generated, which shows bonding interactions with the imido unit.[22] However, the resultant product **9a**-Ru could not be located, and as a result the cycle cannot be continued in this way. Due to the formation of hydrazine and **2**-Ru the catalytic cycle ends endothermically as expected.

If $H_2$ is added to **7**-Ru the H–H bond is cleaved, and the axial imidoruthenium complex **8**-Ru is formed. The newly formed $NH_3$ molecule that is incorporated in this complex has bonding interactions with the imido group. The acti-

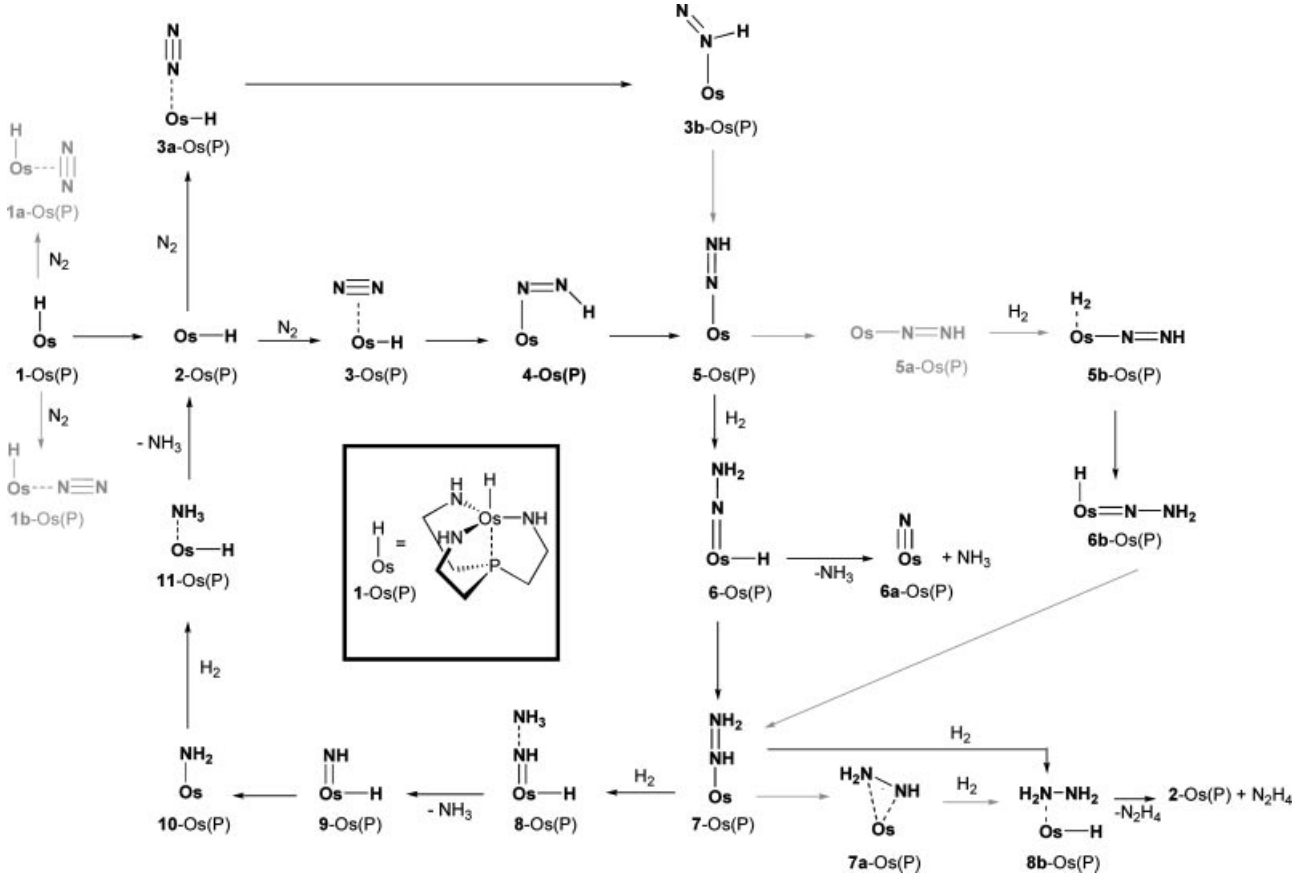
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vation barrier for this reaction ($\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 33.2/42.4 kcal/mol) is significantly higher than the barrier for the conversion of **7a**-Ru to **8a**-Ru ($\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 28.2/28.6 kcal/mol).

Alternatively, the $NH_3$ molecule can be cleaved from **8**-Ru and the resultant imido complex **9**-Ru can then react to give the amido complex **10**-Ru, which requires only a small amount of activation energy ($\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 4.2/4.8 kcal/mol). The reaction of **10**-Ru with $H_2$ cleaves the H–H bond and generates complex **11**-Ru that can be considered as an adduct of **2**-Ru and $NH_3$. This reaction requires an activation energy of $\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 27.5/36.7 kcal/mol. Cleaving $NH_3$ off **11**-Ru generates a second ammonia molecule, and regenerates the catalyst **2**-Ru.[16]

In summary, a closed catalytic cycle could be calculated using **1**-Ru with local minima and transition states that enable a plausible reaction scheme to be suggested. It is interesting to note that the highest activation barriers of this cycle are much lower than those for the molybdenum system. However, some activation enthalpies and Gibb's free energies (i.e. reactions **5**-Ru → **6**-Ru and **7**-Ru → **8**-Ru) have values of ca. 30 and 40 kcal/mol, respectively and thus are probably too high to enable the reaction to occur in practice. Also we note that the usage of the real HIPT ligand seems to influence the reaction trend. Some steps of the cycle (**1**-Ru → **2**-Ru; **3**-Ru → **4**-Ru; **10**-Ru → **11**-Ru, **5b**-Ru → **6b**-Ru) were re-optimized, using the HIPT ligand, by applying QM/MM-methods (see Computational Details). Interestingly, the presence of the real ligand reduces the activation barrier, in comparison to the model ligand, by ca. 10 kcal/mol for the reaction **1**-Ru → **2**-Ru ($\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 30.8/31.4 kcal/mol). Conversely, the activation barriers for the reactions **3**-Ru → **4**-Ru and **5b**-Ru → **6b**-Ru are slightly higher relative to the model ligand. An even clearer increase in the activation barrier was found for the **10**-Ru → **11**-Ru reaction. For this reaction the activation enthalpy $\Delta H^{\ddagger}$ is raised by 3.3 kcal/mol, and the Gibb's free activation energy, $\Delta G^{\ddagger}$, rises by 4.1 kcal/mol relative to the model ligand system. These results indicate that fine tuning of the ligand may be crucial in future experimental work.

In the third part of this evaluation of the potential of transition metal complexes with TREN- and TREN-type ligands, we investigated the behavior of **1**-Os(P). In this complex the ligand core is not tris(2-aminoethyl)amine, but tris(2-aminoethyl)phosphane. Phosphanes of this kind can be obtained synthetically and have been structurally characterized.[23] Similar phosphanes were used for the syntheses of zirconium complexes.[24] In test calculations of a few steps of the cycles involving **1**-Os and **1**-Os(P) it turned out that the usage of the triamidophosphane ligand seems to be slightly more favorable, with regards to activation barriers, than the other ligands discussed thus far. Accordingly, we



Scheme 3. Catalytic cycle as calculated for **1**-Os(P). Compounds and arrows in grey denote structures and reactions which were not located, respectively.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

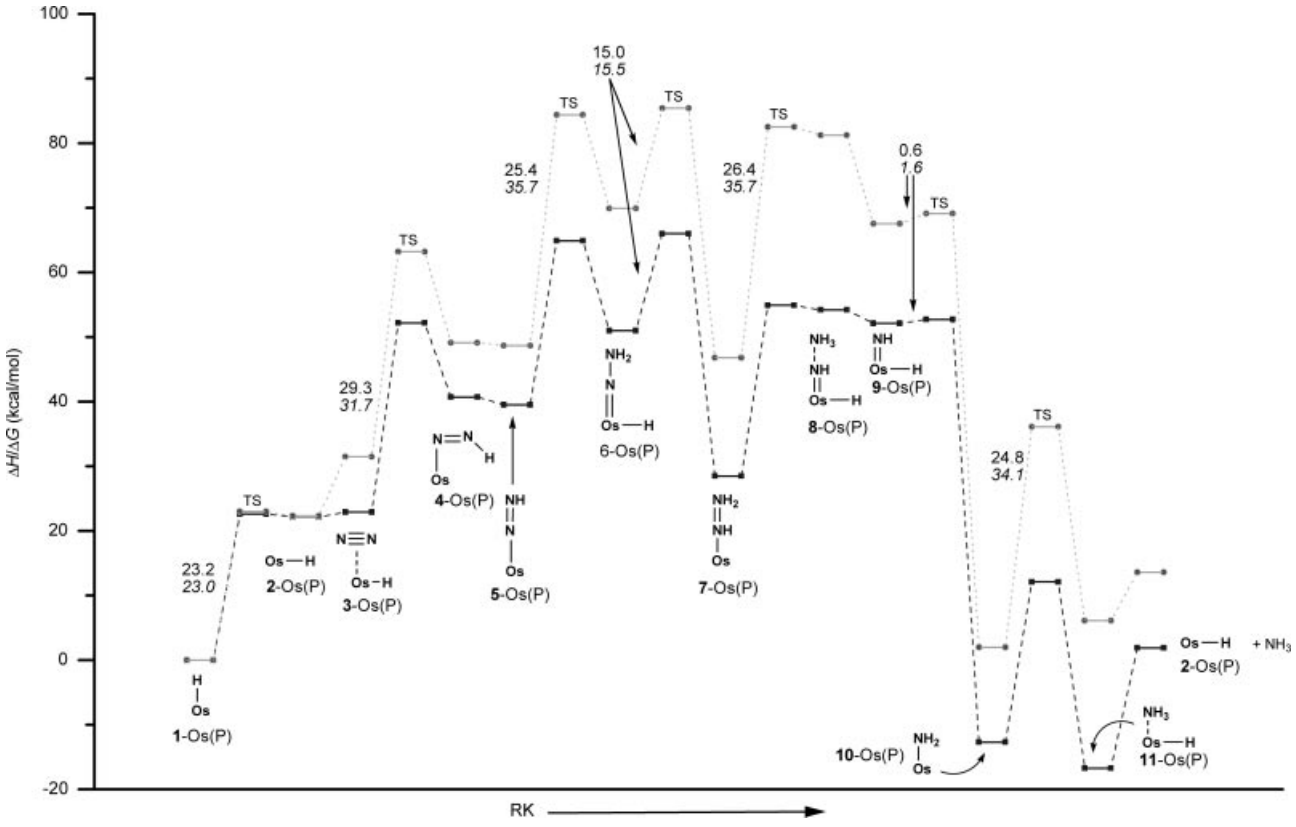


Figure 3. Energy profile ($\Delta H$ [squares; broken lines] and$\Delta G$ [circles; dotted lines], all kcal/mol) as calculated for the main cycle obtained for **1**-Os(P). Relative activation barriers ($\Delta H^{\ddagger}/\Delta G^{\ddagger}$ plain/italics) are noted at the corresponding barriers.

used this ligand for the calculation of the following cycle. All of our investigations hint that the cycle proposed for **1**-Ru would be applicable to **1**-Os(P) with a few small differences.[25] Accordingly the cycle is discussed only briefly. Scheme 3 and Figure 3 show the corresponding catalytic cycle and the energy profile for **1**-Os(P), respectively.

With regards to the main cycle it is striking that some activation barriers and Gibb's free activation energies are lower – in some cases significantly lower – compared to the ruthenium system. For example the Gibb's free activation energy, $\Delta G^{\ddagger}$, for the flipping of the hydride from the axial position in **1**-Ru to the equatorial position in **2**-Ru amounts to 43.2 kcal/mol, while for the conversion of **1**-Os(P) to **2**-Os(P) it is only 23.0 kcal/mol. Also for the conversion of **5**-Os(P) to **6**-Os(P) the Gibb's free activation barrier ($\Delta G^{\ddagger}$ = 35.7 kcal/mol) is lower by 6.5 kcal/mol than the barrier for the conversion of **5**-Ru to **6**-Ru ($\Delta G^{\ddagger}$ = 42.2 kcal/mol). Less pronounced is the reduction in the Gibb's free activation barrier in the osmium system for the conversion of **10**-Os(P) to **11**-Os(P) when compared to the analogous reaction within the ruthenium system. The barrier is $\Delta G^{\ddagger}$ = 34.1 kcal/mol for the conversion of **10**-Os(P) to **11**-Os(P), while for the conversion of **10**-Ru to **11**-Ru 36.7 kcal/mol of energy are required. In an analogous manner to the Ru system, complexes **1a**-Os(P), **1b**-Os(P) and **5a**-Os(P) could not be located. Additionally, relative to the Ru system there is a drastic increase in the activation energy for the conversion of **3**-Os(P) to **4**-Os(P) ($\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 29.3/31.7 kcal/mol with respect to $\Delta H^{\ddagger}/\Delta G^{\ddagger}$ = 19.4/20.9 kcal/mol for the Ru system).

In summary, for **1**-Os(P) a closed catalytic cycle can be calculated for the $N_2$ reduction reaction. In this cycle the highest Gibb's free activation barriers, $\Delta G^{\ddagger}$, using the model ligand, only amounts to 35.7 kcal/mol [**5**-Os(P) → **6**-Os(P) and **7**-Os(P) → **8**-Os(P)],[26] while the activation enthalpy $\Delta H^{\ddagger}$ has a maximum value of 29.3 kcal/mol [**3**-Os(P) → **4**-Os(P)]. Compared to the molybdenum system ($\Delta H^{\ddagger}_{max}$ = 69.1 kcal/mol) the activation energies are generally much lower for this system. These results are encouraging as it can be expected that, as in the case of the ruthenium system, the osmium system with the use of HIPT or other real ligands might prove useful by actively reducing the activation barriers further.

## Summary

We have showed that all three metal hydrides investigated in the calculations reported herein yield closed catalytic cycles for the reduction of $N_2$ to $NH_3$ by $H_2$. The extremely high activation barriers of the molybdenum system, in accordance with experimental work by Schrock et al., hint at the fact that **1**-Mo is not a suitable catalyst for such a $N_2$ reduction reaction. The activation barriers are much lower

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in catalytic cycles incorporating **1**-Ru and **1**-Os(P), however the Gibb's free activation barriers, $\Delta G^{\ddagger}$, have values that are significantly higher than 30 kcal/mol for some reaction steps. As a result, predictions as to the experimental behavior of catalysts of this type cannot be made accurately at this point, and further clarification is need, especially with regards to the influence of real substituents at the ligand core, and the effects of solvent. According to QM/MM calculations for some of the reaction steps for the Ru system, the presence of the HIPT ligand seems to be beneficial with regards to lowering the activation barriers. However, for other steps it seems to generate slightly higher activation barriers. In general it is important to note that by varying the metal center (Mo, Ru, Os), as well as varying the type of ligand, it has been shown clearly that it may be possible to create catalyst systems that lead to reactions with comparatively low activation barriers. We believe that these results are promising, and proved a starting point for further theoretical work.

## Computational Details

The geometry optimizations reported herein were carried out using the Gaussian 03 and the Turbomole 5.7 suite of programs.[27] Table 1 lists relative energies for all compounds. Tables S1 (Mo), S2 (Ru) and S3 (Os) in the supporting information list energies, enthalpies and free enthalpies in atomic units obtained from the different computational studies. Cartesian coordinates for all calculated compounds are contained in the supporting information. Ball-and-Stick representations of the calculated structures are shown in Figures S4 (Mo), S5 (Ru) and S6 (Os) in the supporting information.

**Mo:** The structures were first optimized using Gaussian 03 (B3LYP[28] hybrid function) with the 6-31G(d) basis set[29] for elements C, N and H. For Mo, a quasirelativistic small-core ECP[30] was used with a (441/2111/31) valence basis set. This basis set shall be called basis set BII.[31] The relaxed structures were inputted into frequency calculations to successfully characterize the nature of the stationary points ($i$ = 0 for local minima, and 1 for saddle points of order 1; frequency calculations were carried out throughout this

[a] Structures and energies for compounds located in the triplet state (Mo system only) are included in the supporting information. [b] Calculated on B3LYP/BII. [c] Calculated on B3LYP/BIII. [d] The transition state TS(**7a**,**8a**-Ru) was unequivocally established. However, no energy value for **8a**-Ru is reported here, as no true minimum could be located for this compound. Frequency calculations showed four imaginary frequencies related to skeletal vibrations and $NH_3$ rotations.[22]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

work with $T$ = 298.15 K and $p$ = 1 atm). Furthermore, optimized transition state geometries were inputted into IRC calculations to check if the transition states correspond to the correct reactants and products. The zero-point vibrational energies (*ZPE*) were used without scaling. To gain an insight into the relative energy differences for the different spin states, the optimized structures were then geometry optimized for the triplet state (B3LYP/BII), and for the cases were local minima or transition state structures could be found, their energies, relative to the energy of the singlet state, are reported in Table S1 in the supporting information. To obtain more accurate structures and energies, the B3LYP/BII geometries were inputted into geometry optimization calculations at the B3LYP level of theory employing the TZVP basis set designed by Ahlrichs[32] et al. for elements C, H and N. For Mo, the Stuttgart/Köln relativistic effective core potential was used in combination with a (311111/22111/411) valence basis.[33] This basis set is denoted as basis set BIII. For the calculations of the Mo system the Turbomole 5.7 program was used. In the Discussion section of the text the enthalpies $H$ obtained from the B3LYP/BII calculations are quoted. Comparison of these values with the B3LYP/BIII-derived energies showed that the deviations between these values were small, and consequently do not to require extra discussion (see Table S1, supporting information).

**Ru and Os:** Geometry optimizations were carried out using Gaussian03 (B3LYP) with the TZVP basis set for elements C, H, N, P.[32] For Ru and for Os the Stuttgart/Köln relativistic effective core potential was used in combination with a (311111/22111/411) valence basis.[33] This is denoted as basis set BIII. The stationary points obtained from these calculations were characterized as local minima or transition states according to frequency calculations ($i$ = 0 for local minima, and 1 for saddle points of order 1), and in some cases IRC calculations were carried out. Zero point energies were used without scaling. Relative enthalpies, $H$, and Gibbs free energies, $G$, are listed in Table 1 and are quoted in the Discussion section of the text. Tables S2 and S3 in the supporting information show energies, enthalpies, and free enthalpies in atomic units.

**QM/MM Calculations:** For some ruthenium compounds the HIPT ligand, as developed by Schrock et al., was used. For these large molecules QM/MM calculations were employed using the ONIOM method:[34] The ruthenium center, all atoms of the reacting substrates, the TREN part of the ligand, and the phenyl rings attached to the amido nitrogen centers were treated at the DFT level (BLYP[35] function) using the 6-31G(d) basis set for elements C, H, N. For Ru, a quasirelativistic small-core ECP[29,30] was used with a (441/2111/31) valence basis set. The DFT part of the calculations was run using the density fitting approximation[36] employing the density fitting set developed by Godbout et al.[37] and Sosa et al.[38] The atoms of the phenyl rings bearing the isopropyl groups, as well as the isopropyl groups themselves, were treated at the molecular mechanics level using the UFF force field.[39] The boundary atoms were treated as H atoms at the highest calculation level. Figure 4 gives a graphical example of the two layers. The optimized local minima and transition states were successfully characterized by frequency calculations ($i$ = 0 and $i$ = 1 for minima and saddle points of order 1, respectively).

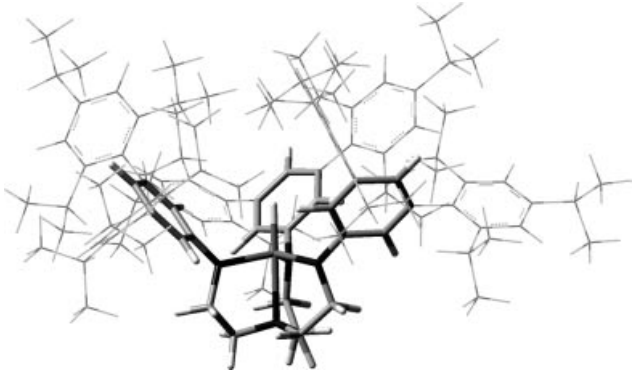

Figure 4. Assignment of atoms to layers in QM/MM calculations with **1**-Ru(HIPT) as an example. The atoms in the high layer are shown with a stick representation, whereas the atoms in the low layer appear as a wireframe representation.

**Supporting Information:** Energies and figures for most of the compounds calculated in this work, as well as the Cartesian coordinates employed.

## Acknowledgments

The generous allocation of computer time by the Calculation and Communication Centre of the RWTH Aachen is gratefully acknowledged.

[14] Reiher et al.[4] noted that in calculations with the B3LYP hybrid function, different substituents at the amido nitrogen centers of **1**-Mo yield pyramidal (H-substituted) and trigonal planar (C-substituted) N centers, which would lead to errors when the energy profiles between compounds with different

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

substituents are compared in detail, and these errors must be considered.

[15] For the Mo system only enthalpies $H$ and $H^{\ddagger}$ are included in the energy profile, as these values clearly show the activation barriers to be very high. Gibb's free energies are expected to be, and were shown by us, to be significantly higher for a few steps (as can be seen in the energy profiles of the Ru and the Os systems), but as no new relevant information can be deduced from the $\Delta G$ curve, it is not included in the energy profile. In the case of the Ru and Os catalysts some of the $H^{\ddagger}$ values are fairly low, which calls for the inclusion of $G$ and $G^{\ddagger}$ in these systems to obtain an impression of how large the differences between the enthalpies $H/H^{\ddagger}$ and Gibb's free energies $G^{\ddagger}/G^{\ddagger}$ really are.

[16] The calculated structures of compounds **4**-Mo and **8**-Mo are in good agreement with the structures carrying the HIPT substituent that have been determined crystallographically by Schrock et al..

[17] Attempts to locate transition states for the cleavage of $NH_3$ from **17**-Mo, as well as $N_2H_4$ from **11**-Mo, were not successful. Instead only local minima were found, in which the N centers of the $NH_3$ and $N_2H_4$ molecules are bridged by the protons at the amido N centers of the complex. For this reason we have not attempted to locate these transition states in the ruthenium and osmium systems. If the real HIPT ligand was employed this would not occur, as in the real system C atoms are attached to the amido N centers.

[22] For complex **8a**-Ru no real minimum could be located, as the corresponding frequency calculation showed the existence of four imaginary vibrations, which can be attributed to $NH_3$ rotations and skeletal vibrations. This is the reason why Table 1 does not contain an entry for **8a**-Ru.

[25] a) Complex **8a**-Os(P), as well as the transition states TS(**7**,**7a**-Os(P)) and TS(**7a**,**10**-Os(P)), could not be located.

[26] For reactions like the conversion of **5**-Os(P) to **6**-Os(P), in which the H–H bond of a $H_2$ molecule is broken, it can be seen that this process is energetically more favorable than in the Ru system (and also the Mo system). However, we agree with the opinion of one referee that these barriers are high. Therefore this issue needs to be addressed in further analyses of the electronic structure of the catalysts, with the aim of developing modified catalyst structures.

# Synthesis, Structure and Conformational Properties of Fluoroformylchlorodifluoroacetyl Disulfide, $FC(O)SSC(O)CF_2Cl$: Conformational Transferability in –C(O)SSC(O)– Compounds

**Mauricio F. Erben,[a] Carlos O. Della Védova,*[a,b] Helge Willner,[c] and Roland Boese[d]**

**Keywords:** Conformation analysis / Sulfur / Vibrational spectroscopy / X-ray diffraction

Pure fluoroformylchlorodifluoroacetyl disulfide, FC(O)SSC(O)$CF_2Cl$, has been prepared by the reaction of FC(O)SCl and $CF_2ClC(O)SH$ in quantitative yield. The conformational properties of the novel molecule have been studied by vibrational spectroscopy (IR – gas phase, Raman – liquid phase) and quantum chemical calculations (B3LYP and MP2 methods). The gaseous compound exhibits a conformational equilibrium at room temperature where the most stable form adopts a $C_1$ symmetry and a *syn*-periplanar (*sp*) orientation of both carbonyl groups with respect to the disulfide bond. A second form, observed in the IR spectrum of the vapor, corresponds to a conformer in which the carbonyl bond of the FC(O) moiety adopts an *anti*-periplanar (*ap*) position with respect to the S–S single bond, and *gauche* with respect to the ClC–C=O moiety in the chlorodifluoroacetyl group. The experimental free energy difference value $\Delta G^0 = G^0_{(ap-sp)} - G^0_{(sp-sp)}$ = 1.4(3) kcal/mol (IR) is reproduced well by the B3YLP/6-311+G(3df) (1.1 kcal/mol) and the MP2/6-31G* (1.8 kcal/mol) methods. In addition, the structure of a single-crystal, grown in situ, was determined by X-ray diffraction analysis at low temperature. The crystalline solid [monoclinic, $P2_1/n$, $a$ = 5.579(3) Å, $b$ = 16.615(7), $c$ = 8.455(4) Å, $\beta$ = 106.876(8)°] consists exclusively of molecules with the (*sp*–*sp*) conformation and the usual *gauche* orientation around the disulfide bond [$\phi$(CS–SC) = 84.2°]. Conformational transferability is thus demonstrated once again for species that contain the –C(O)SSC(O)– group as part of a systematic program designed to analyze the behavior of this class of molecules.

## Introduction

One of the most fundamental concepts in chemistry is that of a functional group; the idea that a linked group of atoms can exhibit a set of characteristic geometric and chemical properties. This concept is especially useful to understand the chemistry of biological macromolecules which consist of polymeric combinations of a small number of building blocks. From this empirical cornerstone of chemistry – atoms and functional groups possess characteristic and additive properties that in many cases exhibit a remarkable transferability between different molecules – a series of methodologies have been developed, especially in relation to the study of protein folding.[1–5] The transferability principle can be used to deduce the properties of large molecules from smaller, readily accessible molecules whose geometric parameters are experimentally known. Knowledge of the structural properties and conformational preference of simple molecules containing distinct functional groups is therefore of prime interest.

Geometric structures of symmetrically substituted noncyclic disulfides, XSSX, in the gas phase are characterized by a *gauche* conformation around the S–S bond, with dihedral angles $\phi$(XS–SX) close to 90° (e.g. 90.76(6)° in HSSH,[6] 87.7(4)° in FSSF,[7] 85.2(2) in ClSSCl,[8] 85.3(37) in $CH_3SSCH_3$,[9] and 104.4(40)° in $CF_3SSCF_3$).[10] In this conformation, the *p*-shaped lone pairs of the sulfur atoms are perpendicular to each other and their mutual repulsion is minimized. Furthermore, such a structure is favored by the anomeric effect by electron donation from the sulfur lone pairs into the empty $\sigma^*$ orbitals of the opposing S–X bonds.[11,12] Disulfides with very bulky substituents, such as *t*BuSS*t*Bu, have dihedral angles which are considerably larger than 90° [$\phi$(CS–SC) = 128.2(27)].[13] On the other hand, the dihedral angle for FC(O)SSC(O)F has been reported to be 82.2(19).[14] Structural data for nonsymmetrically substituted disulfides of the type XSSY are more sparse in both experimental and theoretical terms. $SSCF_3$[15] and $FC(O)SSCH_3$[16] have been studied in the gas phase and display φ(CS–SC) dihedral angles of 95.0(27)° and 83.5(15)°, respectively.

Additionally, the presence of a carbonyl group attached to the S–S bond, as in $FC(O)SSC(O)F$,[17] $FC(O)SSCH_3$,[15] and $FC(O)SSCF_3$,[16] may promote a conformational equilibrium, but this depends on the relative orientation of the C=O and S–S bonds. The *syn*-periplanar (*sp*) orientation, with φ(SS–C=O) = 0°, is the prevailing form for these species.

In order to gain additional experimental and theoretical information about the structural and conformational behavior of acyl-substituted disulfides, we became interested in molecules containing the –C(O)SSC(O)– fragment with two carbonyl groups bonded to the disulfide bond. Thus, fluoroformyltrifluoroacetyl disulfide, $FC(O)SSC(O)CF_3$, has been recently synthesized and its structural properties studied in both the gas and condensed phases.[18] In the present study, we have extended the analysis to the related $FC(O)SSC(O)CF_2Cl$ molecule, a novel compound for which the geometric structure and conformational properties have been determined by experimental and theoretical methods.

## Results

### Synthesis, Characterization, and Physical Properties

The synthesis of $FC(O)SSC(O)CF_2Cl$ was adapted from that recently reported for $FC(O)SSC(O)CF_3$,[18] by the reaction of chlorodifluorothioacetic acid, $CF_2ClC(O)SH$, with fluorocarbonylsulfenyl chloride, FC(O)SCl, according to Equation (1).

$$CF_2ClC(O)SH + FC(O)SCl \rightarrow FC(O)SSC(O)CF_2Cl + HCl \quad (1)$$

The new compound is a colorless liquid with the characteristic overpowering sulfenylcarbonyl odor. In the liquid or gaseous state, the compound is stable for days at room temperature. The vapor pressure, measured in a small section of the vacuum line (total volume ca. 15 mL) with a capacitance manometer over the temperature range 247–291 K, follows the equation $\log p = 5.857 - 2383/T$ (*p*/bar, *T*/K), and gives an extrapolated normal boiling point of 407 K (134 °C).

In the $^{19}F$ NMR spectrum of the liquid, two singlets with an intensity ratio of 1:2 were observed. The more intense signal is located at $\delta$ = –62.6 ppm, whereas the second signal appears at $\delta$ = 42.3 ppm. The related trifluoromethyl species shows corresponding signals at $\delta$ = –74.9 ppm [$CF_3C(O)$– group] and 41.4 ppm [FC(O)– group].[18]

Additional evidence for the identity of $FC(O)SSC(O)CF_2Cl$ comes from the IR spectrum of the vapor and the Raman spectrum of the liquid (Figure 1 and Table SI1 in the Supporting Information). Two intense bands in the carbonyl stretching region at 1847 and 1771 $cm^{-1}$ are characteristic of the FC=O and $CF_2ClC=O$ groups, respectively. The strongest band in the IR spectrum of the vapor centered at 1060 $cm^{-1}$, is assigned to the $F–C_{sp^2}$ stretching mode. In addition, the characteristic disulfide stretching mode is observed in the Raman spectrum of the liquid as a signal of medium intensity at 535 $cm^{-1}$.

### Quantum Chemical Calculations

In a first step, the potential function for the internal rotation around the S–S bond was derived by structure optimizations at fixed φ(CS–SC) dihedral angles, whereas near-*sp* mutual orientations were supposed for both C=O double bonds and the S–S bond. The potential function obtained with the B3LYP/6-31G* method is shown in Figure 2. Minima occur at dihedral angles around ±75°, whereas a rather flat maximum in the region of a *trans* C–S–S–C skeleton is observed, with imaginary frequencies, at φ(CS–SC) = 180°.

Besides the two enantiomeric forms that are related by rotation around the disulfide bond, several conformations are feasible, in principle, for $FC(O)SSC(O)CF_2Cl$, but they depend on the orientation of the C=O bonds of the FC(O) and the $CF_2ClC(O)$ groups. Each of them can be *syn*-periplanar (*sp*) or *anti*-periplanar (*ap*) relative to the S–S bond. This leads to four possible conformers: (*sp–sp*), (*ap–sp*), (*sp–ap*), and (*ap–ap*) [the first orientation refers to the FC(O) group and the second to the $CF_2ClC(O)$ group, see Scheme 1].

The potential functions for the internal rotation around both S–C bonds were calculated (B3LYP/6-31G*) by full geometry optimization at fixed φ(SS–C=O) torsional angles (Figure 3). As expected, both curves possess minima for *sp* [φ(SS–C=O) = 0°] and *ap* [φ(SS–C=O) = 180°] orientations.

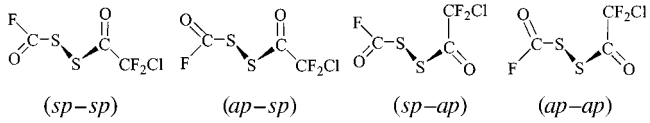

Scheme 1. Representation of the conformers of FC(O)SSC(O)-$CF_2Cl$.

The calculated maxima for near-perpendicular orientations [ϕ(SS–C=O) ≈ 90°] have similar energy values in both cases, which are characterized as torsional transition states (TS, $N_{imag}$ = 1). The geometries of the four minima were fully optimized, including frequency calculations, with the B3LYP method and with the use of the 6-31G* and 6-311+G(3df) basis sets and the MP2/6-31G* approximation. Calculated relative energies (corrected for zero-point energy) and vibrational frequencies of the C=O stretches with their IR intensities are collected in Table 1. All three computational methods predict that the four different conformers correspond to stable structures and agree with respect to the conformational preference. In the lowest-energy conformer, both carbonyl bonds adopt an *sp* orientation with respect to the S–S bond, whereas the second most stable conformer possesses an *ap* orientation of the FC(O) group with respect to the S–S single bond. Moreover, structures with *ap* orientation of the $CF_2ClC(O)$ group with respect to the S–S bond are considerably higher in energy ($\Delta G^0 \approx$ 4.0 kcal/mol or even more) and are not expected to be detectable in our experiments.

[$\phi$(ClC–C=O) = 0°] and *trans* [$\phi$(ClC–C=O) = 180°] forms correspond to torsional transition states ($N_{imag}$ = 1). The calculated barrier heights (corrected for zero-point energies) are 1.1 and 2.5 kcal/mol, respectively.

### Vibrational Spectra

The IR spectrum of the vapor and the Raman spectrum of liquid $FC(O)SSC(O)CF_2Cl$ are shown in Figure 1. Both spectra are similar to those of $FC(O)SSC(O)CF_3$.[18] A tentative assignment of the observed bands was performed by comparison with the calculated spectrum and the approximate description of modes is based on the calculated displacement vectors for the fundamental modes of vibration, as well as on comparisons with the spectra of related molecules, especially FC(O)SSC(O)F[17] and $CF_2ClC(O)Cl$.[19] Experimental and calculated [B3LYP/6-311+G(3df)] frequencies for the (*sp–sp*) and (*ap–sp*) conformers, together with the tentative assignments, are given in the Supporting Information (Table SI1).

The ab initio calculations indicate that the (*sp–sp*) conformer is more stable than the (*ap–sp*) conformer. The vibrational spectra are consistent with this prediction, but the presence of a second conformer in the vapor phase becomes apparent. It is known that the $\nu$(C=O) normal mode of carbonyl compounds is very sensitive to conformational properties.[20,21] As observed in Figure 5, two intense bands occur in the IR spectrum of $FC(O)SSC(O)CF_2Cl$ vapor at 1847 and 1771 $cm^{-1}$, whereas a third band of low intensity appears at 1827 $cm^{-1}$. The first two bands are assigned to the C=O stretching modes of the FC=O and $CF_2ClC$=O groups in the most abundant (*sp–sp*) conformer. Comparison with the calculated frequencies then allows the assignment of the third band to the FC=O group in the (*ap–sp*) form. Thus, the calculated wavenumber difference [B3LYP/6-311+G(3df)] for the C=O stretching mode of the FC(O) group [$\nu$(FC=O), Table 1] between the (*sp–sp*) and the (*ap–sp*) forms is +26 $cm^{-1}$, a value that is in good agreement with the experimentally observed value of +20 $cm^{-1}$. No significant difference is expected in the wavenumbers of the $CF_2ClC$=O stretching mode between the (*sp–sp*) and (*ap–sp*) forms; the calculated difference is about 2 $cm^{-1}$. Accordingly, the stretching mode of the (*ap–sp*) conformer is assigned to the band at 1771 $cm^{-1}$, which is masked by the band of the corresponding stretching mode of the (*sp–sp*) form. The conformational composition was derived from the integrated intensities of the C=O vibrations for the (*sp–sp*) and (*ap–sp*) forms, with the intensities calculated by the B3LYP/6-311+G(3df) method taken into account (Table 1). This analysis leads to a composition of 92(5)% of the more stable (*sp–sp*) form at ambient temperature (the estimated error limit includes uncertainties in the measured areas and in the calculated intensities).

A conformational equilibrium was also evident in the F–C(O) stretching region [$\nu(C_{sp^2}–F)$, Table SI1 given in the Supporting Information] through the presence of two bands in the IR spectrum of the vapor. The more intense band is located at 1060 $cm^{-1}$, which can be assigned to this mode in the main (*sp–sp*) conformer; the second band, at 1089 $cm^{-1}$, can be assigned to the same mode of the less stable (*ap–sp*) form. Quantum chemical calculations correctly reproduce this frequency shift of 19 $cm^{-1}$. According to the calculations, the other fundamental modes of the (*sp–sp*) and (*ap–sp*) conformers either differ by less than 2 $cm^{-1}$ or have too low an intensity to be observed in our experiments.

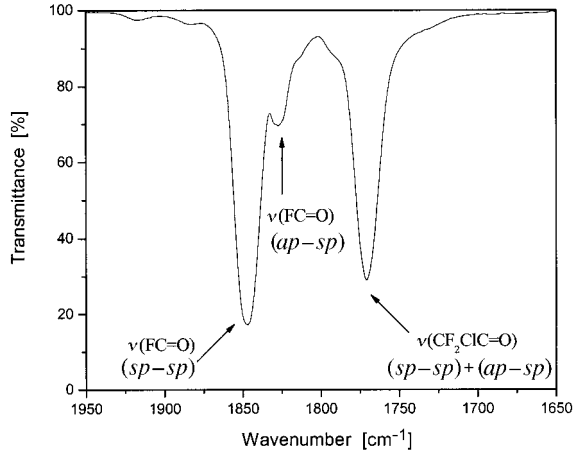

Figure 5. C=O vibrational stretching region in the IR spectrum of gaseous $FC(O)SSC(O)CF_2Cl$ at 5.0 mbar (glass cell, 200 mm optical path length, Si windows, 0.5 mm thick).

### Crystal Structure

Because simple covalent disulfides are liquids or gases at ambient temperatures and because they are frequently labile species, very little is known about their structures in the solid state. Only with the development of special crystallization techniques has it become possible to extend detailed structural studies to the crystalline state. By using the in situ crystallization technique developed at Essen,[22] an appropriate single-crystal of $FC(O)SSC(O)CF_2Cl$ was grown at 193 K. The compound crystallizes in the monoclinic system ($P2_1/n$ spatial group) with the following unit cell dimensions: $a$ = 5.579(3) Å, $b$ = 16.615(7) Å, $c$ = 8.455(4) Å, and $\alpha = \gamma = 90°$ and $\beta$ = 106.876(8)°, $Z$ = 4 (for the full crystallographic data and treatment information, see Table SI2 in the Supporting Information). Only the (*sp–sp*) conformer is observed in the crystal, with a *gauche* orientation around the S–S bond. The structure of the molecule is shown in Figure 6, and Table 2 includes the main geometric parameters derived from the structure refinement, as well as those obtained from quantum chemical calculations. The overall crystal packing, as viewed along the *ab* plane, is shown in Figure 7.

Intermolecular interactions that are dominated by F···F contacts are common for fluorinated molecules where there is no other choice for the stabilization of the packing. According to quantum chemical calculations, F···F contacts in aromatic systems can contribute up to 14 kcal/mol of local stabilization energy.[23] In the present case, the chlorodifluo-

[a] See Figure 6 for atom numbering. [b] Uncertainties are σ values.

romethyl groups interact through C–F···F–C contact which measure 2.817 Å. This value is within the range found in comparable structural studies, in which C–F···F–C contacts of 2.777 and 2.868 Å are identified as packing motifs.[24,25] The sum of the van der Waals radii would suggest 2.7 Å as a contact distance, but this does not obviously hold for carbon-bonded fluorine.

The investigation of short nonbonded intramolecular 1,4 S···O contacts have attracted much attention because S···O distances in the range 2.77–3.16 Å have been observed in crystals.[26] These values are much shorter than the sum of the sulfur and oxygen van der Waals radii (3.3 Å).[27] The presence of such short S···O contacts in these compounds, each of which crystallizes in a different packing environment, indicates that the conformational feature results from a nonbonded intramolecular interaction. Computational results suggest that electronic conjugation gives rise to the observed S···O close contact.[28] In molecules which contain the –C(O)SSC(O)– moiety, there are two 1,4 S···O distances, defined by one sulfur atom of the disulfide bond and the

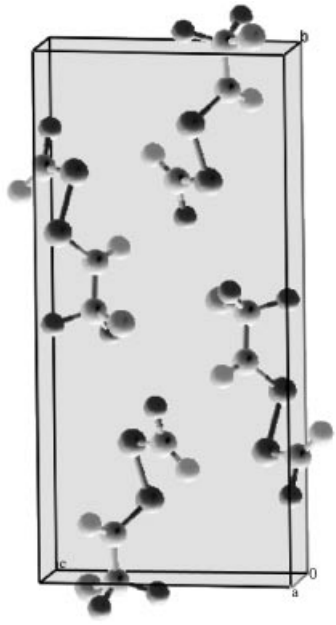

Figure 7. Stereoscopic illustration of the crystal packing of $FC(O)SSC(O)CF_2Cl$ at 193 K.

oxygen atom in the carbonyl group bonded to the other sulfur atom. Following Figure 6, these 1,4 S···O distances for $FC(O)SSC(O)CF_2Cl$ are labeled as S1···O2 and S2···O1, with values of 3.016 Å and 3.078 Å, respectively. The ϕ(SS–C=O) dihedral angles around the corresponding C–S bonds are 4.8 and 0.8°, respectively. Following Burling et al.,[28] these nearly planar conformations favor electronic delocalization of the nonbonded π electrons of the sulfur atom, which results in an increased attractive interaction between the sulfur and oxygen atoms.

## Discussion

According to the vibrational spectra, the title molecule exists in the gas phase as a mixture of two conformers that differ in the relative orientation of the FC(O) group and the S–S single bond, with the *sp* conformer prevailing over the *ap* form. At room temperature, the more stable conformer accounts for 92(5)% of the vapor species. The standard Gibbs free-energy difference [$\Delta G^0 = G^0_{(ap–sp)} - G^0_{(sp–sp)}$] derived from the IR spectrum of the vapor (1.4 kcal/mol) is reproduced satisfactorily at the B3LYP/6-311+G(3df), B3LYP/6-31G*, and MP2/6-31G* levels of calculation. On the other hand, only the *sp* conformation is observed for the mutual orientation of the $CF_2ClC=O$ double bond and the S–S single bond, with a calculated mean value of $\Delta G^0 = G^0_{(sp–ap)} - G^0_{(sp–sp)}$ of 4.7 kcal/mol. This behavior parallels that recently reported for $FC(O)SSC(O)CF_3$, with $\Delta G^0 = G^0_{(ap–sp)} - G^0_{(sp–sp)} = 1.14(15)$ kcal/mol from the IR spectrum of the matrix isolated vapor and *sp* orientation of the S–S single bond with respect to the C=O double bond in the $–C(O)CF_3$ moiety.[18]

The chlorodifluoroacetyl group adopts a *gauche* orientation in the crystal, with a corresponding dihedral angle

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

φ(ClC–C=O) of 102.3(4)° [φ(F3C3–C=O) = 136.4(3)°]. As already commented in this paper, quantum chemical calculations predict a different behavior for a molecule with the (*sp–sp*) conformation, with φ(ClC–C=O) and φ(F3C3–C=O) dihedral angles of 78.9 and 160.7°, respectively. The predominant conformer found experimentally for chlorodifluoroacetyl chloride [$CF_2ClC(O)Cl$] in the gas phase possesses a *gauche* orientation of the chlorine atoms [φ(ClC–C=O) = 104.6(10)°],[29] whereas a second stable conformer where the C–Cl bond eclipses the C=O bond is higher in energy by $\Delta G^0$ = 1.1(3) kcal/mol.[29] From a study of the Raman spectrum of the liquid at different temperatures, a $\Delta H^0$ value of 1.03(11) kcal/mol was determined, whereas for the sample dissolved in liquid xenon, this value decreases to 0.71(17) kcal/mol.[19] For the free molecule of the title compound, this last conformation corresponds to a rotational transition state; the calculated barrier is only 1.1 kcal/mol. Thus, the barrier to rotation appears to be quite low for the chlorodifluoroacetyl moiety, and the discrepancy between the X-ray structure and the calculated geometrical properties probably reflects the distortions induced by the crystal packing.

Transferability is then evident in the conformational properties of $FC(O)SSC(O)CF_2Cl$. Extensive studies of carbonylsulfenyl compounds with the general formula XC(O)SY have established the preference for a *syn*-periplanar conformation around the C–S bond.[20,30–33] In the case of disulfides (so that Y corresponds to an –SR group), the preferred mutual orientation of the C=O and S–S bonds is also *sp*.[12,14–16] It has also been established experimentally that the *ap* conformation appears as a second stable form that makes appreciable contributions to the vapor at room temperature when X is a fluorine atom,[14,17,34,35] whereas only the *sp* conformation is adopted by species containing the $CF_3C(O)S$ moiety.[36–38]

Breitzer et al.[39] have reported the analysis of the crystal structures of several disulfides. A plot of the S–S bond length versus the disulfide torsion angles reveals the greatest density of data points in the bond length region 2.00–2.06 Å and torsion angles between 75 and 90°. A similar pattern has also been observed for the structures of gaseous disulfides. In accordance with this trend, the disulfide bond length and torsion angle in crystalline $FC(O)SSC(O)CF_2Cl$ are 2.029(1) Å and 84.2(2)°, respectively.

The two computational methods we have used predict dihedral angles for the molecular skeleton with values similar to those obtained from the X-ray analysis. The methods are less successful in the reproduction of the lengths of some of the bonds around sulfur. Thus, even with large basis sets [6-311+G(3df)], the B3LYP method predicts the S–X bonds to be too long (by up to 0.026 Å for the S1–C1 bond). While these bonds are better described by the MP2 method with the modest 6-31G* basis set, this method fails to reproduce the C=O double bond lengths well, which are also made out to be too long (0.032 Å for the C1 = O1 bond). In practice, however, the contraction of polar bonds is to be expected upon crystallization and compensation for this phenomenon allows both methodologies to satisfactorily reproduce the molecular dimensions of the crystalline solid.

## Experimental Section and Instrumentation

**General Procedure:** Volatile materials were manipulated in a glass vacuum line equipped with two capacitance pressure gauges (221 AHS-1000 and 221 AHS-10, MKS Baratron, Burlington, MA), three U-traps and valves with PTFE stems (Young, London, UK). The vacuum line was connected to an IR cell (optical path length 200 mm, Si windows 0.5 mm thick) contained in the sample compartment of an FTIR instrument (Impact 400D, Nicolet, Madison, WI). This allowed us to monitor the purification processes and to follow the course of the reactions. The pure compound was stored in flame-sealed glass ampules under liquid nitrogen in a long-term Dewar vessel. The ampules were opened with an ampule key on the vacuum line, an appropriate amount of the compound was taken out for the experiments, and then the ampules were flame-sealed again.[40]

$CF_2ClC(O)SH$ was synthesized by the reaction of either $CF_2ClC(O)Cl$ or $[CF_2ClC(O)]_2O$ (98% Aldrich) with $H_2S$ (98% Linde, Germany) in a metal reactor.[41] This method was adapted from the literature procedure for the synthesis of $CF_3C(O)SH$.[42] $CF_2ClC(O)Cl$ was synthesized by the reaction of chlorodifluoroacetic acid (98% Merck) with $PCl_5$ according to the usual method. FC(O)SCl was obtained by the reaction of commercial ClC(O)SCl (Aldrich 95%) with $SbF_5$ following the reported method.[43,44]

Conventional vacuum techniques were used to condense equimolar quantities (typically 2.5 mmol) of $CF_2ClC(O)SH$ and FC(O)SCl into a 6 mm o.d. glass ampule. The vessel was flame-sealed and placed in a –40 °C ethanol bath. At this temperature, the reaction proceeded rapidly, as judged by the disappearance of the yellow color [due to FC(O)SCl] of the reaction mixture. The mixture was then warmed to –10 °C and preserved at that temperature for about 1 h. Subsequently the products were separated by "trap-to-trap" condensation through traps held at –30 °C, –60 °C and –196 °C. Pure $FC(O)SSC(O)CF_2Cl$ was retained as a colorless liquid in the –60 °C trap. The yield was nearly quantitative and, apart from the HCl generated in the reaction, only minor quantities of OCS and $SiF_4$ were observed as byproducts in the U-trap at –196 °C.

**X-ray Diffraction at Low Temperature:** An appropriate crystal of $FC(O)SSC(O)CF_2Cl$ ca. 0.3 mm in diameter was obtained on the diffractometer at a temperature of 193(2) K with a miniature zone melting procedure with the use of focused infrared laser radiation.[22] The diffraction intensities were measured at low temperatures with a Nicolet R3m/V four-circle diffractometer. Intensities were collected with graphite–monochromatized Mo-$K_\alpha$ radiation with the ω-scan technique. The crystallographic data, conditions and some features of the structure are listed in Table SI2 (Supporting Information). The structure was solved by Patterson syntheses and refined by full-matrix least-squares methods on *F* with the SHELXTL-Plus program.[45] Absorption correction details are given in Table SI2 (Supporting Information). All atoms were assigned anisotropic thermal parameters. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (Fax: +49-7247-808-666, E-mail: crysdata@fiz-karlsruhe.de) on quoting the depository number CSD-416694.

**Vibrational Spectroscopy:** Gas-phase infrared spectra were recorded with a resolution of 1 $cm^{-1}$ in the range 4000–400 $cm^{-1}$ with a Bruker IFS 66v FTIR instrument and Raman spectra of liquid

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$FC(O)SSC(O)CF_2Cl$ with a Bruker RFS 100/S FT-Raman spectrometer. The liquid sample was contained in a 4 mm glass capillary and the spectrum excited with 500 mW of 1064 nm radiation from a Nd:YAG laser (ADLAS, DPY 301, Lübeck, Germany).

**NMR Spectroscopy:** For the $^{19}F$ NMR measurements, neat samples were held in flame-sealed, thin-walled 3 mm o.d. tubes placed inside 5 mm NMR tubes. The spectra were recorded with a Bruker Avance DRX-300 spectrometer operating at 282.41 MHz. The spectrum was measured with the sample at room temperature with a mixture of $CD_3CN$ and $CFCl_3$ as an external lock and reference, respectively.

**Theoretical Calculations:** All quantum chemical calculations were performed with the GAUSSIAN03 program package[46] under the Linda parallel execution environment with two coupled PC's. MP2 and B3LYP methods with standard basis sets up to 6-311+G(3df) and gradient techniques were used for the geometry optimizations and calculation of the vibrational properties. Transition states were optimized by the Synchronous Transit-guided Quasi-Newton (STQN) method, and torsional barrier heights were calculated from the relative energies of the TS and the stable structure with the zero-point energies of the species taken into account. All the computed TS structures show only one imaginary frequency, which corresponds to the torsion involved in the conformational transition.

**Supporting Information** (see footnote on the first page of this article): Observed and calculated vibrational data for (*sp–sp*) and (*ap–sp*) conformers; X-ray crystallographic data and structural refinement details.

## Acknowledgments

Financial support by the Volkswagen-Stiftung and the Deutsche Forschungsgemeinschaft is gratefully acknowledged. The Argentinean authors thank the ANPCYT-DAAD for the German-Argentinean cooperation Awards (PROALAR) and the DAAD Regional Program of Chemistry for Argentina. They also thank the Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), the Comisión de Investigaciones Científicas de la Provincia de Buenos Aires (CIC), República Argentina. They are indebted to the Facultad de Ciencias Exactas, Universidad Nacional de La Plata, República Argentina for financial support. M.F.E. and C.O.D.V. would like to express their gratitude to Holger Pernice, Plácido García, Mike Finze, Stefan Balters, and Stefan von Ahsen for friendship and valuable help in the laboratory work during their stay in Duisburg. C.O.D.V. especially acknowledges the DAAD, which generously sponsors the DAAD Regional Program of Chemistry for the Republica Argentina to support Latin-American students to study for their PhD in La Plata.

# An Experimental and Density Functional Theory Approach Towards the Establishment of Preferential Metal- or Ligand-Based Electron-Transfer Processes in Large Quinonoid-Bridged Diruthenium Complexes $[\{(aap)_2Ru\}_2(\mu\text{-}BL^{2-})]^{n+}$ (aap = 2-Arylazopyridine)

**Sandeep Ghumaan,[a] Sriparna Mukherjee,[a] Sanjib Kar,[a] Dipankar Roy,[a] Shaikh M. Mobin,[a] Raghavan B. Sunoj,*[a] and Goutam Kumar Lahiri*[a]**

**Keywords:** Ruthenium / Bridging ligands / Radical ions / Density functional calculations / EPR spectroscopy

A group of ten quinonoid-bridged diruthenium(II) complexes $[(aap)_2Ru^{II}(\mu\text{-}BL_1^{2-})Ru^{II}(aap)_2](ClO_4)_2$, [**1a**–**1c**]$(ClO_4)_2$ and $[(pap)_2Ru^{II}(\mu\text{-}BL_n^{2-})Ru^{II}(pap)_2](ClO_4)_2$ [**2**–**8**]$(ClO_4)_2$ [aap = 2-arylazopyridine, $NC_5H_4$–N=N–$C_6H_4$(R) {R = H (pap) [**1a**]$(ClO_4)_2$, *m*-Me [**1b**]$(ClO_4)_2$, *m*-Cl [**1c**]$(ClO_4)_2$}; $BL^{2-}$ = 5,8-dioxido-1,4-napthoquinone ($BL_1^{2-}$), 2,3-dichloro-5,8-dioxido-1,4-napthoquinone ($BL_2^{2-}$), 6,11-dioxido-5,12-naphthacenedione ($BL_3^{2-}$), 1,4-dioxido-9,10-anthraquinone ($BL_4^{2-}$), 2,3-dimethyl-1,4-dioxido-9,10-anthraquinone ($BL_5^{2-}$), 6,7-dichloro-1,4-dioxido-9,10-anthraquinone ($BL_6^{2-}$), 1,4-diimino-9,10-anthraquinone ($BL_7^{2-}$), 1,5-dioxido-9,10-anthraquinone ($BL_8^{2-}$)] have been synthesized. The crystal structures of [**1a**]$(ClO_4)_2{\cdot}H_2O$ and [**3**]$(ClO_4)_2$ suggest the preferential crystallization of the *meso* isomer in both cases. The two similar C–O distances in coordinated $BL_1^{2-}$ [C2–O1/C4–O2 1.278(5)/1.291(4) Å] and $BL_3^{2-}$ [C2–O1/C4–O2 1.282(7)/1.280(7) Å] in [**1a**]$(ClO_4)_2$ and [**3**]$(ClO_4)_2$, respectively, and the corresponding intraring distances suggest a delocalized keto-enol state of the coordinated $BL^{2-}$. $[\mathbf{1}\text{–}\mathbf{8}]^{2+}$ exhibit two successive one-electron oxidation processes and multiple reductions in both $CH_3CN$ and $CH_2Cl_2$. The first oxidation potential varies substantially depending on a variety of factors associated with $BL^{2-}$ and follows the order: $[\mathbf{8}]^{2+} >> [\mathbf{2}]^{2+} > [\mathbf{6}]^{2+} > [\mathbf{1a}]^{2+} \geq [\mathbf{4}]^{2+} > [\mathbf{3}]^{2+} > [\mathbf{5}]^{2+} >> [\mathbf{7}]^{2+}$. The separation in potentials between the successive oxidation processes translates to comproportionation constant ($K_c$) values in the ranges $2.5\times10^4$–$2.6\times10^5$ and $1.7\times10^3$–$1.3\times10^6$ in $CH_3CN$ and $CH_2Cl_2$, respectively. The intermediate paramagnetic species $[\mathbf{1}\text{–}\mathbf{8}]^{3+}$ systematically exhibit closely spaced rhombic or axial-type EPR spectra at 77 K corresponding to *g* values close to the free-electron value of 2.0023, thereby suggesting a radical complex formulation of $\{Ru^{II}(\mu\text{-}BL^{\cdot-})Ru^{II}\}$ instead of the usually expected alternative mixed-valence formulation of $\{Ru^{II}(\mu\text{-}BL^{2-})Ru^{III}\}$. Consequently, $[\mathbf{1}\text{–}\mathbf{7}]^{3+}$ display intense near-infrared transitions in the range 1200–1500 nm with a band width at half height ($\Delta\nu_{1/2}$) of 1900–3800 $cm^{-1}$ which is lower than the calculated value of 3800–4600 $cm^{-1}$ obtained using the Hush formula for a localized class II mixed-valence system. Electrogenerated EPR-inactive second-step oxidized species $[\mathbf{1}\text{–}\mathbf{8}]^{4+}$ have been described as spin-coupled radical-bridged mixed-valence ruthenium(II)(III) species, $\{Ru^{II}(\mu\text{-}BL^{\cdot-})Ru^{III}\}$. $[\mathbf{1}\text{–}\mathbf{8}]^{2+}$ exhibit multiple ligand-based reductions involving coordinated $BL^{2-}$ as well as aap. The above preferential metal- or ligand-based accessible electron-transfer processes in the complexes have been further substantiated by DFT calculations on the geometry-optimized structure of $[\mathbf{1a}]^{2+}$.

## Introduction

The design of newer classes of ligand-bridged polyruthenium systems in combination with selective ancillary ligands $[\{(AL)Ru\}_n(\mu\text{-}BL)]^{n+}$ (AL = ancillary ligand and BL = bridging ligand) has drawn special attention in recent years,[1] particularly from the perspective of tuning intermetallic electronic coupling processes in their mixed-valence states, which, in turn, finds partial applications in fabricating molecular electronic devices[2] as well as the theoretical understanding of electron-transfer processes.[3] A large number of polyruthenium derivatives have been studied and a wide variation of coupling aspects, including moderately coupled localized class II, strongly coupled delocalized class III, and hybrid or borderline class II–III situations[4,5] have emerged that primarily depend on the electronic states of the specific set of bridging and ancillary ligands. Although different kinds of molecular frameworks have been utilized as bridging ligands for assembling metal fragments in place, only a limited number of diruthenium complexes with the following redox-active polynucleating quinonoid bridging (BL) units along with selective ancillary ligands (AL) are known so far: 1,10-phenanthroline-5,6-dione (AL =

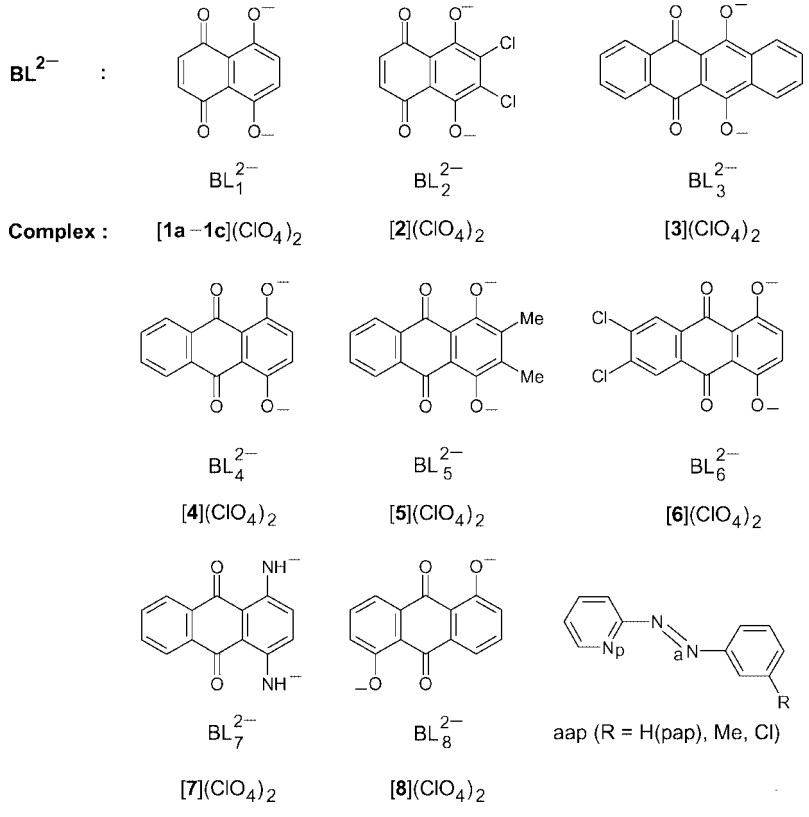
acac$^-$[6]/bpy[7]), 1,10-phenanthroline-5,6-diimine (acac$^-$),[6] 2,5-dioxido-1,4-benzoquininediimines (bpy/acac$^-$),[8] 2,5-dioxido-1,4-benzoquinones (bpy),[9] 5,8-dioxido-1,4-naphthoquinone (bpy),[10] 1,4-dioxidoanthraquinone (bpy),[11] 1,5-dioxidoanthraquinone (bpy),[11] 1,2,4,5-tetraimino-3,6-diketocyclohexane (bpy),[12] 3,3′,4,4′-tetraoxybiphenyl (bpy),[13] 3,3′,4,4′-tetraiminobiphenyl (acac$^-$[14]/bpy[15]), and *p*-benzoquinonediimine(NH$_3$)[16] (bpy = 2,2′-bipyridine, acac$^-$ = acetylacetonate). The remarkable mixing of ruthenium and quinonoid frontier orbitals[17] is expected to facilitate the bridging-ligand-mediated intermetallic coupling processes in such systems; however, it also creates additional challenges in assigning the precise valence state combinations of the metal ion and the bridging ligand in the native state as well as towards the accessible electron-transfer processes. The extent of mixing of ruthenium- and quinonoid-based orbitals and their subsequent participation in the electron-transfer processes are also influenced by the involvement of the ancillary ligands (AL)[8,14,15] in the resultant molecular orbitals, and this is essentially the reason for the present program of developing larger quinonoid-bridged diruthenium complexes encompassing strongly π-accepting 2-arylazopyridine (aap) as ancillary ligands.

The present article thus describes the synthesis of a group of ten diruthenium complexes [(aap)$_2$Ru$^{II}$(μ-BL$_n^{2-}$)-Ru$^{II}$(aap)$_2$](ClO$_4$)$_2$ [**1a**–**1c**](ClO$_4$)$_2$ and [**2**–**8**](ClO$_4$)$_2$ {BL$^{2-}$ = 5,8-dioxido-1,4-napthoquinone (BL$_1^{2-}$), 2,3-dichloro-5,8-dioxido-1,4-napthoquinone (BL$_2^{2-}$), 6,11-dioxido-5,12-naphthacenedione (BL$_3^{2-}$), 1,4-dioxido-9,10-anthraquinone(BL$_4^{2-}$), 2,3-dimethyl-1,4-dioxido-9,10-anthraquinone (BL$_5^{2-}$), 6,7-dichloro-1,4-dioxido-9,10-anthraquinone (BL$_6^{2-}$), 1,4-diimino-9,10-anthraquinone (BL$_7^{2-}$), and 1,5-dioxido-9,10-anthraquinone (BL$_8^{2-}$); aap = 2-arylazopyridine} and the crystal structures of two selected derivatives, namely [**1a**](ClO$_4$)$_2$ and [**3**](ClO$_4$)$_2$. The primary involvement of metal-, bridging-ligand-, or ancillary-ligand-based orbitals or a mixed situation in the accessible electron-transfer processes of the complexes has been scrutinized by UV/Vis/NIR spectroelectrochemistry and EPR investigations in combination with DFT/TDDFT calculations on the selected complex [**1a**]$^{2+}$. The specific effect of aap as an ancillary ligand in [**1**–**8**]$^{n+}$ with special reference to complexes with bpy[10,11] and BL$_1^{2-}$, BL$_4^{2-}$, and BL$_8^{2-}$ as bridging ligands are also highlighted.

## Results and Discussion

### Synthesis and Characterization

The present study deals with the eight quinonoid-based bridging ligands abbreviated as H$_2$BL$_{1-8}$. The bridging ligands differ in terms of their ring size (naphthaquinone- or anthraquinone-based frameworks), the substituents on the rings, and the positions of the donor centers in the rings. H$_2$BL$_7$ is the amine (NH$_2$) version of the hydroxy-containing H$_2$BL$_4$ (Scheme 1).



Scheme 1.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The complexes $[(pap)_2Ru^{II}(\mu\text{-}BL^{2-})Ru^{II}(pap)_2](ClO_4)_2$ {[**1a**]$(ClO_4)_2$ and [**2**–**8**]$(ClO_4)_2$; Scheme 1} were synthesized by following a general procedure involving treatment of the respective quinones ($H_2BL$) with an ethanolic solution of the metal precursor *ctc*-$[Ru^{II}(pap)_2(H_2O)_2](ClO_4)_2$ [pap = 2-phenylazopyridine; *ctc* = *cis*-*trans*-*cis* with respect to the aqua, pyridine ($N_p$), and azo ($N_a$) nitrogen atoms of pap, respectively} in the presence of sodium acetate as base under dinitrogen, followed by chromatographic purification on a neutral alumina column. The complexes [**1b**]$(ClO_4)_2$ and [**1c**]$(ClO_4)_2$ have 2-(*m*-tolylazo)pyridine and 2-(*m*-chlorophenylazo)pyridine, respectively, as ancillary ligands in combination with $BL_1^{2-}$ (Scheme 1).

The *tc*-configuration [*tc* = *trans* and *cis* with respect to the pyridine ($N_p$) and azo ($N_a$) nitrogens, respectively] as well as the $Ru^{II}$ state of the precursor metal fragment $\{Ru^{II}(pap)_2\}$ remain unaltered in complexes [**1**–**8**]$(ClO_4)_2$ (see below).

Although the reactions ideally lead to a mixture of *meso* ($\Delta\Lambda$) and *rac* ($\Delta\Delta/\Lambda\Lambda$) isomers,[18] the appearance of only one band, even on the preparatory TLC plate, in each case suggests either the presence of one particular diastereoisomeric form or an intimate mixture of *meso* and *rac* isomers in solution. The crystal structures of [**1a**]$(ClO_4)_2$ and [**3**]$(ClO_4)_2$ suggest the preferential crystallization of the *meso* isomer in both cases (see below).

The complexes are fairly soluble in polar ($CH_3CN$, DMF) as well as nonpolar ($CH_2Cl_2$) solvents. The diamagnetic (low-spin $Ru^{II}$, $t_{2g}^6$) complexes [**1**–**8**]$(ClO_4)_2$ are 1:2 conductors in $CH_3CN$ and their microanalytical data (C,H,N) are in good agreement with the calculated values (see Exp. Sect.). The formation of the complexes was further confirmed by their electrospray mass spectroscopic data in $CH_3CN$ (see Table 1 and Figure 1). The $^1H$ NMR spectra in $CDCl_3$ or $(CD_3)_2SO$ show partially overlapping signals corresponding to half of the molecule due to internal symmetry (see Figure 2 and Exp. Sect.). The closeness of the chemical shifts of the signals of several protons makes them appear as overlapping clusters. The ν(C=O) stretching frequency of the free $H_2BL$ ligands (1616–1636 $cm^{-1}$) is absent in the IR spectra of the complexes, where a sharp peak appears in the range 1520–1582 $cm^{-1}$, thus indicating a delocalized keto-enol state of the coordinated bridging ligand $BL^{2-}$.[19] The delocalized keto-enol state of $BL^{2-}$ is also clearly evidenced in the crystal structures of [**1a**]$(ClO_4)_2$ and [**3**]$(ClO_4)_2$ (see below). The $ClO_4^-$ vibrations for all the complexes and the NH stretching fre-

quency of the coordinated $BL_7^{2-}$ in [**7**]$(ClO_4)_2$ appear in the expected positions of 1100/625 and 3260 $cm^{-1}$, respectively (see Exp. Sect.).

### Crystal Structures of [1a]$(ClO_4)_2 \cdot H_2O$ and [3]$(ClO_4)_2$

The crystal structures of [**1a**]$(ClO_4)_2 \cdot H_2O$ and [**3**]$(ClO_4)_2$ are shown in Figures 3 and 4, respectively. Selected crystallographic parameters are given in the Exp. Sect. and bond lengths and angles are listed in Table 2. Both structures contain a crystallographic inversion center. Each Ru ion is bonded symmetrically to the dianionic bridging ligand $BL^{2-}$ through the two oxygen donor centers at each end. The Ru centers are nearly coplanar with the bridging ligand; the angles between the planes consisting of the chelate ring containing the Ru ion to the bridging ligand and the planar bridging ligand are 1.57(0.71)° and 3.17(0.81)° for [**1a**]$(ClO_4)_2$ and [**3**]$(ClO_4)_2$, respectively. The $RuO_2N_4$ chromophore is in a distorted octahedral arrangement, as can be seen from the angles around the metal ion (Table 2). The two similar C–O distances in coordinated $BL_1^{2-}$ [C2–O1/C4–O2 1.278(5)/1.291(4) Å] and $BL_3^{2-}$ [C2–O1/C4–O2 1.282(7)/1.280(7) Å] and the corresponding intra-ring distances (Table 2) in [**1a**]$(ClO_4)_2$ and [**3**]$(ClO_4)_2$, respectively, signify the delocalized keto-enol state of the coordinated $BL^{2-}$.[19–21] The calculated (B3LYP/SDD, 6-31G* level of theory) bond lengths/angles and atomic charges of the dianionic form of free $BL_1^{2-}$ (Figure 5 and Table 3; coordinates for the optimized $BL_1^{2-}$ are given in Table S1 in the Supporting Information) also suggest its delocalized state. The $Ru^{II}$–O($BL^{2-}$) distances [Ru1–O1/Ru1–O2 2.025(3)/2.038(3) and 2.009(4)/2.016(4) Å in [**1a**]$(ClO_4)_2$ and [**3**]$(ClO_4)_2$, respectively] agree well with known $Ru^{II}$–O (acetylacetonate, keto-enol delocalized form) distances.[21] The Ru–Ru separations in [**1a**]$(ClO_4)_2$ and [**3**]$(ClO_4)_2$ are 8.327 and 8.338 Å, respectively.

The {Ru(pap)$_2$} fragment is in a *tc*-configuration (*tc* = *trans* and *cis* with respect to the pyridine and azo nitrogens

of pap, respectively), as is the case in the precursor complex.[22] The shortness of the Ru–N(azo) bonds [Ru1–N3 1.957(3) and 2.006(6), Ru1–N6 2.018(3) and1.959(5) Å for [**1a**]$(ClO_4)_2$ and [**3**]$(ClO_4)_2$, respectively] compared to the Ru–N(pyridine) bonds [Ru1–N1 2.041(4) and 2.030(6), Ru1–N4 2.034(4) and2.058(6) Å in [**1a**]$(ClO_4)_2$ and [**3**]$(ClO_4)_2$, respectively] reflects the π-back-bonding interaction $Ru^{II}(d\pi)\rightarrow pap(\pi*)$, where the pap(π*) level is predominantly azo in character.[23] A consequence of this is that the azo(N=N) distances of the coordinated pap ligand [N2–N3 1.284(5) and 1.297(7), N5–N6 1.288(5) and 1.281(8) Å in [**1a**]$(ClO_4)_2$ and [**3**]$(ClO_4)_2$, respectively] are significantly longer than that calculated (B3LYP,6-31G* level of theory) for the free pap ligand (1.259 Å, see Figure 6 and Table 4; coordinates for the optimized pap ligand are given in Table S2 in the Supporting Information), as is also the case in other reported complexes of arylazopyridine ligands.[24]

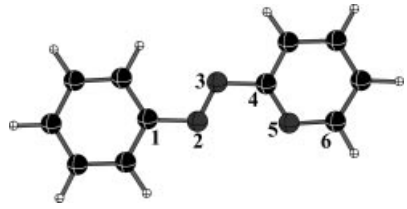

Figure 6. The B3LYP,6-31G*-optimized geometry for the singlet ground state of pap.

The optimized geometry of $[\mathbf{1a}]^{2+}$ is shown in Figure 7 and a selected list of optimized geometrical details of $[\mathbf{1a}]^{2+}$ is provided in Table 2 (coordinates and a full list of bond lengths and angles for the optimized $[\mathbf{1a}]^{2+}$ are provided in Tables S3 and S4, respectively, in the Supporting Information). In general, the computed structural details of $[\mathbf{1a}]^{2+}$ are in good agreement with the experimental param-

eters (Table 2). The calculated bond lengths of the coordinated $BL_1^{2-}$ ligand in $[\mathbf{1a}]^{2+}$ also suggest its delocalized keto-enol nature.

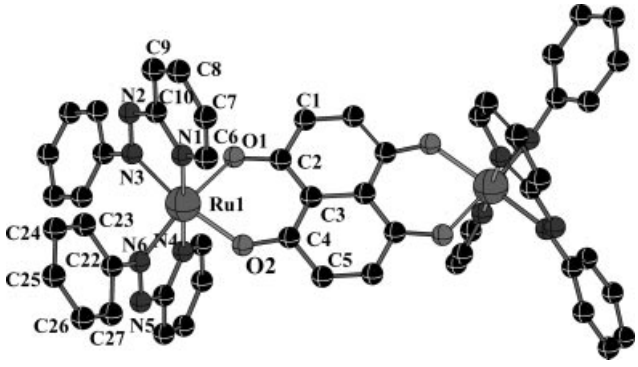

Figure 7. The B3LYP/SDD,6-31G*-optimized geometry for the singlet ground state of $[\mathbf{1a}]^{2+}$.

It should be noted that to the best of our knowledge $[\mathbf{1a}](ClO_4)_2$ and $[\mathbf{3}](ClO_4)_2$ are the first structurally characterized diruthenium complexes bridged by $BL^{2-}$, although the crystal structures of $[\{Co(tripod)\}_2(\mu\text{-}BL_1^{2-})]^{2+}$/$[\{Co(tripod)\}_2(\mu\text{-}BL_4^{2-})]^{2+}$ [tripod = $MeC(CH_2PPh_2)_3$],[25] $[\{Ph_4Sb\}_2(\mu\text{-}BL_1^{2-})]$,[26] $[Cu_2(dien)_2(\mu\text{-}BL_1^{2-})](BPh_4)_2$ (dien = diethylenetriamine),[27] $[\{Fe(salen)\}_2(\mu\text{-}BL_4^{2-})]$ [salen = *N*,*N*′-bis(salicylaldehyde)ethylenediimine],[28] and $[\{Rh(CO)(PPh_3)\}_2(\mu\text{-}BL_7^{2-})]$[29] have been reported.

## Electrochemistry, EPR Spectroscopy, Spectrolectrochemistry, and Density Functional Calculations

Complexes $[\mathbf{1}–\mathbf{8}](ClO_4)_2$ exhibit two successive one-electron oxidation processes and multiple reductions in both $CH_3CN$ and $CH_2Cl_2$ (Figure 8 and Table 5). The first oxidation potential of $BL_1^{2-}$-bridged $[\mathbf{1a}]^{2+}$–$[\mathbf{1c}]^{2+}$ varies slightly based on the electronic effect of the R group attached to the framework of the ancillary ligand (Scheme 1).[30]

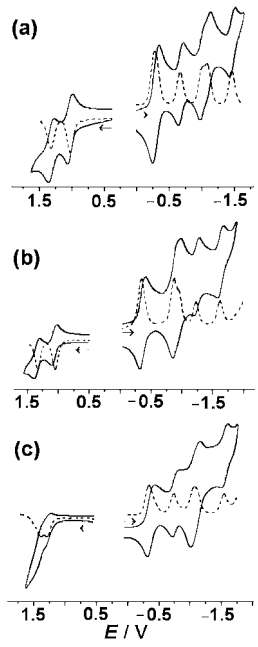

Figure 8. Cyclic voltammograms (—) and differential pulse voltammograms (----) of $10^{-3}$ M solutions of $[\mathbf{1a}](ClO_4)_2$ (a), $[\mathbf{4}](ClO_4)_2$ (b), and $[\mathbf{8}](ClO_4)_2$ (c) in $CH_3CN$/0.1 M $Et_4NClO_4$ at 298 K (scan rate: 50 mV $s^{-1}$).

The potentials of the complexes with pap in combination with different $BL^{2-}$ ligands ($[\mathbf{1a}]^{2+}$ and $[\mathbf{2}]^{2+}$–$[\mathbf{8}]^{2+}$) vary substantially due to a variety of parameters associated with $BL_n^{2-}$, such as (i) the electronic nature of the substituents in $BL_n^{2-}$, (ii) the number of fused rings involved, (iii) the relative position of the oxygen donor centers in the anthracene ring ($BL_4^{2-}$ and $BL_8^{2-}$), and (iv) the difference in donor centers in $BL_4^{2-}$ (oxido) and $BL_7^{2-}$ (iminium). The first oxidation potential follows the order $[\mathbf{8}]^{2+} >> [\mathbf{2}]^{2+} > [\mathbf{6}]^{2+} > [\mathbf{1a}]^{2+} \geq [\mathbf{4}]^{2+} > [\mathbf{3}]^{2+} > [\mathbf{5}]^{2+} >> [\mathbf{7}]^{2+}$ in both $CH_3CN$ and $CH_2Cl_2$ (Table 5). The separation in potentials between the successive oxidation processes ($\Delta E$) translates to the comproportionation constant $K_c$ [derived from $RT\ln K_c = nF(\Delta E)$[31]], which has values in the range of $2.3\times10^2$–$1.2\times10^5$ in $CH_3CN$ (Table 5). The variation of the electronic nature of the substituents in the framework of the ancillary ligands (H, Me, Cl) with the same $BL_1^{2-}$ bridging unit in $[\mathbf{1a}]^{2+}$–$[\mathbf{1c}]^{2+}$ has a small effect on the coupling processes. However, it is significantly large as in pap complexes $[\mathbf{1a}]^{2+}$ and $[\mathbf{2}]^{2+}$–$[\mathbf{8}]^{2+}$ with different $BL_n^{2-}$ ligands. Complex $[\mathbf{8}]^{2+}$ shows the smallest electrochemical coupling ($K_c$) due to its larger Ru–Ru separation, which is a result of the spreading of donor centers (O,O,O,O) over all three available rings in the anthracene backbone unlike all other complexes ($[\mathbf{1}]^{2+}$–$[\mathbf{7}]^{2+}$), where only two consecutive fused rings are involved. The $\Delta E$ value, however, increases in $CH_2Cl_2$ in each case, leading to relatively higher $K_c$ values of $1.7\times10^3$–$1.3\times10^6$ (Table 5). The $K_c$ values of the complexes are suggestive of an electrochemically moderately coupled, localized, class II mixed-valence situation.[32] The only other related diruthenium derivatives of large quinones (Scheme 1) with AL = bpy, namely $[\{(bpy)_2Ru\}_2(\mu\text{-}$

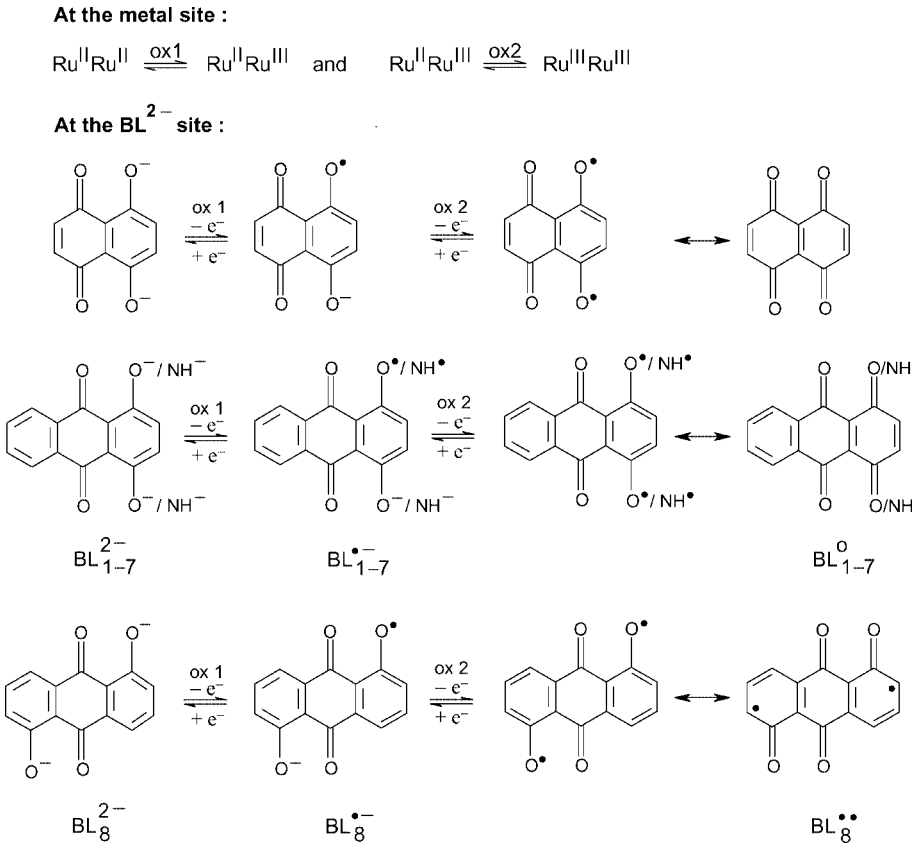
[a] Two-electron transfer process.

$BL_1^{2-})]^{2+}$,[10] $[\{(bpy)_2Ru\}_2(\mu\text{-}BL_4^{2-})]^{2+}$,[11] and $[\{(bpy)_2Ru\}_2(\mu\text{-}BL_8^{2-})]^{2+}$,[11] exhibit $K_c$ values of $1.8\times10^5$, $3.7\times10^4$ and $3.4\times10^2$, respectively, in $CH_3CN$, similar to those of the corresponding pap complexes $[\mathbf{1}]^{2+}$, $[\mathbf{4}]^{2+}$, and $[\mathbf{8}]^{2+}$ (Table 5) in spite of the much stronger π-acceptor characteristics of pap relative to bpy.[33]

Both the metal ion and the bridging ligand in $[\mathbf{1}]^{2+}$–$[\mathbf{8}]^{2+}$ (Scheme 2) are able to undergo successive two-step one-electron oxidations with formation of paramagnetic intermediate species. Therefore, the preferential involvement of metal- or ligand-based frontier orbitals in the first oxidation process was ascertained from the EPR characteris-



Scheme 2.

tics of the electrogenerated one-electron oxidized species in each case. The intermediate paramagnetic species $[\mathbf{1}–\mathbf{8}]^{3+}$ systematically exhibit closely spaced rhombic or axial-type EPR spectra at 77 K (Figure 9 and Table 6). However, analysis of the EPR spectra, especially the small $g$ anisotropy ($\Delta g = g_1 - g_3 = 0.0078–0.0642$) and the average $g$ $\{<g> = [(g_1^2 + g_2^2 + g_3^2)/3]^{1/2} \approx 2.00\}$,[34] which is close to the free electron value of 2.0023, clearly suggest a radical complex[35] with the formulation $Ru^{II}(\mu\text{-}BL^{\cdot-})Ru^{II}$ for $[\mathbf{1}–\mathbf{8}]^{3+}$ instead of the mixed-valence alternative $Ru^{II}(\mu\text{-}BL^{2-})Ru^{III}$. However, the observed small splitting of the EPR spectra implies a minority contribution of a paramagnetic $Ru^{III}$ ion in the singly occupied molecular orbital (SOMO) as well, which leads to the alternative mixed-valence formulation $Ru^{II}(\mu\text{-}BL^{2-})Ru^{III}$.[36] The appreciable effect of the electronic structure of $BL^{2-}$ on the first oxidation potential of $[\mathbf{1}–\mathbf{8}]^{2+}$ (Table 5) indeed justifies its preferential involvement. The above assignments are in good agreement with the computed HOMO energies of $[\mathbf{1a}]^{2+}$ at the B3LYP level (Figure 10 and Table 7). The contribution of 68% $\pi(BL_1^{2-})$ along with 22% $d\pi(Ru)$ in the HOMO level essentially justifies the preferential primary involvement of $BL_1^{2-}$ instead of $Ru^{II}$ in the first oxidized state, as clearly evidenced in the EPR spectra of $[\mathbf{1}–\mathbf{8}]^{3+}$. The intermediate one-electron oxidized species for the analogous bpy complexes $[\{(bpy)_2Ru\}_2(\mu\text{-}BL_1^{2-})]^{3+}$,[10] $[\{(bpy)_2Ru\}_2(\mu\text{-}BL_4^{2-})]^{3+}$,[11] and $[\{(bpy)_2Ru\}_2(\mu\text{-}BL_8^{2-})]^{3+}$[11] were, however, ascribed to a mixed-valence $Ru^{II}Ru^{III}$ situation based on the EPR spectrum of the isolated polycrystalline $[\{(bpy)_2Ru\}_2(\mu\text{-}BL_1^{2-})]^{3+}$ at 77 K ($g_1 = 2.33$, $g_2 = 2.01$, and $g_3 = 1.88$; $\Delta g = 0.45$ and $<g> = 2.08$) and the near-IR transition at 2083 nm in $CH_3CN$ ($\varepsilon = 9120\ M^{-1}cm^{-1}$, $\Delta\nu_{1/2} = 3000\ cm^{-1}$). The preferential involvement of the bridging ligand in the first oxidation process has been described recently in the smaller quinonoid-based diruthenium(II)-bpy complex $[\{(bpy)_2Ru^{II}\}_2(\mu\text{-}H_2L^{2-})]^{2+}$ ($H_2L^{2-}$ = 2,5-dioxido-1,4-benzoquinonediimine).[7] However, the $K_c$ value for the successive oxidation processes in $[\{(bpy)_2Ru^{II}\}_2(\mu\text{-}H_2L^{2-})]^{2+}$ is much higher ($6.5\times10^8$ in $CH_3CN$) than that in the present cases (ca. $10^2$–$10^5$), as normally expected for ligand-based processes.[14,36]

Electrochemically generated further one-electron oxidized species $[\mathbf{1}–\mathbf{8}]^{4+}$ are found to be EPR inactive even when frozen in a glass (77 K). The diamagnetic nature of the doubly oxidized species $[\mathbf{1}–\mathbf{8}]^{4+}$ suggests their probable alternative formulation as $\{Ru^{II}(\mu\text{-}BL^{\circ})Ru^{II}\}$, with involvement of the bridging ligand in the second step oxidation process, or $\{Ru^{II}(\mu\text{-}BL^{\cdot-})Ru^{III}\}$, with involvement of the metal ion in the second step oxidation process and subsequent antiferromagnetic spin pairing of the unpaired electrons associated with $BL^{\cdot-}$ and $Ru^{III}$. The computed orbital compositions in $[\mathbf{1a}]^{2+}$ at the B3LYP level suggest that the HOMO–1 and HOMO–2 are primarily dominated by Ru (61% and 70%, respectively), with only a minor contribution (ca. 10%) from $BL_1^{2-}$ (Figure 10 and Table 7), which rules out the alternative possibility of a bridging-ligand-based second oxidation process. It should be noted that the stabilization of alternative spin-coupled singlet states by the involvement of a mixed-valence $Ru^{II}Ru^{III}$ configuration and an azo anion radical-based bridging ligand in $[(acac)_2Ru^{II}(\mu\text{-}L^{\cdot-})Ru^{III}(acac)_2]$ $\{L^{\cdot-} = NC_5H_4(N{=}N^{\cdot-})H_4C_5N\}$[18a] or partially coupled semiquinone form of 1,10-phenanthroline-5,6-dione ($L_1^{\cdot-}$) bridged $[(acac)_2Ru^{II}(\mu\text{-}L_1^{\cdot-})Ru^{III}(acac)_2]$ (acac = acetylacetonate) has been reported recently.[6] The consideration of a ruthenium-based second-step oxidation process ($Ru^{II}\rightarrow Ru^{III}$) instead of further oxidation of $BL^{\cdot-}$ can easily be understood, particularly in the case of $[\mathbf{8}]^{4+}$, as the alternative option leads to the formation of an unstable diradical-bridged triplet species $Ru^{II}(\mu\text{-}BL_8^{\cdot\cdot})Ru^{II}$ (Scheme 2). It is interesting to note that the occupied frontier orbitals (HOMO to HOMO–2) exhibit a fairly good mixing with the π orbitals of pap in $[\mathbf{1a}]^{2+}$ (Figure 10 and Table 7).

The formulations of analogous two-electron-oxidized bpy complexes $[\{(bpy)_2Ru\}_2(\mu\text{-}BL_1)]^{4+}$[10] and $[\{(bpy)_2Ru\}_2(\mu\text{-}BL_4)]^{4+}/[\{(bpy)_2Ru\}_2(\mu\text{-}BL_8)]^{4+}$ [11] were, on the other hand, proposed as $\{Ru^{II}(\mu\text{-}BL_1^{\circ})Ru^{II}\}$ and $\{Ru^{III}(\mu\text{-}BL_{4/8}^{2-})Ru^{III}\}$, respectively.

| HOMO–5 (–0.387) | 56.8 | 7.0 | 36.0 |

[a] Values in parentheses are orbital energies in atomic units.

Both the ancillary (aap)[37] and bridging ligand ($BL^{2-}$)[10,11] are known to successively accept two electrons each in their LUMOs (Scheme 3), therefore ideally a total of ten one-electron reduction processes (eight from four aap ligands and two from $BL^{2-}$) are expected for $[\mathbf{1}–\mathbf{8}]^{2+}$. The complexes indeed display multiple reductions in $CH_3CN$ or $CH_2Cl_2$ (Figure 8 and Table 5) within the accessible potential limit of –2.0 V. However, instead of ten successive one-electron reduction processes, simultaneous two-electron processes are also detected along with the clear one-electron responses, as confirmed by comparing the current heights of their respective DPVs (differential pulse voltammograms) with that of the coulometrically established one-electron oxidation processes. Since the ruthenium ion in $[\mathbf{1}–\mathbf{8}]^{2+}$ is in the +2 state, aap and $BL^{2-}$ ligands are naturally involved in the reduction processes. Consequently, the reduction potentials vary systematically depending on the electronic structures of both aap and $BL^{2-}$ (Table 5). The two-electron nature of the first reduction process for most of the complexes does not permit the radical intermediate to be electrogenerated (Scheme 3). However, the first one-electron reduced species for $[\mathbf{5}]^{+}$ in $CH_3CN$ displays a free radical EPR signal at 77 K with $g = 1.998$ (Figure 11) without any hyperfine splitting, which might suggest that the unpaired electron resides on the oxygen center of $BL_5^{\cdot 3-}$ instead of the nitrogen center of the azo group of pap.[35,38] The B3LYP/6-31G* Kohn–Sham orbitals show that the LUMO is primarily dominated by the π* orbital of $BL_1^{2-}$ (93%) whereas LUMO+1/LUMO+2 consist of π* orbitals of pap (>90%; Figure 10 and Table 7). The closeness in energy between the $BL_1^{2-}$-based LUMO and the pap-based higher vacant orbitals (LUMO+1/LUMO+2) justifies the observed simultaneous two-electron first step reduction process (Figure 8).

The spectral features of the complexes both in the native state $[\mathbf{1}–\mathbf{8}]^{2+}$ and also in the oxidized $[\mathbf{1}–\mathbf{8}]^{3+}/[\mathbf{1}–\mathbf{8}]^{4+}$ states follow a general trend in $CH_3CN$ (Figure 12 and Table 8). The spectral features of $[\mathbf{1a}–\mathbf{1c}]^{n+}$ ($n$ = 2, 3, 4) in $CH_2Cl_2$ also show a similar general trend and no significant solvent effect on the spectral aspects is observed. Multiple ligand-based π–π*/n–π* transitions appear in the UV region. In addition, intense metal-to-ligand charge transfer (MLCT) transitions are observed near 550 nm, which are associated with a moderately intense shoulder(s) at the lower energy part near 650 nm. The Gaussian analysis of the visible region part of the spectra of $[\mathbf{1a}]^{2+}$ in $CH_3CN$ and $CH_2Cl_2$

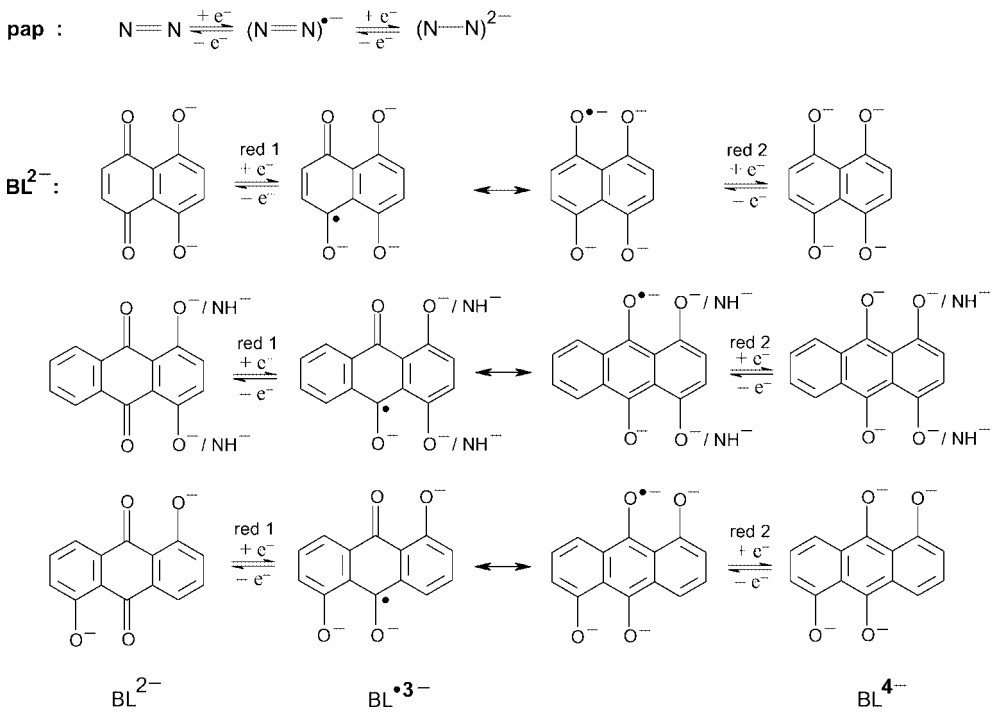

Scheme 3.

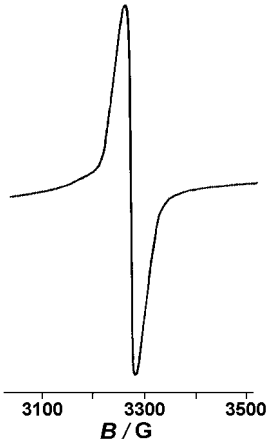

Figure 11. EPR spectrum of $[5]^+$ in $CH_3CN/Et_4NClO_4$ at 77 K.

shows a total of four bands at $\lambda$ ($\varepsilon$) = 742 nm (4396 $M^{-1}cm^{-1}$), 639 (5580), 565 (11821), and 517 (22069) (see part a in Figure 12, inset) and 748 (4800), 656 (5739), 570 (11120), and 522 (23527) (Figure 12, part b, inset), respectively. A selected list of vertical excitation energies computed with the TD-DFT/B3LYP formalism for the B3LYP/SDD,6-31G* geometry of $[\mathbf{1a}]^{2+}$ in its singlet ground state are summarized in Table 9 (complete lists are given in Table S5 in the Supporting Information).[39] Here, a comparison between observed and computed transitions is performed by examining transitions of comparable intensities guided by their respective oscillator strengths and absorptivity values.[40] The nature of the excited states is assigned based on the percent Kohn–Sham orbital contributions of the orbitals involved in the electronic transitions. Based on the oscillator strengths, the comparable predicted transitions appear at $\lambda$ = 743.91 (HOMO→LUMO+1), 696.64 (HOMO→LUMO/HOMO→LUMO+4), 539.14 (HOMO–2→LUMO/HOMO–1→LUMO+2) and 514.30 nm (HOMO–5→LUMO+1/HOMO–4→LUMO+2) (Table 9, Figure 13, and Figure S1 in the Supporting Information).

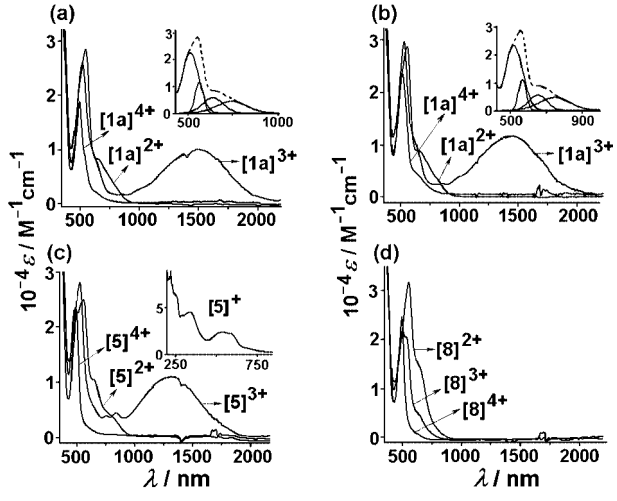

Figure 12. Electronic spectra of (a) $[\mathbf{1a}]^{n+}$ ($n$ = 2–4) in $CH_3CN/Et_4NClO_4$. The inset shows the Gaussian analysis of the visible region of the spectrum for $n$ = 2. (b) $[\mathbf{1a}]^{n+}$ ($n$ = 2–4) in $CH_2Cl_2/Et_4NClO_4$. The inset shows the Gaussian analysis of the visible region of the spectrum for $n$ = 2. (c) $[\mathbf{5}]^{n+}$ ($n$ = 2–4) in $CH_3CN/Et_4NClO_4$. The inset shows the spectrum of $[\mathbf{5}]^+$. (d) $[\mathbf{8}]^{n+}$ ($n$ = 2, 3, 4) in $CH_3CN/Et_4NClO_4$.

The charge-transfer bands of $[\mathbf{1}–\mathbf{8}]^{3+}$ are blue shifted upon oxidation, with a reduction in intensity, and a new low-energy, intense transition appears in the range 1200–

[a] Singlet excitation energies. [b] Wavelength values in nm given in parentheses. [c] $M^{-1}cm^{-1}$. [d] Occupied and virtual orbitals. [e] $BL_1^{2-}$ stands for the bridging ligand and pap represents the 2-(phenylazo)pyridine ligand. [f] Transition coefficients.

1500 nm ($\varepsilon$ = 5000–11000 $M^{-1}cm^{-1}$) with a band width at half height ($\Delta\nu_{1/2}$) of 1900–3800 $cm^{-1}$ (Figure 12 and Table 8). The experimentally obtained $\Delta\nu_{1/2}$ values are smaller than would be expected (3900–4300 $cm^{-1}$) from the Hush formula [$\Delta\nu_{1/2} = (2310\ E_{op})^{1/2}$][41] for a localized class-II mixed-valence system. This disagreement between experimental and calculated $\Delta\nu_{1/2}$ values and the high intensity of the NIR band supports the notion of a ligand-based oxidation to $Ru^{II}(\mu\text{-}BL^{\cdot-})Ru^{II}$ instead of metal-based oxidation to $Ru^{II}(\mu\text{-}BL^{2-})Ru^{III}$, as previously implied by the free-radi-

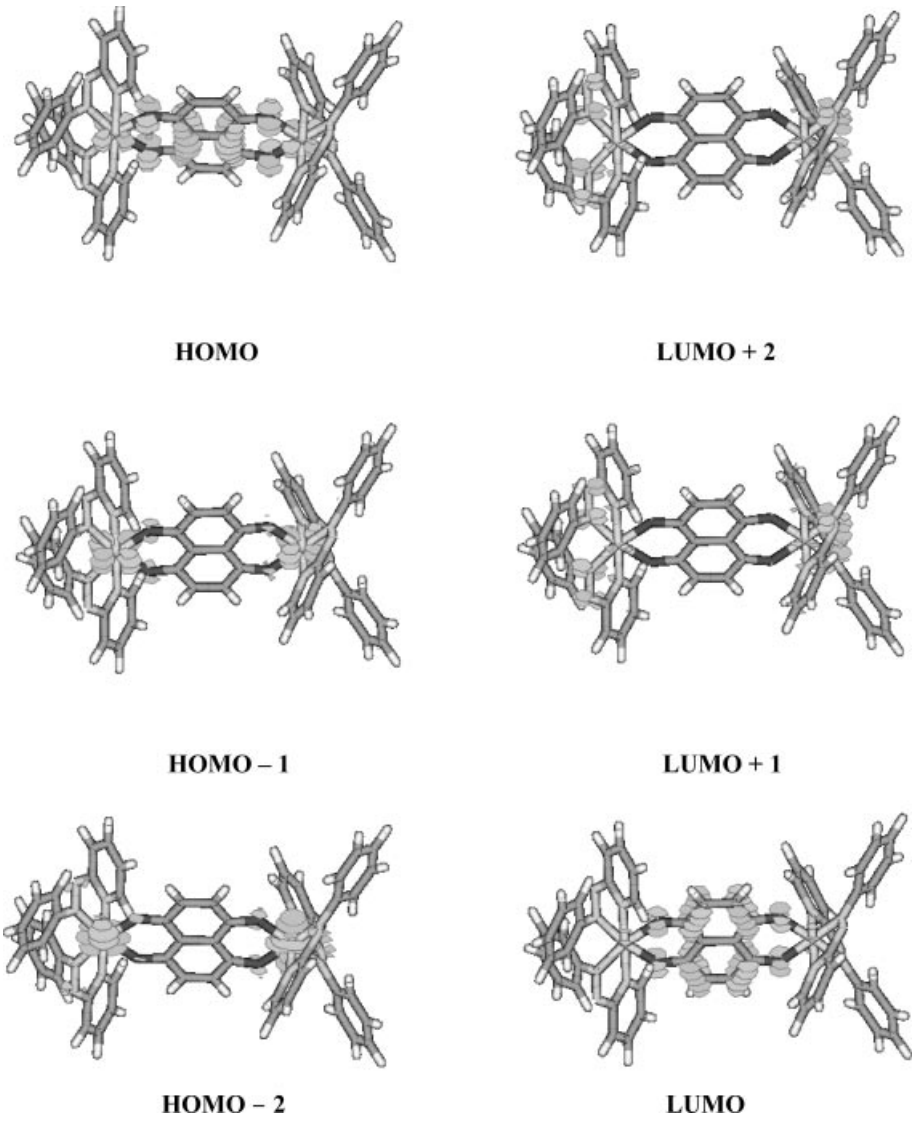

Figure 13. Kohn–Sham orbital contours of the frontier MOs of [**1a**]$^{2+}$ involved in the intense long-wavelength transitions.

cal EPR signal of [**1**–**8**]$^{3+}$ (Table 6). The low-energy NIR band is thus assigned as an intraligand transition involving the reduced component of the bridging ligand to the oxidized SOMO of its counterpart. Although the spectral features of [**8**]$^{2+/3+/4+}$ in the UV/Vis region are akin to those in other complexes, the expected NIR band for the intermediate [**8**]$^{3+}$ has not been detected (Figure 12, d, Table 8). On further oxidation to the spin-coupled diamagnetic $Ru^{II}$(μ-$BL^{\cdot-}$)$Ru^{III}$ state in [**1**–**8**]$^{4+}$, the near-IR band disappears and the charge-transfer (MLCT/LMCT) bands are blue shifted. Unlike other complexes, the low-energy shoulder in [**7**]$^{4+}$ appears as an intense band at 892 nm (Table 8). The reduction of [**5**]$^{2+}$ to the radical species [**5**]$^{\cdot+}$ results in a red shift of the MLCT band from 561 to 597 nm with comparable intensity [Figure 12, c (inset), Table 8].

In summary, experimental results in combination with DFT calculations have established that the large quinonoid ($BL^{2-}$)-bridged diruthenium complexes [$(aap)_2Ru^{II}$(μ-$BL^{2-}$)$Ru^{II}(aap)_2$]$^{2+}$ [**1**–**8**]$^{2+}$ containing strongly π-accepting ancillary ligands (AL = arylazopyridine) undergo preferential first-step oxidation at the bridging ligand to give the paramagnetic radical-bridged diruthenium(II) species [$(aap)_2Ru^{II}$(μ-$BL^{\cdot-}$)$Ru^{II}(aap)_2$]$^{3+}$ [**1**–**8**]$^{3+}$. However, second-step oxidation selectively takes place at the metal center to give antiferromagnetically coupled singlet species, namely the mixed-valence $Ru^{II}Ru^{III}$ species [$(aap)_2Ru^{II}$(μ-$BL^{\cdot-}$)-$Ru^{III}(aap)_2$]$^{4+}$ [**1**–**8**]$^{4+}$, which are bridged by a radical bridging ligand (Scheme 4). Successive reductions, however, take place at the ligand centers. The first-step reduction process takes place either as a single electron transfer to the bridging ligand ($BL^{\cdot3-}$) or, in most cases, as a simultaneous two-electron transfer process involving the bridging ligand (μ-$BL^{4-}$) or a mixed situation of bridging ($BL^{\cdot3-}$) and ancillary ($aap^{\cdot-}$) ligands (Scheme 4).

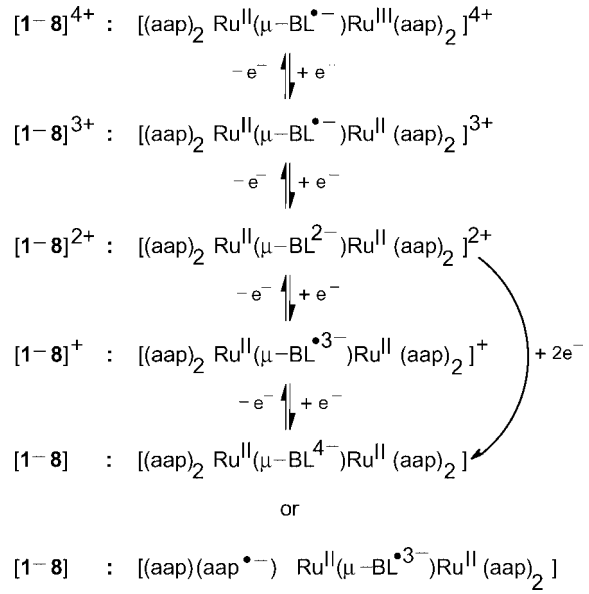

Scheme 4.

## Experimental Section

**Materials and Instrumentation:** The precursor compounds *ctc*-$[Ru(aap)_2(H_2O)_2](ClO_4)_2{\cdot}H_2O$ and aap ligands were prepared according to the reported procedures.[42] The dinucleating ligand precursors 5,8-dihydroxy-1,4-napthoquinone ($H_2BL_1$), 2,3-dichloro-5,8-dihydroxy-1,4-napthoquinone ($H_2BL_2$), 6,11-dihydroxy-5,12-naphthacenedione ($H_2BL_3$), 1,4-dihydroxy-9,10-anthraquinone ($H_2BL_4$), 1,4-dihydroxy-2,3-dimethyl-9,10-anthraquinone ($H_2BL_5$), 6,7-dichloro-1,4-dihydroxy-9,10-anthraquinone ($H_2BL_6$), 1,4-diamino-9,10-anthraquinone ($H_4BL_7$), and 1,5-dihydroxy-9,10-anthraquinone ($H_2BL_8$) were purchased from Aldrich (USA). HPLC-grade solvents were used for spectroscopic and electrochemical studies. UV/Vis/NIR spectra in $CH_3CN$ or $CH_2Cl_2$/0.1 M $Et_4NClO_4$ at 298 K were recorded with a Perkin–Elmer 950 lambda spectrophotometer. FT-IR spectra were recorded with a Nicolet spectrophotometer with samples prepared as KBr pellets. Solution electrical conductivity was checked using a Systronic 305 conductivity bridge. $^1$H NMR spectra were obtained with a 300 or 400 MHz Varian FT spectrometer. The EPR measurements were made with a Varian model 109C E-line X-band spectrometer fitted with a quartz dewar for measurements at 77 K. Cyclic voltammetric, differential pulse voltammetric, and coulometric measurements were carried out using a PAR model 273A electrochemistry system. Platinum wire working and auxiliary electrodes and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. The supporting electrolyte was 0.1 M $[NEt_4]ClO_4$ and the solute concentration was about $10^{-3}$ M. The half-wave potential $E^\circ_{298}$ was set equal to $0.5(E_{pa} + E_{pc})$, where $E_{pa}$ and $E_{pc}$ are the anodic and cathodic cyclic voltammetric peak potentials, respectively. A platinum wire-gauze working electrode was used in the coulometric experiments. The elemental analyses were carried out with a Perkin–Elmer 240C elemental analyzer. Electrospray mass spectra were recorded with a Micromass Q-ToF mass spectrometer.

***CAUTION!*** *Perchlorate salts of metal complexes with organic ligands are potentially explosive. Heating of dried samples must be avoided and handling of small amounts has to proceed with great caution using protection.*

Complexes [**1**–**8**]$(ClO_4)_2$ were prepared by following a general procedure. The details are given for [**1a**]$(ClO_4)_2$.

**[(pap)$_2$Ru$^{II}$(μ-BL$_1^{2-}$)Ru$^{II}$(pap)$_2$](ClO$_4$)$_2$ [1](ClO$_4$)$_2$:** The bridging ligand $H_2BL_1$ (0.013 g, 0.068 mmol) was added to the starting complex *ctc*-$[Ru(aap)_2(OH_2)_2](ClO_4)_2{\cdot}H_2O$ (0.1 g, 0.138 mmol) in absolute ethanol (20 mL) and the resulting mixture was heated to reflux under a dinitrogen atmosphere for 12 h. The initial purple solution gradually changed to violet. The solvent of the reaction mixture was then evaporated to dryness under reduced pressure. The resulting mixture was purified on a neutral alumina column. Initially, a blue compound corresponding to $[Ru(pap)_2Cl_2]$ was eluted with $CH_2Cl_2/CH_3CN$ (15:1 v/v), followed by a violet compound with $CH_2Cl_2/CH_3CN$ (5:1 v/v) corresponding to [**1a**]$(ClO_4)_2$. Evaporation of the solvent under reduced pressure yielded pure complex [**1a**]$(ClO_4)_2$. Yield: 0.046 g (50%). $C_{54}H_{40}Cl_2N_{12}O_{12}Ru_2$: calcd. IR (KBr disk): $\tilde{\nu}$ = 3260, 1087, 625 cm$^{-1}$. $^1$H NMR (400 MHz, $CDCl_3$, 298 K): $\delta$ = 9.55 (s, NH), 8.65 (d, $J$ = 6.0 Hz, 1 H), 8.53 (d, $J$ = 6.0 Hz, 1 H), 8.08 (m, 3 H), 7.33 (d, $J$ = 8.9 Hz, 2 H), 7.20 (m, 8 H), 6.98 (d, $J$ = 7.5 Hz, 3 H), 6.84 (d, $J$ = 7.2 Hz, 3 H) ppm.

**[8](ClO$_4$)$_2$:** Yield: 0.035 g (37%). $C_{58}H_{42}Cl_2N_{12}O_{12}Ru_2$: calcd. C 50.73, H 3.09, N 12.25; found C 50.62, H 3.38, N 12.33. $\Lambda_M$ ($\Omega^{-1}$ cm$^2$ M$^{-1}$) in acetonitrile at 25 °C: 202. IR (KBr disk): $\tilde{\nu}$ = 1088, 622 cm$^{-1}$. $^1$H NMR [400 MHz, $(CD_3)_2SO$, 298 K]: $\delta$ = 8.94 (m, 2 H), 8.32 (m, 2 H), 7.94 (m, 2 H), 7.46 (m, 4 H), 7.30 (m, 5 H), 7.21 (d, $J$ = 8.0 Hz, 1 H), 7.06 (m, 1 H), 6.93 (d, $J$ = 7.6 Hz, 2 H), 6.84 (d, $J$ = 5.6 Hz, 2 H) ppm.

**X-ray Crystallography:** Single crystals of [**1a**](ClO$_4$)$_2$·H$_2$O and [**3**](ClO$_4$)$_2$ were grown by slow evaporation of a 1:1 dichloromethane/hexane solution. Data were collected with an OXFORD XCALIBUR-S CCD diffractometer (see Table 10 for further details). The structures were solved and refined by full-matrix least-squares techniques on $F^2$ with SHELX-97.[43] The absorption corrections were done by multi-scan (SHELXTL program package) and all the data were corrected for Lorentz polarization effects. Hydrogen atoms were included in the refinement process with a riding model. CCDC-606432 {[**1a**](ClO$_4$)$_2$·H$_2$O} and -606433 {[**3**](ClO$_4$)$_2$} contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Details:** Full geometry optimization of [**1a**]$^{2+}$ was carried out using the density functional theory method at the (R)B3LYP level.[44a,44b] All elements except ruthenium were assigned the 6-31G* basis set. The SDD basis set with effective core potential was employed for the ruthenium atoms.[44c,44d] Calculations were performed with Gaussian98 and Gaussian03.[44e,44f] Vertical electronic excitations based on B3LYP optimized geometries were computed using the time-dependent density functional theory (TD-DFT) formalism[44g] with the B3LYP functional using the above combination of basis sets. Molecular orbital compositions were analyzed using the AOMIX program.[44h–44j]

Table 10. Crystallographic data for [**1a**](ClO$_4$)$_2$·H$_2$O and [**3**](ClO$_4$)$_2$.

| | [**1a**](ClO$_4$)$_2$·H$_2$O | [**3**](ClO$_4$)$_2$ |
|---|---|---|
| Formula | $C_{27}H_{20}ClN_6O_7Ru$ | $C_{31}H_{22}ClN_6O_6Ru$ |

**Supporting Information** (for details see the footnote on the first page of this article): Kohn−Sham orbitals of [**1a**]$^{2+}$ (Figure S1); optimized coordinates for $BL_1^{2-}$ (Table S1), pap (Table S2) and [**1a**]$^{2+}$ (Table S3); calculated bond lengths and angles of [**1a**]$^{2+}$ (Table S4) and TD-DFT data for [**1a**]$^{2+}$ (Table S5).

## Acknowledgments

Financial support received from the Department of Science and Technology, and Council of Scientific and Industrial Research, New Delhi (India) is gratefully acknowledged. X-ray structural studies for [**1a**](ClO$_4$)$_2$ and [**3**](ClO$_4$)$_2$ were carried out at the National Single Crystal Diffractometer Facility, Indian Institute of Technology, Bombay. Special acknowledgment is made to the Sophisticated Analytical Instrument Facility (SAIF) and the Computer Center, Indian Institute of Technology Bombay, respectively, for providing the EPR and computational facilities.

# Synthesis of New Phenanthroline-Based Heteroditopic Ligands – Highly Efficient and Selective Fluorescence Sensors for Copper(II) Ions

**Peter Comba,*[a] Roland Krämer,[a] Andriy Mokhir,[a] Kyaw Naing,[a] and Erik Schatz[a]**

**Keywords:** Sensor / Fluorescence / Copper(II) / Selectivity / Ruthenium

The heteroditopic phenanthroline derivatives 5,6-bis(2-pyridylcarboxamido)-1,10-phenanthroline ($H_2L^1$) and 5,6-bis[(4-methoxy-2-pyridyl)carboxamido]-1,10-phenanthroline ($H_2L^2$) have been prepared and characterized, together with their luminescent ruthenium(II) complexes $[Ru(bpy)_2(H_2L^{1,2})](PF_6)_2$ and $[Ru(H_2L^1)_3](PF_6)_2$ and the corresponding iron(II) complex $[Fe(H_2L^1)_3](PF_6)_2$. In these complexes, the metal ion is coordinated by the bidentate phen site of $H_2L$. The luminescence of the ruthenium complexes ($\lambda_{ex}$ = 450 nm, $\lambda_{em}$ ca. 620 nm) is completely quenched by $Cu^{2+}$ ions in the micromolar concentration range and, to a lesser extent, by other metal ions. At pH 5, the response of the luminescent sensors is highly $Cu^{2+}$-selective. Heterodinuclear complexes $[Ru(bpy)_2(LM)](PF_6)_2$, $[Ru(LM)_3](PF_6)_2$, and $[Fe(LM)_3](PF_6)_2$ have been isolated for M = $Cu^{2+}$, $Ni^{2+}$, $Co^{2+}$, and $Pd^{2+}$. It is suggested that M is coordinated to the tetradentate N4 site of L by two deprotonated amide N atoms and two pyridyl groups. This coordination type is confirmed by the EPR spectrum of the compound $[Ru^{II}(bpy)_2(L^1Cu^{II})](PF_6)_2$.

## Introduction

For many good reasons di- and oligonuclear transition-metal complexes are attracting much interest. Cooperativity in general and, more specifically, electron and energy transfer as well as magnetic interactions have been recognized as important and rather general features in biological systems,[1,2] and there is an increasing range of applications in areas such as catalysis,[3,4] analytical chemistry (metal-ion- and anion-selective sensors),[5,6] and information technology (switches).[7] Most of these applications imply that the two metal centers in a dinuclear complex have different functions and, therefore, different properties. Synthetically, the required ligand asymmetry is often a demanding task.[8] An attractive approach is to couple a photoactive coordination site covalently to a ligand, which selectively coordinates another metal ion or has a second coordination center that selectively binds anions or activates substrates. Tris(bipyridine)ruthenium(II)-derived systems have been used frequently in this area,[9,10] and metal-ion- and anion-selective sensors,[10–16] photocatalysts,[12–14] and photoactive pharmaceuticals[15,16] have been reported.

Generally, the synthesis of this type of system relies on a suitable ditopic ligand with a multidentate or macrocyclic donor set, coupled to 1,10-phenanthroline (phen) or 2,2′-bipyridine (bpy). We report here on the synthesis of the two heteroditopic ligands $H_2L^1$ and $H_2L^2$ (Scheme 1) based on 5,6-diamino-1,10-phenanthroline and the synthesis of the corresponding ruthenium(II) complexes ($[Ru(bpy)_2(H_2L^{1,2})]^{2+}$ and $[Ru(H_2L^1)_3]^{2+}$) and their hetero-oligonuclear transition-metal complexes ($[Ru(bpy)_2\{(L^{1,2})M\}]^{2+}$ and $[Ru\{(L^1)M\}_3]^{2+}$, M = divalent transition-metal ion, e.g. $Cu^{2+}$). Of specific interest are the strong and selective coordination of first-row transition-metal ions to the coordina-

tion site offered by $L^1$ and $L^2$ and the quenching of the fluorescence of the tris(bipyridine-type)ruthenium(II) site by this selective coordination event.

## Results and Discussion

### Syntheses and Characterization

The heteroditopic ligands $H_2L^1$ and $H_2L^2$ are prepared in respectable yields from 5,6-diamino-1,10-phenanthroline[17–19] (obtained in high yield by the reduction of 1,10-phenanthroline-5,6-dione dioxime with sodium dithionite[20] or formamidinesulfinic acid[21]) and picolinic acid or its methoxy derivative, respectively (Scheme 1). Because of solubility problems, air sensitivity, and poor reactivity of the amine groups, the acylation is performed under inert conditions in DMF, with DMAP[22] as the acylation catalyst, phenylphosphonic acid dichloride[23–26] as the activation reagent for the carboxylic group, and TEA as base. The $Ru^{2+}$ complexes $[Ru(bpy)_2(H_2L^{1,2})]^{2+}$ and $[Ru(H_2L^1)_3]^{2+}$ are obtained by the usual methods and in high yields.[10] Low-spin $Fe^{2+}$ complexes have also been obtained but are not discussed here in detail. The red mononuclear $Ru^{2+}$ complexes have the characteristic MLCT transitions at around 450 nm, they show resonances in the $^1H$ NMR spectra for the amide protons at around 10.5 ppm and have the expected vibrations for amide bonds in the infrared spectra at approximately 1680 and 1570 $cm^{-1}$, as well as the amide N–H transitions at approximately 3300 $cm^{-1}$. Upon coordination of metal ions to the $L^1$ ($L^2$) sites, the N–H vibration disappears, the amide transitions shift to a lower energy (ca. 30–50 $cm^{-1}$), and the MLCT transitions are shifted to a higher energy.

The EPR spectra of the mono- and tris-$Cu^{II}$ complexes are similar to each other and typical for tetragonal $Cu^{II}$ sites, with $g$ and $A$ values ($g_\parallel = 2.213$, $A_\parallel = 180 \times 10^{-4}$ $cm^{-1}$) that are typical for tetrahedrally distorted coordination sites.[9] The similarity of the EPR spectra indicates that there is no $Cu^{II}\cdots Cu^{II}$ magnetic exchange interaction and only a very weak, i.e. negligible, dipolar coupling interaction (Figure 1b). A model of the structure (Figure 1a), obtained by force field calculations,[27,28] visualizes the $Cu^{II}$ planes that are distorted because of the α-H atoms of the pyridine donors and indicates a distance of ca. 13 Å between the $Cu^{II}$ centers.

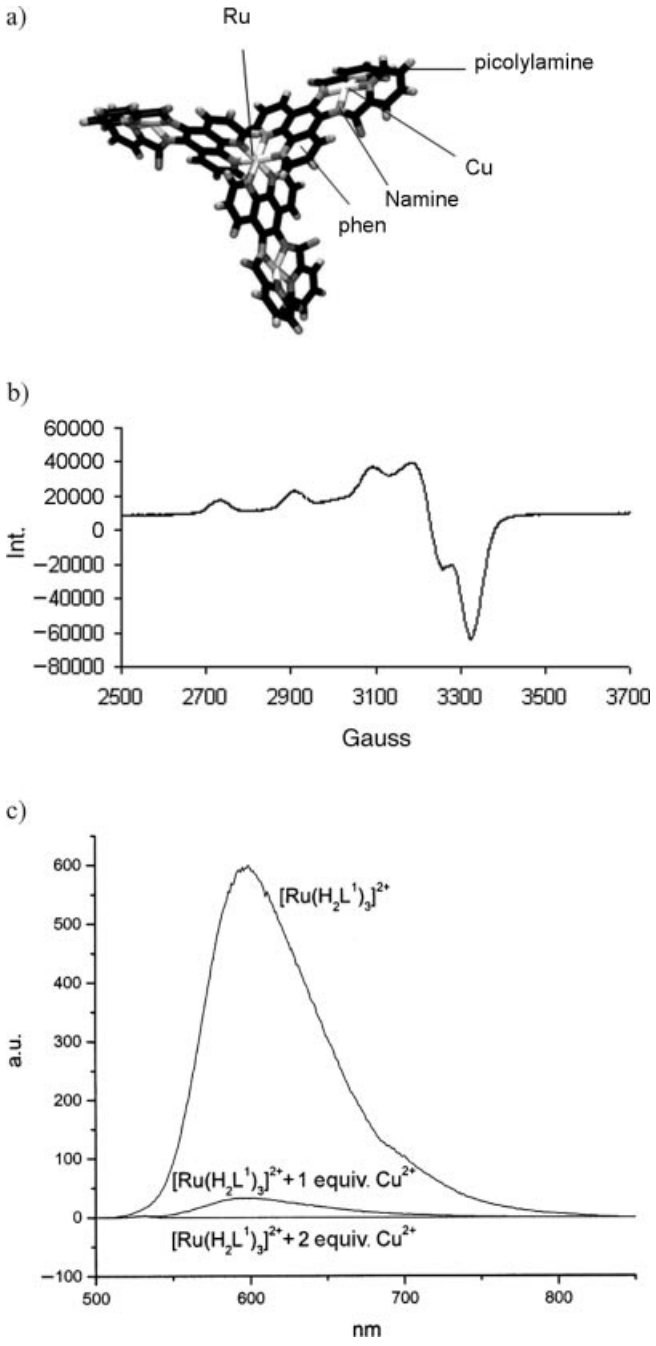

Figure 1. (a) Structural model of $[Ru\{(L^1)Cu\}_3]^{2+}$; (b) X-band EPR spectrum of $[Ru\{\mu\text{-}(L^1)Cu\}_3](PF_6)_2$ (ca. $10^{-3}$ M, DMF-$H_2O$-glass (2:1), 110 K); and (c) relative fluorescence intensities ($\lambda_{ex}$ = 450 nm, $\lambda_{em}$ = 620 nm) in aqueous solution at pH 7 (lutidine buffer) of $[Ru(H_2L^1)_3](PF_6)_2$ alone (10 μM), and after addition of 1 or 2 equiv. $CuSO_4$.

### Fluorescence Measurements

The luminescence spectra of $[Ru(bpy)_2(H_2L^1)]^{2+}$, $[Ru(bpy)_2(H_2L^2)]^{2+}$, and $[Ru(H_2L^1)_3]^{2+}$ are as expected for $Ru^{2+}$ polypyridine chromophores (transition at ca. 620 nm,[13] see Figure 1c); also shown in Figure 1c is the efficient fluorescence quenching of $[Ru(H_2L^1)_3]^{2+}$ with $Cu^{2+}$ ($[Ru^{2+}]/[Cu^{2+}]$ = 1:0, 1:1, 1:2). Similar effects are observed with $[Ru(bpy)_2(H_2L^1)]^{2+}$ and $[Ru(bpy)_2(H_2L^2)]^{2+}$, i.e. these complexes are, as expected, good on/off sensors for metal ions, specifically for $Cu^{2+}$ and $Ni^{2+}$, which have electronic transitions at similar energies and are known to strongly bind to amide donors already at physiological pH.[10,29]

To fully characterize the $L^1$- and $L^2$-based $Cu^{2+}$ sensors, the luminescence intensities (aqueous solutions, $[Ru^{2+}] = 10^{-5}$ M) were studied as a function of pH, buffer base, anion, and $M^{n+}$ concentration (M = $Cu^{2+}$, $Ni^{2+}$, $Co^{2+}$, $Fe^{2+/3+}$, $Zn^{2+}$, $Al^{3+}$, $Nd^{3+}$, $Mn^{2+}$, $Pb^{2+}$, alkali, and alkaline earth

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metal ions; see Table 1 for an overview of the most relevant results.). Buffer bases such as acetate, citrate, carbonate, phosphate, and lutidine as well as EDTA do not quench the fluorescence. Aminoalkylsufonates (e.g., MOPS, MES) lead to an approximately 50% reduction of the luminescence intensity, i.e., these are not suited as buffer bases in our systems. Usual inorganic anions or carboxylates do not affect the fluorescence intensity (see Table 1 and above). In addition, $Al^{3+}$, $Nd^{3+}$, $Mn^{2+}$, $Pb^{2+}$, and group 1 and 2 cations do not alter the luminescence spectra. Interestingly, protonation of the pyridine donors and deprotonation of an amide site lead to drastic changes in the luminescence properties (Figure 2). This is in contrast to other $Ru(bpy)_2$-amide sensors,[10] which have pH-independent luminescence intensities over a pH range of 2–12. This indicates that the published and present systems probably differ with respect to the mechanism of quenching of the excited state [electron (PET) vs. energy transfer (EET)].[12]

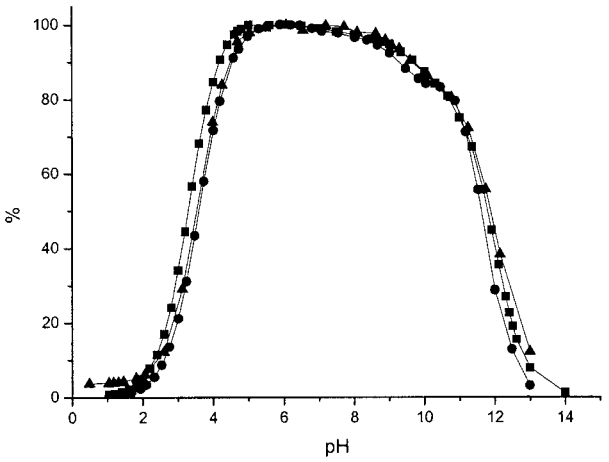

Figure 2. pH-dependence of the relative fluorescence intensity of 10 μM aqueous solutions of the complexes ($\lambda_{ex}$ = 450 nm, $\lambda_{em}$ = 620 nm) $[Ru(bpy)_2(H_2L^1)]^{2+}$ (■), $[Ru(H_2L^1)_3]^{2+}$ (▲), and $[Ru(bpy)_2(H_2L^2)]^{2+}$ (●).

Table 1. Reduction of the fluorescence intensity (in %) of $[Ru(bpy)_2(H_2L^1)]^{2+}$ as a function of added metal ions and pH.

| Added metal ion | pH | % Reduction of fluorescence intensity of $[Ru(bpy)_2(H_2L^1)]^{2+}$ |
|---|---|---|
| 1 equiv. $Cu^{2+}$ | 5 | 99 |
| 2 equiv. $Cu^{2+}$ | 5 | 99 |
| 10 equiv. $Co^{2+}$ | 5 | 2 |
| 10 equiv. $Fe^{2+}$ | 5 | 1 |
| 1 equiv. $Ni^{2+}$ | 5 | 0 |
| 10 equiv. $Ni^{2+}$ | 5 | 5 |
| 10 equiv. $Zn^{2+}$ | 5 | 1 |
| 10 equiv. $Fe^{2+}$ + 1 equiv. $Cu^{2+}$ | 5 | 98 |
| 100 equiv. $Ni^{2+}$ + 1 equiv. $Cu^{2+}$ | 5 | 99 |
| 10 equiv. $Zn^{2+}$ + 1 equiv. $Cu^{2+}$ | 5 | 99 |
| 1 equiv. $Cu^{2+}$ | 7 | 98 |
| 1 equiv. $Co^{2+}$ | 7 | 70 |
| 10 equiv. $Co^{2+}$ | 7 | 90 |
| 10 equiv. $Fe^{2+}$ | 7 | 80 |
| 10 equiv. $Mn^{2+}$ | 7 | 3 |
| 1 equiv. $Ni^{2+}$ | 7 | 80 |
| 10 equiv. $Ni^{2+}$ | 7 | 85 |
| 1 equiv. $Zn^{2+}$ | 7 | 40 |
| 10 equiv. $Pb^{2+}$ | 7 | 0 |
| 10 equiv. $Cu^{2+}$ | 7 | 0 |
| 10 equiv. $Mg^{2+}$ | 7 | 0 |
| 1 equiv. $Cu^{2+}$ + 10 equiv. $Co^{2+}$ | 7 | 99 |
| 1 equiv. $Cu^{2+}$ + 10 equiv. $Fe^{2+}$ | 7 | 99 |
| 1 equiv. $Cu^{2+}$ + 10 equiv. $Pb^{2+}$ | 7 | 99 |

From the plot in Figure 2, it follows that for $[Ru(bpy)_2(H_2L^1)]^{2+}$ the luminescence intensity is virtually constant over the pH range 4.5–8.5. For $[Ru(bpy)_2(H_2L^2)]^{2+}$ and $[Ru(H_2L^{1,2})_3]^{2+}$ the pH ranges of approximately constant luminescence are similar (pH 4.7–9.0). At a lower pH, the fluorescence intensity drops sharply to nearly zero at pH < 2. The sigmoidal curves suggest p$K_a$ values of ≈3, which is in the expected range for substituted pyridine groups [p$K_a$(20–25 °C) = 2.1–2.4].[30] The decrease in the luminescence intensity at high pH (luminescence intensity approximately zero at pH > 14, p$K_a$ ≈ 11.5) suggests a deprotonation of an amide donor, and this also occurs in the expected range [p$K_a$(25 °C) ≈ 12].[33]

Figure 3 shows the pH-dependent luminescence of $[Ru(bpy)_2(H_2L^1)]^{2+}$ together with that of the $[Ru(bpy)_2(H_2L^1)]^{2+}/Cu^{2+}$ system (1 equiv. $Cu^{2+}$). Also shown in Figure 3 is the $Cu^{2+}$-concentration dependence of the fluorescence intensity at pH 4.9 (acetate buffer). At pH 5, no other metal ion leads to any fluorescence quenching, i.e. at pH 5 the $[Ru(bpy)_2(H_2L^1)]^{2+}$ on/off fluorescence sensor is selective for $Cu^{2+}$.

All three systems, $[Ru(bpy)_2(H_2L^1)]^{2+}$, $[Ru(bpy)_2(H_2L^2)]^{2+}$, and $[Ru(H_2L^1)_3]^{2+}$, show very similar behavior with respect to the metal-ion-induced fluorescence quenching, specifically in terms of the metal-ion- and pH-dependencies and the competition with other ligands (Table 1): (i) at pH 5 (acetate buffer), $Cu^{2+}$ is the only metal ion that leads to significant quenching; the addition of an excess of any other metal ion does not have any influence on the fluorescence intensity observed with $Cu^{2+}$ alone; (ii) at pH 7 (lutidine buffer), the reduction of the fluorescence intensity with one equivalent of $Cu^{2+}$ is ≈100%, those due to $Ni^{2+}$, $Fe^{2+/3+}$, $Co^{2+}$, and $Zn^{2+}$ are significantly smaller (40–85%), all other metal ions studied do not lead to any quenching; the kinetics of complex formation with $Ni^{2+}$ is very slow, full equilibration (pH 7; 1 or 10 equiv. $Ni^{2+}$) needs at least 1 h (complexation of all other metal ions is fast, i.e., equilibration within minutes); (iii) at pH 7, acetate does not lead to any significant reduction of the quenching efficiency of $Cu^{2+}$, with citrate there is some competition, and with EDTA fluorescence quenching is only observed after complexation with EDTA is complete [from semiquantitative experiments and the known stability constants $\log K^{ML}$(Cu–acetate) = 1.75,[31] $\log K^{ML}$(Cu–citrate) = 4.5,[32] $\log K^{ML}$(Cu–EDTA) = 19.2,[33] an approximate value of $\log K^{ML}([Ru(bpy)_2\{(H_2L^1)Cu\}]^{2+}) = 12 \pm 2$ may be deduced].

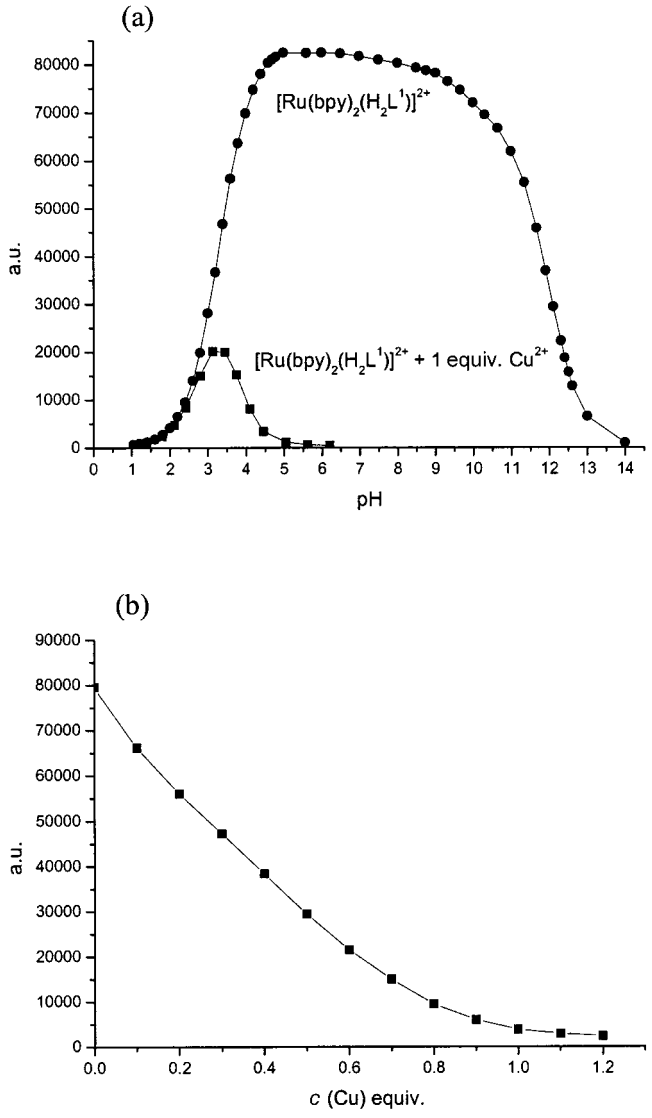

Figure 3. (a) pH-dependence of the luminescence of $[Ru(bpy)_2(H_2L^1)]^{2+}$ (10 μM aqueous solution) with or without 1 equiv. of $Cu^{2+}$, $\lambda_{ex}$ = 450 nm, $\lambda_{em}$ = 620 nm. (b) Fluorimetric titration of $[Ru(bpy)_2(H_2L^1)]^{2+}$ ($10^{-5}$ M) with $Cu^{2+}$ in acetate buffer (100 equiv.) at pH 4.9.

## Conclusions

The synthesis of a rigid ditopic ligand with a 1,10-phenanthroline and a bis(pyridinamide) coordination site, based on a general strategy, which may be used to prepare a variety of 1,10-phenanthroline-derived ditopic ligands with a range of donor sets, has led to $Ru^{2+}$-polypyridine-based fluorescence on/off sensors that are highly selective for $Cu^{2+}$ in aqueous solution at low pH. The rational design of the structure and donor set of the host, which, upon coordination of a metal ion, leads to fluorescence quenching,[34–36] should make possible the development of systems that show a range of specific selectivities in various pH regions.

## Experimental Section

**Materials and Measurements:** Commercially available chemicals were used without further purification; solvents were dried by standard methods; solvents and chemicals for spectroscopy were of the highest possible grade and used as purchased. 1,10-Phenanthroline-5,6-dione dioxime was obtained by oxidation of 1,10-phenanthroline to 1,10-phenanthroline-5,6-dione[37] and subsequent reaction with hydroxylamine.[18] (4-Chloro-2-pyridyl)carboxylic acid methyl ester and (4-methoxy-2-pyridyl)carboxylic acid methyl ester were obtained as described from picolinic acid.[38]

UV/Vis/NIR spectra ($CH_3CN$, ambient temperature) were recorded with a Cary 1E or a JASCO V-570 spectrophotometer. IR spectra (KBr pellets) were obtained with a Perkin–Elmer 16C FTIR instrument. $^1H$ NMR spectra were recorded at room temperature with a Bruker ARX 200 or a Bruker Avance 500 spectrometer; the chemical shifts are relative to the solvent that is used as the internal standard. Electrochemical data were obtained by cyclic voltammetry [100 mV/sec., complex solutions ($2\times10^{-3}$ M), ambient temperature, tetrabutylammonium hexafluorophosphate (0.1 M) in $CH_3CN$], measured with a BAS100B electrochemical analyzer (data analysis with Digisim), by using a glassy carbon working electrode, a Pt-wire auxiliary, and a $Ag/AgNO_3$ reference electrode (0.01 M $AgNO_3$); ferrocene was used as an external standard. EPR spectra were recorded with a Bruker ELEXSYS E500 spectrometer [frozen solutions (approx. $10^{-3}$ M) in $DMF/H_2O$ = 2:1] at 110 K. Mass spectra were recorded with a Finnigan 8400 or a JEOL JMS700 sector field instrument (EI or FAB) with a nitrobenzyl alcohol matrix (Nibeol, NBA) for the FAB spectra; electrospray mass spectra were recorded with a Finnigan TSQ 700 triple-quadrupole or a Q-Tof Ultima API mass spectrometer (Micromass/Waters, ESI) with analyte solutions in acetonitrile or methanol in the concentration range $10^{-6}$–$10^{-5}$ M. For HR-EI, HR-FAB, and HR-ESI spectra deviations from the theoretical mass are generally smaller than 5 mD, the internal standards used are reported with the experimental data. Emission spectra were recorded with a Varian Cary Eclipse fluorescence spectrophotometer at an excitation wavelength of 450 nm (intensities not calibrated). Fluorimetric titrations were performed in aqueous solutions (equilibrated in air, $\mu$ = 0.1; NaCl; the concentrations of the ruthenium complexes were $10^{-5}$ M). Metal ions were added as the chloride, perchlorate, or sulfate salts, and there was no dependence on the type of anion within this group. Standard HCl and NaOH solutions were used for adjusting the pH. Buffers at pH 4.7–5 and 7 were made by using the acetate/acetic acid and the lutidine/lutidinium couples, respectively.

**Syntheses**

**5,6-Diamino-1,10-phenanthroline**[17–19]

**Method A:** A suspension of phenanthroline-5,6-dione dioxime (2.88 g, 12 mmol) in ethanol (80 mL) was heated under $N_2$ (70 °C). A solution of sodium dithionite (85%, 9 g, 45 mmol) in aqueous ammonia (3%, 80 mL) was quickly added. An additional amount of sodium dithionite (85%, 3 g, 15 mmol) in aqueous ammonia (3%, 40 mL) solution was added when the yellow product started to precipitate as yellow flakes after dissolution of the dioxime. The reaction was then kept for 45 min at 85 °C. After being cooled to ambient temperature, the product was filtered under $N_2$, washed 3 times with diluted ammonia and then with THF, and dried overnight under high vacuum. Yield: 2.17 g (10.3 mmol, 86%), deep yellow solid.

**Method B:** Ethanol (150 mL, 50%) and a concentrated ammonia solution (10 mL) were added to a mixture of phenanthroline-5,6-dione dioxime (2.4 g, 10 mmol) and thiourea *S*,*S*-dioxide (5 g, 46.3 mmol) under nitrogen whilst stirring. The mixture was placed in a preheated (80 °C) oil bath and left to react for 45 min. The 5,6-diamino-1,10-phenanthroline started to precipitate after ≈15 min. After being cooled to room temperature, the product was isolated

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

as described above. Yield: 1.79 g (8.1 mmol, 81%). $C_{12}H_{10}N_4 \cdot \frac{1}{6}H_2O$ (213.23): calcd. C 67.59, H 4.88, N 26.27; found C 67.81, H 4.62, N 26.03. MS (EI+): $m/z$ = 210 [$M^+$].

**Potassium Salts of Substituted Picolinic Acids:** KOH (0.95 equiv.) in a minimum amount of EtOH was added to a stirred solution of the methyl ester of the corresponding substituted picolinic acid derivative in dry ethanol (2 mL/mmol). After 6 h, $Et_2O$ (1/5 volume) was added. The product was filtered, washed with EtOH/$Et_2O$, and dried under high vacuum.

**Potassium (4-Cloro-2-pyridyl)carboxylate:** Yield: 84%. M.p. > 350 °C. $C_6H_3ClKNO_2$ (195.64): calcd. C 36.83, H 1.55, N 7.16; found C 36.98, H 1.82, N 7.22. MS (ESI-): $m/z$ = 156 [M – $H^-$]. $^1$H NMR (200 MHz, $D_2O$): $\delta$ = 7.63 (dd, $^3J$ = 5.3 Hz, $^4J$ = 1.9 Hz, 1 H), 7.99 (d, $^4J$ = 1.90 Hz, 1 H), 8.55 (d, $^3J$ 5.3 Hz, 1 H) ppm.

**Potassium (4-Methoxy-2-pyridyl)carboxylate:** (4-Methoxy-2-pyridyl)carboxylic acid methyl ester (0.84 g, 5 mmol) and KOH (0.27 g) were added together to give (4-methoxy-2-pyridyl)carboxylic acid potassium salt (0.76 g). Yield: 80%. M.p. > 350 °C. $C_7H_6KNO_3 \cdot \frac{1}{4}H_2O$ (195.73): calcd. C 42.95, H 3.35, N 7.16; found C 43.06, H 3.21, N 7.17. MS (ESI-): $m/z$ = 152 [M – $H^-$]. $^1$H NMR (200 MHz, $D_2O$): $\delta$ = 3.92 (s, 3 H, OC$H_3$), 7.07 (dd, $^3J$ = 5.8 Hz, $^4J$ = 2.5 Hz, 1 H), 7.46 (d, $^4J$ = 2.5 Hz, 1 H), 8.38 (d, $^3J$ = 5.76 Hz, 1 H) ppm.

**5,6-Bis(2-pyridylcarboxamido)-1,10-phenanthroline, $H_2L^1$:** Picolinic acid (1.11 g, 9 mmol) and DMAP (0.12 g, 1 mmol, 33 mol-%) in absolute DMF (25 mL) were added to a stirred suspension/solution of 5,6-diamino-1,10-phenanthroline (0.63 g, 3 mmol) in a 100-mL Schlenk flask under nitrogen at ambient temperature. TEA (1.4 mL, 10 mmol) was then added by syringe, followed by the addition of phenylphosphonic acid dichloride (0.9 mL, 6.4 mmol) and more TEA (2.8 mL, 20 mmol) over a period of 5 h. After an additional 4 h, the reaction was quenched by the addition of water (1 mL). The product was isolated by precipitation (addition of $H_2O$, 5 volumes), filtration, washing with $H_2O$, and drying under high vacuum. Yield: 0.68 g (1.62 mmol, 54%). M.p. 294–298 °C. $C_{24}H_{16}N_6O_2 \cdot 1\frac{2}{3}\ H_2O$ (450.45): calcd. C 63.99, H 4.33, N 18.66, found C 64.01, H 4.10, N 18.39. MS (ESI+): $m/z$ = 421 [M + $H^+$]. $^1$H NMR (500 MHz, [$D_7$]DMF): $\delta$ = 7.70 (ddd, $^3J$ = 7.6 Hz, $^3J$ = 4.7 Hz, $^4J$ = 1.2 Hz, 2 H, py-*H*), 7.85 (dd, $^3J$ = 8.3 Hz, $^3J$ = 4.2 Hz, 2 H, phen-*H*), 8.11 (td, $^3J$ = 7.7 Hz, $^4J$ = 1.5 Hz, 2 H, py-*H*), 8.25 (ddd,$^3J$ = 7.7 Hz, $^4J$ = 1.2 Hz, $^5J$ = 0.6 Hz, 2 H, py-*H*), 8.62 (dd, $^3J$ = 8.3 Hz, $^4J$ = 1.6 Hz, 2 H, phen-*H*), 8.75 (ddd, $^3J$ = 4.7 Hz, $^4J$ = 1.5 Hz, $^5J$ = 0.6 Hz, 2 H, py-*H*), 9.21 (dd, $^3J$ = 4.2 Hz, $^4J$ = 1.6 Hz, 2 H, phen-*H*), 11.10 (s, 2 H, N*H*) ppm. IR (KBr): 3298 (m), 3236 (m) (N–H); 3076 (w), 3050 (m) (C–H); 1676 (s), 1570 (m) (C=$O_{amide}$); 1616 (m) (C=N); 1590 (m), 1496 (m) (C=C) $cm^{-1}$.

**5,6-Bis[(4-methoxy-2-pyridyl)carboxamido]-1,10-phenanthroline, $H_2L^2$:** Obtained as described above by using 5,6-diamino-1,10-phenanthroline (0.21 g,1 mmol). Yield: 0.25 g, (0.52 mmol, 52%). M.p. 246–249 °C. $C_{26}H_{20}N_6O_4 \cdot 2H_2O$ (516.51): calcd. C 60.46, H 4.68, N 16.27, found C 60.57, H 4.76, N 15.96. MS (ESI+): $m/z$ = 481 [M + $H^+$]. $^1$H NMR (500 MHz, [$D_7$]DMF): $\delta$ = 4.00 (s, 6 H, OC$H_3$), 7.26 (dd, $^3J$ = 5.7 Hz, $^4J$ = 2.6 Hz, 2 H, py-*H*), 7.73 (d, $^4J$ = 2.6 Hz, 2 H, py-*H*), 7.85 (dd, $^3J$ = 8.4 Hz, $^3J$ = 4.2 Hz, 2 H, phen-*H*), 8.57 (d, $^3J$ = 5.7 Hz, 2 H, py-*H*), 8.59 (dd, $^3J$ = 8.4 Hz, $^4J$ = 1.5 Hz, 2 H, phen-*H*), 9.20 (dd, $^3J$ = 4.2 Hz, $^4J$ = 1.5 Hz, 2 H, phen-*H*), 11.02 (s, 2 H, N*H*) ppm. IR (KBr): 3298 (s) (N–H); 3090 (w), 3066 (w), 3010 (w), 2934 (w) (C–H); 1684 (s), 1566 (m) (C=$O_{amide}$); 1602 (s), 1496 (s) (C=N, C=C) $cm^{-1}$.

**5,6-Bis[(4-chloro-2-pyridyl)carboxamido]-1,10-phenanthroline:** Obtained as described above by using 5,6-diamino-1,10-phenanthroline (0.21 g, 1 mmol) and (4-chloro-2-pyridyl)carboxylic acid potassium salt (0.59 g, 3 mmol). Yield: 0.37 g crude product. HR-ESI-MS: calcd. for [M + $H^+$] ($C_{24}H_{15}Cl_2N_6O_2$) 489.0634; found 489.0610 (–2.4 mD, standard: $H_3PO_4$).

**Tris[5,6-bis(2-pyridylcarboxamido)-1,10-phenanthroline]ruthenium Hexafluorophosphate, $[Ru(H_2L^1)_3](PF_6)_2$:** A mixture of $RuCl_3 \cdot 3H_2O$ (0.026 g, 0.1 mmol) and 5,6-bis(2-pyridylcarboxamido)-1,10-phenanthroline (0.15 g, 0.35 mmol) was heated (160 °C) in ethylene glycol (5 mL) for 30 min. After being cooled to room temperature, the mixture was diluted with water (1/6 volume), and the excess ligand was removed by filtration. The complex was precipitated by the addition of $NH_4PF_6$, filtered off, washed with small amounts of $H_2O$ and $Et_2O$, and dried under high vacuum. Yield: 0.11 g (0.06 mmol, 66%) black-violet powder. $C_{72}H_{48}F_{12}N_{18}O_6P_2Ru \cdot 6H_2O$ (1760.25): calcd. C 49.12, H 3.44, N 14.32; found C 49.29, H 3.54, N 13.87. # Titanium(IV) Complexes of Hydrazones and Azines

**Matthew G. Davidson,*[a] Andrew L. Johnson,[a] Matthew D. Jones,*[a] Matthew D. Lunn,[b] and Mary F. Mahon[c]**

**Keywords:** Titanium / Coordination modes / Hydrazones / Azines

The coordination modes of various azines (C=N–N=C) and hydrazones (C=N–$NR_2$) with titanium(IV) are investigated. Five ligands were studied, two hydrazones **1H–2H** and three azines **$3H_2$–$5H_2$**, and it was found that hydrazones form monomers and azines form dimers in the solid state. The hydrogen-bonded arrays observed for the hydrazones were significantly different for the two ligands, with one forming a ribbon like structure and the other a chain. For the azines the supramolecular structures are also discussed. A pronounced twist is observed in the azine ligand upon complexation to the metal centre, which is rationalised in terms of the favourable interactions observed in the solid-state.

## Introduction

There is continuing interest in the synthesis of new titanium(IV) complexes for use in catalysis and supramolecular chemistry.[1–7] As a consequence it is pertinent to design new ligands that may impart different steric effects at the metal centre. Thus, we have investigated the coordination of $Ti^{IV}$ with a variety of hydrazone (C=N–$NR_2$) and azine (C=N–N=C) ligands. To the best of our knowledge, there are only two reported titanium–azine crystal structures and no titanium–hydrazone complexes, where R = H, have been structurally characterised.[8,9] Azine complexes of transition metals, for example ruthenium, iron, copper and zinc are known to form dimers in the solid state, with either a *cis* or *trans* configuration, Figure 1.[10–14]

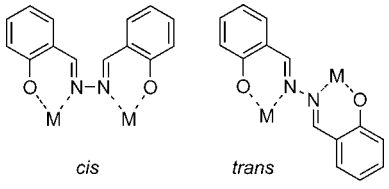

Figure 1. Two possible isomers for azine complexes.

In contrast, hydrazone complexes of transition metals (e.g. vanadium and copper) tend to form monomeric structures.[15–17] Hydrazones (where R = H) can form supramolecular arrays in the solid state due to the presence of the protic $NH_2$ group available for hydrogen bonding, a feature which is being exploited in the crystal engineering field.[18–23] The ligands chosen for this study are shown in Figure 2, with the expectation of conveying different steric demands on the titanium(IV) centre and facilitating the formation of different arrays in the solid state.

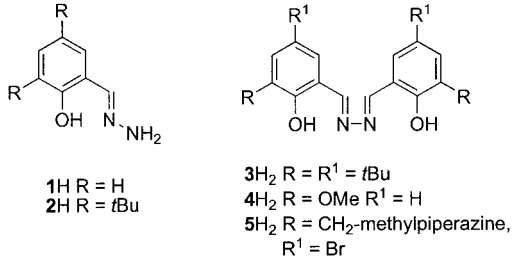

Figure 2. Hydrazones **1**H and **2**H, azines $\mathbf{3}H_2$, $\mathbf{4}H_2$ and $\mathbf{5}H_2$.

## Results and Discussion

Two equivalents of each hydrazone **1**H and **2**H react readily with $Ti(OiPr)_4$ to form the desired complexes $Ti(\mathbf{1})_2(OiPr)_2$ and $Ti(\mathbf{2})_2(OiPr)_2$. Each of the ligands is deprotonated at the phenolic moiety and chelates to the metal centre through the resulting phenoxide and the imine nitrogen of the hydrazone group. The amine group does not coordinate to the metal centre. The coordination sphere of the titanium is completed by two terminal isopropoxide ligands, Figure 3.

Each titanium centre has a distorted octahedral geometry with the two aryl oxide ligands adopting a *trans* configuration and the imine donors assuming a *cis* configuration, see Table 1 for selected bond lengths and angles. The bond lengths and angles are in agreement with literature pre-

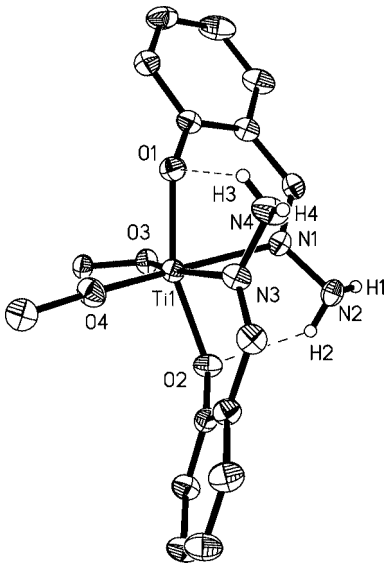

Figure 3. Crystal structure of complex Ti(**1**)$_2$(O*i*Pr)$_2$. Ellipsoids are shown at the 50% probability level, the hydrogen atoms not involved in hydrogen bonding and the isopropoxide methyl groups have been omitted for clarity. The same labelling scheme was used for complex Ti(**2**)$_2$(O*i*Pr)$_2$. The dashed lines represent the *intramolecular* hydrogen bonding, between H(2)–O(2) and H(3)–O(1). The hydrogen atoms were located in the penultimate difference Fourier map and refined freely.

cedent.[24–30] The $^1$H and $^{13}$C NMR spectra of the complexes suggest that the gross solid-state structures are maintained in solution with well-defined resonances for the isopropoxide region.

Table 1. Selected bond lengths [Å] and angles [°] for complexes Ti(**1**)$_2$(O*i*Pr)$_2$ and Ti(**2**)$_2$(O*i*Pr)$_2$.

| | Ti(**1**)$_2$(O*i*Pr)$_2$ | Ti(**2**)$_2$(O*i*Pr)$_2$ |
|---|---|---|
| Ti(1)–O(1) | 1.950(1) | 1.912(2) |
| Ti(1)–O(2) | 1.940(1) | 1.913(2) |
| Ti(1)–O(3) | 1.846(1) | 1.778(2) |
| Ti(1)–O(4) | 1.761(1) | 1.852(2) |
| Ti(1)–N(1) | 2.268(1) | 2.282(2) |
| Ti(1)–N(3) | 2.264(1) | 2.271(2) |
| O(1)–Ti(1)–O(2) | 158.89(5) | 160.80(7) |
| O(3)–Ti(1)–O(4) | 102.79(5) | 101.75(8) |
| O(1)–Ti(1)–O(4) | 97.78(5) | 94.33(7) |
| N(1)–Ti(1)–N(3) | 79.90(5) | 81.86(7) |

Both *intra*- and *intermolecular* hydrogen bonds are observed. The intramolecular hydrogen bonds are shown in Figure 3, where one hydrogen atom of each $NH_2$ group interacts with a phenoxide oxygen centre, see Table 2 for the hydrogen bonding parameters, which are similar for both complexes. The main structural distinction between Ti(**1**)$_2$(O*i*Pr)$_2$ and Ti(**2**)$_2$(O*i*Pr)$_2$ arises due to their patterns of intermolecular hydrogen bonding. For Ti(**1**)$_2$(O*i*Pr)$_2$ both H(1) and H(4) are invoked in hydrogen bonding (Figure 4) forming a ribbon-like structure in the solid state. H(1) bonds to an isopropoxide oxygen {O(3)} of a neighbouring molecule and H(4) binds to a hydrazone $NH_2$ group {N(2)} of a third molecule. For Ti(**2**)$_2$(O*i*Pr)$_2$ only *one* intermolecular hydrogen bond is seen in the solid state, between H(1) and an isopropoxide O(4), and this forms a chain-like structure. The absence of a hydrogen bond from H(4) to N(2) of an adjacent molecule is presumably related to the increase in steric bulk of the ligand.

One equivalent of each azine was treated with two equivalents of Ti(O*i*Pr)$_4$ to form complexes Ti$_2$(**3**)(O*i*Pr)$_6$, Ti$_2$(**4**)(O*i*Pr)$_6$ and Ti$_2$(**5**)(O*i*Pr)$_6$. The structure of Ti$_2$(**4**)(O*i*Pr)$_6$ is shown in Figure 5. In all cases the azine bridges between two titanium centres in a *cis* fashion. The coordination sphere around each titanium atom being completed by coordination of two terminal and two bridging isopropoxide moieties. The titanium centre is pseudooctahedral with the bond lengths and angles in the expected range, Table 3.[24–30] The core of each complex consists of three rings, one Ti$_2$O$_2$ ring made up of the two titanium centres and the two bridging alkoxides, and two five-membered rings made up of the two titanium centres, a bridging alkoxide and the azine N–N bond. The $^1$H and $^{13}$C NMR spectra suggests that the solid-state structure is maintained in solution, with distinct resonances observed for the isopropoxide moieties; for example for the azine complexes three distinct O*i*Pr methine resonances are observed in both the $^1$H and $^{13}$C NMR spectra.

The ligand shows a distortion away from planarity, which manifests itself by analysis of the torsion angle {C(8)–N(1)–N(1A)–C(8A)} of 55.7(4)° for complex Ti$_2$(**4**)(O*i*Pr)$_6$. The ligand distortion suggests that there is little conjugation between the two salicylaldimine units of the azine and that the N–N bond has little π-bonding character. For complex Ti$_2$(**3**)(O*i*Pr)$_6$ this torsion angle is very similar at 53.2(5)° to Ti$_2$(**4**)(O*i*Pr)$_6$. However, there is a significant increase in this torsion angle for complex Ti$_2$(**5**)(O*i*Pr)$_6$ at 66.6(4)°. A possible explanation is that the ligand distorts to form favourable Br···N interactions with a neighbouring molecule, Figure 6. The interaction results in an ordering of the piperazine amine nitrogen atom such that its lone pair is directed towards the bromine atom of a neighbouring molecule, with

Table 2. Summary of the hydrogen bonding parameters for complexes Ti(**1**)$_2$(O*i*Pr)$_2$ and Ti(**2**)$_2$(O*i*Pr)$_2$, the hydrogen atoms were freely refined in all cases. [1]: $-x+1, -y+1, -z+1$; [2]: $x, y, z$; [3]: $-x, -y+1, -z+1$; [4]: $-x+1, y+1/2, -z+1/2$.

a Br–N interaction of 3.034 Å, which falls within the typical range,[33–35] to render the formation of a supramolecular ladder.

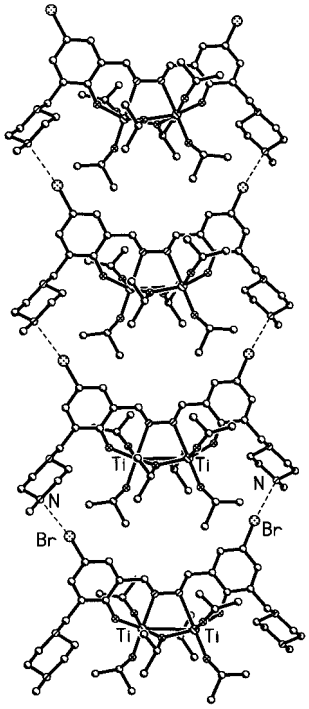

Figure 6. Bromine–nitrogen interactions in complex $Ti_2$(**5**)(O*i*Pr)$_6$.

## Conclusions

In conclusion X-ray structures of five novel titanium(IV) azine and hydrazone complexes are reported. The hydrazone complexes form monomers which have interesting supramolecular structures, with Ti(**1**)$_2$(O*i*Pr)$_2$ forming a ribbon-like array and Ti(**2**)$_2$(O*i*Pr)$_2$ forming a chain-like structure. By increasing the steric bulk the hydrogen bonding motifs are significantly altered. The azine complexes form dimers in the solid state. At the molecular level the substituents on the salicylaldimine aryl oxide groups had little effect on the structures. However, on the supramolecular level introduction of Lewis basic groups in the *ortho* position allowed formation of a weak intramolecular C–H···O interaction and intermolecular N–Br interactions, which induced the formation of a supramolecular ladder.

## Experimental Section

For the preparation and characterisation of complexes, all reactions and manipulations were performed under argon using standard Schlenk or glove-box techniques and all solvents were freshly distilled from suitable drying agents and degassed prior to use. Ligand **1**H was purchased from Aldrich, **2**H and **3**H$_2$–**5**H$_2$ were synthesised using literature procedures[36] and recrystallised from petroleum ether prior to use. Ti(O*i*Pr)$_4$ was purchased from Aldrich and purified by vacuum distillation prior to use. $^1$H/$^{13}$C NMR spectra were recorded with a Bruker Avance 300 MHz spectrometer and referenced to residual solvent peaks. Coupling constants are given in Hertz. Elemental analysis was performed by Mr. A. K. Carver at the Department of Chemistry, University of Bath. Due to the propensity of the complexes to hydrolyse reliable elemental analysis could not be obtained in some cases. Crystallographic data were collected on a Nonius KappaCCD area detector diffractometer using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at a temperature of 150(2) K, and all structures were solved by direct methods and refined on all $F^2$ data using the SHELXL-97 suite of programs.[37] Hydrogen atoms not involved in hydrogen bonding were included in idealised positions and refined using the riding model. Absorption corrections were applied on merit. See Table 4 for full crystallographic parameters.

CCDC-607937 to -607941 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Ti(1)$_2$(O*i*Pr)$_2$:** A solution of salicylaldehyde hydrazone (0.82 g, 6 mmol), was prepared in dry toluene (10 mL) under an inert atmosphere. To this Ti(O*i*Pr)$_4$ (0.9 mL, 3 mmol) was added to give a bright yellow solution. This solution was vigorously stirred for 1 h. The solvent was removed in vacuo to give a pale yellow solid product. This product was suspended in hexane and toluene added until dissolution occurred on warming. Standing at room temperature yielded a crop of yellow blocks. Yield 1.12 g (85%). M.p. 140–143 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 1.04 [d, $J$ = 6 Hz, 12 H, CH(C$H_3$)$_2$], 4.63 [sept, $J$ = 6 Hz, 2 H,C$H$(CH$_3$)$_2$], 5.57 (s, 4 H, NH$_2$), 6.69 (dd, $J$ = 5 and 1 Hz, 2 H, Ar-H), 6.78 (d, $J$ = 8 Hz, 2 H, Ar-H), 7.00 (d, $J$ = 8 Hz, 2 H, Ar-H), 7.18 (m, 2 H, Ar-H), 7.62 (s, 2 H, imine CH) ppm. $^{13}$C{$^1$H} ($CDCl_3$): $\delta$ = 25.6 [CH(*C*H$_3$)$_2$], 79.2 [*C*H(CH$_3$)$_2$], 118.5, 118.9, 122.0, 131.3, 132.3 (Ar), 146.9 (NCH), 162.4 (Ar-O) ppm. $C_{20}H_{28}N_4O_4Ti$ (436.3): calcd. C 55.1, H 6.47, N 12.84; found C 54.8, H 6.40, N 12.70.

**Ti(2)$_2$(O*i*Pr)$_2$:** An analogous procedure to that for Ti(**1**)$_2$(O*i*Pr)$_2$ was followed. Yield 0.39 g (59%), m.p. 220–224 °C (dec.) $^1$H NMR ($CDCl_3$): $\delta$ = 0.90 [two overlaying doublets, $J$ = 6 Hz, 12 H, CH(C$H_3$)$_2$], 1.22 [s, 18 H, C(CH$_3$)$_3$], 1.46 [s, 18 H, C(CH$_3$)$_3$], 4.55 [sept, $J$ = 6 Hz, 2 H, C$H$(CH$_3$)$_2$], 5.48 (s, 4 H, NH$_2$), 6.87 (s, 2 H, Ar-H), 7.29 (s, 2 H, Ar-H), 7.70 (s, 2 H, NCH) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 26.0 [CH(*C*H$_3$)$_2$], 30.2 [C(*C*H$_3$)$_3$], 31.9 [C(*C*H$_3$)$_3$], 34.5 [*C*(CH$_3$)$_3$], 35.6 [*C*(CH$_3$)$_3$], 78.6 [*C*H(CH$_3$)$_2$], 121.2, 125.9, 127.1, 137.6, 139.6 (Ar), 148.7 (NCH), 159.7 (Ar-O) ppm. $C_{36}H_{60}N_4O_4Ti$ (660.8): calcd. C 65.4, H 9.15, N 8.48; found C 66.2, H 9.35, N 7.90.

**Ti$_2$(3)(O*i*Pr)$_6$:** A solution of 2,4-di(*tert*-butyl)salicylaldehyde azine (0.36 g, 1 mmol), was prepared in dry toluene (10 mL) under an inert atmosphere. To this Ti(O*i*Pr)$_4$ (0.6 mL, 2 mmol) was added to give a yellow solution. This solution was vigorously stirred for 1 h. Reduction in volume of the toluene and standing at room temperature yielded a crop of yellow blocks. Yield 0.46 g (57%), m.p. 243–246 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 0.77 [br., 12 H, CH(C$H_3$)$_2$], 1.02 [d, $J$ = 6 Hz, 6 H, CH(C$H_3$)$_2$], 1.20 [d, $J$ = 6 Hz, 6 H, CH(C$H_3$)$_2$], 1.21–1.29 [m, 30 H, 2× CH(C$H_3$)$_2$ and 2× C(CH$_3$)$_3$)], 1.46 [s, 18 H, C(CH$_3$)$_3$], 4.37 [sept, $J$ = 6 Hz, 2 H, C$H$(CH$_3$)$_2$], 4.77 [sept, $J$ = 6 Hz, 2 H, C$H$(CH$_3$)$_2$], 4.88 [sept, $J$ = 6 Hz, 2 H, C$H$(CH$_3$)$_2$], 7.12 (s, 2 H, Ar-H), 7.37 (s, 2 H, Ar-H), 7.89 (s, 2 H, NCH) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 22.0 [CH(*C*H$_3$)$_2$], 22.1 [CH(*C*H$_3$)$_2$], 23.7 [CH(*C*H$_3$)$_2$], 23.7 [CH(*C*H$_3$)$_2$], 23.8 [CH(*C*H$_3$)$_2$], 23.9 [CH(*C*H$_3$)$_2$], 27.9 [C(*C*H$_3$)$_3$], 29.5 [C(*C*H$_3$)$_3$], 32.1 [*C*(CH$_3$)$_3$], 33.3 [*C*(CH$_3$)$_3$], 72.3 [*C*H(CH$_3$)$_2$], 75.1 [*C*H(CH$_3$)$_2$], 75.9 [*C*H(CH$_3$)$_2$], 117.8, 126.2, 127.0, 135.8, 136.4 (Ar), 149.6 (NCH), 159.8 (Ar-O) ppm. $C_{48}H_{84}N_2O_8Ti_2$ (912.9): calcd. C 63.2, H 9.27, N 3.07; found C 63.0, H 9.14, N 3.39.

## COVER PICTURE

**The cover picture shows** some various examples of terminal imido–titanium complexes of the general formula $Ti(=NR)Cl_2(NHMe_2)_2$ that are accessible through the reported one-pot reaction of $Ti(NMe_2)_4$ with a primary amine $RNH_2$ in the presence of excess chlorotrimethylsilane. This procedure appears to be general to the generation of a wide range of imido groups: alkyl-, silyl-, and arylimido groups, as well as functional organoimido, chiral imido, and diimido ligands. $Ti(=NR)Cl_2(NHMe_2)_2$ complexes are of particular interest as organometallic synthons and for further applications in the field of homogeneous catalysis and materials science. The background photo of the famous palm tree vault of the Jacobins church (Toulouse, France, founded in the 13th–14th centuries) symbolizes the diversity of the compounds – arranged in arc around the palm tree vault – that can be prepared by using our promising synthetic strategy, and provides a solid foundation – the pillar – for attractive applications. Details are discussed in the article by C. Lorber et al. on p. 4503 ff. The authors acknowledge Christian Bergounhou (LCC Toulouse) for the Palm Tree photograph.

# Kinetic Evaluation of Ligand Hemilability in Transition Metal Complexes

**Mauro Bassetti*[a]**

**Keywords:** Ligand hemilability / Oxidative addition / Platinum metals / Kinetics / Reaction mechanisms

Hemilability is the property of hybrid ligands to undergo a reversible metal chelate opening process by rupture of the weakest coordinative bond, yielding a coordinatively unsaturated complex. While experimental evidences of the process rely on the observation of fluxional behavior in the metal complex or on the spectroscopic detection of the species with different chelating bites, various effects are speculatively attributed to hemilability. In this review, this property is discussed in the context of its effects on the rate and mechanisms of bimolecular reactions. Examples of kinetics performed on ligand substitution, oxidative addition, alkyne tautomerization, and dehydrobromination reactions illustrate that the ligand hemilability process can be detected through simple kinetic analyses and can be quantitatively evaluated with respect to alternative reaction pathways. Since this concept affects various fields of chemistry, e.g. catalysis, supramolecular chemistry, molecular sensing, and materials, the kinetic approach may assist the rational design of ligands with the expected properties.

## 1. Introduction

Bidentate or polydentate ligands characterized by the presence of different donor atoms (X) bind to metal centers forming complexes with one or more metallacyclic rings. Because of the different strengths of the metal–heteroatom bonds, the metal complex may undergo a ring-opening process by the preferential rupture of the weakest coordinative bond. When the ligand free arm is easily recoordinated, the process becomes reversible (Scheme 1).[1,2]

Scheme 1. Hemilability of a bifunctional ligand $X^1$–$X^2$.

This feature, defined as hemilability, arises from the mixed bonding characteristics of hybrid ligands. It should be emphasized that while the term hybrid identifies the bifunctional structure of the ligand, the term hemilabile refers to the property of undergoing selective metal-donor bond breaking in the corresponding metal complex.[3]

Hemilability has been discussed in excellent reviews written in the last few years, which have focussed on definition and properties, and have described either the different classes of ligands according to the donor atoms involved in the chelate[1] or specific ligand systems with hemilabile character.[2] The use of potentially hemilabile ligands in catalysis has also been reviewed.[4]

The expression "hemilabile ligands" was first formulated by Jeffrey and Rauchfuss,[5] following from the early examples of transition metal complexes with bifunctional ligands.[6] These investigations were motivated by the expectation that bifunctional, for instance phosphane-amine or phosphane-ether, ligands would bind strongly enough to form chelate complexes but would readily dissociate the hard (N or O) ligand component in order to create a vacant site for substrate binding. Since then, the transition metal

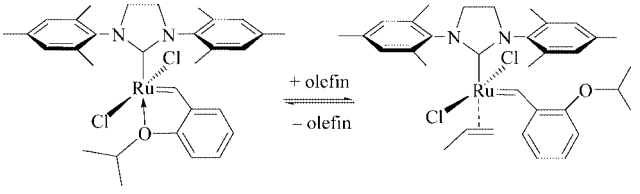
*Mauro Bassetti was born in Milano in 1953. He studied Chemistry at Università "La Sapienza" in Roma, where he obtained the Laurea cum laude in 1978 with a thesis on the mercuration of olefins, under the supervision of Barbara Floris and the late Gabriello Illuminati. He was a National Institute of Health postdoctoral fellow at Auburn University and Virginia Commonwealth University in the years 1979–1982, working with Lidia Vallarino on the synthesis of lanthanide chelate complexes. After joining the Centro CNR di Studio sui Meccanismi di Reazione in 1984, he was a visiting scientist at the University of Sheffield during the 1990s in the group of Peter Maitlis, and at the University of Virginia in 1998. He has been a WG coordinator of projects related to ruthenium chemistry for catalysis, in the program COST Chemistry, Actions D12 and D24. His current research interests include organometallic reaction mechanisms, macrocyclic chemistry, olefin metathesis, and catalytic properties of ruthenium complexes.*

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coordination chemistry of hemilabile ligands has expanded impressively and, while the initial motivation still remains the essential leitmotiv, hemilability is now considered a useful approach to induce molecular activation and create new systems for homogeneous catalysis and functional materials. Ligand design, synthesis of transition metal complexes with enhanced reactivities, biomimetic modelling, enantioselective catalysis, supramolecular coordination chemistry, and sensing of small molecules are some of the topics which have been affected by this concept.[1,2]

As a striking example of the impact that may arise from the strategic use of hemilability in catalysis, it is worth mentioning the case of the Hoveyda–Grubbs catalysts, which have significantly expanded the application profile of olefin metathesis in organic chemistry,[7] a subject now at the forefront of the chemical scenario.[8]

The key feature of these ruthenium complexes is the presence of the bidentate *o*-isopropyloxybenzylidene ligand, which binds to ruthenium through both the carbene functionality and the ethereal oxygen atom. When in action, the molecule allows the coordination of the olefinic substrate by substitution of the bound oxygen moiety (Scheme 2). On the other hand, the ethereal group stabilizes the complex when dormant in solution, thus reducing the decomposition pathways that occur more easily in the corresponding benzylidene phosphane complexes. In addition, this stabilizing effect allows for the recovery of the complex at the end of the reaction by column chromatography.

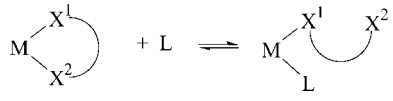


Scheme 2. Activation of a Hoveyda–Grubbs metathesis catalyst by substitution of the oxygen-bound chelate by an olefin.

The combination of a strong, substitutionally inert, and a weak, substitutionally labile, donor atom within the ligand molecular frame is the rationale for obtaining hemilability, which results from the relative metal–donor bond strengths in the complex. In fact, the strong bond ensures stability to the system when monocoordinated, while the weak bond allows for ring opening and closing of the metallacycle. Although it can be generically stated that the net effect arises from a combination of steric and electronic properties, it is nowadays difficult to predict a hemilabile character because of the variety of factors coming into play, for instance relative donicity toward a specific metal ion, interplay of soft and hard donor properties, ring size of the chelate, influence of ancillary ligands, ring substituents, solution effects, etc. The net outcome is that the game of hemilability is ruled by subtle and elusive energy differences, still difficult to control. It is with regard to this that an understanding of this property at a kinetic level may assist a rational design of ligands and complexes with the expected functions.

## 2. Properties of Hemilabile Complexes

The most significant feature exhibited by transition metal complexes of bifunctional ligands with hemilabile character is a fluxional behavior arising from the dissociation and rebinding of the weakly bonding moiety by intramolecular ligand exchange processes (Scheme 1).[9] The exchange involves a transient species which is either coordinatively unsaturated if formed from a dissociative pathway or saturated by solvent or by a counterion molecule. The intimate mechanistic features of fluxional processes of hemilabile systems have been documented in detail and are understood in depth, with a corresponding development of appropriate spectroscopic techniques and evaluative criteria.[1] A second important feature that may arise from hemilability in the complex is the facility to undergo ligand displacement reactions with external molecules, in which a monodentate ligand, a small molecule, or an organic substrate coordinates to the metal ion via the door opened by the substitutionally labile group. Reversible decoordination followed by chelate formation corresponds to hemilability (Scheme 3).[10]



Scheme 3. Substitution reaction in the complex with a hemilabile ligand.

This property moves hemilability from a strictly intramolecular process toward a bimolecular phenomenon, with the obvious implications for molecular sensing, supramolecular design, and enhanced catalytic activity. However, in addition to the isolation of the corresponding substituted complexes and the qualitative observation of intriguing effects in stoichiometric or catalytic reactions, attributed to hemilability, the reaction mechanisms of transition metal complexes with bifunctional ligands in bimolecular reactions have not been studied extensively from the point of view of hemilability. In this regard, since the ring opening represents an easy access to a structural isomer of the chelate complex with altered reactivity, kinetic studies can provide an additional criterion for the identification of hemilability and a quantitative evaluation of its role along the reaction coordinate. In fact, it is within the exclusive realm of chemical kinetics that many reactive species are detected and evaluated, specifically when these are elusive toward any spectroscopic detection.

## 3. Kinetic Studies

Although the mechanisms of metal-chelate ring-opening processes of polydentate ligands have been studied extensively from a kinetic viewpoint,[11] the first article dealing

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

with the reaction of a metal complex of a bifunctional ligand was described by Knebel and Angelici in 1974.[12] The purpose of the work was to study the effect of the chelate ring structure on the rates of ring opening for reactions in which the product contained a bidentate ligand in the monocoordinated mode. This effect was obtained using a series of bifunctional ligands $Ph_2P(CH_2)_2NR_2$ (R = Me, Et, H) and $Ph_2P(CH_2)_3NMe_2$ (P-N) in the reaction of the complexes $[M(CO)_4(\kappa^2\text{-}P,N)]$ (**1**) with carbon monoxide, by taking advantage of the different binding abilities of a relatively inert phosphorus-donor and a labile nitrogen-donor atom. In fact, the substitution reactions of analogous bidentate N–N, S–S, CS–CS, As–As ligands in Cr, Mo, and W complexes had always proceeded with complete displacement of the bidentate ligand, affording no experimental evidence for the ring-opened monodentate species.

The reactions of complexes **1** with CO to give $[Mo(CO)_5(\kappa^1\text{-}P,N)]$ (**2**) were found to be first order in the metal complex and in CO, and second order overall. Such a relatively simple kinetic behavior is in agreement with at least two mechanisms, implying either direct attack of CO on the starting complex or reversible dissociation of the N-donor group followed by CO attack on the five-coordinate intermediate $[Mo(CO)_4(\kappa^1\text{-}P,N)]$ (**3**), this latter case being outlined in Scheme 4.

With the assumption that $k_{-2}$ is negligible, application of the steady-state approximation to the open intermediate yields the rate expression (1) (L = CO), which implies a first-order dependence on the CO concentration in the reasonable case that $k_{-1} >> k_2[CO]$. This is in agreement with the observed linear dependence of the $k_{obs}$ values on the concentration of carbon monoxide.

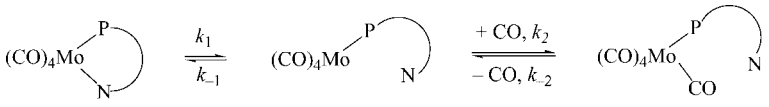
$$k_{obs} = \frac{k_1 k_2[L]}{k_{-1} + k_2[L]} \quad (1)$$

Since the second-order behavior does not give direct evidence for the existence of an intermediate along the reaction pathway, discrimination between the two mechanisms was possible from the observation that the reactivity, expressed by $k_{obs}$, became independent of [CO], hence zero order, upon performing the reaction in the presence of trifluoroacetic acid. This is because of the fast protonation of the nitrogen atom of the intermediate, which prevents any possibility of ring closing, resulting in the starting complex, and allows rapid trapping of the five-coordinate species by CO to give the product $[Mo(CO)_5(\kappa^1\text{-}P,NH^+)]$ (**4**) (Scheme 5).

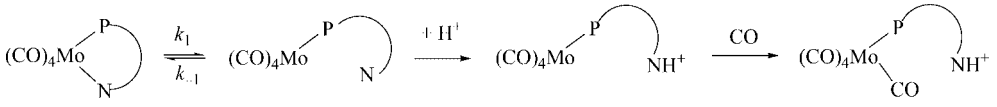
Under these conditions, the rate is only limited by the value of $k_1$. Therefore, the kinetics in the presence of acid allowed the rate constant of the ring-opening process to be obtained, i.e. the Mo–N bond breaking, being $k_{obs} = k_1$. The operation of a purely dissociative mechanism yielding the "open arm" five-coordinate intermediate $[Mo(CO)_4(\kappa^1\text{-}P,NH^+)]$ was supported from the evidence of zero-order dependence on [CO] for the substitution reactions of corresponding monodentate N-ligand complexes under analogous conditions, with a lack of rate enhancements in the presence of acid. The $k_1$ values were found to increase by an order of magnitude with the bulkiness of the N substituents (H = Me > Et) in the five-membered chelate complexes $[Mo(CO)_5(\kappa^2\text{-}P,N)\text{-}Ph_2P(CH_2)_2NR_2]$, while a 50-fold rate increase was observed in the corresponding six-membered chelate (R = Me) as the result of the larger release of ring strain in the transition state.

Having established from kinetic data the hemilabile character of the P–N complexes, the $k_{obs}$/[CO] values in the absence of acid yield $k_1k_2/k_{-1}$, from which the ratio $k_2/k_{-1}$ can be derived. This value represents the competition for the intermediate species between ring closure and reaction with CO. The data indicated that ring closure ($k_{-1}$) is approximately one thousand times faster than the uptake of CO ($k_2$) and that the five-coordinate intermediate is insensitive to the nature of the N donor group or to the size of the incipient ring. Thermodynamic parameters in addition to kinetic data were determined for the reactions of complexes $[M(CO)_4(\kappa^2\text{-}P,N)]$ with carbon monoxide, P–N being a series of *o*-phosphanepyridyl ligands.[13]

These articles represented the most informative kinetic studies on the reaction of a bifunctional system proceeding by substitution of the weakly bound donor moiety with an external ligand, and showing in quantitative terms the competition of the monodentate intermediate between ring closure ($k_{-1}$) and the bimolecular reaction ($k_2$). In these cases, (i) the only reactive pathway is provided by chelate-ring opening, and (ii) the incoming ligand does not participate in further reactions. The backward reaction can be suppressed by trapping the ligand free arm into a group that is



Scheme 4. Mechanism of the substitution reaction of complexes $[M(CO)_4(\kappa^2\text{-}P,N)]$ with carbon monoxide.

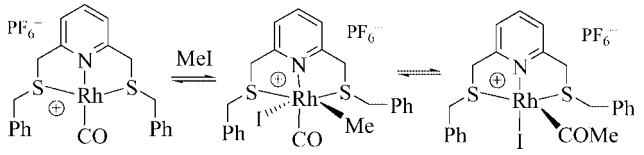


Scheme 5. Mechanism of the substitution reaction of complexes $[M(CO)_4(\kappa^2\text{-}P,N)]$ with carbon monoxide in the presence of acid.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

unsuitable for rebinding, such as by protonation. Kinetics of the acid-promoted chelate-ring opening have often been reported for a variety of transition metal complexes with hybrid ligands.[14]

The case of competitive reactivity of the chelate molecule and of the open monodentate species has emerged during our studies on the reaction of the rhodium(I) carbonyl complex [Rh(κ$^3$-L)(CO)]$PF_6$ (**5**) with methyl iodide, in which L is the tridentate $NS_2$ ligand 2,6-bis(benzylthiomethyl)pyridine binding to rhodium in a square-planar geometry through a *trans*-dithioether coordination. The complex, as well others from the same family containing the $NS_2$ ligand set, exhibits a fluxional behavior at room temperature arising from configurational inversion at the stereogenic sulfur centers and occurring by the debinding and rebinding of the sulfur donor groups.[15] The reaction of **5** with methyl iodide proceeds by consecutive oxidative addition–carbonyl insertion reactions, which is typical of many monodentate and bidentate rhodium(I) carbonyl complexes, and results in the isolation of the final $Rh^{III}$ acyl complex [Rh(κ$^3$-L)(COMe)I]$PF_6$ (**6**) (Scheme 6).[16]



Scheme 6. Consecutive oxidative addition–migratory insertion steps in the reaction of complex **5** with methyl iodide.

Rate studies on the oxidative addition step, giving the intermediate $Rh^{III}$ methyl species [Rh(L)(CO)(Me)I]$PF_6$ (first stage in Scheme 6), have been carried out in solvents of different polarity. The data indicated the presence of two parallel routes, one involving the four-coordinate complex **5**, and one involving a rearranged form of this complex. This evidence emerged from a relatively simple kinetic behavior expressed from the plots of $k_{obs}$ vs. the concentration of MeI in acetonitrile, acetone, and dichloromethane (Figure 1), which showed a linear dependence on MeI and a nonzero intercept on the *y* axis. While the linear dependence identifies a reaction route characterized by the presence of both the rhodium complex and the electrophile in the rate-determining step, overall second-order, the nonzero intercept indicates an alternative pathway that is first order in the rhodium complex but zero order in MeI, in which the electrophile comes into play after the rate-limiting step.

The concept arising from the observed kinetic behavior, represented graphically in Scheme 7, corresponds to the case of a generic substrate S that can react as such (second-order route) or in the form of a more reactive species S* (first-order route) to give the same final product P.[17] The transient molecule S* is either captured by the reagent R with rate $k_2$ or transformed back into the original complex with rate $k_{-1}$. Since both of these steps are faster than its formation, this rearranged form of the starting material is subject only to kinetic but not to spectroscopic detection.

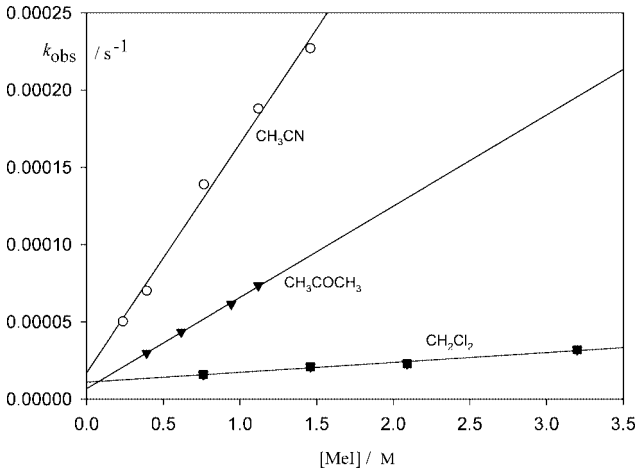


Figure 1. Plot of $k_{obs}$ values for the oxidative addition of methyl iodide to complex [Rh(κ$^3$-L)(CO)]$PF_6$ (**5**) [L = 2,6-bis(benzylthiomethyl)pyridine] in acetonitrile, acetone, and dichloromethane, at 31 °C.

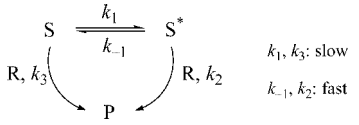


Scheme 7. Schematic representation of parallel first- and second-order routes in the reaction of substrate S with reagent R to give product P.

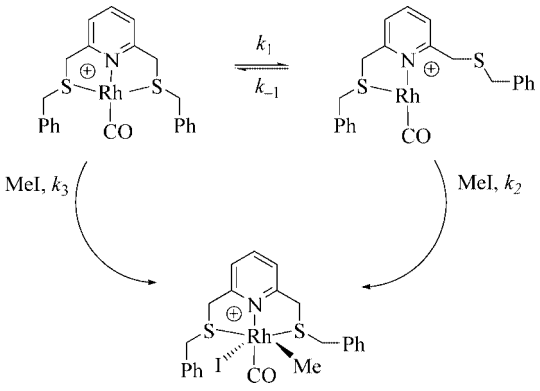
The kinetic analysis of Scheme 7 yields Equation (2) from the application of the steady-state approximation to the intermediate S*.

$$k_{obs} = k_1 + k_3[R] \quad (2)$$

At this stage, the next step takes us from facts to interpretation. Although various speculations can be done as to the origin of a highly reactive species arising from the tridentate complex, logic and indirect evidences suggest that hemilability of the $NS_2$ ligand plays a role in the pathway which is zero order in MeI. In fact, the fluxional character of this system indicates the presence of an equilibration process specifically involving the methylene groups of the ligand. The dissociation of one ligand arm by rupture of the sulfur–rhodium bond would provide a 14 electron and coordinatively unsaturated complex, expected to be highly reactive toward the electrophilic methyl iodide. The mechanistic version of Scheme 7 in terms of the structural features of complex **5** is represented in Scheme 8.

The intercept on the *y* axis represents the rate of formation of the κ$^2$-*N*,*S* complex ($k_1$), which is slower than the reaction with MeI ($k_2$) or the rebinding of the thioether group ($k_{-1}$). Analysis of the first-order rate constants, $k_1$, reveals a small dependence on the nature of the solvent, which is typical for a limiting-ligand dissociative step from a platinum group metal.[18] This is in sharp contrast with the values of the second-order rate constants, $k_3$, which vary by a factor of 20 between the polar solvent acetonitrile and the less polar dichloromethane, implying separation of charge in the attack of rhodium to the methyl group during

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 8. First ($k_1$: slow; $k_2$: fast) and second-order ($k_3$) routes for the reaction of complex **5** with methyl iodide.

the slowest step, clearly associated with methyl iodide bond rupture.[19] Values of $k_1$ and $k_3$, along with the ratios $k_1/([\text{MeI}]\times k_3)$, which represent the relative weight of the two pathways at different concentrations of methyl iodide, are reported in Table 1.

Table 1. Values of rate constants for the reaction of complex $[Rh(\kappa^3\text{-}NS_2)(CO)]PF_6$ (**5**) with MeI in different solvents (31 °C).

| Solvent | $\varepsilon$[a] | $k_1$ / $s^{-1}$ | $k_3$ / $M^{-1}s^{-1}$ | $k_1/k_3\times$[MeI][b] | $k_1/k_3\times$[MeI][c] |
|---|---|---|---|---|---|
| $CH_2Cl_2$ | 9.1 | $1.1\times10^{-5}$ | $6.4\times10^{-6}$ | 3.4 | 1.7 |
| $Me_2CO$ | 20.7 | $6.7\times10^{-6}$ | $5.9\times10^{-5}$ | 0.23 | 0.11 |
| MeCN | 37.5 | $1.7\times10^{-5}$ | $1.4\times10^{-4}$ | 0.24 | 0.12 |

[a] Dielectric constant. [b] $c$ = 0.5 M. [c] $c$ = 1.0 M.

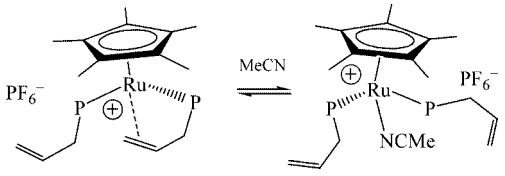
In addition to the fluxional character of complex **5**, a convincing indirect evidence that supports the interpretation based on hemilability is that the reactions of rhodium(I) complexes with MeI, as well as those of platinum group metal complexes in general, display kinetic plots characterized by linear dependence on the electrophilic concentrations and zero intercepts on the $y$ axis, indicating the availability of only one reactive route.[20] Moreover, significant solvent effects are observed in these reactions, which proceed by means of an SN2 pathway, in contrast to the lack of any correlation with the solvent donor ability in the clockwise route ($k_1$) of Scheme 8. A kinetic pattern showing a nonzero intercept was found once in the case of the rhodium(I) complex [Rh(cupf)(CO)($PPh_3$)], containing the bidentate anionic ligand *N*-nitrosophenyloxyamine PhN(NO)-$O^-$ (cupf).[21] In this case, the presence of mixed first- and second-order pathways was interpreted as the result of an intramolecular rearrangement of the complex induced by the attack of solvent and involving a change of the coordinative mode of the bifunctional ligand, thus generating a reactive species in equilibrium with the starting material. Linear plots with a positive intercept on the $y$ axis and described by an equation formally identical to 2 are found for equilibrium processes in which substrate and product remain spectroscopically observable at the end of the reaction. Such a case can be found in the oxidative addition of methyl iodide to the iodocarbonyl complex [Rh(CO)-$(L_{Me})_2$I] containing the N-heterocyclic carbene 3,5-dimethylimidazoline-2-ylidene ($L_{Me}$) ligand.[22] It is usually easy to differentiate between parallel and reversible processes from the final spectra.

An interesting kinetic pattern was observed for the reaction of complex **5** in methanol, in which the $k_{obs}$ values as a function of [MeI] exhibit a saturation behavior, i.e. tend toward a limiting value with increasing concentration of the electrophile.[15] This situation corresponds to the formation of a reactive species in equilibrium with the substrate, often induced by solvent, with comparable values of the forward reaction with the reagent and of the step leading back to the starting material.[23] The kinetic analysis on treatment of the intermediate under steady-state conditions yields the same Equation (1) (L = MeI) which was derived from the case of the P–N complexes **1**, the saturation effect here arising from the similarity of $k_{-1}$ and $k_2$. Although the separate values cannot be determined, the analysis yields the ratio $k_{-1}/k_2$ and the rate constant $k_1$. In the present case, these correspond to 1.8, and to the same rate of methyl iodide attack and ring closure at [MeI] = 1.8 M, and to $1.7\times10^{-4}$ $s^{-1}$, respectively. Therefore, it appears that in methanol the preferred route is the one involving a methanol solvated bidentate $\kappa^2$-*N*,*S* complex, along the clockwise pathway of Scheme 8, with no evidence for the second-order route. For the sake of comparison with the reaction of the bidentate P–N complexes **1** with carbon monoxide, the ratio of ring closure to CO attack ($k_{-1}/k_2$) from the five-coordinate intermediate [Mo(CO)$_4$($\kappa^1$-*P*,N)] is about one thousand at the conditions employed ([CO] = $5\times10^{-3}$ M, 69.6 °C in 1,2-dichlorobutane), while extrapolation at a concentration of carbon monoxide of about 1 M yields a similar ratio to the one observed for the reaction of **5** in methanol.

We have performed rate studies on the second step of the reaction of complex **5** with MeI (Scheme 6), which is the migratory insertion process giving the isolable product $[Rh(\kappa^3\text{-}L)(COMe)I]PF_6$ (**6**). The reaction is characterized by no rate dependence on the MeI concentration as expected for an intramolecular process, and we had no experimental evidence for any role of hemilability. However, in light of more information now available about the reactivity of rhodium(I) complexes with tridentate ligands, it appears that the presence of harder donor atoms or of less flexible ligand structures inhibit the migratory-insertion step. In fact, the oxidative addition of MeI stops at the methyl carbonyl rhodium(I) species for [N–N–N] complexes of 2,6-bis(oxazoline)pyridine,[24] bis(imino)carbazolide,[20q] or of [C–N–C] 2,6-bis(alkylimidazol-2-ylidene)pyridine ligands,[20r] while it proceeds to spontaneous migratory CO insertion for rhodium(III) complexes of hybrid [P–N–O] or [N–O–N] ligands.[25–26] The contribution of the association/dissociation process of a dangling ligand arm in carbonylation reactions was proposed for rhodium(I) complexes of mixed phosphane-phosphite or phosphane-ether bidentate ligands.[2a,c,20e,27]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Analogous cases of parallel first- and second-order kinetics were found in the study of the reactions of ruthenium complexes coordinated by the hybrid allylphosphane ligand, $Ph_2PCH_2CH=CH_2$, which acts in a bidentate fashion through the coordination of both the phosphorus atom and the allylic double bond to the metal center. Mixed alkenyl-phosphane or alkynyl-phosphane ligands have attracted a large interest because of the potential hemilabile character in the corresponding transition metal complexes.[28] The Cp* ruthenium complex $[Ru(\eta^5\text{-}C_5Me_5)\{\kappa^1\text{-}P\text{-}Ph_2PCH_2CH=CH_2\}\{\kappa^3\text{-}P,C,C\text{-}Ph_2PCH_2CH=CH_2\}][PF_6]$ (**7**), containing two molecules of allylphosphane in different, monodentate and bidentate, coordinative modes, reacts with nucleophiles (L = NaNCS, CO, PhC≡CH) yielding corresponding neutral or cationic complexes in which both molecules are monodentate. In addition, complex **7** reversibly binds acetonitrile (Scheme 9).[29]



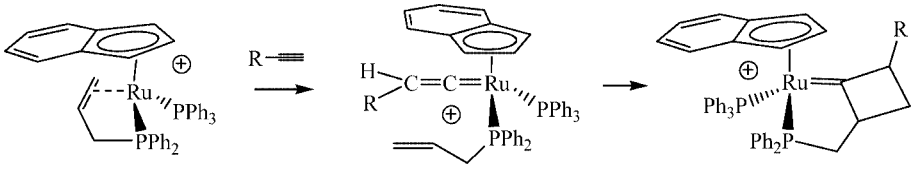
Scheme 9. Reversible coordination of acetonitrile to complex **7**.

These reactions occur readily by substitution of the coordinated alkenyl group, which forms a weaker bond to the metal than the phosphorus donor. The specific hemilabile character of allylphosphane was suggested by a fluxional behavior exhibited by complex **7** at room temperature, and confirmed by variable temperature NMR spectroscopic studies. Substitution reactions and dynamic properties have been interpreted as the result of a dissociative mechanism involving binding and rebinding of the allylic moiety, typical of hemilability. In analogy, the cationic indenyl complexes $[Ru(\eta^5\text{-}C_9H_7)(PPh_3)\{\kappa^3\text{-}P,C,C\text{-}Ph_2PCHRCH=CH_2\}]PF_6$ (**8**, R = H; **9**, R = Me) containing allylphosphane derivatives undergo substitution reactions of the allylic double bond by nitriles (MeCN, BzCN) or by sodium azide yielding the corresponding monodentate cationic or neutral complexes.[30] In contrast with the behavior of the Cp* complex **7**, dynamic processes were not observed in the $^1H$ or $^{31}P$ NMR spectra of complexes **8** or **9**, performed between –90 and 50 °C. Because of their rich chemistry, rate studies were performed on the reactions of these indenyl complexes.

In particular, complex $[Ru(\eta^5\text{-}C_9H_7)\{\kappa^3\text{-}(P,C,C)\text{-}PPh_2(CH_2CH=CH_2)\}(PPh_3)][PF_6]$ (**8**) reacts with terminal alkynes RC≡CH (R = Ph, *p*-$MeC_6H_4$, $SiMe_3$) yielding bicyclic cyclobutadienylidene compounds.[31] This reaction stems from the action of the allylphosphane ligand, which first decoordinates the allylic double bond allowing the incoming alkyne to π-coordinate to ruthenium and then undergoes an unprecedented [2+2] cycloaddition with the tautomerized vinylidene moiety (Scheme 10). The reaction is highly diastereoselective yielding only one isomer of the bicyclic derivative, which contains three stereogenic centers.

In the case of aryl alkynes, the intermediate vinylidene species, observable by $^{31}P$ NMR spectroscopy, were also independently prepared from the corresponding alkynyl derivatives and shown to proceed under thermal activation to the same bicyclic products. In addition to the novelty of such a [2+2] cycloaddition occurring smoothly just above room temperature, the process appears peculiar among those of complexes with hybrid ligands since it involves both a transformation of the alkyne at the metal center and its further reaction with the dissociated arm of the bifunctional molecule.

Although the first step of this process, i.e. the formation of the vinylidene intermediates, is associated with a change of the binding mode of the allylphosphane ligand from $\kappa^3$-*P,C,C* to monodentate $\kappa^1$-*P* coordination, a case of hemilability cannot be identified due to the lack of fluxional behaviour. Kinetic experiments were performed by $^{31}P$ NMR spectroscopy for the formation of the vinylidene species from complex **8** and the aryl alkynes *p*-$XC_6H_4C{\equiv}CH$ (X = H, Cl) in chloroform-*d* solution.[32] The reactions were found to be first order in **8** and the values of $k_{obs}$ were obtained at different concentrations of the alkynes. Figure 2 shows the corresponding plots. Analogous to the results obtained for the rhodium complex **5**, the graph reveals finite intercepts on the *y* axis and points to the mechanistic hypothesis of Scheme 7, which when adapted to the structural features of complex **8** yields Scheme 11. In this case the positive values of the intercepts on the *y* axis represent the rate of dissociation of the allylic double bond from ruthenium ($k_1$). These were found to be $k_1 = 9(\pm2.5)\times10^{-5}\ s^{-1}$ for phenylacetylene and $7(\pm1.5)\times10^{-5}\ s^{-1}$ for *p*-chlorophenylacetylene, corresponding to the rate of formation of the vinylidene species $[Ru(\eta^5\text{-}C_9H_7)(=C=CHC_6H_4\text{-}p\text{-}X)\{\kappa^1\text{-}(P)\text{-}PPh_2(CH_2CH=CH_2)\}(PPh_3)]^+$, existing in equilibrium with the chelate complex. It is worth mentioning that a chelate complex analogous to **8** coordinated by the homoallylphosphane ligand $PPh_2(CH_2CH_2CH=CH_2)$ is inert to-



Scheme 10. Reaction of complex **8** with terminal alkynes.

ward reactions with either nitrile or alkynes.[28] This information indicates that enlarging the chelate by one additional methylene group in the carbon chain imparts greater stability to the ring and to the ruthenium–olefin bond, which does not undergo either spontaneous or induced ring opening.

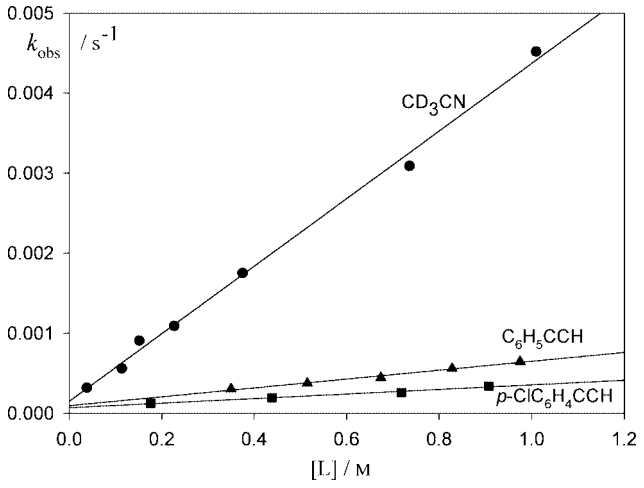

Figure 2. Plot of $k_{obs}$ values for the substitution reaction of complex $[Ru(\eta^5\text{-}C_9H_7)\{\kappa^3\text{-}(P,C,C)\text{-}PPh_2(CH_2CH{=}CH_2)\}(PPh_3)][PF_6]$ (**8**) with $CD_3CN$ (●), compared with the $k_{obs}$ values for the reactions with PhC≡CH (▲) and $p$-$ClC_6H_4C{\equiv}CH$ (■), in [$D_1$]chloroform at 38.1 °C.

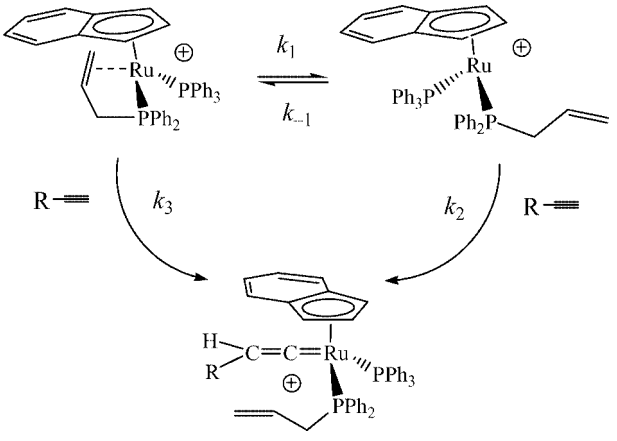

Scheme 11. Direct SN2 attack of the alkyne at complex **8** ($k_3$, slow) or at the transient $[Ru(\eta^5\text{-}C_9H_7)\{\kappa^1\text{-}(P)\text{-}PPh_2(CH_2CH{=}CH_2)\}(PPh_3)][PF_6]$ ($k_2$, fast).

With regard to the mechanistic analysis presented for the reaction of complex **5**, there is an additional feature of relevance in the concept of kinetic detection of hemilability. In fact, the rate data in the case of the $NS_2$ rhodium complex $[Rh(\kappa^3\text{-}L)(CO)]PF_6$ were obtained for the reaction with the same MeI in different solvents, while here different alkynes have been made to react with the indenyl ruthenium complex. The zero-order dependence on the alkyne implicit in the finite $y$ intercept and the observation of Scheme 11 points out that $k_1$ values must be independent not only of the concentration of the alkyne but also of its nature, since the alkyne is supposed to interact with the ruthenium complex after the rate-determining dissociation of the allylic double bond. In agreement with this consideration, the values of the intercept on the $y$ axis obtained from phenylacetylene and $p$-chlorophenylacetylene are the same within experimental error of the measurements. In line with the basic principle of chemical kinetics for which information is attainable only up to the rate-limiting step along the reaction coordinate, the rate of dissociation of the weakest bond of the hybrid ligand is not affected by the evolution of the resulting intermediate. In contrast, the values of the second-order rate constants obtained from the slopes of the linear plots, which are $k_2 = 5.5(\pm0.4)\times10^{-4}$ for phenylacetylene and $2.8(\pm0.3)\times10^{-4}$ $M^{-1}s^{-1}$ for $p$-chlorophenylacetylene, depend on the nature of the alkyne interacting with the metal complex in the slowest step of this pathway. In particular, the smaller value for the $p$-chloro derivative indicates that an electron-withdrawing ring substituent reduces the electron density on the triple bond and its reactivity toward the ruthenium center.

The concept that the rate of formation of a monodentate intermediate arising from ring opening must be independent of the concentration and nature of the reagent found a further example in the reactions of complex **8** with nitriles (L), proceeding quantitatively to the formation of the substituted complexes $[Ru(\eta^5\text{-}C_9H_7)(PPh_3)\{\kappa^1(P)\text{-}Ph_2PCH_2CH{=}CH_2\}(L)]PF_6$ (L = MeCN, BzCN),[30] differently from that of the equilibrium observed for the bisallyl Cp* complex **7** (Scheme 9). The kinetics for the reaction with [$D_3$]acetonitrile exhibited mixed first- and second-order routes, with the second-order rate constant $k_2 = 4.2(\pm0.1)\times10^{-3}$ $M^{-1}s^{-1}$, in agreement with a larger nucleophilic character of a nitrile with respect to an arylalkyne. In contrast, the first-order rate constant $k_1 = 1.5(\pm0.6)\times10^{-4}$ $s^{-1}$ was within experimental error of the values obtained from the reactions with $p$-$XC_6H_4C{\equiv}CH$ (X = H, Cl). Therefore, because of the nature of $k_1$ its value is independent of the reaction in which the coordinatively unsaturated intermediate becomes involved, i.e. of its final destiny. This concept is represented graphically in Scheme 12.

As previously pointed out, consistent circumstantial evidence should assist the proposal of a reaction mechanism, especially when highly reactive or spectroscopically undetectable species are involved. The possibility of an intermediate arising from the dissociation of $PPh_3$ instead of the allylic double bond was excluded by the observation that the rate of the reaction of complex **8** with phenylacetylene was not depressed in the presence of a large excess of the monodentate phosphane. In addition, the attribution of the first-order pathway to a rate-limiting $\eta^5$-$\eta^3$ shift of the indenyl ring can be excluded from the fact that substitution reactions of indenyl complexes exhibit second-order behavior.[33] The substitution reaction in the indenyl complex is first-order overall when the rate-determining dissociation of another ligand generates a 16-electron coordinatively unsaturated species and the free ligand, the indenyl group remains $\eta^5$-bound.[34] What occurs in the case of complex **8** is exactly the intramolecular version of this phenomenon,

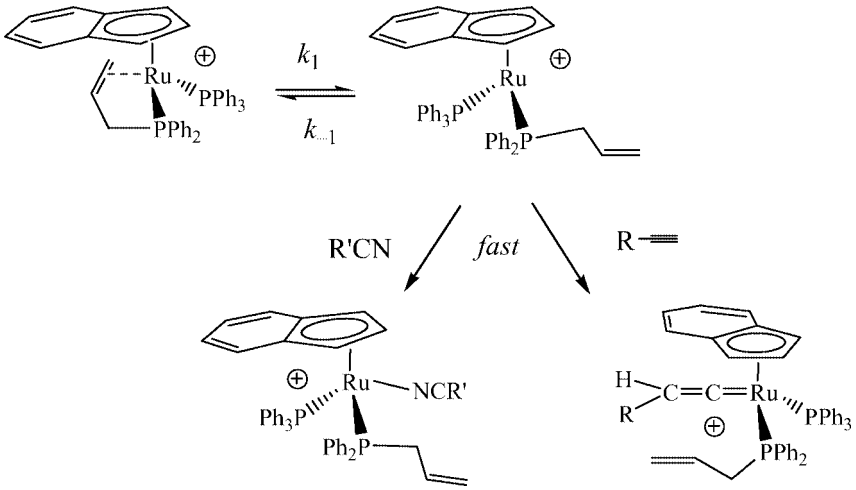


Scheme 12. The reactivity of complex [Ru($\eta^5$-$C_9H_7$){$\kappa^3$-(*P*,*C*,*C*)-$PPh_2(CH_2CH{=}CH_2)$}($PPh_3$)][$PF_6$] is dominated by the rate of dissociation of the allylic double bond ($k_1$).

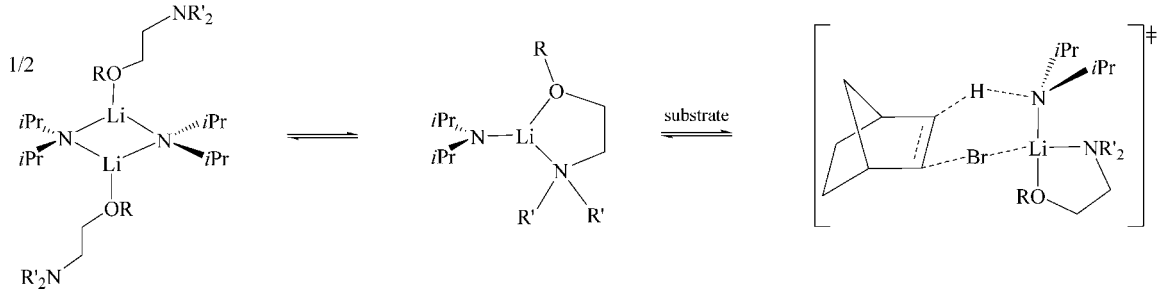
with the allylphosphane ligand remaining bound to the ruthenium through the phosphorus atom. Cases of parallel first- and second-order kinetics involving monodentate ligands and exhibiting the same kinetic pattern observed here were also reported.[35]

A simple analysis of the plots in Figure 1 and Figure 2 allows the contribution of the arm-off mechanism to the overall reactivity to be estimated. This is done graphically from the ratio of $k_1$ over the interpolated $k_{obs}$ value on the *y* axis at a given concentration of the reagent. For instance, the rhodium complex **5** reacts with MeI via the $\kappa^2$-*N*,*S* intermediate for about 10% in acetone or in acetonitrile, and for about 60% in dichloromethane, at [MeI] ≈ 1 M. The contribution of hemilability increases to about 19% in the more polar solvents and to 78% in dichloromethane at [MeI] ≈ 0.5 M. The reaction of the indenyl ruthenium complex **9** proceeds via the monodentate intermediate for about 25% in the case of phenylacetylene and 33% in the case of the *p*-chloroderivative, at an alkyne concentration of 0.5 M. At the same concentration of phenylacetylene, only 5% of the reaction with [$D_3$]acetonitrile occurs via the open arm intermediate of the allylphosphane complex. The effect of hemilability is minimized under those conditions of solvent or reagent that favor the SN2 attack to the chelate complex, while it tends to become dominant at concentrations of the reagent approaching zero.

The substitution reactions of the homoditopic S–S ligands of [Pt(Ph)$_2${$\kappa^2$-(*S*,*S*)-$Ph_2S(CH_2)_nSPh_2$}] (*n* = 2,3) by a diphosphane were found to proceed according to Equation (2), indicating the formation of a monodentate $\kappa^1$-*S* transient species.[36] Parallel first- and second-order kinetics were also observed for the acid-promoted ring opening and displacement by chloride of the bidentate chelate ligand from dichloro[pyridine-2-(α-methoxymethanolato)]-gold(III).[14d]

The effect of hemilabile ligands on the rates of 1,2-dehydrobromination reactions mediated by lithium diisopropylamide (LDA) were studied in detail by Collum and coworkers. The process itself served as the reference reaction for addressing key issues in organolithium chemistry, in particular aggregation and solvation effects.[37] The reaction in the presence of hemilabile O–N ligands instead of BuOMe can be accelerated by up to four orders of magnitude because of the intervention of monomer and dimer based pathways. Kinetic and spectroscopic experiments carried out using either BuOMe, bidentate ethers such as dimethoxyethane, or different hybrid aminoethers have shown that ground state structures are dimeric complexes bearing a monodentate ligand, while transition state structures are chelated monomeric species (Scheme 13).

The subject has been investigated with various approaches, including thermodynamic, kinetic, and computa-



Scheme 13. Equilibrium between dimeric monodentate and monomeric bidentate complexes, and the transition state structure in the 1,2-dehydrobromination of (±)-2-*exo*-bromonorbornane, mediated by lithium diisopropylamide complexes.

tional work, which has allowed the authors to show and prove some fundamental mechanistic concepts. In particular, effects on relative reaction rates were dissected into the rate retarding influence due to ground state stabilization and the rate accelerating influence due to transition state stabilization. The rate acceleration imparted by dimethoxyethane and related aminoethers is due to selective stabilization of the transition state structure arising from a chelate effect of the hybrid ligands, and not to an increased solvation ability with respect to a monodentate ligand. This case, when compared with the examples described previously, shows an opposite situation among the effects, which hybrid hemilabile ligands may exert on the reactivity of a metal center. In fact, while complexes **1**, **5**, and **8** are chelated in the ground state and change into monocoordinated complexes by the arm-off mechanism to become reactive toward a substrate, the lithium diisopropylamide complexes are dimeric monodentate species in solution but use bidentation at the transition state to access lower energy pathways for the reaction. The transition state stabilization and hence the reaction rates can be tuned by changing the structure of the hybrid ligand in the following ways: (i) altering the length of the hydrocarbon chain and so the chelate ring size, (ii) varying the alkyl substituents on both the oxygen and nitrogen donors, (iii) introducing ramification on the carbon chain. A recent work addressing the last issue has concluded that rate accelerations based on the *gem*-dimethyl effect are nonexistent for lithium ion chelation.[38] The *gem*-dimethyl effect applies when destabililizing effects due to unfavorable steric interactions of alkyl substituents in an open carbon chain are alleviated by ring closure and can give pronounced substituent-dependent rate accelerations.[39]

Although many hybrid ligands have been used successfully in catalysis,[2,4] the establishment of contributions from the reversible association/dissociation of one labile function during the catalytic cycle remains a key question, which appears more difficult to address than it is for stoichiometric reactions.[40] Because of the interchange of various metal species, the alternation of dangling or chelate ligand modes may occur frequently during the cycle and affect the relative stability/reactivity in each step. To devise kinetic experiments that are as informative for catalysis as they are for stoichiometric reactions represents an important challenge, however, it is fundamental for understanding the role of hemilability in cyclic multistep processes.

## 4. Concluding Remarks

This review describes the information attainable from kinetic studies about the hemilability of hybrid ligands coordinated to transition metal complexes. In particular, it shows that the kinetic method allows for the detection of the reversible association/dissociation process of the hemilabile ligand function, even in the absence of fluxional behavior, as well as a quantitative evaluation of its weight along the coordinate of a bimolecular reaction. Cases in which the only available reaction pathway involves a transient species arising from dissociation of the ligand arm, cases in which such species reacts in parallel with the chelate complex, and opposite cases in which only the chelate is reactive are described. The kinetic approach may serve as a basis for the rational design of hemilabile systems and for the development of targeted applications.

## Acknowledgments

The author expresses his gratitude to the collaborators and coauthors involved in the studies on hemilability, and in particular to the group of Josè Gimeno in Oviedo, where the chemistry of the indenyl allylphosphane complexes was developed.

[9] In the study of the exchange processes associated with hemilability, various expressions have been introduced to represent the reversible decoordination of one ligand arm: interchange, tick-tock, wind-screen wiper, opening and closing, arm-off mechanism (see ref.[1]).
[10] The formation of a stable monochelate product indicates that selective decoordination of one ligand arm has occurred, but does not imply that the bis-chelate complex was involved in the reversible motion which identifies hemilability.

# Cadmium(II) and Zinc(II) Coordination Polymers with 1D Ladder and 2D Basket Weave Layer Structures Constructed from a New T-Shaped Ligand

**Guoping Yong,[a] Shu Qiao,[a] Yu Xie,[a] and Zhiyong Wang*[a]**

**Keywords:** Pyridinones / Polymers / T-shaped ligands / Luminescence / Coordination modes

A novel imidazo[1,2-*a*]pyridin-2-one ligand, 3,3-bis(carboxymethyl)imidazo[1,2-*a*]pyridin-2-one ($H_2L$), was conveniently synthesized and acts as a three-connecting T-shaped building block. Hydrothermal treatment of the $H_2L$ ligand with $Cd(ClO_4)_2 \cdot 6H_2O$ or $Zn(ClO_4)_2 \cdot 6H_2O$ gives two new coordination polymers, $[CdL(H_2O)_2]_n$ (**1**) or $[ZnL(H_2O)]_n$ (**2**). Compound **1** consists of a rare 1D ladder-like chain and **2** is the first example of a polymer with a 2D basket weave network. Solid-state photoluminescent analyses of **1** and **2** show that they display strong fluorescent emissions.

## Introduction

In the past decades, coordination polymers have been subjected to a vast number of studies owing to their potential applications in catalysis, molecular adsorption, magnetism, nonlinear optics, luminescence, and molecular sensing,[1,2] as well as their intriguing structural motifs.[3] Recently, increasing investigations have been focused on the construction of coordination polymers with the use of heterocyclic carboxylic acids such as pyridine-,[4] pyrazole-,[5] and imidazolecarboxylic acids[6] as building blocks. These building blocks contain multioxygen and nitrogen atoms and can coordinate with metal ions in different ways, which results in the formation of various metal–organic frameworks with specific topologies and useful properties. It is well-known that organic ligands play crucial roles in the design and construction of desirable frameworks because changes in the flexibility, length, and symmetry of the organic ligands can result in a remarkable class of coordination polymers bearing diverse architectures and functions.[7] Our previous work had shown that the N-containing polycarboxylate ligands could be used to construct novel coordination polymers.[8] Herein, we turn our attention to a novel N-containing polycarboxylate ligand, 3,3-bis(carboxymethyl)imidazo[1,2-*a*]pyridin-2-one ($H_2L$). This ligand consists of a rigid imidazo[1,2-*a*]pyridin-2-one ring and flexible diacetic acid moieties; it is possible that the combination of these specialties may lead to the formation of interesting topologies.

A number of infinite ladder-like coordination polymers have been reported;[9] however, most of them were constructed with two-connecting ligands such as 4,4′-bipy. In principle, it is difficult to obtain a T-shaped geometry around the metal center, which is essential for the ladder structure, by using two-connecting ligands.[10] One strategy that can be used to overcome this difficulty is to use three-connecting T-shaped ligands as building units.[11] Hitherto, only a few ladder-like compounds containing T-shaped ligands have been reported.[10–12] Comparatively, less effort has been made in the construction of 2D layers by using three-connecting T-shaped ligands.[11b,13] According to the definition of Wells,[14] five types of 2D architectures (brick wall, herringbone, bilayer, basket weave, and long and short brick) can be expected for a T-shaped geometry, but only the first three types have already been realized so far.[3c]

During our research on the $H_2L$ ligand, we have obtained two new coordination polymers, $[CdL(H_2O)_2]_n$ (**1**) and $[ZnL(H_2O)]_n$ (**2**). The ladder-like chain built from the T-shaped ligand as found in **1** is rare. To the best of our knowledge, compound **2** is the first example of a coordination polymer whose 2D basket weave network is constructed from the combination of metal centers with a T-shaped geometry and ligands with T-shaped structure simultaneously. Herein, we report the syntheses, X-ray single-crystal analyses, and photoluminescent properties of **1** and **2**.

## Results and Discussion

### Synthesis of 3,3-Bis(carboxymethyl)imidazo[1,2-*a*]pyridin-2-one ($H_2L$)

Imidazo[1,2-*a*]pyridine derivatives have been attracting considerable interest because of their significant pharmaceutical importance.[15] They are also versatile intermediates

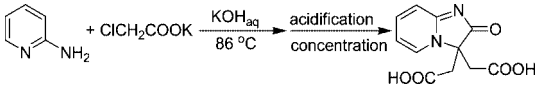
for synthetic transformations.[16] However, less effort has been made in the synthesis of imidazo[1,2-*a*]pyridin-2-one derivatives. We exploit a novel and facile synthetic method for these imidazo[1,2-*a*]pyridin-2-one derivatives (Scheme 1). 3,3-Bis(carboxymethyl)imidazo[1,2-*a*]pyridin-2-one ($H_2L$) was obtained as a free acid from the reaction of potassium chloroacetate and 2-aminopyridine in aqueous alkaline solution heated at 86 °C, followed by acidification of the mixture with aqueous HCl and concentration under boiling conditions. After cooling of the mixture to remove the precipitated KCl (ice bath), the desired acid was precipitated and removed by filtration. The negative ion electrospray mass spectrum ($H_2O$) of $H_2L$ shows the characteristic molecular ion peak around $m/z$ = 248.97, which provides strong evidence for the formula $C_{11}H_{10}N_2O_5$. The molecular structure is also supported by microanalysis, IR, and NMR spectroscopic results.



Scheme 1. Synthesis of 3,3-bis(carboxymethyl)imidazo[1,2-*a*]pyridin-2-one.

### Syntheses of Compounds 1 and 2

Compounds **1** and **2** were readily obtained in good yields (Scheme 2) by treating the corresponding metal perchlorate salts and $H_2L$ in a mixture of DMF and $H_2O$ at 120 °C for two days. Their formulations are supported by IR, microanalysis and thermogravimetric analysis (TGA) results. The phase purities were revealed by powder diffraction patterns of the bulk samples, which are consistent with the theoretical patterns generated from their single-crystal X-ray diffraction data (see Supporting Information).

### Description of Crystal Structure

#### *[CdL(H$_2$O)$_2$]$_n$ (1)*

Compound **1** has a 1D infinite ladder structure that is assembled through metal–nitrogen and metal–oxygen coordination bonds. The coordination geometry of each $Cd^{II}$ ion is a distorted octahedron, in which the $Cd^{II}$ ion is coordinated to two water oxygen atoms, three carboxylate oxygen atoms, and one nitrogen atom from three $L^{2-}$ ligands (Figure 1). The five Cd–O bond lengths range from 2.234(2) to 2.508(2) Å, and the Cd–N bond length is 2.264(2) Å (Table 1).

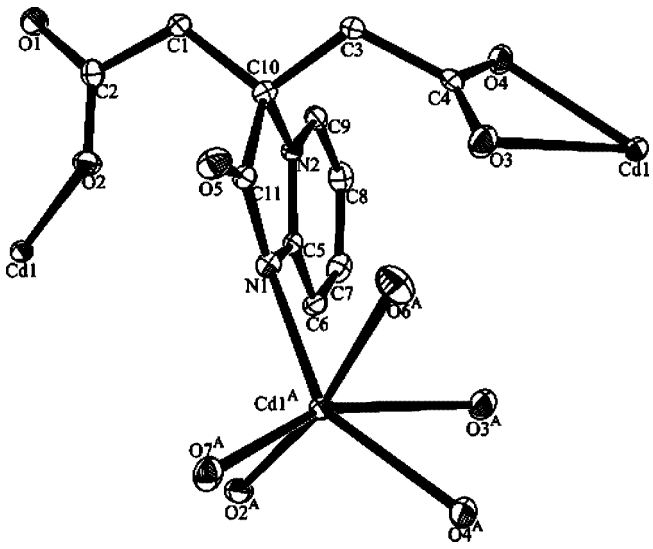

Figure 1. ORTEP drawing at the 50% probability level showing the $Cd^{II}$ coordination environment and T-shaped ligand in **1**. Hydrogen atoms are omitted for clarity. Symmetry code: A: –*x*, –*y*, –*z*.

[a] Symmetry transformations used to generate equivalent atoms: #3: –*x*, –*y*, –*z*. [b] Symmetry transformations used to generate equivalent atoms: #2: –*x* + 1/2, *y* + 1/2, –*z* + 1/2; #3: –*x*, –*y*, –*z*.

As a rail and rung simultaneously, each $L^{2-}$ ligand bridges three Cd atoms through its two carboxylate groups and one nitrogen atom to form a ladder extending along the *a* axis, as shown in Figure 2. As a result, the $L^{2-}$ ligand can be described as a three-connecting T-shaped building block. The Cd atom can be taken as a three-connecting node with a T-shaped geometry if two coordinated water molecules are disregarded. The T-shaped configurations of both the $Cd^{II}$ center and the $L^{2-}$ ligand have thus accommodated the formation of a 1D ladder. Interestingly, the two flexible acetate groups bridge two Cd atoms in the monodentate

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and chelating fashion, respectively, to form the side rail of the ladder, while one nitrogen atom is linked to the third Cd atom. As a result, the rigid imidazo[1,2-*a*]pyridin-2-one ring acts as the rung. Because of the distorted T-joints and the unequal separations between the Cd1 and C10 atoms across the adjacent carboxylate groups, the 1D ladder is composed of two kinds of alternating rhombic rings with step lengths of 4.78 and 5.16 Å, respectively. The structure of **1** is a rare ladder motif consisting of two kinds of step lengths.[17]

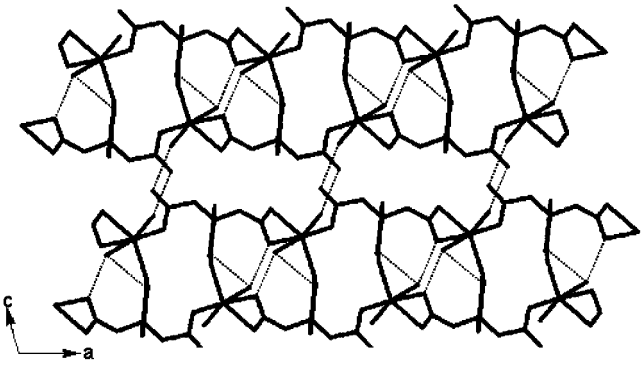

Figure 2. View along the *b* axis of the 2D hydrogen bonding network (dotted lines) of **1**.

As shown in Figure 2, the ladders extending along the *a* axis are organized by the O7···O1 [2.700(2) Å] hydrogen bonds that exist between two adjacent chains to form a layer that lies in the *a*,*c* plane. There are also intra-chained hydrogen bonding interactions [O6···O5 2.856(3) and O6···O3 2.807(3) Å] between coordinating water molecules, carbonyl oxygen atoms, and carboxylate oxygen atoms (Table 2). It is interesting to note that the stack of undulating 2D hydrogen bonding layers through the O···O hydrogen bonding interactions [O7···O5 2.739(3) Å] gives rise to a 3D supramolecular network with rhombic channels occupied by the pendent pyridine rings of the $L^{2-}$ ligands (see Supporting Information).

Table 2. Hydrogen bond geometries for compounds **1** and **2**.

| | D–H···A | *d*(D···A) [Å] | <(D–H···A) [°] |
|---|---|---|---|
| **1**[a] | O6–H01···O3$^{i}$ | 2.807(3) | 153(4) |
| | O6–H02···O5$^{i}$ | 2.856(3) | 149(4) |
| | O7–H03···O5$^{ii}$ | 2.739(3) | 173(4) |
| **2**[b] | O6–H02···O1$^{i}$ | 2.615(3) | 178(4) |
| | O6–H01···O5$^{ii}$ | 2.688(3) | 168(4) |

[a] Symmetry codes for **1**: $^{i}$: $-x$, $-y$, $-z$; $^{ii}$: $-x$, $y+1/2$, $-z+1/2$. [b] Symmetry codes for **2**: $^{i}$: $x-1/2$, $-y-1/2$, $z-1/2$; $^{ii}$: $-x+1/2$, $y+1/2$, $-z+1/2$.

### *[ZnL(H$_2$O)]$_n$ (2)*

Compound **2** possesses a 2D basket weave network based on the three-connecting T-shaped ligand. As shown in Figure 3, each $Zn^{II}$ ion adopts a distorted tetrahedral coordination environment by coordinating one water molecule, two carboxylate oxygen atoms, and one nitrogen atom from three $L^{2-}$ ligands with the Zn–O bond lengths ranging from 1.980(2) to 2.075(2) Å, and the Zn–N bond length of 2.010(2) Å (Table 1).

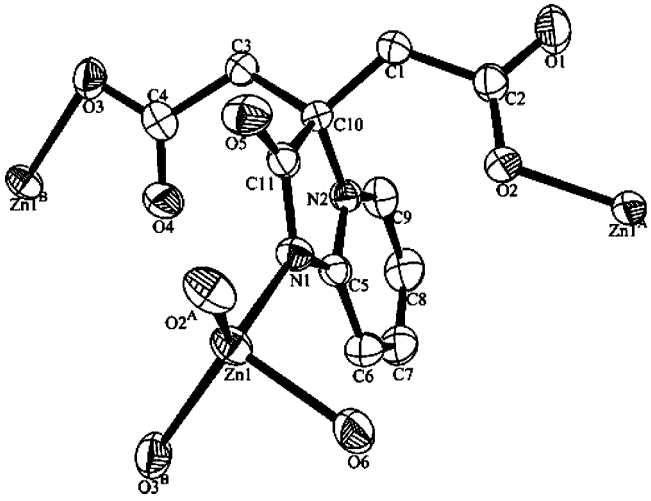

Figure 3. ORTEP drawing at the 50% probability level showing the $Zn^{II}$ coordination environment and T-shaped ligand in **2**. Hydrogen atoms are omitted for clarity. Symmetry code: A: $-x+1/2$, $y+1/2$, $-z+1/2$; B: $-x$, $-y$, $-z$.

The $L^{2-}$ ligand also acts as a three-connecting T-shaped building block, bridging three Zn atoms through its two monodentate carboxylate groups and one nitrogen atom. The Zn atom can also be taken as a three-connecting node with a T-shaped geometry if one coordinated water molecule is disregarded (the aqua ligand does not bridge). Interestingly, four arms (two acetate groups and two imidazo[1,2-*a*]pyridin-2-one rings) from two different $L^{2-}$ ligands bridge two Zn atoms to form a four-membered metallacycle with four three-connecting nodes (two C10 atoms and two Zn1 atoms). Such metallacycles are further extended to form not a ladder as observed in **1**, but a 2D basket weave network lying in the *a*,*b* plane, as shown in Figure 4. In principle, the transformation from the 1D ladder of **1** to the 2D basket weave network of **2** only requires the alternate breaking of opposite side rails of one ladder and then the connection to the neighboring parallel ladders (see Supporting Information). Thus, the present case is the first coordination network having a 2D basket weave architecture that is constructed from the combination of metal ions with T-shaped geometries and ligands with T-shape structures simultaneously. There are intralayered hydrogen bonding interactions [O6···O5 2.688(3) Å] between coordinating water molecules and carbonyl oxygen atoms. It is very interesting to notice that the 2D basket weave network of **2** exhibits beautiful sinusoidal 2D layers extending along the *a*,*c* plane, which further assemble into a 3D supramolecular network through the interlayered hydrogen bonding interactions [O6···O1 2.615(3) Å] (see Supporting Information).

It is worthy to note that the structural differences between **1** and **2** with the same $L^{2-}$ ligands and the same synthetic conditions may mainly be attributed to the radii of the metal atoms with the Cd atom having a larger atomic radius than the Zn atom, which results in different coordi-

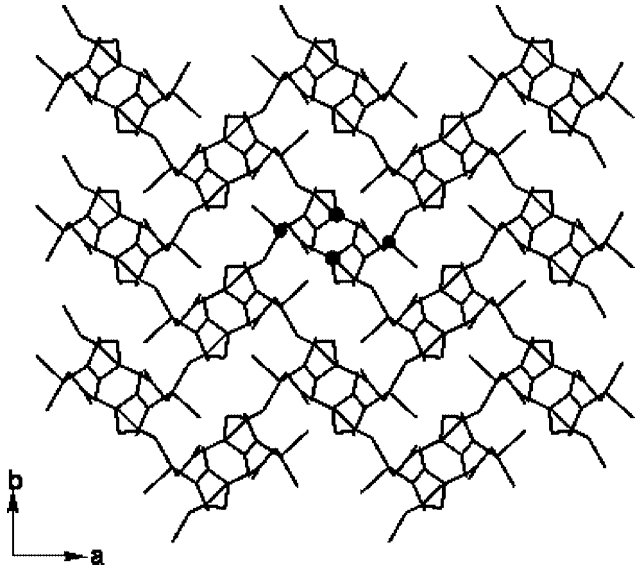

Figure 4. View of the 2D basket weave network lying in the *a*,*b* plane of **2**. Pyridine rings are omitted for clarity, and the black spheres represent three-connecting nodes.

nation environments ($Cd^{II}$ with octahedron geometry and $Zn^{II}$ with tetrahedron geometry).[18]

### Thermogravimetric Analyses

TG analysis of **1** reveals that its first weight loss appears at ca. 152 °C due to the loss of two coordinating water molecules (calcd. 9.1%; found 9.2%). The second weight loss occurs between 252 °C and 550 °C and is characteristic of the decomposition of the organic moiety. Coordination polymer **2** shows the first weight loss at ca.168 °C with the loss of one coordinating water molecule (calcd. 5.4%; found 5.1%), and the second weight loss occurs between 355 °C and 472 °C and is characteristic of the decomposition of the organic moiety (see Supporting Information).

### Photoluminescent Properties

The emission spectra of **1** and **2** in the solid state at room temperature are depicted in Figure 5. Compounds **1** and **2** display similar shoulder peaks, and their maximum emission peaks occur at 400 nm upon excitation at 210 nm and 250 nm, respectively. The emissions of **1** and **2** can probably be assigned to intraligand fluorescent emission,[19] since the free $H_2L$ ligand reveals the same maximum emission band (400 nm) upon excitation at 313 nm (see Supporting Information). These results imply that the coordination of the $L^{2-}$ ligand with the $Cd^{II}$ and $Zn^{II}$ ions, although yielding different topological structures, has no influence on the emission mechanism of the metal coordination polymer.[20] Compared to that of the free $H_2L$ ligand, **1** and **2** show significantly stronger photoluminescence, probably due to the coordination of the $H_2L$ ligand to the metal ions, which increases the ligand conformational rigidity;[21] the nonradiative decay of the intraligand excited state is thereby reduced. The metallacycles of **1** and **2** built by T-shaped $L^{2-}$ ligands probably cause significant enhancement to the rigidity of the ligand. The difference in the emission intensities of **1** and **2** is probably due to the differences in the metal ions and the coordination environment around them.[22] These observations suggest that compounds **1** and **2** may be excellent candidates for potential photoactive materials,[23] since these condensed materials are thermally stable and insoluble in water and common organic solvents.

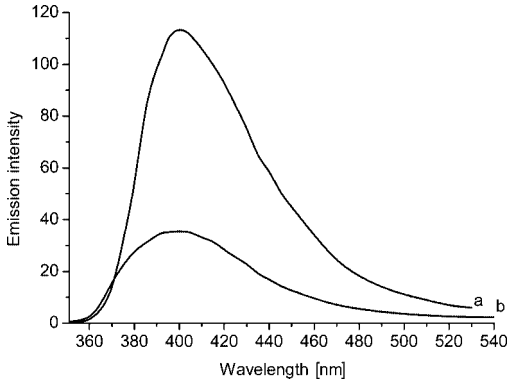

Figure 5. Solid-state emission spectra of a) **1** and b) **2** at room temperature.

## Conclusions

A novel imidazo[1,2-*a*]pyridin-2-one derivative ($H_2L$) was conveniently synthesized and characterized. By a combination of the different coordination environments of the metal ions and the T-shaped coordination mode of the $L^{2-}$ ligand, we have successfully synthesized two new coordination polymers, of which **1** has a rarely reported ladder motif and **2** is the first example having a 2D basket weave network. Toward the synthesis and design of 1D ladder chains or 2D basket weave networks, we think that T-shaped ligands are very suitable and promising for the syntheses of compounds with novel structures such as ladders, brickwalls, herringbones, bilayers, basket weaves, and long and short bricks.

## Experimental Section

**General Methods:** All reagents are commercially available and used as purchased without further purification. Elemental analysis was carried out with an Elementar Vario EL III microanalyser. The FTIR spectra were recorded with a Bruker Vector 22 spectrophotometer in the 4000–400 $cm^{-1}$ region. Mass spectra were obtained by negative ion electrospray ($H_2O$ solution) with a LCQ Advantage Max mass spectrometer. $^1H$- and $^{13}C$ NMR spectra were recorded with a Bruker AV300 and AV400 spectrometer, respectively. The emission spectra for the solid samples were recorded at room temperature with a Hitachi 850 fluorescence spectrophotometer. Thermogravimetric analyses were performed under air with a heating rate of 10 °C $min^{-1}$ with a Shimadzu TGA-50H TG analyzer. Powder X-ray diffraction (PXRD) patterns were obtained with a MXPAHF rotation anode X-ray diffractometer. ***Caution:*** Cd-

$(ClO_4)_2 \cdot 6H_2O$ and $Zn(ClO_4)_2 \cdot 6H_2O$ are potentially explosive and should be used with care!!

**Synthesis of 3,3-Bis(carboxymethyl)imidazo[1,2-*a*]pyridin-2-one ($H_2L$):** A solution of KOH (33.6 g, 0.6 mol) in water (75 mL) was added dropwise to an ice-bath cooled solution of chloroacetic acid (28.4 g, 0.3 mol) in water (75 mL). To the resulting alkaline solution, 2-aminopyridine (9.4 g, 0.1 mol) was slowly added, and the mixture was heated under reflux at 86 °C for 30 h. HCl (6 N, 53 mL) was added to neutralize the solution, which was concentrated under boiling conditions and then cooled (ice-bath) to remove KCl. After the mother liquor (pH = 2–3) was allowed to stand in the refrigerator for three days, the desired acid ($H_2L$) was separated out and collected by filtration. The solid was recrystallized from hot ethanol/water (1:1), and the colorless product was then collected by filtration and air-dried. Yield: 5.75 g (23%, based on 2-aminopyridine). $C_{11}H_{10}N_2O_5$ (250.21): calcd. C 52.80, H 4.03, N 11.20; found C 52.48, H 4.05, N 10.93. MS (ES–, $H_2O$): *m*/*z* = 250 $[M]^+$. $^1H$ NMR (300 MHz, $D_2O$, 25 °C): $\delta$ = 8.77 (d, $^3J_{H,H}$ = 6.8 Hz, 1 H, 5-H), 8.48 (dd, $^3J_{H,H}$ = 6.8, 8.4 Hz, 1 H, 6-H), 7.67 (m, 2 H, 7-H, 8-H), 3.44 (s, 4 H, $CH_2$) ppm. $^{13}C$ NMR (100 MHz, $D_2O$, 25 °C): $\delta$ = 175.5 (C-2), 172.0 (*C*OOH), 153.2 (C-9), 147.9 (C-5), 136.2 (C-7), 120.4 (C-8), 111.6 (C-6), 69.8 (C-3), 42.5 (*C*$H_2$) ppm. IR (KBr pellet): $\tilde{\nu}$ = 3434 (m), 3077(m), 2972(m), 2876(w), 2792(w), 2683(w), 1771(s), 1708(m), 1649(s), 1580(m), 1519(s), 1414(m), 1185(s), 807(m), 598(m), 440(m) $cm^{-1}$.

**Synthesis of $[CdL(H_2O)_2]_n$ (1):** A mixture of $Cd(ClO_4)_2 \cdot 6H_2O$ (0.15 mmol) and $H_2L$ (0.15 mmol) was placed in a heavy-walled Pyrex tube containing DMF (0.3 mL) and $H_2O$ (0.3 mL). The tube was frozen in liquid $N_2$, sealed under vacuum, and then heated at 120 °C for two days. The colorless crystals were collected and washed with ethanol. Yield: 0.042 g [70%, based on $Cd(ClO_4)_2 \cdot 6H_2O$]. $C_{11}H_{12}CdN_2O_7$ (396.63): calcd. C 33.28, H 3.02, N 7.06; found C 33.54, H 2.69, N 7.07. IR (KBr pellet): $\tilde{\nu}$ = 3333 (s), 3053(w), 2967(w), 1709(s), 1653(s), 1593(s), 1559(s), 1496(s), 1440(m), 1391(s), 1348(m), 1297(w), 1227(m), 1162(w), 1140(m), 1089(w), 1026(w), 934(w), 920(m), 839(m), 771(s), 701(m), 606(m), 508(m) $cm^{-1}$.

**Synthesis of $[ZnL(H_2O)]_n$ (2):** A mixture of $Zn(ClO_4)_2 \cdot 6H_2O$ (0.15 mmol) and $H_2L$ (0.15 mmol) was placed in a heavy-walled Pyrex tube containing DMF (0.3 mL) and $H_2O$ (0.3 mL). The tube was frozen in liquid $N_2$, sealed under vacuum, and then heated at 120 °C for two days. The colorless crystals were collected and washed with ethanol. Yield 0.027 g [54%, based on $Zn(ClO_4)_2 \cdot 6H_2O$]. $C_{11}H_{10}N_2O_6Zn$ (331.58): calcd. C 39.81, H 3.01, N 8.44; found C 39.71, H 2.77, N 8.42. IR (KBr pellet): $\tilde{\nu}$ = 3322 (s), 3051(w), 2971(w), 1710(s), 1630(s), 1567(w), 1497(s), 1408(s), 1346(s), 1293(m), 1238(m), 1167(m), 1143(m), 1085(w), 1024(w), 943(w), 916(m), 866(w), 769(s), 703(m), 625(m), 524(m) $cm^{-1}$.

**X-ray Crystallographic Study:** Diffraction intensities for **1** and **2** were collected at 293 K with a Bruker P4 diffractometer by employing graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Empirical absorption correction was applied with the use of the SADABS program.[24] The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ by using the SHELXS-97 and SHELXL-97 programs, respectively.[25] All non-hydrogen atoms were refined anisotropically. The C–H hydrogen atoms were placed in geometrically calculated positions; the O–H hydrogen atoms were located from Fourier difference maps and kept fixed in that position. The selected bond lengths and bond angles for **1** and **2** are listed in Table 1, and the crystallographic data are summarized in Table 3.

Table 3. Crystal data and structure refinement parameters for compounds **1** and **2**.

# Bis(formamidine–urea) Complexes of $Ni^{II}$ and $Cu^{II}$: Synthesis, Characterization, and Reactivity

**David D. Díaz,[a][‡] Sayam Sen Gupta,[a] Jane Kuzelka,[a] Marcin Cymborowski,[c] Michal Sabat,[b] and M. G. Finn*[a]**

**Keywords:** Formamidine ligand / Urea ligand / Nickel / Copper / Catalysis

A novel chelating chiral bis(formamidine–urea) ligand was synthesized and used to prepare the corresponding $Ni^{II}$ and $Cu^{II}$ complexes. Spectroscopic and X-ray crystallographic analysis of the former revealed that the urea moiety of the acyclic tetradentate ligand is deprotonated and binds to the square-planar $Ni^{2+}$ ion through amide nitrogen atoms. This complex showed quasi-reversible redox behavior in cyclic voltammetry, with $E_{1/2}$ = 640 mV vs. $Cp_2Fe^+/Cp_2Fe$ corresponding to the $Ni^{III}/Ni^{II}$ couple. The Cu complex was shown by EPR spectroscopy to also adopt a square-planar geometry [$g_{\|}$ = 2.25 ($A_{\|}$ = 184 G), $g_{\perp}$ = 2.06 at 6 K], and reduction was found to be irreversible, perhaps due to the rigid nature of the tetradentate ligand. The nickel complex was found to be a modestly active catalyst for epoxidation of electron-rich alkenes under Mukaiyama's conditions, likely involving a radical mechanism.

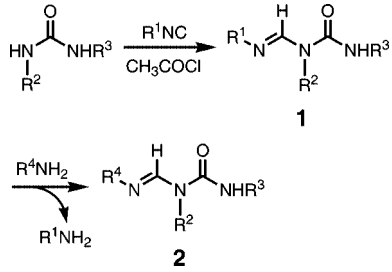
## Introduction

The coordination chemistry of urea and substituted ureas with nickel(II) is a topic of significant interest primarily because these compounds serve as structural and functional models of the metalloenzyme urease.[1–4] This enzyme activates the otherwise inert urea molecule toward hydrolysis by coordination of the substrate to one or both $Ni^{II}$ ions located at the active site, ultimatedly affording carbon dioxide and ammonia.[5–7] Considerable research has been dedicated to investigating the interaction of nickel(II) with urea[1–3,8–10] and urea derivatives.[11–13] X-ray crystallographic analysis of these compounds indicates that the geometry around the metal ion is typically octahedral and coordination of urea to $Ni^{2+}$ occurs predominately through the oxygen atom, although cases in which urea nitrogen atoms are involved in binding have been identified.[13,14] It is possible to stabilize higher oxidation states of nickel by coordination of deprotonated amides, as demonstrated by tetra(amido) macrocyclic ligands.[15,16] Because high-valent nickel complexes are believed to be the active catalytic species in epoxidation reactions,[17] complexes in which urea binds nickel(II) through a deprotonated amide nitrogen atom may function as robust oxidation catalyst precursors.

We recently reported a practical synthesis of the formamidine–ureas **1** by condensation of substituted urea derivatives with isocyanides in the presence of acid chloride (Scheme 1).[18] The imine fragment of these compounds undergoes exchange with primary nitrogen nucleophiles to afford the derivatives **2**, at rates determined primarily by the electron-donating ability of the formamidine–urea substituents.[19–21] Using this synthetic methodology, we report the preparation and characterization of the chiral bis(formamidine–urea) ligand **4** and its mononuclear nickel(II) (**5**) and copper(II) (**6**) complexes (Scheme 2). To the best of our knowledge, this is the first example of a chiral multidentate urea-based acyclic ligand that binds metal ions through the *endo* nitrogen of the deprotonated urea in a square-planar



Scheme 1. Synthesis of formamidine–ureas **1** and subsequent imine exchange with primary amines to afford formamidine–urea derivatives **2**.

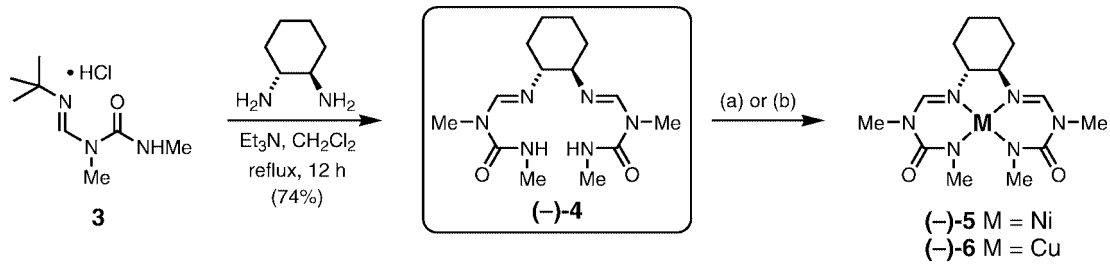

Scheme 2. Synthesis of compounds [Ni($N_4$L)] (**5**) and [Cu($N_4$L)] (**6**). (a) 3 equiv. $Ni(OAc)_2{\cdot}4H_2O$, $CH_3CN$, 45 °C, 91%. (b) 1 equiv. $Cu(OAc)_2{\cdot}H_2O$, $CH_3OH$, 50 °C, 76%.

geometry. The ability of **5** to catalyze olefin epoxidation is also described.

## Results and Discussion

### Synthesis of Ligand $H_2N_4L$ (4) and Coordination Compounds [Ni($N_4$L)] (5) and [Cu($N_4$L)] (6)

The displacement of *tert*-butylamine from 2 equiv. of 1-(*tert*-butyliminomethyl)-1,3-dimethylurea hydrochloride (**3**) and (1*R*,2*R*)-(–)-1,2-diaminocyclohexane afforded the bis(formamidine–urea) ligand **4** in 74% yield (Scheme 2). Although ligand **4** was very easily made, the practical synthesis of bis(formamidine–ureas) cannot yet be said to be modular, because changes in the components gave widely different yields and sometimes severe difficulties in purification (data not shown). Addition of excess nickel(II) acetate to a gently heated solution of **4** in MeCN gave the red-brown complex **5**. Deprotonation of both amide nitrogen atoms of **4** (substantiated by electrospray ionization mass spectrometry with good agreement of the isotopically resolved mass peaks with the theoretical distribution, elemental analysis, and single-crystal X-ray crystallography) was achieved without addition of external base. The analogous reaction of **4** and copper(II) acetate afforded the purple complex **6**, in which ligand **4** was again found to be in its doubly-deprotonated form. Attempts to obtain pure complexes of other transition metals were not successful.

### Structural Characterization of [Ni($N_4$L)] (5)

Single X-ray quality crystals of compound **5** were obtained by slow vapor diffusion of $Et_2O$ into a saturated solution of **5** in $CH_3CN$. X-ray structure analysis revealed the geometry of the metal center to be approximately square planar, as shown in Figure 1. Ligation of the nickel ion by tetradentate **4** is accomplished by the two imine and two deprotonated urea nitrogen atoms. Due to the greater basicity of the oxygen lone pair, it is typical for the urea oxygen atom rather than the nitrogen atom to bind transition metals. Both coordination modes should be accessible with ligand **4**, and we suggest that binding through the nitrogen atom is not geometrically enforced. The preference for N-donor coordination may be linked to the low spin nature of $Ni^{II}$ in **5**. The average $Ni–N_{urea}$ bond length is approximately 1.89 Å, which compares favorably with Ni–N bond lengths in complexes bearing anionic N-based ligands.[8,14,22,23] Deprotonation of the nitrogen atom results in delocalization through the urea moiety as evidenced by the short N(1)–C(1) and N(6)–C(6) distances of ca. 1.34 Å. These bond lengths are in good agreement with those of a related nickel(II) complex bearing both deprotonated NH (N–C ca. 1.31 Å) and neutral $NH_2$ urea groups (N–C ca. 1.43 Å).[8] The geometry at the deprotonated urea nitrogen atom is approximately trigonal planar with bond angles ranging from 111–121°. The Ni atom rests centrally in the binding pocket (the $N_{urea}–Ni–N_{imine}$ bond angles are both approximately 89.5°) and the ligand is twisted to relieve potential steric interactions between the two terminal urea *N*-methyl groups, presumably in a manner dictated by the chiral 1,2-diaminocyclohexane backbone.

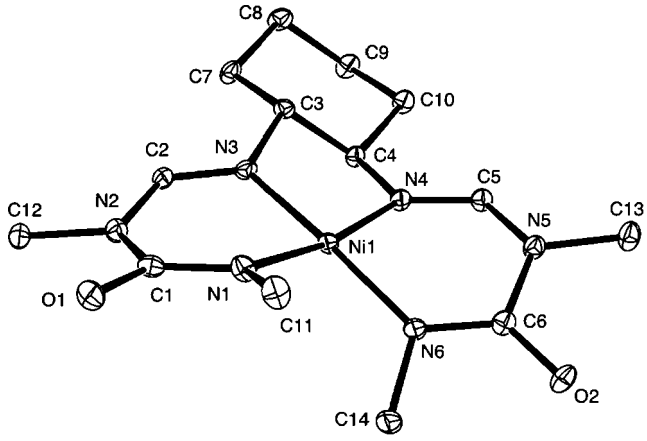

Figure 1. ORTEP diagram of [Ni($N_4$L)] (**5**) showing 50% probability ellipsoids for all non-hydrogen atoms.

### EPR Spectroscopy of [Cu($N_4$L)] (6)

Compound **6** was obtained as a crystalline solid from MeOH/$Et_2O$. The crystals suffered from the same crystallographic difficulties as **5** (pseudomerohedral twinning) and satisfactory refinement of the molecule was not possible. Examination of **6** by EPR spectroscopy, however, provided insight into the metal ion coordination geometry. A frozen glass of **6** (2:1 EtOH/MeOH) gave a four-line EPR spectrum at 6 K typical of square-planar copper(II) compounds, as shown in Figure 2.[24] ESI-MS and elemental

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

analysis of **6** indicate loss of two protons from the ligand, and we speculate that the detailed structure of this compound is very similar to its nickel(II) analogue **5**.

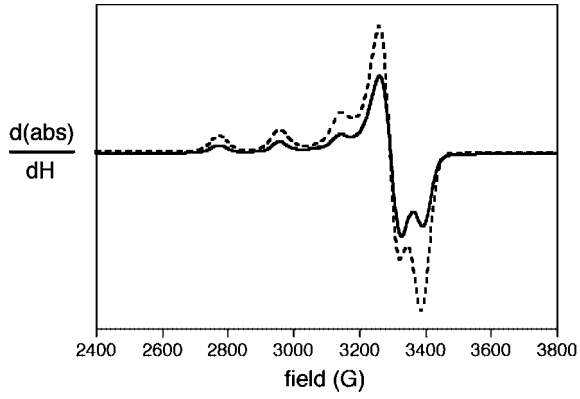

Figure 2. Solid line: X-band EPR spectrum of [Cu($N_4$L)] (**6**) as a frozen solution (5 mM in 2:1 EtOH/MeOH) at 6 K. Dotted line: simulated spectrum giving the values $g_{\|}$ = 2.248 ($A_{\|}$ = 185 G), $g_{\perp}$ = 2.08, linewidth parameter = 55 G.

### Electrochemical Studies

Cyclic voltammograms (CVs) of **5** in $CH_2Cl_2$ were recorded to investigate the ease of oxidation of the $Ni^{II}$ center. The CV of compound **5** reveals a quasi-reversible one-electron redox wave with an $E_{1/2}$ value of 650 mV ($\Delta E_p$ = 80 mV) vs. $Cp_2Fe^+/Cp_2Fe$, corresponding to the $Ni^{III}/Ni^{II}$ couple (see Supporting Information). The $E_{1/2}$ value of **5** is 1.2 V more positive than that of a related square-planar nickel(II) tetra(amide) macrocycle,[15] but comparable to square-planar $[Ni(cyclam)]^{2+}$ ($E_{1/2}$ = 560 mV vs. $Cp_2Fe^+/Cp_2Fe$) and its derivatives.[16,25,26] The deprotonated urea ligand of **5**, therefore, does not favor the formation of a high valent $Ni^{III}$ species. The CV of complex **6** shows an irreversible reduction wave (data not shown). The enforced square-planar geometry of the bis(formamidine–urea) ligand does not permit the corresponding copper(I) species to form. This finding is not surprising, given the preference of $Cu^{I}$ for nonplanar coordination geometries.

### Epoxidation Studies

Nickel(II) complexes of macrocyclic tetraamines such as cyclam,[17] salen-type ligands,[27] and *N*,*N*′-disubstituted oxamides[28] are catalysts for epoxidation reactions using iodosylbenzene or dioxygen (in presence of aldehydes) as oxidants. The similarity in $E_{1/2}$ values between **5** and $[Ni(cyclam)]^{2+}$ complexes prompted us to explore the catalytic activity of **5**, and *trans*-stilbene was chosen as the model substrate for a variety of oxidation conditions. The results of our initial experiments are outlined in Scheme 3. In the presence of 2-methylpropanal, dioxygen and **5** at 50 °C (Mukaiyama's conditions[29]), *trans*-stilbene oxide was produced in 73% yield. The use of aqueous sodium hypochloride with 4-Å molecular sieves afforded the epoxide in 66% yield, but twice as much catalyst was needed, presumably due to partial hydrolysis of **5** in the presence of water (see below). No epoxidation was observed when PhIO was used as terminal oxidant in $CH_2Cl_2$ in the presence of 10 mol-% of **5**, and low yields of epoxide were obtained with *t*BuOOH (10 mol-% **5**, 3 equiv. *t*BuOOH in isooctane, 2 equiv. pyridine, $CH_2Cl_2$). Activated alkenes such as *trans*-anethole were unreactive under Mukaiyama conditions (Table 1), and $Ni(OAc)_2{\cdot}5H_2O$ as catalyst did not promote the epoxidation of substrates for which **5** was effective, demonstrating that complexation of $Ni^{II}$ to **4** is necessary for catalysis.

- **5** (10 mol-%), $O_2$ (1 atm), 2 $Me_2CHCHO$, 50 °C, 1,2-dichloroethane, 15 h, 73%
- **5** (20 mol-%), 4 NaOCl (aq.), 4-Å mol. sieves, r.t., $CH_3CN$, 15 h, 66%
- **5** (10 mol-%), 1 PhIO, r.t., $CH_2Cl_2$, 15 h, no reaction

Scheme 3. Epoxidation of *trans*-stilbene using [Ni($N_4$L)] (**5**) as catalyst under different conditions.

Table 1. Epoxidation of olefins using [Ni($N_4$L)] (**5**) as catalyst under Mukaiyama's conditions (1 equiv. alkene, 0.1 equiv. **5**, 1 atm $O_2$, 2 equiv. isobutyraldehyde, $CH_2Cl_2$, 50 °C, 12–20 h). Yields are of products purified by column chromatography on alumina and giving satisfactory spectroscopic characterization. Isomer ratios were determined by $^1$H NMR spectroscopy.

| Entry | Olefin | Product | Yield [%] |
|---|---|---|---|
| 1 | *trans*-stilbene | *trans*-epoxide | 73 |
| 2 | *cis*-stilbene | *cis*- + *trans*-epoxides | 4, 61 |
| 3 | styrene | epoxide | 58 |
| 4 | α-Me-styrene | epoxide | 51 |
| 5 | *trans*-β-Me-styrene | *trans*-epoxide + benzaldehyde | 62, 4 |
| 6 | *p*-OMe-*trans*-β-Me-styrene | *trans*-epoxide + aldehyde | 65, 5 |
| 7 | 1,2-dihydronaphthalene | epoxide | 26 |
| 8 | cyclohexene | epoxide | 53 |
| 9 | 1-Me-cyclohexene | epoxide | 47 |
| 10 | cyclooctene | epoxide | 51 |
| 11 | 1-octene | epoxide | 49 |
| 12 | 2-hexen-1-ol | epoxide | 31 |
| 13 | 1-bromo-4-pentene | epoxide | 44 |
| 14 | geranyl benzoate | 6,7-epoxide + diepoxide | 41, 29 |

Table 1 summarizes the ability of **5** to epoxidize a variety of unfunctionalized alkenes under Mukaiyama's conditions using 10 mol-% catalyst (the use of less catalyst gives very poor yields of oxidized products after 24 h). Epoxides were obtained in moderate yields from *trans* di- and tri-substituted alkenes (Entries 1, 5, 6, 12, 14). Geranyl benzoate, bearing electronically dissimilar double bonds, afforded a mixture of regioisomers (Entry 14). Both *cis* and *trans* epoxides (1:15, Entry 2) were isolated from *cis*-stilbene, whereas *trans*-stilbene gave the *trans*-epoxide exclusively (Entry 1). In two cases, approximately 5% of benzaldehyde was also formed (Entries 5, 6). Di- and tri-substituted cyclic olefins were found to be modestly reactive (Entries 7, 8, 9, 10). Acid-sensitive epoxides could be isolated in moderate yields (Entries 3, 4, 5, 8), and a variety of functional groups

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were tolerated (Entries 6, 12, 13, 14). However, electron-deficient olefins such as 2-cyclohexen-1-one or methyl methacrylate were unreactive to **5**. No enantiomeric excess was detected in products isolated from reactions catalyzed by enantiopure **5**.

The above observations are all consistent with the dominance of a radical oxidation mechanism. Furthermore, epoxidation does not occur in the presence of the one-electron acceptor 2,6-di-*tert*-butyl-4-methylphenol. Aside from requiring somewhat higher concentrations, the catalytic properties of **5** are similar to those of nickel(II) compounds supported by tetradentate sulfonamide,[26] and di-*N*,*N*′-substituted oxamide ligands,[27] and differ from the cyclam- and salen-based systems, which are not catalytically active under Mukaiyama's conditions. Compound **5**, in the presence of aldehyde and dioxygen, probably generates an acylperoxy radical, as proposed by Valentine and co-workers,[30] which has been shown to be a competent oxidant for olefin epoxidation. Although the $E_{1/2}$ values of **5** and $[Ni(cyclam)]^{2+}$ complexes are comparable, epoxidation of alkenes by **5** and PhIO was not observed. This is probably due to the inability of **5** to generate the kind of high-valent oxo–nickel species that is the active oxidant in such processes.[17]

## Conclusions

Complexes of a bis(formamidine–urea) ligand have been made here for the first time in the form of the mononuclear species [Ni($N_4$L)] (**5**) and [Cu($N_4$L)] (**6**). X-ray crystallography and EPR studies indicate that these coordination compounds adopt a square-planar geometry. In contrast to most nickel(II) urea complexes, the urea component of this multidentate urea-based acyclic ligand binds the metal center through a deprotonated amide nitrogen bond. Examination of **5** by CV indicates that access to the +3 oxidation state is possible, as indicated by quasi-reversible redox waves, although the redox potentials are more comparable to nickel complexes of tetra(amine) ligands than tetra(amido) derivatives. Compound **5** was found to be a moderately active epoxidation catalyst for electron-rich olefins operating by a radical mechanism, as evidenced by product distributions and the quenching of the process upon addition of a radical scavenger. We are currently preparing variations in the general structure, with the goal, among others, of producing a more active and enantioselective $Ni^{II}$ catalyst.

## Experimental Section

**General Remarks:** All solvents and reagents were ACS reagent grade or better and were used as received or purified in an appropriate manner. Compound **3** was synthesized according to the published procedure.[18]

**A) Physical Measurements:** Optical spectra were collected with a Hewlett–Packard 8453 diode-array spectrophotometer. NMR spectra were obtained with a 200 MHz Varian Mercury instrument. Elemental analyses were performed by Microanalytical Labs (Indianapolis, IN), and high-resolution MS by the mass spectrometry facility at The Scripps Research Institute. ESI-MS were recorded with an Agilent 1100 LC/MS spectrometer eluting with $CH_3OH$/$H_2O$ (90:10). IR spectra were obtained with a MIDAC FTIR instrument using samples dispersed on a horizontal attenuated total reflectance (HATR) accessory (Pike Instruments). Melting points were measured in a Thomas Hoover capillary melting point apparatus and are uncorrected. TLC analysis was facilitated by the use of phosphomolybdic acid or anisaldehyde/EtOH stains, in addition to UV light with fluorescent-indicating plates (silica gel on aluminum, Sigma). Analytical HPLC was performed with Hewlett–Packard series 1100 instrument, using a commercial chiral column (Chiralcel OD; *i*PrOH/hexane, 0.5 mL min$^{-1}$).

**B) Electrochemistry:** Cyclic voltammograms were recorded with a Bioanalytical Systems Epsilon potentiostat. The cell contained a glassy carbon working electrode, a Pt wire pseudoreference electrode, and a platinum wire auxiliary electrode, with 0.5 M $Bu_4N(PF_6)$ in $CH_2Cl_2$ as the supporting electrolyte. All measurements were externally referenced to ferrocene.

**C) EPR Study:** Frozen solution EPR spectra of **6** were recorded at 6 K with a Bruker Model E500 of the ELEXSYS series spectrometer operating at 9.47 GHz (University of California, San Diego). The spectrum was simulated using the Bruker SimFonia program as a powder spectrum for $S = 1/2$, $I = 3/2$ (assuming 100% natural abundance $^{63}Cu^{2+}$), with the resulting parameters listed in the caption to Figure 2. The simulated spectrum closely matches the observed one with the use of only an axial g tensor, with no need to include a rhombic distortion.

**D) X-ray Crystallographic Study:** X-ray quality crystals were obtained by slow vapor diffusion of $Et_2O$ into a saturated of **5** in $CH_3CN$. Data collection was carried out at 103 K with a Rigaku R-AXIS RAPID single-crystal diffractometer equipped with the R-AXIS3S area detector.[31] Intensities were corrected for absorption with the transmission factors ranging 0.854–0.900. Successful structure solution by direct methods and full-matrix refinement[32] were accomplished in the monoclinic space group $P2_1$ with two independent molecules of the complex in the unit cell. The final $R$ and $R_w$ values were 0.035 and 0.084, respectively, for 10404 reflections with $I > 2\sigma(I)$. All H atoms were found in difference Fourier maps and refined with isotropic thermal displacement parameters. The final difference Fourier map was essentially featureless with the highest peak of 0.45 e/Å$^3$.

CCDC-615365 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**E) Typical Procedure for Epoxidation Studies:** 2-Methylpropanal (21 μL, 0.22 mmol) and **5** (10 μL of 1.0 M $CH_2Cl_2$, 0.01 mmol) were added to a solution of *trans*-stilbene (20 mg, 0.11 mmol) in 1,2-dichloroethane (1.1 mL) at room temperature. The reaction mixture was warmed to 50 °C and vigorously stirred for 15 h under $O_2$ (1 atm). The solvent was evaporated under reduced pressure and the residue was purified by column chromatography ($SiO_2$, 2% EtOAc/*n*-hexane) to give *trans*-stilbene oxide as a white solid (15.7 mg, 73%).

**Characterization Data**

***N*,*N*′-Dimethyl-*N*-[(*E*)-({1*R*,2*R*)-2-[((*E*)-{methyl[(methylamino)-carbonyl]amino}methylidene)amino]cyclohexyl}imino)methyl]urea ($H_2N_4L$, 4):** $Et_3N$ (0.75 mL, 5.31 mmol) was added to a solution of 1-(*tert*-butyliminomethyl)-1,3-dimethylurea hydrochloride (**3**) (1.0 g, 4.8 mmol) in dry $CH_2Cl_2$ (20 mL) and the resulting solution

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

was stirred for 5 min at room temperature under nitrogen. A solution of (1*R*,2*R*)-(–)-1,2-diaminocyclohexane (188 mg, 1.61 mmol) in dry $CH_2Cl_2$ (5 mL) was added and the mixture was refluxed for 12 h. The solvent was then removed by rotary evaporation and the residue was triturated with THF. The precipitate was separated by filtration and the filtrate was concentrated under reduced pressure. The residue was purified by flash chromatography on silica gel ($MeOH/CH_2Cl_2$, 9:1; $R_f$ = 0.5) to afford **4** as a hygroscopic white solid (370 mg, 74%). $^1H$ NMR ($CDCl_3$): $\delta$ = 1.23–1.39 (m, 6 H), 1.80 (m, 4 H), 2.78 (s, 6 H), 3.12 (s, 6 H), 7.65 (s, 2 H), 9.2 (br. s, 2 H) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 24.9, 26.9, 34.1, 34.3, 70.2, 152.0, 157.0 ppm. IR (thin film): $\tilde{\nu}$ = 3347, 3055, 2937, 2857, 1659, 1545, 1307, 1079 $cm^{-1}$. ESI-MS: +*m*/*z* (rel. int.) = 333 $[M + Na]^+$ (45), 312 (20), 311 $[M + 1H]^+$ (100). HRMS (+*m*/*z*): calcd for $C_{14}H_{27}N_6O_2$, 311.219; found 311.2190. M.p. 136 °C.

**$[Ni(N_4L)]$ (5):** Solid $Ni(OAc)_2{\cdot}4H_2O$ (119 mg, 0.48 mmol) was added to a stirred solution of **4** (50 mg, 0.16 mmol) in $CH_3CN$ (2 mL). The resulting red mixture was heated to 45 °C for 1 min, after which time TLC analysis showed complete consumption of **4**. Excess $Ni(OAc)_2{\cdot}4H_2O$ was removed by filtration and the solvent was evaporated under reduced pressure to afford **5** as a red oil (53 mg, 91%). For epoxidation studies, **5** was recrystallized from $CH_3CN/Et_2O$ to afford a red-brown crystalline solid. $^1H$ NMR (200 MHz, $CD_3OD$): $\delta$ = 1.17–1.23 (m, 4 H), 1.74–1.75 (m, 2 H), 1.94 (s, 2 H), 2.09–2.11 (s, 2 H), 2.41 (s, 6 H), 3.11 (s, 6 H), 7.30 (s, 2 H) ppm. $^{13}C$ NMR (50 MHz, $CD_3OD$): $\delta$ = 25.5, 29.3, 36.7, 38.1, 68.4, 153.5, 158.2 ppm. IR ( thin film): $\tilde{\nu}$ = 3297, 2886, 1687, 1590, 1470, 1289, 983, 858, 757 $cm^{-1}$. ESI-MS: +*m*/*z* (rel. int.) = 366 (100) $[M]^+$, 367 (19) $[M + 1H]^+$, 368 (39) $[M + 2H]^+$, 369 (9), 370 (5), 372 (1). For recrystallized material: $C_{14}H_{24}N_6NiO_2$: calcd. C 45.81, H 6.59, N 22.89; found C 45.86, H 6.64, N 22.91. UV/Vis (MeCN): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 439 nm (23.3).

**$[Cu(N_4L)]$ (6):** Solid $Cu(OAc)_2{\cdot}H_2O$ (31.9 mg, 0.16 mmol) was added to a solution of **4** (50 mg, 0.16 mmol) in MeOH (5 mL) in a single portion. The purple mixture was heated to 50 °C for 5 min, after which time TLC analysis showed complete reaction of **4**. Evaporation of the solvent under reduced pressure afforded a residue that was successively washed with cold $CH_3CN$ (2 × 1 mL) and $Et_2O$ (2 × 1 mL). The resulting solid was dried under high vacuum for 48 h to afford **6** as hygroscopic blue-purple solid (45 mg, 76% yield). Single crystals were grown by slow vapor diffusion of $Et_2O$ into a saturated solution of **6** in MeOH. IR (thin film): $\tilde{\nu}$ = 3238, 2860, 1661, 1598, 1481, 1293, 906, 862, 767 $cm^{-1}$. ESI-MS: +*m*/*z* (rel. int.) = 371 (100) $[M]^+$, 372 (18) $[M + 1H]^+$, 373 (47) $[M + 2H]^+$, 374 (7). $C_{14}H_{24}CuN_6O_2$: calcd. C 45.21, H 6.50, N 22.60; found C 45.22, H 6.49, N 22.62. UV/Vis (MeCN): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 573 nm (119).

**Supporting Information** (see also the footnote on the first page of this article): Two pages with hydrolysis kinetics and cyclic voltammetry data.

## Acknowledgments

We thank the Skaggs Institute for Chemical Biology for support of this work. D. D. thanks the Spanish MECD for a postdoctoral fellowship. We are grateful to Professor Karsten Meyer at the University of California San Diego for allowing us access to his EPR spectrometer, Mr. Patrick Feng for collecting the spectrum of **6**, and Prof. David Goodin of TSRI for its simulation. We also acknowledge Dr. A. D. Lozano at McMaster University for useful suggestions and the Mass Spectrometry Laboratories of TSRI and UAM (SIdI).

# Bis(dithiolene) Molybdenum Complex that Promotes Combined Coupled Electron–Proton Transfer and Oxygen Atom Transfer Reactions: A Water-Active Model of the Arsenite Oxidase Molybdenum Center

**Hideki Sugimoto,*[a] Makoto Tarumizu,[a] Hiroyuki Miyake,[a] and Hiroshi Tsukube[a]**

**Keywords:** Bioinorganic chemistry / Electrochemistry / Molybdenum / Reaction mechanism / S ligands

Combined CEPT (coupled electron–proton transfer)/OAT (oxygen atom transfer) reactions were accomplished in $(Bu_4N)_2[Mo^{IV}O(bdtCl_2)_2]$ (**1**) and $(Bu_4N)_2[Mo^{VI}O_2(bdtCl_2)_2]$ (**2**) complexes in aqueous media. The reaction mechanism of the CEPT reaction was analyzed electrochemically and the conversion of **1** to **2** was revealed to proceed by a two-proton two-electron oxidative process. The structural and reaction profiles provide a new model for the arsenite oxidase catalytic center.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

One of the most challenging themes in the field of bioinorganic chemistry is to develop active site models that work in aqueous media. The molybdenum-containing oxotransferases typically utilize water as the ultimate source or sink of oxygen in the overall catalytic reaction, and the reaction is combined with coupled electron–proton transfer (CEPT) and oxygen atom transfer (OAT) reactions.[1] Thus, a model of the catalytic centers is an intriguing target. Interestingly, in all members of the DMSO reductase family, the molybdenum center consists of reduced ($Mo^{IV}$) and oxidized ($Mo^{VI}$) states, and is essentially coordinated by two dithiolene ligands.[1]

A large number of OAT reactions from the enzymatic substrates, $R_3NO$, $R'_2SO$, or $SeO_4^{2-}$, to the $Mo^{IV}$ complexes that have two dithiolene ligands have been used to model some reductases.[2] Furthermore, OAT reactions from $Mo^{VI}$ complexes having two dithiolene ligands to substrates have also been extensively explored.[3] However, the CEPT process has yet to be accomplished with Mo complexes having dithiolene ligands. Even in the large number of mononuclear $Mo^{VI}$ complexes reported,[4] only two complexes have been reported to promote CEPT processes. $[LMo^{IV}O(py)(SC_6H_5)]$ and $[LMo^{IV}(p\text{-}O\text{-}C_6H_4\text{-}OC_2H_5)_2]\text{-}NO_3$ [L = hydrotris(3,5-dimethyl-1-pyrazolyl-borato)] were successfully converted to $[LMo^{VI}O_2(SC_6H_5)]$ and $[LMo^{VI}O(p\text{-}O\text{-}C_6H_4\text{-}OC_2H_5)_2]NO_3$, respectively, in water-containing solvents by two-step CEPT processes, and the resulting $Mo^{VI}$ complexes exhibited OAT reactions.[5]

We report herein the first example of chemistry that combines CEPT/OAT reactions in molybdenum complexes having dithiolene ligands. The $(Bu_4N)_2[Mo^{IV}O(bdtCl_2)_2]$ complex (**1**) ($bdtCl_2$ = 3,6-dichloro-1,2-benzenedithiolate) is readily converted to $(Bu_4N)_2[Mo^{VI}O_2(bdtCl_2)_2]$ (**2**) in aqueous media ($CH_3CN/H_2O$, 5:7) by a CEPT process, and **2** further transfers the oxygen atom to arsenite. The structures and conversion process of **1**/**2** are very similar to those of the molybdenum center in arsenite oxidase (A.O.) (Scheme 1).[6] The reaction mechanism of the CEPT reactivity of **1** and a difference in the reactivity of **1**, **3** of bdt, and **5** of mnt are discussed (Figure 1: bdt = 1,2-benzenedithiolate and mnt = maleonitrile-1,2-ethylenedithiolate).

We have newly synthesized **1** because the solubility of previously reported $(Et_4N)_2[MoO(bdtCl_2)_2]$[3e] in aqueous media is very low. Five coordinate complex **1** exhibited one reversible $Mo^{V/IV}$ redox couple at 0.04 V (versus SCE) in $CH_3CN/H_2O$ (5:7) solution (pH = 9.0).[7] As the pH of the solution was increased from 9.0 to 12.5, the intensity of the current for the anodic process ($E_{pa}$) increased, whereas that of the cathodic process ($E_{pc}$) decreased (Figure 2, inset). This observation indicates that **1** is irreversibly oxidized at high pH. The electrolysis of the solution at pH = 12.0 and $E$ = 0.2 V was monitored by electronic spectral changes (Figure 2). As the electrolysis proceeded, the band centered at 540 nm increased in intensity and the color of the solution changed from yellow to red. The final spectrum was consistent with the electronic spectrum of **2**. A coulometric measurement during the electrolysis confirmed this reaction to be a two-electron oxidative process.

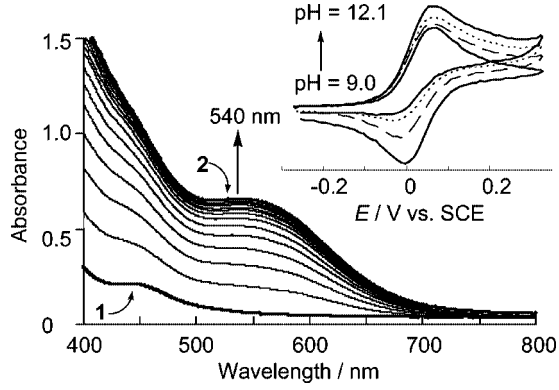

Figure 2. Electronic spectral changes during electrolysis of **1** ($3.5\cdot10^{-4}$ M) at 0.2 V (versus SCE) in $CH_3CN/H_2O$ (5:7) pH = 12.0. Spectra were recorded every six minutes. (inset) pH-dependent cyclic voltammograms (pH = 9.0, 11.3, 11.8, and 12.1, scan rate = 100 mV $s^{-1}$) of **1** ($5.4\cdot10^{-4}$ M) in $CH_3CN/H_2O$ (5:7).

Similarly, chemical oxidation of **1** with 2 equiv. of $K_3[Fe(CN)_6]$ in the presence of 2 equiv. of *t*BuOK in $CH_3CN/H_2O$ (5:7) yielded $(Bu_4N)_2[MoO_2(bdtCl_2)_2]$ (**2**). Isolated **2** exhibited $\nu(Mo{=}O)_{asym}$ at 836 $cm^{-1}$ (IR: solid) and an ESI-MS peak cluster attributed to $\{[Mo^{VI}O_2(bdtCl_2)_2]^{2-} + Bu_4N^+\}^-$ (in $CH_3CN$). When 98% $H_2{}^{18}O$ was used instead of $H_2O$, $(Bu_4N)_2[Mo^{VI}O^{18}O(bdtCl_2)_2]$ (**2a**) was stoichiometrically formed and isolated in 95% yield, which exhibited $\nu(Mo{=}O)_{asym}$ at 801 $cm^{-1}$ (IR: solid) and gave an ESI-MS peak cluster attributed to $\{[Mo^{VI}O^{18}O(bdtCl_2)_2]^{2-} + Bu_4N^+\}^-$ (in $CH_3CN$, Figures 3 and S1).

In nonaqueous $CH_3CN$, **2** was obtained from **1** in the presence of $Bu_4NOH$ by the CEPT process.[8] The reversible $Mo^{V/IV}$ couple at –0.07 V[3e] became an irreversible wave upon addition of $Bu_4NOH$ to the $CH_3CN$ solution of **1**, increasing and decreasing the current intensities of $E_{pa}$ and $E_{pc}$, respectively. A plot of the $\Delta I_{pa}$ value against [$Bu_4NOH$]/[**1**] indicated that 2 equiv. of $Bu_4NOH$ was consumed in the conversion of **1** to **2** (Figure S2). The coulometric and UV/Vis measurements (Figure S3) during the electrolysis at 0.2 V also supported that the conversion of **1** to **2** was a two-electron oxidative process.

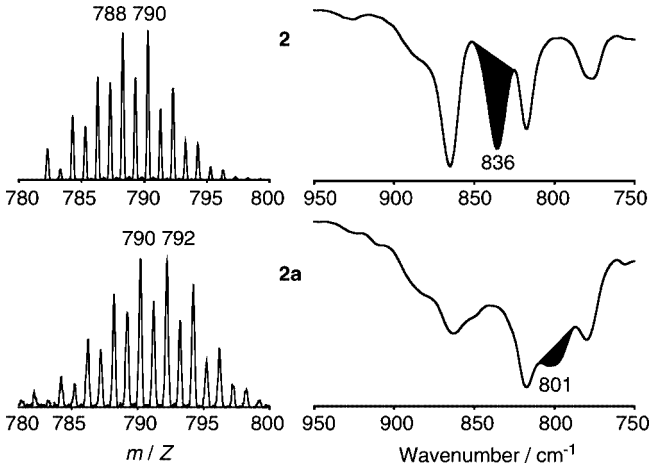

Figure 3. IR (solid) and ESI-MS (in $CH_3CN$) spectra of **2** (upper) with those of **2a** (lower).

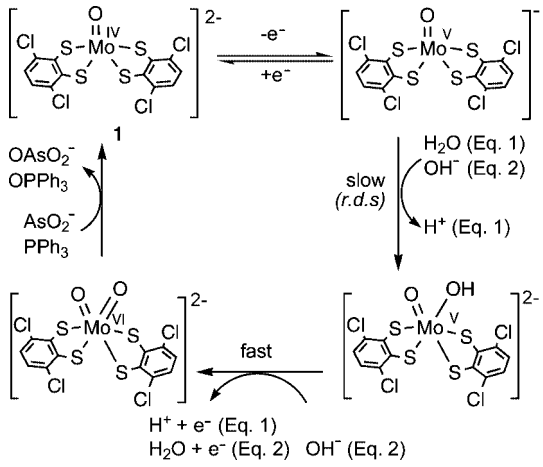
The above results obtained in aqueous and $CH_3CN$ solutions of **1** clearly indicate that the conversion of **1** to **2** occurs by a two-proton two-electron oxidative process. Because the irreversible structural change of **1** to **2** obeys the electrochemical *EC* mechanism, $OH^-$ binding with $[Mo^{V}O(bdtCl_2)_2]^-$ is involved in the rate-determining step (Scheme 2).[9] Stoichiometries of the conversions from **1** to **2** in $CH_3CN/H_2O$ (5:7) and $CH_3CN$ solutions are described in Equations (1) and (2). The reaction mechanism from **1** to **2** is quite different from that of the pyrazolylborate system.[5] The $MoO_2$ core having two $bdtCl_2$ ligands is formed in the $Mo^{VI}$ state and a $Mo^{V}$ species was not detected during the CEPT process. However, both $[LMo^{VI}O_2(SC_6H_5)]$ and $[LMo^{VI}O(p\text{-}O\text{-}C_6H_4\text{-}OC_2H_5)_2]NO_3$ are formed by two-step CEPT processes, in which the $MoO_2$ and MoO cores, respectively, are formed in the $Mo^{V}$ states; the intermediates $[LMo^{V}O_2(SC_6H_5)]^-$ and $[LMo^{V}O(p\text{-}O\text{-}C_6H_4\text{-}OC_2H_5)_2]$ have been characterized.[5,10] Furthermore, the coordination number of the molybdenum center changes from five to six when **1** is converted to **2** in our system, whereas the molybdenum centers maintain their six coordination structures in both the $Mo^{IV}$ and $Mo^{VI}$ complexes in the pyrazolylborate system. The electrochemical behavior of **1** is similar to that of the molybdenum center of arsenite oxidase; in both systems, five coordinate $Mo^{IV}O$ is converted to six coordinate $Mo^{VI}O_2$ by a two-proton two-electron process.[6]

$$[Mo^{IV}O(bdtCl_2)_2]^{2-}\ (\mathbf{1}) + H_2O \rightarrow [Mo^{VI}O_2(bdtCl_2)_2]^{2-}\ (\mathbf{2}) + 2H^+ + 2e^-\ (CH_3CN\text{-}H_2O) \quad (1)$$

$$[Mo^{IV}O(bdtCl_2)_2]^{2-}\ (\mathbf{1}) + 2OH^- \rightarrow [Mo^{VI}O_2(bdtCl_2)_2]^{2-}\ (\mathbf{2}) + H_2O + 2e^-\ (CH_3CN) \quad (2)$$

$[Mo^{IV}O(bdt)_2]^{2-}$ (**3**) and $[Mo^{IV}O(mnt)_2]^{2-}$ (**5**) exhibited markedly different reactivities in the CEPT process from that of **1** under the same conditions ([Mo] = 0.5 mM). Complex **3** was converted to $[Mo^{VI}O_2(bdt)_2]^{2-}$ (**4**) in $CH_3CN$ by a CEPT process in the presence of 2 equiv. of $Bu_4NOH$; however, **3** did not afford **4** by the CEPT process in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2. Proposed mechanism for the conversion of **1** to **2** by the CEPT process in $CH_3CN/H_2O$ (5:7) [Equation (1)] and $CH_3CN$ [Equation (2)] solutions, and further oxygen atom transfer.

$CH_3CN/H_2O$ (5:7). An aspect of the reversible $Mo^{V}/^{IV}$ wave at –0.20 V in $CH_3CN/H_2O$ (5:7) was intact up to pH = 14, and the electrolysis of the solution at 0.1 V resulted in the formation of $[Mo^{V}O(bdt)_2]^-$. On the other hand, **5** decomposed to $Mo_2O_7^{2-}$ by oxidative electrolysis at 0.55 V (versus SCE) both in $CH_3CN/H_2O$ (5:7) and $CH_3CN$ solutions.[11] The drastic difference in the reactivities observed among **1**, **3**, and **5** may be based on the electron donating properties of the dithiolene ligands employed, which controls the stability of each $Mo^{V}O$ center. The values of the $Mo^{V}/^{IV}$ couples (0.04 for **1**, –0.20 V for **3**,[2a] and 0.45 V for **5**[3a] in solutions of $CH_3CN/H_2O$) indicate that the electron donating properties of the dithiolene ligands increases in the order bdt > $bdtCl_2$ > mnt. The comparison of the CEPT reactivity of **1** with those of **3** and **5** suggests that $bdtCl_2$ offers a $Mo^{V}O$ center with suitable acidity to bind $OH^-$ to afford a $Mo^{V}O(OH)$ complex which undergoes successive CEPT processes without decomplexation (Scheme 2).[12] The bdt ligand probably provides a weaker acidic $Mo^{V}O$ center. Thus, the $Mo^{V}O$ complex is stable, less reactive, and does not readily bind to $OH^-$ in aqueous media, in where the activities of both the $Mo^{V}O$ center and the $OH^-$ anion are decreased by the buffer action of $H_2O$. Therefore, $Mo^{V}O$ can bind the $OH^-$ anion of $Bu_4NOH$ in the $CH_3CN$ solution, in where the activities of both the $Mo^{V}O$ center and the $OH^-$ anion are increased by solvent effects. Conversely the mnt ligand provides a $Mo^{V}O$ center with high acidity. Because the $Mo^{V}O$ center is too unstable, it can be concluded that $Mo^{V}O(OH)$ decomposes by oxidative hydrolysis before the complex undergoes the CEPT process, although the decomplexation process is unclear at this stage.

It was found that **2** stoichiometrically oxidized $AsO_2^-$ and $PPh_3$ to $AsO_3^-$ and $OPPh_3$, respectively, and was converted to **1** in the $CH_3CN/H_2O$ solution (Scheme 2).[13]

The present study has achieved, for the first time, a combination of CEPT/OAT reactions in aqueous media for molybdenum complexes having dithiolene ligands (Scheme 2). The $Mo^{IV}O$ complex of $bdtCl_2$, **1**, was converted into the $Mo^{VI}O_2$ complex, **2**, by a one-step CEPT process and the reaction mechanism was analyzed electrochemically. The similarity of the reaction profile of our system with that of the molybdenum center of the arsenite oxidase system suggests that this model can be very helpful in understanding the reaction mechanism occurring at the molybdenum center of the arsenite oxidase as well as to develop active site models that work in water.

## Experimental Section

**General:** All reagents and solvents were used as received unless otherwise noted. $CH_3CN$ was dried with $CaH_2$ and then $P_2O_5$ and distilled under an atmosphere of nitrogen prior to use. A dry 10% $Bu_4NOH/CH_3OH$ solution was purchased from Tokyo Chemical Industry (TCI) and stored in the presence of molecular sieve. Each reaction was carried out under an atmosphere of argon in either a Schlenk tube or a Miwa DB0–1KP glove box.

**Preparations:** All complexes were synthesized under an atmosphere of nitrogen. Complexes **3** and **5** were prepared as described in the literature.[2a,3a]

$(Bu_4N)_2[Mo^{IV}O(bdtCl_2)_2]$ (**1**) was prepared in the same manner as $(Et_4N)_2[Mo^{IV}O(bdtCl_2)_2]$[3e] with the use of $(Bu_4N)_2[Mo^{VI}O_2(bdtCl_2)_2]$ (**2**) instead of $(Et_4N)_2[Mo^{VI}O_2(bdtCl_2)_2]$.[3e] $C_{44}H_{76}Cl_4MoN_2OS_4$ (1015.12): calcd. C 52.06, H 7.55, N 2.76; found C 51.99, H 7.53, N 2.76.

$(Bu_4N)_2[Mo^{VI}O_2(bdtCl_2)_2]$ (**2**): *Method A:* **1** (13.9 mg, 0.014 mmol), $K_3[Fe(CN)_6]$ (9.2 mg, 0.028 mmol), and *t*BuOK (3.1 mg, 0.028 mmol) were dissolved in $CH_3CN/H_2O$ (5:7, 300–420 μL). The red solution was concentrated to about 300 μL. Red microcrystalline powder precipitated out of the solution, which was collected by filtration. Yield: 13.7 mg (95%). $C_{44}H_{76}Cl_4MoN_2O_2S_4$ (1031.11): calcd. C 51.25, H 7.43, N 2.72; found C 50.90, H 7.41, N 2.61. *Method B:* **2** was prepared in the same manner as $(Et_4N)_2[Mo^{VI}O_2(bdtCl_2)_2]$[3e] with the use of $Bu_4NOH$ instead of $Et_4NOH$.

$(Bu_4N)_2[Mo^{VI}O^{18}O(bdtCl_2)_2]$ (**2a**) was prepared by method A as per **2** with the use of 98% $H_2{}^{18}O$ instead of $H_2O$. Yield: 13.7 mg (95%). $C_{44}H_{76}Cl_4MoN_2O^{18}OS_4$ (1033.11): calcd. C 51.15, H 7.41, N 2.71; found C 51.29, H 7.58, N 2.74.

**Physical Measurement:** FTIR spectra were recorded with a Perkin–Elmer Spectrum One. UV/Vis spectra were recorded with a Unisoku USP-801 spectrometer with an optical fiber attachment. Molar absorption coefficients were corrected by measuring $[Ru(2,2'\text{-bipyridyl})_3](PF_6)_2$ as an authentic sample. GC- and ESI-MS spectra were recorded with a Shimazu GC–MS-QP5050A and a JEOL JMS-700S, respectively. Cyclic voltammograms were recorded under an atmosphere of nitrogen with the use of a Hokuto Denko HZ-3000 potentiostat. A three-electrode configuration consisting of a glassy-carbon working electrode, a SCE reference electrode, and a platinum counter electrode was used.

**Supporting Information** (see footnote on the first page of this article): The isotope distribution pattern of the calculated mass spectrum as $\{[MoO^{18}O(bdtCl_2)_2]^{2-} + Bu_4N^+\}^-$ (Figure S1), cyclic voltammograms of **1** in $CH_3CN$ in the presence of 0–2 equiv. $Bu_4NOH$ and a plot of $\Delta I_{pa}$ versus $[Bu_4NOH]/[\mathbf{1}]$ (Figure S2), and electronic spectral changes during electrolysis of **1** in the presence of 2 equiv. $Bu_4NOH$ at 0.2 V (versus SCE) in $CH_3CN$ (Figure S3).

[6] a) P. J. Ellis, T. Conrads, R. Hille, P. Kuhn, *Structure* **2001**, *9*, 125–132; b) T. Conrads, C. Hemann, G. N. George, I. J. Pickering, R. C. Prince, R. Hille, *J. Am. Chem. Soc.* **2002**, *124*, 11276–11277; c) K. R. Hoke, N. Cobb, F. A. Armstrong, R. Hille, *Biochemistry* **2004**, *43*, 1667–1674.

[7] Because **1** still does not dissolve in $H_2O$, mixed solvent, $CH_3CN/H_2O$ (5:7), was used instead. This ratio offered a maximized % volume of $H_2O$.

[8] A dry 10% $Bu_4NOH/CH_3OH$ solution was used.

[9] The $Mo^{IV}$ center of **1** does not bind $H_2O$ or $OH^-$ because the $E_{pa}$ value of the $Mo^{IV/V}$ couple and the electronic spectrum did not change at high concentrations of $OH^-$. $[Mo^{V}O(bdtCl_2)_2]^-$ that was characterized structurally and spectroscopically[3e] was stable only in aqueous media at pH < 9 and in $CH_3CN$.

[10] Recently, it was reported that $[Mo^{VI}(bdt)_3]$ was converted to $[Mo^{VI}OH(bdt)_3]^{2-}$ in the presence of $H_2O$, and the two $[Mo^{VI}(OH)(bdt)_3]^-$ oxidized one $PPh_3$ to give one $OPPh_3$, one $H_2O$, and two $[Mo^{V}(bdt)_3]^-$. In that case, the six coordination structure of $[Mo(bdt)_3]^{n-}$ may require a $Mo^{VI}$ center of strong acidity to bind $OH^-$, whereas in the case of $[MoO(bdtCl_2)_2]^{n-}$, the $Mo^{V}$ center can bind $OH^-$ because of the five coordinate structure. A. Cervilla, F. Perez-Pla, E. Llopis, M. Piles, *Inorg. Chem.* **2005**, *44*, 4106–4108.

[11] $Mo_2O_7^{2-}$ was identified by ESI-MS of the solution. Sarkar et al. reported that the oxidation of $[MoO(mnt)_2]^{2-}$ resulted in the formation of $MoO_4^{2-}$.[3a] In solution, $Mo_2O_7^{2-}$ and $MoO_4^{2-}$ are in an acid–base equilibrium.

[12] The $\nu(Mo^{IV,V}=O)$ stretching values (IR: solid) 910 and 941 $cm^{-1}$ for the $bdtCl_2$ complexes, 905 and 935 $cm^{-1}$ for the bdt complexes, and 928 $cm^{-1}$ [$\nu(Mo^{IV}=O)$] for the mnt complex support that the order of acidity of the molybdenum centers is bdt < $bdtCl_2$ < mnt. The $Mo^{V}$ complex of mnt is too unstable to be isolated and characterized.[3a]

[13] The stoichiometric oxidations of $PPh_3$ and $AsO_2^-$ by **2** were confirmed by $^1H$ NMR, UV/Vis, and ESI-MS spectroscopy. However, the reaction mechanism of the oxidation of $AsO_2^-$ by **2** could not be analyzed because the reaction was too fast to follow. The oxidation of $PPh_3$ by **2** was kinetically analyzed in ref.[3e]

# Supramolecular Intercluster Compounds Consisting of Gold Clusters and Keggin Anions

Martin Schulz-Dobrick[a] and Martin Jansen*[a]

**Keywords:** Supramolecular chemistry / Cluster compounds / Polyoxometalates / Nanomaterials / Gold clusters

Supramolecular intercluster compounds, that is, assemblies of different, well-defined inorganic building blocks with diameters of >1 nm, consisting of $[Au_9(PPh_3)_8]^{3+}$ clusters and Keggin anions $[PW_{12}O_{40}]^{3-}$ were synthesized as single-crystals by a diffusion method. Depending on the solvent combination, two modifications with different core geometries of the gold cluster and different overall packing type can be obtained as a single-phase in macroscopic amounts. This approach leads toward the study of nanostructured matter with high translational symmetry and the principles of nanoscopic self-assembly.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Supramolecular chemistry aims to organize molecular building blocks by means of noncovalent interactions into complex arrangements.[1] Efforts to synthesize suitable building blocks, to develop methods for their assembly, and understand the underlying fundamental principles are currently driven over all magnitudes – ranging from molecules to nano-, *meso*-, and macroscopic compounds.[1,2] In particular, nanoscopic self-assembly is envisioned to be the alternative to lithographic techniques for future electronic or optic devices. By the assembly of different building blocks into superlattices, materials can be obtained that exhibit new properties that are due to cooperative effects. One step in this direction are binary nanoparticle superlattices.[3] Recently, progress has been made in the experimental realization of such compounds, which gives insight into the driving forces of nanoparticle crystallization.[4] Depending on the types of interaction (van der Waals, hard sphere, or ionic interaction) and the relative size of the ligand stabilized nanoparticles, a whole variety of packing types were observed.

Although the principles of self-assembly and the interparticle interactions vary over the different magnitudes, one rule holds for all: the quality of the arrangements depends on the uniformity of the building blocks. This prerequisite is commonly fulfilled very well for a molecular assembly but not for the assembly of nanoparticles (except protein crystallization), which exhibit an intrinsic size distribution. The resulting violations of translational symmetry on the atomic scale would undermine at least some of the enthusiastic expectations connected to the properties of nanostructured matter. Anyhow, such defects would thwart structure determinations with atomic resolution, which is an important prerequisite for a detailed understanding of structure-directing forces and the resulting physical properties. Our approach for overcoming these limitations is based on the generation of supramolecular intercluster compounds (SICC), that is, assemblies of different, well defined, inorganic building blocks with diameters of 1 nm or larger.

The variety of inorganic clusters that have been studied in manifold, and clusters of several nanometers in size have been uniformly synthesized and crystallized.[5,6] Only a few examples of compounds consisting of different inorganic clusters have been reported and all are constructed of different polyoxometalates as anionic building blocks.[7,8]

SICCs can be seen as a bridge between the molecular self-assembly and the self-assembly of nanoparticles. While the latter is dominated by nondirectional interactions of spherical particles leading to more or less densely-packed structures that can mostly be derived from simple ionic or intermetallic compounds, the arrangements in the former are strongly dependent on the shape of the molecules and directional interactions, which can lead to structures with either low symmetry or density. For SICCs, a tendency for structures with a dense packing of the clusters can be expected. However, because of deviations from a perfect spherical shape, local directional, or steric interactions, a wide range of arrangements might be realized. Because of the size of the building blocks, voids filled with solvent molecules are likely to occur in such arrangements. Unlike binary nanoparticle superlattices, it is possible to grow SICCs as single-crystals with high translational order, such that details of the supramolecular arrangements can be elucidated by X-ray diffraction.

## Results and Discussion

In this communication, we report the crystallization and structural characterization of the first supramolecular intercluster compounds consisting of different types of building units, the gold cluster $[Au_9(PPh_3)_8]^{3+}$ and the Keggin anion $\alpha$-$[PW_{12}O_{40}]^{3-}$. It is noteworthy that the $[Au_9(PPh_3)_8]^{3+}$ cluster although being one of the first gold clusters to be discovered,[9,10] accessible in gram-scale quantities, and widely investigated, has never been characterized by single-crystal X-ray diffraction because of heavy disorder. Structural characterization of $Au_9^{3+}$ clusters was successful only by the employment of *para*-substituted ligands.[10–12] In the solid state, two skeletal isomers of $[Au_9(PR_3)]^{3+}$ clusters were found; in solution the clusters undergo fast rearrangements.

The mixing of solutions of $[Au_9(PPh_3)_8](NO_3)_3$ and $(NBu_4)_3[PW_{12}O_{40}]$ in acetonitrile leads to a microcrystalline, orange precipitate of the 1:1 compound $[Au_9(PPh_3)_8][PW_{12}O_{40}]$ (**1**). For growing single-crystals for X-ray diffraction, an interdiffusion method was employed. The building blocks were separately dissolved in solvents of different density and layered carefully on top of each other. Depending on the types of solvents and the concentration, two types of crystals were obtained, orange needles of compound **1** and greenish-black plates or prisms of a second compound **2**. Both compounds contain $[Au_9(PPh_3)_8]^{3+}$ and $\alpha$-$[PW_{12}O_{40}]^{3-}$ in a 1:1 ratio, but exhibit different $Au_9$ skeletal isomers and packing types. Although in some solvent combinations simultaneous growth of both compounds was observed, **1** and **2** can be obtained selectively in DMF-acetonitrile and DMF-acetone, respectively.

Compound **1** crystallizes in the tetragonal space group *P*4/*n* with two formula units in the unit cell.[13] The skeletal geometry of the $[Au_9(PPh_3)_8]^{3+}$ cluster, which is located on a four-fold axis, resembles the shape of a centered crown with eight Au atoms surrounding the central Au1 atom (Figure 1a). The radial Au–Au bond lengths are 266.2(1) pm and 266.9(1) pm and the peripheral bond lengths are 277.7(1) pm and 280.6(1) pm. This centered crown geometry was first observed in the related $[Au_9\{P(p\text{-}C_6H_4OMe)_3\}_8](BF_4)_3$.[12] The central P atom of the Keggin anion $\alpha$-$[PW_{12}O_{40}]^{3-}$ resides on a position exhibiting $\bar{4}$ symmetry (Wyckhoff position 2a) and the whole anion is found to be ordered (Figure 1b). The W–O and P–O bond lengths of this well-known anion are in agreement with those previously found in other crystal structure determinations.[14] Figure 2 shows the overall packing of **1**, which can be derived from the CsCl structure type. Both the gold cluster and the Keggin anion are coordinated by each other in the form of distorted cubes. The distortion originates mainly from the nonspherical shape of the $Au_9$ cluster. Furthermore, the eight peripheral Au atoms can be divided into an upper and lower part of the crown. Four Au atoms, respectively, are bonded to $PPh_3$ ligands pointing directly towards the corners (4 × Au2) and the edges (4 × Au3) of the coordination cube (Figure 3). The distances between the central Au1 and the central P1 of the Keggin anions are 1339 pm and 1444 pm. This separation leads to the slight distortion of the $Au_9$ skeleton from the $D_{4d}$ symmetry with the Au2–Au2 distances [344.8(1) pm] being shorter than the Au3–Au3 distances [350.2(1) pm]. The gold clusters exhibit close contacts not only to the eight Keggin anions (H···O distances 230–250 pm) but also to six neighboring gold clusters (H···H distances <270 pm), which is expected for the CsCl packing type. The Au1–Au1 distances are 1367 pm and 1723 pm and can be regarded as an approximation for the short and long van der Waals diameters of the gold cluster. The van der Waals diameters of $[PW_{12}O_{40}]^{3-}$, which is not perfectly spherical as well, can be estimated to range from 1050 pm to 1350 pm. As both building blocks are oriented with their short diameters parallel to the *c* axis, a relatively dense packing is achieved. The estimated radii ratios of 0.75–0.80 are close to the theoretical value of 0.73, which is calculated for touching spheres with cubic coordination. Although the estimation of the radii ratios for such building blocks with a rather irregular surface seems to be a rough approximation, it can be concluded that the CsCl structure-type is at least a very dense and therefore effective packing for this intercluster compound. A search for voids in the crystal structure (PLATON,[15] probe radius 1.2 Å) led to a value of 11.5% of the accessible volume. The largest voids (202 Å$^3$) can be found in between two adjacent Keggin anions that lie along [001].

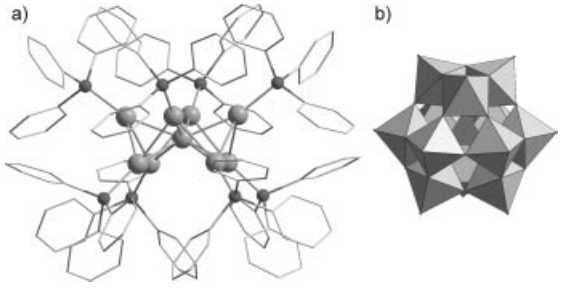

Figure 1. a) Structure of the crown isomer of the $[Au_9(PPh_3)_8]^{3+}$ cluster. Hydrogen atoms are omitted for clarity. b) Structure of the Keggin anion $\alpha$-$[PW_{12}O_{40}]^{3-}$ in polyhedral representation.

Compound **2** crystallizes in the space group *C*2/*c* with four formula units in the unit cell.[13] Different from **1**, the $[Au_9(PPh_3)_8]^{3+}$ cluster is not in the crown skeletal geometry but in a "butterfly-shaped" geometry (Figure 4a), which was first observed in the compound $[Au_9\{P(p\text{-}C_6H_4Me)_3\}_8](PF_6)_3$.[12] The cluster resides on a crystallographic site of $C_2$ symmetry (4e). While the ligand shell exhibits only this $C_2$ symmetry, the symmetry of the Au skeleton is close to $D_{2h}$. The radial Au···Au bond lengths range from 266.1(1) pm to 273.8(1) pm and the corresponding peripheral bond lengths vary from 278.8(1) pm to 292.6(1) pm. Thus, the average Au···Au bond lengths and their variations are considerably larger than those of the crown isomer. The Keggin anion was found to be disordered over two orientations with the resulting superposition exhibiting inversion symmetry (Wyckhoff position 4d). This kind of disorder has been encountered several times before for Keggin anions and can be realized by 90° rotations

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

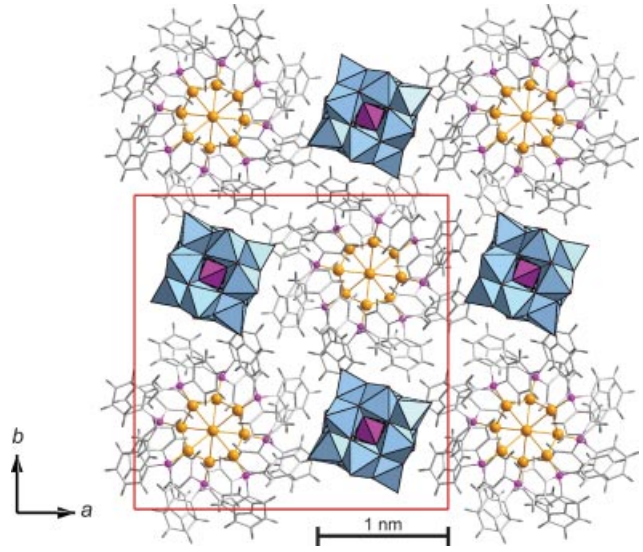

Figure 2. View of the crystal structure along [001]. The Keggin anions are located at $z = 0$ and the gold clusters at $z = 0.42$ and $z = 0.58$, respectively.

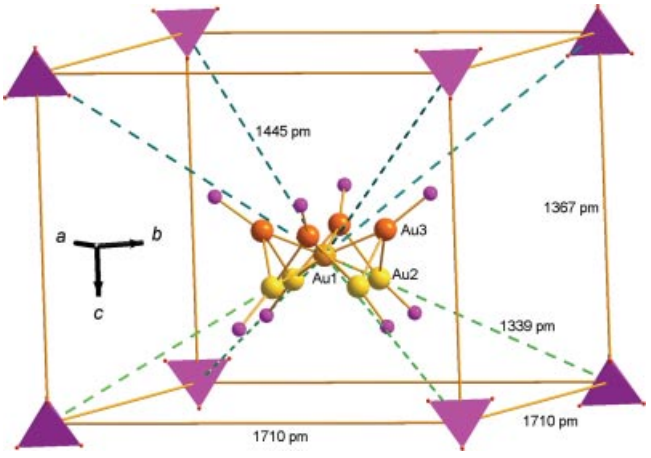

Figure 3. Coordination of the gold cluster by eight anions. The ligands of the peripheral Au atoms are pointing directly towards (Au2, yellow spheres) or in between (Au3, orange spheres) the anions.

along one of the $\bar{4}$ axes of the central tetrahedron.[16] In Figure 4b, it can be seen that the outer silhouette of the two orientations is almost equal, so that this crystallographic disorder is likely to occur. The packing scheme of **2** can be derived from the NaCl structure-type (Figure 5). The Keggin anions are coordinated by six $[Au_9(PPh_3)_8]^{3+}$ clusters (shortest O···H contacts <250 pm) in the form of a distorted octahedra with center-to-center distances of 1300, 1304, and 1391 pm. Vice versa, the gold clusters are coordinated by six Keggin anions octahedrally as well. The gold clusters are oriented in such a way that the eight $PPh_3$ ligands, which surround the Au skeleton in almost a cubic fashion, point towards the eight faces of the coordination octahedron.

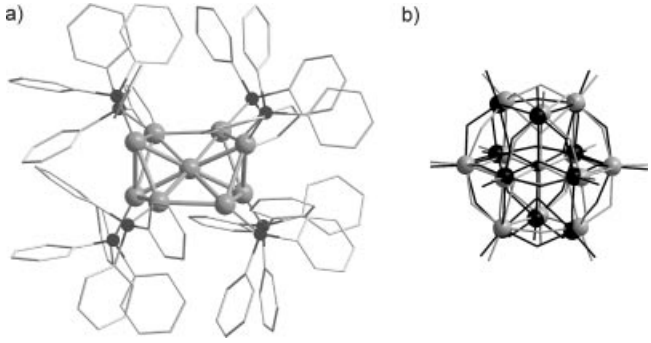

Figure 4. a) Structure of the "butterfly-shaped" isomer of the $[Au_9(PPh_3)_8]^{3+}$ cluster. Hydrogen atoms are omitted for clarity. b) Superposition of the two orientations of the α-$[PW_{12}O_{40}]^{3-}$ anion in **2**.

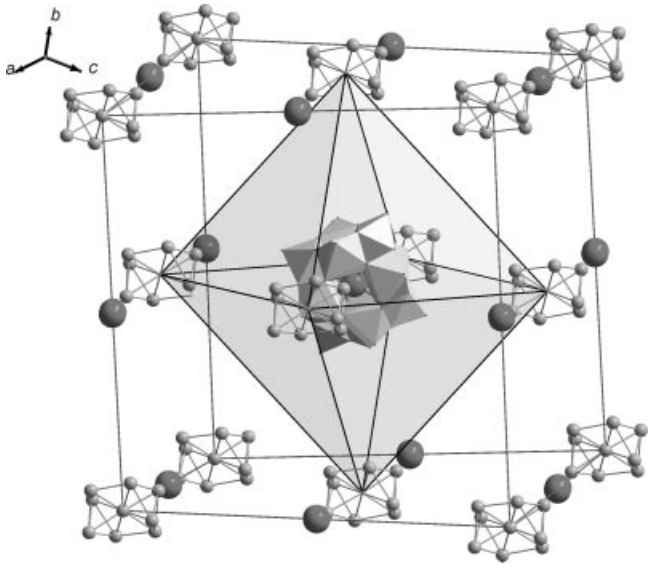

Figure 5. Similarity of the packing of **2** to the NaCl structure type: the gold clusters are packed face-centered cubic and the Keggin anions (dark grey spheres) occupy the octahedral voids.

The effective van der Waals diameter of the "butterfly-shaped" $[Au_9(PPh_3)_8]^{3+}$ isomer can be estimated to be about 1650 pm to 1750 pm. The silhouette of this isomer is more spherical than that of the crown isomer. In case of a regular closed packing of touching hard spheres with this diameter, the octahedral voids could occupy spheres with a diameter not greater than about 700 pm. The diameter of the Keggin anion (1050 pm to 1350 pm) is significantly larger than that, which has several consequences. First, not all of the twelve neighboring gold clusters are in close contact to the central gold cluster. The center-to-center distances in the distorted cuboctahedron vary from 1680 pm to 2108 pm. Furthermore, the misfit of the Keggin anions leads to substantial voids. The solvent accessible volume was calculated to be 19.6%. There appear to be four crystallographically equivalent solvent pockets per unit cell (average coordinates 0, 0.185, 0.25), but single solvent molecules could not be located during crystal structure refinement because of disorder. The crystals lose solvent molecules rapidly upon re-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

moval from the mother liquid. From geometric considerations about six molecules (DMF or acetone) per formula unit would fit into the voids.

## Conclusions

In conclusion, we have synthesized two representatives of SICCs in macroscopic amounts and determined their crystal structures. We think that this may become a versatile and efficient approach to new, well-defined, nanostructured materials. Currently, we are modifying the building-blocks in order to study the underlying principles of such supramolecular structures and their formation.

## Experimental Section

$Au_9(PPh_3)_8(NO_3)_3$ ("$Au_9$") and $Au_8(PPh_3)_8(NO_3)_2$ ("$Au_8$") were prepared by the reduction of $AuPPh_3NO_3$ with $NaBH_4$, and its subsequent reaction with excess triphenylphosphane according to the procedure given in ref.[17] α-$[n Bu_4N]_3PW_{12}O_{40}$ ("$PW_{12}$") was prepared by precipitation of an aqueous solution of commercially available tungstophosphoric acid with $nBu_4NBr$ and subsequent recrystallization from acetone.[18] **1**: Upon mixing acetonitrilic solutions of $Au_9$ and $PW_{12}$, an orange, microcrystalline powder of **1** precipitates immediately. Larger crystals can be obtained by an interdiffusion method, which was optimized in glass tubes with a diameter of 8 mm at 20 °C. Single-crystals of **1** were obtained by the careful layering of $Au_9$ in DMF (0.3 mL, 1 μmol/mL) followed by DMF/acetonitrile (1:1, 1.0 mL), and $PW_{12}$ in acetonitrile (0.3 mL, 1.5 μmol/mL). After several days, orange needles that tend to dendritic intergrowth form. If the diffusion is carried out with $Au_8$ as starting material, the $Au_8$ cluster rearranges back to the $Au_9$ cluster and **1** crystallizes as the only compound, which was checked by X-ray diffractometry. Interestingly, the obtained crystals are larger and less intergrown than those obtained with $Au_9$ as the starting material. Single-crystals suitable for X-ray diffraction were washed with acetonitrile, dried in air, and mounted on glass capillaries. Larger scale synthesis of **1** was carried out in glass tubes with a diameter of 2 cm. $[(nBu_4N)]_3PW_{12}O_{40}$ (133 mg, 36.9 μmol) in DMF (8 mL) was carefully layered with DMF/acetonitrile (1:1, 4 mL), followed by $Au_9(PPh_3)_8(NO_3)_3$ (100 mg, 24.6 μmol) in acetonitrile (8 mL). After 5 to 7 d, the orange needles were collected on a fine glass frit, washed with acetonitrile, and dried under vacuum. Yield: 142 mg (85%). ATR-IR (neat sample), $Au_9(PPh_3)_8^{3+}$: $\tilde{\nu}$ = 1586(w), 1571(w), 1479(m), 1436(m), 1384(w), 1331(w), 1310(w), 1185(w), 1161(w), 1097(m), 1028(w), 987(sh), 738(m), 707(m), 686(m); $PW_{12}O_{40}^{3-}$: $\tilde{\nu}$ = 1079(s), 977(s), 893(m), 808(s). The PXRD pattern corresponds to the calculated pattern from the single-crystal X-ray structure determination (see Supporting Information). Room-temperature unit cell parameters of $a$ = 2433.2 pm and $b$ = 1386.5 pm were determined by the Le Bail method.

The preparation of **2** as a single phase is more difficult, as the formation of **2** and **1** is dependent on the concentrations in the crystallization zone. In 8 mm tubes $Au_9$ in DMF (0.3 mL, 2.5 μmol/mL) followed by DMF/acetone (1:1, 0.8 mL) and $PW_{12}$ in acetone (0.3 mL, 3.0 μmol/mL) are carefully layered. After several days, greenish-black crystals appear, and the solution is still slightly yellow. The crystals lose solvent rapidly upon removal from the mother liquid and, as a consequence, turn opaque and diffract poorly. Thus, single-crystals for X-ray diffraction were directly transferred into inert oil, picked with a loop and cooled with liquid nitrogen. Up-scaling of the crystallization in larger tubes was not successful, as substantial amounts of **1** formed simultaneously. Instead, larger amounts of **2** were prepared by simply filling 12 to 16 of the small tubes at once. Yield: ca. 3.3 mg per tube (ca. 60%). ATR-IR (neat sample), $Au_9(PPh_3)_8^{3+}$: $\tilde{\nu}$ = 1584(w), 1569(w), 1478(m), 1434(m), 1383(w), 1308(w), 1182(w), 1161(w), 1096(m), 1027(w), 986(sh), 740(m), 706(m), 687(m); $PW_{12}O_{40}^{3-}$: $\tilde{\nu}$ = 1077(s), 974(s), 892(s), 806(s). The solvent loss is at least partially reversible. If the dried crystals are put into solvent, they turn transparent again. For powder X-ray diffraction the crystals were washed with DMF/acetone and acetone, dried in air, ground, and filled into a 0.7 mm capillary with additional solvent. The PXRD pattern corresponds to the calculated pattern from the single-crystal X-ray structure determination (see Supporting Information).

**Supporting Information** (see footnote on the first page of this article): Experimental and calculated PXRD patterns of **1** and **2**.

## Acknowledgments

The authors want to thank Dipl.-Chem. Hanne Nuss and Dr. Jürgen Nuss for single-crystal X-ray measurements, Alexandra Müller and Sven Drescher for preparative assistance, and the Fonds der Chemischen Industrie for financial support.

# A General and Facile One-Step Synthesis of Imido–Titanium(IV) Complexes: Application to the Synthesis of Compounds Containing Functionalized or Chiral Imido Ligands and Bimetallic Diimido Architectures

**Christian Lorber,*[a] Robert Choukroun,[a] and Laure Vendier[a]**

**Keywords:** Imido / N ligands / Multiple bonds / Titanium / Synthesis design

One-pot reactions of $Ti(NMe_2)_4$ with a wide range of primary alkyl, aryl, and silylamines $RNH_2$ in the presence of excess chlorotrimethylsilane produced the corresponding imido–titanium(IV) complexes $[Ti(=NR)Cl_2(NHMe_2)_2]$ (**1a–j**), in which R = *t*Bu, 1-adamantane, $Ph_3C$, $Ph_3Si$, Ph, 2,6-*i*$Pr_2$–$C_6H_3$, 2,6-$Cl_2$–$C_6H_3$, 2,6-$Br_2$–4-Me–$C_6H_2$, $C_6F_5$, and 3,5-$(F_3C)_2$–$C_6H_3$. This general synthesis, which starts from commercially available reagents, represents a simple and direct route to imido complexes. Reaction of complexes **1** with pyridine afforded the six-coordinate tris-pyridine adducts $[Ti(=NR)Cl_2(Py)_3]$ (**2**). Another advantage of this method is its tolerance to other functional groups; complexes that contain halides, ether, dialkylamino, cyano, ethynyl, olefin, and nitro substituents on the imido moiety have been prepared. The use of enantiomerically pure primary amines affords the first group of titanium complexes that contain chiral imido groups, and the use of diamines produces diimido complexes. Alternatively, $CH_3I$ has been used as an alkylating agent to generate titanium–imido complexes of the type $[Ti(NR)I_2(THF)_2]_2$. All compounds were fully characterized by spectroscopic methods (IR, $^1H$ NMR, $^{13}C$ NMR) and elemental analysis. Some of the compounds were also analyzed by single-crystal X-ray diffraction studies.

## Introduction

The last two decades have witnessed a strong interest in the coordination chemistry of transition-metal complexes that contain imido ligands $[NR]^{2-}$ (R = alkyl or aryl).[1] The dianionic π-donor terminal imido functional group is involved in many facets of chemistry that can be subdivided into two types: (1) reactions in which the imido group acts as a spectator ligand, the $[NR]^{2-}$ moiety is isolobal with $[C_5H_5]^-$[2] (e.g. in alkene metathesis[3] or olefin polymerization[1c,4–6]), (2) reactions in which the M = NR linkage itself is involved in stoichiometric or catalytic transformations such as metathesis reactions (with imines,[7] nitro- and nitrosoarenes,[8] or oxo–imido exchange[9]), C–H activation,[10] reactions with unsaturated C–C[11] or C–X bonds,[12] alkyne hydroaminations,[13,14] carboamination reactions,[15] and ring-opening reactions of strained heterocycles.[10d,16] Moreover, some imido derivatives have also found applications in material chemistry (OMCVD,[17] polyoxometalate[18]) and have been implicated in the ammoxidation of propene.[19]

As part of an ongoing study of vanadium complexes supported by various ligands,[20] we recently described the synthesis and molecular structure of the new terminal aryl–imido, and rare Cp-free, vanadium(IV)complex $[V(=N–2,6\text{-}iPr_2–C_6H_3)Cl_2(NHMe_2)_2]$.[5] We have further demonstrated that various aryl–imido groups could be very conveniently introduced by a one-pot synthesis from $V(NMe_2)_4$, the corresponding aniline, and chlorotrimethylsilane.[21] We have also studied the coordination chemistry of these new complexes with N- or P-donor neutral ligands,[21,22] and the results suggest that imido compounds of this type could lead to a large variety of vanadium coordination compounds. Furthermore, some of these imido–vanadium species have been shown to possess catalytic activities in olefin polymerization[5] and in alkyne hydroamination.[13a] Terminal imido–titanium complexes $[Ti(=N–t\text{Bu})Cl_2L_n]$ [$L_n$ = $(NHMe_2)_2$, $Py_2$, $Py_3$, TMEDA] have proven to be very useful synthons for the preparation of many other imido derivatives through chloride and/or ligand base exchange metathesis; aryl– and silyl–imido derivatives are available by transimination reactions with the appropriate aryl and silylamine.[6a,13d,17c,23–26] Some of these imido–titanium complexes present potential activity in olefin polymerization,[6] alkyne hydroamination,[13] and have been used for the synthesis of TiN thin films,[17a–17c] which further justifies the quest for the cheapest and the most direct route for the preparation of such useful precursors.

Two routes are commonly employed for the preparation of the now widely used synthon $[Ti(=N–R)Cl_2L_n]$ [$L_n$ = $(NHMe_2)_2$, $Py_3$]. In the first method, $[Ti(=N–tBu)Cl_2Py_3]$ is prepared from $TiCl_4$, $tBuNH_2$, and pyridine.[23] Nevertheless, other analogues (i.e. aryl–imido) cannot be obtained this way, and their synthesis requires a second step that consists of an imido/amine exchange reaction (transimination) of $[Ti(=N–tBu)Cl_2Py_3]$ with the appropriate arylamine.[23] Moreover, the presence of pyridine renders these compounds somewhat insoluble, and pyridine ligands may be unwanted for certain applications. During the course of our studies, imido–titanium complexes $[Ti(=N–R)Cl_2(NHMe_2)_2]$ have been prepared by Mountford et al. with a procedure based on the reaction of $Ti(NMe_2)_2Cl_2$ with a primary alkyl- or arylamine.[26] Although this route appears more general than the one with $TiCl_4$, the precursor $Ti(NMe_2)_2Cl_2$ is not commercially available and needs to be prepared from $TiCl_4$ and $Ti(NMe_2)_4$.[27]

In this paper, and as an extension of our imido–vanadium method[21] to titanium, we report on a very convenient, one-pot synthesis of a series of alkyl–, aryl–, and silyl–imido derivatives of titanium(IV) complexes of the general formula $[Ti(=NR)Cl_2(NHMe_2)_2]$ (**1**), where R is an alkyl-, an aryl-, or a silyl group. Part of this work [synthesis of $Ti(=NPh)Cl_2(NHMe_2)_2$] has been previously communicated.[13a] Our method presents the advantage to afford the imido derivative in one single step with the use of a very simple one-pot synthesis from commercially available $Ti(NMe_2)_4$, the corresponding primary amine $RNH_2$, and an excess of chlorotrimethylsilane. Another important goal of this study was to explore the selectivity and the functional group tolerance of the reaction. Amines that contain additional functionality on their skeletons (e.g. ether, dialkylamino, cyano, ethynyl, olefin, or nitro substituents) were successfully used to generate original imido derivatives. In consequence, our procedure appears to be applicable to a wide range of primary amines including enantiomerically pure amines (to afford chiral imido functions) and diamines (to afford diimido complexes). Related complexes with pyridine ligands prepared by the substitution of the $NHMe_2$ ligands in $[Ti(=NR)Cl_2(NHMe_2)_2]$ by pyridine (Py) donors is also described. Finally, an alternative preparation for the related iodo analogue complex $[Ti(NAr)I_2(thf)_2]_2$ is also described; this method is based on the use of $CH_3I$ instead of $Me_3SiCl$ (Scheme 3).

## Results and Discussion

This work constitutes a systematic investigation of the synthetic and structural chemistry of imido–titanium(IV) complexes of the general formula $[Ti(=NR)Cl_2(NHMe_2)_2]$ that are prepared directly from a one-pot reaction of $Ti(NMe_2)_4$, $RNH_2$, and $Me_3SiCl$, as well as some related compounds. The synthesis and proposed structures of the imido complexes of titanium(IV) are summarized in Schemes 1–3. The structures of eleven complexes are set out in Figures 2–7, and Figures 9, 10, 12, and 14, selected metric data are collected in Tables 1 and 2.

### 1. General Synthesis of the Imido Complexes $[Ti(=NR)Cl_2(NHMe_2)_2]$ and $[Ti(=NR)Cl_2Py_3]$

In our previous study,[21] we described the synthesis of paramagnetic aryl–imido–vanadium complexes $[V(=NAr)Cl_2(NHMe_2)_2]$ from the reaction of an aniline with $V(NMe_2)_4$ in toluene followed by the addition of an excess of chlorotrimethylsilane. Inspired by this result, we attempted to use a similar one-pot synthesis for the production of related titanium–imido analogue complexes, and the scope of this method was first illustrated with a range of primary amines listed in Scheme 2.

Scheme 2. General synthesis of imido–titanium(IV) complexes **1** and **2**.

When a toluene solution of $Ti(NMe_2)_4$ is reacted with one equiv. of $RNH_2$ [with R = *t*Bu, 1-adamantyl, $Ph_3C$, $Ph_3Si$, Ph, 2,6-*i*Pr$_2$–C$_6$H$_3$, 2,6-Cl$_2$–C$_6$H$_3$, 2,6-Br$_2$–4-Me–C$_6$H$_2$, C$_6$F$_5$, and 3,5-(F$_3$C)$_2$–C$_6$H$_3$] and an excess of chlorotrimethylsilane[28] (typically about 8 equiv.) at room temp. overnight, yellow–orange compounds $[Ti(=NR)Cl_2(NHMe_2)_2]$ [R = *t*Bu (**1a**), 1-adamantyl (**1b**), $Ph_3C$ (**1c**), $Ph_3Si$ (**1d**), Ph (**1e**), 2,6-*i*Pr$_2$–C$_6$H$_3$ (**1f**), 2,6-Cl$_2$–C$_6$H$_3$ (**1g**), 2,6-Br$_2$–4-Me–C$_6$H$_2$ (**1h**), C$_6$F$_5$ (**1i**), and 3,5-(F$_3$C)$_2$–C$_6$H$_3$ (**1j**)] are formed exclusively (Scheme 2). These complexes often separated by crystallization (while the reaction proceeds or upon the addition of pentane) as large, generally yellow–orange (for alkyl–imido) or red (for aryl–imido) needles or crystals with good yields (73–96%).

The detailed experimental protocols and full characterization are given in the Experimental Section. Compounds **1a**–**j** have been characterized by infrared spectroscopy (with strong $\nu_{NH}$ absorptions around 3250 cm$^{-1}$), multinuclear NMR spectroscopy, elemental analysis, and by X-ray structure determination for some (vide infra). The products are consistent with the proposed structure of a monomeric five-coordinate compound with 2 dimethylamine ligands that occupy the axes of the bipyramid. This one-pot synthesis cleanly affords a wide range of alkyl–, silyl–, and aryl–imido complexes $Ti(=NR)Cl_2(NHMe_2)_2$. It is important to note that titanium silyl–imido complexes remain comparatively rarer than their alkyl- or aryl analogues.[10b,12d,25,29]

When dissolved in pyridine, bis-dimethylamine adducts **1** are instantly and generally quantitatively converted into tris-pyridine complexes $[Ti(=NR)Cl_2(Py)_3]$ (**2**). In a few cases, it has been reported that the substitution of $NHMe_2$ ligands by pyridine is difficult or produces mixed $NHMe_2$–pyridine adducts.[21,26] Within this study, we have only experienced difficulties (vide infra) in the synthesis of one compound (namely **5** from **4**). We will not insist on this substitution reaction that has already been described by us on vanadium analogues,[21] and by Mountford on titanium complexes,[26] but these tris-pyridine complexes are generally obtained as large crystals with good X-ray quality that facilitates their structural characterization, vide infra (although they are sometimes poorly soluble in common organic solvents). In consequence, in this article we will refer to this substitution reaction only when a related tris-pyridine–imido compound was structurally characterized.

Single crystals of **2d** were grown from a $CH_2Cl_2$/pyridine solution of **2d** layered with pentane at room temp. and were analyzed by X-ray crystallography. A thermal ellipsoid plot is presented in Figure 1 along with selected bond lengths and angles in Table 1.

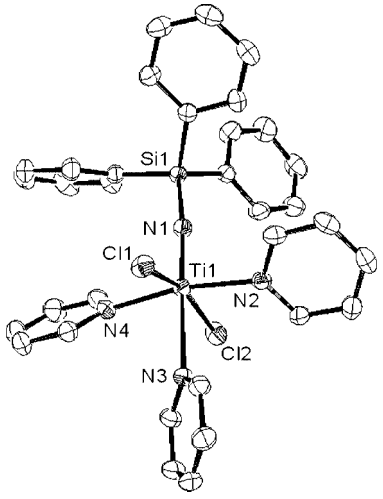

Figure 1. Molecular structure of **2d** with selected bond lengths [Å] and angles [°], which shows 50% probability ellipsoids and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

Compound **2d** adopts a pseudooctahedral geometry around the metal center with mutually *trans* chloride and pyridine ligands. The third pyridine ligand is disposed *trans* to the imido group. Bond lengths and angles are unexceptional and were found to be very similar to those observed in titanium[23,25] and vanadium[21] analogues; the titanium–nitrogen bond lengths of the imido fragment is 1.7110(13) Å, with an almost linear Ti–N$_{imido}$–Si angle [171.12(9)°], and an average Ti–Cl ca. 2.39 Å. The *trans* Ti–N(Py) of 2.4742(14) Å is significantly longer than the average *cis* Ti–N(Py) bond lengths [2.224(2) Å], which reflects the *trans*-labilizing ability of the imido ligand.

### 2. Tolerance to Functional Groups on the Imido Moiety in $[Ti(=NR)Cl_2(NHMe_2)_2]$ and $[Ti(=NR)Cl_2Py_3]$ Complexes

Functionalized organoimido complexes of titanium, that is complexes that contain additional functional groups on the imido moiety, are extremely rare.[23,30] Since we have easy

access to various Ti–imido complexes from readily available amines, it was of interest to probe the tolerance of our synthetic procedure towards the presence of functional groups on the alkyl/arylamine backbone, and also to learn the stability of the resulting functionalized imido compounds. The added functionality of the organoimido compounds may serve as an anchor to graft the complexes to a support, and their reactivity could be studied as well. We have already shown in the previous section that halides and $CF_3$-substituted anilines can be employed, and we have screened several other anilines and amines that contain ether, dialkylamine, cyano, alkyne, olefin, or nitro groups under the same conditions used above [$Ti(NMe_2)_4$, $RNH_2$, $Me_3SiCl$, toluene, room temp.]. These amines are depicted in Figure 2.

The general one-pot procedure proceeded as anticipated with anilines substituted with *p*-$NEt_2$, *p*-CN, *o*-CN, *p*-$HC=CH_2$, *o*-$MeC=CH_2$, *m*-C≡CH, and *m*-$NO_2$ groups with the formation of the expected corresponding bis-dimethylamine adducts $[Ti(=NAr)Cl_2(NHMe_2)_2]$ (**1k**–**q**) [with Ar = *p*-$Et_2N–C_6H_4$ (**1k**), *p*-$NC–C_6H_4$ (**1l**), *o*-$NC–C_6H_4$ (**1m**), *p*-$H_2C=CH–C_6H_4$ (**1n**), *o*-$MeC=CH_2–C_6H_4$ (**1o**), *m*-$HC≡C–C_6H_4$ (**1p**), and *m*-$O_2N$–*o*-$Me–C_6H_3$ (**1q**)]. Not surprisingly, some of these compounds have been easily converted into their tris-pyridine adducts $[Ti(=NAr)Cl_2(Py)_3]$ (**2**) by the addition of an excess of pyridine to the corresponding dimethylamine precursor. Only [Ti(=N–*p*-$NC–C_6H_4$)$Cl_2(Py)_3$] (**2l**) will be described later on as its molecular structure has been established (vide infra). These functional organoimido species have been characterized by means of spectroscopic methods (NMR, IR), and combustion analysis. The solution $^1H$- and $^{13}C$ NMR spectroscopic data present features similar to those of their nonfunctional analogues – a single set of resonances for the coordinated $NHMe_2$ ligands (in **1**) or two different pyridine ligands in the ratio 2:1 (in **2**), and resonances attributable to the or-

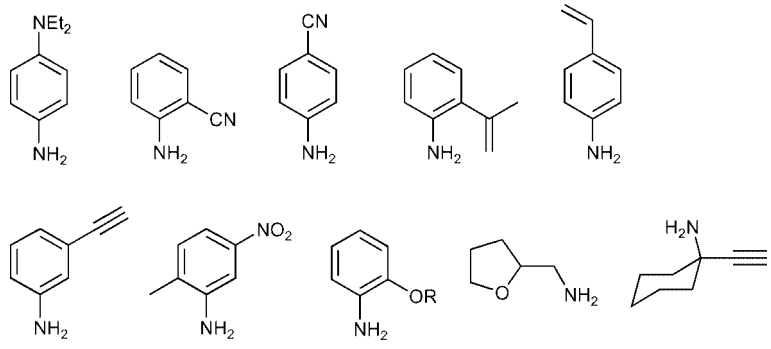

Figure 2. Functional amines used in this study.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ganoimido group. These data are consistent with the functional group that does not interact with the metal center. Indeed, according to the IR data, some of these functional groups are clearly observed in their normal regions ($\nu_{C\equiv N}$ 2243, 2242, and 2221 $cm^{-1}$, respectively, for **1l**, **1m**, and **2l**; $\nu_{C=C}$ 1624 and 1629 $cm^{-1}$, respectively, for **1n** and **2o**; $\nu_{C\equiv C}$ 2208 $cm^{-1}$ for **1p**; $\nu_{NO_2}$ 1517 $cm^{-1}$ for **1q**).

When reacted with $Ti(NMe_2)_4$ in the presence of chlorotrimethylsilane, 1-ethynylcyclohexylamine gave the imido complex $Ti[=N(C_6H_{10}C\equiv CH)]Cl_2(NHMe_2)_2$ (**1r**). Again, spectroscopic ($^1H$- and $^{13}C$ NMR) data suggest that the carbon–carbon triple bond does not coordinate to the titanium center. The corresponding pyridine analogue $[Ti[=N(C_6H_{10}C\equiv CH)]Cl_2(Py)_3]$ (**2r**), formed upon the addition of excess pyridine to **1r**, has been characterized by X-ray structure determination (vide infra) that clearly shows the free C≡C–H fragment.

Single-crystals suitable for X-ray diffraction studies were obtained for these functionalized organoimido compounds from room temp. toluene (**1k**, **1o**), cold toluene/pentane (**1p**), or pyridine-toluene/pentane (**2l**, **2r**) solutions. Thermal ellipsoid plots are presented in Figures 3, 4, 5, 6, 7; selected metric parameters are given in Table 1.

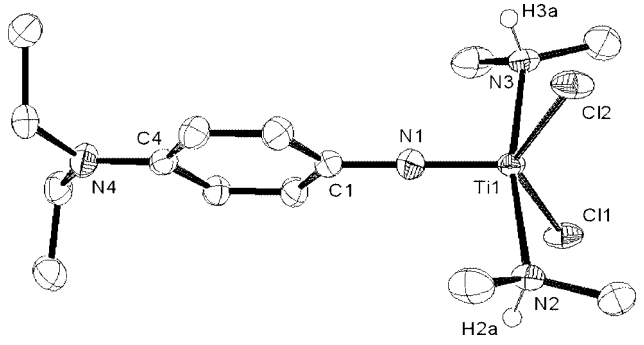

Figure 3. Molecular structure of **1k** with selected bond lengths [Å] and angles [°], which shows 50% probability ellipsoids and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

In the solid state, the molecular structure of the three $NHMe_2$ adducts (**1k**, **1o**, **1p**) is best described as distorted trigonal bipyramid with axial dimethylamine ligands [$\tau$ = 0.58 (**1k**), 0.63 (**1o**), and 0.57 (**1p**)],[31] with $N_{imido}$–Ti–Cl angles in the range 110–115°, and $N_{imido}$–Ti–$N_{NHMe_2}$ angles in the range 93–98°. The distances and angles associated with the titanium center and the ligands are comparable to those found in other $[M(=NR)Cl_2(NHMe_2)_2]$ complexes (M = Ti,[26] V[21]). Adducts **1k**, **1o**, and **1p** exhibit a short Ti–$N_{imido}$ distance of 1.6955(18) Å for **1k**, 1.7028(11) Å for **1o**, and 1.700(2) Å for **1p**. The imido linkage is almost linear [Ti–$N_{imido}$–$C_{ipso}$ angle = 178.21(15), 178.86(10), and 169.4(2)°, respectively, in **1k**, **1o**, and **1p**], and is consistent with the donation of the lone pair on nitrogen to an acceptor orbital on titanium (the imido Ti–N bond can be considered as a triple bond). The crystal structure determinations also unambiguously show noninteracting functional -$NEt_2$ (**1k**), -C(Me)=$CH_2$ (**1o**), and –C≡CH (**1p**) groups, with normal metric parameters that are listed in Table 1. Both of the chlorine atoms occupy equatorial sites

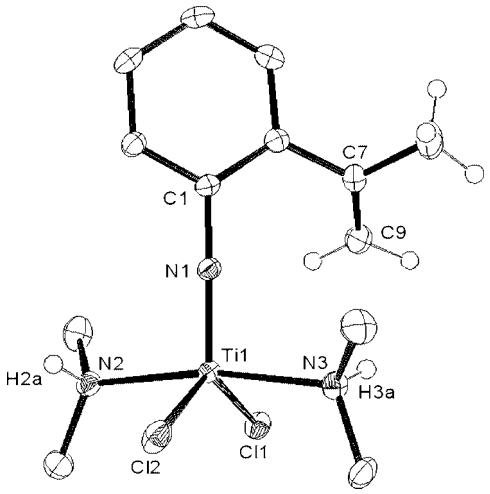

Figure 4. Molecular structure of **1o** with selected bond lengths [Å] and angles [°], which shows 50% probability ellipsoids and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

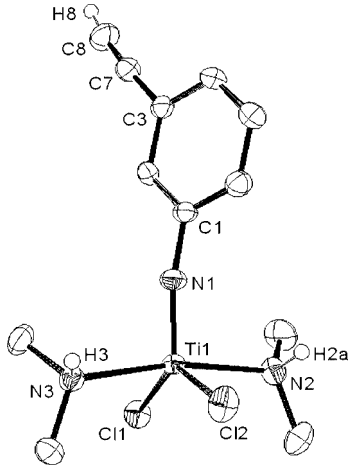

Figure 5. Molecular structure of **1p** with selected bond lengths [Å] and angles [°], which shows 50% probability ellipsoids and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

in the trigonal bipyridine with a Cl1–Ti–Cl2 angle of 132.86(3)°, 131.357(16)°, and 134.01(4) Å for **1k**, **1o**, and **1p**, respectively, and mean Ti–Cl bond lengths of 2.36 Å, 2.34 Å, and 2.33 Å for **1k**, **1o**, and **1p**, respectively. The two *trans* dimethylamino ligands form the axis of the bipyramid, and have mean Ti–$N_{NHMe_2}$ bonds of ca. 2.21 Å for the three compounds. The supramolecular structure is dominated by $Me_2N$–H···Cl hydrogen bonding (NH···Cl bond lengths are in the range 2.391 to 2.708 Å; associated N–H···Cl angles are 164.94 to 147.64°); features that they share with Mountford's related compounds.[26]

An ORTEP drawing of the molecular structure of **2l** and **2r** is shown in Figures 6 and 7, respectively. Crystals of **2r** contain one residual molecule of pyridine (not shown in Figure 6). In **2l**, the Ti–$N_{imido}$ and C≡N vectors lie on a crystallographic two-fold rotation axis. The pendant functional cyano (**2l**) and ethynyl (**2r**) group on the imido moieties do not bind to the titanium center. Compounds **2l** and **2r** adopt a pseudooctahedral geometry around the titanium

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

center similar to the one described above for **2d** (with mutually *trans* chloride and pyridine ligands, the third pyridine ligand is disposed *trans* to the imido group). Bond lengths and angles are normal, and found to be very similar to those observed in titanium[23] and vanadium[21] analogues, as well as in previously described **2d** (Table 1). The titanium–nitrogen bond length of the imido fragments are 1.726(2) Å (**2l**) and 1.6988(12) Å (**2r**) with an angle Ti–$N_{imido}$–$C_{ipso}$ of 180.0° (**2l**) and 174.31(10)° (**2r**), and Ti–Cl bond length of 2.3756(4) Å (**2l**) and 2.4353(5) and 2.3999(5) Å (**2r**).

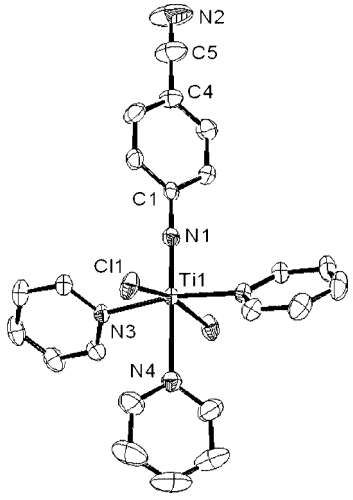

Figure 6. Molecular structure of **2l** with selected bond lengths [Å] and angles [°], which shows 50% probability ellipsoids and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

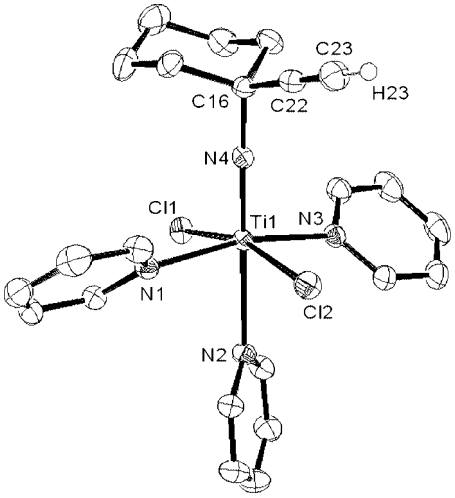

Figure 7. Molecular structure of **2r** with selected bond lengths [Å] and angles [°], which shows 50% probability ellipsoids and partial atom-labeling schemes. Hydrogen atoms and residual solvent (one molecule of pyridine) of crystallization are omitted for clarity.

Unlike the previous functional anilines, however, amines that contain an additional ether-function {i.e. 2-EtO–$C_6H_4NH_2$ and tetrahydrofurfurylamine [$H_2NCH_2$-$(CHO(CH_2)_3)$]} did not generate the bis-dimethylamine adduct, but rather reacted to afford the mono-dimethylamine adduct of the general formula [Ti($NR^o$)$Cl_2$($NHMe_2$)] [with $R^o$ = 2-EtO–$C_6H_4$ (**3**), and $CH_2(CHO(CH_2)_3)$ (**4**)] (Figure 8), as judged by spectroscopic ($NHMe_2$/$NR^o$, 1:1) and analytical data. The $^1$H- and $^{13}$C NMR spectra of **3** reveal diastereotopic methyl groups for the $NHMe_2$ ligand. Because of their poor solubility in common organic solvents, these compounds are probably imido-bridged dimers with the oxygen atom coordinated to the metal center.

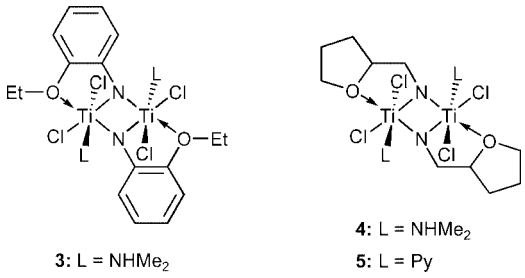

Figure 8. Proposed structure for complexes **3**–**5**.

Indeed, molecular structure determination (Figure 9) has unambiguously established that **3** is the centrosymmetric dimer [Ti[$\mu_2$-[N]-$\eta^1$[O]-N–2-EtO–$C_6H_4$]$Cl_2$($NHMe_2$)]$_2$, with two aryl–imido ligands that bridge two ($Me_2HN$)$Cl_2$Ti moieties. The O atom of the ether function is coordinated *cis* to the N atom of its own ligand set, *trans* to the N atom of the other imido group, and the chlorine atoms are mutually *cis* to one another. The coordination geometry of titanium is distorted octahedral. The $Ti_2N_2$ core is planar (torsion angle 0°) and is characterized by a short Ti···Ti distance common in imido dimers[32] [Ti1···Ti1′ = 2.889(3) Å] with two Ti–$N_{imido}$ bond lengths of 1.830(6) Å and 2.027(6) Å. The ($Me_2HN$)$Cl_2$Ti moiety is normal with the expected Ti–$N_{amine}$ and Ti–Cl bond lengths and angles [Ti–$N_{amine}$ 2.226(6) Å, Ti–Cl avg. 2.346 Å].

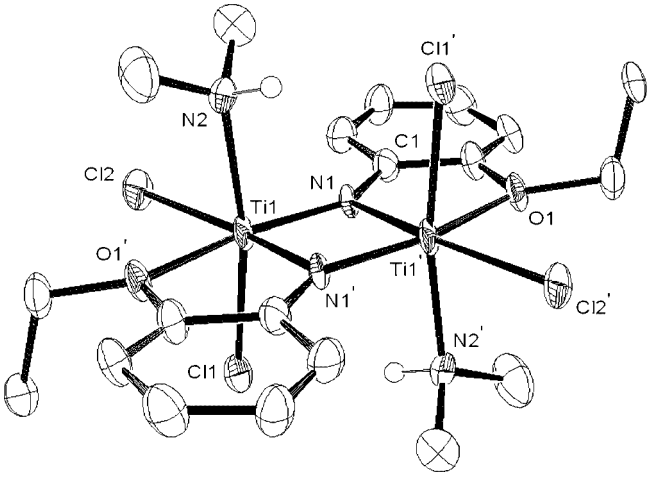

Figure 9. Molecular structure of **3** with selected bond lengths [Å] and angles [°], which shows 50% probability ellipsoids and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

Addition of pyridine to **4** affords the pyridine complex [Ti($\mu$2-[N]-$\eta^1$[O]–$NR^o$)$Cl_2$(Py)]$_2$ (**5**) [$R^o$ = $CH_2(CHO(CH_2)_3)$] and its molecular structure has also been assessed on the basis of X-ray structure determination. The ORTEP

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

drawing is shown in Figure 10, and selected bond lengths and angles are given in Table 2. Like **3**, compound **5** is dimeric in the solid state, and the overall geometry, distances, and angles are broadly comparable to those of **3**. Complex **5** is an imido-bridged dimer with two edge-sharing octahedral metal coordination spheres. Each distorted octahedron is completed by two mutually *cis* chlorine atoms [Ti–Cl avg. 2.367(2) Å, Cl–Ti–Cl 90.69(4)°], one pyridine ligand [Ti–$N_{Py}$ 2.254(3) Å] and the O atom of the furan link [Ti–O 2.177(3) Å]. The $Ti_2N_2$ core is planar (torsion angle 0°) and is characterized by a short Ti···Ti distance [2.8502(13) Å]. The disymmetric imido bridges are characterized by two Ti–$N_{imido}$ bond lengths of 1.821(3) Å and 2.013(3) Å, that are longer by ca. 0.1/0.3 Å than those generally observed in terminal imido complexes. The angle formed by the bridging nitrogen atoms with the two metal centers [Ti–$N_{imido}$–Ti′ = 95.92(14)°] deviates significantly from that expected for an $sp^2$ nitrogen atom. The (Py)$Cl_2$Ti moiety is normal with the expected Ti–$N_{Py}$ and Ti–Cl bond lengths and angles [Ti–$N_{Py}$ 2.254(3) Å, Ti–Cl avg. 2.367(2) Å].

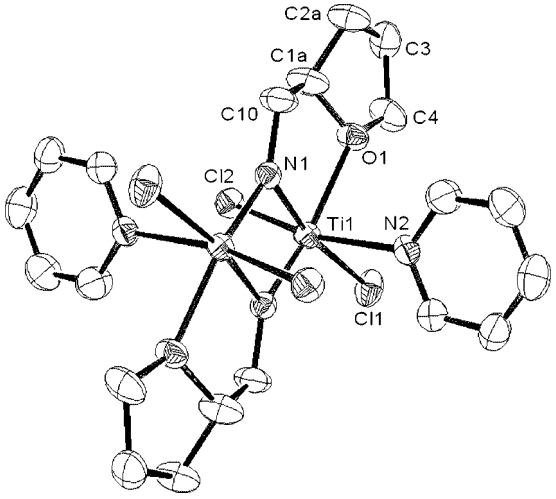

Figure 10. Molecular structure of **5** with selected bond lengths [Å] and angles [°], which shows 50% probability ellipsoids and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

### 3. Application to the Synthesis of Diimido Complexes and Chiral Imido Complexes

In relation to the possible use of chiral imido complexes in catalysis for stereoselective olefin polymerization[33] and their involvement in alkyne/alkene hydroamination,[34] we have initiated the synthesis of chiral imido groups on titanium complexes from enantiomerically pure chiral amines.

Table 2. Comparison of the average interatomic distances [Å] and angles [°] in dimers **3**, **5**, **6***, and **8**.

Following our one-pot procedure, the chiral amine (*S*)-(–)-α-methylbenzylamine was treated with $Ti(NMe_2)_4$ in the presence of excess $Me_3SiCl$, and the resulting yellow complex $[Ti\{=N\text{-}[(S)\text{-}(-)\text{-}CHMePh]\}Cl_2(NHMe_2)_2]$ (**1s***) was obtained in good yields (74%) (Figure 11). By the treatment with pyridine, **1s*** was transformed into the tris-pyridine adduct $[Ti\{=N\text{-}[(S)\text{-}(-)\text{-}CHMePh]\}Cl_2(Py)_3]$ (**2s***). These complexes represent the first examples of a chiral imido group on titanium complexes.[35]

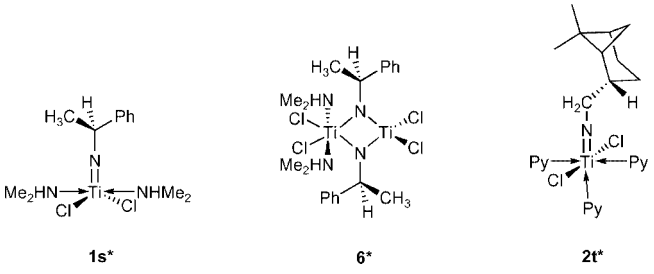

Figure 11. Chiral imido–titanium(IV) complexes.

Single-crystals of **1s*** (yellow blocks) were obtained from a toluene/pentane solution at room temp., and the crystal structure was determined. Complex **1s*** crystallized in the monoclinic space group $P2_1$.[36] A thermal ellipsoid plot is presented in Figure 12 along with selected bond lengths and angles in Table 1. In the solid state, the molecular structure of **1s*** resembles that of other five-coordinate $M(=NR)\text{-}Cl_2(NHMe_2)_2$ complexes described in this article and by others (M = Ti,[26] V[21]), and the metric parameters are comparable [avg. $N_{imido}$–Ti–Cl 109.9°, avg. $N_{imido}$–Ti–$N_{NHMe_2}$ 99.8, Ti–$N_{imido}$ distance of 1.682(4) Å, Ti–$N_{imido}$–C1 angle = 168.8(4)°, Cl–Ti–Cl angle of 140.12(6)°, mean Ti–Cl bond lengths of 2.350 Å, Ti–$N_{amine}$ bond lengths of avg. 2.205 Å]. In this case, the geometry around the metal center is closer to square planar ($\tau$ = 0.34).

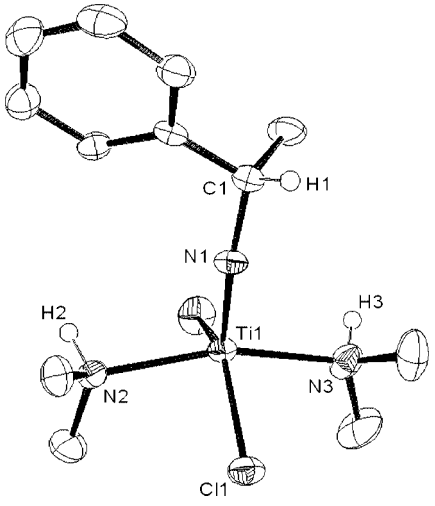

Figure 12. Molecular structure of **1s*** with selected bond lengths [Å] and angles [°], which shows 50% probability ellipsoids and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

Note that when less than 1 equiv. of chiral benzylic amine is used, we have observed by $^1H$ NMR spectroscopy the concomitant formation of another imido species **6*** as a minor side product. The lower solubility of **6*** allowed us to selectively obtain a few crystals and to determine its solid-state structure. **6s*** crystallized in the tetragonal space group $P4_2$. The molecular structure is presented in Figure 13 and selected distances and angles are summarized in Table 2. Compound **6*** is an imido-bridged dimer formulated as $[Cl_2Ti\{\mu\text{-}N\text{-}[(S)\text{-}(-)\text{-}CHMePh]\}_2TiCl_2(NHMe_2)_2]$ that consists of one four- and one six-coordinate titanium center.[37] Molecules of **6*** possess approximately tetrahedral (Ti1) and octahedral (Ti2) metals linked by bridging aryl–imido ligands. The Ti–Cl [average Ti1–Cl 2.25 Å, average Ti2–Cl 2.35 Å] and Ti–$N_{imido}$ [Ti1–N1 1.821(4) Å, Ti1–N2 1.840(4) Å, Ti2–N1 1.965(4) Å, Ti2–N2 1.971(4) Å] distances for Ti2 are longer than those for Ti1 by ca. 0.1 Å (Ti–Cl) and ca. 0.13 Å (Ti–$N_{imido}$), which is consistent with the higher coordination number of Ti2. The torsion angle Ti1–N1–Ti2–N2 of the $Ti_2N_2$ core is 4.5(2)°.

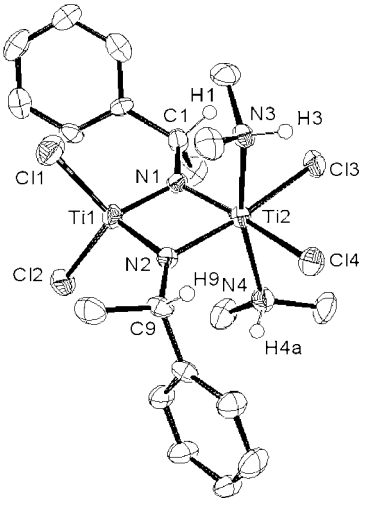

Figure 13. Molecular structure of **6*** with selected bond lengths [Å] and angles [°], which shows 50% probability ellipsoids and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

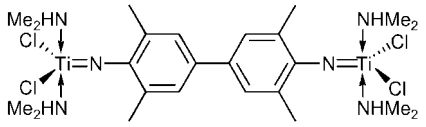
Similarly, we have attempted the synthesis of the related imido complex $[Ti\{=N\text{-}[(-)\text{-}cis\text{-myrtanyl}]\}Cl_2(NHMe_2)_2]$ (**1t***) that has a *cis*-myrtanyl function (Figure 11). However, we have not been able to isolate **1t*** in a pure form – the resulting orange material probably contains a mixture of imido compounds with a lower number of dimethylamine coligands as judged by its poor solubility and by the low *N*-content determined by combustion analysis (unfortunately the $^1H$ NMR spectrum was extremely broad and a full assignment of the signals was not possible). Nevertheless, a subsequent addition of pyridine afforded the desired pyridine complex $[Ti\{=N\text{-}[(-)\text{-}cis\text{-myrtanyl}]\}Cl_2(Py)_3]$ (**2t***) as the unique product.[38]

Interestingly, as an extension, our procedure may be used to generate multimetallic architectures held together by imido functions.[39] For instance, diimido complexes have been obtained directly from diamines. The reaction of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

3,3′,5,5′-tetramethyl[1,1′-biphenyl]-4,4′-diamine ($H_2N$–*BP*–$NH_2$) with 2 equiv. of $Ti(NMe_2)_4$ in the presence of an excess of $Me_3SiCl$ afforded the binuclear derivative $[(Me_2HN)_2Cl_2Ti(=N–BP–N=)TiCl_2(NHMe_2)_2]$ (**7**, Figure 14). Replacement of the dimethylamine ligands was prompted by the addition of pyridine to **7** and afforded the pyridine analogue $[(Py)_3Cl_2Ti(=N–BP–N=)TiCl_2(Py)_3]$ (**8**). An X-ray structure determination of a crystal of **8** (Figure 15 and Table 2) reveals a binuclear titanium complex with a bridging spacer composed of the diimido unit. The two titanium centers have an octahedral geometry with structure, bond lengths, and angles similar to the monometallic species. The titanium–nitrogen bond length of the imido fragments are 1.719(4) Å and 1.710(4) Å, the imido fragment were found to be almost linear [Ti–$N_{imido}$–$C_{ipso}$ 174.6(4)° and 178.1(4)°], and Ti–Cl bond lengths are in the range 2.39–2.42 Å. The dihedral angle between the planes of the two benzene rings of the biphenyl unit is 14.0(2)°.

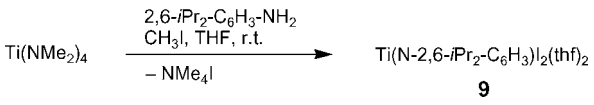


**7**

Figure 14. Diimido-titanium(IV) complex **7**.

### 4. Alternative Synthesis of Imido–Titanium Species

The reaction of $Ti(NMe_2)_4$ with 2,6-*i*$Pr_2$–$C_6H_3NH_2$ in THF with an excess of $CH_3I$ in place of chlorotrimethylsilane can be used to generate an aryl–imido complex. This reaction proceeds at room temperature (Scheme 3), with alkylation of the four dimethylamido groups.[40] After filtration of the insoluble $Me_4NI$ salt, the imido complex formulated as $[Ti(NAr)I_2(thf)_2]$ (**9**) (Ar = 2,6-*i*$Pr_2$–$C_6H_3$), as judged by $^1H$ NMR spectroscopy and combustion analysis, is obtained in 79% yield. This compound is most probably a dimer with bridging iodides as in the structurally established phenylimido analogue $[Ti(=NPh)Cl(\mu\text{-}Cl)(thf)_2]_2$.[4c] This new synthesis could be important as an alternative method for the preparation of imido complexes when N-donor coligands ($NHMe_2$) are not wanted. The scope of this synthesis will be developed elsewhere.



Scheme 3. Alternative synthesis of imido–titanium(IV) compounds.

## Conclusions

We have reported a direct and efficient method to generate titanium(IV) complexes of the type $Ti(=NR)Cl_2(NHMe_2)_2$ from commercially available $Ti(NMe_2)_4$ and a wide range of primary amines under simple and mild conditions. We have also demonstrated the functional group tolerance of this reaction, and it has been applied to the synthesis of titanium complexes that have an additional functionality on the imido moiety. The reactivity of these functionalized imido groups can now be ascertained and the added functionality may also serve as an anchor to graft this species onto a support. Also of great interest, we have been able to prepare complexes with diimido ligands, as well as the first Ti compounds that contain chiral imido supporting ligands. As an alternative method, we have reported some preliminary results on the synthesis of imido–titanium complexes of the type $[Ti(NAr)I_2(thf)_2]_2$ that use $CH_3I$ as a reagent.

## Experimental Section

**General Methods and Instrumentation:** All manipulations were carried out with a standard Schlenk line or dry box techniques under an atmosphere of argon. Solvents were refluxed and dried with the appropriate drying agents under an atmosphere of argon, and collected by distillation. NMR spectra were recorded with a Bruker AM200, AM250, ARX250, DPX300, or Avance500 spectrometers, referenced internally to residual protio-solvent ($^1H$) resonances, and are reported relative to tetramethylsilane ($\delta$ = 0 ppm). $^{19}F$ NMR spectra were recorded with a Bruker AM200 spectrometer (reference $CF_3CO_2H$). $^{29}Si$ NMR spectra were recorded with a Bruker Avance500 spectrometer. Infrared spectra were prepared under an argon atmosphere in a glove box and were recorded with

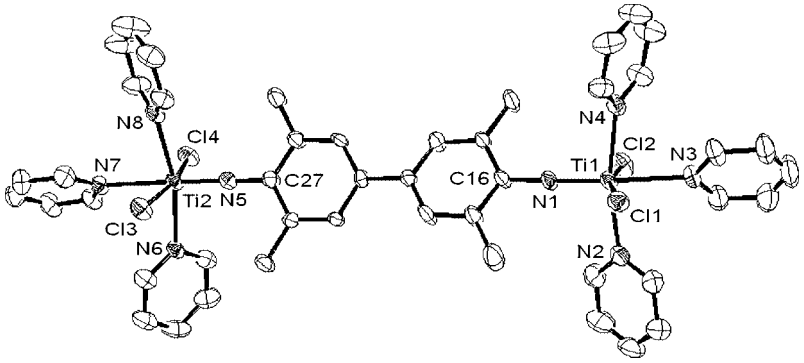


Figure 15. Molecular structure of **8** with selected bond lengths [Å] and angles [°], which shows 50% probability ellipsoids and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

a Perkin–Elmer Spectrum GX FT-IR spectrometer. Elemental analyses were performed at the Laboratoire de Chimie de Coordination (Toulouse, France) (C, H, N) or by the Service Central de Microanalyses du CNRS at Vernaison (France) (C, H, N, Cl).

The $Ti(NMe_2)_4$ used in this study was prepared by a modification of a literature procedure,[41] or purchased from commercial sources (Aldrich, Acros). Liquid anilines and amines were dried with KOH or $CaH_2$, refluxed, distilled, and stored over 4 Å molecular sieves under an argon atmosphere before use. Trimethylchlorosilane was distilled and stored over 4 Å molecular sieves under an argon atmosphere before use. The optical purity of the enantiomerically pure chiral amines used in this study [(*S*)-(–)-α-methylbenzylamine and (–)-*cis*-myrtanylamine] was 98% (Aldrich).

**Crystal Structure Determination:** Crystals of **1k** (dark-green blocks), **1o** (orange plates), **1p** (orange plates), **1s*** (yellow blocks), **2d** (yellow blocks), **2l** (orange plates), **2r** (orange parallelepipeds), **3** (dark-red blocks), **5** (orange blocks), **6*** (green plates), and **8** (orange blocks) were obtained. Crystal data collection and processing parameters are given in Table 3 and Table 4. The selected crystals, sensitive to air and moisture, were mounted on a glass fiber with perfluoropolyether oil and cooled rapidly to 180 K in a stream of cold $N_2$. Data were collected at low temperature (T = 180 K) with a Stoe Imaging Plate Diffraction System (IPDS) equipped with an Oxford Cryosystems Cryostream Cooler Device or an Oxford Diffraction Kappa CCD Excalibur diffractometer equipped with an Oxford Instrument cryojet, with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Final unit cell parameters were obtained by means of a least-squares refinement of a set of 8000 well-measured reflections, and crystal decay was monitored during data collection by the measurement of 200 reflections by image; no significant fluctuation of intensities has been observed. Structures have been solved by means of Direct Methods with the program SIR92,[42] and subsequent difference Fourier maps. Models were refined by least-squares procedures on a $F^2$ with SHELXL-97[43] integrated in the package WINGX version 1.64;[44] empirical absorption corrections were applied on the data.[45] All hydrogen atoms have been located on differences Fourier maps, and introduced into the refinement as fixed contributors with a riding model with an isotropic thermal parameter fixed at 20% higher than those of the $Csp^2$ atoms and 50% for the $Csp^3$ atoms to which they were connected. The methyl groups were refined with the torsion angle as a free variable. Some exceptions for a few specific hydrogen atoms were made, which have been isotropically refined (like nitrogen bound hydrogens). For the seven structures all non-hydrogen atoms were anisotropically refined, and in the last cycles of the refinement weighting schemes were used, where weights are calculated from the following formula: $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$. The poor quality of the structure determination of **3** is due to the small size of the crystal, and was not sufficient to give precise bond lengths and angles. For **8** it was not possible to resolve diffuse electron-density residuals (enclosed solvent molecules). Treatment with the SQUEEZE facility from PLATON,[46] with a localized void of about 1730 $Å^3$ and 75 recovered electrons, resulted in a smooth refinement. Since a few low-order reflections are missing from the data set, the electron count will be underestimated. Thus, the values given for $D_{calc}$, $F(000)$ and the molecular weight are only valid for the ordered part of the structure. For **1s***, the Flack parameter[47] was refined to a value of 0.11(7). Although, the standard deviation on this parameter is rather high, inversion of the configuration gave a value of 0.89, and so the absolute configuration could be determined and it agrees with the synthetic pathway [in addition, the Flack parameter for complex **6***, which is derived from **1s***, was refined to a satisfying value of 0.04(3)]. The deviation of the Flack parameter from 0 is probably due to the weak anomalous diffusion of Ti and Cl atoms. CCDC-608174 to -608184 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[a] Absolute structure parameter 0.04(3).

**[Ti(=NR)Cl$_2$(NHMe$_2$)$_2$] (1a–t). General Synthetic Procedure:** To a toluene solution (5 mL) of Ti(NMe$_2$)$_4$ (250 mg, 1.115 mmol), amine RNH$_2$ (1 equiv. 1.115 mmol) was added at room temperature. To this solution Me$_3$SiCl (1.00 g) was slowly added at room temperature. The resulting solution was stirred overnight at room temp. (or at 60 °C for **1a**, for the other compounds we did not notice significant changes in yields when the reaction was performed at 60 °C). Depending on the amine RNH$_2$ used, the product separates from the solution as a crystalline compound (without or upon the addition of pentane), or the volatiles were removed under reduced pressure. The yellow–orange microcrystalline solid was then washed with pentane (2×10 mL), and dried under vacuum to afford the analytically and spectroscopically pure material. Pure **1** was obtained by recrystallization from toluene/pentane. Yields are calculated on the basis of 250-mg scale reaction of Ti(NMe$_2$)$_4$. Some of these compounds have been prepared with up to 2 g of Ti(NMe$_2$)$_4$ with similar yields.

**[Ti(=N–*t*Bu)Cl$_2$(NHMe$_2$)$_2$] (1a):** Yield 260 mg (93%) (yellow). $^1$H NMR (250 MHz, CD$_2$Cl$_2$): $\delta$ = 3.46 (br. m, 2 H, N*H*), 2.71 (d, $^3J$ = 6.2 Hz, 12 H, NH*Me$_2$*), 1.05 (s, 9 H, *t*Bu) ppm. $^{13}$C{$^1$H} NMR (62.90 MHz, CD$_2$Cl$_2$): $\delta$ = 73.6 (*C*Me$_3$), 41.1 (NH*Me$_2$*), 31.5 (C*Me$_3$*) ppm. IR (KBr): $\tilde{\nu}$ = 3234 (s, NH), 2973 (s), 1517 (m), 1363 (w), 1244 (m), 1184 (m), 1090 (m), 1015 (s), 975 (s), 901 (m), 810 (w), 557 (m), 498 (w) cm$^{-1}$. C$_8$H$_{23}$Cl$_2$N$_3$Ti (280.06): calcd. C 34.31, H 8.28, N 15.00; found C 34.33, H 8.35, N 14.86.

**[Ti(=N–1-Adamantane)Cl$_2$(NHMe$_2$)$_2$] (1b):** Yield 320 mg (80%) (yellow). $^1$H NMR (300 MHz, CD$_2$Cl$_2$): $\delta$ = 3.48 (br. m, 2 H, N*H*), 2.71 (d, $^3J$ = 6.0 Hz, 12 H, NH*Me$_2$*), 1.89 (br. s, 3 H, C*H*$_{ada}$), 1.66 (br. s, 6 H, C*H*$_{2ada}$), 1.48 (br. s, 6 H, C*H*$_{2ada}$) ppm. $^{13}$C{$^1$H} NMR (75.47 MHz, CD$_2$Cl$_2$): $\delta$ = 75.4 (*C*$_q$), 45.4 (*C*$_q$), 41.2 (NH*Me$_2$*), 36.5 (*C*$_{ada}$), 30.1 (*C*$_{ada}$) ppm. IR (KBr): $\tilde{\nu}$ = 3233 (w, NH), 2921 (vs), 1465 (m), 1365 (m), 1237 (s), 1097 (m), 1016 (m), 894 (s), 499 (w) cm$^{-1}$. C$_{14}$H$_{29}$Cl$_2$N$_3$Ti (358.17): calcd. C 46.95, H 8.16, N 11.73; found C 47.05, H 8.19, N 11.60.

**[Ti(=N–CPh$_3$)Cl$_2$(NHMe$_2$)$_2$] (1c):** Yield 475 mg (91%) (yellow). $^1$H NMR (250 MHz, CD$_2$Cl$_2$): $\delta$ = 7.21–7.38 (m, 15 H, C$_6$*H*$_5$), 3.27 (br. sept, 2 H, N*H*), 2.44 (d, $^3J$ = 6.1 Hz, 12 H, NH*Me$_2$*) ppm. $^{13}$C{$^1$H} NMR (62.90 MHz, CD$_2$Cl$_2$): $\delta$ = 147.7, 129.0, 128.0, 126.9 (*C*$_6$H$_5$, one signal not observed), 40.7 (NH*Me$_2$*) ppm. IR (KBr): $\tilde{\nu}$ = 3233 (m, NH), 2929 (m), 2780 (m), 1596 (m), 1467 (m), 1443 (m), 1209 (m), 1020 (m), 991 (w), 893 (m), 755 (m), 699 (s), 636 (m), 420 (m) cm$^{-1}$. C$_{23}$H$_{29}$Cl$_2$N$_3$Ti (466.27): calcd. C 59.25, H 6.27, N 9.01; found: C 59.07, H 6.24, N 8.87.

**[Ti(=N–SiPh$_3$)Cl$_2$(NHMe$_2$)$_2$] (1d):** Yield 490 mg (91%) (yellow). $^1$H NMR (250 MHz, CD$_2$Cl$_2$): $\delta$ = 7.72 (m, 6 H, C$_6$*H*$_5$), 7.38 (m, 9 H, C$_6$*H*$_5$), 3.39 (br. sept, 2 H, N*H*), 2.55 (d, $^3J$ = 6.2 Hz, 12 H, NH*Me$_2$*) ppm. $^{13}$C{$^1$H} NMR (125.81 MHz, CD$_2$Cl$_2$): $\delta$ = 136.9, 135.5, 130.6, 129.7 (*C*$_6$H$_5$), 41.2 (NH*Me$_2$*) ppm. $^{29}$Si NMR (99.40 MHz, CD$_2$Cl$_2$): $\delta$ = –43 ppm. IR (KBr): $\tilde{\nu}$ = 3242 (s, NH), 1465 (m), 1427 (m), 1111 (vs), 893 (w), 703 (s), 507 (s) cm$^{-1}$. C$_{22}$H$_{29}$Cl$_2$N$_3$SiTi (482.34): calcd. C 54.78, H 6.06, N 8.71; found C 54.66, H 6.07, N 8.66.

**[Ti(=N–Ph)Cl$_2$(NHMe$_2$)$_2$] (1e):** Yield 273 mg (81%) (red–orange). $^1$H NMR (250 MHz, CD$_2$Cl$_2$): $\delta$ = 7.07 (t, 2 H, C$_6$*H*$_5$), 6.82 (m, 3 H, C$_6$*H*$_5$), 3.56 (br. sept, 2 H, N*H*), 2.76 (d, $^3J$ = 6.2 Hz, 12 H, NH*Me$_2$*) ppm. C$_{10}$H$_{19}$Cl$_2$N$_3$Ti (300.05): calcd. C 40.03, H 6.38, N 14.00; found C 39.86, H 6.41, N 13.92.

**[Ti(=N–2,6-*i*Pr$_2$–C$_6$H$_3$)Cl$_2$(NHMe$_2$)$_2$] (1f):** Yield 410 mg (96%) (orange). $^1$H NMR (300 MHz, C$_6$D$_6$): $\delta$ = 6.99 (d, $^3J$ = 7.5 Hz, 2 H, C$_6$*H*$_3$), 6.85 (t, $^3J$ = 7.6 Hz, 1 H, C$_6$*H*$_3$), 4.67 (sept, $^3J$ = 6.7 Hz, 2 H, C*H*Me$_2$), 2.91 (br. m, 2 H, N*H*), 2.27 (d, $^3J$ = 6.3 Hz, 12 H, NH*Me$_2$*), 1.44 (d, $^3J$ = 6.9 Hz, 12 H, CH*Me$_2$*) ppm. $^{13}$C{$^1$H} NMR (75.47 MHz, C$_6$D$_6$): $\delta$ = 157.8, 144.7, 123.8, 122.7 (*C*$_6$H$_3$), 40.8 (NH*Me$_2$*), 28.0 (*C*HMe$_2$), 24.6 (CH*Me$_2$*) ppm. IR (KBr): $\tilde{\nu}$ = 3255 (w, NH), 2961 (m), 1465 (s), 1334 (s), 1288 (s), 1021 (m), 896 (m), 753 (s), 668 (vs) cm$^{-1}$. C$_{16}$H$_{31}$Cl$_2$N$_3$Ti (384.21): calcd. C 50.02, H 8.13, N 10.94; found C 49.93, H 8.20, N 10.81.

C 58.13, H 5.09, N 11.79; found C 57.96, H 4.97, N 11.56.

**[Ti{=N–[(–)-*cis*-myrtanyl]}Cl$_2$(Py)$_3$] (2t*):** This compound was prepared from unisolated **1t*** [prepared from Ti(NMe$_2$)$_4$ and (–)-*cis*-myrtanylamine/Me$_3$SiCl as described above for **1a**] with a procedure similar to the one described for **2d**. Yield 250 mg [44% based on starting Ti(NMe$_2$)$_4$] (orange). $^1$H NMR (250 MHz, $C_6D_6$): $\delta$ = 9.45 (br. s, 3 H, Py), 8.81 (br. s, 3 H, Py), 6.85 (br. t, 3 H, Py), 6.58 (br. d, 6 H, Py), 4.00 (s, 1 H, C*H*), 3.58 (dd, $^3J$ = 7.5 Hz, 2 H, C*H*$_2$N), 2.52 (m, 1 H, C*H*), 2.28 (br. s, 2 H, C*H*$_2$), 1.95 (br. m, 1 H, C*H*), 1.83–1.74 (br. s, 3 H, C*H*, C*H*$_2$), 1.35 (m, 1 H, C*H*), 1.11 (s, 3 H, C*H*$_3$), 0.87 (s, 3 H, C*H*$_3$) ppm. $^{13}$C{$^1$H} NMR (125.81 MHz, $C_6D_6$): $\delta$ = 152.2, 151.5, 138.3, 136.8, 124.1, 76.4, 55.1, 44.9, 42.2, 39.1, 34.1, 28.6, 27.1, 23.9, 20.1 ppm. $C_{25}H_{32}Cl_2N_4Ti$ (507.32): calcd. C 59.19, H 6.36, N 11.04; found C 59.04, H 6.35, N 10.91.

**[Ti(N–2-EtO–C$_6$H$_4$)Cl$_2$(NHMe$_2$)$_1$]$_2$ (3):** This compound was obtained from a procedure similar to the one described for **1a**–**t**. Pure **3** was obtained after recrystallization from a THF/toluene solution layered with pentane. Yield 235 mg (70%) (dark red). $^1$H NMR (250 MHz, $CD_2Cl_2$): $\delta$ = 7.58 (dd, $^3J$ = 7.8 Hz, 2 H, C$_6$*H*$_4$), 7.05 (m, 4 H, C$_6$*H*$_4$), 6.91 (dd, $^3J$ = 8.1 Hz, 2 H, C$_6$*H*$_4$), 5.37 (m, 2 H, N*H*), 5.02 (qd, $^3J$ = 7.1 Hz, 4 H, OC*H*$_2$CH$_3$), 2.48 (d, $^3J$ = 5.8 Hz, 6 H, NH*Me$_a$*Me$_b$), 2.35 (d, $^3J$ = 6.1 Hz, 6 H, NHMe$_a$*Me$_b$*), 1.62 (t, $^3J$ = 7.0 Hz, 6 H, OCH$_2$C*H*$_3$) ppm. $^{13}$C{$^1$H} NMR (125.81 MHz, $CD_2Cl_2$): $\delta$ = 144.2, 142.3, 128.2, 126.7, 124.7, 111.4 (*C*$_6$H$_4$), 71.7 (O*C*H$_2$CH$_3$), 42.5 (NH*Me$_a$*Me$_b$), 40.0 (NHMe$_a$*Me$_b$*), 13.40 (OCH$_2$*C*H$_3$) ppm. IR (KBr): $\tilde{\nu}$ = 3149 (w, NH), 2978 (m), 1473 (s), 1254 (s, CO), 1191 (m), 1112 (m), 1041 (m), 1002 (m), 922 (m), 896 (m), 751 (m), 652 (w), 419 (w) cm$^{-1}$. $C_{20}H_{32}Cl_4N_4O_2Ti_2$ (598.04): calcd. C 40.17, H 5.39, N 9.37; found C 40.20, H 5.41, N 9.39.

**[Ti[N–CH$_2$(CH(OCH$_2$)$_3$)]Cl$_2$(NHMe$_2$)$_1$]$_2$ (4):** This compound was obtained from a procedure similar to the one described for **1a**–**t**. Yield 260 mg (89%) (orange). The very poor solubility of **4** in $CD_2Cl_2$ and in [D$_8$]THF precluded its $^1$H and $^{13}$C NMR analysis. In [D$_5$]Py the HNMe$_2$ ligands are displaced by [D$_5$]Py ligands. $^1$H NMR (250 MHz, [D$_5$]Py): $\delta$ = 4.13 (br., 2 H), 3.90–3.25 (br., app t), 1.96 (br., 4 H), 1.75–1.56 (br., 4 H) ppm. IR (KBr): $\tilde{\nu}$ = 3215 (w, NH), 2983 (m), 2917 (s), 2773 (s), 1459 (m), 1257 (w, CO), 1126 (s), 1043 (s), 1029 (s), 981 (m), 893 (m), 821 (m), 699 (m), 463 (m) cm$^{-1}$. $C_{14}H_{32}Cl_4N_4O_2Ti_2$ (525.98): calcd. C 31.97, H 6.13, N 10.65; found C 32.07, H 6.09, N 10.66.

**[Ti[N–CH$_2$(CHO(CH$_2$)$_3$)]Cl$_2$(Py)$_1$]$_2$ (5):** This compound was only obtained as a few red crystals by the crystallization of **4** in pyridine/toluene solutions. Attempted large scale synthesis (even in hot pyridine) gave only insoluble materials (precluding NMR analysis), and with an elemental analysis close to that of **4** which proves that

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the substitution of $NHMe_2$ in **4** by Py is difficult (vide infra). In consequence, **5** was only characterized by X-ray analysis.

**[Ti{=N–[(*S*)-(–)-CHMePh]}$Cl_2(NHMe_2)_1]_2$ (6*):** This compound was observed in the synthesis of **1s*** when only 0.8 equiv. of the chiral amine was treated with $Ti(NMe_2)_4$ (1 equiv.) and $Me_3SiCl$ (10 equiv.). $^1H$ NMR (250 MHz, $CD_2Cl_2$): $\delta$ = 7.70 (d, $^3J$ = 8.3 Hz, 4 H, $C_6H_5$), 7.40 (m, 6 H, $C_6H_5$), 5.62 (q, $^3J$ = 6.8 Hz, 2 H, C*H*Me), 3.00 (br. m, 4 H, N*H*), 2.59 (d, $^3J$ = 6.1 Hz, 6 H, NH$Me_2$), 2.45 (d, $^3J$ = 5.9 Hz, 6 H, NH$Me_2$), 1.80 (d, $^3J$ = 6.8 Hz, 6 H, CH*Me*) ppm.

**[$(Me_2HN)_2Cl_2Ti$(=N–$Me_2C_6H_2$–$C_6H_2Me_2$–N=)$TiCl_2(NHMe_2)_2$] (7):** This compound was obtained from a procedure similar to the one described for **1a**–**t**. Yield 280 mg (77%) (yellow). $^1H$ NMR (250 MHz, $CD_2Cl_2$): $\delta$ = 6.98 (s, 4 H, $C_6H_2$), 3.59 (m, $^3J$ = 6.1 Hz, 4 H, N*H*), 2.75 (d, $^3J$ = 6.2 Hz, 24 H, NH$Me_2$), 2.56 (s, 12 H, $C_6H_2Me_2$) ppm. $^{13}C\{^1H\}$ NMR (125.81 MHz, $CD_2Cl_2$): $\delta$ = 159.4, 134.2, 133.9, 124.9 ($C_6H_2$), 41.0 (NH$Me_2$), 19.0 ($C_6H_2Me_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3251 (s, NH), 2972 (m), 2936 (m), 1465 (m), 1459 (m), 1311 (s), 1117 (w), 1093 (w), 1020 (m), 1006 (m), 894 (m), 859 (m), 803 (w), 758 (w), 735 (w), 462 (w), 415 (w) $cm^{-1}$. $C_{24}H_{44}Cl_4N_6Ti_2$ (654.19): calcd. C 44.06, H 6.78, N 12.85; found C 43.93, H 6.84 N 12.62.

**[$(Py)_3Cl_2Ti$(=N–$Me_2C_6H_2$–$C_6H_2Me_2$–N=)$TiCl_2(Py)_3$] (8):** This compound was obtained from **7** (100 mg) with a procedure similar to the one described for **2d**. Yield 137 mg (94%) (orange). $^1H$ NMR (250 MHz, [$D_5$]Py): $\delta$ = 7.31 (s, 4 H, $C_6H_2$), 2.79 (s, 12 H, Me) ppm. The very poor solubility in $CD_2Cl_2$ precluded its $^{13}C$ NMR analysis. IR (KBr): $\tilde{\nu}$ = 1604 (s), 1444 (vs), 1299 (s), 1217, 1069, 1012 (m), 681 (w), 754 (m), 695 (vs), 637, 429 (m) $cm^{-1}$. $C_{46}H_{46}Cl_4N_8Ti_2$ (948.46): calcd. C 58.25, H 4.89, N 11.81; found C 57.99, H 4.71, N 11.55.

**[$Ti(N$–2,6-$iPr_2$–$C_6H_3)I_2(thf)_2]_2$ (9):** A THF solution (5 mL) of $Ti(NMe_2)_4$ (250 mg, 1.115 mmol) was treated with 2,6-$iPr_2$–$C_6H_3NH_2$ (1 equiv., 1.115 mmol) at room temperature. To this solution, MeI (1.58 g) was slowly and carefully added. The resulting solution was stirred at room temp. for 1 d. Toluene (5 mL) were added and the white precipitate of $Me_4NI$ was filtered and washed with toluene(2 × 3 mL). The volatiles were removed under vacuum, and the resulting sticky solid was washed with pentane (2 × 10 mL) and dried under vacuum to afford the product. Yield 550 mg (79%) (orange). $^1H$ NMR (250 MHz, $C_6D_6$): $\delta$ = 6.96 (d, $^3J$ = 7.7 Hz, 2 H, $C_6H_3$), 6.82 (t, $^3J$ = 7.6 Hz, 1 H, $C_6H_3$), 4.89 (sept, $^3J$ = 6.8 Hz, 2 H, C*H*$Me_2$), 4.32 (br. t, 8 H, O$CH_2$), 1.45 (d, $^3J$ = 6.8 Hz, 12 H, CH$Me_2$), 1.24 (br. t, 8 H, $CH_2$) ppm. $^{13}C\{^1H\}$ NMR (62.90 MHz, $C_6D_6$): $\delta$ = 160.0, 144.3, 125.0, 122.8 ($C_6H_3$), 77.1 (O$CH_2$), 28.6 (*C*H$Me_2$), 25.2 ($CH_2$), 24.8 (CH$Me_2$) ppm. IR (KBr): $\tilde{\nu}$ = 2954 (vs), 1459 (s), 1326 (s), 1279 (s), 1175 (w), 1037 (w), 1011 (s), 921 (m), 853 (vs), 751 (s), 686 (w), 544 (w) $cm^{-1}$. $C_{20}H_{33}I_2NO_2Ti$ (621.16): calcd. C 38.67, H 5.35, N 2.25; found C 35.99, H 4.96, N 2.05 (the elemental analysis always gave low C and N content).

**Supporting Information** (see footnote on the first page of this article): $^1H$ NMR spectra of complexes **1p** and **9**.

[34] For some examples of the use of enantiomerically pure amines as substrates for Ti-catalyzed hydroamination of alkynes, see ref.[13a] and ref.[14c].

[35] For an example of a chiral molybdenum diimido complex, see E. A. Kretzschmar, J. Kipke, J. Sundermeyer, *Chem. Commun.* **1999**, 2381–2388.

[36] Complex **1s*** has also been obtained as yellow needles that crystallized in the orthorhombic space group $P2_12_12_1$ [*a*: 6.5483(2), *b*: 7.7647(3), *c*: 33.3440(9)]. Bond lengths and angles are similar, but the overall structure differs by the position of the N–H bonds: *syn* in the $P\,2_1$ structure versus *anti* in the $P\,2_12_12_1$ structure, and by the NH···Cl network.

[37] Overall, complex **6s*** only differs from **1s*** by the loss of one $NHMe_2$ ligand/Ti center. To explain its formation, we suspect the concomitant formation [when $Ti(NMe_2)_4/R^*NH_2$ ratio > 1] of a small amount of $[TiCl_3(NMe_2)(HNMe_2)]_2$ that would trap some of the $HNMe_2$ ligand needed to form **1s*** and thus **6s*** is formed. These studies, that are related to the mechanism of the general reaction $Ti(NMe_2)_4/RNH_2/Me_3SiCl$, are under current investigations and will be reported in due course.

[38] The chiral imido–vanadium analogue complex has been prepared similarly and its structure has been established by X-ray structure determination. C. Lorber, Unpublished result.

# Slipped μ-Indenyl Triple-Decker Complexes Containing $(C_4Me_4)Co$ and $(C_5R_5)Ru$ Fragments[‡]

**Elena V. Mutseneck,[a] Zoya A. Starikova,[a] Konstantin A. Lyssenko,[a] Pavel V. Petrovskii,[a] Piero Zanello,[b] Maddalena Corsini,[b] and Alexander R. Kudinov*[a]**

**Keywords:** Cobalt / Ruthenium / Sandwich compounds / Triple-decker complexes / Electrochemistry

Slipped triple-decker complexes with a bridging indenyl ligand, namely $[Cb^*Co(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)CoCb^*]^+$ (**2**, $Cb^* = C_4Me_4$) and $[Cb^*Co(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Ru(C_5R_5)]^+$ (R = H, **5a**; Me, **5b**), have been synthesised by electrophilic stacking of $[Cb^*Co(\eta^5\text{-}C_9H_7)]$ (**1**) with $[Cb^*Co(MeCN)_3]^+$ or $[(C_5R_5)Ru(MeCN)_3]^+$ (R = H, Me), respectively. A similar reaction of $[(C_5R_5)Ru(\eta^5\text{-}C_9H_7)]$ (R = H, **3a**; Me, **3b**) with $[Cb^*Co(MeCN)_3]^+$ affords the cations $[(C_5R_5)Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)CoCb^*]^+$ (R = H, **4a**; Me, **4b**), which are isomeric with **5a**,**b**. Stacking of $[Ru(\eta^5\text{-}C_9H_7)_2]$ (**7**) with $[Cb^*Co(MeCN)_3]^+$ or $[Cb^*CoI]_x/TlBF_4$ gives the triple-decker complex $[(\eta^5\text{-}C_9H_7)Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)CoCb^*]^+$ (**8**). Further reaction of **8** with $[Cp^*RuCl]_4/TlBF_4$ unexpectedly affords the slipped tetradecker ruthenium complex $[Cp^*Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)RuCp^*]^{2+}$ (**11**). The structures of **[4b]**$[Co(\eta\text{-}7,8\text{-}C_2B_9H_{11})_2]$ and $[Cp^*Ru(\eta^6\text{-}C_9H_7)]$ (**6**) have been determined by X-ray diffraction, and the electrochemical behaviour of the complexes prepared has been studied.

## Introduction

The presence of two fused π-systems in pentalene, indenyl and naphthalene makes them able to form slipped triple-decker complexes with an *anti* coordination of the metal atoms.[2] The first example of such compounds, $[(\eta^3\text{-allyl})Ni(\mu{:}\eta^5{:}\eta^5\text{-}C_8H_6)Ni(\eta^3\text{-allyl})]$, was described by Miyake and Kanai in 1971.[3] Manriquez et al. have synthesised a series of fused metallocenes with the formula $[Cp^*M(\mu{:}\eta^5{:}\eta^5\text{-}C_8H_6)M'Cp^*]$ (M, M′ = Fe, Co, Ni, Ru) along with other related compounds.[4] Their most interesting feature is a strong electronic interaction between the metal centres, as established by electrochemical and spectroscopic studies. A few μ-naphthalene triple-decker complexes are known: $[(\eta^6\text{-}C_6H_6)Cr(\mu{:}\eta^6{:}\eta^6\text{-}C_{10}H_8)Cr(\eta^6\text{-}C_6H_6)]$,[5] $[(C_5R_5)M(\mu{:}\eta^6{:}\eta^6\text{-}C_{10}H_8)M(C_5R_5)]$ (M = V, Fe[6]), and $[(cod)Ru(\mu{:}\eta^6{:}\eta^6\text{-}C_{10}H_8)Ru(cod)]$.[7] μ-Indenyl derivatives are the least studied, and the first examples, the ruthenium complexes $[(C_5R_5)Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Ru(C_5R_5)]^+$,[8] were prepared by electrophilic stacking of $[(C_5R_5)Ru(\eta^5\text{-}C_9H_7)]$ with $[(C_5R_5)Ru]^+$ fragments.[9]

Recently we have developed convenient methods for the preparation of (tetramethylcyclobutadiene)cobalt complexes.[10–13] The acetonitrile complex $[Cb^*Co(MeCN)_3]^+$ ($Cb^* = C_4Me_4$) has been shown to be the most useful synthon of the Cb*Co fragment. In particular, its reaction with the indenide anion gives the $\eta^5$-indenyl derivative $[Cb^*Co(\eta^5\text{-}C_9H_7)]$ (**1**).[12] Herein we describe the synthesis and electrochemical behaviour of dicobalt and cobalt-ruthenium triple-decker complexes with a bridging indenyl ligand.[14]

## Results and Discussion

### Synthesis

Electrophilic stacking of **1** with $[Cb^*Co(MeCN)_3]^+$ in nitromethane affords the slipped dicobalt triple-decker complex $[Cb^*Co(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)CoCb^*]^+$ (**2**) in 54% yield (Scheme 1). Similar reactions of the $(\eta^5$-indenyl)ruthenium derivatives $[(C_5R_5)Ru(\eta^5\text{-}C_9H_7)]$ (R = H, **3a**; Me, **3b**) give the cobalt-ruthenium complexes $[CpRu(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)CoCb^*]^+$ (**4a**, 23%) and $[Cp^*Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)CoCb^*]^+$ (**4b**, 54%; Scheme 2). Both reactions are reversible, with nucleophilic degradation of the products by acetonitrile being the back reaction. The low yield of **4a** suggests it degrades easier than **4b**, which is apparently connected with the poorer donor ability of the CpRu fragment. Nevertheless, we were able to increase the yield up to 78% by using a fivefold excess of **3a** and removing acetonitrile from the reaction mixture.

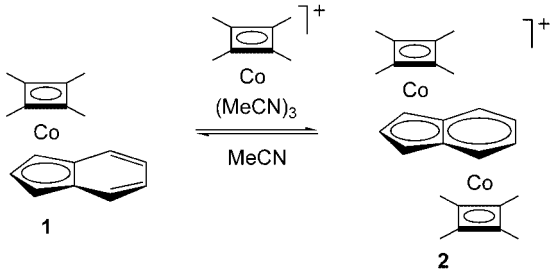
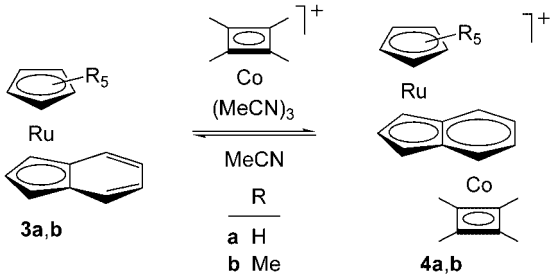
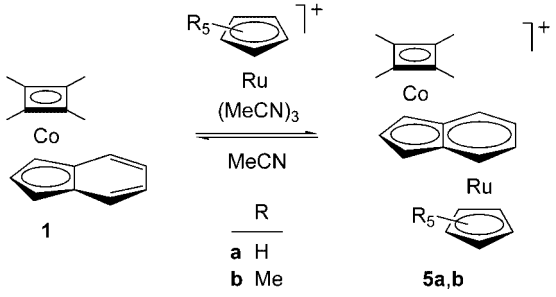


Scheme 1. Synthesis of the $Co_2$ complex **2**.

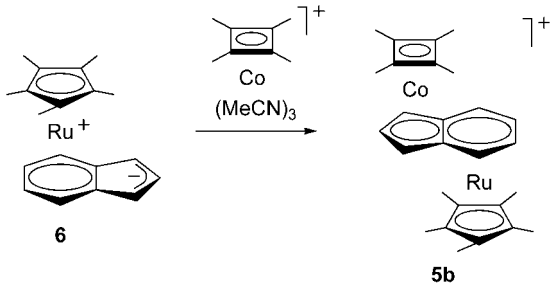


Scheme 2. Synthesis of the CoRu complexes **4a**,**b**.

The cobalt atom in complexes **4a**,**b** is coordinated at the six-membered ring of the indenyl ligand. The isomeric cations $[Cb^*Co(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Ru(C_5R_5)]^+$ (R = H, **5a**; Me, **5b**) with the cobalt atom at the five-membered ring were prepared by stacking of **1** with $[(C_5R_5)Ru(MeCN)_3]^+$ (R = H, Me; Scheme 3). Alternatively, complex **5b** was obtained by treatment of the $\eta^6$-indenyl derivative $[Cp^*Ru(\eta^6\text{-}C_9H_7)]$ (**6**) with $[Cb^*Co(MeCN)_3]^+$ (Scheme 4).

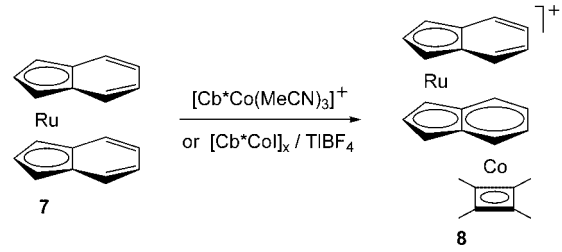


Scheme 3. Synthesis of the CoRu complexes **5a**,**b**.



Scheme 4. Synthesis of **5b** from the $\eta^6$-indenyl complex **6**.

It has been shown previously that stacking of bis(indenyl)ruthenium $[Ru(\eta^5\text{-}C_9H_7)_2]$ (**7**) with $[(C_5R_5)Ru(MeCN)_3]^+$ affords either triple- or tetra-decker complexes such as $[(C_5R_5)Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Ru(\eta^5\text{-}C_9H_7)]^+$ and $[(C_5R_5)Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Ru(C_5R_5)]^{2+}$ as a result of addition of one or two fragments, respectively.[8a] However, a similar reaction of **7** with $[Cb^*Co(MeCN)_3]^+$ gives only the slipped triple-decker complex $[(\eta^5\text{-}C_9H_7)Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)CoCb^*]^+$ (**8**, 15–20%), irrespective of the reagent ratio (Scheme 5). The yield was greatly increased (up to 65%) by using a new method for the generation of the $[Cb^*Co]^+$ fragment. This utilizes halide abstraction from the iodide complex $[Cb^*CoI]_x$ by treatment with $TlBF_4$ in thf. The advantage of this method is the absence of strongly coordinating acetonitrile. In particular, it has proved to be very effective for the preparation of arene complexes $[Cb^*Co(arene)]^+$ containing acceptor ligands (dichlorobenzene, acetophenone and anthracene).[15]



Scheme 5. Synthesis of the CoRu complex **8**.

However, the reaction of **7** with two equivalents of $[Cb^*CoI]_x/TlBF_4$ does not give the expected tetra-decker complex $[Cb^*Co(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)CoCb^*]^{2+}$. We propose that the insolubility of the primary product **8**·$BF_4$ in thf precludes its further stacking reaction.[16] However, the salt $[\mathbf{8}][Co(\eta\text{-}7,8\text{-}C_2B_9H_{11})_2]$, which is well soluble in thf, also proved to be unreactive towards $[Cb^*CoI]_x/Tl[Co(\eta\text{-}7,8\text{-}C_2B_9H_{11})_2]$.

The reaction of the triple-decker cation **8** with the $[Cp^*Ru]^+$ fragment, generated as a labile solvate from $[Cp^*RuCl]_4/TlBF_4$ in $MeNO_2$ (Scheme 6), proved to be very intriguing. A 1:1 molar ratio resulted in a mixture of the slipped triple-decker complexes **8** (25%) and $[Cp^*Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Ru(\eta^5\text{-}C_9H_7)]^+$ (**10**, 15%) along with the slipped tetra-decker complex $[Cp^*Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)RuCp^*]^{2+}$ (**11**, 60%), whereas with a 1:2 ratio only complex **11** (59%) was isolated. The unstable cobalt-ruthenium tetra-decker cation $[Cb^*Co(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Ru(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)RuCp^*]^{2+}$ (**9**) is believed to be an intermediate. Its further degradation leads to the diruthenium cation **10** by elimination of the $[Cb^*Co]^+$ fragment. Subsequent reaction of **10** with a second equivalent of $[Cp^*Ru]^+$ gives the stable $Ru_3$ tetra-decker cation **11**.

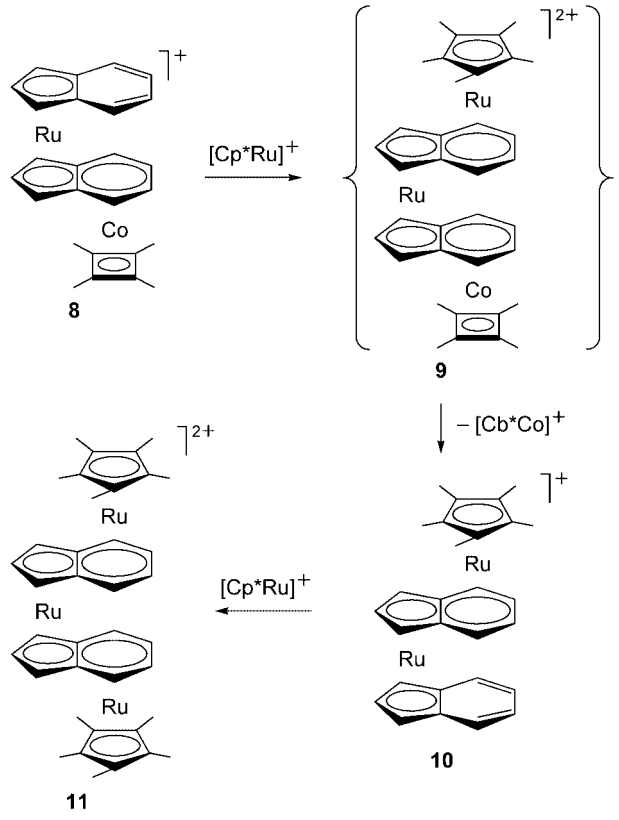
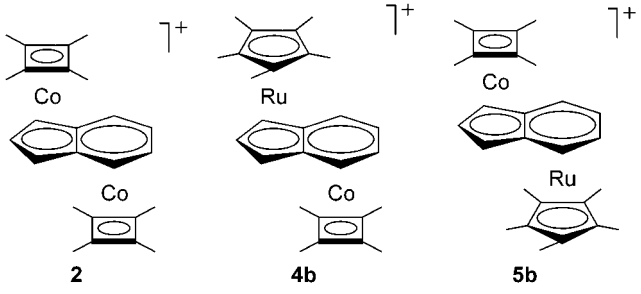


Scheme 6. Formation of the $Ru_3$ complex **11**.

### Nucleophilic Degradation

Nucleophilic degradation of triple-decker complexes by solvent molecules is the back reaction to electrophilic stacking.[17] As shown above, this process complicates the preparation of μ-indenyl triple-decker complexes, stimulating us to study degradation of the permethylated cations **2**, **4b** and **5b** by acetone and acetonitrile.



In accordance with the $^1H$ NMR spectroscopic data, all the cations slowly decompose in [$D_6$]acetone with the formation of a mononuclear $\eta^5$-indenyl complex (**1** or **3b**) and a solvate cationic complex ([Cb*Co($Me_2CO$)$_3$]$^+$ or [Cp*Ru($Me_2CO$)$_3$]$^+$). After one day, the 30% conversion of **4b** was observed. Further standing for one week did not cause any further changes. The behaviour of complexes **2** and **5b** is slightly different: the initially formed mononuclear cobalt compound **1** decomposes within several days, apparently owing to its oxidation by cationic solvate complexes. The absence of secondary processes for **4b** is in agreement with the higher oxidation potential of **3b** (+0.50 V, vide supra) compared with **1** (+0.33 V).[12]

The nucleophilic degradation rate increases in the order **5b** < **2** < **4b**. Cations **2** and **4b** differ by the fragment coordinated at the five-membered ring of the indenyl ligand. The Cp*Ru fragment accepts electron density of this ring to a greater extent than Cb*Co (due to the more covalent bonding of the ruthenium atom), which results in a higher positive charge at the $\eta^6$-coordinated cobalt atom and, as a consequence, to easier degradation of **4b**. Comparing **2** and **5b**, the [Cp*Ru]$^+$ fragment is more strongly bonded with the six-membered ring than [Cb*Co]$^+$, which explains the lower reactivity of **5b**.

Dissolution of complexes **2**, **4b** and **5b** in acetonitrile results in immediate decomposition. In the case of **4b**, a yellow solution was formed. $^1H$ NMR spectroscopy detected the starting compounds, **3b** and [Cb*Co(MeCN)$_3$]$^+$ resulting from nucleophilic degradation. The decomposition of **2** and **5b** leads to green solutions that show only very broad signals indicative of paramagnetic species. This behaviour contradicts with the preparation of triple-decker cations from acetonitrile complexes. However, we have shown that **5b** decomposes only slowly in the presence of two equivalents of MeCN in $CD_2Cl_2$, thus resolving the contradiction. As in the case of degradation by acetone, the more complex behaviour of derivatives **2** and **5b** with the cobalt atom coordinated at the five-membered ring may be explained by the easier oxidation of **1** compared with **3b**.

### X-ray Diffraction Study

The structures of complexes **6** and [**4b**][Co(η-7,8-$C_2B_9H_{11}$)$_2$][18] were investigated by X-ray diffraction (Figures 1 and 2, respectively). Selected bond lengths are given in Tables 1 and 2, respectively.

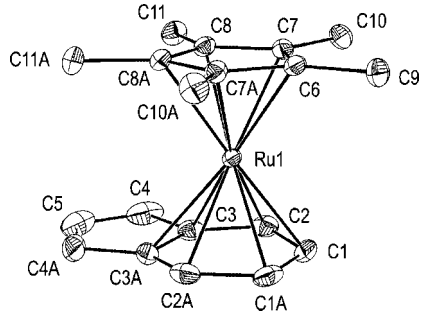


Figure 1. Structure of complex **6**. Ellipsoids are shown at the 50% level.

The structure of **6** is the first example of a mononuclear complex with an $\eta^6$-coordinated indenyl ligand. The structure has a symmetry plane. The ruthenium atom is not quite symmetrically coordinated with the six-membered ring, the distances from the Ru atom to the bridgehead C3 and C3A atoms (2.367 Å) being noticeably longer than other Ru–C distances (2.202 and 2.228 Å). This elongation (0.139–0.165 Å) is much greater than that for the isomeric $\eta^5$-indenyl complex **3b** (0.02–0.06 Å).[19] The six-membered ring

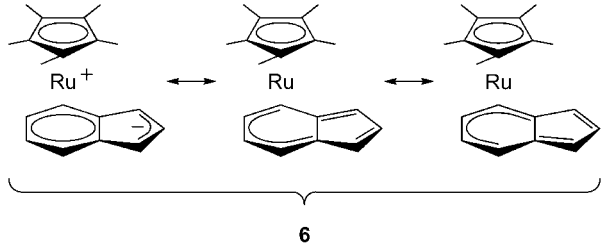
is folded along the line C2–C2a (by 6.4°). For comparison, the distances from the metal atom to the non-bonded carbon atoms of the $\eta^4$-coordinated arene ligand in the ruthenium compound $[(\eta^6\text{-}C_6Me_6)Ru(\eta^4\text{-}C_6Me_6)]$ (av. 3.028 Å) are 0.838–0.950 Å longer than the other Ru–C distances (av. 2.148 Å); the folding angle is 43°.[20] The much shorter elongation for **6**, along with the requirement of an 18-electron configuration, confirms the $\eta^6$-bonding mode of the indenyl ligand.

Compound **6** can be represented by three limiting structures (Scheme 7). The elongation of the Ru–C3(3A) distances and folding of the six-membered ring can be explained by a considerable contribution of the neutral structures with an $\eta^5$-coordinated indenyl ligand. Following the same reasoning, in the case of the related $\eta^6$-fluorenyl-iron[21] and -manganese[22] complexes the six-membered ring is also folded, with considerable elongation of the distance from the metal atom to one of the bridgehead carbon atoms.



Scheme 7. Limiting structures of **6**.

Cation **4b** has a slipped triple-decker structure with a central $\eta^5$:$\eta^6$-indenyl ligand. This ligand is essentially planar, with maximum deviations of the C(24) and C(27) atoms by 0.060 and 0.046 Å, respectively, towards the cobalt atom. The ligand planes are essentially coplanar, the dihedral angles Cp*/$C_9H_7$ and Cb*/$C_9H_7$ being 3.4° and 0.6°, respectively.

A more detailed consideration of the structure revealed a folding of the five- and six-membered rings along the axes C(21)–C(23) (2.5°) and C(24)–C(27) (7.4°). Likewise, the metal atoms are not quite symmetrically coordinated with the rings. For instance, the distances from the Ru atom to the bridgehead C(28) and C(29) atoms (2.217 and 2.218 Å, respectively) are longer than the other Ru–C distances (2.176, 2.176 and 2.186 Å). However, this elongation (0.03–0.04 Å) is rather small and comparable with that for the mononuclear complex **3b** (0.02–0.06 Å),[19] thus confirming the $\eta^5$-bonding mode of the indenyl ligand.[23] The Ru···($\eta^5$-$C_9H_7$) distance (1.835 Å) in cation **4b** is slightly shorter than that in **3b** (1.840 Å),[19] which suggests stronger bonding in the case of **4b**. The Ru···Cp* distance (1.772 Å) in **4b** is also shorter than that in **3b** (1.792 Å).[19]

The bonding of the cobalt atom with the six-membered ring is even more asymmetrical. The Co–C(28) and Co–C(29) distances (2.185 and 2.202 Å, respectively) are longer than the other Co–C distances (2.098, 2.099, 2.099 and 2.102 Å) by 0.09–0.10 Å. This elongation is practically the same as that for the M($\eta^6$-$C_9H_7$) fragment in $[CpRu(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)RuCp^*]^+$ (**12a**; 0.08–0.10 Å)[8a] and $[(cod)Rh(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)Cr(CO)_3]$ (0.09–0.12 Å),[24] slightly longer than that in the naphthalene complex $[Cb^*Co(C_{10}H_8)]^+$ (0.04–0.06 Å)[15] but smaller than in **6** (0.14–0.17 Å), the $\eta^6$-coordination mode in which is clear.

The triple-decker cation **4b** could be considered as an arene complex in which the sandwich compound **3b** acts as a six-electron ligand towards the $[Cb^*Co]^+$ fragment. The Co···Cb* distance in **4b** (1.726 Å) is significantly longer than that for cations $[Cb^*Co(C_6H_6)]^+$ (1.702 Å) and $[Cb^*Co(C_{10}H_8)]^+$ (1.707 Å),[15] thus suggesting the greater acceptor ability of **3b** compared with benzene and naphthalene.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The C–C bonds within the five-membered ring of the indenyl ligand in **4b** are generally longer than those in **3b**. The bond between the bridgehead carbon atoms is the most elongated (1.477 Å in **4b** and 1.446 Å in **3b**), in accordance with a greater loosening of the π bond upon bifacial coordination. A similar elongation has been observed for the triple-decker complex **12a** (av. 1.481 Å).[8a]

### Electrochemistry

In this section we describe the redox properties of the μ-indenyl triple-decker complexes **2**, **4b** and **5a**,**b** and their diruthenium analogues **12a**–**c**. Let us start with the homometallic $Ru_2$ derivatives. In order to understand their electron-transfer ability, Figure 3 compares the cyclic voltammetric response of the building unit **3b** (Figure 3, a) with that of the dinuclear monocation **12b** (Figure 3, b).

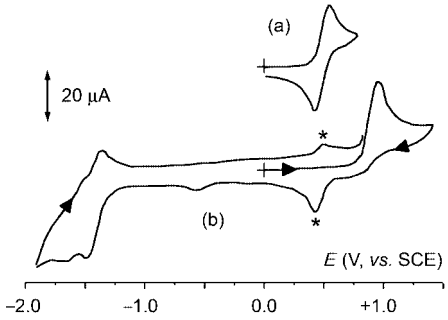


Figure 3. Cyclic voltammetric responses recorded at a platinum electrode for $CH_2Cl_2$ solutions of: a) **3b** ($0.9\times10^{-3}$ M) and b) **12b** ($1.0\times10^{-3}$ M). $[NBu_4]PF_6$ (0.2 M) as supporting electrolyte. Scan rate: 0.5 $V\,s^{-1}$.

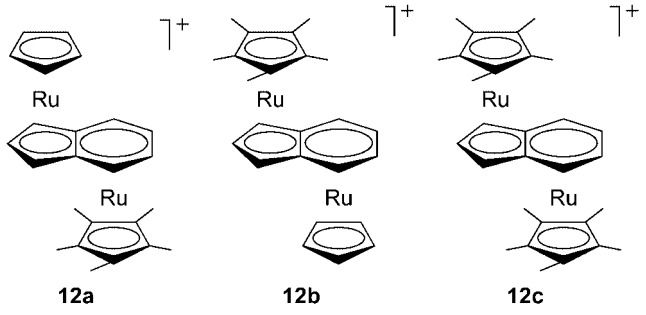


Complex **3b** undergoes a coulometrically measured one-electron oxidation that exhibits features of chemical reversibility on the cyclic voltammetric timescale. In fact, analysis of the responses with progressively increasing scan rates from 0.2 to 1.0 $V\,s^{-1}$ shows that: (i) the current ratio $i_{pc}/i_{pa}$ is constantly equal to 1; (ii) the current function $i_{pa}\cdot v^{-1/2}$ decreases by about 10% with a tenfold increase of the scan rate; and (iii) the peak-to-peak separation increases progressively from 98 to 130 mV. These parameters are diagnostic of a chemically reversible, but electrochemically quasi-reversible, one-electron process.[25] In reality, cyclic voltammetric tests carried out on the exhaustively oxidised solution ($E_w$ = +0.7 V) show partial decomposition of the electrogenerated monocation. A similar behaviour is exhibited by the parent compound **3a** except for the fact that the corresponding monocation is unstable even on the cyclic voltammetric timescale (the $i_{pc}/i_{pa}$ ratio reaches unity only at 5.0 $V\,s^{-1}$).

The voltammetric pattern exhibited by the triple-decker cation **12b** is more complex. It essentially undergoes an irreversible oxidation and a reduction displaying features of partial chemical reversibility. The rather positive and negative potential values of the two processes prevent a reliable determination of the number of electrons involved by controlled potential coulometry. Nevertheless, the cyclic voltammetric comparison with the one-electron oxidation of *N*,*N*-dimethyl-1-[1′,2-bis(diphenylphosphanyl)ferrocenyl]-ethylamine ($E^{\circ\prime}$ = +0.55 V) (an appropriate calibrant due to its similar molecular weight of 625.5)[25] supports the two-electron nature of the anodic step.[26] Since the cathodic process possesses a peak height similar to the anodic one, we assume that the reduction also involves a two-electron process. As a matter of fact, the minor reduction following the main cathodic step can be assigned to the by-product arising from the primary reduction as it tends to disappear with an increase of the scan rate.

We finally underline that the starred peak system that appears in the back-scans after traversing the anodic peak occurs at potential values coincident with those of **3b**, thus suggesting that the electron transfers trigger decomposition of the triple-decker derivative **12b** and regeneration of the precursor **3b**. A qualitatively similar redox picture holds for complexes **12a** and **12c**. The pertinent electrode potentials are compiled in Table 3.

Table 3. Formal electrode potentials [V vs. SCE] and peak-to-peak separations [mV] for the redox processes of the $Ru_2$ complexes and their mononuclear precursors in $CH_2Cl_2$ solution.

| Complex | $E^{\circ\prime}_{Ox}$ | $\Delta E_p$[a] | $E^{\circ\prime}_{Red}$ | $\Delta E_p$[a] |
|---|---|---|---|---|
| **3a** | +0.73[b,c] | 127 | – | – |
| **3b** | +0.50[b,d] | 96 | – | – |
| **12a** | +0.92[a,e,f] | – | –1.74[c,e] | 120 |
| **12b** | +0.92[a,e,f] | – | –1.43[c,e] | 66 |
| **12c** | +0.89[a,e,f] | – | –1.73[c,e] | 110 |
| $FeCp_2$ | +0.39[b] | 72 | | |

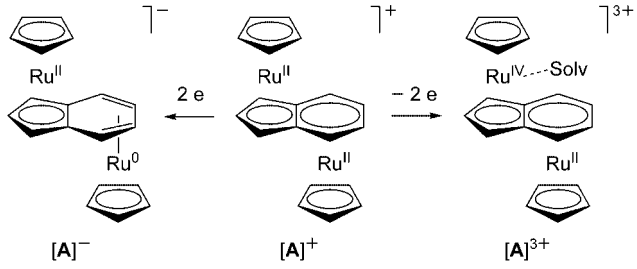
[a] Measured at 0.2 $V\,s^{-1}$. [b] One-electron process. [c] Complicated by chemical reactions. [d] See refs.[19,29] [e] Two-electron process. [f] Peak-potential value for irreversible processes.

In principle, the occurrence of single two-electron processes in binuclear derivatives would imply the lack of any electronic communication between metal centres.[27] We must, however, consider that the two ruthenium centres in cations **12a**–**c** are in different ligand surroundings: one is coordinated to the five-membered ring while the other is coordinated to the six-membered ring, which results in different charges at the metal centres. Therefore, two simultaneous one-electron processes at the two metal centres can be excluded. Most likely, the two-electron reduction occurs at the atom coordinated to the six-membered ring as it has a more positive charge whereas the two-electron oxidation is centred on the ruthenium atom coordinated to the five-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

membered ring. Such an assumption is supported by a comparison between the redox behaviour of ruthenocene and the benzene complex $[CpRu(C_6H_6)]^+$, which can be considered as the fused parts of the parent triple-decker cation $[CpRu(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)RuCp]^+$ ($[\mathbf{A}]^+$). The arene complex is reduced at –2.02 V but not oxidized up to +2.5 V,[28] whereas ruthenocene is oxidized at +0.8 V,[19] but, to the best of our knowledge, is not reduced up to –2 V.

As shown in Scheme 8, the two-electron reduction would result in anion $[\mathbf{A}]^-$, in which one ruthenium atom is $\eta^4$-coordinated to the six-membered ring of the indenyl ligand. Both metal atoms have 18 valence electrons (VE), in accordance with the strong preference of ruthenium for an 18 VE configuration. The two-electron oxidation would give cation $[\mathbf{A}]^{3+}$ with one 16 VE metal centre, which could be stabilized by coordination with a solvent molecule or a counterion (a similar process for mononuclear indenyl complexes is known[29]). Apparently, $[\mathbf{A}]^{3+}$ decomposes to give cation $[\mathbf{3a}]^+$, thereby explaining its appearance in the backscans.



Scheme 8. Reduction and oxidation of $[CpRu(\mu{:}\eta^5{:}\eta^6\text{-}C_9H_7)RuCp]^+$.

Let us now move on to the CoRu complexes **4b** and **5a**,**b**. The pertinent electrode potentials are compiled in Table 4. Cation **4b** obviously represents the simplest comparative connection with the preceding diruthenium derivatives. In fact, as illustrated in Figure 4, it affords a redox profile substantially similar to that of **12b**. The usual comparison with an equimolar amount of *N*,*N*-dimethyl-1-[1′,2-bis(diphenylphosphanyl)ferrocenyl]ethylamine supports the two-electron nature of the anodic process (and hence of the cathodic one). Also in this case, the chemical complication accompanying the oxidation process generates the monomeric building block **3b** (starred peak system).

Table 4. Formal electrode potentials [V vs. SCE] and peak-to-peak separations [mV] for the redox processes of the $Co_2$ complex **2** and CoRu complexes **4** and **5** in $CH_2Cl_2$ solution.

| Complex | $E_{pOx(I)}$ | $E_{pOx(II)}$ | $E^{\circ\prime}_{Red}$ | $\Delta E_p$[a] |
|---|---|---|---|---|
| **2** | +0.72[b] | ≈ +1.6[b,c,d] | –1.74[e] | 74 |
| **4b** | ≈ +0.93[b,e] | ≈ +0.93[b,e] | –1.67[c] | 102 |
| **5a** | +1.04[b,e] | [d] | –1.40[b,c] | – |
| **5b** | +0.70[b,e] | ≈ +1.5[b,e] | –1.81[b,c] | – |

[a] Measured at 0.2 V s$^{-1}$. [b] Peak-potential value for irreversible processes. [c] Two-electron process. [d] Substantially overlapped by the solvent discharge. [e] One-electron process.

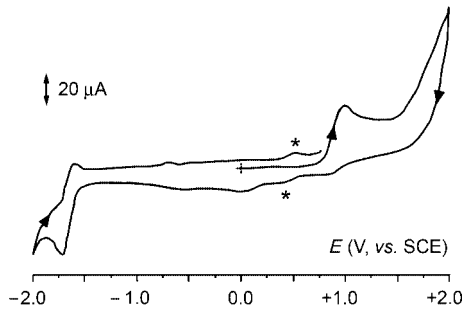


Figure 4. Cyclic voltammetric response recorded at a platinum electrode for a $CH_2Cl_2$ solution of **4b** ($0.8\times10^{-3}$ M). $[NBu_4]PF_6$ (0.2 M) as supporting electrolyte. Scan rate: 0.5 V s$^{-1}$.

In reality, Osteryoung square-wave voltammetry shows a slight inflection of the oxidation process, probably due to a very slight difference between the oxidation potentials of the $Ru^{II/III}$ and the $Ru^{III/IV}$ processes. A difference of about 0.08 V can be estimated from Figure S2 in the Supporting Information, even though the relative peak heights do not seem to support the one-electron nature of both processes. It cannot, however, be ruled out that this apparent discrepancy might be due to the mathematical treatment.

A different redox pattern is exhibited by complexes **5a**,**b**, which have the cobalt atom coordinated to the five-membered ring. As illustrated in Figure 5 for **5b**, they undergo two separate oxidations (the second of which is partially overlapped by the solvent discharge) and one reduction, which are irreversible in character. The peak height of the reduction is about twice that of each oxidation step. Comparison with the response of *N*,*N*-dimethyl-1-[1′,2-bis(diphenylphosphanyl)ferrocenyl]ethylamine supports the one-electron nature of the first anodic step.

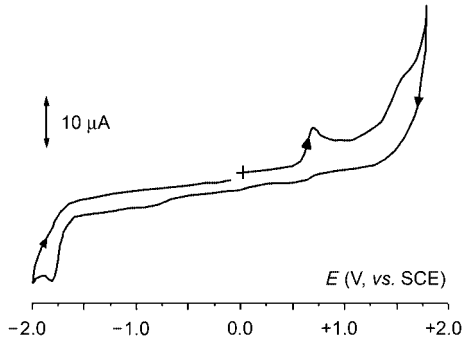

Figure 5. Cyclic voltammetric response recorded at a gold electrode for a $CH_2Cl_2$ solution of **5b** ($1.0\times10^{-3}$ M). $[NBu_4]PF_6$ (0.2 M) as supporting electrolyte. Scan rate: 0.2 V s$^{-1}$.

As a final consideration, we will briefly mention the redox behaviour of the $Co_2$ complex **2**. In $CH_2Cl_2$ solution, it exhibits a cyclic voltammetric profile which is qualitatively reminiscent of that exhibited by complexes **4b** and **5**, even though, as indicated in Table 4, some differences hold in the number of electrons involved either in the cathodic or the most anodic processes.

In view of the preceding discussion on the nucleophilic degradation of the present complexes in MeCN solution, it is interesting to compare the anodic response recorded in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$CH_2Cl_2$ solution with that recorded in MeCN solution, at low temperature (250 K). As illustrated in Figure 6, in MeCN solution the irreversible oxidation of the complex apparently occurs at notably lower potential values ($E_p$ = –0.09 V) and is followed by a main oxidation process with features of chemical reversibility ($E°'$ = +0.22 V). It should be noted that an increase of the temperature makes the two oxidation processes disappear (the first oxidation disappearing more quickly than the second one).

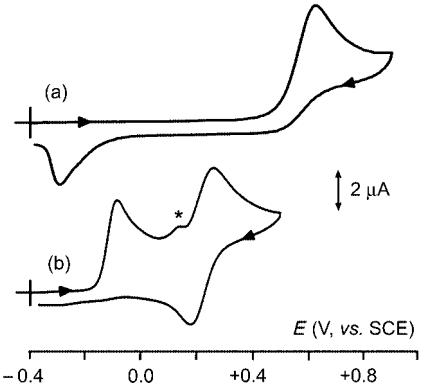

Figure 6. Cyclic voltammetric responses exhibited by **2** at a platinum electrode, under the following experimental conditions: a) $CH_2Cl_2$ solution ($0.7\times10^{-3}$ M), b) MeCN solution ($0.8\times10^{-3}$ M). $[NBu_4]PF_6$ (0.2 M) as supporting electrolyte. $T$ = 250 K. Scan rate: 0.2 V $s^{-1}$.

We would like to assign the second reversible oxidation present in MeCN solution to the decomposition product **1** even though the couple **1**/[**1**]$^+$ exhibits a rather congruent potential value ($E°'$ = +0.33 V) in $CH_2Cl_2$ solution.[12] The starred peak at +0.13 V could be attributed to the second decomposition product $[Cb*Co(MeCN)_3]^+$.[30] The assignment of the first irreversible oxidation is, in reality, rather less straightforward. In fact, even though it is conceivable that the low temperature might attenuate the lability of complex **2**, thus allowing us to detect the oxidation of the residual original product, the difference of about 0.7 V in redox potentials on passing from $CH_2Cl_2$ to MeCN solution makes such a proposal questionable. It is more likely that the first irreversible oxidation is due to the transient product $[Cb*Co(\mu{:}\eta^5{:}\eta^4\text{-}C_9H_7)Co(MeCN)Cb*]^+$, which arises from partial solvolysis of **2**.

## Conclusions

Electrophilic stacking reactions of indenyl sandwich complexes with the acetonitrile derivatives $[Cb*Co(MeCN)_3]^+$ and $[(C_5R_5)Ru(MeCN)_3]^+$ have proved to be effective for the preparation of slipped triple-decker cations. However, the acetonitrile eliminated can induce nucleophilic degradation of the product, thereby reducing the yield. The new method using $[Cb*CoI]_x/TlBF_4$ lacks this limitation and allows to obtain the target compounds in high yield.

## Experimental Section

**General:** All reactions were carried out under argon in anhydrous solvents that were purified and dried using standard procedures. The isolation of products was conducted in air unless otherwise stated. Starting materials were prepared as described in the literature: **1**,[12] **3a**,**b**, **6**,[8a] **7**,[31] $[Cb*Co(CO)_2I]$,[11,12] $[Cb*Co(MeCN)_3]PF_6$,[11,12] $[Cp*RuCl]_4$,[32] $[(C_5R_5)Ru(MeCN)_3]PF_6$[33,34] and $Tl[Co(\eta\text{-}7,8\text{-}C_2B_9H_{11})_2]$.[35] Irradiation was conducted in a Schlenk tube using a high-pressure mercury vapour lamp with phosphor-coated bulb (400 W). Both the tube and the lamp were placed in a vessel of appropriate volume covered inside with aluminium foil; cooling was accomplished with running water. The $^1H$ and $^{11}B$ NMR spectra were recorded with a Bruker AMX 400 spectrometer operating at 400.13 and 128.38 MHz, respectively. Materials and apparatus for electrochemistry have been described elsewhere.[36]

**Preparation of the Benzene Complex $[Cb*Co(C_6H_6)]I$:** A mixture of $[Cb*Co(CO)_2I]$ (3.5 g, 10 mmol), anhydrous aluminium chloride (13.3 g, 100 mmol) and benzene (70 mL) was vigorously stirred under reflux for 8 h. After cooling, the reaction mixture was carefully hydrolysed with cold water (ca. 100 mL). The aqueous phase was separated, filtered and stirred with $Me_3NO{\cdot}2H_2O$ (ca. 0.2 g, 1.2 mmol) and $NaI{\cdot}2H_2O$ (ca. 0.4 g, 2 mmol) for 4 h. The resulting brown precipitate of $[Cb*Co(CO)_2I]$ was filtered off. The filtrate was stirred with $NaI{\cdot}2H_2O$ (2.8 g, 15 mmol) and extracted with $CH_2Cl_2$ (4 × 50 mL). The organic phase was separated, dried under $MgSO_4$ and eluted through a short layer of silica gel (ca. 5 cm) with $CH_2Cl_2$. The filtrate was evaporated in vacuo to about 50 mL and diethyl ether (ca. 100 mL) was added. The yellow solid was filtered off and dried in vacuo. Yield: 2.3 g (63%). $^1H$ NMR ([$D_6$]-acetone): $\delta$ = 6.72 (s, 6 H, $C_6H_6$), 1.70 (s, 12 H, Cb*) ppm. $C_{14}H_{18}CoI$ (372.13): calcd. C 45.18, H 4.87; found C 45.01, H 4.93.

**Preparation of Slipped Triple-Decker Complexes Starting from $[Cb*Co(MeCN)_3]PF_6$ and $[(C_5R_5)Ru(MeCN)_3]PF_6$. $[Cb*Co(\mu,\eta^5{:}\eta^6\text{-}C_9H_7)CoCb*]PF_6$ (2·$PF_6$):** A mixture of $[Cb*Co(MeCN)_3]PF_6$ (57 mg, 0.13 mmol) and **1** (45 mg, 0.16 mmol) in $MeNO_2$ (3 mL) was stirred overnight. The solvent was then removed in vacuo and the residue was dissolved in $CH_2Cl_2$ (ca. 1 mL). Addition of diethyl ether (ca. 10 mL) gave a dark pink precipitate which was twice re-precipitated from $CH_2Cl_2$ by addition of diethyl ether. Yield: 42 mg (54%). $^1H$ NMR ($CDCl_3$): $\delta$ = 6.86 (m, 2 H, 4,7-H), 5.98 (m, 2 H, 5,6-H), 5.32 (t, $^3J$ = 2.4 Hz, 1 H, 2-H), 5.29 (d, $^3J$ = 2.4 Hz, 2 H, 1,3-H), 1.27 (s, 12 H, Cb*, $\eta^6$), 1.23 (s, 12 H, Cb*, $\eta^5$) ppm.[37] $C_{25}H_{31}Co_2F_6P$ (594.34): calcd. C 50.52, H 5.26; found C 50.29, H 5.18.

The following compounds were prepared in a similar way.

**$[Cp*Ru(\mu,\eta^5{:}\eta^6\text{-}C_9H_7)CoCb*]PF_6$ (4b·$PF_6$):** Yellow-orange solid. Yield: 73 mg (79%) from **3b** (56 mg, 0.16 mmol) and $[Cb*Co(MeCN)_3]PF_6$ (61 mg, 0.14 mmol) in $MeNO_2$ (3 mL). $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 6.72 (m, 2 H, 4,7-H), 5.80 (m, 2 H, 5,6-H), 5.00 (d, $^3J$ = 2.4 Hz, 2 H, 1,3-H), 4.86 (t, $^3J$ = 2.4 Hz, 1 H, 2-H), 1.67 (s, 15 H, Cp*), 1.30 (s, 12 H, Cb*) ppm.[37] $C_{27}H_{34}CoF_6PRu$ (663.52): calcd. C 48.87, H 5.16; found C 48.77, H 5.17.

**$[Cb*Co(\mu,\eta^5{:}\eta^6\text{-}C_9H_7)RuCp]PF_6$ (5a·$PF_6$):** All manipulations were carried out under argon. Red solid. Yield: 38 mg (54%) from **1** (37 mg, 0.13 mmol) and $[CpRu(MeCN)_3]PF_6$ (52 mg, 0.12 mmol) in thf (10 mL). $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 6.93 (m, 2 H, 4,7-H), 5.67 (m, 2 H, 5,6-H), 5.20 (br., 2 H, 1,3-H), 5.13 (br., 1 H, 2-H), 4.89 (s, 5 H, Cp), 1.29 (s, 12 H, Cb*) ppm.[37] $C_{22}H_{24}CoF_6PRu{\cdot}0.5CH_2Cl_2$ (635.86): calcd. C 42.50, H 3.96; found C 42.60, H 3.91.

**$[Cb*Co(\mu,\eta^5{:}\eta^6\text{-}C_9H_7)RuCp*]PF_6$ (5b·$PF_6$):** Dark red solid. Yield: 89 mg (79%) from **1** (53 mg, 0.19 mmol) and $[Cp*Ru(MeCN)_3]PF_6$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(86 mg, 0.17 mmol) in $CH_2Cl_2$ (10 mL). Alternatively, this complex was prepared by treatment of **6** (77 mg, 0.22 mmol) with [Cb*Co(MeCN)$_3$]$PF_6$ (83 mg, 0.19 mmol) in thf (10 mL); yield 76 mg (60%). $^1$H NMR ($CD_2Cl_2$): $\delta$ = 6.27 (m, 2 H, 4,7-H), 5.37 (m, 3 H, 2,5,6-H), 5.04 (d, $^3J$ = 2.4 Hz, 2 H, 1,3-H), 1.65 (s, 15 H, Cp*), 1.27 (s, 12 H, Cb*) ppm.[37] $C_{27}H_{34}CoF_6PRu$ (663.52): calcd. C 48.87, H 5.16; found C 48.93, H 5.19.

**[CpRu(μ,η$^5$:η$^6$-$C_9H_7$)CoCb*]$PF_6$ (4a·$PF_6$):** All manipulations were carried out under argon. A mixture of [Cb*Co(MeCN)$_3$]$PF_6$ (52 mg, 0.12 mmol) and **3a** (194 mg, 0.6 mmol) in $MeNO_2$ (3 mL) was stirred for 1 h. The solvent was then removed in vacuo, a new portion of $MeNO_2$ (3 mL) was added and stirring was continued for 1 h. This solvent removal-addition cycle followed by stirring for 1 h was repeated twice more. The volume was then reduced in vacuo to about 0.5 mL. Addition of diethyl ether (10 mL) gave a yellow-orange precipitate, which was twice re-precipitated from $MeNO_2$ by addition of diethyl ether. Yield: 55 mg (78%). $^1$H NMR ($CDCl_3$): $\delta$ = 7.04 (m, 2 H, 4,7-H), 5.81 (m, 2 H, 5,6-H), 5.47 (d, $^3J$ = 2.7 Hz, 2 H, 1,3-H), 5.02 (t, $^3J$ = 2.6 Hz, 1 H, 2-H), 4.45 (s, 5 H, Cp), 4.29 (s, 2 H, $MeNO_2$), 1.35 (s, 12 H, Cb*) ppm.[37] $C_{22}H_{24}CoF_6PRu·0.75MeNO_2$ (639.17): calcd. C 42.75, H 4.14; found C 42.86, H 4.26.

**Preparation of Slipped Triple-Decker Complexes Starting from [Cb*CoI]$_x$. [(η$^5$-$C_9H_7$)Ru(μ,η$^5$:η$^6$-$C_9H_7$)CoCb*]$BF_4$ (8·$BF_4$):** All manipulations were carried out under argon. The iodide complex [Cb*CoI]$_x$ was prepared from [Cb*Co($C_6H_6$)]I and used without further purification. A solution of [Cb*Co($C_6H_6$)]I (100 mg, 0.27 mmol) in acetonitrile (3 mL) was irradiated for 4 h, resulting in a colour change from yellow to red. The solvent was removed in vacuo to give [Cb*Co(MeCN)$_3$]I as a dark-red microcrystalline solid. This was heated in vacuo (ca. 0.01 Torr) at 50–60 °C for 15 min to afford crude [Cb*CoI]$_x$ as a dark-green solid. The latter was dissolved in thf (5 mL) to give a clear, dark-green solution. Complex **7** (106 mg, 0.32 mmol) and $TlBF_4$ (79 mg, 0.27 mmol) were then added and the mixture was stirred overnight. The yellow-orange precipitate was filtered off, washed with diethyl ether and dissolved in $CH_2Cl_2$ (ca. 5 mL). The orange-red solution obtained was filtered and concentrated in vacuo to about 0.5 mL. Addition of diethyl ether (ca. 10 mL) gave an orange solid, which was re-precipitated from $CH_2Cl_2$ by addition of diethyl ether. Yield: 103 mg (65%). $^1$H NMR ($CDCl_3$): $\delta$ = 6.87 (m, 4 H, 4–7-H, η$^5$-$C_9H_7$), 6.49 (m, 2 H, 4,7-H, μ-$C_9H_7$), 5.81 (m, 2 H, 5,6-H, μ-$C_9H_7$), 5.29 (s, 1 H, $CH_2Cl_2$), 5.12 (m, 4 H, 1,3-H, $C_9H_7$), 4.98 (t, $^3J$ = 2.6 Hz, 1 H, 2-H, μ-$C_9H_7$), 4.75 (t, $^3J$ = 2.4 Hz, 1 H, 2-H, η$^5$-$C_9H_7$), 1.35 (s, 12 H, Cb*) ppm.[37] $C_{26}H_{26}BCoF_4Ru·0.5CH_2Cl_2$ (627.77): calcd. C 50.70, H 4.34; found C 50.87, H 4.41. In a similar way, complex 8·$PF_6$ (69%) was prepared using $TlPF_6$ instead of $TlBF_4$.

**[Cp*Ru(μ,η$^5$:η$^6$-$C_9H_7$)CoCb*][Co(η-7,8-$C_2B_9H_{11}$)$_2$] ([4b][Co(η-7,8-$C_2B_9H_{11}$)$_2$]):** The title compound was prepared similar to 8·$BF_4$ from [Cb*Co($C_6H_6$)]I (100 mg, 0.27 mmol), **3b** (112 mg, 0.32 mmol) and Tl[Co(η-7,8-$C_2B_9H_{11}$)$_2$] (143 mg, 0.27 mmol). Yield: 164 mg (72%) of a dark-red solid. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 6.72 (m, 2 H, 4,7-H), 5.77 (m, 2 H, 5,6-H), 5.00 (d, $^3J$ = 2.6 Hz, 2 H, 1,3-H), 4.88 (t, $^3J$ = 2.6 Hz, 1 H, 2-H), 3.95 (br., 4 H, CH), 1.67 (s, 15 H, Cp*), 1.31 (s, 12 H, Cb*) ppm.[37] $^{11}$B NMR: $\delta$ = 5.8 (d, $J_{B,H}$ = 144 Hz, 1 B), 1.4 (d, $J_{B,H}$ = 141 Hz, 1 B), –5.5 (d, $J_{B,H}$ = 107 Hz, 2 B), –6.8 (d, $J_{B,H}$ = 125 Hz, 2 B), –17.3 (d, $J_{B,H}$ = 154 Hz, 2 B), –22.7 (d, $J_{B,H}$ = 168 Hz, 1 B) ppm.

**Formation of the Slipped Tetra-Decker Complex [Cp*Ru(μ,η$^5$:η$^6$-$C_9H_7$)Ru(μ,η$^5$:η$^6$-$C_9H_7$)RuCp*][$PF_6$]$_2$ ([11][$PF_6$]$_2$):** A mixture of 8·$PF_6$ (39 mg, 0.06 mmol), [Cp*RuCl]$_4$ (33 mg, 0.03 mmol) and $TlPF_6$ (42 mg, 0.12 mmol) in $MeNO_2$ (3 mL) was stirred overnight. The solvent was then removed in vacuo. The residue was extracted with $CH_2Cl_2$/petroleum ether (10:1) and filtered. The filtrate was concentrated in vacuo to about 0.5 mL. Addition of petroleum ether (10 mL) gave an orange-red precipitate, which was twice re-precipitated from $CH_2Cl_2$ by addition of petroleum ether. Yield: 28 mg (43%). $^1$H NMR ($CDCl_3$): $\delta$ = 6.38 (m, 4 H, 4,7-H), 5.45 (m, 4 H, 5,6-H), 5.20 (br., 6 H, 1–3-H), 1.66 (s, 30 H, Cp*) ppm. According to $^1$H NMR spectroscopy, a similar reaction with a 4:1 molar ratio of 8·$PF_6$ and [Cp*RuCl]$_4$ resulted in a mixture of complexes **8** (25%), **10** (15%) and **11** (60%).

**X-ray Crystallography:** Crystals of [**4b**][Co(η-7,8-$C_2B_9H_{11}$)$_2$] suitable for X-ray diffraction were grown by slow interdiffusion of a two-phase system containing diethyl ether and a $CH_2Cl_2$ solution of the complex. Crystals of **6** were obtained by cooling a hexane solution to –15 °C. X-ray diffraction experiments were carried out with a Bruker SMART 1000 CCD at 120 K. The adsorption correction was applied semi-empirically using equivalent reflections. Crystallographic data and structure refinement parameters are given in Table 5. All calculations were performed on an IBM PC/AT using the SHELXTL software.[38]

Table 5. Crystallographic data and structure refinement parameters for [**4b**][Co(η-7,8-$C_2B_9H_{11}$)$_2$] and **6**.

| Compound | [**4b**][Co(η-7,8-$C_2B_9H_{11}$)$_2$] | **6** |
|---|---|---|
| Empirical formula | $C_{31}H_{56}B_{18}Co_2Ru$ | $C_{19}H_{21}Ru$ |

# A High-Temperature Multinuclear NMR Study of $Na_3AlF_6$–FeO and $Na_3AlF_6$–$Fe_2O_3$ Melts

**František Šimko,*[a] Aydar Rakhmatullin,[b] Miroslav Boča,[a] Vladimír Daněk,[a] and Catherine Bessada[b]**

**Keywords:** Electrolysis / NMR spectroscopy / Cryolitic melts / Aluminium / Iron

In the Hall–Héroult process for the industrial production of aluminum, iron oxide impurities are known to lower the current efficiency as well as the metal quality. Iron can be present in the di- or trivalent form. The nature of dissolved $Fe^{III}$ and $Fe^{II}$ species and the reactions taking place in cryolitic melts have been investigated by high-temperature NMR spectroscopy. The evolution of $^{27}Al$, $^{23}Na$, and $^{19}F$ NMR chemical shifts are reported in the $Na_3AlF_6$–FeO and $Na_3AlF_6$–$Fe_2O_3$ systems for different iron oxide contents. They express the formation of oxofluoroaluminate species. For the $Na_3AlF_6$–FeO system, the $^{19}F$ signal appears only after 14 minutes at 1020 °C. The line position is shifted with heating time. This evolution is associated with a narrowing of the $^{27}Al$ signal due to a decrease in the content of paramagnetic compounds in the sample. This effect is probably caused by the evaporation of an $Fe^{II}$ compound, as already mentioned in the literature. For the $Na_3AlF_6$–$Fe_2O_3$ system we have never observed the $^{19}F$ NMR spectra over the full heating time (ca. 30 min). This could be due to the influence of paramagnetic $Fe^{III}$ nuclei, probably in $FeF_6^{3-}$ species present in the melt.

## Introduction

Aluminum is produced industrially by the Hall–Héroult electrolytic process. The impurities present during the process represent a critical problem because they negatively influence the current efficiency and may lower the metal quality.[1,2] Iron is one of the predominant impurities in the industrial production and can be present in the di- or trivalent state, especially as oxides (FeO, $Fe_2O_3$). Iron is introduced with the raw materials and/or by corrosion of the different cell parts. The nature of the dissolved species and different reactions taking place upon dissolution of $Fe_2O_3$ and FeO into cryolite (the major component of the electrolyte) is a crucial question. Because of the experimental difficulties due to the corrosive properties of fluoride melts at high temperature, only a few data have been reported, mainly deduced from solubility measurements.[3–9] From cryoscopy measurements, Diep[5] has suggested that $Fe_2O_3$ dissolves in cryolite to form nonvolatile sodium hexafluoroferrite ($Na_3FeF_6$), while for $Fe^{II}O$ the formation of $Na_xFeF_{(2+x)}$ complexes has been assumed by Jentofsen.[8,9] In both systems, the formation of oxofluoroaluminate complexes ($Al_2OF_6^{2-}$ and $Al_2O_2F_4^{2-}$) has also been proposed depending on the iron oxide concentration in the melt. Up to now, no direct detection of the ionic species formed in both kinds of melts has been attempted. Therefore, we propose in this paper to present their in situ NMR description. This spectroscopy is sensitive to the local environment around a selected nucleus, therefore it allows both qualitative and quantitative information about the different species existing in the bath to be determined.[10,11] The presence of $Fe^{II}$ in the melts can cause some paramagnetic effects on the NMR signal of the different nuclei, mainly broadening and shift and shape distortion of the line. These effects can be large enough to dramatically decrease the signal intensity and make any observation impossible. We will try to take advantage of this interaction and its effects on the spectra that we can associate with the detection of $Fe^{II}$ formation in the melt, and its implication on the ionic species.

We report in this paper $^{27}Al$, $^{23}Na$, and $^{19}F$ NMR measurements at high temperature in the $Na_3AlF_6$–FeO and $Na_3AlF_6$–$Fe_2O_3$ binary systems. The combination of the structural information given by the NMR signal of the different nuclei enables us to give the first experimental evidence of the formation of new species due to dissolution of iron oxide in these high-temperature melts.

## Results and Discussion

### $^{27}Al$ NMR Spectra

The HT $^{27}Al$ NMR spectra of molten $Na_3AlF_6$ with different amounts of FeO are shown in Figure 1.

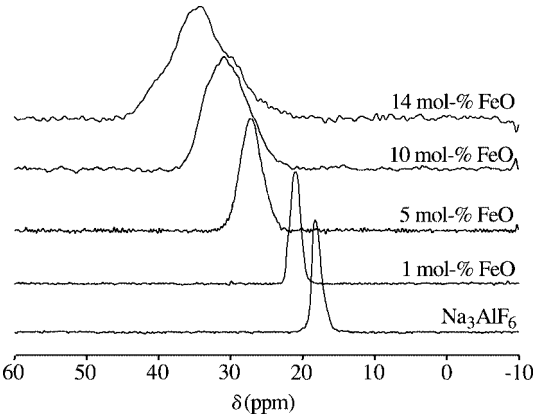

Figure 1. HT $^{27}$Al NMR spectra of $Na_3AlF_6$–FeO melts at 1020 °C.

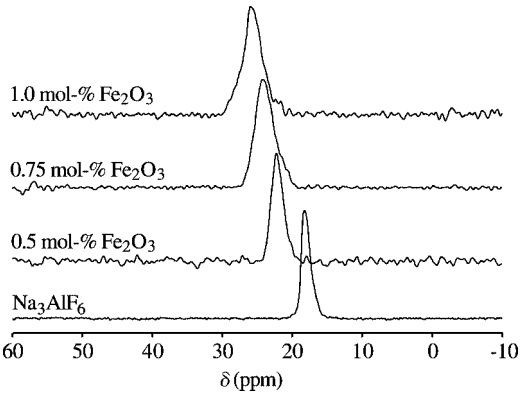

Figure 2. HT $^{27}$Al NMR spectra of $Na_3AlF_6$–$Fe_2O_3$ melts at 1020 °C.

Because of the dynamics existing in the melt, and the rapid exchange between the different possible species involving the nucleus under observation, all the HT NMR spectra consist of a single Lorentzian-shaped line. In pure cryolite, a sharp line at $\delta$ = 18.3 ppm is observed, in good agreement with the value reported by Lacassagne et al.[11] Upon addition of FeO the signal is shifted towards higher chemical shifts and broadens progressively with increased FeO content. For 1 mol-% added FeO, the line position is moved slightly to $\delta$ = 21 ppm, and the linewidth is unchanged. For 14 mol-% FeO, however, the peak is centered at $\delta$ = 34 ppm with an important modification of the lineshape ($\Delta_{1/2}$ = 900 Hz; Table 1). We observe the same kind of evolution for very low $Fe_2O_3$ additions (Figure 2), with a shift of 7 ppm for 1 mol-% added $Fe_2O_3$.

Table 1. Composition, $^{27}$Al and $^{23}$Na NMR chemical shifts, and linewidths in $Na_3AlF_6$–FeO and $Na_3AlF_6$–$Fe_2O_3$ melts at 1020 °C.

| $x$(FeO) [mol-%] | $\delta$($^{27}$Al) [ppm] | $\Delta_{1/2}$ [Hz] | $\delta$($^{23}$Na) [ppm] | $\Delta_{1/2}$ [Hz] |
|---|---|---|---|---|
| 0.0 | 18.8 | 149 | –6.5 | 130 |
| 1 | 21.0 | 179 | –6.4 | 179 |
| 5 | 27.3 | 398 | – | – |
| 10 | 30.9 | 765 | – | – |
| 14 | 34.3 | 903 | – | – |
| $x$($Fe_2O_3$) [mol-%] | $\delta$($^{27}$Al) [ppm] | $\Delta_{1/2}$ [Hz] | $\delta$($^{23}$Na) [ppm] | $\Delta_{1/2}$ [Hz] |
| 0.0 | 18.8 | 149 | –6.5 | 130 |
| 0.5 | 22.2 | 256 | –5.5 | 199 |
| 0. 75 | 24.2 | 326 | –5.0 | 262 |
| 1 | 26.0 | 361 | –4.8 | 296 |

These shifts can be caused by a) a modification in the local environment of the aluminum nucleus and the formation of new aluminum species with higher chemical shifts and b) the existence of unpaired electrons in the system that affect the local magnetic field around the observed nucleus and cause a shift and broadening of the line.

Let us discuss the first point. In the liquid phase, the observed peak position is the average of the chemical shifts of individual species present in the melt weighted by their respective populations [Equation (1)] and $\sum_i X^{Al}(A_i) = 1$.

$$\delta^{Al}{}_{mes} = \sum_i X^{Al}(A_i)\cdot\delta^{Al}(A_i) \quad (1)$$

where $X^{Al}(A_i)$ is the atomic fraction of Al atoms in the $A_i$ species and $\delta^{Al}(A_i)$ its chemical shift.

The $^{27}$Al chemical shift range for aluminum in oxide and fluoride materials is known to correlate strongly with the nature and number of the nearest neighbors around the aluminum atom and thus to its coordination. For $\{AlO_4\}$ tetrahedral sites in oxides the $\delta$ values fall in the range $\delta$ = 55 to 90 ppm and in the range $\delta$ = –20 to +20 ppm for the $\{AlO_6\}$ octahedral sites. $\{AlO_5\}$ groups have been characterized in different aluminosilicate structures with $\delta$ values of about 30 to 40 ppm. In fluorides, significantly different chemical shift ranges have also been reported for $AlF_4^-$, $AlF_5^{2-}$, and $AlF_6^{3-}$ units. They are clearly shifted towards lower chemical shifts: $\delta$ = 4 to –15 ppm for $AlF_6^{3-}$, $\delta$ = 40 to 35 ppm for $AlF_4^-$, and around $\delta$ = 20 ppm for $AlF_5^{2-}$ (Table 2).[10]

Table 2. $^{27}$Al chemical shift ranges for Al–O and Al–F coordination.[11]

| Al coordination | $\delta$($^{27}$Al) [ppm] |
|---|---|
| $AlO_4$ | 90–55 |
| $AlO_5$ | 40–30 |
| $AlO_6$ | 20 to –20 |
| $AlF_4$ | 35–40 |
| $AlF_5$ | 20 |
| $AlF_6$ | 4 to –15 |

These chemical-shift ranges will help us to better understand the chemical-shift evolution measured in the melts. An increase of the $^{27}$Al chemical shift can thus be related to a decrease of the average coordination number of the aluminum atoms and the formation of species with a lower coordination number.

It is also expected that the addition of oxides ($Al_2O_3$, FeO, $Fe_2O_3$) to molten cryolite will result in the formation of oxygen-containing entities, the most probable being the oxofluoroaluminate species $Al_2OF_6^{2-}$ and $Al_2O_2F_4^{2-}$ depending on the oxide content. From an NMR point of view, the local configuration around the aluminum atom in each of these two anions corresponds to tetrahedral environments $\{AlOF_3\}$ and $\{AlO_2F_2\}$. Lacassagne et al.[11] have determined the $^{27}$Al chemical shifts of these species as $\delta^{Al}{}_{Al_2OF_6^{2-}} = 50.0 \pm 0.5$ ppm and $\delta^{Al}{}_{Al_2O_2F_4^{2-}} =$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

58.5 ± 0.5 ppm, which lie between the chemical-shift ranges of $\{AlO_4\}$ and $\{AlF_4\}$ tetrahedral units. The formation of such oxofluoroaluminate species in the melt by dissolution of iron oxides should thus contribute to an increase of the measured $^{27}Al$ chemical shifts in molten cryolite, where aluminum atoms are essentially involved in pure fluoride environments.

Because of the line-shape distortion observed for high FeO amounts it is difficult to interpret the position of the line unambiguously. This distortion can be assigned to a paramagnetic effect that causes a line broadening and should certainly contribute to the shift of the line observed.

Iron in the +2 and +3 oxidation states may exist in a low-spin or a high-spin state, depending on the ligand-field strength. In both systems, $F^-$ and $O^{2-}$ ligands create a rather soft ligand field.[12] Thus, the high-spin state will be preferred [$(t_{2g})^4(e_g)^2$ for $Fe^{II}$ and $(t_{2g})^3(e_g)^2$ for $Fe^{III}$]. This is also supported by the increasing Boltzman distribution of the higher states with temperature increase. The important line broadening indicates that the distribution of local magnetic fields is spread over the sample. The broadening of the resonance signal reflects the extent of interaction between the unpaired electrons and the nucleus.[13]

We can calculate the $^{27}Al$ chemical shifts in the $Na_3AlF_6$–10 mol-% FeO system, by taking into account only the aluminum species involved in the suggested reaction (A).

$$2\,Na_3AlF_6(l) + 2\,FeO(s) \leftrightharpoons 2\,Na_2FeF_4(g) + Na_2Al_2O_2F_4(l) \quad (A)$$

At this FeO concentration, the $Al_2O_2F_4^{2-}$ anion is supposed to be formed in the melt in addition to the fluoroaluminate species $AlF_6^{3-}$, $AlF_5^{2-}$, and $AlF_4^-$ due to a dissociation reaction of unreacted molten cryolite.[1,14–18] Thus, starting from 90 mol of $Na_3AlF_6$ and 10 mol of FeO, we assume the formation of 5 mol of $Al_2O_2F_4^{2-}$ by reaction with 10 mol of $Na_3AlF_6$. After the reaction our system would contain 5 mol of $Al_2O_2F_4^{2-}$ and 80 mol of unreacted $Na_3AlF_6$.

From the mass-balance equation expressed for aluminum, we can calculate the anionic molar fractions of the different species in the melt. $x_i = \frac{N_i}{N_T}$, where $N_i$ is the number of mols of the species $i$ and $N_T$ the total number of mols. The atomic fractions can then be easily deduced and substituted in Equation (2) to give Equation (1).

$$\delta^{27}_{Al}(\text{calcd.})\,[\text{ppm}] = 0.0588\cdot\delta^{27}_{Al}(Al_2O_2F_4^{2-}) + 0.9412\cdot\delta^{27}_{Al}\left(\sum_{x=4}^{6} AlF_x^{(x-3)-}\right) \quad (2)$$

In this calculation, the contribution of unpaired electrons is not taken into account. $\delta^{27}_{Al}\left(\sum_{x=4}^{6} AlF_x^{(x-3)-}\right) = 18.8$ ppm is the chemical shift measured in molten cryolite, and $\delta^{27}_{Al}(Al_2O_2F_4^{2-}) = 58.5$ ppm is the $^{27}Al$ chemical shift value reported by Lacassagne et al.[11] for the $Al_2O_2F_4^{2-}$ species. This gives Equation (3).

$$\delta^{27}_{Al}(\text{calcd.})\,[\text{ppm}] = 0.0588\times 58.5 + 0.9412\times 18.8 = 21.1 \quad (3)$$

This calculated value is different from the experimental chemical shift measured in the melt of $\delta$ = 30.9 ppm. This difference can be associated with the presence of the unpaired electrons of iron in the oxidation state +2, as mentioned above.

In the ($Na_3AlF_6$–$Fe_2O_3$) system the formation of two oxofluoroaluminate anions should be considered even at such a low iron oxide content according to reaction B.[18,19]

$$4\,Na_3AlF_6 + Fe_2O_3 \leftrightharpoons 2\,Na_3FeF_6 + Na_2Al_2O_2F_4 + Na_2Al_2OF_6 + 2NaF \quad (B)$$

Addition of 1 mol of $Fe_2O_3$ to cryolite results in the formation of 1 mol of $Al_2OF_6^{2-}$ and 1 mol of $Al_2O_2F_4^{2-}$ by reaction with 4 mols of $Na_3AlF_6$. After the reaction, the system contains 1 mol of $Al_2OF_6^{2-}$, 1 mol of $Al_2O_2F_4^{2-}$, and 95 mols of unreacted $Na_3AlF_6$ and other species that do not contain Al atoms and thus that will not contribute to the $^{27}Al$ chemical shift. Normalization gives Equations (4) and (5).

$$\delta^{27}_{Al}(\text{calcd.})\,[\text{ppm}] = 0.0103\cdot\delta^{27}_{Al}(Al_2O_2F_4^{2-}) + 0.9794\cdot\delta^{27}_{Al}\left(\sum_{x=4}^{6} AlF_x^{(x-3)-}\right) \quad (4)$$

$$\delta^{27}_{Al}(\text{calcd.})\,[\text{ppm}] = 0.0103\times 50 + 0.0103\times 58 + 0.9794\times 18.3 = 19.0 \quad (5)$$

The difference between the calculated and the experimental chemical shift of $\delta$ = 26.0 ppm can again be attributed to the presence of unpaired electrons of iron in the oxidation state +3.

### $^{23}Na$ NMR Spectra

No significant modifications of the $^{23}Na$ chemical shift were observed in both systems. In the $Na_3AlF_6$–FeO system, when the amount of FeO is increased, the line is enlarged and distorted. This indicates the proximity of a paramagnetic element to the $^{23}Na$ surroundings but no direct bonding in a defined ionic species.

### $^{19}F$ NMR Spectra

No $^{19}F$ NMR signal was detected on melting. This can be explained by the existence of a strong paramagnetic effect that can disturb the signal and make it disappear. For $Na_3AlF_6$-10 mol-% FeO a small $^{19}F$ signal was observed but only after 14 minutes of heating. This means that some reaction has started that changes the local environment around the fluorine atoms.

In order to follow the kinetics of the dissolution of iron oxides in both systems, NMR spectra were recorded successively for the $^{27}Al$ and $^{19}F$ nuclei during 30 minutes at 1020 °C.

The evolution of the $^{19}F$ NMR spectra of the $Na_3AlF_6$-10 mol-% FeO mixture at 1020 °C is shown in Figure 3 as a function of time. When the heating duration is increased the position and the shape of the signal are modified. The signal position moves towards the position measured in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pure cryolite and at the same time the line becomes narrower (Table 3). This evolution can be explained by a continuous evolution of the nucleus shielding due to a decrease of the concentration of paramagnetic compounds in the investigated sample.

| 30 | 23.2 | 441 | 22 | –172.0 | 1494 | | | |
| 31 | 23.2 | 475 | 23 | –184.4 | 1183 | | | |
| | | | 24 | –193.1 | 971 | | | |
| | | | 25 | –194.8 | 829 | | | |

The decreasing concentration of paramagnetic iron in the sample is probably caused by the volatilization of $Fe^{II}$ compounds from the melt. The solidified sample was investigated by X-ray diffraction and no crystalline phase containing iron was detected. This confirms the formation of volatile compounds of the type $Na_xFeF_{2+x}$ ($x$ = 1, 2),[19,20] as already proposed in the literature.[8,9]

The same kind of measurements were made for the second system with $Fe_2O_3$ oxide ($Na_3AlF_6$ + 1 mol-% $Fe_2O_3$). In this case we were not able to observe any $^{19}F$ signal even after more than 30 minutes in the melt. The non-observation of the $^{19}F$ signal suggests the presence of stable, nonvolatile fluoride species in the melt involving the paramagnetic nuclei, probably in the form of $FeF_6^{3-}$ ions.[5,19] The paramagnetic effect seems to be strong enough to strongly affect the signal detection.

In the case of $^{27}Al$ in $Na_3AlF_6$ + 10 mol-% FeO, we observed a particular behavior of the spectrum with time whilst heating, with a shift of the line position and a progressive broadening of the line up to 14 minutes of heating (Figure 4). This evolution is then inversed and we observed a decrease of the chemical shift and a narrowing of the peak. This modification appears approximately at the same time as the $^{19}F$ signal is observed (Figure 3). These observations support the suggestion of a continuous decrease of the concentration of paramagnetic iron in the sample with FeO caused by evaporation of $Fe^{II}$ compounds from the system.

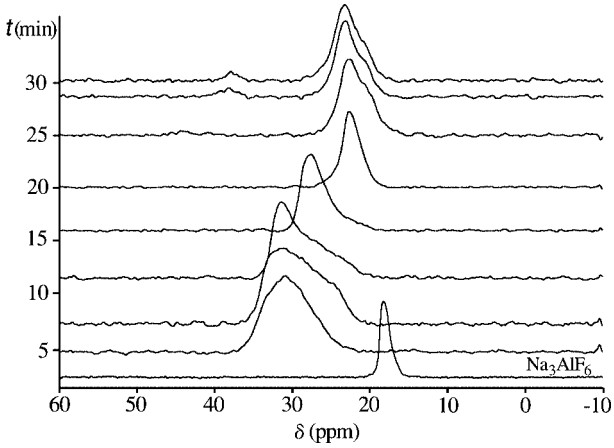

Figure 4. HT $^{27}Al$ NMR spectra of $Na_3AlF_6$–10 mol-% FeO at 1020 °C vs. heating time.

As mentioned above, the calculated value of the $^{27}Al$ chemical shift ($Na_3AlF_6$ + 10 mol-% FeO), assuming reaction B and no influence of the unpaired electrons, is $\delta$ = 20.6 ppm. This calculated value is in good agreement with the experimental value of $\delta$ = 23.0 ppm for the sample after 30 minutes of heating.

In the case of $Fe_2O_3$ (after five minutes of heating), the $^{27}Al$ chemical shift remains constant during further heating (Figure 5). This observation confirms the presence of stable, nonvolatile fluoride species in the melt involving the $Fe^{III}$ paramagnetic iron nuclei.

## Conclusions

High-temperature NMR experiments have been performed in molten cryolite with addition of different amounts of FeO or $Fe_2O_3$. The selective observation of the $^{27}Al$, $^{23}Na$, and $^{19}F$ signals in the melts at 1020 °C and their evolution with increasing iron oxide content has allowed us to confirm the formation of oxofluoroaluminate species. The non-observation of the $^{19}F$ signal caused by the paramagnetic influence of the $Fe^{II}$ ion in the melt is associated with the formation of "fluorinated iron" species. Even though this paramagnetic effect causes a strong broadening and distortion of the signals, we can still take advantage of this interaction and follow the formation and/or loss of the $Fe^{II}$ species. In the $Na_3AlF_6$–FeO melts, the $^{19}F$ signal was finally detected after 14 minutes heating, which would coincide with the evaporation of $Fe^{II}$ species. However, it was not observed at all in the $Na_3AlF_6$–$Fe_2O_3$ system due to the presence of stable, nonvolatile species involving the paramagnetic iron nuclei.

## Experimental Section

Samples were prepared by mixing $Na_3AlF_6$ (natural, from Ivigtut) and FeO or $Fe_2O_3$ (reagent grade, Aldrich). The compositions ranged from 0 to 14 mol-% of FeO and from 0 to 1 mol-% of $Fe_2O_3$ (see Table 1).

All NMR experiments were carried out using a Bruker DSX 400 (9.4 T) NMR spectrometer operating at frequencies of 104.2 MHz for $^{27}Al$, 105.8 MHz for $^{23}Na$, and 376.3 MHz for $^{19}F$. $^{27}Al$, $^{23}Na$, and $^{19}F$ chemical shifts are referenced to 1 M aqueous solutions of $Al(NO_3)_3$, NaCl, and $CFCl_3$ at room temperature, respectively. High temperature (HT) NMR experiments were performed using the previously described laser-heated system developed at the CRMHT (Orléans, France).[13] Every sample was placed in a high purity boron nitride (Carborundum) crucible tightly closed by a screwed BN cap and placed inside the RF coil, in the center of the cryomagnet. The crucible was then heated with a $CO_2$ laser beam ($\lambda$ = 10.6 μm, 120 W). The HT NMR spectra were obtained using single-pulse excitation with 20-, 30-, and 18-μs pulses for $^{27}Al$, $^{23}Na$, and $^{19}F$ measurements, respectively. Recycle delays of between 500 ms and 2 s (for $^{19}F$) were used, and 64 scans were measured to obtain a reliable signal-to-noise ratio. The powder mixtures were heated and melted up to 1020 °C. $^{27}Al$, $^{23}Na$, and $^{19}F$ NMR spectra were recorded for every composition after 4 min for temperature stabilization. In order to follow the kinetics of the iron oxide dissolution, $^{27}Al$, $^{23}Na$, and $^{19}F$ NMR spectra were recorded repeatedly up to 30 min at 1020 °C.

The NMR parameters (chemical shifts, line widths, quadrupolar coupling constants) were fitted to the experimental spectra with the Winfit program.[21]

# Complexation of Uranium(VI) with Thiodiacetic Acid in Solution at 10–85 °C

**Plinio Di Bernardo,*[a] PierLuigi Zanonato,[a] Arturo Bismondo,[b] Huijian Jiang,[c] Alexander Yu. Garnov,[c] Jun Jiang,[c] and Linfeng Rao*[c]**

**Keywords:** Uranium / Thermodynamics / Carboxylate ligands / EXAFS spectroscopy / Temperature effect

The protonation of thiodiacetate and its complexation with uranium(VI) in 1.05 mol kg$^{-1}$ $NaClO_4$ are studied at variable temperatures (10–85 °C). Three $U^{VI}$ complexes ($UO_2L$, $UO_2HL^+$, and $UO_2HL_2^-$, where L is thiodiacetate) are identified in this temperature range. The formation constants and the enthalpies of complexation are determined by potentiometry and calorimetry. The complexation of uranium(VI) with thiodiacetate becomes more endothermic at higher temperatures. However, the complexes become stronger due to increasingly more positive entropies of complexation at higher temperatures, which exceeds the increase in the unfavorable enthalpy of complexation. The values of the heat capacity of complexation ($\Delta C_p°$) are 122 ± 16, 302 ± 26, and 242 ± 23 J K$^{-1}$ mol$^{-1}$ for $UO_2L$, $UO_2HL^+$, and $UO_2HL_2^-$, respectively. The effect of temperature on the thermodynamics of the complexation is discussed in terms of the electrostatic model and the change in the solvent structure.

## Introduction

There has been significant interest in studies of the complexation of actinides with organic materials in solution at elevated temperatures due to the demand for scientific information to aid the safe management of nuclear wastes. The temperature of nuclear wastes in the storage tanks and the vicinity of the waste repository is known or estimated to be significantly above ambient temperature. For example, the temperature in the storage tanks is up to 90 °C and the temperature in the nuclear waste repository could be close to 100 °C thousands of years after the closure of the repository. Failure of the engineering barriers of the waste form could result in the contact of nuclear wastes with groundwater and possible migration of actinides into the environment. Prediction of the chemical behavior of actinides in waste processing and in the repository requires thermodynamic data on the complexation of actinides at elevated temperatures. At present, the majority of the thermodynamic data on actinide complexation are obtained at or near 25 °C.[1] The lack of data at elevated temperatures therefore makes it difficult to predict the behavior of actinides in waste processing and disposal, where elevated temperatures are expected.

While providing data to support the safe management of nuclear wastes, studies of the complexation of actinides at elevated temperatures could improve the fundamental understanding of the coordination chemistry of actinides as well. For example, the change in temperature perturbs the structure of solvent in the bulk and in the vicinity of the ions, alters its dielectric property, and thus affects the energetics of the complexation.[2,3] Therefore, the trends in thermodynamic parameters over a wide range of temperature could provide insight into the nature of the actinide complex and the solvent effect.

The liquid nuclear wastes in storage tanks are complex in composition and extremely diverse in acidity/basicity, ranging from strongly acidic to highly basic solutions. Many ligands could affect the behavior of actinides in liquid nuclear wastes by forming complexes. We have studied a series of mono- and dicarboxylic acids at elevated temperatures, including acetic,[4–7] malonic,[8] and oxydiacetic[9] acids. Some of the ligands exist in the nuclear wastes as degradation products of more complex organic compounds whose complexation with actinides has a direct impact on the behavior of actinides in waste storage and processing. Other ligands may not exist in nuclear wastes, but they are members of a series of structurally related ligands to allow a systematic study to help reveal the structure–function relationship. In this work, the complexation of $U^{VI}$ with thiodiacetate was studied at 10 to 85 °C. This system has been previously studied at 25 °C,[10,11] but not at elevated temperatures. Furthermore, due to the unavailability of tech-

niques to characterize the coordination modes, no structural information on the $U^{VI}$-thiodiacetate complexes in solution was obtained in the earlier studies. Therefore, the primary objectives in this work are: (1) to extend the thermodynamic database for the complexation of $U^{VI}$ with thiodiacetate to elevated temperatures; (2) to gain insight into the energetics of the complexation and the effect of temperature; and (3) to establish the coordination modes in the complexes. Thermodynamic parameters, including formation constants, enthalpy, and entropy, were determined by potentiometry and calorimetry. EXAFS was used, in conjunction with the thermodynamic data, to establish the coordination modes in the complexes.

## Results and Discussion

### Protonation of Thiodiacetate at 10–85 °C

The protonation constants of thiodiacetate at different temperatures were calculated from the data obtained by potentiometry. These constants were then used in the calculation of the enthalpies of protonation from the data obtained by calorimetry at the same temperature. The results are summarized in Table 1. The values obtained at 25 °C are in good agreement with the values at 20 and 25 °C in the literature.[10,12]

As is typical of many carboxylic acids,[13] the enthalpies of protonation of thiodiacetate are small (a few kilojoules per mol) and become more endothermic when the temperature is increased (Table 1). On the other hand, the entropy of protonation increases from 76 $J K^{-1} mol^{-1}$ (10 °C) to 100 $J K^{-1} mol^{-1}$ (85 °C) for HL, and from 130 $J K^{-1} mol^{-1}$ (10 °C) to 172 $J K^{-1} mol^{-1}$ (85 °C) for $H_2L$, thus favoring the protonation at higher temperatures. The increase in the entropy term ($T\Delta S$) is slightly larger than the increase in the enthalpy, which results in a net increase in the protonation constants when the temperature is increased.

Comparison between the thermodynamic functions concerning the protonation reactions of $TDA^{2-}$ and $ODA^{2-}$ may give additional information about these species in solution. Figure 1 shows the entropy and enthalpy of the first protonation of $TDA^{2-}$ and $ODA^{2-}$ ($H + L^{2-} \leftrightharpoons HL^-$) at different temperatures. The entropies of protonation of $TDA^{2-}$ and $ODA^{2-}$ are almost identical in the entire temperature region, whereas the enthalpies of protonation of $TDA^{2-}$ and $ODA^{2-}$ are parallel to each other, with a constant difference of 1.5 $kJ mol^{-1}$, at any given temperature. The fact that the $T\Delta S$ terms for $TDA^{2-}$ and $ODA^{2-}$ are identical at any temperature implies that the same degree of

disorder is generated when these two doubly charged anions are protonated. The fact that the enthalpy of protonation of $ODA^{2-}$ is higher than that of $TDA^{2-}$ at all temperatures probably results from the lower basicity of $ODA^{2-}$ than $TDA^{2-}$, which is due to a higher inductive effect exerted by the ether oxygen in $ODA^{2-}$ than the sulfur in $TDA^{2-}$. Since this inductive effect is likely to be independent of temperature, the difference in the enthalpies of protonation for $TDA^{2-}$ and $ODA^{2-}$ remains constant (approx. 1.5 kJ mol$^{-1}$) at any temperature and parallel trends in the enthalpy are observed.

## Complexation of Uranium(VI) with Thiodiacetate

### *Stability Constants at 10–85 °C*

Two representative potentiometric titrations at 10 and 85 °C are shown in Figure 2. The best model to fit the potentiometric data in the entire temperature range includes the formation of three $U^{VI}$/TDA complexes (ML, MHL, and $MHL_2$):

$UO_2^{2+} + L^{2-} \leftrightharpoons UO_2L(aq)$

$UO_2^{2+} + H^+ + L^{2-} \leftrightharpoons UO_2HL^+$

$UO_2^{2+} + H^+ + 2L^{2-} \leftrightharpoons UO_2HL_2^-$

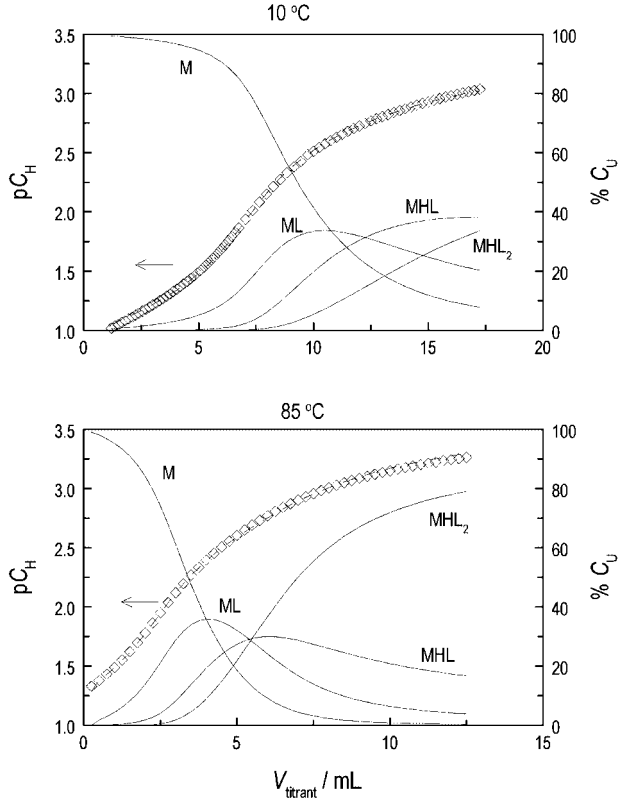

Figure 2. Potentiometric titrations of $U^{VI}$/thiodiacetate complexation. $I$ = 1.05 mol kg$^{-1}$ $NaClO_4$. Top: $T$ = 10 °C; $V^0$ = 32.0 cm$^3$, $C_H^0$ = 110.0 mM, $C_U^0$ = 19.22 mM; titrant $C_H/C_{TDA}$ = 0.485:0.481 M. Bottom: $T$ = 85 °C; $V^0$ = 29.0 cm$^3$, $C_H^0$ = 51.35 mM, $C_U^0$ = 21.19 mM; titrant $C_H/C_{TDA}$ = 0.556:0.556 M. Symbols: ◊: experimental data (p$C_H$); dashed curve: fit (p$C_H$); solid lines: percentage of $U^{VI}$ species (right $y$ axis).

The formation constants and Gibbs free energy of complexation at different temperatures were calculated and are given in Table 2. The model developed for the entire temperature range (from 10 to 85 °C) from this study is identical to the model for 25 °C from a previous study,[11] and the values at 25 °C from both studies agree well (Table 2). The data from this work indicate that the complexation between uranium(VI) and thiodiacetate is enhanced at elevated temperatures. The ML, MHL, and $MHL_2$ complexes at 85 °C are 6, 5, and 40 times as strong as those at 10 °C, respectively. The enhancement of complexation at elevated temperatures is consistent with the predictions by a simple electrostatic model that was developed to interpret the effect of temperature on the formation of lanthanide and actinide carboxylate complexes.[6–9,14]

### *Enthalpy and Entropy of Complexation at 10–85 °C*

A representative set of four calorimetric titrations at 25 °C is shown in part a of Figure 3. Similar titrations with solutions of different concentrations ($C_U$ and $C_H$) were performed at 10, 40, 55, 70, and 85 °C (see Table S3 in the Supporting Information). Using the formation constants of the complexes calculated from potentiometry, in conjunction with the constants and enthalpies of protonation (Table 1), the enthalpies of complexation for ML, MHL, and $MHL_2$ were calculated from the calorimetric titration data (see Table 2).

Using the thermodynamic values for protonation and complexation in Tables 1 and 2, simulated calorimetric titration curves for 10, 40, and 85 °C were calculated (Figure 3, b). The excellent agreement between the curves and experimental points confirms the mutual consistency of the calorimetric and potentiometric data on the complexation as well as the reliability of the data on protonation.

The data in Table 2 show that, as the temperature is increased, both the enthalpy and entropy of complexation increase, making opposite contributions to the temperature effect on the Gibbs free energy (and thus on the overall stability of the complexes). The overall stability constants increase because the increase in the entropy term ($T\Delta S$) exceeds the increase in the enthalpy. These trends are similar to previous observations for the $U^{VI}$/acetate,[7] $U^{VI}$/malonate,[8] and $U^{VI}$/oxydiacetate[9] systems, and are expected for typical hard acid–hard base interactions.[3] The increase of entropy with temperature could be the consequence of a more disordered bulk water structure due to the perturbation by more thermal motion at higher temperatures. In the process of complexation, the solvating water molecules are released to a more disordered bulk solvent. As a result, the gain in the complexation entropy is larger at higher temperatures. Meanwhile, the released water molecules would form fewer and/or weaker hydrogen bonds with the bulk water due to the thermal motion, thus resulting in less favorable enthalpy of complexation at higher temperatures. Detailed discussions on this point are given elsewhere.[6–9,14]

Figure 4 shows that the molar enthalpies of complexation for the three complexes increase monotonously as the temperature is increased. From these data, the heat capacity

### *Coordination Modes*

The results of EXAFS experiments with three $U^{VI}$ solutions are shown in Figure 5 and Table 3. Solution I contains 100% free $UO_2^{2+}$. Speciation calculations with the stability constants in Table 2 indicate that the major species in solution II are $UO_2HL^+$ (51%) and free $UO_2^{2+}$ (30%), while the major species in solution III is $UO_2HL_2^-$ (86%). The FT magnitudes for solutions I and II are quite similar and are fitted with two U–O scattering paths at 1.77–1.78 Å and five U–O scattering paths at 2.40–2.41 Å. The two oxygens at 1.77–1.78 Å are the axial oxygens in the $UO_2^{2+}$ moiety and the five oxygens at 2.40–2.41 Å are from the water and/or the thiodiacetate ligands in the equatorial plane of

Table 3. Fitting parameters for uranium $L_{III}$-edge EXAFS.

| Samples | Shell | $R$[a] [Å] | $N$[a] | $\sigma$[b] [Å] | $\Delta E_0$ [eV] |
|---|---|---|---|---|---|
| Solution I[c] | $U–O_{ax}$ | 0.77 | 1.8 | 0.0385 | –13.69 |
| (0.02 M $U^{VI}$/0.1 M $HClO_4$) | $U–O_{eq}$ | 2.41 | 5.5 | 0.0871 | –13.69 |
| Solution II | $U–O_{ax}$ | 0.78 | 2.0 | 0.0531 | –13.77 |
| (0.02 M $U^{VI}$/0.5 M TDA, pH 2.0) | $U–O_{eq}$ | 2.40 | 5.4 | 0.1040 | –13.77 |
| Solution III | $U–O_{ax}$ | 0.79 | 2.0 | 0.0526 | –16.58 |
| (0.02 M $U^{VI}$/0.5 M TDA, pH 3.5) | $U–O_{eq1}$ | 2.34 | 1.7 | 0.0368 | –16.58 |
| | $U–O_{eq2}$ | 2.49 | 2.7 | 0.0573 | –16.58 |

[a] The 95% confidence limits for the bond lengths ($R$) and coordination numbers ($N$) for each shell are: $U–O_{ax}$ = 0.01 Å and ±15%; $U–O_{eq}$ = 0.02 Å and ±25%, respectively. [b] $\sigma$ is the EXAFS Debye–Waller term which accounts for the effects of thermal and static disorder through damping of the EXAFS oscillations by the factor $\exp(-2k^2\sigma^2)$. [c] Data from ref.[8]

$UO_2^{2+}$. The FT magnitude for solution III shows, besides the prominent peak for the two axial oxygens, two distinct shells in the range of 1.7–2.3 Å (phase shift not corrected) and is fitted with two U–O scattering paths at 2.34 Å and three U–O scattering paths at 2.49 Å. In the following discussion, these structural data are used in conjunction with the thermodynamic parameters of complexation to shed light on the coordination modes in the $UO_2L$, $UO_2HL^+$, and $UO_2HL_2^-$ complexes.

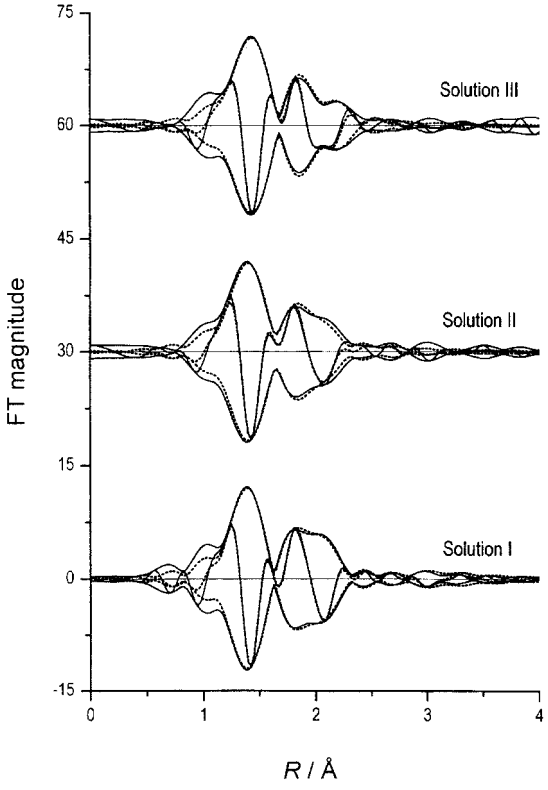

Figure 5. Fourier (FT) transform magnitude $\chi(k)\times k^3$ of the uranium $L_{III}$-edge EXAFS. Solid lines: experimental, dotted lines: fitted. Fitting results are given in Table 3.

### *$UO_2HL_2^-$*

Because this species is dominant (86%) in solution III, it is possible to propose a structure for this species based on the EXAFS data. In this complex, one TDA is fully deprotonated ($L^{2-}$) and the other TDA ligand is partially protonated ($HL^-$). As discussed in a previous study for the complexation of $U^{VI}$ with oxydiacetate (ODA),[9] the partially protonated ligand ($HL^-$) is likely to prefer a "terminal" didentate coordination mode in the complex, leaving the protonated carboxylate group free from metal binding. A proposed structure of the $UO_2HL_2^-$ complex is shown in Figure 6 (a), where one TDA ($L^{2-}$) is coordinated with $U^{VI}$ in a "global" didentate mode while the other TDA ($HL^-$) is in a "terminal" didentate mode similar to that in the uranium(VI) acetate complex described in the literature.[7] The U–O distance in the "global" didentate mode is shorter (2.34 Å) than that in the "terminal" didentate mode (2.49 Å). The oxygen from the water molecule is at a similar distance to the two oxygens of the "terminal" didentate carboxylate group and is not resolved by EXAFS.

### *$UO_2HL^+$*

Solution II contains 51% $UO_2HL^+$ and 30% free $UO_2^{2+}$ (30%). Therefore, the EXAFS data reflect the average coordination of $U^{VI}$ in these two major species. Because the partially protonated TDA ligand ($HL^-$) is likely to take a "terminal" didentate coordination mode in the complex, the structure of the $UO_2HL^+$ complex is proposed as shown in Figure 6 (b). The two oxygens from the terminal carboxylate group and the three oxygens from water molecules are all around 2.40 Å, resulting in a similar coordination shell of five oxygens as in the free $UO_2(H_2O)_5^{2+}$ (Solution I).

### *$UO_2L$*

This complex is not a major species in either solution I or solution II. Therefore, the EXFAS data do not provide information on the coordination mode of TDA in this complex. However, based on the structures of $UO_2HL_2^-$ (Figure 6, a) and $UO_2HL^+$ (Figure 6, b) proposed from the EXFAS data, it is reasonable to assume that the sulfur atom in $UO_2L$ does not participate in bonding with $U^{VI}$. Moreover, since the entropy of complexation primarily reflects the effect of dehydration and chelate formation, comparison of the entropy of complexation between TDA and structurally related dicarboxylates (e.g., ODA) could help reveal the coordination mode(s). A previous study has shown that, at 25 °C, one carboxylate group contributes approximately 50 $J\,K^{-1}\,mol^{-1}$ to the overall entropy of complexation.[9] For example, the value of $\Delta S_{298}$ for the didentate $U^{VI}$–phenylene-1,2-dioxydiacetate complex is 103 $J\,K^{-1}\,mol^{-1}$, while the values of $\Delta S_{298}$ for the tridentate $U^{VI}$–oxydiacetate and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

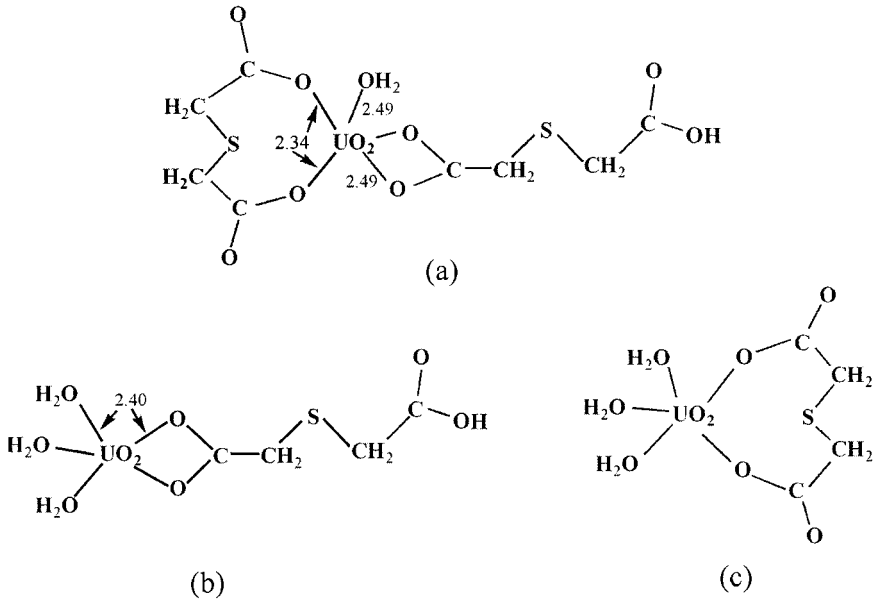

Figure 6. Proposed structures of uranium(VI) thiodiacetate complexes in solution: (a) $UO_2HL_2^-$, (b) $UO_2HL^+$, (c) $UO_2L$(aq), where $L^{2-}$ stands for the thiodiacetate anion.

$U^{VI}$–iminodiacetate complexes are 152 and 161 $J\,K^{-1}\,mol^{-1}$, respectively. The oxydiacetate and iminodiacetate ligands in these complexes are tridentate because the ether oxygen or the nitrogen atoms participate in the complexation.[9] The value of $\Delta S_{298}$ for the $U^{VI}$-TDA complex ($UO_2L$) is 110 $J\,K^{-1}\,mol^{-1}$ from this work (Table 2), similar to that for the didentate $U^{VI}$–phenylene-1,2-dioxydiacetate complex but much smaller than those for the tridentate $U^{VI}$-ODA and $U^{VI}$-IDA complexes. Thus, the thermodynamic data are consistent with a didentate mode in the 1:1 $U^{VI}$-TDA complex. Both carboxylate groups of TDA coordinate with $U^{VI}$ while the sulfur atom does not participate in the complexation. A proposed structure for $UO_2L$ is shown in Figure 6 (c).

## Conclusions

In the temperature range from 10 to 85 °C, three uranium(VI) thiodiacetate complexes ($UO_2L$, $UO_2HL^+$, and $UO_2HL_2^-$) have been identified by potentiometry and calorimetry. Both the enthalpy and entropy of complexation increase as the temperature is increased, although they make opposite contributions to the overall stability of the complexes. The complexes become stronger at higher temperatures due to a larger contribution from the entropy, which exceeds the unfavorable effect of enthalpy. The thermodynamic parameters, in conjunction with the structural information from EXAFS, suggest that TDA coordinates with $U^{VI}$ through the carboxylate group(s) and that the sulfur atom does not participate in the complexation. In $UO_2L$, the fully deprotonated TDA is in a "global" didentate mode through both carboxylate groups. However, in $UO_2HL^+$ and $UO_2HL_2^-$, the partially protonated TDA is probably in a "terminal" didentate mode, with the protonated carboxylate group free from metal bonding.

## Experimental Section

**Chemicals:** All chemicals were reagent grade or higher. Distilled and deionized water was used in preparations of all the solutions. The stock solution of uranium(VI) perchlorate was prepared by dissolving uranium trioxide ($UO_3$) in perchloric acid. The concentration of uranium(VI) in the stock solution was determined by absorption spectrophotometry and fluorimetry.[15] Gran's potentiometric method[16] was used to determine the concentration of perchloric acid in the stock solution. Volumetric standard sodium hydroxide solutions were purchased from Brinkmann Instruments, Inc. or Sigma–Aldrich, Inc. and verified to be carbonate-free prior to use. Solutions of sodium thiodiacetate were prepared by adding calculated amounts of sodium hydroxide to solutions of thiodiacetic acid. The ionic strength of all the solutions used in potentiometry and calorimetry was adjusted to 1.0 M at 25 °C by adding appropriate amounts of sodium perchlorate as the background electrolyte.

**Potentiometry:** The protonation constants of thiodiacetate (TDA) and the stability constants of the uranium(VI) TDA complexes were determined by potentiometric titrations in a temperature range from 10 to 85 °C. A specially designed titration vessel was used to avoid the problem of water condensation during the titrations at temperatures above the ambient. Details of the titration setup have been provided elsewhere.[6]

Electromotive force (EMF, in millivolts) was measured with a Metrohm pH meter (Model 713) equipped with a Ross combination pH electrode (Orion Model 8102). Because potassium perchlorate is much less soluble than sodium perchlorate, precipitation of the former could result in the clogging of the electrode frit glass septum. As a result, the original electrode filling solution (3.0 M potassium chloride) was replaced with 1.0 M sodium chloride. The electrode potential (mV) in acidic solutions can be expressed as Equation (1).

$$E = E^0 + RT/F \ln[H^+] + \gamma_H[H^+] \quad (1)$$

$R$ is the gas constant, $F$ is the Faraday constant, and $T$ is the temperature in Kelvin. The last term in Equation (1), $\gamma_H[H^+]$, is the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

electrode junction potential for the hydrogen ion. Prior to each protonation or complexation titration, an acid/base titration with standard perchloric acid and sodium hydroxide solutions was performed to obtain the parameters $E^0$ and $\gamma_H$. These parameters allowed the calculation of hydrogen ion concentrations from the electrode potential in the subsequent titration. Corrections for the electrode junction potential for the hydroxide ion are not necessary in this work because all the experiments were conducted in acidic solutions, where the junction potential for the hydroxide ion is negligible.

Detailed conditions for the potentiometric titrations are provided in Tables S1 and Table S2 in the Supporting Information. Multiple titrations were conducted at each temperature with solutions of different concentrations ($C_{TDA}$, $C_H$, and $C_U$). 50–70 Data points were collected in each titration. The protonation constants of TDA, $K_{H,M}$, and the formation constants of $U^{VI}$-TDA complexes, $\beta_{j,M}$, on the molarity scale were calculated with the program Hyperquad.[17] To allow the comparison at different temperatures, the constants in molarity were converted into the constants in molality according to Equation (2).[18]

$$\log_{10}K_m = \log_{10}K_M + \Sigma_r v_r \log_{10}\vartheta \quad (2)$$

$K_m$ and $K_M$ are the equilibrium constants of a reaction in molality and molarity, respectively, $\vartheta$ is the ratio of the values of molality to molarity for the specific ionic medium. For the 1.0 M $NaClO_4$ used in this study, $\vartheta$ equals 1.05 L of solution per kilogram of water. $\Sigma_r v_r$ is the sum of stoichiometric coefficients of the reaction ($v_r$ is positive for products and negative for reactants.)

**Calorimetry:** Calorimetry was used to determine the enthalpy of thiodiacetate protonation and complexation with $U^{VI}$. The calorimetric titrations were conducted with both an isoperibol calorimeter (Model ISC-4285, Calorimetry Sciences Corp.) at the Lawrence Berkeley National Laboratory (for $T$ from 25 to 85 °C) and an isothermal microcalorimeter (Thermometric 2277 Thermal Activity Monitor, nanoWatt model) at the University of Padova (for $T$ = 10 °C). The performance of the isoperibol calorimeter was tested by measuring the enthalpy of protonation of 2-bis(2-hydroxyethyl)amino-2-(hydroxymethyl)propane-1,3-diol at different temperatures. The results are –29.1 ± 0.3 kJ mol$^{-1}$ at 45 °C and –29.3 ± 0.3 kJ mol$^{-1}$ at 70 °C, in good agreement with those in the literature (–28.4 ± 0.3 kJ mol$^{-1}$ at 45 °C and –29.3 ± 0.2 kJ mol$^{-1}$ at 70 °C).[19]

Detailed conditions for the calorimetric titrations are provided in Table S3 in the Supporting Information. Multiple titrations were performed at each temperature to obtain the enthalpy of protonation of TDA and the enthalpy of complexation between $U^{VI}$ and TDA, using different concentrations of the titrant or $UO_2(ClO_4)_2$ and $HClO_4$ in the cell. For each titration run, $n$ experimental values of the total heat produced in the reaction vessel ($Q_{ex,j}$, $j$ = 1 to $n$, usually $n$ = 50–70), were calculated as a function of the volume of the added titrant. These values, corrected for the heat of dilution of the titrant ($Q_{dil,j}$, determined in separate runs), gave the net reaction heat: $Q_{r,j} = Q_{exp,j} - Q_{dil,j}$. A quantity, $\Delta h_v$, was then calculated for the stepwise addition by Equation (3).

$$\Delta h_v = \sum_{j=1}^{j=n} (Q_{r,j} - Q_{p,j})/n \quad (3)$$

For the protonation titrations, $Q_{p,j}$ is the heat of water formation and $n$ is the number of mols of TDA in the cell. For the complexation titrations, $Q_{p,j}$ is the sum of the heat calculated for the water formation and ligand protonation while $n$ is the number of mols of $U^{VI}$ in the cell. The enthalpies of reaction were calculated, with a home modified version of the computer program Letagrop,[20] to use $\Delta h_v$ as the error-carrying variable while assigning equal weight to all the titrations with different amounts of uranium(VI) (for the U/TDA systems) or TDA (for the H/TDA systems).

**EXAFS Spectroscopy:** Three uranium(VI) solutions were prepared for EXAFS experiments. Solution I contained 0.02 M $UO_2(ClO_4)_2$ in 0.1 M $HClO_4$ with no thiodiacetic acid. Solutions II and III contained 0.02 M $UO_2(ClO_4)_2$ and 0.5 M thiodiacetic acid at pH 2.0 and 3.5, respectively. Approximately 2 mL of each solution was sealed in a polyethylene tube (5 mm i.d.) and mounted on an aluminum sample positioner with Scotch tape for the experiments.

Uranium $L_{III}$-edge EXAFS spectra were collected at the Stanford Synchrotron Radiation Laboratory (SSRL) on beamline 4-1 under normal ring operating conditions (3.0 GeV, 50–100 mA). Energy scans of the polychromatic X-ray beam were obtained using a Si(220) double-crystal monochromator. The vertical slit width was 0.5 mm, which reduced the effects of beam instabilities and monochromator glitches while providing ample photon flux. The higher order harmonic content of the beam was reduced by detuning the crystals in the monochromator so that the incident flux was reduced to 50% of its maximum at the scan ending energy. The EXAFS data were collected in both the transmission mode using argon-filled ionization chambers and the fluorescence mode using a four-element Ge detector, up to $k_{max} \approx 15$ Å$^{-1}$. Usually three or four scans were performed for each sample. Energy calibration was based on assigning the first inflection point of the absorption edge for uranium dioxide to 17166 eV. The EXAFS spectra were fitted with the R-space X-ray Absorption Package (RSXAP),[21] using parameterized phase and amplitude functions generated by the program FEFF7.[22] Single scattering interactions of U–$O_{ax}$ (axial oxygen) and U–$O_{eq}$ (equatorial oxygen) were included.

**Supporting Information** (see footnote on the first page of this article): Tables S1 and S2: Experimental conditions of potentiometry for proton/thiodiacetate and uranium(VI)/thiodiacetate systems, respectively. Table S3. Experimental conditions of calorimetry for thiodiacetate protonation and uranium(VI)/thiodiacetate complexation.

# A Novel Copper(I) Halide Framework Templated by Organic–Inorganic Hybrid Polyoxometalate Chains Formed In Situ: A New Route for the Design and Synthesis of Porous Frameworks

**Hua Jin,[a] Yanfei Qi,[a] Enbo Wang,*[a] Yangguang Li,[a] Chao Qin,[a] Xinlong Wang,[a] and Song Chang[a]**

**Keywords:** Coordination polymers / Organic–inorganic hybrid composites / Polyoxometalates / Template synthesis

A 1D organic–inorganic hybrid polyoxometalate chain has been used as a non-coordinating anionic template for the construction of a novel 3D copper halide 4,4′-bipy framework, namely $[Cu_3^{I}Cl(4,4'\text{-bipy})_4][Cu^{II}(1,10\text{-phen})_2Mo_8O_{26}]$. X-ray diffraction experiments revealed that the title compound consists of chloride-bridged trinuclear $Cu^{I}$ units linked by neutral organic 4,4′-bipy groups into a 3D framework with hexagon-like channels in which 1D organic–inorganic hybrid polyoxometalate chains reside. This is the first example of a 1D organic–inorganic hybrid polyoxometalate chain functioning as a novel anionic template for the construction of a 3D framework.

## Introduction

Porous materials have attracted much attention because of interest in the creation of nanometer-sized spaces and their potential applications in gas storage, separation, ion exchange, or heterogeneous catalysis.[1] A promising approach toward the synthesis of these porous materials is the design of metal-organic frameworks built up from transition-metal ions and bridging organic ligands.[2] In this field, copper halides bridged by organic species have been subjected to a vast number of studies owing to the fact that the architectures of copper halides can be tuned at the molecular level so as to design and control, at least partly, the molecular structures of the final products,[3] especially since the so-called secondary building block (SBU) concept was proposed and extended by Yaghi and co-workers.[4] However, it is still important to synthesize robust 3D frameworks with high porosity.[5]

Anions are capable of directing the formation of some porous entities through either cation–anion interactions or hydrogen-bonding interactions between an organic host and an anionic guest.[6] Compared to simple anionic templates, POMs are bigger, have more diverse topologies, a higher charge, and are more suitable as guest units in the metal-organic host as they lead to larger pores, channels, and cavities. In this field, several interesting host–guest complex with various dimensional structures have been prepared.[7] Zubieta and co-workers, for example, have reported $[Fe(tpypor)_3Fe][Mo_6O_{19}]\cdot xH_2O$[7a] (tpypor = tetrapyridylporphyrin), which possesses a 3D $[Fe(tpypor)_3Fe]^{2+}$ host framework with a $[Mo_6O_{19}]^{2-}$ molecule encapsulated, and Zheng et al. have recently reported the novel decavanadate-anion-templated copper framework $[Cu_3(2\text{-pzc})_4(H_2O)_2(V_{10}O_{28}H_4)]\cdot 6.5H_2O$ (2-pzc = 2-pyrazinecarboxylate).[7b] In 2002, the Keller group first prepared the novel compound $[Cu_3(4,4'\text{-bipy})_5(MeCN)_2]PW_{12}O_{40}\cdot 2C_6H_5CN$[7c] constructed from a 3D Cu-4,4′-bipy coordination polymer with a large pore as host and Keggin-type heteropolyoxoanions as template. More recently, the 2D layer-like compound $Na_3[4,4'\text{-Hbipy}]\{Cu_4(4,4'\text{-bipy})_8(H_2O)_8\}[PW_{11}CuO_{39}(H_2O)][PW_{10}Cu_2O_{38}(H_2O)_2]\cdot 38H_2O$[7d] with Keggin-type POMs as guests has been characterized by the Dolbecq group. As part of our continuing efforts in the construction of functional porous coordination polymers,[8] we have exploited the Lindquist-type POM $[Mo_6O_{19}]^{2-}$ to synthesize several novel polyoxometalate-templated, supramolecular networks based on lanthanide dimers.[9] To the best of our knowledge, no metal-organic frameworks using an organic–inorganic hybrid polyoxometalate chain as template has been reported thus far.

In the hope that the combination of copper halides with POMs not only shows value-added properties and possible synergistic effects but also allows the creation of new networks with unique physical properties, we report here the unprecedented compound $[Cu_3^{I}Cl(4,4'\text{-bipy})_4][Cu^{II}(1,10\text{-phen})_2Mo_8O_{26}]$ (**1**), which exhibits a novel 3D copper halide 4,4′-bipy framework templated by a 1D organic–inorganic hybrid polyoxometalate chain. Additionally, we have also

prepared another compound by changing the reaction conditions, namely $(H_3O)[Cu^{I}(4,4'\text{-bipy})]_3[Mo_8O_{26}]$, which exhibits a new 2D supramolecular network consisting of β-$[Mo_8O_{26}]^{4-}$ clusters and copper-organonitrogen coordination polymer chains via weak long-range Cu–O interactions.

## Results and Discussion

### Syntheses

The successful isolation of compounds **1** and **2** depends on the use of hydrothermal techniques. Hydrothermal synthesis has recently been proved to be a particularly useful technique for the preparation of organic–inorganic hybrid materials.[10] The exploitation of hydrothermal conditions requires a paradigm shift from the thermodynamic to the kinetic such that equilibrium phases are replaced by structurally more complex metastable phases.[11] In the hydrothermal environment, the reduced viscosity of the solvent results in enhanced rates of solvent extraction of solids and crystal growth from solution. Furthermore, since different solubility problems can be minimized, a variety of organic and inorganic precursors can be introduced. However, hydrothermal synthesis is still a relatively complex process because many factors can influence the outcome of reaction, such as the type of initial reactants, starting concentrations, pH values, reaction time, and temperature.[12]

Parallel experiments showed that the pH value of the reaction system is crucial for the crystallization of compound **1**: dark-green crystals of compound **1** could only be obtained in the pH range 3.9–4.5. In addition, the nature of the divalent transition metal is crucial for the formation of compound **1**. We tried to replace $CuCl_2{\cdot}2H_2O$ with $NiCl_2{\cdot}6H_2O$, $CoCl_2{\cdot}6H_2O$, $MnCl_2{\cdot}4H_2O$, or $FeCl_2{\cdot}4H_2O$ in the synthesis of compound **1**, but no isostructural compounds were obtained. When $CuCl_2{\cdot}2H_2O$ was replaced with $NiCl_2{\cdot}6H_2O$ or $CoCl_2{\cdot}6H_2O$ $[\{Ni(1,10\text{-phen})_2\}_2(\xi\text{-}Mo_8O_{26})]{\cdot}H_2O$[13] or $\{Co(1,10\text{-phen})_3\}_2[Mo_6O_{19}][Mo_8O_{26}]{\cdot}2H_2O$[14] could be synthesized. However, when $CuCl_2{\cdot}2H_2O$ was replaced with $MnCl_2{\cdot}4H_2O$ or $FeCl_3{\cdot}6H_2O$ no crystalline phase was formed. $[Cu(1,10\text{-phen})]_2[\{Cu(1,10\text{-phen})\}_2\text{-}Mo_8O_{26}]{\cdot}2H_2O$[15] could be synthesized without 4,4′-bipy, and compound **2** could be synthesized without 1,10-phen.

### Structure Description

The single X-ray structural analysis revealed that the structure of **1** is constructed from a coordination complex $\{[Cu_3^{I}Cl(4,4'\text{-bipy})_4]\}_n^{2n+}$ scaffolding and encapsulating organic–inorganic hybrid $\{Cu^{II}(1,10\text{-phen})_2Mo_8O_{26}\}_n^{2n-}$ polyoxometalate chains.

The metal-organic framework is composed of hexagon-grid layers pillared by 4,4′-bipy ligands in which there are two distinct copper centers: one resides in the corner of the hexagon lattice in each layer and is additionally coordinated to three nitrogen atoms of 4,4′-bipy and one chlorine atom, while the second copper center is coordinated to two pyridyl nitrogen donors and one chlorine atom, thus two Cu(3) and one Cu(2) are connected into a trinuclear copper cluster through the chlorine atom. The hexagon-grid layer lies parallel to the *ab* plane (Figure 1). Each layer consists of hexagonal lattices, in which the Cu atoms are located at the corners, while the 4,4′-bipy ligands and Cl atoms are located at the edges. As shown in Figure 2, there is no interpenetration between the layers, thus this type of arrangement leads to hexagonal channels of about $5.3\times11.1\times11.1$ Å$^3$, in which organic–inorganic hybrid $\{Cu^{II}(1,10\text{-phen})_2Mo_8O_{26}\}_n^{2n-}$ polyoxometalate chains are located. The octamolybdate $[Mo_8O_{26}]^{4-}$ cluster, which is built up from eight distorted $\{MoO_6\}$ edge-shared octahedra, is a typical β-octamolybdate. The valence sum calculations[16] show that all molybdenum atoms are in the +6 oxidation state; the average value is +5.952. The oxygen atoms can be divided into four categories: 1.694(2)–1.706(3) Å for Mo–O(t), 1.908(2)–2.305(2) Å for Mo–O(μ2), 1.943(8)–2.331(2) Å for Mo–O(μ3), and 2.184(2)–2.462(2) Å for Mo–O(μ5); the mean values are 1.700(1), 1.999(7), 2.146(9), and 2.314(4) Å, respectively. All these bond lengths are within the normal ranges and in close agreement with those described in the literature.[17] It is noteworthy that the polyoxoanion acts as a ligand covalently bonded to two $[Cu^{II}(1,10\text{-phen})_2]^{2+}$ units to form a 1D chain (see Figure 3) through terminal oxygen atoms, with Cu–O distances of 2.663(7) Å.[18] In the $[Cu^{II}(1,10\text{-phen})_2]^{2+}$ unit, Cu is coordinated by four N atoms of two 1,10-phen ligands and one terminal oxygen atom of the β-octamolybdate anion to form a distorted octahedron with Cu–N distances in the range 1.974(3)–2.014(4) Å. Thus, the three crystallographically unique copper atoms have three different coordination geometries: Cu(1) exhibits a octahedral geometry in the

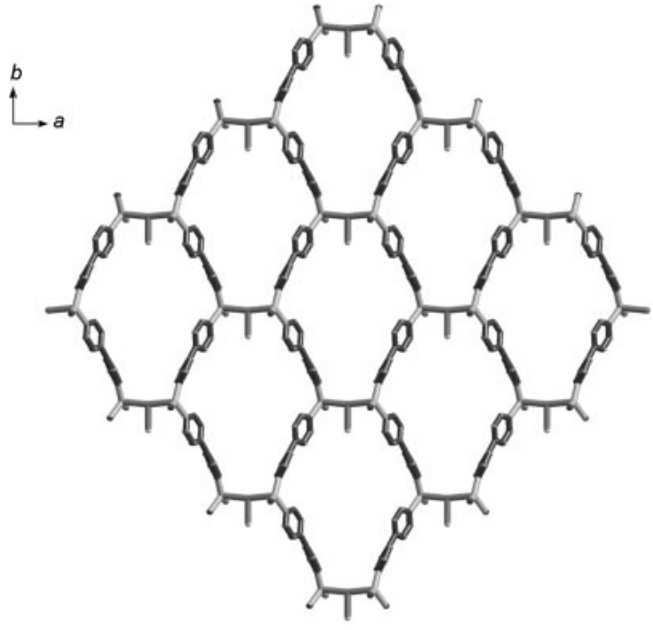

Figure 1. View of the hexagon-grid layer in **1**; all the hydrogen atoms have been omitted for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

form of $\{CuN_4O_2\}$, Cu(2) displays a distorted $\{CuN_3Cl\}$ tetrahedral geometry, while Cu(3) shows trigonal $\{CuN_2Cl\}$ geometry. Valence sum calculations on the Cu sites give values of 1.848, 1.127, and 1.239 for Cu(1), Cu(2), and Cu(3), respectively. Having studied the literature, we noticed that the exploitation of discrete POMs as guests in the construction of 3D frameworks has been reported;[7a,7c] however, there are no examples of organic–inorganic POM chain-templated frameworks to date (see Figure 4a).

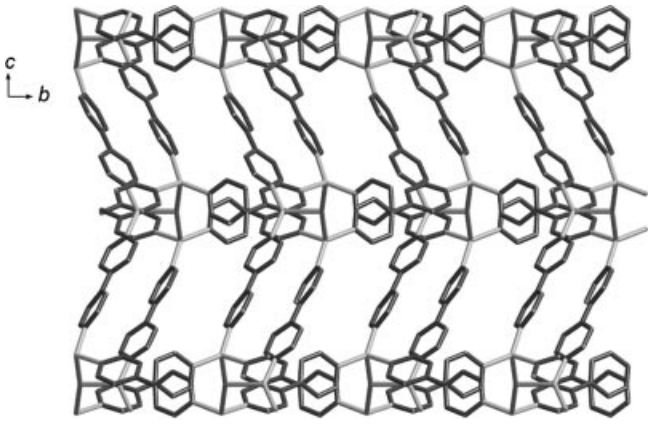

Figure 2. View of the $\{[Cu_3^{I}Cl(4,4'\text{-bipy})_4]\}_n^{2n+}$ coordination complex scaffolding composed of hexagon-grid layers pillared by 4,4′-bipy ligands in **1**; all the hydrogen atoms have been omitted for clarity.

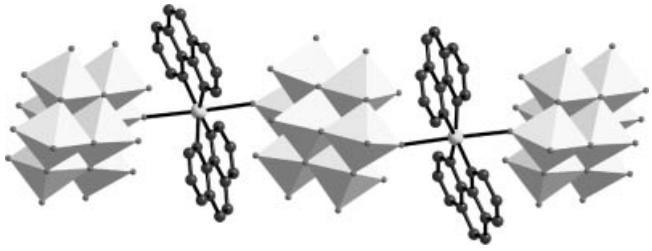

Figure 3. Polyhedral representation of the organic–inorganic hybrid polyoxometalate chain in **1**; all the hydrogen atoms have been omitted for clarity.

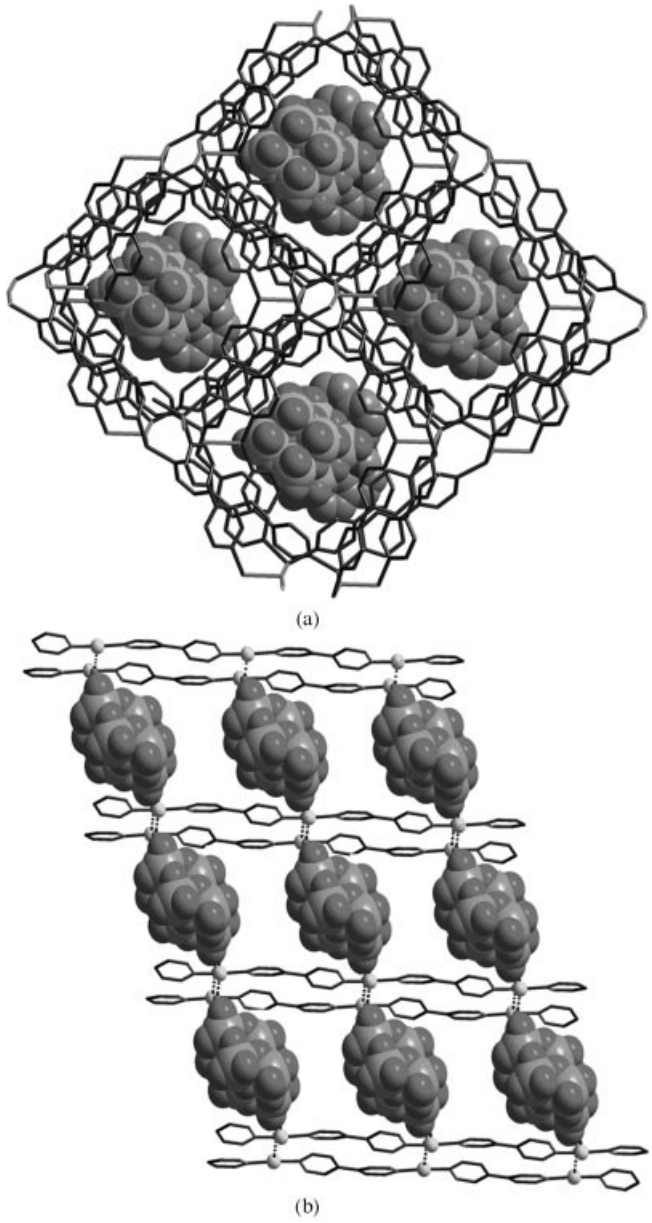

Figure 4. (a) Projection of the 3D framework of **1**; all the hydrogen atoms have been omitted for clarity. (b) View of the 2D supramolecular structure of **2**; all the hydrogen atoms and the water molecules have been omitted for clarity.

The single X-ray structural analysis revealed that the structure of **2** is composed of β-$[Mo_8O_{26}]^{4-}$, $\{Cu(4,4'\text{-bipy})\}_n^{n+}$ chains, and lattice water molecules. The structure of $[Mo_8O_{26}]^{4-}$ is a typical β-$[Mo_8O_{26}]^{4-}$ anion, similar to that of compound **1**. The Mo–O bonds can be divided into four groups, i.e. Mo–$O_t$, Mo–O(μ2), Mo–O(μ3), and Mo–O(μ5) bonds, with bond lengths in the ranges 1.685(2)–1.702(6), 1.746(9)–2.259(8), 2.149(8)–2.394(2), and 2.149(8)–2.450(8) Å, respectively; the mean values are 1.696(9), 1.944(7), 2.104(3), and 2.334(6) Å. All the mean values of the Mo–O distances are shorter than those of compound **1**. These results may be due to the influence of the outer coordination environment in compound **1**.

As shown in Figure 4b, the β-$[Mo_8O_{26}]^{4-}$ clusters link the $\{Cu(4,4'\text{-bipy})\}_n^{n+}$ chains into a 2D supramolecular structure with a weak, long-range Cu–O interaction of 2.501(66)–2.563(27) Å.

## EPR Spectroscopy

The EPR spectrum of **1** at room temperature shows a $Cu^{2+}$ signal with $g_{[par]} = 2.2281$ and $g_{\perp} = 2.0506$ (Figure 5), in good accordance with the valence sum calculation.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

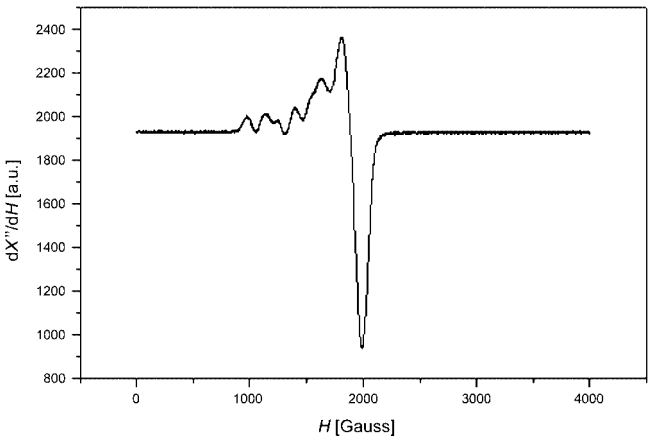

Figure 5. The EPR spectrum of **1**.

### Electrochemistry

The POM-modified carbon paste electrode (CPE) was fabricated as follows: 1.0 g of graphite powder and 40 mg of POM **1** or **2** were mixed and ground together with an agate mortar and pestle to achieve an even, dry mixture. Nujol (0.66 mL) was then added to the mixture and stirred with a glass rod. The homogenized mixture was used to pack 3-mm inner diameter glass tubes, and the surface was wiped with weighing paper. Electrical contact was established with a copper rod through the back of the electrode. Platinum gauze was used as counter electrode and an SCE was used as reference electrode.

Figure S1 shows the voltammetric behavior of the working electrodes made from **1** and **2** in 30 mL of aqueous 1 M $H_2SO_4$ solution at a scan rate of 100 mV s$^{-1}$. It can be seen that one reversible redox peak appears in the potential range –800 to +1000 mV. In compounds **1** and **2**, the mean peak potential $E_{1/2} = (E_{pa} + E_{pc})/2$ is 11.6 and –58.5 mV, respectively. The redox peaks might be ascribed to the $Mo^{VI}/Mo^{V}$ couple.[19]

### FT-IR Spectroscopy

In the IR spectrum of compound **1** (Figure S2), the characteristic bands at 943, 915, 842, 730, 704, and 655 cm$^{-1}$ can be attributed to the Mo=O and Mo–O–Mo vibrations. On comparing the IR spectrum of compound **1** with that of β-$[Mo_8O_{26}]^{4-}$,[20] it can be seen that the shape of the peaks in the range 600–1000 cm$^{-1}$ is nearly identical to that of β-$[Mo_8O_{26}]^{4-}$ except for slight shifts of some peaks due to the effect of coordination, which indicates that the polyoxoanion in compound **1** still retains the basic β-$[Mo_8O_{26}]^{4-}$ structure. This is in agreement with the result of the single-crystal X-ray diffraction analysis. In addition, bands in the 1601–1408 cm$^{-1}$ region can be assigned to characteristic peaks of the ligands 4,4′-bipy and 1,10-phen.

## Conclusions

In summary, compound **1** provides an unprecedented 3D host–guest structure with an organic–inorganic hybrid polyoxometalate chain-like template and confirms the utility of hydrothermal methods for the synthesis of new compounds with novel structures. Furthermore, compound **1** demonstrates that both the vast class of polyoxoanion clusters and organic–inorganic polyoxometalate chains may act as templates in the design of higher organic–inorganic hybrid porous materials. Given the variations in the organic–inorganic polyoxometalate chains and metal-organic frameworks, the scope for the further synthesis of POM-based porous materials appears to be very promising.

## Experimental Section

**Materials:** All chemicals purchased were of reagent grade and were used without further purification.

**Physical Methods:** Elemental analyses (C, H, and N) were performed on a Perkin–Elmer 2400 CHN elemental analyzer. Mo and Cu were determined with a Leaman inductively coupled plasma (ICP) spectrometer. The FTIR spectra were recorded in the range 400–4000 cm$^{-1}$ on an Alpha Centaurt FT/IR spectrophotometer as pressed KBr pellets. TG analyses were performed on a Perkin–Elmer TGA7 instrument in flowing $N_2$ at a heating rate of 10 °C min$^{-1}$. The EPR spectrum was recorded with a Bruker ER 200D spectrometer at room temperature. All electrochemical measurements were carried out on a CHI 660 electrochemical workstation at room temperature (25–30 °C).

**Synthesis of Compound 1:** A mixture of $(NH_4)_6Mo_7O_{24}\cdot 6H_2O$ (0.1 mmol), $CuCl_2\cdot 2H_2O$ (0.3 mmol), 4,4′-bipy (0.3 mmol), 1,10-phen (0.2 mmol), and $H_2O$ (10 mL) was stirred for half an hour in air. The pH was then adjusted to 4.0 with 4 M HCl, and the mixture transferred to a Teflon-lined, 23-mL autoclave and kept at 165 °C for 4 d. After slowly cooling to room temperature, dark-green crystals were filtered off, washed with distilled water, and dried in a desiccator at room temperature. Yield: 0.153 g (54.8% based on Mo). $C_{64}H_{44}ClCu_4Mo_8N_{12}O_{26}$ (2454.2): calcd. C 31.24, H 1.96, Cu 10.34, Mo 31.22, N 6.84; found C 31.54, H 2.13, Cu 10.67, Mo 30.86, N 7.07.

**Synthesis of Compound 2:** A mixture of $(NH_4)_6Mo_7O_{24}\cdot 6H_2O$ (0.1 mmol), $CuCl_2\cdot 2H_2O$ (0.3 mmol), 4,4′-bipy (0.3 mmol), and $H_2O$ (10 mL) was stirred for half an hour in air. The pH was then adjusted to 4.8 with 4 M HCl and the mixture transferred to a Teflon-lined, 23-mL autoclave and kept at 165 °C for 4 d. After slowly cooling to room temperature, orange crystals were filtered off, washed with distilled water, and dried in a desiccator at room temperature. Yield: 0.079 g (37.5% based on Mo). $C_{30}H_{27}Cu_3Mo_8N_6O_{27}$ (1861.7): calcd. C 19.35, H 1.46, Cu 10.24, Mo 41.23, N 4.52; found C 19.49, H 1.53, Cu 10.09, Mo 41.08, N 4.68.

**X-ray Crystallography:** Crystallographic data for **1** and **2** were collected at 298 K with a Rigaku R-axis Rapid IP diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.710373 Å) and the IP technique. The structure was solved by direct methods and refined by full-matrix least-squares on $F^2$ using the SHELXTL-97 crystallographic software package.[21] Anisotropic thermal parameters were used to refine all non-hydrogen atoms. Carbon-bound hydrogen atoms were placed in geometrically calculated positions; oxygen-bound hydrogen atoms were located in the difference Fourier maps. Further details of the X-ray structural analysis are given in Table 1. Selected bond lengths and angles for compounds **1** and **2** are listed in Tables S1 and S2 in the Supporting Information. CCDC-600762 (**1**) and -600763 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free

# Solvent and Ligand Effects on the Structures of Iron Halide Cations in the Gas Phase

Philipp Gruene,[a,b] Claudia Trage,[c] Detlef Schröder,*[a,d] and Helmut Schwarz[a]

**Keywords:** Hydrogen transfer / Iron halides / Ligand effects / Mass spectrometry / Solvent effects

The effects of the oxidation state, the ligand, and the solvent on structures and energetics of cationic iron complexes are investigated by means of electrospray-ionization mass spectrometry. Insights into the potential-energy surfaces of $FeX^+$, $FeX_2^+$, and $XFe(OCH_3)^+$ ions (X = F, Cl, Br, I) with a variable number of coordinated methanol molecules are obtained by means of collision experiments and complementary thermochemical considerations. It is shown that upon change of the halide ligand, the weakly solvated ions respond differentially to the increasing need for stabilization of the partial charge on the metal center. For example, whereas $F_2Fe(CH_3OH)_n^+$ ions tend to lose mainly HF for $n$ = 1–3, the loss of HBr is not observed at all for $Br_2Fe(CH_3OH)_n^+$. Instead, the iron-bromide cations undergo reductive loss of atomic bromine. $Cl_2Fe(CH_3OH)_n^+$ bears an intermediate position in that both reduction as well as elimination of HCl can occur.

## Introduction

One important factor for the success of mass spectrometry as a tool for investigating the elementary steps of various catalytic reactions is its ability to design and to probe model systems of variable complexity. Many experiments focus exclusively on the intrinsic properties of reactive centers by studying isolated, ligand-free atomic metal ions or their clusters, and the knowledge that has been accumulated for these systems is rather astonishing.[1] More complex systems have also been addressed, even including consideration of extrinsic factors such as ligands and counterions.[2–5] While investigations of gaseous metal clusters can largely assist in bridging the gap between gas-phase reactions and heterogeneous catalysis, understanding the often crucial role of the solvent is necessary in order to translate gas-phase chemistry data to processes taking place in solution. Different approaches have been pursued in order to include solvent molecules in mass spectrometry.[6–9] The unique features of electrospray ionization (ESI)[10,11] mass spectrometry allow the straightforward generation of a large number of solvated ions.[3,4,12–15] Here, we report a systematic study of the cationic complexes formed upon ESI of methanolic solutions of $FeX_2$ (X = F, Cl, Br, I) and $FeX_3$ (X = F, Cl, Br). Iron was investigated because of its growing importance in the field of catalysis[16] and biochemistry.[17] Halides were chosen because of their sufficient solubility in organic solvents,[18] which is reflected in their frequent use as catalysts and, additionally, they permit the investigation of periodic trends regarding the role of ligands. Methanol was used for its excellent performance as an ESI solvent and furthermore because it allows for various types of solvation mechanisms, like mere association, solvolysis, hydrogen bonding, etc. and, moreover, also has a potential for bond activation processes.[15]

## Results and Discussion

**$FeX_2$ (X = F, Cl, Br, I):** In general, two different types of mononuclear ions are formed upon ESI of methanolic $FeX_2$ solutions: $XFe(CH_3OH)_n^+$ with $n \leq 5$ and $Fe(OCH_3)(CH_3OH)_n^+$ with $n \leq 3$. In addition, iron clusters of the formal composition $(Fe_mX_{2m-1})(CH_3OH)_n^+$ are formed, in which $m$ can reach numbers of up to six and $n$ up to eight. Reduced clusters of the type $(Fe_mX_{2m-2})(CH_3OH)_n^+$ are only observed for the heavy halogens, i.e. bromine and iodine. Here, we focus on the mononuclear $XFe(CH_3OH)_n^+$ ions. At very low cone voltage (≈0 V), which corresponds to rather mild ionization conditions, multiply solvated complexes $XFe(CH_3OH)_n^+$ with $n$ = 3–5 are formed. With rising cone voltage (30–50 V), the ions lose their weakly bound solvent molecules, and $XFe(CH_3OH)_n^+$ ions with $n$ = 0–3 dominate the spectra. Under these conditions, also $Fe(OCH_3)(CH_3OH)_n^+$ ions with $n$ = 0–3 are observed in substantial quantities. At very high cone voltages, the complexes undergo consecutive fragmentation and are finally reduced to bare atomic iron(I) $Fe^+$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Qualitative insight into the potential-energy surfaces of the solvated iron(II)halide cations and estimations of the binding energies to the solvent molecules are achieved by means of collision-induced dissociation (CID) experiments (Table 1). The exclusive exit channel for $XFe(CH_3OH)_n^+$ cations with $n$ = 3–5 corresponds to the loss of an intact methanol solvent molecule. For $n$ = 4 and 5, the methanol ligands are that weakly bound that they are already lost at thermal energies; accordingly, the determination of *AEs* is not reasonable anymore, because it would result in negative values. The findings for $n$ = 1–3 reveal two trends. First, the binding energies between the metal core and the solvent molecule appear to decrease with increasing solvation. Obviously, the partial charge on the metal center is effectively stabilized by the first methanol molecules, so that additional solvation accompanied by increased steric hindrance becomes less and less significant. Secondly, the binding energies decrease from fluorine to bromine, which can be attributed to the fact that the more electronegative fluorine induces a much higher charge on the metal center than bromine. For $n$ = 0–2 in the case of X = Cl, Br and $n$ = 0, 1 in the case of X = F, the reductive loss of a halogen atom is available as an additional fragmentation channel. Given the qualitative nature of the *AE* measurements, we note in passing that the experimental values for the unsolvated species are in rather good agreement with values reported in the literature ($FeF^+$: 4.5; $FeCl^+$: 3.5; $FeBr^+$: 2.7; $FeI^+$: 2.6 eV).[19–23] Further, the binding energies for the cleavage of the Fe–X-bonds also increase with solvation, the origin of which has been discussed previously.[15]

If solvated with only one or two methanol molecules, the $FFe(CH_3OH)_n^+$ ions exhibit elimination of HF as yet another fragmentation channel. Consequently, the mere description of the complex as a $FeF^+$ core to which the solvent molecules are coordinated seems insufficient, because direct loss of HF from such a structure is considered less likely compared to the loss of the coordinated methanol ligand. Instead, a rearrangement according to Reaction (1) must take place prior to fragmentation.

$$FFe(CH_3OH)_n^+ \rightleftharpoons (HF)Fe(OCH_3)(CH_3OH)_{(n-1)}^+ \quad (1)$$

The breakdown graph (Figure 1) for the CID fragments of mass-selected $FFe(CH_3OH)^+$ provides some further insight into the potential-energy surface of this system. The loss of HF bears the lowest appearance energy of about 0.5 eV and shows a characteristic increase in intensity, reaching a maximum at about $E_{CM}$ = 2 eV, and then declines at higher collision energies, whereas the loss of methanol increases until about $E_{CM}$ = 5 eV. This kind of behavior points to the operation of a kinetic hindrance, i.e. the presence of the two isomers $FFe(CH_3OH)^+$ and (HF)-$Fe(OCH_3)^+$ separated by a barrier that is of comparable height as the appearance energy for the elimination of HF. On the basis of thermochemical considerations, $FFe(CH_3OH)^+$ is indicated to be more stable than (HF)-$Fe(OCH_3)^+$ (see Appendix). However, the loss of HF represents the energetically lowest-lying exit channel. At low collision energies, the system will accordingly rearrange and dissociate to the $Fe(OCH_3)^+$ fragment. Once direct loss of methanol is energetically accessible at about 1.6 eV, this route of fragmentation is preferred, since the density of states for the direct bond cleavage resulting in two molecules is orders of magnitude higher than the density of states for the tight transition state connecting the two tautomers. For a detailed discussion, including DFT calculations, of the related $Cl_2Fe(CH_3OH)^+$/$ClFe(HCl)(OCH_3)^+$ system, see ref.[15]

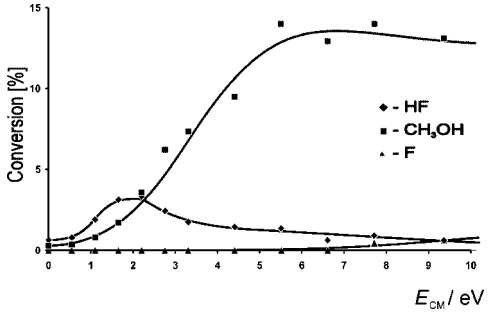

Figure 1. Breakdown graph of the CID fragments of mass-selected $FFe(CH_3OH)^+$ as a function of collision energy in the center of mass frame.

**$FeX_3$ (X = F, Cl, Br):** Three different iron(III) species are formed upon ESI of methanolic $FeX_3$ solutions: $X_2Fe(CH_3OH)_n^+$, $XFe(OCH_3)(CH_3OH)_n^+$, and $Fe(OCH_3)_2(CH_3OH)_n^+$, with $n$ up to five. In addition, some reduced ions are observed, namely, the iron(II)cations $XFe(CH_3OH)_n^+$ and $Fe(OCH_3)(CH_3OH)_n^+$ as well as the formal iron(I) clusters $Fe(CH_3OH)_n^+$. The spectra also show the presence of small amounts of binuclear clusters of the formal compositions $Fe_2X_m(CH_3OH)_n^+$ ($m$ = 3–5, $n$ = 0–4). At low cone voltages, ESI produces by and large the same type of solvated $FeX_2^+$ cations from all three solutions of $FeF_3$, $FeCl_3$, and $FeBr_3$ in methanol, respectively. How-

ever, the similarities vanish once solvation decreases. Hence, the need for stabilization of the partial charge on the metal center is even larger than in the case of the iron(II) compounds. Generally, the ions react in two different ways. The first route corresponds to the elimination of HX resulting in new iron(III) complexes; this pathway is mainly observed for X = F. Alternatively, reductive loss of a halogen atom takes place, which dominates in the case of $FeBr_2^+$ ions. Obviously, there exist substantial differences in the respective potential-energy surfaces regarding the rearrangement/dissociation energy requirements between the two tautomers $X_2Fe(CH_3OH)_n^+$ and $XFe(OCH_3)(HX)(CH_3OH)_{(n-1)}^+$.

All appearance energies for the elimination of methanol from the solvated iron(III) halide cations are larger than those of the corresponding iron(II) species (Table 2 vs. Table 1). This finding can be attributed to the increased partial charge of the metal center, which hence leads to a larger ion-dipole interaction between the metal center and the methanol molecules and thus increased binding energies of the ligands.

Loss of HF from the complexes $F_2Fe(CH_3OH)_n^+$ ($n$ = 1–3) is observed with rather low *AE*s of 0.5 eV, hence suggesting that hydrogen migrations to form the tautomeric ions $FFe(OCH_3)(HF)(CH_3OH)_{(n-1)}^+$ are facile. Evaporations of hydrogen chloride are observed for $Cl_2Fe(CH_3OH)_n^+$ ($n$ = 1, 2). Here, the importance of the oxidation state of the metal becomes evident, for HCl elimination has not been detected for any solvated iron(II) chloride cation. Just like in the case of HF elimination, the *AE*s for the loss of HCl from $Cl_2Fe(CH_3OH)_n^+$ ($n$ = 1, 2) do not change much with the degree of solvation, which can be attributed to the operation of two opposing effects. On the one hand, the partial charge on the metal center is lowered with increasing solvation as discussed above, and accordingly the binding energy to HX, which is based mainly on ion-dipole interaction, decreases. On the other hand, the hydrogen migration, which is crucial for formation of HX, may be favored upon increasing solvation, because the ligands are brought to closer vicinity. The cations $F_2Fe(CH_3OH)_n^+$ ($n$ = 0, 1) and $X_2Fe(CH_3OH)_n^+$ (X = Cl, Br; $n$ = 0–2) exhibit loss of a halogen atom as an additional fragmentation channel, which formally corresponds to a reduction of the oxidation state of the metal. In fact, for all iron(III)-bromide cations the reduction of the metal via elimination of a halogen atom completely suppresses the formation of HX via hydrogen rearrangement. The appearance energies for the dissociation of the $XFe^+$–X-bond of the naked species seem to be somewhat lower compared with existing literature values [$D_o(ClFe^+–Cl$ = 2.19; 2.53)].[21,24,25] Interestingly, the trend of binding energy of the metal-halide bond responds differently to a changing degree of solvation. Whereas with coordination of the first methanol molecule the *AE* for the loss of fluorine increases by as much as 1.4 eV, it changes only by 0.8 and 0.1 eV for the ejection of chlorine and bromine atoms, respectively (Table 2).

Figure 2 shows the breakdown graphs for the CID fragments of mass-selected $X_2Fe(CH_3OH)^+$ ions (X = F, Cl,

Br), and the influence of the halide becomes quite evident upon comparison. For X = F, elimination of HF corresponds to the dominant fragmentation channel with the lowest *AE* and the largest intensity, while evaporation of the solvent exhibits a higher *AE* as well as a lower intensity. Reductive loss of the fluorine atom is negligible over the whole energy regime studied. In the case of X = Cl, the energy behavior reveals a kinetic hindrance of HCl elimination, which still exhibits the lowest *AE* and thus is the most intense fragmentation channel at low collision energies, but becomes less pronounced than evaporation of the solvent at collision energies above 3.3 eV and even less intense than the reductive elimination of atomic chlorine at collision energies above 5 eV. For X = Br, reductive cleavage of the Fe–X-bond even dominates over the loss of the solvent both in terms of appearance energy and intensity.

The assumption that the $X_2Fe(CH_3OH)^+$ isomer is more stable than $XFe(OCH_3)(HX)^+$ implies qualitative potential-energy surfaces for the competing losses of $CH_3OH$, X, and HX as depicted in Figure 3.

On the very left, the energies of the $XFe(CH_3OH)^+$ cation and the halogen radical as well as the naked $FeX_2^+$ cation and the free methanol molecule are shown. The binding energy of the radical to the iron(II) species $\Delta E_1$ and the binding energy of the solvent molecule to the iron(III) halide cation $\Delta E_2$ are assumed to correspond to the *AEs* for the reductive loss of the halogen and the elimination of methanol, respectively. As discussed above for X = F and Cl, the barrier separating the tautomers ($\Delta E_3$) has to be smaller or of comparable height than that of the exit channel for the loss of HX ($\Delta E_5$). Finally, the stability difference of the isomers **A** and **B** ($\Delta E_4$) can be derived by estimations based on Equation (2) and Equation (3), where the key parameters are the changes of Fe-X and H-X binding energies (for details, see Appendix).

$$\Delta_f H(X_2Fe(CH_3OH)^+) = \Delta_f H(FeX_2^+) + \Delta_f H(CH_3OH) - BDE(X_2Fe^+ - (CH_3OH)) \quad (2)$$

$$\Delta_f H(XFe(OCH_3)(HX)^+) = \Delta_f H(XFe(OCH_3)^+) + \Delta_f H(HX) - BDE((OCH_3)XFe^+ - (HX)) \quad (3)$$

Using an approach analogous to that described above for the iron(II) species (also see Appendix), some semi-quantitative estimates can be made for the energy differences $\Delta E_1$–$\Delta E_5$, and the results are summarized in Table 3.

Table 3. Energy differences $\Delta E_1$ to $\Delta E_5$ [eV] (as defined in Figure 3) for the competing losses of methanol, HX, and X from cationic $X_2Fe(CH_3OH)^+$ complexes (X = F, Cl, Br).[a]

| | F | $Cl_{exp}$ | $Cl_{theo}$ | Br |
|---|---|---|---|---|
| $\Delta E_1$ | 3.2 | 2.4 | | 1.5 |
| $\Delta E_2$ | 2.2 | 1.9 | 1.93 | 1.6 |
| $\Delta E_3$ | <0.5 | <1.2 | 1.35 | >0.83 |
| $\Delta E_4$ | <0.5 | <1.2 | 0.83 | >0.83 |
| $\Delta E_5$ | 0.5 | 1.2 | 1.40 | –[b] |

[a] In the estimation of the values for X = F and $Cl_{exp}$, thermodynamic control is assumed. The values of $Cl_{theo}$ are taken from theoretical data given in ref.[15]. [b] Loss of HBr is not observed experimentally.

From the CID experiments alone it cannot be deduced, whether the *AE* of HX elimination is determined by the energy demand of the exit channel (Case **a** in Figure 3), hence the fragmentation is thermodynamically controlled, or if the height of the barrier is crucial (Case **b** in Figure 3) such that the fragmentation is subject to kinetic control.[26] For the system $Cl_2Fe(CH_3OH)^+$, computational results have demonstrated that the fragmentation is subject to thermodynamic control.[15]

Iron(III) alkoxide ions $XFe(OCH_3)(CH_3OH)_n^+$ are formally accessible from $X_2Fe(CH_3OH)_{n+1}^+$ via loss of HX according to Equation (4).

$$X_2Fe(CH_3OH)_{n+1}^+ \rightleftharpoons XFe(OCH_3)(CH_3OH)_n^+ + HX \quad (4)$$

In this respect, the maximum number of coordinated solvent molecules gives a hint, whether the reaction has already taken place in solution or if it occurs only in the ESI process after evaporation. Multiply solvated ions, already present in solution, should appear at the mildest ionization conditions, whereas ions formed via collisional activation in the mass spectrometer should only be produced under more drastic ESI conditions.

For X = F, $FFe(OCH_3)^+$ cations are observed with one or two solvent molecules attached to it. Keeping in mind that solvated $FeF_2^+$ ions lose HF unless more than three methanol molecules are coordinated, this is exactly the result expected for ion formation in the evaporation process. The same holds true for the $ClFe(OCH_3)^+$ ions. Only iron(III) bromide cations never lose HBr in CID experiments, and yet, $BrFe(OCH_3)^+$ ions with up to four coordi-

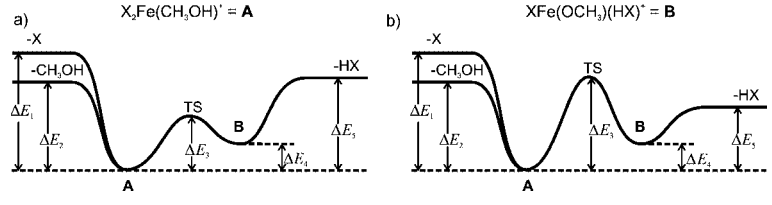

Figure 3. Possible free-energy profiles for the competing losses of methanol, HX, and X (X = F, Cl, Br) from cationic $X_2Fe(CH_3OH)^+$ complexes **A** as well as the isomeric $XFe(OCH_3)(HX)^+$ complexes **B** with the central transition structure lower [case a)] and higher in energy [case b)] than the lowest lying exit channels for ion dissociation. We note in passing that for X = Br the experimental data implies $\Delta E_1 < \Delta E_2$.

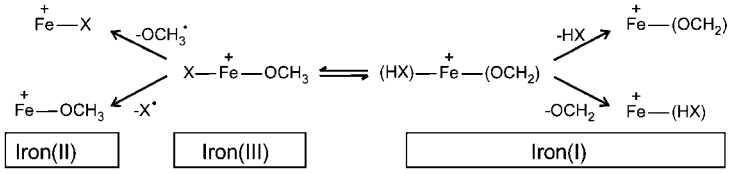

Figure 4. Redox tautomerization in the fragmentations of $XFe(OCH_3)^+$ (X = Cl, Br); loss of $H_2CO$ is only observed for X = Br.

nated methanol molecules are observed in the spectra, thus suggesting that for X = Br, reaction (4) can already occur in solution.

The fragmentation patterns of the two unsolvated ions $ClFe(OCH_3)^+$ and $BrFe(OCH_3)^+$ reveals interesting redox properties of these species. In both cases, loss of hydrogen halide corresponds to the lowest-lying exit channel [*AE*(-HCl) = 0.5 eV; *AE*(-HBr) = 0.7 eV]. This requires a redox tautomerization in which $CH_3O^-$ is oxidized to $H_2CO$ and the electrons are formally transferred intramolecularly to the iron center, leading to an iron(I) complex $(HX)Fe(CH_2O)^+$ (X = Cl, Br) (Figure 4). The ability of methoxo ligands to transfer hydrogen atoms to the metal center via a ß-hydrogen shift has been long known[27,28] and it seems reasonable to assume that hydrogen is transferred to the halide ligand in a similar manner. Such rearrangements, in which an iron(III) species is reduced to iron(I) via a hydrogen transfer, have also been reported for the reaction of bare $Fe^+$ with dimethylperoxide.[29] Nevertheless, a direct tautomerization via a multicentered transition structure is also conceivable.[30]

For $BrFe(OCH_3)^+$, in line with the respective *AE*s, the loss of HBr prevails over the evaporation of $CH_2O$ [*AE*(-$CH_2O$) = 1.5 eV], which indicates a stronger binding of formaldehyde to the metal center than hydrogen bromide. In the case of X = Cl, the difference in bond strength is so distinct that the expulsion of $H_2CO$ is not observed at all upon CID. The *AEs* corresponding to the respective direct homolytic bond cleavages show that breaking of the $ClFe^+$–($OCH_3$) bond is easier [*AE*(-$OCH_3$) = 2.4 eV] than breaking the Cl–$Fe(OCH_3)^+$ bond [*AE*(-Cl) = 3.5 eV]. In contrast, cleavage of the Br–$Fe(OCH_3)^+$ bond [*AE*(-Br) = 2.3 eV] is easier than breaking the $BrFe^+$–($OCH_3$) bond [*AE*(-$OCH_3$) = 2.8 eV]. Once solvent molecules are attached to these complexes, these mechanistically indicative evaporations of formaldehyde are not observed anymore, such that on the basis of the CID experiments, a further distinction of the structures of the parent ions is impossible. When two methanol molecules surround the ion core, i.e. for $XFe(OCH_3)(CH_3OH)_2^+$, the influence of the ligand again becomes most obvious: While the fluoride species loses HF besides methanol, evaporation of the solvent is the only fragmentation channel for $ClFe(OCH_3)(CH_3OH)_2^+$; for X = Br, also reductive cleavage of the iron-halide bond concomitant with the expulsion of atomic bromine from the precursor complex is observed.

## Conclusions

The effects of the formal oxidation state, the nature of the halide, and the number of solvent molecules on the structures and energetics of iron-halide complexes are studied by electrospray mass spectrometry of methanolic $FeX_m$ solutions (X = F, Cl, Br, I; *m* = 2, 3). The most abundant ions formed can be described as consisting of covalently bound $FeX^+$, $FeX_2^+$, and $XFe(OCH_3)^+$ cores, respectively, which are stabilized by various amounts of methanol molecules. For some halide ligands, solvolysis becomes energetically accessible upon collisional excitation once the effects of solvation are less dominant. This effect is particularly pronounced for all species containing fluorine as formation of HF via an intracomplex hydrogen transfer from a methanol molecule provides a strong thermodynamic driving force. The presence of methoxo ligands in turn facilitates the occurrence of C–H bond activation reactions via hydrogen migration leading to iron(I) compounds. In contrast, $Br_2Fe(CH_3OH)_n^+$-ions do not at all undergo intramolecular hydrogen transfer processes, and a pronounced tendency to undergo reductive loss of atomic bromine prevails instead. In comparison of the iron(II)- and iron(III) compounds, in line with general expectations solvation strongly stabilizes the iron(III) state. With decreasing solvation of the iron(III) species, the binding energies of the methanol accordingly enlarge and likewise the probability of the occurrence of redox reactions leading to either iron(II) or even iron(I) compounds increases.

## Experimental Section

The mass spectrometric experiments were carried out with a commercial VG BIO-Q mass spectrometer described elsewhere.[31] In brief, the VG BIO-Q consists of an ESI source combined with a tandem mass spectrometer of QHQ configuration (Q: quadrupole, H: hexapole). In the present experiments, mmolar solutions of anhydrous $FeX_2$ (X = F, Cl, Br, I) and $FeX_3$ (X = F, Cl, Br) in methanol were introduced through a syringe pump (flow rate 5 μL/min) to the fused silica capillary of the ESI source. The source temperature was kept at 80 °C. For each ion of interest, the instrument parameters were optimized for maximal ion abundance. The most crucial parameter is the cone voltage $U_C$ which determines the extent of collisional activation of the ions evolving from solution in the differential pumping system of the ESI source. At low cone voltages, multiply solvated ions are formed, which then lose the weakly bound solvent molecules at increased $U_C$, followed by evaporation of more strongly bound ligands including the cleavage of covalent bonds, electron-transfer processes, and atomic metal cations are obtained at very high cone voltages.

Collision-induced dissociation experiments were performed with Q1-selected ions and xenon was admitted as a collision gas to the hexapole at various collision energies ($E_{lab}$ = 0–40 eV) and a pressure of about $2.5 \cdot 10^{-4}$ mbar, which approximately corresponds to single collision conditions.[31] The product ions formed in the hexa-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pole were then analyzed by scanning Q2. The collision energies were converted into the center-of-mass frame, $E_{CM} = [m/(M + m)] \cdot E_{lab}$, in which $M$ and $m$ are the masses of the collision gas and the ionic species, respectively. Variation of the collision energy led to breakdown diagrams that enabled the determination of phenomenological appearance energies (*AEs*)[32] of the various fragmentation channels by linear extrapolation of the signal onsets to the baseline. The corresponding experimental errors were estimated by applying linear extrapolations with gradients deviating from the best possible fits, but which are still in reasonable agreement with the experimental data. It is to be pointed out that the *AEs* given below do not directly correspond to thermochemical thresholds of the respective ion dissociations, but nevertheless provide a frame for the energy demands of the various fragmentations.

**Appendix. Thermochemical Estimates**

In order to evaluate the stability of the two tautomers $FFe(CH_3OH)^+$ and $(HF)Fe(OCH_3)^+$, their heats of formation are estimated using Equation (5) and (6).[33]

$$\Delta_f H(FFe(CH_3OH)^+) = \Delta_f H(FeF^+) + \Delta_f H(CH_3OH) - BDE(FFe^+ - (CH_3OH)) \quad (5)$$

$$\Delta_f H((HF)Fe(OCH_3)^+) = \Delta_f H(Fe(OCH_3)^+) + \Delta_f H(HF) - BDE((OCH_3)Fe^+ - (HF)) \quad (6)$$

The exact values for the binding energies are unknown and have to be estimated using existing data. The binding energy of methanol to $FeF^+$ must be within the window of the binding energies of methanol to bare $Fe^+$ and to the iron(II)-chloride cation. Both these values can be found in the literature[15,34] (Table 4), and the binding energy to $FeF^+$ is estimated to correspond to their average [Equation (7)]. Note the excellent agreement with the *AE* for the loss of methanol from $FeF^+$ in Table 1.

$$BDE(FFe^+ - (CH_3OH)) \approx \tfrac{1}{2}\left[BDE(Fe^+ - (CH_3OH)) + BDE((Cl)_2Fe^+ - (CH_3OH)\right] = (1.6 \pm 0.3)eV \quad (7)$$

Table 4. Literature thermochemistry used.

| | $\Delta_f H$ [eV] | Ref. | | *BDE* [eV] | Ref. |
|---|---|---|---|---|---|
| $FeF^+$ | 8.0 ± 0.2 | [33] | $Fe^+$–$CH_3OH$ | 1.39 ± 0.09 | [34] |
| $FeOCH_3^+$ | 8.76 ± 0.08 | [28] | $FeCl_2^+$–$CH_3OH$ | 1.79 | [15] |
| $CH_3OH$ | –1.94 ± 0.02 | [39] | $Cu^+$–HF | 0.76 | [35] |
| HF | –2.64 ± 0.01 | [39] | $Cu^+$–$H_2O$ | 1.41 | [35] |
| | | | $Cu^+$–$NH_3$ | 1.98 | [35] |
| | | | $Cr^+$–HF | 0.66 | [36] |
| | | | $Cr^+$–$H_2O$ | 1.23 | [36] |
| | | | $Cr^+$–$NH_3$ | 1.67 | [36] |
| | | | $Fe^+$–$H_2O$ | 1.27 ± 0.05 | [38] |
| | | | $Fe^+$–$H_2O$ | 1.72 ± 0.09 | [37] |

The binding energy of HF to $Fe(OCH_3)^+$ is even more difficult to evaluate. A first simplification is to neglect the methoxide ligand, thus estimating the binding energy of HF to bare $Fe^+$. Unfortunately, even this value is unknown, but values for binding energies of HF to $Cu^+$ and $Cr^+$ exist, as well as values for the binding energies of $H_2O$ and $NH_3$ to $Cu^+$, $Cr^+$, and $Fe^+$.[35–38] On the basis of this data, a rough approximation according to Equation (8), (9), and (10) is possible.

$$BDE(Cu^+ - (HF)) = x_1 \cdot BDE(Cu^+ - (H_2O)) = x_2 \cdot BDE(Cu^+ - (NH_3)) \quad (8)$$

$$BDE(Cr^+ - (HF)) = x_2 \cdot BDE(Cr^+ - (H_2O)) = y_2 \cdot BDE(Cr^+ - (NH_3)) \quad (9)$$

$$BDE(Fe^+ - (HF)) \approx x_{1,2} \cdot BDE(Fe^+ - (H_2O)) \approx y_{1,2} \cdot BDE(Fe^+ - (NH_3)) \quad (10)$$

The resulting binding energies range from 0.66 to 0.69 eV. Obviously the binding energy of HF to the iron(II) species $Fe(OCH_3)^+$ is larger than the one estimated to $Fe^+$; however, this should be a somewhat reasonable value. Inserting all data, including the known values for the heats of formation of $FeF^+$,[28] $Fe(OCH_3)^+$,[33] methanol and HF,[39] the following results are obtained:

$\Delta_f H[FFe(CH_3OH)^+] = (4.5 \pm 0.5)$ eV

$\Delta_f H[(HF)Fe(OCH_3)^+] = (5.5 \pm 0.2)$ eV

As some of the approximations made in the estimation of these quantities are quite crude, we do not claim the exactness of the results; nevertheless these considerations can at least provide a guideline for the understanding of the experimentally observed trends among the different halogens. In the particular case discussed here, the energy difference of about 1 eV clearly implies the conclusion that the iron-fluoride complex $FFe(CH_3OH)^+$ is energetically more favorable than the iron-methoxo isomer $(HF)Fe(OCH_3)^+$.

# Synthesis and Structural Characterization of a Series of Carboxylic Acid Modified Cerium(III) Alkoxides

**Timothy J. Boyle,*[a] Louis J. Tribby,[a] and Scott D. Bunge[a]**

**Keywords:** Metal alkoxides / Cerium alkoxides / Carboxylate ligands / Chelates

A series of cerium alkoxides were synthesized from the reaction of $Ce\{N[Si(CH_3)_3]_2\}_3$ and the appropriate alcohol: neopentyl alcohol [$H–OCH_2C(CH_3)_3$ = H-ONep], *tert*-butyl alcohol [$H–OC(CH_3)_3$ = H-O*t*Bu], *o*-(*tert*-butyl)phenol {$H–OC_6H_4[C(CH_3)_3]$-2 = H-*o*BP}, 2,6-dimethylphenol [$H–OC_6H_3(CH_3)_2$-2,6 = H-DMP], 2,6-diisopropylphenol {$H–OC_6H_3[CH(CH_3)_2]_2$-2,6 = H-DIP}, 2,6-di-*tert*-butylphenol {$H–OC_6H_3[C(CH_3)_3]_2$-2,6 = H-DBP}, or 2,6-diphenylphenol [$H–OC_6H_3(C_6H_5)_2$-2,6 = H-DPP] using toluene (tol), tetrahydrofuran (THF) or pyridine (py). The precursors were characterized as $[Ce(\mu\text{-ONep})_2(ONep)]_4$ (**1**), $Ce_4(\mu_3\text{-O}t\text{Bu})_3(\mu\text{-O}t\text{Bu})_4(O t\text{Bu})_5$ (**2**), $Ce_3(\mu_3\text{-O}t\text{Bu})_3(\mu\text{-O}t\text{Bu})_3(O t\text{Bu})_3(\text{H-O}t\text{Bu})_2$ (**2a**), $Ce(o\text{BP})_3(THF)_3$ (**3**), $[Ce(\mu\text{-DMP})(DMP)_2(solv)_2]_2$ [solv = THF (**4**) and py (**4a**)], $Ce(DIP)_3(THF)_3$ (**5**), $Ce(DPP)_3(THF)_2$ (**6**). Once isolated, several of these species were further reacted with a series of sterically varied carboxylic acid modifiers including isobutyric acid [$H–O_2CCH(CH_3)_2$ = H-OPc] and trimethylacetic acid [$H–O_2CC(CH_3)_3$ = H-OBc]. The products were isolated as $[Ce(OR)(\mu\text{-ORc})(\mu_c\text{-ORc})(py)]_2$ [OR = *o*BP, OBc: **7**; DMP, OPc: **8**; DMP, OBc: **9**; DIP, OPc: **10**]. These compounds were identified by single-crystal X-ray diffraction and powder XRD analyses. Several novel structure types are added to the cerium alkoxide family of compounds.

## Introduction

The role of metal alkoxide [$M(OR)_x$] precursors in ceramic materials synthetic routes such as, chemical solution (or the so-called "sol-gel"), metal organic chemical vapor deposition (MOCVD), or emerging nanoparticle synthetic methods have continued to expand. The growth is mainly due to their commercial availability, low crystallization temperatures, high solubility, high volatility, and other physical properties. In addition, these compounds are easily modified through the manipulation of their ligand set which allows for optimization of the final materials properties without increasing the complexity of the processing conditions. Typically, tailoring hydrolysis and condensation pathways of the $M(OR)_x$ precursors is of interest and accomplished by introducing a variety of ligands, including carboxylic acids (H–ORc). We have previously explored the structures obtained for group 4 alkoxides, modified with a series of H–ORc reagents, including: formic acid ($H–O_2CH$ = H-OFc), acetic acid ($H–O_2CCH_3$ = H-OAc), isobutyric acid [$H–O_2CCH(CH_3)_2$ = H-OPc], trimethylacetic acid [$H–O_2CC(CH_3)_3$ = H-OBc], or *tert*-butylacetic acid [$H–O_2CCH_2C(CH_3)_3$ = H-ONc], in an effort to understand how structure affects the final densification of thin films.[1,2] A number of general constructs were isolated for these systems but the partially hydrolyzed smaller trinuclear species proved to be the most useful for the generation of highly dense $TiO_2$ films and simple dinuclear species for $ZrO_2$ thin films.[1,2]

Recently, we have become interested in thin films of cerium oxide ($CeO_x$) as an anticorrosion material. In addition, $CeO_x$ has demonstrated a wide variety of other applications, such as barrier layers,[3–5] counter electrodes for electrochromic glasses,[6] catalysts,[7–11] electrolytes for solid oxide fuel cells,[12–14] polishing agents for soft and hard optical glasses,[15,16] and numerous other applications. Due to the widespread use of $CeO_x$, it is surprising that only a few structurally characterized cerium alkoxides [$Ce(OR)_3$] have been reported in the literature,[17–29] and no systematic studies were possible from this eclectic mix of potential precursors. Because it is critical to know the structure of the precursor to be able to optimize the properties of the final $CeO_x$ materials, it was necessary to develop a family of well-characterized, systematically structurally diverse $Ce(OR)_3$ precursors. Understanding the structural changes available for these precursors is critical prior to generating tailored-property $CeO_x$ thin films.

Therefore, we undertook the synthesis and characterization of a series of $Ce(OR)_3$ that would fill in several gaps in the alkyl and aryl oxide derivatives to develop a systematic family of structurally characterized $Ce(OR)_3$ complexes which could be used to explore tailored materials. An alcohol amide metathesis reaction pathway was selected to synthesize these compounds [Equation (1)] in toluene (tol),

tetrahydrofuran (THF), or pyridine (py). The products were identified as: $[Ce(\mu\text{-}ONep)_2(ONep)]_4$ where ONep = $OCH_2C(CH_3)_3$ (**1**), $Ce_4(\mu_3\text{-}OtBu)_3(\mu\text{-}OtBu)_4(OtBu)_5$ (**2**), $Ce_3(\mu_3\text{-}OtBu)_3(\mu\text{-}OtBu)_3(OtBu)_3(H\text{-}OtBu)_2$ (**2a**), where $OtBu = OC(CH_3)_3$, $Ce(oBP)_3(THF)_3$ {**3**, *o*BP = $OC_6H_4$-[$C(CH_3)_3$]-2}, $[Ce(\mu\text{-}DMP)(DMP)_2(solv)]_2$ [DMP = $OC_6H_3(CH_3)_2$-2,6, solv = THF (**4**); solv = py (**4a**)], $Ce(DIP)_3(THF)_3$ [**5**, DIP = $OC_6H_3[CH(CH_3)_2]_2$-2,6], and $Ce(DPP)_3(THF)_3$ [**6**, DPP = $OC_6H_3(C_6H_5)_2$-2,6]. Compounds **1**–**5** were further reacted with a series of sterically varied H–ORc modifiers and their products identified as: $[Ce(OR)(\mu\text{-}ORc)(\mu_c\text{-}ORc)(py)]_2$ [OR = *o*BP, OBc (**7**); DMP, OPc (**8**); DMP, OBc (**9**); DIP, OPc (**10**), py = pyridine; $\mu$ = bridging; $\mu_c$ = chelating bridge]. The synthesis, characterization, and crystal structures of **1**–**10** are discussed below.

$$Ce(NR_2)_3 + 3\ H\text{–}OR \rightarrow Ce(OR)_3 + 3\ H\text{–}NR_2 \quad (1)$$

## Results and Discussion

As mentioned previously, we are interested in understanding the structural types available from simple OR- and ORc-modified Ce-based compounds prior to generating tailor-made $CeO_x$ thin films. Only a limited number of X-ray crystallographically characterized $Ce(OR)_3$ species have been reported: $[Ce(\mu\text{-}OiPr)(OiPr)_3(H\text{–}OiPr)]_2$ [O*i*Pr = $OCH(CH_3)_2$],[27,28] $Ce_4(\mu_4\text{-}O)(\mu_3\text{-}OiPr)_2(\mu\text{-}OiPr)_4(OiPr)_8$,[24,29] $Ce_3(\mu_3\text{-}OtBu)_2(\mu\text{-}OtBu)_3(OtBu)_5(NO_3)$,[20] $[Ce(\mu\text{-}OR)(OR)_2]_2$ where OR = O*t*Bu[23] or $OCH(tBu)_2$,[26] $Ce[OC(tBu)_3]_3(CNtBu)_2$,[22] $[Ce\{OCH(tBu)_2\}_3(\mu\text{-}DMAE)]_2$ [DMAE = $Me_2N\text{–}C_2H_4\text{–}NMe\text{–}C_2H_4\text{–}O^-$],[21] and $[Ce\{OC(tBu)_3\}_3]_2(OC_6H_4O)$.[23] In contrast, significantly fewer aryl oxide derivatives have been isolated, including $Ce[OC_6H_3(tBu)_2]_3$,[25] $Ce[OC_6H_3(tBu)_2]_3(CNtBu)$,[25] and $Ce[OC_6H_3(C_6H_5)_2]_3$.[17] It is of note that other Ce-containing species are available with fluorinated ligands, siloxide ligands,[19] or the inclusion of other metals.[30,31]

This nonsystematic family of compounds does not lend insight into the possible structure types available for $CeO_x$ precursors and thus necessitated the controlled synthesis of a series of $Ce(OR)_3$. Initial attempts focused on the aryl oxide ligands due to the dearth of structures available, the ease with which steric bulk can be introduced in the *ortho* positions, and our previous success using these ligands to produce high-quality thin films. We were also interested in several sterically demanding alkyl derivatives ONep and O*t*Bu due to our previous success using these ligands for materials synthesis and their lack of availability in the literature as homoleptic precursors.[20]

### Cerium Alkoxides

Several routes to these $Ce(OR)_3$ were considered prior to initiating this investigation. The first attempts were made using a liquid ammonia route wherein $CeCl_3$ was added to $Na^0$ dissolved in $NH_3$(l) at –78 °C followed by addition of H-DIP in toluene. Crystallization of the hexanes-soluble fraction of this reaction mixture yielded $[Ce(\mu\text{-}DIP)(DIP)_2]_2$. Unfortunately, when altering the pendant chain to an alkyl group, Na contamination was observed.[32] This prevented us from using a standard route to the family of $Ce(OR)_3$ that we were interested in isolating. It was therefore necessary to adjusted our synthetic strategy, and we switched to an amide alcohol metathesis route [Equation (1)] based on our previous success with this route.[32] It is critical for the synthesis of these compounds that a very pure $Ce(NR_2)_3$ be used, which was obtained by repeated sublimations and crystallizations.

### Synthesis

For each reaction, the $Ce(NR_2)_3$ was dissolved in toluene yielding a pale yellow solution. Upon addition of the desired alcohol, the reaction mixture was warmed slightly and turned clear with no precipitates observed for any of these samples. Crystals were isolated by drastically reducing the volume of the reaction and cooling the mixture to –25 °C. FTIR data indicates for each sample that the crystals did not possess any amide ligands and that the alcohols had fully reacted. Solution-state NMR could not be obtained due to the paramagnetic nature of the $Ce^{III}$ species isolated, therefore, it was necessary to obtain single-crystal X-ray structures to identify these compounds. The results of these experiments are shown in Figure 1 to Figure 12 for **1**–**10**, respectively.

### Crystal Structures

For **1**, the least sterically hindering ONep ligand led to the formation of a tetranuclear species, which is identical

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to what was reported for the all of the lanthanide ONep derivative, see Figure 1.[32–34] The central core consists of four Ce metal centers arranged in a square, interconnected by four bridging μ-ONep ligands and one terminal ONep ligand per metal. Each of the Ce cations is five-coordinated adopting a square-base-pyramidal (SBP) geometry. As reported for the other $[Ln(ONep)_3]_4$ species,[32–34] there is significant H-bonding interaction noted for this compound.

Increasing the steric demands from the ONep to the O*t*Bu ligand, under stoichiometric conditions, led to the isolation of another tetranuclear species **2** (Figure 2). For **2**, the four octahedrally bound ($O_h$) metals are again arranged in a square linked by μ-O*t*Bu ligands; however, in contrast to **1**, three $\mu_3$-O*t*Bu link the metal centers: Ce(1), Ce(2), and Ce(3) through the use two of the $\mu_3$-O*t*Bu while the remaining $\mu_3$-O*t*Bu bridges Ce(1), Ce(2), and Ce(4). To complete the $O_h$ geometry, Ce(1), Ce(2) and Ce(3) bind one terminal O*t*Bu ligand each and Ce(4) coordinates two ligands. This structure is similar to what was observed for $Ce_4(\mu_4\text{-}O)[\mu_3\text{-}OCH(CH_3)_2]_2[\mu\text{-}OCH(CH_3)_2]_4[OCH(CH_3)_2]_8$,[24,29] which uses an oxo ligand to achieve this structure; however, this is the first structural arrangement of this type noted for homoleptic $Ln(OR)_3$. When excess H-O*t*Bu is used, a centrosymmetric trinuclear species **2a** (Figure 3), similar to other lanthanide alkoxides is isolated in the presence of Lewis base solvents. For **2a**, each Ce is bound by two $\mu_3$-O*t*Bu, two μ-O*t*Bu and two terminal O*t*Bu ligands adopting a distorted trigonal bipyramidal (TBP) arrangement. By charge balance, two of these ligands must be protonated, as is commonly noted for metal alkoxides.[35,36] The increased steric bulk of the bound Lewis base H-O*t*Bu does not allow for large clusters to form. The mixed charge $NO_3$ derivative $Ce_3[\mu_3\text{-}OC(CH_3)_3]_2[\mu\text{-}OC(CH_3)_3]_3[OC(CH_3)_3]_5(NO_3)$,[20] and other solvated $Ln(OR)_3$ are known to adopt this structure as well.[37] It is interesting to note that the primary alcohol H-ONep is often considered to be less sterically hindering than the tertiary H-O*t*Bu, but in this system, the ONep-ligated species yields Ce metal centers with a lower coordination number. One explanation for this phenomenon may be the significantly greater cone angle swept out by the ONep ligand as compared to that of the O*t*Bu ligand.

Because only slight changes in the structure were noted for the pure alkoxides isolated above, in comparison to the literature species, further probing of the influence of sterics on the structure of these compounds led to an investigation of aryl oxide derivatives. For this system, it was necessary to use Lewis base solvents to maintain solubility. Using an asymmetrically substituted aryl oxide (*o*BP) wherein the steric bulk of one of the *ortho* sites is increased to a *tert*-butyl group, the first mono-substituted alkyl phenoxide lanthanide alkoxide complex was isolated as **3** (Figure 4). It is of note that several lanthanide alkali metal double alkoxides with 4-methylphenoxides[38,39] have been isolated previously.[39,40] The *tert*-butyl groups of the *o*BP ligands all point away from the metal center allowing the coordination of three THF solvent molecules forming a *fac* $O_h$ metal center.

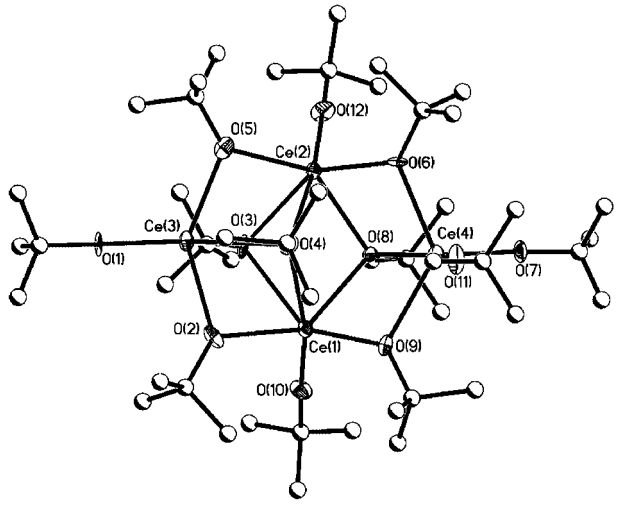

Figure 2. Structure plot of **2**. Thermal ellipsoids of heavy atoms drawn at 30% level. Carbon atoms are drawn as ball and stick for clarity.

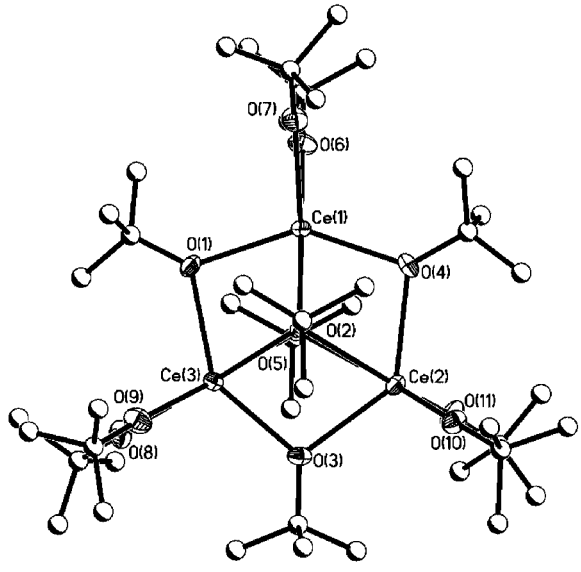

Figure 3. Structure plot of **2a**. Thermal ellipsoids of heavy atoms drawn at 30% level. Carbon atoms are drawn as ball and stick for clarity.

Systematically increasing the steric bulk by placing a methyl group in each *ortho* position, surprisingly led to the isolation of the dinuclear species **4**, shown in Figure 5. Each of the Ce metal centers adopts a distorted $O_h$ geometry by binding two μ-DMP, two terminal DMP, and two THF solvent molecules in the axial position. It was thought that the delicate balance between steric bulk and coordination strength of the solvent allowed a monomer to form as noted for **3** vs. the dinuclear for **4**. Therefore, a stronger Lewis base was used in the synthesis to see if **4** could be converted to a mononuclear species. Surprisingly, switching to py, lead to the isolation of **4a** which adopts an identical dinuclear structure as observed for **4** but the THF ligands are replaced by py ligands (Figure 6). This is the first py adduct of $Ce(OR)_3$ reported to date. Compounds **4** and **4a** are

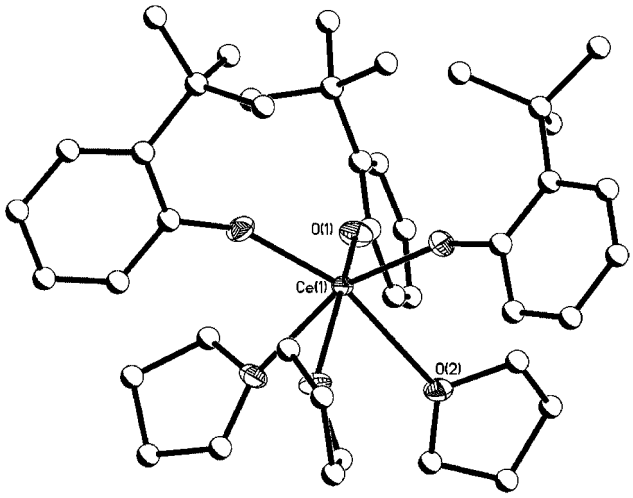

Figure 4. Structure plot of 3. Thermal ellipsoids of heavy atoms drawn at 30% level. Carbon atoms are drawn as ball and stick for clarity.

analogous to $[Y(\mu\text{-DMP})(DMP)_2(THF)]_2$ structure previously reported.[41]

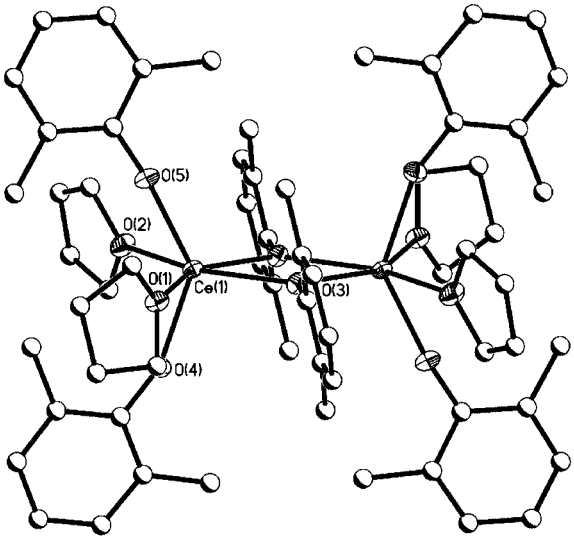

Figure 5. Structure plot of **3a**. Thermal ellipsoids of heavy atoms drawn at 30% level. Carbon atoms are drawn as ball and stick for clarity.

For compound **5** shown in Figure 7, the further increase in steric bulk of the *ortho* positions to isopropyl groups coupled with the use of Lewis base solvents, led to the formation of a monomer. The Ce metal center is $O_h$ bound by three DIP and three THF ligands in a *fac* arrangement, as noted for the *o*BP ligated species and numerous literature reports of solvated lanthanide monomers.[40] In comparison, the larger La cation only used two solvent molecules to complete its coordination sphere for the same ligand set;[42] however, smaller cations have also been found to yield trisolvated species such as $Sm(DIP)_3(THF)_3$.[43] Therefore, the number of solvent molecules coordinated can not be directly related to the size of the cations employed. A similar mononuclear structural arrangement was observed for the DPP (**6**, Figure 8) ligated compound; however, for **6** only two THF molecules are present. The previously reported DPP derivative was also a monomer but had π interactions from the *ortho* phenyl groups,[17–29] therefore, the addition of coordinated solvent noted for **6** is not unexpected. For the $Ln(DPP)_3(THF)_2$ Ln = La,[42,44] Nd,[42,44] Yb[45,46] complexes, the large *trans* effect of the OAr and the THF ligands was also observed for **6**.

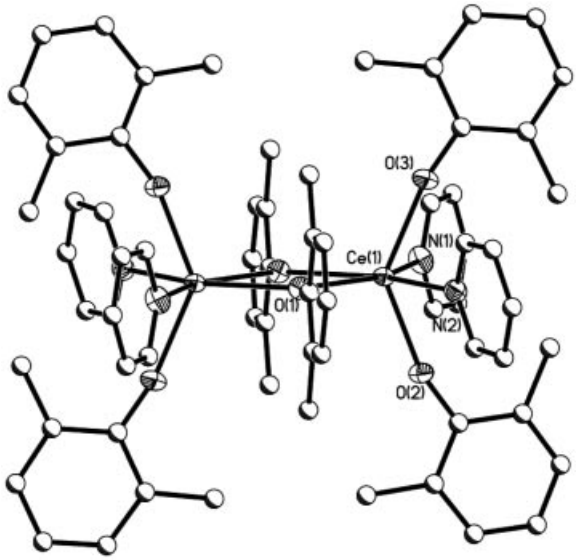

Figure 6. Structure plot of **4**. Thermal ellipsoids of heavy atoms drawn at 30% level. Carbon atoms are drawn as ball and stick for clarity.

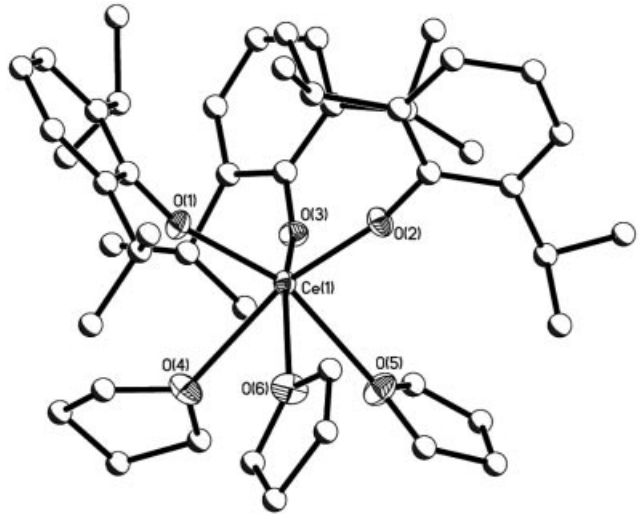

Figure 7. Structure plot of **5**. Thermal ellipsoids of heavy atoms drawn at 30% level. Carbon atoms are drawn as ball and stick for clarity.

The bond lengths and angles of this family of $Ce^{III}$ alkoxides, **1**–**6**, are consistent with those of previously reported $Ce(OR)_3$.[17–29,32–34,47,48] For **1**, as the second largest cation

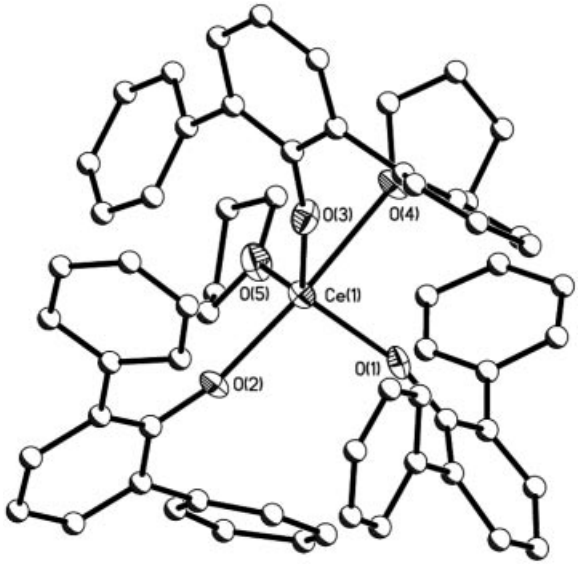

Figure 8. Structure plot of **6**. Thermal ellipsoids of heavy atoms drawn at 30% level. Carbon atoms are drawn as ball and stick for clarity.

in the ONep family of $[Ln(\mu\text{-}ONep)_2(ONep)]_4$ it falls on the long end of the Ln···Ln separations which systematically decrease from 3.86 to 3.28 Å. Terminal Ln–O distances of 2.14 Å for Ce fall within the range 2.16 Å (La, average value) to 1.89 Å (Sc) with an overall average distance of 2.06 Å. Ce is the second largest cation so obviously the Ce–O distance falls at the longer end of the observed bond lengths.

The O*t*Bu derivative **2** was found to adopt a novel structure type and no acceptable models were available for structural comparisons; however, the Ce(III/IV) oxo isopropoxide[24,29] was the closest in terms of connectivity and composition. The average terminal Ce–OR distances of 2.12, Ce(μ-OR) of 2.31, and Ce($\mu_3$-OR) of 2.47 Å were *not* found to be in agreement with **2** [2.24 (terminal), 2.44 (μ) Å]. This is most likely a reflection of the varied oxidation state and oxo species for the Ce(III/IV) oxo isopropoxide[24,29] complex vs. the $Ce^{III}$ alkoxide for **2**. There is also a trinuclear Ce(III/IV) O*t*Bu derivative structurally consistent with **2a**; however, the average Ce–OR, Ce(μ-OR), and Ce($\mu_3$-OR) distances of 2.08, 2.37, and 2.52 Å, respectively, are *not* in agreement with **2a** [2.23 (terminal) and 2.45 (μ) Å]. These differences are not surprising due to the mixed valent Ce(III/IV) species. Because the lanthanides systematically vary in cation size due to the lanthanide contraction, it is valid to use the isostructural La derivatives for metrical comparisons. In general, the bond lengths and angles of **2a** were found to be in agreement with $La_3(O\mathit{t}Bu)_9(H\text{-}O\mathit{t}Bu)_2$.[49] For example, the average $\mu_3$-OR–Ln distances are 2.55 Å for **2a** and 2.57 Å for La.

The dinuclear species **4** and **4a** have average Ce–OR and Ce(μ-OR) distances of 2.25 and 2.45 Å, respectively; **5** has an average Ce–OR distance of 2.22 Å. The dinuclear $O\mathit{t}Bu/OC\mathit{t}Bu_3$,[23] O*i*Pr,[27,28] $OC(CH_3)_2(\mathit{i}Pr)$,[48] and $OC(H)(\mathit{t}Bu)_2$[26] have average distances of 2.14 Å for Ce–OR and 2.36 Å for Ce(μ-OR). The monomeric species that are solvated[17,25,48] also have a similar average Ce–OR distance of 2.17 Å. The mononuclear solvated **6** was found to be in agreement with the metrical data reported for the unsolvated but π-bound DPP;[17–29] the average Ce–OR distances were 2.21 Å for **5** and 2.24 Å for **6**.

### Carboxylic Acid Modified Cerium Alkoxides

It was of interest to add more protective groups to the metal center to reduce the sensitivity to hydrolysis as well as introduce new constructs for $Ce(OR)_3$. This was undertaken using H-ORc. Previous studies[1,50,51] have shown that substantial changes in the rate of hydrolysis and condensation can be wrought through the introduction of H-ORc modifiers both through esterification oxolation pathways and the steric hindrance introduced by the bidentate nature of the ORc ligand. It is of note that the μ- and $\mu_c$-ORc ligands (also referred to as bidentate and tridentate, respectively) have been observed in a variety of lanthanide carboxylate systems wherein over 1500 structures have been identified revealing a variety of binding modes available for Ln–ORc species.[40] A further search of the literature reveals many Ce–ORc compounds have been structurally characterized but the majority of these are the homoleptic species.[52–62] with no structurally characterized carboxylate-modified alkoxide compounds available.

### Synthesis

Therefore, we investigated the modification of the $Ce(OR)_3$ isolated above with a series of sterically varied carboxylic acids. In general, the compounds were dissolved in py and then added to a stirring solution of the carboxylic acid dissolved in py. No precipitates were observed. Because the $Ce^{III}$ metal center is paramagnetic, solution identification of these compounds by NMR methods was not possible. Further, the volatility of the bound solvent prevents clean identification of the bulk powder by thermal elemental analyses. Therefore, while we have isolated numerous powders from these reactions, only those that were structurally characterized will be discussed below.

After numerous attempts, only the OAr–ORc modified species were structurally characterized. This phenomenon was mainly attributed to the ability of the steric bulk of the aryl oxide to prevent larger less soluble precursors to form. This is clearly illustrated by the larger oligomers observed for both the ONep and O*t*Bu ligated species **1**–**2** in comparison to the OAr derivatives **3**–**5**.

### X-ray Crystal Structure

Figure 9 shows the structure plot of **7**, the OBc-modified species of **3** that was isolated as the substituted dinuclear species. The OBc ligands have replaced two of the *o*BP ligands and bridge between the metal centers in two coordination modes: bridging (μ-ORc) and bridging chelating ($\mu_c$-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ORc) modes. By binding two py and the original *o*BP ligands, this forms eight-coordinate Ce metal centers forming a dodecahedron[63] arrangement. Independent of an increase in steric bulk of the pendant ORc chain, an identical core was observed for each of the various modified species [DMP/OPc **8** (Figure 10); DMP/OBc **9** (Figure 11), and DIP/OPc **10** (Figure 12)]. Interestingly, no esterification or redox behavior was noted for any of these reactions which is in stark contrast to the early transition metal ORc-modified compounds, wherein, esterification products were isolated for all but the most sterically hindering ligands.[1,2,64,65]

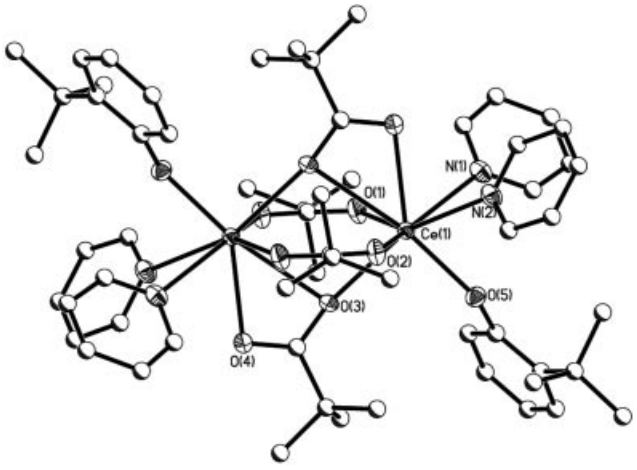

Figure 9. Structure plot of **7**. Thermal ellipsoids of heavy atoms drawn at 30% level. Carbon atoms are drawn as ball and stick for clarity.

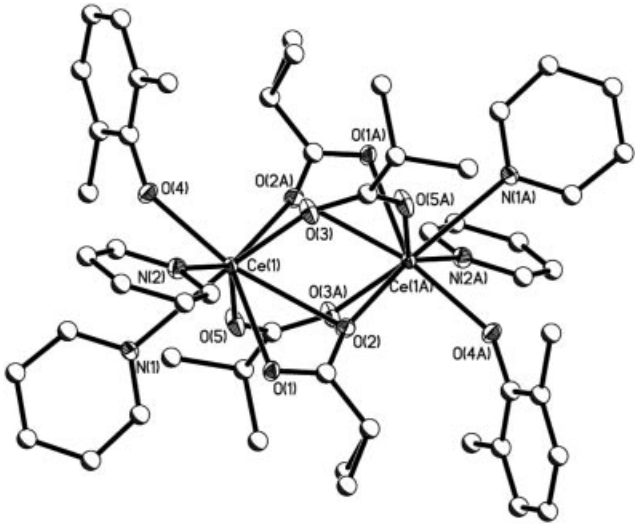

Figure 10. Structure plot of **8**. Thermal ellipsoids of heavy atoms drawn at 30% level. Carbon atoms are drawn as ball and stick for clarity.

The bond lengths and angles of the alkoxides[17–29,32–34,47,48] and the carboxylates moieties[52–62] are consistent with literature reports. The terminal distances of the aryl oxides are on the order of 2.24 to 2.27 Å and as noted above are within the expected range.[17–29,32,33,47,48] The bite angle of the $\mu_c$-ORc in the literature[52–62] have

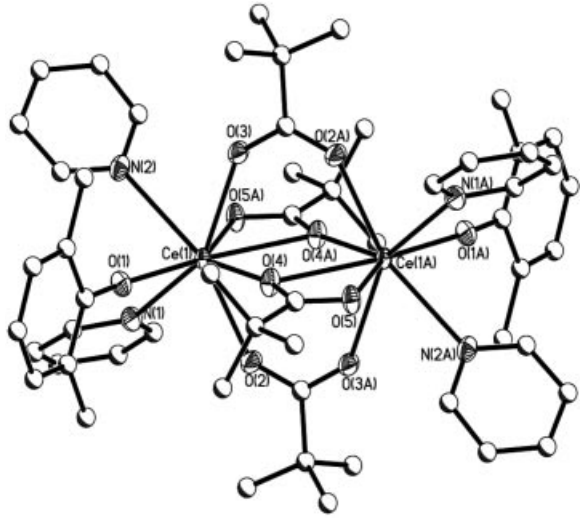

Figure 11. Structure plot of **9**. Thermal ellipsoids of heavy atoms drawn at 30% level. Carbon atoms are drawn as ball and stick for clarity.

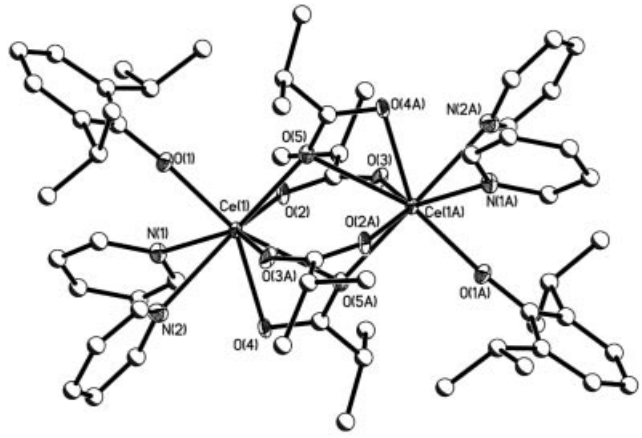

Figure 12. Structure plot of **10**. Thermal ellipsoids of heavy atoms drawn at 30% level. Carbon atoms are drawn as ball and stick for clarity.

values ranging from 116° to 128° with an average value of 120.7°. The angles noted for **7**–**10** (121.3°, 121.3°, 120.9°, 119.6°, respectively) fall within this range. The μ-ORc ligands are limited to a few species with a smaller bite angle range (119° to 126°) with an average value of 123.4°, which is similar to the average values noted for **7**–**10**: 123.8°, 125.2°, 124.9°, 125.6°, respectively.

### Bulk Powder Characterization

In an effort to characterize the bulk powder, several analytical methods were investigated. Typically, solution NMR can be employed to elucidate purity; however, the paramagnetic nature of the $Ce^{III}$ metal centers prevents obtaining any meaningful data by these techniques. Solid-state NMR spectroscopic data also proved inconclusive due to broad and numerous peaks expected for these structures. These phenomena were also attributed to the paramagnetic nature

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the $Ce^{III}$ and packing disorders, because the ligands are not free to rotate in the solid state numerous peaks are often observed.

The elemental analyses of the bulk powders of **1**–**10**, in general, agree with the unsolvated compounds. Compound **4a** is a solvated species and the slight variation in the elemental analysis was attributed to either "trapped" and/or bound solvent. These conditions are often reported to cause variations from ideal conditions.[50,51,66,67] FTIR spectra of **1**–**10** revealed the presence of the appropriate stretches expected for the various alkoxide ligands and shifts of the ORc ligands consistent with them bound to a metal center. It is of note that there are some reports that indicate these compounds can undergo a reaction with KBr under high pressure, yielding spectra that may not reflect the actual species but a metathesis products instead.[68] However, these spectra are useful in terms of identifying the resultant products. Further investigations of these materials by TGA/DTA revealed that most samples did not show consistent weight losses or thermal behavior during processing. This is attributed to high reactivity with the ambient atmosphere as an artefact with our current experimental setup. This led to total weight losses that were rarely in agreement with the crystal structure. Due to the complexity of the above data, it is not possible to conclusively deduce the purity of the bulk powder and alternative methods were investigated.

Therefore, microXRD spectra were obtained on the $Ce(OR)_3$ bulk powders sealed in glass capillary tubes and compared to calculated patterns from the obtained single crystal structures. In general, the resulting spectra matched what was expected for the powder XRD patterns. Figure 13 and Figure 14 show the obtained microXRD results for **2a** and **6** and their general agreement with the theoretical spectrum (inset). The variations noted can be contributed to two factors (i) the calculated patterns generated from the crystal structure are based on a truly random powder and the crystals have preferential orientation and (ii) the powders are not solvated as are the crystal structures. Therefore, an exact match was not obtained; however, the powders do appear to agree to a significant degree with the calculated patterns.

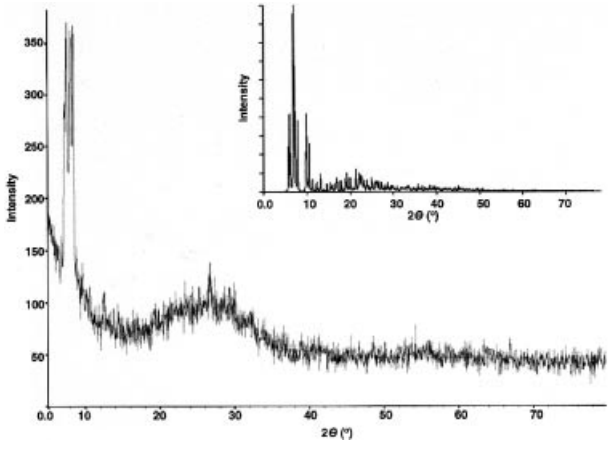

Figure 13. MicroXRD spectrum of **2a**. Inset is the calculated pattern.

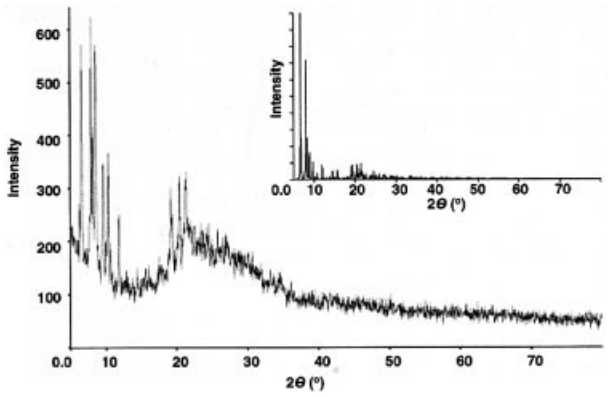

Figure 14. MicroXRD spectrum of **6**. Inset is the calculated pattern.

## Summary and Conclusion

A family of $Ce^{III}$ alkoxides were isolated through an alcohol–amide exchange reaction pathway. In general, as the steric bulk of the pendant alkoxy moiety increased and the presence of a Lewis base, the nuclearity of the molecule decreased. Species ranged from tetra- to mono-nuclear species with several novel solvents as ligands and arrangements noted for this family of compounds. The successful modification of the aryl oxide complexes led to the first alkoxy carboxylate structures isolated for Ce. These compounds were identified as dinuclear species with μ-ORc and $\mu_c$-ORc ligands. The change in steric bulk of the OAr or the ORc ligand had no effect on the final structure. Interestingly, none of the ORc–$Ce(OR)_3$ possessed an oxo species indicating that esterification did not occur. These compounds are being investigated as precursors to $CeO_x$ nanoparticles and thin films wherein the ligand set controls the structure and reactivity, which imparts control to the final properties of these $CeO_x$ materials.

## Experimental Section

All reactions were performed under a dry, inert atmosphere using standard Schlenk line and glovebox techniques. The following chemicals were used as received (Aldrich): $CeBr_3$, $KN[Si(CH_3)_3]_2$ ($KNR_2$), H-ONep, H-O*t*Bu, H-DMP, H-DIP, H-DPP, H-*o*BP, H-OPc, H-OBc, and H-ONc. H-OFc and H-OAc were dried according to literature preparative methods.[69] All solvents were used as received in anhydrous (Sure/Seal™) bottles. $Ce(NR_2)_3$ [where R = $Si(CH_3)_3$] was isolated from the reaction of $CeBr_3$ and 3 equiv. of $KNR_2$.[35,36] FT-IR spectroscopic data were obtained with a Bruker Vector 22 spectrometer using KBr pellets pressed under argon and handled under flowing nitrogen. Elemental analyses were performed with a Perkin–Elmer 2400 CHN-S/O elemental analyzer. Micro powder X-ray diffraction was performed with several samples that were prepared in a glass (Quartz) capillary and mounted vertically on an XYZ stage of a Bruker D8 Discover diffractometer

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

using Cu-$K_\alpha$ radiation ($\lambda$ = 1.5406 Å). The X-ray beam was collimated to 1 mm size and scans are typically taken from 10 to 80 ° $2\theta$ at 0.04 degree steps at 2 s per step. Diffraction scan interpretation was done using MDI, Inc. Jade 7 software.

**General Alkoxide Synthesis:** Due to the similarity of the synthesis of compounds **1**–**6**, a general description will be provided. The appropriate alcohol was dissolved in the solvent of choice and slowly added to a stirring solution of $Ce(NR_2)_3$ dissolved in the same solvent. The resulting solutions were stirred for 12 h and then the volume of the volatile material was drastically reduced by rotary evaporation. After this, the mixture was cooled to –25 °C until crystals formed.

**$[Ce(\mu\text{-}ONep)_2(ONep)]_4$ (1):** Used $Ce(NR_2)_3$ (0.60 g, 0.97 mmol), H-ONep (0.25 g, 2.9 mmol) in toluene (tol). Yield: 87% (0.34 g). FT-IR (KBr): $\tilde{\nu}$ = 2951 (w), 2864 (m), 2803 (m), 2687 (s), 1478 (m), 1460 (m), 1390 (s), 1358 (m), 1254 (s), 1215 (s), 1106 (w), 1059 (m), 1019 (m), 932 (s), 896 (s), 749 (s), 702 (s), 592 (m), 561 (s), 426 (s) $cm^{-1}$. $C_{60}H_{132}Ce_4O_{12}$ (1606.20): calcd C 44.87, H 8.28; found C 44.67, H 8.17.

**$Ce_4(\mu_3\text{-}OtBu)_3(\mu\text{-}OtBu)_4(OtBu)_5$ (2):** Used $Ce(NR_2)_3$ (0.61 g, 0.98 mmol), H-O*t*Bu (0.22 g, 3.0 mmol) in tol. Yield: 89% (0.32 g). FT-IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 2960 (w), 2865 (w), 2150 (s), 2120 (s), 1936 (s), 1848 (s) 1466 (w), 1356 (w), 1187 (w), 974 (w), 929 (w), 878 (w), 829 (w), 767 (w), 740 (w), 693 (s), 677 (s), 655 (s), 595 (m). $C_{48}H_{108}Ce_4O_{12}$ (1437.87): calcd C 40.09, H 7.57; found C 39.78, H 7.68.

**$Ce_3(\mu_3\text{-}OtBu)_3(\mu\text{-}OtBu)_3(OtBu)_3(H\text{-}OtBu)_2$ (2a):** Used $Ce(NR_2)_3$ (0.61 g, 0.98 mmol), H-O*t*Bu (0.29 g, 3.9 mmol) in tol. Yield: 90% (0.36 g). FT-IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 2965 (w), 2925 (w), 2865 (w), 1467 (m), 1370 (m), 1356 (w), 1020 (m), 968 (w), 927 (w), 878 (w), 768 (m), 759 (m), 740 (s), 511 (w), 488 (w). $C_{44}H_{101}Ce_3O_{11}$ (1226.65): calcd. C 43.08, H 8.30; found C 42.78, H 8.09.

**$Ce(oBP)_3(THF)_3$ (3):** Used $Ce(NR_2)_3$ (1.3 g, 2.9 mmol), H-*o*BP (0.91 g, 6.1 mmol) in tol. Yield: 92% (1.5 g). FT-IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 3056 (s), 2952 (m), 1587 (m), 1561 (m), 1478 (w), 1439 (w), 1301 (w), 1260 (w), 1217 (m), 1124 (s), 1088 (s), 1068 (s), 1047 (s), 1035 (s), 1003 (s), 868 (w), 823 (m), 748 (w), 703 (w), 597 (s). $C_{42}H_{63}CeO_6$ (804.09): calcd. C 62.74, H 7.90; found C 62.36, H 7.81.

**$[Ce(\mu\text{-}DMP)(DMP)_2(THF)_2]_2$ (4):** Used $Ce(NR_2)_3$ (0.22 g, 0.35 mmol), H-DMP (0.13 g, 1.10 mmol) in tetrahydrofuran (THF). Yield: 95% (0.22 g). FT-IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 2971 (s), 1591 (m), 1465 (m), 1425 (m), 1367 (s), 1269 (w), 1233 (w), 1211 (w), 1094 (m), 1068 (s), 1027 (m), 850 (w), 761 (m), 697 (m), 678 (s), 565 (s), 524 (s), 492 (s). $C_{64}H_{86}Ce_2O_{10}$ (1295.63): calcd. C 59.33, H 6.69; found C 59.16, H 7.05.

**$[Ce(\mu\text{-}DMP)(DMP)_2(py)_2]_2$ (4a):** $Ce(NR_2)_3$ (0.97 g, 1.6 mmol), H-DMP (0.58 g, 4.7 mmol) in tol and pyridine (py). Yield: 95% (0.98 g). FT-IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 3068 (m), 3049 (m), 3012 (m), 2964 (m), 2909 (s), 1596 (w), 1465 (w), 1442 (w), 1424 (w), 1270 (w), 1234 (w), 1210 (w), 1150 (s), 1092 (w), 1067 (m), 1035 (m), 1003 (m), 850 (w), 837 (w), 747 (w), 621 (m), 564 (s), 526 (m). $C_{68}H_{74}Ce_2N_4O_6$ (1323.61): calcd. C 61.70, H 5.64, N 4.23; found C 60.87, H 5.66, N 4.48.

**$Ce(DIP)_3(THF)_3$ (5):** Used $Ce(NR_2)_3$ (0.22 g, 0.36 mmol), H-DIP (0.19 g, 1.1 mmol) in tol and THF. Yield: 96% (0.22 g). FT-IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 3054 (s), 2958 (w), 2867 (m), 1586 (s), 1380 (s), 1357 (s), 1327 (m), 1264 (w), 1206 (m), 1095 (s), 1042 (m), 1021 (m), 885 (m), 855 (w), 796 (s), 752 (m), 687 (m), 561 (m). $C_{48}H_{75}CeO_6$ (888.25): calcd. C 64.91, H 8.51; for $C_{36}H_{51}CeO_3$ (without 3THF, 671.92): calcd. C 64.35, H 7.65; found C 63.96, H 8.04.

**$Ce(DPP)_3(THF)_2$ (6):** Used $Ce(NR_2)_3$ (0.24 g, 0.39 mmol), H-DPP (g, 1.2 mmol) in THF. Yield: 99% (0.39 g). FT-IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 3054 (m), 3027 (m), 2975 (m), 2874 (m), 1596 (w), 1581 (m), 1495 (w), 1453 (w), 1405 (w), 1307 (w), 1261 (w), 1176 (m), 1156 (s), 1086 (w), 1069 (w), 1025 (w), 914 (m), 856 (w), 803 (s), 702 (w), 626 (s), 600 (w). $C_{62}H_{55}CeO_5$ (1020.24): calcd. C 72.99, H 5.43; found C 72.64, H 5.79.

**General Modified Alkoxide Synthesis:** Due to the similarity of the synthesis of compounds **7**–**10**, a general description will be provided. To a stirring solution of the appropriate $Ce(OR)_3$ (**1**–**5**), 1 equiv. of the appropriate H-ORc was added. The reaction was stirred for 12 h and then the volatile portion was allowed to slowly evaporate until crystals formed.

**$[Ce(oBP)(\mu\text{-}OBc)(\mu_c\text{-}OBc)(py)_2]_2$ (7):** Used compound **3** (0.26 g, 0.32 mmol), H-OBc (0.066 g, 0.65 mmol) in py. Yield: 92% (0.20 g). FT-IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 2962 (m), 1524 (w), 1483 (w), 1459 (w), 1418 (w), 1375 (w), 1224 (m), 1032 (s), 897 (s), 802 (s), 601 (s), 540 (s). $C_{60}H_{82}Ce_2N_4O_{10}$ (1299.58): calcd. C 55.45, H 6.36, N 4.31; found C 55.19, H 6.81, N 4.01.

**$[Ce(DMP)(\mu\text{-}OPc)(\mu_c\text{-}OPc)(py)_2]_2$ (8):** Used compound **4** (0.28 g, 0.22 mmol), H-OPc (0.038 g, 0.43 mmol) in py. Yield: 37% (0.10 g). FT-IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 2968 (w), 2930 (m), 1581 (w), 1477 (w), 1422 (w), 1373 (m), 1359 (m), 1238 (m), 1217 (w), 1092 (w), 1035 (m), 1004 (m), 850 (w), 753 (w), 702 (w), 663 (s), 619 (m), 547 (m), 531 (m), 518 (m). $C_{52}H_{66}Ce_2N_4O_{10}$ (1187.37): calcd. C 52.60, H 5.60, N 4.71; found C 52.39, H 5.52, N 4.19.

**$[Ce(DMP)(\mu\text{-}OBc)(\mu_c\text{-}OBc)(py)_2]_2$ (9):** Used compound **4** (0.44 g, 0.34 mmol), H-OBc (0.069 g, 0.68 mmol) in py. Yield: 53% (0.22 g). FT-IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 3607 (s), 2961 (w), 2929 (w), 2871 (w), 1541 (w), 1483 (w), 1460 (w), 1420 (w), 1375 (w), 1361 (w), 1285 (m), 1263 (w), 1224 (w), 1090 (m), 1033 (m), 896 (w), 839 (m), 803 (m), 791 (m), 756 (m), 700 (m), 601 (w), 552 (m), 517 (s). $C_{56}H_{74}Ce_2N_4O_{10}$ (1243.48): calcd. C 54.09, H 6.00, N 4.50; found C 54.51, H 6.39, N 4.31.

**$[Ce(DIP)(\mu\text{-}OPc)(\mu_c\text{-}OPc)(py)_2]_2$ (10):** Used compound **5** (0.26 g, 0.29 mmol), H-OPc (0.052 g, 0.58 mmol) in py. Yield: 60% (0.12 g). FT-IR (KBr, $cm^{-1}$): $\tilde{\nu}$ = 3062 (s), 3036 (s), 2968 (w), 2930 (m), 2870 (m), 1581 (w), 1477 (w), 1442 (w), 1422 (w), 1373 (m), 1359 (s), 1283 (w), 1263 (m), 1238 (s), 1217 (s), 1092 (m), 1035 (m), 1004 (s), 850 (m), 753 (m), 702 (m), 619 (s), 547 (s), 531 (s), 518 (s). $C_{60}H_{82}Ce_2N_4O_{10}$ (1299.58): calcd. C 55.45, H 6.36, N 4.31; found C 55.90, H 6.81, N 4.33.

**General X-ray Crystal Structure Information:**[70] Each crystal was mounted onto a thin glass fiber from a pool of Fluorolube™ and immediately placed under a liquid $N_2$ stream, on a Bruker AXS diffractometer. The radiation used was graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.7107 Å). The lattice parameters were optimized from a least-squares calculation on carefully centered reflections. Lattice parameter determination and data collection were carried out using SMART Version 5.054 software. Data reduction was performed using SAINT Version 6.01 software. The structure refinement was performed using XSHELL 3.0 software. The data were corrected for absorption using the SADABS program within the SAINT software package. General collection parameters for **1**–**3** and **4**–**10** are shown in Table 1 and Table 2, respectively. Additional information concerning the structure of these compounds can be found by accessing the final CIF files through the Cambridge Crystallographic Data Base. In general, each structure was solved by direct methods. This procedure yielded the heavy atoms,

[a] $R_1 = \Sigma \; | \; |F_o|-|F_c| \; | / \Sigma \; |F_o| \times 100$. [b] $wR_2 = [\Sigma \; w \; (F_o^2-F_c^2)^2/\Sigma \; (w \; |F_o|^2)^2]^{1/2} \times 100$.

along with a number of the C, O, and N atoms when present. Subsequent Fourier synthesis yielded the remaining atom positions. The hydrogen atoms were fixed in positions of ideal geometry and refined within the XSHELL software. These idealized hydrogen atoms had their isotropic temperature factors fixed at 1.2 or 1.5 times the equivalent isotropic *U* of the C atoms to which they were bonded. The final refinement of each compound included anisotropic thermal parameters on all non-hydrogen atoms. Final crystal solutions that contain alkoxides are well known to possess ligand positional disorder issues.

CCDC-614454 to -614465 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Any variations from standard structural solution associated with the representative compounds are discussed below. All CIF files were checked for errors using the free on-line Checkcif service provided by the International Union of Crystallography (available on the Web at http://checkcif.iucr.org/).

# Solvent-Induced Pore-Size Adjustment in the Metal-Organic Framework $[Mg_3(ndc)_3(dmf)_4]$ (ndc = naphthalenedicarboxylate)

**Irena Senkovska[a] and Stefan Kaskel*[a]**

**Keywords:** Metal-organic frameworks / Magnesium / Carboxylate ligands / Adsorption

Two new compounds containing magnesium and the bidentate ligand 2,6-naphthalenedicarboxylate (ndc), namely $[Mg(dmf)_2(H_2O)_4]$·ndc (**1**) (dmf = *N*,*N*-dimethylformamide) and $[Mg_3(ndc)_3(dmf)_4]$ (TUDMOF-2) (**2**), have been obtained from $Mg(NO_3)_2$·$6H_2O$ and the pure acid using a solvothermal route. According to single-crystal X-ray studies both compounds are monoclinic. Complex **1** crystallizes in the space group $P2_1/c$ [$a$ = 12.317(3), $b$ = 12.582(2), $c$ = 15.353(3) Å, $\beta$ = 110.96(3)°]. The compound consists of an isolated tetraaquabis-*N*,*N*-dimethylformamide cation and the deprotonated ligand with hydrogen bonds linking the cations and anions. The metal-organic framework **2** crystallizes in the space group $C2/c$ [$a$ = 13.451(3), $b$ = 18.043(4), $c$ = 20.937(5) Å, $\beta$ = 99.79(3)°] with trinuclear magnesium clusters connected to six dicarboxylate ligands that link the clusters into a three-dimensional network. In contrast to $[Mg_3(ndc)_3(def)_4]$ (def = *N*,*N*-diethylformamide; **3**), the dmf molecules coordinated to magnesium in TUDMOF-2 (**2**) not only cause a distortion of the network but induce accessibility for the adsorption of nitrogen. TUDMOF-2 has a Langmuir surface area of 520 $m^2 g^{-1}$ and a hydrogen adsorption capacity of 0.78 wt.-% at 77 K and 760 Torr.

## Introduction

Metal-organic frameworks (MOFs) are a new family of porous crystalline inorganic–organic hybrid materials that are attracting increasing interest due to their rich structural chemistry and potential applications in gas storage, separation processes, and catalysis.[1] The modular concept allows for a rational design of porous solids in which a multinuclear complex (cluster) is used as a connecting node and an organic bi- or trifunctional linker to link the nodes into a three-dimensional network of predefined topology. An often observed structural motif in transition metal MOFs is the paddle-wheel unit acting as a four-connecting node.[2] Such copper-, zinc-, or molybdenum-containing networks may be useful for hydrogen storage applications.[3] The most prominent 6-connector is the $Zn_4O^{6+}$ cluster in MOF-5 and the IRMOF family.[4]

Although transition-metal-containing MOFs have been widely investigated, the coordination chemistry of alkaline earth metals has until now remained a largely underdeveloped area, and reports on magnesium coordination polymers are very rare.[5] Magnesium carboxylates seldom form coordination polymers and extended three-dimensional structures because of the high affinity of $Mg^{2+}$ for oxygen donor atoms of polar solvents. Additionally, the coordination chemistry of magnesium is less flexible than that of zinc, and octahedral complexes are often found.[6] In the case of polyfunctional ligands used for the synthesis of Mg-based MOFs, competitive coordination by water or other solvent ligands may result in low-dimensional network topologies or isolated complexes, and thus porosity cannot be expected. However, the first magnesium-based metal-organic framework with permanent porosity and accessibility for very small molecules ($H_2$, $O_2$) was recently reported by Dinća and Long.[7] $[Mg_3(ndc)_3(def)_4]$ (**3**) (def = *N*,*N*-diethylformamide) was found to adsorb $O_2$ and $H_2$ preferentially, although the pores were too small to allow the access of $N_2$.

Below we describe the structure of two new magnesium carboxylates, namely $[Mg(dmf)_2(H_2O)_2]$·ndc (**1**) and $[Mg_3(ndc)_3(dmf)_4]$ (TUDMOF-2, **2**). TUDMOF-2 (Technical University Dresden Metal Organic Framework no. 2) has the same network topology as $[Mg_3(ndc)_3(def)_4]$ but the smaller solvent molecule induces significant structural changes, resulting in a larger pore diameter and permanent porosity with pores accessible for $N_2$ molecules.

## Results and Discussion

### Synthesis and Structural Characterization of 1 and 2

Solvothermal reaction of $Mg(NO_3)_2$·$6H_2O$ and ndc in dmf at 110 °C results in the formation of yellow crystals of **2**. White crystals of **1** were obtained from the same reaction carried out in aqueous dmf (5 vol-% $H_2O$). In spite of their

 InterScience © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

very similar synthetic conditions, complexes **1** and **2** have completely different architectures.

Single-crystal X-ray diffraction was used to determine the structure of compound **1**. Instead of carboxylate ligands coordinating to $Mg^{2+}$, the compound consists of isolated $[Mg(H_2O)_4(dmf)_2]^{2+}$ cations and $ndc^{2-}$ anions (Figure 1). The $Mg^{2+}$ ion has a sixfold coordination and is surrounded by four water molecules and two oxygen atoms of dmf molecules, resulting in a somewhat distorted octahedral geometry. Figure 2 shows a packing diagram of **1**. Hydrogen bonds link the water molecules to the carboxylate O atoms (O···O = 2.68–2.75 Å) to form a three-dimensional hydrogen-bonded network.

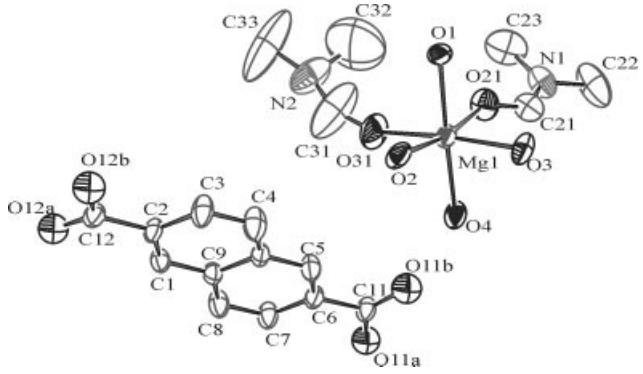

Figure 1. The asymmetric unit and labelling scheme for compound **1**. Displacement ellipsoids are drawn at the 50% probability level. H atoms have been omitted.

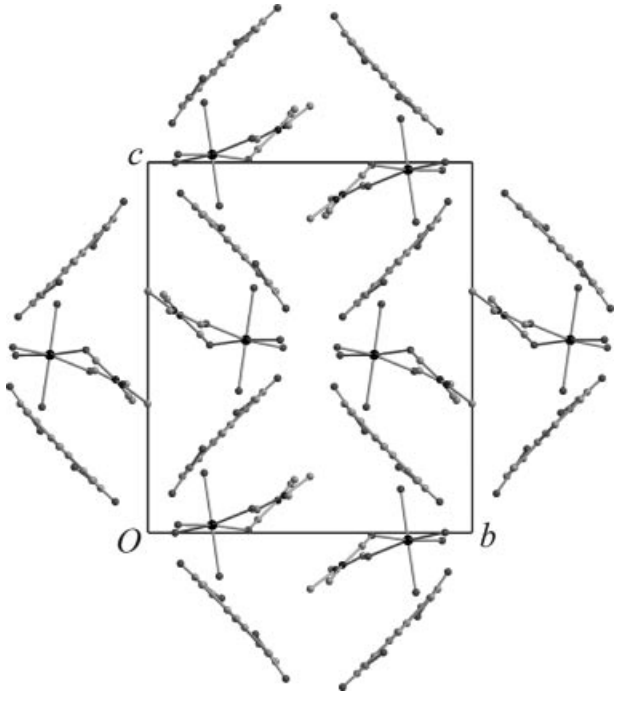

Figure 2. The crystal packing of **1** viewed along the crystallographic *a* axis.

Complex **2** crystallizes in the monoclinic space group *C*2/*c* and is a structural analogue of $[Mg_3(ndc)_3(def)_4]$ (**3**) reported by Dinća and Long.[7] However, the channels in **2** are filled with dmf instead of def, which results in a significantly reduced lattice constant *a* of 13.451 Å compared to that of **3** (*a* = 15.045 Å). All other lattice parameters are very close to those reported for **3** with differences of below 0.1 Å for *b* and *c* and below 2° for the monoclinic angle.

The structure of **2** contains two independent magnesium centers (Figure 3a). Mg1 is positioned on a twofold rotation axis and Mg2 is located at a general position (*8f*). The $ndc^{2-}$ anions are positioned on an inversion center located in the middle of the central C–C bond in the naphthalene system. Two distinct carboxylate coordination modes are observed. The C16 and C26 carboxylate groups form didentate bridges, whereas the C6 carboxylate group chelates to Mg2, with each of the O atoms also bound to Mg1. This tridentate bridging mode is postulated to be an important intermediate in "carboxylate-shift" chemistry[8] and is a key factor for the formation of the trinuclear metal cluster. Consequently, Mg1 is connected to two adjacent Mg2 centers to form a linear $[Mg_3(\mu_3\text{-}O)_2(\mu_2\text{-}O)_4]$ unit with a nonbonding Mg–Mg distance of 3.582(6) Å (Figure 3a). These trinuclear magnesium clusters represent a 6-connecting secondary building unit (Figure 3b).[9] They are linked by naphthalenedicarboxylate bridges to form a three-dimensional network (Figure 3c and Figure 4).

A trinuclear SBU has been reported earlier as a discrete molecular cluster.[10] Furthermore, this structural motif has been found in networks such as $Zn_3(bdc)_3{\cdot}6CH_3OH$ (bdc = benzenedicarboxylate) (MOF-3),[11] $[Cd_3(bdc)_3(L)_2(H_2O)_2]$ (L = 1,4-bis(1,2,4-triazol-1-yl)butane),[12] $[CoT(p\text{-}CO_2)PPCo_{1.5}(C_5H_5N)_3(H_2O)]{\cdot}11C_5H_5N$ (PIZA-1),[13] and $[Co_3(bpdc)_3(bpy)]{\cdot}4dmf{\cdot}H_2O$ (bpdc = biphenyldicarboxylate, bpy = 4,4′-bipyridine) (IRPM-1),[14] each of which contains $M^{II}_3$ clusters linked together to form a rigid framework with accessible internal channels and/or cages and permanent porosity.

In contrast to the compressed central $MgO_6$ octahedron of Mg1 in **3**, the magnesium–oxygen octahedron in the trinuclear cluster of **2** is elongated, with axial Mg1–O61 bond lengths of 2.109(3) Å and equatorial bond lengths of 2.077(3)–2.084(3) Å. The three $Mg^{2+}$ ions in the trinuclear motif form an almost linear chain. The Mg2–Mg1–Mg2$^i$ (symmetry code: *i*: –*x*, *y*, 1/2 – *z*) angle in the $Mg_3$ units of **2** is 174.36(7)° and is thus somewhat smaller than the corresponding angle in **3** [176.14(1)°].

The Mg1–Mg2 distance in **2**, however, is longer than in **3** [3.530(2) Å] because of the longer Mg–O bonds in the former. Thus, the structural changes within the $Mg_3$ cluster are not responsible for the compressed *a* axis, whereas the orientation of the linker in the 6-connecting SBU allows for compression or elongation along the *a* axis, resulting in a high flexibility and breathing of the $Mg_3(ndc)_3$ network.

The reason for the contraction along the *a* axis observed in **2** as compared to **3** is the predefined orientation of solvent molecules upon coordination to Mg2. The ethyl groups of the def molecules in **3** are oriented along the *a* axis and thus occupy more space in this direction. The orientation is similar for dmf in **2**, thus allowing for a compression along the *a* axis. The dmf molecules in **2** can be re-

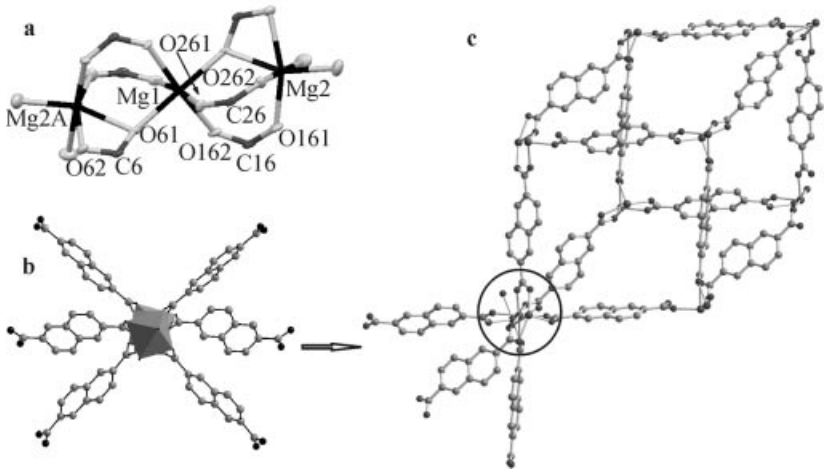

Figure 3. a) Trinuclear Mg-carboxylate cluster; b) representation of the inorganic 6-connecting SBU; c) the three-dimensional network in **2**.

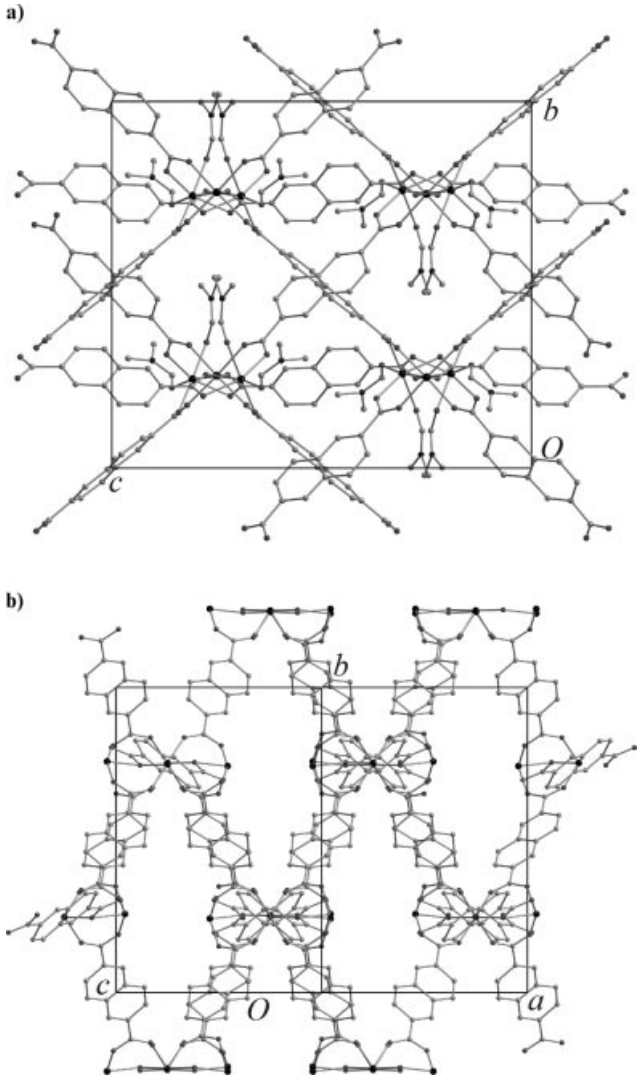

Figure 4. Extended structure of **2** viewed along: a) the crystallographic *a* axis; b) along [101] (dmf molecules have been omitted).

moved from the voids to give a porous network having open magnesium sites. This open framework has channels along the [100] and [101] directions (Figure 4). The minor differences in structure cause significant changes in the gas adsorption properties of **2** and **3**.

### Thermal Stability

Thermogravimetric analysis (TGA) shows the desolvation of compound **1** in one step at a temperature above 90 °C. The weight loss of 41% for **1** from 90 to 170 °C corresponds to the loss of four $H_2O$ and two dmf molecules from the structure (calcd.: 42.13%). The second step in the range from 500 to 540 °C indicates the decomposition of the ligand.

The framework of **2** has a high thermal stability up to 500 °C. For compound **2**, a total weight loss of 29% is observed between 120 and 400 °C, corresponding to four dmf molecules per $Mg_3$ unit. This weight loss is consistent with the elemental analysis and the empirical formula deduced from the single-crystal X-ray analysis. The desolvated framework is hereafter denoted as **2a**. The X-ray powder diffraction pattern of **2** changes after removal of the guest molecules as compared to the product obtained from the solvothermal synthesis. The reflections of **2a** show an apparent shift to the lower angle region, and several of the reflections disappear (Figure 5b), thereby indicating a slight structural deformation of the framework upon desolvation. After treatment of **2a** with dmf, the virgin framework of **2** regenerates (Figure 5a), thus indicating a reversible transformation (Scheme 1).

However, some additional peaks appear too. Treating **2a** with def molecules should afford **3** (Figure 5c) and, due to the larger size of the def molecules, the latter is expected to expand the lattice constant *a* as discussed above. This host flexibility can improve the efficiency of the adsorption by the aid of host structural transformation suited for the guest molecules.[15] The XRD pattern of **2a** shows diffraction peaks similar to those of desolvated **3**. The evacuated framework of **3** is hereafter indicated as **3a**. However, a detailed comparison of the XRD patterns reveals a significant

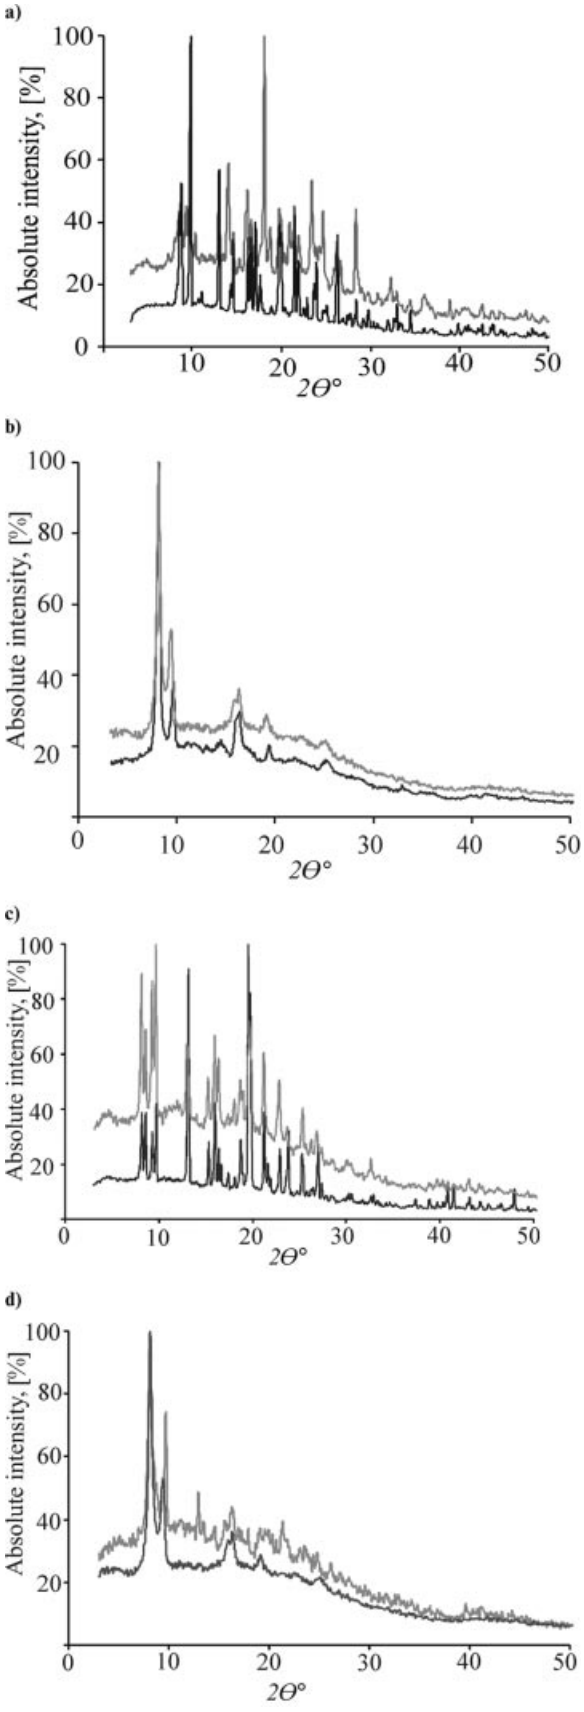

Figure 5. X-ray powder diffraction patterns: a) for **2** as synthesized (black) and **2a** resolvated with dmf (grey); b) for **2a** (black) and **3a** (grey); c) for **3** as synthesized (black) and **2a** resolvated with def (grey); d) for **3a** (black) and **3a** resolvated with dmf (grey).

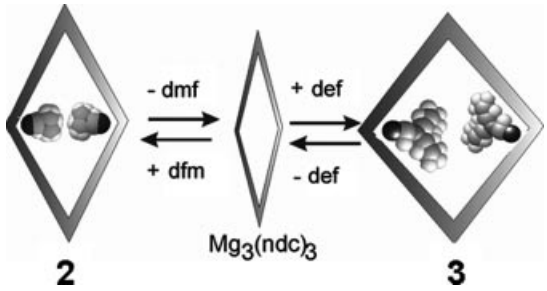

Scheme 1. The reversible structural transformation of **2** and **2a**.

shift for selected peaks (Figure 5b). Treating **2a** with def affords an XRD pattern identical to that of the as-synthesized **3** (Figure 5c). On the other hand, treating **3a** with dmf does not allow us to convert the framework into compound **2** (Figure 5d). Thus, **2** can be converted into **3** via **2a** but not vice versa. The porous materials **2a** and **3a** obtained from the different networks show small structural differences according to the X-ray powder patterns. This resembles a sort of memory effect induced by the different solvents and causes different sorption properties for the two compounds.

## Sorption Properties

Compound **1** is essentially nonporous and has only a low $N_2$ adsorption capacity and a type II adsorption isotherm (Figure 6). Compound **2** shows a type I nitrogen adsorption isotherm at 77 K typical of a microporous material (Figure 6). The sorption isotherm was fitted to a Langmuir equation, resulting in a specific surface area of 520 $m^2 g^{-1}$ for the activated framework.

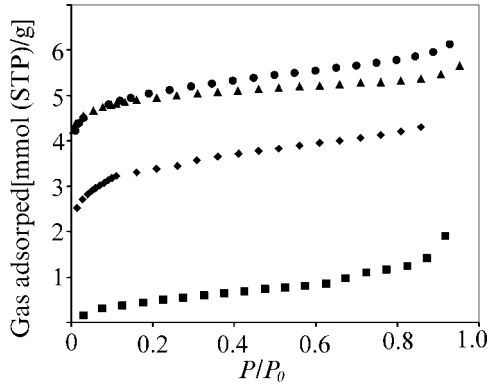

Figure 6. The $N_2$ (triangle), $O_2$ (circle), and $CH_4$ (diamond) adsorption isotherms of $[Mg_3(ndc)_3]$ (**2a**) and the $N_2$ (square) adsorption isotherm of $[Mg(dmf)_2(H_2O)_2]$·ndc (**1**) at 77 K.

Significant differences between $[Mg_3(ndc)_3(dmf)_4]$ (**2**) and $[Mg_3(ndc)_3(def)_4]$ (**3**) are also observed in the gas adsorption properties. The as-synthesized sample of **2** was activated by drying under vacuum at 468 K for 72 h. The mass loss of 28.8% was close to the 29.0% estimated for complete removal of four dmf molecules.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Whereas for **3** essentially no $N_2$ adsorption was detected, for TUDMOF-2 (**2**) the adsorbed amount of nitrogen (5.0 mmol $g^{-1}$ at 0.9 $P/P_0$) is surprisingly large. TUDMOF-2 also shows a type I isotherm for the adsorption of $CH_4$ (kinetic diameter of 3.8 Å) (Figure 6). However, only oxygen and hydrogen adsorption was observed for **3**, thus indicating a limited accessibility only for smaller gas molecules due to the small pore size. The limited accessibility of nitrogen in **3** could indicate incomplete removal of def molecules in the activation, which would cause pore blocking for larger molecules such as $N_2$. The latter is reasonable due to the higher boiling point and more effective encapsulation of def as a result of the larger size of def relative to dmf. Thus, even though a compression of the *a* axis is detected for **2**, the more effective removal of dmf is responsible for a larger pore size in the desolvated form and larger specific pore volume. Another reason for the differences in porosity are the structural differences of **3** and **2**, which result in a memory effect and cause structural differences also in the desolvated forms of **3** and **2**. An indication for the latter is the experimentally observed difference in the XRD powder patterns of the activated forms.

The hydrogen adsorption isotherms measured at 77 K are shown in Figure 7. The hydrogen storage capacity is 3.9 mmol $g^{-1}$ (0.78 wt.-%) at 760 Torr and is thus slightly higher than for $[Mg_3(ndc)_3(def)_4]$ but lower than for other MOFs.[3]

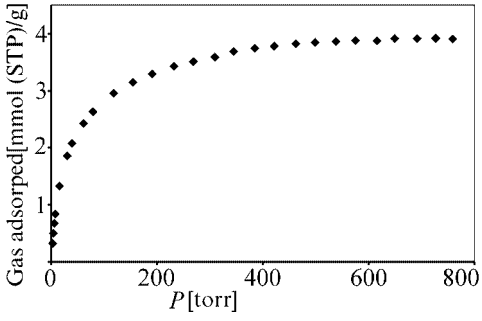

Figure 7. $H_2$ adsorption isotherm of $[Mg_3(ndc)_3]$ (**2a**) at 77 K.

In summary, we have presented two new magnesium carboxylates. Whereas in the presence of water molecules preferred coordination of $H_2O$ and dmf hinders the formation of extended three-dimensional networks, a porous network structure is obtained in the absence of water. The resulting $[Mg_3(ndc)_3(dmf)_4]$ network is microporous, and the pores are accessible for $H_2$, $O_2$, $N_2$, and $CH_4$. Small structural changes induced by coordinating dmf molecules play a key role in adjusting the pore size of the network and are responsible for the size exclusion of nitrogen.

Due to the low weight of magnesium, the design of Mg-MOFs with higher specific surface areas is, in principle, feasible, although identification of suitable structural building units allowing for a high porosity remains a challenge.

## Experimental Section

**General:** All chemicals (Aldrich) were reagent grade and were used as received. Microanalyses (C, H, N) were performed with a Fison's EA1108 CHNS analyzer. IR spectra were recorded as KBr discs using an Excalibur FTS 3000 spectrometer in the range 480–4000 $cm^{-1}$. Powder X-ray diffraction (PXRD) data were collected on a Stoe STADI P powder diffractometer with Cu-$K_{\alpha1}$ radiation. Thermogravimetric analyses were carried out using a Netzsch STA 409 thermal analyzer. Physisorption isotherms were measured at 77 K using a Quantachrome Autosorb1C apparatus. Prior to the measurement, the samples were evacuated at 468 K for 72 h. High purity gases were used (nitrogen: 99.999%, hydrogen: 99.999%, oxygen 99.999%, methane 99.995%). To prevent condensation of $O_2$ and $CH_4$ at 77 K, the oxygen adsorption isotherm was recorded below 156 Torr and the adsorption isotherm of methane was recorded below 9.4 Torr. The specific surface areas and porosity parameters were derived from the $N_2$ adsorption data.

**$[Mg(dmf)_2(H_2O)_4]$·ndc (1):** $Mg(NO_3)_2·6H_2O$ (0.9 g, 3.5 mmol) was mixed with 2,6-naphthalenedicarboxylic acid (0.7 g, 3.24 mmol) in dmf (18 mL) and deionized water (1 mL). The solution was filled in a 40-mL Teflon liner, placed in an autoclave, heated to 373 K for 24 h, and then cooled to room temperature. Colorless crystals of **1** were isolated from the solution at room temperature after several days. Yield: 1.06 g (71%). $C_{18}H_{28}MgN_2O_{10}$ (456.73): calcd. C 47.34, H 6.18, N 6.13; found C 46.87, H 6.28, N 6.33. IR: $\nu_{C=O}$ = 1676 (s), 1659 (vs), 1606 (s), 1560 (s), 1495 (m), 1394 (s), 1358 (s) $cm^{-1}$.

**$[Mg_3(ndc)_3(dmf)_4]$ (2):** A mixture of $Mg(NO_3)_2·6H_2O$ (1.5 g, 5.85 mmol) and 2,6-naphthalenedicarboxylic acid (0.9 g, 4.16 mmol) in dmf (60 mL) was filled in a 250-mL Teflon liner, placed in an autoclave, heated to 383 K for 24 h, and then cooled to room temperature at a rate of 0.05 K $min^{-1}$. The resulting pale-yellow crystals were collected, washed with dmf, and dried under argon to give **2**. Yield: 0.9 g (64.2%). $C_{48}H_{46}Mg_3N_4O_{16}$ (1007.8): calcd. C 57.21, H 4.60, N 5.56; found C 56.77, H 4.36, N 5.81. IR: $\nu_{C=O}$ = 1680 (s), 1655 (s), 1621 (s), 1566 (s), 1497 (m), 1406 (vs), 1359 (m) $cm^{-1}$.

**X-ray Crystallography:** Single-crystal X-ray diffraction data for complexes **1** and **2** were recorded with a STOE IPDS I image plate diffractometer with Mo-$K_\alpha$ radiation. The structures were solved by direct methods with the help of SHELXS-97[16] and refined by full-matrix least-squares techniques using SHELXL-97.[17] Non-hydrogen atoms were refined with anisotropic temperature parameters, and the hydrogen atoms of the ligands and dmf molecules were refined as rigid groups. The hydrogen atoms of the water molecules of **1** were located from the difference Fourier maps. Further details of the structural analysis are summarized in Table 1.

# The Relative Stabilities of 1,3-Diphospha-2-silaallene and Some of Its Isomers

Rudolf Pietschnig*[a] and Andreas Orthaber[a]

**Keywords:** Multiple bonds / Silicon / Phosphorus / Allenes / Ab initio calculations

An ab initio investigation of the relative stability of 1,3-diphospha-2-silaallenes (RP=Si=PR) with respect to potential isomers shows that the allene isomer is not the global minimum throughout a series of several substituents (R = H, $SiH_3$, $CH_3$, Ph, F) – the siladiphosphirene isomer is significantly more stable for all these substituents. The stability of the diphosphasilaallene relative to other isomers depends on the nature of the adjacent substituents. Thus, for simple carbon and silyl substituents alternative ring-closed isomers are favored over the diphosphasilaallene, which, depending on the substituent, can show silylene or phosphasilene character. The results obtained at the DFT level are compared with those at other levels of theory for the parent system.

## Introduction

Numerous investigations dealing with the stabilization and bonding situation of multiply bonded phosphorus and silicon compounds have initiated a fertile research area. Multiple bonds between silicon and phosphorus are synthetically especially challenging due to the high reactivity of such unsaturated systems. Nevertheless, sterically protected Si=P double bonds have been generated and structurally characterized.[1–5] Similarly, phosphaallenes[6–15] as well as silaallenes,[16–19] trisilaallenes,[20–22] and even a 1-phospha-3-silaallene[23] have been synthesized and studied theoretically,[24–30] although the combination of both heteroatoms directly bonded to each other within a single allene system remains unknown so far. Earlier attempts to generate 1,3-diphospha-2-silaallenes by hydrogen chloride abstraction from suitable precursors with sterically hindered bases resulted either in Si–P bond cleavage or addition of the base to the Si–P unit.[31,32] The availability of seemingly suitable precursors of the type $(RPH)_2SiCl_2$ combined with a lack of information concerning the outcome of attempted synthesis of 1,3-diphospha-2-silaallenes prompted us to investigate their stability with respect to possible isomers theoretically. According to our findings, the 1,3-diphospha-2-silaallene structure, despite being a local minimum, is not the global minimum on the potential energy hypersurface. For all substituents considered in our investigation the cyclic siladiphosphirene is by far the most stable isomer. Which isomer is the next most stable one depends significantly on the nature of the adjacent substituent. However, in neither case was the silaallene the second most stable isomer. For systems bearing carbon substituents we find that a cyclic phosphasilene isomer is more stable than the silaallene, while for more electropositive substituents a cyclic diphosphasilylene structure is lower in energy. As our results show, the relative stability of the isomers explored by us strongly depends on the electronic properties of the adjacent substituents.

## Results and Discussion

In order to investigate the energetic separation of 1,3-diphospha-2-silaallene and its isomers, we performed ab initio quantum chemical calculations using the program package Gaussian 03,[33] employing a 6-311G(d) basis set[34–37] at the Hartree–Fock and DFT(B3LYP) level.[38,39] The harmonic vibrational frequencies and their infrared intensities for all of the optimized structures were evaluated by the B3LYP method. Complete reports of the vibrational frequencies and infrared intensities are given in the Supporting Information. These results were used to determine if a structure is a genuine minimum. The final energy values include zero-point correction and thermal correction to 298 K. The reliability of the B3LYP method for the calculation of the structures and the stability of the group of compounds under investigation was tested by the higher correlated MP2 method for the hydrogen-substituted parent systems of all isomers.

For our calculations we considered the diphosphasilaallene structure **1**, the cyclic diphosphasilylene structures with the adjacent substituents adopting a *cis* and a *trans* position (**2** and **3**), the ring-opened diphosphenyl silylene structure **4**, the cyclic phosphasilene **5**, siladiphosphirene **6**, and finally phosphasilyne **7** (Scheme 1). Other isomers such as the vinylidene silylene **8** or phosphanylidenes like **9** were not taken into account since exploratory calculations on the parent system at the B3LYP//6-311G(d) level showed that

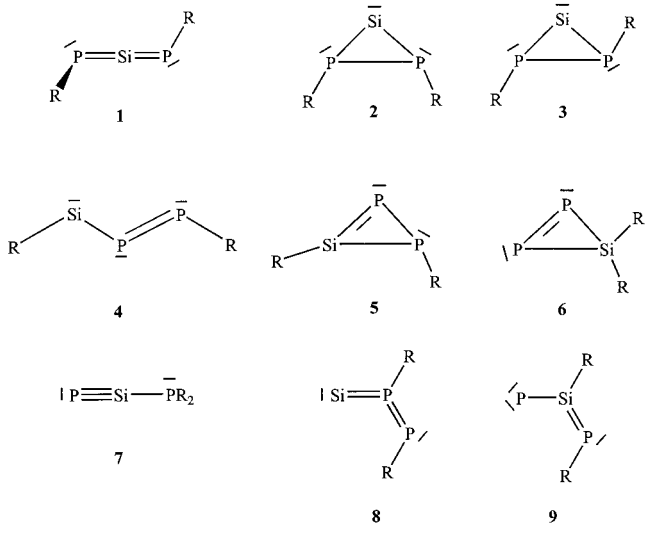
they are roughly 20 kcal mol$^{-1}$ higher in energy than the least stable of the other isomers. To explore the electronic influence of different substituents on the relative energies of these isomers, we investigated the hydrogen-substituted parent systems **1**–**7a**, the silyl derivatives **1**–**7b**, the methyl derivatives **1**–**7c**, the phenyl derivatives **1**–**7d**, and the fluorine-substituted derivatives **1**–**7e**. Since we were mainly interested in exploring the effect of the electronic properties of different substituents on the stability of the 1,3-diphospha-2-silaallene, we focused our attention only on its monomeric isomers. Nevertheless, it is obvious that in the case of insufficient steric protection dimers or oligomers of these isomers will be even lower in energy. Although it appears worthwhile to investigate this aspect, it exceeds the scope of this investigation, which is mainly aimed at the possibility of predicting the electronic influence of the substituents in order to realize the unsaturated isomers discussed herein synthetically.



Scheme 1. Idealized structures of isomers of 1,3-disphospha-2-silaallenes (R = H, $SiH_3$, $CH_3$, Ph, F).

The relative energies obtained for the differently substituted isomers **1**–**7** are summarized in Table 1. As is evident from these data, the 1,3-diphospha-2-silaallene is not the global minimum on the energy hypersurface. Nevertheless, the diphosphasilaallene structure is a local minimum for all these substituents.

For all substituents considered in our investigation (R = H, $SiH_3$, $CH_3$, Ph, F) the siladiphosphirene structure **6** is the most stable isomer. The relative stability of this isomer is most pronounced for the fluorine-substituted **6e** and lowest for the silyl-substituted **6b**. The geometric parameters of this isomer show a related trend (Table 2). As expected, the P=P bond in most examples of isomer **6** shows values typical for a double bond and the Si–P distance is typical for the corresponding single bond. Interestingly, these bonds show a counteracting trend for **6e** and **6b**. Thus, the P=P bond in **6b** (2.056 Å) is the shortest observed in this series while the corresponding Si–P bond is the longest (2.250 Å). The opposite is observed for the highly electronegative fluorine substituted **6e**, which shows the longest P=P bond in this series (2.124 Å) along with the shortest Si–P bond (2.160 Å). In fact for the fluorine derivative, both of these values are right in the middle between typical single and double bonds of these elements. Concomitant with this trend of the bond lengths, the angles associated with the substituents also show related effects. For fluorine as substituent the R–Si–R angle (ca. 105°) is the smallest in this series, while for silyl substituents this angle is the largest (ca. 118°).

Table 2. Geometrical parameters for the structural isomer **6**.

| | P–P [Å] | Si–P [Å] | P–P–Si [°] | R–S–P [°] | P–Si–P [°] | R–Si–R [°] |
|---|---|---|---|---|---|---|
| R = H (**6a**) | 2.069 | 2.220 | 62.28 | 119.19 | 55.58 | 113.09 |
| R = $SiH_3$ (**6b**) | 2.056 | 2.250 | 62.91 | 117.27 | 54.25 | 117.99 |
| R = $CH_3$ (**6c**) | 2.079 | 2.220 | 62.14 | 119.70 | 55.71 | 111.82 |
| R = Ph (**6d**) | 2.078 | 2.220 | 62.24 | 119.70 | 55.72 | 113.20 |
| R = F (**6e**) | 2.124 | 2.160 | 60.56 | 122.03 | 58.88 | 104.94 |

These findings can be rationalized based on the considerations that have been developed for phosphirenes. where the phosphirene ring is considered as the combination of a (hetero)carbene and a triple bond.[40,41] Similarly, the diphosphirene could be considered as the combination of a silylene and P≡P. The stronger the interaction of these fragments, the higher should be the P–Si bond order and hence the shorter this bond length. In contrast, the P–P bond order should be reduced by increasing interaction of $P_2$ with the silylene fragment and the P–P bond length should therefore increase. Consequently, the main effect of the substituents in **6** would be to affect the electronic nature of the silylene fragment and hence the extent of its interaction with the $P_2$ fragment. It is well known that fluoro-substituted silylenes possess a singlet ground state that is more favorable to interact with a $P_2$ unit, while the triplet ground state is stabilized by silyl substituents. The strong interaction between these fragments in **6e** should also be increased

Table 1. Relative energies [kcal mol$^{-1}$] for isomers **1**–**7** including ZPE and thermal energy correction for 298.2 K computed at the B3LYP//6-311g(d) level. TS = one imaginary frequency.

by additional negative hyperconjugation,[42,43] where σ*(Si-F) states act as acceptors towards bonding π(P≡P) states.

Apart from the most stable siladiphosphirene **6**, the nature of the next stable isomer depends significantly on the properties of the adjacent substituent. For the hydrogen- and silyl-substituted species the cyclic diphosphasilylene structure **3** carrying the substituents in a *trans* orientation is the second most stable isomer. Structure **3** is around 8 kcal mol$^{-1}$ more stable than the 1,3-disphospha-2-silaallene structure **1**. For all substituents the *cis* isomer **2a**–**e** is only around 1–4 kcal mol$^{-1}$ less stable than the *trans* isomers **3a**–**e**, thus indicating only a minor repulsive interaction between the substituents. On changing the substituents to methyl or phenyl a somewhat different picture is obtained. In these cases the phosphasilene structure **5**, to which some partial silyl cation character might be attributed, is the second most stable isomer rather than the diphosphasilylene structure **3**. The energy difference between these two isomers is not large (1–4 kcal mol$^{-1}$), however.

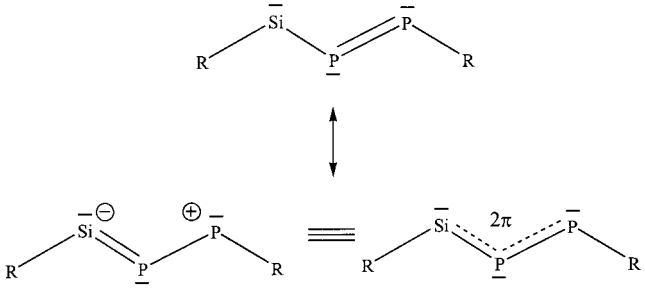
The relative stability of isomers **3** and **5** can be rationalized by taking the charge distribution within the PPSi system into account. On the grounds of Mulliken charges calculated for the phosphorus and silicon atoms within isomers **3** and **5** it is obvious that for hydrogen- and silyl-substituted derivatives the charge distribution differs substantially from the carbon- and fluorine-substituted derivatives. Of the isomers under question those with the more negative (less positive) charge at the more electronegative phosphorus atoms represents the energetically more favored structure (Table 3). Consequently for R = $CH_3$, Ph, and F the phosphasilene isomer **5** is more stable, while the cyclic *trans* isomer **3** is favored for R = H and $SiH_3$.

Table 3. Sums of Mulliken charges for the P and Si atoms in isomers **3** and **5**.

| | Phosphasilene **5** | | *trans* Ring **3** | |
|---|---|---|---|---|
| R = H (**a**) | q(Si) | 0.207 | q(Si) | 0.238 |
| | Σq(PP) | –0.271 | Σq(PP) | –0.348 |
| R = $SiH_3$ (**b**) | q(Si) | 0.126 | q(Si) | 0.200 |
| | Σq(PP) | –0.337 | Σq(PP) | –0.350 |
| R = $CH_3$ (**c**) | q(Si) | 0.459 | q(Si) | 0.220 |
| | Σq(PP) | –0.113 | Σq(PP) | 0.042 |
| R = Ph (**d**) | q(Si) | 0.435 | q(Si) | 0.127 |
| | Σq(PP) | –0.099 | Σq(PP) | 0.197 |
| R = F (**e**) | q(Si) | 0.567 | q(Si) | 0.221 |
| | Σq(PP) | 0.191 | Σq(PP) | 0.514 |

For fluorine as substituent the second most stable isomer is the ring-opened structure **4**. The latter is about 2 kcal mol$^{-1}$ more stable than the cyclic phosphasilene **5e** and about 33 kcal mol$^{-1}$ more stable than the *trans* oriented cyclic structure **3e**. Apart from the global minimum **6e**, structures **4e** and **5e** are the only isomers with direct Si–F bonds, therefore their relative stability is likely to be a consequence of the strength of the silicon–fluorine bond. In contrast, structure **4** is about 10–50 kcal mol$^{-1}$ higher in energy than the second most stable isomer for most other substituents (R = H, $CH_3$, $SiH_3$). In fact, structure **4a**–**c** is the least stable isomer for these substituents and even a transition state for R = $CH_3$ which transforms into **5c** and connects the two enantiomeric forms of **5** as we found based on IRC calculations. Interestingly, the phenyl substituent has a somewhat intermediate position and **4d** is only 10 kcal mol$^{-1}$ less stable than **5d**. This indicates that the π-donor properties of fluorine and phenyl stabilize structure **4**.

For structure **4** a delocalized bond situation can be expected. Formally, this could be described as a silylene-substituted diphosphene. However, it is obvious that other resonance forms have to be considered. This isomer is probably best described as a 2π-SiPP allylic system where significant interaction of the substituents with the central unit can be neglected (Scheme 2). However, such a description requires a planar or nearly planar arrangement of the SiPP unit and the adjacent substituents. According to our findings (Table 4), such a situation is realized only in the methyl- and fluoro-substituted derivatives **4c**,**e** and to a lesser extent for phenyl-substituted **4d**. In contrast, the substituents adjacent to the SiPP unit in the hydrogen- and silyl-substituted derivatives **4a**,**b** deviate by almost 90° from the planar geometry. Nevertheless, the geometric parameters in **4b**,**c** show almost equally long Si–P and P–P bond lengths, which differ by 0.08–0.09 Å. The Si–P distances in **4b**,**c** (2.02 and 2.11 Å, respectively) are in a range for P–Si bond lengths that is significantly shorter than a P–Si single bond (2.25 Å).[3,5] In contrast to the σ-acceptor, π-donor substituents fluorine and phenyl, this P–Si bond length increases substantially to 2.31 and 2.35 Å, which is in the range for a single bond. Hydrogen-substituted **4a** shows an intermediate situation, with an Si–P bond length of 2.22 Å. The central Si–P–P angle follows a similar trend (86–90°) and is markedly smaller for fluorine- and phenyl-substituted derivatives **4d**,**e** than for the other substituents (**4a**–**c**: 117–144°).



Scheme 2. Mesomeric Lewis structures of **4**.

The trends observed for the structures of isomers **4a**–**e** (Table 4) can be interpreted as a dominant contribution of the silylene-substituted diphosphene resonance structure. Interaction of π-donor substituents such as phenyl and fluorine can stabilize the adjacent silylene center to an extent that makes this isomer more stable than the cyclic isomer **3**, as in the case of fluorine. Given a nearly planar arrangement, such a stabilized silylene center (as in **4d**,**e**) shows only a low tendency to interact with the neighboring diphosphene unit. For less stabilized and therefore more electrophilic silylene centers such as in **4c**, interaction with the adjacent diphosphene unit is much stronger. In nonplanar

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

arrangements such as found for **4a**,**b**, an effective Si–P–π interaction is precluded by the geometric situation, which tends to lead to an isolated (i.e. short) P=P bond along with a rather long Si–P bond.

Table 4. Geometric parameters for the structural isomer **4**.

| | Si–P–P [°] | Si–P [Å] | P–P [Å] | R–Si–P [°] | P–P–R [°] | RSi···PR [°] |
|---|---|---|---|---|---|---|
| R = H (**4a**) | 116.93 | 2.220 | 2.040 | 91.27 | 94.87 | 84.80 |
| R = $SiH_3$ (**4b**) | 143.48 | 2.110 | 2.030 | 91.66 | 97.72 | 88.94 |
| R = $CH_3$ (**4c**) | 129.75 | 2.020 | 2.110 | 144.22 | 96.40 | 0.00 |
| R = Ph (**4d**) | 90.00 | 2.310 | 2.060 | 100.41 | 89.99 | 10.06 |
| R = F (**4e**) | 86.13 | 2.350 | 2.020 | 96.05 | 105.33 | 0.00 |

Isomer **3** can be described as a cyclic diphosphasilylene in which the silylene center can interact with the adjacent phosphorus atoms. The structure of this isomer is almost invariant to the adjacent substituents with respect to the central ring (Table 5). Only for R = F it is not a minimum structure and ring opens to **1**. Generally, the Si–P bond length is about 2.28–2.29 Å, in the typical single bond range for these elements. The P–P bond length varies slightly more and is shortest in fluorine-substituted **3e** (2.12 Å); it is between 2.22 and 2.28 Å for the other substituents. The central P–Si–P angle varies only slightly (55–60°) and is close to experimental values in diphosphasiliranes.[44] Similarly, the P–P–Si angle of the three-membered ring shows values in a narrow range between 60–63°. In contrast to the central ring unit, more significant differences are observed for the angles involving the adjacent substituents, i.e. the R–P–Si and the dihedral angle R–P–P–R. For R–P–Si the angle increases with the π-donor character of R. In contrast, the dihedral angle R–P–P–R decreases in the same direction (Table 5).

Table 5. Geometric parameters for the structural isomer **3**.

| | P–Si–P [°] | Si–P [Å] | P–P–Si [°] | R–P–Si [°] | P–P [Å] | R–P–P–R [°] |
|---|---|---|---|---|---|---|
| R = H (**3a**) | 58.85 | 2.290 | 60.57 | 92.79 | 2.259 | 178.26 |
| R = $SiH_3$ (**3b**) | 59.81 | 2.280 | 60.09 | 87.88 | 2.283 | 170.54 |
| R = $CH_3$ (**3c**) | 58.11 | 2.280 | 60.76 | 110.27 | 2.222 | 155.72 |
| R = Ph (**3d**) | 59.11 | 2.260 | 59.25 | 91.05 | 2.266 | 158.22 |
| R = F (**3e**) | 55.05 | 2.290 | 62.47 | 121.05 | 2.123 | 126.79 |

The structural parameters for the 1,3-disphospha-2-silaallenes **1a**–**e** also show some interesting trends depending on the nature of the adjacent substituents (Table 6). The deviation from linearity of the central P=Si=P unit [P–Si–P angle of 135° (**1e**) and 155° (**1d**)] is strongest for the π-donating substituents fluorine and phenyl. Concomitant with this bending is an increase of the P–Si bond length to 2.12 (**1e**) and 2.09 Å (**1d**). The corresponding hydrogen- and silyl-substituted analogues (**1a**,**b** 169–171°) are closer to linearity and the P–Si bond (2.06 Å) is shorter than for the phenyl- and fluorine-substituted derivatives (**1e**,**d**).

Table 6. Geometric parameters for the structural isomer **1**.

| | P–Si–P [°] | Si–P [Å] | R–P–Si [°] | RP···PR [°] |
|---|---|---|---|---|
| R = H (**1a**) | 168.87 | 2.060 | 89.83 | 88.69 |
| R = $SiH_3$ (**1b**) | 171.36 | 2.060 | 93.50 | 89.14 |
| R = $CH_3$ (**1c**) | 161.98 | 2.080 | 102.89 | 90.58 |
| R = Ph (**1d**) | 155.38 | 2.090 | 102.17 | 94.16 |
| R = F (**1e**) | 135.46 | 2.120 | 104.40 | 99.34 |

Among all isomers of 1,3-disphospha-2-silaallene the cyclic phosphasilene **5** shows the least impact of the electronic properties of the substituents on its structural parameters (Table 7). Thus, in **5a**–**e** the formal double bond between the silicon atom and phosphorus atom without any exocyclic substituent shows values in the range of 2.04–2.06 Å. The formal single bond from silicon to the other phosphorus atom is characteristically longer, with values between 2.17 and 2.23 Å that are in agreement with a description as a short single bond. The P–P distances (2.38–2.41 Å) are rather long, and the angles are in a narrow range for all substituents that we investigated. Thus, the P–Si–P angles in **5a**–**e** vary only from 68° to 69° and similarly the P(R)–P–Si angles are all within the range of 58° to 59°.

Table 7. Geometric parameters for the structural isomer **5**.

| | Si–P [Å] | Si–P(R) [Å] | P–P [Å] | P–Si–P [°] | P(R)–P–Si [°] | R–Si–P–R [°] |
|---|---|---|---|---|---|---|
| R = H (**5a**) | 2.046 | 2.210 | 2.410 | 68.91 | 58.79 | 87.74 |
| R = $SiH_3$ (**5b**) | 2.059 | 2.230 | 2.390 | 67.88 | 59.43 | 85.76 |
| R = $CH_3$ (**5c**) | 2.051 | 2.200 | 2.390 | 68.38 | 58.86 | 84.57 |
| R = Ph (**5d**) | 2.057 | 2.200 | 2.380 | 67.95 | 58.94 | 77.88 |
| R = F (**5e**) | 2.040 | 2.170 | 2.380 | 69.02 | 58.06 | 78.60 |

The cyclic isomers of 1,3-diphospha-2-silaallene (**2**, **3**, **5**, and **6**) are generally not as structurally flexible as the ring-opened isomers **1** and **4**. One might be tempted to interpret this rigidity as an indication of a limited or even negligible interaction between the substituents and the cyclic $P_2Si$ unit. However, the presence and significance of such an interaction is evident from the prominent influence of different substituents on the relative stabilities of these isomers, including the cyclic ones.

Finally, the last isomer investigated by us is the phosphanyl-substituted phosphasilyne **7** (Table 8). Since the substituents in this isomer are not bonded directly to a low-valent main group atom, structural differences based on their conjugative properties are not likely to be pronounced. Accordingly, the formal triple bond shows a constant P–Si distance of roughly 1.97 Å for all substituents. The adjacent Si–P single bond (2.23 Å) is shortest for silyl-substituted **7a** and longest for fluorine-substituted **7e** (2.35 Å). The angles around the tricoordinate phosphorus atom are smallest for the hydrogen-substituted compound and largest for its phenyl-substituted congener, which suggests steric reasons for this observation.

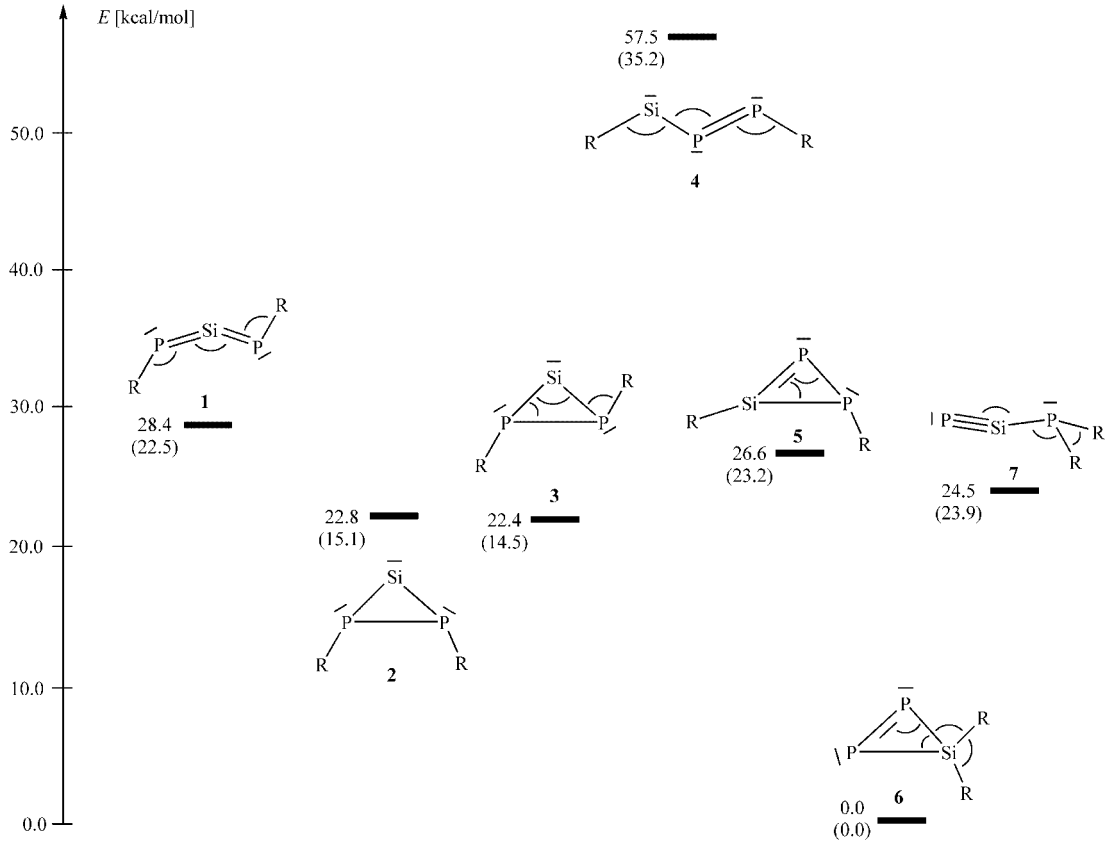
| R = F (**7e**) | 1.976 | 2.350 | 154.16 | 98.81 | 98.56 | 129.99 |

In order to check the reliability of the B3LYP method and the basis set of our choice for the structurally rather flexible compounds investigated here we tested the structure and energy calculations for the hydrogen-substituted parent systems of all isomers by reoptimization using the MP2 method. Table 9 and Scheme 3 summarize the results obtained for isomers **1**–**7a** with the 6-311g(d) and 6-311g(d,p) basis sets using the DFT and MP2 approach to include electron correlation. As is evident from these data, the differences with respect to correlation method and basis set are only marginal and the same trend in the relative energies of isomers **1**–**7a** is observed in all cases, which indicates that the DFT approach is well suited to exploring the energy hypersurface of this type of compounds. A minor issue is observed for isomer **4**, which is the least stable isomer for all methods. Interestingly, structure **4** is identified as a minimum when employing the B3LYP functional while two negative vibrations at low frequency are found at the MP2 level. Bearing in mind that DFT methods are known to sometimes incorrectly predict minima on a very flat energy hypersurface and for spin contaminated states,[45] it might be possible that this isomer could in fact be a transition state in other cases as well. Actually, methyl-substituted **4c** is a TS even at the DFT level and this isomer is generally the least stable one, except for **4d**,**e**. Therefore, for the fluorine-substituted system, where structure **4e** is quite relevant due to its high relative stability, the minimum was confirmed also at the MP2 level.

Table 9. Relative energies [kcal mol$^{-1}$] for isomers **1**–**7a** (R = H) including ZPE and thermal energy correction for 298.2 K at different levels of theory.

| | **1** | **2** | **3** | **4** | **5** | **6** | **7** |
|---|---|---|---|---|---|---|---|
| B3LYP//6-311g(d) | 24.5 | 16.7 | 16.1 | 36.1 | 24.1 | 0.0 | 25.1 |
| B3LYP//6-311g(d,p) | 22.5 | 15.1 | 14.5 | 35.2 | 23.2 | 0.0 | 23.9 |
| MP2//6-311g(d) | 32.3 | 26.1 | 25.9 | 59.2 | 28.0 | 0.0 | 26.2 |
| MP2//6-311g(d,p) | 28.4 | 22.8 | 22.4 | 57.5 | 26.6 | 0.0 | 24.5 |

A limitation of our study that should be relevant for the synthetic realization of such systems is the fact that we focused strictly on the electronic properties of the adjacent substituents and did not consider steric effects and the bulk of the substituents. Nevertheless, it is obvious that sterically very demanding substituents will destabilize structures in which both substituents are connected to the same atom, as



Scheme 3. Overview of relative energies [kcal mol$^{-1}$] for isomers **1**–**7a** (R = H) at the MP2 level (B3LYP in brackets) using a 6-311g(d,p) basis set including ZPE and thermal energy correction for 298.2 K.

in **7** or the global minimum **6**, whereas the other isomers should benefit from such an influence.

In summary, our exploration of the relative stabilities of 1,3-diphospha-2-silaallenes and their isomers shows that the goal to prepare a stable 1,3-diphospha-2-silaallene will be a hard one to achieve as the siladiphosphirene isomer is significantly more stable for all substituents considered in this study. The stability of the diphosphasilaallene relative to other isomers depends strongly on the nature of the adjacent substituents. Thus, for simple carbon and silyl substituents alternative ring-closed isomers are favored over the diphosphasilaallene, which, depending on the substituent, can show silylene or phosphasilene character. Given sufficient steric protection, the latter species themselves will surely be challenging synthetic goals to pursue.

## Computational Details

Quantum chemical calculations were carried out using the Gaussian 03 suite of programs.[33] In related work studying the effect of basis sets and electron correlation on several double-bonded silicon species using different basis sets and several correlation methods, it was found that the geometry is not sensitive to the basis set and good results are expected with standard density functional theory methods.[30,46,47]

The optimized geometry was confirmed as a minimum on the potential surface by second-derivative calculations. All the calculated energy data were corrected with the zero-point energy (ZPE) and the thermal energy correction to 298 K ($E = E_0 + E_{vib} + E_{rot} + E_{transl}$).

**Supporting Information** (see also the footnote on the first page of this article): Complete data of harmonic vibrational frequencies, optimized geometries, total energies ($E$, in hartrees), and number of imaginary vibrational frequencies are provided for all isomers.

# Synthesis and Some Properties of Bis(ruthenocenyl)thiophene Derivatives – Possible Spin-Coupling in the Two-Electron Oxidized Species of Dinuclear Ruthenocenes Bridged by Thiophene Derivatives

**Masaru Sato,*[a] Yusuke Kubota,[a] Atsushi Tanemura,[a] Genta Maruyama,[a] Takashi Fujihara,[a] Juzo Nakayama,[a] Toshiyuki Takayanagi,[a] Kenta Takahashi,[a] and Kei Unoura[b]**

**Keywords:** Metallocenes / Redox chemistry / Cations / Sulfur heterocycles / Oxidation / Metal–metal interactions

The binuclear ruthenocene derivatives bridged by thiophene, 3,4-ethylenedioxythiophene, 2,2′-bithiophene, thieno[3,2-*b*]thiophene, or 3,6-dimethylthieno[3,2-*b*]thiophene were prepared by the Suzuki coupling of 2-ruthenocenyl-4,5-tetramethyl-1,3-dioxaborolane with the corresponding diiodo compounds. In addition, thiophene- and bithiophene-bridged binuclear pentamethylruthenocenes were prepared by the reaction of bis(pentamethylruthenocenyl)diyne and -tetrayne with NaSH, respectively. The cyclic voltammograms of these complexes exhibit one-step two-electron redox waves in the lower potential region (0–0.3 V versus $FcH/FcH^+$). The two-electron oxidized species of the thiophene-bridged binuclear ruthenocene derivatives are comparatively stable and adopt the spin-coupled and structurally isomerized fulvene complex-type structure. The solid structure of the oxidized species of bis(pentamethylruthenocenyl)thiophene was determined by X-ray diffraction analysis. The thieno[3,2-*b*]thiophene-bridged analog shows a temperature-dependent $^1H$ NMR spectrum in $CD_3NO_2$. The dicationic species exist as a $Ru^{II}$–$Ru^{IV}$ mixed-valence species in $CD_3CN$.

## Introduction

Significant interest has been focused on carbon-rich organometallics that contain rigid, π-conjugated chains or aromatics because organometallic assemblies are important for electron-transfer processes,[1] the formation of liquid crystalline materials,[2] and the construction of molecular devices.[3] In particular, numerous investigations have been concentrated on polyynediyl complexes, $[L_nM–(C\equiv C)_m–ML_n]$ ($m$ = 1,2, etc.),[4] because they are attractive candidates for use in the preparation of molecular wires and nanoscale electronic devices; this comes by virtue of their possible charge delocalization along the entire conjugated backbone.[5] Ferrocenyl derivatives also present themselves as fascinating candidates for use in the design of such materials because of a stable one-electron redox system (i.e. stability in both the neutral and oxidized forms).[6] Enormous effort has been expended in the synthesis of dinuclear ferrocene derivatives with π-conjugation.[7] In addition, much attention is currently focused on materials that are based on oligothiophenes and polythiophenes because of their remarkable electronic and optoelectronic properties.[8,9] Therefore, the incorporation of these compounds between two ferrocenyl sites may be expected to promote or inhibit electron delocalization in these types of conjugated systems.[10] Only a few studies have been published with regard to ruthenocene derivatives bridged by π-conjugated chains probably because of the irreversible redox behavior of ruthenocene itself. For example, biruthenocene undergoes one-step two-electron oxidation to afford the dicationic complex that possesses a uniquely coordinated fulvalene as a result of structural isomerization caused by spin-coupling.[11] Bis(ruthenocenyl)oligoenes are oxidized reversibly by the one-step two-electron redox process to afford stable dicationic bis(fulvene)-type complexes.[12] The spin coupling that leads to this structural isomerization is maintained despite the length of the conjugation, at least up to the tetraene derivatives. Bis(ruthenocenyl)ethynes also afford the novel dicationic $\mu_2$-bis(cyclopentadienylidene)ethene diruthenium complexes upon two-electron oxidation.[13] In contrast with the case of the two-electron oxidized species of the oligoene derivatives, the stability of the two-electron oxidized species in the oligoyne derivatives declines with increasing length of the conjugation. In cyclic voltammograms, these dinuclear ruthenocene derivatives show two-electron oxidation waves in the low-potential region, which suggests the formation of a stable, two-electron oxidized

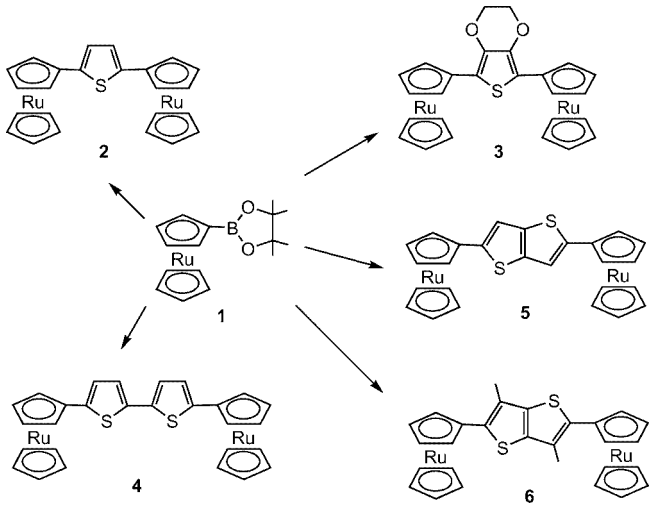
species. However, the bis(ruthenocenyl) derivatives that are bridged by benzenoid aromatics show only a small or no two-electron oxidation wave in their cyclic voltammograms.[14] The published reports on the ferrocenes and transition-metal complexes bridged by thiophene derivatives[9,10] have stimulated us to investigate complexes that incorporate thiophene derivatives between two ruthenocenyl sites because thiophenes have an enhanced olefinic character and have less aromaticity compared with those of benzenoid compounds. In this report, we describe the synthesis and some properties of bis(ruthenocenyl)thiophene derivatives. Recently, a bis(ruthenocenyl)thiophene derivative has been reported to show an interesting redox behavior.[15]



Scheme 1.

## Results and Discussion

### Preparation of Bis(ruthenocenyl)thiophene Derivatives

It has been reported that the Suzuki coupling reaction of 2-ruthenocenyl-4,5-tetramethyl-1,3-dioxaborolane (**1**) with the appropriate halide is a useful method for the preparation of binuclear ruthenocene derivatives bridged by an aromatic compound.[14] Complex **1** was heated with 2,5-diiodothiophene in the presence of (dppf)$PdCl_2$ and 3 M aqueous NaOH in DME in a sealed tube to afford 2,5-bis(ruthenocenyl)thiophene (**2**) in 23% yield. In a similar manner, the reaction of **1** with 3,4-ethylenedioxy-2,5-diiodothiophene, 5,5′-diiodo-2,2′-bithiophene, 2,5-diiodothieno[3,2-*b*]thiophene, or 2,5-diiodo-3,6-dimethylthieno[3,2-*b*]thiophene also proceeded successfully under the similar conditions to afford the corresponding binuclear ruthenocene derivatives **3**, **4**, **5**, or **6** with yields of 33%, 23%, 18%, or 25%, respectively (Scheme 1). Complex **2** was also prepared by the reaction of 1,4-bis(ruthenocenyl)buta-1,3-diyne with NaSH in DMF in an 87% yield. Complexes **2**, **4**, and **5** were scarcely soluble in common organic solvents. Assignment of their structures was carried out on the basis of the corresponding spectroscopic data. For example, the $^1$H NMR spectrum of **4** shows the η-$C_5H_4$-ring protons at $\delta$ = 4.63 and 4.98 ppm as triplets ($J$ = 1.8 Hz), the η-$C_5H_5$-ring protons at $\delta$ = 4.53 ppm as a singlet, and the ring protons of bithiophene at $\delta$ = 6.82 and 6.86 ppm as doublets ($J$ = 3.8 Hz). The $^{13}$C NMR spectrum of **4** supports the structure assigned by the $^1$H NMR spectrum. The structure of **3** was confirmed by single-crystal X-ray diffraction. The crystallographic data are listed in Table 5, and selected bond lengths and angles are listed in Table 1. The ORTEP view of **3** is shown in Figure 1. The two η-$C_5H_4$-ring planes of the ruthenocenyl (abbreviated as Rc hereafter) parts are tilted by 18.89(4)° and 24.83(4)° toward the central thiophene-ring plane probably because of the steric hindrance that is due to the dioxolane ring fused to the thiophene ring. The two η-$C_5H_5$Ru moieties of the Rc parts are positioned on opposite sides of the central thiophene ring. Other bond lengths and angles are the same as those of the ruthenocene and thiophene derivatives.

1,4-Bis(1′′,2′′,3′′,4′′,5′′-pentamethylruthenocenyl)buta-1,3-diyne was allowed to react with NaSH in DMF heated at 100 °C under an argon atmosphere to afford 2,5-bis(1′′,2′′,3′′,4′′,5′′-pentamethylruthenocenyl)thiophene (**7**) in 92% yield. The similar reaction of 1,8-bis-(1′′,2′′,3′′,4′′,5′′-pentamethylruthenocenyl)-1,3,5,7-octatetrayne afforded 5,5′-bis(1′′,2′′,3′′,4′′,5′′-pentamethylruthenocenyl)-2,2′-bithiophene (**8**) in 64% yield (Scheme 2). The structures of these compounds were assigned on the basis of the corresponding $^1$H- and $^{13}$C NMR spectroscopic data. The structure of **7** was also confirmed by X-ray diffraction analysis. The crystallographic data are listed in Table 5, and selected bond lengths and angles are shown in Table 2. The ORTEP view of **7** is shown in Figure 2. The thiophene ring is almost coplanar with the plane of the η-$C_5H_4$-rings of the two 1′,2′,3′,4′,5′-pentamethylruthenocenyl (abbreviated as Rc* hereafter) groups; the twisted angles are 3.60(5)° and 2.36(5)°. The two η-$C_5Me_5$Ru moieties of the Rc* parts adopt the *trans* orientation with respect to the linker ligand. Other bond lengths and angles are the same as the corresponding parameters for the ruthenocene and thiophene derivatives.

## Redox Behavior

The cyclic voltammograms of **2**–**8** were measured in a solution of 0.1 M $n$Bu$_4$NBF$_4$ in $CH_2Cl_2$ with the use of a glassy carbon electrode and a sweep rate of 0.1 V s$^{-1}$ (Figure 3). The electrochemical data are summarized in Table 3. As seen in Figure 3, the cyclic voltammograms are much more complex than those of bis(ruthenocenyl)ethenes that were previously reported to contain a pair of oxidation and reduction waves in a similar region.[12] However, the cyclic voltammograms exhibit a definite oxidation wave near 0.3 V, along with a similar wave near 0.5 V in the Rc series **2**–**6**. The magnitude of the former oxidation wave is almost equal to that of the latter, probably because the electron-rich thiophene bridge promotes the one-step two-electron redox process. This observation differs greatly from the finding that similar dinuclear ruthenocene derivatives bridged by aromatics only show a small or no oxidation wave near 0.3 V.[14] In these complexes, the peak current parameter $I_{pa}$ at about 0.3 V is about 2500 μAV$^{-1/2}$s$^{1/2}$ cm$^{-2}$mM$^{-1}$, with the exception of **4**, and the $n_{app}$ value in the thin-layer coulometry[16] is approximately 2; this suggests that the first oxidation wave near 0.3 V can be assigned to the two-electron oxidation process that corresponds to the Ru$^{II}$–Ru$^{III}$ couple at the two ruthenocenyl sites. The large peak current parameter for the first oxidation peak of **4** appears to be due to an overlap of the first oxidation peak with part of an adjacent, second oxidation peak. Although the redox behavior of the second wave of each complex is relatively complex, the second wave near 0.5 V may be assigned to Ru$^{III}$–Ru$^{IV}$ oxidation. Moreover, if the backwards scan is analyzed at the end of the first wave near 0.3 V, the $I_{pa}$ of this oxidation wave is almost identical to the $I_{pc}$ of the reduction wave near 0.2 V. Surprisingly, in **7** and **8** one oxidation wave and one reduction wave appear near 0.0 V with equal magnitudes, although small additional peaks are also observed. The methyl-substituted ruthenocene ring seems to assist the one-step two-electron redox process. In particular, the oxidation potential of **7** is in the low potential region, which is similar to those of bis(ruthenocenyl)-ethenes (which are comparable to that of ferrocene!).[12] These observations suggest that the redox waves observed at <0.25 V correspond to a one-step two-electron process and that the two-electron oxidized species of complexes **2**–**8** are stable.

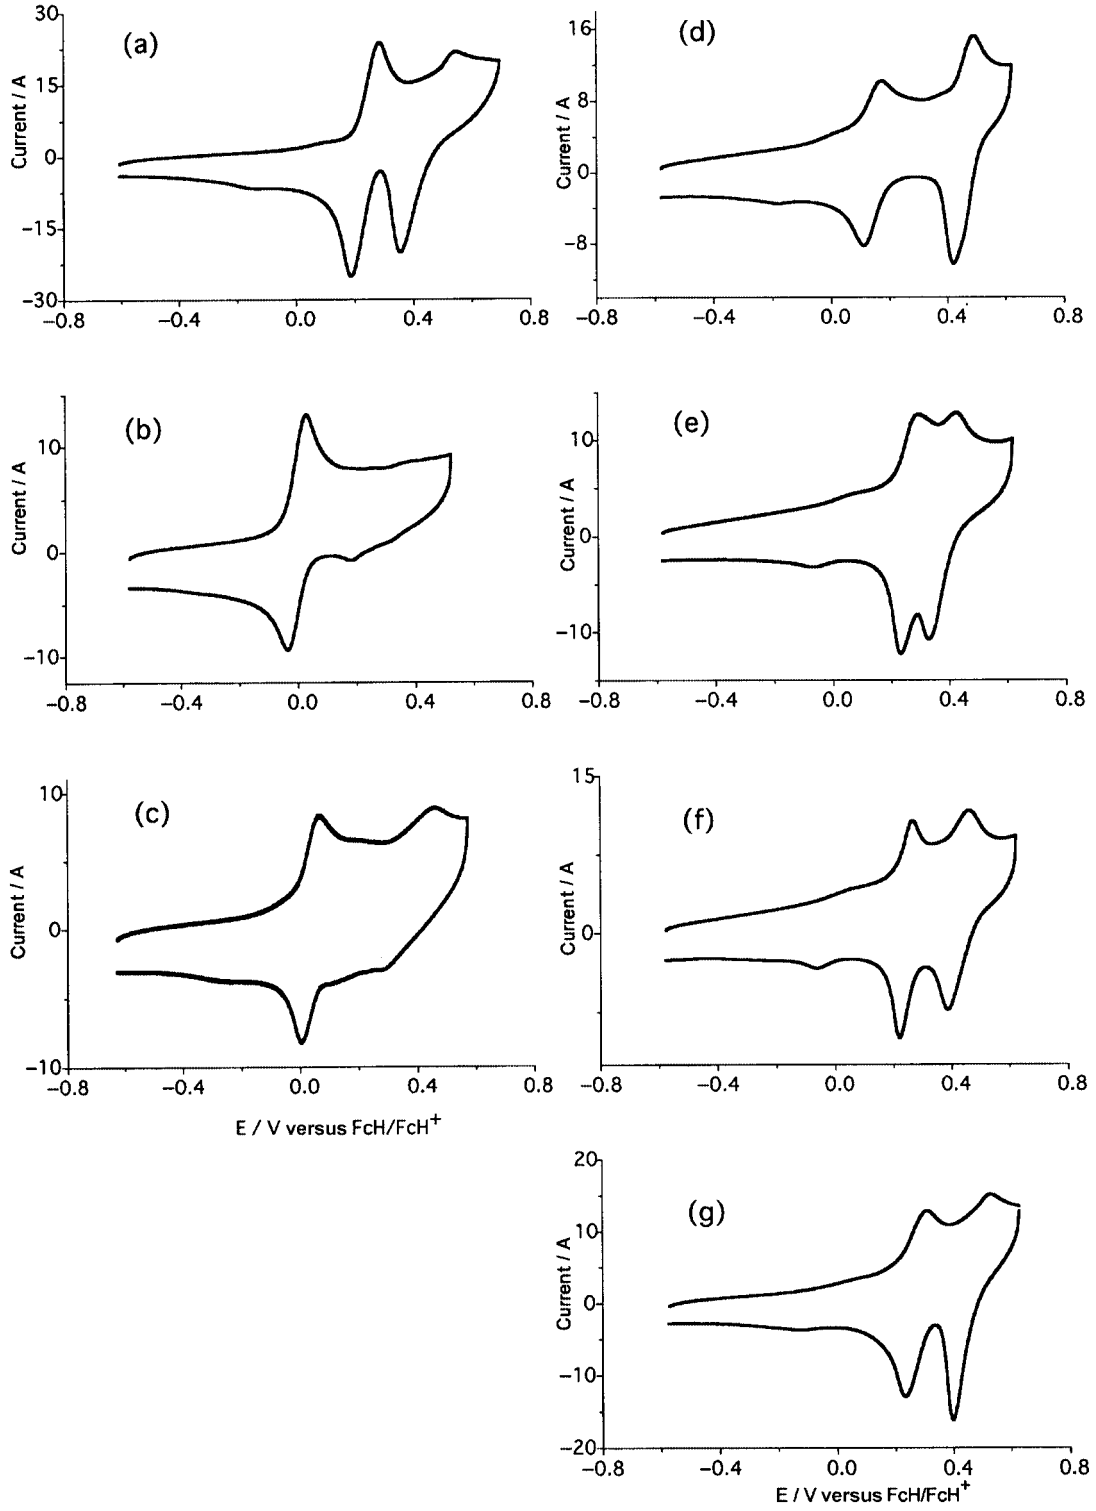

Figure 3. Cyclic voltammograms of **2**–**8**: (a) complex **2**, (b) complex **7**, (c) complex **8**, (d) complex **3**, (e) complex **4**, (f) complex **5**, (g) complex **6**.

It is noteworthy that the oxidation potentials observed for the present complexes show no change or increased only slightly with increases in conjugation of the linker: **2** (+0.281 V) ≈ **5** (+0.265 V) ≈ **4** (+0.276 V), and **7** (+0.028 V) < **8** (+0.069 V). A similar but clearer trend is observed in the Rc*(C≡C)$_n$Rc* series.[13a] However, this tendency is different from that observed for the dinuclear ruthenocene derivatives bridged by oligoenes, the oxidation potentials of which are shifted to a lower potential region with an increase in the number of CH=CH units.[12a] The lower susceptibility of the oxidation potential to the length of conjugation in the present system seems to be related to

[a] Sweep rate = 0.1 $Vs^{-1}$. [b] $E_{1/2} = (E_{pa} + E_{pc})/2$. [c] $\Delta E = E_{pa} - E_{pc}$. [d] Peak current parameter: $U = \mu A V^{-1/2} s^{1/2} cm^{-2} mM^{-1}$. [e] The number of electrons ($n_{app}$) concerned with the first oxidation of the complexes with standard deviation given in parentheses is determined from the results of thin-layer coulometry. [f] The second oxidation is observed at the potential close to the first oxidation. [g] Solubility is too low to determine $n_{app}$.

the fact that the aromaticity of the thiophene ring works as cross-conjugation for the electronic interaction between two metal sites in the bis(ruthenocenyl)thiophene derivatives.

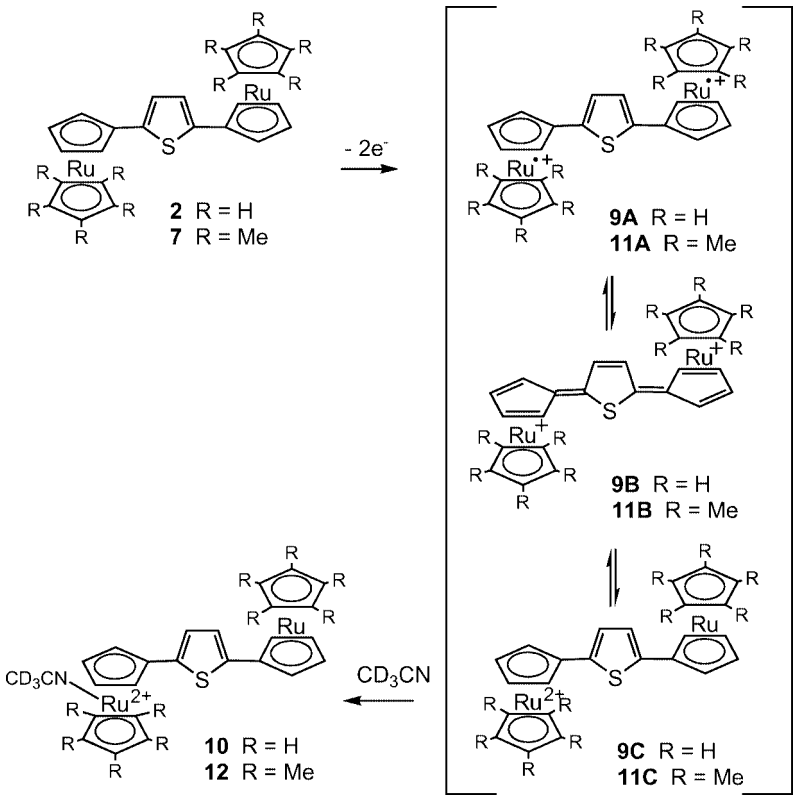
### Chemical Oxidation

A suspension of thiophene-bridged dinuclear ruthenocene **2** in $CHCl_3$ was oxidized with *p*-BQ/$BF_3$·$OEt_2$ (*p*-BQ = *p*-benzoquinone) at 0 °C to yield **9** as fine brown crystals. The deep red–brown solution of **9** in $CD_3NO_2$ was found to be stable at 0 °C. The $^1H$ NMR spectrum shows one singlet for the η-$C_5H_5$ ring protons at $\delta$ = 5.26 ppm, the four signals for the η-$C_5H_4$ ring protons at $\delta$ = 5.75, 5.90, 6.32, and 6.40 (2 H each) ppm, and one singlet for the thiophene ring protons at $\delta$ = 7.46 ppm, which suggest that the molecule has a mirror plane or a center of symmetry but that the α- and β-protons of the η-$C_5H_4$ ring are nonequivalent because of the lack of symmetry in the η-$C_5H_4$ ring. The η-$C_5H_5$ ring ($\Delta\delta$ = 1.61 ppm) and the thiophene ring protons ($\Delta\delta$ = 0.77 ppm) are shifted to a lower field compared with the corresponding signals of **2**, which indicates the accumulation of positive charges on the Rc moiety and the thiophene ring. This type of spectral pattern accords with the appearance of the fulvene complex-type structure (**9B** in Scheme 3), as seen for the oxidized species of bis(ruthenocenyl)ethene.[12] This hypothesis is supported by the $^{13}C$ NMR spectrum of **9** in which signals for the α- and β-η-$C_5H_4$ ring carbons are observed at $\delta$ = 77.42, 78.72, 90.33, and 90.66 ppm. This signal pattern is also observed for [(η-$C_5H_5$)Ru(μ$_2$-η$^6$:η$^6$-$C_5H_4CHCHC_5H_4$)Ru(η-$C_5H_5$)]-$(BF_4)_2$.[12]

Oxidation of **7** with *p*-BQ/$BF_3OEt_2$ in $CH_2Cl_2$ at 0 °C and subsequent dilution with benzene produced **11** as black powdery crystals that are stable when stored in the freezer. The $^1H$ NMR spectrum of the red–violet solution of **11** in $CD_3NO_2$ at –5 °C exhibits the η-$C_5H_4$ ring proton signals at $\delta$ = 5.53 (m, 4 H) and 5.90 (m, 4 H) ppm and the thiophene ring proton signals at $\delta$ = 7.41 ppm. This signal pattern is different from that observed for **9**, which implies that the α- and β-protons of the η-$C_5H_4$ ring are in a symmetrical environment. The signals for the η-$C_5H_4$ ($\Delta\delta$ = 1.30 and 1.33 ppm) and thiophene ring ($\Delta\delta$ = 0.75 ppm) protons in **12** show a lower-field shift similar to those seen for **9**. Therefore, the spectral pattern indicates the presence of species **11A** shown in Scheme 3, in which the two spins of the molecule are coupled to each other, but they do not lead to structural isomerization. However, the $^{13}C$ NMR spectrum of **11** in $CD_3NO_2$ shows four η-$C_5H_4$ ring carbon signals at $\delta$ = 75.85, 77.10, 93.81, and 93.99 ppm. This signal pattern is similar to that seen for **9**, which indicates the presence of a fulvene complex-type structure (**11B**) for the dicationic species. The appearance of two signals for the η-$C_5H_4$ ring protons in the $^1H$ NMR spectrum of **11** in $CD_3NO_2$ may be due to an accidental superimposition because the signals are observed as a quintet and a sextet rather than two triplets, if they are examined in detail. Furthermore, in $CD_2Cl_2$ or $(CD_3)_2CO$ three signals are observed for the η-$C_5H_4$ ring protons.

The NMR spectra of **9** and **11** in $CD_3CN$ show quite different patterns from those in $CD_3NO_2$, and two sets of the signals for the Rc part and the thiophene ring are observed. For example, the set of signals for the Rc ring protons [$\delta$ = 4.57 (s, 5 H), 5.02 (t, 2 H), and 5.36 (t, 2 H) ppm] is similar to that of the neutral ruthenocenyl group, and the other set of signals [$\delta$ = 5.90 (s, 5 H), 6.01 (t, 2 H), 6.27 (t, 2 H) ppm] resembles that of the ruthenocenium cation. The protons of the thiophene ring appear at $\delta$ = 7.40 and 8.05 ppm as doublets ($J$ = 4.5 Hz). The spectral pattern indicates that **9** reacts with $CD_3CN$, passes through intermediate **9C**, to generate $Ru^{II}$–$Ru^{IV}$ mixed-valence complex **10**. Similarly, the $^1H$ NMR spectrum of **11** in $CD_3CN$ shows the presence of mixed-valence complex **12**. This type of conversion has been reported for the dissolution of the two-electron oxidized species of biruthenocene in $CD_3CN$,[11] but has not been observed for the oxidized species of the dinuclear ruthenocenes bridged by oligoenes and oligoynes in $CD_3CN$.[12,13] This difference may be due to the level of stability of the fulvene complex-type structure. It is considered that the two-electron oxidized species of bis(ruthenocenyl)oligoenes are sufficiently stabilized by the fulvene complex-type structure, whereas the fulvene complex-type structure in **9** or **11** is not very stable in solution because of lower spin coupling. These results also suggest that the replacement of the Rc group with the Rc* group exerts little influence on the structures of the two-electron oxidized species of the thiophene-bridged binuclear derivatives.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3.

The oxidation of **7** with ferricenium tetra[3,5-bis(trifluoromethyl)phenyl]borate in $CH_2Cl_2$ yielded stable oxidized species **13** as dark violet fine needles. The $^1H$ NMR spectrum of **13** in $CD_3NO_2$ exhibits two $C_5H_4$-ring protons at $\delta$ = 5.52 (m, 4 H) and $\delta$ = 5.90 (m, 4 H) ppm and shows no change when **13** is cooled to –30 °C ($CH_3NO_2$, m.p. –29 °C). This spectral pattern is similar to that observed for **11**, which suggests that the counter anion has no influence on the degree of structural isomerization. Complex **13** was recrystallized from $CH_2Cl_2$/diethyl ether in diffusion mode to produce black–violet cubes, which were suitable for X-ray diffraction analysis. The crystallographic data for **13** are listed in Table 5, and selected bond lengths and angles are shown in Table 4. The ORTEP view for the cationic part of **13** is shown in Figure 4. The cationic molecule of **13** is located at an inversion center. Two molecules of diethyl ether are involved in the crystal. As seen in Figure 4, a disorder exists in the central thiophene ring of **13**. It is clear that the Rc* part of **13** adopts a fulvene complex-type structure. The Ru(1)–C(16) bond length is 2.111(5) Å, which is somewhat shorter than the corresponding bond lengths observed in $[Ru(\eta\text{-}C_5H_5)(\eta^6\text{-}C_5H_4CH_2)]^+$ [2.272(4) Å],[17] $[(\eta\text{-}C_5Me_5)Ru(\eta^6{:}\eta^6\text{-}C_5H_4CHCHC_5H_4)Ru(\eta\text{-}C_5Me_5)^{2+}$ [2.410 Å],[12] and $[(\eta\text{-}C_5Me_5)Ru(\eta^6{:}\eta^6\text{-}C_5H_4C{=}CC_5H_4)Ru(\eta\text{-}C_5Me_5)^{2+}$ [2.254(3) Å].[13] The C(15)–C(16) bond length is 1.381(7) Å, which is shorter than the $C(sp^2)$–$C(sp^2)$ bond length (1.465 Å). Similar short bond lengths are found in the fulvene complexes $[Ru(\eta\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)]^+$ [1.401(4) Å][18] and $[Ru(\eta\text{-}C_5H_5)(\eta^6\text{-}C_5H_4CH_2)]^+$ [1.405(5) Å].[17] The C(15)–C(16) bond is folded by 30.5° from the $\eta\text{-}C_5H_4$ ring plane. This tilt angle is smaller than those of $[Ru(\eta\text{-}C_5H_5)(\eta^6\text{-}C_5H_4CH_2)]^+$ (42.6°),[17] $[Ru(\eta\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)]^+$ (40.3°),[19] $[(\eta\text{-}C_5Me_5)Ru(\eta^6{:}\eta^6\text{-}C_5H_4CHCHC_5H_4)Ru(\eta\text{-}C_5Me_5)]^{2+}$ (40.4°)[12] and $[(\eta\text{-}C_5Me_5)Ru(\eta^6{:}\eta^6\text{-}C_5H_4C{=}CC_5H_4)Ru(\eta\text{-}C_5Me_5)]^{2+}$ (41.3°),[13b] but close to that of $[(\eta\text{-}C_5H_5)Ru(\eta^6{:}\eta^6\text{-}C_5Me_4C{=}CC_5Me_4)Ru(\eta\text{-}C_5H_5)]^{2+}$ (32.7°).[13a] In addition, some bond alternation is observed in the $\eta\text{-}C_5H_4$ ring of the Rc* moiety. The C(16)–C(17) and C(17)–C(18) bond lengths are 1.753(13) and 1.306(14) Å, respectively, which indicates that the former is a single bond and the latter is a double bond, although these measurements are not precise because of the presence of disorder in the system. This relationship is reverse to that noted for neutral thiophene deriv-

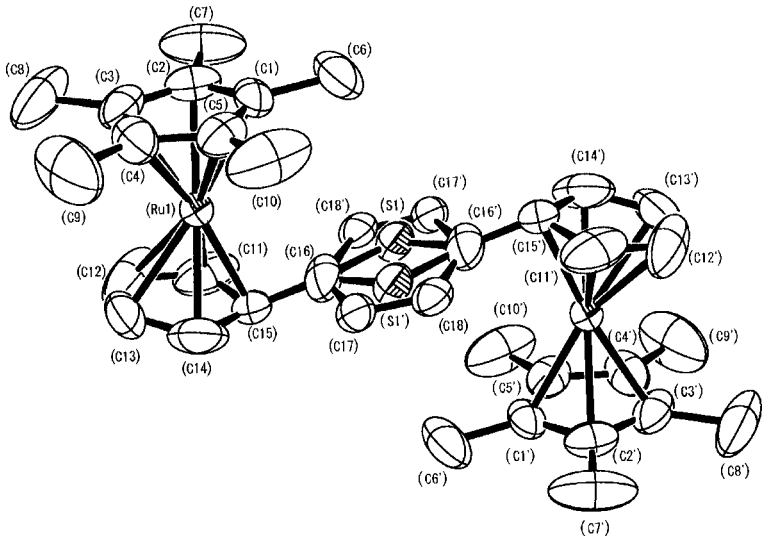

Figure 4. ORTEP view of complex **13**.

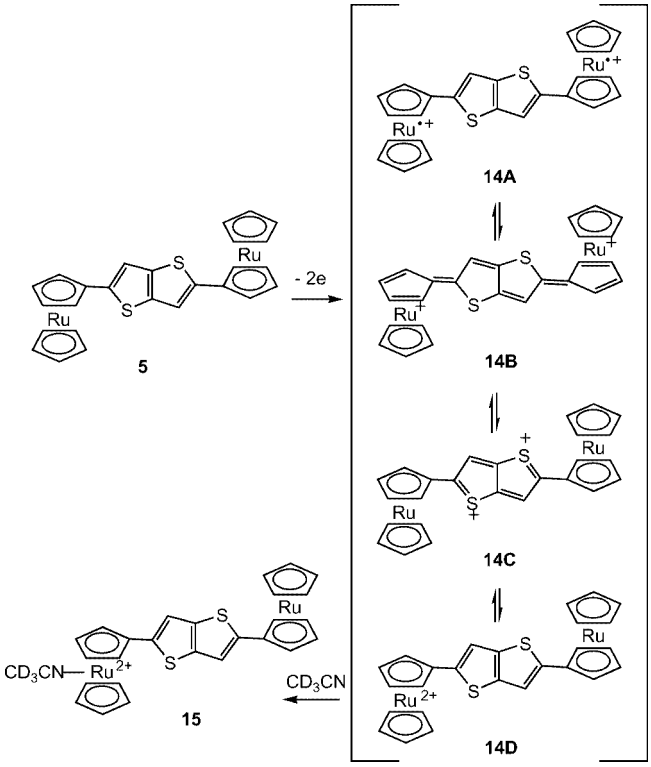
ative **7**. Therefore, the bridging ligand in **13** can be formulated as a fully conjugated 2,5-bis(fulvalenylidene)thiophene.

3,4-Ethylenedioxythiophene derivative **3** and bithiophene derivatives **4** and **8** were oxidized under similar conditions to generate the corresponding oxidized species, which gave no clear-cut $^1$H NMR spectrum of a sole product in $CD_3NO_2$. Oxidation of thieno[3,2-*b*]thiophene derivative **5** under similar conditions afforded two-electron oxidized species **14** as a black powder which is relatively stable at room temperature in the solid form. The $^1$H NMR spectrum of **14** in $CD_3NO_2$ at 20 °C shows η-$C_5H_4$ ring protons as triplets at $\delta$ = 5.93 and 6.30 ppm, which suggests that the structure of **14** has a plane or center of symmetry. The signals for the η-$C_5H_4$ ring protons broaden when the temperature is lowered, and the signal at $\delta$ = 5.93 ppm splits at –30 °C and is clearly observed as two signals at –35 °C (the limit of the measurement). This suggests the presence of a certain dynamic process. The structures **14A**–**14C** shown in Scheme 4 can be attributed to the structure of the two-electron oxidized species **14** in $CD_3NO_2$. The structure at low temperature that produces the four signals for the η-$C_5H_4$ ring protons (albeit two signals were still superimposed) seems to be fulvene complex-type structure **14B**. Thus, the structure at room temperature would be symmetrical structure **14A** or **14C**. The low-field shifts of the proton signals of η-$C_5H_5$ ($\Delta\delta$ = 0.74 ppm), η-$C_5H_4$ ($\Delta\delta$ = 1.25–1.30 ppm), and the thieno[3,2-*b*]thiophene rings ($\Delta\delta$ = 0.52 ppm) upon oxidation of **5** are smaller than those seen for **9**. The small shifts observed for the η-$C_5H_5$ and η-$C_5H_4$ ring protons suggest a decrease in the positive charge on the Ru atom of **14**. The lower-field shift of the thieno[3,2-*b*]thiophene ring protons may be explained by a counterbalancing of the increase in the positive charge by the destruction of the aromaticity in the thiophene ring of **14C**. Thus, **14C** seems to be the preferred structure at room temperature, and the dynamic process described above may be attributed to simultaneous charge transfer between **14B** and **14C**. However, a dynamic process due to spin-coupling and spin uncoupling between **14B** and **14A** cannot presently be ruled out. On the other hand, the $^1$H NMR spectrum of **14** in $CD_3CN$ shows two sets of signals for the (η-$C_5H_5$)Ru(η-$C_5H_4$)-moiety and two signals for the thieno[3,2-*b*]thiophene ring as observed for **10** and **12** in $CD_3CN$, which indicates that **15** reacts with $CD_3CN$ via **14C** to generate $Ru^{II}$–$Ru^{IV}$ mixed-valence complex **15**.



Scheme 4.

### Theoretical Considerations

Density function theory (DFT) calculations were performed for the cationic part of two-electron oxidized species **9**, **11**, and **14**. Because the B3LYP/3-21G level calculation for the optimized structures of **9** and **11** did not reproduce the structures determined by the NMR spectra and X-ray diffraction analyses, local spin density approximation (LSDA) was employed for all calculations described in this paper, and in result could revive the actual structure.

The Rc* part of the two-electron oxidized species of thiophene-bridged complex **11** was found to adopt a fulvene complex-type structure, as shown in Figure 5. Thus, the Ru(1)–C(16) distance was found to be 2.50 Å, which is close to that found experimentally for **13** [2.529(5) Å]. The C(15)–C(16) bond length was calculated to be 1.412 Å, which is similar to that of the coordinated ethene bond and approximates the observed length [1.381(7) Å]. The C(15)–C(16) bond was found to be folded by 31.0° from the η-$C_5H_4$ ring plane, which is consistent with the experimental finding that the tilt angle in **13** is 30.5°, although this angle is smaller than those seen for fulvene complexes [Ru(η-$C_5H_5$)(η$^6$-$C_5H_4CH_2$)]$^+$ (42.6°)[17] and [Ru(η-$C_5Me_5$)(η$^6$-$C_5Me_4CH_2$)]$^+$ (40.3°).[18] The calculated C(16)–C(17) bond length (1.431 Å) resembles a single bond and the C(17)–C(18) bond length (1.354 Å) resembles a double bond, which coincides with the trend observed in **13**. The Mulliken charge distribution in two-electron oxidized species **11** was calculated, in which +0.929 of the positive charge was found to be located on one Ru atom and +0.001 of the positive charge was found to be located on the S atom. These results suggest that the structure of **11B** is that of the two-electron oxidized species **11**.

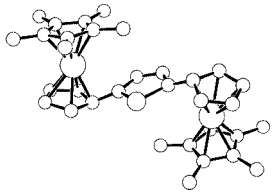

Figure 5. Optimized structure of the dication of **2**.

The optimized structure for the two-electron oxidized species of thieno[3,2-*b*]thiophene-bridged complex **14** was calculated to be also a fulvene complex-type structure (i.e. **14B**). This structure was experimentally detected at low temperature, although it was inconsistent with the structure at room temperature (vide supra). The calculation of the Mulliken charge distribution of **14** assigns a positive charge of about +0.3 on the sulfur atom, which suggests some contribution from **14C**. It was calculated that the conformer that possesses the thiophene ring perpendicular to the η-$C_5H_4$ ring, which explains the $^1$H NMR spectrum at room temperature, has 125 kJ mol$^{-1}$ more energy than the fulvene complex-type structure. In addition, calculations that considered both "broken-symmetry" and higher spin states were carried out. As a result, it was confirmed that the singlet states are electronic ground states in all cases and that the positive charge is equally distributed in the two terminal ruthenocene moieties. However, the lowest triplet states lie only about 40 kJ mol$^{-1}$ higher in energy above the singlet ground states at the DFT levels of theory employed, and the optimized structures of the lowest triplet states have no fulvene complex-type structure. As one possible idea, the triplet state may be the ground state for **14** in solution, but there is no evidence to support this assumption at present. More systematic calculations that include solvent effects will be necessary, but this is beyond the scope of this paper.

## Summary

The binuclear ruthenocene derivatives bridged by thiophene derivatives were newly prepared. The cyclic voltammograms for these complexes exhibited the one-step two-electron redox waves in a lower potential region, contrary to those for derivatives bridged by benzenoid aromatics.[11] This finding is probably related to increases in the electron-rich and olefinic properties of the thiophene derivatives. The stability levels and structures of the two-electron oxidized species were found to be mainly dependent on the types of bridging thiophene derivatives. The two-electron oxidized species of **3**, **4**, and **8** are unstable, whereas those of **2**, **5**, and **7** are stable. The two-electron oxidized species of **2** and **7** adopt the spin-coupled and structurally isomerized fulvene complex-type structures **9B** and **11B**, respectively. The structure of **11B** was determined by X-ray diffraction analysis. If thiophene is regarded as a sulfur-bridged butadiene, the behaviors exhibited upon the oxidation of **2** and **7** is very similar to those seen for bis(ruthenocenyl)butadienes.[12] The two-electron oxidized species **14** derived from **5** was also found to be stable but showed a temperature-dependent $^1$H NMR spectrum in $CD_3NO_2$. This species exists as a fulvene complex-type structure (**14B**) at low temperature, but appears in a different form (**14A** or **14C**) at room temperature. Thus, the behavior of the electronic spins in the two-electron oxidized species of biruthenocenes bridged by thiophene derivatives, that is, the fate of the fulvene complex-type structure, seems to depend largely on the character of the thiophene derivatives, although no product has been detected that corresponds to the appearance of the triplet spins in the two-electron oxidized species of bis(ruthenocenyl)butadiynes.[13]

## Experimental Section

### General

All reactions were carried out under an atmosphere of $N_2$ and/or Ar and workups were performed without precaution to exclude air. NMR spectra were recorded with Bruker AC300P, AM400, or ARX400 spectrometers. Dry solvents were prepared by distillation from the appropriate drying agent prior to use as follows: $CH_2Cl_2$ ($CaH_2$), $ClCH_2CH_2Cl$ ($CaCl_2$), $CH_3CN$ ($CaH_2$), benzene (Na), THF (Na-benzophenone), and DMF ($CaH_2$). 2-Ruthenocenyl-1,3-dioxaborolane (**1**),[14] 1,4-bis(ruthenocenyl)buta-1,3-diyne,[19] 1,4-bis(1′′,2′′,3′′,4′′,5′′-pentamethylruthenocenyl)buta-1,3-diyne,[13]

1,8-bis(1′′,2′′,3′′,4′′,5′′-pentamethylruthenocenyl)octa-1,3,5,7-tetrayne,[13] thieno[3,2-*b*]thiophene,[20] 3,6-dimethylthieno[3,2-*b*]-thiophene,[21] 2,5-diiodo-3,4-ethylenedioxythiophene,[22] dichloro-[1,1′-bis(diphenylphosphanyl)ferrocene]palladium, (dppf)$PdCl_2$,[23] and ferricenium tetra{3,5-bis(trifluoromethyl)phenyl}borate[24] were prepared according to the literature procedures. Other reagents were used as received from commercial suppliers.

Cyclic voltammetric and thin-layer coulometric measurements[16] were carried out with an ALS 400A Electrochemical Analyzer at 20 °C. A three-electrode cell containing of a glassy carbon disk working electrode (diameter 0.3 cm), Pt-coil counter electrode and an Ag/AgCl (3 M NaCl) reference electrode were employed. The ferrocene/ferrecenium ($FcH/FcH^+$) redox couple was used as an internal standard of the potential. Tetrabutylammonium tetrafluoroborate ($n$Bu)$_4BF_4$ (Nacalai Tesque Inc.) was purified by recrystallization to be used as a supporting electrode. All solutions were degassed with high-purity argon prior to the electrochemical measurements.

**2,5-Diiodo-thieno[3,2-*b*]thiophene:** To a solution of thieno[3,2-*b*]-thiophene (0.11 g, 0.80 mmol) in dry benzene (10 mL) was slowly added iodine (0.43 g, 1.70 mmol) and HgO (0.17 g, 0.80 mmol) which were grinded together. The mixture was refluxed for 2 h and then cooled to room temp. After filtration, the residue was washed with $CH_2Cl_2$. The filtrate and the washings were combined, washed with a saturated solution of $Na_2S_2O_3$, and then dried with $MgSO_4$. After evaporation of the solvent, the residue was recrystallized from EtOH. Colorless crystals. Yield 0.20 g, 63%. M.p. 188–189 °C. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 7.35 (s, 2 H, =CH) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 75.6 (=C–I), 127.6 (=CH), 144.0 (=C) ppm. $C_6H_2I_2S_2$ (392.01): calcd. C 18.38, H 0.51; found C 18.56, H 0.44.

**2,5-Diiodo-3,6-dimethylthieno[3,2-*b*]thiophene:** This compound was prepared from 3,6-dimethylthieno[3,2-*b*]thiophene (0.21 g, 1.25 mmol) according to the procedure described above. Colorless crystals. Yield 0.30 g, 58%., M.p. >200 °C. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 2.26 (s, 6 H, Me) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 16.9 (Me), 99.7 (=C–I), 134.3 (=CH), 142.2 (=C) ppm. $C_8H_6I_2S_2$ (420.07): calcd. C 22.87, H 1.44; found C 23.13, H 1.35.

**2,5-Bis(ruthenocenyl)thiophene (2):** *Method A*: A mixture of 1,4-bis(ruthenocenyl)buta-1,3-diyne (0.102 g, 0.2 mmol) and NaSH (0.23 g, 4 mmol) in DMF (10 mL) was heated at 100 °C for 24 h under an atmosphere of Ar. After the reaction was cooled, $H_2O$ (40 mL) was added to the solution, and the mixture was stirred for 0.5 h. The resulting crystals were collected by filtration under reduced pressure. The crystals were recrystallized from $CHCl_3$/hexane (2:1) to afford the title complex (97 mg, 87%) as yellow needles. M.p. 199–199.5 °C. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 4.52 (s, 10 H), 4.60 (t, $J$ = 1.9 Hz, 4 H), 4.94 (t, $J$ = 1.9 Hz, 4 H), 6.69 (s, 2 H) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 69.91 (η-$C_5H_4$), 70.44 (η-$C_5H_4$), 71.74 (η-$C_5H_5$), 84.22 (η-$C_5H_4$-*ipso*), 123.11 (=CH), 146.01 (=CS) ppm. $C_{24}H_{20}Ru_2S$ (542.63): calcd. C 53.12, H 3.72; found C 52.97, H 3.65.

*Method B*: 2,5-Diiodothiophene (0.12 g, 0.30 mmol), **1** (0.29 g, 1.6 mmol), (dppf)$PdCl_2$ (20 mg), DME (3 mL), and NaOH (10% aqueous solution, 3 mL) was sealed in an ample tube under an atmosphere of Ar. The ample tube was heated at 100 °C for 12 h. After the reaction was cooled to room temperature, the contents of the ampule were washed out with $CH_2Cl_2$, and the mixture was filtered. The organic layer was washed with water and then dried with $Mg_2SO_4$. After evaporation, the residue was dissolved in benzene, and the solution was then chromatographed on $Al_2O_3$ by elution with hexane/benzene to afford pale yellow crystals (42 mg, 23%). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 4.52 (s, 10 H), 4.60 (t, $J$ = 2 Hz, 4 H), 4.94 (t, $J$ = 2 Hz, 4 H), 6.69 (s, 2 H) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 69.91, 70.44, 71.74, 84.22, 123.11, 146.01 ppm.

**2,5-Bis(ruthenocenyl)-3,4-ethylenedioxythiophene (3):** This compound was prepared from 2,5-diiodo-3,4-ethylenedioxythiophene according to *Method B* described above. Yellow crystals. Yield 38%. M.p. 253–254 °C. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 4.19 (s, 4 H, $CH_2$), 4.53 (s, 10 H, η-$C_5H_5$), 4.59 (t, $J$ = 1.6 Hz, 4 H, η-$C_5H_4$), 5.00 (t, $J$ = 1.6 Hz, 4 H, η-$C_5H_4$) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 64.59 ($CH_2$), 69.95 (η-$C_5H_4$), 70.12 (η-$C_5H_4$), 71.44 (η-$C_5H_5$), 81.81 (*ipso*- η-$C_5H_4$), 111.52 (=C–S), 137.08 (=C–O) ppm. $C_{26}H_{22}O_2Ru_2S$ (660.66): calcd. C 51.99, H 3.69; found C 52.34, H 3.52.

**5,5′-Bis(ruthenocenyl)-2,2′-bithiophene (4):** This compound was prepared from 5,5′-diiodo-2,2′-bithiophene according to the procedure described above. Yellow crystals. Yield 23%. M.p. 253–254 °C. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 4.53 (s, 10 H, η-$C_5H_5$), 4.63 (t, $J$ = 1.8 Hz, 4 H, η-$C_5H_4$), 4.98 (t, $J$ = 1.8 Hz, 4 H, η-$C_5H_4$), 6.82 (d, $J$ = 3.8 Hz, 2 H, =CH), 6.86 (d, $J$ = 3.8 Hz, 2 H, =CH) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 69.86 (η-$C_5H_4$), 70.63 (η-$C_5H_4$), 71.88 (η-$C_5H_5$), 83.57 (*ipso*-η-$C_5H_4$), 122.94 (=CH), 123.79 (=CH), 135.08 (=C–S), 141.24 (=C–S) ppm. $C_{28}H_{22}Ru_2S_2$·1/4$CHCl_3$ (654.60): calcd. C 51.61, H 3.44; found C 51.50, H 3.35.

**2,5-Bis(ruthenocenyl)thieno[3,2-*b*]thiophene (5):** This compound was prepared from 2,5-diiodothieno[3,2-*b*]thiophene according to the procedure described above (reaction time: 2 h). Yellow crystals. Yield 18%. M.p. >250 °C. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 4.53 (s, 10 H, η-$C_5H_5$), 4.64 (t, $J$ = 1.8 Hz, 4 H, η-$C_5H_4$), 5.00 (t, $J$ = 1.8 Hz, 4 H, η-$C_5H_4$), 7.00 (s, 2 H, =CH) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 69.99 (η-$C_5H_4$), 70.62 (η-$C_5H_4$), 71.90 (η-$C_5H_5$), 115.27 (=CH) ppm. No quaternary carbon was observed because of its insolubility. $C_{26}H_{20}Ru_2S_2$ (598.71): calcd. C 52.16, H 3.37; found C 52.16, H 3.36.

**2,5-Bis(ruthenocenyl)-3,6-dimethylthieno[3,2-*b*]thiophene (6):** This compound was prepared from 2,5-diiodo-3,6-dimethylthieno[3,2-*b*]-thiophene according to the procedure described above (reaction time: 5 h). Yellow crystals. Yield 25%. M.p. >250 °C. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 2.28 (s, 6 H, Me), 4.58 (s, 10 H, η-$C_5H_5$), 4.64 (t, $J$ = 1.7 Hz, 4 H, η-$C_5H_4$), 4.93 (t, $J$ = 1.7 Hz, 4 H, η-$C_5H_4$) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 70.43 (η-$C_5H_4$), 71.73 (η-$C_5H_5$), 71.78 (η-$C_5H_4$), 84.66 (*ipso*-η-$C_5H_4$), 126.03 (=C–C), 135.44 (=C–S), 137.50 (=C–S) ppm. $C_{28}H_{24}Ru_2S_2$ (626.76): calcd. C 53.66, H 3.86; found C 53.48, H 3.56.

**2,5-Bis(1′′,2′′,3′′,4′′,5′′-pentamethylruthenocenyl)thiophene (7):** A mixture of 1,4-bis(1′′,2′′,3′′,4′′,5′′-pentamethylruthenocenyl)buta-1,3-diyne (97 mg, 0.15 mmol) and NaSH (84 mg, 1.5 mmol) in DMF (20 mL) was stirred and heated at 100 °C for 24 h under an atmosphere of Ar. After the reaction was cooled, the mixture was diluted with benzene (50 mL). The solution was washed twice with saturated aqueous LiCl and subsequently with $H_2O$ and then dried with $MgSO_4$. After evaporation, the residue was chromatographed on $Al_2O_3$ (deactivated with 5% $H_2O$) and eluted with hexane/benzene (10:1) to afford the title complex (94 mg, 92%) as yellow solid. M.p. 243 °C. $^1$H NMR (400 MHz, $C_6D_6$): $\delta$ = 1.81 (s, 15 H, Me), 4.23 (t, $J$ = 1.7 Hz, 4 H, η-$C_5H_4$), 4.57 (t, $J$ = 1.7 Hz, 4 H, η-$C_5H_4$) 6.66 (s, 2 H, =CH) ppm. $^{13}$C NMR (100 MHz, $C_6D_6$): $\delta$ = 11.58 (Me), 70.86 (η-$C_5H_4$), 73.20 (η-$C_5H_4$), 84.36 (*ipso* -η-$C_5H_4$), 85.39 (η-$C_5Me_5$), 121.48 (=CH), 137.56 (=C–S) ppm. $C_{34}H_{40}Ru_2S$ (682.90): calcd. C 59.80, H 5.90; found C 59.69, H 5.86.

**5,5′-Bis(1′′,2′′,3′′,4′′,5′′-pentamethylruthenocenyl)-2,2′-bithiophene (8):** This compound was prepared from 1,8-bis(1′′,2′′,3′′,4′′,5′′-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pentamethylruthenocenyl)octa-1,3,5,7-tetrayne according to the procedure described above (reaction temperature: 110 °C). Red–orange solid. Yield 64%. M.p. 230 °C (dec.). $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.79 (s, 30 H, Me), 4.29 (t, $J$ = 1.6 Hz, 4 H, η-$C_5H_4$), 4.53 (t, $J$ = 1.6 Hz, 4 H, η-$C_5H_4$), 6.69 (d, $J$ = 3.8 Hz, 2 H, =CH), 6.90 (d, $J$ = 3.8 Hz, 2 H, =CH) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 11.33 (Me), 70.64 (η-$C_5H_4$), 73.24 (η-$C_5H_4$), 82.96 (*ipso*-η-$C_5H_4$), 85.52 (η-$C_5Me_5$), 121.12 (=CH), 122.81 (=CH), 133.63 (=C–S), 140.07 (=C–S) ppm. $C_{38}H_{42}Ru_2S_2$ (765.02): calcd. C 59.66, H 5.53; found C 59.47, H 5.42.

**Chemical Oxidation of Complex 2:** To a solution of **2** (16.3 mg, 0.03 mmol) and *p*-BQ (6.3 mg, 0.06 mmol) in $CHCl_3$ (3 mL) chilled at 0 °C by an ice bath was added $BF_3$·$OEt_2$ (2 drops from a capillary) under an atmosphere of nitrogen. After the resulting dark brown solution had been stirred for 5 min at 0 °C, dry benzene (3 mL) was added to the solution and then kept for 30 min at the same temperature. The mixture was filtered under reduced pressure and washed with pentane to afford a black powder (16 mg) (The product contained hydroquinone). $^1$H NMR (400 MHz, $CD_3NO_2$, 0 °C): $\delta$ = 5.26 (s, 10 H), 5.75 (br. s, 2 H), 5.90 (br. s, 2 H), 6.32 (br. s, 2 H), 6.40 (br. s, 2 H), 7.46 (s, 2 H) ppm. $^1$H NMR (400 MHz, $CD_3CN$, –5 °C): $\delta$ = 4.57 (s, 5 H, η-$C_5H_5$), 5.02 (t, $J$ = 1.8 Hz, 2 H, η-$C_5H_4$), 5.36 (t, $J$ = 1.8 Hz, 2 H, η-$C_5H_4$), 5.88 (s, 5 H, η-$C_5H_5$), 6.01 (t, $J$ = 2.6 Hz, 2 H, η-$C_5H_4$), 6.27 (t, $J$ = 2.6 Hz, 2 H, η-$C_5H_4$), 7.40 (d, $J$ = 4.5 Hz, 1 H, =CH), 8.05 (d, $J$ = 4.5 Hz, 1 H, =CH) ppm. $^{13}$C NMR (100 MHz, $CD_3NO_2$, –5 °C): $\delta$ = 77.42 (η-$C_5H_4$), 78.72 (η-$C_5H_4$), 86.24 (η-$C_5H_5$), 90.33 (η-$C_5H_4$), 90.66 (η-$C_5H_4$), 92.90 (*ipso*-η-$C_5H_4$), 129.96 (=C–S), 137.01 (=CH) ppm.

**Chemical Oxidation of Complex 7:** *Method A*: To a solution of **7** (20.5 mg, 0.03 mmol) and *p*-BQ (6.3 mg, 0.06 mmol) in dry $CH_2Cl_2$ (3 mL) chilled at 0 °C by an ice bath was added $BF_3$·$OEt_2$ (1 drop from a capillary) under an atmosphere of nitrogen. After the resulting red–violet solution had been stirred for 3 min at 0 °C, dry benzene (6 mL) was added to the solution, and the stirring was then stopped. After the solution had been kept for 30 min at 0 °C, dry benzene (9 mL) was added to the solution, and the solution was then kept for 1 h at the same temperature. The mixture was filtered under reduced pressure and washed with pentane to afford black powdery crystals (16 mg) (The product contained hydroquinone). The crystals were comparably stable when stored in the freezer. The solution of the product in $CD_3NO_2$ or $CD_3CN$ immediately after its preparation produced a clear $^1$H NMR spectrum. $^1$H NMR (400 MHz, $CD_3NO_2$, –5 °C): $\delta$ = 1.79 (s, 30 H), 5.53 (t, $J$ = 2.0 Hz, 4 H), 5.90 (m, 4 H), 7.41 (s, 2 H) ppm. $^1$H NMR (400 MHz, $CD_3CN$, 0 °C): $\delta$ = 1.66 (s, 15 H), 1.92 (s, 15 H), 4.78 (t, $J$ = 1.8 Hz, 2 H), 4.94 (br. s, 2 H), 5.57 (t, $J$ = 2.3 Hz, 2 H), 5.69 (m, 2 H), 7.11 (d, $J$ = 4.6 Hz, 1 H), 7.99 (d, $J$ = 4.6 Hz, 1 H) ppm. $^{13}$C NMR (100 MHz, $CD_3NO_2$, –5 °C): $\delta$ = 7.39 (Me), 75.85 (η-$C_5H_4$), 77.10 (η-$C_5H_4$), 93.81 (η-$C_5H_4$), 93.99 (η-$C_5H_4$), 95.34 (*ipso*-η-$C_5H_4$), 98.49 (η-$C_5Me_5$), 132.93 (=C–S), 136.58 (=CH) ppm.

*Method B*: To a solution of **7** (13.7 mg, 0.02 mmol) in dry $CH_2Cl_2$ (3 mL) was added ferricenium tetra{3,5-bis(trifluoromethyl)-phenyl}borate (42 mg, 0.04 mmol) at 0 °C under an atmosphere of nitrogen. After the resulting red–violet solution had been stirred for 15 min at 0 °C, dry benzene (6 mL) was added to the solution and the stirring was then stopped. After the solution had been kept for 30 min at 0 °C, dry benzene (9 mL) was added to the solution, and the solution was then kept for 1.5 h at the same temperature. The resulting fine crystals were collected by filtration under reduced pressure. Dark red–violet fine crystals (37 mg). $^1$H NMR (400 MHz, $CD_2Cl_2$, 0 °C): $\delta$ = 1.70 (s, 30 H, Me), 5.19 (m, 2 H, η-$C_5H_4$), 5.24 (m, 2 H, η-$C_5H_4$), 5.65 (t, $J$ = 2.1 Hz, 4 H, η-$C_5H_4$), 7.02 (s, 2 H, =CH), 7.56 (br. s, 8 H, $C_6H_3$), 7.72 (br. s, 16 H, $C_6H_3$) ppm. $^1$H NMR (400 MHz, [D$_6$]acetone, 0 °C): $\delta$ = 1.83 (s, 30 H, Me), 5.81 (br. s, 2 H, η-$C_5H_4$), 5.89 (br. s, 2 H, η-$C_5H_4$), 6.17 (br. s, 4 H, η-$C_5H_4$), 7.68 (br. s, 8 H, $C_6H_3$), 7.77 (br. s, 16 H, $C_6H_3$), 7.83 (s, 2 H, =CH) ppm. $^1$H NMR (400 MHz, $CD_3NO_2$, 0 °C): $\delta$ = 1.80 (s, 30 H, Me), 5.52 (m, 4 H, η-$C_5H_4$), 5.90 (m, 4 H, η-$C_5H_4$), 7.41 (s, 2 H, =CH), 7.67 (br. s, 8 H, $C_6H_3$), 7.84 (br. s, 16 H, $C_6H_3$) ppm. $^1$H NMR (400 MHz, $CD_3CN$, –10 °C): $\delta$ = 1.65 (s, 15 H, Me), 1.91 (s, 15 H, Me), 4.78 (t, $J$ = 1.8 Hz, 2 H, η-$C_5H_4$), 4.93 (m, 2 H, η-$C_5H_4$), 5.56 (t, $J$ = 2.4 Hz, 4 H, η-$C_5H_4$), 5.67 (m, 2 H, η-$C_5H_4$), 7.10 (d, $J$ = 4.6 Hz, 1 H, =CH), 7.35 (br. s, 8 H, $C_6H_3$), 7.67 (br. s, 16 H, $C_6H_3$), 7.98 (d, $J$ = 4.6 Hz, 1 H, =CH) ppm. $C_{98}H_{64}B_2F_{48}Ru_2S$ (2409.35): calcd. C 48.85, H 2.68; found C 48.42, H 2.61.

**Chemical Oxidation of Complex 5:** To a solution of **5** (8.0 mg, 0.015 mmol) and *p*-BQ (3.2 mg, 0.03 mmol) in $CHCl_3$ (3 mL) chilled at 0 °C by an ice bath was added $BF_3$·$OEt_2$ (2 drops from a capillary) under an atmosphere of nitrogen. After the resulting dark brown solution had been stirred for 1 h at 0 °C, dry $Et_2O$ (6 mL) was added to the solution and the stirring was then stopped. The solution was kept for 1 h at the same temperature. The reaction was filtered under reduced pressure and washed with pentane to afford black crystals (6.5 mg) that were stable when stored in the freezer. The solution of the product in $CD_3NO_2$ (deep blue–violet) or $CD_3CN$ (deep blue) produced a clear $^1$H NMR spectrum. $^1$H NMR (400 MHz, $CD_3NO_2$, 20 °C): $\delta$ = 5.27 (s, 10 H), 5.93 (t, $J$ = 1.9 Hz, 4 H), 6.30 (t, $J$ = 1.9 Hz, 4 H), 7.53 (s, 2 H) ppm. $^{13}$C NMR (100 MHz, $CD_3NO_2$, 20 °C): $\delta$ = 76.50 (η-$C_5H_4$), 84.18 (η-$C_5H_5$), 88.79 (η-$C_5H_4$), 95.77 (*ipso*- η-$C_5H_4$), 125.88 (=CH) ppm. $^1$H NMR (400 MHz, $CD_3NO_2$, –35 °C): $\delta$ = 5.24 (s, 10 H), 5.88 (br. s, 2 H), 5.98 (br. s, 2 H), 6.27 (br. s, 4 H), 7.51 (s, 2 H) ppm. $^1$H NMR (400 MHz, $CD_3CN$, 0 °C): $\delta$ = 4.55 (s, 5 H), 4.93 (br. s, 2 H), 5.29 (br. s, 2 H), 5.90 (s, 5 H), 6.12 (br. s, 5 H), 6.34 (br. s, 2 H), 7.45 (s, 1 H), 8.32 (s, 1 H) ppm.

### Electronic Structure Calculation

DFT calculations were performed with the Gaussian 03 package program.[25] The calculation at the B3LYP hybrid density-functional levels[26,27] with the 3-21G basis set did not reproduce the optimized structure of the two-electron oxidized species in the present series determined by the NMR spectra and X-ray analysis. In order to understand this source, extensive DFT calculations for ruthenocene ($C_{10}H_{10}Ru$ with $D_{5h}$ symmetry) have also been performed with various combinations of exchange and correlation functionals. As a result, we have chosen to use the local spin density approximation (LSDA) with the Vosko–Wilk–Nusair exchange-correlation potential[28] for the calculation of our systems, because the previous theoretical study[29,30] at this level for ruthenocene showed relatively good agreement with the experimental data and give the order of $3e'_2 < 5a'_1 < 4e''_1$ [$(3e'_2)^4(5a'_1)^2(4e''_1)^0$]. Notice that the HOMO of ruthenocene is an $a_{1g}$ orbital and this gives a significant result in the ionization state of ruthenocene and the structure of the dications of binuclear ruthenocene derivatives. Thus, it may be suggested that the extraction of an electron from the $a_{1g}$ orbital of the ruthenocene moiety of **2** and **7** is likely to cause the deformation of the bridging ligand in **10** and **12**, respectively.

A Stuttgart–Dresden–Bonn quasirelativistic ECP28 MWB (SDD) effective core potential[31] have been employed for ruthenium atoms. The standard 6-311G basis sets were used for C and H atoms, whereas the 6-311G(*d*) basis set was used to describe the

hypervalency of the sulfur atom. In order to further examine the effect of polarization, larger basis sets of 6-311G(*d*) have also been employed for C and H and 6-311G(2*d*) for S.

**Structure Determination**

The crystallographic data are listed in Table 5 for **3**, **7**, and **13**. Data collection of crystal data for **3** and **7** was performed at room temperature with a Mac Science DIP3000 image processor. The structures of **3** and **7** were solved with the Dirdif-Patty method in MAXUS (software package for structure determination) and refined finally by full-matrix least-squares procedure with SHELEX. Crystal data for **13** were collected at –196 °C (liquid $N_2$) with a Bruker Apex diffractometer with graphite monochromated Mo-$K_\alpha$ radiation and an 18-kW rotating anode generator. The structure of **13** was solved and refined by SHELEX. Absorption correction for **3** and **7** was carried out by the Sortav method and anisotropic refinement for non-hydrogen atom was carried out. The hydrogen atoms, located from difference Fourier maps or calculation, were isotropically refined.

CCDC-298964 (**3**), -298965 (**7**), and -298966 (**13**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif..

# Monophosphanes and Diphosphanes with the Hypersilyl Substituent

**Vittorio Cappello,[a] Judith Baumgartner,[a][‡] and Alk Dransfeld,[a][‡‡] and Karl Hassler*[a]**

**Keywords:** Hypersilylphosphanes / Potassium phosphanides / Ab initio calculations / *P*-Silylhalophosphanes / Silicon

The synthesis of $(SiMe_3)_3SiPH_2$ (**1**) (further on denoted as hypersilylphosphane, $HypPH_2$) was achieved by two methods: by the reaction of $(SiMe_3)_3Si(OSO_2CF_3)$ with $PH_3$, and alternatively, by the reaction of $NaPH_2$ with $(SiMe_3)_3SiCl$ (hypersilylchloride). The latter reaction also afforded bis(hypersilyl)phosphane $Hyp_2PH$ (**2**). By the reaction of **1** and known hypersilylbis(trimethylsilyl)phosphane (**3**) with *t*BuOK, the novel hypersilylphosphanides HypPHK (**4**) and $Hyp(SiMe_3)PK$ (**5**) were prepared. Compound **1** also reacted with *n*BuLi to form HypPHLi (**6**) and $HypPLi_2$ (**7**). Furthermore, **3** reacted with hexachloroethane and 1,2-dibromotetrachloroethane to give $HypPCl(SiMe_3)$ (**8**) and $HypPBr(SiMe_3)$ (**9**) as well as $HypPCl_2$ (**10**) and $HypPBr_2$ (**11**). Compounds **4** and **5** reacted smoothly with 1,2-dibromoethane to give diphosphane HypHPPHHyp (**12**) as a mixture of the *meso*- and *rac*-D,L-diastereomers and $Hyp(SiMe_3)PP(SiMe_3)Hyp$ (**13**) as the D,L-modification only. By reducing the known compound *t*BuHypPCl with potassium, the D,L-modification of *t*BuHypPPHyp*t*Bu (**14**) was obtained. All compounds were characterized by $^{29}Si$- and $^{31}P$ NMR spectroscopy and elemental analyses with the exception of the phosphanides which were characterized spectroscopically only. The crystal structures of **3** and **4** and of diphosphanes **10**, **11** and **13** are reported. From temperature-dependent $^{31}P$ NMR experiments, the coalescence temperature for the *meso*↔D,L interconversion of **12** was determined at 110 °C and gave an inversion barrier of roughly 69.4 kJ mol$^{-1}$, which is corroborated by results of ab initio calculations at the B3LYP/6-31G(d) level. Two diastereomeric inversion transition structures for diphosphanes R–PH–PH–R with either a *syn* or an *anti* arrangement of the P–H bond and the phosphorus lone pair of electrons could be located; bulky substituents seem to prefer the *anti* arrangement.

## Introduction

The bulky tris(trimethylsilyl)silyl group, often denoted as the hypersilyl group [a term coined by Nils Wiberg[1] to distinguish it from the tri(*tert*-butyl)silyl group which he named supersilyl], has been used extensively in the past to stabilize and protect uncommon bonding states of main group elements and transition elements. Despite the bulkiness of the group, a number of geminal dihypersilyl derivatives were also synthesized successfully, essentially with heavier main group elements. We will not give a full account of all the compounds that have been prepared so far, as this can be found in refs.[2–4] and the literature cited therein. K. Klinkhammer even succeeded to synthesize $NaSnHyp_3$, the only known compound with three hypersilyl groups on one central atom.[5]

Despite this widespread use of the hypersilyl group, the number of known hypersilyl compounds of the elements of group V (N, P, As, Sb, and Bi) is surprisingly small. With nitrogen, $HypNH_2$, HypNHLi, $HypNH(SiMe_3)$ and $HypNLi(SiMe_3)$ have been described,[6] and some derivatives such as tris(trimethylsilyl)silylamides of zinc,[7] tin and mercury have also been reported.[8]

The first hypersilyl phosphorus compound, HypP*t*BuCl, was described by Cowley.[9] It is a thermally stable silylhalophosphane that undergoes a silicon–halogen exchange reaction at about 100 °C. Hypersilyldiphenylphosphane was prepared for mass spectroscopic purposes in 1993.[10] Regitz et al. introduced the hypersilyl group into 1*H*-phosphirenes, which undergo isomerization to furnish trimethylsilyl-substituted phosphasiletanes upon irradiation.[11] Klingebiel reported the preparation of stable hypersilylfluorophosphanes that have an amino group as the third substituent on the P atom, for instance $(SiMe_3)_2N$.[12] The synthesis of $HypPMe(NRP{=}NR)$ with R = 2,4,6-$(Me_3C)_3C_6H_2$ was reported in 1991.[13] Recently, C. Marschner reported the synthesis of a bis(hypersilyl)phosphane, $Hyp_2PNR$.[14]

In our group, bis(trimethylsilyl)hypersilylphosphane was prepared some years ago by the reaction of bis(trimethylsilyl)lithiumphosphanide with hypersilylchloride (Scheme 1).[15]

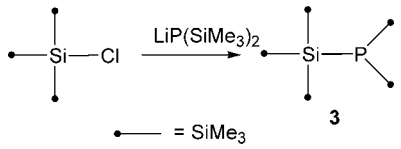


Scheme 1.

Recently, we also reported the synthesis of air-stable tri(hypersilyl)heptaphosphane,[16] which undergoes an interesting reaction with *t*BuOK even at temperatures as low as –60 °C. In the first step of the reaction, a silicon–silicon bond is cleaved with concomitant formation of $tBuOSiMe_3$. The resulting potassium silanide rearranges into a heptaphosphanide anion and bis(trimethylsilyl)silylene that inserts into a P–P bond of the three-membered ring at the base of the $P_7$-cage.[17]

At present, no compounds with the hypersilyl group attached to arsenic, antimony or bismuth are known.

The desire to have at our disposal some hypersilyl–phosphorus synthons which can be used widely, for instance for the preparation of hypersilyldiphosphanes and hypersilyloligophosphanes, motivated us to investigate various possibilities for the preparation of $HypP(SiMe_3)X$ and $HypPX_2$, (X = halogen), HypPHK and $HypP(SiMe_3)K$. Here we report on the successful synthesis of these phosphanes and phosphanides as well as on some reactions they can undergo.

## Results and Discussion

### Syntheses

#### *Synthesis of $HypPH_2$ (1) and $(Hyp)_2PH$ (2)*

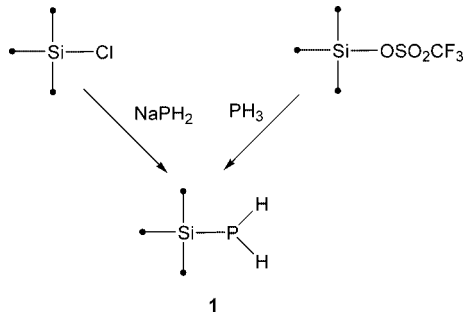
Reactions of silyltriflates with $PH_3$ that form Si–P bonds were first described by W. Uhlig.[18] We transferred this methodology to the synthesis of $(SiMe_3)_3Si(OSO_2CF_3)$ (prepared from $(SiMe_3)_3SiPh$[19] and $HOSO_2CF_3$), which reacts cleanly with $PH_3$ in the presence of triethylamine to give $HypPH_2$ in almost quantitative yield. No disubstitution with the hypersilyl group at the phosphorus atom could be observed in this reaction. An alternative route starts from $NaPH_2$, which can be prepared from $PH_3$ and sodium in liquefied ammonia.[20] If the reaction is heated at reflux in toluene, $(SiMe_3)_3SiCl$ and $NaPH_2$ slowly react over a period of a week to give a 1:1 mixture of hypersilyl- and dihypersilylphosphane (Scheme 2).

As minor byproducts of the reaction that are easily identified with $^{31}P$ NMR spectroscopy, HypPHHPHyp and $P_7Hyp_3$ are also formed, probably through the decomposition of $NaPH_2$ at 110 °C:

$$2\ NaPH_2 \rightarrow Na_2PH + PH_3$$

$$3\ NaPH_2 \rightarrow Na_3P + 2\ PH_3$$

As $HypPH_2$ and $(Hyp)_2PH$ can easily be separated and purified by fractional sublimation in vacuo, this procedure simultaneously affords both phosphanes on a preparative scale.



Scheme 2.

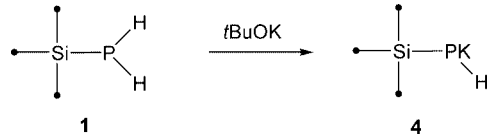
#### *Synthesis of HypPHK (4), $HypP(SiMe_3)K$ (5), and HypPHLi (6)*

It is well known from the work of G. Fritz[21] that P–Si bonds can be cleaved by alkyllithium reagents to form silylated Li-phosphanides. However, these phosphanides are not very stable at room temperature. For instance, $(SiMe_3)_2PP(SiMe_3)Li$ decomposes quickly to form a plethora of compounds such as $P(SiMe_3)_3$, $LiP(SiMe_3)_2$ and $Li_3P$.

To obtain some understanding of the thermal stability of hypersilyllithiumphosphanides, we treated $HypPH_2$ with *n*BuLi in THF at –60 °C. As expected, the only initial product that was formed was HypPHLi, which decomposed slowly to form $HypP(SiMe_3)Li$ and $HypPLi_2$ as well as $(SiMe_3)_2PLi$ besides some other unidentified products. The intensity of the signal in the $^{31}P$ NMR spectrum of HypPHLi gradually diminished with time.

We therefore chose to investigate the reaction of $HypPH_2$ with *t*BuOK. Though *t*BuOK is known to cleave P–Si bonds of $P(SiMe_3)_3$[22] to give $(SiMe_3)_2PK$ and $tBuOSiMe_3$, it was our expectation that the hypersilyl group might not be attacked due to its bulkiness and that PH would be transformed into PK.

As could easily be followed by $^{31}P$ NMR spectroscopy, the reaction cleanly gave HypPHK in about 90% yield in THF. A minor byproduct of the reaction was $HypPK_2$, besides some $HypPH_2$ (Scheme 3). Most importantly, HypPHK turned out to be stable for more than a week at room temperature. It can be crystallized from hexane in the presence of 18-crown-6 for further purification.



Scheme 3.

Because of the bulkiness of the hypersilyl group, *t*BuOK reacts with $HypP(SiMe_3)_2$ by the cleavage of only one trimethylsilyl group to form $HypPK(SiMe_3)$ in excellent yields (>90%). As a minor byproduct, HypPHK was always present in the reaction mixtures. $HypPK_2$ can also be obtained from $HypP(SiMe_3)_2$ by adjusting the stoichiometry, albeit in moderate yields.

### *Synthesis of HypP(SiMe$_3$)H*

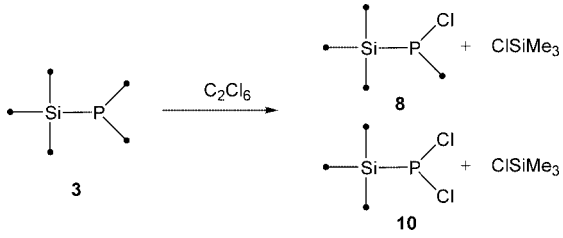
Over a period of three weeks, **3** (Scheme 4) reacts slowly with *t*BuOH at room temperature to form HypP(SiMe$_3$)H and Me$_3$SiO*t*Bu as a byproduct. No cleavage of the hypersilyl–phosphorus bond occurs, and no HypPH$_2$ can be detected in the reaction mixture. HypP(SiMe$_3$)H is easily separated from unreacted **3** by vacuum sublimation.

**3** **5**

Scheme 4.

### *Synthesis of HypPX(SiMe$_3$) and HypPX$_2$, X = Cl, Br (8, 9, 10, 11)*

By the reaction of *t*BuP(SiMe$_3$)$_2$ with C$_2$Cl$_6$, Appel[23] et al. were able to prepare *t*BuP(SiMe$_3$)Cl, the first moderately stable P-chloro–P-silylphosphane with $t_{1/2} \approx 13$ min at ambient temperature. We were curious to know if the substitution of the *t*Bu group with hypersilyl would also give stable chlorosilylphosphanes, which it did. The synthesis was achieved by the reaction of HypP(SiMe$_3$)$_2$ with one or two equiv. of C$_2$Cl$_6$ (Scheme 5). All attempts to crystallize the samples failed despite the fact that the compounds were formed in excellent yields.

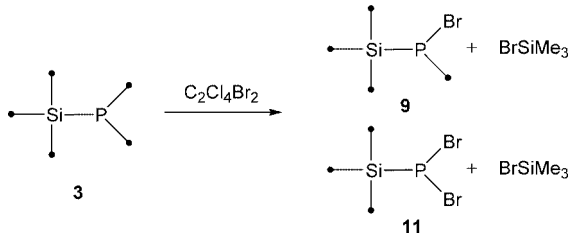


**3** **8** **10**

Scheme 5.

The chlorodisilylphosphane turned out to be astonishingly stable and survived several days heated at 70 °C as a solution in toluene. When heated at reflux in toluene, it decomposed quickly to give a plethora of unidentified products. From the observed shifts in the $^{31}$P NMR spectra it can be concluded that some of these products contain P–P bonds, which supports the evidence that ClSiMe$_3$ is eliminated with concomitant formation of hypersilylphosphanylidene which then undergoes all sorts of insertion reactions. It is of some note that no change in colour occurred upon the thermal elimination of ClSiMe$_3$. The thermal stability of the compound is noticeably decreased in THF, where decomposition occurs at a temperature as low as 40 °C.

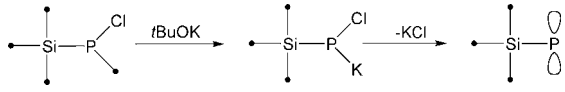
HypP(SiMe$_3$)$_2$ reacts cleanly and quantitatively with BrCl$_2$CCCl$_2$Br to form HypPBr(SiMe$_3$) (**9**) and HypPBr$_2$ (**11**), which are both fairly stable at room temperature (Scheme 6). We were unable to obtain crystals of these two silylhalophosphanes that were suitable for X-ray diffraction experiments. When HypPCl(SiMe$_3$) reacts with BrCl$_2$CCCl$_2$Br, a mixture of HypPBr$_2$ and HypPClBr (≈ 90:10) forms, which can be observed by analysis of the $^{31}$P NMR spectrum.



**3** **9** **11**

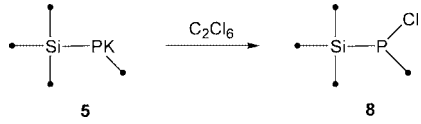
Scheme 6.

As reported elsewhere, HypP(SiMe$_3$)Cl is an excellent precursor to hypersilylphosphanylidene.[24] When it is added dropwise to a solution of *t*BuOK in THF, the colour changes immediately to brown and then to a deep violet and the triphosphaallyl anion [Hyp$_2$P$_3$]$^-$ forms. By reversing the procedure, bis(hypersilyl)diphosphane is formed when a solution of *t*BuOK is added to a solution of HypP(SiMe$_3$)-Cl by dimerization of hypersilylphosphanylidene which is generated under these reaction conditions (Scheme 7).



Scheme 7.

The reaction of HypP(SiMe$_3$)K (**5**) with C$_2$Cl$_6$ does not give HypPClK through Si–P bond cleavage, followed by KCl elimination and formation of the phosphanylidene HypP. Instead, chlorophosphane **8** is formed quantitatively (Scheme 8). A diphosphane is also not formed by the reaction of unreacted **5** with **8**.



**5** **8**

Scheme 8.

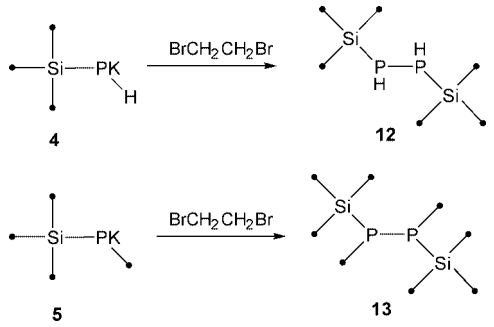
Attempts to prepare a disilylfluorophosphane, HypP(SiMe$_3$)F, by the reaction of **5** with FCl$_2$CCCl$_2$F were unsuccessful.

### *Synthesis of (Hypersilyl)diphosphanes*

HypPHK and HypPK(SiMe$_3$) cleanly react with 1,2-dibromoethane to give the bulky diphosphanes HypPHHPHyp (**12**) and Hyp(SiMe$_3$)PP(SiMe$_3$)Hyp (**13**) Scheme 9. As follows from the $^{31}$P NMR spectra, 1,2-dihypersilyldiphosphane forms as a mixture of *meso*- and *rac*-D,L-diastereomers which differ in their $^{31}$P–$^{31}$P coupling constants (see section NMR spectroscopy). 1,2-Bis(hypersilyl)-1,2-bis(trimethylsilyl)diphosphane shows a single resonance in the $^{31}$P NMR spectrum that originates from the D,L-diastereomers. This interpretation is corroborated by the X-ray structure.

We also investigated the reaction of HypPH$_2$ with *t*Bu$_2$Hg in an attempt to prepare a cyclotetraphosphane

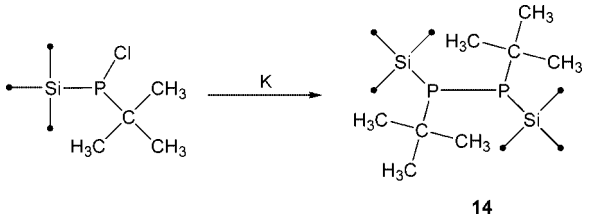
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 9.

which is known to form when $(SiMe_3)PH_2$ is used.[25] Because of the bulkiness of the hypersilyl group, the reaction stops with the formation of bis(hypersilyl)diphosphane even when an excess of $tBu_2Hg$ is used. Here again, a mixture of the *meso*- and *rac*-D,L-diastereomers is formed.

By reducing the known compound *t*Bu(Hyp)PCl[9] with potassium, we were able to prepare the even bulkier diphosphane *t*Bu(Hyp)PP(Hyp)*t*Bu (**14**), which again possesses a single resonance in the $^{31}P$ NMR spectrum (Scheme 10). X-ray diffraction experiments again show that it is the D,L-racemic modification that is formed.



Scheme 10.

We will report on our attempts to prepare tetra(hypersilyl)diphosphane in a forthcoming paper.

## $^{29}Si$ and $^{31}P$ NMR Spectroscopy

### *Shift Data and Coupling Constants*

All compounds were characterized by $^{29}Si$- and $^{31}P$ NMR spectroscopy. The relevant shift data and the coupling constants are summarized in Table 1, which includes data for compounds that were not isolated in their pure form such as HypPClBr.

### *$^{31}P$ NMR Spectrum and Inversion Barrier of Bis(hypersilyl)diphosphane (12)*

Figure 1 presents the experimental proton-coupled $^{31}P$- and $^{1}H$ NMR spectra of **12** which both display two AA′ (or XX′) subspectra of two AA′XX′ spin systems (A = P, X = H) originating from the *meso*- and *rac*-D,L-**12** and the racemic modification. The coupling with the hypersilyl protons is negligibly small, which causes a broadening of the lines only. Because of the size of the hypersilyl group, all diastereomers are expected to adopt the *anti* conformation only at room temperature to minimize the steric repulsion between the two hypersilyl groups (see section X-ray Crystallography).

As Figure 2 shows, with the help of Newman projections, the two phosphorus lone pairs of electrons will be *trans* ($\omega \approx 180°$) to each other for the *meso* form and *gauche* ($\omega \approx 60°$) to each other for the D,L-diastereomer. As is known from numerous studies, the absolute value of the one bond P–P coupling constant $|^1J_{P,P}|$ is large for a *gauche* arrangement of the lone pairs of electrons and comparatively small for the *trans* arrangement.[26] For instance, ab initio calculations at the B3LYP/6-31+G*//B3LYP/IGLO-III level of theory for 180° and 60° electron lone pair dihedral angles of $P_2H_4$ predict $^1J_{P,P}$ values of +2.5 and –187.9 Hz, respectively.[27] For *meso*-1,2-di(*tert*-butyl)diphosphane, –162.7 Hz is reported in the literature and –206.6 Hz is reported for the D,L-diastereomer.[28]

Table 1. Chemical shifts {[ppm], $\delta(^{29}Si)$ against TMS, $\delta(^{31}P)$ against $H_3PO_4$}, and coupling constants [Hz] for hypersilylmonophosphanes and hypersilyldiphosphanes.

| Compound | No. | Solvent | Hypersilyl group | | | | | | $SiMe_3$ group | | | | |

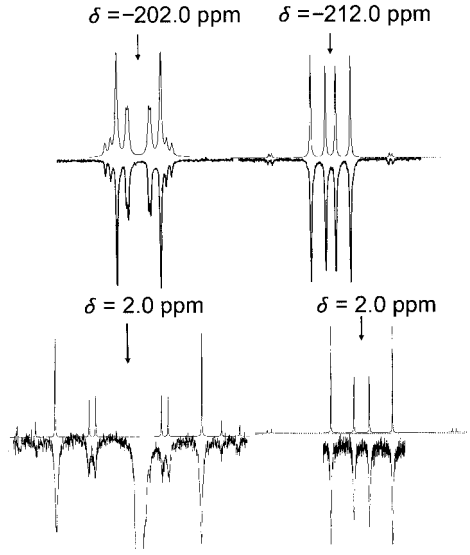

Figure 1. Calculated (positive intensities) and observed $^{31}$P- (top) and $^{1}$H NMR spectra of *meso*- (–202.0, 2.0 ppm, respectively) and D,L-bis(hypersilyl)diphosphane (–212.0, 2.9 ppm).

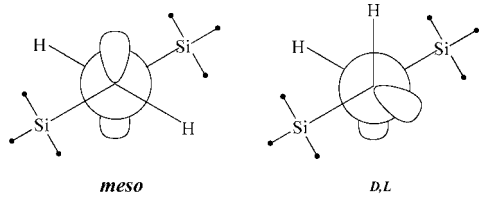

Figure 2. Newman projections for the *anti* conformers [$\omega$(Si–P–P–Si) ≈ 180°] of *meso*- and D,L-HypPHHPHyp.

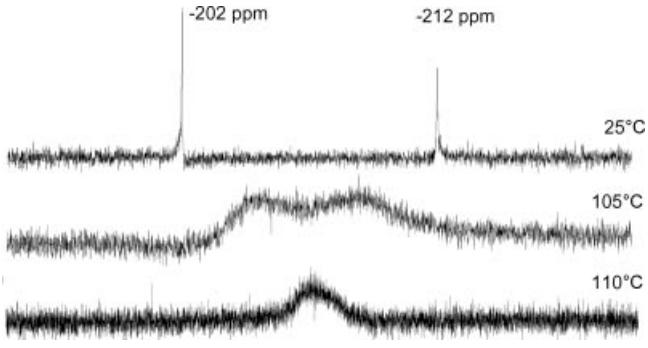

Figure 3. Proton-decoupled $^{31}$P NMR spectrum of a solution of **12** in toluene at three different temperatures. The frequency separation $\delta\nu$ at 25 °C is 1214.2 Hz.

From the simulated spectra, $^{1}J_{P,P}$ values of –80.9 Hz are obtained for the *meso*-diastereomer, and –254.1 Hz for the D,L-diastereomer. The difference is much larger than that of 1,2-di(*tert*-butyl)diphosphane, but it is close to the difference calculated for $P_2H_4$.

Figure 3 presents the proton-decoupled $^{31}$P NMR spectrum of a solution of **12** in toluene at three different temperatures. Coalescence due to rapid interconversion of *meso*↔D,L occurs at $T_c$ = 110 °C. $\Delta G^{\neq}$ can be approximated by $\Delta G^{\neq} = 19.13\ T_c(9.97 + \log T_c/\delta\nu)$[29], the barrier for phosphorus inversion can be estimated to be 69.4 kJ mol$^{-1}$.

### Ab initio Calculation of the Phosphorus Inversion Barrier of 12

Dynamic NMR experiments have been used for the determination of the inversion barriers ($\Delta E_{inv}$) of silylphosphanes as early as 1970. For $C_6H_5P(i\text{Pr})SiMe_3$ and $C_6H_5P(SiMe_2H)_2$ values of 78 and 51 kJ mol$^{-1}$ were reported, respectively.[30,31] These are smaller that those obtained for organophosphanes. The observed lowering of $\Delta E_{inv}$ upon silyl substitution has been related to three effects, which include a destabilization of the pyramidal structure and a stabilization of the transition structure by either π-acceptor or σ-donor properties.[32] Earlier ab initio calculations by one of the authors (A. Dransfeld[33]) predicted that replacement of a hydrogen atom of $PH_3$ with $PH_2$ ($PH_3 \rightarrow H_2PPH_2$) is accompanied by a lowering of $\Delta E_{inv}$ from 147.9 to 114.1 kJ mol$^{-1}$. Thus, disilyldiphosphanes, RHPPHR, are predicted to possess even smaller barriers than those of organophosphanes, which is fully confirmed by the NMR results of **12**.

To gain some deeper understanding of the nature of the inversion barrier of disilyldiphosphanes, ab initio calculations for a small series of representative species, RHPPHR with R = H, Me, $CMe_3$, $SiH_3$, $Si(SiH_3)_3$ and $Si(SiMe_3)_3$, have been performed at the B3LYP/6-31G* level of theory. Optimized transition structures were evaluated on the basis of the analysis of vibration modes at the same level of theory.

An interesting feature of the inversion of these diphosphanes is the occurrence of two alternative, diastereomeric transition structures which we term *anti* and *syn* as they differ by the dihedral angle between the lone pair of electrons at the pyramidal P atom and the P–H bond of the planar (inverting) P atom. Schematic drawings of these structures are presented in Figure 4, and relative energies as well as Mulliken charges of the phosphorus atoms are summarized in Table 2. The reader may note that the *anti* TS of diphosphane $P_iRH–P_pRH$ with the (*R*) configuration at $P_p$ is enantiomeric to the *anti* TS of the corresponding diphosphane with the (*S*) configuration at $P_p$. Therefore, the energy of the *anti* TS and the *syn* TS in Table 2 are independent of the chirality at $P_p$.

For small substituents R = Me and $SiH_3$, the *syn* transition structure is preferred, as seen from Table 2. With increasing bulkiness of the substituent [R = $CMe_3$, $Si(SiH_3)_3$ and $Si(SiMe_3)_3$], the *anti* transition structure with an approximate 180° dihedral angle between the lone pair of electrons at the pyramidal phosphorus and the P–H bond at the inverting P atom becomes lower in energy. Although the preference for the *anti* structure for large R groups is sufficiently explained by steric arguments, the preference for the *syn* geometry in the case of R = methyl is due to conjugation of the lone pair of electrons at the pyramidal P atom with the antibonding $\sigma(P_iH)$ orbital.

| $SiH_3$ | 80.1 | *anti* | –0.07 | –0.32 | 104.8 | *eclipsed* | –0.33 |
| $SiH_3$ | 79.4 | *syn* | –0.06 | –0.33 | | | |
| $SiMe_3$ | 72.2 | *anti* | –0.12 | –0.35 | 96.6 | *eclipsed* | –0.38 |
| $SiMe_3$ | 75.5 | *syn* | –0.10 | –0.37 | | | |
| $Si(SiH_3)_3$ | 76.9 | *anti* | –0.02 | –0.27 | 103.6 | *gauche* | –0.29 |
| $Si(SiH_3)_3$ | 80.6 | *syn* | –0.02 | –0.28 | | | |
| $Si(SiMe_3)_3$ | 74.8 | *anti* | –0.08 | –0.33 | 98.9 | *gauche* | –0.36 |
| $Si(SiMe_3)_3$ | 97.2 | *syn* | –0.08 | | | | |

With a value of 74.8 kJ mol$^{-1}$, the calculated inversion barrier of **12** is in excellent agreement with the experimental value and also fits nicely into trends observed for various R substituents. As reported previously,[33] methyl substituents reduce the inversion barrier more than $PH_3$ does, which is due to electronic effects (σ-acceptor), and *t*Bu decreases the barrier because it destabilizes the steric effects in the pyramidal minimum structure. A distinct lowering of $\Delta E_{inv}$ occurs for a silyl group because of its σ-donor character. Additional steric effects in the minimum structure further reduce $\Delta E_{inv}$ in $H_2P$–$SiMe_3$. Noteworthy, further increase of the bulkiness of R in $H_2PR$ does not lower the barrier more than $H_2P$–$SiMe_3$. In general, donation from the substituent is reflected in the phosphorus charge in the transition state of all of the $H_2P$–$SiX_3$ molecules. The more negatively charged the P atom is in the TS, the lower the $\Delta E_{inv}$. To quantify these trends, results of the calculations for the monophosphanes $H_2PR$ (R = $CX_3$ or $SiX_3$) have been included in Table 2. Here again, transition structures for different R groups are observed which differ in the dihedral angle $\omega$ between a P–H and a C–X or Si–X bond, which we term *syn* ($\omega \approx 0°$) and *gauche* ($\omega \approx 60°$) as shown in Figure 5. For large R groups, the *gauche* TS is adopted.

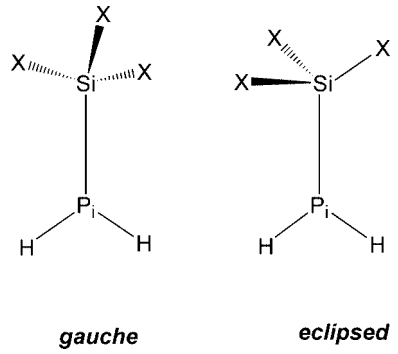

Figure 5. *Gauche* and *eclipsed* transition structures for monophosphanes $H_2PCX_3$ and $H_2PSiX_3$.

Diphosphanes can be considered as phosphanyl substituted monophosphanes. Because of the small electronegativity difference between H and P, $H_2PPHR$ and $H_2PR$ molecules should have similar inversion barriers, and 1,2-disilylated diphosphanes should have smaller inversion barriers, than those of $H_2PPH_2$ and the alkylated derivatives RHPPHR. To some extent, the results summarized in Table 2 confirm these expectations. Silyl substituents do lower $\Delta E_{inv}$, and the $PH_2$ substituent lowers it less than the silyl group $SiH_3$. Both effects ($PH_2$: –32 kJ mol$^{-1}$; $SiH_3$: –44 kJ mol$^{-1}$) are roughly additive, as can be seen for $SiH_3$–PH–PH–$SiH_3$. The calculated barrier is ≈ 80 kJ mol$^{-1}$, the predicted value is ≈ 73 kJ mol$^{-1}$.

## X-ray Crystallography

Compounds **3**, **4**, **12**, **13** and **14** were subjected to single-crystal X-ray analysis; details of the data collection and crystal data have been summarized in the Experimental Section. Selected bond lengths, bond angles and torsion angles are presented in Table 3.

The molecular structure of the 18-crown-6 salt of potassium phosphanide **4** and the arrangement of the molecules in the crystal is presented in Figure 6. Structural reports for potassium phosphanides are available for a small number of compounds only. Examples are K(thf)P($SiMe_3$)$_2$, which displays a ladder-type structure,[22] KHPSi*t*Bu$_3$,[34] polymeric KHPMes* (Mes* = 2,4,6-*t*Bu$_3$C$_6$H$_{12}$)[35] and dimeric [K(thf)$_2$P(2,4,6-Me$_3$C$_6$H$_2$)Si*t*Bu$_2$]$_2$.[36] Because of the large size of the hypersilyl group and the presence of 18-crown-6, each phosphorus atom in **4** is coordinated to one potassium atom only, which is different from the above-mentioned examples where coordination numbers two or three are observed. The potassium phosphorus distance (see Table 3) is 326 pm, which compares well with values between 320–360 pm which are reported in the literature. Each potassium atom, in addition to being coordinated to the P atom and the crown ether, has a contact [$d_{P-C}$ = 335pm] with a methyl group from the hypersilyl group of a

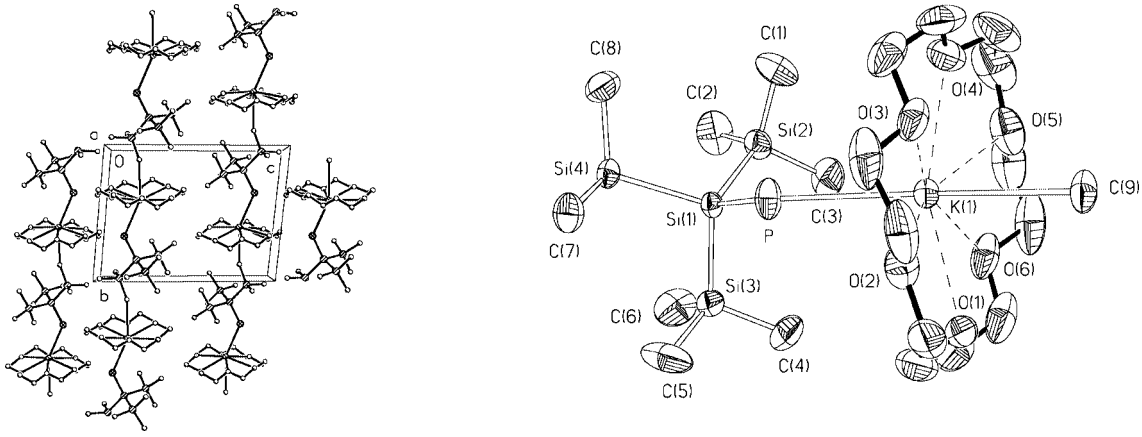

Figure 6. Molecular structure of the 18-crown-6 salt of **4** and arrangement in the crystal.

neighbouring molecule. The structure thus displays a zigzag chain $[PKC(H_3)SiSi]_n$ as shown in Figure 6. Noteworthy, the P–Si–Si angles within the hypersilyl group differ by not more than 5° from each other, which is due to the absence of steric strain. Moreover, the three Si–Si distances in the hypersilyl group are almost equal (233–234 pm), and they are the shortest compared those found for **3**, **12**, **13** and **14**.

The molecular structures of compounds **3**, **12**, **13** and **14** are presented together in Figure 7. The presence of two trimethylsilyl groups in **3** certainly increases the steric strain, which leads to quite long Si–P (231.6 and 228.7 pm) and Si–Si bonds (240.2–242.6 pm). The hypersilyl group is quite severely distorted from local $C_3$ symmetry, with P–Si–Si angles of 108.0°, 121.6° and 103.5°, respectively.

The strain in bis(hypersilyl)diphosphane **12** is considerably smaller than that in **3**, which results in shorter Si–P and Si–Si bonds and smaller variations in the P–Si–Si bond angles (Table 3). The two hydrogen atoms which are attached to the phosphorus atoms are located well inside the molecule and have no noticeable effect on the Si–P–P–Si dihedral angles that the diastereomers possess in the crystal form. Both the *meso*- and the D,L-diastereomers are present, which we corroborated by dissolving a single crystal in toluene and recording a $^{31}P$ NMR spectrum.

Despite the bulkiness of the substituents that diphosphanes **13** and **14** bear, the P–P bond lengths (220 and 216 pm, respectively) are in a range considered as normal. However, P–Si and Si–Si bonds are longer than those found for **4** and **12**. The X-ray structures together with the $^{31}P$ NMR spec-

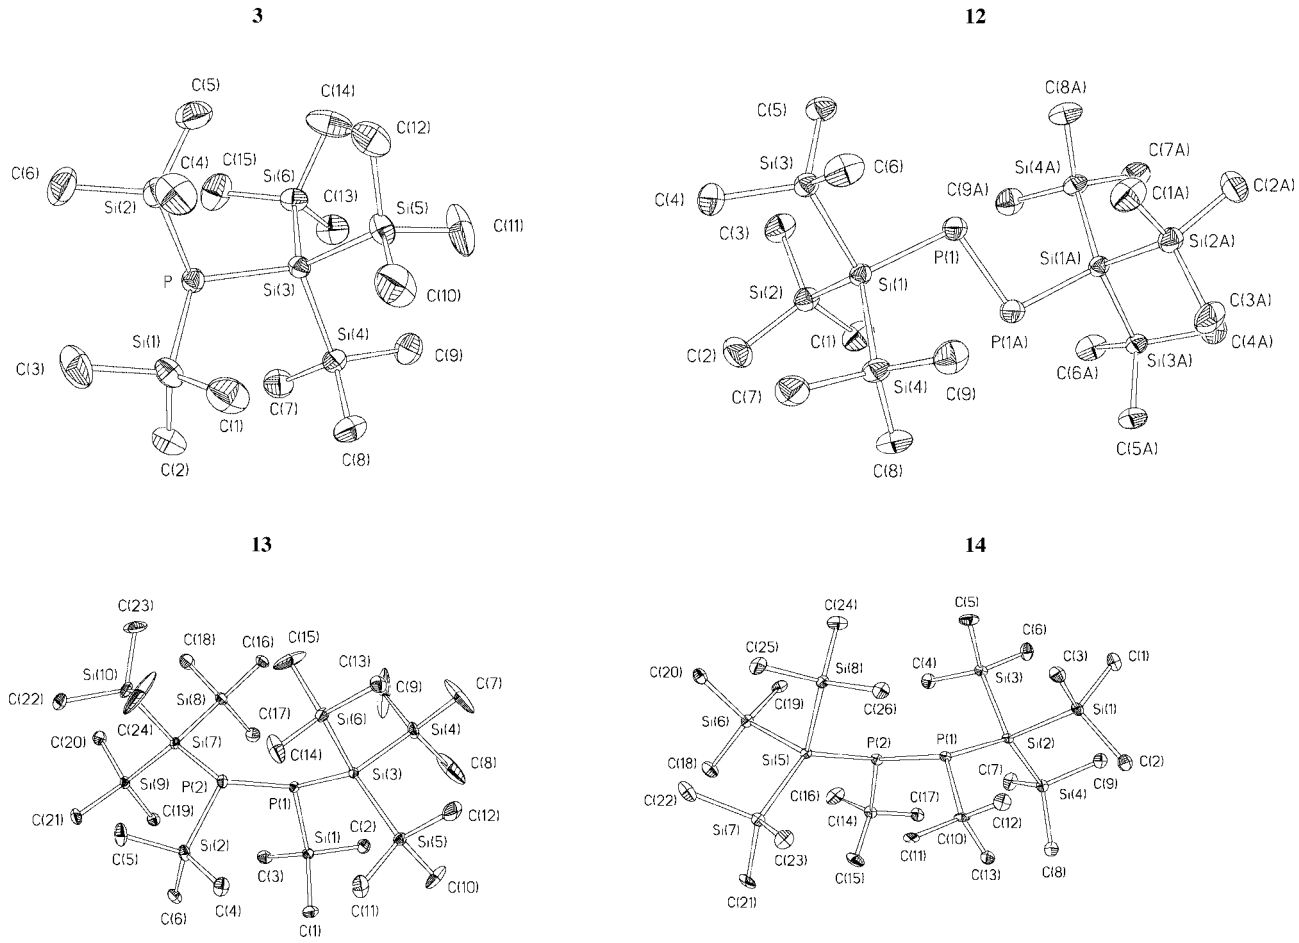

Figure 7. ORTEP plots (30% probabilities) of the molecular structures of **3**, **12**, **13** and **14**.

tra prove that it is the D,L-modifications which are formed exclusively. We were unable to detect even traces of the *meso*-diastereomers. Similar observations were made during the synthesis of $(SiMe_3)PhPPPh(SiMe_3)$, $(SiMe_3)t$BuPP$t$Bu$(SiMe_3)$ and $t$BuPhPPPh$t$Bu. All three diphosphanes display a single resonance in the $^{31}$PNMR spectrum, but it is not clear in all three cases whether it originates from the *meso*- or the D,L-diastereomers.[37]

## Experimental Section

**NMR Spectroscopy:** NMR spectra were recorded with a BRUKER MSL 300 or a VARIAN Unity Inova 300 spectrometer. The $^{29}$Si NMR and $^{31}$P NMR spectra of the samples were measured as solutions in THF or toluene in 10 mm tubes with capillaries of $D_2O$ to serve as an external lock.

**X-ray Structure Analysis:** The crystals were mounted onto the tip of a glass fibre, and the data collection was performed with a BRUKER-AXS SMART APEX CCD diffractometer. Graphite-monochromated Mo-$K_\alpha$ radiation (71.073 pm) was used for the measurements. The data were reduced to $F^2_o$ and corrected for absorption effects with SAINT and SADABS, respectively. The structures were solved by direct methods and refined by full-matrix least-squares method (SHELXL97). All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were located in calculated positions to correspond to standard bond lengths and angles. Relevant data are presented in Table 4. Because of the formation of thin plates, the quality of the structure data for **13** and **14** is poor. All attempts to obtain better crystals failed.

CCDC-605545 (for **3**), -605546 (for **4**), -605542 (for **12**), -605543 (for **13**) and -605544 (for **14**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Ab Initio Calculations:** For geometry optimization, the B3LYP/6-31G(d) method has been applied as implemented in the GAUSSIAN package programs.[38] In the population analysis, the Mulliken method was conducted for both phosphorus atoms.[39] Unless otherwise stated, the optimized structures are minima on the potential energy hypersurfaces (only positive harmonic frequencies at the B3LYP/6-31G(d)//B3LYP/6-31G(d) level). The considered transition structures, TS, were characterized by a single vibration mode of inversion character at phosphorus.

**General Remarks for the Syntheses:** All syntheses and manipulations were carried out under an inert atmosphere of either $N_2$ or Ar with the use of standard Schlenk techniques. Solvents were distilled from sodium, potassium, sodium–potassium alloy or $LiAlH_4$ prior to use. Amines such as $NEt_3$ were dried with molecular sieves. Elemental analyses were performed with a HERAEUS Vario Elementar.

**Synthesis of $HypPH_2$ (1) and $Hyp_2PH$ (2) from $NaPH_2$ and $(SiMe_3)_3SiCl$:** HypCl (13.6 g, 48.1 mmol) was dissolved in a mix-

ture of toluene (30 mL) and $Et_2O$ (30 mL). $NaPH_2$ (5.4 g, 96.2 mmol) was then added, and the suspension was heated at reflux for 2 d. $^{29}$Si NMR spectroscopy was used to monitor the consumption of HypCl. Upon completion, the liquid phase which contained **1** and **2** and traces of $Hyp_3P_7$ was separated from the salts (NaCl) by decantation. The solvent was then removed by evaporation in vacuo. From the oily residue, **1** was separated by fractional distillation, b.p. 65–68 °C (0.03 mbar). It solidified at room temperature to a colourless sticky wax. From the residue, **2** (1.4 g, 11%) can be obtained by sublimation in vacuo at a temperature of 120–125 °C. Compound **2** can also be prepared from HypPHK and HypCl in excellent yield (see later on). Yield of **1** 7.4 g (55%). $C_9H_{29}PSi_4$ (280.66): calcd. C 38.51, H 10.41; found C 38.70, H 9.70.

**Synthesis of $HypPH_2$ (1) from $PH_3$, $HOSO_2CF_3$, and $(SiMe_3)_3SiPh$:** $(SiMe_3)_3SiPh$ (10 g, 28.1 mmol) was dissolved in toluene (50 mL). The solution was cooled to –30 °C, and $CF_3SO_3H$ (4.21 g, 28.1 mmol) was added dropwise over a period of one hour. The reaction mixture was warmed up to room temperature and was stirred for another 2 h. Triethylamine (2.84 g, 28.1 mmol) was then added, and a moderate stream of $PH_3$ was passed through the solution. Immediately, a colourless oil of $[CF_3SO_3]^-[NHEt_3]^+$ formed. After completion, the solution of $HypPH_2$ was separated from the oil by decantation. The solvent then was removed by evaporation in vacuo, and **1** was purified by sublimation as described previously. Yield 75%.

**Synthesis of HypPHK (4):** Compound **1** (0.5 g, 1.80 mmol) was dissolved in toluene (10 mL) and cooled to –50 °C. With vigorous stirring, KO*t*Bu (0.22 g, 2.0 mmol) and 18-crown-6 (0.52 g, 2.0 mmol) was added with a spatula. The solution turned yellow/orange slowly. After 2 h, the reaction was complete. Product **4** crystallized from toluene at –80 °C in the form of yellow crystals that were suitable for X-ray analysis. Yield 0.38 g (≈ 60%).

**Synthesis of $Hyp_2PH$ (2) from 4 and HypCl:** Compound **4** (2.0 mmol; prepared from 0.6 g of **1** as described above) was dissolved in toluene (10 mL). The solution was vigorously stirred and a solution of HypCl (0.56 g, 2.0 mmol) in toluene (10 mL) was added slowly at a temperature of –40 °C. After one hour, the mixture was warmed up to room temperature. The liquid phase was separated from the salts by decantation. Sublimation in vacuo (0.03 mbar, 120–125 °C) afforded **2** (2.46 g, 80%) as a colourless waxy solid. M.p. 160 °C. $C_{18}H_{55}PSi_8$ (527.33): calcd. C 41.00, H 10.51; found C 39.79, H 9.94.

**Synthesis of HypPHLi (6):** $HypPH_2$ (1.67 g, 5.95 mmol) was dissolved in THF (20 mL) and cooled with ice to 0 °C. With constant stirring, *n*BuLi (5.95 mmol, hexane solution) was added with a syringe. The solution turned red slowly. Compound **6** (≈ 95%) was afforded, and traces of $(Me_3Si)_2PLi$, $Li_3P_7$ and $HypPLi_2$ (**7**) could be detected in the solution by $^{31}$P NMR spectroscopy.

**Synthesis of HypP(SiMe$_3$)K (5):** $HypP(SiMe_3)_2$ (1.28 g, 3.01 mmol) was dissolved in toluene (60 mL). The solution was cooled to –50 °C and KO*t*Bu (0.34 g, 3.03 mmol) and 18-crown-6 (0.80 g, 3.03 mmol) was added as a solid. The solution turned orange slowly. After two hours the reaction was complete. From analysis of the $^{31}$P NMR spectrum, a yield of ≈ 95% could be deduced. Minor byproducts were $HypPK_2$ and HypPHK.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Synthesis of HypP(SiMe$_3$)H:** HypP(SiMe$_3$)$_2$ (0.33 g, 0.78 mmol) was dissolved in toluene (60 mL). Dry *t*BuOH (0.06 g) was then added, and the reaction mixture was stirred for three weeks at room temperature. Analysis of the $^{31}$P NMR spectrum revealed a 1:1 mixture of HypP(SiMe$_3$)H and the starting material. If the reaction was heated at 100 °C under a vacuum of 0.03 mbar, HypP(SiMe$_3$)H was obtained as a waxy, colourless solid. $C_{12}H_{37}PSi_5$ (352.86): calcd. C 40.85, H 10.57; found C 39.70, H 10.33.

**Synthesis of HypPHHPHyp (12):** HypPH$_2$ (**1**) (12.1 g, 43.1 mmol) was dissolved in toluene (100 mL). With vigorous stirring, (*t*Bu)$_2$Hg (8.0 g, 26.0 mmol) was added at room temperature. The solution was then heated at 60 °C. After 2 h, a small quantity of mercury had formed and the colour of the solution had turned to a yellowish–green. At –80 °C, crystals of HypPHHPHyp precipitated as yellow needles. Yield 10.8 g (90%).

Alternatively, **1** (1.0 g, 4.0 mmol) was dissolved in toluene (15 mL) and solid KO*t*Bu (0.5 g, 4.5 mmol) and solid 18-crown-6 (1.2 g, 4.5 mmol) was added at –50 °C. The solution turned yellow slowly. After 3 h at –50 °C, $BrCH_2CH_2Br$ (0.43 g, 2.25 mmol) was added. The colour changed immediately to a yellowish–green. The solution was decanted from the salts and stored in a freezer at –80 °C where **12** (1.00 g, 90%) crystallized. $C_{18}H_{56}P_2Si_8$ (559.33): calcd. C 38.65, H 10.09; found C 37.60, H 9.41.

**Synthesis of Hyp(SiMe$_3$)PP(SiMe$_3$)Hyp (13):** HypP(SiMe$_3$)$_2$ (**3**) (1.00 g, 2.35 mmol) was dissolved in toluene (30 mL). With vigorous stirring, solid KO*t*Bu (0.30 g, 2.67 mmol) and solid 18-crown-6 (0.70 g, 2.65 mmol) was added at –50 °C. The solution turned yellow immediately. After three hours the reaction mixture was warmed up to room temperature. The solution of Hyp(SiMe$_3$)PK then was again cooled to –50 °C and $BrCH_2CH_2Br$ (0.25 g, 1.33 mmol) was added. The colour of the solution slowly turned green. After one hour, the salts were separated by decantation and the solution was stored in a freezer at –80 °C. Product **13** (0.62 g, 65%) crystallized as yellowish thin plates. $C_{24}H_{72}P_2Si_{10}$ (703.70): calcd. C 40.96, H 10.31; found C 41.40, H 10.26.

**Synthesis of Hyp(tBu)PP(tBu)Hyp (14):** *t*BuPClHyp (1.00 g, 2.70 mmol) was dissolved in toluene (20 mL). With vigorous stirring, K/Na alloy (5:1; 0.20 g, excess) was added with a syringe at room temperature. The solution was then heated at 80 °C for three hours. The liquid phase was the separated from the salts by decantation and stored at –80 °C in a freezer. Product **14** (0.73 g, 80%) was obtained as yellowish thin plates. $C_{26}H_{72}P_2Si_8$ (671.55): calcd. C 46.50, H 10.72; found C 45.48, H 10.11.

**Synthesis of HypPCl(SiMe$_3$) (8):** HypP(SiMe$_3$)$_2$ (**3**) (1.54 g, 3.62 mmol) was dissolved in toluene (20 mL). With vigorous stirring solid $C_2Cl_6$ (0.86 g, 3.63 mmol) was added. at room temperature. The reaction proceeds slowly and is complete after 24 h at room temperature. After removal of all volatile products by evaporation in vacuo, a nearly pure **8** (1.27 g, 92%) is obtained as a viscous yellowish oil. Further purification by sublimation turned out to be impossible as the compound decomposed quickly when warmed. Attempts to obtain crystals were unsuccessful. $C_{12}H_{36}ClPSi_5$ (387.30): calcd. C 37.21, H 9.37; found C 36.59, H 8.86.

**Synthesis of HypPCl$_2$ (10):** HypP(SiMe$_3$)$_2$ (**3**) (0.27 g, 0.64 mmol) was dissolved in toluene (20 mL) and solid $C_2Cl_6$ (0.35 g, 1.45 mmol) was added with a spatula. After 24 h at room temperature and under vigorous stirring, the reaction was complete. Analysis of the $^{31}$P NMR spectrum revealed that besides HypPCl$_2$ (≈ 70%), cyclotriphosphane P$_3$Hyp$_2$Cl (≈ 15%) and bis(hypersilyl)-bicyclotetraphosphane P$_4$Hyp$_2$ (≈ 15%) were also present in the reaction mixture. Attempts to isolate or purify **10** by fractional crystallization were not successful.

**Synthesis of HypP(SiMe$_3$)Br (9):** HypP(SiMe$_3$)$_2$ (**3**) (1.00 g, 2.35 mmol) was dissolved in toluene (30 mL) and solid $BrCl_2CCCl_2Br$ (0.76 g, 2.35 mmol) was added with a spatula. After two hours at room temperature and vigorous stirring, the reaction was complete. All volatile products were then removed by evaporation in vacuo. Pure **9** (1.0 g, ≈ 100%) was obtained as a yellowish waxy solid. Further purification by sublimation was impossible due to decomposition. Attempts to obtain crystals were also unsuccessful. $C_{12}H_{36}BrPSi_5$ (431.75): calcd. C 33.38, H 8.40; found C 32.49, H 8.33.

**Synthesis of HypPBr$_2$ (11):** HypP(SiMe$_3$)$_2$ (**3**) (0.23 g, 0.54 mmol) was dissolved in toluene (10 mL) and solid $BrCl_2CCCl_2Br$ (0.35 g, 1.08 mmol) was added with a spatula. The colour of the solution turned a yellowish brown. After two hours at room temperature, the reaction was complete. All volatile products were removed by evaporation in vacuo to afford **11** (0.22 g, 95%) of as a yellow, viscous oil. Noticeable amounts of byproducts could not be detected in the analysis of the $^{31}$P NMR spectrum. $C_9H_{27}Br_2PSi_4$ (438.47): calcd. C 24.65, H 6.21; found C 22.87, H 5.26.

# Diastereopure Cationic NCN-Pincer Palladium Complexes with Square Planar $\eta^4$-*N,C,N,O* Coordination

**Silvia Gosiewska,[a] Sara Herreras Martinez,[a] Martin Lutz,[b] Anthony L. Spek,[b] Gerard van Koten,[a] and Robertus J. M. Klein Gebbink*[a]**

**Keywords:** Palladium / NCN-pincer / Amino acids / Ligand design / Hydrogen bonds

Neutral NCN-pincer palladium bromide complex **2** containing the monoanionic, enantiopure pincer ligand 2,6-bis{[(*S*)-2-hydroxymethyl-1-pyrrolidinyl]methyl}phenyl bromide (**1**) with bis-*ortho*-(*S*)-prolinol substituents was synthesized and isolated as a mixture of three stereoisomers [($S_N$,$S_N$,$S_C$,$S_C$), ($R_N$,$S_N$,$S_C$,$S_C$), and ($R_N$,$R_N$,$S_C$,$S_C$)] in a 1:1:1 ratio. Upon abstraction of the bromide ion from the unresolved mixture of **2**, single diastereoisomers of the cationic complexes [**3**]$BF_4$ and [**3**]$PF_6$, respectively, were formed with a unique $\eta^4$-*N,C,N,O* coordination mode of ligand **1**. X-ray crystal structure determination established the intramolecular $\eta^4$-*N,C,N,O* coordination of **1** to palladium where the typical *mer*-$\eta^3$-*N,C,N* pincer coordination is accompanied by coordination of one of the hydroxy groups of the (*S*)-prolinol moieties. The water molecule that was cocrystallized in the crystal structure of [**3**]$PF_6$ does not coordinate to palladium, but instead is involved in a hydrogen bonding network. The catalytic potential of both cationic complexes, [**3**]$BF_4$ and [**3**]$PF_6$, was tested in an aldol reaction of aldehydes with methyl isocyanoacetate to yield the oxazoline products as racemic mixtures.

## Introduction

Organometallic pincer complexes containing the terdentate, monoanionic ECE ligand, (ECE = [2,6-$(ECH_2)_2$-$C_6H_3$]$^-$, where E is a neutral two-electron donor such as $NR_2$, $PR_2$, $AsR_2$, OR, or SR; Figure 1), have attracted widespread interest in catalysis and materials science.[1] The M–C σ bond in these complexes is complemented and stabilized by coordination of the E-donors through a double *ortho*-metalation and results in relatively robust organometallic complexes. Coordination of the two donor E-substituents furthermore controls the accessibility and the electronic fine tuning of the metal. Another important feature of the pincer ligand system is the possibility to introduce stereochemical information at various positions of the pincer skeleton, for example, at the benzylic carbons of the pincer backbone,[2,3] on the donor unit E,[4–7] or a combination of both.[8] Especially in the case of NCN-pincer systems, the presence of stereogenic centers in the N-donor substituents offers facile synthetic access to chiral metal complexes.

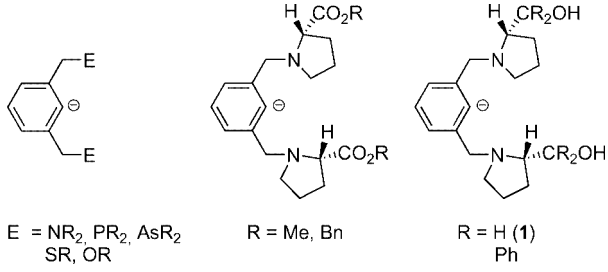

Figure 1. ECE pincer ligands.

Previously, we reported the synthesis and structural analysis of neutral and cationic palladium(II) complexes of monoanionic NCN-pincer ligands in which ester prolinate auxiliaries were used as the N-donor (Figure 1).[9] Depending on both the bulkiness of the prolinate ester substituents and the actual $\eta^3$-*N,C,N* or $\eta^4$-*N,C,N,O* coordination mode of the ligand, the palladium complexes were formed either as mixtures of three diastereoisomers or as single diastereoisomers both in the solid state and solution. These studies led us to develop a new class of enantiopure NCN-pyrrolidine ligands where the ester groupings were replaced by $CR_2OH$ groups (R = H, Ph; Figure 1). Here we present the synthesis of the ligand PhBr$(ProOH)_2$ (**1**), with R = H, and the studies of its coordination toward Pd. In order to probe the stereogenity at Pd in the resulting complexes, we have used these complexes as catalysts in the aldol reaction between benzaldehyde and methyl isocyanoacetate.

## Results and Discussion

### Synthesis

The ligand precursor PhBr(ProOH)$_2$ (**1**) was synthesized in a one-step procedure with the use of 2.5 equiv. of (*S*)-prolinol with respect to 1-bromo-2,6-bis(bromomethyl)benzene in a biphasic $CH_2Cl_2/H_2O$ system with 10% of $n$Bu$_4$NCl as a phase-transfer catalyst and $K_2CO_3$ as the base (Scheme 1).

According to this procedure, ligand precursor **1** was obtained in 58% yield after purification by column chromatography. Phase transfer catalytic conditions were used in order to obtain the desired product in higher yield, since under basic conditions ($Et_3N$) in $CH_2Cl_2$ the yield of **1** was only 24%. Arylpalladium complex **2** was synthesized under an inert atmosphere by the oxidative addition reaction of aryl bromide **1** with $[Pd_2(dba)_3]\cdot CHCl_3$ in degassed benzene at 50 °C. The product was isolated in 63% yield after purification by column chromatography (Scheme 1). $^1$H and $^{13}$C{$^1$H} NMR spectra of the isolated product showed a complicated peak pattern, which was interpreted to result from a mixture of three diastereoisomers in a 1:1:1 molar ratio. Reaction of this mixture of diastereoisomers of **2** with either $AgBF_4$ in acetone/water (10:1, v/v) or with aqueous $NH_4PF_6$ in methanol yielded the cationic complexes [**3**]BF$_4$ and [**3**]PF$_6$ in moderate to good yields (76 and 46%, respectively). Analysis of the NMR spectrum showed the formation of these complexes as single diastereoisomers (vide infra).

All compounds were characterized by $^1$H and $^{13}$C{$^1$H} NMR, IR spectroscopy, ESI-MS, and elemental analysis. The structures of complexes [**3**]BF$_4$ and [**3**]PF$_6$ were confirmed by X-ray crystal structure determination.

### Description of Crystal Structures of [3]BF$_4$ and [3]PF$_6$

Single-crystals suitable for X-ray diffraction were obtained by vapor diffusion of $Et_2O$ into a saturated solution of either [**3**]BF$_4$ in acetone or [**3**]PF$_6$ in $CH_2Cl_2$. Regrettably, all attempts to crystallize **2** failed. In the crystal structures, two independent molecules of both [**3**]BF$_4$ and [**3**]PF$_6$ are present which differ only in the conformation of the noncoordinated hydroxymethylene group of the ligand. One of the independent molecules of [**3**]BF$_4$ is shown in Figure 2, and Quaternion overlay plots of both cations of [**3**]BF$_4$ (left) and [**3**]PF$_6$ (right) are shown in Figure 3. Relevant bond lengths and angles are displayed in Table 1 and crystallographic details are listed in the Experimental Section. Both structures crystallize in chiral space groups and their absolute structure could be determined from the Flack parameter.[10] Besides the two cations of **3** and two $PF_6$ anions, one molecule of water also crystallizes in the asymmetric unit of [**3**]PF$_6$.

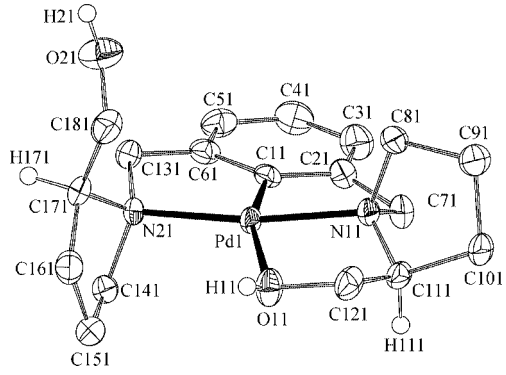

Figure 2. Displacement ellipsoid plot (50% probability) of cation [**3**]BF$_4$; hydrogen atoms of the hydroxy groups and of the stereogenic C-atoms are depicted; the remaining hydrogen atoms and noncoordinated $BF_4$ anions are omitted for clarity. Only one of two independent molecules is shown.

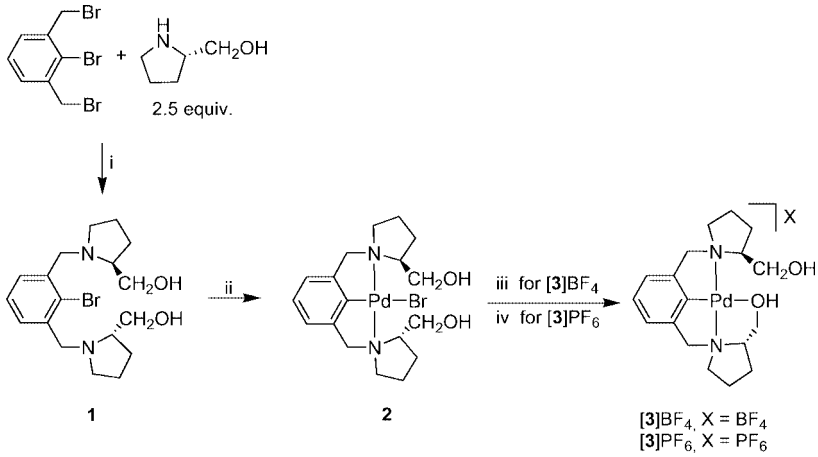
In all four molecules of [**3**]BF$_4$ and [**3**]PF$_6$, the coordinated nitrogen atoms have an ($R_N$) configuration, while the C-stereogenic centers have the expected ($S_C$) configuration. The two independent molecules of [**3**]BF$_4$ and [**3**]PF$_6$ have an essentially identical, four-coordinate $\eta^4$-*N*,*C*,*N*,*O*-ligand coordination around the palladium center that comprises C1, both N atoms, as well as the oxygen atom of one of the hydroxy groups. However, the noncoordinated hydroxy-



Scheme 1. Synthesis of compounds **1**–**3**. Conditions: (i) $K_2CO_3$, $n$Bu$_4$NCl, $CH_2Cl_2/H_2O$, reflux, 16 h; (ii) $[Pd_2(dba)_3]\cdot CHCl_3$, $C_6H_6$, 50 °C, 3 h; (iii) $AgBF_4$, acetone/$H_2O$, room temp.; (iv) $NH_4PF_6/H_2O$, $CH_3OH$, room temp.

methylene groups in [**3**]$BF_4$ and [**3**]$PF_6$ have different orientations. In the structure of [**3**]$BF_4$, both of these groups point towards the palladium center with Pd···O2 distances of 3.966(3) and 2.862(3) Å, whereas in [**3**]$PF_6$, both groups point away from the palladium center and have Pd···O2 distances of 4.680(2) and 4.639(2) Å. These differences result from the different hydrogen bond network that is present in both complexes. The Pd-coordination environment in these complexes, including bond lengths and angles, is very similar to that observed for structurally related cationic NCN-pincer palladium complexes containing methyl or benzyl prolinate substituents, where one carbonyl group of the ester moieties is coordinated to palladium (Figure 1).[9]

In cationic NCN-pincer complexes which do not contain additional donor atoms in the ligand, the *mer*-$\eta^3$-*N*,*C*,*N* coordination of the pincer ligand is complemented by an $\eta^1$-*O* water molecule.[11,12] Apparently, the intramolecular $\eta^1$-*O*-coordination of the hydroxy group of the ligand in [**3**]$BF_4$ and [**3**]$PF_6$ is preferred over water coordination. A water molecule is actually found in the crystal structure of [**3**]$PF_6$; it is however not coordinated to Pd, but instead is involved in a hydrogen bonding network. As a result of the extra $\eta^1$-*O* coordination of the hydroxy group of the ligand, the complexes [**3**]$BF_4$ and [**3**]$PF_6$ lack any element of symmetry, in contrast to the pincer [Pd(NCN)$(OH_2)$]$BF_4$ complexes which usually have an overall $C_2$ symmetry.[12] Importantly, both complexes [**3**]$BF_4$ and [**3**]$PF_6$ exist as single diastereoisomers with an ($R_N$,$R_N$,$S_C$,$S_C$) configuration.

Because of the presence of cocrystallized, noncoordinated water molecules in [**3**]$PF_6$, the hydrogen bond networks and hence the three dimensional structures are very different in the crystal structures of [**3**]$BF_4$ and [**3**]$PF_6$. The relevant distance and angles of the hydrogen bonds for [**3**]$BF_4$ and [**3**]$PF_6$ are shown in Table 2. In the structure of [**3**]$BF_4$, both coordinated and noncoordinated hydroxy groups donate hydrogen bonds, and thus, this results in four independent donor groups. Three fluoride atoms of the first $BF_4$ anion act as acceptors, whereas only one fluoride of the second $BF_4$ is a hydrogen-bond acceptor. This hydrogen bonding arrangement results in discrete aggregates consisting of four cations and four anions (Figure 4).

Table 2. Selected hydrogen bond lengths [Å] and angles [°] of complexes [**3**]$BF_4$ and [**3**]$PF_6$.[a]

| Complex | Donor–H···Acceptor | D–H | H···A | D···A | D–H···A |
|---|---|---|---|---|---|
| [**3**]$BF_4$ | O11–H11···F1$^{i}$ | 0.71(4) | 2.01(4) | 2.717(4) | 170(4) |
| | O12–H12···F8 | 0.76(4) | 1.95(4) | 2.693(3) | 166(4) |
| | O21–H21···F4$^{ii}$ | 0.97(4) | 1.84(6) | 2.777(4) | 161(5) |
| | O22–H22···F2 | 0.79(4) | 2.15(4) | 2.934(3) | 174(4) |
| [**3**]$PF_6$ | O21–H21O···F7$^{iii}$ | 0.71 | 2.53 | 3.043(4) | 131 |

[a] Symmetry operations: *i*: $x-0.5$, $y+0.5$, $z$; *ii*: $1.5-x$, $y+0.5$, $1-z$; *iii*: $1-x$, $y+0.5$, $-z$; *iv*: $1-x$, $y-0.5$, $1-z$; *v*: $1-x$, $y-0.5$, $-z$.

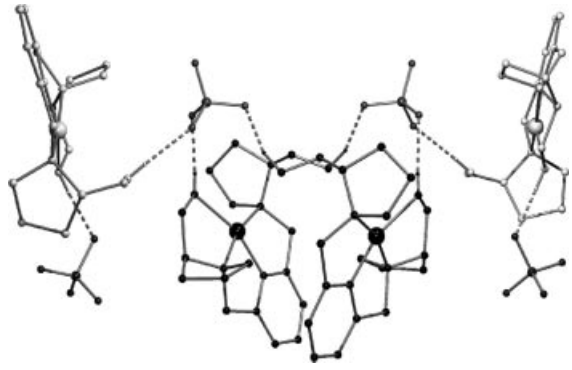

Figure 4. Hydrogen-bonded aggregate of four cations and four anions in [**3**]$BF_4$. Dashed lines indicate hydrogen bonds between the hydroxy groups as donors and the $BF_4$ anions as acceptors. C–H hydrogen atoms are omitted for clarity.

In the crystal structure of [**3**]$PF_6$, both coordinated hydroxy groups of the two independent molecules form intermolecular hydrogen bonds with the noncoordinated hydroxy groups as acceptors, which results in the formation of a hydrogen bonded dimer of two cations of [**3**]$PF_6$. The noncoordinated hydroxy group of the first molecule donates a hydrogen bond with a $PF_6$ fluoride as acceptor, while the noncoordinated hydroxy group of the second molecule forms a hydrogen bond with the water molecule as acceptor. The water molecule forms two hydrogen bonds

with $PF_6$ anions as acceptors. By means of these hydrogen bonds, an infinite two-dimensional network is formed in the crystallographic *b*,*c*-plane (Figure 5).

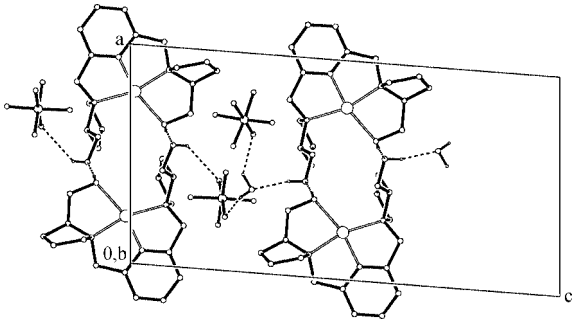

Figure 5. Infinite, two-dimensional hydrogen bond network in [**3**]$PF_6$ in the crystallographic *b*,*c*-plane. View along the *b* axis. Dashed lines indicate hydrogen bonds between the hydroxy groups and water molecules as donors and the $PF_6$ anions as acceptors. Note that the two cations of [**3**] form a hydrogen bonded dimer. C–H hydrogen atoms are omitted for clarity. Only one orientation of the disordered $PF_6$ anion is shown.

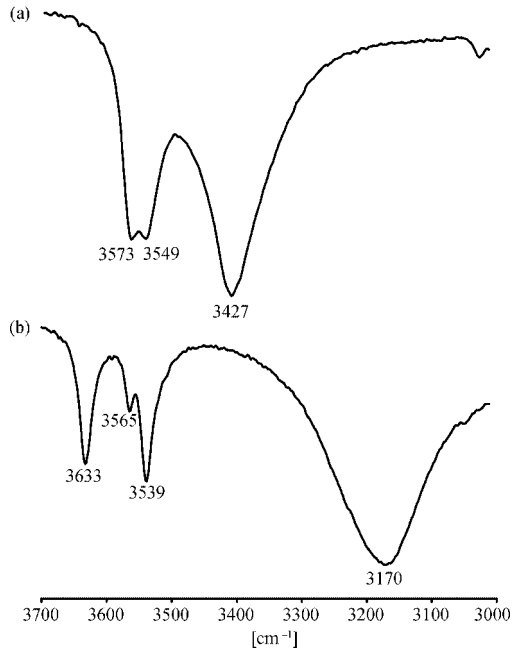

Figure 6. The *ν*(OH) valence vibration region of IR spectra of a) [**3**]$BF_4$ and b) [**3**]$PF_6$.

## IR Spectra

The different bonding nature of the hydroxy groups in **1**–**3** is reflected in their IR spectra in the region of the *ν*(OH) valence vibration. The broader *ν*(OH) band, which in the spectrum of ligand **1** is present at 3410 $cm^{-1}$, is slightly shifted to lower wavenumbers in palladium bromide complex **2** [*ν*(OH) 3383 $cm^{-1}$]. In the spectrum of [**3**]$BF_4$, two sharp vibrations at higher wavenumbers are observed (Figure 6a). The *ν*(OH) at 3427 $cm^{-1}$ is assigned to the vibration of a Pd-coordinated hydroxy group, whereas the second, split band [*ν*(OH) at 3549 and 3573 $cm^{-1}$] is assigned to the two different orientations of the noncoordinated hydroxy group as shown in the X-ray crystal structure.

In the spectrum of [**3**]$PF_6$, one broad vibration at 3170 $cm^{-1}$ and three sharp vibrations at higher wavenumbers appear (Figure 6b). The presence of water in the structure of [**3**]$PF_6$ is represented by the broad vibration at 3170 $cm^{-1}$. The other three *ν*(OH) bands were tentatively assigned to the hydroxy group of the ligands that are coordinated (at 3539 $cm^{-1}$) and noncoordinated (at 3565 and 3633 $cm^{-1}$) to Pd. The dissimilar wavenumbers and shape of the bands of the hydroxy groups that are observed in the IR spectra of [**3**]$PF_6$ compared with the *ν*(OH) in the spectrum of [**3**]$BF_4$ is a consequence of the different hydrogen bonding patterns that are found in the crystal structures of these two compounds. The dominant bands in the spectra of cationic complexes **3** are the typical vibrations belonging to the anions [i.e. $BF_4$ (986 $cm^{-1}$) and $PF_6$ (834 $cm^{-1}$), respectively].

## NMR Studies of Complexes 2–3

The $^1H$ and $^{13}C\{^1H\}$ NMR spectra of neutral complex **2** showed various resonance patterns pointing to the presence of a mixture of species. This observation is in line with those for neutral Pd-halide complexes derived from prolinate ester NCN-pincers.[9] In that case, a mixture of three diastereoisomers [($S_N$,$S_N$,$S_C$,$S_C$), ($R_N$,$S_N$,$S_C$,$S_C$), and ($R_N$,$R_N$,$S_C$,$S_C$)] is present in the temperature range of –80 °C to +95 °C. The $^1H$ and $^{13}C\{^1H\}$ NMR spectra were analyzed for these ester derivatives by applying a number of different one- and two-dimensional NMR techniques [$^1H$-$^1H$ COSY, $^1H$-$^{13}C$ HETCOR, $^1H$ NOESY, EXSY, and DEPT (angle) experiments]. On the basis of the structural similarity with these prolinate ester complexes, the $^1H$ NMR spectroscopic data of **2** were interpreted to result from a 1:1:1 mixture of three diastereoisomers (Figure 7). The ratio of the diastereoisomers of **2** was determined based on the resonances of the aromatic hydrogens ($C_{meta}$ to $C_{ipso}$), which are the only doublet resonances that are well-enough resolved (Figure 8). A full assignment of the $^1H$ and $^{13}C\{^1H\}$ NMR of **2** was not attempted because the aliphatic methylene groups of the pyrrolidine and hydroxymethylene moieties gave very complicated patterns and very similar shifts of the $^{13}C$ atoms.[14] The $^1H$ NMR spectrum of **2** measured in [$D_6$]benzene showed the best-resolved resonances, whereas in [$D_6$]acetone, broader resonances were observed.

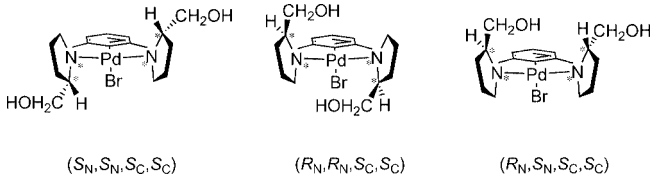

Figure 7. The three diastereoisomers of **2**; hydrogen atoms and the hydroxymethylene groups on the stereogenic carbon atom are depicted; the remaining hydrogen atoms are omitted for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

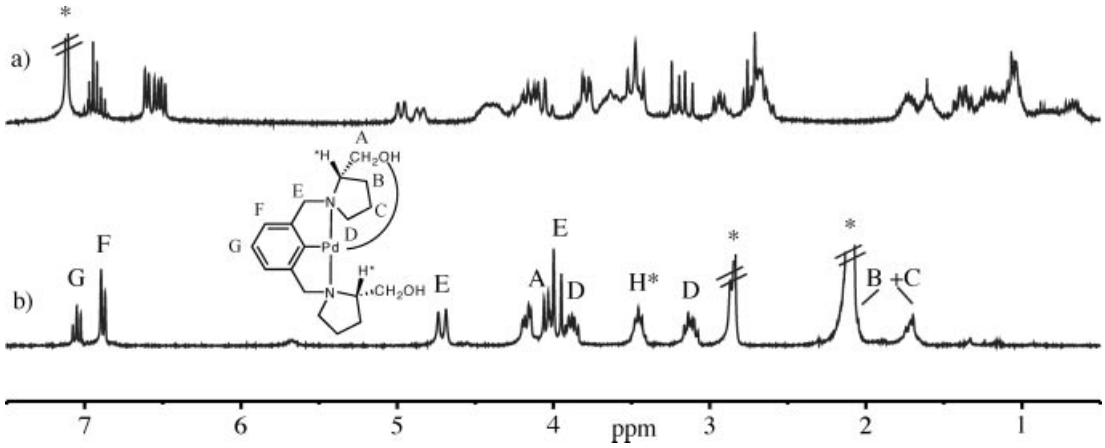

Figure 8. The $^1$H NMR spectra of a) **2** in [D$_6$]benzene and b) [**3**]BF$_4$ in [D$_6$]acetone with the assignment of the hydrogen atoms of the ligand for the cationic complex (asterisk denotes residual solvent peaks).

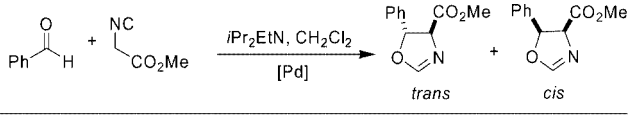
The formation of three isomers of neutral complex **2** is a consequence of the interconversion between the different diastereoisomers that is caused by dissociation of the Pd–N bond followed by pyramidal inversion at nitrogen, rotation, and recoordination. The $^1$H NMR spectrum of **2** (measured in [D$_6$]acetone) was temperature independent in the range between –80 °C to +50 °C, which indicates the presence of all three diastereoisomers in the 1:1:1 ratio in this temperature range. Apparently, the hydroxymethylene groups are too small to prevent the diastereoisomer interconversion even at lower temperatures, and sterically more hindered substituents seemingly have to be part of the pyrrolidine moieties in order to stabilize a single diastereoisomer of the neutral NCN-Pd-Br complex. Indeed, substitution of the hydrogen atoms of the hydroxymethylene group in **2** for phenyl groups resulted in the formation of a single diastereoisomer with the ($R_N$,$R_N$,$S_C$,$S_C$) configuration.[15]

The $^1$H and $^{13}$C{$^1$H} NMR spectra obtained for the cationic complexes [**3**]BF$_4$ and [**3**]PF$_6$ showed one, almost identical resonance pattern. The presence of only one species in the NMR spectrum ($^1$H NMR spectrum of [**3**]BF$_4$ is depicted in Figure 8; aliphatic hydrogen atoms were assigned with $^1$H-$^1$H COSY) and the information obtained from X-ray crystallography leads to the conclusion that a single stereoisomer with the ($R_N$,$R_N$,$S_C$,$S_C$) configuration is present, regardless of the ratio of stereoisomers in starting material **2**. Only in this ($R_N$,$R_N$,$S_C$,$S_C$) conformer, both hydroxymethylene groups point towards the palladium center and are within suitable distance for coordination to the metal (Figures 2 and 3). In the stereoisomers with the ($R_N$,$S_N$,$S_C$,$S_C$) and ($S_N$,$S_N$,$S_C$,$S_C$) configurations either one or both hydroxymethylene moieties point away from palladium; thus, they lack the dual intramolecular coordination ability and these stereoisomers are apparently less favored. In solution, fast exchange of the hydroxy group that is coordinated to the palladium center is anticipated in [**3**]BF$_4$ and [**3**]PF$_6$, and therefore, a resonance pattern in the $^1$H and $^{13}$C{$^1$H} NMR spectra that is consistent with an overall $C_2$ symmetry was observed for both complexes. No spectral changes were observed in their $^1$H NMR spectra in the range between –80 °C to +50 °C. Coordination of one of the hydroxy group to the metal seems crucial for the ultimate stereochemistry of the resulting cationic palladium complexes.

## Catalysis

In the course of this study, the catalytic potential of cationic complexes [**3**]BF$_4$ and [**3**]PF$_6$ was tested in the aldol condensation between aromatic aldehydes and methyl α-isocyanoacetate (MIC) in the presence of 10 mol-% of *i*Pr$_2$EtN at ambient temperature (Table 3). Both complexes were

Table 3. Aldol reaction of methyl α-isocyanoacetate with aldehydes catalyzed by [**3**]PF$_6$ and [**3**]BF$_4$.[a]



| Entry | Aldehyde | Complex | Conv. [%][b] | *trans*/*cis*[b] | *trans* (*ee*) (4*S*,5*R*)[c] |
|---|---|---|---|---|---|
| 1 |  | [**3**]PF$_6$ | 84 | 72/28 | <5 |
| 2 | | [**3**]BF$_4$ | 75 | 69/31 | <5 |

tested in the reaction with benzaldehyde (Entries 1 and 2). As [**3**]$PF_6$ gave the product in slightly higher yield, subsequent reactions with substituted aromatic aldehydes were performed with [**3**]$PF_6$ only (Table 3, Entries 2–5) as the catalyst. The highest *trans*/*cis* ratio and enantioselectivity for the *trans*-oxazoline product was obtained with naphthaldehyde as the substrate (Table 3, entry 5). In all cases, the *trans*-oxazoline derivative was obtained as the major product in good yields, albeit without significant enantioselectivity.

The preference for the *trans*-oxazoline product is commonly observed for achiral and chiral pincer complexes.[2b,3a,3c,5c,5k,5j,6a,16] Apparently, the pyrrolidine moieties with the hydroxymethylene groups are too small to generate a deep cavity around the palladium and the intermediate Pd-enolate complex and it is this cavity that would normally favor the formation of either one of the two enantiomers of the *trans*- or *cis*-oxazoline product.

## Experimental Section

**General:** (*S*)-Prolinol,[18] 2,6-bis(bromomethyl)-1-bromobenzene,[19] and [$Pd_2(dba)_3$·$CHCl_3$][20] were prepared according to previously published procedures. $^1H$ and $^{13}C\{^1H\}$ NMR spectra were recorded with a Varian Inova 300 spectrometer. Optical rotations were measured with a Perkin polarimeter 241. Elemental microanalyses were carried out by Microanalytisches Laboratorium Dornis und Kolbe, Mülheim a.d. Ruhr, Germany. The solid state infrared spectra were recorded with a Perkin–Elmer Spectrum One FTIR instrument. Mass spectrometry was carried out in a Voyager, Biosystems, MALDI-TOF. HPLC analyses were performed with a Perkin–Elmer Series 200 machine, equipped with a Diode Array II detector and LC pump with the use of a Daicel Chiracel OD column.

**2,6-Bis{[(*S*)-2-(hydroxymethyl)-1-pyrrolidinyl]methyl}phenyl Bromide (1):** (*S*)-prolinol (2.5 equiv., 30 mmol, 3 g) and bis(bromomethyl)-phenyl bromide (12 mmol, 4.1 g) were dissolved in $CH_2Cl_2$ (45 mL). Subsequently, to the reaction mixture was added $K_2CO_3$ (3 equiv., 36 mmol, 5 g) dissolved in water (45 mL) followed by the addition of $n$$Bu_4NCl$ (10 mol-%, 1.2 mmol, 0.33 g), and the mixture was vigorously stirred at reflux for 16 h. The organic layer was separated and the water layer was extracted with $CH_2Cl_2$ (2 × 30 mL). The solvent was evaporated in vacuo and the crude oil was purified by column chromatography [$SiO_2$, ethyl acetate/hexane = 5:1]. The product was obtained as a pale yellow solid in 58% yield (3 g). $C_{18}H_{27}BrN_2O_2$ (383.32): calcd. C 56.40, H 7.10, N 7.31; found C 56.29, H 6.93, N 7.24. MALDI-TOF: *m*/*z* = 383.33 [M + H]$^+$. $[\alpha]_D^{21}$ = –65.36 (*c* = 1.07, $CHCl_3$). IR: $\tilde{\nu}$ = 3410 (br), 2948 (s), 2872 (s), 2798 (m), 2758 (m), 1459 (m), 1446 (m), 1424 (m), 1403 (m), 1372 (m), 1351 (m), 1313 (w), 1264 (w), 1244 (w), 1194 (w), 1144 (w), 1113 (w), 1078 (m), 1048 (s), 1024 (s), 971 (w), 920 (w), 901 (w), 854 (w), 805 (w), 792 (w), 763 (w), 732 (m) cm$^{-1}$. $^1H$ NMR (300.1 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.70–1.77 (m, 4 H, C*$CH_2$C$H_2$ ring), 1.82–1.99 (m, 4 H, C*C$H_2$ ring), 2.30–2.39 (m, 2 H, NCH*H* ring), 2.77–2.83 (m, 2 H, C**H*), 2.96–3.02 (m, 2 H, NC*H*H ring), 3.41 (dd, AB, $^2J_{H,H}$ = 11.1 Hz, $^3J_{H,H}$ = 2.1 Hz, $^3J_{H,H}$ = 3.6 Hz, 2 H, C$H_2$OH), 3.70 (dd, AB, $^2J_{H,H}$ = 11.1 Hz, $^3J_{H,H}$ = 2.1 Hz, $^3J_{H,H}$ = 3.6 Hz, 2 H, C$H_2$OH), 3.55 (d, AB, $^2J_{H,H}$ = 13.5 Hz, 2 H, $^2J_{H,H}$ = 13.5 Hz, 2 H, ArC$H_2$N), 4.08 (d, AB, $^2J_{H,H}$ = 13.5 Hz, 2 H, ArC$H_2$N), 7.22–7.33 (m, 3 H) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CDCl_3$, 25 °C): $\delta$ = 23.85 (C*$CH_2$C$H_2$ ring), 27.82 (C*C$H_2$ ring), 54.93 (NC$H_2$ ring), 59.35 (ArC$H_2$N), 62.11 (C$H_2$OH), 65.04 (C*), 126.66 (*C*Br), 127.04 ($C_{para}$ to CBr), 129.93 ($C_{meta}$ to CBr), 139.18 (ArCCH$_2$N) ppm.

**2,6-Bis{[(*S*)-2-(hydroxymethyl)-1-pyrrolidinyl]methyl}phenylpalladium(II) Bromide (2):** Solid [$Pd_2(dba)_3$]·$CHCl_3$ (1.3 mmol, 1.39 g) was added to a solution of **1** (2.6 mmol, 1 g) in degassed benzene (60 mL). The resulting mixture was stirred at 50 °C for 3 h, filtered through Celite, and the solvent was evaporated in vacuo. Purification of the crude product by column chromatography [$SiO_2$, dba was eluted with hexanes/ethyl acetate = 1:1, the product with ethyl acetate/methanol = 5:1] yielded a yellowish solid in 63% yield (0.8 g). $C_{18}H_{27}BrN_2O_2Pd$ (489.74): C 44.14, H 5.56, N 5.72; found C 43.99, H 5.52, N 5.64. MALDI-TOF: *m*/*z* = 490.13 [M + H]$^+$, 410.22 [M – Br]$^+$. $[\alpha]_D^{21}$ = –10 (*c* = 0.6, acetone). IR: $\tilde{\nu}$ = 3383 (br), 2928 (s), 2877 (s), 1573 (w), 1459 (m), 1439 (m), 1429 (m), 1388 (w), 1352 (w), 1263 (w), 1094 (w), 1037 (s), 971 (m), 880 (w), 835 (w), 763 (m), 703 (w) cm$^{-1}$.

**2,6-Bis{[(*S*)-2-(hydroxymethyl)-1-pyrrolidinyl]methyl}phenylpalladium(II) Tetrafluoroborate ([3]$BF_4$):** Solid $AgBF_4$ (0.4 mmol, 80 mg) was added to a solution of **2** (0.4 mmol, 200 mg) in an acetone/water mixture (10:1, 20 mL). The reaction mixture was stirred for 30 min. The resulting suspension was filtered through Celite to yield a colorless filtrate. The solvent was removed in vacuo to leave the title compound as a white solid in 76% yield (153 mg). Crystals suitable for X-ray diffraction were obtained by slow diffusion of $Et_2O$ into an acetone solution of [**3**]$BF_4$. $C_{18}H_{27}BF_4N_2O_2Pd$ (496.74): C 43.53, H 5.48, N 5.64; found C 43.28, H 5.40, N 5.52. MALDI-TOF: *m*/*z* = 410.14 [M – $BF_4$]$^+$. $[\alpha]_D^{21}$ = +83.4 (*c* = 1.05, acetone). IR: $\tilde{\nu}$ = 3573 (m), 3549 (m), 4327 (m), 2973 (m), 2956 (m), 2929 (m), 2886 (m), 1585 (w), 1571 (w), 1461 (m), 1442 (m), 1430 (m), 1363 (w), 1340 (m), 1290 (w), 1270 (w), 1253 (w), 1228 (w), 1216 (w), 1077 (s), 1041 (s), 1010 (s), 986 (s), 955 (m), 899 (m), 861 (w), 842 (w), 823 (w), 761 (m), 701 (w) cm$^{-1}$. $^1H$ NMR (300.1 MHz, [$D_6$]acetone, 25 °C): $\delta$ = 1.64–1.68 (m, 6 H, C*$CH_2$CH*H* ring, C*C$H_2$ ring), 2.04–2.09 (m, 2 H, C*$CH_2$C*H*H ring), 3.08–3.16 (m, 2 H, NCH*H* ring), 3.43–3.46 (m, 2 H, C**H*), 3.88 (quintet, $^3J_{H,H}$ = 5.1 Hz, 2 H, NC*H*H ring), 3.94 (d, AB, $^2J_{H,H}$ = 11.7 Hz, 1 H, CH*H*OH), 4.23 (d, AB, $^2J_{H,H}$ = 11.7 Hz, 1 H, CH*H*OH), 3.98 (d, AB, $^2J_{H,H}$ = 11.4 Hz, 1 H, C*H*HOH), 4.24 (d, AB, $^2J_{H,H}$ = 11.4 Hz, 1 H, C*H*HOH), 3.92 (d, AX, $^2J_{H,H}$ = 14.7 Hz, 4 H, ArC$H_2$N), 4.69 (d, AX, $^2J_{H,H}$ = 14.7 Hz, 4 H, ArC$H_2$N), 5.67 (br. s, 1 H, OH), 6.84 (d, $^3J_{H,H}$ = 7.5 Hz, 2 H), 7.01 (t, $^3J_{H,H}$ = 8.1 Hz, 1 H) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, [$D_6$]acetone, 25 °C): $\delta$ = 21.24 (C*$CH_2$C$H_2$), 24.16 (C*C$H_2$ ring), 60.47 (NC$H_2$), 66.32 (ArC$H_2$N), 68.52 (C*), 69.87 (C$H_2$OH), 120.60 ($C_{meta}$ to $C_{ipso}$), 125.11 ($C_{para}$ to $C_{ipso}$), 146.89 (ArCCH$_2$N), 151.00 ($C_{ipso}$) ppm.

**2,6-Bis{[(*S*)-2-(hydroxymethyl)-1-pyrrolidinyl]methyl}phenylpalladium(II) Hexafluorophosphate ([3]$PF_6$):** An excess of $NH_4PF_6$ (1.5 g) in water (15 mL) was added to a solution of **2** (0.43 mmol, 213 mg) in methanol (15 mL), and the reaction mixture was stirred for 16 h at ambient temperature. Subsequently, water (15 mL) was added to the reaction mixture which resulted in the precipitation of the product. After filtration of the reaction mixture, the crude product was redissolved in acetone and precipitated with $Et_2O$ to afford the product as a light yellow solid in 46% yield (110 mg). Crystals suitable for X-ray diffraction were obtained by slow diffusion of $Et_2O$ into a dichloromethane solution of [**3**]$PF_6$. $C_{18}H_{27}F_6N_2O_2PPd$ (554.8): C 38.97, H 4.91, N 5.05; found C 39.10, H 4.98, N 4.94. MALDI-TOF: *m*/*z* = 410.27 [M – $PF_6$]$^+$. $[\alpha]_D^{21}$ = +77.4 (*c* = 0.5, acetone). **General Procedure for Aldol Condensation of Methyl α-Isocyanoacetate with Aldehydes:** To a solution of the palladium complex (0.016 mmol, 1 mol-%) in $CH_2Cl_2$ (5 mL) was sequentially added methyl α-isocyanoacetate (145 μL, 1.6 mmol), aldehyde (1.6 mmol), and diisopropylethylamine (28 μL, 0.16 mmol). The reaction mixture was stirred at ambient temperature for 24 h. Subsequently, the solvent was evaporated in vacuo, and $^1H$ NMR samples and HPLC samples were prepared. The yield and ratio of *cis*- and *trans*-isomers was determined by $^1H$ NMR and the enantiomeric excess by HPLC. The configurations of the *trans*- and *cis*-product were determined after separation of the *trans*/*cis* mixture (column chromatography, $SiO_2$, ethyl acetate/hexane = 1:2) by $^1H$ NMR analysis of the spectrum with the use of Eu(dcm)$_3$ as the chiral shift reagent.[23]

**X-ray Crystal Structure Determinations:** X-ray intensities were measured with a Nonius Kappa CCD diffractometer with a rotating anode (graphite monochromator, $\lambda$ = 0.71073 Å) up to a resolution of $(\sin\theta/\lambda)_{max}$ = 0.65 $Å^{-1}$ at a temperature of 150 K. The structures were solved with automated Patterson methods[21] ([**3**]BF$_4$) or Direct Methods[22] ([**3**]PF$_6$) and refined with SHELXL-97[23] against $F^2$ of all reflections. Geometry calculations and checks for higher symmetry were performed with the PLATON[13] program. CCDC-605998 (for [**3**]BF$_4$) and -605999 (for [**3**]PF$_6$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**X-ray Crystal Structure Determination of [3]BF$_4$:** $C_{18}H_{27}N_2O_2Pd{\cdot}BF_4$, *FW* = 496.63, yellowish hexagonal plate, 0.30 × 0.30 × 0.06 $mm^3$, monoclinic, C2 (no. 5), $a$ = 18.5640(1), $b$ = 10.7289(1), $c$ = 20.6534(2) Å, $\beta$ = 108.8572(3)°, $V$ = 3892.78(6) $Å^3$, $Z$ = 8, $D_x$ = 1.695 g/$cm^3$. Number of reflections measured: 37429. An absorption correction based on multiple measured reflections was applied ($\mu$ = 1.01 $mm^{-1}$, 0.72–0.94 correction range). Unique reflections: 8777 ($R_{int}$ = 0.052). Non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were located in the difference Fourier map. OH hydrogen atoms were refined freely with isotropic displacement parameters; CH hydrogen atoms were refined with a riding model. Number of parameters refined with one restraint: 521. *R*1/*wR*2 [$I > 2\sigma(I)$]: 0.0277/0.0620. *R*1/*wR*2 (all refl.): 0.0301/0.0647. $S$ = 1.033. Flack parameter[10] $x$ = –0.043(16). Residual electron density between –0.57 and 0.58 e/$Å^3$.

**X-ray Crystal Structure Determination of [3]PF$_6$:** $C_{18}H_{27}N_2O_2Pd{\cdot}PF_6{\cdot}0.5H_2O$, *FW* = 563.79, colorless block, 0.30 × 0.24 × 0.12 $mm^3$, monoclinic, $P2_1$ (no. 4), $a$ = 10.9459(10), $b$ = 9.2189(3), $c$ = 21.5229(9) Å, $\beta$ = 94.430(7)°, $V$ = 2165.4(2) $Å^3$, $Z$ = 4, $D_x$ = 1.729 g/$cm^3$. Number of reflections measured: 59398. An absorption correction based on multiple measured reflections was applied ($\mu$ = 1.00 $mm^{-1}$, 0.77–0.89 correction range). Unique reflections; 9936 ($R_{int}$ = 0.025). Non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were located in the difference Fourier map. OH hydrogen atoms were kept fixed on their located positions, CH hydrogen atoms were refined with a riding model. One $PF_6$ anion was orientationally disordered. Number of parameters refined with 415 restraints: 605. *R*1/*wR*2 [$I > 2\sigma(I)$]: 0.0203/0.0449. *R*1/*wR*2 (all refl.): 0.0246/0.0463. $S$ = 1.040. Flack parameter[10] $x$ = –0.031(15). Residual electron density between –0.34 and 0.44 e/$Å^3$.

# Thermal Evolution of a MgAl Hydrotalcite-Like Material Intercalated with Hexaniobate

Daniel Carriazo,[a] Cristina Martín,[a] and Vicente Rives*[a]

**Keywords:** Layered double hydroxides / Polyoxometalates / Nb-Mg-Al mesoporous oxides / Intercalations

A MgAl hydrotalcite-like material intercalated with hexaniobate has been prepared by the anion exchange method from the corresponding nitrate precursor; the sample and the oxides obtained upon its calcination were characterized by element chemical analysis, powder X-ray diffraction, thermal analyses (thermogravimetric and differential), nitrogen adsorption-desorption isotherms at –196 °C, transmission electron microscopy, and FT-IR and UV/Vis spectroscopy. The results show the formation of a microporous hydrotalcite-type solid with a gallery height of 7.2 Å where the $H_3Nb_6O_{19}^{5-}$ anions are oriented with their $C_3$ axes perpendicular to the layers. This material preserves its layered structure upon calcination up to 400 °C; calcination above this temperature causes decomposition of the hexaniobate and the layered structure collapses, giving rise to amorphous mesoporous solids (Nb-Mg-Al-O) with a large specific surface area (157 $m^2 g^{-1}$). At 800 °C crystallization of $Mg_4Nb_2O_9$ takes place. FT-IR studies on the acid-basic properties carried out by pyridine and 2-propanol adsorption, showed that all solids obtained through hydrotalcite calcination present Lewis-type acid and Brönsted-type basic sites.

## Introduction

Layered Double Hydroxides (LDHs), also known as hydrotalcite-like compounds or anionic clays, are lamellar materials generally described by the empirical formula $M^{2+}_{1-x}M^{3+}_x(OH)_2(A^{m-})_{x/m}\cdot nH_2O$, where $A^{m-}$ is the anion balancing the net positive charge of the brucite-like layers[1–3] developed by a partial $M^{2+}/M^{3+}$ substitution. A large number of compounds with this structure have been synthesized in the last decades varying the nature and the molar ratio of the cations in the layers and the nature of the interlayer anions. These compounds have shown their suitability in different fields, acting as anion scavengers in wastewater, biomolecule reservoirs or as polymer additives to improve its properties.[4–6] Nevertheless, there is no doubt that it is in the field of catalysis where they find the widest number of applications, as catalysts, catalyst precursors or supports.[7] These last applications are mainly due to the fact that calcination of the mentioned materials gives rise to systems constituted by different phases (mixed metal oxides) which usually show higher stability, larger surface development and longer life-time than others prepared by conventional methods.

Polyoxometalates (POMs) are anionic compounds with a cluster structure formed by linked oxygen octahedra coordinating transition metals (V, Mo, W, isopolyoxometalates), although in many cases a heteroatom (P, Si) in a tetrahedrally coordinated unit is included in the structure (heteropolyoxometalates).[8] These compounds have also deserved much attention because of the multiple applications they find in many different fields, such as medicine, materials science and catalysis.[9–11] POMs containing niobium have been scarcely studied and, contrary to those containing V, Mo or W, are synthesized under basic pH conditions.[12] The best-known niobium POM is hexaniobate ($Nb_6O_{19}^{8-}$), which has the Lindqvist structure, and is obtained through alkaline fusion of $Nb_2O_5$. Niobium compounds are extensively used in many heterogeneous catalytic processes where they can act as catalyst supports or as the active phase.[13]

In order to modify the textural properties and to develop acid and electron acceptor centres in the hydrotalcite basic structure and thereby improve its catalytic properties, many authors have reported the intercalation of different oxo- or polyoxometalates between the LDH layers,[14,15] giving rise to very selective catalysts in some oxidation reactions such as dehydrogenation or alkene epoxidation.[16–18] In a previous work Evans et al. reported the intercalation of some hexametalates with the Lindqvist structure [$V_2W_4O_{19}^{4-}$ and $Nb_xW_{6-x}O_{19}^{(x+2)-}$ where $x$ = 2, 3, 4] within the interlayers of hydrotalcite,[19] but a study of the intercalation of hexaniobate is lacking in the literature, and so herein we report the synthesis of a new MgAl LDH intercalated with hexaniobate ($H_3Nb_6O_{19}^{5-}$) prepared by anion exchange, starting from a nitrate LDH (MgAl-$NO_3$) precursor. Its characterization, as well as of the oxides obtained upon its calcination, by element chemical analyses, Powder X-ray Diffraction (PXRD), Thermogravimetric (TG) and Differential

[a] Weight percentage.

Thermal Analyses (DTA), nitrogen adsorption-desorption at –196 °C, Scanning and Transmission Electron Microscopy (SEM and TEM), and Fourier Transform Infrared (FT-IR) and Vis-UV spectroscopy are also reported. Crystalline potassium hexaniobate, which was synthesized for preparation of MgAl-hexaniobate LDH, has also been characterized and used as a reference. The acid-base properties of the solids obtained by calcination of the MgAl-hexaniobate LDH were tested by FT-IR spectroscopy after pyridine or 2-propanol adsorption.

## Results and Discussion

Element chemical analysis carried out for potassium hexaniobate as well as for both layered samples lead to the following formulae: $K_8Nb_6O_{19}\cdot 13H_2O$, $[Mg_{0.67}Al_{0.33}(OH)_2](NO_3)_{0.33}\cdot 0.44H_2O$ and $[Mg_{0.68}Al_{0.32}(OH)_2](H_3Nb_6O_{19})_{0.06}(CO_3)_{0.01}\cdot 0.70H_2O$, respectively (values have been rounded to two figures after the decimal point) (Table 1). This last formula has been calculated considering $H_3Nb_6O_{19}^{5-}$ as the interlayer anion since this is the predominant species at the pH conditions (12.5) at which the exchange process was performed.[13] The amount of interlayer water (0.70 molecules per LDH mol) has been determined from the TG curve (see below). The slight increase of the Mg/Al molar ratio from 2 (MgAl-$NO_3$) to 2.1 (MgAlNb) after the exchange process is probably due to a partial dissolution of the aluminum cations as aluminate as a consequence of its amphoteric character and the extremely high pH used during the exchange process to stabilize the niobium POM, although this small difference could also be ascribed to the experimental error of the technique.

It should be mentioned that different intercalation attempts, such as direct synthesis from metal nitrate salts or exchange using meixnerite (a MgAl LDH containing hydroxyl as the interlayer anion) as a precursor were tested and none of them produced the hexaniobate intercalation, the unique layered phase detected using these synthesis routes being hydrotalcite, MgAl-$CO_3$. Addition of the LDH-$NO_3$ as a slurry, as recommended by other authors to facilitate anion exchange,[20] was also unsuccessful, probably due to changes in pH leading to $Nb_2O_5$ precipitation.

Although the procedure followed to synthesize potassium hexaniobate is described in the literature to produce the single-protonated form, element chemical analyses and the PXRD pattern in Figure 1, from comparison with the JCPDS file 14-0288, confirm that the niobium polyoxometalate formed in this case was octo-potassium hexaniobate ($K_8Nb_6O_{19}\cdot 13H_2O$). To study its thermal stability the PXRD patterns of the products obtained upon its calcination at different temperatures were recorded and are also shown in this Figure. As can be observed, potassium hexaniobate completely decomposes below 300 °C and two different crystallographic forms of potassium niobate, $KNbO_3$, have been identified, one at 300 °C and the other at 600 °C, matching with the 32-0821 and 32-0822 JCPDS files, respectively.

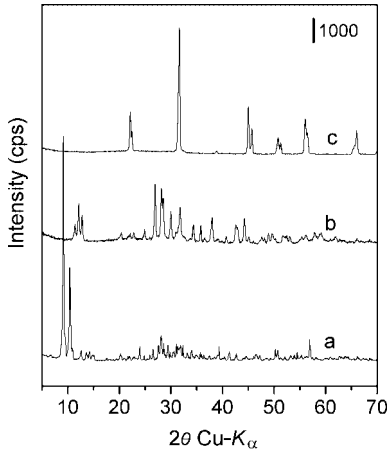

Figure 1. PXRD patterns of $K_8Nb_6O_{19}$ (a) uncalcined, and calcined at (b) 300 °C and (c) 600 °C.

The powder XRD patterns of sample MgAlNb, both original and calcined at increasing temperatures, are shown in Figure 2. The first one is characteristic of materials with the hydrotalcite-like structure in which the intercalation of hexaniobate has led to an increase in the basal spacing from 8.8 Å (corresponding to a phase with intercalated nitrate anions in an upwards configuration) to 12.0 Å, which means a gallery height of 7.2 Å, once the brucite-like layers width (4.8 Å)[21] is subtracted. This value is in agreement with the height of a hexaniobate anion, ($Nb_6O_{19}^{8-}$)[22,23] with its $C_3$ axis perpendicular to the layers (Figure 3). The basal spacing, usually measured from the $d_{003}$ diffraction peak (assuming a$R\bar{3}m$ layers stacking) was calculated in this sample from the positions of the peaks due to other basal planes, (006) and (009), recorded at 6.0 and 4.0 Å, respectively, because the peak due to (003) planes is partially hidden by a broad peak centred at 11 Å. The pattern is similar to that reported by different authors for other POM-LDHs systems.[20,21,24–31] Regarding the broad reflection between 10–12 Å some authors have claimed that it is produced by a poorly crystallized phase of a $M^{2+}/M^{3+}$-POM salt in low quantities,[20,26] while other authors have proposed different alternatives.[27–30] The unexpected low intensity of the peak due to diffraction by the (003) planes (weaker than the other two basal reflections recorded) is due to the presence

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of species (POMs) with high scattering factors in the interlayers.[29]

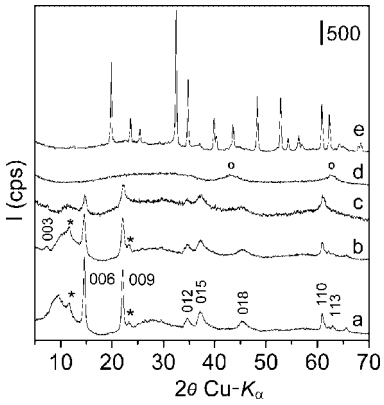

Figure 2. PXRD patterns of samples MgAlNb: (a) uncalcined and calcined at (b) 150 °C, (c) 300 °C, (d) 450 °C and (e) 800 °C. (*) MgAl-$CO_3$; (o) MgO. Miller indexes are labelled for the layered phase.

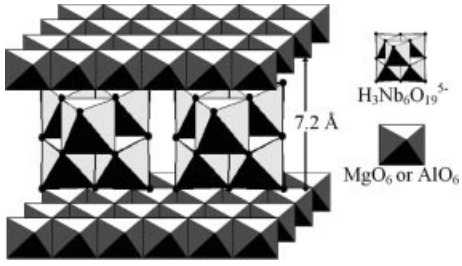

Figure 3. Scheme of MgAl LDH pillared with hexaniobate.

Additionally, and in agreement with the chemical analyses, a small amount of another layered crystalline phase, ascribed to hydrotalcite (MgAl-$CO_3$), is also present, even though extreme care was taken to avoid $CO_2$. This phase could have been formed during the exchange process due to the high affinity that these materials have towards carbonate under the strongly basic conditions (pH = 12.5) at which the reaction was carried out, or it could have been incorporated during post-synthesis treatments while the solid was still wet (during washing or drying processes).

The PXRD pattern recorded for the sample calcined at 150 °C (Figure 2, b) is rather similar to that recorded for the uncalcined one, but a decrease in the intensity of the broad peak centred at 11 Å allows the weak (003) reflection to be distinguished at the position expected (12 Å) taking into account the positions of the peaks due to diffraction by planes (006) and (009). The diffractograms are quite similar for samples calcined below 300 °C, although some differences are observed in the PXRD pattern of the sample calcined at 300 °C, Figure 2 (c); the reflections due to the MgAl-$CO_3$ phase have vanished, and a decrease in the intensities of all the peaks is also observed. The characteristic reflections due to planes (003), (006), (009) and (110) of a hydrotalcite-like material are still observed at 400 °C, which means that the POM ions hosted in the interlayers are thermally more stable than when they are isolated as a potassium salt (decomposition is observed at 300 °C). The PXRD pattern for the sample calcined at 450 °C, Figure 2 (d), is typical of an amorphous material, indicating that the layered structure has collapsed, giving rise to amorphous oxides for which the PXRD diagram shows only weak peaks at 2.1 and 1.5 Å ascribed to the MgO periclase phase (JCPDS file: 4-0829). Similar patterns are observed for samples calcined up to 700 °C, but at 800 °C the PXRD pattern (MgAlNb800, Figure 2, e) shows sharp diffraction maxima characteristic of a crystalline phase ascribed to magnesium niobate, $Mg_4Nb_2O_9$ (JCPDS file: 36-1381). No crystalline phase containing aluminum has been identified at any calcination temperature, suggesting that it must be well dispersed or forming amorphous phases. At these calcination temperatures, the niobium in excess which has not reacted with magnesium (Mg/Nb = 1.8) to form magnesium niobate must be, as well as aluminum, forming an amorphous phase, since no peaks corresponding to crystalline $Nb_2O_5$ were detected by PXRD.

The FT-IR spectra of potassium hexaniobate and of LDH-niobate (MgAlNb sample) are shown in Figure 4. Apart from the bands due to the LDH matrix, the spectra are very similar, suggesting that the hexaniobate structure is maintained after the exchange. Bands at 3462 $cm^{-1}$ (broad) and at 1640 $cm^{-1}$ for the potassium salt are due to the hydroxyl groups stretching mode and the bending mode of water molecules, respectively. The bands due to Nb=O and Nb–O–Nb stretching vibrations are recorded in the 900–400 $cm^{-1}$ range (844, 697, 528, and 415 $cm^{-1}$), in agreement with those previously reported elsewhere for this compound.[32] After intercalation into the LDH structure, bands ascribed to Nb–O stretching modes in hexaniobate units (844, 770, and 542 $cm^{-1}$) are still recorded, together with other bands at 664, 447, and 402 $cm^{-1}$ due to υ(Mg–O) and Mg/Al–OH translational modes of the layers.[33] Another band due to the $\nu_3$ mode of carbonate anions associated to the LDH-carbonate phase identified by XRD is clearly recorded at 1369 $cm^{-1}$.

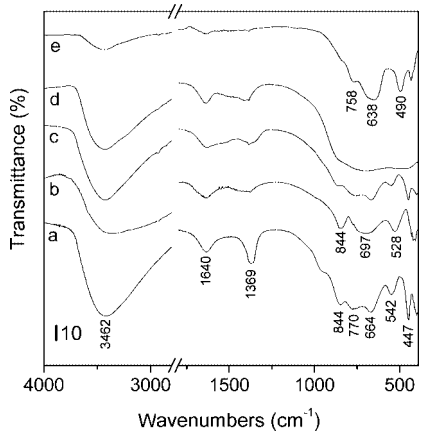

Figure 4. FT-IR spectra of MgAlNb (a) and calcined at (c) 250 °C, (d) 450 °C and (e) 800 °C; (b) FT-IR spectrum of potassium hexaniobate.

The small shift observed for some of the bands ascribed to the hexaniobate unit, when compared with their positions for the potassium salt, is presumably a consequence

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the interaction between the anion and the brucite-like layers.

The FT-IR spectra recorded for calcined MgAlNb samples are also included in Figure 4. Similar spectra to that recorded for the uncalcined sample are observed when the calcination is carried out up to 400 °C, and only an appreciable decrease in the intensity of the bands, especially the one due to carbonate, is observed, in agreement with the PXRD results.

Calcination at 450 °C gives rise to decomposition of hexaniobate and collapse of the layered structure, the spectrum showing a broad band in the 900–400 $cm^{-1}$ range, typical of amorphous oxide species. The spectrum is similar for samples calcined up to 700 °C, but when the solid is calcined at 800 °C, new bands at 758, 638, 490 and 432 $cm^{-1}$ characteristic of the $Mg_4Nb_2O_9$ phase, already identified in this solid by PXRD, develop.

The TG and DTA curves recorded for potassium hexaniobate and the MgAlNb sample are shown in Figure 5. Three thermal effects can be distinguished in the DTA curve of the potassium salt (dashed line in panel A); the first two (at 115 and 290 °C) are endothermic effects and correspond to removal of structural water, the second also coincides with potassium hexaniobate decomposition (observed from the PXRD at 300 °C) to potassium niobate. The exothermic effect recorded at 592 °C can be ascribed to transformation of $KNbO_3$ into another crystalline phase, also observed by PXRD. The TG curve (solid line in panel A) reveals that the structural water, which is the only volatile species in the sample, is lost in different steps. The weight losses represent ca. 16% of the total weight which means 13 water molecules per mol potassium hexaniobate.

Two well-resolved weight losses are recorded in the TG curve for sample MgAlNb (Figure 5B), although the DTA curve shows three endothermic effects; the first one, at 126 °C, can be ascribed to removal of surface adsorbed water. The second effect, at 265 °C is due to removal of interlayer water and the third, recorded at 443 °C, is a consequence of dehydroxylation of the brucite-like layers, matching with the hexaniobate decomposition into amorphous Mg-Al-Nb-O and water, as detected by FT-IR and PXRD between 400 and 450 °C.

Carbonate decomposition to $CO_2$ around 300 °C, as concluded by PXRD and FT-IR spectroscopy, can be partially included in the peak recorded at 265 °C, although its contribution to the weight loss is almost undetectable due to the low amount of $CO_3^{2-}$ present in the sample. Moreover, the peak at 126 °C could be partially due to the evaporation of some intercalated water, because water adsorbed on the external surface of the crystallites generally is totally evolved at 110 °C. This overlap does not allow ascribing accurately the weight loss to the different processes detected. Consequently, the amount of intercalated water given in the formula of the MgAlNb sample (0.70 molecules per mol of LDH) has been determined in an approximate way from the weight loss recorded between 110 and 270 °C.

The UV/Vis spectra (not shown) recorded for all samples show only an absorption band in the UV range, corresponding to a $Nb^{5+}\leftarrow O^{2-}$ charge-transfer process. A shift from 260 (potassium hexaniobate) to 245 nm (MgAlNb) is observed upon intercalation of hexaniobate in the LDH structure (Table 2). This small hypsochromic shift is probably due to the POM confinement within the layered host. No appreciable change is observed in the spectra of the calcined samples, where only a sharper absorption peak at 253 nm is recorded in the spectrum of the sample calcined at 800 °C (Table 2).

The nitrogen adsorption-desorption isotherm recorded for the MgAlNb sample, Figure 6, previously degassed at 120 °C for 2 h, is in between types I and II of the IUPAC classification,[34] characteristic of microporous solids. The specific surface area determined by the BET method is 24 $m^2 g^{-1}$ (Table 2), 40% of which corresponds to adsorption on micropores (as calculated from the t-plot)[35] and the external surface area corresponds to 14 $m^2 g^{-1}$. Layered double hydroxides intercalated with small anions are not microporous, as the width of the interlayer (ca. 3 Å) is not large enough to host nitrogen molecules. Interlayer micro-

Table 2. Specific surface areas ($S_{BET}$: BET method; $S_m$ microporous equivalent surface area, $S_{ext}$ external surface area and $V_t$ total pore volume) and position of the maximum in the UV/Vis spectra for potassium niobate and several layered samples (* determined from the *t*-plot).

| Sample | $S_{BET}$[a] | $S_m$[a]* | $S_{ext}$[a]* | $V_t$[b] | λ[c] |
|---|---|---|---|---|---|
| MgAl-$NO_3$ | 26 | – | 27 | 0.08 | – |
| MgAlNb | 24 | 10 | 14 | 0.06 | 245 |
| MgAlNb500 | 157 | – | 160 | 0.20 | 239 |
| MgAlNb800 | 45 | 6 | 39 | 0.12 | 253 |
| $K_8Nb_6O_{19}$ | 1 | – | – | – | 260 |

[a] $m^2 g^{-1}$. [b] mL $g^{-1}$ (determined at $p/p = 0.95$). [c] nm.

porosity only develops when the interlayers are swelled after intercalation of large anions with a large formal charge, rendering large spaces between them.

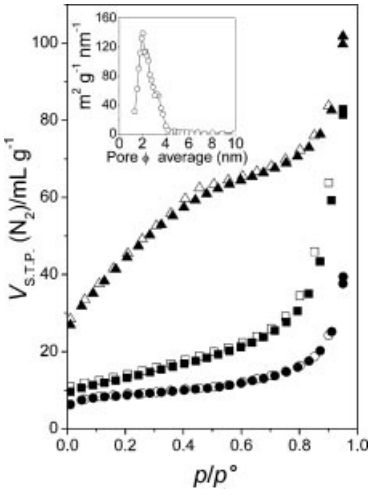

Figure 6. Nitrogen adsorption–desorption isotherms (filled symbols and open symbols, respectively) at –196 °C for the original sample MgAlNb (circles) and calcined at 500 °C (triangles) or 800 °C (squares). The inset shows the pore size distribution for sample MgAlNb500.

The isotherms recorded for the samples calcined between 450 and 600 °C are similar to each other and very different to that recorded for the MgAlNb sample. The isotherm for sample MgAlNb500 (Figure 6) can be classified as type IV, characteristic of mesoporous solids, since it shows a significant increase of the adsorbed amount at an intermediate relative pressure range, produced by a multilayer filling mechanism. The BET surface area for this sample shows an appreciable increase (157 $m^2 g^{-1}$) in comparison to that for the uncalcined one (Table 2). No adsorption on micropores was detected (the zero intercept of the t-plot approached zero) and the corresponding external surface area was calculated as 160 $m^2 g^{-1}$. The pore size distribution plot (Figure 6), shows a very intense and slightly asymmetric curve, which indicates that most of the pores have diameters ranging between 1.8 and 4 nm. A considerable increase in the pore volume (0.20 $cm^3 g^{-1}$) is also observed upon calcination. These textural properties change with calcination above 700 °C. Thus, the MgAlNb800 sample (Figure 6) shows an isotherm similar to that recorded for the pristine layered material. The BET surface area decreases to 45 $m^2 g^{-1}$, probably due to crystallization of magnesium niobate, $Mg_4Nb_2O_9$, (detected by PXRD), although it remains larger than that measured for crystalline potassium hexaniobate and its calcination products (between 1 and 2 $m^2 g^{-1}$), suggesting that other phases corresponding to aluminum-containing amorphous species also exist. For this sample a small fraction of micropores is also found.

Representative scanning and transmission electron micrographs (SEM and TEM) for calcined and uncalcined samples are shown in Figure 7 and Figure 8. At first sight, when potassium hexaniobate crystallizes from solution, enlarged prismatic-shaped crystals are formed. From the SEM micrographs it can be observed that these crystals have a hexagonal section (see parts a and b in Figure 7), and a closer view reveals small, smooth crystalline particles with sizes between 2 and 5 μm (Figure 7, c).

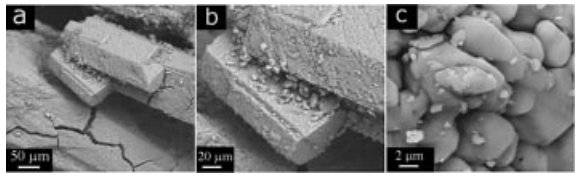

Figure 7. SEM pictures of potassium hexaniobate with different magnification.

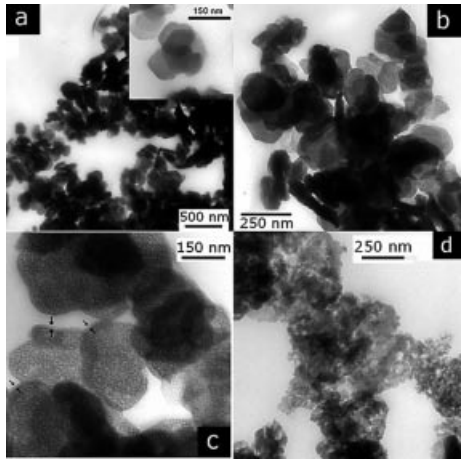

Figure 8. TEM pictures of the original sample MgAlNb (a), inset closer view and calcined at 500 °C (b, c) and 800 °C (d).

The typical hydrotalcite morphology, hexagonal platelet particles, is clearly observed by TEM for the as-synthesized MgAlNb sample (Figure 8, a). The size of the hexagonal crystals is ca. 100 ± 50 nm and their thickness 20 ± 10 nm. Calcination between 450 and 600 °C produces a smoothing of the particle edges (Figure 8, parts b and c), which are now more rounded than those observed for the uncalcined ones. A quite homogeneous pore distribution is simultaneously developed, in agreement with the results obtained by the nitrogen adsorption study. The particles are surrounded by an amorphous wall with a thickness of 10 nm (indicated by arrows in Figure 8, c).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

For the sample calcined at 800 °C (Figure 8, d) the morphology completely changes; aggregates of very small irregular-shaped particles (between 20 and 50 nm) are observed, indicating that the magnesium hexaniobate ($Mg_4Nb_2O_9$) phase (detected by PXRD and FT-IR), is well mixed or embedded in an amorphous phase (formed by Al-Nb oxides).

The textural and morphological properties observed for sample MgAlNb calcined between 450 and 600 °C have not been previously reported for LDH-POM calcined systems.[30,36,37] In these last cases, as well as for LDHs intercalated with permanent (nonvolatile) anions, a decrease in the surface areas is usually observed upon calcination. On the other hand, calcination of hydrotalcites intercalated with volatile anions ($CO_3^{2-}$, $NO_3^-$, etc.)[36,38] results in the development of porosity and, as a consequence, an enhancement of their surface areas. Different factors influence this process, such as the preparation method, nature of the metal ions in the layers, the sort of anion, etc., and it is ascribed to the evolved gases ($NO_2$, $CO_2$, $O_2$, etc.) produced upon anion decomposition, escaping through the crystal basal faces. However, in previous reports where TEM pictures of calcined hydrotalcites are shown,[36] no particles as well defined as in our case have been observed.

Because of the high basicity of the hexaniobate anion in comparison with other polyoxometalates (heptamolybdate or polyoxotungstates), a delay of the reaction between hexaniobate and the magnesium existing in the layers may be produced, enhancing its thermal stability, so POM decomposition and layer dehydroxylation take place in a narrow temperature range. This may be the reason why an amorphous solid (Mg-Al-Nb-O) with these special textural properties is formed.

### Acid-Base Properties

To gain insight into the surface properties of solid MgAlNb500 we have tested its acid-base properties by the adsorption of pyridine and 2-propanol monitored by FT-IR spectroscopy.

### Pyridine Adsorption

The FT-IR spectrum of the MgAlNb500 sample after pyridine adsorption at room temperature and outgassing at the same temperature is shown in part A of Figure 9; only bands at 1608, 1586, 1575, 1487 and 1443 $cm^{-1}$ are recorded, ascribed to modes 8a, 8b, 19a and 19b, respectively, of pyridine bonded to surface Lewis acid sites. The splitting observed for the band originated by mode 8a (1608, 1586 $cm^{-1}$) clearly shows the presence of two different types of surface Lewis acid sites on the surface of this solid. The positions of the bands are similar to those previously recorded upon adsorption of py on alumina, and so the bands here recorded should be ascribed to pyridine adsorbed on tetrahedrally (1608 $cm^{-1}$) or octahedrally coordinated (1586 $cm^{-1}$) $Al^{3+}$ cations,[39] although the first one could also be ascribed to py bonded to coordinatively unsaturated (cus) $Nb^{5+}$ ions, since its position coincides with that of the band recorded after adsorption of pyridine on $Nb_2O_5$.[40] When the outgassing temperature is increased up to 300 °C, Figure 9 (A), the intensity of the bands are markedly reduced, but they are still observed, indicating that the Lewis-type acid centres are strong.

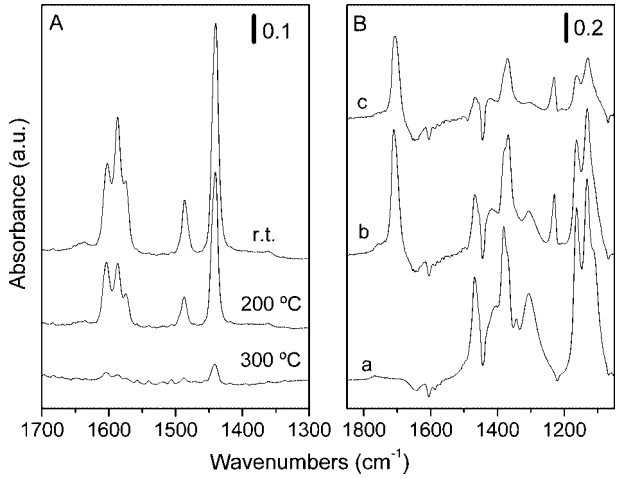

Figure 9. (A) FT-IR spectra of pyridine adsorbed at room temperature on MgAlNb500 and outgassing at the temperatures given (in °C); (B) FT-IR spectra of 2-propanol adsorbed at room temp. on MgAlNb500 (a) and heated at (b) 200 °C and (c) 300 °C.

The FT-IR spectrum of pyridine adsorbed on sample MgAlNb800 (not shown) is similar to that recorded upon adsorption on the sample calcined at 500 °C, where only Lewis acid sites are detected, but they are weaker than for the sample calcined at 500 °C, as they were removed after outgassing merely at 200 °C.

Some authors have reported the existence of Brönsted acid sites in niobium-containing samples when they are exposed to water,[41] but they were not observed in our samples; the FT-IR spectra recorded after adsorption of py on samples previously exposed in situ to water vapour are similar to that recorded for the unwetted samples.

### Isopropanol Adsorption

The FT-IR spectrum of 2-propanol (ISP) adsorbed on sample MgAlNb500 at room temperature is displayed in part B of Figure 9. It shows a broad band at ca. 3255 $cm^{-1}$ (not shown) which corresponds to new surface hydroxyl groups developed on the surface of the solid by a dissociative adsorption mechanism. Sharp bands at 2970, 2936, 2878, and 2728 $cm^{-1}$ correspond to stretching modes of the methyl group and the bands in the low wavenumbers region, at 1468, 1382, 1308, 1164, and 1135 $cm^{-1}$ [ascribed to $\delta(CH_3)$, $\nu(CO)$, and $\nu(CC)$], are characteristic of alcoholate species formed via dissociative adsorption of the ISP molecule. When the solid is heated in situ at increasing temperatures, Figure 9 (B), the intensities of the bands originated by the isopropoxide species decrease; new bands develop above 200 °C at 1709 and 1230 $cm^{-1}$, which correspond to $\nu(C{=}O)$ and $\nu_{as}(C–C–C)$ modes of acetone weakly coordinated through the oxygen atom of the carbonyl group to surface Lewis acid sites. The latter bands disappear upon outgassing at low temperature (100 °C). Adsorption of ISP

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

on sample MgAlNb calcined at 800 °C (not shown) gives rise to similar spectra, although the bands assigned to acetone are less intense.

ISP decomposition to acetone or propene is considered as a test reaction in the study of the acid-base and redox properties of metal oxide heterogeneous catalysts[42,43] since Brönsted acid sites are needed for propene formation via dehydration, while Lewis-type acid and basic, and redox centres are required for acetone formation via oxidative dehydrogenation, but only acid and basic sites if the acetone is produced via simple dehydrogenation. In our case, formation of acetone (detected by FT-IR) has to be produced through this last process, since temperature programmed reduction (TPR) studies carried out on our samples did not show any hydrogen consumption due to $Nb^{5+}$ reduction. The reaction may proceed through the following steps: (1) ISP is first dissociatively adsorbed on Lewis-type acid sites as an isopropoxide species and the proton is adsorbed on basic centres−surface exposed oxide anions−and (2) the abstraction of a second hydrogen atom from the alcohol takes place. On desorption, acetone and $H_2$ are the reaction products.

In summary, Lewis-type acid and Brönsted-type basic centres are present in the calcined samples.

## Conclusions

All the results reported here support the successful intercalation for the first time of hexaniobate between the MgAl brucite-like layers, rendering a new microporous layered material which retains its structure during calcination in air up to 400 °C, i.e., an enhancement in POM thermal stability is achieved upon its intercalation. Calcination at 450 °C produces dehydroxylation of the layered structure and POM decomposition, giving rise to amorphous mesoporous solids, with a large specific surface area (157 $m^2 g^{-1}$); further calcination at 800 °C leads to magnesium niobate crystallization which is embedded in an amorphous Nb-Al-containing phase. All calcined solids show surface Lewis-type acid and Brönsted-type basic sites, which are responsible for acetone formation by simple dehydrogenation of 2-propanol.

In addition to succeeding in preparing a novel, thermally stable MgAl-hexaniobate LDH, an amorphous mesoporous solid, Mg-Al-Nb-O, which seems suitable to be used as a catalyst support or adsorbent, was formed through its calcination between 450–600 °C.

## Experimental Section

All reagents were purchased from Aldrich and used without any further purification.

Potassium hexaniobate ($K_8Nb_6O_{19}·13H_2O$) was synthesized following a preparation method similar to that described elsewhere;[44] $Nb_2O_5$ (13.3 g, 50 mmol) was slowly added to a KOH (26 g, 394 mmol) melt in a nickel crucible; once the addition was completed the mixture was further heated for 30 min and then it was poured into decarbonated water (100 mL). After filtering the solution the volume was reduced to 50 mL and the solution was cooled overnight at 0 °C. The crystals that formed were filtered off and washed with a 1:1 (v/v) ethanol/water mixture and dried under vacuum in a desiccator.

The MgAl-$NO_3$ hydrotalcite−$Mg_2Al(OH)_6(NO_3)·1.33H_2O$−was prepared by coprecipitation from the corresponding metal nitrate salts, following a method previously described:[45] a solution formed by dissolving $Mg(NO_3)_2·6H_2O$ (12.8 g, 50 mmol) and $Al(NO_3)_3·9H_2O$ (9.4 g, 25 mmol) in water (150 mL) was added dropwise under nitrogen to $CO_2$-free water (150 mL). The pH was maintained close to 10 by simultaneous addition of a 2-M NaOH solution, and the mixture was stirred for 24 h at room temperature and then it was treated for five days at 70 °C under hydrothermal conditions in a Teflon-lined steel autoclave at autogenous pressure. The suspension was finally washed with decarbonated water, centrifuged and dried under vacuum.

The MgAl-hexaniobate LDH was prepared by anion exchange, by adding dry $Mg_2Al(OH)_6(NO_3)·1.33H_2O$ (1.0 g, 3.8 mmol) to a solution of $K_8Nb_6O_{19}·13H_2O$ (1.5 g, 1.1 mmol) in $CO_2$-free water (70 mL). The pH finally achieved was 12.5. The mixture was kept under nitrogen and refluxed at 90 °C for 6 h; the resulting solid was centrifuged and washed with boiling water and finally dried under vacuum in a desiccator. The sample obtained in this way is designated as MgAlNb, and the samples obtained upon calcination are labelled as MgAlNbT (where *T* is the calcination temperature in °C).

**Instrumentation:** Element chemical analyses were carried out in Servicio General de Análisis Químico Aplicado (University of Salamanca, Spain); Mg, Al and Nb were determined by atomic absorption in a Mark-2 EEL 240 apparatus, while carbon and nitrogen contents were determined with a CHNS 932 Leco analyzer.

The powder X-ray diffraction (PXRD) patterns were obtained with a Siemens D-500 diffractometer, using Cu-$K_{\alpha 1}$ radiation ($\lambda$ = 1.54050 Å).

Differential thermal analysis (DTA) and thermogravimetric (TG) analysis curves were recorded in DTA-7 and TG-7 instruments, respectively, from Perkin–Elmer. The analyses were carried out in flowing (30 mL $min^{-1}$) oxygen from L'Air Liquide (Spain) at a heating rate of 10 °C $min^{-1}$.

The nitrogen adsorption-desorption isotherms for specific surface area measurements were recorded at –196 °C in a Gemini instrument from Micromeritics. The samples were previously outgassed at 120 °C for 2 h. The pore size distribution plotted for MgAlNb500 was obtained from the Cranston and Inkley method.[46]

The UV/Vis spectra were recorded in the 200–1100 nm range with a Perkin–Elmer Lambda 35 apparatus equipped with a Labsphere RSA-PE-20 accessory by the diffuse reflectance technique; MgO was used as a reference.

Fourier Transform infrared spectra (FT-IR) were collected with a Perkin–Elmer FT-1730 instrument using the KBr pellet technique.

The FT-IR technique was also used to assess the surface acidity/basicity properties using pyridine or 2-propanol as probe molecules. These spectra were recorded with a Perkin–Elmer 16 PC spectrometer using self-supported discs; the sample was degassed in situ in a special cell[47] with $CaF_2$ windows at 400 °C for 2 h at $10^{-4}$ N $m^{-2}$, prior to the adsorption experiments. After degassing, the probe molecule vapour was adsorbed at room temperature and, in the case of pyridine (py), the spectra were recorded after outgassing at increase temperatures (from room temp. to 400 °C), while

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2-propanol (ISP) was adsorbed at room temp. and, without removing the gas phase, the solid was heated at increasing temperatures (100–400 °C).

Scanning electron micrographs (SEM) were obtained with a model 940 Digital Scanning-Microscope from Zeiss.

Transmission electron micrographs (TEM) were obtained with a Zeiss-902 apparatus equipped with a digital camera, the samples were prepared on a copper grid after evaporating a drop of sample dispersed in water.

# Alk-2-ynyl Trimethylsilyl Chalcogenoethers by Nucleophilic Substitution of Propargyl Bromides

**Deeb Taher,[a] Andrew I. Wallbank,[a] Elizabeth A. Turner,[a] Heather L. Cuthbert,[a] and John F. Corrigan*[a]**

**Keywords:** Chalcogens / Silicon / Propargyl complexes

Lithium (trimethylsilyl)chalcogenolates have been generated and used to prepare a series of alk-2-ynyl trimethylsilyl chalcogenoethers from the corresponding propargyl bromides in good yield. The thermal decomposition of the telluroethers has also been studied.

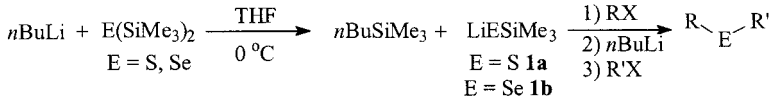
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

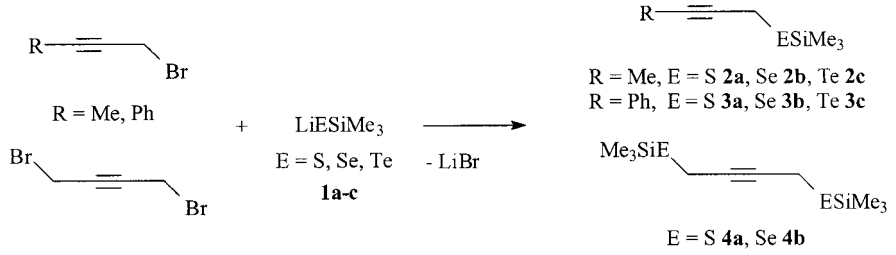
Trimethylsilyl chalcogenoethers of the general formula $RESiMe_3$ (R = alkyl or aryl, E = S, Se, Te) are a powerful class of reagents due to their demonstrated ability to react smoothly with metal salts (M–X) to form metal chalcogenolate cluster and nanocluster complexes $(M–ER)_x$, through the thermodynamically favorable elimination of $XSiMe_3$.[1–9] This includes their use in nanoparticle chemistry, where silylated reagents have been utilized to passivate the surface of metal chalcogenide cores.[10,11]

Despite their wide ranging utility, only a relatively limited number of $RESiMe_3$ reagents of the heavier congeners Se and Te have been reported, and this can likely be attributed to the difficulty of introducing the $Me_3Si$ moiety onto $RE^-$. For the elements Se and Te, this typically involves silylation reactions of salts RE-M[12–29] (M = Li, Na) or REMgX (X = Cl, Br) with $ClSiMe_3$.[30–33]

Segi and co-workers have reported a general route to asymmetric thio- and selenoethers by the in situ generation of $Me_3SiE^-$ nucleophiles from the silylated chalcogenides $E(SiMe_3)_2$ and alkyllithium reagents (Scheme 1).[34] Utilizing this methodology, we set out to combine the reactive lithium (trimethylsilyl)chalcogenolates with a series of propargyl bromides (Scheme 2). The coordination chemistry of both the chalcogen group(s) and the propargyl functionality could provide for a wide variety of structural types when complexed to metal centers.[35] In this paper, we report the preparation and spectral characterization of the series of



Scheme 1. Route to asymmetric chalcogenoethers as reported by Segi et al.[34]



Scheme 2.

Li[$ESiMe_3$] and its utility for the synthesis of propargyl chalcogenoethers. The chalcogenoethers have been characterized by nuclear magnetic resonance spectroscopy and

mass spectrometry, along with decomposition studies of the highly unstable tellurium congeners.

## Results and Discussion

The reagents $LiESiMe_3$ **1a**–**c**, provide ready access to reactive trimethylsilyl chalcogenolate fragments. Reported by Segi as reactive intermediates as part of a catalytic cycle,[39] the use of *n*BuLi and bis(trimethylsilyl) chalcogenide as the starting materials yields the desired product $[Me_3SiE]Li$ through reductive cleavage of the E–Si bond, without any complications due to formation of $Li_2E$.[40] The NMR chemical shifts of **1a**–**c** are reported in Table 1. In compounds **1a**–**c**, the chalcogen centers produce a downfield trend in the $^1H$ and $^{13}C$ chemical shifts and an upfield trend in the $^{29}Si$ NMR going from S < Se < Te. The $^{77}Se$ and $^{125}Te$ chemical shifts values of **1b** and **1c** are similar to those reported for related alkylsilylchalcogenolates[41] and are also close to the values reported for phosphane-stabilized copper trimethylsilylchalcogenolates.[42,43]

Table 1. NMR spectroscopic data for **1a**–**c** in $C_6D_6$. Chemical shifts are reported in ppm.

| | $-Si(CH_3)_3$ $^1H$ | $^{13}C$ | $^{29}Si$ | $^{77}Se/^{125}Te$ |
|---|---|---|---|---|
| **1a** | 0.58 | 7.32 | 7.22 | – |

Chalcogen-substituted propargyl complexes can be prepared from propargyl bromides and metal chalcogenolates,[44–52] although demonstrated radical routes have recently been documented for the preparation of propargyl selenols from diselenides.[53] The demonstrated clean conversion of $E(SiMe_3)_2$ to $[Me_3SiE]Li$ using *n*-butyllithium has allowed for the successful preparation of a range of chalcogenoethers from alkyl bromides, including 1-bromo-2-propyne (propargyl bromide).[34] Our attempts to isolate pure $HC{\equiv}CCH_2ESiMe_3$ under a variety of reaction conditions with either **1a** or **1b** were unsuccessful. On occasion, the desired product was isolated but in extremely low yield, due to either the acidity of the alkynyl proton or the general instability of any $HC{\equiv}CCH_2ESiMe_3$ formed.[50] Indeed, with all propargyl bromides $RC{\equiv}CCH_2Br$ used as the starting materials in this study, the $Me_3SiE^-$ anion proved to be too reactive under the conditions previously reported (thf, 0 °C) for the generation of selenoethers.[34] As nucleophilic displacements of this type are well known to proceed through the expected $S_N2$ reaction mechanism,[50] lower polarity solvents and low reaction temperatures were used to control the reaction. Propargyl–allenyl isomerization via a 1,3-hydride shift is quite common in chalcogen substituted propargyl complexes and in tellurium systems, the allenyl form is generally favored.[50] No evidence for isomerization was observed in this study. The lithium chalcogenolates **1a**–**c** are all soluble in hydrocarbon solvents, presumably due to the presence of the trimethylsilyl groups and the tightly bound thf molecules. Qualitatively, the reactivity of the lithium chalcogenolates increases on going from S < Se < Te and the reactivity of the propargyl bromides $RC{\equiv}CCH_2Br$ increases on going from R = Ph < Me < $BrCH_2$. Slight excesses of the lithium chalcogenolates were used in the preparation of **3a**,**b** and **4a**,**b** to ensure complete consumption of the starting propargyl bromides. The synthesis of **3a** and **4a** required refluxing temperatures of 65 °C and 35 °C, respectively, while the tellurium analogs **2c** and **3c** were not stable for extended periods of time at any accessible temperature, although dilute solutions maintained at –80 °C could be kept for 2 or 3 d before significant decomposition (as evidenced by the precipitation of tellurium metal) occurred. All of the compounds are highly water-, oxygen- and photosensitive. The sulfur and selenium derivatives are highly malodorous oils while the tellurium derivatives are obtained as yellow solids.

Selected NMR spectroscopic data are provided in Table 2. The $^1H$ chemical shifts of the methylene groups attached to the chalcogen centers show an upfield trend upon substitution by a heavier, less electronegative chalcogen while the trimethylsilyl resonances shift downfield. The chemical shifts of 3.05–3.25 ppm for the methylene group in the sulfur derivatives are upfield of those reported for S-aryl-substituted derivatives.[49,54] The $^{13}C$ chemical shifts of the methylene groups remain virtually constant upon varying R but are highly dependent on the chalcogen. The upfield shifts for the methylene carbons attached to selenium and tellurium are consistent with those observed previously[51,55] but were assigned conclusively by heteronuclear single-bond quantum correlation (HSQC) NMR spectroscopy techniques.

Table 2. Selected NMR spectroscopic data for **2**–**4** in $C_6D_6$. Chemical shifts are reported in ppm.

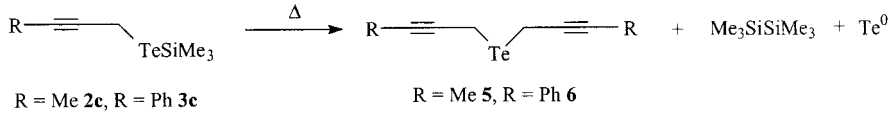
### Thermal Decomposition of 2c and 3c

Initial attempts at extending this chemistry to tellurium met with poor results as the reaction solutions rapidly decomposed to tellurium metal and colored tars. Maintaining the entire reaction at low temperatures resulted in beige-yellow solutions, which would decompose even at –25 °C. Although unstable, $RC{\equiv}CCH_2TeSiMe_3$ (**2c**, R = Me; **3c**, R = Ph) can be isolated provided reaction conditions are maintained below –40 °C. (Scheme 3) Although solid samples of **3c** decomposed significantly at –80 °C after 3 d, the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. Decomposition pathway of **2c** and **3c**.

slightly higher stability vs. **2c** allowed for its decomposition pathway to be studied. An aliquot of a reaction mixture of **3c** was isolated and dried (below –40 °C) and then, over a period of 5 d, the reaction flask was maintained at –25 °C and aliquots were taken and isolated at this temperature to monitor the reaction. $^{125}$Te NMR spectra showed clearly that **3c** ($\delta$ = –56.7 ppm) was converting cleanly to a new compound **6** ($\delta$ = +679.7 ppm) and observation of the flask indicated the presence of $Te^0$. Due to the wide range of $^{125}$Te chemical shifts for telluroethers (e.g. $Me_2Te$ $\delta$ = 0 ppm, $tBu_2Te$ $\delta$ = 999 ppm)[56] and ditellurides ($Me_2Te_2$ $\delta$ = 69 ppm, $MeTe_2tBu$ $\delta$ = 617 ppm)[57] a chemical shift value of +679.7 ppm is not diagnostic. The identity of the species as the telluroether $(PhC{\equiv}CCH_2)_2Te$ **6** could be inferred via the $^{125}$Te-$^1$H spectrum which displayed a quintet at +679.7 ppm ($^2J_{Te-H}$ = 29 Hz) in addition to a multiplet at $\delta$ = –56.7 ppm assigned to **3c**. A $^2J_{TeH}$ value of 29 Hz observed for the peak centered at +679.7 ppm is consistent with this structural assignment.[58] Mass spectra of partially decomposed solutions of **2c** and **3c** were obtained and parent ions for the telluroethers **5** and **6**, respectively, were observed. If samples of **5** and **6** are exposed to the air, further deposition of $Te^0$ is observed and GC-MS analysis of the supernatant displays predominantly the corresponding propargyl alcohol $RC{\equiv}CCH_2OH$. Attempts to synthesize an authentic sample of **6** via the reaction of two equivalents of 1-bromo-3-phenyl-2-propyne with $Na_2Te$ or $Li_2Te$[59] were unsuccessful in our hands due to the formation of the coupled product, 1,6-diphenylhexa-1,5-diyne. The ability of $Te^{2-}$ to couple allyl halides has been reported by Clive and co-workers[60] and is thought to proceed via homolytic fission of the telluroether initially formed. In their study, high reaction temperatures were required to force the elimination of the $Te^0$ but they found that the stability of the organic radical thus generated was the primary thermodynamic barrier. In the case of **6**, both radicals would be extremely delocalized and thus the dissociation may proceed easily. Similar, but more complex reaction mixtures were observed for the attempted synthesis of **5** from $M_2Te$.

## Experimental Section

All syntheses were carried out using standard inert atmosphere Schlenk and glovebox techniques. Bis(trimethylsilyl) sulfide,[36] bis(trimethylsilyl) selenide and bis(trimethylsilyl) telluride were synthesized according to the literature procedure reported for bis(trimethylsilyl) sulfide. 1-Bromo-3-phenyl-2-propyne, 1-bromo-2-butyne and 1,4-dibromo-2-butyne were synthesized from the corresponding propargyl alcohols using phosphorus tribromide.[37] *n*BuLi (1.6 M in hexanes) was used as received from Aldrich Chemical Co. Reaction solvents were dried by passing through packed columns of alumina using commercially available (MBraun) solvent drying towers. $C_6D_6$ was dried with Na/K alloy. Celite was dried under vacuum by heating at 100 °C for several days. NMR spectra were obtained with a Varian INOVA 400 MHz spectrometer. $^1$H and $^{13}$C spectra were referenced to internal solvent peaks relative to tetramethylsilane (TMS) at 0 ppm. $^{77}$Se{$^1$H} and $^{125}$Te{$^1$H} spectra were indirectly referenced to external $PhESiMe_3$ (+85.6, E = Se; +11.6, E = Te) relative to $Me_2E$ at 0 ppm.[26,38] $^{29}$Si spectra were obtained indirectly via a $^1$H{$^{29}$Si} heteronuclear multiple bond correlation (HMBC) pulse sequence with a magnetization transfer time of 83 ms (coupling constant of 6 Hz) and were referenced to internal silicone grease at –21.5 ppm relative to TMS at 0 ppm. Chemical Analyses were performed by Chemisar Laboratories Inc. (Guelph Ontario). Due to their sensitivity, elemental analyses were not possible for the Se/Te derivatives **2b–c**, **3c** and **4b–c**. Mass spectra and precise mass determinations were performed with a Finnigan MAT 8200 instrument. Gas Chromatography-Mass Spectrometry measurements were performed on a Varian CP-3800 Gas Chromatograph with a Varian Saturn 2000 GC-MS analyzer.

**Synthesis of $LiESiMe_3$ (1a–c):** In a modification of the published procedure,[34] bis(trimethylsilyl) sulfide (0.20 mL, 0.953 mmol) was diluted in tetrahydrofuran (THF, 20 mL) and cooled to 0 °C. *n*-Butyllithium (1.6 M in hexanes, 0.60 mL, 0.953 mmol) was added dropwise causing a slight yellow color to develop which faded as the addition was completed. The cooling bath was removed after 30 min and the reaction was stirred for a further 30 min. Removal of the solvent in vacuo afforded an oily white solid, **1a**.

The syntheses of **1b** and **1c** were performed by the same method, although the preparation of **1c** required cooling the reaction solution to –40 °C. While **1a** and **1b** were relatively stable under an inert atmosphere at ambient temperatures, **1c** began to decompose within an hour after drying and so was used immediately in further reactions.

**1a·0.84thf:** $^1$H NMR ($C_6D_6$): $\delta$ = 3.90 (thf), 1.50 (thf), 0.58 (–$SiMe_3$) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 68.81 (thf), 25.45 (thf), 7.32 (–$SiMe_3$) ppm. $^{29}$Si NMR: $\delta$ = 7.2 ppm.

**1b·0.88thf:** $^1$H NMR ($C_6D_6$): $\delta$ = 3.93 (thf), 1.50 (thf), 0.70 (–$SiMe_3$) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 68.99 (thf), 25.44 (thf), 7.87 (–$SiMe_3$) ppm. $^{29}$Si NMR: $\delta$ = 4.10 ppm. $^{77}$Se NMR: $\delta$ = –518.1 ppm.

**1c·3.4thf:** $^1$H NMR ($C_6D_6$): $\delta$ = 3.76 (thf), 1.48 (thf), 0.88 (–$SiMe_3$) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 68.69 (thf), 25.53 (thf), 9.71 (–$SiMe_3$) ppm. $^{29}$Si NMR: $\delta$ = –19.43 ppm. $^1$H NMR ([$H_8$]thf): $\delta$ = 0.33 (–$SiMe_3$) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 9.25 (–$SiMe_3$) ppm. $^{125}$Te{$^1$H} NMR: $\delta$ = –1294.3 ppm.

**Synthesis of 1-Trimethylsilylthio-2-butyne (2a):** A freshly prepared sample of $LiSSiMe_3$ (2.38 mmol) was dissolved in pentane (50 mL). The flask was covered with aluminum foil and cooled to –78 °C. A cold (–78 °C) solution of 1-bromo-2-butyne (0.32 g, 2.38 mmol) in hexane (10 mL) was added dropwise and the solution was stirred at low temperature for 2 h and then the bath was warmed. After stirring at room temperature for 5 h, a ubiquitous white suspension had formed. Reaction completion was confirmed by monitoring via GC-MS and the reaction solution was filtered twice over celite to ensure removal of LiBr. The solvent was removed in vacuo from

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the colorless filtrate to afford analytically pure **2a** as a colorless oil in 60% yield (0.23 g). $^1$H NMR ($C_6D_6$): $\delta$ = 3.10 (q, $^5J$ = 2.6 Hz, 2 H, –$CH_2$–), 1.47 ( t, $^5J$ = 2.6 Hz, 3 H, –$CH_3$,), 0.25 (s, 9 H, –$SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 78.42 (C≡C), 77.97 (C≡C), 14.44 ($CH_2$), 3.35 ($CH_3$), 0.79 (–$SiMe_3$) ppm. $^{29}$Si NMR: $\delta$ = 16.25 ppm. $C_7H_{14}SSi$ (158.3): calcd. C 53.10, H 8.91; found C 52.86, H 9.11. Exact mass: calculated 158.058549, found 158.058489.

**Synthesis of 1-Trimethylsilylseleno-2-butyne (2b):** A freshly prepared sample of $LiSeSiMe_3$ (2.31 mmol) was dissolved in pentane (50 mL). The flask was covered with aluminum foil and cooled to –78 °C. A cold (–78 °C) solution of 1-bromo-2-butyne (0.31 g, 2.31 mmol) in hexane (10 mL) was added dropwise and the solution was stirred at low temperature for 2 h. The bath was warmed and after stirring at room temperature for 2 h, a ubiquitous white suspension had formed. Reaction completion was confirmed by monitoring via GC-MS and the reaction solution and the reaction solution was filtered twice over celite to ensure removal of LiBr. The solvent was removed in vacuo from the filtrate to afford **2b** as a pale yellow oil in 94% yield (0.45 g).$^1$H NMR ($C_6D_6$): $\delta$ = 2.97 (q, $^5J$ = 2.6 Hz, 2 H, –$CH_2$–), 1.49 (t, $^5J$ = 2.6 Hz, 3 H, –$CH_3$), 0.32 (s, 9 H, –$SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 78.53 (C≡C), 78.41 (C≡C), 3.55 ($CH_3$), 2.53 ($CH_2$), 1.49 (–$SiMe_3$) ppm. $^{29}$Si NMR: $\delta$ = 14.3 ppm. $^{77}Se\{^1H\}$ NMR: $\delta$ = 2.1 ppm. Exact mass: calculated 206.002999, found 206.003044.

**Synthesis of 1-Trimethylsilyltelluro-2-butyne (2c):** A freshly prepared sample of $LiTeSiMe_3$ (2.34 mmol) was dissolved in pentane (50 mL) to give a beige solution due to slight decomposition of the $LiTeSiMe_3$. The flask was covered with aluminum foil and cooled to –78 °C. A cold (–78 °C) solution of 1-bromo-2-butyne (0.31 g, 2.34 mmol) in hexane (10 mL) was added dropwise and the solution was stirred at low temperature for 2 h to ensure reaction completion although a white solid was evident after 10 min. Attempts to confirm reaction completion by GC-MS failed as only a small amount of bis(trimethylsilyl) telluride was observed along with several unidentified organic compounds. The beige-yellow suspension was filtered at –78 °C through a cold bath jacketed filter and the receiver flask was also kept at low temperature. Removal of the solvent in vacuo at or below –40 °C afforded a **2c** as a yellow solid which decomposed significantly over a period of three days even when kept at –80 °C. $^1$H NMR ($C_7D_8$, –50 °C): $\delta$ = 2.80 (q, $^5J$ = 2.7 Hz, 2 H, –$CH_2$–), 1.45 (t, $^5J$ = 2.7 Hz, 3 H, –$CH_3$), 0.42 (s, 9 H, –$SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 79.88 (C≡C), 77.11 (C≡C), 5.19 ($CH_3$), 3.61 ($CH_2$), 2.31 (–$SiMe_3$) ppm. $^{29}$Si NMR: $\delta$ = –2.44 ppm. $^{125}Te\{^1H\}$ NMR: $\delta$ = –80.9 ppm.

**Synthesis of 3-Phenyl-1-trimethylsilylthio-2-propyne (3a):** A freshly prepared sample of $LiSSiMe_3$ (2.38 mmol) was dissolved in hexane (50 mL). The flask was covered with aluminum foil and cooled to 0 °C. A cold (0 °C) solution of 1-bromo-3-phenyl-2-propyne (0.44 g, 2.26 mmol) in hexane (10 mL) was added dropwise and the solution was stirred at low temperature for 1 h and then the bath was warmed. After stirring at room temperature for 1 h, the reaction was heated to reflux for 5 h by which time a ubiquitous white suspension had formed. Reaction completion was confirmed by monitoring via GC-MS and the reaction solution and the reaction solution was filtered twice over celite to ensure removal of LiBr. The solvent was removed in vacuo from the colorless filtrate to afford **3a** as a pale yellow oil in 75% yield (0.37 g). $^1$H NMR ($C_6D_6$): $\delta$ = 7.39 (m, 2 H, $H_{ortho}$), 6.97 (m, 3 H, $H_{meta/para}$), 3.25 (s, 2 H, –$CH_2$–), 0.25 (s, 9 H, –$SiMe_3$) ppm. $^{13}C\{^1H\}$: 131.81 ($C_{ortho}$), 128.55 ($C_{para}$), 128.20 ($C_{meta}$), 123.89 ($C_{ipso}$), 88.71 (C≡C), 83.03 (C≡C), 14.73 ($CH_2$), 0.89 (–$SiMe_3$) ppm. $^{29}$Si NMR: $\delta$ = 17.72 ppm. $C_{12}H_{16}SSi$ (220.4): calcd. C 65.39, H 7.32; found C 65.19, H 7.76. Exact mass: calculated 220.074199, found 220.074223

**Synthesis of 3-Phenyl-1-trimethylsilylseleno-2-propyne (3b):** A freshly prepared sample of $LiSeSiMe_3$ (2.31 mmol) was dissolved in pentane (50 mL). The flask was covered with aluminum foil and cooled to –78 °C. A cold (–78 °C) solution of 1-bromo-3-phenyl-2-propyne (0.43 g, 2.19 mmol) in hexane (20 mL) was added dropwise and the solution was stirred at low temperature for 2 h and then the bath was warmed. After stirring at room temperature for 3 h, a yellow solution with a ubiquitous white solid had formed. Reaction completion was confirmed by monitoring via GC-MS and the reaction solution and the reaction solution was filtered twice over celite to ensure removal of LiBr. The solvent was removed in vacuo from the yellow filtrate to afford **3b** as a yellow oil in 80% yield (0.47 g). $^1$H NMR ($C_6D_6$): $\delta$ = 7.41 (m, 2 H, $H_{ortho}$), 6.96 (m, 3 H, $H_{meta/para}$), 3.14 (s, 2 H, –$CH_2$–), 0.34 (s, 9 H, –$SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 131.78 ($C_{ortho}$), 128.54 ($C_{para}$), 128.11 ($C_{meta}$), 124.06 ($C_{ipso}$), 89.39 (C≡C), 83.18 (C≡C), 2.55 ($CH_2$), 1.51 (–$SiMe_3$) ppm. $^{29}$Si NMR: $\delta$ = 13.84 ppm. $^{77}Se\{^1H\}$ NMR: $\delta$ = 12.4 ppm. $C_{12}H_{16}SeSi$ (267.3): calcd. C 53.92, H 6.03; found C 53.83, H 5.85. Exact mass: calculated 268.018649, found 268.018393

**Synthesis of 3-Phenyl-1-trimethylsilyltelluro-2-propyne (3c):** A freshly prepared sample of $LiTeSiMe_3$ (2.34 mmol) was dissolved in pentane (50 mL) to give a beige solution due to slight decomposition of the $LiTeSiMe_3$. The flask was covered with aluminum foil and cooled to –78 °C. A cold (–78 °C) solution of 1-bromo-3-phenyl-2-butyne (0.46 g, 2.34 mmol) in hexane (20 mL) was added dropwise and the solution was stirred at low temperature for 2 h to ensure reaction completion although a white solid was evident after 10 min. Attempts to confirm reaction completion by GC-MS failed as only a small amount of bis(trimethylsilyl) telluride, along with several unidentified organic compounds, was observed. The beige-yellow suspension was filtered at –78 °C through a cold bath jacketed filter and the receiver flask was also kept at low temperature. Removal of the solvent in vacuo at or below –40 °C afforded a **3c** as a yellow solid. Solutions of **3c** decomposed slowly at –25 °C but were more stable at lower temperatures. $^1$H NMR (–80 °C, $C_7D_8$): $\delta$ = 7.39 (m, 2 H, $H_{ortho}$), 6.87 (m, 3 H, $H_{meta/para}$), 2.89 (s, 2 H, –$CH_2$–), 0.42 (s, 9 H, –$SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 131.49 ($C_{ortho}$), 127.86 ($C_{para}$), 125.01 ($C_{meta}$), 123.88 ($C_{ipso}$), 91.27 (C≡C), 81.67 (C≡C), 5.00 ($CH_2$), 2.21 (–$SiMe_3$) ppm. $^{29}$Si NMR: $\delta$ = –0.68 ppm. $^{125}Te\{^1H\}$ NMR: $\delta$ = –56.7 ppm.

**Synthesis of 1,4-Bis(trimethylsilylthio)-2-butyne (4a):** A freshly prepared sample of $LiSSiMe_3$ (2.38 mmol) was dissolved in pentane (50 mL). The flask was covered with aluminum foil and cooled to 0 °C. A solution of 1,4-dibromo-2-butyne (0.24 g, 1.13 mmol) in hexane (2 mL) was added dropwise and the solution was stirred at low temperature for 1 h. The bath was removed and after stirring at room temperature for 1 h, the reaction was heated to reflux for 3 h by which time a ubiquitous white suspension had formed. Reaction completion was confirmed by monitoring with GC-MS and the reaction solution and the reaction solution was filtered twice over celite to ensure removal of LiBr. The solvent was removed in vacuo from the colorless filtrate to afford **4a** as a light colored oil in 74% yield (0.22 g). $^1$H NMR ($C_6D_6$): $\delta$ = 3.05 (s, 2 H, –$CH_2$–), 0.24 (s, 9 H, –$SiMe_3$) ppm. $^{13}C\{^1H\}$: 81.13 (C≡C), 14.29 ($CH_2$), 0.83 (–$SiMe_3$); $^{29}$Si: 15.85 ppm. $C_{10}H_{22}S_2Si_2$ (262.6): calcd. C 45.74, H 8.44; found C 46.20. H 8.29. Exact mass: calculated 262.070150, found 262.070121.

**Synthesis of 1,4-Bis(trimethylsilylseleno)-2-butyne (4b):** A freshly prepared sample of $LiSeSiMe_3$ (2.31 mmol) was dissolved in pen-

tane (50 mL). The flask was covered with aluminum foil and cooled to –78 °C. A cold (–78 °C) solution of 1,4-dibromo-2-butyne (0.23 g, 1.09 mmol) in hexane (20 mL) was added dropwise and the solution was stirred at low temperature for 2 h. The bath was warmed and after stirring at room temperature for 2 h, a pale yellow solution with a ubiquitous white solid had formed. Reaction completion was confirmed by GC-MS and the reaction was filtered to remove the LiBr. The solvent was removed in vacuo from the colorless filtrate to afford **4b** as a pale yellow oil in 80% yield (0.31 g).

N.B. Extreme care to reduce exposure of this compound to ambient light is required as otherwise decomposition to an insoluble white solid occurs. $^1$H NMR ($C_6D_6$): $\delta$ = 2.96 (s, 2 H, –$CH_2$–), 0.32 (s, 9 H, –$SiMe_3$) ppm. $^{13}$C{$^1$H}: 81.87 (C≡C), 2.68 ($CH_2$), 1.87 (–$SiMe_3$) ppm. $^{29}$Si NMR: $\delta$ = 13.69 ppm. $^{77}$Se{$^1$H} NMR: $\delta$ = 4.0 ppm. Exact mass: calculated 357.959049, found 357.958961.

## Acknowledgments

We gratefully acknowledge the Natural Sciences and Engineering Research Council (NSERC) of Canada and the Academic Development Fund (UWO) for funding support. A.I. W. thanks the Government of Ontario for postgraduate scholarships (OGS, OGSST) and D. Hairsine and M.W. Degroot at UWO for the mass spectrometry work. H.L. C. and E.A. T. both thank the NSERC for a postgraduate scholarship.

# Glycol Methyl Ether and Glycol Amine Substituted Titanocenes as Antitumor Agents

**Katja Strohfeldt,[a] Helge Müller-Bunz,[a] Clara Pampillón,[a] Nigel J. Sweeney,[a] and Matthias Tacke*[a]**

**Keywords:** Anticancer drugs / *cis*-Platin / Titanocene / Super hydride / Lithiation / Titanium

6-[4-(2-Methoxyethoxy)phenyl]fulvene (**3a**) and 6-{4-[2-(dimethylamino)ethoxy]phenyl}fulvene (**3b**) were prepared as the starting materials for the synthesis of three different classes of titanocenes, which are *ansa*-titanocenes, diarylmethyl-substituted titanocenes and benzyl-substituted titanocenes. Because the synthetic possibilities seem to be limited, only *ansa*-titanocene {1,2-bis(cyclopentadienyl)-1,2-bis[4-(2-methoxyethoxy)phenyl]ethanediyl}titanium dichloride (**4a**) and benzyl-substituted titanocene bis-{[4-(2-methoxyethoxy)benzyl]cyclopentadienyl}titanium(IV) dichloride (**6a**) were obtained and characterised. The change in the substitution pattern of the phenyl moiety from an oxygen atom to a nitrogen atom had such a big influence on the reaction that not one compound of the three titanocene classes could be synthesised, and it was also not possible to obtain diarylmethyl-substituted titanocenes with the use of either of the fulvenes. When benzyl-substituted titanocene **6a** was tested against pig kidney cells (LLC-PK), an antiproliferative effect that results in an $IC_{50}$ value of 43 μM, was observed. This $IC_{50}$ value is in the lower range of the cytotoxicities evaluated for titanocenes up to now. *ansa*-Titanocene **4a** surprisingly showed, when tested on the same cell line, a proliferative effect together with a fast rate of hydrolysis.

## Introduction

The introduction of *cis*-platin into clinics in 1978 started a broad search for other cytotoxic metal complexes. Despite the resounding success of *cis*-platin and closely related platinum antitumor agents, the movement of other transition-metal anticancer drugs towards the clinic has been exceptionally slow.[1–3] In general, metallocene dichlorides ($Cp_2MCl_2$) with M = Ti, V, Nb and Mo show remarkable antitumor activity,[4,5] and titanocene dichloride, $Cp_2TiCl_2$, has especially become a very promising candidate as an anticancer drug. $Cp_2TiCl_2$ shows medium–high cytotoxicity in vitro and a high efficacy in the animal models. Unfortunately, the efficacy in Phase II clinical trials in patients with metastatic renal-cell carcinoma[6] or metastatic breast cancer[7] was too low to be pursued.

In order to increase the cytotoxicity of $Cp_2TiCl_2$, different highly substituted analogues were synthesised. Within this paper we introduce three different types of substituted titanocenes: *ansa*-titanocenes, diarylmethyl-substituted titanocenes, and benzyl-substituted titanocenes.

*ansa*-Titanocenes, which contain a carbon–carbon bridge, can be synthesised by reacting titanium dichloride with fulvenes.[8–19] By using this method we have synthesised {1,2-bis(cyclopentadienyl)-1,2-bis[4-(dimethylamino)-phenyl]ethanediyl}titanium dichloride (titanocene **X**), which showed an $IC_{50}$ value of $2.7 \times 10^{-4}$ M when tested for cytotoxic effects on the LLC-PK cell line.[16]

The diarylmethyl-substituted titanocene analogues were synthesized and they showed a significant increase in their cytotoxicity. These titanocenes can be obtained by a carbolithiation reaction of 6-arylfulvene with the corresponding aryllithium species followed by transmetallation with titanium tetrachloride.[20] With this new method, bis{bis[4-(dimethylamino)phenyl]methylcyclopentadienyl}titanium(IV) dichloride has been synthesised, which shows an $IC_{50}$ value of $3.8 \times 10^{-5}$ M when tested for cytotoxic effects on the LLC-PK cell line.[20]

A third method that is used for the preparation of benzyl-substituted titanocenes allowed for the synthesis of titanocene **Y**, which is so far our best titanocene in terms of cytotoxicity.[21] Bis-[(4-methoxybenzyl)cyclopentadienyl]-titanium(IV) dichloride (titanocene **Y**), which has an $IC_{50}$ value of $2.1 \times 10^{-5}$ M when tested on the LLC-PK cell line, was synthesised from fulvene and super hydride ($LiBEt_3H$) followed by transmetallation with titanium tetrachloride. The structures of the three mentioned titanocene classes are shown in Figure 1.

The first in vitro and ex vivo tests with titanocenes **X** and **Y** showed that prostate, cervix and renal cell cancer are prime targets for these types of titanocenes. Both titano-

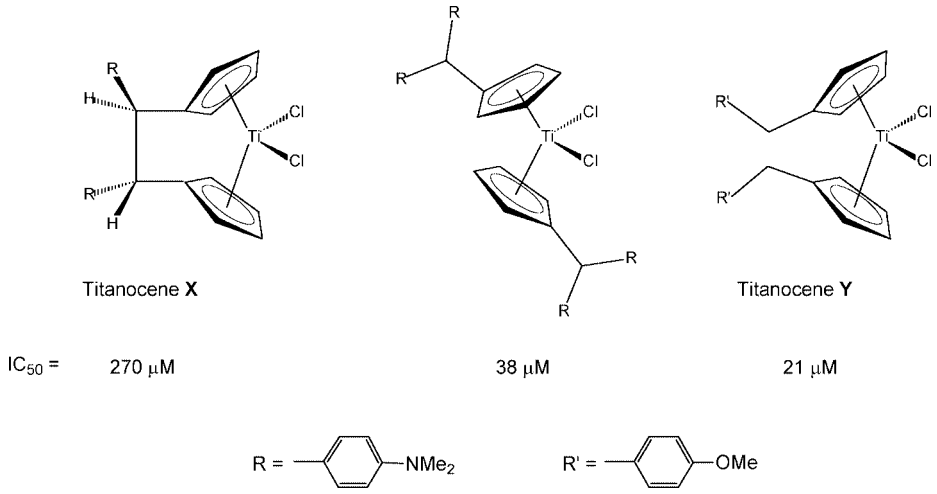

Figure 1. Molecular structures of the titanocenes.

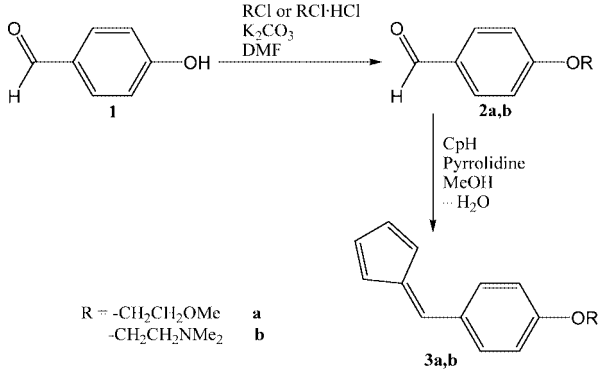
cenes have been studied in a 36 human carcinoma cell panel for their antiproliferative activity.[22] Furthermore, titanocene **X** has been tested on four freshly explanted human tumors.[23] First mechanistic studies showed that both titanocenes induce apoptosis, especially in prostate cancer cells.[24] Furthermore, very successful animal studies with the use of titanocene **Y** on Caki-1 tumor-bearing mice and xenograft Ehrlich's ascites tumor in mice were performed.[25,26]

The main idea behind the research presented in this paper was to convert the methoxy group of titanocene **Y**, our most cytotoxic titanocene, into a glycol methyl ether or glycol amine side chain in order to improve the cytotoxicity and availability in the cell. Within this paper, we present the synthetic possibilities and limits of introducing a glycol methyl ether or a glycol amine group in all three mentioned classes of titanocenes and comparing the antiproliferative effects of the new synthesised titanocenes.

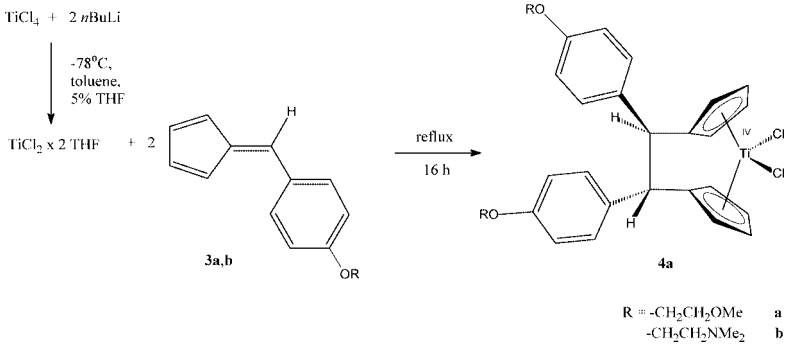
## Results and Discussion

### *Synthesis*

6-Arylfulvenes are the starting materials for all three classes of titanocenes and their main function is to introduce the substitution pattern at the cyclopentadienide rings. These fulvenes can be synthesised according to the published procedure[18] by reacting the corresponding benzaldehyde with cyclopentadiene in the presence of pyrrolidine as a base. Benzaldehydes **2a** and **2b** were not commercially available, and therefore, they were synthesised from 4-hydroxybenzaldehyde (**1**) and the corresponding alkyl chloride.[27] Afterwards, 6-[4-(2-methoxyethoxy)phenyl]fulvene (**3a**) and 4-[2-(dimethylamino)ethoxy]benzaldehyde (**3b**) were obtained in the described condensation reaction as orange solids in yields of 78% and 51%, respectively (Scheme 1).



Scheme 1. Synthesis of fulvenes **3a** and **3b**.



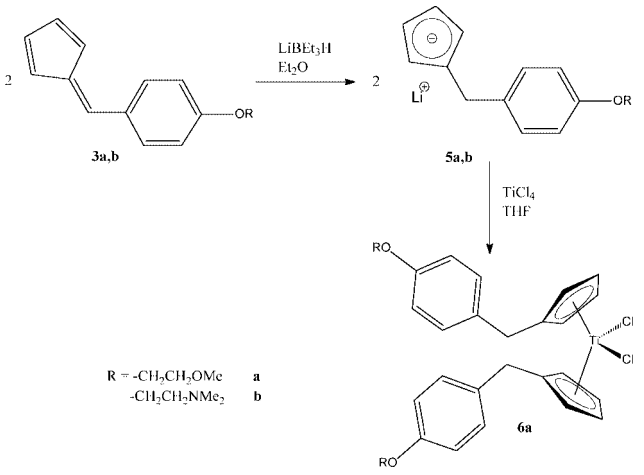
Scheme 2. Synthesis of *ansa*-titanocene **4a**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

*ansa*-Titanocenes can be obtained by the reductive dimerisation of the corresponding fulvene with titanium dichloride (Scheme 2), which is synthesised by the reduction of $TiCl_4$ with *n*BuLi as described in refs.[12,13]

With the use of this method, fulvenes **3a** and **3b** were tested for the synthesis of the corresponding *ansa*-titanocenes. *ansa*-Titanocene **4a** was obtained from fulvene **3a** as a black solid in a yield of 22%, and the determined *cis–trans* ratio at the carbon–carbon bridge was 44:56. Surprisingly, with the use of fulvene **3b** and the above-described procedure, no *ansa*-titanocene was formed and merely a black polymer was obtained.

A second synthetic pathway starting with 6-arylfulvenes leads to the corresponding benzyl-substituted titanocenes. This method includes a hydride transfer to the exocyclic double bond of the fulvene with the use of $LiBEt_3H$ (super hydride) and results in the formation of the appropriate substituted lithium cyclopentadienyl intermediate. Two moles of this lithium intermediate undergo a transmetallation reaction with $TiCl_4$ to give the corresponding unbridged substituted titanocenes (Scheme 3).[21]

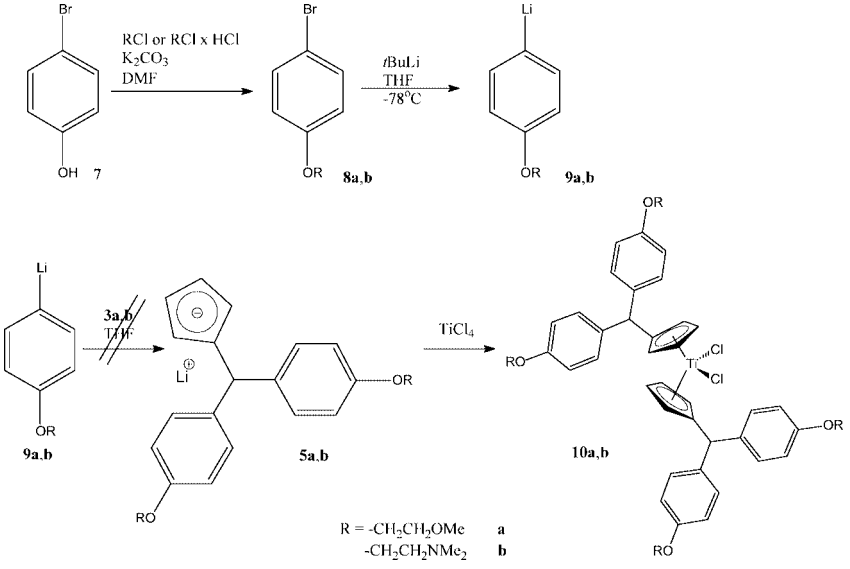


Scheme 3. Synthesis of benzyl-substituted titanocene **6a**.

These benzyl-substituted titanocenes do not have stereocentres; therefore, unlike their *ansa* analogues, stereoisomers of this compound do not exist, which, in terms of in vivo and in vitro cell testing, is advantageous. Our most cytotoxic titanocene, titanocene **Y**, has been synthesised by this reaction.

Again, both fulvenes **3a** and **3b** were tested for their ability to form the corresponding benzyl-substituted titanocenes. With the use of this method, unbridged titanocene **6a** was obtained as a brown solid in a yield of 67% from **3a**. Again, the use of fulvene **3b** did not lead to any success; therefore, the unbridged titanocene substituted with a glycol amine group could not be formed. The reactivity of lithium intermediate **5b** was so high that it immediately decomposed after its formation and substituted lithium cyclopentadienide **5b** could not be isolated and consequently reacted with $TiCl_4$.

A third synthetic route that leads to the formation of achiral diarylmethyl-substituted titanocenes was evaluated again for both fulvenes **3a** and **3b**.[20] The first step was a bromine–lithium exchange reaction and resulted in the formation of lithiated intermediates **9a** and **9b**. Bromine compounds **8a** and **8b** were synthesised beforehand by refluxing 4-hydroxyphenylbromide (**7**) with the appropriate alkyl chloride.[28] Afterwards, lithium intermediates **9a** and **9b** were intended to undergo a carbolithiation reaction that would result in the formation of corresponding substituted lithium cyclopentadienide **5a** and **5b**, which could then be transmetallated with $TiCl_4$ (Scheme 4). However, neither the use of fulvene **3a** nor the use of fulvene **3b** led to the formation of the expected diarylmethyl-substituted titanocene.



Scheme 4. Synthesis of diarylmethyl-substituted titanocene.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Closer investigations of the lithium–bromine exchange reaction showed that the *para*-substituted lithium intermediate was not the only product formed. The formation of a mixture of lithium compounds might be due to the *ortho*-directing property of the glycol methyl ether or glycol amine side chain. To carry out these investigations the bromine compound was treated with *tert*-butyllithium in THF and afterwards reacted with chlorotrimethylsilane.

### Structural Discussion

Suitable single-crystals of titanocene **4a** for X-ray diffraction experiments were obtained by the slow diffusion of pentane into a saturated solution of dichloromethane. The collection and refinement data for **4a** are shown in Table 2.

Because of the presence of stereoisomers, *ansa*-titanocenes seem to be a difficult class of compounds in terms of crystallisation experiments. Therefore, there are very few examples of molecular structures of titanocenes in the crystal form and their crystallisation behaviour strongly depends on the substitution pattern. In the crystal structure of titanocene **4a**, only the *trans* isomer is found, and in accordance with the centrosymmetric space group $P\bar{1}$, the (*R*,*R*)- and (*S*,*S*) isomers are present in equal amounts. The molecule itself has a *pseudo*-$C_2$ symmetry in the solid state. The cyclopentadienyl bond lengths are of the expected values for titanocenes and range from 138 pm to 142 pm, as well as the ring centroid distances to the metal centre (205 and 206 pm). The Ti–Cl bond lengths, both of them being 236 pm, and the Cl–Ti–Cl angle, being 95.0°, are also typical of titanocenes (Table 1). The carbon–carbon *ansa*-bridge has a length of 152 pm and is therefore in the expected range for a carbon–carbon single bond. Despite the *ansa*-bridge, the angle centroid–metal–centroid is 128°, which is nearly the same as that in unbridged titanocene **Y** (131°)[21] and suggests that there is no strain on the ethylene bridge.

One of the glycol methyl ether side chains shows an orientational disorder with O4 and is distributed over two positions. In the final refinement, the position of the two adjacent carbon atoms, C29 and C30, has been treated as unaffected and leads to some unusual bond lengths and angles (Table 1). These unusual bond lengths and angles show that C29 is, in fact, disordered as well and that the two positions are very close to each other (<20 pm). Therefore, the dataset with a resolution of 87 pm does not allow a separate refinement of the two C29 sites.

The unit cell of the determined structure of **4a** shows an absence of any solvent molecules; the assumed free space between the titanocenes is filled by the glycol methyl ether group. This is in contrast to the molecular structure of an analogue of *ansa*-titanocene that is substituted with a pentamethyl phenyl group at the cyclopentadienyl rings. In this analogue, the aromatic substituents form a channel in which the solvent molecules are situated.[18] In terms of biological applications, the absence of solvent molecules in the obtained crystals is advantageous as the compounds are known to be of high purity and the cytotoxic effects that are observed can not be due to the presence of chlorinated solvents.

Table 1. Selected bond lengths and angles for **4a**.

| Bond lengths [Å] | | | |
|---|---|---|---|
| Cl1–Ti | 2.3553(11) | C2–C3 | 1.375(5) |
| Cl2–Ti | 2.3559(11) | C3–C4 | 1.399(5) |

### Cell Tests

The in vitro cytotoxicity of compounds **4a** and **6a** was determined by MTT-based assays[29] that involves a 48 hour drug exposure period, followed by 24 hours of recovery time. Compounds were tested for their activity on pig kidney cells (LLC-PK) and the results are shown in Figures 2 and 3.

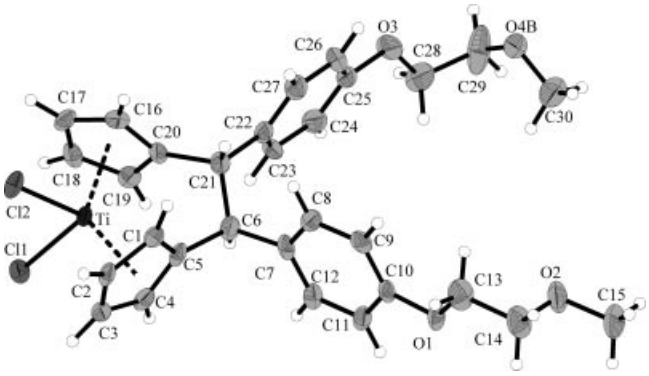

Figure 2. Molecular structure of a crystal of **4a**, thermal ellipsoids are drawn at the 50% probability level and disorder has been neglected.

In our workgroup, *ansa*-titanocenes have been synthesised which show cytotoxic effects with $IC_{50}$ values in the range of 930 to 210 μM when tested on the LLC-PK cell line, depending on the substitution pattern of the phenyl ring. Most of the *ansa*-titanocenes show poor water solubil-

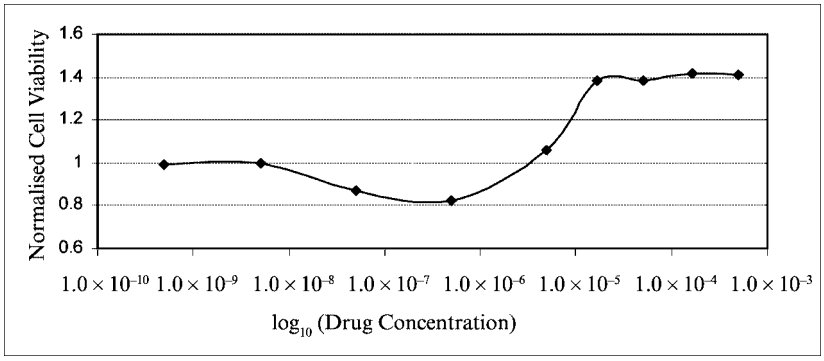

Figure 3. Cytotoxicity curve from typical MTT assays that show the effect of compound **4a** on the viability of pig kidney (LLC-PK) cells.

ity, and therefore, the introduction of the glycol methyl ether group was supposed to improve the water solubility and the availability of the titanocene in the cell.

The water solubility of *ansa*-titanocene **4a** was significantly improved, but unfortunately a few seconds after the titanocene dissolved in the medium, a white solid precipitated despite the fact that the titanocene is completely soluble in 0.7% DMSO. Cell tests with this solution showed very surprising results. *ansa*-Titanocene **4a**, which was dissolved in the medium with 0.7% DMSO, showed nearly no cytotoxic effect under physiological conditions. Quite the opposite result, a proliferative effect, was observed and the cell growth was significantly increased when tested on the LLC-PK cell line. Only at very low concentrations in the range of $10^{-5}$ to $10^{-8}$ M can a small cytotoxic effect be noticed (Figure 3). The proliferative result can be explained by a very fast hydrolysis rate of the *ansa*-titanocene, which results from the substitution pattern of the phenyl rings.

A similar unexpected proliferate effect was observed by G. Jaouen and coworkers when a titanocene derivative of the anticancer drug tamoxifen was tested on the human hormone-dependent breast cancer cell line MCF-7. This compound contains an analogous glycol amine group and further explanations concerning the hydrolysis process can be found within the literature[30] and the studies of P. Sadler.[31]

Cytotoxic studies with the use of analogous benzyl-substituted titanocene **6a** were undertaken in order to determine whether the hydrolysis rate is dependant only on the side chain of the phenyl moiety or whether there is an additional correlation with the structure of the titanocene.

Titanocene **6a** was tested in the typical MTT-based assay with the use of the LLC-PK cell line and it showed an $IC_{50}$ value of 43 μM (Figure 4). However, this value, when compared with that of benzyl-substituted titanocene **Y**, is twice as large. In comparison to *cis*-platin, this represents an approximate thirteen-fold increase. Nevertheless, this value shows an approximate fifty-fold decrease in magnitude when compared with that of titanocene dichloride; its $IC_{50}$ value is $2.0 \times 10^{-3}$ M when tested on the same cell line.[16] Samples prepared for the cell tests showed a significantly slower rate of hydrolysis compared with that of *ansa*-titanocene **4a**. This resulted in the formation of a lesser amount of the white precipitate. Nevertheless, there might still be a rapid rate of hydrolysis, which has a counterproductive impact on the cytotoxic effect.

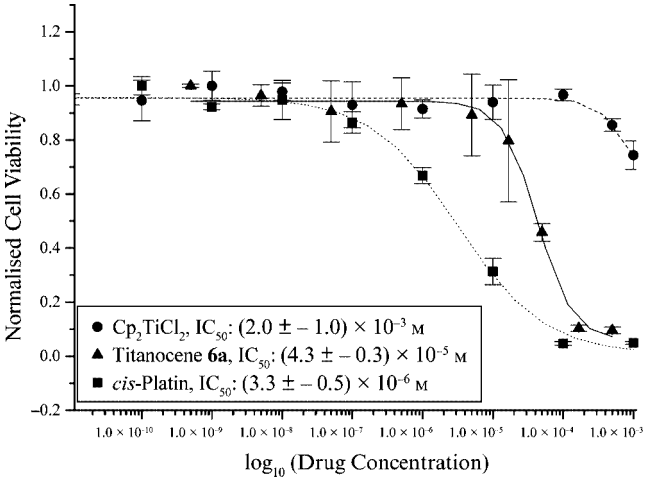

Figure 4. Cytotoxicity curve from typical MTT assays that show the effect of compound **6a** on the viability of pig kidney (LLC-PK) cells.

Furthermore, benzyl-substituted titanocene **6a** does not have stereocentres, and therefore, stereoisomers do not exist, unlike their *ansa* analogue **4a**. In terms of in vivo and in vitro cell testing, this is advantageous. Previously, the presence of unseparated stereoisomers meant that the issue of whether the compounds' cytotoxicities were related to specific isomers was not addressed. This is not of concern for achiral compound **6a**.

## Conclusions and Outlook

6-Arylfulvenes can be very useful starting materials for the synthesis of different types of titanocenes. Fulvenes **3a** and **3b**, which have a glycol methyl ether or a glycol amine side chain at the phenyl moiety, were obtained in good yields as orange solids. Their application towards the synthesis of titanocenes was very limited. Only the glycol methyl ether analogues of *ansa*-titanocene and of benzyl-substituted titanocene were obtained, whereas it was not possible to synthesise any of the three types of titanocenes

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bearing a glycol amine side chain. Both fulvenes could not be used for the successful synthesis of a diarylmethyl-substituted titanocene. This study shows how limited the various methods are and that not every 6-arylfulvene can be used for the synthesis of the corresponding titanocenes.

When tested for cytotoxicity on the LLC-PK cell line, the $IC_{50}$ value of **6a** was in the lower $10^{-5}$ M range and showed a clear dose dependent antiproliferative effect. This represents an increase in cytotoxicity when compared to that of unsubstituted titanocene dichloride; however, **6a** is two times less cytotoxic than the most cytotoxic of the titanocenes so far, titanocene **Y**, which has a methoxybenzyl functionality. Compound **6a** is also approximately fifteen times less cytotoxic than *cis*-platin when tested on the LLC-PK cell line.

Surprisingly, *ansa*-titanocene **4a** showed a proliferative effect when tested on the same cell line. This might be due to the fast rate of hydrolysis, which was observed during the preparation of the sample for the cell tests. Nevertheless, this was the first time that a proliferative effect with this class of titanocenes was observed. We could show that a glycol methyl ether side chain at the phenyl moiety helps to improve the water solubility, but unfortunately it increases the hydrolysis rate as well. Furthermore, we were able to see that the hydrolysis rate is strongly dependent on the class of titanocenes.

Future work will focus on the exchange of the chlorines in order to decrease the hydrolysis rate. If this can be achieved, both titanocenes might be very interesting compounds for further studies in terms of their availability in the cell.

## Experimental Section

**General Conditions:** Titanium tetrachloride, *n*-butyllithium (2.0 M in cyclohexane), *tert*-butyllithium (1.7 M in pentane), 4-hydroxybenzaldehyde, 4-bromophenol, $K_2CO_3$, NaI, DMF, (2-chloroethyl)-methyl ether, 2-(dimethylamino)ethyl chloride and super hydride ($LiBEt_3H$, 1.0 M solution in THF) were obtained commercially from Aldrich Chemical Co. THF, toluene, pentane and diethyl ether were dried with Na and benzophenone. Solvents were freshly distilled and collected under an atmosphere of argon prior to use. Cyclopentadiene was collected under an atmosphere of nitrogen from freshly cracked dicyclopentadiene and pyrrolidine was distilled under an atmosphere of argon prior to use. Manipulations of air- and moisture-sensitive compounds were done with the use of standard Schlenk techniques, under an argon atmosphere. NMR spectra were measured with either a Varian 300 or a Varian 400 spectrometer. Chemical shifts are referenced to TMS. IR spectra were recorded with a Perkin–Elmer Paragon 1000 FT-IR Spectrometer. UV/Vis spectra were recorded with a Unicam UV2 Spectrometer. Electron spray mass spectrometry of **4a** and **6a** were performed with a quadrupole tandem mass spectrometer (Quattro Micro, Micromass/Water's Corp., USA) with the use of solutions that were made up in 50% dichloromethane and 50% methanol.

Single-crystals of **4a** suitable for X-ray diffraction experiments were grown by the diffusion of pentane into a saturated solution of dichloromethane at room temperature. X-ray diffraction data for the compound was collected with a BRUKER Smart Apex diffractometer. A semi-empirical absorption correction on the raw data was performed with the program SADABS.[32] The crystal structure was then solved by direct methods (SHELXS-NT 97)[33] and refined by full-matrix least-squares methods against $F^2$. Further details about the data collection are listed in Table 2, as well as reliability factors. CCDC-610549 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

In vitro cell tests were performed on LLC-PK cells obtained from the ATCC (American Tissue Cell Culture Collection) and maintained in Dulbecco's Modified Eagle Medium containing FCS (foetal calf serum) [10% (v/v)], penicillin streptomycin [1% (v/v)] and L-glutamine [1% (v/v)]. Cells were seeded in 96-well plates containing 200-μL-microtitre wells at a density of 5,000 cells/200 μL of medium and were incubated at 37 °C for 24 h to allow for exponential growth. The compounds used for the testing were then dissolved in a medium solution containing DMSO (0.7%) to obtain stock solutions of $5 \times 10^{-4}$ M in concentration. The cells were then treated with varying concentrations of the compounds and incubated for 48 h at 37 °C. The solutions were then removed from the wells and the cells were washed with PBS (phosphate buffer solution) and fresh medium was added to the wells. After a recovery period of 24 h incubation at 37 °C, individual wells were treated with a solution of MTT (200 μL) [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] in medium. The solution consisted of MTT (30 mg) in the medium (30 mL). The cells were incubated for 3 h at 37 °C. The medium was then removed and the purple formazan crystals were dissolved in DMSO (200 μL per well). Absorbance was then measured at 540 nm by a Wallac Victor (Multilabel HTS Counter) Plate Reader. Cell viability was expressed as a percentage of the absorbance recorded for control wells. The mean values used for the dose response curves represent

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the values obtained from four consistent MTT-based assays for each compound tested.

**4-(2-Methoxyethoxy)benzaldehyde (2a):** This compound was synthesised according to the published procedure and obtained as a nearly colourless oil in a yield of 72%.[27] The spectroscopic data were in correspondence to the published data.

**4-[2-(Dimethylamino)ethoxy]benzaldehyde (2b):** 4-Hydroxybenzaldehyde (1.00 g, 8.19 mmol) was heated at 80 °C together with 2-(dimethylamino)ethyl chloride (1.2 equiv., 1.41 g, 9.83 mmol) and $K_2CO_3$ (4 equiv., 4.52 g, 32.76 mmol) in abs. DMF (50 mL) for 3 d under an atmosphere of argon. $H_2O$ (30 mL) was added, and the reaction mixture was extracted with diethyl ether (4 × 20 mL). The combined organic layers were dried with $Na_2SO_4$ and the solvent was removed in vacuo. A red oil was obtained in a yield of 76%. $^1$H NMR ($CDCl_3$, 300 MHz): $\delta$ = 2.33 [s, 3 H, N(C$H_3$)$_2$], 2.75 [t, $^3J$ = 5.7 Hz, 2 H, (CH$_3$)$_2$NC$H_2$CH$_2$], 4.14 [t, $^3J$ = 5.7 Hz, 2 H, (CH$_3$)$_2$NCH$_2$C$H_2$O], 7.02 (d, $J_{A,B}$ = 8.4 Hz, 2 H, OCC*H*CH), 7.81 (d, $J_{A,B}$ = 8.7 Hz, 2 H, C*H*C), 9.86 (s, 1 H, CHO) ppm.

**6-[4-(2-Methoxyethoxy)phenyl]fulvene (3a):** Pyrrolidine (2.58 mL, 2.20 g, 30.94 mmol) was added to a solution of 4-(2-methoxyethoxy)benzaldehyde (5.20 g, 30.94 mmol) and cyclopentadiene (5.11 mL, 77.34 mmol) in methanol (60 mL). After this addition, the solution turned from colourless to deep red and a solid was formed. After 12 h, acetic acid (1.86 g, 1.77 mL, 30.94 mmol) was added. $H_2O$ (30 mL) was added, and the mixture was extracted with $CH_2Cl_2$ (4 × 20 mL). The combined organic layers were dried with $Na_2SO_4$, and the solvent was removed in vacuo to afford a dark red oil. The crude product was purified on a silica column (15–5 cm) with $CH_2Cl_2$ as the solvent. After removal of the solvent under vacuum, the product was obtained as an orange solid in yield of 78% (5.49 g, 24.07 mmol). $^1$H NMR ($CDCl_3$, 300 MHz): $\delta$ = 2.43 (s, 3 H, OC$H_3$), 2.74 (t, $^3J$ = 5.7 Hz, 2 H, CH$_3$OC$H_2$CH$_2$), 4.11 (t, $^3J$ = 5.7 Hz, 2 H, CH$_3$OCH$_2$C$H_2$), 6.30–6.31, 6.47–6.49, 6.64–6.67, 6.71–6.73 (m, 4 H, C$_5H_4$), 6.95 (d, $J_{A,B}$ = 8.7 Hz, 2 H, OCC*H*CHC), 7.15 (s, 1 H, C$_6$H$_4$C*H*C$_5$H$_4$), 7.56 (d, $J_{A,B}$ = 8.7 Hz, 2 H, OCCHC*H*C) ppm. $^{13}$C NMR ($CDCl_3$, 75 MHz): $\delta$ = 45.9 (O*C*H$_3$), 58.2, 66.1 (2 C) (CH$_3$O*C*H$_2$*C*H$_2$O), 114.9 (2 C) (C-2,6 OC$_6$H$_4$), 119.9 (C$_5$H$_4$*C*HC$_6$H$_4$), 127.4, 129.6, 134.9, 138.3 (4 C) (C-2,3,4,5 C$_5$H$_4$), 132.4 (2 C) (C-3,5 OC$_6$H$_4$), 143.3 (C-1 C$_5$H$_4$), 159.9 (C-1 OC$_6$H$_4$) ppm. $C_{15}H_{16}O_2$ (228.12): calcd. C 78.98, H 7.07; found C, 78.68, H, 7.05.

**6-{4-[2-(Dimethylamino)ethoxy]phenyl}fulvene (3b):** Pyrrolidine (4.97 mL, 4.24 g, 59.55 mmol) was added to a solution of 4-[2-(dimethylamino)ethoxy]benzaldehyde (11.50 g, 59.55 mmol) and cyclopentadiene (9.84 g, 148.88 mmol) in methanol (100 mL). After this addition, the solution turned from colourless to deep red. After 12 h, acetic acid (3.58 g, 3.41 mL, 59.55 mmol) was added. $H_2O$ (40 mL) were added, and the mixture was extracted with $CH_2Cl_2$ (4 × 40 mL). The combined organic layers were dried with $Na_2SO_4$, and the solvent was removed by vacuum to afford a dark red oil. The crude product was purified on an aluminium oxide column (15–5 cm) with $CH_2Cl_2$ as the solvent. After removal of the solvent under vacuum, the product was obtained as an orange solid in yield of 51% (7.34 g, 30.44 mmol). $^1$H NMR ($CDCl_3$, 400 MHz): $\delta$ = 2.35 [s, 6 H, N(C$H_3$)$_2$], 2.75 [t, $^3J$ = 5.7 Hz, 2 H, (CH$_3$)$_2$NC$H_2$CH$_2$], 4.11 [t, $^3J$ = 5.7 Hz, 2 H, (CH$_3$)$_2$NCH$_2$C$H_2$O], 6.30–6.35, 6.45–6.50, 6.65–6.67, 6.70–6.75 (m, 4 H, C$_5H_4$), 6.96 (d, $J_{A,B}$ = 8.6 Hz, 2 H, C-2,6 OC$_6H_4$), 7.15 (s, 1 H, C$_5$H$_4$C*H*C$_6$H$_4$), 7.56 (d, $J_{A,B}$ = 8.6 Hz, 2 H, C-3,5 OC$_6H_4$) ppm. $^{13}$C NMR ($CDCl_3$, 100 MHz): $\delta$ = 46.2 (2 C) [N(*C*H$_3$)$_2$], 58.4 [(CH$_3$)$_2$N*C*H$_2$CH$_2$], 66.2 [(CH$_3$)$_2$NCH$_2$*C*H$_2$O], 115.1 (2 C) (C-2,6 OC$_6$H$_4$), 120.1 (C$_6$H$_4$*C*HC$_5$H$_4$), 127.6 (C$_5$H$_4$), 129.8 (C-4 OC$_6$H$_4$), 130.0 (C$_5$H$_4$), 132.7 (2 C) (C-3,5 OC$_6$H$_4$), 135.1, 138.5 (C$_5$H$_4$), 143.5 (C-1 C$_5$H$_4$), 160.1 (C-1 OC$_6$H$_4$) ppm. $C_{16}H_{19}NO$ (241.15): calcd. C 79.63, H 7.94, N 5.80; found C 79.85, H 7.92, N 5.79.

**{1,2-Dicyclopentadienyl-1,2-bis[4-(2-methoxyethoxy)phenyl]ethanediyl}titanium Dichloride, [1,2-{4-(2-MeO-C$_2$H$_4$O)-C$_6$H$_2$}$_2$C$_2$H$_2${η$^5$-C$_5$H$_4$}$_2$]TiCl$_2$ (4a):** $TiCl_4$ (0.46 mL, 0.79 g, 4.18 mmol) was added to dry toluene (50 mL) and dry THF (5 mL). The solution turned immediately from colourless to pale yellow. The solution was stirred and cooled down to –78 °C and then was treated dropwise with *n*BuLi (4.18 mL, 8.36 mmol). The solution turned from yellow to brown during the addition. After this addition, the mixture was warmed up slowly to room temp., and the solution finally turned black. After 20 h of stirring, a solution of 6-[4-(2-methoxyethoxy)phenyl]fulvene (1.91 g, 8.36 mmol) in dry toluene was added to the solution of $TiCl_2$·2THF at room temp. under an atmosphere of argon. The mixture was then stirred under reflux for another 16 h. The solvent was removed under vacuum. The resulting black solid was extracted with $CH_3Cl$ (3 × 20 mL) and filtered through celite and twice through a Whatman No. 1 filter paper. The solvent was removed under vacuum, and the residue was triturated with pentane (40 mL) to give 0.53 g (22% yield) of a black solid. The ratio of *trans* and *cis* isomers was 44% to 56%. $^1$H NMR ($CDCl_3$, 400 MHz): $\delta$ = 3.42–3.48 (m, 2 H, C$H_3$), 3.69–3.79 (m, 4 H, CH$_3$OC$H_2$CH$_2$), 4.01–4.10 (m, 4 H, CH$_3$OCH$_2$C$H_2$O), 4.68, 5.40 (s, 2 H, *cis*- and *trans*-PhC*H*Cp), 6.12–6.33, 6.76–7.17 (m, 16 H, C$_6H_4$, C$_5H_4$) ppm. $^{13}$C NMR ($CDCl_3$, 100 MHz): $\delta$ = 49.0, 51.8 (2 C) (*cis*- and *trans*-Ph*C*HCp), 57.2 (2 C) (O*C*H$_3$), 65.1, 68.8 (4 C) (O*C*H$_2$*C*H$_2$O), 107.1, 111.3, 111.6, 111.9, 114.1, 114.2, 123.4, 125.3, 125.6, 126.8, 127.1, 127.6, 129.6, 130.7, 134.4, 135.6, 153.9, 154.5 (22 C) (*cis*- and *trans*-$C_6H_4$ and $C_5H_4$) ppm. IR (KBr): $\tilde{\nu}$ = 3104 (m), 2924 (m), 1612 (s), 1514 (s), 1453 (s), 1440 (s), 1254 (w), 1180 (s), 1059 (s), 1037 (s), 860 (m), 771 (m) cm$^{-1}$. UV/Vis ($CH_2Cl_2$): $\lambda$ ($\varepsilon$, L mol$^{-1}$ cm$^{-1}$) = 227 (23600), 271 (19666), 378 (1666), 387 (1767), 524 (233) nm. MS (ESI–): *m*/*z* = 610.99 [M + Cl]$^+$. $C_{30}H_{32}Cl_2O_4Ti$ (574.12): calcd. C 62.63, H 5.61; found C 65.65, H 6.14.

**Bis{[4-(2-methoxyethoxy)benzyl]cyclopentadienyl}titanium(IV) Dichloride, [{η$^5$-C$_5$H$_4$-CH$_2$-C$_6$H$_4$–O(CH$_2$)$_2$OCH$_3$}$_2$Ti]Cl$_2$ (6a):** LiBEt$_3$H (12.44 mL) was concentrated by removal of the solvent by heating it to 90 °C under a vacuum of $10^{-2}$ mbar for 2 h. The concentrated reagent was dissolved in diethyl ether (30 mL) and transferred to a solution of 6-[4-(2-methoxyethoxy)phenyl]fulvene (2.25 g, 9.86 mmol) in diethyl ether (10 mL). The solution was stirred for 20 min and then pentane (40 mL) was added, after which point lithium cyclopentadienide intermediate **5a** precipitated from the solution. The precipitate was immediately filtered, and **5a** was then collected on a frit and washed with pentane (25 mL), dried briefly in vacuo and transferred to a Schlenk flask under an atmosphere of argon. White lithium cyclopentadienide intermediate **5a** (1.88 g, 7.96 mmol, 81% yield) was dissolved in THF (20 mL) and was added dropwise to a solution of $TiCl_4$ (0.44 mL, 3.98 mmol) in THF (80 mL) at 0 °C. The resultant dark red solution was heated under reflux for 16 h. The solution was then cooled, and the solvent was removed under reduced pressure. The remaining residue was extracted with $CH_2Cl_2$ (75 mL) and filtered through celite to remove the LiCl. The dark red filtrate was filtered twice more by gravity filtration. The solvent was removed under reduced pressure to yield a brown solid, which was dried in vacuo (1.54 g, 2.67 mmol, 67% yield). $^1$H NMR ($CDCl_3$, 300 MHz): $\delta$ = 3.44 (s, 6 H, OC$H_3$), 3.74 (t, $^3J$ = 4.6 Hz, 4 H, CH$_3$OC$H_2$CH$_2$), 4.02 (s, 4 H, C$_6$H$_4$C$H_2$C$_5$H$_4$), 4.09 (t, $^3J$ = 4.6 Hz, 4 H, CH$_3$OCH$_2$C$H_2$O), 6.29 (s, 8 H, C$_5H_4$), 6.86, 7.11 (d, $J_{A,B}$ = 8.4 Hz, 8 H, C$_6H_4$) ppm. $^{13}$C NMR ($CDCl_3$, 75 MHz): $\delta$ = 36.0 (2 C) (C$_6$H$_4$*C*H$_2$C$_5$H$_4$), 59.2

(2 C) ($OCH_3$), 67.3, 71.1 (4 C) ($CH_3OCH_2CH_2OC_6H_4$), 114.7, 130.0 (4 C) (C-2,3,5,6 $C_6H_4$), 116.2, 122.2 (8 C) (C-2,3,4,5 $C_5H_4$), 131.7, 137.7 (4 C) (C-1 $C_5H_4$; C-6 $C_6H_4$), 157.5 (2 C) (C-1, $OC_6H_4$) ppm. IR (KBr): $\tilde{\nu}$ = 3104 (m), 2924 (m), 1612 (s), 1514 (s), 1453 (s), 1440 (s), 1254 (w), 1180 (s), 1059 (s), 1037 (s), 860 (m), 771 (m) $cm^{-1}$. MS (ESI–): 611.05 $[M + Cl]^+$. UV/Vis ($CH_2Cl_2$): $\lambda$ ($\varepsilon$, $L\,mol^{-1}\,cm^{-1}$) = 227 (26600), 262 (24600), 316 (8600), 396 (3500), 524(400) nm. $C_{30}H_{34}Cl_2O_4Ti$ (576.13): calcd. C 62.41, H 5.99, Cl 12.28; found C 62.84, H 6.08, Cl 12.12.

**1-Bromo-4-(2-methoxyethoxy)benzene (8a):** This compound was synthesised according to the known procedure and obtained as an orange oil in a yield of 75%.[28] $^1H$ NMR ($CDCl_3$, 400 MHz): $\delta$ = 3.39 (s, 3 H, $OCH_3$), 3.65–3.70 (m, 2 H, $CH_3OCH_2CH_2$), 4.00–4.05 (m, 2 H, $CH_3CH_2CH_2O$), 6.75 (d, $J_{A,B}$ = 9.1 Hz, 2 H, $OCCHCH$), 7.31 (d, $J_{A,B}$ = 8.9 Hz, 2 H, $OCHCHC$) ppm. $^{13}C$ NMR ($CDCl_3$, 100 MHz): $\delta$ = 59.4 ($OCH_3$), 67.7, 71.1 (2 C) ($OCH_2CH_2OCH_3$), 116.6 (2 C) (C-3,5 $BrC_6H_4$), 117.6 (C-1 $BrC_6H_4$), 132.4 (2 C) (C-2,6 $BrC_6H_4$), 158.1 (C-4 $BrC_6H_4$). $C_9H_{11}BrO_2$ (229.99): calcd. C 46.78, H 4.80; found C 46.80, H 4.81.

**1-Bromo-4-[2-(dimethylamino)ethoxy]benzene (8b):** A mixture of 4-bromophenol (3.75 g, 21.81 mmol), NaI (3.25 g, 21.68 mmol), $K_2CO_3$ (4 equiv. 12.03 g, 87.24 mmol) and 2-(dimethylamino)ethyl chloride (3.74 g, 26.17 mmol) in DMF (100 mL) was stirred at 80 °C for 4 d. $H_2O$ (50 mL) was added, and the reaction mixture was extracted with diethyl ether (5 × 50 mL). The combined organic layers were additionally washed with aq. KOH (3 × 20 mL). Afterwards, the aqueous layers were extracted with diethyl ether (5 × 15 mL). The combined organic layers were dried with $Na_2SO_4$ and concentrated in vacuo to give a dark red oil. The oil was distilled at 96 °C ($4 \times 10^{-1}$ mbar) to afford a light yellow oil in a yield of 52% (2.76 g, 11.34 mmol). $^1H$ NMR ($CDCl_3$, 400 MHz): $\delta$ = 2.31 [s, 6 H, $N(CH_3)_2$], 2.69 [t, $^3J$ = 5.7 Hz, 2 H, $(CH_3)_2NCH_2CH_2$], 3.99 [t, $^3J$ = 5.7 Hz, 2 H, $(CH_3)_2NCH_2CH_2O$], 6.78 (d, $J_{A,B}$ = 9.1 Hz, 2 H, $OCHCH$), 7.34 (d, $J_{A,B}$ = 9.1 Hz, 2 H, $OCHCHC$) ppm. $^{13}C$ NMR ($CDCl_3$, 100 MHz): $\delta$ = 46.1 (2 C) $[N(CH_3)_2]$, 58.4 $[(CH_3)_2NCH_2CH_2]$, 66.4 $[(CH_3)_2NCH_2CH_2O]$, 113.0 (C-1 $BrC_6H_4$), 116.6 (2 C) (C-3,5 $BrC_6H_4$), 132.4 (2 C) (C-2,6 $BrC_6H_4$), 158.2 (C-4 $BrC_6H_4$) ppm. $C_{10}H_{14}BrNO$: calcd. C 49.20, H 5.78, N 5.74; found C 48.90, H 5.68, N 5.65.

## Acknowledgments

The authors want to thank the Science Foundation Ireland (SFI) for funding through grant (04/BRG/C0682). In addition, funding from the Higher Education Authority (HEA) and the Centre for Synthesis and Chemical Biology (CSCB) through the HEA PRTLI cycle 3 as well as COST D39 was provided.

# Synthesis and Structure of Pd and Pt Complexes with Doubly Stabilized Phosphorus Ylides

**Marta Carbó,[a] Nérida Marín,[a] Rafael Navarro,[a] Tatiana Soler,[b] and Esteban P. Urriolabeitia*[a]**

**Keywords:** Ylides / Metallacycles / Palladium / Platinum / Coordination modes

The doubly stabilized P-ylide ligands $Ph_3P{=}C(CO_2Me)$-$C(=S)N(H)Ph$ (**L1**), $Ph_3P{=}C(CN)C(=S)N(H)Ph$ (**L2**), and $Ph_3P{=}C(CN)$–[(*E*)-$C(CO_2Me){=}CH(CO_2Me)$] (**L3**) have been prepared and fully characterized. The X-ray structures of **L1** and **L2** are reported. The reactivity of **L1**, **L2**, and **L3** towards cationic $Pd^{II}$ and $Pt^{II}$ precursors with two vacant coordination sites has been studied. Adducts of general formula $[M(C\hat{}X)$-$(\mathbf{L}n)]ClO_4$, $[M(C\hat{}X)(\mathbf{L}n)_2]ClO_4$, and $[M(\mu\text{-}\mathbf{L}n)(C\hat{}X)]_2(ClO_4)_2$ ($C\hat{}X$ = ancillary ligands) were obtained. The ylides **L*n*** coordinate to the metal center through their heteroatoms (O, N, S), while the C bonding of **L*n*** has not been observed in any of the cases studied.

## Introduction

We have recently shown that the α-stabilized P-ylides $Ph_3P{=}C(H)R$ [R = CN, C(O)R′; R′ = Me, Ph, OMe, $NMe_2$] behave as versatile ligands towards $Pd^{II}$ and $Pt^{II}$ precursors, and several coordination modes of these ylides have been characterized. Thus, the ylide can coordinate to the metal center through the $C_\alpha$ atom, the carbonyl oxygen, or the N atom of the cyano group. We have even characterized situations in which the same ylide shows a combination of bonding modes.[1] An interesting fact is that, in spite of the presence of several potential donor atoms on the same ylide, they always behave as ambidentate ligands,[1] that is, using only one donor atom each time. Further replacement of the ylidic H atom by other functional groups increases the functionality of the ylides and should expand their bonding capabilities. In this context, we have now focused our attention on doubly stabilized P-ylides. The introduction of an additional stabilizing functional group can be achieved through several simple synthetic procedures: acylation,[2] reactivity towards alkynes or other unsaturated compounds,[3] reactivity of iminophosphoranes with alkynes,[4] retro-Wittig reactions,[5] and other less common processes.[6]

While the chemistry of P-ylide compounds with two stabilizing groups, and their organic applications, has been the subject of intensive research, their coordination chemistry and bonding properties towards transition metals are scarcely represented.[7] Representative examples are the reaction of $Hg^{II}$ halides $HgX_2$ (X = Cl, Br, I) or different $U^{VI}$ salts with $Ph_3P{=}C[C(O)Me][C(O)Ph]$ (ABPPY), which results in the formation of mono- and dinuclear complexes with the *O*(acetyl)-bonded ABPPY ylide.[7a,7d] It is remarkable that the reactivity of the same $HgX_2$ precursors towards $Ph_3P{=}C(H)C(O)Ph$ (BPPY) results in *C*-bonded mono- and polynuclear complexes.[8] On the other hand, the reaction of $[PtCl_2(NCC_6F_5)_2]$ with $Ph_3P{=}C(H)CO_2Me$ gives the imine-ylide complex $[PtCl_2\{NH{=}C(C_6F_5)$-$C(=PPh_3)C(O)Me\}_2]$,[7b] in which the generated doubly stabilized ylide remains bonded to the Pt center through the imine N atom. As can be observed, all complexes with doubly stabilized ylides share a common feature, namely their bonding to the metal through the heteroatoms. Aiming to expand the knowledge on the bonding properties of doubly stabilized P-ylides, we have studied the reactivity of $Ph_3P{=}C(CO_2Me)C(=S)N(H)Ph]$ (**L1**),[3a] $Ph_3P{=}C(CN)C$-$(=S)N(H)Ph$ (**L2**),[3a] and $Ph_3P{=}C(CN)$–[(*E*)-$C(CO_2$-$Me){=}CH(CO_2Me)]$ (**L3**)[3b] towards orthometalated bis-solvato derivatives of $Pd^{II}$ and $Pt^{II}$. We have found different stoichiometries and different bonding modes for each ylide (monodentate, didentate, chelating, bridging), and we have also found that in none of the cases studied does the ylide bond to the metal center through the ylidic $C_\alpha$ atom.

## Results and Discussion

### Synthesis and Reactivity of L1

The ylide $Ph_3P{=}C(CO_2Me)C(=S)N(H)Ph$ (**L1**) was prepared following reported methods[3a] by treatment of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Ph_3P{=}C(H)CO_2Me$[9b] with phenyl isothiocyanate (PhNCS). Since in the original work this compound was poorly characterized, and also for comparative purposes, a complete characterization of **L1** was performed. The IR spectrum of **L1** shows an intense absorption at 1629 $cm^{-1}$, attributed to the C=O stretch, and two very intense absorptions at 1526 and 1107 $cm^{-1}$, assigned to the stretch of the C=N and C=S bonds of the thioamide group, respectively.[10] The N–H stretch was not observed in the IR spectrum. The $^1H$ NMR spectrum of **L1** shows a very broad singlet at $\delta$ = 12.25 ppm due to the NH proton. This strongly deshielded position can be easily explained by taking into account the formation of an intramolecular hydrogen bond between the NH group and the carbonyl oxygen, as depicted in Figure 1. The formation of this hydrogen bond could also account for the lack of observation of the $\nu_{NH}$ band in the IR spectrum, which is shifted to lower energies with respect to its expected position (about 3400 $cm^{-1}$)[10] and is probably hidden under the polyethylene absorptions (2800–3000 $cm^{-1}$). A similar intramolecular H bond has been found in the related N-ylide $H_5C_5NC[C(O)Ph]C(S)N(H)Ph$.[11] The $^{31}P\{^1H\}$ NMR spectrum of **L1** shows the presence of a single signal at $\delta$ = 11.33 ppm, and the $^{13}C\{^1H\}$ NMR spectrum also shows a good agreement with the proposed structure. Key features are the signal due to the P=C carbon at $\delta$ = 71.48 ppm (d, $^1J_{P,C}$ = 143.1 Hz), and that due to the C=S carbon at $\delta$ = 189.01 ppm (d, $J$ = 16.6 Hz).[12] These observations agree with the structures depicted in Figure 1 for **L1**. The X-ray structure of **L1** has also been determined.

A molecular drawing of **L1** is shown in Figure 2, the most relevant parameters concerning data collection and structure solution and refinement are given in the Experimental Section, and selected bond lengths and angles are collected in Table 1. The molecular skeleton of **L1** is very similar to that reported previously for the closely related ylide $H_5C_5NC[C(O)Ph]C(S)N(H)Ph$.[11] Key features are the cisoid arrangement of the P=C and C=S bonds, also observed in other thiocarbonyl stabilized ylides,[13] and the transoid arrangement of the P=C and C=O bonds, as usually observed in ester-stabilized ylides.[2f,14] The atoms P(1), C(19), C(20), O(1), C(22), S(1), and N(1) are nearly coplanar, since the maximum deviation of the best least-squares plane is 0.13 Å (C20). The P=$C_\alpha$ bond length is elongated [P(1)–C(19) 1.751(2) Å] and both $C_\alpha$–C bond lengths are identical [C(19)–C(22) 1.436(3), C(19)–C(20) 1.437(3) Å]. These values are shorter than the standard value for a $C(sp^2)$–$C(sp^2)$ single bond (1.478 Å),[15] but are longer than those found in free[2f,16] or *O*-bonded[9a,17] ylides [range: 1.366–1.394 Å] containing a single functional group. The C(22)–S(1) bond length [1.690(2) Å] is identical to that found in related ylides [1.693(2) Å],[11] and is slightly longer than usual values for C=S double bonds [1.671 Å].[15] All these facts also show an extensive delocalization of the ylidic charge density through the chain of atoms O(1)–C(20)–C(19)–C(22)–S(1), probably due to the simultaneous presence of two delocalizing groups. In good agreement with the NMR spectroscopic data, an intramolecular hydrogen bond between the NH proton and the carbonyl oxygen can be established and characterized with the following param-

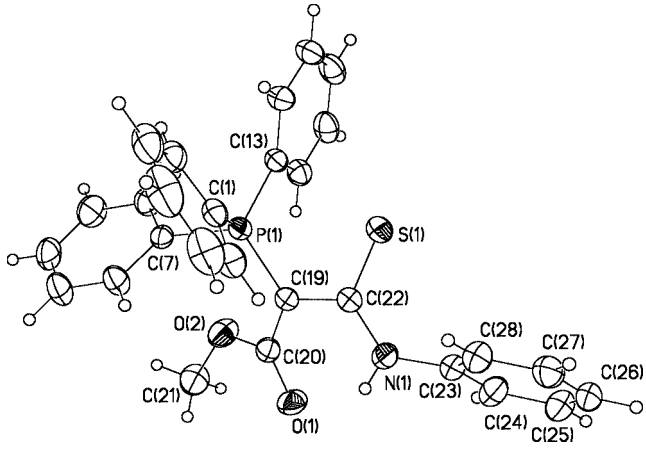

Figure 2. Thermal ellipsoid plot of **L1**. Non-hydrogen atoms are drawn at the 50% probability level.

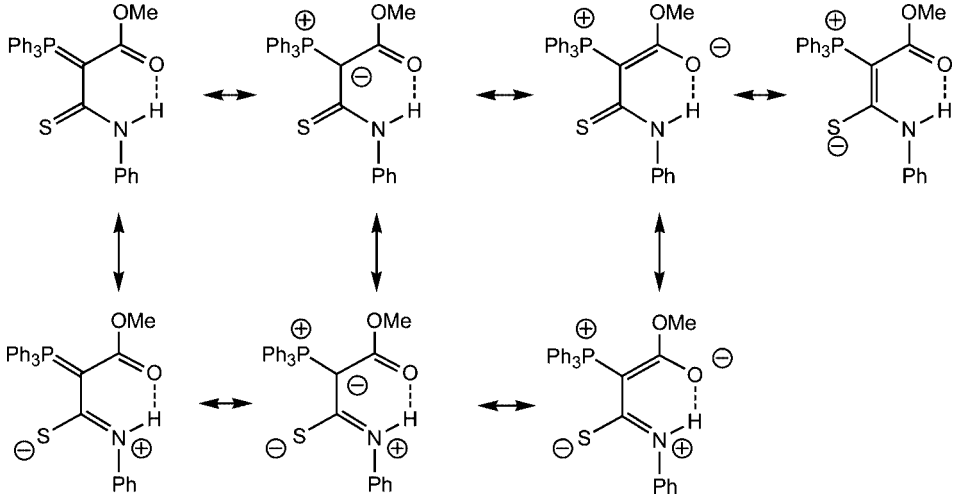

Figure 1. Resonance forms for ligand **L1**.

eters: H(1A)···O(1) 1.939(3) and N(1)···O(1) 2.642(3) Å; N(1)–H(1A)···O(1) 138.14(15)°. The intramolecular P(1)–S(1) distance is 3.034 Å, which is shorter than those found in other ylides[13] and is much shorter than the sum of the van der Waals radii (3.60 Å).[18] The P(1)–C(19)–C(22)–S(1) torsion angle is –8.9° and the P(1)–C(19)–C(22) bond angle is 115.19(15)°, a value smaller than expected for an $sp^2$-hybridised carbon.

Table 1. Selected bond lengths [Å] and angles [°] for **L1**.

The resonance forms shown in Figure 1 suggest that there are at least four potential donor atoms for **L1** (two O atoms, one S, and the $C_\alpha$). We thus explored the reactivity of **L1** towards the bis-solvate complexes $[Pd(C^X)(thf)_2]ClO_4$ (see Scheme 1), prepared as usual by reaction of the corresponding dinuclear chlorido-bridged derivatives with $AgClO_4$ (1:2 molar ratio) in thf. Treatment of freshly prepared solutions of $[M(C^X)(thf)_2]ClO_4$ with **L1** (1:1 molar ratio) in thf at 25 °C resulted in the formation of the cationic derivatives $[Pd(C^X)(\mathbf{L1})]ClO_4$ (**1**–**5**), which show elemental analyses and mass spectra (FAB+) in good agreement with the proposed stoichiometry. The IR spectra of **1**–**5** show several remarkable features: (i) a notable decrease in the position of the $\nu_{CO}$ absorption with respect to free **L1**; (ii) a shift of the $\nu_{CN}$ absorption to high energies with respect to free **L1**, while the $\nu_{CS}$ band is found shifted to lower energies; and (iii) a weak band due to the NH group. All these facts suggest strongly that ligand **L1** is bonded to the Pd atom through the S atom of the thioamide unit and through the carbonyl oxygen of the resonance-stabilized $CO_2Me$ group, and that the ylidic $C_\alpha$ atom is not involved in bonding with the metal atom. This bonding mode also implies that the NH···O hydrogen bond is broken, and hence explains the increase in the NH stretch, since the ylide must rotate around the $C_\alpha$–C(S) bond to adopt the final bonding mode.

The NMR spectra of **1**–**5** give additional structural information. The $^1H$ NMR spectra show that the molecular plane behaves as a symmetry plane, excluding the C coordination of **L1**, and also show a broad signal ($\delta$ = 7.20–7.50 ppm) due to the NH proton. This shift can be explained by the cleavage of the H bond after coordination of **L1**. The $^{13}C\{^1H\}$ NMR spectra of **1**–**5** show a doublet at $\delta$ = 72 ppm ($^1J_{P,C}$ = 104 Hz) due to the ylidic C atom, and the $^{31}P\{^1H\}$ NMR spectra show the presence of a peak at $\delta$ = 19–20 ppm. All these data confirm the absence of an interaction between the $C_\alpha$ atom and the Pd center,[9a] and therefore the S,O bonding mode of **L1**. This should, in principle, give two geometric isomers but, according to the NMR spectroscopic data, only one of them is obtained. A tentative structure, depicted in Scheme 1, can be proposed taking into account the hard/soft nature of the donor atoms bonded directly to the Pd atom and the antisymbiotic effect[19] shown by the Pd center. This reasoning has been successfully applied in the coordination chemistry of α-stabilized ylides.[1a] In agreement with this, it is sensible to suppose that *trans* to the aryl C atom (soft donor) the oxygen atom of **L1** (hard donor) would be more stabilized than the S atom (soft donor).[20]

The S,O-chelating bonding mode can be transformed into an S-monodentate mode by simple addition of L ligands. Thus, complex **4** reacts with $PPh_3$ (1:1 molar ratio) in $CDCl_3$ to give **6** (see Scheme 2). The NMR spectroscopic data of **6** show that the intramolecular H bond has been restored, since the signal attributed to the NH proton ap-

pears at $\delta$ = 11.61 ppm, a position close to that found in free **L1** ($\delta$ = 12.25 ppm). A plausible structure for **6** is shown in Scheme 2, taking into account the known reluctance of $PPh_3$ ligands to coordinate *trans* to metalated $C_{aryl}$ atoms.

### Synthesis and Reactivity of L2

The exchange of the $CO_2Me$ group for the CN group promotes notable differences of reactivity. The ylide $Ph_3P{=}C(CN)C(=S)N(H)Ph$ (**L2**) was prepared following reported methods[3a] by reaction of $Ph_3P{=}C(H)CN$[3d] with PhNCS. The IR spectrum of **L2** shows intense absorptions at 3262 (NH), 2159 (CN), and 1524 and 1108 $cm^{-1}$ (thioamide).[21] The shifts of the CN[22] and thioamide bands suggest an extensive delocalization of the charge density, and this fact agrees with the presence of the resonance forms shown in Figure 3. The $^1H$ NMR spectrum of **L2** shows a singlet at $\delta$ = 8.49 ppm due to the NH proton. This signal is shifted upfield when compared with **L1** meaning, probably, that a similar hydrogen bond is not present in solution. The ylidic $C_\alpha$ atom appears in the $^{13}C\{^1H\}$ NMR spectrum as a doublet at $\delta$ = 49.62 ppm ($^1J_{P,C}$ = 162 Hz), while the CS atom ($\delta$ = 189.68 ppm) appears at higher field than expected (usually about $\delta$ = 205 ppm).[12,21] The X-ray structure of **L2** has also been determined.

The molecular skeleton of **L2** (Figure 4 and Table 2) is very similar to that reported for **L1**, and the geometrical parameters of the P–$C_\alpha$–C(S)–N–C unit are nearly the same as those found in **L1**. For instance, the P–$C_\alpha$ [1.7401(17) Å], $C_\alpha$–$C_\beta$(S) [1.432(2) Å], and $C_\beta$–S [1.6831(17) Å] bond lengths are identical, within experimental error, to the corresponding values found in **L1** [1.751(2), 1.436(3), and 1.690(2) Å, respectively], and similar conclusions can be derived from a comparison of the bond angles. Thus, ligand **L2** also shows an extensive delocalization of the charge density, as can be deduced from the spectroscopic data. The C(1)–N(1) bond length [1.152(2) Å] is slightly longer than those reported for typical C≡N bonds (1.136 Å),[15] but is similar to those found in other cyano-stabilized ylides which contain additional stabilizing groups.[22] This elongation can be related to the presence of an intermolecular hydrogen bond between the N(2)–H(2) dipole of one molecule and the N(1)–C(1) group of another molecule. As a result of this, **L2** forms dimers in the crystal. This H bond is characterized by the following parameters: N(1)···N(2) 3.009(3), N(1)···H(2) 2.251(3) Å; N(1)···H(2)–N(2) 152.23(2)°. The intramolecular P(1)–S(1) distance is 3.090 Å, slightly longer than that found in **L1**, but is shorter

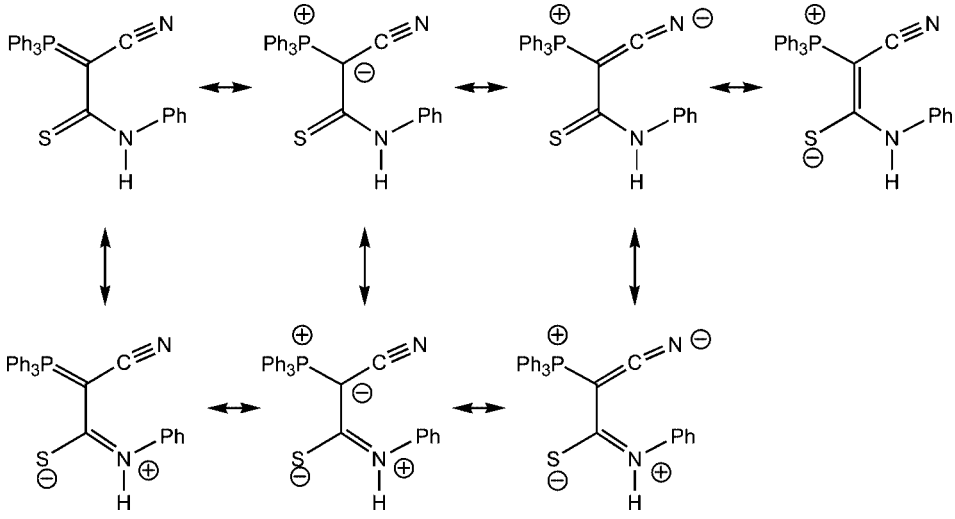

Figure 3. Resonance forms for ligand **L2**.

than the sum of the van der Waals radii (3.60 Å),[18] while the torsion angle P(1)–C(2)–C(3)–S(1) is –10.29°.

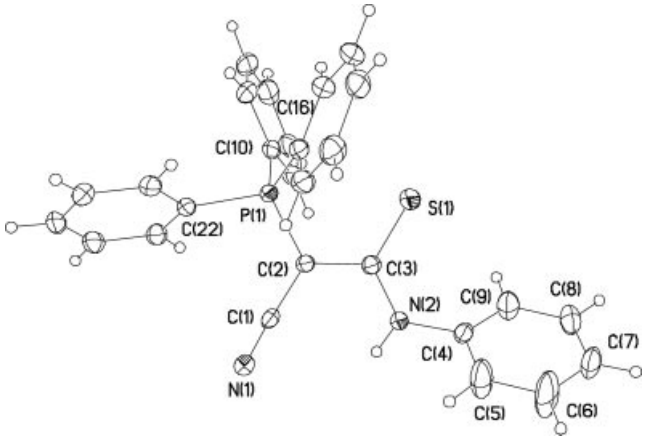

Figure 4. Thermal ellipsoid plot of **L2**. Non-hydrogen atoms are drawn at the 50% probability level.

Table 2. Selected bond lengths [Å] and angles [°] for **L2**.

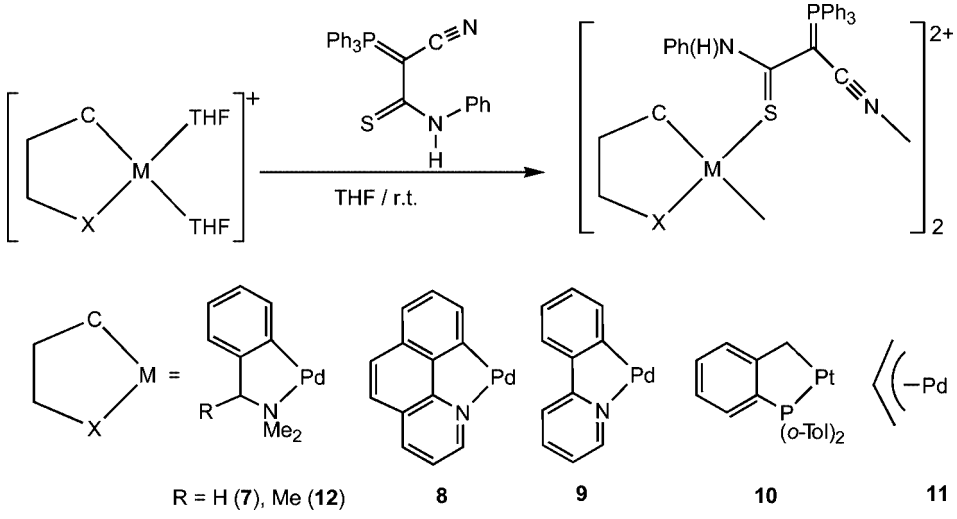
The reaction of $[M(C\hat{}X)(thf)_2]ClO_4$ with **L2** (1:1 molar ratio, thf, room temp.) gives complexes of stoichiometry $[M(C\hat{}X)(\mathbf{L2})](ClO_4)$ (**7**–**12**, Scheme 3). Their mass spectra (FAB+) show intense peaks due to a mononuclear stoichiometry, and those of **10** and **12** show additional peaks at 1968 and 1480 amu, respectively, with the correct isotopic distribution for an $[M_2(C\hat{}X)_2(\mathbf{L2})_2(ClO_4)]^+$ stoichiometry, and suggesting that **7**–**12** are dinuclear in nature. The IR spectra of **7**–**12** show the $\nu_{CN}$ stretch in the 2195–2206 $cm^{-1}$ region, and the $\nu_{CS}$ stretch in the 1027–1064 $cm^{-1}$ range. With these data, two structures can be envisaged: a mononuclear one with **L2** as a $C_\alpha$,S-chelate,[23] and a binuclear compound with the ylide acting as an N,S- or $C_\alpha$,S-bridging ligand. In this case, chelation through the N-cyano and S atoms is discarded because of the constraint imposed by the nitrile group. The measurement of $\Lambda_M$ in solution could be a convenient tool to determine the nuclearity of complexes **7**–**12**, through the determination of the slope of the Onsager equation.[24] However, **7**–**12** are extremely insoluble in the usual noncoordinating solvents and they only show a moderate solubility in strongly coordinating solvents such as dmso or acetonitrile. This means that in solution the solvent could be incorporated into the coordination sphere of the metal, with concomitant changes of nuclearity or bonding modes of the ylide. The IR spectrum of **11** in MeCN shows the absorption of the $\nu_{CS}$ stretch at 1102 $cm^{-1}$, virtually at the same position as in free **L2** (1108 $cm^{-1}$), while the $\nu_{CN}$ stretch appears at 2181 $cm^{-1}$ and two new bands at 2293 and 2248 $cm^{-1}$ are also seen. These facts suggest that MeCN is bonded to the Pd atom replacing the S atom, which is no longer bonded, and that the environment of the C(H)–CN group is the same in solution and in the solid state.

The NMR spectra of **7**–**12** provide additional valuable information. Key features of the NMR spectra are: (i) the behavior of the molecular plane as a symmetry plane; (ii) the low-field shift of $\delta$(P) in the $^{31}P\{^1H\}$ NMR spectrum with respect to **L2**; (iii) the similarity of $\delta(C_\alpha)$ and $^1J_{P,C}$ values in **7**–**12** and in free **L2**.[23] According to our previous experience,[23] all these observations exclude the C coordination of the ylide and strongly suggest the N-cyano bonding of **L2** to the Pd atom. In conclusion, we propose a dinuclear structure with an N,S-bridging ylide ligand for complexes **7**–**12**, as depicted in Scheme 3. Finally, and as explained for **L1**, the absence of symmetry in **L2** should also result in two geometric isomers after coordination. For similar reasons to those reported for complexes **1**–**5**, and also



Scheme 3.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

due to the previously described coordinating behavior of cyano ylides,[23] we propose the bonding of the N atom of the ylide *trans* to the orthometalated C atom.

### Synthesis and Reactivity of L3

The ylide $Ph_3P{=}C(CN)C(CO_2Me){=}C(H)CO_2Me$ (**L3**) was prepared following the procedure reported by Trippett et al.[3b] by reaction of $Ph_3P{=}C(H)CN$[3d] with DMAD (dimethylacetylenedicarboxylate) in refluxing MeOH, as a yellow solid stable to the air and to moisture. The yield for **L3** has been improved with respect to methods reported previously (65% of analytic and spectroscopically pure product vs. 43%). In addition, **L3** has been fully characterized spectroscopically because very few details were given in the original report.[3b] The IR spectrum of **L3** shows absorptions of all expected functional groups, at 2169 ($\nu_{CN}$), 1744, 1689 ($\nu_{COO}$), and 1531 ($\nu_{CC}$) $cm^{-1}$. The NMR parameters of **L3** follow a close relationship with those reported for **L1** and **L2**. For instance, the $^{13}C\{^1H\}$ NMR spectrum shows the signal due to $C_\alpha$ at $\delta$ = 32.27 ppm as a doublet ($^1J_{P,C}$ = 130 Hz) that is strongly downfield shifted with respect to the starting ylide. The $^1H$ NMR spectrum shows the expected signals, although the (*E*)- or (*Z*)-configuration of the C=C double bond is not defined. A 1D-NOESY experiment performed for **L3** shows a small, but detectable, NOE in the signals of the OMe groups when the signal due to the =CH proton ($\delta$ = 4.81 ppm) is irradiated, which clearly agrees with an (*E*) configuration.

The ligand **L3** is multidentate, as is evident from the resonance forms shown in Figure 5. Plausible donor atoms are the $C_\alpha$ atom, the cyano N atom, the carbonyl oxygens, and even the C=C double bond. The reactivity of **L3** towards bis-solvate derivatives of $Pd^{II}$ and $Pt^{II}$ has been studied. The reaction of $[M(C\hat{}X)(thf)_2]ClO_4$ with **L3** (1:1 molar ratio, thf, room temp.) gives solids of stoichiometry $[M(C\hat{}X)(\mathbf{L3})](ClO_4)$ (**13**–**18**), as derived from their elemental analyses (Scheme 4). The mass spectra (FAB+) of **13**–**18** show the presence of peaks due to the stoichiometry $[M(C\hat{}X)(\mathbf{L3})]^+$, with the correct isotopic distribution. We have not observed peaks due to species of higher nuclearity, as observed for **L2**. The use of the ESI-MS as an identification tool of the nuclearity of the species in solution is a well established fact.[25] In the case of complexes **13**–**18**, the analysis of their NCMe solutions only showed, once again, peaks due to the $[M(C\hat{}X)(\mathbf{L3})]^+$ stoichiometry. This fact suggests that these complexes are mononuclear in nature. Additional proof can be derived from molar conductivity measurements[24] and from NMR diffusion experiments.[26]

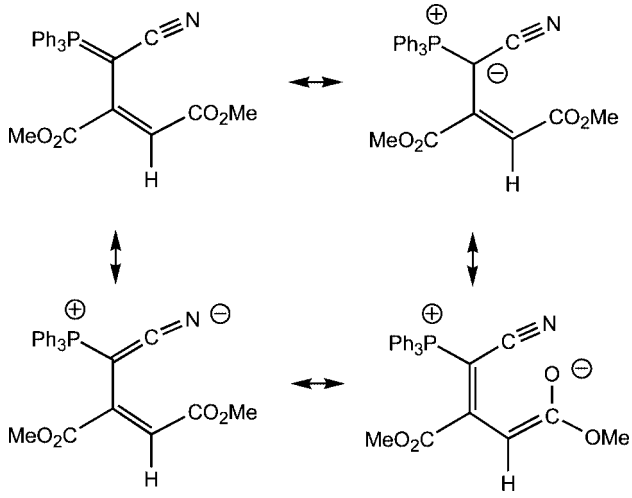


Figure 5. Resonance forms for ligand **L3**.

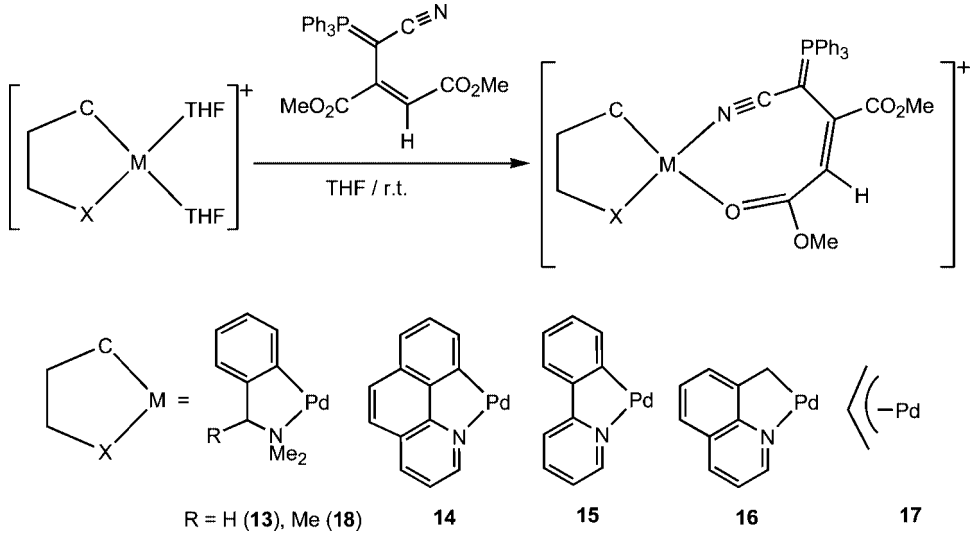
Since these complexes are adequately soluble in the usual organic solvents, the value of the molar conductivity can be determined. For complex **13**, the values determined for $\Lambda_M$ are 114.0 (acetone, $c = 2\times10^{-4}$ M) and 81.7 $\Omega^{-1}cm^2mol^{-1}$ ($MeNO_2$, $c = 1\times10^{-3}$ M). These values are typical of 1:1 electrolytes[3b] and mean that **13**–**18** could be mononuclear with **L3** acting as a chelating ligand. The IR spectra of **13**–**18** show two relevant features: (i) an increase of the $\nu_{CN}$ stretch; and (ii) a slight decrease of one of the $\nu_{CO}$ stretches,



Scheme 4.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

both with respect to **L3**. As we have seen, the increase of the $\nu_{CN}$ stretch could be due either to the C(ylide) or the N(cyano) bonding to the metal, while the decrease of the $\nu_{CO}$ indicates the coordination of the oxygen of one carbonyl group. Interestingly, the IR spectra of **13**–**18** in solution are virtually the same as in the solid state, thereby suggesting that the bonding mode of the ylide remains the same in solution. The NMR spectra of **13**–**18**, measured in nonbonding solvents ($CDCl_3$) and compared with **L3**, show similar features to those described for **L1** and **L2**. The small variations of $\delta$(P), $\delta(C_\alpha)$, and $^1J_{P,C}$ mean that the P=C moiety in coordinated **L3** is not involved in bonding with the Pd atom. According to the IR and NMR spectroscopic data, the ylide **L3** coordinates to the metal center in **13**–**18** through the N atom of the cyano group and through one oxygen atom of one carbonyl group. The mass spectra and the conductivity measurements suggest, in addition, that the complexes are mononuclear and that **L3** acts as a chelating ligand. The pulsed gradient spin-echo (PGSE) NMR diffusion methods (DOSY) have proved to be a valuable tool for the determination of relative molecular sizes in solution.[26] We have compared the diffusion coefficients of one representative of **13**–**18** with those obtained for other mononuclear complexes with the same ligands. We have shown that complexes **1**–**5** behave as mononuclear in solution. The determination of the value of *D* for **3** [8-mq as ancillary ligand, see Equation (1)] gives a value of $5.93\times10^{-10}$ $m^2s^{-1}$ (2 mM, $CDCl_3$, 300 K, $\delta$ = 1.7 ms, $\Delta$ = 100 ms). This value fits very well with that determined for complex **16** (8-mq as ancillary ligand, *D* = $5.92\times10^{-10}$ $m^2s^{-1}$) under the same experimental conditions (2 mM, $CDCl_3$, 300 K, $\delta$ = 1.8 ms, $\Delta$ = 100 ms). Thus, it is sensible to suppose that **13**–**18** are also mononuclear (Scheme 4), even taking into account the geometric constraint imposed by the cyano group. Two factors could contribute to the stabilization of the chelating mode of **L3**. The first one could be the formation of a highly flexible eight-membered ring, and the second one is the possible bent coordination of the CN group, as has been shown previously.[27]

The behavior of the cyclometalated complex [Pt{*o*-$CH_2C_6H_4P(o\text{-tol})_2$}$(S)_2$]$ClO_4$ (S = solvent) towards **L3** is slightly different. In this case, when the reaction is carried out in a 1:1 molar ratio, a low yield of **19** is obtained together with some decomposition to $Pt^0$. The yield of **19** improves up to 80% when the reaction is performed with a 1:2 (Pt/**L3**) molar ratio (see Scheme 5). Even when a substoichiometrict amount of **L3** is employed, complex **19** is the only species isolated. The characterization of **19** is straightforward. The $^1$H NMR spectrum shows the incorporation of two **L3** ligands per cyclometalated unit since only one peak is observed for the Me of the tolyl groups while the peaks due to the ligand appear duplicated. The $^{31}P\{^1H\}$ NMR spectrum shows the presence of three singlets with relative intensities 1:1:1 at $\delta$ = 19.97 (**L3**), 19.69 (**L3**), and 18.09 ppm.

The reluctance of $C_\alpha$ to bond to the metal center is a recurrent fact throughout the bonding modes of **L1**–**L3**. A plausible explanation for this lack of reactivity could be centered on the fact that the charge density of $C_\alpha$ is delocalized throughout the molecular skeleton, including the two stabilizing groups. This should lead to a decrease of the formal charge of $C_\alpha$, which becomes a poor donor and which cannot compete against the heteroatoms present in the same molecule (N, S, O, ...).

## Conclusions

The ylides **L1**, **L2**, and **L3**, all of which contain two stabilizing groups at the ylidic $C_\alpha$ atom, have been prepared and characterized. The X-ray crystal structures of **L1** and **L2** have been determined; they show extensive delocalization of the ylidic charge density. Ligands **L1**–**L3** coordinate to $Pd^{II}$ and $Pt^{II}$ solvates in a variety of forms. Ligand **L1** bonds as a chelate through the S atom and the resonance-stabilized C=O group; ligand **L2** coordinates as a bridging ligand through the S atom and the cyano N atom; and ligand **L3** can coordinate as a chelate, through the cyano N atom and one oxygen of a C=O group, or as a monodentate ligand through the cyano N atom. In spite of the presumed nucleophilic properties of $C_\alpha$, this atom does not coordinate to the metal center in any of the cases studied due to delocalization of its charge density.

## Experimental Section

**CAUTION:** Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small amounts of these materials should be prepared and they should be handled with great caution. See *J. Chem. Educ.* **1973**, *50*, A335–A337.

**General Methods:** Solvents were dried and distilled under argon using standard procedures before use. Elemental analyses were carried out with a Perkin–Elmer 2400-B microanalyser. IR spectra (4000–400 $cm^{-1}$) were recorded with a Perkin–Elmer Spectrum One IR spectrophotometer from nujol mulls between polyethylene sheets. $^1H$ (300.13, 400.13 MHz), $^{13}C\{^1H\}$ (75.47, 100.61 MHz), and $^{31}P\{^1H\}$ (121.49, 161.97 MHz) NMR spectra were recorded in $CDCl_3$, $CD_2Cl_2$, or [D$_6$]DMSO solutions at 25 °C (other temperatures are specified) with Bruker ARX300 and Avance400 spectrometers ($\delta$ in ppm, J in Hz). The $^1H$ and $^{13}C\{^1H\}$ NMR spectra were referenced using the solvent signal as internal standard whereas $^{31}P\{^1H\}$ NMR spectra were externally referenced to $H_3PO_4$ (85%). The $^1H$ SELNO-1D and SELRO-1D NMR experiments were performed with optimized mixing times (D8, P15) depending on the irradiated signal. ESI/APCI mass spectra were recorded using an Esquire 3000 ion-trap mass spectrometer (Bruker Daltonik GmbH, Bremen, Germany) equipped with a standard ESI/APCI source. Samples were introduced by direct infusion with a syringe pump. Nitrogen served both as the nebulizer gas and the dry gas. Helium served as cooling gas for the ion trap and collision gas for $MS^n$ experiments. Other mass spectra (positive ion FAB) were recorded from $CH_2Cl_2$ solutions on a V. G. Autospec spectrometer. The starting materials $Ph_3P{=}C(H)CO_2Me$,[9b] $Ph_3P{=}C(H)CN$,[3d] [Pd(μ-Cl)($C_6H_4CH_2NMe_2$-$C^2$,$N$)]$_2$,[28] [Pd(μ-Cl){$SC_6H_4C(H)MeNMe_2$-$C^2$,$N$}]$_2$,[28] [Pd(μ-Cl)($NC_{13}H_8$-$C^{10}$,$N$)]$_2$,[29] [Pd(μ-Cl)($CH_2NC_9H_6$-$C^8$,$N$)]$_2$,[30] [Pd(μ-Cl)($C_6H_4$-2-$NC_5H_4$-$C^2$,$N$)],[31] [M(μ-Cl)(*o*-$CH_2C_6H_4$)P(*o*-tol)$_2$]$_2$ (M = Pd,[32] Pt[33]), and [Pd(μ-Br)($\eta^3$-$C_3H_5$)]$_2$,[34] were prepared following reported methods. Other reagents such as DMAD ($MeO_2C$-C≡C-$CO_2Me$) or PhN=C=S were purchased from commercial sources (Aldrich) and used without further purification.

**$Ph_3P{=}C(CO_2Me)C(=S)N(H)Ph$ (L1):** The ylide **L1** was prepared following the method described in the literature by Bestmann and Pfohl[3a] by reaction of $Ph_3P{=}C(H)CO_2Me$ with PhNCS in toluene (66% yield). The characterization of **L1** is reported here since no data were given in the original paper. $C_{28}H_{24}NO_2PS$ (469.54): calcd. C 71.62, H 5.15, N 2.98, S 6.83; found C 71.45, H 5.11, N 2.84, S 6.77. MS (FAB+): *m*/*z* (%) 469 (18) [M$^+$]. IR: $\tilde{\nu}$ = 1107 ($\nu_{CS}$), 1526 ($\nu_{CN}$), 1584 (Ph), 1629 ($\nu_{CO}$) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 3.00 (s, 3 H, OMe), 7.03 (tt, $^3J_{H,H}$ = 7.2, $^4J_{H,H}$ = 0.9, 1 H, $H_p$, NPh), 7.24 (t, $^3J_{H,H}$ = 7.2, 2 H, $H_m$, NPh), 7.32–7.51 (m, 9 H, $PPh_3$), 7.69 (dd, 2 H, $H_o$, NPh), 7.73–7.82 (m, 6 H, $H_o$, $PPh_3$), 12.25 (s, 1 H, NH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 49.67 (OMe), 71.47 (d, $^1J_{P,C}$ = 143.1, P=C), 123.71 ($C_{meta}$, NPh), 124.31 ($C_{para}$, NPh), 128.20 ($C_{ortho}$, NPh), 128.36 (d, $^3J_{P,C}$ = 12.7, $C_{meta}$, $PPh_3$), 128.50 (d, $^1J_{P,C}$ = 97, $C_{ipso}$, $PPh_3$), 131.12 (d, $^4J_{P,C}$ = 2.6, $C_{para}$, $PPh_3$), 132.94 (d, $^2J_{P,C}$ = 9.3, $C_{ortho}$, $PPh_3$), 140.38 ($C_{ipso}$, NPh), 168.93 (d, $^2J_{P,C}$ = 16.4, C=O), 189.01 (d, $^2J_{P,C}$ = 16.6, C=S) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 11.33 ppm.

**Synthesis of 1:** $AgClO_4$ (0.045 g, 0.217 mmol) was added to a suspension of [Pd(μ-Cl)($C_6H_4CH_2NMe_2$-$C^2$,$N$)]$_2$ (0.060 g, 0.108 mmol) in dry thf (20 mL) under an Ar atmosphere. The resulting suspension was stirred for 20 min at room temperature with exclusion of light, and then filtered through a Celite pad in order to remove the AgCl. The ylide **L1** (0.102 g, 0.217 mmol) was added to this freshly prepared solution of the solvate derivative. The resulting solution was stirred for 30 min and then the solvent evaporated to dryness. Treatment of the residue with $Et_2O$ (25 mL) and vigorous stirring gave **1** as a yellow solid, which was filtered, washed with additional $Et_2O$ (10 mL), and air dried. Yield: 0.060 g (34.1%). Complex **1** was recrystallized from $CH_2Cl_2$/$Et_2O$ to give yellow crystals of **1**·0.5$CH_2Cl_2$, which were used for analytic and spectroscopic purposes. The amount of $CH_2Cl_2$ was determined by integration of the signal in the $^1H$ NMR spectrum. $C_{37}H_{36}ClN_2O_6PPdS$·0.5$CH_2Cl_2$ (852.06): calcd. C 52.86, H 4.38, N 3.29, S 3.76; found C 52.93, H 4.31, N 3.12, S 3.83. MS (FAB+): *m*/*z* (%) 709 (15) [M – $ClO_4$]$^+$. IR: $\tilde{\nu}$ = 1066 ($\nu_{CS}$), 1575 ($\nu_{CN}$), 1596 ($\nu_{CO}$), 3260 ($\nu_{NH}$) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.81 (s, 6 H, $NMe_2$), 3.08 (s, 3 H, OMe), 4.03 (s, 2 H, $CH_2N$), 6.58–6.61 (m, 2 H, $H_o$, NPh), 6.77–6.82 (m, 2 H, $C_6H_4$), 6.98–7.00 (m, 2 H, $C_6H_4$), 7.21 (m, 3 H, $H_m$, $H_p$, NPh), 7.27 (br. s, 1 H, NH), 7.67–7.96 (m, 15 H, $PPh_3$) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 51.16 ($NMe_2$), 52.80 (OMe), 71.53 (d, $^1J_{P,C}$ = 103.6, P=C), 71.81 ($CH_2N$), 122.42 (d, $^1J_{P,C}$ = 91.3, $C_{ipso}$, $PPh_3$), 123.17, 125.33, 126.00, 133.49, 137.83, 142.57 ($C_6H_4$), 126.06 ($C_{meta}$), 128.20 ($C_{para}$), 129.40 ($C_{ortho}$), 148.65 ($C_{ipso}$) (NPh), 130.69 (d, $^2J_{P,C}$ = 12.5, $C_{ortho}$), 133.67 (d, $^3J_{P,C}$ = 9.9, $C_{meta}$), 134.71 ($C_{para}$) ($PPh_3$), 172.49 (d, $^2J_{P,C}$ = 10.2, C=O), 186.70 (d, $^2J_{P,C}$ = 4.1, CS) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 19.29 ppm.

**Synthesis of 2:** Complex **2** was obtained following the same synthetic procedure as reported for **1**. [Pd(μ-Cl){(*S*)-$C_6H_4CH(Me)NMe_2$-$C^2$,$N$}]$_2$ (0.060 g, 0.103 mmol) was treated with $AgClO_4$ (0.043 g, 0.207 mmol) and **L1** (0.097 g, 0.207 mmol) in thf to give **2** as an orange solid. Yield: 0.113 g (66.3%). Complex **2** was recrystallized from $CH_2Cl_2$/$Et_2O$ to give orange crystals of **2**·0.5$CH_2Cl_2$, which were used for analytic and spectroscopic purposes. The amount of $CH_2Cl_2$ was determined by integration of the signal in the $^1H$ NMR spectrum. $C_{38}H_{38}ClN_2O_6PPdS$·0.5$CH_2Cl_2$ (866.09): calcd. C 53.39, H 4.54, N 3.23, S 3.70; found C 53.28, H 4.34, N 3.39, S 3.88. MS (FAB+): *m*/*z* (%) 723 (30) [M – $ClO_4$]$^+$. IR: $\tilde{\nu}$ = 1080 ($\nu_{CS}$), 1575 ($\nu_{CN}$), 1600 ($\nu_{CO}$), 3220 ($\nu_{NH}$) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.63 (d, $^3J_{H,H}$ = 6.3, 3 H, Me), 2.63 (s, 3 H, $NMe_2$), 2.87 (s, 3 H, $NMe_2$), 3.08 (s, 3 H, OMe), 4.03 (q, 1 H, CH), 6.59 (m, 2 H, $H_o$, NPh), 6.83 (m, 2 H, $C_6H_4$), 6.92–7.03 (m, 2 H, $C_6H_4$), 7.22 (m, 3 H, $H_m$, $H_p$, NPh), 7.25 (br. s, 1 H, NH), 7.65–7.96 (m, 15 H, $PPh_3$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 19.25 ppm.

**Synthesis of 3:** Complex **3** was obtained following the same synthetic procedure as reported for **1**. [Pd(μ-Cl)($CH_2NC_9H_6$-$C^8$,$N$)]$_2$ (0.061 g, 0.107 mmol) was treated with $AgClO_4$ (0.044 g, 0.212 mmol) and **L1** (0.101 g, 0.215 mmol) in thf to give **3** as a yellow solid. Yield: 0.122 g (69.5%). $C_{38}H_{32}ClN_2O_6PPdS$ (817.57): calcd. C 55.83, H 3.94, N 3.42, S 3.92; found C 56.26, H 3.74, N 3.14, S 4.10. MS (FAB+): *m*/*z* (%) 717 (27) [M – $ClO_4$]$^+$. IR: $\tilde{\nu}$ = 1065 ($\nu_{CS}$), 1564 ($\nu_{CN}$), 1599 ($\nu_{CO}$), 3216 ($\nu_{NH}$) $cm^{-1}$. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 3.21 (s, 3 H, OMe), 3.36 (s, 2 H, $CH_2Pd$), 6.57 (br., 2 H, $H_o$, NPh), 7.21 (br. s, 3 H, NH, $NC_9H_6$), 7.51–7.60 [m, 4 H, $H_m$, $H_p$ (NPh), $NC_9H_6$], 7.66–7.80 [m, 10 H, $H_m$, $H_p$ ($PPh_3$) + $NC_9H_6$], 7.90–7.97 (m, 6 H, $H_o$, $PPh_3$), 8.41 (d, $^3J_{H,H}$ = 8.1, 1 H, $NC_9H_6$), 8.66 (br. s, 1 H, $NC_9H_6$) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 21.60 ($PdCH_2$), 52.69 (OMe), 70.63 (d, $^1J_{P,C}$ = 106.1, P=C), 125.08 (d, $^1J_{P,C}$ = 93, $C_{ipso}$, $PPh_3$), 121.98, 124.56, 126.87, 128.25, 137.92, 138.88, 147.42, 149.08, 152.21 ($NC_9H_6$), 126.21 ($C_{meta}$), 128.93 ($C_{para}$), 129.42 ($C_{ortho}$), 148.99 ($C_{ipso}$) (NPh), 130.65 (d, $^2J_{P,C}$ = 11.1, $C_{ortho}$), 133.60 (d, $^3J_{P,C}$ = 9.5, $C_{meta}$), 134.59 ($C_{para}$) ($PPh_3$) ppm; the CO and CS signals were not observed. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 19.69 ppm.

**Synthesis of 4:** Complex **4** was obtained following the same synthetic procedure as reported for **1**. [Pd(μ-Cl)($C_6H_4$-2-$NC_5H_4$-$C^2$,$N$)]$_2$ (0.062 g, 0.105 mmol) was treated with $AgClO_4$ (0.044 g, 0.212 mmol) and **L1** (0.101 g, 0.215 mmol) to give **4** as a yellow

solid. Yield: 0.088 g (50.3%). $C_{39}H_{32}ClN_2O_6PPdS$ (829.58): calcd. C 56.47, H 3.89, N 3.38, S 3.86; found C 56.46, H 3.76, N 3.33, S 4.21. MS (FAB+): *m/z* (%) 729 (30) $[M - ClO_4]^+$. IR: $\tilde{\nu}$ = 1080 ($\nu_{CS}$), 1578 ($\nu_{CN}$), 1600 ($\nu_{CO}$), 3259 ($\nu_{NH}$) $cm^{-1}$. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 3.21 (s, 3 H, OMe), 6.64 (dd, $^3J_{H,H}$ = 5.7, $^4J_{H,H}$ = 1.6, 2 H, $H_o$, NPh), 7.02 (td, $^3J_{H,H}$ = 7.5, $^4J_{H,H}$ = 1.2, 1 H, Phpy), 7.04 (s, 1 H, NH), 7.14 (td, $^3J_{H,H}$ = 6.6, $^4J_{H,H}$ = 1.8, 1 H, Phpy), 7.24–7.27 [m, 4 H, $H_m$+$H_p$ (NPh) + Phpy], 7.32 (td, $^3J_{H,H}$ = 6.6, $^4J_{H,H}$ = 0.9, 1 H, Phpy), 7.55 (d, $^3J_{H,H}$ = 7.5, 1 H, Phpy), 7.68–7.99 (m, 17 H, $PPh_3$ + Phpy), 8.45 (d, $^3J_{H,H}$ = 5.0, 1 H, Phpy) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 53.09 (OMe), 71.67 (d, $^1J_{P,C}$ = 102.8, P=C), 119.59, 123.32, 124.74, 125.77, 130.06, 134.20, 137.82, 140.10, 146.47, 147.07, 164.27 (Phpy), 122.18 (d, $^1J_{P,C}$ = 91, $C_{ipso}$, $PPh_3$), 126.16 ($C_{meta}$), 128.44 ($C_{para}$), 129.50 ($C_{ortho}$), 149.73 ($C_{ipso}$) (NPh), 130.77 (d, $^2J_{P,C}$ = 12.4, $C_{ortho}$), 133.68 (d, $^3J_{P,C}$ = 9.7, $C_{meta}$), 134.78 ($C_{para}$) ($PPh_3$), 186.47 (d, $^2J_{P,C}$ = 4.4, C=S) ppm; the CO signal was not observed. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 19.27 ppm.

**Reaction of 4 with $PPh_3$:** $PPh_3$ was added in small portions to a suspension of **4** in $CD_2Cl_2$ (0.6 mL) in an NMR tube. NMR spectra were measured each time, until complete transformation of **4**. At this point, complete dissolution had occurred. The amount of $PPh_3$ required matched a 1:1 molar ratio (**4**:$PPh_3$), and gave complex **6** as a single isomer in 100% spectroscopic yield. Selected NMR spectroscopic data of **6**: $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 3.00 (s, 3 H, OMe), 6.31 (t, $^3J_{H,H}$ = 6.9, 1 H, Phpy), 6.46–6.59 (m, 6 H, NPh + Phpy), 6.91 (t, $^3J_{H,H}$ = 7.2, 1 H, Phpy), 7.24–7.74 (m, 33 H, $PPh_3$ + Phpy), 7.89 (br. s, 1 H, Phpy), 7.96 (td, $^3J_{H,H}$ = 7.5, $^4J_{H,H}$ = 1.5, 1 H, Phpy), 11.61 (s, 1 H, NH) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 17.65 (P=C), 38.09 ppm (Pd–$PPh_3$).

**Synthesis of 5:** Complex **5** was obtained following the same synthetic procedure as reported for **1**. $[Pd(\mu\text{-}Cl)(bhq\text{-}C,N)]_2$ (bhq = $NC_{13}H_8$; 0.066 g, 0.102 mmol) was treated with $AgClO_4$ (0.042 g, 0.205 mmol) and **L1** (0.096 g, 0.205 mmol) to give **5** as a yellow solid. Yield: 0.115 g (65.7%). Complex **5** was recrystallized from $CH_2Cl_2/Et_2O$ to give crystals of **5**·$0.5CH_2Cl_2$ (determined by NMR), which were used for analytic and spectroscopic purposes. $C_{41}H_{32}ClN_2O_6PPdS{\cdot}0.5CH_2Cl_2$ (896.07): calcd. C 55.62, H 3.71, N 3.13, S 3.58; found C 55.36, H 3.88, N 2.87, S 3.74. MS (FAB+): *m/z* (%) 753 (10) $[M - ClO_4]^+$. IR: $\tilde{\nu}$ = 1060 ($\nu_{CS}$), 1586 (br., $\nu_{CN}$ + $\nu_{CO}$), 3225 ($\nu_{NH}$) $cm^{-1}$. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 3.28 (s, 3 H, OMe), 6.68 (dd, $^3J_{H,H}$ = 5.7, $^4J_{H,H}$ = 1.8, 2 H, $H_o$, NPh), 7.19 (d, $^3J_{H,H}$ = 7.2, 1 H, $NC_{13}H_8$), 7.28 (m, 3 H, $H_m$+$H_p$, NPh), 7.34 (t, $^3J_{H,H}$ = 7.5, 1 H, $NC_{13}H_8$), 7.38 (s, 1 H, NH), 7.63 (m, 2 H, $NC_{13}H_8$), 7.67–7.73 [m, 7 H, $H_m$ ($PPh_3$) + $NC_{13}H_8$], 7.76–7.82 [m, 4 H, $H_p$ ($PPh_3$) + $NC_{13}H_8$], 7.90–7.98 (m, 6 H, $H_o$, $PPh_3$), 8.42 (dd, $^3J_{H,H}$ = 8.1, $^4J_{H,H}$ = 1.2, 1 H, $H_4$, $NC_{13}H_8$), 8.66 (dd, $^3J_{H,H}$ = 5.1, 1 H, $H_2$, $NC_{13}H_8$) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 53.12 (OMe), 72.07 (d, $^1J_{P,C}$ = 103.0, P=C), 122.31 (d, $^1J_{P,C}$ = 91.2, $C_{ipso}$, $PPh_3$), 122.40, 122.46, 124.01, 124.06, 127.49, 128.96, 131.22, 134.44, 137.89, 138.31, 141.93, 146.27, 153.71 ($NC_{13}H_8$), 126.09 ($C_{meta}$), 128.30 ($C_{para}$), 129.45 ($C_{ortho}$), 147.33 ($C_{ipso}$) (NPh), 130.71 (d, $^2J_{P,C}$ = 12.5, $C_{ortho}$), 133.74 (d, $^3J_{P,C}$ = 9.4, $C_{meta}$), 134.69 ($C_{para}$) ($PPh_3$), 172.82 (d, $^2J_{P,C}$ = 10.0, C=O), 186.38 (d, $^2J_{P,C}$ = 4.7, C=S) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 19.62 ppm.

**$Ph_3P$=C(CN)C(S)N(H)Ph (L2):** PhN=C=S (0.543 mL, 0.614 g, 4.55 mmol) was added to a suspension of $Ph_3P$=C(H)CN (1.370 g, 4.55 mmol) in freshly distilled toluene (50 mL). The resulting mixture was refluxed for 1 h and then stirred for 72 h at 25 °C to give a yellow suspension. This suspension was evaporated to dryness and the residue treated with $Et_2O$ (50 mL) to give **L2** as a white solid. Yield: 1.122 g (56.5%). $C_{27}H_{21}N_2PS$ (436.52): calcd. C 74.29, H 4.85, N 6.41, S 7.34; found C 74.78, H 4.84, N 7.11, S 7.63. MS (FAB+): *m/z* (%) 437 (100) $[M + H]^+$. IR: $\tilde{\nu}$ = 1108 ($\nu_{CS}$), 1524 ($\nu_{C=N}$), 2159 ($\nu_{CN}$), 3262 ($\nu_{NH}$) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.09 (t, 1 H, $H_{para}$, Ph), 7.28 (t, $^3J_{HmHp}$ = $^3J_{HmHo}$ = 7.5, 2 H, $H_{meta}$, Ph), 7.41–7.52 [m, 8 H, $H_{meta}$($PPh_3$) + $H_{ortho}$(Ph)], 7.56–7.60 (m, 3 H, $H_{para}$, $PPh_3$), 7.71–7.80 (m, 6 H, $H_{ortho}$, $PPh_3$), 8.49 (br. s, 1 H, NH) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 49.62 (d, $^1J_{P,C}$ = 162, P=C), 120.99 (d, $^1J_{P,C}$ = 20.7, $C_{ipso}$, $PPh_3$), 124.02 ($C_{meta}$, Ph), 125.16 ($C_{para}$, Ph), 125.29 (CN), 128.47 ($C_{ortho}$, Ph), 128.96 (d, $^3J_{P,C}$ = 13, $C_{meta}$, $PPh_3$), 132.65 (d, $^4J_{P,C}$ = 2.8, $C_{para}$, $PPh_3$), 133.75 (d, $^2J_{P,C}$ = 9.8, $C_{ortho}$, $PPh_3$), 139.47 (d, $^4J_{P,C}$ = 1.5, $C_{ipso}$, Ph), 189.68 (d, $^2J_{P,C}$ = 15.4, C=S) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 14.80 (s, C=$PPh_3$) ppm.

**Synthesis of 7:** $AgClO_4$ (0.053 g, 0.257 mmol) was added to a suspension of $[Pd(\mu\text{-}Cl)(C_6H_4CH_2NMe_2\text{-}C^2,N)]_2$ (0.071 g, 0.128 mmol) in 20 mL of freshly distilled thf under argon. The resulting mixture was stirred at room temperature with exclusion of light for 30 min, then filtered through a Celite pad. This freshly prepared solution was treated with a stoichiometric amount of **L2** (0.112 g, 0.257 mmol) giving, after a few seconds, a deep yellow precipitate of **7**. This suspension was stirred at room temperature for an additional 20 min, then the yellow solid was filtered, washed with thf (5 mL) and $Et_2O$ (20 mL), dried by suction, and subsequently identified as **7**. Yield: 0.141 g (70.5%). $C_{36}H_{33}ClN_3O_4PPdS$ (776.57): calcd. C 55.68, H 4.28, N 5.41, S 4.13; found C 55.81, H 4.50, N 5.11, S 4.03. MS (FAB+): *m/z* (%) 676 (100) $[M/2 - ClO_4]^+$. IR: $\tilde{\nu}$ = 1060 ($\nu_{CS}$), 1558 ($\nu_{C=N}$), 2196 ($\nu_{CN}$), 3203 ($\nu_{NH}$) $cm^{-1}$. $^1H$ NMR ([$D_6$]DMSO): $\delta$ = 2.24 (s, 6 H, $NMe_2$), 3.53 (s, 2 H, $CH_2N$), 6.26 (d, $^3J_{H,H}$ = 7.5, 1 H, $C_6H_4$), 6.64 (m, 1 H, $C_6H_4$), 6.76 (d, $^3J_{H,H}$ = 6.6, 1 H, $C_6H_4$), 6.84 (t, $^3J_{H,H}$ = 6.9, 1 H, $C_6H_4$), 7.13–7.19 (m, 3 H, $H_o$+$H_p$, Ph), 7.28 (t, $^3J_{H,H}$ = 7.2, 2 H, $H_m$, Ph), 7.73–7.93 (m, 15 H, $PPh_3$), 10.33 (s, 1 H, NH) ppm. $^{31}P\{^1H\}$ NMR ([$D_6$]DMSO): $\delta$ = 20.22 (s, C=$PPh_3$) ppm.

**Synthesis of 8:** Complex **8** was prepared following a synthetic procedure similar to that reported for **7**. Thus, $[Pd(\mu\text{-}Cl)(bhq\text{-}C,N)]_2$ (bhq = $C_{13}H_8N$, 0.078 g, 0.122 mmol) was treated with $AgClO_4$ (0.050 g, 0.244 mmol) and **L2** (0.110 g, 0.244 mmol), in thf (20 mL), to give **8** as a yellow solid. Yield: 0.110 g (55%). $C_{40}H_{29}ClN_3O_4PPdS$ (820.58): calcd. C 58.55, H 3.56, N 5.12, S 3.91; found C 58.85, H 3.41, N 4.76, S 3.82. MS (FAB+): *m/z* (%) 720 (27) $[M/2 - ClO_4]^+$. Thus, [Pd(μ-Cl){(*S*)-$C_6H_4CH(Me)NMe_2$-$C^2$,*N*}]$_2$ (0.0725 g, 0.125 mmol) was treated with $AgClO_4$ (0.052 g, 0.250 mmol) and **L3** (0.111 g, 0.25 mmol), in thf (20 mL), to give **18** as a yellow solid. Yield: 0.1964 g (98.2%). $C_{36}H_{36}ClN_2O_8PPd$ (797.52): calcd. C 54.22, H 4.55, N 3.51; found C 54.20, H 4.47, N 3.30. MS (ESI, positive ions): *m*/*z* = 696.9 [M – $ClO_4$]$^+$. IR: $\tilde{\nu}$ = 1558 ($\nu_{CC}$), 1698 ($\nu_{COO}$), 1732 ($\nu_{COO}$), 2199 ($\nu_{CN}$) cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 1.45 (d, $^3J_{H,H}$ = 6.0, 3 H, CMe), 2.52 (s, 3 H, $NMe_2$), 2.70 (s, 3 H, $NMe_2$), 3.48 (s, 3 H, OMe), 3.67–3.74 (br. s, 4 H, OMe+CH), 4.81 (s, 1 H, =CH), 6.37 (d, $^3J_{H,H}$ = 7.8, 1 H, $C_6H_4$), 6.67–6.73 (m, 2 H, $C_6H_4$), 6.92 (t, $^3J_{H,H}$ = 7.8, 1 H, $C_6H_4$), 7.24–7.75 (m, 15 H, $PPh_3$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 18.91 (Me), 34.45 (d, $^1J_{P,C}$ = 127.3, P=C), 46.15 ($NMe_2$), 51.16 (OMe), 51.49 ($NMe_2$), 53.16 (OMe), 74.85 (CHN), 102.70 (d, $^4J_{P,C}$ = 4.9, =CH), 119.85 (d, $^1J_{P,C}$ = 91.9, $C_{ipso}$, $PPh_3$), 122.15, 122.92, 125.10, 125.34, 152.21 ($C_6H_4$; $C_2$ was not observed), 125.95 (d, $^2J_{P,C}$ = 16.2, CN), 130.03 (d, $^3J_{P,C}$ = 12.9, $C_{meta}$, $PPh_3$), 133.99 (d, $^2J_{P,C}$ = 10.4, $C_{ortho}$, $PPh_3$), 134.42 (d, $^4J_{P,C}$ = 2.3, $C_{para}$, $PPh_3$), 149.78 (d, $^2J_{P,C}$ = 7.6, =C), 165.82 ($CO_2$), 168.04 (d, $^3J_{P,C}$ = 10.8, $CO_2$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 20.17 (s, C=$PPh_3$) ppm.

**Synthesis of 19:** Complex **19** was prepared following a synthetic procedure similar to that reported for **13**. Thus, [Pt(μ-Cl){*o*-$CH_2C_6H_4P$(*o*-$MeC_6H_4)_2$}]$_2$ (0.103 g, 0.096 mmol) was treated with $AgClO_4$ (0.040 g, 0.192 mmol) and **L3** (0.170 g, 0.384 mmol), in thf (20 mL), to give **19** as a yellow solid. Yield: 0.161 g (80.2%). $C_{71}H_{64}ClN_2O_{12}P_3Pt$ (1460.76): calcd. C 58.38, H 4.42, N 1.92; found C 59.05, H 4.29, N 1.65. MS (FAB+): *m*/*z* (%) 941 (100) [M – ylide – $ClO_4$]$^+$. IR: $\tilde{\nu}$ = 1564 ($\nu_{CC}$), 1699 ($\nu_{COO}$), 1733 ($\nu_{COO}$), 2198 ($\nu_{CN}$) cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 2.26 (s, 6 H, Me), 3.19 (s, 3 H, OMe), 3.48 (s, 2 H, $PtCH_2$), 3.50 (s, 6 H, 2 OMe), 3.69 (s, 3 H, OMe), 4.80 (s, 1 H, =CH), 4.85 (s, 1 H, =CH), 6.85–7.76 (m, 42 H, $PPh_3$ + $C_6H_4$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 12.19 ($PtCH_2$), 23.08 (d, $^3J_{P,C}$ = 7.0, Me), 33.94 (d, $^1J_{P,C}$ = 127.7, P=C), 34.31 (d, $^1J_{P,C}$ = 128.3, P=C), 51.10 (OMe), 51.20 (OMe), 52.21 (OMe), 52.78 (OMe), 102.44 (d, $^4J_{P,C}$ = 6.5, =CH), 103.25 (d, $^4J_{P,C}$ = 5.2, =CH), 120.29 (d, $^1J_{P,C}$ = 92.1, $C_{ipso}$, $PPh_3$), 120.62 (d, $^1J_{P,C}$ = 92.1, $C_{ipso}$, $PPh_3$), 124.04 (d, $^2J_{P,C}$ = 15.9, CN), 125.07 (d, $^2J_{P,C}$ = 16.2, CN), 126.04 (d, $J_{P,C}$ = 10.8, $C_6H_4$), 129.77 (d, $^3J_{P,C}$ = 12.9, $C_{meta}$, $PPh_3$), 130.13 (d, $^3J_{P,C}$ = 12.9, $C_{meta}$, $PPh_3$), 131.30 (d, $J_{P,C}$ = 8.9, $C_6H_4$), 131.71 (d, $J_{P,C}$ = 11.6, $C_6H_4$), 133.33 (d, $J_{P,C}$ = 5.0, $C_6H_4$), 133.34 (d, $J_{P,C}$ = 25.5, $C_6H_4$), 133.88 (d, $^2J_{P,C}$ = 10.4, $C_{ortho}$, $PPh_3$), 134.40 (d, $^4J_{P,C}$ = 2.6, $C_{para}$, $PPh_3$), 134.74 (d, $^4J_{P,C}$ = 1.9, $C_{para}$, $PPh_3$), 141.59 (d, $J_{P,C}$ = 10.7, $C_6H_4$), 149.18 (d, $^2J_{P,C}$ = 30.9, =C), 149.29 (d, $^2J_{P,C}$ = 30.3, =C), 157.26 (d, $^1J_{P,C}$ = 27.0, $C_6H_4$), 165.83 (COO), 165.99 (COO), 167.68 (d, $^3J_{P,C}$ = 13.9, COO), 167.82 (d, $^3J_{P,C}$ = 15.9, COO) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 18.09 ($^1J_{Pt,P}$ = 4605, C^P–Pt), 19.69 (C=$PPh_3$), 19.97 (C=$PPh_3$) ppm.

**Crystallography. Data Collection:** X-ray quality crystals were grown by slow vapor diffusion of $Et_2O$ into a $CH_2Cl_2$ solution of the corresponding crude compound. A single crystal of dimensions 0.25×0.18×0.16 mm$^3$ (**L1**) or 0.30×0.24×0.06 mm$^3$ (**L2**) was mounted at the end of a quartz fiber in a random orientation and covered with epoxy. Data collection was performed on a Bruker Smart CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). A hemisphere of data was collected in each case based on three $\omega$-scan runs (starting $\omega$ = –30°) at values $\varphi$ = 0°, 90° and 180° with the detector at 2$\theta$ = 30°. For each of these runs, frames (606, 435, and 230, respectively) were collected at 0.3° intervals and 10 s per frame. The diffraction frames were integrated using the program SAINT[35] and the integrated intensities were corrected for absorption with SADABS.[36]

**Structure Solution and Refinement:** The structures were solved and developed by Patterson and Fourier methods.[37] All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were placed at idealized positions and treated as riding atoms. Each hydrogen atom was assigned an isotropic displacement parameter equal to 1.2-times the equivalent isotropic displacement parameter of its parent atom. The structures were refined to $F_o^2$, and all reflections were used in the least-squares calculations.[38]

**Crystallographic Data for L1:** $C_{28}H_{24}NO_2PS$, $M$ = 469.51, $T$ = 291(2) K, monoclinic $C2/c$, $a$ = 26.710(3), $b$ = 9.5585(1), $c$ =

20.620(2) Å, $\beta$ = 114.396(2)°, $V$ = 4794.4(9) Å$^3$, $Z$ = 8, $D_{calcd.}$ = 1.301 Mg m$^{-3}$, $\mu$ = 0.228 mm$^{-1}$, a total of 15869 reflections were collected, of which 5764 [$R_{int}$ = 0.0366] independent reflections were used in the refinement of 299 parameters and 0 restraints. The final $R$ factors were $R_1$ = 0.0516, $wR_2$ = 0.1129 for $I > 2\sigma(I)$ and $R_1$ = 0.0940, $wR_2$ = 0.1303 for all reflections, Goof = 1.022.

**Crystallographic Data for L2:** $C_{27}H_{21}N_2PS$, $M$ = 436.49, $T$ = 100(1) K, monoclinic $P2_1/c$, $a$ = 11.1040(2), $b$ = 12.2318(2), $c$ = 16.2397(2) Å, $\beta$ = 94.980(1)°, $V$ = 2197.38(6) Å$^3$, $Z$ = 4, $D_{calcd.}$ = 1.319 Mg m$^{-3}$, $\mu$ = 0.238 mm$^{-1}$, a total of 37050 reflections were collected, of which 5033 [$R_{int}$ = 0.0546] independent reflections were used in the refinement of 284 parameters and 0 restraints. The final $R$ factors were $R_1$ = 0.0433, $wR_2$ = 0.1048 for $I > 2\sigma(I)$ and $R_1$ = 0.0548, $wR_2$ = 0.1095 for all reflections, Goof = 1.061.

CCDC-612165 (for **L1**) and -612166 (for **L2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

Funding by the Dirección General de Investigación Científica y Técnica (DGICYT) Spain (projects CTQ2005-01037 and CTQ2005-03141) is gratefully acknowledged. T.S. thanks the MECD (Spain) for a postdoctoral fellowship.

# Synthesis, Characterization, and Catalytic Applications of Palladacyclic Complexes Bearing C,N,S-Donor Ligands

**Ming-Tsz Chen,[a] Chi-An Huang,[a] and Chi-Tien Chen*[a]**

**Keywords:** Palladacyclic complexes / Pendant thioether / Suzuki reaction / Heck reaction / Palladium

The preparations of novel tridentate C,N,S-donor ligand precursors, PhN=C($CMe_2$)(NPh)C=N($CH_2$)$_2$SR [R = $CMe_3$ (**2**); R = Ph (**3**)] are described. Treatment of **2** and **3** with 1 equiv. of $Pd(OAc)_2$ affords the orthometallated palladium(II) complexes [PhN=C($CMe_2$)(N-$\eta^1$-Ph)C=N($CH_2$)$_2$SR]Pd(OAc) [R = $CMe_3$ (**4**); R = Ph (**5**)]. Reaction of **4** and **5** with an excess of LiCl in methanol affords the orthometallated palladium(II) complexes [PhN=C($CMe_2$)(N-$\eta^1$-Ph)C=N($CH_2$)$_2$SR]PdCl [R = $CMe_3$ (**6**); R = Ph (**7**)]. Crystal structures are reported for compounds **3** and **4**. The application of these novel palladacyclic complexes as catalyses for the Suzuki and Heck reactions with aryl halide substrates was examined.

## Introduction

Due to the powerful application of, and versatile methods for, the formation of carbon-carbon bonds, palladium-catalyzed coupling reactions have been an attractive area of research.[1–19] Among these studies, the search for appropriate ancillary ligands that can serve as catalyst precursors is of current interest. Palladacycles bearing a metallated carbon atom and dative group(s) are the most active catalyst precursors for the promotion of such reactions.[2–8,11–17,19] These complexes are usually formed as dinuclear species with bridged ligands, or as mononuclear species in the presence of ligands with neutral dative groups. In order to improve the stability and efficiency of catalytic palladium complexes, various families of palladium based catalyst precursors have been developed. Recently, some sulfur containing palladacycles that function as excellent catalyst precursors for coupling reactions have been reported. [20–30] Their success in catalyzing cross-coupling reactions encouraged us to study the catalytic performance exhibited by palladacycles with pendant thioether functionalities. Following our previous work on four-membered ring diimino palladacycles,[31] we report here the synthesis and characterization of novel mononuclear palladacycles incorporating unsymmetrical C,N,S-donor ligands. Their catalytic activities toward the Suzuki and Heck reactions were investigated.

## Results and Discussion

### Syntheses and Characterization of Ligand Precursors and Palladacycles

Pre-ligand compound **1** was prepared by the reaction of 2,2-dimethyl-*N*,*N*′-diphenylpropanediimidoyl dichloride with 3.0 equiv. of 2-chloroethylamine hydrochloride in the presence of 4.0 equiv. of $NEt_3$ using a similar procedure to that reported in the literature.[31] The new ligand precursors **2** and **3** were synthesized from **1** via a nucleophilic substitution reaction with the corresponding thiol [R = $C(CH_3)_3$ for **2**; R = Ph for **3**].[20] Compounds **1**, **2**, and **3** were characterized by NMR spectroscopy and elemental analysis, which indicated that they are four-membered ring diimine compounds with the different functionalities. A summary of the synthetic route and the proposed structures is shown in Scheme 1. The X-ray structure of **3** features a four-membered diimine ring bearing a pendant thioether functional group. The molecular structure is shown in Figure 1, and selected bond lengths and angles are listed in Table 1. The C(1)–N(1) [1.253(2) Å] and C(3)–N(3) [1.257(2) Å] bond lengths are consistent with these bonds possessing significant double bond character, and the bond angles around the imino C and N atoms are indicative of $sp^2$ hybridized centers.

Treatment of **2** and **3** with 1 equiv. of $Pd(OAc)_2$ at room temperature yields complexes **4** and **5**, respectively, as pale brown solids. Similar to the results reported previously,[31] an additional tertiary carbon was found in the phenyl ring region of the $^{13}C\{^1H\}$ NMR spectrum that indicates the presence of a metallated carbon atom, which was created during the reactions. Crystals of **4** suitable for structural determination were obtained from a $CH_2Cl_2$/hexane solu-

tion. The molecular structure is shown in Figure 2, and selected bond lengths and angles are listed in Table 2. The bond angles [in the range of 84.62(8) to 93.47(12)°] around the palladium metal center indicate that the complex has a slightly distorted square planar geometry, in which the palladium metal center is coordinated to one imine nitrogen atom, one thioether sulfur atom, one carbon atom, and one OAc oxygen atom. The N–Pd–$C_{metallated}$ bite angle [93.47(12)°] involving the imino nitrogen and metallated carbon atoms is similar to those [93.20(104)°, 93.77(8)°, and 94.51(10)°] found in our previous work.[31] The N–Pd–S bite angle [84.62(8)°] involving the imino nitrogen atom and the pendant group is in the range [84.46(10)–85.1(1)°] found for C,N,S-donor complexes with two carbon spacer atoms

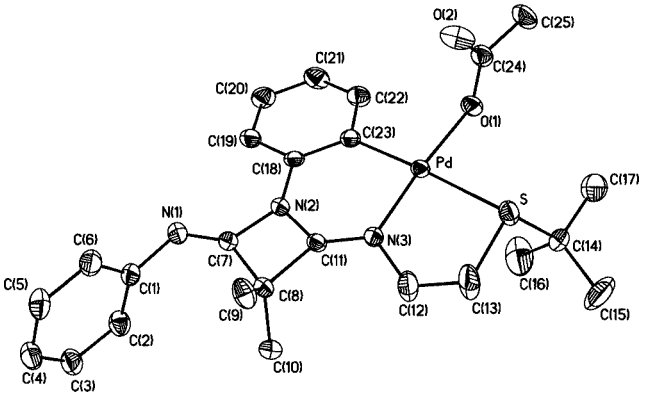

Figure 2. Molecular structure of complex **4**. Hydrogen atoms bound to carbon atoms have been omitted for clarity. Dichloromethane and water molecules are omitted for clarity.

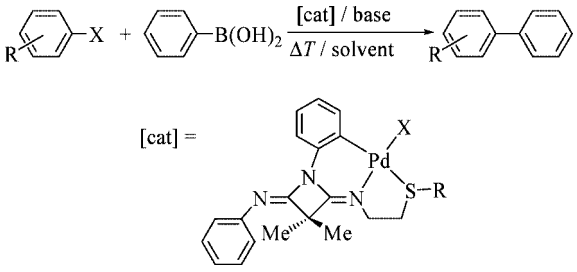
between the nitrogen and sulfur atoms.[32–34] The Pd–S bond length [2.4093(9) Å] is in the range [2.240(1)–2.422(1) Å] found for palladium complexes containing thioether functionalities.[23,25,30,32–37] The Pd–$C_{metallated}$ bond length [2.022(4) Å] is in the range [1.964(3)–2.034(2) Å] found for palladacycles with metallated carbon.[23,31–34,38] The Pd–$N_{C=N}$ bond length [2.011(3) Å] is within the range [1.985(3)–2.098(2) Å] found for palladacycles.[31–34,38] The Pd–$O_{OAc}$ bond length [2.036(2) Å] is comparable to those [2.0027(9)–2.105(2) Å] found in the literature.[31,39–41] The reaction of **4** and **5** with an excess of lithium chloride, in methanol at room temperature, yielded complexes **6** and **7**, respectively, as yellow solids.[42] Compounds **6** and **7** were characterized by NMR spectroscopy and elemental analysis. Basically, **6** and **7** are quite similar to **4** and **5**, but with Cl coordinated to the metal centre instead of an OAc group.

## Catalytic Studies

Due to the success of some sulfur containing palladacycles in catalyzing cross-coupling reactions,[20–30] the palladacycles discussed above are expected to catalyze carbon-carbon coupling reactions. For the purpose of comparing the reactivity of complexes **4**–**7** with other palladacycles, the Suzuki reaction was chosen to demonstrate the catalytic activities of these sulfur containing complexes, as shown in Scheme 2. The potential catalyst precursor candidates **4**–**7** were investigated in the coupling of 4-bromoacetophenone with phenylboronic acid at 50 °C, over a period of 1 h on a 1 mol-% scale. Selected results are listed in Table 3. The optimum conditions for the reaction were found to be $K_3PO_4$/toluene, $Cs_2CO_3$/DMA, and $Cs_2CO_3$/DMF for **4** (entries 1–3); $K_3PO_4$/DMF for **5** (entry 4); $Cs_2CO_3$/THF, $Cs_2CO_3$/toluene, and $Cs_2CO_3$/DMA for **6** (entries 5–7); $Cs_2CO_3$/THF for **7** (entry 8). Higher reactivity was observed, under optimum conditions, for palladacycles containing a pendant *t*BuS moiety. Moreover, compounds containing an acetate group demonstrated slightly higher catalytic activities than those containing a Cl group.



Scheme 2. Application of the palladacycles in the Suzuki reaction.

Although both sets of optimized conditions, $K_3PO_4$/toluene and $Cs_2CO_3$/DMF, for **4** exhibited similar conversion levels with electronically activated aryl bromide (entries 1–2 and 9–12), poor conversion levels were observed for reactions with electronically deactivated compounds using $Cs_2CO_3$/DMF (entries 14–15 and 17–18). Therefore the op-

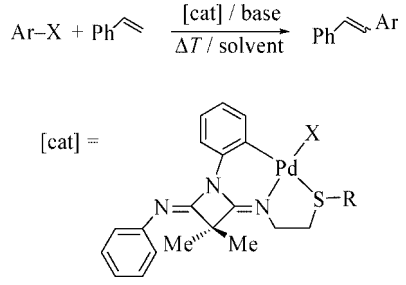
timized conditions, $K_3PO_4$/toluene, were chosen for use in further studies to examine the limitations of the catalytic capability of compound **4**. Due to the high reactivity of **4**, lower catalyst concentrations were required, catalyst/substrate ratios from $10^{-4}$ to $2\times10^{-5}$ were employed, leading to turnover numbers of up to 48000 within a 5 h period (entries 19–20). Similar conditions were applied during the reaction of the electronically activated aryl chloride with 1 mol-% catalyst loading; however, poor conversion levels were observed after 4 h (entry 21). Surprisingly, the percentage conversion increased to 85% after 4 h (entry 22) using $Cs_2CO_3$/DMF. These conditions were employed in a reaction using methyl 4-chlorobenzoate and resulted in percentage conversion levels of up to 72% within 4 h (entry 23). A similar conversion level was observed using electronically deactivated aryl chloride and 4-chloroanisole as substrates; however, the reaction took up to 7 h (entry 24). In order to compare the catalytic activities with the sulfur containing palladacycles,[22] the optimized conditions at 110 °C and 135 °C were employed in the reaction with 4-bromotoluene as the substrate, this gave conversion levels of up to 99% within 0.75 h (entries 13 and 16). A similar conversion level was observed using electronically activated aryl chloride and 4-chloroacetophenone as the substrates; however, the reaction took up to 4 h at 135 °C (entry 25).

In order to determine the influence of the pendant functionality on the catalytic activity,[21] compounds **4**–**7** were investigated as catalysts in the Heck coupling reaction of 4-bromoacetophenone with styrene at 135 °C over a period of 1.5 h on a 1 mol-% scale, as shown in Scheme 3. Selected results are listed in Table 4. The optimum conditions were found to be $Cs_2CO_3$/DMF for **4** (entry 1); KF/DMA for **5** (entry 2); $K_3PO_4$/DMA for **6** (entry 3); KF/DMA for **7** (entry 4). High reactivity was observed for **4** under optimized conditions. A similar conversion level was observed using methyl 4-bromobenzoate as the substrate (entry 5). Similar conditions were applied to the reactions employing the electronically deactivated aryl bromide compounds; however, the reactions took up to 6 h (4-bromotoluene) and 12 h (4-bromoanisole) at 135 °C (entries 6 and 7). Lower catalyst concentrations, catalyst/substrate ratios of $10^{-3}$ to $10^{-5}$, led to percentage conversion levels of 81% after 6 h and 21% after 24 h (entries 8 and 9). Compound **4** also showed catalytic activity for reactions involving both electronically activated and deactivated aryl chlorides; however, higher catalyst loadings were necessary (entries 10 and 11).



Scheme 3. Application of the palladacycles in the Heck reaction.

## Summary

Mononuclear phosphane-free palladacycles have been prepared using tridentate ligands containing carbon, nitrogen, and sulfur. Under optimized conditions, palladacycle **4** exhibits catalytic activity comparable to existing sulfur containing palladacyclic systems employed in the Suzuki coupling reaction. Complex **4** exhibits higher catalytic activity in some cases than in others. The catalyst productivity for the coupling of an electronically activated aryl bromide with phenylboronic acid was observed with a turnover of up to 48000 during a 5 h period. Complex **4** also demonstrates catalytic activity with less reactive aryl chlorides containing both electron withdrawing and electron donating groups. In the case of the four-membered diimine palladacyclic system, the thioether containing palladacycle exhibits better catalytic activity for the Heck coupling reaction than the nitrogen containing palladacycles reported in our previous work. Studies relating to the fine-tuning of the ligands, and investigations into further catalytic applications for metal complexes are currently underway.

Table 4. Heck coupling reactions catalysed by the new palladium complexes.[a]

## Experimental Section

**General Procedure:** All manipulations were carried out under nitrogen using standard Schlenk-line or drybox techniques. Solvents (THF, toluene, $CH_2Cl_2$ and hexane) were refluxed over an appropriate drying agent and distilled prior to use. Methanol (Merck, 99.9%), DMA (TEDIA, 99%) and DMF (TEDIA, 95%) were used as supplied. Deuterated solvents were dried over molecular sieves.

$^1H$ and $^{13}C\{^1H\}$ NMR spectra were recorded on Varian Gemini-200 (200 MHz), Varian Mercury-400 (400 MHz) and Varian Inova-600 (600 MHz) spectrometers. Spectra were recorded in chloroform-*d* at ambient temperature unless otherwise stated, and referenced internally to the residual solvent peak, and reported as parts per million relative to tetramethylsilane. Elemental analyses were performed with an Elementar Vario ELIV instrument.

Chemicals were used as supplied unless otherwise stated. $NEt_3$ was dried with $CaH_2$ and distilled before use. 2,2-Dimethyl-*N*,*N*′-diphenyl-malonamide and 2,2-dimethyl-*N*,*N*′-diphenylpropanediimidoyl dichloride were prepared by a method reported in the literature.[31]

**PhN=C$^A$(C$^B$Me$_2$)(N$^B$Ph)C$^C$=N(CH$_2$)$_2$Cl(*C$^A$–N$^B$*)(*C$^B$–C$^C$*) (1):** To a flask containing 2,2-dimethyl-*N*,*N*′-diphenylpropanediimidoyl dichloride (2.5 g, 8.0 mmol) and $NEt_3$ (4.5 mL, 32 mmol), 40 mL $CH_2Cl_2$, 2-chloroethylamine hydrochloride (2.8 g, 24 mmol) was added at 0 °C. The reaction mixture was warmed to room temperature and left to react overnight. After 14 h of stirring, the volatiles were removed in vacuo, and the residue was extracted with 30 mL toluene. After removal of solvent, the residue was washed with 5 mL hexane to afford a white solid. Yield, 1.84 g, 70.5%. $^1H$ NMR (600 MHz, $CDCl_3$): $\delta$ = 1.46 [s, 6 H, C(C$H_3$)$_2$], 3.74 [m, 4 H, (C$H_2$)$_2$], 6.94 (d, $^3J$ = 7.2 Hz, 2 H, *o*-Ph), 7.08 (t, $^3J$ = 7.8 Hz, 1 H, *p*-Ph), 7.16 (t, $^3J$ = 7.2 Hz, 1 H, *p*-Ph), 7.30 (t, $^3J$ = 7.8 Hz, 2 H, *m*-Ph), 7.39 (t, $^3J$ = 7.8 Hz, 2 H, *m*-Ph), 8.27 ppm (d, $^3J$ = 7.8 Hz, 2 H, *o*-Ph). $^{13}C\{^1H\}$ NMR (150 MHz, $CDCl_3$): $\delta$ = 21.7 [s, C(*C*H$_3$)$_2$], 45.0 [s, (*C*H$_2$)$_2$], 50.4 [s, (*C*H$_2$)$_2$], 58.0 [s, *tert*-*C*(CH$_3$)$_2$], 119.4, 121.4, 123.4, 124.6, 128.7 (overlap) (*o*, *m*, *p*-$C_6H_5$), 137.1, 146.7, 157.8, 159.6 ppm (two $C_{ipso}$-$C_6H_5$ and two *C*=*N* groups). $C_{19}H_{20}N_3Cl$ (325.84): calcd. C 70.04, H 6.19, N 12.90; found C 69.88, H 6.28, N 12.74.

**PhN=C$^A$(C$^B$Me$_2$)(N$^B$Ph)C$^C$=N(CH$_2$)$_2$S(CMe$_3$)(*C$^A$–N$^B$*)(*C$^B$–C$^C$*) (2):** To a flask containing **1** (0.49 g, 1.5 mmol) and $K_2CO_3$ (0.62 g, 4.5 mmol), 40 mL DMF, 2-methyl-2-propanethiol (0.34 mL, 3.0 mmol) was added. The reaction mixture was heated to 70 °C and left to react overnight. After 16 h of stirring, the resulting suspension was cooled to room temperature. Water (ca. 30 mL) was added into the suspension, which was then put into the fridge, and subsequently afforded a white solid. Yield, 0.49 g, 85.4%. $^1H$ NMR (600 MHz, $CDCl_3$): $\delta$ = 1.35 [s, 9 H, C(C$H_3$)$_3$], 1.45 [s, 6 H, C(C$H_3$)$_2$], 2.80 (t, $^3J$ = 7.2 Hz, 2 H, C$H_2$), 3.57 (t, $^3J$ = 7.8 Hz, 2 H, C$H_2$), 6.93 (d, $^3J$ = 7.2 Hz, 2 H, *o*-Ph), 7.07 (t, $^3J$ = 7.2 Hz, 1 H, *p*-Ph), 7.14 (t, $^3J$ = 7.2 Hz, 1 H, *p*-Ph), 7.28 (t, $^3J$ = 7.8 Hz, 2 H, *m*-Ph), 7.38 (t, $^3J$ = 7.8 Hz, 2 H, *m*-Ph), 8.27 ppm (d, $^3J$ = 7.8 Hz, 2 H, *o*-Ph). $^{13}C\{^1H\}$ NMR (150 MHz, $CDCl_3$): $\delta$ = 21.7 [s, C(*C*H$_3$)$_2$], 30.2 (s, *C*H$_2$), 31.0 [s, C(*C*H$_3$)$_3$], 42.2 [s, *C*(CH$_3$)$_3$], 49.1 (s, *C*H$_2$), 58.0 [s, *C*(CH$_3$)$_2$], 119.4, 121.5, 123.3, 124.4, 128.6 (overlap) (*C*H-$C_6H_5$), 137.2, 146.8, 158.0, 158.4 ppm (two $C_{ipso}$-$C_6H_5$, and two *C*=*N* groups). $C_{23}H_{29}N_3S$ (379.56): calcd. C 72.78, H 7.70, N 11.07; found C 72.35, H 7.30, N 11.01.

**PhN=C$^A$(C$^B$Me$_2$)(N$^B$Ph)C$^C$=N(CH$_2$)$_2$SPh(*C$^A$–N$^B$*)(*C$^B$–C$^C$*) (3):** The procedure for the preparation of **3** was similar to that used for **2**. A white solid was obtained. Yield, 0.46 g, 91.0%. $^1H$ NMR (600 MHz, $CDCl_3$): $\delta$ = 1.34 [s, 6 H, C(C$H_3$)$_2$], 3.19 (t, $^3J$ = 7.2 Hz, 2 H, C$H_2$), 3.63 (t, $^3J$ = 7.2 Hz, 2 H, C$H_2$), 6.91 (d, $^3J$ = 7.2 Hz, 2 H, *o*-Ph), 7.06 (t, $^3J$ = 7.2 Hz, 1 H, *p*-Ph), 7.14 (t, $^3J$ = 7.2 Hz, 1 H, *p*-Ph), 7.16 (t, $^3J$ = 7.2 Hz, 1 H, *p*-Ph), 7.26 (m, overlap, 4 H, Ph), 7.37 (m, overlap, 4 H, Ph), 8.24 ppm (d, $^3J$ = 7.8 Hz, 2 H, *o*-Ph). $^{13}C\{^1H\}$ NMR (150 MHz, $CDCl_3$): $\delta$ = 21.5 [s, C(*C*H$_3$)$_2$], 35.2 (s, *C*H$_2$), 48.3 (s, *C*H$_2$), 58.0 [s, *C*(CH$_3$)$_2$], 119.4, 121.4, 123.3, 124.5, 126.1, 128.6 (overlap), 128.9, 129.3 (*C*H-$C_6H_5$), 136.1, 137.1, 146.7, 157.9, 168.8 ppm (three $C_{ipso}$-$C_6H_5$, and two *C*=*N* groups). $C_{25}H_{25}N_3S$ (399.55): calcd. C 55.56, H 4.48, N 7.78; found C 55.47, H 4.070, N 7.80.

**General Procedure for the Suzuki-Type Coupling Reaction:** Prescribed amounts of catalyst, base (2.0 equiv.), boronic acid (1.5 equiv.), and aryl halide (1.0 equiv.) were placed under nitrogen in a Schlenk tube. Solvent (2 mL) was added by syringe, and the reaction mixture was heated at the prescribed temperature for the prescribed amount of time.

**General Procedure for the Heck Reaction:** Prescribed amount of catalysts, base (1.5 equiv.) and aryl halide (1 equiv.) were placed under nitrogen in a Schlenk tube. Solvent (2 mL) and styrene (1.3 equiv.) were added by syringe, and the reaction mixture was heated at the prescribed temperature for the prescribed amount of time.

**Crystal Structure Data:** Crystals were grown from $CHCl_3$ solution (**3**) or a $CH_2Cl_2$/hexane solution (**4**), and then isolated by filtration. Suitable crystals of **3** or **4** were sealed in thin walled glass capillaries under nitrogen and mounted on a Bruker AXS SMART 1000 diffractometer. Absorption corrections were based on symmetry equivalent reflections and applied using the SADABS program. Space group determinations were based on the Laue symmetries and systematic absences exhibited by the diffraction patterns, and were confirmed by the structure solutions. The structures were solved by direct methods using the SHELXTL package. All non-hydrogen atoms were located from successive difference Fourier maps, and hydrogen atoms were refined using a riding model. Anisotropic thermal parameters were used for all non-hydrogen atoms, and fixed isotropic parameters were used for the hydrogen atoms. The asymmetric unit of **4** contains a severely disordered molecule of dichloromethane, and a molecule of water. Crystallographic data collection and refinement details are given in Table 5.

Table 5. Summary of crystal data for compounds **3** and **4**.

| | **3** | **4** |
|---|---|---|
| Formula | $C_{25}H_{25}N_3S$ | $C_{26}H_{35}Cl_2N_3O_3PdS$ |
| Fw | 399.54 | 646.93 |
| $T$ [K] | 293(2) | 293(2) |
| Crystal system | triclinic | monoclinic |
| Space group | $P\bar{1}$ | $C2/c$ |
| $a$ [Å] | 7.9986(8) | 22.7849(14) |
| $b$ [Å] | 11.6307(11) | 13.2886(8) |
| $c$ [Å] | 12.1069(11) | 20.8977(13) |
| $\alpha$ [°] | 90.187(2) | 90 |
| $\beta$ [°] | 98.050(2) | 112.7370(10) |
| $\gamma$ [°] | 100.699(2) | 90 |
| $V$ [Å$^3$] | 1095.32(18) | 5835.7(6) |
| $Z$ | 2 | 8 |
| $\rho_{calc}$ [Mg/m$^3$] | 1.211 | 1.473 |
| $\mu$(Mo-$K_\alpha$) [mm$^{-1}$] | 0.163 | 0.922 |
| Reflections collected | 6263 | 16054 |
| No. of parameters | 262 | 335 |
| $R1$[a] | 0.0491 | 0.0422 |
| $wR2$[a] | 0.1452 | 0.1332 |
| GoF[b] | 1.065 | 1.14 |

[a] $R1 = [\Sigma(|F_o| - |F_c|)/\Sigma |F_o|]$; $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$, $w$ = 0.10. [b] GoF = $[\Sigma w(F_o^2 - F_c^2)^2/(N_{rflns} - N_{params})]^{1/2}$.

CCDC-269677 and -269678 for compounds **3** and **4** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# pH-Driven $Cu^{2+}$ Translocation in Ferrocene-Containing Ligands

**Piersandro Pallavicini,*[a] Giacomo Dacarro,*[a] Carlo Mangano,[a] Stefano Patroni,[a] Angelo Taglietti,[a] and Robertino Zanoni[b]**

**Keywords:** Molecular devices / Macrocyclic ligands / Copper / Ferrocene / N ligands

The ligands **L1**$H_4$, **L2**$H_2$, and **L**3$H_4$ have been synthesized, featuring two, one, and two ferrocene-functionalized diamino-diamido compartments, respectively. The coordination chemistry of the ligands towards $Cu^{2+}$ has been fully characterized by means of potentiometric and spectrophotometric titrations, which allowed us to determine the protonation constants of the ligands, the formation constants of their complexes, and their coordination geometry. **L1**$H_4$ and **L2**$H_2$ feature additional diaminopyridine and bis(aminoquinoline) binding sites, respectively, and are capable of the pH-driven translocation of two and one $Cu^{2+}$ cations, respectively. Electrochemical experiments (CV) coupled with pH-metric titrations demonstrate that while the coordination of $Cu^{2+}$ to the compartments more distant from ferrocene (Fc), i.e. diaminopyridine in **L1**$H_4$ and bis(aminoquinoline) in **L2**$H_2$ leaves the oxidation potential of Fc unchanged, the translocation of the $Cu^{2+}$ cation(s) inside the diamino-diamido compartment(s) is signaled by a peculiar lowering of the Fc oxidation potential.

## Introduction

The controlled translocation of metal cations is a recent development of coordination chemistry in solution based on the concepts elaborated by supramolecular chemistry,[1] and is at the edge of one of the hot topics of nanotechnology, i.e. molecular machines and controlled motions at the molecular level.[2]

However, few papers have been published so far in this field. As a first example, the chemically promoted redox-driven translocation of one iron cation inside a polytopic ligand was reported by the group of Shanzer in 1995,[3a] and the same author reported the redox-controlled translocation of one copper cation in 2002.[3b]

Using a different approach, we are involved in a long-term research effort concerning the translocation of transition metal cations in aqueous solutions driven by the variation of a classical bulk property, i.e. pH.[4,5] This approach has also been exploited by a few other groups.[6] Recent results obtained by our group include the simultaneous pH-driven translocation of two $Cu^{2+}$ cations inside large macrocyclic ligands containing two dioxo232 and two diaminopyridine binding sites, and functionalized either with a benzyl[7] or a propargyl[8] unit on the central carbon of the malonic amide groups. For the latter examples, the pH-driven double translocation process can be summarized as follows: at slightly acidic or neutral pH values, the two $Cu^{2+}$ cations reside in the diaminopyridine compartments (Scheme 1: $[\mathbf{BZ}H_4Cu_2]^{4+}$ blue, $\lambda_{max}$ = 660 nm, and $[\mathbf{PG}H_4Cu_2]^{4+}$ blue, $\lambda_{max}$ = 660 nm) but when the pH is raised enough, the two dioxo232 compartments lose their amido protons and the $Cu^{2+}$ cations move inside the very effective diamino-diimido binding units to form a neutral complex ($[\mathbf{BZ}Cu_2]$ and $[\mathbf{PG}Cu_2]$ in Scheme 1). The overall molecular shape and $Cu^{2+}$ coordination number and geometry in the neutral complexes depend on the bulkiness of the substituent: the slim propargyl allows folding and apical coordination of one pyridine to each $Cu^{2+}$ cation (square-pyramidal geometry, purple, $\lambda_{max}$ = 575 nm), while the bulky benzyl prevents folding, resulting in square-planar $Cu^{2+}$ cations (pink, $\lambda_{max}$ = 515 nm). Visual and instrumental recognition of the double movement is based on the color change.

In this paper we report a double pH-driven $Cu^{2+}$ translocation inside the ligand **L1**$H_4$, whose backbone is identical to that of **BZ**$H_4$ and **PG**$H_4$ but features two ferrocene (Fc) groups instead of benzyl and propargyl moieties. For sake of comparison the Fc-containing **L2**$H_2$ and **L**3$H_4$ ligands, which are capable of single $Cu^{2+}$ translocation and inclusion of two $Cu^{2+}$ cations with no translocation, respectively, on changing pH, have also been studied. As Fc is reversibly oxidizable and its potential is significantly influenced by nearby charges or dipoles, the study of the Fc redox potential as a function of the absence/presence and position of $Cu^{2+}$ cation(s) in these new systems has two goals: i) obtaining an electrochemical signal, as an alternative to color[4,7,8] or fluorescence changes,[4,5] that can be

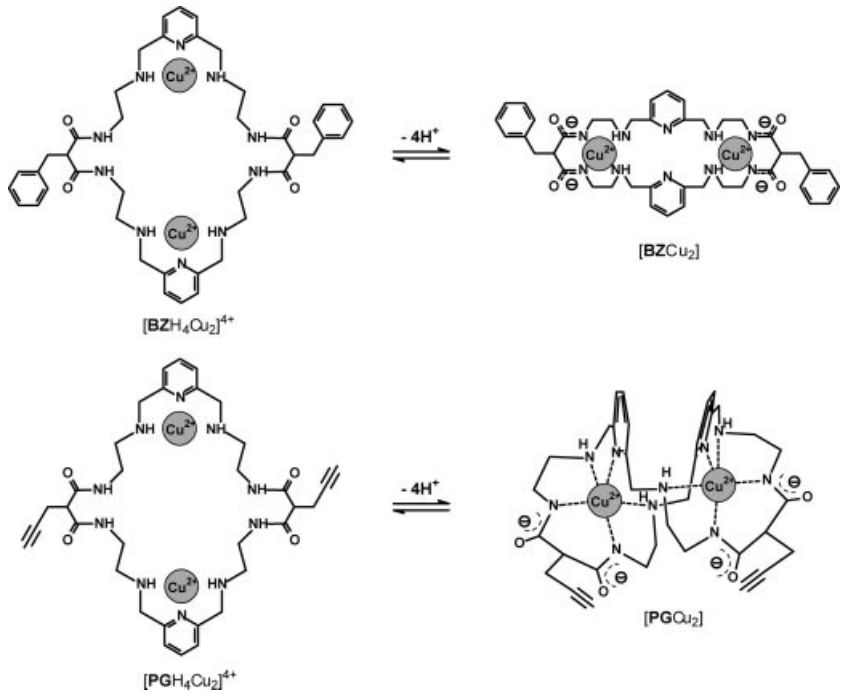
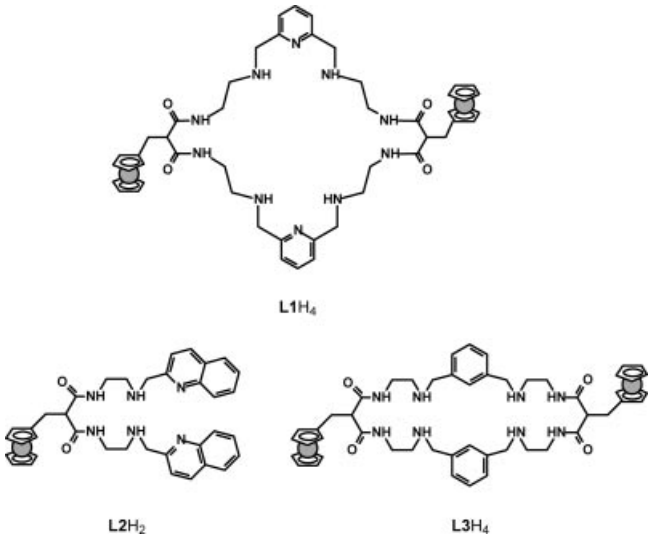


Scheme 1. Pictorial representation of pH-driven double $Cu^{2+}$ translocation (upper equilibrium, ref.[6]) and pH-driven double $Cu^{2+}$ translocation plus folding (lower equilibrium, ref.[7]) in ligands **BZ**$H_4$ and **PG**$H_4$.

used to monitor the position(s) of the cation(s) inside the ligands; and ii) evaluating how a change in the overall charge and in the charge distribution upon $Cu^{2+}$ translocation can electrostatically influence the space region occupied by ferrocenes. These are linked to a long-term research project of ours concerning the grafting of ligands on Si surfaces,[9] which may be achieved by surface reactions of the propargyl groups[10] and is thus accessible for ligands like **PG**$H_4$.



Accordingly, we report here the full characterization in aqueous solution of ligands **L1**$H_4$, **L2**$H_2$, and **L3**$H_4$ and of their copper complexes, by means of the determination of the protonation and complexation constants of the forms present in the pH range 2–12. The pH values between which double and single $Cu^{2+}$ translocation takes place in **L1**$H_4$ and **L2**$H_2$, respectively, are determined. The nature and the coordination geometry of the pertinent copper complexes are investigated by UV/Vis spectroscopy. Finally, electrochemical (CV) investigations on the Fc redox potential have been carried out in aqueous solution as a function of pH, in the presence and in the absence of $Cu^{2+}$, to determine the effect of the metal cations and of their positions on the Fc oxidation potential.

## Results and Discussion

### Copper Complexes in Aqueous Solution and pH-Driven Translocation

The protonation and complexation constants of the ferrocene-containing ligands **L1**$H_4$, **L2**$H_2$, and **L3**$H_4$ were determined by means of potentiometric titrations in a water/dioxane (1:4, v/v) mixture due to the hydrophobic nature of the ferrocene molecule, which does not allow solubilization of the three ligands in pure water. Titrations were carried out automatically by addition of base to solutions containing first ligand only plus excess acid (for the determination of the protonation constants) and then to solutions containing ligand, the pertinent quantity of $Cu(CF_3SO_3)_2$ (2, 1, and 2 equiv. in the case of **L1**$H_4$, **L2**$H_2$, and **L3**$H_4$, respectively), and excess acid. The $\log K$ (protonation and complexation) values were obtained by elaboration of the emf vs. volume of added base data obtained by means of the Hyperquad program suite.[11] Experimental conditions

| $LH_2 + Cu^{2+} \leftrightharpoons [LH_2Cu]^{2+}$ | 10.90(0.01) |
| $[LH_3]^+ + Cu^{2+} \leftrightharpoons [LH_3Cu]^{3+}$ | 14.86(0.01) |
| $LH_2 + Cu^{2+} + H_2O \leftrightharpoons [LH_2Cu(OH)]^+ + H^+$ | 5.04(0.01) |
| $LH_2 + Cu^{2+} \leftrightharpoons [LCu] + 2H^+$ | –2.56(0.02) |

[a] Data obtained in dioxane/water (8:2, v/v), 0.05 M $NaNO_3$, $T$ = 25 °C.

The number and $\log K$ values of the found protonation steps are in agreement with those already described for similar ligands in the same solvent mixture.[4,5] The formation constants of the copper complexes of the three ligands and the relative equilibria are reported, as logarithmic values, in Tables 2 (**L1**$H_4$ and **L3**$H_4$) and 3 (**L2**$H_2$) The distribution diagrams in Figure 1 (parts A–C), in which the percentage of each species (with respect to total ligand) is expressed as a function of pH, can be drawn from the data in all these tables.

From Figure 1 (A) it can be seen that the system containing ligand **L1**$H_4$ and $Cu^{2+}$ in a 1:2 molar ratio allows the efficient translocation of the two $Cu^{2+}$ cations.

The species $[\mathbf{L1}H_4Cu_2]^{4+}$ (see Scheme 2) contains the neutral ligand and two copper cations, each of which is chelated to the tridentate diaminopyridine units. The large formation constant of this species (24.12 log units) reflects the chelating nature of the two donor sets and the coordination of two $Cu^{2+}$ cations, and is in good agreement with the values already found for the analogous species $[\mathbf{BZ}H_4Cu_2]^{4+}$ and $[\mathbf{PG}H_4Cu_2]^{4+}$ (Scheme 1, $\log K$ = 25.31[7] and 25.30,[8] respectively). This species is the prevalent one in a large pH range (i.e. between pH 3 and 7), and accounts for over 95% at 3.7 < pH < 5.9. Its formulation was confirmed by mass spectrometry (ESI) with solutions containing ligand and $Cu(CF_3SO_3)_2$ in a 1:2 stoichiometry and with the pH set at between 4 and 5. Peaks were observed for $[\mathbf{L1}H_4Cu_2 - H]^{3+}$, $[\mathbf{L1}H_4Cu_2 + CF_3SO_3]^{3+}$, and $[\mathbf{L1}H_4Cu_2 + 2CF_3SO_3]^{2+}$ (*m*/*z* 368, 369; 418, 419; and 701, 703 respectively). In the analogous complexes $[\mathbf{BZ}H_4Cu_2]^{4+}$ and $[\mathbf{PG}H_4Cu_2]^{4+}$, each $Cu^{2+}$ cation was found to be five-coordinate (diaminopyridine chelate + two water molecules) with a trigonal-bipyramidal geometry on the basis of the visible absorption spectra. A d–d absorption band centered at 670 nm ($\varepsilon$ = 190 $M^{-1}cm^{-1}$) can also be observed for $[\mathbf{L1}H_4Cu_2]^{4+}$ when spectra are taken at 3.7 < pH < 5.9, despite the absorption band of ferrocene in the visible range ($\lambda_{max}$ = 440 nm, $\varepsilon$ = 186 $M^{-1}cm^{-1}$). Figure 2 shows a spectrum taken for this species at pH 5.1. The solution has a green color due to the combination of blue (band at 670 nm) and yellow-orange (ferrocene band at 440 nm).

On increasing the pH above 6, the two hydroxide species $[\mathbf{L1}H_4Cu_2(OH)]^{3+}$ and $[\mathbf{L1}H_4Cu_2(OH)_2]^{2+}$ are formed by deprotonation of the coordinated water molecules. A p$K_a$ of 7.19 and 8.68 may be calculated for the first and second deprotonation steps. These values are too large to suggest bridging of $OH^-$ between the two $Cu^{2+}$ cations.[12] The d–d absorption band of coordinated copper does not change significantly on passing from $[\mathbf{L1}H_4Cu_2]^{4+}$ to $[\mathbf{L1}H_4Cu_2(OH)]^{3+}$ and $[\mathbf{L1}H_4Cu_2(OH)_2]^{2+}$ (a shift of $\lambda_{max}$ to 675 nm and a lowering of $\varepsilon$ to 160 are observed), similarly to the analogous complexes of **BZ**$H_4$ and **PG**$H_4$.[7,8] When the pH is raised to above 9.8 the solution takes a brown-purple color due to the neutral species $[\mathbf{L1}Cu_2]$, which is the prevalent one at pH > 10.8 (> 95% at pH > 11.3). In this species the two $Cu^{2+}$ cations have translocated inside the diamino-diimido compartments (see Scheme 2). Mass spectra measured at pH > 11.3 display the peak for $[\mathbf{L1}Cu_2 + H]^+$ (*m*/*z* 1101, 1103). The interpretation of the UV/Vis spectrum of this species is complicated by the presence of the ferrocene band. While the band at 670 nm disappears when $[\mathbf{L1}Cu_2]$ is formed (see part A of Figure 1, black triangles, for an $Abs_{670}$ vs. pH plot), the band for this species falls under the Fc absorption, as can be seen in Figure 2 for a spectrum taken at pH 11.5. The effect of the formation of $[\mathbf{L1}Cu_2]$ is to shift the apparent absorption maximum of Fc to longer wavelengths and to increase the intensity of the band. Subtracting the spectrum at pH 5.1 from that at pH 11.5 gives the profile shown in the inset of Figure 2, which gives an indication that the absorption maximum of $[\mathbf{L1}Cu_2]$ is closer to 515 nm (absorption of $[\mathbf{BZ}Cu_2]$[7]) than to 575 nm (absorption of $[\mathbf{PG}Cu_2]$[8]). This

Table 2. Formation constants of the $Cu^{2+}$-containing species for the ligands featuring two dioxo232 compartments. Column 1 reports the relative equilibrium for each value relative to a generic tetra-amido ligand $LH_4$. Uncertainties are indicated in parentheses.[a]

| | **L1**$H_4$ | **L3**$H_4$ |
|---|---|---|
| $LH_4 + 2Cu^{2+} \leftrightharpoons [LH_4Cu_2]^{4+}$ | 24.12(0.01) | 10.63(0.01) |
| $LH_4 + 2Cu^{2+} + H_2O \leftrightharpoons [LH_4Cu_2(OH)]^{3+} + H^+$ | 16.93(0.02) | –1.23(0.02) |

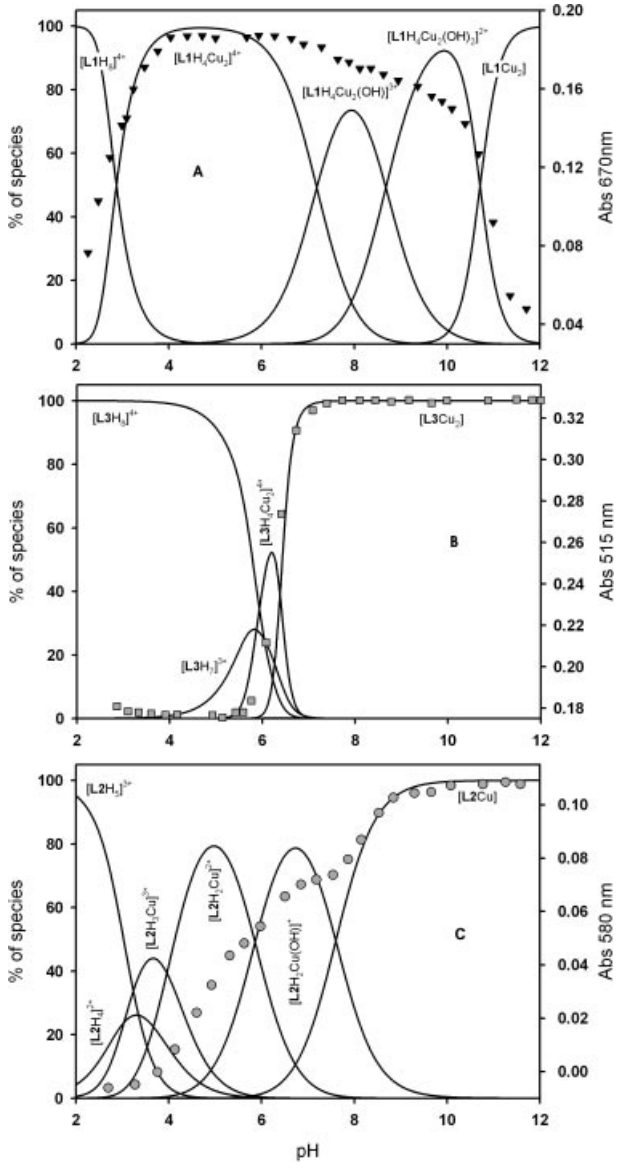

Figure 1. Distribution diagrams for the three systems, expressed as percentage of species (with respect to total ligand) vs. pH. Each diagram has been calculated for a $10^{-3}$ M ligand concentration. The species relative to each curve are reported on the diagram. A: **L1**$H_4$ + $2Cu^{2+}$; black triangles indicate the absorbance at 670 nm (i.e. at $\lambda_{max}$ for $[\mathbf{L1}H_4Cu_2]^{4+}$) vs. pH. B: **L3**$H_4$ + $2Cu^{2+}$; grey squares indicate the absorbance at 515 nm (i.e. at the expected maximum of absorption for the $Cu^{2+}$-centered d–d transition) vs. pH. C: **L2**$H_2$ + $Cu^{2+}$; grey circles indicate the absorbance at 580 nm (i.e. at $\lambda_{max}$ for [**L2**Cu]) vs. pH.

fits well with a structure in which each $Cu^{2+}$ is square planar, as shown in Scheme 2, which is indeed what would be expected if we consider the bulkiness of the ferrocene group, which should prevent the folding of the ligand structure and thus not allow apical coordination of $Cu^{2+}$ by the pyridine moiety.[8]

According to these findings, translocation of the $Cu^{2+}$ cations from the diaminopyridine compartments to the diamino-diimido ones (and vice versa) can occur as shown in Scheme 2, i.e. by changing the pH between two values chosen in the range 3.7–5.9 and >11.3. The movement is reversible and can be performed repeatedly, as confirmed by adding first excess base to a solution at pH 4.0 and then the same quantity of acid 10 times: the recorded spectra for $[\mathbf{L1}H_4Cu_2]^{4+}$ and [**L1**$Cu_2$] are superimposable, apart from a negligible lowering of the intensity due to dilution. Kinetic characterization of the translocation process is beyond the scope of this paper. However, it can be noticed that the process is relatively fast: an instantaneous (i.e. not progressive) color change was observed visually upon addition of acid or base, and even though only a few seconds were needed to add the acid or base and transfer a sample of the bulk solution to a cuvette, the sequence of constant absorption spectra obtained subsequently indicated that the translocation process was already complete. In this connection, the question may be raised whether the cation translocation is an *intra-* or an *inter*molecular process. Careful kinetic measurements would be needed to give a reliable answer to this question, and again these are outside the scope of this paper. However, the hypothesis that the movement is intramolecular can be put forward. First of all it should be stressed that the probability of the translocation process is much higher between two compartments belonging to the same ligand molecule than between two compartments of different ligand molecules (binding of $Cu^{2+}$ to the starting compartment means that the receiving compartment belonging to the same molecule would feel an enormously increased local concentration of $Cu^{2+}$). Moreover, kinetic studies carried out on closely related systems always show the intramolecular nature of the cation translocation processes.[4a,5]

It is interesting to compare these findings with those found for the non-translocating system containing the macrocyclic bis-dioxo232 ligand **L3**$H_4$ and $Cu^{2+}$ in a 1:2 molar ratio. In this case, the structure of the ligand does not allow chelation and formation of stable $Cu^{2+}$ complexes, apart from the square-planar, neutral bis-$Cu^{2+}$ species [**L3**$Cu_2$], which is obtained by the release of the four amido protons. Accordingly, the distribution diagram (Figure 1, B) is dominated by the tetraprotonated, non-metalated species $[\mathbf{L3}H_8]^{4+}$ and by [**L3**$Cu_2$], which is prevalent at pH > 6.2 and accounts for more than 95% at pH 6.8. Indeed, a species in which two $Cu^{2+}$ cations interact with the free ligand, i.e. $[\mathbf{L3}H_4Cu_2]^{4+}$, is observed with a very low formation constant (10.63 log units), and may be representative of the coordination of each $Cu^{2+}$ to a single amine nitrogen. This species forms in low quantities and in a limited pH range (it goes over 5% only between pH 5.6 and 6.5, reaching a maximum of around 50%) and is not competitive with respect to [**L3**$Cu_2$]. As a consequence, no translocation is possible in this system and formation of the neutral, square-planar species [**L3**$Cu_2$] is anticipated, on the pH axis, with respect to what is found for [**L1**$Cu_2$]. In particular, [**L3**$Cu_2$] goes over 95% at pH > 6.8, while [**L1**$Cu_2$] goes over 95% at pH > 11.3, with a dramatic shift of 4.5 pH units. As regards the UV/Vis spectra, at acidic pH values this system displays only the ferrocene absorption ($\lambda_{max}$ = 440 nm, $\varepsilon$ = 210 $M^{-1}cm^{-1}$, orange color) in the visible

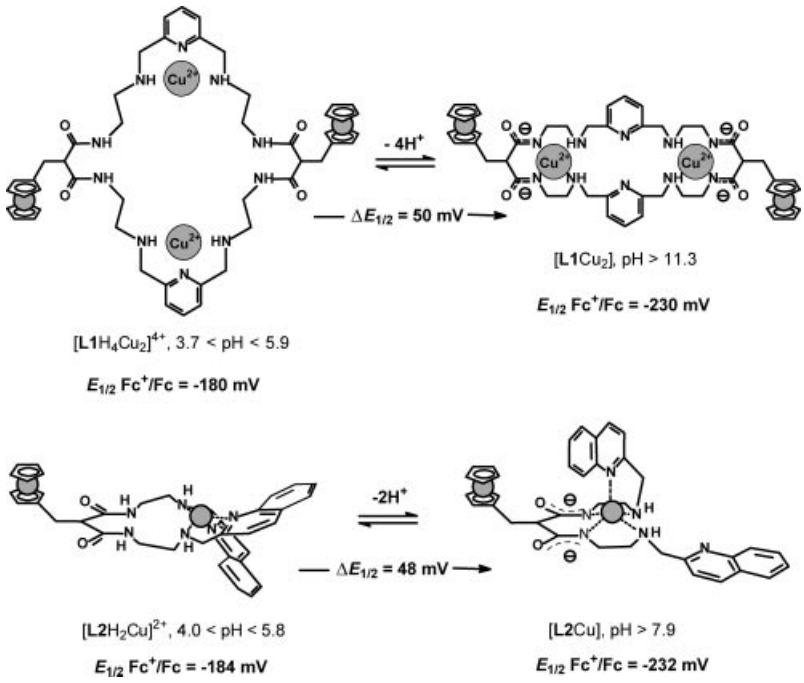

Scheme 2. Pictorial representation of pH-driven double $Cu^{2+}$ translocation and pH-driven single $Cu^{2+}$ translocation plus folding in ligands **L1**$H_4$ and **L2**$H_2$. The change in the Fc oxidation potential, which depends on the position(s) of the $Cu^{2+}$ cation(s), is also evidenced.

range, as can be seen in part B of Figure 2 (spectrum measured at pH 4.0). At the pH values in which the formation of [**L3**$Cu_2$] begins, the Fc band shifts to longer wavelengths, increases in intensity, and gains a shoulder due to the intrinsic absorption of $Cu^{2+}$ inside the diamino-diimido compartments (the solution takes a brown-purple color). Above pH 7 a series of superimposable spectra are obtained. Figure 2 (part B) also shows a spectrum recorded at pH 8.5. The inset B of Figure 2 displays the profile obtained by subtracting the spectrum recorded at pH 4.0 from that recorded at pH 8.5: noticeably, a curve similar to the inset A of Figure 2 is obtained, which can be considered a further indication of the square-planar nature of $Cu^{2+}$ in [**L1**$Cu_2$]. Moreover, plotting the absorbance at 515 nm vs. pH gives a profile (Figure 1 B, grey triangles) that perfectly superimposes the profile of the percentage of [**L3**$Cu_2$] vs. pH.

Finally, the behavior of the system containing **L2**$H_2$ and one equivalent of $Cu^{2+}$ was examined. In this case, the structure of the ligand allows only single $Cu^{2+}$ translocation. Indeed, the ligand resembles two very similar ones that we have already studied, in which a benzyl group[4b] or a propargyl group[8] are present instead of $FcCH_2$ in the same position. In both cases, a single pH-driven $Cu^{2+}$ translocation is possible from the bis(aminoquinoline) compartment to the diamino-diimido one, and vice versa. However, translocation is accompanied by an overall folding of the system as the $Cu^{2+}$ cation coordinated in the diamino-diimido compartment is also apically coordinated by quinoline. We have recently demonstrated that this kind of translocation + folding process always takes place when $Cu^{2+}$ moves in open (i.e. non-cyclic) ligands of this kind, independently of the nature of the substituent on the central carbon of the malonic amide group.[8] Accordingly, we would expect a behavior like that sketched in Scheme 2 for **L2**$H_2$/$Cu^{2+}$, and this is confirmed by the experimental results. Calculation of the potentiometric titrations and formation constants allows us to draw the distribution diagram for this system (Figure 2, C). [**L2**$H_2$Cu]$^{2+}$ is the species in which the $Cu^{2+}$ cation is coordinated by the two bis(aminoquinoline) chelating units (plus one water molecule), as has already been found for the systems based on similar benzyl- and propargyl-containing ligands.[4b,8] It forms at pH values above 3 and is prevalent between 4.0 and 5.8, reaching a maximum of 80% at pH 5.1. In the UV/Vis spectra (Figure 2 C, spectrum taken at pH 5.2), beside the ferrocene absorption (somewhat masked by the strong quinoline absorption band, which has a shoulder in the visible range), a d–d transition is observed at 660 nm ($\varepsilon$ = 90 $M^{-1}cm^{-1}$), typical of trigonal-bipyramidal $Cu^{2+}$ in these kind of complexes.[4b,8] At a pH between 4 and 6 the solution has a green color due to a combination of the ferrocene absorption and the $Cu^{2+}$ d–d transition. Mass spectra (ESI) reveal the expected peaks at *m*/*z* 730, 732 for [**L2**$H_2$Cu-H]$^+$ and at *m*/*z* 880, 882 for [**L2**$H_2$Cu + $CF_3SO_3$]$^+$. On raising the pH the monohydroxide species [**L2**$H_2$Cu(OH)]$^+$ forms, with $Cu^{2+}$ remaining in the bis(aminoquinoline) compartment, thanks to the deprotonation of coordinated water. The absorption spectrum of this species is similar to that of [**L2**$H_2$Cu]$^{2+}$. What is observed is a moderate shift of the absorption maximum towards shorter wavelengths and no perceivable change in the color of the solution. The solution color changes when the pH is raised over 7 and [**L2**Cu] forms in significant amounts. This species is that in which $Cu^{2+}$ has translocated into the diamino-diimido compartment. It becomes prevalent above pH 7.9 and accounts for over 95% at a pH above 9.5. At this pH or higher, the

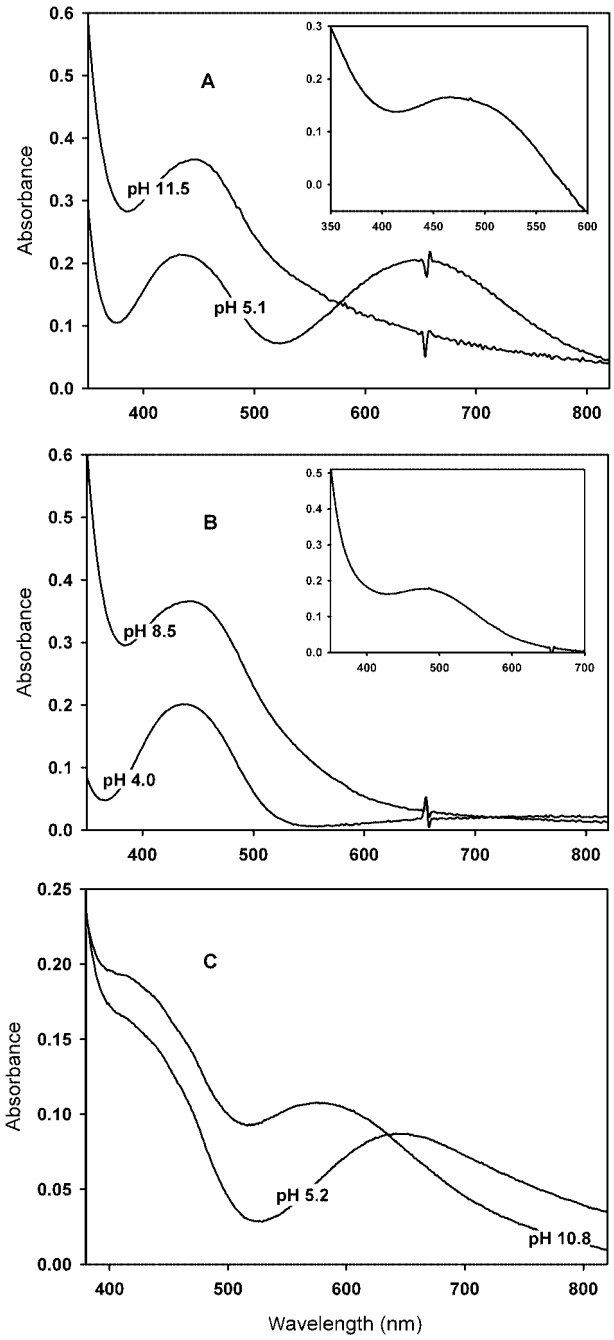

Figure 2. A: absorption spectra for the system $\mathbf{L1}H_4$ + $2Cu^{2+}$ at $1.1\times10^{-3}$ M ligand concentration; the spectrum recorded at pH 5.1 belongs to $[\mathbf{L1}H_4Cu_2]^{4+}$, the spectrum recorded at pH 11.5 belongs to $[\mathbf{L1}Cu_2]$. Subtraction of the spectrum at pH 5.1 from the spectrum at pH 11.5 is shown in the inset. B: Absorption spectra for the system $\mathbf{L3}H_4$ + $2Cu^{2+}$ at $1.0\times10^{-3}$ M ligand concentration; the spectrum recorded at pH 4.0 belongs to $[\mathbf{L3}H_8]^{4+}$ and the very weak and large band (between 600 and 900 nm) is due to free $Cu^{2+}$ (not complexed at this pH value, see also Figure 1, B), i.e. it is the d–d transition of the solvated cation; the spectrum recorded at pH 8.5 belongs to $[\mathbf{L3}Cu_2]$; the subtraction of spectrum at pH 4.0 from spectrum at pH 8.5 is shown in the inset. C: Absorption spectra for the system $\mathbf{L2}H_4$ + $Cu^{2+}$ at $1.0\times10^{-3}$ M ligand concentration; the spectrum recorded at pH 5.2 belongs to $[\mathbf{L2}H_2Cu]^{2+}$, the spectrum recorded at pH 10.8 belongs to [**L2**Cu].

solution display a green/brown color and the UV/Vis spectra show that the $Cu^{2+}$ d–d band has shifted to 580 nm ($\varepsilon$ = 110 $M^{-1}cm^{-1}$). This is the typical value for a pentacoordinate, square-pyramidal $Cu^{2+}$ cation inside a diamino-diimido compartment and apically coordinated by quinoline.[4b,8] (Figure 2 C, spectrum taken at pH 10.8). By means of a coupled pH-metric/spectrophotometric titration it is possible to obtain a plot of the absorbance at 580 nm vs. pH (part C of Figure 1, grey circles), which shows superimposition with the relevant percentage of species vs. pH curves. The observed step profile of $Abs_{580}$ vs. pH is due to the fact that both $[\mathbf{L2}H_2Cu]^{2+}$ and $[\mathbf{L2}H_2Cu(OH)]^{+}$ also have a significant absorbance at 580 nm. The ESI mass spectra show a peak at *m*/*z* 730, 732 for $[\mathbf{L2}Cu + H]^{+}$. Accordingly, single $Cu^{2+}$ translocation plus folding can take place, as illustrated in Scheme 2. The reversibility of the backwards and forwards movements was checked by preparing a solution of $[\mathbf{L2}H_2Cu]^{2+}$ at pH 5.2 and adding first excess strong base and then the same quantity of strong acid for ten cycles, always obtaining superimposable spectra for $[\mathbf{L2}H_2Cu]^{2+}$ and [**L2**Cu], with a negligible effect due to dilution.

## The Effect of the Translocation Process on the Ferrocene Oxidation Potential

A huge number of multicomponent molecular systems that contain Fc and one or more binding units are capable of electrochemically signaling the coordination of metal cations to the binding units or the protonation of the donor atoms of the latter. The proximity of $M^{n+}$ (or, for example, of $NH_2^+$) makes the oxidation potential of Fc increase due to obvious electrostatic repulsion effects between the positive charge and ferricinium.[13]

We first examined the effect of protonation of the amine groups on the Fc oxidation potential in our ligands in the absence of metal cations. Each ligand was dissolved in the same solvent used for complexation studies (dioxane/water, 4:1 v/v) to a $10^{-3}$ M concentration, with 0.1 M $NaNO_3$ as the background electrolyte, and a series of CV experiments were carried out spanning the 2–12 pH interval by means of addition of excess standard $HNO_3$ and microadditions of standard NaOH. Quite interestingly, the oxidation potential of Fc does not change significantly with protonation, even at the lower limit of the examined interval, i.e. pH 2. At the more acidic pH values the found $E_{1/2}$ values are –175, –178, and –170 mV for the species $[\mathbf{L1}H_8]^{4+}$, $[\mathbf{L2}H_5]^{3+}$, and $[\mathbf{L3}H_8]^{4+}$ respectively (potential values referenced to $Ag/Ag^+$ electrode; see Exp. Sect. for details), while at more basic values the measured values are –182, –184, and –180 mV for $\mathbf{L1}H_4$, $\mathbf{L2}H_2$, and $\mathbf{L3}H_4$, respectively (reversible waves are found in all cases, with a peak separation of around 120 mV at a scan rate of 400 mV $s^{-1}$). These values are close to the average for a mono-alkyl-substituted ferrocene, and the absence of significant changes on protonation is indeed not unexpected as it has already been demonstrated that a distance of more than three carbon atoms between ferrocene and the group changing its charge makes any electrostatic effects almost negligible.[14] However it is

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

worth stressing that even in +4 charged systems as $[\mathbf{L1}H_8]^{4+}$ and $[\mathbf{L3}H_8]^{4+}$ the peripheral ferrocene moieties do not experience any significant change (<10 mV) in the potential of their oxidation process.

After obtaining these data we examined the effect on the Fc oxidation potential of the presence/absence of $Cu^{2+}$ cations, and of their translocation, in the three ligands by means of coupled pH-metric titrations and electrochemical measurements. We coupled pH-metric titrations and CV measurements by adding base to acidic solutions containing ligand + $2Cu^{2+}$ (**L1**$H_4$ and **L3**$H_4$) or ligand + $Cu^{2+}$ (**L2**$H_2$). In the case of the double translocating system **L1**$H_4$/$2Cu^{2+}$ at the pH values at which $[\mathbf{L1}H_4Cu_2]^{4+}$, $[\mathbf{L1}H_4Cu_2(OH)]^{3+}$, and $[\mathbf{L1}H_4Cu_2(OH)_2]^{3+}$ exist, the $E_{1/2}$ for $Fc^+$/Fc oxidation remains constant at –180 mV vs. $Ag^+$/Ag (reversible, peak separation = 120 mV at a scan rate of 400 mV $s^{-1}$), i.e. roughly the same value observed both for the free and the protonated ligand. This clearly indicates that when the $Cu^{2+}$ cations are located in the diamino-pyridine compartments they are too far from Fc to exert any significant effect on it. On the other hand, when the pH is raised enough (>9.8) to translocate the two $Cu^{2+}$ cations inside the deprotonated dioxo232 compartments and form [**L1**$Cu_2$], a significant shift in the Fc redox potential is observed, with $E_{1/2}$ decreasing to a final value of –230 mV vs. $Ag^+$/Ag (reversible, peak separation = 120 mV at a scan rate of 400 mV $s^{-1}$), obtained at pH values above 11.2, i.e. where [**L1**$Cu_2$] accounts for more than 95% of the species present in solution. A nice superimposition of the $E_{1/2}$ vs. pH profile is observed with the formation curve of [**L1**$Cu_2$], as shown in Figure 3. It should be noted that the *lowering* of the oxidation potential of ferrocene due to the presence of a nearby metal cation is unusual but not new, as has already been reported in a ligand containing ferrocene and a simple dioxo232 ligand.[15] The overall charge in the complex is zero, but in each $Cu^{2+}$/diamino-diimido compartment a dipole is formed by $Cu^{2+}$ and the two negative charges (delocalized between the oxygen atoms and the conjugated imido nitrogens) that points its negative end towards the region of space in which the ferrocene moiety is located.

The same kind of result is found for the single $Cu^{2+}$ translocating system **L2**$H_2$/$Cu^{2+}$. At the pH values in which $Cu^{2+}$ is in the bis(aminoquinoline) compartment (up to pH 6) the observed $E_{1/2}$ for Fc oxidation is –184 mV (i.e. roughly the same as for the free or protonated ligand), while a negative shift is observed when the pH is raised and [**L2**Cu] begins to form. A final value of –232 mV vs. $Ag^+$/Ag is observed at pH 9.5 or higher ([**L2**Cu] > 95%).

Accordingly, this behavior allows electrochemical signaling of the pH-driven translocation of the $Cu^{2+}$ cations. Moreover, this result gives a clear indication that the two different positions in which the $Cu^{2+}$ cations can be located should have sharply different effects (e.g. as regards electrical capacity) on a surface to which **L1**$H_4$ and **L2**$H_2$ ligands are grafted by reaction of a $HC{\equiv}C–CH_2–$ group bound to the same carbon bearing the $FcCH_2$ substituent. Finally, it should be mentioned that, obviously, the same negative shift effect is observed for the **L3**$H_4$/$2Cu^{2+}$ system. However, as in this case no species exists to any significant degree in which the $Cu^{2+}$ cations are located on the ligand, except [**L3**$Cu_2$], a shift in the ferrocene $E_{1/2}$ is observed on going from the protonated ligand (–180 mV) to the [**L3**$Cu_2$] complex (–224 mV), i.e. it is not due to a translocation process.

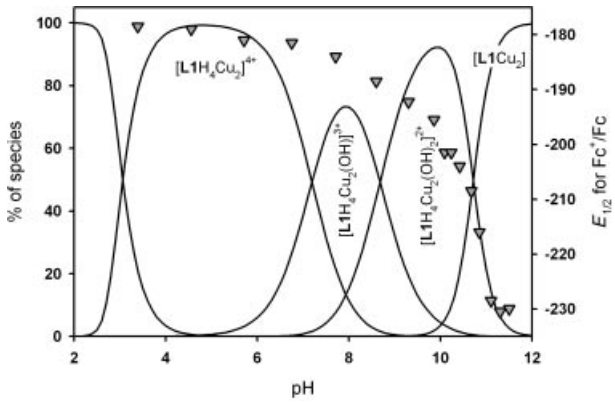

Figure 3. Distribution diagram for the system **L1**$H_4$/$2Cu^{2+}$ at $10^{-3}$ M ligand concentration, with superimposed (grey triangles) $E_{1/2}$ values for the $Fc^+$/Fc couple as a function of pH, showing the negative shift that occurs on changing the position of the copper cations from the diaminopyridine to the diamino-diimido units.

## Conclusions

Two new ligands have been studied in which double and single pH-driven $Cu^{2+}$ translocation has been demonstrated to take place. Due to the bulkiness of the ferrocene group, in the macrocyclic and double translocating system (**L1**$H_4$/$2Cu^{2+}$), translocation to the diamino-diimido compartments produces an authentic square planar $Cu^{2+}$ complex. On the other hand, in the open ligand and single translocating system (**L2**$H_2$/$Cu^{2+}$) translocation to the diamino-diimido compartment results in a five-coordinate $Cu^{2+}$ center, with one quinoline folding to coordinate copper in one of its apical positions. From an electrochemical point of view, positioning of the $Cu^{2+}$ cations in the compartments that are more distant from the Fc unit does not influence its redox potential at all. However, translocation inside the diamino-diimido compartments influences the oxidation of the ferrocene groups, which becomes easier by around 50 mV, thus allowing electrochemical signaling of the pH-driven translocation process. The unusual negative shift of the Fc oxidation potential on complexation of $Cu^{2+}$ in the diamino-diimido compartment reflects the formation of a dipole that has its negative end pointing towards the region of space in which the ferrocene is located. Beside adding an electrochemical tool for signaling cation translocation processes, this work also gives an indication that, if molecules with the same structure as those studied here could be grafted on a conducting surface through the covalent binding of groups located in the same position as ferrocene, the surface could change its properties (e.g. impedance) upon translocation of the $Cu^{2+}$ cation(s).

## Experimental Section

**Synthesis:** The syntheses of the three ligands use $N^1$,$N^3$-bis(2-aminoethyl)-2-(ferrocenylmethyl)malonamide (Ferrocene-methyldioxo232) as the starting material, which was prepared according to a literature procedure.[15] 2-Quinolinecarboxaldehyde and 2,6-pyridinedicarboxaldehyde were purchased from Aldrich and used without further purification.

**L1**$H_4$**:** 2,6-Pyridinedicarboxaldehyde (134 mg, 1 mmol) was dissolved in 60 mL of $CH_3CN$. Ferrocene-methyldioxo232 (386 mg, 1 mmol) dissolved in 40 mL of $CH_3CN$ was then added dropwise over a 2 h period under nitrogen and the mixture was kept under magnetic stirring overnight. An orange brown product (the tetraimino macrocycle) was collected by suction filtration, dissolved in methanol, and reduced with excess $NaBH_4$ (600 mg for each mol of C=N, considering 100% yield from the previous step), which was added in small portions, at room temperature, to avoid foaming. After the addition, the mixture was heated at reflux for 2 h, then cooled to room temperature and the solvent evaporated on a rotary evaporator. Water (100 mL) was added to the crude semisolid mixture, and the hydrolyzed suspension was extracted with three 30-mL portions of $CH_2Cl_2$. The organic portions were gathered, dried with $MgSO_4$, filtered, and the solvent removed on a rotary evaporator to give a yellow solid (237.5 mg, 0.243 mmol, 47.1% yield). ESI-MS: *m*/*z* 979 [**L1**$H_4$ + H]$^+$. $^1$H NMR (DMSO): $\delta$ = 7.94 (t, 4 H, CO-N*H*-$CH_2$), 7.68 (t, 2 H, py-H), 7.24 (d, 4 H, py-H), 4.11 (s, 10 H, H of ferrocene), 4.02 (s, 4 H, H of ferrocene), 4.00 (s, 4 H, H of ferrocene), 3.4–3.0 [m, 14 H, amine protons + CO-C*H*(*R*)-CO + CO-NH-C$H_2$], 2.74 (d, 4 H, Fc-C$H_2$-CH), 2.50 (m, C$H_2$-NH-$CH_2$ + DMSO) ppm. $C_{50}H_{62}Fe_2N_{10}O_4{\cdot}CH_2Cl_2$ (1063.7): calcd. C 57.63, H 6.07, N 13.18; found C 57.58, H 6.05, N 13.15.

**L2**$H_2$**:** Quinoline-2-carboxaldehyde (628.7 mg, 4 mmol) was dissolved in 20 mL of ethanol. Ferrocenemethyl-dioxo232 (772 mg, 2 mmol) was dissolved in 30 mL of ethanol and added dropwise at room temperature, with magnetic stirring, under nitrogen. After 18 h the solution (containing the diimine) was treated in situ with excess $NaBH_4$ (600 mg for each mol of C=N). The subsequent workup was identical to that of **L1**$H_4$. A brown oily product was obtained, which was transformed into a yellow solid after repeated washing with diethyl ether (1.21 g, 90% yield). ESI-MS: *m*/*z* 669 [**L2**$H_2$ + H]$^+$. $^1$H NMR (DMSO): $\delta$ = 8.5–7.5 (m, 14 H, quinoline protons and CO-N*H*-$CH_2$), 4.2–3.8 (m, 13 H, H of ferrocene and NH-C$H_2$-quinoline), 3.2 (m, 5 H, CO-CHR-CO and CO-NH-C$H_2$), 2.8 (d, 2 H, Fc-C$H_2$-CH), 2.6 (t, 4 H, C$H_2$-NH-$CH_2$) ppm. $C_{38}H_{40}FeN_6O_2{\cdot}H_2O$ (686.6): calcd. C 66.47, H 6.16, N 12.24; found C 66.44, H 6.18, N 12.21.

**L3**$H_4$**:** The synthesis of this ligand followed the same procedure described for **L1**$H_4$, but with isophthalaldehyde instead of 2,6-pyridinedicarboxaldehyde. The product was obtained as a yellow solid in 60.6% yield. ESI-MS: *m*/*z* 977 [**L3**$H_4$ + H]$^+$. $^1$H NMR (DMSO): $\delta$ = 7.86 (s, 4 H, CO-N*H*-$CH_2$), 7.15–7.25 (m, 8 H, H of the phenyl rings), 4.10 (s, 10 H, H of ferrocene), 4.02 (s, 4 H, H of ferrocene), 3.99 (s, 4 H, H of ferrocene), 3.61 (s, 8 H, NH-C$H_2$-arene), 3.35 (broad, 4 H, amine protons), 3.2–3.0 [m, 10 H, CO-C*H*(*R*)-CO + CO-NH-C$H_2$], 2.74 (d, 4 H, Fc-C$H_2$-CH), 2.50 (m, C$H_2$-NH-$CH_2$ + DMSO) ppm. $C_{52}H_{64}Fe_2N_8O_4{\cdot}0.5CH_2Cl_2$ (1019.3): calcd. C 61.86, H 6.43, N 10.99; found C 61.89, H 6.45, N 11.02.

**Potentiometric Titrations:** Protonation equilibria for ligands **L1**$H_4$, **L2**$H_2$, and **L3**$H_4$ were studied in dioxane/water (8:2, v/v) made up to 0.05 M in $NaNO_3$, thermostatted at 25 °C, with a Radiometer automatic system (Titralab TIM900) under nitrogen. In a typical experiment, a volume of 20 mL of a $10^{-3}$ M ligand solution was treated with 1.0 M standard $HNO_3$ in a quantity corresponding to the mols of ligand multiplied by the number of basic groups (amines + quinolines or pyridines) and augmented by two. Titrations were run by adding 20-μL portions of standard 0.1 M NaOH and collecting 80–100 points for each titration. Complexation equilibria were studied by means of titrations run under the same conditions, except that the starting solutions also contained $Cu(CF_3SO_3)_2$ in a 1:1 (**L2**$H_2$) or 2:1 (**L1**$H_4$ and **L3**$H_4$) molar ratio with respect to the ligand. Prior to each potentiometric titration, a titration according to the Gran method[16] was run to determine the $E°$ of the glass electrode in the chosen conditions. Protonation data (emf vs. volume of added base) were processed with the Hyperquad package[11] to determine protonation constants.

**Spectrophotometric Titrations:** Coupled spectrophotometric–pH-metric titrations were run with a procedure and under conditions similar to that described for potentiometric titrations. However, in this case, standard base was added manually by means of a 10- or 20-μL Rainin Pipet-Lite pipette. After each addition, a portion of the solution was transferred into a quartz cuvette and its absorption spectrum recorded. After recording the spectrum, the solution was transferred back to the bulk solution. The spectra recorded after each addition were associated with a pH value measured in the bulk solution by means of a glass electrode.

**Electrochemistry:** Cyclic voltammetric measurements were carried out in a three electrode cell, using a platinum electrode as the working electrode, a silver/silver ion electrode as the reference [clean silver wire into an electrolyte containing silver ion. The electrode filling solution was dioxane/water (8:2, v/v) made up to $7\times10^{-3}$ M in $AgNO_3$, with 0.1 M $NaNO_3$ as the background electrolyte]. Dioxane/water (8:2, v/v) was used as solvent, made up to 0.1 M in $NaNO_3$. Ligand + metal solutions were at concentrations $\geq 5\times10^{-4}$ M. pH was regulated by means of microadditions of standard acid or base, and checked with a glass electrode dipped in the electrochemical solution before measurements. Scan rates were in the 200–400 mV $s^{-1}$ range.

**Instrumentation:** Mass spectra were recorded with a Finnigan MAT TSQ 700 instrument, and NMR spectra with a Bruker AMX 400. Spectrophotometric measurements were performed with a diode array HP 8452A spectrophotometer or a Varian CARY 1000 SCAN spectrophotometer. The pH-metric titrations were made with a Radiometer TitraLab 90 titration system. Electrochemistry was obtained with a BAS100B/W instrument.

# Size- and Shape-Controlled Synthesis and Assembly of a Silver Nanocomplex in UV-Irradiated TSA Solution

**Liangbao Yang,[a] Yuhua Shen,*[a] Anjian Xie,[a] Jianjun Liang,[b] Shikuo Li,[a] and Qingfeng Zhang[a]**

**Keywords:** Nanostructures / Silver / Photochemistry / Self-assembly

In this paper we describe the size-controlled synthesis of a silver nanocomplex based on the reduction of silver nitrate ($AgNO_3$) by UV-irradiated tungstosilicate acid [$H_4(SiW_{12}O_{40})$, TSA] solution. This method allows the synthesis of ellipsoidal particles with an average size that is tunable between 2.4 and 84 nm by varying the molar ratio of silver nitrate to TSA, the pH of the reaction solution, and the reaction temperature. Silver nanorods can be formed from the ellipsoidal nanoparticles by controlling the aging time. The formation mechanism of these nanorods is also discussed. The nanoparticles are characterized by UV/Vis spectroscopy, FTIR spectroscopy, XRD analysis, XPS, electron diffraction (ED), TEM, and with a Zetasizer instrument.

## Introduction

Metal nanoparticles are being investigated in considerable detail due to their exciting potential applications in catalysis,[1] biological and chemical sensing,[2,3] and optoelectronics.[4] One of the most important current challenges is to develop experimental recipes that would enable nanoparticle shape-control in addition to size and polydispersity. A number of nanoparticle morphologies such as wires,[5] rods,[6] cubes,[7] and nanotriangles/prisms[8] can now be routinely synthesized by different chemical methods.

Silver nanoparticles, in particular, are of great interest because of their ability to efficiently interact with light by virtue of plasmon resonances, which are the collective oscillations of the conduction electrons in the metal. Silver nanoparticles certainly have the potential to be the building blocks of future photonic and plasmonic devices as the field of nanotechnology matures.

A requirement for this progress is the development of a method that can reliably produce large quantities of silver nanoparticles with a controlled size distribution as different applications will require particles with various dimensions and the ability to tailor surface chemistry. The ideal method of synthesis should yield essentially naked particles so that different surface functionalities can be readily introduced for template-assisted or self-assembly based fabrication methods for nanoscale devices.

The use of tungstosilicate acid [$H_4(SiW_{12}O_{40})$, TSA] to synthesize silver nanoparticles is an important synthetic method. TSA ions form a subset of polyoxometalates of the Keggin structure. These polyoxometalates have the general formula $(XM_{12}O_{40})^{(8-n)-}$, where M is W or Mo and X is a heteroatom such as P, Si, or Ge, with $n$ being the valency of X.[9] The TSA ions, accompanying cations, and other components such as water are arranged in a well-defined secondary three-dimensional structure, the stability of which depends on the nature of the counterions, the amount of water, etc.[10] It is well known that Keggin ions undergo stepwise multielectron redox processes without a structural change[11] and can be reduced electrolytically, photochemically, and chemically (with suitable reducing agents). They are a large category of metal oxygen cluster anions with well-defined structures and properties and have diverse applications in the fields of analytical chemistry, biochemistry, and solid state devices, and have been used as antiviral and antitumor reagents. Their redox chemistry is characterized by their ability to accept and release a certain number of electrons, in distinct steps, without decomposition.[12] Recently, Papaconstantinou and co-workers have shown that photochemically reduced polyoxometalates of the Keggin structure phosphotungstic acid $(PW_{12}O_{40})^{3-}$[13] lead to the formation of the corresponding metal nanoparticles. Sastry and co-workers have used $(PW_{12}O_{40})^{3-}$ ions for making phase-pure core–shell nanoparticles.[14] They have also used $(PW_{12}O_{40})^{3-}$ ions as a template for the in-situ growth of metal nanoparticles,[15,16] star-shaped calcium carbonate crystals,[17] and CdS nanoparticles.[18]

$(PW_{12}O_{40})^{3-}$ is stable at a pH of around 1, whereas TSA is stable up to a pH of about 5.[5] It should be noted that these two Keggin ions have a similar photochemical behavior except that the reaction rates with $(PW_{12}O_{40})^{3-}$ appear to be about two to three times faster than those with TSA.[19] This faster reaction rate often leads to difficulty in controlling the morphologies of the particles, therefore TSA is preferable. In this paper, a general synthetic method that produces silver nanoparticles in water is proposed. The method offers the advantages of being easily scalable and able to produce particles that exhibit long-term stability. The sizes of the synthesized particles can be varied from several to eighty nanometers simply by varying the reaction conditions such as the molar ratio of silver nitrate to TSA, the pH value of the reaction solution, or the reaction temperature. At the same time, silver nanorods can be obtained by varying the aging time. The role of the TSA in directing the morphology of the Ag-TSA colloidal particles for the growth of nanoparticles of a range of chemical compositions is an exciting aspect of the work with important future implications in nanoparticle design. Another area where applications of such composites could arise is in the area of catalysis. Combining the Keggin-ion scaffold with catalytically active metal nanoparticles, such as Rh or Pd, could lead to novel catalysts wherein the Keggin ion and metal components catalyze different reactions simultaneously.[16] To the best of our knowledge, this is the first time to study the size-controlled and shape-controlled synthesis of silver nanoparticles by the templates of TSA colloidal particles. The TSA template may be removed by simple dissolution in an alkaline medium leaving behind reasonably intact silver nanoparticle superstructures. Presented below are details of this investigation.

## Results and Discussion

A representative Keggin structure $(SiW_{12}O_{40})^{4-}$ was chosen to study the reaction between $(SiW_{12}O_{40})^{5-}$ and $Ag^+$ ions. The $(SiW_{12}O_{40}]^{5-}$ ion was obtained by photolysis ($\lambda >$ 280 nm) of a deaerated 2-propanol/$(SiW_{12}O_{40})^{4-}$ aqueous solution, in the presence of, for instance, 2-propanol as a sacrificial reagent[20] [Equation (1)].

$$2(SiW_{12}O_{40})^{4-} + (CH_3)_2CHOH \rightarrow 2(SiW_{12}O_{40})^{5-} + (CH_3)_2C{=}O + 2H^+ \quad (1)$$

After UV irradiation, the above solution gradually turned from colorless to grey (Ag) [Equation (2)]. This should be due to two reasons: one is the ability of the reduced $(SiW_{12}O_{40})^{5-}$ to transfer the electrons efficiently to silver ions;[21] the other is the lower potential of the one-equivalent-reduced tungstate couple $(SiW_{12}O_{40})^{4-}$/$(SiW_{12}O_{40})^{5-}$ (0.057 V vs. NHE;) relative to $Ag^+/Ag^0$ (0.799 V vs. NHE).

$$(SiW_{12}O_{40})^{5-} + Ag^+ \rightarrow (SiW_{12}O_{40})^{4-} + Ag \quad (2)$$

Furthermore, TSA ions can be utilized cyclically as oxidizing agent or reducing agent according to Equations (1) and (2).

Figure 1 shows the UV/Vis spectra recorded for a mixture of 1 mM $AgNO_3$ and 1 mM TSA at different stages of treatment. Prior to UV irradiation, it can be seen that there is no absorption in the visible region (0 h, Figure 1A), whereas after UV irradiation absorption bands are observed in the region 460–478 nm with the reaction time ranging from 20 to 300 min. These absorption bands are characteristic of silver nanoparticles and are caused by excitation of surface-plasmon vibrations.[22] Figure 1B shows the changes of wavelength and absorbance with different reaction time. From Figure 1, we can see that the absorption band becomes sharper and the resonance intensity increases, both of which are due to the increase of the number of silver nanoparticles during the whole process. A gradual shift of surface plasmon band (from 460 to 478 nm) is commensurate with the increasing $(SiW_{12}O_{40})^{5-}$ mol fraction. It can be seen that all the peaks are located at positions between those for pure $(SiW_{12}O_{40})^{5-}$ and Ag nanoparticle plasmon bands (730 and 413 nm, respectively, as reported

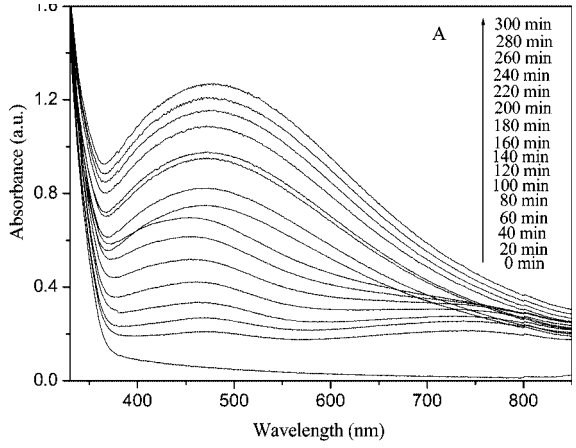

Figure 1. (A) UV/Vis spectra (330–850 nm) recorded for an aqueous mixture of 1 mM $AgNO_3$ and 1 mM TSA at different times of treatment. 0 h: before UV irradiation; 20–300 min: after UV irradiation. (B) Changes of wavelength and absorbance with reaction time. The inset shows one of the spectra of Figure 1A in the region from 210 to 330 nm.

earlier).[13,23,24] The presence of only one plasmon resonance, which shifts gradually from nanosilver to $(SiW_{12}O_{40})^{5-}$ ion particle plasmon bands clearly suggests the formation of TSA-silver nanocomposites rather than a segregated structure, as two bands would be observed in the latter case.[14] Thus, the UV-irradiated TSA ions reduce the $Ag^+$ ions, presumably on the surface of the TSA colloidal particles. It is notable that, in all experiments, the tungstosilicate acid structure remains intact in the process, as determined by the stability of the absorbance peak at 263 nm (shown in the inset of Figure 1B), which is characteristic of the oxidized form of TSA.[13]

In order to study the interaction between $AgNO_3$ and TSA during UV irradiation, the dynamic process of Ag-TSA colloid formation was analyzed by monitoring the conductance of a mixture consisting of equal volumes of 1 mM TSA and 1 mM $AgNO_3$ solutions (the conductance value of 1 mM aqueous TSA is 1.060 mS while that of 1 mM $AgNO_3$ is 0.532 mS). Figure 2 shows the conductance of the Ag-TSA reaction mixture measured as a function of the reaction time. After $AgNO_3$ is added to the TSA solution, it can be seen that the conductivity increases slowly. The reason for this is that the silver cations react with TSA anions to form a strong electrostatic complexation in solution. During complexation of silver ions with TSA anions, it is expected that the mobility of ions in solution would decrease, although the concentration of the ions increases swiftly. As UV irradiation progresses, the silver ions are reduced. At the end of the reaction the silver ions have been reduced completely, complexation of the silver cations and TSA anions in solution disappears, and plenty of TSA anions are generated. This means that the solution conductivity increases steadily and saturates after about 5 h of reaction, which is therefore an estimate of the optimum reaction time for the formation of this colloidal Ag nanocomplex.

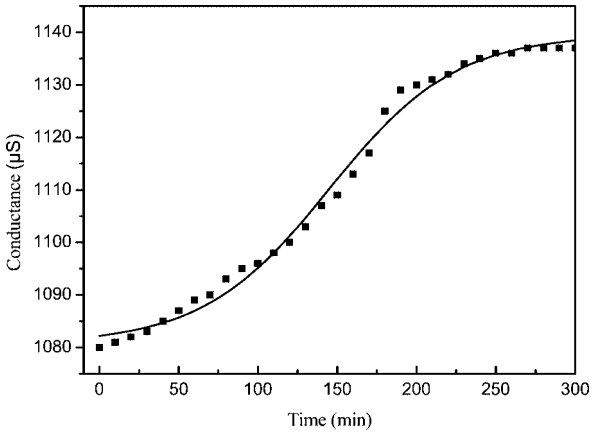

Figure 2. Conductivity measured as a function of time after mixing equal-volume aqueous solutions of 1 mM TSA and 1 mM $AgNO_3$ and irradiating for 5 h.

The XRD pattern recorded from a drop-coated film of the UV-irradiated sample on a glass substrate is shown in Figure 3. The (111), (200), (220), and (311) Bragg reflections of face-centered cubic (fcc) silver are clearly observed. Some of the Bragg reflections corresponding to the TSA structure (indicated by an asterisk) indicate that the formation of silver nanoparticles on the $Ag^+$-TSA colloidal particle template does not disrupt the basic structure of TSA. The XRD pattern recorded from a drop-coated film of the Ag-TSA nanocomplex solution after alkali dissolution of the TSA scaffold is shown as curve b in Figure 3. It is clear that the Bragg reflections of the TSA scaffold have disappeared, leaving behind just the Bragg reflections of the Ag nanoparticle assembly.

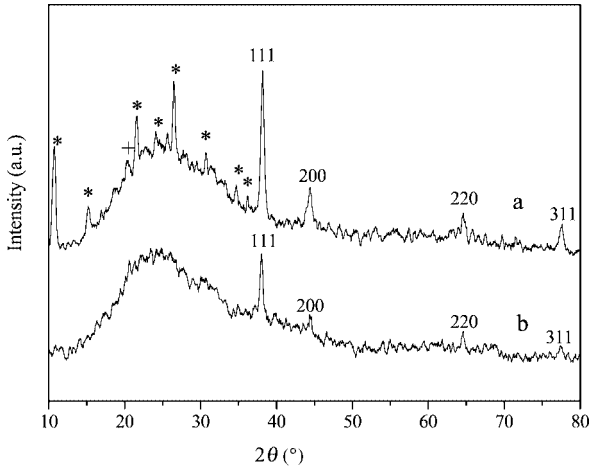

Figure 3. XRD patterns recorded from drop-coated films on glass substrates of silver nanoparticles synthesized by reaction of UV-irradiated TSA solution with aqueous $AgNO_3$ before (curve a) and after base treatment (curve b). The Bragg reflections marked * correspond to TSA.

Figure 4 shows the XPS $W_{4f}$ and $Ag_{3d}$ core-level spectra recorded from drop-coated films of the Ag-TSA solution on a Si (111) substrate. Figure 4A shows the $W_{4f}$ spectrum recorded from the Ag-TSA film. This spectrum can be resolved into spin-orbit pairs (splitting $\approx$ 2.15 eV) with a $4f_{7/2}$ binding energy (BE) of 35.19 eV (curve 1 in Figure 4A). Figure 4B shows the $Ag_{3d}$ core-level spectrum. The $Ag_{3d}$ spectrum resolves into two spin-orbit components. The Ag $3d_{5/2}$ and $3d_{3/2}$ peaks occur at a BE of 367.8 and 373.8 eV, respectively, and correspond to metallic silver.[25] The result demonstrates that only one form of Ag is present in solution, in the form of $Ag^0$. There is no evidence for additional components in the $Ag_{3d}$ spectrum, which indicates the complete reduction of the $Ag^+$ ions in the UV-irradiated TSA solution.

Figure 5A–D show representative TEM images recorded from a drop-coated film of the Ag-TSA solution after aging for 1, 6, 24, and 48 h, respectively. Figure 5A clearly show that there are only densely populated ellipsoidal or irregular structures. The crystalline nature of the silver nanoparticles forming the ellipsoidal or irregular crystal is revealed by the typical electron diffraction pattern shown in the inset of Figure 5A. The four fringe patterns observed, with spacings of 2.360, 2.021, 1.408, and 1.230 Å, are consistent with the fcc polycrystalline silver (111), (200), (220), and (311) spacings of 2.359, 2.044, 1.445, and 1.231 Å. Figure 5D shows

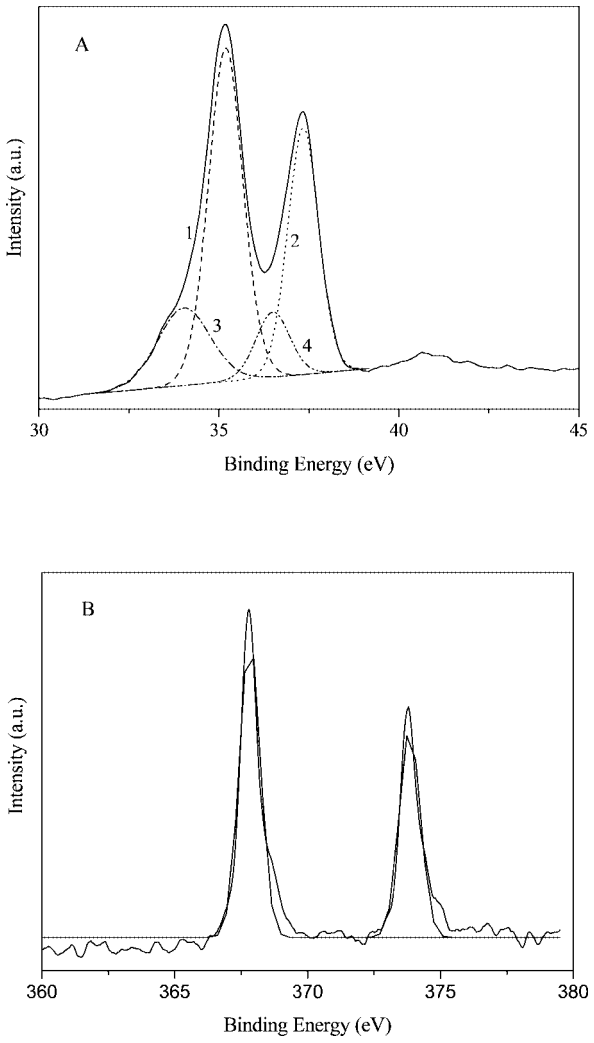

Figure 4. XPS recorded from drop-coated films of the Ag-TSA solution on a Si(111) substrate. (A) W 4f core-level spectrum together with two spin-orbit pairs (1, 2 and 3, 4). (B) Ag 3d core-level spectrum.

a representative TEM image recorded from a drop-coated film of the silver-nanocomplex solution after aging for 48 h. The surface of the rods is smooth and their structure is well-defined, with an average length and diameter of 1250 and 80 nm, respectively (a particle-size-distribution measurement was made from 140 nanorods). The aspect ratio (AR) of the silver nanorods in Figure 5D is estimated to be $13.2 \pm 5.0$. From the TEM image, it can be seen that the nanorods are smooth. In addition to the rod-shaped silver crystals, a lot of irregular crystals are also observed at the bottom left-hand corner of the image (Figure 5D), which implies that the nanorods possibly develop from the original irregular crystals.

The crystallinity of the nanorods was further studied by electron diffraction. As can be seen in the inset of Figure 5D, the ED patterns demonstrate the highly crystalline nature of the particles. From the electron diffraction analysis, the reflection assignments agree well with the results of nanowires reported previously,[26–28] thus demonstrating

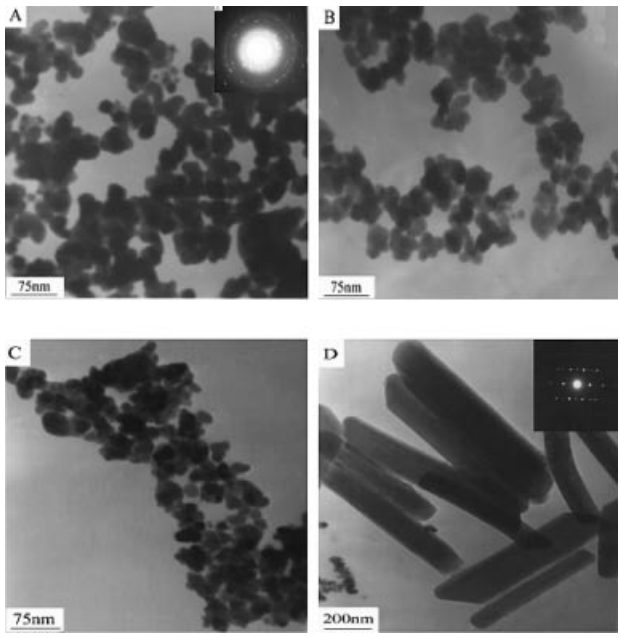

Figure 5. Representative TEM images of Ag nanocrystals obtained at different aging times after reaction (A–D). The insets in A and D are the electron diffraction patterns.

that the rod is formed by a cyclic penta-tetrahedral twin crystal in which five {111} twin boundaries are arranged radially to the [110] direction of the elongation axis. The rod has a pentagonal cross-section and is bound by five {100} side faces and five {111} faces at each end. In accordance with this structure feature, the rod should grow through the decahedral twinned particles with a diameter similar to the transverse length of the rods. The longitudinal and transverse lengths of the rods normally increase in the cases of smaller amounts of seeds. The rod formation possibly occurs in the early aggregation step of the initial particles.

It has been noticed that this kind of reaction takes place within a few seconds.[16] A lot of silver is generated in the first few seconds, so silver "seeds" can be formed, although no silver nanorods are generated at this stage. However, this in itself is not enough to form silver nanorods from silver seeds. Nanorod nucleation is thought to require twinned seed particles, so seed aggregation as a source of twinning may be an important step of nanorod synthesis.[29] On the other hand, the distance between two silver seeds is short, therefore some silver monomers can easily move and adsorb onto the deposited seeds and these aggregated seeds can form nanorods by subsequent recrystallization. So, we think that the growth mode for nanorods in our work is a type of seed-mediated growth mechanism.[29–31]

To understand the formation of large silver nanorod assemblies better, the kinetics of crystallization were monitored as a function of aging time. After aging for 1 h, ellipsoidal or irregular-shaped particles were obtained (Figure 5A). After aging for 6 h the long, irregular crystals begin to take shape and the number of ellipsoidal crystals decreases (Figure 5B). This is the initial stage of silver nano-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rod formation from ellipsoidal silver particle seeds. After aging for 24 h (Figure 5C) the Ag nanorods have almost formed, and when the aging time is prolonged to 48 h the silver nanorods grow into a well-organized shape (Figure 5D). The silver cubes are stable when they are separated from solvents. We found that the dry silver cubes do not change at all after being kept in air for several months.

To discount the possibility of UV-irradiated 2-propanol being the reducing agent for silver ions and thus for nanoparticle formation, a control experiment was performed in which 2 mL of 2-propanol was added to 20 mL of a 1 mM aqueous, deaerated solution of $AgNO_3$ and irradiated for 5 h. There was no change in color of the $AgNO_3$ solution after UV irradiation, which indicates that the product of UV-irradiated 2-propanol is not responsible for the reduction of $AgNO_3$. In the UV/Vis spectrum, the characteristic silver absorption band cannot be observed (see UV/Vis spectrum in Figure S1 in the Supporting Information).

Figure 6 shows the dependence of the particle diameter on the different molar ratios of $Ag^+$ ion to TSA. Parts A–D of Figure 6 show four samples of Ag-TSA nanoparticles corresponding to 1:10, 1:4, 1:2, and 2:1 molar ratios, respectively. These samples have mean diameters of 2.4, 22, 38, and 75.3 nm, respectively. As demonstrated in Figure 6, the size of these Ag-TSA nanoparticles can be conveniently controlled simply by varying the molar ratio, which changes from 0.1 to 2. The diameter increases monotonically from about 2.4 to about 75.3 nm. However, the growth rate decreases gradually, and when the molar ratio is above 2 there is only a small increase in the diameter of the silver nanoparticles. We also noticed that the color reflects the nanoparticle size in our experiments. By following the evolution of the color changes, we observed that a black color represents a colloidal size of about 70 nm and that the suspension of 10-nm-diameter Ag-TSA nanoparticles has, in fact, a grayish appearance, although it appears at lower concentrations. These changes may be directly related to the absorption features of the particles in the visible region of the spectra. It is not unusual that the size of the particles increases as a result of decreasing the relative concentrations of the reducing agent. This behavior is similar to that found in many chemical reduction approaches to nanosystems because the nucleation and growth sequences are both affected by the relative concentrations of the reducing agent and the precursor.[32] In our case, we think that the nucleation process is overwhelmingly faster than particle growth at the higher relative concentrations of the reducing agent, which results in smaller sized particles.

Figure 7 shows the dependence of the Ag-TSA nanoparticles' diameter on the pH of the solution. Parts A–D of Figure 8 show four samples of Ag-TSA nanoparticles corresponding to pH 1, 2, 3, and 4, respectively. The mean diameters of these four samples are 82, 22.8, 5.7, and 2.8 nm, respectively. Figure 7 clearly shows that the diameter decreases continuously with an increase in pH from 1 to 4. However, the rate of decrease diminishes gradually, and when the pH is near 4 there is only a small decrease in the diameter of the nanoparticles. The variation of pH does not

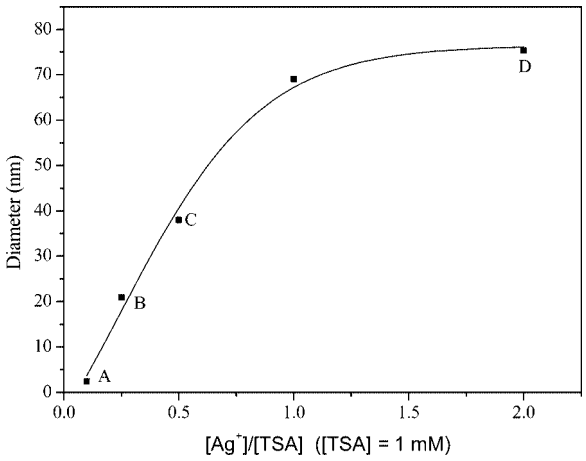

Figure 6. Dependence of the Ag-TSA nanoparticle diameter on the different molar ratio of $Ag^+$ ion to TSA. A–D show four samples of Ag-TSA nanoparticles corresponding to 1:10, 1:4, 1:2, and 2:1 molar ratios ($T$ = 20 °C; [$Ag^+$] = 1 mM; reaction time: 5 h; aging time: 1 h).

alter the rate of metal ions' recovery during the reaction.[33] In other words, varying the pH does not alter the redox power of TSA, so the influence of pH on the particle diameter has nothing to do with this. We suppose that an electrostatic interaction leads to the dependence of the particle diameter on pH. Thus, with a decrease in pH the electrostatic interaction between the silver cations and TSA anions in solution becomes weaker, which allows the size of the particles to increase.

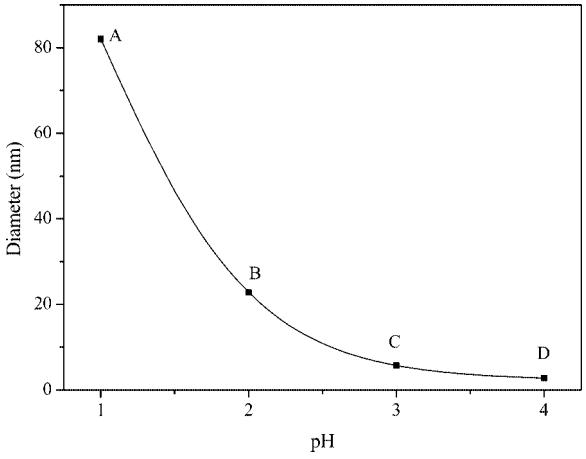

Figure 7. Dependence of the Ag-TSA nanoparticle diameters on pH. A–D show four samples of Ag-TSA nanoparticles with different diameters obtained at pH 1, 2, 3, and 4, respectively ($T$ = 20 °C; [TSA] = 1 mM; [Ag+] = 1 mM; reaction time: 5 h; aging time: 1 h).

The dependence of the diameter of the Ag-TSA nanoparticles on temperature was also studied, as shown in Figure 8. Parts A–D of Figure 8 show four samples of Ag-TSA nanoparticles with different diameters obtained at 20, 40, 60, and 80 °C, respectively. The mean diameters of these four samples are 38, 7.6, 3.4, and 2.7 nm. As demonstrated in Figure 8, the size of these colloids can be conveniently controlled by simply varying the temperature. That is, the

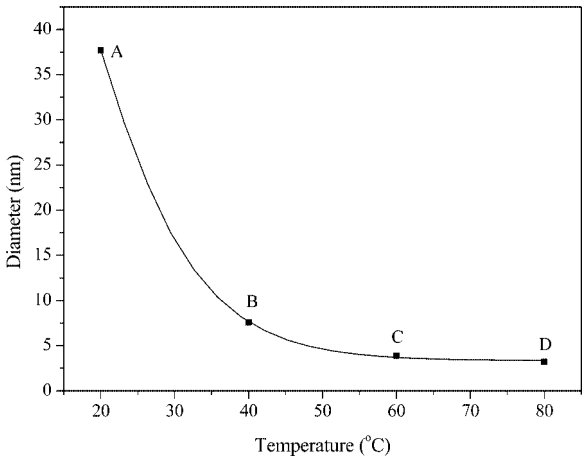

Figure 8. Dependence of the Ag-TSA nanoparticle diameters on reaction temperature. A–D show four samples of Ag-TSA nanoparticles with different diameters obtained at 20, 40, 60,and 80 °C, respectively.

diameter undergoes a continuous decrease with increasing temperature. However, the decrease rate diminishes gradually, and at 80 °C only a small decrease of the diameter of the particles is observed. With increasing temperature the silver ions have higher energies, which are larger than the affinity between TSA ions and silver ions, therefore these silver ions can move anywhere in the solution. That is to say, with an increase of temperature the rate of nucleation of silver nanoparticles accelerates, therefore the nucleation process is faster than the particle growth under these conditions and the size of the particles decreases.

To sum up, since the size of these Ag-TSA nanoparticle colloids can be conveniently controlled by simply varying the molar ratio of silver nitrate to TSA, the pH of the reaction solution, or the reaction temperature, the procedure described here should provide an effective route to ellipsoidal nanoparticles of Ag with controllable size. In principle, this procedure can be extended to several other noble metals that have been prepared as nanoparticles by reduction with TSA.

## Conclusions

In conclusion, a facile method has been proposed to synthesize size-controlled silver nanocomplexes. The size of the nanoparticles can be controlled by varying the reaction conditions, and nanorods of silver can be formed by prolonging the aging time. The rods are found to generate through aggregation to form decahedral seeds followed by elongation along the [110] direction. The possibility of using the TSA framework as a UV-switchable reducing matrix is exciting and may be extended to the creation of other highly organized hybrid inorganic structures with possible applications in nanomaterials.

## Experimental Section

**Materials:** $H_4(SiW_{12}O_{40})$ (TSA), $AgNO_3$, and 2-propanol were all obtained as A.R. grade from Shanghai Reagent Co. All other reagents were used as received.

**Synthesis of the Silver Nanocomplex:** In a typical experiment, 2-propanol (2 mL) and an aqueous deaerated solution of $AgNO_3$ (20 mL, 1 mM) were added to an aqueous deaerated solution of TSA (20 mL) under continuous stirring for 10 min and then allowed to age for 30 min. This mixture was irradiated with UV light (Pyrex filter, >280 nm, 450 W Hanovia medium pressure lamp) for 5 h. The solution changed to gray gradually, thus indicating the formation of silver nanoparticles. The corresponding control experiments under different reaction conditions, such as molar ratio of silver nitrate to TSA, pH of the reaction solution, and reaction temperature are similar to the above experiments.

To discount the possibility of UV-irradiated 2-propanol being the reducing agent for silver ions, and thus for nanoparticle formation, a control experiment was performed in which 2 mL of 2-propanol was added to 20 mL of a 1 mM aqueous deaerated solution of $AgNO_3$ and irradiated for 5 h.

**Sample Characterization:** UV/Vis spectroscopy measurements of the Ag-TSA solution at different stages of treatment were carried out with a TU-1901 model UV/Vis double beam spectrophotometer (Beijing Purkinje General Instrument Co., Ltd, China) operating at a resolution of 2 nm. XPS measurements of the silver nanoparticles synthesized by reduction of $Ag^+$ ions in a UV-irradiated TSA solution were carried out with a VG ESCALAB MKII instrument at a pressure greater than $10^{-6}$ Pa. The general scan and Ag 3d and W 4f core-level spectra were recorded with non-monochromated Mg-$K_\alpha$ radiation (photon energy = 1253.6 eV). The core-level binding energies (BEs) were aligned with respect to the C 1s binding energy (BE) of 285 eV. Samples for TEM analysis were prepared by drop-coating films of the Ag-TSA solution at different stages of reaction on carbon-coated copper TEM grids, allowing the grid to stand for 2 min, and then removing the excess solution with blotting paper. TEM measurements were performed with a JEM model 100SX electron microscope instrument (Japan Electron Co.) at an accelerating voltage of 80 kV. Selected-area electron diffraction measurements of the Ag nanoparticles were also carried out. XRD analysis of drop-coated films of the Ag-TSA solution on glass substrates was carried out with a MAP18AHF instrument (Japan MAC Science Co.). Conductance measurements were carried out to characterize the interaction between $Ag^+$ ions and TSA. The conductance of a mixture consisting of equal volumes of 1 mM TSA and 1 mM silver nitrate solutions was investigated. The conductivity of this solution as a function of reaction time was measured with a DDSJ-308A model conductivity meter (Shanghai Precision & Scientific Instrument Co., Ltd). The size distributions of nanoparticles were measured by PCS on a Zetasizer $3000HS_A$ instrument (Malvern Instruments Limited) at different molar ratios of silver nitrate to TSA, pH of the reaction solution, and reaction temperature.

**Supporting Information** (see footnote on the first page of this article): UV/Vis spectrum of a mixture of 2 mL 2-propanol and 20 mL of a 1 mM aqueous, deaerated solution of $AgNO_3$ after irradiation for 5 h.

# Mixed Amido/Imido/Guanidinato Complexes of Tantalum: Effects of Ligand Substitution on Thermal Properties

**Arne Baunemann,[a] Manuela Winter,[a] Karoly Csapek,[a] Christian Gemel,[a] and Roland A. Fischer*[a]**

**Keywords:** X-ray diffraction / Chelates / N ligands / Tantalum / Nitrides

Mixed amido/imido/guanidinato tantalum complexes $[Ta(NR^1R^2)\{C(NR^1R^2)(NR^3)_2\}_2(NR^4)]$ [$R^1$,$R^2$ = methyl, ethyl; $R^3$ = cyclohexyl (cy), isopropyl; $R^4$ = *tert*-butyl, *n*-propyl] have been synthesized by the insertion of carbodiimides into tantalum–amide bonds. All compounds have been characterized by means of NMR spectroscopy, mass spectrometry, and CHN analysis. Additionally, single crystal structures of five compounds (**4**: $R^1$ = Me, $R^2$ = Et, $R^3$ = *i*Pr, $R^4$ = *t*Bu; **5**: $R^1$, $R^2$ = Et, $R^3$ = *i*Pr, $R^4$ = *t*Bu; **6**: $R^1$, $R^2$ = Me, $R^3$ = cy, $R^4$ = *t*Bu; **8**: $R^1$, $R^2$ = Et, $R^3$ = cy, $R^4$ = *t*Bu; **9**: $R^1$, $R^2$ = Et, $R^3$ = *i*Pr, $R^4$ = *n*Pr) have been determined and relevant structural issues are discussed. The thermal properties of all complexes have been investigated by TGA/DTA measurements. Thus, complexes originating from diisopropylcarbodiimide (*i*Pr-cdi) are significantly more volatile than complexes derived from dicyclohexylcarbodiimide (cy-cdi). In contrast, variations of $R^1$, $R^2$, and $R^4$ have only a small impact on the thermal behavior of the complexes. Finally, selected compounds have been pyrolyzed at 600 °C, and the decomposition products studied by GC-MS and $^1$H NMR spectroscopy.

## Introduction

Thin films of tantalum nitride (TaN) play an important role in the ongoing process of device optimization in microelectronics. Conducting TaN films serve as gate electrode materials in metal oxide semiconductor field-effect transistors as well as diffusion barriers for the inhibition of copper or silver diffusion into the silicon substrates.[1] A rough literature survey shows that 492 patents on the production, processing, and use of TaN films were filed in 2005 alone. TaN thin films can be deposited by various methods, including sputtering processes and gas-phase deposition techniques such as MOCVD (metal organic chemical vapor deposition), plasma-enhanced CVD (PECVD), or atomic layer deposition (ALD). These gas-phase-based techniques make use of binary metal halides, although more recently metal-organic tantalum coordination complexes have also been used. Key parameters for precursors in MOCVD or ALD processes include volatility, thermal decomposition behavior, chemical reactivity, accessibility, and safety issues. Several tantalum–ligand systems have been tested for the deposition of TaN films, amongst which mixed amido/imido tantalum complexes are the most prominent.[2] While most compounds in this class are liquid and have a sufficiently high vapor pressure, they tend to be chemically and thermally rather fragile and show problems in terms of long-term stability at vaporization temperatures as well as a high sensitivity towards moisture or reactive gases. Thus, the use of didentate ligands such as hydrazines has been suggested.[3] In this paper we wish to report on an extension of this approach by introducing guanidinates as suitable chelating ligands for mixed amido/imido tantalum complexes. The use of guanidinates has already shown promising results for the deposition of Ti(C)N or $HfO_2$ thin films in CVD processes.[4,5] Moreover, we recently published a communication on the synthesis and characterization of mixed amido/imido/guanidinato complexes **3**–**5** and showed the successful deposition of conductive, almost carbon-free TaN (C content $< 1\%$) thin films using compound **4** as a single source precursor.[6] This is a rather surprising result considering the fact that less complex amido/imido compounds of tantalum with a considerably lower relative carbon content produce films with much higher carbon contents of around 10%.[7] These results encouraged us to carry out a more detailed examination of the tantalum guanidinato/amido/imido complex system and the impact of substituent variations at different ligand sites on the chemical and thermal properties of the resulting complexes. Table 1 gives a summary of all complexes synthesized and characterized in this paper.

## Results and Discussion

Two basic pathways are known in the literature for the synthesis of metal guanidinate complexes: (i) salt metathesis reactions in which sodium or lithium guanidinates are treated with the metal halides[4,8] and (ii) the insertion of carbodiimides into metal–amido bonds, which is a more convenient pathway that does not involve the formation of LiX or NaX byproducts.[6,9] In the case of tantalum guanidinates, previous work from Tin et al. includes the synthesis of $[Ta(NMe_2)_4\{C(NMe_2)(NR'')_2\}]$ (R″ = cy, *i*Pr) as well as the preparation of tantalum complexes of the neutral, protonated guanidine ligand.[10] The large variety of compounds published before 2001 have been summarized in a recent review.[11]

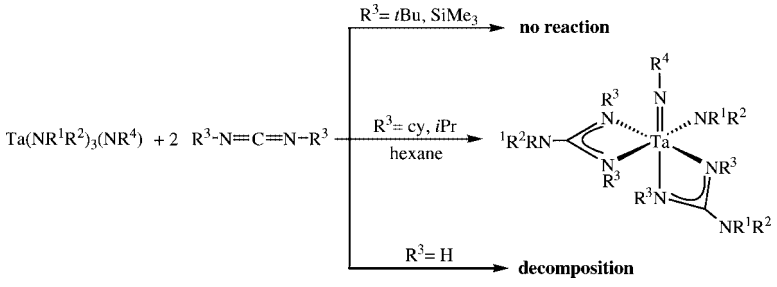
The synthesis of the starting compounds $[Ta(NR^1R^2)_3(NR^4)]$ followed published procedures.[12] At first the intermediate compound $[TaCl_3(N\text{-}n\text{Pr})(py)_2]$ (**1**) was formed by reaction of $TaCl_5$ with *n*-propylamine, chlorotrimethylsilane, and pyridine. It should be noted that on scaling up the literature procedure it is possible to keep the amount of solvent almost constant by increasing the amount of pyridine, which significantly increases the solubility of **1** in toluene and thus allows the separation of the product from the precipitated ammonium salts (see Experimental Section). In a second step, this pyridine-stabilized salt was treated with $LiNEt_2$ in order to form $[Ta(NEt_2)_3(N\text{-}n\text{Pr})]$ (**2**). Higher yields of **2** can be obtained when stoichiometric amounts of lithium amide are added to **1** at –60 °C instead of an excess at room temperature. The mixed amido/imido tantalum complexes were then treated with the respective carbodiimides in hexane to give the guanidinato/amido/imido complexes **3**–**10** (Scheme 1).

The synthesis of **3**–**5** has already been described in a previous communication.[6a] It is noteworthy that no insertion products could be isolated when sterically encumbering carbodiimides such as $(t\text{Bu})_2C_2N$ or $(SiMe_3)_2C_2N$ were used, even after refluxing the reaction mixtures for 24 h in the presence of a large excess of the carbodiimides. On the other hand, reaction with the unsubstituted carbodiimide (which exists as its tautomer $H_2NC{\equiv}N$) did not lead to isolable products but instead gave an orange solid which is insoluble in organic solvents. It is likely that transamination reactions lead to the formation of insoluble, oligomeric tantalum amides.

Compounds **3**–**10** can be prepared in high yields (>80%) and are white solids with rather high melting points of 195–230 °C. All compounds are highly soluble in hexane, benzene, or toluene and their elemental analyses are in good agreement with their suggested molecular formulae. The mass spectra of **3**–**10** show differences between the bis(cyclohexyl)carbodiimide (cy-cdi) containing compounds and their (*i*Pr-cdi) based congeners. Thus, the intensities of the $[M^+]$ peaks of **6**, **7**, **8**, and **10** (cy-cdi) are below 1% of the base peak (if visible at all), while they are above 10% for **3**, **4**, **5**, and **9** (*i*Pr-cdi). As will be shown below, this is consistent with the thermal properties of these compounds, since cy-cdi based compounds generally show significant decomposition during evaporation. The most intense peaks for **6**, **7**, **8**, and **10** are observed at *m*/*z* 41, 43 and 55 and are due to the cyclohexyl fragments $C_3H_5^+$, $C_3H_7^+$, and $C_4H_7^+$.

### NMR Analysis

All NMR assignments are based on two-dimensional NMR spectra of the previously published compounds **3**–**5**.[6a] The $^1H$ NMR spectra of **3**–**10** show rather large differences in the exact chemical shifts of the diastereotopic alkyl substituents of the Ta-amido groups, which also show a hindered rotation due to the partial π character of the Ta–N bond. In the case of the dimethyl-substituted amido group (**6**), the two singlets are separated by 0.5 ppm and in the case of the diethyl-substituted amido group (**8**, **9**, and **10**), the four doublets of quartets ($ABX_3$ spin system) are found in a range of 1.5 ppm. Of these four multiplets, three are close to each other while the other is strongly high-field shifted, probably because of the anisotropic magnetic field of the guanidinate π systems. The $^1H$ and $^{13}C$ NMR spectra



Scheme 1. Synthesis of compounds **3**–**10**.

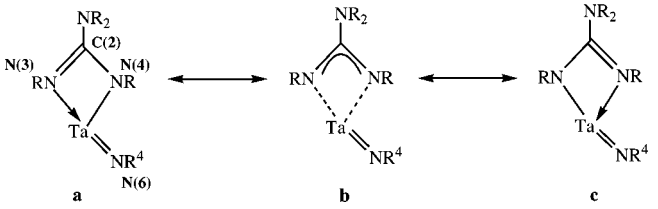
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of **7** (MeEtN substitution) could not be fully assigned due to the formation of rotational isomers, which leads to a mixture of several interconvertible isomers and thus highly complex solution spectra. The $^1$H NMR spectra of the cycdi based complexes **6**, **7**, **8**, and **10** show broad signals for the cyclohexyl groups, with only the $C_\alpha$ proton being slightly low-field shifted. The assignment of all $^{13}$C NMR spectra, with the exception of **7**, was straightforward and is therefore not discussed here in detail.

### X-ray Analysis

Single crystals of **4**, **5**, **6**, **8**, and **9** were obtained by recrystallization of the compounds from toluene at –30 °C. Several attempts to obtain crystals of **7** or **10** suitable for single-crystal X-ray analysis failed. Compounds **4** and **5** crystallize in an orthorhombic crystal system while the crystal systems of **6**, **8**, and **9** are of lower symmetry, i.e. monoclinic for **6** and **8** and triclinic for **9**. The molecular structures of **6** and **9** are displayed in Figure 1 as representatives of all solid-state structures.[13] Table 2 contains bond lengths, angles, and dihedral angles for all the above complexes.

The molecular structures of all compounds are very similar to each other and to that of compound **3**, which has already been discussed in an earlier publication.[6a] Thus, only the solid-state structure of **6** will be discussed here in more detail. The tantalum(V) center in **6** is sixfold coordinated by two didentate guanidinato ligands, one amido, and one imido group, resulting in a highly distorted octahedron. The Ta–N(6)–C(18) unit of the imido ligand is almost linear [170.6(4)°] and the Ta–N(6) bond is relatively short (1.79 Å), which indicates an almost sp-hybridized imido ligand. Due to the strong π-donating effect of this imido ligand,[14] the Ta(1)–N(3) bond of the guanidinato ligand opposite to the imido group is lengthened [2.437(5) Å], while the second Ta–N bond in the same guanidinato ligand [Ta(1)–N(4) = 2.123(5) Å] is considerably shorter. Obviously, the π-donating effect of the imido group results in an unsymmetrical charge distribution within the delocalized π system of the guanidinato ligand, which is also well reflected in a rather large difference in the N–C bond lengths [N(3)–C(2) = 1.308(9), N(4)–C(2) = 1.363(9) Å]. Scheme 2 illustrates the mesomeric structures for the metal–guanidinato interactions, with structure **a** describing best the observed bond lengths in the solid-state structure.



Scheme 2. Mesomeric structures for metal–guanidinato interactions.

The second guanidinato ligand [N(1)–C(1)–N(2)] is more symmetric – the two Ta–N bond lengths are 2.168(6) Å [Ta–N(1)] and 2.279(5) Å [Ta(1)–N(2)]. Again, the longer Ta–N bond is found *trans* to the more basic ligand, i.e. the amido group. The noncoordinated $NR_2$ groups of the guanidinato ligands are almost planar, with angular sums around the nitrogen atoms of 355.1° and 359°, respectively. A rather weak π-donating effect of the $NR_2$ groups to the guanidinato π-systems is suggested by a relatively large tilt angle of the C–N–C planes of 45.3° and 40.6°, respectively, which is obviously an effect of the steric repulsions of the alkyl substituents. However, an even weaker interaction is found in $[Ta(NMe_2)_4\{C(NMe_2)(N\text{-}cy)_2\}]$,[10a] which shows a tilt angle of the two CNC planes of more than 80°. Indeed, the C–N bond length of the exocyclic nitrogen ligand to the guanidinato core is elongated by 0.03 Å compared to **6**.

### Analysis of Thermal Properties

The thermal properties of compounds **6**–**10** were analyzed by classic melting point determinations, standard TG/DTA measurements, isothermal analyses, and sublimation

[a] The data of **3** have already been published and are only given here for comparison.

experiments under vacuum conditions. The melting points of all compounds are relatively high (195–232 °C, see Table 1) and cannot be rationalized by the type of ligand substitution ($R^1$–$R^4$). It can be concluded from the DTA spectra that the melting process is accompanied by the initiation of decomposition reactions. The compounds do not melt fully at the documented temperatures but undergo some sort of waxy transition phase over a temperature range of approximately 5 °C (vide infra).

The nature of the carbodiimide substituents (cy vs. *i*Pr) has a big influence on the volatility of the compounds. Thus, **3**, **4**, **5**, and **9** (*i*Pr-cdi) can be sublimed without any residues at 120 °C in vacuo ($10^{-4}$ mbar) whereas **6**, **7**, **8**, and **10** (cy-cdi) do not sublime at all under these conditions. Isothermal studies at 120 °C underline these results. After 240 min at ambient pressure the weight loss of **3**, **4**, **5**, and **9** is approximately 10% in all cases, while compounds **6** and **7**, for example, show a weight loss of only 2.5% (Figure 2). The mass transport of these complexes is highest for **9** (4.9 $\mu g\,min^{-1}$) and significantly lower for **6** and **7** (0.93 and 0.59 $\mu g\,min^{-1}$, respectively). The simplest explanation for this observation is the higher molecular masses of the cy-cdi based compounds. However, by changing $R^1$ and $R^2$ from methyl to ethyl (e.g. **3** to **5**) no significant effect on the volatility is observed. Obviously, the variation of $R^3$ has a significant effect on the interactions between the molecules in the solid state, for example by a different packing of the moieties.

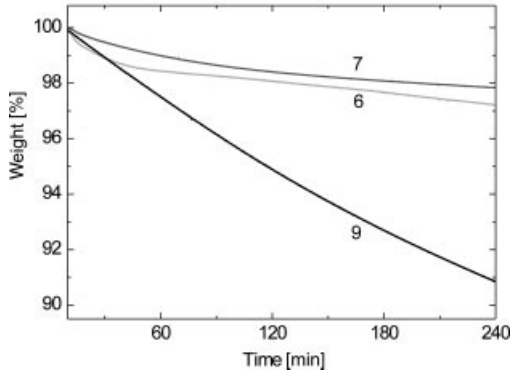

Figure 2. Isothermal analysis of **6**, **7**, and **9**. The spectra were recorded at a temperature of 120 °C, 300 sccm nitrogen flow for 4 h. Heating from 25 °C to 120 °C at a rate of 10 °C $min^{-1}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The residual masses after TG/DTA measurements from cy-cdi based complexes are higher than the theoretical masses (residual masses for **6**–**8**, **10**: 29–35%, theoretical content of TaN: 22–24%). This indicates the incorporation of significant amounts of carbon during the decomposition. In contrast, the *i*Pr-cdi based complexes **4**, **5**, and **9** show considerably lower residual masses and thus cleaner decomposition processes (residual masses: 10–12%, theoretical content of TaN: 27–28%).

With the exception of **7**, all compounds show one or two endothermic peaks at temperatures below their melting/decomposition points (Figure 3). Due to the fact that no weight loss can be observed in any case, a phase change of the solids is possibly responsible for this behavior. This phase change is not reversible, which means that running a program in which the sample is heated, cooled down, and heated again shows endothermic peaks only in the first period of heating. The position of the peaks is strongly dependent on the nature of the alkyl substituents $R^1$, $R^2$, and $R^3$. Going from methyl to ethyl for the amido substituents $R^1$ and $R^2$ results in a shift of these peaks to higher temperatures (**3**→**4**→**5**: 52 °C→70 °C→110 °C; **6**→**8**: 112 °C→139 °C). The same is true for the variation of $R^3$ from *i*Pr to cy (**3**→**6**: 52 °C→112 °C; **5**→**8**: 110 °C→139 °C; **9**→**10**: 82 °C→140 °C). It can be concluded, that the onset of the temperature for phase changes depends on the mobility of the molecules in the solid state, which supposedly increases with higher chain lengths and/or size of the substituents.

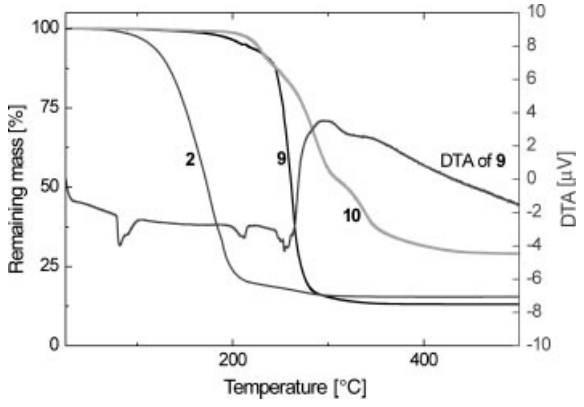

Figure 3. TG/DTA spectrum of **9** and TG curves of **2** and **10**. Heating rate: 5 °C min$^{-1}$.

### Decomposition Experiments of 3–5

The nature of the thermal decomposition of potential MOCVD precursors into the desired materials is crucial. Thus, compounds **3**–**5** were evaporated at 120 °C in vacuo, with a constant flow of argon providing a continuous transport of the precursor through a decomposition tube at 600 °C (Figure 4). The decomposition products were subsequently trapped at –196 °C (liquid nitrogen) in a slightly modified cooling trap. After full evaporation of the precursor (300 mg), deuterated benzene was injected into the cooling trap, and the resulting $C_6D_6$ solutions analyzed by $^1$H NMR spectroscopy and GC-MS measurements. The $^1$H NMR spectra revealed the formation of the corresponding free amines for **3**–**5** ($HNMe_2$, HNMeEt and $HNEt_2$), small amounts of $t$BuNH$_2$ (resulting from the former imido ligand), as well as free carbodiimide. At these very high temperatures (600 °C) carbodiimide could be released from the guanidinato ligand by deinsertion analogous to the behavior of amidinate complexes.[15] It should be noted that although these compounds represent the major part of decomposition products, smaller peaks were also present which could not be unequivocally assigned. GC-MS measurements confirm these $^1$H NMR results and additionally show the presence of small amounts of isopropylamine as well as several unidentified species containing the carbodiimide group. Although the relatively large variety of decomposition products suggests rather complex decomposition mechanisms, preliminary MOCVD experiments of compound **4** as a single-source precursor showed the possibility of carbon-free (atomic concentration < 1%)[6] TaN deposition, which requires clean thermal decomposition processes.

Figure 4. Setup for the decomposition experiments of **3**–**5**.

## Conclusions

We have presented the synthesis and characterization of several new guanidinato/amido/imido complexes of the type $[Ta(NR^1R^2)\{C(NR^1R^2)(NR^3)_2\}_2(NR^4)]$ {$R^1$,$R^2$ = methyl, ethyl; $R^3$ = cyclohexyl (cy), isopropyl; $R^4$ = *tert*-butyl, *n*-propyl}. All complexes are structurally very similar, the bond lengths and angles of the solid-state structures showing only minor variations. TG/DTA measurements and isothermal studies reveal the low volatility of the cy-cdi based complexes. This is rather unexpected considering the fact that the structural and chemical behaviors of compounds **3**–**10** are very similar. Thus, cy-cdi based complexes are, in general, not suitable for MOCVD purposes due to a supposedly weak precursor transport. However, application of the compounds derived from cy-cdi in liquid injection MOCVD is feasible. The choice of substituents of the amido or imido groups does not seem to have a significant impact on the thermal behavior of the resulting complexes. Finally, thermal decomposition experiments of **3**–**5** clearly show that highly complex pyrolysis reactions are taking place, although they lead to a clean decomposition of the selected precursors in all cases.

## Experimental Section

All manipulations of air- and moisture-sensitive compounds were performed on a conventional vacuum/argon line using standard

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Schlenk techniques. Preparations of samples for further analysis were carried out in argon-filled glove boxes. All solvents were purified by an MBraun solvent purification system (SPS) and stored over activated molecular sieves (4 Å). $C_6D_6$ was degassed and dried with activated molecular sieves. Elemental analysis was performed by the analytical service of our Chemistry Department (CHNSO Vario EL 1998). $^1H$ and $^{13}C$ NMR spectra were recorded on a Bruker Advance DPX-250 spectrometer. EI mass spectra were recorded with a Varian MAT spectrometer. Simultaneous TG/DTA analysis was carried out using a Seiko TG/DTA 6300S11 at ambient pressure (sample weight ≈ 10 mg). GC-MS measurements were carried out on a Shimadzu QP2010 instrument at a column temperature of 290 °C. The tantalum-containing starting compounds, namely [Ta(NMe$_2$)$_3$(N-*t*Bu)], [Ta(NMeEt)$_3$(N-*t*Bu)], [Ta(NEt$_2$)$_3$(N-*t*Bu)], and [Ta(NEt$_2$)$_3$(N-*n*Pr)] were synthesized in batches of 15–40 g following modified literature procedures.[12] Reagents were purchased from the following companies and used without further purification: butyllithium (1.6 N solution in hexane, Merck), diethylamine (>99% purity, Merck), methylethylamine (> 97% purity, Fluka), pyridine (Normapur grade, VWR), chlorotrimethylsilane (98%, Acros), lithium dimethylamide (95%, Aldrich), diisopropylcarbodiimide (99%, careful: very toxic, Acros), and dicyclohexylcarbodiimide (99%, Aldrich). The synthesis and characterization of **3**–**5** was described in a previous publication.[6a] For a brief summary of the crystallographic data see Table 3. CCDC-611058 to -611062 (**4**–**6**, **8**, and **9**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**[TaCl$_3$(N-*n*Pr)(py)$_2$] (1):** *N*-Propylamine (20.2 mL, 14.52 g, 246 mmol) and chlorotrimethylsilane (15 mL, 118 mmol) were added to a cooled suspension of TaCl$_5$ (20 g, 55.8 mmol) in toluene (150 mL). The color of the suspension changed to slight yellow-greenish. After stirring the reaction mixture at room temperature for 25 min, pyridine was added (25 mL, 24.5 g, 310 mmol). After 24 h, the clear, yellow-green solution was filtered, and the solvents removed in vacuo. The crude product was recrystallized from hot toluene (100 °C, ca. 120 mL). Yield: 22.2 g (44.2 mmol, 79% based on TaCl$_5$). $C_{13}H_{17}Cl_3N_3Ta$ (502.63): calcd. C 31.13, H 3.39, N 8.38; found C 31.14, H 3.67, N 8.67. All other analyses (NMR, MS) were in accordance with the previously published results.

**[Ta(NEt$_2$)$_3$(N-*n*Pr)] (2):** A suspension of lithium diethylamide (62 mmol) was prepared in situ by adding 40 mL of a 1.6 M BuLi solution (hexane) to diethylamine (7.5 mL, 62 mmol) at –60 °C. After stirring the reaction mixture for 24 h at room temperature, the resulting suspension was added to a suspension of **1** (10 g, 20.8 mmol) in hexane at –60 °C. The reaction mixture slowly turned yellow/orange and was filtered after stirring for an additional 24 h. The yellow/orange filtrate was concentrated in order to obtain the dark orange product **2**. Yield: 8.38 g (18.4 mmol, 92% based on **1**). $C_{15}H_{37}N_4Ta$ (454.43): calcd. C 39.65, H 8.20, N 12.33; found C 39.87, H 7.80, N 12.49. All other analyses (NMR, MS) were in accordance with the previously published results.

**[Ta(NMe$_2$){(N-cy)$_2$C(NMe$_2$)}$_2$(N-*t*Bu)] (6):** A solution of dicyclohexylcarbodiimide (1.52 g, 7.83 mmol) in hexane (20 mL) was added to a solution of [Ta(NMe$_2$)$_3$(N-*t*Bu)] (1.55 g, 4.03 mmol) in hexane (40 mL). The temperature of the solution increased to about 45 °C

Table 3. Crystallographic data and structure refinement details for **4**, **5**, **6**, **8**, and **9**.

# Mechanochemical Control of Synthesis and Structures of Aqua-Bridged Binuclear Nickel(II) Benzoate Complexes

**Anirban Karmakar,[a] Rupam J. Sarma,[a] and Jubaraj B. Baruah*[a]**

**Keywords:** Nickel / Aqua-bridged complexes / Solvation / Hydrogen bonds

Synthetic and structural aspects of a few binuclear nickel(II) complexes, having two bridging carboxylate groups and aqua groups are reported. Intramolecular O–H···O hydrogen bonding interactions between the bridging aqua group and the monodentate benzoate groups stabilises the bridging structures. Aqua-bridged nickel(II) benzoate complex is stable irrespective of solvent system and also can include solvent molecules such as toluene and benzene. A mixed chloro, aqua and 4-chloro-benzoato-bridged $Ni^{II}$ binuclear complex was synthesised and structurally characterised.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

The crystal structures of the active sites of binuclear nickel(II) metallo-enzymes have shown that the metal centres are bridged by carboxylates as well as water or hydroxide ions.[1] The binuclear metal active site of the urease isolated from *Klebseilla aerogenes*, has aqua-bridged binuclear nickel(II) centres with pseudo-octahedral and square-pyramid geometry around the nickel ions.[2] So the design of binuclear aqua-bridged nickel(II) complexes is important in biological modelling.[3] Study of the structure and properties of binuclear transition-metal complexes containing bridging groups such as aqua groups[3] are expected to increase our understanding of the crucial factors that determine the catalytic activity of metalloenzymes.[4] We recently described the synthesis and catalytic activity of a binuclear nickel(II) benzoate complex that contains an aqua group in the bridging position.[5] We also communicated that the solid state and solution synthetic route results in a variation of the structure of nickel carboxylate complexes.[5] In the biological environment the reactions of substrates takes place in confined media, so, it is necessary to understand how different types of motifs can be developed from the complexes that have close structural resemblance to biological active sites. It is also necessary to understand the stability of such complexes in the presence of various neutral molecules in the lattice. With these objectives in mind we investigated multiple component solid-state synthesis of binuclear nickel(II) carboxylate complexes and the structural aspects of aqua-bridged nickel complexes in the presence of different neutral molecules in the lattice.

## Results and Discussion

We have observed that the reaction of nickel(II) chloride hexahydrate, and sodium benzoate in 1:2 stoichiometry (Scheme 1) in the solid-state followed by addition of pyridine gave the nickel(II) benzoate complex, **2a**. The synthetic procedure is important because the analogous reaction in solution results in the formation of a mononuclear species.[6] The complex is soluble in chloroform, benzene or toluene and could subsequently be crystallised from benzene in $P2_1/c$ space group as light blue blocks. The crystal structure of **2a** shows that each of the nickel centres have octahedral geometry involving two bridging benzoate groups (Figure 1), two coordinated pyridine molecules and a monodentate benzoate apart from a bridging aqua group;

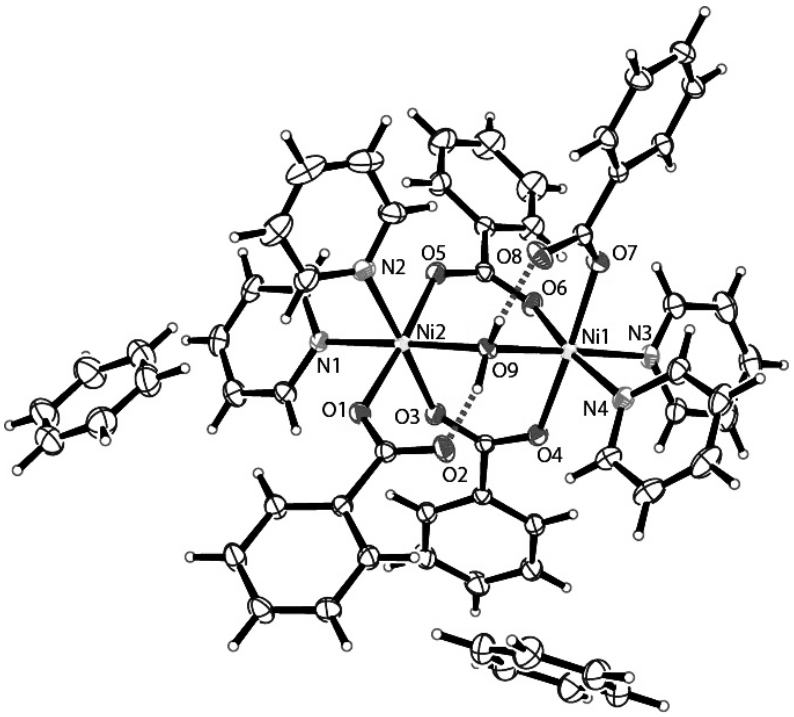

Figure 1. Crystal structure of **2a** with included benzene molecules (thermal ellipsoids drawn to 30% probability).

the Ni(1)···Ni(2) distance in this complex is 3.506(3) Å. The monodentate benzoate groups are intramolecularly hydrogen-bonded to the bridging aqua group through O(9)–H···O(2) [2.565(3) Å, 166(3)°] and O(9)–H···O(8) [2.572(3) Å, 170(3)°] interactions. The Ni(1)–O(9) and Ni(2)–O(9) bond lengths in this complex are 2.093(2) and 2.094(2) Å while the corresponding Ni(1)–O(9)–Ni(2) bond angle is 113.7(8)°.

There is a distorted octahedral geometry around each of the nickel centres. The compound has an absorption maximum at 645 nm due to a $^3A_2$ to $^3T_1$ transition arising from $d^8$-electronic configuration in a weak field. The assembly is stabilised by weak aromatic C–H···π interactions ($d_{C\cdots\pi}$ 3.87 Å) involving the C60–H of the benzene molecule as the donor and the aromatic ring of the benzoate groups of the molecule as the acceptor. In this case, the self-assembly of the binuclear nickel(II) benzoate complex leads to the inclusion of two benzene molecules in the crystal lattice that are stabilised by weak intermolecular C–H···π interactions.

The complex $[Ni_2(H_2O)(O_2CPh)_4(Py)_4]$ when crystallised from toluene results in the formation of a polymorph that contains included benzoic acid and toluene molecules and we have reported this structure in the past.[5] When this complex was dissolved in ethanol and layered over water the complex $[Ni_2(H_2O)(O_2CPh)_4(Py)_4]H_2O$ (**2b**) was crystallised; the crystals were found to have crystallised in the orthorhombic *Pbcn* space group. The structure of this complex is shown in Figure 2. Intra-molecular O(4)–H···O(2) [2.573(17) Å, 166(3)°] hydrogen bonding interactions are also observed between the bridging aqua group and the monodentate benzoate group as shown in Figure 2. It is observed that the Ni(1)–O(4) bond length in **2b** is 2.104(9) Å, which is slightly longer than that in **2a**, while the Ni(1)–O(4)–Ni(1′) bond angle is 115.25(8)°. This complex, **2b**, is a polymorph of **2a** and is characterised by a similar binuclear nickel(II) core except for the presence of a lattice water molecule that is intermolecularly hydrogen-bonded to the monodentate benzoate group through O(6)–H···O(2) [2.910(2) Å, 164(3)°] interactions. Solid-state FT-IR spectroscopy of this complex shows broad signals at 3537 and 3478 $cm^{-1}$ arising from intramolecular and intermolecularly hydrogen bonded O–H stretching vibrations. In methanol, the UV/Visible spectrum of **2b** shows an absorption band at 648 nm that may be assigned to the $^3A_2$ to $^3T_1$ transition.

Addition of pyridine to a mixture of nickel(II) chloride hexahydrate, 1-naphthoic acid and potassium hydroxide in toluene/methanol (1:1 v/v) gave a blue solution, from which the corresponding aqua-bridged binuclear complex, $[Ni_2(H_2O)(O_2CNp)_4(Py)_4]$ (**2c**), was obtained (where Np is naphthyl). The crystal structure of the complex is shown in Figure 3 (a), which shows that the bridging aqua group is hydrogen bonded to the monodentate naphthoate group through O(9)–H···O(8) [2.566(4) Å, 169(5)°] and O(9)–H···O(2) [2.533(4) Å, 162(6)°] interactions. The structure of the complex shows that the two nickel(II) centres are bridged by a water molecule and two naphthoate groups such that the Ni(1)–O(9)–Ni(2) bond angle is 117.78(9)°, with a Ni(1)···Ni(2) distance of 3.593(7) Å.

In a similar manner to the one discussed above, a corresponding binuclear nickel(II) complex of 2-nitrobenzoic acid was also prepared and could be crystallised from toluene as blue-green plates in the *C*2/*c* space group. Crystal structure analysis shows that the corresponding aqua bridge

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

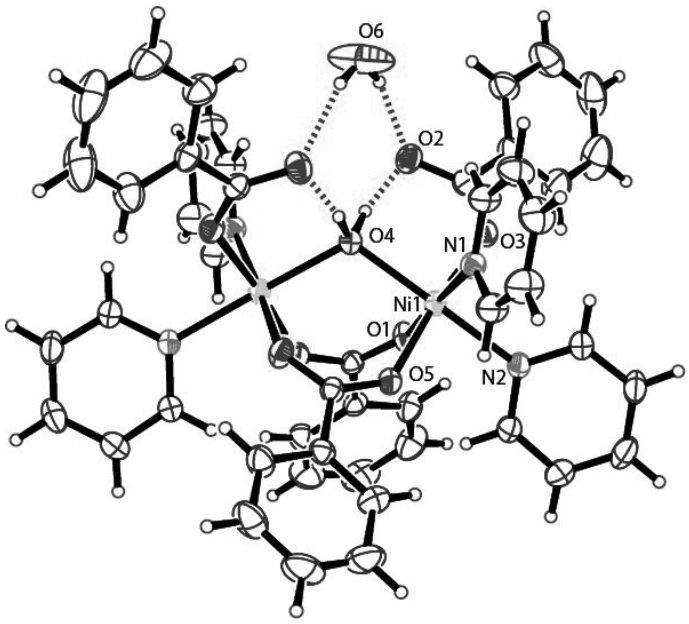

Figure 2. The structure of **2b** containing a hydrogen-bonded water molecule; symmetry for equivalent atoms [ $-x$, $y$, $-z + 1/2$] (thermal ellipsoids drawn to 30% probability).

in the binuclear nickel(II) complex with 2-nitrobenzoic acid **2d** is structurally similar to that of **2c** (Figure 3, b). It is observed that solvent molecules are not included in the crystal lattice of this complex apparently due to the steric crowding caused by the nitro substituent on the aromatic carboxylic acid molecules. As described earlier, each nickel(II) centre in complex **2d** is coordinated to the monodentate benzoate groups and two pyridine molecules, apart from the two bridging benzoate and bridging aqua group, which gives a six-coordinate octahedral geometry. The aqua molecule in this complex is intramolecularly hydrogen bonded to the monodentate benzoate through O(9)–H···O(2) [2.571(16) Å, 167(2)°] interactions; in this case the Ni(1)–O(9) bond length is 2.089(9) Å with the Ni(1)–O(9)–Ni(2) bond angle being 117.05(8)°.

So far in the above reactions we have obtained systematically aqua-bridged complexes, starting from nickel(II) chloride as the inorganic salt. However, in the reaction of 4-chlorobenzoic acid under analogous conditions a chloro-bridged complex $[Ni_2(H_2O)(Cl)(O_2CAr)_3(Py)_4]$ (**2e**) was formed. The crystal structure of this complex revealed the presence of an aqua bridge (Figure 4) and a benzoate bridge unlike complexes **2a**–**2d**, along with a chloride bridging group between the two nickel centres. In this case the presence of three monodentate 4-chlorobenzoate groups led to the binuclear tribridged $[Ni_2(H_2O)(Cl)(O_2CAr)_3(Py)_4]$

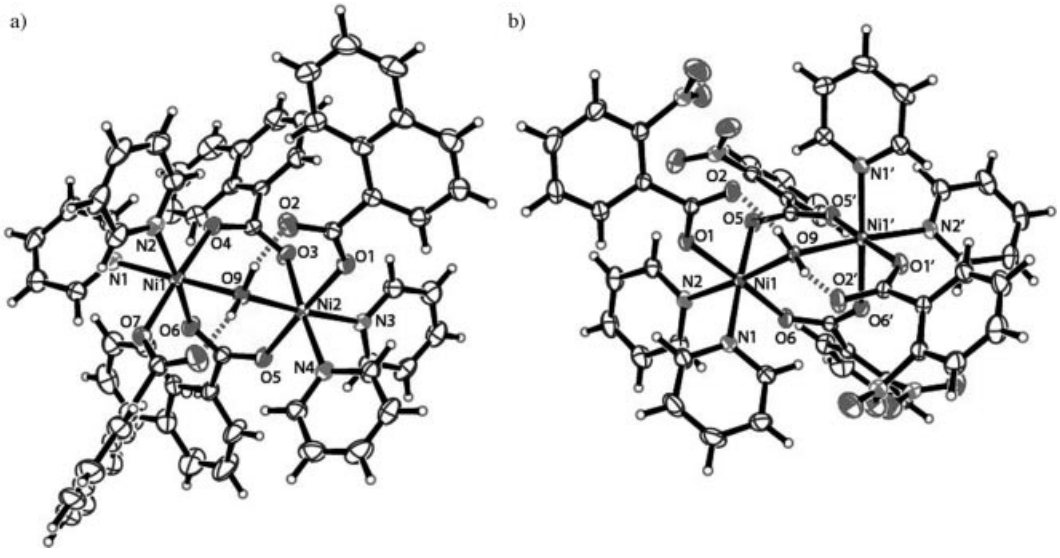

Figure 3. Crystal structures of (a) **2c** and (b) **2d** showing the intramolecular hydrogen bonding interactions between the bridging aqua molecule and the monodentate carboxylate groups (thermal ellipsoids drawn to 30% probability).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

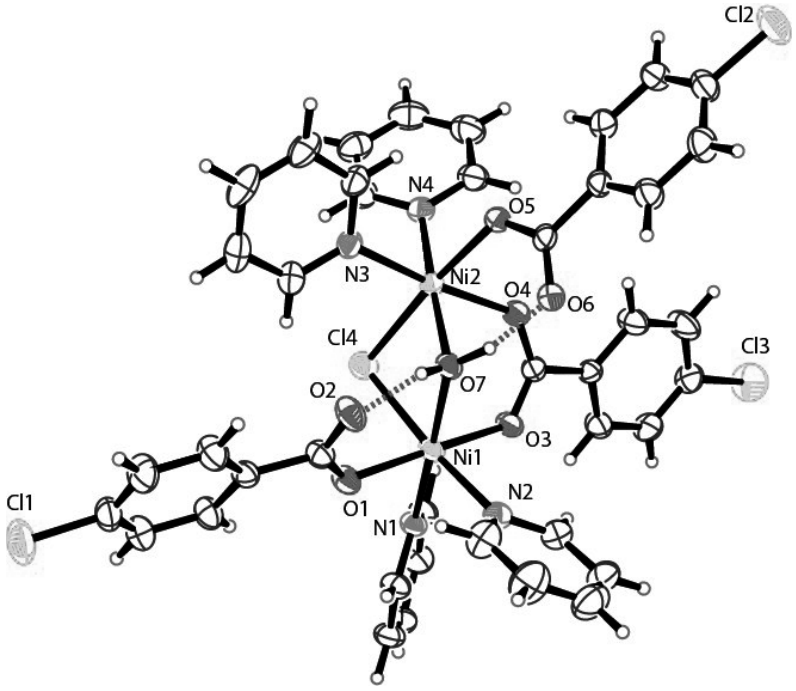

Figure 4. Crystal structure of **2e** (thermal ellipsoids drawn to 30% probability).

complex, (**2e**) as shown in Figure 4. The complex also has distorted octahedral geometry around the nickel centres and has an electronic absorption at 633 nm due to the $^3A_2$ to $^3T_1$ transition.

It is observed that in complex **2e**, the bridging aqua molecule is intramolecularly hydrogen bonded to the carboxylate units of the monodentate 4-chlorobenzoate groups via O(7)–H···O(2) [2.593(3) Å, 165(3)°] and O(7)–H···O(6) [2.561(3) Å, 165(4)°] interactions. The corresponding Ni(1)–O(7) and Ni(2)–O(7) bond lengths are 2.126(2) and 2.121(2) Å respectively while the Ni(1)–O(7)–Ni(2) bond angle is found to be 101.18(9)°. Although the Ni(1)···Ni(2) distance is 3.281(2) Å it is substantially shorter than **2a** or **2c** (Table 1). The reported values for Ni···Ni distance of separation in aqua-bridged complexes ranges from 3.497–3.676 Å.[7] However, the effect of the substituent on the aromatic ring as well as solvation on the Ni–$O_{aqua}$–Ni angle becomes prominent in the complexes **2c** and **2d**, which are close to the reported bond angles.[7] When the Ni–$O_{aqua}$–Ni angles among **2a** and **2b** are compared it is found that **2a** < **2b**. This happens because the hydrogen bonding interaction of the bridging water molecules in each case is different. In the case of complex **2b**, the hydrogen bonding interaction involving the interstitial water molecules draws the carbonyl closer, making the Ni–$O_{aqua}$–Ni bond angle smaller than in **2a**. In the case of complex **2e** the bond angle is the smallest in comparison to **2a**–**2d** because both the chloro and aqua groups bridge it.

## Conclusion

In summary, we have described the synthetic and structural aspects of a few binuclear nickel(II) complexes, having two bridging carboxylate groups and aqua groups. Intramolecular O–H···O hydrogen bonding interactions between the bridging aqua group and the monodentate benzoate groups are observed in these complexes which add to the stability of the bridging structure. From this structural study on aqua-bridged structures we could show the structural implications of solvent molecules in different types of co-crystals. Aqua-bridged nickel(II) benzoate complexes are stable irrespective of solvent system and also can include solvent molecules such as toluene and benzene. A mixed chloro, aqua and 4-chloro-benzoato-bridged $Ni^{II}$ binuclear complex is formed from the reaction of 4-chlorobenzoate with nickel(II) chloride in the presence of pyridine. This suggests that a substituent on the aromatic ring has a role in deciding the mechanochemical process during the solid-state synthesis.

## Experimental Section

The reagents used were procured from commercial sources (Sigma–Aldrich or Fluka) and used as received unless otherwise stated. Solvents such as benzene, toluene, methanol and acetonitrile were distilled and used.

The X-ray data were collected at 296 K with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) with a Bruker Nonius SMART CCD diffractometer equipped with a graphite monochromator (Table 2). The SMART software was used for data collection and also for indexing the reflections and determining the unit cell parameters; the collected data were integrated using SAINT software. The structures were solved by direct methods and refined by full-matrix least-squares calculations using the SHELXTL software.[8] All the non-H atoms were refined in the anisotropic approximation against $F^2$ of all reflections. The H-atoms, except those attached to N, O and F were placed at their calculated positions and refined in the isotropic approximation; those attached to heteroatoms (N, O and F) were located in the difference Fourier maps, and refined with isotropic displacement coefficients.

CCDC numbers 614270–614274 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Preparation of 2a:** Nickel(II) chloride hexahydrate (0.238 g, 1 mmol) and sodium benzoate (0.28 g, 2 mmol) were finely ground in a mortar and heated at 100 °C for 15 min. The solid mixture was cooled to room temperature and transferred into a round-bottomed flask and benzene (20 mL) was added and the heterogeneous mixture was stirred at room temp. for 5 min followed by the addition of pyridine (0.158 g, 2 mmol). The blue supernatant liquid was filtered off and was left undisturbed. Blue crystals were collected after 3 d and dried in air. Yield: 0.371 g, 34% (based on Ni). FT-IR (KBr): $\tilde{\nu}$ = 3412 (b), 3065 (w), 3032 (w), 1630 (s), 1602 (m), 1572 (m), 1530 (w), 1481 (w), 1445 (m), 1394 (s), 1215 (m), 1067 (m), 1037 (m), 814 (m), 757 (m), 716 (s), 696 (s), 676 (s) cm$^{-1}$. $\lambda_{max}$(methanol) = 645 nm, $\varepsilon$ = 18.91 M$^{-1}$ cm$^{-1}$, 383 nm, $\varepsilon$ = 65.6 M$^{-1}$ cm$^{-1}$

**Preparation of 2b:** Benzoic acid (0.24 g, 2 mmol), potassium hydroxide (0.116 g, 2 mmol) and nickel(II) chloride hexahydrate (0.238 g, 1 mmol) were finely ground in the mortar and heated at 100 °C for 15 min. The solid mixture was cooled to room temperature and transferred into a round-bottomed flask. Toluene (20 mL) was added to the solid mass and the heterogeneous mixture was stirred at room temperature for 5 min. To this mixture pyridine (0.158 g, 2 mmol) was added. The residue was filtered off and the blue filtrate was left undisturbed. From this solution blue crystals were obtained after 3 d and dried in air. The blue crystals were further dissolved in ethanol and water (1:1) mixture (5 mL) to obtain crystals of **2b**. Yield: 0.553 g, 58% (based on Ni). FT-IR (KBr): $\tilde{\nu}$ = 3537 (w), 3478 (w), 3060 (w), 2065 (w), 1630 (s), 1602 (m), 1572 (s), 1528 (m), 1484 (m), 1447 (s), 1397 (s), 1215 (m), 1152 (w), 1070 (m), 1039 (m), 825 (s), 760 (m), 720 (s), 697 (s), 674 (s) cm$^{-1}$. $\lambda_{max}$(methanol) = 648 nm, $\varepsilon$ = 16.55 M$^{-1}$ cm$^{-1}$; 389 nm, $\varepsilon$ = 36.63 M$^{-1}$ cm$^{-1}$.

The complexes **2c**–**2e** were prepared from the corresponding acid in an analogous manner to that for **2b**. However, for the crystallisations different solvents were used.

**2c:** Crystallised from a toluene and methanol mixture (1:1). Yield: 0.296 g, 26%. IR (KBr): $\tilde{\nu}$ = 3423 (w), 3043 (m), 2071 (w), 1626 (s), 1614 (s), 1588 (w), 1525 (w), 1484 (w), 1445 (m), 1410 (s), 1374 (s), 1256 (w), 1215 (m), 1152 (w), 1070 (w), 1039 (w), 891 (w), 861 (m), 787 (s), 697 (s), 655 (m), 628 (w) cm$^{-1}$. $\lambda_{max}$(methanol) 649 nm, $\varepsilon$ = 19.53 M$^{-1}$ cm$^{-1}$; 388 nm, $\varepsilon$ = 55.45 M$^{-1}$ cm$^{-1}$.

**2d:** Crystallised from toluene. Yield: 0.235 g, 21%. IR (KBr): $\tilde{\nu}$ = 3445 (m), 3071 (m), 2071 (w), 1637 (s), 1604 (m), 1555 (w), 1520 (s), 1486 (m), 1448 (s), 1396 (s), 1363 (s), 1303 (w), 1218 (w), 1155 (w), 1071 (w), 858 (w), 824 (m), 781 (m), 736 (s), 701 (s) $cm^{-1}$. $\lambda_{max}$(acetonitrile) = 638 nm, $\varepsilon$ = 12.09 $M^{-1}cm^{-1}$.

**2e:** Crystallised from an ethanol and acetonitrile mixture (2:1). Yield: 0.134 g, 14%. IR (KBr): $\tilde{\nu}$ = 3420 (w), 3065 (w), 1703 (w), 1614 (s), 1566 (w), 1533 (w), 1484 (w), 1445 (m), 1400 (s), 1218 (m), 1166 (m), 1091 (m), 1039 (w), 1012 (w), 850 (w), 820 (m), 772 (m), 697 (m), 631 (w), 532 (s) $cm^{-1}$. $\lambda_{max}$ (methanol) 633 nm, $\varepsilon$ = 24.42 $M^{-1}cm^{-1}$; 389 nm, $\varepsilon$ = 40.92 $M^{-1}cm^{-1}$.

# A Binuclear Isocyanide Azadithiolatoiron Complex Relevant to the Active Site of Fe-Only Hydrogenases: Synthesis, Structure and Electrochemical Properties

**Jun Hou,[a] Xiaojun Peng,*[a] Jifeng Liu,[b] Yunling Gao,[b] Xing Zhao,[a] Shang Gao,[a] and Keli Han[b]**

**Keywords:** Bioinorganic chemistry / Density functional calculations / Hydrogenases / Iron / Isocyanide ligands

An aromatic isocyanide-substituted diiron complex **5** has been synthesized as a mimic for the active site of Fe-only hydrogenases. Its structure has been fully characterized by X-ray crystallography. The 4-iodophenylisocyanide ligands in **5** are in the basal positions and are nearly parallel to each other, with π–π stacking interactions. Four isomeric geometries of complex **5** have been optimized by DFT calculations, and the electrochemical properties of **5** have been investigated by cyclic voltammetry in the absence and presence of *p*-toluenesulfonic acid (HOTs). Analysis of the cyclic voltammetric curve indicates that the reduction event at about –1.43 V is electrocatalytically active to proton reduction. This potential is more positive than that of any functionalized propanedithiolatodiiron complex.

## Introduction

Proton reduction to hydrogen in proteins, according to the reaction $2H^+ + 2e^- \rightleftarrows H_2$, is catalyzed in a highly efficient manner by Fe-only hydrogenases ([Fe]$H_2$ases), with rates in the range of 6000–9000 per second.[1–3] Because of this significant efficiency, [Fe]$H_2$ases have drawn considerable attention from chemists in the past few years.

As revealed by a combination of X-ray crystallography[4,5] and IR spectroscopy,[6,7] the active site of [Fe]$H_2$ases is comprised of a 2Fe2S subunit linked to a 4Fe4S cluster by a cysteinyl-S bridge. The 4Fe4S unit is probably responsible for electron transfer while the 2Fe2S subsite is utilized as a catalytic center for hydrogen formation and activation. The two iron atoms in the 2Fe2S subunit are bridged by the sulfur atoms of a propanedithiolato (PDT) ligand and bear the biologically unusual ligands CO and $CN^-$. Theoretical studies support the assignment of the bridging ligand as having the structure $–SCH_2NCH_2S–$ (ADT),[8,9] and the nitrogen heteroatom likely plays an important role in $H_2$ production in the natural system.

The unique structure of the active site has inspired bioinorganic chemists to synthesize structural and functional models.[10–15] Numerous biomimetic models of the PDT-[16] or ADT-bridged[17,18] all-carbonyl diiron complexes, as well as of their isocyanide,[19,20] thioether,[21–23] and phosphane/cyano-substituted[24,25] analogues have been prepared. Recently, Pickett and co-workers have reported their assembly by linking of an $[Fe_4S_4]$ cluster to a diiron unit, which offers the prospect of understanding the catalytic mechanisms of [Fe]$H_2$ases.[26] Rauchfuss et al. have developed syntheses of mixed-ligand diferrous dithiolate complexes by the oxidative decarbonylation of diiron dithiolates,[27,28] and Darensbourg and co-workers have described the electrocatalytic production of $H_2$ by PDT-bridged diiron derivatives [(μ-PDT)$Fe_2(CO)_4(PR_3)_2$] in the presence of the weak acid HOAc.[29,30] Rauchfuss et al. have demonstrated that the mixed-ligand substituted diiron system [(μ-PDT)$Fe_2(CO)_4$-$PMe_3(CN)]^-$ is an electrocatalyst for $H_2$ production with the strong acid *p*-toluenesulfonic acid (HOTs).[31,32] However, relatively more negative potentials are required to drive the reduction of protons to $H_2$ with these synthetic systems. Sun and co-workers have reported that the introduction of nitrogen in the ADT bridge shifts the reduction potential to a more positive value.[33] Thus, the synthesis of functionalized azadithiolatodiirons may be an alternative in the search for synthetic catalysts with [Fe]$H_2$ase-like capability. Although ADT-bridged diiron complexes have been extensively studied,[34–39] to the best of our knowledge there is no report on the electrocatalytic reduction of protons catalyzed by functionally substituted azadithiolatodiiron derivatives in the literature to date. With this in mind, we present here a binuclear isocyanide azadithiolatoiron complex **5** in which the isocyanide ligand was chosen because it can be used as a surrogate for the relevant $CN^-$ without complicating the reactivity of the cyanide nitrogen in catalytic reactions.[19,20] We describe the preparation, structural charac-

terization, and DFT calculations of the possible isomers of **5**, as well as the electrochemical properties of **5** in the absence and presence of the moderately strong acid HOTs.

## Results and Discussion

### Synthesis and Spectroscopic Characterization of Complexes 3 and 5

The complex [{(μ-$SCH_2$)$_2$N(4-$CH_3C_6H_4$)}$Fe_2(CO)_6$] (**3**) was prepared by a similar procedure to that reported by Rauchfuss (Scheme 1).[34] The lithium salt of hexacarbonyldisulfidodiiron (**1**),[40] freshly derived from [(μ-S)$_2$$Fe_2$-$(CO)_6$], was treated with *N*,*N*-bis(chloromethyl)-4-methylaniline (**2**) to give complex **3** in moderate yield. The synthesis of [{(μ-$SCH_2$)$_2$N(4-$CH_3C_6H_4$)}$Fe_2(CO)_4$(4-$IC_6H_4NC$)$_2$] (**5**) from complex **3** and 4-iodophenylisocyanide (**4**) turned out to be a challenge. Treatment of **3** with two equivalents of **4** in $CH_2Cl_2$ or $CH_3CN$ solution afforded complex **5** in very low yield, and attempts to afford disubstituted isocyanide derivative **5** in refluxing MeCN solution by Rauchfuss' protocol[19] were unsuccessful because **4** is thermally unstable. However, reaction of complex **3** with **4** in $CH_3CN$/$CH_2Cl_2$ (2:1, v/v) solution in the presence of the decarbonylating agent $Me_3NO{\cdot}2H_2O$ at room temperature gave the desired product **5** in reasonable yield after purification by column chromatography on silica gel. Complexes **3** and **5** are stable to air in the solid state but moderately sensitive in solution.

Complexes **3** and **5** were characterized by IR and $^1$H and $^{13}$C NMR spectroscopy and mass spectrometry. The IR spectrum of complex **3** in $CH_2Cl_2$ shows three major bands in the CO region at 2071, 2030, and 2000 cm$^{-1}$, in agreement with those of other azadithiolatodiiron derivatives.[34–36] The IR spectrum of complex **5** in $CH_2Cl_2$ exhibits NC bands at 2122 and 2094 cm$^{-1}$ and CO bands at 1996, 1980, and 1950 cm$^{-1}$. Compared with the signals of **3**, the stretching frequencies of CO are shifted to lower wavenumbers by about 50 cm$^{-1}$ on average, consistent with the better electron-donating ability of 4-iodophenylisocyanide with respect to the CO ligand. This indicates that the introduction of aromatic isocyanide ligands to the diiron center increases the electron density of the Fe–Fe bond.

### Structures of Complexes 3 and 5

The solid-state structures of **3** and **5** were determined by X-ray diffraction. The structure of **3** is shown in Figure 1 and selected bond lengths and bond angles are listed in Table 1. The 2Fe2S unit has a pseudo-square-pyramidal geometry, similar to those of previously reported azadithiolatodiiron derivatives.[34–36] The 4-methylphenyl ring slants towards the Fe(2)$(CO)_3$ unit, and the axis containing N(1), C(9), C(12), and C(15) atoms is nearly parallel to the apical C(6)O(6) ligand on the Fe(2) atom. It is noteworthy that the C(6)–Fe(2)–Fe(1) angle is about 7° larger than the C(2)–Fe(1)–Fe(2) angle, thus indicating an interaction between the arene group and Fe(2)$(CO)_3$ unit. The Fe–Fe distance of 2.5090(10) Å agrees well with those found in other (μ-ADT)$Fe_2(CO)_6$ structures.

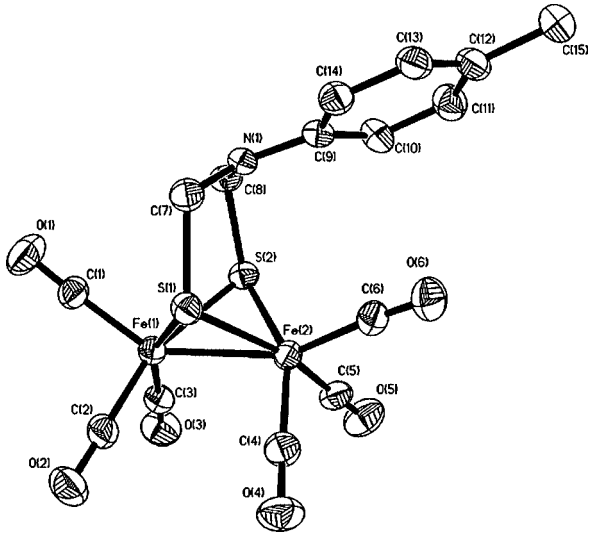

Figure 1. ORTEP view of **3** (ellipsoids at 30% probability level).

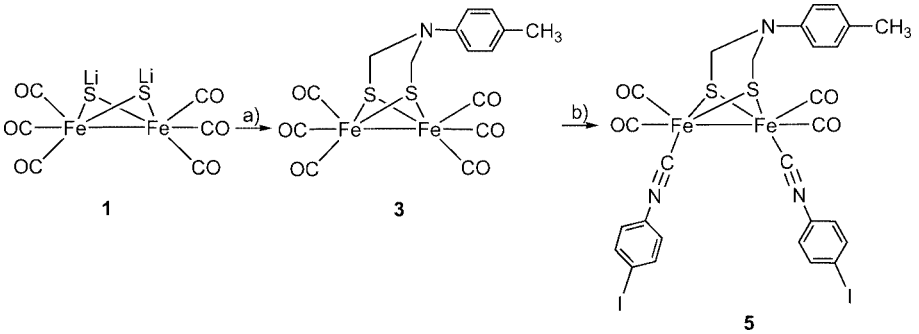
The molecular structure of **5** in the solid state is displayed in Figure 2 and selected lengths and angles are listed in Table 2. Like the "parent" **3**, the central 2Fe2S unit of **5** adopts a face-shared bi-octahedral structure. The Fe–Fe bond length of 2.5121(11) Å is somewhat longer than that observed in **3** and is similar to that found in an isocyanide-substituted PDT-bridged diiron complex.[20] This indicates that the metal–metal distance in diiron(I) compounds is



Scheme 1. a) $(ClCH_2)_2N(4\text{-}CH_3C_6H_4)$ (**2**), thf, –78 °C, 2 h; b) 4-iodophenyl isocyanide (**4**), $Me_3NO{\cdot}2H_2O$, $CH_3CN/CH_2Cl_2$ (1:1, v/v), room temp., 48 h.

| | | C(7)–N(1)–C(8) | 113.8(5) |

slightly affected by the nature of terminal ligands with a better electron-donating ability. The p-π conjugation between the 4-methylphenyl ring and the bridging N p orbital is somewhat weakened, therefore the bridging N atom is not in the plane defined by the atoms C(12), C(10), and C(19). The sum of the C–N–C angles around N(3) is 354°. The 4-methylphenyl ring in an axial position is approximately parallel to the apical carbonyl ligand C(22)O(3) on the Fe(2) site, as found in **3**. The C(20)–Fe(2)–Fe(1) angle in **5** [156.5(2)°] is enlarged by about 3.6° compared to the corresponding angle [C(6)–Fe(2)–Fe(1)] in **3** [152.83(19)°], thus suggesting the effect of the phenylisocyanide ligands on the diiron unit. The C(7)–N(1)–C(4) angle [177.3(7)°] on the Fe(1) unit is relatively linear, whereas the C(21)–N(2)–C(23) angle [168.1(7)°] on the Fe(2) unit is slightly bent. The bending at the N(2) atom is probably due to a steric influence of the bulky isocyanide ligands. The average Fe–C(N) distance of 1.846(6) Å is slightly larger than that of Fe–C(O) [av. 1.7805(7) Å]. It is interesting to note that the two phenylisocyanide ligands in the basal positions on each iron unit are nearly parallel to each other, thus indicating a crystal stacking interaction between them. Figure 3 displays the packing view along the *b* axis. It shows π–π stacking interactions of the 4-iodophenylisocyanide ligands within the column. Complex **5** is unusual compared to related diiron isocyanide complexes where the two isocyanide ligands are in apical positions in the solid state and are not parallel to each other.[20]

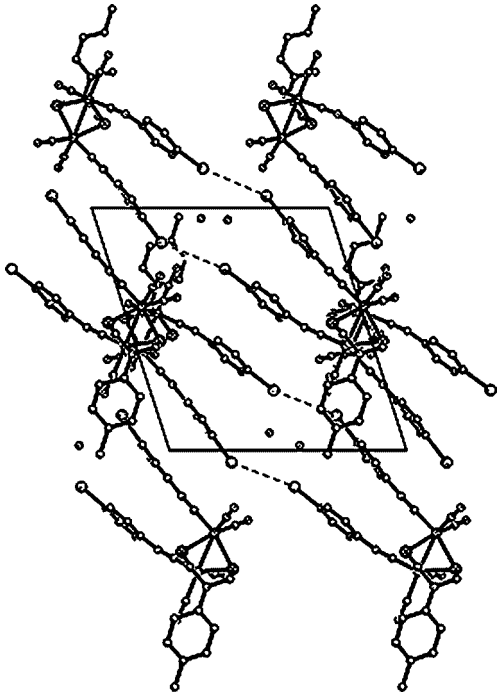

Figure 3. Crystal packing diagram for **5** viewed along the *b* axis. Thermal ellipsoids are drawn at the 50% possibility level.

In contrast to the solid structure, complex **5** exists as isomers, with two different CN stretching frequencies at 2122 and 2094 $cm^{-1}$, respectively, in solution. This phenomenon is analogous to that described for the related isocyanide
